**Algorithm.** Let  $H$  be a  $k \times r$  rectangular grid graph. Let  $\mathcal{B} = \{B_1, B_2, \dots, B_p\}$  be an almost partition of  $H$  into blocks of size  $k \times \text{mcc}(G)$  such that  $V(B_i) = \bigcup_{j=(i-1)(\text{mcc}(G)-1)+1}^{i(\text{mcc}(G)-1)+1} C_j(H)$ , for each  $i \in [p]$  where  $p = (r-1)/(\text{mcc}(G)-1)$ . Here, we consider the case where  $r-1$  is a multiple of  $\text{mcc}(G)-1$ . Note that each block  $B_i$  is a  $k \times \text{mcc}(G)$  rectangular grid graph, and for all  $i \in [p-1]$ ,  $B_i$  and  $B_{i+1}$  share a boundary column.

We can restate the  $k \times r$ -GRID EMBEDDING problem as follows: is  $G$  a subgraph of  $H$ ? As  $H$  is a planar graph,  $G$  must be planar. So, we first check if  $G$  is planar. Let  $\text{Comp}(G) = \{G_1, G_2, \dots, G_t\}$  be the set of all non-isomorphic connected components of  $G$ . For every  $i \in [t]$ , let  $\text{num}(G_i)$  be the number of times  $G_i$  appears in  $G$ . As the size of any connected component of  $G$  is at most  $\text{mcc}(G)$ , any connected component  $C$  of  $G$  (when embedded as a subgraph of  $H$ , if possible) intersects (i) only one block  $B_i$  (in particular, it does not intersect either the right or the left boundary of  $B_i$ ), or (ii) exactly two consecutive blocks  $B_i$  and  $B_{i+1}$  through the right boundary column of  $B_i$ , or (iii) exactly three consecutive blocks  $B_{i-1}$ ,  $B_i$  and  $B_{i+1}$  through the left and right boundary columns of  $B_i$ .

Based on the above observation, we compute the set  $\mathcal{S}$  of all the possible snapshots of a  $k \times \text{mcc}(G)$  rectangular grid graph  $R$ , i.e. the set of all the subgraphs of  $R$ , and the left and right adjacencies between snapshots. For every subgraph  $S$  of  $R$ , if  $\mathcal{FC}(S) \subseteq \text{Comp}(G)$ ,

■ **Figure 2** A  $5 \times 6$  rectangular grid graph  $H$ , its boundary columns and a subgraph  $S$  of  $H$  shown by colored vertices and thick colored edges. The blue, red and orange colored connected components belong to  $\mathcal{FC}(S)$ ,  $\mathcal{LC}(S)$  and  $\mathcal{RC}(S)$ , respectively.

then we add  $S$  to  $\mathcal{S}$ . Note that, if there exists a connected component of  $S$  in  $\mathcal{FC}(S)$  that does not belong to  $\text{Comp}(G)$ , then  $S$  cannot “contribute to” a valid solution. We also find the set, denoted **Source**, of snapshots that may correspond to  $B_1$  and the set, denoted **Sink**, of snapshots that may correspond to  $B_p$ . Note that we make this distinction, as except for blocks  $B_1$  and  $B_p$ , all the other blocks share both boundary columns, but  $B_1$  ( $B_p$ ) only share their right (left) boundary column. So for every  $S \in \mathcal{S}$ , if  $\mathcal{LC}(S) \subseteq \text{Comp}(G)$ , then add  $S$  to **Source**, and if  $\mathcal{RC}(S) \subseteq \text{Comp}(G)$ , then add  $S$  to **Sink**. For every snapshot  $S \in \mathcal{S}$  and  $i \in [t]$ , let  $\text{freq}_{\text{cen}}(G_i, S)$  be the number of times  $G_i$  appears in  $\mathcal{FC}(S)$ . Similarly, for every snapshot  $S \in \text{Source}$  ( $S \in \text{Sink}$ ) and  $i \in [t]$ , let  $\text{freq}_{\text{left}}(G_i, S)$  ( $\text{freq}_{\text{right}}(G_i, S)$ ) be the number of times  $G_i$  appears in  $\mathcal{LC}(S)$  ( $\mathcal{RC}(S)$ ).

We now find the set  $\text{Adj} \subseteq \mathcal{S} \times \mathcal{S}$  of all possible adjacencies between pairs of snapshots in  $\mathcal{S}$ . Let  $R'$  be a  $k \times (2\text{mcc}(G) - 1)$  rectangular grid graph. We divide  $R'$  into two blocks  $B'_1$  and  $B'_2$  of size  $k \times \text{mcc}(G)$  such that  $V(B'_1) = \bigcup_{i=1}^{\text{mcc}(G)} C_i(R')$  and  $V(B'_2) = \bigcup_{i=\text{mcc}(G)}^{2\text{mcc}(G)-1} C_i(R')$ . For every  $i \in \{1, 2\}$  and subgraph  $S'$  of  $R'$ , let  $S'_i = S'[V(S') \cap V(B'_i)]$  be the subgraph of  $S'$  in block  $B'_i$ . We look only at those subgraphs  $S'$  for which both  $S'_1$  and  $S'_2$  belong to  $\mathcal{S}$ . For every such  $S'$ , we add the pair  $(S'_1, S'_2)$  to  $\text{Adj}$  if all the connected components of  $S'_1 \cup S'_2 = S'$  that intersect both  $B'_1$  and  $B'_2$  (i.e., intersect column  $C_{\text{mcc}(G)}(R')$ ) belong to  $\text{Comp}(G)$ . Let  $\mathcal{BC}(S'_1, S'_2)$  be the set of all the connected components of  $S'_1 \cup S'_2 = S'$  that intersect the column  $C_{\text{mcc}(G)}(R')$  but intersect neither  $C_1(R')$  nor  $C_{2\text{mcc}(G)-1}(R')$ . For every  $i \in [t]$ , we denote the number of times  $G_i$  appears in  $\mathcal{BC}(S'_1, S'_2)$ , by  $\text{freq}_{\text{boun}}(G_i, (S'_1, S'_2))$ .

For every pair of snapshots  $(start, end)$  such that  $start \in \text{Source}$  and  $end \in \text{Sink}$  and a set  $\mathcal{S}' \subseteq \mathcal{S}$  of snapshots, we create a directed graph  $D$  as follows. We add all the snapshots in  $\mathcal{S}'$  as vertices of  $D$ , and for every pair of snapshots  $S, S' \in \mathcal{S}'$ , if  $(S, S') \in \text{Adj}$ , then add an arc from  $S$  to  $S'$  in  $D$ . We then add both  $start$  and  $end$  as vertices of  $D$  and for every snapshot  $S \in \mathcal{S}$ , if  $(start, S) \in \text{Adj}$  ( $(S, end) \in \text{Adj}$ ), add an arc from  $start$  to  $S$  ( $S$  to  $end$ ) in  $D$ . We then find the number of times  $X(S, S')$ , each arc  $(S, S')$  should be duplicated in  $D$  to get a new multidigraph  $D'$  such that we get a (connected) Eulerian trail in  $D'$  from  $start$  to  $end$  of length  $p$  and all the connected components of  $G$  are covered by the Eulerian trail. Finally, we use the path to get the correspondence between the blocks of  $H$  and the snapshots in  $\mathcal{S}'$  with a correct placement from left to right. The algorithm to find  $D'$  proceeds as follows.

- Find the set  $\mathcal{T}$  of all spanning trees of the underlying undirected graph of  $D$ .
- For every spanning tree  $T \in \mathcal{T}$ , solve the following ILP to find  $X(S, S')$  for every edge  $(S, S') \in E(D)$ .

$$\forall S \in V(D) \setminus \{start, end\} : \sum_{(S, S') \in E(D)} X(S, S') = \sum_{(S'', S) \in E(D)} X(S'', S). \quad (1a)$$

$$\sum_{(start, S) \in E(D)} X(start, S) = 1. \quad (1b)$$

$$\sum_{(S, end) \in E(D)} X(S, end) = 1. \quad (1c)$$

$$\sum_{(S, S') \in E(D)} X(S, S') = p - 1. \quad (1d)$$

$$\forall i \in [t] : \text{freq}_{\text{left}}(G_i, start) + \sum_{(S, S') \in E(D)} X(S, S') \cdot \text{freq}_{\text{boun}}(G_i, (S, S')) + \sum_{S \in V(D)} \left( \sum_{(S, S') \in E(D)} X(S, S') \right) \cdot \text{freq}_{\text{cen}}(G_i, S) + \text{freq}_{\text{right}}(G_i, end) = \text{num}(G_i). \quad (1e)$$

$$\forall (S, S') \in E(T) : X(S, S') + X(S', S) \geq 1. \quad (1f)$$

$$\forall (S, S') \in E(D) \setminus E(T) : X(S, S') \geq 0. \quad (1g)$$

- If the ILP returns a feasible solution, then return **Yes**.

Recall that we run the algorithm for every possible  $D$ . If for none of them we return **Yes**, we eventually return **No**. Equation 1f ensures that the digraph  $D'$  is connected, and, in this context, recall that we go over all the possible spanning trees to check all the different possible connectivities between the vertices of  $D'$ . Equations 1a, 1b and 1c ensure that there exists an Eulerian trail in  $D$  from  $start$  to  $end$ . Equation 1d ensures that the total number of edges in  $D'$  is  $p - 1$ , which in turn means that the Eulerian trail from  $start$  to  $end$  in  $D'$  is of length  $p$ , which is equal to the number of required blocks. Given a multidigraph  $D'$ , each connected component of  $G$  can “contribute to” only one set out of  $\mathcal{LC}(start)$ ,  $\mathcal{BC}(S', S'')$ ,  $\mathcal{FC}(S)$  and  $\mathcal{RC}(end)$ , for  $S, S', S'' \in \mathcal{S}'$  such that  $(S', S'') \in E(D)$ , as there exists no  $S \in \mathcal{S}'$  such that  $(S, start) \in E(D)$  or  $(end, S) \in E(D)$ . So, Equation 1e ensures that all the connected components of  $G$  are covered by the path exactly once. ◀

## 4 Distance Approximation Parameter

In this section, we consider the distance approximation parameter, and sketch the proofs of Theorems 1.3 and 1.4. The proof of Theorem 1.5 is deferred to the full version.

### 4.1 Para-NP-hardness with Respect to $a_G$ on General Graphs

We show a reduction from SAT to GRID EMBEDDING where  $a_G$  is upper bounded by a constant if the output is a **Yes** instance. For this purpose, we present the *battery gadget* (see Figure 3), composed of a  $13 \times 9$  rectangle. It has a *positive side* and a *negative side*, two *wire vertices* and six *synchronization vertices* attached to the top and bottom sides of the rectangle. On the top and bottom halves of the gadget, it has an optional extra edge, called the *positive voltage* and the *negative voltage*, respectively. We describe the battery gadget by a boolean pair  $H = (x_1, x_2)$ ,  $x_1, x_2 \in \{0, 1\}$  where  $x_1 = 1$  (resp.  $x_2 = 1$ ) if and only if we added the positive voltage edge (resp. negative voltage edge).

Given an instance  $\pi$  of SAT with variables  $x_1, \dots, x_n$  and clauses  $\mu_1, \dots, \mu_m$ , the reduction output is  $\text{reduc}(\pi) = G_\pi$  where  $G_\pi$  defined as follows.  $G_\pi$  is composed of  $m \cdot n$  battery gadgets ordered in a “matrix shape”, i.e. the battery gadget  $H_{i,j}$  is located at the  $i$ -th “row” and  $j$ -th “column” (see Figure 4). Every column  $j \in [n]$  of gadgets corresponds to the variable  $x_j$ , and every row  $i \in [m]$  of gadgets corresponds to the clause  $\mu_i$ . Now, for each  $i \in [m]$  and  $j \in [n]$  we set  $H_{i,j} = (x_1^{i,j}, x_2^{i,j})$  where  $x_1^{i,j} = 0$  (resp.  $x_2^{i,j} = 0$ ) if and only if

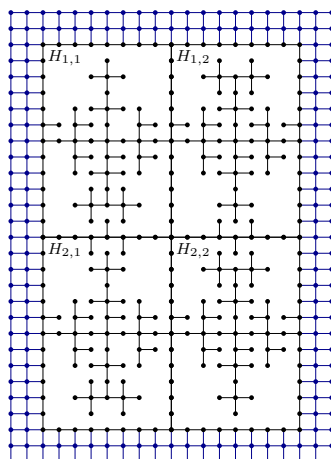

■ **Figure 3** The battery gadget. The positive side is in blue and the negative side is in red. The positive voltage is in dashed blue and the negative voltage is in dashed red. The wire vertices are numbered 1, 2. The synchronization vertices are numbered 3 to 8.

the literal  $x_j$  (resp.  $\bar{x}_j$ ) appears in  $\mu_i$ . We add the positive (resp. negative) voltage edge to the gadget  $H_{i,j}$  if and only if the literal  $x_j$  (resp.  $\bar{x}_j$ ) does not appear in  $\mu_i$ . In addition, the “matrix” of battery gadgets is encircled by an  $m \times n$ -grid frame (see Figure 4). Lastly, we delete the “redundant” topmost and bottommost synchronization edges, i.e. those not attached to a side shared by two rectangles. More precisely, for every  $j \in [n]$ , we delete the three edges attached to the top side of the rectangle of  $H_{1,j}$  and the three edges attached to the bottom side of the rectangle of  $H_{m,j}$ . Observe that each synchronization vertex is common to two battery gadgets, that is, for every  $i \in [m-1]$  and  $j \in [n]$ , the synchronization vertices 3, 4, 5 of  $H_{i+1,j}$  are the synchronization vertices 6, 7, 8 of  $H_{i,j}$ .

For the correctness of the reduction, we distinguish between “parts” (of the graph) that must have a fixed embedding and “parts” that might have several embeddings. We show that the embedding of the  $m \times n$ -grid frame is “almost fixed”. More precisely, the embedding is fixed once we choose an embedding of three specific vertices of it. Intuitively, the “shape” of the  $m \times n$ -grid frame is fixed in every embedding, up to “rotation” of the frame in 90, 180 or 270 degrees, or “movement” (shifting) to another “location”, which are immaterial for our purposes. In addition to the  $m \times n$ -grid frame, the embeddings of the sides of the rectangles, as well as the “middle crossing lines”, of the battery gadgets are also fixed once we choose an embedding for the aforementioned three vertices.

Now, observe that given a battery gadget, we might be able to choose to embed the positive or the negative side on the top of the gadget. For a battery gadget  $H$  with a grid graph embedding  $f$ , we set  $p_f(H) = +$  if the positive side of the gadget is embedded to the top of the gadget; otherwise the negative side is embedded to the top of the gadget, and we set  $p_f(H) = -$ . In addition, we denote by  $V_f(H)$  the voltage of the side of the battery gadget that  $f$  embeds at the top of  $H$ . That is, given  $H = (x_1, x_2)$ , if  $p_f(H) = +$ , then  $V_f(H) = x_1$ , and if  $p_f(H) = -$ , then  $V_f(H) = x_2$ .

Next, we show that for any  $j \in [n]$ , the gadgets in the  $j$ -th column are “synchronized”: for every  $1 \leq i, i' \leq m$ ,  $p_f(H_{i,j}) = p_f(H_{i',j})$ . For intuition, observe that the six synchronization vertices in the battery gadget maybe embedded inside or outside the rectangle and consider two adjacent battery gadget in the same column,  $H_{i,j}$  and  $H_{i+1,j}$ . If  $p_f(H_{i+1,j}) = +$ , then vertices 1 and 3 of  $H_{i+1,j}$  (see Figure 3) must be embedded outside  $H_{i+1,j}$ , so they are embedded inside  $H_{i,j}$ . Then, in  $H_{i,j}$  the positive side cannot be embedded at the bottom, and hence  $p_f(H_{i,j}) = +$ . Similarly, if  $p_f(H_{i+1,j}) = -$ , then vertex 4 must be embedded outside  $H_{i+1,j}$ , so it is embedded inside  $H_{i,j}$ . Then, in  $H_{i,j}$  the negative side cannot be embedded at the bottom, and hence  $p_f(H_{i,j}) = -$ . Formally, we prove the following.

■ **Figure 4** Construction of  $G_\pi$  where  $\pi = (\bar{x}_1 \vee x_2) \wedge (x_1 \vee x_2)$ . The  $2 \times 2$ -grid frame is in blue.

► **Lemma 4.1 (\*)**. *Let  $\pi$  be an instance of SAT with  $n$  variables and  $m$  clauses. Let  $f$  be a grid graph embedding of  $G_\pi$ . For every  $j \in [n]$ , there exists  $p_j \in \{+, -\}$  such that for every  $i \in [m]$  it follows that  $p_f(H_{i,j}) = p_j$ .*

Next, we show that for every  $i \in [m]$ , there exists  $j \in [n]$  such that  $V_f(H_{i,j}) = 0$ . As intuition, note that if vertex 1 of  $H_{i,j}$  is embedded inside  $G_{i,j}$  and  $V_f(G_{i,j}) = 1$ , then it must be that vertex 2 is embedded outside  $G_{i,j}$ . So, since vertex 1 must be embedded inside  $G_{i,1}$  and vertex 2 must be embedded inside  $G_{i,n}$ , there must be a  $j$  such that  $V_f(H_{i,j}) = 0$ .

► **Lemma 4.2 (\*)**. *Let  $\pi$  be an instance of SAT with  $n$  variables and  $m$  clauses. Let  $f$  be a grid graph embedding of  $G_\pi$ . For every  $i \in [m]$ , there exists  $j \in [n]$  such that  $V_f(H_{i,j}) = 0$ .*

We are ready to prove the reverse direction of the correctness of the reduction. Due to lack of space, we omit proof of the forward direction.

► **Lemma 4.3**. *Let  $\pi$  be an instance of SAT with  $n$  variables and  $m$  clauses. Then  $G_\pi$  is a grid graph if and only if  $\pi$  is a Yes instance of SAT.*

**Partial proof.** Let  $f$  be a grid graph embedding of  $G_\pi$ . By Lemma 4.1, for every  $j \in [n]$ , there exists  $p_j \in \{+, -\}$  such that for every  $i \in [m]$ ,  $p_f(H_{i,j}) = p_j$ . We define  $s : \{x_1, \dots, x_n\} \rightarrow \{T, F\}$  as follows. For  $j \in [n]$ ,  $s(x_j) = T$  if  $p_j = +$ ; otherwise,  $s(x_j) = F$ . We show that  $s$  is a satisfying assignment for  $\pi$ . Let  $i \in [m]$ . By Lemma 4.2, there exists  $j \in [n]$  such that  $V_p(i, j) = 0$ . If  $p(i, j) = p_j = +$ , then  $x_1^{(i,j)} = 0$ , and by the definition of  $G_\pi$ ,  $x_j$  appears in  $\mu_i$ . By the definition of  $s$ , since  $p_j = +$ , we get that  $s(x_j) = T$ , therefore  $\mu_i$  is satisfied. Similarly, if  $p(i, j) = p_j = -$ , then  $x_2^{(i,j)} = 0$ , and by the definition of  $G_\pi$ ,  $\bar{x}_j$  appears in  $\mu_i$ . By the definition of  $s$ , since  $p_j = -$ , we get that  $s(x_j) = F$ , therefore  $\mu_i$  is satisfied. So,  $\pi$  is a Yes instance of SAT. ◀

It only remains to show is that the distance approximation of  $G_\pi$  is bounded by a constant if  $G_\pi$  is a grid graph. Due to lack of space, we omit this proof.

► **Lemma 4.4 (\*)**. *Let  $\pi$  be an instance of SAT. If  $G_\pi$  is a grid graph, then for every grid graph embedding  $f$  of  $G_\pi$  it follows that  $a_f \leq 234$ .*

Using Lemma 4.3 and Lemma 4.4, we can conclude Theorem 1.3.

■ **Figure 5** Sorting the vertices  $u$  of a  $k \times r$  grid into small rectangles.

### 4.2 $k \times r$ -GRID EMBEDDING IS FPT WITH RESPECT TO $k + a_G$

We present an FPT algorithm with respect to  $k + a_G$  for  $k \times r$ -GRID EMBEDDING. The idea is as follows. We guess a leftmost vertex  $v$  in the  $k \times r$  grid (i.e. satisfying  $f_{\text{col}}(v) = 0$ ). Then, going from left to right, we divide the  $k \times r$  grid into  $\lceil \frac{r}{k+a_G} \rceil$  “small rectangles” of size  $k \times (a_G + k)$ , except the last which might be smaller. After this, we sort the vertices into the small rectangles: We put each vertex  $u$ , having graph distance  $d(v, u)$  from  $v$ , in the  $\lceil \frac{d(v, u)}{k+a_G} \rceil$ -th rectangle; if no such rectangle exists, we put  $u$  in the  $(\lceil \frac{d(v, u)}{k+a_G} \rceil - 1)$ -th rectangle, if this rectangle does not exist as well (as  $\lceil \frac{d(v, u)}{k+a_G} \rceil - 1$  is too large), we can conclude that we have a no-instance. In particular, we show that in every  $k \times r$  grid graph embedding  $f$  of  $G$  with  $a_f = a_G$  where  $v$  is a leftmost vertex, every  $u$  is embedded either in its sorted rectangle or the previous one. For intuition, observe that  $u$  cannot be embedded into a farther rectangle as then its shortest path(s) from  $v$  cannot be embedded. On the other hand, if  $u$  is embedded into a closer rectangle, then the embedding does not respect the distance approximation. After we know the “approximate location” of each vertex, we try to find a  $k \times r$  grid graph embedding of  $G$  using an iterative algorithm.

We start by proving the correctness of the “location approximation” of each vertex. To this end, for any  $0 \leq s \leq t$ , we define  $C_f(s, t) = \{u \in V \mid s \leq f_{\text{col}}(u) \leq t\}$  and  $D_v(s, t) = \{u \in V \mid s \leq d(v, u) \leq t\}$ . See Figure 5.

► **Lemma 4.5 (\*)**. *Let  $G = (V, E)$  be a  $k \times r$  grid graph, and let  $f$  be a  $k \times r$  grid graph embedding of  $G$ . Let  $v \in V$  such that  $f_{\text{col}}(v) = 0$ . Let  $u \in V$  be a vertex. Then  $u \in C_f(d(v, u) - a_f - k, d(v, u))$ , and  $u \in D_v(f_{\text{col}}(u), f_{\text{col}}(u) + a_f + k)$ .*

Therefore, every vertex must be embedded either in its sorted rectangle or in the one to its left. In light of this, we try to find a  $k \times r$  embedding of  $G$  by iteration on the small rectangles from left to right. At each step, we seek  $k \times (a_f + k)$  embeddings for the vertices in the current rectangle and for a subset  $U$  of the vertices of the next rectangles. For each such embedding, we only need to store the following information: the subset  $U$  and the “right column” of the embedding (so as to “glue” embeddings of adjacent rectangles properly). In the next rectangle, we try to embed (using brute-force) the vertices we did not embed in the previous rectangle (those outside  $U$ ) and some of the vertices of its next rectangle, such that the left column of the current embedding “agrees” with the right column of the embedding of the previous rectangle. Note that at each step we only store “FPT amount” of information, and so we use only “FPT runtime”. A formal description of the algorithm can be found in the full version. Here, we directly proceed to state the correctness.

► **Lemma 4.6 (\*)**. *There exists an algorithm that given a graph and  $k, r \in \mathbb{N}$  runs in time  $\mathcal{O}(|V|^2 (ka_G)^{\mathcal{O}(ka_G + k^2)})$  and returns “Yes instance” if and only if  $G$  is a  $k \times r$  grid graph.*

Using Lemma 4.6, we can conclude Theorem 1.4.

## Abstract

---

We present a  $\frac{5}{3}$ -approximation algorithm for the matching augmentation problem (MAP): given a multi-graph with edges of cost either zero or one such that the edges of cost zero form a matching, find a 2-edge connected spanning subgraph (2-ECSS) of minimum cost.

A  $\frac{7}{4}$ -approximation algorithm for the same problem was presented recently, see Cheriyan, et al., “The matching augmentation problem: a  $\frac{7}{4}$ -approximation algorithm,” *Math. Program.*, 182(1):315–354, 2020.

Our improvement is based on new algorithmic techniques, and some of these may lead to advances on related problems.

## 1 Introduction

The design and analysis of algorithms for problems in network design is a core topic in Theoretical Computer Science and Combinatorial Optimization. Algorithmic research on problems such as the minimum spanning tree problem and the Traveling Salesman Problem (TSP) started decades ago and is a thriving area even today. One of the key problems in this area is the minimum-cost 2-ECSS (2-edge connected spanning subgraph) problem: Given an undirected graph  $G = (V, E)$  and a nonnegative cost for each edge  $e \in E$ , denoted  $\text{cost}(e)$ , find a minimum-cost spanning subgraph  $H = (V, F)$ ,  $F \subseteq E$ , that is 2-edge connected. Throughout, we use  $n := |V|$  to denote the number of nodes of  $G$ . (Recall that a graph is 2-edge connected if it is connected and has no “cut edges”, or equivalently, each of its nontrivial cuts has  $\geq 2$  edges.) This problem is NP-hard, and the best approximation guarantee known, due to [22], is 2.

On the other hand, the best “hardness of approximation threshold” known is much smaller; for example, it is  $(1 + \frac{\rho_{VC3}}{104})$  for the unweighted problem, where  $1 + \rho_{VC3}$  is the “hardness of approximation threshold” for the minimum vertex cover problem on a graph with

maximum degree 3, [10, Theorem 5.2]. Also, the best lower bound known on the integrality ratio of the standard LP relaxation (for minimum-cost 2-ECSS) is around 1.5 (thus, well below 2), see [5].

## 1.1 FAP, TAP and MAP

Given this significant gap between the lower bounds and the upper bounds, research in this area over the last two decades has focused on the case of zero-one cost functions (every edge has a cost of zero or one). Let us call an edge  $e \in E$  with  $\text{cost}(e) = 0$  a zero-edge, and let us call an edge  $e \in E$  with  $\text{cost}(e) = 1$  a unit-edge. Intuitively, the zero-edges define some existing network that we wish to augment (with unit-edges) such that the augmented network is resilient to the failure of any one edge. We may assume that the zero-edges form a forest; otherwise, there is at least one cycle  $C$  formed by the zero edges, and in that case, we may contract  $C$ , solve the problem on the resulting graph  $G/C$ , find a solution (edge set)  $F$ , and return  $F \cup C$  as a solution of the original problem. Consequently, the minimum-cost 2-ECSS problem with a zero-one cost function is called the *Forest Augmentation Problem* or FAP. The challenge is to design an approximation algorithm with guarantee strictly less than 2 for FAP.

A well known special case of FAP is TAP, the *Tree Augmentation Problem*: the set of zero-edges forms a spanning tree. The first publication to break the “2-approximation barrier” for TAP is [14] (2003), and since then there have been several important advances, including recent work, see [11, 17, 1, 19, 4, 9, 13].

Recently, see [2], there has been progress on another important (in our opinion) special case of FAP called the *Matching Augmentation Problem* or MAP: Given a multi-graph with edges of cost either zero or one such that the zero-edges form a matching, find a 2-ECSS of minimum cost. From the view-point of approximation algorithms, MAP is “complementary” to TAP, in the sense that the forest formed on  $V(G)$  by the zero-edges has many connected components, each with one node or two nodes, whereas this forest has only one connected component in TAP.

## 1.2 Previous literature and possible approaches for attacking MAP

There is a large body of work on network design and the design of algorithms (for finding optimal solutions, as well as for finding approximately optimal solutions); see the books in the area [20, 25, 18]. Unfortunately, none of these results and methods has helped to break the “2-approximation barrier” for FAP (to the best of our knowledge).

Powerful and versatile methods such as the *primal-dual method* (see [25, 12]) and the *iterative rounding method* (see [18, 16]) have been developed for problems in network design, but the provable approximation guarantees for these methods are  $\geq 2$ . (These methods work by rounding LP relaxations; informally speaking, the approximation guarantee is proved via an upper bound of 2 per iteration on the “integral cost incurred” versus the “chargeable LP cost”, and it is plausible that the factor of 2 cannot be improved for this type of analysis.)

Combinatorial methods that may also exploit lower-bounds from LP relaxations have been developed for approximation algorithms for unweighted minimum-cost 2-ECSS, e.g.,  $\frac{4}{3}$ -approximation algorithms are presented in [24, 21, 15]. For the unweighted problem, there is a key lower bound of  $n$  on  $\text{opt}$  (since any solution must have  $\geq n$  edges, each of cost one). This fails to hold for MAP; indeed, the analogous lower bound on  $\text{opt}$  is  $\frac{1}{2}n$  for MAP. This rules out any direct extension of these combinatorial methods (for the unweighted problem) to prove approximation guarantees below 2 for MAP.

Recently, Traub and Zenklusen [23] presented an approximation algorithm for Weighted TAP with guarantee  $1 + (\ln 2) + \epsilon < 1.7$ , via a so-called relative greedy algorithm, based on previous work by Cohen and Nutov [6] that, in turn, is based on earlier work by Zelikovsky on the Steiner Tree problem [26]. While the result of Traub and Zenklusen is a major advance in the area, the core ideas of the relative greedy algorithm are well known, and, as yet, there is no advance on FAP via relative greedy algorithms. (Informally speaking, Weighted TAP is a special case of SCP (the Set Covering Problem), and the method of Cohen and Nutov exploits special properties of the SCP instances associated with TAP, whereas, to the best of our knowledge, this paradigm does not extend to FAP.)

### 1.3 Our results and techniques

Our main contribution is a  $\frac{5}{3}$ -approximation algorithm for MAP, improving on the  $\frac{7}{4}$  approximation guarantee of [2], see Theorems 12, 13.

At a high level (hiding many important points), our algorithm is based on a “discharging scheme” where we compute a lower bound on  $opt$  (the optimal value) and fix a “budget” of  $\alpha$  times this lower bound (where  $\alpha > 1$  is a constant), “scatter” this budget over the graph  $G$ , use the budget to buy some edges to obtain a “base graph”, then traverse the “base graph” and buy more edges to augment the “base graph”, so that (eventually) we have a 2-ECSS whose cost is within the budget of  $\alpha$  times our lower bound. We mention that several of the results cited above are based on discharging schemes, e.g., [24, 11, 17, 15, 2]. In some more detail, but still at a high level, we follow the method of [2]. (Our presentation can be read independently of [2]; we have repeated a few definitions and statements of results from [2].) We first pre-process the input instance  $G$ , with the goal of removing all “obstructions” (e.g., cut nodes), and we decompose  $G$  into a list of “well structured” sub-instances  $G_1, G_2, \dots$  that are pairwise edge-disjoint. Now, consider one of these sub-instances  $G_i$  (it has none of the “obstructions”). We compute a subgraph  $H_i$  whose cost is a lower bound on  $opt(G_i)$ . Finally, we augment  $H_i$  to make it 2-edge connected, and use a credit-based analysis to prove an approximation guarantee.

A 2-edge cover is a subgraph that has at least two edges incident to every node. The minimum-cost 2-edge cover is the key subgraph used as a lower bound in our algorithm; we refer to it as D2. (D2 can be computed in polynomial time via extensions of Edmonds’ algorithm for computing a minimum-cost perfect matching.) Since every 2-ECSS is a 2-edge cover, we have  $\text{cost}(\text{D2}) \leq opt$ . So, by transforming D2 to a 2-ECSS of cost  $\leq \frac{5}{3}\text{cost}(\text{D2})$ , we achieve our claimed approximation guarantee.

Our pre-processing includes several new ideas, and moreover, it is essential to handle new “obstructions” that are not handled in [2]; indeed, [2] has tight examples such that  $opt/\text{cost}(\text{D2}) \geq \frac{7}{4} - \epsilon$  (for some  $\epsilon > 0$ ). Although our algorithm handles several new “obstructions”, our analysis and proofs for the pre-processing are simple. One of our key tools (for our pre-processing analysis) is to prove a stronger guarantee of  $\max(opt, \frac{5}{3}opt - 2)$  rather than just  $\frac{5}{3}opt$ . When we analyze our decomposition of an instance into sub-instance(s), then this additive term of  $-2$  is useful in combining solutions back together at the end of the algorithm (when we “undo” the decomposition of  $G$  into sub-instances  $G_1, G_2, \dots$ ). (Our analysis of pre-processing is omitted in this paper, due to space constraints; it is given in the full paper, [3].)

Our main algorithm (following [2]) has two key subroutines for transforming a D2 of a “well structured” sub-instance  $G_i$  to a 2-ECSS of  $G_i$  while ensuring that the total cost is  $\leq \frac{5}{3}\text{cost}(\text{D2})$ .

- (i) **Bridge covering step:** The goal is to augment edges such that each connected component of our “current solution graph”  $H_i$  is 2-edge-connected; we start with  $H_i := D2(G_i)$ . Our analysis is based on a new and simple credit scheme that bypasses some difficulties in the credit scheme of [2].
- (ii) **Gluing step:** Finally, this step merges the (already 2-edge connected) connected components of  $H_i$  to form a 2-ECSS of the sub-instance  $G_i$ . A key part of this step handles so-called “small 2ec-blocks”; these are cycles of cost 2 that occur as connected components of  $D2(G_i)$  and stay unchanged through the bridge covering step. Observe that a “small 2ec-block” has only  $\frac{4}{3}$  credits (it has a “budget” of  $(\frac{5}{3})(2)$ , and after paying for its two unit-edges, there is only  $\frac{4}{3}$  credits available). Our gluing step applies a careful swapping of unit-edges for the “small 2ec-blocks” while it merges the connected components of  $H_i$  into a 2-ECSS, and ensures that the net augmentation cost does not exceed the available credit.

There are well-known polynomial time algorithms for implementing all of the basic computations in this paper, see [20]. We state this explicitly in all relevant results (e.g., Theorem 12), but we do not elaborate on this elsewhere.

## 2 Preliminaries

This section has definitions and preliminary results. Our notation and terms are consistent with [7], and readers are referred to that text for further information.

Let  $G = (V, E)$  be a (loop-free) multi-graph with edges of cost either zero or one such that the edges of cost zero form a matching. We take  $G$  to be the input graph, and we use  $n$  to denote  $|V(G)|$ . Let  $M$  denote the set of edges of cost zero. Throughout, the reader should keep in mind that  $M$  is a matching; this fact is used in many of our proofs without explicit reminders. We call an edge of  $M$  a *zero-edge* and we call an edge of  $E - M$  a *unit-edge*.

We denote the cost of an edge  $e$  of  $G$  by  $\text{cost}(e)$ . For a set of edges  $F \subseteq E(G)$ ,  $\text{cost}(F) := \sum_{e \in F} \text{cost}(e)$ , and for a subgraph  $G'$  of  $G$ ,  $\text{cost}(G') := \sum_{e \in E(G')} \text{cost}(e)$ .

For ease of exposition, we often denote an instance  $G, M$  by  $G$ ; then, we do not have explicit notation for the edge costs of the instance, but the edge costs are given implicitly by  $\text{cost} : E(G) \rightarrow \{0, 1\}$ , and  $M$  is given implicitly by  $\{e \in E(G) : \text{cost}(e) = 0\}$ .

For a positive integer  $k$ , we use  $[k]$  to denote the set  $\{1, \dots, k\}$ .

We use the standard notion of contraction of an edge, see [20, p.25]. For a graph  $H$  and a set of its nodes  $S$ ,  $\Gamma_H(S) := \{w \in V(H) - S : v \in S, vw \in E(H)\}$ , thus,  $\Gamma_H(S)$  denotes the set of neighbours of  $S$ . For a graph  $H$  and a set of nodes  $S \subseteq V(H)$ ,  $\delta_H(S)$  denotes the set of edges that have one end node in  $S$  and one end node in  $V(H) - S$ . Moreover,  $H[S]$  denotes the subgraph of  $H$  induced by  $S$ , and  $H - S$  denotes the subgraph of  $H$  induced by  $V(H) - S$ . For a graph  $H$  and a set of edges  $F \subseteq E(H)$ ,  $H - F$  denotes the graph  $(V(H), E(H) - F)$ . For any subgraph  $K$  of a graph  $H$  with  $V(K) \subsetneq V(H)$ , an *attachment* of  $K$  is a node of  $K$  that has a neighbour in  $V(H) - V(K)$ .

We may use relaxed notation for singleton sets, and, we may not distinguish between a subgraph and its node set; for example, given a graph  $H$  and a set  $S$  of its nodes, we use  $E(S)$  to denote the edge set of the subgraph of  $H$  induced by  $S$ .

## 2.1 2EC, 2NC, bridges and D2

A multi-graph  $H$  is called  $k$ -edge connected if  $|V(H)| \geq 2$  and for every  $F \subseteq E(H)$  of size  $< k$ ,  $H - F$  is connected. Thus,  $H$  is 2-edge connected if it has  $\geq 2$  nodes and the deletion of any one edge results in a connected graph. A multi-graph  $H$  is called  $k$ -node connected if  $|V(H)| > k$  and for every  $S \subseteq V(H)$  of size  $< k$ ,  $H - S$  is connected. We use the abbreviations *2EC* for “2-edge connected,” and *2NC* for “2-node connected.”

We assume w.l.o.g. that the input  $G$  is 2EC. Moreover, for some (but not all) of our discussions, we assume that there are  $\leq 2$  copies of each edge (in the multi-graph under consideration); this is justified since an edge-minimal 2-ECSS cannot have three or more copies of any edge (see Proposition 1 below).

For any instance  $H$ , let  $opt(H)$  denote the minimum cost of a 2-ECSS of  $H$ . When there is no danger of ambiguity, we use  $opt$  rather than  $opt(H)$ .

By a *bridge* we mean an edge of a connected (sub)graph whose removal results in two connected components, and by a *cut node* we mean a node of a connected (sub)graph whose deletion results in two or more connected components. We call a bridge of cost zero a *zero-bridge* and we call a bridge of cost one a *unit-bridge*.

By a *2ec-block* we mean a maximal connected subgraph with two or more nodes that has no bridges. We call a 2ec-block *pendant* if it is incident to exactly one bridge. We call a 2ec-block *small* if it has  $\leq 2$  unit-edges, and we call it *large* otherwise.

For a 2EC graph  $G$  and a cut node  $v$  of  $G$ , a *2ec- $v$ -block* means the subgraph of  $G$  induced by  $\{v\} \cup V(C)$  where  $C$  is one of the connected components of  $G - v$ .

The next result characterizes edges that are not essential for 2-edge connectivity.

► **Proposition 1.** *Let  $H$  be a 2EC graph and let  $e = vw$  be an edge of  $H$ . If  $H - e$  has two edge-disjoint  $v, w$  paths, then  $H - e$  is 2EC.*

The next lemma partially characterizes the cuts of size  $\leq 2$  in a graph obtained by “uncontracting” a set of nodes of a 2EC graph.

► **Lemma 2.** *Let  $H$  be a 2EC graph and let  $C \subsetneq V(H)$  be a set of nodes such that the induced subgraph  $H[C]$  is connected. Suppose that  $H^*$  is a 2-ECSS of  $H/C$ . Let  $H'$  be the spanning subgraph of  $H$  with edge set  $E(C) \cup E(H^*)$ . Then  $H'$  is a connected graph such that each of its bridges (if any) is in  $E(C)$ .*

By a *2-edge cover* (of  $G$ ) we mean a set of edges  $F$  of  $G$  such that each node  $v$  is incident to at least two edges of  $F$  (i.e.,  $F \subseteq E(G) : |\delta_F(v)| \geq 2, \forall v \in V(G)$ ). By  $D2(G)$  we mean any minimum-cost 2-edge cover of  $G$  ( $G$  may have several minimum-cost 2-edge covers, and  $D2(G)$  may refer to any one of them); when there is no danger of ambiguity, we use  $D2$  rather than  $D2(G)$ .

By a *bridgeless 2-edge cover* (of  $G$ ) we mean a 2-edge cover (of  $G$ ) that has no bridges.

The next result follows from Theorem 34.15 in [20, Chapter 34].

► **Proposition 3.** *There is a polynomial-time algorithm for computing  $D2$ .*

The next result states the key lower bound used by our approximation algorithm.

► **Lemma 4.** *Let  $H$  be any 2EC graph. Then we have  $opt(H) \geq cost(D2(H))$ .*

For any fixed positive integer  $z$  (thus,  $z = O(1)$ ) and any instance of MAP, in time  $O(1)$ , we can determine whether the instance has  $opt > z$ , and if not, then we can find an optimal 2-ECSS of the instance.

► **Lemma 5.** *Let  $H$  be an instance of MAP, and let  $z$  be a fixed positive integer. There is an  $O(1)$ -time algorithm to determine whether  $\text{opt}(H) \geq z$ . Moreover, if  $\text{opt}(H) \leq z$ , then a minimum-cost 2-ECSS of  $H$  can be found in  $O(1)$  time.*

## 2.2 Obstructions for the approximation guarantee

There are several obstructions (e.g., cut nodes) that prevent our algorithm (and analysis) from achieving our target approximation factor of  $\frac{5}{3}$ . We eliminate all such obstructions in a pre-processing step that takes the given instance  $G$  of MAP (the input) and replaces it by a list of sub-instances  $G_1, G_2, \dots$ , such that (a) none of the obstructions occurs in a sub-instance  $G_i$ , (b) the edge-sets of the sub-instances are pairwise-disjoint, and (c) given a 2-ECSS of each sub-instance  $G_i$  of approximately optimal cost, we can construct a 2-ECSS of  $G$  of cost  $\leq \frac{5}{3}\text{opt}(G)$ . (Precise statements are given later.) The obstructions for our algorithm are:

- |                      |              |
|----------------------|--------------|
| (i) cut nodes,       | (v) S{3, 4}, |
| (ii) parallel edges, | (vi) R4,     |
| (iii) zero-cost S2,  | (vii) R8.    |
| (iv) unit-cost S2,   |              |

Below, we formally define each of these obstructions. Four of these obstructions were introduced in [2], and readers interested in a deeper understanding may refer to that paper, in particular, see the remark after [2, Theorem 6] and see [2, Figure 2] for instances  $G$  of MAP that contain cut nodes, parallel edges, zero-cost S2s, or R4s such that  $\text{opt}(G)/\text{cost}(\text{D2}(G)) \approx 2$ ; informally speaking, an approximation algorithm based on the lower bound  $\text{cost}(\text{D2}(G))$  on  $\text{opt}(G)$  fails to beat the approximation threshold of 2 in the presence of any of these four obstructions.

► **Definition 6.** *By a zero-cost S2 (also called a bad-pair), we mean a zero-edge  $e$  and its end nodes,  $u, v$ , such that  $G - \{u, v\}$  has  $\geq 2$  connected components.*

► **Definition 7.** *By a unit-cost S2, we mean a unit-edge  $e$  and its end nodes,  $u, v$ , such that  $G - \{u, v\}$  has  $\geq 2$  connected components; moreover, in the graph  $G/\{u, v\}$ , there exist two distinct 2ec- $\hat{v}$ -blocks  $B_1, B_2$  incident to the contracted node  $\hat{v}$  such that  $\text{opt}(B_i) \geq 3$  and  $B_i$  has a zero-edge incident to the contracted node,  $\forall i \in [2]$ .*

► **Definition 8.** *By an S{3, 4}, we mean an induced 2NC subgraph  $C$  of  $G$  with  $|V(C)| \in \{3, 4\}$  that has a spanning cycle of cost two such that  $G - V(C)$  has  $\geq 2$  connected components, and the cut  $\delta(V(C))$  has no zero-edges; moreover, in the graph  $G/C$ , there exist two distinct 2ec- $\hat{v}$ -blocks  $B_1, B_2$  incident to the contracted node  $\hat{v}$  that have  $\text{opt}(B_1) \geq 3$  and  $\text{opt}(B_2) \geq 3$ .*

► **Definition 9.** *By an R4 (also called a redundant 4-cycle), we mean an induced subgraph  $C$  of  $G$  with four nodes such that  $V(C) \neq V(G)$ ,  $C$  contains a 4-cycle of cost two, and  $C$  contains a pair of nonadjacent nodes that each have degree two in  $G$ .*

► **Definition 10.** *By an R8, we mean an induced subgraph  $C$  of  $G$  with eight nodes such that  $V(C) \neq V(G)$ ,  $C$  contains two disjoint 4-cycles  $C_1, C_2$  with  $\text{cost}(C_i) = 2, \forall i \in [2]$ ,  $C$  has exactly two attachments  $a_1, a_2$  where  $a_i \in C_i, \forall i \in [2]$ , and both end nodes of the (unique) unit-edge of  $C_i - a_i$  are adjacent to  $C_{3-i}, \forall i \in [2]$ .*

### 3 Outline of the algorithm

This section has an outline of our algorithm. We start by defining an instance of MAP $\star$ .

► **Definition 11.** *An instance of MAP $\star$  is an instance of MAP with  $\geq 12$  nodes that contains*

- no cut nodes,
- no parallel edges,
- no zero-cost S2,
- no unit-cost S2,
- no S{3, 4},
- no R4, and
- no R8.

In this section and Section 4, we sketch how to “decompose” any instance of MAP  $G$  with  $|V(G)| \geq 12$  into a collection of instances  $G_1, \dots, G_k$  of MAP such that (a) either  $|V(G_i)| < 12$  or  $G_i$  is an instance of MAP $\star$ ,  $\forall i \in [k]$ , (b) the edge sets  $E(G_1), \dots, E(G_k)$  are pairwise disjoint (thus  $E(G_1), \dots, E(G_k)$  forms a subpartition of  $E(G)$ ), and (c) a 2-ECSS  $H$  of  $G$  can be obtained by computing 2-ECSSes  $H_1, \dots, H_k$  of  $G_1, \dots, G_k$ . Moreover, the approximation guarantee is preserved, meaning that  $\text{cost}(H) \leq \frac{5}{3} \text{opt}(G) - 2$  provided  $\text{cost}(H_i) \leq \max(\text{opt}(G_i), \frac{5}{3} \text{opt}(G_i) - 2), \forall i \in [k]$ .

---

#### Algorithm (outline).

- (0) apply the pre-processing steps (see below and see Section 4) to obtain a collection of instances  $G_1, \dots, G_k$  such that either  $|V(G_i)| < 12$  or  $G_i$  is an instance of MAP $\star$ ,  $\forall i \in [k]$ ;  
     **for** each  $G_i$  ( $i = 1, \dots, k$ ),  
     **if**  $|V(G_i)| < 12$
  - (1) exhaustively compute an optimum 2-ECSS  $H_i$  of  $G_i$  via Lemma 5;  
     **else**
  - (2.1) compute  $D2(G_i)$  in polynomial time (w.l.o.g. assume  $D2(G_i)$  contains all zero-edges of  $G_i$ );
  - (2.2) then apply “bridge covering” from Section 5 to  $D2(G_i)$  to obtain a bridgeless 2-edge cover  $\tilde{H}_i$  of  $G_i$ ;
  - (2.3) then apply the “gluing step” from Section 6 to  $\tilde{H}_i$  to obtain a 2-ECSS  $H_i$  of  $G_i$ ;  
     **endif**;
  - endfor**;
  - (3) finally, output a 2-ECSS  $H$  of  $G$  from the union of  $H_1, \dots, H_k$  by undoing the transformations applied in step (0).
- 

The pre-processing of step (0) consists of several reductions; most of these reductions are straightforward, but we have to prove that the approximation guarantee is preserved when we “undo” each of these reductions. These proofs are given in the full paper, [3].

---

#### Pre-processing – Step (0) of Algorithm.

**While** the current list of sub-instances  $G_1, G_2, \dots$  has a sub-instance  $G_i$  that has  $\geq 12$  nodes and is not an instance of MAP $\star$  (assume that  $G_i$  is 2EC):

**if**  $G_i$  is not 2NC:

- (i) (handle a cut-node)  
     let  $v$  be a cut node of  $G_i$ , and let  $B_1, \dots, B_k$  be the 2ec- $v$ -blocks of  $G_i$ ; replace  $G_i$  by  $B_1, \dots, B_k$  in the current list;
- else** apply exactly one of the following steps to  $G_i$ :

- (ii) (handle a pair of parallel edges)
    - let  $\{e, f\}$  be a pair of parallel edges of  $G_i$  (one of the edges in  $\{e, f\}$  is a unit-edge);
    - discard a unit-edge of  $\{e, f\}$  from  $G_i$ ;
  - (iii) (handle an “S obstruction”)
    - (a) (handle a unit-cost S2)
    - (b) (handle a zero-cost S2)
    - (c) (handle an  $S\{3, 4\}$ )

let  $C$  denote a subgraph of  $G_i$  that is, respectively, (a) a unit-cost S2, (b) a zero-cost S2, or (c) an  $S\{3, 4\}$ ;

contract  $C$  to obtain  $G_i/C$  and let  $\hat{v}$  denote the contracted node; let  $B_1, \dots, B_k$  be the  $2\text{ec-}\hat{v}$ -blocks of  $G_i/C$ ; replace  $G_i$  by  $B_1, \dots, B_k$  in the current list;
  - (iv) (handle an “R obstruction”)
    - (a) (handle an R4)
    - (b) (handle an R8)

let  $C$  denote a subgraph of  $G_i$  that is, respectively, (a) an R4, or (b) an R8;

contract  $C$  to obtain  $G_i/C$ , and replace  $G_i$  by  $G_i/C$  in the current list;
- 

Our  $\frac{5}{3}$  approximation algorithm for MAP follows from the following theorem.

► **Theorem 12.** *Given an instance of  $\text{MAP}\star$   $G'$ , there is a polynomial-time algorithm that obtains a 2-ECSS  $H'$  such that  $\text{cost}(H') \leq \max(\text{opt}(G'), \frac{5}{3}\text{opt}(G') - 2)$ .*

We use a credit scheme to prove this theorem; the details are presented in Sections 5 and 6. The algorithm starts with  $\text{D2}(G')$  as the current graph, and assigns  $\frac{5}{3}$  tokens to each unit-edge of  $\text{D2}(G')$ ; each such edge keeps one unit to pay for itself and the other  $\frac{2}{3}$  is taken to be credit of the edge; thus, the algorithm has  $\frac{2}{3}\text{cost}(\text{D2}(G'))$  credits at the start; the algorithm uses the credits to pay for the augmenting edges “bought” in steps (2.2) or (2.3) (see the outline); also, the algorithm may “sell” unit-edges of the current graph (i.e., such an edge is permanently discarded and is not contained in the 2-ECSS output by the algorithm).

The factor  $\frac{5}{3}$  in our approximation guarantee is tight in the sense that there exists an instance  $G$  of  $\text{MAP}\star$  such that  $\text{opt}(G)/\text{cost}(\text{D2}(G)) \geq \frac{5}{3} - \epsilon$ , for any small positive number  $\epsilon$ . The instance  $G$  consists of a root 2ec-block  $B_0$ , say a 6-cycle of cost 6,  $v_1, \dots, v_6, v_1$ , and  $\ell \gg 1$  copies of the following gadget that are attached to  $B_0$ . The gadget consists of a 6-cycle  $C = u_1, \dots, u_6, u_1$  of cost 3 that has alternating zero-edges and unit-edges; moreover, there are three unit-edges between  $C$  and  $B_0$ :  $v_1u_1, v_3u_3, v_5u_5$ . Observe that a (feasible) 2-edge cover of this instance consists of  $B_0$  and the 6-cycle  $C$  of each copy of the gadget, and it has cost  $6 + 3\ell$ . Observe that for any 2-ECSS and for each copy of the gadget, the six edges of  $C$  as well as (at least) two of the edges between  $C$  and  $B_0$  are contained in the 2-ECSS. Thus,  $\text{opt}(G) \geq 6 + 5\ell$ , whereas  $\text{cost}(\text{D2}(G)) \leq 6 + 3\ell$ .

#### 4 Pre-processing

Due to space constraints, we only state our main result for pre-processing and skip several lemmas that are needed to prove this result. These lemmas and their proofs are given in the full paper, [3].

► **Theorem 13.** *Suppose that there is an approximation algorithm that given an instance  $H$  of  $\text{MAP}\star$ , finds a 2-ECSS of cost  $\leq \max(\text{opt}(H), \alpha \text{opt}(H) - 2)$ . Then, given an instance  $G$  of MAP, there is a polynomial-time algorithm to find a 2-ECSS of cost  $\leq \max(\text{opt}(G), \alpha \text{opt}(G) - 2)$ .*

**5 Bridge covering**

The results in this section are based on the prior results and methods of [2, 8], but the goal in these previous papers is to obtain an approximation guarantee of  $\frac{7}{4}$  for MAP, whereas our goal is an approximation guarantee of  $\frac{5}{3}$ . Our credit invariant is presented in Section 5.1 below, and it is based on the credit invariant in [8].

In this section and in Section 6, we assume that the input is an instance of MAP $\star$ . For notational convenience, we denote the input by  $G$ . Recall that  $G$  is a simple, 2NC graph on  $\geq 12$  nodes, and  $G$  has no zero-cost S2, no unit-cost S2, no  $S\{3, 4\}$ , no R4, and no R8. Recall that a 2ec-block is called small if it has  $\leq 2$  unit-edges, and is called large otherwise. Since  $G$  is 2NC and simple, a small 2ec-block is either a 3-cycle with one zero-edge and two unit-edges, or a 4-cycle with alternating zero-edges and unit-edges.

Each unit-edge  $e$  of D2 starts with  $\frac{5}{3}$  tokens, and from this, one unit is kept aside (to pay for  $e$ ), and the other  $\frac{2}{3}$  is defined to be the credit of  $e$ . Our overall goal is to find a 2-ECSS  $H'$  of  $G$  of cost  $\leq \frac{5}{3}\text{cost}(D2)$ , and we keep  $\frac{2}{3}\text{cost}(D2)$  from our budget in the form of credit while using the rest of our budget for “buying” the unit-edges of D2. We use the credit for “buying” unit-edges that are added to our current graph during the bridge covering step or the gluing step. (In the gluing step, we may “sell” unit-edges of our current graph, that is, we may permanently discard some unit-edges of our current graph; thus, our overall budgeting scheme does not rely solely on credits.)

We use  $H$  to denote the current graph of the bridge covering step; initially,  $H = D2$ .

The outcome of the bridge covering step is stated in the following result.

► **Proposition 14.** *At the termination of the bridge covering step,  $H$  is a bridgeless 2-edge cover; moreover, every small 2ec-block of  $H$  has  $\geq \frac{4}{3}$  credits and every large 2ec-block of  $H$  has  $\geq 2$  credits. The bridge covering step can be implemented in polynomial time.*

■ **Figure 1** Illustration of an iteration of our bridge-covering step. Solid lines indicate edges of the graph  $H$ , and (blue) dash-dotted lines indicate edges of  $E(G) - E(H)$ . The pseudo-ear  $R, f_1, C_1, f_2, C_2, f_3$  covers the bridge  $ru$  of  $C_0$  (right subfigure). Thick lines indicate the edges  $f_1, f_2, f_3$  of the pseudo-ear.

A brief overview of the bridge covering step follows: The goal is to add “new” edges to  $H$  to obtain a bridgeless 2-edge cover, and to pay for these “new” edges from credits available in  $H$  while preserving a credit invariant (stated below). In each iteration, we pick a connected component  $C_0$  of  $H$  such that  $C_0$  has a bridge, then we pick any pendant 2ec-block  $R$  of  $C_0$ , then we add a set of edges  $\{f_1, \dots, f_k\} \subseteq E(G) - E(H)$  that “covers” the unique bridge of  $C_0$  incident to  $R$  (possibly,  $k = 1$ ). Informally speaking, this step merges  $k - 1$  connected components  $C_1, C_2, \dots, C_{k-1}$  of  $H$  with  $C_0$  (see the discussion below). Each

connected component of  $H$  has one unit of so-called c-credit (by the credit invariant stated below), and we take this credit from each of  $C_1, C_2, \dots, C_{k-1}$  and use that to pay for  $k-1$  of the newly added edges. The challenge is to find one more unit of credit (since we added  $k$  edges), and this is the focus of our analysis given below.

By [2, Section 5.1, Proposition 5.20], we may assume without loss of generality that D2 has the following properties:

(\*) D2 contains all the zero-edges. Every pendant 2ec-block of D2 that is incident to a zero-bridge is a large 2ec-block.

Recall that  $H$  denotes the current graph, and initially,  $H = \text{D2}$ . We call a node  $v$  of  $H$  a *white* node if  $v$  belongs to a 2ec-block of  $H$ , otherwise, we call  $v$  a *black* node.

It is convenient to define the following multi-graphs: let  $\tilde{H}$  be the multi-graph obtained from  $H$  by contracting each 2ec-block  $B_i$  of  $H$  into a single node that we will denote by  $B_i$ . Observe that each connected component of  $\tilde{H}$  is a tree (possibly, an isolated node). We call a node  $v$  of the multigraph  $\tilde{H}$  black if it is the image of a black node of  $H$ , otherwise, we call  $v$  a white node. Each 2ec-block of  $H$  maps to a white node of  $\tilde{H}$ . Each bridge of  $H$  maps to a bridge of  $\tilde{H}$ . Clearly, each black node of  $\tilde{H}$  is incident to  $\geq 2$  bridges of  $\tilde{H}$ .

Similarly, let  $\tilde{G}$  be the multi-graph obtained from  $G$  by contracting each 2ec-block  $B_i$  of  $H$  into a single node.

## 5.1 Credit invariant

We re-assign the credits of D2 such that the following credit invariant holds for  $H$  at the start/end of every iteration in the bridge covering step.

For a black node  $v$  of  $H$ , we use  $\deg_H^{(1)}(v)$  to denote the number of unit-bridges incident to  $v$  in  $H$ .

### Credit invariant for $H$

- (a) each connected component is assigned at least one credit (called c-credit);
- (b) each connected component that is a small 2ec-block is assigned  $\frac{1}{3}$  credits (called b-credit);
- (c) every other 2ec-block is assigned at least one credit (called b-credit);
- (d) each black node  $v$  is assigned  $\frac{1}{3} \deg_H^{(1)}(v)$  credits (called n-credit).

Note that the four types of credit are distinct, and the invariant gives lower bounds. For example, a connected component that is a large 2ec-block has one c-credit and at least one b-credit.

► **Lemma 15.** *The initial credits of D2 can be re-assigned such that (the initial)  $H = \text{D2}$  satisfies the credit invariant.*

## 5.2 Analysis of a pseudo-ear augmentation

In this subsection, our goal is to show that a so-called pseudo-ear augmentation can be applied to  $H$  whenever a connected component of  $H$  has a bridge, such that the cost of the newly added unit-edges is paid from the credits released by the pseudo-ear augmentation, and moreover, the credit invariant is preserved.

In the graph  $H$ , let  $C_0$  be a connected component that has a bridge, let  $R$  be a pendant 2ec-block of  $C_0$ , and let  $ru$  be the unique bridge (of  $C_0$ ) incident to  $R$ , where  $r \in V(R)$ .

► **Definition 16.** A pseudo-ear of  $H$  w.r.t.  $C_0$  starting at  $R$  is a sequence  $R, f_1, C_1, f_2, C_2, \dots, f_{k-1}, C_{k-1}, f_k$ , where  $C_0, C_1, \dots, C_{k-1}$  are distinct connected components of  $H$ ,  $f_1, \dots, f_k \in E(G) - E(H)$ , each  $f_i, i \in [k-1]$ , has one end node in  $C_{i-1}$  and the other end node in  $C_i$ ,  $f_1$  has an end node in  $R$ , and  $f_k$  has one end node in  $C_{k-1}$  and one end node in  $C_0 - V(R)$ . The end node of  $f_k$  in  $C_0 - V(R)$  is called the head node of the pseudo-ear.

Any shortest (w.r.t. the number of edges) path of  $C_0$  between  $r$  and the head node of the pseudo-ear is called the witness path of the pseudo-ear.

Our plan is to find a pseudo-ear (as above) such that for any witness path  $Q$ , there is at least one unit of credit in  $Q - r$ . Let  $R^{new}$  denote the 2ec-block that results from the addition of the pseudo-ear; thus,  $R^{new}$  contains  $R \cup Q$ . The b-credit of  $R$  is transferred to  $R^{new}$ ; thus,  $R^{new}$  satisfies part (c) of the credit invariant; see Proposition 19 below. After we add the pseudo-ear to  $H$ , the credits of  $Q - r$  are released (they are no longer needed for preserving the credit invariant, because  $Q \cup R$  is merged into  $R^{new}$ ). Informally speaking, we use the credits released from  $Q - r$  to pay for the cost of the last unit-edge added by the pseudo-ear augmentation.

In the graph  $\tilde{G}$ , let  $\tilde{C}_0$  denote the tree corresponding to  $C_0$  and let  $\tilde{R}$  denote the leaf of  $\tilde{C}_0$  corresponding to  $R$ . Let  $\tilde{P}$  be a shortest (w.r.t. the number of edges) path of  $\tilde{G} - E(\tilde{C}_0)$  that has one end node at  $\tilde{R}$  and the other end node at another node of  $\tilde{C}_0$ . Then  $\tilde{P}$  corresponds to a pseudo-ear  $R, f_1, C_1, \dots, C_{k-1}, f_k$ ; the sequence of edges of  $E(\tilde{G}) - E(\tilde{H})$  of  $\tilde{P}$  corresponds to  $f_1, \dots, f_k$  and the sequence of trees  $\tilde{C}_1, \dots, \tilde{C}_{k-1}$  of  $\tilde{P}$  corresponds to  $C_1, \dots, C_{k-1}$ .

It is easy to find a pseudo-ear such that any witness path  $Q$  has  $\geq 2$  edges. To see this, observe that  $G - u$  is connected (since  $G$  is 2NC); let  $P$  be a shortest (w.r.t. the number of edges) path between  $R$  and  $C_0 - V(R)$  in  $G - u$ ; then  $P$  corresponds to our desired pseudo-ear, and the head node is the end node of  $P$  in  $C_0 - u - V(R)$ . Clearly, any path of  $C_0$  between  $r$  and the head node has  $\geq 2$  edges, hence, any witness path of the pseudo-ear has  $\geq 2$  edges.

In each iteration (of bridge covering), we compute a pseudo-ear using a polynomial-time algorithm that is presented in the proof of Proposition 18, see below.

The next lemma is used to lower bound the credit of a witness path.

► **Lemma 17.** Let  $\Psi$  be a pseudo-ear of  $H$  w.r.t.  $C_0$  starting at  $R$ , let  $Q$  be a witness path of  $\Psi$ , and let  $ru$  be unique bridge of  $C_0$  incident to  $R$ . Suppose that  $Q$  satisfies one of the following:

- (a)  $Q$  contains a white node distinct from  $r$ , or
- (b)  $Q$  contains exactly one white node and  $\geq 3$  bridges, or
- (c)  $Q$  contains exactly one white node, exactly two bridges, and a black node  $v$  such that  $\deg_H^{(1)}(v) \geq 2$ .

Then  $Q - r$  has at least one credit, and that credit is not needed for the credit invariant of the graph resulting from the pseudo-ear augmentation that adds  $\Psi$  to  $H$ .

► **Proposition 18.** There is a polynomial-time algorithm for finding a pseudo-ear (of  $H$  w.r.t.  $C_0$  starting at  $R$ ) such that any witness path  $Q$  of the pseudo-ear satisfies one of the three conditions of Lemma 17.

► **Proposition 19.** Suppose that  $H$  satisfies the credit invariant, and a pseudo-ear augmentation is applied to  $H$ . Then the resulting graph  $H^{new}$  satisfies the credit invariant.

**Proof of Proposition 14.** The proof follows from Lemmas 15, 17, and Propositions 18, 19, and the preceding discussion.

Each iteration, i.e., each pseudo-ear augmentation, can be implemented in polynomial time, and the number of iterations is  $\leq |E(D2)|$ .

At the termination of bridge covering, each connected component of  $H$  is a 2ec-block that has one c-credit and either one b-credit, or (in the case of a small 2ec-block)  $\frac{1}{3}$  b-credits. By summing the two types of credit, it follows that each small 2ec-block has  $\frac{4}{3}$  credits and each large 2ec-block has  $\geq 2$  credits. ◀

## 6 The gluing step

In this section, we focus on the gluing step, and we assume that the input is an instance of MAP $\star$ . For notational convenience, we denote the input by  $G$ . Recall that  $G$  is a simple, 2NC graph on  $\geq 12$  nodes, and  $G$  has no zero-cost S2, no unit-cost S2, no S{3, 4}, no R4, and no R8. (In this section, we use all the properties of  $G$  except the absence of unit-cost S2s.)

There are important differences between our gluing step and the gluing step of [2]. Our gluing step (and overall algorithm) beats the  $\frac{7}{4}$  approximation threshold because our pre-processing step eliminates the S{3, 4} obstruction and the R8 obstruction (these obstructions are not relevant to other parts of our algorithm). In the full version of the paper, see [3, Appendix], we present instances  $G$  of MAP that contain S{3, 4}s (respectively, R8s) and contain none of the other six obstructions such that  $\text{opt}(G)/\text{cost}(D2(G)) \approx \frac{7}{4}$ .

We use  $H$  to denote the current graph of the gluing step. At the start of the gluing step,  $H$  is a simple, bridgeless graph of minimum degree two; thus, each connected component of  $H$  is 2EC; clearly, the 2ec-blocks of  $H$  correspond to the connected components of  $H$ . Recall that a 2ec-block of  $H$  is called small if it has  $\leq 2$  unit-edges, and is called large otherwise. Observe that a small 2ec-block of  $H$  is either a 3-cycle with one zero-edge and two unit-edges, or a 4-cycle with alternating zero-edges and unit-edges.

The following result summarizes this section:

► **Proposition 20.** *At the termination of the bridge-covering step, let  $H$  denote the bridgeless 2-edge cover computed by the algorithm and suppose that each small 2ec-block of  $H$  has  $\frac{4}{3}$  credits and each large 2ec-block of  $H$  has  $\geq 2$  credits. Let  $\gamma$  denote  $\text{credit}(H)$ . Assume that  $H$  contains all zero-edges. Then the gluing step augments  $H$  to a 2-ECSS  $H'$  of  $G$  (by adding edges and deleting edges) such that  $\text{cost}(H') \leq \text{cost}(H) + \gamma - 2$ . The gluing step can be implemented in polynomial time.*

Our gluing step applies a number of iterations. Each iteration picks two or more 2ec-blocks of  $H$ , and merges them into a new large 2ec-block by adding some unit-edges and possibly deleting some unit-edges such that the following invariant holds for  $H$  at the start/end of every iteration of the gluing step.

### Invariants for the gluing step:

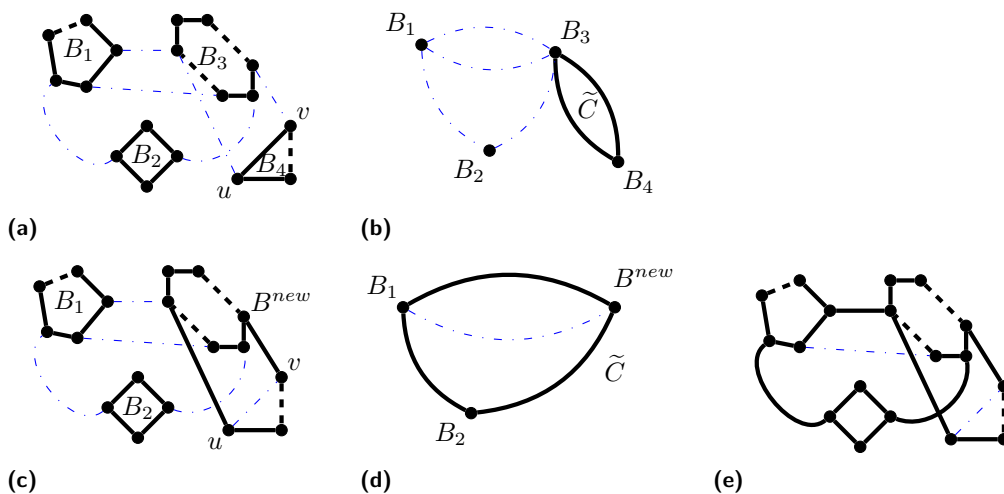

- $H$  is a simple, bridgeless graph of minimum degree two (hence, the 2ec-blocks of  $H$  correspond to the connected components of  $H$ );
- (credit invariant) each small 2ec-block of  $H$  has  $\frac{4}{3}$  credits and each large 2ec-block of  $H$  has  $\geq 2$  credits.

It is convenient to define the following multi-graph: let  $\tilde{G}$  be the multi-graph obtained from  $G$  by contracting each 2ec-block  $B_i$  of  $H$  into a single node that we will denote by  $B_i$  (thus, the notation  $B_i$  refers to either a 2ec-block of  $H$  or a node of  $\tilde{G}$ ). Observe that  $\tilde{G}$  is 2EC. We call a node of  $\tilde{G}$  small (respectively, large) if the corresponding 2ec-block of  $H$  is

small (respectively, large). The gluing step “operates” on  $G$  and never refers to  $\tilde{G}$ ; but, for our discussions and analysis, it is convenient to refer to  $\tilde{G}$ . (Note that  $\tilde{G}$  changes in each iteration, since the current graph  $H$  changes in each iteration.)

Suppose that  $\tilde{G}$  has  $\geq 2$  nodes and has no small nodes. Then, we pick any (large) node  $\tilde{v}$  of  $\tilde{G}$ . Since  $\tilde{G}$  is 2EC, it has a cycle  $\tilde{C}$  incident to  $\tilde{v}$ . Let  $|\tilde{C}|$  denote the number of edges of  $\tilde{C}$ ; note that  $|\tilde{C}| \geq 2$ . Our iteration adds to  $H$  the unit-edges corresponding to  $\tilde{C}$ . The credit available in  $H$  for the 2ec-blocks incident to  $\tilde{C}$  is  $\geq 2|\tilde{C}|$  and the cost of the augmentation is  $|\tilde{C}|$ ; hence, we have surplus credit of  $2|\tilde{C}| - |\tilde{C}| \geq 2$ . The surplus credit is given to the new large 2ec-block. Clearly, the credit invariant is preserved.

In general, small nodes may be present in  $\tilde{G}$ . If we apply the above scheme and find a cycle  $\tilde{C}$  incident only to small nodes with  $|\tilde{C}| \leq 5$ , then we fail to maintain the credit invariant (since only  $|\tilde{C}|/3$  credits are available for the new large 2ec-block). Consider a special case when  $\tilde{G}$  has a small node  $\mathcal{A}$  that has a unique neighbour  $B$  and  $B$  is large; clearly, there are  $\geq 2$  parallel edges between  $\mathcal{A}$  and  $B$ . Below, we show that  $\mathcal{A}$  and  $B$  can be merged to form a new large 2ec-block using an augmentation of net cost one, rather than two, by deleting one or more unit-edges of  $\mathcal{A}$ ; then we have surplus credit  $\geq 2$  for the new large 2ec-block. For example, if  $\mathcal{A}$  is a 3-cycle of  $H$ , then there exists a unit-edge  $uw$  of  $\mathcal{A}$  such that  $G$  has edges  $uv_1$  and  $wv_2$  where  $v_1, v_2 \in B$ ; so the augmentation adds the unit-edges  $uv_1$  and  $wv_2$  to  $H$  and discards  $uw$  from  $H$ .

■ **Figure 2** Two iterations of our gluing step are illustrated. At each iteration, solid lines indicate unit-edges of  $H$ , dashed lines indicate zero-edges of  $H$ , and (blue) dash-dotted lines indicate edges of  $E(G) - E(H)$ . Subfigures (a), (b) show Iteration 1. (a) The input graph  $G$  and a bridgeless 2-edge cover  $H$  of  $G$ . (b) The graph  $\tilde{G}$  of the graphs  $G, H$  in (a). The small node  $B_4$  has a unique neighbour  $B_3$  which is large. The first iteration augments via  $\tilde{C} = B_4, B_3, B_4$ . Subfigures (c), (d) show Iteration 2. (c) The graphs  $G$  and  $H$  after the first iteration.  $B_3$  and  $B_4$  have been merged to form  $B^{new}$  by adding two unit-edges to  $H$  and deleting the unit-edge  $uw$  from  $H$ . (d) The graph  $\tilde{G}$  of the graphs  $G, H$  in (c). All nodes of  $\tilde{G}$  are large. The second iteration augments via  $\tilde{C} = B_1, B_2, B^{new}, B_1$ . Subfigure (e) shows the output 2-ECSS of our gluing step.

We present key definitions and results on small 2ec-blocks in Section 6.1. Our algorithm for the gluing step is presented in Section 6.2.

### 6.1 Analysis of small 2ec-blocks

In this subsection, we focus on the small 2ec-blocks of  $H$  and we present the definitions and results that underlie our algorithm for the gluing step. Recall that  $G$  has  $\geq 12$  nodes.

■ **Figure 3** Illustrations of swappable edges and swappable pairs of small 2ec-blocks. Solid lines indicate unit-edges of  $H$ , dashed lines indicate zero-edges of  $H$ , and (blue) dash-dotted lines indicate edges of  $E(G) - E(H)$ . (a) The 2ec-block  $B_1$  has a swappable edge  $uv$ , and the 2ec-block  $B_2$  has a swappable pair  $\{x, y\}$ . (b) The 2ec-block  $B_1$  has two swappable edges:  $uv$  is good, and  $vw$  is bad. The swappable pair  $\{x, y\}$  of the 2ec-block  $B_2$  is good.

► **Definition 21.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . A unit-edge  $uw$  of  $\mathcal{A}$  is called *swappable* if both  $u$  and  $w$  are attachments of  $\mathcal{A}$  in  $G$  (that is,  $G$  has an edge  $ux$  where  $x \in V(G) - \mathcal{A}$  and  $G$  has an edge  $wy$  where  $y \in V(G) - \mathcal{A}$ ).

► **Definition 22.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . A pair of nodes  $\{u, w\}$  of  $\mathcal{A}$  is called a *swappable pair* if either (i)  $uw$  is a swappable edge of  $\mathcal{A}$ , or (ii) both  $u$  and  $w$  are attachments of  $\mathcal{A}$  in  $G$ ,  $u, w$  are not adjacent in  $\mathcal{A}$  (note that  $\mathcal{A}$  is a 4-cycle in this case), and the other two nodes of  $\mathcal{A}$  are adjacent in  $G$  (that is,  $E(G) - E(H)$  has a “diagonal edge” between the other two nodes of  $\mathcal{A}$ ).

► **Definition 23.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . A swappable pair  $\{u, w\}$  of  $\mathcal{A}$  is called *good* if there are distinct 2ec-blocks  $B_u$  and  $B_w$  ( $\mathcal{A} \neq B_u \neq B_w \neq \mathcal{A}$ ) such that  $G$  has an edge  $ux$  where  $x \in B_u$  and  $G$  has an edge  $wy$  where  $y \in B_w$ ; otherwise,  $\{u, w\}$  is called a *bad swappable pair* of  $\mathcal{A}$ . A *good* (respectively, *bad*) *swappable edge* of  $\mathcal{A}$  is defined similarly.

► **Remark 24.** Observe that each iteration merges two or more 2ec-blocks of  $H$  (see the discussion following Proposition 20). Consider a small 2ec-block  $\mathcal{A}$  of  $H$  that stays unchanged over several iterations. After one of these iterations, a swappable pair  $\{u, w\}$  of  $\mathcal{A}$  may change from good to bad, but  $\{u, w\}$  cannot change from bad to good.

► **Lemma 25.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . If  $\mathcal{A}$  is adjacent (in  $G$ ) to a unique 2ec-block  $B$ , then  $B$  is large. (That is, if there is 2ec-block  $B$  such that  $\Gamma_G(V(\mathcal{A})) \subseteq V(B)$ , then  $B$  is large.)

► **Lemma 26.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . Then  $\mathcal{A}$  has at least one swappable pair. Moreover, if  $\mathcal{A}$  is a 3-cycle, then  $\mathcal{A}$  has at least one swappable edge.

► **Lemma 27.** Let  $\mathcal{A}$  be a small 2ec-block of  $H$ . If  $\mathcal{A}$  is a 3-cycle, and  $\mathcal{A}$  is adjacent (in  $G$ ) to at least two other 2ec-blocks, then it has a good swappable edge.

Suppose that the current graph  $H$  has no good swappable pairs, that is, for every small 2ec-block  $\mathcal{A}$  of  $H$ , every swappable pair of  $\mathcal{A}$  is bad. To “merge away” the remaining small 2ec-blocks of  $H$ , we construct the following auxiliary digraph  $D^{aux}$ : there is a node for each 2ec-block of  $H$ , and we call the nodes corresponding to the small 2ec-blocks the *red* nodes, and the other nodes the *green* nodes; for each small 2ec-block  $\mathcal{A}$  of  $H$  and each of its swappable pairs  $\{u, w\}$ ,  $D^{aux}$  has an arc  $(\mathcal{A}, B)$  where  $B$  corresponds to the unique 2ec-block  $B$  of  $H$  such that  $\Gamma_G(\{u, w\}) \subseteq V(B) \cup V(\mathcal{A})$ . Observe that each red node of  $D^{aux}$  has at least one outgoing arc.

► **Lemma 28.** *Suppose that there exist no good swappable pairs. Then,  $D^{aux}$  does not have a pair of red nodes  $\mathcal{A}_1, \mathcal{A}_2$  such that  $(\mathcal{A}_1, \mathcal{A}_2)$  is the unique outgoing arc of  $\mathcal{A}_1$  and  $(\mathcal{A}_2, \mathcal{A}_1)$  is the unique outgoing arc of  $\mathcal{A}_2$  (that is, if  $D^{aux}$  has a directed 2-cycle  $C$  on the red nodes, then one of the red nodes incident to  $C$  has  $\geq 2$  outgoing arcs).*

By the above lemma,  $D^{aux}$  either has an arc  $(\mathcal{A}, B)$  from a red node  $\mathcal{A}$  to a green node  $B$ , or it has a directed path  $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3$  on three red nodes. In both cases, we can apply a merge step to obtain a new large 2ec-block (i.e., a green node) while preserving the credit invariant. More details are presented in the next subsection.

## 6.2 Algorithm for the gluing step

In this subsection, we explain the working of the algorithm for the gluing step, based on the results in the previous subsection.

Consider any small 2ec-block  $\mathcal{A}$  that has a good swappable pair  $\{u, w\}$  such that  $u$  is adjacent (in  $G$ ) to another 2ec-block  $B_u$ , and  $w$  is adjacent (in  $G$ ) to another 2ec-block  $B_w$ , and  $\mathcal{A} \neq B_u \neq B_w \neq \mathcal{A}$ . Observe that  $G - V(\mathcal{A})$  is connected, otherwise,  $\mathcal{A}$  would be an  $S\{3, 4\}$  of  $G$  (the arguments in the proof of Lemma 25 can be used to verify this statement). Hence,  $\tilde{G} - \mathcal{A}$  has a path between  $B_u$  and  $B_w$ ; adding the edges  $\mathcal{A}B_u$  and  $\mathcal{A}B_w$  to this path gives a cycle  $\tilde{C}$  of  $\tilde{G}$ . We merge the 2ec-blocks incident to  $\tilde{C}$  into a new large 2ec-block by adding the unit-edges corresponding  $\tilde{C}$  to  $H$ . Moreover, if  $uw \in E(\mathcal{A})$ , then we discard  $uw$  from  $H$ , otherwise,  $\mathcal{A}$  is a 4-cycle (with two zero-edges) and  $E(G) - E(H)$  has a unit-edge  $f$  between the two nodes of  $\mathcal{A} - \{u, w\}$ , and in this case, we add the edge  $f$  to  $H$  and we discard the two unit-edges of  $\mathcal{A}$  from  $H$ . The credit available in  $H$  for  $\tilde{C}$  is  $\geq \frac{4}{3}|\tilde{C}|$  and the net cost of the augmentation is  $|\tilde{C}| - 1$ ; hence, we have surplus credit of  $\frac{1}{3}|\tilde{C}| + 1 \geq 2$  (since  $|\tilde{C}| \geq 3$ ). The surplus credit is given to the new large 2ec-block.

The gluing step applies the above iteration until there are no good swappable pairs in the current graph  $H$ . Then the auxiliary digraph  $D^{aux}$  is constructed. By Lemma 28,  $D^{aux}$  has either (i) an arc  $(\mathcal{A}, B)$  from a red node  $\mathcal{A}$  to a green node  $B$ , or (ii) a directed path  $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3$  on three red nodes.

In the first case,  $\mathcal{A}$  is a small 2ec-block,  $B$  is a large 2ec-block, and  $\mathcal{A}$  has a swappable pair  $\{u, w\}$  such that  $\mathcal{A} \cup B$  contains all neighbours (in  $G$ ) of  $\{u, w\}$ . We merge  $\mathcal{A}$  and  $B$  into a new large 2ec-block as follows. We add two unit-edges between  $\mathcal{A}$  and  $B$  to  $H$  (one edge is incident to  $u$  and the other edge is incident to  $w$ ). Moreover, if  $uw \in E(\mathcal{A})$ , then we discard  $uw$  from  $H$ , otherwise,  $\mathcal{A}$  is a 4-cycle (with two zero-edges) and  $E(G) - E(H)$  has a unit-edge  $f$  between the two nodes of  $\mathcal{A} - \{u, w\}$ , and in this case, we add the edge  $f$  to  $H$  and we discard the two unit-edges of  $\mathcal{A}$  from  $H$ . The credit available in  $H$  for  $\mathcal{A} \cup B$  is  $\geq \frac{4}{3} + 2$  and the net cost of the augmentation is one; hence, we have surplus credit of  $\frac{1}{3} + 2 \geq 2$ . The surplus credit is given to the new large 2ec-block. Consider the second case. Then  $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3$  are small 2ec-blocks such that  $\mathcal{A}_1$  has a swappable pair  $u_1 w_1$  such that  $\Gamma_G(\{u_1, w_1\}) \subseteq V(\mathcal{A}_1) \cup V(\mathcal{A}_2)$ , and  $\mathcal{A}_2$  has a swappable pair  $u_2 w_2$  such that  $\Gamma_G(\{u_2, w_2\}) \subseteq V(\mathcal{A}_2) \cup V(\mathcal{A}_3)$ . We add two unit-edges between  $\mathcal{A}_1$  and  $\mathcal{A}_2$  to  $H$  (one edge is incident to  $u_1$  and the other edge is incident to  $w_1$ ), and then we either discard one unit-edge from  $H$  (if  $u_1 w_1 \in E(\mathcal{A}_1)$ ) or we add another

edge to  $H$  and discard two unit-edges of  $\mathcal{A}_1$  from  $H$  (if  $u_1w_1 \notin E(\mathcal{A}_1)$ ). We apply a similar augmentation to  $\mathcal{A}_2$  and  $\mathcal{A}_3$  using the swappable pair  $\{u_2, w_2\}$ . The credit available in  $H$  for  $\mathcal{A}_1 \cup \mathcal{A}_2 \cup \mathcal{A}_3$  is  $\geq (3 \cdot \frac{4}{3}) = 4$  and the net cost of the augmentation is two; hence, we have surplus credit of  $\geq 4 - 2$ . The surplus credit is given to the new large 2ec-block.

By repeatedly applying the above iteration (that merges red nodes of  $D^{aux}$  into green nodes), we obtain a current graph  $H$  that has no small 2ec-blocks. As discussed above, the merge step is straightforward when all 2ec-blocks of  $H$  are large.

► **Lemma 29.** *After every merge step, the subgraph  $B^{new}$  constructed by that step (that is a so-called large 2ec-block) is 2EC.*

---

## Abstract

Many public transportation systems are unable to keep up with growing passenger demand as the population grows in urban areas. The slow or lack of improvement for public transportation pushes people to use private transportation modes, such as carpooling and ridesharing. However, the occupancy rate of personal vehicles has been dropping in many cities. In this paper, we describe a centralized transit system that integrates public transit and ridesharing, which matches drivers and transit riders such that the riders would result in shorter travel time using both transit and ridesharing. The optimization goal of the system is to assign as many riders to drivers as possible for ridesharing. We give an exact approach and approximation algorithms to achieve the optimization goal. As a case study, we conduct an extensive computational study to show the effectiveness of the transit system for different approximation algorithms, based on the real-world traffic data in Chicago City; the data sets include both public transit and ridesharing trip information. The experiment results show that our system is able to assign more than 60% of riders to drivers, leading to a substantial increase in occupancy rate of personal vehicles and reducing riders' travel time.

## 1 Introduction

As the population grows in urban areas, commuting between and within large cities is time-consuming and resource-demanding. Due to growing passenger demand, the number of vehicles on the road for both public and private transportation has increased to handle the demand. Public transportation systems are unable to keep up with the demand in terms of service quality. This pushes people to use personal vehicles for work commute. In the United States, personal vehicles are the main transportation mode [6]. However, the occupancy rate of personal vehicles in the U.S. is 1.6 persons per vehicle in 2011 [12, 24] (and decreased to 1.5 persons per vehicle in 2017 [6]), which can be a major cause for congestion and pollution. This is the reason municipal governments encourage the use of public transit; the major drawback of public transit is the inconvenience of last mile and/or first mile transportation compared to personal vehicles [28]. With the increasing popularity in ridesharing/ridehailing service, there may be potential in integrating private and public transportation. From the research report of [9], it is recommended that public transit agencies should build on mobility innovations to allow public-private engagement in ridesharing because the use of shared

modes increases the likelihood of using public transit. As pointed out by Ma et al. [20], some basic form of collaboration between MoD (mobility-on-demand) services and public transit already exists (for first and last mile transportation). There is an increasing interest for collaboration between private companies and public sector entities [22].

The sparseness of transit networks usually is the main cause of the inconvenience in public transit. Such transit networks have infrequent transit schedule and can cause customers to have multiple transfers. In this paper, we investigate the potential effectiveness of integrating public transit with ridesharing to increase ridership in such sparse transit networks and reduce traffic congestion for work commute (not very short trips). For example, people who drive their vehicles to work can pick-up *riders*, who use public transit regularly, at designated locations and drop-off them at some transit stops, and then those riders can take public transit to their destinations. In this way, riders are presented with a cheaper alternative than ridesharing for the entire trip, and it is more convenient than using public transit only. The transit system also gets a higher ridership, which matches the recommendation of [9] for a more sustainable transportation system. Our research focuses on a centralized system that is capable of matching drivers and riders satisfying their trips' requirements while achieving some optimization goal; the requirements of a trip may include an origin and a destination, time constraints, capacity of a vehicle, and so on. When a rider is assigned a driver, we call this *ridesharing route*, and it is compared with the fastest *public transit route* for this rider which uses only public transit. If the ridesharing route is faster than the public transit route, the ridesharing route is provided to both the rider and driver. To increase the number of rider participants, our system-wide optimization goal is to maximize the number of riders, each of whom is assigned a ridesharing route. We call this the *maximization problem* (formal definition in Section 2).

In the literature, there are many papers about standalone ridesharing/carpooling, from theoretical to empirical studies (e.g., [1, 4, 14, 29]). For literature reviews on ridesharing, readers are referred to [2, 10, 21, 27]. On the other hand, there are only few papers study the integration of public transit with dynamic ridesharing. Aissat and Varone [3] and Huang et al. [17] proposed approaches which find a route with ridesharing that substitutes part of a public transit route for each rider in the first-come first-serve basis (system-wide optimization goal is not considered). Ma [19] and Stiglic et al. [26] proposed models to integrate ridesharing and public transit as graph matching problems to achieve system-wide optimization goals; their approaches are similar, except the work in [26] supports more rideshare match types. The graph matching problems in [19, 26] are formulated as integer linear program (ILP) and solved by standard branch and bound (CPLEX). The optimization goal in [19] is to minimize the cost related to waiting time and travel time, but ridesharing routes are not guarantee to be better than transit route. Although the optimization goal in [26] aligns with ours, there are some limitations in their approach; they limit at most two riders for each rideshare match, each rider must travel to the transit stop that is closest to the rider's destination, and more importantly, ridesharing routes assigned to riders can be longer than public transit routes.

In this paper, we use a similar model as in [19, 26]. We extend the work in [26] to eliminate the limitations described above and give approximation algorithms for the optimization problem to ensure solution quality. Our discrete algorithms allow to control the trade-off between quality and computational time. Our main contributions are summarized as follows:

1. We give an exact algorithm approach (an ILP formulation based on a hypergraph representation) for integrating public transit and ridesharing.
2. We prove our maximization problem is NP-hard and give a 2-approximation algorithm for the problem. We show that previous  $O(k)$ -approximation algorithms [5, 7] for the  $k$ -set packing problem are 2-approximation algorithms for our maximization problem. Our algorithm is more time and space efficient than previous algorithms.

3. As a case study, we conduct an extensive numerical study based on real-life data in Chicago City to evaluate the potential of having an integrated transit system and the effectiveness of different approximation algorithms.

The rest of the paper is organized as follows. In Section 2, we give the preliminaries of the paper, describe a centralized system that integrates public transit and ridesharing, and define the maximization problem. In Section 3, we describe our exact algorithm approach. We then propose approximation algorithms in Section 4. We discuss our numerical experiments and results in Section 5. Finally, Section 6 concludes the paper.

## 2 Problem definition and preliminaries

In the problem *multimodal transportation with ridesharing* (MTR), we have a centralized system, and for every fixed time interval, the system receives a set  $\mathcal{A} = D \cup R$  of trips with  $D \cap R = \emptyset$ , where  $D$  is the set of driver trips and  $R$  is the set of rider trips. Each trip is expressed by an integer label  $i$  and consists of an individual, a vehicle (for driver trip) and some requirements. A connected public transit network with a fixed timetable  $T$  is given. We assume that for any source  $o$  and destination  $d$  in the public transit network,  $T$  gives the fastest travel time from  $o$  to  $d$ . A *ridesharing route*  $\pi_i$  for a rider  $i \in R$  is a travel plan using a combination of public transportation and ridesharing to reach  $i$ 's destination satisfying  $i$ 's requirements, whereas a *public transit route*  $\hat{\pi}_i$  for a rider  $i$  is a travel plan using only public transportation. The multimodal transportation with ridesharing problem asks to provide at least one feasible route ( $\pi_i$  or  $\hat{\pi}_i$ ) for every rider  $i \in R$ . We denote an instance of multimodal transportation with ridesharing problem by  $(N, \mathcal{A}, T)$ , where  $N$  is an edge-weighted directed graph (network) for both private and public transportation. We call a public transit station or stop just *station*. The terms rider and passenger are used interchangeably (although passenger emphasizes a rider has been provided with a ridesharing route).

The requirements of each trip  $i$  in  $\mathcal{A}$  are specified by  $i$ 's parameters submitted by the individual. The parameters of a trip  $i$  contain an origin location  $o_i$ , a destination location  $d_i$ , an earliest departure time  $\alpha_i$ , a latest arrival time  $\beta_i$  and a maximum trip time  $\gamma_i$ . A driver trip  $i$  also contains a capacity  $n_i$  of the vehicle, a limit  $\delta_i$  on the number of stops a driver wants to make to pick-up/drop-off passengers, and an optional path to reach its destination. The maximum trip time  $\gamma_i$  of a driver  $i$  includes a travel time from  $o_i$  to  $d_i$  and a detour time limit  $i$  can spend for offering ridesharing service. A rider trip  $i$  also contains an acceptance rate  $\theta_i$  for a ridesharing route  $\pi_i$ , that is,  $\pi_i$  is given to rider  $i$  if  $t(\pi_i) \leq \theta_i \cdot t(\hat{\pi}_i)$  for every public transit route  $\hat{\pi}_i$  and  $0 < \theta_i \leq 1$ , where  $t(\cdot)$  is the travel time. Such a route  $\pi_i$  is called an *acceptable ridesharing route* (acceptable route for brevity). For example, suppose the best public transit route  $\hat{\pi}_i$  takes 100 minutes for  $i$  and  $\theta_i = 0.9$ . An acceptable route  $\pi_i$  implies that  $t(\pi_i) \leq \theta_i \cdot t(\hat{\pi}_i) = 90$  minutes. We consider two match types for practical reasons.

- **Type 1 (rideshare-transit):** a driver may make multiple stops to pick-up different passengers, but makes only one stop to drop-off all passengers. In this case, the *pick-up locations* are the passengers' origin locations, and the *drop-off location* is a public station.
- **Type 2 (transit-rideshare):** a driver makes only one stop to pick-up passengers and may make multiple stops to drop-off all passengers. In this case, the *pick-up location* is a public station and the *drop-off locations* are the passengers' destination locations.

Riders and drivers specify one of the match types to participate in; they are allowed to choose both in hope to increase the chance being selected, but the system will assign them only one of the match types such that the optimization goal of the MTR problem is achieved, which is to assign acceptable routes to as many riders as possible. Formally, the **maximization problem** we consider is to maximize the number of passengers, each of whom is assigned an acceptable route  $\pi_i$  for every  $i \in R$ .

For a driver  $i$  and a set  $J \subseteq R$  of riders,  $\sigma(i) = \{i\} \cup J$  is called a *feasible match* if the routes for all trips of  $\sigma(i)$  satisfy the requirements (constraints) specified by the parameters of the trips collectively as listed below (a summary of notation and constraints can be found in [13], Section 3.2):

1. *Ridesharing route constraint*: for  $J = \{j_1, \dots, j_k\}$ , there is a path  $(o_i, o_{j_1}, \dots, o_{j_k}, s, d_i)$  in  $N$ , where  $s$  is the drop-off location for Type 1 match; or there is a path  $(o_i, s, d_{j_1}, \dots, d_{j_k}, d_i)$  in  $N$ , where  $s$  is the pick-up location for Type 2 match.
2. *Capacity constraint*:  $1 \leq |J| \leq n_i$ .
3. *Acceptable constraint*: each passenger  $j \in J$  is given an acceptable route  $\pi_j$  offered by  $i$ .
4. *Travel time constraint*: each trip  $j \in \sigma(i)$  departs from  $o_j$  no earlier than  $\alpha_j$ , arrives at  $d_j$  no later than  $\beta_j$ , and the total travel duration of  $j$  is at most  $\gamma_j$ .
5. *Stop constraint*: the number of unique locations visited by driver  $i$  to pick-up (for Type 1) or drop-off (for Type 2) all passengers of  $\sigma(i)$  is at most  $\delta_i$ .

Two feasible matches  $\sigma(i), \sigma(i')$  are *disjoint* if  $\sigma(i) \cap \sigma(i') = \emptyset$ . Then, the maximization problem considered is to find a set of pairwise disjoint feasible matches such that the number of passengers included in the feasible matches is maximized.

Intuitively, a rideshare-transit (Type 1) feasible match  $\sigma(i)$  is that all passengers in  $\sigma(i)$  are picked-up at their origins and dropped-off at a station, and then  $i$  drives to destination  $d_i$  while each passenger  $j$  of  $\sigma(i)$  takes transit to destination  $d_j$ . A transit-rideshare (Type 2) feasible match  $\sigma(i)$  is that all passengers in  $\sigma(i)$  are picked-up at a station and dropped-off at their destinations, and then  $i$  drives to destination  $d_i$  after dropping the last passenger. We give algorithms to find pairwise disjoint feasible matches to maximize the number of passengers included in the matches. We describe our algorithms for Type 1 only. Algorithms for Type 2 can be described with the constraints on the drop-off location and pick-up location of a driver exchanged, and we omit the description. Further, it is not difficult to extend to other match types, such as rideshare only and park-and-ride, as described in [26].

### 3 Exact algorithm

An exact algorithm for the maximization problem is presented in this section, which is similar to the matching approach described in [4, 23] for ridesharing and in [19, 26] for MTR. The exact algorithm is summarized as follows. First, we compute all feasible matches for each driver  $i$ . Then, we create a bipartite (hyper)graph  $H(D, R, E)$ , where  $D(H)$  is the set of drivers, and  $R(H)$  is the set of riders. There is a hyperedge  $e = (i, J)$  in  $E(H)$  between  $i \in D(H)$  and a non-empty subset  $J \subseteq R(H)$  if  $\{i\} \cup J$  is a feasible match, denoted by  $\sigma_J(i)$ , for driver  $i$ . An example is given in Figure 1. Any driver  $i$  and rider  $j$  with no feasible match is removed from  $D(H)$  and  $R(H)$  respectively, namely, no isolated vertex (such riders must use public transit routes). For an edge  $e = (i, J)$ , let  $A(e) = \{i\} \cup J$  and  $p(e) = |J|$  be the

■ **Figure 1** A bipartite hypergraph for all possible matches of an instance  $(N, \mathcal{A}, T)$ .

number of riders represented by  $e$ . For a trip  $j \in \mathcal{A}$ , define  $E_j = \{e \in E \mid j \in A(e)\}$  to be the set of edges in  $E$  associated with  $j$ . To solve the maximization problem, we give an integer program (ILP) formulation:

$$\text{maximize} \quad \sum_{e \in E(H)} p(e) \cdot x_e \quad (1)$$

$$\text{subject to} \quad \sum_{e \in E_j} x_e \leq 1, \quad \forall j \in \mathcal{A} \quad (2)$$

$$x_e \in \{0, 1\}, \quad \forall e \in E(H) \quad (3)$$

The binary variable  $x_e$  indicates whether the edge  $e = (i, J)$  is in the solution ( $x_e = 1$ ) or not ( $x_e = 0$ ). If  $x_e = 1$ , it means that all passengers in  $J$  are served by  $i$ . Inequality (2) in the ILP formulation guarantees that each driver serves at most one feasible set of passengers and each passenger is served by one driver. Note that the ILP (1)-(3) is similar to a set packing formulation. An advantage of this ILP formulation is that the number of constraints is substantially decreased, compared to traditional ridesharing formulation. From Observation 1 in [25], it is not difficult to see that the following result holds (a proof of Theorem 1 is given in [13], Sections 3.1).

► **Theorem 1.** *Given a bipartite graph  $H(D, R, E)$  representing an instance of the multimodal transportation with ridesharing maximization problem, an optimal solution to the ILP (1)-(3) is an optimal solution to the maximization problem and vice versa.*

**Computing feasible matches.** Let  $i$  be a driver in  $D$  and  $n_i$  be the capacity of  $i$  (maximum number of riders  $i$  can serve). The maximum number of feasible matches for  $i$  is  $\sum_{p=1}^{n_i} \binom{|R|}{p}$ . Assuming the capacity  $n_i$  is a small constant (which is reasonable in practice), the above summation is polynomial in  $R$ , that is,  $O((|R|+1)^{n_i})$ . Let  $K = \max_{i \in D} n_i$  be the maximum capacity among all vehicles (driver trips). Then, in the worst case,  $|E(H)| = O(|D| \cdot (|R|+1)^K)$ . We compute all feasible matches for each trip in two phases. In phase one, for each driver  $i$ , we find all feasible matches  $\sigma(i) = \{i, j\}$  with one rider  $j$ . In phase two, for each driver  $i$ , we compute all feasible matches  $\sigma(i) = \{i, j_1, \dots, j_p\}$  with  $p$  riders, based on the feasible matches  $\sigma(i)$  with  $p-1$  riders computed previously, for  $p=2$  and upto the number of passengers  $i$  can serve. Complete description and algorithms (Algorithm 1 for phase one and Algorithm 2 for phase two) for computing the feasible matches can be found in Sections 3.2.1 and 3.2.2 of [13]. We make two simplifications in our algorithms:

- Given a source station  $s_o$  and a destination  $d_i$  of trip  $i$  with departure time  $t$  at  $s_o$ , we use a simplified transit system in our experiments to calculate the fastest public transit route from  $s_o$  to  $d_i$ .
- We use a simplified model for the transit waiting time and ridesharing service time (time it takes to pick-up and drop-off riders, walking time between locations and stations).

As shown in [13](Section 3.2.2), we compute a feasible path with minimum travel time for driver  $i$  to pick-up  $p$  passengers in each feasible match  $\sigma(i)$ .

## 4 NP-hardness and approximation algorithms

We show that the maximization problem is NP-hard and give approximation algorithms for the problem. When every edge in  $H(D, R, E)$  consists of only two vertices (one driver and one passenger), the maximization problem is equivalent to the maximum matching, which can be solved in polynomial time (e.g., [16]). However, if the edges consist of more than two

vertices, they become hyperedges. In this case, the ILP (1)–(3) becomes a formulation of the maximum weighted set packing problem (MWSP), which is NP-hard [11, 18]. In fact, ILP (1)–(3) formulation gives a special case of MWSP (due to the structure of  $H(D, R, E)$ ). We prove that this special case is also NP-hard, and by Theorem 1, the maximization problem is NP-hard (a proof of Theorem 2 is in [13], Section 4.1).

► **Theorem 2.** *The maximization problem is NP-hard.*

Next, we describe approximation algorithms for the maximization problem. For consistency, we follow the convention in [5, 7] that a  $\rho$ -approximation algorithm for a maximization problem is defined as  $\rho \cdot w(\mathcal{C}) \geq OPT$  for  $\rho > 1$ , where  $w(\mathcal{C})$  and  $OPT$  are the values of approximation and optimal solutions respectively.

#### 4.1 2-Approximation algorithm

We first give a simple 2-approximation algorithm for our maximization problem. For a maximization problem instance  $H(D, R, E)$ , we use  $\Gamma$  to denote a current partial solution, which consists of a set of matches represented by the hyperedges in  $E(H)$ . Let  $P(\Gamma) = \bigcup_{e \in \Gamma} J_e$  (called *covered passengers*). Initially,  $\Gamma = \emptyset$ . In each iteration, we add a match with the most number of uncovered passengers to  $\Gamma$ , that is, select an edge  $e = (i, J_e)$  such that  $|J_e \setminus P(\Gamma)|$  is maximum, and then add  $e$  to  $\Gamma$ . Remove  $E_e = \bigcup_{j \in A(e)} E_j$  from  $E(H)$  ( $E_j$  is defined in Section 3). Repeat until  $P(\Gamma) = R$  or  $|\Gamma| = |D|$ . The pseudo code of ImpGreedy is shown in Algorithm 3. In the ImpGreedy algorithm, when an edge  $e$  is added to  $\Gamma$ ,  $E_e$  is removed from  $E(H)$ , so Property 3 holds for  $\Gamma$ .

► **Property 3.** *For every  $i \in D$ , at most one edge  $e$  from  $E_i$  can be selected in any solution.*

- 5 **end**

---

##### 4.1.1 Analysis of ImpGreedy Algorithm

Let  $\Gamma = \{x_1, x_2, \dots, x_a\}$  be a solution found by Algorithm 3, where  $x_i$  is the  $i^{\text{th}}$  edge added to  $\Gamma$ . Throughout the analysis, we use  $OPT$  to denote an optimal solution, that is,  $P(OPT) \geq P(\Gamma)$ . Further,  $\Gamma_i = \bigcup_{1 \leq b \leq i} x_b$  for  $1 \leq i \leq a$ ,  $\Gamma_0 = \emptyset$  and  $\Gamma_a = \Gamma$ . The driver of match  $x_i$  is denoted by  $d(x_i)$ . The main idea of our analysis is to add up the maximum difference between the number of covered passengers by selecting  $x_i$  in  $\Gamma$  and not selecting  $x_i$  in  $OPT$ . For each  $x_i \in \Gamma$ , by Property 3, there is at most one  $y \in OPT$  with  $d(y) = d(x_i)$ . We order  $OPT$  and introduce dummy edges to  $OPT$  such that  $d(y_i) = d(x_i)$  for  $1 \leq i \leq a$ . Formally, for  $1 \leq i \leq a$ , define

$$OPT(i) = \{y_1, \dots, y_i \mid 1 \leq b \leq i, d(y_b) = d(x_b) \text{ if } y_b \in OPT, \text{ otherwise } y_b \text{ a dummy edge}\}.$$

A dummy edge  $y_b \in OPT(i)$  is defined as  $d(y_b) = d(x_b)$  with  $J_{y_b} = \emptyset$ . The gap of an edge  $x_i \in \Gamma$  is defined as

$$\text{gap}(x_i) = |J_{y_i}| - |J_{x_i} \setminus P(\Gamma_{i-1})| + |J'_{x_i}|,$$

where  $J'_{x_i} = (J_{x_i} \setminus P(\Gamma_{i-1})) \cap P(OPT \setminus \Gamma)$  is the maximum subset of passengers in  $J_{x_i} \setminus P(\Gamma_{i-1})$  that are also covered in  $OPT \setminus \Gamma$ . The intuition is that the sum of  $\text{gap}(x_i)$  for all  $x_i \in \Gamma$  states the maximum possible number of passengers may not be covered by  $\Gamma$ . Let  $P(OPT(i)) = \bigcup_{1 \leq b \leq i} J_{y_b}$  and  $P(OPT'(i)) = \bigcup_{1 \leq b \leq i} J'_{x_b}$  for any  $i \in [1, \dots, a]$ . Then the maximum gap between  $\Gamma$  and  $OPT$  can be calculated as  $\sum_{x \in \Gamma_a} \text{gap}(x) = |P(OPT(a))| + |P(OPT'(a))| - |P(\Gamma_a)|$ . First, we show that  $P(OPT) = P(OPT(a)) \cup P(OPT'(a))$ .

► **Proposition 4.** *Let  $\Gamma = \{x_1, \dots, x_a\}$ ,  $P(OPT(a)) = \bigcup_{1 \leq i \leq a} J_{y_i}$  and  $P(OPT'(a)) = \bigcup_{1 \leq i \leq a} J'_{x_i}$ . Then,  $P(OPT) = P(OPT(a)) \cup P(OPT'(a))$ .*

**Proof.** By definition,  $P(OPT) = P(OPT(a)) \cup P(OPT \setminus OPT(a))$ . For any  $z$  in  $OPT \setminus OPT(a)$ ,  $d(z) \neq d(x)$  for every  $x \in \Gamma$ . If  $J_z \setminus P(\Gamma) \neq \emptyset$ , then  $z$  would have been found and added to  $\Gamma$  by Algorithm 3. Hence,  $J_z \setminus P(\Gamma) = \emptyset$ , implying  $J_z \subseteq P(OPT'(a))$  and  $P(OPT \setminus OPT(a)) \subseteq P(OPT'(a))$ . ◀

► **Lemma 5.** *Let  $OPT$  be an optimal solution and  $\Gamma = \{x_1, x_2, \dots, x_a\}$  be a solution found by the algorithm. For any  $1 \leq i \leq a$ ,  $\sum_{x \in \Gamma_i} \text{gap}(x) = |P(OPT(i))| - |P(\Gamma_i)| + |P(OPT'(i))| \leq |P(\Gamma_i)|$ .*

**Proof.** Recall that  $OPT(i) = \{y_1, \dots, y_i\}$  as defined above. For  $y_b \in OPT(i)$ ,  $1 \leq b \leq i$ ,  $d(y_b) = d(x_b)$ . We prove the lemma by induction on  $i$ . Base case  $i = 1$ :  $|P(OPT(1))| - |P(\Gamma_1)| + |P(OPT'(1))| \leq |P(\Gamma_1)|$ . By definition,  $\text{gap}(x_1) = |J_{y_1}| - |J_{x_1} \setminus \Gamma_0| + |J'_{x_1}|$ . Since  $x_1$  is selected by the algorithm, it must be that  $|J_{x_1}| \geq |J_u|$  for all  $u \in V(G')$ , so  $|J_{y_1}| \leq |J_{x_1}|$ . Thus,

$$\begin{aligned} \text{gap}(x_1) &= |J_{y_1}| - |J_{x_1} \setminus \Gamma_0| + |J'_{x_1}| \\ &\leq |J'_{x_1}| \leq |J_{x_1}|. \end{aligned}$$

Assume the statement is true for  $i-1 \geq 1$ , that is,  $\sum_{x \in \Gamma_{i-1}} \text{gap}(x) \leq |P(\Gamma_{i-1})|$ , and we prove for  $i \leq a$ . By the induction hypothesis, both  $P(OPT(i-1))$  and  $P(OPT'(i-1))$  are included in the calculation of  $\sum_{x \in \Gamma_{i-1}} \text{gap}(x)$ . More precisely,  $\sum_{x \in \Gamma_{i-1}} \text{gap}(x) = |P(OPT(i-1))| - |P(\Gamma_{i-1})| + |P(OPT'(i-1))| \leq |P(\Gamma_{i-1})|$ . If  $|J_{y_i}| \leq |J_{x_i} \setminus P(\Gamma_{i-1})|$ , the lemma is true since we can assume  $|J'_{x_i}| \leq |J_{x_i}|$ . Suppose  $|J_{y_i}| > |J_{x_i} \setminus P(\Gamma_{i-1})|$ . Before  $x_i$  is selected, the algorithm must have considered  $y_i$  and found that  $|J_{x_i} \setminus P(\Gamma_{i-1})| \geq |J_{y_i} \setminus P(\Gamma_{i-1})|$ . Then,  $|J_{y_i}| > |J_{x_i} \setminus P(\Gamma_{i-1})| \geq |J_{y_i} \setminus P(\Gamma_{i-1})|$ , implying  $J_{y_i} \cap P(\Gamma_{i-1}) \neq \emptyset$ . We have

$$|J_{x_i} \setminus P(\Gamma_{i-1})| + |J_{y_i} \cap P(\Gamma_{i-1})| \geq |J_{y_i} \setminus P(\Gamma_{i-1})| + |J_{y_i} \cap P(\Gamma_{i-1})| = |J_{y_i}|. \quad (4)$$

Let  $J''_{y_i} \subseteq (J_{y_i} \cap P(\Gamma_{i-1}))$  be the set of passengers covered by  $P(OPT(i-1)) \cup P(OPT'(i-1))$ , namely  $J''_{y_i} \subseteq (P(OPT(i-1)) \cup P(OPT'(i-1)))$ . Then by the induction hypothesis,

$$\sum_{x \in \Gamma_{i-1}} \text{gap}(x) \leq |P(\Gamma_{i-1})| - |J_{y_i} \cap P(\Gamma_{i-1})| + |J''_{y_i}|. \quad (5)$$

Adding  $\sum_{x \in \Gamma_{i-1}} \text{gap}(x)$  and  $\text{gap}(x_i)$  together:

$$\begin{aligned}
 & \left( \sum_{x \in \Gamma_{i-1}} \text{gap}(x) \right) + (\text{gap}(x_i)) \\
 &= |P(\text{OPT}(i-1))| - |P(\Gamma_{i-1})| + |P(\text{OPT}'(i-1))| + |J_{y_i} \setminus J''_{y_i}| - |J_{x_i} \setminus P(\Gamma_{i-1})| + |J'_{x_i}| \\
 &\leq (|P(\Gamma_{i-1})| - |J_{y_i} \cap P(\Gamma_{i-1})| + |J''_{y_i}|) + |J_{y_i} \setminus J''_{y_i}| - |J_{x_i} \setminus P(\Gamma_{i-1})| + |J'_{x_i}| \quad \text{by (5)} \\
 &= |P(\Gamma_{i-1})| - |J_{y_i} \cap P(\Gamma_{i-1})| + |J_{y_i}| - |J_{x_i} \setminus P(\Gamma_{i-1})| + |J'_{x_i}| \\
 &\leq |P(\Gamma_{i-1})| - |J_{y_i} \cap P(\Gamma_{i-1})| + |J_{y_i} \cap P(\Gamma_{i-1})| + |J'_{x_i}| \quad \text{by (4)} \\
 &= |P(\Gamma_{i-1})| + |J'_{x_i}| \leq |P(\Gamma_{i-1})| + |J_{x_i} \setminus P(\Gamma_{i-1})| \quad \text{by definition of } J'_{x_i} \\
 &= P(\Gamma_i)
 \end{aligned}$$

Therefore, by the property of induction, the lemma holds.  $\blacktriangleleft$

► **Theorem 6.** *Given the hypergraph instance  $H(D, R, E)$ . Algorithm 3 computes a solution  $\Gamma$  to  $H$  such that  $2|P(\Gamma)| \geq |P(\text{OPT})|$ , where  $\text{OPT}$  is an optimal solution, with running time  $O(|D| \cdot |E|)$  and  $|E| \leq |D| \cdot (|R| + 1)^K$ .*

**Proof.** Let  $\Gamma = \{x_1, \dots, x_a\}$ ,  $P(\text{OPT}(a)) = \bigcup_{1 \leq i \leq a} J_{y_i}$  and  $P(\text{OPT}'(a)) = \bigcup_{1 \leq i \leq a} J'_{x_i}$ . By Proposition 4,  $P(\text{OPT}) = P(\text{OPT}(a)) \cup P(\text{OPT}'(a))$ , and by Lemma 5,  $|P(\text{OPT}(a))| + |P(\text{OPT}'(a))| - |P(\Gamma_a)| \leq |P(\Gamma_a)|$ . We have

$$|P(\text{OPT})| \leq |P(\text{OPT}(a))| + |P(\text{OPT}'(a))| \leq 2|P(\Gamma)|.$$

In each iteration of the while-loop, it takes  $O(E)$  to find an edge  $x$  with maximum  $|J_x \setminus P(\Gamma)|$ , and there are at most  $|D|$  iterations. Hence, Algorithm 3 runs in  $O(|D| \cdot |E|)$  time.  $\blacktriangleleft$

## 4.2 Approximation algorithms for maximum weighted set packing

We briefly explain the algorithms for the maximum weighted set packing problem, which solve our maximization problem. Given a universe  $\mathcal{U}$  and a family  $\mathcal{S}$  of subsets of  $\mathcal{U}$ , a *packing* is a subfamily  $\mathcal{C} \subseteq \mathcal{S}$  of sets such that all sets in  $\mathcal{C}$  are pairwise disjoint. Every subset  $S \in \mathcal{S}$  has at most  $k$  elements and is given a real weight. The maximum weighted  $k$ -set packing problem (MWSP) asks to find a packing  $\mathcal{C}$  with the largest total weight. We can see that the maximization problem on  $H(D, R, E)$  is a special case of the maximum weighted  $k$ -set packing problem, where the trips of  $D \cup R$  is the universe  $\mathcal{U}$  and  $E(H)$  is the family  $\mathcal{S}$  of subsets, and every  $e \in E(H)$  represents at most  $k = K + 1$  trips ( $K$  is the maximum capacity of all vehicles). Hence, solving MWSP also solves our maximization problem. Hazan et al. [15] showed that the  $k$ -set packing problem cannot be approximated to within  $O(\frac{k}{\ln k})$  in general unless  $P = NP$ . Chandra and Halldórsson [7] presented a  $\frac{2(k+1)}{3}$ -approximation and a  $\frac{2(2k+1)}{5}$ -approximation algorithms (refer to as *BestImp* and *AnyImp* respectively), and Berman [5] presented a  $(\frac{k+1}{2} + \epsilon)$ -approximation algorithm (refer to as *SquareImp*) for the weighted  $k$ -set packing problem (here,  $k = K + 1$ ), where the latter still has the best approximation ratio. These three algorithms in [5, 7] (*AnyImp*, *BestImp* and *SquareImp*) solve the weighted  $k$ -set packing problem by first transferring it into a weighted independent set problem, which consists of a vertex weighted graph  $G(V, E)$  and asks to find a maximum weighted independent set in  $G(V, E)$ . These algorithms use a greedy algorithm (refer to as *Greedy*) to find an initial independent set solution  $I$  and then use local searches to improve the weight of the solution. Algorithm *Greedy* can be summarized as follows: Select a vertex  $u \in V(G)$  with largest weight and add  $u$  to  $I$ . Eliminate  $u$  and all  $u$ 's neighbors from being selected. Repeatedly select the largest weight vertex until all vertices are eliminated from  $G$ .

To apply these algorithms to our maximization problem, we need to convert the bipartite hypergraph  $H(D, R, E)$  to a weighted independent set instance  $G(V, E)$ . The details of the conversion can be found in [13], Section 4.3. Notice that Algorithm 3 is a simplified version of algorithm Greedy, and Greedy is used to get an initial solution in algorithms AnyImp, BestImp and SquareImp. From Theorem 6, we have Corollary 7.

► **Corollary 7.** *Greedy, AnyImp, BestImp and SquareImp algorithms compute a solution to  $H(D, R, E)$  with 2-approximation ratio.*

Since Algorithm 3 finds a solution directly on  $H(D, R, E)$  without converting it to  $G(V, E)$  and solving the independent set problem of  $G(V, E)$ , it is more time and space efficient than the algorithms for MWSP. In the rest of this paper, Algorithm 3 is referred to as ImpGreedy.

## 5 Numerical experiments

We create a simulation environment consists of a centralized system that integrates public transit and ridesharing. We implement our proposed approximation algorithm (ImpGreedy) and Greedy, AnyImp and BestImp algorithms for the  $k$ -set packing problem to evaluate the benefits of having an integrated transportation system supporting public transit and ridesharing. The exact algorithm, ILP (1)-(3), is not evaluated because it takes too long to complete for the instances in our study. The results of SquareImp are not discussed because its performance is same as AnyImp; this is due to the implementation of the search/enumeration order of the vertices and edges in the independent set instance  $G(V, E)$  being fixed, and each vertex in  $V(G)$  has integer weight. We use a simplified transit network of Chicago to simulate the public transit and ridesharing.

### 5.1 Description and characteristics of datasets

We built a simplified transit network of Chicago to simulate practical scenarios of public transit and ridesharing. The roadmap data of Chicago is retrieved from OpenStreetMap<sup>1</sup>. We used the GraphHopper<sup>2</sup> library to construct the logical graph data structure of the roadmap. The Chicago city is divided into 77 officially community areas, each of which is assigned an area code. We examined two different dataset in Chicago to reveal some basic traffic pattern (the datasets are provided by the Chicago Data Portal (CDP) and Chicago Transit Authority (CTA)<sup>3</sup>, maintained by the City of Chicago). The first dataset is bus and rail ridership, which shows the monthly averages and monthly totals for all CTA bus routes and train station entries. We denote this dataset as *PTR*, *public transit ridership*. The PTR dataset contains data for the month June, 2019. The second dataset is rideshare trips reported by Transportation Network Providers (sometimes called rideshare companies) to the City of Chicago. We denote this dataset as *TNP*. The TNP dataset range is chosen from June 3rd, 2019 to June 30th, 2019, total of 4 weeks of data. Table 1 and Table 2 show some basic stats of both datasets.

We examined the 12 busiest bus routes based on the total ridership and selected 7 out of the 12 routes as listed in Table 1 to build the transit network. We also selected all major trains/metro lines within Chicago. Each record in the TNP dataset describes a passenger trip

## 39:10 Multimodal Transportation with Ridesharing of Personal Vehicles

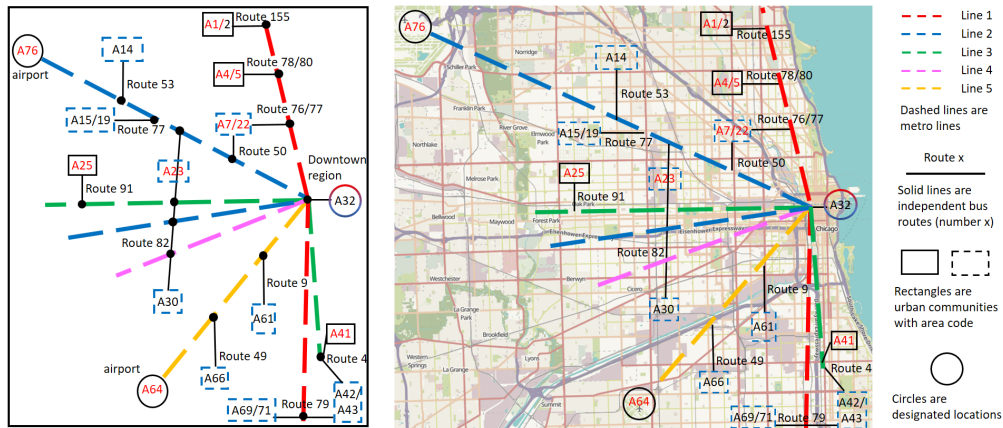

■ **Table 1** Basic stats of the PTR dataset.

Total Bus Ridership	20,300,416
Total Rail Ridership	19,282,992
12 busiest bus routes	3, 4, 8, 9, 22, 49, 53, 66, 77, 79, 82, 151
The busiest bus routes selected	4, 9, 49, 53, 77, 79, 82

■ **Table 2** Basic stats of the TNP dataset.

# of original records	8,820,037
# of records considered	7,427,716
# of shared trips	1,015,329
# of non-shared trips	6,412,387
The most visited community areas selected	1, 4, 5, 7, 22, 23, 25, 32, 41, 64, 76

served by a driver who provides the rideshare service; a trip record consists of the pick-up and drop-off time and the pick-up and drop-off community area of the trip, and exact locations are provided sometimes. We selected 11 of the 20 most visited areas as listed in Table 2 (area 32 is Chicago downtown, areas 64 and 76 are airports) to build the transit network for our simulation. From the selected bus routes, trains and community areas, we create a simplified public transit network connecting the selected areas, depicted in Figure 2. More details on selecting areas and the public transit network are included in [13] (Section 5.1).

■ **Figure 2** Simplified public transit network of Chicago with 13 urban communities and 3 designated locations. Figure on the right has the Chicago city map overlay for scale.

The travel time between two locations uses the fastest/shortest route computed by GraphHopper, based on personal cars. The shortest paths are **computed in real-time**, unlike many previous simulations where the shortest paths are precomputed and stored. As stated in Section 3, waiting time and service time are considered in a simplified model; we multiply a small constant  $\epsilon > 1$  to the fastest route to mimic waiting time and service time.

### 5.2 Generating instances

In our simulation, we partition each day from 6:00 to 23:59 into 72 time intervals (each has 15 minutes), and we only focus on weekdays. To see ridesharing traffic pattern, we calculated the average number of served trips per hour for each day of the week using the TNP dataset. The dashed (orange) line and solid (blue) line of the plot in Figure (3a) represent shared trips and non-shared trips respectively. A set of trips are called *shared trips* if this set of trips are matched for the same vehicle consecutively such that their trips may potentially overlap (one or more passengers are in the same vehicle). For all other trips, we call them *non-shared trips*. The number of trips generated for each interval is plotted in Figure (3b), which is a

(a) Average numbers of shared and non-shared trips in TNP dataset. (b) Total number of driver and rider trips generated for each time interval.

■ **Figure 3** Plots for the number of trips for every hour from data and generated.

scaled down and smoothed version of the TNP dataset for weekdays. The ratio between the number of drivers and riders generated is roughly 1:3 (1 driver and 3 riders) for each interval. Such a ratio is chosen because it should reflect the system's potential as capacity of 3 is common for most vehicles. For each time interval, we first generate a set  $R$  of riders and then a set  $D$  of drivers. We do not generate a trip where its origin and destination are close.

The main idea of generating rider trips is described as follows. Each day is divided into 6 different consecutive time periods (each consists of multiple time intervals): morning rush, morning normal, noon, afternoon normal, afternoon rush, and evening time periods. Each time period determines the probability and distribution of origins and destinations. Based on the PTR dataset and Rail Capacity Study [8], many riders are going into downtown in the morning and leaving downtown in the afternoon. To generate a rider trip  $j$  during a time period, we first select a *pick-up area* and a *drop-off area* randomly following the probability distribution for the time period (e.g., downtown is selected with higher probability as drop-off area for the morning rush period). The origin  $o_j$  and destination  $d_j$  are random points within the pick-up and drop-off areas respectively. The above is repeated until  $a_t$  riders are generated, where  $a_t + a_t/3$  (riders + drivers) is the total number of trips for time interval  $t$  shown in Figure (3b). The probability distribution for each time period and detailed description of generating rider trips can be found in Section 5.2 of [13].

The main idea of generating driver trips is described as follows. We examined the TNP dataset to create a grid heatmap (Figure 8 in [13]) for traffic for each hour. Each cell  $(c, r)$  in the heatmap represents the the average number of trips per hour originated from area  $c$  to destination area  $r$  in the transit network (Figure 2). Let  $d(c, r, h)$  be the value at the cell  $(c, r)$  for origin  $c$ , destination  $r$  and hour  $h$  in the heatmap. Let  $P(c, h) = \sum_r d(c, r, h)$  be the sum of the values of the whole column  $c$  for hour  $h$ . Given a time interval  $t$  in hour  $h$ , let  $c_t$  be the number of generated riders with origin in area  $c$ ; and for each area  $c$ , we generate  $c_t/3$  drivers such that each driver  $i$  has origin  $o_i = c$  and destination  $d_i = r$  with probability  $d(c, r, h)/P(c, h)$ . The probability of selecting an airport as destination is fixed at 5%.

After the origin and destination of a rider/driver trip have been determined, we decide other parameters of the trip (e.g., the vehicle capacity of a driver  $i$  is at most 6). Details of these parameters are specified in Section 5.2 of [13].

When the number of trips increases, the running time for Algorithm 2 and the time needed to construct the  $k$ -set packing instance also increase. In a practical setup, we may restrict the number of feasible matches a driver can have. Each match produced by Algorithm 1 is called a *base match*. To make the simulation feasible, we heuristically limit the numbers of base matches for each driver and each rider and the number of total feasible matches for each

driver. We use  $(x\%, y, z)$ , called *reduction configuration* (*Config* for short), to denote that for each driver  $i$ , the number of base matches of  $i$  is reduced to  $x$  percentage and at most  $y$  total feasible matches are computed for  $i$ ; and for each rider  $j$ , at most  $z$  base matches containing  $j$  are used. Details of the reduction procedure can be found in the end of Section 5.2 of [13].

### 5.3 Computational results

We use the same transit network and same set of generated trip data for all algorithms. All experiments were implemented in Java and conducted on Intel Core i7-2600 processor with 1333 MHz of 8 GB RAM available to JVM. Since the optimization goal is to assign feasible acceptable routes to as many riders as possible, the performance measure is focused on the number of riders served by ridesharing routes, followed by the total time saved for the riders as a whole. The base case instance uses the parameter setting described in Section 5.2 and Config (30%, 600, 20). The experiment results are shown in Table 3. The results of

■ **Table 3** Base case solution comparison between the approximation algorithms.

	ImpGreedy	Greedy	AnyImp	BestImp
Total number of riders served	27413	27413	28248	28258
Avg number of riders served per interval	380.736	380.736	392.333	392.472
Total time saved of all riders (minute)	354568.2	354568.2	365860.6	365945.8
Avg time saved of riders per interval (minute)	4924.56	4924.56	5,081.40	5082.58
Total number of riders and public transit duration	45314 and 1383743.97 minutes			

ImpGreedy and Greedy are aligned since they are essentially the same algorithm – 60.5% of total passengers are assigned ridesharing routes and 25.6% of total time are saved. The results of AnyImp and BestImp are similar because of the density of the graph  $G(V, E)$ . For AnyImp and BestImp, roughly 62.4% of total passengers are assigned ridesharing routes and 26.4% of total time are saved. On average, passengers are able to reduce their travel duration from 30.5 minutes to 22.5 minutes by using public transit plus ridesharing. The results of these four algorithms are not too far apart. However, it takes too long for AnyImp and BestImp to run to completion. A 10-second limit is set for both algorithms in each iteration for finding an independent set improvement. With this time limit, AnyImp and BestImp run to completion within 15 minutes for almost all intervals. We also recorded the mean occupancy rate of drivers. The mean occupancy rate is calculated as, in each interval, the number of passengers served divided by the number of drivers who serve them. The results are depicted in Figure 9 in [13], which show that mean occupancy rate of a personal vehicle is 2.9–3 (including the driver) on average. Further discussions can be found in [13] (Section 5.3).

Another major component of the experiment is to measure the computational time of the algorithms, which is highly affected by the base match reduction configurations. By reducing more matches, we are able to improve the running time of AnyImp and BestImp significantly, but sacrifice performance slightly. We tested 12 different Configs:

- *Small1* (20%,300,10), *Small2* (20%,600,10), *Small3* (20%,300,20), *Small4-10* (20%,600,20), *Medium1* (30%,300,10), *Medium2* (30%,600,10), *Medium3* (30%,300,20), *Medium4-10* (30%,600,20), *Large1* (40%,300,10), *Large2* (40%,600,10), *Large3-10* (40%,300,20), and *Large4-10* (40%,600,20).

Configs with label “-10” have a 10-second limit to find an independent set improvement, and all other Configs have 20-second limit. Notice that all 12 Configs have the same sets of driver/rider trips and base match sets but generate different feasible match sets. The

■ **Figure 4** Average performance of peak and off-peak hours for different configurations.

performance and running time results of all 12 Configs are depicted in Figures 4 and 5 respectively. The results are divided into peak and off-peak hours for each Config (averaging all intervals of peak hours and off-peak hours). The running time of ImpGreedy and Greedy are within seconds for all Configs for each interval. On the other hand, it may not be practical to use AnyImp and BestImp for peak hours since they require around 15 minutes for most Configs. Since AnyImp and BestImp provide better performance than ImpGreedy/Greedy when each Config is compared side-by-side, one can use ImpGreedy/Greedy for peak hours and AnyImp/BestImp for off-peak hours so that it becomes practical. The increase in

■ **Figure 5** Average running time of peak and off-peak hours for different configurations.

performance from Small1 to Small3 is much larger than that from Small1 to Small2 (same for Medium and Large), implying any parameter in a Config should not be too small. The increase in performance from Large1 to Large4 is higher than that from Medium1 to Medium4 (similarly for Small). Therefore, a balanced configuration is more important than a configuration emphasizes only one or two parameters.

Because ImpGreedy does not create the independent set instance, it runs quicker than Greedy. More importantly, ImpGreedy uses less memory space than Greedy does. We tested ImpGreedy and Greedy with the following Configs: *Huge1* (100%,600,10), *Huge2* (100%,2500,20) and *Huge3* (100%,10000,30) (these Configs have the same sets of driver/ rider trips and base match sets as those in the previous 12 Configs). The focus of these Configs is to see if Greedy can handle large number of feasible matches. The results are shown in Table 4. Greedy cannot run to completion for all Configs because in many intervals, the whole graph  $G(V, E)$  of the independent set instance is too large to hold in memory. The average number of edges for afternoon peak hours is 0.02, 0.38 and 5.47 billion for *Huge1*, *Huge2* and *Huge3* respectively. Further, the time it takes to create  $G(V, E)$  excess practicality. Hence, using Greedy (AnyImp/BestImp) for large instances may not be practical. In addition, the performance of ImpGreedy with *Huge3* is better than that of AnyImp/BestImp with Large4.

■ **Table 4** The results of ImpGreedy and Greedy using Unlimited reduction configurations.

ImpGreedy	Huge1	Huge2	Huge3
Avg running time for peak/off-peak hours (sec)	0.08 / 0.03	0.43 / 0.12	1.2 / 0.29
Avg number of riders served for peak/off-peak hours	406.9 / 339.0	458.8 / 355.4	484.1 / 361.9
Avg time saved of riders per interval (sec)	284891.8	302774.1	310636.9
Greedy	Huge1	Huge2	Huge3
Avg running time	N/A	N/A	N/A
Avg instance size $G(V, E)$ of afternoon peak ( $ E(G) $ )	0.02 billion	0.38 billion	5.47 billion
Avg time creating $G(V, E)$ of afternoon peak (sec)	14.6	320.9	3726.79

We also looked at the total running times of the approximation algorithms including the time for computing feasible matches (Algorithms 1 and 2). The running time of Algorithm 1 solely depends on computing the shortest paths between the trips and stations. Table 5 shows that Algorithm 1 runs to completion within 500 seconds for each interval on average for peak hours. As for Algorithm 2, when many trips' origins/destinations are concentrated

■ **Table 5** Average computational time (in seconds) of peak hours for all algorithms.

	Alg1	Alg2	ImpGreedy	Greedy	AnyImp	BestImp	Total computational time			
							ImpGreedy	Greedy	AnyImp	BestImp
Small3	485.2	26.8	0.021	2.0	840.5	876.4	512.1	514.1	1352.5	1388.5
Small4	485.2	28.2	0.029	3.6	599.1	629.9	513.4	517.0	1112.5	1143.3
Medium3	485.2	43.6	0.031	3.7	1312.1	1371.0	532.5	543.0	1840.9	1899.9
Medium4	485.2	50.1	0.048	7.7	971.5	990.0	535.3	543.0	1506.8	1525.3
Large4	485.2	72.0	0.076	12.2	1121.3	1167.2	557.3	569.5	1678.6	1724.4
Huge3	485.2	339.4	1.2	N/A	N/A	N/A	825.8	N/A	N/A	N/A

in one area, the running time increases significantly, especially for drivers with high capacity. Combining the results of this and previous (Table 4) experiments, ImpGreedy is capable of handling large instances while providing quality solution compared to other approximation algorithms.

From the experiment results in Figures 4 and 5, it is beneficial to dynamically select different algorithms and reduction configurations for each interval depending on the number of trips. With large problem instances, previous approximation algorithms are not efficient (time and memory consuming), so they require aggressive reduction to reduce the instance size. On the other hand, ImpGreedy is much faster and capable of handling large instances. The running time of ImpGreedy can also be an advantage to improve the quality of solutions. For example, as shown in Figures 4 and 5, for the same set of drivers and riders, ImpGreedy assigns more riders when taking Medium/Medium4 as inputs than AnyImp/BestImp on Small1/Small2, and uses less time than AnyImp/BestImp. When the size of an instance is not small and a solution must be computed within some time-limit, ImpGreedy has a distinct advantage over the previous approximation algorithms.

## 6 Conclusion

Based on real-world transit datasets in Chicago, our study has shown that integrating public and private transportation can benefit the transit system as a whole, more than 60% of the passenger are assigned ridesharing routes and able to save 25% of travel time. Majority of the drivers are matched with at least one passenger, and vehicle occupancy rate has improved

close to 3 (including the driver) on average. These results suggest that ridesharing can be a complement to public transit. Our experiments show that the whole system is capable of handling more than 1100 trip requests in real-time using ordinary computer hardware. The performance results of ImpGreedy may be further improved by extending it with the local search strategy. Perhaps the biggest challenge for scalability comes from computing the base matches (Algorithm 1) since it has to compute many shortest paths; it may be worth to apply heuristics to speed-up Algorithm 1. To better understand practicality, a more sophisticated simulation incorporating traffic and transit schedule and demand may be needed.

## Abstract

---

Sequence alignment supports numerous tasks in bioinformatics, natural language processing, pattern recognition, social sciences, and other fields. While the alignment of two sequences may be performed swiftly in many applications, the simultaneous alignment of multiple sequences proved to be naturally more intricate. Although most multiple sequence alignment (MSA) formulations are NP-hard, several approaches have been developed, as they can outperform pairwise alignment methods or are necessary for some applications. Taking into account not only similarities but also the lengths of the compared sequences (i.e. normalization) can provide better alignment results than both unnormalized or post-normalized approaches. While some normalized methods have been developed for pairwise sequence alignment, none have been proposed for MSA. This work is a first effort towards the development of normalized methods for MSA. We discuss multiple aspects of normalized multiple sequence alignment (NMSA). We define three new criteria for computing normalized scores when aligning multiple sequences, showing the NP-hardness and exact algorithms for solving the NMSA using those criteria. In addition, we provide approximation algorithms for MSA and NMSA for some classes of scoring matrices.

## 1 Introduction

Sequence alignment lies at the foundation of bioinformatics. Several procedures rely on alignment methods for a range of distinct purposes, such as detection of sequence homology, secondary structure prediction, phylogenetic analysis, identification of conserved motifs or genome assembly. On the other hand, alignment techniques have also been reshaped and found applications in other fields, such as natural language processing, pattern recognition, or social sciences [1, 3, 8, 18].

---

<sup>1</sup> Corresponding author

Given its range of applications in bioinformatics, extensive efforts have been made to improve existing or developing novel methods for sequence alignment. The simpler ones compare a pair of sequences in polynomial time on their lengths, usually trying to find editing operations (insertions, deletions, and substitutions of symbols) that transform one sequence into another while maximizing or minimizing some objective function called edit distance [16]. This concept can naturally be generalized to align multiple sequences [28], adding another new layer of algorithmic complexity, though. In this case, most multiple sequence alignment (MSA) formulations lead to NP-hard problems [13]. Nevertheless, a variety of methods suitable for aligning multiple sequences have been developed, as they can outperform pairwise alignment methods on tasks such as phylogenetic inference [21], secondary structure prediction [12] or identification of conserved regions [24].

In order to overcome the cost of exact solutions, a number of MSA heuristics have been developed in recent years, most of them using the so-called progressive or iterative methods [17, 23, 25, 27]. Experimental data suggest that the robustness and accuracy of heuristics can still be improved, however [28].

Most approaches for pairwise sequence alignment define edit distances as absolute values, lacking some normalization that would result in edit distances relative to the lengths of the sequences. However, some applications may require sequence lengths to be taken into account. For instance, a difference of one symbol between sequences of length 5 is more significant than between sequences of length 1000. In addition, experiments suggest that normalized edit distances can provide better results than both unnormalized or post-normalized edit distances [18]. While normalized edit distances have been developed for pairwise sequence alignment [6, 18], none have been proposed for MSA to the best of our knowledge.

In this work, we propose exact and approximation algorithms for normalized MSA (NMSA). This is a first step towards the development of methods that take into account the lengths of sequences for computing edit distances when multiple sequences are compared.

The remainder of this paper is organized as follows. Section 2 introduces concepts related to sequence alignment and presents normalized scores for NMSA, followed by the complexity analysis of NMSA using those scores in Section 3. Next, Sections 4 and 5 describe exact and approximation algorithms, respectively. Section 6 closes the paper with the conclusion and prospects for future work.

## 2 Preliminaries

An *alphabet*  $\Sigma$  is a finite non-empty set of *symbols*. A finite sequence  $s$  with  $n$  symbols in  $\Sigma$  is seen as  $s(1) \cdots s(n)$ . We say that the *length* of  $s$ , denoted by  $|s|$ , is  $n$ . The (sub)sequence  $s(p) \cdots s(q)$  of  $s$ , with  $1 \leq p \leq q \leq n$ , is denoted by  $s(p:q)$ . If  $p > q$ ,  $s(p:q)$  is the *empty* sequence, whose length is zero, and it is denoted by  $\varepsilon$ . We denote the sequence resulting from the concatenation of sequences  $s$  and  $t$  by  $st$ . A sequence of  $n$  symbols  $\mathbf{a}$  is denoted by  $\mathbf{a}^n$ . A  $k$ -tuple  $S$  over  $\Sigma^*$  is called a  $k$ -*sequence* and we write  $s_1, \dots, s_k$  to refer to  $S$ , where  $s_i$  is the  $i$ -th sequence in  $S$ . Let  $\Sigma_- := \Sigma \cup \{-\}$ , where  $- \notin \Sigma$  and the symbol  $-$  is called a *space*. Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence. An *alignment* of  $S$  is a  $k$ -tuple  $A = [s'_1, \dots, s'_k]$  over  $\Sigma_-^*$ , where (a) each sequence  $s'_h$  is obtained by inserting spaces in  $s_h$ ; (b)  $|s'_h| = |s'_i|$  for each pair  $h, i$ , with  $1 \leq h, i \leq k$ ; and (c) there is no  $j$  in  $\{1, \dots, k\}$  such that  $s'_1(j) = \dots = s'_k(j) = -$ . Notice that  $k$ -tuples over  $\Sigma_-^*$  are written enclosed by square brackets “[ ]”. The sequence  $[s'_1(j), \dots, s'_k(j)]$  is the *column*  $j$  of the alignment  $[s'_1, \dots, s'_k]$ . We denote the column  $j$  of the alignment  $A$  by  $A(j)$  and by  $A[j_1:j_2]$  the columns  $j_1, j_1 + 1, \dots, j_2$  of  $A$ . We say that the pair  $[s'_h(j), s'_i(j)]$  *aligns* in  $A$  or, simply, that  $s'_h(j)$  and  $s'_i(j)$  are *aligned* in  $A$ , and  $|A| = |s'_i|$  is the *length* of the alignment  $A$ . It is easy to check that  $\max_i \{|s_i|\} \leq |A| \leq \sum_i |s_i|$ .

An alignment can be used to represent *editing operations* of *insertions*, *deletions* and *substitutions* of symbols in sequences, where the symbol  $-$  represents insertions or deletions. An alignment can also be represented in the matrix format. Thus, alignments  $[aaa-, ab--, -cac]$  and  $[-aaa-, ab---, -ca-c]$  of  $aaa, ab, cac$  can be represented respectively as

$$\begin{bmatrix} a & a & a & - \\ a & b & - & - \\ - & c & a & c \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} - & a & a & a & - \\ a & b & - & - & - \\ - & c & a & - & c \end{bmatrix}.$$

Let  $I = \{i_1, \dots, i_m\} \subseteq \{1, \dots, k\}$  be a set of indices such that  $i_1 < \dots < i_m$  and let  $A = [s'_1, \dots, s'_k]$  be an alignment of  $S = s_1, \dots, s_k$ . We write  $S_I$  to denote the  $m$ -tuple  $s_{i_1}, \dots, s_{i_m}$ . The alignment of  $S_I$  induced by  $A$  is the alignment  $A_I$  obtained from the alignment  $A$ , considering only the corresponding sequences in  $S_I$  and, from the resulting structure, removing columns where all symbols are  $-$ . In the following example,  $A = [aaa-, ab--, -cac]$  is an alignment of  $aaa, ab, cac$  and

$$\begin{bmatrix} a & a & a \\ a & b & - \end{bmatrix}$$

is an alignment of  $aaa, ab$  induced by  $A$ . We denote by  $\mathcal{A}_S$  the set of all alignments of  $S$ .

For a problem  $P$ , we call  $\mathbb{I}_P$  the set of instances of  $P$ . If  $P$  is a decision problem, then  $P(I) \in \{\text{Yes}, \text{No}\}$  is the image of an instance  $I$ . If  $P$  is an optimization (minimization) problem, there is a set  $\text{Sol}(I)$  for each instance  $I$ , a function  $v$  defining a non-negative rational number for each  $X \in \text{Sol}(I)$ , and a function  $\text{opt}_v(I) = \min_{X \in \text{Sol}(I)} \{v(X)\}$ . We use  $\text{opt}$  instead of  $\text{opt}_v$  if  $v$  is obvious. Let  $\mathbf{A}(I)$  be a solution computed by an algorithm  $\mathbf{A}$  with input  $I$ , and  $\mathbf{A}(I) \geq \text{opt}(I)$ . We say that  $\mathbf{A}$  is an  $\alpha$ -approximation for  $P$  if  $\mathbf{A}(I) \leq \alpha \text{opt}(I)$ , for each  $I \in \mathbb{I}_P$ , with  $\alpha \geq 1$ . We say that  $\alpha$  is an *approximation factor* for  $P$ .

The *alignment problem* is a collection of decision and optimization problems whose instances are finite subsets of  $\Sigma^*$  and  $\text{Sol}(S) = \mathcal{A}_S$ , for each instance  $S$ . Function  $v$ , used for scoring alignments, is called *criterion* for  $P$  and we call  $v[A]$  the *cost of the alignment*  $A$ . The  *$v$ -optimal alignment*  $A$  of  $S$  is such that  $v[A] = \text{opt}(S)$ . Thus, we state the following general optimization problems using the criterion  $v$ :

► **Problem 1 (Alignment with criterion  $v$ ).** Given a  $k$ -sequence  $S$ , with  $k \in \mathbb{N}$ , find a  $v$ -optimal alignment of  $S$ .

We also need the decision version of the alignment problem with criterion  $v$ , where we are given a  $k$ -sequence  $S$  and a number  $d \in \mathbb{Q}_{\geq}$ , and we want to decide whether there exists an alignment  $A$  of  $S$  such that  $v[A] \leq d$ .

Usually the cost of an alignment  $v$  is defined from a scoring matrix. A *scoring matrix*  $\gamma$  is a rational matrix such that the elements in  $\Sigma_-$  are indices of its rows and columns. For  $\mathbf{a}, \mathbf{b} \in \Sigma_-$  and a scoring matrix  $\gamma$ , we denote by  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}}$  the entry of  $\gamma$  in line  $\mathbf{a}$  and column  $\mathbf{b}$ . The value  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}}$  defines the score for a substitution if  $\mathbf{a}, \mathbf{b} \in \Sigma$ , for an insertion if  $\mathbf{a} = -$ , and for a deletion if  $\mathbf{b} = -$ . The entry  $\gamma_{- \rightarrow -}$  is not defined.

Given a scoring function  $v_\gamma$  for alignments that depends on a scoring matrix  $\gamma$ , we say that two scoring matrices  $\gamma$  and  $\rho$  are *equivalent* considering  $v$  when  $v_\gamma[A] \leq v_\gamma[B]$  if and only if  $v_\rho[A] \leq v_\rho[B]$  for any pair of alignments  $A, B$  of sequences  $s, t$ . If  $\rho$  is a matrix obtained from  $\gamma$  by multiplying each entry of  $\gamma$  by a constant  $c > 0$ , then  $v_\rho[A] = c v_\gamma[A]$  and  $vN_\rho[A] = c vN_\gamma[A]$ , which implies that  $\gamma$  and  $\rho$  are equivalent. As a consequence, when the scoring function is  $vA_\gamma$  or  $vN_\gamma$  and it is convenient, we can suppose that all entries of  $\gamma$  are integers instead of rationals, according to the definition.

A  $k$ -vector  $\vec{j} = [j_1, \dots, j_k]$  is a  $k$ -tuple, where  $j_i \in \mathbb{N} = \{0, 1, 2, \dots\}$ . We say that  $j_i$  is the  $i$ -th element of  $\vec{j}$ . The  $k$ -vector  $\vec{0}$  is such that all its elements are zero. If  $\vec{j}$  and  $\vec{h}$  are  $k$ -vectors, we write  $\vec{j} \leq \vec{h}$  if  $j_i \leq h_i$  for each  $i$ ; and  $\vec{j} < \vec{h}$  if  $\vec{j} \leq \vec{h}$  and  $\vec{j} \neq \vec{h}$ . A sequence of  $k$ -vectors  $\vec{j}_1, \vec{j}_2, \dots$  is in *lexicographical order* if  $\vec{j}_i \leq \vec{j}_{i+1}$  for each  $i$ .

Consider  $S = s_1, \dots, s_k$  a  $k$ -sequence with  $n_i = |s_i|$  for each  $i$  and  $\vec{n} = [n_1, \dots, n_k]$ . Let  $V_{\vec{n}} = \{\vec{j} : \vec{j} \leq \vec{n}\}$  be the set of all  $k$ -vectors  $\vec{j}$  such that  $\vec{j} \leq \vec{n}$ . For example, if  $k = 3$  and  $\vec{n} = [1, 2, 1]$ , then  $V_{\vec{n}} = \{[x, y, z] : x, y, z \in \mathbb{N}, x \leq 1, y \leq 2, z \leq 1\}$ . Notice that if  $n_i = n$  for all  $i$ , then  $|V_S| = (n+1)^k$ . Define  $S(\vec{j}) = s_1(j_1), \dots, s_k(j_k)$  a column  $\vec{j}$  in  $S$  and we say that  $S(1:\vec{j}) = s_1(1:j_1), \dots, s_k(1:j_k)$  is the *prefix of  $S$  ending in  $\vec{j}$* . Thus,  $S = S(1:\vec{n})$ . Besides that, if  $A$  is an alignment and  $\vec{v} = [j, j, \dots, j]$ , then  $A[\vec{v}] = A(j)$ .

Denote by  $\mathcal{B}^k$  the set of  $k$ -bit vectors  $[b_1, \dots, b_k]$ , where  $b_i \in \{0, 1\}$  for each  $i$ . Now, for  $\vec{b} \leq \vec{j}$ , define  $\vec{b} \cdot S(\vec{j}) = [x_1, \dots, x_k] \in \Sigma^k$  such that  $x_i = s_i(j_i)$  if  $b_i = 1$  and  $x_i = -$  otherwise. Therefore, given an alignment  $A$  of  $S(1:\vec{j})$ , there exists  $\vec{b} \in \mathcal{B}^k$ , with  $\vec{b} \leq \vec{j}$ , such that  $A(|A|) = \vec{b} \cdot S(\vec{n})$ . In other words, if  $\vec{n} = [n_1, \dots, n_k]$  and  $\vec{b} = [b_1, \dots, b_k]$ , we have  $b_i = 1$  if and only if  $s_i(n_i)$  is in the  $i$ -th row of the last column of  $A$ . We also define the operation  $\vec{j} - \vec{b} = [j_1 - b_1, \dots, j_k - b_k]$ . Notice that  $|\mathcal{B}_k| = 2^k$ .

Consider a scoring matrix  $\gamma$ . Let  $s, t \in \Sigma^*$ , with  $n = |s|, m = |t|$ . A simple criterion for scoring alignments using the function  $vA_\gamma$  follows. For an alignment  $[s', t']$  of  $s, t$  we define

$$vA_\gamma[s', t'] = \sum_{j=1}^{|[s', t']|} \gamma_{s'(j) \rightarrow t'(j)}.$$

We say that  $vA_\gamma[s', t']$  is a  $vA_\gamma$ -score of  $s, t$ . The optimal function for this criterion is denoted by  $\text{opt}A_\gamma$  and an alignment  $A$  of  $s, t$  is called an *A-optimal alignment* of  $s, t$  if  $vA_\gamma[A] = \text{opt}A_\gamma(s, t)$ .

Now, suppose that  $n \geq m$ . Needleman and Wunch [20] proposed an  $O(n^2)$ -time algorithm for computing  $\text{opt}A_\gamma(s, t)$ . If  $\text{opt}A_\gamma$  is a Levenstein distance, Masek and Paterson [19] presented an  $O(n^2/\log n)$ -time algorithm using the “*Four Russian’s Method*”. Crochemore, Landau and Ziv-Ukelson [11] extended this result for real arrays, describing an  $O(n^2/\log n)$ -time algorithm. Indeed, there is no algorithm to determine  $\text{opt}A_\gamma(s, t)$  in  $O(n^{2-\delta})$ -time for any  $\delta > 0$ , unless SETH is false [7]. Andoni, Krauthgamer and Onak [2] described a nearly linear time algorithm approximating the edit distance within an approximation factor  $\text{poly}(\log n)$ . Later, Chakraborty et al. [10] presented an  $O(n^{2-2/7})$ -time  $\alpha$ -approximation for this problem, where  $\alpha$  is constant.

Marzal and Vidal [18] defined another criterion for scoring alignments of two sequences called  $vN_\gamma$ -score, which is a normalization of  $vA_\gamma$ -score, as follows:

$$vN_\gamma[A] = \begin{cases} 0, & \text{if } |A| = 0, \\ vA_\gamma[A]/|A|, & \text{otherwise.} \end{cases}$$

The optimal function for this criterion is  $\text{opt}N_\gamma(s, t) = \min_{A \in \mathcal{A}_{s,t}} \{vN_\gamma[A]\}$ , and an *N-optimal alignment*  $A$  of  $s, t$  is such that  $vN_\gamma[A] = \text{opt}N_\gamma(s, t)$ .

A naive dynamic programming algorithm was proposed by Marzal and Vidal [18] to obtain an N-optimal alignment of two sequences in  $O(n^3)$ -time. Using fractional programming, Vidal, Marzal and Aibar [26] presented an algorithm with running time  $O(n^3)$ , requiring  $O(n^2)$ -time in practice, similarly to the classical (unnormalized) edit distance algorithm. Further, Arslan and Egecioglu [6] described an  $O(n^2 \log n)$ -time algorithm to solve this problem.

Let  $A$  be an A-optimal alignment of maximum length of 2-sequence  $S = s, t$ , with  $|s| = n$  and  $|t| = m$ . Considering  $\vec{n} = [n, m]$  and  $\vec{b}$  a bit vector such that  $A(|A|) = \vec{b} \cdot S(\vec{n})$ , the length of a maximum length A-optimal alignment of  $S(1:\vec{n} - \vec{b})$  must be  $|A| - 1$ . Thus, the maximum length  $L(n, m)$  can be found by a dynamic programming formula as following:

$$L(0, 0) = 0, \quad L(0, j) = j, \quad L(i, 0) = i,$$

$$L(i, j) = \max \left\{ \begin{array}{ll} L(i-1, j), & \text{if } d(i, j) = d(i-1, j) + \gamma_{s(i) \rightarrow -} \\ L(i, j-1), & \text{if } d(i, j) = d(i, j-1) + \gamma_{-\rightarrow t(j)} \\ L(i-1, j-1), & \text{if } d(i, j) = d(i-1, j-1) + \gamma_{s(i) \rightarrow s(j)} \end{array} \right\} + 1, \quad i, j > 0,$$

where  $d(i, j) = \text{opt}A_\gamma(s(1:i), t(1:j))$ . Therefore, the maximum length A-optimal alignment of  $s, t$  can be obtained in  $O(nm)$ -time. The following theorem shows that we can propose a simple approximation algorithm to find an A-optimal alignment of maximum length.

► **Theorem 2.1.** *Let  $s, t$  be sequences of lengths  $n, m$ , respectively, and let  $L(n, m)$  be the maximum length of an A-optimal alignment of  $s, t$ . Then,*

$$\text{opt}A_\gamma(s, t)/L(n, m) \leq 2 \text{opt}N_\gamma(s, t),$$

and it can be computed in  $O(n^2)$ -time if  $n = m$ . Moreover, this ratio is tight, i.e., for any positive rational  $\varepsilon$ , there exists a scoring matrix  $\gamma$ , sequences  $s, t$  and an A-optimal alignment of  $s, t$  with maximum length  $A$  such that  $\text{opt}A_\gamma(s, t)/|A| = vA_\gamma[A]/|A| = (2 - \varepsilon) \text{opt}N_\gamma(s, t)$ .

**Proof.** Let  $A$  be an A-optimal alignment with maximum length computed by the heuristic above in  $O(nm)$ -time and space. Let  $B$  be an N-optimal alignment. Thus,  $vA_\gamma[A] \leq vA_\gamma[B]$ . Moreover,  $|B| \leq n + m \leq 2 \max\{n, m\} \leq 2|A|$ , that is,  $|A| \geq |B|/2$ . Therefore,  $vN_\gamma[A] = \frac{vA_\gamma[A]}{|A|} \leq \frac{vA_\gamma[B]}{|A|} \leq \frac{vA_\gamma[B]}{|B|/2} = 2 \text{opt}N_\gamma(s, t)$ .

We present now two sequences and a scoring matrix  $\gamma$  such that the solution given by the heuristic is at least  $2 - \varepsilon$  times the  $vN_\gamma$ -score of an N-optimal alignment, for any  $\varepsilon$  in  $\mathbb{Q}_>$ . Let  $\Sigma = \{\mathbf{a}, \mathbf{b}\}$ ,  $\gamma$  be a scoring matrix such that  $\gamma_{\mathbf{a} \rightarrow -} = \gamma_{\mathbf{b} \rightarrow -} = 1/\varepsilon$  and  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = 2/\varepsilon - 1$  and  $\mathbf{a}^n, \mathbf{b}^n \in \Sigma^*$ , with  $n$  in  $\mathbb{N}^*$ . Observe that the  $vA_\gamma$ -score of any alignment of  $(\mathbf{a}^n, \mathbf{b}^n)$ , where  $[\mathbf{a}, \mathbf{b}]$  is aligned in  $k$  columns, is  $2n/\varepsilon - k$ . Thus,  $\text{opt}A_\gamma(\mathbf{a}^n, \mathbf{b}^n) = \min_{0 \leq k \leq n} \{2n/\varepsilon - k\} = 2n/\varepsilon - n = (2/\varepsilon - 1)n$  which implies  $[\mathbf{a}^n, \mathbf{b}^n]$  is the A-optimal alignment with maximum length. Since  $\text{opt}N_\gamma(\mathbf{a}^n, \mathbf{b}^n) \leq vN_\gamma([\mathbf{a}^n, \mathbf{b}^n]) = 1/\varepsilon$ , it follows

$$\frac{\text{opt}A_\gamma(s, t)}{|[\mathbf{a}^n, \mathbf{b}^n]|} = \frac{vA_\gamma(s, t)}{|[\mathbf{a}^n, \mathbf{b}^n]|} = \frac{(2/\varepsilon - 1)n}{n} = (2 - \varepsilon)/\varepsilon \geq (2 - \varepsilon) \text{opt}N_\gamma(\mathbf{a}^n, \mathbf{b}^n). \quad \blacktriangleleft$$

We define now classes of scoring matrices. The usual class of scoring matrices  $\mathbb{M}^C$  has the following properties: for all symbols  $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \Sigma_-$ , we have (a)  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} > 0$  if  $\mathbf{a} \neq \mathbf{b}$ , and  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = 0$  if  $\mathbf{a} = \mathbf{b}$ ; (b)  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = \gamma_{\mathbf{b} \rightarrow \mathbf{a}}$ ; and (c)  $\gamma_{\mathbf{a} \rightarrow \mathbf{c}} \leq \gamma_{\mathbf{a} \rightarrow \mathbf{b}} + \gamma_{\mathbf{b} \rightarrow \mathbf{c}}$ . The class  $\mathbb{M}^A$  of scoring matrices is such that, for all symbols  $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \Sigma$ , we have (a)  $\gamma_{\mathbf{a} \rightarrow -} = \gamma_{-\rightarrow \mathbf{a}} > 0$ ; (b)  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} > 0$  if  $\mathbf{a} \neq \mathbf{b}$ , and  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = 0$  if  $\mathbf{a} = \mathbf{b}$ ; (c) if  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} < \gamma_{\mathbf{a} \rightarrow -} + \gamma_{-\rightarrow \mathbf{b}}$ , then  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = \gamma_{\mathbf{b} \rightarrow \mathbf{a}}$ ; (d)  $\gamma_{\mathbf{a} \rightarrow -} \leq \gamma_{\mathbf{a} \rightarrow \mathbf{b}} + \gamma_{\mathbf{b} \rightarrow -}$ ; and (e)  $\min\{\gamma_{\mathbf{a} \rightarrow \mathbf{c}}, \gamma_{\mathbf{a} \rightarrow -} + \gamma_{-\rightarrow \mathbf{c}}\} \leq \gamma_{\mathbf{a} \rightarrow \mathbf{b}} + \gamma_{\mathbf{b} \rightarrow \mathbf{c}}$ . Moreover, the class  $\mathbb{M}^N$  is such that (a)  $\mathbb{M}^N \subseteq \mathbb{M}^A$  and (b)  $\gamma_{\mathbf{a} \rightarrow -} \leq 2\gamma_{\mathbf{b} \rightarrow -}$  for each  $\mathbf{a}, \mathbf{b} \in \Sigma$ .

For a set  $S$ , we say that the (distance) function  $f : S \times S \rightarrow \mathbb{R}$  is a *metric* on  $S$  if, for all  $s, t, u \in S$ , the distance  $f$  satisfies: (1)  $f(s, s) = 0$  (*reflexive*); (2)  $f(s, t) > 0$  if  $s \neq t$  (*positive*); (3)  $f(s, t) = f(t, s)$  (*symmetry*); and (4)  $f(s, u) \leq f(s, t) + f(t, u)$  (*triangle inequality*).

If a given criterion  $v$  depends on a scoring matrix  $\gamma$  and it is a metric on  $\Sigma^*$ , we say that the scoring matrix  $\gamma$  *induces* a  $v$ -distance on  $\Sigma^*$ . Sellers [22] showed that matrices in  $\mathbb{M}^C$  induce an  $\text{opt}A_\gamma$ -distance on  $\Sigma^*$  and Araujo and Soares [5] showed that  $\gamma \in \mathbb{M}^A$  if and only if  $\gamma$  induces an  $\text{opt}A_\gamma$ -distance on  $\Sigma^*$ . Furthermore,  $\gamma \in \mathbb{M}^N$  if and only if  $\gamma$  induces an  $\text{opt}N_\gamma$ -distance on  $\Sigma^*$ . Figure 1 shows the relationship between these classes.

## 2.1 $v\text{SP}_\gamma$ -score for $k$ sequences

Consider a scoring matrix  $\gamma$ . Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence and  $A = [s'_1, \dots, s'_k]$  be an alignment of  $S$ . The criterion  $v\text{SP}_\gamma$ , also called *SP-score*, for scoring the alignment  $A$  is

$$v\text{SP}_\gamma[A] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k vA_\gamma[A_{\{h, i\}}]. \quad (1)$$

■ **Figure 1** Relationship between scoring matrices. Araujo and Soares [5] showed that  $M^C \subseteq M^A$ ,  $M^N \subseteq M^A$ ,  $M^C \not\subseteq M^N$  and  $M^N \not\subseteq M^C$ . Moreover, the scoring matrix  $\gamma$  such that  $\gamma_{a \rightarrow a} = 0$  for each  $a$  and  $\gamma_{a \rightarrow b} = 1$  for each  $a \neq b$  is in  $M^C \cap M^N$ , which implies that  $M^C \cap M^N \neq \emptyset$ .

We define  $\text{optSP}_\gamma$  as the optimal function for the criterion  $v\text{SP}_\gamma$ . An alignment  $A$  of  $S$  such that  $v\text{SP}_\gamma[A] = \text{optSP}_\gamma(S)$  is called  *$v\text{SP}_\gamma$ -optimal alignment*. Regardless its decision or optimization version, we call this the *multiple sequence alignment problem (MSA)*. Formally,

► **Problem 2 (Multiple sequence alignment)**. Let  $\gamma$  be a fixed scoring matrix. Given a  $k$ -sequence  $S$ , find a  $v\text{SP}_\gamma$ -optimal alignment of  $S$ .

In order to compute  $\text{optSP}_\gamma$ , we extend the definition of  $v\text{SP}_\gamma$  considering a column of an alignment  $A = [s'_1, \dots, s'_k]$  as its parameter. Thus,  $v\text{SP}_\gamma(A(j)) = \sum_{i < h} \gamma_{s'_i(j) \rightarrow s'_h(j)}$  assuming that  $\gamma_{- \rightarrow -} = 0$  and

$$\text{optSP}_\gamma(S) = \text{optSP}_\gamma(S(1:\vec{n})) = \min_{\vec{b} \in \mathcal{B}^k, \vec{b} \leq \vec{j}} \{ \text{optSP}_\gamma(S(1:\vec{n} - \vec{b})) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{n})] \}. \quad (2)$$

Recurrence (2) can be computed using a dynamic programming algorithm, obtaining  $D(\vec{j}) = \text{optSP}_\gamma(S(1:\vec{j}))$  for all  $\vec{j} \leq \vec{n}$ . This task can be performed by generating all indexes of  $D$  in lexicographical order, starting with  $D(\vec{0}) = 0$ , as presented in Algorithm 1.

■ **Algorithm 1**  $v\text{SP}_\gamma$ -optimal alignment of  $S$ .

---

**Input:**  $S = s_1, \dots, s_k \in (\Sigma^*)^k$

**Output:**  $\text{optSP}_\gamma(S)$

- 1:  $D(\vec{0}) \leftarrow 0$
  - 2: **for** each  $\vec{j} \leq \vec{n}$  in lexicographical order **do**
  - 3:    $D(\vec{j}) \leftarrow \min_{\vec{b} \in \mathcal{B}^k, \vec{b} \leq \vec{j}} \{ D(\vec{j} - \vec{b}) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{j})] \}$
  - 4: **return**  $D(\vec{n})$
- 

Suppose that  $|s_i| = n$  for each  $i$ . Notice that the space to store the matrix  $D$  is  $\Theta((n+1)^k)$  and thus Algorithm 1 uses  $\Theta((n+1)^k)$ -space. Besides that, Algorithm 1 checks, in the worst case,  $\Theta(2^k)$  entries for computing all entries in the matrix  $D$  and each computation spends  $\Theta(k^2)$ -time. Therefore, its running time is  $O(2^k k^2 (n+1)^k)$ . Observe that when the distances between sequences are small, not all entries in  $D$  need to be computed, such as in the Carrillo and Lipman's algorithm [9].

## 2.2 $V_\gamma^i$ -score for $k$ sequences

In this section we define a new criteria to normalize the  $v\text{SP}_\gamma$ -score of a multiple alignment. The symbol - aligned to the same symbol - does not contribute to the definition of scoring, and thus this entry is not defined. However, as all the criteria are additive, it is convenient to consider  $\gamma_{- \rightarrow -} = 0$ . The new criteria for aligning sequences takes into account the length of the alignments according to the following:

$$V_\gamma^1[A] = \begin{cases} 0, & \text{if } |A| = 0, \\ v\text{SP}_\gamma[A]/|A|, & \text{otherwise,} \end{cases} \quad (3)$$

$$V_\gamma^2[A] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k vN_\gamma[A_{\{h,i\}}], \quad (4)$$

$$V_\gamma^3[A] = \begin{cases} 0, & \text{if } |A| = 0, \\ vSP_\gamma[A] / (\sum_{h=1}^{k-1} \sum_{i=h+1}^k |A_{\{h,i\}}|), & \text{otherwise.} \end{cases} \quad (5)$$

We define  $\text{optNSP}_\gamma^z$  as the optimal function for the criterion  $V_\gamma^z$ . An alignment  $A$  of  $S$  such that  $V_\gamma^z[A] = \text{optNSP}_\gamma^z(S)$  is called  $V_\gamma^z$ -*optimal alignment*. Moreover, regardless its decision or optimization version, we establish the *criterion  $V_\gamma^z$  for the normalized multiple sequence alignment problem (NMSA- $z$ )*, for  $z = 1, 2, 3$ . Formally,

► **Problem 3** (Normalized multiple sequence alignment with score  $V_\gamma^z$ ). Let  $\gamma$  be a fixed scoring matrix and  $z \in \{1, 2, 3\}$ . Given a  $k$ -sequence  $S$ , find a  $V_\gamma^z$ -optimal alignment of  $S$ .

### 3 Complexity

We study now the complexity of the multiple sequence alignment problem for each new criterion defined in Section 2. We consider the decision version of the computational problems and we prove **NMSA- $z$**  is NP-complete for each  $z$  when the following additional restrictions for the scoring matrix  $\gamma$  hold:  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = \gamma_{\mathbf{b} \rightarrow \mathbf{a}}$  and  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = 0$  if and only if  $\mathbf{a} = \mathbf{b}$  for each pair  $\mathbf{a}, \mathbf{b} \in \Sigma_-$ . Elias [13] shows that, even considering such restrictions, **MSA** is NP-complete. We show a polynomial time reduction from **MSA** to **NMSA- $z$** .

Consider a fixed alphabet  $\Sigma$  and a scoring matrix  $\gamma$  with the restrictions above. Let  $\sigma \notin \Sigma_-$  be a new symbol and  $\Sigma^\sigma = \Sigma \cup \{\sigma\}$ . Let  $G$  be a fixed (constant) positive integer such that each entry in  $\gamma$  is at most  $G$ . We define a scoring matrix  $\gamma^\sigma$  such that  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}}^\sigma = \gamma_{\mathbf{a} \rightarrow \mathbf{b}}, \gamma_{\mathbf{a} \rightarrow \sigma}^\sigma = \gamma_{\sigma \rightarrow \mathbf{a}}^\sigma = G$  and  $\gamma_{\sigma \rightarrow \sigma}^\sigma = 0$ , for each pair  $\mathbf{a}, \mathbf{b} \in \Sigma_-$ .

For an instance  $(S = s_1, \dots, s_k, C)$  of **MSA**, let  $S^L = s_1\sigma^L, \dots, s_k\sigma^L$ , where  $L = Nk^2MG$ ,  $M = \max_i\{|s_i|\}$  and  $N = \binom{k}{2}M$ . Define  $l$  as the *tail length* of an alignment  $A$  if  $A[i, j] = \sigma$  for each  $i = 1, \dots, k$  and  $j = l + 1, l + 2, \dots, |A|$ , i.e., every symbol in the last  $l$  columns of  $A$  is  $\sigma$ . We say that an alignment of  $S^L$  is *canonical* if its tail length is  $L$ . If  $A = [s''_1, \dots, s''_k]$  is an alignment of  $S$ , we denote by  $A^L$  the canonical alignment  $[s''_1\sigma^L, \dots, s''_k\sigma^L]$  of  $S^L$ . The two following results are useful to prove Theorem 3.3, which is the main result of this section. The proofs of these two lemmas can be found in [4].

► **Lemma 3.1.** *There exists a canonical alignment of  $S^L$  which is  $V_{\gamma^\sigma}^z$ -optimal for each  $z$ .*

► **Lemma 3.2.** *If  $C \geq k^2MG$ , then  $\text{MSA}(S, C) = \text{NMSA-}z(S^L, C^z) = \text{Yes}$ , for each  $z$ .*

► **Theorem 3.3.** *NMSA- $z$  is NP-complete for each  $z$ .*

**Proof.** Given a  $k$ -sequence  $S$  over  $\Sigma^*$ , an alignment  $A$  of  $S$  and a integer  $C$ , it is easy to check in polynomial time on the length of  $A$  that  $V_\gamma^z[A] \leq C$ , for  $z \in \{1, 2, 3\}$ , and then **NMSA- $z$**  is in NP.

Consider now  $C^1 := C^2 := C/L, C^3 := C/(\binom{k}{2}L)$  and  $L := Nk^2MG$  and then we prove that  $\text{MSA}(S, C) = \text{Yes}$  if and only if  $\text{NMSA-}z(S^L, C^z) = \text{Yes}$  for each  $z \in \{1, 2, 3\}$ . If  $C \geq k^2MG$ , the Lemma 3.2 holds trivially. Thus, we assume  $C < k^2MG$ . Suppose that  $\text{MSA}(S, C) = \text{Yes}$  and, hence, there exists an alignment  $A$  such that  $vSP_\gamma[A] \leq C$ :

$$V_{\gamma^\sigma}^1[A^L] = \frac{vSP_{\gamma^\sigma}[A^L]}{|A^L|} \leq \frac{vSP_{\gamma^\sigma}[A^L]}{L} = \frac{vSP_\gamma[A]}{L} \leq \frac{C}{L} = C^1,$$

$$V_{\gamma^\sigma}^2[A^L] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k \frac{vA_{\gamma^\sigma}[A^L_{\{h,i\}}]}{|A^L_{\{h,i\}}|} \leq \sum_{h=1}^{k-1} \sum_{i=h+1}^k \frac{vA_{\gamma^\sigma}[A^L_{\{h,i\}}]}{L} = \frac{vSP_{\gamma^\sigma}[A^L]}{L} = \frac{vSP_\gamma[A]}{L} \leq \frac{C}{L} = C^2,$$

$$V_{\gamma\sigma}^3[A^L] = \frac{vSP_{\gamma\sigma}[A^L]}{\sum_{h=1}^{k-1} \sum_{i=k+1}^k |A_{\{h,i\}}^L|} \leq \frac{vSP_{\gamma\sigma}[A^L]}{\sum_{h=1}^{k-1} \sum_{i=k+1}^k L} = \frac{vSP_{\gamma\sigma}[A^L]}{\binom{k}{2}L} = \frac{vSP_{\gamma\sigma}[A]}{\binom{k}{2}L} \leq \frac{C}{\binom{k}{2}L} = C^3,$$

where the first inequality in each equation follows since either  $A^L$  or each alignment induced by  $A^L$  has length at least  $L$  and the second inequality follows since  $vSP_{\gamma\sigma}[A] \leq C$ . Thus, if  $\mathbf{MSA}(S, C) = \text{Yes}$  then  $\mathbf{NMSA}\text{-}z(S^L, C^z) = \text{Yes}$ .

Suppose that  $\mathbf{NMSA}\text{-}z(S^L, C^z) = \text{Yes}$ . It follows from Lemma 3.1 that, for each  $z$ , there exists a canonical alignment  $A^L$  such that  $V_{\gamma\sigma}^z[A^L] \leq C^z$ . Thus, considering  $V_{\gamma\sigma}^1[A^L] \leq C^1$ , we have

$$\begin{aligned} vSP_{\gamma}[A] &= vSP_{\gamma\sigma}[A^L] = (N+L) \frac{vSP_{\gamma\sigma}[A^L]}{N+L} \leq (N+L) \frac{vSP_{\gamma\sigma}[A^L]}{|A^L|} = (N+L) V_{\gamma\sigma}^1[A^L] \\ &\leq (N+L) C^1 = (N+L) \frac{C}{L} = \frac{NC}{L} + C < \frac{Nk^2MG}{L} + C = 1 + C, \end{aligned}$$

where the first equality holds since  $A^L$  is canonical, the first inequality holds since  $|A^L| \leq N+L$  and the second and the third inequalities hold by hypothesis. Considering  $V_{\gamma\sigma}^2[A^L] \leq C^2$ , we have

$$\begin{aligned} vSP_{\gamma}[A] &= vSP_{\gamma\sigma}[A^L] = (N+L) \frac{vSP_{\gamma\sigma}[A^L]}{N+L} = (N+L) \sum_{h=1}^{k-1} \sum_{i=h+1}^k \frac{vA_{\gamma\sigma}[A_{\{h,i\}}^L]}{N+L} \\ &\leq (N+L) \sum_{h=1}^{k-1} \sum_{i=h+1}^k \frac{vA_{\gamma\sigma}[A_{\{h,i\}}^L]}{|A_{\{h,i\}}^L|} = (N+L) V_{\gamma\sigma}^2[A^L] \\ &\leq (N+L) C^2 = (N+L) \frac{C}{L} = \frac{NC}{L} + C < \frac{Nk^2MG}{L} + C = 1 + C, \end{aligned}$$

where the first equality holds since  $A^L$  is canonical, the first inequality holds since, for each  $h, i$ ,  $|A_{\{h,i\}}^L| \leq N+L$ , and the second and the third inequalities hold by hypothesis. And finally, considering  $V_{\gamma\sigma}^3[A^L] \leq C^3$ , we have

$$\begin{aligned} vSP_{\gamma}[A] &= vSP_{\gamma\sigma}[A^L] = (N + \binom{k}{2}L) \frac{vSP_{\gamma\sigma}[A^L]}{N + \binom{k}{2}L} \\ &\leq (N + \binom{k}{2}L) \frac{vSP_{\gamma\sigma}[A^L]}{\sum_{h=1}^{k-1} \sum_{i=h+1}^k |A_{\{h,i\}}^L|} = (N + \binom{k}{2}L) V_{\gamma\sigma}^3[A^L] \leq (N + \binom{k}{2}L) C^3 \\ &= (N + \binom{k}{2}L) \frac{C}{\binom{k}{2}L} = \frac{NC}{\binom{k}{2}L} + C < \frac{Nk^2MG}{\binom{k}{2}L} + C = \frac{1}{\binom{k}{2}} + C \leq 1 + C, \end{aligned}$$

where the first equality holds since  $A^L$  is canonical, the first inequality holds since the sum of lengths of two sequences induced by a canonical alignment is at most  $N + \binom{k}{2}L$  and the second and the third inequalities hold by hypothesis.

Therefore, if  $\mathbf{NMSA}\text{-}z(S^L, C^z) = \text{Yes}$  then  $vSP_{\gamma}[A] < 1 + C$ , for any  $z \in \{1, 2, 3\}$ . Since the entries in the scoring matrix are integers, we have that  $vSP_{\gamma}[A]$  is an integer. And since  $C$  is an integer, it follows that  $vSP_{\gamma}[A] \leq C$ .  $\blacktriangleleft$

## 4 Exact algorithms

### 4.1 NMSA-1

Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence and  $A = [s'_1, \dots, s'_k]$  be an alignment of  $S$ . As defined in Equation (3),  $V_\gamma^1[A]$  takes into account the length of  $A$ , and the optimal function is given by  $\text{opt}V_\gamma^1(S) = \min_{A \in \mathcal{A}_S} \{V_\gamma^1[A]\}$ . The  $V_\gamma^1$ -optimal alignment of  $S$  is an alignment  $A$  such that  $V_\gamma^1[A] = \text{opt}V_\gamma^1(S)$ . Thus, in **NMSA-1** we are given a  $k$ -sequence  $S$  and we want to compute  $\text{opt}V_\gamma^1(S)$  for a fixed matrix  $\gamma$ . We can solve **NMSA-1** by calculating the minimum SP-score considering every possible length of an alignment. That is, we compute the entries of a table  $D$  indexed by  $V_S \times \{0, 1, \dots, N\}$ , where  $N = \sum_{i=1}^k |s_i|$ . The entry  $D(\vec{v}, L)$  stores the score of an alignment of  $S(\vec{v})$  of length  $L$  with lowest SP-score. Notice that  $D(\vec{0}, 0) = 0$ ,  $D(\vec{v} \neq \vec{0}, 0) = D(\vec{0}, L \neq 0) = \infty$ . Therefore, the table entries can be calculated as:

$$D(\vec{v}, L) = \begin{cases} 0, & \text{if } \vec{v} = \vec{0}, L = 0, \\ \infty, & \text{if } \vec{v} = \vec{0}, L \neq 0 \text{ or } \vec{v} \neq \vec{0}, L = 0, \\ \min_{\vec{b} \in \mathcal{B}_k, \vec{b} \leq \vec{v}} \{D(\vec{v} - \vec{b}, L - 1) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{v})]\}, & \text{otherwise.} \end{cases}$$

Table  $D$  is computed for all possible values of  $L = 0, \dots, N$ . Consequently,  $\text{opt}V_\gamma^1(S) = \min_L \{D(\vec{n}, L)/L\}$  is returned. Algorithm 2 describes this procedure more precisely.

■ **Algorithm 2**  $V_\gamma^1$ -optimal alignment of  $S$ .

---

**Input:**  $k$ -sequence  $S = s_1, \dots, s_k$  such that  $n_i = |s_i|$

**Output:**  $\text{opt}V_\gamma^1(S)$

- 1:  $D(\vec{0}, 0) \leftarrow 0$
  - 2: **for** each  $L \neq 0$  **do**  $D(\vec{0}, L) \leftarrow \infty$
  - 3: **for** each  $\vec{v} \neq \vec{0}$  **do**  $D(\vec{v}, 0) \leftarrow \infty$
  - 4: **for** each  $\vec{0} < \vec{v} \leq \vec{n}$  in lexicographical order **do**
  - 5:   **for** each  $L \leftarrow 1, 2, \dots, N$  **do**
  - 6:      $D(\vec{v}, L) \leftarrow \min_{\vec{b} \in \mathcal{B}_k, \vec{b} \leq \vec{v}} \{D(\vec{v} - \vec{b}, L - 1) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{v})]\}$
  - 7: **return**  $\min_L \{D(\vec{n}, L)/L\}$
- 

Suppose that  $n_i = |s_i| = n$  for each  $i$ . Notice that the space to store the matrix  $D$  is  $\Theta(N(n+1)^k)$ . The time consumption of Algorithm 2 corresponds to the time needed to fill the table  $D$  up, plus the running time of line 7. Each entry of  $D$  can be computed in  $O(2^k k^2)$ -time. Therefore, the algorithm spends  $O(2^k k^2 \cdot N(n+1)^k)$ -time to compute the entire table  $D$ , since  $D$  has  $\Theta(N(n+1)^k)$  entries. Line 7 is computed in  $\Theta(N)$ -time. Therefore, the running time of Algorithm 2 is  $O(2^k k^2 \cdot N(n+1)^k) + \Theta(N) = O(2^k k^2 \cdot N(n+1)^k)$ . If  $N = kn$ , it follows that the total running time is  $O(2^k k^3 (n+1)^{k+1})$ .

### 4.2 NMSA-2

Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence and  $A = [s'_1, \dots, s'_k]$  be an alignment of  $S$ . As defined in Equation (4),  $V_\gamma^2[A]$  takes into account the length of the induced alignment  $A$ , and the optimal function is given by  $\text{opt}V_\gamma^2(S) = \min_{A \in \mathcal{A}_S} \{V_\gamma^2[A]\}$ . The  $V_\gamma^2$ -optimal alignment of  $S$  is an alignment  $A$  such that  $V_\gamma^2[A] = \text{opt}V_\gamma^2(S)$ . Then, in **NMSA-2** we are given a  $k$ -sequence  $S$  and we want to compute  $\text{opt}V_\gamma^2(S)$  for a fixed matrix  $\gamma$ .

Let  $\vec{L} = [L_{12}, L_{13}, \dots, L_{1k}, L_{23}, \dots, L_{2k}, \dots, L_{(k-1)k}]$  be a  $\binom{k}{2}$ -vector indexed by sets of two integers  $\{h, i\}$  such that  $1 \leq h < i \leq k$  and  $L_{hi}$  denotes the element of  $\vec{L}$  of index  $\{h, i\}$ . The lengths of the induced alignments by an alignment can be represented by a vector

$\vec{L}$ . Thus, if  $A$  is an alignment and  $|A_{\{h,i\}}| = L_{hi}$  for each pair  $h, i$ , we say that  $\vec{L}$  is the *induced length* of  $A$ . For a  $k$ -sequence  $S = s_1, \dots, s_k$ , where  $n_i = |s_i|$  for each  $i$ , we define  $\mathbb{L} = \{\vec{L} = [L_{12}, L_{13}, \dots, L_{1k}, L_{23}, \dots, L_{2k}, \dots, L_{(k-1)k}] : 0 \leq L_{hi} \leq n_h + n_i\}$ . Note that if  $n$  is the length of each sequence in  $S$ , then  $|\mathbb{L}| = (2n+1)^{\binom{k}{2}}$ . Let  $\vec{b} = [b_1, \dots, b_k]$  be a  $k$ -bit vector. Overloading the minus operator “ $-$ ”, we define  $\vec{L} - \vec{b}$  to be a  $\binom{k}{2}$ -vector  $\vec{L}'$  which is obtained from  $\vec{L}$  and from  $\vec{b}$  such that, for each pair  $h, i$ , we have  $L'_{hi} = L_{hi}$  if  $b_h = b_i = 0$ , and  $L'_{hi} = L_{hi} - 1$ , otherwise. Observe that if  $\vec{L}$  is the induced length of an alignment  $A$  of  $S(\vec{v})$  and  $\vec{b}$  is a  $k$ -bit vector such that  $\vec{b} \cdot S(\vec{v})$  is the last column of  $A$ , then  $\vec{L}' = \vec{L} - \vec{b}$  is the induced length of the alignment  $A(1:|A| - 1)$ .

Let  $\vec{\gamma}$  be a vector of  $\binom{k}{2}$  scoring matrices indexed by two integers  $\{h, i\}$ , with  $1 \leq h < i \leq k$ . We denote by  $\gamma^{(hi)}$  the element of  $\vec{\gamma}$  with index  $\{h, i\}$ . Then, we have  $\vec{\gamma} = [\gamma^{(12)}, \gamma^{(13)}, \dots, \gamma^{(1k)}, \gamma^{(23)}, \dots, \gamma^{(2k)}, \dots, \gamma^{((k-1)k)}]$ , and define the  $\vec{\gamma}$ -SP-score of  $A$  as  $vSP_{\vec{\gamma}}[A] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k vA_{\gamma^{(hi)}}[A_{\{h,i\}}]$ . If we define the  $\vec{\gamma}$ -SP-score of a vector  $\vec{\sigma} = [\sigma_1, \dots, \sigma_k]$  in  $\Sigma$  as  $vSP_{\vec{\gamma}}[\vec{\sigma}] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k \gamma_{\sigma_h \rightarrow \sigma_i}^{(hi)}$ , then we can alternatively calculate the  $\vec{\gamma}$ -SP-score of the alignment  $A$  as  $vSP_{\vec{\gamma}}[A] = \sum_j vSP_{\vec{\gamma}}[A(j)]$ .

### 4.2.1 Computing $\text{optV}_{\vec{\gamma}}^2$

In this section we describe an algorithm in two steps for computing  $\text{optV}_{\vec{\gamma}}^2$  for a given  $k$ -sequence  $S$ : in Step 1 we consider the particular case where we have three sequences, and in Step 2 we treat the general case.

#### Step 1: $k = 3$

Let  $S = s_1, s_2, s_3$  be a 3-sequence. Suppose that we have induced lengths  $\vec{\mathcal{L}} = [\mathcal{L}_{12}, \mathcal{L}_{13}, \mathcal{L}_{23}]$  of a  $V_{\vec{\gamma}}^2$ -optimal alignment  $A$  of  $S$ . In consequence, we have that  $\mathcal{L}_{hi} = |A_{\{h,i\}}|$  for each pair  $h, i$ . Notice that knowing the lengths  $\mathcal{L}_{12}, \mathcal{L}_{13}$  and  $\mathcal{L}_{23}$  does not imply knowing the  $V_{\vec{\gamma}}^2$ -optimal alignment  $A$ . In general, we cannot even infer what  $|A|$  is. For example, the alignments

$$\begin{bmatrix} s_1(1) & s_1(2) & - \\ s_2(1) & - & s_2(2) \\ - & s_3(1) & s_3(2) \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} s_1(1) & s_1(2) & - & - \\ s_2(1) & - & s_2(2) & - \\ s_3(1) & - & - & s_3(2) \end{bmatrix}$$

have different lengths but same induced lengths for  $s_1, s_2, s_3$ , where  $|s_1| = |s_2| = |s_3| = 2$  and  $\mathcal{L}_{12} = \mathcal{L}_{13} = \mathcal{L}_{23} = 3$ . However, if we know  $\vec{\mathcal{L}} = [\mathcal{L}_{12}, \mathcal{L}_{13}, \mathcal{L}_{23}]$ , we have

$$\begin{aligned} \text{optV}_{\vec{\gamma}}^2(S) &= \min_{A \in \mathcal{A}_S : \mathcal{L}_{hi} = |A_{\{h,i\}}|, \forall h,i} \left\{ \sum_{h=1}^{k-1} \sum_{i=h+1}^k vA_{\gamma^{(hi)}}[A_{\{h,i\}}] / \mathcal{L}_{hi} \right\} \\ &= \min_{A \in \mathcal{A}_S} \left\{ \sum_{h=1}^{k-1} \sum_{i=h+1}^k vA_{\gamma^{(hi)}}[A_{\{h,i\}}] \right\}, \end{aligned}$$

where  $\gamma^{(hi)}$  is a scoring matrix obtained by multiplying the elements of  $\gamma$  by  $1/\mathcal{L}_{hi}$ . Since we guarantee it is the induced length of an alignment  $V_{\vec{\gamma}}^2$ -optimal, we fix  $\vec{\mathcal{L}}$  and compute  $\vec{\gamma}$  in order to calculate the entries of a table  $D_{\vec{\mathcal{L}}}$ , such that

$$D_{\vec{\mathcal{L}}}(\vec{v} = [v_1, v_2, v_3], \vec{L} = [L_{12}, L_{13}, L_{23}]) = \min_{A \in \mathcal{A}_{S(\vec{v})}, \mathcal{L}_{hi} = |A_{\{h,i\}}|, \forall h,i} \left\{ \sum_{h < i} vA_{\gamma^{(hi)}}[A_{\{h,i\}}] \right\}$$

corresponds to the score of an alignment with the lowest  $\vec{\gamma}$ -SP-score when the induced length is  $\vec{L}$ . The table  $D_{\vec{\mathcal{L}}}$  can then be computed using the following recurrence

$$D_{\vec{\mathcal{L}}}(\vec{v}, \vec{L}) = \begin{cases} 0, & \text{if } \vec{v} = \vec{0}, \vec{L} = \vec{0}, \\ \infty, & \text{if } \vec{v} = \vec{0}, \vec{L} \neq \vec{0} \text{ or } \vec{v} \neq \vec{0}, \vec{L} = \vec{0}, \\ \min_{\vec{b} \in \mathcal{B}_k, \vec{b} \leq \vec{v}, \vec{b} \leq \vec{L}} \{ D_{\vec{\mathcal{L}}}(\vec{v} - \vec{b}, \vec{L} - \vec{b}) + vSP_{\vec{\gamma}}[\vec{b} \cdot S(\vec{v})] \}, & \text{otherwise,} \end{cases}$$

where  $\vec{b} \leq \vec{L}$  is also an overloading, meaning that  $\vec{L} - \vec{b} \geq \vec{0}$ .

In this case, if  $\vec{\mathcal{L}}$  is the induced length of a  $V_\gamma^2$ -optimal alignment of  $S$ , then  $\text{opt}V_\gamma^2(S) = D_{\vec{\mathcal{L}}}(\vec{n}, \vec{\mathcal{L}})$ . If each sequence has length  $n$ , then the total space to store the table  $D_{\vec{\mathcal{L}}}$  is  $(2n+1)^{\binom{3}{2}} \cdot (n+1)^3 = \Theta(n^6)$ . When  $\vec{\mathcal{L}}$  is unknown, the computation must be repeated for each  $\vec{\mathcal{L}} \in \mathbb{L}$ , but the space can be reused and no additional space required. If  $\vec{\mathcal{L}}$  is known, the algorithm runs to compute all entries of  $D_{\vec{\mathcal{L}}}$ . As  $D_{\vec{\mathcal{L}}}$  has  $\Theta(n^6)$  entries and each entry takes  $O(1)$ -time to be computed, the total time spent is  $O(n^6)$ . If  $\vec{\mathcal{L}}$  is unknown, the time needed to compute  $\vec{\mathcal{L}}$  must be multiplied by the total of elements in  $\mathbb{L}$  which is  $(2n+1)^3$ . Therefore, in the latter case, the total time is  $O(n^6 \cdot (2n+1)^3) = O(n^9)$ .

## Step 2: $k > 3$

Algorithm 3 is a natural extension of the algorithm described in Step 1. Given a scoring matrix  $\gamma$  and an induced length  $\vec{\mathcal{L}}$ , let  $\gamma \times \vec{\mathcal{L}} = [\gamma^{(12)}, \dots, \gamma^{(k(k-1))}]$  be the vector of  $\binom{k}{2}$  scoring matrices, where  $\gamma^{(hi)}$  is obtained dividing each entry of  $\gamma$  by  $\mathcal{L}_{hi}$  for each  $h < i$ .

### Algorithm 3 $V_\gamma^2$ -optimal alignment of $S$ .

**Input:** A  $k$ -sequence  $S = s_1, \dots, s_k$  such that  $n_i = |s_i|$

**Output:**  $\text{opt}V_\gamma^2(S)$

---

```

1: for each  $\vec{\mathcal{L}} \in \vec{\mathbb{L}}$  do
2:    $D_{\vec{\mathcal{L}}}(\vec{0}, \vec{0}) \leftarrow 0$ 
3:   for each  $\vec{L} \neq \vec{0}$  do  $D_{\vec{\mathcal{L}}}(\vec{0}, \vec{L}) \leftarrow \infty$ 
4:   for each  $\vec{v} \neq \vec{0}$  do  $D_{\vec{\mathcal{L}}}(\vec{v}, \vec{0}) \leftarrow \infty$ 
5:    $\vec{\gamma} \leftarrow \gamma \times \vec{\mathcal{L}}$ 
6:   for each  $\vec{0} < \vec{v} \leq \vec{n}$  in lexicographical order do
7:     for each  $\vec{L} \neq \vec{0}$  in lexicographical order do
8:        $D_{\vec{\mathcal{L}}}(\vec{v}, \vec{L}) = \min_{\vec{b} \in \mathcal{B}^k, \vec{b} \leq \vec{v}, \vec{b} \leq \vec{L}} \{D_{\vec{\mathcal{L}}}(\vec{v} - \vec{b}, \vec{L} - \vec{b}) + v\text{SP}_{\vec{\gamma}}[\vec{b} \cdot S(\vec{v})]\}$ 
9: return  $\min_{\vec{\mathcal{L}} \in \vec{\mathbb{L}}} \{D_{\vec{\mathcal{L}}}(\vec{n}, \vec{\mathcal{L}})\}$ 

```

---

For  $k$  sequences of length  $n$ , Algorithm 3 needs  $(2n+1)^{\binom{k}{2}} \cdot (n+1)^k$  space to store the table  $D_{\vec{\mathcal{L}}}$ . For each of the  $(2n+1)^{\binom{k}{2}}$  values  $\vec{\mathcal{L}} \in \vec{\mathbb{L}}$ , table  $D_{\vec{\mathcal{L}}}$  is recalculated. Since the computation of each entry takes  $O(2^k k^2)$ -time, the total time is

$$O(2^k k^2 \cdot (2n+1)^{\binom{k}{2}} \cdot (2n+1)^{\binom{k}{2}} (n+1)^k) = O((1 + 1/(2n+1))^k (2n+1)^{k^2} k^2).$$

If  $k \leq 2n+1$ , the total time can be written as  $O((2n+1)^{k^2} k^2)$ , since  $(1 + 1/k)^k \leq e = 2.718281828\dots$ . Notice that  $(1 + 1/(2n+1))^k \leq (1 + 1/k)^k \leq e$  is also constant.

## 4.3 NMSA-3

Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence and  $A = [s'_1, \dots, s'_k]$  be an alignment of  $S$ . As defined in Equation (5),  $V_\gamma^3[A]$  takes into account the length of  $A$ , and the optimal function is given by  $\text{opt}V_\gamma^3(S) = \min_{A \in \mathcal{A}_S} \{V_\gamma^3[A]\}$ . The  $V_\gamma^3$ -optimal alignment of  $S$  is an alignment  $A$  such that  $V_\gamma^3[A] = \text{opt}V_\gamma^3(S)$ . Then NMSA-3 is defined as follows: for a fixed matrix  $\gamma$ , given a  $k$ -tuple  $S$ , determine  $\text{opt}V_\gamma^3(S)$ .

### 4.3.1 Computing $\text{opt}V_\gamma^3$

Here, each entry  $D(\vec{v}, L)$  of  $D$  stores the SP-score of an alignment  $A$  of the prefix  $S(\vec{v})$  with the lowest SP-score, such that  $\sum_{i < h} |A_{\{i, h\}}| = L$ . If  $\vec{b}$  is a  $k$ -vector, define  $\|\vec{b}\| = \sum_{h < i} b_h b_i$ . Notice that if  $\vec{v} - \vec{b}$  is the last column of an alignment  $A$  and  $L = \sum_{h=1}^{k-1} \sum_{i=h+1}^k |A_{\{h, i\}}|$

## 40:12 Algorithms for Normalized Multiple Sequence Alignments

is the sum of lengths of the alignments induced by  $A$ . Thus, the sum of lengths of the alignments induced by  $A(1:|A| - 1)$  is  $L - \|\vec{b}\|$ . Therefore,

$$D(\vec{v}, L) = \begin{cases} 0, & \text{if } \vec{v} = \vec{0}, L = 0, \\ \infty, & \text{if } \vec{v} = \vec{0}, L \neq 0 \text{ or } \vec{v} \neq \vec{0}, L = 0, \\ \{D(\vec{v} - \vec{b}, L - \|\vec{b}\|) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{v})]\}, & \text{otherwise.} \end{cases}$$

Algorithm 4 provides more details about the procedure for computing  $\text{optV}_\gamma^3$ .

■ **Algorithm 4**  $V_\gamma^3$ -optimal alignment of  $S$ .

**Input:** a  $k$ -sequence  $S = s_1, \dots, s_k$  such that  $n_i = |s_i|$

**Output:**  $\text{optV}_\gamma^3(S)$

---

```

1:  $D(\vec{0}, 0) \leftarrow 0$ 
2: for each  $L \neq 0$  do  $D(\vec{0}, L) \leftarrow \infty$ 
3: for each  $\vec{v} \neq \vec{0}$  do  $D(\vec{v}, 0) \leftarrow \infty$ 
4: for each  $\vec{0} < \vec{v} \leq \vec{n}$  in lexicographical order do
5:   for  $L \leftarrow 1, 2, \dots, N(k-1)$  do
6:      $D(\vec{v}, L) \leftarrow \min_{\vec{b} \in \mathcal{B}^k, \vec{b} \leq \vec{v}, \|\vec{b}\| \leq L} \{D(\vec{v} - \vec{b}, L - \|\vec{b}\|) + v\text{SP}_\gamma[\vec{b} \cdot S(\vec{v})]\}$ 
7: return  $\min_L \{D(\vec{n}, L)/L\}$ 

```

---

Assume that all sequences in  $S$  have length  $n$ . The table  $D$  is computed for all possible values of  $L = 1, \dots, \binom{k}{2}(2n) (= nk^2 - nk)$  and, after this, we determine  $\text{optSP}_\gamma(S) = \min_L \{D(\vec{n}, L)/L\}$ . Thus, table  $D$  needs space equivalent to  $(nk^2 - nk + 1) \cdot (n + 1)^k = \Theta(k^2(n + 1)^{k+1})$ . Since the time required to determine each entry of  $D$  is  $O(2^k k^2)$ , the running time of Algorithm 4 is  $O(2^k k^4 (n + 1)^{k+1})$ .

## 5 Approximation algorithms for MSA and NMSA-2

Gusfield [15] described a 2-approximation algorithm for **MSA**. It assumes that  $\gamma \in \mathbb{M}^{\mathbb{C}}$ . In this section, we adapt Gusfield's algorithm, proposing a 6-approximation algorithm for **MSA** when  $\gamma \in \mathbb{M}^{\mathbb{A}}$  and a 12-approximation algorithm for **NMSA-2** problem when  $\gamma \in \mathbb{M}^{\mathbb{N}}$ .

We consider here a generic function  $v$  to score an alignment of a 2-sequence such that  $\text{opt}(s, s) = 0$  (identity) and  $\text{opt}(s, t) = \text{opt}(t, s)$  (symmetry), where  $\text{opt}(s, t)$  is the score of a  $v$ -optimal alignment of a 2-sequence  $s, t$ . Notice that  $vA_\gamma$  and  $vN_\gamma$  have these properties when  $\gamma \in \mathbb{M}^{\mathbb{A}}$  and  $\gamma \in \mathbb{M}^{\mathbb{N}}$ , respectively. Let  $S$  be a  $k$ -sequence and  $A$  in  $\mathcal{A}_S$  be an alignment. We define  $V$  and  $\text{OPT}$  as functions such that  $V[A] = \sum_{h=1}^{k-1} \sum_{i=h+1}^k v[A_{\{h,i\}}]$  and  $\text{OPT}(S) = \min_{A \in \mathcal{A}_S} V(A)$ . Thus, a  $V$ -optimal alignment is an alignment  $A$  such that  $V[A] = \text{OPT}(S)$ .

Let  $c$  be an integer with  $1 \leq c \leq k$ . A *star*  $X$  with center  $c$  of  $S = s_1, \dots, s_k$ , also called a  $c$ -star, is a collection of  $k - 1$  alignments: alignment  $X_h = [s'_h, s_c^h]$  of  $s_h, s_c$ , for each  $h < c$ , where  $v[s'_h, s_c^h] = v[s_c^h, s'_h]$ , and alignment  $X_h = [s_c^h, s'_h]$  of  $s_c, s_h$ , for each  $h > c$ , where  $v[s_c^h, s'_h] = v[s'_h, s_c^h]$ . The set of all  $c$ -stars is denoted by  $\mathcal{X}_c$ . The score of the  $c$ -star  $X$  is  $\text{cStar}(X) = \sum_{h \neq c} v[X_h]$  and a  $v$ -optimal star is one whose score is  $\text{optStar}(S) = \min_{X \in \mathcal{X}_c, c \in \mathbb{N}} \{\text{cStar}(X)\}$ . Notice that  $\text{optStar}(S) = \min_c \{\sum_{h \neq c} \text{opt}(s_h, s_c)\}$ , and if  $v = vA_\gamma$  and  $\gamma \in \mathbb{M}^{\mathbb{A}}$ ,  $\text{optStar}(S)$  can be computed in  $O(k^2 n^2)$ -time, and if  $v = vN_\gamma$  and  $\gamma \in \mathbb{M}^{\mathbb{N}}$ ,  $\text{optStar}(S)$  can be computed in  $O(k^2 n^3)$ -time when  $|s_i| \leq n$ , for each  $s_i$  in  $S$ .

We say that an alignment  $A$  of a  $k$ -sequence  $S$  and a  $c$ -star  $X$  of  $S$  are *compatible* ( $A$  is compatible with  $X$  or  $X$  is compatible with  $A$ ) in  $S$  when either  $A_{\{h,c\}}$  or  $A_{\{c,h\}}$  is equal to  $X_h$ , for each  $h$ . It is easy to obtain, from an alignment  $A$  and  $c$  in  $\mathbb{N}$ , the unique  $c$ -star  $X$

that is compatible with  $A$ . On the other hand, it is known from Feng and Doolittle [14] that one can find an alignment  $A$  compatible with a given  $c$ -star  $X$  in  $O(kn)$ -time, where  $|s_i| \leq n$  for each sequence  $s_i$  in the  $k$ -sequence  $S$ . In this case, there exists one or more compatible alignments with  $X$ .

The next result is a straightforward consequence of a result from Gusfield [15], where  $v$  is the scoring function. See the proof in [4].

► **Lemma 5.1.** *Given a  $k$ -sequence  $S$ ,  $\text{optStar}(S) \leq (2/k) \text{OPT}(S)$ .*

From now on, we consider  $v = vA_\gamma$ , or  $v = vN_\gamma$  and  $\gamma = \mathbb{M}^A$  or  $\gamma = \mathbb{M}^N$ , respectively. Let  $s, t \in \Sigma^*$  be sequences. Suppose that  $A = [s', t']$  is an alignment of  $s, t$ . We say that a column  $j$  is *splittable in  $A$*  if  $s'(j) \neq -, t'(j) \neq -$  and  $\min\{\gamma_{t'(j) \rightarrow -}, \gamma_{s'(j) \rightarrow -}\} \leq \gamma_{s'(j) \rightarrow t'(j)}$ . Let  $J := \{j_i \in \mathbb{N} : 1 \leq j_1 < \dots < j_m \leq |A| \text{ and } j_i \text{ is splittable in } A\}$ . An  $A$ -*splitting* is the alignment

$$\begin{bmatrix} s'(1:j_1-1) & s'(j_1) & - & s'(j_1+1:j_2-1) & s'(j_2) & - & \dots & s'(j_m+1:|A|) \\ t'(1:j_1-1) & - & t'(j_1) & t'(j_1+1:j_2-1) & - & t'(j_2) & \dots & t'(j_m+1:|A|) \end{bmatrix}.$$

We say that  $J$  is *required to split  $A$* . The following proposition is used to check properties of an  $A$ -splitting. See its proof in [4].

► **Proposition 5.2.** *Consider  $\gamma \in \mathbb{M}^A$  and  $\mathbf{a}, \mathbf{b} \in \Sigma$ . If  $\gamma_{\mathbf{a} \rightarrow -} > \gamma_{\mathbf{a} \rightarrow \mathbf{b}}$  or  $\gamma_{\mathbf{a} \rightarrow -} > \gamma_{\mathbf{b} \rightarrow \mathbf{a}}$ , then  $\gamma_{\mathbf{a} \rightarrow \mathbf{b}} = \gamma_{\mathbf{b} \rightarrow \mathbf{a}}$ .*

Let  $X = \{X_1, \dots, X_{c-1}, X_{c+1}, X_k\}$  be a  $c$ -star. The  $X$ -*starsplitting* is the  $c$ -star  $Y = \{Y_1, \dots, Y_{c-1}, Y_{c+1}, Y_k\}$ , where  $Y_j$  is the  $X_j$ -splitting for each  $j$ . The next result shows that the  $v$ -score of the star  $Y$  is bounded by the  $v$ -score of the star  $X$  when  $\gamma \in \mathbb{M}^A$  and  $v = vA_\gamma$ , or  $\gamma \in \mathbb{M}^N$  and  $v = vN_\gamma$ . Thus, as a consequence of Proposition 5.2, we have the following lemma. The formal proof can be seen in [4].

► **Lemma 5.3.** *Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence,  $X$  be a  $c$ -star of  $S$ ,  $Y$  be the  $X$ -starsplitting and  $v$  be a function to score alignments. Consider  $\gamma \in \mathbb{M}^A$  and  $v = vA_\gamma$ , or  $\gamma \in \mathbb{M}^A$  and  $v = vN_\gamma$ . Then,  $Y$  is also a  $c$ -star and  $c\text{Star}(Y) \leq 3 c\text{Star}(X)$ .*

**Proof sketch.** As a consequence of  $\gamma \in \mathbb{M}^A$  and Proposition 5.2, we have that  $Y$  is also a  $c$ -star. Let  $h \in \{1, \dots, k\}$  and  $J$  be a set required to split  $X$ . We prove that  $vA_\gamma[Y_h] \leq 3vA_\gamma[X_h]$  and  $vN_\gamma[Y_h] \leq 3vN_\gamma[X_h]$  hold since  $\gamma \in \mathbb{M}^A$  when  $v = vA_\gamma$  and  $\gamma \in \mathbb{M}^N$  when  $v = vN_\gamma$ , and  $J \subseteq \{1, 2, \dots, |A|\}$ . Therefore, in these cases, we have

$$c\text{Star}(Y) = \sum_{h \neq c} v[Y_h] = \sum_{h < c} v[Y_h] + \sum_{h > c} v[Y_h] \leq 3 \sum_{h \neq c} v[X_h] = 3c\text{Star}(X). \quad \blacktriangleleft$$

Notice that the time consumption for computing an  $X$ -splitting from  $X$  is  $O(kn)$  when  $|s_i| \leq n$ , for each  $s_i \in S$ . Considering a star  $X$  of  $S = s_1, \dots, s_k$ , there can exist many compatible alignments with a  $v$ -star  $Y$  which is a  $X$ -splitting. Let `COMPATIBLEALIGN` be a subroutine that receives the  $c$ -star  $Y$  and returns an alignment  $A$  compatible with  $Y$ . It is quite simple: if symbols  $s_h(j_1)$  and  $s_c(j_2)$  are aligned in  $X_h$ , they are also aligned in  $A$ ; otherwise,  $s_h(j)$  aligns only with  $-$  in  $A$ . This property is enough to guarantee the approximation factor of `MSA` and `NMSA-2`.

Let  $Q_{\max} := \max_{\mathbf{a} \in \Sigma} \{\gamma_{\mathbf{a} \rightarrow -}, \gamma_{- \rightarrow \mathbf{a}}\}$  and consider the following result, whose proof can be found in [4].

► **Proposition 5.4.** *Let  $S$  be a  $k$ -sequence,  $X$  be a  $c$ -star of  $S$  and  $Y$  be a  $X$ -starsplitting. Assume that  $\gamma \in \mathbb{M}^A$  and that  $\text{COMPATIBLEALIGN}(Y)$  returns  $A = [s'_1, \dots, s'_k]$ . If  $h \neq c$  and  $i \neq c$ , we have that*

- (i)  $\gamma_{s'_h(j) \rightarrow s'_i(j)} \leq \gamma_{s'_h(j) \rightarrow s'_c(j)} + \gamma_{s'_c(j) \rightarrow s'_i(j)}$  for each  $j = 1, \dots, |A|$ , and
- (ii)  $vN_\gamma[A_{\{h,i\}}] \leq 2Q_{\max}$  when  $\gamma \in \mathbb{M}^N$ .

Proposition 5.4 is an auxiliary result to show the following lemma.

► **Lemma 5.5.** *Let  $S$  be a  $k$ -sequence,  $X$  be a  $c$ -star of  $S$ ,  $Y$  be a  $X$ -starsplitting and  $\text{COMPATIBLEALIGN}(Y) = A$ . Then, for each  $h < i$ ,  $h \neq c$  and  $i \neq c$ ,*

- (i)  $vA_\gamma[A_{\{h,i\}}] \leq vA_\gamma[A_{\{h,c\}}] + vA_\gamma[A_{\{c,i\}}]$  when  $\gamma \in \mathbb{M}^A$ , and
- (ii)  $vN_\gamma[A_{\{h,i\}}] \leq 2(vN_\gamma[A_{\{h,c\}}] + vN_\gamma[A_{\{c,i\}}])$  when  $\gamma \in \mathbb{M}^N$ .

**Proof.** Let  $A = [s'_1, \dots, s'_k]$  and  $Z = \{j : s'_c(j) \neq - \text{ and } s'_h(j) = s'_i(j) = -\}$ . We have  $vA_\gamma[A_{\{h,i\}}] \leq vA_\gamma[A_{\{h,c\}}] + vA_\gamma[A_{\{c,i\}}] - \sum_{j \in Z} (\gamma_{- \rightarrow s'_c(j)} + \gamma_{s'_c(j) \rightarrow -})$  from a consequence of Proposition 5.4. Besides, since  $\gamma \in \mathbb{M}^A$ , we have that  $\gamma_{- \rightarrow s'_c(j)}, \gamma_{s'_c(j) \rightarrow -} > 0$ . It implies that (i) is proven.

For proving (ii), observe first that, by definition of  $\mathbb{M}^N$ , we have that  $Q_{\max} \leq \gamma_{- \rightarrow s'_c(j)} + \gamma_{s'_c(j) \rightarrow -}$  for every  $j$ . Furthermore, following these statements, we have that

$$\begin{aligned} vN_\gamma[A_{\{h,i\}}] &= \frac{vA_\gamma[A_{\{h,i\}}]}{|A_{\{h,i\}}|} \\ &\leq \frac{vA_\gamma[A_{\{h,i\}}] + 2 \cdot Q_{\max} |Z|}{|A_{\{h,i\}}| + |Z|} \\ &\leq 2 \cdot \frac{vA_\gamma[A_{\{h,i\}}] + Q_{\max} |Z|}{|A_{\{h,i\}}| + |Z|} \end{aligned} \quad (6)$$

$$\leq 2 \cdot \frac{vA_\gamma[A_{\{h,c\}}] + vA_\gamma[A_{\{c,i\}}] - \sum_{j \in Z} (\gamma_{- \rightarrow s'_c(j)} + \gamma_{s'_c(j) \rightarrow -}) + Q_{\max} |Z|}{|A_{\{h,i,c\}}| - |Z| + |Z|} \quad (7)$$

$$\begin{aligned} &\leq 2 \cdot \frac{vA_\gamma[A_{\{h,c\}}] + vA_\gamma[A_{\{c,i\}}] - Q_{\max} |Z| + Q_{\max} |Z|}{|A_{\{h,i,c\}}| - |Z| + |Z|} \\ &= 2 \cdot \left( \frac{vA_\gamma[A_{\{h,c\}}]}{|A_{\{h,i,c\}}|} + \frac{vA_\gamma[A_{\{c,i\}}]}{|A_{\{h,i,c\}}|} \right) \end{aligned} \quad (8)$$

$$\leq 2 \cdot (vN_\gamma[A_{\{h,c\}}] + vN_\gamma[A_{\{c,i\}}]), \quad (9)$$

where the first inequality of (6) is a consequence of Proposition 5.4 and the second inequality follows since every entry of  $\gamma$  is nonnegative, (7) follows from the result in the first paragraph and from  $|A_{\{h,i\}}| = |A_{\{h,i,c\}}| - |Z|$ , (8–9) follow as a consequence of the definition of  $Q_{\max}$ , and as a consequence of  $|A_{\{h,c\}}| \leq |A_{\{h,i,c\}}|$  and  $|A_{\{c,i\}}| \leq |A_{\{h,i,c\}}|$ . ◀

We can now describe the approximation algorithm (Algorithm 5).

■ **Algorithm 5** Approximation algorithm for MSA and NMSA-2.

**Input:**  $k$ -sequence  $S = s_1, \dots, s_k$

**Output:**  $v[A]$ , where  $A$  is an alignment of  $S$ , and  $vSP_\gamma[A] \leq 6 \text{optSP}_\gamma(S)$  if  $v = vA_\gamma$  and  $\gamma \in \mathbb{M}^A$ , and  $V_\gamma^2[A] \leq 12 \text{optNSP}_\gamma^2(S)$  if  $v = vN_\gamma$  and  $\gamma \in \mathbb{M}^N$ .

- 1: Let  $X$  be a  $v$ -optimal star of  $S$  with center  $c$
- 2: Compute the  $X$ -splitting  $Y$
- 3:  $A \leftarrow \text{COMPATIBLEALIGN}(Y)$
- 4: **return**  $v[A]$

Clearly, Algorithm 5 is correct. Furthermore, Lemmas 5.1, 5.3 and 5.5 are auxiliary to prove its approximation factor. Since the running time of COMPATIBLEALIGN is  $O(k^2n)$ , a straightforward running time analysis allows us to state the following theorem. The detailed proof is presented in [4].

► **Theorem 5.6.** *Let  $S = s_1, \dots, s_k$  be a  $k$ -sequence and  $\gamma$  be a scoring matrix. Then, Algorithm 5 computes  $v[A]$  correctly:*

- (i) *in  $O(k^2n^2)$ -time such that  $v\text{SP}_\gamma[A] \leq 6 \text{optSP}_\gamma(S)$ , if  $v = vA_\gamma$  and  $\gamma = \mathbb{M}^A$ , or*
- (ii) *in  $O(k^2n^3)$ -time such that  $V_\gamma^2[A] \leq 12 \text{optNSP}_\gamma^2(S)$ , if  $v = vN_\gamma$  and  $\gamma \in \mathbb{M}^N$ , where  $A$  is the alignment of  $S$  computed by the algorithm.*

## 6 Conclusion and future work

We presented and discussed several aspects of normalized multiple sequence alignment (NMSA). We defined three new criteria for computing normalized scores when aligning multiple sequences, showing the NP-hardness and exact algorithms for solving the NMSA- $z$  given criterion  $V_\gamma^z$  for each  $z$ . In addition, we adapted an existing 2-approximation algorithm for MSA when the scoring matrix  $\gamma$  is in the common class  $\mathbb{M}^C$ , leading to a 6-approximation algorithm for MSA when  $\gamma$  is in the broader class  $\mathbb{M}^A \supseteq \mathbb{M}^C$ , and to a 12-approximation for NMSA-2 when  $\gamma$  is in  $\mathbb{M}^N \subseteq \mathbb{M}^A$ , a slightly more restricted class compared to  $\mathbb{M}^A$  such that the cost of a deletion for any symbol is at most twice the cost for any other.

This work is an effort to expand the boundaries of multiple sequence alignment algorithms towards normalization, an unexplored domain that can produce results with higher accuracy in some applications. In future work, we will implement our algorithms in order to verify how large are the sequences that our algorithms are able to handle. Also, we plan to perform practical experiments, measuring how well alignments provided by our algorithms and other MSA algorithms agree with multiple alignment benchmarks. In addition, we intend to measure the accuracy of phylogenetic tree reconstruction based on our alignments for simulated and real genomes. Finally, we will work on heuristics and parallel versions of our algorithms in order to faster process large datasets.

## Abstract

We study a generalization of  $k$ -center clustering, first introduced by Kavand et. al., where instead of one set of centers, we have two types of centers,  $p$  red and  $q$  blue, and where each red center is at least  $\alpha$  distant from each blue center. The goal is to minimize the covering radius. We provide an approximation algorithm for this problem, and a polynomial-time algorithm for the constrained problem, where all the centers must lie on a line  $\ell$ .

## 1 Introduction

The  $k$ -center problem is a well-known geometric location problem, where we are given a set  $P$  of  $n$  points in a metric space and a positive integer  $k$ , and the task is to find  $k$  balls of minimum radius whose union covers  $P$ . This problem can be used to model the following facility location scenario. Suppose we want to open  $k$  facilities (such as supermarkets) to serve the customers in a city. It is common to assume that a customer shops at the facility closest to their residence. Thus, we want to locate  $k$  locations to open the facilities, so that the maximum distance between a customer and their nearest facility is minimized. The problem was first shown to be NP-hard by Megiddo and Supowit [12] for Euclidean spaces. We consider a variation of this classic problem where instead of just one set of centers, we consider two sets of centers, one of size  $p$ , and the other of size  $q$ , but with the constraint that each center of the first set is separated by a distance of at least some given  $\alpha$  from each center of the second set. This follows from a more practical facility location scenario, where we want to open two types of facilities (say “Costco’s” and “Sam’s club”). Each facility type wants to cover all the customers within the minimum possible distance (similar to the  $k$ -center clustering objective), but the facilities want to be separated from each other to avoid crowding or getting unfavorably affected by competition from the other.

The  $k$ -center problem has a long history. In 1857 Sylvester [15] presented the 1-center problem for the first time, and Megiddo [11] gave a linear time algorithm for solving this problem, also known as the minimum enclosing ball problem, in 1983, using linear programming. Hwang et al. [9] showed that the Euclidean  $k$ -center problem in the plane can be solved in  $n^{O(\sqrt{k})}$ . Agarwal and Procopiuc [1] presented an  $n^{O(k^{1-1/d})}$ -time algorithm for solving the  $k$ -center problem in  $\mathbb{R}^d$  and a  $(1 + \epsilon)$ -approximation algorithm with running time  $O(n \log k) + (k/\epsilon)^{O(k^{1-1/d})}$ .

Due to the importance of this problem, many researchers have considered variations of the basic problem to model different situations. Brass et al. studied the constrained version of the  $k$ -center problem in which the centers are constrained to be co-linear [4], also considered previously for  $k = 1$  by Megiddo [11]. They gave an  $O(n \log^2 n)$ -time algorithm when the line is fixed in advance. Also, they solved the general case where the line has an arbitrary orientation in  $O(n^4 \log^2 n)$  expected time. They presented an application of the constrained  $k$ -center in wireless network design: For a given set of  $n$  sensors (which are modeled as points), we want to locate  $k$  base servers (centers of balls) for receiving the signal from the sensors. The servers should be connected to a power line, so they have to lie on a straight line which models the power line. Other variations have also been considered [8, 2, 3] for  $k = 1$ . For  $k \geq 2$ , variants have been studied as this has applications to the placement of base stations in wireless sensor networks [5, 13, 14].

Hwang et al. [9] studied a variant somewhat opposite to our variant. In their variant, for a given constant  $0 \leq \alpha \leq 1$ , the  $\alpha$ -connected two-center problem is to find two balls of minimum radius  $r$  whose union covers the points, and the distance of the two centers is at most  $2(1 - \alpha)r$ , i.e., any two of those balls intersect such that each ball penetrates the other to a distance of at least  $2\alpha r$ . They presented an  $O(n^2 \log^2 n)$  expected-time algorithm.

The variant we consider was first considered by Kavand et. al. [10]. They termed it as the  $(n, 1, 1, \alpha)$ -center problem. They aimed to find two balls each of which covers the entire point set, the radius of the bigger one is minimized, and the distance of the two centers is at least  $\alpha$ . They presented an  $O(n \log n)$ -time algorithm for this problem and a linear time algorithm for its constrained version using the furthest point Voronoi diagram.

This paper considers the generalization of the problem defined by [10], and we denote it by  $(n, p \wedge q, \alpha)$  problem. We explain our choice of notation, particularly the  $\wedge$  sign, in Section 2. For a given set  $P$  of  $n$  points in a metric space and integers  $p, q \geq 1$ , we want to find  $p + q$  balls of two different types, called **red** and **blue** with the minimum radius such that  $P$  is covered by the  $p$  red balls and also covered by the second type of  $q$  blue balls, and the distance of the centers of each red ball from the centers of the blue balls is at least  $\alpha$ . In addition to one example mentioned before, another motivating application of the  $(n, p \wedge q, \alpha)$  problem would be to locate  $p$  police stations and  $q$  hospitals in an area such that the distance between each police station and a hospital is not smaller than a predefined distance  $\alpha$  for the convenience of patients. By locating hospitals and police stations at an admissible distance from each other, patients stay away from crowd and noise while the clients have access to hospitals and police stations that are close enough to them. Moreover, it is obviously desirable that the maximum distance between a client and its nearest police station as well as its nearest hospital is minimized. In addition to this general problem we also consider the constrained version due to its applicability in many situations, where the centers are constrained to lie on a given line.

**Paper organization.** In Section 2, we present the formal problem statement and the definitions required in the sequel. In Section 3, we present an  $O(1)$  factor approximation algorithm for the problem in Euclidean spaces. Then, in Section 4, we present a polynomial-time algorithm for the constrained problem. We conclude in Section 5.

## 2 Problem and Definitions

Let  $\mathcal{M}$  denote a metric space. Let  $\text{dist}(p, q)$  denote the distance between points  $p, q$  in  $\mathcal{M}$ . For a point  $x \in \mathcal{M}$  and a number  $r \geq 0$  the ball  $\mathbb{B}(x, r)$  is the set of points with distance at most  $r$  from  $x$ , i.e.,  $\mathbb{B}(x, r) = \{p \in \mathcal{M} \mid \text{dist}(x, p) \leq r\}$  is the *closed* ball of radius  $r$  with center  $x$ .

In the  $\alpha$ -separated red-blue clustering problem we are given a set  $P$  with  $n$  points in some metric space  $\mathcal{M}$ , integers  $p > 0, q > 0$ , and a real number  $\alpha > 0$ . For a given number  $r \geq 0$ ,  $p$  points  $c_1, \dots, c_p$  in  $\mathcal{M}$  (with possibly repeating points) called the red centers and  $q$  points  $d_1, \dots, d_q$  in  $\mathcal{M}$  (with possibly repeating points) called the blue centers are said to be a **feasible solution** for the problem, with **radius of covering**  $r$  if they satisfy,

- **Covering constraints:** The union of the balls  $\bigcup_{i=1}^p \mathbb{B}(c_i, r)$  (called the red balls) covers  $P$ , and the union of the balls  $\bigcup_{j=1}^q \mathbb{B}(d_j, r)$  (called the blue balls) covers  $P$ .
- **Separation constraint:** For each  $1 \leq i \leq p, 1 \leq j \leq q$  we have  $\text{dist}(c_i, d_j) \geq \alpha$ , i.e., the red and blue centers are separated by at least a distance of  $\alpha$ .

If there exists a feasible solution for a certain value of  $r$ , such an  $r$  is said to be feasible for the problem. The goal of the problem is to find the minimum possible value of  $r$  that is feasible.

We denote this problem as the  $(n, p \wedge q, \alpha)$ -problem. The  $\wedge$  in the notation stresses the fact that *both* the red balls *and* the blue balls cover  $P$ . Let  $r_{p \wedge q, \alpha}(P)$  denote the optimal radius for this problem. When  $P, p, q, \alpha$  are clear from context sometimes we will also denote this by  $r^*$ . Also, let  $r_k(P)$  denote the optimal  $k$ -center clustering radius, for all  $k \geq 1$ . To be clear, the centers in the  $k$ -center clustering problem can be any points in  $\mathcal{M}$ , not necessarily belonging to  $P$ . If that is the requirement, the problem is the *discrete*  $k$ -center clustering problem.

For this paper, we will always be concerned with  $\mathcal{M} = \mathbb{R}^d$ , but we will use the notations as defined above without qualifying the metric space. We let  $P = \{p_1, \dots, p_n\}$  where  $p_i = (p_{i1}, p_{i2}, \dots, p_{id})$ . We also consider the *constrained*  $\alpha$ -separated red-blue clustering problem (when  $\mathcal{M} = \mathbb{R}^d$ ) we are given a line  $\ell$  and all the red and blue centers are constrained to lie on the line  $\ell$ . Without loss of generality, we will assume that  $\ell$  is the  $x$ -axis since this can be achieved by an appropriate affine transformation of space. Moreover, we will use the same notation for the optimal radii and centers. For the constrained problem we need some additional definitions and notations. We assume that no two points in  $P$  have the same distance from  $\ell$ . (This general position assumption can however be removed.) For each point  $p_i$ , we consider the set of points on the line ( $x$ -axis) such that the ball of radius  $r$  centered at one of those points can cover  $p_i$ . This is the intersection of  $\mathbb{B}(p_i, r)$  with the  $x$ -axis, see Figure 1. Assuming this intersection is not empty, let the interval be  $I_i(r) = [a_i(r), b_i(r)]$ . Denote the set of all intervals as  $\mathcal{I}(r) = \{I_1(r), \dots, I_n(r)\}$  where we assume that the numbering is in the sorted order of intervals: those with earlier left endpoints are before, and for the same left endpoints the ones with earlier right endpoint occurs earlier in the order. Notice that feasibility of radius  $r$  means that there exist two hitting sets for the set of intervals  $\mathcal{I}(r)$ , the red centers and the blue centers such that they satisfy the separation constraint.

The interval endpoints  $a_i(r), b_i(r)$  can be computed by solving the equation,

$$(x - p_{i1})^2 + p_{i2}^2 + \dots + p_{id}^2 = r^2,$$

for  $x$ . Thus, they are given by  $a_i(r) = p_{i1} - \sqrt{r^2 - \sum_{j=2}^d p_{ij}^2}$ , and  $b_i(r) = p_{i1} + \sqrt{r^2 - \sum_{j=2}^d p_{ij}^2}$ . It is easy to see that for the range of  $r$  where the intersection is non-empty,  $a_i(r)$  is a strictly decreasing function of  $r$  and  $b_i(r)$  is a strictly increasing function of  $r$ .

**Model of computation.** We remark that our model of computation is the Real RAM model, where the usual arithmetic operations are assumed to take  $O(1)$  time.

■ **Figure 1** The functions  $a_i(r), b_i(r)$ .

**3** Approximation algorithms for the  $(n, p \wedge q, \alpha)$  problem in  $\mathbb{R}^d$

The  $(n, p \wedge q, \alpha)$  problem is NP-hard when  $p, q$  are part of the input, since the  $k$  center problem clearly reduces to the  $(n, p \wedge q, \alpha)$  problem when  $\alpha = 0$  and  $p = q = k$ . Here we show an approximation algorithm for the problem as well as one with a better approximation factor for the constrained problem. We assume that  $p \leq q$ , wlog.

Here we show that there is a constant factor algorithm for the  $(n, p \wedge q, \alpha)$  problem in  $\mathbb{R}^d$ . We need a few preliminary results.

► **Lemma 1.** *Suppose that  $r \geq \alpha/2$  is a number such that there are points  $x_1, \dots, x_p$  satisfying  $P \subseteq \bigcup_{i=1}^p B(x_i, r)$ . Then, there are  $(p+q)$  points  $c_1, \dots, c_p, d_1, \dots, d_q$  all such that the following are met,*

- (I) Separation constraint:  $\text{dist}(c_i, d_j) \geq \alpha$  for all  $i, j$ , and,
- (II) Covering constraints:  $P \subseteq \bigcup_{i=1}^p B(c_i, 7r)$ , and,  $P \subseteq \bigcup_{j=1}^q B(d_j, 7r)$ .

**Proof.** First, from the points  $x_1, \dots, x_p$  we choose a maximal subset of them such that the distance between each pair of them is at least  $4r$ . This can be done by a simple scooping algorithm that starts with  $x_1$  as first point, then throws away all points  $x_i$  (for  $i > 1$ ) with  $\text{dist}(x_1, x_i) < 4r$ , then choose any one of the remaining points and proceed analogously.

Suppose after this (with some renaming) the points that remain are,  $x_1, \dots, x_t$ , where  $1 \leq t \leq p$ . Then, one can easily show that,  $P \subseteq \bigcup_{i=1}^t B(x_i, 5r)$ .

■ **Figure 2** Illustration for proof of Lemma 1.

Now, we choose the  $p$  red centers  $c_1, \dots, c_p$  at the points  $x_1, \dots, x_t$  such that each of them is chosen. Notice that this is possible since  $t \leq p$ . If  $t < p$ , some may be co-located at one  $x_i$ , though. Then, let  $d_1, \dots, d_q$  be any points on the surface of those balls (i.e., on the spheres). Since  $t \leq q$  we have enough points to hit all the balls. If necessary we can co-locate some points  $d_j$  to hit the target number  $q$ . See Figure 2.

The covering constraints are met since as remarked above, the balls of radius  $5r$  around all  $c_i$  (i.e., around all  $x_i$ ) covers  $P$ . Similarly, by the triangle inequality and because  $\alpha \leq 2r$ , the balls of radius  $7r$  around the  $d_j$  cover  $P$ .

To see the separation constraint, let  $c_i, d_j$  be any red and blue centers as defined above. Suppose  $c_i$  is located at the center  $x_a$  where  $1 \leq a \leq t$ , and  $d_j$  is located on the surface of the ball  $B(x_b, \alpha)$  where  $1 \leq b \leq t$ . If  $a = b$ , then since  $c_i$  is at the center and  $d_j$  on the surface of the ball  $B(x_a, \alpha)$  their distance is exactly  $\alpha$ . If, on the other hand,  $a \neq b$ , then by the triangle inequality we have that,  $\text{dist}(x_a, d_j) + \text{dist}(d_j, x_b) \geq \text{dist}(x_a, x_b) \geq 4r$ . Now,  $c_i = x_a$ , and  $\text{dist}(d_j, x_b) = \alpha \leq 2r$ , and so,  $\text{dist}(c_i, d_j) \geq 4r - 2r = 2r \geq \alpha$ , as desired.  $\blacktriangleleft$

► **Lemma 2.** *We have that,  $r_{p \wedge q, \alpha}(P) \geq \alpha/2$ .*

**Proof.** Consider any point  $p_l$ . This point is in some red ball  $B(c_i, r)$  and in some blue ball  $B(d_j, r)$ . Thus, by the triangle inequality,  $\text{dist}(c_i, d_j) \leq \text{dist}(c_i, p_l) + \text{dist}(p_l, d_j) \leq 2r$ . On the other hand,  $\alpha \leq \text{dist}(c_i, d_j)$ . Thus,  $\alpha \leq 2r$  and the claim follows.  $\blacktriangleleft$

Observe that since  $p \leq q$ ,  $r_p(P) \geq r_q(P)$ .

► **Lemma 3.** *We have that,  $r_{p \wedge q, \alpha}(P) \geq r_p(P)$ .*

**Proof.** Consider a feasible solution with the radius  $r^* = r_{p \wedge q, \alpha}(P)$ . The  $p$  red balls cover  $P$  with radius  $r^*$ . Thus,  $r^* \geq r_p(P)$ , since by definition,  $r_p(P)$  is the minimum  $p$ -center clustering radius.  $\blacktriangleleft$

Now, for the  $O(1)$  approximation to  $r_{p \wedge q, \alpha}(P)$  notice that we can easily compute by adapting Gonzalez's algorithm [7] a 2-approximation to the  $p$ -center clustering problem, i.e., to  $r_p(P)$ . (This is standard and well-known so we omit the details.) In other words we have now computed,  $p$  centers  $x_1, \dots, x_p$  all in  $P$ , and a radius  $r \leq 2r_p(P)$  such that balls  $B(x_i, r)$  cover  $P$ . We now consider the radius  $r' = \max(r, \alpha/2)$ , and clearly the balls  $B(x_i, r')$  also define such a covering. Now, using Lemma 1 we can find a feasible solution with radius at most  $7r' \leq 14r$ . Thus, we have shown the following theorem.

► **Theorem 4.** *Let  $r^*$  be the optimal radius for the  $\alpha$ -separated red blue clustering problem on an  $n$  point set  $P$  with parameters  $p, q \geq 1$ . Then, we can compute in polynomial-time, a feasible solution where the covering radius is at most  $14r^*$ .*

This approximation factor can be improved for the constrained problem, i.e., where all the centers are constrained to be on a fixed line  $\ell$ . The details can be found in the full version of this paper [6].

## 4 Polynomial-time algorithm for the constrained problem

Our basic approach will be to do a binary search for the optimal radius. We first present an algorithm to decide if a given value of the radius  $r$  is feasible. Then, we present an algorithm to determine a finite set of values such that the optimal radius must be within that set. Then, a binary search using the feasibility testing algorithm gives us the optimal radius.

## 4.1 Deciding feasibility for given radius $r$

Given a radius  $r > 0$  we give a polynomial-time method to decide if there is a solution to the constrained  $(n, p \wedge q, \alpha)$  problem with covering radius  $r$ . The algorithm is a dynamic programming algorithm. One of the challenges encountered is that the centers can be anywhere on the line, and thus a naive implementation of dynamic programming does not work since there are not finitely many sub-problems. As such, we first show how we can compute a finite set  $\mathcal{C}(r)$  of  $O(n^2)$  points such that if  $r$  is feasible, one can find a feasible solution with covering radius  $r$  with centers belonging to  $\mathcal{C}(r)$ .

### 4.1.1 Candidate points for the centers

Consider all the end-points of the intervals in  $\mathcal{I}(r)$ , i.e.,  $a_i(r), b_i(r)$ , and consider the sorted order of them. Assume that in sorted order the points are renamed to  $x_1, x_2, \dots, x_{2n}$  (possibly some of them are co-located). As remarked before, the feasibility problem is equivalent to finding two hitting sets for the intervals in  $\mathcal{I}(r)$  that satisfy the separation constraints. As in standard in such hitting set problems, we look at the *faces* of the arrangement of the intervals. Some of these faces might be open intervals, or half-open intervals, or even singleton points. Notice that all faces are disjoint by definition. It is easy to see that if  $F$  is such a face, then a point in the closure  $\bar{F}$  of  $F$  will hit at least the same intervals as points in  $F$  hit. To avoid confusion when we refer to faces vs. their closures, in the remaining discussion we will always say face  $F$  for the original face and closure face  $\bar{F}$  when referring to one of the closures (even though they may be the same set of points).

We explain now, why considering face closures is valid. Suppose a certain center belongs to a face  $F$  and suppose it is allowable to choose **any** point close enough to one of its boundary points, such that the separation constraints are met. Then, it is also valid to choose it at the boundary point and respecting the separation constraint since the separation constraint is that distance between the red and blue centers is  $\geq \alpha$  as opposed to a strict inequality  $> \alpha$ . Therefore, it is valid to replace faces with their closures.

To compute all the closures of the faces in the arrangement of the  $\mathcal{I}(r)$ , we sort the  $x_i$  and we retain all the consecutive intervals  $[x_i, x_{i+1}]$  that do not lie outside any of the intervals  $I_i(r)$ . This can be done by a simple line sweep algorithm. Notice that there are only  $O(n)$  such closure faces.

Next, we define a sequence for each such closure face. Consider such a closure face,  $[x_i, x_{i+1}]$  that is the **starting closure face** for this sequence. Consider the sequence,  $x_i, x_i + \alpha, x_i + 2\alpha, \dots$ . We only want to retain, for each closure face, (at most) the first three points that hit the closure face. So, given any starting closure face  $[x_i, x_{i+1}]$  there are only  $O(n)$  points in this sequence since it is bounded by the number of closure faces (in fact beyond the starting closure face  $[x_i, x_{i+1}]$ ) times three. Let the sequence of points that result due to starting closure face  $[x_j, x_{j+1}]$  be denoted by  $\text{SEQ}_j$ . We have the following lemma,

► **Lemma 5.** *For each starting closure face,  $[x_i, x_{i+1}]$  the associated sequence  $\text{SEQ}_i$  can be computed in  $O(n)$  time.*

**Proof.** We consider each closure face and compute the points of this sequence that possibly lie in this closure face. Consider such a closure face  $[x_j, x_{j+1}]$ . For a member of  $\text{SEQ}_i$  to lie in this closure face there is an integer  $k$  such that  $x_j \leq x_i + k\alpha \leq x_{j+1}$ . This is equivalent to,  $\frac{x_j - x_i}{\alpha} \leq k \leq \frac{x_{j+1} - x_i}{\alpha}$ . Thus, to find the first three points of  $\text{SEQ}_i$  hitting the closure face, we only need to find the three smallest integers in the interval,  $[\frac{x_j - x_i}{\alpha}, \frac{x_{j+1} - x_i}{\alpha}]$ , if there are such. This can be done in  $O(1)$  time per closure face. Since there are  $O(n)$  closure faces, the entire sequence can be constructed in  $O(n)$  time. ◀

Computing such sequence for each closure face as starting closure face leads to a total of  $O(n^2)$  points, and can be computed in  $O(n^2)$  time overall by the previous lemma. The set  $\mathcal{C}(r)$  is the set of the points in all these sequences. Let the sorted order of points in this set be denoted by  $c_1, c_2, \dots, c_m$  where  $m = O(n^2)$ . Thus  $\mathcal{C}(r) = \{c_1, \dots, c_m\}$ . For any such point  $c_k$  denote by  $s(k)$  the first index  $j$  such that  $c_j - c_k \geq \alpha$ . If there is no such point, let  $s(k) = m + 1$ . Notice that we can compute  $s(k)$  by a successor query in  $O(\log n)$  time if the set  $\mathcal{C}(r)$  is sorted. The following lemma says that we can assume that the centers (of both colors) are in  $\mathcal{C}(r)$ .

► **Lemma 6.** *Suppose that the constrained  $(n, p \wedge q, \alpha)$  problem has a feasible solution with covering radius  $r$ . Then there is a solution with all centers belonging to  $\mathcal{C}(r)$ .*

**Proof.** Consider a feasible solution with  $p$  red centers and  $q$  blue centers. First, we remark that we can assume, wlog, that in any face  $F$  there are at most two points, one red and one blue. This is true because having more than one red or more than one blue point in a face does not affect the covering constraints, as each point in a face hits (i.e., belongs to) the exact same set of intervals by definition. Thus, we may assume that there are at most  $T \leq (p + q)$  such centers, since we might need to throw away some of them when two centers of the same color belong to one face. Let the  $T$  centers be  $u_1, \dots, u_T$  where any of them can be red or blue. We show how to construct iteratively another feasible solution where all the centers are in  $\mathcal{C}(r)$ .

We will proceed face by face, and consider all the centers within the face. We know that there are at most two centers within a face. Moreover, if there are two they are of different colors. Our basic strategy is to move the first center left till we can, while remaining within the closure of the face, without violating any separation constraint. If there is only one point in a face, we are done. Otherwise, once the position of the first point is fixed, the second point can be similarly moved left until its position is determined within  $\mathcal{C}(r)$ . Let the sorted order of faces be  $F_1, F_2, \dots, F_N$  where  $N = O(n)$ .

We construct a new sequence  $v_1, \dots, v_T$  where  $v_i$  is assigned color of  $u_i$  and is obtained by shifting  $u_i$  to the left (so that it will lie in  $\mathcal{C}(r)$ , but never leaving closure of the face it belongs to). We prove the following claim by induction, which implies the claim that all the  $v_i$  belong to  $\mathcal{C}(r)$ .

▷ **Claim 7.** For each  $k \geq 1$ , all the points  $u_i$  belonging to face  $F_k$  are mapped to points  $v_i$  (belonging to  $\bar{F}_k$ ) such that, the at most two such  $v_i$ , lie on consecutive points of the same sequence  $\text{SEQ}_j$  for some  $j$ .

Consider the base case  $k = 1$ . If there are no points in  $F_1$ , the claim holds vacuously. If there is only one point in  $F_1$ , slide it left until it hits the boundary of  $F_1$ . This does not violate any constraints. The claim holds true trivially. Suppose there are two points in  $F_1$ . Now,  $\bar{F}_1 = [x_1, x_2]$  and after sliding the first point left till it coincides with  $x_1$ , and thus in  $\text{SEQ}_1$ , the second point clearly satisfies  $u_2 - x_1 \geq \alpha$  since even before the sliding the inequality was satisfied. Notice that the points are of different color. Thus we can place the second point  $v_2$  at  $x_1 + \alpha \in \text{SEQ}_1$  and they are consecutive points of  $\text{SEQ}_1$ .

Suppose that the claim is true up-to  $k$ . We now consider the case  $k + 1$ . Again, as before if there are no points in  $F_{k+1}$  the claim holds vacuously. If there is only one point, we slide it left to the first point in  $\mathcal{C}(r)$  which is allowable for it. The meaning of allowable is the following. Suppose this point is  $v_s$ . Then, if  $v_{s-1}$ , which is in a previous face, is of the same color as  $v_s$ , then  $v_s$  can be anywhere within its face. If it is of different color, then  $v_s$  has to be at least at  $v_{s-1} + \alpha$ . Since the starting point of the closure  $\bar{F}_{k+1}$  is in  $\mathcal{C}(r)$ , as is  $v_{s-1} + \alpha$

if it lies in  $\bar{F}_{k+1}$ , while sliding left we will hit a point in  $\mathcal{C}(r)$  eventually and we stop there. Now consider, the case where there are two points  $u_i, u_{i+1}$  in  $F_{k+1}$ . After  $v_i$  has been placed at its position in  $\mathcal{C}(r)$  as outlined for the case of single point in  $F_{k+1}$ , suppose it belongs to  $\text{SEQ}_j$  for some  $j$ . Clearly it is at most the second point, of  $\text{SEQ}_j$  in  $\bar{F}_{k+1}$  as the second point is already  $\alpha$  ahead of the first point of  $\text{SEQ}_j$  in  $\bar{F}_{k+1}$ . Now,  $u_{i+1} - v_i \geq \alpha$ . Thus, we can place the second point of  $F_{k+1}$  at the next point of  $\text{SEQ}_j$  in  $\bar{F}_{k+1}$ , which exists in  $\bar{F}_{k+1}$  since the next point is  $v_i + \alpha$  which is in  $\bar{F}_{k+1}$  by assumption. We observe that all claims hold true.  $\blacktriangleleft$

### 4.1.2 The dynamic programming algorithm

The dynamic programming algorithm computes two tables,  $\text{CanCover}^{\text{R}}[\mathcal{I}_1, \mathcal{I}_2, a, b, k]$ , and  $\text{CanCover}^{\text{B}}[\mathcal{I}_1, \mathcal{I}_2, a, b, k]$  of Boolean **True**, **False**. Here,  $\mathcal{I}_1, \mathcal{I}_2$  are prefixes of intervals of  $\mathcal{C}(r)$  (when they are ordered by their left and right end-points), and  $0 \leq a \leq p, 0 \leq b \leq q$  are integers, and  $1 \leq k \leq (m+1)$  is also an integer. The table entry  $\text{CanCover}^{\text{R}}[\mathcal{I}_1, \mathcal{I}_2, a, b, k]$  is **True**, if there is a hitting set consisting of (at most)  $a$  red points that hit the intervals in  $\mathcal{I}_1$ , (at most)  $b$  blue points that hit the intervals in  $\mathcal{I}_2$  and with the constraint that the first point to be possibly put is red and at  $c_k$  if  $k < m$ . Here  $k > m$  represents that there is no where to really put the first red point. Notice that the separation constraint between red/blue points must be met. Similarly the table entry  $\text{CanCover}^{\text{B}}[\mathcal{I}_1, \mathcal{I}_2, a, b, k]$  is true if the first point is blue and at  $c_k$  (for  $k \leq m$ ). Assuming that the above tables have been computed, we can answer whether the radius  $r$  is feasible by computing the following expression, where we denote  $\mathcal{I}(r)$  by  $\mathcal{I}$  for brevity,

$$\begin{aligned} & \text{CanCover}^{\text{R}}[\mathcal{I}, \mathcal{I}, p, q, 1] \vee \dots \vee \text{CanCover}^{\text{R}}[\mathcal{I}, \mathcal{I}, p, q, m] \\ & \quad \vee \\ & \text{CanCover}^{\text{B}}[\mathcal{I}, \mathcal{I}, p, q, 1] \vee \dots \vee \text{CanCover}^{\text{B}}[\mathcal{I}, \mathcal{I}, p, q, m]. \end{aligned}$$

In the above expression, we try to hit all the intervals in  $\mathcal{I}$  by both red and blue points and we try all possible starting locations and color for the first point. We know that the centers can be assumed to belong to  $\mathcal{C}(r) = \{c_1, \dots, c_m\}$ .

Now we present the recursive definition of the algorithm to fill the tables. We only present the definitions for  $\text{CanCover}^{\text{R}}[\cdot]$  but there is an entirely similar definition for  $\text{CanCover}^{\text{B}}[\cdot]$  with the roles of red and blue interchanged.

$$\text{CanCover}^{\text{R}}[\mathcal{I}_1, \mathcal{I}_2, a, b, k] = \begin{cases} \text{False} & \text{if } (\mathcal{I}_1 \neq \emptyset \wedge a = 0) \vee (\mathcal{I}_2 \neq \emptyset \wedge b = 0) \vee (\mathcal{I}_1 \cup \mathcal{I}_2 \neq \emptyset \wedge k > m), \\ \text{True} & \text{if } (\mathcal{I}_1 = \emptyset \wedge \mathcal{I}_2 = \emptyset), \\ \text{False} & \text{if there exists an interval in } \mathcal{I}_1 \cup \mathcal{I}_2 \text{ ending before } c_k, \\ B_a \vee B_b & \text{otherwise.} \end{cases}$$

The first case means that if there are not any red centers to put while some unhit intervals remain in  $\mathcal{I}_1$ , or not any blue centers to put but unhit intervals in  $\mathcal{I}_2$ , or if we have already passed over all centers ( $k > m$ ) but any unhit red or blue intervals remain, we return false. The next case means that if that all intervals have been hit already we should return true. The penultimate case means that if the first point  $c_k$  is so far ahead that at least one interval in  $\mathcal{I}_1 \cup \mathcal{I}_2$  ends before it, then there can be no solution. This is true because any later points, red or blue, will only be ahead of  $c_k$  and thus the ended interval cannot be hit. The last case

uses Boolean variables  $B_a, B_b$  that are defined as follows, and they also capture the main recursive cases. As required by the definition of the function, we must put the next center as red and at  $c_k$ . This would cause some intervals in  $\mathcal{I}_1$  to be hit by  $c_k$ . We remove those intervals from  $\mathcal{I}_1$ . Let  $\mathcal{I}'_1$  be the intervals in  $\mathcal{I}_1$  not hit by  $c_k$ . It is easy to see that if  $\mathcal{I}_1$  is a prefix of  $\mathcal{I}$ , then so is  $\mathcal{I}'_1$ . The definitions of  $B_a, B_b$  are as follows.

$$B_a \leftarrow (\mathcal{I}_1 = \emptyset) \vee \bigvee_{j=k+1}^m \text{CanCover}^R[\mathcal{I}'_1, \mathcal{I}_2, a-1, b, j]$$

This assignment ensures that if  $\mathcal{I}_1 = \emptyset$ , then we never really try to put any red point. If not, then we try all possibilities for the next position of the red point. Notice that putting another red point at  $c_k$  is not necessary so we start with the remaining positions and go up to  $m$ . The coverage requirements for blue points and their numbers remain unchanged. The red number decreases by 1. The Boolean  $B_b$  has the following definition,

$$B_b \leftarrow (\mathcal{I}_2 = \emptyset) \vee \bigvee_{j=s(k)}^m \text{CanCover}^B[\mathcal{I}'_1, \mathcal{I}_2, a-1, b, j].$$

This is because, if the next point (after the current red one) is to be blue, it can only be at index  $s(k)$  or later. Thus we look-up  $\text{CanCover}^B[\mathcal{I}'_1, \mathcal{I}_2, a-1, b, j]$  for all such possible  $j$ . The first check  $\mathcal{I}_2 = \emptyset$  means that if the blue intervals have already been hit, we do not need to put any blue point later. Both the tables  $\text{CanCover}^R[\cdot], \text{CanCover}^B[\cdot]$  are filled simultaneously by first filling in the entries fitting the base cases, and then traversing them in order of increasing  $a$ , increasing  $b$ , decreasing  $k$ , and increasing  $\mathcal{I}_1, \mathcal{I}_2$  (i.e., the smaller prefixes come earlier). It is easy to see that the traversal order meets the dependencies as written in the recursive definitions.

**Analysis.** First, observe that computing the candidate centers can be done in  $O(n^2)$  time as implied by Lemma 5 and the following discussion. Moreover, the successor points  $s(k)$  can all be computed in total  $O(n^2 \log n)$  time by first sorting  $\mathcal{C}(r)$  and then followed by successor queries. The time however is dominated by the main dynamic programming algorithm. Observe that there are  $O(n)$  prefixes, and  $m = O(n^2)$  possible center locations. Thus there are in total  $O(n^4 pq)$  entries to be filled. Except for the base cases, filling in an entry requires looking up  $O(n^2)$  previous entries, as well as some computation such as finding which intervals are not hit by the current point. Such queries can be handled easily for all the intervals say in  $\mathcal{I}_1$  wrt the point  $c_k$  in  $O(n)$  time. Thus for a particular table entry, we require  $O(n^2)$  time. Overall we will take  $O(n^6 pq)$  time. We get the following theorem,

► **Theorem 8.** *For the constrained  $(n, p \wedge q, \alpha)$  problem where the centers are constrained to lie on the  $x$ -axis, given a radius  $r$ , it can be decided if  $r$  is feasible in time  $T_{DP}(n, p, q) = O(n^6 pq)$ . Moreover, if  $r$  is feasible, a feasible solution with covering radius  $r$  can also be computed in the same time.*

To justify the comment about the feasible solution, note that by standard dynamic programming techniques, we can also remember while computing the table entries the solution, and it can be output at the end.

## 4.2 Candidate values for $r$

In this section, we will find a discrete candidate set for the optimal radii that facilitates a polynomial-time algorithm for solving the constrained  $(n, p \wedge q, \alpha)$  problem as presented in Section 4.3. For this purpose, we need to determine some properties of an optimal solution.

## 41:10 Separated Red Blue Center Clustering

First, we define a standard form solution and describe an easy approach to convert a feasible solution to the standard form. Then we present a lemma for proving a property of an optimal solution. Finally, we compute a finite candidate set for optimal radii.

Let  $U = \{u_1, u_2, \dots, u_{p+q}\}$  be a feasible solution with covering radius  $r$ . The closure face that contains  $u_i$  is denoted by  $[x_{i,1}(r), x_{i,2}(r)]$ , where  $x_{i,1}(r)$  and  $x_{i,2}(r)$  are the endpoints of some intervals (i.e.,  $a_j(r)$  or  $b_j(r)$ ). Since  $u_i$ s are on the  $x$ -axis, be a slight abuse of notation, we let  $u_i$  denotes the  $x$ -coordinate of point  $u_i$ . For a given feasible solution  $U = \{u_1, u_2, \dots, u_{p+q}\}$ , its **standard** form has two following properties:

1. If  $u_1$  and  $u_{p+q}$  are on the endpoints.
2. Any two consecutive same color centers are on the endpoints.

**Converting a given solution to standard form.** If  $u_1$  (resp.  $u_{p+q}$ ) is not on an endpoint, we move it to the left (resp. right) to hit  $x_{1,1}(r)$  (resp.  $x_{p+q,2}(r)$ ). For every pair of two consecutive same color centers  $u_i$  and  $u_{i+1}$ ,  $1 \leq i \leq p+q-1$ , if  $u_i$  is not on an endpoint, we move it to the right to hit  $x_{i,2}(r)$  and if  $u_{i+1}$  is not on an endpoint we move it to the left to hit  $x_{i+1,1}(r)$ .

Clearly, the standard form solution as constructed above satisfies the covering and separation constraints. Let  $S(k, j)$  denote a sequences of  $j+1$  consecutive centers in  $U$  starting from  $u_k$ , i.e.,  $(u_k, u_{k+1}, \dots, u_{k+j})$ . A sequence  $S(k, j)$  is called **alternate** if for all  $i, k \leq i \leq k+j-1$ ,  $u_i$  and  $u_{i+1}$  have different colors and centers  $u_k$  and  $u_{k+j}$  are on the endpoints and the other centers of the sequence are not on the endpoints (such a center is called **internal**).

Now note that if  $U$  is a standard solution, then the consecutive red-blue centers can be clustered in some alternate sequences. These alternate sequences can be provided by scanning the centers from left to right and clustering a couple of consecutive blue-red centers between two endpoints that include a center. To this end, we have the following simple approach:

**Clustering centers in alternate sequences.** Let  $u_{cur}$  be the first center that has not been visited yet. At the beginning,  $u_{cur} = u_1$ . Let  $u_i$  be the next closest different color center to  $u_{cur}$ . All centers from  $u_{cur}$  to  $u_{i-1}$  should be on the endpoints since they are the same color. We can construct the next sequence from  $k = i-1$ , i.e., we add  $u_{i-1}$  and  $u_i$  to a sequence. There are two events:

**Event 1:**  $u_i$  is on an endpoint, so the sequence is completed. If there are any unvisited centers, we continue scanning the centers by starting from  $u_i$ , i.e., we mark  $u_i$  as unvisited, set  $u_{cur} = u_i$ , and proceed as before until there is no unvisited center.

**Event 2:**  $u_i$  is not on an endpoint. Consider  $u_{i+1}$ .  $u_{i+1}$  and  $u_i$  should have different colors since  $U$  is standard. We add  $u_{i+1}$  to the sequence. If there are any unvisited centers, consider  $u_{i+2}$  and check Events 1 or 2 for  $i = i+2$ .

Note that some of the centers may belong to two alternate sequences (e.g., a center on an endpoint with different color adjacent centers) and some of them may not be in a sequence (e.g., a center with same-color adjacent centers).

Now we prove a property of the optimal solutions in standard form for being able to find a discrete candidate set for the optimal radii.

► **Lemma 9.** *Let  $U = \{u_1, u_2, \dots, u_{p+q}\}$  be a feasible solution for the constrained  $(n, p \wedge q, \alpha)$  problem with radius of covering  $r$ . If the distance between any two endpoints of the intervals in  $\mathcal{C}(r)$  is not  $t\alpha$ , where  $t \in \mathbb{Z}, 0 \leq t \leq p+q-1$ , then the constrained  $(n, p \wedge q, \alpha)$  problem has a feasible solution with radius less than  $r$ .*

**Proof.** We will show that there is a real number  $0 < \epsilon < r$  such that the constrained  $(n, p \wedge q, \alpha)$  problem has a feasible solution with radius of covering  $r - \epsilon$ . To this end, we obtain a set of centers,  $\bar{U}$ , from the given feasible solution  $U$  and show that the set of balls centered at the points in  $\bar{U}$  with radius  $r - \epsilon$  is a feasible solution for the problem. First, we need to modify  $U$  to find a feasible solution with the property that any two consecutive blue and red centers are at a distance strictly greater than  $\alpha$  (not exactly  $\alpha$ ). Then we use it for finding a solution,  $\bar{U}$ , with radius of covering  $r - \epsilon$  (that is explained later).

First of all, we convert  $U$  to standard form and compute all alternate sequences of the standard solution. Then we use them to find a feasible solution with the property that any two consecutive blue and red centers are at a distance of strictly greater than  $\alpha$ . Note that by the Lemma's assumption, each alternate sequence  $S(k, j)$  has at least a pair of two consecutive centers at a distance of strictly greater than  $\alpha$  (since each distance is at least  $\alpha$  and sum of them is not  $j\alpha$ ). But we need to have this strict inequality for all such pairs. So in each sequence  $S(k, j)$ , if there are two consecutive centers  $u_{k+i}$  and  $u_{k+i+1}$  at a distance of exactly  $\alpha$ , we should perturb the internal centers such that the distance between any two consecutive blue and red centers is strictly greater than  $\alpha$ .

For perturbing the internal centers of each alternate sequence  $S(k, j)$ , if  $j = 1$ , then  $u_{k+1} - u_k > \alpha$ , because  $u_k$  and  $u_{k+1}$  are on the endpoints so  $u_{k+1} - u_k \neq \alpha$ . If  $j > 1$ , we proceed by induction on the number of the pairs with the distance of  $\alpha$  which is denoted by  $n_{k,j}$ . For  $n_{k,j} = 1$ , let  $u_{k+i}, u_{k+i+1} \in S(k, j)$  such that  $u_{k+i+1} - u_{k+i} = \alpha$ . Since  $j > 1$ , at least one of  $u_{k+i}$  and  $u_{k+i+1}$  is internal, say  $u_{k+i}$ . Since  $n_{k,j} = 1$ ,  $u_{k+i} - u_{k+i-1} > \alpha$ . So we can shift  $u_{k+i}$  toward  $u_{k+i-1}$  infinitesimally such that  $u_{k+i} - u_{k+i-1} > \alpha$  and we still have  $u_{k+i+1} - u_{k+i} > \alpha$ . Assume for the induction hypothesis that for all integers  $m > 1$ , in a sequence  $S(k, j)$  with  $n_{k,j} < m$ , including a pair of consecutive red and blue centers at a distance greater than  $\alpha$ , we can perturb the internal centers such that all distances between two consecutive centers are strictly greater than  $\alpha$ . Now assume that  $n_{k,j} = m > 1$ . For some  $0 \leq i \leq j - 1$ , let  $u_{k+i}, u_{k+i+1} \in S(k, j)$  such that  $u_{k+i+1} - u_{k+i} = \alpha$ .  $S(k, j)$  has a pair of two consecutive centers at a distance greater than  $\alpha$ . This pair belongs to one of the sequences  $S(k, i)$  or  $S(k + i + 1, j)$ , say  $S(k, i)$ . It is clear that  $n_{k,i} < m$ , so by the induction hypothesis, we can perturb the internal centers of  $S(k, i)$  such that all distances between two consecutive centers are strictly greater than  $\alpha$ . Next, we can move  $u_{k+i}$  toward  $u_{k+i-1}$  infinitesimally such that  $u_{k+i} - u_{k+i-1} > \alpha$  and we now also have  $u_{k+i+1} - u_{k+i} > \alpha$ . Now we add  $u_{k+i}$  to  $S(k + i + 1, j)$  to obtain  $S(k + i, j)$  in which the distance between centers  $u_{k+i}$  and  $u_{k+i+1}$  is greater than  $\alpha$ . Since  $n_{k+i,j} < m$ , again by the induction hypothesis, we can perturb the internal centers of  $S(k + i, j)$  such that all distances between two consecutive centers are strictly greater than  $\alpha$ . It means that  $S(k, j)$  no longer contains a consecutive pair with distance  $\alpha$ .

Now we can compute  $\bar{U}$ . Let  $0 < \epsilon < r$  be a positive real number to be fixed later. If  $u_i$  is on an endpoint, say  $x_{i,1}(r)$ , let  $\bar{u}_i = x_{i,1}(r - \epsilon)$ , otherwise,  $\bar{u}_i = u_i$ . Notice that by our assumptions, there is no solution for  $t = 0$  so all endpoints are distinct. As such for an  $u_i$  on an endpoint, it is never on two endpoints simultaneously and its movement is unambiguously determined. We will show that there exists an  $\epsilon$  such that  $\bar{U} = \{\bar{u}_1, \bar{u}_2, \dots, \bar{u}_{p+q}\}$  is a feasible solution with radius of covering  $r - \epsilon$ , i.e.,  $\bar{U}$  should satisfy the covering and separation constraints. To this end, firstly, after decreasing  $r$  to  $r - \epsilon$ , the relative order of the endpoints of the intervals should not change, i.e., the displacement of an endpoint of a face  $F_i$  should be less than  $\|F_i\|/2$ , where  $\|F_i\|$  is the distance between the endpoints of face  $F_i$ . Secondly, for satisfying the covering constraint, the internal centers should remain in their faces, i.e.,  $x_{i,1}(r - \epsilon) < \bar{u}_i < x_{i,2}(r - \epsilon)$ . So the displacement of point  $x_{i,1}$  (resp.  $x_{i,2}$ ) should be less

## 41:12 Separated Red Blue Center Clustering

than  $u_i - x_{i,1}(r)$  (resp.  $x_{i,2}(r) - u_i$ ). Finally, for satisfying the separation constraint, in each sequence  $S(k, j)$ , we should have  $\bar{u}_{k+1} - \bar{u}_k \geq \alpha$  and  $\bar{u}_{k+j} - \bar{u}_{k+j-1} \geq \alpha$  (note that the distance between two internal centers does not change), i.e., the displacement of the endpoint that contains  $u_k$  (resp.  $u_{k+j}$ ) should be less than  $u_{k+1} - u_k - \alpha$  (resp.  $u_{k+j} - u_{k+j-1} - \alpha$ ). Therefore, by choosing real numbers  $\delta_1, \delta_2, \delta_3$  as follows, and  $0 < \delta < \min\{\delta_1, \delta_2, \delta_3\}$ , because of continuity of the movement of endpoints on line  $\ell$ , we can obtain a positive  $\epsilon$  such that the displacement of an endpoint becomes at most  $\delta$  when the radius decreases to  $r - \epsilon$ .

$$\begin{aligned} 0 < \delta_1 &< 1/2 \min_{1 \leq i \leq 2n-1} \{\|F_i\|\} \\ 0 < \delta_2 &< \min_{\forall S(k,j)} \left\{ \min_{k+1 \leq i \leq k+j-1} \{u_i - x_{i,1}(r), x_{i,2}(r) - u_i\} \right\} \\ 0 < \delta_3 &< \min_{\forall S(k,j)} \{u_{k+1} - u_k - \alpha, u_{k+j} - u_{k+j-1} - \alpha\} \end{aligned}$$

Consequently, there exists a non-zero  $\epsilon > 0$  such that the balls centered at points in  $\bar{U}$  with covering radius  $r - \epsilon$  is a feasible solution.  $\blacktriangleleft$

By Lemma 9, in the optimal solution, there is at least a pair of two endpoints at distance  $t\alpha$ , where  $t \in \mathbb{Z}, 0 \leq t \leq p + q - 1$ . The interval endpoints  $a_i(r)$  and  $b_i(r)$  are given by  $a_i(r) = p_{i1} - \sqrt{r^2 - \sum_{j=2}^d p_{ij}^2}$ , and  $b_i(r) = p_{i1} + \sqrt{r^2 - \sum_{j=2}^d p_{ij}^2}$ , so, a candidate set for the optimal radius can be computed by solving the following equations for all  $1 \leq i, k \leq n$  and  $t \in \mathbb{Z}, 0 \leq t \leq p + q - 1$ :

$$p_{i1} \pm \sqrt{r^2 - \sum_{j=2}^d p_{ij}^2} - p_{k1} \pm \sqrt{r^2 - \sum_{j=2}^d p_{kj}^2} = t\alpha,$$

since at least one of those equalities holds true. Due to our general position assumption, i.e., no two points in  $P$  have the same distance from  $\ell$ , these equations have a finite number of solutions. This is not too hard to show. See the full version of this paper [6] for the details. (We remark that the general position assumption can be removed. Without the assumption, Lemma 9 needs an amended statement and proof. Due to space constraints, we do not show this here. The amended statement and proof can be found in the full version of this paper [6].)

By solving these equations, we obtain  $O(n^2(p+q))$  candidates for the optimal radius and this proves the following lemma.

► **Lemma 10.** *There is a set of  $O(n^2(p+q))$  numbers, such that the optimal radius  $r_{p \wedge q, \alpha}(P)$  is one among them, and this set can be constructed in  $O(n^2(p+q))$  time.*

### 4.3 Main result

By first computing the candidates for  $r^*$  and then performing a binary search over them using the feasibility testing algorithm, we can compute the optimal radius. Thus we have the following theorem.

► **Theorem 11.** *The constrained  $(n, p \wedge q, \alpha)$  problem can be solved in  $O(n^2(p+q) + T_{DP}(n, p, q) \log n) = O(n^6 pq \log n)$  time.*

## 5 Conclusions

Improving the approximation factor of our main approximation algorithm (Theorem 4) and the running time of our polynomial-time algorithm for the constrained problem (Theorem 11) are obvious candidates for problems for future research work. Apart from this, it seems that a multi-color generalization of the  $k$ -center problem is worth studying for modeling similar practical applications. Here we want  $k$  different colored centers, and balls of each color covering all of  $P$  but with the separation constraints more general, i.e., between the centers of colors  $i, j$  the distance must be at least some given  $\alpha_{ij}$ . It seems that new techniques would be required for this general problem.

## Abstract

We initiate the theoretical study of EXT-TSP, a problem that originates in the area of profile-guided binary optimization. Given a graph  $G = (V, E)$  with positive edge weights  $w : E \rightarrow \mathbb{R}^+$ , and a non-increasing discount function  $f(\cdot)$  such that  $f(1) = 1$  and  $f(i) = 0$  for  $i > k$ , for some parameter  $k$  that is part of the problem definition. The problem is to sequence the vertices  $V$  so as to maximize  $\sum_{(u,v) \in E} f(|d_u - d_v|) \cdot w(u, v)$ , where  $d_v \in \{1, \dots, |V|\}$  is the position of vertex  $v$  in the sequence.

We show that EXT-TSP is APX-hard to approximate in general and we give a  $(k + 1)$ -approximation algorithm for general graphs and a PTAS for some sparse graph classes such as planar or treewidth-bounded graphs.

Interestingly, the problem remains challenging even on very simple graph classes; indeed, there is no exact  $n^{o(k)}$  time algorithm for trees unless the ETH fails. We complement this negative result with an exact  $n^{O(k)}$  time algorithm for trees.

## 1 Introduction

Profile-guided binary optimization (PGO) is an effective technique in modern compilers to improve performance by optimizing how binary code is laid out in memory. At a very high level, the idea is to collect information about typical executions of an application and then use this information to re-order how code blocks are laid out in the binary to minimize instruction cache misses, which in turn translates into running time performance gains. Newell and Pupyrev [20] recently introduced an optimization problem, which they call the Extended TSP (EXT-TSP) problem that aims at maximizing the number of block transitions that do not incur a cache miss.

The input to the EXT-TSP problem is a weighted directed graph  $G = (V, E)$ , which in the context of PGO corresponds to the control flow representation of the code we are trying to optimize: Every node  $u \in V$  corresponds to a basic block of code (for the purposes of this paper we can think of each of these blocks as a single instruction that takes a fixed amount of memory to encode); every edge  $(u, v) \in E$  represents the possibility of an execution jumping from  $u$  to  $v$ , and the weight  $w(u, v)$  captures how many times the profiler recorded said jump during the data collection phase. Our ultimate goal is to find a linear ordering of the nodes, each of which represents a possible code layout of the binary; we let this linear ordering be encoded by a one-to-one function  $d : V \rightarrow \{1, \dots, |V|\}$ . Finally, each edge  $(u, v)$

contributes  $f(|d_u - d_v|) \cdot w(u, v)$  to the objective, where  $|d_u - d_v|$  is the distance between the edge endpoints in the linear ordering, and  $f(\cdot)$  is a non-increasing discount function such that  $f(1) = 1$  and  $f(i) = 0$  for  $i > k$ , where  $k = O(1)$  is part of the problem definition.

Newell and Pupyrev [20] designed and evaluated heuristics for EXT-TSP leading to significantly faster binaries. Their implementation is available in the open source project Binary Optimization and Layout Tool (BOLT) [17, 20, 22]. In their experiments, they found that setting  $k$  to be a small constant<sup>1</sup> and  $f(|d_u - d_v|) = \left(1 - \frac{|d_u - d_v|}{k}\right)$  for  $1 < |d_u - d_v| < k$ , yields the best results. The high level intuition is that the discount factor is a proxy for the probability that taking the jump causes a cache miss. Thus, the EXT-TSP objective aims at maximizing the number of jumps that do not cause a cache miss.

In this paper we initiate the theoretical study of EXT-TSP by providing a variety of hardness and algorithmic results for solving the problem both in the approximate and the exact sense in both general and restricted graph classes.

## 1.1 Our results

We show that EXT-TSP is APX-hard to approximate in general. We give a polynomial time  $(k + 1)$ -approximation algorithm and a  $n^{O(\frac{k}{\epsilon})}$  time  $(2 + \epsilon)$ -approximation for general graphs. We also give a  $n^{O(\frac{k}{\epsilon})}$  time  $(1 + \epsilon)$ -approximation for some sparse graphs classes such as planar or treewidth-bounded graphs.

Interestingly, the problem remains challenging even on very simple graph classes; indeed, there is no exact  $n^{O(k)}$  time algorithm for trees unless the ETH fail. Finally, we complement this negative result with an exact  $n^{O(k)}$  time algorithm for trees.

## 1.2 Related work

PGO techniques have been studied extensively in the compiler’s community. Code re-ordering is arguably the most impactful optimization among existing PGO techniques [22]. The classical approach for code layout is initiated by Pettis and Hansen [24], who formulated the problem of finding an ordering of basic blocks as a variant of the maximum directed TRAVELING SALESMAN PROBLEM on a control flow graph. They describe two greedy heuristics for positioning of basic blocks. Later, one of the heuristics (seemingly producing better results) has been adopted by the community, and it is now utilized by many modern compilers and binary optimizers, including LLVM and GCC. Very recently, Newell and Pupyrev [20] extended the classical model and suggested a new optimization problem, called EXTENDED-TSP. With an extensive evaluation of real-world and synthetic applications, they found the objective of EXT-TSP is closely related to the performance of a binary; thus, an improved solution of the problem yields faster binaries. We refer to [20] for a complete background on this literature.

The problem of laying out data in memory to minimize the cache misses has been studied in the Algorithms community [1, 12, 19, 30]. In this setting a number of requests arrives online and our job is to design an eviction policy [31]. Even though ultimately, we are also concerned with minimizing cache misses, there are two main differences: first, the profile data gives us information about future request that we can exploit to improve locality; second, this optimization is done at the compiler, which does not have control over the operating system’s cache eviction policy. The benchmark used for online algorithms is the competitive

---

<sup>1</sup> To be more specific,  $k$  is the number of blocks that can fit into 1024 bytes of memory.

ratio: the number of cache misses incurred by the online algorithm divided by the number of cache misses incurred by an optimal algorithm that knows the entire sequence of requests in advance. It is known that the best competitive ratio is  $\Theta(k)$  for deterministic algorithms and is  $\Theta(\log k)$  [1], where  $k$  is the size of the cache.

There are many classical optimization problems that seek for to sequence the vertex set of a graph to optimizing some objective function. The two most closely related to our problem are MAX TSP and MIN BANDWIDTH.

An instance of MAX TSP consists of a weighted undirected graph and our objective is to sequence the vertex set to maximize the weight of adjacent nodes. The problem is known to be APX-hard [23] and a number of approximation algorithms are known [4, 7, 13, 15, 16, 18, 21, 28], with the best being the  $5/4$ -approximation of Dudycz *et al.* [7] that runs in  $O(n^3)$ .

An instance of MIN BANDWIDTH consists of an undirected graph and our objective is to sequence the vertex set to minimize the maximum distance between the endpoints of any edge in the graph. The problem admits an  $n^{O(b)}$  time exact algorithm [26], where  $b$  is the bandwidth of the graph. On the negative side, there is no exact  $g(b)n^{o(b)}$  time algorithm [5] and unless the ETH fails, even in trees of pathwidth at most two. Several poly-logarithmic approximation algorithms exist for different graphs classes [9, 11, 14]; on the other hand, it is NP-hard to approximate the problem within any constant even for caterpillars [6].

A somewhat related problem is the MIN LINEAR ARRANGEMENT problem. An instance consists of an undirected graph and our objective is to sequence the vertex set to minimize the sum of the distances between the endpoints of each edge in the graph. Minimizing this objective function is equivalent to maximizing the EXT TSP objective function with the discount function  $f(i) = 1 - i/n$ . MIN LINEAR ARRANGEMENT admits polynomial-time exact algorithms on trees [29]; however, we are not aware of any results for higher treewidth. There are several poly-logarithmic approximation algorithms [3, 8, 10, 25] based on the spreading metrics technique of Even *et al.* [8]; however it is unclear how these techniques can be made to work for EXT TSP. Moreover, for our applications, we are interested in the regime where  $k \ll n$ , so this connection does not yield a result of practical relevance.

## 2 Problem definition and hardness

An instance of EXT-TSP problem consists of a directed graph  $G = (V, E)$  with positive edge weights  $w : E \rightarrow R^+$  and a non-increasing discount function  $f(\cdot)$  where  $f(1) = 1$  and  $f(i) = 0$  for  $i > k$ , where  $k$ , where  $k$  is a parameter that is part of the problem definition. The problem is to sequence the vertices  $V$  so that  $d_v \in \{1, \dots, |V|\}$  is position of vertex  $v$  with the objective to maximize

$$\sum_{(u,v) \in E} f(|d_u - d_v|) \cdot w(u, v)$$

The first thing to notice is that the fact that we could have defined the problem on an undirected graph since the contribution of an edge  $(u, v)$  to the objective only depends on its weight and the distance between its two endpoints, and is independent of whether it is a forward or a backward jump. Indeed, we can reduce the undirected case to the directed case and vice versa: Given an undirected graph, we can orient the edges arbitrarily; while given a directed graph we can combine pairs of anti-parallel edges into a single edge by adding up their weight.

In order to simplify our exposition, from now on we assume the input graph is undirected. Right away, this allows us to relate EXT-TSP to MAX TSP and MIN BANDWIDTH, which in turn yields the following hardness results. Finally, for the sake of succinctness, we extend the edge weight function to subsets of edges; namely,  $w(S) = \sum_{e \in S} w(e)$  for  $S \subseteq E$ .

■ **Figure 1** Dangling nodes of a root connected component  $C$ .

► **Theorem 1.** *The EXT-TSP problem exhibits the following hardness:*

1. *it is APX-hard, even when  $k = 1$ ,*
2. *does not admit an exact  $n^{o(k)}$  time algorithm unless the ETH fails, even in trees.*

**Proof.** For the first part, we use the relation between EXT-TSP and MAX TSP, which is known to be APX-hard [23]. Recall that the objective of the latter problem is to maximize  $\sum_{(u,v) \in E: |d_u - d_v| = 1} w(u,v)$  given an undirected graph. We can reduce an instance of MAX TSP to an undirected instance of EXT-TSP with  $k = 1$  where  $f(1) = 1$  and  $f(2) = 0$ . Therefore, EXT-TSP is APX-hard even when  $k = 1$ .

For the second part, we use the relation to MIN BANDWIDTH. Recall that the objective of the latter problem is to minimize  $\max_{(u,v) \in E} |d_u - d_v|$ , the optimal value of this objective is called the *bandwidth* of the graph. Given an instance  $G$  with bandwidth  $b$ , consider the EXT-TSP instance where  $f(i) = 1$  for  $0 \leq i \leq k$  and  $f(k+1) = 0$ ; if  $k = b$  then the objective of this instance must be  $w(E)$  as there exists a sequencing where the endpoints of every edge are within at most  $k$  of one another. It follows that, if we could have an  $n^{o(k)}$  time algorithm for EXT-TSP that implies an  $n^{o(b)}$  time algorithms, which does not exist even for very simple trees unless the ETH fails [5]. ◀

### 3 Exact Algorithms

In this section we complement the hardness from the previous section by developing an exact algorithm for trees whose running time is polynomial when  $k = \mathcal{O}(1)$ .

► **Theorem 2.** *There is an  $n^{O(k)}$  time algorithm for solving EXT-TSP optimally on trees.*

**Proof.** Let  $T$  be the input tree. Consider an optimal solution OPT, and let  $O$  be the set of *realized edges*, that is, the subset of edges whose endpoints are at distance at most  $k$  in OPT. Without loss of generality we assume that each connected component of  $O$  is laid out in a contiguous stretch in the optimal sequencing. Using this simple insight, we use dynamic programming (DP) to build a solution for the connected component  $C$  that has the root of the tree, and solve separately the subtree rooted at nodes that are not in  $C$  but that have a parent in  $C$ ; we call such nodes *dangling nodes* of  $C$  (see Figure 1). Without loss of generality, we assume that  $|C| \geq k$ . If  $C$  happens to be smaller, we can guess the optimal sequencing for  $C$  (there are only  $n^{k-1}$  choices), solve separately the subproblems rooted at dangling nodes of  $C$ , and keep the best solution.

Our algorithm is based on a subtle DP formulation. Each DP state represents succinctly a partial solution for a subtree of  $T$ , and it is defined by a tuple  $(z, \sigma, R)$ , where

- $z \in V$  is the root of the subtree of  $T$  we are trying to solve,
- $\sigma$  is a sequence of *exactly*  $k$  nodes in  $T_z$ , the subtree of  $T$  rooted at  $z$ ,
- $R$  is the set of edges incident on  $\sigma$  that have already been realized.

Figure 2 Two example showing the entry ports of a node  $t \in T_z \setminus \sigma$ . On the left, all entry ports of  $t$  are open, while on the right all entry ports of  $t$  are closed.

It is worth noting that although the structure of the DP states builds on that used in the algorithm of Saxe [26] for MIN BANDWIDTH, the fact that we do not necessarily realize all edges means we need new ideas and a more involved DP formulation to solve EXT-TSP.

Our high level goal is to build an edge weighted graph  $H$  over these tuples plus two dummy source and sink nodes  $s$  and  $t$  such that every optimal solution to the EXT-TSP problem on the subtree  $T_z$  induces an  $s$ - $t$  path whose weight equals the value of this solution; and conversely, every  $s$ - $t$  path induces an EXT-TSP solution of  $T_z$  whose value equals the weight of the path. Thus, once the graph is defined and the equivalence established, solving EXT-TSP amounts to a shortest path computation in  $H$ .

To provide some motivation and intuition on the definitions that will follow, consider an optimal solution of  $T_z$  realizing a subset of edges  $O$ , where  $C$  is the connected component of  $(T_z, O)$  that contains the root  $z$ , and let  $\tau$  be the optimal sequence for  $C$ . Note that  $\tau$  realizes  $O[C]$ , and by our earlier assumption  $|\tau| \geq k$ . For each  $j \in \{1, \dots, |C| - k + 1\}$  we let  $\sigma^j$  be the subsequence of  $\tau$  from  $j$  to  $j + k - 1$  and we let  $R^j$  be the subset of edges realized by the first  $j + k - 1$  positions of  $\tau$  that have at least one endpoint in  $\sigma^j$ . Then the path induced by  $\tau$  in  $H$  will be

$$s \rightarrow (z, \sigma^1, R^1) \rightarrow (z, \sigma^2, R^2) \rightarrow \dots \rightarrow (z, \sigma^{|C|-k+1}, R^{|C|-k+1}) \rightarrow t$$

The weight of the first edge  $s \rightarrow (z, \sigma^1, R^1)$  will be defined as the contribution of  $\sigma^1$  to the objective, that is the total discounted (according to  $\sigma^1$ ) weight of edges  $R^1$ . The weight of the last edge  $(z, \sigma^{|C|-k+1}, R^{|C|-k+1}) \rightarrow t$  will be defined as the value of the subproblems defined by dangling nodes of  $\sigma^{|C|-k+1}$  not spanned by  $R^{|C|-k+1}$ . Finally, the weight of an edge  $(z, \sigma^j, R^j) \rightarrow (z, \sigma^{j+1}, R^{j+1})$  will be defined as the value of the subproblem defined by dangling nodes of  $\sigma^j \setminus \sigma^{j+1}$  not spanned by  $R^{j+1}$  plus the discounted weight of  $R^{j+1} \setminus R^j$ . Since we do not double count any contributions, the weight of the path adds up to the value of the optimal solution for  $T_z$ .

Our goal is to impose some restrictions on the vertices and edges in  $H$  so that every  $s$ - $t$  path induces a solution of equal value in  $T_z$ . To that end we will define the notion of valid tuples and valid edges, but before we do that, we must introduce a few more concepts.

Given a tuple  $(z, \sigma, R)$  we say that a node  $u \in \sigma$  is an *entry port* for a node  $t \in T_z \setminus \sigma$  if the unique path  $P$  from  $t$  to  $u$  in  $T$  does not go through any other vertex in  $\sigma$ ; furthermore, we say that  $u$  is a *closed entry port* of  $t$  if the edge in  $P$  out of  $u$  is in  $R$ , otherwise, we say  $u$  is an *open entry port* of  $t$ . Finally, we say that  $t \in T_z \setminus \sigma$  is *reachable* if all the entry ports of  $t$  are open. See Figure 2 for an example illustrating these definitions.

A tuple  $(z, \sigma, R)$  is *valid* if for every  $t \in T_z \setminus \sigma$  the entry ports  $u \in \sigma$  for  $t$  are either all closed or all open. Indeed if  $(z, \sigma, R)$  was part of the path induced by some  $\tau$  then either  $t$  comes before  $\sigma$  in  $\tau$ , in which case  $t$  subtree spanned between the entry ports of  $t$  must have been already realized; or  $t$  comes after  $\sigma$  in  $\tau$ , in which case said subtree will be realized later on. Thus, we can focus only on valid tuples. We define a graph  $H$  over the valid tuples where we put a directed edge  $(z, \sigma, R) \rightarrow (z, \sigma', R')$  if:

## 42:6 On the Extended TSP Problem

- $\sigma'$  is obtained from  $\sigma$  by appending a reachable node (reachable with respect to the first tuple)  $v$  to  $\sigma$  and removing the first node  $u$  in  $\sigma$ ,
- $R'$  equals  $R$  minus edges in  $R$  that are incident on  $u$  but not on any other node in  $\sigma$ , plus edges from  $v$  to  $\sigma$ ,
- $(u, \text{parent}(u)) \in R \cup R'$ ,
- for each child  $c$  of  $u$  such that  $(c, u) \notin R \cup R'$ ,  $u$  is the unique (open) entry port of  $c$  (defined with respect to the first tuple) and  $v \notin T_c$ ; we call such  $c$ , a *dangling child* of  $u$ .

Furthermore, we define the weight of such an edge to be the discounted weight of newly realized edges (namely,  $R' \setminus R$ ) plus the total value of the optimal solutions for subtrees defined by dangling children of  $u$ . Note that the  $R' \setminus R$  must connect  $v$  to other nodes in  $\sigma$ , so we have all the information needed to discount their weight.

Finally, we connect  $s$  to each tuple  $(z, \sigma, R)$  where  $R$  is the set of edges with both endpoints in  $\sigma$  and the weight of the edge is the discounted (w.r.t.  $\sigma$ ) weight of  $R$ ; and we connect each tuple  $(z, \sigma, R)$  to  $t$  if the only reachable nodes adjacent to  $\sigma$  are dangling children and we set the weight of the edge to be the total value of the subproblems defined by those dangling children.

Given a path  $P$  in  $H$  we define  $\tau$  to be the induced solution by taking the  $\sigma$  of the first tuple in the path, and then extending the ordering by appending the new node of the  $\sigma$  in the next tuple and so on. Similarly, we can define the inverse operation: Given a sequencing  $\tau$  realizing a connected component of nodes that have the root of the tree, then we can define a sequence of tuples such that the sequence of tuples induces  $\tau$ .

▷ **Claim 3.** Let  $P$  be a path out of  $s$  in  $H$  inducing some ordering  $\tau$ . Then  $\tau$  realizes exactly the union of all the  $R$ -sets in  $P$ .

The claim is easy to prove by induction on the length of the sequence. If the sequence has only one tuple  $(z, \sigma, R)$ , then  $\tau = \sigma$  and  $R$  is the set of edges realized by  $\sigma$ , so the claim follows. Otherwise, if the last two tuples are  $(z, \sigma, R)$  and  $(z, \sigma', R')$  and  $v$  is the last node in  $\tau$  then  $R' \setminus R$  is the set of edges realized by  $\tau$  incident on  $v$  and we can use induction to account for the rest.

In order to prove the correctness of our dynamic programming formulation, we need to argue that every solution  $\tau$  to the original problem induces a path of equivalent cost, and vice-versa.

▷ **Claim 4.** Let  $\tau$  be the sequence of nodes in the connected component  $C$  of edges realized by the optimal solution OPT having  $z$ . The sequence of tuples induced by  $\tau$  forms a valid  $s$ - $t$  path whose weight equals

$$\sum_{(u,v) \in T[C]} f(|d_u - d_v|)w(u, v) + \sum_{\substack{u \notin C \\ \text{parent}(u) \in C}} \text{OPT}[T_u],$$

where  $d_u$  is the position of  $u$  in  $\tau$ .

If the sequence is a path, then by Claim 3,  $\tau$  realizes precisely the union of the  $R$ -sets in the sequence, and the weight of the path is precisely as stated in the claim. It only remains to show that the sequence is indeed a path. Consider two consecutive tuples  $(z, \sigma, R)$  and  $(z, \sigma', R')$  along the sequence. Our goal is to show that there is an edge connecting them. The first two conditions of a valid edge definition hold by definition of the induced sequence of tuples. For the third condition, note that  $(u, \text{parent}(u))$  must be realized by  $\tau$  and so  $\text{parent}(u)$  must occur within  $k$  positions of  $u$  so the edge must appear in  $R \cup R'$  and the

condition holds. For the fourth condition, if we let  $c$  be a child of  $u$  such that  $(c, u) \notin R \cup R'$ , we note that  $\tau$  cannot realize this edge after  $\sigma'$ , so it must be the case that  $v \notin T[c]$  (otherwise  $v$  would be disconnected from the root in  $C$ ) and that  $c$  is dangling child of  $u$  (otherwise  $c$  has a descendant in  $\sigma$  that would be disconnected from the root in  $C$ ).

▷ **Claim 5.** For a given  $s$ - $t$  path in  $H$ , let  $\tau$  be the ordering induced by the path. Then the set of edges realized by  $\tau$  forms a connected component  $C$  that contains the root and the weight of the path equals

$$\sum_{(u,v) \in T[C]} f(|d_u - d_v|)w(u, v) + \sum_{\substack{u \notin C \\ \text{parent}(u) \in C}} \text{OPT}[T_u],$$

where  $d_u$  is the position of  $u$  in  $\tau$ .

By Claim 3,  $\tau$  realizes precisely the union of the  $R$ -sets in the sequence. For every  $v \in \tau$  other than  $z$ , we argue that  $(v, \text{parent}(v))$  is realized by  $\tau$ . Indeed, let  $(z, \sigma, R)$  be the last tuple such that  $v \in \sigma$ . If  $(z, \sigma, R)$  is not the last tuple, by the third existence condition on the edge to the next tuple guarantees that  $(u, \text{parent}(u))$  is realized. If  $(z, \sigma, R)$  is the last tuple, by the existence condition on the edge to  $t$ , all reachable nodes adjacent to  $\sigma$  are dangling, in particular  $\text{parent}(u)$  is not reachable. Therefore, since  $(v, \text{parent}(v))$  is realized for all  $v$ , using induction we get that  $v$  must be connected all the way to the root with realized edges. Therefore the vertices in  $\tau$  form a connected subtree containing the root  $z$ , and the set of realized edges is precisely this subtree.

All this effort would be for naught, unless we could represent  $H$  succinctly. Recall that every node in  $H$  is a tuple  $(z, \sigma, R)$ ; clearly, there are only  $n$  choices for  $z$  and only  $n^k$  choices for  $\sigma$ ; furthermore, for an edge to be in  $R$ , since  $\sigma$  is a contiguous chunk of size  $k$ , they can only realize edges with connection to the previous  $k$  nodes, thus, we can represent  $R$  succinctly by listing those additional  $k$  nodes. Overall, there are  $n^{2k+1}$  edges in  $H$ ; we can list the outgoing neighboring tuples in  $O(n)$  time per tuple<sup>2</sup>. Therefore, we can run Dijkstra in  $O(n^{2k+2})$  time and identify the connected component of  $z$ . Since this has to be done for every node in  $T$ , we gain an extra factor of  $n$  for a running time of  $O(n^{2k+3})$ . ◀

## 4 Approximation Algorithms for special graph classes

In this section, we show that we can get very good approximations for special graph classes that go beyond trees.

► **Theorem 6.** *There is an  $n^{O(\frac{kt}{\epsilon})}$  time  $(1 + \epsilon)$ -approximation for EXT-TSP in graphs with a tree decomposition of tree-width  $t$ .*

**Proof.** Let  $T$  be the tree decomposition of our input graph  $G$  and let  $h = \lceil 1/\epsilon \rceil$ . To simplify the presentation of our algorithm we define an auxiliary problem, where the goal is to partition the vertex set into clusters of size at most  $hk$  and order each part separately, the EXT-TSP objective is computed for each part and summed up. If we let OPT be the value of the optimal solution for the original problem, we claim that OPT', the value of the optimal solution for the auxiliary problem is not much lower; more precisely,

$$\text{OPT}' \geq \frac{h-1}{h} \text{OPT}.$$

<sup>2</sup> We do not attempt to optimize this running time.

To see this, suppose that  $\text{OPT}$  lists the vertices in the order  $v_1, v_2, \dots, v_n$ . We pick a random threshold  $\alpha$  u.a.r. from  $\{0, 1, \dots, k-1\}$ , and cluster vertices together so that for each  $j$  we have a cluster  $\{v_{hkj+1+\alpha}, \dots, v_{hk(j+1)+\alpha}\}$ , yielding a solution to the auxiliary problem. Note that the probability of an edge that is realized by  $\text{OPT}$  must have endpoints that are at most  $k$  apart in the ordering, so there is only a  $1/h$  chance of that edge not being present in  $\text{OPT}'$ . Although this is a randomized construction, and it just shows that  $E[\text{OPT}'] \geq \frac{h-1}{h} \text{OPT}$ , it is easy to see that there must exist a value of  $\alpha$  that yields the desired bound<sup>3</sup>.

Given a tree decomposition for  $G$  with treewidth  $t$ , and a bag  $B$  in the decomposition we denote with  $T[B]$  the subset of vertices in the original graph spanned by the sub-decomposition rooted at  $B$ . For each  $u \in B$  we define a collection orderings of subsets  $\mathcal{S}_u$ , such that for an ordering  $\sigma$  of a subset  $S \subseteq V$  of vertices to be in  $\mathcal{S}_u$  we require that:

- $|S| \leq hk$ ,
- $u \in S$ , and
- the subgraph  $(S, \{(a, b) \in E[S] : |\sigma(a) - \sigma(b)| \leq k\})$  is connected.

We define a dynamic programming formulation for our auxiliary problem as follows. For each bag  $B$  in the decomposition and each  $|S|$ -tuple  $(\sigma_u : u \in B)$  where  $\sigma_u \in \mathcal{S}_u$ , we create a dynamic programming state  $A[B, (\sigma_u : u \in B)]$  that corresponds to the cost of the best solution for  $T[B]$  where each  $\sigma_u$  is the ordering of one of the clusters in the solution of the auxiliary problem. To keep the requirements feasible we ask that for any  $u, v \in B$  either  $\sigma_u = \sigma_v$ , or  $\sigma_u$  and  $\sigma_v$  do not share any vertices.

We work with a nice tree decomposition with join, forget, and introduce nodes. To define the recurrence for  $A$  we consider each case.

- Join node: Here we have two children with the same bag as the node. We simply pass the tuple constraining the solution space to each child. To compute its value we add the value of the two children and subtract the contribution of edges inside of  $B$  to avoid double counting. Notice that the distance between the endpoints of  $E[B]$  is specified by  $(\sigma_u : u \in B)$  so we can compute the appropriate discount of these edges.
- Introduce node: Here we have a single child with a bag having one fewer element; call it  $u$ . We remove  $\sigma_u$  from the tuple and  $u$  from  $B$ . To compute its value we add the contribution of edges between  $u$  and other nodes in  $\sigma_u$  to the value of the child. Again, we can use  $\sigma_u$  to discount the weight of these edges accordingly.
- Forget node: Here we have a single child with a bag with one additional element, call it  $u$ . To compute its value we need to guess the  $\sigma_u$  in the optimal solution. If  $u$  happens to already be in the sequence  $\sigma_v$  of some  $v \in B$  then  $\sigma_u = \sigma_v$ . Otherwise, we must guess  $\sigma_u$  by picking  $hk$  vertices from  $T[B] \setminus \cup_{v \in B} \sigma_v$  and checking that  $\sigma_u \in \mathcal{S}_u$ . Going over all possible valid states for the child bag and keeping the state with highest value yields the value of the state of the parent bag.

For the correctness, notice that there is no loss of information in the case of a introduce node. Let  $u$  be the node begin introduced. Either  $u$  is the only vertex in common between  $B$  and  $\sigma_u$ , in which case  $u$  is the only vertex in  $T[B]$  by virtue of  $\sigma_u$  being connected in  $G$ , and so it is safe to forget  $\sigma_u$  together with  $u$  in the child node. Or, there exists another  $v \in B - u$  such that  $v \in \sigma_u$ , which case  $\sigma_v = \sigma_u$  and so the information about the constraints we imposed in  $u$ 's part are preserved further down the decomposition.

<sup>3</sup> Note that the argument is non-constructive in the sense that given  $G$  it is not clear how to partition  $G$  into clusters of size  $hk$  so that  $\text{OPT}' \geq \frac{h-1}{h} \text{OPT}$ . The argument only guaranteed the existence of such a clustering.

For the correctness of the forget node case, note that the component that  $u$  belong to in the optimal solution is connected and that  $B$  acts like a separator from  $T[B]$  to the rest of the graph, so if  $u$  is not in the same component as any node in  $B$ , then it must be in a component with only nodes in  $T[B] \setminus \cup_{v \in B} \sigma_v$ .

There are  $n^{hkt+1}$  states in the decomposition and each one is considered once by a state associated with the parent bag in the decomposition, so the overall work is linear on the number of the states. We can enumerate the states on the fly by paying another  $O(n)$  term per state so the total running time is  $n^{hkt+2}$ .

Now, setting  $h = 1 + 1/\epsilon$ , the optimal solution found by DP is bound to be a  $1 + \epsilon$  approximation for the original problem in  $n^{O(\frac{k}{\epsilon})}$  as promised in the Theorem statement. ◀

We can use this result to obtain a  $(1 + \epsilon)$ -approximation for planar graphs.

► **Corollary 7.** *There is an  $n^{O(\frac{k}{\epsilon^2})}$  time  $(1 + \epsilon)$ -approximation for EXT-TSP in planar graphs.*

**Proof.** Using Baker’s technique [2] we can find an  $\ell$ -outerplanar subgraph  $G'$  of the input graph  $G$  such that value of the optimal solution to the EXT-TSP in  $G'$  is at least  $1 - 2/\ell$  the value of the optimal solution in  $G$ . Since the treewidth of  $G'$  is no more than  $3\ell$ , we can use the algorithm from Theorem 6 get a  $1 + \epsilon'$  approximation in  $G'$  in  $n^{O(\frac{k}{\epsilon'})}$  time. Setting  $\epsilon' = \epsilon/3$  and  $\ell = 6/\epsilon$ , we get the desired result for any  $\epsilon \leq 1$ . ◀

## 5 Approximation Algorithms for general graph

### 5.1 Greedy

Consider the following greedy algorithm: Start with an arbitrary vertex, and on each step append a vertex with the heaviest edge to the last-added vertex. That is, if  $u$  is the last-added vertex, then we append the vertex  $v$  maximizing  $w(u, v)$  where  $v \in V$  has not yet been added to the solution.

► **Lemma 8.** *Greedy is a  $2k$ -approximation and this is tight. It can be implemented to run in  $O(m \log n)$  time.*

**Proof.** Let  $O$  be the edges realized by the optimal solution and let  $u_1, u_2, \dots, u_n$  be the order computed by the greedy algorithm. Let  $d_u^*$  be the position of  $u$  in the optimal solution. Observe that the value of the greedy solution is at least  $\sum_{i=1}^{n-1} f(1)w(u_i, u_{i+1}) = \sum_{i=1}^{n-1} w(u_i, u_{i+1})$  as  $f(1) = 1$ . We partition  $O$  as follows, for each  $u_i$  we have a part  $O_i = \{(u_i, u_j) \in O : j > i\}$ . Using the fact that  $f$  is non-increasing and the definition of the greedy algorithm,  $f(|d_u^* - d_v^*|)w(u, v) \leq w(u, v) \leq w(u_i, u_{i+1})$  for all  $(u, v) \in O_i$ , and  $|O_i| \leq 2k$ . Thus, the value of the optimal solution is

$$\sum_{i=1}^{n-1} \sum_{(u,v) \in O_i} f(|d_u^* - d_v^*|)w(u, v) \leq 2k \sum_{i=1}^{n-1} w(u_i, u_{i+1}).$$

Thus, greedy is a  $2k$ -approximation.

To show that the analysis is tight, consider the following instance with  $n = (2k + 1)\ell$  consisting of  $\ell$   $2k$ -stars with the centers of the stars connected with a path of length of length  $\ell - 1$ . All edges have weight 1. The discount function  $f$  is such that  $f(i) = 1$  when  $i \leq k$  and  $f(i) = 0$  when  $i > k$ . The optimal solution sequences one star after the other and achieves a total cost of  $2k\ell$ . While the greedy solution may start at the center of the “left most star” and traverse the centers of all star and then add  $k$  pendant nodes, achieving a total cost of  $\ell - 1 + k$ . By making  $\ell$  large we get an approximation ratio that tends to  $2k$ .

■ **Figure 3** Tight instance for greedy. Optimal solution can realize  $2k\ell$  edges while Greedy may end up realizing only  $\ell - 1 + k$  edges.

For the implementation, we need to maintain a maximum priority queue with the nodes that are yet to be added to the greedy solution. The value associated with node  $u$  is the weight of the edge connecting  $u$  to the last node in the current partial greedy solution. When a new node is added to the greedy solution, this causes the priority of certain vertices to be updated (up for those incident on  $u$  or down for those incident on the second last-node of the partial solution, or either direction if incident on both nodes). The key observation is that each edge can cause the priority of a node to be changed twice (once when the first endpoint is added to the solution and again when that endpoint stops being the last node of the greedy solution). Therefore, the total number of priority updates is  $O(m)$ , which using a simple binary heap yields the desired time. ◀

### 5.2 Cycle cover based algorithm

We can do slightly better if we use a maximum weight cycle cover as the basis for our solution. A similar approach has been used to design approximation algorithms for max-TSP [13].

► **Theorem 9.** *There is a polynomial time  $\left(1 + \frac{1}{k+1}\right)$   $k$ -approximation for EXT-TSP in general graphs.*

**Proof.** Let  $A$  be a maximum weight set of edges such that the degree of every node is at most 2. This problem is also known as maximum weight simple 2-matching and can be reduced to regular maximum weight matching [27, Ch. 30]. Note that  $A$  is a collection of paths and cycles in  $G$ . If there exists a cycle  $C$  in  $A$ , we break  $C$  by removing the lightest edge. This gives us a collection of paths  $A'$ . Sequencing each path gives a solution to the EXT-TSP problem with value at least  $w(A')$ .

Now, given a solution to the EXT-TSP problem with value  $\text{OPT}$ , we claim that we can construct a solution to the degree bounded problem that has value at least  $\text{OPT}/k$ . To see this, note that the weight of the edges whose endpoints are at distance *exactly*  $i$  for  $i = 1, \dots, k$  is a candidate solution for  $A$ . It follows then that  $w(A) \geq \text{OPT}/k$ .

This is because the edges that are counted towards the objective in EXT-TSP have maximum degree  $2k$  and that solution can be scaled down by a factor of  $k$  to get a fractional solution to an exact LP formulation of the degree bounded problem. Thus, we get that  $w(A) \geq \text{OPT}/k$ .

Let  $\text{ALG}$  be the value of the solution found by our algorithm. Consider a cycle  $C$  in  $A$  with length  $\ell = |C|$ . Let  $e$  be the edge in  $C$  with minimum weight. Therefore,  $C$  contributes at least  $w(C) - w(e) + f(\ell - 1)w(e)$  to  $\text{ALG}$ . Since  $w(e) \leq w(C)/\ell$ , we can further simplify the previous expression to

$$w(C) \left(1 - \frac{1 - f(\ell - 1)}{\ell}\right).$$

Now if each cycle  $C$  in  $A$  had length at least  $\ell > k + 1$ , the weight of  $C \cap A'$  would be at least  $w(C) \left(1 - \frac{1}{k+2}\right)$ . Let ALG be the cost of the solution found by our algorithm. Then

$$\text{ALG} \geq w(A') \geq \frac{k+1}{k+2} w(A) \geq \frac{k+1}{(k+2)k} \text{OPT},$$

which matches the approximation factor of  $k + 1$  promised in the theorem statement. Unfortunately, cycles can be as small as  $\ell = 3$ , which depending on  $f$  could yield a worse approximation factor, so we need a different approach to our analysis.

Let  $\ell^*$  be the number in  $[3, 4, \dots, k + 2]$  maximizing  $\frac{1-f(\ell^*-1)}{\ell^*}$ . Using the same reasoning as above, we see that

$$\text{ALG} \geq w(A) \left(1 - \frac{1 - f(\ell^* - 1)}{\ell^*}\right).$$

The first thing to note is that if  $\ell^* = k + 2$  then the above analysis yield the desired approximation, so from now one assume  $\ell^* < k + 2$  and  $\frac{1-f(\ell^*-1)}{\ell^*} > \frac{1}{k+2}$ , or equivalently, that

$$1 - \frac{\ell^*}{k+2} > f(\ell^* - 1).$$

Consider the edges realized by the optimal solution and split them into  $X$  and  $Y$ . The first set,  $X$ , are the edges whose endpoints are at distance at most  $\ell^* - 2$  from each other; the second set,  $Y$ , are the edges whose endpoints are at distance between  $\ell^* - 1$  and  $k$ . Notice that

$$\text{OPT} \leq w(X) + f(\ell^* - 1)w(Y),$$

since all edges in  $Y$  are discounted at least  $f(\ell^* - 1)$ , and that

$$w(A) \geq \max \left\{ \frac{w(X)}{\ell^* - 2}, \frac{w(Y)}{k - \ell^* - 2} \right\},$$

since we can use the same scaling argument on  $X$  or  $Y$  but using a smaller scaling factor since the vertices in those edges sets have smaller degrees; namely,  $2\ell^* - 2$  and  $2(k - \ell^* - 1)$  respectively. Putting the above two inequalities together we get

$$\begin{aligned} \text{OPT} &\leq (\ell^* - 2)w(A) + f(\ell^* - 1)(k - \ell^* - 2)w(A) \\ &\leq \frac{(\ell^* - 2) + f(\ell^* - 1)(k - \ell^* - 2)}{\left(1 - \frac{1-f(\ell^*-1)}{\ell^*}\right)} \text{ALG}. \end{aligned}$$

Think of the above upper bound on the approximation ratio  $\text{OPT}/\text{ALG}$  as a function of  $f(\ell^* - 1)$ . We want to find the value  $0 \leq f(\ell^* - 1) \leq 1 - \ell^*/(k + 2)$  that yields the worst bound on the approximation ratio. The upper bound is the ratio of two linear functions of  $f(\ell^* - 1)$  and is thus maximized when either  $f(\ell^* - 1) = 0$  or  $f(\ell^* - 1) = 1 - \ell^*/(k + 2)$ . If  $f(\ell^* - 1) = 0$ , the ratio simplifies to  $\frac{\ell^*-2}{1-1/\ell^*}$ , which in turn is maximized at  $\ell^* = k + 2$  and yields a ratio of  $k + \frac{k}{k+1}$ , as desired. Finally, if  $f(\ell^* - 1) = 1 - \ell^*/(k + 2)$ , we again get the same approximation ratio. ◀

### 5.3 Local search algorithm

So far all the algorithms we have presented in this section have polynomial running times that are independent of  $k$ . If we are willing to have algorithms that run in  $n^{O(k)}$  we can get arbitrarily good approximations.

Our local search algorithm is parameterized by an integer value  $\ell \geq k$ . The algorithm maintains a solution  $\tau$  and performs local search moves where some subset of  $\ell$  nodes are taken out of  $\tau$  and sequenced optimally and attached to the end of the solution. At each step we perform the best such move and we stop once there is no move that improves the solution.

► **Lemma 10.** *A local optimal solution is a  $2 + \frac{2}{\ell/k-1}$  approximation for the EXT-TSP in general graphs.*

**Proof.** We will use the following notation throughout this proof: For a given solution  $\tau$  and a permutation  $\sigma$  of  $\ell$  elements, let  $\tau - \sigma$  the permutation of  $n - k$  elements that we get by removing the nodes in  $\sigma$  from  $\tau$ . Also, let  $\tau|\sigma$  be the permutation obtained by concatenating  $\sigma$  to  $\tau - \sigma$ . Finally, let  $w_\sigma(\tau)$  be the discounted weight of edges realized by  $\tau$  that are incident on vertices in  $\sigma$ , and  $w(\tau)$  be the discounted weight of all edges realized by  $\tau$ , i.e. the value of  $\tau$ .

Assume that  $\tau$  is locally optimal; namely, that no local move can improve its value:

$$w(\tau) \geq w(\tau|\sigma) \quad \forall \sigma : |\sigma| = \ell.$$

Notice that  $w(\tau) \leq w(\tau - \sigma) + w_\sigma(\tau)$  and that  $w(\tau|\sigma) \geq w(\tau - \sigma) + w(\sigma)$ . Therefore, a weaker necessary condition for being locally optimal is that

$$w_\sigma(\tau) \geq w(\sigma) \quad \forall \sigma : |\sigma| = \ell.$$

Let us build a collection for  $n + \ell$  sub-sequences of the optimal solution by sliding a window of size  $\ell$  over OPT. Call the resulting collection  $S$ . Adding up the above inequality for all  $\sigma \in S$  we get

$$\sum_{\sigma \in S} w_\sigma(\tau) \geq \sum_{\sigma \in S} w(\sigma).$$

Notice that every edge realized by  $\tau$  can appear in at most  $2\ell$  terms in the left-hand side of the above inequality (this is because every endpoint appears in at most  $\ell$  permutations), while every edge realized by OPT must appear in at least  $\ell - k$  terms in the right-hand side of the above inequality. These observation imply the following relation between  $\tau$  and OPT

$$2\ell w(\tau) \geq (\ell - k)w(\text{OPT}),$$

which in turn finish off the proof of the lemma. ◀

Of course, the issue with the above algorithm is that it is not clear how to compute a locally optimal solution. However, we can use the standard technique of only making a move if it improves the value of the objective by at least  $\delta/nw(\text{OPT})$ . This guarantees that we do not perform more than  $n/\delta$  and degrades the approximation ratio by no more than  $2\delta$ . This yields an algorithm that runs in  $O(n^{\ell+1}/\delta)$  time.

## 6 Conclusions and open problems

Our results can be generalized slightly. For example, one can get similar results for discount functions  $f$  that are non-symmetric (i.e.,  $f(u, v) \neq f(v, u)$ ), or when the block sizes are non-uniform. There are, however, some interesting questions that remain unanswered:

1. Is there a polynomial-time  $O(1)$ -approximation, independent of  $k$ ?
2. Is there an exact  $\mathcal{O}(f(k, t)n^{O(k)})$  time algorithm where  $t$  is the treewidth of the instance?

On the other hand, there are a few things that we can rule out. Note that we cannot expect  $(1 + \epsilon)$ -approximations even in  $n^{O(k)}$  time since that would contradict APX-hardness of MAX TSP, and we cannot expect to get exact algorithms for bounded treewidth instances in  $n^{o(k)}$  time either due to MIN BANDWIDTH hardness.

## Abstract

We give a probabilistic analysis of the unit-demand Euclidean capacitated vehicle routing problem in the random setting, where the input distribution consists of  $n$  unit-demand customers modeled as independent, identically distributed uniform random points in the two-dimensional plane. The objective is to visit every customer using a set of routes of minimum total length, such that each route visits at most  $k$  customers, where  $k$  is the capacity of a vehicle. All of the following results are in the random setting and hold asymptotically almost surely.

The best known polynomial-time approximation for this problem is the iterated tour partitioning (ITP) algorithm, introduced in 1985 by Haimovich and Rinnooy Kan [15]. They showed that the ITP algorithm is near-optimal when  $k$  is either  $o(\sqrt{n})$  or  $\omega(\sqrt{n})$ , and they asked whether the ITP algorithm was “also effective in the intermediate range”. In this work, we show that when  $k = \sqrt{n}$ , the ITP algorithm is at best a  $(1 + c_0)$ -approximation for some positive constant  $c_0$ .

On the other hand, the approximation ratio of the ITP algorithm was known to be at most  $0.995 + \alpha$  due to Bompadre, Dror, and Orlin [10], where  $\alpha$  is the approximation ratio of an algorithm for the traveling salesman problem. In this work, we improve the upper bound on the approximation ratio of the ITP algorithm to  $0.915 + \alpha$ . Our analysis is based on a new lower bound on the optimal cost for the metric capacitated vehicle routing problem, which may be of independent interest.

## 1 Introduction

**Unit-Demand Euclidean CVRP.** In the *capacitated vehicle routing problem (CVRP)*, we are given a set of  $n$  customers and a depot. There is an unlimited number of identical vehicles, each of an integer capacity  $k$ . The route of a vehicle starts at the depot and returns there after visiting at most  $k$  customers. The objective is to visit every customer, using a set of routes of minimum total length. Vehicle routing is a basic type of problems in operations research, and several books (see [3, 11, 14, 25] among others) have been written on those problems. We study the *unit-demand Euclidean* version of the problem, in which each customer has unit demand, all locations (the customers and the depot) lie in the two-dimensional plane, and distances are given by the Euclidean metric. The unit-demand Euclidean CVRP is a generalization of the Euclidean traveling salesman problem and is known to be NP-hard for all  $k \geq 3$  (see [5]). Unless explicitly mentioned, all CVRP instances in this paper are assumed to be unit-demand Euclidean.

**ITP Algorithm.** The best known polynomial-time approximation for the CVRP is a very simple algorithm, called *iterated tour partitioning (ITP)*. This algorithm first computes a traveling salesman tour (ignoring the capacity constraint) using some other algorithm, then partitions the tour into segments such that the number of customers in each segment is at most  $k$ , and finally connects the endpoints of each segment to the depot so as to make a tour. The ITP algorithm was introduced and refined by Haimovich and Rinnooy Kan [15] and Altinkemer and Gavish [2] in the 1980s. Its performance is parameterized by the choice of traveling salesman tour: the approximation ratio of the ITP algorithm is  $1 + \alpha$ , where  $\alpha$  is the approximation ratio of the algorithm used to compute the traveling salesman tour in the first step. Since the Euclidean traveling salesman problem admits a *polynomial-time approximation scheme (PTAS)* by Arora [4] and Mitchell [20],  $\alpha$  can be set to any constant strictly greater than 1.

**Random Setting.** Given the difficult challenges posed by the CVRP, researchers turned to an analysis beyond worst case, by making some probabilistic assumptions on the distribution of the input instance. In 1985, Haimovich and Rinnooy Kan [15] gave the first probabilistic analysis on the ITP algorithm for the CVRP, where the customers are *independent, identically distributed (i.i.d.)* random points. An event  $\mathcal{E}$  occurs *asymptotically almost surely (a.a.s.)* if  $\lim_{n \rightarrow \infty} \mathbb{P}[\mathcal{E}] = 1$ . They showed that, the ITP algorithm is a.a.s. an  $(\alpha + o(1))$ -approximation for the CVRP when  $k$  is either  $o(\sqrt{n})$  or  $\omega(\sqrt{n})$ .<sup>1</sup> The performance of the ITP algorithm in the intermediate range of  $k = \Theta(\sqrt{n})$  was unknown. They asked in [15] whether the ITP algorithm was “also effective in the intermediate range”.

In our work, we study this question raised by Haimovich and Rinnooy Kan [15]. We give a probabilistic analysis of the ITP algorithm when the points are i.i.d. random, with a focus on the range of  $k = \Theta(\sqrt{n})$ . Our first main result is a lower bound: even in the random setting, the ITP algorithm is at best a  $(1 + c_0)$ -approximation a.a.s., for some constant  $c_0 > 0$  (Theorem 1), see Section 3.

► **Theorem 1.** *Consider the iterated tour partitioning algorithm for the unit-demand Euclidean capacitated vehicle routing problem. Let  $V$  be a set of  $n$  i.i.d. uniform random points in  $[0, 1]^2$ . Let  $k = \sqrt{n}$ . For some fixed depot  $O \in \mathbb{R}^2$ , there exists a constant  $c_0 > 0$ , such that, for any constant  $\alpha > 1$ , there exists an  $\alpha$ -approximate traveling salesman tour on  $V \cup \{O\}$ , such that the approximation ratio of the algorithm is at least  $1 + c_0$  asymptotically almost surely.*

► **Remark.** The  $\alpha$ -approximate traveling salesman tour in Theorem 1 is constructed using Karp’s partitioning algorithm [16].

On the other hand, the approximation ratio of the ITP algorithm is at most  $1 + \alpha$  due to Altinkemer and Gavish [2]. In 2007, this ratio was improved by Bompadre, Dror, and Orlin [10] to  $0.995 + \alpha$ , a.a.s., when the points are i.i.d. uniform random in the unit square.<sup>2</sup> Here, using a different approach (Theorem 4), we further improve the upper bound on the approximation ratio in this random setting to  $0.915 + \alpha$ , a.a.s. (Theorem 2), see Section 4. We generalize our results to multiple depots in the full version of the paper.

<sup>1</sup> As observed in [15], a solution of the ITP algorithm consists of two types of costs: the *radial cost* and the *local cost*. When  $k$  is  $o(\sqrt{n})$  or  $\omega(\sqrt{n})$ , one of the two types dominates, the reason for which the solution is an  $(\alpha + o(1))$ -approximation (or even a  $(1 + o(1))$ -approximation for the case of  $k = o(\sqrt{n})$ ).

<sup>2</sup> The analysis in [10] focused on the case of  $\alpha = 1$ , though that analysis can be easily generalized to any  $\alpha \geq 1$ . Bompadre, Dror, and Orlin [10] noted in their work that a ratio of  $0.985 + \alpha$  is achievable without giving the proof.

► **Theorem 2.** *Consider the iterated tour partitioning algorithm for the unit-demand Euclidean capacitated vehicle routing problem. Let  $V$  be a set of  $n$  i.i.d. uniform random points in  $[0, 1]^2$ . Let  $k$  be any integer in  $[1, n]$ . Let the depot  $O$  be any point in  $\mathbb{R}^2$ . For any constant  $\alpha \geq 1$  and any  $\alpha$ -approximate traveling salesman tour on  $V \cup \{O\}$ , the approximation ratio of the algorithm is at most  $0.915 + \alpha$  asymptotically almost surely.*

## 1.1 Other Related Work

**PTAS and Quasi-PTAS Results for the CVRP.** Despite the difficulty of the CVRP, there has been progress on several special cases. A series of papers designed PTAS algorithms for small  $k$ : work by Haimovich and Rinnooy Kan [15], when  $k$  is constant; by Asano et al. [5] extending techniques in [15], for  $k = O(\log n / \log \log n)$ ; and by Adamaszek, Czumaj, and Lingas [1], when  $k \leq 2^{\log^{f(\epsilon)}(n)}$ . For higher dimensional Euclidean metrics, Khachay and Dubinin [17] gave a PTAS for fixed dimension  $\ell$  and  $k = O(\log^{\frac{1}{\ell}}(n))$ . For unbounded  $k$ , Das and Mathieu [13] designed a quasi-polynomial time approximation scheme.

**Probabilistic Analyses.** The instance distribution when the customers are i.i.d. random points is perhaps the most natural probabilistic setting. In that setting, Rhee [23] and Daganzo [12] analyzed the value of an optimal solution to the CVRP for the case when  $k$  is fixed. Baltz et al [6] studied the multiple depot vehicle routing problem when both the customers and the depots are i.i.d. random points and assuming unlimited tour capacity.

**Analyses of the ITP Algorithm.** Because of the popularity of the ITP algorithm, its approximation ratio has already been much studied and bounds were utilized in a design of best-to-date approximation algorithms for the CVRP, see, e.g., [9]. In the metric version of the CVRP, the approximation ratio of the ITP algorithm is at most  $1 + (1 - \frac{1}{k})\alpha$  due to Altinkemer and Gavish [2]. Bompadre, Dror, and Orlin [9] reduced this bound by a factor of  $\Omega(\frac{1}{k^3})$ . On the other hand, Li and Simchi-Levi [18] showed that the ITP algorithm is at best a  $(2 - \frac{1}{k})$ -approximation algorithm on general metrics even if  $\alpha = 1$ . Despite of a huge amount of research, the ITP algorithm by Haimovich and Rinnooy Kan [15] and Altinkemer and Gavish [2] remains the polynomial-time algorithm with the best approximation guarantee for the Euclidean CVRP.

**Other Applications of the ITP Algorithm.** Very recently, Blauth, Traub, and Vygen [8] exploited properties of tight instances in the analysis of the ITP algorithm, and used those properties in their design of the best-to-date approximation algorithm for metric CVRP with a ratio of  $1 + \alpha - \epsilon$ , where  $\epsilon$  is roughly  $\frac{1}{3000}$ .

Because of its simplicity, the ITP algorithm is versatile and has been adapted to other vehicle routing problems. For example, Mosheiov [21] studied the vehicle routing with pick-up and delivery services. They showed that the ITP algorithm is efficient through worst-case analysis and numerical tests. Li, Simchi-Levi, and Desrochers [19] considered the vehicle routing problem with constraints on the total distance traveled by each vehicle. They showed that the ITP algorithm has a good worst-case performance when the number of vehicles is relatively small.

## 1.2 Overview of Techniques

To show that the ITP algorithm is at best a  $(1 + c_0)$ -approximation for the CVRP in the random setting (Theorem 1), we construct a significantly better solution.

In the random setting, one may view an ITP solution as partitioning the unit square into small regions and dedicating one tour to each small region. The cost of the solution is then roughly the sum of two terms: the *radial cost*, incurred by traveling between the depot and the small region; and the *local cost*, incurred by traveling from customer to customer within the small region.

To improve that solution, the idea is that instead of traveling straight between the depot and the small region, a smarter tour might as well make some small detours to visit some additional nearby customers en route to the small region. We call that a *mixed tour*. This modification of the solution has a positive effect because those nearby customers are covered at little additional cost, thus saving the local cost of covering those customers; but it also has a negative effect because visiting those nearby customers uses up some of the tour's capacity, and to account for that the definition of the small regions must be adjusted, and their area shrunk. Controlling the two competing effects so that on balance the net result is an improvement requires a delicate definition of regions. We start by decomposing the plane into regions of three types. Then we construct a solution in which a single tour may visit regions of different types, see Figure 1. The mixed structure of the tours enables us to show that the constructed solution has significantly smaller cost. See Section 3 for more details.

Our proof of the improved upper bound on the approximation ratio of the ITP algorithm in the random setting (Theorem 2) relies on a new lower bound on the optimal cost (Theorem 11). To achieve the new lower bound, we consider the gap between the average distance to the depot and the maximum distance to the depot among all points in a single tour of an optimal solution. Intuitively, if this gap is large, then the gap itself contributes to the lower bound on the optimal cost; and if this gap is small, then there are many points whose distances to the depot is close to the maximum distance, and the total local cost of those points contributes to the lower bound. Our analysis for the lower bound is completely different from [10] and enables us to obtain a better approximation ratio of  $0.915 + \alpha$ .

Our new lower bound on the optimal cost also enables us to generalize our results to the setting of multiple depots. This lower bound holds in the metric CVRP in general, and may be of independent interest.

► **Remark.** The restriction to i.i.d. uniform random points in  $[0, 1]^2$  is made to simplify the presentation. With extra work, our analysis can be extended to higher dimensional Euclidean spaces, to general density functions, and to general bounded supports (though the approximation guarantees in those settings may differ from that in Theorem 2).

## 2 Notations and Preliminaries

Let  $\delta(\cdot, \cdot)$  denote the Euclidean distance between two points or between a point and a set of points. For any path  $P$  of points  $x_1, x_2, \dots, x_m$  in  $\mathbb{R}^2$  where  $m \in \mathbb{N}$ , define  $\text{cost}(P) = \sum_{i=1}^{m-1} \delta(x_i, x_{i+1})$ .

**Capacitated Vehicle Routing Problem (CVRP).** Given a set  $V$  of  $n$  points in  $\mathbb{R}^2$ , a depot  $O$  in  $\mathbb{R}^2$ , and an integer capacity  $k \in [1, n]$ , the goal is to find a collection of tours covering  $V$  of minimum total cost, such that each tour visits  $O$  and at most  $k$  points in  $V$ . Let  $\text{OPT}$  denote the value of an optimal solution to the CVRP.

For any point  $x \in V$ , let  $\ell(x) = \delta(O, x)$ . Let  $\text{rad}$  denote the *radial cost*, defined by  $\text{rad} = \frac{2}{k} \cdot \sum_{x \in V} \ell(x)$ .

► **Lemma 3** ([15]). *Let  $T^*$  be an optimal traveling salesman tour on  $V \cup \{O\}$ . Then  $\text{OPT} \geq \max(\text{rad}, \text{cost}(T^*))$ .*

**Iterated Tour Partitioning (ITP).** We review the *iterated tour partitioning (ITP)* algorithm defined by Altinkemer and Gavish [2]. The ITP algorithm consists of a preprocessing phase and a main phase. In the preprocessing phase, it runs an approximation algorithm for the traveling salesman problem on  $V \cup \{O\}$ . Let  $\alpha$  denote the approximation ratio of this algorithm. Let  $T = (O, x_1, x_2, \dots, x_n, O)$  denote the resulting traveling salesman tour. In the main phase, the ITP algorithm selects the best of the  $k$  solutions constructed as follows. For each  $i \in [1, k]$ , let  $n_i = \lceil (n - i)/k \rceil + 1$  and define a solution  $S_i$  to the CVRP to be the union of the  $n_i$  tours  $(O, x_1, \dots, x_i, O)$ ,  $(O, x_{i+1}, \dots, x_{i+k}, O)$ ,  $(O, x_{i+k+1}, \dots, x_{i+2k}, O)$ ,  $\dots$ ,  $(O, x_{i+(n_i-2)k+1}, \dots, x_n, O)$ . In other words, the solution  $S_i$  partitions the traveling salesman tour  $T$  into segments with  $k$  points each, except possibly the first and the last segments. The output of the ITP algorithm is a solution among  $S_1, \dots, S_k$  that achieves the minimum cost. It is easy to see that the main phase of the ITP algorithm can be carried out in  $O(nk)$  time.<sup>3</sup>

Let  $\text{ITP}(T)$  denote the cost of the output solution. The following classic bound on  $\text{ITP}(T)$  was due to Altinkemer and Gavish [2] and, together with Lemma 3, immediately implies that the ITP algorithm is a  $(1 + \alpha)$ -approximation, where  $\alpha$  is the approximation ratio of the traveling salesman tour  $T$ .

► **Lemma 4** ([2]). *Let  $T$  be any traveling salesman tour on  $V \cup \{O\}$ . Then*

$$\text{OPT} \leq \text{ITP}(T) \leq \text{rad} + \left(1 - \frac{1}{k}\right) \cdot \text{cost}(T).$$

**Probabilistic Analysis of the Traveling Salesman Problem.** Beardwood, Halton, and Hammersley [7] analyzed the value of an optimal solution to the traveling salesman problem in the random setting.

► **Lemma 5** ([7, 24]). *Let  $V$  be a set of  $n$  i.i.d. uniform random points with bounded support in  $\mathbb{R}^2$ . Let  $M$  denote the measure of the support. Let  $T^*$  denote an optimal traveling salesman tour on  $V$ . Then there exists a universal constant  $\beta$  such that, for any  $\epsilon > 0$ , we have*

$$\lim_{n \rightarrow \infty} \frac{\text{cost}(T^*)}{\sqrt{M \cdot n}} = \beta, \quad \text{with probability 1.}$$

*In addition,  $\beta_0 < \beta < \beta_1$ , where  $\beta_0 = 0.62866$  and  $\beta_1 = 0.92117$ .*

► **Remark.** Up to scaling, Lemma 5 holds for any support that is a rectangle with constant aspect ratio.

### 3 Lower Bound on the Approximation Ratio

In this section, we prove Theorem 1 by providing a lower bound on the approximation ratio  $\text{ITP}(T)/\text{OPT}$  of the ITP algorithm, where  $T$  is a traveling salesman tour. Let the depot  $O = (\frac{1}{2}, -1000)$ . Lemmas 6 and 7 are the key ingredients in the proof of Theorem 1.

► **Lemma 6.** *Let  $\beta$  be defined as in Lemma 5. Then there exists a constant  $c_1 \in (0, \beta)$  such that for any  $\epsilon_1 > 0$ ,  $\text{OPT} < (1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - c_1\sqrt{n}$ , a.a.s.*

► **Lemma 7.** *Let  $\beta$  be defined as in Lemma 5. Then for any  $\alpha > 1$ , there exists an  $\alpha$ -approximate traveling salesman tour  $T$  on  $V \cup \{O\}$ , such that for any  $\epsilon_1 > 0$ ,  $\text{ITP}(T) > (1 - \epsilon_1)(\text{rad} + \beta\sqrt{n})$ , a.a.s.*

<sup>3</sup> The running time of the main phase can even be improved to  $O(n)$ .

Lemma 6 contains main novelties in this section. The proof of Lemma 7 is in the full version of the paper. First, we show how Lemmas 6 and 7 imply Theorem 1.

**Proof of Theorem 1 using Lemmas 6 and 7.** Let  $\epsilon_1 > 0$  be a constant to be set later. From Lemma 6, there exists an absolute constant  $c_1 \in (0, \beta)$ , such that  $\text{OPT} < (1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - c_1\sqrt{n}$ , a.a.s. From Lemma 7, for any  $\alpha > 1$ , there exists an  $\alpha$ -approximate traveling salesman tour  $T$  on  $V \cup \{O\}$ , such that  $\text{ITP}(T) > (1 - \epsilon_1)(\text{rad} + \beta\sqrt{n})$ , a.a.s. Hence

$$\frac{\text{ITP}(T)}{\text{OPT}} > \frac{(1 - \epsilon_1)(\text{rad} + \beta\sqrt{n})}{(1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - c_1\sqrt{n}}, \quad \text{a.a.s.}$$

To analyze  $\text{rad}$ , let  $L$  be the expectation of  $\ell(x)$  for  $x \in [0, 1]^2$  with uniform distribution. Since the depot  $O$  is at a constant distance from  $[0, 1]^2$ ,  $L$  is a constant. By the law of large numbers,

$$\left| \frac{1}{n} \sum_{x \in V} \ell(x) - L \right| < \epsilon_1, \quad \text{a.a.s.}$$

Recall that  $\text{rad} = \frac{2}{\sqrt{n}} \sum_{x \in V} \ell(x)$ . Hence  $(L - \epsilon_1) \cdot 2\sqrt{n} < \text{rad} < (L + \epsilon_1) \cdot 2\sqrt{n}$ , a.a.s. Denoting the function  $f$  as

$$f(\epsilon_1) = \frac{(1 - \epsilon_1)(2L - 2\epsilon_1 + \beta)}{(1 + \epsilon_1)(2L + 2\epsilon_1 + \beta) - c_1},$$

we have

$$\frac{\text{ITP}(T)}{\text{OPT}} > f(\epsilon_1), \quad \text{a.a.s.}$$

Since  $L$ ,  $\beta$  and  $c_1$  are positive constants and  $c_1 < \beta$  (Lemma 6), we have

$$\lim_{\epsilon_1 \rightarrow 0} f(\epsilon_1) = 1 + \frac{c_1}{2L + \beta - c_1}.$$

Let  $c_0 = \frac{1}{2} \cdot \frac{c_1}{2L + \beta - c_1}$ , which is a positive constant. Choosing  $\epsilon_1$  small enough such that  $f(\epsilon_1) > 1 + c_0$ , we have

$$\frac{\text{ITP}(T)}{\text{OPT}} > f(\epsilon_1) > 1 + c_0, \quad \text{a.a.s.}$$

The claim follows. ◀

The rest of the section is dedicated to prove Lemma 6.

Without loss of generality, we assume that  $\epsilon_1 \leq 1$ , since otherwise it suffices to prove the claim for the case of  $\epsilon_1 = 1$ . We construct a solution to the CVRP whose cost is less than  $(1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - c_1\sqrt{n}$ , a.a.s., where the constant  $c_1 > 0$  will be chosen at the end of the proof.

### 3.1 Decomposition of the Plane

In order to construct a solution to the CVRP, we describe a decomposition of  $[0, 1]^2$  into rectangles of three types. Let  $\epsilon_2 = \frac{\epsilon_1}{10}$ . We partition<sup>4</sup>  $[0, 1]^2$  into a lower part  $[0, 1] \times [0, \frac{3+\epsilon_2}{4}]$  which is a rectangle of type III, and a collection of *boxes* of the form  $[(i-1)D, iD] \times [\frac{3+\epsilon_2}{4}, 1]$ , with  $D = n^{-1/4}$  and  $1 \leq i \leq 1/D$ . For simplicity, assume that  $1/D$  is an integer. See Figure 1a.

---

<sup>4</sup> The decomposition is a partition except for the boundaries, that have measure 0.

Next, we decompose each box, see Figure 1b. Let  $m = \frac{5}{40-\beta} \cdot n^{1/4}$ . For simplicity, assume that  $m$  is an integer. The upper half of a box is partitioned into  $m$  *type I rectangles* of the form  $[(i-1)D, iD] \times [1 - (j-1)H, 1 - jH]$ , where  $H = \frac{1-\epsilon_2}{8 \cdot m}$  and  $1 \leq j \leq m$ . The lower left part of a box is partitioned into  $2m$  slices such that each slice is a *type II rectangles* of the form  $[(i-1)D + (j-1)W, (i-1)D + jW] \times [\frac{3+\epsilon_2}{4}, \frac{7+\epsilon_2}{8}]$ , with  $W = \frac{\beta}{10} \cdot n^{-1/2}$  and  $1 \leq j \leq 2m$ . The rest of the box is a single *type III rectangle*.

For any rectangle  $R$  in the resulting decomposition, let  $n_R$  denote the number of points of  $V$  that are in the rectangle  $R$ , and let  $M_R$  denote the measure of the rectangle  $R$ . The following fact relates  $n_R$  with  $M_R$ .

► **Fact 8.** *A.a.s. the following event  $\mathcal{E}$  occurs:  $(1 - \epsilon_2) \cdot M_R \cdot n < n_R < (1 + \epsilon_2) \cdot M_R \cdot n$  for all rectangles  $R$  in the resulting decomposition.*

**Proof.** Let  $R$  be any rectangle in the resulting decomposition. Observe that  $M_R = \Omega(1/\sqrt{n})$ . The expectation of  $n_R$  is  $M_R \cdot n = \Omega(\sqrt{n})$ . By Chernoff bound,

$$\mathbb{P}[n_R \leq (1 - \epsilon_2)M_R \cdot n] \leq e^{-\Omega(\sqrt{n})} \quad \text{and} \quad \mathbb{P}[n_R \geq (1 + \epsilon_2)M_R \cdot n] \leq e^{-\Omega(\sqrt{n})}.$$

Since there are  $\Theta(\sqrt{n})$  rectangles in the decomposition, the event  $\mathcal{E}$  occurs with probability at least  $1 - \Theta(\sqrt{n}) \cdot e^{-\Omega(\sqrt{n})} = 1 - o(1)$ . ◀

From now on, we condition on the occurrence of  $\mathcal{E}$  in Fact 8.

### 3.2 Construction of a Solution

To construct a relative cheap solution, the main observation is that it is profitable for a tour to visit points in rectangles of both types I and II. In each box, there are  $m$  rectangles of type I and  $2m$  rectangles of type II. We form  $m$  groups with those, such that each group contains one rectangle of type I and two rectangles of type II. For each group, we cover the points in the group by a particular tour on these points in addition to the depot  $O$ , in a way to be described shortly. For all points in the rectangles of type III, we construct an optimal solution to the CVRP on those points with depot  $O$  and with capacity  $\sqrt{n}$ .

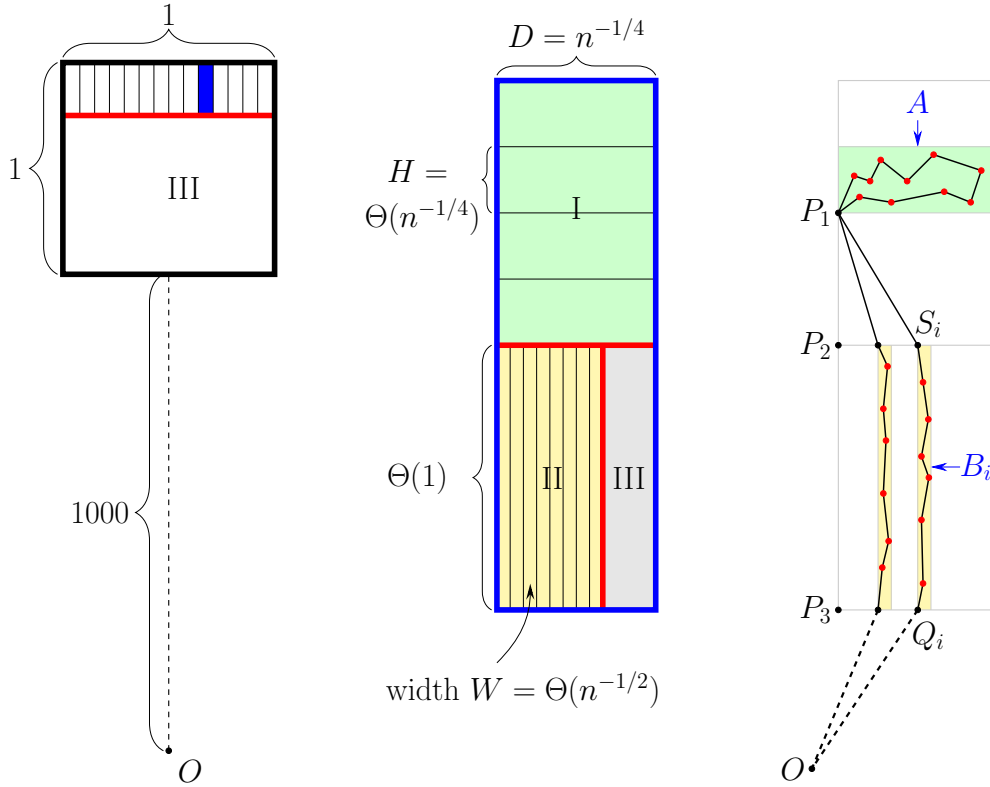

A *mixed tour* is a tour covering points in rectangles of types I and II. Consider a box  $\mathcal{B}$  and a group in  $\mathcal{B}$  consisting of a rectangle  $A$  of type I and two rectangles  $B_1$  and  $B_2$  of type II. We construct a specific mixed tour  $T_{\text{mix}}$  defined as follows.

Let  $P_1$  denote the bottom left corner of the rectangle  $A$ . Let  $T_0$  denote an optimal traveling salesman tour on the points in  $A \cup \{P_1\}$ . For each  $i \in \{1, 2\}$ , we define an  $O$ -to- $P_1$  path  $T_i$  visiting the points in  $B_i$  as follows. Let  $S_i$  and  $Q_i$  denote the top left and bottom left corners of the rectangle  $B_i$ . Let  $T_i$  denote the concatenation of the segment  $OQ_i$ , a  $Q_i$ -to- $S_i$  path visiting the points in  $B_i$  in non-decreasing order on the  $y$ -coordinate (breaking ties arbitrarily), and the segment  $S_iP_1$ . Finally, the tour  $T_{\text{mix}}$  is defined as the concatenation of  $T_0$ ,  $T_1$ , and  $T_2$ . See Figure 1c. This completes our construction.

Since the measure of  $A$  is  $D \cdot H$  and the measure of  $B_i$  (for each  $i \in \{1, 2\}$ ) is  $\frac{1-\epsilon_2}{8} \cdot W$ , Event  $\mathcal{E}$  implies that the total number of points in  $A \cup B_1 \cup B_2$  is at most

$$(1 + \epsilon_2) \left( D \cdot H + 2 \cdot \frac{1 - \epsilon_2}{8} \cdot W \right) \cdot n = (1 + \epsilon_2)(1 - \epsilon_2)n^{-1/2} \cdot n < \sqrt{n},$$

so the constructed solution is feasible.

(a)  $[0, 1]^2$  decomposition. (b) Box decomposition. (c) A mixed tour.

■ **Figure 1** Decomposition and tour construction. Figure 1a illustrates the decomposition of  $[0, 1]^2$ . The highlighted area in Figure 1a represents a box. Figure 1b illustrates the decomposition of a box into rectangles of types I, II, and III. Figure 1c describes a tour covering points in one rectangle  $A$  of type I and in two rectangles  $B_i$ , for  $i \in \{1, 2\}$ , of type II.

### 3.3 Cost of a Mixed Tour

Consider any mixed tour  $T_{\text{mix}}$ . We follow the same notations as in Section 3.2. From the construction,

$$\text{cost}(T_{\text{mix}}) = \text{cost}(T_0) + \text{cost}(T_1) + \text{cost}(T_2). \tag{1}$$

Let  $T_A^*$  denote an optimal traveling salesman tour on the points in  $A$ . The cost of  $T_0$  is at most  $\text{cost}(T_A^*)$  plus the cost of the detour to include the point  $P_1$ . The cost of the detour is less than  $2(D + H)$ , so

$$\text{cost}(T_0) < \text{cost}(T_A^*) + 2(D + H). \tag{2}$$

Let  $n_1$  and  $n_2$  denote the number of points of  $V$  that are in  $B_1$  and  $B_2$ , respectively. The costs of  $T_1$  and  $T_2$  are bounded by the following fact, whose proof is in the full version of the paper.

► **Fact 9.** For  $i \in \{1, 2\}$ , we have

$$\text{cost}(T_i) < \delta(O, P_1) + \frac{1}{4000} + n_i W + (W + 2D). \tag{3}$$

From Equations (1)–(3), and using the definition of  $W$ , we have

$$\text{cost}(T_{\text{mix}}) < \text{cost}(T_A^*) + 2\delta(O, P_1) + \frac{1}{2000} + \frac{\beta}{10} \cdot \frac{n_1 + n_2}{\sqrt{n}} + (2W + 6D + 2H). \quad (4)$$

It remains to bound  $\delta(O, P_1)$ . Observe that by the definition of  $\ell(\cdot)$  and the triangle inequality, and since the height of a box  $\mathcal{B}$  is less than  $\frac{1}{4}$ ,

$$\delta(O, P_1) < \begin{cases} \ell(x) + D + H & \text{for any } x \in A, \\ \ell(x) + \frac{1}{4} + D + H & \text{for any } x \in B_1 \cup B_2. \end{cases}$$

Let  $V_{\text{mix}}$  denote the set of the points of  $V$  in  $A \cup B_1 \cup B_2$ . By averaging we have

$$\delta(O, P_1) < \frac{1}{|V_{\text{mix}}|} \left( \sum_{x \in V_{\text{mix}}} \ell(x) \right) + \frac{1}{|V_{\text{mix}}|} \frac{n_1 + n_2}{4} + (D + H).$$

Since the measure of  $A \cup B_1 \cup B_2$  is  $(1 - \epsilon_2)n^{1/2}$ , Event  $\mathcal{E}$  implies that  $|V_{\text{mix}}| > (1 - \epsilon_2)^2 \cdot \sqrt{n}$ , which is at least  $\frac{\sqrt{n}}{1 + \epsilon_1}$  since  $\epsilon_2 = \frac{\epsilon_1}{10}$ . Hence

$$\delta(O, P_1) < \frac{1 + \epsilon_1}{\sqrt{n}} \left[ \left( \sum_{x \in V_{\text{mix}}} \ell(x) \right) + \frac{n_1 + n_2}{4} \right] + (D + H). \quad (5)$$

Since  $n_1 + n_2 = \Theta(\sqrt{n})$ , we have  $(2W + 6D + 2H) + 2(D + H) < \frac{\epsilon_1}{\sqrt{n}} \cdot \frac{\beta}{10} \cdot (n_1 + n_2)$  when  $n$  is large enough. From Equations (4) and (5), we conclude that

$$\text{cost}(T_{\text{mix}}) < \text{cost}(T_A^*) + \frac{1 + \epsilon_1}{\sqrt{n}} \left[ 2 \left( \sum_{x \in V_{\text{mix}}} \ell(x) \right) + \left( \frac{\beta}{10} + \frac{1}{2} \right) (n_1 + n_2) \right] + \frac{1}{2000}. \quad (6)$$

### 3.4 Cost of the Solution

#### 3.4.1 Solution in the Rectangles of Types I and II

Let  $V_I$  and  $V_{II}$  denote the subsets of the points of  $V$  that are in the rectangles of type I and type II, respectively. Let  $K$  denote the number of mixed tours. We have  $K = n^{1/4} \cdot m = \frac{5}{40 - \beta} \cdot \sqrt{n}$ . Applying Equation (6) on each mixed tour and summing, we have

$$\text{cost}(\mathcal{S}_{\text{mix}}) \leq Y + \frac{1 + \epsilon_1}{\sqrt{n}} \left[ 2 \left( \sum_{x \in V_I \cup V_{II}} \ell(x) \right) + \left( \frac{\beta}{10} + \frac{1}{2} \right) |V_{II}| \right] + \frac{\sqrt{n}}{400 \cdot (40 - \beta)}, \quad (7)$$

where  $Y$  denotes the overall cost of  $T_A^*$  over all rectangles  $A$  of type I.

To analyze  $Y$ , we consider any rectangle  $A$  of type I. The measure of  $A$  is  $M_A = D \cdot H = (1 - \epsilon_2) \left(1 - \frac{\beta}{40}\right) \frac{1}{\sqrt{n}}$ . The event  $\mathcal{E}$  implies that

$$(1 - \epsilon_2)^2 \cdot \left(1 - \frac{\beta}{40}\right) \cdot \sqrt{n} < n_A < \left(1 - \frac{\beta}{40}\right) \cdot \sqrt{n}. \quad (8)$$

We investigate the expectation of  $\text{cost}(T_A^*)$ . By a construction given in [7], there exists a constant  $C$  such that the cost of an optimal traveling salesman tour through any  $n_A$  points in  $A$  is at most  $C\sqrt{M_A \cdot n_A}$ . Together with Lemma 5, it follows that

$$\mathbb{E}[\text{cost}(T_A^*)] < (1 + \epsilon_2) \cdot \beta \sqrt{M_A \cdot n_A} < (1 + \epsilon_2) \cdot \beta \left(1 - \frac{\beta}{40}\right),$$

### 43:10 Probabilistic Analysis of Euclidean Capacitated Vehicle Routing

for  $n$  large enough (and thus  $n_A$  large enough). Since there are  $K = \Theta(\sqrt{n})$  rectangles  $A$  of type I, by the law of large numbers,

$$Y = \sum_A \text{cost}(T_A^*) < (1 + \epsilon_2) \cdot K \cdot (1 + \epsilon_2) \cdot \beta \left(1 - \frac{\beta}{40}\right), \quad \text{a.a.s.}$$

On the other hand, summing Equation (8) over all  $A$ , we have

$$|V_I| = \sum_A n_A > K \cdot (1 - \epsilon_2)^2 \cdot \left(1 - \frac{\beta}{40}\right) \cdot \sqrt{n}.$$

Therefore,

$$Y < (1 + \epsilon_2)^2 \cdot \frac{1}{(1 - \epsilon_2)^2} \cdot \frac{\beta \cdot |V_I|}{\sqrt{n}} < (1 + \epsilon_1) \cdot \frac{\beta \cdot |V_I|}{\sqrt{n}}, \quad \text{a.a.s.},$$

where the last inequality follows since  $\epsilon_2 = \frac{\epsilon_1}{10}$ . From Equation (7), we conclude that, a.a.s.,

$$\text{cost}(\mathcal{S}_{\text{mix}}) \leq \frac{1 + \epsilon_1}{\sqrt{n}} \left[ 2 \left( \sum_{x \in V_I \cup V_{II}} \ell(x) \right) + \beta \cdot |V_I| + \left( \frac{\beta}{10} + \frac{1}{2} \right) |V_{II}| \right] + \frac{\sqrt{n}}{400 \cdot (40 - \beta)}. \quad (9)$$

#### 3.4.2 Solution in the Rectangles of Type III

Let  $\hat{V}$  denote the subset of the points of  $V$  that are in the rectangles of types III. Let  $\hat{T}$  denote an optimal traveling salesman tour on  $\hat{V} \cup \{O\}$ . Let  $\hat{\mathcal{S}}$  denote an optimal solution to the CVRP on  $\hat{V}$  with depot  $O$  and with capacity  $k = \sqrt{n}$ . By Lemma 4,

$$\text{cost}(\hat{\mathcal{S}}) \leq \frac{2}{\sqrt{n}} \left( \sum_{x \in \hat{V}} \ell(x) \right) + \text{cost}(\hat{T}).$$

The cost of  $\hat{T}$  is at most the cost  $C_{\text{TSP}}$  of an optimal traveling salesman tour on  $\hat{V}$  plus the detour to visit  $O$ . Since the distance between the depot and any point in  $[0, 1]^2$  is  $O(1)$ , the cost of the detour is  $O(1)$ , so  $\text{cost}(\hat{T}) \leq C_{\text{TSP}} + O(1)$ .

Next, we analyze  $C_{\text{TSP}}$ . Let  $L$  denote the width of a type III rectangle inside a box. Then  $L = D - W \cdot m = \Theta(n^{-1/4})$ . We observe that the length of a side of any type III rectangle is either  $L$  or  $\omega(L)$ . So we partition every type III rectangle into squares of side length  $L$ . For each square, consider an optimal traveling salesman tour on the points inside that square. Let  $Z$  denote the overall cost of the optimal traveling salesman tours inside all squares from all rectangles of type III. Then  $C_{\text{TSP}}$  is at most  $Z$  plus the total lengths of the boundaries of all squares. Using the same argument from Section 3.4.1, we have

$$Z < \left(1 + \frac{\epsilon_1}{3}\right) \cdot \frac{\beta \cdot |\hat{V}|}{\sqrt{n}}, \quad \text{a.a.s.}$$

Since the boundary length of each square is negligible compared with the TSP cost inside that square, we have

$$C_{\text{TSP}} = (1 + o(1)) \cdot Z < \left(1 + \frac{\epsilon_1}{2}\right) \cdot \frac{\beta \cdot |\hat{V}|}{\sqrt{n}}, \quad \text{a.a.s.}$$

Noting that  $|\hat{V}| = \Theta(n)$ , we have

$$\text{cost}(\hat{T}) \leq C_{\text{TSP}} + O(1) < (1 + \epsilon_1) \cdot \frac{\beta \cdot |\hat{V}|}{\sqrt{n}}, \quad \text{a.a.s.}$$

Therefore,

$$\text{cost}(\hat{\mathcal{S}}) \leq \frac{2}{\sqrt{n}} \left( \sum_{x \in \hat{V}} \ell(x) \right) + \frac{1 + \epsilon_1}{\sqrt{n}} \cdot \beta \cdot |\hat{V}|, \quad \text{a.a.s.} \quad (10)$$

### 3.4.3 The Global Solution

Let  $\mathcal{S} = \mathcal{S}_{\text{mix}} \cup \hat{\mathcal{S}}$  denote the global solution. From Equations (9) and (10), and using  $\frac{2}{\sqrt{n}} \cdot \sum_{x \in V} \ell(x) = \text{rad}$  and  $V_I \cup V_{II} \cup \hat{V} = V$ , we have

$$\text{cost}(\mathcal{S}) \leq (1 + \epsilon_1) \left[ \text{rad} + \beta \cdot \frac{|V|}{\sqrt{n}} - \left( \beta - \frac{\beta}{10} - \frac{1}{2} \right) \frac{|V_{II}|}{\sqrt{n}} \right] + \frac{\sqrt{n}}{400 \cdot (40 - \beta)}, \quad \text{a.a.s.} \quad (11)$$

Observe that the rectangles of type II have an overall measure of  $(1 - \epsilon_2) \cdot \frac{\beta}{8 \cdot (40 - \beta)}$ . Event  $\mathcal{E}$  implies that  $|V_{II}| > (1 - \epsilon_2)^2 \cdot \frac{\beta \cdot n}{8 \cdot (40 - \beta)} > \frac{1}{1 + \epsilon_1} \cdot \frac{\beta \cdot n}{8 \cdot (40 - \beta)}$  since  $\epsilon_2 = \frac{\epsilon_1}{10}$ . By Lemma 5,  $\beta > \beta_0 = 0.62866$ . Thus  $\frac{9\beta}{10} - \frac{1}{2} > 0$ . From Equation (11), we have, a.a.s.,

$$\begin{aligned} (1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - \text{cost}(\mathcal{S}) &\geq (1 + \epsilon_1) \cdot \left( \frac{9\beta}{10} - \frac{1}{2} \right) \cdot \frac{|V_{II}|}{\sqrt{n}} - \frac{\sqrt{n}}{400 \cdot (40 - \beta)} \\ &> \left( \frac{9\beta}{10} - \frac{1}{2} \right) \cdot \frac{\beta\sqrt{n}}{8 \cdot (40 - \beta)} - \frac{\sqrt{n}}{400 \cdot (40 - \beta)} \\ &= \frac{\sqrt{n}}{8 \cdot (40 - \beta)} \cdot \left( \left( \frac{9\beta}{10} - \frac{1}{2} \right) \cdot \beta - \frac{1}{50} \right) \\ &> \frac{\sqrt{n}}{8 \cdot (40 - \beta_0)} \cdot \left( \left( \frac{9\beta_0}{10} - \frac{1}{2} \right) \cdot \beta_0 - \frac{1}{50} \right). \end{aligned}$$

Let  $c_1$  denote the leading constant in the above bound, i.e.,

$$c_1 = \frac{1}{8 \cdot (40 - \beta_0)} \cdot \left( \left( \frac{9\beta_0}{10} - \frac{1}{2} \right) \cdot \beta_0 - \frac{1}{50} \right).$$

The value of  $c_1$  is roughly 0.000068. We conclude that

$$\text{cost}(\mathcal{S}) < (1 + \epsilon_1)(\text{rad} + \beta\sqrt{n}) - c_1\sqrt{n}, \quad \text{a.a.s.}$$

We complete the proof of Lemma 6.

## 4 Upper Bound on the Approximation Ratio

In this section, we prove Theorem 2 by providing an upper bound on the approximation ratio  $\text{ITP}(T)/\text{OPT}$  of the ITP algorithm, where  $T$  is a traveling salesman tour.

Let  $\lambda$  and  $\epsilon$  be positive constants such that  $\lambda + \epsilon < 1$ . We analyze the performance of the ITP algorithm with respect to  $\lambda$  and  $\epsilon$ . The values of  $\lambda$  and  $\epsilon$  will be set in the end of the proof.

### 4.1 Structural analysis

► **Lemma 10.** *Let  $T = (O, y_1, y_2, \dots, y_m, O)$  be any tour starting and ending at  $O$ . Let  $L = \frac{1}{m} \left( \sum_{j=1}^m \ell(y_j) \right)$ . Let  $\Delta = \max_{1 \leq j \leq m} \{\ell(y_j)\} - L$ . Then there exists a set  $W \subseteq \{y_1, \dots, y_m\}$  which is of cardinality greater than  $(\lambda + \epsilon) \cdot m - 1$  such that*

$$\text{cost}(T) \geq 2 \left( L - \frac{\lambda + \epsilon}{1 - \lambda - \epsilon} \cdot \Delta \right) + \sum_{x \in W} \delta(x, W \setminus \{x\}).$$

## 43:12 Probabilistic Analysis of Euclidean Capacitated Vehicle Routing

**Proof.** Let  $W$  denote the set of points  $x$  such that  $\ell(x) \geq L - \frac{\lambda+\epsilon}{1-\lambda-\epsilon} \cdot \Delta$ , other than the last one in the order of traversal by  $T$  starting from  $O$ . Tour  $T$  must first travel through a path to a first point of  $W$ , paying at least  $L - \frac{\lambda+\epsilon}{1-\lambda-\epsilon} \cdot \Delta$ , then proceed from each point  $x$  of  $W$  through a path to another point of  $W$ , paying at least  $\delta(x, W \setminus \{x\})$ , and finally, go to one more point such that  $\ell(x) \geq L - \frac{\lambda+\epsilon}{1-\lambda-\epsilon} \cdot \Delta$ , and travel from there through a path back to the depot, paying at least  $L - \frac{\lambda+\epsilon}{1-\lambda-\epsilon} \cdot \Delta$ . Hence the cost of  $T$  is at least as stated in Lemma 10.

Next, we bound the size of  $W$ . When  $\Delta = 0$ , we have  $\ell(y_j) = L$  for all  $j \in [1, m]$ . Hence  $|W| = m - 1$ , which is greater than  $(\lambda + \epsilon) \cdot m - 1$ , since  $\lambda + \epsilon < 1$ . The claim follows.

It remains to analyze the case when  $\Delta > 0$ . Every point of  $T$  is at distance at most  $L + \Delta$  from the depot. Letting  $m'$  denote the number of points whose distance from the depot is at least  $L - \frac{\lambda+\epsilon}{1-\lambda-\epsilon} \cdot \Delta$ , we have

$$mL = \sum_{j=1}^m \ell(y_j) < m'(L + \Delta) + (m - m') \left( L - \frac{\lambda + \epsilon}{1 - \lambda - \epsilon} \cdot \Delta \right).$$

Since  $1 - \lambda - \epsilon > 0$ , this implies  $m' - (\lambda + \epsilon) \cdot m > 0$ , hence  $|W| = m' - 1 > (\lambda + \epsilon) \cdot m - 1$ . ◀

The following result is a strengthening of the lower bound  $\text{OPT} \geq \text{rad}$  from Lemma 3, and will lead to our improved analysis of the ITP algorithm.

► **Theorem 11.** *Let  $\lambda$  and  $\epsilon$  be positive constants such that  $\lambda + \epsilon < 1$ . Let  $V$  be a set of  $n$  points in any distance metric. Let  $k = \omega(1)$ . There exists a set  $U \subseteq V$  which is of cardinality greater than  $(\lambda + \frac{\epsilon}{2}) \cdot n$  for  $n$  large enough, and such that*

$$\text{OPT} \geq \text{rad} + (1 - \lambda - \epsilon) \left( \sum_{x \in U} \delta(x, U \setminus \{x\}) \right).$$

**Proof.** Let  $T_1, \dots, T_q$  be the tours in an optimal solution to the CVRP. Let  $m_i$  be the number of points in  $V$  that are visited by the tour  $T_i$ . Up to combining tours that visit few points, we may assume that  $m_i > \frac{k}{2}$  for all but at most one tour, so  $q \leq \frac{2n}{k} + 1 = o(n)$ .

For each tour  $T_i$ , define the corresponding  $L_i$ ,  $\Delta_i$ , and  $W_i$  with respect to the tour  $T_i$  using the notations of Lemma 10. By summation, letting  $U = \bigcup_i W_i$ , Lemma 10 then implies (using  $q = o(n)$ ,  $n$  large enough, and  $\delta(x, W_i \setminus \{x\}) \geq \delta(x, U \setminus \{x\})$ )

$$|U| = \sum_{i \leq q} |W_i| > \left( (\lambda + \epsilon) \sum_i m_i \right) - q = (\lambda + \epsilon) \cdot n - q > \left( \lambda + \frac{\epsilon}{2} \right) \cdot n$$

and

$$\sum_i \text{cost}(T_i) \geq \left( \sum_i 2 \left( L_i - \frac{\lambda + \epsilon}{1 - \lambda - \epsilon} \cdot \Delta_i \right) \right) + \left( \sum_{x \in U} \delta(x, U \setminus \{x\}) \right). \quad (12)$$

On the other hand, we trivially have

$$\sum_i \text{cost}(T_i) \geq \sum_i 2(L_i + \Delta_i). \quad (13)$$

A linear combination of Equation (12) with coefficient  $(1 - \lambda - \epsilon)$  and of Equation (13) with coefficient  $(\lambda + \epsilon)$  leads to:

$$\text{OPT} = \sum_i \text{cost}(T_i) \geq \left( \sum_i 2L_i \right) + (1 - \lambda - \epsilon) \left( \sum_{x \in U} \delta(x, U \setminus \{x\}) \right).$$

Observe that

$$\sum_i 2L_i = \sum_i \sum_{x \in T_i} \frac{2\ell(x)}{m_i} \geq \sum_i \sum_{x \in T_i} \frac{2\ell(x)}{k} = \sum_{x \in V} \frac{2\ell(x)}{k} = \text{rad.}$$

The Lemma follows. ◀

## 4.2 Probabilistic Analysis

The following result suggests that the closest point distance follows the law of large numbers. It is a corollary of Theorem 2.4 in [22].<sup>5</sup>

► **Lemma 12** ([22]). *Let  $\mathcal{P}$  be a homogeneous Poisson point process of intensity 1 on  $\mathbb{R}^2$  and  $\delta_{\mathcal{P}}$  denote the distance from the origin of  $\mathbb{R}^2$  to a closest point in  $\mathcal{P}$  by the Euclidean norm. Let  $V$  be a set of  $n$  i.i.d. uniform random points. Then, given any bounded function  $\phi : [0, \infty) \rightarrow [0, \infty)$ , as  $n \rightarrow \infty$  we have:*

$$\frac{1}{n} \sum_{x \in V} \phi(\sqrt{n} \cdot \delta(x, V \setminus \{x\})) \rightarrow \mathbb{E}[\phi(\delta_{\mathcal{P}})].$$

Lemma 12 provides the rigorous setting enabling us to derive a new lower bound on the sum of the closest point distances over a subset of a set of i.i.d. uniform random points, which we now state.

► **Lemma 13.** *Let  $V$  be a set of  $n$  i.i.d. uniform random points. Let  $U$  be any subset of  $V$  such that  $|U| > (\lambda + \frac{\epsilon}{2}) \cdot n$ . Then, asymptotically almost surely,*

$$\sum_{x \in U} \delta(x, V \setminus \{x\}) > (\xi_{\lambda} - \epsilon) \cdot \sqrt{n},$$

where  $\xi_{\lambda}$  is a constant defined by

$$\xi_{\lambda} := \frac{1}{2} \operatorname{erf} \left( \sqrt{\ln \frac{1}{1-\lambda}} \right) - (1-\lambda) \cdot \sqrt{\frac{1}{\pi} \cdot \ln \frac{1}{1-\lambda}}$$

in which  $\operatorname{erf}(\cdot)$  is the Gauss error function  $\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-t^2} dt$ .

**Proof.** Recall the definition of  $\delta_{\mathcal{P}}$  from Lemma 12. By definition of the Poisson point process, the probability  $g(r)$  of the event  $\delta_{\mathcal{P}} \leq r$  equals  $1 - e^{-\pi r^2}$ .

Let  $Z \subseteq V$  be the set of points  $x \in V$  such that  $\delta(x, V \setminus \{x\}) \leq \frac{r_0}{\sqrt{n}}$ , with  $r_0 = \sqrt{\frac{1}{\pi} \cdot \ln \frac{1}{1-\lambda}}$ . We apply Lemma 12 with  $\phi$  equals  $\phi_1$ , the indicator function of whether  $r \leq r_0$ , to obtain that, as  $n \rightarrow \infty$ ,

$$\frac{|Z|}{n} \rightarrow \mathbb{E}[\phi_1(\delta_{\mathcal{P}})] = g(r_0) = \lambda.$$

Thus  $|Z| \leq (\lambda + \frac{\epsilon}{2}) \cdot n < |U|$ , a.a.s. Since  $Z$  consists of the points  $x \in V$  with the smallest values of  $\delta(x, V \setminus \{x\})$ , we have

$$\sum_{x \in U} \delta(x, V \setminus \{x\}) \geq \sum_{x \in Z} \delta(x, V \setminus \{x\}), \quad \text{a.a.s.} \tag{14}$$

<sup>5</sup> To apply Theorem 2.4 in [22], we consider a *directed* graph  $G$  with vertex set  $V$ , such that from every vertex  $x \in V$ , there is a unique outgoing edge, let it be  $(x, y)$ , where  $y$  is the closest point to  $x$  among the points in  $V \setminus \{x\}$ , breaking ties arbitrarily. Theorem 2.4 in [22] is interpreted with reference to Remark (h) in [22].

### 43:14 Probabilistic Analysis of Euclidean Capacitated Vehicle Routing

To analyze  $\sum_{x \in Z} \delta(x, V \setminus \{x\})$ , we define a bounded function  $\phi_2$  as follows.

$$\phi_2(r) = \begin{cases} r, & r \leq r_0 \\ 0, & \text{otherwise.} \end{cases}$$

Applying Lemma 12 with  $\phi = \phi_2$ , we have, as  $n \rightarrow \infty$ ,

$$\frac{1}{n} \sum_{x \in Z} \sqrt{n} \cdot \delta(x, V \setminus \{x\}) \rightarrow \mathbb{E}[\phi_2(\delta_{\mathcal{P}})],$$

thus

$$\sum_{x \in Z} \delta(x, V \setminus \{x\}) > (\mathbb{E}[\phi_2(\delta_{\mathcal{P}})] - \epsilon) \cdot \sqrt{n}, \quad \text{a.a.s.} \quad (15)$$

Observe that  $\mathbb{E}[\phi_2(\delta_{\mathcal{P}})] = \int_0^\infty \phi_2(r) \cdot g'(r) dr = \int_0^{r_0} r \cdot g'(r) dr$ , where  $g'(r) = 2\pi r \cdot e^{-\pi r^2}$ . Integrating by parts, recalling the definition of the Gauss error function, and plugging in the value of  $r_0$ , we have

$$\mathbb{E}[\phi_2(\delta_{\mathcal{P}})] = \left( \int_0^{r_0} e^{-\pi r^2} dr \right) - \left[ r \cdot e^{-\pi r^2} \right]_0^{r_0} = \left[ \frac{\text{erf}(\sqrt{\pi} \cdot r)}{2} - r \cdot e^{-\pi r^2} \right]_0^{r_0} = \xi_\lambda.$$

The claim follows. ◀

### 4.3 Proof of Theorem 2

Let  $T$  denote an  $\alpha$ -approximate traveling salesman tour on  $V \cup \{O\}$ , where  $\alpha \geq 1$  is a constant. When  $k = O(1)$ , for any  $\epsilon > 0$ ,  $\text{ITP}(T) < (1 + \epsilon)\text{OPT}$  a.a.s. according to [15], which implies the claim. In the following, we assume that  $k = \omega(1)$ .

According to Lemma 4, we have

$$\text{ITP}(T) < \text{cost}(T) + \text{rad.}$$

First, we bound  $\text{cost}(T)$ . Letting  $T^*$  denote an optimal traveling salesman tour on  $V \cup \{O\}$ , we have  $\text{cost}(T) \leq \alpha \cdot \text{cost}(T^*)$ . By Lemma 5, the value of an optimal traveling salesman tour on  $V$  is less than  $(\beta + \frac{\epsilon}{2}) \cdot \sqrt{n}$ , a.a.s. Since the distance between the depot and any point in  $[0, 1]^2$  is  $O(1)$ , we have  $\text{cost}(T^*) < (\beta + \frac{\epsilon}{2}) \cdot \sqrt{n} + O(1)$ , which is less than  $(\beta + \epsilon) \cdot \sqrt{n}$  when  $n$  is large enough. Thus  $\text{cost}(T) < \alpha(\beta + \epsilon) \cdot \sqrt{n}$ , a.a.s.

Next, we analyze  $\text{rad}$ . By Theorem 11, for some  $U \subseteq V$  of size greater than  $(\lambda + \frac{\epsilon}{2})n$  we have

$$\text{rad} \leq \text{OPT} - (1 - \lambda - \epsilon) \left( \sum_{x \in U} \delta(x, U \setminus \{x\}) \right).$$

By Lemma 13 and the fact that  $\delta(x, U \setminus \{x\}) \geq \delta(x, V \setminus \{x\})$ , we have a.a.s.

$$\sum_{x \in U} \delta(x, U \setminus \{x\}) > (\xi_\lambda - \epsilon) \cdot \sqrt{n}.$$

Noting that  $1 - \lambda - \epsilon > 0$ , we have

$$\text{rad} \leq \text{OPT} - (1 - \lambda - \epsilon) \cdot (\xi_\lambda - \epsilon) \cdot \sqrt{n}.$$

■ **Figure 2** Plot of the function  $h(\lambda) = (1 - \lambda) \cdot \xi_\lambda$  for  $\lambda \in [0, 1)$ . The maximum value of  $h(\lambda)$  is greater than 0.078674, which is achieved when  $\lambda$  is roughly 0.62468.

Combining the above bounds gives a.a.s.

$$\text{ITP}(T) < \text{OPT} + (\alpha(\beta + \epsilon) - (1 - \lambda - \epsilon) \cdot (\xi_\lambda - \epsilon)) \cdot \sqrt{n}. \quad (16)$$

Note that the coefficient of  $\sqrt{n}$  in Equation (16) must be positive, because  $\text{ITP}(T) \geq \text{OPT}$  (Lemma 4). Using Lemmas 3 and 5, and assuming  $\epsilon < \beta$ , we have a.a.s.  $\sqrt{n} < \frac{\text{cost}(T^*)}{\beta - \epsilon} \leq \frac{\text{OPT}}{\beta - \epsilon}$ , and substituting into Equation (16) gives a.a.s.

$$\text{ITP}(T) < \left( 1 + \frac{\alpha(\beta + \epsilon) - (1 - \lambda - \epsilon) \cdot (\xi_\lambda - \epsilon)}{\beta - \epsilon} \right) \cdot \text{OPT}.$$

Since  $\beta$  is a positive constant (Lemma 5), choosing  $\lambda$  to maximize  $(1 - \lambda) \cdot \xi_\lambda$  and  $\epsilon$  small enough yields

$$\frac{\text{ITP}(T)}{\text{OPT}} < 1 + \alpha - \frac{\max_\lambda \{(1 - \lambda) \cdot \xi_\lambda\}}{\beta} + 0.00001.$$

A numerical calculation (Figure 2) gives  $\max_\lambda \{(1 - \lambda) \cdot \xi_\lambda\} > 0.078674$ , and Lemma 5 tells us that  $\beta < \beta_1 = 0.92117$ . Substituting those values concludes the proof.

## Abstract

Given two sets  $S$  and  $T$  of points in the plane, of total size  $n$ , a many-to-many matching between  $S$  and  $T$  is a set of pairs  $(p, q)$  such that  $p \in S$ ,  $q \in T$  and for each  $r \in S \cup T$ ,  $r$  appears in at least one such pair. The cost of a pair  $(p, q)$  is the (Euclidean) distance between  $p$  and  $q$ . In the minimum-cost many-to-many matching problem, the goal is to compute a many-to-many matching such that the sum of the costs of the pairs is minimized. This problem is a restricted version of minimum-weight edge cover in a bipartite graph, and hence can be solved in  $O(n^3)$  time. In a more restricted setting where all the points are on a line, the problem can be solved in  $O(n \log n)$  time [3]. However, no progress has been made in the general planar case in improving the cubic time bound. In this paper, we obtain an  $O(n^2 \cdot \text{poly}(\log n))$  time exact algorithm and an  $O(n^{3/2} \cdot \text{poly}(\log n))$  time  $(1 + \epsilon)$ -approximation in the planar case.

## 1 Introduction

Let  $G = (V = S \cup T, E)$  be a simple bipartite graph where each edge has a non-negative real weight, and no vertex is isolated. The *many-to-many* matching problem on  $G$  is to find a subset of edges  $E' \subseteq E$  of minimum total weight such that for each vertex  $v \in V$  there is an edge in  $E'$  incident on  $v$ . This is often referred to as the *minimum-weight edge cover* problem. A standard method to compute a minimum-weight edge cover of  $G$  in polynomial-time is to reduce the problem to the minimum-weight perfect matching problem on an equivalent graph, see [15, 3, 4, 5]. Since the reduction takes  $O(|V| + |E|)$  time, the running time is the same as the fastest known algorithm for computing a minimum-weight perfect matching. A faster  $\frac{3}{2}$ -approximation algorithm is proposed in [5].

Motivated by the computational problems in musical rhythm theory, Colannino et al. [3] studied the many-to-many matching problem in a geometric setting. Suppose we are given two sets  $S$  and  $T$  of points in the plane, of total size  $n$ . A *many-to-many* matching between  $S$  and  $T$  is a set of pairs  $(p, q)$  such that  $p \in S$ ,  $q \in T$  and for each  $r \in S \cup T$ ,  $r$  appears in at least one such pair. The *cost of a pair*  $(p, q)$  is the (Euclidean) distance  $d(p, q)$  between  $p$

and  $q$ . The *cost of a set of pairs* is the sum of the costs of the pairs in the set. In the geometric *minimum-cost many-to-many matching* problem, the goal is to compute a many-to-many matching such that the cost of the corresponding set of pairs is minimized. For points on a line, an  $O(n \log n)$  time dynamic-programming algorithm is proposed in [3]. In the same paper, the importance of the many-to-many matching problem for points in the plane is stated in the context of melody matching. Furthermore, the authors state that this version in the plane is an important open problem, especially since geometry has helped in designing efficient algorithms for the computation of the minimum-weight perfect matching for points in the plane (see, e.g., [16, 17]). Several variants of the 1-dimensional many-to-many matching problem are considered in [12, 13, 14].

## 1.1 Our Results and Techniques

In this work, we design several exact and approximation algorithms for minimum-cost many-to-many matching in the plane, thus affirmatively addressing the open problem posed by [3]. First, we obtain an  $O(n^2 \cdot \text{poly}(\log n))$  time<sup>1</sup> exact algorithm for this problem using a connection to minimum-weight perfect matching. We note that our time-bound matches the time bound for solving minimum-weight bipartite matching for points in the plane. Next, for any  $\epsilon > 0$ , we obtain a  $(1 + \epsilon)$ -approximation algorithm for this problem with improved  $O((1/\epsilon^c) \cdot n^{3/2} \cdot \text{poly}(\log n))$  running time for some small constant  $c$ . We also obtain a simple 2-approximation in  $O(n \log n)$  time.

Next, we give an overview of our techniques. A major reason behind the scarcity of results for geometric many-to-many-matching is the lack of techniques to directly approach this problem. The  $O(n^3)$  algorithm known for general graphs reduces the problem to (minimum-weight) bipartite perfect matching and uses a graph matching algorithm to solve the problem on the new instance. However, this standard reduction [9] from many-to-many matching to regular matching changes the weights of the edges in a convoluted manner. Hence, even if one starts with the planar Euclidean distances, the new interpoint distances in the constructed instance cannot be embedded in the plane or even in any metric space. As the algorithms for planar bipartite (perfect) matching heavily exploit the properties of the plane, they cannot be employed for solving the new instance of bipartite perfect matching. Thus, even though there is a wealth of literature for planar bipartite matching, no progress has been made in understanding the structure of many-to-many matching in the plane.

In our approach, we use a rather unconventional connection to bipartite perfect matching. First, we use a different reduction to convert our instance of many-to-many matching in the plane to an equivalent instance of bipartite perfect matching. The new instance cannot be embedded in the plane, however it does not modify the original distances between the points. Rather the new bipartite graph constructed is the union of (i) the original geometric bipartite graph, (ii) a new bipartite clique all of whose edges have the same weight and (iii) a linear number of additional edges. Thus, even though we could not use a planar matching algorithm directly, we could successfully use ideas from the literature of planar matching exploiting the structure of the constructed graph. A similar reduction was used in [4] in the context of computation of link distance of graphs. However, we cannot use this reduction directly, as we cannot afford to explicitly store the constructed graph which contains  $\Omega(n^2)$  edges. Recall that we are aiming for an  $O((1/\epsilon^c) \cdot n^{3/2} \cdot \text{poly}(\log n))$  time bound. Nevertheless, we exploit the structure of this graph to implicitly store it in  $O(n)$  space.

---

<sup>1</sup> We use the notation  $\text{poly}()$  to denote a polynomial function.

In Section 3, we show that the Hungarian algorithm can be implemented on our constructed graph in  $O(n^2 \cdot \text{poly}(\log n))$  time using ideas from planar matching. To obtain a subquadratic time bound, we implement the algorithm due to Gabow and Tarjan [6]. A straightforward implementation of this algorithm might need  $\Omega(n^2)$  time. We note that this algorithm has been used in several works on planar matching for obtaining efficient algorithms [11, 17, 2]. Our algorithm is closest to the one in [17] among these algorithms from a moral point of view. The difference is that their algorithm is for planar points. However, we deal with a graph which is partly embeddable. Nevertheless, in Section 4, we show that using additional ideas and data structures, the Gabow-Tarjan algorithm can be implemented in  $O(n^{3/2} \cdot \text{poly}(\log n))$  time, albeit with a  $(1 + \epsilon)$ -factor loss on the quality of the solution.

## 2 Preliminaries

In the *bipartite perfect matching* problem, we are given an edge-weighted bipartite graph  $G = (R, B, E)$  containing a perfect matching, and the goal is to find a perfect matching having the minimum cost or sum of the edge-weights. For our convenience, sometimes we would assume that the edges of  $G$  are not given explicitly. For example,  $R$  and  $B$  might be two sets of points in the plane, and  $G$  is the complete bipartite graph induced by the bipartition  $(R, B)$ . In this case, the points in  $R \cup B$  can be used to implicitly represent the graph  $G$ . In our case, we will use similar implicit representation of input graphs for designing subquadratic algorithm. Now, we have the following lemma, which reduces our problem to an equivalent instance of bipartite perfect matching.

► **Lemma 1.** *Given an instance  $I'$  of minimum-cost many-to-many matching, one can compute in  $O(n \log n)$  time an instance of bipartite perfect matching  $I$  such that (i) if there is a many-to-many matching for  $I'$  of cost  $C$ , there is a perfect matching for  $I$  of cost at most  $C$ , and (ii) if there is a perfect matching for  $I$  of cost  $C$ , there is a many-to-many matching for  $I'$  of cost  $C$ .*

■ **Figure 1** The figure on the left shows an instance  $I'$  of minimum-cost many-to-many matching along with the interpoint distances, where  $S = \{u_1, u_2\}$  and  $T = \{v_1, v_2, v_3\}$ . The right figure depicts the graph constructed from  $I'$  along with the edge weights, where  $R_0 = \{u_1, u_2\}$ ,  $R_1 = \{\hat{v}_1, \hat{v}_2, \hat{v}_3\}$ ,  $B_0 = \{v_1, v_2, v_3\}$  and  $B_1 = \{\hat{u}_1, \hat{u}_2\}$ . Solution pairs (or edges) are shown in bold.

**Proof.** Given the instance  $I'$  consisting of the two sets of points  $S$  and  $T$ , we construct a bipartite graph  $G = (R = R_0 \cup R_1, B = B_0 \cup B_1, E)$ , where  $R_0 = S$ ,  $B_0 = T$ ,  $R_1$  contains copies of the points in  $T$ ,  $B_1$  contains copies of the points in  $S$ .  $E$  contains

all the edges of  $E_0 = R_0 \times B_0$  and  $E_1 = R_1 \times B_1$ , and also the ones in  $E_2 = \{(u, \hat{u}) \mid u \in R_0, \hat{u} \text{ is the copy of } u \text{ in } B_1\}$  and  $E_3 = \{(\hat{v}, v) \mid v \in B_0, \hat{v} \text{ is the copy of } v \text{ in } R_1\}$ . The weight of each edge  $(u, v) \in E_0$  is the distance between the points  $u$  and  $v$ . The weight of each edge in  $E_1$  is 0. The weight of any edge  $(u, \hat{u}) \in E_2$  is the distance between  $u \in S$  and its closest neighbor in  $T$ . The weight of any edge  $(\hat{v}, v) \in E_3$  is the distance between  $v \in T$  and its closest neighbor in  $S$ . See Figure 1 for an example. Note that  $G$  can be represented implicitly in  $O(n)$  space, where  $|S \cup T| = n$ . Let  $I$  be the constructed instance of bipartite perfect matching that consists of  $G$ . As the closest neighbors of  $n$  points in the plane can be found in total  $O(n \log n)$  time using Voronoi diagram, construction of  $G$  takes  $O(n \log n)$  time.

Now, suppose  $I'$  has a many-to-many matching  $M'$ . Consider the pairs in  $M'$  as the edges of a graph  $G'$  with vertices being the points in  $S \cup T$ . We will use the term pairs and edges in  $G'$  interchangeably. First, note that wlog we can assume that  $G'$  does not contain any path of length 3. Otherwise, we can remove the middle edge of such a path from  $M'$ , and  $M'$  still remains a many-to-many matching. Thus, each component in  $G'$  is a star. We compute a perfect matching in  $G$  from  $M'$  as follows. For each star in  $G'$  having only one edge  $(u, v)$  with  $u \in S, v \in T$ , add  $(u, v) \in E_0$  to  $M$ . Also, add the edge  $(\hat{u}, \hat{u}) \in E_1$  to  $M$ . Now, consider any star  $H = \{(u, v_1), (u, v_2), \dots, (u, v_t)\}$  in  $G'$ ; wlog assume that  $u \in S$ . Add  $(u, v_1) \in E_0$  to  $M$ . Also, add the edge  $(\hat{v}_1, \hat{u}) \in E_1$  to  $M$ . For each  $2 \leq i \leq t$ , add the edge  $(\hat{v}_i, v_i) \in E_3$  to  $M$ . It is not hard to verify that all the vertices of  $G$  are matched in  $M$ . Also, as the weight of a star edge  $(u, v_i)$  above is at least the weight of  $(\hat{v}_i, v_i)$  in  $G$  by definition, the cost of  $M$  is at most the cost of  $M'$ .

Next, suppose  $I$  has a perfect matching  $M$ ; we construct a many-to-many matching  $M'$  for  $I'$ . Consider any  $u \in S = R_0$ . If  $(u, \hat{u}) \in M$ , add the pair  $(u, u')$  to  $M'$ , where  $u'$  is the closest neighbor of  $u$  in  $T$ . Otherwise,  $u$  is matched (in  $M$ ) to some  $v_1 \in B_0$ . In this case, simply add the pair  $(u, v_1)$  to  $M'$ . Similarly, consider any  $v \in T = B_0$ . If  $(\hat{v}, v) \in M$ , add the pair  $(v', v)$  to  $M'$ , where  $v'$  is the closest neighbor of  $v$  in  $S$ . Otherwise,  $v$  is matched (in  $M$ ) to some  $u_1 \in R_0$ . In this case, simply add the pair  $(u_1, v)$  to  $M'$ . It is not hard to verify that  $M'$  is a many-to-many matching, and the cost of  $M'$  is same as the cost of  $M$ . ◀

Now, consider any matching in a graph. An *alternating* path is a path whose edges alternate between matched and unmatched edges. Similarly, one can define *alternating* cycles and trees. A vertex is called *free* if it is not matched. An *augmenting* path is an alternating path which starts and ends at free vertices. Given an augmenting path  $P$  w.r.t. a matching  $M$ , we can augment  $M$  by one edge if we remove the edges of  $P \cap M$  from  $M$  and add the edges in  $P \setminus M$  to  $M$ . The new matching is denoted by  $M \oplus P$ . Throughout the paper,  $m$  and  $n$  denote the number of edges and vertices, respectively, unless otherwise specified. We denote the weight or cost of an edge  $(u, v)$  by  $c(u, v)$ . In our discussions, a path can be treated as an ordered set of vertices or edges depending on the context.

### 3 An Exact Algorithm

Consider the instance  $I$  obtained by the reduction in Lemma 1. In this section, we prove the following theorem.

► **Theorem 2.** *Bipartite perfect matching can be solved exactly on  $I$  in time  $O(n^2 \cdot \text{poly}(\log n))$ , and hence there is an  $O(n^2 \cdot \text{poly}(\log n))$  time exact algorithm for minimum-cost many-to-many matching.*

In the rest of this section, we prove Theorem 2. To prove this theorem we use the Hungarian algorithm [10] for computing a (minimum-cost) bipartite perfect matching.

In the Hungarian algorithm, there is a dual variable  $y(v)$  corresponding to each vertex  $v$ . Every feasible matching  $M$  must satisfy the following two conditions.

$$y(u) + y(v) \leq c(u, v) \text{ for every edge } (u, v) \quad (1)$$

$$y(u) + y(v) = c(u, v) \text{ for every edge } (u, v) \in M \quad (2)$$

Given any matching  $M$  and an augmenting path  $P$ , the net-cost or augmentation cost is defined as,

$$\phi(P) = \sum_{(u,v) \in P \setminus M} c(u, v) - \sum_{(u,v) \in P \cap M} c(u, v)$$

$\phi(P)$  is basically the cost increment for augmenting  $M$  along  $P$ . The net-cost of any alternating cycle can be defined in the same way. The Hungarian algorithm starts with an empty matching  $M$ . In every iteration, it computes an augmenting path of the minimum net-cost and augments the current matching. The algorithm halts once a perfect matching is found. If there is a perfect matching in the graph, this algorithm returns one after at most  $n$  iterations. Moreover, an augmenting path can be found in  $O(m)$  time leading to  $O(mn)$  running time in total.

It is possible to show that any perfect matching is a minimum-cost matching if and only if there is no negative net-cost alternating cycle with respect to it. Moreover, a feasible matching with dual values  $\{y(v)\}$  satisfies this property. Thus, it is sufficient to find a perfect matching that is feasible.

For finding an augmenting path, a Hungarian search procedure is employed. Hungarian search uses Dijkstra's shortest path algorithm to find a minimum net-cost path in the graph where the value  $y(u) + y(v)$  is subtracted from the weight of each edge  $(u, v)$ . This along with the first feasibility condition ensure that each edge has a non-negative weight, and hence there is no negative cycle in the graph. So, one can correctly employ Dijkstra's algorithm to find such a shortest path. Finally, one can show that the minimum net-cost augmenting path with original weights corresponds to a shortest path with the modified weights, and vice versa. After augmenting the current matching with the newly found path, the dual values are adjusted appropriately to ensure feasibility of the new matching.

Now, we describe in detail how the Hungarian search procedure is implemented in each iteration. An edge  $(u, v)$  is called *admissible* if  $y(u) + y(v) = c(u, v)$ . It can be shown that it suffices to find an augmenting path consisting of only admissible edges. Let  $M$  be the current matching and  $F$  be the free vertices of  $R$ . To obtain the desired augmenting path, a forest  $\mathcal{F}$  is grown whose roots are in  $F$ . Each tree in  $\mathcal{F}$  is an augmenting tree rooted at a vertex in  $F$ . Once  $\mathcal{F}$  contains an augmenting path the search is completed. At any moment, let  $R'$  be the vertices of  $R$  in  $\mathcal{F}$  and  $B'$  be the vertices of  $B$  not in  $\mathcal{F}$ . Initially,  $R' = F$  and  $B' = B$ . Also, let

$$\delta = \min_{\{u \in R', v \in B'\}} c(u, v) - y(u) - y(v).$$

Note that  $\delta = 0$  means there is an admissible edge. In each step, if  $\delta = 0$ , an admissible edge  $(u, v)$  is selected where  $u \in R'$  and  $v \in B'$ . If  $v$  is free,  $(u, v)$  is added to  $\mathcal{F}$  and the desired augmenting path is found. Otherwise, let  $v$  be matched to  $u'$  (which is not in  $\mathcal{F}$  by an invariant). In this case, the edges  $(u, v)$  and  $(v, u')$  are added to  $\mathcal{F}$ ;  $u'$  is added to  $R'$  and  $v$  is removed from  $B'$ .

If at some moment,  $\delta$  becomes more than 0 (no admissible edge), we perform dual adjustments. In particular, for each  $u \in R'$ ,  $y(u)$  is updated to  $y(u) + \delta$  and for each  $v \in \mathcal{F} \cap B$ ,  $y(v)$  is updated to  $y(v) - \delta$ . This ensures that at least one edge becomes admissible, e.g., the edge corresponding to which the  $\delta$  value is achieved. Thus, eventually the search halts with an augmenting path in  $\mathcal{F}$ .

It can be shown that if  $\delta$  can be computed efficiently, then the desired augmenting path can also be found efficiently [6, 1, 16]. For that purpose, another variable  $\Delta$  is maintained. Also, for each vertex  $v$ , a weight  $\sigma_v$  is stored. In the beginning of each step,  $\Delta = 0$ ,  $\sigma_v = y(v)$ . When the edges  $(u, v)$  and  $(v, u')$  are added to  $\mathcal{F}$ ,  $\sigma_{u'}$  is updated to  $y(u') - \Delta$  and  $\sigma_v$  is updated to  $y(v) + \Delta$ . Once  $\delta$  becomes more than 0,  $\Delta$  is updated to  $\Delta + \delta$ .

Note that the weight of a vertex is updated only once when it is added to  $\mathcal{F}$ . We have the following observation.

► **Observation 3** ([6, 1, 16]). *For each  $u \in R'$ , the current dual value of  $u$ ,  $y(u)$ , is equal to  $\sigma_u + \Delta$ . For each  $v \in \mathcal{F} \cap B$ , the current dual value of  $v$ ,  $y(v)$ , is equal to  $\sigma_v - \Delta$ .*

It follows from the above observation that  $\delta$  can be equivalently expressed as follows.

$$\delta = \min_{u \in R', v \in B'} \{c(u, v) - \sigma_u - \sigma_v\} - \Delta.$$

Hence, Hungarian search boils down to the following task ignoring the trivial details. We need to maintain two sets  $R' \subseteq R$  and  $B' \subseteq B$ . Initially,  $B' = B$ . In each step, a vertex  $r$  is added to  $R'$  and a vertex  $b$  is removed from  $B'$ . Additionally, each vertex  $v$  has a weight  $\sigma_v$ . In every step, the goal is to maintain the bichromatic closest pair, which is the pair  $(r, b) \in R' \times B'$  with the minimum  $c(r, b) - \sigma_r - \sigma_b$  value. In the following, we construct a data structure that can be used to perform the above task (a Hungarian search) in  $O(n \cdot \text{poly}(\log n))$  time. As we need at most  $n$  such searches, Theorem 2 follows.

Recall that in our instance  $I$ , we are given the graph  $G = (R = R_0 \cup R_1, B = B_0 \cup B_1, E)$ , where  $R_1$  contains copies of the vertices in  $B_0$ ,  $B_1$  contains copies of the vertices in  $R_0$ .  $E = E_0 \cup E_1 \cup E_2 \cup E_3$ , where  $E_0 = R_0 \times B_0$ ,  $E_1 = R_1 \times B_1$ ,  $E_2 = \{(u, \hat{u}) \mid u \in R_0, \hat{u} \in B_1\}$ , and  $E_3 = \{(\hat{v}, v) \mid v \in B_0, \hat{v} \in R_1\}$ . Let  $n = |R| = |B|$ .

Our data structure  $\mathcal{D}$  is a collection of three data structures. First, we construct the dynamic bichromatic closest pair data structure from [8] for the two point sets  $R_0$  and  $B_0$  with the distance function  $c(r, b) - \sigma_r - \sigma_b$  for each pair  $(r, b)$ . We refer to this data structure as  $\mathcal{D}_1$ . Initially, it contains only the points in  $R' \cup B'$ . Next, we construct two max-heaps  $H_1^r$  and  $H_1^b$  for the vertices in  $R_1 \cap R'$  and  $B_1 \cap B'$ , respectively. Initially,  $H_1^r$  contains vertices in  $R'$  and  $H_1^b$  contains all the vertices in  $B_1$ . The key value of each vertex  $v$  is its weight  $\sigma_v$ . Using  $H_1^r$  and  $H_1^b$ , the pair  $(u, v) \in (R_1 \cap R') \times (B_1 \cap B')$  with the maximum  $\sigma_u + \sigma_v$  value can be found in  $O(1)$  time. We also construct another min-heap  $H_{23}$  to store the edges in  $E_2 \cup E_3$  with key value  $c(r, b) - \sigma_r - \sigma_b$  for each pair  $(r, b)$ . Initially, it is empty. In every iteration, it contains only those edges  $(u, v)$  such that  $u \in R'$  and  $v \in B'$ . We also maintain a global closest pair  $(r, b)$  over the three data structures  $\mathcal{D}_1$ ,  $H_1^r \cup H_1^b$  and  $H_{23}$  with the minimum key value  $c(r, b) - \sigma_r - \sigma_b$ .

Using  $\mathcal{D}$ , we implement each step as follows. If  $v \in B_0$ , remove  $v$  from  $\mathcal{D}_1$ . Also remove  $(\hat{v}, v)$  from  $H_{23}$  if it is in  $H_{23}$ . If  $v \in B_1$ , remove  $v$  from  $H_1^b$ . Also remove the edge  $(u', v)$  with  $u' \in R_0$  from  $H_{23}$  if its in  $H_{23}$ . If  $u \in R_0$ , add  $u$  to  $\mathcal{D}_1$ . Also add the edge  $(u, \hat{u})$  to  $H_{23}$  if  $\hat{u} \in B'$ . If  $u \in R_1$ , add  $u$  to  $H_1^r$ . Also add the edge  $(u, v')$  with  $v' \in B_0$  to  $H_{23}$  if  $v' \in B'$ .

It is not hard to verify that at each step the correct global closest pair is stored in  $\mathcal{D}$ . The correctness for  $\mathcal{D}_1$  and  $H_{23}$  follow trivially. Also, as the weight of the edges in  $E_1$  are same, it is sufficient to find a pair  $(u, v) \in E_1$  for which  $\sigma_u + \sigma_v$  value is maximized. As  $E_1$  contains all the edges in  $R_1 \times B_1$ , equivalently it suffices to find a  $u \in R_1$  with the maximum  $\sigma_u$  value and a  $v \in B_1$  with the maximum  $\sigma_v$  value.

We note that the total number of steps in a Hungarian search is at most  $n$ . Also,  $O(n)$  operations (insertions, deletions and searching) on  $\mathcal{D}_1$  can be performed in amortized  $O(n \cdot \text{poly}(\log n))$  time [8]. The construction time and space of  $\mathcal{D}_1$  are also  $O(n \cdot \text{poly}(\log n))$ . Moreover, the  $O(n)$  operations on all max-heaps can be performed in total  $O(n \log n)$  time. It follows that Hungarian search can be implemented in  $O(n \cdot \text{poly}(\log n))$  time leading to the desired running time of our algorithm.

#### 4 An Improved $(1 + \epsilon)$ -approximation

Consider the instance  $I$  obtained by the reduction in Lemma 1. In this section, we prove the following theorem.

► **Theorem 4.** *A  $(1 + \epsilon)$ -approximate bipartite perfect matching for  $I$  can be computed in time  $O((1/\epsilon^c) \cdot n^{3/2} \cdot \text{poly}(\log n))$  for some constant  $c$ , and hence there is an  $O((1/\epsilon^c) \cdot n^{3/2} \cdot \text{poly}(\log n))$  time  $(1 + \epsilon)$ -approximation algorithm for minimum-cost many-to-many matching.*

In the rest of this section, we prove Theorem 4. In particular, we show that the bipartite perfect matching algorithm by Gabow and Tarjan [6] can be implemented on the instance  $I$  in the mentioned time.

The Gabow-Tarjan algorithm is based on a popular scheme called the bit-scaling paradigm. The algorithm is motivated by two classic matching algorithms: Hopcroft-Karp [7] for maximum cardinality bipartite matching with  $O(m\sqrt{n})$  running time and Hungarian algorithm [10] for minimum-cost bipartite matching with  $O(mn)$  running time. The Hopcroft-Karp algorithm chooses an augmenting path of the shortest length. The Hungarian algorithm, as mentioned before, chooses an augmenting path whose augmentation cost is the minimum. When the weights on the edges are small an augmenting path of the shortest length approximates the latter path. The Gabow-Tarjan algorithm scales the weights in a manner so that all the effective weights are small. This helps to combine the ideas of the two algorithms, which leads towards an  $O(m\sqrt{n} \log(nN))$  time algorithm for (minimum-cost) bipartite perfect matching, where  $N$  is the largest edge weight.

Next, we describe the Gabow-Tarjan algorithm. This algorithm is based on the ideas of the Hungarian algorithm. However, here instead of a feasible matching we compute a *1-feasible* matching. A matching  $M$  is called 1-feasible if it satisfies the following two conditions.

$$y(u) + y(v) \leq c(u, v) + 1 \text{ for every edge } (u, v) \tag{3}$$

$$y(u) + y(v) = c(u, v) \text{ for every edge } (u, v) \in M \tag{4}$$

Note that the only difference is that now the sum of dual variables  $y(u) + y(v)$  can be 1 plus the cost of the edge. This additive error of 1 on every unmatched edge ensures that longer augmenting paths have larger cost. As an effect, the algorithm picks short augmenting paths as in the Hopcroft-Karp algorithm.

A *1-optimal* matching is a perfect 1-feasible matching. Note that a 1-optimal matching costs more than the original optimal matching. However, as the error is at most +1 for every edge, one can show the following.

► **Lemma 5 ([6]).** *Let  $M$  be a 1-optimal matching and  $M'$  be any perfect matching. Then  $c(M') \geq c(M) - n$ .*

It follows from the above lemma that, to annihilate the error introduced, one can scale the weight of each edge by a factor of  $(n + 1)$ , and then with the scaled weights the cost of a 1-optimal matching is same as the cost of any optimal matching. Let  $\bar{c}(u, v)$  be the scaled cost of  $(u, v)$ , i.e.,  $\bar{c}(u, v) = (n + 1) \cdot c(u, v)$ . Let  $k = \lfloor \log((n + 1)N) \rfloor + 1$  be the maximum number of bits needed to represent any new weight.

The Gabow-Tarjan algorithm runs in  $k$  different scales. In each scale  $i$  ( $1 \leq i \leq k$ ), the most significant  $i$  bits of  $\bar{c}(u, v)$  are used for defining the current cost of each edge  $(u, v)$ . The dual values are also modified to maintain 1-feasibility of an already computed perfect matching in the following way:  $y(v) \leftarrow 2y(v) - 1$  for every vertex  $v$ . Then with the current edge costs and dual values, the algorithm computes a 1-optimal matching.

By the above claim, that any 1-optimal matching is also optimal with scaling factor  $n + 1$ , the 1-optimal matching computed by the algorithm at  $k$ -th scale must be optimal.

To find a 1-optimal matching on a particular scale a procedure called *match* is employed which we describe below. Before that we need a definition. Consider any 1-feasible matching  $M$ . An edge  $(u, v)$  is called *eligible* if it is in  $M$  or  $y(u) + y(v) = c(u, v) + 1$ . It can be shown that for the purpose of computing a 1-optimal matching it suffices to consider the augmenting paths which consist of eligible edges only.

**The *match* procedure**

Initialize all the dual variables  $y(v)$  to 0 and  $M$  to  $\emptyset$ . Repeat the following two steps until a perfect matching is obtained in step 1.

1. Find a maximal set  $\mathcal{A}$  of augmenting paths of eligible edges. For each path  $P \in \mathcal{A}$ , augment the current matching  $M$  along  $P$  to obtain a new matching which is also denoted by  $M$ . For each vertex  $v \in P \cap B$ , decrease  $y(v)$  by 1. (This is to ensure that the new matching  $M$  also is 1-feasible.) If  $M$  is perfect, terminate.
2. Employ a Hungarian search to adjust the values of the dual variables (by keeping  $M$  1-feasible), and find an augmenting path of eligible edges.

Note that the number of free vertices in every iteration of *match* is at least 1 less than that in the previous iteration, as step 2 always ends with finding an augmenting path. By also showing that the dual value of a variable is increased by at least 1 in every call of Hungarian search, they proved that  $O(\sqrt{n})$  iterations are sufficient to obtain a 1-optimal matching. It can be shown that each iteration of *match* can be executed in general bipartite graphs in  $O(m)$  time leading to the complexity of  $O(m\sqrt{n})$  in each scale. As we have  $O(\log(nN))$  scales, in total the running time is  $O(m\sqrt{n} \log(nN))$ .

Next, we use the Gabow-Tarjan algorithm to compute a perfect matching for our instance of bipartite perfect matching. In particular, we show that by exploiting the structure of our instance, it is possible to implement every iteration of *match* in  $O(n \cdot \text{poly}(\log n))$  time. First, we show that one can consider a modified instance with bounded aspect ratio of the weights, for the purpose of computing a  $(1 + \epsilon)$ -approximation. For this, we need the following theorem. (The proofs of the results marked with  $(*)$  are deferred to the full version.)

► **Theorem 6**  $(*)$ . *There is an  $O(n \log n)$  time 2-approximation algorithm for minimum-cost many-to-many matching.*

The algorithm in Theorem 6 is fairly simple. For each point in a set ( $S$  or  $T$ ), it adds the pair corresponding to its nearest neighbor in the other set.

Let  $\text{OPT}$  be the optimal cost of perfect matching on the instance  $I$ . Recall that the instance  $I$  consists of the graph  $G = (R = R_0 \cup R_1, B = B_0 \cup B_1, E)$ . Given the implicit representation of  $G$ , we compute a 2-approximate solution for minimum-cost many-to-many

matching on the two sets of points  $R_0$  and  $B_0$  using the algorithm in Theorem 6. Let  $C$  be the cost of this solution. By Lemma 1,  $\text{OPT} \leq C \leq 2\text{OPT}$ . We construct a new instance  $I_1$  which consists of the implicit representation of the same graph  $G$ . Additionally, we assume that any edge with weight more than  $C$  in  $I_1$  will not be part of the solution, and each edge has cost at least  $\epsilon C/(2n)$ . Note that it is not possible to explicitly set the weight of each and every edge if we are allowed to spend  $o(n^2)$  time. Thus, for the time being, we make the above assumptions implicitly. Later, we will make them explicit in our algorithm. Note that the construction time of  $I_1$  is dominated by the time of the 2-approximation algorithm, which is  $O(n \log n)$ . We obtain the following lemma.

► **Lemma 7** (\*). *Given  $I$ , one can compute in  $O(n \log n)$  time another instance  $I_1$  of bipartite perfect matching, such that (i) the weight of every edge is in  $[\epsilon C/(2n), C]$  where  $\text{OPT} \leq C \leq 2\text{OPT}$ , (ii)  $I_1$  has a perfect matching of weight at most  $(1 + \epsilon)\text{OPT}$ , and (iii) any perfect matching in  $I_1$  of weight  $C'$  is also a perfect matching in  $I$  of weight at most  $C'$ .*

Henceforth, we solve the problem on  $I_1$ . Note that the minimum edge weight in  $I_1$  is  $\epsilon C/(2n)$  and the maximum is  $C$ . By scaling the weights by  $2n/(\epsilon C)$ , we can assume wlog that the edge weights in  $I_1$  are in  $[1, n^2]$ . Moreover, we can assume that each edge weight  $w$  is rounded up to the nearest integer at least  $w$ . We can afford to remove the fractions, as each fraction costs less than 1, which is at most  $\epsilon \text{OPT}/n$  w.r.t. the original weights. For our convenience, we also divide the weights into  $O(\log_{1+\epsilon} n)$  classes as follows. For each weight  $a$  (an integer) with  $(1 + \epsilon)^i \leq a < (1 + \epsilon)^{i+1}$ ,  $a$  is rounded to the largest integer in the range  $[(1 + \epsilon)^i, (1 + \epsilon)^{i+1})$ , where  $0 \leq i \leq \lceil 2 \log_{1+\epsilon} n \rceil$ . We denote this largest integer corresponding to the  $i$ -th weight class by  $w_i$ . We note that the above weight scalings are performed implicitly. It is not hard to verify that these still preserve a  $(1 + O(\epsilon))$ -approximate solution, which is sufficient for our purpose. Henceforth, we treat  $\epsilon$  as a constant and hide function of  $\epsilon$  in time complexity as a constant in  $O()$  notation. It will not be hard to verify that the dependency on  $\epsilon$  that we hide is  $(1/\epsilon)^c$  for some true small constant  $c$ .

To implement the Gabow-Tarjan algorithm, we show how the *match* procedure can be implemented efficiently. To implement step 1 of *match*, we store the information about the input graph  $G$  in a data structure that we refer to as MATCH. We allow the following operation on MATCH. In the following, we denote the current matching by  $M$ .

**FIND\_MAXIMAL\_APS.** Find a maximal set of vertex disjoint augmenting paths of eligible edges with respect to  $M$ .

Given the MATCH data structure, we implement the step 1 of *match* as follows. The dual values are stored in an array indexed by the vertices. Note that the dual values remain fixed in step 1 while the augmenting paths are found. Afterwards, the dual values are updated. We first make a call to FIND\_MAXIMAL\_APS to obtain a maximal set  $\mathcal{A}$  of paths. For each  $P \in \mathcal{A}$ , we augment  $M$  along  $P$  to obtain a new matching  $M$ . Also, for each  $v \in P \cap B$ , we decrease  $y(v)$  by 1.

In Section 5, we show how to construct and maintain MATCH so that the above subroutine can be performed in time  $O(n \cdot \text{poly}(\log n))$ . The building time of MATCH is  $O(n \cdot \text{poly}(\log n))$ , and it takes  $O(n \cdot \text{poly}(\log n))$  space. Thus, by noting that  $\mathcal{A}$  contains disjoint paths, step 1 can be implemented in  $O(n \cdot \text{poly}(\log n))$  time and space.

We also need another data structure which will help us implement step 2 of *match*, which we refer to as the Hungarian search data structure. As described before, Hungarian search boils down to maintaining a bichromatic closest pair  $(r, b)$  of two sets with the minimum  $c(r, b) - \sigma_r - \sigma_b$  value. However, here we have to be more careful, as for an unmatched

eligible edge  $(u, v)$ ,  $y(u) + y(v) = c(u, v) + 1$ . In contrast, in the Hungarian algorithm, we had  $y(u) + y(v) = c(u, v)$  in that case. Hence, we have to consider the  $c(u, v) + 1 - y(u) - y(v)$  value as the distance of such an unmatched pair  $(u, v)$ . This apparently makes our life harder, as now we have to deal with two types of distance functions: one for matched pairs and one for unmatched pairs. However, we use the following observation to consider only one type of distances, which follows from our description of Hungarian search in Section 3.

► **Observation 8.** *Consider any matched edge  $(u, v)$  with  $u \in R$  and  $v \in B$ . In the Hungarian search, if  $u \in R'$ , i.e.,  $u$  is already in the forest, then  $v$  must also be in the forest, i.e.,  $v \notin B'$ .*

Recall that for computing  $\delta$ , we look into the pairs  $(u, v)$  where  $u \in R'$  and  $v \in B'$ . By the above observation, it suffices to probe only unmatched edges. Hence, we can again work with only one distance function  $c(r, b) + 1 - \sigma_r - \sigma_b$  for the purpose of computing  $\delta$ . As the  $+1$  term is common in all distances, we also drop that, and work with our old distance function.

In Section 5, we show how to construct and maintain Hungarian search data structure so that the task of maintaining closest pair can be performed in total  $O(n \cdot \text{poly}(\log n))$  time. Moreover, the data structure uses  $O(n \cdot \text{poly}(\log n))$  construction time and space.

► **Lemma 9.** *Using the MATCH and Hungarian search data structures, one can implement the Gabow-Tarjan algorithm on the instance  $I_1$  in time  $O(n^{3/2} \cdot \text{poly}(\log n))$ , i.e., a minimum cost bipartite perfect matching in  $I_1$  can be computed in time  $O(n^{3/2} \cdot \text{poly}(\log n))$ .*

## 5 Data Structures

### 5.1 The MATCH Data Structure

We would like to construct a data structure where given a matching at a fixed scale, a maximal set of augmenting paths can be computed efficiently. In particular, we are given the graph  $G = (R = R_0 \cup R_1, B = B_0 \cup B_1, E)$ , where  $R_1$  contains copies of the vertices in  $B_0$ ,  $B_1$  contains copies of the vertices in  $R_0$ .  $E = E_0 \cup E_1 \cup E_2 \cup E_3$ , where  $E_0 = R_0 \times B_0$ ,  $E_1 = R_1 \times B_1$ ,  $E_2 = \{(u, \hat{u}) \mid u \in R_0, \hat{u} \in B_1\}$ , and  $E_3 = \{(\hat{v}, v) \mid v \in B_0, \hat{v} \in R_1\}$ . Let  $n = |R| = |B|$ . Also, note that each edge weight is an integer  $w_i$  for  $0 \leq i \leq \lceil (c' \log n) / \epsilon \rceil$ , where  $c'$  is a constant. Let  $E_i^0$  be the set of edges in  $R_0 \times B_0$  with weights  $w_i$ . We define a bi-clique cover for each  $E_i^0$  as a collection  $\mathcal{C}_i = \{(P_{i1}, Q_{i1}), (P_{i2}, Q_{i2}), \dots, (P_{it(i)}, Q_{it(i)})\}$  where  $P_{ij} \subseteq R_0$ ,  $Q_{ij} \subseteq B_0$ , all the edges in  $P_{ij} \times Q_{ij}$  are in  $E_i^0$  and  $\bigcup_{j=1}^{t(i)} P_{ij} \times Q_{ij} = E_i^0$ . The size of  $E_i^0$  is  $\sum_{j=1}^{t(i)} |P_{ij}| + |Q_{ij}|$ . Given the points in  $R_0$  and  $B_0$ , using standard range searching data structures, one can compute such a bi-clique cover of size  $O((n/\epsilon) \log^2 n)$  in  $O((n/\epsilon) \log^2 n)$  time. We note that bi-clique covers are also used for the algorithm in [17]. Let  $\mathcal{C} = \mathcal{C}_i$ . Thus  $\mathcal{C}$  can be computed in  $O((n/\epsilon^2) \log^3 n)$  time and space.

In MATCH we store the bi-clique covers in  $\mathcal{C}$  corresponding to the edges in  $E_0$ . Also, we store the edges in  $E_2$  along with their weights in an array  $A_2$  indexed by the vertices of  $R_0$  and the edges in  $E_3$  and their weights in an array  $A_3$  indexed by the vertices of  $B_0$ . For finding an augmenting path efficiently, we need to store additional information. Before describing that, we describe in more detail how the augmenting paths are found.

The maximal set of augmenting paths are found by a careful implementation of depth first search. In this implementation, vertices can be labeled as marked. Initially all vertices are unmarked. We select any free unmarked vertex of  $R$  and initialize a path  $P$  at that vertex.  $P$  is extended from the last vertex  $u$  (in  $R$  as an invariant) as follows. We probe an eligible edge  $(u, v)$ . If  $v$  is already marked, the next eligible edge is considered. If no such

edge exists, the last two edges (one unmatched and one matched) are deleted from  $P$ . If  $P$  becomes empty, a new path is initialized. For the remaining cases, the following subroutine is called.

**AUGMENTING\_PATH**( $v$ ). If  $v$  is unmarked and free, we have found an augmenting path;  $v$  is marked,  $P$  is added to  $\mathcal{A}$  and a new path is initialized. In this case, return DONE. If  $v$  is unmarked, but matched with another vertex  $w$ ,  $(u, v)$  and  $(v, w)$  are added to  $P$ ;  $v, w$  are marked and the extension continues from  $w$  (in  $R$ ).

► **Observation 10** (\*). *In the above procedure, we always maintain the invariant that when we extend a path it suffices to probe only unmatched edges.*

Note that in the above procedure we cannot afford to probe all the unmatched edges. So, we have to implement the above step carefully. First, note that an edge  $(u, v)$  ( $u \in R$ ) is never scanned twice. When  $(u, v)$  is probed the first time, if  $v$  is unmarked, it becomes marked in all the cases. Also, once  $v$  is marked,  $(u, v)$  is never used to extend  $P$ . Thus, we can eliminate  $(u, v)$  from further probing.

From the above discussion, as  $E_2$  and  $E_3$  contain  $O(n)$  edges in total they can be probed in  $O(n)$  time. However,  $E_0$  and  $E_1$  contain  $\Omega(n^2)$  edges and thus for probing them we need specialized data structures. Next, we describe those.

Let  $c(u, v)$  be the weight of  $(u, v)$  at the current scale.  $y(u)$  is the dual value of the vertex  $u$  which remains fixed throughout the augmenting paths finding process. Again consider the bi-clique covers in  $\mathcal{C}$ . For each  $0 \leq i \leq \lceil (c' \log n)/\epsilon \rceil$ ,  $w_i$  denotes the weight of the edges in  $i$ -th class. Also, let  $\ell$  be the weight class to which the edges in  $E_1$  belong, i.e., all of their weights are  $w_\ell$ . For each such  $i$  and  $1 \leq j \leq t(i)$ , we store in  $match$  the vertices of  $Q_{ij}$  in a Red-Black tree  $T_{ij}$  with  $w_i + 1 - y(v)$  as the key of each such vertex  $v$ . Moreover, for each  $u \in R_0$ , we keep an ordered set of indexes  $I(u) = \{(i, j) \mid u \in P_{ij}\}$ . Similarly, define the index set  $I(v)$  for  $v \in B_0$ . We also store the vertices of  $B_1$  in a Red-Black tree  $T_1$  with  $w_\ell + 1 - y(v)$  as the key of  $v \in B_1$ .

► **Observation 11**. *MATCH uses  $O(n \cdot \text{poly}(\log n))$  construction time and space.*

The above space bound follows from the fact that the space complexity of MATCH is dominated by the space needed for the Red-Black trees, which is  $O(|B_1|) + \sum_{(i,j)} O(|Q_{ij}|) = O((n/\epsilon^2) \log^3 n)$ , as a Red-Black tree uses linear space. The time bound follows trivially.

**FIND\_MAXIMAL\_APS**. Let  $F$  be the set of free vertices and  $\Pi$  be the set of vertices that are already marked. Initially  $\Pi = \emptyset$ . Let  $\mathcal{A}$  be the set of augmenting paths found so far, which is initialized to  $\emptyset$ . For each vertex  $u \in R_1$ , set its  $E_1$ -failed flag to 0. While there is a vertex  $r_1 \in (R \cap F) \setminus \Pi$ , do the following.

- Initialize a path  $P$  at  $r_1$ .
- While  $P$  is not empty, do the following.
  - Let  $P = \{r_1, b_1, \dots, r_{\tau-1}, b_{\tau-1}, r_\tau\}$  be the current augmenting path that we need to extend.
  - (Case 1.  $r_\tau \in R_0$ ) Access the array  $A_2$  to find whether the copy of  $r_\tau$  in  $B_1$ , i.e.,  $\hat{r}_\tau$ , is marked and  $(r_\tau, \hat{r}_\tau)$  is eligible.
    - \* If  $\hat{r}_\tau$  is unmarked and  $(r_\tau, \hat{r}_\tau)$  is eligible, call the subroutine AUGMENTING\_PATH( $\hat{r}_\tau$ ). If this subroutine returns DONE, terminate this while loop. Otherwise, jump to the next iteration.

- \* Otherwise, search the Red-Black tree  $T_{ij}$  where  $(i, j)$  is the first index in  $I(r_\tau)$ , to find a vertex  $b_\tau$  with key value  $y(r_\tau)$ . If such a vertex  $b_\tau$  is found, call the subroutine  $\text{AUGMENTING\_PATH}(b_\tau)$ . Remove  $b_\tau$  from all the Red-Black trees with indexes in  $I(b_\tau)$ , as it is marked in the subroutine. If this subroutine returns DONE, terminate this while loop. Otherwise, jump to the next iteration. If no such vertex  $b_\tau$  is found in  $T_{ij}$ , remove the index  $(i, j)$  from  $I(r_\tau)$  and repeat the above step (performed for  $(i, j)$ ) for the next index in  $I(r_\tau)$ . If  $I(r_\tau)$  becomes empty, remove  $r_\tau$  and  $b_{\tau-1}$  from  $P$ , and continue to the next iteration.
- (Case 2.  $r_\tau \in R_1$ ) Access the array  $A_3$  to find whether the original copy of  $r_\tau$  in  $B_0$ , say  $v$ , is marked and  $(r_\tau, v)$  is eligible. If  $v$  is unmarked and  $(r_\tau, v)$  is eligible, call the subroutine  $\text{AUGMENTING\_PATH}(v)$ . If this subroutine returns DONE, terminate this while loop. Otherwise, jump to the next iteration. If  $E_1$ -failed is not set, i.e., it is 0 for  $r_\tau$ , search the Red-Black tree  $T_1$  to find a vertex  $b_\tau$  with key value  $y(r_\tau)$ . If such a vertex  $b_\tau$  is found, call the subroutine  $\text{AUGMENTING\_PATH}(b_\tau)$ . Remove  $b_\tau$  from  $T_1$ , as it is marked in the subroutine. If this subroutine returns DONE, terminate this while loop. Otherwise, jump to the next iteration. If no such vertex  $b_\tau$  is found in  $T_1$ , set  $E_1$ -failed flag for  $r_\tau$  to 1, remove  $r_\tau$  and  $b_{\tau-1}$  from  $P$ , and continue to the next iteration.

The above procedure is self-explanatory. Next, we prove its correctness and bound the implementation time.

► **Lemma 12** (\*). *FIND\_MAXIMAL\_APS correctly computes a maximal set of disjoint augmenting paths.*

► **Lemma 13** (\*). *FIND\_MAXIMAL\_APS can be implemented in  $O(n \cdot \text{poly}(\log n))$  time.*

## 5.2 Hungarian Search Data Structure

Recall that in Hungarian search, we need to maintain two sets  $R' \subseteq R$  and  $B' \subseteq B$ . Initially,  $R' = \emptyset$  and  $B' = B$ . In each iteration, a vertex is added to  $R'$  and removed from  $B'$ . Additionally, each vertex  $v$  has a weight  $\sigma_v$ . In every iteration, the goal is to maintain the bichromatic closest pair, which is the pair  $(u, v) \in R' \times B'$  with the minimum  $c(u, v) - \sigma_u - \sigma_v$  value.

Consider the bi-clique cover  $\mathcal{C}$  and in particular a pair  $(P_{ij}, Q_{ij})$  in  $\mathcal{C}$ . Then any edge in  $P_{ij} \times Q_{ij}$  has the same weight  $w_i$ . Thus, the pair  $(u, v)$  with the maximum  $\sigma_u + \sigma_v$  value has the minimum  $c(u, v) - \sigma_u - \sigma_v$  value in  $P_{ij} \times Q_{ij}$ . In other words, it is sufficient to keep track of a vertex  $u \in P_{ij}$  with the maximum  $\sigma_u$  value and a vertex  $v \in Q_{ij}$  with the maximum  $\sigma_v$  value.

Now, we describe the Hungarian Search data structure. For each index  $(i, j)$  in  $\mathcal{C}$ , we construct two max-heaps  $H_{ij}^r$  and  $H_{ij}^b$ , for  $P_{ij} \cap R'$  and  $Q_{ij} \cap B'$ , respectively. Initially,  $H_{ij}^r$  is empty and  $H_{ij}^b$  contains all the vertices in  $Q_{ij}$ . The key value of each vertex  $v$  is its weight  $\sigma_v$ . Note that using  $H_{ij}^r$  and  $H_{ij}^b$ , the pair  $(u, v) \in (P_{ij} \cap R') \times (Q_{ij} \cap B')$  with the maximum  $\sigma_u + \sigma_v$  value can be found in  $O(1)$  time. Similarly, we construct two heaps  $H_1^r$  and  $H_1^b$  for the vertices in  $R_1 \cap R'$  and  $B_1 \cap B'$ , respectively. Initially,  $H_1^r$  is empty and  $H_1^b$  contains all the vertices in  $B_1$ . The key value of each vertex  $v$  is its weight  $\sigma_v$ . Again using  $H_1^r$  and  $H_1^b$ , the pair  $(u, v) \in (R_1 \cap R') \times (B_1 \cap B')$  with the maximum  $\sigma_u + \sigma_v$  value can be found in  $O(1)$  time. We also construct another max-heap  $H_{23}$  to store the edges in  $E_2 \cup E_3$ . Initially, it is empty. In every iteration, it contains only those edges  $(u, v)$  such that  $u \in R'$  and

$v \in B'$ . Finally, to keep track of the global maximum pair, we create another max-heap  $H$ .  $H$  stores a maximum pair of  $(P_{ij} \cap R') \times (Q_{ij} \cap B')$  for each index  $(i, j)$  and maximum pairs of  $(R_1 \cap R') \times (B_1 \cap B')$  and  $H_{23}$ .

Note that the space complexity of the data structure is  $\sum_{(i,j)} O(|P_{ij}| + |Q_{ij}|) + O(n) = O((n/\epsilon^2) \log^3 n)$ . This follows, as a max-heap uses linear space.

► **Observation 14.** *The Hungarian Search data structure uses  $O(n \cdot \text{poly}(\log n))$  construction time and space.*

Next, we describe a procedure which will help us implement Hungarian search. This procedure takes a pair  $(u, v)$  as input, where  $u \in R \setminus R'$  and  $v \in B'$ . We need to add  $u$  to  $R'$  and remove  $v$  from  $B'$  while maintaining the correct maximum pair.

**UPDATE\_CLOSEST\_PAIR( $u, v$ ).** If  $v \in B_0$ , remove  $v$  from all  $H_{ij}^b$  that contains  $v$ . Also remove  $(\hat{v}, v)$  from  $H_{23}$  if its in  $H_{23}$ . If  $v \in B_1$ , remove  $v$  from  $H_1^b$ . Also remove the edge  $(u', v)$  with  $u' \in R_0$  from  $H_{23}$  if its in  $H_{23}$ . If  $u \in R_0$ , add  $u$  to all  $H_{ij}^r$  such that  $P_{ij}$  contains  $u$ . Also add the edge  $(u, \hat{u})$  to  $H_{23}$  if  $\hat{u} \in B'$ . If  $u \in R_1$ , add  $u$  to  $H_1^r$ . Also add the edge  $(u, v')$  with  $v' \in B_0$  to  $H_{23}$  if  $v' \in B'$ . Update the maximum pairs in  $H$  accordingly by selecting the updated maximum pairs from the other max-heaps.

► **Lemma 15** (\*). *Hungarian search can be performed in  $O(n \cdot \text{poly}(\log n))$  time.*

## Abstract

We study the problem of augmenting a metric graph by adding  $k$  edges while minimizing the radius of the augmented graph. We give a simple 3-approximation algorithm and show that there is no polynomial-time  $(5/3 - \epsilon)$ -approximation algorithm, for any  $\epsilon > 0$ , unless  $P = NP$ .

We also give two exact algorithms for the special case when the input graph is a tree, one of which is generalized to handle metric graphs with bounded treewidth.

## 1 Introduction

We study the problem of minimizing the radius of a metric graph by inserting  $k$  new edges.

Let  $G = (V, E)$  be a non-negative weighted graph with  $n$  vertices, and  $V^2$  be the set of all possible edges on  $V$ . A non-edge of  $G$ , also referred to as shortcut, is an edge in  $\bar{E} = V^2 \setminus E$ . The graph distance  $d_G(u, v)$  between two vertices  $u, v \in V$  is the smallest weight of any path in  $G$  joining  $u$  and  $v$ . The eccentricity of a vertex  $v \in V$  is the maximum graph distance between  $v$  and any vertex in  $V$ . The radius of  $G$  is the minimum eccentricity of any vertex in  $G$  and the center of  $G$  is a vertex with minimum eccentricity.

The radius of a graph is closely related to the diameter. The diameter of a graph is the maximum graph distance between any pair of vertices. The problem of minimizing the diameter of a graph by adding  $k$  new edges has been extensively studied [2, 6, 7, 8, 9, 14] and has applications in areas such as communication networks, information networks, flight scheduling and protein interaction.

In the general case each added edge may also have a cost, and the edge augmentation problem for minimizing the radius or diameter can then be seen as a bicriteria optimization problem. The two criteria are: (1) the total cost of the added edges, and (2) the radius or diameter of the augmented graph. A bicriteria optimization problem is then either (1) given a budget on the total cost of the added edges, minimize the radius or diameter, or (2) given a target on the radius or diameter of the augmented graph, minimize the total cost of the added edges. For radius, the first bicriteria optimization problem is formally defined as follows.

- **PROBLEM:** Bounded Cost Minimum Radius Edge Addition (BCMR)
- **INPUT:** An undirected graph  $G = (V, E)$  with weight function  $\ell : V^2 \rightarrow \mathbb{R}^+ \cup \{0\}$ , a cost function  $\varsigma : \bar{E} \rightarrow \mathbb{R}^+ \cup \{0\}$  and a positive number  $B$ .
- **GOAL:** Add a set  $F \subseteq \bar{E}$  with  $\sum_{e \in F} \varsigma(e) \leq B$  such that the radius of  $\hat{G} = (V, E \cup F)$  is minimized.

In this paper we consider the BCMR problem restricted to the special case when the costs are unit and the weights satisfy the triangle inequality. That is, given a metric graph  $G = (V, E, \ell)$ , add  $k = \lfloor B \rfloor$  shortcuts to  $G$  to minimize the radius of the augmented graph. We will refer to our restricted variant of the BCMR problem as the metric BCMR problem.

### Related results

To the best of the authors' knowledge there is only one paper on the BCMR problem. Johnson and Wang [13] showed a linear-time algorithm for the special case when  $k = 1$  and  $G$  is a path embedded in a metric space. They considered the continuous version where the center of the graph can be in the interior of an edge. However, the closely related problem of minimizing the diameter of the augmented graph has a long and rich history.

The problem of minimizing the diameter of the augmented graph such that the total cost of the shortcuts is within a budget (referred to as BCMD) and the problem of minimizing the cost of added shortcuts such that the diameter of the augmented graph is within a given value (referred to as BDMC) were shown to be NP-hard in [16] and  $W[2]$ -hard in [9, 11]. Li et al. [14] gave a constant factor approximation algorithm for the BCMD problem restricted to unit weights and unit costs. Later Bilò et al. [2] improved the analysis of Li et al.'s algorithm. Bilò et al.'s analysis also implies that Li et al.'s algorithm gives a 4-approximation for BCMD on metric graphs. Demaine and Zadimoghaddam [7] considered a variant of BCMD where the costs are unit and all non-edges have length  $\delta$ , where  $\delta$  is a small constant compared to the diameter of the graph. We will refer to this model as the DZ model. Demaine and Zadimoghaddam gave a constant factor approximation algorithm for the BCMD problem in the DZ model, which was later improved by Bilò et al. [2]. For the general BCMD problem where the weights and costs are arbitrary integers, Frati et al. [9] gave a 4-approximate Fixed-Parameter Tractable (FPT) algorithm (under the cost parameter). More restricted variants of the BCMD problem have also been considered in the literature, where the input graph is either a path or a tree and one shortcut is added. Section 1.1 in [13] gives a nice overview of these results.

Compared to the BCMD problem, the BDMC problem is traditionally harder to approximate. Dodis and Khanna [8] studied the BDMC problem in depth and gave extensive inapproximability results for different weight and cost functions. They also gave almost matching upper bounds for these variants of the BDMC problem.

### Our results

In this paper we study the metric BCMR problem. Our main results are:

1. A simple  $O(kn(m+n \log n))$  time 3-approximation algorithm and a  $(5/3-\epsilon)$  approximation hardness bound, even for metric BCMR on geometric graph<sup>1</sup>.
2. An exact  $O(n^3 \log n)$  time algorithm for metric BCMR when the input graph is a tree and an exact  $O((k^2b^2 + kb^32^b) \cdot n^{2b+2})$  time algorithm when the input graph has treewidth  $b - 1$ .

Our second result shows that the metric BCMR problem on trees is in  $P$ , while whether the BCMD problem on trees is in  $P$  is still an open problem, even for unit weights and unit costs.

---

<sup>1</sup> A geometric graph is a graph where all vertices are embedded in the Euclidean space.

Similar to Lemma 3 in [7], we can prove that any  $\alpha$ -approximation for the BCMR problem is a  $2\alpha$ -approximation for the corresponding BCMD problem. Thus our algorithm for BCMR on metric graphs with bounded treewidth is a 2-approximation for BCMD on metric graphs with bounded treewidth, which is slightly better than Li et al.'s 4-approximation (however, their result holds for metric graphs).

## Paper organization

The rest of the paper is organized as follows. The 3-approximation algorithm for the metric BCMR problem is presented in Section 2 and the approximation hardness results are given in Section 3. Section 4 describes our algorithms for the metric BCMR problem on trees. Finally, we present an algorithm on graphs with bounded treewidth in Section 5.

## 2 3-approximation algorithm

Let  $G = (V, E, \ell)$  and  $k$  be an instance of the metric BCMR problem. Let  $F^*$  be an optimal solution for the instance, and let  $c^*$  be a center of  $G^* = (V, E \cup F^*, \ell)$ .

If the center  $c^*$  is known, then the metric BCMR problem is just adding  $k$  shortcuts to minimize the eccentricity of  $c^*$ . However, since  $c^*$  is not known, we will just try every vertex in  $V$  as a candidate. We define the Graph Augmentation Eccentricity Minimization problem, GAEM for short, as follows: given a metric graph  $G = (V, E, \ell)$ , an integer  $k$  and a vertex  $s$  in  $V$ , add  $k$  shortcuts in  $\bar{E}$  to  $G$  such that the eccentricity of  $s$  is minimized. Obviously solving GAEM for every vertex in  $V$  gives us an optimal solution to the metric BCMR problem. Thus in the rest of this paper we will focus our attention on solving the GAEM problem.

The following lemma gives an important property for the GAEM problem, which we will utilize throughout the paper. The proof can be found in Appendix A.

► **Lemma 1.** *Given a metric graph  $G = (V, E, \ell)$ , an integer  $k$  and a vertex  $s$  in  $V$  for the GAEM problem, there is an optimal solution where every shortcut is incident to  $s$ .*

Lemma 1 allows us to only consider solutions in which all the shortcuts are incident to  $s$ . It also applies when we consider approximate solutions. Our 3-approximation algorithm uses the well-known farthest-first traversal technique popularized by Gonzalez [12]. Next we state the approximation algorithm.

■ **Algorithm 1** FarthestAdditionGAEM( $G, k, s$ ).

---

**Require:** A metric graph  $G = (V, E, \ell)$ , an integer  $k$  and a vertex  $s$  in  $V$ .

**Ensure:** An approximate optimal solution for the GAEM instance.

```

1:  $\hat{G} \leftarrow G$ 
2: for  $i \leftarrow 1$  to  $k$  do
3:   find the vertex  $u$  farthest from  $s$  in  $\hat{G}$ .
4:   add  $(s, u)$  to  $\hat{G}$ .
5: end for
6: return  $\hat{G}$ 

```

---

The approximation bound of Algorithm 1 is given in Lemma 2. The proof is found in Appendix B.

► **Lemma 2.** *Algorithm 1 is a 3-approximation algorithm for the GAEM problem.*

## 45:4 Augmenting Graphs to Minimize the Radius

Algorithm 1 is very simple and can be implemented using standard graph algorithms. Let  $n = |V|$  and  $m = |E|$ . In each iteration of the for loop, we use Dijkstra's algorithm to compute the single-source shortest paths from  $s$  to all other vertices in  $V$ . Using Fibonacci heaps [10], Dijkstra's algorithm runs in time  $O(m' + n \log n)$ , where  $m' < m + k$ . Without loss of generality, we may assume that  $k \leq n - 1 \leq m$ . The total running time is thus  $O(km + kn \log n)$ .

Running Algorithm 1 for  $n$  times gives our main result in this section.

► **Theorem 3.** *There is an  $O(kn(m + n \log n))$  time, 3-approximation algorithm for the metric BCMR problem.*

When the input graph is unweighted or in the DZ model, arguments similar to the proof of Lemma 2 give an approximation factor of 2. For unweighted graphs, the 3-approximation algorithm runs in  $O(knm)$  time by using BFS instead of Dijkstra's algorithm in Step 3 of Algorithm 1. Note that for general metric graphs we cannot use BFS in Step 3.

### 3 Approximation hardness

We show the approximation hardness of the metric BCMR problem by showing the approximation hardness of the GAEM problem. This follows from the fact that any polynomial time  $\alpha$ -approximation algorithm for GAEM will trivially lead to a polynomial time  $\alpha$ -approximation algorithm for the metric BCMR problem. The hardness proof is done using a reduction from the Dominating Set problem.

Given a graph  $G = (V, E)$  and an integer  $k$ , the Dominating Set decision problem asks whether there is a subset  $S \subset V$  of size  $k$  such that every vertex not in  $S$  is adjacent to a vertex in  $S$ . The GAEM decision problem is: given a metric graph  $G = (V, E, \ell)$ , a vertex  $s \in V$ , an integer  $k$  and a target value  $r$ , decide if there is a set  $F$  of  $k$  shortcuts such that their addition to  $G$  reduces the eccentricity of  $s$  to at most  $r$ .

■ **Figure 1** Reduction from the Dominating Set decision problem. Edges in  $E'$  are colored blue and have weight 2. All shortcuts are dashed and have weight 1.

► **Theorem 4.** *For any  $\epsilon > 0$ , finding a  $(\frac{5}{3} - \epsilon)$  approximate solution for the GAEM problem is NP-hard.*

**Proof.** Let  $G = (V, E)$  be a graph. Let  $I = (G, k)$  be an instance of the Dominating Set decision problem. We transform  $I$  into an instance  $I' = (G', s, k, 3)$  of the GAEM decision problem by adding an extra vertex  $s$ , that is,  $G' = (V' = V \cup \{s\}, E' = E, \ell)$ . We set the weight function  $\ell$  as: the weight of any shortcut in  $[V']^2 \setminus E'$  is 1 and the weight of any edge in  $E'$  is 2. See Figure 1. Note that  $\ell$  satisfies triangle inequality.

If there is a dominating set  $S \subset V$  of size  $k$  in  $G$ , we can choose the same  $k$  vertices in  $G'$  and add  $k$  shortcuts from  $s$  to every vertex in this subset. It follows that every vertex in  $V$  is connected to  $s$  by 1 shortcut and at most 1 edge in  $E$ . The eccentricity of  $s$  is thus at most 3.

If we can add  $k$  shortcuts to  $G'$  such that the eccentricity of  $s$  in the resulting graph is at most 3, we can add such  $k$  shortcuts which are all incident to  $s$ , by Lemma 1. For such  $k$  shortcuts, all other vertices of the shortcuts except  $s$  form a subset  $S' \subset V$  of size  $k$ . Since the eccentricity of  $s$  is at most 3, every vertex in  $V \setminus S'$  must be adjacent to a vertex in  $S'$  by an edge in  $E$ . Thus  $S'$  is dominating set of  $G$ .

Any vertex that is connected to  $s$  through 1 shortcut and 1 edge in  $E$  has distance 3 to  $s$ . Any vertex that is connected to  $s$  through 1 shortcut and 2 edges in  $E$  has distance 5 to  $s$ . If there is a  $(\frac{5}{3} - \epsilon)$  approximation algorithm for the GAEM problem then we can use it to solve  $I'$  and thus any dominating set instance. Thus finding a  $(\frac{5}{3} - \epsilon)$  approximate solution for the GAEM problem is NP-hard. ◀

The same construction can be used for the DZ model while only modifying the length function. Assuming the length of all non-edges to be very small, we get:

► **Lemma 5.** *For any  $\epsilon > 0$ , finding a  $(2 - \epsilon)$  approximate solution for the GAEM problem in the DZ model is NP-hard.*

Note that this is a tight lower bound since Algorithm 1 is a 2-approximation algorithm for the GAEM problem in the DZ model.

Somewhat surprising is that the GAEM problem on geometric graphs (the weights are Euclidean distances) is as hard to approximate as the GAEM problem. This is stated in Lemma 6 and the proof is found in Appendix C.

► **Lemma 6.** *For any  $\epsilon > 0$ , finding a  $(\frac{5}{3} - \epsilon)$  approximate solution for the GAEM problem on geometric graphs is NP-hard.*

## 4 The GAEM problem on metric trees

In this section we consider the GAEM problem on trees. We give two algorithms: (1) a near quadratic-time algorithm, and (2) a slower algorithm with running time  $O(\min\{k^2n^3, n^4\})$ . The first algorithm is more efficient and elegant, however, we are not able to generalize it to graphs of bounded treewidth. Therefore we will describe the second algorithm below (Section 4.1) while the description of the first algorithm can be found in Appendix D. We state the result of the first algorithm here:

► **Theorem 7.** *The GAEM problem on trees can be solved in  $O(n^2 \log n)$  time.*

Note that while Theorem 7 proves that the metric BCMR problem on trees can be solved in polynomial time, the complexity status for the BCMR problem on trees remains open, even for unit weights and unit costs.

Throughout this section we will assume that the input tree has degree at most 3. Otherwise, we transform it into a tree of degree 3 by splitting vertices with degree greater than 3. When a vertex of degree 3 is picked as the root, we split the vertex and get a binary tree. In the following, we assume that the input is a binary tree rooted at  $s$ .

### 4.1 The second algorithm for trees

By Lemma 1 all the shortcuts we add are incident to  $s$ . For a binary tree  $T = (V, E, \ell)$  rooted at  $s$ , we aim to add  $k$  shortcuts all incident to  $s$  so that the eccentricity of  $s$  in the augmented graph is minimized.

Our algorithm is a dynamic programming approach with three parameters. Before we define the subproblems we need to define some notations.

For a vertex  $v$  in  $V$ , let  $lc(v)$  and  $rc(v)$  denote the left and right child of  $v$ , respectively. Let  $T_v$  denote the subtree of  $T$  rooted at  $v$ . Let  $D^\uparrow(v) = \bigcup_{u \in T \setminus T_v} \{d_T(v, u) + |us|\}$  and let  $D^\downarrow(v) = \bigcup_{u \in T_v} \{d_T(v, u) + |us|\}$ . Each distance in  $D^\uparrow(v)$  is the weight of a tree path from  $v$  to a vertex  $u$  in  $T \setminus T_v$ , plus the shortcut  $(u, s)$ . The distances in  $D^\downarrow(v)$  are defined in the same way but through a vertex  $u$  in  $T_v$ . This is illustrated in Fig. 2(a), where the weight of the blue path is in  $D^\uparrow(v)$  and the weight of the red path is in  $D^\downarrow(v)$ . Note that the number of distances in  $D^\downarrow(v)$  is  $|T_v|$  and the number of distances in  $D^\uparrow(v)$  is  $|T \setminus T_v|$ . In our recursion we will need the subset  $D^\downarrow(v, d)$  of  $D^\downarrow(v)$  containing all distances in  $D^\downarrow(v)$  that are at least  $d$ .

For a subtree  $T_v$  and three parameters  $d^\uparrow$ ,  $d^\downarrow$  and  $\bar{k}$ , the subproblem is to find a set of  $\bar{k}$  shortcuts from  $s$  to vertices in  $T_v$  so that the maximum distance from vertices in  $T_v$  to  $s$  is minimized. The parameter  $d^\uparrow$  is the (assumed) weight of the shortest path from  $v$  to  $s$  via the parent of  $v$  (thus through a shortcut added to a vertex out of  $T_v$ ), and the parameter  $d^\downarrow$  is the (assumed) weight of the shortest path from  $v$  to  $s$  *not* going through the parent of  $v$  (thus through one of the  $\bar{k}$  shortcuts). Note that  $d^\uparrow$  is in  $D^\uparrow(v)$  and its path goes through shortcut  $(v^\uparrow, s)$  for some vertex  $v^\uparrow$  in  $T \setminus T_v$ . Also  $d^\downarrow$  is in  $D^\downarrow(v)$  and its path goes through shortcut  $(v^\downarrow, s)$  for some vertex  $v^\downarrow$  in  $T_v$ .

For given  $d^\uparrow$ ,  $d^\downarrow$  and  $\bar{k}$ , let  $R_v[d^\uparrow][d^\downarrow][\bar{k}]$  denote the minimum maximum distance from a vertex in  $T_v$  to  $s$ , when  $\bar{k}$  shortcuts are allowed to be added from  $s$  to vertices in  $T_v$ .

We have two base cases. If  $\bar{k} = 0$  then, by definition,  $d^\downarrow = \infty$  and

$$R_v[d^\uparrow][d^\downarrow][0] = d^\uparrow + \max_{u \in T_v} \{d_T(u, v)\},$$

and if  $v$  is a leaf and  $\bar{k} = 1$  then

$$R_v[d^\uparrow][d^\downarrow][1] = |vs|.$$

Next we state the recursion. Depending on the location of  $v^\downarrow$ , we have three different cases for  $\bar{k} > 0$ : (a)  $v^\downarrow$  lies in  $T_{lc(v)}$ , (b)  $v^\downarrow$  lies in  $T_{rc(v)}$ , or (c)  $v = v^\downarrow$  which implies that there is a shortcut connecting  $s$  to  $v$ . In all three cases, the allowed  $\bar{k}$  shortcuts are split between  $T_{lc(v)}$  and  $T_{rc(v)}$ .

**Case (a):  $v^\downarrow$  lies in  $T_{lc(v)}$ .**

$$R_v[d^\uparrow][d^\downarrow][\bar{k}] = \min_{1 \leq k' \leq \bar{k}} \{ \max\{R_{lc(v)}[d^\uparrow + |v, lc(v)|][d^\downarrow - |v, lc(v)|][k']\}, \\ \min_{d \in D^\downarrow(rc(v), d^\downarrow - |v, rc(v)|)} \{R_{rc(v)}[\min\{d^\uparrow, d^\downarrow\} + |v, rc(v)|][d][\bar{k} - k']\}, \min\{d^\uparrow, d^\downarrow\} \},$$

where  $\hat{k} = \min\{\bar{k}, |T_{lc(v)}|\}$ . Note that  $k'$  shortcuts are added to vertices in  $T_{lc(v)}$  and  $\bar{k} - k'$  shortcuts are added to vertices in  $T_{rc(v)}$ . Since  $v^\downarrow$  lies in  $T_{lc(v)}$ , the second parameter to  $R_{lc(v)}$  equals  $d^\downarrow - |v, lc(v)|$  and the second parameter to  $R_{rc(v)}$  is at least  $d^\downarrow - |v, rc(v)|$ . See Figure 2(b). Finally,  $\min\{d^\uparrow, d^\downarrow\}$  is the distance from  $v$  to  $s$ .

■ **Figure 2** (a) Shortest paths from  $v$  to  $s$ . (b)  $v^\downarrow$  lies in  $T_{lc(v)}$ . (c) Illustrating the list structures defined in Section 4.1.1.

**Case (b):  $v^\downarrow$  lies in  $T_{rc(v)}$ .**

$$R_v[d^\uparrow][d^\downarrow][\bar{k}] = \min_{1 \leq k' \leq \bar{k}} \{ \max\{R_{rc(v)}[d^\uparrow + |v, rc(v)|][d^\downarrow - |v, rc(v)|][k'],$$

$$\min_{d \in D^\downarrow(lc(v), d^\downarrow - |v, lc(v)|)} \{R_{lc(v)}[\min\{d^\uparrow, d^\downarrow\} + |v, lc(v)|][d][\bar{k} - k']\}, \min\{d^\uparrow, d^\downarrow\} \},$$

where  $\hat{k} = \min\{\bar{k}, |T_{rc(v)}|\}$ . The formula is symmetric to the formula for Case (a).

**Case (c):  $v = v^\downarrow$ .**

$$R_v[d^\uparrow][d^\downarrow][\bar{k}] = \min_{0 \leq k' \leq \bar{k}} \{ \max\{ \min_{d_l \in D^\downarrow(lc(v), |s, lc(v)|)} \{R_{lc(v)}[|s, v| + |v, lc(v)|][d_l][k']\},$$

$$\min_{d_r \in D^\downarrow(rc(v), |s, rc(v)|)} \{R_{rc(v)}[|s, v| + |v, rc(v)|][d_r][\bar{k} - k' - 1]\}, |vs| \} \},$$

where  $\hat{k} = \min\{\bar{k} - 1, |T_{lc(v)}|\}$ . The distance from  $v$  to  $s$  equals  $|vs|$ .

### 4.1.1 Data structures for DP

For efficient computation we define:

$$W_v[d^\uparrow][d^\downarrow][\bar{k}] = \min_{d \in D^\downarrow(v, d^\downarrow)} \{R_v[d^\uparrow][d][\bar{k}]\}.$$

Then the  $\min_{d \in D^\downarrow(\dots)}$  terms in the formulae of  $R_v$  in the last subsection are replaced by  $W_v$  terms. By definition,  $W_v$  can be computed from  $R_v$  in an ordered manner.

For efficiency, we will use the following list structure for  $R_v$  and  $W_v$  in the dynamic programming steps. The first level is a list,  $L^\uparrow$ , ordered on the values of  $d^\uparrow$ . Each node in  $L^\uparrow$  contains a second level list, denoted  $L^\downarrow$ , ordered on the values of  $d^\downarrow$ . And each node in  $L^\downarrow$  contains two arrays of size at most  $k$ , one for  $R_v$  and one for  $W_v$ . See Fig. 2(c).

The dynamic programming is done in a bottom-up manner. At a leaf node  $v$ ,  $d^\uparrow$  has  $n - 1$  values and  $d_v^\downarrow$  has one value. We perform a tree traversal starting from  $v$  to get all the values of  $d^\uparrow$ , and order these values in  $L^\uparrow$ . For each  $d^\uparrow$  value, build an  $L^\downarrow$  list containing one node. At an internal node  $v$ , the values of its  $L^\uparrow$  are obtained from the  $L^\downarrow$  of its right child and the  $L^\uparrow$  of its left child. Its  $L^\downarrow$  is formed by merging the  $L^\downarrow$  lists of its left and right child. The array elements of  $R_v$  are computed by using the formulae in the last subsection. Array elements of  $W_v$  are computed accumulatively from the array elements of  $R_v$ .

To get the shortcuts of an optimal solution, we need to keep some additional information. At a node  $v$ , the  $L^\uparrow$  list also stores the vertex  $v^\uparrow$  for each  $d^\uparrow$  value. The  $L^\downarrow$  list also stores the  $v^\downarrow$  for each  $d^\downarrow$  value. At an internal node  $v$ , when we use the formulae of  $R_v$  to compute an array element, we also keep track of the array elements of  $lc(v)$ 's structure and  $rc(v)$ 's structure that together give the solution for the current array element of  $R_v$ . When using the formula of  $W_v$ , we keep track of the array element of  $R_v$  that gives the value for the current array element of  $W_v$ . We can then backtrack with the above information to get the shortcuts of the optimal solution. The extra information we kept is constant per array element.

### 4.1.2 Running time

To analyze the running time, we first give two bounds. Their proofs are available in Appendix E.  $T$  is a rooted binary tree with  $n$  vertices.

► **Lemma 8.**  $\sum_{v \in T} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq n^2$ .

► **Corollary 9.**  $\sum_{v \in T} |T_v| \cdot \min\{|T_{lc(v)}|, |T_{rc(v)}|\} \leq 2n^2 + n \log n$ .

At a leaf node  $v$ , the tree traversal for computing values of  $d^\uparrow$  takes  $O(n)$  time. Sorting these values takes  $O(n \log n)$  time. Plus computing  $R_v$  and  $W_v$ , we spend  $O(n \log n)$  time in total. At an internal node  $v$ ,  $O(n)$  time is spent on obtaining the sorted  $d^\uparrow$  values for  $L^\uparrow$  and the sorted  $d^\downarrow$  values for  $L^\downarrow$ .  $0 \leq k' \leq \min\{\bar{k}, |T_{vs}|\}$ , where  $|T_{vs}| = \min\{|T_{lc(v)}|, |T_{rc(v)}|\}$ .  $\bar{k} \leq \min\{k, |T_v|\}$ . Thus computing the array elements of  $R_v$  for given  $d^\uparrow$  and  $d^\downarrow$  takes  $O(\min\{k^2, |T_v| \cdot |T_{vs}|\})$  time. Both  $d^\uparrow$  and  $d^\downarrow$  have at most  $n$  values. Using  $O(k^2)$  as the upper bound gives a total running time of  $O(k^2 n^3)$ . Using  $O(|T_v| \cdot |T_{vs}|)$  as the upper bound gives a total running time  $\sum_{v \in T} n^2 \cdot |T_v| \cdot |T_{vs}| = O(n^4)$ , by Corollary 9. So the total running time is  $O(\min\{k^2 n^3, n^4\})$ . To use less space, we can use *depth first search*. The space requirement is thus  $O(k^2 n^2)$ , and we get:

► **Theorem 10.** *When the input graph is a tree embedded in a metric space, GAEM can be solved in  $O(\min\{k^2 n^3, n^4\})$  time, using  $O(k^2 n^2)$  storage.*

## 5 Metric BCMR on graphs with bounded treewidth

Treewidth, introduced by Robertson and Seymour [15], measures how similar a graph is to a tree. Many NP-hard graph problems can be solved efficiently when the input graph is restricted to graphs with bounded treewidth [1, 3]. The notion of treewidth is based on the notion of tree decomposition of a graph.

► **Definition 11** ([15]). *A tree decomposition of a graph  $G = (V, E)$ , denoted by  $TD(G)$ , is a pair  $(X, T)$  in which  $T = (I, F)$  is a tree and  $X = \{X_i | i \in I\}$  is a family of subsets of  $V(G)$  such that:*

1.  $\bigcup_{i \in I} X_i = V$ ;
2. for each edge  $e = \{u, v\} \in E$  there exists an  $i \in I$  such that both  $u$  and  $v$  belong to  $X_i$ ;  
and
3. for all  $v \in V$ , the set of nodes  $\{i \in I | v \in X_i\}$  forms a connected subtree of  $T$ .

$X_i$ , a subset of  $V(G)$ , is called the *bag* of node  $i$ . The maximum size of a bag in  $TD(G)$  minus one is called the *width* of the tree decomposition. The *treewidth* of a graph, denoted as  $tw(G)$ , is the minimum width over all possible tree decompositions of the graph. The

problem of deciding whether the treewidth of a given graph is at most  $k$  is NP-complete. However, there are efficient constructive algorithms when  $k$  is small ( $k \leq 4$ ) or the input graph is outerplanar. There are also FPT approximation algorithms that guarantee a constant approximation factor [4].

A *nice* tree decomposition  $(X = \{X_i | i \in I\}, T = (I, F))$  is a tree decomposition such that  $|I| = O(\text{tw}(G) \cdot |V|)$ ,  $T$  is a rooted binary tree with three types of internal nodes:

1. a join node that has two children  $lc(i), rc(i)$ ,  $X_{lc(i)} = X_{rc(i)} = X_i$ .
2. a forget node that has one child  $lc(i)$ ,  $X_i \subset X_{lc(i)}$  and  $|X_i| = |X_{lc(i)}| - 1$ .
3. an introduce node that has one child  $lc(i)$ ,  $X_{lc(i)} \subset X_i$  and  $|X_{lc(i)}| = |X_i| - 1$ .

Note that a tree decomposition can be transformed into a nice tree decomposition in linear time.

In this section, we assume that a nice tree decomposition  $(X, T)$  for  $G$  with width  $\text{tw}(G)$  is given. We also assume that the bags of the root and the leaves are empty. Let  $T_i$  denote the subtree of  $T$  rooted at node  $i$ . Let  $X_{T_i} = \bigcup_{i \in T_i} X_i$  and  $b = \text{tw}(G) + 1$ .

We solve GAEM for graphs with bounded treewidth by generalizing the dynamic programming algorithm described in Section 4.1 for trees. Consider a tree  $\hat{T} = (\hat{V}, \hat{E})$ . A node  $\hat{v}$  in  $\hat{V}$  is the link point between the two subtrees  $\hat{T}_{\hat{v}}$  and  $\hat{T} \setminus (\hat{T}_{\hat{v}} \setminus \{\hat{v}\})$ .

A tree decomposition defines a sequence of separators of the graph. The separator is the link between the two separated parts of the graph. For any  $V' \subseteq V$ , let  $G(V')$  denote the subgraph of the input graph  $G$  induced by vertices in  $V'$ . For a node  $i$  of  $T$  in  $(X, T)$ ,  $X_i$  is a separator between  $G(X_{T_i})$  and  $G(V \setminus (X_{T_i} \setminus X_i))$ . Each vertex in  $X_i$  is a link point. For each vertex  $v_{i,j}$  in  $X_i$ , let  $D^\uparrow(v_{i,j}) = \bigcup_{u \in V \setminus (X_{T_i} \setminus X_i)} (d_G(v_{i,j}, u) + |us|)$  and let  $D^\downarrow(v_{i,j}) = \bigcup_{u \in X_{T_i}} (d_G(v_{i,j}, u) + |us|)$ . Each distance in  $D^\uparrow(v_{i,j})$  is the weight of a path from  $v_{i,j}$  to a vertex  $u$  in  $V \setminus (X_{T_i} \setminus X_i)$ , plus the shortcut  $(u, s)$ . We say the distance is *realized* by  $u$ . The distances in  $D^\downarrow(v_{i,j})$  are defined in the same way but through a vertex  $u$  in  $X_{T_i}$ . As in Section 4.1 we will need the subset  $D^\downarrow(v_{i,j}, d)$  of  $D^\downarrow(v_{i,j})$ , containing all distances in  $D^\downarrow(v_{i,j})$  that are at least  $d$ .

At node  $i$  of  $(X, T)$ , let  $t_i^\uparrow = (d_{i,1}^\uparrow, \dots, d_{i,|X_i|}^\uparrow)$  denote a tuple where  $d_{i,j}^\uparrow \in D^\uparrow(v_{i,j})$  is the weight of the shortest path from  $v_{i,j}$  to  $s$  going through a shortcut added to a vertex in  $V \setminus (X_{T_i} \setminus X_i)$ ,  $1 \leq j \leq |X_i|$ . Similarly we can define  $t_i^\downarrow = (d_{i,1}^\downarrow, \dots, d_{i,|X_i|}^\downarrow)$ . Let  $v_{i,j}^\uparrow, 1 \leq j \leq |X_i|$  denote the vertex in  $V \setminus (X_{T_i} \setminus X_i)$  that realizes  $d_{i,j}^\uparrow$ , and  $v_{i,j}^\downarrow$  denote the vertex in  $X_{T_i}$  that realizes  $d_{i,j}^\downarrow$ . We say that  $d_{i,j}^\uparrow$  and  $d_{i,j}^\downarrow$  are *components* of  $t_i^\uparrow$  and  $t_i^\downarrow$ , respectively. For a given node  $i$  and three parameters  $t_i^\uparrow, t_i^\downarrow$  and  $\bar{k}$  the subproblem is to find a set of  $\bar{k}$  shortcuts from  $s$  to vertices in  $X_{T_i}$  so that the maximum distance from vertices in  $X_{T_i}$  to  $s$  is minimized, assuming the distance tuples  $t_i^\uparrow$  and  $t_i^\downarrow$ .

Before we define the recursive steps we will need a few more notations. Let  $R_i[t_i^\uparrow][t_i^\downarrow][\bar{k}]$  denote the minimum maximum distance from a vertex in  $X_{T_i}$  to  $s$ , where  $\bar{k}$  shortcuts are allowed to be added between  $s$  and vertices in  $X_{T_i}$ , assuming the distance tuples  $t_i^\uparrow$  and  $t_i^\downarrow$ .

In Section 4.1, we defined  $W_{\hat{v}}$  for a link point  $\hat{v}$  between  $\hat{T}_{\hat{v}}$  and  $\hat{T} \setminus (\hat{T}_{\hat{v}} \setminus \{\hat{v}\})$ . For graphs of bounded treewidth we have  $|X_i|$  link points at node  $i$  of  $(X, T)$ . Assume  $i$  is a join node with left child  $lc(i)$  and right child  $rc(i)$ . A component  $d_{i,j}^\downarrow$  of  $t_i^\downarrow$  is realized by a vertex  $v_{i,j}^\downarrow$ . If  $v_{i,j}^\downarrow$  is in the left subtree  $T_{lc(i)}$  of  $T_i$  then  $d_{rc(i),j}^\downarrow$  must be at least  $d_{i,j}^\downarrow$ . The reverse is symmetrically true. So we let  $t_i^\downarrow = (t_{i1}^\downarrow, t_{i2}^\downarrow) = \{d_{i,1}^\downarrow, \dots, d_{i,|X_i|}^\downarrow\}$  be the  $t^\downarrow$  parameter to a  $W_i$ . If  $d_{i,j}^\downarrow \in t_{i1}^\downarrow$  then the component equals  $d_{i,j}^\downarrow$ . If  $d_{i,j}^\downarrow \in t_{i2}^\downarrow$  then the component is at least  $d_{i,j}^\downarrow$ .

## 45:10 Augmenting Graphs to Minimize the Radius

Thus

$$W_i[t_i^\uparrow][t_i^\downarrow] = (t_{i1}^\downarrow; t_{i2}^\downarrow)[\bar{k}] = \min\{R_i[t_i^\uparrow][d_{i,1}, \dots, d_{i,|X_i|}][\bar{k}]\},$$

where  $d_{i,j} = d_{i,j}^\downarrow$  if  $d_{i,j}^\downarrow \in t_{i1}^\downarrow$  and  $d_{i,j} \in D^\downarrow(v_{i,j}, d_{i,j}^\downarrow)$  if  $d_{i,j}^\downarrow \in t_{i2}^\downarrow$ . There are  $2^{|X_i|} - 1$  nonempty subset of  $X_i$ , so we need to define  $2^{|X_i|} - 1$   $W_i$ s with different components in  $t_{i1}^\downarrow$  and  $t_{i2}^\downarrow$ .

**Additional complexity for graphs with bounded treewidth.** The definitions and notations above corresponds closely to similar concepts in Section 4.1. However, there are a couple of complications that we have to take care of specifically for graphs with bounded treewidth. Firstly, we have to handle the three types of nodes (join, introduce and forget nodes) differently. This will be discussed in detail below. Secondly, two aspects of the computation at a node of  $(X, T)$  become more complex.

1. *Feasible* values of  $t_i^\uparrow$  and  $t_i^\downarrow$ . Not every combination of the values of each  $d_{i,j}^\downarrow$  forms a feasible value of  $t_i^\uparrow$ . We say a  $t_i^\uparrow$  is *feasible* only if it can be realized by some set of shortcuts (The formal definition appears in Appendix F).
2. There are  $(2^{|X_i|} - 1)$   $W_i$ s to be computed from  $R_i$ .

We discuss how to handle these two problems in Appendix F.

Next we explain the recursion steps at join, introduce and forget nodes.

**Join nodes.** A join node  $i$  has two children  $lc(i)$  and  $rc(i)$ . We need to compute  $R_i$  from  $R_{lc(i)}$ ,  $W_{lc(i)}$ ,  $R_{rc(i)}$  and  $W_{rc(i)}$ . More specifically, we need to determine the tuples  $t_{lc(i)}^\uparrow$ ,  $t_{lc(i)}^\downarrow$ ,  $t_{rc(i)}^\uparrow$  and  $t_{rc(i)}^\downarrow$  from  $t_i^\uparrow$  and  $t_i^\downarrow$ .

A partition of  $V$  for the separations between  $i$  and its children is shown in Figure 3(a). We use three copies of  $X_i$  for ease of illustration. For a component  $d_{i,j}^\downarrow$  of  $t_i^\downarrow$ ,  $v_{i,j}^\downarrow$  can be a vertex in  $X_i$ , or in  $(X_{T_{lc(i)}} \setminus X_i)$ , or in  $(X_{T_{rc(i)}} \setminus X_i)$ . If  $v_{i,j}^\downarrow$  is in  $X_i$ , both  $d_{lc(i),j}^\downarrow$  and  $d_{rc(i),j}^\downarrow$  equal  $d_{i,j}^\downarrow$ . Any path from  $v_{i,j}$  to  $s$  that goes through a shortcut incident to a vertex in  $X_{T_{rc(i)}} \setminus X_i$  has weight at least  $d_{lc(i),j}^\downarrow$  so we can set  $d_{lc(i),j}^\uparrow = d_{i,j}^\uparrow$ , and similarly  $d_{rc(i),j}^\uparrow = d_{i,j}^\uparrow$ .

If  $v_{i,j}^\downarrow$  is in  $X_{T_{lc(i)}} \setminus X_i$ , then  $d_{lc(i),j}^\downarrow = d_{i,j}^\downarrow$  and  $d_{rc(i),j}^\downarrow$  is at least  $d_{i,j}^\downarrow$ . Any path from  $v_{i,j}$  to  $s$  that goes through a shortcut incident to a vertex in  $X_{T_{rc(i)}} \setminus X_i$  has length at least  $d_{lc(i),j}^\downarrow$  so we can set  $d_{lc(i),j}^\uparrow = d_{i,j}^\uparrow$ . For  $rc(i)$ , it is possible that  $d_{i,j}^\downarrow < d_{i,j}^\uparrow$ , so we set  $d_{rc(i),j}^\uparrow = \min\{d_{i,j}^\uparrow, d_{i,j}^\downarrow\}$ . The case when  $v_{i,j}^\downarrow$  is in  $X_{T_{rc(i)}} \setminus X_i$  is handled symmetrically.

The recursive relation for  $R_i$  is then:

$$R_i[t_i^\uparrow][t_i^\downarrow][\bar{k}] = \min_{k_1, k_2} \{ \max\{ W_{lc(i)}[t_{lc(i)}^\uparrow][t_{lc(i)}^\downarrow; t_{lc(i)2}^\downarrow][k_1], \\ W_{rc(i)}[t_{rc(i)}^\uparrow][t_{rc(i)1}^\downarrow; t_{rc(i)2}^\downarrow][k_2] \} \},$$

where  $k_1$  plus  $k_2$  equals  $\bar{k}$  plus the number of shortcuts added to vertices in  $X_i$ . The  $t^\uparrow$  and  $t^\downarrow$  tuples for  $W_{lc(i)}$  and  $W_{rc(i)}$  are derived as discussed above. Note that when  $t_{lc(i)2}^\downarrow = \emptyset$ ,  $W_{lc(i)} = R_{lc(i)}$ .

Next we analyze the time spent at a join node. As shown in Appendix F, computing all feasible values of  $t_i^\uparrow$  and  $t_i^\downarrow$  for  $R_i$  requires  $O(bn^b)$  time. For a given  $t_i^\uparrow$  value, computing  $R_i$  for all feasible values of  $t_i^\downarrow$  and  $\bar{k}$  takes  $O(k^2b \cdot |X_{T_i}|^{|X_i|}) = O(k^2bn^b)$  time. As discussed in Appendix F, computing all values for a  $W_i$  takes  $O(kb^2n^{2b})$  time. Since there are  $(2^b - 1)$  different  $W_i$ s the total time spent at a join node is  $O((k^2b + kb^22^b) \cdot n^{2b})$ .

■ **Figure 3** (a) Partition of  $V$  at a join node  $i$  for the separations between  $i$  and its children. (b) Separation at an introduce node  $i$ ,  $v_{i,|X_i|}$  is colored blue.

**Introduce node.** Consider an introduce node  $i$  and let  $c(i)$  be its child. Without loss of generality, let  $v_{i,|X_i|}$  be the vertex introduced at  $i$ . From the property of a tree decomposition, any path from  $v_{i,|X_i|}$  to a vertex in  $\{X_{T_i} \setminus X_i\}$  must go through a vertex in  $X_i \setminus \{v_{i,|X_i|}\}$ , see Fig. 3(b). We compute  $R_i$  from  $R_{c(i)}$  or  $W_{c(i)}$ . For given  $t_i^\uparrow$ ,  $t_i^\downarrow$  and  $\bar{k}$ , we need to determine the corresponding  $t_{c(i)}^\uparrow$  and  $t_{c(i)}^\downarrow$ . We consider two cases, depending on whether  $v_{i,|X_i|}$  is incident to one of the  $\bar{k}$  shortcuts, or not.

1.  $d_{i,|X_i|}^\downarrow \neq |s, v_{i,|X_i|}|$ , that is,  $v_{i,|X_i|}$  is not incident to any of the  $\bar{k}$  shortcuts. For any  $d_{i,j}^\uparrow$ ,  $j \neq |X_i|$ , the corresponding  $d_{c(i),j}^\uparrow$  is realized by the same vertex as  $d_{i,j}^\uparrow$ . Thus  $d_{c(i),j}^\uparrow = d_{i,j}^\uparrow$ , where  $j \neq |X_i|$ . Similarly,  $d_{c(i),j}^\downarrow = d_{i,j}^\downarrow$ , where  $j \neq |X_i|$ . For given  $t_i^\uparrow$ ,  $t_i^\downarrow$  and  $\bar{k}$  at introduce node  $i$ , the maximum distance from all vertices in  $X_{T_{c(i)}}$  to  $s$  is  $R_{c(i)}[t_{c(i)}^\uparrow][t_{c(i)}^\downarrow][\bar{k}]$ . The distance from  $v_{i,|X_i|}$  to  $s$  is the minimum of  $d_{i,|X_i|}^\uparrow$  and  $d_{i,|X_i|}^\downarrow$ . As a result we have:

$$R_i[t_i^\uparrow][t_i^\downarrow][\bar{k}] = \max\{R_{c(i)}[t_i^\uparrow \setminus d_{i,|X_i|}^\uparrow][t_i^\downarrow \setminus d_{i,|X_i|}^\downarrow][\bar{k}], \min\{d_{i,|X_i|}^\uparrow, d_{i,|X_i|}^\downarrow\}\}.$$

2.  $d_{i,|X_i|}^\downarrow = |s, v_{i,|X_i|}|$ , that is,  $v_{i,|X_i|}$  is incident to one of the  $\bar{k}$  shortcuts. By definition,  $d_{c(i),j}^\uparrow$ ,  $j \neq |X_i|$ , equals the minimum of  $d_{i,j}^\uparrow$  and  $d_G(v_{i,j}, v_{i,|X_i|}) + |s, v_{i,|X_i|}|$ . For any such  $d_{i,j}^\downarrow$ ,  $j \neq |X_i|$ , that  $v_{i,j}^\downarrow$  is not  $v_{i,|X_i|}$ , the corresponding  $d_{c(i),j}^\downarrow$  equals  $d_{i,j}^\downarrow$ . For any such  $d_{i,j}^\downarrow$ ,  $j \neq |X_i|$ , that  $v_{i,j}^\downarrow$  is  $v_{i,|X_i|}$ , the corresponding  $d_{c(i),j}^\downarrow$  is greater than  $d_{i,j}^\downarrow$ . For given  $t_i^\uparrow$ ,  $t_i^\downarrow$  and  $\bar{k}$  at an introduce node  $i$ , the maximum distance from all vertices in  $X_{T_{c(i)}}$  to  $s$  is  $W_{c(i)}[t_{c(i)}^\uparrow][t_{c(i)}^\downarrow][\bar{k} - 1]$ . The distance from  $v_{i,|X_i|}$  to  $s$  is  $|s, v_{i,|X_i|}|$ . Thus,

$$R_i[t_i^\uparrow][t_i^\downarrow][\bar{k}] = \max\{W_{c(i)}[(d_{c(i),1}^\uparrow, \dots, d_{c(i),|X_i|-1}^\uparrow)][(t_{c(i)1}^\downarrow; t_{c(i)2}^\downarrow)][\bar{k} - 1], |s, v_{i,|X_i|}|\},$$

where  $d_{c(i),j}^\uparrow = \min\{d_{i,j}^\uparrow, d_G(v_{i,j}, v_{i,|X_i|}) + |s, v_{i,|X_i|}|\}$ , for  $j < |X_i|$ . If  $d_{i,j}^\downarrow$  is not realized by  $v_{i,|X_i|}$ , for  $j < |X_i|$ , then  $d_{c(i),j}^\downarrow = d_{i,j}^\downarrow$  and is a component of  $t_{c(i)1}^\downarrow$ . Otherwise,  $d_{c(i),j}^\downarrow > d_{i,j}^\downarrow$  and is a component of  $t_{c(i)2}^\downarrow$ .

The time required to compute the  $R_i$  values is  $O(kbn^{2b})$ . The  $W_i$ s are computed from  $R_i$  in the same way as for a join node, hence, in totally  $O(kb^22^bn^{2b})$  time. As a result, the time spent at an introduce node is  $O(kb^22^b \cdot n^{2b})$ .

**Forget node.** Assume  $i$  is a forget node and  $c(i)$  is its child. Without loss of generality, assume  $v_{c(i),|X_{c(i)}|}$  is the vertex forgotten at  $i$ . As usual, we compute  $R_i$  from values of  $R_{lc(i)}$  or  $W_{c(i)}$ .  $v_{i,j} = v_{c(i),j}$ ,  $j < |X_{c(i)}|$ . By definition,  $d_{c(i),j}^\uparrow = d_{i,j}^\uparrow$ , for all  $j < |X_{c(i)}|$ . In the input graph  $G$ , any path from  $v_{c(i),|X_{c(i)}|}$  to a vertex in  $V \setminus X_{T_i}$  must go through a vertex in  $X_i$ . Thus the corresponding  $d_{c(i),|X_{c(i)}|}^\uparrow$  equals  $\min\{d_{i,j}^\uparrow + d_G(v_{i,j}, v_{c(i),|X_{c(i)}|}) \mid j < |X_{c(i)}|\}$ . By definition,  $d_{c(i),j}^\downarrow = d_{i,j}^\downarrow$  for all  $j < |X_{c(i)}|$ . However,  $d_{c(i),|X_{c(i)}|}^\downarrow$  can take a number of different values. The only constraint is that it forms a feasible  $t_{c(i)}^\downarrow$  together with all other  $d_{c(i),j}^\downarrow$  values,  $j < |X_{c(i)}|$ . Thus  $R_i$  is computed from  $W_{c(i)}$  where  $d_{c(i),|X_{c(i)}|}^\downarrow$  is the only component in  $t_{c(i)2}^\downarrow$  and takes the minimum value that forms a feasible  $t_{c(i)}^\downarrow$  with all other  $d_{c(i),j}^\downarrow$ ,  $j < |X_{c(i)}|$ .

$$R_i[t_i^\uparrow][t_i^\downarrow][\bar{k}] = W_{c(i)}[t_{c(i)}^\uparrow][t_{c(i)1}^\downarrow = t_i^\downarrow; t_{c(i)2}^\downarrow][\bar{k}],$$

where  $d_{c(i),|X_{c(i)}|}^\downarrow \in t_{c(i)2}^\downarrow$ . The  $W_i$ s are computed from  $R_i$  as before. The time spent at a forget node is  $O(kb^22^b \cdot n^{2b})$ .

Since there are  $O(bn)$  nodes in a nice tree decomposition we conclude this section with the following theorem.

► **Theorem 12.** *When the input graph  $G$  is a metric graph with bounded treewidth, GAEM problem can be solved in  $O((k^2b^2 + kb^32^b) \cdot n^{2b+1})$  time, where  $b = tw(G) + 1$ . The metric BCMR problem on graphs with bounded treewidth can be solved in  $O((k^2b^2 + kb^32^b) \cdot n^{2b+2})$  time.*

**A Proof of Lemma 1**

► **Lemma 1** Given a metric graph  $G = (V, E, \ell)$ , an integer  $k$  and a vertex  $s$  in  $V$  for the GAEM problem, there is an optimal solution where every shortcut is incident to  $s$ .

**Proof.** Let  $F^*$  be an optimal solution and  $G^* = (V, E \cup F^*, \ell)$ . Let  $ecc^*(s)$  be the eccentricity of  $s$  in  $G^*$  and let  $T$  be the shortest path tree rooted at  $s$ . If every edge in  $F^*$  is incident to  $s$  then the lemma immediately holds. Otherwise there exists at least one edge  $(p, q)$  in  $F^*$  that is not incident to  $s$ . We will show that  $(p, q)$  can be replaced by either  $(s, p)$  or  $(s, q)$  such that the eccentricity of  $s$  in the resulting graph does not increase.

If  $(p, q)$  is an edge in  $T$ , then there is a subset  $U$  of  $V$  that go through  $(p, q)$  on their shortest paths to  $s$  in  $T$ . Without loss of generality assume  $d_T(p, s) < d_T(q, s)$ , as shown in Fig. 4. The set  $U$  is the vertices in the subtree  $T_q$  of  $T$  rooted at  $q$ . By triangle inequality  $|sq| \leq d_T(s, q)$ . Replace  $(p, q)$  by  $(s, q)$  to get  $T'$ . Then every vertex in  $T'_q$  now has a path to  $s$  no longer than its shortest path in  $T$ , and every vertex not in  $T_q$  can still use their shortest path in  $T$ . Consequently,  $ecc(s)$  in  $T'$  is at most  $ecc^*(s)$ .

If  $(p, q)$  is not an edge in  $T$  then replace  $(p, q)$  by either  $(s, p)$  or  $(s, q)$ . Since every vertex can still use its shortest path in  $T$  the eccentricity of  $s$  does not increase. ◀

■ **Figure 4** (a) An example where all the edges of the graph have unit length. The two shortcuts in red show an optimal solution for the GAEM instance with  $k = 2$ . (b) Illustrating the proof for Lemma 1.

**B Proof of Lemma 2**

► **Lemma 2** *Algorithm 1 is a 3-approximation algorithm for the GAEM problem.*

**Proof.** Let  $A = \{q_1, q_2, \dots, q_t\}$  be the set of vertices that are adjacent to  $s$  in  $G$ . If Algorithm 1 adds less than  $k$  shortcuts, the augmentation is optimal. Otherwise, let  $U = \{p_1, p_2, \dots, p_k\}$  be the set of vertices such that  $(s, p_i) (i = 1, \dots, k)$  is a shortcut added by Algorithm 1. Remember from Lemma 1 there is always an optimal solution  $F^*$  where all the shortcuts are incident to  $s$ . Assume  $B = \{c_1, c_2, \dots, c_k\}$  is the set of vertices such that  $(s, c_i)$  is a shortcut in  $F^*$ . Let  $\text{ecc}^*(s)$  denote the eccentricity of  $s$  in  $G^* = (V, E \cup F^*, \ell)$ .  $A \cup B$  is the set of vertices that are adjacent to  $s$  in  $G^*$ . Any vertex  $w$  other than  $s$  must go through exactly one vertex  $v$  in  $A \cup B$  (may be itself) on its shortest path to  $s$  in  $G_s^*$ . Let  $S(v), v \in A \cup B$  denote the set of vertices that go through  $v$  on their shortest paths to  $s$  in  $G^*$ .  $\{S(v) : v \in A \cup B\}$  forms a partition of all the vertices other than  $s$ . We need to prove that the graph distance from  $w$  to  $s$  in  $\hat{G}$  is at most  $3\text{ecc}^*(s)$ .

If  $v \in A$ ,  $d_G(w, s) \leq \text{ecc}^*(s)$  so the distance from  $w$  to  $s$  in  $\hat{G}$  is at most  $\text{ecc}^*(s)$ . If any  $p_i \in U$  is in a  $S(q_j)$  where  $q_j \in A$ ,  $d_G(p_i, s) \leq \text{ecc}^*(s)$ . At the time  $p_i$  is picked by Algorithm 1,  $p_i$  is the farthest vertex to  $s$ , so Algorithm 1 returns an optimal solution. What is left is when  $v \in B$  and no  $p_i \in U$  is in any  $S(q_j)$  where  $q_j \in A$ . Any  $p_i$  must be in some  $S(c_i)$  where  $c_i \in B$ .

If there is a  $p_i \in U$  in  $S(v)$ , as in Figure 5(a), there is a path from  $w$  to  $s$  in  $\hat{G}$  that goes through  $v$  and  $p_i$  and has weight  $d_G(w, v) + d_G(v, p_i) + |sp_i|$ . Both  $d_G(w, v)$  and  $d_G(v, p_i)$  are at most  $\text{ecc}^*(s)$ . By the triangle inequality,  $|sp_i| \leq \text{ecc}^*(s)$ . Thus the distance from  $w$  to  $s$  in  $\hat{G}$  is at most  $3\text{ecc}^*(s)$ .

Otherwise, there is no  $p_i \in U$  in  $S(v)$ .  $|U| = |B|$ . By the pigeonhole principle, there must exist a vertex  $v' \in B$  such that two vertices  $p_l, p_m \in U$  are in  $S(v')$ , as shown in Figure 5(b). Without loss of generality, assume  $p_l$  is picked before  $p_m$  in  $\hat{G}$ . When  $p_m$  is about to be added a shortcut, it is the farthest vertex to  $s$ . The distance from  $w$  to  $s$  in  $\hat{G}$  is thus at most  $d_G(p_m, v') + d_G(v', p_l) + |sp_l| \leq 3\text{ecc}^*(s)$ , which is an upper bound of  $p_m$ 's distance to  $s$  before it is added a shortcut. ◀

■ **Figure 5** (a) There is a vertex  $p_i \in U$  in  $S(v)$ . (b) There is no vertex  $p_i \in U$  in  $S(v)$ .

**C Proof of Lemma 6**

► **Lemma 6** For any  $\epsilon > 0$ , finding a  $(\frac{5}{3} - \epsilon)$  approximate solution for the GAEM problem on geometric graphs is NP-hard.

**Proof.** In [5], Chang and Nemhauser proved that the Dominating Set decision problem for bipartite graphs is NP-hard. We use a reduction from this problem to show the approximation hardness of GAEM on geometric graphs.

Let  $G = (V = V_1 \cup V_2, E)$  be a bipartite graph where  $V_1$  and  $V_2$  are disjoint and every edge in  $E$  connects one vertex in  $V_1$  to one vertex in  $V_2$ . Let  $I = (G, k)$ ,  $k < |V_1 \cup V_2|$ , be an instance of the Dominating Set decision problem for bipartite graphs. Without loss of generality, assume  $|V_1| \geq |V_2|$  and let  $m = |V_1|$ . We can embed  $G$  in the plane. Place vertices in  $V_1$  at positions  $(0, 0), (\epsilon/2(m-1), \epsilon/2(m-1)), \dots, (\epsilon/2, \epsilon/2)$  and place vertices in  $V_2$  at positions  $(2, 0), (2 - \epsilon/2(m-1), 2 - \epsilon/2(m-1)), \dots, (2 - \epsilon(n-1)/2(m-1), 2 - \epsilon(n-1)/2(m-1))$ . Then add vertex  $s$  at position  $(1, 0)$ . See Figure 6. We have a graph  $G' = (V' = V \cup \{s\}, E' = E, \ell)$  where  $\ell$  is the Euclidean distance function.  $I$  is transformed into an instance  $I' = (G', s, k, 3)$  of GAEM on geometric graphs. For any point  $p$  in  $V_1$  and any point  $q$  in  $V_2$ , we have  $1 - \epsilon/2 \leq |sp| \leq 1$  and  $2 - \epsilon \leq |pq| \leq 2$ .  $G$  has a dominating set of size  $k$  if and only if we can add  $k$  shortcuts to  $G'$  so that the eccentricity of  $s$  in the resulting graph is at most 3. The shortest path from a vertex to  $s$  that goes through 1 shortcut and 2 edges in  $E$  has length at least  $5 - 5\epsilon/2$ . Since  $3 \cdot (\frac{5}{3} - \epsilon) = 5 - 3\epsilon < 5 - 5\epsilon/2$ , a  $(\frac{5}{3} - \epsilon)$  approximation algorithm for GAEM on geometric graphs solves  $I'$  and thus any instance of the Dominating Set decision problem. ◀

■ **Figure 6** A bipartite graph embedded in the plane.

**D An  $O(n^2 \log n)$  time algorithm for GAEM on trees**

We first devise an  $O(\min\{k^2n, n^2\})$  time algorithm that solves the decision problem of GAEM on trees. Then we search for an optimal solution by using the decision algorithm as a subroutine.

**D.1 The decision algorithm**

Given a value  $D$ , the decision algorithm decides whether we can add  $k$  shortcuts all incident to  $s$  to the input tree such that the eccentricity of  $s$  in the augmented graph is at most  $D$ . We introduce some notations that will be used in the discussion.

Let  $d_T(u, v)$  denote the distance between any two vertices  $u$  and  $v$  in  $T$ . Let  $\zeta$  be a set of  $\bar{k}$  ( $\bar{k} \leq k$ ) shortcuts added to vertices in  $T_v$ , where  $T_v$  is the subtree of  $T$  rooted at  $v$ . If from a vertex in  $T_v$  we can go along a path inside  $T_v$  and then through a shortcut in  $\zeta$  to reach  $s$  within distance  $D$ , we say this vertex is covered by  $\zeta$ , for example the red vertex

## 45:16 Augmenting Graphs to Minimize the Radius

in Figure 7(a); otherwise we say it is uncovered by  $\zeta$ . Let  $U_v(\zeta)$  denote the set of vertices uncovered by  $\zeta$  in  $T_v$ . When  $U_v(\zeta)$  is empty, we say  $T_v$  is covered by  $\zeta$ ; otherwise we say  $T_v$  is uncovered by  $\zeta$ . To reach  $s$  within  $D$  from an uncovered vertex in  $U_v(\zeta)$ , we have to go along a path out of  $T_v$  and then through a shortcut<sup>2</sup> added to a vertex in  $T \setminus T_v$ , if at all possible. See the red vertex  $p$  in Figure 7(b) for an example. Let  $g_v(\zeta) = \max_{u \in U_v(\zeta)} d_T(u, v)$  denote the maximum distance from a vertex in  $U_v(\zeta)$  to  $v$  in  $T$ . Let  $d_v(\zeta)$  denote the length of the shortest path from  $v$  to  $s$  that goes through a shortcut in  $\zeta$ .

The decision algorithm is used to solve an optimization problem. The optimization problem aims to find shortcuts that are optimal in incurring a “Yes” solution to the decision problem. Generally, given any integer  $\bar{k} \leq k$  and any vertex  $v$ , the optimization problem is to add  $\bar{k}$  shortcuts to vertices in  $T_v$  so that they are optimal in incurring a “Yes” solution to the decision problem on  $T$ . Before we formally define the meaning of being optimal in incurring a “Yes” solution, we first give a supporting lemma.

As discussed above,  $\zeta$  is a set of  $\bar{k}$  shortcuts added to vertices in  $T_v$ .

■ **Figure 7** (a)  $\bar{k}$  shortcuts are added to  $T_v$ . (b) Some vertices in  $T_v$  are uncovered.

► **Lemma 13.** *If  $U_v(\zeta)$  is nonempty and  $\zeta$  is part of a “Yes” solution to the decision problem of GAEM on  $T$ , then in the “Yes” solution*

- 1) *all vertices in  $U_v(\zeta)$  go through the same shortcut added to a vertex in  $T \setminus T_v$  on their shortest paths to  $s$ .*
- 2) *vertices in  $T \setminus T_v$  does not go through any shortcut in  $\zeta$  on their shortest paths to  $s$ .*

**Proof.** In the “Yes” solution, all vertices in  $U_v(\zeta)$  must first go up to  $v$ , then follow the  $v - s$  shortest path which cannot go through a shortcut in  $\zeta$ . So property 1) is true.  $U_v(\zeta)$  is nonempty, thus

$$g_v(\zeta) + d_v(\zeta) > D. \quad (1)$$

Let  $\gamma$  denote the shortcut that the shortest paths from vertices in  $U_v(\zeta)$  to  $s$  go through. If  $\gamma$  is incident to a vertex in  $T_v$ 's sibling  $T_w$ , for example the darkred vertex  $o$  in Figure 7(b), we have

$$g_v(\zeta) + |uv| + |uw| + d_w(\zeta') \leq D, \quad (2)$$

where  $\zeta'$  is the set of shortcuts added to vertices in  $T_w$ . Equation 1 and 2 imply that  $d_v(\zeta) > |uw| + d_w(\zeta')$ , which means for every vertex in  $T \setminus T_v$ , the shortest path through  $\gamma$  to  $s$  is shorter than any shortest path through a shortcut in  $\zeta$ . If  $\gamma$  is incident to a vertex in

<sup>2</sup> For ease of discussion, we consider the edges that are incident to  $s$  in  $T$  as pre-added shortcuts.

$T \setminus T_v \setminus T_w$ , like the blue vertex in Figure 7(b), we can similarly show that for every vertex in  $T \setminus T_v$ , a shortest path through  $\gamma$  to  $s$  is shorter than any shortest path through a shortcut in  $\zeta$ . Property 2) is proved. ◀

We now discuss the meaning of a  $\zeta$  being optimal in incurring a “Yes” solution to the decision problem on  $T$ . Consider two sets  $\zeta_1$  and  $\zeta_2$ :

1. if both  $U_v(\zeta_1)$  and  $U_v(\zeta_2)$  are nonempty. Without loss of generality, assume  $g_v(\zeta_1) < g_v(\zeta_2)$ . Assume  $\zeta_2$  is part of a “Yes” solution to the decision problem. Replace  $\zeta_2$  by  $\zeta_1$ . Lemma 13 implies that the resulting solution is still a “Yes” solution. The reverse is not true.  $\zeta_1$  place lower requirement on shortcuts added to vertices outside  $T_v$ . Thus  $\zeta_1$  is better in making a “Yes” solution to the decision problem than  $\zeta_2$ .
2. one of  $U_v(\zeta_1)$  and  $U_v(\zeta_2)$  is empty while the other is nonempty. Without loss of generality, assume  $U_v(\zeta_1)$  is empty. Assume  $\zeta_2$  is part of a “Yes” solution to the decision problem. Replace  $\zeta_2$  by  $\zeta_1$ . From Lemma 13(b), the resulting solution is still a “Yes” solution.  $\zeta_1$  places no requirement on the shortcuts added to vertices in  $T \setminus T_v$  but  $\zeta_2$  does. Thus  $\zeta_1$  is better in making a “Yes” solution to the decision problem than  $\zeta_2$ .
3. both  $U_v(\zeta_1)$  and  $U_v(\zeta_2)$  are empty. Assume  $d_v(\zeta_1) < d_v(\zeta_2)$ . If  $\zeta_2$  is part of a “Yes” solution to the decision problem, replacing  $\zeta_2$  by  $\zeta_1$  will still give a “Yes” solution. But for vertices in  $T \setminus T_v$ ,  $\zeta_1$  provides better shortcut than  $\zeta_2$ . Thus  $\zeta_1$  is better in making a “Yes” solution to the decision problem.

We can formally define the above *better in making a ‘Yes’ solution* relation on  $\zeta$ s. Use  $\prec$  to denote this relation. Then

$$\begin{aligned}
 &U_v \text{ empty, smaller } d_v \prec U_v \text{ empty, greater } d_v \\
 &\prec U_v \text{ nonempty, smaller } g_v \prec U_v \text{ nonempty, greater } g_v.
 \end{aligned}$$

A  $\zeta$  that has no other  $\zeta$ s preceding it in the  $\prec$  relation is an optimal  $\zeta$ .

The optimization problem is well-defined. By the optimal substructure of the optimization problem, we can use dynamic programming to solve the problem. Let  $opt(v, \bar{k})$  denote an optimal solution of the problem on  $T_v$  with  $\bar{k}$ . When a solution uncovers  $T_v$ , we keep track of  $g_v$ . When a solution covers  $T_v$ , we keep track of  $d_v$ . The recursive formula of  $opt(v, \bar{k})$  is:

$$opt(v, \bar{k}) = \min_{\prec} \{combine(f, opt(lc(v), k'), opt(rc(v), \bar{k} - k' - f)) | 0 \leq k' \leq \bar{k} - f, f = 0/1\},$$

where  $\min_{\prec}$  is the “minimum” in relation “ $\prec$ ” and  $f$  flags whether a shortcut is added to  $v$ . When combining the optimal sub-solutions of the left child  $lc(v)$  and the right child  $rc(v)$ ,

■ **Figure 8** (a)  $(s, v)$  is not added as a shortcut. (b)  $(s, v)$  is added as a shortcut.

there are two cases: 1)  $v$  is not added a shortcut, 2)  $v$  is added a shortcut. For case 1),  $k'$  shortcuts are added to vertices in  $T_{lc(v)}$  and  $\bar{k}-k'$  shortcuts are added to vertices in  $T_{rc(v)}$ . For case 2),  $k'$  shortcuts are added to vertices in  $T_{lc(v)}$  and  $\bar{k}-1-k'$  shortcuts are added to vertices in  $T_{rc(v)}$ . See Figure 8 for an illustration. The *combine* procedures for case 1) and case 2) are similar and we only discuss case 1) below.  $combine(0, opt(lc(v), k'), opt(rc(v), \bar{k}-k'))$  works as follows:

**Case 1:**  $opt(lc(v), k')$  covers  $T_{lc(v)}$  and  $opt(rc(v), \bar{k}-k')$  covers  $T_{rc(v)}$ . Check if  $\min\{|v, lc(v)| + d_{lc(v)}, |v, rc(v)| + d_{rc(v)}\} \leq D$ . If so,  $v$  and all other vertices in  $T_v$  are covered and  $d_v = \min\{|v, lc(v)| + d_{lc(v)}, |v, rc(v)| + d_{rc(v)}\}$ ; else  $T_v$  is uncovered and  $g_v = 0$ .

**Case 2:**  $opt(lc(v), k')$  covers  $T_{lc(v)}$  and  $opt(rc(v), \bar{k}-k')$  uncovers  $T_{rc(v)}$ . We need to check whether vertices in  $T_{rc(v)}$  uncovered by  $opt(rc(v), \bar{k}-k')$  is covered by  $opt(lc(v), k')$ . Check if  $g_{rc(v)} + |v, rc(v)| + |v, lc(v)| + d_{lc(v)} \leq D$ . If so,  $T_v$  is covered and  $d_v = |v, lc(v)| + d_{lc(v)}$ ; else  $T_v$  is uncovered and  $g_v = g_{rc(v)} + |v, rc(v)|$ .

**Case 3:**  $opt(lc(v), k')$  uncovers  $T_{lc(v)}$  and  $opt(rc(v), \bar{k}-k')$  covers  $T_{rc(v)}$ . Symmetric to case 2.

**Case 4:**  $opt(lc(v), k')$  uncovers  $T_{lc(v)}$  and  $opt(rc(v), \bar{k}-k')$  uncovers  $T_{rc(v)}$ .  $T_v$  is uncovered and  $d_v = \max\{g_{lc(v)} + |v, lc(v)|, g_{rc(v)} + |v, rc(v)|\}$ .

It is not hard to verify the correctness of the procedure.  $combine(1, opt(lc(v), k'), opt(rc(v), \bar{k}-k'))$  works similarly and is left to the interested reader. The combining procedure at the root is slightly different at the root, we omit the details here.

All that is left is analyzing the running time of the dynamic programming. Once  $opt(lc(v), k')$  and  $opt(rc(v), \bar{k}-k')$  are known, the *combine* procedure takes constant time. Thus we only need to count the number of times  $combine(0, \dots)$  and  $combine(1, \dots)$  are called for computing every  $opt(v, \bar{k})$ .  $\bar{k} \leq \min\{k, |T_v|\}$  and  $k' \leq \min\{\bar{k}, |T_{lc(v)}|\}$ . Using  $\bar{k} \leq k$  and  $k' \leq \bar{k}$  as upper bounds, at a vertex  $v$ ,  $combine(0, \dots)$  is called  $O(\sum_{\bar{k}=1}^k \bar{k}) = O(k^2)$

times. Similarly,  $combine(0, \dots)$  is called  $O(k^2)$  times. So we spend  $O(k^2)$  time at a vertex  $v$ . This gives a total running time of  $O(k^2n)$ . We also use  $\bar{k} \leq |T_v|$  and  $k' \leq |T_{lc(v)}|$  as upper bounds. We assume that  $T_{lc(v)} = T_{vs}$ , otherwise we can just swap  $lc(v)$  and  $rc(v)$ . Thus for all vertices in  $T$ ,  $combine(0, \dots)$  is called  $O(\sum_{v \in T} |T_v| \cdot |T_{vs}|) = O(n^2)$  times, by Lemma 9.

Similarly, for all vertices,  $combine(1, \dots)$  is called  $O(n^2)$  times. This gives a total running time of  $O(n^2)$ . Thus the total running time is  $O(\min\{k^2n, n^2\})$ .

► **Theorem 14.** *The decision problem of GAEM on trees can be solved in  $O(\min\{k^2n, n^2\})$  time.*

## D.2 The search algorithm

For any solution of  $k$  shortcuts all incident to  $s$ , there is a farthest vertex  $v$  to  $s$  in the augmented graph. The shortest path from  $s$  to  $v$  goes from  $s$  to a vertex  $u$  (which may be  $v$ ) through a shortcut or an edge in  $T$ , then follows the shortest path from  $u$  to  $v$  in  $T$ . Both  $u$  and  $v$  are vertices in  $T$ . So there are at most  $n^2$  possible values for the eccentricity of  $s$  in any augmented graph.

► **Lemma 15.** *There are at most  $n^2$  possible values for the eccentricity of  $s$  in any augmented graph where all shortcuts are incident to  $s$ .*

Since our input is a tree, we can compute all possible values in  $O(n^2)$  time. Then we sort the values and do a binary search over the sorted values, using the decision algorithm as a subroutine. The minimum value for which the decision algorithm returns a “Yes” solution is the minimum eccentricity incurred by an optimal solution. We can find an optimal solution in  $O(\min\{k^2n, n^2\} \cdot \log n + n^2 \log n) = O(n^2 \log n)$  time.

► **Theorem 16.** *GAEM on trees can be solved in  $O(n^2 \log n)$  time.*

## E

 Proofs of Lemma 8 and Corollary 9

► **Lemma 8**  $\sum_{v \in T} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq n^2$ .

**Proof.** We use induction on the number of tree nodes to prove the bound. When  $n = 1$ , the tree contains only one node and the bound holds trivially.

Assume  $\sum_{v \in T} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq n^2$  holds for all  $n < k$ . Then for trees of size  $n = k$ ,  $\sum_{v \in T} |T_{lc(v)}| \cdot |T_{rc(v)}| = \sum_{v \in T_{lc(s)}} |T_{lc(v)}| \cdot |T_{rc(v)}| + \sum_{v \in T_{rc(s)}} |T_{lc(v)}| \cdot |T_{rc(v)}| + |T_{lc(s)}| \cdot |T_{rc(s)}|$ , where  $s$  is the root of  $T$ . By the induction hypothesis,  $\sum_{v \in T_{lc(s)}} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq |T_{lc(s)}|^2$ ,  $\sum_{v \in T_{rc(s)}} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq |T_{rc(s)}|^2$ . Thus  $\sum_{v \in T} |T_{lc(v)}| \cdot |T_{rc(v)}| \leq |T_{lc(s)}|^2 + |T_{rc(s)}|^2 + |T_{lc(s)}| \cdot |T_{rc(s)}| \leq (|T_{lc(s)}| + |T_{rc(s)}|)^2 < n^2$ . ◀

► **Corollary 9**  $\sum_{v \in T} |T_v| \cdot \min\{|T_{lc(v)}|, |T_{rc(v)}|\} \leq 2n^2 + n \log n$ .

**Proof.** Let  $T_{vs}$  be the subtree rooted at a child of  $v$  such that  $|T_{vs}| = \min\{|T_{lc(v)}|, |T_{rc(v)}|\}$ . We know that  $\sum_{v \in T} |T_v| \cdot |T_{vs}| = \sum_{v \in T} (|T_{lc(v)}| + |T_{rc(v)}| + 1) \cdot |T_{vs}|$ , and by Lemma 8,  $\sum_{v \in T} (|T_{lc(v)}| + |T_{rc(v)}|) \cdot |T_{vs}| \leq 2n^2$ . For  $\sum_{v \in T} |T_{vs}|$ , we can see that a node in  $T$  is counted at most  $\log n$  times since for any  $T_v$ , only nodes in the subtree rooted at a child of  $v$  with fewer nodes are counted. Thus  $\sum_{v \in T} |T_{vs}| \leq n \log n$  and the corollary follows. ◀

## F

 How to compute feasible values and  $W_i$ s

We first formally define what is a feasible  $t_i^\uparrow$  value. The definition of a feasible  $t_i^\downarrow$  value is similar. Let  $t_i^\uparrow = (d_{i,1}^\uparrow, \dots, d_{i,|X_i|}^\uparrow)$ . For any two components  $d_{i,k}^\uparrow$  and  $d_{i,l}^\uparrow$ , the length of the shortest path from  $v_{i,k}$  to  $s$  that goes through shortcut  $(v_{i,l}, s)$  has to be at least  $d_{i,k}^\uparrow$ , otherwise  $d_{i,k}^\uparrow$  would have a smaller value. Conversely, the length of the shortest path from  $v_{i,l}$  to  $s$  that goes through shortcut  $(v_{i,k}, s)$  has to be at least  $d_{i,l}^\uparrow$ . The definition follows.

► **Definition 17.** *Let  $t_i^\uparrow = (d_{i,1}^\uparrow, \dots, d_{i,|X_i|}^\uparrow)$ .  $t_i^\uparrow$  is feasible if and only if for any  $1 \leq k < l \leq |X_i|$ ,  $d_G(v_{i,k}, v_{i,l}^\uparrow) + |v_{i,l}^\uparrow, s| \geq d_{i,k}^\uparrow$  and  $d_G(v_{i,l}, v_{i,k}^\uparrow) + |v_{i,k}^\uparrow, s| \geq d_{i,l}^\uparrow$ .*

To save space, we store feasible values of  $t_i^\uparrow$  (and  $t_i^\downarrow$ ) in a multilist. As a preprocessing step, we compute distances between any pair of vertices in  $G$  by using an all-pairs shortest paths algorithm. The distance between any pair of vertices in  $G$  can then be obtained in constant time. Let  $\mathcal{L}_i^\uparrow$  denote the multilevel list for  $t_i^\uparrow$ . Levels of  $\mathcal{L}_i^\uparrow$  are contain ordered values of  $d_{i,1}^\uparrow, \dots, d_{i,|X_i|}^\uparrow$ , respectively. We store the sorted values of  $\{d_G(v_{i,j}, u) + |us| \mid u \in V \setminus (X_{T_i} \setminus X_i)\}$  for each  $v_{i,j} \in X_i$  in a list  $l_j^\uparrow$ , separately. We build  $\mathcal{L}_i^\uparrow$  from  $\{l_j^\uparrow\}$ .

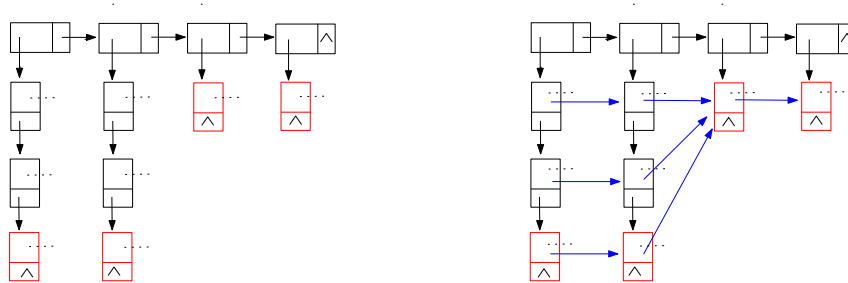

Besides  $d_{i,j}^\uparrow$  value, each node of the first level of  $\mathcal{L}_i^\uparrow$  stores a  $(|X_i| - 1)$ -level list. Each node of a second level of  $\mathcal{L}_i^\uparrow$  stores a  $(|X_i| - 2)$ -level list, and so on. Generally, a node in a  $k$ th ( $1 \leq k \leq |X_i|$ ) level list stores a  $(|X_i| - k)$ -level list. A  $k$ th level list is built recursively as follows. Assume  $d_{i,1}^\uparrow, \dots, d_{i,k-1}^\uparrow$  are the distance values contained in nodes of previous levels. We build this  $k$ th level list by  $l_k^\uparrow, \dots, l_{|X_i|}^\uparrow$ . For each  $d_{i,k}^\uparrow$  value in  $l_k^\uparrow$ , we check whether

the condition in Definition 17 is satisfied between  $d_{i,k}^\uparrow$  and each of  $d_{i,1}^\uparrow, \dots, d_{i,k-1}^\uparrow$ . If so, we create a node with the current  $d_{i,k}^\uparrow$  value, and build its  $(|X_i| - k)$ -level list recursively by  $l_{k+1}^\uparrow, \dots, l_{|X_i|}^\uparrow$ . In this way, we can build  $\mathcal{L}_i^\uparrow$  in  $O(bn^b)$  time. An example  $\mathcal{L}_i^\uparrow$  is shown in Figure 9(a). The  $d_{i,2}^\uparrow$  value stored at a red node in a vertical (second level) list is realized by the same vertex as the  $d_{i,1}^\uparrow$  value stored at its first level list node. Feasible values of  $t_i^\downarrow$  are constructed in the same way. To access values of  $R_i$  fast, we can encode feasible  $t_i^\uparrow$  and  $t_i^\downarrow$  values as indices into a multidimensional array. We can then access  $R_i$  values in  $O(b)$  time.

► **Lemma 18.** *For any node  $i$  of  $(X, T)$ , the feasible values of  $t_i^\uparrow$  ( $t_i^\downarrow$ ) can be computed in  $O(bn^b)$  time.  $R_i$  values can be accessed in  $O(b)$  time.*

We now discuss how to compute a  $W_i$ . The feasible  $t_i^\downarrow$  values for a  $W_i$  are just the feasible  $t_i^\downarrow$  values for  $R_i$ . However, to deal with the components in  $t_{i2}^\downarrow$ , we build the multilist for  $t_i^\downarrow$  by using components in  $t_{i1}^\downarrow$  for the first  $|t_{i1}^\downarrow|$  levels and using components in  $t_{i2}^\downarrow$  for the remaining  $|t_{i2}^\downarrow|$  levels. After building the multilist for  $t_i^\downarrow$  in this order, we compute values of  $W_i$  in  $|t_{i2}^\downarrow|$  rounds. Assume  $t_{i2}^\downarrow = (d_{i,j_1}^\downarrow, \dots, d_{i,j_s}^\downarrow)$ . The first round computes values such that  $d_{i,j_1}^\downarrow, \dots, d_{i,j_{s-1}}^\downarrow$  are fixed while  $d_{i,j_s}^\downarrow$  is greater than or equal to the specified value. The second round computes values such that  $d_{i,j_1}^\downarrow, \dots, d_{i,j_{s-2}}^\downarrow$  are fixed while  $d_{i,j_{s-1}}^\downarrow, d_{i,j_s}^\downarrow$  are greater than or equal to the specified values. And so on. By adding links between nodes in the multilist, each round build its result on the previous round. An example is shown in Figure 9(b). In the example,  $t_{i2}^\downarrow = t_i^\downarrow$  and  $|X_i| = 2$ . The links added for the 2nd round are drawn in blue.

► **Lemma 19.** *For a given  $t_i^\uparrow$ ,  $W_i$  values for all feasible  $t_i^\downarrow$  and  $\bar{k}$  can be computed in  $O(kb^2n^b)$  time. All values of a  $W_i$  can be computed in  $O(kb^2n^{2b})$  time.*

■ **Figure 9** (a)  $\mathcal{L}_i^\downarrow$  where  $|X_i| = 2$ . (b) Blue links between nodes in  $\mathcal{L}_i^\downarrow$ . The value stored in the pointed to node is greater than or equal to the value stored in the pointed from node.

# Linear-Time Approximation Scheme for $k$ -Means Clustering of Axis-Parallel Affine Subspaces

## Abstract

In this paper, we present a linear-time approximation scheme for  $k$ -means clustering of *incomplete* data points in  $d$ -dimensional Euclidean space. An *incomplete* data point with  $\Delta > 0$  unspecified entries is represented as an axis-parallel affine subspace of dimension  $\Delta$ . The distance between two incomplete data points is defined as the Euclidean distance between two closest points in the axis-parallel affine subspaces corresponding to the data points. We present an algorithm for  $k$ -means clustering of axis-parallel affine subspaces of dimension  $\Delta$  that yields an  $(1 + \epsilon)$ -approximate solution in  $O(nd)$  time. The constants hidden behind  $O(\cdot)$  depend only on  $\Delta, \epsilon$  and  $k$ . This improves the  $O(n^2d)$ -time algorithm by Eiben et al. [SODA'21] by a factor of  $n$ .

## 1 Introduction

Clustering is a fundamental research topic in computer science, which arises in various applications [13], including pattern recognition and classification, data mining, image analysis, and machine learning. In clustering, the objective is to group a set of data points into clusters so that the points from the same cluster are similar to each other. Usually, input points lie in a high-dimensional space, and the similarity between two points is defined as their distance. Two of the popular clusterings are  $k$ -median and  $k$ -means clusterings. In the  $k$ -means clustering problem, we wish to partition a given point set into  $k$  clusters to minimize the sum of squared distances of each point to its cluster center. Similarly, in the  $k$ -median clustering problem, we wish to partition a given point set into  $k$  clusters to minimize the sum of distances of each point to its cluster center.

In this paper, we consider clustering for *incomplete data points*. The analysis of incomplete data is a long-standing challenge in practical statistics. There are lots of scenarios where entries of points of a given data set are incomplete [2]. For instance, a few questions are left blank on a questionnaire; weather records for a region omit the figures for one weather station for a short period because of a malfunction; stock exchange data is absent for one stock on one day because of a trading suspension. Various heuristic, greedy, convex optimization, statistical, or even ad hoc methods were proposed throughout the years in different practical domains to handle missing data [2].

Gao et al. [10] introduced a geometric approach to deal with incomplete data points for clustering problems. An *incomplete* point has one or more unspecified entries, which can be represented as an axis-parallel affine subspace. The distance between two incomplete data

points is defined as the Euclidean distance between two closest points in the axis-parallel affine subspaces corresponding to the data points. Since the distance between an axis-parallel affine subspace and a point is well-defined, the classical clustering problems such as  $k$ -means,  $k$ -median, and  $k$ -center can be defined on a set of axis-parallel affine subspaces.

The  $k$ -center problem in this setting was studied by [10, 11, 15]. Gao et al. [10, 11] focused on the  $k$ -center clustering for  $k \leq 3$ , and presented an approximation algorithm for the  $k$ -center clustering of axis-parallel affine subspaces. Later, Lee and Schulman [15] improved the running time of the algorithm by Gao et al., and then presented an  $O(nd)$ -time approximation algorithm for the  $k$ -center clustering problem for a larger  $k$ . The constant hidden behind  $O(\cdot)$  depends on  $\Delta, \epsilon$  and  $k$ . Moreover, they showed that the running time of an approximation algorithm with any approximation ratio cannot be polynomial in even one of  $k$  and  $\Delta$  unless  $P = NP$ , and thus the running time of their algorithm is almost tight.

Very recently, Eiben et al. [7] presented an approximation algorithm for the  $k$ -means clustering of  $n$  axis-parallel affine subspaces of dimension  $\Delta$ . Their algorithm yields an  $(1 + \epsilon)$ -approximate solution in  $O(n^2 d)$  time with probability  $O(1)$ . The constant hidden behind  $O(\cdot)$  depends on  $\Delta, \epsilon$  and  $k$ . Since the best-known algorithm for the  $k$ -center clustering in this setting runs in time linear in both  $n$  and  $d$  (but exponential in both  $k$  and  $\Delta$ ), it is a natural question if a similar time bound can be achieved for the  $k$ -means clustering. In this paper, we resolve this natural question by presenting an  $(1 + \epsilon)$ -approximation algorithm for the  $k$ -means clustering problem running in time linear in  $n$  and  $d$ .

**Related work.** The  $k$ -median and  $k$ -means clustering problems for *points* in  $d$ -dimensional Euclidean space have been studied extensively. Since these problems are NP-hard even for  $k = 2$  or  $d = 2$  [3, 16, 18], the study of  $k$ -means and  $k$ -median clusterings have been devoted to obtain  $(1 + \epsilon)$ -approximation algorithms for these problems [1, 5, 8, 12, 14]. These algorithms run in time polynomial time in the input size if one of  $k$  and  $d$  is constant. Indeed, it is NP-hard to approximate Euclidean  $k$ -means clustering within a factor better than a certain constant larger than one [4]. That is, the  $k$ -means clustering problem does not admit a PTAS for arbitrary  $k$  and  $d$  unless  $P=NP$ .

Also, the clustering problems for *lines* (which are not necessarily axis-parallel) also have been studied [17, 19]. More specifically, Ommer and Malik [19] presented a heuristic for  $k$ -median clustering of lines in three-dimensional space. Later, Marom and Feldman [17] presented an algorithm for computing a coresets of size  $dk^{O(k)} \log n/\epsilon^2$ , which gives a polynomial-time  $(1 + \epsilon)$ -approximation algorithm for the  $k$ -means clustering of lines in  $d$ -dimensional Euclidean space.

**Our results.** We present an algorithm for  $k$ -means clustering of axis-parallel affine subspaces of dimension  $\Delta$  that yields an  $(1 + \epsilon)$ -approximate solution in  $2^{O(\frac{\Delta^4 k}{\epsilon} (\log \frac{\Delta}{\epsilon} + k))} dn$  time with a constant probability. This improves the previously best-known algorithm by Eiben et al [7], which takes  $2^{O(\frac{\Delta^7 k^3}{\epsilon} (\log \frac{k\Delta}{\epsilon}))} dn^2$  time. Since it is a generalization of the  $k$ -means clustering problem for points ( $\Delta = 0$ ), it does not admit a PTAS for arbitrary  $k$  and  $d$  unless  $P=NP$ . Similarly to Lee and Schulman [15], we show in the full version of this paper that an approximation algorithm with any approximation ratio cannot run in polynomial time in even one of  $k$  and  $\Delta$  unless  $P=NP$ . The running time of our algorithm is almost tight in the sense that it is linear in  $nd$  and exponential in  $k$  and  $\Delta$ .

► **Theorem 1** ([4, 15]). *No algorithm for computing an  $(1+\alpha)$ -approximate  $k$ -means clustering runs in time polynomial of  $n, d$  and  $\Delta$  (or polynomial of  $n, d$  and  $k$ ) unless  $P=NP$ .*

This lower bound does not rule out the possibility that this problem can be solved in  $O(nd + f(k, \Delta))$  time for an exponential function  $f$  of  $k$  and  $\Delta$ . However, it seems hard to achieve this goal using the framework of Kumar et al. [14] and Ackermann et al. [1] as their algorithms (for the standard clustering problem) also run in  $O(nd \cdot f(k))$  time for an exponential function  $f$  of  $k$ .

► **Remark 2.** Although it seems hard to achieve a significantly better running time using the framework of Ackermann et al., there is a merit of using this framework: we can handle outliers without additional effort as shown in [9]. Details will be discussed in Conclusion.

## 2 Preliminaries

We consider points in  $\mathbb{R}^d$  with missing entries in some coordinates. Let us denote the missing entry value by  $\otimes$ , and let  $\mathbb{H}^d$  denote the set of elements of  $\mathbb{R}^d$  where we allow some coordinates to take the value  $\otimes$ . Furthermore, we call a point in  $\mathbb{H}^d$  a  $\Delta$ -missing point if at most  $\Delta$  of its coordinates have value  $\otimes$ . We use  $[k]$  to denote the set  $\{1, \dots, k\}$  for any integer  $k \geq 1$ . For any point  $u \in \mathbb{H}^d$  and an index  $i \in [d]$ , we use  $(u)_i$  to denote the entry of the  $i$ -th coordinate of  $u$ . If it is clear from the context, we simply use  $u_i$  to denote  $(u)_i$ . Throughout this paper, we use  $i$  or  $j$  to denote an index of the coordinates of a point, and  $t$  to denote an index of a sequence (of points or sets). We use  $(u_t)_{t \in [k]}$  to denote a  $k$ -tuple consisting of  $u_1, u_2, \dots, u_k$ .

**Distance between two  $\Delta$ -missing points.** The *domain* of a point  $u$  in  $\mathbb{H}^d$ , denoted by  $\text{DOM}(u)$ , is defined as the set of coordinate-indices  $i \in [d]$  with  $(u)_i \neq \otimes$ . For a set  $I$  of coordinate-indices in  $[d]$ , we say that  $u$  is *fully defined* on  $I$  if  $\text{DOM}(u) \subseteq I$ . Similarly, we say that  $u$  is *partially defined* on  $I$  if  $\text{DOM}(u) \cap I \neq \emptyset$ . For a set  $P$  of points of  $\mathbb{H}^d$  and a set  $I$  of coordinate-indices in  $[d]$ , we use  $\text{FD}(P, I)$  to denote the set of points of  $P$  fully defined on  $I$ . Similarly, we use  $\text{PD}(P, I)$  to denote the set of points of  $P$  partially defined on  $I$ . The *null* point is a point  $p \in \mathbb{H}^d$  such that  $(p)_i = \otimes$  for all indices  $i \in [d]$ . With a slight abuse of notation, we denote the null point by  $\otimes$  if it is clear from the context. Also, we sometimes use  $I_t$  to denote  $\text{DOM}(u_t)$  if it is clear from the context.

Notice that a  $\Delta$ -missing point in  $\mathbb{H}^d$  can be considered as a  $\Delta$ -dimensional affine subspace in  $\mathbb{R}^d$ . The distance between two  $\Delta$ -missing points in  $\mathbb{H}^d$  is defined as the Euclidean distance between their corresponding  $\Delta$ -dimensional affine subspaces in  $\mathbb{R}^d$ . More generally, we define the *distance* between two points  $x$  and  $y$  in  $\mathbb{H}^d$  on a set  $I \subseteq [d]$  as

$$d_I(x, y) = \sqrt{\sum_{i \in I} |x_i - y_i|^2},$$

where  $|a - b| = 0$  for  $a = \otimes$  or  $b = \otimes$  by convention.

**The  $k$ -Means clustering of  $\Delta$ -missing points.** In this paper, we consider the  *$k$ -means clustering* of  $\Delta$ -missing points of  $\mathbb{H}^d$ . As in the standard setting (for  $\Delta = 0$ ), we wish to partition a given point set  $P$  into  $k$  clusters to minimize the sum of squared distances of each point to its cluster center. For any partition  $(P_t)_{t \in [k]}$  of  $P$  into  $k$  clusters such that each cluster  $P_t$  is associated with a cluster center  $c_t \in \mathbb{R}^d$ , the *cost* of the partition is defined as the sum of squared distances of each point in  $P$  to its cluster center.

To be more precise, we define the *clustering cost* as follows. For a set  $P \subset \mathbb{H}^d$  and a  $\Delta$ -missing point  $y$ , we use  $\text{COST}(P, y)$  to denote the sum of squared distances of each point in  $P$  to  $y$ . We also define the cost on a coordinate set  $I \subseteq [d]$ , denoted by  $\text{COST}_I(P, y)$ , as

the sum of squared distances on  $I$  between the points in  $P$  and their cluster centers. That is,  $\sum_{x \in P} d_I(x, y)^2$ . For convention,  $\text{COST}_i(P, y) = \text{COST}_{\{i\}}(P, y)$  for  $i \in [d]$ . The clustering cost  $\text{COST}((P_t)_{t \in [k]}, (c_t)_{t \in [k]})$  of clustering  $((P_t)_{t \in [k]}, (c_t)_{t \in [k]})$  is defined as  $\sum_{t \in [k]} \text{COST}(P_t, c_t)$ .

Now we introduce two properties of an optimal clustering  $((P_t^*)_{t \in [k]}, (c_t^*)_{t \in [k]})$  that minimizes the clustering cost, which will be frequently used throughout this paper. For each cluster  $P_t^*$ ,  $\text{COST}(P_t^*, c_t)$  is minimized when  $c_t$  is the *centroid* of  $P_t^*$  [7]. That is,  $c_t^*$  is the centroid of  $P_t^*$ . For a set  $P$  of points in  $\mathbb{H}^d$ , the *centroid* of  $P$ , denoted by  $c(P)$ , is defined as

$$(c(P))_i = \begin{cases} \otimes & \text{if } \text{PD}(P, i) = \emptyset, \\ \frac{\sum_{u \in \text{PD}(P, i)} u_i}{|\text{PD}(P, i)|} & \text{otherwise.} \end{cases}$$

Also, the clustering cost is minimized when  $(P_t^*)_{t \in [k]}$  forms the Voronoi partition of  $P$  induced by  $(c_t^*)_{t \in [k]}$  [7]. That is,  $(P_t^*)_{t \in [k]}$  is the partition of  $P$  into  $k$  clusters in such a way that  $c_t^*$  is the closest cluster point from any point  $p$  in  $P_t^*$ .

**Sampling.** Our algorithm uses random sampling to compute an approximate  $k$ -means clustering. Lemma 3 is a restatement of [1, Lemma 2.1], and Lemma 4 is used in [7] implicitly. Since Lemma 4 is not explicitly stated in [7], we give a sketch of the proof in the full version of this paper [6].

► **Lemma 3** ([1, Lemma 2.1]). *Assume that we are given a set  $P$  of points in  $\mathbb{H}^d$ , an index  $i \in [d]$ , and an approximation factor  $\alpha > 0$ . Let  $Q$  be a subset of  $P$  with  $|\text{PD}(Q, i)| \geq c|P|$  for some constant  $c$ , which is not given explicitly. Then we can compute a point  $x$  of  $\mathbb{R}$  in  $O(|P|d m_{\alpha, \delta})$  time satisfying with probability  $\frac{1-\delta}{5} 2^{\Omega(-m_{\alpha, \delta} \log(\frac{1}{c} m_{\alpha, \delta}))}$  that*

$$\text{COST}_i(Q, x) \leq (1 + \alpha) \text{COST}_i(Q, c(Q)),$$

where  $m_{\alpha, \delta} \in O(1/(\alpha\delta))$ .

► **Lemma 4** ([7]). *Assume that we are given a set  $P$  of  $\Delta$ -missing points in  $\mathbb{H}^d$  and an approximation factor  $\alpha > 0$ . Let  $Q$  be a subset of  $P$  with  $|Q| \geq c|P|$  for some constant  $c$  with  $0 < c < 1$ , which is not given explicitly. Then we can compute a  $\Delta$ -missing point  $u \in \mathbb{H}^d$  in  $O(|P|d\lambda)$  time satisfying with probability  $\frac{c^{8(\Delta+1)\lambda+1}}{4(4\Delta)^{8\Delta\lambda}}$  that*

$$\text{COST}_I(Q, u) < (1 + \alpha) \text{COST}_I(Q, c(Q)),$$

where  $I$  denotes the domain of  $u$ , and  $\lambda = \max\{(\frac{3}{\alpha})^{1/(2\Delta)}, (128\Delta^3)^{1/(2\Delta)}\}$ .

### 3 Overview of the Algorithm

We first briefly describe a  $(1 + \epsilon)$ -approximation algorithm for  $k$ -means clustering for points in  $d$ -dimensional Euclidean space given by Kumar et al. [14]. Let  $P$  be a set of  $n$  points in  $\mathbb{R}^d$ , and  $((P_t^*)_{t \in [k]}, (c_t^*)_{t \in [k]})$  be an optimal  $k$ -means clustering for  $P$ .

**Sketches of [1] and [14].** The algorithm of Kumar et al. [14] consists of several phases of two types: sampling phases and pruning phases. Their idealized strategy is as follows. At the beginning of a phase, it decides the type of the phase by computing the index  $t$  that maximizes  $|P_t^*|$ . If the cluster center of  $P_t^*$  has not been obtained, the algorithm enters the sampling phase. This algorithm picks a random sample of a constant size from  $P$ , and hopefully this sample would contain enough random samples from  $P_t^*$ . Then one can compute a good approximation  $c_t$  to  $c_t^*$  using Lemma 3.

If it is not the case, the algorithm enters a pruning phase, and it assigns each point to its closest cluster if their distance is at most  $L$ , where  $L$  denotes the smallest distance between two cluster centers we have obtained so far. They repeat this until all cluster centers are obtained, and finally obtain a good approximation to  $(P_t^*)_{t \in [k]}$ .

However, obviously, it is hard to implement this idealized strategy. To handle this, they try all possibilities (for both pruning and sampling phases and for all indices  $t \in [k]$  to be updated for sampling phases), and return the best solution found this way. Kumar et al. [14] showed that their algorithm runs in  $O(2^{(k/\epsilon)^{O(1)}} dn)$  time, and returns an  $(1 + \epsilon)$ -approximate  $k$ -means clustering with probability  $1/2$ . Later, Ackermann et al. [1] gave a tighter bound on the running time of this algorithm.

**Sketch of Eiben et al. [7].** To handle  $\Delta$ -missing points, Eiben et al. generalized the algorithm in [14]. Their idealized strategy can be summarized as follows. It maintains  $k$  centers  $(u_t)_{t \in [k]}$ , which are initially set to the null points. In each sampling phase, it obtains one (or at least  $\lfloor d \rfloor - \Delta$ ) coordinate of one of the centers.

At the beginning of a phase, it decides the type of the phase by computing the index  $t$  that maximizes  $|\text{PD}(P_t^*, [d] - I_t)|$ . A sampling phase happens if  $|\text{PD}(P_t^*, [d] - I_t)| > c|R|$ , where  $R$  denotes the number of points which are not yet assigned to any cluster. In this case, a random sample of constant size from  $R$  would contain enough random samples from  $|\text{PD}(P_t^*, j)|$  with  $j \in [d] - I_t$ . Thus, using the random sample, one can obtain a good approximation to  $(c_t^*)_j$ .

Otherwise, a pruning phase happens. In a pruning phase, the algorithm assigns points which are not yet assigned to any cluster to clusters. Here, a main difficulty is that even though the distance between a point  $p$  in  $R$  and its closest center  $u_t$  is at most  $L$ , where  $L$  denotes the distance between two cluster centers,  $p$  is not necessarily in  $P_t^*$ . They resolved this in a clever way by ignoring  $\Delta$  coordinates for comparing the distances from two cluster centers.

**Comparison of our contribution and Eiben et al. [7].** Our contribution is two-fold: the dependency on  $n$  decreases to  $O(n)$  from  $O(n^2)$ , and the dependency of  $\Delta$  and  $k$  decreases significantly. First, the improvement on the dependency of  $n$  comes from introducing a faster and simpler procedure for a pruning phase. In the previous algorithm, it cannot be guaranteed that a constant fraction of points of  $R$  is removed from  $R$ . This yields the quadratic dependency of  $n$  in their running time. We overcome the difficulty they (and we) face in a pruning phase in a different way. For each subset  $T$  of  $[k]$ , we consider the set  $S_T$  of points  $x \in R$  such that  $\text{DOM}(x) \subset I_t$  for every  $t \in T$  and  $\text{DOM}(x) \not\subset I_{t'}$  for every  $t' \notin T$ . Then  $S_T$ 's for all subsets  $T \subset [k]$  form a partition of  $R$ . In a pruning phase, we choose the set  $S_T$  that maximizes  $|S_T|$ . We show that the size of  $S_T$  is at least a constant fraction of  $|R|$  (unless we enter the sampling phase). Moreover, in this case, if the distance between a point  $p$  in  $S_T$  and its closest center  $u_t$  is at most  $L$ , where  $L$  denotes the distance between two cluster centers, it holds that  $p \in P_t^*$ .

Second, we improved the dependency of  $\Delta$  and  $k$  using the framework of Ackermann et al. [1]. To adapt this framework for our problem, we are required to handle several technical difficulties. This is mainly because the center of each cluster changes during the execution of the algorithm in our case unlike the standard setting considered in [1].

Due to the lack of space, some proofs are omitted. All missing proofs can be found in the full version of this paper.

**4 For  $k$ -Means Clustering**

In this section, we describe and analyze for a  $k$ -means clustering algorithm. Let  $\mathcal{U} = \langle u_1, u_2, \dots, u_k \rangle$  be a sequence of points in  $\mathbb{H}^d$ .

**4.1 Algorithm Using the Counting Oracle**

We first sketch an algorithm for  $k$ -clustering assuming that we can access the *counting oracle*. Let  $\langle P_1^*, \dots, P_k^* \rangle$  be an optimal  $k$ -clustering for  $P$  induced by the centroids  $\langle c_1^*, \dots, c_k^* \rangle$ . The counting oracle takes a subset of  $P$  and a cluster-index  $t \in [k]$ , and it returns the number of points in the subset which are contained in  $P_t^*$ . Then in Section 4.3, we show how to compute an approximate clustering without the counting oracle.

The algorithm consists of several phases of two types: a *sampling phase* or a *pruning phase*. We initialize  $\mathcal{U}$  to a  $k$ -tuple of null points. In a sampling phase, we obtain values of  $(u_t)_j$  for indices  $t \in [k]$  and  $j \in [d]$  which were set to  $\otimes$ . Also, we assign points of  $P$  to one of the  $k$  clusters in sampling and pruning phases. The pseudocode of the algorithm is described in Algorithm 1. At any moment during the execution of the algorithm, we maintain a set  $R$  of remaining points and a  $k$ -tuple  $\mathcal{U} = \langle u_1, \dots, u_k \rangle$  of (partial) centers in  $\mathbb{H}^d$ . We let  $I_t$  be  $\text{DOM}(u_t)$ . Initially,  $R$  is set to  $P$ , and  $\mathcal{U}$  is set to the  $k$ -tuple of null points. The algorithm terminates if  $R = \emptyset$ , and finally  $\mathcal{U}$  becomes a set of points in  $\mathbb{R}^d$ .

We consider the partition  $\mathcal{F}$  of  $R$  defined as follows. For a subset  $T$  of  $[k]$ , let  $S_T$  denote the set of points  $x \in R$  such that  $\text{DOM}(x) \subset I_t$  for every  $t \in T$  and  $\text{DOM}(x) \not\subset I_{t'}$  for every  $t' \notin T$ . Let  $\mathcal{F} = \{S_T \mid T \text{ is a proper subset of } [k]\}$ . The following lemma shows that  $\mathcal{F}$  is a partition of  $R$ .

► **Lemma 5.** *For any point  $x \in R$ , there exists a unique set in  $\mathcal{F}$  containing  $x$ .*

At the beginning of each phase, we decide the type of the current phase. Let  $t$  be the cluster-index of  $[k]$  that maximizes  $|\text{PD}(R \cap P_t^*, [d] - I_t)|$ , where  $R$  is the set of points of  $P$  which are not assigned to any cluster. The one of the following cases always happen:  $|\text{PD}(R \cap P_t^*, [d] - I_t)| \geq c|R|$ , or there exists a set  $T$  of cluster-indices in  $[k]$  such that  $|S_T \cap (\cup_{t \in T} P_t^*)| \geq c|R|$  for any constant  $c < 1/(2^k + k)$ , which will be specified later.<sup>1</sup>

► **Lemma 6.** *One of the following always holds for any constant  $c < 1/(2^k + k)$ .*

- $|\text{PD}(R \cap P_t^*, [d] - I_t)| \geq c|R|$  for a cluster-index  $t \in [k]$ , or
- $|S_T \cap (\cup_{t \in T} P_t^*)| \geq c|R|$  for a proper subset  $T$  of  $[k]$ .

**Sampling phase.** If the first case happens, we enter a sampling phase. Let  $\alpha$  be a constant, which will be specified later. We use it as an approximation factor used in Lemmas 3 and 4 for sampling. If  $I_t$  is empty, we replace  $u_t$  with a  $\Delta$ -missing point in  $\mathbb{H}^d$  obtained from Lemma 4. If  $I_t$  is not empty, then it is guaranteed that  $|I_t|$  is at least  $d - \Delta$ . We compute the coordinate-index  $j$  in  $[d] - I_t$  that maximizes  $|\text{PD}(R \cap P_t^*, j)|$  using the counting oracle. Clearly,  $(u_t)_j = \otimes$  and  $|\text{PD}(R \cap P_t^*, j)|$  is at least  $c|R|/\Delta$ . Then we replace  $(u_t)_j$  with a value obtained from Lemma 3. At the end of the phase, we check if  $\text{FD}(R, \cap_{t \in [k]} I_t)$  is not empty. If it is not empty, we assign those points to their closest cluster centers.

**Pruning phase.** Otherwise, we enter a pruning phase. Instead of obtaining a new coordinate value of  $u_t$ , we assign points of  $R$  to cluster centers in a pruning phase. To do this, we find a proper subset  $T$  of  $[k]$  which maximizes  $|S_T|$ . Then among the points of  $S_T$ , we choose the  $|S_T|/2$  points closest to their closest centers in  $\mathcal{U}_T$ , where  $\mathcal{U}_T$  is the set of all  $u_t$  for  $t \in T$ . Then we assign each of them to its closest center in  $\mathcal{U}_T$ . In this way, points in  $\cup_{t' \notin T} P_{t'}^*$  might be assigned (incorrectly) to  $u_t$  for a cluster-index  $t \in T$ . We call such a point a *stray point*.

## 4.2 Analysis of the Approximation Factor

In this section, we analyze the approximation factor of the algorithm. We let  $\mathcal{S}$  be the sequence of sampling phases happened during the execution of the algorithm. At the end of the algorithm,  $\mathcal{U}$  becomes a  $(1 + \epsilon)$ -approximate clustering as we will see later. In the following, we use  $\mathcal{C} = \langle c_1, \dots, c_k \rangle$  to denote the output of the algorithm. For a sequence  $T$  of cluster-indices, we use  $\mathcal{C}_T$  to denote a  $|T|$ -tuple consisting of  $c_t$  for  $t \in T$ . Let  $\text{OPT}_k(P)$  denote the clustering cost of an optimal  $k$ -means clustering of  $P$ .

► **Lemma 7.** *The size of  $\mathcal{S}$  is at most  $k(\Delta + 1)$ .*

**Preliminaries.** Recall that  $\mathcal{S}$  denotes the sequence of sampling phases. Here, we represent a sampling phase as the pair  $(t, I)$ , where  $t$  is the cluster-index considered in the sampling phase, and  $I$  is the set of indices  $i$  such that  $(u_t)_i$  is obtained during the sampling phase.

<sup>1</sup> We set  $\alpha = \epsilon/3$ , and  $c = \frac{\alpha}{8 \cdot 2^k k^2 (\Delta + 1)}$ .

Note that the size of  $I$  is either one or at least  $d - \Delta$  for any sampling phase. Also, for  $s = (t, I) \in \mathcal{S}$ , we let  $t^s = t$  and  $I^s = I$ . For each sampling phase  $s = (t, I)$ , let  $R^s$  be the set of points of  $P_t^*$  which are not assigned at the *beginning* of the phase. Furthermore, let  $I_t^s$  denote  $\text{DOM}(u_t)$  we have at the end of the sampling phase  $s$  for a cluster-index  $t' \in [k]$ . For two sampling phases  $s$  and  $s'$  in  $\mathcal{S}$ , we use  $s \preceq s'$  if  $s$  comes before  $s'$  in  $\mathcal{S}$  or equals to  $s'$ . We denote  $P_T^* = \cup_{t \in T} P_t^*$  and  $P_{\bar{T}}^* = \cup_{t' \notin T} P_{t'}^*$ .

**Sketch.** A point of  $P$  is assigned to one of the clusters during a sampling phase or a pruning phase. That is, at the end of the execution of the algorithm,  $P$  is partitioned into  $k$  clusters  $P_1, \dots, P_k$ . Note that it is not necessarily a Voronoi partition of  $P$  with respect to  $\mathcal{C}$ . Our goal in this section is that the clustering cost  $\text{COST}((P_t)_{t \in [k]}, (c_t)_{t \in [k]})$  is at most  $(1 + \epsilon)\text{OPT}_k(P)$ . We first show that the clustering cost induced by non-stray points is  $(1 + \alpha)\text{OPT}_k(P)$ , and then show that the clustering cost induced by stray points is  $\alpha\text{OPT}_k(P)$ .

For this, we use the two following technical lemmas. Lemma 8 is a consequence of Lemmas 3 and 4, and Claim 9 follows from construction. Proofs can be found in the Appendix of the full version [6].

► **Lemma 8.**  $\sum_{s \in \mathcal{S}} \text{COST}_{I^s}(R^s, c_{t^s}) \leq (1 + \alpha)\text{OPT}_k(P)$  with a probability at least  $p^k q^{k\Delta}$ , where  $q$  and  $p$  are the probabilities in Lemmas 3 and 4.

▷ **Claim 9.** For a sampling phase  $s'$  in  $\mathcal{S}$  and a proper subset  $T$  of  $[k]$ , let  $X$  be a point subset of  $S_T$  which are not assigned at the end of a sampling phase  $s'$ . Then

$$\text{COST}(X \cap P_T^*, \mathcal{C}_T) \leq \sum \text{COST}_{I^s}(\text{PD}(X \cap P_{t^s}^*, I^s), c_{t^s}),$$

where the summation is taken over all sampling phases  $s$  in  $\mathcal{S}$  with  $s \preceq s'$  and  $t^s \in T$ .

#### 4.2.1 Clustering Cost Induced by Non-Stray Points

We first show that the clustering cost induced by non-stray points is at most  $(1 + \alpha)\text{OPT}_k(P)$ . There are two types of non-stray points: the points assigned during the sampling phases, and the points assigned during the pruning phases which are not stray. The first term in the following lemma is the clustering cost induced by points of the first type, and the second term is the clustering cost induced by points of the second type. For a proper subset  $T$  of  $[k]$ , let  $A_T^s$  be the set of points in  $S_T$  assigned to  $\mathcal{U}$  during the consecutive pruning phases lying between two adjacent sampling phases  $s$  and  $s'$  with  $s \preceq s'$ .

► **Lemma 10.** Let  $S$  be the set of points assigned during the sampling phases.

$$\text{COST}(S, \mathcal{C}) + \sum_{s \in \mathcal{S}} \sum_{T \subsetneq [k]} \text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) \leq (1 + \alpha)\text{OPT}_k(P),$$

with a probability at least  $p^k q^{k\Delta}$ , where  $q$  and  $p$  are the probabilities in Lemmas 3 and 4.

**Proof.** A point  $p \in S$  is assigned to its closest center in  $\mathcal{C}$ . This is because we assign a point during a sampling phase only if it is fully defined on  $\text{DOM}(u_t)$  for all cluster-indices  $t \in [k]$ . Thus the following holds.

$$\text{COST}(S, \mathcal{C}) \leq \sum_{t \in [k]} \text{COST}(S \cap P_t^*, c_t) = \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(\text{PD}(S \cap R^s, I), c_{t^s}).$$

For the second term of this claim, we have the following:

$$\begin{aligned}
\sum_{s' \in \mathcal{S}} \sum_{T \subsetneq [k]} \text{COST}(A_T^{s'} \cap P_T^*, \mathcal{C}_T) &\leq \sum_{s' \in \mathcal{S}} \sum_{T \subsetneq [k]} \sum_{\substack{s \preceq s' \\ t^s \in T}} \text{COST}_{I^s}(\text{PD}(A_T^{s'} \cap P_{t^s}^*, I^s), c_{t^s}) \\
&= \sum_{s \in \mathcal{S}} \sum_{s \preceq s'} \sum_{t^s \in T \subsetneq [k]} \text{COST}_{I^s}(\text{PD}(A_T^{s'} \cap P_{t^s}^*, I^s), c_{t^s}) \\
&\leq \sum_{s \in \mathcal{S}} \sum_{s \preceq s'} \sum_{t^s \in T \subsetneq [k]} \text{COST}_{I^s}(\text{PD}(A_T^{s'} \cap R^s, I^s), c_{t^s}) \\
&\leq \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(\text{PD}(A \cap R^s, I^s), c_{t^s}),
\end{aligned}$$

where  $A$  denotes the set of points of  $P$  assigned during all pruning phases. The first inequality holds by Claim 9. The second and the last inequalities hold since they change only the ordering of summation. The third inequality holds since  $A_T^{s'} \cap P_{t^s}^* \subset R^s$  if  $s \preceq s'$ .

By combining previous properties together with Claim 9, we have:

$$\begin{aligned}
\text{COST}(\mathcal{S}, \mathcal{C}) + \sum_{s \in \mathcal{S}} \sum_{T \subsetneq [k]} \text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) &\leq \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(\text{PD}(S \cap R^s, I^s), c_{t^s}) \\
&\quad + \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(\text{PD}(A \cap R^s, I^s), c_{t^s}) \\
&\leq \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(R^s, c_{t^s}) \\
&\leq (1 + \alpha) \text{OPT}_k(P). \quad \blacktriangleleft
\end{aligned}$$

## 4.2.2 Clustering Cost Induced by Stray Points

Now we show that the clustering cost induced by stray points is  $\alpha \text{OPT}_k(P)$ . Recall that the stray points are assigned to clusters during pruning phases. We first analyze the clustering cost by considering consecutive pruning phases lying between two adjacent sampling phases of  $\mathcal{S}$ . Then we show that the overall clustering cost induced by stray points.

### 4.2.2.1 During consecutive pruning phases

Consider a sequence  $\mathcal{P}$  of the consecutive pruning phases lying between two adjacent sampling phases  $s$  and  $s'$  in  $\mathcal{S}$  with  $s \preceq s'$ . Let  $N$  denote the number of pruning phases in  $\mathcal{P}$ . For a proper subset  $T$  of  $[k]$ , recall that  $A_T^s$  denotes the set of points in  $S_T$  assigned to  $\mathcal{U}$  during the phases in  $\mathcal{P}$ . During this period,  $u_t$  remains the same for each cluster-index  $t \in [k]$ . By definition,  $A_T^s \cap P_T^*$  is the set of stray points assigned during the pruning phases in  $\mathcal{P}$ . For each pruning phase of  $\mathcal{P}$ , we choose a subset  $T$  of  $[k]$  and assign a half of  $S_T$  to  $\mathcal{U}$ . Here, note that distinct pruning phases of  $\mathcal{P}$  might choose distinct subsets  $T$ . Therefore, there might be more than one subsets  $T$  of  $[k]$  with  $A_T^s \neq \emptyset$ .

We first analyze the clustering cost induced by stray points assigned during the pruning phases in  $\mathcal{P}$ . Recall that  $R^s$  denotes the set of points of  $P$  which are not yet assigned to any cluster at the end of the sampling phase  $s$ . Let  $S_T^s$  denotes the set of points of  $x \in R^s$  such that  $\text{DOM}(x) \subset I_t$  for every  $t \in T$  and  $\text{DOM}(x) \not\subset I_{t'}$  for every  $t' \notin T$ .

► **Lemma 11.**  $\sum_{T \subsetneq [k]} \text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) \leq 8 \cdot 2^k ck \cdot \sum_{T \subsetneq [k]} \text{COST}(S_T^s \cap P_T^*, \mathcal{C}_T)$ .

**Proof (Sketch).** Since  $S_T^s$ 's form a partition of  $R^s$ , it suffices to fix a proper subset  $T$  of  $[k]$  and show that  $\text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) \leq 8 \cdot 2^k ck \cdot \text{COST}(S_T^s \cap P_T^*, \mathcal{C}_T)$ . We partition  $A_T^s$  into  $N$  subsets so that  $A_T^{(x)}$  is the set of points of  $S_T$  assigned to  $\mathcal{U}$  at the  $x$ th pruning phase of  $\mathcal{P}$ . By construction, in the  $x$ th pruning phase, there exists a unique index-set  $T$  with  $A_T^{(x)} \neq \emptyset$ . Let  $\mathcal{X}_T$  be the increasing sequence of indices  $x$  of  $[N]$  with  $A_T^{(x)} \neq \emptyset$ .

For any consecutive indices  $x$  and  $x'$  in  $\mathcal{X}_T$  with  $x' < x$  and any proper subset  $T$  of  $[k]$ , we show that the clustering cost induced by stray points assigned during the  $x'$ th pruning phase of  $\mathcal{P}$  is at most  $8 \cdot 2^k ck$  times the clustering cost induced by non-stray points assigned during the  $x$ th pruning phase of  $\mathcal{P}$ . Also, we analyze the clustering cost induced by stray points assigned during the last phase of  $\mathcal{P}$  similarly. The clustering cost induced by all non-stray points assigned during the pruning phases of  $\mathcal{P}$  is at most  $\sum_{T \subseteq [k]} \text{COST}(S_T^s \cap P_T^*, \mathcal{C}_T)$ , and thus the lemma holds. Details can be found in the full version of this paper.  $\blacktriangleleft$

#### 4.2.2.2 During the entire pruning phases

Recall that  $\mathcal{S}$  denotes the sequence of sampling phases, and each sampling phase is represented as  $(t, I)$ , where  $t$  is the cluster-index considered in the sampling phase, and  $I$  is the set of indices  $i$  such that  $(u_t)_i$  is obtained during the sampling phase.

The following lemma gives an upper bound of the total cost induced by the stray points.

► **Lemma 12.**  $\sum_{s \in \mathcal{S}} \sum_{T \subseteq [k]} \text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) \leq 8 \cdot 2^k ck^2 (\Delta + 1)(1 + \alpha) \text{OPT}_k(P)$ ,

with a probability at least  $p^k q^{k\Delta}$ , where  $q$  and  $p$  are the probabilities in Lemmas 3 and 4.

**Proof.** The lemma holds by the following inequalities. The first and second inequalities hold by Claims 11 and 9, respectively. The third one holds since it changes only the ordering of summation. The fourth one holds since for a fixed sampling phase  $s'$  in  $\mathcal{S}$ ,  $S_T^{s'}$  are disjoint for all proper subsets  $T$  of  $[k]$ . Also notice that, for two sampling phases  $s, s'$  in  $\mathcal{S}$  and a proper subset  $T$  of  $[k]$ ,  $R^s$  contains  $S_T^{s'} \cap P_{t^s}^*$  if  $s \preceq s'$ . The fifth one holds since the size of  $\mathcal{S}$  is at most  $k(\Delta + 1)$ . The last two hold by the definition of  $\text{COST}(\cdot)$ .

$$\begin{aligned}
\sum_{s \in \mathcal{S}} \sum_{T \subseteq [k]} \text{COST}(A_T^s \cap P_T^*, \mathcal{C}_T) &\leq 8 \cdot 2^k ck \sum_{s \in \mathcal{S}} \sum_{T \subseteq [k]} \text{COST}(S_T^s \cap P_T^*, \mathcal{C}_T) \\
&\leq 8 \cdot 2^k ck \sum_{s' \in \mathcal{S}} \sum_{T \subseteq [k]} \sum_{\substack{s \preceq s' \\ t^s \in T}} \text{COST}_{I^s}(\text{PD}(S_T^{s'} \cap P_{t^s}^*, I^s), c_{t^s}) \\
&= 8 \cdot 2^k ck \sum_{s \in \mathcal{S}} \sum_{s \preceq s'} \sum_{t^s \in T \subseteq [k]} \text{COST}_{I^s}(\text{PD}(S_T^{s'} \cap P_{t^s}^*, I^s), c_{t^s}) \\
&\leq 8 \cdot 2^k ck \sum_{s \in \mathcal{S}} \sum_{s \preceq s'} \text{COST}_{I^s}(\text{PD}(R^s, I^s), c_{t^s}) \\
&\leq 8 \cdot 2^k ck^2 (\Delta + 1) \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(\text{PD}(R^s, I^s), c_{t^s}) \\
&\leq 8 \cdot 2^k ck^2 (\Delta + 1) \sum_{s \in \mathcal{S}} \text{COST}_{I^s}(R^s, c_{t^s}), \\
&\leq 8 \cdot 2^k ck^2 (\Delta + 1)(1 + \alpha) \text{OPT}_k(P). \quad \blacktriangleleft
\end{aligned}$$

We can obtain the following lemma by combining Lemma 10 and Lemma 12.

► **Lemma 13.** For a constant  $\alpha > 0$ , the algorithm returns an  $(1 + 8 \cdot 2^k ck^2 (\Delta + 1))(1 + \alpha)$ -approximate  $k$ -means clustering for  $P$  with probability at least  $p^k q^{k\Delta}$ , where  $q$  and  $p$  are the probabilities in Lemmas 3 and 4.

```

---

### 4.3 Algorithm without Counting Oracle

The algorithm we have described uses the counting oracle in two places: determining the type of the phase and selecting a pair of the cluster-index and coordinate-index to be updated in a sampling phase. In this section, we explain how to avoid using the counting oracle. To do this, we simply try all possible cases: run both phases and update each possible cluster for all indices during a sampling phase. The main algorithm, *k*-Means  $(\mathcal{U}, R)$ , is described in Algorithm 2. Its input consists of cluster centers  $\mathcal{U}$  of a partial clustering of  $P$  and a set  $R$  of points of  $P$  which are not yet assigned. Finally, *k*-Means  $(\otimes_k, P)$  returns an  $(1 + 8 \cdot 2^k ck^2(\Delta + 1))(1 + \alpha)$ -approximate *k*-means clustering of  $P$ , where  $\otimes_k$  denotes the *k*-tuple of  $\mathbb{H}^d$  of null points.

The clustering cost returned by *k*-Means  $(\otimes_k, P)$  is at most the cost returned by the algorithm which uses the counting oracle in Section 4.1. In the following, we analyze the running time of *k*-Means  $(\otimes_k, P)$ . Let  $T(n, \delta)$  be the running of *k*-Means  $(\mathcal{U}, R)$  when  $n = |R|$  and  $\delta = \sum_{t \in [k]} \min\{d - |I_t|, \Delta + 1\}$ . Here,  $\delta$  is an upper bound on the number of updates required to make  $I_t = [d]$  for every cluster-index  $t$  in  $[k]$ . Then we have the following recurrence relation for  $T(n, \delta)$ .

▷ **Claim 14.**  $T(n, \delta) \leq \delta \cdot T(n, \delta - 1) + T\left(\left(1 - \frac{1}{2^{k+1}-2}\right)n, \delta\right) + O\left(\frac{k\delta\Delta^3 dn}{\alpha}\right)$

*Proof.* In a sampling phase, *k*-Means calls itself at most  $\delta$  times recursively with different parameters. Each recursive call takes  $T(n, \delta - 1)$  time. Also, the time for updating cluster centers takes  $O(\delta\Delta^3 dn/\alpha)$  in total by Lemma 3 and 4. For a pruning phase, we compute  $|R \cap S_T|$  for each  $T \subsetneq [k]$  in total  $O(dn)$  time, and then choose the first half of  $S_T$  in increasing order of the distances from  $u_T$  in total  $O(kdn)$  time. The recursive call invoked in the pruning phase takes  $T\left(\left(1 - \frac{1}{2^{k+1}-2}\right)n, \delta\right)$  time. We have  $\delta + 1$  clusterings returned by recursive calls in total, and we can choose  $c_{[k]}$  in  $O(\delta kdn)$  time. Thus, the claim holds. ◁

By solving the recurrence relation, we can obtain an upper bound of  $T(n, \delta)$ .

▷ **Claim 15.**  $T(n, \delta) \leq (2\delta(2^k - 1))^{2\delta+1} (1 + \frac{1}{2^{k+1}-3})^{\delta^2} \Delta^3 kdn/\alpha$

We obtain the following theorem by setting  $\alpha = \epsilon/3$ , and  $c = \frac{\alpha}{8 \cdot 2^k k^2 (\Delta+1)}$ .

► **Theorem 16.** *Given a  $\Delta$ -missing  $n$ -point set  $P$  in  $\mathbb{H}^d$ , a  $(1 + \epsilon)$ -approximate solution to the  $k$ -means clustering problem can be found in  $2^{O(\max\{\Delta^4 k(\log \Delta + k), \frac{\Delta^k}{\epsilon}(\log \frac{1}{\epsilon} + k)\})} dn$  time with a constant probability  $1/2$ .*

## 5 Concluding Remarks

In this paper, we gave a linear-time approximation algorithm for  $k$ -means clustering on axis-parallel affine subspaces. Our algorithm runs in time linear in  $nd$ , which is the size of the input. The bound is almost tight in the sense that no  $(1 + \epsilon)$ -approximation algorithm for this problem runs in time polynomial in even one of  $k$  and  $\Delta$ .

Our algorithm is based on the framework of Kumar et al. [14] and Ackerman et al. [1]. One merit of using this framework is that we can handle outliers without additional effort as shown in [9]. In this case, the goal is to minimize the clustering cost allowing to remove a small portion of the input data. The problem of computing a  $k$ -means clustering of missing data has not been explicitly considered in the presence of outliers. However, the observation of [9] allows us to extend our algorithm to handle outliers.

A main idea of [9] for clustering points in  $\mathbb{R}^d$  is as follows. Let  $m$  be the number of outliers (the number of points which are allowed to be removed). Consider an optimal  $k$ -means clustering  $(P_1^*, \dots, P_k^*)$  of the input point set  $P$  after removing  $m$  outliers. Then the largest cluster, say  $P_1^*$ , has size at least  $(|P| - m)/k$ . Then by picking a random sample of a constant size (but the sample size depends on  $m$ ), one can compute a good approximation to  $c(P_1^*)$  using Lemma 3. Using this observation, Feng et al. [9] showed that the algorithm by Kumar et al. [14] (using a parameter slightly larger than the standard one for Lemma 3) computes the cluster centers of an approximation  $k$ -means clustering in the presence of  $m$  outliers. Then the  $m$  points farthest from the cluster centers are  $m$  outliers.

The observation by Feng et al. also holds for  $\Delta$ -missing points. In a sampling phase, the set  $R$  of remaining points contains at most  $m$  outliers. This means that the largest set  $S_T$  contains at least  $|R|/(2^k + k + m)$  points of  $P_T^*$ . Therefore, we can apply Lemma 6 using a constant  $c < 1/(2^k + k + m)$ . Thus we can handle  $m$  outliers in  $O(nd)$  time, where the constant hidden behind  $O(\cdot)$  depends on  $m$ .

As mentioned in Introduction, the lower bound in Theorem 1 does not rule out the possibility that this problem can be solved in  $O(nd + f(k, \Delta))$  time for an exponential function  $f$  of  $k$  and  $\Delta$ . Moreover, it seems hard to achieve this goal using the framework of Kumar et al. [14] and Ackermann et al. [1] as their algorithms also run in  $O(nd \cdot f(k))$  time for an exponential function of  $k$ . It is an interesting open question whether one can improve the running time to  $O(nd + f(k, \Delta))$ . Also, obtaining a coresets for this problem is also an interesting open question.

## Abstract

In this paper, we present an algorithm for computing a feedback vertex set of a unit disk graph of size  $k$ , if it exists, which runs in time  $2^{O(\sqrt{k})}(n+m)$ , where  $n$  and  $m$  denote the numbers of vertices and edges, respectively. This improves the  $2^{O(\sqrt{k} \log k)}n^{O(1)}$ -time algorithm for this problem on unit disk graphs by Fomin et al. [ICALP 2017]. Moreover, our algorithm is optimal assuming the exponential-time hypothesis. Also, our algorithm can be extended to handle geometric intersection graphs of similarly sized fat objects without increasing the running time.

## 1 Introduction

The FEEDBACK VERTEX SET problem is a classical and fundamental graph problem, which is one of Karp's 21 NP-complete problems. Given an undirected graph  $G = (V, E)$  and an integer  $k$ , the goal is to find a set  $S$  of vertices of size  $k$  such that every cycle of  $G$  contains at least one vertex of  $S$ . In other words, this problem asks to find a set  $S$  of vertices of size  $k$  whose removal from  $G$  results in a forest. This problem has been studied extensively from the viewpoint of exact exponential-time algorithms [13], parameterized algorithms [6, 18], and approximation algorithms [1].

In this paper, we study the FEEDBACK VERTEX SET problem from the viewpoint of parameterized algorithms. When the parameter is the size  $k$  of a feedback vertex set, the best known parameterized algorithm takes  $3.62^k n^{O(1)}$  time [18]. On the other hand, it is known that no algorithm for FEEDBACK VERTEX SET runs in  $2^{o(k)} n^{O(1)}$  time assuming the exponential-time hypothesis (ETH) [8]. For special classes of graphs such as planar graphs and  $H$ -minor-free graphs for any fixed  $H$ , there are  $2^{O(\sqrt{k})} n^{O(1)}$ -time algorithms for the FEEDBACK VERTEX SET problem [10]. Moreover, for planar graphs, FEEDBACK VERTEX SET admits a linear kernel [4].

We present a subexponential-time algorithm for FEEDBACK VERTEX SET on *geometric intersection graphs*, which can be considered as a natural generalization of planar graphs. Consider a set  $F$  of geometric objects (for example, disks and polygons) in the plane. The *intersection graph*  $G[F]$  for  $F$  is defined as the undirected graph whose vertices correspond to the objects in  $F$  such that two vertices are connected by an edge if and only if the two objects corresponding to them intersect. In the case that  $F$  is a set of disks, its intersection graph is called a *disk graph*, which has been studied extensively for various algorithmic problems [5, 7, 17]. It can be used as a model for broadcast networks: The disks of  $F$

represent transmitter-receiver stations with the same transmission power. A planar graph can be represented as a disk graph, and thus the class of disk graphs is a generalization of the class of planar graphs.

**Previous Work.** Prior to our work, the best known algorithm for FEEDBACK VERTEX SET parameterized by the size  $k$  of a feedback vertex set on unit disk graphs takes  $2^{O(\sqrt{k} \log k)} n^{O(1)}$  time [14, 16]. Since the best known lower bound on the computation time is  $2^{o(\sqrt{n})}$  assuming the exponential-time hypothesis (ETH) [9], it is a natural question if FEEDBACK VERTEX SET on unit disk graphs can be solved optimally. De Berg et al. [9] presented an (non-parameterized) ETH-tight algorithm for this problem, which runs in  $2^{O(\sqrt{n})}$  time. However, it was not known if there is an ETH-tight parameterized algorithm for FEEDBACK VERTEX SET on unit disk graphs.

Recently, several NP-complete problems have been studied for unit disk graphs (and geometric intersection graphs) from the viewpoint of parameterized algorithms, for example, the STEINER TREE, FEEDBACK VERTEX SET, VERTEX COVER,  $k$ -PATH and CYCLE PACKING problems [2, 14, 19]. In the case of VERTEX COVER, the work by de Berg et al. [9] implies an ETH-tight parameterized algorithm. Also, in the case of  $k$ -PATH problem, Fomin et al. [15] presented an ETH-tight parameterized algorithm which runs in  $2^{O(\sqrt{k})} O(n+m)$  time. However, for the other problems, there is a gap between the running time of the best known algorithms and the best known lower bounds.

**Our Result.** In this paper, we present an ETH-tight parameterized algorithm for the FEEDBACK VERTEX SET problem on unit disk graphs, which runs in  $2^{O(\sqrt{k})} (n+m)$  time, where  $n$  and  $m$  denote the numbers of vertices and edges, respectively. This improves the  $2^{O(\sqrt{k} \log k)} n^{O(1)}$ -time algorithm for this problem on unit disk graphs by Fomin et al. [14]. Moreover, unlike the algorithm in [14], our algorithm works on the graph itself and do not require the geometric representation. Also, our algorithm indeed handles geometric intersection graphs of similarly sized fat objects in the plane without increasing the running time, which will be defined in Section 2.1.

## 2 Preliminaries

For a graph  $G = (V, E)$ , let  $V(G)$  and  $E(G)$  denote the sets of vertices and edges, respectively. For a subset  $S$  of  $V$ , let  $G[S]$  be the subgraph of  $G$  induced by  $S$ . Also, let  $G - S$  be the subgraph of  $G$  induced by  $V - S$ .

### 2.1 Geometric Intersection Graphs

For a constant  $0 < \alpha < 1$ , an object  $o \subseteq \mathbb{R}^2$  is said to be  $\alpha$ -fat if there are two disks  $B_1$  and  $B_2$  with  $B_1 \subseteq o \subseteq B_2$  such that the radius ratio of  $B_1$  to  $B_2$  is at least  $\alpha$ .<sup>1</sup> See Figure 1(a). For example, a disk is a 1-fat object, and a square is a  $1/\sqrt{2}$ -fat object. We call a set  $F$  of  $\alpha$ -fat objects a *similarly sized set* if the ratio of the largest diameter to the smallest diameter of the objects in  $F$  is bounded by a fixed constant  $\gamma$ . For an  $\alpha$ -fat object  $o$  of  $F$ , there are two *concentric* disks  $B_3$  and  $B_4$  with  $B_3 \subseteq o \subseteq B_4$  such that the radius ratio of  $B_3$  and  $B_4$  is at least  $\alpha/2$ . We consider the center of  $B_3$  and  $B_4$  as the *center* of  $o$ . For convenience, we assume that the smallest diameter of the objects of  $F$  is one.

<sup>1</sup> An *object* is a point set in the plane, which is not necessarily connected.

■ **Figure 1** (a) A  $\frac{r_1}{r_2}$ -fat object. (b) The drawing of the geometric intersection graph  $G[F]$ .

The *intersection graph*  $G[F]$  of a set  $F$  of objects in  $\mathbb{R}^2$  is defined as the graph whose vertex set is  $F$  and two vertices are connected by an edge if and only if their corresponding objects intersect. The *drawing* of the intersection graph  $G[F]$  is a representation of  $G[F]$  in the plane such that the vertices lie on the centers of the objects of  $F$  and the edges are drawn as line segments. See Figure 1(b). We sometimes use an intersection graph  $G[F]$  and its drawing interchangeably if it is clear from the context.

In this paper, we focus on geometric intersection graphs of objects in the *plane* only. Because FEEDBACK VERTEX SET on unit ball graphs in  $\mathbb{R}^3$  has no subexponential-time algorithm parameterized by  $k$  unless ETH fails [16].

## 2.2 Tree Decomposition and Weighted Width

A *tree decomposition* of a graph  $G = (V, E)$  is defined as a pair  $(T, \beta)$ , where  $T$  is a tree and  $\beta$  is a mapping from nodes of  $T$  to subsets of  $V$  (called bags) with the following properties. Let  $\mathcal{B} := \{\beta(u) : u \in V(T)\}$  be the set of bags of  $T$ .

1. For any vertex  $u \in V$ , there is at least one bag in  $\mathcal{B}$  which contains  $u$ ;
2. For any edge  $(u, v) \in E$ , there is at least one bag in  $\mathcal{B}$  which contains both  $u$  and  $v$ .
3. For any vertex  $u \in V$ , the subset of bags of  $\mathcal{B}$  containing  $u$  forms a subtree of  $T$ .

The *width* of a tree decomposition is defined as the size of its largest bag minus one, and the *treewidth* of  $G$  is the minimum width among the tree decompositions of  $G$ . In this paper, as in [9], we use the notion of *weighted treewidth* introduced by [20]. Here, assume that each vertex  $v$  has its weight. The weight of each bag is defined as the sum of the weights of the vertices in the bag, and the *weighted width* of tree decomposition is defined as the maximum weight of the bags. The *weighted treewidth* of a graph  $G$  is the minimum weighted width among the tree decompositions of  $G$ .

## 2.3 $\kappa$ -Partition and $\mathcal{P}$ -Contraction

We use the concept of  $\kappa$ -partitions and  $\mathcal{P}$ -contractions introduced by de Berg et al. [9]. Let  $G[F] = (V, E)$  be a geometric intersection graph of a set  $F$  of similarly sized  $\alpha$ -fat objects. A  $\kappa$ -partition of  $G$  is a partition  $\mathcal{P} = (P_1, \dots, P_t)$  of  $V$  such that  $G[P_i]$  is connected and is the union of at most  $\kappa$  cliques for every partition class  $P_i$ . Given a  $\kappa$ -partition  $\mathcal{P}$ , we consider a graph obtained by contracting the vertices in the same partition class to a single vertex and removing all loops and parallel edges. We call the resulting graph the  $\mathcal{P}$ -contraction of  $G$  and denote it by  $G_{\mathcal{P}}$ . The weight of each vertex of  $G_{\mathcal{P}}$  is defined as  $\lceil \log |P_i| \rceil + 1$ , where  $P_i$  denotes the partition class of  $\mathcal{P}$  defining the vertex.

A *greedy partition* is a notion from De berg et al. [9]. For the given geometric intersection graph  $G[F]$ , they iteratively pick one geometric object, then construct a partition class which consist of the objects adjacent to the picked object. They denote the final partition by the greedy partition. Since all objects are  $\alpha$ -fat, the greedy partition is  $\kappa$ -partition of  $G[F]$  and moreover has maximum degree  $\delta$  for constants  $\kappa$  and  $\delta$ . Given a greedy partition  $\mathcal{P}$ , they showed that the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{n})$ . Moreover, they presented a  $2^{O(\sqrt{n})}$ -time algorithm for computing a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{n})$ .

## 2.4 Overview of Our Algorithm

Our algorithm consists of two steps: computing a (weighted) tree decomposition of  $G_{\mathcal{P}}$ , and then using a dynamic programming on the tree decomposition. As in [9], we first compute a greedy partition. Then we show that the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{k})$  if  $(G, k)$  is a **yes**-instance. To do this, we first show that the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{k})$  if  $G$  has  $O(\sqrt{k})$  vertices of degree at least three in Section 3. Then we show that  $G$  has  $O(\sqrt{k})$  vertices of degree at least three in Section 4.1.

Using this fact, we compute a constant approximation to the weighted treewidth of  $G_{\mathcal{P}}$ . If it is  $\omega(\sqrt{k})$ , we conclude that  $(G, k)$  is a **no**-instance immediately. Otherwise, we compute a feedback vertex set of size  $k$ , if it exists, using dynamic programming on a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{k})$ . The dynamic programming algorithm is described in Section 4.2.

## 3 Tree Decomposition and Weighted Treewidth

In this section, we present the first step of our algorithm: computing a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$  for a greedy partition  $\mathcal{P}$  of a geometric intersection graph  $G$ , where  $U$  denotes the set of vertices of  $G$  of degree at least three in  $G$ . More precisely, we prove the following theorem.

► **Theorem 1.** *Let  $G$  be an intersection graph of similarly sized  $\alpha$ -fat objects with  $n$  vertices and  $m$  edges, and let  $\mathcal{P}$  be a greedy partition of  $G$ . Then the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{|U|})$ , where  $U$  denotes the set of vertices of  $G$  of degree at least three in  $G$ . Moreover, we can compute a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$  in  $2^{O(\sqrt{|U|})}(n + m)$  time without using a geometric representation of  $G$ .*

In the following, let  $G$  be an intersection graph of similarly sized  $\alpha$ -fat objects,  $\mathcal{P}$  be a greedy partition of  $G$ , and  $U$  be the set of vertices of  $G$  of degree at least three in  $G$ . In Section 3.1, we prove the first part of the theorem, and in Section 3.2, we prove the second part of the theorem.

### 3.1 Weighted Treewidth of the $\mathcal{P}$ -contraction

We first show that the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{|U|})$ . To do this, we transform  $G$  into a planar graph  $H$ . As we did for  $G$ , we compute the  $\mathcal{P}$ -contraction of  $H$ , and remove degree-2 vertices of the  $\mathcal{P}$ -contractions of  $H$  and  $G$  in a specific way. In this way, we obtain  $\bar{H}_{\mathcal{P}}$  and  $\bar{G}_{\mathcal{P}}$  of complexity  $O(\sqrt{|U|})$ . Also, we assign the weight to each vertex of the resulting graphs. Then we transform a balanced separator of  $\bar{H}_{\mathcal{P}}$  of weight  $O(\sqrt{|U|})$  into a balanced separator of  $\bar{G}_{\mathcal{P}}$  of weight  $O(\sqrt{|U|})$ . Using a weighted balanced separator, we compute a tree decomposition of  $\bar{G}_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$ , and then transform it into a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$ .

■ **Figure 2** (a) The Delaunay triangulation  $H$  of the vertex set of  $V(G)$ . The vertices of  $G$  of degree at most two are colored blue. (b)  $\mathcal{P}$  partitions  $V$  into five subsets. Each subset of  $\mathcal{P}$  is contained in a single pink region. Then the  $\mathcal{P}$ -contraction of  $H$  is the cycle consisting of five edges. (c) Each subset of  $\mathcal{P}$  consists of the black points contained in a single pink region.

**Delaunay triangulation and its contraction:  $H$  and  $H_{\mathcal{P}}$ .** Consider the Delaunay triangulation  $H$  of the point set  $V(G)$ . Here, we consider  $V(G)$  as the set of the centers of the objects defining  $G$ . We consider the Delaunay triangulation  $H$  as an edge-weighted plane graph such that the *length* of each edge is the Euclidean distance between their endpoints. The Delaunay triangulation  $H$  is a *5.08-spanner* of the complete Euclidean graph defined by  $V(G)$  [12]. That is, for any two points  $u$  and  $v$  of  $V(G)$ , the length of the shortest path in  $H$  between  $u$  and  $v$  is at most 5.08 times their Euclidean distance.

Notice that  $H$  might contain an edge which is not an edge of  $G$ . However, the following still holds as  $G$  is a subgraph of the complete Euclidean graph. For any edge  $(u, v)$  in  $G$ , there is a  $u$ - $v$  path in  $H$  consisting of  $5.08\|uv\|$  edges. Recall that  $\alpha$  is the measure for the fatness of the objects defining  $G$ , which is a constant. Let  $H_{\mathcal{P}}$  be the  $\mathcal{P}$ -contraction of  $H$ . Note that  $V(G_{\mathcal{P}}) = V(H_{\mathcal{P}})$ . For a vertex  $v$  of  $G_{\mathcal{P}}$  or  $H_{\mathcal{P}}$ , we let  $P(v)$  to denote the partition class of  $\mathcal{P}$  corresponding to  $v$ . See Figure 2(b).

**Partition  $\bar{\mathcal{P}}$  of  $U$ :  $\bar{G}_{\mathcal{P}}$  and  $\bar{H}_{\mathcal{P}}$ .** The size of  $G_{\mathcal{P}}$  and  $H_{\mathcal{P}}$  might be  $\Theta(n)$  even if  $|U|$  is small. Recall that  $U$  is the set of vertices of  $G$  of degree at least three in  $G$ . To obtain a balanced separator of  $G_{\mathcal{P}}$  of small weight, we compute a new graph  $\bar{G}_{\mathcal{P}}$  and  $\bar{H}_{\mathcal{P}}$  of size  $O(|U|)$  as follows.

Let  $\mathcal{P} = (P_1, \dots, P_t)$ , which is a partition of  $V(G)$ . Using this, we consider the partition  $\bar{\mathcal{P}} = (\bar{P}_1, \dots, \bar{P}_t)$  of  $U$  such that  $\bar{P}_i = P_i \cap U$ . Note that  $\bar{P}_i = \emptyset$  if every vertex of  $P_i$  has degree at most two in  $G$ . We first ignore the empty partition classes from  $\bar{\mathcal{P}}$ , and let  $\bar{G}_{\mathcal{P}}$  and  $\bar{H}_{\mathcal{P}}$  be the  $\bar{\mathcal{P}}$ -contraction of  $G$  and the  $\bar{\mathcal{P}}$ -contraction of  $H$ , respectively. We add several edges to  $\bar{G}_{\mathcal{P}}$  and  $\bar{H}_{\mathcal{P}}$  by considering the empty partition classes of  $\bar{\mathcal{P}}$  as follows. Since  $G[P_i]$  is connected and consists of  $\kappa$  cliques,  $G[P_i]$  is a simple cycle or a simple path if  $\bar{P}_i = \emptyset$ . Let  $P_{\emptyset}$  be the union of  $P_i$ 's for all indices with  $\bar{P}_i = \emptyset$ . Then each connected component of  $G[P_{\emptyset}]$  is also a simple cycle or a simple path. If the connected component is a simple cycle, no vertex in the component is connected by a vertex of  $U$  in  $G$ . Otherwise, the endpoints of the simple path, say  $p$  and  $q$ , are contained in  $U$ . In this case, we connect the vertices of  $\bar{G}_{\mathcal{P}}$  (and  $\bar{H}_{\mathcal{P}}$ ) by an edge unless this edge forms a loop. See Figure 2(c).

For a vertex  $\bar{v}$  of  $\bar{G}_{\mathcal{P}}$  or  $\bar{H}_{\mathcal{P}}$ , we let  $\bar{P}(\bar{v})$  be the partition class of  $\bar{\mathcal{P}}$  corresponding to  $\bar{v}$ . By construction,  $\bar{P}(\bar{v})$  is not empty for any vertex  $\bar{v}$ . Each vertex  $\bar{v}$  of  $\bar{G}_{\mathcal{P}}$  has a *g-weight*  $g(\bar{v}) = \lceil \log |\bar{P}(\bar{v})| \rceil + 1$ . Also, each vertex  $\bar{v}$  of  $\bar{H}_{\mathcal{P}}$  has a *h-weight*  $h(\bar{v}) = \sum_{\bar{u} \in N(\bar{v})} (\lceil \log |\bar{P}(\bar{u})| \rceil + 1)$ , where  $N(\bar{v})$  is the set of vertices  $\bar{u}$  of  $\bar{H}_{\mathcal{P}}$  such that there is a  $\bar{u}$ - $\bar{v}$  path in  $\bar{H}_{\mathcal{P}}$  consisting of at most  $t = (\delta + 1)(10.16(\alpha\gamma)^{-1})^2\pi$  vertices.

■ **Figure 3** (a) A balanced separator  $S$  of  $\bar{H}_{\mathcal{P}}$  consists of the red vertices. (b) A balanced separator  $S'$  of  $\bar{G}_{\mathcal{P}}$  consists of the red vertices and the orange vertices. The vertices whose distance from the red vertices are at most  $t = 1$  are colored with orange.

► **Observation 2.** A vertex  $\bar{v}$  of  $\bar{H}_{\mathcal{P}}$  has a constant degree, and thus the size of  $N(\bar{v})$  is  $O(1)$ .

**Balanced separator of  $\bar{H}_{\mathcal{P}}$  of small  $h$ -weights.** For a vertex-weighted graph  $G'$  and a subgraph  $H'$ , we denote the sum of the weights of the vertices of  $H'$  by the *weight* of  $H'$ . a subset  $S$  of  $V(G')$  is called a *balanced separator* of  $G'$  if the weight of each connected component of  $G' - S$  is at most  $2/3$  of the weight of  $G'$ . The *weight* of a balanced separator  $S$  of  $G'$  is the sum of the weights of the vertices of  $S$ . Djidjev [11] showed that a planar graph  $G'$  has a balanced separator of weight  $O(\sqrt{\sum_{v \in V} w(v)^2})$ , where  $w(v)$  is the weight of a vertex  $v$ .

The following lemma implies that  $\bar{H}_{\mathcal{P}}$  has a balanced separator of  $h$ -weight  $O(\sqrt{|U|})$ .

► **Lemma 3.** The sum of  $h(\bar{v})^2$  for all vertices  $\bar{v}$  of  $\bar{H}_{\mathcal{P}}$  is  $O(|U|)$ .

**Proof.** Let  $\bar{v}$  be a vertex of  $\bar{H}_{\mathcal{P}}$ . The  $h$ -weight of  $\bar{v}$  is the sum of  $g(\bar{u}) = (\lceil \log |\bar{P}(\bar{u})| \rceil + 1)$  for all vertices  $\bar{u}$  of  $N(\bar{v})$  by definition. By Cauchy-Schwarz inequality,  $(\sum_{\bar{u} \in N(\bar{v})} g(\bar{u}))^2$  is at most  $|N(\bar{v})|(\sum_{\bar{u} \in N(\bar{v})} g(\bar{u})^2)$ . Since the size of  $N(\bar{v})$  is at most a constant, say  $c$ , we have the following inequality.

$$\sum_{\bar{v} \in V} h(\bar{v})^2 \leq c \cdot \sum_{\bar{v} \in V} \sum_{\bar{u} \in N(\bar{v})} g(\bar{u})^2 = c \cdot \sum_{\bar{u} \in V} \sum_{\bar{v} \in N(\bar{u})} g(\bar{u})^2,$$

where  $V$  denotes the vertex set of  $\bar{H}_{\mathcal{P}}$ . Since  $\sum_{\bar{v} \in N(\bar{u})} g(\bar{u})^2 = |N(\bar{u})|g(\bar{u})^2 \leq c \cdot g(\bar{u})^2$ , we finally have the following.

$$\sum_{\bar{v} \in V} h(\bar{v})^2 \leq c^2 \cdot \sum_{\bar{u} \in V} g(\bar{u})^2 = c^2 \cdot \sum_{\bar{u} \in V} (\lceil \log |\bar{P}(\bar{u})| \rceil + 1)^2 = O\left(\sum_{\bar{u} \in V} |\bar{P}(\bar{u})|\right) = O(|U|).$$

Here, the second equality holds because  $2x \geq (\log x + 1)^2$  for all values  $x \geq 1$ . Also, the last equality holds because  $\bar{P}$  is a partition of  $U$ . ◀

**Balanced separator of  $\bar{G}_{\mathcal{P}}$  of small  $g$ -weight.** Let  $S$  be a balanced separator of  $\bar{H}_{\mathcal{P}}$  of  $h$ -weight  $O(\sqrt{|U|})$ . Let  $S'$  be the union of  $N(\bar{v})$  for all  $\bar{v} \in S$ . Recall that  $|V(\bar{G}_{\mathcal{P}})| = |V(\bar{H}_{\mathcal{P}})|$ . The sum of the  $g$ -weights of the vertices of  $S'$  is  $O(\sqrt{|U|})$  by definition of the  $g$ - and  $h$ -weights. Therefore, it suffices to show that the weight of each connected component of  $\bar{G}_{\mathcal{P}} - S'$  is at most  $2/3$  of the weight of  $\bar{G}_{\mathcal{P}}$ .

► **Lemma 4.** *For any edge  $(u, v)$  of  $G_{\mathcal{P}}$ , there is a  $u$ - $v$  path in  $H_{\mathcal{P}}$  consisting of  $t$  vertices.<sup>2</sup>*

**Proof.** Consider an edge  $(u, v)$  of  $G_{\mathcal{P}}$ . By construction, there is an edge  $(p, q)$  in  $G$  such that  $p \in P(u)$  and  $q \in P(v)$ . Recall that Delaunay triangulation is a 5.08-spanner of the complete Euclidean graph. Therefore, there exists a  $p$ - $q$  path  $\tau$  in  $H$  such that the sum of the lengths (Euclidean distance between two endpoints) of the edges is at most  $5.08\|pq\|$ .

We claim that  $\tau$  intersects at most  $(\delta + 1)(10.16(\alpha\gamma)^{-1})^2\pi$  partition classes of  $\mathcal{P}$ , where  $\delta$  is the maximum degree of  $G_{\mathcal{P}}$ ,  $\alpha$  is the measure for the fatness of the objects, and  $\gamma$  is the ratio of the largest and smallest diameters of the objects. Consider a *grid* of the plane, which is a partition of the plane into axis-parallel squares (called *cells*) with diameter  $1/\sqrt{2}$ . Recall that the smallest diameter of the objects defining  $G$  is one. For a cell  $\sigma$ , we denote the set of vertices of  $G$  contained in  $\sigma$  by  $P_{\sigma}$ . By definition,  $P_{\sigma}$  forms a clique in  $G$ . Since the maximum degree  $\delta$  of  $G_{\mathcal{P}}$  is constant, at most  $\delta + 1$  partition classes of  $\mathcal{P}$  has their vertices in  $P_{\sigma}$ . Note that every object is contained in a ball of radius  $(\alpha\gamma)^{-1}$ . Therefore,  $\|pq\| \leq 2(\alpha\gamma)^{-1}$ . Then, the Euclidean length of  $\tau$  is at most  $10.16(\alpha\gamma)^{-1}$ . This implies that  $\tau$  is contained in a ball of radius  $10.16(\alpha\gamma)^{-1}$  centered at  $p$ . In other words,  $\tau$  intersects at most  $(10.16(\alpha\gamma)^{-1})^2\pi$  cells. Since each cell intersects at most  $\delta + 1$  partition classes of  $\mathcal{P}$ ,  $\tau$  intersects  $(\delta + 1)(10.16(\alpha\gamma)^{-1})^2\pi$  partition classes. Let  $t = (\delta + 1)(10.16(\alpha\gamma)^{-1})^2\pi$ .

Then we consider a  $u$ - $v$  path in  $H_{\mathcal{P}}$  obtained by replacing each point in  $\tau$  to its contracted point in  $H_{\mathcal{P}}$ . This path now consists of  $t$  different vertices of  $H_{\mathcal{P}}$ , but it is not necessarily simple. We can obtain a simple path by removing duplicated subpaths that have same endpoints. Then we obtain a simple path of consisting of  $t$  vertices. This completes the proof. ◀

► **Lemma 5.** *For any edge  $(\bar{u}, \bar{v})$  of  $\bar{G}_{\mathcal{P}}$ , there is a  $\bar{u}$ - $\bar{v}$  path in  $\bar{H}_{\mathcal{P}}$  consisting of  $t$  vertices.*

**Proof.** We consider an edge  $(\bar{u}, \bar{v})$  of  $\bar{G}_{\mathcal{P}}$ . Let  $u$  and  $v$  be the vertices of  $G_{\mathcal{P}}$  with  $P(u) \cap U = \bar{P}(\bar{u})$  and  $P(v) \cap U = \bar{P}(\bar{v})$ . By construction, either there is an edge  $(u, v)$  in  $G_{\mathcal{P}}$ , or there is a  $u$ - $v$  path in  $G_{\mathcal{P}}$  such that no internal vertex is contained in  $U$ . We consider these two cases separately.

- **Case 1.  $(u, v)$  is an edge of  $G_{\mathcal{P}}$ .** In this case, there is a  $u$ - $v$  path  $\tau_1$  in  $H_{\mathcal{P}}$  consisting of  $t$  vertices by Lemma 4. Let  $I$  be the sequence of the indices of the partition classes of  $\mathcal{P}$  corresponding to the vertices of  $\tau_1$ . Then let  $I'$  be the subsequence of  $I$  consisting of the indices  $j$  with  $\bar{P}_j \neq \emptyset$ . If  $I = I'$ , then  $\bar{H}_{\mathcal{P}}$  has a  $\bar{u}$ - $\bar{v}$  path consisting of  $s$  vertices. Otherwise, since the internal vertices of  $\tau_1$  has degree at least two in  $H_{\mathcal{P}}$ , the vertices of  $\bar{H}_{\mathcal{P}}$  corresponding to  $\bar{P}(i)$  and  $\bar{P}(j)$  are connected by an edge for every consecutive indices  $i$  and  $j$  of  $I'$ . Therefore, there exists a  $\bar{u}$ - $\bar{v}$  path in  $\bar{H}_{\mathcal{P}}$  consisting of  $t$  vertices.
- **Case 2. There is a  $u$ - $v$  path  $\tau'$  in  $G_{\mathcal{P}}$  with no internal vertices in  $U$ .** Recall that  $V(G_{\mathcal{P}}) = V(H_{\mathcal{P}})$ . If  $\tau'$  entirely exists in  $H_{\mathcal{P}}$ , there is an edge  $(\bar{u}, \bar{v})$  in  $\bar{H}_{\mathcal{P}}$ , and thus we are done. If it is not the case, let  $(u', v')$  be an edge in  $\tau'$  which does not exist in  $H_{\mathcal{P}}$ . By Lemma 4, there is a  $u'$ - $v'$  path in  $H_{\mathcal{P}}$  consisting of  $t$  vertices. Since the internal vertices of  $\tau'$  have degree exactly two, the  $u'$ - $v'$  path contains both  $u$  and  $v$ . Therefore, the subgraph of the  $u'$ - $v'$  path lying between  $u$  and  $v$  is a  $u$ - $v$  path in  $H_{\mathcal{P}}$  consisting of at most  $t$  vertices. Then similarly to Case 1, we can show that there is a  $\bar{u}$ - $\bar{v}$  path in  $\bar{H}_{\mathcal{P}}$  consisting of  $t$  vertices.

Therefore, for an edge  $(\bar{u}, \bar{v})$  in  $\bar{G}_{\mathcal{P}}$ , there is a  $\bar{u}$ - $\bar{v}$  path in  $\bar{H}_{\mathcal{P}}$  consisting of at most  $t$  vertices. This completes the proof. ◀

<sup>2</sup> Recall that  $t = (\delta + 1)(10.16(\alpha\gamma)^{-1})^2\pi$ .

► **Lemma 6.** *The weight of each connected component of  $\tilde{G}_{\mathcal{P}} - S'$  is at most  $2/3$  of the weight of  $\tilde{G}_{\mathcal{P}}$ .*

**Proof.** We show that each connected component of  $\tilde{G}_{\mathcal{P}} - S'$  is a subset of a connected component of  $\tilde{H}_{\mathcal{P}} - S$ . This implies that each connected component of  $\tilde{G}_{\mathcal{P}} - S'$  consists of at most  $2|V(\tilde{G}_{\mathcal{P}})|/3$  vertices since  $S$  is a balanced separator of  $G_{\mathcal{P}}$ , and  $V(\tilde{G}_{\mathcal{P}}) = V(\tilde{H}_{\mathcal{P}})$ .

To show this, consider an edge  $(a, b)$  of  $\tilde{G}_{\mathcal{P}} - S'$ . We claim that  $a$  and  $b$  are contained in the same connected component of  $\tilde{H}_{\mathcal{P}} - S$ . By Lemma 5, there is an  $a$ - $b$  path in  $\tilde{H}_{\mathcal{P}}$  consisting of  $t$  vertices. If this path contains a vertex of  $S$ , then  $a$  and  $b$  are contained in  $S'$  by construction, which makes a contradiction. Therefore, an  $a$ - $b$  path in  $\tilde{H}_{\mathcal{P}}$  does not intersect  $S$ , which means that  $a$  and  $b$  are contained in the same connected component of  $\tilde{H}_{\mathcal{P}} - S$ .

Therefore, each connected component of  $\tilde{G}_{\mathcal{P}} - S'$  is a subset of the connected component of  $\tilde{H}_{\mathcal{P}} - S$ , and the lemma holds. ◀

**Tree decomposition of  $\tilde{G}_{\mathcal{P}}$ .** To construct a tree decomposition of  $\tilde{G}_{\mathcal{P}}$ , we observe that any subgraph of  $\tilde{G}_{\mathcal{P}}$  also has a balanced separator of small weight. Let  $A$  be a connected component of  $\tilde{G}_{\mathcal{P}} - S'$ . Then consider the subgraph  $\tilde{H}_{\mathcal{P}}[A]$  of  $\tilde{H}_{\mathcal{P}}$  induced by the vertices in  $A$ . Since  $\tilde{H}_{\mathcal{P}}[A]$  is planar, it has a balanced separator with small  $h$ -weight, and thus  $A$  has a balanced separator with small  $g$ -weight. Therefore, we can recursively compute a balanced separator for every connected component of  $\tilde{G}_{\mathcal{P}} - S'$ .

We compute a tree decomposition of each connected component of  $\tilde{G}_{\mathcal{P}} - S'$  recursively, and then we connect those trees by one additional empty bag, and add the separator to all bags of the resulting tree. Since the weight of the connected components decreases geometrically, the maximum weight of the bags is  $O(\sqrt{|U|})$ . Therefore, we can compute a tree decomposition  $(T, \beta)$  of  $\tilde{G}_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$ .

**Tree decomposition of  $G_{\mathcal{P}}$ .** The remaining step is computing a tree decomposition of  $G_{\mathcal{P}}$  from  $(T, \beta)$ . Then we start with the pair  $(T, \beta)$ , and then add several nodes (and bags) to  $T$  and add several vertices to the bags of  $\beta$  as follows.

Let  $Q$  be the set of vertices  $u$  of  $G_{\mathcal{P}}$  with  $P(u) \cap U \neq \emptyset$ , and let  $Q^c$  be the set of vertices of  $G_{\mathcal{P}}$  not in  $Q$ . For any vertex  $v$  of  $Q$ , there is a vertex  $\bar{v}$  in  $\tilde{G}_{\mathcal{P}}$  with  $P(v) \cap U = \bar{P}(\bar{v})$ , and thus  $\bar{v}$  is contained in bags of  $(T, \beta)$ . We replace  $\bar{v}$  with  $v$  in the bags of  $(T, \beta)$  containing  $v$ .

On the other hand, for a vertex  $v$  of  $Q^c$ ,  $P(v) \cap U = \emptyset$ , and thus no vertex of  $\tilde{G}_{\mathcal{P}}$  corresponds to  $v$ . Thus we are required to insert  $v \in Q$  into  $T'$ . Recall that every vertex in  $Q$  has degree one or two in  $G$ , and thus it also has degree one or two in  $G_{\mathcal{P}}$ . Also,  $G_{\mathcal{P}}$  is connected.<sup>3</sup> Therefore,  $G_{\mathcal{P}}[Q]$  consists of a number of simple paths and isolated vertices, all of which are connected to at most two vertices of  $Q$ . Thus, there are the following four cases.

- **Case 1.** An isolated vertex  $v$  is connected to only one vertex  $u \in Q$ . For a bag  $\beta(x)$  of  $(T, \beta)$  containing  $u$ , we add a leaf with bag  $\{u, v\}$  as a child of  $x$ .
- **Case 2.** An isolated vertex  $v$  is connected to exactly two vertices  $u, w \in Q$ . By construction, there is an edge  $(u, w)$  in  $\tilde{G}_{\mathcal{P}}$ . Then, there is a bag  $\beta(x)$  of  $T$  containing both  $\bar{u}$  and  $\bar{w}$ . We add a leaf with bag  $\{u, v, w\}$  as a child of  $x$ .
- **Case 3.** A simple  $v$ - $v'$  path  $(v_1, \dots, v_k)$  is connected to exactly one vertex  $u \in Q$ . Note that either  $v$  or  $v'$  is connected to  $u$ , but not both. Without loss of generality, we assume

<sup>3</sup> We assume that the input intersection graph  $G$  is connected, and thus  $G_{\mathcal{P}}$  is connected by construction.

that there is an edge  $(u, v)$  in  $G_{\mathcal{P}}$ . For a bag  $\beta(x)$  of  $T$  containing  $u$ , we add a node  $x_1$  with bag  $\{u, v\}$  as a child of  $x$ . For  $1 < t < k$ , we add a node  $x_t$  with bag  $\{v_t, v_{t+1}\}$  as a child of  $x_{t-1}$ .

- **Case 4.** A simple  $v$ - $v'$  path  $(v_1, \dots, v_k)$  is connected to two vertices  $u, w \in Q$ . In this case,  $v$  is connected to one of  $u$  and  $w$ , say  $u$ , and  $v'$  is connected to the other vertex, say  $w$ . Since  $\tilde{G}_{\mathcal{P}}$  has an edge  $(\bar{u}, \bar{w})$ , there is a bag  $\beta(x)$  of  $T$  that contains both  $u$  and  $w$ , where  $\bar{u}$  and  $\bar{w}$  are the vertices of  $\tilde{G}_{\mathcal{P}}$  corresponding to  $u$  and  $w$ , respectively. We add a node  $x_1$  with bag  $(u, w, v, v')$  as a child of  $x$ . For  $1 < t < k/2$ , we add a node  $x_t$  with bag  $\{v_t, v_{t+1}, v_{k-t}, v_{k-t+1}\}$  as a child of  $x_{t-1}$ .

In this way,  $(T, \beta)$  is a tree decomposition of  $G_{\mathcal{P}}$ . Now we analyze the weight of a bag of  $(T, \beta)$ . Since we replace  $\bar{v}$  with  $v$  for a vertex  $v$  of  $Q$  in the bags of  $(T, \beta)$ , the weight of a bag  $B$  of  $(T, \beta)$  consisting of vertices of  $Q$  increases. Let  $v$  be a vertex of  $Q$ , and let  $\bar{v}_i$  be the vertex of  $\tilde{G}_{\mathcal{P}}$  corresponding to  $v$ . Since  $P(v)$  is composed of at most  $O(1)$  cliques, it contains at most  $O(1)$  vertices of  $V \setminus U$ . Note that  $B$  contains  $O(\sqrt{|U|})$  vertices because the weighted width of the tree decomposition of  $\tilde{G}_{\mathcal{P}}$  is  $O(\sqrt{|U|})$ . Therefore, the weight of  $B$  increases by  $O(\sqrt{|U|})$  after replacing vertices of  $\tilde{G}_{\mathcal{P}}$  with vertices of  $G_{\mathcal{P}}$ . Thus, the weight of a bag consisting of vertices of  $Q$  is  $O(\sqrt{|U|})$ .

Now we show that the weight of a bag containing a vertex of  $Q^c$  is  $O(\sqrt{|U|})$ . Every vertex  $v \in Q^c$  is a contraction of simple paths or simple cycles of length at most  $O(1)$  in  $G$ . In particular, its weight in  $G_{\mathcal{P}}$  is  $O(1)$ . Since a bag containing a vertex of  $Q^c$  consists of at most two vertices of  $Q^c$  and at most two vertices of  $Q$ , the weight of the bag is  $O(\sqrt{|U|})$ .

### 3.2 Computing a Tree Decomposition of Small Weighted Width

We can compute a tree decomposition of weighted treewidth  $O(\sqrt{|U|})$  of  $G_{\mathcal{P}}$  using the algorithm proposed by de Berg et al. [9], which computes a tree decomposition of weighted width  $O(w)$  of  $G_{\mathcal{P}}$  assuming that the weighted treewidth of  $G_{\mathcal{P}}$  is  $w$ . This algorithm runs in  $2^{O(w)}(n+m)$  time. This algorithm works on the graph itself even if the geometric representation is unknown. In this section, we briefly describe how the algorithm proposed by de Berg et al. [9] for computing such a tree decomposition works.

A *blowup* of a vertex  $v$  by an integer  $t$  results in a graph where we replace a single vertex  $v$  into a clique of size  $t$ , in which we connect every vertex to the neighbor vertices of  $v$ . We denote the set of vertices in the clique by  $\mathcal{B}(v)$ . For the graph  $G_{\mathcal{P}}$ , we construct an unweighted graph  $G_{\mathcal{B}}$  by blowing up each vertex  $v$  by an integer  $\lceil g(v) \rceil$  where  $g(v) = \log |P(v)| + 1$ . We compute a tree decomposition of  $G_{\mathcal{B}}$ , denoted by  $(T_{\mathcal{B}}, \sigma_{\mathcal{B}})$ . Then we compute a tree decomposition of  $G_{\mathcal{P}}$  by using the same tree layout of  $T_{\mathcal{B}}$ . In particular, we add a vertex  $v \in G_{\mathcal{P}}$  to a bag if and only if the bag in  $T_{\mathcal{B}}$  contains all vertices of  $\mathcal{B}(v)$ . The Lemma 2.9 and Lemma 2.10 of [9] prove the correctness of this algorithm.

The remaining step is computing a tree decomposition of  $G_{\mathcal{B}}$ . We apply a constant-factor approximation algorithm for computing an optimal tree decomposition [8]. By Theorem 1 and Lemma 2.9 of [9], the treewidth of  $G_{\mathcal{B}}$  is  $O(\sqrt{|U|})$ . Therefore, the algorithm returns a tree decomposition of  $G_{\mathcal{B}}$  of width  $O(\sqrt{|U|})$ . This algorithm takes a  $2^{O(tw(G_{\mathcal{B}}))}n = 2^{O(\sqrt{|U|})}(n+m)$  time, and therefore, we can compute a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{|U|})$  without using the geometric representation of the graph. This completes the proof of Theorem 1.

## 4 Computing a Feedback Vertex Set

In this section, we present a  $2^{O(\sqrt{k})}(n+m)$ -time algorithm for finding a feedback vertex set of size  $k$  for the intersection graph  $G[F] = (V, E)$  of similarly sized fat objects in the plane.

To do this, we first show that  $G$  has  $O(k)$  vertices of degree at least three if it has a feedback vertex set of size at most  $k$  in Section 4.1. Therefore, by Theorem 1, for a greedy partition  $\mathcal{P}$  of  $G$ , the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{k})$  if  $(G, k)$  is a **yes**-instance.

To use this fact, we first compute such a greedy partition  $\mathcal{P}$  in  $O(n+m)$  time using the algorithm in [9]. Then we check if the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{k})$  in  $2^{O(\sqrt{k})}(n+m)$  time. If it is  $\omega(\sqrt{k})$ , we conclude that  $(G, k)$  is a **no**-instance immediately. Otherwise, we compute a feedback vertex set of size  $k$ , if it exists, using dynamic programming on a tree decomposition of  $G_{\mathcal{P}}$  of weighted width  $O(\sqrt{k})$ . De Berg et al. [9] presented a dynamic programming algorithm for FEEDBACK VERTEX SET which runs in  $2^{O(\sqrt{w})}(n+m)$  time, where  $w$  is the weighted treewidth of  $G_{\mathcal{P}}$ . We can use this algorithm, but for completeness, we briefly describe this algorithm in Section 4.2.

### 4.1 Weighted Treewidth for a Yes-Instance

We first remove all degree-1 vertices from  $G$  and denote it by  $G'$ . This reduction is feasible because no cycle encounters a degree-1 vertex. We next show that  $G'$  has  $O(k)$  vertices of degree at least three if it has a feedback vertex set of size  $k$ . We consider a partition of the plane into axis-parallel squares (called *cells*) with diameter  $1/\sqrt{2}$ , which we call the *grid*. Recall that we let the smallest diameter of the objects defining  $G$  be one. For a cell  $\sigma$ , let  $P(\sigma)$  be the set of the centers of the objects defining  $G$ . By definition,  $P(\sigma)$  forms a clique in  $G$ . We say a grid cell is a *neighbor* of another grid cell if the smallest distance between two points from the two cells is at most  $2\alpha\gamma$ , where  $\alpha$  is the measure for the fatness of the objects of  $F$ , and  $\gamma$  is the ratio of the largest and the smallest diameter of the objects. We say a grid cell  $\sigma$  is *heavy* if  $P(\sigma)$  consists of at least three points, and *light*, otherwise. Let  $P_h$  denote the set of vertices contained in the heavy cells, and let  $P_\ell$  denote the set of vertices contained in the light cells.

The following lemma implies that  $G_{\mathcal{P}}$  has a weighted treewidth of  $O(\sqrt{k})$  if it has a feedback vertex set of size  $k$ . The proof of the following lemma is inspired by the proof of [8, Lemma 9.1].

Note that the weighted treewidth of  $G$  is at most the weighted treewidth of  $G'$  plus one. Also,  $(G, k)$  is a **yes**-instance of FEEDBACK VERTEX SET if and only if  $(G', k)$  is a **yes**-instance of FEEDBACK VERTEX SET.

► **Lemma 7.**  *$G'$  has  $O(k)$  vertices of degree at least three if  $(G', k)$  is a **yes**-instance of FEEDBACK VERTEX SET, where  $G'$  is the graph obtained from  $G$  by removing all degree-1 vertices.*

**Proof.** If  $G'$  has a feedback vertex set of size  $k$ , the number of heavy cells is at most  $k$ , and the size of  $P_h$  is at most  $3k$ . This is because all but two of the vertices contained in the same cell must be contained in a feedback vertex set of  $G$ . In the following, we show that the number of vertices of  $P_\ell$  of degree at least three is at most  $O(k)$ .

To do this, consider the subgraph  $G_\ell$  of  $G'$  induced by  $P_\ell$ . We first observe that every vertex of  $G_\ell$  has degree at most  $4(\alpha\gamma)^2$  in  $G_\ell$ . (But note that its degree in  $G'$  might be larger than  $4(\alpha\gamma)^2$ .) Moreover,  $G_\ell$  also has a feedback vertex set of size  $k$ . Let  $X$  be a feedback vertex set of  $G_\ell$  of size  $k$ , and let  $Y$  be the set of vertices of  $G_\ell$  not contained in  $X$ . By definition, the subgraph  $G[Y]$  of  $G_\ell$  induced by  $Y$  is a forest. The number of vertices

of degree at least three is linear in the number of leaf nodes of the trees. Since  $G'$  has no degree-1 vertex, a leaf node of  $G[Y]$  is incident to a vertex of  $X \cup P_h$  in  $G'$ . Each vertex in  $X \cup P_h$  is incident to at most  $4(\alpha\beta)^2$  vertices of  $Y$ . Since  $|X \cup P_h|$  is  $O(k)$ , the total number of vertices of leaf nodes is  $O(k)$ , and thus, the total number of vertices of degree at least three of  $G_\ell$  (and  $G'$ ) is  $O(k)$ .  $\blacktriangleleft$

► **Lemma 8.** *For a greedy partition  $\mathcal{P}$ , the weighted treewidth of  $G_{\mathcal{P}}$  is  $O(\sqrt{k})$  if  $(G, k)$  is a *yes-instance* of FEEDBACK VERTEX SET.*

## 4.2 Dynamic Programming

By combining Lemma 7 and Theorem 1, we can obtain a tree decomposition of weighted width  $O(\sqrt{k})$  if a geometric intersection graph  $G$  has a feedback vertex set of size  $k$ . De Berg et al. [9] showed how to compute a feedback vertex set of size  $k$  in  $2^{O(\sqrt{w})}$  poly  $n$  time, where  $w$  denotes the weighted treewidth of  $G_{\mathcal{P}}$ . In this section, we briefly describe how this algorithm works.

Given a tree decomposition  $(T, \beta)$  of a graph  $G'$ , algorithm for solving FEEDBACK VERTEX SET computes for each bag  $\beta(t)$  and each subset  $S \subseteq \beta(t)$  together with the connectivity information  $\eta$  of the vertices of  $S$ , the maximum size  $c[t, S, \eta]$  of a feedback vertex set  $\hat{S}$  of  $G[t]$  with  $\hat{S} \cap \beta(t) = S$  satisfying the connectivity information  $\eta$ , where  $G[t]$  denotes the subgraph of  $G$  induced by the vertices appearing in bags in the subtree of  $T$  rooted at  $t$ .

Let  $t$  be a node of a tree decomposition  $(T, \beta)$  of  $G_{\mathcal{P}}$ . Recall that each vertex  $v$  of  $\beta(t)$  corresponds to the partition class  $P(v)$ . Let  $X_t = \bigcup_{v \in \beta(t)} P(v)$ . A feedback vertex set contains at least  $|C| - 2$  vertices of a clique  $C$ . Therefore, since from each partition class we can exclude  $O(1)$  vertices (at most two vertices from each clique), the number of subsets  $\hat{S}$  that need to be considered is at most

$$\prod_{v \in \beta(t)} |P(v)|^2 = \exp\left(\sum_{C \in \beta(t)} 2 \log |P(v)|\right) = 2^{O(\sqrt{k})}.$$

Therefore, we can track connectivity of these subsets by applying the rank-based approach of [3], which allows us to keep the number of equivalence relations considered single-exponential in  $O(\sqrt{k})$ . Assuming that we have  $c[t', \cdot, \cdot]$  for all descendants  $t'$  of  $t$  in  $T$  and their connectivity information, we can compute  $c[t, S, \eta]$  in  $2^{O(\sqrt{k})}$  time. Since the number of nodes in the tree decomposition is  $O(kn)$ , the total running time of the dynamic programming algorithm is  $2^{O(\sqrt{k})}(n + m)$ . Therefore, we have the following theorem.

► **Theorem 9.** *Given a intersection graph  $G$  of similarly sized fat objects in the plane (without its geometric representation), we can compute a feedback vertex set of size  $k$  in  $2^{O(\sqrt{k})}(n + m)$  time, if it exists.*

## Abstract

We present streaming algorithms for the graph  $k$ -matching problem in both the insert-only and dynamic models. Our algorithms, while keeping the space complexity matching the best known upper bound, have optimal or near-optimal update time, significantly improving on previous results. More specifically, for the insert-only streaming model, we present a one-pass randomized algorithm that runs in optimal  $\mathcal{O}(k^2)$  space and has optimal  $\mathcal{O}(1)$  update time, and that, *w.h.p.* (with high probability), computes a maximum weighted  $k$ -matching of a weighted graph. Previously, the best upper bound on the update time was  $\mathcal{O}(\log k)$ , which was achieved by a deterministic streaming algorithm that however only works for unweighted graphs [16]. For the dynamic streaming model, we present a one-pass randomized algorithm that, *w.h.p.*, computes a maximum weighted  $k$ -matching of a weighted graph in  $\tilde{O}(Wk^2)$  space<sup>1</sup> and with  $\tilde{O}(1)$  update time, where  $W$  is the number of distinct edge weights. Again the update time of our algorithm improves the previous best upper bound  $\tilde{O}(k^2)$  [7]. Moreover, we prove that in the dynamic streaming model, any randomized streaming algorithm for the problem requires  $k^2 \cdot \Omega(W(\log W + 1))$  bits of space. Hence, both the space and update-time complexities achieved by our algorithm in the dynamic model are near-optimal. A streaming approximation algorithm for  $k$ -matching is also presented, whose space complexity matches the best known upper bound with a significantly improved update time.

## 1 Introduction

Streaming algorithms for graph matching have been studied extensively, in which most of the work has been focused on approximating a maximum matching. A graph *stream*  $\mathcal{S}$  for an underlying graph  $G$  is a sequence of edge operations. In the *insert-only* streaming model, each operation is an edge-insertion, while in the *dynamic* streaming model each operation is either an edge-insertion or an edge-deletion (with a specified weight if  $G$  is weighted). The majority of the work on streaming algorithms for graph matching has been on the (simpler) insert-only model. More recently, streaming algorithms for graph  $k$ -matching

---

<sup>1</sup> The notation  $\tilde{O}()$  hides a poly-logarithmic factor in the input size.

(i.e., constructing a matching of  $k$  edges in an unweighted graph or a maximum weighted matching of  $k$  edges in a weighted graph), in both insert-only and dynamic models, have drawn increasing interests [7, 8, 9, 16].

The performance of streaming algorithms is measured by the limited memory (*space*) and the limited processing time per item (*update time*). For the space complexity, a lower bound  $\Omega(k^2)$  has been known for the graph  $k$ -matching problem on unweighted graphs for randomized streaming algorithms, even in the simpler insert-only model [7]. Nearly space-optimal streaming algorithms for graph  $k$ -matching have been developed [7].

The current paper will be focused on the update time of streaming algorithms for graph  $k$ -matching. While there has been much work on space complexity of streaming algorithms for graph matching, much less is known regarding the update time complexity of the problem. Note that the update time sometimes could be even more important than the space complexity [25], since the data stream can come at a very high rate. If the update processing does not catch the updating rate, the whole system may fail (see, e.g., [3, 34]).

We start with the insert-only model. We present a one-pass randomized streaming algorithm that constructs a maximum weighted  $k$ -matching in a weighted graph. Our algorithm runs in  $\mathcal{O}(k^2)$  space and has  $\mathcal{O}(1)$  update time, both are optimal. Our techniques rely on partitioning the graph (using hashing), and defining an auxiliary graph whose vertices are the different parts of the partition. The auxiliary graph is updated during the stream. By querying this auxiliary graph, the algorithm can compute a “compact” subgraph of size  $\mathcal{O}(k^2)$  that, *w.h.p.*, contains the edges of the desired  $k$ -matching. A maximum weighted  $k$ -matching can then be extracted from this compact subgraph.

Previously, Fafianie and Kratsch [16] studied kernelization streaming algorithms in the insert-only model. Their result implies a one-pass deterministic streaming algorithm for  $k$ -matching on unweighted graphs that uses  $\mathcal{O}(k^2)$  space and  $\mathcal{O}(\log k)$  update time. In comparison, our algorithm achieves the same space complexity but has optimal update time  $\mathcal{O}(1)$ . While improving the update time from  $\mathcal{O}(\log k)$  on the deterministic algorithm to  $\mathcal{O}(1)$  on randomized algorithms for unweighted graphs may not look surprising, our streaming algorithm with optimal space and update time for weighted graphs is a significant advance.

We then study steaming algorithms for graph  $k$ -matching in the dynamic model. We give a one-pass randomized streaming algorithm that, for a weighted graph  $G$  containing a  $k$ -matching, constructs a maximum weighted  $k$ -matching of  $G$  with probability at least  $1 - \frac{11}{20k^3 \ln(2k)}$ , and in case  $G$  does not contain a  $k$ -matching, reports correctly. The algorithm runs in  $\tilde{\mathcal{O}}(Wk^2)$  space and has  $\tilde{\mathcal{O}}(1)$  update time, where  $W$  is the number of distinct weights in the graph. This result directly implies a one-pass randomized streaming algorithm for unweighted  $k$ -matching running in  $\tilde{\mathcal{O}}(k^2)$  space with  $\tilde{\mathcal{O}}(1)$  update time.

In order to achieve the faster update time, we prove a structural result that can be useful in its own right for  $k$ -subset problems. Intuitively, the result states that, for any  $k$ -subset  $S \subseteq U$ , *w.h.p.* we can compute  $k$  subsets  $T_1, \dots, T_k$  of  $U$  that interact “nicely” with  $S$ . More specifically, (1) the sets  $T_i$ , for  $i \in [k]$ , are pairwise disjoint, (2)  $S$  is contained in their union  $\bigcup_{i \in [k]} T_i$ , and (3) each  $T_i$  contains exactly one element of  $S$ . We then apply the above result to obtain the sets  $T_i$  of vertices that *w.h.p.* induce the edges of the desired  $k$ -matching. Afterwards, we use  $\ell_0$ -sampling to select a smaller subset of edges induced by the vertices of the  $T_i$ ’s that *w.h.p.* contains the desired  $k$ -matching. From this smaller subset of edges, a maximum weighted  $k$ -matching can be extracted.

Employing lower bounds for communication complexity protocols, we prove that, modulo a poly-logarithmic function of the input size, the space complexity  $\tilde{\mathcal{O}}(Wk^2)$  achieved by our algorithm is optimal with respect to both  $k$  and  $W$ . More specifically, neither the linear

term  $W$  nor the quadratic function  $k^2$  in the space complexity of our algorithm for weighted  $k$ -matching can be improved/reduced (by more than a poly-logarithmic function). Given that our algorithms have  $\tilde{O}(1)$  update time, this implies that our algorithms are essentially near-optimal in terms of both space and update time complexities.

Chitnis et al. [7] proposed a streaming algorithm on the dynamic model for maximum matching. Under the promise that the cardinality of the maximum matching is not larger than  $k$  during the entire graph stream, their algorithm runs in space  $\tilde{O}(k^2)$  and has update time  $\tilde{O}(1)$  for unweighted graphs. The assumption that the cardinality of the maximum matching is at most  $k$  during the entire graph stream is essential for their techniques to work since it is used to upper bound the number of vertices of degree larger than or equal to  $10k$  by  $\mathcal{O}(k)$ , and the number of edges whose both endpoints have degree bounded by  $10k$  by  $\mathcal{O}(k^2)$ . They also developed a streaming algorithm that approximates the maximum matching for unweighted graphs. These two algorithms can be combined to construct a  $k$ -matching with update time  $\tilde{O}(k^2)$  and space  $\tilde{O}(k^2)$  for unweighted graphs. The algorithm for unweighted graphs can be extended to construct a maximum weighted  $k$ -matching for weighted graphs, which runs in space  $\tilde{O}(Wk^2)$  with update time  $\tilde{O}(k^2)$ . In comparison, our algorithm keeps the space complexity  $\tilde{O}(Wk^2)$  while has significantly improved update time  $\tilde{O}(1)$ .

A byproduct of our result is a one-pass streaming approximation algorithm that, for any  $\epsilon > 0$ , *w.h.p.* computes a  $k$ -matching that is within a factor of  $1 + \epsilon$  from a maximum weighted  $k$ -matching in  $G$ . The algorithm runs in  $\tilde{O}(k^2 \epsilon^{-1} \log W')$  space and has  $\tilde{O}(1)$  update time, where  $W'$  is the ratio of the maximum edge-weight to the minimum edge-weight in  $G$ . This result improves the update time complexity over the approximation result in [7], which has the same space complexity but has update time  $\tilde{O}(k^2)$ .

We observe that most work on weighted graph streams, including our current paper, assumes that the weight of an edge remains the same during the stream (see, e.g., [1, 2, 7, 20, 23]). To justify this assumption, we present an interesting lower bound result showing that, if this assumption is lifted, then the space complexity of the  $k$ -matching problem is at least linear in the size of the graph, and hence, can be much larger than the desirable space complexity for streaming algorithms.

The paper is organized as follows. Section 2 provides necessary definitions and a brief review on the related research. Improved streaming algorithms for graph  $k$ -matching in insert-only model and in dynamic model are presented and discussed in sections 3-5. Some lower bound results are give in section 6. Section 7 concludes with remarks.

## 2 Preliminaries

We refer to the following books for more detailed definitions [14, 15, 30]. We use “*u.a.r.*” as an abbreviation for “uniformly at random”. For an integer  $i$ , let  $[i]^-$  denote the set  $\{0, 1, \dots, i-1\}$ ,  $[i]$  the set  $\{1, \dots, i\}$ , and  $\lfloor i \rfloor$  the binary representation of  $i$ .

**Computational Model and Problem Definition.** In a parameterized graph streaming problem  $Q$ , we are given an instance of the form  $(\mathcal{S}, k)$ , where  $\mathcal{S}$  is graph stream of some underlying graph  $G$  and  $k \in \mathbb{N}$ , and we are asked to compute a solution for  $(\mathcal{S}, k)$  [9]. A  $k$ -matching in a graph  $G$  is a matching of  $k$  edges in  $G$ . We study the following problems:

- p-MATCHING: Given a graph stream  $\mathcal{S}$  of an unweighted graph  $G$  and a parameter  $k$ , compute a  $k$ -matching in  $G$  or report that no  $k$ -matching exists.
- p-WT-MATCHING: Given a graph stream  $\mathcal{S}$  of a weighted graph  $G$  and a parameter  $k$ , compute a  $k$ -matching of maximum weight in  $G$  or report that no  $k$ -matching exists.

We will assume that  $V(G) = [n]^-$ , and that the length of  $\mathcal{S}$  is polynomial in  $n$ . We will design parameterized streaming algorithms for the above problems. Our algorithms first sample a subgraph  $G'$  of the underlying graph  $G$  in the stream such that *w.h.p.*  $G'$  contains a desired  $k$ -matching of  $G$  if and only if  $G$  has one. In the case where the size of  $G'$  is a function of  $k$ , such algorithms are referred to as *kernelization streaming algorithms* [7]. We note that result in [7] also computes a subgraph containing the edges of the desired matching, without computing the matching itself, as there are efficient algorithms for extracting the desired matching from that subgraph [18].

**$\ell_0$ -Sampler.** Let  $\mathcal{S} = (i_1, \Delta_1), \dots, (i_p, \Delta_p), \dots$  be a stream of updates of an underlying vector  $\mathbf{x} \in \mathbb{R}^n$ , where  $i_j \in [n]$  and  $\Delta_j \in \mathbb{R}$ . The  $j$ -th update  $(i_j, \Delta_j)$  updates the  $i_j$ -th coordinate of  $\mathbf{x}$  by setting  $\mathbf{x}_{i_j} = \mathbf{x}_{i_j} + \Delta_j$ . Fix a parameter  $0 < \delta < 1$ . An  $\ell_0$ -sampler for  $\mathbf{x} \neq 0$  either fails with probability at most  $\delta$ , or conditioned on not failing, for any non-zero coordinate  $\mathbf{x}_j$  of  $\mathbf{x}$ , returns the pair  $(j, \mathbf{x}_j)$  with probability  $\frac{1}{\|\mathbf{x}\|_0}$ , where  $\|\mathbf{x}\|_0$  is the  $\ell_0$ -norm of  $\mathbf{x}$ , which is the same as the number of non-zero coordinates of  $\mathbf{x}$ . (We refer to [12].)

► **Lemma 1** (Follows from Theorem 2.1 in [7]). *Let  $0 < \delta < 1$  be a parameter. There exists an  $\ell_0$ -sampler algorithm that, given a dynamic graph stream, either returns FAIL with probability at most  $\delta$ , or returns an edge chosen u.a.r. from the edges of the stream that have been inserted and not deleted. This algorithm can be implemented using  $\mathcal{O}(\log^2 n \cdot \log(\delta^{-1}))$  bits of space and  $\tilde{O}(1)$  update time, where  $n$  is the number of vertices in the underlying graph.*

We give a brief review on the known work that is related to our current paper.

Most work on graph matching in the streaming model has focused on approximating a maximum matching (e.g., [4, 5, 19, 21, 22, 24, 26, 31]), with the majority of the work pertaining to the (simpler) insert-only model. The most relevant to ours are [7, 8, 9, 16], which studied parameterized streaming algorithms for the maximum matching problem.

Under the promise that the cardinality of the maximum matching at *every* instant of the stream is at most  $k$ , the authors of [8, 9] presented a one-pass dynamic streaming algorithm that *w.h.p.* computes a maximum matching in an unweighted graph stream. The algorithms given in [8, 9] run in  $\tilde{O}(k^2)$  space and the algorithm in [9] has  $\tilde{O}(k^2)$  update time.

The authors of [7] considered the problem of computing maximum matchings in the dynamic streaming model. For an unweighted graph  $G$ , under the promise that the cardinality of the maximum matching at every instant of the stream is at most  $k$ , a sketch-based algorithm is presented, which *w.h.p.* computes a maximum matching of  $G$ , runs in  $\tilde{O}(k^2)$  space, and has  $\tilde{O}(1)$  update time. They proved an  $\Omega(k^2)$  lower bound on the space complexity of any randomized algorithm for the parameterized maximum matching problem, even in the insert-only model, thus showing that the space complexity of their algorithm is optimal (modulo a poly-logarithmic factor). The algorithm for unweighted graphs has been extended to weighted graphs: under the same promise, there is an algorithm for computing a maximum weighted matching that runs in space  $\tilde{O}(k^2 W)$  and has  $\tilde{O}(1)$  update time, where  $W$  is the number of distinct edge weights. For unweighted graphs with larger matchings, an approximation algorithm is proposed [7]. Specifically, if the graph contains matchings of size larger than  $k$ , then for any  $1 \leq \alpha \leq \sqrt{k}$  and  $0 < \epsilon \leq 1$ , there exists an  $\tilde{O}(k^2 \alpha^{-3} \epsilon^{-2})$ -space algorithm that returns a matching of size at least  $\frac{(1-\epsilon)k}{2\alpha}$ . The algorithm has  $\tilde{O}(k^2 \alpha^{-2} \epsilon^{-2})$  update time.

Fafianie and Kratsch [16] studied kernelization streaming algorithms in the insert-only model for the NP-hard  $d$ -SET MATCHING problem (among others), which for  $d = 2$ , is equivalent to the  $k$ -matching problem on unweighted graphs. Their result implies a one-pass kernelization streaming algorithm for  $k$ -matching in unweighted graphs that computes a kernel of size  $\mathcal{O}(k^2 \log k)$ , runs in  $\mathcal{O}(k^2)$  space, and has  $\mathcal{O}(\log k)$  update time.

Chen et al. [6] studied algorithms for  $k$ -matching on the RAM model with limited computational resources, which is clearly very different from the streaming model. In order to translate their algorithm to the streaming model, it would require  $\Omega(nk)$  space and multiple passes. However, we remark that one of the steps of our algorithm in the insert-only model was inspired by the construction of reduced graphs introduced in [6].

Finally, there has been work on computing matchings in special graph classes, and with respect to parameters other than the cardinality of the matching (e.g., see [27, 28]).

### 3 Algorithms in Insert-Only Streaming Model

In this section, we give a streaming algorithm for P-WT-MATCHING, and hence for p-MATCHING as a special case, in the insert-only model. We start with some notations.

Given a weighted graph  $G = (V = [n]^-, E)$  along with a weight function  $wt : E(G) \rightarrow \mathbb{R}_{\geq 0}$ , and a parameter  $k$ , we define a new function  $\beta : E(G) \rightarrow \mathbb{R}_{\geq 0} \times [n]^- \times [n]^-$  as follows: for  $e = [u, v] \in E$ , where  $u < v$ , let  $\beta(e) = (wt(e), u, v)$ . Observe that  $\beta$  is injective.

Define a partial order relation  $\prec$  on  $E(G)$  as follows: for any two distinct edges  $e, e' \in E(G)$ ,  $e \prec e'$  if  $\beta(e)$  is lexicographically smaller than  $\beta(e')$ . For a vertex  $v \in V$  and an edge  $e$  incident to  $v$ , define  $\Gamma_v$  to be the sequence of edges incident to  $v$ , sorted in a decreasing order w.r.t.  $\prec$ . We say that  $e$  is the  $i$ -heaviest edge w.r.t.  $v$  if  $e$  is the  $i$ -th element in  $\Gamma_v$ .

Let  $f : V \rightarrow [4k^2]^-$  be a hash function, and let  $H$  be a subgraph of  $G$ . The function  $f$  partitions  $V(H)$  into a collection of subsets  $\mathcal{V} = \{V_0, V_1, \dots, V_{4k^2-1}\}$ , where each  $V_i$  consists of the vertices in  $V(H)$  that have the same image under  $f$ . A matching  $M$  in  $H$  is said to be *nice* w.r.t.  $f$  if no two vertices of  $M$  belong to the same  $V_i$  in  $\mathcal{V}$ . When the function  $f$  is clear from the context, we will simply say that “ $M$  is nice.” We define the *compact* subgraph of  $H$  under  $f$ , denoted  $Compact(H, f)$ , as the subgraph of  $H$  consisting of the edges  $e$  in  $H$  whose endpoints belong to different subsets  $V_i$  and  $V_j$  in  $\mathcal{V}$ , with  $i \neq j$ , and such that  $\beta(e)$  is the maximum over all edges between  $V_i$  and  $V_j$ . Finally, we define the *reduced compact* subgraph of  $H$  under  $f$ , denoted  $Red-Com(H, f)$ , by (1) for each pair  $(V_i, V_j)$  of subsets, selecting edges  $e \in Compact(H, f)$  with endpoints in  $V_i$  and  $V_j$  such that  $e$  is among the  $8k$  heaviest edges incident to vertices in  $V_i$  and among the  $8k$  heaviest edges incident to vertices in  $V_j$  (in both subsets, if there are not that many edges, then include all edges); and then (2) retaining from the selected edges in (1) the  $q = k(16k - 1)$  heaviest edges (again if there are not that many edges, include all edges). We have the following:

► **Lemma 2.** *The subgraph  $Compact(H, f)$  has a nice  $k$ -matching if and only if  $Red-Com(H, f)$  has a nice  $k$ -matching. If this is the case, then the weight of a maximum weighted nice  $k$ -matching in  $Compact(H, f)$  is equal to that in  $Red-Com(H, f)$ .*

**Proof.** Define the auxiliary weighted graph  $\Phi$  whose vertices are the subsets  $V_i$  in the collection  $\mathcal{V}$ , where  $i \in [4k^2]^-$ , such that there is an edge  $[V_i, V_j]$  in  $\Phi$  if some vertex  $u \in V_i$  is adjacent to some vertex  $v \in V_j$  in  $Compact(H, f)$ . We associate with edge  $[V_i, V_j]$  the value  $\beta([u, v])$  and associate the edge  $[u, v]$  with  $[V_i, V_j]$ . Obviously, there is one-to-one correspondence between the nice  $k$ -matchings in  $Compact(H, f)$  and the  $k$ -matchings in  $\Phi$ . Let  $\mathcal{H}$  be the subgraph of  $\Phi$  formed by selecting edges  $[V_i, V_j]$  such that  $[V_i, V_j]$  is among the  $8k$  heaviest edges incident to  $V_i$  and among the  $8k$  heaviest edges incident to  $V_j$ . Let  $\mathcal{H}'$  consist of the  $q = k(16k - 1)$  heaviest edges in  $\mathcal{H}$  (if  $\mathcal{H}$  has at most  $q$  edges, let  $\mathcal{H}' = \mathcal{H}$ ). Since there is a one-to-one correspondence between the nice  $k$ -matchings in  $Compact(H, f)$  and the  $k$ -matchings of  $\Phi$ , it suffices to prove the statement of the lemma with respect to matchings in  $\Phi$  and  $\mathcal{H}'$ : namely, if  $\Phi$  has a maximum weighted  $k$ -matching  $M$  then  $\mathcal{H}'$  has a maximum weighted  $k$ -matching of the same weight as  $M$ .

Suppose that  $\Phi$  has a maximum weighted  $k$ -matching  $M$ . Choose  $M$  such that the number of edges in  $M$  that remain in  $\mathcal{H}$  is maximized. We first show that all the edges in  $M$  remain in  $\mathcal{H}$ . Suppose not, then there is an edge  $[V_{i_0}, V_{i_1}] \in M$  such that  $[V_{i_0}, V_{i_1}]$  is not among the  $8k$  heaviest edges incident to one of its endpoints, say  $V_{i_1}$ . Since  $|V(M)| = 2k < 8k$ , it follows that there is a heaviest edge  $[V_{i_1}, V_{i_2}]$  incident to  $V_{i_1}$  such that  $\beta([V_{i_1}, V_{i_2}]) > \beta([V_{i_0}, V_{i_1}])$  and  $V_{i_2} \notin V_M$ . If  $[V_{i_1}, V_{i_2}] \in \mathcal{H}$ , then  $(M - [V_{i_0}, V_{i_1}]) + [V_{i_1}, V_{i_2}]$  is a maximum weighted  $k$ -matching of  $\Phi$  that contains more edges of  $\mathcal{H}$  than  $M$ , contradicting our choice of  $M$ . It follows that  $[V_{i_1}, V_{i_2}] \notin \mathcal{H}$ . Then,  $[V_{i_1}, V_{i_2}]$  is not among the  $8k$  heaviest edges incident to  $V_{i_2}$ . Now apply the above argument to  $V_{i_2}$  to select the heaviest edge  $[V_{i_2}, V_{i_3}]$  such that  $\beta([V_{i_2}, V_{i_3}]) > \beta([V_{i_1}, V_{i_2}]) > \beta([V_{i_0}, V_{i_1}])$  and  $V_{i_3} \notin V_M$ . By applying the above argument  $j$  times, we obtain a sequence of  $j$  vertices  $V_{i_1}, V_{i_2}, \dots, V_{i_j}$ , such that (1)  $\{V_{i_2}, \dots, V_{i_j}\} \cap V_M = \emptyset$ ; and (2)  $V_{i_a} \neq V_{i_b}$  for every  $a \neq b \in [j]$ , which is guaranteed by  $\beta([V_{i_a}, V_{i_{a+1}}]) < \beta([V_{i_{a+1}}, V_{i_{a+2}}]) < \dots < \beta([V_{i_{b-1}}, V_{i_b}])$  and  $[V_{i_a}, V_{i_{a+1}}]$  is the heaviest edge incident to  $V_{i_a}$  such that  $V_{i_{a+1}} \notin V_M$ . Since  $\Phi$  is finite, the above process must end at an edge  $e$  not in  $M$  and such that  $\beta(e)$  exceeds  $\beta([V_{i_0}, V_{i_1}])$ , contradicting our choice of  $M$ . Therefore,  $M \subseteq E(\mathcal{H})$ .

Now, choose a maximum weighted  $k$ -matching of  $\mathcal{H}$  that maximizes the number of edges retained in  $\mathcal{H}'$ . Without loss of generality, call it  $M$ . We prove that the edges of  $M$  are retained in  $\mathcal{H}'$ , thus proving the lemma. Suppose that this is not the case. Since each vertex in  $V(M)$  has degree at most  $8k$  and one of its edges must be in  $M$ , the number of edges in  $\mathcal{H}$  incident to the vertices in  $M$  is at most  $2k(8k - 1) + k = k(16k - 1) = q$ . It follows that there is an edge  $e$  in  $\mathcal{H}'$  whose endpoints are not in  $M$  and such that  $\beta(e)$  is larger than the  $\beta()$  value of some edge in  $M$ , contradicting our choice of  $M$ .  $\blacktriangleleft$

► **Lemma 3.** *Let  $f : V \rightarrow [4k^2]^-$  be a hash function, and let  $H$  be a subgraph of  $G$ . There is an algorithm **Alg-Reduce**( $H, f$ ) that constructs  $\mathcal{Red-Com}(H, f)$  and has both its time and space complexities bounded by  $\mathcal{O}(|H| + k^2)$ .*

We now present the streaming algorithm  $\mathcal{A}_{\text{Insert}}$  for P-WT-MATCHING. Let  $(\mathcal{S}, k)$  be an instance of p-WT-MATCHING, where  $\mathcal{S} = (e_1, wt(e_1)), \dots, (e_i, wt(e_i)), \dots$ . For  $i \in \mathbb{N}$ , let  $G_i$  be the subgraph of  $G$  consisting of the first  $i$  edges  $e_1, \dots, e_i$  of  $\mathcal{S}$ , and for  $j \leq i$ , let  $G_{j,i}$  be the subgraph of  $G$  whose edges are  $\{e_j, \dots, e_i\}$ ; if  $j > i$ , we let  $G_{j,i} = \emptyset$ . Let  $f$  be a hash function chosen u.a.r. from a universal set  $\mathcal{H}$  of hash functions mapping  $V$  to  $[4k^2]^-$ . The algorithm  $\mathcal{A}_{\text{Insert}}$ , after processing the  $i$ -th element  $(e_i, wt(e_i))$ , computes two subgraphs  $G_i^f$  and  $G_i^s$  defined as follows. For  $i = 0$ ,  $G_i^f = G_i^s = \emptyset$ . For  $i > 0$ , let  $\hat{i}$  be the largest multiple of  $q$  that is smaller than  $i$ , that is,  $i = \hat{i} + p$ , where  $0 < p \leq q$ ; and let  $i^*$  be the largest multiple of  $q$  that is smaller than  $\hat{i}$  if  $\hat{i} > 0$ , and 0 otherwise. The subgraph  $G_i^f$  is defined only when  $i$  is a multiple of  $q$ , and is defined recursively for  $i = j \cdot q > 0$  as  $G_i^f = \mathcal{Red-Com}(G_i^f \cup G_{i^*+1, \hat{i}})$ ; that is,  $G_i^f$  is the reduced compact subgraph of the graph consisting of  $G_i^f$  plus the subgraph consisting of the edges encountered after  $e_{i^*}$ , starting from  $e_{i^*+1}$  up to  $e_i$ . The subgraph  $G_i^s$  is defined as  $G_i^s = G_i^f \cup G_{i^*+1, i}$ ; that is,  $G_i^s$  consists of the previous (before  $i$ ) reduced compact subgraph plus the subgraph consisting of the edges starting after  $i^*$  up to  $i$ . We refer to Figure 1 for an illustration of the definitions of  $G_i^f$  and  $G_i^s$ .

► **Lemma 4.** *For each  $i \geq 1$ , if  $G_i$  contains a maximum weighted  $k$ -matching, then with probability at least  $1/2$ ,  $G_i^s$  contains a maximum weighted  $k$ -matching of  $G_i$ .*

**Proof.** Let  $M = \{[u_0, u_1], \dots, [u_{2k-2}, u_{2k-1}]\}$  be a maximum weighted  $k$ -matching in  $G_i$ , and let  $V_M = \{u_0, \dots, u_{2k-1}\}$ . Since  $f$  is a hash function chosen u.a.r. from a universal set  $\mathcal{H}$  of hash functions mapping  $V$  to  $[4k^2]^-$ , with probability at least  $1/2$ ,  $f$  is perfect w.r.t.  $V_M$  [11]. Now, suppose that  $f$  is perfect w.r.t.  $V_M$ . Thus,  $M$  is a nice matching (w.r.t.  $f$ ) in  $G_i$ . By the

Figure 1 Illustration of the definitions of  $G_i^f$  and  $G_i^s$ .

definition of  $Compact(G_i, f)$ , there is a set  $M'$  of  $k$  edges  $M' = \{[u'_0, u'_1], \dots, [u'_{2k-2}, u'_{2k-1}]\}$  in  $Compact(G_i, f)$  such that  $\{f(u'_{2i}), f(u'_{2i+1})\} = \{f(u_{2i}), f(u_{2i+1})\}$  and  $\beta([u'_{2i}, u'_{2i+1}]) \geq \beta([u_{2i}, u_{2i+1}])$  for  $i \in [k]^-$ . It follows that  $wt([u'_{2i}, u'_{2i+1}]) \geq wt([u_{2i}, u_{2i+1}])$  for  $i \in [k]^-$ . Therefore,  $Compact(G_i, f)$  contains a maximum weighted  $k$ -matching of  $G_i$ , namely  $\{[u'_0, u'_1], \dots, [u'_{2k-2}, u'_{2k-1}]\}$ ; moreover, this matching is nice. By Lemma 2,  $Red-Com(G_i, f)$  contains a maximum weighted  $k$ -matching of  $Compact(G_i, f)$ .

Next, we prove that  $G_i^s$  contains a maximum weighted  $k$ -matching of  $G_i$ . If  $i \leq 2q$ , then  $G_i^s = G_{1,i} = G_i$  by definition, and hence  $G_i^s$  contains a maximum weighted  $k$ -matching of  $G_i$ . Suppose now that  $i > 2q$ . By definition,  $G_i^s = G_i^f \cup G_{i^*+1,i}$ . (Recall that, by definition,  $G_q^f = \emptyset$ ,  $G_{2q}^f = Red-Com(G_q^f \cup G_{1,q})$ ,  $G_{3q}^f = Red-Com(G_{2q}^f \cup G_{q+1,2q})$ ,  $\dots$ ,  $G_i^f = Red-Com(G_{i^*}^f \cup G_{i^*-q+1,i^*})$ .) For each  $j \geq 1$  that is multiple of  $q$ , let  $\mathcal{G}_j$  be the graph consisting of the edges that are in  $G_j^f \cup G_{j^*+1,\hat{j}}$  but are not kept in  $G_j^f$ . Consequently,  $(\bigcup_{q \leq j < \hat{i}, j \text{ is a multiple of } q} \mathcal{G}_j) \cup G_{i^*}^f = G_i^s$ . By the definition of  $Red-Com(G_i, f)$ , it is easy to verify that  $Red-Com(G_i, f)$  does not contain the edges in  $\mathcal{G}_j$ , for each  $j \geq 1$ . It follows that  $Red-Com(G_i, f)$  is a subgraph of  $G_i^s$ , and hence,  $G_i^s$  contains a maximum weighted  $k$ -matching of  $Red-Com(G_i, f)$ , and hence of  $Compact(G_i, f)$  by the above discussion. Since  $Compact(G_i, f)$  contains a maximum weighted  $k$ -matching of  $G_i$ ,  $G_i^s$  contains a maximum weighted  $k$ -matching of  $G_i$ . It follows that, with probability at least  $1/2$ ,  $G_i^s$  contains a maximum weighted  $k$ -matching of  $G_i$ . ◀

The algorithm  $\mathcal{A}_{Insert}$ , when queried at the end of the stream, either returns a maximum weighted  $k$ -matching of  $G$  or the empty set. To do so, at every instant  $i$ , it will maintain a subgraph  $G_i^s$  that will contain the edges of the desired matching, from which this matching can be extracted. To maintain  $G_i^s$ , the algorithm keeps track of the subgraphs  $G_{i-1}^s$ ,  $G_i^f$ , the edges  $e_{i^*+1}, \dots, e_i$ , and will use them in the computation of the subgraph  $G_i^s$  as follows. If  $i$  is not a multiple of  $q$ , then  $G_i^s = G_{i-1}^s + e_i$ , and the algorithm simply computes  $G_i^s$  as such. Otherwise (i.e.,  $i$  is a multiple of  $q$ ),  $G_i^s = G_i^f \cup G_{i^*+1,i}$ , and the algorithm uses  $G_i^f$  and  $G_{i^*+1,i} = \{e_{i^*+1}, \dots, e_i\}$  to compute and return  $G_i^s$ ; however, in this case (i.e.,  $i$  is a multiple of  $q$ ), the algorithm will additionally need to have  $G_i^f$  already computed, in preparation for the potential computations of subsequent  $G_j^s$ , for  $j \geq i$ . By Lemma 3, the subgraph  $G_i^f$  can be computed by invoking the algorithm **Alg-Reduce** in Lemma 3 on  $G_i^f \cup G_{i^*+1,\hat{i}}$ , which runs in time  $\mathcal{O}(q)$ . Note that both  $G_i^f$  and  $G_{i^*+1,\hat{i}}$  are available to  $\mathcal{A}_{Insert}$  at each of the steps  $\hat{i} + 1, \dots, i$ . Therefore, the algorithm will stagger the  $\mathcal{O}(q)$  many operations needed for the computation of  $G_i^f$  uniformly (roughly equally) over each of the steps  $\hat{i} + 1, \dots, i$ ,

yielding an  $\mathcal{O}(1)$  operations per step. Note that all the operations in **Alg-Reduce** can be explicitly listed, and hence, splitting them over an interval of  $q$  steps is easily achievable. Combining the above discussions and lemmas, we conclude with:

► **Lemma 5.** *The algorithm  $\mathcal{A}_{\text{Insert}}$  runs in space  $\mathcal{O}(k^2)$  and has update time  $\mathcal{O}(1)$ .*

► **Theorem 6.** *Let  $0 < \delta < 1$  be a parameter. There is an algorithm for P-WT-MATCHING such that, on input  $(S, k)$ , the algorithm outputs a matching  $M'$  satisfying that (1) if  $G$  contains a  $k$ -matching then, with probability at least  $1 - \delta$ ,  $M'$  is a maximum weighted  $k$ -matching of  $G$ ; and (2) if  $G$  does not contain a  $k$ -matching then  $M' = \emptyset$ . The algorithm runs in  $\mathcal{O}(k^2 \log \frac{1}{\delta})$  space and has  $\mathcal{O}(\log \frac{1}{\delta})$  update time. In particular, for any constant  $\delta$ , the algorithm runs in space  $\mathcal{O}(k^2)$  and has  $\mathcal{O}(1)$  update time.*

**Proof.** Run  $\lceil \log \frac{1}{\delta} \rceil$ -many copies of algorithm  $\mathcal{A}_{\text{Insert}}$  in parallel (i.e., using dove-tailing). Then, by the end of the stream, there are  $\lceil \log \frac{1}{\delta} \rceil$  copies of  $G_m^s$ , where  $m$  is the length of the stream. Let  $G'$  be the union of all the  $G_m^s$ 's produced by the runs of  $\mathcal{A}_{\text{Insert}}$ . If  $G'$  has a  $k$ -matching, let  $M'$  be a maximum weighted  $k$ -matching of  $G'$ ; otherwise, let  $M' = \emptyset$ .

By Lemma 4, if  $G_m$ , i.e.,  $G$ , contains a maximum weighted  $k$ -matching, with probability at least  $1/2$ , one copy of  $G_m^s$  contains a maximum weighted  $k$ -matching of  $G$ . Hence, with probability at least  $1 - (1/2)^{\lceil \log \frac{1}{\delta} \rceil} \geq 1 - \delta$ ,  $G'$  contains a maximum weighted  $k$ -matching of  $G$ . It follows that if  $G$  contains a maximum weighted  $k$ -matching  $M$  then, with probability at least  $1 - \delta$ ,  $G'$  contains a maximum weighted  $k$ -matching of the same weight as  $M$  and hence  $M'$  is a maximum weighted  $k$ -matching of  $G$ .

Observe that the graph  $G'$  is a subgraph of  $G$ . Therefore, statement (2) in the theorem clearly holds true. By Lemma 5, the above algorithm runs in space  $\mathcal{O}(k^2 \log \frac{1}{\delta})$  and has update time  $\mathcal{O}(\log \frac{1}{\delta})$ , thus completing the proof. ◀

## 4 The Toolkit

In this section, we prove a theorem that can be useful in its own right for subset problems, that is, problems in which the goal is to compute a  $k$ -subset  $S$  ( $k \in \mathbb{N}$ ) of some universe  $U$  such that  $S$  satisfies certain prescribed properties. Intuitively, the theorem states that, for any  $k$ -subset  $S \subseteq U$ , *w.h.p.* we can compute  $k$  subsets  $T_1, \dots, T_k$  of  $U$  that interact “nicely” with  $S$ . More specifically, (1) the sets  $T_i$ , for  $i \in [k]$ , are pairwise disjoint, (2)  $S$  is contained in their union  $\bigcup_{i \in [k]} T_i$ , and (3) each  $T_i$  contains exactly one element of  $S$ .

The above theorem will be used in Section 5 to design algorithms for p-MATCHING and p-WT-MATCHING in the dynamic streaming model. Intuitively speaking, the theorem will be invoked to obtain the sets  $T_i$  of vertices that *w.h.p.* induce the edges of the desired  $k$ -matching; however, these sets may not necessarily constitute the desired subgraph as they may not have “small” cardinalities. Sampling techniques will be used to select a smaller set of edges induced by the vertices of the  $T_i$ 's that *w.h.p.* contains the edges of the  $k$ -matching.

A family  $\mathcal{H}$  of hash functions, each mapping  $U$  to  $[r]^-$ , is called  $\kappa$ -wise independent if for any  $\kappa$  distinct keys  $x_1, x_2, \dots, x_\kappa \in U$ , and any  $\kappa$  (not necessarily distinct) values  $a_1, a_2, \dots, a_\kappa \in [r]^-$ , we have  $\Pr_{h \in \mathcal{H}}[h(x_1) = a_1 \wedge h(x_2) = a_2 \wedge \dots \wedge h(x_\kappa) = a_\kappa] = \frac{1}{r^\kappa}$ .

Let  $\mathbb{F}$  be a finite field. A  $\kappa$ -wise independent family  $\mathcal{H}$  of hash functions can be constructed as follows (See Construction 3.32 in [35]):  $\mathcal{H} = \{h_{a_0, a_1, \dots, a_{\kappa-1}} : \mathbb{F} \rightarrow \mathbb{F}\}$ , where  $h_{a_0, a_1, \dots, a_{\kappa-1}}(x) = a_0 + a_1x + \dots + a_{\kappa-1}x^{\kappa-1}$  for  $a_0, \dots, a_{\kappa-1} \in \mathbb{F}$ .

The following theorem is proved in [35], and will be used in our discussion.

► **Theorem 7** (Corollary 3.34 in [35]). *For every  $u, d, \kappa \in \mathbb{N}$ , there is a family of  $\kappa$ -wise independent functions  $\mathcal{H} = \{h : \{0, 1\}^u \rightarrow \{0, 1\}^d\}$  such that choosing a random function from  $\mathcal{H}$  takes space  $\mathcal{O}(\kappa \cdot (u + d))$ . Moreover, evaluating a function from  $\mathcal{H}$  takes time polynomial in  $u, d, \kappa$ .*

To prove our theorem, we proceed in two phases. We give an intuitive description of these two phases. In the first phase, we choose a hashing function  $f$  u.a.r. from an  $\mathcal{O}(\ln k)$ -wise independent set of hash functions, which hashes  $U$  to a set of  $d_1 = \mathcal{O}(k/\ln k)$  integers. We use  $f$  to partition the universe  $U$  into  $d_1$ -many subsets  $U_i$ . Afterwards, we choose  $d_1$  families  $F_0, \dots, F_{d_1-1}$  of hash functions, each containing  $d_2 = \mathcal{O}(\ln k)$  functions, chosen independently and u.a.r. from a universal set of hash functions. The family  $F_i, i \in [d_1]^-$ , will be used restrictively to map the elements of  $U_i$ . Since each family  $F_i$  is chosen from a universal set of hash function, for the subset  $S_i = S \cap U_i$ , w.h.p.  $F_i$  contains a hash function  $f_i$  that is perfect w.r.t.  $S_i$ ; that is, under the function  $f_i$  the elements of  $S_i$  are distinguished. This concludes the first phase of the process, which is described in **Algorithm 1**.

■ **Algorithm 1** : An algorithm for partitioning  $U$  and constructing families of hash functions.

---

**Input:**  $|U|, k \in \mathbb{N}$  where  $|U| > 1$

**Output:** A family of sets of hash functions

- 1: let  $u$  and  $d$  be the unique positive integers satisfying  $2^{u-1} < |U| \leq 2^u$  and  $2^{d-1} < \frac{k}{\ln k} \leq 2^d$
  - 2: choose  $f$  u.a.r. from  $\mathcal{H}$ , where  $\mathcal{H} = \{h : \{0, 1\}^u \rightarrow \{0, 1\}^d\}$  is a  $\lceil 12 \ln k \rceil$ -wise independent set of hash functions
  - 3: let  $\mathcal{H}'$  be a set of universal hash functions from  $U$  to  $[\lceil 13 \ln k \rceil^2]^-$
  - 4: let  $F_i$ , for  $i \in [2^d]^-$ , be a set of  $\lceil 8 \ln k \rceil$  hash functions chosen independently and u.a.r. from  $\mathcal{H}'$
  - 5: return  $\{f, F_0, \dots, F_{2^d-1}\}$
- 

In the second phase, we define a relation  $\mathcal{G}$  (from  $U$ ) that, for each  $x \in U$ , associates a set  $\mathcal{G}(x)$  of integers. This relation extends the hash functions in the  $F_j$ 's above by (1) ensuring that elements in different parts of  $U$  (w.r.t. the partitioning) are distinguished, in the sense that they are associated with subsets of integers that are contained in disjoint intervals of integers; and (2) maintaining the property that elements of the same part  $U_j$  that are distinguished under some function in  $F_j$  remain so under the extended relation. To do so, for each part  $U_j$ , we associate an “offset” and create a large gap between any two (consecutive) offsets; we will ensure that all the elements in the same  $U_j$  fall within the same interval determined by two consecutive offsets. To compute the set  $\mathcal{G}(x)$ , for an element  $x \in U_j$ , we start with an offset  $o_j$  that depends solely on  $U_j$  ( $o_j = j \cdot d_2 \cdot d_3$  in **Algorithm 2**), and consider every function in the family  $F_j$  corresponding to  $U_j$ . For each such function  $h_i$ , we associate an offset  $o'_i$  ( $o'_i = (i-1) \cdot d_3$  in **Algorithm 2**), and for  $x$  and that particular function  $h_i$ , we add to  $\mathcal{G}(x)$  the value  $g(j, i, x) = o_j + o'_i + h_i(x)$ . The above phase is described in **Algorithm 2**.

Now that the relations  $\mathcal{G}(x)$ , for  $x \in U$ , have been defined, we will show in the following theorem that, for any  $k$ -subset  $S$  of  $U$ , w.h.p. there exist  $k$  distinct elements  $i_0, \dots, i_{k-1}$ , such that their pre-images  $\mathcal{G}^{-1}(i_0), \dots, \mathcal{G}^{-1}(i_{k-1})$  are pairwise disjoint, contain all elements of  $S$ , and each pre-image contains exactly one element of  $S$ ; those pre-images serve as the desired sets  $T_i$ , for  $i \in [k]$ .

Consider **Algorithm 1** and **Algorithm 2**, and refer to them for the terminologies used in the subsequent discussions. For  $i \in [d_1 \cdot d_2 \cdot d_3]^-$ , define  $T_i = \{x \in U \mid i \in \mathcal{G}(x)\}$ . We define next two sequences of intervals, and prove certain properties about them, that will

■ **Algorithm 2** : An algorithm that defines the relation  $\mathcal{G}$  from  $U$  to  $[d_1 \cdot d_2 \cdot d_3]^-$ .

**Input:**  $x \in U$ ,  $k \in \mathbb{N}$ ,  $\{f, F_0, \dots, F_{d_1-1}\}$  is from Algorithm 1, where  $|F_0| = \dots = |F_{d_1-1}|$

**Output:** a set  $\mathcal{G}(x)$

- 1: let  $d_2 = |F_0| = \dots = |F_{d_1-1}|$  and  $d_3 = \lceil 13 \ln k \rceil^2$
- 2:  $\mathcal{G}(x) = \emptyset$
- 3: compute  $f(\lfloor x \rfloor)$  and let  $j$  be the integer such that  $\lfloor j \rfloor = f(\lfloor x \rfloor)$
- 4: **for**  $i = 1$  to  $d_2$  **do**
- 5:   let  $h_i$  be the  $i$ -th function in  $F_j$  (assuming an arbitrary ordering on  $F_j$ )
- 6:   let  $g(j, i, x) = j \cdot d_2 \cdot d_3 + (i - 1) \cdot d_3 + h_i(x)$  and let  $\mathcal{G}(x) = \mathcal{G}(x) \cup \{g(j, i, x)\}$
- 7: return  $\mathcal{G}(x)$

be used in the proof of Theorem 9. For  $q \in [d_1 \cdot d_2]^-$ , let  $I_q = \{r \mid q \cdot d_3 \leq r < (q + 1) \cdot d_3\}$ . For  $t \in [d_1]^-$ , let  $I'_t = \{r \mid t \cdot d_2 \cdot d_3 \leq r < t \cdot d_2 \cdot d_3 + d_2 \cdot d_3\}$ . Note that each interval  $I'_t$  is partitioned into the  $d_2$ -many intervals  $I_q$ , for  $q = t \cdot d_2, \dots, t \cdot d_2 + d_2 - 1$ .

► **Lemma 8.** *The following statements hold: (A) For any two distinct integers  $a, b \in I_q$ , where  $q \in [d_1 \cdot d_2]^-$ , we have  $T_a \cap T_b = \emptyset$ . (B) For  $t \in [d_1]^-$ , we have  $\mathcal{G}(U_t) \subseteq I'_t$ . Moreover, for any  $a \in I'_t, b \in I'_s$ , where  $s \neq t$ , we have  $T_a \cap T_b = \emptyset$ .*

► **Theorem 9.** *For any subset  $S \subseteq U$  of cardinality  $k \geq 2$ , with probability at least  $1 - \frac{4}{k^3 \ln k}$ , there exist  $k$  sets  $T_{i_0}, \dots, T_{i_{k-1}}$  such that: (1)  $|T_{i_j} \cap S| = 1$  for  $j \in [k]^-$ , (2)  $S \subseteq \cup_{j \in [k]^-} T_{i_j}$ , and (3)  $T_{i_j} \cap T_{i_l} = \emptyset$  for  $j \neq l \in [k]^-$ .*

**Proof.** For  $j \in [d_1]^-$ , let  $U_j$  be the set of elements in  $U$  whose image is  $\lfloor j \rfloor$  under  $f$  (defined in Step 2 of **Algorithm 1**), that is  $U_j = \{y \in U \mid f(\lfloor y \rfloor) = \lfloor j \rfloor\}$ . Clearly, the sets  $U_j$ , for  $j \in [d_1]^-$ , partition the universe  $U$ . We will show that, with probability at least  $1 - \frac{4}{k^3 \ln k}$ , there exist  $k$  sets  $T_{i_0}, \dots, T_{i_{k-1}}$  that satisfy conditions (1)–(3) in the statement of the theorem.

Let  $S \subseteq U$  be any subset such that  $|S| = k$ . For  $j \in [d_1]^-$  and  $y \in S$ , let  $X_{y,j}$  be the random variable defined as  $X_{y,j} = 1$  if  $f(\lfloor y \rfloor) = \lfloor j \rfloor$  and 0 otherwise. Let  $X_j = \sum_{y \in S} X_{y,j}$ , and  $S_j = \{y \in S \mid f(\lfloor y \rfloor) = \lfloor j \rfloor\}$ . Thus,  $|S_j| = X_j$ . Since  $f$  is  $\lceil 12 \ln k \rceil$ -wise independent, the random variables  $X_{y,j}$ , for  $y \in S$ , are  $\lceil 12 \ln k \rceil$ -wise independent and  $\Pr(X_{y,j} = 1) = \frac{1}{d_1}$ . Thus,  $E[X_j] = |S| \cdot \frac{1}{d_1}$ . Since  $d_1 = 2^d$  and  $2^{d-1} < \frac{k}{\ln k} \leq 2^d$  by definition, we have  $\frac{k}{\ln k} \leq d_1 < \frac{2k}{\ln k}$  and  $\frac{\ln k}{2} < E[X_j] \leq \ln k$ . Applying Theorem 2 in [33] with  $\mu = E[X_j]$  and  $\delta = \frac{12 \ln k}{E[X_j]} > 1$ , we get  $\Pr(X_j \geq (1 + \delta)E[X_j]) \leq e^{-E[X_j]\delta/3} = \frac{1}{k^4}$ . Since  $E[X_j] \leq \ln k$  and  $\delta = \frac{12 \ln k}{E[X_j]}$ , we have  $(1 + \delta)E[X_j] \leq 13 \ln k$ . Hence,  $\Pr(X_j \geq 13 \ln k) \leq \Pr(X_j \geq (1 + \delta)E[X_j]) \leq \frac{1}{k^4}$ . Let  $\mathcal{E}$  denote the event  $\bigwedge_{i \in [d_1]^-} (X_i \leq 13 \ln k)$ . By the union bound, we have  $\Pr(\mathcal{E}) \geq 1 - \frac{d_1}{k^4} \geq 1 - \frac{2}{k^3 \ln k}$ , where the last inequality holds since  $d_1 < 2k / \ln k$ .

Assume that event  $\mathcal{E}$  occurs, i.e., that  $|S_j| \leq 13 \ln k$  holds for  $j \in [d_1]^-$ . Consider Step 4 in **Algorithm 1**. Fix  $j \in [d_1]^-$ , and let  $E_j$  be the event that  $F_j$  does not contain any perfect hash function w.r.t.  $S_j$ . Let  $h$  be a hash function picked from  $\mathcal{H}'$  u.a.r. Since  $|S_j| \leq 13 \ln k$  (by assumption), by Theorem 11.9 in [11], with probability at least  $1/2$ ,  $h$  is perfect w.r.t.  $S_j$ . Since  $F_j$  consists of  $\lceil 8 \ln k \rceil$  hash functions chosen independently and u.a.r. from  $\mathcal{H}'$ , we have  $\Pr(E_j) \leq (1/2)^{\lceil 8 \ln k \rceil} < \frac{1}{k^4}$ . Applying the union bound, we have  $\Pr(\cup_{j \in [d_1]^-} E_j) \leq \frac{d_1}{k^4} < \frac{2}{k^3 \ln k}$ . Let  $\mathcal{E}'$  be the event that there exist  $d_1$  functions  $f_0, f_1, \dots, f_{d_1-1}$  such that  $f_j \in F_j$  and  $f_j$  is perfect w.r.t.  $S_j$ ,  $j \in [d_1]^-$ . Therefore,  $\Pr(\mathcal{E}') \geq \Pr(\mathcal{E})(1 - \Pr(\cup_{j \in [d_1]^-} E_j)) \geq 1 - \frac{4}{k^3 \ln k} + \frac{4}{k^6 \ln^2 k} \geq 1 - \frac{4}{k^3 \ln k}$ . Suppose that such a set  $\{f_0, \dots, f_{d_1-1}\}$  of functions exists. Let  $\eta(q)$  be the iteration number  $i$  in Step 5 of **Algorithm 2** during which  $f_q \in F_q$  is chosen, for  $q \in [d_1]^-$ . We define the following (multi-)set  $B$  as follows. For each  $q \in [d_1]^-$ , and for

element  $x \in S_q$ , add to  $B$  the element  $g(q, \eta(q), x)$  defined in Steps 5–6 of **Algorithm 2** (by  $\{f, f_0, \dots, f_{k-1}\}$ ). Observe that, by the definition of  $B$ , for every  $x \in S$ , there exists  $a \in B$  such that  $x \in T_a$ . We will show next that  $B$  contains exactly  $k$  distinct elements, and that, for any  $a \neq b \in B$ , it holds that  $T_a \cap T_b = \emptyset$ . The above will show that the sets  $\{T_a \mid a \in B\}$  satisfy conditions (1)–(3) of the theorem, thus proving the theorem.

It suffices to show that for any two distinct elements of  $S$ , the corresponding elements added to  $B$  are distinct. Let  $x_1$  and  $x_2$  be two distinct elements of  $S$ . Assume that  $x_1 \in S_j$  and  $x_2 \in S_l$ , where  $j, l \in [d_1]^-$ . We distinguish two cases based on whether or not  $j = l$ .

If  $j = l$ , we have  $g(j, \eta(j), x_1) = j \cdot d_2 \cdot d_3 + (\eta(j) - 1) \cdot d_3 + f_j(x_1)$  and  $g(j, \eta(j), x_2) = j \cdot d_2 \cdot d_3 + (\eta(j) - 1) \cdot d_3 + f_j(x_2)$ . Since  $f_j$  is perfect w.r.t.  $S_j$ , we have  $g(j, \eta(j), x_1) \neq g(j, \eta(j), x_2)$ . Moreover, both  $g(j, \eta(j), x_1)$  and  $g(j, \eta(j), x_2)$  are in  $I_{j \cdot d_2 + (\eta(j) - 1)}$  (since  $0 \leq h_j(x_1), h_j(x_2) < d_3$ ), where  $j \cdot d_2 + (\eta(j) - 1) \leq (d_1 - 1) \cdot d_2 + (d_2 - 1) \in [d_1 \cdot d_2]^-$ . By part (A) of Lemma 8, it holds that  $T_{g(j, \eta(j), x_1)} \cap T_{g(j, \eta(j), x_2)} = \emptyset$ .

Suppose now that  $j \neq l$ . By definition of  $S_j, S_l, U_j, U_l$ , we have  $S_j \subseteq U_j$  and  $S_l \subseteq U_l$ . Consequently,  $g(j, \eta(j), x_1) \in \mathcal{G}(U_j)$  and  $g(l, \eta(l), x_2) \in \mathcal{G}(U_l)$  hold. By part (B) of Lemma 8, we have  $\mathcal{G}(U_j) \subseteq I'_j$  and  $\mathcal{G}(U_l) \subseteq I'_l$ . Therefore,  $g(j, \eta(j), x_1) \neq g(l, \eta(l), x_2)$ . Moreover,  $T_{g(j, \eta(j), x_1)} \cap T_{g(l, \eta(l), x_2)} = \emptyset$  holds by part (B) of Lemma 8 as well.  $\blacktriangleleft$

**► Theorem 10.** *Algorithm 1 runs in space  $\mathcal{O}(k + (\log k)(\log |U|))$ , and Algorithm 2 runs in space  $\mathcal{O}(\log k)$  and in time polynomial in  $\log |U|$ .*

**Proof.** In **Algorithm 1**, since  $f$  is  $\lceil 12 \ln k \rceil$ -wise independent, by Theorem 7, storing  $f$  uses space  $\mathcal{O}(\ln k \cdot \max\{u, d\}) = \mathcal{O}((\log k)(\log |U|))$  (since  $k \leq |U|$ ). Storing a universal hash function uses  $\mathcal{O}(1)$  space, and thus storing  $\{F_0, \dots, F_{d_1-1}\}$  uses  $\mathcal{O}(d_1 \cdot d_2) = \mathcal{O}(k)$  space. Therefore, **Algorithm 1** can be implemented in space  $\mathcal{O}(k + (\log k)(\log |U|))$ .

For **Algorithm 2**, since  $\mathcal{G}(x)$  contains exactly  $d_2$  elements, storing  $\mathcal{G}(x)$  takes  $\mathcal{O}(d_2) = \mathcal{O}(\ln k)$  space. In Step 3, again by Theorem 7, computing  $f(\lfloor x \rfloor)$  takes time polynomial in  $\log |U|$  and  $\log k$ , since  $f$  is a  $\lceil 12 \ln k \rceil$ -wise independent hash function from  $\{0, 1\}^u$  to  $\{0, 1\}^d$ . Computing  $j$  in Step 3 takes time polynomial in  $d = \mathcal{O}(\log k)$  since  $f(\lfloor x \rfloor) \in \{0, 1\}^d$ . Therefore, Step 3 can be performed in time polynomial in  $\log |U|$  and  $\log k$ , and hence polynomial in  $\log |U|$  (since  $k \leq |U|$ ). Step 6 can be implemented in time polynomial in  $\log k$ , since  $|F_j| = \lceil 8 \ln k \rceil$ . Altogether, **Algorithm 2** takes time polynomial in  $\log |U|$ . This completes the proof.  $\blacktriangleleft$

## 5 Algorithms in Dynamic Streaming Model

In this section, we present results on p-MATCHING and p-WT-MATCHING in the dynamic streaming model. The algorithm uses the toolkit developed in the previous section, together with the  $\ell_0$ -sampling technique discussed in Section 2. We first give a high-level description of how the algorithm works.

Let  $\mathcal{S}$  be a graph stream of a weighted graph  $G = (V = [n]^-, E)$  along with the weight function  $wt : E(G) \rightarrow \mathbb{R}_{\geq 0}$ , and  $k$  be a parameter. Suppose  $G$  has  $W$  distinct weights. We will hash the vertices of the graph to a range  $R$  of size  $\mathcal{O}(k \log^2 k)$ . For each element  $(e = [u, v], wt(e), op) \in \mathcal{S}$ , where  $op$  is either insertion or deletion, we use the relation  $\mathcal{G}$ , discussed in Section 4, and compute the two sets  $\mathcal{G}(u)$  and  $\mathcal{G}(v)$ . For each  $i \in \mathcal{G}(u)$  and each  $j \in \mathcal{G}(v)$ , we associate an instance of an  $\ell_0$ -sampler primitive, call it  $\mathcal{C}_{i,j,wt(u,v)}$ , and update it according to the operation  $op$ . Recall that it is assumed that the weight of every edge does not change throughout the stream.

The solution computed by the algorithm consists of a set of edges created by invoking each of the  $\tilde{O}(Wk^2)$   $\ell_0$ -sampler algorithms to sample at most one edge from each  $\mathcal{C}_{i,j,w}$ , for each pair of  $i, j$  in the range  $R$  and each edge-weight of the graph stream.

The intuition behind the above algorithm (i.e., why it achieves the desired goal) is the following. Suppose that there exists a maximum weighted  $k$ -matching  $M$  in  $G$ , and let  $M = \{[u_0, u_1], \dots, [u_{2k-2}, u_{2k-1}]\}$ . By Theorem 9, *w.h.p.* there exist  $i_0, \dots, i_{2k-1}$  in the range  $R$  such that  $u_j \in T_{i_j}$ , for  $j \in [2k]^-$ , and such that the  $T_{i_j}$ 's are pairwise disjoint. Consider the  $k$   $\ell_0$ -samplers  $\mathcal{C}_{i_{2j}, i_{2j+1}, wt(u_{2j}, u_{2j+1})}$ , where  $j \in [k]^-$ . Then, *w.h.p.*, the  $k$  edges sampled from these  $k$   $\ell_0$ -samplers are the edges of a maximum weighted  $k$ -matching (since the  $T_{i_j}$ 's are pairwise disjoint) whose weight equals that of  $M$ .

■ **Algorithm 3** The streaming algorithm  $\mathcal{A}_{dynamic}$  in the dynamic streaming model.

---

---

**$\mathcal{A}_{dynamic}$ -Preprocess: The preprocessing algorithm**

---

**Input:**  $n = |V(G)|$  and a parameter  $k \in \mathbb{N}$

- 1: let  $\mathcal{C}$  be a set of  $\ell_0$ -samplers and  $\mathcal{C} = \emptyset$
  - 2: let  $\{f, F_0, F_1, \dots, F_{d_1-1}\}$  be the output of **Algorithm 1** on input  $(n, 2k)$
- 

**$\mathcal{A}_{dynamic}$ -Update: The update algorithm**

---

**Input:** An update  $(e = [u, v], wt(e), op) \in \mathcal{S}$ , where  $op$  is either insertion or deletion

- 1: let  $\mathcal{G}(u)$  be the output of **Algorithm 2** on input  $(u, 2k, \{f, F_0, F_1, \dots, F_{d_1-1}\})$
  - 2: let  $\mathcal{G}(v)$  be the output of **Algorithm 2** on input  $(v, 2k, \{f, F_0, F_1, \dots, F_{d_1-1}\})$
  - 3: **for**  $i \in \mathcal{G}(u)$  and  $j \in \mathcal{G}(v)$  **do**
  - 4:     **if**  $\mathcal{C}_{i,j,wt(uv)} \notin \mathcal{C}$  **then**
  - 5:         create the  $\ell_0$ -sampler  $\mathcal{C}_{i,j,wt(uv)}$
  - 6:     feed  $\langle [u, v], op \rangle$  to the  $\ell_0$ -sampler algorithm  $\mathcal{C}_{i,j,wt(u,v)}$  with parameter  $\delta$
- 

**$\mathcal{A}_{dynamic}$ -Query: The query algorithm after an update**

---

- 1: let  $E' = \emptyset$
  - 2: **for** each  $\mathcal{C}_{i,j,w} \in \mathcal{C}$  **do**
  - 3:     apply the  $\ell_0$ -sampler  $\mathcal{C}_{i,j,w}$  with parameter  $\delta$  to sample an edge  $e$
  - 4:     **if**  $\mathcal{C}_{i,j,w}$  does not FAIL **then** set  $E' = E' \cup \{e\}$
  - 5: return a maximum weighted  $k$ -matching in  $G' = (V(E'), E')$  if any; otherwise, return  $\emptyset$
- 

Choose  $\delta = \frac{1}{20k^4 \ln(2k)}$ . Let  $\mathcal{A}_{dynamic}$  be the algorithm consisting of the sequence of three subroutines/algorithms  **$\mathcal{A}_{dynamic}$ -Preprocess**,  **$\mathcal{A}_{dynamic}$ -Update**, and  **$\mathcal{A}_{dynamic}$ -Query**, where  **$\mathcal{A}_{dynamic}$ -Preprocess** is applied at the beginning of the stream,  **$\mathcal{A}_{dynamic}$ -Update** is applied after each operation, and  **$\mathcal{A}_{dynamic}$ -Query** is applied whenever the algorithm is queried for a solution after some update operation. Without loss of generality, and for convenience, we will assume that the algorithm is queried at the end of the stream  $\mathcal{S}$ , even though the query could take place after any arbitrary operation.

► **Lemma 11.** *Let  $M'$  be the matching obtained by applying the algorithm  $\mathcal{A}_{dynamic}$  with  **$\mathcal{A}_{dynamic}$ -Query** invoked at the end of  $\mathcal{S}$ . If  $G$  contains a  $k$ -matching then, with probability at least  $1 - \frac{11}{20k^3 \ln(2k)}$ ,  $M'$  is a maximum weighted  $k$ -matching of  $G$ .*

► **Theorem 12.** *The algorithm  $\mathcal{A}_{dynamic}$  outputs a matching  $M'$  such that (1) if  $G$  contains a  $k$ -matching then, with probability at least  $1 - \frac{11}{20k^3 \ln(2k)}$ ,  $M'$  is a maximum weighted  $k$ -matching of  $G$ ; and (2) if  $G$  does not contain a  $k$ -matching then  $M' = \emptyset$ . Moreover, the algorithm  $\mathcal{A}_{dynamic}$  runs in  $\tilde{O}(Wk^2)$  space and has  $\tilde{O}(1)$  update time.*

**Proof.** First, observe that  $G'$  is a subgraph of  $G$ , since it consists of edges sampled from subsets of edges in  $G$ . Therefore, statement (2) in the theorem clearly holds true. Statement (1) follows from Lemma 11. Next, we analyze the update time of algorithm  $\mathcal{A}_{dynamic}$ .

From **Algorithm 1** and **Algorithm 2**, we have  $d_1 = O(\frac{k}{\ln k})$ ,  $d_2 = O(\ln k)$ ,  $d_3 = O(\ln^2 k)$  and  $|F_i| = O(\ln k)$  for  $i \in [d_1]^-$ . Thus,  $|\mathcal{G}(u)| = O(\ln k)$  holds for all  $u \in V$ . For the update time, it suffices to examine Steps 1–6 of  **$\mathcal{A}_{dynamic}$ -Update** By Theorem 10, Steps 1–2 take time polynomial in  $\log n$ , which is  $\tilde{O}(1)$ . For Step 4, we can index  $\mathcal{C}$  using a sorted sequence of triplets  $(i, j, w)$ , where  $i, j \in [d_1 \cdot d_2 \cdot d_3]^-$  and  $w$  ranges over all possible weights. Since  $d_1 = O(\frac{k}{\ln k})$ ,  $d_2 = O(\ln k)$  and  $d_3 = O(\ln^2 k)$ , we have  $|\mathcal{C}| = O((d_1 \cdot d_2 \cdot d_3)^2 \cdot W) = O(Wk^2 \ln^4 k) = \tilde{O}(Wk^2)$ . Using binary search on  $\mathcal{C}$ , one execution of Step 4 takes time  $O(\log W + \log k)$ . Since  $|\mathcal{G}(u)| = O(\ln k)$  for every  $u \in V$ , and since by Lemma 1 an  $\ell_0$ -sampler algorithm has  $\tilde{O}(1)$  update time, Steps 3–6 take time  $O(\ln^2 k) \cdot (O(\log W + \log k) + \tilde{O}(1)) = \tilde{O}(1)$ . Therefore, the overall update time is  $\tilde{O}(1)$ .

Now, we analyze the space complexity of the algorithm. First, consider  **$\mathcal{A}_{dynamic}$ -Preprocess**. Obviously, Step 1 uses  $O(1)$  space. Steps 1–2 use space  $O(k + (\log k)(\log n))$  (including the space used to store  $\{f, F_0, \dots, F_{d_1-1}, \mathcal{C}\}$ ) by Theorem 10. Altogether,  **$\mathcal{A}_{dynamic}$ -Preprocess** runs in space  $O(k + (\log k)(\log n))$ . Next, we discuss  **$\mathcal{A}_{dynamic}$ -Update**. Steps 1–2 take space  $O(\ln k)$  by Theorem 10. Observe that the space used in Steps 3–6 is dominated by the space used by the set  $\mathcal{C}$  of  $\ell_0$ -samplers. Since  $\delta = \frac{1}{20k^4 \ln(2k)}$ , an  $\ell_0$ -sampler algorithm uses space  $O(\log^2 n \cdot \log k)$ , by Lemma 1. Since  $|\mathcal{C}| = O(Wk^2 \ln^4 k)$ , Steps 3–6 use space  $O(Wk^2 \log^2 n \log^5 k) = \tilde{O}(Wk^2)$ . Finally, consider  **$\mathcal{A}_{dynamic}$ -Query** The space in Steps 1–4 is dominated by the space used by  $\mathcal{C}$  and the space needed to store the graph  $G'$ , and hence  $E'$ . By the above discussion,  $\mathcal{C}$  takes space  $\tilde{O}(Wk^2)$ . Since at most one edge is sampled from each  $\ell_0$ -sampler instance and  $|\mathcal{C}| = O(Wk^2 \ln^4 k)$ , we have  $|E'| = |\mathcal{C}| = \tilde{O}(Wk^2)$ . Step 5 utilizes space  $O(|E'|)$  [17, 18]. Therefore,  **$\mathcal{A}_{dynamic}$ -Query** runs in space  $\tilde{O}(Wk^2)$ . It follows that the space complexity of  $\mathcal{A}_{dynamic}$  is  $\tilde{O}(Wk^2)$ . ◀

Using Theorem 12, and following the same approach in [7], we obtain the following:

► **Theorem 13.** *Let  $0 < \epsilon < 1$ . There exists an algorithm for  $p$ -WT-MATCHING that computes a matching  $M'$  such that (1) if  $G$  contains a maximum weighted  $k$ -matching  $M$ , then with probability at least  $1 - \frac{11}{20k^3 \ln(2k)}$ ,  $wt(M') > (1 - \epsilon)wt(M)$ ; and (2) if  $G$  does not contain a  $k$ -matching then  $M' = \emptyset$ . Moreover, the algorithm runs in  $\tilde{O}(k^2 \epsilon^{-1} \log W')$  space and has  $\tilde{O}(1)$  update time, where  $W'$  is the ratio of the max weight to min weight.*

**Proof.** For each edge  $e \in E$ , round  $wt(e)$  and assign it a new weight of  $(1 + \epsilon)^i$  such that  $(1 + \epsilon)^{i-1} < wt(e) \leq (1 + \epsilon)^i$ . Thus, there are  $O(\epsilon^{-1} \log W')$  distinct weights after rounding. By Theorem 12, the space and update time are  $\tilde{O}(k^2 \epsilon^{-1} \log W')$  and  $\tilde{O}(1)$  respectively, and the success probability is at least  $1 - \frac{11}{20k^3 \ln(2k)}$ . Now we prove that  $wt(M') > (1 - \epsilon)wt(M)$ .

Let  $e \in M$  and let  $e'$  be the edge sampled from the  $\ell_0$ -sampler that  $e$  is fed to. It suffices to prove that  $wt(e') > (1 - \epsilon)wt(e)$ . Assume that  $wt(e)$  is rounded to  $(1 + \epsilon)^i$ . Then,  $wt(e')$  is rounded to  $(1 + \epsilon)^j$  as well. If  $wt(e') \geq wt(e)$ , we are done; otherwise,  $(1 + \epsilon)^{i-1} < wt(e') < wt(e) \leq (1 + \epsilon)^i$ . It follows that  $wt(e') > (1 + \epsilon)^{i-1} \geq wt(e)/(1 + \epsilon) > (1 - \epsilon)wt(e)$ . ◀

The following theorem is a consequence of Theorem 12 (applied with  $W = 1$ ):

► **Theorem 14.** *There is an algorithm for  $p$ -MATCHING that computes a matching  $M'$  satisfying that (1) if  $G$  contains a  $k$ -matching then, with probability at least  $1 - \frac{11}{20k^3 \ln(2k)}$ ,  $M'$  is a  $k$ -matching of  $G$ ; and (2) if  $G$  does not contain a  $k$ -matching then  $M' = \emptyset$ . Moreover, the algorithm runs in  $\tilde{O}(k^2)$  space and has  $\tilde{O}(1)$  update time.*

## 6 Lower Bound

In this section, we discuss lower bounds on the space complexity of randomized streaming algorithms for  $p$ -MATCHING in the insert-only model (hence also in the dynamic model), and for  $p$ -WT-MATCHING in the dynamic model. These lower bound results, in conjunction with the algorithms given in the previous sections, show that the space complexity achieved by our algorithms is optimal (modulo a poly-logarithmic factor in the input size).

We will use the *one-way communication model* to prove lower bounds on the space complexity of randomized streaming algorithms for  $p$ -MATCHING and  $p$ -WT-MATCHING. In this model, there are two parties, Alice and Bob, each receiving  $x$  and  $y$  respectively, who wish to compute  $f(x, y)$ . Alice is permitted to send Bob a single message  $M$ , which only depends on  $x$  and Alice's random coins. Then Bob outputs  $b$ , which is his guess of  $f(x, y)$ . Here,  $b$  only depends on  $y, M$ , and Bob's random coins. We say the protocol computing  $f$  with success probability  $1 - \delta$  if  $\Pr(b = f(x, y)) \geq 1 - \delta$  for every  $x$  and  $y$ .

For  $p$ -MATCHING, we have the following theorem, which is implied from the space complexity lower-bound proof given in [7] for maximum matching.

► **Theorem 15** ([7]). *Any randomized streaming algorithm for  $p$ -MATCHING that, with probability at least  $2/3$ , computing a  $k$ -matching uses  $\Omega(k^2)$  bits.*

For  $p$ -WT-MATCHING, we start by defining the following problem:

PARTIAL MAXIMIZATION: Alice has a sequence  $a = \langle a_1, a_2, \dots, a_n \rangle$  of numbers, where each  $a_i \in [1, n^{1+\epsilon}]$ , and Bob has a subset  $T \subset [n]$ . Compute  $\max_{i \in [n] \setminus T} a_i$ .

Let  $X, Y, Z, Z_1, Z_2$  be random variables. Define the *Shannon entropy* of  $X$  as  $H(X) = \sum_x \Pr(X = x) \log\left(\frac{1}{\Pr(X=x)}\right)$ . Define the *conditional entropy* of  $Z_1$  given  $Z$  as  $H(Z_1 | Z) = \sum_z H(Z_1 | Z = z) \Pr(Z = z)$ , and the *mutual information* as  $I(Z_1; Z) = H(Z) - H(Z | Z_1)$ . Define the *conditional mutual information* of  $Z_1, Z_2$  given  $Z$  as  $I(Z_1; Z_2 | Z) = H(Z_1 | Z) - H(Z_1 | Z_2, Z)$ .  $X \rightarrow Y \rightarrow Z$  is said to form a *Markov chain* if the conditional distribution of  $Z$  depends only on  $Y$  and is conditionally independent of  $X$ .

► **Theorem 16.** *For any constant  $0 \leq \delta < 1$ , any randomized one-way communication protocol for PARTIAL MAXIMIZATION with success probability at least  $1 - \delta$  has communication complexity  $\Omega(n \log n)$  bits.*

**Proof.** The proof has a similar fashion as Augmented Indexing problem [29, 10]. Consider the case where each  $X_j$ , for  $j \in [n]$ , is picked uniformly at random from  $[(j-1) \cdot n^\epsilon + 1, j \cdot n^\epsilon]$ . Note that  $X_1 < X_2 < \dots < X_n$  and that  $H(X_j) = \epsilon \log n$  for each  $j \in [n]$ . For each  $j \in [n]$ , let  $T_j = [j+1, n]$  and let  $X'_j$  be Bob's guess of  $\max_{i \in [n] \setminus T_j} X_i = X_j$ . Let  $M$  be the message sent from Alice to Bob. Since  $\Pr(X'_j = X_j) \geq 1 - \delta$  and  $X_j \rightarrow (M, X_{j+1}, X_{j+2}, \dots, X_n) \rightarrow X'_j$  is a Markov chain, by Fano's Inequality [13], for all  $j \in [n]$ , we have  $H(X_j | M, X_{j+1}, \dots, X_n) \leq \delta \cdot \epsilon \log n + 1$ , and hence,

$$\begin{aligned} I(X_j; M | X_{j+1}, \dots, X_n) &= H(X_j | X_{j+1}, \dots, X_n) - H(X_j | M, X_{j+1}, \dots, X_n) \\ &= H(X_j) - H(X_j | M, X_{j+1}, \dots, X_n) \\ &\geq (1 - \delta)\epsilon \log n - 1, \end{aligned}$$

where the second equality holds because  $X_j, X_{j+1}, \dots, X_n$  are mutually independent. By Theorem 2.5.2 of [13],  $H(M) \geq I(X_1, X_2, \dots, X_n; M) = \sum_{j=1}^n I(X_j; M | X_{j+1}, \dots, X_n) = \Omega(n \log n)$ . Finally, by Theorem 2.6.4 of [13] the message  $M$  has at least  $2^{\Omega(n \log n)}$  possibilities, hence the length of the longest possible  $M$  is  $\Omega(n \log n)$ , completing the proof. ◀

Theorem 16, plus a reduction from the PARTIAL MAXIMIZATION problem to the p-WT-MATCHING problem with parameter value  $k = 1$ , gives directly the following result.

► **Theorem 17.** *Any randomized streaming algorithm for p-WT-MATCHING that has success probability at least  $2/3$  requires space  $k^2 \cdot \Omega(W(\log W + 1))$ .*

## 7 Concluding Remarks

In this paper, we presented streaming algorithms for the fundamental  $k$ -matching problem, for both unweighted and weighted graphs, and in both the insert-only and dynamic streaming models. While matching the best space complexity of known algorithms, which has been proved to be either optimal or near-optimal, our algorithms have much faster update times. For the insert-only model, our algorithm is optimal in both space and update time complexities. For the dynamic model, according to the new lower bounds we developed, our algorithms are near-optimal (i.e., optimal up to a poly-logarithmic factor) in both space and update time complexities. Our result for the weighted  $k$ -matching problem was achieved using a newly-developed structural result that is of independent interest. We believe that our results and techniques can have wider applicability for other fundamental graph problems.

Most work on weighted graph streams, including ours, assumes that the weight of an edge is unchanged in the stream [1, 2, 7, 20, 23]. We give an interesting observation below to justify this assumption and show that, if this assumption is lifted, then the space complexity of the  $k$ -matching problem can be much larger than the desirable space complexity for streaming algorithms. This lower bound is derived by a reduction from the following problem:

Given a data stream  $\mathcal{S}' = x_1, x_2, \dots, x_m$ , where  $x_i \in \{1, \dots, n'\}$ , let  $c_i = |\{j \mid x_j = i\}|$  be the number of occurrences of  $i$  in the stream  $\mathcal{S}'$ . Compute  $F_\infty = \max_{1 \leq i \leq n'} c_i$ .

► **Theorem 18** ([32]). *For data streams of length  $m$ , any randomized streaming algorithm computing  $F_\infty$  to within a  $(1 \pm 0.2)$  factor with probability  $2/3$  requires space  $\Omega(\min\{m, n'\})$ .*

Now we consider the p-WT-MATCHING problem in the more generalized dynamic streaming model, in which an instance of p-WT-MATCHING is given by a parameter  $k$  and a stream  $\mathcal{S} = (e_{i_1}, \Delta_1(e_{i_1})), \dots, (e_{i_j}, \Delta_j(e_{i_j})), \dots$  of updates of edge weights in the underlying graph  $G$ , where the update  $(e_{i_j}, \Delta_j(e_{i_j}))$  changes the current weight  $wt(e_{i_j})$  of edge  $e_{i_j}$  to  $wt(e_{i_j}) = wt(e_{i_j}) + \Delta_j(e_{i_j})$ , assuming  $wt(\cdot) = 0$  initially and  $wt(\cdot) \geq 0$  for all updates. This model generalizes the dynamic graph streaming model in [7].

► **Theorem 19.** *Under the more generalized dynamic streaming model, any randomized streaming algorithm that, with probability at least  $2/3$ , approximates the maximum weighted 1-matching of the graph to a factor of  $6/5$  uses space  $\Omega(\min\{m, \frac{(n-1)(n-2)}{2}\})$ .*

**Proof.** Given a data stream  $\mathcal{S}' = x_1, x_2, \dots, x_m$ , where each  $x_i \in \{1, \dots, n'\}$ , we define a graph stream  $\mathcal{S}$  for a weighted graph  $G$  on  $n$  vertices, where  $n$  satisfies  $(n-1)(n-2)/2 < n' \leq n(n-1)/2$ . Let  $V = \{0, \dots, n-1\}$  be the vertex-set of  $G$ . We first define a bijective function  $\chi : \{(i, j) \mid i < j \in [n]^-\} \rightarrow [\frac{n(n-1)}{2}]$ . Let  $\chi^{-1}$  be the inverse function of  $\chi$ . Then, we can translate  $\mathcal{S}'$  to a general dynamic graph streaming  $\mathcal{S}$  of underlying weighted graph  $G$  by corresponding with  $x_i$  the  $i$ -th element  $(\chi^{-1}(x_i), 1)$  of  $\mathcal{S}$ , for  $i \in [m]$ . Observe that computing  $F_\infty$  of  $\mathcal{S}'$  is equivalent to computing a maximum weighted 1-matching for the graph stream  $\mathcal{S}$  of  $G$ . Let  $uv$  be a maximum weighted 1-matching of  $\mathcal{S}$ , then  $\chi(uv)$  is  $F_\infty$  of  $\mathcal{S}'$ . By Theorem 18, it follows that any randomized approximation streaming algorithm that approximates the maximum weighted 1-matching of  $G$  to a  $\frac{6}{5}$ -factor with probability at least  $2/3$  uses space  $\Omega(\{m, \frac{(n-1)(n-2)}{2}\})$ , thus completing the proof. ◀

## Abstract

*Two-way online correlated selection (two-way OCS)* is an online algorithm that, at each timestep, takes a pair of elements from the ground set and irrevocably chooses one of the two elements, while ensuring negative correlation in the algorithm's choices. Whilst OCS was initially invented by Fahrback, Huang, Tao, and Zadimoghaddam to break a natural long-standing barrier in the edge-weighted online bipartite matching problem, it is an interesting technique on its own due to its capability of introducing a powerful algorithmic tool, namely negative correlation, to online algorithms. As such, Fahrback et al. posed two tantalizing open questions in their paper, one of which was the following: Can we obtain *n-way OCS* for  $n > 2$ , in which the algorithm can be given  $n > 2$  elements to choose from at each timestep?

In this paper, we affirmatively answer this open question by presenting a *three-way OCS*. Our algorithm uses two-way OCS as its building block and is simple to describe; however, as it internally runs two instances of two-way OCS, one of which is fed with the output of the other, the final output probability distribution becomes highly elusive. We tackle this difficulty by approximating the output distribution of OCS by a flat, less correlated function and using it as a safe “surrogate” of the real distribution. Our three-way OCS also yields a 0.5093-competitive algorithm for edge-weighted online matching, demonstrating its usefulness.

## 1 Introduction

*Online correlated selection (OCS)* is an online algorithm that, at each timestep, takes a subset of the ground set as the input and irrevocably chooses a single element from the subset. When every input subset has cardinality  $n$ , we call it *n-way OCS* in particular. The aim of online correlated selection is to ensure a certain level of negative correlation in the choice made by the algorithm. For example, suppose we run a two-way OCS and afterwards specify  $m$  timesteps that contained some common element. The probability that this element was never chosen would be  $(1/2)^m$  if the algorithm made independent and uniformly random choices; the goal of two-way OCS is to reduce this probability by introducing negative correlations. (See Definition 4 for a full definition that quantifies the desired amount of reduction.)

---

OCS was first invented by Fahrbach, Huang, Tao, and Zadimoghaddam [10] to attack the edge-weighted online bipartite matching problem. Negative correlation has proven to be a very powerful technique in approximation algorithms design (see, e.g., [34, 2, 7] for a limited list of examples); this suggests that OCS as well bears high potential as a general tool in online algorithms design rather than as a specialized technique to solve a particular problem. This opportunity was also observed by the breakthrough paper of Fahrbach et al. [10] and recently exemplified by Huang, Zhang, and Zhang [23], who devised a certain variant of OCS called *panoramic OCS* to solve the AdWords problem with general bids.

In light of such value of OCS as an algorithmic tool, Fahrbach et al. [10] raised in their paper two follow-up questions that arise quite naturally: Can we improve the performance of their two-way OCS? Can we obtain an  $n$ -way OCS for  $n > 2$ ? This paper affirmatively answers the latter question. In this paper, we present a simple *three-way OCS* and analyze its performance. We will also show that our three-way OCS can be used to improve the previous competitive ratio of 0.5086 due to Fahrbach et al. to give a new 0.5093-competitive algorithm for edge-weighted online bipartite matching.

In fact, the construction itself of our three-way OCS is easy to describe. It internally executes two instances of two-way OCS. Upon arrival of a triple, we choose two of the three elements uniformly at random, and let the first two-way OCS choose one of them. We then pass its output, along with the element that was left out of the first OCS, to the second OCS. The second OCS chooses one of these two elements; this choice becomes the final output of this timestep.

In Section 3, we analyze the performance of our three-way OCS for a special case first: we bound the probability that a certain element, say  $u$ , is never chosen for  $k$  consecutive timesteps whose triples contain  $u$ . It is not that we require these  $k$  timesteps to be consecutive in the original input: they need to be consecutive in the subsequence of timesteps on which  $u$  appeared in the triple. By the definition of two-way  $\gamma$ -OCS, the probability that the second two-way OCS never chooses  $u$  is no greater than  $(1/2)^j(1 - \gamma)^{\max(j-1, 0)}$  for some constant  $\gamma$ , where  $j$  is the number of times  $u$  was passed to the second OCS during those  $k$  timesteps. Since this bound depends only on  $j$ , the question really reduces to determining (the probability distribution of)  $j$ .

In order for  $u$  to be passed to the second OCS, it needs to be either left out of the first OCS or output by it. It is easy to count how many times  $u$  is left out of the first OCS: this follows a binomial distribution. Therefore, the challenge is in counting the number of times  $u$  is output by the first OCS. Unfortunately, its probability distribution highly depends on the actual *input* to the first OCS, rather than the number of times  $u$  is shown to the first OCS. Nonetheless, the following observation is crucial in coping with this difficulty: the probability distribution of the number of times Fahrbach et al.'s two-way OCS chooses  $u$  is a unimodal symmetric distribution. Recall that the probability that the second OCS never chooses  $u$  is bounded by  $(1/2)^j(1 - \gamma)^{\max(j-1, 0)}$ , which is “nearly” convex. Therefore, even though we cannot exactly calculate the probability distribution of  $j$  without the full knowledge of the input, the above observation implies that we can instead use a “flatter” unimodal symmetric distribution in lieu of the actual distribution of  $j$ . Thanks to the near-convexity, this would give a valid upper bound on the probability. We formalize what a “flatter” distribution is by defining the notion of *central dominance* as follows.

► **Definition 1 (Central Dominance).** *Given two discrete symmetric probability distributions  $D_1$  and  $D_2$  on  $\{0, 1, \dots, x\}$  whose probability mass functions are  $p_1$  and  $p_2$ , respectively, we say  $D_1$  centrally dominates  $D_2$  if there exists  $z \in [0, \frac{x}{2}]$  such that, for any integer  $y \in [\frac{x}{2} - z, \frac{x}{2} + z]$ ,  $p_1(y) \geq p_2(y)$ , and for any integer  $y \in [0, \frac{x}{2} - z) \cup (\frac{x}{2} + z, x]$ ,  $p_1(y) \leq p_2(y)$ .*

We then construct our “surrogate” distribution that is centrally dominated by any possible probability distribution of  $j$ . This distribution depends only on the number of times the first OCS is given  $u$ . It is therefore much more amenable and allows us to obtain a bound on the probability that our three-way OCS never chooses  $u$  from the given consecutive triples.

In Section 4, we generalize this bound to the non-consecutive case, i.e., a disjoint set of consecutive subsequences of timesteps containing  $u$ . To obtain this bound, we perform a set of surgical operations that modify the input to the first OCS, which are designed to reduce negative correlation. These operations are inspired by those of Fahrbach et al. [10] that they used to obtain a similar generalization. In our case, however, we face a new obstacle: previously, it sufficed to bound only the probability that the two-way OCS never chooses a given element, since the output of that OCS was the final output. Our final output on the other hand is determined by the second OCS, and if our modification changes the output distribution of the first OCS, this may affect the output of the second OCS in an obscure way. We prove that a set of careful surgical operations can remove all correlations while ensuring that the bound is not affected. Once the correlations are removed, the general-case bound can be simply given as the product of our bounds from Section 3 for single subsequences.

► **Theorem 2** (simplified). *Consider a set of  $m$  disjoint consecutive subsequences of timesteps whose triples contain some element  $u$  of the ground set. Let  $k_1, \dots, k_m$  be the lengths of these subsequences. The probability that our three-way OCS never chooses  $u$  from these  $m$  subsequences is at most*

$$\prod_{i=1}^m \left[ \left( \frac{2}{3} \right)^{k_i} (1 - \delta_1)^{\max(k_i - 1, 0)} (1 - \delta_2)^{\max(k_i - 2, 0)} \right],$$

where  $\delta_1 = 0.0309587$  and  $\delta_2 = 0.0165525$ .

Our three-way OCS can be applied to edge-weighted and unweighted online bipartite matching [33].

## 1.1 Related Work

Introduced by Karp, Vazirani, and Vazirani [25], the unweighted online bipartite matching has been intensively and extensively studied with alternative proofs [16, 4, 8, 9] and under various settings including stochastic models [12, 29, 17, 32, 13, 20], fully online models [18, 19, 22], and general arrival models [14]. The study of edge-weighted online bipartite matching problem was initiated by Kalyanasundaram & Pruhs [24] and Khuller, Mitchell, & Vazirani [27], who independently considered this problem under the metric assumption. Feldman, Korula, Mirrokni, Muthukrishnan, and Pál [11] first investigated the edge-weighted version on arbitrary weights with free disposal, and more thorough understanding of this problem was achieved by subsequent work [28, 10]. Other variants and applications of online bipartite matching have been studied as well, including AdWords [31, 23], vertex-weighted version [1, 21, 13], stochastic or random arrival models [17, 26, 6, 20], and the windowed version [3]. We refer interested readers to the survey of Mehta [30].

**Recent related works.** Recently, after the authors independently obtained the present results but prior to announcing them, the authors learned that two closely related papers were announced on arXiv [15, 5].

The other open question raised by Fahrbach et al. [10] than the one answered by this paper was to improve two-way OCS. Gao, He, Huang, Nie, Yuan, and Zhong [15] addresses this question by giving a novel automata-based OCS, successfully departing from the previous

matching-based approach: their two-way OCS is a 0.167-OCS. In addition to this, they also give an improved primal-dual analysis and a variant of two-way OCS specifically adapted for edge-weighted online bipartite matching, yielding a 0.519-competitive algorithm. Finally, they consider a weaker relaxed notion of OCS called *semi-OCS*, where the probability bound holds only for consecutive prefixes. They provide a multi-way version of this semi-OCS that leads to a 0.593-competitive algorithm for unweighted/vertex-weighted online bipartite matching.

Blanc and Charikar [5] generalize Fahrbach et al.'s definition of OCS in two ways and give  $m$ -way OCS for any  $m$ . One of the two generalizations, called  $(F, m)$ -OCS, gives the probability bound specified as a discrete function rather than a fixed-form formula such as  $(1/2)^j(1 - \gamma)^{\max(j-1, 0)}$ . The other is called *continuous OCS*, which allows an element of the ground set to appear in a subset “to a fraction”, where the probability bound is now specified as a continuous function. Their continuous OCS along with their improved primal-dual analysis gives a 0.5368-competitive algorithm for edge-weighted online bipartite matching.

Considering these new results, an interesting question is whether the techniques from these papers and our independent result can together bring improvements in OCS or related problems such as online matching. In fact, since our framework treats the second two-way OCS as a black-box, any improved two-way OCS can be directly plugged into our three-way OCS. Combining the new two-way 0.167-OCS of Gao et al. [15] with our results, for example, immediately yields a 0.5132-competitive algorithm for edge-weighted online bipartite matching.

## 2 Preliminaries

In this section, we present some notation, definitions, and previous results to be used throughout this paper. Let us first introduce the definition of  $n$ -way OCS and two-way  $\gamma$ -OCS.

► **Definition 3** ( $n$ -way OCS). *Given a ground set, an  $n$ -way OCS is an online algorithm that, at each iteration, takes a subset of size  $n$  as the input and irrevocably chooses an element from the subset.*

For any element  $u$  of the ground set, we say a subsequence of subsets containing  $u$  is *consecutive* if every subset containing  $u$  that arrives between the first and last subsets of the subsequence is also in the subsequence. We also say that two or more subsequences of subsets containing  $u$  are *disjoint* if no two of these subsequences share a subset.

For example, suppose we are given  $\{u, v\}$ ,  $\{u, w\}$ ,  $\{v, w\}$ ,  $\{u, x\}$ , and  $\{u, y\}$  during five timesteps, in that order. Observe that  $(\{u, v\}, \{u, w\}, \{u, x\})$  is a consecutive subsequence containing  $u$ , but  $(\{u, v\}, \{u, x\}, \{u, y\})$  is not because  $\{u, w\}$  appears between  $\{u, v\}$  and  $\{u, x\}$ . Note also that  $(\{u, v\}, \{u, w\})$  and  $(\{u, y\})$  constitute a set of (two) disjoint consecutive subsequences containing  $u$ .

► **Definition 4** (Two-way  $\gamma$ -OCS). *A two-way  $\gamma$ -OCS is a two-way OCS such that, for any element  $u$  and a set of  $m$  disjoint consecutive subsequences of pairs containing  $u$  of lengths  $k_1, \dots, k_m$ , the probability that  $u$  never gets chosen by the OCS from any of the given subsequences is at most  $\prod_{i=1}^m (\frac{1}{2})^{k_i} (1 - \gamma)^{\max(k_i-1, 0)}$ .*

Fahrbach et al. [10] presents two versions of two-way OCS with varying performance guarantees. We will use both in later sections. For the sake of completeness, we present a full description of the two-way 1/16-OCS of Fahrbach et al. below.

**1/16-OCS.** We will define what is called the *ex-ante graph* first. Although the algorithm does not need to explicitly construct this graph, it helps simplify the presentation. The vertices of the ex-ante graph correspond to the input pairs. For each pair, say  $\{u, v\}$ , we introduce an edge between this pair and the immediately following pair that contains  $u$ , and likewise for  $v$ . For example, if an element  $u$  appears at timesteps 2, 4, and 7, pairs 2 and 4 are adjacent, and so are 4 and 7. This implies that every vertex has degree of at most 4. We annotate each edge with the common element that caused this edge. For example, if two pairs  $i = \{u, v\}$  and  $j = \{v, w\}$  are adjacent due to  $v$ , let  $(i, j)_v$  denote the edge (and its annotation). Note that the ex-ante graph may have parallel edges (with different annotations).

The algorithm samples exactly three random bits for each pair (or vertex). We will use them to define what is called the *ex-post graph* and further determine the output of the algorithm. The ex-post graph is on the same set of vertices. The first random bit is used to determine if the vertex becomes a “sender” or a “receiver”. If it becomes a sender, we use the second random bit to choose one of the two elements of the pair, and the sender will “want” to select the edge to the immediately following pair that shares the chosen element (if it exists). Similarly, if a vertex becomes a receiver, we use the second random bit to choose one element, and the receiver will “want” to select the edge to the immediately preceding pair that shares the element. Each edge of the ex-ante graph enters the ex-post graph if and only if both of its endpoints want to select the edge. Observe that the ex-post graph is a matching in the ex-ante graph.

Finally, the output of the algorithm is determined as follows. For every unmatched vertex, its output is determined solely by its third random bit. For each edge in the ex-post graph, we negatively correlate the choice of the two endpoints: we use the third random bit of the sender to determine the output of the sender, and the output of the receiver is determined so that the decision made for the shared element is the opposite. For example, if we have an edge annotated with  $u$  in the ex-post graph and the sender did not choose  $u$ , we choose  $u$  for the receiver; otherwise, we do not choose  $u$  for the receiver. The third random bit of the receiver is discarded.

► **Lemma 5** (Fahrbach et al. [10]). *This algorithm is a two-way  $\frac{1}{16}$ -OCS.*

This algorithm also has the following useful property.

► **Lemma 6** (Fahrbach et al. [10]). *Given a consecutive subsequence of pairs containing an element of length  $k$  input to this algorithm, the probability that there does not exist any edges in the subgraph of the ex-post graph induced by the consecutive pairs is at most  $(1 - 1/16)^{\max(k-1, 0)}$ .*

The other version is a  $\frac{13\sqrt{13}-35}{108}$ -OCS.

► **Lemma 7** (Fahrbach et al. [10]). *There exists a two-way  $\frac{13\sqrt{13}-35}{108}$ -OCS.*

In the *unweighted online bipartite matching problem*, we are given a bipartite graph  $G = (L \cup R, E)$  where we only know  $L$  in advance. Each vertex  $v \in R$  arrives one by one, and the edges adjacent with  $v$  are only then revealed. Upon each arrival of  $v$ , we irrevocably decide whether we match  $v$ , and if so, to which exposed adjacent vertex in  $L$  we match. The objective is to find a matching of the maximum size in  $G$ .

In the *edge-weighted online bipartite matching problem with free disposal*, we are given a bipartite graph  $G = (L \cup R, E)$  as well as an edge weight  $w_{uv} \geq 0$  for each  $(u, v) \in E$ , where we only know  $L$  in advance, again. Each vertex  $v \in R$  arrives one at a timestep, and the

edges adjacent with  $v$  and their edge weights are disclosed at that time. Upon each arrival of  $v$ , we decide whether we match  $v$ , and if so, to which adjacent vertex in  $L$  we match. We remark that  $v$  can be matched to a vertex  $u$  that is already matched, after disposing of the edge incident with  $u$  in the current matching (*free disposal*). The objective is to find a maximum-weight matching in  $G$ .

### 3 Three-Way Online Correlated Selection

In this section, we present our three-way OCS and analyze it by considering the special case where we are interested in a single consecutive subsequence of triples containing a common element. We will extend this to the general case in Section 4.

#### 3.1 Algorithm

Let  $\mathcal{A}$  and  $\mathcal{B}$  be two-way OCS algorithms whose random choices are independent. In particular, we choose Fahrback et al.'s 1/16-OCS as  $\mathcal{A}$  and  $\frac{13\sqrt{13}-35}{108}$ -OCS as  $\mathcal{B}$ . Let  $\gamma_{\mathcal{A}} := 1/16$  and  $\gamma_{\mathcal{B}} := \frac{13\sqrt{13}-35}{108}$ . We use the 1/16-OCS as  $\mathcal{A}$  due to its property that, in its ex-post graph, each edge's existence is determined by (the random bits of) its endpoints only.

Upon arrival of a triple, say  $\{u, v, w\}$ , we choose a pair uniformly at random out of  $\{\{u, v\}, \{u, w\}, \{v, w\}\}$ . We refer to this step as the *random pair choice phase*. Without loss of generality, suppose that  $\{u, v\}$  is chosen. We then input  $\{u, v\}$  to  $\mathcal{A}$  and let it choose one element from the pair. Let us say (without loss of generality again) that  $u$  is returned by  $\mathcal{A}$ . Now we let  $\mathcal{B}$  choose one element from  $\{u, w\}$ . The element chosen by  $\mathcal{B}$  is the final output of this iteration.

#### 3.2 Overview of the Analysis

The goal of Section 3 is to prove the following theorem.

► **Theorem 8.** *Consider a consecutive subsequence of timesteps whose triples contain some element  $u$  of the ground set. Let  $k$  be the length of the subsequence. The probability that our three-way OCS never chooses  $u$  during these  $k$  timesteps is at most*

$$\eta(k) := c_1 t_1^k + c_2 t_2^k - c_3 t_3^k - c_4 t_4^k$$

for some  $c_1 \approx 0.957795$ ,  $c_2 \approx 0.176756$ ,  $c_3 \approx 0.011047$ ,  $c_4 \approx 0.131738$ ,  $t_1 \approx 0.630024$ ,  $t_2 \approx 0.599919$ ,  $t_3 \approx 0.148345$ , and  $t_4 = 0.3125$ , which is bounded from above by

$$\left(\frac{2}{3}\right)^k (1 - \delta_1)^{\max(k-1, 0)} (1 - \delta_2)^{\max(k-2, 0)},$$

where  $\delta_1 = 0.0309587$  and  $\delta_2 = 0.0165525$ .

In what follows, we will fix an arbitrary set of random choices made during the random pair choice phase, and condition on them. Let  $x$  be the number of pairs containing  $u$  from the subsequence that are passed to  $\mathcal{A}$ . Observe that these pairs also form a consecutive subsequence to  $\mathcal{A}$ , and that the number of  $u$ 's that are left out of the first OCS is  $k - x$ .

For  $y = 0, \dots, x$ , let  $p(x, y)$  be the (conditional) probability that  $\mathcal{A}$  returns  $y$  number of  $u$ 's from these pairs. Then, we can see that the (conditional) probability that  $u$  never gets chosen from the given consecutive triples is bounded from above by

$$\sum_{y=0}^x p(x, y) \left(\frac{1}{2}\right)^{k-x+y} (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)} \quad (1)$$

by Lemma 7 and the fact that the pairs containing  $u$  passed to  $\mathcal{B}$  are also consecutive (see also Definition 4). To simplify the presentation, we introduce two shorthands: for a probability mass function  $p'$  defined on  $\{0, \dots, x\}$ , let

$$\theta(x, p') := \sum_{y=0}^x p'(y) \cdot \left(\frac{1}{2}\right)^y (1 - \gamma_{\mathcal{B}})^{y-1}; \text{ and} \tag{2}$$

$$\theta'(x, p') := \sum_{y=0}^x p'(y) \cdot \left(\frac{1}{2}\right)^y (1 - \gamma_{\mathcal{B}})^{\max(y-1, 0)}. \tag{3}$$

Observe that (1) is equal to  $\left(\frac{1-\gamma_{\mathcal{B}}}{2}\right)^{k-x} \theta(x, p(x, \cdot))$  if  $k > x$  and  $\theta'(k, p(k, \cdot))$  otherwise (if  $k = x$ ).

We would like to bound (1), but unfortunately,  $p(x, y)$  depends on the actual input to  $\mathcal{A}$ , not just  $x$ . Yet, we can circumvent this problem by exploiting the behavior of  $\mathcal{A}$ . Recall that  $\mathcal{A}$  constructs the ex-post graph (which is a matching in the ex-ante graph) and negatively correlate the two endpoints of each edge in the ex-post graph. Therefore, when we consider the subgraph of the ex-post graph induced by the given consecutive pairs, we can observe that

- for each edge in this subgraph, exactly one  $u$  is chosen from its two endpoints, and
- if a vertex is isolated in this subgraph,  $u$  is chosen with probability  $1/2$ , independently from the other vertices.

This observation implies that the probability distribution  $p(x, \cdot)$  is a unimodal symmetric distribution. Moreover, the more likely  $\mathcal{A}$  puts an edge in the ex-post graph, the pointier the distribution would be. Using this property, we will construct an imaginary probability distribution  $\{p^*(x, y)\}_{y=0, \dots, x}$  such that

- $p^*(x, y)$  is flatter than (or, formally, centrally dominated by) any distribution  $p$  that results from  $\mathcal{A}$  (see the proof of Lemma 10); and
- $p^*(x, y)$  only depends on  $x$ , not the input itself.

We will further demonstrate that, in (2) and (3), substituting  $p'$  with a centrally dominated distribution would only overestimate (2) and (3) (Lemma 9). Intuitively speaking, this is because  $(1/2)^y(1 - \gamma_{\mathcal{B}})^{y-1}$  and  $(1/2)^y(1 - \gamma_{\mathcal{B}})^{\max(y-1, 0)}$  are (nearly) convex functions.

Thus, the probability that our three-way OCS never chooses  $u$  from the given consecutive triples can finally be bounded from above by

$$\eta(k) := \sum_{x=0}^k \text{binom}\left(k, x, \frac{2}{3}\right) \left[ \sum_{y=0}^x p^*(x, y) \left(\frac{1}{2}\right)^{k-x+y} (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)} \right], \tag{4}$$

where  $\text{binom}(k, x, r)$  represents the probability of the binomial distribution for  $x$  successes out of  $k$  trials with probability  $r$  (Lemma 11).

### 3.3 Using a Centrally Dominated Distribution

Recall that  $k$  denotes the length of the subsequence, i.e., the number of triples, and  $x$  denotes the number of pairs containing  $u$  passed to  $\mathcal{A}$ . Let  $y$  be the number of  $u$ 's returned by  $\mathcal{A}$ ; then,  $\mathcal{B}$  receives a consecutive subsequence of pairs containing  $u$  of length  $k - x + y$ .

We remark that the probability that  $u$  is never chosen by  $\mathcal{B}$ , conditioned on the event that  $\mathcal{A}$  takes  $x$  pairs containing  $u$  and outputs  $y$  number of  $u$ 's, can be bounded by  $\left(\frac{1}{2}\right)^{k-x+y} \cdot (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)}$  from Lemma 7. Note that this bound depends only on the lengths  $k$ ,  $x$ , and  $y$ , not the actual input to  $\mathcal{B}$ .

For  $\mathcal{A}$ , on the other hand, we need to calculate the probability that exactly  $y$  number of  $u$ 's are chosen by  $\mathcal{A}$  from the given subsequence of pairs. However, this probability distribution highly depends on the input to  $\mathcal{A}$ ; therefore, we cannot conveniently fix a distribution parameterized by length  $x$  anymore. Nonetheless, we will show that there exists a bounding distribution, depending only on  $x$ , such that it yields a valid upper bound on the probability that  $u$  is never chosen by our entire algorithm from the given subsequence of triples.

### 3.3.1 Central Dominance

To construct the bounding distribution, we need the notion of central dominance. Recall the definition.

► **Definition 1** (Central Dominance). *Given two discrete symmetric probability distributions  $D_1$  and  $D_2$  on  $\{0, 1, \dots, x\}$  whose probability mass functions are  $p_1$  and  $p_2$ , respectively, we say  $D_1$  centrally dominates  $D_2$  if there exists  $z \in [0, \frac{x}{2}]$  such that, for any integer  $y \in [\frac{x}{2} - z, \frac{x}{2} + z]$ ,  $p_1(y) \geq p_2(y)$ , and for any integer  $y \in [0, \frac{x}{2} - z) \cup (\frac{x}{2} + z, x]$ ,  $p_1(y) \leq p_2(y)$ .*

Intuitively speaking, this definition indicates how flat a symmetric probability distribution is. Following is the lemma that formalizes why a flat distribution helps bound the probability that  $u$  never gets chosen from our three-way OCS. The definitions of  $\theta(\cdot, \cdot)$  and  $\theta'(\cdot, \cdot)$  can be found in (2) and (3), respectively. It is easy to intuitively see that the first half of the lemma should hold; yet,  $\theta'$  is only *nearly* convex and requires some work.

► **Lemma 9.** *Suppose we are given two discrete symmetric distributions  $D_1$  and  $D_2$  on  $\{0, 1, \dots, x\}$  whose probability mass functions are  $p_1$  and  $p_2$ , respectively. If  $D_1$  centrally dominates  $D_2$ , we have  $\theta(x, p_1) \leq \theta(x, p_2)$  and  $\theta'(x, p_1) \leq \theta'(x, p_2)$ .*

**Proof.** If  $x = 0, 1$ , it is trivial since there is only one possible symmetric distribution. Now we assume that  $x \geq 2$ . Given a discrete symmetric distribution with a probability mass function  $p$ , let us consider the following operation: For some  $w, z \in [0, \frac{x}{2}]$  such that  $w > z$ , we decrease  $p(\frac{x}{2} - z)$  and  $p(\frac{x}{2} + z)$  by some  $\epsilon > 0$ , and increase  $p(\frac{x}{2} - w)$  and  $p(\frac{x}{2} + w)$  by  $\epsilon$ , instead. We can observe that  $p$  still forms a valid probability distribution, and changes  $\theta(x, p)$  by

$$\Delta\theta(x, p) = \epsilon \left(\frac{1}{2}\right)^{x/2} (1 - \gamma_{\mathcal{B}})^{x/2-1} \left[ \left(\frac{1 - \gamma_{\mathcal{B}}}{2}\right)^w + \left(\frac{1 - \gamma_{\mathcal{B}}}{2}\right)^{-w} - \left(\frac{1 - \gamma_{\mathcal{B}}}{2}\right)^z - \left(\frac{1 - \gamma_{\mathcal{B}}}{2}\right)^{-z} \right].$$

Let  $\alpha := (1 - \gamma_{\mathcal{B}})/2$  and  $f(t) := \alpha^t + \alpha^{-t}$ . Since  $f'(t) = \ln \alpha \cdot (\alpha^t - \alpha^{-t})$ , we can verify that  $f(t)$  is increasing on  $t \geq 0$ . Hence, we can see that

$$\Delta\theta(x, p) = \epsilon \left(\frac{1}{2}\right)^{x/2} (1 - \gamma_{\mathcal{B}})^{x/2-1} (f(w) - f(z)) \geq 0.$$

Since  $D_1$  centrally dominates  $D_2$ , we can transform  $p_1$  into  $p_2$  by transferring the mass through a few times of the above operation with proper  $w$ 's,  $z$ 's, and  $\epsilon$ 's. For each application,  $\theta(x, p)$  only increases, yielding that  $\theta(x, p_1) \leq \theta(x, p_2)$ .

Proving the other statement is more subtle. Suppose we transform  $p_1$  into  $p_2$  through the same method. If we increase the probabilities of  $\frac{x}{2} - w$  and  $\frac{x}{2} + w$  where  $w < \frac{x}{2}$ , we can apply to the above analysis since the change of  $\theta'(x, p)$  is exactly the same as  $\Delta\theta(x, p)$ .

It remains to consider when the probabilities of 0 and  $x$  get increased by  $\epsilon$ . Assume that we instead decrease the probabilities of  $\frac{x}{2} - z$  and  $\frac{x}{2} + z$  where  $0 \leq z \leq \frac{x}{2} - 1$ . The change of  $\theta'(x, p)$  would be

$$\Delta\theta'(x, p) := \epsilon \left[ 1 + \left(\frac{1}{2}\right)^x (1 - \gamma_{\mathcal{B}})^{x-1} - \left(\frac{1}{2}\right)^{x/2-z} (1 - \gamma_{\mathcal{B}})^{x/2-z-1} - \left(\frac{1}{2}\right)^{x/2+z} (1 - \gamma_{\mathcal{B}})^{x/2+z-1} \right].$$

Let  $\beta := (1/2)^{x/2}(1 - \gamma_{\mathcal{B}})^{x/2-1}$  and  $g(z) := (2/(1 - \gamma_{\mathcal{B}}))^z$ . We then rewrite  $\Delta\theta'(x, p)$  as

$$\Delta\theta'(x, p) = \epsilon [1 + \beta^2(1 - \gamma_{\mathcal{B}}) - \beta(g(z) + 1/g(z))].$$

The partial derivative of  $\Delta\theta'(x, p)$  with respect to  $z$  is

$$\frac{\partial\Delta\theta'(x, p)}{\partial z} = -\epsilon\beta \ln\left(\frac{2}{1 - \gamma_{\mathcal{B}}}\right) \left[ \left(\frac{2}{1 - \gamma_{\mathcal{B}}}\right)^z - \left(\frac{1 - \gamma_{\mathcal{B}}}{2}\right)^z \right].$$

Note that  $\frac{\partial\Delta\theta'(x, p)}{\partial z} \leq 0$  for  $z \geq 0$ . Thus, we can bound  $\Delta\theta'(x, p)$  from below by plugging  $z = \frac{x}{2} - 1$ , i.e.,

$$\Delta\theta'(x, p) \geq \epsilon \left[ \frac{1}{2} - \frac{1 + \gamma_{\mathcal{B}}}{2} \left(\frac{1}{2}\right)^{x-1} (1 - \gamma_{\mathcal{B}})^{x-2} \right].$$

Since  $x \geq 2$ , we have

$$\Delta\theta'(x, p) \geq \epsilon \left[ \frac{1}{2} - \frac{1 + \gamma_{\mathcal{B}}}{4} \right] \geq 0,$$

where the last inequality comes from the fact that  $\gamma_{\mathcal{B}} < 1$ . ◀

### 3.3.2 Bounding Distribution

In this section, we construct the bounding distribution. As was noted earlier,  $\mathcal{A}$  negatively correlates the endpoints of every edge of the ex-post graph. Therefore, we can write the probability  $p(x, y)$  that the two-way OCS chooses precisely  $y$  number of  $u$ 's out of the given  $x$  consecutive pairs if we are given  $q \in \mathbb{R}_+^{\lfloor x/2 \rfloor + 1}$  defined as follows: for  $i = 0, \dots, \lfloor \frac{x}{2} \rfloor$ ,  $q_i$  is the probability that exactly  $i$  edges of the ex-post graph have both endpoints in the given subsequence. Note that  $\sum_{i=0}^{\lfloor x/2 \rfloor} q_i = 1$ . We have

$$p(x, y) = q_0 \cdot \binom{x}{y} \left(\frac{1}{2}\right)^x + q_1 \cdot \binom{x-2}{y-1} \left(\frac{1}{2}\right)^{x-2} + \dots + q_{\lfloor x/2 \rfloor} \cdot \binom{x-2\lfloor x/2 \rfloor}{y-\lfloor x/2 \rfloor} \left(\frac{1}{2}\right)^{x-2\lfloor x/2 \rfloor},$$

where  $\binom{b}{c} := 0$  if  $b < c$  or  $c < 0$ .

Note that  $q$  (and therefore in turn  $p$ ) depends on the actual input to  $\mathcal{A}$ . Given any probability vector  $q \in \mathbb{R}_+^{\lfloor x/2 \rfloor + 1}$ , let  $D(q)$  (or  $D(q_0, \dots, q_{\lfloor x/2 \rfloor})$ ) denote the probability distribution  $\{p(x, y)\}_{y=0, \dots, x}$ . It is easy to verify that, for all  $q$ ,  $D(q)$  is a valid probability distribution that is symmetric on  $y = \frac{x}{2}$ .

Now we construct the bounding distribution. For  $x = 0, \dots, k$ , let  $\alpha_x := (1 - \gamma_{\mathcal{A}})^{\max(x-1, 0)}$  for  $\gamma_{\mathcal{A}} = 1/16$ . We choose  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$  as our bounding distribution. Let  $p^*(x, \cdot)$  be the probability mass function of the bounding distribution, i.e., for each  $y = 0, \dots, x$ ,

$$p^*(x, y) := \begin{cases} \alpha_x \left(\frac{1}{2}\right)^x, & \text{if } y = 0 \text{ or } y = x, \\ \alpha_x \binom{x}{y} \left(\frac{1}{2}\right)^x + (1 - \alpha_x) \binom{x-2}{y-1} \left(\frac{1}{2}\right)^{x-2}, & \text{otherwise.} \end{cases}$$

Following is a key lemma to show that  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$  is a good choice of the centrally dominated distribution.

► **Lemma 10.** *Given a consecutive subsequence of pairs containing  $u$  of length  $x$  ( $0 \leq x \leq k$ ), let  $q \in \mathbb{R}_+^{\lfloor x/2 \rfloor + 1}$  be the probability vector realized by  $\mathcal{A}$ : i.e.,  $q_i$  is the probability that exactly  $i$  edges of the ex-post graph have both endpoints in the given subsequence. We then have  $\theta(x, p(x, \cdot)) \leq \theta(x, p^*(x, \cdot))$  and  $\theta'(x, p(x, \cdot)) \leq \theta'(x, p^*(x, \cdot))$ , where  $p(x, \cdot)$  follows the distribution  $D(q)$ .*

**Proof.** For  $x = 0, 1$ , it is easy to see that  $p(x, y) = p^*(x, y)$  for every possible  $y$  since  $q_0 = 1 = \alpha_x$ . For  $x \geq 2$ , we construct intermediate distributions as follows:

$$\begin{aligned} D_0 &:= D(q_0, 1 - q_0, 0, \dots, 0), \\ D_1 &:= D(q_0, q_1, 1 - q_0 - q_1, \dots, 0), \\ &\dots, \\ D_{\lfloor x/2 \rfloor - 1} &:= D(q_0, q_1, q_2, \dots, 1 - \sum_{i=0}^{\lfloor x/2 \rfloor - 1} q_i) = D(q). \end{aligned}$$

We claim that  $D_0$  centrally dominates  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$  and, for each  $j = 1, \dots, \lfloor \frac{x}{2} \rfloor - 1$ ,  $D_j$  centrally dominates  $D_{j-1}$ . Then, by repeatedly applying Lemma 9, we can prove the lemma.

Let us first prove that  $D_0$  centrally dominates  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$ . Since both distributions are symmetric, it is sufficient for us to consider  $y \in [0, \frac{x}{2}]$ . By Lemma 6, we have  $q_0 \leq \alpha_x$ . If  $q_0 = \alpha_x$ ,  $D_0$  is equivalent to  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$ , completing the proof. We now assume  $q_0 < \alpha_x$ . If  $y = 0$ ,  $D_0$  has the smaller probability. This implies that there must exist a point in  $[1, \frac{x}{2}]$  where  $D_0$  has the greater probability since both distributions are valid.

Let  $y^*$  be the smallest such point. We show that for any integer  $y \in [y^*, \frac{x}{2}]$ ,  $D_0$  has the greater probability. Let  $g(y) := (q_0 - \alpha_x) \binom{x}{y} \left(\frac{1}{2}\right)^x + (\alpha_x - q_0) \binom{x-2}{y-1} \left(\frac{1}{2}\right)^{x-2}$  be the subtraction of the probability of  $D_0$  from that of  $D(\alpha_x, 1 - \alpha_x, 0, \dots, 0)$  at point  $y$ . It suffices to prove that  $g(y)$  is non-decreasing on  $[y^*, \frac{x}{2}] \subseteq [1, \frac{x}{2}]$ . By rewriting the formula, we have  $g(y) = (\alpha_x - q_0) \binom{x}{y} \left(\frac{1}{2}\right)^x \left(\frac{y(x-y)}{4x(x-1)} - 1\right)$ , and it is not hard to see that the function is increasing on  $[1, \frac{x}{2}]$ .

A similar argument can be applied to show that, for each  $j = 1, \dots, \lfloor \frac{x}{2} \rfloor - 1$ ,  $D_j$  centrally dominates  $D_{j-1}$ . Indeed, if  $q_j = 1 - \sum_{i=0}^{j-1} q_i$ ,  $D_j$  is equivalent to  $D_{j-1}$ . We thus assume that  $q_j < 1 - \sum_{i=0}^{j-1} q_i$ . Observe that  $D_j$  has the same probabilities as  $D_{j-1}$  for  $y = 0, \dots, j-1$ , and has the smaller probability for  $y = j$ ; hence, there exists a point in  $[j+1, \frac{x}{2}]$  where  $D_j$  has the greater probability, and let  $y^*$  be the smallest such value. Again, let  $g(y)$  be the difference obtained by subtracting the probability of  $D_{j-1}$  from that of  $D_j$  at point  $y$ . We can write

$$\begin{aligned} g(y) &= \left(1 - \sum_{i=0}^j q_i\right) \left[ \binom{x-2j-2}{y-j-1} \left(\frac{1}{2}\right)^{x-2j-2} - \binom{x-2j}{y-j} \left(\frac{1}{2}\right)^{x-2j} \right] \\ &= \left(1 - \sum_{i=0}^j q_i\right) \binom{x-2j}{y-j} \left(\frac{1}{2}\right)^{x-2j} \left[ \frac{(y-j)(x-y-j)}{4(x-2j)(x-2j-1)} - 1 \right], \end{aligned}$$

implying that  $g(y)$  is increasing on  $[y^*, \frac{x}{2}] \subseteq [j+1, \frac{x}{2}]$ . ◀

We are now ready to bound the probability that our three-way OCS never chooses the element  $u$  from the consecutive subsequence of triples of length  $k$ . Let  $\text{binom}(k, x, r)$  be the probability mass function of the binomial distribution for  $x$  successes out of  $k$  trials with probability  $r$ , i.e.,  $\text{binom}(k, x, r) := \binom{k}{x} r^x (1-r)^{k-x}$ . Finally, we define  $\eta(k)$  as follows and it will be the desired bound.

$$\eta(k) := \sum_{x=0}^k \text{binom} \left( k, x, \frac{2}{3} \right) \left[ \sum_{y=0}^x p^*(x, y) \left( \frac{1}{2} \right)^{k-x+y} (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)} \right].$$

► **Lemma 11.** *Given a consecutive subsequence of triples containing  $u$  of length  $k$ , the probability that our three-way OCS never chooses  $u$  from the subsequence is at most  $\eta(k)$ .*

**Proof.** Conditioned on the pairs selected by the random pair choice phase, let  $x$  be the number of pairs containing  $u$  inserted into  $\mathcal{A}$ . Recall that these pairs form a consecutive subsequence. Let  $p(x, y)$  denote the probability that  $\mathcal{A}$  returns  $y$  number of  $u$ 's from this subsequence. Note that  $p$  follows  $D(q)$  for some  $q$ .

Note that, if  $\mathcal{A}$  returns  $y$  number of  $u$ 's,  $\mathcal{B}$  eventually takes  $k - x + y$  consecutive pairs that originate from the given consecutive triples. By Lemma 7, we can see that the probability that  $u$  is never selected from the given consecutive subsequences of triples is bounded from above by

$$\sum_{y=0}^x p(x, y) \left( \frac{1}{2} \right)^{k-x+y} (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)},$$

which can be rewritten as  $\left( \frac{1-\gamma_{\mathcal{B}}}{2} \right)^{k-x} \theta(x, p(x, \cdot))$  if  $x < k$  or  $\theta'(k, p(x, \cdot))$  if  $x = k$ . In any case, by Lemma 10, it can be further bounded by

$$\sum_{y=0}^x p^*(x, y) \left( \frac{1}{2} \right)^{k-x+y} (1 - \gamma_{\mathcal{B}})^{\max(k-x+y-1, 0)}.$$

It is noteworthy that this value depends only on the number  $x$  of  $u$ 's selected by the random pair choice phase. Observe that the probability that  $x$  pairs containing  $u$  are chosen from  $k$  consecutive triples by the random pair choice phase is exactly  $\text{binom}(k, x, 2/3)$ , completing our proof. ◀

It still remains to calculate the bounds on  $\eta(k)$  in the same form as stated in Theorem 8. We refer the interested readers to [33].

## 4 General Bound

We now extend our discussion to the general case and provide a bound for a set of disjoint consecutive subsequences. The following theorem states this bound.

► **Theorem 2 (restated).** *Consider a set of  $m$  disjoint consecutive subsequences of triples containing an element  $u$ . Let  $k_1, \dots, k_m$  be the lengths of these subsequences. The probability that our three-way OCS never chooses  $u$  from these  $m$  subsequences is at most  $\prod_{i=1}^m \eta(k_i)$ .*

Let  $\mathbf{k} = (k_1, \dots, k_m)$  be a vector whose  $i$ -th entry is the length of the  $i$ -th subsequence. In what follows, we fix (and condition upon) the choices made by the *random pair choice phase*. Let  $\mathbf{x} := (x_1, \dots, x_m)$  be the (now constant) vector whose  $i$ -th entry represents the number of pairs containing  $u$  from the  $i$ -th subsequence that are passed to  $\mathcal{A}$ . For  $\mathbf{y} := (y_1, \dots, y_m) \leq \mathbf{x}$ , let  $p(\mathbf{x}, \mathbf{y})$  be the conditional probability that  $\mathcal{A}$  chooses  $y_i$  number of  $u$ 's from the  $i$ -th subsequence of pairs for all  $i$ . Finally, let  $p_0$  be the probability that our three-way OCS never chooses  $u$ . By Lemma 7, we can observe that  $p_0$  is no greater than

$$\sum_{\mathbf{y} \leq \mathbf{x}} p(\mathbf{x}, \mathbf{y}) \prod_{i=1}^m \left( \frac{1}{2} \right)^{k_i - x_i + y_i} (1 - \gamma_{\mathcal{B}})^{\max(k_i - x_i + y_i - 1, 0)}. \tag{5}$$

To prove the desired bound, we will first present how we can modify the input to  $\mathcal{A}$  without ever decreasing (5). After finitely many modifications, we will be able to “decouple” the random choices across different subsequences.

Recall that each pair inserted into  $\mathcal{A}$  takes three independent random bits. The first random bit determines if the pair is a sender or a receiver. The second random bit decides which adjacent vertex to correlate. The third random bit selects an element to be output for this pair, unless the pair becomes matched as a receiver. Note that, with the first two random bits, the ex-post graph can be determined.

For each vertex  $j$  containing  $u$  in the ex-ante graph, let  $\text{pred}(j, u)$  and  $\text{pred}(j, -u)$  be the immediate predecessor of  $j$  linked by  $u$  and by the other element than  $u$ , respectively. Without loss of generality, let  $v$  be the other element of  $j$  than  $u$ . If we have  $j'$  and  $j$ , residing in different subsequences and  $j'$  appearing before  $j$ , such that

- (A)  $j' = \text{pred}(j, u)$  or  $j' = \text{pred}(j, -u)$  (or both); or
- (B) there exists  $\hat{j}$  such that
  - $\hat{j} = \text{pred}(j', u)$  or  $\hat{j} = \text{pred}(j', -u)$ ,
  - $\hat{j} = \text{pred}(j, -u)$ , and
  - $\hat{j}$  is not contained in any subsequence,

we call them *violations*. In particular, the first type of violations are called Type A violations and the other Type B. Our goal is to modify the input so that there are no violations while (5) never decreased.

For notational simplicity, we let  $\phi(y) := \left(\frac{1}{2}\right)^{k-x+y} (1 - \gamma_B)^{\max(k-x+y-1, 0)}$  for all  $y = 0, \dots, x$ . Observe that  $\phi(y)$  is decreasing over  $y$ . We can now consider (5) as the expected value of  $\prod_{i=1}^m \phi(y_i)$ .

**Removing Type A Violations.** Let us first consider the case when  $j' = \text{pred}(j, u) = \text{pred}(j, -u)$ . We build the new input to  $\mathcal{A}$  by inserting  $\bar{j}_1 = (u, \star)$  and  $\bar{j}_2 = (v, \diamond)$  right before  $j$  is input where  $\star$  and  $\diamond$  are elements appearing nowhere else and  $\star \neq \diamond$ .

Let us fix some random bits of  $\mathcal{A}$ : one can think of this as further conditioning on those bits. In particular, we will fix the first two random bits of every pair except for  $\bar{j}_1$  and  $\bar{j}_2$ .

Suppose for now that the random bits dictate that neither  $(j', j)_u$  nor  $(j', j)_v$  is present in the ex-post graph of the original input. We claim that the probability distribution  $p$  conditioned on this event stays the same even after the modification and therefore the “contribution” to the expectation (5) is not affected either (or in other words, the conditional expectation remains equal).

We will show a stronger statement that the marginal probability distribution of the pairs in the subsequences stays the same. (Then the probability distribution  $p$  will automatically be the same.) Note that the ex-post graph of the two inputs will look almost identical, except for possible addition of some edges incident with  $\bar{j}_1$  or  $\bar{j}_2$ . Therefore, the output choice of every pair in the subsequences will be determined by the same random bit in both inputs, except that, it may be the case that  $j$  was not adjacent with any pair in the ex-post graph of the original input but becomes a receiver of  $\bar{j}_1$  (or  $\bar{j}_2$ ) after the modification. In this case, the output choice of  $j$  was determined by the third random bit of  $j$  before but by that of  $\bar{j}_1$  (or  $\bar{j}_2$ ) now. However, the only pair in the subsequence whose output choice is determined by the third random bit of  $\bar{j}_1$  (or  $\bar{j}_2$ ) is  $j$ . Moreover, the third random bits of the pairs are i.i.d.; hence, the marginal distribution of the pairs in the subsequences stays the same, as was claimed.

Now consider the remaining case where  $j'$  and  $j$  are adjacent in the ex-post graph of the original input. In this case, we will show that the conditional expectation cannot decrease (as opposed to staying the same). To ease the argument, we will fix more random bits (and

argue that the conditional expectation cannot decrease in all cases): we fix the third random bits of all pairs, except for  $j'$ ,  $j$ ,  $\bar{j}_1$ , and  $\bar{j}_2$ . Let  $z'$  be the number of  $u$ 's chosen from the subsequence containing  $j'$ , except for  $j'$  itself, in the original input. (Since we did not fix the third random bit of  $j'$ , we cannot determine what the output choice of  $j'$  is.) Similarly, let  $z$  be the number of  $u$ 's chosen from the subsequence containing  $j$ , except for  $j$  itself.

In the original input, note that the output choice of  $j'$  and  $j$  are both determined by the third random bit of  $j'$ . That is, with probability  $1/2$ ,  $z'$  and  $z+1$  respectively are the number of  $u$ 's chosen from the subsequences containing  $j'$  and  $j$ , and with probability  $1/2$ ,  $z'+1$  and  $z$  are. In the modified input, however, while we do not know whether  $j'$  is adjacent with  $\bar{j}_1$  or  $\bar{j}_2$  in the ex-post graph,  $\bar{j}_1$  and  $\bar{j}_2$  can each be adjacent with at most one pair in the ex-post graph. Therefore, in the marginal distribution of the pairs in the subsequences, the output choice of  $j'$  is independent from all other pairs, including  $j$ . This shows that the number of  $u$ 's chosen from the subsequence containing  $j'$  in the modified input is  $z'$  with probability  $1/2$  and  $z'+1$  with probability  $1/2$ , and independently from that, the number of  $u$ 's from the subsequence containing  $j$  is  $z$  with probability  $1/2$  and  $z+1$  with probability  $1/2$ .

Let us now calculate the increase of the conditional expectation of  $\prod_{i=1}^m \phi(y_i)$ , but since we are only interested in its sign, we will ignore the common terms, i.e.,  $\phi(y_i)$ 's for the subsequences other than ones containing  $j$  and  $j'$ . Note that

$$\begin{aligned} & \frac{1}{4} [\phi(z')\phi(z) + \phi(z')\phi(z+1) + \phi(z'+1)\phi(z) + \phi(z'+1)\phi(z+1)] \\ & - \frac{1}{2} [\phi(z')\phi(z+1) + \phi(z'+1)\phi(z)] \\ = & \frac{1}{4} (\phi(z') - \phi(z'+1))(\phi(z) - \phi(z+1)) \geq 0, \end{aligned}$$

where the inequality follows from the fact that  $\phi(y)$  is decreasing over  $y$ . This shows our claim.

Let us now consider the case where  $j' = \text{pred}(j, u) \neq \text{pred}(j, -u)$  or vice versa. In this case, we insert  $\bar{j} = (u, \star)$  or  $\bar{j} = (v, \star)$  right before  $j$ , where  $\star$  again is a unique element. A similar argument shows that we can show that (5) can only increase in the new input.

**Removing Type B Violations.** We build the new input to  $\mathcal{A}$  by inserting  $\bar{j} = (v, \star)$  right before  $j$ , where  $\star$  is a new unique element. Let us fix the first two random bits of every pair (including  $\bar{j}$ ). We claim that the marginal distributions of the pairs in the subsequences are identical in both inputs.

Consider the ex-post graph of the two inputs. They will be almost identical only with the following possible differences:

- $(\hat{j}, j)$  may be only in the original ex-post graph;
- $(\hat{j}, \bar{j})$  or  $(\bar{j}, j)$  may be only in the new ex-post graph.

For each pair  $x$  in the subsequences, the ex-post graph determines, among the third random bits of all pairs, which one determines the output choice of  $x$ .

Suppose  $(\hat{j}, j)$  is in the original ex-post graph. In this case,  $j$  is the only pair in the subsequences whose output choice is determined by the third random bit of  $\hat{j}$ . (Recall that  $\hat{j}$  is not in any subsequence.) In the modified input, if  $(\bar{j}, j)$  is in the ex-post graph,  $j$  will be the only pair in the subsequences whose output choice is determined by the third random bit of  $\bar{j}$ . If  $(\bar{j}, j)$  is not in the ex-post graph,  $j$  will be the only pair whose output choice is determined by  $j$ . Note that the output choice of every other pair in the subsequences is determined by the same random bit in both inputs. Again, since the third random bits of the pairs are i.i.d., this shows that the marginal distribution stays the same.

## 49:14 Making Three out of Two: Three-Way Online Correlated Selection

Suppose now  $(\hat{j}, j)$  is not in the original ex-post graph. Let us focus on  $j$ , since it is the only pair whose output choice may be determined by a different random bit in the modified input. If  $j$  was adjacent with another pair in the original ex-post graph, the edge will remain in the new ex-post graph, too, in which case there is nothing to prove. Otherwise, it may be the case that  $(\bar{j}, j)$  may be newly introduced as an edge in the ex-post graph, but this only means that  $j$  will be the only pair in the subsequences whose output choice is determined by the third random bit of  $\bar{j}$  (instead of  $j$ ). The marginal distribution therefore stays the same.

**Further Modification.** We can remove all Type A and Type B violations after finitely many modifications of the input. We can interpret  $\mathcal{A}$  as an algorithm that first constructs the ex-ante graph using the first two random bits and then determines the output using only the third random bits. Our next modification will delete some edges directly from the ex-ante graph rather than modifying the input pairs. (You could alternatively think of this edge being “disabled,” which can never appear in the ex-post graph even if it is chosen by the first two random bits of the pairs.) We will now show how we can modify this input graph without affecting (5). Suppose we have some pair  $j'$  and  $j$  such that

- $j'$  appears before  $j$ ,
- $j'$  and  $j$  are adjacent in the ex-ante graph, and
- $j$  is not in any subsequence.

If we delete this edge from the ex-ante graph, this can change the output choice of only  $j$  in  $\mathcal{A}$ 's output. (Imagine we fix all random bits, and we can easily observe this fact.) Therefore, we can safely delete all such edges without affecting the marginal distribution of the pairs in the subsequences.

Once we remove all such edges, the following argument shows that no two pairs in different subsequences can belong to the same connected component of the ex-ante graph: since two pairs that are not in any subsequences cannot be adjacent, the only way of having two pairs from different subsequences in the same connected component is by having a direct edge in-between (which would be a Type A violation) or a length-2 path whose “midpoint” is a predecessor of the two pairs (which would be a Type B violation: note that, in the definition of Type B violation,  $\hat{j}$  cannot be  $\text{pred}(j, u)$  because  $j'$  appears before  $j$ ).

**Conclusion.** Let  $p'(\mathbf{x}, \mathbf{y})$  be the probability that  $\mathcal{A}$  chooses  $y_i$  number of  $u$ 's from the  $i$ -th subsequence of pairs for all  $i$  in the *modified* input. We have so far shown that

$$p_0 \leq \sum_{\mathbf{y} \leq \mathbf{x}} p'(\mathbf{x}, \mathbf{y}) \prod_{i=1}^m \left(\frac{1}{2}\right)^{k_i - x_i + y_i} (1 - \gamma_{\mathcal{B}})^{\max(k_i - x_i + y_i - 1, 0)}.$$

For each  $i$ , let  $p'_i(x_i, y_i)$  be the probability that  $\mathcal{A}$  chooses  $y_i$  number of  $u$ 's from the  $i$ -th subsequence of pairs. Since  $\mathcal{A}$  may introduce negative correlation only on those pair of vertices that are adjacent in the ex-ante graph, output choices made across different connected components of the ex-ante graph will be independent. This implies that  $p'(\mathbf{x}, \mathbf{y}) = \prod_{i=1}^m p'_i(x_i, y_i)$ , yielding

$$\begin{aligned} p_0 &\leq \sum_{\mathbf{y} \leq \mathbf{x}} p'(\mathbf{x}, \mathbf{y}) \prod_{i=1}^m \left(\frac{1}{2}\right)^{k_i - x_i + y_i} (1 - \gamma_{\mathcal{B}})^{\max(k_i - x_i + y_i - 1, 0)} \\ &= \sum_{\mathbf{y} \leq \mathbf{x}} \prod_{i=1}^m p'_i(x_i, y_i) \left(\frac{1}{2}\right)^{k_i - x_i + y_i} (1 - \gamma_{\mathcal{B}})^{\max(k_i - x_i + y_i - 1, 0)} \end{aligned}$$

$$\begin{aligned}
&= \prod_{i=1}^m \sum_{y_i=0}^{x_i} p'_i(x_i, y_i) \left(\frac{1}{2}\right)^{k_i-x_i+y_i} (1-\gamma_{\mathcal{B}})^{\max(k_i-x_i+y_i-1,0)} \\
&\leq \prod_{i=1}^m \sum_{y_i=0}^{x_i} p^*(x_i, y_i) \left(\frac{1}{2}\right)^{k_i-x_i+y_i} (1-\gamma_{\mathcal{B}})^{\max(k_i-x_i+y_i-1,0)},
\end{aligned}$$

where the last inequality follows from the proof of Lemma 11. Since  $p^*(x, \cdot)$  depends only on  $x$ , rather than the actual input, the bound on  $p_0$  we obtain depends only on  $\mathbf{x}$ . Let  $\text{binom}(\mathbf{k}, \mathbf{x}, r) := \prod_{i=1}^m \text{binom}(k_i, x_i, r)$ . Now the probability that our three-way OCS never chooses  $u$  from the given subsequences is no greater than

$$\begin{aligned}
&\sum_{\mathbf{x} \leq \mathbf{k}} \text{binom}\left(\mathbf{k}, \mathbf{x}, \frac{2}{3}\right) \left[ \prod_{i=1}^m \sum_{y_i=0}^{x_i} p^*(x_i, y_i) \left(\frac{1}{2}\right)^{k_i-x_i+y_i} (1-\gamma_{\mathcal{B}})^{\max(k_i-x_i+y_i-1,0)} \right] \\
&= \sum_{\mathbf{x} \leq \mathbf{k}} \left[ \prod_{i=1}^m \text{binom}\left(k_i, x_i, \frac{2}{3}\right) \right] \left[ \prod_{i=1}^m \sum_{y_i=0}^{x_i} p^*(x_i, y_i) \left(\frac{1}{2}\right)^{k_i-x_i+y_i} (1-\gamma_{\mathcal{B}})^{\max(k_i-x_i+y_i-1,0)} \right] \\
&= \prod_{i=1}^m \sum_{x_i=0}^{k_i} \text{binom}\left(k_i, x_i, \frac{2}{3}\right) \left[ \sum_{y_i=0}^{x_i} p^*(x_i, y_i) \left(\frac{1}{2}\right)^{k_i-x_i+y_i} (1-\gamma_{\mathcal{B}})^{\max(k_i-x_i+y_i-1,0)} \right] \\
&= \prod_{i=1}^m \eta(k_i).
\end{aligned}$$

This completes the proof of Theorem 2.

## 5 Application to Online Bipartite Matching

Our three-way OCS can be applied to online bipartite matching problems. While the algorithm and the factor-revealing LP had to be generalized to a higher dimension, our algorithm and analysis are still analogous to Fahrback et al. [10]. We refer the interested readers to [33].

► **Theorem 12.** *There exists a 0.5096-competitive algorithm for unweighted online bipartite matching.*

► **Theorem 13.** *There exists a 0.5093-competitive algorithm for edge-weighted online bipartite matching with free disposal.*

## Abstract

The car-sharing problem, proposed by Luo, Erlebach and Xu in 2018, mainly focuses on an online model in which there are two locations: 0 and 1, and  $k$  total cars. Each request which specifies its pick-up time and pick-up location (among 0 and 1, and the other is the drop-off location) is released in each stage a fixed amount of time before its specified start (i.e. pick-up) time. The time between the booking (i.e. released) time and the start time is enough to move empty cars between 0 and 1 for relocation if they are not used in that stage. The model, called  $kS2L-F$ , assumes that requests in each stage arrive sequentially regardless of the same booking time and the decision (accept or reject) must be made immediately. The goal is to accept as many requests as possible. In spite of only two locations, the analysis does not seem easy and the (tight) competitive ratio (CR) is only known to be 2.0 for  $k = 2$  and 1.5 for a restricted value of  $k$ , i.e., a multiple of three. In this paper, we remove all the holes of unknown CR's; namely we prove that the CR is  $\frac{2k}{k+\lceil k/3 \rceil}$  for all  $k \geq 2$ . Furthermore, if the algorithm can delay its decision until all requests have come in each stage, the CR is improved to roughly  $4/3$ . We can take this advantage even further, precisely we can achieve a CR of  $\frac{2+R}{3}$  if the number of requests in each stage is at most  $Rk$ ,  $1 \leq R \leq 2$ , where we do not have to know the value of  $R$  in advance. Finally we demonstrate that randomization also helps to get (slightly) better CR's.

## 1 Introduction

Our problem in this paper is the *online car-sharing problem*. In car-sharing (not only for cars, but also for other resources like bikes and shuttle-buses), there are several service stations in the city, for instance in residential areas and downtown, at popular sightseeing spots, and so on. Customers can make a request with a pick-up time and place and a drop-off time and place. The decision for accepting or rejecting a request should be made in an online fashion and we want to maximize the profit by accepting as many requests as possible. Relocation of (unused) resources is usually possible with a much smaller or even negligible costs. (It is seen occasionally that a truck is carrying bikes for this purpose.) Theoretical studies of this problem have started rather recently and turned out to be nontrivial even for two locations.

**Model.** We basically follow the problem setting of previous studies by Luo et al. [7–10] with main focus to that of two locations and  $k$  servers (i.e. cars). The two locations are denoted by 0 and 1 and  $k(\geq 2)$  servers are initially located at location 0. The travel time from 0 to 1 and 1 to 0 is the same, denoted by  $t$ . The problem for  $k$  servers and two locations is called the  $kS2L$  problem for short.

■ **Figure 1** The car-sharing problem with two locations.

We denote the  $i$ -th request by  $r_i = (\tilde{t}_i, t_i, p_i)$  which is specified by the *release time* or the *booking time*  $\tilde{t}_i$ , the *start time*  $t_i$ , and the *pick-up location*  $p_i \in \{0, 1\}$  (the *drop-off location* is  $1 - p_i$ ). If  $r_i$  is accepted, the server must pick up the customer at  $p_i$  at time  $t_i$  and drop off the customer at  $1 - p_i$  at time  $t_i + t$ . Suppose for each  $r_i$ ,  $t_i$  is an integer multiple of the travel time between location 0 and 1, i.e.,  $t_i = vt$  for some  $v \in \mathbb{N}$ . We assume that  $t_i - \tilde{t}_i$  is equal to a fixed value  $a$ , where  $a \geq t$  for all requests. Without loss of generality, assume  $a = t$ . Then we are only interested in a discrete-time stage, denoted by  $0, 1, 2, \dots$

Each server can only serve one request at a time. Serving a request yields a fixed positive profit  $y$ . A server used for a request with  $p_i = 0$  ( $p_i = 1$ , resp.) cannot be used for a request with  $p_{i+1} = 0$  ( $p_{i+1} = 1$ , resp.) in the next stage. We allow *empty movements*, i.e., a server can be moved from one location to the other without serving any request. An empty movement spends time  $t$ , but takes no cost. The goal of the  $kS2L$  problem is to maximize the total profit by serving a set of online requests. Note that the performance of an online scheduling algorithm is typically evaluated by *competitive analysis*. More precisely, the quality of an online algorithm is measured by the worst case ratio, called *competitive ratio* (CR), which is defined to be the fraction of the profit of the offline optimal algorithm over that of the online algorithm. The offline algorithm is aware of all requests in advance. If an online algorithm is randomized, we use expected values for the output of the online algorithm. The online algorithm is called  $1/\delta$ -competitive, if for any instances, the profit of the algorithm is at least  $\delta$  times the offline optimal profit. So far the current model is exactly the same as  $kS2L-F$  in [7–10], although no randomized cases were discussed in these papers.

**Simultaneous Decision Model.** Recall that in the  $kS2L$  model, two (or more) inputs with *the same booking time* still have an order. Thus we can equivalently think that if  $r_1, \dots, r_d$  are requests with booking time  $t$ , they are coming later than  $t - 1$  and before or at  $t$ , one by one. Each of them should get a decision (accept or reject) immediately before the next request. The adversary can change  $r_i$  after looking at the response of the online algorithm against  $r_1, \dots, r_{i-1}$ .

This setting sounds reasonable as an online model, but the following question seems also natural; what if requests with the same booking time come exactly at the same time, the online player can see all of them and can make decisions all together simultaneously at the booking moment (equivalently the requests arrive in the same fashion as above but the player can delay his/her online decisions until the booking moment). In this study we also consider this new model, denoted by  $kS2L-S$ . We further extend the model, assuming that the number of requests with the same booking time is at most  $Rk$  for some constant  $R$ . We call the generalized model  $RkS2L-S$ . Notice that having more than  $k$  requests at the same location with the same booking time never helps. Therefore, we only need to study the range

$0 \leq R \leq 2$  and  $kS2L-S$  means the special case that  $R = 2$ . Our algorithm for  $RkS2L-S$  is *adaptive* in the sense that it automatically accommodates the value of  $R$ , which does not have to be known in advance.

**Prior work.** The car-sharing problem has received a considerable amount of attention in recent years. Luo et al. [7] studied the problem with a single server and two locations with both fixed booking time and variable booking time. Here “variable booking time” essentially means that requests with start time  $t$  may come after requests with start time  $t - 1$ . They gave lower bounds on the CR for both fixed and variable booking time under the positive empty movement assumption. Later, Luo et al. [8] studied the car-sharing problem with two servers and two locations, i.e.  $2S2L$ . They considered only the problem with fixed booking time and proposed an online algorithm which can achieve a tight bound of two. Luo et al. [9] studied the car-sharing problem with  $k$  servers and two locations, for both fixed booking time ( $kS2L-F$ ) and variable booking time ( $kS2L-V$ ). Namely they showed the CR is at least 1.5 for all  $k$  and at most 1.5 for  $k = 3i$  for  $kS2L-F$  and at least  $5/3$  for all  $k$  and at most  $5/3$  for  $k = 5i$  for  $kS2L-V$ . Very recently, Luo et al. [10] studied the car-sharing problem on a star network with  $k$  servers as well as two types of travel time: a unit travel time and an arbitrary travel time.

In comparison with the online setting, Böhmová et al. [3] considered the offline car-sharing problem in which all input requests are known in advance. The objective is to minimize the number of vehicles while satisfying all the requests. The offline (i.e. static) problem can be solved in polynomial time. Another closely related problem is the on-line dial-a-ride problem (OLDARP), where objects are transported between given points in a metric space. The problem has been studied widely. The goal is to minimize the total makespan [1, 2] or the maximum flow time [6]. Christman et al. [4] studied a variation of OLDARP where each request yields a revenue. Yi et al. [12] studied another variation of OLDARP where each request has a deadline, having a similar flavor as car sharing.

**Our contribution.** Recall that the tight CR of  $kS2L-F$  is 1.5 for  $k = 3i$  [9] and 2 for  $k = 2$  [8], but open for other  $k$ 's. In this paper, we show that it is  $\frac{2k}{k+\lceil k/3 \rceil}$  for all  $k \geq 2$  and 1.5 for all  $k \geq 2$  if randomization is allowed. For  $kS2L-S$  that allows the online player to delay its decision, it is shown that we can indeed take this advantage. Namely the tight CR for  $kS2L-S$  is  $\frac{2k}{k+\lceil k/2 \rceil}$  for all  $k \geq 2$  and  $4/3$  for all  $k \geq 2$  if randomization is allowed. For  $RkS2L-S$  (we can assume  $1 \leq R \leq 2$  without loss of generality), it is shown that the CR is strictly improved if  $R < 2$ , namely the tight CR (for randomized algorithms) is improved to  $(2 + R)/3$ . Note that if  $R = 1.1$  (the number of requests at each stage exceeds  $k$  by at most 10%), the CR becomes at most 1.034.

The basic idea of our algorithms is “greedy” and “balanced”. Both notions have already appeared in [9], but our implementation of them is significantly different from theirs. More importantly, our analysis is completely new; namely we use a simple mathematical induction (augmented by two interesting parameters other than the profit itself) while a classification of request types was used in [9].

The merit of our new analysis is demonstrated more clearly in  $kS2L-S$  than in the original  $kS2L-F$ . Therefore we present the results for  $kS2L-S$  first and then those for  $kS2L-F$ ; the deterministic case in Section 2 and the randomized case in Section 3.  $RkS2L-S$  is discussed in Section 4, where we introduce two magic numbers calculated from the number of requests in each stage. Finally all matching lower bounds are given in Section 5.

■ **Table 1** Overview of known and new results.

## 2 Deterministic algorithms

As mentioned in the previous section, we first discuss the basic GBA that works for the  $k$ S2L-S model and then its accept/reject version that works for the original  $k$ S2L-F model. The analysis for the former will carry over to that of the latter pretty well. The following table summarizes our notations which are used in the rest of the paper.

### Notation

$k$	The number of total servers
$(0, 1)$ :	Requests from location 0 to 1
$(1, 0)$ :	Requests from location 1 to 0
$Il_i$ :	The number of $(0,1)$ 's requested in stage $i$ with start time $i$
$Ir_i$ :	The number of $(1,0)$ 's requested in stage $i$ with start time $i$
$Gl_i$ :	The number of $(0,1)$ 's accepted by the algorithm in stage $i$
$Gr_i$ :	The number of $(1,0)$ 's accepted by the algorithm in stage $i$
$Gf_i$ :	The number of servers not used, i.e., $k - Gr_i - Gl_i$
$Ol_i$ :	The number of $(0,1)$ 's accepted by OPT in stage $i$
$Or_i$ :	The number of $(1,0)$ 's accepted by OPT in stage $i$
$Of_i$ :	The number of servers not used, i.e., $k - Or_i - Ol_i$

Suppose there are  $x$  and  $x'$  servers at location 0 and  $y$  and  $y'$  servers at location 1 at time  $i$ , where  $x$  servers will serve  $(0,1)$ 's with start time  $i$  but  $x'$  servers are not used. Similarly,  $y$  servers will serve  $(1,0)$ 's but  $y'$  servers not. Then at time  $i + 1$  we can use  $x$  servers for  $(1,0)$ 's and  $y$  servers for  $(0,1)$ 's. Furthermore,  $x' + y'$  servers are available for requests of both directions since the requests with start time  $i + 1$  come at time  $i$  and we can move  $x' + y'$  servers to whichever locations as we like. Now we introduce *stages* and say we have  $x$  ( $= Gl_i$ ) servers at location 1,  $y$  ( $= Gr_i$ ) servers at location 0, and  $x' + y'$  ( $= Gf_i$ ) “floating” servers in stage  $i + 1$ . We also denote the *server allocation* at time  $i + 1$  as  $[y, x' + y', x]$  using the new notation  $[-, -, -]$ . Note that we need to have artificial  $Gr_0, Gl_0$  and  $Gf_0$  for stage 1 whose values are 0, 0, and  $k$ , respectively.

Now the idea of this new greedy balanced algorithm can be illustrated as follows. Let  $k = 100$  and suppose requests in stage 1 are  $(Il_1, Ir_1) = (100, 100)$ . As described above, the server allocation in stage 1 is  $[0, 100, 0]$ , and hence accepted requests,  $(Gl_1, Gr_1)$ , can be anything like  $(100, 0)$ ,  $(75, 25)$  or  $(0, 100)$ . However, if  $(100, 0)$  is selected, then the server allocation in stage 2 is  $[0, 0, 100]$  and the adversary would send  $(Il_2, Ir_2) = (100, 0)$  for

stage 2, by which no servers are available for the online player. Since the almighty adversary can select  $(0,100)$  in stage 1 and he/she can accept all the requests in stage 2, the CR would be 2. Thus one can easily see that the best thing an algorithm can do is to accept  $(Gl_1, Gr_1) = (50, 50)$  in stage 1 to secure a CR of 1.5. This is the notion of “Balanced”. Note that requests denoted by  $(Il_2, Ir_2) = (100, 0)$  have booking time 1, but a booking time of requests (and when they actually come) is no longer important once we know  $(Il_i, Ir_i)$  and the server allocation  $[Gr_{i-1}, Gf_{i-1} = k - Gl_{i-1} - Gr_{i-1}, Gl_{i-1}]$  in stage  $i$ . Thus we will simply use “requests for stage  $i$ ” without mentioning their booking time.

What if  $(Il_1, Ir_1) = (60, 20)$ ? In this case,  $(Gl_1, Gr_1) = (60, 20)$  is the best, i.e., the strategy is a simple “Greedy” one. If  $(Il_1, Ir_1) = (100, 30)$ , our selection is  $(Gl_1, Gr_1) = (70, 30)$ , namely “Greedy” but as “Balanced” as possible. Algorithm 1 realizes this idea almost as it is and it will also be a core of all the subsequent algorithms in this paper.

■ **Algorithm 1** GBA( $k$ ): Greedy Balanced Algorithm.

---

**Input:**  $Il_i$  and  $Ir_i$  are the numbers of  $(0,1)$ 's and  $(1,0)$ 's in stage  $i$ , respectively. An integer  $k$  is the number of total servers. The server allocation at the beginning of stage  $i$  is  $[Gr_{i-1}, Gf_{i-1}, Gl_{i-1}]$ , namely  $Gr_{i-1}$  and  $Gl_{i-1}$  servers at locations 0 and 1, respectively and  $Gf_{i-1} = k - Gl_{i-1} - Gr_{i-1}$  floating servers.

**Output:**  $Gl_i$  and  $Gr_i$  are the numbers of accepted  $(0,1)$ 's and  $(1,0)$ 's, respectively.

```

1: if  $Gr_{i-1} + Gf_{i-1} \leq \lfloor k/2 \rfloor$  or  $Il_i \leq \lfloor k/2 \rfloor$  then
2:    $Gl_i \leftarrow \min\{Il_i, Gr_{i-1} + Gf_{i-1}\}$ ;  $Gr_i \leftarrow \min\{Ir_i, Gl_{i-1} + Gf_{i-1}, k - Gl_i\}$ ;
3: else
4:   if  $Gl_{i-1} + Gf_{i-1} \leq \lfloor k/2 \rfloor$  or  $Ir_i \leq \lfloor k/2 \rfloor$  then
5:      $Gr_i \leftarrow \min\{Ir_i, Gl_{i-1} + Gf_{i-1}\}$ ;  $Gl_i \leftarrow \min\{Il_i, Gr_{i-1} + Gf_{i-1}, k - Gr_i\}$ ;
6:   else
7:      $Gr_i \leftarrow \lfloor k/2 \rfloor$ ;  $Gl_i \leftarrow \lceil k/2 \rceil$ ;
8:   end if
9: end if
10: return  $Gl_i$  and  $Gr_i$ 

```

---

Recall that floating servers in stage  $i$  are actually sit at location 0 or 1 at time  $i - 1$ , say 30 ones at location 0 and 10 at location 1 among 40 floating ones. So if we need 20 floating servers in stage  $i$  at location 1, we need to move 10 servers from location 0 to 1 using the duration from time  $i - 1$  to  $i$ . However, we do not describe this empty movement in our algorithms since it is easily seen and its cost is free in our model.

Observe that the greedy part of Algorithm 1 appears in lines 1 and 2 for  $(0,1)$ 's and in lines 4 and 5 for  $(1,0)$ 's. If the condition in line 1 is met, then we accept  $(0,1)$ 's until we have exhausted the servers or the  $(0,1)$ 's available in this stage. After that we accept as many  $(1,0)$ 's as possible. It works similarly for lines 4 and 5. If neither the condition in line 1 nor the one in line 4 is met, we just split the requests almost evenly in line 7. The following theorem shows that GBA achieves the optimal  $\frac{4}{3}$ -competitiveness for all even  $k$  and approaches this value when  $k$  is a large odd number. In the rest of this paper, we use ALG to denote an online algorithm and OPT an offline optimal scheduler in general.

► **Theorem 1.** *GBA is a  $1/\delta$ -competitive algorithm for  $kS2L-S$  for any  $k \geq 2$ , where  $\delta = \frac{k + \lfloor k/2 \rfloor}{2k}$ .*

■ **Figure 2** Server allocation in GBA.

**Proof.** In order to prove the theorem, we consider the following six key values:

$$A_i = \sum_{j=1}^i (Gr_j + Gl_j), \quad B_i = \sum_{j=1}^i (Or_j + Ol_j),$$

$$X_i = A_i + Gr_i + Gf_i, \quad Y_i = B_i + Or_i + Of_i,$$

$$U_i = A_i + Gl_i + Gf_i, \quad V_i = B_i + Ol_i + Of_i.$$

Our goal is to bound  $A_i$  by  $B_i$ . To do so, it is popular to use a potential function for competitive analysis, which is typically the difference between configurations of ALG and OPT. In our present case, it may be the difference between server allocations of GBA and OPT. It turns out, however, that this configuration difference or a similar one is unlikely to work since we still have a freedom for server selection which is not controlled by this difference strongly. Instead we introduce four parameters,  $X_i$ ,  $Y_i$ ,  $U_i$  and  $V_i$ , which play a key role in our proof. Note that  $X_i$  and  $Y_i$  denote the total revenue of GBA and OPT respectively for the first  $i+1$  stages assuming that the adversary tries to penalize the algorithm choice by introducing  $k$   $(0,1)$ 's in stage  $i+1$ ; the last two values,  $U_i$  and  $V_i$ , denote the total revenue of GBA and OPT respectively for the first  $i+1$  stages assuming that the adversary tries to penalize the algorithm choice by introducing  $k$   $(1,0)$ 's in stage  $i+1$ . Intuitively, GBA balances the accepted requests in both directions and guarantees that the CR's in these two instances ( $\frac{Y_i}{X_i}$  and  $\frac{V_i}{U_i}$ , respectively) are not too large. It turns out that taking care of these two extreme instances is sufficient to keep the CR low for all instances.

In order to prove that the algorithm is  $1/\delta$ -competitive, we show that the set of the following inequalities (i) to (iii), denoted by  $S(n)$ ,

$$(i) A_n \geq \delta B_n, \quad (ii) X_n \geq \delta Y_n, \quad (iii) U_n \geq \delta V_n$$

hold for every  $n$  by induction.

For the base case,  $n = 0$ , we have  $A_0 = B_0 = Gr_0 = Gl_0 = Or_0 = Ol_0 = 0$  and  $Gf_0 = Of_0 = k$ . Thus the three inequalities hold since  $\delta \leq 1$ .

Now the main part of the proof is proving  $S(n)$  assuming, as stated in the induction hypothesis, that  $S(j)$  holds for all  $0 \leq j \leq n-1$ . Note that we can rewrite  $A_i$ ,  $B_i$ ,  $X_i$  and so on as follows:

$$A_i = A_{i-1} + Gl_i + Gr_i, \quad B_i = B_{i-1} + Ol_i + Or_i,$$

$$X_i = A_{i-1} + k + Gr_i, \quad Y_i = B_{i-1} + k + Or_i,$$

$$U_i = A_{i-1} + k + Gl_i, \quad V_i = B_{i-1} + k + Ol_i.$$

Since  $Ol_i \leq \min\{Il_i, Or_{i-1} + Of_{i-1}\}$  and  $Or_i \leq \min\{Ir_i, Ol_{i-1} + Of_{i-1}\}$ , the following lemma is obvious, but will be used frequently.

► **Lemma 2.**  $Ol_i \leq Il_i$ ,  $Ol_i \leq Or_{i-1} + Of_{i-1}$ ,  $Or_i \leq Ir_i$ , and  $Or_i \leq Ol_{i-1} + Of_{i-1}$ .

Now we are ready to prove the theorem. Suppose line 2 is executed. Then the following (L1) or (L2) holds for the value of  $G\ell_i$  and (R1), (R2) or (R3) for the value of  $Gr_i$ . Similarly if line 5 is executed, (R1) or (R2) holds for  $Gr_i$  and (L1), (L2) or (L3) for  $G\ell_i$ .

$$\begin{aligned} \text{(L1)} \quad G\ell_i &= Il_i, \quad \text{(L2)} \quad G\ell_i = Gr_{i-1} + Gf_{i-1}, \quad \text{(L3)} \quad G\ell_i = k - Gr_i (\geq \lfloor k/2 \rfloor), \\ \text{(R1)} \quad Gr_i &= Ir_i, \quad \text{(R2)} \quad Gr_i = G\ell_{i-1} + Gf_{i-1}, \quad \text{(R3)} \quad Gr_i = k - G\ell_i (\geq \lfloor k/2 \rfloor). \end{aligned}$$

Note that the condition “ $\geq \lfloor k/2 \rfloor$ ” in (L3) and (R3) comes from the conditions in lines 1 and 4, respectively. Now we consider stage  $n$  and show that if (L1), (L2) or (L3) holds, the induction (iii) holds, if (R1), (R2) or (R3) hold, the induction (ii) holds and if any one of the nine combinations  $\{(L1), (L2), (L3)\} \times \{(R1), (R2), (R3)\}$  holds, (i) holds. First suppose (L1) holds. Then since  $Ol_n \leq Il_n$  by Lemma 2

$$\begin{aligned} U_n &= A_{n-1} + k + G\ell_n = A_{n-1} + k + Il_n, \\ V_n &= B_{n-1} + k + Ol_n \leq B_{n-1} + k + Il_n. \end{aligned}$$

Thus (iii) is true by the induction hypothesis on (i). Similarly for (L2), i.e., by Lemma 2

$$\begin{aligned} U_n &= A_{n-1} + k + G\ell_n = A_{n-1} + k + Gr_{n-1} + Gf_{n-1}, \\ V_n &= B_{n-1} + k + Ol_n \leq B_{n-1} + k + Or_{n-1} + Of_{n-1}. \end{aligned}$$

Thus (iii) is proved by the hypothesis on (ii). Finally for (L3),

$$\begin{aligned} U_n &= A_{n-1} + k + G\ell_n \geq A_{n-1} + k + \lfloor k/2 \rfloor, \\ V_n &= B_{n-1} + k + Ol_n \leq B_{n-1} + k + k, \end{aligned}$$

then use the hypothesis on (i) to claim (iii).

The proof that (R1) or (R2) or (R3) implies (ii) is similar and omitted.

Finally we show that (i) follows from any combination. Observe that (L1) and (R1) obviously implies (i) since no algorithms accept more requests than requested. All combinations including (L3) or (R3) are also obvious since GBA accepts  $k$  requests. Similarly for (L2) and (R2) when  $Gf_{i-1} = 0$  (otherwise impossible). The remaining cases are (L1) and (R2), and (L2) and (R1). For the former, by Lemma 2

$$\begin{aligned} A_n &= A_{n-1} + G\ell_n + Gr_n = A_{n-1} + Il_n + G\ell_{n-1} + Gf_{n-1}, \\ B_n &= B_{n-1} + Ol_n + Or_n \leq B_{n-1} + Il_n + Ol_{n-1} + Of_{n-1}, \end{aligned}$$

and we can use the hypothesis on (iii). (L2) and (R1) is similar and omitted.

What remains is the case that line 7 is executed. Observe that line 7 gives us  $G\ell_n \geq \lfloor k/2 \rfloor$ ,  $Gr_n \geq \lfloor k/2 \rfloor$  and  $G\ell_n + Gr_n = k$ . We have already shown that the first one implies (iii), the second one (ii) and the third one means all the servers accept requests and is obviously enough for (i). Thus the theorem is proved. ◀

As seen in GBA and its analysis, a dangerous situation for the online player is that ALG accepts too many requests of one direction when it is possible. If ALG knows the total number of requests in each direction in advance, we can avoid this situation rather easily. Now we discuss  $kS2L-F$ , in which ALG does not know the total number of requests in advance. A simple and apparent solution is to stop accepting requests of one direction when its number gets to some value, even if more requests of that direction are coming and could

be accepted. In the next algorithm, ARGBA, we set this value as  $2k/3$ . It then turns out, a little surprisingly, that the analysis for Theorem 1 is also available for the new algorithm almost as it is.

■ **Algorithm 2** ARGBA( $k$ ): Accept or reject GBA.

**Input:** The server location is  $[Gr_{i-1}, Gf_{i-1} = k - Gl_{i-1} - Gr_{i-1}, Gl_{i-1}]$  at the beginning of this stage  $i$ . Requests are coming sequentially, each of which,  $r$ , is (0,1) or (1,0).  $k$  is the total number of servers.

**Output:** Immediate accept or reject for  $r$ .  $Gl_i$  and  $Gr_i$  for the next server allocation.

```

1:  $Gl_i \leftarrow 0$ ;  $Gr_i \leftarrow 0$ ,  $Al_i \leftarrow 0$ ;  $Ar_i \leftarrow 0$  ( $Al_i$  ( $Ar_i$ , resp.) is the number of (0,1)'s ((1,0)'s, resp.) received in this stage so far.)
2: while a new request  $r$  comes do
3:   if  $r$  is (0,1) then
4:      $Al_i \leftarrow Al_i + 1$ ;
5:     if  $Al_i < Gr_{i-1} + Gf_{i-1}$  and  $Al_i < 2k/3$  and  $Gl_i + Gr_i < k$  then
6:       accept  $r$ ;  $Gl_i \leftarrow Gl_i + 1$ ;
7:     else
8:       reject  $r$ ;
9:     end if
10:  else (namely,  $r$  is (1,0))
11:     $Ar_i \leftarrow Ar_i + 1$ ;
12:    if  $Ar_i < Gl_{i-1} + Gf_{i-1}$  and  $Ar_i < 2k/3$  and  $Gl_i + Gr_i < k$  then
13:      accept  $r$ ;  $Gr_i \leftarrow Gr_i + 1$ ;
14:    else
15:      reject  $r$ ;
16:    end if
17:  end if
18: end while
19: return  $Gl_i$  and  $Gr_i$ 

```

► **Theorem 3.** ARGBA is a  $1/\delta$ -competitive algorithm for  $kS2L-F$  for any  $k \geq 2$ , where  $\delta = \frac{k + \lfloor k/3 \rfloor}{2k}$ .

**Proof.** Observe that once a (0,1) (similarly for (1,0)) is rejected, then subsequent ones are all rejected. Let  $X_i$  and  $Y_i$  be the last (0,1) and (1,0), respectively, that are accepted and  $Gl_i$  and  $Gr_i$  be their numbers after lines 6 and 10, respectively. Also, let  $Il_i$  and  $Ir_i$  be the total numbers of (0,1)'s and (1,0)'s in stage  $i$ , respectively (only used for analysis). Suppose the last accepted (0,1) has gone through the conditions in line 5. Then, one can see that the next (0,1), if any, is blocked by one of these conditions and thus one of the following four conditions, (L1) through (L4), is met. Similarly for (1,0)'s, one of (R1) through (R4) is met.

$$\begin{aligned}
& \text{(L1) } Gl_i = Il_i, \quad \text{(L2) } Gl_i = Gr_{i-1} + Gf_{i-1}, \quad \text{(L3) } Gl_i = \lceil 2k/3 \rceil, \\
& \quad \quad \quad \text{(L4) } Gl_i + Gr_i = k \text{ and } Gl_i \geq \lfloor k/3 \rfloor \text{ and } Gr_i \geq \lfloor k/3 \rfloor, \\
& \text{(R1) } Gr_i = Ir_i, \quad \text{(R2) } Gr_i = Gl_{i-1} + Gf_{i-1}, \quad \text{(R3) } Gr_i = \lceil 2k/3 \rceil, \\
& \quad \quad \quad \text{(R4) } Gl_i + Gr_i = k \text{ and } Gl_i \geq \lfloor k/3 \rfloor \text{ and } Gr_i \geq \lfloor k/3 \rfloor.
\end{aligned}$$

Note that the lower bound condition in (L4) and (R4) is correct since otherwise the second condition in line 5 or 11 should have been met before.

Now consider stage  $n$ . In a way similar to the proof of Theorem 1, we can show that one of (L1) to (L4) (with subscript  $n$  replacing  $i$ ) implies the induction (iii). In fact, the reason is exactly the same for (L1) and (L2) as before. Using  $G\ell_i \geq \lfloor k/3 \rfloor$  in (L4) we have

$$\begin{aligned} U_n &= A_{n-1} + k + G\ell_n \geq A_{n-1} + k + \lfloor k/3 \rfloor, \\ V_n &= B_{n-1} + k + O\ell_n \leq B_{n-1} + k + k, \end{aligned}$$

and then use the hypothesis on (i) to claim (iii) (recall that our target CR is relaxed to  $\frac{2k}{k + \lfloor k/3 \rfloor}$ ). (L3) obviously implies  $G\ell_i \geq \lfloor k/3 \rfloor$ .

Also we can show, though omitted, that one of (R1) to (R4) (with subscript  $n$  replacing  $i$ ) implies the induction (ii).

We can furthermore show that any one of the 16 combinations of (L1) to (L4) and (R1) to (R4) implies (i): If a combination includes one of (L3), (L4), (R3) and (R4), then (i) is obvious since ARGBA accepts at least  $\lceil 2k/3 \rceil$  requests in this stage. So we only have to consider the four combinations ((L1) or (L2), and (R1) or (R2)), and these cases already appeared in the proof of Theorem 1, which concludes the proof. ◀

### 3 Randomized Algorithms

Notice that the CR of GBA is 2 when  $k = 2$ . The reason is simple, i.e., the existence of the ceiling function, namely if we can accept a fractional request, our CR would be  $4/3$ . Of course it is impossible to accept a request by one third, but it is possible to accept that request with probability  $1/3$ , which has the same effect as accepting it by one third in terms of an expected number.

We define the following function for probabilistic rounding. Let  $x$  be a (possibly fractional) non-negative number. Then define

$$\text{prrd}(x) = \begin{cases} \lceil x \rceil & \text{with probability } x - \lfloor x \rfloor \\ \lfloor x \rfloor & \text{with probability } 1 - (x - \lfloor x \rfloor) \end{cases}$$

For instance,  $\text{prrd}(3.3)$  is 4 with probability 0.3 and 3 with probability 0.7.  $\text{prrd}(3)$  is always 3. Note  $E[\text{prrd}(x)] = x$ . Now we are ready to introduce the Probabilistic GBA.

■ **Algorithm 3** PrGBA( $k$ ): Probabilistic GBA.

---

1: The same as Algorithm 1 except that line 7 is replaced as follows:  $Gr_i \leftarrow \text{prrd}(k/2)$  and  $G\ell_i \leftarrow k - Gr_i$

---

▶ **Theorem 4.** *PrGBA is a  $4/3$ -competitive algorithm for  $kS2L$ -S for any  $k \geq 2$ .*

**Proof.** Observe the induction in the proof of the deterministic case. The base case is fine with  $\delta = 3/4$ , and we can keep using this  $3/4$  unless line 7 is executed. Since the expected value of  $Gr_i$  and  $G\ell_i$  are both  $k/2$  when the modified line 7 is executed, we can remove the ceiling sign from the description of the algorithm. Thus our new CR is  $2k/(k + k/2) = 4/3$ . ◀

■ **Algorithm 4** PrARGBA( $k$ ): Probabilistic ARGBA.

---

1: ARGBA is modified as follows: Suppose the three conditions in line 5 are all met and  $0 < 2k/3 - A\ell^{j-1} < 1$ . Then accept  $r_i^j$  and increase  $G\ell_i$  if  $\text{prrd}(2k/3 - A\ell^{j-1}) = 1$ , otherwise reject it. Similarly for line 11.

---

► **Theorem 5.** *PrARGBA is a 1.5-competitive algorithm for  $kS2L-F$  for any  $k \geq 2$ .*

**Proof.** The same idea as the proof of Theorem 4. If this modified part is executed, the expected value of  $Gl_i$  is  $2k/3$  and hence the expected value of  $Gr_i$  is  $k/3$  if  $Gl_i + Gr_i = k$ . Thus the worst case of deterministic ARGBA,  $Gl_i = \lceil 2k/3 \rceil$  and  $Gr_i = \lfloor k/3 \rfloor$ , can be avoided. ◀

#### 4 Adaptive GBA

$kS2L-S$  gives the online player the advantage of an advance knowledge of the number of requests in the current stage. GBA does exploit this advantage, but not fully. Suppose  $(Il_1, Ir_1) = (50, 100)$ . GBA accepts the same number, 50, of  $(0,1)$ 's and  $(1,0)$ 's in stage 1. Then the adversary sends  $(Il_2, Ir_2) = (100, 0)$ , resulting in that only 50  $(0,1)$ 's can be accepted by GBA in stage 2, but 100  $(0,1)$ 's by OPT which could accept 100  $(1,0)$ 's in stage 1. Thus the CR in these two steps is  $4/3$ .

Now what about accepting roughly 28.57  $(0,1)$ 's and 71.43  $(1,0)$ 's in stage 1 (recall we can handle fractional numbers due to randomized rounding)? Then the best the adversary can do is to provide  $(Il_2, Ir_2) = (100, 0)$  or  $(0, 50)$ , in both of which the CR is  $200/171.43 \approx 150/128.57 \approx 1.17$ , significantly better than 1.5 of GBA. This is the basic idea of our new algorithm, AGBA. These key values 28.57 and 71.43 are denoted by  $\alpha_i$  and  $\beta_i$ , respectively. The ultimate goal of AGBA is to accept exactly  $\alpha_i$   $(0,1)$ 's and  $\beta_i$   $(1,0)$ 's while the ultimate goal of GBA was to accept  $k/2$   $(0,1)$ 's and  $k/2$   $(1,0)$ 's. If this goal is unachievable, to be figured out from the values of  $Il_i, Ir_i, Gl_{i-1}, Gr_{i-1}$  and  $Gf_{i-1}$ , both algorithms simply turn greedy.

■ **Algorithm 5** AGBA( $k$ ): Adaptive GBA.

**Input:** The same as GBA

**Output:** The same as GBA

```

1: if  $R_i = (Il_i + Ir_i)/k \geq 1$  then
2:    $\alpha_i = \frac{(1-R_i)k+3Il_i}{2+R_i}; \beta_i = \frac{(1-R_i)k+3Ir_i}{2+R_i};$ 
3: else
4:    $\alpha_i = Il_i; \beta_i = Ir_i;$ 
5: end if
6: if  $Gr_{i-1} + Gf_{i-1} < \alpha_i$  then
7:    $Gl_i \leftarrow Gr_{i-1} + Gf_{i-1}; Gr_i \leftarrow \min\{Ir_i, Gl_{i-1}\};$ 
8: else
9:   if  $Gl_{i-1} + Gf_{i-1} < \beta_i$  then
10:     $Gl_i \leftarrow \min\{Il_i, Gr_{i-1}\}; Gr_i \leftarrow Gl_{i-1} + Gf_{i-1};$ 
11:   else
12:     $Gl_i \leftarrow \text{prrd}(\alpha_i);$ 
13:     $Gr_i \leftarrow \beta_i;$ 
14:   end if
15: end if
16: return  $Gl_i$  and  $Gr_i$ 

```

Suppose  $Il_i + Ir_i$  is at most  $kR_i$  for stage  $i$ . As mentioned in a moment, we do not lose generality if  $R_i$  is restricted to  $1 \leq R_i \leq 2$ , under which the CR of AGBA is bounded by  $(2+R)/3$ , where  $R$  is the maximum value of  $R_i$  in the whole stages. We do not know  $R$  in advance and AGBA does not have to, either.

The competitive analysis is given by the following theorem. Note that if the input in stage  $i$  includes more than  $k$  (0,1)'s, we can select an arbitrary subset of size  $k$  and similarly for (1,0)'s. This guarantees that  $R \leq 2$  and the case that  $Il_i + Ir_i < k$  is covered by  $R = 1$ . Thus the restriction of  $R$ ,  $1 \leq R \leq 2$ , makes sense. Also, note that  $\alpha_i + \beta_i = k$  whenever  $R_i \geq 1$ . AGBA uses  $R_i$  but not  $R$ .  $R = \max\{R_i\}$  by definition and so  $\delta \leq \delta_i$  (where  $\delta_i$  is the local value of  $\delta$  in this stage, see its definition at Lemma 8) for all  $i$ .

► **Theorem 6.** *Suppose the number of requests is limited to at most  $Rk$  in all stages for some  $R$  such that  $1 \leq R \leq 2$  and  $Rk$  is an integer. Then AGBA solves  $RkS2L-S$  and is  $1/\delta$ -competitive, where  $\delta = 3/(2 + R)$ .*

**Proof.** Because of the probabilistic rounding used in lines 12, the expected values of  $G\ell_i$  and  $Gr_i$  are  $\alpha_i$  and  $\beta_i$ , respectively, if this part is executed. We need two lemmas; the second one illustrate a tricky nature of  $\alpha_i$  and  $\beta_i$ .

► **Lemma 7.** *For any  $R_i \geq 0$ ,  $\alpha_i \leq Il_i$  and  $\beta_i \leq Ir_i$ . Also,  $\alpha_i + \beta_i \leq k$ .*

**Proof.** A simple calculation of the formulas in line 2 is enough if the condition  $Il_i + Ir_i \geq k$  is met. Otherwise it is also obvious by line 4. ◀

► **Lemma 8.** *Let  $\delta_i = \min\{1, 3/(2 + R_i)\}$ . Then  $k + \beta_i = \delta_i(k + Ir_i)$  and  $k + \alpha_i = \delta_i(k + Il_i)$ .*

**Proof.** If  $R_i < 1$  then  $\delta_i = 1$ ,  $\alpha_i = Il_i$  and  $\beta_i = Ir_i$ , so the lemma is obviously true. Otherwise, a simple calculation:

$$k + \alpha_i = k + \frac{(1 - R_i)k + 3Il_i}{2 + R_i} = \frac{3k + 3Il_i}{2 + R_i} = \delta_i(k + Il_i).$$

Similarly for the other. ◀

The basic strategy of the proof is the same as Theorem 1. We consider the following four conditions for the values of  $G\ell_i$  and  $Gr_i$ . Suppose line 7 is executed. Then  $G\ell_i$  satisfies (L2) and  $Gr_i$  satisfies (R1). Similarly if line 10 is executed, (L1) and (R2) hold.

$$(L1) G\ell_i = \min\{Il_i, Gr_{i-1}\}, (L2) G\ell_i = Gr_{i-1} + Gf_{i-1},$$

$$(R1) Gr_i = \min\{Ir_i, G\ell_{i-1}\}, (R2) Gr_i = G\ell_{i-1} + Gf_{i-1}.$$

Now consider stage  $n$ . It is shown that (L1) or (L2) implies (iii) of the induction. For (L2), the analysis is the same as before and omitted. For (L1), using Lemma 2 for  $V_n$ , we have

$$U_n = A_{n-1} + k + G\ell_n = A_{n-1} + k + \min\{Il_n, Gr_{n-1}\},$$

$$V_n = B_{n-1} + k + Ol_n \leq B_{n-1} + k + Il_n.$$

If  $\min\{Il_n, Gr_{n-1}\} = Il_n$ , then we are done using the hypothesis (i). Otherwise recall that the condition of line 9,  $G\ell_{n-1} + Gf_{n-1} < \beta_n$ , is met. So we have  $Gr_{n-1} = k - (G\ell_{n-1} + Gf_{n-1}) \geq k - \beta_n \geq \alpha_n$  (by Lemma 7 for the last inequality) and thus we can use Lemma 8 and the hypothesis on (i) to claim (iii). The proof that (R1) or (R2) implies (ii) is very similar and omitted.

Next we prove that each of the four combinations implies (i). (L1) and (R1), and (L2) and (R2) are obvious since AGBA is as efficient as OPT or accepts  $k$  requests (recall  $\min\{Il_n, Gr_{n-1}\} \geq \alpha_n$  and  $\min\{Ir_n, G\ell_{n-1}\} \geq \beta_n$  mentioned above and by Lemma 7). For (L1) and (R2), using Lemma 2 and  $\alpha_n \leq Il_n$ , we have

$$A_n = A_{n-1} + G\ell_n + Gr_n = A_{n-1} + \min\{I\ell_n, Gr_{n-1}\} + G\ell_{n-1} + Gf_{n-1},$$

$$B_n = B_{n-1} + O\ell_n + Or_n \leq B_{n-1} + I\ell_n + O\ell_{n-1} + Of_{n-1}.$$

Thus the hypothesis on (iii) or  $Gr_{n-1} + G\ell_{n-1} + Gf_{n-1} = k$  implies that  $A_n \geq \delta B_n$ . (L2) and (R1) are similar.

The remaining case is the one that lines 12 and 13 are executed. If  $G\ell_n = \alpha_n$ , we have  $U_n = A_{n-1} + k + \alpha_n$  and thus we can use Lemma 8 to claim (iii) as shown above. Similarly for  $Gr_n$  and (ii). (i) is obvious since  $G\ell_i + Gr_i = k$ , completing the proof. ◀

## 5 CR Lower Bounds

The CR's given so far are all tight. In this section we prove matching lower bounds for  $kS2L-S$ , for  $kS2L-F$ , for  $kS2L-F$  with randomization, and for  $RkS2L-S$  with randomization (including for  $kS2L-S$  with randomization as a special case).

► **Theorem 9.** *No deterministic online algorithms for the  $kS2L-S$  problem can achieve a CR of less than  $\frac{2k}{k+\lceil k/2 \rceil}$ .*

**Proof.** Let  $\mathcal{A}$  be any deterministic algorithm. The adversary requests  $k$  (0,1)'s and  $k$  (1,0)'s in stage 1.  $\mathcal{A}$  accepts  $k_\ell$  (0,1)'s and  $k_r$  (1,0)'s. If  $k_\ell \leq \lfloor k/2 \rfloor$ , then the adversary requests  $k$  (1,0)'s (and zero (0,1)'s) in stage 2. The profit of  $\mathcal{A}$  is  $k_\ell + k_r$  in stage 1, and at most  $(k - k_\ell - k_r) + k_\ell$  in stage 2. Therefore, the total profit of  $\mathcal{A}$  is at most  $k + k_\ell \leq k + \lfloor k/2 \rfloor$ . The profit of OPT is  $2k$ , and the theorem is proved. If  $k_\ell > \lfloor k/2 \rfloor$ , then  $k_r \leq \lfloor k/2 \rfloor$ . Now the adversary requests  $k$  (0,1)'s in stage 2. The profit of  $\mathcal{A}$  and OPT are exactly the same as above and we may omit the rest of calculation. Thus the bound is tight. ◀

► **Theorem 10.** *No deterministic online algorithms for the  $kS2L-F$  problem can achieve a CR of less than  $\frac{2k}{k+\lceil k/3 \rceil}$ .*

**Proof.** Let  $\mathcal{A}$  be any deterministic algorithm. The basic idea is similar to [9]. The adversary gives  $k$  (0,1)'s (sequentially) for stage 1. If  $\mathcal{A}$  accepts at most  $\lfloor 2k/3 \rfloor$  ones, then the adversary stops his/her requests and the game ends. Thus the CR is at least  $\frac{k}{\lfloor 2k/3 \rfloor}$ . Otherwise, if  $\mathcal{A}$  accepts  $\lfloor 2k/3 \rfloor$  or more, then the adversary gives another  $k$  (1,0)'s for stage 1 and  $k$  (0,1)'s for stage 2. Since  $\mathcal{A}$  has accepted at least  $\lfloor 2k/3 \rfloor$  (0,1)'s in stage 1,  $\mathcal{A}$  cannot use those servers for the (0,1)'s for stage 2. Hence  $\mathcal{A}$  can accept at most  $k$  requests in stage 1 and at most  $k - \lfloor 2k/3 \rfloor$  requests in stage 2, meaning at most  $2k - \lfloor 2k/3 \rfloor = k + \lfloor k/3 \rfloor$  requests in total. OPT can accept  $k$  (1,0)'s in stage 1 and  $k$  (0,1)'s in stage 2, i.e.,  $2k$  in total. Thus the CR is at least  $\frac{2k}{k+\lceil k/3 \rceil}$ . Since  $\frac{2k}{k+\lceil k/3 \rceil} \leq \frac{k}{\lfloor 2k/3 \rfloor}$  for all  $k$  (this can be verified by checking for  $k = 3j$ ,  $k = 3j + 1$  and  $k = 3j + 2$ ), the theorem is proved. ◀

► **Theorem 11.** *No randomized online algorithms for the  $kS2L-F$  problem can achieve a CR of less than 1.5.*

**Proof.** The proof is almost the same as that of Theorem 10. Since the adversary has the full information (other than random values) of ALG, he/she can compute the expected value of ALG's output. So what we have to do is just removing the floor and ceiling signs from the previous proof and considering the resulting numbers as expected values. The proof is complete since the previous deterministic OPT has a profit of at least  $2k$ . ◀

► **Theorem 12.** *No randomized online algorithms for the  $RkS2L-S$  problem can achieve a CR of less than  $\frac{2+R}{3}$ .*

**Proof.** Let  $\mathcal{A}$  be any randomized algorithm. The adversary requests  $\lfloor Rk/2 \rfloor$  (0,1)’s and  $\lceil Rk/2 \rceil$  (1,0)’s in stage 1 ( $\lfloor Rk/2 \rfloor + \lceil Rk/2 \rceil = Rk$  by the integrality condition).  $\mathcal{A}$  accepts  $k\ell$  (0,1)’s and  $kr$  (1,0)’s. Let  $\alpha = \frac{(1-R)k + 3\lfloor \frac{Rk}{2} \rfloor}{2+R}$  and if  $E[k\ell] \leq \alpha$  (note that the adversary has the full information of  $\mathcal{A}$ , so it can compute  $E[k\ell]$ ), then the adversary requests  $k$  (1,0)’s (and zero (0,1)’s) in stage 2. The profit of  $\mathcal{A}$  is at most

$$k + E[k\ell] \leq k + \alpha = k + \frac{(1-R)k + 3\lfloor \frac{Rk}{2} \rfloor}{2+R} = \frac{3(k + \lfloor \frac{Rk}{2} \rfloor)}{2+R}.$$

The profit of OPT is  $k + \lfloor Rk/2 \rfloor$ , and the theorem is proved. If  $E[k\ell] > \alpha$  then let  $\beta = \frac{(1-R)k + 3\lceil \frac{Rk}{2} \rceil}{2+R}$ , and it is easy to see that  $\alpha + \beta = k$ . Hence we have  $E[kr] \leq \beta$  because  $E[k\ell] + E[kr] = E[k\ell + kr] \leq k$ . Now the adversary requests  $k$  (0,1)’s. The profit of  $\mathcal{A}$  and OPT are exactly the same as above by replacing  $\lfloor \frac{Rk}{2} \rfloor$  with  $\lceil \frac{Rk}{2} \rceil$ . We may omit the rest of calculation. Note that although the two input instances provide a tight lower bound for the competitive ratio, applying Yao’s Minimax theorem on any probability distribution over these two input instances does not provide the same tight bound. ◀

## 6 Concluding Remarks

We have presented a different greedy and balanced algorithm with a new analysis which fully exploits the notion of “floating servers,” and the arguments of the mathematical induction using supplementary parameters  $X_i$  and  $U_i$  (and their OPT counterparts). We believe that the analysis technique is powerful for future studies of many extensions of the car sharing problem, which would be worthwhile to investigate for practical purposes. In particular, relaxation of the rental period condition should be challenging and important.

## Abstract

Consider the problem where  $n$  jobs, each with a release time, a deadline and a required processing time are to be feasibly scheduled in a single- or multi-processor setting so as to minimize the total energy consumption of the schedule. A processor has two available states: a *sleep state* where no energy is consumed but also no processing can take place, and an *active state* which consumes energy at a rate of one, and in which jobs can be processed. Transitioning from the active to the sleep does not incur any further energy cost, but transitioning from the sleep to the active state requires  $q$  energy units. Jobs may be preempted and (in the multi-processor case) migrated.

The single-processor case of the problem is known to be solvable in polynomial time via an involved dynamic program, whereas the only known approximation algorithm for the multi-processor case attains an approximation factor of 3 and is based on rounding the solution to a linear programming relaxation of the problem. In this work, we present efficient and combinatorial approximation algorithms for both the single- and the multi-processor setting. Before, only an algorithm based on linear programming was known for the multi-processor case. Our algorithms build upon the concept of a *skeleton*, a basic (and not necessarily feasible) schedule that captures the fact that some processor(s) must be active at some time point during an interval. Finally, we further demonstrate the power of skeletons by providing a 2-approximation algorithm for the multiprocessor case, thus improving upon the recent breakthrough 3-approximation result. Our algorithm is based on a novel rounding scheme of a linear-programming relaxation of the problem which incorporates skeletons.

## 1 Introduction

Energy consumption is one of the most important aspects of computing environments as supported, for example, by the fact that data centers already account for more than 1% of global electricity demand, and are forecast to reach 8% by 2030 [10]. With that in mind, modern hardware increasingly incorporates power-management capabilities. However, in order to take full advantage of these capabilities algorithms in general, and scheduling algorithms in particular, must take energy consumption into consideration – on top of the classical algorithm complexity measures of time and space.

In this work we study *power-down mechanisms* which are one of the most popular power-management techniques available on modern hardware. In the most basic setting, the processor (or device) can reside either in an *active* state in which processing can take place, or in a *sleep* state of negligible energy-consumption in which no processing can take place. Since transitioning the processor from the sleep to the active state requires energy, the scheduler would like to satisfy all the processing requirements, while making use of the sleep state as efficiently as possible. To give some intuition, it is preferable to reside in the sleep state for fewer but longer time-intervals than frequently switching between the two states.

A bit more formally, consider a set of  $n$  jobs, each with a release time, a deadline and a processing-time requirement, to be feasibly scheduled on either a single or a multi-processor system that is equipped with a powerdown mechanism. When the (each) processor resides in the active state it consumes energy at a rate of one, whereas it does not consume any energy when in the sleep state. Transitioning from the sleep state to the active state requires a constant amount of energy (the *wake-up cost*), whereas transitioning from the active state to the sleep state is free of charge (this is w.l.o.g., since positive energy cost could be folded onto the wake-up cost). Jobs can be preempted and (in the multi-processor setting) migrated, but every job can be processed on at most one machine at any given time. The objective is to produce a feasible schedule (assuming that such a schedule exists) which consumes the minimum amount of energy. In Graham's notation, and with  $E$  being the appropriate energy function, the problems we study can be denoted as  $1|r_j; \bar{d}_j; \text{pmtn}|E$  and  $m|r_j; \bar{d}_j; \text{pmtn}|E$  respectively.

The problem was first stated in its *single-processor* version by Irani et al. [9] along with an  $O(n \log n)$ -time 2-approximation algorithm for it. The algorithm, called *Left-to-Right* greedily keeps the processor at its current state for as long as possible. The problem plays a central role in the area of energy efficient algorithms [8], and the exact complexity of it was only resolved by Baptiste et al. [5] (and a bit earlier for the special case of unit-processing-time jobs [4]), who gave an exact polynomial-time algorithm for the problem. Their algorithm is based on a dynamic programming approach, which at least for the arbitrary processing-time case is rather involved, and obtains a running time of  $O(n^5)$ .

When considering the *multi-processor* setting, it is unclear how to adapt the aforementioned dynamic programming approach to the *multi-processor* setting, while enforcing that a job does not run in parallel to itself. Additionally, several structural properties that had proven useful in the analysis of the single-processor setting do not carry over to the multiprocessor setting. Only very recently, an approximation algorithm for the problem that attains a non-trivial approximation guarantee was presented by Antoniadis et al. [2]. Their algorithm is based on carefully rounding a relaxation of a linear programming formulation for the problem and has an approximation ratio of 3. They also show that their approach gives an LP-based 2-approximation algorithm for the single-processor case. We note that whether the problem is NP-hard or not in the multiprocessor-setting remains a major open question.

## 1.1 Formal Problem Statement and Preliminaries

Consider a set of jobs  $\{j_1, j_2, \dots, j_n\}$ ; job  $j_i$  has release time  $r_i$ , deadline  $d_i$  and a processing requirement of  $p_i$ , where all these quantities are non-negative integers. Let  $r_{\min}$  and  $d_{\max}$  be the earliest release time and furthest deadline of any job; it is no loss of generality to assume  $r_{\min} = 0$  and  $d_{\max} = D$ . For  $t \in \mathbb{Z}_{\geq 0}$ , let  $[t, t+1]$  denote the  $t^{\text{th}}$  *time-slot*. Let  $I = [t, t']$ ,  $t, t' \in \mathbb{Z}_{\geq 0}$ ,  $t < t'$  be an *interval*. The length of  $I$ , denoted by  $|I|$  is  $t' - t$ . Finally, we use  $t \in I = [a, b]$  to denote  $a \leq t \leq b$  and call interval  $[r_i, d_i]$  the *span* of job  $i$ .

Two intervals  $I_1 = [a_1, b_1]$  and  $I_2 = [a_2, b_2]$  *overlap* if there is a  $t$  such that  $t \in I_1$  and  $t \in I_2$ . Thus two intervals which are right next to each other would also be considered overlapping. Intervals which do not overlap are considered *disjoint*.  $I_1$  is *contained* in  $I_2$ , denoted  $I_1 \subseteq I_2$ , if  $a_2 \leq a_1 < b_1 \leq b_2$  and it is *strictly contained* in  $I_2$ , denoted  $I_1 \subset I_2$ , if  $a_2 < a_1 < b_1 < b_2$ .

At any time-slot, a processor can be in one of two states: the *active*, or the *sleep* state. For each time-slot that a processor is in the active state, it requires one unit of power whereas no power is consumed in the sleep state. However,  $q$  units of energy (called *wake up* energy) are expended when the processor transitions from the sleep to the active state. In its active state, the processor can either process a job (in which case we refer to it as being *busy*) or just be *idle*. On the other hand the processor cannot perform any processing while in the sleep state. Note that whenever a period of inactivity is at least  $q$  time-slots long then it is worthwhile to transition to the sleep state, whereas if it is less than  $q$  time-slots long then it is preferable to remain in the active state.

A processor can process at most one job in any time-slot and a job cannot be processed on more than one processor in a time-slot. However, job preemption and migration are allowed, i.e., processing of a job can be stopped at any time and resumed later on the same or on a different processor. A job  $j_i$  must be processed for a total of  $p_i$  time-slots within the interval  $[r_i, d_i]$ . Any assignment of jobs to processors and time slots satisfying the above conditions is called a (feasible) *schedule*. We assume that the processor is initially in the sleep state. Therefore, the energy consumed by a schedule is the total length of the intervals during which the processor is active plus  $q$  times the number of intervals in which the processor is active. The objective of the problem is to find a schedule which consumes minimum energy.

We will use  $P$  to denote the sum of all the processing times, ie.  $P = \sum_{i=1}^n p_i$ . We will use  $OPT$  to denote a fixed optimal solution and  $Q$  to denote the total wake up cost incurred by  $OPT$ . Given a solution  $S$  (not necessarily feasible), by *maximal gaps* of  $S$ , we will refer to intervals  $[a, b]$  such that there are no active time slots in  $[a, b]$  and processor is active at time slots  $a - 1$  and  $b$ . An interval  $[a, b]$  of  $S$  is *active* if the processor is active in all time slots in  $[a, b]$  and inactive in time slots  $a - 1$  and  $b$ .

Given a single processor instance, a schedule is called a *skeleton* if for all jobs  $j_i$ , there is at least one active interval overlapping with the span of  $j_i$ . In other words, there must be at least one active time slot in  $[r_i - 1, d_i + 1]$ . Note that a skeleton need not be a feasible solution. A *minimum cost skeleton* is a skeleton of minimal energy consumption over all skeletons.

In the following we let  $(x)^+$  to stand for  $x$  if  $x \geq 0$  and 0 otherwise. Due to space constraints omitted proofs are deferred to the appendix.

## 1.2 Our Contribution

We study the problem in both the single-processor and the multi-processor setting. Our core technical contribution is that of introducing the concept of minimum cost skeletons. We then employ this concept to design combinatorial and efficient approximation algorithms for single and multi-processor setting. Finally we demonstrate how skeletons can also be useful in strengthening the LP-formulation of the problem with additional constraints by giving the first known  $(2 + \epsilon)$ -approximation algorithm for the multi-processor case. More formally, our contribution is based on the following.

### Single Processor

We begin by introducing the notion of skeletons for single-processor instances, and presenting a simple dynamic programming algorithm for computing minimum cost skeletons in Section 2. Roughly speaking, a skeleton is a (not necessarily feasible) solution which overlaps with the span of every job. Apart from providing a lower bound for the cost of the optimal solution  $OPT$ , a skeleton has useful structural properties that allow us to convert it into a feasible solution without much overhead. The first result in which we demonstrate this, is the following.

► **Theorem 1.** *There exists an  $O(n \log n)$ -time algorithm that computes a solution of cost at most  $OPT + P$ .*

The algorithm produces a solution of cost at most  $OPT + P$ , where  $OPT$  is the cost of optimal solution and  $P$  is the sum of processing times. Since  $P \leq OPT$  this implies another 2-approximation algorithm, thus matching algorithm Left-to-Right of [9] in both running time and approximation guarantee.

We further build upon the ideas of Section 2 in Section 3 to give a  $O(n \log n)$ -time algorithm that also builds upon a minimum cost skeleton in order to compute a solution of cost at most  $OPT + P/(\alpha - 1) + Q(2\alpha + 1)$ . Here  $Q$  is the total wake up cost incurred by the optimal solution and  $\alpha$  is any real number greater than 1. We show how this result can be used in order to obtain a  $O(n \log^2 n)$  algorithm that computes a near optimal solution when  $P \gg Q$  (which in most scenarios is the practically relevant case) or  $Q \gg P$ :

► **Theorem 2.** *Let  $t = \max\{P/Q, Q/P\}$ . Then there exists a  $O(n \log^2 n)$  time algorithm which computes a solution of cost at most  $OPT(1 + 8t^{-1/2})$ .*

Note, that this implies a  $(1 + \epsilon)$ -approximation algorithm when  $t \geq 8/\epsilon^2$ , whereas Left-to-Right by Irani et al. [9] remains a 2-approximation algorithm even in that case.

Finally, we give an algorithm that is also an  $35/18 \approx 1.944$ -approximation algorithm in  $O(n \log n)$ -time, improving upon the greedy 2-approximation algorithm of Irani et al. [9]:

► **Theorem 3.** *There is a  $\frac{35}{18}$  approximation algorithm for the single processor case in  $O(n \log n)$  time.*

Although (as already mentioned) Baptiste et al. [5] present an exact algorithm for the problem, it is based on a rather involved dynamic program. In contrast, our algorithms have as their main advantages that they are combinatorial in nature, simple to implement, it has an improved approximation-ratio compared to all other non-exact algorithms for the problem and even obtains a near-optimal solution for the interesting and practically relevant case of  $P \gg Q$  in near linear time.

### Multiple Processors

Although the notion of a skeleton does not naturally extend to the multi-processor setting, it is possible to define skeletons for that setting so as to capture the same intuition. In Section 4 we do exactly that before presenting a polynomial-time algorithm for computing minimum-cost multi-processor skeletons. In Section 5, we give an algorithm to convert any skeleton into a feasible solution while increasing the cost by a factor of at most 6:

► **Theorem 4.** *There exists a combinatorial 6-approximation algorithm for the multi-processor case of the problem.*

This implies the first combinatorial constant-factor approximation algorithm for the multiprocessor case. The arguments required in its analysis are however much more delicate and involved than the single processor case and heavily build upon the tools developed in [2].

Finally, in Section 6 we further demonstrate the power of skeletons by using them to develop a  $(2+\epsilon)$ -approximation algorithm for the multi-processor case. Thus we improve upon the recent breakthrough 3-approximation from [2]. We note, that obtaining any non-trivial approximation guarantee in the multiprocessor setting has been a long standing open problem (see [5]).

► **Theorem 5.** *There exists a  $(2 + \epsilon)$ -approximation algorithm for the problem on parallel machines.*

More specifically, we are able to strengthen the linear program used in [2] with additional constraints that are guided by the definition of skeletons. We note that it is unclear whether the rounding scheme used in [2] can take advantage of these new constraints. To that end we devise a novel rounding technique, and also show that the considered linear program has an integrality gap of at most 2. In other words, we show the following result.

► **Theorem 6.** *There exists a pseudo-polynomial time 2-approximation algorithm for deadline scheduling on parallel processors.*

Theorem 6 when combined with standard arguments, which were already presented in [2], then implies Theorem 5.

### 1.3 Further Related Work

The single-processor setting has also been studied in combination with the other popular power-management mechanism of *speed-scaling* where the processor can additionally vary its speed while in the active state where the power consumption grows convexly in the speed. This allows for increased flexibility, as in some cases it may be beneficial to spend some more energy by increasing the speed in the active state in order to incur larger savings by transitioning the processor to the sleep state for longer periods of inactivity. This technique is commonly referred to as *race to idle* in the literature. The combined problem is known to be **NP**-hard [1, 11] and to admit a fully polynomial time approximation scheme (FPTAS) [3].

Finally, the problem of minimizing the number of gaps in the schedule, i. e., the number of contiguous intervals during which the processor is idle. Note that with respect to exact solutions our problem generalizes that of minimizing the number of gaps. Chrobak et al. [6] present a simple  $O(n^2 \log n)$ -time, 2-approximation algorithm for the problem of minimizing the number of gaps on single processor with unit-processing times. Demaine et al. [7] give an exact algorithm for the problem of minimizing the number of gaps in the multi-processor setting with unit-processing-times.

## 2 Computing Minimum Cost Skeletons for a Single Processor

The goal of this section is to prove Theorem 1. Any solution to the minimum cost skeleton problem can be seen as a (non-overlapping) set of active intervals separated by a set of maximal gaps. In this spirit one interpretation of a skeleton is that of a set of active intervals which overlaps with the span of every job. An equivalent definition for a skeleton is a set of maximal gaps such that the span of no job is properly contained inside any maximal gap: if there is at least one active time-slot in  $[r_i - 1, d_i + 1]$  then the span of job  $i$  is not contained in a maximal gap and vice versa. As we will see, this alternative viewpoint will be useful in designing a near linear time algorithm for computing a minimum cost skeleton.

► **Definition 7. Gap Skeleton Problem.** Find a set of maximal gaps  $G_1, G_2, \dots, G_k$  such that for each job  $j_i$ ,  $[r_i - 1, d_i + 1] \not\subseteq G_p$  for  $p = 1, 2, \dots, k$  and the quantity  $\sum_{i=1}^k (|G_i| - q)^+$  is maximized.

Observe that we may w.l.o.g. restrict ourselves to input instances with at least two jobs, and may only consider minimum cost skeletons, the leftmost interval of which begins at  $d_{min}$  and the rightmost active interval ends at  $r_{max}$  (or else we can transform them to a skeleton satisfying the property without increasing their cost). We call such skeletons *nice*. For the purpose of computing a minimum cost skeleton, we shall restrict our attention to nice skeletons only. The maximal gaps of a nice skeleton form a feasible solution to the gap skeleton problem. By construction, the sum of costs of a nice skeleton and the corresponding gap skeleton is exactly equal to  $r_{max} - d_{min} + q$ . Hence, the problem of finding a minimum cost skeleton is in fact equivalent to finding a maximum cost gap skeleton. We now show how to compute a maximum gap skeleton by using dynamic programming.

Without loss of generality, we may also assume that maximal gaps in any maximum cost gap skeleton start and end at one of the points in  $T = \cup_{i=1}^n \{r_i, d_i\}$  (otherwise we could increase the length of maximal gaps, without thereby decreasing the cost of the solution). A maximal gap  $[x, y]$  is called *right maximal* if there exists a  $j_i$  such that  $d_i = y$  and  $r_i > x$ . Without loss of generality, we may assume that there exists an optimal solution to maximum gap skeleton problem in which all the gaps are right maximal (we can always convert any given optimal solution to one containing only right maximal gaps). Let us rename  $T = \cup_{i=1}^n \{r_i, d_i\}$  to  $T = \{t_1, t_2, \dots, t_{2n}\}$  such that  $t_1 \leq t_2 \leq \dots \leq t_{2n}$ . Observe that for any  $t \in T$ , at most one right maximal gap can have its left endpoint at  $t$  and hence there can be a total of at most  $2n$  right maximal gaps.

We can list all the right maximal gaps in  $O(n \log n)$  time as follows: we sort all the  $r_i$ 's in  $O(n \log n)$  time and then for each  $t \in T$ , we compute the first  $r_i$  to the right of  $t$ . Then  $[t, d_i]$  is the unique right maximal gap starting at  $t$ . Since for each  $t$ , the above can be done in  $O(\log n)$  time (by using binary search), all the right maximal gaps can be computed in  $O(n \log n)$  time.

Let  $T_i = \{t_i, t_{i+1}, \dots, t_{2n}\}$ ,  $i = 1, \dots, 2n$  and  $A[i]$  be the maximum value of the gap skeleton problem when restricted to  $T_i$ . By the discussion above, we may restrict our attention to only the right maximal gaps. Observe that  $A[2n] = 0$  and  $A[1]$  gives the value of maximum cost gap skeleton.  $A$  satisfies the following recurrence: let  $g = [t_i, t_j]$  be the right maximal gap starting at  $t_i$ . In the optimal solution, either a right maximal gap starts at  $t_i$  or it doesn't, giving  $A[i] = \max\{(t_j - t_i - q)^+ + A[j + 1], A[i + 1]\}$ . Using the above recurrence,  $A[1], \dots, A[2n]$  can be computed in  $O(n)$  time. Hence, by the equivalence of the two problems, a skeleton with minimum cost can be computed in  $O(n \log n)$  time.

► **Theorem 8.** A minimum cost skeleton can be computed in  $O(n \log n)$  time.

Since any feasible solution to the minimum energy scheduling problem is also a skeleton, the following follows:

► **Observation 9.** The minimum cost skeleton has value at most  $OPT$ .

In Lemma 10 we show how to convert a skeleton into a feasible solution in  $O(n \log n)$  time with an additional cost of at most  $P$ . Along with Theorem 8 and Observation 9, this completes the proof of Theorem 1

► **Lemma 10.** Let  $S$  be any feasible skeleton and  $P_S$  be the maximum total volume of jobs that can be feasibly processed in it. Then we can convert  $S$  into a feasible solution  $S'$  with an additional cost of  $P - P_S$  in  $O(n \log n)$  time.

### 3 Improved Approximation Algorithms

We further develop the ideas introduced in the last section to give fast and improved approximation algorithm for the minimum energy scheduling problem. The main insight is to compute a minimum cost skeleton after scaling the wake up cost and then using Lemma 10 to find a feasible solution. As we will show, this leads to near optimal solutions in case  $P \gg Q$  or  $P \ll Q$ .

Let  $\alpha > 1$  be a real number and  $S_\alpha$  be the minimum cost skeleton obtained by scaling the wake up cost by  $\alpha$ .  $S_\alpha$  can be computed in  $O(n \log n)$  time by Theorem 8. Let  $F_\alpha$  be the solution obtained by converting  $S_\alpha$  into a feasible solution using Lemma 10. The following theorem bounds the cost of  $F_\alpha$  in terms of  $P, Q$  and  $\alpha$ .

► **Theorem 11.** *The cost of  $F_\alpha$  is at most  $OPT + 2(\alpha + 1)Q + P/(\alpha - 1)$ .*

**Proof.** Let  $OPT$  be a fixed optimal solution to the original instance. We abuse notation and also use  $OPT$  to denote the cost of the solution. To bound the cost of  $F_\alpha$ , we will first convert  $OPT$  into  $S_\alpha$  in a series of steps, while carefully accounting for changes in the cost, and the total volume of jobs that can be processed. Since  $F_\alpha$  can be obtained from  $S_\alpha$  by using Lemma 10 with a further increase in cost equal to the missing volume, this will allow us to obtain the desired bound. Let  $g = [a, b]$  be any maximal gap in  $OPT$ . We first show that at most two active intervals of  $S_\alpha$  overlap with  $g$ . The proof of this claim follows a similar proof found in Irani et al. [9].

▷ **Claim 12.** At most two active intervals of  $S_\alpha$  overlap with any maximal gap  $g$  of  $OPT$ .

Let  $g$  be a maximal gap of  $OPT$  and  $I_1, I_2$  be the two intervals of  $S_\alpha$  that overlap with  $g$  (it is of course possible that either one or both of these intervals are empty). Recall that  $|I_1 \cap g|$  and  $|I_2 \cap g|$  denote the length of overlap between  $g$  and  $I_1, I_2$  respectively.

▷ **Claim 13.**  $|I_1 \cap g| \leq \alpha q$  and  $|I_2 \cap g| \leq \alpha q$ .

**Proof.** Let  $I_1 \cap g = [a, b]$ . For the sake of contradiction, suppose that  $|I_1 \cap g| > \alpha q$ . Observe that span of no job is strictly contained inside  $I_1 \cap g$ , ie. for no  $j_k, [r_k, d_k] \subset I_1 \cap g$  (otherwise job  $j_k$  would not be scheduled in  $OPT$  at all). This implies that  $S_\alpha$  remains a valid skeleton even if we make all the time slots in  $[a, b]$  inactive. This operation decreases the total length of active intervals in  $S_\alpha$  by  $|a - b| > \alpha q$  while introducing at most one new active interval. This implies that  $S_\alpha$  is not the optimal skeleton with wake up cost equal to  $\alpha q$ , a contradiction (as making all time slots in  $[a, b]$  will give a lower cost skeleton). Hence,  $|I_1 \cap g| \leq \alpha q$ . A similar argument shows that  $|I_2 \cap g| \leq \alpha q$ . ◁

We first transform  $OPT$  so that its active intervals contain the active intervals of  $S_\alpha$ . More formally:

▷ **Claim 14.** We can modify  $OPT$  while increasing the cost by at most  $2(\alpha + 1)Q$  so that for any active interval  $I_\alpha \in S_\alpha$ , there exists an active interval  $I_o \in OPT$  such that  $I_\alpha \subseteq I_o$ .

**Proof.** We transform every maximal gap  $g$  of  $OPT$  as follows. Let  $I_1, I_2$  be two active intervals of  $S_\alpha$  that overlap with  $g$ . We add (active) intervals  $I_1 \cap g$  and  $I_2 \cap g$  to  $OPT$ . The additional cost incurred is  $2q + |I_1 \cap g| + |I_2 \cap g| \leq 2q + \alpha q + \alpha q = 2(\alpha + 1)q$ . The condition of the claim clearly holds after we perform the above transformation for every maximal gap of  $OPT$ . The total cost incurred over all maximal gaps is  $2(\alpha + 1)Q$  and the claim follows. ◁

Let  $OPT_1$  be the solution obtained after the modification in Claim 14. Let  $OPT_1 \setminus S_\alpha$  denote the set of active intervals formed by taking the difference of active time slots in  $OPT_1$  and  $S_\alpha$ . Let  $G_\alpha$  be the set of all maximal gaps of  $S_\alpha$ . By Claim 14, for every active interval  $I \in OPT_1 \setminus S_\alpha$ , there exists a maximal gap  $g_\alpha \in G_\alpha$  such that  $I \subseteq g_\alpha$ . We convert  $OPT_1$  into  $S_\alpha$  by removing all the active intervals in  $OPT_1 \setminus S_\alpha$ . To bound the cost of  $OPT_1$ , we need to consider the following possibilities:

- $I \subset g_\alpha$ : In this case, removing  $I$  doesn't create any new active intervals in  $OPT_1$ . Hence, decrease in the cost of  $OPT_1$  is equal to the length of  $I$ . Also, the reduction in the total volume of jobs that can be scheduled in  $OPT_1$  is at most  $|I|$ .
- $I = g_\alpha$ : In this case, removing  $I$  creates a new interval in  $OPT_1$ . Hence, total cost of  $OPT_1$  decreases by  $|I| - q$ . Also, reduction in the total volume of jobs that can be scheduled in  $OPT_1$  is at most  $|I|$ .

Let  $A$  the set of intervals such that  $I \in OPT_1 \setminus S_\alpha = g_\alpha$ . We need the following bound on the cardinality of  $A$  to finish the proof.

▷ **Claim 15.**  $q|A| \leq P/(\alpha - 1)$ .

*Proof.* Recall that we compute  $S_\alpha$  by scaling the wake up cost by  $\alpha$ , hence any maximal gap of  $S_\alpha$  has length at least  $\alpha q$ . Since for any interval  $I \in A$ , there exists a maximal gap  $g_\alpha \in S_\alpha$  such that  $I = g_\alpha$ , we have  $|I| \geq \alpha q$  for any  $I \in A$ . We now show that there can't be more than  $q$  idle time slots in  $I$  in any feasible schedule of  $OPT$ .

Fix a feasible schedule of jobs in  $OPT$ . Since  $I = g_\alpha$  and  $S_\alpha$  is a feasible skeleton, there is no  $k$  such that span of  $j_k$  is strictly contained in  $I$ . Let  $J_1$  be the set of jobs which overlap with the left end point of  $I$  and  $J_2$  be the set of jobs which overlap only with the right end point of  $I$ . Note it is possible that some job is included in both  $J_1$  and  $J_2$ . By shifting the jobs in  $J_1$  to as far left as possible and those in  $J_2$  to as far right as possible, we may assume that all the idle slots in  $I$  appear contiguously. If the length of this idle interval is more than  $q$ , then its removal decreases the cost of the solution without affecting the feasibility, thus contradicting the fact that  $OPT$  is a minimum cost solution. Hence, there cannot be more than  $q$  idle slots in any  $I \in A$  in any feasible schedule of  $OPT$ . This implies that at least  $|I| - q$  volume of jobs is processed in  $I$  in any feasible schedule of  $OPT$ . Hence,  $P \geq \sum_{I \in A} (|I| - q) \geq (\alpha - 1)q|A|$  and the statement of the claim follows. ◁

We are now ready to bound the cost of the final solution. By the case analysis above, the cost of  $S_\alpha$  is at most  $OPT_1 - \sum_{I \in OPT_1 \setminus S_\alpha} |I| + q|A| \leq OPT + 2(\alpha + 1)Q - \sum_{I \in OPT_1 \setminus S_\alpha} |I| + q|A|$ . The total volume of jobs that can be processed in  $S_\alpha$  is at least  $P - \sum_{I \in OPT_1 \setminus S_\alpha} |I|$ . Hence, using Lemma 10 to convert  $S_\alpha$  into a feasible solution gives that the total cost of  $S_\alpha$  is at most  $OPT + 2(\alpha + 1)Q - \sum_{I \in OPT_1 \setminus S_\alpha} |I| + q|A| + \sum_{I \in OPT_1 \setminus S_\alpha} |I| = OPT + 2(\alpha + 1)Q + q|A| \leq OPT + 2(\alpha + 1)Q + P/(\alpha - 1)$ . This completes the proof of the theorem. ◀

We are now ready to prove the two main theorems of this section. We start with Theorem 2.

**Proof of Theorem 2.** We construct a series of solutions,  $F_0, F_1, F_2, F_4, \dots, F_{2^{\lceil \log \lceil n \rceil}}$  as follows:  $F_0$  is the solution given by Theorem 1 of cost at most  $OPT + P$ . For each  $i \geq 1$ , we construct  $F_i$  by setting  $\alpha = \sqrt{P/iq}$  in Theorem 11. Our solution  $F$  is obtained by taking the minimum cost solution among all the  $F_i$ 's. Since, each of  $F_i$ 's can be constructed in  $O(n \log n)$  time,  $F$  can be constructed in  $O(n \log^2 n)$  time. We now show that  $F$  has the desired approximation guarantee. First note that  $OPT \geq P + Q$  and  $t \geq 1$ . If  $P \leq Q$ , then  $F_0$  has cost at most  $OPT + P = OPT(1 + \frac{P}{OPT}) \leq OPT(1 + \frac{P}{P+Q}) \leq$

$OPT(1 + t^{-1}) \leq OPT(1 + 8t^{-1/2})$ . Now consider the case when  $P > Q$ . One can verify that for  $\alpha \geq 1$ ,  $f(\alpha) = Q(2\alpha + 2) + P/(\alpha - 1)$  has a unique minimum at  $\alpha^* = \sqrt{P/2Q} + 1$ . We must have used exactly one  $\alpha \in [\alpha^*, \sqrt{2\alpha^*}]$  to construct one of the  $F_i$ 's. Since,  $f(\alpha)$  has a unique minimum in  $\alpha \geq 1$ , it follows that it is increasing in  $[\alpha^*, \sqrt{2\alpha^*}]$ . Hence, there exists an  $F_i$  with cost no more than guaranteed by setting  $\alpha = 2\alpha^*$  in Theorem 11. A straightforward calculation shows that  $f(2\alpha^*) \leq 8\sqrt{PQ}$ . Hence,  $F$  has cost at most  $OPT + 8\sqrt{PQ} \leq OPT(1 + \frac{8\sqrt{PQ}}{P+Q}) \leq OPT(1 + \frac{8\sqrt{t}}{t+1}) \leq OPT(1 + 8t^{-1/2})$ . ◀

Finally, we give a  $O(n \log n)$  algorithm that has a performance guarantee better than 2.

**Proof of Theorem 3.** We construct two solutions: first one of cost at most  $OPT + P$  (by using Theorem 1) and second one of cost at most  $OPT + 8Q + P/2$  (by using Theorem 11). In case  $P \leq 17Q$ , the first solution has cost at most  $OPT + P \leq OPT + 17(P + Q)/18 \leq OPT \cdot 35/18$ . In case  $P > 17Q$ , the second solution has cost at most  $OPT + 8Q + P/2 \leq OPT + 8(1/18) \cdot OPT + 1/2 \cdot OPT = (1 + 8/18 + 1/2) \cdot OPT = OPT \cdot 35/18$ . ◀

## 4 Skeletons for Parallel Processors

In this section, we extend the idea of skeletons from the single processor setting to the multi-processor one. We design an efficient and combinatorial algorithm for finding the minimum cost skeleton. In the next section we then show how this skeleton can be used to design a combinatorial approximation algorithm for the multi-processor setting. Let  $T$  be as defined in the last section, i. e.  $T = \cup_{i=1}^n \{r_i, d_i\}$ . For any  $t_i, t_j \in T$  such that  $t_i < t_j$ , let  $l(t_i, t_j)$  be the maximum number of processors that can be blacked out in  $[t_i, t_j]$ . More formally,  $l(t_i, t_j)$  is the maximum number of processors so that there exists a feasible schedule using at most on  $m - l(t_i, t_j)$  many processors at any timeslot  $t \in [t_i, t_j]$ . Equivalently, at some time  $t \in [t_i, t_j]$ , at least  $m - l(t_i, t_j)$  processors must be active in any feasible solution. We are now ready to define skeleton for the multi-processor case.

► **Definition 16.** *A set of active intervals (not necessarily feasible) is called a **skeleton** if for any time interval  $[t_i, t_j]$ , there exists a  $t \in [t_i, t_j)$  such that at least  $m - l(t_i, t_j)$  processors are active at timeslot  $t$ .*

By the definition of  $l(t_i, t_j)$  and the definition of multi-processor skeletons, it directly follows that every feasible solution is also a skeleton. Hence, the cost of the optimal skeleton is a lower bound on the cost of an optimal solution.

We note that all  $l(t_i, t_j)$ 's can be computed in polynomial time: there are  $O(n^2)$  possible pairs  $(t_i, t_j)$  and for each pair, the value  $l(t_i, t_j)$  can be computed in  $O(F \log m)$  time by using binary search ( $F$  here denotes the time needed to check feasibility of an instance, which can also be done in polynomial time as we will see in the next section). Therefore, the total time required to compute all  $l(t_i, t_j)$ 's is  $O(Fn^2 \log m)$ .

### 4.1 Computing Minimum Cost Skeleton for Parallel Processors

We show how an optimal multi-processor skeleton can be computed by combining up to  $m$  many distinct single-processor skeletons. To that end, let  $\mathcal{I}_k$  be the set of all tuples  $(t_i, t_j)$  such that  $m - l(t_i, t_j) \geq k$ . Each of  $\{I_k\}_{k=1}^m$  can be thought of as defining an instance of the minimum skeleton problem for a single processor as follows: for each  $I = [a, b] \in \mathcal{I}_k$ , we have a job with release time  $a$ , deadline  $b$  and a unit processing requirement. We can compute the minimum skeleton  $S_k$  for each  $k = 1, 2, \dots, m$  using Theorem 8. It remains to show that  $\{S_k\}_{k=1}^m$  is indeed the desired optimal skeleton.

► **Lemma 17.**  $\{S_k\}_{k=1}^m$  is an optimal skeleton for the multi-processor case.

**Proof.** Let  $O$  be the optimal multi-processor skeleton for an arbitrary given instance. Without loss of generality, we may assume that  $O$  has a laminar structure, i.e. each active interval on processor  $k+1$  is a subset of some active interval on processor  $k$ . Let  $O_k$  be the set of active intervals on processor  $k$  in the optimal solution and  $l_i$  be the total length of active intervals on processor  $i$ . We consider  $O = \{O_k\}_{k=1}^m$  such that it is lexicographically maximal with respect to the  $m$ -tuple  $(l_1, l_2, \dots, l_m)$ , and it differs from  $\{S_k\}_{k=1}^m$  in least number of processors among those lexicographically maximal ones. If  $O_k = S_k$  for  $1 \leq k \leq m$ , then the lemma follows. For the sake of contradiction, let us assume that  $O_k \neq S_k$ , for some  $k$ .

▷ **Claim 18.**  $O_r$  is a feasible skeleton for the single processor instance  $\mathcal{I}_r$ ,  $1 \leq r \leq m$ .

**Proof.** Suppose the statement of the claim doesn't hold. Then there exists an interval  $[t_i, t_j]$  such that  $m - l(t_i, t_j) \geq r$  but there is no active interval overlapping  $[t_i, t_j]$  in  $O_r$ . Since the optimal solution  $O$  is laminar, there is no active interval overlapping  $[t_i, t_j]$  for any  $O_i$ ,  $r \leq i \leq m$ . This implies that the number of active interval at any time in  $[t_i, t_j]$  in  $O$  is at most  $r - 1 < m - l(t_i, t_j)$ . This contradicts the feasibility of the optimal solution and the claim follows. ◁

▷ **Claim 19.** The solution obtained by replacing the intervals on processor  $k$  in the optimal solution, i.e.  $O_k$  by  $S_k$  is a feasible multi-processor skeleton.

**Proof.** Suppose the statement of the claim doesn't hold. Then there exists an interval  $[t_i, t_j]$  such that some active interval in  $O_k$  overlaps with  $[t_i, t_j]$  but no active interval in  $S_k$  overlaps with  $[t_i, t_j]$ . Since the optimal solution  $O$  is laminar, this implies that some active interval in  $O_\ell$  overlaps with  $[t_i, t_j]$  for any  $1 \leq \ell \leq k$ . Hence,  $m - l(t_i, t_j) \geq k$ , which implies that some active interval in  $S_k$  must overlap with  $[t_i, t_j]$ . This contradicts our assumption and the claim follows. ◁

Since  $O_k$  is a feasible solution to  $\mathcal{I}_k$  and  $S_k$  is an optimal solution for  $\mathcal{I}_k$ , cost of  $S_k$  is at most the cost of  $O_k$ . Hence, replacing  $O_k$  by  $S_k$  gives a feasible skeleton without increasing the cost. The new solution as constructed above is laminar as well, otherwise we could move active time slots from a higher numbered processor to a lower numbered processor, contradicting our assumption that the optimal solution is the largest in lexicographical ordering  $(l_1, l_2, \dots, l_m)$ . Thus we have obtained a different optimal solution which matches  $\{S_i\}_{i=1}^m$  on more processors. This contradicts our choice of the optimal skeleton and the lemma follows. ◀

## 5 Converting a Minimum Cost Skeleton into a Feasible Solution

As argued in Lemma 17, the cost of the obtained optimal skeleton is at most the cost of an optimal solution. However, the optimal skeleton may not be a feasible solution. In this section we show how to overcome this by transforming the optimal skeleton  $\{S_k\}_{k=1}^m$  into a feasible solution while increasing its energy cost by at most a factor 6. This transformation consists of two phases: the *extension phase* and the *tripling phase*. In the following subsections we describe each one of them in more detail.

## 5.1 Extension Phase

The extension phase of the transformation is inspired by a similar transformation performed in [2]. For the sake of completeness we give a brief and high-level description of the required terminology and results and refer the interested reader to [2] for the details.

We begin by introducing the notions of *forced volume* and of *deficiency*:

► **Definition 20** ([2]). *The forced volume of a job  $j_i$  with respect to an interval  $[a, b]$ , is defined as  $\text{fv}(j_i, [a, b]) := \max\{0, p_i - (|[r_i, d_i] \setminus [a, b]|)\}$ . Let  $\mathcal{D}$  be a set of disjoint intervals. The forced volume of job  $j_i$  with respect to  $\mathcal{D}$  is defined as  $\text{fv}(j_i, \mathcal{D}) := \max\{0, p_i - |[r_i, d_i] - \sum_{D \in \mathcal{D}} |D \cap [r_i, d_i]|\}$ .*

Intuitively,  $\text{fv}(j_i, [a, b])$  is the minimum volume of  $j_i$  that must be processed during  $[a, b]$  in any feasible schedule, and  $\text{fv}(j_i, \mathcal{D})$  is the amount of volume that must be processed within the intervals of  $\mathcal{D}$  in any feasible schedule.

► **Definition 21** ([2]). *Let  $\mathcal{D}$  be a set of disjoint intervals, and  $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$  be a set of not necessarily disjoint intervals with the property, that for any time-point  $t$ ,  $m_t := |\{i \in \mathcal{I} : I_i \cap t \neq \emptyset\}| \leq m$  holds. Furthermore let  $\mathcal{J}$  be a set of jobs. The deficiency of  $\mathcal{D}$  with respect to  $\mathcal{I}$  and  $\mathcal{J}$ , denoted by  $\text{def}(\mathcal{D}, \mathcal{I}, \mathcal{J})$ , is the non-negative difference between the sum of the forced volume of all jobs of  $\mathcal{J}$  with respect to  $\mathcal{D}$  and the total volume that can be processed in  $\mathcal{D}$  within  $\mathcal{I}$ . Thus*

$$\text{def}(\mathcal{J}, \mathcal{D}, \mathcal{I}) = \max \left( 0, \sum_{j \in \mathcal{J}} \text{fv}(j, \mathcal{D}) - \sum_{t: [t, t+1] \subseteq \mathcal{D}} m_t \right).$$

In [2], a decision problem called **deadline-scheduling-on-intervals** was introduced. More formally, problem **deadline-scheduling-on-intervals** takes as input  $k$  (not necessarily disjoint) supply-intervals  $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$  and the set  $\mathcal{J}$  of jobs (each with a release-time, a deadline and processing volume), and asks whether the jobs of  $\mathcal{J}$  can be feasibly scheduled on  $\mathcal{I}$ . In [2] a polynomial-time algorithm *DSI-ALG* was presented that decides **deadline-scheduling-on-intervals**. Furthermore, in case the input instance is infeasible, *DSI-ALG* returns a *minimal* set of intervals  $\mathcal{D} = \{D_1, D_2, \dots, D_\ell\}$  of maximum deficiency with respect to  $\mathcal{I}$ . The following theorem follows from Section 4 in [2] (more specifically the first statement appears in [2] as Theorem 4.1, the last one as Claim 4.2, and the polynomial-time algorithm is described and analyzed throughout Section 4):

► **Theorem 22** ([2]). *An instance of **deadline-scheduling-on-intervals** is feasible iff no set of disjoint intervals has positive deficiency. Additionally, there is a polynomial-time algorithm that decides if a given instance to **deadline-scheduling-on-intervals** is feasible and if it is not, then a minimal set of disjoint intervals of maximum deficiency with respect to the instance is returned. Furthermore, increasing the volume of supply intervals at any time point in the minimal set of maximum deficiency by one unit decreases the maximum deficiency by one unit.*

Finally, [2] presents a polynomial time algorithm *EXT-ALG* which extends a supply interval  $I' \in \mathcal{I}$  (a property that we will use later, is that  $I'$  is chosen so that it overlaps some  $D' \in \mathcal{D}$  without containing  $D'$ , i.e,  $D' \not\subseteq I'$  but  $D' \cap I' \neq \emptyset$ ) by one time slot so as to decrease the total deficiency of the set of intervals of maximum deficiency  $\mathcal{D}$  by one. This is repeated until the resulting set of supply intervals becomes feasible. Since the maximal deficiency at the beginning was at most the total processing time  $P$  of all jobs, the total increase in energy consumption by extending the supply intervals could also only have been at most  $P$ .

The extension phase consists of repeatedly extending the intervals of  $\{S_k\}_{k=1}^m$  via algorithm EXT-ALG until this is not possible anymore. Assume that at this point  $\{S_k\}_{k=1}^m$  has been extended to an interval set  $\mathcal{I}$ . The extension phase thus terminates either because  $\mathcal{I}$  is a feasible instance for  $\mathcal{J}$  (and by Theorem 22 no set of disjoint intervals has positive deficiency with respect to  $\mathcal{I}$  and  $\mathcal{J}$ ) or because the minimal set  $\mathcal{D}$  of maximum deficiency returned by DSI-ALG does not contain any interval  $D'$  such that  $I' \cup D' \neq \emptyset$  and  $I' \not\supseteq D'$  holds for some  $I' \in \mathcal{I}$ . In the later case  $\mathcal{I}$  is still not feasible, and a further transformation (described in the next subsection) is required. The extension phase as stated now is pseudo-polynomial but can be carried out in polynomial time by using standard techniques (see [2] for more details). From the argument from [2] as well as the discussion above, the following lemma follows:

► **Lemma 23.** *The energy-cost of the schedule  $\mathcal{I}$  differs from that of  $\{S_k\}_{k=1}^m$  by at most an additive factor of  $P$ . Furthermore  $\mathcal{I}$  is either feasible, or contains no interval  $I' \in \mathcal{I}$  that overlaps but does not contain an interval from the minimal set of intervals of maximum deficiency  $\mathcal{D}$ .*

## 5.2 Tripling Phase

In case the extension phase terminated with an infeasible solution, then, by Lemma 23, there is no interval  $I' \in \mathcal{I}$  such that  $I'$  overlaps some interval  $D' \in \mathcal{D}$  without containing it. In that case, we need to perform the tripling phase, in which we carefully power on further machines at specific times so as to make the instance feasible. Let  $m_t$  be the number of machines active at time  $t$  in  $\mathcal{I}$ . We create a new solution  $\mathcal{I}'$  by setting  $m'_t = \min\{3m_t, m\}$ . In Lemma 24, we show that  $\mathcal{I}'$  is a feasible solution to the original instance. By construction, the total cost of intervals in  $\mathcal{I}'$  is at most thrice that of  $\mathcal{I}$ . From the above discussion and Lemma 23, it follows that the algorithm consisting of the tripling and the extension phase is a 6-approximation algorithm. In other words Theorem 4 follows.

► **Lemma 24.**  *$\mathcal{I}'$  is a feasible solution to the original instance.*

## 6 A 2-Approximation Algorithm for Multiple Processors

In this section we prove Theorem 5 thus improving upon the recent 3-approximation algorithm of [2]. To achieve this, we introduce additional constraints to the linear programming (LP) relaxation of [2] and devise a new rounding scheme to harness the power of new constraints. In the remainder of the section, we prove that our rounding technique gives a pseudo-polynomial time 2-approximation algorithm – thus also showing an upper bound of 2 on the integrality-gap of the LP. By using standard arguments, this directly implies  $(2 + \epsilon)$ -approximation algorithm in polynomial time (see [2] for more details).

We now give a brief description of the LP relaxation of [2]. For every possible interval  $I \subseteq [0, D]$ , there is an associated variable  $x_I$ ,  $0 \leq x_I \leq m$  which indicates the number of times  $I$  is picked in the solution. The objective is to minimize the total energy consumption, ie.  $\sum_I x_I (|I| + q)$ .  $m_t$  denotes the number of processors that are active during time slot  $t$  (or equivalently total capacity of active intervals in time slot  $t$ ) and  $f(i, t)$  denotes the volume of job  $i$  that is processed in time slot  $t$ . The constraints of the LP are self explanatory; the interested reader is referred to [2] for the details.

In the following we describe the additional constraints (in bold). Recall that for any interval  $[a, b]$ ,  $l(a, b) \in \mathbb{Z}_{\geq 0}$  is the maximum number of machines that can remain inactive throughout interval  $[a, b]$  without affecting the feasibility of the instance (see Section 4). This implies that at least  $m - l(a, b)$  active intervals are overlapping with  $[a, b]$  in any feasible schedule. We add a constraint capturing this fact for every  $[a, b] \subseteq [0, D]$ .

$$\begin{aligned}
& \text{minimize} && \sum_I (|I| + q)x_I \\
& \text{subject to} && \\
& m_t = && \sum_{I: [t, t+1] \in I} x_I && 0 \leq t < D \\
& m_t \geq && \sum_{i: r_i \leq t \leq d_i - 1} f(i, t) && 0 \leq t < D \\
& p_i = && \sum_{t=r_i}^{d_i-1} f(i, t) && 0 \leq i \leq n \\
& \sum_{I: [a, b] \cap I \neq \emptyset} x_I \geq && m - l(a, b) && 0 \leq a < b \leq D \\
& f(i, t) \in && [0, 1] && \forall i, t \\
& x_I, m_t \in && [0, m] && \forall t, I \subseteq [0, D]
\end{aligned}$$

Suppose the optimum fractional solution to the linear program has value  $f$ . For reasons that will become apparent later, we would like to use an optimum solution maximizing the value  $\sum_t \min(m_t, 1)$ . In order to compute such a solution we solve a second linear program that is based on the previous one, as follows: we introduce a new set of variables  $y_t$  and additional constraints  $y_t \leq m_t$  and  $0 \leq y_t \leq 1$  for each time slot  $t$ . By adding constraint  $\sum_I x_I (|I| + q) = f$  we enforce that the resulting solution has energy cost equal to  $f$  and is therefore also optimal. Finally we set the objective function to maximize  $\sum_t y_t$ .

Let  $F = \{I : x_I > 0\}$  be the optimal fractional solution after solving the second LP. Let  $\epsilon = \gcd_{i \in F}(x_I)$ . We create  $x_I/\epsilon$  copies of each  $I \in F$  to assume that all intervals in  $F$  have the same  $x_I$  value (note that  $F$  is a multiset). If there exist  $[a, b], [c, d], a < c < b < d$  with  $x_{[a, b]}, x_{[c, d]} = \epsilon$ , we replace them by  $[a, d], [b, c]$  with  $x_{[a, d]}, x_{[b, c]} = \epsilon$ . It is easily verified that this process doesn't affect the feasibility of the solution. This process is repeated until no such pair of intervals remain in the instance. We therefore assume from now on, that the intervals in  $F$  are non-crossing. We would like to stress that the above is done only for the ease of analysis and during the course of the proof, it will be clear that we don't actually need to do this.

We partition the time slots in  $[0, D]$  into *blocks* and *non-blocks* as follows. A duration  $[a, b]$  is called a block iff  $m_t \in [0, 1)$  for all  $a \leq t \leq b - 1$  and  $m_{a-1}, m_b \geq 1$ . A duration  $[a, b]$  is called a non-block iff  $m_t \in [1, m]$  for all  $a \leq t \leq b - 1$  and  $m_{a-1}, m_b < 1$ . The following lemma leverages the new constraints and lower bounds the total weight of intervals of  $F$  contained in a non-block. The proof of this lemma crucially uses the fact that  $F$  is an optimum solution maximizing the value  $\sum_t \min(m_t, 1)$ .

► **Lemma 25.** *Let  $N = [a, b]$  be a non-block. If there exists a  $t \in [a, b - 1]$  such that  $m_t > 1$ , then  $\sum_{I: I \cap [a, b] \neq \emptyset} x_I \geq 2$ .*

**Proof.** By noting that a non-block is a maximal contiguous set of time intervals with  $m_t \geq 1$ , intervals in  $F$  are laminar and  $m_t > 1$  for some  $t \in [a, b]$ , there must exist an  $I \in F$  such that  $I \subseteq [a, b]$ . Let  $F'$  be the solution obtained by replacing  $I = [l, r]$  by  $I' = [l + 1, r]$  in  $F$ . Since  $F$  is a fractional solution with minimum cost,  $F'$  must be infeasible. Let  $\mathcal{D} = \{D_1, D_2, \dots, D_\ell\}$  be the *minimal* set of disjoint intervals of maximum deficiency (with respect to  $\mathcal{I}$ ) as returned by Theorem 22 and  $J'$  be the set of jobs such that  $fv(j_i, \mathcal{D}) > 0$  for all  $j_i \in J'$ . Note that the deficiency of  $\mathcal{D}$  with respect to the current solution is  $\epsilon$ . Let  $m'_t$  be defined with respect to  $F'$ .

Suppose there exists a  $t$  such that  $[t, t + 1] \subseteq D \in \mathcal{D}$ ,  $[t - 1, t]$  is part of a non-block and  $[t, t + 1]$  is part of a block (or vice versa). This implies that  $m'_t < 1$  and  $m'_{t-1} \geq 1$ . Since  $m'_{t-1} > m'_t$ , there exists an  $I' \in F'$  which ends at  $t$ . If we extend  $I'$  to the right by 1 unit, deficiency would decrease by  $\epsilon$  (by Theorem 22) and we will obtain a feasible

solution different from  $F$ , with greater value of  $\sum_t \min(m_t, 1)$  (as extending  $J'$  implies setting  $m'_t = m_t + \epsilon > m_t$ ). Hence, no  $D \in \mathcal{D}$  overlaps with a block and non-block simultaneously. Thus we can partition the intervals in  $\mathcal{D}$  depending on whether they are contained in a block or a non-block. Let  $\mathcal{D}_{NB} \subseteq \mathcal{D}$  and  $\mathcal{D}_B \subseteq \mathcal{D}$  be the intervals of  $\mathcal{D}$  contained in blocks and non-blocks respectively.

Let  $D_1, D_2 \in \mathcal{D}$  be such that  $D_1, D_2$  do not belong to the same block or the same non-block. Suppose there exists a  $j_i \in J'$  such that  $[r_i, d_i] \cap D_1 \neq \emptyset$  and  $[r_i, d_i] \cap D_2 \neq \emptyset$ . Then there must exist a  $t$  such that  $[t, t+1] \subseteq [r_i, d_i]$  and  $m_t < 1$ . Since  $fv(j_i, \mathcal{D} \cup [t, t+1]) = fv(j_i, \mathcal{D}) + 1$  and  $m_t < 1$ , we have that the deficiency of  $\mathcal{D} \cup [t, t+1]$  is strictly more than the deficiency of  $\mathcal{D}$ . This contradicts the fact that  $\mathcal{D}$  has maximum deficiency and hence no job in  $J'$  overlaps with distinct  $D_i, D_j$ . Therefore jobs in  $J'$  can be partitioned according to the block or non-block they overlap with. Let  $J'_N \subseteq J'$  be the set of jobs with positive forced volume overlapping with the non-block  $N$  and  $\mathcal{D}_N \subseteq \mathcal{D}_{NB}$  be the set of intervals of  $\mathcal{D}$  overlapping with  $N$ .

Observe that  $\mathcal{D}_N$  must contain the time slot  $[l, l+1]$  and hence is non-empty (recall that  $[l, r]$  was replaced by  $[l+1, r]$  in  $F$  to obtain  $F'$ ). Also,  $J'_N \neq \emptyset$ , otherwise  $\mathcal{D} \setminus \mathcal{D}_N$  would have been the minimal set with maximum deficiency. Hence,  $def(J'_N, \mathcal{D}_N, F') > 0$ . Let  $x$  be the left end point of leftmost interval in  $\mathcal{D}_N$  and  $y$  be the right end point of the rightmost interval in  $\mathcal{D}_N$ . Since  $m'_t \geq 1$  for all  $[t, t+1] \in [x, y] \subseteq N$  and  $def(J'_N, \mathcal{D}_N, F') > 0$ , there must exist a time slot  $t \in [x, y-1]$  such that  $m_t \geq 2$  in any integer feasible solution. This implies that  $m - l(x, y) \geq 2$  and hence  $\sum_{I: I \cap [a, b] \neq \emptyset} x_I \geq m - l(a, b) \geq 2$ .  $\blacktriangleleft$

### Rounding Scheme

We next convert/round  $F$  into an integral solution in a series of steps. We will denote the three intermediate solutions by  $F_1, F_2, F_3$  and the corresponding  $m'_t$ s as  $m_t^1, m_t^2, m_t^3$ . Let  $T_N, T_B$  be the set of time slots in non-blocks and blocks respectively. Let  $P_F$  be the total available capacity in  $F$  (ie.  $P = \sum_t m_t$ ) and  $P_B, P_N$  be the total available capacity in the blocks and non-blocks respectively. Let  $Q_F$  be the total wake up cost incurred by  $F$ , ie.  $Q_F = q \sum_I x_I$ . Then  $Cost(F) = P_F + Q_F$  and  $P_F = P_B + P_N$ . For each non-block  $N = [a, b]$  such that  $m_t > 1$  for some  $t \in [a, b-1]$ , we add an additional supply interval  $[a, b]$  with  $x_{[a, b]} = 1$  to  $F$  and call this solution  $F_1$ .

$\triangleright$  **Claim 26.**  $Cost(F_1) \leq Cost(F) + P_N + Q_F$ .

*Proof.*  $F_1$  is constructed by adding an interval  $[a, b]$  with  $x_{[a, b]} = 1$  for a non-block  $[a, b]$  if  $m_t > 1$  for some  $t \in [a, b]$ . For each time slot  $t$  in a non-block, we have  $m_t \geq 1$  and hence the total length of new intervals added is at most  $\sum_{[t, t+1] \subseteq T_N} m_t \leq P_N$ . If we add an additional interval for a non-block  $[a, b]$ , then  $\sum_{I: I \cap [a, b] \neq \emptyset} x_I \geq 2$  (by Lemma 25). Since the intervals in  $F$  are non-crossing, the above implies that the total weight of intervals which are completely contained in  $[a, b]$  is at least 1. Thus the wakeup cost of each new interval can be charged to the wakeup cost of intervals completely contained inside the corresponding non-block, and the total additional wake up cost incurred is no more than  $Q_F$ .  $\blacktriangleleft$

We convert  $F_1$  into  $F_2$  by deleting the portions of existing intervals in  $F$  such that for each time slot  $t \in T_N$ , we have the property  $m_t^2 = \lfloor m_t^1 \rfloor$ . This operation might increase the total wake up cost, but since the processing cost gets decreased by at least as much, the overall cost of the solution does not increase. This allows us to state the following.

$\triangleright$  **Claim 27.**  $Cost(F_2) \leq Cost(F) + P_N + Q_F$ . Also,  $m_t^2$  is an integer and  $m_t^2 \geq m_t$  for each time slot  $t \in T_N$ .

We now describe our third transformation. As discussed earlier, we may again assume that all the intervals in  $F_2$  have a weight of exactly  $\epsilon$  and are non-crossing. Consider the single machine instance  $J_S = J_N \cup J_B$ , where  $J_B = \{j_i | j_i \in J, [r_i, d_i] \subseteq T_B\}$  consists of jobs in  $J$  which are completely contained inside some block and  $J_N$  consists of additional jobs defined as follows: for each time slot  $t \in T_N$ , there is a job  $j_t$  with release time  $t$ , deadline  $t + 1$  and a processing requirement of 1. We now pick a subset  $F'_2$  of intervals in  $F_2$  which form a feasible solution to the following LP relaxation of the minimum cost skeleton.

$$\begin{aligned} \min \quad & \sum_I x_I(q + |I|) \\ & \sum_{I:t \in I} x_I \leq 1 \quad \forall t \in [0, D] \\ & \sum_{I:I \cap [r_i, d_i] \neq \emptyset} x_I \geq 1 \quad \forall i \in [1, n] \\ & x_I \geq 0 \quad \forall I \subseteq [a, b] \end{aligned}$$

$F'_2 \subseteq F_2$  is the set of intervals of maximum total length such that the total weight of intervals containing any particular time slot is at most 1. It is worth noting that any interval containing a time slot of some block is a part of  $F'_2$ . The proof of the following claim is deferred to the full version.

▷ **Claim 28.**  $F'_2$  is a feasible fractional skeleton for  $J_S$ .

In the full version, we also show that the LP relaxation for the minimum cost skeleton is exact. Hence, there exists an integer skeleton  $J_S$  of cost no more than  $F'_2$ . Then our solution  $F_3$  is  $(F \setminus F'_2) \cup S$ . Observe that  $\text{Cost}(F_3) \leq \text{Cost}(F_2)$  and  $m_t^3$  is an integer for every time slot  $t$ . We may therefore assume that  $x_I = 1$  for each  $I \in F_3$ . We now describe the final phase our algorithm, where we convert  $F_3$  into a feasible solution by extending some existing intervals using *EXT-ALG* (see Section 5). If  $F_3$  is a feasible solution, our algorithm terminates. Otherwise we find a disjoint minimal set of intervals of maximum deficiency  $\mathcal{D} = \{D_1, D_2, \dots, D_k\}$  guaranteed by Theorem 22. In each subsequent iteration, we use *EXT-ALG* to extend an interval of  $F_3$  by 1 unit, thereby reducing the maximum deficiency by 1. Claim 29 shows that if the current solution is infeasible and it is not possible to extend an interval to reduce the deficiency, then the original instance is infeasible. Hence the extension phase of the algorithm terminates with a feasible solution.

▷ **Claim 29.** Let  $F_{curr}$  be the current solution. If  $F_{curr}$  is infeasible and for all  $I \in F_{curr}$  the following is true: if  $I \cap D_i \neq \emptyset$ , then  $D_i \subseteq I$ , then the original instance is infeasible.

The deficiency at the start of the extension phase can be at most  $P_B$  as  $m_t^3 \geq m_t$  for  $t \in T_N$ . Since we decrease the deficiency by 1 in each iteration, there can be at most  $P_B$  iterations of the extension phase. In each step we increase the cost of the solution by 1, hence cost of the final solution is at most  $\text{Cost}(F_3) + P_B \leq \text{Cost}(F) + P_N + Q_F + P_B = \text{Cost}(F) + P + Q_F \leq 2\text{Cost}(F)$ . This shows that the integrality gap of the LP relaxation is at most 2. To compute  $F_1, F_2, F_3$ , we only need the value of  $m_t$ 's and don't need to create multiple copies of intervals in our solution. Thus our rounding algorithm can be implemented in pseudo-polynomial time and this completes the proof of Theorem 6.

## Abstract

In the Online Machine Covering problem jobs, defined by their sizes, arrive one by one and have to be assigned to  $m$  parallel and identical machines, with the goal of maximizing the load of the least-loaded machine. Unfortunately, the classical model allows only fairly pessimistic performance guarantees: The best possible deterministic ratio of  $m$  is achieved by the Greedy-strategy, and the best known randomized algorithm has competitive ratio  $\tilde{O}(\sqrt{m})$  which cannot be improved by more than a logarithmic factor.

Modern results try to mitigate this by studying semi-online models, where additional information about the job sequence is revealed in advance or extra resources are provided to the online algorithm. In this work we study the Machine Covering problem in the recently popular *random-order* model. Here no extra resources are present, but instead the adversary is weakened in that it can only decide upon the input set while jobs are revealed uniformly at random. It is particularly relevant to Machine Covering where lower bounds are usually associated to highly structured input sequences.

We first analyze Graham's Greedy-strategy in this context and establish that its competitive ratio decreases slightly to  $\Theta\left(\frac{m}{\log(m)}\right)$  which is asymptotically tight. Then, as our main result, we present an improved  $\tilde{O}(\sqrt[4]{m})$ -competitive algorithm for the problem. This result is achieved by exploiting the extra information coming from the random order of the jobs, using sampling techniques to devise an improved mechanism to distinguish jobs that are relatively large from small ones. We complement this result with a first lower bound showing that no algorithm can have a competitive ratio of  $O\left(\frac{\log(m)}{\log \log(m)}\right)$  in the random-order model. This lower bound is achieved by studying a novel variant of the Secretary problem, which could be of independent interest.

## 1 Introduction

We study the *Machine Covering* problem, a fundamental load balancing problem where  $n$  jobs have to be assigned (or scheduled) onto  $m$  identical parallel machines. Each job is characterized by a non-negative size, and the goal is to maximize the smallest machine load. This setting is motivated by applications where machines consume resources in order to work, and the goal is to keep the whole system active for as long as possible. Machine Covering has found additional applications in the sequencing of maintenance actions for

aircraft engines [20] and in the design of robust Storage Area Networks [41]. The offline problem, also known as Santa-Claus or Max-Min Allocation Problem, received quite some research interest, see [44, 10, 6] and references therein. In particular, the problem is known to be strongly NP-hard but to allow for a Polynomial-Time Approximation Scheme (PTAS) [44].

This paper focuses on the online version of the problem, where jobs arrive one by one and must be assigned to some machine upon arrival. Lack of knowledge about future jobs can enforce very bad decisions in terms of the quality of the constructed solutions: In a classical lower bound sequence,  $m$  jobs of size 1 arrive first to the system and they must be assigned to  $m$  different machines by a competitive deterministic online algorithm. Then subsequent  $m - 1$  jobs of size  $m$  arrive, which make the online algorithm perform poorly, see Figure 1. Indeed, the best possible deterministic algorithm achieves a competitive ratio of  $m$  [44], and if randomization is allowed, the best known competitive ratio is  $\tilde{O}(\sqrt{m})$ , which is best possible up to logarithmic factors [7]. The corresponding lower bound also uses that the online algorithm cannot schedule the first  $m$  jobs correctly, at least not with probability exceeding  $\frac{1}{\sqrt{m}}$ .

■ **Figure 1** The instance showing that no deterministic algorithm is better than  $m$ -competitive for Machine Covering. To the left, the best possible solution that an online algorithm can construct achieves minimum load 1. To the right, the optimal minimum load is  $m$ .

Such restrictive facts have motivated the study of different semi-online models that provide extra information [7, 14, 34, 37] or extra features [41, 42, 22, 16] to the online algorithm.

This work studies the Online Machine Covering problem in the increasingly popular *random-order* model. In this model, jobs are still chosen worst possible by the adversary but they are presented to the online algorithm in a uniformly random order. The random-order model derives from the Secretary Problem [13, 35] and has been applied to a wide variety of problems such as generalized Secretary problems [32, 8, 33, 18, 9], Scheduling problems [39, 38, 2, 3], Packing problems [30, 31, 5, 4], Facility Location problems [36] and Convex Optimization problems [25] among others. See also [26] for a survey chapter. It is particularly relevant to Machine Covering, where hard instances force online algorithms to make an irredeemable mistake right on the first  $m$  jobs due to some hidden large job class at the end.

Indeed, we show that the competitive ratio of Graham’s Greedy-strategy improves from  $m$  to  $O\left(\frac{m}{\log(m)}\right)$ , and that this is asymptotically tight. We also develop an  $\tilde{O}(\sqrt[3]{m})$ -competitive algorithm, providing evidence that known hardness results rely on “pathological” inputs, and complement it by proving that no algorithm can be  $O\left(\frac{\log(m)}{\log \log(m)}\right)$ -competitive in this model.

## 1.1 Related Results

The most classical Scheduling problem is *Makespan Minimization* on parallel and identical machines. Here, the goal is dual to Machine Covering; one wants to minimize the maximum load among the machines. This problem is strongly NP-hard and there exists a PTAS [27]. The online setting received considerable research attention, and already in 1966 Graham

showed that his famous Greedy-strategy is  $(2 - 1/m)$ -competitive. A long line of research [21, 11, 29, 1, 19] starting in the 1990s lead to the currently best competitive ratio of 1.9201 due to Fleischer and Wahl [19]. Regarding lower bounds, again after a sequence of results [17, 12, 24] the current best one is 1.88 [40].

The landscape for Online Machine Covering differs considerably from Online Makespan Minimization as discussed before, which has motivated the study of semi-online models to deal with the implied hard restrictions. If the value of the optimal minimum load of the instance is known in advance, Azar et al. have shown that a simple greedy algorithm already is  $(2 - 1/m)$ -competitive and that no algorithm can attain a competitive ratio better than  $7/4$  [7]. These bounds were improved by Ebenlendr et al. to  $11/6$  and 1.791 respectively [14]. In the *bounded migration* model, whenever a job of size  $p$  arrives, older jobs of total size at most  $\beta \cdot p$  can be reassigned to different machines. Sanders et al. [41] provide a 2-competitive algorithm for  $\beta = 1$ . Later results [42, 22] study the interplay between improved competitive ratios and larger values of  $\beta$ . Another semi-online model provides the online algorithm with a *reordering buffer*, which is used to rearrange the input sequence “on the fly”. Epstein et al. [16] provide a  $(H_{m-1} + 1)$ -competitive algorithm using a buffer of size  $m - 1$ , and show that this ratio cannot be improved for any sensible buffer size. These and many more semi-online models have also been studied for Makespan Minimization, see the survey in [15] and references therein.

The first Scheduling result in the random-order model is due to Osborn and Torng [39]. They establish that the Greedy-strategy for Makespan Minimization does not achieve a competitive ratio better than 2 for general  $m$ . Recently, [2, 3] show that for Makespan Minimization the random-order model allows for better performance guarantees than the classical model. Molinaro [38] has studied the Online Load Balancing problem with the objective to minimize general  $l_p$ -norms of the machine loads, providing an algorithm that returns solutions of expected norm  $(1 + \varepsilon)\text{OPT} + O\left(\frac{p}{\varepsilon}(m^{1/p} - 1)\right)$  in the random-order model, where OPT denotes the optimal norm. Göbel et al. [23] have studied Average Weighted Completion Time Minimization on one machine in the random-order model. Their competitive ratio is logarithmic in the input length  $n$  for general job sizes and constant if all jobs have size 1. To the best of our knowledge, no previous result is known for Online Machine Covering in the random-order model.

## 1.2 Our Contribution

We first establish that the Greedy-strategy is  $\Theta\left(\frac{m}{\log(m)}\right)$ -competitive in the random-order model. This is only a tiny, albeit significant improvement compared to worst-case orders. Since the bound is tight, more refined strategies that make particular use of the characteristics of the random-order model are required. The analysis also gives first intuitions about what these characteristics are and also about the techniques used to analyze the main algorithm.

The following theorem summarizes the central result of this paper.

► **Theorem 1.** *There exists a  $\tilde{O}(\sqrt[4]{m})$ -competitive algorithm for the online Machine Covering problem in the random-order model.*

In the classical online Machine Covering problem, difficult instances are usually related to the inability of distinguishing “small” and “large” jobs induced by a lack of knowledge about large job classes hidden at the end of the sequence. Figure 1 depicts the easiest example on which deterministic schedulers cannot perform well as they cannot know that the first  $m$  jobs are tiny. Azar and Epstein [7] ameliorate this by maintaining a randomized threshold, which is used to distinguish small and large job sizes. They have to correctly classify up to  $m$  large

jobs with constant probability while controlling the total size of incorrectly classified small jobs, which leads to their randomized competitive ratio of  $\tilde{O}(\sqrt{m})$ . However, their lower bound shows that general randomized algorithms are still unable to schedule the first  $m$  jobs correctly with probability exceeding  $\frac{1}{\sqrt{m}}$ , again due to relevant job classes being hidden at the end of the input.

Random-order arrival makes such hiding impossible. This already helps the Greedy-strategy as now large jobs in the input are evenly distributed instead of being clustered at the end. Our  $\tilde{O}(\sqrt[4]{m})$ -competitive algorithm enhances the path described previously by making explicit use of the no-hiding-feature; it determines those large jobs the adversary would have liked to hide. Information about large job sizes is, as is common in Secretary problems, estimated in a sampling phase, which returns a threshold distinguishing all except for  $\sqrt{m}$  of the large jobs. This reduction by a square root carries over to the competitive ratio: We now can allow to misclassify these remaining  $\sqrt{m}$  jobs with a higher probability, which in turn leads to a better classification of small jobs and a better competitive ratio of  $\tilde{O}(\sqrt[4]{m})$ .

We complement the upper bound of  $\tilde{O}(\sqrt[4]{m})$  with a lower bound of  $\omega\left(\frac{\log(m)}{\log\log(m)}\right)$  for the competitive ratio in the random-order model. Lower bounds in the random-order model are usually considered hard to devise since one cannot hide larger pieces of input. Instead of hiding large job classes, we figuratively make them hard to distinguish by adding noise. To this end, we study a novel variant of the Secretary problem, the *Talent Contest* problem, where the goal is to find a good but not too good candidate (or secretary).

More in detail, we want to pick the  $K$ -th best among a randomly permuted input set of candidates. Unlike classical Secretary problems (or the more general Postdoc problem [43]), we may pick several candidates as long as they are not better than the  $K$ -th candidate. Furthermore, we interview candidates  $t$  times and make a decision at each arrival. In this setting, information gained by earlier interviews helps the decisions required in later ones. It can be proven that the expected number of times the desired candidate can be correctly identified relates to the ability of distinguishing exactly the  $m - 1$  largest jobs from a Machine Covering instance in the random-order model, and hence bounding the aforementioned expected value allows us to obtain the desired hardness result.

### 1.3 Organization of the paper

In Section 2 we provide the required definitions and tools, and then in Section 3 analyze the Greedy-algorithm in the context of random-order arrival. In Section 4 we present our main algorithm and its analysis. Section 5 then introduces the Talent Contest Problem and concludes with a lower bound for the best competitive ratio in the random-order model. Due to space constraints, some proofs from Section 5 are deferred to the full version of the paper.

## 2 Preliminaries

In this section we introduce the main definitions and tools that are used along this work.

In the Machine Covering problem, we are given  $n$  jobs  $\mathcal{J} = \{J_1, \dots, J_n\}$ , specified by their non-negative sizes  $p_i$ , which are to be assigned onto  $m$  parallel and identical machines. The *load*  $l_M$  of a machine  $M$  is the sum of the sizes of all the jobs assigned to it. The goal is to maximize the minimum load among the machines, i.e. to maximize  $\min_M l_M$ .

To an online algorithm, jobs are revealed one-by-one and each has to be assigned permanently and irrevocably before the next one is revealed. Formally, given the symmetric group  $S_n$  on  $n$  elements, each permutation  $\sigma \in S_n$  defines the order in which the elements of

$\mathcal{J}$  are revealed, namely  $\mathcal{J}^\sigma = (J_{\sigma(1)}, \dots, J_{\sigma(n)})$ . Classically, the performance of an online algorithm  $A$  is measured in terms of competitive analysis. That is, if we denote the minimum machine load of  $A^1$  on  $\mathcal{J}^\sigma$  by  $A(\mathcal{J}^\sigma)$  and the minimum machine load an optimal offline algorithm may achieve by  $\text{OPT}(\mathcal{J})$  (which is independent of the order  $\sigma$ ), one is interested in finding a small (*adversarial*) *competitive ratio*  $c = \sup_{\mathcal{J}} \sup_{\sigma \in S_n} \frac{\text{OPT}(\mathcal{J})}{A(\mathcal{J}^\sigma)}$ .

In the random-order model, the job order is chosen uniformly at random. We consider the permutation group  $S_n$  as a probability space under the uniform distribution. Then, given an input set  $\mathcal{J}$  of size  $n$ , we charge  $A$  *random-order cost*  $A^{\text{rom}}(\mathcal{J}) = \mathbf{E}_{\sigma \sim S_n} [A(\mathcal{J}^\sigma)] = \frac{1}{n!} \sum_{\sigma \in S_n} A(\mathcal{J}^\sigma)$ . The *competitive ratio in the random-order model* of  $A$  is  $c = \sup_{\mathcal{J}} \frac{\text{OPT}(\mathcal{J})}{A^{\text{rom}}(\mathcal{J})}$ . Throughout this work we will assume that  $n$  is known to the algorithm; this assumption is common in the literature and it can be proven that it does not help in the adversarial setting, see the full version of the article for details. When clear from the context, we will omit the dependency on  $\mathcal{J}$ .

Given  $0 \leq i \leq n$ , let  $P_i = P_i[\mathcal{J}]$  refer to the size of the  $i$ -th largest job in  $\mathcal{J}$ . Given  $i \geq 1$ , we define  $L_i := \sum_{j \geq i} P_j$  to be the total size of jobs smaller than  $P_i$ . Note that the terminology 'smaller' uses an implicit tie breaker since there may be jobs of equal sizes.

### 3 Properties and Analysis of the Greedy-strategy

We now proceed with some useful properties of Graham's Greedy-strategy. Recall that this algorithm always schedules an incoming job on some least loaded machine breaking ties arbitrarily. The following two lemmas recall useful standard properties of the algorithm, which will help us later to restrict ourselves to simpler special instances.

► **Lemma 2.** *The minimum load achieved by the Greedy-strategy is at least  $P_m$ .*

**Proof.** If the  $m$  largest jobs get assigned to different machines, the bound holds directly. On the other hand, if one of the  $m$  largest jobs  $J_j$  gets assigned to a machine that already had one of the  $m$  largest jobs  $J_{j'}$ , of size  $P_{j'}$ , then at the arrival of  $J_j$  the minimum load was at least  $P_{j'} \geq P_m$ , concluding the claim as the minimum load does not decrease through the iterations. ◀

► **Lemma 3.** *The minimum load achieved by the Greedy-strategy is, for each  $i \in \{1, \dots, m\}$ , bounded below by  $\frac{L_i}{m} - P_i$ .*

**Proof.** For each machine  $M$ , let  $J_{\text{last}}(M)$  be the last job assigned to machine  $M$ . Let  $\mathcal{J}_{\text{last}}$  be the set of all these last jobs. If  $ALG$  denotes the minimum load achieved by the Greedy-strategy, then the load of each machine  $M$  in the schedule is at most  $ALG + J_{\text{last}}(M)$  as jobs are iteratively assigned to a least loaded machine. Now remove the  $i - 1$  largest jobs in  $\mathcal{J}_{\text{last}}$  from the solution and let  $\tilde{L}$  denote the total size of the remaining jobs in  $\mathcal{J}_{\text{last}}$ . Then the total size of all remaining jobs is at most  $m \cdot ALG + \tilde{L}$ . On the other hand, since we only removed  $i - 1$  jobs, the total size of the remaining jobs is at least  $L_i$ . Since  $\tilde{L} \leq (m - i + 1) \cdot P_i$ , we have that  $L_i \leq m \cdot ALG + (m - i + 1) \cdot P_i$ . Hence, the minimum load achieved by the Greedy-strategy is at least  $\frac{L_i}{m} - \frac{m-i+1}{m} P_i \geq \frac{L_i}{m} - P_i$ . ◀

With these tools we can now prove that the Greedy-strategy has a competitive ratio of at most  $O\left(\frac{m}{H_m}\right)$  in the random-order model, where  $H_m = \sum_{i=1}^m \frac{1}{i}$  denotes the  $m$ -th harmonic number. We also describe a family of instances showing that this analysis is asymptotically tight.

<sup>1</sup> In case  $A$  is randomized, we then refer to the expected minimum load.

<sup>2</sup> Using the convention that  $0/0 = 1$  and  $a/0 = \infty$  for  $a > 0$ .

■ **Figure 2** A possible order  $\mathcal{J}^\sigma$  for an instance with  $\tilde{k} < m$  large (dark) jobs. They partition the sequence into sets of small (light) jobs, each one having total size  $S_i(\mathcal{J}^\sigma)$ ,  $i = 0, \dots, \tilde{k}$ .

► **Theorem 4.** *The Greedy-strategy is  $(2 + o_m(1)) \frac{m}{H_m}$ -competitive in the random-order model.*

**Proof.** Thanks to Lemma 2 we can assume that  $P_m \leq \frac{H_m}{2m} \text{OPT}$ . We say that a job is *large* if its size is larger than  $\frac{H_m}{2m} \text{OPT}$ , otherwise it is small. Let  $\tilde{k} < m$  be the number of large jobs in the instance. Note that  $L_{\tilde{k}+1} \geq (m - \tilde{k}) \text{OPT}$  since in the optimal solution at most  $\tilde{k}$  machines receive large jobs. Using Lemma 3 we may assume  $\tilde{k} \geq m - H_m$ , as otherwise we are done.

For a given order  $\mathcal{J}^\sigma$  and  $0 \leq i \leq \tilde{k}$ , let  $S_i(\mathcal{J}^\sigma)$  be the total size of small jobs preceded by precisely  $i$  large jobs with respect to  $\mathcal{J}^\sigma$  (see Figure 2). We will prove that the minimum load achieved by the Greedy-strategy is at least  $\min \left\{ \sum_{i=0}^{\tilde{k}} \frac{S_i(\mathcal{J}^\sigma)}{m-i} - \frac{H_m}{2m} \text{OPT}, \frac{H_m}{2m} \right\} \text{OPT}$ .

A machine is said to be *full* once it receives a large job, and notice that we can assume that no full machine gets assigned further jobs as otherwise the minimum load would be already at least  $\frac{H_m}{2m} \text{OPT}$ . Consider the set of small jobs that arrive to the system before the first large job in the sequence. At this point the average load of the machines is exactly  $\frac{S_0(\mathcal{J}^\sigma)}{m}$  and, since the upcoming large job gets assigned to a least loaded machine, the average load of the remaining machines is still at least  $\frac{S_0(\mathcal{J}^\sigma)}{m}$ . Now the upcoming small jobs that arrive before the second large job in the sequence get assigned only to these non-full machines, whose average load is now at least  $\frac{S_0(\mathcal{J}^\sigma)}{m} + \frac{S_1(\mathcal{J}^\sigma)}{m-1}$ . Since the following large job gets assigned to the least loaded of these machines, the average load of the remaining ones is still lower-bounded by this quantity. By iterating this argument, it can be seen that the average load of the machines containing only small jobs is at least  $\frac{1}{m-\tilde{k}} \sum_{i=0}^{\tilde{k}} \frac{S_i(\mathcal{J}^\sigma)}{m-i}$ . Since in a Greedy-strategy the load of two machines cannot differ by more than the size of the largest job assigned to them, we conclude that the minimum load achieved by the algorithm is at least  $\sum_{i=0}^{\tilde{k}} \frac{S_i(\mathcal{J}^\sigma)}{m-i} - \frac{H_m}{2m} \text{OPT}$ .

Now let us understand the random variable  $S(\mathcal{J}^\sigma) = \sum_{i=0}^{\tilde{k}} \frac{S_i(\mathcal{J}^\sigma)}{m-i}$ . If we pick  $\sigma \sim S_n$  uniformly at random and consider the number  $s(J)$  of large jobs that precede any fixed small job  $J$ , this number is uniformly distributed between 0 and  $\tilde{k}$ . Then we can rewrite  $S(\mathcal{J}^\sigma) = \sum_{i=0}^{\tilde{k}} \frac{S_i(\mathcal{J}^\sigma)}{m-i} = \sum_{J \text{ small}} \frac{p_J}{m-s(J)}$ . Since  $\mathbf{E}[\frac{1}{m-s(J)}] = \sum_{i=0}^{\tilde{k}} \frac{1}{\tilde{k}+1} \frac{1}{m-i} = \frac{H_m - H_{m-\tilde{k}-1}}{\tilde{k}+1}$  we get by linearity of expectation that

$$\begin{aligned} \mathbf{E}[S(\mathcal{J}^\sigma)] &= \sum_{J \text{ small}} p_J \frac{H_m - H_{m-\tilde{k}-1}}{\tilde{k}+1} \\ &= \frac{H_m - H_{m-\tilde{k}-1}}{\tilde{k}+1} L_{\tilde{k}+1} \\ &\geq \frac{(m - \tilde{k})(H_m - H_{m-\tilde{k}-1})}{\tilde{k}+1} \frac{L_{\tilde{k}+1}}{m - \tilde{k}}. \end{aligned}$$

Notice that  $\frac{L_{\tilde{k}+1}}{m-\tilde{k}}$  is a lower bound for  $\text{OPT}$ , which we will use later. The first factor is decreasing as a function of  $\tilde{k} \leq m-1$ , and consequently the expression is at least  $\frac{H_m}{m}$ . Thus

$$\mathbf{E}[S(\mathcal{J}^\sigma)] \geq \frac{H_m}{m} \cdot \frac{L_{\tilde{k}+1}}{m-\tilde{k}}.$$

We also get  $\text{Var} \left[ \frac{1}{m-s(J)} \right] \leq \mathbf{E} \left[ \left( \frac{1}{m-s(J)} \right)^2 \right] = \sum_{i=0}^{\tilde{k}} \frac{1}{\tilde{k}+1} \frac{1}{(m-i)^2} \leq \frac{1}{\tilde{k}+1} \sum_i \frac{1}{i^2} \leq \frac{1}{\tilde{k}+1} \frac{\pi^2}{6}$ . Using that  $\tilde{k} \geq m - H_m$ , we broadly bound  $\tilde{k}$  via  $\tilde{k} + 1 \geq \frac{m}{2} \geq \frac{m(m-\tilde{k})^2}{2H_m^2}$ . Substituting this in the previous bound yields  $\text{Var} \left[ \frac{1}{m-s(J)} \right] \leq \frac{H_m^2}{m} \frac{1}{(m-\tilde{k})^2} \frac{\pi^2}{3}$ . Moreover, for two small jobs  $J_i$  and  $J_j$  we have  $\text{Cov} \left[ \frac{1}{m-s(J_i)}, \frac{1}{m-s(J_j)} \right] \leq \left( \text{Var} \left[ \frac{1}{m-s(J_i)} \right] \text{Var} \left[ \frac{1}{m-s(J_j)} \right] \right)^{1/2} \leq \frac{H_m^2}{m} \frac{1}{(m-\tilde{k})^2} \frac{\pi^2}{3}$ . For  $i \neq j$  this bound is pessimistic. The correlation between  $s(J_i)$  and  $s(J_j)$  is positive but tiny. We use this covariance to bound  $\text{Var}[S(\mathcal{J}^\sigma)] = \sum_{J \text{ small}} \frac{p_J}{m-s(J)}$ .

$$\begin{aligned} \text{Var}[S(\mathcal{J}^\sigma)] &= \sum_{J_i, J_j \text{ small}} p_i p_j \text{Cov} \left[ \frac{1}{m-s(J_i)}, \frac{1}{m-s(J_j)} \right] \\ &\leq \sum_{J_i \text{ small}} p_i \cdot \sum_{J_j \text{ small}} p_j \cdot \frac{H_m^2}{m} \frac{1}{(m-\tilde{k})^2} \frac{\pi^2}{3} \\ &\leq \frac{\pi^2}{3} \frac{H_m^2}{m} \left( \frac{L_{\tilde{k}+1}}{m-\tilde{k}} \right)^2. \end{aligned}$$

The last inequality uses again that  $L_{\tilde{k}+1} \geq (m-\tilde{k})\text{OPT}$ . Hence, the standard deviation  $\text{SD}[S(\mathcal{J}^\sigma)]$  is at most  $C^{3/2} \frac{L_{\tilde{k}+1}}{m-\tilde{k}}$  for  $C = \sqrt[3]{\frac{\pi^2}{3} \frac{H_m^2}{m}} = \Theta \left( \sqrt[3]{\frac{(\log(m))^2}{m}} \right)$ . Chebyshev's inequality, which allows to bound the probability of deviating from the mean in terms of the standard deviation, yields

$$\begin{aligned} \mathbf{P} \left[ S(\mathcal{J}^\sigma) \leq \left( \frac{H_m}{m} - C \right) \text{OPT} \right] &\leq \mathbf{P} \left[ S(\mathcal{J}^\sigma) \leq \left( \frac{H_m}{m} - C \right) \frac{L_{\tilde{k}+1}}{m-\tilde{k}} \right] \\ &\leq \mathbf{P} \left[ |\mathbf{E}[S(\mathcal{J}^\sigma)] - S(\mathcal{J}^\sigma)| \geq C^{-1/2} \cdot \sigma[S(\mathcal{J}^\sigma)] \right] \\ &\leq C. \end{aligned}$$

We conclude that with probability  $1 - C$  the minimum load achieved by the Greedy-strategy exceeds  $\min \left\{ S(\mathcal{J}^\sigma) - \frac{H_m}{2m}, \frac{H_m}{2m} \right\} \text{OPT} \geq \frac{H_m}{m} \left( \frac{1}{2} - C \right) \text{OPT}$ . Thus its competitive ratio in the random-order model is at most  $(1 - C) \frac{m}{H_m} \frac{1}{\left( \frac{1}{2} - C \right)} = (2 + o_m(1)) \frac{m}{H_m}$ . ◀

► **Theorem 5.** *The Greedy-strategy is not better than  $\frac{m}{H_m}$ -competitive in the random-order model.*

**Proof.** Consider the following instance for  $\varepsilon > 0$ : Job set  $\mathcal{J}$  consists of  $m - 1$  jobs of size 1 and  $\frac{1}{\varepsilon}$  jobs of size  $\varepsilon$ . It is not difficult to see that  $\text{OPT} = 1$  by assigning the jobs of size 1 to different machines and the jobs of size  $\varepsilon$  together on the remaining machine. Following a similar approach as the one above, interpreting the jobs of size 1 as large and the rest as small, we can prove that for any given order  $\mathcal{J}^\sigma$ , the expected minimum load achieved by the Greedy-strategy is at most  $\sum_{i=0}^{m-1} \frac{S_i(\mathcal{J}^\sigma)}{m-i} + \varepsilon m$ . If now  $\sigma \sim S_n$  is chosen uniformly at random, then the minimum load achieved by the Greedy-strategy is at most  $\sum_{i=0}^{m-1} \frac{1}{m(m-i)} + \varepsilon m = \frac{H_m}{m} + \varepsilon m$ . In particular, the competitive ratio in the random-order model of the Greedy-strategy is at most  $1 / \left( \frac{H_m}{m} + \varepsilon m \right)$  which approaches  $\frac{m}{H_m}$  as  $\varepsilon \rightarrow 0$ . ◀

#### 4 An $\tilde{O}(\sqrt[4]{m})$ -competitive algorithm

We now describe an improved competitive algorithm for the problem further exploiting the extra features of the random-order model. More in detail, we devise a sampling-based method to classify relatively large jobs (with respect to OPT). After this, we run a slight adaptation

■ **Figure 3** A comparison of the solution returned by the Greedy-strategy (left) and the optimal solution (right) for some order  $\sigma$  of the instance defined in Theorem 4. Dark jobs have size 1 and the remaining jobs have size  $\varepsilon > 0$ .

of the algorithm *Partition* due to Azar and Epstein [7] in order to distinguish large jobs that our initial procedure could not classify, leading to strictly better approximation guarantees (see Algorithm 1 for a description). We will assume w.l.o.g. that job sizes are rounded down to powers of 2, which induces an extra multiplicative factor of at most 2 in the competitive ratio.

#### 4.1 Simple and Proper Inputs

Given an input sequence  $\mathcal{J}$ , we call any job  $J$  *large* if its size is larger than  $\frac{\text{OPT}[\mathcal{J}]}{100\sqrt[4]{m}}$ , and we call it *small* otherwise. Let  $k = k[\mathcal{J}]$  be the number of large jobs in  $\mathcal{J}$ . Let  $L_{\text{small}} = L_{k+1}$  be the total size of small jobs. The following definition allows to recognize instances where the Greedy-strategy performs well, see Proposition 7.

► **Definition 6.** We call the input set  $\mathcal{J}$  *simple* if either

- The set  $\mathcal{J}$  has size  $n < m$ ,
- There are at least  $m$  large jobs, i.e.  $k \geq m$ , or
- There are at most  $m - \frac{\sqrt[4]{m^3}}{50}$  large jobs, i.e.  $k \leq m - \frac{\sqrt[4]{m^3}}{50}$ .

Note that the first condition is mostly included for ease of notation; the third condition implies that sequences with  $n < m - \frac{\sqrt[4]{m^3}}{50}$  are simple, which is good enough for our purposes but somewhat clumsy to refer to.

► **Proposition 7.** The Greedy-strategy achieves minimum load at least  $\frac{\text{OPT}}{100\sqrt[4]{m}}$  on simple inputs.

**Proof.** We consider each case from Definition 6 separately:

- If the instance has less than  $m$  jobs,  $\text{OPT} = 0$  and every algorithm is optimal.
- If there are at least  $m$  large jobs in the instance, then the minimum load achieved by the Greedy algorithm is at least  $P_m \geq \frac{\text{OPT}}{100\sqrt[4]{m}}$  thanks to Lemma 2.
- If there are at most  $m - \frac{\sqrt[4]{m^3}}{50}$  large jobs, then  $L_{k+1} \geq \frac{\sqrt[4]{m^3}}{50}\text{OPT}$  as there are at least  $\frac{\sqrt[4]{m^3}}{50}$  machines without large jobs in the optimal solution. If we apply Lemma 3 with  $i = k + 1$ , the minimum load achieved by the Greedy algorithm is at least  $\frac{\text{OPT}}{100\sqrt[4]{m}}$ . ◀

For an input set  $\mathcal{J}$  which is not simple, let  $d := \lceil \log_2(m - k) \rceil$ . Note that  $0 \leq d \leq \lceil \frac{3}{4} \log(m) \rceil$ . We say that such an instance  $\mathcal{J}$  is *proper* (of degree  $d$ ).

Algorithm 1 guesses a value  $t$  with probability  $\Omega(1/\log(m))$  to address in a different way simple instances (case  $t = -1$ ) and proper instances of degree  $t$  for each  $0 \leq t \leq \lceil \frac{3}{4} \log(m) \rceil$ , at the expense of an extra logarithmic factor in the competitive ratio. By Proposition 7, simple instances are sufficiently handled by the Greedy-strategy. From now on we will focus on proper instances of degree  $d$  and show that the corresponding case when  $t = d$  in Algorithm 1 returns a  $O(\sqrt[4]{m})$ -approximate solution.

■ **Algorithm 1** The online Algorithm for Random-Order Machine Covering.

---

**Input:** Job sequence  $\mathcal{J}^\sigma$ ,  $m$  identical parallel machines.

- 1: Guess  $t \in \{-1, 0, 1, \dots, \lceil \frac{3}{4} \log(m) \rceil\}$  uniformly at random.
  - 2: **if**  $t = -1$ , **then** Run the Greedy-strategy and **return** the computed solution.
  - 3: **else** Partition the machines into  $2^t$  *small* machines and  $m - 2^t$  *large* machines.
- 

*Phase 1 – Sampling.*

---

- 4: Schedule the first  $n/8$  jobs iteratively into a least loaded large machine.
  - 5: Let  $P^\uparrow$  be the  $\left(\frac{m-2^t}{8} - \frac{\sqrt{m}}{2}\right)$ -th largest job size among these first  $n/8$  jobs.
- 

*Phase 2 – Partition.*

---

- 6:  $\tau \leftarrow 0$
  - 7: **for**  $j = \frac{n}{8} + 1, \dots, n$  **do**
  - 8:     **if**  $p_{\sigma(j)} \geq P^\uparrow$ , **then** Schedule job  $J_{\sigma(j)}$  onto a least loaded large machine.
  - 9:     **if**  $p_{\sigma(j)} > \tau$ , **then** Update  $\tau$  to  $p_{\sigma(j)}$  with probability  $\frac{1}{9 \cdot 2^t \sqrt{m}}$ .
  - 10:    **if**  $p_{\sigma(j)} \leq \tau$ , **then** Schedule job  $J_{\sigma(j)}$  onto a least loaded small machine.
  - 11:    **if**  $p_{\sigma(j)} > \tau$ , **then** Schedule job  $J_{\sigma(j)}$  onto a least loaded large machine.
  - 12: **end for**
  - 13: **return** the computed solution.
- 

## 4.2 Algorithm for Proper Inputs of Degree $d$

Let  $\mathcal{J}$  be proper of degree  $d$  and assume without loss of generality that its size  $n$  is divisible by 8 (an online algorithm can always simulate up to 7 extra jobs of size 0 to reduce to this case). The algorithm, assuming  $d$  is guessed correctly, chooses  $2^d$  *small* machines  $\mathcal{M}_{\text{small}}$ , while the other machines  $\mathcal{M}_{\text{large}}$  are called *large machines*. The algorithm will always assign the incoming job either to a least loaded small or to a least loaded large machine, the only choice it has to make is to which set of machines the job will go. Theoretically, the goal would be to assign all large jobs to large machines and all small ones to small machines according to our definition. Large and small jobs, unfortunately, cannot be distinguished by an online algorithm with certainty. Instead, we have to use randomization and expect a small error. We aim for a small one-sided error, meaning that we want to avoid misclassifying large jobs at all cost while incorrectly labeling very few small jobs as large.

The algorithm starts with a *sampling phase*: the first  $\frac{n}{8}$  jobs will be used for sampling purposes, and since we yet lack good knowledge about what should be considered large, these jobs will all be assigned to large machines. Let  $P^\uparrow$  be the element of rank  $\frac{m-2^d}{8} - \frac{\sqrt{m}}{2}$  among these elements. The following lemma shows that  $P^\uparrow$  can be used as a threshold to distinguish most of the large jobs from small ones.

► **Lemma 8.** *For proper sequences, it holds that  $\mathbf{P}[P_{k-8\sqrt{m-2^d}} \geq P^\uparrow \geq P_k] \geq \frac{1}{3}$ .*

**Proof.** Let  $n_{\text{large}}$  be the number of large jobs among the first  $\frac{n}{8}$  jobs in the sequence. Notice that  $n_{\text{large}}$  obeys an hypergeometric distribution with parameters  $N = n$  (size of the total population),  $K = k$  (number of elements with the desired property) and  $r = \frac{n}{8}$  (size of the sample). This implies that  $\mathbf{E}_{\sigma \sim S_n}[n_{\text{large}}] = \frac{k}{8} \geq \frac{m-2^d}{8}$ . Moreover

$$\text{Var}[n_{\text{large}}] = \frac{n}{8} \cdot \frac{k}{n} \cdot \frac{n-k}{n} \cdot \frac{7n}{8(n-1)} = \frac{7}{64} \cdot \frac{k(n-k)}{n-1} < \frac{m}{8}.$$

■ **Figure 4** The classification of large (dark) and small (light and dashed) jobs. During sampling, all small jobs are misclassified (dashed ones). Threshold  $P^\uparrow$  classifies large jobs, while threshold  $\tau$  classifies small jobs. Jobs in between are conservatively classified as large, since misclassifying large jobs is fatal. Increasing  $\tau$  due to a small job is a helpful event as less small jobs will be misclassified. On the other hand, increasing  $\tau$  due to a large job below  $P^\uparrow$  is a fatal event as large jobs will be misclassified. The choice of  $P^\uparrow$  ensures that fatal events are unlikely to happen.

If we use Cantelli's inequality, a one-sided version of Chebyshev's inequality, then

$$\mathbf{P}[P^\uparrow < P_k] = \mathbf{P}\left[n_{\text{large}} < \frac{m-2^d}{8} - \frac{\sqrt{m}}{2}\right] \leq \mathbf{P}\left[n_{\text{large}} < \mathbf{E}[n_{\text{large}}] - \frac{\sqrt{m}}{2}\right] \leq \frac{m/8}{\frac{m}{8} + \frac{m}{4}} = \frac{1}{3}.$$

Consider now  $n'_{\text{large}}$  to be the number of the  $k - 8\sqrt{m} - 2^d$  largest jobs among the  $\frac{n}{8}$  first jobs in the sequence. Similarly as before,  $n'_{\text{large}}$  obeys an hypergeometric distribution with parameters  $N = n$ ,  $K = k - 8\sqrt{m} - 2^d$  and  $r = \frac{n}{8}$ , which implies that  $\mathbf{E}_{\sigma \sim S_n}[n'_{\text{large}}] = \frac{k-2^d-8\sqrt{m}}{8} < \frac{m-2^d}{8} - \sqrt{m}$ . Here we use that  $k \leq m$ . Furthermore  $\text{Var}[n'_{\text{large}}] = \frac{n}{8} \cdot \frac{k-8\sqrt{m}-2^d}{n}$ .  $\frac{n-k+8\sqrt{m}+2^d}{n} \cdot \frac{7n}{8(n-1)} \leq \frac{m}{8}$ . Then, using again Cantelli's inequality, we obtain that

$$\begin{aligned} \mathbf{P}[P_{k-8\sqrt{m}-2^d} < P^\uparrow] &= \mathbf{P}\left[n'_{\text{large}} \geq \frac{m-2^d}{8} - \frac{\sqrt{m}}{2}\right] \\ &\leq \mathbf{P}\left[n'_{\text{large}} \geq \mathbf{E}[n'_{\text{large}}] + \frac{\sqrt{m}}{2}\right] \leq \frac{m/8}{\frac{m}{8} + \frac{m}{4}} = \frac{1}{3}. \end{aligned}$$

We conclude that  $\mathbf{P}[P_{k-8\sqrt{m}-2^d} \geq P^\uparrow \geq P_k] = 1 - \mathbf{P}[P_{k-8\sqrt{m}-2^d} < P^\uparrow] - \mathbf{P}[P^\uparrow < P_k] \geq 1/3$ . ◀

After the aforementioned sampling phase is finished and  $P^\uparrow$  is known, the algorithm will enter a *partition phase*. If a job now has size at least  $P^\uparrow$ , it is assigned to the large machines as it will be large with high probability. The large jobs below this value are the most difficult to assign. To this end, we define a *threshold value*  $\tau$ , which we initialize to 0. If the incoming job has size at most  $\tau$  we simply assign it to a least loaded small machine, but whenever we encounter a job  $J$  of size  $p > \tau$ , we set  $\tau = p$  with probability  $\frac{1}{9 \cdot 2^d \sqrt{m}}$ . If now  $p \leq \tau$ , which could happen if we just increased  $\tau$ , we schedule  $J$  on the least loaded small machine. Else,  $J$  is assigned to the least loaded machine in  $\mathcal{M}_{\text{large}}$  (see Figure 4 for a depiction of the procedure). As the following lemma shows, this procedure distinguishes all the large jobs with constant probability.

► **Lemma 9.** *All large jobs are scheduled onto large machines with constant probability.*

**Proof.** Let us assume that  $P_{k-8\sqrt{m}-2^d} \geq P^\dagger \geq P_k$ . Now, the statement of the lemma can only be wrong if we decided to increase  $\tau$  when encountering some large job of size less than  $P^\dagger$ . By assumption there are less than  $8\sqrt{m} + 2^d$  such jobs. The desired probability is thus at least

$$\left(1 - \frac{1}{9 \cdot 2^d \sqrt{m}}\right)^{8\sqrt{m}+2^d} \geq 1 - \frac{8\sqrt{m} + 2^d}{9 \cdot 2^d \sqrt{m}} \geq 1 - \frac{8}{9 \cdot 2} - \frac{1}{9\sqrt{m}} > \frac{4}{9}.$$

The first inequality is Bernoulli's inequality, the second one uses that  $d \geq 1$ . The lemma follows by multiplying with the probability from Lemma 8.  $\blacktriangleleft$

We call an input sequence *orderly* if it satisfies the properties of Lemmas 8 and 9. The following lemma shows that the total size of misclassified small jobs can be, in expectation, bounded from above. This proof is an adaptation of one of the results from Azar and Epstein [7], which we present for the sake of completeness.

► **Lemma 10.** *The expected total size of small jobs scheduled onto small machines is at least  $\frac{31}{800\sqrt[4]{m}}L_{\text{small}}$ , even when conditioned on the input sequence being orderly.*

**Proof.** Let  $L'_{\text{small}}$  be the random variable corresponding to the size of small jobs assigned to large machines in the sampling phase. Since jobs appear in random order, we have that

$$\mathbf{E}_{\sigma \sim S_n}[L'_{\text{small}}] = \frac{1}{n!} \sum_{J_i \text{ small}} \frac{n}{8} \cdot (n-1)! \cdot p_i = \frac{1}{8}L_{\text{small}}.$$

Let us now bound the total size of misclassified small jobs in the partition phase. We will define, for a given set of  $18 \cdot 2^d \sqrt[4]{m}$  small jobs of the same size  $p_i$  (recall that jobs are rounded down to powers of 2), the following event: after  $9 \cdot 2^d \sqrt[4]{m}$  jobs from the set arrived,  $\tau$  is at least  $p_i$ . If this were not the case,  $\tau$  was never updated at any of these  $9 \cdot 2^d \sqrt[4]{m}$  first jobs albeit being smaller than  $p_i$ . The probability for this is at most

$$\left(1 - \frac{1}{9 \cdot 2^d \sqrt[4]{m}}\right)^{9 \cdot 2^d \sqrt[4]{m}} \leq e^{-\frac{1}{\sqrt[4]{m}}} \leq 1 - \frac{1}{2\sqrt[4]{m}},$$

where we used the fact that  $e^{-x} \leq 1 - \frac{x}{2}$  if  $0 \leq x \leq 1$ . This implies that the probability of the previous event occurring is at least  $\frac{1}{2\sqrt[4]{m}}$ .

Let  $\mathcal{S}$  be the set of small jobs remaining after the sampling phase. We will partition  $\mathcal{S}$  into batches of  $18\sqrt[4]{m}$  jobs of the same size. There will be jobs that are not assigned to any batch because there are not enough jobs of the same size to complete it, but the total size of these jobs is at most

$$18 \cdot 2^d \sqrt[4]{m} \sum_{i \geq 1} \frac{\text{OPT}}{100\sqrt[4]{m} \cdot 2^i} \leq \frac{18 \cdot 2^{d-1} \cdot \text{OPT}}{25} \leq \frac{18L_{\text{small}}}{25},$$

where the last inequality holds as there are at least  $2^{d-1}$  machines in the optimal solution without large jobs. For each of the batches, the probability of assigning at least half of its size to small machines is bounded below by the probability of the previously described event occurring, which is at least  $\frac{1}{2\sqrt[4]{m}}$ . Hence, the expected total size of small jobs assigned to small machines is at least

$$\frac{1}{2\sqrt[4]{m}} \cdot \frac{1}{2} \sum_{J_i \in \mathcal{S}} p_i \geq \frac{1}{4\sqrt[4]{m}} \cdot \left(1 - \frac{1}{8} - \frac{18}{25}\right) L_{\text{small}} = \frac{31}{800\sqrt[4]{m}} L_{\text{small}}.$$

To observe that we can condition on the sequence being orderly, it suffices to note that the arguments work for every way to fix  $P^\dagger$  and that they do not make any assumptions on  $\tau$  being increased at large jobs.  $\blacktriangleleft$

Putting all the previous ingredients together we can conclude the following proposition.

► **Proposition 11.** *The previously described algorithm is  $O(\sqrt[d]{m})$ -competitive in the random-order model for the case of proper inputs of degree  $d$ .*

**Proof.** By assumption, all  $k \geq m - 2^d$  large jobs are scheduled onto large machines. A lower bound of  $P_k = \frac{\text{OPT}}{100 \sqrt[d]{m}}$  for the minimum load achieved in the large machines follows then from Lemma 2. By Lemma 3, the minimum load among small machines is at least  $\frac{31}{800 \sqrt[d]{m}} \frac{L_{\text{small}}}{2^d} - \frac{\text{OPT}}{100 \sqrt[d]{m}}$ . The proposition follows from observing that  $L_{\text{small}} \geq 2^{d-1} \text{OPT}$  since the optimal solution contains at least  $m - k \geq 2^{d-1}$  machines with only small jobs. ◀

### 4.3 The Final Algorithm

As discussed before, our final algorithm first guesses whether the instance is simple or proper of degree  $d$ . Then we apply the appropriate algorithm, the Greedy-strategy or the previously described algorithm for the right degree. Since there are  $O(\log(m))$  many possibilities, this guessing induces an extra logarithmic factor on the final competitive ratio, which concludes the proof of Theorem 1 restated below.

► **Theorem 1.** *There exists a  $\tilde{O}(\sqrt[d]{m})$ -competitive algorithm for the online Machine Covering problem in the random-order model.*

## 5 A Lower Bound for the Random-Order Model

The main difficulty for Online Machine Covering algorithms, including our main result, is to tell large jobs apart from the largest small jobs. In this section we prove that doing so is, to a certain extent, inherently hard. The main difference to adversarial models is that hardness is not obtained through withholding information but rather through obscuring it. This relates to some studied variants of the classical Secretary Problem such as the Postdoc Problem [43] but requires additional features particularly catered to our needs.

### 5.1 The Talent Contest Problem

Consider the following selection problem: To a yearly talent show contest  $n$  candidates apply. To appeal to a general audience, we try to exclude the best candidates because an imperfect performance is more entertaining, but we also want to have at least an appropriate candidate who can be presented as the winner. To do so, each candidate will participate in  $t$  trials (each trial is considered as an arrival) and we must decide for every arrival if we mark the candidate or not, meaning that we consider her to be the  $K$ -th best candidate or worse. The global order in which candidates arrive for trials is uniformly distributed, thus at later trials we have much more information to go by. Our final goal is to maximize the number of trials for which we successfully marked the  $K$ -th best candidate without marking any better candidate.

Formally, the *Talent Contest* problem is specified by three parameters  $K$ ,  $n$  and  $t$ , where  $K \leq n$ . Candidates have pairwise different non-negative valuations  $v_1, v_2, \dots, v_n$ , and each candidate arrives  $t$  times; the arrival order is chosen uniformly at random. The valuation of each candidate is revealed when the candidate arrives for the first time. We may decide to mark each arrival or not, though once the next candidate arrives such marking decision is permanent. For each value  $1 \leq h \leq t$  we get one point if we marked the  $h$ -th arrival of the  $K$ -th best candidate, but not the  $h$ -th arrival of any better candidate. In

particular, we can get up to  $t$  points in total, one for each value of  $h$ . Let  $P(K, t, n)$  be the expected number of points the optimal online algorithm scores given the three values  $K, t$  and  $n$ . Similar to the classical Secretary problem, we are mostly interested in the limit case  $P(K, t) = \lim_{n \rightarrow \infty} P(K, t, n)$ .

We require for our desired results one extra technical definition. Given  $\lambda \geq 1$ , we call the valuations of candidates  $\lambda$ -steep if all candidate valuations are guaranteed to be at least by a factor  $\lambda$  apart, i.e.  $\min_{v_i > v_j} \frac{v_i}{v_j} \geq \lambda$ . It is possible to prove the following bound on the expected value  $P(K, t)$ , whose proof we defer to the full version of the paper.

► **Lemma 12.** *It holds that  $P(K, t) \leq \frac{\zeta(t/2)(t+1)^{t/2}}{2\pi\sqrt{K}}$ , where  $\zeta$  is the Riemann Zeta Function. This bound still holds if we restrict ourselves to  $\lambda$ -steep valuations for some  $\lambda \geq 1$ .*

Roughly speaking, the proof relies on the fact that if an algorithm manages to perform relatively well in the Talent Contest problem, then it could be used to guess the value of a binomially distributed random variable. For the latter problem, difficulty can be directly established. However, the proof involves more technical aspects as some few irregular orders do not allow this reduction and have to be excluded beforehand. The property of  $\lambda$ -steepness is ensured by choosing  $\mu$  sufficiently large and applying the transformation  $v \mapsto \mu^v$  to each valuation.

## 5.2 Reduction to Machine Covering

It is possible to show that the Talent Contest problem and the Online Machine Covering problem in the random-order model are related as the following lemma states.

► **Lemma 13.** *Given  $K$  and  $t$ , let  $m = (K - 1) \cdot t + 1$ . No (possibly randomized) algorithm for Machine Covering in the random-order model on  $m$  machines can be better than  $\frac{t}{P(K,t)+1}$ -competitive.*

**Proof.** Let  $\lambda > t$ . Consider any instance of the Talent Contest problem with  $\lambda$ -steep valuations. We will treat the arrival sequence of candidates as a job sequence, where each arrival corresponds to a job of size given by the valuation of the corresponding candidate. We call the  $m - 1 = t(K - 1)$  jobs corresponding to the arrivals of the  $K$  largest candidates *large*. The  $t$  jobs corresponding to the next candidate are called *medium*. Notice that the size of a medium job is at most  $\frac{OPT}{t}$  as evidenced by the schedule that assigns each large job on a separate machine and the  $t$  medium jobs onto the single remaining machine. Jobs which are neither large nor medium have total size at most  $t \sum_{i=1}^{\infty} \lambda^{-i} \frac{OPT}{t} = \frac{OPT}{\lambda-1}$  and are thus called *small*. They will become negligible for  $\lambda \rightarrow \infty$ .

Consider an online algorithm  $\mathcal{A}_{MC}$  for Machine Covering in the random-order model. We will derive an algorithm  $\mathcal{A}_{TC}$  for the Talent Contest problem as follows:  $\mathcal{A}_{TC}$  marks each job that gets assigned to a machine that already contains a job of the same size. Let  $P$  be the number of points this strategy gets. We will first show that the schedule of  $\mathcal{A}_{MC}$  contains a machine which has at most  $P + 1$  medium jobs and no big job. For this we consider any fixed input order, and if  $\mathcal{A}_{MC}$  is randomized, we consider any fixed outcome of its coin tosses.

For  $2 \leq i \leq t$ , let  $w_i$  be an indicator variable that is 1 if  $\mathcal{A}_{TC}$  gains a point for the  $i$ -th arrival, i.e. if it marks the  $i$ -th arrival of the  $K$ -th best candidate but not the  $i$ -th arrival of a better candidate;  $w_i = 0$  otherwise. Let also  $r_i$  be an indicator variable that is 1 if  $\mathcal{A}_{TC}$  marked the  $i$ -th arrival of the  $K$ -th best candidate but still loses due to also marking the  $i$ -th arrival of a better candidate. Finally, let  $\mathcal{M}_{\text{small}}$  be the machines which do not receive a large job in the schedule of  $\mathcal{A}_{MC}$ , and let  $Z_{\text{med}}$  be the average number of medium jobs on machines in  $\mathcal{M}_{\text{small}}$ . Our intermediate goal is to show that  $Z_{\text{med}} < 2 + \sum_{i=2}^t w_i$ .

Since there are only  $m - 1$  large jobs, of which at least  $\sum_{i=2}^t r_i$  are scheduled on a machine already containing a large job, we have that  $|\mathcal{M}_{\text{small}}| \geq 1 + \sum_{i=2}^t r_i$ . Let  $d \geq 0$  such that  $|\mathcal{M}_{\text{small}}| = 1 + d + \sum_{i=2}^t r_i$ . Now, observe that  $\sum_{i=2}^t (w_i + r_i)$  counts the number of medium jobs that are placed on a machine already containing a medium job. Thus, the number of medium jobs on machines in  $\mathcal{M}_{\text{small}}$  is at most  $|\mathcal{M}_{\text{small}}| + \sum_{i=2}^t (w_i + r_i) = 1 + d + \sum_{i=2}^t (w_i + 2r_i)$ . Now we can bound the average number of medium jobs on  $\mathcal{M}_{\text{small}}$ , namely  $Z_{\text{med}} \leq \frac{1+d+\sum_{i=2}^t (w_i+2r_i)}{1+d+\sum_{i=2}^t r_i}$ . Let us assume that  $Z_{\text{med}} \geq 2$ ; then the term on the right hand side increases if we set  $d$  and all  $r_i$  to zero, and we obtain that  $Z_{\text{med}} \leq 1 + \sum_{i=2}^t w_i$  and thus  $Z_{\text{med}} < 2 + \sum_{i=2}^t w_i$ . To derive this inequality we assumed that  $Z_{\text{med}} \geq 2$  but it is trivially true if  $Z_{\text{med}} < 2$ .

Now, let  $z_{\text{med}}$  be the least number of medium jobs on a machine in  $\mathcal{M}_{\text{small}}$ . Then  $z_{\text{med}} \leq Z_{\text{med}} < 2 + \sum_{i=2}^t w_i$ . Since  $z_{\text{med}}$  and the right hand side are both integers, it holds that  $z_{\text{med}} \leq 1 + \sum_{i=2}^t w_i$ . Since  $\sum_{i=2}^t w_i = P$ , the number of points obtained by algorithm  $\mathcal{A}_{TC}$  for the Talent Contest problem, we have shown that the schedule of  $\mathcal{A}_{MC}$  contains a machine  $M$  with at most  $P + 1$  medium jobs and no large one as desired.

As argued before, each medium job has size at most  $\frac{\text{OPT}}{t}$  and the small jobs have total size at most  $\frac{\text{OPT}}{\lambda-1}$  in total. Thus, machine  $M$  has load at most  $\frac{P+1}{t}\text{OPT} + \frac{\text{OPT}}{\lambda-1}$ . In conclusion, the expected load of the least loaded machine in the schedule of  $\mathcal{A}_{MC}$  is at most  $\frac{P(K,t)+1}{K}\text{OPT} + \frac{\text{OPT}}{\lambda-1}$ , given a worst-case input for the Talent Contest Problem. This concludes the proof by taking  $\lambda \rightarrow \infty$ .  $\blacktriangleleft$

By setting  $K = (t+1)^t$  and combining this with the lower bound in Lemma 12, we obtain the following general lower bound.

► **Theorem 14.** *The competitive ratio of no online algorithm for Machine Covering in the random-order model, deterministic or randomized, is better than  $\frac{\lfloor e^{W(\ln(m))} \rfloor - 1}{1.16+o(1)}$ . Here,  $W(x)$  is the Lambert  $W$ -function, i.e. the inverse to  $x \mapsto xe^x$ . In particular, no algorithm can be  $O\left(\frac{\log(m)}{\log \log(m)}\right)$ -competitive for Online Machine Covering in the random-order model.*

**Proof.** Let  $K = (t+1)^t$ . Then Lemma 12 yields  $P(K, t) \leq \frac{\zeta(t/2)}{2\pi} \leq 1.16+o(1)$ . By Lemma 13 no algorithm can be better than  $\left(\frac{t}{1.16+o(1)}\right)$ -competitive for  $m = (K-1) \cdot t + 1 < (t+1)^{t+1}$ . We can always add a few jobs of large enough size so that the lower bound extends to larger numbers of machines. The theorem follows since the inverse function of  $x \mapsto (t+1)^{t+1}$  is  $t \mapsto e^{W(\ln(m))} - 1$ ; the second part uses the identity  $W(x) \geq \log(x) - \log \log(x) + \omega(1)$ , see [28].  $\blacktriangleleft$

---

# Nearly-Tight Lower Bounds for Set Cover and Network Design with Deadlines/Delay

Noam Touitou

Tel Aviv University, Israel

---

## Abstract

---

In network design problems with deadlines/delay, an algorithm must make transmissions over time to satisfy connectivity requests on a graph. To satisfy a request, a transmission must be made that provides the desired connectivity. In the deadline case, this transmission must occur inside a time window associated with the request. In the delay case, the transmission should be as soon as possible after the request's release, to avoid delay cost.

In FOCS 2020, frameworks were given which reduce a network design problem with deadlines/delay to its classic, offline variant, while incurring an additional competitiveness loss factor of  $O(\log n)$ , where  $n$  is the number of vertices in the graph. Trying to improve upon this loss factor is thus a natural research direction.

The frameworks of FOCS 2020 also apply to *set cover with deadlines/delay*, in which requests arrive on the elements of a universe over time, and the algorithm must transmit sets to serve them. In this problem, a universe of sets and elements is given, requests arrive on elements over time, and the algorithm must transmit sets to serve them.

In this paper, we give nearly tight lower bounds for set cover with deadlines/delay. These lower bounds imply nearly-tight lower bounds of  $\Omega(\log n / \log \log n)$  for a few network design problems, such as node-weighted Steiner forest and directed Steiner tree. Our results imply that the frameworks in FOCS 2020 are essentially optimal, and improve quadratically over the best previously-known lower bounds.

## 1 Introduction

### Network Design with Deadlines

In network design problems with deadlines, one is given a set of connectivity requests. Each connectivity request has an associated time window, starting with a release time and ending with a deadline. The input also contains items, with associated costs; usually, these items are some characteristic of a given graph, such as the edges or the nodes. A solution consists of a set of *transmissions*, taking place at various points in time, where each transmission is of some set of items. Such a solution is feasible if for every connectivity request, there exists a transmission which occurs within the request's time window, and provides the connectivity desired by the request.

This general description captures many network design problems. Two concrete examples are node-weighted Steiner forest and directed Steiner tree, both of which are considered in this paper.

- In *node-weighted Steiner forest with deadlines*, the items are the nodes of a given graph, with associated costs. A connectivity request is of some pair of terminal nodes in the graph, demanding that a connection be made between these nodes. A set of items (i.e.

- nodes) which satisfies a request must contain a path connecting the request's terminal nodes; such a set must be transmitted within the request's time window to satisfy that request.
- In *directed Steiner tree with deadlines*, the items are the edges of a directed graph, with associated costs. A unique node in the graph is designated as the root of the graph; each connectivity request is of some terminal node, demanding its connection to the root node. A set of items (i.e. edges) which satisfies a request must contain a directed path connecting the request's terminal node to the root. Such a satisfying set must be transmitted within the request's time window for the solution to be feasible.

Network design with deadlines has been studied in the online setting, in which the algorithm constructs a solution as time advances, deciding at each point in time whether (and what) to transmit at that time. Each request is revealed to the algorithm at the request's release time. In line with previous work, we consider the clairvoyant model, where all parameters of the request are revealed at release time (in particular its deadline).

A more general model is *network design with delay*. In this model, each request has a (nondecreasing, continuous) delay function in lieu of a deadline. Each request can be served by a satisfying transmission after its release time. However, in addition to the cost of transmissions, a solution must also pay the *delay cost* of each request – the value of its delay function at the time of the earliest transmission which satisfies it (after its release time). This model can easily be seen to generalize the deadline model.

In [8], a framework for network design problems with deadlines is presented. This framework is in fact a polynomial-time reduction from online network design with deadlines to offline, classic network design: given a  $\gamma$ -approximation algorithm for the offline problem, the framework yields an  $O(\gamma \log |U|)$ -competitive algorithm for the online problem with deadlines, where  $U$  is the set of items. For most problems, in which the items are either the nodes or edges of a given simple graph  $G = (V, E)$ , we have that  $\log |U| = O(\log n)$  – we only consider such problems in this paper. A similar framework for network design with delay is also given in [8], also based on a reduction with  $O(\log n)$  loss<sup>1</sup>.

In [8], a lower bound of  $\Omega(\sqrt{\log n})$  is given on the competitiveness of any (randomized) algorithm for specific network design problems (node-weighted Steiner tree and directed Steiner tree). This implies that *every* reduction incurs a loss factor of  $\Omega(\sqrt{\log n})$  (indeed, this information-theoretic lower bound applies even when we allow exponential time, which admits a 1-approximation for the offline problem). This leaves a quadratic gap between the upper and lower bounds; a natural research question would be to close this gap. In this paper, we give a negative answer to this question; in fact, we show that the framework of [8] is essentially tight.

### Set Cover with Deadlines

The lower bounds of  $\Omega(\sqrt{\log n})$ -competitiveness for node-weighted Steiner tree and directed Steiner tree stem from a lower bound for the problem of set cover with deadlines, which is a special case of both problems. In the problem of set cover with deadlines, one is given a universe which consists of a set of elements  $E$  and a collection  $S$  of subsets from  $E$ , where the sets have costs. The input contains a set of requests, such that each request has an

---

<sup>1</sup> The reduction for the delay case given in [8] is to the prize-collecting offline problem, a similar offline problem which is almost always approximable to the same degree as the classic offline problem (up to some small constant).

associated element in  $E$  and a time window (release time and deadline). A solution consists of a set of transmissions, each of which occurs at some point in time, and consists of some set in  $S$ . A solution is feasible if the associated element of every request belongs to the set of some transmission which occurs during the request's time window. While not classically considered a network design problem, the set cover with deadlines problem does conform to the model of this paper: the sets are the items of the problem, and the requests are of specific elements.

Set cover with deadlines is indeed a special case of both node-weighted Steiner forest with deadlines and directed Steiner tree with deadlines, as seen by folklore reductions. In both reductions, the set cover input is reduced to graph comprising a root node, “set” nodes and “element” nodes, where the root node must connect to “element” nodes through the “set” nodes; see [8] for a full description of these reductions.

The best known lower bounds for competitiveness in the set cover with deadlines problem, described in [3], are  $\Omega(\sqrt{\log \ell})$  and  $\Omega(\sqrt{\log m})$ , where  $\ell$  and  $m$  are the number of elements and the number of sets in the universe, respectively. In this paper, we improve these lower bounds to  $\Omega\left(\frac{\log \ell}{\log \log \ell}\right)$  and  $\Omega\left(\frac{\log m}{\log \log m}\right)$  respectively.

## 1.1 Our Results

In this paper, we present lower bounds for three network design problems with deadlines which are tight up to a log log factor. For set cover with deadlines or delay, where  $\ell$  and  $m$  are the number of elements and sets respectively, we prove the following theorem.

► **Theorem 1.1.** *There exist  $\Omega\left(\frac{\log \ell}{\log \log \ell}\right)$  and  $\Omega\left(\frac{\log m}{\log \log m}\right)$  lower bounds on the competitiveness on any randomized online algorithm for set cover with deadlines (or delay).*

For node-weighted Steiner tree with deadlines and directed Steiner tree with deadlines or delay, for a graph with  $n$  vertices, we prove the following theorems.

► **Theorem 1.2.** *There exists an  $\Omega\left(\frac{\log n}{\log \log n}\right)$  lower bound on the competitiveness on any randomized online algorithm for node-weighted Steiner tree with deadlines (or delay).*

► **Theorem 1.3.** *There exists an  $\Omega\left(\frac{\log n}{\log \log n}\right)$  lower bound on the competitiveness on any randomized online algorithm for directed Steiner tree with deadlines (or delay).*

The lower bounds of Theorems 1.1–1.3 are nearly tight – the framework of [8] implies  $O(\log n)$ -competitive algorithms for both node-weighted Steiner forest with deadlines and directed Steiner tree with deadlines, as well as  $O(\log m)$ - and  $O(\log \ell)$ -competitive algorithms for set cover with deadlines<sup>2</sup>.

We prove the lower bounds of Theorems 1.1–1.3 for the deadline case only; as deadlines are a special case of delay, the lower bounds apply to the delay model as well.

## 1.2 Our Techniques

The lower bounds of this paper stem from describing a sequence of adversaries  $(\mathcal{A}_0, \mathcal{A}_1, \dots)$  for set cover with deadlines. As we advance in this sequence, we describe adversaries that use a larger universe, and force a worse competitive ratio on the online algorithm. The growth rate of the universe ( $\ell$  and  $m$ ) together with the growth rate of the competitive ratio yields the desired lower bound.

<sup>2</sup> Note that the  $O(\log \ell)$ -competitive algorithm is not a direct application of the framework of [8], but requires a simple observation.

We construct each adversary  $\mathcal{A}_i$  recursively from the description of  $\mathcal{A}_{i-1}$ . The universe of  $\mathcal{A}_i$ , the elements  $E_i$  and sets  $S_i$ , consists of multiple copies of  $E_{i-1}$  and  $S_{i-1}$ , but these copies are interleaved in a way that creates increasing difficulty for the algorithm with each iteration. As for requests,  $\mathcal{A}_i$  makes recursive calls to  $\mathcal{A}_{i-1}$  on copies of  $E_{i-1}$  (which appear inside  $E_i$ ) which have the structure of  $\mathcal{A}_{i-1}$  locally – specifically, restricting the sets of  $S_i$  to this copy of  $E_{i-1}$  yields a copy of  $S_{i-1}$ .

While the recursive nature of the construction is similar to the adversary in [3], the underlying idea is different: in [3], the main idea of the adversary was to present the algorithm with two options for sets, an “expensive” option (which serves some additional long-term requests) and a “cheap” option (which only serves the most urgent requests). The idea was to exploit the fact that the algorithm doesn’t know whether investing in preparation for the future would pay off. However, our construction relies on a different principle – we present the algorithm with *many* different options for sets (the number of which grows logarithmically with the universe), the costs of which are identical (i.e. there is no cheap option). The online algorithm will either pick some small number of these options (in which case it would probably miss the correct one), or pick many of these options (which would be very expensive compared to the optimal solution).

### 1.3 Related Work

Classic online variants for network design problems have been studied extensively in the past. In such variants, the requests arrive over a sequence, and the items are bought rather than transmitted, such that a bought item can be used until the end of the input sequence. Some such problems were studied in [26, 23, 9, 29, 24, 1].

The relationship between this classic online and network design with deadlines is interesting: the clairvoyant deadlines model, considered in this paper, is more closely related to the offline problem (as shown in [8]), and can be much easier than the classic online variant. However, the *nonclairvoyant* deadlines model, where the deadline becomes known only at the end of the request’s time window, is as hard as the classic online variant: the reduction showing this for set cover appears in [3].

The online set cover with deadlines/delay problem was first presented by Carrasco *et al.* [19], who gave tight upper- and lower-bounds of logarithmic competitiveness in the number of requests in the input. In [3], bounds referring to the size of universe (sets and elements) were given, including an  $O(\log \ell \log m)$ -competitive algorithm. This upper bound of  $O(\log \ell \log m)$  applies to the nonclairvoyant setting. As nonclairvoyant set cover with deadlines/delay generalizes the classic online set cover, this algorithm is thus optimal for the class of polynomial, randomized algorithms, conditioned on  $\text{NP} \subsetneq \text{BPP}$  [28].

A specific network design problem which was previously considered is facility location with deadlines/delay. In this problem, requests arrive on the nodes of a graph, and a transmission consists of a facility at some node, to which some pending requests are connected. In [7],  $O(\log^2 n)$ -competitive randomized algorithms for facility location with deadlines/delay were presented, which only worked for the uniform case (i.e. identical facility opening costs), where  $n$  is the number of nodes in the graph. These results were then improved to deterministic  $O(\log n)$ -competitive algorithms for both deadlines and delay in [8].

Another network design problem with deadlines/delay is multilevel aggregation, which is in fact Steiner tree with deadlines/delay where the underlying metric space is a tree. This problem was first presented by Bienkowski *et al.* [10], as a generalization to the previously studied TCP acknowledgement [20, 27, 17] and joint replenishment [18, 15, 11] problems. The algorithm of Bienkowski *et al.* had competitiveness which was exponential in the depth of the tree  $D$ . This was first improved to  $O(D)$  for the deadline case by Buchbinder *et al.* [16] and then to  $O(D^2)$  for the general delay case by [7].

Other problems with deadlines/delay, outside of network design, have also seen significant interest. The  $k$ -server problem with delay was presented in [5], and studied in [14, 7, 25]. Interestingly, this problem is related to the network design problem of multilevel aggregation, as discussed in [7].

Min-cost perfect matching with delays, presented in [21] is another such problem. This problem is only tractable for specific delay functions (e.g. linear and concave), and is studied in [2, 22, 21, 4, 12, 13, 6].

## 2 Preliminaries

Since our results for node-weighted Steiner forest and directed Steiner tree stem from our result for set cover through a folklore reduction, we only provide a formal description for set cover with deadlines.

### Set cover with deadlines

In the set cover with deadlines problem, one is given a universe which consists of elements  $E$  and a collection of sets  $S$ , such that  $s \subseteq E$  for every  $s \in S$ . In addition, each set  $s \in S$  has a cost  $c(s)$ . Additionally, the input contains a set of requests  $Q$ . Each request  $q \in Q$  has an associated element  $e_q \in E$ , a release time  $r_q$  and a deadline  $d_q$  (such that  $r_q < d_q$ ).

A solution for the input is some collection of (instantaneous) transmissions  $\{T_1, \dots, T_k\}$  at various points in time, such that each transmission is of some set  $s_T$ . The cost of this solution is  $\sum_{i=1}^k c(s_{T_i})$ , i.e. the sum of costs of transmitted sets. Note that a set can be transmitted more than once in a solution; in this case, the set's cost is incurred more than once. A solution is *feasible* if for each request  $q \in Q$ , there exists a transmission  $T$  at some time between  $r_q$  and  $d_q$  such that  $e_q \in s_T$ . In words, a set containing the element requested by  $q$  must be transmitted within  $q$ 's time window.

Rigorously, the events at time  $t$  occur in the following order: first, any transmitted sets at  $t$  serve pending requests; then, any request  $q$  with  $r_q = t$  is released. Thus, in order to serve a request  $q$ , a transmission must take place in the half-open time window  $(r_q, d_q]$ . We remark that the results of this paper hold for any choice of order, and that our specific order is chosen for ease of presentation. (Indeed, our lower bound can be stated with distinct release/deadline times, which would bypass this issue.)

### The online setting

An online algorithm receives the universe (i.e.  $E$ ,  $S$  and  $\{c(s)\}_{s \in S}$ ) up front, while the requests  $Q$  are revealed to the algorithm as time advances. Specifically, each request  $q \in Q$  appears to the online solution only upon its release time  $r_q$ . We consider the *clairvoyant* model, in which all parameters of the request  $q$  are revealed at  $r_q$  (in particular its deadline  $d_q$ ).

At any point in time, the algorithm is allowed to make a transmission  $T$  of any set  $s$  (thus incurring a cost of  $c(s)$ ).

## 3 Lower Bound for Set Cover

In this section, we describe and analyze an oblivious adversary for set cover with deadlines, which we then use to prove Theorems 1.1–1.3.

We define the sequence  $(\ell_i)_{i=0}^\infty$  recursively by  $\ell_0 := 1$  and by  $\ell_i := (6i + 1)\ell_{i-1}$  for  $i > 0$ . Similarly, we define the sequence  $(m_i)_{i=0}^\infty$  recursively by  $m_0 := 1$  and by  $m_i := 4i \cdot m_{i-1}$  for  $i > 0$ . We prove the following lemma.

► **Lemma 3.1.** *For every index  $i$ , there exists an oblivious adversary  $\mathcal{A}_i$  which generates a set cover with deadlines instance on a universe with  $\ell_i$  elements and  $m_i$  sets, such that any deterministic algorithm is at least  $\Omega(i)$ -competitive against  $\mathcal{A}_i$ .*

Lemma 3.1, together with Yao's principle and some folklore reductions, is later used to prove Theorems 1.1–1.3.

### 3.1 The Set Cover Adversary

To prove Lemma 3.1, we now introduce the oblivious adversary  $\mathcal{A}_i$ . This adversary  $\mathcal{A}_i$  provides a universe with elements  $E_i$  and set collection  $S_i$ . The adversary always provides unweighted instances, i.e. the cost of every set in  $S_i$  is always 1.

#### The Universe of $\mathcal{A}_i$

In the base case of  $i = 0$ , we have a universe of a single element, ( $E_0 = \{e\}$ ) and a single set ( $S_0 = \{s\}$ ).

For  $i > 0$ , we construct the universe of  $\mathcal{A}_i$  recursively from the universe of  $\mathcal{A}_{i-1}$ . Define  $b_i := 2i$ . The set  $E_i$  contains copies of elements from  $E_{i-1}$ . Specifically, each element  $e \in E_{i-1}$  has the following copies:

1. The copy  $e^s$  (define  $E_{i-1}^s := \{e^s | e \in E_{i-1}\}$ ). This copy is called the *special* copy.
2. The  $b_i$  copies  $e^{a,1}, \dots, e^{a,b_i}$  (for every  $j$ , define  $E_{i-1}^{a,j} := \{e^{a,j} | e \in E_{i-1}\}$ ). These are called the *ancillary* copies of elements.
3. The  $b_i$  copies  $e^{p,1}, \dots, e^{p,b_i}$  (for every  $j$ , define  $E_{i-1}^{p,j} := \{e^{p,j} | e \in E_{i-1}\}$ ). These are called the *positive* copies of elements.
4. The  $b_i$  copies  $e^{n,1}, \dots, e^{n,b_i}$  (for every  $j$ , define  $E_{i-1}^{n,j} := \{e^{n,j} | e \in E_{i-1}\}$ ). These are called the *negative* copies of elements.

The elements of the instance of  $\mathcal{A}_i$  are defined as

$$E_i := E_{i-1}^s \cup \left( \bigcup_{j=1}^{b_i} E_{i-1}^{a,j} \right) \cup \left( \bigcup_{j=1}^{b_i} E_{i-1}^{p,j} \right) \cup \left( \bigcup_{j=1}^{b_i} E_{i-1}^{n,j} \right)$$

We can now observe that  $|E_i| = (3b_i + 1)|E_{i-1}| = (6i + 1)|E_i|$ . Since  $|E_0| = 1$ , for every  $i$  we have  $|E_i| = \ell_i$ , as required by Lemma 3.1.

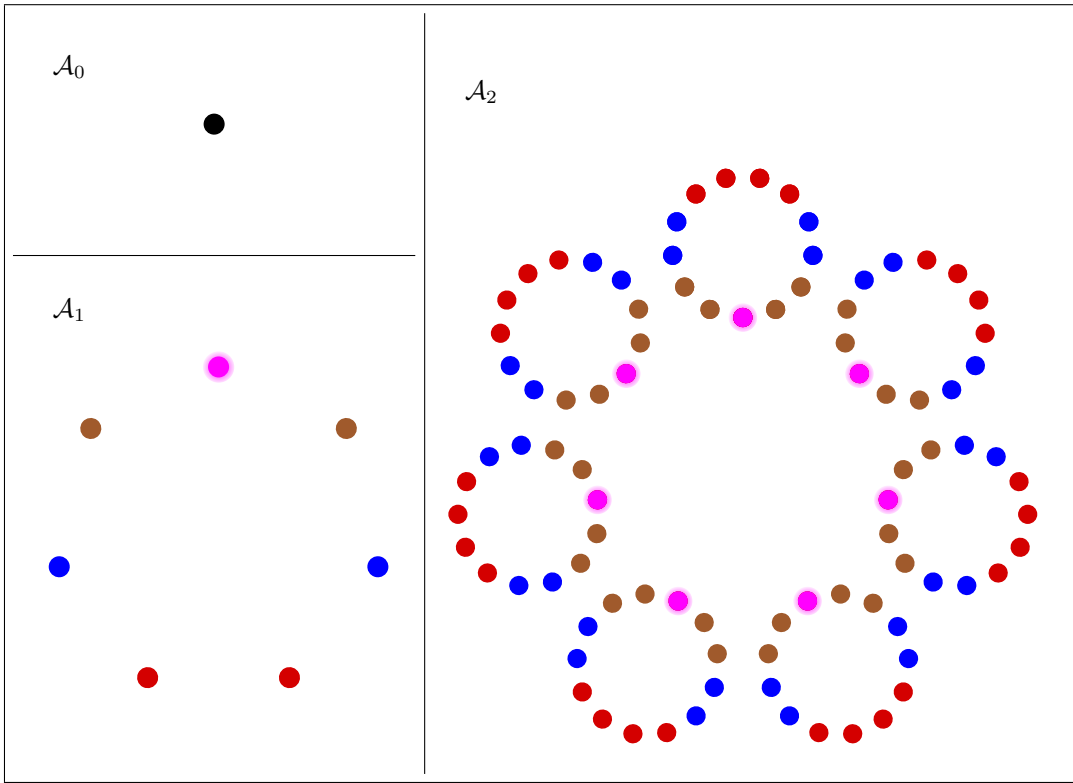

Figure 1 shows the elements of  $\mathcal{A}_0$  (upper left),  $\mathcal{A}_1$  (lower left) and  $\mathcal{A}_2$  (right). Each element in  $\mathcal{A}_1$  and  $\mathcal{A}_2$  is a copy of an element from the universe of the previous adversary; each copy is special (purple), ancillary (brown), positive (blue) or negative (red).

As for the sets, each set  $s \in S_{i-1}$  has the following copies in  $S_i$ :

1. The  $b_i$  copies  $s^{p,1}, \dots, s^{p,b_i}$ , such that

$$s^{p,j} = \bigcup_{e \in s} \{e^s, e^{a,j}, e^{p,j}\}$$

(for each  $j$ , we define  $S_{i-1}^{p,j} := \{s^{p,j} | s \in S_{i-1}\}$ ). These copies are called the *positive* copies of sets.

■ **Figure 1** The Elements of  $\mathcal{A}_0$ ,  $\mathcal{A}_1$  and  $\mathcal{A}_2$ .

2. The  $b_i$  copies  $s^{n,1}, \dots, s^{n,b_i}$ , such that

$$s^{n,j} = \bigcup_{e \in s} \left( \{e^{n,j}\} \cup \left( \bigcup_{j' \neq j} \{e^{p,j'}\} \right) \right)$$

(for each  $j$ , we define  $S_{i-1}^{n,j} := \{s^{n,j} \mid s \in S_{i-1}\}$ ). These copies are called the *negative* copies of sets.

Note that holds that  $|S_i| = 2b_i \cdot |S_{i-1}| = 4i \cdot |S_{i-1}|$ . Combined with the fact that  $|S_0| = 1$ , for every  $i$  we have  $|S_i| = m_i$ , as required by Lemma 3.1.

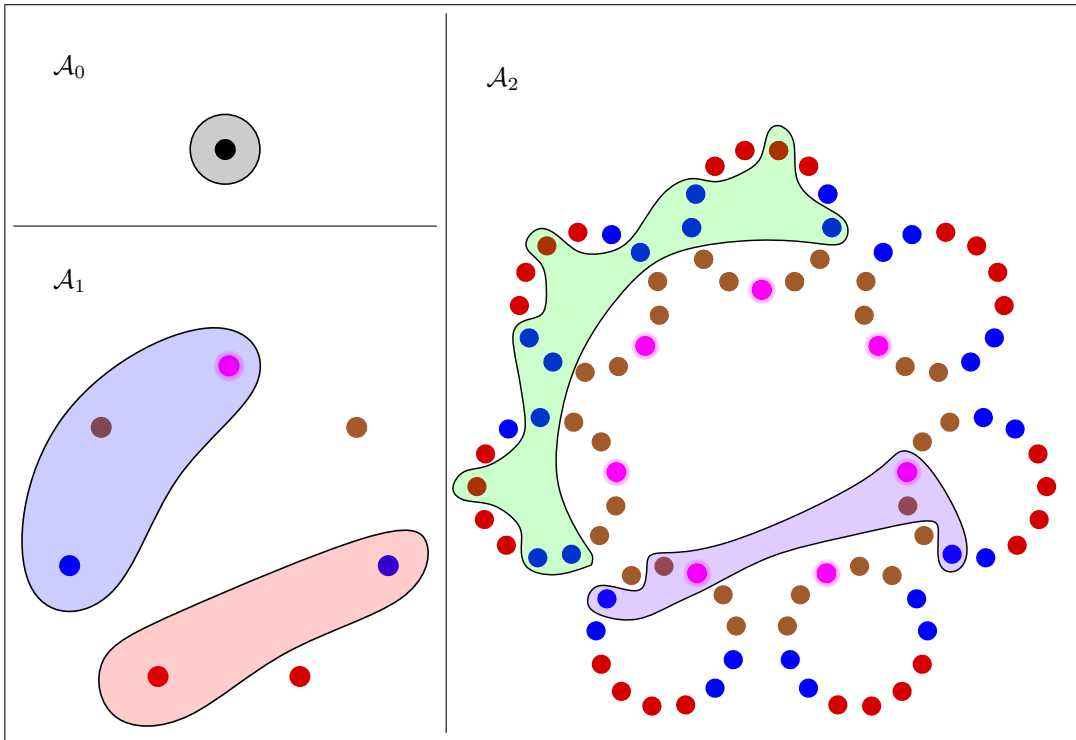

Figure 2 shows some (not all) of the sets in  $\mathcal{A}_0$ ,  $\mathcal{A}_1$  and  $\mathcal{A}_2$ . The gray set in  $S_0$  is the only set of that universe. The blue and red sets in  $S_1$  are positive and negative copies of the gray set, respectively. The purple set in  $S_2$  is a positive copy of the red set. The green set in  $S_2$  is a negative copy of the blue set.

### Request sequence of $\mathcal{A}_i$

We now describe the sequence of requests generated by  $\mathcal{A}_i$ .

#### Recursive calls to $\mathcal{A}_{i-1}$

For  $i > 0$ , the adversary  $\mathcal{A}_i$  relies on recursive calls to  $\mathcal{A}_{i-1}$ . Note that the elements  $E_i$  comprise copies of  $E_{i-1}$  ( $E_{i-1}^s, E_{i-1}^{p,j}$ , et cetera). Thus, for any copy  $E'_{i-1}$  of  $E_{i-1}$ , it is well-defined to call  $\mathcal{A}_{i-1}$  on  $E'_{i-1}$ : we release a request on a copy  $e' \in E'_{i-1}$  of  $e \in E_{i-1}$  whenever a request is released on  $e$  by  $\mathcal{A}_{i-1}$ .

■ **Figure 2** Some Example Sets in  $\mathcal{A}_0$ ,  $\mathcal{A}_1$  and  $\mathcal{A}_2$ .

For abbreviation, we use the superscript denoting the copy of the elements on the adversary. For example, calling  $\mathcal{A}_{i-1}^{\mathbf{P},j}$  means calling  $\mathcal{A}_{i-1}$  on the copy  $E_{i-1}^{\mathbf{P},j}$ .

**Adversary time bounds**

As we would like to pack multiple recursive  $\mathcal{A}_{i-1}$  adversaries into one timeline, we would like to bound each  $\mathcal{A}_{i-1}$  by some time interval, so that we can charge the algorithm for solving each  $\mathcal{A}_{i-1}$  disjointly.

Define  $T_i$  for  $i \geq 0$  recursively by  $T_0 = 1$  and  $T_i = 2b_i \cdot T_{i-1}$ . Informally,  $T_i$  defines a time interval which contains  $\mathcal{A}_i$ ; formally, each request  $q$  which  $\mathcal{A}_i$  can possibly release has  $[r_q, d_q] \subseteq [0, T_i]$  (this can be verified for the construction of  $\mathcal{A}_i$  we describe next).

**Requests of  $\mathcal{A}_i$**

For the case that  $i = 0$ , the adversary releases at time 0 a single request  $q$  on the single element in  $E_0$ , such that  $d_q = 1$ .

For the case of  $i > 0$ , the adversary  $\mathcal{A}_i$  is given in Procedure 1; we now provide a verbal description of that procedure. The adversary  $\mathcal{A}_i$  uses  $b_i$  phases, each of which takes  $2T_{i-1}$  time, and makes two recursive calls to  $\mathcal{A}_{i-1}$ . In the beginning of each phase  $k$ , “background” requests are released on the elements in some positive copies of  $E_{i-1}$ , with deadlines at the end of the phase (i.e.  $2T_{i-1}$  time after release). These requests are released on copies of  $E_{i-1}$  whose index is in some set  $M$ , where  $M$  initially consists of all  $b_i$  indices of positive copies of  $E_{i-1}$ . In the first half of each phase, i.e. the first  $T_{i-1}$  time units,  $\mathcal{A}_i$  calls  $\mathcal{A}_{i-1}^{\mathbf{S}}$  (and waits  $T_{i-1}$  time for its completion). Then,  $\mathcal{A}_i$  chooses an index  $j_k$  to remove from  $M$ , and calls  $\mathcal{A}_{i-1}^{\mathbf{N},j_k}$  which occurs in the second half of the phase.

### Intuitive Explanation

The intuition behind this construction of  $\mathcal{A}_i$  is the following. When the online algorithm handles the first recursive call in a phase, it has some choices to make. First, it has the standard choices to make when addressing  $\mathcal{A}_{i-1}$  – that is, which sets from  $S_{i-1}$  to transmit. In addition, for each set in  $S_{i-1}$  that it wishes to transmit, it must choose the appropriate copy from  $S_i$ . Note that the only copies of a set  $s \in S_{i-1}$  which can be used to solve  $\mathcal{A}_{i-1}^s$  are the positive copies, i.e.  $s^{\mathbf{P}:j}$  for some index  $j$ ; moreover, since this first recursive call is on the special copies, *all* choices of  $j$  are possible. (The purpose of the special copies is exactly this: to be at the intersection of positive copies of sets, and force the algorithm to make a choice.)

However, transmitting these positive copies of sets serves an additional purpose – serving the background requests on  $M$ . For this reason, the online algorithm should choose to transmit  $s^{\mathbf{P}:j}$  for some  $j \in M$ . But note that for earlier phases, the set  $M$  is rather large – its size is  $\Omega(i)$ . The size of  $M$  prohibits the algorithm from transmitting every positive copy in  $M$  of every set – otherwise, the algorithm would incur a great cost. Instead, the algorithm must focus on a small subset of  $M$ , which leaves many background requests unsatisfied.

The optimal solution, on the other hand, is provided a “shortcut”: it uses the second recursive call of the phase, which is to  $\mathcal{A}_{i-1}^{\mathbf{n}:j_k}$ , to serve all background requests except for those on  $E_{i-1}^{\mathbf{P}:j_k}$ . The requests on  $E_{i-1}^{\mathbf{P}:j_k}$  are served by the optimal solution in the first recursive call to  $\mathcal{A}_{i-1}^s$ , where the solution only transmits copies from  $S_{i-1}^{\mathbf{P}:j_k}$ . Note that such efficient handling of the background requests cannot be achieved by the online algorithm, since it does not have knowledge of  $j_k$  during the first half of phase  $k$ .

Near the end of a phase, when the online algorithm has (with high probability) a large amount of pending background requests to serve, the algorithm must incur the cost of an (offline) set cover for those pending requests; the only purpose of ancillary element copies is to keep the cost of this offline cover large, which ensures high costs for the algorithm. (Specifically, the ancillary element copies ensure that each positive set copy  $s$  has an element unique to  $s$ , which forces  $s$  to be part of the offline set cover; this is used in Proposition 3.4.)

#### ■ Procedure 1 Adversary $\mathcal{A}_i$ .

---

```

1 Function CREATEINSTANCE
2   Start with  $M \leftarrow \{1, 2, \dots, b_i\}$ .
3   for  $k$  from 1 until  $b_i$  do
4     // Start phase  $k$  at time  $2(k-1)T_{i-1}$ , by releasing background requests and
      calling  $\mathcal{A}_{i-1}^s$ .
5     For every  $j \in M$ , release a request on every element in  $E_{i-1}^{\mathbf{P}:j}$ , with a deadline
      that's  $2T_{i-1}$  time in the future.
6     Call  $\mathcal{A}_{i-1}^s$  and wait  $T_{i-1}$  time until its completion.
7     //  $T_{i-1}$  time after the start of phase  $k$ , call the second  $\mathcal{A}_{i-1}$  on a random
      negative copy of  $E_{i-1}$ .
8     Choose  $j_k \in M$  uniformly at random from  $M$ .
9     Call  $\mathcal{A}_{i-1}^{\mathbf{n}:j_k}$  and wait  $T_{i-1}$  time until its completion.
10    Set  $M \leftarrow M \setminus \{j_k\}$ .

```

---

The timeline of a possible instance created by  $\mathcal{A}_2$  is shown in Figure 3. This figure shows  $b_2 = 4$  phases, each of which contains two calls to  $\mathcal{A}_{i-1}$ . In this figure,  $\mathcal{A}_2$  randomly chose the permutation (4, 2, 1, 3) of the elements of  $[b_2]$ . The arrows above each phase show the release

■ **Figure 3** Request Timeline of  $\mathcal{A}_2$ .

times and deadlines of background requests – these requests are released at the beginning of each phase, and have deadlines at the end of the phase. Above the arrows are the sets of elements on which background requests are released.

### 3.2 Analysis

We now analyze the adversary described above, thus proving Lemma 3.1.

#### The Optimal Solution

The following lemma describes the optimal solution for instances generated by the adversary  $\mathcal{A}_i$ . Not only do they have a low cost relative to the algorithm, but they also buy every set exactly once, which is useful due to recursion.

► **Lemma 3.2.** *For every  $i$ , and for every instance generated by  $\mathcal{A}_i$ , there exists an offline solution that buys every set in  $S_i$  exactly once, and thus has cost  $m_i$ .*

**Proof.** The proof is by induction on  $i$ . For  $i = 0$ , the adversary  $\mathcal{A}_i$  releases a single request on a single element at time 0, with deadline at time 1. Thus, transmitting the single set in  $m$  at any time during the interval  $(0, 1]$  is a feasible solution.

Assume that the lemma holds for  $\mathcal{A}_{i-1}$  – i.e. there exists an offline solution SOL which buys every set in  $S_{i-1}$  exactly once.

Now, consider an instance generated by  $\mathcal{A}_i$ . This instance was generated in  $b_i$  phases, each associated with some index in  $[b_i]$  (the index chosen randomly by  $\mathcal{A}_i$  in this phase). These indices form a permutation on the elements of  $[b_i]$ , and we write them as a sequence  $(j_k)_{k=1}^{b_i}$ , such that  $j_k$  is the index chosen by  $\mathcal{A}_i$  in phase  $k$ .

We now describe an offline solution for the instance generated by  $\mathcal{A}_i$ . Upon phase  $k$ , consider the call to  $\mathcal{A}_{i-1}^s$  in the beginning of the phase. In the original universe of  $\mathcal{A}_{i-1}$ , i.e.  $E_{i-1}$  and  $S_{i-1}$ , the induction hypothesis implies that there exists an offline solution SOL for this instance which transmits every set of  $S_{i-1}$  exactly once. Thus, a solution for  $\mathcal{A}_{i-1}^s$  would be to transmit any positive copy of the set  $s$  whenever SOL transmits  $s$ . Our offline solution to  $\mathcal{A}_i$  will transmit only the positive copies of index  $j_k$ , i.e.  $s^{P,j_k}$  instead of  $s$ .

As for the call to  $\mathcal{A}_{i-1}^{n,j_k}$ , which is the second recursive call in phase  $k$ , we use a similar argument: we use the offline solution SOL for  $\mathcal{A}_{i-1}$  in the original universe of  $\mathcal{A}_{i-1}$ , and transmit  $s^{n,j_k}$  whenever SOL transmits  $j$ .

Observe that this offline solution for the instance generated by  $\mathcal{A}_i$  is feasible:

- The requests inside recursive calls to  $\mathcal{A}_i$  are satisfied from the induction hypothesis.
- The requests outside recursive calls, i.e. the background requests released in the beginning of the phase, are also satisfied: in each phase  $k$ , we transmit all sets in  $S_{i-1}^{P,j_k}$  (which satisfy all requests on  $E_{i-1}^{P,j_k}$ ) and  $S_{i-1}^{n,j_k}$  (which satisfy all requests on  $E_{i-1}^{P,j}$  for every  $j \neq j_k$ ).

Now note that all sets in  $S_i$  are bought exactly once: this is since in phase  $k$  the algorithm buys all sets from  $S_{i-1}^{\mathbf{p},j_k}$  and  $S_{i-1}^{\mathbf{n},j_k}$  exactly once (and no other sets). Since  $(j_k)_{k=1}^{b_i}$  are a permutation of  $[b_i]$ , this yields the desired claim.  $\blacktriangleleft$

## The Cost of the Algorithm

We now bound the expected cost of the algorithm. For every  $i$ , define  $c_i := \frac{i}{8}$ . The main result here is the following lemma.

► **Lemma 3.3.** *For every  $i$ , and for every deterministic online algorithm ALG against the adversary  $\mathcal{A}_i$ , it holds that the expected cost of the algorithm during the interval  $(0, T_i]$  is at least  $c_i \cdot m_i$  (where the expectation is over the random choices of  $\mathcal{A}_i$ ).*

We prove Lemma 3.3 by induction. For the base case of  $i = 0$ , note that this trivially holds for  $\mathcal{A}_i$ : the algorithm must transmit a set during  $(0, 1]$  at cost 1, which is more than  $\frac{1}{8}$ . For every  $i > 0$ , assuming that the lemma holds for  $i - 1$ , we prove the lemma for  $\mathcal{A}_i$ . We also henceforth fix ALG to be the online deterministic algorithm which runs against the adversary  $\mathcal{A}_i$ . Slightly abusing notation, we also use ALG to refer to the cost of the online algorithm during the interval  $(0, T_i]$ ; indeed, costs outside this interval are irrelevant to Lemma 3.3.

First, we show an important property of the universe of  $\mathcal{A}_i$ . For every universe with elements  $E$  and sets  $S$ , denote by  $\text{sc}(E, S)$  the cost of the optimal (classic, offline) set cover solution for this universe. For all (reasonable) universes, buying all sets is a feasible set cover solution; Proposition 3.4 shows that for the universe of  $\mathcal{A}_i$ , buying all sets is in fact the *only* solution.

► **Proposition 3.4.** *For every  $i$ , it holds that  $\text{sc}(E_i, S_i) = m_i$ .*

**Proof of Proposition 3.4.** Clearly, buying each set in  $S_i$  is a feasible solution of cost  $m_i$ . It now show that each set must be bought, which proves the proposition. To this end, we prove that for each set  $s \in S_i$  there exists an element  $e \in E_i$  such that  $e$  is in  $s$ , but in no other set in  $S_i$ . If this indeed holds for each  $s \in S_i$ , each set must be bought, completing the proof.

We prove this claim by induction on  $i$ . For the base case of  $i = 0$  this trivially holds. Now, for  $i > 0$ , assume that for each set  $\bar{s} \in S_{i-1}$  there exists an element in  $E_{i-1}$  which is in  $\bar{s}$  and in no other set in  $S_{i-1}$ .

Now, consider any set  $s \in S_i$ . This set is a copy of some set  $\bar{s} \in S_{i-1}$ , for which the induction hypothesis provides an element  $\bar{e} \in E_{i-1}$  which is in  $\bar{s}$  and not in any other set in  $S_{i-1}$ .

1. If  $s$  is a positive copy of  $\bar{s}$ , i.e.  $s = \bar{s}^{\mathbf{p},j}$  for some  $j$ , then observe the element  $e := \bar{e}^{\mathbf{a},j} \in E_i$ . It holds that  $e$  is in  $s$  but in no other set in  $S_i$ .
2. If  $s$  is a negative copy of  $\bar{s}$ , i.e.  $s = \bar{s}^{\mathbf{n},j}$  for some  $j$ , then observe the element  $e := \bar{e}^{\mathbf{n},j} \in E_i$ . It holds that  $e$  is in  $s$  but in no other set in  $S_i$ .

This completes the proof of the claim, and thus the proposition.  $\blacktriangleleft$

Note again that Proposition 3.4 refers to the offline cost of covering *the universe* of  $\mathcal{A}_i$ ; this is not the same as the cost of the optimal solution against  $\mathcal{A}_i$  (for example, ancillary copies in the universe are never requested by  $\mathcal{A}_i$ , and are only useful for future recursion).

We would now like to give a lower bound for the expected cost of the algorithm at each phase. For every phase  $k$ , let  $\text{ALG}_k$  be the cost of ALG during the phase  $k$ , i.e. during the time interval  $((2k - 2)T_{i-1}, 2kT_{i-1}]$ .

► **Lemma 3.5.** *For every phase  $k$ , it holds that:*

1. *If  $k \leq \frac{b_i}{2}$ , then  $\mathbb{E}[\text{ALG}_k] \geq (c_{i-1} + \frac{1}{4}) \cdot 2m_{i-1}$*
2. *If  $k > \frac{b_i}{2}$ , then  $\mathbb{E}[\text{ALG}_k] \geq c_{i-1} \cdot 2m_{i-1}$*

**Proof.** Fix any phase  $k$ , which starts at time  $\tau := 2(k-1) \cdot T_{i-1}$ . For this proof, fix the set of random choices made by  $\mathcal{A}_i$  until the start of phase  $k$ ; henceforth in the proof the expectations are thus only on random choices from phase  $k$  onwards. Since we bound the expected cost of the algorithm for every possible set of choices made up to phase  $k$  by  $\mathcal{A}_i$ , this lower bound also applies in expectation over those choices.

Let  $M$  denote the value of the variable of the same name in  $\mathcal{A}_i$  at the beginning of phase  $k$  (recall that  $M \subseteq [b_i]$  is a set of indices). Since we have fixed the random choices of  $\mathcal{A}_i$  before phase  $k$ , the set  $M$  is some fixed set.

We divide the transmissions made by the algorithm during the phase into three disjoint parts:

- Part  $P_1$ : transmissions of positive sets during  $(\tau, \tau + T_{i-1}]$  (the first half of the phase).
- Part  $P_2$ : transmissions of negative sets from  $S_{i-1}^{\mathbf{n}, j^k}$  during  $(\tau + T_{i-1}, \tau + 2T_{i-1}]$  (the second half of the phase).
- Part  $P_3$ : transmissions not in  $P_1, P_2$ .

We denote the number of transmissions in  $P_\ell$  (equivalently: the total cost of such transmissions) by  $C_\ell$ .

**Part  $P_1$ .** Observe that the positive sets are the only sets that can be used for  $\mathcal{A}_{i-1}^{\mathbf{s}}$  in the first part of the phase. Also note that intersecting all positive sets with  $E_{i-1}^{\mathbf{s}}$  yields a collection of sets which is identical to  $S_{i-1}$ ; that is, for every set  $s \in \bigcup_j S_{i-1}^{\mathbf{p}, j}$ , there exists a set  $s' \in S_{i-1}$  such that

$$s \cap E_{i-1}^{\mathbf{s}} = \{e^{\mathbf{s}} | e \in s'\}$$

(specifically, the set  $s'$  is such that  $s$  is a positive copy of  $s'$ )

Thus, covering the elements of  $E_{i-1}^{\mathbf{s}}$  with these sets is as hard as covering the elements of  $E_{i-1}$  with  $S_{i-1}$ . Now, recall the induction hypothesis made for Lemma 3.3, which implied that the expected cost of this part of the algorithm is at least  $c_{i-1} \cdot m_{i-1}$ .

**Part  $P_2$ .** Note that the sets of  $S_{i-1}^{\mathbf{n}, j^k}$  are the only sets that contain elements from  $E_{i-1}^{\mathbf{n}, j^k}$ , and are thus the only sets that can be used to serve  $\mathcal{A}_{i-1}^{\mathbf{n}, j^k}$ . Also note that intersecting the sets of  $S_{i-1}^{\mathbf{n}, j^k}$  with the elements  $E_{i-1}^{\mathbf{n}, j^k}$  yields a collection of sets which is identical to  $S_{i-1}$  (in a similar way to the argument for  $P_1$ ) We can thus again apply the induction hypothesis, and see that the expected cost of the algorithm in buying the sets of  $S_{i-1}^{\mathbf{n}, j^k}$  must be at least  $c_{i-1} \cdot m_{i-1}$ .

Combining Parts  $P_1$  and  $P_2$ , we have

$$\mathbb{E}[C_1] + \mathbb{E}[C_2] \geq c_{i-1} \cdot 2m_{i-1} \tag{1}$$

Equation (1) immediately implies the second claim of this lemma. It remains to prove the first claim.

Assume henceforth that  $k \leq \frac{b_i}{2}$ . If it holds that  $\mathbb{E}[C_1] \geq \frac{b_i}{4} \cdot m_{i-1}$ , then since  $\frac{b_i}{4} \cdot m_{i-1} = \frac{i}{2} \cdot m_{i-1} \geq (c_{i-1} + \frac{1}{2})m_{i-1}$ , we have  $\mathbb{E}[C_1] + \mathbb{E}[C_2] \geq (c_{i-1} + \frac{1}{4}) \cdot 2m_{i-1}$ , which completes the proof of the second claim.

We therefore assume henceforth that  $\mathbb{E}[C_1] < \frac{b_i}{4} \cdot m_{i-1}$ .

**Part  $P_3$ .** Consider the background requests of phase  $k$  which were released on  $E_{i-1}^{\mathbf{P},j}$ , for any index  $j \in M$ . As the restriction of  $S_i$  to  $E_{i-1}^{\mathbf{P},j}$  is identical to  $S_{i-1}$ , Proposition 3.4 implies  $\text{sc}(E_{i-1}^{\mathbf{P},j}, S_i) = m_{i-1}$ . Thus, the algorithm has to transmit at least  $m_{i-1}$  sets that contain elements from  $E_{i-1}^{\mathbf{P},j}$  during the phase.

Consider the sets transmitted in Part  $P_1$ . These sets are all positive sets. Each such positive set  $s^{\mathbf{P},j}$ , for some  $j$ , does not contain any positive elements outside  $E_{i-1}^{\mathbf{P},j}$ . Denote by  $C_1^j$  the number of sets from  $S_{i-1}^{\mathbf{P},j}$  transmitted in  $P_1$ , such that  $C_1 = \sum_j C_1^j$ . Then we know that for each  $j \in M$  we have that in  $P_2$  and  $P_3$  together, there must be at least  $m_{i-1} - C_1^j$  transmissions of sets containing elements from  $E_{i-1}^{\mathbf{P},j}$ .

Now, observe that choosing  $j = j_k$ , Part  $C_2$  transmits only sets from  $S_{i-1}^{\mathbf{n},j_k}$ , which do not contain elements from  $E_{i-1}^{\mathbf{P},j_k}$ . This thus yields a lower bound of  $C_3 \geq m_{i-1} - C_1^{j_k}$ .

Overall, we have that:

$$\begin{aligned} \mathbb{E}[C_3] &\geq \sum_{j \in M} \Pr(j_k = j) \cdot \mathbb{E}\left[m_{i-1} - C_1^j \mid j_k = j\right] = \frac{1}{|M|} \sum_{j \in M} \left(m_{i-1} - \mathbb{E}\left[C_1^j \mid j_k = j\right]\right) \\ &= \frac{1}{|M|} \sum_{j \in M} \left(m_{i-1} - \mathbb{E}\left[C_1^j\right]\right) = m_{i-1} - \frac{1}{|M|} \mathbb{E}[C_1] \geq m_{i-1} - \frac{2}{b_i} \mathbb{E}[C_1] \geq \frac{m_{i-1}}{2} \end{aligned}$$

The second equality is due to the fact that  $C_1^j$  is independent of the choice of  $j_k$  (indeed, the choice of  $j_k$  only affects the input from time  $\tau + T_{i-1}$ ). The second inequality is from the fact that  $k \leq \frac{b_i}{2}$ , which implies that  $|M| \geq \frac{b_i}{2}$ . The third inequality is from  $\mathbb{E}[C_1] < \frac{b_i}{4} \cdot m_{i-1}$ . Combining this with Equation (1), we obtain

$$\mathbb{E}[C_1] + \mathbb{E}[C_2] + \mathbb{E}[C_3] \geq 2c_{i-1} \cdot m_{i-1} + \frac{m_{i-1}}{2} = \left(c_{i-1} + \frac{1}{4}\right) \cdot 2m_{i-1} \quad \blacktriangleleft$$

**Proof of Lemma 3.3.** It holds that

$$\begin{aligned} \mathbb{E}[\text{ALG}] &= \sum_{k=1}^{b_i} \mathbb{E}[\text{ALG}_k] \geq \frac{b_i}{2} \left(c_{i-1} + \frac{1}{4}\right) \cdot 2m_{i-1} + \frac{b_i}{2} c_{i-1} \cdot 2m_{i-1} \\ &= \left(c_{i-1} + \frac{1}{8}\right) 2b_i \cdot m_{i-1} = c_i m_i \end{aligned}$$

where the first inequality is due to applying Lemma 3.5 to the phases (using the stronger claim for the earlier phases and the weaker claim for the later phases), and the final equality uses the fact that  $m_i = 2b_i \cdot m_{i-1}$ .  $\blacktriangleleft$

**Proof of Lemma 3.1.** The lemma results immediately from Lemmas 3.2 and 3.3.  $\blacktriangleleft$

### 3.3 Proofs of Theorems

We now use the construction above to prove the main theorems of this paper.

**Proof of Theorem 1.1.** Lemma 3.1 implies that any deterministic algorithm is  $\Omega(i)$ -competitive against  $\mathcal{A}_i$ , which uses a universe of  $\ell_i$  elements and  $m_i$  sets. Yao's principle now implies that for every randomized online algorithm, there exists an instance with  $\ell_i$  and  $m_i$  on which its competitive ratio is  $\Omega(i)$ .

For the set-based bound, note that  $m_i = 4^i \cdot i! \leq (4i)^i$ , which implies  $i \geq \frac{\log m_i}{4 \log i}$ . Now observe that  $m_i \geq 2^i$  and thus  $i \leq \log m_i$ . Together with the previous observation, we have that  $i = \Omega\left(\frac{\log m_i}{\log \log m_i}\right)$ , which yields the desired  $\Omega\left(\frac{\log m}{\log \log m}\right)$ -competitiveness lower bound.

For the element-based bound, note that  $2^i \leq \ell_i \leq (7i)^i$ . A similar argument thus yields that  $i = \Omega\left(\frac{\log \ell_i}{\log \log \ell_i}\right)$ , which gives us the  $\Omega\left(\frac{\log \ell}{\log \log \ell}\right)$ -competitiveness lower bound.  $\blacktriangleleft$

**Proofs of Theorems 1.2 and 1.3.** There exist folklore reductions from set cover to node-weighted Steiner tree and directed Steiner tree, which reduce a set cover instance with  $\ell$  elements and  $m$  sets to graphs with  $\ell + m + 1$  nodes. These reductions carry over to the deadline/delay setting (for a detailed description of these reductions, see e.g. [8]).

Now,  $\mathcal{A}_i$  as described for set cover yields a graph with  $\ell_i + m_i + 1$  nodes, which is at most  $3 \cdot (7i)^i$  nodes (and more than  $2^i$  nodes). Lemma 3.1, together with argument identical to the proof of Theorem 1.1, yield an  $\Omega\left(\frac{\log n}{\log \log n}\right)$  on the competitiveness of any randomized algorithm. ◀

## 4 Discussion and Open Problems

In this paper, we presented nearly-logarithmic lower bounds on competitiveness for some network design problems with deadlines (which therefore also apply to the delay cases). In [8], a framework is shown which solves every network design with deadlines problem using an approximation algorithm for the corresponding offline problem, losing a logarithmic factor in competitiveness; our results thus show that this logarithmic factor is nearly optimal.

However, the problems we consider in this paper might be tougher than other network design problems with deadlines. While our paper shows that logarithmic loss in approximation ratio is necessary for the general case, there exist many network design problems for which no superconstant lower bound on competitiveness exists. Examples of such problems with deadlines are (edge-weighted) Steiner tree and Steiner forest, facility location, and multicut. Resolving the competitive ratio for these problems remains an interesting open problem.

## Abstract

A version of time-bounded Kolmogorov complexity, denoted  $KT$ , has received attention in the past several years, due to its close connection to circuit complexity and to the Minimum Circuit Size Problem  $MCSP$ . Essentially all results about the complexity of  $MCSP$  hold also for  $MKTP$  (the problem of computing the  $KT$  complexity of a string). Both  $MKTP$  and  $MCSP$  are hard for  $SZK$  (Statistical Zero Knowledge) under  $BPP$ -Turing reductions; neither is known to be  $NP$ -complete.

Recently, some hardness results for  $MKTP$  were proved that are not (yet) known to hold for  $MCSP$ . In particular,  $MKTP$  is hard for  $DET$  (a subclass of  $P$ ) under nonuniform  $\leq_m^{NC^0}$  reductions. In this paper, we improve this, to show that  $\overline{MKTP}$  is hard for the (apparently larger) class  $NISZK_L$  under not only  $\leq_m^{NC^0}$  reductions but even under projections. Also  $\overline{MKTP}$  is hard for  $NISZK$  under  $\leq_m^{P/poly}$  reductions. Here,  $NISZK$  is the class of problems with non-interactive zero-knowledge proofs, and  $NISZK_L$  is the non-interactive version of the class  $SZK_L$  that was studied by Dvir et al.

As an application, we provide several improved worst-case to average-case reductions to problems in  $NP$ , and we obtain a new lower bound on  $MKTP$  (which is currently not known to hold for  $MCSP$ ).

## 1 Introduction

The study of time-bounded Kolmogorov complexity is tightly connected to the study of circuit complexity. Indeed, the measure that we study most closely in this paper, denoted  $KT$ , was initially defined in order to capitalize on the framework of Kolmogorov complexity in investigations of the Minimum Circuit Size Problem ( $MCSP$ ) [4]. If  $f$  is a bit string of length  $2^k$  representing the truth-table of a  $k$ -ary Boolean function, then  $KT(f)$  is polynomially

related to the size of the smallest circuit computing  $f$ . Thus the problem of computing KT complexity (denoted MKTP) was initially viewed as a more-or-less equivalent encoding of MCSP, and it is still the case that all theorems that have been proved about the complexity of MCSP hold also for MKTP (such as those in [5, 9, 10, 17, 21–24, 30, 31, 33, 34]).

In recent years, however, a few hardness results were proved for MKTP that are not yet known to hold for MCSP [7, 8]. We believe that these results can be taken as an indication of what is likely to be true also for MCSP. The present work gives significantly improved hardness results for MKTP.

Reducibility and completeness are the most effective tools in the arsenal of complexity theory for giving evidence of intractability. However, it is not clear whether MCSP or MKTP is NP-complete; neither can be shown to be NP-complete – or even hard for ZPP – under the usual  $\leq_m^P$  reductions without first showing that  $\text{EXP} \neq \text{ZPP}$ , a long-standing open problem [17, 31].

The strongest hardness results that have been proved thus far for MCSP and MKTP are that both are hard for SZK under BPP-Turing reductions [5]. SZK is the class of problems that have Statistical Zero Knowledge Interactive Proofs, and contains many problems of interest to cryptographers. Indeed, if MCSP (or MKTP) is in P/poly, then there are no cryptographically-secure one-way functions [26].

Our main results involve improving the hardness results for MKTP, by reducing the number of queries from polynomially-many, to one. In the paragraphs that follow, we explain the sense in which we accomplish this goal. Along the way, we also obtain a new circuit lower bound for MKTP; it remains unknown whether this circuit lower bound also holds for MCSP.

SZK is not known to be contained in NP; until such a containment can be established, there is no hope of improving the BPP-Turing reduction of [5] to a  $\leq_m^P$  reduction. But we come close in this paper. NISZK is the “non-interactive” subclass of SZK; it contains intractable problems if and only if SZK does [18]. We show that  $\overline{\text{MKTP}}$  is hard for NISZK under  $\leq_m^{P/\text{poly}}$  reductions. (Thus, instead of asking many queries, as in [5], a single query suffices.<sup>1</sup>) Our proof also shows that MKTP is hard for NISZK under BPP reductions that ask only one query. Combined with [18], this shows that MKTP is hard for SZK under *non-adaptive* BPP reductions, yielding a modest improvement over [5]; this has implications regarding the study of worst-case to average-case reductions. (See Section 1.1.)

But  $\leq_m^{P/\text{poly}}$  reductions are still quite powerful. There is great interest currently in proving lower bounds for MCSP, MKTP, and related problems such as MKtP (the problem of computing a different kind of time-bounded Kolmogorov complexity, due to Levin [28]) on very limited classes of circuits and formulae, as part of the “hardness magnification” program. For instance, if modest lower bounds can be shown on the size required to compute MKtP on de Morgan formulae augmented with PARITY gates at the leaves, then EXP is not contained in non-uniform  $\text{NC}^1$  [32]. Also, there is great interest in finding lower bounds against a variety of other models, such as depth-three threshold gates, or circuits consisting of polynomial threshold gates [27]. If a lower bound is known against one of these limited classes of circuits for some problem  $A$  that is reducible to, say, MKTP or MKtP under  $\leq_m^{P/\text{poly}}$  reductions, it implies nothing about the complexity of MKTP or MKtP, since the circuitry involved in computing the reduction is much more powerful than the circuitry in the class of circuits for which the lower bound is known.

---

<sup>1</sup> Some readers may have mistakenly believed that we view our work as a step toward showing that MKTP (or MCSP) is hard for SZK under (uniform)  $\leq_m^P$  reductions. We do not. In fact, some of us doubt that hardness under uniform deterministic reductions holds.

Thus there is a great deal of interest in considering reductions that are much less powerful than  $\leq_m^{P/poly}$  reductions. For extremely weak (uniform) notions of reducibility (such as log-time reductions), it is known that MCSP and MKTP are *not* hard for any complexity class that contains the PARITY function [31]. However, this non-hardness result relies on uniformity; it was later shown that MKTP is hard for the complexity class DET under *nonuniform*  $\leq_m^{NC^0}$  reductions [8].

However, even  $\leq_m^{NC^0}$  reductions are too powerful a tool, when one is interested in lower bounds against the classes of circuits discussed above, since they do not seem to be closed under  $\leq_m^{NC^0}$  reductions. This motivates consideration of the most restrictive type of reduction that we will be considering: projections.

A projection is a reduction that is computed by a circuit consisting only of wires and NOT gates. Each output bit is either a constant, or is connected by a wire to a (possibly negated) input bit. All of the classes of circuits mentioned above (and – indeed – most conceivable classes of circuits) are closed under projections.

Prior to our work, the result of [8] showing that MKTP is hard for DET under  $\leq_m^{NC^0}$  reductions was improved, to show that MKTP is hard for DET even under projections [3]. Since DET is a subclass of P, this provides little ammunition when one is seeking to prove that MKTP is intractable. One of our main contributions is to show that  $\overline{\text{MKTP}}$  is hard for  $\text{NISZK}_L$  under projections. As a corollary, we obtain that MKTP cannot be computed by THRESHOLD $\circ$ MAJORITY circuits of size  $2^{n^{o(1)}}$ . This lower bound relies on the fact that MKTP is hard under projections.

The reader will not be familiar with  $\text{NISZK}_L$ ; this complexity class makes its first appearance in the literature here. It is the “non-interactive” counterpart to the complexity class  $\text{SZK}_L$  that was studied previously by Dvir et al. [15], and was shown there to contain several important natural problems of interest to cryptographers (such as Discrete Log and Decisional Diffie-Hellman).  $\text{NISZK}_L$  contains intractable problems if and only if  $\text{SZK}_L$  does (see Section 2). Thus, for the first time, we show that MKTP is hard under projections for a complexity class that is widely believed to contain intractable problems. Our hardness results carry over immediately to MKtP and to similar problems defined in terms of general Kolmogorov complexity; no hardness results under projections had been known previously for those problems. We present some complete problems for  $\text{NISZK}_L$  and establish some other basic facts about this class in Section 4.

## 1.1 Average-Case Complexity

Building on the techniques introduced in [20], we are able to establish new insights regarding the relationship between worst-case and average-case complexity. In Theorem 35, capitalizing on the fact that essentially every circuit complexity class  $\mathcal{C}$  is closed under projections, we show that if  $\text{NISZK}_L$  does not lie in  $\text{OR} \circ \mathcal{C}$ , then there are problems  $A$  in NP that cannot be solved *in the average case* by errorless heuristics in  $\mathcal{C}$ . For instance, if one were able to show that there is *any* problem  $\text{NISZK}_L$  (including, but not limited to, some of the candidate one-way functions believed to reside there) that cannot be solved *in the worst case* by depth-four  $\text{ACC}^0$  circuits, it would follow that there are problems in NP that are hard-on-average for depth-three  $\text{ACC}^0$  circuits. Such conclusions would *not* follow if our reductions to MKTP had merely been computable in  $\text{AC}^0$  or  $\text{NC}^0$ .

We are also able to shed more light on worst-case to average-case reductions, in the form that they were studied by Bogdanov and Trevisan [14]. Bogdanov and Trevisan showed that there were severe limits on the complexity of problems whose worst-case complexity could be reduced to the average-case complexity of problems in NP via *non-adaptive* reductions; all such problems lie in  $\text{NP/poly} \cap \text{coNP/poly}$ . But it was not known how large this class of

problems could be. Hirahara showed that every problem in SZK has an *adaptive* worst-case to average-case reduction to a problem in NP [20], but the upper bound of  $\text{NP/poly} \cap \text{coNP/poly}$  proved by Bogdanov and Trevisan does not apply for adaptive reductions. As a consequence of our Corollary 17, showing that MKTP is hard for SZK under nonadaptive BPP reductions, we are able to show (in Corollary 37) that the class identified by Bogdanov and Trevisan lies in the narrow range between SZK and  $\text{NP/poly} \cap \text{coNP/poly}$ .

► **Remark.** This is an illustration of the utility of studying MKTP, as an example of a theorem that does not explicitly mention MKTP or MCSP, but which was proved via the study of MKTP. No such argument based on MCSP is known. We believe that MKTP can in fact be viewed as a *particularly convenient* formulation of MCSP, since (a) KT complexity is closely related to circuit size, (b) essentially all theorems known to hold for MCSP also hold for MKTP, (c) some arguments that one might intend to formulate in terms of MCSP elude current approaches, but can instead be successfully carried through by use of MKTP. Furthermore, theorems proved for MKTP may serve as an indication of what is likely to be true for MCSP as well.

The rest of the paper is organized as follows: Our  $\leq_m^{\text{P/poly}}$ -hardness theorem for MKTP is proved in Section 3. Then, after establishing some basic facts about  $\text{NISZK}_L$  in Section 4, in Section 5 we show that  $\overline{\text{MKTP}}$  is hard for  $\text{NISZK}_L$  under projections. We present applications of our reductions and implications for average-case complexity in Section 6.

Due to space limitations, some proofs have been omitted from the version of this work that appears in the ISAAC proceedings. The interested reader is encouraged to consult [6] for complete details.

## 2 Preliminaries

### 2.1 Complexity Classes and Reducibilities

We assume familiarity with the complexity classes P, NP, L, BPP, and P/poly. We also make use of the circuit complexity classes  $\text{AC}^0$  and  $\text{NC}^0$ . For the purposes of this paper,  $\text{AC}^0$  can be understood as the set of problems for which there is a family of circuits  $\{C_n : n \in \mathbb{N}\}$  with unbounded-fan-in AND and OR gates (and NOT gates of fan-in 1) of polynomial size and constant depth.  $\text{NC}^0$  is defined similarly, but with AND and OR gates of bounded fan-in (and thus each output bit depends on only a constant number of bits of the input). We deal primarily with the “nonuniform” versions of these complexity classes (which means that the mapping  $n \mapsto C_n$  need not be computable).

*Branching programs* are a circuit-like model of computation that can be used to characterize logspace computation. A *branching program* is a directed acyclic graph with a single source and two sinks labeled 1 and 0, respectively. Each non-sink node in the graph is labeled with a variable in  $\{x_1, \dots, x_n\}$  and has two edges leading out of it: one labeled 1 and one labeled 0. A branching program computes a Boolean function  $f$  on input  $x = x_1 \dots x_n$  by first placing a pebble on the source node. At any time when the pebble is on a node  $v$  labeled  $x_i$ , the pebble is moved to the (unique) vertex  $u$  that is reached by the edge labeled 1 if  $x_i = 1$  (or by the edge labeled 0 if  $x_i = 0$ ). If the pebble eventually reaches the sink labeled  $b$ , then  $f(x) = b$ . Branching programs can also be used to compute functions  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$ , by concatenating  $n$  branching programs  $p_1, \dots, p_n$ , where  $p_i$  computes the function  $f_i(x) =$  the  $i$ -th bit of  $f(x)$ . For more information on the definitions, backgrounds, and nuances of these complexity classes, circuits, and branching programs, see the text by Vollmer [35].

A *promise problem*  $\Pi$  is a pair of disjoint sets  $(\Pi_{\text{YES}}, \Pi_{\text{NO}})$ . A *solution* to a promise problem is any set  $A$  such that  $\Pi_{\text{YES}} \subseteq A$  and  $\Pi_{\text{NO}} \subseteq \overline{A}$ . A *don't-care instance* of  $\Pi$  is any string that is not in  $\Pi_{\text{YES}} \cup \Pi_{\text{NO}}$ . A *language*  $A$  can be viewed as a promise problem that has no don't-care instances.

Given any class  $\mathcal{C}$  of functions, there is an associated notion of  $m$ -reducibility or *many-one reducibility*: For two languages  $A$  and  $B$ , we say that  $A \leq_m^{\mathcal{C}} B$  if there is a function  $f$  in  $\mathcal{C}$  such that  $x \in A$  iff  $f(x) \in B$ . This notion of reducibility extends naturally to promise problems, mapping yes-instances to yes-instances, and no-instances to no-instances. The most familiar notion of  $m$ -reducibility is Karp reducibility:  $\leq_m^P$ ; NP-completeness is most commonly defined in terms of Karp reducibility. However, in this paper, we will frequently be reducing problems that are not known to reside in NP to MKTP, which does lie in NP. Thus it is clear that a more powerful notion of reducibility is required. Some of our results are most conveniently stated in terms of  $\leq_m^{P/poly}$  reductions (i.e., reductions computed by nonuniform polynomial-size circuits). We also consider restrictions of  $\leq_m^{P/poly}$  reductions, computed by nonuniform  $AC^0$  and  $NC^0$  circuits:  $\leq_m^{AC^0}$  and  $\leq_m^{NC^0}$ . Finally we also consider *projections* ( $\leq_m^{proj}$ ), which are functions computed by  $NC^0$  circuits that have only NOT gates. That is, in a projection, each output bit is either a constant 0 or 1, or is connected by a wire to an input bit or its negation.

We will also make reference to various types of *Turing reducibility*, which are defined in terms of oracle Turing machines, or in terms of circuit families that are augmented with “oracle gates”. For instance, we say that  $A \leq_T^{BPP} B$  if there is a probabilistic polynomial time oracle Turing machine  $M$  with oracle  $B$  that accepts every  $x \in A$  with probability  $\frac{2}{3}$  and rejects every  $x \in \bar{A}$  with probability  $\frac{2}{3}$ . Note that the computation tree of such a BPP-Turing reduction can contain an exponential number of queries to different elements of  $B$ . Just as  $BPP \subseteq P/poly$ , it also holds that  $A \leq_T^{BPP} B$  implies  $A \leq_T^{P/poly} B$ . Thus, on any input  $x$ , the circuit computing the  $P/poly$ -Turing reduction queries only a polynomial number of elements of  $B$ . It was shown in [5] that every problem in SZK (that is, every problem with a statistical zero knowledge proof system) is  $\leq_T^{BPP}$ -reducible (and hence  $\leq_T^{P/poly}$ -reducible) to MCSP and to MKTP. The question of interest to us here is: Is it necessary to ask so many queries? What can we do if we ask only one query? What can be reduced to MKTP via a  $\leq_m^{P/poly}$  reduction?

The complexity class with which we are primarily concerned in this paper is the class of problems that have non-interactive statistical zero knowledge proof systems: NISZK. NISZK was originally defined and studied by Blum et al. [13]. The definition below (in terms of promise problems) is due to Goldreich et al. [18].

► **Definition 1.** A non-interactive statistical zero-knowledge proof system for a promise problem  $\Pi$  is defined by a triple of probabilistic machines  $P$ ,  $V$ , and  $S$ , where  $V$  and  $S$  are polynomial-time and  $P$  is computationally unbounded, and a polynomial  $r(n)$  (which will give the size of the random reference string  $\sigma$ ), such that:

1. (Completeness) For all  $x \in \Pi_{YES}$ , the probability that  $V(x, \sigma, P(x, \sigma))$  accepts is at least  $1 - 2^{-|x|}$ .
2. (Soundness) For all  $x \in \Pi_{NO}$ , the probability that  $V(x, \sigma, P(x, \sigma))$  accepts is at most  $2^{-|x|}$ .
3. (Zero Knowledge) For all  $x \in \Pi_{YES}$ , the statistical distance between the following two distributions bounded by  $1/\beta(|x|)$ 
  - a. Choose  $\sigma$  uniformly from  $\{0, 1\}^{r(|x|)}$ , sample  $p$  from  $P(x, \sigma)$ , and output  $(p, \sigma)$ .
  - b.  $S(x)$  (where the coins for  $S$  are chosen uniformly at random.)

where  $\beta(n)$  is superpolynomial, and the probabilities in Conditions 1 and 2 are taken over the random coins of  $V$  and  $P$ , and the choice of  $\sigma$  uniformly from  $\{0, 1\}^{r(n)}$ .

NISZK is the class of promise problems for which there is a non-interactive statistical zero knowledge proof system.

NISZK is not known to be closed under complementation; co-NISZK is defined as the class of promise problems  $\Pi = (\Pi_{YES}, \Pi_{NO})$  such that  $(\Pi_{NO}, \Pi_{YES})$  is in NISZK. It is known that  $SZK = NISZK$  iff  $NISZK = \text{co-NISZK}$ , and that every promise problem in SZK efficiently (and non-adaptively) Turing-reduces to a problem in NISZK [18]. Thus NISZK contains intractable problems if and only if SZK does.

A subclass of SZK, which we will denote by  $SZK_L$ , in which the verifier  $V$  and simulator  $S$  are restricted to being logspace machines, was defined and studied by Dvir et al. [15]. Among other things, they showed that many of the important natural problems in SZK lie in  $SZK_L$ , including Graph Isomorphism, Quadratic Residuosity, Discrete Log, and Decisional Diffie-Helman. The non-interactive version of  $SZK_L$ , which we denote by  $NISZK_L$ , has not been studied previously, but it figures prominently in our results.

► **Definition 2.** *The formal definition of  $NISZK_L$  is obtained by replacing each occurrence of “polynomial-time” in Definition 1 with “logspace”. (It is important to note that, in this model, the logspace-bounded verifier  $V$  and simulator  $S$  are allowed two-way access to the reference string  $\sigma$  and to their polynomially-long sequences of probabilistic coin flips.)*

The reduction presented in [18] carries over directly to the logspace setting, showing that  $NISZK_L$  contains intractable problems if and only if  $SZK_L$  does. In particular, we have:

► **Proposition 3.** *Every promise problem in  $SZK_L$  is non-adaptively  $AC^0$ -Turing-reducible to a problem in  $NISZK_L$ .*

■ **Figure 1** Diagram showing the classes NISZK, co-NISZK, and SZK. The shaded oval represents NP. Every problem in co-NISZK is  $\leq_m^{P/poly}$ -reducible to MKTP.

## 2.2 KT Complexity

The measure KT was defined in [4]. We provide a reproduction of that definition below.

► **Definition 4 (KT).** *Let  $U$  be a universal Turing machine. For each string  $x$ , define  $KT_U(x)$  to be*

$$\min\{|d| + T : (\forall \sigma \in \{0, 1, *\}) (\forall i \leq |x| + 1) U^d(i, \sigma) \text{ accepts in } T \text{ steps iff } x_i = \sigma\}$$

*We define  $x_i = *$  if  $i > |x|$ ; thus, for  $i = |x| + 1$  the machine accepts iff  $\sigma = *$ . The notation  $U^d$  indicates that the machine  $U$  has random access to the description  $d$ .*

To understand the motivation for this definition, see [4]. Briefly: KT is a version of time-bounded Kolmogorov complexity that (in contrast to other notions of resource-bounded Kolmogorov complexity that have been considered) is polynomially-related to circuit complexity. The minimum KT problem, henceforth MKTP, is defined below.

► **Definition 5 (MKTP).** *Suppose  $y \in \{0, 1\}^n$  and  $\theta \in \mathbb{N} \setminus \{0\}$ , then*

$$\text{MKTP} = \{(y, \theta) \mid \text{KT}(y) \leq \theta\}.$$

*In this paper when we view MKTP as a promise problem, yes-instances will be considered those that are in the language, and no-instances those that are not in the language.*

### 3 MKTP is Hard For NISZK

In this section, we prove our first hardness result for MKTP; MKTP is hard for co-NISZK under  $\leq_m^{\text{P/poly}}$  reductions. In order to prove hardness, it suffices to provide a reduction from the *entropy approximation* problem: EA, which is known to be complete for NISZK under  $\leq_m^{\text{P}}$  reductions [18].

► **Definition 6 (Promise-EA).** *Let a circuit  $C : \{0, 1\}^m \rightarrow \{0, 1\}^n$  represent a probability distribution  $X$  on  $\{0, 1\}^n$  induced by the uniform distribution on  $\{0, 1\}^m$ . We define Promise-EA to be the promise problem*

$$\begin{aligned} \text{EA}_{\text{YES}} &= \{(C, k) \mid H(X) > k + 1\} \\ \text{EA}_{\text{NO}} &= \{(C, k) \mid H(X) < k - 1\} \end{aligned}$$

where  $H(X)$  denotes the entropy of  $X$ .

We will make use of some machinery that was developed in [7], in order to relate the entropy of a distribution to the KT complexity of samples taken from the distribution. However, these tools are only useful when applied to distributions that are sufficiently “flat”. The next subsection provides the necessary tools to “flatten” a distribution.

#### 3.1 Flat Distributions

A distribution is considered *flat* if it is uniform on its support. Goldreich et al. [18] formalized a relaxed notion of flatness, termed  $\Delta$ -flatness, which relies on the concept of  $\Delta$ -typical elements. The definitions of both concepts follow:

► **Definition 7 ( $\Delta$ -typical elements).** *Suppose  $X$  is a distribution with element  $x$  in its support. We say that  $x$  is  $\Delta$ -typical if,*

$$2^{-\Delta} \cdot 2^{-H(X)} < \Pr[X = x] < 2^{\Delta} \cdot 2^{-H(X)}.$$

► **Definition 8 ( $\Delta$ -flatness).** *Suppose  $X$  is a distribution. We say that  $X$  is  $\Delta$ -flat if for every  $t > 0$  the probability that an element of the support,  $x$ , is  $t \cdot \Delta$ -typical is at least  $1 - 2^{-t^2+1}$ .*

► **Lemma 9 (Flattening Lemma, [18]).** *Suppose  $X$  is a distribution such that for all  $x$  in its support  $\Pr[X = x] \geq 2^{-m}$ . Then  $X^k$  is  $(\sqrt{k} \cdot m)$ -flat.*

Observe that if  $X$  is a distribution represented by a circuit  $C : \{0, 1\}^m \rightarrow \{0, 1\}^n$ , then the hypothesis of the Flattening Lemma holds for  $m$ . Note also that, for any distribution  $X$ ,  $H(X^k) = k \cdot H(X)$ . Thus the entropy of the distribution  $X^k$  grows linearly with respect to  $k$ , while the deviation from flatness diminishes much more rapidly with respect to  $k$ .

### 3.2 Encoding and Blocking

The *Encoding Lemma* is the primary tool that was developed in [7] to give short descriptions of samples from a given distribution. Below, we give a precise statement of the version of the Encoding Lemma that is stated informally as Remark 4.3 of [7]. (Although the statement there is informal, the proof of the Encoding Lemma that is given there does yield our Lemma 11.) First, we need to define  $\Lambda$ -encodings.

► **Definition 10** ( $\Lambda$ -encodings). *Let  $R : S \rightarrow T$  be a random variable that induces a distribution  $X$ . The  $\Lambda$ -heavy elements of  $T$  are those elements  $\lambda$  such that  $\Pr[X = \lambda] > 1/2^\Lambda$ . A  $\Lambda$ -encoding of  $R$  is given by a mapping  $D : [N] \rightarrow S$  such that for every  $\Lambda$ -heavy element  $\lambda$ , there exists  $i \in [N]$  such that  $R(D(i)) = \lambda$ . We refer to  $\lceil \log(N) \rceil$  as the length of the encoding. The function  $D$  is also called the decoder for the encoding.*

► **Lemma 11** (Encoding Lemma). *[7, Lemma 4.1] Consider an ensemble  $\{R_x\}$  of random variables that sample distributions on strings of some length  $\text{poly}_1(|x|)$ , where there are circuits  $C_x$  of size  $\text{poly}_2(|x|)$  representing each  $R_x$ . Then there is a polynomial  $\text{poly}_3$  such that, for every integer  $\Lambda$ , each  $R_x$  has a  $\Lambda$ -encoding of length  $\Lambda + \log(\Lambda) + O(1)$  that is decodable by circuits of size  $\text{poly}_3(|x|)$ .*

By itself, the Encoding Lemma says nothing about KT complexity. The other important ingredient in the toolbox developed in [7] is the *Blocking Lemma*, which refers to the process of chopping a string into blocks. Let  $y$  be a string of length  $tn$ , which we think of as being the concatenation of  $t$  samples  $y_i$  of a distribution  $X$  on strings of length  $n$ . Thus  $y = y_1 \dots y_t$ . Let  $r = \lceil t/b \rceil$ . Equivalently, we consider  $y$  to be equal to  $z_1 \dots z_r$  where each  $z_i$  is a string of length  $bn$  sampled according to  $X^b$ . (In the case when  $|y|$  is not a multiple of  $b$ ,  $z_r$  is shorter; this does not affect the analysis. We call the strings  $z_i$  the *blocks* of  $y$ .)

► **Lemma 12** (Blocking Lemma). *[7, Lemma 3.3] Let  $\{T_x\}$  be an ensemble of sets of strings such that all strings in  $T_x$  have the same length  $\text{poly}(|x|)$ . Suppose that for each  $x \in \{0, 1\}^*$  and for each  $b \in \mathbb{N}$  there is an integer  $\Lambda_b$  and a random variable  $R_{x,b}$  whose image contains  $(T_x)^b$ , and such that  $R_{x,b}$  is computable by a circuit of size  $\text{poly}(|x|, b)$  and has a  $\Lambda_b$ -encoding of length  $s'(x, b)$  decodable by a circuit of size  $\text{poly}(|x|, b)$ . Then there are constants  $c_1$  and  $c_2$  so that, for every constant  $\alpha > 0$ , every  $t \in \mathbb{N}$ , every sufficiently large  $x$ , and every  $\lceil t^\alpha \rceil$ -suitable  $y \in (T_x)^t$ ,*

$$\text{KT}(y) \leq t^{1-\alpha} \cdot s'(x, \lceil t^\alpha \rceil) + t^{\alpha c_1} \cdot |x|^{c_2}.$$

Here, we say that  $y \in (T_x)^t$  is  $b$ -suitable if each block of  $y$  (of length  $bn$ ) is  $\Lambda_b$ -heavy.

With the Encoding and Blocking Lemmas in hand, we can now show how to give upper and lower bounds on the KT complexity of concatenated samples from a distribution. The following lemma gives the upper bound.

► **Lemma 13.** *Suppose  $X$  is a distribution sampled by a circuit  $C_x : \{0, 1\}^m \rightarrow \{0, 1\}^n$  of size polynomial in  $|x|$ . For every polynomial  $w = w(|x|)$  with  $|x| \leq w$ , there exist constants  $c_0, c_2$ , and  $\alpha_0$  such that for every sufficiently large polynomial  $t$  and for all large  $x$ , if  $y$  is the concatenation of  $t$  samples from  $X$ , then with probability at least  $(1 - 1/2^{2^{|x|}})$ ,*

$$\text{KT}(y) \leq tH(X) + wm(t^{1-\alpha_0/2}) + t^{1-\alpha_0}|x|^{c_0+c_2}$$

We now turn to a lower bound on  $\text{KT}(y)$ .

► **Lemma 14.** Let  $\text{poly}(|x|)$  denote some fixed polynomial in  $|x|$ , and let  $\alpha_0$  be such that  $0 < \alpha_0 < 1/2$ . For all large  $x$ , if  $X$  is a distribution sampled by a circuit  $C_x : \{0, 1\}^m \rightarrow \{0, 1\}^n$  of polynomial size, then it holds that for every  $w$  and every  $t > w^4$ , if  $y$  is sampled from  $X^t$ , then with probability at least  $1 - 2^{-w^2}$ ,

$$\text{KT}(y) \geq tH(X) - wm\sqrt{t} - t^{1-\alpha_0}\text{poly}(|x|)$$

### 3.3 Reducing co-NISZK to MKTP

► **Theorem 15.** MKTP is hard for co-NISZK under P/poly many-one reductions.

**Proof.** We prove the claim by reduction from the NISZK-complete problem EA. Let  $x = (C_x, k)$  be an arbitrary instance of Promise-EA, where  $C_x : \{0, 1\}^m \rightarrow \{0, 1\}^n$  is a circuit that represents distribution  $X$ . Let  $w = 2|x|$ , and let  $\alpha_0, c_0$ , and  $c_2$  be the constants from Lemma 13. Let  $\lambda = wm t^{1-\alpha_0/2}$ . Pick the polynomial  $t$  so that  $t(|x|) > 2(\lambda + t^{1-\alpha_0}|x|^{c_0+c_2})$  and  $w^4 < t$  (and note that all large polynomials have this property). Construct  $y$  as  $t$  samples from  $X$ . Let  $\theta = tk + \lambda + t^{1-\alpha_0}|x|^{c_0+c_2}$ . We claim that, with probability at least  $1 - \frac{1}{2^{2|x|}}$ , if  $(X, k) \in \text{EA}_{YES}$ , then  $(y, \theta) \in \text{MKTP}_{NO}$  and if  $(X, k) \in \text{EA}_{NO}$ , then  $(y, \theta) \in \text{MKTP}_{YES}$ .

If  $(X, k) \in \text{EA}_{NO}$ , then  $H(X) < k$ . Then by Lemma 13, we have that, with high probability,

$$\begin{aligned} \text{KT}(y) &\leq tH(X) + \lambda + t^{1-\alpha_0}|x|^{c_0+c_2} \\ &< tk + \lambda + t^{1-\alpha_0}|x|^{c_0+c_2} \\ &= \theta \end{aligned}$$

thus  $\text{KT}(y) \leq \theta$ , and thus  $(y, \theta) \in \text{MKTP}_{YES}$ .

If  $(X, k) \in \text{EA}_{YES}$ , then  $H(X) > k + 1$ . Then by Lemma 14, with probability at least  $1 - 2^{-w^2} > 1 - 2^{2|x|}$ , we have that

$$\begin{aligned} \text{KT}(y) &\geq tH(X) - wm\sqrt{t} - t^{1-\alpha_0}|x|^{c_0+c_2}, \\ &> tH(X) - \lambda - t^{1-\alpha_0}|x|^{c_0+c_2} && \text{(since } \alpha_0 < 1/2\text{)} \\ &> t(k+1) - \lambda - t^{1-\alpha_0}|x|^{c_0+c_2} \\ &> tk + \lambda + t^{1-\alpha_0}|x|^{c_0+c_2} && \text{(since } t > 2(\lambda + t^{1-\alpha_0}|x|^{c_0+c_2})\text{)} \\ &= \theta \end{aligned}$$

thus  $\text{KT}(y) > \theta$ , and thus  $(y, \theta) \in \text{MKTP}_{NO}$ .

We have shown that there is a polynomial-time-computable function  $f$ , such that, if  $x \in \text{EA}_{YES}$ , then with high probability (for random  $r$ )  $f(x, r) = (y, \theta)$  is in  $\text{MKTP}_{NO}$ , and if  $x \in \text{EA}_{NO}$ , then with high probability  $f(x, r) = (y, \theta)$  is in  $\text{MKTP}_{YES}$ . By a standard counting argument (similar to the proof that  $\text{BPP} \subseteq \text{P/poly}$ ), since the probability of success for either bound is greater than  $(1 - 1/2^{2^n})$ , we can fix a sequence of random bits to hardwire in to this reduction and obtain a family of circuits computing a  $\leq_m^{\text{P/poly}}$  reduction from any problem in NISZK to  $\overline{\text{MKTP}}$ . ◀

► **Corollary 16.** MKTP is hard for NISZK under BPP reductions that make at most one query along any path of the BPP machine.

**Proof.** This follows from the proof of Theorem 15. Namely, on input  $x = (C_x, k)$ , construct the string  $y$  consisting of  $t$  random samples from  $C_x$  and query the oracle on  $(y, \theta)$ . On Yes-instances,  $y$  will have KT complexity greater than  $\theta$  (with high probability), and on No-instances,  $y$  will have KT complexity less than  $\theta$  (with high probability). ◀

► **Corollary 17.** *MKTP is hard for SZK under non-adaptive BPP-Turing reductions.*

**Proof.** Recall from [18] that SZK reduces to Promise-EA via non-adaptive (deterministic) reductions. The result is now immediate, from Corollary 16. ◀

## 4 A Complete Problem for $\text{NISZK}_L$

Having established a hardness result for MKTP under  $\leq_m^{\text{P/poly}}$  reductions, we now establish an analogous hardness result under the much more restrictive  $\leq_m^{\text{proj}}$  reductions. For this, we first need to present a complete problem for  $\text{NISZK}_L$ .

Recall that the NISZK-complete problem EA deals with the question of approximating the entropy of a distribution represented by a circuit. In order to talk about  $\text{NISZK}_L$ , we shall need to consider probability distributions that are represented using restricted class of circuits. In particular, we shall focus on a problem that we denote  $\text{EA}_{\text{NC}^0}$ .

► **Definition 18** (Promise- $\text{EA}_{\text{NC}^0}$ ). *Promise- $\text{EA}_{\text{NC}^0}$  is the promise problem obtained from Promise-EA, by considering only instances  $(C, k)$  such that  $C$  is a circuit of fan-in two gates, where no output gate depends on more than four input gates.*

It is not surprising that  $\text{EA}_{\text{NC}^0}$  is complete for  $\text{NISZK}_L$ . The completeness proof that we present owes much to the proof presented by Dvir et al. [15] (showing that an  $\text{NC}^0$ -variant of the SZK-complete problem ENTROPYDIFFERENCE is complete for  $\text{SZK}_L$ ) and to the proof presented by Goldreich et al. [18] showing that EA is complete for NISZK. We will need to make use of various detailed aspects of the constructions presented in this prior work, and thus we will present the full details here.

First, we show membership in  $\text{NISZK}_L$ .

### 4.1 Membership in $\text{NISZK}_L$

► **Theorem 19.** *Promise- $\text{EA}_{\text{NC}^0} \in \text{NISZK}_L$*

The following corollary is a direct analog to [18, Proposition 1].

► **Corollary 20.** *If  $\Pi$  is any promise problem that is  $\leq_m^L$  reducible to  $\text{EA}_{\text{NC}^0}$ , then  $\Pi \in \text{NISZK}_L$ .*

We close this section by presenting an example of a well-studied natural problem in  $\text{NISZK}_L$ . (A graph is said to be *rigid* if it has no nontrivial automorphism.)

► **Corollary 21.** *The Non-Isomorphism Problem for Rigid Graphs lies in  $\text{NISZK}_L$*

**Proof.** First note that the proof of Theorem 19 carries over to show that a problem that we may call  $\text{EA}_{\text{BP}}$  (defined just as  $\text{EA}_{\text{NC}^0}$  but where the distribution is represented as a branching program instead of as an  $\text{NC}^0$  circuit) also lies in  $\text{NISZK}_L$ . Now observe that the reduction given in Section 3.1 of [7] shows how to take as input two rigid graphs on  $n$  vertices  $(G_0, G_1)$  and build a branching program that takes as input a bitstring  $w$  of length  $t$  and  $t$  permutations  $\pi_1, \dots, \pi_t$  and output the sequence of  $t$  permuted graphs  $\pi_i(G_{w_i})$ . It is observed in [7] that this distribution has entropy  $t(1 + \log n!)$  if the graphs are non-isomorphic, and has entropy at most  $t \log n!$  otherwise. ◀

## 4.2 Hardness for NISZK<sub>L</sub>

In order to re-use the tools developed in [18], we will follow the structure of the proof given there, showing that EA is hard for NISZK. Namely, we introduce the problem SDU (STATISTICAL DISTANCE FROM UNIFORM) and its NC<sup>0</sup> variant, and prove hardness for SDU<sub>NC<sup>0</sup></sub>.

► **Definition 22** (SDU and SDU<sub>NC<sup>0</sup></sub>). *Consider Boolean circuits  $C_X : \{0, 1\}^m \rightarrow \{0, 1\}^n$  representing distributions  $X$ . The promise problem*

$$\text{SDU} = (\text{SDU}_{YES}, \text{SDU}_{NO})$$

is given by

$$\begin{aligned} \text{SDU}_{YES} &\stackrel{\text{def}}{=} \{C_X : \Delta(X, U_n) < 1/n\} \\ \text{SDU}_{NO} &\stackrel{\text{def}}{=} \{C_X : \Delta(X, U_n) > 1 - 1/n\} \end{aligned}$$

where  $\Delta(X, Y) = \sum_{\alpha} |\Pr[X = \alpha] - \Pr[Y = \alpha]|/2$ .

SDU<sub>NC<sup>0</sup></sub> is the analogous problem, where the distributions  $X$  are represented by NC<sup>0</sup> circuits where no output bit depends on more than four input bits.

It is shown in [18, Lemma 4.1] that  $C_X$  is in SDU if and only if  $(C_X, n - 3)$  is in EA. This yields the following corollary:

► **Corollary 23.**  $\text{SDU}_{\text{NC}^0} \leq_{\text{m}}^{\text{proj}} \text{EA}_{\text{NC}^0}$ .

**Proof.** This is trivial if we assume an encoding of SDU<sub>NC<sup>0</sup></sub> instances, such that the NC<sup>0</sup> circuits  $C_X : \{0, 1\}^m \mapsto \{0, 1\}^n$  are encoded by strings of length given by the standard pairing function  $\frac{m^2 + 3m + 2mn + n + n^2}{2}$ , so that the length of an instance of SDU<sub>NC<sup>0</sup></sub> completely determines  $n$ . (An NC<sup>0</sup> circuit with  $m$  inputs and  $n$  outputs has a description of size  $O(n \log m)$ , and thus it is easy to devise a padded encoding of this much larger length.) Thus, in the projection circuit computing the reduction  $C_X \mapsto (C_X, n - 3)$ , the output bits encoding  $n - 3$  are hardwired to constants, and the input bits encoding  $C_X$  are copied directly to the output. ◀

► **Theorem 24.** *Promise-EA<sub>NC<sup>0</sup></sub> and Promise-SDU<sub>NC<sup>0</sup></sub> are hard for NISZK<sub>L</sub> under  $\leq_{\text{m}}^{\text{proj}}$  reductions.*

**Proof.** By Corollary 23, it suffices to show hardness for SDU<sub>NC<sup>0</sup></sub>. In order to establish hardness, we need to develop the machinery of *perfect randomized encodings*, which were developed by Applebaum et al. [12] and then were applied in the setting of SZK<sub>L</sub> by Dvir et al. [15]. Due to space limitations, we refer the reader to [6] for the discussion of perfect randomized encodings.

### 4.2.1 SDU<sub>NC<sup>0</sup></sub> is Complete for NISZK<sub>L</sub>

We now have all of the tools required to complete the proof of Theorem 24.

Let  $\Pi$  be an arbitrary promise problem in NISZK<sub>L</sub> with proof system  $(P, V)$  and simulator  $S$  and let  $x$  be an instance of  $\Pi$ . Recall that the job of the simulator  $S$  is to take a string  $x$  and some uniformly-generated random bits as input, and produce as output a transcript of the form  $(\sigma, p)$ , such that the probability that any transcript  $(\sigma, p)$  is output by  $S$  is very close to the probability that, on input  $x$  with shared randomness  $\sigma$ , the prover  $P$  sends message  $p$  to the verifier  $V$ . Let  $M_x(s)$  denote a routine that simulates  $S(x)$  with randomness  $s$  to obtain a transcript  $(\sigma, p)$ ; if  $V(x, \sigma, p)$  accepts, then  $M_x(s)$  outputs  $\sigma$ , otherwise it outputs  $0^{|\sigma|}$ . (We can assume without loss of generality that  $|\sigma| = |x|^k$ .) It is shown in [18, Lemma 4.2] that the map  $x \mapsto M_x$  is a reduction of  $\Pi$  to SDU:

## 54:12 Cryptographic Hardness Under Projections for Kolmogorov Complexity

▷ **Claim 25.** If  $x \in \prod_{YES}$ , then  $\Delta(M_x, U_{|x|^k}) < 1/|x|^k$ , and  $x \in \prod_{NO}$  implies  $\Delta(M_x, U_{|x|^k}) > 1 - 1/|x|^k$ .

The proof of the preceding claim in [18, Lemma 4.2] actually shows a stronger result. It shows that, if the statistical difference between the output distribution of the simulator and the distribution of true transcripts is at most  $1/e(n)$ , then the statistical difference of  $M_x$  and the uniform distribution is at most  $1/e(n) + 2^{-n}$  on inputs of length  $n$ . Thus, using Definition 1 (which is equivalent to the definition of NISZK given in [18]), the simulator produces a distribution that differs from the uniform distribution by only  $1/n^{\omega(1)}$ . Thus we have the following claim:

▷ **Claim 26.** Let  $c \in \mathbb{N}$ . Then for all large  $x$ , If  $x \in \prod_{YES}$ , then  $\Delta(M_x, U_{|x|^k}) < 1/|x|^{kc}$ , and  $x \in \prod_{NO}$  implies  $\Delta(M_x, U_{|x|^k}) > 1 - 1/|x|^{kc}$ .

Furthermore, it is also shown in [18, Lemma 3.1] that EA has a NISZK protocol in which the completeness error, soundness error, and simulator deviation are all at most  $2^{-m}$  on inputs of length  $m$ . Furthermore, that proof carries over to show that  $\text{EA}_{\text{BP}} \in \text{NISZK}_L$  with these same parameters. Thus we obtain the following fact, which we will use later in Section 6.

▷ **Claim 27.** Let  $c \in \mathbb{N}$ . Then for all large  $x$ , If  $x$  is a Yes-instance of  $\text{EA}_{\text{BP}}$ , then  $\Delta(M_x, U_{|x|^k}) < 1/2^{|x|^{c-1}}$ , and if  $x$  is a No-instance of  $\text{EA}_{\text{BP}}$ , then  $\Delta(M_x, U_{|x|^k}) > 1 - 1/2^{|x|^{c-1}}$ .

Since  $S$  runs in logspace, each bit of  $M_x(s)$  can be simulated with a branching program  $Q_x$ . Furthermore, it is straightforward to see that there is an  $\text{AC}^0$ -computable function that takes  $x$  as input and produces an encoding of  $Q_x$  as output, and it can even be seen that this function can be a *projection*. (To see this, note that in the standard construction of a Turing machine from a logspace-bounded Turing machine  $S$  (with input  $(x, s)$ ) each node of the branching program has a name that encodes a configuration of the machine, a time step, and the position of the input head. This branching program can be constructed in  $\text{AC}^0$ , given only the *length* of  $x$ . In order to construct  $Q_x$ , it suffices merely to hardwire in the transitions from any node that is “scanning” some bit position  $x_i$ . That is, if the transition out of node  $v$  goes to node  $v_0$  if  $x_i = 0$  and to node  $v_1$  if  $x_i = 1$ , then in the adjacency matrix for  $Q_x$ , entry  $(v, v_1) = x_i$  and entry  $(v, v_0)$  is  $\neg x_i$ . This is clearly a projection.)

Now apply the projection of [6, Lemma 37] to (each output bit of) the branching program  $Q_x$  of size  $\ell$ , to obtain an  $\text{NC}^0$  circuit  $C_x$  computing a perfect randomized encoding with blowup  $b = 2^{|x|^k \binom{\ell}{2} - 1}$ . ( $C_x$  has  $\log b + |x|^k$  output bits.)

Now consider  $|H(C_x) - H(U_{\log b + |x|^k})|$ . By [6, Lemma 28] this is equal to  $|H(Q_x) + \log b - H(U_{\log b + |x|^k})|$ . Since  $H(Q_x) = H(M_x)$  and  $H(U_{\log b + |x|^k}) = \log b + H(U_{|x|^k})$ , we have that  $|H(C_x) - H(U_{\log b + |x|^k})| = |H(M_x) - H(U_{|x|^k})|$ . The proof of Theorem 24 is now complete, by appeal to Claim 26. ◀

## 5 Hardness of MKTP under Projections

► **Theorem 28.** MKTP is hard for  $\text{co-NISZK}_L$  under nonuniform  $\leq_m^{\text{AC}^0}$  reductions.

An immediate corollary (making use of the “Gap Theorem” of [1]) is that MKTP is hard for  $\text{co-NISZK}_L$  under  $\leq_m^{\text{NC}^0}$  reductions. Below, we improve this, showing hardness under projections.

► **Corollary 29.** MKTP is hard for  $\text{co-NISZK}_L$  under nonuniform  $\leq_m^{\text{NC}^0}$  reductions.

► **Corollary 30.** MKTP is hard for  $\text{co-NISZK}_L$  under nonuniform  $\leq_m^{\text{proj}}$  reductions.

**Proof.** We now need to claim that the  $\text{AC}^0$ -computable reduction of Theorem 28 can be replaced by a projection. Note that, since  $\text{SDU}_{\text{NC}^0}$  is complete for  $\text{NISZK}_L$  under projections, and since the reduction from  $\text{SDU}_{\text{NC}^0}$  to  $\text{EA}_{\text{NC}^0}$  given in Corollary 23 always uses the same entropy bound  $n - 3$ , we have that it suffices to consider  $\text{EA}_{\text{NC}^0}$  instances  $x = (C_x, k)$  where the bound  $k$  depends only on the length of  $x$ . Thus the bound  $\theta$  produced by our  $\text{AC}^0$  reduction also depends only on the length of  $x$ , and hence can be hardwired in.

We now need only consider the string  $y$ . The  $\leq_m^{\text{AC}^0}$  reduction presented in the proof of Theorem 28 takes as input  $C_x$  and  $r$  and produces the bits of  $y$  by feeding bits of  $r$  into  $C_x$ . Let us recall where the  $\text{NC}^0$  circuitry producing the  $i$ -th bit of  $y$  comes from.

[6, Lemma35] shows how to take an arbitrary branching program and encode the problem of whether the program accepts as a question about the entropy of a distribution represented as a matrix of degree-three polynomials. Each term in this matrix is of the form  $\sum_{j,k} R_1(i,k) L(k,j) R_2(j,m)$ , where the matrices  $R_1$  and  $R_2$  are the same for all inputs of the same length. Thus we need only concern ourselves with the matrix  $L$ .

In Section 4.2.1, it is observed that, given an instance  $x$  of a promise problem in  $\text{NISZK}_L$ , the branching program  $Q_x$  that is used, in order to build the matrix  $L$ , can be constructed from  $x$  by means of a projection. The “input” to this branching program  $Q_x$  is a sequence of random bits (part of the random sequence  $r$  that is hardwired in, in order to create the nonuniform  $\text{AC}^0$  reduction in the proof of Theorem 28). Thus, the only entries of the matrix  $L$  that depend on  $x$  are entries of the form  $(u, v)$  where  $u$  and  $v$  are configurations of a logspace machine, where the machine is scanning  $x_i$  in configuration  $u$ , and it is possible to move to configuration  $v$ . [6, Lemma 37] then shows how to construct  $\text{NC}^0$  circuitry for each term in the degree-three polynomial constructed from  $Q_x$  in the proof of [6, Lemma 35]. The important thing to notice here is that each output bit in the  $\text{NC}^0$  circuit depends on at most one term of one of the degree-three polynomials, and hence it depends on at most one entry of the matrix  $L$  – which means that it depends on at most one bit of the string  $x$ .

Thus, consider any bit  $y_i$  of the string  $y$  produced by the nonuniform  $\text{AC}^0$  reduction from Theorem 28. Either  $y_i$  does not depend on any bit of  $x$ , or it depends on exactly one bit  $x_j$  of  $x$ . In the latter case, either  $y_i = x_j$  or  $y_i = \neg x_j$ . This defines the projection, as required. ◀

The following corollary was pointed out to us by Rahul Santhanam.

► **Corollary 31.** MKTP does not have  $\text{THRESHOLD} \circ \text{MAJORITY}$  circuits of size  $2^{n^{o(1)}}$ .

**Proof.** This is immediate from the lower bound on the Inner Product mod 2 function that is presented in [16]. (See also [11] for a slightly stronger lower bound.) ◀

It should be noted that it remains unknown whether MCSP has  $\text{THRESHOLD} \circ \text{MAJORITY}$  circuits of polynomial size.

## 6 An Application: Average-Case Complexity

The efficient reductions that we have presented have some immediate applications regarding worst-case to average-case reductions. First, we recall the definition of errorless heuristics:

► **Definition 32.** Let  $A$  be any language. An errorless heuristic for  $A$  is an algorithm (or oracle)  $H$  such that, for every  $x$ ,  $H(x) \in \{\text{YES}, \text{NO}, ?\}$ , and

- $H(x) = \text{YES}$  implies  $x \in A$ .
- $H(x) = \text{NO}$  implies  $x \notin A$ .

## 54:14 Cryptographic Hardness Under Projections for Kolmogorov Complexity

► **Definition 33.** A language  $A$  has no average-case errorless heuristics in  $\mathcal{C}$  if, for every polynomial  $p$ , and every errorless heuristic  $H \in \mathcal{C}$  for  $A$ , there exist infinitely many  $n$  such where  $\Pr_{x \in U_n}[H(x) = ?] > 1 - 1/p(n)$ .

In order to state our first theorem relating to average-case complexity, we need the following circuit-based definition:

► **Definition 34.** Let  $\mathcal{C}$  be any complexity class. (Usually, we will think of  $\mathcal{C}$  being a class defined in terms of circuits, and the definition is thus phrased in terms of circuits, although it can be adapted for other complexity classes as well.) The class  $\text{OR} \circ \mathcal{C}$  is the class of problems that can be solved by a family of circuits whose output gate is an unbounded fan-in OR gate, connected to the outputs of circuits in the class  $\mathcal{C}$ .

If problems in  $\text{NISZK}_L$  are hard in the worst case, then there are problems in NP that are hard on average:

► **Theorem 35.** Let  $\mathcal{C}$  be any complexity class that is closed under  $\leq_m^{\text{proj}}$  reductions. If  $\text{NISZK}_L \not\subseteq \text{OR} \circ \mathcal{C}$ , then there is a set  $A$  in NP that has no average-case errorless heuristics in  $\mathcal{C}$ .

The following definition is implicit in the work of Bogdanov and Trevisan [14].

► **Definition 36.** A worst-case to errorless average-case reduction from a promise problem  $\Pi$  to a language  $A$  is given by a polynomial  $p$  and BPP machine  $M$ , such that  $A$  is accepted by  $M^H$  for every oracle errorless heuristic  $H$  for  $A$  such that  $\Pr_{x \in U_n}[H(x) = ?] < 1 - 1/p(n)$ .

► **Corollary 37.** There is a problem  $A \in \text{NP}$  such that there is a non-adaptive worst-case to errorless average-case reduction from every problem in SZK to  $A$ .

► **Remark.** It is implicitly shown by Hirahara [20] that Corollary 37 holds under *adaptive* reductions. The significance of the improvement from adaptive and non-adaptive reductions lies in the fact that Bogdanov and Trevisan showed that the problems in NP for which there is a non-adaptive worst-case to errorless average-case reduction to a problem in NP lie in  $\text{NP/poly} \cap \text{coNP/poly}$  [14, Remark (iii) in Section 4]. Thus SZK may be close to the largest class of problems for which non-adaptive worst-case to errorless average-case reductions to problems in NP exist.

The worst-case to average-case reductions of Definition 36, must work for *every* errorless heuristic that has a sufficiently small probability of producing “?” as output. If we consider a less-restrictive notion (allowing a different reduction for different errorless heuristics) then in some cases we can lower the complexity of the reduction from BPP to  $\text{AC}^0$ .

► **Definition 38.** Let  $\mathcal{D}$  be a complexity class, and let  $\mathcal{R}$  be a class of reducibilities. We say that errorless heuristics for language  $A$  are average-case hard for  $\mathcal{D}$  under  $\mathcal{R}$  reductions if, for every polynomial  $p$  and every errorless heuristic  $H$  for  $A$  where  $\Pr_{x \in U_{|x|}}[H(x) = ?] < 1 - 1/p(|x|)$ , and for every language  $B \in \mathcal{D}$ , there is a reduction  $r \in \mathcal{R}$  reducing  $B$  to  $H$ .

► **Corollary 39.** There is a language  $A \in \text{NP}$ , such that errorless heuristics for  $A$  are average-case hard for  $\text{SZK}_L$  under non-adaptive  $\text{AC}^0$ -Turing reductions.

► **Corollary 40.** Let  $\mathcal{C}$  be any class that is closed under non-adaptive  $\text{AC}^0$ -Turing reductions. If  $\text{SZK}_L \not\subseteq \mathcal{C}$ , then there is a problem in NP that has no average-case errorless heuristic in  $\mathcal{C}$ .

**Proof.** If  $\text{SZK}_L \not\subseteq \mathcal{C}$ , then by Proposition 3,  $\text{NISZK}_L$  is also not contained in  $\mathcal{C}$ . The result is now immediate from Theorem 35. ◀

► Remark. Building on earlier work of Goldwasser et al. [19], average-case hardness results for some subclasses of  $P$  based on reductions computable by constant-depth threshold circuits were presented in [2]. (Although certain aspects of the reductions presented in [2, 19] are computable in  $AC^0$ , in order to obtain deterministic worst-case algorithms, MAJORITY gates are required in those constructions.) We are not aware of any prior work that provides average-case hardness results based on reductions computable in  $AC^0$ , particularly for classes that are believed to contain problems whose complexity is suitable for cryptographic applications.

## 7 Conclusion and Open Problems

By focusing on non-uniform versions of  $\leq_m^P$  reductions, we have shed additional light on how MKTP relates to subclasses of SZK. Some researchers are of the opinion that MCSP (and MKTP) are likely complete for NP under some type of reducibility, and some recent progress seems to support this [25]. For those who share this opinion, a plausible first step would be to show that MKTP is hard not only for co-NISZK, but also for NISZK, under  $\leq_m^{P/poly}$  reductions. (Work by Lovett and Zhang points out obstacles to providing such a reduction via “black box” techniques [29].) And of course, it will be very interesting to see if our hardness results for MKTP hold also for MCSP.

Duquesne University, Pittsburgh, PA, USA

---

## Abstract

Testing whether the observed data conforms to a purported model (probability distribution) is a basic and fundamental statistical task, and one that is by now well understood. However, the standard formulation, *identity testing*, fails to capture many settings of interest; in this work, we focus on one such natural setting, *identity testing under promise of permutation*. In this setting, the unknown distribution is assumed to be equal to the purported one, up to a relabeling (permutation) of the model: however, due to a systematic error in the reporting of the data, this relabeling may not be the identity. The goal is then to test identity under this assumption: equivalently, whether this systematic labeling error led to a data distribution statistically far from the reference model.

## 1 Introduction

Imagine you painstakingly gathered observations, data point after data point, and managed to form an accurate estimate of the data distribution; unfortunately, you did not record the labels correctly, and due to a systematic error the data labels have been permuted in an unknown and arbitrary way. You did make your best educated guess to fix this though, and are confident the data, once carefully relabeled, *should* reflect the reality. Can you check this, without having to go through the whole process of obtaining an entirely new dataset?

In this paper, we are concerned with a variant of identity testing which captures the above scenario, where one is promised that the unknown distribution is equal to the reference distribution  $\mathbf{q}$  *up to a permutation of the domain*. Formally, the algorithm has access to i.i.d. samples from a probability distribution  $\mathbf{p}$  over a finite domain  $[n] := \{1, 2, \dots, n\}$  such that  $\mathbf{p} \circ \pi = \mathbf{q}$  for some (unknown)  $\pi \in \mathcal{S}_n$ , and, on input  $0 \leq \varepsilon' < \varepsilon \leq 1$ , must output **yes** or **no** such that

- if  $d_{TV}(\mathbf{p}, \mathbf{q}) \leq \varepsilon'$ , then the algorithm outputs **yes** with probability at least  $2/3$ ;
- if  $d_{TV}(\mathbf{p}, \mathbf{q}) > \varepsilon$ , then the algorithm outputs **no** with probability at least  $2/3$ .

When  $\varepsilon' = 0$ , the task is termed *identity testing (under promise of permutation)*; otherwise, it is *tolerant identity testing*. It is worth noting that this permutation promise fundamentally changes the problem, and makes it incomparable to the standard identity testing problem. As an illustrative example, it is known that *uniformity testing*, where the reference distribution  $\mathbf{q}$  is uniform over  $[n]$ , is the “hardest” case of identity testing, with sample complexity  $\Theta(\sqrt{n})$  and  $\Theta(n/\log n)$  for the testing and tolerant testing versions, respectively [18, 22, 23, 13]. However, it is easy to see that under the permutation promise, uniformity testing is a trivial problem which can be solved with *zero* samples: any permutation of the uniform distribution is itself the uniform distribution.

Our results further demonstrate this stark difference, showing how the difficulty of testing and tolerant testing differ under this promise. In particular, we show an exponential gap between the sample complexities of non-tolerant and tolerant identity testing under this promise: to the best of our knowledge, this constitutes the first example of such a gap between the tolerant and non-tolerant version of a problem in distribution testing.

## 1.1 Our results

Our results show that, quite surprisingly, the promise of equality up to permutation of the domain fundamentally changes the sample complexity landscape, and is both qualitatively and quantitatively different from what one could expect from the known bounds on identity and tolerant identity testing without this promise.

Our first set of results indeed establishes that, in contrast to the  $\Theta(\sqrt{n})$  sample complexity of “regular” identity testing, identity testing under promise of permutation has sample complexity merely *polylogarithmic* in the domain size:

► **Theorem 1** (Theorems 5 and 8, (Informal)). *Identity testing under promise of permutation has sample complexity  $\Theta(\log^2 n)$ , where  $n$  is the domain size.*

Given the fact that (regular) tolerant identity testing has sample complexity nearly quadratically higher than (regular) identity testing, one could conjecture that the sample complexity tolerant testing under our promise remains polylogarithmic. Our next set of results shows that this is far from being the case: instead, allowing for some noise tolerance makes the promise of equality up to permutation essentially useless, as the sample complexity blows up *exponentially*, growing from polylogarithmic to nearly linear in the domain size:

► **Theorem 2** (Theorems 8 and 9, (Informal)). *Tolerant identity testing under promise of permutation has sample complexity  $\Theta(n^{1-o(1)})$ , where  $n$  is the domain size.*

We also show that relaxing the tolerance allowed from additive (as in the usual tolerant testing setting) to multiplicative in the distance parameter does not really help, as the sample complexity still remains polynomial:

► **Theorem 3** (Theorem 17, (Informal)). *Multiplicative-factor tolerant identity testing under promise of permutation, where one needs to distinguish between  $\varepsilon$ -close and  $C\varepsilon$ -far, has sample complexity  $\Omega(\sqrt{n})$  for any constant factor  $C > 1$ , where  $n$  is the domain size.*

We emphasize once more that those results, and in particular the lower bounds, do not follow from the known results on standard identity testing, as the promise of equality up to permutation, by strengthening the promise, drastically changes the problem. In particular, the case where the reference  $\mathbf{q}$  is uniform, while known to be the hardest case for identity and tolerant identity testing, is actually a trivially easy case under our promise (as any distribution promised to be a permutation of the uniform distribution is, of course, the uniform distribution itself.)

## 1.2 Previous work

Distribution testing has a long history in Statistics, that one can trace back to the work of Pearson [12]. More recently, from the computer science perspective, Goldreich, Goldwasser, and Ron initiated the field of property testing [14]; of which distribution testing emerged through the seminal work of Batu, Fortnow, Rubinfeld, Smith, and White [2]. We refer the reader to the survey [5] for a review of the area of distribution testing.

Among the problems tackled in this field, *identity testing* (also known as goodness-of-fit or one-sample testing), in which the goal is to decide whether an unknown probability distribution  $\mathbf{p}$  is equal to a purported model  $\mathbf{q}$ , has received significant attention. It is known that for identity testing with any reference distribution  $\mathbf{q}$  over a domain of size  $n$ ,  $\Theta(\sqrt{n})$  samples are necessary and sufficient [18, 7, 1, 23]; moreover, the exact asymptotic dependence on the distance parameter and the probability of error of the test [15, 9], as well as some good understanding of the dependence on the reference distribution  $\mathbf{q}$  itself [23, 4], are now understood. Further, we also have tight bounds for the harder problem where one seeks to allow for some noise in the data (i.e., perform *tolerant* identity testing, where the algorithm has to accept distributions sufficient close to the reference  $\mathbf{q}$ ):  $\Theta(n/\log n)$  samples, a nearly linear dependence on the domain size, are known to be necessary and sufficient [20, 21, 22, 16].

However, how the identity testing problem changes under natural constraints on the input data, or under some variations of the formulation, remains largely unexplored. Among the works concerned with such problems, [3, 8] consider identity testing under monotonicity or  $k$ -modality constraints; and [10] focuses on a broad class of shape constraints on the density. Finally, [6] focuses on a variant of identity testing, “identity up to binning,” where two distributions are considered equal if some binning of the domain can make them coincide. To the best of our knowledge, the question considered in the present work, albeit arguably quite natural, has not been previously considered in the Statistics or distribution testing literature.

**Organization.** We provide in Section 3.1 our algorithm for testing identity under promise of permutation, before complementing it in Section 3.2 by our matching lower bound. Section 4 is then concerned with the upper and lower bounds for the tolerant version of the problem; the bulk of which lies in proving the two lower bounds.

## 2 Preliminaries

Let  $\mathcal{S}_n$  denote the set of permutations of  $[n] := \{1, 2, \dots, n\}$ . We identify a probability distribution  $\mathbf{p}$  over  $[n]$  with its probability mass function (pmf), that is, a function  $\mathbf{p}: [n] \rightarrow [0, 1]$  such that  $\sum_{i=1}^n \mathbf{p}(i) = 1$ . For a subset  $S \subseteq [n]$ , we then write  $\mathbf{p}(S) = \sum_{i \in S} \mathbf{p}(i)$  for the probability mass assigned to  $S$  by  $\mathbf{p}$ . Given two probability distributions  $\mathbf{p}, \mathbf{q}$  over  $[n]$ , their total variation distance is

$$d_{\text{TV}}(\mathbf{p}, \mathbf{q}) = \sup_{S \subseteq [n]} (\mathbf{p}(S) - \mathbf{q}(S)) = \frac{1}{2} \|\mathbf{p} - \mathbf{q}\|_1 \quad (1)$$

where  $\|\mathbf{p} - \mathbf{q}\|_1 = \sum_{i=1}^n |\mathbf{p}(i) - \mathbf{q}(i)|$  is the  $\ell_1$  distance between the two pmfs. In what follows, given a probability distribution  $\mathbf{q}$  over  $[n]$ , we define

$$\Pi_n(\mathbf{q}) := \{ \mathbf{q} \circ \pi : \pi \in \mathcal{S}_n \}, \quad (2)$$

the set of distributions equal to  $\mathbf{q}$  up to permutation of the domain.

Finally, we will rely on the so-called DKW inequality, which roughly states that  $O(1/\varepsilon^2)$  samples from any univariate distribution suffice to learn it to Kolmogorov distance  $\varepsilon$  with high probability: this is a result due to Dvoretzky, Kiefer, and Wolfowitz from 1956 [11] (with the optimal constant due to Massart, in 1990 [17]).

► **Theorem 4 (DKW Inequality).** *Let  $\hat{\mathbf{p}}$  denote the empirical distribution on  $m$  i.i.d. samples from an arbitrary distribution  $\mathbf{p}$  on  $\mathbb{R}$ . Then, for every  $\varepsilon > 0$ ,*

$$\Pr[d_{\text{K}}(\hat{\mathbf{p}}, \mathbf{p}) > \varepsilon] \leq 2e^{-2m\varepsilon^2},$$

where, for two univariate distributions  $\mathbf{p}, \mathbf{q}$ ,  $d_{\text{K}}(\mathbf{p}, \mathbf{q}) = \sup_{x \in \mathbb{R}} |\mathbf{p}((-\infty, x]) - \mathbf{q}((-\infty, x])|$  denotes the Kolmogorov distance between  $\mathbf{p}$  and  $\mathbf{q}$ .

### 3 Testing

In this section, we establish our matching upper and lower bounds for testing under promise of permutation, Theorems 8 and 9.

#### 3.1 Upper bound

We begin by proving our  $O(\log^2 n)$  upper bound for identity testing under promise of permutation.

► **Theorem 5.** *There exists an algorithm (Algorithm 1) which, for any reference distribution  $\mathbf{q}$  over  $[n]$  and any  $0 < \varepsilon \leq 1$ , given  $O\left(\frac{\log^2 n}{\varepsilon^4}\right)$  samples from an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $\mathbf{p} = \mathbf{q}$  and (ii)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon$ .*

**Proof.** We first partition the domain into  $L := O(\log(n/\varepsilon)/\varepsilon)$  buckets  $B_1, \dots, B_L$ , where

$$B_\ell := \left\{ i \in [n] : \frac{1}{(1+\varepsilon/4)^\ell} < \mathbf{q}(i) \leq \frac{1}{(1+\varepsilon/4)^{\ell-1}} \right\}, \quad 1 \leq \ell \leq L-1 \quad (3)$$

and  $B_L := \left\{ i \in [n] : \mathbf{q}(i) \leq \frac{1}{(1+\varepsilon/4)^{L-1}} \right\}$ . Note that since  $\mathbf{q}$  is known, we can exactly compute the partition  $B_1, \dots, B_L$ , and in particular those  $L$  sets can be efficiently obtained.

■ **Algorithm 1** Algorithm for identity testing under promise of permutation.

**Require:** Reference distribution  $\mathbf{q}$ , distance parameter  $\varepsilon \in (0, 1]$ , sample access to  $\mathbf{p} \in \Pi_n(\mathbf{q})$

- 1: Set  $L \leftarrow 1 + \left\lceil \frac{\log(4n/\varepsilon)}{\log(1+\varepsilon/4)} \right\rceil = O\left(\frac{\log(n/\varepsilon)}{\varepsilon}\right)$ ,  $\delta \leftarrow \frac{\varepsilon}{4(L-1)}$
- 2: Compute the bucketing  $B_1, \dots, B_L$ , as in (3)
- 3: Using  $O(1/\delta^2)$  samples from  $\mathbf{p}$ , use the empirical estimator to learn the distribution

$$\hat{\mathbf{p}} := (\mathbf{p}(B_1), \dots, \mathbf{p}(B_L))$$

over  $[L]$  to Kolmogorov distance  $\frac{\delta}{3}$ , with probability of error  $1/10$ . Let  $\hat{\mathbf{p}}$  be the output.

- 4: **if**  $\hat{\mathbf{p}}(B_L) > \frac{3\varepsilon}{8}$  or there exists  $\ell^*$  such that  $|\hat{\mathbf{p}}(\{\ell^*, \dots, L-1\}) - \mathbf{q}(\bigcup_{\ell=\ell^*}^{L-1} B_\ell)| > \frac{\delta}{3}$  **then**
- 5:     **return no**
- 6: **else**
- 7:     **return yes**
- 8: **end if**

For our choice of  $L$ ,  $\frac{1}{(1+\varepsilon/4)^{L-1}} \leq \frac{\varepsilon}{4n}$ , so the last bucket  $B_L$  has small probability mass under the reference distribution:  $\mathbf{q}(B_L) \leq \frac{\varepsilon}{4}$ . Now, distinguishing with high constant probability between  $\mathbf{p}(B_L) \leq \frac{\varepsilon}{4}$  and  $\mathbf{p}(B_L) \geq \frac{\varepsilon}{2}$  can be done with  $O(1/\varepsilon)$  samples, so we can detect a discrepancy in  $B_L$  with high probability if there is one (we will argue this part formally at the end of the proof). Consequently, we hereafter assume that  $\mathbf{p}(B_L) < \frac{\varepsilon}{2}$ .

If  $\mathbf{p} = \mathbf{q}$ , clearly  $\mathbf{p}(B_L) \leq \frac{\varepsilon}{4}$  (so the first check above passes) and  $\mathbf{q}(B_\ell) = \mathbf{p}(B_\ell)$  for all  $1 \leq \ell \leq L-1$ . However, if  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon$ , then  $\sum_{\ell=1}^{L-1} \sum_{i \in B_\ell} |\mathbf{p}(i) - \mathbf{q}(i)| > 2\varepsilon - \frac{3\varepsilon}{4} = \frac{5\varepsilon}{4}$ . Moreover, letting  $\pi \in \mathcal{S}_n$  be the permutation such that  $\mathbf{p} = \mathbf{q} \circ \pi$ , consider the set  $S \subseteq [n]$  of elements which  $\pi$  maps to an element from the same bucket:

$$S := \{ i \in [n] \setminus B_L : \exists \ell \in [L-1], i \in B_\ell, \pi(i) \in B_\ell \}.$$

For each such element  $i$ , by definition of the bucketing,  $|\mathbf{p}(i) - \mathbf{q}(i)| = |\mathbf{q}(i) - \mathbf{q}(\pi(i))| \leq \frac{\varepsilon}{4} \mathbf{q}(i)$ . It follows that the elements from  $S$  amount for a total  $\ell_1$  distance of at most  $\frac{\varepsilon}{4}$ , and therefore a constant fraction of the distance between  $\mathbf{p}$  and  $\mathbf{q}$  comes from the set  $T := [n] \setminus (B_L \cup S)$  of elements that  $\pi$  “moves to a different bucket:”

$$\frac{5}{4} \varepsilon < \sum_{i \in S} |\mathbf{p}(i) - \mathbf{q}(i)| + \sum_{i \in T} |\mathbf{p}(i) - \mathbf{q}(i)| \leq \frac{\varepsilon}{4} \mathbf{q}(S) + \sum_{i \in T} |\mathbf{p}(i) - \mathbf{q}(i)| \leq \frac{\varepsilon}{4} + \sum_{i \in T} |\mathbf{p}(i) - \mathbf{q}(i)|$$

that is,  $\sum_{i \in T} |\mathbf{p}(i) - \mathbf{q}(i)| > \varepsilon$ .

Partition the set  $T$  by setting  $T_\ell := T \cap B_\ell$ , for  $\ell \in [L-1]$ . Rewriting the above inequality, we obtained that

$$\sum_{i \in T} |\mathbf{p}(i) - \mathbf{q}(i)| = \sum_{\ell=1}^{L-1} \sum_{i \in T_\ell} |\mathbf{p}(i) - \mathbf{q}(i)| > \varepsilon. \quad (4)$$

We will use this to prove the following result.

▷ **Claim 6.** Suppose that  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon$ . Then there exists some  $\ell^* \in [L-1]$  such that  $\left| \mathbf{p}(\bigcup_{\ell=\ell^*}^{L-1} B_\ell) - \mathbf{q}(\bigcup_{\ell=\ell^*}^{L-1} B_\ell) \right| > \delta$ , where  $\delta = \frac{\varepsilon}{4(L-1)}$ .

*Proof.* We note that since  $\mathbf{p}(B_\ell) = \mathbf{p}(S_\ell) + \mathbf{p}(T_\ell)$  and that  $\mathbf{p}(S_\ell) = \mathbf{q}(S_\ell)$  (by definition of  $S_\ell \subseteq S$ )<sup>1</sup> for every  $\ell$ , it suffices to prove the statement for  $T_\ell$ , that is, that there exists  $\ell^*$  such that

$$\left| \mathbf{p}\left(\bigcup_{\ell=\ell^*}^{L-1} T_\ell\right) - \mathbf{q}\left(\bigcup_{\ell=\ell^*}^{L-1} T_\ell\right) \right| > \delta.$$

The key property we will use is that, for every  $\ell < \ell'$ , we have  $\mathbf{q}(i) \geq \mathbf{q}(j)$  for every  $i \in B_\ell, j \in B_{\ell'}$ . This property, which follows from the definition of bucketings, guarantees that if  $\pi$  maps an element  $i \in T_{\ell'}$  to element  $\pi(i) \in T_\ell$ , then  $\mathbf{p}(i) \geq \mathbf{q}(i)$ .

Let  $U, V \subseteq [L-1]$  be the buckets whose probability mass under  $\mathbf{p}$  is greater than or equal to (resp., less than or equal to) the probability mass under  $\mathbf{q}$ , i.e.,

$$U := \{ \ell \in [L-1] : \mathbf{p}(T_\ell) \geq \mathbf{q}(T_\ell) \}, \quad V := \{ \ell \in [L-1] : \mathbf{p}(T_\ell) \leq \mathbf{q}(T_\ell) \}$$

This lets us rewrite (4) as

$$\varepsilon < \sum_{\ell \in U} \sum_{i \in T_\ell} |\mathbf{p}(i) - \mathbf{q}(i)| + \sum_{\ell \in V} \sum_{i \in T_\ell} |\mathbf{p}(i) - \mathbf{q}(i)|$$

and so at least one of the two terms in the RHS must exceed  $\frac{\varepsilon}{2}$ . Without loss of generality, suppose  $\sum_{\ell \in U} \sum_{i \in T_\ell} |\mathbf{p}(i) - \mathbf{q}(i)| > \frac{\varepsilon}{2}$ . This implies there exists  $\ell^* \in U$  such that  $\sum_{i \in T_{\ell^*}} |\mathbf{p}(i) - \mathbf{q}(i)| > \frac{\varepsilon}{2(L-1)}$ ; we will focus on this  $\ell^*$ .

Partition  $T_{\ell^*}$  further into  $T_{\ell^*}^+$  and  $T_{\ell^*}^-$ , where  $T_{\ell^*}^+$  (resp.  $T_{\ell^*}^-$ ) is the set of elements  $i \in T_{\ell^*}$  such that  $\pi(i)$  belongs to a bucket  $B_\ell$  with  $\ell < \ell^*$  (resp.,  $\ell > \ell^*$ ). Note that, for any  $i \in T_{\ell^*}^+$ , we then have  $\mathbf{p}(i) = \mathbf{q}(\pi(i)) \geq \mathbf{q}(i)$ , and conversely for  $i \in T_{\ell^*}^-$ : so that we can rewrite the above as

$$\frac{\varepsilon}{2(L-1)} < (\mathbf{p}(T_{\ell^*}^+) - \mathbf{q}(T_{\ell^*}^+)) + (\mathbf{q}(T_{\ell^*}^-) - \mathbf{p}(T_{\ell^*}^-))$$

<sup>1</sup> Indeed, we have  $\mathbf{p}(S_\ell) = \sum_{i \in S_\ell} \mathbf{p}(i) = \sum_{i \in S_\ell} \mathbf{q}(\pi(i)) = \mathbf{q}(\pi^{-1}(S_\ell))$ , and  $\pi(S_\ell) = S_\ell$  by definition.

## 55:6 Identity Testing Under Label Mismatch

Now, since  $\mathbf{p}(T_{\ell^*}) \geq \mathbf{q}(T_{\ell^*})$  (as  $\ell^* \in U$ ), we have  $\mathbf{p}(T_{\ell^*}^+) - \mathbf{q}(T_{\ell^*}^+) \geq \mathbf{q}(T_{\ell^*}^-) - \mathbf{p}(T_{\ell^*}^-)$  and therefore  $\mathbf{p}(T_{\ell^*}^+) - \mathbf{q}(T_{\ell^*}^+) > \frac{\varepsilon}{4(L-1)}$ . This implies the claim: indeed, we then have

$$\mathbf{p}(\cup_{\ell=\ell^*}^{L-1} T_\ell) > \mathbf{q}(\cup_{\ell=\ell^*}^{L-1} T_\ell) + \frac{\varepsilon}{4(L-1)}$$

since  $T_{\ell^*}$  “receives” a difference of at least  $\frac{\varepsilon}{4(L-1)}$  probability mass from lower-index buckets, and besides this the total probability mass of the suffix of buckets  $\cup_{\ell=\ell^*}^{L-1} T_\ell$  cannot decrease by any internal swap of elements. ◀

With the above claim in hand, we can conclude the analysis. Indeed, as the sets  $B_1, \dots, B_L$  are known, one can estimate the induced probability distribution  $\bar{\mathbf{p}} := (\mathbf{p}(B_1), \dots, \mathbf{p}(B_L))$  to Kolmogorov distance  $\frac{\delta}{3}$  (with probability at least 9/10) using  $O(1/\delta^2) = O(L^2/\varepsilon^2) = O(\log^2(n/\varepsilon)/\varepsilon^4)$  samples (this follows from Theorem 4). Let  $\hat{\mathbf{p}}$  be the resulting distribution over  $[L]$ . Whenever this step is successful (i.e., with probability at least 9/10, the following holds.

- If  $\mathbf{p} = \mathbf{q}$ , then  $|\hat{\mathbf{p}}(L) - \mathbf{q}(B_L)| \leq \frac{\delta}{3}$ , so  $\hat{\mathbf{p}}(B_L) \leq \frac{\varepsilon}{4} + \frac{\delta}{3} \leq \frac{3}{8}\varepsilon$ ; and  $|\hat{\mathbf{p}}(\{\ell^*, \dots, L-1\}) - \mathbf{q}(\cup_{\ell=\ell^*}^{L-1} B_\ell)| \leq \frac{\delta}{3}$  for all  $\ell$ . Thus, the test accepts.
- If  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon$ , then either
  - $\mathbf{p}(B_L) > \frac{\varepsilon}{2}$ , in which case  $\hat{\mathbf{p}}(L) \geq \frac{\varepsilon}{2} - \frac{\delta}{3} > \frac{3}{8}\varepsilon$  and the test rejects; or
  - $\mathbf{p}(B_L) \leq \frac{\varepsilon}{2}$ , in which case by Claim 6 there exists some  $\ell^* \in [L-1]$  such that  $|\mathbf{p}(\cup_{\ell=\ell^*}^{L-1} B_\ell) - \mathbf{q}(\cup_{\ell=\ell^*}^{L-1} B_\ell)| > \delta$ . Then,

$$\left| \hat{\mathbf{p}}(\{\ell^*, \dots, L\}) - \mathbf{q}\left(\bigcup_{\ell=\ell^*}^{L-1} B_\ell\right) \right| \geq \left| \mathbf{p}\left(\bigcup_{\ell=\ell^*}^{L-1} B_\ell\right) - \mathbf{q}\left(\bigcup_{\ell=\ell^*}^{L-1} B_\ell\right) \right| - \frac{\delta}{3} > \frac{2}{3}\delta$$

and the test rejects.

This concludes the proof of correctness of the algorithm. The claimed sample complexity readily follows from our choice of  $\delta = \Theta(L/\varepsilon)$  and the  $O(1/\delta^2)$  sample complexity of learning an arbitrary real-valued distribution to Kolmogorov distance  $\delta$ . ◀

► **Remark 7 (On the tolerance of the tester).** We note that the above analysis establishes a slightly stronger statement; namely, that the testing algorithm allows for some small tolerance, accepting distributions that are  $O(\varepsilon/\log n)$ -close to  $\mathbf{q}$ , and rejecting those that are  $\varepsilon$ -far. As we will see later, this  $\Omega(\log n)$  factor in the amount of tolerance is essentially optimal, as by Theorem 17 reducing it to  $o(\log n)$  would require sample complexity  $n^{1/2-o(1)}$ .

### 3.2 Lower bound

In this section, we show that the  $O(\log^2 n)$  upper bound from the previous section is tight, by proving a matching lower bound on the sample complexity of identity testing under promise of permutation.

► **Theorem 8.** *Any algorithm which, given a reference distribution  $\mathbf{q}$  over  $[n]$ ,  $0 < \varepsilon \leq 1$  such that  $\varepsilon = \tilde{\Omega}(1/n^{1/4})$ , and sample access to an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least 2/3 between (i)  $\mathbf{p} = \mathbf{q}$  and (ii)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon$ , must have sample complexity  $\Omega\left(\frac{\log^2 n}{\varepsilon^2}\right)$ .*

**Proof.** We first describe a construction with constant distance  $\varepsilon = 1/9$ , leading to an  $\Omega(\log^2 n)$  lower bound; before explaining how to obtain the claimed  $\Omega\left(\frac{1}{\varepsilon^2} \log^2 n\right)$  lower bound from it. Our lower bound will rely on a reference distribution  $\mathbf{q}$  piecewise-constant

on  $L = \Theta(\log n)$  buckets, where bucket  $\ell$  has a number of elements proportional to  $2^\ell$ . The first and last buckets (that is, the smallest and largest) will each have total probability mass  $1/3$  under  $\mathbf{q}$ , and be uniform. The remaining “middle”  $L - 2$  buckets all have  $1/(3(L - 2))$  total probability mass, and are uniform as well. We then build a family of perturbations  $\{\mathbf{p}_\pi = \mathbf{q} \circ \pi\}_\pi \subseteq \Pi_n(\mathbf{q})$ , such that under each perturbation  $\mathbf{p}_\pi$  the middle buckets keep the exact same total probability mass  $1/(3(L - 2))$ , by “cascading” mass from one bucket to the next. Details follow.

Set  $L := \Theta(\log n)$  to be the largest integer such that  $L2^L \leq \sqrt{n}$ , and assume for convenience that  $\lceil \sqrt{n} \rceil$  is a multiple of 3. The  $\ell$ th bucket  $B_\ell$ , for  $0 \leq \ell \leq L - 2$ , has size

$$|B_\ell| = \lceil \sqrt{n} \rceil \cdot 2^\ell$$

and  $|B_{L-1}| = 2(L - 2)|B_{L-2}|$ , so that  $\frac{n}{8} \leq \sum_{\ell=0}^{L-1} |B_\ell| = \lceil \sqrt{n} \rceil \cdot 2^{L-1}(L - 1) \leq n$ . (We hereafter focus on the first part of the domain, and will ignore the last  $n - \sum_{\ell=0}^{L-1} |B_\ell|$  elements.) Note that each bucket contains at least  $\sqrt{n}$  elements by construction, and has a size which is a multiple of 3. The reference distribution  $\mathbf{q}$  is then uniform inside each bucket, where

- $\mathbf{q}(B_0) = \mathbf{q}(B_{L-1}) = \frac{1}{3}$ , and
- $\mathbf{q}(B_\ell) = \frac{1}{3(L-2)}$  for all  $0 < \ell < L - 1$ .

In particular, our choice of  $|B_{L-1}|$  ensures that each element of the last bucket, under  $\mathbf{q}$ , will have probability mass

$$\frac{1}{3|B_{L-1}|} = \frac{1}{2} \cdot \frac{1}{3(L-2)|B_{L-2}|}$$

that is, half the probability mass of elements of the  $(L - 2)$ th bucket.

Each perturbation will then have the same distribution over buckets:

- each of the  $L - 2$  middle buckets  $B_\ell$  is (independently) partitioned uniformly at random into 3 sets  $S_{\ell,1}, S_{\ell,2}, S_{\ell,3}$  of equal size. The permutation then swaps  $S_{\ell,2} \cup S_{\ell,3}$  and  $S_{\ell+1,1}$ , for  $1 \leq \ell \leq L - 3$  (note that indeed  $|S_{\ell,2} \cup S_{\ell,3}| = |S_{\ell+1,1}|$ , but  $\mathbf{q}(S_{\ell,2} \cup S_{\ell,3}) = 2\mathbf{q}(S_{\ell+1,1}) = \frac{2}{9(L-2)}$ ).
- a uniformly random subset  $S_0 \subseteq B_0$  of size  $\frac{|B_0|}{3(2L-5)} = O(|S_{1,1}|/L)$  is selected, and the permutation swaps it with a uniformly random subset  $T_1 \subseteq S_{1,1}$  of equal size. By choice of the size, we had  $\mathbf{q}(S_0) = \frac{2}{9(2L-5)}$  and  $\mathbf{q}(T_1) = \frac{1}{9(2L-5)(L-2)}$ , so that  $\mathbf{q}(S_0) - \mathbf{q}(T_1) = \frac{1}{9(L-2)}$ .
- similarly, the subset  $S_{L-2,2} \cup S_{L-2,3}$  of size  $\frac{2}{3}|B_{L-2}| = \frac{|B_{L-1}|}{3(L-2)}$  is swapped with a uniformly random subset  $T_{L-1} \subseteq B_{L-1}$  of equal size. By choice of the size, we had  $\mathbf{q}(S_{L-2,2} \cup S_{L-2,3}) = \frac{2}{9(L-2)}$  and  $\mathbf{q}(T_{L-1}) = \frac{1}{9(L-2)}$ , so that again  $\mathbf{q}(S_{L-2,2} \cup S_{L-2,3}) - \mathbf{q}(T_{L-1}) = \frac{1}{9(L-2)}$ .

As a result, we get that for each such perturbation  $\mathbf{p} = \mathbf{q} \circ \pi$ ,  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) \geq \frac{1}{9}$ . The construction is illustrated in Figure 1.

By a birthday paradox-type argument, no element will be sampled twice unless the number of samples is at least  $\Omega(1/\sqrt{\sum_{i=1}^n \mathbf{p}(i)^2}) = \Omega(1/\sqrt{n \max_{i \in [n]} \mathbf{p}(i)}) = \Omega(n^{1/4})$ , which is far beyond the polylogarithmic regime we are working in. By construction, under each  $\mathbf{p}$ , all  $L - 2$  middle buckets have exactly the same probability mass  $\frac{1}{3(L-2)}$ , and elements inside are perturbed randomly, either having probability (compared to  $\mathbf{q}$ ) multiplied by 2 with probability  $1/3$  or divided by 2 with probability  $1/3$ . Because of the uniformly random choice of the 3-way partition inside each bucket and the fact that each of all those inner

■ **Figure 1** Reference distribution  $\mathbf{q}$  and example of perturbation  $\mathbf{p}$ , for  $L = 5$ . Note that the total probability mass of each bucket of  $\mathbf{q}$  is preserved under  $\mathbf{p}$ , except for the first and last one whose mass decreases and increases by  $\Theta(1/L)$ , respectively.

partitions are chosen independently across buckets, the information from those  $L - 2$  buckets does not provide any advantage in distinguishing them from  $\mathbf{p}$  unless the same element is hit twice.<sup>2</sup>

This addresses the case of the middle  $L - 2$  buckets. Turning to the remaining two, the probability mass of both end buckets, under any perturbation  $\mathbf{p}$ , deviates from what it is under  $\mathbf{q}$  by an additive  $\delta := \frac{1}{9(L-2)}$ . Since those buckets each have total probability mass  $1/3$  under  $\mathbf{p}$  and  $1/3 \pm \delta$  under each  $\mathbf{q}$  and we do not see any collisions with high probability, detecting this requires  $\Omega(1/\delta^2) = \Omega(\log^2 n)$  samples, giving the lower bound for constant  $\varepsilon = 1/9$ .

To obtain the inverse quadratic dependence on the distance parameter, one can then simply repeat the above argument for any  $0 < \varepsilon < 1/9$  by replacing our reference distribution  $\mathbf{q}$  and all the perturbations  $\mathbf{p}_\pi = \mathbf{q} \circ \pi$  by the mixtures

$$\mathbf{q}_\varepsilon := (1 - 9\varepsilon)\mathbf{u} + 9\varepsilon\mathbf{q}, \quad \mathbf{p}_{\varepsilon,\pi} := (1 - 9\varepsilon)\mathbf{u} + 9\varepsilon\mathbf{p}_\pi = \mathbf{q}_\varepsilon \circ \pi$$

the last equality crucially using the fact that the uniform distribution  $\mathbf{u}$  (over the domain) is invariant by permutation. Note that every such  $\mathbf{p}_{\varepsilon,\pi}$  then does belong to  $\Pi_n(\mathbf{q}_\varepsilon)$ , and is at total variation distance exactly  $\varepsilon$  from  $\mathbf{q}_\varepsilon$ . Moreover, we can repeat the previous argument *mutatis mutandis*: (i) the middle buckets provide no information whatsoever unless an element is seen twice, which requires  $\Omega(n^{1/4}/\varepsilon)$  samples (the extra  $1/\varepsilon$  due to our mixture with weight  $9\varepsilon$ ); while the two outer buckets have a discrepancy only  $\delta := \frac{\varepsilon}{L-2}$ , which to be detected requires at least  $\Omega(1/\delta^2) = \Omega((\log^2 n)/\varepsilon^2)$  samples overall. The minimum of these two quantities gives the claimed lower bound, as long as  $n^{1/4}/\varepsilon = \Omega((\log^2 n)/\varepsilon^2)$ , that is,  $\varepsilon = \Omega((\log^2 n)/n^{1/4})$ . ◀

<sup>2</sup> That is, conditioned on seeing each element of those  $L - 2$  buckets at most once, the conditional distribution over those  $L - 2$  buckets under (i)  $\mathbf{q}$  and (ii) the uniform mixture of all perturbations  $\mathbf{p}$  are indistinguishable.

## 4 Tolerant testing

We now turn to the task of *tolerant* testing. As mentioned in the introduction, tolerant testing is well known to be harder than standard (non-tolerant) testing, with a nearly quadratic gap for the standard identity testing problem ( $\sqrt{n}$  vs.  $\frac{n}{\log n}$  sample complexity). Surprisingly, we are able to show that under the promise of permutation, the task does not suffer a merely polynomial blowup – the sample complexity of tolerant identity testing becomes *exponentially* harder than that of standard testing, jumping from  $\log^2 n$  to  $n^{1-o(1)}$ .

The first component, an  $O(n/\log n)$  upper bound for tolerant testing under promise of permutation (Theorem 9), is straightforward, and simply follows from the corresponding upper bound absent this promise. A much more challenging task is in establishing the lower bound. We actually provide two lower bounds: the first, an  $\Omega(n^{1-o(1)})$  lower bound (Theorem 10), applies for the usual setting of tolerant testing with an additive gap  $\delta$  between  $\varepsilon'$  and  $\varepsilon$ . The second (Theorem 17) is an  $\Omega\left(\sqrt{n/2^{O(C)}}\right)$  sample complexity lower bound for any  $C$ -factor approximation of the distance, that is to distinguish between  $\varepsilon$ -close and  $C\varepsilon$ -far.

### 4.1 Upper bound

The claimed upper bound readily follows from the analogous upper bound on tolerant testing *without* the promise of permutation, due to Valiant and Valiant [22, Theorem 4] (see, also, [16]). Indeed, any such estimator can be used for our problem, ignoring the additional promise of identity up to permutation.

► **Theorem 9.** *There exists an algorithm which, for any reference distribution  $\mathbf{q}$  over  $[n]$  and any  $0 \leq \varepsilon, \delta \leq 1$  such that  $\delta = \Omega(1/\sqrt{\log n})$ , and given  $O\left(\frac{n}{\delta^2 \log n}\right)$  samples from an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) \leq \varepsilon$  and (ii)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon + \delta$ .*

We note that the requirement  $\delta = \Omega(1/\sqrt{\log n})$  has been relaxed in [16].

### 4.2 Lower bound

In this section, we prove the theorem below, our lower bound on the sample complexity of tolerant testing under promise of permutation. Before doing so, we emphasize that the known  $\Omega\left(\frac{n}{\delta^2 \log n}\right)$  sample complexity lower bound for tolerant testing *absent* this promise does not apply to our setting, as the promise of permutation makes the testing problem easier. In particular, the hard instances used to prove the aforementioned  $\Omega\left(\frac{n}{\delta^2 \log n}\right)$  lower bound do not satisfy this promise.<sup>3</sup>

► **Theorem 10.** *Any algorithm which, given a reference distribution  $\mathbf{q}$  over  $[n]$ ,  $0 < \varepsilon, \delta \leq 1$ , and sample access to an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) \leq \varepsilon$  and (ii)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon + \delta$ , must have sample complexity  $\Omega(\delta^2 n^{1-O(1/\log(1/\delta))})$ .*

<sup>3</sup> One can also note that the lower bound for “standard” tolerant testing is obtained by choosing the reference distribution to be uniform over  $[n]$ . Under promise of permutation, this particular instance of the problem is trivial, as any permutation of the uniform distribution is still the uniform distribution.

## 55:10 Identity Testing Under Label Mismatch

**Proof.** In what follows, we assume that  $\delta = \Omega(1/\sqrt{n})$ , as otherwise there is nothing to prove. Let  $k \geq 1$  be an integer to be chosen during the course of the analysis (we will set  $k = \Theta(1/\delta)$ ), and write  $n = 2mk^2$  for some integer  $m \geq 1$  (this can be done without loss of generality, as our assumption on  $\delta$  ensures that  $n \geq 2mk^2$ ). For  $1 \leq \ell \leq 2k$ , we define the integer interval  $I_{k,\ell} := [k] + (\ell - 1)k$ , so that  $[2k^2] = \bigcup_{\ell=1}^{2k} I_{k,\ell}$ .

Given two distributions  $\mathbf{p}, \mathbf{q}$  over  $[k]$ , we define families of distributions  $\mathcal{C}_{\mathbf{p},\mathbf{q}}$  and  $\mathcal{F}_{\mathbf{p},\mathbf{q}}$  over  $[n]$  as follows: first, we consider the distributions  $\mathbf{c}, \mathbf{f}$ , each over  $[2k^2]$ , obtained by “repeating and alternating”  $\mathbf{p}$  and  $\mathbf{q}$  as follows:

- For  $1 \leq \ell \leq k$  and  $j \in I_{k,\ell}$ ,  $\mathbf{c}(j) = \frac{1}{2k}\mathbf{p}(j)$ .
- For  $1 \leq \ell \leq k$  and  $j \in I_{k,k+\ell}$ ,  $\mathbf{c}(j) = \frac{1}{2k}\mathbf{q}(j)$ .

■ **Figure 2** An example of  $\mathbf{c}$  (top),  $\mathbf{f}$  (middle), and  $\mathbf{r}$  (bottom) over  $[2k^2]$ , for  $k = 5$ ; here, we took  $\mathbf{p} = \frac{1}{16}(3, 2, 6, 4, 1)$  and  $\mathbf{q} = \frac{1}{18}(2, 5, 4, 4, 3)$ .

We obtain  $\mathbf{f}$  over  $[2k^2]$  in a similar fashion, but swapping  $I_{k,\ell}$  and  $I_{k,k+\ell}$ :

- For  $1 \leq \ell \leq k$  and  $j \in I_{k,\ell}$ ,  $\mathbf{f}(j) = \frac{1}{2k}\mathbf{q}(j)$ .
- For  $1 \leq \ell \leq k$  and  $j \in I_{k,k+\ell}$ ,  $\mathbf{f}(j) = \frac{1}{2k}\mathbf{p}(j)$ .

Further, we define our “reference” distribution  $\mathbf{r}$  over  $[2k^2]$  as

- For  $1 \leq \ell \leq k$  and  $j \in I_{k,\ell}$ ,  $\mathbf{r}(j) = \frac{1}{2k}\mathbf{p}(\ell)$ .
- For  $k + 1 \leq \ell \leq 2k$  and  $j \in I_{k,\ell}$ ,  $\mathbf{r}(j) = \frac{1}{2k}\mathbf{q}(\ell)$ .

We also define the reference distribution  $\mathbf{r}_{\mathbf{p},\mathbf{q}}^*$  over  $[n] = [2k^2m]$  by concatenating  $m$  copies of  $\mathbf{r}$  and normalizing the result; that is,

$$\mathbf{r}_{\mathbf{p},\mathbf{q}}^* := \frac{1}{2m}(\mathbf{r} \sqcup \mathbf{r} \sqcup \cdots \sqcup \mathbf{r}),$$

where  $\sqcup$  denotes the vector concatenation. Note that both  $\mathbf{c}$  and  $\mathbf{f}$  are permutations of  $\mathbf{r}$ , and that  $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = \|\mathbf{f}\|_1 = 1$ . Next, we bound the gap between  $d_{\text{TV}}(\mathbf{f}, \mathbf{r})$  and  $d_{\text{TV}}(\mathbf{c}, \mathbf{r})$ , relating it to the distance between  $\mathbf{p}$  and  $\mathbf{q}$ .

▷ **Claim 11.**  $d_{\text{TV}}(\mathbf{f}, \mathbf{r}) \geq d_{\text{TV}}(\mathbf{c}, \mathbf{r}) + \frac{1}{k}d_{\text{TV}}(\mathbf{p}, \mathbf{q})$

*Proof.* We will analyze the contributions to  $d_{\text{TV}}(\mathbf{c}, \mathbf{r})$  and  $d_{\text{TV}}(\mathbf{c}, \mathbf{f})$  on  $I_{k,\ell}$  and  $I_{k,k+\ell}$  for  $1 \leq \ell \leq k$ . Without loss of generality, we can assume that  $\mathbf{p}, \mathbf{q}$  are non-decreasing. Then, from our definition of  $\mathbf{c}, \mathbf{r}$ , and  $\mathbf{f}$ , we have

$$\begin{aligned} d_{\text{TV}}(\mathbf{f}, \mathbf{r}) &= \frac{1}{4k} \sum_{i=1}^k \sum_{j=1}^k (|\mathbf{p}(i) - \mathbf{q}(j)| + |\mathbf{q}(i) - \mathbf{p}(j)|) = \frac{1}{2k} \left( \sum_{i=1}^k \sum_{j=1}^k |\mathbf{p}(i) - \mathbf{q}(j)| \right) \\ &= \frac{1}{2k} \left( \sum_{i=1}^k |\mathbf{p}(i) - \mathbf{q}(i)| + \sum_{i=1}^k \sum_{j=1}^{i-1} (|\mathbf{p}(i) - \mathbf{q}(j)| + |\mathbf{p}(j) - \mathbf{q}(i)|) \right) \\ d_{\text{TV}}(\mathbf{c}, \mathbf{r}) &= \frac{1}{4k} \sum_{i=1}^k \sum_{j=1}^k (|\mathbf{p}(i) - \mathbf{p}(j)| + |\mathbf{q}(i) - \mathbf{q}(j)|) \\ &= \frac{1}{2k} \sum_{i=1}^k \sum_{j=1}^{i-1} ((\mathbf{p}(i) - \mathbf{p}(j)) + (\mathbf{q}(i) - \mathbf{q}(j))) \end{aligned}$$

where for the last equality we used the assumption that  $\mathbf{p}, \mathbf{q}$  were non-decreasing to write

$$\sum_{i=1}^k \sum_{j=1}^k |\mathbf{p}(i) - \mathbf{p}(j)| = \sum_{i=1}^k \sum_{j=1}^{i-1} (\mathbf{p}(i) - \mathbf{p}(j)) + \sum_{i=1}^k \sum_{j=i+1}^k (\mathbf{p}(j) - \mathbf{p}(i)) = 2 \sum_{i=1}^k \sum_{j=1}^{i-1} (\mathbf{p}(i) - \mathbf{p}(j)),$$

The conclusion then follows from recalling that  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) = \frac{1}{2} \sum_{i=1}^k |\mathbf{p}(i) - \mathbf{q}(i)|$ , and observing that  $(\mathbf{p}(i) - \mathbf{p}(j)) + (\mathbf{q}(i) - \mathbf{q}(j)) = (\mathbf{p}(i) - \mathbf{q}(j)) + (\mathbf{q}(i) - \mathbf{p}(j)) \leq |\mathbf{p}(i) - \mathbf{q}(j)| + |\mathbf{p}(j) - \mathbf{q}(i)|$ . ◁

To define  $\mathcal{C}_{\mathbf{p},\mathbf{q}}$  and  $\mathcal{F}_{\mathbf{p},\mathbf{q}}$ , we will need one further piece of notation. We denote by  $\mathcal{B}_k \subseteq \mathcal{S}_{2k^2}$  the set of all permutations of  $[2k^2]$  “respecting the buckets,” that is,

$$\mathcal{B}_k := \{ \pi \in \mathcal{S}_{2k^2} : \pi(I_{k,\ell}) = I_{k,\ell} \forall \ell \in [2k] \}$$

We then let

$$\mathcal{C}_{\mathbf{p},\mathbf{q}} = \left\{ \frac{1}{2mk} (\mathbf{c} \circ \pi_1 \sqcup \mathbf{c} \circ \pi_2 \sqcup \cdots \sqcup \mathbf{c} \circ \pi_m) : \pi_1, \dots, \pi_m \in \mathcal{B}_k \right\}$$

and

$$\mathcal{F}_{\mathbf{p},\mathbf{q}} = \left\{ \frac{1}{2mk} (\mathbf{f} \circ \pi_1 \sqcup \mathbf{f} \circ \pi_2 \sqcup \cdots \sqcup \mathbf{f} \circ \pi_m) : \pi_1, \dots, \pi_m \in \mathcal{B}_k \right\}$$

where as before  $\sqcup$  denotes the vector concatenation; that is, we stitch together  $m$  blocks, each consisting on a permuted version of either  $\mathbf{c}$  or  $\mathbf{f}$ . Note that since  $n = m \cdot 2k^2$  and each  $\mathbf{c}$  (resp.  $\mathbf{f}$ ) is a  $(2k^2)$ -dimensional vector,  $\mathcal{C}_{\mathbf{p},\mathbf{q}}$  and  $\mathcal{F}_{\mathbf{p},\mathbf{q}}$  are indeed families of probability distributions over  $[n]$ , and  $\mathcal{C}_{\mathbf{p},\mathbf{q}}, \mathcal{F}_{\mathbf{p},\mathbf{q}} \subseteq \Pi_n(\mathbf{r}_{\mathbf{p},\mathbf{q}}^*)$ .

The construction above allows us to convert any two distributions  $\mathbf{p}, \mathbf{q}$  with sufficiently many matching moments to families of distributions (whose elements are all permutations of a single reference one) hard to distinguish:

## 55:12 Identity Testing Under Label Mismatch

▷ **Claim 12.** There exists some absolute constant  $c > 0$  such that, if  $\mathbf{p}, \mathbf{q}$  have matching first  $r$ -way moments, it is impossible to distinguish a uniformly random element of  $\mathcal{C}_{\mathbf{p}, \mathbf{q}}$  from a uniformly random element of  $\mathcal{F}_{\mathbf{p}, \mathbf{q}}$  given fewer than  $cm^{1-\frac{1}{r+1}}$  samples.

*Proof.* By assumption on  $\mathbf{p}, \mathbf{q}$  and our construction of  $\mathbf{c}, \mathbf{f}$  from them, for every of the  $m$  contiguous blocks of  $2k^2$  elements, the  $r$ -way moments of the corresponding conditional distributions exactly match. Given that a uniformly element drawn of  $\mathbf{p}'$  from  $\mathcal{C}_{\mathbf{p}, \mathbf{q}}$  and  $\mathbf{q}'$  from  $\mathcal{F}_{\mathbf{p}, \mathbf{q}}$  corresponds to independent permutations inside each block, any block in which fewer than  $r + 1$  samples falls brings exactly zero information about whether it comes from  $\mathbf{p}'$  or  $\mathbf{q}'$  (specifically, one could simulate the distribution of those  $s < r + 1$  samples without getting any sample from the real distribution). Since each of these  $m$  blocks has total probability  $1/m$  under both  $\mathbf{p}'$  and  $\mathbf{q}'$ , by a generalized birthday paradox (see, e.g., [19]), with probability at least  $9/10$  no block will receive more than  $r$  samples unless the total number of samples is at least  $cm^{1-\frac{1}{r+1}}$ , for some absolute constant  $c > 0$ . ◁

It remains to specify *which* pair of distributions with “sufficiently many matching moments” we will use. While we could argue directly about the existence of such a pair of distributions with desirable properties, it is simpler to leverage a construction due to Valiant and Valiant [22], which exhibits the desired properties.

▷ **Claim 13.** There exists some  $\varepsilon_0 > 0$  such that the following holds. For every sufficiently large  $r$ , there exists a pair of distributions (without loss of generality, non-decreasing)  $\mathbf{p}_{VV}, \mathbf{q}_{VV}$  over  $k = O(r2^r)$  elements with matching first  $r$ -way moments, but  $d_{TV}(\mathbf{p}_{VV}, \mathbf{q}_{VV}) \geq \varepsilon_0$ .

*Proof.* This follows from the lower bound construction of [22]. ◁

We will rely on this pair of distributions  $\mathbf{p}_{VV}, \mathbf{q}_{VV}$ , and hereafter write  $\mathcal{C}, \mathcal{F}$ , and  $\mathbf{r}^*$  for  $\mathcal{C}_{\mathbf{p}_{VV}, \mathbf{q}_{VV}}, \mathcal{F}_{\mathbf{p}_{VV}, \mathbf{q}_{VV}}$ , and  $\mathbf{r}_{\mathbf{p}_{VV}, \mathbf{q}_{VV}}^*$ , respectively.

▷ **Claim 14.** For every  $\mathbf{p}' \in \mathcal{C}$  and  $\mathbf{q}' \in \mathcal{F}$ , we have  $d_{TV}(\mathbf{q}', \mathbf{r}^*) > d_{TV}(\mathbf{p}', \mathbf{r}^*) + \frac{\varepsilon_0}{k}$ .

*Proof.* Due to the definition of  $\mathcal{C}, \mathcal{F}$ , and  $\mathbf{r}^*$  as  $m$ -fold concatenations, and since  $\mathbf{r}$  is invariant by permutations from  $\mathcal{B}_k$ , it is sufficient to prove the claim for  $\mathbf{p}_{VV}, \mathbf{q}_{VV}$ , and  $\mathbf{r}$  (over  $[2k^2]$ ). The claimed bound then immediately follows from Claim 11. ◁

To finish the argument, it only remains to combine the various claims. We choose  $k \geq \frac{\varepsilon_0}{\delta}$  and  $m = n/(2k^2) \geq 1$  (since  $\delta = \Omega(1/\sqrt{n})$ ). By Claim 13, we can then set  $r := \Omega(\log k)$  and obtain, from Claim 12, a sample complexity lower bound of

$$\Omega\left(m^{1-\frac{1}{r+1}}\right) = \Omega\left(\delta^2 n^{1-O\left(\frac{1}{\log(1/\delta)}\right)}\right)$$

as desired. ◀

The theorem immediately implies the following two corollaries.

► **Corollary 15.** For every  $c > 0$ , there exists some  $\delta > 0$  such that the following holds. Any algorithm which, given a reference distribution  $\mathbf{q}$  over  $[n]$ ,  $\varepsilon \in (0, 1)$ , and sample access to an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $d_{TV}(\mathbf{p}, \mathbf{q}) \leq \varepsilon$  and (ii)  $d_{TV}(\mathbf{p}, \mathbf{q}) > \varepsilon + \delta$ , must have sample complexity  $\Omega(n^{1-c})$ .

► **Corollary 16.** Any algorithm which, given a reference distribution  $\mathbf{q}$  over  $[n]$ ,  $\varepsilon \in (0, 1)$ , and sample access to an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $d_{TV}(\mathbf{p}, \mathbf{q}) \leq \varepsilon$  and (ii)  $d_{TV}(\mathbf{p}, \mathbf{q}) > \varepsilon + 1/2\sqrt{\log n}$ , must have sample complexity  $\frac{n}{2^{O(\sqrt{\log n})}}$ .

## Tolerant testing $C$ -approximation

We now turn to our second tolerant testing lower bound, which applies to algorithms providing a  $C$ -factor approximation of the distance to the reference distribution.

► **Theorem 17.** *Any algorithm which, given a reference distribution  $\mathbf{q}$  over  $[n]$ ,  $C \geq 2$ , and sample access to an unknown distribution  $\mathbf{p} \in \Pi_n(\mathbf{q})$ , distinguishes with probability at least  $2/3$  between (i)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) \leq \frac{1}{4^{C-1}}$  and (ii)  $d_{\text{TV}}(\mathbf{p}, \mathbf{q}) \geq \frac{C}{4^{C-1}}$ , must have sample complexity  $\Omega(\sqrt{\frac{n}{4^C}})$ .*

► **Remark 18.** As discussed in Remark 7, Theorem 17 is essentially optimal, as it matches (up to polylogarithmic factors in the sample complexity) the upper bound from Theorem 5 when  $C = \Theta(\log n)$ .

**Proof of Theorem 17.** We will prove the theorem via a sequence of lemmas. We will assume that  $C \geq 2$  is an integer, and we define  $m = 2^C - 1$ . Our proof will proceed similarly to the proof of Theorem 10. We will begin by working over  $[m(2^{C+1} + 2^{C-1} - 3)]$ . Throughout this section, we partition  $[m(2^{C+1} + 2^{C-1} - 3)]$  into  $C + 1$  buckets, which we will denote  $B_0, B_1, \dots, B_C$ , such that each  $B_i$  is a set of consecutive integers,  $|B_C| = m2^{C-1}$ ,  $|B_0| = m$ , and  $|B_i| = m2^{i+1}$  for  $1 \leq i \leq C - 1$ . For convenience, we define  $s := m(4C - 1)2^{C-1}$ .

We define a distribution  $\mathbf{r}$  in the following way:

- For each  $j \in B_0$ ,  $\mathbf{r}(j) = \frac{2^C}{s}$ .
- For each  $1 \leq i \leq C - 1$  and  $j \in B_i$ ,  $\mathbf{r}(j) = \frac{2^{C-i}}{s}$ .
- For each  $j \in B_C$ ,  $\mathbf{r}(j) = \frac{1}{s}$ .

We define two distributions  $\mathbf{p}$  and  $\mathbf{q}$  such that  $\mathbf{p}$  and  $\mathbf{q}$  are hard to distinguish with few samples, such that  $d_{\text{TV}}(\mathbf{r}, \mathbf{p})$  and  $d_{\text{TV}}(\mathbf{r}, \mathbf{q})$  are far apart. We define  $\mathbf{q}$  in the following way:

- For each  $j \in B_0$ ,  $\mathbf{q}(j) = \frac{2^{C-1}}{s}$ .
- For each  $1 \leq i \leq C - 1$ ,
  - For  $j$  in the first  $m2^i$  elements of  $B_i$ ,  $\mathbf{q}(j) = \frac{2^{C-i-1}}{s}$ .
  - For  $j$  in the next  $m2^{i-1}$  elements of  $B_i$ ,  $\mathbf{q}(j) = \frac{2^{C-i}}{s}$ .
  - For  $j$  in the last  $m2^{i-1}$  elements of  $B_i$ ,  $\mathbf{q}(j) = \frac{2^{C-i+1}}{s}$ .
- For each  $j \in B_C$ ,  $\mathbf{q}(j) = \frac{2}{s}$ .

We define  $\mathbf{p}$  as follows:

- For each  $j \in B_0$ ,
  - If  $j$  is in the first  $2^{C-1}$  elements of  $B_0$ , then  $\mathbf{p}(j) = \frac{1}{s}$ .
  - If  $j$  is in the last  $m - 2^{C-1} = 2^{C-1} - 1$  elements of  $B_0$ , then  $\mathbf{p}(j) = \frac{2^C}{s}$ .
- For each  $1 \leq i \leq C - 1$  and  $j \in B_i$ ,  $\mathbf{p}(j) = \mathbf{r}(j) = \frac{2^{C-i}}{s}$ .
- For each  $j \in B_C$ ,
  - If  $j$  is in the first  $(m - 1)2^{C-1}$  elements of  $B_C$ , then  $\mathbf{p}(j) = \frac{1}{s}$ .
  - If  $j$  is in the last  $2^{C-1}$  elements of  $B_j$ , then  $\mathbf{p}(j) = \frac{2^C}{s}$ .

► **Lemma 19.** *For  $0 \leq i \leq C$ ,  $\sum_{j \in B_i} \mathbf{p}(j) = \sum_{j \in B_i} \mathbf{q}(j)$ .*

**Proof.** The proof is simply direct calculation. Observe that in bucket  $C$ ,

$$\begin{aligned} s \sum_{j \in B_C} \mathbf{q}(j) &= m2^{C-1} \cdot 2 = (m - 1)2^{C-1} + (m + 1)2^{C-1} \\ &= (m - 1)2^{C-1} \cdot 1 + 2^C \cdot 2^{C-1} = s \sum_{j \in B_C} \mathbf{p}(j). \end{aligned}$$

## 55:14 Identity Testing Under Label Mismatch

In bucket 0, we have

$$\begin{aligned} s \sum_{j \in B_0} \mathbf{q}(j) &= m \cdot 2^{C-1} = (m-1)2^{C-1} + 2^{C-1} = (2^C - 2)2^{C-1} + 2^{C-1} \\ &= (2^{C-1} - 1) \cdot 2^C + 2^{C-1} \cdot 1 = s \sum_{j \in B_0} \mathbf{p}(j). \end{aligned}$$

For  $1 \leq i \leq C-1$ , we have

$$\begin{aligned} s \sum_{j \in B_i} \mathbf{p}(j) &= m2^{i+1} \cdot 2^{C-i} \\ &= m(2^i + 2(2^{i-1}) + 2^{i+1})2^{C-1-i} \\ &= m2^i \cdot 2^{C-i-1} + m2^{i-1} \cdot 2^{C-i} + m2^{i-1} \cdot 2^{C-i+1} \\ &= s \sum_{j \in B_i} \mathbf{q}(j). \end{aligned}$$

The claim follows by dividing the equalities by  $s$ . ◀

► **Lemma 20.**  $d_{\text{TV}}(\mathbf{r}, \mathbf{q}) = \frac{C}{4C-1}$

**Proof.** By direct calculation,

$$\begin{aligned} 2s d_{\text{TV}}(\mathbf{r}, \mathbf{q}) &= s \sum_{j=1}^s |\mathbf{r}(j) - \mathbf{q}(j)| \\ &= m2^{C-1}(2-1) + m(2^C - 2^{C-1}) \\ &\quad + \frac{1}{2} \sum_{i=1}^{C-1} (m2^i(2^{C-i} - 2^{C-i-1}) + m2^{i-1}(2^{C-i+1} - 2^{C-i})) \\ &= m2^C + \sum_{i=1}^{C-1} (2^{i-1}m2^{C-i} + m2^{C-1-i}2^i) \\ &= m2^C + \sum_{i=1}^{C-1} (m2^{C-1} + m2^{C-1}) \\ &= Cm2^C. \end{aligned}$$

Dividing both sides by  $2s$  yields the lemma. ◀

► **Lemma 21.** For every  $0 \leq i \leq C$ ,  $\mathbf{p}(B_i) \leq \frac{2}{C+1}$  (and similarly for  $\mathbf{q}(B_i)$ ).

**Proof.** We apply Lemma 19 and directly calculate. For bucket  $C$ , we get

$$\mathbf{p}(B_C) = \mathbf{q}(B_C) = \frac{2}{s} \cdot m2^C - 1 = \frac{2}{4C-1}.$$

For bucket 0, we get

$$\mathbf{p}(B_0) = \mathbf{q}(B_0) = \frac{2^{C-1}}{s} \cdot m = \frac{1}{4C-1}.$$

For  $1 \leq i \leq C-1$ , we get

$$\mathbf{q}(B_i) = \mathbf{p}(B_i) = \frac{2^i}{s} \cdot m(2^{C+1-i}) = \frac{4}{4C-1}.$$

The claim follows by observing that  $\frac{4}{4C-1} \leq \frac{2}{C+1}$  when  $C \geq \frac{3}{2}$ . ◀

► **Lemma 22.**  $d_{\text{TV}}(\mathbf{r}, \mathbf{p}) = \frac{1}{4^C - 1}$

**Proof.** By direct calculation,

$$2s d_{\text{TV}}(\mathbf{r}, \mathbf{p}) = 2^{C-1} \cdot (2^C - 1) + 2^{C-1} \cdot (2^C - 1) = 2^C (2^C - 1) = m 2^C.$$

Dividing both sides by  $2s$  yields the lemma. ◀

Let  $w = m(2^{C+1} + 2^{C-1} - 3)$ . We assume that  $n$  is a multiple of  $w$ , and define  $t := \frac{n}{w}$ . To define  $\mathcal{C}$  and  $\mathcal{F}$  over  $[n]$ , we will need one further piece of notation. We denote by  $\mathcal{B}'_w \subseteq \mathcal{S}_w$  the set of all permutations of  $[w]$  “respecting the buckets,” that is, for every  $0 \leq i \leq C$ ,

$$\mathcal{B}'_w = \{\pi \in \mathcal{S}_w : \pi(B_i) = B_i \forall i \in \{0, 1, \dots, C\}\}$$

We then let  $\mathbf{r}^* := \frac{1}{t}(\mathbf{r} \sqcup \mathbf{r} \sqcup \dots \sqcup \mathbf{r})$  as well as

$$\mathcal{C} = \left\{ \frac{1}{t}(\mathbf{c} \circ \pi_1 \sqcup \mathbf{c} \circ \pi_2 \sqcup \dots \sqcup \mathbf{c} \circ \pi_t) : \pi_1, \dots, \pi_t \in \mathcal{B}'_w \right\}$$

$$\mathcal{F} = \left\{ \frac{1}{t}(\mathbf{f} \circ \pi_1 \sqcup \mathbf{f} \circ \pi_2 \sqcup \dots \sqcup \mathbf{f} \circ \pi_t) : \pi_1, \dots, \pi_t \in \mathcal{B}'_w \right\}$$

where as before  $\sqcup$  denotes vector concatenation. Since  $d_{\text{TV}}(\mathbf{r}, \mathbf{c} \circ \pi) = d_{\text{TV}}(\mathbf{r}, \mathbf{c})$  and  $d_{\text{TV}}(\mathbf{r}, \mathbf{f} \circ \pi) = d_{\text{TV}}(\mathbf{r}, \mathbf{f})$  for all  $\pi \in \mathcal{B}'_w$ , we have that  $d_{\text{TV}}(\mathbf{r}^*, \mathbf{p}) = \frac{1}{4^C - 1}$  for every distribution  $\mathbf{p} \in \mathcal{C}$ , and  $d_{\text{TV}}(\mathbf{r}^*, \mathbf{q}) = \frac{1}{4^C - 1}$  for every distribution  $\mathbf{q} \in \mathcal{F}$ . Further, repeating the same partitioning of each interval of  $s$  elements of  $[n]$  into buckets  $B_0, B_1, \dots, B_C$ , we have  $t(C+1)$  buckets, such that distinguishing a distribution in  $\mathcal{C}$  from a distribution in  $\mathcal{F}$  requires seeing at 2 samples in at least one of these buckets. Since the probability mass on each of the buckets is at most  $\frac{2}{t(C+1)}$  by Lemma 21, at least  $\Omega(\sqrt{t(C+1)}) = \Omega(\sqrt{n(C+1)/w})$  queries to distinguish in  $\mathcal{C}$  from a distribution in  $\mathcal{F}$ , completing the proof of Theorem 17. ◀

## Abstract

---

In recent years, high dimensional expanders have been found to have a variety of applications in theoretical computer science, such as efficient CSPs approximations, improved sampling and list-decoding algorithms, and more. Within that, an important high dimensional expansion notion is *cosystolic expansion*, which has found applications in the construction of efficiently decodable quantum codes and in proving lower bounds for CSPs.

Cosystolic expansion is considered with systems of equations over a group where the variables and equations correspond to faces of the complex. Previous works that studied cosystolic expansion were tailored to the specific group  $\mathbb{F}_2$ . In particular, Kaufman, Kazhdan and Lubotzky (FOCS 2014), and Evra and Kaufman (STOC 2016) in their breakthrough works, who solved a famous open question of Gromov, have studied a notion which we term “parity” expansion for small sets. They showed that small sets of  $k$ -faces have proportionally many  $(k + 1)$ -faces that contain *an odd number* of  $k$ -faces from the set. Parity expansion for small sets could then be used to imply cosystolic expansion only over  $\mathbb{F}_2$ .

In this work we introduce a stronger *unique-neighbor-like* expansion for small sets. We show that small sets of  $k$ -faces have proportionally many  $(k + 1)$ -faces that contain *exactly one*  $k$ -face from the set. This notion is fundamentally stronger than parity expansion and cannot be implied by previous works.

We then show, utilizing the new unique-neighbor-like expansion notion introduced in this work, that cosystolic expansion can be made *group-independent*, i.e., unique-neighbor-like expansion for small sets implies cosystolic expansion *over any group*.

## 1 Introduction

### High dimensional expanders

High dimensional expanders are the high dimensional analog of expander graphs. A  $d$ -dimensional simplicial complex is a hypergraph with hyperedges of size at most  $d + 1$  which is downwards closed, i.e., if  $\sigma$  is an hyperedge and  $\tau \subset \sigma$  then  $\tau$  is also an hyperedge. A hyperedge of size  $k + 1$  is called a  $k$ -face of the complex.

In recent years, high dimensional expanders have found a variety of applications in theoretical computer science, such as efficient CSPs approximations [2], improved sampling algorithms [5, 4, 3, 8, 7, 6, 16], improved list-decoding algorithms [11, 1], sparse agreement tests [12, 9, 19] and more.

An especially important high dimensional expansion notion is *cosystolic expansion*. It has been shown to be a key ingredient in the construction of efficiently decodable quantum LDPC codes with a large distance [15], and recently it has been used in the construction of explicit 3XOR instances that are hard for the Sum-of-Squares hierarchy [10].

### Cosystolic expansion as an expanding system of equations

A simplicial complex can be viewed as forming a *system of equations* over some group  $G$ . Consider a  $d$ -dimensional simplicial complex and some dimension  $k < d$ . The variables of the system are the  $k$ -faces of the complex, and the equations are defined by the  $(k+1)$ -faces; each  $(k+1)$ -face  $\sigma$  corresponds to the equation  $\sum_{i=0}^{k+1} \tau_i = 0$ , where  $\tau_i$  are the  $k$ -faces contained in  $\sigma$  and the sum is performed over the group (e.g., addition modulo 2 when the group is  $\mathbb{F}_2$ ).

For any assignment of values to the variables which does not satisfy all the equations, there are two measures of interest. One measure is the fraction of unsatisfied equations (out of all the equations), and the second measure is the fraction of variables (out of all the variables) that their value needs to be changed in order to satisfy all the equations. The second measure is also called the *distance* of the assignment from a satisfying assignment.

A system of equations is said to be *expanding* if for any assignment of values to the variables it holds that either all the equations are satisfied or the fraction of unsatisfied equations is proportional to the distance of the assignment from a satisfying assignment. A  $d$ -dimensional simplicial complex is said to be a *cosystolic expander* over a group  $G$  if for all  $k < d$ , the system of equations formed by its  $k$ -faces is expanding.

As a simple example, consider a 1-dimensional simplicial complex (i.e., a graph) and the field  $\mathbb{F}_2$ . The variables of the system are the vertices of the graph, and the equations are  $v_i + v_j = 0 \pmod{2}$  for each edge  $\{v_i, v_j\}$ . In this case, if the given graph is an expander graph (i.e., each subset of vertices has proportionally many outgoing edges), then the system of equations is expanding. This is true since each assignment of values over  $\mathbb{F}_2$  to the vertices can be identified with a subset of vertices, and the unsatisfied equations are exactly the outgoing edges of this set.

### Parity expansion for small sets

Kaufman, Kazhdan and Lubotzky [18], and Evra and Kaufman [14] in their breakthrough works proved the existence of cosystolic expanders of every dimension, solving a famous open question of Gromov [17]. In their works they have studied a notion which we term “parity” expansion for small sets: They have shown that certain high dimensional expansion properties imply that small sets of  $k$ -faces have proportionally many  $(k+1)$ -faces that contain *an odd number* of  $k$ -faces from the given set. Then they utilized this property in order to imply cosystolic expansion over the group  $\mathbb{F}_2$ .

### $\delta_1$ -expansion for small sets

In this work we study a fundamentally stronger “unique-neighbor-like” expansion in simplicial complexes, which we call  $\delta_1$ -*expansion*. Let  $X$  be a  $d$ -dimensional simplicial complex and  $A$  a set of  $k$ -faces in  $X$ . We define  $\delta_1(A)$  to be the set of  $(k+1)$ -faces which contain *exactly one*  $k$ -face from  $A$ . We say that  $A$  is  $\delta_1$ -*expanding* if the fraction of  $(k+1)$ -faces in  $\delta_1(A)$  (out of all the  $(k+1)$ -faces) is proportional to the fraction of  $k$ -faces in  $A$  (out of all the  $k$ -faces). Our main result is that certain high dimensional expansion properties imply that small sets are  $\delta_1$ -expanding.

### $\delta_1$ -expansion and group-independent cosystolic expansion

The strength of our  $\delta_1$ -expansion can be demonstrated by its relation to cosystolic expansion. As explained above, cosystolic expansion is considered with a system of equations over a group. Hence, when proving cosystolic expansion, one has to take the group into account. For instance, previous works could obtain cosystolic expansion only over  $\mathbb{F}_2$ , because only over  $\mathbb{F}_2$  there is an equivalence between an unsatisfied equation and an equation that contains an odd number of non-zero variables.

The  $\delta_1$ -expansion property that we study in this work has the interesting property that it can make cosystolic expansion to be *group-independent*, i.e., it implies cosystolic expansion over any group. The key point is that an equation with exactly one non-zero variable must be unsatisfied *regardless of the group*. Thus, even though cosystolic expansion is defined over a group,  $\delta_1$ -expansion implies it over any group.

We expect that this stronger  $\delta_1$ -expansion notion may have further implications to quantum codes and CSPs lower bounds.

### On the novelty of our work

We would like to provide a general outline of the differences between our work and previous works [18, 14].<sup>1</sup>

One fundamental difference is the object we analyze. The major part of previous works is dedicated to the analysis of the expansion of *arbitrary small sets*. In our work, the main analysis is focused on the expansion of “structured” *small sets* (given by the coboundary of a small set). We use a similar machinery as in previous works, but we leverage the extra structure of the small sets in order to obtain the stronger  $\delta_1$ -expansion.

We note that it is not trivial how to utilize this extra structure of small sets in order to obtain  $\delta_1$ -expansion. One cannot just plug it in the proof of previous works and obtain  $\delta_1$ -expansion. It requires a completely different proof strategy, which we describe next.

Briefly, the proof strategy of [18] and [14] is as follows. Given a small set  $A$  of  $k$ -faces, they define a notion of “fat” faces, where an  $\ell$ -face,  $\ell \leq k$ , is considered fat if a large fraction of the  $k$ -faces that contain it belongs to  $A$ . It is trivial that in dimension  $\ell = k$ , the set  $A$  sits only on fat  $k$ -faces, since every  $k$ -face that belongs to  $A$  is fat (because the only  $k$ -face that contains a  $k$ -face is itself). It is also trivial that in dimension  $\ell = -1$ ,  $A$  sits only on thin  $(-1)$ -faces, since the only  $(-1)$ -face is the empty set which is contained in all of the  $k$ -faces of the complex, and  $A$  is a small set of  $k$ -faces. Therefore, there must exist a dimension  $\ell \leq k$  for which a transition from mostly fat faces to mostly thin faces occurs, i.e., in dimension  $\ell$ ,  $A$  sits mostly on fat  $\ell$ -faces, and in dimension  $\ell - 1$ ,  $A$  sits mostly on thin  $(\ell - 1)$ -faces. Their argument is then that the fat  $\ell$ -faces contribute to the parity expansion of  $A$ , whereas the thin  $(\ell - 1)$ -faces account for a negligible error term.

The proof strategy in our work is essentially the opposite. A fat face, which contributes to the parity expansion in the works of [18] and [14], does not have a large  $\delta_1$ , and hence it is impossible to obtain  $\delta_1$ -expansion from the fat faces. Our main idea is to gain the  $\delta_1$ -expansion *from the thin faces*. We observe that if a set sits mostly on thin faces of *one dimension below* then it has a large  $\delta_1$ . Thus, it is crucial for us to show that a small set  $A$

---

<sup>1</sup> Informal note: We are aware that the following explanation might seem not entirely clear at this stage of the paper for an unfamiliar reader. Nevertheless, since we have been repeatedly asked for the differences between our work and previous works, it is important for us to point that out as early as possible. We hope that the main ideas are still clear, even if not all the details are.

of  $k$ -faces actually sits mostly on thin faces of one dimension below. Using the terminology of previous paragraph, we have to show that the transition from mostly fat faces to mostly thin faces happens in dimension  $k$  itself.

This is where the “structure” comes into play. By considering small sets that are obtained as a coboundary of another set, we know that their own coboundary is 0. Without getting too much into the details, it allows us to bound the fraction of fat faces of dimension  $\ell$  by the fraction of fat faces of dimension  $\ell - 1$ , for every  $0 \leq \ell \leq k - 1$ . Thus, since there are no fat faces in dimension  $-1$  (because  $A$  is small), we conclude that there are no fat faces at any dimension! Therefore,  $A$  sits mostly on thin  $(k - 1)$ -faces and hence has a large  $\delta_1$ .

### 1.1 Some basic definitions

#### Coboundary and cosystolic expansion

For the sake of introduction we formally define coboundary and cosystolic expansions only over the field  $\mathbb{F}_2$ . The general definitions will be given in section 2.

Recall that a  $d$ -dimensional simplicial complex  $X$  is a downwards closed  $(d+1)$ -hypergraph. A  $k$ -face of  $X$  is a hyperedge of size  $k + 1$ , and the set of  $k$ -faces of  $X$  is denoted by  $X(k)$ . An assignment of values from  $\mathbb{F}_2$  to the  $k$ -faces,  $k \leq d$ , is called a  $k$ -cochain, and the space of all  $k$ -cochains over  $\mathbb{F}_2$  is denoted by  $C^k(X; \mathbb{F}_2)$ .

Any assignment to the  $k$ -faces  $f \in C^k(X; \mathbb{F}_2)$  induces an assignment to the  $(k + 1)$ -faces by the coboundary operator  $\delta$ . For any  $(k + 1)$ -face  $\sigma = \{v_0, \dots, v_{k+1}\}$ ,  $\delta(f)(\sigma)$  is defined by

$$\delta(f)(\sigma) = \sum_{i=0}^{k+1} f(\sigma \setminus \{v_i\}) \pmod{2}.$$

We can view the complex as inducing a system of equations, where the equations are determined by the coboundary operator; i.e., each  $(k + 1)$ -face  $\sigma \in X(k + 1)$  defines the equation  $\delta(f)(\sigma) = 0$ . The assignments that satisfy all the equations are called the  $k$ -cocycles and denoted by

$$Z^k(X; \mathbb{F}_2) = \{f \in C^k(X; \mathbb{F}_2) \mid \delta(f) = \mathbf{0}\}.$$

One can check that  $\delta(\delta(f)) = \mathbf{0}$  always holds; i.e., every assignment that is obtained as a coboundary of one dimension below satisfies all the equations. These assignments, that are the coboundary of an assignment of one dimension below, are called the  $k$ -coboundaries and denoted by

$$B^k(X; \mathbb{F}_2) = \{\delta(f) \mid f \in C^{k-1}(X; \mathbb{F}_2)\}.$$

Note that  $B^k(X; \mathbb{F}_2) \subseteq Z^k(X; \mathbb{F}_2) \subseteq C^k(X; \mathbb{F}_2)$ .

For a  $d$ -dimensional simplicial complex  $X$ , let  $P_d : X(d) \rightarrow \mathbb{R}_{\geq 0}$  be a probability distribution over the  $d$ -faces of the complex. For simplicity, we will assume in this work that  $P_d$  is the uniform distribution. This probability distribution over the  $d$ -faces induces a probability distribution  $P_k$  for every dimension  $k < d$  by selecting a  $d$ -face  $\sigma_d$  according to  $P_d$  and then selecting a  $k$ -face  $\sigma_k \subset \sigma_d$  uniformly at random.

The weight of any  $k$ -cochain  $f \in C^k(X; \mathbb{F}_2)$  is defined by

$$\|f\| = \Pr_{\sigma \sim P_k} [f(\sigma) \neq 0],$$

i.e., the (weighted) fraction of non-zero elements in  $f$ . The distance between two  $k$ -cochains  $f, g \in C^k(X; \mathbb{F}_2)$  is defined as  $\text{dist}(f, g) = \|f - g\|$ .

We can now introduce the notions of coboundary and cosystolic expansion. As mentioned, a complex is said to be a cosystolic expander if for any assignment that does not satisfy all the equations it holds that the fraction of unsatisfied equations is proportional to the distance of the assignment from a satisfying assignment. Formally:

► **Definition 1.1** (Cosystolic expansion). *A  $d$ -dimensional simplicial complex  $X$  is said to be an  $(\varepsilon, \mu)$ -cosystolic expander over  $\mathbb{F}_2$ , if for every  $k < d$ :*

1. *For any  $f \in C^k(X; \mathbb{F}_2) \setminus Z^k(X; \mathbb{F}_2)$  it holds that*

$$\frac{\|\delta(f)\|}{\text{dist}(f, Z^k(X; \mathbb{F}_2))} \geq \varepsilon,$$

where  $\text{dist}(f, Z^k(X; \mathbb{F}_2)) = \min\{\text{dist}(f, g) \mid g \in Z^k(X; \mathbb{F}_2)\}$ .

2. *For any  $f \in Z^k(X; \mathbb{F}_2) \setminus B^k(X; \mathbb{F}_2)$  it holds that  $\|f\| \geq \mu$ .*

The second condition in the definition ensures that the complex cannot be split into many small pieces, i.e., any satisfying assignment that is not obtained as a coboundary must be large.

Coboundary expansion has been introduced by Linial and Meshulam [20] and independently by Gromov [17]. It is a similar but stronger notion than cosystolic expansion. The main difference is that the only satisfying assignments in a coboundary expander are coboundaries (unlike cosystolic expansion, where there could be satisfying assignments which are not coboundaries as long as they are large). Formally:

► **Definition 1.2** (Coboundary expansion). *A  $d$ -dimensional simplicial complex  $X$  is said to be an  $\varepsilon$ -coboundary expander over  $\mathbb{F}_2$  if for every  $k < d$  and  $f \in C^k(X; \mathbb{F}_2) \setminus B^k(X; \mathbb{F}_2)$  it holds that*

$$\frac{\|\delta(f)\|}{\text{dist}(f, B^k(X; \mathbb{F}_2))} \geq \varepsilon,$$

where  $\text{dist}(f, B^k(X; \mathbb{F}_2)) = \min\{\text{dist}(f, g) \mid g \in B^k(X; \mathbb{F}_2)\}$ .

### Local spectral expansion

Another notion of high dimensional expansion, called *local spectral expansion* is concerned with the spectral properties of local parts of the complex.

For every face  $\sigma \in X$ , its local view, also called its *link*, is a  $(d - |\sigma| - 1)$ -dimensional simplicial complex defined by  $X_\sigma = \{\tau \setminus \sigma \mid \sigma \subseteq \tau \in X\}$ . The probability distribution over the top faces of  $X_\sigma$  is induced from the probability distribution of  $X$ , where for any top face  $\tau \in X_\sigma(d - |\sigma| - 1)$ , its probability is the probability to choose  $\sigma \cup \tau$  in  $X$  conditioned on choosing  $\sigma$ . Since we assume in this work that the probability distribution over the top faces of  $X$  is the uniform distribution, it follows that the probability distribution over the top faces of  $X_\sigma$  is the uniform distribution.

We can now introduce the notion of a local spectral expander.

► **Definition 1.3** (Local spectral expansion). *A  $d$ -dimensional simplicial complex  $X$  is called a  $\lambda$ -local spectral expander if for every  $k \leq d - 2$  and  $\sigma \in X(k)$ , the underlying graph<sup>2</sup> of  $X_\sigma$  is a  $\lambda$ -spectral expander.*

<sup>2</sup> The graph whose vertices are  $X_\sigma(0)$  and its edges are  $X_\sigma(1)$ .

## 1.2 Summary of main results

Our main result is a “unique-neighbor-like” expansion for non-local small sets, which we call  $\delta_1$ -expansion. We start with the definition of the  $\delta_1$  of a set.

► **Definition 1.4** ( $\delta_1$ ). *Let  $X$  be a  $d$ -dimensional simplicial complex. For any set of  $k$ -faces  $A \subseteq X(k)$ ,  $0 \leq k \leq d-1$ , we define  $\delta_1(A) \subseteq X(k+1)$  to be the set of  $(k+1)$ -faces that contain exactly one  $k$ -face from  $A$ .*

Towards proving that small sets have a large  $\delta_1$  we introduce an intermediate notion of *non-local sets*. Roughly speaking, we say that a set of  $k$ -faces is non-local if its “local view” in almost all of the  $(k-1)$ -faces resemble the global picture.

In order to define this notion of non-local sets, we first define the *localization* of a set to a link of a face. For any set  $A \subseteq X(k)$  and an  $\ell$ -face  $\sigma \in X(\ell)$ ,  $\ell < k$ , the localization of  $A$  to the link of  $\sigma$  is a set of  $(k-\ell-1)$ -faces in the link of  $\sigma$  defined by

$$A_\sigma = \{\tau \in X_\sigma(k-\ell-1) \mid \sigma \cup \tau \in A\}.$$

We also add a useful definition of a mutual weight of two sets. For  $\ell < k$  and two sets  $A \subseteq X(k), B \subseteq X(\ell)$  we define their mutual weight by

$$\|(A, B)\| = \Pr_{\sigma_k \sim P_k, \sigma_\ell \subset \sigma_k} [\sigma_k \in A \wedge \sigma_\ell \in B],$$

where  $\sigma_k$  is chosen according to the distribution  $P_k$  and  $\sigma_\ell$  is an  $\ell$ -face chosen uniformly from  $\sigma_k$  (i.e.,  $\sigma_\ell$  is chosen according to  $P_\ell$  conditioned on  $\sigma_k$  being chosen). This notion captures how much the sets are related. For instance, if  $\|(A, B)\| \approx \|A\|$ , it means that  $A$  contains mostly faces from  $B$ .

We can now define non-local sets.

► **Definition 1.5** (Non-local sets). *Let  $X$  be a  $d$ -dimensional simplicial complex and  $0 < \eta, \varepsilon < 1$ . For any set of  $k$ -faces  $A \subseteq X(k)$ ,  $0 \leq k \leq d-1$ , we define the following set of  $(k-1)$ -faces:*

$$S_{k-1} = \{\sigma \in X(k-1) \mid \|A_\sigma\| \leq \eta\}.$$

*We say that  $A$  is  $(\eta, \varepsilon)$ -non-local if  $\|(A, S_{k-1})\| \geq (1-\varepsilon)\|A\|$ .*

As a simple example of a “local” set, consider a set of edges  $A$  composed of all the edges touching a single vertex. In this case,  $\|(A, S_0)\| = (1/2)\|A\|$ . It can be easily checked that in this example, all triangles contain either 0 or 2 edges. As can be seen from this example, local sets are not necessarily  $\delta_1$ -expanding.

The first theorem we show is that non-local sets are  $\delta_1$ -expanding.

► **Theorem 1.6** (Non-local sets are  $\delta_1$ -expanding - informal). *Let  $X$  be a  $d$ -dimensional local spectral expander. For any  $A \subseteq X(k)$ ,  $1 \leq k \leq d-1$ , if  $A$  is non-local then  $\|\delta_1(A)\| \geq \Omega(\|A\|)$ .*

We consider now a bounded degree local spectral expander whose links are coboundary expanders, where a complex is said to be  $q$ -bounded degree if every vertex is contained in at most  $q$  top faces. We show that every set of unsatisfied equations can be treated as if it is non-local. Specifically, we consider sets of the form  $\text{supp}(\delta(f))$  for a  $k$ -cochain  $f \in C^k(X; G)$ , over some group  $G$ . We show a procedure that is given a  $k$ -cochain  $f$  such that  $\|\delta(f)\|$  is small, and returns a  $k$ -cochain  $f'$  which is close to  $f$  such that  $\delta(f')$  is non-local.

► **Theorem 1.7** (Correction algorithm – informal). *Let  $X$  be a  $d$ -dimensional bounded degree local spectral expander with coboundary expanding links over a group  $G$ . For any  $f \in C^k(X; G)$ ,  $1 \leq k \leq d - 2$ , if  $\|\delta(f)\|$  is sufficiently small, then  $f$  is close to a  $k$ -cochain  $f' \in C^k(X; G)$  such that  $\delta(f')$  is small and non-local. Furthermore, there is an efficient algorithm that is given  $f$  and finds  $f'$ .*

We conclude by a similar reduction as in [18] in order to obtain cosystolic expansion over any group. [18] and [14] could obtain cosystolic expansion only over  $\mathbb{F}_2$  because their expansion for small sets only guaranteed that they touch many faces of one dimension above an odd number of times. Since we show here  $\delta_1$ -expansion for such sets, we obtain cosystolic expansion which does not depend on the group.

► **Theorem 1.8** (Cosystolic expansion over any group – informal). *Let  $X$  be a  $d$ -dimensional bounded degree local spectral expander with coboundary expanding links over a group  $G$ . Then the  $(d - 1)$ -skeleton<sup>3</sup> of  $X$  is a cosystolic expander over  $G$ .*

A concrete example of simplicial complexes for which our theorems apply to are the famous Ramanujan complexes [25, 24], which are the high dimensional analog of the celebrated LPS Ramanujan graphs [23]. These complexes are local spectral expanders [14] and their links, called spherical buildings, are coboundary expanders [22]. We note that [22] proved that spherical buildings are coboundary expanders only over  $\mathbb{F}_2$ , but their proof can be easily generalized to any abelian group by considering localizations with orientations of  $k$ -cochains. As for non-abelian groups, [13] proved that spherical buildings are coboundary expanders over non-abelian groups as well. For more on Ramanujan complexes, we refer the reader to [21].

► **Corollary 1.9** (Ramanujan complexes are cosystolic expanders over any group). *Let  $X$  be a  $d$ -dimensional Ramanujan complex. If  $X$  is sufficiently thick<sup>4</sup>, then the  $(d - 1)$ -skeleton of  $X$  is a cosystolic expander over any group  $G$ .*

### 1.3 Organization

In section 2 we provide some required preliminaries. In section 3 we prove the  $\delta_1$ -expansion and cosystolic expansion results over abelian groups. In section 4 we provide the definitions for cochains over non-abelian groups and we repeat the same process as in section 3, but this time for non-abelian groups. The general strategy is the same for abelian and non-abelian groups, but the details are different, hence we split them into different sections.

## 2 Preliminaries

### Coboundary and cosystolic expansion over abelian groups

Let  $X$  be a  $d$ -dimensional simplicial complex and  $G$  an abelian group<sup>5</sup>. We first consider an ordered version of the complex and denote it by  $\vec{X}$ , where

$$\vec{X} = \{(v_0, \dots, v_k) \mid k \leq d, \{v_0, \dots, v_k\} \in X\},$$

i.e.,  $\vec{X}$  contains all possible orderings of every face in  $X$ .

<sup>3</sup> The complex which contains the faces of  $X$  up to dimension  $d - 1$ .

<sup>4</sup> The explanation of the “thickness” of a Ramanujan complex is out of scope of this paper. It is only important for us that a Ramanujan complex can be made arbitrarily thick in order to satisfy the required criteria.

<sup>5</sup> For simplicity we deal here only with abelian groups. We discuss non-abelian groups in section 4.

A  $k$ -cochain over  $G$ ,  $k \leq d$ , is an antisymmetric function  $f : \vec{X}(k) \rightarrow G$ , where  $f$  is said to be antisymmetric if for any permutation  $\pi \in \text{Sym}(k+1)$ ,

$$f((v_{\pi(0)}, v_{\pi(1)}, \dots, v_{\pi(k)})) = \text{sgn}(\pi) f((v_0, v_1, \dots, v_k)).$$

The space of all  $k$ -cochains over  $G$  is denoted by  $C^k(X; G)$ .

Any  $k$ -cochain is an assignment to the  $k$ -faces and it induces a  $(k+1)$ -cochain, i.e., an assignment to the  $(k+1)$ -faces, by the coboundary operator  $\delta$ . For any ordered  $(k+1)$ -face  $\sigma = (v_0, \dots, v_{k+1})$ ,  $\delta(f)(\sigma)$  is defined by

$$\delta(f)(\sigma) = \sum_{i=0}^{k+1} (-1)^i f(v_0, \dots, v_{i-1}, v_{i+1}, \dots, v_{k+1}),$$

where the sum is performed over the group. It is not hard to check that for every  $k$  and  $f \in C^k(X; G)$ ,  $\delta(f)$  is antisymmetric, i.e., a  $(k+1)$ -cochain.

We can view the complex as inducing a system of equations, where the equations are determined by the coboundary operator; i.e., each  $(k+1)$ -face  $\sigma \in X(k+1)$  defines the equation  $\delta(f)(\sigma) = 0$  (note that the ordering of the face does not matter for the satisfaction of the equation). The assignments that satisfy all the equations are called the  $k$ -cocycles and denoted by

$$Z^k(X; G) = \{f \in C^k(X; G) \mid \delta(f) = \mathbf{0}\}.$$

One can check that  $\delta(\delta(f)) = \mathbf{0}$  always holds; i.e., every assignment that is obtained as a coboundary of one dimension below satisfies all the equations. These assignments, that are the coboundary of an assignment of one dimension below, are called the  $k$ -coboundaries and denoted by

$$B^k(X; G) = \{\delta(f) \mid f \in C^{k-1}(X; G)\}.$$

Note that  $B^k(X; G) \subseteq Z^k(X; G) \subseteq C^k(X; G)$ .

Recall that the weight of a  $k$ -cochain  $f \in C^k(X; G)$  is defined by

$$\|f\| = \Pr_{\sigma \sim P_k} [f(\sigma) \neq 0],$$

i.e., the (weighted) fraction of non-zero elements in  $f$ . Since the weight of a cochain is dependent only on its non-zero elements, it is often convenient to consider the set  $\text{supp}(f)$  (i.e., the set of non-zero elements in  $f$ ) and define equivalently

$$\|f\| = \|\text{supp}(f)\| = \Pr_{\sigma \sim P_k} [\sigma \in \text{supp}(f)].$$

For simplicity, we might abuse the notation and write  $\sigma \in f$  where we mean that  $\sigma \in \text{supp}(f)$ .

Now, the formal definitions of coboundary and cosystolic expansion over general abelian groups are identical to definitions 1.1 and 1.2 given in the introduction, with the replacement of  $\mathbb{F}_2$  by an abelian group  $G$ .

### Links and localization

Recall that the link of a  $k$ -face  $\sigma \in X(k)$  is a  $(d-k-1)$ -dimensional complex defined by  $X_\sigma = \{\tau \setminus \sigma \mid \sigma \subseteq \tau \in X\}$ , where the probability distribution over faces of  $X_\sigma$  is induced from the probability distribution over faces of  $X$ . Since we assume in this work that  $P_d$  is

the uniform distribution over the  $d$ -faces of  $X$ , it follows that the probability distribution over the top faces of  $X_\sigma$  is the uniform distribution. In the rest of the paper, we will omit the explicit probability distribution when it is clear from the context.

Recall also that cochains over abelian groups are defined on ordered faces of the complex. For convenience sake, we fix an arbitrary ordering of the faces so that for any face  $\sigma \in X$  there is a unique corresponding ordered face  $\vec{\sigma} \in \vec{X}$ .

For two disjoint ordered faces  $\vec{\sigma} = (v_0, \dots, v_k)$  and  $\vec{\tau} = (u_0, \dots, u_\ell)$  we denote their concatenation by  $\vec{\sigma\tau} = (v_0, \dots, v_k, u_0, \dots, u_\ell)$ . For any  $k$ -face  $\sigma \in X(k)$  and a  $(k + \ell + 1)$ -cochain  $f \in C^{k+\ell+1}(X; G)$ , the *localization* of  $f$  to the link of  $\sigma$  is an  $\ell$ -cochain in the link of  $\sigma$ ,  $f_\sigma \in C^\ell(X_\sigma; G)$  defined as follows. For any ordered  $\ell$ -face  $\vec{\tau} \in \vec{X}_\sigma(\ell)$ ,  $f_\sigma(\vec{\tau}) = f(\vec{\sigma\tau})$ , where  $\vec{\sigma\tau}$  is the concatenation of  $\vec{\sigma}$  (i.e., the unique corresponding ordered face of  $\sigma$ ) and  $\vec{\tau}$ .

By the law of total probability, the weight of any  $k$ -cochain  $f \in C^k(X; G)$  can be decomposed as a sum of its weight in the links of the  $\ell$ -faces of the complex:

► **Lemma 2.1.** *Let  $X$  be a  $d$ -dimensional simplicial complex and  $G$  an abelian group. For every  $f \in C^k(X; G)$ ,  $k \leq d$  and  $\ell < k$ ,*

$$\|f\| = \sum_{\tau \in X(\ell)} \|(f, \tau)\|,$$

where  $\|(f, \tau)\|$  is the mutual weight of  $\text{supp}(f) \subseteq X(k)$  and  $\{\tau\} \subseteq X(\ell)$ .

**Proof.** It follows immediately from the definitions:

$$\|f\| = \Pr_{\sigma \sim P_k} [\sigma \in \text{supp}(f)] = \sum_{\tau \in X(\ell)} \Pr_{\sigma \sim P_k, \tau' \subset \sigma} [\sigma \in \text{supp}(f) \wedge \tau' = \tau] = \sum_{\tau \in X(\ell)} \|(f, \tau)\|,$$

where the second equality follows from the law of total probability. ◀

### Minimal and locally minimal cochains

One of the technical notions we use in this work is the notion of a minimal cochain. We say that a  $k$ -cochain  $f \in C^k(X; G)$  is *minimal* if its weight cannot be reduced by adding a coboundary to it, i.e., for every  $g \in B^k(X; G)$  it holds that  $\|f\| \leq \|f - g\|$ . Recall that the distance of  $f$  from the coboundaries is defined by  $\text{dist}(f, B^k(X; G)) = \min\{\text{dist}(f, g) \mid g \in B^k(X; G)\}$ . Since  $\mathbf{0} \in B^k(X; G)$ , it follows that for every  $f \in C^k(X; G)$ ,  $\|f\| \geq \text{dist}(f, B^k(X; G))$ . Hence,  $f$  is minimal if and only if  $\|f\| = \text{dist}(f, B^k(X; G))$ .

We also define the notion of a locally minimal cochain, where we say that  $f \in C^k(X; G)$  is *locally minimal* if for every vertex  $v$ , the localization of  $f$  to the link of  $v$  is minimal in the link, i.e.,  $f_v$  is minimal in  $X_v$  for every  $v \in X(0)$ .

### Cheeger inequality for graphs

A 1-dimensional simplicial complex  $X$  is just a graph. In this case the known Cheeger inequality gives the following (see e.g. [18] for a proof):

► **Lemma 2.2.** *Let  $X$  be a 1-dimensional simplicial complex which is a  $\lambda$ -spectral expander graph. For any set of vertices  $A \subseteq X(0)$  it holds that*

1.  $\|E(A, \bar{A})\| \geq 2(1 - \lambda) \|A\| \|\bar{A}\|,$
2.  $\|E(A)\| \leq (\|A\| + \lambda) \|A\|,$

where  $E(A, \bar{A})$  is the set of edges with one endpoint in  $A$  and one endpoint in  $\bar{A}$ , and  $E(A)$  is the set of edges with both endpoints in  $A$ .

### 3 Result for abelian groups

#### 3.1 Non-local sets are $\delta_1$ -expanding

In this section we show our results for abelian groups.

Our first theorem is that non-local sets in a local spectral expander have  $\delta_1$  that is proportional to their size. We prove Theorem 1.6 which we restate here in a formal way.

► **Theorem 3.1** (Non-local sets are  $\delta_1$ -expanding). *Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander and  $0 < \eta, \varepsilon < 1$ . For any  $A \subseteq X(k)$ ,  $0 \leq k \leq d-1$ , such that  $A$  is  $(\eta, \varepsilon)$ -non-local it holds that*

$$\|\delta_1(A)\| \geq \left(1 - \binom{k+2}{k} (\lambda + \eta + 2\varepsilon)\right) \|A\|.$$

**Proof.** Recall that we denote by  $S_{k-1}$  the set of  $(k-1)$ -faces  $\sigma \in X(k-1)$  satisfying  $\|A_\sigma\| \leq \eta$ . Let us define the following sets of  $(k+1)$ -faces:

- $\Gamma(A) = \{\tau \in X(k+1) \mid \exists \sigma \in A \text{ s.t. } \sigma \subset \tau\}$ .
- $\Gamma(A, \overline{S_{k-1}}) = \{\tau \in X(k+1) \mid \exists \sigma \in A, \sigma' \in \overline{S_{k-1}} \text{ s.t. } \sigma' \subset \sigma \subset \tau\}$ .
- $\Upsilon = \{\tau \in X(k+1) \mid \exists \sigma, \sigma' \in A \text{ s.t. } \sigma, \sigma' \subset \tau, \sigma \cap \sigma' \in S_{k-1}\}$ .

In words:  $\Gamma(A)$  is the set of all  $(k+1)$ -faces that contain a  $k$ -face from  $A$ ,  $\Gamma(A, \overline{S_{k-1}})$  is the set of all  $(k+1)$ -faces that contain a  $k$ -face from  $A$  which contains a  $(k-1)$ -face from  $\overline{S_{k-1}} = X(k-1) \setminus S_{k-1}$ , and  $\Upsilon$  is the set of all  $(k+1)$ -faces that contain two  $k$ -faces from  $A$  such that their intersection is a  $(k-1)$ -face from  $S_{k-1}$ .

Note that for every  $\tau \in \Gamma(A) \setminus \Gamma(A, \overline{S_{k-1}})$  one of the following cases must hold: Either  $\tau$  contains exactly one  $k$ -face from  $A$ , i.e.,  $\tau \in \delta_1(A)$ , or  $\tau$  contains at least two  $k$ -faces from  $A$  such that their intersection belongs to  $S_{k-1}$ , i.e.,  $\tau \in \Upsilon$ . It follows that

$$\|\delta_1(A)\| \geq \|\Gamma(A) \setminus (\Gamma(A, \overline{S_{k-1}}) \cup \Upsilon)\| \geq \|\Gamma(A)\| - \|\Gamma(A, \overline{S_{k-1}})\| - \|\Upsilon\|. \quad (1)$$

Let us bound each of the above terms separately. First, by simple laws of probability

$$\begin{aligned} \|\Gamma(A)\| &= \Pr[\sigma_{k+1} \in \Gamma(A)] \\ &\geq \Pr[\sigma_{k+1} \in \Gamma(A) \wedge \sigma_k \in A] \\ &= \Pr[\sigma_k \in A] \cdot \Pr[\sigma_{k+1} \in \Gamma(A) \mid \sigma_k \in A] \\ &= \Pr[\sigma_k \in A] = \|A\|. \end{aligned} \quad (2)$$

Second, again by laws of probability

$$\begin{aligned} \|\Gamma(A, \overline{S_{k-1}})\| &= \Pr[\sigma_{k+1} \in \Gamma(A, \overline{S_{k-1}})] \\ &= \frac{\Pr[\sigma_{k+1} \in \Gamma(A, \overline{S_{k-1}}) \wedge \sigma_k \in A \wedge \sigma_{k-1} \notin S_{k-1}]}{\Pr[\sigma_k \in A \wedge \sigma_{k-1} \notin S_{k-1} \mid \sigma_{k+1} \in \Gamma(A, \overline{S_{k-1}})]} \\ &\leq (k+2)(k+1) \Pr[\sigma_k \in A \wedge \sigma_{k-1} \notin S_{k-1}] \\ &= (k+2)(k+1) \|(A, \overline{S_{k-1}})\| \\ &\leq (k+2)(k+1)\varepsilon \|A\|, \end{aligned} \quad (3)$$

where the first inequality holds since the probability that  $\sigma_k \in A$  and  $\sigma_{k-1} \notin S_{k-1}$  given that  $\sigma_{k+1} \in \Gamma(A, \overline{S_{k-1}})$  is at least  $1/((k+2)(k+1))$ , and the second inequality follows since  $A$  is an  $(\eta, \varepsilon)$ -non-local set.

Lastly, consider a  $(k + 1)$ -face  $\tau \in \Upsilon$ . By definition,  $\tau$  contains two  $k$ -faces  $\sigma, \sigma' \in A$  such that  $\sigma \cap \sigma' \in S_{k-1}$ . Let us denote  $\tilde{\tau} = \sigma \cap \sigma'$ . Note that  $\tau$  is seen in the link of  $\tilde{\tau}$  as an edge between two vertices in  $A_{\tilde{\tau}}$ , i.e.,  $\tau \setminus \tilde{\tau} \in E(A_{\tilde{\tau}})$ . Thus,

$$\begin{aligned}
 \|\Upsilon\| &= \sum_{\tau \in \Upsilon} \Pr[\sigma_{k+1} = \tau] \\
 &= \sum_{\tau \in \Upsilon} \frac{\Pr[\sigma_{k+1} = \tau \wedge \sigma_{k-1} = \tilde{\tau}]}{\Pr[\sigma_{k-1} = \tilde{\tau} \mid \sigma_{k+1} = \tau]} \\
 &\leq \sum_{\tau \in \Upsilon} \binom{k+2}{k} \Pr[\sigma_{k+1} = \tau \mid \sigma_{k-1} = \tilde{\tau}] \cdot \Pr[\sigma_{k-1} = \tilde{\tau}] \\
 &\leq \binom{k+2}{k} \sum_{\sigma \in S_{k-1}} \|E(A_\sigma)\| \cdot \Pr[\sigma_{k-1} = \sigma] \\
 &\leq \binom{k+2}{k} \sum_{\sigma \in S_{k-1}} (\|A_\sigma\| + \lambda) \|A_\sigma\| \cdot \Pr[\sigma_{k-1} = \sigma] \\
 &\leq \binom{k+2}{k} (\eta + \lambda) \sum_{\sigma \in S_{k-1}} \|(A_\sigma, \sigma)\| \leq \binom{k+2}{k} (\eta + \lambda) \|A\|,
 \end{aligned} \tag{4}$$

where the third inequality follows since  $X$  is a  $\lambda$ -local spectral expander, and the fourth inequality follows since  $\sigma \in S_{k-1}$ .

Substituting (2), (3) and (4) in (1) finishes the proof.  $\blacktriangleleft$

An immediate corollary of Theorem 3.1 is that any non-local cocycle must be zero.

**► Corollary 3.2 (Non-local cocycles vanish).** *For any  $d \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \lambda, \eta, \varepsilon < 1$  such that  $\lambda + \eta + 2\varepsilon \leq 2/(d + 1)^2$  the following holds: Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander. For any  $f \in Z^k(X; G)$ ,  $0 \leq k \leq d - 1$ , if  $f$  is  $(\eta, \varepsilon)$ -non-local then  $f = \mathbf{0}$ .*

**Proof.** Since  $f$  is  $(\eta, \varepsilon)$ -non-local, then by Theorem 3.1 it holds that

$$\|\delta_1(f)\| \geq \frac{\|f\|}{d + 1}.$$

On the other hand,  $f \in Z^k(X; G)$  and hence  $\|\delta_1(f)\| \leq \|\delta(f)\| = 0$ . It follows that  $f = \mathbf{0}$  as required.  $\blacktriangleleft$

### 3.2 The correction procedure

Our aim now is to show a correction procedure for small coboundaries. We show an algorithm that gets a cochain  $f$  such that  $\|\delta(f)\|$  is small and returns a cochain  $f'$  by making a few changes to  $f$  such that  $\delta(f')$  is non-local.

We start by showing that any small and locally minimal cocycle is non-local. We note that the following proposition is the main technical contribution of our work.

**► Proposition 3.3 (Small and locally minimal cocycles are non-local).** *For any  $d \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \beta, \varepsilon < 1$  there exist  $0 < \lambda, \eta \leq \varepsilon$  such that the following holds: Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links. For any  $f \in Z^k(X; G)$ ,  $1 \leq k \leq d - 1$ , if  $\|f\| \leq \eta^{2^{k+1}-1}$  and locally minimal then  $f$  is  $(\eta, \varepsilon)$ -non-local.*

## 56:12 Unique-Neighbor-Like Expansion and Group-Independent Cosystolic Expansion

In order to prove Proposition 3.3 we need a few more definitions and lemmas. The proofs of the lemmas can be found in the full version of the paper. Let  $f \in C^k(X; G)$ ,  $0 \leq k \leq d-1$ . Recall that  $S_{k-1}$  is the set of  $(k-1)$ -faces  $\sigma$  satisfying  $\|f_\sigma\| \leq \eta$ . For any  $-1 \leq i \leq k-2$ , we define the following set of  $i$ -faces:

$$S_i = \{\sigma \in X(i) \mid (\overline{S_{i+1}})_\sigma \leq \eta^{2^{k-i-1}}\}.$$

We first show that if  $\|f\|$  is sufficiently small then  $\|S_{-1}\| = 1$ , i.e., the empty set belongs to  $S_{-1}$ . We will use the following lemma:

► **Lemma 3.4.** *Let  $X$  be a  $d$ -dimensional simplicial complex,  $G$  an abelian group and  $0 < \eta < 1$ . For any  $f \in C^k(X; G)$ ,  $0 \leq k \leq d$ , if  $\|f\| \leq \eta^{2^{k+1}-1}$  then  $\|S_{-1}\| = 1$ .*

Let  $\Upsilon \subseteq X(k+1)$  be the set of  $(k+1)$ -faces which contain two  $i$ -faces  $\sigma, \sigma' \in \overline{S_i}$  such that  $\sigma \cap \sigma' \in S_{i-1}$ . We show that  $\|\Upsilon\|$  is a negligible fraction of  $\|f\|$ .

► **Lemma 3.5.** *Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander,  $G$  an abelian group and  $0 < \eta < 1$  such that  $\lambda \leq \eta^{2^{d-1}}$ . For any  $f \in C^k(X; G)$ ,  $0 \leq k \leq d-1$ , it holds that*

$$\|\Upsilon\| \leq \eta \binom{k+2}{2} 2^{k+2} \|f\|.$$

For any  $\sigma \in X(i)$ , denote by  $f \downarrow \sigma$  the set of  $k$ -faces  $\tau \in f$  which have a sequence of containments of faces from  $\overline{S_j}$ ,  $i < j < k$ , down to  $\sigma$ . Formally,

$$f \downarrow \sigma = \{\tau \in f \mid \exists \tau_{k-1} \in \overline{S_{k-1}}, \dots, \tau_{i+1} \in \overline{S_{i+1}} \text{ s.t. } \tau \supset \tau_{k-1} \supset \dots \supset \tau_{i+1} \supset \sigma\}.$$

We show that for any cocycle  $f \in Z^k(X; G)$  and  $0 \leq i \leq k-1$ , the fraction of  $f$  that sits on  $i$ -faces from  $\overline{S_i}$  is approximately the fraction of  $f$  that sits on  $(i-1)$ -faces from  $\overline{S_{i-1}}$ .

► **Lemma 3.6.** *Let  $X$  be a  $d$ -dimensional simplicial complex such that its links are  $\beta$ -coboundary expanders over an abelian group  $G$ . For any locally minimal  $f \in Z^k(X; G)$ ,  $1 \leq k \leq d-1$ , and  $0 \leq i \leq k-1$  it holds that*

$$\sum_{\sigma \in \overline{S_i}} \|(f \downarrow \sigma, \sigma)\| \leq \frac{1}{\beta} \left( (k+1-i)(i+1) \sum_{\sigma' \in \overline{S_{i-1}}} \|(f \downarrow \sigma', \sigma')\| + \|\Upsilon\| \right).$$

We can now prove Proposition 3.3.

**Proof of Proposition 3.3.** Let

$$\eta = \frac{\beta^{d-1} \varepsilon}{2^d ((d+1)!)^2} \quad \text{and} \quad \lambda = \eta^{2^{d-1}}.$$

Applying Lemma 3.6 on dimension  $i = k-1, k-2, \dots, 0$  step after step yields

$$\begin{aligned} \|(f, \overline{S_{k-1}})\| &= \sum_{\sigma \in \overline{S_{k-1}}} \|(f \downarrow \sigma, \sigma)\| \\ &\leq \frac{1}{\beta} \|\Upsilon\| + \frac{1}{\beta} \cdot 2 \cdot k \sum_{\sigma \in \overline{S_{k-2}}} \|(f \downarrow \sigma, \sigma)\| \\ &\leq \frac{1}{\beta} \|\Upsilon\| + \frac{1}{\beta^2} \cdot 2 \cdot k \|\Upsilon\| + \frac{1}{\beta^2} \cdot 2 \cdot k \cdot 3 \cdot (k-1) \sum_{\sigma \in \overline{S_{k-3}}} \|(f \downarrow \sigma, \sigma)\| \\ &\leq \left( \frac{1}{\beta} + \frac{1}{\beta^2} \cdot 2 \cdot k + \dots + \frac{1}{\beta^k} (k!)^2 \right) \|\Upsilon\| + \frac{1}{\beta^k} (k!)^2 (k+1) \sum_{\sigma \in \overline{S_{-1}}} \|(f \downarrow \sigma, \sigma)\| \\ &= \left( \frac{1}{\beta} + \frac{1}{\beta^2} \cdot 2 \cdot k + \dots + \frac{1}{\beta^k} (k!)^2 \right) \|\Upsilon\| \leq k \beta^{-k} (k!)^2 \|\Upsilon\| \end{aligned} \tag{5}$$

Substituting Lemma 3.5 in (5) completes the proof. ◀

Now, the idea of the correction algorithm is to make  $\delta(f)$  locally minimal by correcting  $f$  in a few local parts. The algorithm runs in iterations, where at every iteration it does the following one step of correction.

► **Lemma 3.7** (One step of correction). *Let  $X$  be a  $d$ -dimensional simplicial complex and  $G$  an abelian group. For any  $f \in C^k(X; G)$ ,  $1 \leq k \leq d - 1$ , if  $f$  is not locally minimal then there exists a vertex  $v \in X(0)$  and a  $(k - 1)$ -cochain  $g \in C^{k-1}(X; G)$  such that  $\|g\| \leq k \|v\|$  and  $\|f - \delta(g)\| < \|f\|$ .*

**Proof.** Since  $f$  is not locally minimal, there exists a vertex  $v \in X(0)$  such that  $f_v$  is not minimal in  $X_v$ . By definition there exists a  $(k - 2)$ -cochain  $h \in C^{k-2}(X_v; G)$  in the link of  $v$  such that  $\|f_v - \delta(h)\| < \|f_v\|$ . Define  $g \in C^{k-1}(X; G)$  by

$$g(\sigma) = \begin{cases} h(\tau) & \sigma = v\tau, \\ 0 & \text{otherwise.} \end{cases}$$

Note that  $g_v = h$ , therefore  $\|f - \delta(g)\| < \|f\|$ . Furthermore, since  $g(\sigma) = 0$  for every  $\sigma$  which does not contain  $v$  it follows that

$$\|g\| = \Pr[\sigma_{k-1} \in g] = \frac{\Pr[\sigma_{k-1} \in g \wedge \sigma_0 = v]}{\Pr[\sigma_0 = v \mid \sigma_{k-1} \in g]} \leq k \|v\|. \quad \blacktriangleleft$$

We use Lemma 3.7 iteratively to prove Theorem 1.7 which we restate here in a formal way.

► **Theorem 3.8** (Correction algorithm). *For any  $d, q \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \beta, \varepsilon < 1$  there exist constants  $0 < \lambda, \eta \leq \varepsilon$  such that the following holds: Let  $X$  be a  $d$ -dimensional  $q$ -bounded degree  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links. For any  $f \in C^k(X; G)$ ,  $1 \leq k \leq d - 2$ , if  $\|\delta(f)\| \leq \eta^{2^{k+2}-1}$  then there exists  $f' \in C^k(X; G)$  such that  $\text{dist}(f, f') \leq q \binom{d}{k+1} \|\delta(f)\|$ ,  $\|\delta(f')\| \leq \|\delta(f)\|$ , and  $\delta(f')$  is  $(\eta, \varepsilon)$ -non-local.*

**Proof.** Let  $\lambda$  and  $\eta$  be as in Proposition 3.3. Apply Lemma 3.7 for  $\delta(f)$  step by step until no more corrections are possible. Since at every step the weight decreases, this process terminates after some  $r \geq 0$  steps. Denote by  $v_1, v_2, \dots, v_r$  the vertices and by  $g_1, g_2, \dots, g_r$  the  $k$ -cochains given by applying Lemma 3.7 for  $r$  steps, where at step  $i$  we apply it for  $\delta(f - g_1 - \dots - g_{i-1})$ .

Let  $f' = f - g_1 - g_2 - \dots - g_r$ . Since the norm of  $\delta(f)$  decreases at every step of correction, it follows that  $\|\delta(f')\| \leq \|\delta(f)\| \leq \eta^{2^{k+2}-1}$ . Furthermore, since no more corrections are possible, it must be that  $\delta(f')$  is locally minimal. Thus, by Proposition 3.3,  $\delta(f')$  is  $(\eta, \varepsilon)$ -non-local.

It is left to show that  $\|f - f'\|$  is proportional to  $\|\delta(f)\|$ . By definition, for any  $\sigma \in X(k+1)$  it holds that  $\|\sigma\| \geq \left(|X(d)| \binom{d+1}{k+2}\right)^{-1}$ , hence  $r \leq |X(d)| \binom{d+1}{k+2} \|\delta(f)\|$ . Thus,

$$\begin{aligned} \text{dist}(f, f') &= \|g_1 + g_2 + \dots + g_r\| \leq \sum_{i=1}^r (k+1) \|v_i\| \\ &\leq |X(d)| \binom{d+1}{k+2} (k+1) \frac{q}{|X(d)|(d+1)} \|\delta(f)\| \leq \binom{d}{k+1} q \|\delta(f)\| \end{aligned}$$

which finishes the proof. ◀

### 3.3 Cosystolic expansion

We use a similar reduction as in [18] in order to show that  $\delta_1$ -expansion of small sets implies cosystolic expansion over any abelian group. Recall that a complex is a cosystolic expander if the following two properties hold: (1) The systems of equations are expanding, i.e., any assignment that does not satisfy all the equations has a large fraction of unsatisfied equations (proportional to the distance from a satisfying assignment). (2) Every cocycle which is not a coboundary is large. We use the following lemmas which their proofs can be found in the full version of the paper.

► **Lemma 3.9** (The systems of equations are expanding). *For any  $d, q \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \beta < 1$  there exist  $0 < \lambda, \eta < 1$  such that the following holds: Let  $X$  be a  $d$ -dimensional  $q$ -bounded degree  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links over  $G$ . For any  $f \in C^k(X; G) \setminus Z^k(X; G)$ ,  $1 \leq k \leq d - 2$ , it holds that*

$$\|\delta(f)\| \geq \min \left\{ \eta^{2^{k+2}-1}, \frac{1}{q \binom{d}{k+1}} \right\} \cdot \text{dist}(f, Z^k(X; G)).$$

► **Lemma 3.10** (Every cocycle which is not a coboundary is large). *For any  $d \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \beta < 1$ , there exists  $0 < \lambda, \eta < 1$  such that the following holds: Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links over  $G$ . For any  $f \in Z^k(X; G) \setminus B^k(X; G)$ ,  $0 \leq k \leq d - 1$ , it holds that  $\|f\| \geq \eta^{2^d - 1}$ .*

Theorem 1.8, which we restate here in a formal way, follows immediately from the above two lemmas.

► **Theorem 3.11** (Cosystolic expansion over any abelian group). *For any  $d, q \in \mathbb{N}$ , an abelian group  $G$ , and  $0 < \beta < 1$  there exist  $0 < \lambda, \eta < 1$  such that the following holds: Let  $X$  be a  $d$ -dimensional  $q$ -bounded degree  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links over  $G$ . Then the  $(d - 1)$ -skeleton of  $X$  is an  $(\varepsilon, \mu)$ -cosystolic expander over  $G$ , where*

$$\varepsilon = \min \left\{ \eta^{2^d - 1}, \frac{1}{qd^{d/2}} \right\} \quad \text{and} \quad \mu = \eta^{2^d - 1}.$$

**Proof.** Immediate from Lemmas 3.9 and 3.10. ◀

## 4 Result for non-abelian groups

### 4.1 Non-abelian groups

When the group is non-abelian, the coboundary operator is defined only in dimensions 0 and 1, and its definition is more delicate. Let  $G$  be a group with a multiplicative operation. The coboundary of a 0-cochain  $f \in C^0(X; G)$  is a 1-cochain  $\delta(f)$  defined by

$$\delta(f)(u, v) = f(u)f(v)^{-1}.$$

The coboundary of a 1-cochain  $g \in C^1(X; G)$  is a 2-cochain  $\delta(g)$  defined by

$$\delta(g)(u, v, w) = g(u, v)g(v, w)g(w, u).$$

One can check that for  $f \in C^i(X; G)$ ,  $i \in \{0, 1\}$ ,  $\delta(f)$  is an antisymmetric functions, i.e.,  $\delta(f)$  is an  $(i + 1)$ -cochain.

The distance between two cochains  $f, g \in C^i(X; G)$  is defined by  $\text{dist}(f, g) = \|gf^{-1}\|$ , where  $gf^{-1}(\sigma) = g(\sigma)f(\sigma)^{-1}$  for every  $\sigma \in \vec{X}(i)$ .

Similar to the abelian case, we say that  $f \in C^i(X; G)$  is a cocycle if  $\delta(f) = \mathbf{1}$ .<sup>6</sup> The distance of a cochain  $f \in C^i(X; G)$  from the  $i$ -cocycles is defined by

$$\text{dist}(f, Z^i(X; G)) = \min\{\text{dist}(f, g) \mid g \in Z^i(X; G)\}.$$

In order to measure the distance of a 1-cochain from the 1-coboundaries, we define an action of  $C^0(X; G)$  on  $C^1(X; G)$ , where for  $f \in C^0(X; G)$  and  $g \in C^1(X; G)$ ,  $f.g(u, v)$  is defined by

$$f.g(u, v) = f(u)g(u, v)f(v)^{-1}.$$

Now, the distance of  $g$  from the 1-coboundaries is defined by

$$\text{dist}(g, B^1(X; G)) = \min\{\text{dist}(g, f.g) \mid f \in C^0(X; G)\}.$$

## 4.2 Weakly-non-local sets and cosystolic expansion

In the case of a non-abelian group, we cannot get the same non-local property as in abelian groups, rather we get a slightly weaker notion which we call *weakly-non-local*. Roughly speaking, a set of  $k$ -faces in a given complex is weakly-non-local if its  $k$ -faces are evenly distributed on their  $(k - 2)$ -subfaces.

► **Definition 4.1** (Weakly-non-local sets). *Let  $X$  be a  $d$ -dimensional simplicial complex and  $0 < \eta, \varepsilon, \alpha < 1$ . For any set of  $k$ -faces  $A \subseteq X(k)$ ,  $1 \leq k \leq d - 1$ , we define the following set of  $(k - 2)$ -faces:*

$$S_{k-2} = \{\sigma \in X(k - 2) \mid \|A_\sigma\| \leq \eta\}.$$

*We say that  $A$  is  $(\eta, \varepsilon, \alpha)$ -weakly-non-local if  $\|S_{k-2}\| \geq 1 - \varepsilon \|A\|$  and for every  $\tau \in X(k - 1)$  it holds that  $\|A_\tau\| \leq 1 - \alpha$ .*

We show that this weakly-non-local property also implies that the set is  $\delta_1$ -expanding.

► **Theorem 4.2** (Weakly-non-local sets are  $\delta_1$ -expanding). *Let  $X$  be a  $d$ -dimensional  $\lambda$ -local spectral expander and  $0 < \eta, \varepsilon, \alpha < 1$ . There exists a constant  $c = c(d, \lambda, \eta, \varepsilon, \alpha)$  such that for any  $A \subseteq X(k)$ ,  $1 \leq k \leq d - 1$ , if  $A$  is  $(\eta, \varepsilon, \alpha)$ -weakly-non-local then*

$$\|\delta_1(A)\| \geq c \|A\|.$$

*In particular, if  $\varepsilon \leq \alpha/3d^3$ ,  $\lambda \leq \varepsilon^2$  and  $\eta \leq \varepsilon^3$  then  $\|\delta_1(A)\| \geq \alpha \|A\|$ .*

The rest of the steps are similar to the abelian case (with modifications for non-abelian groups) and can be found in the full version of the paper. We just state here the final theorem for cosystolic expansion over non-abelian groups.

► **Theorem 4.3** (Cosystolic expansion over any group). *For any group  $G$ ,  $q \in \mathbb{N}$  and  $0 < \beta < 1$  there exist  $0 < \lambda, \eta < 1$  such that the following holds: Let  $X$  be a 3-dimensional  $q$ -bounded degree  $\lambda$ -local spectral expander with  $\beta$ -coboundary expanding links over  $G$ . Then the 2-skeleton of  $X$  is an  $(\varepsilon, \mu)$ -cosystolic expander over  $G$ , where*

$$\varepsilon = \min \left\{ \frac{\beta\eta}{2}, \frac{1}{2q} \right\} \quad \text{and} \quad \mu = \frac{\beta\eta}{2}.$$

<sup>6</sup> It is common to denote the identity element of a multiplicative group by 1 and not by 0 as in an additive group.

## Abstract

---

We consider evacuation of a group of  $n \geq 2$  autonomous mobile agents (or robots) from an unknown exit on an infinite line. The agents are initially placed at the origin of the line and can move with any speed up to the maximum speed 1 in any direction they wish and they all can communicate when they are co-located. However, the agents have different wireless communication abilities: while some are fully wireless and can send and receive messages at any distance, a subset of the agents are *senders*, they can only transmit messages wirelessly, and the rest are *receivers*, they can only receive messages wirelessly. The agents start at the same time and their communication abilities are known to each other from the start. Starting at the origin of the line, the goal of the agents is to collectively find a target/exit at an unknown location on the line while minimizing the *evacuation time*, defined as the time when the last agent reaches the target.

We investigate the impact of such a mixed communication model on evacuation time on an infinite line for a group of cooperating agents. In particular, we provide evacuation algorithms and analyze the resulting competitive ratio ( $CR$ ) of the evacuation time for such a group of agents. If the group has two agents of two different types, we give an *optimal* evacuation algorithm with competitive ratio  $CR = 3 + 2\sqrt{2}$ . If there is a single sender or fully wireless agent, and multiple receivers we prove that  $CR \in [2 + \sqrt{5}, 5]$ , and if there are multiple senders and a single receiver or fully wireless agent, we show that  $CR \in [3, 5.681319]$ . Any group consisting of only senders or only receivers requires competitive ratio 9, and any other combination of agents has competitive ratio 3.

## 1 Introduction

Search by a group of cooperating autonomous mobile robots for a target in a given domain is a fundamental topic in the theoretical computer science. In the search problem one is interested in finding a target at an unknown location as soon as possible. In the related *evacuation problem* one is interested in optimizing the time it takes the last robot in the group to find the target, often called the *exit*. There has been a lot of interest in trying to understand the impact of communication between agents on the search and evacuation time in the distributed computing area. The design of optimal robot trajectories leading to tight bounds depends not only on the fault-tolerant characteristics of the agents but also on the communication model employed (see [14, 16]). In previous works, agents are assumed to either have full wireless communication abilities, i.e., they can both transmit and receive messages across any distance [10], or limited distance [4], or they have no wireless communication abilities, and can only communicate when they are *face-to-face (F2F)*, i.e., co-located. In terms of communication abilities, the agents are identical.

The present work considers evacuation on an infinite line by a group  $G$  of cooperating robots (initially located at the origin) whose wireless communication abilities are different, which compel them to employ a *mixed* communication model. At a *rudimentary* level they can always communicate reliably using F2F. However, some agents in  $G$  are *senders* that can transmit messages wirelessly at any distance but only receive F2F, yet others are *receivers* in that they can receive messages wirelessly from any distance but can transmit only F2F, and the remaining are fully wireless, and can both send and receive messages wirelessly. This situation might occur because it is cheaper to build agents with limited wireless capabilities, or because the sender or receiver module failed in receiver or sender robots, respectively. Further, we assume the capabilities of the robots are known to each other in advance and remain the same for the duration of an evacuation algorithm. Robots can move at any speed up to maximum 1. We give upper and lower bounds on the competitive ratio of evacuation algorithms, depending on the number of senders and receivers among the agents.

If there are at least two fully wireless agents in the group, then the optimal competitive ratio is 3, see [10]. By pairing up a sender and a receiver we can simulate a fully wireless agent. Consequently, if there is one fully wireless agent, one sender agent, and one receiver agent, the competitive ratio is 3. Consider now the case when there is one fully wireless agent, and one or more senders. Since the sender agents cannot receive wireless transmissions, the sending capabilities of the fully wireless agent are useless, and it is equivalent to a receiver agent. Similarly if there is one fully wireless agent, and one or more receivers, the receiving module in the fully wireless agent is useless, and it is equivalent to a sender agent.

Thus we no longer consider fully wireless agents, and only consider sender and receiver agents. When all of the agents are senders, or all of them are receivers, the only possible mode of communication between agents is F2F; in this case, it has previously been demonstrated that the optimal competitive ratio of evacuation for  $n$  F2F agents is 9. If there are at least two sender agents and two receiver agents, by pairing up sender and receiver agents, we obtain a competitive ratio of 3. It follows that the only interesting cases to consider are when there is exactly one sender and one receiver; one sender and several receivers; one receiver and several senders. These are the cases investigated in detail in this paper.

### 1.1 Model and preliminaries

We consider the problem of evacuation by  $n \geq 2$  mobile agents beginning at the origin of the infinite line. All agents are assumed to have maximum speed 1 and can move in either the positive direction (referred to as moving to the right) or the negative direction (referred

to as moving to the left). The agents may change their speed and the direction of motion instantaneously and arbitrarily often. Moreover, the robots can choose any speed as long as it does not exceed the maximum speed 1.

All agents have the ability to communicate F2F, however the wireless communication abilities of the agents are limited and are not all the same. Indeed the group of  $n$  agents consists of a subset of agents that can only send wireless messages, called *senders*, and a subset that can only receive wireless messages, called *receivers*. We represent by  $n_s \geq 0$  and  $n_r = n - n_s$  the number of senders and receivers respectively.

The cost of an algorithm for the evacuation problem on a given instance of the problem is the time the *last* agent reaches the target, called the *evacuation time*. We denote by  $E(\mathcal{A}, x)$  the evacuation time of algorithm  $\mathcal{A}$  when the target is at location  $x$ . Note that an offline algorithm in which agents know the position of the target can reach it in time  $|x|$ . The goal is to minimize the *competitive ratio*, denoted by CR, defined as the supremum, over all possible target locations, of the normalized cost  $E(\mathcal{A}, x)/|x|$ , i.e.,  $\text{CR}(\mathcal{A}) := \sup_{|x|>1} \frac{E(\mathcal{A}, x)}{|x|}$ .

An evacuation algorithm can be primarily viewed as a set of trajectories, one for each agent. The trajectory of an agent specifies where the agent should be located at any given time. More specifically, the trajectory of an agent is a continuous mapping from the non-negative reals (i.e. time) to the reals (i.e., position on the line). In general, we will represent the trajectory of an agent using the notation  $X = X(t)$  with the interpretation that the agent with trajectory  $X$  will be located at position  $X(t)$  at time  $t$ . Due to our assumption that the agents have maximum unit speed, an agent trajectory  $X$  must satisfy  $|X(t') - X(t)| \leq t' - t$ ,  $\forall t' \geq t \geq 0$ . Agents are assumed to begin their search at the origin and so we must also have  $X(0) = 0$ . Taken together, these equations imply that  $|X(t)| \leq t$ ,  $\forall t \geq 0$ .

We assume that the agents are labelled so that we may assign a specific trajectory to a specific agent. Each agent is assumed to know the trajectory of all other agents. All agents follow their assigned trajectories until they either find the target or are otherwise notified of the target's location. What an agent does in the event that it finds the target depends on the communication ability of the finder and of the other agents. For example, if the finder is a sender and all other agents are receivers, then the sender can immediately notify the other agents who can then proceed to move at full speed to the target. On the other hand, if the finder is a receiver, then it must move to notify another agent(s) of the target's location. In any case, the cost of the algorithm will depend both on the trajectories assigned to the agents to search for the target, as well as the subsequent phase of informing all agents, and the agents travelling to the target.

## 1.2 Related work

Search by a single agent on the infinite line was initiated independently by Beck [6, 7, 8] and Bellman [9]. These seminal papers proved the competitive ratio 9 for search on an infinite line and also gave the impetus for additional studies, including those by Gal [20] which proposes a minimax solution for a game in which player I chooses a real number and player II seeks it by choosing a trajectory represented by a positive function, Friestedt [18], Friestedt and Heath [19], and Baeza-Yates et.al.[2, 3] where search by agents in domains other than the line were proposed, e.g. the ‘‘Lost Cow’’ problem in the plane or at the origin of  $w$  concurrent rays. Additional information on search games and rendezvous can also be found in the book [1].

Group search on an infinite line has been researched in several papers and under various models. Evacuation by multiple cooperating robots was proposed in [10], for the case where the robots can communicate only F2F. More recently, search on the line was considered for

two robots which have distinct speeds in [5] and in [17] when turning costs are taken into account. In addition, in two papers [11, 12] the authors are concerned with minimizing the energy consumed during the search.

There are several types of robot communication models in the literature. The most restricted type of robot communication is F2F in which robots may exchange messages only when they are co-located. At the other extreme is wireless in which robots may communicate regardless of how far apart they are [13]. A model where the wireless communication range is limited has been explored for the equilateral triangle domain in [4].

Within these communication models researchers have considered search with crash [16] and Byzantine [14] faults. The former are innocent faults caused by robot sensor malfunctioning causing the robots an inability to communicate and/or perform their tasks. The latter, however, are malicious faults (intentionally or otherwise) in that the robots may lie and communicate maliciously the wrong information. Lower bounds for search in the crash fault model are proved in [22] and for Byzantine faults in [23]. The competitive ratio for search and evacuation in the near majority case (of  $n = 2f + 1$  robots with  $f$  faulty) is a notoriously hard problem and additional results can be found in the recent paper [15]. Additional information and results can also be found in the recent PhD thesis [21].

In our paper we investigate evacuation time by agents with different wireless communication abilities; as stated earlier, some of them can only transmit wirelessly but not receive, and the others can only receive messages sent wirelessly but not transmit. To our knowledge, in all previous works, the communication abilities of agents were identical; group search or evacuation by agents of different communication abilities has not been studied before.

### 1.3 Results

As mentioned above, we need to consider three cases: when there is exactly one sender and one receiver; one sender and several receivers; one receiver and several senders. In Section 2 we give evacuation algorithms and analyze upper bounds on the competitive ratios for each of these three cases. When we have one receiver and one sender agent, i.e.,  $n_s = n_r = 1$ , we give an evacuation algorithm whose competitive ratio is at most  $3 + 2\sqrt{2}$ . In case when we have one sender and several receivers, i.e.,  $n_s = 1$  and  $n_r > 1$  our evacuation algorithm has competitive ratio at most 5, and when  $n_s > 1$  and  $n_r = 1$  we specify an algorithm with competitive ratio at most  $\approx 5.681319$ . These results can be found in Theorems 1, 2, and 3 respectively.

In Section 3 we consider lower bounds on the competitive ratio of evacuation algorithms for only the cases with only one sender agent, i.e.,  $n_s = 1$ . In particular, we prove a lower bound matching our upper bound for the case of  $n_s = n_r = 1$ , which proves the optimality of our algorithm. For the case of  $n_s = 1$  and  $n_r > 1$  we demonstrate that the evacuation cannot be completed with a competitive ratio less than  $2 + \sqrt{5}$ . We conclude the paper with a discussion of open problems in Section 4.

## 2 Evacuation Algorithms and their Competitive Ratios

In this section we give evacuation algorithms for our communication model and investigate their competitive ratios. We consider separately the cases, first the single sender and single receiver, second the single sender and multiple receivers, and lastly the multiple senders and single receiver.

### 2.1 One sender, one receiver

► **Theorem 1.** *When  $n_s = n_r = 1$  there exists an evacuation algorithm with competitive ratio  $3 + 2\sqrt{2}$ .*

**Proof.** The proof is constructive and based on the following algorithm: the receiver moves to the left at unit speed and the sender moves to the right with speed  $\sqrt{2} - 1$ . If the sender finds the target first then it notifies the receiver (wirelessly) and the receiver moves at unit speed to the target. If the receiver finds the target first then it moves at unit speed to the right until it reaches the sender at which time both agents will move at full speed back to the target. We illustrate this algorithm in Figure 1 using a space-time diagram which plots an agent’s position on the  $x$ -axis, and uses the  $y$ -axis to indicate the flow of time.

■ **Figure 1** The trajectories of the agents when the target is at location  $+x$  (left) and  $-x$  (right). The sender is colored red and the receiver is blue. A dashed line indicates when an agent deviates from its assigned search trajectory. Significant times and positions are indicated.

Suppose that the target is at location  $x > 1$ . The sender will find this target first and will do so at the time  $\frac{x}{\sqrt{2}-1} = (1 + \sqrt{2})x$ . The sender immediately notifies the receiver which is at location  $-(1 + \sqrt{2})x$ . Moving at unit speed, the receiver will travel distance  $x + (1 + \sqrt{2})x = (2 + \sqrt{2})x$  to reach the target and will arrive at time  $(1 + \sqrt{2})x + (2 + \sqrt{2})x = (3 + 2\sqrt{2})x$ . The competitive ratio when  $x > 1$  is thus  $3 + 2\sqrt{2}$ .

Suppose now that the target is at location  $-x < -1$ . The receiver will find the target first and will do so at the time  $x$ . The receiver must move to notify the sender who is located at  $(\sqrt{2} - 1)x$  at time  $x$ . Hence, the distance between the agents is  $x + (\sqrt{2} - 1)x = \sqrt{2}x$  and the receiver will need to cross this distance with a relative speed of  $1 - (\sqrt{2} - 1) = 2 - \sqrt{2}$ . The receiver will thus take time  $\frac{\sqrt{2}x}{2-\sqrt{2}} = \frac{x}{\sqrt{2}-1} = (1 + \sqrt{2})x$ , and both agents will take an additional time  $(1 + \sqrt{2})x$  to reach the target. The time to evacuate is thus  $x + 2(1 + \sqrt{2})x = (3 + 2\sqrt{2})x$ , and, evidently, the competitive ratio in this case is also  $3 + 2\sqrt{2}$ . ◀

Notice that in the algorithm of Theorem 1 it is essential that the sender moves initially at speed less than 1.

### 2.2 One sender, multiple receivers

► **Theorem 2.** When  $n_s = 1$  and  $n_r > 1$  there exists an evacuation algorithm with competitive ratio 5.

**Proof sketch.** The proof is constructive and based on the following algorithm: one receiver moves to the left at unit speed and one receiver moves to the right at unit speed. When one of the receivers finds the target it immediately moves to notify the sender (and all other agents) at the origin. The sender immediately notifies the remaining receiver, and all agents proceed to the target at unit speed. The complete analysis of this algorithm appears in Appendix A. ◀

### 2.3 Multiple senders, one receiver

► **Theorem 3.** When  $n_s > 2$  and  $n_r = 1$  there exists an algorithm  $\mathcal{A}$  with competitive ratio  $CR(\mathcal{A}) < 5.681319$ . More exactly, the competitive ratio is upper bounded by

$$CR(\mathcal{A}) \leq 1 + \frac{1 + v_r}{1 - v_r} \left( \frac{1 + 4v_r - v_r^2}{v_r(3 - v_r)} \right) \tag{1}$$

with  $v_r$  chosen to be the root of the equation  $v_r^4 - 16v_r^3 + 26v_r^2 + 8v_r - 3 = 0$  satisfying  $0 \leq v_r < 1$ .

The proof of this result is much more involved than the previous two cases. When there are more than two senders, all but two of the senders will remain at the origin until they are notified of the target (at which time they move to the announced location). Thus, in the rest of this section we will present our algorithm for the specific case of two senders and one receiver, i.e.,  $n_s = 2$  and  $n_r = 1$ .

■ **Figure 2** Trajectories of the agents for the evacuation algorithm  $EVAC_{RAYS}(v_r)$ . The sender trajectories are red, and the receiver trajectory is blue.

**High level idea.** The robots jointly maintain an interval around the origin of positions that have already been explored by at least one robot. They wish to expand this interval at a fast pace while maintaining the ability to notify all robots quickly in case an exit is found

by at least one robot. The idea behind our algorithm is to make one sender responsible for extending the right end of the searched interval, and another sender responsible for extending the left end of the searched interval. The receiver zig-zags around the origin (with the lengths of zigs and zags increasing in rounds), so that if one of the senders finds an exit, the receiver is “close” to the other sender and can quickly notify it via F2F. In order for this idea to work, the senders cannot simply move away from the origin at full speed, but instead they perform zig-zags of their own (however, unlike the receiver their zig-zags are drifting away from the origin). One can think of a sender as first extending the searched region for a while and then coming back partway towards the origin to get notified by the receiver about what’s happening on the other side of the origin. This strategy is illustrated in Figure 2. When the exit is found by one of the senders, the receiver goes to intercept the other sender and they both move towards the exit.

An interesting feature of the algorithm is that the zig-zag trajectory of the receiver non trivially overlaps with the zig-zag trajectories of the senders, i.e., it does not simply touch them. For example, take a particular time when the receiver meets the right sender for the first time during one zig-zag round. Then the receiver and the right sender travel to the right together for some time. During this time the left sender extends the searched region on the left. If an exit is found by the left sender at this point, this is good – both the right sender and receiver will learn about it instantaneously and will start moving towards the exit. However, the right sender and receiver cannot keep travelling together for very long, since the trajectory needs to have certain symmetries, lest the left sender gets too far. Thus, at some point the receiver and the right sender part ways with the receiver moving towards the left sender and the right sender continuing to the right. At precisely this point, the left sender stops extending the search interval and starts to move towards the receiver (this situation is indicated by dashed lines in Figure 2). Intuitively, this is a good timing for the left sender to switch direction, because otherwise if it finds an exit soon after the receiver and right sender part ways then the receiver would not be able to catch up with the right sender for quite a while (until the right sender’s next “zag”).

Formalizing and analyzing this algorithm takes a lot of work and careful calculations, which are deferred to the appendix. Here, we just state some of the main ingredients. We begin by introducing a class of search trajectories that are parameterized by a four-tuple  $[\eta, v_0, v_1, \gamma]$  where:  $\eta = \pm 1$ , and  $v_0, v_1$ , and  $\gamma$  are real numbers satisfying  $0 \leq v_0 \leq 1$ ,  $-1 \leq v_1 < v_0$ , and  $0 < \gamma \leq 1$ .

■ **Algorithm 1** RAYS( $\eta, v_0, v_1, \gamma$ ).

---

**Begin:** Move to location  $\eta\gamma$  and wait until time  $\frac{\gamma}{v_0}$ .

1: **repeat**

2:     Move in direction  $-\eta$  at unit speed until my position  $x$  at time  $t$  satisfies  $\frac{x}{t} = \eta v_1$ ;

3:     Move in direction  $\eta$  at unit speed until my position  $x$  at time  $t$  satisfies  $\frac{x}{t} = \eta v_0$ ;

**:End**

---

An example of this type of search trajectory is illustrated in Figure 3. As one can observe, after an initial setup phase, the trajectory RAYS( $\eta, v_0, v_1, \gamma$ ) will bounce back and forth between two space-time rays with slopes  $\frac{\eta}{v_0}$  and  $\frac{\eta}{v_1}$ . The parameter  $\gamma$  dictates the “beginning” position on the ray with slope  $\frac{\eta}{v_0}$ , and  $\eta$  is a symmetry parameter in the sense that trajectories RAYS( $\pm 1, v_0, v_1, \gamma$ ) are reflections of each other about the time-axis. Although the above specification of the trajectory RAYS( $\eta, v_0, v_1, \gamma$ ) is simple to understand, it will be more convenient to express these trajectories in terms of their *turning-points* – space-time points at

■ **Figure 3** Example of the trajectory  $\text{RAYS}(1, v_0, v_1, \gamma)$ .

which an agent changes its travel direction, and between which an agent moves at constant unit speed. One can observe from Figure 3 that the turning-points of  $\text{RAYS}(\eta, v_0, v_1, \gamma)$  are precisely the points where the trajectory bounces off the rays with slopes  $\frac{\eta}{v_0}$  and  $\frac{\eta}{v_1}$ . The next lemma provides expressions for the turning-points of the trajectory  $\text{RAYS}(\eta, v_0, v_1, \gamma)$ .

► **Lemma 4.** *The turning-points  $(D_j, T_j)$ ,  $j = 0, 1, \dots$ , of the trajectory  $\text{RAYS}(\eta, v_0, v_1, \gamma)$  are given by*

$$D_j = \eta\gamma \left[ \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} \right]^{\lfloor \frac{j}{2} \rfloor} \begin{cases} 1, & \text{even } j \\ \frac{v_1(1+v_0)}{v_0(1+v_1)}, & \text{odd } j \end{cases}, \quad T_j = \frac{D_j}{\eta} \begin{cases} \frac{1}{v_0}, & \text{even } j \\ \frac{1}{v_1}, & \text{odd } j. \end{cases}$$

We will describe our evacuation algorithm in terms of the trajectories  $\text{RAYS}(1, v_0, v_1, \gamma)$ . To this end, we represent by  $X_{\pm}(t)$  the trajectories of the senders and we refer to the sender with trajectory  $X_+$  (resp.  $X_-$ ) as the *right-sender* (resp. *left-sender*). We use  $X_r(t)$  to represent the trajectory of the receiver. The turning-points of the trajectories  $X_{\pm}$  will be represented by  $(D_j^{\pm}, T_j^{\pm})$ , and the turning-points of the trajectory  $X_r$  will be represented by  $(D_j^r, T_j^r)$ . With this notation our evacuation algorithm can be expressed as in Algorithm 2. We refer to this algorithm by  $\text{EVAC}_{\text{RAYS}}(v_r)$ .

■ **Algorithm 2**  $\text{EVAC}_{\text{RAYS}}(v_r)$ ,  $0 \leq v_r < 1$ .

1:

$$X_{\pm}(t) = \text{RAYS}(\pm 1, v_0, v_1, \gamma_{\pm}), \quad X_r(t) = \text{RAYS}(1, v_r, -v_r, 1). \quad (2)$$

$$v_0 = \frac{v_r(3-v_r)}{1+v_r}, \quad v_1 = \frac{v_r(1-v_r)}{1+3v_r}, \quad \gamma_+ = \frac{3-v_r}{1-v_r}, \quad \gamma_- = \frac{3-v_r}{1-v_r} \frac{1+v_r}{1-v_r} \quad (3)$$

Figure 2 illustrates the trajectories of the agents for the algorithm  $\text{EVAC}_{\text{RAYS}}(v_r)$ . The choices of  $v_0, v_1, \gamma_{\pm}$  in (3) ensure that the trajectories enjoy a number of important properties, some of which are evident in Figure 2. One immediately obvious property is the fact that the right/left-sender spends all of its time to the right/left of the origin (and hence the naming convention). Some other properties that are evident in Figure 2 are given in Observation 5.

► **Observation 5.** For all  $k = 0, 1, 2, \dots$  the following properties hold for the algorithm  $EVAC_{\text{RAYS}}(v_r)$ :

1. the receiver reaches its turning point  $2k+1$  (resp.  $2k+2$ ) at the same time the right-sender (resp. left-sender) reaches its turning-point  $2k$ .
2. the receiver and right-sender (resp. left-sender) are co-located at all times in the interval  $[T_{2k+1}^+, T_{2k+2}^r]$  (resp.  $[T_{2k+1}^-, T_{2k+3}^r]$ ),

In order to establish these properties, we carefully calculate the turning points of all agents in terms of the parameter  $v_r$ . The following lemmas summarize the calculations, which are carried out in Appendix A due to space limit. Equipped with these formulas, Observation 5 follows, which is also demonstrated in the appendix.

► **Lemma 6.** The turning-points of the receiver are

$$D_j^r = (-1)^j \left( \frac{1+v_r}{1-v_r} \right)^j, \quad T_j^r = \frac{1}{v_r} \left( \frac{1+v_r}{1-v_r} \right)^j.$$

► **Lemma 7.** The turning-points of the right-sender are

$$D_j^+ = v_r T_j^r \begin{cases} \frac{3-v_r}{1-v_r}, & \text{even } j \\ \frac{1-v_r}{1+v_r}, & \text{odd } j \end{cases}, \quad T_j^+ = T_j^r \begin{cases} \frac{1+v_r}{1-v_r}, & \text{even } j \\ \frac{1+3v_r}{1+v_r}, & \text{odd } j \end{cases}$$

► **Lemma 8.** The turning-points of the left-sender are

$$D_j^- = -v_r T_{j+1}^r \begin{cases} \frac{3-v_r}{1-v_r}, & \text{even } j \\ \frac{1-v_r}{1+v_r}, & \text{odd } j \end{cases}, \quad T_j^- = T_{j+1}^r \begin{cases} \frac{1+v_r}{1-v_r}, & \text{even } j \\ \frac{1+3v_r}{1+v_r}, & \text{odd } j \end{cases}.$$

The next theorem provides an expression for the competitive ratio of  $EVAC_{\text{RAYS}}(v_r)$  as a function of  $v_r$  (see Appendix A for the proof).

► **Theorem 9.** The competitive ratio of algorithm  $EVAC_{\text{RAYS}}(v_r)$  satisfies

$$CR \leq 1 + \frac{1+v_r}{1-v_r} \left( \frac{1+4v_r-v_r^2}{v_r(3-v_r)} \right).$$

Now that we have an expression for a bound on the competitive ratio we can finally prove Theorem 3.

**Proof (Theorem 3).** We need to optimize the competitive ratio with respect to  $v_r$  and so we need to compute the derivative of the right hand side of (7). This is most easily done with the aid of a computer. We find that

$$\frac{d}{dv_r} \left[ 1 + \frac{1+v_r}{1-v_r} \left( \frac{1+4v_r-v_r^2}{v_r(3-v_r)} \right) \right] = \frac{v_r^4 - 16v_r^3 + 26v_r^2 + 8v_r - 3}{v_r^2(3-v_r)^2(1-v_r)^2}$$

and so the optimum choice of  $v_r$  is a root of the quartic equation  $v_r^4 - 16v_r^3 + 26v_r^2 + 8v_r - 3 = 0$  satisfying  $0 \leq v_r < 1$ . Numerically solving this equation for  $v_r$  yields  $v_r \approx 0.228652$ . For this choice of  $v_r$  one can confirm that  $CR < 5.681319$ . ◀

### 3 Lower bounds

In this section we investigate lower bounds on the competitive ratio of evacuation in our communication model. Our goal is the proof of the following theorem:

► **Theorem 10.** *Let  $\mathcal{A}$  be an evacuation algorithm for one sender and  $n_r \geq 1$  receivers.*

$$CR(\mathcal{A}) \geq \begin{cases} 3 + 2\sqrt{2}, & n_r = 1 \\ 2 + \sqrt{5}, & n_r > 1 \end{cases}.$$

We will need to introduce a number of concepts and definitions. The first definition concerns the knowledge that is available to an agent at a given time.

► **Definition 11.** *An agent is said to know of a location  $x$  at time  $t$  if it has direct or indirect knowledge of  $x$  at time  $t$ . An agent with direct knowledge of  $x$  at time  $t$  has visited location  $x$  at a time  $t' \leq t$ . An agent has indirect knowledge of  $x$  at time  $t$  if it can be notified of  $x$  at a time  $t' \leq t$ .*

The direct knowledge of an agent depends only on its own trajectory, whereas an agent's indirect knowledge depends on both its own and the other agents' trajectories. We define the direct knowledge set  $K_X^D(t)$  as the set of all locations that the agent with trajectory  $X$  has direct knowledge of at time  $t$ . We similarly define the indirect knowledge set  $K_X^I(t; \mathcal{A})$ . The (total) knowledge set is the set  $K_X(t; \mathcal{A}) = K_X^D(t) \cup K_X^I(t; \mathcal{A})$ . We make the following simple observation which results from the unit speed assumption.

► **Observation 12.**  $K_X^D(t) \subseteq [X(t) - t, X(t) + t]$ .

We can use the knowledge set of an agent to lower bound the competitive ratio.

► **Lemma 13.** *For any evacuation algorithm  $\mathcal{A}$ , any  $X \in \mathcal{A}$ , and any time  $t > 0$  we have*

$$CR(\mathcal{A}) \geq \sup_{x \notin K_X(t; \mathcal{A})} \frac{|X(t) - x| + t}{|x|}.$$

Thus, we can derive a lower bound on the competitive ratio by bounding the size of an agent's knowledge set.

We define the functional  $\mu(X)$  which maps a search trajectory to a non-negative real number:

$$\mu(X) =: \limsup_{t \rightarrow \infty} \frac{|X(t)|}{t}. \quad (4)$$

The quantity  $\mu(X)$  can be thought of as an upper bound on the average rate at which the direct knowledge of an agent with trajectory  $X$  grows. We naturally extend the definition of  $\mu$  to take as input an evacuation algorithm:

$$\mu(\mathcal{A}) := \max_{X \in \mathcal{A}} \mu(X). \quad (5)$$

In Appendix B we establish several properties of  $\mu(X)$  and  $K_X$  (and relationships between them) for trajectories  $X$  in evacuation algorithms. These are used in the proofs of the following theorems, from which Theorem 10 follows.

► **Theorem 14.** *Let  $\mathcal{A}$  be an evacuation for one sender and one receiver. Then  $CR(\mathcal{A}) \geq 3 + 2\sqrt{2}$ .*

**Proof.** Let  $\mathcal{A} = \{S, R\}$  with  $S$  and  $R$  the trajectories of the sender and receiver respectively. We must have  $\mu(S) < \mu(\mathcal{A}) = \mu(R)$  since otherwise the competitive ratio is at least 9. Then, Lemma 26 states that

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{(1 + \mu(R))(1 + \mu(S))}{\mu(R)(1 - \mu(S))}$$

and from Lemma 29 we have

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{(1 + \mu(S))(1 + \mu(R))}{\mu(S)(1 + \mu(S))} = \frac{1 + \mu(R)}{\mu(S)}$$

where we have used the fact that  $\mathcal{A}' = \{S\}$  when there is only one receiver. We therefore have

$$\text{CR}(\mathcal{A}) \geq 1 + \max \left\{ \frac{(1 + \mu(R))(1 + \mu(S))}{\mu(R)(1 - \mu(S))}, \frac{1 + \mu(R)}{\mu(S)} \right\}.$$

The first term in the max decreases with  $\mu(R)$  and the second term increases with  $\mu(R)$  and so our best-lower bound is achieved when increasing  $\mu(R)$  is such that the two terms are equal. We find that we need

$$\mu(R) = \frac{\mu(S)(1 + \mu(S))}{1 - \mu(S)}.$$

We then find that

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{1 + \frac{\mu(S)(1 + \mu(S))}{1 - \mu(S)}}{\mu(S)} = 1 + \frac{1}{\mu(S)} + \frac{1 + \mu(S)}{1 - \mu(S)}.$$

Let  $g(u) = \frac{1}{u} + \frac{1+u}{1-u}$  and observe that

$$\begin{aligned} \frac{dg(u)}{du} &= -\frac{1}{u^2} + \frac{1}{1-u} + \frac{1+u}{(1-u)^2} \\ &= -\frac{1}{u^2} + \frac{2}{(1-u)^2} = \frac{(1-u)^2 - 2u^2}{u^2(1-u)^2} = \frac{(1-u-\sqrt{2}u)(1-u+\sqrt{2}u)}{u^2(1-u)^2} \\ &= \frac{[1 - (1 + \sqrt{2})u][1 - (1 - \sqrt{2})u]}{u^2(1-u)^2}. \end{aligned}$$

From this last expression it is clear that  $g(u)$  is minimized when  $u = \frac{1}{1+\sqrt{2}} = \sqrt{2} - 1$ . The minimum is

$$g(\sqrt{2} - 1) = \sqrt{2} + 1 + \frac{\sqrt{2}}{2 - \sqrt{2}} = 2 + 2\sqrt{2}$$

and we can conclude that

$$\text{CR}(\mathcal{A}) \geq 3 + 2\sqrt{2}. \quad \blacktriangleleft$$

► **Corollary 15.** *The evacuation algorithm for one sender and one receiver given in the proof of Theorem 1 is optimal.*

► **Theorem 16.** *Let  $\mathcal{A}$  be an evacuation for one sender and  $n_r > 1$  receivers. Then  $\text{CR}(\mathcal{A}) \geq 2 + \sqrt{5}$ .*

## 57:12 Group Evacuation on a Line by Agents with Different Communication Abilities

**Proof.** Let  $\mathcal{A} = \{S, R, R', \dots\}$  with  $S$  the trajectory of the sender,  $R$  the trajectory of the receiver with largest value of  $\mu(R)$ , and  $R'$  the trajectory of the receiver with second largest  $\mu(R')$ . We must have  $\mu(S) < \mu(\mathcal{A}) = \mu(R)$  since otherwise the competitive ratio is at least 9. Then, Lemma 26 states that

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{(1 + \mu(R))(1 + \mu(S))}{\mu(R)(1 - \mu(S))}$$

and from Lemma 29 we have

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{(1 + \mu(\mathcal{A}'))(1 + \mu(R))}{\mu(\mathcal{A}')(1 + \mu(S))}.$$

If  $\mu(\mathcal{A}') = \mu(S)$  then it follows from Theorem 14 that we will have  $\text{CR}(\mathcal{A}) \geq 3 + 2\sqrt{2}$ . Thus, we assume that  $\mu(S) < \mu(\mathcal{A}')$ . Then  $\mu(R') = \mu(\mathcal{A}')$  and we have

$$\text{CR}(\mathcal{A}) \geq 1 + \max \left\{ \frac{(1 + \mu(R))(1 + \mu(S))}{\mu(R)(1 - \mu(S))}, \frac{(1 + \mu(R'))(1 + \mu(R))}{\mu(R')(1 + \mu(S))} \right\}.$$

The second term in the max increases with decreasing  $\mu(R')$  and the first term does not depend on  $\mu(R')$ . Thus, we set  $\mu(R')$  as large as possible, i.e., we take  $\mu(R') = \mu(R)$ . Then

$$\text{CR}(\mathcal{A}) \geq 1 + \max \left\{ \frac{(1 + \mu(R))(1 + \mu(S))}{\mu(R)(1 - \mu(S))}, \frac{(1 + \mu(R))^2}{\mu(R)(1 + \mu(S))} \right\}.$$

Now both terms in the max increase with decreasing  $\mu(R)$  and so we take  $\mu(R)$  as large as possible, i.e.,  $\mu(R) = 1$ . Then

$$\text{CR}(\mathcal{A}) \geq 1 + 2 \max \left\{ \frac{1 + \mu(S)}{1 - \mu(S)}, \frac{2}{1 + \mu(S)} \right\}.$$

The first term in the max increases with  $\mu(S)$  and the second term decreases with  $\mu(S)$  and so our best-lower bound is achieved when  $\mu(S)$  is such that the two terms are equal. We find that we need  $(1 + \mu(S))^2 = 2(1 - \mu(S))$  or

$$\mu(S)^2 + 4\mu(S) - 1 = 0.$$

The only non-negative solution to this quadratic equation is

$$\mu(S) = \frac{-4 + \sqrt{20}}{2} = \sqrt{5} - 2$$

and we can conclude that

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{4}{\sqrt{5} - 1} = 1 + \frac{4(\sqrt{5} + 1)}{4} = 2 + \sqrt{5}$$

as required. ◀

Our upper bound for the case that  $n_s = 1$  and  $n_r > 1$  was  $5 > 2 + \sqrt{5}$  and so either the lower bound is not tight and/or the upper bound must come down. If one refers to the proof of Theorem 16 then one can observe that our best lower bound was achieved when  $\mu_s = \sqrt{5} - 2$  and  $\mu_1 = \mu_2 = 1$ . However, one can easily confirm that any algorithm with  $\mu_1 = \mu_2 = 1$  has a competitive ratio of at least 5 and so it is evident that, at least, the lower bound is not tight. Thus, in order to make progress on this problem, we believe a different lower bounding technique will be required.

## 4 Conclusions

We have introduced a novel communication model that puts an interesting twist on the classic linear group search problem. We provide upper bounds on the evacuation for the three interesting combinations of agents – one sender and one receiver, one sender and multiple receivers, and multiple senders and one receiver. We demonstrate that our algorithm for the case of one sender and one receiver is optimal by providing a lower bound matching our upper bound. For the case of one sender and two receivers we provide a non-trivial lower bound of  $2 + \sqrt{5}$  which compares to our upper bound of 5. We do not provide any non-trivial lower bounds for the case of multiple senders and one receiver and it is believed that this is the most difficult case to do so (indeed, the upper bound for this case was considerably more complex than the other two cases).

The most immediate open problems concern the lower bounds for the cases of multiple senders and multiple receivers. For the multiple receiver case we provided arguments demonstrating that the lower bound presented here cannot be tight and so in order to close the gap between the lower and upper bounds a different lower bounding technique will be required. Of course, it can also be the case that the upper bound must come down as well (although this does not seem likely). We did not attempt to provide a lower bound for the case of multiple senders (there is a trivial lower bound of 3 which can be derived by considering the first time any agent reaches location  $\pm x$ ).

Our upper bounds on the evacuation seem to hint at the fact that it is better to “listen” than it is to “speak” since our upper bound for the case of multiple receivers is 5 and for multiple senders it is  $\approx 5.681319$  (and we do not believe that these can be improved). Closing the gap between the upper and lower bounds would be interesting even just from the standpoint of answering the question of whether or not it is better to “listen” than it is to “speak”.

## A Proofs for Section 2 (Evacuation Algorithms and their Competitive Ratios)

► **Theorem 17** (Theorem 2 restated). *When  $n_s = 1$  and  $n_r > 1$  there exists an evacuation algorithm with competitive ratio 5.*

**Proof.** The proof is constructive and based on the following algorithm: one receiver moves to the left at unit speed and one receiver moves to the right at unit speed. When one of the receivers finds the target it immediately moves to notify the sender (and all other agents) at the origin. The sender immediately notifies the remaining receiver, and all agents proceed to the target at unit speed. An illustration of this algorithm is provided in Figure 4 for the case that the target is at location  $-x < -1$ . The situation is symmetric when  $x > 1$ .

Suppose that the target is at location  $-x < -1$ . The left receiver will find this target first and will do so at the time  $x$ . It then immediately moves to the origin to notify the sender, arriving at time  $2x$ . The sender notifies the right receiver who is at location  $2x$ . The right receiver then moves at unit speed to the target arriving at time  $5x$ . The competitive ratio is thus 5. The case when  $x > 1$  is totally symmetric and also yields a competitive ratio of 5. ◀

► **Lemma 18** (Lemma 4 restated). *The turning-points  $(D_j, T_j)$ ,  $j = 0, 1, \dots$ , of the trajectory  $\text{RAYS}(\eta, v_0, v_1, \gamma)$  are given by*

$$D_j = \eta\gamma \left[ \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} \right]^{\lfloor \frac{j}{2} \rfloor} \begin{cases} 1, & \text{even } j \\ \frac{v_1(1+v_0)}{v_0(1+v_1)}, & \text{odd } j \end{cases}, \quad T_j = \frac{D_j}{\eta} \begin{cases} \frac{1}{v_0}, & \text{even } j \\ \frac{1}{v_1}, & \text{odd } j. \end{cases}$$

57:16 Group Evacuation on a Line by Agents with Different Communication Abilities

Unrolling this recursion then gives

$$D_j = \left[ \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} \right]^{\lfloor \frac{j}{2} \rfloor} \begin{cases} D_0, & \text{even } j \\ D_1, & \text{odd } j \end{cases} = \gamma \left[ \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} \right]^{\lfloor \frac{j}{2} \rfloor} \begin{cases} 1, & \text{even } j \\ \frac{v_1(1+v_0)}{v_0(1+v_1)}, & \text{odd } j \end{cases}$$

where we have used the fact that  $D_0 = \gamma$ , and our expression for  $D_j$  when  $j$  is odd. ◀

► **Lemma 19** (Lemma 6 restated). *The turning-points of the receiver are*

$$D_j^r = (-1)^j \left( \frac{1+v_r}{1-v_r} \right)^j, \quad T_j^r = \frac{1}{v_r} \left( \frac{1+v_r}{1-v_r} \right)^j.$$

**Proof.** With  $X_r(t) = \text{RAYS}(1, -v_r, v_r, 1)$  it follows from Lemma 4 that for even  $j$  we have

$$D_j^r = \left[ \frac{(1+v_r)(1+v_r)}{(1-v_r)(1-v_r)} \right]^{\lfloor \frac{j}{2} \rfloor} = \left( \frac{1+v_r}{1-v_r} \right)^{2\lfloor \frac{j}{2} \rfloor} = \left( \frac{1+v_r}{1-v_r} \right)^j.$$

and for odd  $j$  we similarly find that  $D_j^r = -\left( \frac{1+v_r}{1-v_r} \right)^j$ . Thus, for  $j$  even or odd we have

$D_j^r = (-1)^j \left( \frac{1+v_r}{1-v_r} \right)^j$ . The times  $T_j^r$  are

$$T_j^r = D_j^r \begin{cases} \frac{1}{v_r}, & \text{even } j \\ -\frac{1}{v_r}, & \text{odd } j. \end{cases} = (-1)^j \frac{D_j^r}{v_r} = \frac{1}{v_r} \left( \frac{1+v_r}{1-v_r} \right)^j.$$

◀

We note the following identities concerning the turning-points  $(D_j^r, T_j^r)$  which we will use these identities often and without reference.

$$T_j^r = \frac{1+v_r}{1-v_r} T_{j-1}^r = \frac{1-v_r}{1+v_r} T_{j+1}^r, \quad D_j^r = -\frac{1+v_r}{1-v_r} D_{j-1}^r = -\frac{1-v_r}{1+v_r} D_{j+1}^r.$$

► **Lemma 20** (Lemma 7 restated). *The turning-points of the right-sender are*

$$D_j^+ = v_r T_j^r \begin{cases} \frac{3-v_r}{1-v_r}, & \text{even } j \\ \frac{1-v_r}{1+v_r}, & \text{odd } j \end{cases}, \quad T_j^+ = T_j^r \begin{cases} \frac{1+v_r}{1-v_r}, & \text{even } j \\ \frac{1+3v_r}{1+v_r}, & \text{odd } j \end{cases}$$

**Proof.** With  $X_+(t) = \text{RAYS}(1, v_0, v_1, \gamma_+)$  it follows from Lemma 4 that

$$D_j^+ = \gamma_+ \left[ \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} \right]^{\lfloor \frac{j}{2} \rfloor} \begin{cases} 1, & \text{even } j \\ \frac{v_1(1+v_0)}{v_0(1+v_1)}, & \text{odd } j \end{cases}, \quad T_j^+ = D_j^+ \begin{cases} \frac{1}{v_0}, & \text{even } j \\ \frac{1}{v_1}, & \text{odd } j. \end{cases}$$

With  $v_0$  and  $v_1$  given by (3) we have

$$\begin{aligned} \frac{(1-v_1)(1+v_0)}{(1+v_1)(1-v_0)} &= \frac{\left(1 - \frac{v_r(1-v_r)}{1+3v_r}\right) \left(1 + \frac{v_r(3-v_r)}{1+v_r}\right)}{\left(1 + \frac{v_r(1-v_r)}{1+3v_r}\right) \left(1 - \frac{v_r(3-v_r)}{1+v_r}\right)} \\ &= \frac{(1+2v_r+v_r^2)(1+3v_r+v_r(1-v_r))}{(1+3v_r+v_r(1-v_r))(1-2v_r+v_r^2)} = \left( \frac{1+v_r}{1-v_r} \right)^2 \end{aligned}$$

We also observe that

$$\begin{aligned} \frac{v_1(1+v_0)}{v_0(1+v_1)} &= \frac{\frac{v_r(1-v_r)}{1+3v_r} \left(1 + \frac{v_r(3-v_r)}{1+v_r}\right)}{\frac{v_r(3-v_r)}{1+v_r} \left(1 + \frac{v_r(1-v_r)}{1+3v_r}\right)} \\ &= \frac{v_r(1-v_r)(1+v_r+v_r(3-v_r))}{v_r(3-v_r)(1+3v_r+v_r(1-v_r))} = \frac{1-v_r}{3-v_r} = \frac{1}{\gamma_+}. \end{aligned}$$

Substituting these last two results into our expression for  $D_j^+$  then yields

$$D_j^+ = \left(\frac{1+v_r}{1-v_r}\right)^{2\lfloor \frac{j}{2} \rfloor} \begin{cases} \gamma_+, & \text{even } j \\ 1, & \text{odd } j \end{cases} = \begin{cases} \gamma_+ \left(\frac{1+v_r}{1-v_r}\right)^j, & \text{even } j \\ \left(\frac{1+v_r}{1-v_r}\right)^{j-1}, & \text{odd } j \end{cases} = v_r T_j^r \begin{cases} \frac{3-v_r}{1-v_r}, & \text{even } j \\ \frac{1-v_r}{1+v_r}, & \text{odd } j \end{cases}$$

as required.

For  $T_j^+$  we have

$$T_j^+ = D_j^+ \begin{cases} \frac{1}{v_0}, & \text{even } j \\ \frac{1}{v_1}, & \text{odd } j. \end{cases} = v_r \begin{cases} \frac{\gamma_+ T_j^r}{v_0}, & \text{even } j \\ \frac{1}{v_1} T_{j-1}^r, & \text{odd } j. \end{cases}$$

We observe that

$$\frac{\gamma_+}{v_0} = \frac{\frac{3-v_r}{1-v_r}}{\frac{v_r(3-v_r)}{1+v_r}} = \frac{1}{v_r} \left(\frac{1+v_r}{1-v_r}\right)$$

and thus

$$T_j^+ = v_r \begin{cases} \frac{1}{v_r} \left(\frac{1+v_r}{1-v_r}\right) T_j^r, & \text{even } j \\ \frac{1+3v_r}{v_r(1-v_r)} T_{j-1}^r, & \text{odd } j \end{cases} = \begin{cases} T_{j+1}^r, & \text{even } j \\ \frac{1+3v_r}{1-v_r} T_{j-1}^r, & \text{odd } j \end{cases} = T_j^r \begin{cases} \frac{1+v_r}{1-v_r}, & \text{even } j \\ \frac{1+3v_r}{1+v_r}, & \text{odd } j \end{cases}.$$

This completes the proof. ◀

► **Lemma 21** (Lemma 8). *The turning-points of the left-sender are*

$$D_j^- = -v_r T_{j+1}^r \begin{cases} \frac{3-v_r}{1-v_r}, & \text{even } j \\ \frac{1-v_r}{1+v_r}, & \text{odd } j \end{cases}, \quad T_j^- = T_{j+1}^r \begin{cases} \frac{1+v_r}{1-v_r}, & \text{even } j \\ \frac{1+3v_r}{1+v_r}, & \text{odd } j \end{cases}.$$

**Proof.** The proof is essentially identical to the proof of Lemma 7. ◀

► **Observation 22** (Observation 5 restated). *For all  $k = 0, 1, 2, \dots$  the following properties hold for the algorithm  $EVAC_{RAVS}(v_r)$ :*

1. *the receiver reaches its turning point  $2k+1$  (resp.  $2k+2$ ) at the same time the right-sender (resp. left-sender) reaches its turning-point  $2k$ .*
2. *the receiver and right-sender (resp. left-sender) are co-located at all times in the interval  $[T_{2k+1}^+, T_{2k+2}^r]$  (resp.  $[T_{2k+1}^-, T_{2k+3}^r]$ ),*

**Proof.** (Observation 5) We will prove the properties for the right-sender only. Those for the left-sender follow in a nearly identical manner.

The first statement we want to prove is: “the receiver reaches its turning point  $2k+1$  at the same time the right-sender reaches its turning-point  $2k$ ”. The receiver reaches its turning-point  $2k+1$  at time  $T_{2k+1}^r$ . The right-sender reaches its turning-point  $2k$  at time  $T_{2k}^+$  and by Lemma 7 we have  $T_{2k}^+ = \frac{1+v_r}{1-v_r} T_{2k}^r = T_{2k+1}^r$ , which proves the statement.

■ **Figure 5** Setup for the proof of Theorem 9. The turning-point  $2k$  of each agent is indicated. On the left the target is found at time  $t_* \leq T_{2k+1}^-$  and on the right the target is found at time  $t_* > T_{2k+1}^-$ .

The second statement we want to prove is: “the receiver and right-sender are co-located at all times in the interval  $[T_{2k+1}^+, T_{2k+2}^+]$ ”. During the interval  $[T_{2k+1}^+, T_{2k+2}^+]$  the right-sender will be moving to the right along the space-time line

$$t = x - D_{2k+1}^+ + T_{2k+1}^+ = x - v_r \frac{1 - v_r}{1 + v_r} T_{2k+1}^r + \frac{1 + 3v_r}{1 + v_r} T_{2k+1}^r = x + \frac{1 + 2v_r + v_r^2}{1 + v_r} T_{2k+1}^r$$

and finally

$$t = x + (1 + v_r) T_{2k+1}^r. \quad (6)$$

During the interval  $[T_{2k+1}^r, T_{2k+2}^r]$  the receiver will be moving to the right along the space-time line

$$t = x - D_{2k+2}^r + T_{2k+2}^r = x - v_r T_R(k+2) + T_R^{2k+2} = x + (1 - v_r) T_{2k+2}^r = x + (1 + v_r) T_{2k+1}^r.$$

We can thus conclude that the right-sender and receiver will be travelling along the same space-time line and will be co-located during the interval  $[T_{2k+1}^+, T_{2k+2}^+] \cap [T_{2k+1}^r, T_{2k+2}^r] = [T_{2k+1}^+, T_{2k+2}^r]$ . ◀

▶ **Theorem 23** (Theorem 9 restated). *The competitive ratio of algorithm  $EVAC_{\text{RAYS}}(v_r)$  satisfies*

$$CR \leq 1 + \frac{1 + v_r}{1 - v_r} \left( \frac{1 + 4v_r - v_r^2}{v_r(3 - v_r)} \right).$$

**Proof.** Due to the symmetry between the right/left-senders, we may assume without loss of generality that the target is found by the right-sender. Moreover, the sequence of intervals  $(D_{2k}^+, D_{2k+2}^+]$ ,  $k = 0, 1, 2, \dots$ , collectively covers the entire line extending from  $D_0^+$  to  $+\infty$  and so we may assume without loss of generality that the target is at location  $x_* \in (D_{2k}^+, D_{2k+2}^+]$ , for some fixed value of  $k \geq 0$ .

The right-sender will reach  $x_*$  while travelling to the right between its turning points  $2k + 1$  and  $2k + 2$ , and, we demonstrated in the proof of Observation 5 that while doing so this sender will be moving along the space-time line with equation (6). Thus, the time  $t_*$  at which the right-sender reaches the target is

$$t_* = x_* + (1 + v_r)T_{2k+1}^r.$$

After reaching the target the right-sender will wirelessly notify the receiver and the receiver will move to notify the left-sender. There are two cases to consider, each of which is illustrated in Figure 5. In the first case – left side of Figure 5 – the target is found at location  $x_*$  such that  $t_* \leq T_{2k+1}^-$ . We know from Observation 5 that the receiver will be co-located with the left-receiver at all times within the interval  $[T_{2k+1}^-, T_{2k+3}^r]$ , and before time  $T_{2k+1}^-$  the receiver and left-sender will be moving towards each other, each at unit speed. Thus, the earliest time that the left-sender could be notified of the target is at the time  $T_{2k+1}^-$ . Evidently, the evacuation time for this case is

$$\begin{aligned} E &= T_{2k+1}^- + |x_* - D_{2k+1}^-| = x_* + \frac{1 + 3v_r}{1 + v_r}T_{2k+2}^r + v_r \frac{1 - v_r}{1 + v_r}T_{2k+2}^r \\ &= x_* + \frac{1 + 3v_r + v_r(1 - v_r)}{1 + v_r}T_{2k+2}^r. \end{aligned}$$

and the competitive ratio is

$$\text{CR} = \frac{E}{x_*} = 1 + \frac{\frac{1+3v_r+v_r(1-v_r)}{1+v_r}T_{2k+2}^r}{x_*}.$$

The competitive ratio increases with decreasing  $x_*$ , and with  $x_* > D_{2k}^+ = v_r \frac{3-v_r}{1-v_r}T_{2k}^r$  we get

$$\begin{aligned} \text{CR} &\leq 1 + \frac{1 + 3v_r + v_r(1 - v_r)}{1 + v_r} \frac{T_{2k+2}^r}{v_r \frac{3-v_r}{1-v_r}T_{2k}^r} \\ &= 1 + \frac{1 + 3v_r + v_r(1 - v_r)}{1 + v_r} \cdot \frac{1 - v_r}{v_r(3 - v_r)} \cdot \frac{(1 + v_r)^2}{(1 - v_r)^2} \\ &= 1 + \frac{1 + v_r}{1 - v_r} \left( \frac{1 + 3v_r + v_r(1 - v_r)}{v_r(3 - v_r)} \right) = 1 + \frac{1 + v_r}{1 - v_r} \left( \frac{1 + 4v_r - v_r^2}{v_r(3 - v_r)} \right). \end{aligned}$$

and finally

$$\text{CR} \leq 1 + \frac{1 + v_r}{1 - v_r} \left( \frac{1 + 4v_r - v_r^2}{v_r(3 - v_r)} \right). \tag{7}$$

The second case – the right side of Figure 5 – occurs when the target is found at a time  $t_* \in (T_{2k+1}^-, T_{2k+2}^+) = (T_{2k+1}^-, T_{2k+3}^r]$ . The left-sender and receiver are co-located during the time interval  $(T_{2k+1}^-, T_{2k+3}^r]$ , and so the left-sender will be notified of the target at time  $t_*$ . By referring to Figure 5 one can observe that the evacuation time for this case will be  $2(t_* - T_{2k+1}^-)$  more than the evacuation time of the previous case, i.e.,

$$E = x_* + \frac{1 + 3v_r + v_r(1 - v_r)}{1 + v_r}T_{2k+2}^r + 2(t_* - T_{2k+1}^-).$$

Since  $t_* = x_* + (1 + v_r)T_{2k+1}^r = x_* + (1 - v_r)T_{2k+2}^r$  and  $T_{2k+1}^- = \frac{1+3v_r}{1+v_r}T_{2k+2}^r$  we get

$$\begin{aligned} E &= 3x_* + \frac{1 + 3v_r + v_r(1 - v_r)}{1 + v_r}T_{2k+2}^r + 2 \left( (1 - v_r) - \frac{1 + 3v_r}{1 + v_r} \right) T_{2k+2}^r \\ &= 3x_* + \frac{1 + 3v_r + v_r(1 - v_r) + 2(1 + v_r)(1 - v_r) - 2(1 + 3v_r)}{1 + v_r}T_{2k+2}^r \\ &= 3x_* + \frac{-(1 + 3v_r) + (2 + 3v_r)(1 - v_r)}{1 + v_r}T_{2k+2}^r \\ &= 3x_* + \frac{1 - v_r(2 + 3v_r)}{1 + v_r}T_{2k+2}^r \end{aligned}$$

and the competitive ratio is

$$\text{CR} = 3 + \frac{1 - v_r(2 + 3v_r)}{1 + v_r} \frac{T_{2k+2}^r}{x_*}$$

When  $v_r(2 + 3v_r) \geq 1$  the competitive ratio is  $\leq 3$ . When  $v_r(2 + 3v_r) < 1$  the competitive ratio is  $> 3$  and increases with decreasing  $x_*$ , or, equivalently, with decreasing  $t_*$ . Thus, we should take  $t_*$  arbitrarily close to  $T_{2k+1}^-$ . However,  $t_* = T_{2k+1}^-$  gave the best-case evacuation time for the case that  $t_* \leq T_{2k+1}^-$ . We can thus conclude that a worst-case competitive ratio can be achieved when  $t_* \leq T_{2k+1}^-$  and the competitive ratio of the algorithm is upper bounded by (7).  $\blacktriangleleft$

## B Proofs for Section 3 (Lower bounds)

► **Lemma 24.** *Let  $X$  be a search trajectory. If  $\mu(X) < 1$  then for all  $0 < \epsilon < 1 - \mu(X)$  there exists a time  $T > 0$  such that*

$$K_X^D(t) \subseteq \left[ -\frac{(\mu(X) + \epsilon)(t - X(t))}{1 + \mu(X) + \epsilon}, \frac{(\mu(X) + \epsilon)(t + X(t))}{1 + \mu(X) + \epsilon} \right], \quad \forall t > T.$$

*In the case of  $\mu(X) = 1$  the parameter  $\epsilon$  can be taken to be 0 in the above expression.*

**Proof.** By the definition of  $\mu(X)$ , it follows that for all  $\epsilon > 0$  there exists a time  $T' > 0$  such that

$$-(\mu(X) + \epsilon)t \leq X(t) \leq (\mu(X) + \epsilon)t, \quad \forall t > T'. \quad (8)$$

Moreover, when  $\mu(X) = 1$  the  $\epsilon$  can be taken to be 0, since  $|X(t)| \leq t$ .

In order to have direct knowledge of location  $x$  at time  $t > T'$  there must exist a time  $t' \leq t$  such that  $X(t') = x$ . The unit speed of the agents implies that  $|X(t) - x| \leq t - t'$  or

$$t' - t + X(t) \leq x \leq t + X(t) - t'. \quad (9)$$

Assume that  $t' > T'$ . Then we can combine (8) and (9) to get

$$\max\{-(\mu(X) + \epsilon)t', t' - t + X(t)\} \leq x \leq \min\{(\mu(X) + \epsilon)t', t + X(t) - t'\}. \quad (10)$$

On the left, the first term in the max decreases with  $t'$  and the second term increases with  $t'$ . Thus, the best lower bound is achieved when the two terms are equal. This will occur when

$$t' = \frac{t - X(t)}{1 + \mu(X) + \epsilon}.$$

For this value of  $t'$  we get

$$x \geq -\frac{(\mu(X) + \epsilon)(t - X(t))}{1 + \mu(X) + \epsilon}.$$

At time  $t$  we have  $X(t) \leq (\mu(X) + \epsilon)t$  and thus

$$t' = \frac{t - X(t)}{1 + \mu(X) + \epsilon} \geq \frac{t - (\mu(X) + \epsilon)t}{1 + \mu(X) + \epsilon} = \frac{1 - \mu(X) - \epsilon}{1 + \mu(X) + \epsilon}t.$$

Hence, we will have  $t' > T'$  for all

$$t > T = \frac{1 + \mu(X) + \epsilon}{1 - \mu(X) - \epsilon}T'. \quad (11)$$

When  $\mu(X) = 1$  the above expression is vacuously true, since  $T'$  can be taken to be 0.

In a similar manner, we get from the right side of (10) that

$$x \leq \frac{(\mu(X) + \epsilon)(t + X(t))}{1 + \mu(X) + \epsilon}.$$

for all  $t$  satisfying (11). This completes the proof.  $\blacktriangleleft$

In a similar manner we can bound the total knowledge available to an agent that can only receive messages face-to-face.

► **Lemma 25.** *Let  $\mathcal{A}$  be an evacuation algorithm and let  $X_{f2f} \in \mathcal{A}$  represent the trajectory of an agent that can only receive messages face-to-face. If  $\mu(X_{f2f}) < 1$  then for all  $0 < \epsilon < 1 - \mu(X_{f2f})$  there exists a time  $T > 0$  such that*

$$K_{X_{f2f}}(t; \mathcal{A}) \subseteq \left[ -\frac{(\mu(\mathcal{A}) + \epsilon)(t - X_{f2f}(t))}{1 + \mu(\mathcal{A}) + \epsilon}, \frac{(\mu(\mathcal{A}) + \epsilon)(t + X_{f2f}(t))}{1 + \mu(\mathcal{A}) + \epsilon} \right], \quad \forall t > T.$$

In the case of  $\mu(X_{f2f}) = 1$  the parameter  $\epsilon$  can be taken to be 0 in the above expression.

**Proof.** When  $\mu(X) < 1$  it follows from the definitions of  $\mathcal{A}$  and  $\mu(X)$  that there exists a time  $T' > 0$  such that for any  $X \in \mathcal{A}$  we have

$$-(\mu(\mathcal{A}) + \epsilon)t \leq X(t) \leq (\mu(\mathcal{A}) + \epsilon)t, \quad \forall t > T', \quad \forall X \in \mathcal{A}. \quad (12)$$

In order to have direct knowledge of location  $x$  at time  $t > T'$  there must exist a time  $t' \leq t$  such that  $X_{f2f}(t') = x$ . The unit speed of the agents implies that  $|X_{f2f}(t) - x| \leq t - t'$  or that (9) must be satisfied by the trajectory  $X_{f2f}$  at time  $t$ .

In order to have indirect knowledge of location  $x$  at time  $t$  there must exist another agent that visits  $x$  at time  $t' \leq t$  and can reach location  $X_{f2f}(t)$  by time  $t$ . Indeed, this agent must be able to catch the agent with trajectory  $X_{f2f}$  at or before time  $t$ , and the agent with trajectory  $X_{f2f}$  will be at location  $X_{f2f}(t)$  at time  $t$ . Thus, in order to have indirect knowledge of  $x$ , the unit speed condition implies again that  $|X_{f2f}(t) - x| \leq t - t'$  or that (9) is satisfied. To complete the proof we follow the same steps of the proof of Lemma 24 except with (12) used in place of (8).  $\blacktriangleleft$

We will now focus on the case that there is only a single sender involved in the evacuation. The sender can only be communicated with face-to-face and so Lemma 25 applies in this case. We can use it to get the following result.

► **Lemma 26.** *Let  $\mathcal{A}$  be an evacuation algorithm with one sender and let  $S \in \mathcal{A}$  represent the trajectory of this sender. If  $\mu(S) = 1$  then  $CR(\mathcal{A})$  is unbounded. If  $\mu(S) < 1$  then we have*

$$CR(\mathcal{A}) \geq 1 + \frac{(1 + \mu(\mathcal{A}))(1 + \mu(S))}{\mu(\mathcal{A})(1 - \mu(S))}.$$

**Proof.** If  $\mu(S) = 1$  then the previous lemma tells us that  $K_S(t; \mathcal{A}) = [-\frac{t-S(t)}{2}, \frac{t+S(t)}{2}]$ . Suppose without loss of generality that  $S(t) = t$ . Then  $K_S(t) = [0, t]$  and by Lemma 13 we have

$$CR(\mathcal{A}) \geq \sup_{x \notin K_S(t; \mathcal{A})} \frac{|X(t) - x| + t}{|x|} = \sup_{\epsilon > 1} \frac{2t + \epsilon}{\epsilon} > 2t + 1.$$

Since the above holds for infinitely many arbitrary large  $t$  values, we conclude that  $CR(\mathcal{A})$  is unbounded.

Suppose now that  $\mu(S) < 1$ . Then for all  $0 < \epsilon < 1 - \mu(S)$  there exists a time  $T$  such that

$$K_S(t; \mathcal{A}) \subseteq \left[ -\frac{(\mu(\mathcal{A}) + \epsilon)(t - S(t))}{1 + \mu(\mathcal{A}) + \epsilon}, \frac{(\mu(\mathcal{A}) + \epsilon)(t + S(t))}{1 + \mu(\mathcal{A}) + \epsilon} \right], \forall t > T.$$

Moreover, from the definition of  $\mu(X)$  it follows that for any  $\Delta > 0$  there exists a time  $\tau$  such that  $|S(\tau)| = \mu(S)\tau \pm o(\tau)$ . Take  $\Delta > T$  and assume without loss of generality that  $S(\tau) = \mu(S)\tau \pm o(\tau)$ . Then

$$K_S(\tau; \mathcal{A}) \subseteq \left[ -\frac{(\mu(\mathcal{A}) + \epsilon)(1 - \mu(S))\tau}{1 + \mu(\mathcal{A}) + \epsilon}, \frac{(\mu(\mathcal{A}) + \epsilon)(1 + \mu(S))\tau}{1 + \mu(\mathcal{A}) + \epsilon} \right]$$

and

$$\begin{aligned} CR(\mathcal{A}) &\geq \sup_{x \notin K_S(\tau; \mathcal{A})} \frac{|S(\tau) - x| + \tau}{|x|} \\ &= 1 + \sup_{\epsilon' > 0} \frac{(1 + \mu(S))\tau}{\frac{(\mu(\mathcal{A}) + \epsilon)(1 - \mu(S))\tau}{1 + \mu(\mathcal{A}) + \epsilon} + \epsilon'} = 1 + \frac{(1 + \mu(\mathcal{A}) + \epsilon)(1 + \mu(S))}{(\mu(\mathcal{A}) + \epsilon)(1 - \mu(S))} \\ &> 1 + \frac{(1 + \mu(\mathcal{A}))(1 + \mu(S))}{\mu(\mathcal{A})(1 - \mu(S))} \left[ \frac{1}{1 + \frac{\epsilon}{\mu(\mathcal{A})}} \right]. \end{aligned}$$

The term in square brackets approaches 1 from below as  $\epsilon \rightarrow 0$  and thus for any fixed  $\delta > 0$  we can choose  $\epsilon > 0$  small enough that

$$CR(\mathcal{A}) > 1 - \delta + \frac{(1 + \mu(\mathcal{A}))(1 + \mu(S))}{\mu(\mathcal{A})(1 - \mu(S))}.$$

◀

► **Corollary 27.** *Let  $\mathcal{A}$  be an evacuation algorithm with one sender and let  $S \in \mathcal{A}$  represent the trajectory of this sender. If  $\mu(S) = \mu(\mathcal{A})$  we have  $CR(\mathcal{A}) \geq 9$ .*

**Proof.** With  $\mu(S) = \mu(\mathcal{A})$  we have from Lemma 26 that

$$CR(\mathcal{A}) \geq 1 + \frac{(1 + \mu(S))^2}{\mu(S)(1 - \mu(S))}$$

for all  $\delta > 0$ . Let  $g(u) = \frac{(1+u)^2}{u(1-u)}$  and observe that

$$\begin{aligned} \frac{dg(u)}{du} &= \frac{2(1+u)}{u(1-u)} - \frac{(1+u)^2(1-2u)}{u^2(1-u)^2} = (1+u) \left[ \frac{2u(1-u) - (1+u)(1-2u)}{u^2(1-u)^2} \right] \\ &= (1+u) \left[ \frac{2u - 2u^2 - 1 + 2u - u + 2u^2}{u^2(1-u)^2} \right] = \frac{(1+u)(3u-1)}{u^2(1-u)^2}. \end{aligned}$$

From this last expression it is clear that  $u = 1/3$  is the only non-negative minimizer. When  $u = 1/3$  we find  $g(1/3) = \frac{(1+\frac{1}{3})^2}{\frac{1}{3}(1-\frac{1}{3})} = 8$  and thus we can conclude that  $\text{CR}(\mathcal{A}) > 9 - \delta$  for arbitrary  $\delta > 0$  as required. ◀

In the next lemma we consider the knowledge set of the receivers.

► **Lemma 28.** *Let  $\mathcal{A}$  be an evacuation algorithm with one sender and at least one receiver. Let  $S$  be the trajectory of the sender and suppose that  $\mu(S) < \mu(\mathcal{A})$ . Let  $R$  be the trajectory of a receiver with  $\mu(R) = \mu(\mathcal{A})$ . If  $\mu(R) < 1$  then for all  $0 < \epsilon < 1 - \mu(R)$  there exists a time  $T > 0$  such that*

$$K_R(t; \mathcal{A}) = K_S(t; \mathcal{A}) \cup \left[ -\frac{(\mu(R) + \epsilon)(t - R(t))}{1 + \mu(R) + \epsilon}, \frac{(\mu(R) + \epsilon)(t + R(t))}{1 + \mu(R) + \epsilon} \right], \quad \forall t > T.$$

In the case of  $\mu(R) = 1$  the parameter  $\epsilon$  can be taken to be 0 in the above expression.

**Proof.** The receivers can receive wireless messages from the sender and so at any time they know what the sender knows. If we exclude knowledge from the sender, a receiver can only possess direct knowledge, or receive knowledge indirectly from a different receiver. However, receivers can't send messages and so communication between receivers is face-to-face. Thus, to complete the proof, we only need to invoke Lemma 25. ◀

► **Lemma 29.** *Let  $\mathcal{A}$  be an evacuation algorithm with one sender and at least one receiver. Let  $S \in \mathcal{A}$  represent the trajectory of this sender; let  $R \in \mathcal{A}$  represent the trajectory of the receiver with the largest value of  $\mu(R)$ ; and define  $\mathcal{A}' = \mathcal{A} \setminus \{R\}$ . Then, we have*

$$\text{CR}(\mathcal{A}) \geq 1 + \frac{(1 + \mu(\mathcal{A}'))(1 + \mu(R))}{\mu(\mathcal{A}')(1 + \mu(S))}.$$

**Proof.** We make use of Lemma 28. If  $\mu(R) = 1$  then

$$K_R(t; \mathcal{A}) = K_S(t; \mathcal{A}) \cup \left[ -\frac{t - R(t)}{2}, \frac{t + R(t)}{2} \right].$$

If  $\mu(R) < 1$  then for all  $0 < \epsilon < 1 - \mu(R)$  there exists a time  $T_R > 0$  such that

$$K_R(t; \mathcal{A}) = K_S(t; \mathcal{A}) \cup \left[ -\frac{(\mu(R) + \epsilon)(t - R(t))}{1 + \mu(R) + \epsilon}, \frac{(\mu(R) + \epsilon)(t + R(t))}{1 + \mu(R) + \epsilon} \right], \quad \forall t > T_R.$$

Moreover, for any  $\Delta > 0$  there exists a time  $\tau > \Delta$  such that  $|R(t)| = \mu(R)\tau$ . Assume without loss of generality that  $R(\tau) = \mu(R)\tau$ . Then  $K_R(\tau; \mathcal{A}) = K_S(\tau; \mathcal{A}) \cup [0, \tau]$  if  $\mu(R) = 1$  and for  $\mu(R) < 1$  we can take any  $\Delta > T_R$  to get

$$K_R(\tau; \mathcal{A}) = K_S(\tau; \mathcal{A}) \cup \left[ -\frac{(\mu(R) + \epsilon)(1 - \mu(R))\tau}{1 + \mu(R) + \epsilon}, \frac{(\mu(R) + \epsilon)(1 + \mu(R))\tau}{1 + \mu(R) + \epsilon} \right].$$

In light of the proof of Lemma 26 and its corollary, it is clear that unless the sender can increase the lower bound of the receiver's knowledge, we will find that  $\text{CR}(\mathcal{A})$  is unbounded when  $\mu(R) = 1$ , and when  $\mu(R) < 1$  we will get  $\text{CR}(\mathcal{A}) > 9 - \delta$  for all  $\delta > 0$ . Thus, we assume that the sender can increase the lower bound of the receiver's knowledge.

Consider the knowledge set  $K_S(t; \mathcal{A})$  of the sender. Since this must extend the knowledge of the receiver with trajectory  $R$  we can exclude this receiver from the computation of  $K_S(t; \mathcal{A})$ . Thus, if we take  $\mathcal{A}' = \mathcal{A} \setminus \{R\}$  we can invoke Lemma 25 with respect to  $\mathcal{A}'$  to conclude that for all  $0 < \epsilon < 1 - \mu(S)$  there exists a time  $T_S > 0$  such that

$$K_S(t; \mathcal{A}') \subseteq \left[ -\frac{(\mu(\mathcal{A}') + \epsilon)(t - S(t))}{1 + \mu(\mathcal{A}') + \epsilon}, \frac{(\mu(\mathcal{A}') + \epsilon)(t + S(t))}{1 + \mu(\mathcal{A}') + \epsilon} \right], \quad \forall t > T_S.$$

We can take  $\Delta > \max\{T_R, T_S\}$  so that  $\tau > T_S$  and as a result

$$K_S(\tau; \mathcal{A}) \subseteq \left[ -\frac{(\mu(\mathcal{A}') + \epsilon)(\tau - S(\tau))}{1 + \mu(\mathcal{A}') + \epsilon}, \frac{(\mu(\mathcal{A}') + \epsilon)(\tau + S(\tau))}{1 + \mu(\mathcal{A}') + \epsilon} \right].$$

By definition of  $\mu(S)$ , at any time  $t > T_s$  we have  $|S(t)| \leq (\mu(S) + \epsilon)t$  and thus

$$K_S(\tau; \mathcal{A}) \subseteq \left[ -\frac{(\mu(\mathcal{A}') + \epsilon)(1 + \mu(S) + \epsilon)\tau}{1 + \mu(\mathcal{A}') + \epsilon}, \frac{(\mu(\mathcal{A}') + \epsilon)(1 + \mu(S) + \epsilon)\tau}{1 + \mu(\mathcal{A}') + \epsilon} \right].$$

By Lemma 13 we then have

$$\begin{aligned} \text{CR}(\mathcal{A}) &\geq \sup_{x \notin K_R(\tau; \mathcal{A})} \frac{|R(\tau) - x| + \tau}{|x|} \\ &= 1 + \sup_{\epsilon' > 0} \frac{(1 + \mu(R))\tau}{\frac{(\mu(\mathcal{A}') + \epsilon)(1 + \mu(S))\tau}{1 + \mu(\mathcal{A}') + \epsilon} + \epsilon'} = 1 + \frac{(1 + \mu(\mathcal{A}') + \epsilon)(1 + \mu(R))}{(\mu(\mathcal{A}') + \epsilon)(1 + \mu(S) + \epsilon)} \\ &> 1 + \frac{(1 + \mu(\mathcal{A}'))(1 + \mu(R))}{\mu(\mathcal{A}')(1 + \mu(S))} \left[ \frac{1}{1 + \frac{\epsilon}{\mu(\mathcal{A}')}} \right] \left[ \frac{1}{1 + \frac{\epsilon}{\mu(S)}} \right]. \end{aligned}$$

It is clear that  $\mu(S) > 0$  (and, thus, also  $\mu(\mathcal{A}') > 0$ ) since otherwise the sender would not extend the receiver's knowledge. Then both of the terms in square brackets approach 1 from below as  $\epsilon \rightarrow 0$  and so we can choose  $\epsilon > 0$  small enough that for any fixed  $\delta > 0$  we have

$$\text{CR}(\mathcal{A}) > 1 - \delta + \frac{(1 + \mu(\mathcal{A}'))(1 + \mu(R))}{\mu(\mathcal{A}')(1 + \mu(S))}$$

as required. ◀

# Lower Bounds for Induced Cycle Detection in Distributed Computing

François Le Gall ✉

---

## Abstract

The distributed subgraph detection asks, for a fixed graph  $H$ , whether the  $n$ -node input graph contains  $H$  as a subgraph or not. In the standard CONGEST model of distributed computing, the complexity of clique/cycle detection and listing has received a lot of attention recently.

In this paper we consider the induced variant of subgraph detection, where the goal is to decide whether the  $n$ -node input graph contains  $H$  as an *induced* subgraph or not. We first show a  $\tilde{\Omega}(n)$  lower bound for detecting the existence of an induced  $k$ -cycle for any  $k \geq 4$  in the CONGEST model. This lower bound is tight for  $k = 4$ , and shows that the induced variant of  $k$ -cycle detection is much harder than the non-induced version. This lower bound is proved via a reduction from two-party communication complexity. We complement this result by showing that for  $5 \leq k \leq 7$ , this  $\tilde{\Omega}(n)$  lower bound cannot be improved via the two-party communication framework.

We then show how to prove stronger lower bounds for larger values of  $k$ . More precisely, we show that detecting an induced  $k$ -cycle for any  $k \geq 8$  requires  $\tilde{\Omega}(n^{2-\Theta(1/k)})$  rounds in the CONGEST model, nearly matching the known upper bound  $\tilde{O}(n^{2-\Theta(1/k)})$  of the general  $k$ -node subgraph detection (which also applies to the induced version) by Eden, Fiat, Fischer, Kuhn, and Oshman [DISC 2019].

Finally, we investigate the case where  $H$  is the diamond (the diamond is obtained by adding an edge to a 4-cycle, or equivalently removing an edge from a 4-clique), and show non-trivial upper and lower bounds on the complexity of the induced version of diamond detecting and listing.

## 1 Introduction

**Background.** The subgraph detection problem asks us to decide if the  $n$ -node input graph contains a copy of some fixed subgraph  $H$  or not. This problem has received a lot of attention in the past 40 years, and has recently been investigated in the setting of distributed computing as well. There are actually two versions for this problem. The first version simply requires to decide if the input network contains  $H$ . The second version cares about induced  $H$ , and asks to decide if the input network contains a *vertex-induced* copy of  $H$ . We refer to Figure 1 for an illustration of the difference between the two versions. In this paper we call the former version “non-induced  $H$  detection” and the latter version “induced  $H$  detection”.

■ **Figure 1** This graph contains a 4-cycle as a subgraph but not an induced 4-cycle.

When considering subgraph detection in the (synchronous) distributed setting, the communication network is identified with the input graph, i.e., we ask whether the  $n$ -node communication network contains  $H$  as a subgraph (induced or non-induced, depending on the version considered). The complexity is characterized by the number of rounds of (synchronous) communication needed to solve the problem. For networks with unbounded bandwidth (the so-called LOCAL model in distributed computing), both versions of the subgraph detection problem are essentially trivial: for any  $O(1)$ -node subgraph  $H$ , the problem can be solved in  $O(1)$  rounds by a naive approach. For networks with bounded bandwidth (the so-called CONGEST model in distributed computing, in which the size of each message is restricted to  $O(\log n)$  bits), on the other hand, the same approach may take many more rounds due to possible congestion in the network (see the next paragraph for the definition of the CONGEST model). This is one of the reasons why the subgraph detection problem is interesting in the distributed setting. In the last few years, there has been significant progress in understanding the complexity of the non-induced subgraph detection in the CONGEST model.

**The CONGEST model.** In this paper we use the standard CONGEST model, as used in prior works [2, 3, 5, 8, 9, 11, 14, 16, 22]. In the CONGEST model, a distributed network of  $n$  computers is represented as a simple undirected graph  $G = (V, E)$  of  $n$  nodes, where each node corresponds to a computational device, and each edge corresponds to a communication link. Each node  $v \in V$  initially has a  $\Theta(\log n)$ -bit unique identifier  $\text{ID}(v)$ , and knows the list of IDs of its neighbors and the parameter  $n = |V|$ . The communication proceeds in synchronous rounds. In each round, each  $v \in V$  can perform unlimited local computation, and can send an  $O(\log n)$ -bit distinct message to each of its neighbors.

When considering subgraph detection in the CONGEST model, the communication network is identified with the input graph, i.e., we ask whether the  $n$ -node communication network contains  $H$  as a subgraph. If the network contains  $H$  as a subgraph, at least one node outputs 1 (Yes), otherwise all nodes output 0 (No). We assume that each node knows the graph  $H$  to be detected. The complexity is characterized by the number of rounds of communication needed to solve the problem.

**Non-induced subgraph detection in the distributed setting.** Typical examples of the non-induced subgraph detection in the CONGEST model that have been studied intensively are cliques and cycles. For cliques, the first sublinear-round algorithm of  $k$ -clique detection in the CONGEST model is due to Izumi and Le Gall [22], for  $k = 3$  (i.e., triangle detection), which runs in  $\tilde{O}(n^{2/3})$  rounds. Later, the complexity was brought down to  $\tilde{O}(\sqrt{n})$  by Chang et al. [8], and then further to  $\tilde{O}(n^{1/3})$  by Chang and Saranurak [9]. These upper bounds also hold for 3-clique listing,<sup>1</sup> and the  $\tilde{O}(n^{1/3})$  upper bound is tight up to polylogarithmic factors due to the lower bounds by Pandurangan, Robinson and Scquizzato [28] and Izumi and Le

<sup>1</sup> The listing version of the problem asks to list all instances of  $H$  in the graph.

Detecting a $k$ -node tree	$O(k^k)$	[17, 24]	CONGEST	

Gall [22]. For  $k$ -cliques with  $k \geq 4$ , the first sublinear algorithm of  $k$ -clique listing is due to Eden et al. [14]. They showed that one can list all  $k$ -cliques in  $\tilde{O}(n^{5/6})$  rounds for  $k = 4$  and  $\tilde{O}(n^{21/22})$  rounds for  $k = 5$ . These results were improved to  $\tilde{O}(n^{k/(k+2)})$  rounds for all  $k \geq 4$  by Censor-Hillel, Le Gall, and Leitersdorf [5], and very recently,  $\tilde{O}(n^{1-2/k})$  rounds for all  $k \geq 4$  by Censor-Hillel et al. [2]. The latter bound is tight up to polylogarithmic factors due to the lower bounds by [16].

For  $k$ -cycles with  $k \geq 4$ , it is known that non-induced  $k$ -cycle ( $C_k$ ) detection requires  $\Omega(ex(n, C_k)/n)$  rounds by Drucker et al. [13], where  $ex(n, C_k)$  is the Turán number of  $k$ -cycle (Turán number  $ex(n, C_k)$  is the maximum number of edges in an  $n$ -node graph which does not have a  $k$ -cycle as a subgraph). This implies the  $\tilde{\Omega}(n)$  lower bounds for odd  $k$  and  $\tilde{\Omega}(\sqrt{n})$  lower bound for  $k = 4$ . Korhonen and Rybicki [24] showed  $\tilde{O}(n)$ -round algorithms of non-induced  $k$ -cycle detection for any odd constant  $k$ . They also showed the  $\tilde{\Omega}(\sqrt{n})$  lower bounds for even  $k \geq 6$ . For  $k = 4$ , an optimal algorithm for non-induced 4-cycle detection is known due to drucker et al. [13]. For even  $k \geq 6$ , Fischer et al. [16] showed an  $\tilde{O}(n^{1-\frac{1}{k(k-1)}})$ -round algorithm, and this was improved to  $\tilde{O}(n^{1-2/\Theta(k^2)})$  by Eden et al. [14]. Recently, Censor-Hillel et al. [4] showed that for  $3 \leq k \leq 5$ , non-induced  $C_{2k}$  detection can be solved in  $\tilde{O}(n^{1-1/k})$  rounds.

We refer to Table 1 for the summary of all these results.

**Induced subgraph detection in the distributed setting.** All of the above results for cycles are only for the non-induced distributed subgraph detection problem. While for the case of cliques, non-induced detection and induced subgraph detection are the same problem, this is not the case for cycles (see again Figure 1 for an illustration). For instance, if we want to know if the input graph contains a chordless cycle, we need to consider the induced version. In the centralized (i.e., non-distributed) setting, the induced version of subgraph detection has thus also been extensively studied [10, 15, 20, 25, 27, 30], leading to several algorithms that significantly differ from the algorithms for the non-induced version of the problem.

Despite its importance, the induced version has almost not been studied at all in the distributed setting. The only known results on the complexity of the induced subgraph detection problem in the CONGEST model are generic bounds describing how large the round

■ **Table 2** Our results on the round complexity of induced-subgraph detecting, and the corresponding known results. Here  $n$  denotes the number of nodes in the network.

Problem	Time Bound	Reference	Model
induced $k$ -node subgraph detection	$\tilde{O}(n^{2-2/(3k+1)})$	[14]	CONGEST
induced $k$ -cycle detection	$\Omega(n/\log n)$ , for $k \geq 4$	Theorem 1	CONGEST
	$\Omega(n^{2-1/\lceil k/8 \rceil} / \log n)$ , for $k \geq 8$	Theorem 2	CONGEST
induced diamond listing	$\tilde{O}(n^{5/6})$	Theorem 7	CONGEST
	$\Omega(\sqrt{n}/\log n)$	Theorem 5	CONGEST

complexity can be with respect to the number of nodes in the subgraph: Fischer et al. [16] constructed a family of graphs  $H$  with  $\Theta(k)$  nodes such that (induced and non-induced)  $H$  detection requires  $\Omega(n^{2-1/k}/\log n)$  rounds. Later, Eden et al. [14] showed that the  $n^{1/k}$  term cannot be removed, and also showed that for any  $k$ -node subgraph  $H$ , induced  $H$  detection can be solved in  $\tilde{O}(n^{2-\frac{2}{3k-2}}) = \tilde{O}(n^{2-\Theta(1/k)})$  rounds. These results, however, actually hold for the non-induced version as well. Therefore, to our knowledge, it is still open whether there exists a graph  $H$  such that the round complexities of non-induced  $H$  detection and induced  $H$  detection are different in the CONGEST model.

**Our results.** In this paper we answer this question. More precisely, we seek to improve our understanding of the round complexity of the distributed induced subgraph detection in the CONGEST model by showing lower bounds for constant-length cycles. We refer to Table 2 for the summary of our results.

We first show that for any  $k \geq 4$ , detecting an induced  $k$ -cycle requires a near-linear amount of rounds; previously, no lower bound for induced cycle detection was known.

► **Theorem 1.** *For any  $k \geq 4$ , deciding if a graph contains an induced  $k$ -cycle requires  $\Omega(n/\log n)$  rounds in the CONGEST model.*

For  $k = 4$ , the trivial solution of induced  $k$ -cycle detection is to have each node send its entire neighborhood to all its neighbors, which can be done in  $O(n)$  rounds. Therefore, our bound in Theorem 1 is tight up to logarithmic factor. Since, as already mentioned, the non-induced version of 4-cycle detection has complexity  $\tilde{\Theta}(\sqrt{n})$ , Theorem 1 proves that the induced version is significantly harder in the CONGEST model.

We then show stronger lower bounds for induced  $C_k$ -detection for larger values of  $k$ .

► **Theorem 2.** *For any constant  $k = 8\ell + m$  where  $\ell \geq 1$  and  $m \in \{0, 1, \dots, 7\}$ , deciding if a graph contains an induced  $k$ -cycle requires  $\Omega(n^{2-1/\ell}/\log n)$  rounds in the CONGEST model, even when the diameter of the network is 3.*

These bounds are asymptotically tight with respect to  $k$ , since for any  $k$ -node subgraph  $H$ , induced  $H$  detection can be solved in  $\tilde{O}(n^{2-\Theta(1/k)})$  rounds by the algorithm of [14]. We can summarize this as follows.

► **Corollary 3.** *The round complexity of induced  $k$ -cycle detection in the CONGEST model is  $\tilde{\Theta}(n^{2-\Theta(1/k)})$ .*

For small  $k$ , there still exist gaps between our lower bounds and known upper bounds. For instance, we do not know if induced 5-cycle detection can be solved in  $\tilde{O}(n)$  rounds. This leads to the following question: can we show any improved lower bounds in the case of  $k \geq 5$ ? We complement our results by showing that reductions from two-party communication

complexity, which is the technique we used to show our lower bounds (as well as most of the other lower bounds in the literature), do not have the ability to derive better lower bounds for the case of  $k \leq 7$ .

► **Theorem 4 (Informal statement).** *For  $k = 5, 6, 7$  and any  $\varepsilon > 0$ , reductions from two-party communication complexity cannot give an  $\tilde{\Omega}(n^{1+\varepsilon})$  lower bound for induced  $C_k$  detection in the CONGEST model.*

Theorem 4 is shown via an argument similar to the arguments in [11, 14]. These papers showed that reductions from two-party communication complexity (more precisely, the *family of lower bound graphs* technique) cannot show  $\tilde{\Omega}(n^{1/2+\varepsilon})$  lower bounds of 4-clique detection and (non-induced) 6-cycle detection. As mentioned above, to date, all known lower bounds on the subgraph detection in the CONGEST model used reductions from two-party communication complexity. Therefore, Theorem 4 shows that we need a fundamentally different approach to improve these lower bounds.

The graph that is obtained by removing one edge from a 4-clique is called a *diamond*. Diamonds are interesting since it is in some sense intermediate between 4-cycle and 4-clique. We show a lower bound of induced diamond listing in the CONGEST model.

► **Theorem 5.** *Listing all induced diamonds requires  $\Omega(\sqrt{n}/\log n)$  rounds in the CONGEST model.*

We also prove the same result as in Theorem 4 for induced diamond listing.

► **Theorem 6 (Informal statement).** *For any  $\varepsilon > 0$ , reductions from two-party communication complexity cannot give an  $\tilde{\Omega}(n^{1/2+\varepsilon})$  lower bound for induced diamond listing in the CONGEST model.*

Finally, we show that induced diamond listing can be done in sublinear rounds.

► **Theorem 7.** *There exists an algorithm that solves induced diamond listing in  $\tilde{O}(n^{5/6})$  rounds in the CONGEST model.*

Due to space constraints, the proofs of Theorem 6 and Theorem 7 are omitted from the main body of this paper – they can be found in Appendix C and Appendix D.

**Other related works.** Several works investigate the complexity of subgraph detection in other models of distributed computing. In the powerful CONGESTED CLIQUE model, which allows global communication, the induced subgraph detection (and even listing) can be solved in sublinear rounds [12]: for any  $k$ -node subgraph  $H$ , induced  $H$  detection and listing can be solved in  $O(n^{1-2/k})$  rounds. This algorithm was used as a subroutine to construct sublinear-round CONGEST algorithms for clique detection and listing [2, 5, 8, 9, 21, 22]. In the CONGESTED CLIQUE model, for any constant  $k \geq 3$ ,  $k$ -cycle can be detected in  $O(2^{O(k)}n^{0.158})$  rounds by an algebraic algorithm which uses the matrix multiplication [6] and for  $k \geq 2$ ,  $2k$ -cycle can be detected in  $O(1)$  rounds [4]. In the QUANTUM CONGEST model, in which each node represents a quantum computer and each edge represents a quantum channel, Izumi, Le Gall and Magniez [21] showed that triangle detection can be solved in  $\tilde{O}(n^{1/4})$  rounds by using quantum distributed search [26] which is the distributed implementation of Grover's quantum search. For any  $\varepsilon > 0$ , showing a lower bound of  $\Omega(n^\varepsilon)$  on directed triangle detection implies strong circuit complexity lower bounds [4]. These bounds are included in Table 1.

Other relevant works include constant-round detection of constant-sized trees in the CONGEST model [17, 24], and investigations of the distributed subgraph detection problem in the framework of *property testing* [3, 18, 19].

**Recent independent work.** Lower bounds for induced cycle detection similar to some of the bounds in our paper have been concurrently (and independently) obtained very recently by Korhonen and Nikabadi [23]. They showed the following results using graph constructions different from ours (but still using reductions from two-party communication complexity):

- $\Omega(n/\log n)$  lower bound for induced  $2k$ -cycle detection for  $k \geq 3$ ,
- $\Omega(n/\log n)$  lower bound for a multicolored variant of  $k$ -cycle detection for  $k \geq 4$ .

## 2 Preliminaries

To prove lower bounds, we use reductions from two-party communication complexity problems. This is the common technique to show lower bounds in the CONGEST model [16, 7, 11, 13, 1]. Here we give the precise definition of the *family of lower bound graphs*, which is the standard notion to show these lower bounds (see, e.g., [7]).

► **Definition 8** (Family of Lower Bound Graphs). *Given an integer  $K$ , a boolean function  $f : \{0, 1\}^K \times \{0, 1\}^K \rightarrow \{0, 1\}$  and a graph predicate  $P$ , a set of graphs  $\{G_{x,y} = (V, E_{x,y}) \mid x, y \in \{0, 1\}^K\}$  is called a family of lower bound graphs with respect to  $f$  and  $P$  if the following hold:*

1. *The set of vertices  $V$  is the same for all the graphs in the family, and has a fixed partition  $V = V_A \cup V_B$ . The set of edges of the cut  $E_{cut} = E(V_A, V_B)$  is the same for all graphs in the family.*
2. *Given  $x, y \in \{0, 1\}^K$ ,  $E(V_A, V_A)$  only depends on  $x$ .*
3. *Given  $x, y \in \{0, 1\}^K$ ,  $E(V_B, V_B)$  only depends on  $y$ .*
4.  *$G_{x,y}$  satisfies  $P$  if and only if  $f(x, y) = 1$ .*

► **Theorem 9** ([7]). *Fix a boolean function  $f : \{0, 1\}^K \times \{0, 1\}^K \rightarrow \{0, 1\}$  and a graph predicate  $P$ . If there exists a family of lower bound graphs  $\{G_{x,y}\}$  with respect to  $f$  and  $P$ , then any randomized algorithm for deciding  $P$  in the CONGEST model takes  $\Omega(CC^R(f)/|E_{cut}| \log n)$ , where  $CC^R(f)$  is the randomized communication complexity of  $f$ .*

Throughout this paper, we use the set-disjointness function  $DISJ_K : \{0, 1\}^K \times \{0, 1\}^K \rightarrow \{0, 1\}$ . For two bit strings  $x, y \in \{0, 1\}^K$ ,  $DISJ_K(x, y)$  is equal to 0 if and only if there exists some index  $i \in [K]$  such that  $x_i = y_i = 1$ . It is well known that  $CC^R(DISJ_K) = \Omega(K)$  [29].

## 3 Lower Bounds for $k$ -cycles, $k \geq 4$

In this section we prove Theorem 1. To prove Theorem 1, we describe families of lower bound graphs with respect to the set-disjointness function of the two-party communication complexity, and the predicate  $P$  that says the graph does not contain an induced  $k$ -cycle. We start by describing the fixed graph construction for the case of  $k = 4$ , and then define the corresponding family of lower bound graphs.

**The fixed graph construction.** Create a graph  $G$  as follows: The vertex set is  $A_1 \cup A_2 \cup B_1 \cup B_2$  such that  $A_1$  and  $B_2$  are  $n$ -vertex cliques and  $A_2$  and  $B_1$  are a set of  $n$  vertices with no edges inside of them. Denote the vertices in  $G$  as  $A_i = \{a_i^1, \dots, a_i^n\}$ ,  $B_i = \{b_i^1, \dots, b_i^n\}$  for  $i \in \{1, 2\}$ . We add edges  $(a_i^j, b_i^j)$ ,  $(a_i^j, b_j^i)$  for all  $i \in [n]$ .

**Creating  $G_{x,y}$ .** For two input bit strings  $x, y \in \{0, 1\}^{n^2}$  and  $i, j \in [n]$ , we denote the  $(i + (j - 1)n)$ -th bit of  $x$  and  $y$  as  $x_{ij}$  and  $y_{ij}$ . Edges corresponding to inputs are added as follows (see Figure 2 for the illustration):

■ **Figure 2** An illustration of  $G_{x,y}$  for the case of  $n = 3$ . The graph contains a copy of induced  $C_4$  if and only if it holds that  $x_{ij} = y_{ij} = 1$  for some index  $i, j \in [n]$ . This illustration shows the case of  $x_{3,1} = y_{3,1} = 1$ .

- We add an edge between  $a_1^i$  and  $a_2^j$  if and only if  $x_{ij} = 1$ .
- We add an edge between  $b_1^i$  and  $b_2^j$  if and only if  $y_{ij} = 1$ .

This concludes the description of  $G_{x,y}$ . Next, we prove that the family  $\{G_{x,y} | x, y \in \{0, 1\}^{n^2}\}$  is a family of lower bound graphs with respect to set-disjointness and the predicate that says the graph does not contain an induced 4-cycle.

▷ **Claim 10.**  $G_{x,y}$  contains an induced  $C_4$  if and only if there exists a pair of index  $i, j \in [n]$  such that  $x_{ij} = y_{ij} = 1$ .

*Proof.* Let  $U = \{v_1, v_2, v_3, v_4\}$  be a subset of  $V$ . It is clear that if it holds  $|U \cap S| = 4$  for some  $S \in \{A_1, A_2, B_1, B_2\}$ , then  $U$  does not induce  $C_4$ . We analyse  $U$  as follows:

- If it holds  $|U \cap A_1| = 3$  or  $|U \cap B_2| = 3$ ,  $U$  induces a triangle.
- If it holds  $|U \cap A_2| = 3$  or  $|U \cap B_1| = 3$ ,  $U$  induces at most three edges.
- If it holds  $|U \cap A_1| = 2$  or  $|U \cap B_2| = 2$ , and  $U$  induces a 4-cycle, the other two vertices of  $U$  are both in  $A_2$  or both in  $B_1$ . However, It is impossible since there is no edge between any two vertices in  $A_2$  and any two vertices in  $B_1$ .
- If it holds  $|U \cap A_2| = 2$  or  $|U \cap B_1| = 2$ , the two vertices does not share neighbors. Hence,  $U$  does not induce a 4-cycle.

Now all we need is to verify whether four vertices  $a_1^i, a_2^j, b_1^k,$  and  $b_2^\ell$  induce a 4-cycle or not. If  $(a_1^i, a_2^j, b_1^k, b_2^\ell)$  induces a 4-cycle, we can say that  $i = k$  since  $a_1^i$  has to be connected to  $a_2^j$  and  $b_1^k$  (similarly we can say  $j = \ell$ ). It is straightforward to show that  $(a_1^i, a_2^j, b_1^i, b_2^j)$  induces a 4-cycle if and only if  $x_{ij} = y_{ij} = 1$ . ◀

**Proof of Theorem 1.** Divide the vertices of the graph  $G_{x,y}$  into  $V_A = A_1 \cup A_2$  and  $V_B = B_1 \cup B_2$ . The size of the cut is  $|E_{cut}| = |E(V_A, V_B)| = 2n$ . Claim 10 shows that the family of the graphs  $\{G_{x,y} | x, y \in \{0, 1\}^{n^2}\}$  is a family of lower bound graphs for  $f = \text{DISJ}_{n^2}$  and a predicate that says the graph include an induced  $C_4$ . Hence, using Theorem 9 and  $CC^R(\text{DISJ}_{n^2}) = \Theta(n^2)$ , any randomized algorithms for induced 4-cycle detection in the CONGEST model requires  $\Omega(n/\log n)$ .

To extend this result to  $k$ -cycles for  $k \geq 5$ , we modify the graph  $G_{x,y}$  as follows:

- For any  $i \in [n]$ , replace the edge  $(a_1^i, b_1^i)$  to a path with  $\lceil \frac{k-4}{2} \rceil + 2$  vertices.
- For any  $i \in [n]$ , replace the edge  $(a_2^i, b_2^i)$  to a path with  $\lfloor \frac{k-4}{2} \rfloor + 2$  vertices. ◀

■ **Figure 3** An illustration of the fixed part of  $G_{x,y}$ . Some edges are bundled for clarity. Observe that  $A_1^i \subseteq A_1$  and  $A_2^j \subseteq A_2$  are connected by additional edges iff  $x_{i,j} = 1$ . Also,  $B_1^i \subseteq B_1$  and  $B_2^j \subseteq B_2$  are connected by additional edges iff  $y_{i,j} = 1$ .

#### 4 Lower Bounds for Larger Cycles

In this section we prove Theorem 2, i.e., we show subquadratic, but superlinear lower bounds for induced cycles  $C_{k \geq 8}$ , which gives nearly tight bounds for induced cycles  $C_{k \geq 8}$  with respect to  $k$ . The main difficulty to obtain the bounds of Theorem 2 is to reduce the size of the cut edges of graphs while retaining the ability to simulate the set-disjointness function of size  $\Omega(n^2)$ . We overcome this difficulty by considering induced cycles that go around  $G_{x,y}$  more than once instead of cycles that go around  $G_{x,y}$  exactly once (we pay for this by an increased size of a cycle). This enables us to reduce the size of cut edges.

##### 4.1 The fixed graph construction

We refer to Figure 3 for an illustration of the construction.

**Vertices.** We define the sets of vertices as follows:

- $A_k = A_k^1 \cup \dots \cup A_k^n$ , where  $A_k^i = \{a_k^{i,j} \mid 0 \leq j \leq \ell - 1\}$  for  $i \in [n]$  and  $k \in \{1, 2\}$ .
- $B_k = B_k^1 \cup \dots \cup B_k^n$ , where  $B_k^i = \{b_k^{i,j} \mid 0 \leq j \leq \ell - 1\}$  for  $i \in [n]$  and  $k \in \{1, 2\}$ .
- $U_A = \{u_A^i \mid 0 \leq i \leq \ell n^{1/\ell}\}$ ,  $L_A = \{l_A^i \mid 0 \leq i \leq \ell n^{1/\ell}\}$ .
- $U_B = \{u_B^i \mid 0 \leq i \leq \ell n^{1/\ell}\}$ ,  $L_B = \{l_B^i \mid 0 \leq i \leq \ell n^{1/\ell}\}$ .

Each  $S \in \{A_1, A_2, B_1, B_2\}$  contains  $\ell n$  vertices, and they are divided into  $n$  subsets of size  $\ell$ . Each  $C \in \{U_A, U_B, L_A, L_B\}$  contains  $\ell n^{1/\ell}$  vertices. The number of vertices  $V = A_1 \cup A_2 \cup B_1 \cup B_2 \cup U_A \cup L_A \cup U_B \cup L_B$  is  $\Theta(\ell n + \ell n^{1/\ell}) = \Theta(n)$ .

**Edges.** First, we add  $2\ell n^{1/\ell}$  edges  $\{(u_A^i, u_B^i), (l_A^i, l_B^i) \mid i \in [\ell n^{1/\ell}]\}$ . Then, we consider a map from  $[n]$  to  $[\ell n^{1/\ell}]^\ell$ , where  $[\ell n^{1/\ell}]^\ell$  is  $\ell$  times direct product of the set  $[\ell n^{1/\ell}]$ . Since

$$\binom{\ell n^{1/\ell}}{\ell} = \frac{\ell n^{1/\ell}}{\ell} \cdot \frac{\ell n^{1/\ell} - 1}{\ell - 1} \cdots \frac{\ell n^{1/\ell} - \ell + 1}{1} \geq \left(\frac{\ell n^{1/\ell}}{\ell}\right)^\ell = n$$

holds, there exists an injection  $\sigma : [n] \rightarrow [\ell n^{1/\ell}]^\ell$ . We arbitrarily choose one of these injections. For  $i \in [n]$ , we denote  $\sigma(i) = \{k_1, \dots, k_\ell\} \in [\ell n^{1/\ell}]^\ell$ . For all  $i \in [n], j \in [\ell]$ , we add the edge sets  $\{(a_1^{i,j}, u_A^{k_j}) \mid i \in [n], j \in [\ell]\}$ ,  $\{(a_2^{i,j}, l_A^{k_j}) \mid i \in [n], j \in [\ell]\}$ ,  $\{(b_1^{i,j}, u_B^{k_j}) \mid i \in [n], j \in [\ell]\}$ , and  $\{(b_2^{i,j}, l_B^{k_j}) \mid i \in [n], j \in [\ell]\}$ . Now we can determine exactly  $\ell$  vertices of  $U_A$  that are adjacent to vertices of  $A_1^i$ . We denote them  $Code(A_1^i) \subseteq U_A$ . In the same way, we determine the vertex sets  $Code(A_2^i) \subseteq L_A$ ,  $Code(B_1^i) \subseteq U_B$ , and  $Code(B_2^i) \subseteq L_B$  by using the same  $\sigma$ . Since  $\sigma$  is an injection, it holds that  $Code(A_1^i) \neq Code(A_1^j)$ ,  $Code(A_2^i) \neq Code(A_2^j)$ ,  $Code(B_1^i) \neq Code(B_1^j)$ , and  $Code(B_2^i) \neq Code(B_2^j)$  for  $i \neq j$ .

In addition, we add the following edges.

- For any  $i, j \in [n]$ , add edges between  $u \in A_1^i, v \in A_1^j$  if and only if  $i \neq j$ .
- For any  $i, j \in [n]$ , add edges between  $u \in B_2^i, v \in B_2^j$  if and only if  $i \neq j$ .

If  $\ell \geq 2$ , we add the following edges.

- For any  $i, j \in [n]$ , add edges between  $u \in A_2^i, v \in A_2^j$  if and only if  $i \neq j$ .
- For any  $i, j \in [n]$ , add edges between  $u \in B_1^i, v \in B_1^j$  if and only if  $i \neq j$ .

## 4.2 Creating $G_{x,y}$

Note that for  $\ell = 1$ , the fixed part of  $G_{x,y}$  in this section is exactly the same as the fixed part of graphs for induced 8-cycles in Section 3. Hence, we only describe the case  $\ell \geq 2$ . Given two binary strings  $x, y \in \{0, 1\}^{n^2}$ , we add the following edges:

- For  $i, j \in [n]$ , add edges  $\{(a_1^{i,k+1}, a_2^{j,k}) \mid k \in [\ell - 1]\} \cup \{(a_1^{i,1}, a_2^{j,\ell})\}$ , if and only if  $x_{i,j} = 1$ .
- For  $i, j \in [n]$ , add edges  $\{(b_1^{i,k}, b_2^{j,k}) \mid k \in [\ell]\}$ , if and only if  $y_{i,j} = 1$ .

This concludes the description of  $G_{x,y}$ . We show the following theorem which says that  $\{G_{x,y}\}$  is a family of lower bound graphs. Due to space constraint, the proof is moved to the Appendix.

► **Theorem 11.**  $G_{x,y}$  contains an induced  $8\ell$ -cycle if and only if  $\text{DISJ}_{n^2}(x, y) = 0$ .

Having constructed a family of lower bound graphs, we are now ready to prove Theorem 2.

**Proof of Theorem 2.** Theorem 11 implies that a family of graphs

$$\left\{G_{x,y} = (V_A \cup V_B, E_{x,y}) \mid x, y \in \{0, 1\}^{n^2}\right\}$$

where  $V_A = A_1 \cup A_2 \cup U_A \cup L_A$ ,  $V_B = B_1 \cup B_2 \cup U_B \cup L_B$  is a family of lower bound graphs with respect to the set disjointness function  $\text{DISJ}_{n^2}$  and the graph predicate is whether the graph has a copy of an induced  $C_{8\ell}$  or not with cut size  $\ell n^{1/\ell}$ . To bound the diameter of the network to 3, we add nodes  $c_A$  to  $V_A$  and  $c_B$  to  $V_B$  such that  $c_A$  is connected to all nodes in  $V_A$  and  $c_B$  is connected to all nodes in  $V_B$ . Finally, we add an edge  $(c_A, c_B)$ . The above modification does not effect to the existence of induced  $8\ell$ -cycles: If we choose  $c_A$  as one of the cycle nodes, then we cannot choose more than two  $V_A$  nodes as cycle nodes. However, we cannot choose more than  $8\ell - 4$  nodes from  $V_B$  due to Lemma 16 of Appendix A, which also holds after this modification. The theorem is proved by applying Theorem 9 (for  $m = 0$ ).

Slightly modifying the graphs gives the same complexity for the case of  $k = 8\ell + m$  where  $m \in \{1, 2, \dots, 7\}$ :

- Replace each edge  $e \in U_A \times U_B$  by a path of length  $\lfloor m/2 \rfloor$ .
- Replace each edge  $e \in L_A \times L_B$  by a path of length  $\lceil m/2 \rceil$ . ◀

## 5 Limitation of the Two-Party Communication Framework

Since no  $\tilde{O}(n)$ -round algorithm for detecting an induced  $k$ -cycle for  $k \geq 5$  is known, the main question is whether our lower bound can be improved or not. In this section, we show that the family of lower bound graphs cannot derive any better lower bounds for detecting an induced  $k$ -cycle for  $k \leq 7$ , by giving a two-party communication protocol for listing  $k$ -cycles for  $k \leq 7$  in the vertex partition model which is defined as follows.

► **Definition 12** (Vertex Partition Model, [11]). *Given a graph  $G = (V_A \cup V_B, E_A \cup E_B \cup E_{cut})$  where  $E_A = E(V_A, V_A)$ ,  $E_B = E(V_B, V_B)$  and  $E_{cut} = E(V_A, V_B)$ , the vertex partition model is a two-party communication model in which Alice receives  $G_A = (V_A, E_A \cup E_{cut})$  as the input and Bob receives  $G_B = (V_B, E_B \cup E_{cut})$  as the input. For any graph  $H$ , the  $O(k)$  communication protocol for induced  $H$  listing is a protocol such that*

- The players communicate  $O(k)$  bits in the protocol.
- At the end of the protocol, the players have their lists of  $H$ , denoted by  $A_H, B_H$ , such that all of copies of  $H$  in the input graph  $G$  are contained in either  $A_H$  or  $B_H$ .

► **Theorem 13.** *There is a two-party communication protocol in the vertex partition model for listing all induced  $k$ -cycles for  $k \leq 7$  that uses  $\tilde{O}(n|E_{cut}|)$  bits of communication where  $E_{cut}$  is the set of cut edges in the input graph.*

**Proof.** Let  $V'_A(V'_B)$  be a set of  $V_A(V_B)$  vertices which are incident to some cut edge. The protocol is as follows:

1. Bob sends all edges  $E_B \cap \{V'_B \times V_B\}$  to Alice in  $\tilde{O}(n|E_{cut}|)$  bits since the number of edges Bob sends to Alice is less than

$$\sum_{v \in V'_B} \deg_{V_B}(v) \leq \sum_{v \in V'_B} n = n|E_{cut}|.$$

2. Alice sends all edges  $E_A \cap \{V'_A \times V_A\}$  to Bob in  $\tilde{O}(n|E_{cut}|)$  bits since the number of edges Alice sends to Bob is less than

$$\sum_{v \in V'_A} \deg_{V_A}(v) \leq \sum_{v \in V'_A} n = n|E_{cut}|.$$

Consider Alice has to list all induced  $k$ -cycles such that at least  $\lfloor k/2 \rfloor$  vertices of them are in  $V_A$ . Let  $U$  be a set of vertices in a copy of an induced  $k$ -cycle Alice should list in the input graph  $G$ . Since  $k \leq 7$ ,  $U$  contains at most three vertices in  $V_B$ . If  $U$  has at least one vertex in  $V_B$ , then the  $k$ -cycle induced by  $U$  has two cut edges. Therefore, we have  $U \times U \subseteq E_A \cup E_{cut} \cup \{E_B \cap \{V'_B \times V_B\}\}$ . Step 1 of the protocol enables Alice to list all induced  $k$ -cycles she should list. Similarly, step 2 of the protocol enables Bob to list all induced  $k$ -cycles he should list. Now all induced  $k$ -cycles of the input graph  $G$  are in either the list of Alice or the list of Bob. ◀

► **Theorem 4** (Formal statement). *For any  $\varepsilon > 0$ , no family of lower bound graphs gives an  $\tilde{\Omega}(n^{1+\varepsilon})$  lower bound of induced  $k$ -cycle detection for  $k \leq 7$ .*

■ **Figure 4** The cut edges in the family of lower bound graphs for listing diamonds. Many edges are omitted for clarity.

**Proof.** For the family of lower bound graphs

$$\{G_{x,y} = (V_A \cup V_B, E_A \cup E_B \cup E_{cut}) \mid x, y \in \{0, 1\}^K\}$$

for  $f : \{0, 1\}^K \times \{0, 1\}^K \rightarrow \{0, 1\}$  and the property which says that the graph contains an induced  $k$ -cycle, we can show an  $\tilde{\Omega}(CC^R(f)/|E_{cut}|)$  lower bound for induced  $k$ -cycle detection. On the other hand, we can solve  $f$  by  $\tilde{O}(n|E_{cut}|)$  bits of communication through the protocol of the vertex partition model in Theorem 13. Then it holds  $|E_{cut}| = \tilde{\Omega}(CC^R(f)/n)$ , implying that for any  $\varepsilon > 0$ , we cannot derive an  $\tilde{\Omega}(n^{1+\varepsilon})$  lower bound for induced  $k$ -cycle listing by the family of lower bound graphs. ◀

## 6 Lower Bound for Diamond Listing

We know that the round complexity of 4-clique detection is  $\tilde{\Theta}(\sqrt{n})$ , and induced 4-cycle detection is  $\tilde{\Theta}(n)$ . The only four-node graph that lies between 4-clique and 4-cycle is the *diamond*, which is the four-node graph obtained by removing one edge from a 4-clique. Intuitively, the complexity of diamond detection seems to be somewhere between the complexity of 4-clique and the complexity of 4-cycle. In this section, we make this intuition precise, and we show a lower bound for induced diamond listing (this result is complemented by the upper bound of Theorem 7 shown in Appendix D). Our construction of the family of lower bound graphs is similar to [11], but has the following differences. The graphs of [11] have two sets of vertices  $A$  and  $B$ , and edges between  $A$  and  $B$  are added randomly so that the size of the cut edges is  $O(n^{3/2})$ . In this random graph, *w.h.p.*, the number of tuples of the form  $(a_1, a_2, b_1, b_2)$  where  $a_1, a_2 \in A$  and  $b_1, b_2 \in B$  which corresponds to the  $i$ -th bit of the input strings  $x, y$  is  $\Omega(n^2)$ : a tuple  $(a_1, a_2, b_1, b_2)$  induces a 4-clique if and only if  $x_i = y_i = 1$ . However, in the case of diamonds, the number of tuples which correspond to the input is  $o(n^2)$ . To avoid this, we construct the family of lower bound graphs in a different way. This makes it much easier to analyze the properties of the graph.

**The fixed graph construction.** We refer to Figure 4 for an illustration. The set of vertices is  $V = A \cup B \cup B'$  such that  $A, B$  and  $B'$  are sets of  $n$  vertices. Each vertex is denoted as follows:

- $A = A_1 \cup A_2 \cup \dots \cup A_{\sqrt{n}}$ , where  $A_i = \{a_i^j \mid j \in [\sqrt{n}]\}$  for all  $i \in [\sqrt{n}]$ .
- $B = B_1 \cup B_2 \cup \dots \cup B_{\sqrt{n}}$ , where  $B_i = \{b_i^j \mid j \in [\sqrt{n}]\}$  for all  $i \in [\sqrt{n}]$ .
- $B' = \{b'_i \mid i \in [n]\}$ .

We add the edge set  $\{(a_i^j, b'_{j+(i-1)\sqrt{n}}) \mid i, j \in [\sqrt{n}]\}$ . For any  $i, j \in [\sqrt{n}]$ , we choose a bijection uniform randomly from all possible bijection  $\sigma : A_i \rightarrow B_j$ , and denote it  $\sigma_{i,j} : A_i \rightarrow B_j$ . Then, we add the edge set  $\{(a_i^k, \sigma_{i,j}(a_i^k)) \mid i, j \in [\sqrt{n}], k \in [\sqrt{n}]\}$ .

**Creating  $G_{x,y}$ .** We call a pair  $(a_i^j, a_k^\ell)$  is good iff  $|N(a_i^j) \cap N(a_k^\ell)| = 1$ , where  $N(u)$  is a set of neighbors of a vertex  $u$ . Let  $P_A$  be the set of good pairs in  $A \times A$ . That is,  $P_A := \{(a_i^j, a_k^\ell) \mid |N(a_i^j) \cap N(a_k^\ell)| = 1, i, j, k, \ell \in [\sqrt{n}]\}$ .

► **Lemma 14.** *There is a graph  $G$  created by the above procedure, in which it holds that  $|P_A| = \Omega(n^2)$ .*

The proof of Lemma 14 can be found in Appendix B. Consider the graph  $G$  in which  $|P_A| = \Omega(n^2)$ . Let  $\mathcal{H} = \emptyset$ . We partition  $A$  randomly into two sets  $A^*$  and  $A \setminus A^*$  so that  $|A^*| = n/2$ . For a pair  $(a_1, a_2) \in P_A$ , there is only one vertex  $b_1 \in N(a_1) \cap N(a_2)$ . For  $a_1$ , there is only one vertex  $b_2 \in N(a_1) \cap B'$ . We add a quadruple  $(a_1, a_2, b_1, b_2)$  to  $\mathcal{H}$  iff  $|\{a_1, a_2\} \cap A^*| = 1$ . This condition holds with probability  $\frac{1}{2}$ . Then, we remove  $(a_1, a_2)$  from  $P_A$ . We continue this operation until  $P_A$  becomes the empty set. Therefore, after this process, there are  $|\mathcal{H}| = \Omega(n^2)$  quadruples in  $\mathcal{H}$  with high probability, using Chernoff bound. We label  $\mathcal{H}$  as  $\mathcal{H} = \{h_1, h_2, \dots, h_{|\mathcal{H}|}\}$  and relabel quadruples as  $h_k = (a_{k,1}, a_{k,2}, b_{k,1}, b_{k,2})$ . Consider two bit strings  $x, y \in \{0, 1\}^{|\mathcal{H}|}$ . We create a graph  $G_{x,y}$  by adding edges to  $G$  as follows:

- If  $x_k = 1$ , we add an edge between  $a_{k,1}$  and  $a_{k,2}$ .
- If  $y_k = 1$ , we add an edge between  $b_{k,1}$  and  $b_{k,2}$ .

For a quadruple  $D = (u_1, u_2, u_3, u_4)$  of vertices, we say that  $D$  is an  $(i, j)$ -diamond when

- $(u_1, u_2, u_3, u_4)$  induces a diamond,
- $|A \cap \{u_1, u_2, u_3, u_4\}| = i$  and  $|(B \cup B') \cap \{u_1, u_2, u_3, u_4\}| = j$ .

► **Lemma 15.**  *$G_{x,y}$  contains a  $(2,2)$ -diamond if and only if there exists a pair of indices  $i, j \in [\sqrt{|\mathcal{H}|}]$  such that  $x_{ij} = y_{ij} = 1$ .*

**Proof.** It is clear that if  $x_k = y_k = 1$ , then  $h_k = (a_{k,1}, a_{k,2}, b_{k,1}, b_{k,2})$  induces a diamond. Consider four vertices  $a_1, a_2 \in A, b_1, b_2 \in B \cup B'$  that induce a  $(2,2)$ -diamond. If it holds that  $(b_1, b_2) \notin E$ , then  $(a_1, a_2) \in E$ . Thus, a pair  $(a_1, a_2)$  is good. It contradicts that vertices  $a_1, a_2, b_1$ , and  $b_2$  induce a diamond. Assume that  $(b_1, b_2) \in E$ . Without loss of generality, we assume  $b_1 \in B, b_2 \in B'$ . Since a pair  $(a_1, a_2)$  is good,  $b_1 = N(a_1) \cap N(a_2)$  and  $(a_1, a_2) \in E$ . Then, there is an index  $k \in [|\mathcal{H}|]$  such that  $h_k = (a_1, a_2, b_1, b_2)$  since  $(a_2, b_2) \notin E$  holds. ◀

**Proof of Theorem 5.** Consider that Alice and Bob construct the graph  $G_{x,y}$  where  $V_A = A, V_B = B \cup B'$ . By simulating an  $r$ -round CONGEST algorithm  $\mathcal{A}$  that solves listing all diamonds, they can compute the set disjointness function of size  $|\mathcal{H}| = \Omega(n^2)$ : Bob tells Alice if there exists a  $(2,2)$ -diamond in the output of vertices simulated by Bob by sending 1 bit. Then, from Lemma 15, Alice knows  $\text{DISJ}_{|\mathcal{H}|}(x, y)$  since Alice can know whether  $G_{x,y}$  contains a  $(2,2)$ -diamond. The number of edges between Alice and Bob is  $n^{3/2} + n = \Theta(n^{3/2})$ . Hence,  $O(rn^{3/2} \log n) = \Omega(|\mathcal{H}|)$  and this means  $r = \Omega(\sqrt{n}/\log n)$ . ◀

## A Proof of Theorem 11

We first show the following two lemmas.

► **Lemma 16.** *Any subset of vertices  $\mathcal{C} \subseteq V$  of size  $8\ell$  in  $G_{x,y}$  which induces  $C_{8\ell}$  contains at most  $\ell$  vertices in  $S$  where  $S \in \{A_1, A_2, B_1, B_2\}$ .*

**Proof.** It is enough to check the case of  $S = A_1$ . Let  $c$  be the number of index  $i \in [n]$  such that  $|\mathcal{C} \cap A_1^i| > 0$ . At first, observe that if it holds that  $|\mathcal{C} \cap A_1^i| \geq 1$ ,  $|\mathcal{C} \cap A_1^j| \geq 1$ , and  $|\mathcal{C} \cap A_1^k| \geq 1$  for some distinct  $i, j, k \in [n]$ ,  $\mathcal{C}$  induces a triangle. Hence, we have  $c \leq 2$ . The proof is completed by the following case analysis.

1. **The case of  $\ell \geq 3$ :** Suppose that  $|\mathcal{C} \cap A_1| > \ell$ . Then we have  $c = 2$ . Let  $i, j \in [n]$  be the indices such that  $|\mathcal{C} \cap A_1^i| \geq |\mathcal{C} \cap A_1^j| > 0$ . If  $|\mathcal{C} \cap A_1^i| = 1$ , then  $|\mathcal{C} \cap A_1^j| \geq 3$ . This is not possible since the vertices in  $\mathcal{C} \cap A_1^j$  are connected at least three vertices in  $\mathcal{C} \cap A_1^i$ . If  $|\mathcal{C} \cap A_1^i| \geq 2$ , then  $|\mathcal{C} \cap A_1^j| \geq 2$ . This is not possible since  $\mathcal{C}$  contains a 4-cycle in this case.

2. **The case of  $\ell = 2$ :** Suppose that  $|\mathcal{C} \cap A_1| > \ell = 2$ . Then we have  $c = 2$  and let  $i, j \in [n]$  be the indices such that  $|\mathcal{C} \cap A_1^i| \geq |\mathcal{C} \cap A_1^j| > 0$ . If  $|\mathcal{C} \cap A_1^i| = 2$  and  $|\mathcal{C} \cap A_1^j| = 2$ , then  $\mathcal{C}$  induces  $C_4$ . Hence, we consider  $|\mathcal{C} \cap A_1^i| = 2$  and  $|\mathcal{C} \cap A_1^j| = 1$ . Denote  $\{a_1^{i,1}, a_1^{i,2}\} = \mathcal{C} \cap A_1^i, \{u\} = \mathcal{C} \cap A_1^j$ . Then,  $(a_1^{i,1}, u), (a_1^{i,2}, u) \in E \cap \{\mathcal{C} \times \mathcal{C}\}$ . The other edges which incident on  $a_1^{i,1}, a_1^{i,2}$  are both in  $A_2$  or both in  $U_A$ .
- a. In the former case, we have that  $\mathcal{C} \cap A_2 = A_2^k = \{a_2^{k,1}, a_2^{k,2}\}$  for some  $k \in [n]$ , otherwise  $\mathcal{C}$  includes an induced 5-cycle. Observe that due to our construction of  $G_{x,y}$ , six vertices in  $\mathcal{C}$  are automatically determined to  $Code(A_2^k), Code(B_2^k)$ , and  $B_2^k$ . It can be easily checked that no matter how we choose the remaining vertices,  $\mathcal{C}$  does not induce a 16-cycle.
  - b. In the latter case, it is automatically determined that  $\mathcal{C}$  includes  $Code(A_1^i), Code(B_1^i)$ , and  $B_1^i$ , due to our construction of  $G_{x,y}$ . In addition,  $\mathcal{C}$  includes  $B_2^k, Code(B_2^k), Code(A_2^k)$  for some  $k \in [n]$ . Then,  $\mathcal{C}$  does not induce a 16-cycle since two vertices of  $Code(A_2^k)$  do not share neighbors. ◀

► **Lemma 17.** Any subset of vertices  $\mathcal{C} \subseteq V$  of size  $8\ell$  in  $G_{x,y}$  which induces  $C_{8\ell}$  contains  $\ell$  vertices in  $S$ , where  $S \in \{A_1, A_2, B_1, B_2, U_A, U_B, L_A, L_B\}$ .

**Proof.** For  $S \subseteq V$ , we denote  $z(S) = |\mathcal{C} \cap S|$ . Observe that the number of edges in  $E_{\mathcal{C}}$  between  $A_1$  and  $U_A$  is at least  $z(U_A)$  since each vertex in  $\mathcal{C} \cap U_A$  has at least one neighbor in  $\mathcal{C} \cap A_1$ . On the other hand, the number of edges in  $E_{\mathcal{C}}$  between  $A_1$  and  $U_A$  is at most  $z(A_1)$  since each vertex in  $\mathcal{C} \cap A_1$  has at most one neighbor in  $\mathcal{C} \cap U_A$ . Hence, we have that  $z(A_1) \geq z(U_A)$ . Similar observation shows that  $z(A_2) \geq z(L_A)$ ,  $z(B_1) \geq z(U_B)$ , and  $z(B_2) \geq z(L_B)$ . Then, it holds that

$$\begin{aligned} 8\ell &= z(A_1) + z(A_2) + z(U_A) + z(L_A) + z(B_1) + z(B_2) + z(U_B) + z(L_B) \\ &\leq 2(z(A_1) + z(A_2) + z(B_1) + z(B_2)). \end{aligned}$$

From Lemma 16, we have  $z(A_1) = z(A_2) = z(B_1) = z(B_2) = \ell$ . We also have  $z(U_A) = z(L_A) = z(U_B) = z(L_B) = \ell$  since

$$4\ell = z(U_A) + z(L_A) + z(U_B) + z(L_B) \blacktriangleright$$

**Proof of Theorem 11.** Let  $\mathcal{C} \subseteq V$  be a set of  $8\ell$  vertices which induces an  $8\ell$ -cycle in  $G_{x,y}$ . From Lemma 16 and Lemma 17,  $\mathcal{C}$  contains  $\ell$  vertices in each  $A_1^i, A_2^j, B_1^s$ , and  $B_2^t$  for some  $i, j, s, t \in [n]$ . Since  $A_1^i$  must be connected to  $\mathcal{C} \cap U_A$ , it holds  $Code(A_1^i) = \mathcal{C} \cap U_A$ . Similarly, we have that  $Code(A_2^j) = \mathcal{C} \cap L_A$ ,  $Code(B_1^s) = \mathcal{C} \cap U_B$ , and  $Code(B_2^t) = \mathcal{C} \cap L_B$ . It can be easily checked that  $\mathcal{C} = A_1^i \cup A_2^j \cup B_1^s \cup B_2^t \cup Code(A_1^i) \cup Code(A_2^j) \cup Code(B_1^s) \cup Code(B_2^t)$  induces  $C_{8\ell}$  iff  $i = s, j = t$ , and  $x_{i,j} = y_{i,j} = 1$ . ◀

## B Proof of Lemma 14

Let  $N(a_i^j) = \{b_1, b_2, \dots, b_{\sqrt{n}}\}$  be the set of neighbors of  $a_i^j$  in  $B$ . Consider  $A_k$  such that  $k \neq i$ . For any  $b_l \in N(a_i^j)$ , just one vertex that is connected to  $b_l$  is chosen uniformly at random from  $A_k$ . For  $a \in A_k$ , let  $X(a)$  be the indicator variable of the event “the pair  $(a, a_i^j)$  forms a good pair”. Then, the expected value of  $X(a)$  is  $E(X(a)) = \sqrt{n} \cdot \frac{1}{\sqrt{n}} \cdot \left(\frac{\sqrt{n}-1}{\sqrt{n}}\right)^{\sqrt{n}-1} \geq 1/e$ . Hence, the expected value of the number of vertices in  $A_k$  that form good pairs with  $a_i^j$  is greater than  $\sqrt{n}/e$  by linearity of expectation. The expected value of the number of vertices that form good pairs with  $a_i^j$  is  $\sqrt{n}/e \times (\sqrt{n} - 1) = \Omega(n)$ . Again, by using linearity of expectation, the expected value  $E(|P_A|) \geq \Omega(n) \cdot n/2 = \Omega(n^2)$ . This means that there exists a graph with the condition holds. ◀

■ **Figure 5** Three types of diamonds which have exactly two vertices in  $V_A$ .

### C Proof of Theorem 6

We show the two-party communication protocol for listing diamonds by modifying the protocol for listing cliques in [11]. More precisely, we show the following theorem.

► **Theorem 18.** *There is a two-party communication protocol in the vertex partition model for listing all diamonds that uses  $\tilde{O}(\sqrt{n}|E_{cut}|)$  communication where  $E_{cut}$  is a set of cut edges in the input graph.*

**Proof.** If  $|E_{cut}| \geq n^{3/2}$ , Alice can send  $E_A$  to Bob within  $O(\sqrt{n}|E_{cut}|)$  bits of communication since it holds  $\sqrt{n}|E_{cut}| \geq n^2$ . Suppose that  $|E_{cut}| < n^{3/2}$ . Since Alice (and Bob) can list all diamonds in which three or four vertices in Alice's side without communication, we only care about diamonds in which exactly two vertices are in Alice's side. Let  $V_A^{heavy} = \{v \in V_A : \deg_{V_B}(v) > \deg_{V_A}/\sqrt{n}\}$  and  $V_A^{light} = V_A \setminus V_A^{heavy}$ . As shown in Figure 5, there are three possible cases.

- To list diamonds of case 1, we can use the protocol for listing cliques in [11]. This requires  $O(\sqrt{n}|E_{cut}|)$  bits.
- To list diamonds of case 2, Alice sends edges  $E_A \cap \{V_A^{heavy} \times V_A\}$  to Bob. This requires  $O(\sqrt{n}|E_{cut}|)$  bits since the number of edges Alice sends to Bob is less than

$$\sum_{v \in V_A^{heavy}} \deg_{V_A}(v) \leq \sum_{v \in V_A^{heavy}} \sqrt{n} \cdot \deg_{V_B}(v) = \sqrt{n}|E_{cut}|.$$

- To list diamonds of case 3, for every  $v \in V_A^{light}$ , Bob sends edges  $E_B \cap \{N_{V_B}(v) \times N_{V_B}(v)\}$  to Alice. This requires  $O(\sqrt{n}|E_{cut}|)$  bits since the number of edges Bob sends to Alice is less than

$$\sum_{v \in V_A^{light}} (\deg_{V_B}(v))^2 \leq \sum_{v \in V_A^{light}} \frac{\deg_{V_A}(v)}{\sqrt{n}} \cdot \deg_{V_B}(v) \leq \sqrt{n} \sum_{v \in V_A^{light}} \deg_{V_B}(v) \leq \sqrt{n}|E_{cut}|. \blacktriangleleft$$

► **Theorem 6 (Formal statement).** *No family of lower bound graphs gives an  $\tilde{\Omega}(n^{1/2+\varepsilon})$  lower bound of induced diamond listing for any  $\varepsilon > 0$ .*

**Proof.** Exactly the same as how Theorem 4 was proved from Theorem 13. ◀

## D Sublinear-round listing of induced diamonds (Theorem 7)

Assume that, for some edge subset  $E' \subseteq E$  where  $|E'| = c|E|$  for some constant  $c > 0$ , all cliques that contain at least one edge from  $E'$  are listed by a procedure  $\mathcal{A}$ . We recursively apply  $\mathcal{A}$  for  $E \setminus E'$  since remaining cliques are the ones whose edges are in  $E \setminus E'$ . After  $O(\log n)$  levels of recursion of  $\mathcal{A}$ , all cliques in the original graph are listed since removing edges does not increase the number of cliques. Fastest (and optimal) clique listing algorithms [9, 2] use this recursive method. On the other hand, this cannot be used for induced subgraphs since removing edges may increase the number of induced subgraphs (e.g., removing one edge from a 4-clique creates an additional diamond). Instead, we can use  $K_4$  listing algorithm of [14] to list induced diamonds. The algorithm begins by computing the decomposition of edge set, in which the edge set are decomposed into two subsets: edges that induce clusters with low mixing time and edges between clusters. The clusters satisfy the following:

► **Definition 19** ( $\delta$ -cluster). *For an  $n$ -node graph  $G = (V, E)$  and a subgraph  $G' = (V', E')$  of  $G$ ,  $G'$  is called a  $\delta$ -cluster if the following condition holds:*

1. *Mixing time of  $G'$  is  $O(\text{poly log}(n))$ ,*
2. *For any  $v \in V'$ ,  $\deg_{E'}(v) = \Omega(n^\delta)$ .*

► **Lemma 20** (Expander Decomposition, Lemma 9 of [14]). *For a  $n$ -node CONGEST network  $G = (V, E)$ , we can find, w.h.p., in  $\tilde{O}(n^{1-\delta})$  rounds, a decomposition of  $E$  to  $E = E_m \cup E_s$  satisfying the following conditions.*

1.  $E_m$  is the union of at most  $s = O(\log n)$  sets,  $E_m = \bigcup_{i=1}^s E_m^i$ , where each  $E_m^i$  is the vertex-disjoint union of  $O(n^{1-\delta})$   $\delta$ -clusters,  $C_i^1, \dots, C_i^{k_i}$ .  
The set  $E_m^i$  is called  $i$ -th level of the decomposition. We say that a node  $u$  belongs to cluster  $C_i^j$  if at least one of  $u$ 's edges is in  $C_i^j$ .
2. Each level- $i$  cluster  $C_i^j$  has a unique identifier, which is a pair of the form  $(i, x)$  where  $x \in [n^{1-\delta}]$ , and an unique leader node, which is some node in the cluster. Each node  $u$  knows the identifier of all the clusters  $C_i^j$  to which  $u$  belongs, the leaders for those clusters, and it knows which of its edges belong to which clusters.
3.  $E_s = \bigcup_{v \in V} E_{s,v}$ , where  $E_{s,v}$  is a subset of edges incident to  $v$  and  $|E_{s,v}| \leq n^\delta \log n$ . Each vertex  $v$  knows  $E_{s,v}$ .

The reason that the expander decomposition is used in the distributed subgraph detection is that  $\delta$ -clusters can simulate CONGESTED CLIQUE style algorithms efficiently:

► **Lemma 21** (Lemma 13 of [14]). *For a constant  $0 < \varepsilon \leq 1$ , suppose an edge set  $E'$  is partitioned between the nodes of a  $\delta$ -cluster  $C$ , so that each node  $u \in C$  initially knows a subset  $E'_u$  of size at most  $O(n^{2-\varepsilon})$ . Then a simulation of  $t$  rounds of the CONGESTED CLIQUE algorithm on  $G' = (V, E')$  can be performed in  $\tilde{O}(n^{2-\delta-\varepsilon} + t \cdot n^{2-2\delta})$  rounds, with success probability  $1 - \frac{1}{n^2}$ .*

Roughly speaking, a  $\delta$ -cluster can simulate 1 round of a CONGESTED CLIQUE style algorithm in  $\tilde{O}(n^{2-2\delta})$  rounds.

After doing the decomposition  $E = E_m \cup E_s$ , the high-level approach of  $K_4$  listing algorithm of [14] is as follows:

1. To list  $K_4$  in  $E_s$ , we can use the trivial algorithm since the subgraph induced by  $E_s$  is sparse.

2. To list  $K_4$  which contains at least one edge in  $E_m$ , each cluster  $C$  gathers outside edges which are incident to a cluster node in  $\tilde{O}(n)$  rounds so that the number of edges gathered by each node of  $C$  is  $\tilde{O}(n^2)$ . All nodes that are outside of  $C$  with many neighbors in  $C$  send all edges incident to them. This can be done efficiently since they have enough communication bandwidth to  $C$ . Then,  $C$  simulates  $K_4$  listing algorithm of the CONGESTED CLIQUE model.
3. Note that each outside node  $u$  with small bandwidth to  $C$  have no ability to send all edges incident to it in  $\tilde{O}(n)$  rounds. However,  $u$  can quickly gather all cluster edges that would belong to some  $K_4$  which contains  $u$  since the number of cluster neighbors of  $u$  is small.

The difference is that in the case of diamonds, there are several types of diamonds which are listed in step 2 and step 3 of above algorithm (see Figure 6). For a cluster  $C$ , we call a node  $v$  is  $C$ -heavy when  $v$  does not belong to  $C$  and has more than  $n^\varepsilon$  neighbors in  $C$ . The algorithm for listing induced diamonds is as follows:

1. First, we run the expander decomposition of Lemma 20 in  $\tilde{O}(n^{1-\delta})$  rounds.
2. To list diamonds in  $E_s$ , each node  $u$  sends the edges of  $E_s$  that are incident on  $u$  to all neighbors. This requires  $\tilde{O}(n^\delta)$  rounds.
3. Each  $C$ -heavy node  $v$  sends  $N(v)$  to  $C$  in  $O(n^{1-\varepsilon})$  rounds by partitioning  $N(v)$  into  $|N(v) \cap C| = \Omega(n^\varepsilon)$  subsets of size  $|N(v)|/|N(v) \cap C| = O(n^{1-\varepsilon})$  and sending each subset to a different neighbor in  $C$ . Then, since each  $C$ -node  $u$  receive at most  $n \cdot n^{1-\varepsilon} = n^{2-\varepsilon}$  edges, we can list all induced diamonds which contains at least one edge from some cluster  $C$ , and contains a  $C$ -heavy node, in  $\tilde{O}(n^{2-\delta-\varepsilon} + \sqrt{n} \cdot n^{2-2\delta})$  rounds by the algorithm of Lemma 21.
4. Each  $C$ -light node  $u$  sends  $N(u) \cap C$  to all its neighbors in  $O(n^\varepsilon)$  rounds. Then, each node  $v$  received  $N(u) \cap C$  from  $u$  compute the following set locally:

$$\begin{aligned} \mathcal{L}_v^1 &= \{ \{u, c_1, c_2\} \mid u \in N(v) \text{ is } C\text{-light}, c_1, c_2 \in C, c_1 \in N(v) \cap N(u), c_2 \in N(u) \setminus N(v) \}, \\ \mathcal{L}_v^2 &= \{ \{u, c_1, c_2\} \mid u \notin N(v) \text{ is } C\text{-light}, c_1, c_2 \in C, c_1, c_2 \in N(v) \cap N(u), \\ &\quad (u, c_1), (u, c_2), (v, c_1), \text{ and } (v, c_2) \in E_s. \}, \end{aligned}$$

where  $\mathcal{L}_v^1$  and  $\mathcal{L}_v^2$  correspond to the rightmost and leftmost diamonds in Figure 6, respectively. Note that we do not have to care about the leftmost diamond of Figure 6 which contains an edge from another cluster  $C'$ : Among the leftmost diamonds  $\{u, v, c_1, c_2\}$  of Figure 6, where  $c_1, c_2$  belong to  $C$  and  $u, v$  are  $C$ -light nodes, we only need to enumerate the diamonds whose four edges  $(u, c_1), (u, c_2), (v, c_1)$  and  $(v, c_2)$  are  $E_s$ -edges. This is because, for instance, if  $(u, c_1)$  is  $C'$ -edge for some cluster  $C'$ , then this diamond is treated by the cluster  $C'$  as the middle or rightmost diamond in Figure 6. Since each node sends its  $E_s$ -edges to all its neighbors in step 2,  $v$  knows the four edges  $(u, c_1), (u, c_2), (v, c_1)$  and  $(v, c_2)$  even when  $u \notin N(v)$ . Then,  $v$  construct the following list of edge queries locally:

$$\mathcal{Q}_{v, c_1} = \{ \{c_1, c_2\} \mid \exists u \in N(v) : \{u, c_1, c_2\} \in \mathcal{L}_v^1 \text{ or } \exists u \notin N(v) : \{u, c_1, c_2\} \in \mathcal{L}_v^2 \}.$$

We have  $|\mathcal{Q}_{v, c_1}| = O(n^\varepsilon)$ : if  $c_1$  received  $\{c_1, c_2\} \in \mathcal{Q}_{v, c_1}$ , then  $c_2 \in N(v) \cap C$  by definition. On the other hand, since  $v$  is  $C$ -light,  $|N(v) \cap C| = O(n^\varepsilon)$  holds. Each node  $v$  sends  $\mathcal{Q}_{v, c_1}$  to  $c_1$ , and  $c_1$  responds with  $\mathcal{Q}_{v, c_1} \cap (\{c_1\} \times N(c_1))$  in  $O(n^\varepsilon)$  rounds. Therefore, in  $O(n^\varepsilon)$  rounds, we can list all induced diamonds which contains at least one edge from some cluster  $C$ , and does not contain  $C$ -heavy nodes.

■ **Figure 6** Three types of diamonds that contain at least one edge from  $E_m$ . Red edges in the figure correspond to  $E_m$ -edges, i.e., edges belong to some cluster  $C$ . Heavy node represents a  $C$ -heavy node, i.e., a node which does not belong to  $C$ , but has more than  $n^\varepsilon$  neighbors in  $C$ . Light node represents a  $C$ -light node.

Taking parameters  $\delta = 5/6$  and  $\varepsilon = 1/2$  (same as in the algorithm of [14]), we get the following theorem.

► **Theorem 7.** *Listing all induced diamonds can be done in  $\tilde{O}(n^{5/6})$  rounds with high probability in the CONGEST model.*

# Distributed Approximations of $f$ -Matchings and $b$ -Matchings in Graphs of Sub-Logarithmic Expansion

## Abstract

---

We give a distributed algorithm which given  $\epsilon > 0$  finds a  $(1 - \epsilon)$ -factor approximation of a maximum  $f$ -matching in graphs  $G = (V, E)$  of sub-logarithmic expansion. Using a similar approach we also give a distributed approximation of a maximum  $b$ -matching in the same class of graphs provided the function  $b : V \rightarrow \mathbb{Z}^+$  is  $L$ -Lipschitz for some constant  $L$ . Both algorithms run in  $O(\log^* n)$  rounds in the LOCAL model, which is optimal.

## 1 Introduction

A matching in a graph  $G = (V, E)$  is a set of edges  $M \subseteq E$  such that every vertex  $v \in V$  belongs to at most one edge  $e \in M$ . Although the concept of a matching can be generalized in a few different ways, two natural and useful notions that have been considered in this context are that of an  $f$ -matching and a  $b$ -matching. Let  $G = (V, E)$  be a (simple) graph and let  $f : V \rightarrow \mathbb{Z}^+$ . A set  $M \subseteq E$  is called an  $f$ -matching in  $G$  if for every  $v \in V$ ,  $v$  is incident to at most  $f(v)$  edges from  $M$ . Given a function  $b : V \rightarrow \mathbb{Z}^+$ , a  $b$ -matching in  $G$  is a function  $x : E \rightarrow \mathbb{N}$  such that for every vertex  $v \in V$ ,  $\sum_{y \in N(v)} x(vy) \leq b(v)$ . Sometimes an  $f$ -matching is called a simple  $b$ -matching (a capacitated  $b$ -matching with bound one for capacities) [15].

In particular, in the case when  $f = 1$  ( $b = 1$ ), then an  $f$ -matching ( $b$ -matching) is simply a matching. The main difference between  $f$ -matchings and  $b$ -matchings is that in the case of  $b$ -matchings  $x : E \rightarrow \mathbb{N}$  and the corresponding assignment  $x$  for  $f$ -matching satisfies  $x : E \rightarrow \{0, 1\}$ . We shall use  $\nu_f(G)$  and  $\nu_b(G)$  to denote the maximum  $f$ -matching and  $b$ -matching, that is  $\nu_f(G) = \max\{|M| : M \text{ is an } f\text{-matching in } G\}$  and  $\nu_b(G) = \max\{\sum_{e \in E} x(e) : x \text{ is a } b\text{-matching in } G\}$ . In addition, we use  $\nu(G)$  for the size of a maximum matching in  $G$ .

We will use the LOCAL model from Peleg's book [14]. In this model a distributed network is modeled as an undirected graph with vertices corresponding to computational units and edges representing bidirectional links between them. The computations are synchronized, and in each round every vertex can send and receive messages from its neighbors, and, in addition, can perform some local computations. Neither the size of messages sent nor the amount of computations is restricted in any way. In addition, vertices have unique identifiers from  $\{1, \dots, n\}$  where  $n$  is the order of the graph.

## 1.1 Related Work

Although distributed algorithms for matchings have been studied extensively, little is known about  $f$ -matchings and  $b$ -matchings.

A maximal matching gives a  $1/2$ -factor approximation of a maximum and there has been some success in designing distributed algorithms that find a maximal matching. Seminal papers of Hanćkowiak, Karoński and Panconesi [8, 9] give deterministic poly-logarithmic algorithms for the maximal matching problem. Recently, a faster distributed algorithm for the maximal matching problem was given by Fischer [5]. This algorithm runs in  $O(\log^2 |V| \log \Delta)$  rounds in graphs  $G = (V, E)$  of maximum degree  $\Delta$ . At the same time Kuhn et al. [12] showed that finding a maximal matching in a graph  $G$  of order  $n$  and maximum degree  $\Delta$  requires  $\Omega(\log \Delta / \log \log \Delta + \sqrt{\log n / \log \log n})$  rounds.

Distributed approximations for the maximum matching problem which run in a poly-logarithmic number of rounds are known [2, 3]. Quite recently, Ghaffari, Harris and Kuhn [6] gave a  $O(\log^2 n \log^5(\Delta/\epsilon^9))$  algorithm that finds a  $(1 - \epsilon)$ -factor approximation of a maximum matching in a graph on  $n$  vertices with maximum degree  $\Delta$ , and Harris [10] gave fast approximation algorithms for weighted maximum matching and hypergraph matching.

As impressive as these algorithms are, their time complexity is often prohibitively high. Not surprisingly, there has been a lot of interest in designing faster distributed algorithms for special classes of graphs. For planar graphs, there is a distributed deterministic algorithm [4] which given  $\epsilon > 0$  finds in a graph  $G$  of order  $n$  in  $O(\log^* n)$  rounds, a matching  $M$  such that  $|M| \geq (1 - \epsilon)\nu(G)$ . This algorithm proceeds in two main steps. First, an ad-hoc procedure is used to reduce a given graph  $G = (V, E)$  to a graph  $G' = (V', E')$  such that (1)  $|V'|$  is proportional to the size of a maximum matching and (2) a maximum matching in  $G'$  is also maximum in  $G$  and (3)  $G'$  is still planar. Second, a clustering algorithm is used to partition  $V'$  into sets  $V_1, \dots, V_i$  so that it is possible to quickly find optimal solutions in graphs  $G'[V_i]$  and combine them to obtain a good approximation in the whole graph  $G'$  and so  $G$ .

The notions of an  $f$ -matching and  $b$ -matching are significantly more general. Very little is known about the distributed complexity of  $f$ -matchings except what can be concluded from the case  $f = 1$ . Using the Tutte's construction (see for example [15]) one can reduce  $b$ -matchings to matchings but this reduction infuses potentially large complete bipartite graphs.

Hanćkowiak [7] gave a poly-logarithmic running time algorithm for the maximal  $f$ -matching problem in general graphs which builds on the approach for matchings [8]. In addition, extending the approach for matchings, Fischer [5] managed to give a deterministic distributed algorithm for  $(1/2 - \epsilon)$ -approximating a maximum  $f$ -matching in general graphs that runs in  $O(\log^2 \Delta \log 1/\epsilon + \log^* |V|)$  rounds. In the case of a maximum  $b$ -matching it is possible to reduce it to the problem of a maximum matching but the reduction leads to graphs which can potentially contain large complete bipartite graphs. Consequently, the graph obtained after reduction can have minors of large cliques. As a result, maximum matching algorithms that exploit sparseness conditions cannot be invoked in the graph obtained by the reduction.

## 1.2 Results

We will give approximation algorithms for  $f$ -matchings and  $b$ -matchings. Although our primary interest comes from graphs that are  $K_m$ -minor-free for a fixed integer  $m$ , it is possible to phrase the results in terms of graphs of sub-logarithmic expansion which generalize the former class. (See Section 2 for definitions.)

Our first contribution is a distributed algorithm which given a graph  $G = (V, E)$  of sub-logarithmic expansion and  $\epsilon > 0$  finds a  $(1 - \epsilon)$ -factor approximation of a maximum  $f$ -matching in  $G$ . The algorithm runs in  $O(\log^* |V|)$  rounds (Theorem 7). The algorithm proceeds in two main steps, the first, described in detail in what follows, reduces the input graph to a graph in which a maximum  $f$ -matching is proportional to the number of vertices and the second invokes the clustering procedure of Amiri et al. [1].

The case of  $b$ -matchings is surprisingly more subtle in the realm of sparse graphs and our approach requires an additional assumption about function  $b$ . Specifically, we shall require that  $b$  is  $L$ -Lipschitz for some constant  $L$ , which is known to the algorithm. Under the same regime as  $f$ -matchings, we again give a  $O(\log^* |V|)$ -time distributed  $(1 - \epsilon)$ -factor approximation (Theorem 17).

It is known [4] that finding a constant approximation of a maximum matching or maximum independent set in a cycle on  $n$  vertices requires  $\Omega(\log^* n)$  rounds and so the running time in Theorem 7 and Theorem 17 cannot be improved.

Algorithms for both theorems use in their second main step, i.e. the clustering procedure, the procedure of Amiri et al. [1] which is based on the algorithm of Czygrinow et al. [4]. However the first main step of both algorithms, i.e. the reduction phase is new and relies on the Gallai-Edmonds theorem [11]. The rest of the paper is structured as follows. In Section 2 we introduce necessary terminology. In Section 3 we discuss  $f$ -matchings and Section 4 is devoted to  $b$ -matchings.

## 2 Preliminaries

For a positive integer  $r$  and a graph  $H$ , we say that  $H$  is a *minor of depth  $r$*  of graph  $G = (V, E)$  if for some subgraph  $G' = (V', E')$  of  $G$  it is possible to partition  $V'$  into sets  $V_1, \dots, V_l$  so that for every  $i$ ,  $G'[V_i]$  has radius at most  $r$  and the graph obtained by contracting each  $V_i$  to a vertex is isomorphic to  $H$ . We will set  $\nabla_r(G) = \max_H \frac{|E(H)|}{|V(H)|}$  where the maximum is taken over all minors  $H$  of depth  $r$  of  $G$ . A graph  $G$  is said to have a *bounded expansion* if there exists  $g : \mathbb{N} \rightarrow \mathbb{N}$  such that for every  $r \in \mathbb{N}$ ,  $\nabla_r(G) \leq g(r)$ . Note that surprisingly many classes of graphs have bounded expansion and we refer to [13] for an extensive discussion. In this paper, we will consider graphs  $G$  of sub-logarithmic expansion, that is graphs  $G$  such that  $\nabla_r(G) \leq g(r)$  for some  $g(r) \in o(\log r)$ . The class was introduced by Amiri et al. [1] where it is shown that the clustering algorithm from [4] works in this more general setting. In the case graph  $G$  is  $K_m$ -minor-free for some fixed  $m$ ,  $\nabla_r(G)$  can be bounded from above by a constant which depends on  $m$  only and so graphs of sub-logarithmic expansion include graphs that are  $K_m$ -minor-free for a fixed  $m$ . In addition, we obviously have  $\nabla_r(G) \leq \nabla_{r+1}(G)$ .

Our analysis relies on the Gallai-Edmonds theorem. To state it we need some additional terminology. A  $k$ -factor of a graph  $G$  is a spanning  $k$ -regular subgraph of  $G$ . In particular, a 1-factor is a perfect matching. For a graph  $H$ , we use  $\mathcal{C}_H$  to denote the set of (connected) components of  $H$ . A graph  $H$  is called *factor-critical* if, for every  $v \in V(H)$ , graph  $H - v$  has a 1-factor. Note that a component with only one vertex is factor-critical. Gallai-Edmonds theorem (see for example Kotlov [11]) will play a major role in our analysis. For a graph  $G = (V, E)$  let  $A$  be the set of vertices  $v \in V$  such that there is a maximum matching in  $G$  that does not cover  $v$ . Let  $B := N(A) = \{v \in V \setminus A \mid \exists w \in A vw \in E\}$ , and let  $C := V \setminus (A \cup B)$ . Clearly,  $\{A, B, C\}$  is a partition  $V$  (although some sets can be empty) which we will call a *Gallai-Edmonds decomposition* of graph  $G$ . We have the following theorem.

► **Theorem 1** (Gallai-Edmonds Theorem). *Let  $G = (V, E)$  be a graph and let  $\{A, B, C\}$  be a Gallai-Edmonds decomposition of  $G$ . Then the following conditions hold.*

- (a) *Every odd component  $H$  of  $G - B$  is factor-critical and  $V(H) \subseteq A$ .*
- (b) *Every even component  $H$  of  $G - B$  has a perfect matching and  $V(H) \subseteq C$ .*
- (c) *For every non-empty subset  $X \subseteq B$ ,  $N(X)$  has vertices from more than  $|X|$  odd components of  $G - B$ .*

In particular, in view of Hall's theorem,  $B$  is matchable to the set of odd components in  $G - B$ .

Fix  $g : \mathbb{N} \rightarrow \mathbb{N}$  such that  $g(r) = o(\log r)$  and  $\nabla_r(G) \leq g(r)$ . It will be convenient to define  $D := 2 \cdot g(1)$ . Although the algorithms do not need to have perfect information about  $g$ , they certainly need to know  $D$ . By definition, for every subgraph  $H$  of  $G$  we have

$$\sum_{v \in V(H)} \deg_H(v) \leq D \cdot |V(H)|. \quad (1)$$

We will call a clique  $S$  an  $i$ -clique if  $|S| = i$ .

► **Lemma 2.** *Let  $G$  be a graph of order  $n$ ,  $D$  be such that  $\nabla_0(G) \leq D/2$  and let  $i \geq 2$ . Then there is a vertex  $v \in V(G)$  that belongs to at most  $\binom{D}{i-1}$   $i$ -cliques.*

**Proof.** Note that the statement is true when  $i = 2$ . For  $i \geq 3$ , let  $v$  be a vertex of minimum degree which by (1) is at most  $D$ . Then every  $i$ -clique containing  $v$  is a subset of  $N[v]$ . ◀

### 3 $f$ -matchings

Assume that  $G$  satisfies  $\nabla_r(G) \leq g(r)$  and  $D = 2 \cdot g(1)$ . We call  $u, v \in V(G)$   $i$ -clones if  $N(u) = N(v)$  and  $|N(u)| = i$ . Note that we consider open neighborhoods and so if  $uv$  is an edge then  $u$  and  $v$  are not clones. The relation of being  $i$ -clones,  $\sim_i$ , is symmetric, transitive, and reflexive on the set  $V_i := \{v \mid \deg(v) = i\}$ . Let  $v_1, \dots, v_l$  be  $i$ -clones such that  $N(v_1) = \{u_1, \dots, u_i\}$  and  $l \geq i + 1$ . Since for every  $j \in \{1, \dots, i\}$ ,  $\deg(u_j) \geq l \geq i + 1$ ,  $u_j$  cannot be an  $i$ -clone of any other vertex.

In the first phase of the algorithm we trim graph  $G$ , discard some edges, and delete isolated vertices so that for the trimmed graph  $G'$  we have  $\nu_f(G') = \nu_f(G)$  and  $\nu_f(G') = \Omega(|G'|)$ . Phase 1 is split into two procedures DISCARD EDGES and TRIMMING.

■ **Procedure** DISCARD EDGES  $(G, i)$ .

- 
- Let  $G'$  be the graph obtained from  $G$  by deleting the following edges. For every equivalence class  $\{v_1, \dots, v_l\}$  of  $\sim_i$  in  $V_i$  which satisfies  $f(v_1) \geq f(v_2) \geq \dots \geq f(v_l)$ :
    - If  $l \geq D$  and  $N(v_1) = \{u_1, \dots, u_i\}$  then, assuming  $f(u_1) \leq f(u_j)$  for every  $j \in \{1, \dots, i\}$ , delete edges  $u_1 v_j$  for  $j > \max\{f(u_1), D\}$ .
  - Return  $G'$ .
- 

We will first show that graph  $G'$  obtained by DISCARD EDGES has the same size of a maximum  $f$ -matching as  $G$  does.

► **Lemma 3.** *Let  $i \in \mathbb{Z}^+$  and let  $G'$  denote the graph returned by DISCARD EDGES  $(G, i)$ . Then*

$$\nu_f(G') = \nu_f(G).$$

■ **Figure 1** Case 2 of the proof of Lemma 3.

**Proof.** Clearly  $\nu_f(G') \leq \nu_f(G)$ . To prove the opposite inequality consider  $f$ -matching  $F$  in  $G$  of size  $\nu_f(G)$  that contains as few edges from  $E(G) \setminus E(G')$  as possible. Note that only edges incident to  $u_1$  are removed from  $G$ . Suppose  $F$  contains  $u_1v_k$  for some  $k > \max\{f(u_1), D\}$ . Thus from all edges  $u_1v_1, \dots, u_1v_{f(u_1)}$  that are in  $G'$ , at least one of them, say  $u_1v_1$ , is not in  $F$ .

**Case 1:** If  $u_jv_1 \in F$  for at most  $f(v_1) - 1$  edges  $u_jv_1$ , then consider  $F' = F - u_1v_k + u_1v_1$  and note that  $F'$  is an  $f$ -matching of size  $|F|$  with fewer edges from  $E(G) \setminus E(G')$  than  $F$ .

**Case 2:** For some  $j \in \{1, \dots, i\}$ ,  $u_jv_1 \in F$  but  $u_jv_k \notin F$ . Then consider  $F' = F - u_1v_k - u_jv_1 + u_1v_1 + u_jv_k$ .

If none of the cases 1 and 2 hold, then  $v_1$  is incident to  $f(v_1)$  edges  $v_1u_j \in F$  such that  $j \geq 2$  and  $v_k$  is incident to  $f(v_1) + 1$  edges from  $F$  because we have that  $u_jv_k \in F$  whenever  $u_jv_1 \in F$  and additionally  $u_jv_k \in F$ . Thus  $f(v_k) > f(v_1)$ , but by definition of the algorithm,  $f(v_k)$  is at most  $f(v_j)$  for every  $j \leq \max\{f(u_1), D\}$ . ◀

We now consider the main trimming procedure.

■ **Procedure** TRIMMING( $G$ ).

- 
- For  $i = D - 1$  downto 1, let  $G := \text{DISCARD\_EDGES}(G, i)$ .
  - Let  $H$  be obtained from  $G$  by deleting all isolated vertices.
  - Return  $H$ .
- 

Let  $H$  be the graph returned by TRIMMING( $G$ ) for the original graph  $G$ . In addition, we use  $G_i$  to denote graph  $G$  for which we call DISCARD EDGES( $G, i$ ) in the  $i$ th iteration of the loop in step one. Before proving our main lemma, we show the following observation.

► **Lemma 4.** Let  $1 \leq k \leq D - 1$ , and let  $Y = \{y_1, \dots, y_j\}$ ,  $|Y| = j$ , be  $k$ -clones in  $H$  such that  $N_H(y_1) = \{u_1, \dots, u_k\}$ . Then

$$j \leq D \cdot f^*,$$

where  $f^* = \min_{1 \leq i \leq k} \{f(u_i)\}$ .

**Proof.** We claim that  $y_1, \dots, y_j$  are  $k$ -clones in  $G_k$ . First note that in view of the main step of DISCARD EDGES, if  $x$  is a vertex in  $G$  such that  $\text{deg}_{G_l}(x) \geq D$  for some  $l < D$ , then  $\text{deg}_H(x) \geq D$ . Indeed,  $v_j$  has degree less than  $D$  as  $l < D$ , moreover for  $u_1$  edges  $u_1v_j$  can be deleted, but DISCARD EDGES always keeps at least  $D$  edges incident to  $u_1$ .

We clearly have  $N_H(y_l) \subseteq N_{G_k}(y_l)$  for every  $l = 1, \dots, j$ . Suppose  $k = \deg_H(y_l) < \deg_{G_k}(y_l)$  for some  $l$ . Then  $y_l$  had some edges deleted from the set of edges incident to  $y_l$  in  $G_k$  in iteration  $i$  for some  $i \leq k$ . However in iteration  $i$ , we delete edges incident to vertices of degree  $i$  or vertices of degree larger than  $D$ , keeping at least  $D$  of them. Thus either  $\deg_H(y_l) < k$ , which is not possible, or  $\deg_H(y_l) \geq D$ , contradicting  $k \leq D - 1$ .

Since  $y_1, \dots, y_j$  are  $k$ -clones in  $G_k$ , we have  $j \leq \max\{f^*, D\}$  after step two of DISCARD EDGES( $G_k, k$ ). Consequently,  $j \leq D \cdot f^*$  because  $f^*$  and  $D$  are at least one.  $\blacktriangleleft$

By Lemma 3, we have

$$\nu_f(H) = \nu_f(G), \quad (2)$$

and  $H$  has no isolated vertices.

We will now establish our second fact which shows that  $\nu_f(H)$  is proportional to the order of  $H$ .

**► Lemma 5.** *Let  $G$  be a graph such that  $\nabla_1(G) \leq D/2$  and let  $H$  be obtained by calling TRIMMING( $G$ ). Then  $\nu_f(H) \geq c_D |V(H)|$  for some  $c_D$  which depends on  $D$  only.*

**Proof.** We will use Theorem 1. Let  $\{A, B, C\}$  be a Gallai-Edmonds decomposition of  $H$ . Then the size of a maximum matching in  $H$  is  $\Omega(|B| + \sum_W |W|)$  where the sum is taken over components  $W$  of  $H - B$  of order at least two. Since a maximum  $f$ -matching has size larger than or equal to the size of a maximum matching,

$$\nu_f(H) = \Omega(|B| + \sum_W |W|).$$

Let  $X$  be the set of components of  $H - B$  of size one. We will identify each component from  $X$  with the vertex it contains. Since  $H$  has no isolated vertices, every component from  $X$  has at least one neighbor in  $B$ . Let  $Y$  be the set of components in  $X$  which have at least  $D$  neighbors in  $B$ . We have  $D \cdot |Y| \leq |E_H(Y, B)| \leq D(|Y| + |B|)/2$  from (1), and so  $|Y| \leq |B|$ . Thus  $\nu_f(H) = \Omega(|Y|)$ . For  $i = 1, \dots, D - 1$ , let  $X_i \subseteq X$  denote the set of components that have exactly  $i$  neighbors in  $B$ . In the rest of the argument we will show that for  $i \in \{1, \dots, D - 1\}$ ,  $\nu_f(H) = \Omega_D(|X_i|)$ . Given that this is the case, we can conclude

$$\nu_f(H) = \Omega(|B| + \sum_W |W| + |Y| + \sum_{i < D} |X_i|) = \Omega_D(|V(H)|).$$

**▷ Claim 6.** For  $i \in \{1, \dots, D - 1\}$ ,  $\nu_f(H) = \Omega_D(|X_i|)$ .

**Proof.** Let  $H^* := (B, \emptyset)$  be the edge-less graph on the set  $B$ . Order the vertices in  $X_i$  and proceed one by one for as long as possible using the following procedure. Take  $y \in X_i$ . If  $N_H(y)$  is not an  $i$ -clique in  $H^*$ , then take two non-adjacent vertices  $v_1, v_2$  from  $N_H(y) \subseteq B$ , add an edge between them to  $H^*$ , and delete  $y$  from  $X_i$ . Formally, we delete all edges incident to  $y$  except  $yv_1, yv_2$  and contract the edge  $yv_1$ . Let  $X_i^*$  denote the set of deleted vertices. Then  $|X_i^*| = |E(H^*)| \leq \nabla_1(G)|B| \leq D|B|/2$ . We will now bound the number of remaining vertices. Unlike the previous part of the argument, we will show that there is an  $f$ -matching  $F$  in  $H$  such that  $|F| \geq \Omega_D(|X_i \setminus X_i^*|)$ .

For every vertex  $y \in X_i \setminus X_i^*$ ,  $N_H(y)$  is an  $i$ -clique in  $H^*$ , and if  $y, y' \in X_i \setminus X_i^*$  are such that  $N_H(y) = N_H(y')$ , then  $y$  and  $y'$  are  $i$ -clones. We will put weights on these cliques. Specifically, the weight of an  $i$ -clique  $T$  is the number of vertices  $y$  in  $X_i \setminus X_i^*$  such that  $N_H(y) = T$ . By Lemma 4, for every  $i$ -clique  $T$  in  $H^*$ , the weight of  $T$  satisfies  $\omega(T) \leq D \cdot f_T$ , where  $f_T = \min_{u \in T} f(u)$ . In addition, we have

$$\sum_T \omega(T) = |X_i \setminus X_i^*|. \quad (3)$$

We will now assign  $i$ -cliques to vertices from  $B$  so that the following conditions hold:

- If  $T$  is assigned to  $v$ , then  $v \in T$ ;
- There are at most  $\binom{D}{i-1}$  cliques assigned to every vertex  $v$ ;
- Every  $i$ -clique in  $H^*$  is assigned to exactly one vertex from  $B$ .

This is possible, because by Lemma 2, there is a vertex  $v$  in  $B$  which is in at most  $\binom{D}{i-1}$   $i$ -cliques  $T$  in  $H^*$ . We assign these cliques to  $v$  and continue the process (note that  $\nabla_0(H^* - v) \leq \nabla_0(H^*)$ ). Let  $E_v$  denote the set of cliques assigned to  $v$ . For every  $T \in E_v$ , the weight satisfies  $\omega(T) \leq D \cdot f_T \leq D \cdot f(v)$  because  $v \in T$ . Let  $T_v \in E_v$  be an  $i$ -clique in  $E_v$  of the largest weight. Then, by (3),

$$\sum_v \omega(T_v) \geq \sum_v \sum_{T \in E_v} \omega(T) / \binom{D}{i-1} = \frac{\sum_T \omega(T)}{\binom{D}{i-1}} = |X_i \setminus X_i^*| / \binom{D}{i-1}.$$

Since  $f(x) \geq 1$  for every  $x$ , we can select  $\lceil \omega(T_v)/D \rceil \leq f(v)$  vertices  $y \in X_i \setminus X_i^*$  to get star  $F_v$  with center at  $v$  and selected vertices  $y$  as its leaves. Since  $F_u \cap F_v = \emptyset$  when  $u \neq v$ ,  $\bigcup F_v$  is an  $f$ -matching in  $H$  of size at least  $|X_i \setminus X_i^*| / (D \cdot \binom{D}{i-1})$ . Consequently,

$$|X_i| = |X_i^*| + |X_i \setminus X_i^*| = O_D(|B|) + O_D(\nu_f(H)) = O_D(\nu_f(H)). \quad \triangleleft$$

That concludes the proof of Lemma 5. ◀

We will now proceed to Phase 2 of the algorithm. For this phase we need to know that the graph  $G$  has sub-logarithmic expansion  $g$ . Note that to use the algorithm in Phase 2, constant  $c_D$  (or a bound for it) must be provided and, in addition, the algorithm from [1] which is used in step 2 requires some knowledge of the function  $g$ .

■ **Procedure** APPROXIMATION( $G, \epsilon, g$ ).

- 
- Use TRIMMING( $G$ ) to obtain graph  $H$ .
  - Use the algorithm from [1] to find a partition of  $V(H)$  into sets  $V_1, \dots, V_i$  such that  $\text{diam}(V_i) = O_{\epsilon, D}(1)$  and the number of edges with endpoints in different sets  $V_i$  is at most  $\epsilon \cdot c_D |H|$ .
  - Find an optimal solution  $F_i$  in  $H[V_i]$  and return  $\bigcup F_i$ .
- 

► **Theorem 7.** *There is a distributed algorithm which given a graph  $G$  on  $n$  vertices of expansion  $g$  such that  $g(r) = o(\log r)$  and  $\epsilon > 0$  finds an  $f$ -matching  $F$  in  $G$  such that  $|F| \geq (1 - \epsilon)\nu_f(G)$ . The algorithm runs in  $O_{\epsilon, D}(\log^* n)$  rounds.*

**Proof.** Use APPROXIMATION( $G, \epsilon, g$ ). By (2),  $\nu_f(H) = \nu_f(G)$  and by Lemma 5,  $\nu_f(H) \geq c_D |H|$ . We have

$$\nu_f(G) \leq \sum_i |F_i| + \epsilon \cdot c_D |V(H)| \leq |F| + \epsilon \nu_f(G).$$

TRIMMING runs in the number of rounds which depends on  $D$  only and the running time of the algorithm from [1] is  $O(\log^* n)$ . ◀

## 4 $b$ -matchings

In this section, we will discuss maximum  $b$ -matchings. All graphs are finite and simple. As before, we will consider graphs with sub-logarithmic expansion  $g$  and set  $D := 2 \cdot g(1)$ .

► **Definition 8.** Given a (simple) graph  $G = (V, E)$  and a function  $b : V \rightarrow \mathbb{Z}^+$ , let  $\nu_b(G) = \max\{\sum_{e \in E} x(e)\}$  where the maximum is taken over all functions  $x : E \rightarrow \mathbb{N}$  such that for every vertex  $v \in V$ ,  $\sum_{y \in N(v)} x(vy) \leq b(v)$ .

In our reduction algorithm, we will assume that  $b$  is  $L$ -Lipschitz for some given constant  $L$ , that is  $b : (V, d_1) \rightarrow (\mathbb{Z}^+, d_2)$  satisfies  $d_2(b(u), b(v)) \leq Ld_1(u, v)$  for any  $u, v \in V$ , where  $d_1$  is the metric determined by the distance in graph  $G = (V, E)$  and  $d_2(a, b) = |a - b|$ . The condition will be of no relevance if  $u$  and  $v$  are in different connected components of  $G$ .

To start the analysis we have the following observation.

► **Fact 9.** Let  $G = (V, E)$  be a graph with  $\nabla_0(G) \leq D/2$  and let  $b : V \rightarrow \mathbb{Z}^+$ . Define  $\omega : E \rightarrow \mathbb{Z}^+$  as

$$\omega(uv) := \min\{b(u), b(v)\}. \quad (4)$$

Then (a)  $\omega(E) \leq D \cdot b(V)$  and (b)  $\nu_b(G) \leq \omega(E)$ .

**Proof.** We shall prove (a) by induction on  $|V|$ . The base case is obvious. For the inductive step, by (1), the average degree of  $G$  is at most  $D$  and so there is a vertex  $v \in V$  of degree at most  $D$ . By induction,  $\omega(E(G - v)) \leq D \cdot b(V \setminus \{v\})$  and the weight on edges incident to  $v$  is at most  $D \cdot b(v)$  by (4). For (b), if  $x : E \rightarrow \mathbb{N}$  is such that  $x(E) = \nu_b(G)$ , then for every  $e \in E$ ,  $x(e) \leq \omega(e)$ . ◀

The general idea behind the approach is the same as in the case of  $f$ -matchings. We first reduce graph  $G$  using the notion of  $i$ -clones and then apply clustering. However, the reduction and the fact that it accomplishes the desired result (Lemma 16) require additional care.

■ **Procedure** `MODIFY( $G, b, i$ )`.

- 
- Let  $G'$  be the graph obtained from  $G$  by deleting the following edges. For every equivalence class  $\{v_1, \dots, v_l\}$  of  $\sim_i$  in  $V_i$  in parallel:
    - If  $l > D$  and  $N(v_1) = \{u_1, \dots, u_i\}$ , then delete vertices  $v_{D+1}, \dots, v_l$ . Set  $b'(v_D) := b(v_D) + \dots + b(v_l)$  and  $b'(w) := b(w)$  for any other vertex  $w$ .
  - Return  $(G', b')$ .
- 

For a graph  $G = (V, E)$  and  $v \in V$ , we used  $E_G(v)$  to denote the set of edges  $e \in E$  such that  $v \in e$ .

► **Fact 10.** Let  $(G', b')$  denote the pair returned by `MODIFY( $G, b, i$ )`.

(a) Then  $\nu_{b'}(G') = \nu_b(G)$ .

(b) For every  $u \in V(G')$  either  $\deg_{G'}(u) \geq D$  or  $N_{G'}(u) = N_G(u)$ .

**Proof.** We will first show part (a). Let  $x : E(G) \rightarrow \mathbb{N}$  be a maximum  $b$ -matching in  $G$  and let  $a_p = \sum_{k=1}^i x(v_p u_k)$ . Let  $x'$  be obtained by setting  $x'(v_D u_k) := \sum_{p=D}^l x(v_p u_k)$  and  $x'(v_j u_k) := x(v_j u_k)$  for  $j < D$ . Then  $x' : E(G') \rightarrow \mathbb{N}$  and for every  $k \in \{1, \dots, i\}$ ,

$$\sum_{e \in E_G(u_k)} x(e) = \sum_{e \in E_{G'}(u_k)} x'(e)$$

as the total value of  $x$  on edges between  $u_k$  and  $v_1, \dots, v_l$  stays the same. Obviously, for  $j < D$ , we have  $\sum_{k=1}^i x'(v_j u_k) = \sum_{k=1}^i x(v_j u_k)$  and, in addition,

$$\sum_{k=1}^i x'(v_D u_k) = \sum_{p=D}^l a_p \leq \sum_{p=D}^l b(v_p) = b'(v_D)$$

as  $a_p \leq b(v_p)$ . Thus  $x'$  is a  $b'$ -matching in  $G'$  of the same value as  $x$ .

Similarly, let  $x' : E(G') \rightarrow \mathbb{N}$  be a maximum  $b'$ -matching in  $G'$ . Then  $\sum_{e \in E_{G'}(u_k)} x'(e) \leq b'(u_k) = b(u_k)$  for every  $k \in \{1, \dots, i\}$ , and  $\sum_{k=1}^i x'(v_D u_k) \leq b'(v_D)$ . For  $p > D$ , taking  $a_p$  to be the maximum value such that  $0 \leq a_p \leq b(v_p)$  and  $\sum_{k=1}^i x'(v_D u_k) - a_p \geq 0$ , we can write  $a_p = \sum_{k=1}^i a_{pi}$  where  $0 \leq a_{pi} \leq x'(v_D u_k)$  and assign  $a_{pi}$  to  $v_p u_k$  so that the total of  $a_p$  is reassigned from  $E(\{v_D\}, \{u_1, \dots, u_i\})$  to  $E(\{v_p\}, \{u_1, \dots, u_i\})$ . Proceeding one by one with  $p = D + 1, \dots, l$  gives  $x : E(G) \rightarrow \mathbb{N}$  such that  $x(E(G)) = x'(E(G'))$  and  $x$  is a  $b$ -matching in  $G$ .

For part (b), removing vertices  $v_j$  for  $j > D$  only affects the neighborhoods of vertices  $u_1, \dots, u_i$ . However, for every  $k \in \{1, \dots, i\}$ ,  $\deg_{G'}(u_k) \geq D$  as we keep  $D$  of  $i$ -clones from  $v_1, \dots, v_l$ .  $\blacktriangleleft$

After  $\text{MODIFY}(G, b, i)$  we obtain a graph  $(G', b')$ , where some vertices were removed from  $G$  and for some vertices  $v$ , we have  $b(v) < b'(v)$ . In this cases  $v$  will be called *special*. Note that it is easy to reverse  $\text{MODIFY}$  and obtain  $x$  on  $G$  from  $x'$  on  $G'$  by making special vertices distribute  $x'$  to deleted vertices as described in the proof.

We will now obtain a reduction of  $G$  which will be used in further computations.

**Procedure**  $\text{REDUCTION}(G, b)$ .

- 
1. For  $i = D - 1$  downto 1, let  $(G, b) := \text{MODIFY}(G, b, i)$ .
  2. Return  $(G, b)$ .
- 

**► Lemma 11.** *Let  $(G', b')$  denote the pair returned by  $\text{REDUCTION}(G, b)$ . Then we have the following:*

- (a)  $\nu_{b'}(G') = \nu_b(G)$ ;
- (b) *For every  $i < D$ , if  $S \subseteq V$  has size  $i$ , then there are at most  $D$   $i$ -clones  $v$  in  $G'$  such that  $N_{G'}(v) = S$ .*

**Proof.** The first part follows from Fact 10 (a). For the second part, if  $w_1, \dots, w_l$  are  $i$ -clones in  $G'$  and  $N_{G'}(w_1) = S$ , then, by Fact 10 (b), we have  $N_{G'}(w_k) = S$  for every  $k \in \{1, \dots, l\}$ . Consequently,  $w_1, \dots, w_l$  are  $i$ -clones in the original graph  $G$  and all graphs obtained in step one of  $\text{REDUCTION}(G, b)$ . Therefore, in the  $i$ th iteration, all but at most  $D$  of  $w_1, \dots, w_l$  are removed, and so  $l \leq D$ .  $\blacktriangleleft$

To prove our main fact (Lemma 16) we need some additional preparation. In the proof of the main lemma, we will use the Tutte's construction that reduce the problem of  $b$ -matchings to matchings.

**► Definition 12.** *Let  $\tilde{G} = (\tilde{V}, \tilde{E})$  be obtained from  $G = (V, E)$  as follows. Replace vertex  $v$  from  $V$  with an independent set  $U_v$  of size  $|U_v| = b(v)$  so that for  $i \neq j$ ,  $U_v \cap U_w = \emptyset$ . If  $vw \in E$  then add all edges  $xy$  to  $\tilde{E}$  for every  $x \in U_v$  and  $y \in U_w$ .*

The following fact is easy to see [16]:

► **Fact 13.**  $\nu_b(G) = \nu(\tilde{G})$ .

Let  $\{\tilde{A}, \tilde{B}, \tilde{C}\}$  be a Gallai-Edmonds decomposition of  $\tilde{G}$ . Recall that properties of the decomposition are given before Theorem 1.

► **Lemma 14.** *Let  $G = (V, E)$  and  $\tilde{G} = (\tilde{V}, \tilde{E})$ . Then partition  $\{U_v \mid v \in V\}$  of  $\tilde{V}$  is a refinement of  $\{\tilde{A}, \tilde{B}, \tilde{C}\}$ .*

**Proof.** Let  $v \in V$  and let  $U_v = \{v_1, \dots, v_k\}$ .

- Suppose for some  $i$ ,  $v_i \in \tilde{A}$  and let  $\tilde{M}$  be a maximum matching in  $\tilde{G}$  that does not cover  $v_i$ . If  $v_j$  is covered by  $\tilde{M}$ , then  $v_j w \in \tilde{M}$  for some  $w \in \tilde{V}$ . By the construction,  $v_i w \in \tilde{E}$  and so  $\tilde{M} - v_j w + v_i w$  is a maximum matching that does not cover  $v_j$ . Consequently,  $v_j \in \tilde{A}$ .
- If  $v_i \in \tilde{B}$  then  $v_i \notin \tilde{A}$  and  $v_i w \in \tilde{E}$  for some  $w \in \tilde{A}$ . For any  $j \in \{1, \dots, k\}$ , by the previous observation  $v_j \notin \tilde{A}$  and by the construction  $v_j w \in \tilde{E}$ . Thus  $v_j \in \tilde{B}$ .
- If  $v_i \in \tilde{C}$  then for any  $j$ ,  $v_j \in \tilde{C}$ , because otherwise  $v_j \in \tilde{A} \cup \tilde{B}$  which in view of previous observations gives  $v_i \in \tilde{A} \cup \tilde{B}$ . ◀

Lemma 14 easily gives the following fact.

► **Fact 15.** *Let  $\tilde{H}$  be a component of  $\tilde{G} - \tilde{B}$  that satisfies  $|V(\tilde{H})| \geq 2$  and let  $v \in V(G)$ . If  $U_v \cap V(\tilde{H}) \neq \emptyset$ , then  $U_v \subseteq V(\tilde{H})$ .*

**Proof.** Suppose  $u \in U_v \cap V(\tilde{H})$ . Since  $|V(\tilde{H})| \geq 2$ , there is  $w \in V(\tilde{H})$  such that  $uw \in \tilde{E}$ . By construction, for every  $u' \in U_v$ ,  $u'w \in \tilde{E}$ . By Theorem 1,  $u \notin \tilde{B}$  and so by Lemma 14,  $u' \notin \tilde{B}$ . Consequently, since  $\tilde{H}$  is a component in  $\tilde{G} - \tilde{B}$ ,  $u' \in V(\tilde{H})$ . ◀

We can now prove the main lemma. We will define  $\omega$  on the edges set of  $G'$  where  $(G', b')$  is returned by  $\text{REDUCTION}(G, b)$  for the original graph  $G$  and function  $b$ , that is  $\omega : E(G') \rightarrow \mathbb{Z}^+$  as  $\omega(uv) = \min\{b'(u), b'(v)\}$ .

► **Lemma 16.** *For every  $D, L \in \mathbb{Z}^+$  there is  $c_{D,L} > 0$  such that the following holds. Let  $G$  be a graph with  $\nabla_1(G) \leq D/2$ , let  $b : V \rightarrow \mathbb{Z}^+$  be  $L$ -Lipschitz, and let  $(G', b')$  be the pair returned by  $\text{REDUCTION}(G, b)$ . Then*

$$\nu_{b'}(G') \geq c_{D,L} \cdot \omega(E(G')). \quad (5)$$

**Proof.** Consider  $\tilde{G}$  obtained from  $G'$  and let  $\{\tilde{A}, \tilde{B}, \tilde{C}\}$  be the Gallai-Edmonds decomposition of  $\tilde{G}$ . By Lemma 14, suppressing each set  $U_v$  to  $v$  gives partition  $\{A, B, C\}$  of  $V(G)$  defined as  $A = \bigcup_{U_v \subseteq \tilde{A}} \{v\}$ ,  $B = \bigcup_{U_v \subseteq \tilde{B}} \{v\}$ ,  $C = \bigcup_{U_v \subseteq \tilde{C}} \{v\}$ .

Let  $\tilde{H}$  be a component of  $\tilde{G} - \tilde{B}$  such that  $|V(\tilde{H})| \geq 2$  and let  $H$  be obtained by suppressing each  $U_v \subseteq V(\tilde{H})$  to  $v$ . If  $|V(\tilde{H})|$  is even then  $\tilde{H}$  has a perfect matching  $\tilde{M}$  by Theorem 1, and by Lemma 14,  $H$  contains a  $b'$ -matching  $x_H : E(H) \rightarrow \mathbb{N}$  such that for each vertex  $v \in V(H)$ ,  $\sum_{e \in E_H(v)} x_H(e) = b'(v)$ . Thus

$$x_H(E(H)) = \sum_{v \in V(H)} b'(v). \quad (6)$$

If  $|V(\tilde{H})|$  is odd, then  $|V(\tilde{H})| \geq 3$  and  $\tilde{H}$  is factor-critical. Consequently, there is a  $b'$ -matching  $x_H$  in  $H$  such that  $\sum_{e \in E_H(v)} x_H(e) = b'(v) - 1$  for any specified vertex  $v \in V(H)$  and  $\sum_{e \in E_H(w)} x_H(e) = b'(w)$  for every vertex  $w \in V(H) \setminus \{v\}$ . Therefore,

$$x_H(E(H)) = \left( \sum_{v \in V(H)} b'(v) \right) - 1 > \frac{1}{2} \sum_{v \in V(H)} b'(v). \quad (7)$$

In addition, by Lemma 1, we know that  $\tilde{B}$  is matchable to the set of odd components in  $\tilde{G} - \tilde{B}$ , and so, by Lemma 14, there is a  $b'$ -matching  $x_B$  in  $G'$  such that

$$x_B(E(B, V \setminus B)) = |\tilde{B}| = \sum_{v \in B} b'(v). \quad (8)$$

Let  $G_1 := G'[B \cup \bigcup V(H)]$  where the union is over all components  $H$  of  $G' - B$  that satisfy  $|V(\tilde{H})| \geq 2$ . By (6), (7), there is  $b'$ -matching  $x$  in  $G_1$  such that

$$x(E(G')) \geq \frac{1}{2} \sum_H \sum_{v \in V(H)} b'(v) \quad (9)$$

where the sum is taken over all components  $H$  in  $G' - B$  of order at least two. Since  $\frac{1}{2}(c + d) \leq \max\{c, d\}$ , by (8) and (9), there is a  $b'$ -matching  $x$  in  $G'$  (not necessarily  $G_1$ ), such that

$$x(E(G')) > \frac{1}{2} \left( x_B(E(B, V \setminus B)) + \frac{1}{2} \sum_H \sum_{v \in V(H)} b'(v) \right) \geq b'(V(G_1))/4 > \omega(E(G_1))/(4 \cdot D)$$

where the last inequality follow from Fact 9 (a).

We will now bound the weight of the edges of  $G'$  that are not in  $G_1$ . Let  $\tilde{U}$  be the set of components of size one in  $\tilde{G} - \tilde{B}$ , and let  $U$  be obtained by suppressing each  $U_v \subseteq \tilde{U}$  to  $v$ . Note that each  $u \in U$  is a component of size one in  $G' - B$ .

Let  $U' \subseteq U$  denote the set of vertices  $u \in U$  such that  $\deg_{G'}(u) = |N_{G'}(u) \cap B| \geq D$ . From (1), for every set  $S \subseteq U'$ ,

$$D|S| \leq |E(G'[S, N_{G'}(S)])| \leq D(|N_{G'}(S)| + |S|)/2$$

which gives  $|S| \leq |N_{G'}(S)|$ . Thus, by Hall's theorem, there is a matching of  $U'$  in  $G'[U', B]$ . Let  $\{uv_u \mid u \in U', v_u \in B\}$  be such a matching, and let  $H := G'[U', B]$ . We have  $|U'| \leq |B|$  and there is orientation  $\vec{H}$  of the edges of  $H$  such that  $\Delta^+(\vec{H}) \leq D$ . By definition of  $\omega$ , for  $v \in B$ ,  $\omega(E(v, N^+(v))) \leq D \cdot b'(v)$ . Similarly for  $u \in U'$ ,

$$\omega(E(u, N^+(u))) \leq D \cdot b'(u) = D \cdot b(u) \leq D \cdot (b(v_u) + L) \leq D \cdot (b'(v_u) + L) \leq D(L + 1)b'(v_u)$$

because  $b \leq b'$ ,  $b$  is  $L$ -Lipschitz, and  $\text{REDUCTION}(G, b)$  does not change the values of  $b$  for vertices of degree at least  $D$ . Consequently,

$$\omega(E(H)) \leq D(L + 2) \sum_{v \in B} b'(v) = D(L + 2) \cdot x_B(E(B, V \setminus B)).$$

Let  $U'' := U \setminus U'$  and for  $1 \leq i < D$ , let  $U_i \subseteq U''$  denote the set of vertices  $u \in U''$  such that  $\deg_{G'}(u) = |N_{G'}(u) \cap B| = i$ . Let  $S_v = N_{G'}(v) \cap B$  for  $v \in U_i$ , and note that by Lemma 11 part (b) for any  $v \in U_i$  there are at most  $D$  vertices  $w \in U_i$  such that  $S_w = S_v$ . Out of these vertices  $w$  all but at most one satisfy  $b(w) = b'(w)$  and potentially there is one vertex, called special vertex,  $w$  such that  $b(w) < b'(w)$ .

Before continuing with the main line of the argument we observe that if  $w \in S_v$  for some  $v \in U_i$ , then  $b(w) = b'(w)$ . Indeed, for  $b'(w)$  to be larger than  $b(w)$ ,  $w$  would have to have at least  $D$  clones in  $G$  and  $v$  would be the neighbor of all of them. However,  $\deg_{G'}(v) = i < D$  and by Fact 10 (b),  $N_G(v) = N_{G'}(v)$  and so  $v$  cannot have  $D$  neighbors in  $B$ .

## 59:12 Distributed Approximations of $f$ -Matchings and $b$ -Matchings

We will now go back to the main line of the argument which is similar to the proof of Claim 6. Starting with  $H^* := (B, \emptyset)$ , we add edges to  $H^*$  as in the proof of Claim 6, i.e. if for  $u \in U_i$ , there are  $v, w \in N_{G'}(u) \subseteq B$  such that  $vw$  is not already in  $E(H^*)$ , then add  $vw$  to  $E(H^*)$  and remove  $u$  from  $U_i$ . We continue the process for as long as possible. After it ends,  $H^*$  satisfies  $|E(H^*)| \leq D|B|/2$  because  $\nabla_1(G) \leq D/2$ .

Let  $U'_i$  denote vertices from  $U_i$  that correspond to edges of  $H^*$  and let  $U''_i = U_i \setminus U'_i$ . As before, there is an orientation of the edges of  $H^*$  such that the maximum out-degree is at most  $D$ . If the arc  $(v_1, v_2)$  is obtained by suppressing vertex  $u$  from  $U_i$ , then we say that  $u$  belongs to  $v_1$ . Let  $W_v$  denote the set of vertices that belong to  $v$ . Then  $|W_v| \leq D$  and for every  $u \in W_v$ ,  $\omega(uv) \leq b'(v) = b(v)$  by the previous observation. Since  $b$  is  $L$ -Lipschitz, the total weight of edges incident to vertices from  $W_v$  is at most  $Di(2L+1)$  because if  $u \in W_v$  and  $uv' \in E(G')$  for some  $v' \in B$  then  $\omega(uv') \leq b'(v') = b(v') \leq b(v) + 2L \leq (2L+1)b(v) = (2L+1)b'(v)$ . Consequently, the total weight of edges incident to vertices from  $U'_i$  is at most  $Di(2L+1) \sum_{v \in B} b'(v) = Di(2L+1)x_B(E(B, V \setminus B))$ .

Now consider  $U''_i$ . By construction, for every  $u \in U''_i$ ,  $N_{H^*}(u)$  is a clique on  $i$  vertices. Since  $\nabla_0(H^*) < D/2$ , by Lemma 2, we can assign  $i$ -cliques in  $H^*$  to vertices from  $B$  so that each vertex has at most  $\binom{D}{i-1}$  cliques assigned to it. If  $K_1, \dots, K_l$  are assigned to  $v$ , then the number of vertices  $u$  in  $U''_i$  such that  $N_{H^*}(u) = K_j$  for some  $j \in \{1, \dots, l\}$  is at most  $Dl \leq D \binom{D}{i-1}$ , and the weight on edges incident to them is at most  $Di(2L+1) \binom{D}{i-1} b'(v)$ . Consequently, the weight of edges incident to vertices from  $U''_i$  is at most  $Di(2L+1) \binom{D}{i-1} \sum_{v \in B} b'(v) = Di(2L+1) \binom{D}{i-1} x_B(E(B, V \setminus B))$ . As a result, the weight of edges incident to vertices from  $U_i$  is at most  $Di(2L+1)(1 + \binom{D}{i-1})\nu_{b'}(G')$ . Summing over  $i = 1, \dots, D-1$  shows that the weight of edges of  $G'$  that are not in  $G_1$  is  $O(\nu_{b'}(G'))$ , completing the proof of (5).  $\blacktriangleleft$

As in the case of  $f$ -matchings, next algorithm uses constant  $c_{D,L}$  and so it needs to know  $L$  and  $D = 2 \cdot g(1)$ , but the clustering procedure from [1] also needs some information about  $g$ .

### ■ Procedure $b$ -MATCHING APPROXIMATION( $G, b, g, L, \epsilon$ ).

- 
- Use REDUCTION( $G, b$ ) to obtain graph  $G'$  and function  $b'$ .
  - Define the weights  $\omega$  on  $E(G')$  as in (4). Use the algorithm from [1] to find a partition of  $V(G')$  into sets  $V'_1, \dots, V'_l$  such that  $\text{diam}_{G'}(V'_i) = O_{\epsilon, L, D}(1)$  and the total weight of edges with endpoints in different sets  $V'_i$  is at most  $\epsilon \cdot c_{D,L} \omega(E(G'))$ .
  - Find an optimal solution  $x'_i$  in  $G'[V'_i]$  and let  $x' : E(G') \rightarrow \mathbb{N}$  be given by  $x'(e) := x'_i(e)$  if  $e \in E(G'[V'_i])$  and  $x'(e) := 0$  otherwise. This gives (using the formula in MODIFY) solution  $x$  in  $G$ . Return  $x$ .
- 

► **Theorem 17.** *There is a distributed algorithm which given graph  $G = (V, E)$  on  $n$  vertices,  $\epsilon > 0$  and two functions  $b$  and  $g$  such that  $\nabla_r(G) \leq g(r) = o(\log r)$ , and  $b : V' \rightarrow \mathbb{Z}^+$  is  $L$ -Lipschitz, finds a  $b$ -matching  $x$  in  $(G, b)$  such that  $\sum_{e \in E} x(e) \geq (1 - \epsilon)\nu_b(G)$ . The algorithm runs in  $O_{\epsilon, L, g}(\log^* n)$  rounds.*

**Proof.** Use  $b$ -MATCHING APPROXIMATION( $G, b, g, L, \epsilon$ ) and note that  $x'$  is a  $b'$ -matching in  $G'$ , and so  $x$  is a  $b$ -matching in  $G$ . By Lemma 11,  $\nu_{b'}(G') = \nu_b(G)$  and by Lemma 5,  $\nu_{b'}(G') \geq c_{D,L} \omega(E(G'))$ . Consequently,

$$\begin{aligned} \nu_b(G) &= \nu_{b'}(G') \leq \sum_i x'_i(E(G'[V'_i])) + \epsilon \cdot c_{D,L} \omega(E(G')) \\ &\leq \sum_{e \in E(G)} x(e) + \epsilon \nu_{b'}(G') = \sum_{e \in E(G)} x(e) + \epsilon \nu_b(G). \end{aligned}$$

REDUCTION runs in the number of rounds which depends on  $D$  only and the running time of the algorithm from [1] is  $O_{\epsilon,L,g}(\log^* n)$ . Obtaining solution  $x$  from  $x'$  requires only a constant number of steps. ◀

## Abstract

In a 2-dimensional (2D) pattern matching problem, the text is arranged as a matrix  $M[1..n, 1..n]$  and consists of  $N = n \times n$  symbols drawn from alphabet set  $\Sigma$  of size  $\sigma$ . The query consists of a  $m \times m$  square matrix  $P[1..m, 1..m]$  drawn from the same alphabet set  $\Sigma$  and the task is to find all the locations in  $M$  where  $P$  appears as a (contiguous) submatrix. The patterns can be of any size, but as long as they are square in shape data structures like suffix trees and suffix array exist [5, 8] for the task of efficient pattern matching. These are essentially 2D counterparts of classic suffix trees and arrays known for traditional 1-dimensional (1D) pattern matching. They work based on linearization of 2D suffixes which would preserve the prefix match property (i.e., every pattern match is a prefix of some suffix).

The main limitation of the suffix trees and the suffix arrays (in 1D) was their space utilization of  $O(N \log N)$  bits, where  $N$  is the size of the text. This was suboptimal compared to  $N \log \sigma$  bits of space, which is information theoretic optimal for the text. With the advent of the field of succinct/compressed data structures, it was possible to develop compressed variants of suffix trees and array based on Burrows-Wheeler Transform and LF-mapping (or  $\Phi$  function) [7, 4, 15]. These data structures indeed achieve  $O(N \log \sigma)$  bits of space or better. This gives rise to the question: analogous to 1D case, can we design a succinct or compressed index for 2D pattern matching? Can there be a 2D compressed suffix tree? Are there analogues of Burrows-Wheeler Transform or LF-mapping? The problem has been acknowledged for over a decade now and there have been a few attempts at applying  $\Phi$  function [1] and achieving entropy based compression [10]. However, achieving the complexity breakthrough akin to 1D case has yet to be found.

In this paper, we still do not know how to answer suffix array queries in  $O(N \log \sigma)$  bits of space - which would have led to efficient pattern matching. However, for the first time, we show an interesting result that it is indeed possible to compute inverse suffix array (ISA) queries in near compact space in  $O(\text{polylog} n)$  time. Our 2D succinct text index design is based on two 1D compressed suffix trees and it takes  $O(N \log \log N + N \log \sigma)$  bits of space which is much smaller than its naive design that takes  $O(N \log N)$  bits.

Although the main problem is still evasive, this index gives a hope on the existence of a full 2D succinct index with all functionalities similar to that of 1D case.

## 1 Introduction

In the classical pattern matching problem we are given a text  $T[1..n]$  over an alphabet  $\Sigma$ , which is a finite totally ordered set of size  $\sigma$  and a pattern  $P[1..m]$  drawn from the same alphabet set. The task is to find locations of all occurrences of pattern  $P$  in  $T$ . This has been a classic field of research since last 50 years and many algorithms were developed to achieve this task in optimal time complexity of  $O(n + m)$  [9]. In data structural sense, the problem becomes to index the text so that patterns can be taken as queries. Data structures like suffix trees were proposed for this task which took optimal  $O(n)$  (words of) space and optimal

$O(m)$  time for the query. It was seen that even though taking theoretically optimal space, the space utilization of suffix trees often times could be 50 times the size of original text data. Space saving structures like suffix arrays were introduced which showed substantial space savings at the cost of slightly worse query times. However, when measured in bits, these still take  $O(n \log n)$  bits as against the information theoretic optimal of  $O(n \log \sigma)$  bits. FM-Index [4] and compressed suffix array (CSA) [7] were the first to achieve this goal. Introduction of the compressed suffix tree (CST) ensured full-functionalities of suffix trees simulated in compressed space of  $O(n \log \sigma)$  bits (or even lower in entropy compressed sense) [15]. This led to the field of compressed text indexing which has seen a myriad of results in last two decades with many positive developments [13].

There are other variants of text-indexing problems where suffix trees and suffix arrays exist but their compressed counterparts have yet to be found. One of the problems which has proven to be hard in this context is the problem of 2D pattern matching.

In the 2D pattern matching problem, the text is arranged as a matrix  $M[1..n, 1..n]$  and consists of  $N = n \times n$  symbols drawn from the alphabet  $\Sigma$  of size  $\sigma$ . The query consists of  $m \times m$  square matrix  $P[1..m, 1..m]$  drawn from the same alphabet set  $\Sigma$  and the task is to find all the locations in  $M$  where  $P$  appears as a (contiguous) submatrix. The patterns can be of any size, but as long as they are square in shape the data structures like suffix trees and suffix array exist [5, 8]. The suffix starting from any location  $M[i, j]$  is the largest square matrix which fits within  $M$  and whose top-left corner is  $M[i, j]$ . The suffixes can be linearized [5] and indexed using a trie akin to the 1D suffix tree. The problem of designing an index for 2D pattern matching in compact  $O(N \log \sigma)$  space (based on suffix trees/arrays BWT or otherwise) has been long open. There were some attempts and partial results [1, 10] but they mainly focused on entropy compression, without first addressing the more fundamental problem of achieving the optimal space complexity (compact space). This gives rise to some fundamental questions: analogous to 1D case, can we design a succinct or compressed index for 2D pattern matching? Can there be a compressed suffix tree?

However, achieving the complexity breakthrough similar to 1D case has yet to be found, in this paper, we present a text index that can answer inverse suffix array (ISA) queries in near compact space in  $O(\text{polylog}(n))$  time. We show this by introducing a novel technique named LFISA-mapping that is an analogue of LF-mapping operation typically associated with Burrows–Wheeler Transform. This technique works with *linearization* scheme of Reference [5]. Our 2D succinct text index design is based on two 1D compressed suffix trees, and it takes  $O(N \log \log N + N \log \sigma)$  bits of space as compared to previous non-compact space of  $O(N \log N)$  bits.

## 2 Preliminaries

First, we show an overview of the classical pattern matching problem and its associated terminology. Next, we extend the same for the 2D pattern matching problem, where we provide additional definitions associated with the problem.

### 2.1 Classical Pattern Matching Problem

Let  $S = \{T[i..n] | 1 \leq i \leq n\}$  be the set of all the suffixes of  $T$ . The *suffix tree* (denoted by  $ST$ ) of  $T$  is an edge-labeled compact trie constructed from all the suffixes in  $S$  [12, 16, 3, 17]. In the suffix tree, concatenating all the edge labels on a particular root-to-leaf path, we get one of the suffixes in  $S$ . In other words, each leaf of  $ST$  corresponds to a suffix of  $T$ . Additionally, as each suffix  $T[i..n]$  in  $S$  is uniquely identified with its starting position  $i$  in  $T$ , we can map

text positions to leaves of ST. Upon traversal of the leaves from left-to-right, we get suffixes sorted lexicographically, and storing the corresponding text positions in an array gives an indexing data structure called *suffix array* (SA) [11]. Here by  $i = \text{SA}[r]$ , we mean that the leaf with its corresponding text position  $i$  is the  $r^{\text{th}}$  leftmost leaf ( $\ell_r$ ) in ST. In other words,  $r$  is the lexicographical order or *rank* of the suffix  $T[i..n]$ . Similarly, the *inverse suffix array* (ISA) is defined as  $\text{ISA}[i] = \text{SA}^{-1}[i] = r$ . In other words, the inverse suffix array maps each text position  $i$  to the leaf position  $r$  in ST.

The LF-mapping is the relation between the leaves  $\ell_r$  and  $\ell_{r'}$  ( $\text{LF}(r) = r'$ ) such that their corresponding text positions are  $i$  and  $i - 1$  respectively. Formally, LF-mapping is defined in terms of the suffix array as  $\text{LF}(r) = \text{SA}^{-1}[\text{SA}[r] - 1]$ . But the index such as the FM-index efficiently computes the LF-mapping using the *Burrows Wheeler Transform* (BWT) [2] of the original text along with some auxiliary counting data structures. This computation lies at the heart of BWT based text indexes that enables them to answer pattern matching queries without actually storing the costly suffix array and instead replacing it with a *sampled suffix array*.

On the contrary, just storing a CSA in itself does not provide all the required functionalities that a full CST provide. Therefore, a CST with full functionalities is needed and is realised using three components: 1) its underlying CSA 2) the *compressed tree topology* that provides navigational operations where each operation takes  $O(1)$  time and 3) some auxiliary data structures providing the *longest common prefix* (LCP) information. Moreover, the full list of operations supported by CST is given in the Appendix. Out of which one of the most important operations is to answer inverse suffix array queries i.e. given CSA, an ISA entry can be decoded in  $O(\log^\epsilon N)$  time for some constant  $\epsilon > 0$ . Now in the ensuing subsection, we formally go over the 2D pattern matching problem and associated terminology.

## 2.2 2D Pattern Matching Problem

Let  $M$  be a square matrix of dimension  $N = n \times n$  where every element  $M[i, j]$  is taken from an alphabet  $\Sigma$  which is a finite totally ordered set of size  $\sigma$ . The query consists of a square pattern  $P[1..m, 1..m]$  also drawn from  $\Sigma$  and the goal is to find all the occurrences of  $P$  in  $M$ .

In a 1D text, an  $i^{\text{th}}$  suffix is the largest substring of the text starting from the  $i^{\text{th}}$  position i.e.  $T[i..n]$ . Similarly, this way of defining a *suffix* can be extended to 2D suffixes of a matrix. A 2D suffix  $S_{i,j}^{2D}$  defined for a position  $(i, j)$  is the largest square submatrix of  $M$  starting at  $(i, j)$  position i.e.  $M[i..i+l, j..j+l]$ , where  $l = n - \max(i, j)$ . Giancarlo [6] proposed a way of *linearization* of 2D suffixes such that they follow the constraints of *completeness* and *common prefix property* similar to 1D suffixes. The *completeness* constraint is that every square submatrix of  $M$  in the linear form must correspond to some *prefix* (whatever the definition of *prefix* is) of some suffix of  $M$  each represented linearly. The *common prefix constraint* is that a square submatrix of  $M$  should be a *prefix* of some suffixes of  $M$  after linearizing them. Giancarlo proposed *Lsuffix* which is a linear representation of a 2D suffix. Here  $L$  stands for *linear*. An *Lsuffix*  $S_{i,j}^L$  of a 2D suffix  $S_{i,j}^{2D}$  is the concatenation of strings  $a_0, a_1, a_2, \dots, a_l$  where  $a_0 = M[i, j]$  and  $a_k = M[i+k, j..j+k-1] \cdot M[i..i+k, j+k]$  which is of length  $2k+1$  and  $l = n - \max(i, j)$  for  $k \neq 0$  (see Figure 1 for example). Here  $\alpha \cdot \beta$  refers to the concatenation of the strings  $\alpha$  and  $\beta$ .

Let  $S^L$  be the set of all such *Lsuffixes* of  $M$ . Here  $|S^L| = N$  as there are total  $N$  suffixes. Let  $\text{ST}^L$  be the compact trie (suffix tree) constructed from *Lsuffixes* in  $S^L$  (also known as *Lsuffix tree*). The uncompressed version of  $\text{ST}^L$  [5] takes  $\Theta(N \log N)$  bits of space which is very large compared to the optimal space required to store the original matrix  $M$  i.e.  $N \lceil \log \sigma \rceil$ . Similarly, the uncompressed version of suffix array ( $\text{SA}^L$ ) [8] for such suffixes also

**Figure 1** Lsuffixes and LF-mapping. a) *Splitting of an Lsuffix*: The characters inside the circle are a part of the horizontal suffix  $S_{i-1, j-1}^H = abcde\dots$  and it resides on the horizontal suffix tree. Similarly, The characters inside the triangle are a part of the vertical suffix  $S_{i, j-1}^V = fkpu\dots$  and this suffix resides on the vertical suffix tree. Additionally, the linear form of the 2D suffix starting from the position  $(i, j)$  is formed by the characters inside the rectangle i.e.  $S_{i, j}^L = g \cdot l \cdot hm \cdot qr \cdot ins \cdot vwx \cdot joty$  and it resides on the Lsuffix tree (the biggest tree on the right). Here  $\alpha \cdot \beta$  denotes concatenation of strings  $\alpha$  and  $\beta$ . Now the Lsuffix starting at the position  $(i-1, j-1)$  is formed by characters of these three sequences i.e.  $S_{i-1, j-2}^L = a \cdot f \cdot bg \cdot kl \cdot chm \cdot pqr \cdot dins \cdot vwx \cdot ejoty$  b) *LF-mapping*: LF-mapping takes from the leaf corresponding to the Lsuffix starting at position  $(i, j)$  to that of Lsuffix starting at position  $(i-1, j-1)$ . A lot of new characters are introduced in doing so. Therefore, the LF-mapping operation in case of 2D pattern matching problem is not trivial to evaluate.

requires  $\Theta(N \log N)$  bits of space. The suffix array and inverse suffix array is defined in a similar fashion as defined in the linear case. For suffix array, given the rank  $r$ , it outputs the position in the matrix of the corresponding Lsuffix  $S_{i, j}^L$  i.e.  $SA^L[r] = (i, j)$ . Furthermore, inverse suffix array is defined as  $ISA^L[i, j] = r$ . Additionally, we introduce the LF-mapping with respect to the 2D case (LF<sup>L</sup>-mapping) and we define it as follows,

$$LF^L(r) = ISA^L[i-1, j-1], \text{ where } SA^L[r] = (i, j)$$

Here,  $ISA^L[0, j'] = ISA^L[i', 0] = \emptyset$ . In other words, LF<sup>L</sup>-mapping operation outputs the rank of the Lsuffix  $S_{i-1, j-1}^L$  given the rank of Lsuffix  $S_{i, j}^L$  (i.e. it goes diagonally above). Figure 1 shows an example of a particular LF-mapping operation and how new characters get introduced when going from Lsuffix  $S_{i, j}^L$  to  $S_{i-1, j-1}^L$  in contrast to the addition of only one character (in front) in the case of 1D suffixes i.e. going from  $T[i..n]$  to  $T[i-1..n]$ . This is the reason why it is not trivial to evaluate LF-mapping for the 2D case.

As the LF<sup>L</sup>-mapping is related to the SA<sup>L</sup>, we introduce a similar mapping for ISA which we call *LF-mapping for ISA* (LFISA<sup>L</sup>). We define it as,

$$LFISA^L(i, j) = ISA^L[i-1, j-1]$$

Here, for computational purposes, we provide  $ISA^L[i, j]$  as an additional parameter. The pseudocode for computing  $LFISA^L(i, j, ISA^L[i, j])$  is given in Section 7. In other words, given the position and the rank of the Lsuffix  $S_{i, j}^L$ , LFISA<sup>L</sup>-mapping outputs the rank of the Lsuffix  $S_{i-1, j-1}^L$  (diagonally above). Now, in order to compute the value of any ISA<sup>L</sup> entry, as storing the entire ISA<sup>L</sup> takes much space, we sample it and store only those  $ISA^L[i, j]$  values such that  $i = 1 + (k-1)\Delta$  where  $k = \{1, 2, \dots, \lceil \frac{\sqrt{N}}{\Delta} \rceil\}$ . This reduces the problem of computing an ISA<sup>L</sup> value to computing at most  $\Delta$  LFISA<sup>L</sup>-mapping operations. Now, in the latter sections,

we show how to compute LFISA<sup>L</sup>-mapping in  $t_{\text{LFISA}} = O((\log N / \log \log N)^3)$  time using our  $O(N \log \sigma + N \log \log N)$ -bit index. Therefore, ISA<sup>L</sup> value for any position in the matrix can be calculated in  $t_{\text{ISA}} = \Delta \cdot t_{\text{LFISA}} = O(\log N \cdot t_{\text{LFISA}})$  time as we take  $\Delta = O(\log N)$  for our case.

Till now, succinct versions of 2D text indexes have been evasive because the intuition behind the pattern matching in 1D case does not extend directly to the 2D case due to the non trivial nature of 2D LF-mapping. However, this does not restrict us from asking the fundamental question as to whether it is possible to design a compact text index for matrices. In this paper, we propose the design of a text index that can atleast answer inverse suffix array queries in near compact space using LFISA<sup>L</sup>-mapping. Although, a solution to the main question evades us, this is a ray of hope. Now, the following theorem states the objective of the paper more formally as,

► **Theorem 1.** *The text index for matrix  $M$  of size  $N = n \times n$  can be encoded in  $O(N \log \sigma + N \log \log N)$ -bit space and any entry in the inverse suffix array ISA<sup>L</sup> can be decoded in time  $O(\log N \cdot t_{\text{LFISA}})$  where  $t_{\text{LFISA}} = O((\log N / \log \log N)^3)$*

**Proof.** See Sections 8.1 and 8.2 for the proof. ◀

**Our approach.** The intuition here is that we split the Lsuffix for which we need the ISA value into three subsequences, and thereby solve the problem for each subsequence to eventually solve for the main Lsuffix. We discuss this splitting in detail in the later section. But in order to understand this dividing strategy, first we define what we call *horizontal* and *vertical suffixes* (or in short Hsuffix and Vsuffix respectively) and also how they relate to Lsuffixes.

### 3 Horizontal and Vertical Suffixes

Firstly, given a matrix  $M$ , we linearize it horizontally by concatenating all the rows of  $M$  one after another to get a single 1D text  $T^H$  of length  $N$ . The set of all the suffixes of  $T^H$  is defined as  $S^H = \{T^H[i..N] | 1 \leq i \leq N\}$ . We denote such suffixes as horizontal or Hsuffixes. Let  $ST^H$  be the compressed suffix tree obtained from all the Hsuffixes of text  $T^H$ . Secondly, by concatenating all the columns into a single text  $T^V$  we linearize  $M$  vertically. The set of all the suffixes of  $T^V$  is defined as  $S^V = \{T^V[i..N] | 1 \leq i \leq N\}$ . Such suffixes are denoted as vertical or Vsuffixes. Here, let  $ST^V$  be the compressed suffix tree constructed from such Vsuffixes of  $T^V$ . From the context of  $M$ , Hsuffix and Vsuffix starting from  $M[i, j]$  are written as

$$S_{i,j}^H = M[i, j..n] \cdot M[i + 1, 1..n] \cdot M[i + 2, 1..n] \cdot \dots \cdot M[n, 1..n]$$

$$S_{i,j}^V = M[i..n, j] \cdot M[1..n, j + 1] \cdot M[1..n, j + 2] \cdot \dots \cdot M[1..n, n]$$

Finally, as  $ST^H$  and  $ST^V$  are the compact versions of the original suffix trees, they only occupy  $O(N \log \sigma)$  bits of space which is very close to the space required by the original matrix [15]. Their full functionalities are provided in the Appendix. Next, we relate all these defined suffixes.

### 4 Splitting of an Lsuffix

In this section, we show how to split an Lsuffix into three different subsequences. Given an Lsuffix  $S_{i,j}^L$  in the 2D form, we can split it into three subsequences: 1) The horizontal subsequence (i.e. the first row  $M[i, j..n]$ ), 2) The vertical subsequence (i.e. the first column  $M[i + 1..n, j]$ ) and 3) The subsequence (linear form) of the remaining square submatrix

i.e.  $S_{i+1,j+1}^L$ . An example of such a splitting is provided in Figure 1. Here,  $M[i, j..n]$  and  $M[i+1..n, j]$  subsequences come from the Hsuffix  $S_{i,j}^H$  and Vsuffix  $S_{i+1,j}^V$  respectively. Let us denote  $h_k$  and  $v_k$  as the  $(k+1)^{th}$  characters of  $M[i, j..n]$  and  $M[i+1..n, j]$  respectively. Now, as mentioned before an Lsuffix  $S_{i,j}^L$  is the concatenation of strings  $a_0, a_1, a_2, \dots, a_l$  where  $a_0 = M[i, j]$  and  $a_k = M[i+k, j..j+k-1] \cdot M[i..i+k, j+k]$  which is of length  $2k+1$  and  $l = n - \max(i, j)$  for  $k \neq 0$ . Similarly, let  $S_{i+1,j+1}^L$  be the concatenation of strings  $b_0, b_1, b_2, \dots, b_{l-1}$  where  $b_0 = M[i+1, j+1]$  and  $b_k = M[(i+1)+k, (j+1)..(j+1)+k-1]M[(i+1)..(i+1)+k, (j+1)+k]$  when  $k \neq 0$ . For simplicity we break each  $a_k$  and  $b_k$  into two parts as follows,

$$\begin{aligned} a'_k &= M[i+k, j..j+k-1] \\ a''_k &= M[i..i+k, j+k] \\ b'_k &= M[(i+1)+k, (j+1)..(j+1)+k-1] \\ b''_k &= M[(i+1)..(i+1)+k, (j+1)+k] \end{aligned}$$

We can write  $a_k$  in terms of  $h_k$  and  $v_k$   $b_k$  as follows,

$$\begin{aligned} a'_k &= M[i+k, j..j+k-1] = v_{k-1}b'_{k-1} \\ a''_k &= M[i..i+k, j+k] = h_k b''_{k-1} \end{aligned}$$

Therefore, we can say that  $a_k$  is the concatenation of strings  $v_{k-1}, b'_{k-1}, h_k, b''_{k-1}$  where  $b'_0 = \emptyset$  and  $b''_0 = b_0$  and  $a_0 = h_0$  as  $h_0 = M[i, j]$ . We want to redirect the reader's attention to Figure 1 where we showcase an example that helps in better understanding of the above concept.

Now, given  $a_k$  we can get  $v_{k-1}, b'_{k-1}, h_k, b''_{k-1}$  as  $v_{k-1}$  and  $h_k$  are characters and  $b'_{k-1}$  and  $b''_{k-1}$  are the strings of length  $k-2$  and  $k-1$  respectively. Here  $v_{k-1}$  and  $h_k$  can be thought of as delimiters of the string  $a_k$  and these two uniquely breaks down  $a_k$  into its constituents. Now since we know that given  $a_k$  we can get  $v_{k-1}, b'_{k-1}, h_k, b''_{k-1}$  and vice versa, we denote the *horizontal component* of the entire Lsuffix  $S_{i,j}^L$  by  $hc(S_{i,j}^L) = h_0 h_1 h_2 \dots h_l$ . Similarly, we denote the *vertical component* by  $vc(S_{i,j}^L) = v_0 v_1 v_2 \dots v_{l-1}$  and the *square component* by  $sc(S_{i,j}^L) = b_0 b_1 b_2 \dots b_{l-1}$ . Likewise, we can define the same for any prefix  $pf$  of the Lsuffix  $S_{i,j}^L$ . We can state the following fact about the relation between the length of the three components of the prefix  $pf$  of  $S_{i,j}^L$  and its length. Here, by length, we mean the length of the string.

► **Fact 2.**  $\text{length}(pf) = \text{length}(hc(pf)) + \text{length}(vc(pf)) + \text{length}(sc(pf))$

Now, intuitively we use such a splitting to evaluate a single LFISA-mapping operation. Next, we go over some of the basic terminologies of a suffix tree that will be needed in understanding the construction stage of our text index.

## 5 Terminology of a Suffix Tree (ST)

A suffix tree is an edge-labelled compact trie. We call any character on the edge of the suffix tree be represented as a *point*. Given any point  $c$  on the ST,  $\text{string}(c)$  represents the concatenation of all the characters from root to that point (including  $c$ ) along the root to  $c$  path of ST. The string depth of a point  $c$  on a path of ST is given by the length of  $\text{string}(c)$  i.e.  $\text{depth}(c) = \text{length}(\text{string}(c))$ . A node of the ST is also a point as that node is represented by the character just above it. The locus  $u$  of a point  $c$  is the highest node of ST such that  $\text{string}(c)$  is the prefix of  $\text{string}(u)$  (lets denote it as  $u = \text{locus}(c)$ ). Now, we define whether

a point  $c$  is marked or not as  $\text{marked}(c) = 1$  or  $0$  respectively. The leftmost and rightmost leaves in the subtree of a particular point  $c$  are given as  $\text{lleaf}(c)$  and  $\text{rleaf}(c)$  respectively. Here  $\text{lleaf}(c)$  and  $\text{rleaf}(c)$  give the leaf rank from left in  $\text{ST}$ . In general, we denote  $r^{\text{th}}$  leftmost leaf of  $\text{ST}$  as  $\ell_r$ . Let  $\text{lca}(c_1, c_2)$  be the *lowest common ancestor* of points  $c_1$  and  $c_2$ . The lowest common ancestor as the name suggests is the common ancestor node of two points and is the farthest from the root.

## 6 Computing LFISA-mapping in time $O((\log N / \log \log N)^3)$ using Compact Space

Just to recall, we have three suffix trees based on three different types of suffix definitions as shown before, i.e.  $\text{ST}^{\text{L}}$ ,  $\text{ST}^{\text{H}}$  and  $\text{ST}^{\text{V}}$ . Here, we store  $\text{ST}^{\text{H}}$  and  $\text{ST}^{\text{V}}$  as compressed suffix trees (CST) [15] with full functionalities (See Theorem 10 and 11 in Appendix) and they together occupy only  $O(N \log \sigma) + O(N \log \sigma) = O(N \log \sigma)$  bits of space. On the contrary, we won't be storing the entire  $\text{ST}^{\text{L}}$  but only the compressed topology of the tree that has navigational functionalities each supported in constant time and occupies  $4N + o(N)$  bits of space (See Theorem 10 in Appendix). In the ensuing subsection, firstly we show a scheme of marking some relevant points on these trees (construction stage) and then explain how this will help in computing LFISA-mapping.

### 6.1 Marking Scheme and Mapping

Firstly, we mark some nodes on Lsuffix tree  $\text{ST}^{\text{L}}$ . We mark a node  $v_i^{\text{L}}$  of  $\text{ST}^{\text{L}}$  such that  $v_i^{\text{L}} = \text{lca}(\ell_{(i-1)g+1}, \ell_{ig})$ , where  $i = \{1, 2, \dots, \lceil \frac{N}{g} \rceil\}$  and  $g$  is the *grouping factor*. Furthermore, we define  $G_i = [(i-1)g+1, ig]$  as the *grouping interval*. For our case, we shall use  $g = \lceil \log^3 N \rceil$ . Hence, the total number of marked nodes on  $\text{ST}^{\text{L}}$  is bounded by  $O(\frac{N}{\log^3 N})$ . Now, we define *marked ancestor*, *lowest marked ancestor*, *cover* of a leaf and *coveredby*( $v^{\text{L}}$ ) set of a marked node as follows:

► **Definition 3** (Marked Ancestor). *A marked node  $v^{\text{L}}$  is the marked ancestor of a leaf  $\ell$  if  $v^{\text{L}}$  lies on the path from root to leaf  $\ell$  in the suffix tree.*

► **Definition 4** (Lowest Marked Ancestor). *A node  $v^{\text{L}}$  is the lowest marked ancestor of the leaf  $\ell$  if it is the lowest (one with the maximum string depth) among all the marked ancestors of  $\ell$ .*

► **Definition 5** (Cover). *A node  $v^{\text{L}}$  is the cover of the leaf  $\ell$  if it is the lowest marked ancestor of  $\ell$ .*

► **Definition 6** (coveredby( $v^{\text{L}}$ ) set). *A coveredby( $v^{\text{L}}$ ) set is the set of the leaves for which  $v^{\text{L}}$  is the cover.*

As mentioned before in Section 4 showcasing the splitting of an Lsuffix, given a marked node  $v^{\text{L}}$ , its associated string i.e.  $\text{string}(v^{\text{L}})$  can be split into its horizontal, vertical and square components i.e.  $\text{hc}(\text{string}(v^{\text{L}}))$ ,  $\text{vc}(\text{string}(v^{\text{L}}))$  and  $\text{sc}(\text{string}(v^{\text{L}}))$  respectively. For a marked node  $v^{\text{L}}$  in  $\text{ST}^{\text{L}}$ , we mark a point  $p^{\text{H}}$  in  $\text{ST}^{\text{H}}$  corresponding to its horizontal component such that  $\text{string}(p^{\text{H}}) = \text{hc}(\text{string}(v^{\text{L}}))$ . Similarly, we mark points  $p^{\text{V}}$  and  $p^{\text{L}}$  corresponding to its vertical and square components in  $\text{ST}^{\text{V}}$  and  $\text{ST}^{\text{L}}$  respectively. We call them the *shadow* points. Just to recall, a point is any character on the edge of the suffix tree. Note that  $v^{\text{L}}$  is not the same marked node as  $p^{\text{L}}$  even though they are marked on the same tree (see Figure 2). We repeat the above process for every marked node on  $v^{\text{L}}$  in  $\text{ST}^{\text{L}}$ .

At the end of the marking process, let  $MP^H$ ,  $MP^V$  and  $MP^L$  be the sets of all the shadow points on  $ST^H$ ,  $ST^V$  and  $ST^L$  respectively. Hence, a marked node  $v^L$  in  $ST^L$  can be viewed as a unique triplet of shadow points in  $ST^H$ ,  $ST^V$  and  $ST^L$  i.e.  $v^L = (p^H, p^V, p^L)$ . Therefore, the total number of shadow points in each tree is bounded. Formally, we have  $|MP^H|$ ,  $|MP^V|$  and  $|MP^L|$  as bounded by  $O(\frac{N}{\log^3 N})$ , where  $|X|$  is the cardinality of the set  $X$ . Due to this one-to-one correspondence between a marked node and the triplet of shadow points, we define a set  $U \subseteq MP^H \times MP^V \times MP^L$  which consists of only those triplets of shadow points which come from the marked nodes.

Now, we state our central task as follows,

Given  $ISA^L[i, j]$ , compute  $ISA^L[i - 1, j - 1]$ .

We shall preprocess the text and construct data structures that will take near compact space and achieve this task in  $O(\text{polylog}N)$  time. The main step in this is computing  $LFISA^L(i, j, ISA^L[i, j])$ . In the following subsection, we show the details on how to achieve this, and thereafter we outline the pseudocode for the same as  $LFISA^L(i, j, ISA^L(i, j))$  in the subsection 6.2.3.

## 6.2 Computing $LFISA^L(\cdot)$

In the section, we show the details for the evaluation of  $LFISA^L(i, j, ISA^L[i, j])$  given the matrix position  $(i, j)$  and  $ISA^L[i, j]$ . Firstly, using the  $\text{inverse}(\cdot)$  function of  $ST^H$  and  $ST^V$  (See Theorem 10 in Appendix), we evaluate the inverse suffix array values  $ISA^H[i - 1, j - 1]$  and  $ISA^V[i, j - 1]$  respectively. For simplicity, let  $ISA^L[i, j] = r$ ,  $ISA^H[i - 1, j - 1] = h$ ,  $ISA^V[i, j - 1] = v$ ,  $ISA^L[i - 1, j - 1] = LFISA^L(i, j, ISA^L[i, j]) = s$ .

As inverse suffix array values are related to the leaves of the suffix tree, let  $\ell_h$ ,  $\ell_v$  and  $\ell_r$  be  $h^{th}$ ,  $v^{th}$  and  $r^{th}$  leftmost leaves in their respective suffix trees. The aim here is to find the leaf  $\ell_s$  in  $ST^L$  using the information provided by the shadow points of our index along the root-to-leaf paths of  $\ell_h$ ,  $\ell_v$  and  $\ell_r$  in  $t_{LFISA}$  time. We shall use some auxiliary data structures that we introduce in the latter subsections.

Given  $(h, v, r)$ , we define a set as  $A = \{(p^H, p^V, p^L) \in U \mid \ell_h, \ell_v \text{ and } \ell_r \text{ lie in the respective subtrees of } p^H, p^V \text{ and } p^L\}$ . To put it another way,  $A$  is a set of valid triplets of shadow points that lie on the root-to-leaf paths of  $\ell_h$ ,  $\ell_v$  and  $\ell_r$  in their respective trees. Out of all the valid triplets that are in  $A$ , let a specific triplet or its corresponding marked node  $v_{max}^L$  be defined as follows,

$$v_{max}^L = \underset{v^L = (p^H, p^V, p^L) \in A}{\text{argmax}} (\text{depth}(\text{string}(v^L))).$$

Recall that there is a one-to-one correspondence between the marked nodes in  $ST^L$  and triplets in  $U$ .

Lemma 7 proves that the marked node  $v_{max}^L$  is the *lowest marked ancestor (or cover)* of the leaf  $\ell_s$ . Therefore, the marked node  $v_{max}^L$  along with some augmenting information shown in later subsection, will lead us to the leaf  $\ell_s$  which is what we are interested in as. Hence, we call the above query as *lowest marked ancestor query*.

► **Lemma 7.** *The marked node  $v_{max}^L$  in  $ST^L$  is the lowest marked ancestor (or cover) of the leaf  $\ell_s$ .*

**Proof.** Firstly, we prove that any valid triplet  $v^L = (p^H, p^V, p^L) \in A$  is the marked ancestor of the leaf  $\ell_s$ . As  $p^H$  is the shadow point on the root-to-leaf path of  $\ell_h$ ,  $\text{string}(p^H)$  is the prefix of the horizontal suffix  $S_{i-1, j-1}^H$  as we have  $\text{ISA}^H[i-1, j-1] = h$ . Similarly,  $\text{string}(p^V)$  and  $\text{string}(p^L)$  are the prefixes of the vertical suffix  $S_{i, j-1}^V$  and  $\text{Lsuffix } S_{i, j}^L$  respectively.

Furthermore, as the  $\text{string}(p^H)$ ,  $\text{string}(p^V)$  and  $\text{string}(p^L)$  are the horizontal, vertical and square components of the  $\text{string}(v^L)$  respectively (as per the marking scheme), one of the occurrences of  $\text{string}(v^L)$  in its 2D form is at matrix position  $(i-1, j-1)$ . Therefore, it is a prefix of the suffix starting at the position  $(i-1, j-1)$  which in its linear form is represented as  $S_{i-1, j-1}^L$ . Therefore, the triplet node  $v^L$  lies on the root-to-leaf path of the leaf representing the  $\text{Lsuffix } S_{i-1, j-1}^L$  and that leaf is  $\ell_s$ . Hence,  $v^L$  is a *marked ancestor* of  $\ell_s$ . The same is true for  $\forall v^L \in A$ .

Moreover, as  $v_{max}^L \in A$  and is the output of the lowest marked ancestor query that maximizes over string depth over all triplets  $v^L \in A$ , it is the *lowest marked ancestor or cover* of  $\ell_s$ . ◀

Now as we are interested in obtaining cover  $v_{max}^L$ , we reduce the above lowest marked ancestor query to a *stabbing-max* query. This reduction is interesting and useful in our context due to the result mentioned in Theorem 8. The details concerning this reduction is discussed in the next subsection. Furthermore, after finding the cover  $v_{max}^L$ , in order to uniquely go to the correct leaf  $\ell_s$  we store additional augmenting information [discussed in latter subsection]. This shows the computation of an  $\text{LFISA}^L$  operation. The time or query complexity of such an operation is discussed in the Section 7.

### 6.2.1 Reduction to 3-dimensional (3D) Stabbing-Max Query

In this section, we show how to reduce that the aforementioned lowest marked ancestor query to a *3D stabbing-max* query. In [14], the authors proves the following theorem,

► **Theorem 8** ([14]). *Given a set  $I$  of  $n$  3D rectangles in  $\mathbb{R}^3$ , where each rectangle  $rec$  has a weight  $w(rec)$  associated to it, finding a rectangle with maximum weight containing (or stabbed by) the 3D query point  $q$  can be done in  $O((\frac{\log n}{\log \log n})^3)$  time using a data structure occupying  $O(n(\frac{\log n}{\log \log n})^2)$  space.*

We define the sides of the 3D rectangle  $rec$  for each marked node  $v^L = (p^H, p^V, p^L)$  in  $U$  as follows:

$$\begin{aligned} (x_{left}, x_{right}) &= (\text{lleaf}(p^H), \text{rleaf}(p^H)) \\ (y_{up}, y_{down}) &= (\text{lleaf}(p^V), \text{rleaf}(p^V)) \\ (z_{front}, z_{back}) &= (\text{lleaf}(p^L), \text{rleaf}(p^L)) \\ w(rec) &= \text{depth}(\text{string}(v^L)) \end{aligned}$$

This shows that each triplet in  $U$  or its corresponding marked node  $v^L$  in  $\text{ST}^L$  is uniquely represented as a weighted rectangle.

Next, we define the 3D query point as  $q = (h, v, r)$ . Therefore, the output of this 3D stabbing-max query is the rectangle with maximum weight i.e. the rectangle corresponding to the cover of the leaf  $\ell_s$  ( $v_{max}^L$ ). Furthermore, after obtaining the cover of the leaf, we shall provide details on what augmenting information to store in order to get the desired leaf uniquely, i.e.  $\ell_s$  in the next subsection.

■ **Figure 2** For a particular marked node  $v^L$  in  $ST^L$  (shown in red color), the array `INLEFT` corresponding to  $v^L$  stores the start of its associated intervals. Likewise, the array `INLEN` stores the length of such intervals and the array `PSLEN` is the prefix-sum array of `INLEN`. The points  $(p^L, p^H, p^V)$  are the shadow points of  $v^L$  (shown as X in the figure shown on the right side).

### 6.2.2 Augmenting Information for getting $\ell_s$ from its Cover

In this section, we explain the procedure of obtaining the correct leaf  $\ell_s$  from its cover  $v^L$  by storing the leaf's rank  $q$  (say). Here, we define the task for this section as: Given  $q$  and  $v^L$ , find the  $q^{th}$  leftmost leaf in `coveredby`( $v^L$ ) (See Definition 6 of `coveredby`( $v^L$ )).

Now the challenge lies due to the fact that  $v^L$  may have multiple marked nodes in its subtree and due to that there may be leaves in its subtree whose lowest marked ancestor or cover is not  $v^L$ . Therefore, the set of leaves for which  $v^L$  is the cover i.e. `coveredby`( $v^L$ ) can be represented as a set of contiguous intervals. Let us denote it as  $CI = \{I_1, I_2, \dots, I_k\}$ . Here,  $I_i = [a_i, b_i]$  where  $i \in \{1, 2, \dots, k\}$  and all the leaves between  $\ell_{a_i}$  and  $\ell_{b_i}$  belongs to `coveredby`( $v^L$ ). Here  $CI$  denotes covered intervals.

Lemma 9 proves that the total number of such intervals is bounded by  $O(\sigma)$ , i.e.  $k = O(\sigma)$ . Additionally, it establishes that the total number of leaves for which  $v^L$  is the cover is bounded by  $\sum_{a=1}^k |I_a| = O(k \log^3 N) = O(\sigma \log^3 N)$  where  $|I|$  is the length of the interval  $I$ . Furthermore, as there is a one-to-one correspondence between each marked node and a rectangle as shown before, we store the augmenting information for each rectangle rather than storing it explicitly for the marked node. Let the rectangle associated with  $v^L$  be denoted as  $rec$ . Therefore, let  $CI_{rec} = CI$ .

► **Lemma 9.** *The total number of intervals in  $CI_{rec}$  is bounded by  $O(\sigma)$  and the total number of leaves for which any marked node (here  $v^L$ ) is the cover is bounded by  $O(\sigma \log^3 N)$ .*

**Proof.** Let  $c^L$  be one of the child nodes of  $v^L$ . Assume that  $lleaf(c^L)$  and  $rleaf(c^L)$  lie inside the intervals  $I_i$  and  $I_j$  respectively. First, we prove that  $I_i$  and  $I_j$  are consecutive intervals.

Suppose there is an interval  $I_k$  between  $I_i$  and  $I_j$ . This means that  $I_k$  is entirely contained inside the subtree of  $c^L$ . In other words, there is an interval of leaves  $I_k$  completely inside the subtree of  $c^L$  for which  $v^L$  is the cover. This implies that there is at least one grouping interval of leaves completely contained inside the subtree of  $c^L$  for which  $v^L$  is the lowest common ancestor (lca) of its leftmost and rightmost leaves (See marking scheme for details). But this is not possible as for  $v^L$  to be the lca, the leftmost and rightmost leaves of that grouping interval should exist on two separate downward branches of  $v^L$ . This is the contradiction. Therefore, this means that there is no grouping interval completely contained inside the subtree of the child node  $c^L$ . Hence, there is no  $I_k$  that is entirely contained inside the subtree of  $c^L$ .

This means  $I_i$  and  $I_j$  are consecutive intervals. Therefore, the subtree of a child node of  $v^L$  overlaps with at most 2 consecutive intervals in  $CI_{rec}$ . Furthermore, there are at most  $\sigma$  child nodes of  $v^L$ . Hence, the total number of intervals in  $CI_{rec}$  is bounded by  $O(\sigma)$ .

Secondly, there are at most  $O(\sigma)$  grouping intervals under the subtree of  $v^L$  for which  $v^L$  is the lca of its leftmost and rightmost leaves, as each grouping interval need to span over two separate downward branches of  $v^L$  for  $v^L$  to be that lca. Additionally, the total number of leaves in all such grouping intervals combined is bounded by  $O(\sigma \cdot g) = O(\sigma \cdot \log^3 N)$  where  $g$  is the grouping factor. This implies that the total number of leaves for which  $v^L$  is the lowest marked ancestor or the cover is bounded by the same factor i.e.  $O(\sigma \log^3 N)$ . ◀

As the set of leaves for which  $v^L$  is the cover, is divided into contiguous intervals of leaves (as shown above), to go from the cover  $v^L$  to the output leaf  $\ell_s$ , first we store some information to retrieve which interval that leaf belongs to and then where exactly that leaf is inside that interval.

For each marked node (here  $v^L$  or its associated  $rec$ ) firstly we store the start of each interval in an array  $INLEFT_{rec}[\cdot]$ . Additionally, we store the size of such intervals in another array  $INLEN_{rec}[\cdot]$ . Moreover, we store the prefix-sum array of  $INLEN_{rec}[\cdot]$  in an array  $PSLEN_{rec}[\cdot]$  (See Figure 2 for example). Now as we are not storing the entire  $ISA^L[\cdot, \cdot]$  because it requires  $O(\log N)$  bits for each leaf instead we store what we call a  $miniISA^L[\cdot, \cdot]$ , where we store just a  $O(\log \sigma + \log \log^3 N)$ -bit number for each matrix position  $(i, j)$ . This is because each entry in the  $miniISA^L[i, j]$  is the lexicographical rank of the leaf associated with  $ISA^L[i, j]$  under its lowest marked ancestor and the total number of leaves for which a marked node is the lowest marked ancestor is bounded by  $O(\sigma \log^3 N)$  (Lemma 9). Now let  $miniISA^L[i, j] = q$ . First we do binary search of  $q$  in  $PSLEN_{rec}[\cdot]$  and get the index  $e$  such that the value of  $PSLEN_{rec}[e]$  is the largest number smaller than  $q$ . Now return the final output  $s = INLEFT_{rec}[e] + (q - PSLEN_{rec}[e])$ .

### 6.2.3 Pseudocode of LFISA<sup>L</sup>-mapping Operation

Now, we outline the pseudocode for LFISA<sup>L</sup>-mapping operation.

■ **Algorithm 1** LFISA<sup>L</sup>( $i, j, ISA^L(i, j)$ ).

---

```

1:  $h = ST^H.inverse(i, j)$ 
2:  $v = ST^V.inverse(i, j)$ 
3:  $s = ISA^L[i, j]$ 
4:  $rec = 3d\_stabbing\_max(h, v, s)$ 
5:  $q = miniISA^L[i, j]$ 
6:  $e = binary\_search(PSLEN_{rec}, q)$ 
7:  $s = INLEFT_{rec}[e] + (q - PSLEN_{rec}[e])$ 
8: return  $s$ 

```

---

## 7 Space and Time Complexity Analysis

### 7.1 Space Complexity

After the end of the construction phase, we have three suffix trees in our index based on three different types of suffix definitions, along with some auxiliary structures that are actually stored. The horizontal and vertical suffix trees i.e.  $ST^H$  and  $ST^V$  are stored as compact suffix trees (See Theorem 10 and 11 in Appendix) which together occupy

$O(N \log \sigma) + O(N \log \sigma) = O(N \log \sigma)$  bits of space. On the contrary, we only store the compressed topology for the Lsuffix tree  $ST^L$  rather than storing the entire suffix tree (See Theorem 10 in Appendix). This compressed topology provides navigational functionalities, and overall it occupies  $4N + o(N)$  bits of space.

As previously mentioned in the marking scheme section, the number of marked nodes on  $ST^L$  is bounded by  $O(N/\log^3 N)$ . Thus, the number of their corresponding shadow points on  $ST^L$ ,  $ST^H$  and  $ST^V$  are also bounded by  $O(N/\log^3 N)$ . Additionally, due to one-to-one correspondence between marked nodes and 3D rectangles, the number of such rectangles is also bounded by the same factor.

Each rectangle has a set of arrays associated with it. The length of each of these arrays ( $INLEFT_{rec}[\cdot]$ ,  $INLEN_{rec}[\cdot]$ ,  $PSLEN_{rec}[\cdot]$ ) is the number of intervals under the marked node of that rectangle. As per the marking scheme, the number of grouping intervals is bounded by  $O(N/\log^3 N)$ . Therefore, the total number of intervals across all the rectangles is also bounded by  $O(N/\log^3 N)$  [Implication from Lemma 9]. Each number in these auxiliary data structures take  $O(\log N)$  bits to store. Identifiers for each marked node or shadow points also take at most  $O(\log N)$  bits. Thus, the storage space for all the auxiliary structures is bounded by  $O(N/\log^2 N) = o(N)$  bits.

If there are  $t$  rectangles, the data structure for stabbing-max query takes  $O(t(\log t/\log \log t)^2)$  [14] which is  $O(t \log^2 t)$  space. By taking  $t = O(N/\log^3 N)$ , we get that stabbing-max data structure takes  $O(N/\log N)$  words of space which is bounded by  $O(N)$  bits of space.

Finally, for our  $miniSA^L$  structure, we simply store a matrix of dimensions  $n \times n$ , with each entry  $miniSA^L[i, j]$  taking  $O(\log \sigma + \log \log N)$  bits. This is because any entry in  $miniSA^L$  writes a position of the desired leaf among at most  $\sigma \log^3 N$  leaves which have the same lowest marked node. Thus, in total we get  $O(N \log \sigma + N \log \log N)$  bits for this part. Additionally, we store the sampled inverse suffix array which has  $O(N/\log N)$  elements where each element takes  $O(\log N)$  bits. Therefore, in total it takes  $O(N)$ -bits of space.

After summing up all five parts that are considered, we get  $O(N \log \sigma) + o(N) + O(N) + O(N \log \sigma + N \log \log N) + O(N)$  bits. This simplifies to  $O(N \log \sigma + N \log \log N)$  bits as claimed in Theorem 1.

## 7.2 Time Complexity

For the time complexity of query evaluation, as a key component, we first focus on computing  $LFISA^L$ -mapping operation. We follow the pseudocode step by step for this. The first two steps take  $t_{inverse}$  as given by CST which is  $O(\log^\epsilon n)$  (See Theorem 11 in Appendix). The third step is constant time since the value is provided as a part of the function. The main time consuming part is the stabbing-max data structure which takes  $O((\log N/\log \log N)^3)$  time. Finding corresponding marked node can be done in  $O(1)$  time using succinct tree data structure and searching for prefix sum in the array associated with the rectangle can be done via binary search in  $O(\log N)$  time. Thus, our dominating and main query bound for  $LFISA^L$ -mapping operation is  $O((\log N/\log \log N)^3)$ . Finally, considering that our query algorithm for  $ISA^L$  can have at most  $\log N$  applications of  $LFISA^L$ , we get our query-time bound as  $O(\log^4 N/(\log \log N)^3)$  (as claimed in Theorem 1).

## 8 Conclusion

To conclude, we provide an  $O(N \log \sigma + N \log \log N)$ -bit index that supports inverse suffix array queries in  $O(\log^4 N / (\log \log N)^3)$  time. Even though the main goal of developing 2D text index which can allow pattern matching i.e. to compute suffix array (SA) value or LF values efficiently is not achieved, we think this is a significant step forward in understanding the structure of the problem. Exploring the inter-relations here may lead us to better tools to compute LF operation efficiently in compact space.

## Abstract

We present a linear space data structure for Dynamic Evaluation of  $k$ -CNF Boolean Formulas which achieves  $O(m^{1-1/k})$  query and variable update time where  $m$  is the number of clauses in the formula and clauses are of size at most a constant  $k$ . Our algorithm is additionally able to count the total number of satisfied clauses. We then show how this data structure can be parallelized in the PRAM model to achieve  $O(\log m)$  span (i.e. parallel time) and still  $O(m^{1-1/k})$  work. This parallel algorithm works in the stronger Binary Fork model.

We then give a series of lower bounds on the problem including an average-case result showing the lower bounds hold even when the updates to the variables are chosen at random. Specifically, a reduction from  $k$ -Clique shows that dynamically counting the number of satisfied clauses takes time at least  $n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$ , where  $2 \leq \omega < 2.38$  is the matrix multiplication constant. We show the Combinatorial  $k$ -Clique Hypothesis implies a lower bound of  $m^{(1-k^{-1/2})(1-o(1))}$  which suggests our algorithm is close to optimal without involving Matrix Multiplication or new techniques. We next give an average-case reduction to  $k$ -clique showing the prior lower bounds hold even when the updates are chosen at random. We use our conditional lower bound to show any Binary Fork algorithm solving these problems requires at least  $\Omega(\log m)$  span, which is tight against our algorithm in this model. Finally, we give an unconditional linear space lower bound for Dynamic  $k$ -CNF Boolean Formula Evaluation.

## 1 Introduction

Boolean formula evaluation is a fundamental problem in computer science. There are many cases when one might want to evaluate the formula multiple times on related inputs. For example some SAT solving algorithms evaluate all inputs within some small Hamming Ball around certain variable settings, requiring many evaluations of a Boolean formula on very similar inputs [39, 22, 35]. Another example is systems safety monitoring where one needs

to check whether certain safety constraints have been violated [32, 18]. One may wonder whether the new values in these settings can be calculated significantly faster than the time it takes to reevaluate the entire formula.

In this paper we define a dynamically updating version of evaluating formulas on Boolean variables in which variables are allowed to change value and the data-structure must maintain whether the formula is still true and, in a harder version, the total number of currently satisfied clauses. In particular, we are given a Boolean expression in  $k$ -CNF (where  $k$  is taken to be a constant) with  $n$  variables and with  $m$  clauses. We achieve a sub-linear time update cost for a generalized version of this problem, including counting the number of satisfied clauses, and show a work-efficient parallelization (Section 3). We give lower bounds on the space and time complexity of this problem, including a fine-grained average-case lower bound when all the updates are given at random (Section 4). We find it exciting that these average-case lower bounds are as strong as our worst case lower bounds, and that only a small gap remains between those and our algorithmic upper bound.

The computational complexity of evaluating Boolean formulas has been well studied, showing the problem is in  $\text{ALOGTIME}$  [17] and the related Boolean Circuit Evaluation problem is complete for  $NC^1$  [16]. There is even a classification of Boolean Formulas under various families of allowed connectives [38]. Since we deal with formulas in  $k$ -CNF form, this restriction of the problem would lie in  $\text{AC}0$ , as it is by definition depth 2. However, when we consider the counting version in which we keep track of the number of clauses currently satisfied, it must be outside  $\text{AC}0$  since it can trivially solve the Parity problem [25].

There has been significant work in the fine-grained complexity of dynamic problems which give conditional lower bounds for a variety of problems such as dynamic shortest path, graph connectivity, bipartite matching, max-flow, and graph diameter [37, 36, 3, 28, 20, 29]. Our results on the fine-grained complexity of Dynamic Boolean Formula Evaluation add to this body of knowledge, more importantly it brings the field of average-case fine-grained complexity to dynamic problems and data-structures. Although Alberts-Henzinger give algorithms for some average-case dynamic problems [5], but we're not aware of any work on average-case lower bounds.

Common fine-grained complexity assumptions were used to establish the average-case hardness of evaluating certain types of polynomials over finite fields in [7]. This was used to show the average-case hardness of counting the number of  $k$ -cliques in certain easy to sample random graphs [27]. This was then adapted to Erdős-Rényi random graphs in [14] and to counting bicliques in [30]. More recently, hardness for evaluating lower dimensional polynomials has been established from even weaker assumptions than those standard in fine-grained complexity and these have been used to give average-case hardness for a variety of problems such as Edit Distance and Max-Flow [21].

One of the goals of average-case fine-grained complexity is the development of fine-grained cryptography where one hopes to actually prove cryptographic security from fine-grained complexity assumptions and may offer cryptographic protocols that remain secure even if more common cryptographic assumptions turn out to be false. One-way functions and public key cryptography which is unconditionally secure against  $\text{AC}0$  circuits was shown in [24]. In [8] fine-grained proof of work was shown from standard fine-grained complexity assumptions. Finally, one-way functions and public key encryption were built based on the average-case complexity of zero- $k$ -clique [34].

## 2 Preliminaries

We study the problem of dynamically updating queries to a Boolean formula. We define this problem formally and then define the hypotheses from which we get lower bounds for this dynamic problem. Note that in this paper we treat  $k$  as a constant.

► **Definition 1.** In *Dynamic Boolean Formula Evaluation* you are given a fixed  $k$ -CNF formula  $\phi$  with  $m$  clauses and  $n$  variables. Further, the variables are given as an array  $\vec{x}$  and initially set to true. The objective is to maintain a data-structure which can answer whether the formula evaluated on the current setting of the variables evaluates to true, subject to updates which flip the value of a single variable. Specifically an update is given as a single index  $i \in [0, n - 1]$  indicating  $\vec{x}[i] = !\vec{x}[i]$ .

In the counting version of the problem, *Counting Dynamic  $k$ -CNF Boolean Formula*, the query instead asks how many clauses are set false. In the *parity* version of the dynamic formula evaluation problem the queries ask for the parity of the number of clauses set false.

### 2.1 Computational Hypotheses

We get computational lower bounds on the dynamic formula evaluation problem from variants of the  $k$ -clique problem. In this context  $\omega$  is the matrix multiplication constant, that is, the smallest real number such that an algorithm exists with running time  $O(n^{\omega+o(1)})$  exists for matrix multiplication. It is known that  $\omega \in [2, 2.37286]$  [6].

► **Definition 2.** The  $k$ -clique hypothesis states that the  $k$ -clique problem requires  $n^{\omega k/3 - o(k)}$  time with randomized or deterministic algorithms [2].

The next hypothesis has to do with combinatorial algorithms. These are an informally defined set of algorithms which use only “combinatorial methods”, specifically excluding fast matrix multiplication. Although informal, these lower bounds can help inform algorithm design. In our case, the hypothesis will also allow for a better presentation of the reduction and analysis. For a discussion of this hypothesis see [1].

► **Definition 3.** The combinatorial  $k$ -clique hypothesis states that for combinatorial algorithms the  $k$ -clique problem requires  $n^{k - o(1)}$  time with randomized or deterministic algorithms [1].

There exist decision to parity reductions for the clique problem. Goldreich defines  $CC_2^{(\ell)}(G)$  as the parity of the count of the number of  $\ell$  cliques in  $G$ .

► **Theorem 4** (Decision to parity  $\ell$ -clique [26, Theorem 1]). For every integer  $\ell \geq 3$ , there is a randomized reduction of determining whether a given  $n$ -vertex graph contains an  $\ell$ -clique to computing  $CC_2^{(\ell)}$  on  $n$ -vertex graphs such that the reduction runs in time  $O(n^2)$ , and makes  $\exp(\ell^2)$  queries, and has error probability at most  $1/3$ .

### 2.2 Binary-Forking Model

The Binary-forking model [12, 4, 9, 10, 11, 23], formally defined in [12], is designed to capture the performance of algorithms in the modern multicore shared-memory machines. In this model, the computation starts with a single thread, and as the computation progresses threads are created dynamically and *asynchronously*. The binary-forking model better captures the asynchronous events such as cache misses, varying clock speed, interrupts, etc., than the well-studied and stronger PRAM model [31] where computation progresses synchronously. Since modern multicore architectures employ multiple caches, processor

pipelining, branch prediction, hyper-threading, etc., many asynchronous events arise in the system, thus demanding the development of a parallel computation model where computation can proceed asynchronously.

Computations in the binary-forking model can be described as max-degree 3 series-parallel directed acyclic graphs (DAGs). A node in the DAG represents a thread's instruction and each node has at most two children. The root of the DAG is the first instruction of the starting thread. If node  $u$  denotes the  $i$ -th instruction of thread  $t$  and  $u$  has only one child  $v$ , then  $v$  denotes the  $(i + 1)$ -th instruction of the same thread  $t$ . If node  $u$  has two children  $v$  and  $w$ , then  $v$  represents the  $(i + 1)$ -th instruction of the same thread  $t$  and  $w$  represents the first instruction of the new forked thread  $t'$ . Note that whether  $w$  represents the 1-st thread  $t'$  or the  $(i + 1)$ -th instruction of thread  $t$  is arbitrary, we just want to model the overall structure of the computation. The binary-forking model includes “join” instructions to join the forking threads which are modeled as nodes with two incoming edges.

The work of the computation is the number of nodes in the series-parallel DAG and the span of the computation is the length of the longest path in the DAG assuming unbounded resources such as processors and space.

### 3 Algorithm

In this section we first describe our main algorithm which achieves an update time of  $O(m^{1-\frac{1}{k}})$ , and then we describe how to parallelize it in the PRAM model with total work  $O(m^{1-\frac{1}{k}})$  and span (parallel time)  $O(\log m)$ . We assume  $k$  is a constant.

#### 3.1 Main Algorithm

The high level idea is to take as input a formula  $\phi$  and handle the variables which appear in many clauses (high frequency) and variables that appear in relatively few clauses (low frequency) with different methods. For a low frequency variable we simply update each clause in which it is involved. For high frequency variables we group all clauses with roughly the same structure together and simply track the number of clauses with that structure. Fundamentally, we will try to track for each clause how many variables are set true and how many are set false.

► **Theorem 5.** *Given a  $k$ -CNF formula  $\phi$  with  $m$  clauses and  $n$  variables there is an algorithm which takes  $O(km)$  preprocessing time and every further update takes  $O(m^{1-1/k})$  time to solve the dynamic formula evaluation problem as well as the counting and parity variants of the dynamic formula evaluation problem.*

**Proof.** Given the formula  $\phi$  with  $m$  clauses split the variables into two sets:  $H$  for high frequency variables and  $L$  for low frequency variables. Variables in  $H$  appear in at least  $\lambda$  clauses. Variables in  $L$  appear in fewer than  $\lambda$  clauses. Let  $\vec{a}$  be the current assignment, without loss of generality assume the starting assignment is the all true assignment ( $\vec{a} = \vec{1}$ ).

Our goal will be to spend  $O(\lambda)$  time updating each variable in  $L$  when it flips value. We want to build a structure to make updates of variables in  $H$  faster than the number of clauses that contain them. First, we will have  $k + 1$  variables  $count_0, \dots, count_k$ . The variable  $count_i$  will track the count of the number of clauses with  $i$  literals set true. Now we will build  $k$  arrays  $A_1, \dots, A_k$ . The  $A_i$  array will keep track of clauses with  $i$  high frequency variables. An entry  $A_i[x_1][x_2] \dots [x_i][j]$  will hold a number. That number will be the count of the number of clauses that contain literals  $x_1, \dots, x_i \in H$  and have  $j$  variables (not necessarily from  $x_1, \dots, x_i$ ) set true. Note, although we construct the  $A_i$  based only on high frequency variables, there may be many clauses with a mix of high and low frequency variables and

these arrays help track all of those clauses. So each  $A_i$  has a total of  $(2|H|)^i \cdot k$  entries, each entry has a number in  $[0, m]$ . There are  $2|H|$  literals for the high-frequency variables (both  $x$  and  $\bar{x}$ ), each of the  $i$  chosen literals can be any one of those  $2|H|$  literals, and for each of these combinations we can have up to  $k$  literals true in a clause. Since ordering is equivalent, this is actually an over-count of what is needed, but we work with this number for convenience. For convenience and uniqueness, we give all variables an arbitrary order and only fill out entries where  $x_1 < x_2 < \dots < x_i$ . We maintain another helpful Boolean array  $S$  that tracks the current settings of all variables:  $S[x_i]$  indicates the current value of  $x_i$ . Yet another array allows the variables in  $L$  to have quick update times. We build the array  $B$  of size  $2|L|$  where  $B[x]$  contains a representation of the at most  $\lambda$  clauses in which the literal  $x \in L$  appears. This is  $2|L|$  because we have both  $x$  and  $\bar{x}$ . We want these representations to include a marking for which of the variables are high frequency variables.

**Preprocessing.** We fill in  $B$  with the representations of all clauses for low frequency variables. Recall that we mark each clause with which of the variables in the clause are high frequency. Set  $S[x_i] = \text{True}$  for all  $x_i$ . For all the  $A_i$  we go through all  $m$  clauses in  $\phi$  and update the counts. Consider the following example and a clause  $c = (x_1 \vee x_2 \vee \dots \vee x_k)$  where the  $x_i$  are literals. Suppose our initial assignment  $\vec{a} = \vec{1}$  sets  $\ell$  literals to true and  $i$  of the literals are high frequency variables,  $x_1, \dots, x_i \in H$ , then increment  $A_i[x_1] \dots [x_i][\ell]$  by one. We also want to update  $count_0, \dots, count_k$ ; note that  $count_\ell$  is simply a sum of all entries  $A_i[*] \dots [*][\ell]$  for all  $i$ . We can also compute these in the preprocessing stage in  $O(km + (2|H|)^k \cdot k^2)$  time to initialize the arrays and by simply evaluating each clause. We will later see that this is  $O(km)$  with our selection of the size of  $|H|$ .

Now every entry  $A_i[x_1] \dots [x_i][\ell]$  is a count of how many clauses with the associated literals have  $\ell$  of those literals set to true. We want to maintain this.

**Updates for variables in  $L$ .** If we flip a variable  $x_L \in L$  then go to  $S[x_i]$  to see the current setting, call it  $b$ . Flip it so that now  $S[x_L] = \bar{b}$ . Next read  $B[x_L]$  and  $B[\bar{x}_L]$  to get all clauses containing  $x_L$ . We will deal with each clause differently depending on how many high frequency variables it has.

If the clause  $c$  has no high frequency variables, then read the  $k$  entries  $S$  for the settings of the variable to determine how many literals were set true before the flip. Let  $\ell$  denote this number. Now, by flipping  $x_L$  we either increment or decrement the number of literals in  $c$  that are set true (either  $+1$  or  $-1$  depending on the original setting and the literal). Suppose the new number of literals set true is  $\ell + \Delta$ , then we decrement  $count_\ell$  and increment  $count_{\ell+\Delta}$  (the clause is moving from being an  $\ell$  literal true clause to an  $\ell + \Delta$  clause). All of this takes  $O(k)$  time.

If the clause  $c$  has  $i > 0$  high frequency variables, then we have to make changes to  $A_i$  as well. First, we read the  $k$  entries for variable settings in  $S$  to evaluate the clause. Suppose the high frequency variables are  $x_1, \dots, x_i$  and that  $c$  had  $\ell$  literals set true before the flip. Suppose that after the flip of  $x_L$  the clause  $c$  has  $\ell + \Delta$  literals set true. Then we decrement  $A_i[x_1] \dots [x_i][\ell]$  and increment  $A_i[x_1] \dots [x_i][\ell + \Delta]$ . As before we decrement  $count_\ell$  and increment  $count_{\ell+\Delta}$ . This takes  $O(k)$  time. With at most  $\lambda$  clauses, the total time is  $O(k\lambda)$ .

The variable  $count_0$  now holds the correct total for the number of unsatisfied clauses.

**Updates for variables in  $H$ .** Now suppose we are flipping a variable in  $H$ ,  $x_H$ . For a variable in  $H$  we cannot look at all of its clauses. However, we can look at all of the relevant entries in  $A_i$  arrays. First in  $O(1)$  time read our previous setting  $b = S(x_H)$  and update  $S(x_H) = \bar{b}$ .

Now update the  $A_i$  arrays. For all  $i \in [1, k]$  we will read all the entries that involve our variable  $x_H$ . Note that there are  $2 \cdot (2|H|)^{i-1} \cdot k$  entries with  $x_H$  in each  $A_i$ , and so  $O((2n)^{k-1})$  entries in total since  $|H| < n$  and  $k$  is assumed to be constant. Without loss of generality assume that  $b = True$  and we are flipping the variable from false to true. Also, for convenience of notation assume that  $x_H$  is the first variable in our arbitrary order (if instead  $x_H$  appears elsewhere simply access with the variables in order). Then for all  $(2n)^{i-1}$  choices of variables  $x_2, \dots, x_i$  we will do the following (from  $v = 0$  to  $v = k$ ):

$$A_i[x_H][x_2] \dots [x_i][v] = \begin{cases} 0 & \text{if } v = k \\ A_i[x_H][x_2] \dots [x_i][v+1] & \text{if } v < k \end{cases}$$

and (from  $v = k$  to  $v = 0$ )

$$A_i[\bar{x}_H][x_2] \dots [x_i][v] = \begin{cases} 0 & \text{if } v = 0 \\ A_i[\bar{x}_H][x_2] \dots [x_i][v-1] & \text{if } v > 0 \end{cases}.$$

The above procedure simply moves the appropriate number of clauses up or down a bucket depending on whether the literal is now true or false. If  $x_H$  appears, it used to be true and is now false. So, every clause with  $x_H$  now has one fewer literal true, we can move all those clauses into the bucket of the array one below it. If  $\bar{x}_H$  appears, it used to be false and is now set true. So we can move all those clauses to the buckets above them. We also have to update our counts. If you move  $t$  clauses from  $A_i[*] \dots [v]$  to  $A_i[*] \dots [v + \Delta]$  then decrement  $count_v$  by  $t$  and increment  $count_{v+\Delta}$  by  $t$ .

The variable  $count_0$  now holds the correct total for the number of unsatisfied clauses.

Each entry  $A_i[*] \dots [v]$  takes  $O(1)$  time to update (or  $O(\lg(n))$  time in the RAM model instead of word RAM). We need to update a total of  $O(k(2|H|)^{k-1})$  entries.

**Overall Runtime and Space.** The space usage is  $m+n+k(2|H|)^k$ . The runtime is (assuming  $k$  is a constant)  $O(\lambda + |H|^{k-1})$ . Now, we can bound  $|H| < km/\lambda$  and so the runtime is  $O(\lambda + (m/\lambda)^{k-1})$ . Optimizing, we choose  $\lambda = (m/\lambda)^{k-1}$ , and get  $\lambda = m^{(k-1)/k} = m^{1-1/k}$ . For a total claimed runtime of  $O(m^{1-1/k})$ . ◀

This algorithm gives a non-trivial improvement over the naive algorithm which requires  $\Theta(m)$  time updates. We will discuss lower bounds in Section 4, where we are able to show this runtime is close to optimal if the  $k$ -clique hypothesis is true (for example a runtime of  $O(n)$  are ruled out).

### 3.2 A Parallel Algorithm

We now show how to parallelize the algorithm of Section 3.1 in the PRAM CREW (concurrent read exclusive write) model [31]. Our results also hold in a more restrictive parallel model called the binary-forking model [12].

► **Theorem 6.** *Given a  $k$ -CNF formula  $\phi$  with  $m$  clauses and  $n$  variables there is a parallel algorithm (in PRAM CREW model and the binary-forking model) which for each variable-update performs  $O(m^{1-\frac{1}{k}})$  work in expectation and achieves  $O(\log m)$  span (parallel runtime) with high probability (in the number of clauses) to solve the dynamic formula evaluation problem.*

**Proof.** We use the same arrays in the parallel algorithm as in the serial algorithm to achieve the work and span bounds.

**Updates for low frequency variables.** There are at most  $\lambda$  clauses where low frequency variable  $x_L$  might appear. For each clause  $c$  where  $x_L$  appears, we do the following. Without loss of generality assume that clause  $c$  has  $i$  high-frequency variables  $x_1, x_2, \dots, x_i$  and has  $\ell$  true literals before flipping  $x_L$ . Let  $\ell + \Delta$  be the number of true literals in  $c$  after the flip.

We update  $A_i[x_1] \dots [x_i][\ell], A_i[x_1] \dots [x_i][\ell + \Delta]$ ,  $\text{count}_\ell$ , and  $\text{count}_{\ell+\Delta}$  for each clause  $c$  where  $x_L$  appears.

It might happen that multiple clauses trigger updates to the same entry  $A_i$  or  $\text{count}_\ell$ , since multiple clauses may have the same set of high-frequency variables and the same number of true literals. When multiple updates try to edit the same entry in parallel, write-write conflicts (race conditions) arise which lead to incorrect answers. We resolve race condition using  $O(\lambda)$  extra space as follows.

Since  $x_L$  is a low-frequency variable,  $x_L$  could appear in  $\lambda$  clauses at most. Suppose that each  $A_i[x_1] \dots [x_i][\ell]$  has an ID. We allocate two arrays each of size  $O(\lambda)$ . One array is used to compute the  $\text{count}_\ell$ s and the other array is used to compute the  $A_i$ s. For each of the  $\lambda$  clauses, we allocate a designated  $O(1)$  space in each array. Recall that  $\text{count}_\ell$  denotes the number of clauses with  $\ell$  literals set true. We would like to update  $\text{count}_\ell$  after flipping variable  $x_L$ .

We now describe how we decrement  $\text{count}_\ell$  and increment  $\text{count}_{\ell+\Delta}$  for each clause  $c$ . Each  $c$  computes corresponding  $\text{count}_\ell$  and  $\text{count}_{\ell+\Delta}$  (as in the serial version) in  $O(k)$  time ( $k$  is a constant here) and write them in the designated location in the array allocated to compute  $\text{count}_\ell$  (see Figure 1 in the Appendix A). We perform *semisort* [13] (i.e. collect equal values in groups) on the array so that all the  $\text{count}_i$  comes before all the  $\text{count}_j$  where  $i < j$ . The randomized semisort algorithm [13] performs  $O(\lambda)$  work in expectation and takes  $O(\log \lambda)$  parallel time with high probability. After that we do a binary reduction to get the correct  $\text{count}_i$ s. We do this binary reduction in  $O(\log \lambda)$  parallel time. Note that we avoid race conditions by updating  $\text{count}_i$  in different locations.

Similar analysis holds to calculate the  $A_i$ s where we store the the value of the  $A_i$ s according to their IDs. Hence, a low frequency is updated in  $O(\log \lambda)$  parallel time and uses  $O(\lambda)$  extra space.

**Updates for high frequency variables.** We do not parse the clauses where the high frequency variable occurs. Instead, we update the corresponding  $A_i$ s and  $\text{count}_i$ s as follows.

(from  $v = 0$  to  $v = k$ ):

$$A_i[x_H][x_2] \dots [x_i][v] = \begin{cases} 0 & \text{if } v = k \\ A_i[x_H][x_2] \dots [x_i][v + 1] & \text{if } v < k \end{cases}$$

and (from  $v = k$  to  $v = 0$ )

$$A_i[\bar{x}_H][x_2] \dots [x_i][v] = \begin{cases} 0 & \text{if } v = 0 \\ A_i[\bar{x}_H][x_2] \dots [x_i][v - 1] & \text{if } v > 0 \end{cases}.$$

In short, if  $x_H$  appears it used to be true and is now false. So, every clause with  $x_H$  now has one fewer literal true, we can move all those clauses into the bucket of the array one below it. If  $\bar{x}_H$  appears it used to be false and is now set true. So we can move all those clauses to the buckets above them.

We can do all these updates in parallel in  $O(1)$  parallel time. We update the  $\text{count}_\ell$  after we update the  $A_i$ s. We update  $O(k \cdot 2|H|^{k-1})$  entries of  $A_i$  where  $x_H$  is present. If we move  $t$  clauses from  $A_i[*] \dots [v]$  to  $A_i[*] \dots [v + \Delta]$  then we decrement  $\text{count}_v$  by  $t$  and

increment  $count_{v+\Delta}$  by  $t$ . As multiple  $A_i$  entries may update the same  $count_i$  entry, we use an array of  $O(k \cdot 2|H|^{k-1})$  extra space to avoid the race condition for parallel updates. Like before, we semisort the array based on the  $v$  of  $A_i[*] \dots [*][v]$ . Then we perform a parallel sum of the the entries with the same  $v$  and then add/subtract this sum to  $count_i$ . Combining all these the span to update a high frequency variable is  $O(\log |H|) = O(\log n)$ .

As we set  $\lambda = m^{1-\frac{1}{k}}$ , the span to update a low frequency variable is  $O(\log \lambda) = O(\log m)$  and a high frequency variable is  $O(\log n)$ . Since we do not increase the work asymptotically, the work in this parallel algorithm remains the same as in the serial version. Hence, total work performed is  $O(\lambda) = O(m^{1-\frac{1}{k}})$  in expectation. The span is  $O(\log m)$  w.h.p. due to semisort. ◀

We could replace the randomized semisort algorithm with a deterministic sorting algorithm. Cole-Ramachandran's [19] deterministic sorting algorithm performs  $O(x \log x)$  work and takes  $O(\log x \log \log x)$  span to sort  $x$  items in the binary-forking model (in PRAM CREW model also) giving the following theorem.

► **Theorem 7.** *Given a  $k$ -CNF formula  $\phi$  with  $m$  clauses and  $n$  variables there is a deterministic parallel algorithm (in PRAM CREW model and the binary-forking model) which for each variable update performs  $O(m^{1-\frac{1}{k}} \log m)$  work and achieves  $O(\log m \log \log m)$  span (parallel running time) to solve the dynamic formula evaluation problem.*

## 4 Lower Bounds for Dynamic Formula Evaluation

In this section we present lower bounds for the dynamic formula evaluation problem on  $k$ -CNF formulas. First, we present an unconditional linear lower bound on the space of the data-structure. Next, we present a series of conditional lower bounds on the running times of preprocessing, updates, and queries. These are based on the  $k$ -Clique Hypothesis. This culminates in an average-case lower bound for random updates to the variables based on counting  $k$ -cliques in Erdős-Rényi graphs. Finally, we present a conditional lower bound on the span of the algorithm in the binary forking model. Recall that we are treating  $k$  as a constant in this section.

### 4.1 Linear Space Lower Bound

We show a space lower bound linear in the number of variables by a reduction from INDEX [33]. Details can be found in the Appendix.

► **Theorem 8.** *Every randomized algorithm for dynamic-formula-evaluation which correctly decides that the formula for each variable flip (with  $n$  variables,  $O(n)$  clauses, and clause size at least 2) is satisfied or not with probability strictly larger than  $1/2$ , uses  $\Omega(n)$  space in the worst case.*

### 4.2 The $k$ -Clique Hypotheses and a General Reduction

We give these lower bounds from hypotheses related to the  $\ell$ -clique problem. We will use  $k$  for the  $k$ -CNF Dynamic Counting Boolean Formula problem we reduce to. First, let us present a generic reduction from all  $\ell$ -clique instances to a dynamic formula evaluation formula  $\phi$  on  $n = |V|$  variables, where each given instance of  $\ell$ -clique will correspond to a single setting of the variables  $X$ .

► **Lemma 9.** *Consider a graph  $G$ , where we have not yet decided what edges exist or don't. There are  $|V|$  vertices and  $\binom{|V|}{2}$  potential edges. There exists a formula  $\phi_\ell$  with  $n = \binom{|V|}{2}$  variables, width  $k = \binom{\ell}{2}$  clauses, and a total of  $m = \binom{|V|}{\ell}$  clauses such that when the  $n$  variables  $X$  are set with a 1 if the edge exists in  $G$  and 0 if the edge doesn't exist then the number of false clauses in  $\phi_\ell(X)$  corresponds to the number of  $k$  cliques in  $G$ .*

Next we want a useful lemma which will help us bound the preprocessing time. We will use many smaller instances of the clique problem so that our number of update calls to our data-structure is large compared to its initial size. Variations on this lemma are folklore, but a proof is provided for completeness.

► **Lemma 10.** *Assume (existence/counting/parity) (combinatorial)  $\ell$ -clique requires  $|V|^{c\ell(1-o(1))}$  time for some constant  $c$ . Let  $T(\cdot)$  be the time to solve a single instance when given a list of instances. Then giving correct answers to  $g^\ell$  instances each of size  $|U| = \ell|V|/g$  takes  $g^\ell T(|U|)$  time which is at least  $|V|^{c\ell(1-o(1))}$  time.*

*Consider value  $0 < d < c \leq 1$  where we insist that  $(\ell|V|/g)^\ell = \Theta(|V|^{d\ell})$  then  $T(|U|)$  requires at least  $|U|^{(c-\frac{1+d}{d})\ell(1-o(1))}$  time.*

**Proof.** Partition the vertex set into  $V_1, \dots, V_g$  each partition of size  $|V|/g$ . Now we form  $g^\ell$  instances each of size at most  $|U| = \ell|V|/g$ . These instances are all possible choices of at most  $\ell$  of our vertex sets merged together. Using inclusion exclusion we can count the number of cliques in the original graph using calls to these problems. This inclusion and exclusion also allows parity to solve parity. We will find a clique in these instances if and only if there is at least one clique in the original graph.

Given this reduction we can solve a (existence/counting/parity) (combinatorial)  $\ell$ -clique problem with answers to  $g^\ell$  instances each of size  $|U| = \ell|V|/g$ , giving the first statement.

For the second statement note that  $g = \Theta(|V|^{1-d})$ . Then note that  $|U| = \Theta(|V|^d)$ . Now we can say that  $T(|U|)$  must be at least  $|V|^{(c-1+d)\ell(1-o(1))}$  time. So, in terms of  $|U|$ ,  $T(|U|)$  must be at least

$$|U|^{(c-\frac{1+d}{d})\ell(1-o(1))}. \quad \blacktriangleleft$$

Note that when  $c = 1$  you get no loss in efficiency regardless of the constant  $d < 1$  you pick. This case of  $c = 1$  happens for combinatorial  $\ell$ -clique. It is why we use it as an example. It simplifies the reduction to not worry about the loss that comes from a large  $d$ .

### 4.3 From the Combinatorial $k$ -Clique Hypothesis

Using the reduction in the prior section, we give a lower bound from the combinatorial  $\ell$ -clique hypothesis. Note how we choose the value of  $d$  for the reduction from Lemma 10. We want  $d$  to be small so that our preprocessing time is small. This is what will cause inefficiency in the future reductions when  $c \neq 1$ ; we lose efficiency in the reduction when  $d$  is small.

► **Theorem 11.** *Assume  $\ell$  is a constant. If the combinatorial  $\ell$ -clique hypothesis is true then any combinatorial algorithm  $A$  for the Dynamic Counting Boolean Evaluation problem,  $U(n, m, k)$ , with polynomial preprocessing time  $P(n, m, k) = \text{poly}(n) \cdot \text{poly}(m) \cdot \text{poly}(k)$  requires  $m^{(1-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U(n, m, k)$  requires at least  $n^{(1-o(1))(\sqrt{2k}-2)/2}$  time.*

#### 4.4 From the $k$ -Clique Hypothesis

We will now use the same reduction style as the previous section. However, now  $c$  from Lemma 10 will be  $c = \omega/3$  instead of 1. Here  $\omega$  is the matrix multiplication exponent constant. The analysis proceeds similarly to that of Section 4.3. Details are in the Appendix.

► **Theorem 12.** *Assume  $\ell$  is a constant. If the  $\ell$ -clique hypothesis is true then any algorithm  $\mathcal{A}$  for the Dynamic Counting Boolean Evaluation problem,  $U(n, m, k)$ , with polynomial preprocessing time  $P(n, m, k) = O(m)$  requires  $m^{\left(\frac{2\omega-3}{3} - k^{-1/2}\right)(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U(n, m, k)$  requires at least  $n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$  time.*

#### 4.5 Random Input Implications

Our goal is to show that with a worst-case fixed formula, specifically our  $k$ -clique formula, it is still hard to evaluate updates to the formula when the *updates are random*. We will show lower bounds against algorithms which always correctly implement updates, but, are allowed error when responding to queries. The queries this dynamic formula evaluation algorithm must support are queries on the number of falsified clauses.

For this result we will use a theorem from [26]<sup>1</sup>. At a high level, they show that the counting/parity  $l$ -clique problem requires just as long over the uniform average-case distribution as it does in the worst-case when  $l$  is a constant. First we will define the model of average-case inputs we are considering.

► **Definition 13.** *Let Average-Case counting dynamic formula evaluation (AC#DFE) be the problem where you are given a worst-case formula to evaluate but random (so average-case) updates on the variables. More specifically, you are given a worst-case formula  $\phi$ , and a series of updates where each update flips the assignment of a uniformly random chosen variable. A data structure  $D$  for AC#DFE with error probability  $\epsilon$  takes as input a worst-case  $\phi$  and after each random update answers the count of the number of false clauses in the formula with probability  $1 - \epsilon$ .*

► **Definition 14 (Erdős-Rényi graphs).** *Create a graph with  $|V|$  vertices and no edges to start with. Now, for every pair of vertices in the graph iid include an edge between them with probability  $1/2$ . Thus, every potential edge in the graph appears with probability  $1/2$  independently from all other edges.*

Now we can describe one theorem from [26]. First we start by using a piece of their notation. Define  $CC_2^{(\ell)}(G)$  as the parity of the count of the number of  $\ell$  cliques in  $G$ .

► **Theorem 15 (Average-Case  $\ell$ -clique [26, Theorem 2]).** *For every integer  $\ell \geq 3$ , there is a randomized reduction of computing  $CC_2^{(\ell)}$  on the worst-case  $n$ -vertex graph to correctly computing  $CC_2^{(\ell)}$  on at least a  $1 - \exp(-\ell^2)$  fraction of the  $n$ -vertex graphs such that the reduction runs in time  $O(n^2)$ , makes  $\exp(\ell^2)$  queries, and has error probability at most  $1/3$ .*

So, up to sub-polynomial factors, average-case counting and parity  $\ell$ -clique are just as hard on average as worst-case parity  $\ell$ -clique. Now, we can use these reductions to show lower bounds for our problem with random inputs. First, we will show that if you start

<sup>1</sup> For an alternate presentation of the parity proof of this result see [15]. The formulation from [26] is easier to build on in this case.

from a graph and make  $\binom{n}{2} \lg^2(n)$  random edge flips the resulting graph is drawn from a distribution that has total variation distance less than  $2^{-\Omega(\lg^2(n))}$  from an Erdős-Rényi graph. Note that, on an intuitive level, this means that when we sample from our edge flipping distribution we “look like” we are sampling an Erdős-Rényi graph a  $1 - 2^{-\Omega(\lg^2(n))}$  fraction of the time. Since our reduction represents edges as variables, flipping a random variable is like flipping an edge in the original graph, and we want to argue that after not too many flips we have a random looking graph.

► **Lemma 16.** *Given a graph  $G$  let the procedure  $F$  be the process of selecting a uniformly random pair of vertices  $(u, v)$  and either deleting edge  $(u, v)$  if it exists or inserting  $(u, v)$  if it doesn't exist.*

*If we run the procedure  $F \Theta\left(\binom{n}{2} \lg^2(n)\right)$  times on any graph  $G$  the resulting distribution over graphs has total variation distance at most  $n^{2-\Omega(\lg(n))}$  from the distribution over Erdős-Rényi graphs.*

The high level idea for the reduction is to take the worst-case reduction from the prior section and at the last step add the randomized reduction. Specifically, in the worst case we show that solving a list of instances  $G_1, \dots, G_x$  is still hard. Now, for the average-case we will use the [26] reduction to turn each  $G_i$  into  $\exp(\ell^2)$  queries on random graphs, call these  $G_i^{(1)}, \dots, G_i^{(\exp(\ell^2))}$ . Note that these graphs each look random, but have correlations. So, we can't ask the same AC#DFE data structure about two of these. However, we can spin up  $\exp(\ell^2)$  instances of data structures for AC#DFE:  $D_1, \dots, D_{\exp(\ell^2)}$ . We will, implicitly, give the data structure  $D_j$  graphs  $G_1^{(j)}, \dots, G_x^{(j)}$ . These will be totally uncorrelated (each are randomized under different random bits). This will correspond to random updates on variables (which in our worst-case reduction correspond to edges in the graph).

We will show in this next theorem that even with random updates, the same lower bounds hold (up to factors in time of  $2^{2k}$ , which if  $k$  is a constant is simply a constant).

► **Theorem 17.** *Let  $k$  be a constant. Say there is a data structure  $D$  that can solve the AC#DFE problem on worst-case  $k$ -CNF formulas  $\phi$  with error  $\epsilon < \exp(-2k)/3$  with  $P_D(n, m, k)$  pre-processing time and  $U_D(n, m, k)$  time per query and update. We will note the lower bounds for combinatorial  $D$  from the combinatorial  $\ell$ -clique hypothesis. We will also note the lower bound for general  $D$  from the  $\ell$ -clique hypothesis.*

- *If  $D$  is a combinatorial data structure, the combinatorial  $\ell$ -clique hypothesis is true, and  $P_D(n, m, k) = \text{poly}(n) \cdot \text{poly}(m) \cdot \text{poly}(k)$ , then  $U_D(n, m, k)$  requires  $m^{(1-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U_D(n, m, k)$  requires at least  $n^{(1-o(1))(\sqrt{2k}-2)/2}$  time.*
- *If the  $\ell$ -clique hypothesis is true and  $P_D(n, m, k) = O(m)$  then  $U_D(n, m, k)$  requires  $m^{(\frac{2\omega-3}{3}-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U_D(n, m, k)$  requires at least  $n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$  time.*

**Proof.** First, let us describe the general reduction regardless of the hypothesis we start with. We take the list of  $|V|^{\ell(1-d)}$  sub-problems  $G_1, \dots, G_{|V|^{\ell(1-d)}}$  and on each instance individually we run the reduction from Theorem 15. So we take each problem,  $G_i$ , of size  $|V|^d$  and use Theorem 15 to make a list of  $s = \exp(\ell^2)$  queries  $G_i^{(1)}, \dots, G_i^{(s)}$ . Now, we spin up  $s$  different instances of  $D$ , call them  $D_1, \dots, D_s$ . Consider sampling the updates from  $G_i^{(j)}$  to  $G_{i+1}^{(j)}$  uniformly at random from all random series of updates of length  $s = \Theta(n^2 \lg^2(n))$  that flip edges to  $G_{i+1}^{(j)}$ . Because every variable corresponds to an edge in the graph flipping a variable and flipping an edge is a one to one relationship. So, after this series of flips that look uniformly random up to a TVD of  $n^{-\Omega(\lg(n))}$  (by Lemma 16) we get the answer to the number of  $\ell$ -cliques in  $G_{i+1}^{(j)}$ ! By the claims of the Theorem statement each  $D_j$  has an error rate of

$\epsilon < \exp(-2k)/3$  on the random updates of the average-case distribution of AC#DFE our TVD tells us that the error rate of  $D_j$  on this “nearly random” set of updates is at most  $\epsilon + n^{\Omega(\lg(n))}$ . Now note that if each instance  $D_1, \dots, D_s$  gives us the correct answer we can correctly answer our query on all  $G_i$  by Theorem 15. So, we get a correct answer on the worst-case  $G_i$  with probability  $2/3 - \exp(\ell^2) n^{-\Omega(\lg(n))}$ , note this is large enough that this procedure can be repeated to boost this probability. Note this means we get the same lower bounds as we did in the worst-case, but with an overhead of  $\exp(\ell^2)$  which is a constant from our perspective.

First we discuss the combinatorial  $k$ -clique case. Start by taking the reduction from Theorem 11. So if  $D$  is a combinatorial data structure, the combinatorial  $\ell$ -clique hypothesis is true, and  $P_D(n, m, k) = \text{poly}(n) \cdot \text{poly}(m) \cdot \text{poly}(k)$ , then  $U_D(n, m, k)$  requires  $m^{(1-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U_D(n, m, k)$  requires at least  $n^{(1-o(1))(\sqrt{2k}-2)/2}$  time.

Finally, we will address the  $\ell$ -clique hypothesis. As before we will get the same lower bounds, up to a factor of  $\exp(\ell^2)$  which is a constant from our perspective. So if the  $\ell$ -clique hypothesis is true and  $P_D(n, m, k) = O(m)$  then  $U_D(n, m, k)$  requires  $m^{(\frac{2\omega-3}{3}-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U_D(n, m, k)$  requires at least  $n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$  time. ◀

#### 4.6 Span Lower Bound in the Binary-Forking Model

In the Appendix we prove an  $\Omega(\log n)$  span lower bound in the binary forking model. This lower bound only requires that the work of the algorithm is  $\Omega(n^c)$  for some constant  $c$ , and is thus a weaker condition than the  $k$ -Clique Hypothesis.

► **Theorem 18.** *The span per update for dynamic boolean formula evaluation is  $\Omega(\log n)$  in the binary forking model.*

## 5 Conclusion and Open Problems

Defining Dynamic Boolean Formula Evaluation and giving a data-structure with sub-linear update time is an important first step in characterizing the complexity of this problem. Our data-structure is simple enough and provides a large enough benefit for small  $k$  that we hope it will inspire practical implementations. On the theoretical side, although we give upper and lower bounds that show roughly what the complexity of this problem should be, there is still a significant gap between them and plenty of room to generalize both types of results.

With a more careful analysis both our algorithms and lower bounds should hold for some small super-constant  $k$ . Improving this analysis may be of interest, but more importantly finding both algorithms and lower bounds that work for a greater range of  $k$ , especially when  $k = m^c$  for some constant  $c$ .

Closing the gap between our lower and upper bounds is one obvious open question. The conditional lower bound giving  $\frac{1}{\sqrt{k}}$  comes directly cliques containing  $l^2$  edges. Thus perhaps one should be trying to use graph problems with sparse structures rather than dense ones. However, one needs to be careful because there is only a single  $k$ -clique on  $k$  vertices whereas there can be many isomorphic sparse structures. The larger issues comes from the factor of the matrix multiplication constant in our lower bound. We see this disappear with the combinatorial  $l$ -clique conjecture which suggests either 1) Dynamic Boolean Formula Evaluation can be solved much faster, but doing so will likely require linear-algebraic techniques or some other fundamentally different approach, 2) we need a slightly more clever reduction. A common solution to strengthening “combinatorial” fine-grained

assumptions is to move to a weighted version of the problem. However, the OR of variables is symmetric under permutation and thus does not appear to be something that supports any sort of arithmetic at the clause level. Further, our algorithms fundamentally require this symmetry and will fail when trying to generalize in this direction.

Further, it would be interesting to have conditional lower bounds for the pure Dynamic Boolean Formula problem rather than the counting version which seems much stronger. Both giving lower bounds for more restricted versions of the problem and generalizing the algorithm to handle more general formulas seems of interest. Generalizing the depth of the formula (no longer requiring CNF form) is another obvious direction.

We believe that a  $\log(n)$ -span lower bound should hold in a stronger model such as CREW PRAM. Both improved lower bounds and whether there are better algorithms in stronger concurrent data-structures models remains an interesting question to explore. Depth 2 Boolean formulas being in AC0 strongly suggests at least this special case should be able to be parallelized more efficiently, perhaps at the cost of work-efficiency.

One obvious problem to consider is a version of Dynamic Boolean Formula Evaluation in which the formula itself can be altered, instead of or in addition to the values of the variables. These problems are equivalent in the DynamicSAT case, but looking for sub-linear update cost we have much less leeway in the efficiency of this reduction. We believe minor alterations to our current algorithm will allow it to handle the insertion and deletion of literals and clauses with the same amortized worst-case cost by simply rebuilding the table whenever variables pass some threshold for their frequency of appearing in clauses. However, de-amortizing this does not seem at all obvious.

---

## A Parallel Algorithm Figure

■ **Figure 1** Clause  $c$  writes whether count $_{\ell}$  and count $_{\ell+1}$  increment or decrement in their designated locations (in color pink). We then semisort so that all the updates corresponding to count $_{\ell}$  come in adjacent locations (in color yellow for count $_{\ell}$ ). After that we do a binary reduction to get the net update to count $_{\ell}$ .

## B Lower Bounds Omitted Proofs

### B.1 Proof of Linear Space Lower Bound

► **Theorem 19.** *Every randomized algorithm for dynamic-formula-evaluation which correctly decides that the formula for each variable flip (with  $n$  variables,  $O(n)$  clauses, and clause size at least 2) is satisfied or not with probability strictly larger than  $1/2$ , uses  $\Omega(n)$  space in the worst case.*

**Proof.** We prove this using communication complexity, specifically, reducing the problem to the INDEX problem.

**INDEX problem.** Alice gets an  $n$ -bit string  $x \in \{0, 1\}^n$  and Bob gets an integer  $i \in \{1, n\}$ . Alice can communicate to Bob, but Bob cannot send messages to Alice. The goal is to find out  $x_i$ , the  $i$ -th index of  $x$ .

We know the lower bound of the randomized one-way communication complexity of INDEX is  $\Omega(n)$  [33].

We now do the following reduction. Given  $x \in \{0, 1\}^n$ , Alice constructs a CNF formula  $F$  as follows. There are  $n$  clauses and  $2n$  variables in  $F$ . For  $1 \leq j \leq n$ , clause  $C_j = (v_{j,1} \wedge v_{j,2})$ . If  $x_j = 1$ , we assign  $v_{j,1} = \text{TRUE}$  and  $v_{j,2} = \text{FALSE}$ . Otherwise, we assign  $v_{j,1} = \text{FALSE}$  and  $v_{j,2} = \text{TRUE}$ . Note that in formula  $F$ , every clause is initially satisfied and only one variable is TRUE in every clause.

Now given index  $i$ , we flip variable  $v_{i,1}$ . If the formula remains satisfied, then  $x_i = 0$  in Alice's string, otherwise,  $x_i = 1$ . ◀

### B.2 Proofs about $k$ -Clique reduction General Reduction

► **Lemma 20.** *Consider a graph  $G$ , where we have not yet decided what edges exist or don't. There are  $|V|$  vertices and  $\binom{|V|}{2}$  potential edges. There exists a formula  $\phi_k$  with  $n = \binom{|V|}{2}$  variables, width  $k = \binom{\ell}{2}$  clauses, and a total of  $m = \binom{|V|}{\ell}$  clauses such that when the  $n$  variables  $X$  are set with a 1 if the edge exists in  $G$  and 0 if the edge doesn't exist then the number of false clauses in  $\phi_k(X)$  corresponds to the number of  $k$  cliques in  $G$ .*

**Proof.** In this reduction we will use variables to represent possible edges in the graph and we will use clauses to detect cliques. Let us index our variables  $X$  with two numbers  $i, j$  such that  $X[i, j]$  is a variable if  $i < j$  and  $i, j \in [|V|]$ . We will treat  $X[i, j]$  as the variable corresponding to if the edge  $(i, j)$  exists in  $G$ . Now, for all  $i_1 < \dots < i_\ell$  where  $i_1, \dots, i_\ell \in [|V|]$  add the following clause to  $\phi_k$ :

$$(\bar{X}[i_1, i_2] \vee \bar{X}[i_1, i_3] \vee \dots \vee \bar{X}[i_1, i_\ell] \vee \bar{X}[i_2, i_3] \vee \dots \vee \bar{X}[i_{\ell-1}, i_\ell]).$$

Note that if the nodes  $i_1, \dots, i_\ell$  in  $G$  are a  $\ell$ -clique given the setting of edges implied by  $X$ , then this clause is false if any of the edges among vertices 1 to  $\ell$  are missing.

Each clause has size  $k = \binom{\ell}{2}$ . There are a total of  $m = \binom{|V|}{\ell}$  clauses. We need one variable per potential edge in the graph, so there are  $n = \binom{|V|}{2}$  variables. Given a setting of  $X$  we have a corresponding graph  $G$ , and the number of false clauses in  $\phi_k$  is exactly equal to the number of  $\ell$ -cliques in  $G$ . ◀

► **Theorem 21.** *Assume  $\ell$  is a constant. If the combinatorial  $\ell$ -clique hypothesis is true then any combinatorial algorithm  $\mathcal{A}$  for the Dynamic Counting Boolean Evaluation problem,  $U(n, m, k)$ , with polynomial preprocessing time  $P(n, m, k) = \text{poly}(n) \cdot \text{poly}(m) \cdot \text{poly}(k)$  requires  $m^{(1-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U(n, m, k)$  requires at least  $n^{(1-o(1))(\sqrt{2k-2})/2}$  time.*

**Proof.** We are given an instance  $G$  of the  $\ell$ -clique problem with  $|V|$  vertices and  $|E| = O(|V|^2)$  edges. By the combinatorial  $\ell$ -clique hypothesis this problem requires  $|V|^{\ell(1-o(1))}$  time.

First note that, with Lemma 10, we want  $c = 1$  from our combinatorial  $k$ -clique hypothesis. Next assume that  $P(n, m, k) = (n \cdot m \cdot k)^f$  for some constant  $f$ . Now set  $d = \frac{(1-\epsilon)\ell}{(\ell+2)f}$  for some constant  $\epsilon > 0$ . Recall, with these settings, we can say that solving all  $|V|^{\ell(1-d)}$  clique problems requires  $|V|^{\ell(1-o(1))}$  time. This can be stated as a time for each of the problems of size  $|V|^d$ , they each require  $(|V|^d)^\ell$  time.

Now we will use Lemma 9 to produce our formula  $\phi$  on our problems of size  $|V'| = |V|^d$ . Note that  $n = \binom{|V'|}{2} = \Theta(|V'|^2)$  and  $k = \binom{\ell}{2} = \ell(\ell+1)/2$  and  $m = \binom{|V'|}{\ell} = \Theta(|V'|^\ell)$ . Finally, observe  $P(n, m, k) = O((|V|^{\ell(\ell+2)})^f)$  which can be written as  $P(n, m, k) = O((|V|^{\ell(1-\epsilon)})^f)$ . Thus all of the updates we do to solve our clique problem must take  $|V|^{\ell(1-o(1))}$  time.

Note that with at most  $|E'| = O(|V|^{2d})$  variable updates we can cause the number of false clauses in  $\phi_\ell$  to be equal to the number of  $\ell$ -cliques in a new instance. So  $|V|^{2d}$  updates should take at least  $(|V|^d)^\ell$  time. Further,  $U(n, m, k)$  must be at least  $|V|^{d(\ell-2)(1-o(1))} = |V'|^{(\ell-2)(1-o(1))}$ . Now, lets re-state this in terms of  $n, m, k$ . First lets add our value of  $m$  into this equation:

$$|V'|^{(\ell-2)(1-o(1))} = m^{(1-o(1))(\ell-2)/\ell} = m^{(1-2/\ell)(1-o(1))}.$$

We can also write in terms of  $n$ :

$$|V'|^{(\ell-2)(1-o(1))} = n^{(1-o(1))(\ell-2)/2}.$$

Now note that  $2\sqrt{k} > \ell > \sqrt{2k}$ . So we can re-write our above equations as

$$|V'|^{(\ell-2)(1-o(1))} = m^{(1-1/\sqrt{k})(1-o(1))},$$

and

$$|V'|^{(\ell-2)(1-o(1))} = n^{(1-o(1))(\sqrt{2k}-2)/2}. \quad \blacktriangleleft$$

► **Theorem 22.** *Assume  $\ell$  is a constant. If the  $\ell$ -clique hypothesis is true then any algorithm  $A$  for the Dynamic Counting Boolean Evaluation problem,  $U(n, m, k)$ , with polynomial preprocessing time  $P(n, m, k) = O(m)$  requires  $m^{(\frac{2\omega-3}{3}-k^{-1/2})(1-o(1))}$  time. We can also state the lower bound in terms of the number of variables  $n$ , in which case  $U(n, m, k)$  requires at least  $n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$  time.*

Using in  $\omega = 2.37286$  (from the best current upper bound [6]) these lower bounds per update are:  $m^{(0.5819-k^{-1/2})(1-o(1))}$  and  $n^{0.5819\sqrt{2k}-1-o(\sqrt{k})}$ .

Using  $\omega = 2$  (the smallest value  $\omega$  could be) the lower bounds per update are:  $m^{(1/3-k^{-1/2})(1-o(1))}$  and  $n^{\sqrt{2k}/3-1-o(\sqrt{k})}$ .

**Proof.** We are given an instance  $G$  of the  $\ell$ -clique problem with  $|V|$  vertices and  $|E| = O(|V|^2)$  edges. By the  $\ell$ -clique hypothesis we have that this problem requires  $|V|^{(1-o(1))\omega\ell/3}$  time.

First note that with Lemma 10, we want  $c = \omega/3$  from our  $l$ -clique hypothesis. Next we assumed that  $P(n, m, k) = O(m)$ . Now set  $d = \frac{(1-\epsilon)\omega}{3}$  for some constant  $\epsilon > 0$  to be set later. Recall, with these settings we can say that solving all  $|V|^{\ell(1-d)}$  clique problems requires  $|V|^{(1-o(1))\omega\ell/3}$  time. For convenience call  $\delta = \epsilon\omega/3$ . This can be stated as a time for each of the problems of size  $|V|^d$ , they each require time

$$R(|V|) = (|V|^d)^{\frac{c-1+d}{d}\ell(1-o(1))} = (|V|^d)^{\frac{2\omega-3-\delta}{3-\delta}\ell(1-o(1))}.$$

## 61:18 Dynamic Boolean Formula Evaluation

We will use the reduction from Lemma 9. Let  $|V'| = |V|^d$ . Now let's note that  $n = \binom{|V'|}{2} = \Theta(|V'|^2)$  and  $k = \binom{\ell}{2} = \ell(\ell+1)/2$  and  $m = \binom{|V'|}{\ell} = \Theta(|V'|^\ell)$ .

Now note that as before if  $P(n, m, \ell) = O(m)$  then it is also  $O(|V|^{d\ell})$  which can be restated as  $|V|^{(1-\epsilon)\omega\ell/3}$ . This is small enough that the updates must take  $|V|^{(1-o(1))\omega\ell/3}$  time.

We require  $O(|V|^{2d})$  updates per instance. And each instance requires  $R(|V|)$  time. So each update requires  $R(|V|)|V|^{-2d}$  time which we can expand to

$$(|V|^d)^{\left(\frac{2\omega-3-\delta}{3-\delta}\right)\ell(1-o(1))-2}$$

time. Now note that  $2\sqrt{k} > \ell > \sqrt{2k}$ . If we re-state this with  $m$  we get:

$$m^{\left(\frac{2\omega-3-\delta}{3-\delta}\right)(1-o(1))-1/\sqrt{k}}$$

If we treat  $\epsilon$  as a parameter we tune to be arbitrarily small we can re-state as follows:

$$m^{\frac{2\omega-3}{3}-1/\sqrt{k}-\epsilon'}$$

where  $\epsilon'$  is some other arbitrarily small constant (a function of  $\epsilon$  implicitly). So, if someone claims they have update time

$$m^{\frac{2\omega-3}{3}-1/\sqrt{k}-\gamma}$$

for a fixed constant  $\gamma$  then we can tune  $\epsilon$  sufficiently small for that to give a contradiction from the  $k$ -clique hypothesis.

Now, if we state in terms of  $n = O(|V'|^2)$

$$n^{\left(\frac{2\omega-3-\delta}{6-2\delta}\right)\ell(1-o(1))-1}$$

we can use the same trick with  $\epsilon'$  to get the simplified version

$$n^{\left(\frac{2\omega-3}{6}-\epsilon'\right)\ell-1} = \Omega\left(n^{\left(\frac{2\omega-3}{6}-\epsilon'\right)\sqrt{2k}-1}\right)$$

which gives a lower bound of

$$n^{\frac{2\omega-3}{6}\sqrt{2k}-1-o(\sqrt{k})}$$

time per update. ◀

► **Lemma 23.** *Given a graph  $G$  let the procedure  $F$  be the process of selecting a uniformly random pair of vertices  $(u, v)$  and either deleting edge  $(u, v)$  if it exists or inserting  $(u, v)$  if it doesn't exist.*

*If we run the procedure  $F$   $\Theta\left(\binom{n}{2} \lg^2(n)\right)$  times on any graph  $G$  the resulting distribution over graphs has total variation distance at most  $n^{-\Omega(\lg(n))}$  from the distribution over Erdős-Rényi graphs.*

**Proof.** Let  $p = \binom{n}{2}^{-1}$ , the probability any given edge is selected to be flipped by  $F$ . Let  $s = \Theta\left(\binom{n}{2} \lg^2(n)\right)$ , the number of times we run  $F$ .

For any given edge  $(u, v)$  it is flipped a Binomially distributed number of times  $B(s, p)$ . The  $\Pr[B(s, p) \equiv 0 \pmod{2}] = 1/2 + (1-2p)^s/2$ , which is the probability that  $(u, v)$  stays an edge if it started with one and continues to have no edge if started without one. If this were an Erdős-Rényi graph the probability an edge exists is  $1/2$  iid. So on each edge the TVD from the probability of  $1/2$  is  $(1-2p)^s$ . Now note that  $(1-2p)^s = (1-2p)^{(2/(2p))\Theta(\lg^2(n))} < e^{-\Omega(\lg^2(n))} < n^{-\Omega(\lg(n))}$ .

We can now union bound over all edges to get a TVD between running the procedure  $F$   $\binom{n}{2} \lg^2(n)$  times and Erdős-Rényi graphs of at most  $n^{-\Omega(\lg(n))} = 2^{-\Omega(\lg^2(n))}$ . ◀

### B.3 Proof of Span Lower Bound in the Binary-Forking Model

► **Theorem 24.** *The span per update for dynamic boolean formula evaluation is  $\Omega(\log n)$  in the binary forking model.*

**Proof.** We first show the work lower bound for a single update (or, the time required per update), and then using the work lower bound we compute the span lower bound in the binary-forking model. From Theorem 12, we know that the lower bound of work per update is  $n^c$  where  $c = \Theta(1)$  for constant  $k$ .

In the binary forking model [12], it takes  $\Omega(\log t)$  time to launch  $t$  threads. This is due to spawning  $t$  threads in a binary tree fashion where there are  $t$  leaves in the binary tree and the height is  $\log t$ . The height  $\log t$  specifies the span of this launching process.

Let  $p$  be the number of processors used for the dynamic formula evaluation problem with  $n$  variables. The span  $T_\infty(n)$  in the binary forking model is lower bounded by  $n^c/p$  and  $\log p$ . Combining them, we get the following:

$$T_\infty(n) = \Omega(n^c/p + \log p)$$

Minimizing  $T_\infty(n)$  over values of  $p$ , we get  $T_\infty(n) = \Omega(\log n)$ . ◀

# Shortest Beer Path Queries in Outerplanar Graphs

## Abstract

A *beer graph* is an undirected graph  $G$ , in which each edge has a positive weight and some vertices have a beer store. A *beer path* between two vertices  $u$  and  $v$  in  $G$  is any path in  $G$  between  $u$  and  $v$  that visits at least one beer store.

We show that any outerplanar beer graph  $G$  with  $n$  vertices can be preprocessed in  $O(n)$  time into a data structure of size  $O(n)$ , such that for any two query vertices  $u$  and  $v$ , (i) the weight of the shortest beer path between  $u$  and  $v$  can be reported in  $O(\alpha(n))$  time (where  $\alpha(n)$  is the inverse Ackermann function), and (ii) the shortest beer path between  $u$  and  $v$  can be reported in  $O(L)$  time, where  $L$  is the number of vertices on this path. Both results are optimal, even when  $G$  is a beer tree (i.e., a beer graph whose underlying graph is a tree).

## 1 Introduction

Imagine that you are going to visit a friend and, not wanting to show up empty handed, you decide to pick up some beer along the way. In this paper we determine the fastest way to go from your place to your friend’s place while stopping at a beer store to buy some drinks.

A *beer graph* is a undirected graph  $G = (V, E)$ , in which each edge  $(u, v)$  has a positive weight  $\omega(u, v)$  and some of the vertices are beer stores. For two vertices  $u$  and  $v$  of  $G$ , we define the *shortest beer path* from  $u$  to  $v$  to be the shortest (potentially non-simple) path that starts at  $u$ , ends at  $v$ , and visits at least one beer store. We denote this shortest path by  $SP_B(u, v)$ . The *beer distance*  $\text{dist}_B(u, v)$  between  $u$  and  $v$  is the weight of the path  $SP_B(u, v)$ , i.e., the sum of the edge weights on  $SP_B(u, v)$ .

Observe that even though the shortest beer path from  $u$  to  $v$  may be a non-simple path, it is always composed of two simple paths: the shortest path from  $u$  to a beer store and the shortest path from this same beer store to  $v$ . Thus, when looking at the shortest beer path problem, we often need to consider the shortest path between vertices. We denote the shortest path in  $G$  from  $u$  to  $v$  by  $SP(u, v)$  and we use  $\text{dist}(u, v)$  to denote the weight of this path. We also say that  $\text{dist}(u, v)$  is the *distance* between  $u$  and  $v$  in  $G$ .

To the best of our knowledge, the problem of computing shortest beer paths has not been considered before. Let  $s$  be a fixed source vertex of  $G$ . Recall that Dijkstra’s algorithm computes  $\text{dist}(s, v)$  for all vertices  $v$ , by maintaining a “tentative distance”  $\delta(v)$ , which is the weight of the shortest path from  $s$  to  $v$  computed so far. If we also maintain a “tentative beer distance”  $\delta_B(v)$  (which is the weight of the shortest beer path from  $s$  to  $v$  that has been found so far), then a modification of Dijkstra’s algorithm allows us to compute  $\text{dist}_B(s, v)$  for all vertices  $v$ , in  $O(|V| \log |V| + |E|)$  total time.

As far as we know, no non-trivial results are known for beer distance queries. In this case, we want to preprocess the beer graph  $G$  into a data structure, such that, for any two query vertices  $u$  and  $v$ , the shortest beer path  $\text{SP}_B(u, v)$ , or its weight  $\text{dist}_B(u, v)$ , can be reported.

## 1.1 Our Results

We present data structures that can answer shortest beer path queries in outerplanar beer graphs. Recall that a graph  $G$  is *outerplanar*, if  $G$  can be embedded in the plane, such that all vertices are on the outer face, and no two edges cross.

Our first result is stated in terms of the inverse Ackermann function. We use the definition as given in [3]: Let  $A_0(i) = i + 1$  and, for  $\ell \geq 0$ ,  $A_{\ell+1}(i) = A_\ell^{(i+1)}(i + 8)$ , where  $A_\ell^{(i+1)}$  is the function  $A_\ell$  iterated  $i + 1$  times. We define  $\alpha(m, n)$  to be the smallest value of  $\ell$  for which  $A_\ell(\lfloor m/n \rfloor) > n$ , and we define  $\alpha(n) = \alpha(n, n)$ .

► **Theorem 1.** *Let  $G$  be an outerplanar beer graph with  $n$  vertices. For any integer  $m \geq n$ , we can preprocess  $G$  in  $O(m)$  time into a data structure of size  $O(m)$ , such that for any two query vertices  $u$  and  $v$ , both  $\text{dist}(u, v)$  and  $\text{dist}_B(u, v)$  can be computed in  $O(\alpha(m, n))$  time.*

By taking  $m = n$ , both the preprocessing time and the space used are  $O(n)$ , and for any two query vertices  $u$  and  $v$ , both  $\text{dist}(u, v)$  and  $\text{dist}_B(u, v)$  can be computed in  $O(\alpha(n))$  time.

As another example, let  $\log^* n$  be the number of times the function  $\log$  must be applied, when starting with the value  $n$ , until the result is at most 1, and let  $\log^{**} n$  be the number of times the function  $\log^*$  must be applied, again starting with  $n$ , until the result is at most 1. Let  $m = n \log^{**} n$ . Since  $\alpha(m, n) = O(1)$ , we obtain a data structure with space and preprocessing time  $O(n \log^{**} n)$  that can answer both distance and beer distance queries in  $O(1)$  time.

As we mentioned before, beer distance queries have not been considered for any class of graphs. In fact, the only result on (non-beer) distance queries in outerplanar graphs that we are aware of is by Djidjev *et al.* [5]. They show that an outerplanar graph with  $n$  vertices can be preprocessed in  $O(n \log n)$  time into a data structure of size  $O(n \log n)$ , such that any distance query can be answered in  $O(\log n)$  time. Our result in Theorem 1 significantly improves their result.

We also show that the result in Theorem 1 is optimal for beer distance queries, even if  $G$  is a *beer tree* (i.e., a beer graph whose underlying graph is a tree). We do not know if the query time is optimal for (non-beer) distance queries.

Our second result is on reporting the shortest beer path between two query vertices.

► **Theorem 2.** *Let  $G$  be an outerplanar beer graph with  $n$  vertices. We can preprocess  $G$  in  $O(n)$  time into a data structure of size  $O(n)$ , such that for any two vertices  $u$  and  $v$ , the shortest beer path from  $u$  to  $v$  can be reported in  $O(L)$  time, where  $L$  is the number of vertices on this beer path.*

Observe that the query time in Theorem 2 does not depend on the number  $n$  of vertices of the graph. Again, we are not aware of any previous work on reporting shortest beer paths. Djidjev *et al.* [5] show that, after  $O(n \log n)$  preprocessing and using  $O(n \log n)$  space, the shortest (non-beer) path between two query vertices can be reported in  $O(\log n + L)$  time, where  $L$  is the number of vertices on the path.

## 1.2 Preliminaries and Organization

Throughout this paper, we only consider outerplanar beer graphs  $G$ . The number of vertices of  $G$  is denoted by  $n$ . It is well known that  $G$  has at most  $2n - 3$  edges. As in [5], we say that  $G$  satisfies the *generalized triangle inequality*, if for every edge  $(u, v)$  in  $G$ ,  $\text{dist}(u, v) = \omega(u, v)$ , i.e., the shortest path between  $u$  and  $v$  is the edge  $(u, v)$ .

The outerplanar graph  $G$  is called *maximal*, if adding an edge between any two non-adjacent vertices of  $G$  results in a graph that is not outerplanar. In this case, the number of edges is equal to  $2n - 3$ . A maximal outerplanar graph  $G$  is 2-connected, each internal face of  $G$  is a triangle and the outer face of  $G$  forms a Hamiltonian cycle. In such a graph, edges on the outer face will be referred to as *external* edges, where all other edges will be referred to as *internal* edges.

The *weak dual* of a maximal outerplanar graph  $G$  is the graph  $D(G)$  whose node set is the set of all internal faces of  $G$ , and in which  $(F, F')$  is an edge if and only if the faces  $F$  and  $F'$  share an edge in  $G$ ; see Figure 1. For simplicity, we will refer to  $D(G)$  as the dual of  $G$ . Observe that  $D(G)$  is a tree with  $n - 2$  nodes, each of which has degree at most three.

■ **Figure 1** A maximal outerplanar graph shown in black. Its dual is shown in red.

If  $H$  is a subgraph of the beer graph  $G$ , and  $u$  and  $v$  are vertices of  $H$ , then  $\text{dist}(u, v, H)$  and  $\text{dist}_B(u, v, H)$  denote the distance and beer distance between  $u$  and  $v$  in  $H$ , respectively. The shortest beer path in  $H$  between  $u$  and  $v$  must be entirely within  $H$ . Observe that we use the shorthand  $\text{dist}(u, v)$  for  $\text{dist}(u, v, G)$ , and  $\text{dist}_B(u, v)$  for  $\text{dist}_B(u, v, G)$ .

It will not be surprising that the algorithms for computing shortest beer paths use the dual  $D(G)$ . Thus, our algorithms will need some basic data structures on trees. These data structures will be presented in Section 2.

In Section 3, we will prove Theorem 1 for maximal outerplanar beer graphs. We also prove that the result in Theorem 1 is optimal, even for beer trees. The proof of Theorem 2, again for maximal outerplanar beer graphs, will be presented in Section 4. The extensions of these theorems to arbitrary outerplanar beer graphs will be given in the full version of this paper. The full version will also present an  $O(n)$ -time algorithm for computing the single-source shortest beer path tree for any given source vertex.

## 2 Query Problems on Trees

Our algorithms for computing beer shortest paths in an outerplanar graph  $G$  will use the dual of  $G$ , which is a tree. In order to obtain fast implementations of these algorithms, we need to be able to solve several query problems on this tree. In this section, we present all query problems that will be used in later sections.

► **Lemma 3.** *Let  $T$  be a tree with  $n$  nodes that is rooted at an arbitrary node. We can preprocess  $T$  in  $O(n)$  time, such that each of the following queries can be answered in  $O(1)$  time:*

1. *Given a node  $u$  of  $T$ , return its level, denoted by  $\text{level}(u)$ , which is the number of edges on the path from  $u$  to the root.*
2. *Given two nodes  $u$  and  $v$  of  $T$ , report their lowest common ancestor, denoted by  $\text{LCA}(u, v)$ .*
3. *Given two nodes  $u$  and  $v$  of  $T$ , decide whether or not  $u$  is in the subtree rooted at  $v$ .*
4. *Given two distinct nodes  $u$  and  $v$  of  $T$ , report the second node on the path from  $u$  to  $v$ .*
5. *Given three nodes  $u, v$ , and  $w$ , decide whether or not  $w$  is on the path between  $u$  and  $v$ .*

**Proof.** The first claim follows from the fact that by performing an  $O(n)$ -time pre-order traversal of  $T$ , we can compute  $level(u)$  for each node  $u$ . A proof of the second claim can be found in Harel and Tarjan [6] and Bender and Farach-Colton [2]. The third claim follows from the fact that  $u$  is in the subtree rooted at  $v$  if and only if  $LCA(u, v) = v$ . A proof of the fourth claim can be found in Chazelle [4, Lemma 15]. The fifth claim follows from the following observations. Assume that  $u$  is in the subtree rooted at  $v$ . Then  $w$  is on the path between  $u$  and  $v$  if and only if  $LCA(u, w) = w$  and  $w$  is in the subtree rooted at  $v$ . The case when  $v$  is in the subtree rooted at  $u$  is symmetric. Assume that  $LCA(u, v) \notin \{u, v\}$ . Then  $w$  is on the path between  $u$  and  $v$  if and only if  $w$  is on the path between  $u$  and  $LCA(u, v)$  or  $w$  is on the path between  $v$  and  $LCA(u, v)$ . ◀

## 2.1 Closest-Colour Queries in Trees

Let  $T$  be a tree with  $n$  nodes and let  $\mathcal{C}$  be a set of *colours*. For each colour  $c$  in  $\mathcal{C}$ , we are given a path  $P_c$  in  $T$ . Even though these paths may share nodes, each node of  $T$  belongs to at most a constant number of paths. This implies that the total size of all paths  $P_c$  is  $O(n)$ . We assume that each node  $u$  of  $T$  stores the set of all colors  $c$  such that  $u$  is on the path  $P_c$ .

In a *closest-colour query*, we are given two nodes  $u$  and  $v$  of  $T$ , and a colour  $c$ , such that  $u$  is on the path  $P_c$ . The answer to the query is the node on  $P_c$  that is closest to  $v$ . Refer to Figure 2 for an illustration.

■ **Figure 2** A tree  $T$  and a collection of coloured paths. For a query with nodes  $u$  and  $v$ , and color “red”, the answer is the node  $w$ .

► **Lemma 4.** *After an  $O(n)$ -time preprocessing, we can answer any closest-colour query in  $O(1)$  time.*

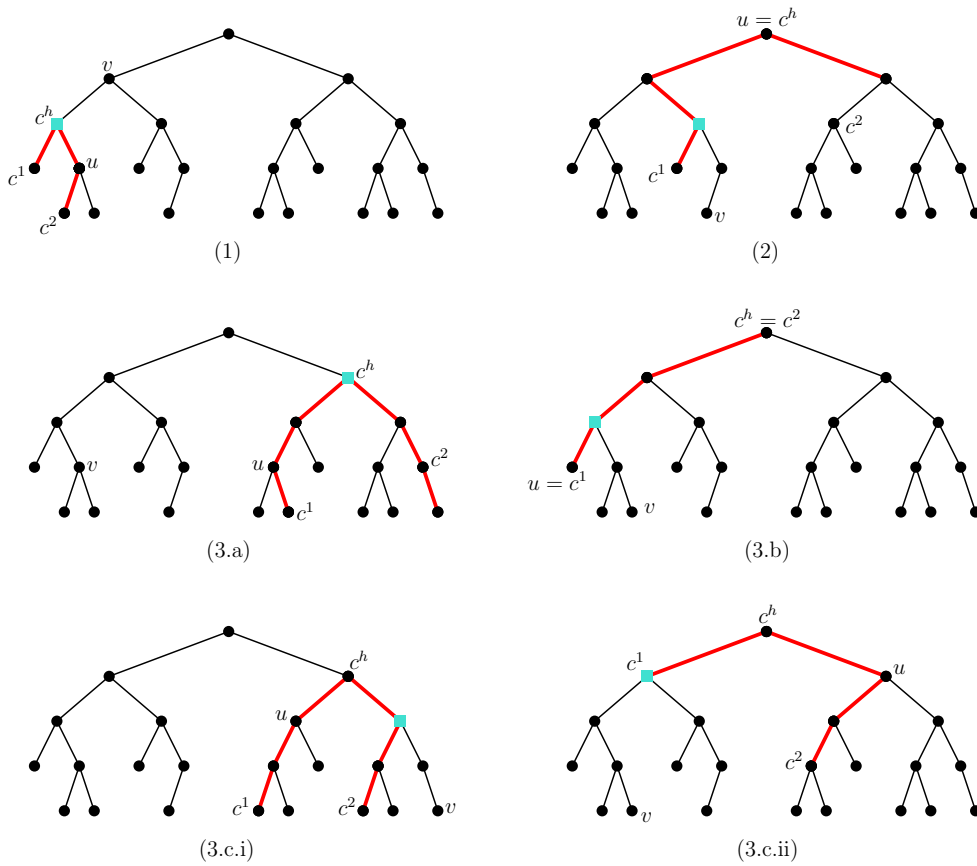

**Proof.** We take an arbitrary node of  $T$  and make it the root. Then we preprocess  $T$  such that each of the queries in Lemma 3 can be answered in  $O(1)$  time.

For each colour  $c$ , let  $c^1$  and  $c^2$  be the end nodes of the path  $P_c$ , and let  $c^h$  be the highest node on  $P_c$  in the tree (i.e., the node on  $P_c$  that is closest to the root). With each node of  $P_c$ , we store pointers to  $c^1$ ,  $c^2$ , and  $c^h$ .

Since each node of  $T$  is in a constant number of coloured paths, we can compute the pointers for all the coloured paths in  $O(n)$  total time.

The query algorithm does the following. Let  $u$  and  $v$  be two nodes of  $T$ , and let  $c$  be a colour such that  $u$  is on the  $c$ -coloured path  $P_c$ .

If  $u = v$  or  $v$  is also on  $P_c$ , then we return the node  $v$ . From now on, assume that  $u \neq v$  and  $v$  is not on  $P_c$ . Below, we consider all possible cases, which are illustrated in Figure 3.

■ **Figure 3** Illustrating all possible cases in the proof of Lemma 4. The path  $P_c$  is red and the blue square indicates the node that is returned by the closest-colour query.

1. If  $\text{LCA}(u, v) = v$ , then  $u$  is in the subtree rooted at  $v$ . In this case, we return  $c^h$ , the highest  $c$ -coloured node.
2. Assume that  $\text{LCA}(u, v) = u$ . Then  $v$  is in the subtree rooted at  $u$ . The closest  $c$ -coloured node to  $v$  is either  $\text{LCA}(v, c^1)$  or  $\text{LCA}(v, c^2)$ . Since  $v$  is lower than  $u$  in the tree, we know that the closest  $c$ -coloured node to  $v$  is at  $\text{level}(u)$  or greater. If  $\text{level}(\text{LCA}(v, c^1)) > \text{level}(\text{LCA}(v, c^2))$ , then  $\text{LCA}(v, c^1)$  is lower in the tree and closer to  $v$ , so we return  $\text{LCA}(v, c^1)$ . Otherwise,  $\text{LCA}(v, c^2)$  is lower in  $T$  or equal to both  $\text{LCA}(v, c^1)$  and  $u$ , so we return  $\text{LCA}(v, c^2)$ .
3. Assume that  $\text{LCA}(u, v) \neq u$  and  $\text{LCA}(u, v) \neq v$ . Then  $u$  and  $v$  are in different subtrees of  $\text{LCA}(u, v)$ .
  - a. If  $\text{level}(c^h) > \text{level}(\text{LCA}(u, v))$ , then we return  $c^h$ .
  - b. If  $\text{level}(c^h) < \text{level}(\text{LCA}(u, v))$ , then we return  $\text{LCA}(u, v)$ .
  - c. Assume that  $\text{level}(c^h) = \text{level}(\text{LCA}(u, v))$ . Observe that exactly one end node of the  $c$ -coloured path is in the subtree rooted at  $u$ .
    - i. If  $c^1$  is in the subtree rooted at  $u$ , then we return  $\text{LCA}(v, c^2)$ .
    - ii. If  $c^2$  is in the subtree rooted at  $u$ , then we return  $\text{LCA}(v, c^1)$ .

Using Lemma 3, each of these case takes  $O(1)$  time. Therefore, the entire query algorithm takes  $O(1)$  time. ◀

## 2.2 Path-Sum Queries in Trees

Let  $(W, \oplus)$  be a semigroup. Thus,  $W$  is a set and  $\oplus : W \times W \rightarrow W$  is an associative binary operator. We assume that for any two elements  $s$  and  $s'$  in  $W$ , the value of  $s \oplus s'$  can be computed in  $O(1)$  time.

Let  $T$  be a tree with  $n$  nodes in which each edge  $e$  stores a value  $s(e)$ , which is an element of  $W$ . For any two distinct nodes  $u$  and  $v$  in  $T$ , we define their *path-sum*  $\text{PS}(u, v)$  as follows: Let  $e_1, e_2, \dots, e_k$  be the edges on the path in  $T$  between  $u$  and  $v$ . Then we define  $\text{PS}(u, v) = \oplus_{i=1}^k s(e_i)$ .

Chazelle [4] considers the problem of preprocessing the tree  $T$ , such that for any two distinct query nodes  $u$  and  $v$ , the value of  $\text{PS}(u, v)$  can be reported. (See also Alon and Schieber [1], Thorup [8], and Chan *et al.* [3].) Chazelle's result is stated in terms of the inverse Ackermann function; see Section 1.1.

► **Lemma 5.** *Let  $T$  be a tree with  $n$  nodes in which each edge stores an element of the semigroup  $(W, \oplus)$ . For any integer  $m \geq n$ , we can preprocess  $T$  in  $O(m)$  time into a data structure of size  $O(m)$ , such that any path-sum query can be answered in  $O(\alpha(m, n))$  time.*

► **Remark 6.** Assume that  $(W, \oplus)$  is the semigroup, where  $W$  is the set of all real numbers and the operator  $\oplus$  takes the minimum of its arguments. In this case, we will refer to a query as a *path-minimum query*. For this semigroup, the result of Lemma 5 is optimal: Any data structure that can be constructed in  $O(m)$  time has worst-case query time  $\Omega(\alpha(m, n))$ . To prove this, assume that we can answer any query in  $o(\alpha(m, n))$  time. Then the on-line minimum spanning tree verification problem on a tree with  $n$  vertices and  $m \geq n$  queries can be solved in  $o(m \cdot \alpha(m, n))$  time, by performing a path-maximum query for the endpoints of each edge  $e$  and checking that the weight of  $e$  is larger than the path-maximum. This contradicts the lower bound for this problem proved by Pettie [7].

## 3 Beer Distance Queries in Maximal Outerplanar Graphs

Let  $G$  be a maximal outerplanar beer graph with  $n$  vertices that satisfies the generalized triangle inequality. We will show how to preprocess  $G$ , such that for any two vertices  $u$  and  $v$ , the weight,  $\text{dist}_B(u, v)$ , of a shortest beer path between  $u$  and  $v$  can be reported. Our approach will be to define a special semigroup  $(W, \oplus)$ , such that each element of  $W$  “contains” certain distances and beer distances. With each edge of the dual  $D(G)$ , we will store one element of the set  $W$ . As we will see later, a beer distance query can then be reduced to a path-sum query in  $D(G)$ . Thus, by applying the results of Section 2.2, we will obtain a proof of Theorem 1.

We will need the first claim in the following lemma. The second claim will be used in Section 4.

► **Lemma 7.** *Consider the beer graph  $G$  as above.*

1. *In  $O(n)$  total time, we can compute  $\text{dist}_B(u, u)$  for each vertex  $u$  of  $G$ , and  $\text{dist}_B(u, v)$  for each edge  $(u, v)$  in  $G$ .*
2. *After an  $O(n)$ -time preprocessing of  $G$ , we can report,*
  - a. *for any query edge  $(u, v)$  of  $G$ , the shortest beer path between  $u$  and  $v$  in  $O(L)$  time, where  $L$  is the number of vertices on this path,*
  - b. *for any query vertex  $u$  of  $G$ , the shortest beer path from  $u$  to itself in  $O(L)$  time, where  $L$  is the number of vertices on this path.*

**Proof.** We choose an arbitrary face  $R$  of  $G$  and make it the root of  $D(G)$ . Let  $(u, v)$  be any edge of  $G$ . This edge divides  $G$  into two outerplanar subgraphs, both of which contain  $(u, v)$  as an edge. Let  $G_{uv}^R$  be the subgraph that contains the face  $R$ , and let  $G_{uv}^{-R}$  denote the other subgraph. Note that if  $(u, v)$  is an external edge, then  $G_{uv}^R = G$  and  $G_{uv}^{-R}$  consists of the single edge  $(u, v)$ . By the generalized triangle inequality, the shortest beer path between  $u$  and  $v$  is completely in  $G_{uv}^R$  or completely in  $G_{uv}^{-R}$ . The same is true for the shortest beer path from  $u$  to itself. Thus, for each edge  $(u, v)$  of  $G$ ,

$$\text{dist}_B(u, v) = \min(\text{dist}_B(u, v, G_{uv}^R), \text{dist}_B(u, v, G_{uv}^{-R})),$$

$$\text{dist}_B(u, u) = \min(\text{dist}_B(u, u, G_{uv}^R), \text{dist}_B(u, u, G_{uv}^{-R})).$$

By performing a post-order traversal of  $D(G)$ , we can compute  $\text{dist}_B(u, v, G_{uv}^R)$  and  $\text{dist}_B(u, u, G_{uv}^{-R})$  for all edges  $(u, v)$ , in  $O(n)$  total time. After these values have been computed, we perform a pre-order traversal of  $D(G)$  and obtain  $\text{dist}_B(u, v, G_{uv}^R)$  and  $\text{dist}_B(u, u, G_{uv}^R)$ , again for all edges  $(u, v)$ , in  $O(n)$  total time. The details will be given in the full version of this paper. ◀

In the rest of this section, we assume that all beer distances in the first claim of Lemma 7 have been computed.

For any two distinct internal faces  $F$  and  $F'$  of  $G$ , let  $Q_{F,F'}$  be the union of the two sets

$$\{(u, v, \text{dist}(u, v), D) \mid u \text{ is a vertex of } F, v \text{ is a vertex of } F'\}$$

and

$$\{(u, v, \text{dist}_B(u, v), \text{BD}) \mid u \text{ is a vertex of } F, v \text{ is a vertex of } F'\},$$

where the “bits”  $D$  and  $\text{BD}$  indicate whether the tuple represents a distance or a beer distance. In words,  $Q_{F,F'}$  is the set of all shortest path distances and all shortest beer distances between a vertex in  $F$  and a vertex in  $F'$ . Since each internal face has three vertices, the set  $Q_{F,F'}$  has exactly 18 elements.

▶ **Observation 8.** *Let  $u$  and  $v$  be vertices of  $G$ , and let  $F$  and  $F'$  be internal faces that contain  $u$  and  $v$  as vertices, respectively.*

1. *If  $F = F'$ , then we can determine both  $\text{dist}(u, v)$  and  $\text{dist}_B(u, v)$  in  $O(1)$  time.*
2. *If  $F \neq F'$  and we are given the set  $Q_{F,F'}$ , then we can determine both  $\text{dist}(u, v)$  and  $\text{dist}_B(u, v)$  in  $O(1)$  time.*

**Proof.** First assume that  $F = F'$ . If  $u = v$ , then  $\text{dist}(u, v) = 0$  and  $\text{dist}_B(u, v)$  has been precomputed. If  $u \neq v$ , then  $(u, v)$  is an edge of  $G$  and, thus,  $\text{dist}(u, v) = \omega(u, v)$  and  $\text{dist}_B(u, v)$  has been precomputed.

Assume that  $F \neq F'$ . If we know the set  $Q_{F,F'}$ , then we can find  $\text{dist}(u, v)$  and  $\text{dist}_B(u, v)$  in  $O(1)$  time, because these two distances are in  $Q_{F,F'}$ . ◀

In the rest of this section, we will show that Lemma 5 can be used to compute the set  $Q_{F,F'}$  for any two distinct internal faces  $F$  and  $F'$ .

▶ **Lemma 9.** *For any edge  $(F, F')$  of  $D(G)$ , the set  $Q_{F,F'}$  can be computed in  $O(1)$  time.*

**Proof.** Let  $u$  be a vertex of  $F$  and let  $v$  be a vertex of  $F'$ . Consider the subgraph  $G[F, F']$  of  $G$  that is induced by the four vertices of  $F$  and  $F'$ ; this subgraph has five edges. By the generalized triangle inequality,  $\text{dist}(u, v) = \text{dist}(u, v, G[F, F'])$ . Thus,  $\text{dist}(u, v)$  can be computed in  $O(1)$  time.

We now show how  $\text{dist}_B(u, v)$  can be computed in  $O(1)$  time. If  $u = v$  or  $(u, v)$  is an edge of  $G$ , then  $\text{dist}_B(u, v)$  has been precomputed. Assume that  $u \neq v$  and  $(u, v)$  is not an edge of  $G$ . Let  $w$  and  $w'$  be the two vertices that are shared by  $F$  and  $F'$ . Since any path in  $G$  between  $u$  and  $v$  contains at least one of  $w$  and  $w'$ ,  $\text{dist}_B(u, v)$  is the minimum of

1.  $\text{dist}_B(u, w) + \omega(w, v)$ ,
2.  $\omega(u, w) + \text{dist}_B(w, v)$ ,
3.  $\text{dist}_B(u, w') + \omega(w', v)$ ,
4.  $\omega(u, w') + \text{dist}_B(w', v)$ .

Since  $(u, w)$ ,  $(w, v)$ ,  $(u, w')$ , and  $(w', v)$  are edges of  $G$ , all terms in these four sums have been precomputed. Therefore,  $\text{dist}_B(u, v)$  can be computed in  $O(1)$  time.

We have shown that each of the 18 elements of  $Q_{F, F'}$  can be computed in  $O(1)$  time. Therefore, this entire set can be computed in  $O(1)$  time. ◀

► **Lemma 10.** *Let  $F$ ,  $F'$ , and  $F''$  be three pairwise distinct internal faces of  $G$ , such that  $F'$  is on the path in  $D(G)$  between  $F$  and  $F''$ . If we are given the sets  $Q_{F, F'}$  and  $Q_{F', F''}$ , then the set  $Q_{F, F''}$  can be computed in  $O(1)$  time.*

**Proof.** Let  $u$  be a vertex of  $F$  and let  $v$  be a vertex of  $F''$ . Since  $G$  is an outerplanar graph, any path in  $G$  between  $u$  and  $v$  must contain at least one vertex of  $F'$ . It follows that

$$\text{dist}(u, v) = \min\{\text{dist}(u, w) + \text{dist}(w, v) \mid w \text{ is a vertex of } F'\}.$$

Thus, since  $(u, w, \text{dist}(u, w), D) \in Q_{F, F'}$  and  $(w, v, \text{dist}(w, v), D) \in Q_{F', F''}$ , the value of  $\text{dist}(u, v)$  can be computed in  $O(1)$  time.

■ **Figure 4** Any beer path from  $u$  to  $v$  contains at least one vertex of  $F'$ . In (a), we consider the shortest beer path from  $u$  to  $w$ , followed by the shortest path from  $w$  to  $v$ . In (b), we consider the shortest path from  $u$  to  $w$ , followed by the shortest beer path from  $w$  to  $v$ .

By a similar argument,  $\text{dist}_B(u, v)$  is equal to (refer to Figure 4)

$$\min\{\min(\text{dist}_B(u, w) + \text{dist}(w, v), \text{dist}(u, w) + \text{dist}_B(w, v)) : w \text{ is a vertex of } F'\}.$$

All values  $\text{dist}(u, w)$ ,  $\text{dist}(w, v)$ ,  $\text{dist}_B(u, w)$ , and  $\text{dist}_B(w, v)$  are encoded in the sets  $Q_{F, F'}$  and  $Q_{F', F''}$ . Therefore, we can compute  $\text{dist}_B(u, v)$  in  $O(1)$  time.

Thus, since each of the 18 elements of  $Q_{F, F''}$  can be computed in  $O(1)$  time, the entire set can be computed in  $O(1)$  time. ◀

We define

$$W = \{Q_{F, F'} \mid F \text{ and } F' \text{ are distinct internal faces of } G\} \cup \{\perp\},$$

where  $\perp$  is a special symbol. We define the operator  $\oplus : W \times W \rightarrow W$  in the following way.

1. If  $F$  and  $F'$  are distinct internal faces of  $G$ , then  $Q_{F,F'} \oplus Q_{F,F'} = Q_{F,F'}$ .
2. If  $F$ ,  $F'$ , and  $F''$  are pairwise distinct internal faces of  $G$  such that  $F'$  is on the path in  $D(G)$  between  $F$  and  $F''$ , then  $Q_{F,F'} \oplus Q_{F',F''} = Q_{F,F''}$ .
3. In all other cases, the operator  $\oplus$  returns  $\perp$ .

It is not difficult to verify that  $\oplus$  is associative, implying that  $(W, \oplus)$  is a semigroup. By Lemma 9, we can compute  $Q_{F,F'}$  for all edges  $(F, F')$  of  $D(G)$ , in  $O(n)$  total time.

Recall from Lemma 3 that, after an  $O(n)$ -time preprocessing, we can decide in  $O(1)$  time, for any three internal faces  $F$ ,  $F'$ , and  $F''$  of  $G$ , whether  $F'$  is on the path in  $D(G)$  between  $F$  and  $F''$ . Therefore, using Lemma 10, the operator  $\oplus$  takes  $O(1)$  time to evaluate for any two elements of  $W$ .

Finally, let  $F$  and  $F'$  be two distinct internal faces of  $G$ , and let  $F = F_0, F_1, F_2, \dots, F_k = F'$  be the path in  $D(G)$  between  $F$  and  $F'$ . Then  $Q_{F,F'} = \oplus_{i=0}^{k-1} Q_{F_i, F_{i+1}}$ . Thus, if we store with each edge of the tree  $D(G)$ , the corresponding element of the semigroup, then computing  $Q_{F,F'}$  becomes a path-sum query as in Section 2.2.

To summarize, all conditions to apply Lemma 5 are satisfied. As a result, we have proved Theorem 1 for maximal outerplanar graphs that satisfy the generalized triangle inequality.

### The Result in Theorem 1 is Optimal

In Section 2.2, see also Remark 6, we have seen path-minimum queries in a tree, in which each edge  $e$  stores a real number  $s(e)$ . In such a query, we are given two distinct nodes  $u$  and  $v$ , and have to return the smallest value  $s(e)$  among all edges  $e$  on the path between  $u$  and  $v$ . Lemma 5 gives a trade-off between the preprocessing and query times when answering such queries.

Let  $D$  be an arbitrary data structure that answers beer distance queries in any beer tree. Let  $P(n)$ ,  $S(n)$ , and  $Q(n)$  denote the preprocessing time, space, and query time of  $D$ , respectively, when the beer tree has  $n$  nodes. We will show that  $D$  can be used to answer path-minimum queries.

Consider an arbitrary tree  $T$  with  $n$  nodes, such that each edge  $e$  stores a real number  $s(e)$ . We may assume without loss of generality that  $0 < s(e) < 1$  for each edge  $e$  of  $T$ .

By making an arbitrary node the root of  $T$ , the number of edges on the path in  $T$  between two nodes  $u$  and  $v$  is equal to

$$\text{level}(u) + \text{level}(v) - 2 \cdot \text{level}(\text{LCA}(u, v)).$$

Thus, by Lemma 3, after an  $O(n)$ -time preprocessing, we can compute the number of edges on this path in  $O(1)$  time.

We create a beer tree  $T'$  as follows. Initially,  $T'$  is a copy of  $T$ . For each edge  $e = (u, v)$  of  $T'$ , we introduce a new node  $x_e$  and replace  $e$  by two edges  $(u, x_e)$  and  $(v, x_e)$ ; we assign a weight of 1 to each of these two edges. In the current tree  $T'$ , none of the nodes has a beer store. For every node  $x_e$  in  $T'$ , we introduce a new node  $x'_e$ , add the edge  $(x_e, x'_e)$ , assign a weight of  $s(e)$  to this edge, and make  $x'_e$  a beer store. Finally, we construct the data structure  $D$  for the resulting beer tree  $T'$ . Since  $T'$  has  $n + 2(n - 1) = 3n - 2$  nodes, it takes  $P(3n - 2) + O(n)$  time to construct  $D$  from the input tree  $T$ . Moreover, the amount of space used is  $S(3n - 2) + O(n)$ .

Let  $u$  and  $v$  be two distinct nodes in the original tree  $T$ , let  $\pi$  be the path in  $T$  between  $u$  and  $v$ , and let  $\ell$  be the number of edges on  $\pi$ . The corresponding path  $\pi'$  in  $T'$  between  $u$  and  $v$  has weight  $2\ell$ .

For any edge  $e$  of  $T$ , let  $\pi'_e$  be the beer path in  $T'$  that starts at  $u$ , goes to  $x_e$ , then goes to  $x'_e$  and back to  $x_e$ , and continues to  $v$ .

If  $e$  is an edge of  $\pi$ , then the weight of  $\pi'_e$  is equal to  $2\ell + 2 \cdot s(e)$ , which is less than  $2\ell + 2$ . On the other hand, if  $e$  is an edge of  $T$  that is not on  $\pi$ , then the weight of  $\pi'_e$  is at least  $2\ell + 2 + 2 \cdot s(e)$ , which is larger than  $2\ell + 2$ . It follows that the shortest beer path in  $T'$  between  $u$  and  $v$  visits the beer store  $x'_e$ , where  $e$  is the edge on  $\pi$  for which  $s(e)$  is minimum.

Thus, by computing  $\ell$  and querying  $D$  for the beer distance in  $T'$  between  $u$  and  $v$ , we obtain the smallest value  $s(e)$  among all edges  $e$  on the path in  $T$  between  $u$  and  $v$ . The query time is  $Q(3n - 2) + O(1)$ .

By combining this reduction with Remark 6, it follows that the result of Theorem 1 is optimal.

#### 4 Reporting Shortest Beer Paths in Maximal Outerplanar Graphs

Let  $G$  be a maximal outerplanar beer graph with  $n$  vertices that satisfies the generalized triangle inequality. In this section, we show that, after an  $O(n)$ -time preprocessing, we can report, for any two query vertices  $s$  and  $t$ , the shortest beer path  $\text{SP}_B(s, t)$  from  $s$  to  $t$ , in  $O(L)$  time, where  $L$  is the number of vertices on this path. As before,  $D(G)$  denotes the dual of  $G$ .

► **Observation 11.** *Let  $v$  be a vertex of  $G$ . The faces of  $G$  containing  $v$  form a path of nodes in  $D(G)$ .*

Define  $P_v$  to be the path in  $D(G)$  formed by the faces of  $G$  containing the vertex  $v$ . Let  $G[P_v]$  be the subgraph of  $G$  induced by the faces of  $G$  containing  $v$ . Note that  $G[P_v]$  has a fan shape. Let  $\text{CW}(v)$  denote the clockwise neighbor of  $v$  in  $G[P_v]$  and let  $\text{CCW}(v)$  denote the counterclockwise neighbor of  $v$  in  $G[P_v]$ . We will refer to the clockwise path from  $\text{CW}(v)$  to  $\text{CCW}(v)$  in  $G[P_v]$  as the  $v$ -chain and denote it by  $\rho_v$ . (Refer to Figure 5.)

■ **Figure 5** A maximal outerplanar graph  $G$ . The subgraphs  $G[P_v]$  and  $G[P_u]$  are shown in red and blue, respectively. Both the  $v$ -chain  $\rho_v$  and the  $u$ -chain  $\rho_u$  are shown in bold. Both paths  $P_v$  and  $P_u$  are shown in black. Observe that  $P_u$  is a single node.

► **Lemma 12.** *After an  $O(n)$ -time preprocessing, we can answer the following queries, for any three query vertices  $v$ ,  $u$ , and  $w$ , such that both  $u$  and  $w$  are on the  $v$ -chain  $\rho_v$ :*

1. Report the weight  $\text{dist}(u, w, \rho_v)$  of the path from  $u$  to  $w$  along  $\rho_v$  in  $O(1)$  time.
2. Report the path  $\text{SP}(u, w, \rho_v)$  from  $u$  to  $w$  along  $\rho_v$  in  $O(L)$  time, where  $L$  is the number of vertices on this path.

**Proof.** For any vertex  $v$  and any vertex  $u$  on  $\rho_v$ , we store the weight of the path from  $u$  to  $\text{CW}(v)$  along  $\rho_v$ . Observe that

$$\text{dist}(u, w, \rho_v) = |\text{dist}(u, \text{CW}(v), \rho_v) - \text{dist}(w, \text{CW}(v), \rho_v)|.$$

Any exterior edge in  $G$  is in exactly one chain and any interior edge in  $G$  is in exactly two chains. Thus, the sum of the number of edges on each chain is proportional to the number of edges of  $G$ , which is  $O(n)$ . ◀

► **Lemma 13.** *After an  $O(n)$ -time preprocessing, we can answer the following query in  $O(1)$  time: Given three query vertices  $v$ ,  $u$ , and  $w$ , such that both  $u$  and  $w$  are vertices of  $G[P_v]$ , report  $\text{dist}(u, w)$ , i.e., the distance between  $u$  and  $w$  in  $G$ .*

**Proof.** We get the following cases; the correctness follows from the generalized triangle inequality:

1. If  $u = w$  then  $\text{dist}(u, w) = 0$ .
2. If  $u = v$  then  $(u, w)$  is an edge and we return  $\omega(u, w)$ . Similarly if  $w = v$ , we return  $\omega(u, w)$ .
3. Otherwise  $u$  and  $w$  are both on  $\rho_v$  and we return  $\min(\text{dist}(u, w, \rho_v), \omega(u, v) + \omega(v, w))$ . ◀

► **Lemma 14.** *After an  $O(n)$ -time preprocessing, we can report, for any three vertices  $v$ ,  $u$ , and  $w$ , such that both  $u$  and  $w$  are vertices of  $G[P_v]$ ,  $\text{SP}(u, w)$  in  $O(L)$  time, where  $L$  is the number of vertices on the path.*

**Proof.** Using Lemma 13, we can determine in  $O(1)$  if the shortest path from  $u$  to  $w$  goes through  $v$  or follows the  $v$ -chain  $\rho_v$ . (Refer to Figure 6). If it goes through  $v$ , then  $\text{SP}(u, w) = (u, v, w)$ . Otherwise,  $\text{SP}(u, w)$  takes the path along  $\rho_v$  and by Lemma 12, we can find this path in  $O(L)$  time. ◀

■ **Figure 6** Two possible cases for the shortest path between  $u$  and  $w$ : (a) it goes through vertex  $v$  (shown in dashed red), or (b) it goes through the vertices of the  $v$ -chain between  $u$  and  $w$  (shown in dashed blue).

► **Lemma 15.** *After an  $O(n)$ -time preprocessing, we can report, for any three vertices  $v$ ,  $u$  and  $w$ , such that both  $u$  and  $w$  are vertices of  $G[P_v]$ , the beer distance  $\text{dist}_B(u, w)$  in  $O(1)$  time. The corresponding shortest beer path  $\text{SP}_B(u, w)$  can be reported in  $O(L)$  time, where  $L$  is the number of vertices on the path.*

**Proof.** Recall from Lemma 7 that we can compute  $\text{dist}_B(u, v)$  for every edge  $(u, v)$  in  $G$ , and  $\text{dist}_B(v, v)$  for every vertex  $v$  in  $G$ , in  $O(n)$  time.

Let  $\rho_v = (\text{CW}(v) = u_1, u_2, \dots, u_N = \text{CCW}(v))$ . Let  $A_v[\ ]$  be an array of size  $N - 1$ . For  $i = 1, \dots, N - 1$ , we set  $A_v[i] = \text{dist}_B(u_i, u_{i+1}) - \omega(u_i, u_{i+1})$ . Recall that by the generalized triangle inequality,  $\omega(u_i, u_{i+1}) = \text{dist}(u_i, u_{i+1})$ . Therefore,  $A[i]$  holds the difference between the weights of the shortest path from  $u_i$  to  $u_{i+1}$  and the shortest beer path from  $u_i$  to  $u_{i+1}$ . After preprocessing the array  $A_v[\ ]$  in  $O(N)$  time, we can conduct range minimum queries

## 62:12 Shortest Beer Path Queries in Outerplanar Graphs

in  $O(1)$  time. (Bender and Farach-Colton [2] show that these queries are equivalent to LCA-queries in the Cartesian tree of the array.) Thus, for each  $v$ -chain of  $N$  nodes, we spend  $O(N)$  time processing the  $v$ -chain. Since every edge is in at most two chains, processing all  $v$ -chains takes  $O(n)$  time and space.

Given two vertices  $u$  and  $w$  of  $G[P_v]$ , we determine the beer distance  $\text{dist}_B(u, w)$  as follows:

1. If  $u = w$  then  $\text{dist}_B(u, w)$  has already been computed by Lemma 7.
2. If  $u = v$  or  $w = v$ , then there is an edge from  $v$  to the other vertex. Thus,  $\text{dist}_B(u, w)$  has already been computed by Lemma 7.
3. Otherwise,  $u, w$  and  $v$  are three distinct vertices. Assume without loss of generality that  $w$  is clockwise from  $u$  on the  $v$ -chain. We take the minimum of the following two cases:
  - a. The shortest beer path from  $u$  to  $w$  that goes through  $v$ . Since a beer store must be visited before or after  $v$ , this beer path has a weight of  $\min(\text{dist}_B(u, v) + \omega(v, w), \omega(u, v) + \text{dist}_B(v, w))$ .
  - b. The shortest beer path through the vertices of the  $v$ -chain. Note that this beer path will visit each vertex on the  $v$ -chain between  $u$  and  $w$ , but may go off the  $v$ -chain to visit a beer store. On  $\text{SP}_B(u, w)$ , there is one pair of vertices,  $u_i$  and  $u_{i+1}$ , such that a beer path is taken between  $u_i$  and  $u_{i+1}$ , and  $u_i$  and  $u_{i+1}$  are adjacent on the  $v$ -chain; refer to Figure 7. The shortest path is taken between all other pairs of adjacent vertices on the  $v$ -chain. From Lemma 12, we can compute  $\text{dist}(u, w, \rho_v)$  in  $O(1)$  time. The shortest beer path through the vertices of the  $v$ -chain has a weight of  $\text{dist}(u, w, \rho_v) + A_v[i]$ , where  $A_v[i]$  is the additional distance needed to visit a beer store between  $u_i$  and  $u_{i+1}$ . Let  $u$  be the  $j^{\text{th}}$  vertex on  $\rho_v$  and let  $w$  be the  $k^{\text{th}}$  vertex in  $\rho_v$ . Then  $A_v[i]$  is the minimum value in  $A_v[j, \dots, k - 1]$ . We can determine  $A_v[i]$  in constant time using a range minimum query.

Note that in case 1 and case 2,  $\text{SP}_B(u, w)$  can be constructed in  $O(L)$  time by Lemma 7. For case 3 (a) let  $p = (u, v, w)$  and for case 3 (b) let  $p = \text{SP}(u, w, \rho_v)$ . Let  $u_i, u_{i+1}$  be the pair of adjacent vertices on  $p$  between which a beer path was taken. Using Lemma 7 we can find  $\text{SP}_B(u_i, u_{i+1})$  in  $O(L)$  time. We obtain  $\text{SP}_B(u, w)$  by replacing the edge  $(u_i, u_{i+1})$  in  $p$  with  $\text{SP}_B(u_i, u_{i+1})$ . ◀

■ **Figure 7** Both figures show a shortest beer path from  $u$  to  $w$  through the vertices on the  $v$ -chain. Thicker edges on the blue beer path are edges that are traversed twice; once in each direction.

### Answering Shortest Beer Path Queries

Recall that, for any vertex  $v$  of  $G$ ,  $P_v$  denotes the path in  $D(G)$  formed by the faces of  $G$  containing  $v$ . Moreover,  $G[P_v]$  denotes the subgraph of  $G$  induced by these faces.

Consider two query vertices  $s$  and  $t$  of  $G$ . Our goal is to compute the shortest beer path  $SP_B(s, t)$ .

Let  $F_s$  and  $F_t$  be arbitrary faces containing  $s$  and  $t$ , respectively. If  $t$  is in  $G[P_s]$  then, by Lemma 15, we can construct  $SP_B(s, t)$  in  $O(L)$  time. For the remainder of this section, we assume that  $t$  is not in  $G[P_s]$ . To find  $SP_B(s, t)$ , we start by constructing a directed acyclic graph (DAG),  $H$ . In this DAG, vertices will be arranged in columns of constant size, and all edges go from left to right between vertices in adjacent columns. In  $H$ , each column will contain one vertex that is on  $SP_B(s, t)$ . First we will construct  $H$  and then we will show how we can use  $H$  to construct  $SP_B(s, t)$ . The entire construction is illustrated in Figure 8.

► **Observation 16.** Any interior edge  $(a, b)$  of  $G$  splits  $G$  into two subgraphs such that if  $s$  is in one subgraph and  $t$  is in the other, then any path in  $G$  from  $s$  to  $t$  must visit at least one of  $a$  and  $b$ .

Let  $P$  be the unique path between  $F_s$  and  $F_t$  in  $D(G)$ . Consider moving along  $P$  from  $F_s$  to  $F_t$ . Let  $F_1$  be the node on  $P_s$  that is closest to  $F_t$ , and let  $F'_1$  be the successor of  $F_1$  on  $P$ . Note that, by Lemmas 3 and 4, we can find  $F_1$  and  $F'_1$  in  $O(1)$  time.<sup>1</sup> Let  $e_1 = (a_1, b_1)$  be the edge in  $G$  shared by the faces  $F_1$  and  $F'_1$ . Since  $SP_B(s, t)$  must visit both of these faces, by Observation 16, at least one of  $a_1$  or  $b_1$  is on the shortest beer path.

We place  $s$  in the first column of  $H$  and  $a_1$  and  $b_1$  in the second column of  $H$ . We then add two directed edges from  $s$  to  $a_1$ , one with weight  $\text{dist}(s, a_1)$  and the other with weight  $\text{dist}_B(s, a_1)$ . Similarly, we add two directed edges from  $s$  to  $b_1$  with weights  $\text{dist}(s, b_1)$  and  $\text{dist}_B(s, b_1)$ .

■ **Figure 8** An outerplanar graph  $G$  (a) and the DAG  $H$  constructed for the shortest beer path query from  $s$  to  $t$  (b). The path  $P$  from  $F_s$  to  $F_t$  is shown in red. Each edge  $e_i = (a_i, b_i)$  such that  $e_i$  is shared by  $F_i$  and  $F'_i$  is shown in blue. The green edges of  $H$  represent the beer edges.

When  $i \geq 2$  we construct the  $(i + 1)^{th}$  column of  $H$  in the following way. Let  $e_{i-1} = (a_{i-1}, b_{i-1})$  be the edge shared by the faces  $F_{i-1}$  and  $F'_{i-1}$ . The  $i^{th}$  column of  $H$  contains the vertices  $a_{i-1}$  and  $b_{i-1}$ . Note that  $F'_{i-1}$  is in both  $P_{b_{i-1}}$  and  $P_{a_{i-1}}$ . Using Lemma 4, we find the node  $F_i^b$  on  $P_{b_{i-1}}$  that is closest to  $F_t$ . If the vertex  $a_{i-1}$  is not in  $F_i^b$ , then we let  $F_i = F_i^b$ . Otherwise, we let  $F_i$  be the node on  $P_{a_{i-1}}$  that is closest to  $F_t$ .

<sup>1</sup> To apply Lemma 4, we consider each vertex of  $G$  to be a colour. For each vertex  $v$  of  $G$ , the  $v$ -coloured path in the tree  $D(G)$  is the path  $P_v$ . The face  $F_1$  is the answer to the closest-colour query with nodes  $F_s$  and  $F_t$  and colour  $s$ .

## 62:14 Shortest Beer Path Queries in Outerplanar Graphs

If  $t$  is not a vertex of  $F_i$ , then let  $F'_i$  be the node that follows  $F_i$  on  $P$ ; we find  $F'_i$  using Lemma 3. Let  $e_i = (a_i, b_i)$  be the edge of  $G$  shared by the faces  $F_i$  and  $F'_i$ . In the  $(i+1)^{th}$  column, we place  $a_i$  and  $b_i$ . For each  $u \in \{a_{i-1}, b_{i-1}\}$  and each  $v \in \{a_i, b_i\}$  we add two directed edges  $(u, v)$  to the DAG, one with weight  $\text{dist}(u, v)$  and the other with weight  $\text{dist}_B(u, v)$ . If  $F_i$  is in  $P_{a_{i-1}}$ , all these vertices are in  $G[P_{a_{i-1}}]$ ; otherwise,  $F_i$  is in  $P_{b_{i-1}}$ , and all these vertices are in  $G[P_{b_{i-1}}]$ . Thus, by Lemmas 13 and 15, we can find the distances and beer distances to assign to these edges in constant time.

If  $t$  is in  $F_i$ , then in the  $(i+1)^{th}$  column we only place the vertex  $t$ . In this case, for each  $u \in \{a_{i-1}, b_{i-1}\}$ , we add two directed edges  $(u, t)$  to the DAG with weights  $\text{dist}(u, t)$  and  $\text{dist}_B(u, t)$ . At this point we are done constructing  $H$ .

We define a *beer edge* to be an edge of  $H$  that was assigned a weight of a beer path during the construction of  $H$ . We find the beer distance from  $s$  to  $t$  in  $G$  using the following dynamic programming approach in  $H$ .

Let  $M$  denote the number of columns in  $H$ . For  $i = 3, \dots, M$  and for all  $u$  in the  $i^{th}$  column of  $H$ , compute

$$\text{dist}_B(s, u) = \min \begin{cases} \text{dist}_B(s, a_{i-2}) + \text{dist}(a_{i-2}, u) \\ \text{dist}(s, a_{i-2}) + \text{dist}_B(a_{i-2}, u) \\ \text{dist}_B(s, b_{i-2}) + \text{dist}(b_{i-2}, u) \\ \text{dist}(s, b_{i-2}) + \text{dist}_B(b_{i-2}, u) \end{cases}$$

and

$$\text{dist}(s, u) = \min \begin{cases} \text{dist}(s, a_{i-2}) + \text{dist}(a_{i-2}, u) \\ \text{dist}(s, b_{i-2}) + \text{dist}(b_{i-2}, u) \end{cases}$$

The vertices  $a_{i-2}$  and  $b_{i-2}$  occur in the  $(i-1)^{th}$  column. Thus,  $\text{dist}_B(s, a_{i-2})$ ,  $\text{dist}_B(s, b_{i-2})$ ,  $\text{dist}(s, a_{i-2})$ , and  $\text{dist}(s, b_{i-2})$  will be computed before computing the values for the  $i^{th}$  column. We get  $\text{dist}(a_{i-2}, u)$ ,  $\text{dist}_B(a_{i-2}, u)$ ,  $\text{dist}(b_{i-2}, u)$  and  $\text{dist}_B(b_{i-2}, u)$  from the weights of the DAG-edges between the  $(i-1)^{th}$  and  $i^{th}$  columns of  $H$ .

By keeping track of which expression produced  $\text{dist}_B(s, u)$  and  $\text{dist}(s, u)$ , we can backwards reconstruct the shortest beer path in the DAG. Knowing the shortest beer path in the DAG enables us to construct the corresponding beer path in  $G$  as follows.

1. Define  $P_{st}$  to be an empty path.
2. For each edge  $(w, v)$  of the shortest beer path in the DAG.
  - a. If  $(w, v)$  was a beer edge, let  $P_{wv} = \text{SP}_B(w, v)$ , which can be constructed in time proportional to its number of vertices via Lemma 15.
  - b. Otherwise, let  $P_{wv} = \text{SP}(w, v)$  which can be constructed in time proportional to its number of vertices as seen in Lemma 14.

Let  $P_{st} = P_{st} \cup P_{wv}$ .

3. Return  $P_{st}$ , which is equal to  $\text{SP}_B(w, v)$ .

Let  $L$  denote the number of vertices on  $\text{SP}_B(s, t)$ . In order for the above query algorithm to take  $O(L)$  time, the size of the DAG must be  $O(L)$ . The following three lemmas will show this to be true.

► **Lemma 17.** For  $2 \leq i < M - 1$ ,  $F_i$  contains either  $a_{i-1}$  or  $b_{i-1}$ , but not both.

**Proof.** Recall that we defined  $F_i^b$  to be the last node on  $P$  that is also on  $P_{b_{i-1}}$ . We similarly define  $F_i^a$  to be the last node on  $P$  that is also on  $P_{a_{i-1}}$ . From the way we choose  $F_i$ ,  $F_i$  is either  $F_i^b$  or  $F_i^a$ . We only choose  $F_i = F_i^b$  after having checked that  $a_{i-1}$  is not in  $F_i^b$ ; thus in this case we can be sure that  $F_i$  only contains  $b_{i-1}$ .

Assume for the purpose of contradiction that we choose  $F_i = F_i^a$  and  $b_{i-1}$  is also in  $F_i$ . Let the third vertex of  $F_i$  be  $c$ . Let the face on  $P$  immediately following  $F_i$  be  $F'_i$ . The edge shared by  $F_i$  and  $F'_i$  is either  $(b_{i-1}, c)$  or  $(a_{i-1}, c)$ . If  $(b_{i-1}, c)$  is the shared edge, then  $F'_i$  is a face closer to  $F_t$  that contains  $b_{i-1}$  and not  $a_{i-1}$ , so we would have chosen  $F_i = F_i^b$ , which is a contradiction. Otherwise,  $(a_{i-1}, c)$  is the edge shared by  $F_i$  and  $F'_i$ , which implies that there is a face containing  $a_{i-1}$  closer to  $F_t$  in  $P$  than  $F_i^a$ , which contradicts the definition of  $F_i^a$ . ◀

► **Lemma 18.** *Every vertex of  $G$  appears in at most one column of  $H$ .*

**Proof.** Since  $(a_1, b_1)$  is an edge shared by both the last face of  $P$  containing  $s$  and the first face of  $P$  that does not contain  $s$  it is not possible for either of these vertices to be the vertex  $s$ . Thus,  $s$  will only be represented by the vertex in the first column of  $H$ . By stopping the construction of  $H$  as soon as we add a vertex representing  $t$ , we ensure that  $H$  only contains one vertex corresponding to the vertex  $t$  in  $G$ .

For  $2 \leq i \leq M - 2$ , consider the vertex  $a_{i-1}$  in  $G$  represented by a vertex in the  $i^{\text{th}}$  column of  $H$ . If  $F_i = F_i^a$  then by definition of  $F_i^a$ ,  $F'_i$  does not contain  $a_{i-1}$ . Since  $(a_i, b_i)$  is an edge of  $F'_i$ ,  $a_i \neq a_{i-1}$  and  $b_i \neq a_{i-1}$ . Because the face  $F'_i$  is closer to  $F_t$  than  $F_i^a$ ,  $a_{i-1}$  is not a vertex on any of the faces on the path from  $F'_i$  to  $F_t$ . Thus, subsequent columns of  $H$  will not contain vertices representing the vertex  $a_{i-1}$  in  $G$ .

If  $F_i = F_i^b$  then by Lemma 17,  $a_{i-1}$  is not in  $F_i$  and since  $(a_i, b_i)$  is an edge of  $F_i$ ,  $a_i \neq a_{i-1}$  and  $b_i \neq a_{i-1}$ . Because  $F_i$  is a face on  $P$  closer to  $F_t$  than  $F_{i-1}$  (a face that contains  $a_{i-1}$ ) it follows from Observation 11 that none of the faces on  $P$  from  $F_{i-1}$  to  $F_t$  will have the vertex  $a_{i-1}$  on their face and, thus,  $a_{i-1}$  will not be represented by vertices in subsequent columns of  $H$ .

By switching the roles of  $a_{i-1}$  with  $b_{i-1}$  in the above reasoning we can see that this also holds for  $b_{i-1}$ . ◀

► **Lemma 19.** *The number of vertices and edges of  $H$  is  $O(L)$ .*

**Proof.** By Observation 16 and Lemma 18, the number of columns of  $H$  is at most  $L$ . Since each column has at most two vertices, each of which having at most four outgoing edges, the total number of vertices and edges of  $H$  is  $O(L)$ . ◀

Observe that the total preprocessing time is  $O(n)$ . For two query vertices  $s$  and  $t$ , the DAG,  $H$ , can be constructed in  $O(L)$  time. Finally, the dynamic programming algorithm on  $H$  takes  $O(L)$  time. Thus, we have proved Theorem 2 for maximal outerplanar graphs that satisfy the generalized triangle inequality.

## Abstract

The problem of graph REACHABILITY is to decide whether there is a path from one vertex to another in a given graph. In this paper, we study the REACHABILITY problem on three distinct graph families - intersection graphs of Jordan regions, unit contact disk graphs (penny graphs), and chordal graphs. For each of these graph families, we present space-efficient algorithms for the REACHABILITY problem.

For intersection graphs of Jordan regions, we show how to obtain a “good” *vertex separator* in a space-efficient manner and use it to solve the REACHABILITY in polynomial time and  $O(m^{1/2} \log n)$  space, where  $n$  is the number of Jordan regions, and  $m$  is the total number of crossings among the regions. We use a similar approach for chordal graphs and obtain a polynomial time and  $O(m^{1/2} \log n)$  space algorithm, where  $n$  and  $m$  are the number of vertices and edges, respectively. However, for unit contact disk graphs (penny graphs), we use a more involved technique and obtain a better algorithm. We show that for every  $\epsilon > 0$ , there exists a polynomial time algorithm that can solve REACHABILITY in an  $n$  vertex directed penny graph, using  $O(n^{1/4+\epsilon})$  space. We note that the method used to solve penny graphs does not extend naturally to the class of geometric intersection graphs that include arbitrary size cliques.

## 1 Introduction

Given a directed graph  $G = (V, E)$  and two of its vertices  $s$  and  $t$ , the problem of REACHABILITY is to decide if there exists a path from  $s$  to  $t$  in  $G$ . REACHABILITY is one of the fundamental problems in theoretical computer science, and for directed and undirected graphs the problem is known to be complete for the classes NL and L, respectively (see [26, 28]). The famous open question  $L \stackrel{?}{=} NL$  essentially asks if there exists a deterministic log-space algorithm for REACHABILITY or not. Note that REACHABILITY can be solved in  $\Theta(n \log n)$  space and optimal time by using standard graph traversal algorithms such as DFS and BFS. Furthermore, it is known that this problem can be solved in  $\Theta(\log^2 n)$ -space and  $n^{\Theta(\log n)}$  time [32].

In the realm of space-efficient algorithms, the primary objective is to optimize the space-complexity of an algorithm while maintaining a polynomial-time bound. Wigderson asked in his survey of REACHABILITY problems [33], whether there is an algorithm for REACHABILITY that runs in  $O(n^{1-\epsilon})$  space (for some  $\epsilon > 0$ ) and polynomial time. Barnes et al. [6] partially answered this question and showed that REACHABILITY on general graphs can be solved in polynomial time and  $O(n/2^{\Theta(\sqrt{\log n})})$  space. This result is followed by numerous works on various restricted graph families.

Asano and Doerr [3] presented an algorithm for grid graphs that uses  $O(n^{1/2+\varepsilon})$ -space, for any small  $\varepsilon > 0$ . Imai et al. [23] achieved the similar space bound for planar graphs. Later, Asano et al. [4] improved the space bound to  $\tilde{O}(n^{1/2})$  for planar graphs. Recently, this bound has been improved to  $O(n^{1/4+\varepsilon})$  for grid graphs [24]. Besides, Chakraborty et al. [10] studied REACHABILITY for graphs with higher genus and gave an  $\tilde{O}(n^{2/3}g^{1/3})$ -space bound algorithm, and an  $\tilde{O}(n^{2/3})$  space algorithm for H minor-free graphs.

For layered planar graphs, Chakraborty and Tewari [11] showed that there is an  $O(n^\varepsilon)$ -space and polynomial algorithm. Gupta et al. [20] showed that given a pair  $\{s, t\}$  and an embedding of an  $O(\log n)$  genus graphs, REACHABILITY from  $s$  to  $t$  in  $G$  can be decided *unambiguously* in logspace (i.e. REACHABILITY is in the class UL).

Tree-decomposition and associated *treewidth* is an important notion of the graphs. Many problems which are computationally hard on general graphs are efficiently solvable on graphs of bounded Treewidth [1]. Graphs of small Treewidth also have small *vertex-separators*, which is a small set of vertices of the graph, removal of which divides the graph into pieces whose size are at most a fraction of the original graph. Recently, Jain and Tewari [25] showed that given an  $n$  vertex directed graph of treewidth  $w$  along with its tree decomposition, there exists an algorithm for REACHABILITY problem that runs polynomial time and  $O(w \log n)$  space. They achieved this result by using the vertex separator of small Treewidth graphs. In fact, they formalized the connection between *Vertex Separator* and REACHABILITY problems, which has several consequences. For the sake of completeness, we state their result below.

► **Theorem 1** ([25]). *Let  $\mathcal{G}$  be a class of directed graphs and  $w : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$  be a function. If there exist an  $O(w(n, m) \log n)$  space and polynomial time algorithm, that given a graph  $G \in \mathcal{G}$  of  $n$  vertices and  $m$  edges, and a set  $U$  of  $V(G)$ , outputs a separator of  $U$  in underlying undirected graph of  $G^1$  of size  $O(w(n, m))$ , then there exists an algorithm to decide REACHABILITY in  $G$  that uses  $O(w(n, m) \log n)$  space and polynomial time.*

In this paper, we study the REACHABILITY problem on directed geometric graph families. Many important graph families can be described as intersection graphs of more restricted types of set families. More often than not, the geometric intersection graph families provide additional geometric structures that help to generate efficient algorithms. Many problems that are NP-complete on general graphs are tractable on geometric intersection graphs [13, 22]. Indeed, such advantages have been exploited for space-efficient algorithms as well. We refer to the survey on geometric algorithms with limited work-space [5].

In this work, we make progress towards answering the question raised by Wigderson in his survey [33]. We primarily design and use the *Vertex separator* of some geometric graphs space-efficiently. Previously, vertex separators in the context of geometric graphs have been studied by Fox and Pach [16], who established several geometric extensions of the famous Lipton-Tarjan separator theorem [27]. Recently, Carmi et al. [8], and Hoffmann et al. [21] established improved bounds on the size of separators for some restricted classes of geometric graphs.

## 1.1 Our Contribution

We study the REACHABILITY problem on three different graph families – intersection Graphs of Jordan Regions, Unit Contact Disk Graphs (Penny Graphs) and Chordal Graphs.

---

<sup>1</sup> For a directed graph  $G$ , its *underlying undirected graph* is the graph formed by removing the orientation of all the edges.

First, in Section 2, we show that given a collection of Jordan regions, there exists a polynomial time algorithm that computes a separator of size  $O(m^{1/2})$  using  $O(m^{1/2} \log n)$  space, where  $n$  is the number of Jordan regions and  $m$  is the total number of crossings among those regions. Then, by combining this with Theorem 1, we note that REACHABILITY on directed intersection graphs of Jordan regions can be solved in polynomial time and  $O(m^{1/2} \log n)$  space.

In Section 3, we present a space-efficient algorithm for REACHABILITY on penny graphs that uses  $O(n^{1/4+\epsilon})$  space and polynomial time. Since penny graphs are a subclass of planar graphs, REACHABILITY can be solved for penny graphs in  $O(n^{1/2} \log n)$  space. However, to reduce the space complexity, we use an involved technique. First, we use the axis-parallel separator of Carmi et al. [8] repeatedly to form rectangular subdivision such that each cell of a subdivision contains a bounded size subgraph of the input graph. Then using these subdivisions, we construct a smaller auxiliary graph that preserves REACHABILITY information. Finally, using a notion of *pseudo-separator*, we solve REACHABILITY in this auxiliary graph in a space-efficient manner. Note that, there exists a  $O(n^{1/4+\epsilon})$  space and polynomial time algorithm for reachability in grid graphs [24]. Since grid graphs are a subclass of penny graphs, our result is a generalization and improvement of previously known results.

Finally, in Section 4, we adopt the algorithm of [19] for REACHABILITY on chordal graphs to provide a space-efficient and polynomial time algorithm.

Even though chordal graphs seem to be an exception in the context of geometric graph families, we note that there exists work representing chordal graphs as a subfamily of string graphs [12]. Moreover, it is known that chordal graphs can be characterized as intersection graphs of sub-trees of a tree [18], and interval graphs are a subfamily of chordal graphs.

## 1.2 Preliminaries

Throughout the text, we denote the set  $\{1, 2, \dots, n\}$  as  $[n]$ . For a graph  $G = (V, E)$  and a subset  $U \subseteq V$ ,  $G[U]$  denotes the subgraph induced on  $U$ . Given a graph  $G = (V, E)$  with vertex set  $V$  and edge set  $E$ , a weight function  $w : V \rightarrow R_{\geq 0}$  is a non-negative function on  $V$  such that the sum of the weights is 1. For any subset  $S \subseteq V$ , the weight  $w(S)$  is defined to be  $\sum_{v \in S} w(v)$ . A separator in a graph  $G$  with respect to a weight function  $w$  is a subset  $S \subseteq V$  of vertices such that there is a partition  $V = S \cup V_1 \cup V_2$  such that  $w(V_1), w(V_2) \leq 2/3$  and there are no edges between  $V_1$  and  $V_2$ . If the weight function is not specified, it is assumed that  $w(v) = \frac{1}{|V|}$ , for every vertex  $v$ . We refer to Arora and Barak [2] for a basic understanding of the model and terminologies for space-efficient algorithms.

## 2 Intersection Graphs of Jordan Regions

In this section, we study the REACHABILITY problem on the intersection graphs of Jordan regions. Let  $\mathcal{C}$  be a set such that each element  $C$  of  $\mathcal{C}$  is a simply connected compact region in a plane bounded by a closed Jordan curve. Let  $G(\mathcal{C})$  be an intersection graph on  $\mathcal{C}$ , where two distinct elements  $C_1, C_2 \in \mathcal{C}$  are adjacent if and only if their intersection is not empty. Additionally, each edge of  $G(\mathcal{C})$  is a directed edge. A Jordan region  $A$  *contains* another Jordan region  $B$  if  $A \subseteq \text{int}(B)$ , where  $\text{int}(B)$  is the interior of  $B$ . We assume that no point is a boundary point of three elements of  $\mathcal{C}$ , and each element of  $\mathcal{C}$  intersects at least one other element of  $\mathcal{C}$ . Further, we may assume that the number of such intersection points is finite. In [16], Fox and Pach showed the existence of a  $O(m^{1/2})$ -size separator on a collection of Jordan regions, where  $m$  is the total number of crossings points in the boundary of Jordan regions.

■ **Figure 1** (a) An illustration of the planar embedding of the curves in  $\mathcal{C}$ . The black disk points are the intersection points from set  $A(\mathcal{C})$ , and the blue square points the three extra points from set  $B(\mathcal{C})$ . (b) An illustration of a face in the embedding and its corresponding planar triangulation. (c) Traversal of the left-face of the edge  $e = (u, v)$ .

For the purpose of computation, we work with those classes of Jordan regions that can be represented compactly, i.e., the set of  $n$  Jordan regions can be represented by  $\text{poly}(n)$  bits. Furthermore, we assume that basic operations, such as determining the intersection point of two Jordan regions and outputting a constant number of points of given Jordan regions, can be performed in log-space. We prove the following theorem about the separator. Note that any *vertex separator* of an intersection graph does not rely on the direction of the edges. Hence for ease of explanation, we drop the directions from the input graph  $G(\mathcal{C})$ .

► **Theorem 2.** *Let  $\mathcal{C}$  be a collection of Jordan regions, and let  $G(\mathcal{C})$  be an intersection graph on  $\mathcal{C}$ . Let  $w$  be a weight function on  $\mathcal{C}$ . There exists a polynomial time algorithm that takes as an input the set  $\mathcal{C}$  and outputs a separator of  $G(\mathcal{C})$  with respect to  $w$ , of size  $O(m^{1/2})$  using  $O(m^{1/2} \log n)$  space.*

We assume that the sum of the weights of the given Jordan regions is one. Let  $H(\mathcal{C})$  be the set of *heavy* regions in  $\mathcal{C}$  whose weight is more than  $1/m^{1/2}$ , and let  $L(\mathcal{C})$  be set of regions in  $\mathcal{C}$  that are involved<sup>2</sup> in at least  $\frac{1}{3}m^{1/2}$  containments with other elements of  $\mathcal{C}$ . Let  $I(\mathcal{C}) = \mathcal{C} \setminus (H(\mathcal{C}) \cup L(\mathcal{C}))$ . We define a planar graph  $G_P(\mathcal{C})$ . The vertex set of this graph is the union of two subsets, i.e.,  $A(\mathcal{C}) \cup B(\mathcal{C})$ , where  $A(\mathcal{C})$  is the set of all intersection points that lie on the boundary of at least one element of  $I(\mathcal{C})$  and  $B(\mathcal{C})$  is a collection of points not in  $A(\mathcal{C})$  such that the boundary of each  $C \in I(\mathcal{C})$  contains precisely three points in  $B(\mathcal{C})$ . There exists an edge between two vertices of  $G_P(\mathcal{C})$  if and only if there are consecutive points along the boundary of an element of  $I(\mathcal{C})$ ; see Figure 1(a).

To see that the defined graph is planar, we see that we have added a vertex at every point of intersection of the boundary of the given Jordan curves. We can now draw the edges along the boundary. We proceed with the following lemmas.

► **Lemma 3.** *There exists a log-space algorithm that takes as an input a set of Jordan regions  $\mathcal{C}$  and outputs a graph  $G_P(\mathcal{C})$ .*

**Proof.** First of all, note that there exists a log-space subroutine that on an input Jordan region  $C$  of  $\mathcal{C}$  determines if  $C$  is in  $L(\mathcal{C})$ . To do this, the subroutine iterates over all Jordan regions in  $\mathcal{C}$  and calculates the total number of containment with which  $C$  is involved. The weight of each Jordan region comes with the input. Hence it is enough for us to determine if a Jordan region  $C$  of  $\mathcal{C}$  belongs to the set  $I(\mathcal{C})$ . In order to construct the planar graph, we essentially need to know  $I(\mathcal{C})$ . Thereby concluding the proof of the Lemma. ◀

<sup>2</sup> We say that a region  $C_1$  is involved in a *containment* with a region  $C_2$  if either  $C_1$  contains  $C_2$  or  $C_2$  contains  $C_1$ .

Next, we triangulate  $G_P(\mathcal{C})$ , and denote the triangulated planar graph by  $G_T(\mathcal{C})$ . This triangulation can be obtained in log-space using the following lemma

► **Lemma 4.** *There exists an algorithm that takes a planar graph in the input and returns a triangulated planar graph in log-space.*

**Proof.** Consider a planar graph  $G_P$ . The embedding of a planar graph can be computed in log-space [15]. Note that an edge  $e_1 = (u_1, v_1)$  in  $G_P$  is part of two faces in the planar embedding of the graph. We call them the left and the right face, respectively. We explain how to traverse the left face of  $e_1$  in log-space. In order to do this, we start by traversing  $e_1$  to one of its endpoint (say  $v_1$ ) and take the edge clockwise next to  $e_1$ , that is incident on  $v_1$ . Let  $e_2$  be such an edge; see Figure 1. We continue the traversal along the edge  $e_3$ , which is the edge clockwise next to  $e_2$  from the endpoint  $v_2$  of  $e_2$ , and so on. In general, if we reach at the vertex  $v_i$  using the edge  $e_i$ , we continue along the edge clockwise next to  $e_i$  from  $v_i$ . Clearly, by following this procedure, we can traverse the boundary of the face. In order to prove this lemma, it is sufficient to show that given two vertices  $u_l$  and  $v_l$  of the input planar graph  $G_P$ , whether an edge  $e_l$  can be added between them in log-space as part of the triangulation. We assume that the vertices of the input graph  $G_P$  are indexed by an integer from 1 to  $k$ , for some  $k \in [n]$ . For each edge  $e$  that is incident with  $u$ , we first traverse the left face of  $e$  and see if (i)  $v$  is present in that face, (ii) either  $u$  or  $v$  is the lowest-indexed vertex of that face. There is a triangulated edge between  $u$  and  $v$  if and only if both these conditions are true for any such edge  $e$ ; see Figure 1(b). This concludes the proof of the lemma. ◀

Let  $d(\mathcal{C})$  be the number of points on the boundary of  $\mathcal{C}$  that belong to the vertex set of  $G_T(\mathcal{C})$ . For a vertex  $v$  in  $G_T(\mathcal{C})$ , we define a new weight function  $\text{weight}(v)$  as follows:

**Case 1:**  $v$  is part of two boundaries  $C_1$  and  $C_2$  of  $\mathcal{C}$ ,  $\text{weight}(v) = \frac{w(C_1)}{d(C_1)} + \frac{w(C_2)}{d(C_2)}$ .

**Case 2:**  $v$  is in the boundary of only one element  $C_1$  of  $\mathcal{C}$ ,  $\text{weight}(v) = \frac{w(C_1)}{d(C_1)}$ .

Fox and Pach [16] used the idea to find a cycle-separator in this triangulated graph  $G_T(\mathcal{C})$  and used it to construct a separator of the original geometric intersection graph. Instead, we will use the result of Imai et al. [23] to obtain such a separator in a space-efficient manner.

► **Lemma 5** ([23]). *Let  $G$  be a triangulated planar graph. There exists a polynomial time algorithm that uses  $O(\sqrt{n} \log n)$  space to output a separator of  $G$  of size  $O(\sqrt{n})$ .*

Now, consider the set of regions of  $\mathcal{C}$  whose boundary contains at least one of the points of the separator returned by the algorithm of Imai et al. on  $G_T(\mathcal{C})$ . We denote these regions by  $\text{sep}(\mathcal{C})$ . In the following, we show that this set is indeed the required separator. Moreover, this set can be calculated within the required space-time bounds.

► **Lemma 6.** *The set  $\text{sep}(\mathcal{C})$  is a separator of the intersection graph of  $\mathcal{C}$*

**Proof.** First of all, note that  $G_T(\mathcal{C})$  is a triangulated planar graph. Let  $S$  be the separator of this graph returned by the algorithm of Imai et al. [23]. For a triangulated graph, we observe that the separator  $S$  is a cycle. Let  $V_0$  be the set of all elements of  $\mathcal{C}$  that are either not in  $I(\mathcal{C})$ , or whose boundary contains a vertex of  $S$ . Let  $K_1$  and  $K_2$  be the set of vertices that are *inside* and *outside* the cycle  $S$ , respectively. Let  $V_i$  (for  $i \in \{1, 2\}$ ) be the set of elements of  $I(\mathcal{C})$ , such that all vertex of  $V(G_T(\mathcal{C}))$  which are on its boundary belong to the component  $K_i$ . It is easy to see that  $V_0$ ,  $V_1$ , and  $V_2$  are pairwise disjoint sets, and their union

is  $\mathcal{C}$ . If  $V_0$  has a weight of at least  $1/3$ , then we see that it act as a trivial separator. Hence, for the rest of this proof, we assume that the weight of  $V_0$  is less than  $1/3$ . Thus, we can also see that the weight of  $V_i$  is at most  $2/3$ . It only remains to show that there is no edge between a vertex of  $V_1$  and a vertex of  $V_2$ .

Let us assume, w.l.o.g., that the weight of  $V_2$  is greater than the weight of  $V_1$  and hence greater than  $1/3$ . In order to show that there is no edge between a vertex of  $V_1$  and a vertex of  $V_2$ , let us assume to the contrary that there is one such edge. Since  $V_1$  and  $V_2$  are on two different sides of a closed Jordan curve, there exists an element  $v$  of  $V_1$  that contains in its interior all the elements of  $V_2$ . The number of elements in  $V_2$  is at least  $\frac{1}{3}m^{1/2}$  contradicting the fact that  $v$  belongs to  $I(\mathcal{C})$ . ◀

Next, in the final lemma, we argue about the space-complexity of the above mentioned procedure.

► **Lemma 7.** *There exists a polynomial time algorithm that takes as an input  $\mathcal{C}$  and outputs the set  $\text{sep}(\mathcal{C})$  in  $O(m^{1/2} \log n)$  space.*

**Proof.** We first see that on input  $\mathcal{C}$ , the graph  $G_T(\mathcal{C})$  contains  $O(m)$  vertices. We can output this graph in log-space (see Lemma 4). Then, using the planar separator algorithm of Imai et al. [23], we can get a set of  $O(m^{1/2})$  vertices which acts as the separator of this graph. This process can be done in  $O(m^{1/2} \log n)$  space and polynomial time. Once we obtain this set, it is possible to construct  $\text{sep}(\mathcal{C})$  by using this set. ◀

This completes the proof of Theorem 2. Then, by combining Theorem 2 and Theorem 1, we conclude the following.

► **Corollary 8.** *There exists an algorithm that solves the REACHABILITY on the directed intersection graph of Jordan regions in polynomial time and  $O(m^{1/2} \log n)$  space.*

### 3 Unit Contact Disk Graphs (Penny Graphs)

We now study the REACHABILITY problem on directed unit contact disk graphs (penny graphs). Penny graphs are also known as unit coin graphs [9]. Let  $G = (D, E)$  be a directed penny graph, where  $D = \{d_1, \dots, d_n\}$  is a set of unit disks, and there is an edge  $e \in E$  between two disks  $d_i$  and  $d_j$  (for some  $i, j \in [n]$ ) if  $d_i$  and  $d_j$  touch each other. Moreover, each edge in  $e \in E$  is a directed edge.

We prove the following theorem.

► **Theorem 9.** *For every  $\varepsilon > 0$ , there exists a polynomial time algorithm that can solve REACHABILITY in an  $n$  vertex directed penny graph, using  $O(n^{1/4+\varepsilon})$  space.*

We know that given a set of  $n$  unit disks with  $m$  intersections, there exists an axis-parallel line intersecting  $O(\sqrt{m+n})$  disks such that each half-plane separated by that line contains at most  $4n/5$  disks [8]. They call such a separator a *balanced separator*. We first describe that how such a balanced separator can be obtained in a space-efficient manner.

Let  $R$  be a rectangular bounding box that contains the disks in  $D$ . Our algorithm to solve the REACHABILITY problem on penny graphs consists of four steps: (1) we find the balanced separators and use them to obtain a rectangular subdivision of the plane, (2) create an auxiliary graph, (3) obtain a pseudo-separator, (4) solve the REACHABILITY.

### 3.1 Obtaining Rectangular Subdivision

In this step, the direction of the edges of  $G$  is not relevant, so we simply consider the input as a set  $D$  of unit non-overlapping unit disks. The main idea is to divide the rectangle  $R$  into smaller rectangles such that each smaller rectangle contains at most  $n^{1-\varepsilon}$  unit disks, and the number of unit disks intersecting the boundary of any rectangle is at most  $n^{1/2+\varepsilon/2}$ .

In what follows, we describe a sweeping procedure. We discuss primarily in terms of vertical sweeping, and the the horizontal sweeping is done similarly.

We consider the disks in sorted order based on the x-coordinates of their corresponding centers, which can be easily done in log-space. Consider a vertical sweep line  $\ell$ . We start with the leftmost disk from  $D$  and sweep until we find a balanced separator that is intersecting  $O(\sqrt{m+n})$  many disks such that each half-plane separated by that line contains at most  $4n/5$  disks. If we do not find any such vertical separator, then we apply the same procedure with a horizontal sweep line (say  $\ell'$ ) sweeping from top to bottom. From Theorem 2 in [8], we know that there exists an axis-parallel balanced separator. Therefore, we shall obtain a balanced separator by doing this procedure.

When the sweep line  $\ell$  encounters or leaves a disk, we call it an event. There are precisely  $2n$  number of *events*. Note that it is possible to test by using  $\log n$  space whether a disk  $d_i$  intersects the line  $\ell$ . We maintain a counter  $c_\ell$  corresponding to the sweep line  $\ell$ . At each event  $k$  (for some  $k \in [n]$ ), we determine the number of disks that intersect  $\ell$ , by checking each disk that whether it is intersecting with  $\ell$  or not in log-space. Then, when the next event happens, we increase the value of the counter by 1 if it intersects a new disk, or decrease it by 1, otherwise. By using this procedure, we can find a separator line  $\ell$ , that is, a balanced separator. It is also clear that we can determine such a separator by using  $\log n$  space. Once we find such a separator, we only store the  $x$ -coordinate (resp.  $y$ -coordinate) of the vertical line  $\ell$  (resp. horizontal line  $\ell'$ ). Note that it is possible to find the actual set of disks that form such a separator in log-space when needed.

We subdivide the rectangles repeatedly until each of the rectangles has smaller than  $n^{1-\varepsilon}$  disks. Initially, we have the rectangle  $R$  containing all the disks. Let  $\mathcal{R}_0 = \{R\}$  be the initial set of rectangles. After step  $i$ , we have the rectangles  $\mathcal{R}_i$  be the set of rectangles, and We pick the rectangle with more than  $n^{1-\varepsilon}$  disks and subdivide it further using the above process to get  $\mathcal{R}_{i+1}$ . See Figure 2 for an illustration.

■ **Figure 2** An illustration of the rectangular subdivision by using the balanced separators. The blue disks are the ones intersected by the balanced separator lines, and the red disks are contained inside the rectangles.

We calculate the number of separators required to reach this termination point. From [8], we know that one  $\sqrt{m+n}$  size separator guarantees that on each side there are at most  $\frac{4n}{5}$  disks. Since the class of penny graphs is a subclass of planar graphs, the total number of

edges is at most  $3n - 6$ . Now at each step, we have obtained a *balanced separator* whenever it has satisfied the criteria. We need  $O(n^\varepsilon)$  many separators to have at most  $O(n^{1-\varepsilon})$  disks in each cell. To store these line separators, we need to use  $O(n^\varepsilon \log n)$  space.

The initial graph  $G$  is divided into  $n^\varepsilon \times n^\varepsilon$  rectangles obtained from the above procedure. Let  $\mathcal{Z}$  be the set of all rectangles. The idea is to reduce the size of the graph  $G$  by dropping the disks that are completely contained inside some rectangle and are not touched or intersected by its boundary line. However, while reducing the size of the number of disks, we need to ensure that the REACHABILITY information is fully preserved between any pair of disks in  $G$ . For that, we proceed to the next step and build an auxiliary graph.

### 3.2 Building Auxiliary Graph

For a rectangle  $R$ , let  $G_R$  be the graph defined as follows. The vertex set of  $G_R$  is the set of all disks which intersect at least one of the boundaries of  $R$ . We add an edge from a vertex  $u$  to a vertex  $v$  in  $G_R$  if there is a directed path from  $u$  to  $v$ , which contains only the disks present inside the rectangle  $R$ . Let  $v_1$  be an arbitrary disk, and let  $\{v_1, \dots, v_k\}$  be the sets of disks intersecting the boundary of  $R$  in the anti-clockwise order. We place the disk centers on the boundary while preserving (1) the order of them on the boundary, (2) each vertex  $v_i$  is on the side of the boundary that it intersects. However, if it is intersected by more than one side (one vertical and one horizontal) then we create an additional dummy vertex (say  $v'_i$ ) and assign  $v_i$  and  $v'_i$  to the horizontal and vertical side, respectively. Moreover, we add a bidirectional edge between  $v_i$  and  $v'_i$ . see Figure 3(b)) for an illustration.

The edges of  $G_R$  are drawn in the following manner. If there is an edge between two vertices that are on different sides, then we give a directed straight line edge. Otherwise, we join them by a directed circular arc. Moreover, we ensure that there is a crossing between two edges  $(v_i, v_k)$  and  $(v_l, v_j)$  in the drawing if and only if there is an ordering on the boundary which is one of the followings - 1.  $\{v_i \prec v_l \prec v_k \prec v_j\}$ , 2.  $\{v_j \prec v_l \prec v_k \prec v_i\}$ , 3.  $\{v_l \prec v_i \prec v_j \prec v_k\}$ , 4.  $\{v_l \prec v_i \prec v_j \prec v_k\}$ . Clearly, there exists such a drawing as their arc edges can be drawn arbitrarily close to the boundary lines.

■ **Figure 3** An illustration of the representation of the graph  $G_R$ , (a) the blue disks are the vertices of  $G_R$  intersecting the boundary of the rectangle (b) drawing of  $G_R$ .

Now, by combining the graphs defined for each rectangle, we define the auxiliary graph  $Aux_\varepsilon(G)$ , for  $0 < \varepsilon < 1$ . The vertex set of  $Aux_\varepsilon(G)$  is  $\bigcup_{R \in \mathcal{Z}} V(G_R)$  and the edge set is  $\bigcup_{R \in \mathcal{Z}} E(G_R)$ . Notice that  $Aux_\varepsilon(G)$  might have parallel edges, since there exists paths between vertices in two adjacent rectangles, and in that case we keep both of these edges in their respective rectangles. The total number of vertices in each cell is  $O(n^{1-\varepsilon})$ . Hence the total number of vertices in  $Aux_\varepsilon(G)$  is  $O(n^{1/2+\varepsilon/2})$ . We point out that we do not store  $Aux_\varepsilon(G)$  explicitly because that requires too much space. Instead, we deal with each cell recursively when the subroutine queries for an edge in that cell of  $Aux_\varepsilon(G)$ . Now, we prove the following property about the auxiliary graph.

► **Lemma 10.** *Let  $G$  be a penny graph and  $e = (v_i, v_j)$  and  $e' = (v_k, v_l)$  be two edges in  $Aux_\varepsilon(G)$ . If  $e$  and  $e'$  cross each other, then  $Aux_\varepsilon(G)$  also contains the edges  $(v_i, v_l)$  and  $(v_k, v_j)$ .*

**Proof.** Consider two edges  $e = (v_i, v_j)$  and  $e' = (v_k, v_l)$  be two edges in  $Aux_\varepsilon(G)$ . From the definition, these edges corresponding to the directed paths in the input graph  $G$ . From the construction, we know that the ordering of the end vertices are one of the following -  $\{v_i \prec v_l \prec v_k \prec v_j\}$ ,  $\{v_j \prec v_l \prec v_k \prec v_i\}$ ,  $\{v_l \prec v_i \prec v_j \prec v_k\}$ ,  $\{v_l \prec v_i \prec v_j \prec v_k\}$ . Now, we know that the corresponding directed paths are fully embedded inside the grid cell. If two directed path intersects in the Auxiliary graph (based on our definition) of an input penny graph, that is embedded inside a rectangle, then they must have one common vertex; see Figure 4. Otherwise, it will not admit a planar embedding. Hence, there must be directed path from  $v_i$  to  $v_l$ , and  $v_k$  to  $v_j$ . Thereby proving the lemma. ◀

■ **Figure 4** An illustration of two directed paths inside a grid cell.

### 3.3 Constructing Pseudo-Separator

An essential property of a vertex separator is that, for any two vertices  $u$  and  $v$ , a path between them must contain a vertex from the separator if  $u$  and  $v$  lie in two different components with respect to the separator. We use a separator construction for the auxiliary graph  $Aux_\varepsilon(G)$ . However, note that  $Aux_\varepsilon(G)$  is not a planar graph anymore. Therefore, we need a special kind of separator, which we call a *pseudo-separator*.

The notion of the pseudo-separator was introduced by Jain and Tewari [24] in the context of grid graphs. However, since the class of Penny graphs is a superclass of grid graphs, it is not possible to use their idea directly.

Let  $G$  be a penny graph and  $H = (V_1, E_1)$  be a vertex induced subgraph of  $Aux_\varepsilon(G)$  with  $h$  vertices. Let  $f : \mathbb{N} \rightarrow \mathbb{N}$  be a function. A subgraph  $C = (V_2, E_2)$  of  $H$  is said to be an  $f(h)$ -PseudoSeparator of  $H$ , if the size of every connected component in  $H \cdot C$  is at most  $f(h)$ , where the graph  $H \cdot C = (V_3, E_3)$  is defined as  $V_3 = V_1 \setminus V_2$  and  $E_3 = E_1 \setminus \{e \in E_1 \mid \exists e' \in E_2, e \text{ crosses } e'\}$ . The size of  $C$  is the total number of vertices and edges of  $C$  summed together.

The general idea of our approach is the following. Consider a vertex induced subgraph  $H$  of  $Aux_\varepsilon(G)$ . We choose a maximal subset of edges such that  $H$  is a planar graph, thus admits a planar embedding. Next, we triangulate this chosen sub-graph. We show that until this point, each operation can be performed in log-space. Then, we use the algorithm of Imai et al. [23] to obtain a separator of the triangulated graph. In what follows, we describe these procedures in detail.

We start with a maximal planar graph  $H(Aux_\varepsilon(G))$  of  $Aux_\varepsilon(G)$ . The vertex set of  $H(Aux_\varepsilon(G))$  is same as the vertex set of  $Aux_\varepsilon(G)$ . For each rectangle, we index the vertices in ascending order while traversing them in anti-clockwise direction. For each rectangle  $R$ , an

edge  $e_l = (u_l, v_l)$  of  $G_R$  is added to  $H(Aux_\varepsilon(G))$  if there is no edge  $e_k = (u_k, v_k)$  such that the ordering of the vertices is one of the following -  $\{u_k \prec u_l \prec v_k \prec v_l\}$ ,  $\{v_k \prec u_l \prec u_k \prec v_l\}$ ,  $\{u_k \prec v_l \prec v_k \prec u_l\}$ ,  $\{u_k \prec v_l \prec v_k \prec u_l\}$ . We prove that,  $H(Aux_\varepsilon(G))$  is indeed a maximal planar graph of  $Aux_\varepsilon(G)$ .

► **Lemma 11.**  $H(Aux_\varepsilon(G))$  is a maximal planar graph of  $Aux_\varepsilon(G)$ .

Proof of Lemma 11 can be found in the full version [7].

Next, we triangulate  $H(Aux_\varepsilon(G))$  by adding the boundary edges. Then for each rectangle, we consider a face of  $H(Aux_\varepsilon(G))$  and add the edges to complete the triangulation by a similar procedure described in Lemma 4 from Section 2. Moreover, the direction of the edges are arbitrary. Let  $\hat{H}(Aux_\varepsilon(G))$  be the triangulated graph. Note that this procedure can be done in log-space. Next, we use a Lemma from [23] that is stated below.

► **Lemma 12** ([23]). *For each  $\beta > 0$ , there exists a polynomial time algorithm and  $\tilde{O}(h^{1/2+\beta/2})$  space algorithm that takes a  $h$ -vertex planar graph  $P$  as input and outputs a set of vertices  $S$ , such that  $|S|$  is  $O(h^{1/2+\beta/2})$  and removal of  $S$  disconnects the graph into components of size  $O(h^{1-\beta})$ .*

Next, we construct the pseudo-separator  $S_H(Aux_\varepsilon(G))$  by using the following steps. First, by Lemma 12 we find a set  $S$  in  $\hat{H}(Aux_\varepsilon(G))$  that divides it into components of size  $O(h^{1-\beta})$ , where  $h$  is the number vertices in  $\hat{H}(Aux_\varepsilon(G))$ . We add the vertices and edges of  $S$  to the vertex and edge set of  $S_H(Aux_\varepsilon(G))$ , respectively. However, there is a small caveat to use Lemma 12 on  $\hat{H}(Aux_\varepsilon(G))$ . In order to triangulate the graph, we have added edges that were originally not part of the auxiliary graph. Therefore, for each edge  $e_k = (u_k, v_k)$  of the triangulation that is present in some rectangle  $\mathcal{R}$ , we consider a set of at most four edges of  $Aux_\varepsilon(G)$  that form a so-called *shield* around the edge  $e_k$ . Two of these edges start from  $u_k$  ending at two vertices  $v_p, v'_p$ , where  $v_p$  and  $v'_p$  are the closest point to the left and closest point to the right of  $u_k$ , respectively, in the total ordering of the boundary vertices. The other two edges start from  $v_k$  and end at two vertices  $u_q, u'_q$ , where  $u_q$  and  $u'_q$  are the closest points to the right and the left of  $v_k$  respectively, in the total ordering of boundary vertices. See Figure 5(a) for an illustration. Later, we argue that if these edges do not exist, and the cycle separator intersects the corresponding triangulation edge, then there must be other edges chosen in the maximal planar graph intersecting that triangulation edge, and hence this gives a contradiction.

In order to prove that  $S_H(Aux_\varepsilon(G))$  is indeed a pseudo-separator, we need a property of triangulated graphs from [25].

► **Lemma 13** ([25]). *Let  $G$  be a triangulated planar graph and  $S$  be a subset of its vertices. For every pair of vertex  $u, v$  which belong to different components of  $G \setminus S$ , there exists a cycle in  $G[S]$ , such that  $u$  and  $v$  belong to different sides of this cycle.*

Next, we prove the Lemma about pseudo-separator.

► **Lemma 14** (Pseudo-Separator Lemma). *Let  $G$  be a penny graph and  $H(Aux_\varepsilon(G))$  be a vertex induced subgraph of  $Aux_\varepsilon(G)$ . The graph  $S_H(Aux_\varepsilon(G))$  is a  $h^{1-\beta}$ -pseudo-separator of  $H(Aux_\varepsilon(G))$ .*

**Proof.** Let  $S$  be a set of vertices chosen from  $\hat{H}(Aux_\varepsilon(G))$  by using Lemma 12. The claim is that if two vertices  $u$  and  $v$  belong to two different components in  $\hat{H}(Aux_\varepsilon(G)) \setminus S$ , then a path between  $u$  and  $v$  in  $G$  either takes a vertex of  $S_H(Aux_\varepsilon(G))$  or crosses an edge of

■ **Figure 5** An illustration of the pseudo-separator. The red edge is an edge of the triangulation and part of the red cycle separator. The yellow edges are chosen to form the shield (a) when the proper shield exists (b) otherwise.

$S_H(Aux_\varepsilon(G))$ . Note that due to Lemma 13, we know that  $u$  and  $v$  are on two different sides of a cycle of  $S$ . Thus, any edge drawn in the plane connecting  $u$  and  $v$  (not necessarily a straight line edge) crosses the cycle of  $S$ . If the path crosses non-triangulation edge or an edge which is shielded properly (see Figure 5(a)), we are done as the path will intersect an edge of  $S_H(Aux_\varepsilon(G))$ . The other situation is when such a path intersects a triangulation edge. We prove by contradiction that this can not happen. Assume that it does happen (see Figure 5(b)). Let  $e_r$  be the triangulation edge intersected by the edge  $e_b$  of the path from  $u$  to  $v$ . Now, since  $e_b$  is not chosen in the maximal planar graph, this means there exist other edges chosen in the  $H(Aux_\varepsilon(G))$ . Let  $e_o$  and  $e'_o$  be two such edges with maximum width on either side of the triangulated edge (see the orange edges in Figure 5(b)). By Lemma 10, there exists an edge  $e_g$  from the tail of  $e_o$  to the head of  $e'_o$  (the green path in Figure 5(b)). Since this edge  $e_g$  also crosses the triangulation edge  $e_r$ , it is not present in the maximal planar graph. Any edge that is present in maximal planar graph and crosses  $e_g$  contradicts the fact that  $e_o$  and  $e'_o$  are of maximum width. There are other cases when either  $e_o$  or  $e'_o$  is not present, but they can be handled similarly. Thereby concluding the proof of the Lemma. ◀

### 3.4 The Algorithm

Let  $H$  be a vertex induced subgraph of an auxiliary graph. We first explain how to solve REACHABILITY in  $H$ . Initially,  $H$  is the whole auxiliary graph, and we wish to find the REACHABILITY between given two vertices  $s$  and  $t$  of  $H$ .

By using Lemma 14, we find a pseudo-separator  $S$  of  $H$ . W.l.o.g., assume that  $s$  and  $t$  are both in  $S$ . The pseudo-separator divides the graph into components  $C_1, C_2, \dots, C_k$ , for  $k \in [h]$ . We maintain a set of vertices  $M$  that we call *marked* vertex set. We use an array of size at most  $|S|$  to mark a set of vertices  $M_1$  of the pseudo-separator. Additionally, for each edge of the pseudo-separator we have at most one associated vertex, and they form the set  $M_2$ . Then,  $M = M_1 \cup M_2$  is called a *marked* vertex set.

Throughout the algorithm, we maintain that if a vertex is marked, then there is a path from  $s$  to that vertex in the auxiliary graph. Initially, only the vertex  $s$  is marked. We then perform  $h$  iterations. In each iteration, we update the set of marked vertices as follows:

**Step 1.** For every vertex of  $S$ , we mark it if there is a path from an already marked vertex to it such that the internal vertices of that path all belong to only one component  $C_i$ , for  $i \in [h]$ . We check this by recursively running our algorithm on the subgraph of  $H$  induced by the vertex set  $C_i$ .

**Step 2.** For each edge  $e$  of  $S$ , the algorithm sets the associated marked vertex to  $u$  if the following three conditions are satisfied: (a) There exists an edge  $e' = (u, v)$  which crosses  $e$ , (b) there exists a path from a marked vertex to  $u$  such that the internal vertices of that path all belong to only one component  $C_i$  (we check this by recursively running our algorithm on the vertex induced subgraph of  $C_i$ ), (c)  $e'$  is the closest such edge to  $u$ .

Finally, we output 'YES' if and only if  $t$  is marked at the end of these iterations.

### 3.5 Correctness

Let  $P$  be a path from  $s$  to  $t$  in  $H$ . Suppose  $P$  passes through the components  $C_{\sigma_1}, C_{\sigma_2}, \dots, C_{\sigma_l}$  (each  $\sigma_i$  is a value in  $[k]$ ) in this order. By the definition of a pseudo-separator, the path can go from one component,  $C_{\sigma_i}$  to the next component  $C_{\sigma_{i+1}}$  in the following ways only:

**Case 1:** The path exits  $C_{\sigma_i}$  and enters  $C_{\sigma_{i+1}}$  through a vertex  $w$  of the pseudo-separator.

**Case 2:** The path exits  $C_{\sigma_i}$  and enters  $C_{\sigma_{i+1}}$  through an edge  $e' = (u, v)$  whose tail is in  $C_{\sigma_i}$  and head is in  $C_{\sigma_{i+1}}$ . This edge will cross an edge  $e = (x, y)$  of the pseudo-separator.

We see that after the  $i$ -th iteration, our algorithm will traverse the fragment of the path in the component  $C_{\sigma_i}$  and either mark in **Case 1** its endpoint or in **Case 2** a vertex  $u'$  such that the edge  $(u', v)$  exist. Thus,  $t$  will be marked after  $l$  iterations if and only if there is a path from  $s$  to  $t$  in  $H$ . Since  $l$  can be at most  $h$ , these many iterations would suffice.

From the above discussion, we know how to solve REACHABILITY on the auxiliary graph with the desired space-bound. To solve the problem on the input graph, we find the rectangular subdivision of the input graph. Then, we form the auxiliary graph by solving each rectangle recursively. Next, we solve the REACHABILITY problem on the auxiliary graph by following the above procedure. We have shown earlier that the reachability information of the input graph is fully preserved in the auxiliary graph. Hence, it is possible to report the solution of the input directed penny graph from the solution on the auxiliary graph.

### 3.6 Space-Complexity

The space complexity of our algorithm is dominated by the space required to store the *marked* vertices. Since there can be only  $h^{1/2+\varepsilon/2}$  such vertices, we need  $O(h^{1/2+\varepsilon/2} \log n)$  space. It is easy to see that for every  $\varepsilon' > 0$ , there exists an  $\varepsilon > 0$  such that  $O(h^{1/2+\varepsilon/2} \log n) = O(h^{1/2+\varepsilon'})$ . Note that, for the input auxiliary graph  $H$ , our algorithm recurses on vertex induced subgraphs whose size is  $O(h^{1-\varepsilon})$ . Hence, the depth of recursion is bounded by a constant. This increases the space required by at most a constant factor. Since the number of vertices in the initial auxiliary graph was itself  $O(n^{1/2+\varepsilon/2})$ , we get the desired space bound.

From the correctness and the space-complexity analysis of the algorithm, we conclude the proof of Theorem 9

## 4 Chordal Graphs

In this section, we study the REACHABILITY problem on directed chordal graphs and design a space-efficient algorithm. A graph is said to be chordal if every cycle of length at least four has a *chord*, which is an edge joining two vertices that are not adjacent on the cycle. A *directed* chordal graph is a graph whose underlying undirected graph is chordal. See [14, 17, 31] for the basic theory on chordal graphs. We adopt the algorithm of Gilbert et al. [19] for *Vertex Separator* and analyze to obtain the desired space-bound. In [25], it was noted that REACHABILITY on chordal graphs could be solved in a space-efficient manner, however, without any formal explanation. Here we provide a detailed analysis of this claim.

Let  $G = (V, E)$  be a directed chordal graph. For the sake of completeness, we will state some of the known results that are relevant to us. Chordal graphs are also known as *triangulated graphs*, *monotone transitive graphs*, *rigid circuit graphs*, *perfect elimination graphs* in the literature.

### Finding Separator

Gilbert et al. [19] presented  $O(mn)$ -time algorithm for finding *Vertex Separator* on chordal graphs. Furthermore, a better algorithm of time complexity  $O(m)$  is also shown. We design a space-efficient algorithm for Vertex separator that uses  $O(m^{1/2} \log n)$  space and polynomial time. We adopt the  $O(mn)$ -time algorithm from [19] and analyze it to provide the desired space-bound. In order to do that, we allow time complexity that is much larger than  $O(mn)$  but remains polynomial in  $n$ . We proceed with the following lemma: A similar property is somewhat implicitly used by [19].

► **Lemma 15.** *Let  $G$  be a chordal graph and let  $C$  be a clique. Let  $A$  be the largest component in  $G \setminus C$ . Then, either of the following two statements is true:*

- *There exists a vertex  $v$  in  $C$  which is not adjacent to any vertex in  $A$ .*
- *There exists a vertex  $u$  in  $A$  which is adjacent to every vertex in  $C$ .*

We need several definitions and structural properties of the Chordal graphs in order to prove this Lemma. However, some of the properties are well-known results for chordal graphs. We proceed with the following definitions.

► **Definition 16.** *Let  $G$  be a graph and  $v$  be a vertex of  $G$ . The deficiency of  $v$ , denoted by  $D(v)$  is defined as follows:  $D(v) = \{\{u_1, u_2\} \mid \{u_1, v\} \in E(G), \{u_2, v\} \in E(G) \text{ and } \{u_1, u_2\} \notin E(G)\}$*

► **Definition 17.** *Let  $G$  be a graph and  $v$  be a vertex of  $G$ . We define the graph  $G_v$  as follows:  $G_v = (V(G) \setminus \{v\}, E(G[V(G) \setminus \{v\}]) \cup D(v))$ . We say that the graph  $G_v$  is formed by eliminating  $v$  from  $G$ .*

► **Definition 18.** *When a sequence of vertices is eliminated from a graph, the edges in the deficiencies that are added are called fill-in edges. A simplicial vertex of a graph is a vertex that has a deficiency of 0.*

We state the following known facts about the chordal graphs. The following Lemmas are due to [14, 17, 30, 29, 31]. For the sake of completion, we state them here in the form that we will be using and provide their proofs.

► **Lemma 19.** *Let  $G$  be a chordal graph and  $a$  and  $b$  be two vertices in  $V(G)$ . Let  $S$  be a set of vertices of  $G$  such that: 1)  $a$  and  $b$  are in different components of the graph  $G \setminus S$ ; 2) there exists no proper subset  $S' \subseteq S$  such that vertices  $a, b$  are in different components of the graph  $G \setminus S'$ . If these conditions hold, then the set  $S$  forms a clique in  $G$ .*

**Proof.** Let  $C_a$  and  $C_b$  be the components in  $G \setminus S$  containing  $a$  and  $b$ , respectively. Note that, each vertex  $s \in S$  is adjacent to some vertices in  $C_a$ , and some vertices in  $C_b$ . Consider two vertices  $x, y \in S$ . Let  $\mathcal{P}_a$  be the shortest path between  $x$  and  $y$  in  $G[C_a \cup \{x, y\}]$ . Similarly, let  $\mathcal{P}_b$  be the shortest path between  $x$  and  $y$  in  $G[C_b \cup \{x, y\}]$ . The paths  $\mathcal{P}_a$  and  $\mathcal{P}_b$  together forms a cycle. Hence, there must be an edge between  $x$  and  $y$ , since it is the only *chord* that is possible. This argument holds for any pair of vertices in  $S$ . This completes the proof. ◀

► **Lemma 20.** *Let  $G$  be a chordal graph and let  $C$  be any clique of  $G$ . Then, either  $G$  is a complete graph, or there is a vertex  $v \in G \setminus C$  that is simplicial.*

**Proof.** We prove this by induction on  $|G|$ . The base case  $|G| = 1$  is trivial. Let us assume that the Lemma holds for all  $G$  such that  $|G| \leq k$ , for some  $k \in [n]$ . Now,  $G$  be a graph such that  $|G| = k + 1$ . If  $G$  is not a complete graph then, let  $a, b$  be two vertices of  $G$ , that are not adjacent. Due to Lemma 19, there exists a set  $S$  that separates  $a$  and  $b$ . Let  $C_a, C_b$ , be the corresponding components  $G$  containing  $a$  and  $b$ , respectively. Note that, the vertices in  $C \setminus S$  should be in one component. W.l.o.g., assume that they belong to  $C_a$ . Consider the graph  $G_b = G[S \cup C_b]$ . We have  $|G_b| \leq k$ . Hence, by induction, either  $G_b$  is a clique or there is a vertex  $u \notin S$ , that is *simplicial* in  $G_b$ . In either of the cases, there exists a vertex  $u \notin S$  that is simplicial in  $G_b$  since  $G_b$  must contain at least one vertex, not in  $S$ . Note,  $u$  is a simplicial vertex in  $G$  since  $u$  is not adjacent to a vertex in any component other than  $C_b$ . This completes the proof.  $\blacktriangleleft$

► **Corollary 21.** *Let  $G$  be a chordal graph and  $C$  be a clique. Let  $A$  be the largest component in  $G \setminus C$ . If  $B$  is a non-empty subset of  $A$ , then  $B$  contains a vertex whose neighbours in  $G[B \cup C]$  forms a clique.*

► **Lemma 22** ([19]). *Let  $a_0, a_1, \dots, a_k$  be an elimination ordering for a graph  $G$ . Let  $v$  and  $w$  be nonadjacent vertices of  $G$ . Then  $\{v, w\}$  is a fill-in edge if and only if there is a path from  $v$  to  $w$  consisting of vertices that are eliminated earlier than both  $v$  and  $w$ .*

Now, we have the ingredients to prove the main Lemma 15.

**Proof.** Let  $G$  be a chordal graph, and let  $C$  be a clique. Let  $A$  be the largest component in  $G \setminus C$ . Let us assume that each vertex  $v \in C$  is adjacent to at least one vertex in  $A$ . We will show that under this assumption, there exists a vertex  $u$  in  $A$  that is adjacent to each vertex in  $C$ , thereby proving the Lemma.

It is known that a vertex induced subgraph of a chordal graph is also a chordal graph. Hence, the subgraph  $G_0 := G[A \cup C]$  is a chordal graph. Due to Lemma 20, we know that there is a vertex  $u_0 \in G_0 \setminus C$ , that is simplicial, whose neighbors form a clique. Let  $G_1 := G[(A \cup C) \setminus \{u_0\}]$ . Similarly, let  $u_1$  be a vertex in  $G_1 \setminus C$  that is simplicial. In general, let  $u_i$  be a vertex in  $G_i \setminus C$  whose neighbours forms a clique, where  $G_i$  is defined as  $G[(A \cup C) \setminus \{u_0, u_1, \dots, u_{i-1}\}]$ . Let  $k$  be an integer such that  $G_{k+1} = G[C]$ . We claim that  $u_k$  is adjacent to every vertex of  $C$ .

Consider a vertex  $x$  in  $C$ . Since  $A$  is connected and by our assumption,  $x$  is adjacent to a vertex of  $A$ , there is a path from  $x$  to  $u_k$  in  $G[A \cup C]$  that uses only vertices of  $A$ . Lemma 22 says that if  $\{x, u_k\}$  is not an edge of  $G[A \cup C]$ , then it is a fill-in edge. But a perfect elimination ordering has no fill-in, so  $x$  is adjacent to  $u_k$  in  $G[A \cup C]$ . Thus  $u_k$  is adjacent to every vertex of  $C$ . This completes the proof.  $\blacktriangleleft$

Given the above lemma, the algorithm for finding a separator in a chordal graph is rather straightforward, as also observed by [19]. The algorithm is described in the following Procedure 1.

The correctness of the algorithm directly comes from Lemma 15. We show that this algorithm uses  $O(m^{1/2} \log n)$  space.

## Space-Complexity

To see that the above algorithm can be implemented in  $O(m^{1/2} \log n)$ -space and polynomial time, we first recall that the separator  $S$  always forms a clique in the graph. Since the size of a clique is upper-bounded by  $m^{1/2}$ , it will require at most  $O(m^{1/2} \log n)$  space to store the clique.

■ **Algorithm 1** Vertex Separator in Chordal Graphs.

---

**Input:** A chordal graph  $G$   
**Output:** A separator  $S$  of  $G$  of size  $\sqrt{m}$

- 1  $S \leftarrow \emptyset$ ;
- 2 **while** *there exists a component  $A$  of  $G \setminus S$  that has weight more than  $n/2$*  **do**
- 3     **while** *there exists a vertex  $x$  of  $S$  that is adjacent to no vertex of  $A$*  **do**
- 4          $S \leftarrow S \setminus \{x\}$ ;
- 5     **end**
- 6      $v \leftarrow$  a vertex of  $A$  adjacent to every vertex of  $S$ ;
- 7      $S \leftarrow S \cup \{v\}$ ;
- 8 **end**
- 9 Return  $S$ ;

---

Now, to implement the algorithm, we need to calculate the weights of each of the connected components of  $G \setminus S$ . However, we cannot afford to store these components explicitly, since the number of vertices present in these components could be large. Instead, we identify a component with the lowest-index vertex present in it. We call the lowest-index vertex a *marker* of the component. In order to check that whether a vertex  $v$  is a *marker*, we run Reingold's undirected REACHABILITY algorithm to see if it is not connected with any vertex  $u$  in  $G \setminus S$  such that the index of  $u$  is lower than  $v$ . Also, to know the size of the connected component for a marker vertex  $v$ , we use Reingold's algorithm [28] to count the number of vertices that are connected to it. Therefore it is possible to count the weight of any component of  $G \setminus S$  in the desired space-bound. We conclude the following theorem.

► **Theorem 23.** *Given a chordal graph  $G = (V, E)$ , there exists an algorithm that computes a  $\sqrt{m}$  separator in polynomial time by using  $O(m^{1/2} \log n)$ -space.*

From Theorem 23 and Theorem 1, we have the following corollary.

► **Corollary 24.** *There exists an algorithm that solves the REACHABILITY problem for chordal graphs by using  $O(m^{1/2} \log n)$ -space and polynomial time.*

## 5 Conclusion

We studied REACHABILITY problem on three important graph families and obtained space-efficient algorithms for each of these classes. An interesting open problem is whether one can obtain a space-efficient algorithm for intersection graphs of Jordan regions when the embedding of the graph is not provided in the input. Another important open problem is to study the REACHABILITY for unit disk intersection graphs and obtain a space-efficient algorithm. Our method that we used for unit contact disk graphs does not generalize to the case of unit disk intersection graphs, as in the latter case, there can be arbitrarily large directed cliques, and it is not possible to obtain auxiliary graphs while preserving reachability information between every pair of vertices. However, we believe that our method can be used to solve to REACHABILITY for other classes of geometric contact graphs.

## Abstract

We revisit the fundamental problem of compressing an integer dictionary that supports efficient rank and select operations by exploiting two kinds of regularities arising in real data: *repetitiveness* and *approximate linearity*. Our first contribution is a Lempel-Ziv parsing properly enriched to also capture approximate linearity in the data and still be compressed to the  $k$ th order entropy. Our second contribution is a variant of the block tree structure whose space complexity takes advantage of both repetitiveness and approximate linearity, and results highly competitive in time too. Our third and final contribution is an implementation and experimentation of this last data structure, which achieves new space-time trade-offs compared to known data structures that exploit only one of the two regularities.

## 1 Introduction

We focus on the fundamental problem of representing an ordered dictionary  $A$  of  $n$  distinct elements drawn from the integer universe  $[u] = \{0, \dots, u\}$  while supporting the operation  $\text{rank}(x)$ , that returns the number of elements in  $A$  which are  $\leq x$ ; and  $\text{select}(i)$ , that returns the  $i$ th smallest element in  $A$ .

Rank/select dictionaries are at the heart of virtually any compact data structure [34], such as text indexes [15, 18, 20, 22, 30, 36], succinct trees and graphs [32, 41], hash tables [4], permutations [3], etc. Unsurprisingly, the literature is abundant in solutions, e.g. [2, 8, 21, 24, 31, 37, 40, 41]. Yet, the problem of designing theoretically and practically efficient rank/select structures is anything but closed. The reason is threefold. First, there is an ever-growing list of applications of compact data structures (in bioinformatics [13, 29], information retrieval [33], and databases [1], just to mention a few) each having different characteristics and requirements on the use of computational resources, such as time, space, and energy consumption. Second, the hardware is evolving [23], sometimes requiring new data structuring techniques to fully exploit it, e.g. larger CPU registers, new instructions, parallelism, next-generation memories such as PMem. Third, data may present different kinds of regularities, which require different techniques that exploit them to improve the space-time performance.

Among the latest of such regularities to be exploited, there is a geometric concept of *approximate linearity* [7]. Regard  $A$  as a sorted array  $A[1, n]$ , so that  $\text{select}(i)$  can be implemented as  $A[i]$ . The idea is to first map each element  $A[i]$  to a point  $(i, A[i])$  in the Cartesian plane, for  $i = 1, 2, \dots, n$ . Intuitively, any function  $f$  that passes through all the points in this plane can be thought of as an encoding of  $A$  because we can recover  $A[i]$  by querying  $f(i)$ . Now the challenge is to find a representation of  $f$  which is both fast to be computed and compressed in space. To this end, the authors of [7] implemented  $f$  via a piecewise linear model whose error, measured as the vertical distance between the prediction and the actual value of  $A$ , is bounded by a given integer parameter  $\varepsilon$ .

► **Definition 1.** A piecewise linear  $\varepsilon$ -approximation for the integer array  $A[1, n]$  is a partition of  $A$  into subarrays such that each subarray  $A[i, j]$  of the partition is covered by a segment, represented by a pair  $\langle \alpha, \beta \rangle$  of numbers, such that  $|(\alpha \cdot k + \beta) - A[k]| \leq \varepsilon$  for each  $k \in [i, j]$ .

Among all possible piecewise linear  $\varepsilon$ -approximations, one aims for the most succinct one, namely the one with the least amount of segments. This is a classical computational geometry problem that admits an  $\mathcal{O}(n)$ -time algorithm [38]. The structure introduced by [7], named LA-vector, uses this succinct piecewise linear  $\varepsilon$ -approximation as a lossy representation of  $A$ , and it mends the information loss by storing the vertical errors into an array  $C$  of  $\lceil \log(2\varepsilon + 1) \rceil$ -bit integers, called corrections (all logarithms are to the base two). To answer  $\text{select}(i)$ , the LA-vector uses a constant-time rank structure on a bitvector of size  $n$  to find the segment  $\langle \alpha, \beta \rangle$  covering  $i$ , and it returns the value  $\lfloor (\alpha \cdot i + \beta) \rfloor + C[i]$ . The  $\text{rank}(x)$  operation is implemented via a sort of binary search that exploits the information encoded in the piecewise linear  $\varepsilon$ -approximation [7]. In practical implementations, we allocate  $c \geq 0$  bits for each correction and set  $\varepsilon = 2^c - 1$ . The space usage in bits of an LA-vector consists therefore of a term  $\mathcal{O}(nc)$  accounting for the corrections array  $C$ , and a term  $\mathcal{O}(wm)$ , where  $w$  is the word size, that grows with the number of segments  $m$  in the piecewise linear  $\varepsilon$ -approximation. Despite the apparent simplicity of the piecewise linear representation, the experiments in [7] show that the LA-vector offers the fastest  $\text{select}$  and competitive rank performance with respect to several well-established structures implemented in the `sds1` library [19]. In addition to its good practical performance, recent results [14, 17] have shown there are also theoretical reasons that justify the effectiveness of the piecewise linear  $\varepsilon$ -approximation in certain contexts.

Despite their succinctness and power in capturing linear trends, piecewise linear  $\varepsilon$ -approximations still lack the capacity to find and exploit one fundamental source of compressibility arising in real data: *repetitiveness* [35]. Although the input consists in an array  $A$  of strictly increasing values, there can be significant repetitiveness in the differences between consecutive elements. Consider the gap-string  $S[1, n]$  defined as  $S[i] = A[i] - A[i - 1]$ , with  $A[0] = 0$ , and suppose the substring  $S[i, j]$  has been encountered earlier at  $S[i', i' + j - i]$  (we write  $S[i, j] \equiv S[i', i' + j - i]$ ). Then, instead of finding a new set of segments  $\varepsilon$ -approximating the subarray  $A[i, j]$ , we can use the segments  $\varepsilon$ -approximating the subarray  $A[i', j']$  properly shifted. Note that, even if  $A[i', j']$  is covered by many segments, the same shift will transform all of them into an approximation for  $A[i, j]$  (see example in Figure 1). Therefore, in this case, we would need to store only the *shift* and the *reference* to the segments of  $A[i', j']$ . The LA-vector is unable to take advantage of such regularities. In the extreme case where  $A$  consists of the concatenation of a small subarray  $A'$  shifted by some amounts  $\Delta_i$ s for  $k$  times, that is  $A = A', A' + \Delta_1, A' + \Delta_2, \dots, A' + \Delta_{k-1}$ , the overall cost of representing  $A$  with an LA-vector will be roughly  $k + 1$  times the cost of representing  $A'$ .

The goal of this paper is to harness the repetitions in the gap-string  $S$  to make the LA-vector repetition aware. In fact, the approximate linearity and the repetitiveness of a string are different proxies of its compressibility and therefore it is interesting to take both of

■ **Figure 1** The points in the top-right circle follows the same “pattern” (i.e. the same distance between consecutive points) of the ones in the bottom-left circle. A piecewise linear  $\varepsilon$ -approximation for the top-right set can be obtained by shifting the segments for the bottom-left set.

them into account. Take as an example an order- $h$  De Bruijn binary sequence  $B[1, 2^h]$  and define  $A[i] = 2i + B[i]$ , then the line with slope 2 and intercept 0 is a linear approximation of the entire array  $A$  with  $\varepsilon = 1$ . Conversely, following the argument above and considering the gap-string  $S[i] = A[i] - A[i - 1] = 2 + B[i] - B[i - 1]$ , we would not find repetitions longer than  $h - 1$  in  $S$ . The challenge is to devise techniques that are able to exploit both the presence of repetitions in the gap-string  $S$  and the presence of subarrays in  $A$  which can be linearly  $\varepsilon$ -approximated well, while still supporting efficient rank/select primitives on  $A$ . We point out that, although in this paper we consider only linear approximations, our techniques can be applied also to other data approximation functions, such as polynomials and rational functions.

**Our contribution in context.** The most common approach in the literature to design a *succinct* dictionary for a set of distinct integers  $A$  over the universe  $\{0, \dots, u\}$  is to represent  $A$  using the characteristic bitvector  $\mathbf{bv}(A)$ , which has length  $u + 1$  and is such that  $\mathbf{bv}(A)[i] = 1$  iff  $i \in A$ . In this paper, we use instead linear  $\varepsilon$ -approximations of  $A$  and the gap string  $S$ , and we show how to modify two known compression methods so that they can take advantage of approximate linearity. The first method is the Lempel-Ziv (LZ) parsing [26–28, 44], which is one of the best-known approaches to exploit repetitiveness [35]. The second method is the block tree [5], which is a recently proposed query-efficient alternative to LZ-parsing and grammar-based representations [6] suitable also for highly repetitive inputs since its space usage can be bounded in terms of the string complexity measure  $\delta$  (see [25, 35] for the definition and significance of this measure).

Our first contribution is a novel parsing scheme, the  $LZ_\varepsilon^\rho$  parsing, whose phrases are a combination of a backward copy and a linear  $\varepsilon$ -approximation, i.e., a segment and the corresponding correction values. The  $LZ_\varepsilon^\rho$  parsing encapsulates a piecewise linear  $\varepsilon$ -approximation of the array  $A$  and supports efficient rank/select primitives on  $A$ . Surprisingly, this combination uses space bounded by the  $k$ th order entropy  $H_k(S)$  of the gap-string  $S$  (see [26] for the definition and significance of  $k$ th order entropy). More precisely (Theorems 7 and 9), if  $\sigma$  denotes the number of distinct gaps in  $S$ , the  $LZ_\varepsilon^\rho$  parsing supports rank in  $\mathcal{O}(\log^{1+\rho} n + \log \varepsilon)$  time and select in  $\mathcal{O}(\log^{1+\rho} n)$  time using  $nH_k(S) + \mathcal{O}(n/\log^\rho n) + o(n \log \sigma)$

bits of space, for any positive  $\rho$  and  $k = o(\log_\sigma n)$ , plus the space to store the segments and the correction values that are used to advance the parsing (like the explicit characters in traditional LZ-parsing).

The best succinct data structure based on  $\text{bv}(A)$  is the one by Sadakane and Grossi [43] that supports constant-time **rank** and **select** in  $uH_k(\text{bv}(A)) + \mathcal{O}(u \log \log u / \log u)$  bits of space. This space bound cannot be compared to ours since it is given in terms of  $H_k(\text{bv}(A))$  instead of  $H_k(S)$ . To achieve space  $nH_k(S)$  one can use an entropy-compressed representation of  $S$  enriched with auxiliary data structures to support **rank/select** on  $A$ . For example, by sampling one value of  $A$  out of  $\log n$  and performing a binary search followed by a prefix sum of the gaps one can support  $\mathcal{O}(\log n)$ -time **rank** and **select** queries. Using the representation of [16], this solution uses  $nH_k(S) + \mathcal{O}(n \log u / \log n) + o(n \log \sigma) = nH_k(S) + o(n \log u)$  bits of space, which is worse in space than our solution but faster in query time. Other trade-offs are possible: the crucial point however is that none of the known techniques is able to exploit simultaneously the presence of exact repetitions and approximate linearity in the input data as instead our  $LZ_\varepsilon^\rho$  does. In the best scenario,  $LZ_\varepsilon^\rho$  parsing uses segments to quickly consume any approximate linearity in  $A$  thus potentially reducing significantly the number of LZ-phrases. On the other hand, if  $A$  cannot be linearly approximated, segments will be short and the overall space occupancy of  $LZ_\varepsilon^\rho$  parsing will be  $nH_k(S) + o(n \log \sigma)$  bits, i.e. no worse than a traditional LZ-parsing.

Our second contribution is the block- $\varepsilon$  tree, an orchestration of block trees [5, 25] and linear  $\varepsilon$ -approximations. The main idea is to build the block tree over the gap-string  $S$  and to prune the subtrees whose corresponding subarray can be covered more succinctly using a linear  $\varepsilon$ -approximation in place of a block (sub)tree. We show that this solution supports **rank** in  $\mathcal{O}(\log \log \frac{u}{\delta} + \log \frac{n}{\delta} + \log \varepsilon)$  time and **select** in  $\mathcal{O}(\log \frac{n}{\delta})$  time using  $\mathcal{O}(\delta \log \frac{n}{\delta} \log n)$  bits of space in the worst case, where  $\delta$  is the string complexity of  $S$  [25, 35].

A block tree built on  $\text{bv}(A)$ , instead, supports **rank** and **select** in  $\mathcal{O}(\log \frac{u}{\delta'})$  time using  $\mathcal{O}(\delta' \log \frac{u}{\delta'} \log u)$  bits of space, where  $\delta'$  is the string complexity measure on  $\text{bv}(A)$ . The time and space bounds achieved by the block tree and by our block- $\varepsilon$  tree are not comparable due to the use of  $\delta'$  instead of  $\delta$ . Therefore, as our third contribution, we provide an implementation of our block- $\varepsilon$  tree built on  $S$ , and we compare it with the standard block tree built on  $\text{bv}(A)$ . Our proposal turns out to be more space-efficient for some of the experimented sparse datasets and, as far as query time is concerned, it is  $2.19\times$  faster in **select**, and it is either faster ( $1.32\times$ ) or slower ( $1.27\times$ ) in **rank** than the block tree.

In the Conclusions, we comment on several research directions that naturally arise from the novel approaches described in this paper.

## 2 Tools

We use as a black box the Elias-Fano [9, 10] representation for compressing and random-accessing monotone integer sequences [34, §4.4].

► **Lemma 2** (Elias-Fano encoding). *We can store a sequence of  $n$  increasing positive integers over a universe of size  $u$  in  $n \lceil \log \frac{u}{n} \rceil + 2n + o(n) = n \log \frac{u}{n} + \mathcal{O}(n)$  bits and access any integer of the sequence in  $\mathcal{O}(1)$  time.*

Henceforth, we always assume that a piecewise linear  $\varepsilon$ -approximation for an input array  $A$  is the most succinct one in terms of the number of segments, or equivalently, that we always maximise the length  $\ell$  of the subarray  $A[i, i + \ell - 1]$  covered by a segment starting at  $i$ . This is possible thanks to the algorithm of O'Rourke [38], which in optimal  $\mathcal{O}(n)$  time computes the piecewise linear  $\varepsilon$ -approximation with the smallest number of segments for the set of points  $\{(i, A[i]) \mid i = 1, \dots, n\}$ .

Another key tool that we use is LZ-end [27]. Formally, the LZ-end parsing of a text  $T[1, n]$  is a sequence  $f_1, f_2, \dots, f_z$  of phrases, such that  $T = f_1 f_2 \dots f_z$ , built as follows. If  $T[1, i]$  has been parsed as  $f_1 f_2 \dots f_{q-1}$ , the next phrase  $f_q$  is obtained by finding the longest prefix of  $T[i+1, n]$  that appears also in  $T[1, i]$  ending at a phrase boundary, i.e. the longest prefix of  $T[i+1, n]$  which is a suffix of  $f_1 \dots f_r$  for some  $r \leq q-1$ . If  $T[i+1, j]$  is the prefix with the above property, the next phrase is  $f_q = T[i+1, j+1]$  (notice the addition of  $T[j+1]$  to the longest copied prefix). The occurrence in  $T[1, i]$  of the prefix  $T[i+1, j]$  is called the *source* of the phrase  $f_q$ .

Although LZ-end is less powerful than the classic LZ77 parsing, which allows the *end* of a source to be anywhere in  $T[1, i]$ , it compresses any text  $T$  up to its  $k$ th order entropy, and it is more efficient than LZ77 in extracting any substring of  $T$ .

With the advent of large datasets containing many repetitions, researchers have observed that the entropy does not always provide a meaningful lower bound to the information content of such datasets [27]. Recently, [35] has given a complete picture of several alternative measures of information content and has shown that they are all lower bounded by the complexity measure  $\delta$  defined as  $\max\{T(k)/k \mid 1 \leq k \leq n\}$ , where  $T(k)$  is the number of distinct length- $k$  substrings of  $T$  [42]. In [25], it is shown that using the block tree [5] it is possible to represent a text  $T[1, n]$  in space bounded in terms of  $\delta$  while supporting:  $\text{rank}_a(i)$ , which returns the number of occurrences of the character  $a$  in  $T[1, i]$ , and  $\text{select}_a(j)$ , which returns the position of the  $j$ th occurrence of  $a$  in  $T$ . Specifically, their block tree supports  $\text{rank}_a$  and  $\text{select}_a$  in  $\mathcal{O}(\log \frac{n}{\delta})$  time using  $\mathcal{O}(\sigma \delta \log \frac{n}{\delta} \log n)$  bits of space.

### 3 Two novel LZ-parsings: $\text{LZ}_\varepsilon$ and $\text{LZ}_\varepsilon^\rho$

Assume that  $A$  contains distinct positive elements and consider the gap-string  $S[1, n]$  defined as  $S[i] = A[i] - A[i-1]$ , where  $A[0] = 0$ . To make the LA-vector repetition aware, we parse  $S$  via a strategy that combines linear  $\varepsilon$ -approximation with LZ-end parsing. We generalise the phrases of the LZ-end parsing in a way that they are a “combination” of a backward copy ending at a phrase boundary (as in the classic LZ-end), computed over the gap-string  $S$ , plus a segment covering a subarray of  $A$  with an error of at most  $\varepsilon$  (unlike classic LZ-end, which instead adds a single trailing character). We call this parsing the  $\text{LZ}_\varepsilon$  parsing of  $S$ .

Suppose that  $\text{LZ}_\varepsilon$  has partitioned  $S[1, i]$  into  $Z[1], Z[2], \dots, Z[q-1]$ . We determine the next phrase  $Z[q]$  as follows (see Figure 2):

1. We compute the longest prefix  $S[i+1, j]$  of  $S[i+1, n]$  that is a suffix of the concatenation  $Z[1] \dots Z[r]$  for some  $r \leq q-1$  (i.e. the source must end at a previous phrase boundary).
2. We find the longest subarray  $A[j, h]$  that may be  $\varepsilon$ -approximated linearly, as well as the slope and intercept of such approximation. Note that using the algorithm of [38] the time complexity of this step is  $\mathcal{O}(h-j)$ , i.e. linear in the length of the processed array.

The new phrase  $Z[q]$  is then the substring  $S[i+1, j] \cdot S[j+1, h]$ . If  $h = n$ , the parsing is complete. Otherwise, we continue the parsing with  $i \leftarrow h+1$ . As depicted in Figure 2, we call  $S[i+1, j]$  the *head* of  $Z[q]$  and  $S[j+1, h]$  the *tail* of  $Z[q]$ . Note that the tail covers also the value  $A[j]$  corresponding to the head’s last position  $S[j]$ . When  $S[i+1, j]$  is the empty string (e.g. at the beginning of the parsing), the head is empty, and thus no backward copy is executed. In the worst case, the longest subarray we can  $\varepsilon$ -approximate has length 2, which nonetheless guarantees that  $Z[q]$  is nonempty. Experiments in [7] show that the average segment length ranges from 76 when  $\varepsilon = 31$  to 1480 when  $\varepsilon = 511$ .

■ **Figure 2** Computation of the next phrase  $Z[q]$  in the parsing of the gap-string  $S$  of the array  $A$ , where the prefix  $S[1, i]$  has already been parsed into  $Z[1], Z[2], \dots, Z[q-1]$ .

If the complete parsing consists of  $\lambda$  phrases, we store it using:

- An integer vector  $\text{PE}[1, \lambda]$  (Phrase Ending position) such that  $h = \text{PE}[q]$  is the ending position of phrase  $Z[q]$ , that is,  $Z[q] = S[i+1, h]$ , where  $i = \text{PE}[q-1] + 1$ .
- An integer vector  $\text{HE}[1, \lambda]$  (Head Ending position) such that  $j = \text{HE}[q]$  is the last position of  $Z[q]$ 's head. Hence,  $Z[q]$ 's head is  $S[\text{PE}[q-1] + 1, \text{HE}[q]]$ , and  $Z[q]$ 's tail is  $S[\text{HE}[q] + 1, \text{PE}[q]]$ .
- An integer vector  $\text{HS}[1, \lambda]$  (Head Source) such that  $r = \text{HS}[q]$  is the index of the last phrase in  $Z[q]$ 's source. Hence, the head of  $Z[q]$  is a suffix of  $Z[1] \cdots Z[r]$ . If the head of  $Z[q]$  is empty then  $\text{HS}[q] = 0$ .
- A vector of pairs  $\text{TL}[1, \lambda]$  (Tail Line) such that  $\text{TL}[q] = \langle \alpha_q, \beta_q \rangle$  are the coefficients of the segment associated to the tail of  $Z[q]$ . By construction, such segment provides a linear  $\varepsilon$ -approximation for the subarray  $A[\text{HE}[q], \text{PE}[q]]$ .
- A vector of arrays  $\text{TC}[1, \lambda]$  (Tail Corrections) such that  $\text{TC}[q]$  is an array of length  $\text{PE}[q] - \text{HE}[q] + 1$  providing the corrections for the elements in the subarray  $A[\text{HE}[q], \text{PE}[q]]$  covered by  $Z[q]$ 's tail. By construction, such corrections are smaller than  $\varepsilon$  in modulus.

Using the values in  $\text{TL}$  and  $\text{TC}$  we can recover the subarrays  $A[j, h]$  corresponding to the phrases' tails. We show that using all the above vectors we can recover the whole array  $A$ .

► **Lemma 3.** *Let  $S[i+1, j]$  denote the head of phrase  $Z[q]$ , and let  $r = \text{HS}[q]$  and  $e = \text{PE}[r]$ . Then, for  $t = i+1, \dots, j$ , it holds*

$$A[t] = A[t - (j - e)] + (A[j] - A[e]), \quad (1)$$

where  $A[j]$  (resp.  $A[e]$ ) can be retrieved in constant time from  $\text{TL}[q]$  and  $\text{TC}[q]$  (resp.  $\text{TL}[r]$  and  $\text{TC}[r]$ ).

**Proof.** By construction,  $S[i+1, j]$  is identical to a suffix of  $Z[1] \cdots Z[r]$ . Since such a suffix ends at position  $e = \text{PE}[r]$ , it holds  $S[i+1, j] \equiv S[e - j + i + 1, e]$  and

$$\begin{aligned} A[t] &= A[j] - (S[j] + S[j-1] + \cdots + S[t+1]) \\ &= (A[j] - A[e]) + A[e] - (S[e] + S[e-1] + \cdots + S[t+1 - (j-e)]) \\ &= (A[j] - A[e]) + A[t - (j-e)]. \end{aligned}$$

For the second part of the lemma, we notice that  $A[j]$  is the first value covered by  $Z[q]$ 's tail, while  $A[e]$  is the last value covered by  $Z[r]$ 's tail. ◀

Using the above lemma, we can show by induction that given a position  $t \in [1, n]$  we can retrieve  $A[t]$ . The main idea is to use a binary search on  $\text{PE}$  to retrieve the phrase  $Z[q]$  containing  $t$ . Then, if  $t \geq \text{HE}[q]$ , we get  $A[t]$  from  $\text{TL}[q]$  and  $\text{TC}[q]$ ; otherwise, we use Lemma 3 and get  $A[t]$  by retrieving  $A[t - (j - e)]$  using recursion. In the following, we will formalise this intuition in a complete algorithm, but before doing so, we need to introduce some additional notation.

■ **Figure 3** The  $LZ_\epsilon$  parsing with the definition of meta-characters. Cells represent meta-characters, and the coloured cells are also tails.  $Z[7]$ 's head consists of a copy of a substring that starts inside  $Z[2]$  and ends at the end of  $Z[5]$  (notice the diagonal patterns in  $Z[7]$ 's head with the same colours of the tails in  $Z[2] \cdots [5]$ ). Meta-characters in  $Z[7]$ 's head are defined from the meta-characters in the copy. Note that  $Z[7]$ 's first meta-character is a suffix of  $Z[2]$ 's first meta-character.

Using the  $LZ_\epsilon$  parsing, we partition the string  $S$  into *meta-characters* as follows. The first phrase in the parsing  $Z[1] = S[1, PE[1]]$  is our first meta-character (note  $Z[1]$  has an empty head, so  $HE[1] = 0$  and the pair  $\langle TL[1], TC[1] \rangle$  encodes the subarray  $A[0, PE[1]]$ ). Now, assuming we have already parsed  $Z[1] \cdots Z[q - 1]$  and partitioned  $S[1, PE[q - 1]]$  into meta-characters, we partition the next phrase  $Z[q]$  into meta-characters as follows:  $Z[q]$ 's tail will form a meta-character by itself, while  $Z[q]$ 's head “inherits” the partition into meta-characters from its source. Indeed, recall that  $Z[q]$ 's head is a copy of a suffix of  $Z[1] \cdots Z[r]$ , with  $r = HS[q]$ . Such a suffix, say  $S[a, b]$ , belongs to the portion of  $S$  already partitioned into meta-characters. Since by construction  $Z[r]$ 's tail is a meta-character  $X_r$ , we know that  $X_r$  is a suffix of  $S[a, b]$ . Working backwards from  $X_r$  we obtain the sequence  $X_0 \cdots X_r$  of meta-characters covering  $S[a, b]$ . Note that it is possible that  $X_0$ , the meta-character containing  $S[a]$ , starts before  $S[a]$ . We thus define  $X'_0$  as the suffix of  $X_0$  starting at  $S[a]$  and define the meta-character partition of  $Z[q]$ 's head as  $X'_0 X_1 \cdots X_r$ . This process is depicted in Figure 3. Note that each meta-character is either the tail of some phrase or it is the suffix of a tail. We do not really compute the meta-characters but only use them in our analysis, as in the following result.

► **Lemma 4.** *Algorithm 1 computes  $select(t) = A[t]$  in  $\mathcal{O}(\log \lambda + M_{\max})$  time, where  $\lambda$  is the number of phrases in the  $LZ_\epsilon$  parsing and  $M_{\max}$  is the maximum number of meta-characters in a single phrase.*

**Proof.** The correctness of the algorithm follows by Lemma 3. To prove the time bound, observe that Line 2 clearly takes  $\mathcal{O}(\log \lambda)$  time. Let  $\ell$  denote the number of meta-characters between the one containing position  $t$  up to the end of  $Z[q]$ . We show by induction on  $\ell$  that  $SELECT-AUX(t, q)$  takes  $\mathcal{O}(\ell)$  time. If  $\ell = 1$ , then  $t$  belongs to  $Z[q]$ 's tail, and the value  $A[t]$  is retrieved in  $\mathcal{O}(1)$  time from  $TL[q]$  and  $TC[q]$ .

If  $\ell > 1$ , the algorithm retrieves the value  $A[t']$  from a previous phrase  $Z[q']$ , with  $q' = r - k$ , where  $k$  is the number of times Line 13 is executed. Since  $Z[q]$  meta-characters are induced by those in its source, we get that the number of meta-characters between the one containing  $t'$  and the end of  $Z[r]$  is  $\ell - 1$ , and the number of meta-characters between the one containing  $t'$  and the end of  $Z[q']$  is  $\ell' \leq \ell - 1 - k$ . By the inductive hypothesis, the call to  $SELECT-AUX(t', q')$  takes  $\mathcal{O}(\ell')$ , and the overall cost of  $SELECT-AUX(t, q)$  is  $\mathcal{O}(k) + \mathcal{O}(\ell') = \mathcal{O}(\ell)$ , as claimed. ◀

It is easy to see that for some input  $t$  Algorithm 1 takes  $\Theta(M_{\max})$  time. To reduce the complexity, we now show how to modify the parsing so that  $M_{\max}$  is upper bounded by a user-defined parameter  $M > 1$ . The resulting parsing could contain some repeated phrases, but note that Lemma 4 does not require the phrases to be different: repeated phrases will only affect the space usage.

**Algorithm 1** Recursive select procedure.

---

1:	<b>procedure</b> SELECT( $t$ )	
2:	$q \leftarrow$ the smallest $i$ such that $\text{PE}[i] \geq t$ , found via a binary search on PE	
3:	<b>return</b> SELECT-AUX( $t, q$ )	
4:	<b>procedure</b> SELECT-AUX( $t, q$ )	$\triangleright$ Invariant: $\text{PE}[q - 1] < t \leq \text{PE}[q]$
5:	<b>if</b> $t > \text{HE}[q]$ <b>then</b>	$\triangleright$ If $t$ belongs to the tail of $Z[q]$
6:	<b>return</b> $A[t]$	$\triangleright A[t]$ is computed from $\text{TL}[q], \text{TC}[q]$
7:	$r \leftarrow q' \leftarrow \text{HS}[q]$	$\triangleright$ The head of $Z[q]$ is a suffix of $Z[1] \cdots Z[r]$
8:	$j \leftarrow \text{HE}[q]$	$\triangleright j$ is the last position of the head of $Z[q]$
9:	$e \leftarrow \text{PE}[r]$	$\triangleright e$ is the last position of $Z[r]$
10:	$\Delta \leftarrow A[j] - A[e]$	$\triangleright \Delta$ can be computed in $\mathcal{O}(1)$ time by Lemma 3
11:	$t' \leftarrow t - (j - e)$ ;	$\triangleright A[t] = A[t'] + \Delta$ by Lemma 3
12:	<b>while</b> $t' > \text{PE}[q']$ <b>do</b>	$\triangleright$ Find the phrase $Z[\cdot]$ containing $t'$
13:	$q' \leftarrow q' - 1$	$\triangleright$ Go back one word
14:	<b>return</b> SELECT-AUX( $t', q'$ ) + $\Delta$	$\triangleright$ The returned value is $A[t]$ by Lemma 3

---

**Figure 4** The  $LZ_\epsilon$  parsing of the same string of Figure 3 with  $M = 5$ . The phrase  $Z[7]$  from Figure 3 is invalid since it has 13 meta-characters.  $Z[7]$  head can have at most 4 meta-characters, so we define  $Z[7]$  by setting  $\text{HS}[7] = 3$  (Step 2b). Next, we define  $Z[8]$  by setting  $\text{HS}[8] = 4$  (Step 2c).

To build a  $LZ_\epsilon$  parsing in which each phrase contains at most  $M$  meta-characters, we proceed as follows. Assuming  $S[1, i]$  has already been parsed as  $Z[1], \dots, Z[q - 1]$ , we first compute the longest prefix  $S[i + 1, j]$  which is a suffix of  $Z[1] \cdots Z[r]$  for some  $r < q$ . Let  $m$  denote the number of meta-characters in  $S[i + 1, j]$ . Then (see Figure 4):

1. If  $m < M$ , then  $Z[q]$  is defined as usual with  $\text{HS}[q] = r$ . Since  $Z[q]$ 's tails constitute an additional meta-character,  $Z[q]$  has  $m + 1 \leq M$  meta-characters, as required.
2. Otherwise, if  $m \geq M$ , we do the following.
  - a. We scan  $S[i + 1, j]$  backward dropping copies of  $Z[r], Z[r - 1], \dots$  until we are left with a prefix  $S[i + 1, k_s]$  containing less than  $M$  meta-characters. By construction,  $S[i + 1, k_s]$  is a suffix of  $Z[1] \cdots Z[s]$  for some  $s < r$  and since each phrase contains at most  $M$  meta-characters,  $S[i + 1, k_s]$  is non-empty.
  - b. We define  $Z[q]$  by setting  $S[i + 1, k_s]$  as its head,  $\text{HS}[q] = s$ , and by defining  $Z[q]$ 's tail as usual.
  - c. Next, we consider  $Z[s + 1] \equiv S[k_s, k_{s+1}]$ . By construction,  $Z[s + 1]$  contains at most  $M$  meta-characters while  $S[i + 1, k_{s+1}]$  contains more than  $M$  meta-characters. If  $Z[q]$  ends before position  $k_{s+1}$  (i.e.  $\text{PE}[q] < k_{s+1}$ ), we define an additional phrase  $Z[q + 1]$  with heads equal to  $S[\text{PE}[q] + 1, k_{s+1}]$ ,  $\text{HS}[q + 1] = s + 1$  and with a tail defined as usual. This ensures that  $Z[q]$  alone or  $Z[q]Z[q + 1]$  contains at least  $M$  meta-characters.

**Lemma 5.** *The  $LZ_\epsilon$  parsing with limit  $M$  contains at most  $2n/M$  repeated phrases.*

**Proof.** In the algorithm described above, repeated phrases are created only at Steps 2b and 2c. Indeed, both  $Z[q]$  defined in Step 2b and  $Z[q+1]$  defined in Step 2c could be identical to a previous phrase. However, the concatenation  $Z[q]Z[q+1]$  covers at least  $S[i+1, k_{s+1}]$  so by construction contains *at least*  $M$  meta-characters. Hence, Steps 2b and 2c can be executed at most  $n/M$  times. ◀

In the following, let  $\sigma$  denote the number of distinct gaps in  $S$  (i.e., the alphabet size of  $S$ ), for any  $\rho > 0$ , we denote by  $LZ_\epsilon^\rho$  the parsing computed with the above algorithm with  $M = \log^{1+\rho} n$ . The following lemma shows that the space to represent the parsing can be bounded in terms of the  $k$ th order entropy of the gap-string  $S$  plus  $o(n \log \sigma)$  bits.

► **Lemma 6.** *Let  $\sigma$  denote the number of distinct gaps in  $S$ . The arrays PE, HE, and HS produced by the  $LZ_\epsilon^\rho$  parsing can be stored in  $nH_k(S) + \mathcal{O}(n/\log^\rho n) + o(n \log \sigma)$  bits for any positive  $k = o(\log_\sigma n)$ , and still support constant-time access to their elements.*

**Proof.** Let  $\lambda$  denote the number of phrases in the parsing. We write  $\lambda = \lambda_r + \lambda_d$ , where  $\lambda_r$  is the number of repeated phrases, and  $\lambda_d$  is the number of distinct phrases. By Lemma 5 it is  $\lambda_r \leq n/(2 \log^{1+\rho} n)$ , while for the number  $\lambda_d$  of distinct phrases it is [27, Lemmas 3.9 and 3.10]

$$\lambda_d = \mathcal{O}\left(\frac{n}{\log_\sigma n}\right) \quad \text{and} \quad \lambda_d \log \lambda_d \leq nH_k(S) + \lambda_d \log \frac{n}{\lambda_d} + \mathcal{O}(\lambda_d(1 + k \log \sigma)) \quad (2)$$

for any constant  $k \geq 0$ . The vectors PE and HE contain  $\lambda$  increasing values in the range  $[1, n]$ . We encode each of them in  $\lambda \log \frac{n}{\lambda} + \mathcal{O}(\lambda)$  bits using Lemma 2. Since  $f(x) = x \log(n/x)$  is increasing for  $x \leq n/e$  and  $\lambda = \mathcal{O}(n/\log_\sigma n)$ , it is  $\lambda \log \frac{n}{\lambda} + \mathcal{O}(\lambda) = \mathcal{O}(n(\log \sigma)(\log \log n)/\log n) = o(n \log \sigma)$ .

We encode HS using  $\lambda$  cells of size  $\lceil \log \lambda \rceil = \log \lambda + \mathcal{O}(1)$  bits for a total of

$$\lambda_r \log(\lambda_r + \lambda_d) + \lambda_d \log(\lambda_r + \lambda_d) + \mathcal{O}(\lambda) \quad \text{bits.}$$

Since  $\lambda_d = \mathcal{O}(n/\log_\sigma n)$  and  $\lambda_r = \mathcal{O}(n/\log^{1+\rho} n)$ , it is  $\lambda_d + \lambda_r = \mathcal{O}(n/\log_\sigma n)$  and the first term is  $\mathcal{O}(n/\log^\rho n)$ . The second term can be bounded by noticing that, if  $\lambda_d \leq \lambda_r$ , the second term is smaller than the first. Otherwise, from (2) we have

$$\lambda_d \log(\lambda_r + \lambda_d) \leq \lambda_d \log(2\lambda_d) \leq nH_k(S) + \lambda_d \log \frac{n}{\lambda_d} + \mathcal{O}(\lambda_d(1 + k \log \sigma)).$$

By the same reasoning as above, we have  $\lambda_d \log \frac{n}{\lambda_d} = o(n \log \sigma)$  and  $\lambda_d(1 + k \log \sigma) = \mathcal{O}((nk \log \sigma)/\log_\sigma n) = o(n \log \sigma)$  for  $k = o(\log_\sigma n)$ . ◀

Combining Lemma 6 with 4 and recalling that  $\log \lambda = \mathcal{O}(\log^{1+\rho} n)$ , we get

► **Theorem 7.** *Let  $\sigma$  denote the number of distinct gaps in  $S$ . Using the  $LZ_\epsilon^\rho$  parsing we can compute  $\text{select}(t)$  in  $\mathcal{O}(\log^{1+\rho} n)$  time using  $nH_k(S) + \mathcal{O}(n/\log^\rho n) + o(n \log \sigma)$  bits of space plus the space used for the  $\lambda$  segments (array TL) and for the corrections of the elements in  $A$  covered by the tails in the parsing (array TC), for any positive  $k = o(\log_\sigma n)$ .*

In the proof of Lemma 6 one can see the interplay between the term  $\mathcal{O}(n/\log^\rho n)$  coming from the repeated phrases and the term  $o(n \log \sigma)$  coming from the distinct phrases in  $LZ_\epsilon^\rho$ . In particular, if  $\sigma$  is small (i.e., there are few distinct gaps), then  $o(n \log \sigma)$  becomes  $\mathcal{O}(n \log \log n/\log n)$  and the space bound turns out to be  $nH_k(S) + \mathcal{O}(n/\log^\rho n)$  bits. Also, note that the number of segments  $\lambda$  in  $LZ_\epsilon^\rho$  is always smaller than the number of segments in a plain LA-vector. Also, the total length of the  $LZ_\epsilon^\rho$  tails is always smaller than  $n$ . Hence, our approach is no worse than the LA-vector in space.

We now show that the  $LZ_\varepsilon^\rho$  parsing support efficient rank queries. The starting point is the following lemma, whose proof is analogous to the one of Lemma 3.

► **Lemma 8.** *Let  $S[i+1, j]$  denote the head of phrase  $Z[q]$ , and let  $r = \text{HS}[q]$  and  $e = \text{PE}[r]$ . Then, for any  $v$  such that  $A[i] < v \leq A[j]$ , it holds  $\text{rank}(v) = \text{rank}(v - (A[j] - A[e])) + (j - e)$ .*

► **Theorem 9.** *Using the  $LZ_\varepsilon^\rho$  parsing we can compute  $\text{rank}(v)$  in  $\mathcal{O}(\log^{1+\rho} n + \log \varepsilon)$  time within the space stated in Theorem 7.*

**Proof.** We answer  $\text{rank}(v)$  with an algorithm similar to Algorithm 1. First, we compute the index  $q$  of the phrase  $Z[q]$  such that  $A[\text{PE}[q-1]] < v \leq A[\text{PE}[q]]$  with a binary search on the values  $A[\text{PE}[i]]$ . If the parsing has  $\lambda$  phrases this takes  $\mathcal{O}(\log \lambda)$  time, since we can retrieve  $A[\text{PE}[i]]$  in constant time using  $\text{PE}[i]$ ,  $\text{TL}[i]$  and  $\text{TC}[i]$ .

Next, we set  $j = \text{HE}[q]$  and compare  $v$  with  $A[j]$  (which again we can retrieve in constant time since it is the first value covered by  $Z[q]$ 's tail). If  $v \geq A[j]$ , we return  $j$  plus the rank of  $v$  in  $A[j, \text{PE}[q]]$ , which we can compute in  $\mathcal{O}(\log \varepsilon)$  time from  $\text{TL}[q]$  and  $\text{TC}[q]$  using the algorithm in [7, §4]. If  $v < A[j]$ , we set  $e = \text{PE}[\text{HS}[q]]$  and compute  $\text{rank}(v)$  recursively using Lemma 8. Before the recursive call, we need to compute the index  $q'$  of the phrase such that  $A[\text{PE}[q'-1]] < v' \leq A[\text{PE}[q']]$ , for  $v' = v - (A[j] - A[e])$ . To this end, we execute the same while loop as the one in Lines 12–13 of Algorithm 1 with the test  $t' > \text{PE}[q']$  replaced by  $v' > A[\text{PE}[q']]$ . Reasoning as in the proof of Lemma 4, we get that the overall time complexity is  $\mathcal{O}(\log \lambda + M_{\max} + \log \varepsilon) = \mathcal{O}(\log^{1+\rho} n + \log \varepsilon)$ . ◀

#### 4 The block- $\varepsilon$ tree

In this section, we design a repetition aware version of the LA-vector by following an approach that focuses on query efficiency and uses space bounded in terms of the complexity measure  $\delta$  reviewed in Section 2. We do so by building a variant of the block tree [5] on a combination of the gap-string  $S$  and the piecewise linear  $\varepsilon$ -approximation. We name this variant block- $\varepsilon$  tree, and show that it achieves time-space bounds which are competitive with the ones achieved by block trees and LA-vectors [7] because it combines both forms of compressibility discussed in this paper: repetitiveness and approximate linearity.

The main idea of the block- $\varepsilon$  tree consists in first building a traditional block tree structure over the gap-string  $S[1, n]$  of  $A$ . Recall that every node of the block tree represents a substring of  $S$ , and thus it implicitly represents the corresponding subarray of  $A$ . Then, we prune the tree by dropping the subtrees whose corresponding subarray of  $A$  can be covered more succinctly by segments and corrections (i.e. whose LA-vector representation wins over the block-tree representation). Note that, compared to LA-vector, we do not encode segments and corrections corresponding to substrings of  $S$  that have been encountered earlier, that is, we exploit the repetitiveness of  $S$  to compress the piecewise linear  $\varepsilon$ -approximation at the core of LA-vector. On the other hand, compared to block trees, we drop subtrees whose substrings can be encoded more efficiently by segments and corrections, that is, we exploit the approximate linearity of subarrays of  $A$ . Below we detail how to orchestrate this interplay to achieve efficient queries and compressed space occupancy in the block- $\varepsilon$  tree.

For simplicity of exposition, assume that  $n = \delta 2^h$  for some integer  $h$ , where  $\delta$  is the string complexity of  $S$ . The block- $\varepsilon$  tree is organised into  $h' \leq h$  levels. The first level (level zero) logically divides the string  $S$  into  $\delta$  blocks of size  $s_0 = n/\delta$ . In general, blocks at level  $\ell$  have size  $s_\ell = n/(\delta 2^\ell)$ , because they are recursively halved until possibly reaching the last level  $h = \log \frac{n}{\delta}$ , where blocks have size  $s_h = 1$ .

At any level, if two blocks  $S_q$  and  $S_{q+1}$  are consecutive in  $S$  and they form the leftmost occurrence in  $S$  of their content, then we say that both  $S_q$  and  $S_{q+1}$  are marked. A marked block  $S_q$  that is not in the last level becomes an internal node of the tree. Such an internal node has two children corresponding to the two equal-size sub-blocks in which  $S_q$  is split into. On the other hand, an unmarked block  $S_r$  becomes a leaf of the tree because, by construction, its content occurs earlier in  $S$  and thus we can encode it by storing (i) a leftward pointer  $q$  to the marked blocks  $S_q, S_{q+1}$  at the same level  $\ell$  containing its leftmost occurrence, taking  $\log \frac{n}{s_\ell}$  bits; (ii) the offset  $o$  of  $S_r$  into the substring  $S_q \cdot S_{q+1}$ , taking  $\log s_\ell$  bits. Furthermore, to recover the values of  $A$  corresponding to  $S_r$ , we store (iii) the difference  $\Delta$  between the value of  $A$  corresponding to the beginning of  $S_r$  and the value of  $A$  at the pointed occurrence of  $S_r$ , taking  $\log u$  bits. Overall, each unmarked block needs  $\log n + \log u$  bits of space.

To describe the pruning process, we first define a cost function  $c$  on the nodes of the block- $\varepsilon$  tree. For an unmarked block  $S_r$ , we define the cost  $c(S_r) = \log n + \log u$ , which accounts for the space in bits taken by  $q$ ,  $o$  and  $\Delta$ . For a marked block  $S_q$  at the last level  $h$ , we define the cost  $c(S_q) = \log u$ , which accounts for the space in bits taken by its single corresponding element of  $A$ . Instead, consider a marked block  $S_q$  at level  $\ell < h$  for which there exists a segment approximating with error  $\varepsilon_q \leq \varepsilon$  the corresponding elements of  $A$ . Suppose  $\varepsilon_q$  is minimal, that is, there is no  $\varepsilon' < \varepsilon_q$  such that there exists a segment  $\varepsilon'$ -approximating those same elements of  $A$ . Let  $\kappa$  be the space in bits taken by the parameters  $\langle \alpha, \beta \rangle$  of the segment, e.g.  $\kappa = 2 \log u + \log n$  if we encode  $\beta$  in  $\log u$  bits and  $\alpha$  as a rational number with a  $\log u$ -bit numerator and a  $\log n$ -bit denominator [7, §2]. We assign to such  $S_q$  a cost  $c(S_q)$  defined recursively as

$$c(S_q) = \min \begin{cases} \kappa + s_\ell \log \varepsilon_q + \log \log u \\ 2 \log n + \sum_{S_x \in \text{child}(S_q)} c(S_x) \end{cases} \quad (3)$$

The first branch of Equation (3) accounts for an encoding of the subarray of  $A$  corresponding to  $S_q$  via an  $\varepsilon_q$ -approximate segment, the corrections of  $\log \varepsilon_q$  bits for each of the  $s_\ell$  elements in  $S_q$ , and the exponent  $y$  of  $\varepsilon_q = 2^y - 1$  to keep track of its value, respectively. The second branch of Equation (3) accounts for an encoding that recursively splits  $S_q$  into two children, i.e. an encoding via two  $\log n$ -bit pointers plus the optimal cost of the children. Finally, if there is no linear  $\varepsilon$ -approximation (and thus no  $\varepsilon_q$ -approximation with  $\varepsilon_q \leq \varepsilon$ ) for  $S_q$ , we assign to such  $S_q$  the cost indicated in the second branch of Equation (3).

A postorder traversal of the block- $\varepsilon$  tree is sufficient to assign a cost to its nodes and possibly prune some of its subtrees. Specifically, after recursing on the two children of a marked block  $S_q$  at level  $\ell$ , we check if the first branch of Equation (3) gives the minimum. In that case, we prune the subtree rooted at  $S_q$  and store instead the encoding of the block via the parameters  $\langle \alpha, \beta \rangle$  and the  $s_\ell$  corrections in an array  $C_q$ . As a technical remark, this pruning requires fixing the destination of any leftward pointer that starts from an unmarked block  $S_r$  and ends to a (pruned) descendant of  $S_q$ . For this purpose, we first make  $S_r$  pointing to  $S_q$ . Then, since any leftward pointer points to a *pair* of marked blocks (unless the offset is zero), both or just one of them belongs to the pruned subtree. In the second case, we require an additional pointer from  $S_r$  to the block that does not belong to the pruned subtree. This additional pointer does not change the asymptotic complexity of the structure. Overall, this pruning process yields a tree with  $h' \leq h$  levels.

In the full paper, we show how to support **rank** and **select** queries on the block- $\varepsilon$  tree in worst-case  $\mathcal{O}(\log \log_w \frac{u}{\delta} + h' + \log \varepsilon)$  time and  $\mathcal{O}(h')$  time, respectively.

We observe that the block- $\varepsilon$  tree achieves space-time complexities no worse than a standard block tree construction on  $S$ . This is due to the pruning of subtrees guided by the space-conscious cost function  $c(\cdot)$  and by the resulting reduction in the number of levels,

which positively impact the query time. Compared to LA-vector, the block- $\varepsilon$  tree can take advantage of repetitions and avoid the encoding of subarrays of  $A$  corresponding to repeated substrings of  $S$ . Furthermore, since the block- $\varepsilon$  tree allocates the most succinct encoding for a subarray of  $A$  by considering the smallest  $\varepsilon_q \leq \varepsilon$  giving a linear  $\varepsilon_q$ -approximation, it could be regarded as the repetition-aware analogous of the space-optimised LA-vector [7, §6], in which all values of  $\varepsilon = 0, 2^0, 2^1, \dots, 2^{\log u}$  are considered. The block- $\varepsilon$  tree has the advantage of potentially storing fewer corrections at the cost of storing the tree topology. Using the straightforward pointer-based encoding we discussed above, the tree topology takes  $\mathcal{O}(\delta \log \frac{n}{\delta} \log n)$  bits in the worst case, but for the next section we implement a more succinct pointerless encoding (details in the full paper). We notice, nonetheless, that the more repetitive is the string  $S$ , the smaller is  $\delta$ , thus the overhead of the tree topology gets negligible.

Finally, we mention that the block- $\varepsilon$  tree could employ other compressed rank-select dictionaries in its nodes, yielding a hybrid compression approach [39] that can benefit from the orchestration of bicriteria optimisation and proper pruning of its topology to achieve the best space occupancy, given a bound on the query time, or vice versa (à la [12, 17, 39]).

## 5 Experiments

We implemented the block- $\varepsilon$  tree, as it is the simplest and most practical contribution of this paper.

We compare our block- $\varepsilon$  tree with the block tree of [5], built on the characteristic bitvector  $\text{bv}(A)$ , and with the space-optimised LA-vector of [7]. All these implementations are written in C++ and build on the `sds1` library [19]. For both the block tree and the block- $\varepsilon$  tree, we use a branching factor of two and vary the length  $b$  of the last-level blocks as  $b \in \{2^3, 2^4, \dots, 2^9\}$ . Due to space limitations, we do not show the full space-time trade-off of each structure but report only the most space-efficient configurations. A comparison with other rank/select dictionaries is beyond the scope of our work, and it was already investigated in the literature for the individual LA-vector and the block tree [5, 7]. On the other hand, we note that our experimental study is the first to compare LA-vectors and block trees.

As datasets, we use (i) three postings lists with different densities  $n/u$  from the GOV2 inverted index [39]; (ii) six integers lists obtained by enumerating the positions of the first, second and third most frequent character in each of the Burrows-Wheeler transform of two text files: URL and 5GRAM [7]; (iii) three integers lists obtained by enumerating, respectively, the positions of both Ts and Gs, of Ts, and of Gs in the Burrows-Wheeler transform of the first gigabyte of the human reference genome GRCh38.p13.

For each tested structure, query operation, and dataset, we generate a batch of  $10^5$  random queries and measure the average query time in nanoseconds and the space occupancy of the structure in bits per integer on a machine with 202 GB of RAM and a 2.30 GHz Intel Xeon Gold 5118 CPU.

Table 1 shows the results. First and foremost, we note that LA-vector is  $10.51\times$  faster in select and  $4.69\times$  faster in rank than the block tree on average, while for space there is no clear winner over all the datasets. This comparison, which was not known in the literature, illustrates that the combination of approximate linearity and repetitiveness is interesting not only from a theoretical point of view, as commented in the introduction, but also from a practical point of view.

Let us now compare the performance of our block- $\varepsilon$  tree against the block tree and the LA-vector. The block- $\varepsilon$  tree is  $2.19\times$  faster in select than the block tree, and it is either faster ( $1.32\times$ ) or slower ( $1.27\times$ ) in rank. With respect to LA-vector, the block- $\varepsilon$  tree is always

■ **Table 1** The performance of LA-vector, the block tree over the characteristic bitvector  $\text{bv}(A)$  and the block- $\varepsilon$  tree over twelve datasets of different size  $n$  and universe size  $u$ . The **select** and **rank** columns show the average query time of the operations in nanoseconds. The space of each structure is shown in Bits Per Integer (BPI). For the block tree and the block- $\varepsilon$  tree, the value  $b$  denotes the length of the last-level block that gave the most space-efficient configuration.

slower. But, for what concerns the space, the block- $\varepsilon$  tree improves both the LA-vector and the block tree in the sparsest GOV2 and DNA, and in the vast majority of the remaining datasets it is the second-best structure for space occupancy (except for the densest GOV2, URL and 5GRAM). This shows that space-wise, the block- $\varepsilon$  tree can be a robust data structure in that it often achieves a good compromise by exploiting both kinds of regularities: repetitiveness (block trees) and approximate linearity (LA-vectors).

For future work, we believe the block- $\varepsilon$  tree can be improved along at least two avenues. First, the block- $\varepsilon$  tree at a certain level is constrained to use fixed-length blocks (and thus segments), whilst the LA-vector minimises its space occupancy using segments whose start/end positions do not have to coincide with a subdivision in blocks. Removing this limitation, inherited from the block tree, would help to better capture approximate linearity and improve the space occupancy of the block- $\varepsilon$  tree. Second, the block- $\varepsilon$  tree captures the repetitiveness of the gap string  $S$ , while for the densest datasets of Table 1 it appears worthwhile to consider the repetitiveness in  $\text{bv}(A)$ , as done by the block tree. Therefore, adapting our pruning strategy to  $\text{bv}(A)$  is likely to improve the space occupancy in these densest datasets (though, the space-time bounds will then depend on  $u$  instead of  $n$ ).

## 6 Conclusions

We introduced novel compressed rank/select dictionaries by exploiting two sources of regularity arising in real data: repetitiveness and approximate linearity. Our first contribution, the  $LZ_\varepsilon^p$  parsing, combines backward copies with linear  $\varepsilon$ -approximation thus supporting efficient queries within a space complexity bounded by the  $k$ th order entropy of the gaps in the input data. Our second contribution, the block- $\varepsilon$  tree, is a structure that adapts smoothly to both sources of regularities by offering an improved query-time efficiency compared to  $LZ_\varepsilon^p$ . We experimented with a preliminary implementation of the block- $\varepsilon$  tree showing that it effectively exploits both repetitiveness and approximate linearity.

Our study opens up a plethora of opportunities for future research. Firstly, we notice that the PGM-index [17] is also based on a variant of the piecewise linear  $\varepsilon$ -approximation, and thus it can still benefit from the ideas presented in this paper to make its space occupancy repetition aware. Secondly, the compression of segments and corrections in both  $LZ_\varepsilon^p$  and

the block- $\varepsilon$  tree is an orthogonal problem for which one can devise further compression mechanisms (see e.g. [17, Theorem 3]). Thirdly, the construction of the  $LZ_\varepsilon^p$  phrases and the block- $\varepsilon$  tree could be investigated inside a bicriteria framework, which seeks to optimise the query time and space usage under some given constraints [11]. Finally, inspired by our preliminary results, we plan to engineer a more query-efficient implementation of the block- $\varepsilon$  tree that computes an optimal node pruning using a family of compressed data structures in addition to  $\varepsilon$ -approximate segments.

---

## Abstract

Data masking is a common technique for sanitizing sensitive data maintained in database systems, and it is also becoming increasingly important in various application areas, such as in record linkage of personal data. This work formalizes the Pattern Masking for Dictionary Matching (PMDM) problem. In PMDM, we are given a dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a query string  $q$  of length  $\ell$ , and a positive integer  $z$ , and we are asked to compute a smallest set  $K \subseteq \{1, \dots, \ell\}$ , so that if  $q[i]$  is replaced by a wildcard for all  $i \in K$ , then  $q$  matches at least  $z$  strings from  $\mathcal{D}$ . Solving PMDM allows providing data utility guarantees as opposed to existing approaches.

We first show, through a reduction from the well-known  $k$ -Clique problem, that a decision version of the PMDM problem is NP-complete, even for strings over a binary alphabet. We thus approach the problem from a more practical perspective. We show a combinatorial  $\mathcal{O}((d\ell)^{|K|/3} + d\ell)$ -time and  $\mathcal{O}(d\ell)$ -space algorithm for PMDM for  $|K| = \mathcal{O}(1)$ . In fact, we show that we cannot hope for a faster combinatorial algorithm, unless the combinatorial  $k$ -Clique hypothesis fails [Abboud et al., SIAM J. Comput. 2018; Lincoln et al., SODA 2018]. We also generalize this algorithm for the problem of masking multiple query strings simultaneously so that every string has at least  $z$  matches in  $\mathcal{D}$ .

Note that PMDM can be viewed as a generalization of the decision version of the dictionary matching with mismatches problem: by querying a PMDM data structure with string  $q$  and  $z = 1$ , one obtains the minimal number of mismatches of  $q$  with any string from  $\mathcal{D}$ . The query time or space of all known data structures for the *more restricted* problem of dictionary matching with at most  $k$  mismatches incurs some exponential factor with respect to  $k$ . A simple exact algorithm for PMDM runs in time  $\mathcal{O}(2^\ell d)$ . We present a data structure for PMDM that answers queries over  $\mathcal{D}$  in time  $\mathcal{O}(2^{\ell/2}(2^{\ell/2} + \tau)\ell)$  and requires space  $\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$ , for any parameter  $\tau \in [1, d]$ .

We complement our results by showing a two-way polynomial-time reduction between PMDM and the Minimum Union problem [Chlamtáč et al., SODA 2017]. This gives a polynomial-time  $\mathcal{O}(d^{1/4+\epsilon})$ -approximation algorithm for PMDM, which is tight under a plausible complexity conjecture.

## 1 Introduction

Let us start with a true incident to illustrate the essence of the computational problem formalized in this work. In the Netherlands, water companies bill the non-drinking and drinking water separately. The 6th author of this paper had direct debit for the former but not for the latter. When he tried to set up the direct debit for the latter, he received the following masked message by the company:

```
Is this you?
Initial: S. Name: P***** E-mail address: s*****13@g***1.com
Bank account number: NL10RABO*****11.
```

The rationale of the data masking is: the client should be able to identify themselves, to help the companies *link* the client’s profiles, but not infer the identity of any other client, so that clients’ privacy is preserved. Thus, the masked version of the data is required to conceal as few symbols as possible but correspond to a sufficient number of other clients.

This requirement can be formalized as the Pattern Masking for Dictionary Matching (PMDM) problem: Given a dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a query string  $q$  of length  $\ell$ , and a positive integer  $z$ , PMDM asks to compute a smallest set  $K \subseteq \{1, \dots, \ell\}$ , so that if  $q[i]$ , for all  $i \in K$ , is replaced by a wildcard,  $q$  matches at least  $z$  strings from  $\mathcal{D}$ . The PMDM problem applies data masking, a common operation to sanitize personal data maintained in database systems [1, 26, 56]. In particular, PMDM lies at the heart of record linkage of databases containing personal data [23, 39, 40, 52, 59, 61], which is the main application we consider in this work.

*Record linkage* is the task of identifying records that refer to the same entities across databases, in situations where no entity identifiers are available in these databases [22, 32, 47]. This task is of high importance in various application domains featuring personal data, ranging from the health sector and social science research, to national statistics and crime and fraud detection [23, 36]. In a typical setting, the task is to link two databases that contain names or other attributes, known collectively as quasi-identifiers (QIDs) [60]. The similarity between each pair of records (a record from one of the databases and a record from the other) is calculated with respect to their values in QIDs, and then all compared record pairs are classified into matches (the pair is assumed to refer to the same person), non-matches (the two records in the pair are assumed to refer to different people), and potential matches (no decision about whether the pair is a match or non-match can be made) [22, 32]. Unfortunately, potential matches happen quite often [9]. A common approach [52, 59] to deal with potential matches is to conduct a manual clerical review, where a domain expert

looks at the attribute values in record pairs and then makes a manual match or non-match decision. At the same time, to comply with policies and legislation, one needs to prevent domain experts from inferring the identity of the people represented in the manually assessed record pairs [52]. The challenge is to achieve desired data protection/utility guarantees; i.e. enabling a domain expert to make good decisions without inferring peoples' identities.

To address this challenge, we can solve PMDM twice, for a potential match  $(q_1, q_2)$ . The first time we use as input the query string  $q_1$  and a reference dictionary (database)  $\mathcal{D}$  containing personal records from a sufficiently large population (typically, much larger than the databases to be linked). The second time, we use as input  $q_2$  instead of  $q_1$ . Since each masked  $q$  derived by solving PMDM matches at least  $z$  records in  $\mathcal{D}$ , the domain expert would need to distinguish between at least  $z$  individuals in  $\mathcal{D}$  to be able to infer the identity of the individual corresponding to the masked string. The underlying assumption is that  $\mathcal{D}$  contains one record per individual. Also, some wildcards from one masked string can be superimposed on another to ensure that the expert does not gain more knowledge from combining the two strings, and the resulting strings would still match at least  $z$  records in  $\mathcal{D}$ . Thus, by solving PMDM in this setting, we provide privacy guarantees alike  $z$ -map [57]; a variant of the well-studied  $z$ -anonymity [54] privacy model.<sup>1</sup> In  $z$ -map, each record of a dataset must match at least  $z$  records in a reference dataset, from which the dataset is derived. In our setting, we consider a pattern that is not necessarily contained in the reference dataset. Offering such privacy is desirable in real record linkage systems where databases containing personal data are being linked [23, 40, 61]. On the other hand, since each masked  $q$  contains the minimum number of wildcards, the domain expert is still able to use the masked  $q$  to meaningfully classify a record pair as a match or as a non-match. Offering such utility is again desirable in record linkage systems [52]. Record linkage is an important application for our techniques, because no existing approach can provide privacy and utility guarantees when releasing linkage results to domain experts [41]. In particular, existing approaches [40, 41] recognize the need to offer privacy by preventing the domain expert from distinguishing between a small number of individuals, but they provide *no algorithm* for offering such privacy, let alone an algorithm offering utility guarantees as we do.

A secondary application where PMDM is of importance is *query term dropping*, an information retrieval task that seeks to drop keywords (terms) from a query, so that the remaining keywords retrieve a sufficiently large number of documents. This task is performed by search engines, such as Google [8], and by e-commerce platforms such as e-Bay [42], to improve users' experience [29, 58] by making sufficiently many search results available to users. For example, e-Bay applies query term dropping, removing one term, in our test query:

```
Query: vacuum database cleaner
Query results: 0 results found for vacuum database cleaner
               42 results found for vacuum cleaner
```

We could perform query term dropping by solving PMDM in a setting where strings in a dictionary correspond to document terms and a query string corresponds to a user's query. Then, we provide the user with the masked query, after removing all wildcards, and with its matching strings from the dictionary. Query term dropping is a relevant application for our techniques, because existing techniques [58] do not minimize the number of dropped terms. Rather, they drop keywords randomly, which may unnecessarily shorten the query,

<sup>1</sup> The notation used for such privacy models is generally  $k$  instead of  $z$ , e.g.  $k$ -anonymity [55, 57].

or drop keywords based on custom rules, which is not sufficiently generic to deal with all queries. More generally, our techniques can be applied to drop terms from any top- $z$  database query [33] to ensure there are  $z$  results in the query answer.

**Related Algorithmic Work.** Let us denote the wildcard symbol by  $\star$  and provide a brief overview of works related to PMDM, the main problem considered in this paper.

- *Partial Match:* Given a dictionary  $\mathcal{D}$  of  $d$  strings over an alphabet  $\Sigma = \{0, 1\}$ , each of length  $\ell$ , and a string  $q$  over  $\Sigma \sqcup \{\star\}$  of length  $\ell$ , the problem asks whether  $q$  matches any string from  $\mathcal{D}$ . This is a well-studied problem [14, 18, 35, 46, 50, 51, 53]. Patrascu [50] showed that any data structure for the Partial Match problem with cell-probe complexity  $t$  must use space  $2^{\Omega(\ell/t)}$ , assuming the word size is  $\mathcal{O}(d^{1-\epsilon}/t)$ , for any constant  $\epsilon > 0$ . The key difference to PMDM is that the wildcard positions in the query strings are fixed.
- *Dictionary Matching with  $k$ -errors:* A similar line of research to that of Partial Match has been conducted under the Hamming and edit distances, where, in this case,  $k$  is the maximum allowed distance between the query string and a dictionary string [11, 12, 15, 17, 25, 64]. The structure of Dictionary Matching with  $k$ -errors is very similar to Partial Match as each wildcard in the query string gives  $|\Sigma|$  possibilities for the corresponding symbol in the dictionary strings. On the other hand, in Partial Match the wildcard positions are fixed. The PMDM problem is a generalization of the decision version of the Dictionary Matching with  $k$ -errors problem (under Hamming distance): by querying a data structure for PMDM with string  $q$  and  $z = 1$ , one obtains the minimum number of mismatches of  $q$  with any string from  $\mathcal{D}$ , which suffices to answer the decision version of the Dictionary Matching with  $k$ -errors problem. The query time or space of all known data structures for Dictionary Matching with  $k$ -mismatches incurs some exponential factor with respect to  $k$ . In [24], Cohen-Addad et al. showed that, in the pointer machine model, for the reporting version of the problem, one cannot avoid exponential dependency on  $k$  either in the space or in the query time. In the word-RAM model, Rubinfeld showed that, conditional on the Strong Exponential Time Hypothesis [16], any data structure that can be constructed in time polynomial in the total size  $|\mathcal{D}|$  of the strings in the dictionary cannot answer queries in time strongly sublinear in  $|\mathcal{D}|$ .

We next provide a brief overview of other algorithmic works related to PMDM.

- *Dictionary Matching with  $k$ -wildcards:* Given a dictionary  $\mathcal{D}$  of total size  $N$  over an alphabet  $\Sigma$  and a query string  $q$  of length  $\ell$  over  $\Sigma \sqcup \{\star\}$  with up to  $k$  wildcards, the problem asks for the set of matches of  $q$  in  $\mathcal{D}$ . This is essentially a parameterized variant of the Partial Match problem. The seminal paper of Cole et al. [25] proposed a data structure occupying  $\mathcal{O}(N \log^k N)$  space allowing for  $\mathcal{O}(\ell + 2^k \log \log N + |\text{output}|)$ -time querying. This data structure is based on recursively computing a heavy-light decomposition of the suffix tree and copying the subtrees hanging off light children. Generalizations and slight improvements have been proposed in [13], [43], and [28]. In [13] the authors also proposed an alternative data structure that instead of a  $\log^k N$  factor in the space complexity has a multiplicative  $|\Sigma|^{k^2}$  factor. Nearly-linear-sized data structures that essentially try all different combinations of letters in the place of wildcards and hence incur a  $|\Sigma|^k$  factor in the query time have been proposed in [13, 44]. On the lower bound side, Afshani and Nielsen [3] showed that, in the pointer machine model, essentially any data structure for the problem in scope must have exponential dependency on  $k$  in either the space or the query time, explaining the barriers hit by the existing approaches.
- *Enumerating Motifs with  $k$ -wildcards:* Given an input string  $s$  of length  $n$  over an alphabet  $\Sigma$  and positive integers  $k$  and  $z$ , this problem asks to enumerate all motifs over  $\Sigma \sqcup \{\star\}$  with up to  $k$  wildcards that occur at least  $z$  times in  $s$ . As the size of the output is exponential in  $k$ , the enumeration problem has such a lower bound. Several approaches

exist for efficient motif enumeration, all aimed at reducing the impact of the output's size: efficient indexing to minimise the output delay [7, 30]; exploiting a hierarchy of wildcards positions according to the number of occurrences [10]; or defining a subset of motifs of fixed-parameter tractable size (in  $k$  or  $z$ ) that can generate all the others [5, 48, 49].

**Our Contributions.** We consider the word-RAM model of computations with  $w$ -bit machine words, where  $w = \Omega(\log(d\ell))$ , for stating our results. We make the following contributions:

1. (Section 3) A reduction from the  $k$ -Clique problem to a decision version of the PMDM problem, which implies that PMDM is NP-hard, even for strings over a binary alphabet.
2. (Section 4) A combinatorial  $\mathcal{O}((d\ell)^{k/3} + d\ell)$ -time and  $\mathcal{O}(d\ell)$ -space algorithm for PMDM if  $k = |K| = \mathcal{O}(1)$ , which is optimal if the combinatorial  $k$ -Clique hypothesis is true.
3. (Section 5) We consider a generalized version of PMDM, referred to as MPMDM: we are given a collection  $\mathcal{M}$  of  $m$  query strings (instead of one query string) and we are asked to compute a smallest set  $K$  so that, for every  $q$  from  $\mathcal{M}$ , if  $q[i]$ , for all  $i \in K$ , is replaced by a wildcard, then  $q$  matches at least  $z$  strings from dictionary  $\mathcal{D}$ . We show an  $\mathcal{O}((d\ell)^{k/3} z^{m-1} + d\ell)$ -time algorithm for MPMDM, for  $k = |K| = \mathcal{O}(1)$  and  $m = \mathcal{O}(1)$ .
4. (Section 6) A data structure for PMDM that answers queries over  $\mathcal{D}$  in  $\mathcal{O}(2^{\ell/2}(2^{\ell/2} + \tau)\ell)$  time and requires space  $\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$ , for any parameter  $\tau \in [1, d]$ .
5. (Section 7) A polynomial-time  $\mathcal{O}(d^{1/4+\epsilon})$ -approximation algorithm for PMDM, which we show to be tight under a plausible complexity conjecture.

Let us now discuss why our data structure results (Section 6) cannot be directly obtained using data structures for Dictionary Matching with  $k$ -wildcards. Conceivably, one could construct such a data structure, and then iterate over all subsets of  $\{1, \dots, \ell\}$ , querying for the masked string. Existing data structures for dictionary matching with wildcards (cf. [13, Table 1], [44], and [28]), that allow querying a pattern with at most  $\ell$  wildcards, have

- (a) either  $\Omega(\min\{\sigma^\ell, d\})$  query time, thus yielding  $\Omega(2^\ell \cdot \min\{\sigma^\ell, d\})$  query time for our problem, and space  $\Omega(d\ell)$ , a trade-off dominated by the SMALL- $\ell$  algorithm (cf. our Table 1);
- (b) or  $\Omega(\ell)$  query time, thus yielding  $\Omega(2^\ell \ell)$  query time for our problem, and  $\Omega(d\ell \log^\ell \log(d\ell))$  space, a trade-off dominated by the DS SIMPLE (cf. our Table 1).

## 2 Definitions and Notation

**Strings.** An *alphabet*  $\Sigma$  is a finite nonempty set whose elements are called *letters*. We assume throughout an integer alphabet  $\Sigma = [1, |\Sigma|]$ . Let  $x = x[1] \cdots x[n]$  be a *string* of length  $|x| = n$  over  $\Sigma$ . For two indices  $1 \leq i \leq j \leq n$ ,  $x[i..j] = x[i] \cdots x[j]$  is the *substring* of  $x$  that starts at position  $i$  and ends at position  $j$  of  $x$ . By  $\varepsilon$  we denote the *empty string* of length 0. A *prefix* of  $x$  is a substring of  $x$  of the form  $x[1..j]$ , and a *suffix* of  $x$  is a substring of  $x$  of the form  $x[i..n]$ . A *dictionary* is a collection of strings. We also consider alphabet  $\Sigma_\star = \Sigma \sqcup \{\star\}$ , where  $\star$  is a *wildcard* letter that is not in  $\Sigma$  and *matches* all letters from  $\Sigma_\star$ . Then, given a string  $x$  over  $\Sigma_\star$  and a string  $y$  over  $\Sigma$  with  $|x| = |y|$ , we say that  $x$  *matches*  $y$  if and only if  $x[i] = y[i]$  or  $x[i] = \star$ , for all  $1 \leq i \leq |x|$ . Given a string  $x$  of length  $n$  and a set  $S \subseteq \{1, \dots, n\}$ , we denote by  $x_S = x \otimes S$  the string obtained by first setting  $x_S = x$  and then  $x_S[i] = \star$ , for all  $i \in S$ . We then say that  $x$  is *masked* by  $S$ .

The main problem considered in this paper is the following.

## PATTERN MASKING FOR DICTIONARY MATCHING (PMDM)

**Input:** A dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a string  $q$  of length  $\ell$ , and a positive integer  $z$ .

**Output:** A smallest set  $K \subseteq \{1, \dots, \ell\}$  such that  $q_K = q \otimes K$  matches at least  $z$  strings from  $\mathcal{D}$ .

We refer to the problem of computing only the size  $k$  of a smallest set  $K$  as PMDM-SIZE. We also consider the data structure variant of the PMDM problem in which  $\mathcal{D}$  is given for preprocessing, and  $q, z$  queries are to be answered on-line. Throughout, we assume that  $k \geq 1$  as the case  $k = 0$  corresponds to the well-studied dictionary matching problem for which there exists a classic optimal solution [4]. We further assume  $z \leq d$ ; otherwise the PMDM has trivially no solution. In what follows, we use  $N$  to denote  $d\ell$ .

**Tries.** Let  $\mathcal{M}$  be a finite set containing  $m > 0$  strings over  $\Sigma$ . The *trie* of  $\mathcal{M}$ , denoted by  $\mathcal{R}(\mathcal{M})$ , contains a node for every distinct prefix of a string in  $\mathcal{M}$ ; the root node is  $\varepsilon$ ; the set of leaf nodes is  $\mathcal{M}$ ; and edges are of the form  $(u, \alpha, u\alpha)$ , where  $u$  and  $u\alpha$  are nodes and  $\alpha \in \Sigma$  is the label. The *compact trie* of  $\mathcal{M}$ , denoted by  $\mathcal{T}(\mathcal{M})$ , contains the root, the branching nodes, and the leaf nodes of  $\mathcal{R}(\mathcal{M})$ . Each maximal branchless path segment from  $\mathcal{R}(\mathcal{M})$  is replaced by a single edge, and a fragment of a string  $M \in \mathcal{M}$  is used to represent the label of this edge in  $\mathcal{O}(1)$  space. The size of  $\mathcal{T}(\mathcal{M})$  is thus  $\mathcal{O}(m)$ . The most well-known example of a compacted trie is the suffix tree of a string: the compacted trie of all the suffixes of the string [62]. To access the children of a trie node by the first letter of their edge label in  $\mathcal{O}(1)$  time we use perfect hashing [27]. In this case, the claimed complexities hold *with high probability* (w.h.p., for short), that is, with probability at least  $1 - N^{-c}$  (recall that  $N = d\ell$ ), where  $c > 0$  is a constant fixed at construction time. Assuming that the children of every trie node are sorted by the first letters of their edge labels, randomization can be avoided at the expense of a  $\log |\Sigma|$  factor incurred by binary searching for the appropriate child.

### 3 PMDM-Size is NP-hard

We show that the following decision version of PMDM-SIZE is NP-complete.

#### $k$ -PMDM

**Input:** A dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a string  $q$  of length  $\ell$ , and positive integers  $z \leq d$  and  $k \leq \ell$ .

**Output:** Is there a set  $K \subseteq \{1, \dots, \ell\}$  of size  $k$ , such that  $q_K = q \otimes K$  matches at least  $z$  strings from  $\mathcal{D}$ ?

Our reduction is from the well-known NP-complete  $k$ -CLIQUE problem [37]: Given an undirected graph  $G$  on  $n$  nodes and a positive integer  $k$ , decide whether  $G$  contains a clique of size  $k$  (a *clique* is a subset of the nodes of  $G$  that are pairwise adjacent).

► **Theorem 1.** *Any instance of the  $k$ -CLIQUE problem for a graph with  $n$  nodes and  $m$  edges can be reduced in  $\mathcal{O}(nm)$  time to a  $k$ -PMDM instance with  $\ell = n$ ,  $d = m$  and  $\Sigma = \{\mathbf{a}, \mathbf{b}\}$ .*

**Proof.** Let  $G = (V, E)$  be an undirected graph on  $n = |V|$  nodes numbered 1 through  $n$ , in which we are looking for a clique of size  $k$ . We reduce  $k$ -CLIQUE to  $k$ -PMDM as follows. Consider the alphabet  $\{\mathbf{a}, \mathbf{b}\}$ . Set  $q = \mathbf{a}^n$ , and for every edge  $(u, v) \in E$  such that  $u < v$ , add string  $\mathbf{a}^{u-1}\mathbf{b}\mathbf{a}^{v-u-1}\mathbf{b}\mathbf{a}^{n-v}$  to  $\mathcal{D}$ . Set  $z = k(k-1)/2$ . Then  $G$  contains a clique of size  $k$ , if and only if  $k$ -PMDM returns a positive answer. This can be seen by the fact that cliques of

**Figure 1** An example of the reduction from  $k$ -CLIQUE to  $k$ -PMDM. The solution for both is  $\{1, 2, 3\}$  as shown. Note that, for  $k = 4$ , the instance of 4-PMDM would need  $z = 6$  matches; neither this many matches can be found in  $\mathcal{D}$  nor a 4-clique can be found in the graph.

size  $k$  in  $G$  are in one-to-one correspondence with subsets  $K \subseteq \{1, \dots, n\}$  of size  $k$  for which  $q_K$  matches  $z$  strings from  $\mathcal{D}$ : the elements of  $K$  correspond to the nodes of a clique and the  $z$  strings correspond to its edges.  $k$ -PMDM is clearly in NP and the result follows. ◀

An example of the reduction from  $k$ -CLIQUE to  $k$ -PMDM is shown in Figure 1.

► **Corollary 2.**  $k$ -PMDM is NP-complete for strings over a binary alphabet.

Our reduction (Theorem 1) shows that solving  $k$ -PMDM efficiently even for strings over a binary alphabet would imply a breakthrough for the  $k$ -CLIQUE problem for which it is known that, in general, no fixed-parameter tractable algorithm with respect to parameter  $k$  exists unless the Exponential Time Hypothesis (ETH) fails [19, 34]. That is,  $k$ -CLIQUE has no  $f(k)n^{o(k)}$  time algorithm, and is thus W[1]-complete (again, under the ETH hypothesis). On the upper bound side,  $k$ -CLIQUE can be trivially solved in  $\mathcal{O}(n^k)$  time (enumerating all subsets of nodes of size  $k$ ), and this can be improved to  $\mathcal{O}(n^{\omega k/3})$  time for  $k$  divisible by 3 using square matrices multiplication ( $\omega$  is the exponent of square matrix multiplication). However, for general  $k \geq 3$  and any constant  $\epsilon > 0$ , the  $k$ -CLIQUE hypothesis states that there is no  $\mathcal{O}(n^{(\omega/3-\epsilon)k})$ -time algorithm and no combinatorial  $\mathcal{O}(n^{(1-\epsilon)k})$ -time algorithm [2, 45, 63].

In particular, assuming that the  $k$ -CLIQUE hypothesis is true, due to Theorem 1, we cannot hope to devise a combinatorial algorithm for  $k$ -PMDM requiring  $\mathcal{O}((d\ell)^{(1-\epsilon)k/3})$  time, for any  $k \geq 3$  and  $\epsilon > 0$ , since  $d\ell = nm$ . In Section 4, we show a combinatorial  $\mathcal{O}((d\ell)^{k/3})$ -time algorithm, for constant  $k \geq 3$ , for the optimization version of  $k$ -PMDM (seeking to maximize the matches), which can then be trivially applied to solve  $k$ -PMDM in the same time complexity, thus matching the above conditional lower bound.

Given an undirected graph  $G$ , an *independent set* is a subset of nodes of  $G$  such that no two distinct nodes of the subset are adjacent. Let us note that the problem of computing a maximum clique in a graph  $G$ , which is equivalent to that of computing the maximum independent set in the complement of  $G$ , cannot be  $n^{1-\epsilon}$ -approximated in polynomial time, for any  $\epsilon > 0$ , unless  $P = NP$  [31, 65].

Any algorithm solving PMDM-SIZE can be trivially applied to solve  $k$ -PMDM.

► **Corollary 3.** PMDM-SIZE is NP-hard for strings over a binary alphabet.

## 4 Exact Algorithms for a Bounded Number $k$ of Wildcards

We consider the following problem, which we solve by exact algorithms.

HEAVIEST  $k$ -PMDM  
**Input:** A dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a string  $q$  of length  $\ell$ , and a positive integer  $k \leq \ell$ .  
**Output:** A set  $K \subseteq \{1, \dots, \ell\}$  of size  $k$  such that  $q_K = q \otimes K$  matches the maximum number of strings in  $\mathcal{D}$ .

We will show the following result, which we will employ to solve the PMDM problem.

► **Theorem 4.** *HEAVIEST  $k$ -PMDM for  $k = \mathcal{O}(1)$  can be solved in  $\mathcal{O}(N + \min\{N^{k/3}, \ell^k\})$  time, where  $N = d\ell$ .*

A *hypergraph*  $H$  is a pair  $(V, E)$ , where  $V$  is the set of nodes of  $H$  and  $E$  is a set of non-empty subsets of  $V$ , called *hyperedges* – in order to simplify terminology we will simply call them edges. Hypergraphs are a generalization of graphs in the sense that an edge can connect more than two nodes. Recall that the size of an edge is the number of nodes it contains. The *rank* of  $H$ , denoted by  $r(H)$ , is the maximum size of an edge of  $H$ .

We refer to a hypergraph  $H \times K = (K, \{e : e \in E, e \subseteq K\})$ , where  $K$  is a subset of  $V$ , as a  $|K|$ -*section*.  $H \times K$  is the hypergraph induced by  $H$  on the nodes of  $K$ , and it contains all edges of  $H$  whose elements are all in  $K$ . A hypergraph is *weighted* when each of its edges is associated with a weight. We define *the weight* of a weighted hypergraph as the sum of the weights of all of its edges. In what follows, we also refer to weights of nodes for conceptual clarity; this is equivalent to having a singleton edge of equal weight consisting of that node.

We define the following auxiliary problem on hypergraphs (see also [20]).

HEAVIEST  $k$ -SECTION

**Input:** A weighted hypergraph  $H = (V, E)$ , with  $E$  given as a list, and an integer  $k > 0$ .

**Output:** A subset  $K$  of size  $k$  of  $V$  such that  $H \times K$  has maximum weight.

When  $k = \mathcal{O}(1)$ , we preprocess the edges of  $H$  as follows in order to have  $\mathcal{O}(1)$ -time access to any queried edge. We represent each edge as a string, whose letters correspond to its elements in increasing order. Then, we sort all such strings lexicographically using radix sort in  $\mathcal{O}(|E|)$  time and construct a trie over them. An edge can then be accessed in  $\mathcal{O}(k \log k) = \mathcal{O}(1)$  time by a forward search starting from the root node of the trie.

A polynomial-time  $\mathcal{O}(n^{0.697831+\epsilon})$ -approximation for HEAVIEST  $k$ -SECTION, for any  $\epsilon > 0$ , for the case when all hyperedges of  $H$  have size at most 3 was shown in [20] (see also [6]).

Two remarks are in place. First, we can focus on edges of size up to  $k$  as larger edges cannot, by definition, exist in any  $k$ -section. Second, HEAVIEST  $k$ -SECTION is a generalization of the problem of deciding whether a  $(c, k)$ -hyperclique (i.e. a set of  $k$  nodes whose subsets of size  $c$  are all in  $E$ ) exists in a graph, which in turn is a generalization of  $k$ -CLIQUE. Unlike  $k$ -CLIQUE, the  $(c, k)$ -hyperclique problem is not known to benefit from fast matrix multiplication in general; see [45] for a discussion on its hardness.

► **Lemma 5.** *HEAVIEST  $k$ -PMDM can be reduced to HEAVIEST  $k$ -SECTION for a hypergraph with  $\ell$  nodes and  $d$  edges in  $\mathcal{O}(N)$  time, where  $N = d\ell$ .*

**Proof.** We first compute the set  $M_s$  of positions of mismatches of  $q$  with each string  $s \in \mathcal{D}$ . We ignore strings from  $\mathcal{D}$  that match  $q$  exactly, as they will match  $q$  after changing any set of letters of  $q$  to wildcards. This requires  $\mathcal{O}(d\ell) = \mathcal{O}(N)$  time in total.

Let us consider an empty hypergraph (i.e. with no edges)  $H$  on  $\ell$  nodes, numbered 1 through  $\ell$ . Then, for each string  $s \in \mathcal{D}$ , we add  $M_s$  to the edge-set of  $H$  if  $|M_s| \leq k$ ; if this edge already exists, we simply increment its weight by 1.

We set the parameter  $k$  of HEAVIEST  $k$ -SECTION to the parameter  $k$  of HEAVIEST  $k$ -PMDM. We now observe that for  $K \subseteq V$  with  $|K| = k$ , the weight of  $H \times K$  is equal to the number of strings that would match  $q$  after replacing with wildcards the  $k$  letters of  $q$  at the positions corresponding to elements of  $K$ . The statement follows. ◀

■ **Figure 2** An example of the reduction from HEAVIEST  $k$ -PMDM to HEAVIEST  $k$ -SECTION. The solutions are at the bottom. Each edge has its weight in brackets and the total weight is  $d = 6$ .

An example of the reduction in Lemma 5 is shown in Figure 2.

The next lemma gives a straightforward solution to HEAVIEST  $k$ -SECTION. It is analogous to algorithm SMALL- $\ell$ , presented in Section 6, but without the optimization in computing sums of weights over subsets. It implies a linear-time algorithm for HEAVIEST 1-SECTION.

► **Lemma 6.** HEAVIEST  $k$ -SECTION, for any constant  $k$ , can be solved in  $\mathcal{O}(|V|^k + |E|)$  time and  $\mathcal{O}(|V| + |E|)$  space.

**Proof.** For every subset  $K \subseteq V$  of size at most  $k$ , we sum the weights of all edges corresponding to its subsets. There are  $\binom{|V|}{k} = \mathcal{O}(|V|^k)$  choices for  $|K|$ , each having  $2^k - 1$  non-empty subsets: for every subset, we can access the corresponding edge (if it exists) in  $\mathcal{O}(1)$  time. ◀

We next show that for the cases  $k = 2$  and  $k = 3$ , there exist more efficient solutions. In particular, we provide a linear-time algorithm for HEAVIEST 2-SECTION.

► **Lemma 7.** HEAVIEST 2-SECTION can be solved in  $\mathcal{O}(|V| + |E|)$  time.

**Proof.** Let  $K$  be a set of nodes of size 2 such that  $H \times K$  has maximum weight. We decompose the problem in two cases. For each of the cases, we give an algorithm that considers several 2-sections such that the heaviest of them has weight equal to that of  $H \times K$ .

*Case 1.* There is an edge  $e = K$  in  $E$ . For each edge  $e \in E$  of size 2, i.e. edge in the classic sense, we compute the sum of its weight and the weights of the nodes that it is incident to. This step requires  $\mathcal{O}(|E|)$  time.

*Case 2.* There is no edge equal to  $K$  in  $E$ . We compute  $H \times \{v_1, v_2\}$ , where  $v_1, v_2$  are the two nodes with maximum weight, i.e. max and second-max. This step takes  $\mathcal{O}(|V|)$  time.

In the end, we return the heaviest 2-section among those returned by the algorithms for the two cases, breaking ties arbitrarily. ◀

We next show that for  $k = 3$  the result of Lemma 6 can be improved when  $|E| = o(|V|^2)$ .

► **Lemma 8.** HEAVIEST 3-SECTION can be solved in time  $\mathcal{O}(|V| \cdot |E|)$  using  $\mathcal{O}(|V| + |E|)$  space.

**Proof.** Let  $K$  be a set of nodes of size 3 such that  $H \times K$  has maximum weight. We decompose the problem into the following three cases.

*Case 1.* There is an edge  $e = K$  in  $E$ . We go through each edge  $e \in E$  of size 3 and compute the weight of  $H \times e$  in  $\mathcal{O}(1)$  time. This takes  $\mathcal{O}(|E|)$  time in total. Let the edge yielding the maximum weight be  $e_{\max}$ .

*Case 2.* There is no edge of size larger than one in  $H \times K$ . We compute  $H \times \{v_1, v_2, v_3\}$ , where  $v_1, v_2, v_3$  are the three nodes with maximum weight, i.e. max, second-max and third-max. This step takes  $\mathcal{O}(|V|)$  time.

## 65:10 Pattern Masking for Dictionary Matching

*Case 3.* There is an edge of size 2 in  $H \times K$ . We can pick an edge  $e$  of size 2 from  $E$  in  $\mathcal{O}(|E|)$  ways and a node  $v$  from  $V$  in  $\mathcal{O}(|V|)$  ways. We compute the weight of  $H \times (e \cup \{v\})$  for all such pairs. Let the pair yielding maximum weight be  $(e', u')$ .

Finally, the maximum weight of  $H \times K'$  for  $K' \in \{e_{\max}, \{v_1, v_2, v_3\}, e' \cup \{u'\}\}$  is equal to the weight of  $H \times K$ , breaking ties arbitrarily.  $\blacktriangleleft$

► **Lemma 9.** *HEAVIEST  $k$ -SECTION for an arbitrarily large constant  $k \geq 4$  can be solved in time  $\mathcal{O}((|V| \cdot |E|)^{k/3})$  using  $\mathcal{O}(|V| + |E|)$  space.*

**Proof.** If  $|E| > |V|^2$ , then the simple algorithm of Lemma 6 solves the problem in time

$$\mathcal{O}(|V|^k + |E|) = \mathcal{O}(|V|^{k/3}(|V|^2)^{k/3} + |E|) = \mathcal{O}((|V| \cdot |E|)^{k/3})$$

and linear space. We can thus henceforth assume that  $|E| \leq |V|^2$ .

Let  $K$  be a set of nodes of size at most  $k$  such that  $H \times K$  has maximum weight. If  $H \times K$  contains isolated nodes (i.e. nodes not contained in any edge), they can be safely deleted without altering the result. We can thus assume that  $H \times K$  does not contain isolated nodes, and that  $|V| \leq k|E|$  since otherwise the hypergraph  $H$  would contain isolated nodes.

We first consider the case that the rank  $r(H \times K) > 1$ , i.e. there is an edge of  $H \times K$  of size at least 2. We design a branching algorithm that constructs several candidate sets; the ones with maximum weight will have weight equal to that of  $H \times K$ . We will construct a set of nodes  $X$ , starting with  $X := \emptyset$ . For each set  $X$  that we process, let  $Z_X$  be the superset of  $X$  of size at most  $k$  such that  $H \times Z_X$  has maximum weight. We have the following two cases:

*Case 1.* There is an edge  $e$  in  $H \times Z_X$  that contains at least two nodes from  $Z_X \setminus X$ . To account for this case, we select every possible such edge  $e$ , set  $X := X \cup e$ , and continue the branching algorithm.

*Case 2.* Each edge in  $H \times Z_X$  contains at most one node from  $Z_X \setminus X$ . In this case we conclude the branching algorithm as follows. For every node  $v \in V \setminus X$  we compute its weight as the total weight of edges  $Y \cup \{v\} \in E$  for  $Y \subseteq X$  in  $\mathcal{O}(2^k) = \mathcal{O}(1)$  time. Finally, in  $\mathcal{O}(|V|k) = \mathcal{O}(|V|)$  time we select  $k - |X|$  nodes with largest weights and insert them into  $X$ . The total time complexity of this step is  $\mathcal{O}(|V|)$ . This case also works if  $|X| = k$  and then its time complexity is only  $\mathcal{O}(1)$ .

The correctness of this branching algorithm follows from an easy induction, showing that at every level of the branching tree there is a subset of  $K$ .

Let us now analyze the time complexity of this branching algorithm. Each branching in Case 1 takes  $\mathcal{O}(|E|)$  time and increases the size of  $|X|$  by at least 2. At every node of the branching tree we call the procedure of Case 2. It takes  $\mathcal{O}(|V|)$  time if  $|X| < k$ .

If the procedure of Case 2 is called in a non-leaf node of the branching tree, then its  $\mathcal{O}(|V|)$  running time is dominated by the  $\mathcal{O}(|E|)$  time that is required for further branching since we have assumed that  $|V| \leq k|E|$ . Hence, it suffices to bound (a) the total time complexity of calls to the algorithm for Case 2 in leaves that correspond to sets  $X$  such that  $|X| < k$  and (b) the total number of leaves that correspond to sets  $X$  such that  $|X| = k$ .

If  $k$  is even, (a) is bounded by  $\mathcal{O}(|E|^{(k-2)/2}|V|)$  and (b) is bounded by  $\mathcal{O}(|E|^{k/2})$ . Hence, (b) dominates (a) and we have

$$\mathcal{O}(|E|^{k/2}) = \mathcal{O}(|E|^{k/3}|E|^{k/6}) = \mathcal{O}(|E|^{k/3}|V|^{k/3}). \quad (1)$$

If  $k$  is odd, (a) is bounded by  $\mathcal{O}(|E|^{(k-1)/2}|V|)$  and (b) is bounded by  $\mathcal{O}(|E|^{(k-1)/2})$ , which is dominated by (a). By using (1) for  $k - 3$  we also have:

$$\mathcal{O}(|E|^{(k-1)/2} \cdot |V|) = \mathcal{O}(|E|^{(k-3)/2} \cdot |E| \cdot |V|) = \mathcal{O}((|E| \cdot |V|)^{(k-3)/3} \cdot |E| \cdot |V|) = \mathcal{O}((|E| \cdot |V|)^{k/3}).$$

We now consider the case that  $r(H \times K) = 1$ . We use the algorithm for Case 2 above that works in  $\mathcal{O}(|V|)$  time, which is  $\mathcal{O}(|V| \cdot |E|)$ . ◀

Lemmas 5-9 imply Theorem 4, which we employ iteratively to obtain the following result.

► **Theorem 10.** *PMDM can be solved in time  $\mathcal{O}(N + \min\{N^{k/3}, \ell^k\})$  using space  $\mathcal{O}(N)$  if  $k = \mathcal{O}(1)$ , where  $N = d\ell$ .*

**Proof.** We apply Lemma 5 to obtain a hypergraph with  $|V| = \ell$  and  $|E| = d$ . Starting with  $k = 1$  and for growing values of  $k$ , we solve HEAVIEST  $k$ -SECTION until we obtain a solution of weight at least  $z$ , employing either only Lemma 6, or Lemmas 6, 7, 8, 9 for  $k = 1, 2, 3$  and  $k \geq 4$ , respectively. We obtain  $\mathcal{O}(N + \min\{N^{k/3}, \ell^k\})$  time and  $\mathcal{O}(N)$  space. ◀

## 5 Exact Algorithms for a Bounded Number $m$ of Query Strings

Recall that masking a potential match  $(q_1, q_2)$  in record linkage can be performed by solving PMDM twice and superimposing the wildcards (see Section 1). In this section, we consider the following generalized version of PMDM to perform the masking simultaneously. The advantage of this approach is that it minimizes the final number of wildcards in  $q_1$  and  $q_2$ .

MULTIPLE PATTERN MASKING FOR DICTIONARY MATCHING (MPMDM)

**Input:** A dictionary  $\mathcal{D}$  of  $d$  strings, each of length  $\ell$ , a collection  $\mathcal{M}$  of  $m$  strings, each of length  $\ell$ , and a positive integer  $z$ .

**Output:** A smallest set  $K \subseteq \{1, \dots, \ell\}$  such that, for every  $q$  from  $\mathcal{M}$ ,  $q_K = q \otimes K$  matches at least  $z$  strings from  $\mathcal{D}$ .

Let  $N = d\ell$ . We show the following theorem.

► **Theorem 11.** *MPMDM can be solved in time  $\mathcal{O}(N + \min\{N^{k/3}z^{m-1}, \ell^k\})$  if  $k = \mathcal{O}(1)$  and  $m = \mathcal{O}(1)$ , where  $N = d\ell$ .*

We use a generalization of HEAVIEST  $k$ -SECTION in which the weights are  $m$ -tuples that are added and compared component-wise, and we aim to find a subset  $K$  such that the weight of  $H \times K$  is at least  $(z, \dots, z)$ . An analogue of Lemma 6 holds without any alterations, which accounts for the  $\mathcal{O}(N + \ell^k)$ -time algorithm. We adapt the proof of Lemma 9 as follows. The branching remains the same, but we have to tweak the final step, that is, what happens when we are in Case 2. For  $m = 1$  we could simply select a number of largest weights, but for  $m > 1$  multiple criteria need to be taken into consideration. All in all, the problem reduces to a variation of the classic Multiple-Choice Knapsack problem [38], which we solve using dynamic programming. Overall, we pay an additional  $\mathcal{O}(z^{m-1})$  factor in the complexity of handling of Case 2, which yields the complexity of Theorem 11.

## 6 A Data Structure for PMDM Queries

We next show algorithms and data structures for the PMDM problem under the assumption that  $2^\ell$  is reasonably small. We measure space in terms of  $w$ -bit machine words, where  $w = \Omega(\log(d\ell))$ , and focus on showing space vs. query-time trade-offs for answering  $q, z$  PMDM queries over  $\mathcal{D}$ . A summary of the complexities of the data structures is shown in Table 1. Specifically, algorithm SMALL- $\ell$  and data structure SIMPLE are used as building blocks in the more involved data structure SPLIT underlying the following theorem.

► **Theorem 12.** *There exists a data structure that answers  $q, z$  PMDM queries over  $\mathcal{D}$  in time  $\mathcal{O}(2^{\ell/2}(2^{\ell/2} + \tau)\ell)$  w.h.p. and requires space  $\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$ , for any  $\tau \in [1, d]$ .*

## 65:12 Pattern Masking for Dictionary Matching

■ **Table 1** Basic complexities of the data structures from Section 6.

Data structure	Space	Query time
Algorithm SMALL- $\ell$	$\mathcal{O}(d\ell)$	$\mathcal{O}(2^\ell \ell + d\ell)$
DS SIMPLE	$\mathcal{O}(2^\ell d)$	$\mathcal{O}(2^\ell \ell)$
DS SPLIT, any $\tau$	$\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$	$\mathcal{O}(2^{\ell/2} \cdot (2^{\ell/2} + \tau)\ell)$
DS SPLIT for $\tau = 2^{\ell/4}\sqrt{d}$	$\mathcal{O}(2^{\ell/2}d)$	$\mathcal{O}(2^\ell \ell + 2^{3\ell/4}\sqrt{d}\ell)$

**Algorithm SMALL- $\ell$ :  $\mathcal{O}(d\ell)$  Space,  $\mathcal{O}(2^\ell \ell + d\ell)$  Query Time.** No data structure on top of the dictionary  $\mathcal{D}$  is stored. In the query algorithm, we initialize an array  $A$  of size  $2^\ell$  with zeros. For an  $\ell$ -bit vector  $m$ , by  $K_m \subseteq \{1, \dots, \ell\}$  let us denote the set of the positions of set bits of  $m$ . Now for every possible  $\ell$ -bit vector  $m$  we want to compute the number of strings in  $\mathcal{D}$  that match  $q_{K_m} = q \otimes K_m$ .

To this end, for every string  $s \in \mathcal{D}$ , we compute the set  $K$  of positions in which  $s$  and  $q$  differ. For  $m$  that satisfies  $K = K_m$ , we increment  $A[m]$ . This computation takes  $\mathcal{O}(d\ell)$  time and  $\mathcal{O}(1)$  extra space. Then we apply a folklore dynamic-programming-based approach to compute array  $B$ , which is defined as follows:

$$B[m] = \sum_{j \in S(m)} A[j], \text{ where } S(m) = \{j \in [1, 2^\ell] : K_j \subseteq K_m\}.$$

In other words,  $B[m]$  stores the number of strings from  $\mathcal{D}$  that match  $q_{K_m}$ . It takes  $\mathcal{O}(\ell 2^\ell)$  time and  $\mathcal{O}(2^\ell)$  extra space. Thus, overall, the (query) time required by algorithm SMALL- $\ell$  is  $\mathcal{O}(\ell 2^\ell + d\ell)$ , the data structure space is  $\mathcal{O}(d\ell)$ , and the extra space is  $\mathcal{O}(2^\ell)$ .

We first present SIMPLE, an auxiliary data structure, which we will apply later on to construct DS SPLIT, a data structure with the space/query-time trade-off of Theorem 12.

**DS SIMPLE:  $\mathcal{O}(2^\ell d)$  Space,  $\mathcal{O}(2^\ell \ell)$  Query Time.** We initialize an empty set  $\mathcal{Q}$ . For each possible subset of  $\{1, \dots, \ell\}$  we do the following. We mask the corresponding positions in all strings from  $\mathcal{D}$  and then sort the masked strings lexicographically. By iterating over the lexicographically sorted list of the masked strings, we count how many copies of each distinct (masked) string we have in our list. We insert each such (masked) string to  $\mathcal{Q}$  along with its count. After processing all  $2^\ell$  subsets, we construct a compacted trie for the strings in  $\mathcal{Q}$ ; each leaf corresponds to a unique element of  $\mathcal{Q}$ , and stores this element's count. The total space occupied by this compacted trie is thus  $\mathcal{O}(2^\ell d)$ . Upon an on-line query  $q$  (of length  $\ell$ ) and  $z$ , we apply all possible  $2^\ell$  masks to  $q$  and read the count for each of them from the compacted trie in  $\mathcal{O}(\ell)$  time per mask. Next, we show how to decrease the exponential dependency on  $\ell$  in the space complexity when  $2^\ell = o(d)$ , incurring extra time in the query.

**DS SPLIT:  $\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$  Space,  $\mathcal{O}(2^{\ell/2} \cdot (2^{\ell/2} + \tau)\ell)$  Query Time, for any  $\tau$ .** This trade-off is relevant when  $\tau = \omega(\sqrt{d})$ ; otherwise the DS SIMPLE is better. We split each string  $p \in \mathcal{D}$  roughly in the middle, to prefix  $p_L$  and suffix  $p_R$ ; specifically,  $p = p_L p_R$  and  $|p_L| = \lceil \ell/2 \rceil$ . We create dictionaries  $\mathcal{D}_L = \{p_L : p \in \mathcal{D}\}$  and  $\mathcal{D}_R = \{p_R : p \in \mathcal{D}\}$ . Let us now explain how to process  $\mathcal{D}_L$ ; we process  $\mathcal{D}_R$  analogously. Let  $\lambda = \lceil \ell/2 \rceil$ . We construct DS SIMPLE over  $\mathcal{D}_L$ . This requires space  $\mathcal{O}(2^{\ell/2}d)$ . Let  $\tau$  be an input parameter, intuitively used as the minimum frequency threshold. For each of the possible  $2^\lambda$  masks, we can have at most  $\lfloor d/\tau \rfloor$  (masked) strings with frequency at least  $\tau$ . Over all masks, we thus have at most  $2^\lambda \lfloor d/\tau \rfloor$  such strings, which we call  $\tau$ -frequent. For every pair of  $\tau$ -frequent strings, one from  $\mathcal{D}_L$  and one from  $\mathcal{D}_R$ , we store the number of occurrences of their concatenation in  $\mathcal{D}$  using a compacted trie as in DS SIMPLE. This requires space  $\mathcal{O}(2^\ell d^2/\tau^2)$ .

■ **Figure 3** Let  $\tau = 3$ . If both  $q'_L$  and  $q'_R$  are 3-frequent (we check this using the counts of DS SIMPLE), we read the count for  $q'_L q'_R$  from the compacted trie of DS SPLIT. If  $q'_L$  is 3-infrequent, we apply SMALL- $\ell$  on  $q_R$  and the dictionary consisting of at most  $\tau = 3$  strings from  $\mathcal{D}_R$  corresponding to the right halves of strings in  $\mathcal{D}_L$  that match  $q'_L$ .

Consider  $\mathcal{D}_L$ . For each mask  $i$  and each string  $p_L \in \mathcal{D}_L$ , we can afford to store the list of all strings in  $\mathcal{D}_L$  that match  $p_L \otimes i$ . Note that we have computed this information when sorting for constructing DS SIMPLE over  $\mathcal{D}_L$ . This information requires space  $\mathcal{O}(2^{\ell/2}d)$ . Thus, DS SPLIT requires  $\mathcal{O}(2^\ell d^2/\tau^2 + 2^{\ell/2}d)$  space overall.

Let us now show how to answer an on-line  $q, z$  query. Let  $q = q_L q_R$  with  $|q_L| = \lceil \ell/2 \rceil$ . We iterate over all possible  $2^\ell$  masks.

For a mask  $i$ , let  $q' = q \otimes i$ . We split  $q'$  into two halves,  $q'_L$  and  $q'_R$  with  $q' = q'_L q'_R$  and  $|q'_L| = \lceil \ell/2 \rceil$ . First, we check whether each of  $q'_L$  and  $q'_R$  is  $\tau$ -infrequent using the DS SIMPLE we have constructed for  $\mathcal{D}_L$  and  $\mathcal{D}_R$ , respectively, in time  $\mathcal{O}(\ell)$ . We have the following two cases (inspect also Figure 3).

- If both halves are  $\tau$ -frequent, we can read the frequency of their concatenation using the stored compacted trie in time  $\mathcal{O}(\ell)$ .
- Else, at least one of the two halves is  $\tau$ -infrequent. Assume without loss of generality that  $q'_L$  is  $\tau$ -infrequent. Let  $\mathcal{F}$  be the dictionary consisting of at most  $\tau$  strings from  $\mathcal{D}_R$  that correspond to the right halves of strings in  $\mathcal{D}_L$  that match  $q'_L$ . Naïvely counting how many elements of  $\mathcal{F}$  match  $q'_R$  could require  $\Omega(\tau\ell)$  time, and thus  $\Omega(2^\ell\tau\ell)$  overall. Instead, we apply algorithm SMALL- $\ell$  on  $q_R$  and  $\mathcal{F}$ . The crucial point is that if we ever come across  $q'_L$  again (for a different mask on  $q$ ), we will not need to do anything. We can maintain whether  $q'_L$  has been processed by temporarily marking the leaf corresponding to it in DS SIMPLE for  $\mathcal{D}_L$ . Thus, overall, we perform the SMALL- $\ell$  algorithm  $\mathcal{O}(2^{\ell/2})$  times, each time in  $\mathcal{O}((2^{\ell/2} + \tau)\ell)$  time. This completes the proof of Theorem 12.

**Efficient Construction.** For completeness, we next show how to construct DS SPLIT in  $\mathcal{O}(d\ell \log(d\ell) + 2^\ell d\ell + 2^\ell \ell d^2/\tau^2)$  time. We preprocess  $\mathcal{D}$  by sorting its letters in  $\mathcal{O}(d\ell \log(d\ell))$  time. The DS SIMPLE for  $\mathcal{D}_L$  and  $\mathcal{D}_R$  can then be constructed in  $\mathcal{O}(2^{\ell/2}d\ell)$  time. We then create the compacted trie for pairs of  $\tau$ -frequent strings. For each of the  $2^\ell$  possible masks, say  $i$ , and each string  $p \in \mathcal{D}$ , we split  $p' = p \otimes i$  in the middle to obtain  $p'_L$  and  $p'_R$ . If both  $p'_L$  and  $p'_R$  are  $\tau$ -frequent then  $p'$  will be in the set of strings for which we will construct the compacted trie for pairs of  $\tau$ -frequent strings. The counts for each of those strings can be read in  $\mathcal{O}(\ell)$  time from a DS SIMPLE over  $\mathcal{D}$ , which we can construct in time  $\mathcal{O}(2^\ell d\ell)$  – this data structure is then discarded. The compacted trie construction requires time  $\mathcal{O}(2^\ell \ell d^2/\tau^2)$ .

**Comparison of the Data Structures.** DS SIMPLE has lower query time than algorithm SMALL- $\ell$ . However, its space complexity can be much higher. DS SPLIT can be viewed as an intermediate option. For  $\tau$  as in Table 1, it has lower query time than algorithm SMALL- $\ell$  for

## 65:14 Pattern Masking for Dictionary Matching

$d = \omega(2^{3\ell/2})$ , while keeping moderate space complexity. DS SPLIT always has higher query time than DS SIMPLE, but its space complexity is lower by a factor of  $2^{\ell/2}$ . For example, for  $d = 2^{2\ell}$  we get the complexities shown in Table 2.

■ **Table 2** Basic complexities of the data structures from Section 6 for  $d = 2^{2\ell}$ .

Data structure	Space	Query time
Algorithm SMALL- $\ell$	$\mathcal{O}(2^{2\ell}\ell)$	$\mathcal{O}(2^{2\ell}\ell)$
DS SIMPLE	$\mathcal{O}(2^{3\ell})$	$\mathcal{O}(2^{\ell}\ell)$
DS SPLIT for $\tau = 2^{5\ell/4}$	$\mathcal{O}(2^{5\ell/2})$	$\mathcal{O}(2^{7\ell/4}\ell)$

## 7 Approximation Algorithm for PMDM

Clearly, PMDM is at least as hard as PMDM-SIZE because it also outputs the positions of the wildcards (set  $K$ ). Thus, PMDM is also NP-hard. In what follows, we show existence of a polynomial-time approximation algorithm for PMDM whose approximation factor is given with respect to  $d$ . Specifically, we show the following approximation result for PMDM.

► **Theorem 13.** *For any constant  $\epsilon > 0$ , there is an  $\mathcal{O}(d^{1/4+\epsilon})$ -approximation algorithm for PMDM, whose running time is polynomial in  $N$ , where  $N = d\ell$ .*

Our result is based on the Minimum Union (MU) problem [21], which we define next.

MINIMUM UNION (MU)

**Input:** A collection  $\mathcal{S}$  of  $d$  sets over a universe  $U$  and a positive integer  $z \leq d$ .

**Output:** A collection  $\mathcal{T} \subseteq \mathcal{S}$  with  $|\mathcal{T}| = z$  such that the size of  $\cup_{S \in \mathcal{T}} S$  is minimized.

To illustrate the MU problem, consider an instance of it where  $U = \{1, 2, 3, 4, 5\}$ ,  $\mathcal{S} = \{\{1\}, \{1, 2, 3\}, \{1, 3, 5\}, \{3\}, \{3, 4, 5\}, \{4\}, \{4, 5\}, \{5\}\}$ , with  $d = |\mathcal{S}| = 8$ , and  $z = 4$ . Then  $\mathcal{T} = \{\{3\}, \{3, 4, 5\}, \{4\}, \{4, 5\}\}$  is a solution because  $|\mathcal{T}| = z = 4$  and  $|\cup_{S \in \mathcal{T}} S| = 3$  is minimum. The MU problem is NP-hard and the following approximation result is known.

► **Theorem 14** ([21]). *For any constant  $\epsilon > 0$ , there is an  $\mathcal{O}(d^{1/4+\epsilon})$ -approximation algorithm for MU, whose running time is polynomial in the size of  $\mathcal{S}$ .*

► **Theorem 15.** *PMDM can be reduced to MU in time polynomial in  $N$ .*

**Proof.** We reduce the PMDM problem to MU in polynomial time as follows. Given any instance  $\mathcal{I}_{\text{PMDM}}$  of PMDM, we construct an instance  $\mathcal{I}_{\text{MU}}$  of MU in time  $\mathcal{O}(d\ell)$  by performing the following steps:

1. The universe  $U$  is set to  $\{1, \dots, \ell\}$ .
2. We start with an empty collection  $\mathcal{S}$ . Then, for each string  $s_i$  in  $\mathcal{D}$ , we add member  $S_i$  to  $\mathcal{S}$ , where  $S_i$  is the set of positions where string  $q$  and string  $s_i$  have a mismatch. This can be done trivially in time  $\mathcal{O}(d\ell)$  for all strings in  $\mathcal{D}$ .
3. Set the  $z$  of the MU problem to the  $z$  of the PMDM problem.

Thus, the total time  $\mathcal{O}(d\ell)$  needed for Steps 1 to 3 above is clearly polynomial in the size of  $\mathcal{I}_{\text{PMDM}}$ .

▷ **Claim 16.** For any solution  $\mathcal{T}$  to  $\mathcal{I}_{\text{MU}}$  and any solution  $K$  to  $\mathcal{I}_{\text{PMDM}}$ ,  $|K| = |\cup_{S \in \mathcal{T}} S|$ .

Proof. Let  $\mathcal{F} \subseteq \mathcal{D}$  consist of  $z$  strings that match  $q_K$ . Further, let the set  $\mathcal{F}^*$  consist of the elements of  $\mathcal{S}$  corresponding to strings in  $\mathcal{F}$ . We have  $|\cup_{S \in \mathcal{T}} S| \leq |\cup_{S \in \mathcal{F}^*} S| \leq |K|$ .

Now, let  $C = \cup_{S \in \mathcal{T}} S$ . Then,  $q_C = q \otimes C$  matches at least  $z$  strings from  $\mathcal{D}$  and hence  $|K| \leq |C| = |\cup_{S \in \mathcal{T}} S|$ .  $\triangleleft$

To conclude the proof, it remains to show that given a solution  $\mathcal{T}$  to  $\mathcal{I}_{\text{MU}}$  we can obtain a solution  $K$  to  $\mathcal{I}_{\text{PMDM}}$  in time polynomial in the size of  $\mathcal{I}_{\text{MU}}$ . This readily follows from the proof of the above claim: it suffices to set  $K = \cup_{S \in \mathcal{T}} S$ .  $\blacktriangleleft$

**Proof of Theorem 13.** The reduction in Theorem 15 implies that there is a polynomial-time approximation algorithm for PMDM. In particular, Theorem 14 provides an approximation guarantee for MU that depends on the number of sets of the input  $\mathcal{S}$ . In Step 2 of the reduction of Theorem 15, we construct *one* set for the MU instance per *one* string of the dictionary  $\mathcal{D}$  of the PMDM instance. Also, from the constructed solution  $\mathcal{T}$  to the MU instance, we obtain a solution  $K$  to the PMDM instance by simply substituting the positions of  $q$  corresponding to the elements of the sets of  $\mathcal{T}$  with wildcards. This construction implies the approximation result of Theorem 13 that depends on the size of  $\mathcal{D}$ .  $\blacktriangleleft$

**Sanity Check.** Theorem 1 (reduction from  $k$ -CLIQUE to  $k$ -PMDM) and Theorem 13 (approximation algorithm for PMDM) do not contradict the inapproximability results for the maximum clique problem (see Section 3), since our reduction from  $k$ -CLIQUE to  $k$ -PMDM cannot be adapted to a reduction from maximum clique to PMDM-SIZE.

**Two-Way Reduction.** Chlamtáč et al. [21] also show that their polynomial-time  $\mathcal{O}(d^{1/4+\epsilon})$ -approximation algorithm for MU is tight under a plausible conjecture for the so-called Hypergraph Dense vs Random problem. In what follows, we also show that approximating the MU problem can be reduced to approximating PMDM in polynomial time and hence the same tightness result applies to PMDM.

► **Theorem 17.** *MU can be reduced to PMDM in time polynomial in the size of  $\mathcal{S}$ .*

**Proof.** Let  $||\mathcal{S}||$  denote the total number of elements in the  $d$  members of  $\mathcal{S}$ . We reduce the MU problem to the PMDM problem in polynomial time as follows. Given any instance  $\mathcal{I}_{\text{MU}}$  of MU, we construct an instance  $\mathcal{I}_{\text{PMDM}}$  of PMDM by performing the following steps:

1. Sort the union of all elements of members of  $\mathcal{S}$ , and assign to each element  $j$  a unique rank  $\text{rank}(j) \in \{1, \dots, |U|\}$ . Set  $\ell = |U|$ . This can be done in  $\mathcal{O}(|\mathcal{S}| \log |\mathcal{S}|)$  time.
2. Set the query string  $q$  equal to the string  $\mathbf{a}^\ell$  of length  $\ell$ . For each set  $S_i$  in  $\mathcal{S}$ , construct a string  $s_i = \mathbf{a}^\ell$ , set  $s_i[\text{rank}(j)] := \mathbf{b}$  if and only if  $j \in S_i$ , and add  $s_i$  to dictionary  $\mathcal{D}$ . This can be done in  $\mathcal{O}(d\ell)$  time.
3. Set the  $z$  of the PMDM problem equal to the  $z$  of the MU problem. This can be done in  $\mathcal{O}(1)$  time.

Thus, the total time  $\mathcal{O}(d\ell \log(d\ell))$  needed for Steps 1 to 3 above is clearly polynomial in the size of  $\mathcal{I}_{\text{MU}}$  as  $\ell \leq ||\mathcal{S}||$ .

A proof of the following claim is analogous to that of Claim 16.

▷ **Claim 18.** For any solution  $\mathcal{T}$  to  $\mathcal{I}_{\text{MU}}$  and any solution  $K$  to  $\mathcal{I}_{\text{PMDM}}$ ,  $|K| = |\cup_{S \in \mathcal{T}} S|$ .

To conclude the proof, it remains to show that, given a solution  $K$  to  $\mathcal{I}_{\text{PMDM}}$ , we can obtain a solution  $\mathcal{T}$  to  $\mathcal{I}_{\text{MU}}$  in time polynomial in the size of  $\mathcal{I}_{\text{PMDM}}$ . It suffices to pick  $z$  sets in  $\mathcal{S}$  that are subsets of  $K$ . Their existence is guaranteed by construction, because such

sets correspond to the at least  $z$  strings in  $\mathcal{D}$  that have  $\mathbf{b}$  in a subset of the positions in  $K$ . This selection can be done naïvely in  $\mathcal{O}(|\mathcal{S}|)$  time. Finally, the above claim guarantees that they indeed form a solution to  $\mathcal{I}_{\text{MU}}$ . ◀

## Abstract

We study the problem of designing a *resilient* data structure maintaining a tree under the Faulty-RAM model [Finocchi and Italiano, STOC’04] in which up to  $\delta$  memory words can be corrupted by an adversary. Our data structure stores a rooted dynamic tree that can be updated via the addition of new leaves, requires linear size, and supports *resilient* (weighted) level ancestor queries, lowest common ancestor queries, and bottleneck vertex queries in  $O(\delta)$  worst-case time per operation.

**2012 ACM Subject Classification** Theory of computation → Data structures design and analysis

## 1 Introduction

Due to a diverse spectrum of reasons, ranging from manufacturing defects to charge collection, the data stored in modern memories can sometimes face corruptions, a problem that is exacerbated by the recent growth in the amount of stored data. To make matters worse, even a single memory corruption can cause classical algorithms and data structures to fail catastrophically. One mitigation approach relies on low-level error-correcting schemes that transparently detect and correct such errors. These schemes however either require expensive hardware or employ space-consuming replication strategies. Another approach, which has recently received considerable attention [8, 17, 19, 23, 24, 25, 27], aims to design *resilient* algorithms and data structures that are able to remain operational even in the presence of memory faults, at least with respect to the set of uncorrupted values.

In this paper we consider the problem of designing resilient data structures that store a *dynamic* rooted tree  $T$  while answering several types of queries. More formally, we focus on maintaining a tree that initially consists of a single vertex (the root of the tree) and can be dynamically augmented via the  $\text{AddLeaf}(v)$  operation that appends a new leaf as a child of an existing vertex  $v$ .<sup>1</sup> It is possible to *query*  $T$  in order to obtain information about its current topology. We mainly concerned on the following well-known query types:

---

<sup>1</sup> In the literature this setting is also called *incremental* or *semi-dynamic* to emphasize that arbitrary insertions and deletions of tree vertices/edges are not supported. In this paper, unless otherwise specified, we follow the terminology of [14] by considering *dynamic* trees that only support insertion of leaves.

**(Weighted) Level Ancestor Queries:** Given a vertex  $v$  and an integer  $k$ , the query  $\text{LA}(v, k)$  returns the  $k$ -parent of  $v$ , i.e., the vertex at distance  $k$  from  $v$  among the ancestors of  $v$ . In the weighted version of the problem each vertex of the tree  $T$  is associated with a small (polylogarithmic) positive integer weight, and a query needs to report the closest ancestor  $u$  of  $v$  such that the total weight of the path from  $v$  to  $u$  in  $T$  is at least  $k$ .

**Lowest Common Ancestor Queries:** Given two vertices  $u, v$ , the query  $\text{LCA}(u, v)$  returns the vertex at maximum depth in  $T$  that is simultaneously and ancestor of both  $u$  and  $v$ .

**Bottleneck Queries:** In this problem, each vertex has an associated integer weight and, given two vertices  $u, v$ , a  $\text{BVQ}(u, v)$  query reports the minimum/maximum-weight vertex in the path between  $u$  and  $v$  in  $T$ .<sup>2</sup> It is worth noticing that, when  $T$  is a path, the above problem can be seen as a dynamic version of the classical *range minimum query* problem. In the range minimum query problem, a query  $\text{RMQ}(i, j)$  reports the minimum element between the  $i$ -th and the  $j$ -th element of a (static) input sequence [4].

For all of the above problems, *linear-size non-resilient* data structures supporting both the `AddLeaf` and the query operations in constant worst-case time are known [2, 11]. It is then natural to investigate what can be achieved for the above problem when the sought data structures are required to withstand memory faults.

To precisely capture the behaviour of resilient algorithms, one needs to employ a model of computation that takes into account potential memory corruptions. To this aim, we adopt the *Faulty-RAM* model introduced by Finocchi and Italiano in [19]. This model is similar to the classical RAM model except that all but  $O(1)$  memory words can be subject to corruptions that alter their contents to an arbitrary value. The overall number of corruptions is upper bounded by a parameter  $\delta$  and such corruptions are chosen in a *worst-case* fashion by a computationally unbounded *adversary*.

A simple error-correcting strategy based on replication provides a general scheme for obtaining resilient versions of any classical *non-resilient* data structure at a cost of a  $\Theta(\delta)$  blowup in both the time needed for each operation and the size of the data structure. This space overhead is undesirable, especially when  $\delta$  can be large. For the above reason, the main goal in the area is obtaining compact solutions with a particular focus on linear-size data structures [8, 16, 17, 18, 19, 23, 24, 27]. However, for linear-size data structures, even  $\delta = \omega(1)$  corruptions can be already sufficient for the adversary to irreversibly corrupt some of the stored elements [16]. The solution adopted in the literature is that of suitable relaxing the notion of correctness by only requiring queries to answer correctly with respect to the portions of the data structure that are uncorrupted. Notice that this is not easy to obtain since corruptions in unrelated parts of the data structure can still misguide the execution of a query (see [16] for a discussion).<sup>3</sup>

## 1.1 Our results

We design a data structure maintaining a dynamic tree that can be updated via the addition of new leaves, and supports *resilient* (weighted) LA, LCA, and BVQ queries.

<sup>2</sup> It is easy to see that this also captures the well-known *bottleneck edge query* variant [12], in which weights are placed on edges instead of vertices.

<sup>3</sup> For example, the authors of [16] consider the problem of designing linear-size resilient dictionaries adopt a notion of *resilient search* that requires the search procedure to answer correctly w.r.t. all uncorrupted keys (see Section 1.2 for a more precise definition). Notice how the classical solutions based on search trees do not meet this requirement since a single unrelated corruption can destroy the tree path leading to the sought key.

■ **Figure 1** Illustration of resilient LA queries. The current tree  $T$  logically maintained by the data structure is depicted in (a). In this example, each vertex maintains a reference to its parent in  $T$ . In (b) some of the parent-child relationships have been altered by the adversary by corrupting the nodes highlighted in red. Since the algorithm cannot distinguish corrupted memory words from uncorrupted ones, its (defective) view of  $T$  is shown in (c). Nevertheless, a resilient data structure must still be able to correctly answer queries involving uncorrupted paths. For example, the query  $\text{LA}(v, k)$  is required to answer correctly for all (meaningful) values of  $k$  since the path from  $v$  to the root is uncorrupted, while query  $\text{LA}(w, k)$  is required to answer correctly for  $k \leq 2$ . Since  $u$  is corrupted, the query  $\text{LA}(u, k)$  is allowed to answer incorrectly for every value of  $k$ .

Our data structure stores each vertex of the current tree  $T$  in a single memory word of  $\Theta(\log n)$  bits. We will say that a vertex  $v$  is corrupted if the memory word associated with  $v$  has been modified by the adversary. A resilient query is required to correctly report the answer when no vertex in the tree path between the two vertices explicitly or implicitly defined by the query is corrupted. For example, a  $\text{LA}(v, k)$  query correctly reports the  $k$ -parent  $u$  of  $v$  whenever every vertex in the unique path from  $u$  to  $v$  in  $T$  is uncorrupted.

We deem our notion of resilient query to be quite natural since in any reasonable representation of  $T$  the adversary can locally corrupt the parent-children relationship and hence change the observed topology of  $T$ . See Figure 1 for an example.

Our data structure occupies linear (w.r.t. the current number of nodes) space, and supports the **AddLeaf** operation and **LA**, **BVQ**, and **LCA** queries in  $O(\delta)$  worst-case time. For weighted **LA** queries, the above bound on the query time holds as long as  $\delta = O(\text{polylog} n)$ .

We point out that our solution is obtained through a general vertex-coloring scheme which is, in turn, used to “shrink”  $T$  down to a compact tree  $Q$  of size  $O(n/\delta)$  that can be made resilient via replication. Each edge of  $Q$  represents a path of length  $\delta$  between two consecutive colored nodes in  $T$ . If no corruption occurs, this coloring scheme is regular and will color all vertices having a depth that is a multiple of  $\delta$ . While it is possible for corruptions to *locally* destroy the above pattern, our coloring is able to automatically recover as soon as we move away from the corrupted portions of the tree. We feel that such a scheme can be of independent interest as a useful tool to design other resilient data structures involving dynamic trees.

We leave the problem of understanding whether, similarly to other resilient data structures [16, 24], one can prove a lower bound of  $\Omega(\delta)$  on the time needed to perform **AddLeaf** operation and/or to answer our queries.

## 1.2 Related work

**Non-resilient data structures.** Before discussing the known result in our faulty memory model, we first give an overview of the closest related results in the fault-free case. Since the landscape of data structures that answer queries on dynamic trees is vast and diverse, we will focus only on the best-known data-structures capable of answering **LA**, **BVQ**, or **LCA** queries.

As far as LA queries are concerned, the problem has been first formalized in [5] and in [14]. Both papers consider the case in which the tree  $T$  is *static* and show how to build, in linear-time, a data structure that requires linear space and that answers queries in constant worst-case time (albeit the hidden constant in [5] is quite large). A simple and elegant construction achieving the same (optimal) asymptotic bounds is given in [3]. In [14], the *dynamic* version of the problem was also considered: the authors provide a data structure supporting both LA queries and the `AddLeaf` operation in constant *amortized* time. The best known *dynamic* data structure is the one of [2], which implements the above operations in constant *worst-case* time. This data structure also supports constant-time BVQ queries and constant-time weighted LA queries when the vertex weights are polylogarithmically bounded integers. Moreover, the solution of [2] also provides amortized bounds for the problem of maintaining a forest of  $n$  nodes under *link* operations (i.e., edge additions that connect two vertices in different trees of the forest) and LA queries. In this case, a sequence of  $m$  operations requires  $O(m\alpha(m, n))$  time, where  $\alpha$  is the inverse Ackermann function.

Regarding BVQ queries with integer weights, in addition to the solution discussed above (which supports leaf additions and queries in constant-time), [7] shows how to also support leaf deletions using  $O(1)$  amortized time per update and constant worst-case query time.

The problem of answering LCA queries is a fundamental problem which has been introduced in [1]. In [22], Harel and Tarjan show how to preprocess in linear time any *static* tree in order to build a linear-space data structure that is able to answer LCA queries in  $O(1)$  time. The case of *dynamic* trees is also well-understood: it is possible to simultaneously support (i) insertions of leaves and internal nodes, (ii) deletion of leaves and internal nodes with a single child, and (iii) LA queries, in constant worst-case time per operation [11].

**Resilient data structures.** As already mentioned, the Faulty-RAM model has been introduced in [19] and used in the context of resilient data structures in [17] where the authors focused on designing resilient dictionaries, i.e., dynamic sets that support insertions, deletions, and lookup of elements. Here the lookup operation is only required to answer correctly if either (i) the searched key  $k$  is in the dictionary and is uncorrupted, or (ii)  $k$  is not in the dictionary and no corrupted key equals  $k$ . The best-known (linear-size) resilient dictionary is provided in [8] and supports each operation in the optimal  $O(\log n + \delta)$  worst-case time, where  $n$  is the number of stored elements. The Faulty-RAM model has also been adopted in [24], where the authors design a (linear-size) resilient priority queue, i.e., a priority queue supporting two operations: *insert* (which adds a new element in the queue) and *deletemin*. Here *deletemin* deletes and returns either the minimum uncorrupted value or one of the corrupted values. Each operation requires  $O(\log n + \delta)$  amortized time, while  $\Omega(\log n + \delta)$  time is needed to answer an *insert* followed by a *deletemin*.

The Faulty-RAM model has also been adopted in the context of designing resilient algorithms. We refer the reader to [23] for a survey on this topic.

A resilient dictionary for a variant of the Faulty-RAM model in which the set of corruptible memory words is random (but still unknown to the algorithm) has been designed in [25].

In a broader sense, problems that involve non-reliable computation have received considerable attention in the literature, especially in the context of sorting and searching. See for example [9, 10, 13, 15, 20, 21, 26].

### 1.3 Structure of the paper

The paper is organized as follows. Section 2 introduces the used notation and formally defines the Faulty-RAM model. It also briefly describes the error-correcting replication strategy mentioned in the introduction. For technical convenience, in Section 3 and 4 we describe our

data structure for LA queries only. This allows us to introduce all the ideas behind the more general coloring scheme discussed above. As a warm up, we first consider the simpler case in which the tree  $T$  is *static* and is already known at construction time (Section 3), and we then tackle the dynamic version of the problem (Section 4) for which we give our main result. Due to space limitation, the description of how to modify our data structure to handle the other types of queries is omitted and can be found in the full version of the paper.

## 2 Preliminaries

**Notation.** Let  $T$  be a rooted tree. For each node  $v \in T$ , we denote with  $\text{parent}(v)$  the parent of  $v$ . If  $\pi$  is a path, we denote by  $|\pi|$  its length, i.e., the number of its edges. Given any two nodes  $u, v$ , we denote by  $d_T(u, v)$  the length of the (unique) path between  $u$  and  $v$  in  $T$ . Moreover, if  $\pi$  traverses  $u$  and  $v$ , we denote by  $\pi[u : v]$  the subpath of  $\pi$  between  $u$  and  $v$ , endpoints included. We will use round brackets instead of square brackets to denote that the corresponding endpoint is excluded (so that, e.g.,  $\pi(u : v]$  denotes the subpath of  $\pi$  between  $u$  and  $v$  where  $u$  is excluded and  $v$  is included).

**Faulty memory model.** We now formally describe the *Faulty-RAM* model introduced by Finocchi and Italiano in [19]. In this model the memory is divided in two regions: a *safe region* with  $O(1)$  memory locations, whose locations are known to the algorithm designer, and the (unreliable) *main memory*. An adaptive adversary can perform up to  $\delta$  corruptions, where a corruption consists in instantly modifying the content of a word from the main memory. The adversary knows the algorithm and the current contents of the memory, has an unbounded computational power, and can simultaneously perform one or more corruptions at any point in time. The safe region cannot be corrupted by the adversary and there is no error-detection mechanism that allows the algorithm to distinguish the corrupted memory locations from the uncorrupted ones.

Without assuming the existence of  $O(1)$  words of safe memory, no reliable computation is possible: in particular, the safe memory can store the code of the algorithm itself, which otherwise could be corrupted by the adversary.

As observed in [16] (and already mentioned in the introduction), there is a simple strategy that allows any non-fault tolerant data structure on the RAM model to also work on the Faulty-RAM model, albeit with multiplicative  $\Theta(\delta)$  blow-up in its time and space complexities. Essentially, such a solution implements a trivial error-correcting mechanism by simulating each memory word  $w$  in the RAM model with a set  $W$  of  $2\delta + 1$  memory words in the Faulty-RAM model: writing a value  $x$  to  $w$  means writing  $x$  to all words in  $W$ , and reading  $w$  means computing the majority value of the words in  $W$  (which can be done in  $O(\delta)$  time, and  $O(1)$  space using the safe memory region and the Boyer-Moore majority vote algorithm [6]). We refer to such technique as the *replication strategy*.

## 3 Warming Up: LA queries in Static Trees

In order to introduce our ideas, in this section we will show how to build a simplified version of our resilient data structure when the tree  $T$  cannot be dynamically modified. Our simplified data structure requires linear space and answers level-ancestor queries in  $O(\delta)$  time. As opposed to our *dynamic* data structure, in this special case the tree  $T$  must be known in advance and hence we need to initialize our data structure from an input tree  $T$ . For simplicity, we assume that no corruptions occur while our data structure is being built. Notice that this assumption can be removed by carefully using the replication strategy described in Section 2.

■ **Algorithm 1** Answers a level ancestor query  $\text{LA}(v, k)$  in the special case of static trees.

---

```

1 if  $k \leq 2\delta$  then return  $\text{climb}(v, k)$  ;
2 Climb up the tree  $T$  from  $v$  for  $2\delta$  nodes searching a black node;
3 if the previous procedure did not find a black node then return error;
4  $v' \leftarrow$  a black node found in the previous procedure;
5  $d \leftarrow$  distance between  $v'$  and  $v$ ;  $k' \leftarrow k - d$ ;
6  $u' \leftarrow \text{LA}_Q(q_{v'}, \lfloor k'/\delta \rfloor)$ ;
7  $k_{\text{rest}} \leftarrow k' - \lfloor k'/\delta \rfloor \cdot \delta$ ;
8 return  $\text{climb}(u', k_{\text{rest}})$ ;

```

---

**Description of the Data Structure.** Let  $T$  be a rooted tree with  $n$  nodes. To define the data structure for  $T$ , we need to divide the nodes of  $T$  into two sets: the *black* nodes and the *white* nodes. We define the set of black nodes to ensure that its cardinality is  $O(n/\delta)$ : a node  $v$  in  $T$  is *black* if we simultaneously have that (i) its depth in  $T$  is a multiple of  $\delta$ , and (ii) the subtree of  $T$  rooted in  $v$  has height at least  $\delta - 1$ . A node  $v$  in  $T$  is *white* if it is not black. We notice that for each black  $v$  node in  $T$  there are at least  $\delta$  distinct nodes (i.e., all the vertices in the path from  $v$  to any vertex having depth  $\delta - 1$  in the subtree of  $T$  rooted at  $v$ ), thus implying that the total number of black nodes in  $T$  is at most  $n/\delta$ .

If we define a relation of parenthood for the black nodes of  $T$ , we can define a new *black tree*  $Q$  in which each vertex  $\bar{v}$  is associated with black vertex  $v$  of  $T$ . The parent of  $\bar{v}$  in  $Q$  is the vertex  $\bar{u}$  corresponding to the lowest black proper ancestor  $u$  of  $v$  in  $T$ . See Figure 2 for an example.

Our data structure stores the (colored) tree  $T$ , as described in the following, along with an additional data structure  $D_Q$  that is able to answer LA queries on  $Q$ . The tree  $T$  is stored as an array of records, where each record is associated with a vertex of  $T$ , occupies  $\Theta(\log n)$  bits, and is stored in a single memory word. The memory word associated with a node  $v$  stores:

- a pointer  $p_v$  to  $\text{parent}(v)$ , if any. If  $v$  is the root of  $T$  then  $p_v = \text{null}$ ;
- a pointer  $q_v$  to the corresponding node  $\bar{v}$  in  $Q$ , if any. If no such node exists, i.e. if  $v$  is white, then  $q_v = \text{null}$ .

Moreover we maintain, for each vertex  $\bar{v}$  of  $Q$ , a pointer to the corresponding vertex  $v$  of  $T$  as satellite data. The data structure  $D_Q$  is the resilient version of any (non-resilient) data structure that is capable of answering LA queries on static trees in constant time and requires linear space (see, e.g., the data structure in [3]).

As we observed before, any data structure can be made resilient with a multiplicative  $\Theta(\delta)$  blow-up in its time and space complexities. In our case, since the number of vertices in  $Q$  is  $O(n/\delta)$ , the final space required to store  $D_Q$  is  $O(n)$  and the query time becomes  $O(\delta)$ . Notice that, in spite of the (at most  $\delta$ ) memory corruptions performed by the adversary, the data structure  $D_Q$  always returns the correct answer to all possible LA queries on  $Q$ . We will denote by  $\text{LA}_Q(\bar{v}, k)$  the level-ancestor query on  $Q$ , which returns the vertex of  $T$  corresponding to the  $k$ -parent of  $v$  in  $Q$ .

**The resilient level-ancestor query.** In this section we show how to implement our resilient LA query. We start by defining a routine that will be useful in the sequel: if  $v$  is a node of  $T$  and  $i$  is a non-negative integer, we denote by  $\text{climb}(v, i)$  a procedure that returns the vertex reached by a walk on  $T$  that starts from  $v$  and iteratively moves to the parent of the current vertex  $i$  times. When the procedure encounters a vertex  $u$  with pointer  $p_u = \text{null}$  that has

**Figure 2** Left: A static tree  $T$  that has been colored according to the scheme in Section 3 for  $\delta = 3$ . Right: the corresponding black tree  $Q$ . We also show the path climbed while answering the query  $\text{LA}(v, k)$  with  $k = 8$ . In this case  $d = 3$ ,  $\lfloor k'/\delta \rfloor = 1$  and  $k_{\text{rest}} = 2$ . Notice how  $Q$  is used to quickly reach  $u'$  from  $v'$ .

to be followed,  $\text{climb}(v, i)$  reports that the root has been reached. Notice that  $\text{climb}(v, i)$  requires  $O(i)$  time and, whenever no corrupted vertices are encountered during the walk, it correctly returns the  $i$ -parent of  $v$ . Although the  $\text{climb}(\cdot, \cdot)$  procedure could immediately be used to answer an LA query, doing so require  $\Omega(n)$  time in the worst case. To improve the query time we use the data structure  $D_Q$  described above and we distinguish between *short* and *long* LA queries depending on the value of  $k$ .

Short queries, i.e., queries  $\text{LA}(v, k)$  with  $k \leq 2\delta$ , are handled by simply invoking  $\text{climb}(v, k)$  and, from the above observation, it follows that this is a resilient query. For longer queries the idea is that of locating a nearby black ancestor of  $v$ , performing an  $\text{LA}_Q$  query on  $Q$  to quickly reach a black descendant  $u'$  of the  $k$ -parent  $w$  of  $v$  such that  $d(u', w) \leq \delta$ , and finally using the  $\text{climb}$  procedure once more to reach  $w$  from  $u'$ . See Algorithm 1.

During the execution of our resilient query algorithm we always ensure that all followed pointers are valid. Since we are dealing with a static tree  $T$ , we can handle invalid pointers simply by halting the whole query procedure and reporting an error. A slightly more sophisticated handling of invalid pointers will be used to tackle the dynamic case. An example LA query is given in Figure 2.

The correctness of the above algorithm immediately follows from the fact that, when no vertex between  $v$  and the  $k$ -th ancestor  $v$  is corrupted,  $v$  must have a black ancestor at distance at most  $2\delta$  and from the fact that the replication strategy ensures that all queries on  $Q$  are always answered correctly.<sup>4</sup>

To show that Algorithm 1 answers an LA query in  $O(\delta)$  time, we notice that the  $\text{climb}$  operations in lines 1 and 8 require time  $O(\delta)$ , and so does line 2. Moreover, the query to  $D_Q$  (line 6) can also be performed in  $O(\delta)$  time as discussed above.

#### 4 LA queries in dynamic trees

In this section we provide our main result for LA queries. In the full version of the paper, we show how our ideas can be extended to also handle weighted LA, BVQ, and LCA queries.

<sup>4</sup> Here the distance of  $2\delta$  is essentially tight as it can be seen, e.g., by considering a tree  $T$  consisting of a path of length  $2\delta - 2$  rooted in one of its endpoints. The only black vertex of  $T$  is the root. Notice how the vertex  $u$  at depth  $\delta$  is white since the subtree of  $T$  rooted in  $u$  has height  $\delta - 2$ .

## 4.1 Description of the Data Structure

Some of the key ideas behind our data structure for LA queries in dynamic trees are extensions of the ones used for static case. Namely, the nodes of  $T$  are colored with either *black* or *white*, the set of *black* nodes will have size  $O(n/\delta)$ , and it will correspond to the vertex set of an auxiliary *black forest*  $Q$ . Ideally, in absence of corruptions,  $Q$  is exactly the black tree as defined in the static case, namely the tree in which the parent of each (black) node  $\bar{v}$  in  $Q$  is the vertex  $\bar{u}$  associated with the lowest black proper ancestor  $u$  of  $v$  in  $T$ .

Moreover, we would still like the vertices of  $T$  having a depth that is a multiple of  $\delta$  to be colored black, similarly to the static case. However, we can no longer afford to maintain such a rigid coloring scheme since the tree is now being dynamically constructed via successive `AddLeaf` operations, and the adversary's corruptions might cause vertices to become miscolored. We will however ensure that such a regular coloring pattern will be followed by the portions of  $T$  that are sufficiently distant from the adversary's corruptions. This will allow us to answer LA queries using a strategy similar to the one employed for the static case.

Our data structure stores the following information. The record of a node  $v$  maintains, in addition to the pointer  $p_v$  to its parent and to the pointer  $q_v$  to the corresponding node  $\bar{v}$  in  $Q$  (if any), an additional field  $\text{flag}_v$ . Intuitively,  $\text{flag}_v$  can be thought of as a Boolean value in  $\{\perp, \top\}$ . The initial value of a flag is  $\perp$  and we say that the flag is *unspent*. Spending a flag means setting it to  $\top$ . We will spend these flags to “pay” for the creation of new black nodes. Spent flags will also signal the presence of a nearby black ancestor.

For technical reasons, we also allow an unspent flag  $\text{flag}_v$  to be additionally *annotated* with a pair  $(x, i)$  where  $x$  is (the name of) a node and  $i$  is an integer. In practice this amounts to setting  $\text{flag}_v$  to  $(x, i)$ , which is logically interpreted as  $\perp$ . Such an annotated flag is still unspent. This provides an additional safeguard against corruptions that may occur during the execution of our leaf insertion algorithm (see Section 4.2).

The node records are stored into a dynamic array  $\mathcal{A}$ , whose current size  $n$  is kept in the safe region of memory. This array supports both elements insertions and random accesses in constant worst-case time.<sup>5</sup>

The pointer  $p_v$  is then the index (in  $\{0, \dots, n-1\}$ ) of the record corresponding to the parent of  $v$  in  $\mathcal{A}$ . Initially,  $\mathcal{A}$  only contains the root  $r$  of  $T$  at index 0. Moreover, we will always store new leaves at the end of  $\mathcal{A}$  so that, in absence of corruptions, the index of a vertex  $v$  in  $\mathcal{A}$  is always smaller than the index of any of its descendants. As a consequence, whenever we observe the index stored in pointer  $p_v$  is greater than or equal to the index of  $v$  itself, we know that  $v$  must have been corrupted by the adversary. We find convenient to use the above fact to simplify the handling of corrupted vertices: whenever we encounter an invalid pointer  $p_v \geq v$  we treat it as being equal to 0, i.e., an invalid pointer  $p_v$  always refers to the root  $r$  of  $T$ . This rule also applies to any read pointer, including those accessed by the `climb( $\cdot$ ,  $\cdot$ )` procedure already defined in Section 3.

Then the (possibly corrupted) contents of  $\mathcal{A}$ , at any point in time, induce a *noisy tree*  $\mathcal{T}$  whose root is  $r$ , and the parent of each vertex  $v \neq r$  is the vertex pointed by  $p_v$  according to the above rule. Clearly, if no corruptions occur  $T$  and  $\mathcal{T}$  coincide.

<sup>5</sup> The standard textbook technique which handles insertions into already full array by moving the current elements into a new array of double capacity already achieves  $O(1)$  amortized time per insertion. With some additional technical care, the above bound also holds in the worst case. The idea is to distribute the work needed to move elements into the new array over the insertions operations that would cause the current array to become full (it suffices to move 2 elements per insertion). Using this scheme, at any point in time, each element is stored into a single memory word.

Moreover, we store a resilient data structure  $D_Q$  that, in addition to the already-defined  $\text{LA}_Q(\bar{v}, k)$  query, also supports the following additional operations in  $O(\delta)$  time.

$\text{NewTree}_Q(v)$ : Given a vertex  $v$  of  $T$ , it creates a new tree in the forest  $Q$  consisting of a single vertex  $\bar{v}$  associated to  $v$ , and it returns a pointer to  $\bar{v}$ .

$\text{AddLeaf}_Q(\bar{u}, v)$ : Given a vertex  $\bar{u}$  of  $Q$ , and a vertex  $v$  of  $T$ , it creates a new vertex  $\bar{v}$  associated to  $v$  as a children of  $\bar{u}$  in  $Q$ . Finally, it returns a pointer to the newly added vertex  $\bar{v}$ .

This data structure  $D_Q$  is the resilient version, obtained using the replication strategy, of the linear-size data structure that supports both the  $\text{AddLeaf}$  operation and  $\text{LA}$  queries in constant time [2]. Notice that  $D_Q$  always returns the correct answer to all possible  $\text{LA}$  queries on  $Q$ . Moreover, once we ensure that the number of vertices that become black (and hence the size of  $Q$ ) is always  $O(n/\delta)$ , we have that the (resilient) data structure  $D_Q$  requires  $O(n)$  space (this will be shown formally in the proof Theorem 6).

## 4.2 The AddLeaf operation

Before describing our implementation of the  $\text{AddLeaf}$  operation, it is useful to give some additional definitions. We say that  $v$  is *near-a-black* in a tree  $\tilde{T}$  if there exists some  $k \in \{1, 2, \dots, \delta\}$  such that the  $k$ -parent of  $v$  in  $\tilde{T}$  is black. Moreover, we say that  $v$  is *black-free* in  $\tilde{T}$  if no  $k$ -parent of  $v$  in  $\tilde{T}$  for  $k \in \{1, 2, \dots, 2\delta - 1\}$  is black.

The procedure  $\text{AddLeaf}(x_{par})$  takes a vertex  $x_{par}$  of  $T$  as input and adds a new child  $x$  of  $x_{par}$  to  $T$  (see Algorithm 2). The record corresponding to new vertex  $x$  is appended at the end of the dynamic array  $\mathcal{A}$ . For simplicity we will assume that, during the execution of  $\text{AddLeaf}(x_{par})$ , the record of vertex  $x$  is never corrupted by the adversary. This can be guaranteed without loss of generality since a (temporary) record for  $x$  can be kept in safe memory and copied back to  $\mathcal{A}$  (which is stored in the unreliable main memory) at the end of the procedure.

Our algorithm consists of a first *discovery* phase and possibly of a second additional *execution* phase. The aim of the discovery phase is that of exploring the current tree by climbing up to  $3\delta - 1$  levels of  $\mathcal{T}$  from  $x$  while gathering information for the second phase. In order to do so, Algorithm 2 climbs  $\delta$  levels of  $\mathcal{T}$  from the newly inserted node  $x$ , reaching a vertex  $y$ , and checks during the process that all the flags associated with the traversed nodes are unspent. If any of these flags is spent, we immediately return from the  $\text{AddLeaf}(x_{par})$  procedure without performing the execution phase. Otherwise, the algorithm climbs  $2\delta - 1$  further levels from  $y$  to determine whether  $y$  appears to be black-free or near-a-black. In the latter case, it keeps track of the distance  $\ell$  from  $y$  to the closest black proper ancestor  $y'$  of  $y$  that is encountered. If  $y$  is neither black-free nor near-a-black, we return from the  $\text{AddLeaf}(x_{par})$  procedure (without performing the execution phase), otherwise we move on to the execution phase. A technical detail of the discovery phase is the following: while climbing from  $x_{par}$  to  $y$ , the generic  $i$ -th unspent flag is annotated with  $(x, i)$  (possibly overwriting any existing previous annotation) and will be checked by the execution phase. Recall that these flags remain unspent.

The execution phase once again climbs  $\delta$  levels of  $\mathcal{T}$  starting from  $x$ , with the goal of changing the color of an existing white vertex to black (hence creating a corresponding black node in  $Q$ ). This is guaranteed to happen unless the annotations of the unspent flags set during the discovery phase reveal that one such vertex has been corrupted in the meantime. The creation of a new black vertex in  $Q$  is “paid for” by *spending* these  $\delta$  unspent flags (i.e., setting them to  $\top$ ). The position of the new black vertex depends on whether  $y$  was

```

1 Add a new record  $x$  at the end of  $\mathcal{A}$ ;  $p_x \leftarrow x_{par}$ ;  $\text{flag}_x \leftarrow \perp$ ;  $q_x \leftarrow \text{null}$ ;
   // Discovery Phase
2  $y \leftarrow x$ ; // Check the flags of the lowest  $\delta$  proper ancestors of  $x$ 
3 for  $i = 1, \dots, \delta$  do
4   if  $y = r$  then return  $x$ ;
5    $y \leftarrow p_y$ ;
6   if  $\text{flag}_y = \top$  then return  $x$ ; // Return immediately if a spent flag is found
7    $\text{flag}_y \leftarrow (x, i)$ ; // Annotate  $\text{flag}_y$ 

   // Check whether  $y$  is near-a-black.
   //  $\ell$  will be the distance to the closest proper black ancestor  $y'$  of  $y$ , if any
8  $y' \leftarrow y$ ;  $\ell \leftarrow 0$ ; near_black  $\leftarrow$  false;
9 while  $\ell < \delta$  and  $y' \neq r$  and near_black = false do
10   $y' \leftarrow p_{y'}$ ;  $\ell \leftarrow \ell + 1$ ;
11  if  $y'$  is black then near_black  $\leftarrow$  true;

   // If  $y$  is not near-a-black, check whether it is black-free
12 if near_black = false then
13   $z \leftarrow y'$ ;
14  for  $\delta - 1$  times do
15    if  $z = r$  then break;
16     $z \leftarrow p_z$ ;
17    if  $z$  is black then return  $x$ ;

   // Execution Phase. (Node  $y$  was either near-a-black or black-free)
   // Acquire the flags of the lowest  $\delta$  proper ancestors of  $x$ 
18  $z \leftarrow x$ ;
19 for  $i = 1, \dots, \delta$  do
20  if  $z = r$  then return  $x$ ;
21   $z \leftarrow p_z$ ;
22  if  $\text{flag}_z \neq (x, i)$  then return  $x$ ; // Check the annotation of  $\text{flag}_z$ 
23  if near_black = true and  $i = \ell$  then  $x' \leftarrow z$ ; //  $y'$  is the  $\delta$ -parent of  $x'$ 
24   $\text{flag}_z \leftarrow \top$ ; // Spend  $\text{flag}_z$ 

25 if near_black = true then
26   $q_{x'} \leftarrow \text{AddLeaf}_Q(q_{y'}, x')$ ;
27 else
28   $q_y \leftarrow \text{NewTree}_Q(y)$ ;
29 return  $x$ ;

```

---

near-a-black or black-free. In the former case the vertex  $y'$  discovered in the first phase will be the  $\delta$ -parent of the new black vertex  $x'$ , and a new leaf  $\bar{x}'$  is appended to  $\bar{y}'$  in  $Q$ . In the latter case,  $y$  will become black and a new tree containing a single vertex  $\bar{y}$  is added to  $Q$ . Notice that, if a vertex  $b$  is colored black during the  $\text{AddLeaf}$  operation, the execution phase always spends  $\text{flag}_b$ .

### 4.3 Analysis of the data structure

In this section we analyze our data structure. The core of the analysis is to show that the  $\text{AddLeaf}$  operation in Algorithm 2 guarantees that in  $\mathcal{T}$ , if we are sufficiently distant from all the corrupted vertices, the black nodes are regularly distributed. The formal property

■ **Figure 3** An example showing that an uncorrupted path  $\pi$  (depicted in blue) can exhibit an irregular pattern of black vertices (d). Situation (a) can be reached when the adversary corrupts  $r$  by setting  $\text{flag}_r = \top$  before the insertions of the other nodes take place. To obtain (b), the adversary can set  $\text{flag}_u = \text{flag}_v = \top$ , thus corrupting  $u$  and  $v$  before  $u$  and  $v$ 's descendants are inserted. If the adversary sets  $\text{flag}_u$  and  $\text{flag}_v$  back to  $\perp$  before  $x, y$ , and  $z$  are inserted (in this order), we arrive in configuration (c) in which  $b_1, b_2$ , and  $b_3$  have been colored black. Inserting the remaining vertices yields (d).

is stated in Lemma 5. We first need to prove auxiliary properties. In Figure 3 we give an example that shows that, even in an uncorrupted path, if we are not sufficiently distant from corruptions, the black nodes can form irregular patterns in the path.

The following lemma shows that if the flag of a vertex  $w$  appears to be spent, then either there must be a nearby black ancestor of  $w$ , unless a nearby corruption occurred. See Figure 4 (a).

► **Lemma 1.** *Let  $w$  and  $z$  be two nodes such that  $z$  is the  $\delta$ -parent of  $w$  in  $T$  and such that no node in the path  $\pi$  from  $z$  to  $w$  in  $T$  has been corrupted. If  $\text{flag}_w = \top$ , then there exists a black node in  $\pi(z : w)$ .*

**Proof.** Let  $x$  be the node whose insertion in  $T$  caused  $\text{flag}_w$  to be set to  $\top$ . Moreover, let  $P$  be the path of length  $\delta$  from  $x$  to  $y$  traversed in the discovery phase of Algorithm 2 in lines 2–7. Similarly, let  $P'$  be the path from  $x$  to  $y$  traversed in the execution phase of Algorithm 2 in lines 18–24.

Clearly,  $P'$  contains  $w$ . Moreover, if  $w$  is the  $i$ -th node traversed in  $P'$ , then  $\text{flag}_w = (x, i)$  in the execution phase and (since  $w$  is uncorrupted),  $\text{flag}_w$  was set to  $(x, i)$  in the discovery phase. As a consequence,  $w$  is also the  $i$ -th node in  $P$  and  $P[y : w] = P'[y : w]$ . Hence,  $y$  is at distance at most  $\delta - 1$  from  $w$  in  $P$  (and in  $T$ ) showing that  $z$  is a proper ancestor of  $y$ . Therefore all nodes in  $P'[y : w]$  are uncorrupted, and the loop in lines 18–24 of Algorithm 2 is executed to completion. This ensures that the execution phase will color a node  $b$  black. We distinguish two cases depending on whether  $y$  was observed to be near-a-black or black-free in the discovery phase.

If  $y$  is black-free, then  $b$  is exactly  $y$  and the claim follows. Otherwise,  $y$  is near-a-black and the discovery phase computed the distance  $\ell$  between  $x$  and its closest black proper ancestor. If  $\ell \geq i$ , then Algorithm 2 colors a vertex in  $P(z : w] = \pi(z : w]$  black. Otherwise, if  $\ell < i$ , the discovery phase observed that the  $\ell$ -parent  $y'$  of  $y$  was black. Since  $\ell < \delta$ ,  $y'$  lies in  $\pi(z : y]$ . ◀

Next lemma shows that an uncorrupted path of length at least  $3\delta$  must contain a black vertex.

■ **Figure 4** (a) Graphical representation of the proof of Lemma 1, for  $\delta = 5$ . (b), (c), (d): Representations of the statements of Lemma 3, Lemma 4, and Lemma 5, respectively.

► **Lemma 2.** *Let  $x$  and  $z$  be nodes in  $T$  such that  $z$  is the  $3\delta$ -parent of  $x$  in  $T$  and such that no node in the path  $\pi$  from  $x$  to  $z$  in  $T$  has been corrupted. Then, there exists a black node  $w$  in  $\pi[z : x]$ .*

**Proof.** Since no vertex in  $\pi$  has been corrupted, the path  $\pi$  must also belong to the noisy tree  $\mathcal{T}$ . In the rest of the proof we assume that  $\pi[z : x]$  contains no black nodes and show that this leads to a contradiction.

Let  $y$  the  $\delta$ -parent of  $x$  in  $\pi$  and let  $t_x$  be the time at which the  $\text{AddLeaf}(\cdot)$  operation that adds  $x$  to  $T$  is invoked. We know that, at time  $t_x$ , there exists no node  $w$  in  $\pi[y : x]$  such that  $\text{flag}_w = \top$  since otherwise Lemma 1 would immediately imply the existence of a black node in  $\pi[z : w]$  contradicting the initial assumption. Then, the invocation of Algorithm 2 that inserts  $x$  also performs its execution phase.

Moreover,  $y$  must be black-free at time  $t_x$ , and hence it is colored black during such a phase (refer to the pseudocode of Algorithm 2, and recall that a black-free node is not near-a-black). Since  $y$  is not corrupted it must still be black, leading to a contradiction. ◀

Recall that we would like each uncorrupted path to contain a black vertex every  $\delta$  levels. Consider an uncorrupted path  $\pi$  of length between  $\delta$  and  $2\delta$  with a single black vertex  $z$  on top. Then, the vertex at distance  $\delta$  from  $z$  is “overdue” to become black. Next lemma shows that all flags associated with descendants of the overdue vertex in  $\pi$  must be unspent. In some sense, the data structure is preparing to recolor the missing black vertex. This will happen once  $\delta$  unspent flags are available. See Figure 4 (b).

► **Lemma 3.** *Let  $x$  and  $z$  be two nodes in  $T$  such that:  $z$  is an ancestor of  $x$  in  $T$ , no node in the path  $\pi$  from  $z$  to  $x$  in  $T$  has been corrupted, and  $\delta \leq |\pi| < 2\delta$ . We have that, immediately after vertex  $x$  is inserted, if the only black vertex in  $\pi$  is  $z$  then all the nodes  $w$  in  $\pi$  at distance at least  $\delta$  from  $z$  in  $T$  are such that  $\text{flag}_w \neq \top$ .*

**Proof.** Since no vertex in  $\pi$  has been corrupted, the path  $\pi$  must also belong to the noisy tree  $\mathcal{T}$ . In what follows, we prove that, immediately after vertex  $x$  is inserted, the existence of a node  $w$  between  $x$  and  $z$  in  $\pi$  such that  $d_{\mathcal{T}}(w, z) \geq \delta$  and  $\text{flag}_w = \top$  leads to a contradiction. Indeed, since  $\text{flag}_w = \top$ , Lemma 1 implies the existence of a black node in  $\pi[z : w]$ , and this contradicts the fact that  $z$  is the only black node in  $\pi[z : x]$ . ◀

The next technical lemma is about the timing at which vertices of a long uncorrupted path become black. This will be instrumental to prove Lemma 5. See Figure 4 (c).

► **Lemma 4.** *Let  $u$  and  $v$  be two nodes in  $T$  such that  $u$  is an ancestor of  $v$ ,  $d_T(u, v) \geq 3\delta$  and no node in the path  $\pi$  from  $v$  to  $u$  in  $T$  has been corrupted. Let  $y$  (resp.  $x$ ) be the node in  $\pi$  at distance  $2\delta$  (resp.  $3\delta$ ) from  $u$  in  $\pi$ . Let  $t'_v$  (resp.  $t'_x$ ) be the time immediately after the vertex  $v$  (resp.  $x$ ) is inserted. If the node  $y$  is black at time  $t'_v$ , then there exists a node  $w'$  in  $\pi[y : x]$  that is black at time  $t'_x$ .*

**Proof.** Since no vertex in  $\pi$  has been corrupted, the path  $\pi$  must also belong to the noisy tree  $\mathcal{T}$ . In the rest of the proof we assume towards a contradiction that  $y$  is black at time  $t'_v$ , yet there are no black nodes in  $\pi[y : x]$  at time  $t'_x$ .

Let  $z$  be the  $\delta$ -parent of  $y$  in  $\pi$ . Let  $\bar{t}_y$  be the time immediately before  $y$  is colored black. At time  $\bar{t}_y$  there are only two possible scenarios:

**Scenario 1:** At time  $\bar{t}_y$ , the node  $y$  is black-free;

**Scenario 2:** At time  $\bar{t}_y$ , the node  $z$  is the only black node in  $T$  in  $\pi[z : y]$ .

We denote with  $t_x$  the time immediately before vertex  $x$  is inserted in  $T$  and we consider the two scenarios separately (notice that  $\bar{t}_y$  refers to a later time than  $t_x$ ). We split scenario 1 into two additional subcases:

**Subcase 1.1:** at time  $t_x$  all the nodes  $w$  in  $\pi[y : x]$  are such that  $\text{flag}_w \neq \top$ ;

**Subcase 1.2:** at time  $t_x$  there is a node  $w$  in  $\pi[y : x]$  such that  $\text{flag}_w = \top$ .

We start considering subcase 1.1. Since  $\bar{t}_y$  follows  $t_x$ , and  $y$  is black-free at time  $\bar{t}_y$ , vertex  $y$  must also be black-free at time  $t_x$ . Then, during the insertion of  $x$ , Algorithm 2 colors  $y$  black yielding a contradiction.

We now analyze subcase 1.2. Since  $\text{flag}_w = \top$ , Lemma 1 implies the existence of a black node  $b$  in  $\pi[w, z]$  and, since we assume that there are no black nodes in  $\pi[y : x]$ ,  $b$  is in  $\pi(z : y)$ . This shows that  $y$  cannot be black-free at time  $\bar{t}_y$  and contradicts the hypothesis of scenario 1.1.

We now consider Scenario 2, which we subdivide into three subcases:

**Subcase 2.1.** at time  $t_x$  all the nodes  $w$  in  $\pi[y : x]$  are such that  $\text{flag}_w \neq \top$  and  $z$  is white;

**Subcase 2.2.** at time  $t_x$  all the nodes  $w$  in  $\pi[y : x]$  are such that  $\text{flag}_w \neq \top$  and  $z$  is black;

**Subcase 2.3.** at time  $t_x$  there is a node  $w$  in  $\pi[y : x]$  such that  $\text{flag}_w = \top$ .

We start by handling subcase 2.1. For the initial assumption, and for definition of this case, we have that there are no black nodes in  $\pi[z : x]$  at time  $t_x$ . Since  $z$  is colored black at some time  $\bar{t}_z$  following  $t_x$ , we know that the  $\delta - 1$  nodes ancestor of  $z$  are not black at time  $t_x$ , since this is incompatible with the fact that  $z$  will become black. Since  $\pi$  is not corrupted, we know that  $y$  is black-free in  $T$  at time  $t_x$ . This implies that  $y$  is colored black during the insertion of  $x$  in  $T$ , and hence  $y$  is black at time  $t'_x$  contradicting our hypotheses.

We proceed by analyzing subcase 2.2. At time  $\bar{t}_y$  all nodes in  $\pi[z : y]$ , except for  $z$ , are white and hence the same is true at time  $t_x$ . Since  $z$  is black at time  $t_x$  and  $\text{flag}_w \neq \top$  for all nodes  $w$  in  $\pi[y : x]$ , the **AddLeaf** procedure adding  $x$  will color  $y$  black. Hence  $y$  is black at time  $t'_x$ . This is a contradiction.

We now consider subcase 2.3. Together with Lemma 1,  $\text{flag}_w = \top$  implies the existence of a black node  $b$  in  $\pi(z : w)$ . Since we assume all the nodes in  $\pi[y : x]$  to be white, the black node  $b$  is in  $\pi(z, y)$ , contradicting the hypothesis of scenario 2. ◀

Now, we are ready to prove our main property about the pattern of black vertices discussed at the beginning of this section. See Figure 4 (d).

► **Lemma 5.** *Let  $u$  and  $v$  be two nodes in  $T$  such that  $u$  is an ancestor of  $v$ , the distance between  $u$  and  $v$  is at least  $7\delta$ , and no node in the path  $\pi$  from  $u$  to  $v$  has been corrupted. Let  $\tilde{u}$  be the node at distance  $5\delta$  from  $u$  in  $\pi$  and let  $\tilde{v}$  be the node at distance  $\delta$  from  $v$  in  $\pi$ . Then there is a black node  $w^*$  in  $\pi[\tilde{u} : v]$  such that:*

- *The distance between  $w^*$  and  $\tilde{u}$  is at most  $\delta$ .*
- *A generic node in  $\pi[w^* : \tilde{v}]$  at distance  $d$  from  $w^*$  is black iff  $d$  is a multiple of  $\delta$ . Moreover, if  $w$  is a black vertex in  $\pi(w^*, \tilde{v})$  and  $\bar{w}$  is the associated black vertex in  $Q$ , the parent of  $\bar{w}$  in  $Q$  corresponds to the  $\delta$ -parent of  $w$  in  $\pi$ .*

**Proof.** Since no vertex in  $\pi$  has been corrupted, the path  $\pi$  must also belong to the noisy tree  $\mathcal{T}$ . Then, Lemma 2 ensures that, at any time following the insertion of  $\tilde{u}$  in  $T$ , there exists a black ancestor  $y$  of  $\tilde{u}$  such that  $d_\pi(y, \tilde{u}) \leq 3\delta$ . Such a vertex  $y$  is the  $\delta$ -parent of some vertex  $x$  in  $\pi$ . We denote by  $u'$  the  $2\delta$ -parent of  $y$  in  $\pi$  and by  $t'_x$  the time immediately after  $x$  is inserted. Since the length of  $\pi[u' : v]$  is at least  $3\delta$  and  $y$  must be black when  $v$  is inserted, we can invoke Lemma 4 to conclude that there exists a node in  $\pi[y : x]$  that is black at time  $t'_x$ . We choose  $w_0$  as the closest ancestor of  $x$  that is black at time  $t'_x$ . Moreover, for  $i = 1, \dots, \lfloor \pi[w_0 : v] / \delta \rfloor$  we let  $w_i$  be the unique vertex at distance  $\delta i$  from  $w_0$  in  $\pi[w_0, v]$ . Finally, let  $t'_i$  be the time immediately after the insertion of  $w_i$  into  $T$ .

We will prove by induction on  $i \geq 1$  that (i) at time  $t'_i$ , all vertices  $w_0, w_1, \dots, w_{i-1}$  are black; (ii) from time  $t'_i$  onward, all vertices in  $\pi[w_0, w_i]$  that do not belong to  $\{w_0, w_1, \dots, w_i\}$  are white.

We start by considering the base case  $i = 1$ . Regarding (i), we know that  $w_0$  is black at time  $t'_x$ , and hence  $w_0$  is also black at time  $t'_1$  (which cannot precede  $t'_x$ ). Regarding (ii), by our choice of  $w_0$  we know that at time  $t'_x$ , the only black vertex in  $\pi[w_0, x]$  is  $w_0$ . Moreover, Algorithm 2 can only color a node  $b$  black if none of the  $\delta - 1$  lowest proper ancestors of  $b$  is black. This implies that no vertex in  $\pi(w_0, w_1)$  will be colored black.

We now assume that the claim is true up to  $i \geq 1$  and prove it for  $i + 1$ . We first argue that the following property holds: (\*) at time  $t'_{i+1}$  all vertices in  $\pi(w_i : w_{i+1})$  are white. Indeed, suppose towards a contradiction that there exists some black vertex  $b$  in  $\pi(w_i : w_{i+1})$  at time  $t'_{i+1}$ . When  $b$  was colored black, either its  $\delta$ -parent  $b'$  was black or  $b$  was black-free. In the former case we immediately have a contradiction since  $b'$  must be a vertex of  $\pi(w_{i-1}, w_i)$  but all such vertices are white by the induction hypothesis. In the latter case  $b$  must have been colored black after the insertion of  $w_i$  but, by the induction hypothesis, we know that from time  $t'_i$  onwards  $w_{i-1}$  is black. This contradicts the hypothesis that  $b$  was black-free.

Next, we prove (i). Suppose towards a contradiction that  $w_i$  is white at time  $t'_{i+1}$ . Then, using (\*) and the induction hypothesis, we can invoke Lemma 3 on the subpath of  $\pi$  between  $w_{i-1}$  and the parent of  $w_{i+1}$  to conclude that all nodes  $w$  in  $\pi[w_i : w_{i+1})$  are such that  $\text{flag}_w \neq \top$ . Hence, during the insertion of  $w_{i+1}$ , Algorithm 2 reaches line 8 and checks whether  $w_i$  is near-a-black. Since this is indeed the case, a new black vertex is created in  $\pi[w_i : w_{i+1})$ , providing the sought contradiction. Let  $\bar{w}_i$  (resp.  $\bar{w}_{i-1}$ ) be the vertex in  $Q$  associated with  $w_i$  (resp.  $w_{i-1}$ ). Notice that this argument also shows that, at time  $t'_{i+1}$ ,  $\bar{w}_i$  is a child of  $\bar{w}_{i-1}$  in  $Q$  since  $w_i$  becomes black after time  $t'_i$  and not later than time  $t'_{i+1}$ , when  $w_{i-1}$  was already black.

To prove (ii) it suffices to notice that, by inductive hypothesis, we only need to argue about the nodes in  $\pi(w_i : w_{i+1})$ . From (\*) we know that these nodes are white at time  $t'_{i+1}$ , while (i) ensures that  $w_i$  is black at time  $t'_{i+1}$ . Then, a similar argument to the one used in the base case shows that Algorithm 2 will never color any node in  $\pi(w_i : w_{i+1})$  black (as long as the nodes in  $\pi$  remain uncorrupted). This concludes the proof by induction.

Let  $w'$  be the node at distance  $\delta$  from  $\tilde{u}$  in  $\pi[\tilde{u} : v]$ . Notice that  $w_0$  belongs to  $\pi[u : w']$ . If  $w_0$  lies in  $\pi(\tilde{u} : w')$ , we can choose  $w^* = w_0$ . Otherwise,  $w_0$  is an ancestor of  $\tilde{u}$  and, from (i) and (ii), there is exactly one black vertex  $b$  in  $\pi(\tilde{u} : w')$  and we choose  $w^* = b$ . ◀

■ **Algorithm 3** Answers a level ancestor query  $\text{LA}(v, k)$  in dynamic trees.

---

```

1 if  $k \leq 7\delta$  then
2   return  $\text{climb}(v, k)$ ;
3  $\bar{v} \leftarrow \text{climb}(v, \delta)$ ;
4 Climb up the tree  $\mathcal{T}$  from  $\bar{v}$  for up to  $\delta$  nodes searching a black node;
5 if the previous procedure did not find a black node then
6   return error;
7  $v' \leftarrow$  a black node found in the previous procedure;
8  $d \leftarrow$  distance between  $v'$  and  $v$ ;
9  $k' \leftarrow k - d - 5\delta$ ;
10  $u' \leftarrow \text{LA}_Q(q_{v'}, \lfloor k'/\delta \rfloor)$ ;
11  $k_{\text{rest}} \leftarrow k' - \lfloor k'/\delta \rfloor \cdot \delta + 5\delta$ ;
12 return  $\text{climb}(u', k_{\text{rest}})$ ;

```

---

The above lemma suggests a natural query algorithm. The query procedure is similar to the one for static case. When  $k \leq 7\delta$  we climb in  $\mathcal{T}$  the nodes of the path from  $v$  to the  $k$ -parent of  $v$  in a trivial way. Otherwise, Lemma 5 ensures that if no vertex in the path  $P$  from  $v$  to its level ancestor in  $T$  was corrupted by the adversary, then every other  $\delta$ -th vertex of  $P$  is colored black except, possibly, for an initial subpath of length  $\delta$  and for a trailing subpath of length  $5\delta$ . The query procedure explicitly “climbs” these portions of  $P$  and queries  $D_Q$  to quickly skip over its remaining “middle” part. The pseudo-code is given in Algorithm 3.

We are now ready to prove the main theorem of this section.

► **Theorem 6.** *Our data structure requires linear space, supports the **AddLeaf** operation in  $O(\delta)$  worst-case time, and can answer resilient LA queries in  $O(\delta)$  worst-case time.*

**Proof.** The correctness of the query immediately follows from Lemma 5. Moreover, the time required to perform an **AddLeaf** or an LA operation is  $O(\delta)$  since in both cases  $O(\delta)$  vertices of  $\mathcal{T}$  are visited and a single  $O(\delta)$ -time operation involving  $D_Q$  is performed.

We now discuss the size of our data structure. Clearly, the space used to store the vector  $\mathcal{A}$  of all records is  $O(n)$ . We only need to argue about the size of  $D_Q$ . Recall that  $D_Q$  is the resilient version, obtained using the replication strategy, of the data structure that requires linear space, takes constant time to answer each LA query and to perform each **AddLeaf** operation [2]. In order to show that  $D_Q$  requires  $O(n)$  space we will argue that the number of black vertices is  $O(\frac{n}{\delta})$ . As consequence we have that the size of  $D_Q$  is  $O(n)$ .

To bound the number of vertices in  $Q$ , notice that in order to add a new vertex to  $Q$  we need to spend  $\delta$  flags that were previously unspent. Moreover, a spent flag never becomes unspent unless the adversary corrupts the record of the corresponding node (by using one of its  $\delta$  corruptions). As a consequence the nodes in  $Q$  are at most  $(n + \delta)/\delta = O(n/\delta)$ . ◀

# Computing Shapley Values for Mean Width in 3-D

Shuhao Tan   

Department of Computer Science, University of Maryland, College Park, MD, USA

---

## Abstract

The Shapley value is a classical concept from game theory, which is used to evaluate the importance of a player in a cooperative setting. Assuming that players are inserted in a uniformly random order, the Shapley value of a player  $p$  is the expected increase in the value of the characteristic function when  $p$  is inserted. Cabello and Chan (SoCG 2019) recently showed how to adapt this to a geometric context on planar point sets. For example, when the characteristic function is the area of the convex hull, the Shapley value of a point is the average amount by which the convex-hull area increases when this point is added to the set. Shapley values can be viewed as an indication of the relative importance/impact of a point on the function of interest.

In this paper, we present an efficient algorithm for computing Shapley values in 3-dimensional space, where the function of interest is the mean width of the point set. Our algorithm runs in  $O(n^3 \log^2 n)$  time and  $O(n)$  space. This result can be generalized to any point set in  $d$ -dimensional space ( $d \geq 3$ ) to compute the Shapley values for the mean volume of the convex hull projected onto a uniformly random  $(d-2)$ -subspace in  $O(n^d \log^2 n)$  time and  $O(n)$  space. These results are based on a new data structure for a dynamic variant of the convolution problem, which is of independent interest. Our data structure supports incremental modifications to  $n$ -element vectors (including cyclical rotation by one position). We show that  $n$  operations can be executed in  $O(n \log^2 n)$  time and  $O(n)$  space.

## 1 Introduction

Given a point set  $P$  in  $d$ -dimensional space, many different functions can be applied to extract information about the set's geometric structure. Often, this involves properties of the convex hull of the set, such as its surface area and mean width. In the context of approximation, a natural question involves the “impact” that any given point of  $P$  has on the measure of interest. One method for modeling the notion of impact arises from the concept of the Shapley value (defined below) in the context of cooperative games in game theory. In this paper, we will present an efficient algorithm to compute the Shapley values for points in 3-D where the payoff of a point set is defined as the mean width of its convex hull.

Formally, a *coalition game* consists of a set of players  $N$  and a characteristic function  $v : 2^N \rightarrow \mathbb{R}$ , where  $v(\emptyset) = 0$ . In our setting, we take the players to be a point set  $N \subset \mathbb{R}^3$  and consider the characteristic function  $v(Q) = w(\text{conv}(Q))$  for  $Q \subset N$ , where  $\text{conv}(Q)$  denotes the convex hull of  $Q$ , and  $w(\text{conv}(Q))$  denotes the mean width of  $\text{conv}(Q)$ . (Formal definitions will be given in Section 2.)

To define Shapley values, let  $\pi$  be a uniformly random permutation of  $N$ , and  $P_N(\pi, i)$  be the set of players in  $N$  that appear before player  $i$  in the permutation  $\pi$ . The *Shapley value* of player  $i \in N$  is defined to be the expected increase in  $v$  induced by the addition of player  $i$ , that is,

$$\phi(i) = \mathbb{E}_\pi[v(P_N(\pi, i) \cup \{i\}) - v(P_N(\pi, i))]. \quad (1)$$

Thus, the Shapley value represents the expected marginal contribution of  $i$  to the objective function over all permutations of  $N$ .

There are wide applications of Shapley values. A survey by Winter [27] and a book dedicated to this topic [24] provide insights on how the concept can be interpreted and applied in multiple ways, such as utility of players, allocation of resources of the grand coalition and measure of power in a voting system. Moreover, the values can be characterized axiomatically, making it the only natural quantity that satisfies certain properties. More details can be found in standard game theory textbooks ([14], [8, Chapter 5], [22, Section 9.4]).

In convex geometry and measure theory, *intrinsic volumes* are a key concept to characterize the “size” and “shape” of a convex body regardless of the translation and rotation in its underlying space. For example, Steiner’s formula [12] relates intrinsic volumes to the volume of the Minkowski-sum of a convex body and a ball. In general, one can define *valuation* to be a class of measure-like maps on open sets in a topological space. A formal definition of this concept can be found in [4, 16]. Functions such as volume and surface area fall into this class. Hadwiger’s Theorem [13, 17] asserts that every valuation that is continuous and invariant under rigid motion in  $\mathbb{R}^d$  is a linear combination of intrinsic volumes. In  $d$ -dimensional space, the  $d$ -th,  $(d - 1)$ -st and first intrinsic volumes are proportional to the usual Lebesgue measure, the surface area and the mean width, respectively [25, Chapter 4]. Cabello and Chan [7] presented efficient algorithms to compute Shapley values for area and perimeter for a point set in 2-D, which can be naturally extended to volume and surface area in 3-D. An algorithm that efficiently computes Shapley values for mean width in 3-D will then imply an algorithm that efficiently computes Shapley values for any continuous valuation in 3-D.

### Related work

The problem of computing Shapley values for area functions on a point set was introduced by Cabello and Chan [7]. They provided algorithms to compute Shapley values for area of convex hull, area of minimum enclosing disk, area of anchored rectangle, area of bounding box and area of anchored bounding box for a point set in 2-D. They also gave algorithms for the hull perimeter by slightly modifying these algorithms. All the quantities they considered are defined in 2-D space. Although their algorithms naturally extend to higher dimension, there are interesting applications of Shapley values in higher dimension that have yet been explored. The mean width considered in this paper is one such example.

Cabello and Chan also drew connections between computing Shapley values and stochastic computational geometry models. There have been many studies on the behavior of the convex hull under unipoint model where each point has an existential probability, for example see [1, 10, 15, 19, 26, 28]. In particular, Xue et al. [28] discussed the expected diameter and width of the convex hull. Huang et al. [15] presented a way to construct  $\epsilon$ -coreset for directional width under the model.

Mean width is often considered in the context of random polytopes in stochastic geometry. Müller [21] showed the asymptotic behavior of the mean width for a random polytope generated by sampling points on a convex body. Böröczyky [6] refined the result under the assumption that the convex body is smooth. Alonso-Gutiérrez and Prochno [3] considered

the case when the points are sampled inside an isotropic convex body. However, these results only consider the statistics when the number of points is large and the results are asymptotic. This paper views mean width on a computational perspective instead.

### Our contributions

We show that the Shapley values for mean width of the convex hull for a point set in  $\mathbb{R}^3$  can be computed in  $O(n^3 \log^2 n)$  time and  $O(n)$  space. Our approach is similar to the one used by Cabello and Chan for the case of the convex-hull area, in the sense that we look at the incremental formation of convex hull and consider the contribution of individual geometric objects. In our case, we break down the mean width and express that in terms of quantities related only to edges and then apply the linearity of Shapley values.

A major difference is that the expression for mean width contains angle at the edge, making the calculation for the probability term for Shapley values depend on the intersection of two halfspaces as opposed to only one halfspace. This prompts an expression that looks like a convolution. This convolution only changes slightly when evaluated from one point to another. The setup can be captured as an instance of dynamic convolution, where one can change the convolution kernel at any position, and query any single position in the vector involved in the convolution. Algebraic computations of this form were explored by Reif and Tate [23]. Frandsen et al. [11] gave a worst-case lower bound of  $\Omega(\sqrt{n})$  time per operation for this problem. By exploiting the structure of sweeping by polar angle, we obtain a variant of dynamic convolution, where we have a pointer to the convolution kernel and another pointer to the convolution result. We are only allowed to query at the pointer, update the convolution kernel at the pointer and move the pointers by one position. We present an online data structure for this variant that has  $O(n \log^2 n)$  overall time for  $n$  operations. There are some occurrences of algebraic computation in computational geometry, but many works [2, 5, 7, 18] do not have such dynamic setting and rely mostly on computing a single convolution or multi-point evaluation of polynomials. Only a few (see, e.g., [9]) employed a dynamic data structure. We believe our data structure is of independent interest for algorithms based on sweeping.

## 2 Preliminaries

**Mean width.** The mean width of a compact convex body  $X$  can be seen as the mean 1-volume of  $X$  projected on a uniformly random 1-subspace. More formally, let  $X \subset \mathbb{R}^d$  be a compact convex body. For  $1 \leq s \leq d$ , the *mean  $s$ -projection* of  $X$  is defined as:

$$M_s(X) = \int_{Q^s} |X_u| f_s(u) du, \quad (2)$$

where  $Q^s$  is the set of  $s$ -subspace,  $X_u$  is the projection of  $X$  on  $u$ ,  $|\cdot|$  is the volume or the canonical measure in the underlying space,  $f_s$  is the probability density function for uniformly sampling  $s$ -subspace from  $Q^s$ .

In this manner, the mean width of a point set  $P$  can be defined as  $M_1(\text{conv}(P))$  where  $\text{conv}(P)$  is the convex hull of  $P$ . It turns out that the mean  $s$ -projection of a convex polytope ( $1 \leq s \leq d - 2$ ) can be decomposed into values only related to its  $s$ -faces.

For a vertex of a polygon in 2-D, its interior angle can be naturally defined as the angle containing points within the polygon. And its exterior angle is the complement of the interior angle. This notion can be similarly generalized to higher dimensional faces in higher dimension. More formally, let  $X \subset \mathbb{R}^d$  be a convex polytope. Let  $V$  be a  $s$ -face of  $X$ . Let  $Q(V)$  be

## 67:4 Computing Shapley Values for Mean Width in 3-D

the set of halfspaces such that  $V$  is on the hyperplanes defining the halfspace. The *exterior angle* of  $V$  is defined as  $\psi(V) = \frac{|\{q \in Q(V) : X \subset q\}|}{|Q(V)|}$ . Let  $n(q)$  be the normal vector contained by the halfspace  $q$ . The *interior angle* of  $V$  is defined as  $\chi(V) = \frac{|\{q \in Q(V) : \exists p \in V, \exists \epsilon > 0, p + \epsilon n(q) \in X\}|}{|Q(V)|}$ . Moreover, when  $s = d - 2$ , and  $V \neq X$ , we have  $\chi(V) + \psi(V) = 1/2$  for all  $s$ -face  $V$  of  $X$ .

► **Lemma 1** (Miles [20]). *Let  $X \subset \mathbb{R}^d$  be a convex polytope, and  $1 \leq s \leq d - 2$ . Let  $V_s(X)$  be the set of  $s$ -face of  $X$ . We have:*

$$M_s(X) = C_{s,d} \sum_{V \in V_s(X)} |V| \psi(V). \quad (3)$$

where  $C_{s,d}$  is some constant related to  $s$  and  $d$ , in particular,  $C_{1,3} = 1/2$ .

**Random permutations.** When considering random permutations, it is common to compute probabilities where constraints on the order of appearance of disjoint sets are imposed. The following lemma follows from simple counting where a proof can be found in [7].

► **Lemma 2.** *Let  $N$  be a set with  $n$  elements. Let  $\{x\}$ ,  $A$  and  $B$  be disjoint sets. The probability that all of  $A$  appears before  $x$  and all of  $B$  appears after  $x$  in a uniformly random permutation  $\pi$  is  $\frac{|A|!|B|!}{(|A|+|B|+1)!}$ .*

**Assumptions.** We assume points in 3-D are of general positions where no three points are co-linear and no four points are co-planar. All points are assumed distinct. Throughout the paper, we often look at the projection of a 3-D point  $p$  on a plane, we will still use the same symbol  $p$  when looking on the plane for simplicity. We also assume a unit-cost real-RAM model of computation, where any arithmetic operation between two real numbers costs unit time, and a real number costs unit space to store.

### 3 Dynamic Convolution with Local Updates and Queries

Before presenting the algorithm to compute mean width, we first present a data structure that is central to the algorithm.

We consider a variant of dynamic convolution where only local updates and queries are permitted. More formally, let  $g : \mathbb{Z} \rightarrow \mathbb{R}$  be a fixed function where we can evaluate  $g(x)$  in constant time for any  $x$ . Let  $f : \mathbb{Z} \rightarrow \mathbb{R}$  initially be a zero function where we can change its values later. Let  $p, c \in \mathbb{Z}$  be two variables initially 0. We want to design a data structure that supports the following operations:

QUERY	UPDATE( $x$ )	INCP	DECP
Output $\sum_{i \in \mathbb{Z}} f(i+c)g(i)$	$f(p) \leftarrow f(p) + x$	$p \leftarrow p + 1$	$p \leftarrow p - 1$
ROTATELEFT	ROTATERIGHT		
$c \leftarrow c + 1$	$c \leftarrow c - 1$		

Let  $f^{(i)}$  be the  $f$  after the  $i$ -th operation, so  $f^{(0)} = 0$ . And similarly for  $p^{(i)}$ , and  $c^{(i)}$ . We can make the following observations:

► **Lemma 3.** *For any  $0 \leq i < j$ ,  $\max \text{supp}(f^{(j)} - f^{(i)}) - \min \text{supp}(f^{(j)} - f^{(i)}) \leq j - i$ , where  $\text{supp}(f)$  is the support of  $f$ .*

**Proof.** There are at most  $j - i$  INCP or DECP operations between the  $i$ -th and the  $j$ -th operation, so  $\max_{i \leq k \leq j} p^{(k)} - \min_{i \leq k \leq j} p^{(k)} \leq j - i$ . And we have  $\max \text{supp}(f^{(j)} - f^{(i)}) \leq \max_{i \leq k \leq j} p^{(k)}$  and  $\min \text{supp}(f^{(j)} - f^{(i)}) \geq \min_{i \leq k \leq j} p^{(k)}$ . ◀

■ **Figure 1** An example for  $n = 13 = 2^3 + 2^2 + 2^0$ . Each box represents an operation.

► **Corollary 4.** For any  $0 \leq i < j$ ,  $|\text{supp}(f^{(j)} - f^{(i)})| \leq j - i$ .

► **Lemma 5.** For any  $0 \leq i < j$ ,  $\max_{i \leq k \leq j} c^{(k)} - \min_{i \leq k \leq j} c^{(k)} \leq j - i$ .

**Proof.** There are at most  $j - i$  ROTATELEFT or ROTATERIGHT operations between the  $i$ -th and the  $j$ -th operation. ◀

► **Lemma 6.** For any  $0 \leq i < j$ ,  $\sum_k f^{(j)}(k + c)g(k) = \sum_k f^{(i)}(k + c)g(k) + \sum_k (f^{(j)} - f^{(i)})(k + c)g(k)$ .

From Lemma 6, we can see that it is possible to break the operations into chunks, and only consider the changes on  $f$  for each chunk. Lemma 3 ensures that the actual differences are proportional to the size of a chunk. So the idea is: after a chunk of size  $m$  is finished, we pre-compute all queries for the next  $m$  operations by considering all possible changes in  $c$ . We incrementally build different levels of chunks so that after finishing a chunk, we merge it with smaller chunks to build a larger chunk. Lemma 5 and Corollary 4 ensure that the prediction only depends on a small set of values of  $g$ . More specifically, we will use chunks sizes with power of two based on the binary form of the number of operations so far and merge chunks when needed. A binary-counter-like argument can be applied to achieve a amortized time of  $O(\log^2 n)$  per operation.

We maintain chunks of changes based on the binary representation of the number of operations we have seen so far. Assume we've just performed the  $k$ -th operation. Let  $b(k, i)$  be the  $i$ -th bit from right in the binary representation of  $k$ . We can write  $k = \sum_{i: b(k, i)=1} 2^i$  and we are going to use chunks of size  $2^i$  for  $b(k, i) = 1$ , where larger chunks are closer to the start of operations. Let  $i_1 < i_2 < \dots < i_q$  be the  $i$ 's such that  $b(k, i) = 1$ , and  $d(l) = \sum_{j=1}^l 2^{i_j}$ . Let  $s(j) = k - d(j)$  and  $e(j) = k - d(j - 1)$ .  $(s(j), e(j)]$  represents the range of the  $j$ -th chunk. In other words, we split the operations into chunks of size  $2^{i_q}, 2^{i_{q-1}}, \dots, 2^{i_1}$ . We maintain chunks of changes as  $H(i_j) = f^{(e(j))} - f^{(s(j))}$ . See Figure 1 for an example. Moreover, for each chunk, we maintain an array of predicted queries  $A(i_j)$  on the chunk  $H(i_j)$ , so that  $A(i_j, 2^{i_j} + c) = \sum_p H(i_j)(p + c^{(e(j))} + c)g(p)$  for  $-2^{i_j} \leq c \leq 2^{i_j}$ . We also maintain an array of  $I$  so that  $I(i_j) = c^{(k)} - c^{(e(j))}$ .

Assume we have  $A$ ,  $H$ , and  $I$  after  $n$  operations, the  $(n+1)$ -st operation can be performed easily: QUERY should output  $\sum_p f^{(n)}(p + c^{(n)})g(p)$ , and we have:

$$\begin{aligned} \sum_p f^{(n)}(p + c^{(n)})g(p) &= \sum_p \left( \sum_{i_j: b(n, i_j)=1} f^{(e(j))} - f^{(s(j))} \right) (p + c^{(n)})g(p) \\ &= \sum_{i_j: b(k, i_j)=1} \sum_p (f^{(e(j))} - f^{(s(j))})(p + c^{(e(j))} + I(i_j))g(p) \\ &= \sum_{i_j: b(k, i_j)=1} \sum_p H(i_j)(p + c^{(e(j))} + I(i_j))g(p) \\ &= \sum_{i_j: b(k, i_j)=1} A(i_j, 2^{i_j} + I(i_j)). \end{aligned}$$

So we can answer query by performing a summation over  $A$ . UPDATE is handled by simply documenting the change. INCP and DECP are handled by incrementing and decrementing  $p$ , respectively. ROTATELEFT and ROTATERIGHT are handled by incrementing and decrementing all entries of  $I$ , respectively.

After each operation, an additional maintaining step is performed to ensure  $A$ ,  $H$ ,  $I$  contain the correct information for the following operations. Assume that we want to maintain the data structure after the  $n$ -th operation, we record the change in  $f$  as  $\Delta f = f^{(n)} - f^{(n-1)}$ . Observe that  $A(i)$  doesn't change if  $b(n, i) = b(n-1, i)$ . Let  $i^* = \min\{i : b(n, i) = 1\}$ , then only  $A(i)$ 's such that  $i \leq i^*$  change. Moreover,  $A(i)$  becomes empty if  $i < i^*$ . Similar phenomenon can be seen in the increment of a binary counter. We expect:

$$\begin{aligned} A(i^*, 2^{i^*} + c) &= \sum_p H(i^*)(p + c^{(n)} + c)g(p) \\ &= \sum_p (f^{(n)} - f^{(n-2^{i^*})})(p + c^{(n)} + c)g(p) \\ &= \sum_p \left( \Delta f + \sum_{j=0}^{i^*-1} f^{(n-2^j)} - f^{(n-2^{j+1})} \right) (p + c^{(n)} + c)g(p) \\ &= \sum_p \left( \Delta f + \sum_{j=0}^{i^*-1} H(j) \right) (p + c^{(n)} + c)g(p). \end{aligned}$$

So we can merge  $\Delta f$  and  $\{H(j) : j < i^*\}$  to get  $H(j^*) = f^{(n)} - f^{(n-2^{i^*})}$ , and compute  $A(i^*, 2^{i^*} + c) = \sum_p H(i^*)(p + c^{(n)} + c)g(p)$  for all  $-2^{i^*} \leq c \leq 2^{i^*}$ . This is almost a convolution. To see it clearer, let  $L = \min \text{supp } H(i^*)$  and  $R = \max \text{supp } H(i^*)$ , we can rewrite the expression as  $A(i^*, 2^{i^*} + c) = \sum_{p=L}^R H(i^*)(p)g(p - c^{(n)} - c)$ . We now want to shift the origin so that  $\text{supp } H$  can start at 0 to conform to the definition of a convolution. Let  $H'(p) = H(i^*)(L + p)$  for  $0 \leq p \leq R - L$ , and  $H'(p) = 0$  otherwise. Let  $g'(p) = g(-p + L - c^{(n)} + 2^{i^*+1})$ , for  $0 \leq p \leq 3 \cdot 2^{i^*}$ , and  $g'(p) = 0$  otherwise. we have:

$$\begin{aligned} A(i^*, 2^{i^*} + c) &= \sum_{p=L}^R H(i^*)(p)g(p - c^{(n)} - c) \\ &= \sum_{p=0}^{R-L} H(i^*)(L + p)g(p - c + L - c^{(n)}) \\ &= \sum_{p=0}^{R-L} H'(p)g'(2^{i^*+1} + c - p) \\ &= H' * g'[2^{i^*+1} + c] \end{aligned}$$

Where  $H' * g'$  is the discrete convolution of  $H'$  and  $g'$ .

By Lemma 3,  $R - L \leq 2^{i^*}$ , so  $0 \leq 2^{i^*+1} + c - p \leq 3 \cdot 2^{i^*}$ . We can treat both  $H'$  and  $g'$  as circular vectors of size  $3 \cdot 2^{i^*}$ , and compute  $H' * g'[2^{i^*} + c]$  for all  $-2^{i^*} \leq c \leq 2^{i^*}$  by the Fast Fourier Transform. We then use the result to construct  $A(i^*)$ . We set  $I(i^*) = 0$ , and clear all  $A(i)$ ,  $H(i)$ , and  $I(i)$  where  $i < i^*$ .

Now that we have a way to maintain  $A$ ,  $H$ , and  $I$ , the following Lemma shows that the QUERY operation always succeed, i.e.,  $-2^i \leq I(i) \leq 2^i$ .

► **Lemma 7.** *After the  $n$ -th operation, for any  $i_j$  such that  $b(n, i_j) = 1$ ,  $|c^{(n)} - c^{(e(j))}| \leq 2^{i_j}$ .*

**Proof.**  $|c^{(n)} - c^{(e(j))}| \leq \max_{e(j) \leq k \leq n} c^{(k)} - \min_{e(j) \leq k \leq n} c^{(k)} \leq n - e(j) = d(j-1) \leq \sum_{k=0}^{i_j-1} 2^k = 2^{i_j}$ .  $\blacktriangleleft$

We now analyze the complexity of the data structure:

► **Theorem 8.** *There is a data structure that supports  $n$  operations for Dynamic Convolution with Local Updates and Queries in  $O(\log^2 n)$  amortized time and  $O(n)$  space.*

**Proof.** Without considering the additional maintaining step after each operation, it is easy to see a single INCP, DECP, or UPDATE takes  $O(1)$  time. Likewise a single ROTATELEFT, ROTATERIGHT, or QUERY takes  $O(\log n)$  time since the number of bits in the binary representation of  $n$  is  $O(\log n)$ .

In the maintaining step, whenever the  $i$ -th bit in the binary representation of  $n$  changes from 0 to 1, we need to merge changes of total size  $O(2^i)$ , run FFT on two arrays of size  $3 \cdot 2^i$ , and clear histories of total size  $O(2^i)$ . These in all take  $O(2^i \log(2^i))$  time where the bottleneck is FFT. Like the analysis in binary counter,  $i$ -th bit flips from 0 to 1 in every  $2^i$  operations, so the total time spent on maintaining step is:  $\sum_{i=0}^{\log n} \frac{n}{2^i} O(2^i \log(2^i)) = O\left(n \sum_{i=0}^{\log n} i \log(2)\right) = O(n \log^2 n)$ .

Adding two parts, the total time for  $n$  operation is  $O(n \log^2 n)$ , yielding an amortized time of  $O(\log^2 n)$  per operation.

At any point, the space used by the data structure is linear to the size of  $A, H, I$ , even during the maintaining step. So the space complexity is  $O\left(\sum_{i=0}^{\log n} 2^i\right) = O(n)$ .  $\blacktriangleleft$

► **Corollary 9.** *Let  $g : \mathbb{Z} \rightarrow \mathbb{R}$  be a fixed function where we can evaluate  $g(x)$  in constant time. Let  $Q$  be a queue with elements in  $\mathbb{R}$ . There is a data structure that supports  $n$  operations in  $O(\log^2 n)$  amortized time and  $O(n)$  space, where each operation is either pushing to the tail of  $Q$ , popping from the head of  $Q$  or querying  $\sum_{i=1}^{|Q|} Q(i)g(|Q| - i)$ .*

**Proof.** We use two instances of data structure  $I_1 = (f_1, g_1, p_1, c_1)$  and  $I_2 = (f_2, g_2, p_2, c_2)$  from Theorem 8. We make  $g_1(x) = g_2(x) = g(-x)$ . Whenever we want to perform a push  $x$ , we perform UPDATE( $x$ ), ROTATELEFT and INCP on  $I_1$ , and perform ROTATELEFT on  $I_2$ . Whenever we want to perform a pop  $x$ , we perform UPDATE( $-x$ ) and INCP on  $I_2$ . Whenever we want to query, we query both  $I_1$  and  $I_2$  and return the sum. Each operation to the queue expands to constant number of operations on  $I_1$  and  $I_2$ , so the running time is still  $O(\log^2 n)$  amortized and the space is  $O(n)$ .  $\blacktriangleleft$

## 4 Computing Shapley Value of Mean Width in 3-D

### 4.1 Classification of Cases

Let  $X$  be a convex polyhedron in 3-D, Lemma 1 becomes:

$$M_1(X) = \frac{1}{2} \sum_{e \in E(X)} l(e)\psi(e), \quad (4)$$

where  $E(X)$  is the set of edges of  $X$  and  $l(e)$  is the length of edge  $e$ .

Let  $N \subset \mathbb{R}^3$  be a point set. Let  $n$  be the number of points in the point set. The mean width we are considering is  $M_1(\text{conv}(N))$ . Given a permutation  $\pi$ , and a point  $p \in N$ , for convenience we define  $C(\pi, p) = \text{conv}(P_N(\pi, p) \cup \{p\})$  and  $C'(\pi, p) = \text{conv}(P_N(\pi, p))$ . We then define the contribution of  $p$  under permutation  $\pi$  to be:

$$\Delta(\pi, p) = M_1(C(\pi, p)) - M_1(C'(\pi, p)). \quad (5)$$

## 67:8 Computing Shapley Values for Mean Width in 3-D

When there are at least three points in  $N$ , we have  $\psi(e) = 1/2 - \chi(e)$  for all  $e \in E(N)$ . In the case where  $N$  is an edge  $e$ , we have  $\psi(e) = 1$ . It is also clear that a single point has width 0. So for  $p \in N$ , when considering the Shapley value  $\phi(p)$ , we can classify the permutations into three cases:

- CASE 1: There is one point before  $p$  in the permutation. i.e., after inserting  $p$ , the point set forms a line segment.
- CASE 2: There are two points before  $p$  in the permutation. i.e., after inserting  $p$ , the point set forms a triangle.
- CASE 3: There are three or more points before  $p$  in the permutation.

In other words, we can write  $\phi(p)$  as:

$$\phi(p) = \sum_{\pi} \frac{\Delta(\pi, p)}{n!} = \sum_{\pi: \text{Case 1}} \frac{\Delta(\pi, p)}{n!} + \sum_{\pi: \text{Case 2}} \frac{\Delta(\pi, p)}{n!} + \sum_{\pi: \text{Case 3}} \frac{\Delta(\pi, p)}{n!}. \quad (6)$$

For Case 1, we can rewrite the summation as:

$$\begin{aligned} \sum_{\pi: \text{Case 1}} \frac{\Delta(\pi, p)}{n!} &= \sum_{\substack{q \in P \\ q \neq p}} \sum_{\pi: \pi = (q, p, \dots)} \frac{\Delta(\pi, p)}{n!} = \sum_{\substack{q \in P \\ q \neq p}} \sum_{\pi: \pi = (q, p, \dots)} \frac{d(p, q)/2}{n!} \\ &= \sum_{\substack{q \in P \\ q \neq p}} \frac{d(p, q)}{2} \Pr(\pi = (q, p, \dots)) = \sum_{\substack{q \in P \\ q \neq p}} \frac{d(p, q)}{2} \frac{1}{n(n-1)}. \end{aligned} \quad (7)$$

Here  $d(\cdot, \cdot)$  is the Euclidean distance function. So for any  $p$ , we can compute the summation in  $O(n)$  time by enumerating  $q$ . And it takes  $O(n^2)$  in total to compute for every  $p$ .

For Case 2, we can rewrite the summation as:

$$\begin{aligned} \sum_{\pi: \text{Case 2}} \frac{\Delta(\pi, p)}{n!} &= \sum_{\substack{q, r \in P \\ p, q, r \text{ are distinct}}} \sum_{\pi: \pi = (q, r, p, \dots)} \frac{\Delta(\pi, p)}{n!} \\ &= \sum_{\substack{q, r \in P \\ p, q, r \text{ are distinct}}} \sum_{\pi: \pi = (q, r, p, \dots)} \frac{\frac{d(p, q) + d(r, q) + d(p, r)}{4} - \frac{d(r, q)}{2}}{n!} \\ &= \sum_{\substack{q, r \in P \\ p, q, r \text{ are distinct}}} \frac{d(p, q) + d(p, r) - d(r, q)}{4} \Pr(\pi = (q, r, p, \dots)) \\ &= \sum_{\substack{q, r \in P \\ p, q, r \text{ are distinct}}} \frac{d(p, q) + d(p, r) - d(r, q)}{4} \frac{1}{n(n-1)(n-2)}. \end{aligned} \quad (8)$$

Like Case 1, we can compute the summation in  $O(n^2)$  time by enumerating  $q$  and  $r$ . And it takes  $O(n^3)$  in total to compute for every  $p$ .

In Case 3, each edge we are considering has two faces attached to it. In other words, each edge can be characterized by the common edge shared by two triangles formed by four points. We can denote an edge by  $(q, r, t_1, t_2)$ , where  $(q, r)$  is the edge and is the common edge of  $\triangle qrt_1$  and  $\triangle qrt_2$ . Without loss of generality, we assume unordered tuples when writing  $(q, r)$  and  $(t_1, t_2)$  to avoid double-counting. The exterior angle is completely determined by the quadruple. In case the convex hull has only 3 points, we allow  $t_1 = t_2$ . We can then apply Lemma 1 and express  $M_1(\text{conv}(N'))$  for a point set  $N'$  as:

■ **Figure 2** Change of edges when  $p$  is inserted, showing only the part visible to  $p$ . Red edges: edges added to the convex hull. Blue edges: edges removed from the convex hull. Orange edges: edges with angle changed.

$$\begin{aligned}
 M_1(\text{conv}(N')) &= \frac{1}{2} \sum_{e \in E(\text{conv}(N'))} l(e)\psi(e) = \frac{1}{2} \sum_{\substack{e=(q,r,t_1,t_2) \\ q,r,t_1,t_2 \in N' \\ \Delta qrt_1, \Delta qrt_2 \text{ are faces of } \text{conv}(N')}} l(e)\psi(e) \\
 &= \frac{1}{2} \sum_{\substack{e=(q,r,t_1,t_2) \\ q,r,t_1,t_2 \in N'}} d(q,r)\psi(e) I_{\text{conv}(N')}(q,r,t_1,t_2)
 \end{aligned}$$

where we use an indicator variable:

$$I_X(q,r,t_1,t_2) = \begin{cases} 1 & \Delta qrt_1, \Delta qrt_2 \text{ are faces of convex polyhedron } X \\ 0 & \text{otherwise} \end{cases}$$

Conditioning on  $\pi$  being Case 3, we can write  $\Delta(\pi, p)$  as:

$$\Delta(\pi, p) = \frac{1}{2} \sum_{\substack{e=(q,r,t_1,t_2) \\ q,r,t_1,t_2 \in N}} l(e)\psi(e) (I_{C(\pi,p)}(q,r,t_1,t_2) - I_{C'(\pi,p)}(q,r,t_1,t_2))$$

We can write in the form of expectation as:

$$\begin{aligned}
 \sum_{\pi: \text{Case 3}} \frac{\Delta(\pi, p)}{n!} &= \mathbb{E}_\pi[\Delta(\pi, p) | \pi : \text{Case 3}] \Pr(\pi : \text{Case 3}) \\
 &= \frac{1}{2} \sum_{\substack{e=(q,r,t_1,t_2) \\ q,r,t_1,t_2 \in N}} l(e)\psi(e) \mathbb{E}_\pi [I_{C(\pi,p)}(q,r,t_1,t_2) - I_{C'(\pi,p)}(q,r,t_1,t_2) | \pi : \text{Case 3}] \Pr(\pi : \text{Case 3})
 \end{aligned}$$

Observe that  $I_{C(\pi,p)}(q,r,t_1,t_2) = 1$  implies  $\pi$  being Case 3. The summation reduces to:

$$\frac{1}{2} \sum_{q,r \in N} \sum_{\substack{t_1, t_2 \in N \\ e=(q,r,t_1,t_2)}} l(e)\psi(e) \mathbb{E}_\pi [I_{C(\pi,p)}(q,r,t_1,t_2) - I_{C'(\pi,p)}(q,r,t_1,t_2)] \tag{9}$$

Now consider the impact when inserting  $p$  to  $P_N(\pi, p)$ . The convex hull does not change if  $p$  is inside  $C'(\pi, p)$ . Otherwise if we treat  $C'(\pi, p)$  as an opaque object, all the faces visible to  $p$  will be removed in  $C(\pi, p)$  and a pyramid-like cone with apex at  $p$  will be added to  $C(\pi, p)$ . In terms of edges, there are three types of edges: edges removed, edges added and edges with angle changed. See Figure 2 for an illustration.

■ **Figure 3** Projection of  $N$  along  $qr$ . Edge  $qr$  gets removed when forming  $\text{conv}(P_N(\pi, p) \cup \{p\})$  if and only if (a)  $p$  is not in the cone formed by  $qr$ ,  $t_1$  and  $t_2$ , (b)  $q$ ,  $r$ ,  $t_1$  and  $t_2$  appear before  $p$  in  $\pi$  and (c) No point outside the cone (red point) appears before  $p$  in  $\pi$ .

As we are using a 4-tuple to represent an edge in the summation, edges with angles changed can be seen as removal and addition with different  $(t_1, t_2)$ . We have:

$$\begin{aligned}
 & I_{C(\pi, p)}(q, r, t_1, t_2) - I_{C'(\pi, p)}(q, r, t_1, t_2) \\
 = & \begin{cases} -1 & (q, r, t_1, t_2) \text{ is an edge of } C'(\pi, p) \text{ and visible to } p \\ 1 & (q, r, t_1, t_2) \text{ is an edge of } C(\pi, p) \text{ and } p \in \{t_1, t_2\} \\ 1 & (q, r, t_1, t_2) \text{ is an edge of } C(\pi, p) \text{ and } p \in \{q, r\} \\ 0 & \text{otherwise} \end{cases}
 \end{aligned}$$

The first three cases are correspondent to blue+orange, orange and red edges in Figure 2 respectively. So we can write:

$$\begin{aligned}
 & \mathbb{E}_\pi [I_{C(\pi, p)}(q, r, t_1, t_2) - I_{C'(\pi, p)}(q, r, t_1, t_2)] \\
 = & \Pr((q, r, t_1, t_2) \text{ is an edge of } C(\pi, p) \text{ and } p \in \{t_1, t_2\}) \\
 & + \Pr((q, r, t_1, t_2) \text{ is an edge of } C(\pi, p) \text{ and } p \in \{q, r\}) \\
 & - \Pr((q, r, t_1, t_2) \text{ is an edge of } C'(\pi, p) \text{ and visible to } p)
 \end{aligned} \tag{10}$$

This gives us a way to split the final summation in Equation 9 further into 3 summations. We will show how to compute them efficiently in the following subsection.

## 4.2 Handling Case 3

The idea is to enumerate edges  $(q, r)$  and compute  $\sum_{\substack{t_1, t_2 \in N \\ e=(q, r, t_1, t_2)}} l(e)\psi(e) \Pr(\cdot)$  for all  $p$  where  $\Pr(\cdot)$  is one of the three probabilities in Equation 10.

**$(q, r, t_1, t_2)$  is an edge of  $C'(\pi, p)$  and visible to  $p$**

Given a pair of points  $(q, r)$ , we look at the projection of  $N$  along the direction of  $qr$ .

- **Lemma 10.**  *$(q, r, t_1, t_2)$  is an edge of  $C'(\pi, p)$  and visible to  $p$  if and only if*
- (a)  $p$  is not in the cone formed by  $qr$ ,  $t_1$  and  $t_2$ .
  - (b)  $q$ ,  $r$ ,  $t_1$  and  $t_2$  appear before  $p$  in  $\pi$ .
  - (c) No point outside the cone appears before  $p$  in  $\pi$ .

■ **Figure 4** Partition of points based on whether a point is left to  $p - qr$  or right to  $p - qr$ . Red points are left, and blue points are right.

**Proof.** (b) is immediate as we need  $q, r, t_1$  and  $t_2$  to be in  $P_N(\pi, p)$  so that the edge can be in  $C'(\pi, p)$ . Given (b),  $(q, r, t_1, t_2)$  is an edge of  $C'(\pi, p)$  if and only if  $\Delta qrt_1$  and  $\Delta qrt_2$  form two supporting planes of  $P_N(\pi, p)$  if and only if no point outside the cone appears before  $p$  in  $\pi$ . Finally,  $(q, r, t_1, t_2)$  is visible to  $p$  if and only if  $pq$  and  $pr$  are completely outside  $C'(\pi, p)$  if and only if  $p$  is not in the cone formed by  $qr, t_1$  and  $t_2$ . See Figure 3 for an example. ◀

Treat  $qr$  as the origin and let  $p_1, p_2, \dots, p_{n-2}$  be the rest of the points in  $N$  sorted by polar angles relative to  $qr$ . In other words,  $p_1, p_2, \dots, p_{n-2}$  is the order of points when we sweep a ray starting from  $qr$  around counterclockwise, initially to the direction of positive  $x$ -axis. Let  $\theta_i$  be the polar angle of  $p_i$ . For convenience, we treat the sequence  $p_1, p_2, \dots, p_{n-2}$  as a cyclic array, in the sense that  $p_{n-1} = p_1$ . Moreover, when we iterate through the sequence,  $\theta_i$  is non-decreasing. In other words, when we iterate  $p_1, p_2, \dots, p_{n-1}, p_n, \dots$ , although  $p_{n-1}$  and  $p_1$  are the same point, we treat  $\theta_{n-1} = \theta_1 + 2\pi$ .

Let  $W_{qr}(p_i, p_j)$  be the number of points in the cone formed by  $qr, p_i$  and  $p_j$ . Let  $g(i) = 4!(n - 5 - i)! / (n - i)!$ . For a point  $p$  outside the cone, Lemma 2 gives us:

$$\Pr((q, r, p_i, p_j) \text{ is an edge of } C'(\pi, p) \text{ and visible to } p) = g(W_{qr}(p_i, p_j)) \tag{11}$$

Let  $S(i)$  be the set of pairs  $(p_j, p_k)$  such that  $p_i$  is not in the cone formed by  $qr, p_j$  and  $p_k$ . We assume  $j \leq k$  and the cone is formed by sweeping from  $p_j$  to  $p_k$  counterclockwise. For a given point  $p_i$ , Lemma 10 and Equation 11 gives:

$$\begin{aligned} & \sum_{\substack{t_1, t_2 \in N \\ e=(q, r, t_1, t_2)}} l(e)\psi(e) \Pr((q, r, t_1, t_2) \text{ is an edge of } C'(\pi, p) \text{ and visible to } p_i) \\ &= \sum_{(p_j, p_k) \in S(i)} d(q, r) \left( \frac{1}{2} - \frac{\theta_k - \theta_j}{2\pi} \right) g(W_{qr}(p_j, p_k)) \end{aligned}$$

Splitting the summation we get:

$$d(q, r) \left( \sum_{(p_j, p_k) \in S(i)} \frac{1}{2} g(W_{qr}(p_j, p_k)) - \sum_{(p_j, p_k) \in S(i)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k)) \right) \tag{12}$$

We now show how to compute  $\sum_{(p_j, p_k) \in S(i)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k))$  for all  $i$ . For each point  $p$ , we partition the point set by whether a point is left to  $p - qr$  or right to  $p - qr$ . As shown in Figure 4, we define:

$$L(p) = \{p' \in N : (p - qr) \times (p' - qr) > 0\} \quad R(p) = \{p' \in N : (p - qr) \times (p' - qr) < 0\} \tag{13}$$

## 67:12 Computing Shapley Values for Mean Width in 3-D

■ **Figure 5** When changing from  $S(i)$  to  $S(i+1)$ , pairs formed between  $p_{i+1}$  and  $L(p_{i+1}) \cup \{p_{i+1}\}$  are removed and pairs formed between  $p_i$  and  $R(p_i) \cup \{p_i\}$  are added. Left:  $p_{i+1} \in L(p_i)$ . Right:  $p_{i+1} \in R(p_i)$ .

Consider the difference between  $S(i)$  and  $S(i+1)$ . It is easy to see:

$$\begin{aligned} \sum_{(p_j, p_k) \in S(i+1)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k)) &= \sum_{(p_j, p_k) \in S(i)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k)) \\ &+ \sum_{p_j \in R(p_i) \cup \{p_i\}} \frac{\theta_i - \theta_j}{2\pi} g(W_{qr}(p_i, p_j)) \\ &- \sum_{p_j \in L(p_{i+1}) \cup \{p_{i+1}\}} \frac{\theta_j - \theta_{i+1}}{2\pi} g(W_{qr}(p_j, p_{i+1})) \end{aligned} \quad (14)$$

as demonstrated in Figure 5. We can further write:

$$\begin{aligned} &\sum_{p_j \in R(p_i) \cup \{p_i\}} \frac{\theta_i - \theta_j}{2\pi} g(W_{qr}(p_i, p_j)) \\ &= \theta_i \sum_{p_j \in R(p_i) \cup \{p_i\}} \frac{1}{2\pi} g(W_{qr}(p_i, p_j)) - \sum_{p_j \in R(p_i) \cup \{p_i\}} \frac{\theta_j}{2\pi} g(W_{qr}(p_i, p_j)) \end{aligned} \quad (15)$$

We will show how to compute  $\sum_{p_j \in R(p_i) \cup \{p_i\}} f(j)g(W_{qr}(p_i, p_j))$  for an arbitrary function  $f$  and for all  $i$  at the same time. Equation 15 can then be computed by using  $f(j) = 1/2\pi$  and  $f(j) = \theta_j/2\pi$ , respectively.

If we sort the points in  $R(p_i) \cup \{p_i\}$  by polar angles as  $q_1, q_2, \dots, q_l$ , where  $l = |R(p_i) \cup \{p_i\}|$ , it is easy to see  $W_{qr}(p_i, q_j) = l - j$  for  $1 \leq j \leq l$ . In other words, the number of points within the cone formed by  $qr$ ,  $p_i$ , and  $q_j$  is equal to the distance between  $q_j$  and  $p_i$  in the sequence  $p_1, p_2, \dots$ .

Now we consider an instance of the data structure from Corollary 9. We use  $g(i) = 4!(n-5-i)/(n-i)!$  as the function used by the data structure. We start by choosing an arbitrary point  $p_i$  and consider a ray opposite to  $p_i - qr$ . We sweep this ray counterclockwise until hitting  $p_i$ , for each point  $p_j$  hit by the ray, we perform a push  $f(j)$  to the data structure. After we hit  $p_i$ , we perform a query and the result is exactly  $\sum_{p_j \in R(p_i) \cup \{p_i\}} f(j)g(W_{qr}(p_i, p_j))$ . Next we sweep the ray to  $p_{i+1}$  and pop all the points that are left to  $p_{i+1}$ . They should all appear at the head of the data structure. We then perform a query and the result is exactly  $\sum_{p_j \in R(p_{i+1}) \cup \{p_{i+1}\}} f(j)g(W_{qr}(p_i, p_j))$ . We keep sweeping, popping and querying until coming back to  $p_{i+n-3}$  which is  $p_{i-1}$ . During this process, each point gets pushed and popped at most twice and we perform  $n-2$  queries. So the running time is  $O(n \log^2 n)$  and the space complexity is  $O(n)$  according to Corollary 9.

■ **Figure 6** Projection of  $N$  along  $qr$ . Edge  $qr$  gets added when forming  $\text{conv}(P_N(\pi, p) \cup \{p\})$  if and only if (a)  $q, r$  and  $t_2$  appear before  $p$  in  $\pi$  (b) No point outside the cone formed by  $qr, p$  and  $t_2$  (red point) appears before  $p$  in  $\pi$ .

Hence we can compute  $\sum_{p_j \in R(p_i) \cup \{p_i\}} \frac{\theta_i - \theta_j}{2\pi} g(W_{qr}(p_i, p_j))$  for all  $i$  in  $O(n \log^2 n)$  time and  $O(n)$  space. With the same idea but sweeping the other way around, we can also compute  $\sum_{p_j \in L(p_{i+1}) \cup \{p_{i+1}\}} \frac{\theta_j - \theta_{i+1}}{2\pi} g(W_{qr}(p_j, p_{i+1}))$  for all  $i$  in the same time and space complexity.

Next we only need to compute  $\sum_{(p_j, p_k) \in S(i)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k))$  for a single  $i$  and then used the pre-computed result to update to next  $\sum_{(p_j, p_k) \in S(i+1)} \frac{\theta_k - \theta_j}{2\pi} g(W_{qr}(p_j, p_k))$  in constant time. Like in the previous case, we need to compute summations of the form  $\sum_{(p_j, p_k) \in S(i)} f(j)g(W_{qr}(p_j, p_k))$ . We again use an instance of data structure from Corollary 9 and use the same  $g$  as above. We start by pushing  $p_{i+1}$  and sweep counterclockwise. For each point hit, we first pop all the points that are left to the point, push the point to the data structure and finally perform a query. We stop after hitting  $p_{i+n-3}$  which is  $p_{i-1}$ . The sum of all the queries will then be  $\sum_{(p_j, p_k) \in S(i)} f(j)g(W_{qr}(p_j, p_k))$ . In this procedure, each point is pushed and popped at most once, and  $n - 3$  queries are made. So it takes  $O(n \log^2 n)$  time and  $O(n)$  space to compute for a single  $i$ . After that it takes  $O(n)$  time to compute for all  $i$  by transitioning from  $i$  to  $i + 1$  in constant time.

Using the same idea, we can compute the other part of Equation 12 in  $O(n \log^2 n)$  time and  $O(n)$  space as well.

For a fixed pair  $(q, r)$ , it takes  $O(n \log n)$  to sort other points by polar angles on the projected plane. And it takes  $O(n)$  to pre-compute  $g$ . Hence, it takes  $O(n \log^2 n)$  time and  $O(n)$  space to compute  $\sum_{e=(q,r,t_1,t_2)} \sum_{t_1, t_2 \in N} l(e)\psi(e) \Pr(\cdot)$  for all  $p$  for the case where  $(q, r, t_1, t_2)$  is edge of  $C'(\pi, p)$  and visible to  $p$ . And it takes  $O(n^3 \log^2 n)$  time and  $O(n)$  space overall by enumerating all pairs of  $(q, r)$ .

### $(q, r, t_1, t_2)$ is an edge of $C(\pi, p)$ and $p \in \{t_1, t_2\}$

Again we fix a pair  $(q, r)$ , and look at the projection of  $N$  along the direction of  $qr$ . Without loss of generality, assume  $p = t_1$  in this case.

► **Lemma 11.**  $(q, r, p, t_2)$  is edge of  $C(\pi, p)$  if and only if

- (a)  $q, r$  and  $t_2$  appear before  $p$  in  $\pi$ .
- (b) No point outside the cone formed by  $qr, p$  and  $t_2$  appears before  $p$  in  $\pi$ .

## 67:14 Computing Shapley Values for Mean Width in 3-D

The proof will be almost the same as the proof for Lemma 10. See Figure 6 for an illustration.

In this case

$$\Pr((q, r, p, t_2) \text{ is an edge of } C(\pi, p)) = \frac{3!(n-4-W_{qr}(p, t_2))!}{(n-W_{qr}(p, t_2))!} \quad (16)$$

We have a slightly different  $g(i) = 3!(n-4-i)/(n-i)!$ . Any point except  $p$  can form a cone with  $p$ . So we can write

$$\begin{aligned} & \sum_{\substack{t_2 \in N \\ e=(q,r,p_i,t_2)}} l(e)\psi(e) \Pr((q, r, p, t_2) \text{ is an edge of } C(\pi, p)) \\ &= \sum_{p_j \in R(p_i)} d(q, r) \left( \frac{1}{2} - \frac{\theta_i - \theta_j}{2\pi} \right) g(W_{qr}(p_i, p_j)) \\ &+ \sum_{p_j \in L(p_i)} d(q, r) \left( \frac{1}{2} - \frac{\theta_j - \theta_i}{2\pi} \right) g(W_{qr}(p_j, p_i)) \end{aligned} \quad (17)$$

In Subsection 4.2, we've shown how to compute summations with very similar form as summations in Equation 17. The only differences are that we take  $p_j \in R(p_i)$  instead of  $p_j \in R(p_i) \cup \{p_i\}$  and we have a slightly different  $g$  here. But clearly these don't change the asymptotic running time. Hence it takes  $O(n^3 \log^2 n)$  time in total and  $O(n)$  space by using the same method.

### **$(q, r, t_1, t_2)$ is an edge of $C(\pi, p)$ and $p \in \{q, r\}$**

Without loss of generality, assume  $p = q$ . We look at the projection of  $N$  along the direction of  $pr$ .

► **Lemma 12.**  *$(p, r, t_1, t_2)$  is edge of  $C(\pi, p)$  if and only if*

- (a)  $r, t_1$  and  $t_2$  appear before  $p$  in  $\pi$ .
- (b) No point outside the cone formed by  $pr, t_1$  and  $t_2$  appears before  $p$  in  $\pi$ .

The proof will be almost the same as the proof for Lemma 10. See Figure 7 for an illustration.

In this case

$$\Pr((p, r, t_1, t_2) \text{ is an edge of } C(\pi, p)) = \frac{3!(n-4-W_{qr}(t_1, t_2))!}{(n-W_{qr}(t_1, t_2))!} \quad (18)$$

And we use  $g(i) = 3!(n-4-i)/(n-i)!$ . In this case, any pair  $(t_1, t_2)$  with  $t_1 \neq t_2$  will contribute to result. So we can write

$$\begin{aligned} & \sum_{\substack{t_1, t_2 \in N \\ e=(p,r,t_1,t_2)}} l(e)\psi(e) \Pr((p, r, t_1, t_2) \text{ is an edge of } C(\pi, p)) \\ &= \frac{1}{2} \sum_{p_k} \sum_{p_j \in R(p_k)} d(p, r) \left( \frac{1}{2} - \frac{\theta_k - \theta_j}{2\pi} \right) g(W_{qr}(p_k, p_j)) \\ &+ \frac{1}{2} \sum_{p_k} \sum_{p_j \in L(p_k)} d(p, r) \left( \frac{1}{2} - \frac{\theta_j - \theta_k}{2\pi} \right) g(W_{qr}(p_j, p_k)) \end{aligned} \quad (19)$$

■ **Figure 7** Projection of  $N$  along  $pr$ . Edge  $pr$  gets added when forming  $\text{conv}(P_N(\pi, p) \cup \{p\})$  if and only if (a)  $r$ ,  $t_1$  and  $t_2$  appear before  $p$  in  $\pi$  (b) No point outside the cone formed by  $pr$ ,  $t_1$  and  $t_2$  (red point) appears before  $p$  in  $\pi$ .

We have a factor of  $\frac{1}{2}$  because each pair is counted twice. In the previous case, all the inner summations have been pre-computed. So for a fixed  $(p, r)$ , the summation can be computed in  $O(n)$  time given previous computation. Hence in total it takes  $O(n^3)$  time and no additional space to compute this case.

Now that all the cases take no more than  $O(n^3 \log^2 n)$  time and  $O(n)$  space to compute, we present our main theorem:

► **Theorem 13.** *Shapley values for mean width for a point set in 3-D can be computed in  $O(n^3 \log^2 n)$  time and  $O(n)$  space.*

## 5 Discussion

We have presented an algorithm to compute Shapley values of a point set in 3-D with respect to the mean width of its convex hull. We provided an efficient algorithm based on a data structure for a variant of dynamic convolution. We believe the data structure may be of independent interest.

Our algorithm naturally extends to higher dimension to compute Shapley values for  $M_{d-2}(\text{conv}(P))$  for a  $d$ -dimensional point set  $P$ . This relies on the fact that the orthogonal space of a  $(d-2)$ -face is a plane. In general, it takes  $O(n^d \log^2 n)$  time to compute the Shapley values. It is also known that for a convex polytope  $X$ ,  $M_{d-1}(X)$  is equivalent to the  $(d-1)$ -volume of the boundary of  $X$  up to some constant [20]. Hence the algorithm by Cabello and Chan [7] with natural extension can be used to compute Shapley values for  $M_{d-1}(\text{conv}(P))$  in  $O(n^d)$  time. It would be natural to ask whether there are efficient algorithms to compute  $M_i(\text{conv}(P))$  in general.

We can also consider  $\epsilon$ -coreset of Shapley values for geometric objects. Let  $P$  be a set of geometric objects and  $v$  be a characteristic function on  $P$ . We can define the  $\epsilon$ -coreset  $\tilde{P}$  to be a weighted set of geometric objects such that, for any geometric objects  $x$ ,  $(1 - \epsilon)\phi_{P \cup \{x\}}(x) \leq \phi_{\tilde{P} \cup \{x\}}(x) \leq (1 + \epsilon)\phi_{P \cup \{x\}}(x)$  where  $\phi_N$  means that the underlying player set for the Shapley value is  $N$ . Intuitively,  $\phi_{P \cup \{x\}}(x)$  means the contribution  $x$  makes when  $x$  is added as an additional player. Does  $\tilde{P}$  exist? If so, what is the upper and lower bound of its size? How fast can we find a coreset?

# Simple Envy-Free and Truthful Mechanisms for Cake Cutting with a Small Number of Cuts

Takao Asano 

Chuo University, Tokyo, Japan

---

## Abstract

For the cake-cutting problem, Alijani, et al. [2, 25] and Asano and Umeda [4, 5] gave envy-free and truthful mechanisms with a small number of cuts, where the desired part of each player's valuation function is a single interval on a given cake. In this paper, we give envy-free and truthful mechanisms with a small number of cuts, which are much simpler than those proposed by Alijani, et al. [2, 25] and Asano and Umeda [4, 5]. Furthermore, we show that this approach can be applied to the envy-free and truthful mechanism proposed by Chen, et al. [13], where the valuation function of each player is more general and piecewise uniform. Thus, we can obtain an envy-free and truthful mechanism with a small number of cuts even if the valuation function of each player is piecewise uniform, which solves the future problem posed by Alijani, et al. [2, 25].

## 1 Introduction

The problem of dividing a cake among players in a fair manner has attracted the attention of mathematicians, economists, political scientists and computer scientists [6, 7, 11, 13, 14, 15, 16, 22, 23, 24] since it was first considered by Banach and Knaster [11] and Steinhaus [27, 28]. The cake-cutting problem is often used as a metaphor for prominent real-world problems that involve the division of a heterogeneous divisible good [10, 14, 26, 32].

Formally, the cake-cutting problem is stated as follows [13]: Given a divisible heterogeneous cake  $C$  represented by an interval  $[0, 1)$  and  $n$  players  $N = \{1, 2, \dots, n\}$  where each player  $i \in N$  has a valuation function  $v_i$  over the cake  $C$ , divide the cake  $C$  and find an allocation of the cake  $C$  to the players that satisfies one or several fairness criteria. In the cake cutting literature, one of the most important criteria is *envy-freeness* [7]. In an envy-free allocation, each player considers her/his own allocation at least as good as any other player's allocation.

A *piece*  $A$  of cake  $C$  is a finite union of disjoint subintervals  $X$  of  $C$ . A piece  $A$  can also be viewed as a set of disjoint subintervals  $X$  of  $C$ . For a general valuation function  $v_i$  of player  $i \in N$  which is integrable or piecewise continuous, the value  $V_i(A)$  of a piece  $A$  of cake  $C$  for player  $i$  can be written by  $\int_{x \in A} v_i(x) dx$ . Thus, the value  $V_i(A)$  of the piece  $A$  of disjoint subintervals  $X$  of  $C$  for player  $i$  is  $V_i(A) = \sum_{X \in A} V_i(X)$ .

Since general valuation functions may not have a finite discrete representation as an input to the cake-cutting problem, most algorithms and computational complexity analyses are based on oracle computation models. Among them a most popular computation model for general integrable valuation functions is the Robertson-Webb model based on two types of queries: evaluation and cut [24]. For envy-freeness, Stromquist [23, 30] showed that there is no finite envy-free cake cutting algorithm that outputs a contiguous allocation to each player for any  $n \geq 3$ , although an envy-free allocation with a contiguous interval allocation to each player is guaranteed to exist [29, 31]. Note that any cake cutting algorithm that outputs a

contiguous allocation to each player uses  $n - 1$  cuts on the cake  $C$ . If a contiguous allocation to each player is not required, Aziz and Mackenzie [6] showed that there is an envy-free cake cutting algorithm with  $O(n^{n^{n^{n^n}}})$  queries. Procaccia showed that any envy-free cake cutting algorithm requires  $\Omega(n^2)$  queries [21]. Furthermore, Deng, Qi and Saberi [14] showed that finding an envy-free allocation using  $n - 1$  cuts on cake  $C$  is PPAD-complete when valuation functions are given explicitly by polynomial-time algorithms, although their result requires very general (e.g., non-additive, non monotone) valuation functions [18].

In recent papers, some restricted classes of valuation functions have been studied [7, 8, 10, 12, 13, 20]. Piecewise uniform and piecewise constant valuation functions are two special classes of valuation functions [2, 7, 13, 25]. For a nonnegative valuation function  $v$  on cake  $C$ , let  $D(v) = \{x \in C \mid v(x) > 0\}$ . Thus, we can consider that  $D(v)$  consists of several disjoint maximal contiguous intervals. Then  $v$  is called *piecewise uniform* if  $v(x) = v(y)$  holds for all  $x, y \in D(v)$ . Similarly,  $v$  is called *piecewise constant* if, for each contiguous interval  $I$  in  $D(v)$ ,  $v(x') = v(x'')$  holds for all  $x', x'' \in I$ . Note that  $v(x) \neq v(y)$  may hold for  $x \in I$  and  $y \in J$  when  $I, J$  are two distinct maximal contiguous intervals in  $D(v)$  of piecewise constant valuation  $v$ . Thus, a piecewise uniform valuation is always piecewise constant. One of the most important properties of these valuation functions is that they can be described concisely. Kurokawa, Lai, and Procaccia [19] proved that finding an envy-free allocation in the Robertson-Webb model when the valuation functions are piecewise uniform is as hard as solving the problem without any restriction on the valuation functions.

The cake-cutting problem has been studied not only from the viewpoint of computational complexity but also from the game theoretical point of view [2, 7, 8, 9, 13, 20, 25]. Chen, Lai, Parkes, and Procaccia [13] considered a strong notion of truthfulness (denoted by strategy-proofness), in which the players' dominant strategies are to reveal their true valuations over the cake. They presented an envy-free and truthful mechanism for the cake-cutting problem based on maximum flow and minimum cut techniques [34] when the valuation functions are piecewise uniform. Aziz and Ye [7] considered the problem when valuation functions are piecewise constant and piecewise uniform. They designed three algorithms CCEA, MEA, and CSD for piecewise constant valuations, which partially solve an open problem for piecewise constant valuations posed by Chen et al. in [13]. They showed that CCEA runs in  $O(n^5 M^2 \log(\frac{n^2}{M}))$  time, where  $M$  is the number of subintervals defined by the union of discontinuity points of the players' piecewise constant valuations ( $M \leq 2 \sum_{i \in N} m_i$  where  $m_i$  is the number of maximal contiguous intervals in  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of piecewise constant valuation  $v_i$ ). They also showed that, when CCEA and MEA are restricted to piecewise uniform valuations, CCEA and MEA become essentially the same as the mechanism in [13]. However, note that CCEA, MEA and the mechanism in [13] for dividing the cake use  $\Omega(nM)$  cuts [2, 25].

Alijani, Farhadi, Ghodsi, Seddighin, and Tajik [2, 25] considered that the number of cuts is important and considered the following cake-cutting problem by requiring  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of piecewise uniform valuation  $v_i$  of each player  $i \in N$  to be a single contiguous interval  $C_i$  in cake  $C$ : Given a divisible heterogeneous cake  $C$ ,  $n$  strategic players  $N = \{1, 2, \dots, n\}$  with valuation interval  $C_i \subseteq C$  of each player  $i \in N$ , find a mechanism for dividing  $C$  into pieces and allocating pieces of  $C$  to  $n$  players  $N$  to meet the following conditions: (i) the mechanism is envy-free; (ii) the mechanism is truthful; and (iii) the number of cuts made on cake  $C$  is small. And they gave an envy-free and truthful mechanism with at most  $2n - 2$  cuts [2, 25], although their original mechanism is not actually envy free [5] and corrected later by themselves. Asano and Umeda [4, 5] also gave an alternative envy-free and truthful mechanism with at most  $2n - 2$  cuts.

In this paper, we give envy-free and truthful mechanisms with a small number of cuts, which lead to a much simpler mechanism than those proposed by Alijani, et al. [2, 25] and Asano and Umeda [4, 5]. Thus, we can obtain a much simpler envy-free and truthful mechanism with at most  $2n - 2$  cuts which runs in  $O(n^3)$  time for the above cake-cutting problem. Furthermore, we show that this approach can be applied to the envy-free and truthful mechanism proposed by Chen, et al. [13] for the more general cake-cutting problem where the valuation function  $v_i$  of each player  $i \in N$  is piecewise uniform. Thus, this approach can make their envy-free and truthful mechanism use at most  $2M - 2$  cuts and we solve the open problem posed by Alijani, et al. [2, 25], where  $M \leq 2 \sum_{i \in N} m_i$  and  $m_i$  is the number of maximal contiguous intervals in  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of  $v_i$  as mentioned above.

## 2 Preliminaries

We are given a divisible heterogeneous cake  $C = [0, 1) = \{x \mid 0 \leq x < 1\}$ <sup>1</sup>,  $n$  strategic players  $N = \{1, 2, \dots, n\}$  with valuation interval  $C_i = [\alpha_i, \beta_i) = \{x \mid 0 \leq \alpha_i \leq x < \beta_i \leq 1\} \subseteq C$  of each player  $i \in N$ . We denote by  $\mathcal{C}_N$  the (multi-) set of valuation intervals of all the players  $N$ , i.e.,  $\mathcal{C}_N = (C_1, C_2, \dots, C_n)$ . We also write  $\mathcal{C}_N = (C_i : i \in N)$ . Valuation intervals  $\mathcal{C}_N$  is called *solid*, if, for every  $x \in C$ , there is a player  $i \in N$  whose valuation interval  $C_i \in \mathcal{C}_N$  contains  $x$ . As in [2, 4, 7, 25], we will assume that  $\mathcal{C}_N$  is solid, i.e.,  $\bigcup_{C_i \in \mathcal{C}_N} C_i = C$ , throughout this paper.

A union  $X$  of mutual disjoint sets  $X_1, X_2, \dots, X_k$  is denoted by  $X = X_1 + X_2 + \dots + X_k = \sum_{\ell=1}^k X_\ell$ . A *piece*  $A_i$  of cake  $C$  is a union of mutually disjoint subintervals  $A_{i_1}, A_{i_2}, \dots, A_{i_{k_i}}$  of  $C$ . Thus,  $A_i = A_{i_1} + A_{i_2} + \dots + A_{i_{k_i}} = \sum_{\ell=1}^{k_i} A_{i_\ell}$ . A partition  $A_N = (A_1, A_2, \dots, A_n)$  of cake  $C$  into  $n$  disjoint pieces  $A_1, A_2, \dots, A_n$  is called an *allocation* of  $C$  to  $n$  players  $N$  if each piece  $A_i = \sum_{\ell=1}^{k_i} A_{i_\ell}$  is allocated to player  $i \in N$ . We also write  $A_N = (A_i : i \in N)$ . Thus, in allocation  $A_N = (A_i : i \in N)$  of  $C$  to  $n$  players  $N$ ,  $\sum_{i \in N} A_i = C$  holds and  $A_i = \sum_{\ell=1}^{k_i} A_{i_\ell}$  is called an *allocated piece* of  $C$  to player  $i \in N$ .

For an interval  $X = [x', x'')$ , we denote by  $cl(X)$  the *closure* of  $X$  and thus  $cl(X) = [x', x''] = \{x \mid x' \leq x \leq x''\}$ . For an interval  $X = [x', x'')$  of  $C$ , the *length* of  $X$ , denoted by  $len(X)$ , is defined by  $x'' - x'$ . For a piece  $A = \sum_{\ell=1}^k X_\ell$  of cake  $C$ , the *length* of  $A$ , denoted by  $len(A)$ , is defined by the total sum of  $len(X_\ell)$ , i.e.,  $len(A) = \sum_{\ell=1}^k len(X_\ell)$ . For each  $i \in N$  and valuation interval  $C_i$  of player  $i$ , the *value* of piece  $A = \sum_{\ell=1}^k X_\ell$  for player  $i$ , denoted by  $V_i(A)$ , is the total sum of  $len(X_\ell \cap C_i)$ , i.e.,  $V_i(A) = \sum_{\ell=1}^k len(X_\ell \cap C_i)$ . For an allocation  $A_N = (A_i : i \in N)$  of cake  $C$  to  $n$  players  $N$ , if  $V_i(A_i) \geq V_i(A_j)$  for all  $j \in N$ , then the allocated piece  $A_i$  to player  $i$  is called *envy-free* for player  $i$ . If, for every player  $i \in N$ , the allocated piece  $A_i$  to player  $i$  is envy-free for player  $i$ , then the allocation  $A_N = (A_i : i \in N)$  to  $n$  players  $N$  is called *envy-free*.

Let  $\mathcal{M}$  be a mechanism (i.e., a polynomial-time algorithm in this paper) for the cake-cutting problem. Let  $\mathcal{C}_N = (C_i : i \in N)$  be an arbitrary input to  $\mathcal{M}$  and  $A_N = (A_i : i \in N)$  be an allocation of cake  $C$  to  $n$  players  $N$  obtained by  $\mathcal{M}$ . If  $A_N = (A_i : i \in N)$  for every input  $\mathcal{C}_N = (C_i : i \in N)$  to  $\mathcal{M}$  is envy-free then  $\mathcal{M}$  is called *envy-free*.

Now, assume that only player  $i \in N$  gives a false valuation interval  $C'_i$  and let  $C'_N(i) = (C'_j : j \in N)$  (all the other players  $j \neq i$  give true valuation intervals  $C_j$  and thus  $C'_j = C_j$  for each  $j \neq i$ ) be an input to  $\mathcal{M}$  and let an allocation of cake  $C$  to  $n$  players  $N$  obtained

<sup>1</sup> We assume  $C = [0, 1) = \{x \mid 0 \leq x < 1\}$ . We also assume, if an interval  $X = [x', x'') = \{x \mid x' \leq x < x''\}$  of  $C = [0, 1)$  is cut at  $y \in X$  with  $x' < y < x''$  then  $X$  is divided into two subintervals  $X' = [x', y)$  and  $X'' = [y, x'')$ .

by  $\mathcal{M}$  be  $A'_N(i) = (A'_j : j \in N)$ . The values of  $A_i = \sum_{\ell=1}^{k_i} A_{i_\ell}$  and  $A'_i = \sum_{\ell=1}^{k'_i} A'_{i_\ell}$  for player  $i$  are  $V_i(A_i) = \sum_{\ell=1}^{k_i} \text{len}(A_{i_\ell} \cap C_i)$  and  $V_i(A'_i) = \sum_{\ell=1}^{k'_i} \text{len}(A'_{i_\ell} \cap C_i)$  (note that  $V_i(A'_i) \neq \sum_{\ell=1}^{k'_i} \text{len}(A'_{i_\ell} \cap C'_i)$ ). If  $V_i(A_i) \geq V_i(A'_i)$ , then there is no merit for player  $i$  to give false  $C'_i$  and player  $i$  will report true valuation interval  $C_i$  to  $\mathcal{M}$ . For each player  $i \in N$ , if this holds for all such  $C'_i$ 's, then  $\mathcal{M}$  is called *truthful* (allocation  $A_N = (A_i : i \in N)$  obtained by  $\mathcal{M}$  is also called *truthful*).

For valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  and an interval  $X = [x', x'']$  of cake  $C$ , let  $N(X)$  be the set of players  $i$  in  $N$  whose valuation interval  $C_i$  is contained in  $X$  and let  $\mathcal{C}_{N(X)}$  be the (multi-) set of valuation intervals in  $\mathcal{C}_N$  which are contained in  $X$ . Thus,  $N(X) = \{i \in N \mid C_i \subseteq X, C_i \in \mathcal{C}_N\}$  and  $\mathcal{C}_{N(X)} = (C_i \in \mathcal{C}_N : i \in N(X))$ . The *density* of interval  $X = [x', x'']$  of  $C$ , denoted by  $\rho(X)$ , is defined by  $\rho(X) = \frac{\text{len}(X)}{|N(X)|} = \frac{x''-x'}{|N(X)|}$ . The density  $\rho(X)$  is the average length of pieces of the players in  $N(X)$  when the part  $X$  of cake  $C$  is divided among the players in  $N(X)$ . Let  $\mathcal{X}$  be the set of all nonempty intervals in  $C$ . Let  $\rho_{\min}$  be the minimum density among the densities of all nonempty intervals in  $C$ , i.e.,  $\rho_{\min} = \min_{X \in \mathcal{X}} \rho(X)$ . Let  $\mathcal{X}_{\min} = \{X \in \mathcal{X} \mid \rho(X) = \rho_{\min}\}$ . Thus,  $\mathcal{X}_{\min}$  is the set of all intervals of minimum density in  $C$ . Note that, for each interval  $X = [x', x''] \in \mathcal{X}_{\min}$ , there are valuation intervals  $C_i = [\alpha_i, \beta_i], C_j = [\alpha_j, \beta_j] \in \mathcal{C}_N$  with  $x' = \alpha_i$  and  $x'' = \beta_j$ . Thus, the set of all intervals of minimum density in  $C$  can be computed in  $O(n^2)$  time. An interval  $X \in \mathcal{X}_{\min}$  is called a *maximal interval of minimum density* if no other interval of  $\mathcal{X}_{\min}$  contains  $X$  properly. A *minimal interval of minimum density* is similarly defined.

### 3 Core Mechanism $\mathcal{M}_1$

For cake  $C = [0, 1)$ ,  $n$  strategic players  $N = \{1, 2, \dots, n\}$ , and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with  $C_i = [\alpha_i, \beta_i] \subseteq C$  of each player  $i \in N$ , each mechanism  $\mathcal{M}$  in [2, 25] and [4, 5] uses a small number of cuts and finds an allocation  $A_N = (A_i : i \in N)$  to players  $N$  satisfying the following: (a)  $\mathcal{M}$  is envy-free; (b)  $\mathcal{M}$  is truthful; (c)  $A_i \subseteq C_i$  for each  $i \in N$ ; and (d)  $\sum_{i \in N} A_i = C$ . However, their mechanisms were quite complicated.

In this paper, we give a much simpler envy-free and truthful mechanism with a small number of cuts. For this purpose, we first give a core mechanism  $\mathcal{M}_1$  which assumes that cake  $C = [0, 1)$  is an interval of minimum density  $\rho_{\min}$  in  $C = [0, 1)$  (thus,  $\rho_{\min} = \frac{1}{n}$ ).

#### Algorithm 1 Core Mechanism $\mathcal{M}_1$ .

---

**Input:** Cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$  and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i] \subseteq C$  of each player  $i \in N$  and  $\bigcup_{C_i \in \mathcal{C}_N} C_i = C$ , where  $C = [0, 1)$  is an interval of minimum density  $\rho_{\min} = \frac{1}{n}$  in cake  $C = [0, 1)$ .

**Output:** Allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$ ,  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$ .

sort  $\mathcal{C}_N = (C_i : i \in N)$  in a lexicographic order with respect to  $(\beta_i, \alpha_i)$  and assume

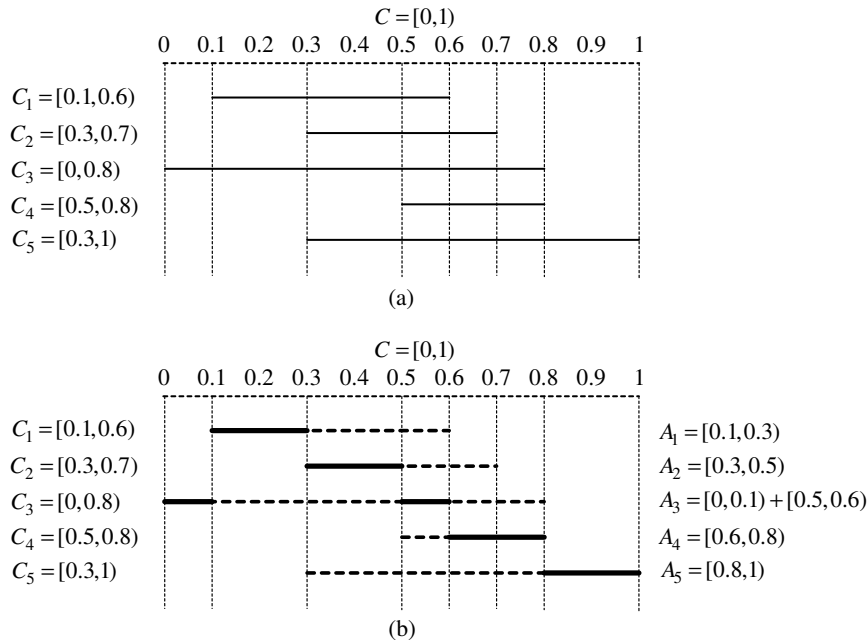

$C_1 \leq C_2 \leq \dots \leq C_n$  in this lexicographic order;

set  $A_1 = [a_1, b_1] \subseteq C_1$  with length  $\rho_{\min}$  such that  $a_1 = \alpha_1$  and  $b_1 = \alpha_1 + \rho_{\min}$ ;

**for**  $i = 2$  **to**  $n$  **do**

set  $A_i = [a_i, b_i] \setminus \sum_{\ell=1}^{i-1} A_\ell$  with length  $\rho_{\min}$  such that  $[a_i, b_i] \subseteq C_i$  and  $a_i$  is the leftmost endpoint in  $C_i \setminus \sum_{\ell=1}^{i-1} A_\ell$ ;

---

■ **Figure 1** (a) Solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with  $\rho(C) = \rho_{\min} = 0.2$ . (b) Allocation  $A_N = (A_i : i \in N)$  obtained by  $\mathcal{M}_1$ .

Figure 1 shows an example of solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with  $\rho(C) = \rho_{\min} = 0.2$  and an allocation  $A_N = (A_i : i \in N)$  obtained by  $\mathcal{M}_1$ .

► **Theorem 1.** For cake  $C = [0, 1]$ ,  $n$  players  $N = \{1, 2, \dots, n\}$ , and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i]$  of each player  $i \in N$  and  $\bigcup_{C_i \in \mathcal{C}_N} C_i = C$ , let  $C = [0, 1]$  be an interval of minimum density  $\rho_{\min} = \frac{1}{n}$  in cake  $C = [0, 1]$ . Then,  $\mathcal{M}_1$  finds an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$  in  $O(n \log n)$  time. Furthermore, the number of cuts made by  $\mathcal{M}_1$  on cake  $C$  is at most  $2n - 2$ .

**Proof.** The number of cuts made on cake  $C$  is clearly at most  $2n - 2$ , since  $\mathcal{M}_1$  uses at most two cuts at  $a_i$  and  $b_i$  for each  $i \in N$  to obtain  $A_i$  and no cut is required at  $0, 1$  of cake  $C = [0, 1]$ . Similarly, it can be easily shown that  $\mathcal{M}_1$  runs in  $O(n \log n)$  time, since lexicographical sorting of  $\mathcal{C}_N = (C_i : i \in N)$  requires  $O(n \log n)$  time and  $a_i, b_i$  for each  $i \in N$  can be found in  $O(\log n)$  time based on appropriate data structures.

We next prove the proposition that  $\mathcal{M}_1$  correctly finds an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$  by induction on  $n$ .

If  $n = 1$  then the proposition is clearly true.

Now we assume that the proposition is true for  $n - 1$  players and consider  $n \geq 2$  players. Of course,  $A_1 = [a_1, b_1] \subseteq C_1 = [\alpha_1, \beta_1]$  with  $a_1 = \alpha_1$  and  $b_1 = \alpha_1 + \rho_{\min}$  (thus of length  $\rho_{\min}$ ) is allocated to player 1, since  $\rho(C_1) \geq \rho_{\min}$  and thus the length of  $C_1$  is  $\beta_1 - \alpha_1 \geq \rho_{\min}$ . Then we delete  $A_1 = [a_1, b_1]$  and virtually consider  $a_1 = b_1$  (we call this as *virtual shrinking* of hollow interval  $A_1$  after deletion of  $A_1$ ). Note that, since we performed virtual shrinking of hollow interval  $A_1 = [a_1, b_1]$  and virtually considered  $a_1 = b_1$ , the remaining cake  $C' = C \setminus A_1$  may be considered as a single interval and each  $C'_k = C_k \setminus A_1$  ( $k \in N \setminus \{1\}$ ) may also be considered as a single interval. Thus, the resulting cake-cutting problem may be considered to be the same as the original cake-cutting problem, that is, it consists of cake  $C' = C \setminus A_1$

which is a single interval, players  $N' = N \setminus \{1\}$ , and valuation intervals  $\mathcal{C}'_{N'}$  with a single interval  $C'_k = C_k \setminus A_1 \subseteq C'$  of each remaining player  $k \in N'$ . The solidness of  $\mathcal{C}'_{N'}$  (i.e.,  $\bigcup_{C'_i \in \mathcal{C}'_{N'}} C'_i = C'$ ) also holds, which can be obtained as follows.

If  $\alpha_1 > 0$  then there is a valuation interval  $C_j = [\alpha_j, \beta_j] \in \mathcal{C}_N$  with  $\alpha_j = 0$  and  $\beta_j \geq \beta_1$  by the solidness of  $\mathcal{C}_N$  (i.e.,  $\bigcup_{C_i \in \mathcal{C}_N} C_i = C$ ) and the fact that  $\mathcal{C}_N$  was sorted in the lexicographic order, and thus,  $\bigcup_{C'_i \in \mathcal{C}'_{N'}} C'_i = C'$ .

If  $\alpha_1 = 0$  then let  $\alpha = \min\{\alpha_i \mid C_i = [\alpha_i, \beta_i] \in \mathcal{C}_N \setminus \{C_1\}\} < 1$ . Then we have  $\alpha \leq \rho_{\min}$ , since if  $\alpha > \rho_{\min}$  then, for interval  $X = [\alpha, 1)$ , we would have  $N(X) = N' = N \setminus \{1\}$  and  $\rho(X) = \frac{\text{len}(X)}{|N(X)|} = \frac{1-\alpha}{n-1} < \rho_{\min}$  by  $\rho_{\min} = \frac{1}{n}$ , a contradiction since  $\rho_{\min}$  is the minimum density of all intervals of  $C$  and thus  $\rho(X) \geq \rho_{\min}$ . This implies that  $\bigcup_{C'_i \in \mathcal{C}'_{N'}} C'_i = C'$  even if  $\alpha_1 = 0$ .

The density  $\rho'$  of intervals in this resulting cake-cutting problem can be easily shown to satisfy  $\rho'(X') \geq \rho_{\min}$  for each nonempty interval  $X'$  of  $C'$  and  $\rho'(C') = \rho_{\min}$ . Actually,  $\rho'(C') = \frac{\text{len}(C')}{|N'|} = \frac{1-\rho_{\min}}{n-1} = \frac{1-\frac{1}{n}}{n-1} = \frac{1}{n} = \rho_{\min}$ . Each nonempty interval  $X' \subseteq C'$  can be written by  $X' = X \setminus A_1$  for some interval  $X = [x', x''] \subseteq C$ . Let  $Y = X' \cup A_1 = X \cup A_1$  (it is possible that there are many  $X$ , but  $Y$  is uniquely determined). Of course,  $X' = Y \setminus A_1$ .

If  $Y$  is not a single interval of  $C$ , then  $\text{cl}(X) \cap \text{cl}(A_1) = [x', x''] \cap [\alpha_1, \alpha_1 + \rho_{\min}] = \emptyset$  (i.e.,  $x' < x'' < \alpha_1 < \alpha_1 + \rho_{\min}$  or  $\alpha_1 < \alpha_1 + \rho_{\min} < x' < x''$ ), which implies that there is unique  $X \subseteq C$  with  $X' = X \setminus A_1 = Y \setminus A_1 = X$  and  $\rho'(X') = \rho(X) \geq \rho_{\min}$ .

Thus, we can assume that  $Y$  is a single interval  $Y = [y', y'']$  of  $C$  with  $y' \leq \alpha_1 < \alpha_1 + \rho_{\min} \leq y''$  by  $A_1 = [\alpha_1, \alpha_1 + \rho_{\min}] \subseteq Y = X \cup A_1$ . For each  $k \in N' = N \setminus \{1\}$  and  $C_k = [\alpha_k, \beta_k] \in \mathcal{C}_N$ , if  $C_k \subseteq Y$ , then we have  $\emptyset \neq C'_k = C_k \setminus A_1 \in \mathcal{C}'_{N'}$  and  $C'_k \subseteq X' = Y \setminus A_1$  (since if  $C_k \subseteq A_1$  then  $\beta_k \leq \alpha_1 + \rho_{\min} \leq \beta_1$  by  $A_1 = [\alpha_1, \alpha_1 + \rho_{\min}] \subseteq C_1 = [\alpha_1, \beta_1]$  and we would have  $\beta_k = \alpha_1 + \rho_{\min} = \beta_1$  and  $A_1 = C_1$  by the fact that  $\mathcal{C}_N = (C_i : i \in N)$  was sorted in a lexicographic order with respect to  $(\beta_i, \alpha_i)$ , and thus  $\rho(A_1) \leq \frac{1}{2}\rho_{\min} < \rho_{\min}$ , a contradiction). Similarly, if  $C_k \not\subseteq Y$ , then it is clear that  $\emptyset \neq C'_k = C_k \setminus A_1 \in \mathcal{C}'_{N'}$  and  $C'_k \not\subseteq X' = Y \setminus A_1$ . Thus,  $N'(X') = \{k \in N' \mid C'_k \in \mathcal{C}'_{N'}, C'_k \subseteq X'\} = \{k \in N \setminus \{1\} \mid C_k \in \mathcal{C}_N, C_k \subseteq Y\} = N(Y) \setminus \{1\}$ . This implies  $|N'(X')| = |N(Y)| - 1$  or  $|N'(X')| = |N(Y)|$ . If  $1 \notin N(Y)$  (i.e., if  $C_1 = [\alpha_1, \beta_1] \not\subseteq Y = [y', y'']$ ) then  $y'' < \beta_1$  by  $y' \leq \alpha_1$  and we have  $N(Y) = \emptyset$  since  $\mathcal{C}_N = (C_i : i \in N)$  was sorted in a lexicographic order with respect to  $(\beta_i, \alpha_i)$ . Thus, if  $1 \notin N(Y)$  then  $|N'(X')| = |N(Y)| = 0$  and  $\rho'(X') = \frac{\text{len}(X')}{|N'(X')|} = \infty \geq \rho_{\min}$ . Now, assume  $1 \in N(Y)$ . Then,  $|N'(X')| = |N(Y)| - 1$  and, by  $\text{len}(Y) = |N(Y)|\rho(Y)$  and  $\rho(Y) \geq \rho_{\min}$ , we have  $\rho'(X') = \frac{\text{len}(X')}{|N'(X')|} = \frac{\text{len}(Y) - \text{len}(A_1)}{|N(Y)| - 1} = \frac{|N(Y)|\rho(Y) - \rho_{\min}}{|N(Y)| - 1} \geq \frac{|N(Y)|\rho_{\min} - \rho_{\min}}{|N(Y)| - 1} = \rho_{\min}$ .

Thus, since we performed virtual shrinking of hollow interval  $A_1 = [a_1, b_1)$  and virtually considered  $a_1 = b_1$ , the resulting cake-cutting problem with density  $\rho'$  may be considered to be the same as the original cake-cutting problem, that is, it consists of cake  $C' = C \setminus A_1$  which is a single interval of length  $1 - \frac{1}{n}$  and  $\rho'(C') = \rho'_{\min} = \rho_{\min} = \frac{1}{n}$ , players  $N' = N \setminus \{1\}$ , and solid valuation intervals  $\mathcal{C}'_{N'}$  with a single interval  $C'_k = C_k \setminus A_1 \subseteq C'$  of each remaining player  $k \in N'$  and  $\bigcup_{C'_i \in \mathcal{C}'_{N'}} C'_i = C'$ . Note that the lexicographic order of  $\mathcal{C}'_{N'}$  is the same as that of  $\mathcal{C}_{N'}$  and  $C'_2 \leq \dots \leq C'_n$  holds. Note also that, if we consider the cake  $C'$  of length  $1 - \frac{1}{n}$  as being of length 1 by virtually multiplying  $\frac{n}{n-1}$  then the minimum density  $\rho'_{\min} = \rho_{\min} = \frac{1}{n}$  will become  $\rho'_{\min} = \frac{1}{n-1}$  and we can use induction hypothesis as usual.

By induction hypothesis, the proposition is true in the resulting cake-cutting problem and we can obtain an allocation  $A'_{N'} = (A'_i : i \in N')$  with  $A'_i \subseteq C'_i$  and  $\text{len}(A'_i) = \rho_{\min}$  for each  $i \in N'$  and  $\sum_{i \in N'} A'_i = C'$ . From  $A'_{N'} = (A'_i : i \in N')$ , we can obtain an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in N'$  as follows: if  $A'_i = [a'_i, b'_i]$  contains the virtually shrunken interval  $A_1 = [a_1, b_1)$  then let  $A_i = [a_i, a_1) + [b_1, b_i]$  by considering  $a_1 \neq b_1$ ; otherwise, let  $A_i = A'_i$ . This is called *inverse virtual shrinking* of  $A_1$ . Thus, the proposition is true for  $n$  players.  $\blacktriangleleft$

#### 4 Application to Mechanism of Asano and Umeda [4]

For a given input of cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$ , and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i)$  of each player  $i \in N$ , the mechanism of Asano and Umeda [4] first finds all the maximal intervals of minimum density  $\rho_{\min}$ . Let  $H_1 = [h'_1, h''_1), \dots, H_L = [h'_L, h''_L)$  be all the maximal intervals of minimum density  $\rho_{\min}$  in cake  $C = [0, 1)$ . Their mechanism then cuts cake  $C = [0, 1)$  at both endpoints of each  $H_\ell$  ( $\ell = 1, \dots, L$ ). As shown in [4], the closures of two distinct maximal intervals of minimum density are disjoint and these cuts at both endpoints of each maximal interval of minimum density can be done independently. By these cuts, the original cake-cutting problem is reduced into two types of cake-cutting subproblems of type (i) and type (ii) as follows:

- (i) the cake-cutting problem within each maximal interval  $H_\ell = [h'_\ell, h''_\ell)$  ( $\ell = 1, \dots, L$ ) of minimum density (which consists of cake  $H_\ell$ , players  $N(H_\ell)$  whose valuation intervals are in  $H_\ell$  and valuations  $\mathcal{C}_{N(H_\ell)}$  with density  $\rho$ ); and
- (ii) the cake-cutting problem obtained by deleting all  $H_\ell = [h'_\ell, h''_\ell)$  ( $\ell = 1, \dots, L$ ), i.e., the cake-cutting problem for cake  $C' = C \setminus \sum_{\ell=1}^L H_\ell$ , players  $N' = N \setminus \sum_{\ell=1}^L N(H_\ell)$  and valuations  $\mathcal{C}'_{N'}$  (which consists of valuations  $C'_k = C_k \setminus \sum_{\ell=1}^L H_\ell \neq \emptyset$  for all  $k \in N'$ ) with density  $\rho'$  and  $\bigcup_{C'_k \in \mathcal{C}'_{N'}} C'_k = C'$ .

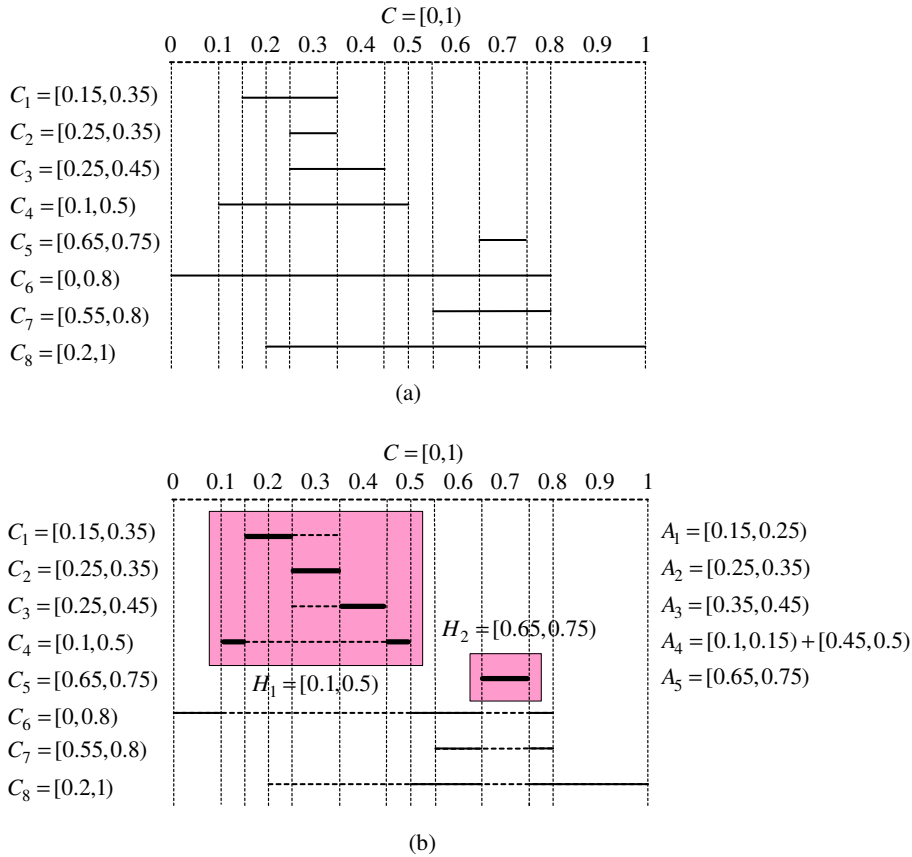

Note that the cake-cutting problem of type (i) is almost the same as the original cake-cutting problem, since cake  $H_\ell$  is a single interval, each valuation  $C_k \in \mathcal{C}_{N(H_\ell)}$  is also a single interval, and the valuation intervals  $\mathcal{C}_{N(H_\ell)}$  is solid as shown in [4]. Thus, based on the core mechanism  $\mathcal{M}_1$  (Algorithm 1), for each  $\ell = 1, \dots, L$ , we can find an allocation  $A_{N(H_\ell)} = (A_i : i \in N(H_\ell))$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in N(H_\ell)$  and  $\sum_{i \in N(H_\ell)} A_i = H_\ell$ .

On the other hand, the cake-cutting problem of type (ii) is different from the original cake-cutting problem, because the resulting cake  $C' = C \setminus \sum_{\ell=1}^L H_\ell$  may become a set of two or more disjoint intervals and each remaining valuation  $C'_k = C_k \setminus \sum_{\ell=1}^L H_\ell \neq \emptyset$  may also become a set of two or more disjoint intervals. However, the cake-cutting problem of type (ii) can be solved in almost the same way by *virtually shrinking* all  $H_\ell$ . That is, we virtually shrink each *hollow interval*  $H_\ell = [h'_\ell, h''_\ell)$  (since  $H_\ell$  was already deleted) and virtually consider  $h'_\ell = h''_\ell$ . By virtually shrinking of all  $H_\ell = [h'_\ell, h''_\ell)$ , cake  $C' = C \setminus \sum_{\ell=1}^L H_\ell$  becomes a single interval  $C'^{(S)}$ , players  $N' = N \setminus \sum_{\ell=1}^L N(H_\ell)$  remains the same, each valuation  $C'_k \in \mathcal{C}'_{N'}$  becomes a single interval  $C'^{(S)}_k$  of  $C'^{(S)}$ , and the valuation intervals  $\mathcal{C}'^{(S)}_{N'} = (C'^{(S)}_k : k \in N')$  becomes solid (i.e.,  $\bigcup_{k \in N'} C'^{(S)}_k = C'^{(S)}$ ). Thus, by virtually shrinking of all  $H_\ell$ , the cake-cutting problem of type (ii) above can be reduced to the cake-cutting problem of type (i) for cake  $C'^{(S)}$ , players  $N' = N \setminus \sum_{\ell=1}^L N(H_\ell)$ , solid valuation intervals  $\mathcal{C}'^{(S)}_{N'} = (C'^{(S)}_k : C'_k \in \mathcal{C}'_{N'})$  with  $\bigcup_{k \in N'} C'^{(S)}_k = C'^{(S)}$  and the same density  $\rho'^{(S)} = \rho'$ , which can be solved recursively. Note that, if  $\rho(C) > \rho_{\min}$  then the minimum density  $\rho'_{\min}$  of intervals in the cake-cutting problem of type (ii) satisfies  $\rho'_{\min} > \rho_{\min}$  as shown in [4, 5].

From an allocation  $A'_{N'} = (A'^{(S)}_k : k \in N')$  to players  $N'$  where  $A'^{(S)}_k$  is the allocated piece of cake  $C'^{(S)}$  to player  $k \in N'$  with  $A'^{(S)}_k \subseteq C'^{(S)}_k$  and  $\sum_{i \in N'} A'^{(S)}_i = C'^{(S)}$ , we obtain an allocation  $A'_{N'} = (A'_k : k \in N')$  to players  $N'$  where  $A'_k$  is the allocated piece of cake  $C'$  to player  $k$  with  $A'_k \subseteq C'_k$  and  $\sum_{i \in N'} A'_i = C'$  as follows: if  $A'^{(S)}_k$  contains a shrunken interval  $H_\ell^{(S)}$  of hollow interval  $H_\ell$ , then let  $A'_k$  be the set of disjoint intervals obtained from  $A'^{(S)}_k$  by restoring each shrunken interval  $H_\ell^{(S)}$  in  $A'^{(S)}_k$  to the original hollow interval  $H_\ell = [h'_\ell, h''_\ell)$ ; otherwise, let  $A'_k = A'^{(S)}_k$ . They called this *inverse shrinking* of all  $H_\ell$  ( $\ell = 1, \dots, L$ ) in [4].

We call the method based on the core mechanism  $\mathcal{M}_1$  (Algorithm 1) described above the *modified mechanism of Asano and Umeda*. The details are in Section 5. Note that all the maximal intervals of minimum density  $\rho_{\min}$  can be obtained in  $O(n^2)$  time, since there are

■ **Figure 2** (a) Example of  $C_N = (C_i : i \in N)$ . (b) The maximal intervals  $H_1, H_2$  of minimum density  $\rho_{\min} = 0.1$ , with  $N(H_1) = \{1, 2, 3, 4\}$ ,  $A_{N(H_1)} = (A_i : i \in N(H_1))$ ,  $N(H_2) = \{5\}$ ,  $A_{N(H_2)} = (A_5)$  in the 1st iteration.

at most  $2n$  endpoints of the valuation intervals in  $C_N$  and the endpoints of each interval of minimum density are endpoints of some valuation intervals. The number of cuts made over  $C$  is also at most  $2n - 2$ . Envy-freeness and truthfulness will be given in Section 5, although they were given in [5] (also given in [2, 13, 25]). Thus, the following theorem holds as in [4].

► **Theorem 2.** *The modified mechanism of Asano and Umeda correctly finds, in  $O(n^3)$  time, an envy-free and truthful allocation  $A_N = (A_i : i \in N)$  of cake  $C$  to  $n$  players  $N$  with  $A_i \subseteq C_i$  for each player  $i \in N$  and  $\sum_{i \in N} A_i = C$ . Furthermore, the number of cuts made over  $C$  by the mechanism is at most  $2n - 2$ .*

For an input example in Figure 2(a), the modified mechanism of Asano and Umeda works as shown in Figure 2(b) and Figure 3.

## 5 Details of Modified Mechanism of Asano and Umeda

As we described in Section 4, Mechanism of Asano and Umeda [4] can be significantly simplified based on  $\mathcal{M}_1$  (Algorithm 1). Actually,  $\mathcal{M}_1$  can be slightly modified and used as Procedure  $\text{CutMaxInterval}(\cdot, \cdot, \cdot)$  in Mechanism of Asano and Umeda [4] as follows.

■ **Figure 3** The second and third iterations for the example in Figure 2. In the second iteration, the minimum density is  $\rho_{\min} = 0.15$  and  $N(H_1) = \{6, 7\}$ ,  $A_6 = [0, 0.1) + [0.5, 0.55)$  and  $A_7 = [0.55, 0.65) + [0.75, 0.8)$ . In the third (last) iteration, the minimum density is  $\rho_{\min} = 0.2$  and  $N(H_1) = \{8\}$  and  $A_8 = [0.8, 1)$ .

■ **Procedure**  $\text{CutMaxInterval}(R, H, \mathcal{D}_R)$ .

**Input:** Cake  $H = [h', h'')$ , players  $R$  and solid valuation intervals  $\mathcal{D}_R = (D_i : i \in R)$  with valuation interval  $D_i = [\alpha'_i, \beta'_i) \subseteq H$  of each player  $i \in R$  and

$\bigcup_{D_i \in \mathcal{D}_R} D_i = H$ , where  $H$  is an interval of minimum density  $\rho_{\min}$  in  $H$ .

**Output:** Allocation  $A_R = (A_i : i \in R)$  with  $A_i \subseteq D_i$  and  $\text{len}(A_i) = \rho_{\min}$  for each  $i \in R$  and  $\sum_{i \in R} A_i = H$ .

sort  $\mathcal{D}_R = (D_i = [\alpha'_i, \beta'_i) : i \in R)$  in a lexicographic order with respect to  $(\beta'_i, \alpha'_i)$  and assume  $R = \{r_1, r_2, \dots, r_{|R|}\}$  and  $D_{r_1} \leq D_{r_2} \leq \dots \leq D_{r_{|R|}}$  in this order;

set  $A_{r_1} = [a_{r_1}, b_{r_1}) \subseteq D_{r_1}$  with length  $\rho_{\min}$  such that  $a_{r_1} = \alpha'_{r_1}$  and  $b_{r_1} = \alpha'_{r_1} + \rho_{\min}$ ;

**for**  $i = 2$  **to**  $|R|$  **do**

set  $A_{r_i} = [a_{r_i}, b_{r_i}) \setminus \sum_{\ell=1}^{i-1} A_{r_\ell}$  with length  $\rho_{\min}$  such that  $[a_{r_i}, b_{r_i}) \subseteq D_{r_i}$  and

$a_{r_i}$  is the leftmost endpoint in  $D_{r_i} \setminus \sum_{\ell=1}^{i-1} A_{r_\ell}$ ;

Thus, our modified mechanism of Asano and Umeda can be written as follows (we omit inverse virtual shrinking).

■ **Algorithm 2** Modified Mechanism of Asano and Umeda.

**Input:** Cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$  and solid valuation intervals

$\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i) \subseteq C$  of each player  $i \in N$  and  $\bigcup_{C_i \in \mathcal{C}_N} C_i = C$ .

**Output:** Allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  for  $i \in N$  and  $\sum_{i \in N} A_i = C$ .  
 $\text{CutCake}(N, C, \mathcal{C}_N)$ ;

Now we will give a proof of envy-freeness and truthfulness of Modified Mechanism of Asano and Umeda (Algorithm 2) described in Theorem 2, which is almost the same as given in [13, 25].

Let  $T$  be the number of recursive calls  $\text{CutCake}(\cdot, \cdot, \cdot)$  in Modified Mechanism of Asano and Umeda (Algorithm 2). Note that, although we use  $D^{(S)}$ ,  $D_k^{(S)} \in \mathcal{D}_{P'}^{(S)}$ ,  $\mathcal{D}_{P'}^{(S)}$  in  $\text{CutCake}(P', D^{(S)}, \mathcal{D}_{P'}^{(S)})$  which are obtained from  $D'$ ,  $D'_k \in \mathcal{D}'_{P'}$ ,  $\mathcal{D}'_{P'}$  by virtual shrinking of all  $H_1, \dots, H_L$ , we will not distinguish them from now on, since we just performed *virtual*

■ **Procedure** CutCake( $P, D, \mathcal{D}_P$ ).

---

**Input:** Cake  $D$  which can be considered to be a single interval, players  $P$ , and solid valuation intervals  $\mathcal{D}_P = (D_i : i \in P)$  with valuation interval  $D_i = [\alpha'_i, \beta'_i] \subseteq D$  of each player  $i \in P$  and  $\bigcup_{D_i \in \mathcal{D}_P} D_i = D$  (the density of each interval  $X$  of  $D$  is denoted by  $\rho(X)$ ).

**Output:** Allocation  $A_P = (A_i : i \in P)$  with  $A_i \subseteq D_i$  for  $i \in P$  and  $\sum_{i \in P} A_i = D$ . Find all the maximal intervals of minimum density  $\rho_{\min}$  in the cake-cutting problem with cake  $D$ , players  $P$  and solid valuation intervals  $\mathcal{D}_P$ ;

Let  $H_1 = [h'_1, h''_1], \dots, H_L = [h'_L, h''_L]$  be all the maximal intervals of minimum density  $\rho_{\min}$ ;

**for**  $\ell = 1$  **to**  $L$  **do**

cut cake  $D$  at both endpoints  $h'_\ell, h''_\ell$  of  $H_\ell$ ;

$R_\ell = \{k \in P \mid D_k \subseteq H_\ell, D_k \in \mathcal{D}_P\}$ ;  $\mathcal{D}_{R_\ell} = (D_k \in \mathcal{D}_P : k \in R_\ell)$ ;

CutMaxInterval( $R_\ell, H_\ell, \mathcal{D}_{R_\ell}$ );

$P' = P$ ;  $D' = D$ ;

**for**  $\ell = 1$  **to**  $L$  **do**  $P' = P' \setminus R_\ell$ ;  $D' = D' \setminus H_\ell$ ;

//  $P' = P \setminus \sum_{\ell=1}^L R_\ell$  and  $D' = D \setminus \sum_{\ell=1}^L H_\ell$

**if**  $P' \neq \emptyset$  **then**

$\mathcal{D}'_{P'} = \emptyset$ ;

**for** each  $D_k \in \mathcal{D}_P$  with  $k \in P'$  **do**  $D'_k = D_k \setminus \sum_{\ell=1}^L H_\ell$ ;  $\mathcal{D}'_{P'} = \mathcal{D}'_{P'} + \{D'_k\}$ ;

Let  $D^{(S)}, D_k^{(S)} \in \mathcal{D}'_{P'}, \mathcal{D}_{P'}^{(S)}$  be obtained from  $D', D'_k \in \mathcal{D}'_{P'}, \mathcal{D}'_{P'}$  by virtual shrinking of all  $H_1, \dots, H_L$ ;

CutCake( $P', D^{(S)}, \mathcal{D}_{P'}^{(S)}$ );

---

*shrinking*. Thus, we consider  $D^{(S)} = D', (D_k^{(S)} \in \mathcal{D}_{P'}^{(S)}) = (D'_k \in \mathcal{D}'_{P'})$  and  $\mathcal{D}_{P'}^{(S)} = \mathcal{D}'_{P'}$ . We denote by CutCake( $P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}}$ ) the  $t$ -th recursive call of CutCake( $\cdot, \cdot, \cdot$ ). Note that the first call of CutCake( $\cdot, \cdot, \cdot$ ) is CutCake( $N, C, \mathcal{C}_N$ ). Let  $\rho_{\min}^{(t)}$  be the minimum density of the cake cutting problem with cake  $D^{(t)}$ , players  $P^{(t)}$  and the solid valuation intervals  $\mathcal{D}_{P^{(t)}}$ . Clearly,  $C = D^{(1)} \supset D^{(2)} \supset \dots \supset D^{(T)}$  and  $N = P^{(1)} \supset P^{(2)} \supset \dots \supset P^{(T)}$ . Furthermore, as shown in [4, 5], the inequality

$$\rho_{\min}^{(1)} < \rho_{\min}^{(2)} < \dots < \rho_{\min}^{(T)}$$

holds. We denote by CutMaxInterval( $R_\ell^{(t)}, H_\ell^{(t)}, \mathcal{D}_{R_\ell^{(t)}}$ ) the CutMaxInterval( $\cdot, \cdot, \cdot$ ) called in CutCake( $P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}}$ ), where  $H_\ell^{(t)}$  is a maximal interval of minimum density  $\rho_{\min}^{(t)}$  in cake  $D^{(t)}$ , players  $P^{(t)}$  and solid valuation intervals  $\mathcal{D}_{P^{(t)}}$  by virtually shrinking of hollow pieces in  $C \setminus D^{(t)}$ . For each player  $i \in N$ , there is  $t \in \{1, \dots, T\}$  such that allocation  $A_i \subseteq C_i$  to player  $i$  is determined in CutMaxInterval( $R_\ell^{(t)}, H_\ell^{(t)}, \mathcal{D}_{R_\ell^{(t)}}$ ). Thus, it is clear that Modified Mechanism of Asano and Umeda (Algorithm 2) finds an allocation  $A_N = (A_i : i \in N)$  of cake  $C$  to  $n$  players  $N$  with  $A_i \subseteq C_i$  for each player  $i \in N$  and  $\sum_{i \in N} A_i = C$ .

Envy-freeness can be proved as follows (which is almost the same as given in [13, 25]). Let  $A_i \subseteq C_i$  to player  $i$  be determined in CutMaxInterval( $R_\ell^{(t)}, H_\ell^{(t)}, \mathcal{D}_{R_\ell^{(t)}}$ ) called in the  $t$ -th recursive call CutCake( $P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}}$ ). Thus,  $V_i(A_i) = \text{len}(A_i) = \rho_{\min}^{(t)}$ . Similarly, let  $A_j \subseteq C_j$  to player  $j$  be determined in CutMaxInterval( $R_{\ell'}^{(t')}, H_{\ell'}^{(t')}, \mathcal{D}_{R_{\ell'}^{(t)'}}$ ) called in the  $t'$ -th recursive call CutCake( $P^{(t')}, D^{(t')}, \mathcal{D}_{P^{(t)'}}$ ). If  $t' \leq t$  then  $V_i(A_j) = \text{len}(A_j \cap C_i) \leq \text{len}(A_j) = \rho_{\min}^{(t')} \leq \rho_{\min}^{(t)} = \text{len}(A_i) = V_i(A_i)$ . Otherwise (i.e., if  $t' > t$ ), although  $V_j(A_j) = \text{len}(A_j) = \rho_{\min}^{(t')} > \rho_{\min}^{(t)} = \text{len}(A_i) = V_i(A_i)$ , we have  $A_j \cap C_i = \emptyset$  and  $V_i(A_j) = \text{len}(A_j \cap C_i) = 0 \leq \rho_{\min}^{(t)} = \text{len}(A_i) = V_i(A_i)$ . Thus, envy-freeness is clear.

Truthfulness can be proved as follows. Assume that only player  $i \in N$  gives a false valuation interval  $C'_i$  and let  $\mathcal{C}'_N(i) = (C'_j : j \in N)$  be an input to Modified Mechanism of Asano and Umeda (Algorithm 2) and  $A'_N(i) = (A'_j : j \in N)$  be the obtained allocation of cake  $C$  to  $n$  players  $N$  (in the argument below, we assume that  $\mathcal{C}'_N(i) = (C'_j : j \in N)$  is solid, although this restriction can be removed by a little more complicated argument). Let  $A_i \subseteq C_i$  to player  $i$  be determined in  $\text{CutMaxInterval}(R_\ell^{(t)}, H_\ell^{(t)}, \mathcal{D}_{R_\ell^{(t)}})$  called in the  $t$ -th recursive call  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}})$ . Similarly, let  $A'_i \subseteq C'_i$  with  $A'_i = \sum_{\ell'=1}^{k'_i} A'_{i,\ell'}$  to player  $i$  be determined in  $\text{CutMaxInterval}(R_{\ell'}^{(t')}, H_{\ell'}^{(t')}, \mathcal{D}'_{R_{\ell'}^{(t')}})$  called in the  $t'$ -th recursive call  $\text{CutCake}(P^{(t')}, D^{(t')}, \mathcal{D}'_{P^{(t')}})$ . Thus,  $V_i(A_i) = \text{len}(A_i) = \rho_{\min}^{(t)}$  and  $V_i(A'_i) = \sum_{\ell'=1}^{k'_i} \text{len}(A'_{i,\ell'} \cap C_i) \leq \sum_{\ell'=1}^{k'_i} \text{len}(A'_{i,\ell'}) = \rho'_{\min}^{(t')}$ , where  $\rho'_{\min}^{(t')}$  is the minimum density of the intervals in cake  $D^{(t')}$  with  $P^{(t')}$  and  $\mathcal{D}'_{P^{(t')}})$ . We divide the case into two cases: (i)  $\rho'_{\min}^{(t')} \leq \rho_{\min}^{(t)}$ ; and (ii)  $\rho'_{\min}^{(t')} > \rho_{\min}^{(t)}$ .

(i)  $\rho'_{\min}^{(t')} \leq \rho_{\min}^{(t)}$ . In this case, it is clear that  $V_i(A_i) = \text{len}(A_i) = \rho_{\min}^{(t)} \geq \rho'_{\min}^{(t')} = \sum_{\ell'=1}^{k'_i} \text{len}(A'_{i,\ell'}) \geq \sum_{\ell'=1}^{k'_i} \text{len}(A'_{i,\ell'} \cap C_i) = V_i(A'_i)$ .

(ii)  $\rho'_{\min}^{(t')} > \rho_{\min}^{(t)}$ . In this case,  $t' \geq t$  holds, which can be shown as follows.

Suppose contrarily that  $t' < t$ . Then for two inputs  $\mathcal{C}_N = (C_j : j \in N)$  and  $\mathcal{C}'_N(i) = (C'_j : j \in N)$ , Modified Mechanism of Asano and Umeda (Algorithm 2) makes the same behavior before the  $t'$ -th recursive calls  $\text{CutCake}(P^{(t')}, D^{(t')}, \mathcal{D}_{P^{(t')}})$  and  $\text{CutCake}(P^{(t')}, D^{(t')}, \mathcal{D}'_{P^{(t')}})$ . Thus,  $P^{(t'')} = P^{(t'')}$ ,  $D^{(t'')} = D^{(t'')}$  and  $\mathcal{D}'_{P^{(t'')}} \setminus \{D_i^{(t'')}\} = \mathcal{D}_{P^{(t'')}} \setminus \{D_i^{(t'')}\}$  for each  $t'' = 1, \dots, t'$ , where  $D_i^{(t'')} = C_i \cap D^{(t'')}$  and  $D'_i{}^{(t'')} = C'_i \cap D^{(t'')}$ . Let  $X = [x', x'']$  be a maximal interval of minimum density  $\rho_{\min}^{(t')}$  in  $D^{(t')} = D^{(t')}$ . Thus,  $\rho^{(t')}(X) = \rho_{\min}^{(t')}$ . Furthermore,  $D_i^{(t')} = C_i \cap D^{(t')} \not\subseteq X$ , since otherwise (i.e., if  $D_i^{(t')} \subseteq X$ )  $A_i$  to player  $i$  would be determined in the  $t'$ -th recursive call  $\text{CutCake}(P^{(t')}, D^{(t')}, \mathcal{D}_{P^{(t')}})$ , which is a contradiction (since  $t > t'$  and  $A_i$  is determined in the  $t$ -th call  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}})$ ). Thus, if  $D'_i{}^{(t')} = C'_i \cap D^{(t')} \not\subseteq X$  then  $\rho^{(t')}(X) = \rho^{(t')}(X)$  holds by  $D_i^{(t')} \not\subseteq X$ , and otherwise (i.e., if  $D'_i{}^{(t')} \subseteq X$ )  $\rho^{(t')}(X) < \rho^{(t')}(X)$  holds by  $D_i^{(t')} \not\subseteq X$ . This implies that  $\rho^{(t')}(X) \leq \rho^{(t')}(X)$  and  $\rho'_{\min}^{(t')} \leq \rho^{(t')}(X) \leq \rho^{(t')}(X) = \rho_{\min}^{(t')} < \rho'_{\min}^{(t')}$  by  $t' < t$ . However, this is a contradiction, since  $\rho'_{\min}^{(t')} > \rho_{\min}^{(t)}$  in this case.

Thus, we have  $t' \geq t$  in this case of  $\rho'_{\min}^{(t')} > \rho_{\min}^{(t)}$ . As we mentioned above, for two inputs  $\mathcal{C}_N = (C_j : j \in N)$  and  $\mathcal{C}'_N(i) = (C'_j : j \in N)$ , Modified Mechanism of Asano and Umeda (Algorithm 2) makes the same behavior before the  $t$ -th recursive calls  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}})$  and  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}'_{P^{(t)}})$ . Thus,  $P^{(t)} = P^{(t)}$ ,  $D^{(t)} = D^{(t)}$  and  $\mathcal{D}'_{P^{(t)}} \setminus \{D_i^{(t)}\} = \mathcal{D}_{P^{(t)}} \setminus \{D_i^{(t)}\}$ , where  $D_i^{(t)} = C_i \cap D^{(t)}$  and  $D'_i{}^{(t)} = C'_i \cap D^{(t)}$ . For each player  $j \in N$  with  $A_j$  determined in  $\text{CutMaxInterval}(R_\ell^{(t)}, H_\ell^{(t)}, \mathcal{D}_{R_\ell^{(t)}})$  in the  $t$ -th call  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}_{P^{(t)}})$ , let  $A'_j$  be determined in the  $t'_j$ -th call  $\text{CutCake}(P^{(t'_j)}, D^{(t'_j)}, \mathcal{D}'_{P^{(t'_j)}})$ . Thus  $t'_j \geq t$ .

We will show that  $\rho'_{\min}^{(t)} \geq \rho_{\min}^{(t)}$ . If  $t' = t$  then this is true since  $\rho'_{\min}^{(t)} = \rho'_{\min}^{(t')} > \rho_{\min}^{(t)}$ . Now we assume  $t' > t$ . Let  $X = [x', x'']$  be a maximal interval of minimum density  $\rho_{\min}^{(t)}$  in  $D^{(t)} = D^{(t)}$ . Thus,  $\rho^{(t)}(X) = \rho_{\min}^{(t)}$ . Furthermore,  $D'_i{}^{(t)} = C'_i \cap D^{(t)} \not\subseteq X$  holds, since otherwise (i.e., if  $D'_i{}^{(t)} \subseteq X$ )  $A'_i$  to player  $i$  would be determined in the  $t$ -th recursive call  $\text{CutCake}(P^{(t)}, D^{(t)}, \mathcal{D}'_{P^{(t)}})$  and  $t' = t$  (which contradicts  $t' > t$ ). Thus, if  $D_i^{(t)} = C_i \cap D^{(t)} \not\subseteq X$ , then  $\rho^{(t)}(X) = \rho^{(t)}(X)$  by  $D_i^{(t)} \not\subseteq X$  and  $\rho'_{\min}^{(t)} = \rho^{(t)}(X) = \rho^{(t)}(X) \geq \rho_{\min}^{(t)}$ . If  $D'_i{}^{(t)} \subseteq X$ , then  $\rho^{(t)}(X) > \rho^{(t)}(X)$  by  $D_i^{(t)} \not\subseteq X$  and  $\rho'_{\min}^{(t)} = \rho^{(t)}(X) > \rho^{(t)}(X) \geq \rho_{\min}^{(t)}$ . By the argument above, we have  $\rho'_{\min}^{(t)} \geq \rho_{\min}^{(t)}$ .

Thus, for each  $j \in R_\ell^{(t)} \setminus \{i\}$ , we have  $\text{len}(A'_j) = \rho_{\min}^{(t'_j)} \geq \rho_{\min}^{(t)} \geq \rho_{\min}^{(t)}$  and  $A'_j \subseteq C_j \cap D^{(t)} = C_j \cap D^{(t)} \subseteq H_\ell^{(t)}$ . By  $\sum_{j \in N} A'_j = C$  and  $\sum_{j \in R_\ell^{(t)}} A'_j = (\cup_{j \in R_\ell^{(t)}} C_j) \cap D^{(t)} = H_\ell^{(t)}$ , we have

$$\begin{aligned} V_i(A'_i) &= \text{len}(A'_i \cap C_i) = \text{len}(A'_i \cap C_i \cap D^{(t)}) \\ &\leq \text{len}(H_\ell^{(t)}) - \sum_{j \in R_\ell^{(t)} \setminus \{i\}} \text{len}(A'_j \cap C_j \cap D^{(t)}) = \text{len}(H_\ell^{(t)}) - \sum_{j \in R_\ell^{(t)} \setminus \{i\}} \text{len}(A'_j) \\ &\leq \text{len}(H_\ell^{(t)}) - \rho_{\min}^{(t)} (|R_\ell^{(t)}| - 1) = |R_\ell^{(t)}| \rho_{\min}^{(t)} - \rho_{\min}^{(t)} (|R_\ell^{(t)}| - 1) \\ &= \rho_{\min}^{(t)} = V_i(A_i). \end{aligned}$$

Thus, truthfulness of Modified Mechanism of Asano and Umeda (Algorithm 2) is proved.

## 6 Second Mechanism $\mathcal{M}_2$

In this section, we give the second version  $\mathcal{M}_2$  which can be applied to the envy-free and truthful mechanism proposed by Chen, et al. [13] where the valuation function of each player is more general and piecewise uniform. We are given a cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$ , and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i) \subseteq C$  of each player  $i \in N$  as before. We are also given  $(s_i : i \in N)$  such that there is an allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  with  $A'_i \subseteq C_i$  and  $s_i = \text{len}(A'_i) > 0$  for each  $i \in N$  and  $\sum_{i \in N} A'_i = C$  (thus  $\sum_{i \in N} s_i = 1$ ). Note that there is no need to have such an allocation  $A'_N = (A'_i : i \in N)$  in hand.

Then  $\mathcal{M}_2$  is almost the same as  $\mathcal{M}_1$  and can be written as follows.

### Algorithm 3 Second Mechanism $\mathcal{M}_2$ .

---

**Input:** Cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$  and solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  with valuation interval  $C_i = [\alpha_i, \beta_i)$  of each player  $i \in N$  and  $\cup_{C_i \in \mathcal{C}_N} C_i = C$  and  $(s_i : i \in N)$  for players  $N$  such that there is an allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  with  $A'_i \subseteq C_i$  and  $\text{len}(A'_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A'_i = C$  (thus  $\sum_{i \in N} s_i = 1$ ).

**Output:** Allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$ .

sort  $\mathcal{C}_N = (C_i : i \in N)$  in a lexicographic order with respect to  $(\beta_i, \alpha_i)$  and assume  $C_1 \leq C_2 \leq \dots \leq C_n$  in this lexicographic order;

set  $A_1 = [a_1, b_1) \subseteq C_1$  with length  $s_1$  such that  $a_1 = \alpha_1$  and  $b_1 = \alpha_1 + s_1$ ;

**for**  $i = 2$  **to**  $n$  **do**

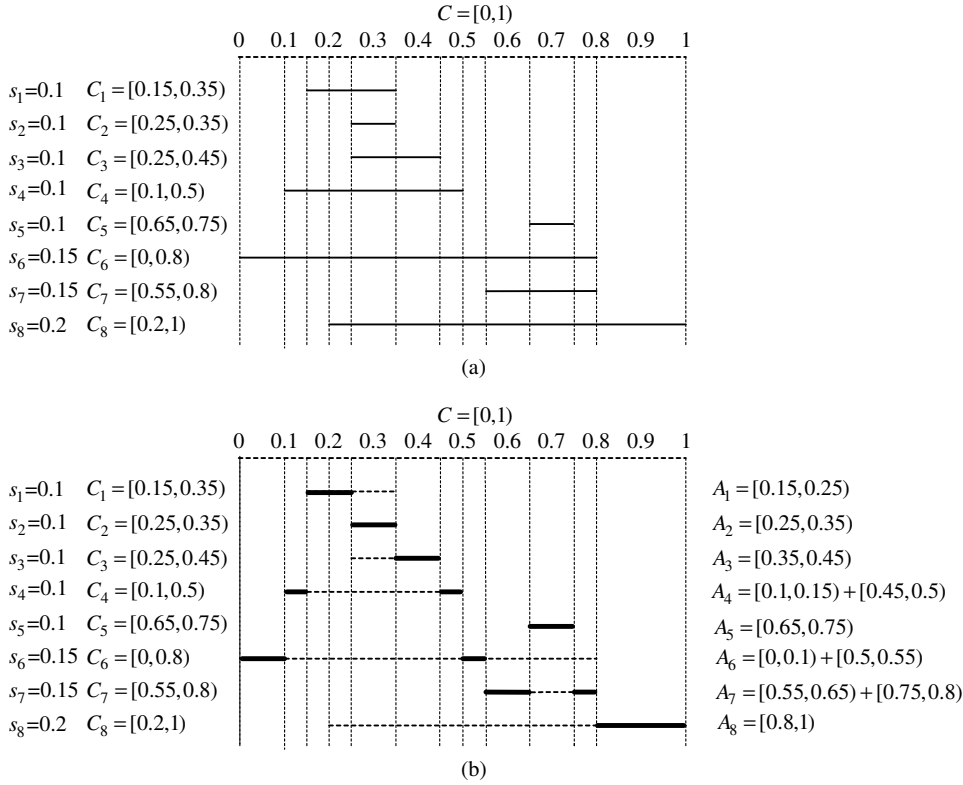

set  $A_i = [a_i, b_i) \setminus \sum_{\ell=1}^{i-1} A_\ell$  with length  $s_i$  such that  $[a_i, b_i) \subseteq C_i$  and  $a_i$  is the leftmost endpoint in  $C_i \setminus \sum_{\ell=1}^{i-1} A_\ell$ ;

---

Figure 4 shows an example of solid valuation intervals  $\mathcal{C}_N = (C_i : i \in N)$  and  $(s_i : i \in N)$  with  $\sum_{i \in N} s_i = 1$  and an allocation  $A_N = (A_i : i \in N)$  obtained by  $\mathcal{M}_2$ . By an argument similar to one in Proof of Theorem 1 we have the following theorem.

► **Theorem 3.**  $\mathcal{M}_2$  correctly finds an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$  in  $O(n \log n)$  time. Furthermore, the number of cuts made by  $\mathcal{M}_2$  on cake  $C$  is at most  $2n - 2$ .

**Proof.** Since the time complexity  $O(n \log n)$  and the number of cuts at most  $2n - 2$  can be obtained by the same argument as in Proof of Theorem 1, we only prove that  $\mathcal{M}_2$  correctly finds an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$ ,  $\text{len}(A_i) = s_i$  and  $\sum_{i \in N} A_i = C$ .

■ **Figure 4** (a) Example of  $\mathcal{C}_N = (C_i : i \in N)$  and  $(s_i : i \in N)$  with  $\sum_{i \in N} s_i = 1$ . (b) Allocation  $A_N = (A_i : i \in N)$  obtained by  $\mathcal{M}_2$ .

Suppose contrarily that  $\mathcal{M}_2$  could not set  $A_i \subseteq C_i$  with length  $s_i$  for some  $i \in N$ . Let  $j$  be the minimum among such  $i$ s and let  $J = \{1, 2, \dots, j\}$ . Of course,  $j > 1$ , since we assumed that there is an allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  with  $A'_i \subseteq C_i$  and  $\text{len}(A'_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A'_i = C$  (thus  $C_1 = [\alpha_1, \beta_1]$  is of length at least  $s_1$  and  $A_1 = [a_1, b_1] = [\alpha_1, \alpha_1 + s_1] \subseteq C_1$ ). Now we consider valuation intervals  $\mathcal{C}_J = (C_i : i \in J)$ . Note that each  $C_i = [\alpha_i, \beta_i] \in \mathcal{C}_J$  satisfies  $\beta_i \leq \beta_j$ , since  $\mathcal{C}_N = (C_i : i \in N)$  was sorted in the lexicographic order with respect to  $(\beta_i, \alpha_i)$ . Thus,  $\mathcal{M}_2$  could set  $A_i = [a_i, b_i] \setminus \sum_{\ell=1}^{i-1} A_\ell \subseteq C_i = [\alpha_i, \beta_i]$  with length  $s_i$  for each  $i \in J \setminus \{j\}$  but could not set  $A_j = [a_j, b_j] \setminus \sum_{\ell=1}^{j-1} A_\ell \subseteq C_j = [\alpha_j, \beta_j]$  with length  $s_j$ . This implies that  $C_j \setminus \sum_{\ell=1}^{j-1} A_\ell$  is of length  $s'_j < s_j$ . Let

$$A''_i = A_i \quad (i \in J \setminus \{j\}), \quad A''_j = C_j \setminus \sum_{\ell=1}^{j-1} A''_\ell = [a_j, \beta_j] \setminus \sum_{\ell=1}^{j-1} A_\ell.$$

Thus,  $\sum_{i \in J} A''_i$  of allocation  $(A''_i : i \in J)$  consists of several maximal contiguous intervals. Let  $I = [a, b)$  be the rightmost maximal contiguous interval among the maximal contiguous intervals in  $\sum_{i \in J} A''_i$  (Figure 5). Thus,  $b = \beta_j$ . Define  $K \subseteq J$  by

$$K = \{j\} \cup \{i \in J \mid A''_i \cap I \neq \emptyset\}.$$

Now we consider valuation intervals  $\mathcal{C}_K = (C_i : i \in K)$ . Then each  $C_i \in \mathcal{C}_K$  is contained in  $I$ , which can be obtained as follows.

■ **Figure 5** Illustration of  $I = [a, b)$  and  $I' = [a', a)$ .

Of course,  $C_j = [\alpha_j, \beta_j)$  is contained in  $I$ . Actually, since  $C_j \setminus \sum_{\ell=1}^{j-1} A''_\ell = [a_j, \beta_j) \setminus \sum_{\ell=1}^{j-1} A_\ell$  is of length  $s'_j < s_j$  and  $A''_j = C_j \setminus \sum_{\ell=1}^{j-1} A''_\ell = [a_j, \beta_j) \setminus \sum_{\ell=1}^{j-1} A_\ell$ , we have: if  $A''_j = \emptyset$  then  $C_j \subseteq \sum_{\ell=1}^{j-1} A''_\ell$  and a single contiguous interval  $C_j$  is contained in the rightmost maximal contiguous interval  $I$  in  $\sum_{\ell=1}^j A''_\ell = \sum_{\ell=1}^{j-1} A''_\ell$  (i.e.,  $C_j \subseteq I$ ); and otherwise (i.e., if  $A''_j \neq \emptyset$ ),  $C_j \subseteq A''_j \cup \sum_{\ell=1}^{j-1} A''_\ell = \sum_{\ell=1}^j A''_\ell$  and a single contiguous interval  $C_j$  is contained in the rightmost maximal contiguous interval  $I$  in  $\sum_{\ell=1}^j A''_\ell$ .

Now suppose that there were  $i \in K \setminus \{j\}$  such that  $C_i \in \mathcal{C}_K$  is not contained in  $I$ . Thus,  $I = [a, b)$  is a proper subinterval of  $[0, b) = [0, \beta_j)$  (i.e.,  $a > 0$ ) and  $C_i = [\alpha_i, \beta_i) \in \mathcal{C}_K \setminus \{C_j\}$  contains a point  $x$  in  $[0, b) \setminus I = [0, a)$ . Let  $k \in K \setminus \{j\}$  be the minimum among such  $i$ s and let  $x_k$  be a point of  $C_k = [\alpha_k, \beta_k) \in \mathcal{C}_K$  contained in  $[0, a) = [0, b) \setminus I$ . Note that  $C_k \cap I \supseteq A''_k \cap I \neq \emptyset$  since  $k \in K \setminus \{j\} \subseteq J \setminus \{j\}$ . Thus,  $\beta_k \leq \beta_j$  and  $\alpha_k \leq x_k < a \leq a'_k < \beta_k$  for some  $a'_k \in A''_k \cap I \neq \emptyset$ . Furthermore, since we chose  $I = [a, b) \neq [0, b)$  as the rightmost maximal contiguous interval among the maximal contiguous intervals in  $\sum_{i \in J} A''_i$ , we have  $\sum_{i \in J} A''_i \neq [0, b) = [0, \beta_j)$ . Let  $I' = [a', a)$  be the rightmost maximal contiguous interval in  $[0, b) \setminus \sum_{i \in J} A''_i$  (Figure 5). Since  $C_k = [\alpha_k, \beta_k)$  is a contiguous interval and satisfies  $\alpha_k \leq x_k < a \leq a'_k < \beta_k$ , we can choose  $x_k$  with  $x_k \in I' \cap C_k \neq \emptyset$ . Thus,  $x_k \notin A''_k$  by  $I' \cap A''_k \subseteq I' \cap \sum_{i \in J} A''_i = \emptyset$ . Then, however,  $\mathcal{M}_2$  would have tried to include  $x_k$  into  $A''_k$  rather than  $a'_k \in A''_k \cap I \neq \emptyset$ , because  $\mathcal{M}_2$  sets  $A''_k = A_k = [a_k, b_k) \setminus \sum_{\ell=1}^{k-1} A''_\ell \subseteq C_k$  with length  $s_k$  such that  $a_k$  is the leftmost endpoint in  $C_k \setminus \sum_{\ell=1}^{k-1} A''_\ell$ . This is a contradiction.

Thus, each  $C_i \in \mathcal{C}_K$  is contained in  $I$  and  $\bigcup_{i \in K} C_i \subseteq I$ . By the argument above, we have

$$\bigcup_{i \in K} C_i = I = \sum_{i \in K} A''_i,$$

since  $A''_h \cap I = \emptyset$  for  $h \in J \setminus K$  and  $I = \sum_{i \in J} A''_i \cap I = \sum_{i \in K} A''_i \cap I \subseteq \sum_{i \in K} A''_i \subseteq \sum_{i \in K} C_i$  by the definitions of  $I$  and  $K$  and  $A''_i \subseteq C_i$  for each  $i \in K$ . Thus,

$$\sum_{i \in K} \text{len}(A''_i) = s'_j + \sum_{i \in K \setminus \{j\}} s_i = \text{len}(I) = b - a < s_j + \sum_{i \in K \setminus \{j\}} s_i$$

since  $s'_j < s_j$ . However, this is a contradiction, since we assumed that there is an allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  with  $A'_i \subseteq C_i$  and  $\text{len}(A'_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A'_i = C$ , and thus

$$s_j + \sum_{i \in K \setminus \{j\}} s_i = \sum_{i \in K} \text{len}(A'_i) \leq \text{len}\left(\bigcup_{i \in K} C_i\right) = \text{len}(I) = b - a.$$

Thus,  $\mathcal{M}_2$  correctly finds an allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$ ,  $\text{len}(A_i) = s_i$  and  $\sum_{i \in N} A_i = C$ . ◀

## 7 Application to Mechanism of Chen et al. [13]

By Theorem 3, in order to obtain an envy-free and truthful allocation  $A_N = (A_i : i \in N)$  with  $A_i \subseteq C_i$  and  $\text{len}(A_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A_i = C$ , we only need  $(s_i : i \in N)$  such that there is an envy-free and truthful allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  with  $A'_i \subseteq C_i$  and  $\text{len}(A'_i) = s_i$  for each  $i \in N$  and  $\sum_{i \in N} A'_i = C$ . Thus, Theorem 3 can be applied to the mechanism of Chen, et al. [13] where the valuation function  $v_i$  of each player  $i \in N$  is more general and piecewise uniform: Given a cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$  and solid piecewise uniform valuation functions  $(v_i : i \in N)$  such that  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of each valuation function  $v_i$  consists of  $m_i \geq 1$  maximal contiguous intervals  $C_{i_1}, \dots, C_{i_{m_i}}$  in  $C$  and  $\bigcup_{i \in N} D(v_i) = C$ .

The mechanism of Chen, et al. [13] finds an envy-free and truthful allocation  $A'_N = (A'_i : i \in N)$  such that  $\sum_{i \in N} A'_i = C$  and  $A'_i = \sum_{j=1}^{m_i} A'_{i_j}$  with  $A'_{i_j} \subseteq C_{i_j}$  for each  $i \in N$  and for each  $j = 1, 2, \dots, m_i$ . Thus, we can set  $s_{i_j} = \text{len}(A'_{i_j})$  and apply Theorem 3 to obtain an envy-free and truthful allocation  $A_N = (A_i : i \in N)$  such that  $A_i = \sum_{j=1}^{m_i} A_{i_j}$  for each  $i \in N$  with  $A_{i_j} \subseteq C_{i_j}$  and  $\text{len}(A_{i_j}) = s_{i_j}$  for each  $j = 1, 2, \dots, m_i$  with at most  $2(\sum_{i \in N} m_i) - 2$  cuts. Note that, we can delete all  $C_{i_j}$  if  $s_{i_j} = \text{len}(A'_{i_j}) = 0$ , and thus, we can assume  $s_{i_j} = \text{len}(A'_{i_j}) > 0$  for each  $i \in N$  and for each  $j = 1, 2, \dots, m_i$ .

In summary, we have the following corollary.

► **Corollary 4.** *Suppose that we are given  $(s_{i_j} : i \in N, j = 1, 2, \dots, m_i)$  such that there is an envy-free and truthful allocation  $A'_N = (A'_i : i \in N)$  to players  $N$  satisfying  $\sum_{i \in N} A'_i = C$  and  $A'_i = \sum_{j=1}^{m_i} A'_{i_j}$  with  $A'_{i_j} \subseteq C_{i_j}$  and  $\text{len}(A'_{i_j}) = s_{i_j} > 0$  for each  $i \in N$  and for each  $j = 1, 2, \dots, m_i$  for the cake-cutting problem with cake  $C = [0, 1)$ ,  $n$  players  $N = \{1, 2, \dots, n\}$  and solid piecewise uniform valuation functions  $(v_i : i \in N)$  such that  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of each piecewise uniform valuation function  $v_i$  consists of  $m_i \geq 1$  maximal contiguous intervals  $C_{i_1}, \dots, C_{i_{m_i}}$  in  $C$  and  $\bigcup_{i \in N} D(v_i) = C$  (such  $A'_N = (A'_i : i \in N)$  to players  $N$  can be obtained, for example, by Mechanism of Chen, et al. [13]). Then, Second Mechanism  $\mathcal{M}_2$  (Algorithm 3) correctly finds an envy-free and truthful allocation  $A_N = (A_i : i \in N)$  with  $\sum_{i \in N} A_i = C$  and  $A_i = \sum_{j=1}^{m_i} A_{i_j}$  with  $A_{i_j} \subseteq C_{i_j}$  and  $\text{len}(A_{i_j}) = s_{i_j}$  for each  $i \in N$  and for each  $j = 1, 2, \dots, m_i$  in  $O(\sum_{i \in N} m_i \log \sum_{i \in N} m_i)$  time. Furthermore, the number of cuts made by  $\mathcal{M}_2$  on cake  $C$  is at most  $2(\sum_{i \in N} m_i) - 2$ . Thus, Mechanism of Chen, et al. [13] can be implemented to make at most  $2(\sum_{i \in N} m_i) - 2$  cuts on cake  $C$ .*

## 8 Concluding Remarks

We gave a much simpler envy-free and truthful mechanism with a small number of cuts for the cake-cutting problem posed in [2, 25]. Furthermore, we showed that this approach can be applied to the envy-free and truthful mechanism proposed by Chen, et al. [13] for the more general cake-cutting problem where the valuation function of each player is piecewise uniform. Thus, we can make their envy-free and truthful mechanism use  $2 \sum_{i \in N} m_i - 2$  cuts and settle the problem posed by [2, 25], where  $m_i$  is the number of maximal contiguous intervals in  $D(v_i) = \{x \in C \mid v_i(x) > 0\}$  of each player  $i$ 's piecewise uniform valuation  $v_i$ .

If we require the piecewise uniform valuation  $v_i$  of each player  $i$  to be a single contiguous interval  $C_i$  in cake  $C$ , then Modified Mechanism of Asano and Umeda can be implemented to run in  $O(n^2 \log n)$  time based on parametric flows on the network arising from valuation intervals  $C_i$  [3] (Parametric flows and parametric searching have been studied by many researchers [1, 17, 33]). We expect this would lead to a faster envy-free and truthful mechanism for the general piecewise uniform valuations.

## Abstract

In this paper, we study the problem of maximizing the difference between an adaptive submodular (revenue) function and a non-negative modular (cost) function. The input of our problem is a set of  $n$  items, where each item has a particular state drawn from some known prior distribution. The revenue function  $g$  is defined over items and states, and the cost function  $c$  is defined over items, i.e., each item has a fixed cost. The state of each item is unknown initially and one must select an item in order to observe its realized state. A policy  $\pi$  specifies which item to pick next based on the observations made so far. Denote by  $g_{avg}(\pi)$  the expected revenue of  $\pi$  and let  $c_{avg}(\pi)$  denote the expected cost of  $\pi$ . Our objective is to identify the best policy  $\pi^o \in \arg \max_{\pi} g_{avg}(\pi) - c_{avg}(\pi)$  under a  $k$ -cardinality constraint. Since our objective function can take on both negative and positive values, the existing results of submodular maximization may not be applicable. To overcome this challenge, we develop a series of effective solutions with performance guarantees. Let  $\pi^o$  denote the optimal policy. For the case when  $g$  is adaptive monotone and adaptive submodular, we develop an effective policy  $\pi^l$  such that  $g_{avg}(\pi^l) - c_{avg}(\pi^l) \geq (1 - \frac{1}{e} - \epsilon)g_{avg}(\pi^o) - c_{avg}(\pi^o)$ , using only  $O(n\epsilon^{-2} \log \epsilon^{-1})$  value oracle queries. For the case when  $g$  is adaptive submodular, we present a randomized policy  $\pi^r$  such that  $g_{avg}(\pi^r) - c_{avg}(\pi^r) \geq \frac{1}{e}g_{avg}(\pi^o) - c_{avg}(\pi^o)$ .

## 1 Introduction

Maximizing a submodular function subject to practical constraints has attracted increased attention recently [3, 16, 17, 7]. Submodularity encodes a natural diminishing returns property, which can be found in a wide variety of machine learning tasks such as active learning [3], virtual marketing [16, 17], sensor placement [7], and data summarization [8]. Under the non-adaptive setting, where one must select a group of items all at once, [11] shows that a classic greedy algorithm achieves  $1 - 1/e$  approximation ratio for the problem of maximizing a monotone and non-negative submodular function subject to a cardinality constraint. For non-monotone and non-negative objectives, [1] obtains an approximation of  $1/e + 0.004$ .

Very recently, [4] studies the problem of maximizing the difference between a monotone non-negative submodular function and a non-negative modular function. Given that the objective function of the above problem may take both positive and negative values, most existing technologies, which require the objective function to take only non-negative values, can not provide nontrivial approximation guarantees. They overcome this challenge by developing a series of effective algorithms. In this paper, we extend their work to the adaptive setting by considering the problem of adaptive regularized submodular maximization, i.e., our goal is to adaptively select a group of items to maximize the difference between an adaptive submodular (revenue) function and a non-negative modular (cost) function. We next provide

more details about our adaptive setting. Following the framework of adaptive submodular maximization [3], a natural stochastic variant of the classical non-adaptive submodular maximization problem, we assume that each item is in a particular state drawn from a known prior distribution. The state of each item is unknown initially and one must select an item before observing its state. A policy  $\pi$  specifies which item to pick next based on the observations made so far. Note that the decision on selecting an item is irrevocable, that is, we can not discard any item that is previously selected. The revenue function  $g$  is defined over items and states, and the cost function  $c$  is defined over items. Note that there are two sources of randomness that make our problem more complicated than its non-adaptive counterpart. One is the random realization of items' states, and the other one is the random decision that is made by the policy. We use  $g_{avg}(\pi)$  to denote the expected revenue of  $\pi$  and let  $c_{avg}(\pi)$  denote the expected cost of  $\pi$ . Our objective is to identify the best policy:

$$\max_{\pi} g_{avg}(\pi) - c_{avg}(\pi)$$

under a  $k$ -cardinality constraint. The above formulation has its applications in many domains [5, 12]. When  $g_{avg}(\pi)$  represents the revenue of  $\pi$  and  $c_{avg}(\pi)$  encodes the cost of  $\pi$ , the above formulation is to maximize profits. In general, the above formulation may be interpreted as a regularized submodular maximization problem under the adaptive setting. Since our objective function can take on both negative and positive values, the existing results of non-monotone adaptive submodular maximization [14, 15], which require the objective function to take only non-negative values, may not be applicable.

Our contribution is threefold. We first consider the case when the revenue function  $g$  is adaptive monotone and adaptive submodular. Letting  $\pi^o$  denote the optimal policy, we develop an effective policy  $\pi^d$  such that  $g_{avg}(\pi^d) - c_{avg}(\pi^d) \geq (1 - \frac{1}{e})g_{avg}(\pi^o) - c_{avg}(\pi^o)$ , using  $O(kn)$  value oracle queries. Our second result is the development of a faster policy  $\pi^l$  such that  $g_{avg}(\pi^l) - c_{avg}(\pi^l) \geq (1 - \frac{1}{e} - \epsilon)g_{avg}(\pi^o) - c_{avg}(\pi^o)$ , using only  $O(n\epsilon^{-2} \log \epsilon^{-1})$  value oracle queries. For the case when  $g$  is (non-monotone) adaptive submodular, we present a randomized policy  $\pi^r$  such that  $g_{avg}(\pi^r) - c_{avg}(\pi^r) \geq \frac{1}{e}g_{avg}(\pi^o) - c_{avg}(\pi^o)$ .

## 2 Related Work

Submodular maximization is a well-studied topic due to its applications in a wide range of domains including active learning [3], virtual marketing [16, 17], sensor placement [7]. Most of existing studies focus on the non-adaptive setting where one must select a group of items all at once. [11] shows that a classic greedy algorithm, which iteratively selects the item that has the largest marginal revenue on top of the previously selected items, achieves a  $1 - 1/e$  approximation ratio when maximizing a monotone non-negative submodular function subject to a cardinality constraint. The problem of maximizing a sum of a non-negative monotone submodular function and an (arbitrary) modular function is first studied in [13]. Notably, their objective function may take on negative values. [2] develops a faster algorithm using a surrogate objective that varies with time. For the case of a cardinality constraint and a non-negative  $c$ , [4] develops the first practical algorithm. Their results have been enhanced by [5] for the unconstrained case. Recently, [6, 12] extend this study to streaming and distributed settings. Our work is different from theirs in that we focus on the adaptive setting [3, 14, 15]. Moreover, we consider a more general problem of maximizing the difference of a non-negative *non-monotone* adaptive submodular function and a non-negative modular function.

### 3 Preliminaries

In the rest of this paper, we use  $[m]$  to denote the set  $\{0, 1, \dots, m\}$ . We mostly follow [3] and adopt similar notations.

#### 3.1 Items and States

The input of our problem is a set  $E$  of  $n$  items. Each item  $e \in E$  is in a random state  $\Phi(e) \in O$  where  $O$  represents the set of all possible states. We use a function  $\phi : E \rightarrow O$ , called a *realization*, to represent the realized states of all items, i.e.,  $\phi(e)$  represents a realization of  $\Phi(e)$ . There is a known prior probability distribution  $p = \{\Pr[\Phi = \phi] : \phi \in U\}$  over all possible realizations  $U$ . The state  $\Phi(e)$  of each item  $e \in E$  is unknown initially and one must select  $e$  before observing its realized state. If we select multiple items  $S \subseteq E$ , then we are able to observe a *partial realization*  $\psi : S \rightarrow O$  and  $\text{dom}(\psi) = S$  is called the *domain* of  $\psi$ . A partial realization  $\psi$  is said to be consistent with a realization  $\phi$ , denoted  $\phi \sim \psi$ , if they are equal everywhere in  $\text{dom}(\psi)$ . A partial realization  $\psi$  is said to be a *subrealization* of  $\psi'$ , denoted  $\psi \subseteq \psi'$ , if  $\text{dom}(\psi) \subseteq \text{dom}(\psi')$  and they are equal everywhere in the domain  $\text{dom}(\psi)$  of  $\psi$ . Let  $p(\phi | \psi)$  denote the conditional distribution over realizations conditioned on a partial realization  $\psi$ :  $p(\phi | \psi) = \Pr[\Phi = \phi | \Phi \sim \psi]$ . In the rest of this paper, we use uppercase letters to denote random variables, and lowercase letters for realizations. For example,  $\Psi$  refers to a random variable, and  $\psi$  is a realization of  $\Psi$ .

#### 3.2 Revenue and Cost

For a set  $Y \subseteq E$  of items and a realization  $\phi$ , let  $g(Y, \phi)$  represent the revenue of selecting  $Y$  conditioned on  $\phi$ , where  $g$  is called *revenue function*. Moreover, each item  $e \in E$  has a fixed cost  $c_e$ . For any set subset of items  $Y \subseteq E$ , let  $c(Y) = \sum_{e \in Y} c_e$  denote the total cost of  $Y$ , where  $c$  is called *cost function*.

#### 3.3 Problem Formulation

A policy specifies which item to select next based on the partial realization observed so far. Mathematically, we represent a policy using a function  $\pi$  that maps a set of observations to a distribution  $\mathcal{P}(E)$  of  $E$ :  $\pi : 2^E \times O^E \rightarrow \mathcal{P}(E)$ .

► **Definition 1** ([3], Policy Concatenation). *Given two policies  $\pi$  and  $\pi'$ , let  $\pi @ \pi'$  denote a policy that runs  $\pi$  first, and then runs  $\pi'$ , ignoring the observation obtained from running  $\pi$ .*

► **Definition 2** ([3], Level- $t$ -Truncation of a Policy). *Given a policy  $\pi$ , we define its level- $t$ -truncation  $\pi_t$  as a policy that runs  $\pi$  until it selects  $t$  items.*

For each realization  $\phi$ , let  $E(\pi, \phi)$  denote the subset of items selected by  $\pi$  under realization  $\phi$ . Note that  $E(\pi, \phi)$  is a random variable. The expected revenue  $g_{avg}(\pi)$  of a policy  $\pi$  can be written as

$$g_{avg}(\pi) = \mathbb{E}_{\Phi, \Pi}[g(E(\pi, \Phi), \Phi)]$$

where the expectation is taken over possible realizations according to  $p$  and the internal randomness of the policy. Similarly, the expected cost  $c_{avg}(\pi)$  of a policy  $\pi$  can be written as

$$c_{avg}(\pi) = \mathbb{E}_{\Phi, \Pi}[c(E(\pi, \Phi))]$$

## 69:4 Adaptive Regularized Submodular Maximization

We next introduce the conditional expected marginal revenue  $g(e \mid \psi)$  of  $e$  conditioned on a partial realization  $\psi$ :

$$g(e \mid \psi) = \mathbb{E}_{\Phi}[g(\text{dom}(\psi) \cup \{e\}, \Phi) - g(\text{dom}(\psi), \Phi) \mid \Phi \sim \psi]$$

where the expectation is taken over  $\Phi$  with respect to  $p(\phi \mid \psi) = \Pr(\Phi = \phi \mid \Phi \sim \psi)$ .

► **Definition 3** ([3], Adaptive Submodularity). *For any two partial realizations  $\psi$  and  $\psi'$  such that  $\psi \subseteq \psi'$ , we assume that the following holds for each  $e \in E \setminus \text{dom}(\psi')$ :*

$$g(e \mid \psi) \geq g(e \mid \psi') \quad (1)$$

Let  $\Omega = \{\pi \mid \forall \phi \in U^+, |E(\pi, \phi)| \leq k\}$  denote the set of all policies that select at most  $k$  items where  $U^+ = \{\phi \in U \mid p(\phi) > 0\}$ , our objective is listed in below:

$$\max_{\pi \in \Omega} g_{\text{avg}}(\pi) - c_{\text{avg}}(\pi) \quad (2)$$

Before presenting our solutions to the above problem, we introduce some additional notations. By abuse of notation, for any partial realization  $\psi$ , we define  $g(\psi) = \mathbb{E}_{\Phi \sim \psi}[g(\text{dom}(\psi), \Phi)]$ . We next introduce two useful functions:  $G_i$ , the distorted objective function, and  $H_i$ , which is used to analyze the trajectory of  $G_i$ . For any partial realization  $\psi$ , and any iteration  $i \in [k]$  of our algorithms, we define

$$G_i(\psi) = \left(1 - \frac{1}{k}\right)^{k-i} g(\psi) - c(\text{dom}(\psi))$$

For any partial realization  $\psi$ , and any iteration  $i \in [k-1]$  of our algorithms, we define

$$H_i(\psi, e) = \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi) - c_e$$

### 4 Monotone $g$ : Adaptive Distorted Greedy Policy

We start with the case when  $g$  is adaptive submodular and *adaptive monotone* [3], i.e., for any realization  $\psi$ , the following holds for each  $e \in E \setminus \text{dom}(\psi)$ :  $g(e \mid \psi) \geq 0$ . Our approach is a natural extension of the *Distorted-Greedy* algorithm, the first practical non-adaptive algorithm developed in [4]. Note that there are two factors that make our problem more complicated than its non-adaptive counterpart. First, since the objective function is defined over random realization, the key of analysis is to estimate the expected utility under the distribution of realizations  $p$ . Second, the policy itself might produce random outputs even under the same realization, this adds an additional layer of difficulty to the design and analysis of our policy. To address the above complications, we develop an *Adaptive Distorted Greedy Policy*  $\pi^d$  such that  $g_{\text{avg}}(\pi^d) - c_{\text{avg}}(\pi^d) \geq \left(1 - \frac{1}{e}\right) g_{\text{avg}}(\pi^o) - c_{\text{avg}}(\pi^o)$ , where  $\pi^o$  denotes the optimal policy. We next explain the idea of  $\pi^d$  (Algorithm 1), then analyze its performance bound.

#### 4.1 Design of $\pi^d$

We first add a dummy item  $d$  to the ground set, such that,  $c_d = 0$ , and for any partial realization  $\psi$ , we have  $g(d \mid \psi) = 0$ . Let  $E' = E \cup \{d\}$ . We add this to ensure that our policy will not select an item that has a negative profit. Note that  $d$  can be safely removed from the final solution without affecting its performance.  $\pi^d$  performs in  $k$  iterations: It starts with an empty set. In each iteration  $i \in [k-1]$ , let  $\psi_i$  denote the current partial realization,  $\pi^d$  selects an item  $e_i$  that maximizes  $H_i(\psi_i, \cdot)$ :

$$e_i \leftarrow \arg \max_{e \in E'} H_i(\psi_i, e)$$

After observing the state  $\Phi(e_i)$  of  $e_i$ , we update the current partial realization  $\psi_{i+1}$  using  $\psi_i \cup \{(e_i, \Phi(e_i))\}$  and enter the next iteration. This process iterates until all  $k$  items have been selected.

■ **Algorithm 1** Adaptive Distorted Greedy Policy  $\pi^d$ .

- 
- 1:  $S_0 = \emptyset; i = 0; \psi_0 = \emptyset$ .
  - 2: **while**  $i < k$  **do**
  - 3:    $e_i \leftarrow \arg \max_{e \in E'} H_i(\psi_i, e)$ ;
  - 4:    $S_{i+1} \leftarrow S_i \cup \{e_i\}$ ;
  - 5:    $\psi_{i+1} \leftarrow \psi_i \cup \{(e_i, \Phi(e_i))\}; i \leftarrow i + 1$ ;
  - 6: **return**  $S_k$
- 

## 4.2 Performance Analysis

We first present three preparatory lemmas which are used to lower bound the marginal gain in the distorted objective. Recall that  $\Psi_{i+1}$  refers to a random variable, and  $\psi_{i+1}$  is a realization of  $\Psi_{i+1}$ .

► **Lemma 4.** *In each iteration of  $\pi^d$ ,*

$$\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] = H_i(\psi_i, e_i) + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i)$$

**Proof.** We start with the case when  $e_i \in \text{dom}(\psi_i)$ ,

$$\begin{aligned} & \mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\ &= \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) - \left(1 - \frac{1}{k}\right)^{k-i} g(\psi_i) \\ &= \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) - \left(1 - \frac{1}{k}\right) \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\ &= \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\ &= H_i(\psi_i, e_i) + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \end{aligned}$$

The last equality is due to  $H_i(\psi_i, e_i) = 0$  when  $e_i \in \text{dom}(\psi_i)$ . We next prove the case when  $e_i \notin \text{dom}(\psi_i)$ ,

$$\begin{aligned} & \mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\ &= \mathbb{E}_{\Phi \sim \psi_i} \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i \cup \{\Phi(e_i)\}) \right. \\ & \quad \left. - c(\text{dom}(\psi_i) \cup \{e_i\}) - \left( \left(1 - \frac{1}{k}\right)^{k-i} g(\psi_i) - c(\text{dom}(\psi_i)) \right) \right] \\ &= \mathbb{E}_{\Phi \sim \psi_i} \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i \cup \{\Phi(e_i)\}) \right. \\ & \quad \left. - c(\text{dom}(\psi_i) \cup \{e_i\}) - \left( \left(1 - \frac{1}{k}\right)^{k-i} g(\psi_i) - c(\text{dom}(\psi_i)) \right) \right] \\ &= \mathbb{E}_{\Phi \sim \psi_i} \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i \cup \{\Phi(e_i)\}) \right. \\ & \quad \left. - c(\text{dom}(\psi_i) \cup \{e_i\}) - \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} \left(1 - \frac{1}{k}\right) g(\psi_i) - c(\text{dom}(\psi_i)) \right) \right] \\ &= \mathbb{E}_{\Phi \sim \psi_i} \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} (g(\psi_i \cup \{\Phi(e_i)\}) - g(\psi_i)) \right] - c_{e_i} + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \end{aligned}$$

## 69:6 Adaptive Regularized Submodular Maximization

$$\begin{aligned}
&= g(e_i \mid \psi_i) - c_{e_i} + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\
&= H_i(\psi_i, e_i) + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i)
\end{aligned}$$

The fourth equality is due to  $e_i \notin \text{dom}(\psi_i)$ .  $\blacktriangleleft$

► **Lemma 5.** *In each iteration of  $\pi^d$ ,*

$$H_i(\psi_i, e_i) \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{\text{avg}}(\pi^o) - g_{\text{avg}}(\pi_i^d)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)]$$

**Proof.** Let  $A_e$  be an indicator that  $e$  is selected by the optimal solution  $\pi^o$  conditioned on a partial realization  $\psi_i$ , then we have

$$\begin{aligned}
H_i(\psi_i, e_i) &= \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e_i \mid \psi_i) - c_{e_i} \\
&= \max_{e \in E'} \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) - c_e \right] \\
&\geq \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) - c_e \right] \\
&= \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) \right] - \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \times c_e \\
&= \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \left[ \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) \right] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)] \\
&\geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{\text{avg}}(\pi^o) - g_{\text{avg}}(\pi_i^d)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)]
\end{aligned}$$

The second equality is due to the design of  $\pi^d$ , i.e., it selects an item  $e_i$  that maximizes  $H_i(\psi_i, \cdot)$ . The first inequality is due to  $\sum_{e \in E'} \Pr[A_e = 1] \leq k$  since  $\pi^o$  selects at most  $k$  items. The third equality is due to the assumption that  $\Pr[A_e = 1]$  is the probability that  $e$  is selected by  $\pi^o$  conditioned on  $\psi_i$ . The second inequality is due to  $g$  is adaptive submodular.  $\blacktriangleleft$

► **Lemma 6.** *In each iteration of  $\pi^d$ ,*

$$\mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{\text{avg}}(\pi^o) - \frac{1}{k} c_{\text{avg}}(\pi^o)$$

**Proof.** We first prove that for any fixed partial realization  $\psi_i$ , the following inequality holds:

$$\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{\text{avg}}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)] \quad (3)$$

Due to Lemma 4, we have

$$\begin{aligned}
&\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\
&= H_i(\psi_i, e_i) + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\
&\geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{\text{avg}}(\pi^o) - g_{\text{avg}}(\pi_i^d)] \\
&\quad - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)] + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\
&= \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{\text{avg}}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{\text{avg}}(\pi^o)]
\end{aligned}$$

The inequality is due to Lemma 5 and the second equality is due to  $\mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi_i^d)] = g(\psi_i)$ . Now we are ready to prove this lemma.

$$\begin{aligned}
& \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\
& \geq \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\
& = \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o)] \right] - \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\
& = \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o)
\end{aligned}$$

The inequality is due to (3). ◀

We next present the first main theorem of this paper.

► **Theorem 7.**  $g_{avg}(\pi^d) - c_{avg}(\pi^d) \geq \left(1 - \frac{1}{e}\right) g_{avg}(\pi^o) - c_{avg}(\pi^o)$ .

**Proof.** According to the definition of  $G_k$ , we have  $\mathbb{E}_{\Psi_k} [G_k(\Psi_k)] = \mathbb{E}_{\Psi_k} \left[ \left(1 - \frac{1}{k}\right)^0 g(\Psi_k) - c(\text{dom}(\Psi_k)) \right] = g_{avg}(\pi^d) - c_{avg}(\pi^d)$  and  $\mathbb{E}_{\Psi_0} [G_0(\Psi_0)] = \mathbb{E}_{\Psi_0} \left[ \left(1 - \frac{1}{k}\right)^k g(\Phi(S_0)) - c(\text{dom}(\Psi_0)) \right] = 0$ . Hence,

$$\begin{aligned}
& g_{avg}(\pi^d) - c_{avg}(\pi^d) = \mathbb{E}_{\Psi_k} [G_k(\Psi_k)] - \mathbb{E}_{\Psi_0} [G_0(\Psi_0)] \\
& = \mathbb{E}_{\Psi_{k-1}} [\mathbb{E}_{\Phi \sim \Psi_{k-1}} [G_k(\Psi_k)]] - \mathbb{E}_{\Psi_0} [\mathbb{E}_{\Phi \sim \Psi_0} [G_0(\Psi_0)]] \\
& = \sum_{i \in [k-1]} (\mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1})]] - \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_i(\Psi_i)]]) \\
& = \sum_{i \in [k-1]} \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\
& \geq \sum_{i \in [k-1]} \left( \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o) \right) \\
& = \sum_{i \in [k-1]} \left( \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o) \right) - c_{avg}(\pi^o) \\
& \geq \left(1 - \frac{1}{e}\right) g_{avg}(\pi^o) - c_{avg}(\pi^o)
\end{aligned}$$

The first inequality is due to Lemma 6. ◀

## 5 Monotone $g$ : Linear-time Adaptive Distorted Greedy Policy

We next propose a faster algorithm *Linear-time Adaptive Distorted Greedy Policy*, denoted by  $\pi^l$ , for the case when  $g$  is adaptive monotone. As compared with  $\pi^d$  whose running time is  $O(nk)$ , our new policy  $\pi^l$  achieves nearly the same performance guarantee with  $O(n \log \frac{1}{\epsilon})$  value oracle queries. Our design is inspired by the sampling technique developed in [10] for maximizing a monotone and submodular function. Very recently, [14] extends this approach to the adaptive setting to develop a linear-time adaptive policy for maximizing an adaptive submodular and adaptive monotone function. In this work, we apply this technique to design a linear-time adaptive policy for our adaptive regularized submodular maximization problem. Note that our objectives are not adaptive monotone and they may take negative values.

## 5.1 Design of $\pi^l$

We present the details of our algorithm in Algorithm 2. We first add a set  $D$  of  $k-1$  dummy items to the ground set, such that, each dummy item  $d \in D$  has zero cost, i.e.,  $\forall d \in D, c_d = 0$ , and for any  $d \in D$ , and any partial realization  $\psi$ , we have  $g(d | \psi) = 0$ . Let  $E' = E \cup D$ . We next explain the idea of  $\pi^l$ : It starts with an empty set. In each iteration  $i \in [k-1]$ ,  $\pi^l$  first samples a set  $R_i$  of size  $\frac{n}{k} \log \frac{1}{\epsilon}$  uniformly at random, then adds an item  $e_i$  with the largest  $H_i(\psi_i, \cdot)$  from  $R_i$  to the solution. After observing the state  $\Phi(e_i)$  of  $e_i$ , we update the current partial realization  $\psi_{i+1}$  using  $\psi_i \cup \{(e_i, \Phi(e_i))\}$  and enter the next iteration. This process iterates until all  $k$  items have been selected. It is worth noting that the technique of lazy updates [9] can be used to further accelerate the computation of our algorithms in practice.

■ **Algorithm 2** Linear-time Adaptive Distorted Greedy Policy  $\pi^l$ .

---

```

1:  $S_0 = \emptyset; i = 0; \psi_0 = \emptyset.$ 
2: while  $i < k$  do
3:    $R_i \leftarrow$  a random set sampled uniformly at random from  $E'$ ;
4:    $e_i \leftarrow \arg \max_{e \in R_i} H_i(\psi_i, e);$ 
5:    $S_{i+1} \leftarrow S_i \cup \{e_i\};$ 
6:    $\psi_{i+1} \leftarrow \psi_i \cup \{(e_i, \Phi(e_i))\}; i \leftarrow i + 1;$ 
7: return  $S_k$ 

```

---

## 5.2 Performance Analysis

We first present three preparatory lemmas.

► **Lemma 8.** *In each iteration of  $\pi^l$ ,*

$$\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] = \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i)$$

The above lemma immediately follows from Lemma 4.

► **Lemma 9.** *In each iteration of  $\pi^l$ ,  $\mathbb{E}_{e_i} [H_i(\psi_i, e_i)] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o) - g_{avg}(\pi_i^l)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)].$*

**Proof.** Let  $A_e$  be an indicator that  $e$  is selected by the optimal solution  $\pi^o$  conditioned on a partial realization  $\psi_i$ . Let  $B_e$  be an indicator that  $e$  is selected by  $\pi^l$  in iteration  $i$  conditioned on a partial realization  $\psi_i$ . Let  $M(\psi_i)$  denote the top  $k$  items with the largest marginal contribution to  $\psi_i$  in terms of  $H_i(\psi_i, \cdot)$ , i.e.,  $M(\psi_i) \leftarrow \arg \max_{S \subseteq E', |S|=k} \sum_{e \in S} H_i(\psi_i, e)$ . Then we have

$$\begin{aligned} & \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] \\ &= \sum_{e \in E'} \Pr[B_e = 1] \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e | \psi_i) - c_e \right) \\ &\geq \Pr[R_i \cap M(\psi_i) \neq \emptyset] \frac{1}{k} \sum_{e \in M(\psi_i)} \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e | \psi_i) - c_e \right) \\ &\geq (1 - \epsilon) \frac{1}{k} \sum_{e \in M(\psi_i)} \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e | \psi_i) - c_e \right) \\ &\geq (1 - \epsilon) \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e | \psi_i) - c_e \right) \\ &\geq (1 - \epsilon) \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o) - g_{avg}(\pi_i^l)] - (1 - \epsilon) \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \end{aligned}$$

The second inequality is due to Lemma 4 in [14], where they show that  $\Pr[R_i \cap M(\psi_i) \neq \emptyset] \geq 1 - \epsilon$  given that  $R_i$  has size of  $\frac{n}{k} \log \frac{1}{\epsilon}$ . The third inequality is due to  $\sum_{e \in E'} \Pr[A_e = 1] \leq k$ . The last inequality is due to  $g$  is adaptive submodular and  $c$  is modular.  $\blacktriangleleft$

► **Lemma 10.** *In each iteration of  $\pi^l$ ,*

$$\begin{aligned} & \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\ & \geq (1 - \epsilon) \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} g_{avg}(\pi^o) - (1 - \epsilon) \frac{1}{k} c_{avg}(\pi^o) \end{aligned}$$

**Proof.** We first show that for any fixed partial realization  $\psi_i$ ,

$$\begin{aligned} & \mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\ & \geq (1 - \epsilon) \left( \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \right) \end{aligned} \quad (4)$$

Due to Lemma 8, we have

$$\begin{aligned} & \mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\ & = \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] + \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} g(\psi_i) \\ & \geq (1 - \epsilon) \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o) - g_{avg}(\pi_i^l)] \\ & \quad - (1 - \epsilon) \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] + \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} g(\psi_i) \\ & = (1 - \epsilon) \left( \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \right) \\ & \quad + \epsilon \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} g(\psi_i) \\ & \geq (1 - \epsilon) \left( \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \right) \end{aligned}$$

The first inequality is due to Lemma 9, the second equality is due to  $\mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi_i^l)] = g(\psi_i)$ , and the last inequality is due to  $g$  is non-negative. Now we are ready to prove this lemma.

$$\begin{aligned} & \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\ & \geq (1 - \epsilon) \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\ & = (1 - \epsilon) \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o)] \right] - \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\ & = (1 - \epsilon) \frac{1}{k} (1 - \frac{1}{k})^{k-(i+1)} g_{avg}(\pi^o) - (1 - \epsilon) \frac{1}{k} c_{avg}(\pi^o) \end{aligned}$$

The first inequality is due to (4).  $\blacktriangleleft$

We next present the second main theorem of this paper.

► **Theorem 11.**  $g_{avg}(\pi^l) - c_{avg}(\pi^l) \geq (1 - \frac{1}{e} - \epsilon) g_{avg}(\pi^o) - c_{avg}(\pi^o)$ .

**Proof.** According to the definition of  $G_k$ , we have  $\mathbb{E}_{\Psi_k} [G_k(\Psi_k)] = \mathbb{E}_{\Psi_k} [(1 - \frac{1}{k})^0 g(\Psi_k) - c(\text{dom}(\Psi_k))] = g_{avg}(\pi^l) - c_{avg}(\pi^l)$  and  $\mathbb{E}_{\Psi_0} [G_0(\Psi_0)] = \mathbb{E}_{\Psi_0} [(1 - \frac{1}{k})^k g(\Phi(S_0)) - c(\text{dom}(\Psi_0))] = 0$ . Hence,

$$\begin{aligned}
& g_{avg}(\pi^l) - c_{avg}(\pi^l) \\
&= \mathbb{E}_{\Psi_k}[G_k(\Psi_k)] - \mathbb{E}_{\Psi_0}[G_0(\Psi_0)] \\
&= \mathbb{E}_{\Psi_{k-1}}[\mathbb{E}_{\Phi \sim \Psi_{k-1}}[G_k(\Psi_k)]] - \mathbb{E}_{\Psi_0}[\mathbb{E}_{\Phi \sim \Psi_0}[G_0(\Psi_0)]] \\
&= \sum_{i \in [k-1]} (\mathbb{E}_{\Psi_i}[\mathbb{E}_{\Phi \sim \Psi_i}[G_{i+1}(\Psi_{i+1})]] - \mathbb{E}_{\Psi_i}[\mathbb{E}_{\Phi \sim \Psi_i}[G_i(\Psi_i)]]) \\
&= \sum_{i \in [k-1]} \mathbb{E}_{\Psi_i}[\mathbb{E}_{\Phi \sim \Psi_i}[G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\
&\geq \sum_{i \in [k-1]} \left( (1-\epsilon) \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o) - (1-\epsilon) \frac{1}{k} c_{avg}(\pi^o) \right) \\
&= \sum_{i \in [k-1]} \left( (1-\epsilon) \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o) \right) - (1-\epsilon) c_{avg}(\pi^o) \\
&\geq (1-\epsilon) \left(1 - \frac{1}{e}\right) g_{avg}(\pi^o) - (1-\epsilon) c_{avg}(\pi^o) \\
&\geq \left(1 - \frac{1}{e} - \epsilon\right) g_{avg}(\pi^o) - c_{avg}(\pi^o)
\end{aligned}$$

The first inequality is due to Lemma 10. ◀

## 6 Non-monotone $g$ : Adaptive Random Distorted Greedy Policy

We next discuss the case when  $g$  is non-monotone adaptive submodular. We present an *Adaptive Random Distorted Greedy Policy*  $\pi^r$  for this case.

### 6.1 Design of $\pi^r$

The detailed implementation of  $\pi^r$  is listed in Algorithm 3. We first add a set  $D$  of  $k-1$  dummy items to the ground set, such that, for any  $d \in D$ , and any partial realization  $\psi$ , we have  $c_d = 0$  and  $g(d \mid \psi) = 0$ . Let  $E' = E \cup D$ .  $\pi^r$  runs round by round: Starting with an empty set. In each iteration  $i \in [k-1]$ ,  $\pi^r$  randomly selects an item from the set  $M(\psi_i)$ . Recall that  $M(\psi_i)$  is a set of  $k$  items that have the largest  $H_i(\psi_i, \cdot)$ , i.e.,

$$M(\psi_i) \leftarrow \arg \max_{S \subseteq E'; |S|=k} \sum_{e \in S} H_i(\psi_i, e)$$

After observing the state  $\Phi(e_i)$  of  $e_i$ , we update the current partial realization  $\psi_{i+1}$  using  $\psi_i \cup \{(e_i, \Phi(e_i))\}$  and enter the next iteration. This process iterates until all  $k$  items have been selected.

■ **Algorithm 3** Adaptive Random Distorted Greedy Policy  $\pi^r$ .

- 
- 1:  $S_0 = \emptyset; i = 0; \psi_0 = \emptyset$ .
  - 2: **while**  $i < k$  **do**
  - 3:    $M(\psi_i) \leftarrow \arg \max_{S \subseteq E'; |S|=k} \sum_{e \in S} H_i(\psi_i, e)$ ;
  - 4:   sample  $e_i$  uniformly at random from  $M(\psi_i)$ ;
  - 5:    $S_{i+1} \leftarrow S_i \cup \{e_i\}$ ;
  - 6:    $\psi_{i+1} \leftarrow \psi_i \cup \{(e_i, \Phi(e_i))\}$ ;  $i \leftarrow i + 1$ ;
  - 7: **return**  $S_k$
-

## 6.2 Performance Analysis

We first present three preparatory lemmas. The first lemma immediately follows from Lemma 4.

► **Lemma 12.** *In each iteration of  $\pi^r$ ,*

$$\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] = \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i)$$

► **Lemma 13.** *In each iteration of  $\pi^r$ ,  $\mathbb{E}_{e_i} [H_i(\psi_i, e_i)] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - g_{avg}(\pi_i^r) - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)]$ .*

**Proof.** Recall that  $A_e$  is an indicator that  $e$  is selected by the optimal solution  $\pi^o$  conditioned on a partial realization  $\psi_i$ ,

$$\begin{aligned} & \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] \\ &= \frac{1}{k} \sum_{e \in M(\psi_i)} \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) - c_e \right) \\ &\geq \frac{1}{k} \sum_{e \in E'} \Pr[A_e = 1] \left( \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(e \mid \psi_i) - c_e \right) \\ &\geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - g_{avg}(\pi_i^r) - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \end{aligned}$$

The equality is due to the design of  $\pi^r$ , i.e., it selects an item  $e_i$  uniformly at random from  $M(\psi_i)$ . The first inequality is due to  $\sum_{e \in E'} \Pr[A_e = 1] \leq k$  since  $\pi^o$  selects at most  $k$  items, and  $M(\psi_i)$  contains a set of  $k$  items that have the largest  $H_i(\psi_i, \cdot)$ . The second inequality is due to  $g$  is adaptive submodular and  $c$  is modular. ◀

► **Lemma 14.** *In each iteration of  $\pi^r$ ,*

$$\mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-1} g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o)$$

**Proof.** We first show that for any fixed partial realization  $\psi_i$ ,

$$\mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \quad (5)$$

Due to Lemma 12, we have

$$\begin{aligned} & \mathbb{E}_{\Phi \sim \psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\psi_i)] \\ &= \mathbb{E}_{e_i} [H_i(\psi_i, e_i)] + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\ &\geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - g_{avg}(\pi_i^r) \\ &\quad - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] + \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g(\psi_i) \\ &= \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \psi_i} [c_{avg}(\pi^o)] \end{aligned}$$

## 69:12 Adaptive Regularized Submodular Maximization

The first inequality is due to Lemma 13. The second equality is due to  $\mathbb{E}_{\Phi \sim \psi_i} [g_{avg}(\pi_i^r)] = g(\psi_i)$ . The last inequality is due to  $g$  is non-negative. Now we are ready to prove this lemma.

$$\begin{aligned}
& \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\
& \geq \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o @ \pi_i^r)] - \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\
& = \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \mathbb{E}_{\Phi \sim \Psi_i} [g_{avg}(\pi^o @ \pi_i^r)] \right] - \mathbb{E}_{\Psi_i} \left[ \frac{1}{k} \mathbb{E}_{\Phi \sim \Psi_i} [c_{avg}(\pi^o)] \right] \\
& = \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} g_{avg}(\pi^o @ \pi_i^r) - \frac{1}{k} c_{avg}(\pi^o) \\
& \geq \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-(i+1)} \left(1 - \frac{1}{k}\right)^i g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o) \\
& = \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-1} g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o)
\end{aligned}$$

The first inequality is due to (5), and the second inequality is due to Lemma 1 in [14], where they show that  $g_{avg}(\pi^o @ \pi_i^r) \geq \left(1 - \frac{1}{k}\right)^i g_{avg}(\pi^o)$ . ◀

We next present the third main theorem of this paper.

► **Theorem 15.**  $g_{avg}(\pi^r) - c_{avg}(\pi^r) \geq \frac{1}{e} g_{avg}(\pi^o) - c_{avg}(\pi^o)$ .

**Proof.** According to the definition of  $G_k$ , we have  $\mathbb{E}_{\Psi_k} [G_k(\Psi_k)] = \mathbb{E}_{\Psi_k} [(1 - \frac{1}{k})^0 g(\Psi_k) - c(\text{dom}(\Psi_k))] = g_{avg}(\pi^r) - c_{avg}(\pi^r)$  and  $\mathbb{E}_{\Psi_0} [G_0(\Psi_0)] = \mathbb{E}_{\Psi_0} [(1 - \frac{1}{k})^k g(\Phi(S_0)) - c(\text{dom}(\Psi_0))] = 0$ . Hence,

$$\begin{aligned}
g_{avg}(\pi^r) - c_{avg}(\pi^r) &= \mathbb{E}_{\Psi_k} [G_k(\Psi_k)] - \mathbb{E}_{\Psi_0} [G_0(\Psi_0)] \\
&= \mathbb{E}_{\Psi_{k-1}} [\mathbb{E}_{\Phi \sim \Psi_{k-1}} [G_k(\Psi_k)]] - \mathbb{E}_{\Psi_0} [\mathbb{E}_{\Phi \sim \Psi_0} [G_0(\Psi_0)]] \\
&= \sum_{i \in [k-1]} (\mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1})]] - \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_i(\Psi_i)]]) \\
&= \sum_{i \in [k-1]} \mathbb{E}_{\Psi_i} [\mathbb{E}_{\Phi \sim \Psi_i} [G_{i+1}(\Psi_{i+1}) - G_i(\Psi_i)]] \\
&\geq \sum_{i \in [k-1]} \left( \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-1} g_{avg}(\pi^o) - \frac{1}{k} c_{avg}(\pi^o) \right) \\
&= \sum_{i \in [k-1]} \frac{1}{k} \left(1 - \frac{1}{k}\right)^{k-1} g_{avg}(\pi^o) - c_{avg}(\pi^o) \\
&\geq \frac{1}{e} g_{avg}(\pi^o) - c_{avg}(\pi^o)
\end{aligned}$$

The first inequality is due to Lemma 14. ◀

## 7 Conclusion

In this paper, we study the adaptive regularized submodular maximization problem. Because our objective function may take both negative and positive values, most existing technologies of submodular maximization do not apply to our setting. We develop a series of effective policies for this problem.

## Abstract

For an abelian group  $\Gamma$ , a  $\Gamma$ -labelled graph is a graph whose vertices are labelled by elements of  $\Gamma$ . We prove that a certain collection of edge sets of a  $\Gamma$ -labelled graph forms a delta-matroid, which we call a  $\Gamma$ -graphic delta-matroid, and provide a polynomial-time algorithm to solve the separation problem, which allows us to apply the symmetric greedy algorithm of Bouchet to find a maximum weight feasible set in such a delta-matroid. We present two algorithmic applications on graphs; MAXIMUM WEIGHT PACKING OF TREES OF ORDER NOT DIVISIBLE BY  $k$  and MAXIMUM WEIGHT  $S$ -TREE PACKING. We also discuss various properties of  $\Gamma$ -graphic delta-matroids.

## 1 Introduction

We introduce the class of  $\Gamma$ -graphic delta-matroids arising from graphs whose vertices are labelled by elements of an abelian group  $\Gamma$ . This allows us to show that the following problems are solvable in polynomial time by using the symmetric greedy algorithm [1].

MAXIMUM WEIGHT PACKING OF TREES OF ORDER NOT DIVISIBLE BY  $k$

**Input:** An integer  $k \geq 2$ , a graph  $G$ , and a weight  $w : E(G) \rightarrow \mathbb{Q}$ .

**Problem:** Find vertex-disjoint trees  $T_1, T_2, \dots, T_m$  for some  $m$  such that  $|V(T_i)| \not\equiv 0 \pmod{k}$  for each  $i \in \{1, \dots, m\}$  and  $\sum_{i=1}^m \sum_{e \in E(T_i)} w(e)$  is maximized.

For a vertex set  $S$  of a graph  $G$ , a subgraph of  $G$  is an  $S$ -tree if it is a tree intersecting  $S$ .

MAXIMUM WEIGHT  $S$ -TREE PACKING

**Input:** A graph  $G$ , a nonempty subset  $S$  of  $V(G)$ , and a weight  $w : E(G) \rightarrow \mathbb{Q}$ .

**Problem:** Find vertex-disjoint  $S$ -trees  $T_1, T_2, \dots, T_m$  for some  $m$  such that  $\bigcup_{i=1}^m V(T_i) = V(G)$  and  $\sum_{i=1}^m \sum_{e \in E(T_i)} w(e)$  is maximized.

Let  $\Gamma$  be an abelian group. We assume that  $\Gamma$  is an additive group. A  $\Gamma$ -labelled graph is a pair  $(G, \gamma)$  of a graph  $G$  and a map  $\gamma : V(G) \rightarrow \Gamma$ . A subgraph  $H$  of  $G$  is  $\gamma$ -nonzero if, for each component  $C$  of  $H$ ,

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- (G1)  $\sum_{v \in V(C)} \gamma(v) \neq 0$  or  $\gamma|_{V(C)} \equiv 0$ , and
- (G2) if  $\gamma|_{V(C)} \equiv 0$ , then  $G[V(C)]$  is a component of  $G$ .

A subset  $F$  of  $E(G)$  is  $\gamma$ -nonzero in  $G$  if a subgraph  $(V(G), F)$  is  $\gamma$ -nonzero. A subset  $F$  of  $E(G)$  is *acyclic* in  $G$  if a subgraph  $(V(G), F)$  has no cycle.

Bouchet [1] introduced delta-matroids which are set systems  $(E, \mathcal{F})$  satisfying certain axioms. Our first theorem proves that the set of acyclic  $\gamma$ -nonzero sets in a  $\Gamma$ -labelled graph  $(G, \gamma)$  forms a delta-matroid, which we call a  $\Gamma$ -graphic delta-matroid. For sets  $X$  and  $Y$ , let  $X \Delta Y = (X - Y) \cup (Y - X)$ .

► **Theorem 1.** *Let  $\Gamma$  be an abelian group and  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. If  $\mathcal{F}$  is the set of acyclic  $\gamma$ -nonzero sets in  $G$ , then the following hold.*

- (1)  $\mathcal{F} \neq \emptyset$ .
- (2) For  $X, Y \in \mathcal{F}$  and  $e \in X \Delta Y$ , there exists  $f \in X \Delta Y$  such that  $X \Delta \{e, f\} \in \mathcal{F}$ .

Bouchet [1] proved that the symmetric greedy algorithm finds a maximum weight set in  $\mathcal{F}$  for a delta-matroid  $(E, \mathcal{F})$ . But it requires the *separation oracle*, which determines, for two disjoint subsets  $X$  and  $Y$  of  $E$ , whether there exists a set  $F \in \mathcal{F}$  such that  $X \subseteq F$  and  $F \cap Y = \emptyset$ . We provide the separation oracle that runs in polynomial time for  $\Gamma$ -graphic delta-matroids given by  $\Gamma$ -labelled graphs. As a consequence, we prove the following theorem.

**MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET**

**Input:** A  $\Gamma$ -labelled graph  $(G, \gamma)$  and a weight  $w : E(G) \rightarrow \mathbb{Q}$ .

**Problem:** Find an acyclic  $\gamma$ -nonzero set  $F$  in  $G$  maximizing  $\sum_{e \in F} w(e)$ .

► **Theorem 2.** *MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET is solvable in polynomial time.*

From Theorem 2, we can easily deduce that both MAXIMUM WEIGHT PACKING OF TREES OF ORDER NOT DIVISIBLE BY  $k$  and MAXIMUM WEIGHT  $S$ -TREE PACKING are solvable in polynomial time.

► **Corollary 3.** *MAXIMUM WEIGHT PACKING OF TREES OF ORDER NOT DIVISIBLE BY  $k$  is solvable in polynomial time.*

**Proof.** Let  $\Gamma = \mathbb{Z}_k$  and  $\gamma : V(G) \rightarrow \mathbb{Z}_k$  be a map such that  $\gamma(v) = 1$  for each  $v \in V(G)$ . Then, an edge set  $F$  is an acyclic  $\gamma$ -nonzero set in  $(G, \gamma)$  if and only if there exist vertex-disjoint trees  $T_1, \dots, T_m$  for some  $m$  such that  $\bigcup_{i=1}^m E(T_i) = F$  and  $|V(T_i)| \not\equiv 0 \pmod{k}$  for each  $i \in \{1, \dots, m\}$ . ◀

► **Corollary 4.** *MAXIMUM WEIGHT  $S$ -TREE PACKING is solvable in polynomial time.*

**Proof.** We may assume that every component of  $G$  has a vertex in  $S$ . Let  $\Gamma = \mathbb{Z}$  and  $\gamma : V(G) \rightarrow \mathbb{Z}$  be a map such that

$$\gamma(v) = \begin{cases} 1 & \text{if } v \in S, \\ 0 & \text{otherwise.} \end{cases}$$

Then, an edge set  $F$  is an acyclic  $\gamma$ -nonzero set in  $(G, \gamma)$  if and only if there exist vertex-disjoint  $S$ -trees  $T_1, \dots, T_m$  for some  $m$  such that  $\bigcup_{i=1}^m V(T_i) = V(G)$  and  $\bigcup_{i=1}^m E(T_i) = F$ . ◀

One of the major motivations to introduce  $\Gamma$ -graphic delta-matroids is to generalize the concept of graphic delta-matroids introduced by Oum [8], which are precisely  $\mathbb{Z}_2$ -graphic delta-matroids. Oum [8] proved that every minor of graphic delta-matroids is graphic. We will prove that every minor of a  $\Gamma$ -graphic delta-matroid is  $\Gamma$ -graphic.

A delta-matroid  $(E, \mathcal{F})$  is *even* if  $|X \Delta Y|$  is even for all  $X, Y \in \mathcal{F}$ . Oum [8] proved that every graphic delta-matroid is even. We characterize even  $\Gamma$ -graphic delta-matroids as follows.

► **Theorem 5.** *Let  $\Gamma$  be an abelian group. Then a  $\Gamma$ -graphic delta-matroid is even if and only if it is graphic.*

Bouchet [2] proved that for a symmetric or skew-symmetric matrix  $A$  over a field  $\mathbb{F}$ , the set of index sets of nonsingular principal submatrices of  $A$  forms a delta-matroid, which we call a delta-matroid *representable over  $\mathbb{F}$* . Oum [8] proved that every graphic delta-matroid is representable over  $\text{GF}(2)$ . Our next theorem partially characterizes a pair of an abelian group  $\Gamma$  and a field  $\mathbb{F}$  such that every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ .

If  $\mathbb{F}_1$  is a subfield of a field  $\mathbb{F}_2$ , then  $\mathbb{F}_2$  is an *extension field* of  $\mathbb{F}_1$ , denoted by  $\mathbb{F}_2/\mathbb{F}_1$ . The *degree* of a field extension  $\mathbb{F}_2/\mathbb{F}_1$ , denoted by  $[\mathbb{F}_2 : \mathbb{F}_1]$ , is the dimension of  $\mathbb{F}_2$  as a vector space over  $\mathbb{F}_1$ .

► **Theorem 6.** *Let  $p$  be a prime,  $k$  be a positive integer, and  $\mathbb{F}$  be a field of characteristic  $p$ . If  $[\mathbb{F} : \text{GF}(p)] \geq k$ , then every  $\mathbb{Z}_p^k$ -graphic delta-matroid is representable over  $\mathbb{F}$ .*

For a prime  $p$ , an abelian group is an *elementary abelian  $p$ -group* if every nonzero element has order  $p$ .

► **Theorem 7.** *Let  $\mathbb{F}$  be a finite field of characteristic  $p$  and  $\Gamma$  be an abelian group. If every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ , then  $\Gamma$  is an elementary abelian  $p$ -group.*

Theorems 6 and 7 allow us to partially characterize pairs of a finite field  $\mathbb{F}$  and an abelian group  $\Gamma$  for which every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$  as follows. We omit its easy proof.

► **Corollary 8.** *Let  $\Gamma$  be a finite abelian group of order at least 2 and  $\mathbb{F}$  be a finite field.*

- (i) *For every prime  $p$  and integers  $1 \leq k \leq \ell$ , every  $\mathbb{Z}_p^k$ -graphic delta-matroid is representable over  $\text{GF}(p^\ell)$ .*
- (ii) *If every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ , then  $\Gamma$  is isomorphic to  $\mathbb{Z}_p^k$  and  $\mathbb{F}$  is isomorphic to  $\text{GF}(p^\ell)$  for a prime  $p$  and positive integers  $k$  and  $\ell$ .*

We suspect that the following could be the complete characterization.

► **Conjecture 9.** *Let  $\Gamma$  be a finite abelian group of order at least 2 and  $\mathbb{F}$  be a finite field. Then every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$  if and only if  $(\Gamma, \mathbb{F}) = (\mathbb{Z}_p^k, \text{GF}(p^\ell))$  for some prime  $p$  and positive integers  $k \leq \ell$ .*

This paper is organized as follows. In Section 2, we review some terminologies and results on delta-matroids and graphic delta-matroids. In Section 3, we introduce  $\Gamma$ -graphic delta-matroids. We show that the class of  $\Gamma$ -graphic delta-matroids is closed under taking minors in Section 4. In Section 5, we present a polynomial-time algorithm to solve MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET, proving Theorem 2. We characterize even  $\Gamma$ -graphic delta-matroids in Section 6. In Section 7, we prove Theorems 6 and 7. We provide some proofs in the full version when lemmas and theorems are marked by \*.

## 2 Preliminaries

In this paper, all graphs are finite and may have parallel edges and loops. A graph is *simple* if it has neither loops nor parallel edges. For a graph  $G$ , *contracting* an edge  $e$  is an operation to obtain a new graph  $G/e$  from  $G$  by deleting  $e$  and identifying ends of  $e$ . For a set  $X$  and

a positive integer  $s$ , let  $\binom{X}{s}$  be the set of  $s$ -element subsets of  $X$ . For two sets  $A$  and  $B$ , let  $A\Delta B = (A - B) \cup (B - A)$ . For a function  $f : X \rightarrow Y$  and a subset  $A \subseteq X$ , we write  $f|_A$  to denote the restriction of  $f$  on  $A$ .

**Delta-matroids.** Bouchet [1] introduced delta-matroids. A *delta-matroid* is a pair  $M = (E, \mathcal{F})$  of a finite set  $E$  and a nonempty set  $\mathcal{F}$  of subsets of  $E$  such that if  $X, Y \in \mathcal{F}$  and  $x \in X\Delta Y$ , then there is  $y \in Y\Delta X$  such that  $X\Delta\{x, y\} \in \mathcal{F}$ . We write  $E(M) = E$  to denote the *ground set* of  $M$ . An element of  $\mathcal{F}$  is called a *feasible set*. An element of  $E$  is a *loop* of  $M$  if it is not contained in any feasible set of  $M$ . An element of  $E$  is a *coloop* of  $M$  if it is contained in every feasible set of  $M$ .

**Minors.** For a delta-matroid  $M = (E, \mathcal{F})$  and a subset  $X$  of  $E$ , we can obtain a new delta-matroid  $M\Delta X = (E, \mathcal{F}\Delta X)$  from  $M$  where  $\mathcal{F}\Delta X = \{F\Delta X : F \in \mathcal{F}\}$ . This operation is called *twisting* a set  $X$  in  $M$ . A delta-matroid  $N$  is *equivalent* to  $M$  if  $N = M\Delta X$  for some set  $X$ .

If there is a feasible subset of  $E - X$ , then  $M \setminus X = (E - X, \mathcal{F} \setminus X)$  is a delta-matroid where  $\mathcal{F} \setminus X = \{F \in \mathcal{F} : F \cap X = \emptyset\}$ . This operation of obtaining  $M \setminus X$  is called the *deletion* of  $X$  in  $M$ . A delta-matroid  $N$  is a *minor* of a delta-matroid  $M$  if  $N = M\Delta X \setminus Y$  for some subsets  $X, Y$  of  $E$ .

A delta-matroid is *normal* if  $\emptyset$  is feasible. A delta-matroid is *even* if  $|X\Delta Y|$  is even for all feasible sets  $X$  and  $Y$ . It is easy to see that all minors of even delta-matroids are even.

The following theorem gives the minimal obstruction for even delta-matroids, which is implied by Bouchet [3, Lemma 5.4].

► **Theorem 10** (Bouchet [3]). *A delta-matroid is even if and only if it does not have a minor isomorphic to  $(\{e\}, \{\emptyset, \{e\}\})$ .*

It is easy to observe the following.

► **Lemma 11.** *Let  $N$  be a minor of a delta-matroid  $M$  such that  $|E(M)| > |E(N)|$ . Then there exists an element  $e \in E(M) - E(N)$  such that  $N$  is a minor of  $M \setminus e$  or a minor of  $M\Delta\{e\} \setminus e$ .*

**Representable delta-matroids.** For an  $R \times C$  matrix  $A$  and subsets  $X$  of  $R$  and  $Y$  of  $C$ , we write  $A[X, Y]$  to denote the  $X \times Y$  submatrix of  $A$ . For an  $E \times E$  square matrix  $A$  and a subset  $X$  of  $E$ , we write  $A[X]$  to denote  $A[X, X]$ , which is called an  $X \times X$  *principal* submatrix of  $A$ .

For an  $E \times E$  square matrix  $A$ , let  $\mathcal{F}(A) = \{X \subseteq E : A[X] \text{ is nonsingular}\}$ . We assume that  $A[\emptyset]$  is nonsingular and so  $\emptyset \in \mathcal{F}(A)$ . Bouchet [2] proved that,  $(E, \mathcal{F}(A))$  is a delta-matroid if  $A$  is an  $E \times E$  symmetric or skew-symmetric matrix. A delta-matroid  $M = (E, \mathcal{F})$  is *representable over* a field  $\mathbb{F}$  if  $\mathcal{F} = \mathcal{F}(A)\Delta X$  for a symmetric or skew-symmetric matrix  $A$  over  $\mathbb{F}$  and a subset  $X$  of  $E$ . Since  $\emptyset \in \mathcal{F}(A)$ , it is natural to define representable delta-matroids with twisting so that the empty set is not necessarily feasible in representable delta-matroids.

A delta-matroid is *binary* if it is representable over  $\text{GF}(2)$ . Note that all diagonal entries of a skew-symmetric matrix are zero, even if the characteristic of a field is 2.

► **Proposition 12** (Bouchet [2]). *Let  $M = (E, \mathcal{F})$  be a delta-matroid. Then  $M$  is normal and representable over a field  $\mathbb{F}$  if and only if there is an  $E \times E$  symmetric or skew-symmetric matrix  $A$  over  $\mathbb{F}$  such that  $\mathcal{F} = \mathcal{F}(A)$ .*

► **Lemma 13** (Geelen [5, page 27]). *Let  $M$  be a delta-matroid representable over a field  $\mathbb{F}$ . Then  $M$  is even if and only if  $M$  is representable by a skew-symmetric matrix over  $\mathbb{F}$ .*

**Pivoting.** For a finite set  $E$  and a symmetric or skew-symmetric  $E \times E$  matrix  $A$ , if  $A$  is represented by

$$A = \begin{matrix} & X & Y \\ X & \alpha & \beta \\ Y & \gamma & \delta \end{matrix}$$

after selecting a linear ordering of  $E$  and  $A[X] = \alpha$  is nonsingular, then let

$$A * X = \begin{matrix} & X & Y \\ X & \alpha^{-1} & \alpha^{-1}\beta \\ Y & -\gamma\alpha^{-1} & \delta - \gamma\alpha^{-1}\beta \end{matrix}$$

This operation is called *pivoting*. Tucker [11] proved that when  $A[X]$  is nonsingular,  $A * X[Y]$  is nonsingular if and only if  $A[X\Delta Y]$  is nonsingular for each subset  $Y$  of  $E$ . Hence, if  $X$  is a feasible set of a delta-matroid  $M = (E, \mathcal{F}(A))$ , then  $M\Delta X = (E, \mathcal{F}(A * X))$ . It implies that all minors of delta-matroids representable over a field  $\mathbb{F}$  are representable over  $\mathbb{F}$  [4].

**Greedy algorithm.** Let  $M = (E, \mathcal{F})$  be a set system such that  $E$  is finite and  $\mathcal{F} \neq \emptyset$ . A pair  $(X, Y)$  of disjoint subsets  $X$  and  $Y$  of  $E$  is *separable* in  $M$  if there exists a set  $F \in \mathcal{F}$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ . The following theorem characterizes delta-matroids in terms of a greedy algorithm. Note that this greedy algorithm requires an oracle which answers whether a pair  $(X, Y)$  of disjoint subsets  $X$  and  $Y$  of  $E$  is separable in  $M$ .

► **Theorem 14** (Bouchet [1]; see Moffatt [7]). *Let  $M = (E, \mathcal{F})$  be a set system such that  $E$  is finite and  $\mathcal{F} \neq \emptyset$ . Then  $M$  is a delta-matroid if and only if the symmetric greedy algorithm in Algorithm 1 gives a set  $F \in \mathcal{F}$  maximizing  $\sum_{e \in F} w(e)$  for each  $w : E \rightarrow \mathbb{R}$ .*

**Graphic delta-matroids.** Oum [8] introduced graphic delta-matroid. A *graft* is a pair  $(G, T)$  of a graph  $G$  and a subset  $T$  of  $V(G)$ . A subgraph  $H$  of  $G$  is  *$T$ -spanning* in  $G$  if  $V(H) = V(G)$ , for each component  $C$  of  $H$ , either

- (i)  $|V(C) \cap T|$  is odd, or
- (ii)  $V(C) \cap T = \emptyset$  and  $G[V(C)]$  is a component of  $G$ .

An edge set  $F$  of  $G$  is  *$T$ -spanning* in  $G$  if a subgraph  $(V(G), F)$  is  $T$ -spanning in  $G$ . For a graft  $(G, T)$ , let  $\mathcal{G}(G, T) = (E(G), \mathcal{F})$  where  $\mathcal{F}$  is the set of acyclic  $T$ -spanning sets in  $G$ . Oum [8] proved that  $\mathcal{G}(G, T)$  is an even binary delta-matroid. A delta-matroid is *graphic* if it is equivalent to  $\mathcal{G}(G, T)$  for a graft  $(G, T)$ .

### 3 Delta-matroids from group-labelled graphs

Let  $\Gamma$  be an abelian group. A  $\Gamma$ -labelled graph  $(G, \gamma)$  is a pair of a graph  $G$  and a map  $\gamma : V(G) \rightarrow \Gamma$ . We say  $\gamma \equiv 0$  if  $\gamma(v) = 0$  for all  $v \in V(G)$ . A  $\Gamma$ -labelled graph  $(G, \gamma)$  and a  $\Gamma'$ -labelled graph  $(G', \gamma')$  are *isomorphic* if there are a graph isomorphism  $f$  from  $G$  to  $G'$  and a group isomorphism  $\phi : \Gamma \rightarrow \Gamma'$  such that  $\phi(\gamma(v)) = \gamma'(f(v))$  for each  $v \in V(G)$ .

■ **Algorithm 1** Symmetric greedy algorithm.

---

A subgraph  $H$  of  $G$  is  $\gamma$ -nonzero if, for each component  $C$  of  $H$ ,

(G1)  $\sum_{v \in V(C)} \gamma(v) \neq 0$  or  $\gamma|_{V(C)} \equiv 0$ , and

(G2) if  $\gamma|_{V(C)} \equiv 0$ , then  $G[V(C)]$  is a component of  $G$ .

An edge set  $F$  of  $E(G)$  is  $\gamma$ -nonzero in  $G$  if a subgraph  $(V(G), F)$  is  $\gamma$ -nonzero. An edge set  $F$  of  $E(G)$  is *acyclic* in  $G$  if a subgraph  $(V(G), F)$  has no cycle.

For an abelian group  $\Gamma$  and a  $\Gamma$ -labelled graph  $(G, \gamma)$ , let  $\mathcal{F}$  be the set of acyclic  $\gamma$ -nonzero sets in  $G$ . Now we are ready to show Theorem 1, which proves that  $(E(G), \mathcal{F})$  is a delta-matroid. We denote  $(E(G), \mathcal{F})$  by  $\mathcal{G}(G, \gamma)$ . A delta-matroid  $M$  is  $\Gamma$ -graphic if there exist a  $\Gamma$ -labelled graph  $(G, \gamma)$  and  $X \subseteq E(G)$  such that  $M = \mathcal{G}(G, \gamma) \Delta X$ .

► **Theorem 1.** *Let  $\Gamma$  be an abelian group and  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. If  $\mathcal{F}$  is the set of acyclic  $\gamma$ -nonzero sets in  $G$ , then the following hold.*

(1)  $\mathcal{F} \neq \emptyset$ .

(2) For  $X, Y \in \mathcal{F}$  and  $e \in X \Delta Y$ , there exists  $f \in X \Delta Y$  such that  $X \Delta \{e, f\} \in \mathcal{F}$ .

**Proof.** By considering each component, we may assume that  $G$  is connected. If  $\gamma \equiv 0$ , then we choose a vertex  $v$  of  $G$  and a map  $\gamma' : V(G) \rightarrow \Gamma$  such that  $\gamma'(u) \neq 0$  if and only if  $u = v$ . Then the set of acyclic  $\gamma$ -nonzero sets in  $G$  is equal to the set of acyclic  $\gamma'$ -nonzero sets in  $G$ . Hence, we can assume that  $\gamma$  is not identically zero. Therefore, a subgraph  $H$  of  $G$  is  $\gamma$ -nonzero if and only if  $\sum_{u \in V(C)} \gamma(u) \neq 0$  for each component  $C$  of  $H$ .

Let us first prove (1), stating that  $\mathcal{F} \neq \emptyset$ . Let  $S = \{v \in V(G) : \gamma(v) \neq 0\}$  and  $T$  be a spanning tree of  $G$ . Then by the assumption, we have  $S \neq \emptyset$ . We may assume that  $\sum_{u \in V(G)} \gamma(u) = 0$  because otherwise  $E(T)$  is acyclic  $\gamma$ -nonzero in  $G$ . Let  $e$  be an edge of  $T$  such that one of two components  $C_1$  and  $C_2$  of  $T \setminus e$  has exactly one vertex in  $S$ . Then  $\sum_{u \in V(C_1)} \gamma(u) = -\sum_{u \in V(C_2)} \gamma(u) \neq 0$ . So  $E(T) - \{e\}$  is acyclic  $\gamma$ -nonzero in  $G$ , and (1) holds.

Now let us prove (2). We proceed by induction on  $|E(G)|$ . It is obvious if  $|E(G)| = 0$ . If there is an edge  $g = vw$  in  $X \cap Y$ , then let  $\gamma' : V(G/g) \rightarrow \Gamma$  such that, for each vertex  $x$  of  $G/g$ ,

$$\gamma'(x) = \begin{cases} \gamma(v) + \gamma(w) & \text{if } x \text{ is the vertex of } G/g \text{ corresponding to } g, \\ \gamma(x) & \text{otherwise.} \end{cases}$$

Then both  $X - \{g\}$  and  $Y - \{g\}$  are acyclic  $\gamma'$ -nonzero sets in  $G/g$ . Let  $e \in (X - \{g\}) \Delta (Y - \{g\}) = X \Delta Y$ . By the induction hypothesis, there exists  $f \in X \Delta Y$  such that  $(X - \{g\}) \Delta \{e, f\}$  is an acyclic  $\gamma'$ -nonzero set in  $G/g$ .

We now claim that  $X \Delta \{e, f\}$  is an acyclic  $\gamma$ -nonzero set in  $G$ . It is obvious that  $X \Delta \{e, f\}$  is acyclic in  $G$ . If  $\gamma' \equiv 0$ , then  $\gamma(v) = -\gamma(w) \neq 0$  and  $\gamma(u) = 0$  for every  $u$  in  $V(G) - \{v, w\}$ . Then  $X$  is not  $\gamma$ -nonzero, contradicting our assumption. Hence,  $\gamma' \neq 0$  and let  $C$  be a component of  $(V(G), X \Delta \{e, f\})$ . If  $C$  contains  $g$ , then  $\sum_{u \in V(C)} \gamma(u) = \sum_{u \in V(C/g)} \gamma'(u) \neq 0$ . If  $C$  does not contain  $g$ , then  $\sum_{u \in V(C)} \gamma(u) = \sum_{u \in V(C)} \gamma'(u) \neq 0$ . It implies that  $X \Delta \{e, f\}$  is  $\gamma$ -nonzero in  $G$ , so the claim is verified.

Therefore we may assume that  $X \cap Y = \emptyset$ . Let  $H_1 = (V(G), X)$  and  $H_2 = (V(G), Y)$ .

► **Case 1.**  $e \in X$ .

Let  $C$  be the component of  $H_1$  containing  $e$  and  $C_1, C_2$  be two components of  $C \setminus e$ . If both  $\sum_{u \in V(C_1)} \gamma(u)$  and  $\sum_{u \in V(C_2)} \gamma(u)$  are nonzero, then  $X \Delta \{e\}$  is acyclic  $\gamma$ -nonzero and so we can choose  $f = e$ . So we may assume that  $\sum_{u \in V(C_1)} \gamma(u) = 0$  and therefore

$$\sum_{u \in V(C_2)} \gamma(u) = \sum_{u \in V(C)} \gamma(u) - \sum_{u \in V(C_1)} \gamma(u) \neq 0.$$

If there exists  $f \in Y$  joining a vertex in  $V(C_1)$  to a vertex in  $V(G) - V(C_1)$ , then  $X \Delta \{e, f\}$  is acyclic  $\gamma$ -nonzero. Therefore, we may assume that there is a component  $D_1$  of  $H_2$  such that  $V(D_1) \subseteq V(C_1)$ . Since  $\sum_{u \in V(D_1)} \gamma(u) \neq 0$ , there is a vertex  $x$  of  $D_1$  such that  $\gamma(x) \neq 0$ . So  $\gamma|_{V(C_1)} \neq 0$  and there is an edge  $f$  of  $C_1$  such that one of the components of  $C_1 \setminus f$ , say  $U$ , has exactly one vertex  $v$  with  $\gamma(v) \neq 0$ . If  $U'$  is the component of  $C_1 \setminus f$  other than  $U$ , then  $\sum_{u \in V(U')} \gamma(u) = -\sum_{u \in V(U)} \gamma(u) \neq 0$ . So  $X \Delta \{e, f\}$  is acyclic  $\gamma$ -nonzero.

► **Case 2.**  $e \in Y$ .

Let  $\tilde{H} = (V(G), X \cup \{e\})$ . If  $\tilde{H}$  contains a cycle  $D$ , then, since  $X$  and  $Y$  are acyclic,  $D$  is a unique cycle of  $\tilde{H}$  and there is an edge  $f \in E(D) - Y$ . Then  $X \Delta \{e, f\}$  is acyclic  $\gamma$ -nonzero. Therefore, we can assume that  $e$  joins two distinct components  $C', C''$  of  $H_1$ .

Since  $\sum_{u \in V(C')} \gamma(u) \neq 0$ , there is an edge  $f$  of  $C'$  such that one of the components of  $C' \setminus f$ , say  $U$ , has exactly one vertex  $v$  with  $\gamma(v) \neq 0$ . If  $U'$  is the component of  $C' \setminus f$  other than  $U$ , then  $\sum_{u \in V(U')} \gamma(u) = -\sum_{u \in V(U)} \gamma(u) \neq 0$ . So  $X \Delta \{e, f\}$  is acyclic  $\gamma$ -nonzero. ◀

## 4 Minors of group-labelled graphs

Let  $\Gamma$  be an abelian group. Now we define minors of  $\Gamma$ -labelled graphs as follows. Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph and  $e = uv$  be an edge of  $G$ . Then  $(G, \gamma) \setminus e = (G \setminus e, \gamma)$  is the  $\Gamma$ -labelled graph obtained by *deleting* the edge  $e$  from  $(G, \gamma)$ . For an isolated vertex  $v$  of  $G$ ,  $(G, \gamma) \setminus v = (G \setminus v, \gamma|_{V(G) - \{v\}})$  is the  $\Gamma$ -labelled graph obtained by *deleting* the vertex  $v$  from  $(G, \gamma)$ . If  $e$  is not a loop, then let  $(G, \gamma)/e = (G/e, \gamma')$  such that, for each  $x \in V(G/e)$ ,

$$\gamma'(x) = \begin{cases} \gamma(u) + \gamma(v) & \text{if } x \text{ is the vertex of } G/e \text{ corresponding to } e, \\ \gamma(x) & \text{otherwise.} \end{cases}$$

## 70:8 $\Gamma$ -Graphic Delta-Matroids and Their Applications

If  $e$  is a loop, then let  $(G, \gamma)/e = (G, \gamma) \setminus e$ . Contracting the edge  $e$  is an operation obtaining  $(G, \gamma)/e$  from  $(G, \gamma)$ . For an edge set  $X = \{e_1, \dots, e_t\}$ , let  $(G, \gamma)/X = (G, \gamma)/e_1/\dots/e_t$  and  $(G, \gamma) \setminus X = (G \setminus X, \gamma)$ . A  $\Gamma$ -labelled graph  $(G', \gamma')$  is a *minor* of  $(G, \gamma)$  if  $(G', \gamma')$  is obtained from  $(G, \gamma)$  by deleting some edges, contracting some edges, and deleting some isolated vertices. Let  $\kappa(G, \gamma)$  be the number of components  $C$  of  $G$  such that  $\gamma(x) = 0$  for all  $x \in V(C)$ . An edge  $e$  of  $G$  is a  $\gamma$ -bridge if  $\kappa((G, \gamma) \setminus e) > \kappa(G, \gamma)$ . A non-loop edge  $e = uv$  of  $G$  is a  $\gamma$ -tunnel if, for the component  $C$  of  $G$  containing  $e$ , the following hold:

- (i) For each  $x \in V(C)$ ,  $\gamma(x) \neq 0$  if and only if  $x \in \{u, v\}$ .
- (ii)  $\gamma(u) + \gamma(v) = 0$ .

From the definition of a  $\gamma$ -tunnel, it is easy to see that an edge  $e$  is a  $\gamma$ -tunnel in  $G$  if and only if  $\kappa((G, \gamma)/e) > \kappa(G, \gamma)$ .

The following lemmas are analogous to properties of graphic delta-matroids in Oum [8, Propositions 8, 9, 10, and 11].

► **Lemma 15 (\*)**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph and  $e$  be an edge of  $G$ . The following are equivalent.*

- (i) *Every acyclic  $\gamma$ -nonzero set in  $G$  contains  $e$ .*
- (ii) *The edge  $e$  is a  $\gamma$ -bridge in  $G$ .*
- (iii) *Every  $\gamma$ -nonzero set in  $G$  contains  $e$ .*

► **Lemma 16 (\*)**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. Then, for an edge  $e$  of  $G$ ,*

$$\mathcal{G}((G, \gamma) \setminus e) = \begin{cases} \mathcal{G}(G, \gamma) \setminus e & \text{if } e \text{ is not a } \gamma\text{-bridge,} \\ \mathcal{G}(G, \gamma) \Delta \{e\} \setminus e & \text{otherwise.} \end{cases}$$

► **Lemma 17 (\*)**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph and  $e$  be a non-loop edge of  $G$ . Then the following are equivalent.*

- (i) *No acyclic  $\gamma$ -nonzero set in  $G$  contains  $e$ .*
- (ii) *The edge  $e$  is a  $\gamma$ -tunnel in  $G$ .*
- (iii) *No  $\gamma$ -nonzero set in  $G$  contains  $e$ .*

► **Lemma 18 (\*)**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. Then, for an edge  $e$  of  $G$ ,*

$$\mathcal{G}((G, \gamma)/e) = \begin{cases} \mathcal{G}(G, \gamma) \Delta \{e\} \setminus e & \text{if } e \text{ is neither a loop nor a } \gamma\text{-tunnel,} \\ \mathcal{G}(G, \gamma) \setminus e & \text{otherwise.} \end{cases}$$

We omit the proof of the following lemma.

► **Lemma 19**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph and  $v$  be an isolated vertex of  $G$ . Then  $\mathcal{G}((G, \gamma) \setminus v) = \mathcal{G}(G \setminus v, \gamma|_{V(G) - \{v\}})$ .*

► **Proposition 20**. *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph and  $M = \mathcal{G}(G, \gamma) \Delta X$  for some  $X \subseteq E(G)$ .*

- (i) *If  $(G', \gamma')$  is a minor of  $(G, \gamma)$ , then  $\mathcal{G}(G', \gamma')$  is a minor of  $M$ .*
- (ii) *If  $M'$  is a minor of  $M$ , then there exists a minor  $(G', \gamma')$  of  $(G, \gamma)$  such that  $M' = \mathcal{G}(G', \gamma') \Delta X'$  for some  $X' \subseteq E(G')$ .*

**Proof.** We may assume that  $X = \emptyset$ . Lemmas 16, 18, and 19 imply (i) and Lemmas 11, 16, 18, and 19 imply (ii). ◀

## 5 Maximum weight acyclic $\gamma$ -nonzero set

In this section, we prove that one can find a maximum weight acyclic  $\gamma$ -nonzero set in a  $\Gamma$ -labelled graph  $(G, \gamma)$  in polynomial time by applying the symmetric greedy algorithm on  $\Gamma$ -graphic delta-matroids. Let us first state the problem.

MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET

**Input:** A  $\Gamma$ -labelled graph  $(G, \gamma)$  and a weight  $w : E(G) \rightarrow \mathbb{Q}$ .

**Problem:** Find an acyclic  $\gamma$ -nonzero set  $F$  in  $G$  maximizing  $\sum_{e \in F} w(e)$ .

Recall that Theorem 14 allows us to find a maximum weight feasible set in a delta-matroid by using the symmetric greedy algorithm in Algorithm 1. As we proved that the set of acyclic  $\gamma$ -nonzero sets in a  $\Gamma$ -labelled graph  $(G, \gamma)$  forms a  $\Gamma$ -graphic delta-matroid in Section 3, we can apply Theorem 14 to solve MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET, but it requires a subroutine that decides in polynomial time whether a pair of two disjoint sets  $X$  and  $Y$  of  $E(G)$  is separable in  $\mathcal{G}(G, \gamma)$ . In the remainder of this section, we focus on developing this subroutine.

We assume that the addition of two elements of  $\Gamma$  and testing whether an element of  $\Gamma$  is zero can be done in time polynomial in the length of the input.

► **Theorem 21.** *Given a  $\Gamma$ -labelled graph  $(G, \gamma)$  and disjoint subsets  $X, Y$  of  $E(G)$ , one can decide in polynomial time whether  $G$  has an acyclic  $\gamma$ -nonzero set  $F$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ .*

To prove Theorem 21, we will characterize separable pairs  $(X, Y)$  in  $\mathcal{G}(G, \gamma)$ . Recall that, for a  $\Gamma$ -labelled graph  $(G, \gamma)$ ,  $\kappa(G, \gamma)$  is the number of components  $C$  of  $G$  such that  $\gamma|_{V(C)} \equiv 0$ .

► **Lemma 22.** *Let  $\Gamma$  be an abelian group and  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. Then  $\kappa((G, \gamma) \setminus e) \geq \kappa(G, \gamma)$  and  $\kappa((G, \gamma)/e) \geq \kappa(G, \gamma)$  for every edge  $e$  of  $G$ .*

**Proof.** We may assume that  $G$  is connected and  $\kappa(G, \gamma) = 1$ . Then  $\gamma \equiv 0$  and therefore  $\kappa((G, \gamma) \setminus e) \geq 1$  and  $\kappa((G, \gamma)/e) = 1$ . ◀

► **Lemma 23.** *Let  $\Gamma$  be an abelian group,  $(G, \gamma)$  be a  $\Gamma$ -labelled graph, and  $X$  be an acyclic set of edges of  $G$ . Let  $\gamma' : V(G/X) \rightarrow \Gamma$  be a map such that  $(G/X, \gamma') = (G, \gamma)/X$ . Then the following hold.*

- (1) *If  $\kappa((G, \gamma)/X) = \kappa(G, \gamma)$  and  $F$  is an acyclic  $\gamma'$ -nonzero set in  $G/X$ , then  $F \cup X$  is an acyclic  $\gamma$ -nonzero set in  $G$ .*
- (2) *If  $\kappa((G, \gamma)/X) > \kappa(G, \gamma)$ , then  $G$  has no acyclic  $\gamma$ -nonzero set containing  $X$ .*

**Proof.** Let us first prove (1). By considering each component, we may assume that  $G$  is connected. Since  $X$  is acyclic,  $F \cup X$  is acyclic in  $G$ .

If  $\kappa((G, \gamma)/X) = \kappa(G, \gamma) = 1$ , then  $\gamma \equiv 0$  and  $F$  is the edge set of a spanning tree of  $G/X$  by (G2). Hence  $F \cup X$  is the edge set of a spanning tree of  $G$ , which implies that  $F \cup X$  is acyclic  $\gamma$ -nonzero in  $G$ .

If  $\kappa((G, \gamma)/X) = \kappa(G, \gamma) = 0$ , then let  $H' = (V(G/X), F)$  be a subgraph of  $G/X$  and  $H = (V(G), F \cup X)$  be a subgraph of  $G$ . Then, for each component  $C$  of  $H$ , there exists a component  $C'$  of  $H'$  such that  $C' = C/(E(C) \cap X)$ . Then  $\sum_{u \in V(C)} \gamma(u) = \sum_{u \in V(C')} \gamma'(u) \neq 0$  by (G1). Hence  $F \cup X$  is an acyclic  $\gamma$ -nonzero set in  $G$  and (1) holds.

Now let us prove (2). We proceed by induction on  $|X|$ .

## 70:10 $\Gamma$ -Graphic Delta-Matroids and Their Applications

If  $|X| = 1$ , then  $e \in X$  is a  $\gamma$ -tunnel and by Lemma 17, there is no acyclic  $\gamma$ -nonzero set containing  $X$ . So we may assume that  $|X| > 1$ . Let  $e \in X$  and  $X' = X - \{e\}$ .

By the induction hypothesis, we may assume that  $\kappa((G, \gamma)/X') = \kappa(G, \gamma)$ . Let  $\gamma'' : V(G/X') \rightarrow \Gamma$  be a map such that  $(G/X', \gamma'') = (G, \gamma)/X'$ . Since  $\kappa((G, \gamma)/X) = \kappa((G, \gamma)/X'/e) > \kappa((G, \gamma)/X')$ , by the induction hypothesis,  $G/X'$  has no acyclic  $\gamma''$ -nonzero set containing  $e$ . Therefore,  $G$  has no acyclic  $\gamma$ -nonzero set containing  $X$ . ◀

► **Lemma 24.** *Let  $\Gamma$  be an abelian group,  $(G, \gamma)$  be a  $\Gamma$ -labelled graph, and  $Y$  be a set of edges of  $G$ . Then the following hold.*

(1) *If  $\kappa((G, \gamma) \setminus Y) = \kappa(G, \gamma)$  and  $F$  is an acyclic  $\gamma$ -nonzero set in  $G \setminus Y$ , then  $F$  is an acyclic  $\gamma$ -nonzero set in  $G$ .*

(2) *If  $\kappa((G, \gamma) \setminus Y) > \kappa(G, \gamma)$ , then  $G$  has no acyclic  $\gamma$ -nonzero set  $F$  such that  $Y \cap F = \emptyset$ .*

**Proof.** Let us first prove (1). By considering each component, we may assume that  $G$  is connected.

If  $\kappa((G, \gamma) \setminus Y) = \kappa(G, \gamma) = 1$ , then  $\gamma \equiv 0$  and the set  $F$  is the edge set of a spanning tree of  $G \setminus Y$  by (G2). Then  $F$  is an acyclic  $\gamma$ -nonzero set in  $G$ .

If  $\kappa((G, \gamma) \setminus Y) = \kappa(G, \gamma) = 0$ , then for each component  $C$  of  $G \setminus Y$ , we have  $\gamma|_{V(C)} \not\equiv 0$ . Then,  $\sum_{v \in V(C)} \gamma(v) \neq 0$  for each component  $C$  of  $(V(G), F)$ . So  $F$  is an acyclic  $\gamma$ -nonzero set in  $G$ .

Let us show (2). We proceed by induction on  $|Y|$ . If  $|Y| = 1$ , then  $e \in Y$  is a  $\gamma$ -bridge so it is done by Lemma 15. Now we assume  $|Y| \geq 2$ . Let  $e \in Y$  and  $Y' = Y - \{e\}$ . By the induction hypothesis, we may assume that  $\kappa(G \setminus Y', \gamma) = \kappa(G, \gamma)$ . Since  $\kappa(G \setminus Y, \gamma) = \kappa(G \setminus Y' \setminus e, \gamma) > \kappa(G \setminus Y', \gamma)$ , by the induction hypothesis, every acyclic  $\gamma$ -nonzero set in  $G \setminus Y'$  contains  $e$ . Since every acyclic  $\gamma$ -nonzero set  $F$  in  $G$  not intersecting  $Y'$  is an acyclic  $\gamma$ -nonzero set in  $G \setminus Y'$ , every acyclic  $\gamma$ -nonzero set in  $G$  intersects  $Y$ . ◀

► **Proposition 25.** *Let  $\Gamma$  be an abelian group and  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. Let  $X$  and  $Y$  be disjoint subsets of  $E(G)$  such that  $X$  is acyclic in  $G$ . Then  $\kappa((G, \gamma)/X \setminus Y) = \kappa(G, \gamma)$  if and only if  $G$  has an acyclic  $\gamma$ -nonzero set  $F$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ .*

**Proof.** Let us prove the forward direction. By Lemma 22,  $\kappa((G, \gamma)/X \setminus Y) = \kappa((G, \gamma)/X) = \kappa(G, \gamma)$ . Let  $\gamma' : V(G/X \setminus Y) \rightarrow \Gamma$  be a map such that  $(G/X \setminus Y, \gamma') = (G, \gamma)/X \setminus Y$ . By (1) of Theorem 1, there exists an acyclic  $\gamma'$ -nonzero set  $F'$  in  $G/X \setminus Y$ . Since  $\kappa((G, \gamma)/X \setminus Y) = \kappa((G, \gamma)/X)$ ,  $F'$  is acyclic  $\gamma'$ -nonzero in  $G/X$  by (1) of Lemma 24. Since  $\kappa((G, \gamma)/X) = \kappa(G, \gamma)$ ,  $F := F' \cup X$  is acyclic  $\gamma$ -nonzero in  $G$  by (1) of Lemma 23. Therefore,  $F$  is an acyclic  $\gamma$ -nonzero set in  $G$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ .

Now let us prove the backward direction. Let  $F$  be an acyclic  $\gamma$ -nonzero set in  $G$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ . Let  $\gamma' : V(G/X) \rightarrow \Gamma$  be a map such that  $(G/X, \gamma') = (G, \gamma)/X$ . Then  $F - X$  is an acyclic  $\gamma'$ -nonzero set in  $G/X$  not intersecting  $Y$ , so we have  $\kappa((G, \gamma)/X \setminus Y) = \kappa((G, \gamma)/X)$  by (2) of Lemma 24. Since  $F$  is an acyclic  $\gamma$ -nonzero set containing  $X$  in  $G$ , we have  $\kappa((G, \gamma)/X) = \kappa(G, \gamma)$  by (2) of Lemma 23. ◀

**Proof of Theorem 21.** Given a  $\Gamma$ -labelled graph  $(G, \gamma)$  and disjoint subsets  $X, Y$  of  $E(G)$ , we can compute  $\kappa((G, \gamma)/X \setminus Y)$  in polynomial time and therefore, by Proposition 25, we can decide whether there exists an acyclic  $\gamma$ -nonzero set  $F$  in  $G$  such that  $X \subseteq F$  and  $Y \cap F = \emptyset$ . ◀

Now we are ready to show Theorem 2

► **Theorem 2.** *MAXIMUM WEIGHT ACYCLIC  $\gamma$ -NONZERO SET is solvable in polynomial time.*

**Proof.** Let  $M = \mathcal{G}(G, \gamma)$  be a  $\Gamma$ -graphic delta-matroid. The set of acyclic  $\gamma$ -nonzero sets in  $G$  is equal to the set of feasible sets of  $M$ . By Theorem 21, we can decide in polynomial time whether a pair  $(X, Y)$  of disjoint subsets  $X$  and  $Y$  of  $E(G)$  is separable in  $M$ . It implies that the symmetric greedy algorithm in Algorithm 1 for  $M$  and  $w$  runs in polynomial time. By Theorem 14, we can obtain an acyclic  $\gamma$ -nonzero set  $F$  in  $G$  maximizing  $\sum_{e \in F} w(e)$ . ◀

## 6 Even $\Gamma$ -graphic delta-matroids

In this section, we show that every even  $\Gamma$ -graphic delta-matroid is graphic.

► **Lemma 26** (\*). *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph, and  $\eta : V(G) \rightarrow \mathbb{Z}_2$  such that  $\eta(v) = 0$  if and only if  $\gamma(v) = 0$  for each  $v \in V(G)$ . If  $\mathcal{G}(G, \gamma)$  is even, then, for each connected subgraph  $H$  of  $G$ ,  $\sum_{u \in V(H)} \eta(u) = 0$  if and only if  $\sum_{u \in V(H)} \gamma(u) = 0$ .*

► **Proposition 27.** *Let  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. If  $\mathcal{G}(G, \gamma)$  is even, then there is a map  $\eta : V(G) \rightarrow \mathbb{Z}_2$  such that  $\mathcal{G}(G, \gamma) = \mathcal{G}(G, \eta)$ .*

**Proof.** Let  $\eta : V(G) \rightarrow \mathbb{Z}_2$  is a map such that, for every  $u \in V(G)$ ,  $\eta(u) = 0$  if and only if  $\gamma(u) = 0$ . Let  $F$  be a set of edges of  $G$ . Then, for each component  $C$  of  $(V(G), F)$ ,  $\gamma|_{V(C)} \equiv 0$  if and only if  $\eta|_{V(C)} \equiv 0$  and, by Lemma 26,  $\sum_{u \in V(C)} \gamma(u) \neq 0$  if and only if  $\sum_{u \in V(C)} \eta(u) \neq 0$ . Therefore,  $F$  is acyclic  $\gamma$ -nonzero in  $G$  if and only if it is acyclic  $\eta$ -nonzero in  $G$ . ◀

We are ready to prove Theorem 5.

► **Theorem 5.** *Let  $\Gamma$  be an abelian group. Then a  $\Gamma$ -graphic delta-matroid is even if and only if it is graphic.*

**Proof of Theorem 5.** Let  $M$  be an even  $\Gamma$ -graphic delta-matroid. By twisting, we may assume that  $M = \mathcal{G}(G, \gamma)$  for a  $\Gamma$ -labelled graph  $(G, \gamma)$ . By Proposition 27,  $M$  is  $\mathbb{Z}_2$ -graphic. Conversely, Oum [8, Theorem 5] proved that every graphic delta-matroid is even. ◀

## 7 Representations of $\Gamma$ -graphic delta-matroids

We aim to study the condition on an abelian group  $\Gamma$  and a field  $\mathbb{F}$  such that every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ . Recall that a delta-matroid  $M = (E, \mathcal{F})$  is representable over  $\mathbb{F}$  if there is an  $E \times E$  symmetric or skew-symmetric  $A$  over  $\mathbb{F}$  such that  $\mathcal{F} = \{F \subseteq E : A[X]$  is nonsingular $\} \Delta X$  for some  $X \subseteq E$ . If every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ , then to prove this, we will construct symmetric matrices over  $\mathbb{F}$  representing  $\Gamma$ -graphic delta-matroids.

For a graph  $G = (V, E)$ , let  $\vec{G}$  be an orientation obtained from  $G$  by arbitrarily assigning a direction to each edge. Let  $I_{\vec{G}} = (a_{ve})_{v \in V, e \in E}$  be a  $V \times E$  matrix over  $\mathbb{F}$  such that, for a vertex  $v \in V$  and an edge  $e \in E$ ,

$$a_{ve} = \begin{cases} 1 & \text{if } v \text{ is the head of a non-loop edge } e \text{ in } \vec{G}, \\ -1 & \text{if } v \text{ is the tail of a non-loop edge } e \text{ in } \vec{G}, \\ 0 & \text{otherwise.} \end{cases}$$

► **Lemma 28.** *Let  $G = (V, E)$  be a graph and  $\vec{G}_1, \vec{G}_2$  be orientations of  $G$ . If  $W \subseteq V$ ,  $F \subseteq E$ , and  $|W| = |F|$ , then  $\det(I_{\vec{G}_1}[W, F]) = \pm \det(I_{\vec{G}_2}[W, F])$ .*

## 70:12 $\Gamma$ -Graphic Delta-Matroids and Their Applications

**Proof.** The matrix  $I_{\vec{G}_1}$  can be obtained from  $I_{\vec{G}_2}$  by multiplying  $-1$  to some columns. ◀

By slightly abusing the notation, we simply write  $I_G$  to denote  $I_{\vec{G}}$  for some orientation  $\vec{G}$  of  $G$ . The following two lemmas are easy exercises.

► **Lemma 29** (see Oxley [9, Lemma 5.1.3]). *Let  $G$  be a graph and  $F$  be an edge set of  $G$ . Then  $F$  is acyclic if and only if column vectors of  $I_G$  indexed by the elements of  $F$  are linearly independent.*

► **Lemma 30** (see Matoušek and Nešetřil [6, Lemma 8.5.3]). *Let  $G = (V, E)$  be a tree. Then  $\det(I_G[V - \{v\}, E]) = \pm 1$  for any vertex  $v \in V$ .*

► **Lemma 31** (\*). *Let  $\Gamma$  be an abelian group with at least one nonzero element, and  $(G, \gamma)$  be a  $\Gamma$ -labelled graph. Then there is a  $\Gamma$ -labelled graph  $(H, \eta)$  such that*

- (i)  $\eta(v) \neq 0$  for each vertex  $v \in V(H)$  and
- (ii)  $(G, \gamma)$  is a minor of  $(H, \eta)$ .

► **Theorem 32** (Binet-Cauchy theorem). *Let  $X$  and  $Y$  be finite sets. Let  $M$  be an  $X \times Y$  matrix and  $N$  be a  $Y \times X$  matrix with  $|Y| \geq |X| = s$ . Then*

$$\det(MN) = \sum_{S \in \binom{Y}{s}} \det(M[X, S]) \cdot \det(N[S, X]).$$

It is straightforward to prove the following lemma from the Binet-Cauchy theorem.

► **Corollary 33.** *Let  $X, Y, Z$  be finite sets. Let  $L, M, N$  be  $X \times Y, Y \times Z, Z \times X$  matrices, respectively, with  $|Y|, |Z| \geq |X| = s$ . Then*

$$\det(LMN) = \sum_{S \in \binom{Y}{s}, T \in \binom{Z}{s}} \det(L[X, S]) \cdot \det(M[S, T]) \cdot \det(N[T, X]).$$

► **Theorem 6** (\*). *Let  $p$  be a prime,  $k$  be a positive integer, and  $\mathbb{F}$  be a field of characteristic  $p$ . If  $[\mathbb{F} : \text{GF}(p)] \geq k$ , then every  $\mathbb{Z}_p^k$ -graphic delta-matroid is representable over  $\mathbb{F}$ .*

Now we show that for some pairs of an abelian group  $\Gamma$  and a finite field  $\mathbb{F}$ , not every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ . Let  $R(n; m)$  be the Ramsey number that is the minimum integer  $t$  such that any coloring of edges of  $K_t$  into  $m$  colors induces a monochromatic copy of  $K_n$ .

► **Theorem 34** (Ramsey [10]). *For positive integers  $m$  and  $n$ ,  $R(n; m)$  is finite.*

► **Corollary 35.** *Let  $k$  be a positive integer and  $\mathbb{F}$  be a finite field of order  $m$ . If  $N \geq R(k; m)$ , then each  $N \times N$  symmetric matrix  $A$  over  $\mathbb{F}$  has a  $k \times k$  principal submatrix  $A'$  such that all non-diagonal entries are equal.*

► **Lemma 36** (\*). *Let  $\mathbb{F}$  be a field. If every  $\mathbb{Z}_2$ -graphic delta-matroid is representable over  $\mathbb{F}$ , then the characteristic of  $\mathbb{F}$  is 2.*

► **Theorem 7** (\*). *Let  $\mathbb{F}$  be a finite field of characteristic  $p$ , and  $\Gamma$  be an abelian group. If every  $\Gamma$ -graphic delta-matroid is representable over  $\mathbb{F}$ , then  $\Gamma$  is an elementary abelian  $p$ -group.*

# An Approximation Algorithm for Maximum Stable Matching with Ties and Constraints

Yu Yokoi  

National Institute of Informatics, Hitotsubashi, Chiyoda-ku, Tokyo, Japan

---

## Abstract

We present a polynomial-time  $\frac{3}{2}$ -approximation algorithm for the problem of finding a maximum-cardinality stable matching in a many-to-many matching model with ties and laminar constraints on both sides. We formulate our problem using a bipartite multigraph whose vertices are called workers and firms, and edges are called contracts. Our algorithm is described as the computation of a stable matching in an auxiliary instance, in which each contract is replaced with three of its copies and all agents have strict preferences on the copied contracts. The construction of this auxiliary instance is symmetric for the two sides, which facilitates a simple symmetric analysis. We use the notion of matroid-kernel for computation in the auxiliary instance and exploit the base-orderability of laminar matroids to show the approximation ratio.

In a special case in which each worker is assigned at most one contract and each firm has a strict preference, our algorithm defines a  $\frac{3}{2}$ -approximation mechanism that is strategy-proof for workers.

## 1 Introduction

The *college admission problem* (CA) is a many-to-one generalization of the well-known *stable marriage problem* [18,32,34], introduced by Gale and Shapley [16]. An instance of CA involves two disjoint agent sets called students and colleges. Each agent has a strict linear order of preference over agents on the opposite side, and each college has an upper quota for the number of assigned students. It is known that any instance of CA has a stable matching, we can find it efficiently, and all stable matchings have the same cardinality.

Recently, matching problems with constraints have been studied extensively [6,9,15,27,28]. Motivated by the matching scheme used in the higher education sector in Hungary, Biró et al. [4] studied CA *with common quotas*. In this problem, in addition to individual colleges, certain subsets of colleges, called *bounded sets*, have upper quotas. Such constraints are also called *regional caps* or *distributional constraints*, and they have been studied in [17,29]. Meanwhile, motivated by academic hiring, Huang [21] introduced the *classified stable matching problem*. This is an extension of CA in which each individual college has quotas for subsets of students, called *classes*. Its many-to-many generalizations have been studied in [14,44].<sup>1</sup>

---

<sup>1</sup> In [14,17,21,44], not only upper quotas but also lower quotas are considered. With lower quotas, the existence of stable matching is not guaranteed. In this paper, we consider only upper quotas.

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

For these models, the laminar structure of constraints is commonly found to be the key to the existence of a stable matching. A family  $\mathcal{L}$  of sets is called *laminar* if any  $L, L' \in \mathcal{L}$  satisfy  $L \subseteq L'$  or  $L \supseteq L'$  or  $L \cap L' = \emptyset$  (also called *nested* or *hierarchical*). In [4, 21], the authors showed that a stable matching exists in their models if regions or classes form laminar families, whereas the existence is not guaranteed in the general case. Furthermore, in the laminar case, a stable matching can be found efficiently, and all stable matchings have the same cardinality. Applications with laminar constraints have been discussed in [29].

The purpose of this paper is to introduce ties to a matching model with laminar constraints. In the previous studies described above, the preferences of agents were assumed to be strictly ordered. However, ties naturally arise in real problems. Matching models with ties have been studied widely in the literature [18, 23, 34], where the preference of an agent is said to contain a *tie* if she is indifferent between two or more agents on the opposite side. When ties are allowed, the existence of a stable matching is maintained; however, stable matchings vary in cardinalities. As it is desirable to produce a large matching in practical applications, we consider the problem of finding a maximum-cardinality stable matching.

Such a problem is known to be difficult even in the simple matching model without constraints. The problem of finding a maximum stable matching in the setting of *stable marriage with ties and incomplete lists*, called MAX-SMTI, is NP-hard [24, 35], as is obtaining an approximation ratio within  $\frac{33}{29}$  [43]. For its approximability, several algorithms with improved approximation ratios have been proposed [25, 26, 30, 31, 36, 38]. The current best ratio is  $\frac{3}{2}$  by a polynomial-time algorithm proposed by McDermid [36] as well as linear-time algorithms proposed by Paluch [38] and Király [31]. The  $\frac{3}{2}$ -approximability extends to the settings of CA with ties [31] and the student-project allocation problem with ties [8].

**Our Contribution.** We present a polynomial-time  $\frac{3}{2}$ -approximation algorithm for the problem of finding a maximum-cardinality stable matching in a many-to-many matching model with ties and laminar constraints on both sides. We call this problem MAX-SMTI-LC and formulate it using a bipartite multigraph, where we call the two vertex sets *workers* and *firms*, respectively, and each edge a *contract*. Each agent has upper quotas on a laminar family defined on incident contracts. Our formulation can deal with each agent's constraints, such as *classified stable matching*. Furthermore, distributional constraints such as CA *with common quotas* can be handled by considering a dummy agent that represents a consortium of the agents on one side (see the remark at the end of Section 2). Our algorithm runs in  $O(k \cdot |E|^2)$  time, where  $E$  is the set of contracts and  $k$  is the maximum level of nesting of laminar constraints. The *level of nesting* of a laminar family  $\mathcal{L}$  is the maximum length of a chain  $L_1 \subsetneq L_2 \subsetneq \dots \subsetneq L_k$  of members of  $\mathcal{L}$ ; hence,  $k \leq |E|$ .

Our algorithm is described as the computation of a stable matching in an auxiliary instance. Here, we explain the ideas underlying the construction of the auxiliary instance, which is inspired by the algorithms of Király [31] and Hamada, Miyazaki, and Yanagisawa [19].

First, we briefly explain Király's  $\frac{3}{2}$ -approximation algorithm for MAX-SMTI [31]. In this algorithm, each worker makes proposals from top to bottom in her list sequentially, as with the worker-oriented Gale–Shapley algorithm. A worker rejected by all firms is given a second chance for proposals. Each firm prioritizes a worker in the second cycle over a worker in the first cycle if they are tied in its preference list. This idea of *promotion* is used to handle ties in firms' preference lists. To handle ties in workers' lists, Király's algorithm lets each worker prioritize a currently unmatched firm over a currently matched firm if they are tied in her preference list. This priority rule depends on the states of firms at each moment, which makes the algorithm complicated when we introduce constraints on both sides.

Then, we introduce the idea of the algorithm of Hamada et al. [19], who proposed a worker-strategy-proof algorithm for MAX-SMTI that attains the  $\frac{3}{2}$ -approximation ratio when ties appear only in workers' lists. They modified Király's algorithm such that each worker's proposal order is predetermined and is not affected by the history of the algorithm. Their algorithm can be seen as a Gale–Shapley-type algorithm in which each worker makes proposals twice to each firm in a tie before proceeding to the next tie, and each firm prioritizes second proposals over first proposals regardless of its preference. By combining their algorithm with the promotion operation of Király's algorithm, we obtain a Gale–Shapley-type algorithm in which each worker makes at most three proposals to each firm.

Based on these observations, we propose a method for transforming a MAX-SMTI-LC instance  $I$  into an auxiliary instance  $I^*$ , which is also a MAX-SMTI-LC instance. Each contract  $e_i$  in  $I$  is replaced with three copies  $x_i, y_i, z_i$  in  $I^*$ . Each agent has a strict preference on the copied contracts, which reflects the priority rules in the algorithms of Király and Hamada et al. The instance  $I^*$  has an upper bound 1 for each triple  $\{x_i, y_i, z_i\}$  and also has constraints corresponding to those in  $I$ . The construction of  $I^*$  is completely symmetric for workers and firms. We show that, for any stable matching  $M^*$  of  $I^*$ , its projection  $M := \{e_i \mid \{x_i, y_i, z_i\} \cap M^* \neq \emptyset\}$  is a  $\frac{3}{2}$ -approximate solution for  $I$ . Both the stability and the approximation ratio of  $M$  are implied by the stability of  $M^*$  in  $I^*$ , and the process of computing  $M^*$  is irrelevant. Thus, our method enables us to conduct a symmetric and static analysis even with constraints.

Because the auxiliary instance  $I^*$  has no ties, we can find a stable matching of  $I^*$  efficiently by using the matroid framework of Fleiner [12, 13]. In the analysis of the approximation ratio, we exploit the fact that the family of feasible sets defined by laminar constraints forms a matroid with a property called *base-orderability*.

In the last section, we show that the result of Hamada et al. [19] mentioned above is generalized to a many-to-one matching setting with laminar constraints on the firm side. In other words, if we restrict MAX-SMTI-LC such that each worker is assigned at most one contract and each firm has a strict preference, then we can provide a worker-strategy-proof mechanism that returns a  $\frac{3}{2}$ -approximate solution. We obtain this conclusion using the strategy-proofness result of Hatfield and Milgrom [20].

**Paper Organization.** The remainder of this paper is organized as follows. Section 2 formulates our matching model, while Section 3 describes our algorithm. Section 4 presents a lemma on base-orderable matroids that is the key to our proof of the approximation ratio. Sections 5 and 6 are devoted to the proofs of correctness and time complexity, respectively. Section 7 investigates strategy-proof approximation mechanisms for our model.

Throughout the paper, we denote the set of non-negative integers by  $\mathbf{Z}_+$ . For a subset  $S \subseteq E$  and an element  $e \in E$ , we denote  $S + e := S \cup \{e\}$  and  $S - e := S \setminus \{e\}$ .

## 2 Problem Formulation

An instance of the *stable matching with ties and laminar constraints*, which we call SMTI-LC, is a tuple  $I = (W, F, E, \{\mathcal{L}_a, q_a, P_a\}_{a \in W \cup F})$  defined as follows. Let  $W$  and  $F$  be disjoint finite sets called *workers* and *firms*, respectively. We call  $a \in W \cup F$  an *agent* when we do not distinguish between workers and firms. We are provided a set  $E$  of *contracts*. Each contract  $e \in E$  is associated with one worker and one firm, denoted by  $\partial_W(e)$  and  $\partial_F(e)$ , respectively. Multiple contracts are allowed to exist between a worker–firm pair. Then,  $(W, F; E)$  is represented as a bipartite multigraph in which  $W$  and  $F$  are vertex sets, and each  $e \in E$  is an edge connecting  $\partial_W(e)$  and  $\partial_F(e)$ . For each  $a \in W \cup F$ , we denote the set of associated contracts by  $E_a$ , i.e.,

## 71:4 Maximum Stable Matching with Ties and Constraints

$$E_w := \{e \in E \mid \partial_W(e) = w\} \quad (w \in W), \quad E_f := \{e \in E \mid \partial_F(e) = f\} \quad (f \in F).$$

Then, the family  $\{E_w \mid w \in W\}$  forms a partition of  $E$ , as does  $\{E_f \mid f \in F\}$ .

Each agent  $a \in W \cup F$  has a laminar family  $\mathcal{L}_a$  of subsets of  $E_a$  and a quota function  $q_a: \mathcal{L}_a \rightarrow \mathbf{Z}_+$ . For any subset  $M \subseteq E$  of contracts and an agent  $a \in W \cup F$ , we denote by  $M_a := M \cap E_a$  the set of contracts assigned to  $a$ . We say that  $M$  is *feasible* for  $a \in W \cup F$  if

$$\forall L \in \mathcal{L}_a: |M_a \cap L| \leq q_a(L).$$

A set  $M \subseteq E$  is called a *matching* if it is feasible for all agents in  $W \cup F$ .

Each agent  $a \in W \cup F$  has a preference list  $P_a$  that consists of all elements in  $E_a$  and may contain ties. In this paper, a preference list is written in one row, from left to right according to preference, where two or more contracts with equal preference are included in the same parentheses. For example, if the preference list  $P_a$  of an agent  $a \in W \cup F$  is represented as

$$P_a: e_2 \ (e_1 \ e_4) \ e_3,$$

then  $e_2$  is  $a$ 's top choice,  $e_1$  and  $e_4$  are the second choices with equal preference, and  $e_3$  is the last choice. For contracts  $e, e' \in E_a$ , we write  $e \succ_a e'$  if  $a$  prefers  $e$  to  $e'$ . Furthermore, we write  $e \succeq_a e'$  if  $e \succ_a e'$  or  $a$  is indifferent between  $e$  and  $e'$  (including the case  $e = e'$ ).

For a matching  $M \subseteq E$ , a contract  $e \in E \setminus M$ , and an associated agent  $a \in \{\partial_W(e), \partial_F(e)\}$ , we say that  $e$  is *free* for  $a$  in  $M$  if

- $M_a + e$  is feasible for  $a$ , or
- there is  $e' \in M_a$  such that  $e \succ_a e'$  and  $M_a + e - e'$  is feasible for  $a$ .

In other words, a contract  $e$  is free for an agent  $a$  if  $a$  has an incentive to add  $e$  to the current assignment possibly at the expense of some less preferred contract  $e'$ . A contract  $e \in E \setminus M$  *blocks*  $M$  if  $e$  is free for both  $\partial_W(e)$  and  $\partial_F(e)$ . A matching  $M$  is *stable* if there is no contract in  $E \setminus M$  that blocks  $M$ .

The goal of our problem MAX-SMTI-LC is to find a maximum-cardinality stable matching for a given SMTI-LC instance. Because MAX-SMTI-LC is a generalization of the NP-hard problem MAX-SMTI, we consider the approximability. Similarly to the case of MAX-SMTI, for the problem MAX-SMTI-LC, a 2-approximate solution can be easily obtained using an arbitrary tie-breaking method (see the full version [45] for the proof). In the next section, we present a  $\frac{3}{2}$ -approximation algorithm.

► **Remark.** We demonstrate that SMTI-LC includes several models investigated in previous works, which implies that our algorithm finds  $\frac{3}{2}$ -approximate solutions for the problems of finding maximum-cardinality stable matchings in those models with ties.

First, SMTI and the stable  $b$ -matching problem are special cases such that  $E \subseteq W \times F$  and  $\mathcal{L}_a = \{E_a\}$  for every  $a \in W \cup F$ . Furthermore, the two-sided laminar classified stable matching problem [14, 21], if lower quotas are absent, is a special case with  $E \subseteq W \times F$ .

To represent CA with laminar common quotas [4], let  $W$  be the set of students and let  $F := \{f\}$ , where  $f$  is regarded as a consortium of all colleges in  $C$ . The set of contracts is defined by  $E := \{(w, f, c) \mid \text{a college } c \in C \text{ is acceptable for a student } w \in W\}$ , where  $\partial_W(e) = w$ ,  $\partial_F(e) = f$  for any  $e = (w, f, c)$ . Note that  $E = E_f$ . A quota for a region  $C' \subseteq C$  is then represented as a quota for the set  $\{(w, f, c) \in E \mid c \in C'\} \subseteq E_f$ . Thus, laminar common quotas can be represented as constraints on a laminar family on  $E_f$ .

For the student-project allocation problem [8], let  $W$  and  $F$  be the sets of students and lecturers, respectively, and  $E := \{(w, f, p) \mid \text{a project } p \text{ acceptable for } w \in W \text{ is offered by } f \in F\}$ . Let  $E_{f,p} \subseteq E_f$  be the set of contracts associated with a project  $p$  offered by a lecturer  $f$ . Then, the lecturer's upper quota and projects' upper quotas define two-level laminar constraints on the family  $\mathcal{L}_f = \{E_f\} \cup \{E_{f,p} \mid p \text{ is offered by } f\}$ .

For the above-mentioned settings, we can appropriately set the preferences of agents such that the stability in the previous works coincides with the stability in SMTI-LC.

### 3 Algorithm

Our approximation algorithm for MAX-SMTI-LC consists of three steps: (i) construction of an auxiliary instance, (ii) computation of any stable matching of this auxiliary instance, and (iii) mapping the obtained matching to a matching of the original instance. In what follows, we describe how to construct an auxiliary instance  $I^*$  from a given instance  $I$  and how to map a matching of  $I^*$  to that of  $I$ .

Let  $I = (W, F, E, \{\mathcal{L}_a, q_a, P_a\}_{a \in W \cup F})$  be an instance of MAX-SMTI-LC, where the set  $E$  of contracts is represented as  $E = \{e_i \mid i = 1, 2, \dots, n\}$ . We construct an auxiliary instance  $I^* = (W, F, E^*, \{\mathcal{L}_a^*, q_a^*, P_a^*\}_{a \in W \cup F})$ , which is also an SMTI-LC instance; however, each preference list  $P_a^*$  does not contain ties.

The sets of workers and firms in  $I^*$  are the same as those in  $I$ . The set  $E^*$  of contracts in  $I^*$  is given as  $E^* = \{x_i, y_i, z_i \mid i = 1, 2, \dots, n\}$ , where  $x_i, y_i$ , and  $z_i$  are copies of  $e_i$ ; hence,  $\partial_W(x_i) = \partial_W(y_i) = \partial_W(z_i) = \partial_W(e_i)$  and  $\partial_F(x_i) = \partial_F(y_i) = \partial_F(z_i) = \partial_F(e_i)$ . We define a mapping  $\pi : 2^{E^*} \rightarrow 2^E$  by  $\pi(S^*) = \{e_i \mid \{x_i, y_i, z_i\} \cap S^* \neq \emptyset\}$  for any  $S^* \subseteq E^*$ .

For any agent  $a \in W \cup F$ , the laminar family  $\mathcal{L}_a^*$  and the quota function  $q_a^* : \mathcal{L}_a^* \rightarrow \mathbf{Z}_+$  are defined as follows. For each  $e_i \in E_a$ , we have  $\{x_i, y_i, z_i\} \in \mathcal{L}_a^*$  and  $q_a^*(\{x_i, y_i, z_i\}) = 1$ . For each  $L \in \mathcal{L}_a$ , we have  $L^* := \{x_i, y_i, z_i \mid e_i \in L\} \in \mathcal{L}_a^*$  and  $q_a^*(L^*) = q_a(L)$ . These are all that  $\mathcal{L}_a^*$  contains. Then, for any set  $M^* \subseteq E^*$  of contracts, we see that  $M^*$  is feasible for  $a$  in  $I^*$  if and only if  $M^*$  contains at most one copy of each  $e_i \in E_a$  and the set  $\pi(M^*)$  is feasible for  $a$  in  $I$ .

The preference list  $P_w^*$  of each worker  $w \in W$  is defined as follows. Take a tie  $(e_{i_1} e_{i_2} \cdots e_{i_\ell})$  in  $P_w$ . We replace it with a strict linear order of  $2\ell$  contracts  $x_{i_1} x_{i_2} \cdots x_{i_\ell} y_{i_1} y_{i_2} \cdots y_{i_\ell}$ . Apply this operation to all the ties in  $P_w$ , where we regard a contract not included in any tie as a tie of length one. Next, at the end of the resultant list, append the original list  $P_w$  with each  $e_i$  replaced with  $z_i$  and all the parentheses omitted. Here is a demonstration. If the preference list of a worker  $w$  is

$$P_w : ( e_2 \ e_6 ) \ e_1 \ ( e_3 \ e_4 ),$$

then her list in  $I^*$  is

$$P_w^* : x_2 \ x_6 \ y_2 \ y_6 \ x_1 \ y_1 \ x_3 \ x_4 \ y_3 \ y_4 \ z_2 \ z_6 \ z_1 \ z_3 \ z_4.$$

The preference list  $P_f^*$  of each firm  $f \in F$  is defined in the same manner, where the roles of  $x_i$  and  $z_i$  are interchanged. For example, if the preference list of a firm  $f$  is

$$P_f : e_3 \ ( e_2 \ e_4 \ e_7 ) \ e_5,$$

then its list in  $I^*$  is

$$P_f^* : z_3 \ y_3 \ z_2 \ z_4 \ z_7 \ y_2 \ y_4 \ y_7 \ z_5 \ y_5 \ x_3 \ x_2 \ x_4 \ x_7 \ x_5.$$

Thus, we have defined the auxiliary instance  $I^*$ . As this is again an SMTI-LC instance, a stable matching of  $I^*$  is defined as before. The existence of a stable matching of  $I^*$  is guaranteed by the existing framework of Fleiner [12,13], as will be explained in Section 6. Here is the main theorem of this paper, which states that any stable matching of  $I^*$  defines a  $\frac{3}{2}$ -approximate solution for  $I$ .

► **Theorem 1.** *For a stable matching  $M^*$  of  $I^*$ , let  $M := \pi(M^*)$ . Then,  $M$  is a stable matching of  $I$  with  $|M| \geq \frac{2}{3}|M_{\text{OPT}}|$ , where  $M_{\text{OPT}}$  is a maximum-cardinality stable matching of  $I$ .*

We prove Theorem 1 in Section 5. This theorem guarantees the correctness of Algorithm 1.

■ **Algorithm 1**  $\frac{3}{2}$ -approximation algorithm for MAX-SMTI-LC.

---

**Input:** An instance  $I = (W, F, E, \{\mathcal{L}_a, q_a, P_a\}_{a \in W \cup F})$ .

**Output:** A stable matching  $M$  with  $|M| \geq \frac{2}{3}|M_{\text{OPT}}|$ , where  $M_{\text{OPT}}$  is an optimal solution.

- 1: Construct an auxiliary instance  $I^*$ .
  - 2: Find any stable matching  $M^*$  of  $I^*$ .
  - 3: Let  $M = \pi(M^*)$  and return  $M$ .
- 

Clearly, the first and third steps of Algorithm 1 can be performed efficiently. Furthermore, the second step can be executed in polynomial time by applying the generalized Gale–Shapley algorithm of Fleiner [12,13]. In Section 6, we will explain this more precisely and present the time complexity represented in the following theorem.

► **Theorem 2.** *One can find a stable matching  $M$  of  $I$  with  $|M| \geq \frac{2}{3}|M_{\text{OPT}}|$  in  $O(k \cdot |E|^2)$  time, where  $M_{\text{OPT}}$  is a maximum-cardinality stable matching and  $k$  is the maximum level of nesting of laminar families  $\mathcal{L}_a$  ( $a \in W \cup F$ ).*

## 4 Base-orderable Matroids

For the proofs of Theorems 1 and 2, we introduce some concepts related to matroids (see, e.g., Oxley [37] for more information on matroids).

For a finite set  $E$  and a family  $\mathcal{I} \subseteq 2^E$ , a pair  $(E, \mathcal{I})$  is called a *matroid* if the following three conditions hold: (I1)  $\emptyset \in \mathcal{I}$ , (I2)  $S \subseteq T \in \mathcal{I}$  implies  $S \in \mathcal{I}$ , and (I3) for any  $S, T \in \mathcal{I}$  with  $|S| < |T|$ , there exists  $e \in T \setminus S$  such that  $S + e \in \mathcal{I}$ .

For a matroid  $(E, \mathcal{I})$ , each member of  $\mathcal{I}$  is called an *independent set*. An independent set is called a *base* if it is inclusion-wise maximal in  $\mathcal{I}$ . We denote the family of all bases by  $\mathcal{B}$ . By the matroid axiom (I3), it follows that  $|B_1| = |B_2|$  holds for any bases  $B_1, B_2 \in \mathcal{B}$ .

► **Definition 3** (Base-orderable Matroid). *A matroid  $(E, \mathcal{I})$  is called base-orderable if for any two bases  $B_1, B_2 \in \mathcal{B}$ , there exists a bijection  $\varphi: B_1 \rightarrow B_2$  with the property that, for every  $e \in B_1$ , both  $B_1 - e + \varphi(e)$  and  $B_2 + e - \varphi(e)$  are bases.*

A class of base-orderable matroids includes *gammoids* (see [7] and [42, Theorem 42.12]), and gammoids include laminar matroids described below (see [10] and [11, Section 2.3.1]).

► **Example 4** (Laminar Matroid). For a laminar family  $\mathcal{L}$  on  $E$  and a function  $q: \mathcal{L} \rightarrow \mathbf{Z}_+$ , define  $\mathcal{I} = \{S \subseteq E \mid \forall L \in \mathcal{L}: |S \cap L| \leq q(L)\}$ . Then,  $(E, \mathcal{I})$  is a base-orderable matroid.

A matroid is *laminar* if it can be defined in the above-mentioned manner for some  $\mathcal{L}$  and  $q$ .

Base-orderability is known to be closed under the following operations (see, e.g., [5, 22]).

**Contraction.**<sup>2</sup> For a matroid  $(E, \mathcal{I})$  and any  $S \in \mathcal{I}$ , define  $\mathcal{I}_S := \{T \subseteq E \setminus S \mid S \cup T \in \mathcal{I}\}$ . Then,  $(E \setminus S, \mathcal{I}_S)$  is a matroid. If  $(E, \mathcal{I})$  is base-orderable, then so is  $(E \setminus S, \mathcal{I}_S)$ .

**Truncation.** For a matroid  $(E, \mathcal{I})$  and any integer  $p \in \mathbf{Z}_+$ , define  $\mathcal{I}_p := \{S \in \mathcal{I} \mid |S| \leq p\}$ . Then,  $(E, \mathcal{I}_p)$  is a matroid. If  $(E, \mathcal{I})$  is base-orderable, then so is  $(E, \mathcal{I}_p)$ .

**Direct Sum.** For matroids  $(E_j, \mathcal{I}_j)$  ( $j = 1, 2, \dots, \ell$ ) such that  $E_j$  are all pairwise disjoint, let  $E := E_1 \cup E_2 \cup \dots \cup E_\ell$  and  $\mathcal{I} := \{S_1 \cup S_2 \cup \dots \cup S_\ell \mid S_j \in \mathcal{I}_j \text{ (} j = 1, 2, \dots, \ell)\}$ . Then,  $(E, \mathcal{I})$  is a matroid. If all  $(E_j, \mathcal{I}_j)$  are base-orderable, then so is  $(E, \mathcal{I})$ .

On the intersection of two base-orderable matroids, we show the following property, which plays a key role in proving the  $\frac{3}{2}$ -approximation ratio of our algorithm. This generalizes the fact that, if (one-to-one) bipartite matchings  $M$  and  $N$  satisfy  $|M| < \frac{2}{3}|N|$ , then  $M \Delta N$  contains a connected component that forms an alternating path of length at most three.

► **Lemma 5.** *For base-orderable matroids  $(E, \mathcal{I}_1)$  and  $(E, \mathcal{I}_2)$ , suppose that  $S, T \in \mathcal{I}_1 \cap \mathcal{I}_2$  and  $|S| < \frac{2}{3}|T|$ . If  $S + e \notin \mathcal{I}_1 \cap \mathcal{I}_2$  for every  $e \in T \setminus S$ , then there exist distinct elements  $e_i, e_j, e_k$  such that  $e_i, e_k \in T \setminus S$ ,  $e_j \in S \setminus T$ , and the following conditions hold:*

- $S + e_i \in \mathcal{I}_1$ ,
- both  $S + e_i - e_j$  and  $T - e_i + e_j$  belong to  $\mathcal{I}_2$ ,
- both  $S - e_j + e_k$  and  $T + e_j - e_k$  belong to  $\mathcal{I}_1$ ,
- $S + e_k \in \mathcal{I}_2$ .

**Proof.** By the matroid axiom (I3), there is a subset  $A_1 \subseteq T \setminus S$  such that  $|A_1| = |T| - |S|$  and  $S_1 := S \cup A_1 \in \mathcal{I}_1$ . Then,  $|S_1| = |T|$ ; hence,  $|S_1 \setminus T| = |T \setminus S_1|$ . Let  $(E', \mathcal{I}'_1)$  be a matroid obtained from  $(E, \mathcal{I}_1)$  by contracting  $S_1 \cap T$  and truncating with size  $|S_1 \setminus T|$ , i.e.,  $E' = E \setminus (S_1 \cap T)$  and  $\mathcal{I}'_1 := \{R \subseteq E' \mid R \cup (S_1 \cap T) \in \mathcal{I}_1, |R| \leq |S_1 \setminus T|\}$ . Then,  $S_1 \setminus T$  and  $T \setminus S_1$  are bases of  $(E', \mathcal{I}'_1)$ . As  $(E', \mathcal{I}'_1)$  is base-orderable, there is a bijection  $\varphi_1: S_1 \setminus T \rightarrow T \setminus S_1$  such that both  $(S_1 \setminus T) - e + \varphi_1(e)$  and  $(T \setminus S_1) + e - \varphi_1(e)$  are bases of  $(E', \mathcal{I}'_1)$  for every  $e \in S_1 \setminus T$ . By the definition of  $\mathcal{I}'_1$ , this implies that both  $S - e + \varphi_1(e)$  and  $T + e - \varphi_1(e)$  belong to  $\mathcal{I}_1$  for every  $e \in S_1 \setminus T$ . By the same argument, there exists  $A_2 \subseteq T \setminus S$  such that  $|A_2| = |T| - |S|$  and  $S_2 := S \cup A_2 \in \mathcal{I}_2$ , and there exists a bijection  $\varphi_2: S_2 \setminus T \rightarrow T \setminus S_2$  such that both  $S - e + \varphi_2(e)$  and  $T + e - \varphi_2(e)$  belong to  $\mathcal{I}_2$  for every  $e \in S_2 \setminus T$ .

We represent  $\varphi_1$  and  $\varphi_2$  using a bipartite graph as follows. Note that, for each  $\ell \in \{1, 2\}$ , we have  $S_\ell \setminus T = S \setminus T$  and  $T \setminus S_\ell = T \setminus (S \cup A_\ell) \subseteq T \setminus S$ . Let  $S \setminus T$  and  $T \setminus S$  be two vertex sets and let  $M_\ell := \{(e, \varphi_\ell(e)) \mid e \in S \setminus T\}$  for  $\ell = 1, 2$ . Then, each  $M_\ell$  is a one-to-one matching that covers  $S \setminus T$  and  $T \setminus (S \cup A_\ell)$ . Note that the sets  $A_1, A_2 \subseteq S \setminus T$  are mutually disjoint since, otherwise, some  $e \in A_1 \cap A_2$  satisfies  $S + e \in \mathcal{I}_1 \cap \mathcal{I}_2$ , which contradicts the assumption. Then,  $|T \setminus (S \cup A_1 \cup A_2)| = |T \setminus S| - |A_1| - |A_2| = |T \setminus S| - 2|T| + 2|S|$ . Therefore, at most  $2(|T \setminus S| - 2|T| + 2|S|)$  vertices in  $S \setminus T$  are adjacent to  $T \setminus (S \cup A_1 \cup A_2)$  via the edges in  $M_1 \cup M_2$ . Because  $|S \setminus T| - 2(|T \setminus S| - 2|T| + 2|S|) = -3|S| + 2|T| + |S \cap T| > -3 \cdot \frac{2}{3}|T| + 2|T| + |S \cap T| \geq 0$ , there exists  $\tilde{e} \in S \setminus T$  that is not adjacent to  $T \setminus (S \cup A_1 \cup A_2)$  via  $M_1 \cup M_2$ . This implies that  $\varphi_2(\tilde{e}) \in A_1$  and  $\varphi_1(\tilde{e}) \in A_2$ ; hence,  $S + \varphi_2(\tilde{e}) \in \mathcal{I}_1$  and  $S + \varphi_1(\tilde{e}) \in \mathcal{I}_2$ . Let  $e_i := \varphi_2(\tilde{e})$ ,  $e_j := \tilde{e}$ , and  $e_k := \varphi_1(\tilde{e})$ . Then, these three elements satisfy all the required conditions. ◀

<sup>2</sup> Contraction is defined for any subset of  $E$  [37]; however this paper uses only contraction by independent sets.

## 5 Correctness

This section is devoted to showing Theorem 1, which establishes the correctness of Algorithm 1.

As in Section 3, let  $I$  be an SMTI-LC instance with  $E = \{e_i \mid i = 1, 2, \dots, n\}$  and let  $I^*$  be the auxiliary instance  $I^*$ , whose contract set is  $E^* = \{x_i, y_i, z_i \mid i = 1, 2, \dots, n\}$ .

For any agent  $a \in W \cup F$ , let  $E_a^* = \{x_i, y_i, z_i \mid e_i \in E_a\}$  and define families  $\mathcal{I}_a$  and  $\mathcal{I}_a^*$  by

$$\begin{aligned}\mathcal{I}_a &= \{S \subseteq E_a \mid \forall L \in \mathcal{L}_a : |S \cap L| \leq q_a(L)\}, \\ \mathcal{I}_a^* &= \{S^* \subseteq E_a^* \mid \forall L^* \in \mathcal{L}_a^* : |S^* \cap L^*| \leq q_a^*(L^*)\},\end{aligned}$$

i.e.,  $\mathcal{I}_a$  and  $\mathcal{I}_a^*$  are the families of feasible sets in  $I$  and  $I^*$ , respectively. Then,  $(E_a, \mathcal{I}_a)$  and  $(E_a^*, \mathcal{I}_a^*)$  are laminar matroids and base-orderable. The definitions of  $\mathcal{L}_a^*$  and  $q_a^*$  imply the following fact. Recall that  $\pi : 2^{E^*} \rightarrow 2^E$  is defined by  $\pi(S^*) = \{e_i \mid \{x_i, y_i, z_i\} \cap S^* \neq \emptyset\}$ .

► **Observation 6.** *For a set  $S^* \subseteq E_a^*$ , we have  $S^* \in \mathcal{I}_a^*$  if and only if  $|\{x_i, y_i, z_i\} \cap S^*| \leq 1$  for every  $e_i \in E_a$  and  $\pi(S^*) \in \mathcal{I}_a$ .*

Take any stable matching  $M^*$  of  $I^*$  and let  $M := \pi(M^*)$ . As  $M^*$  is feasible in  $I^*$ , it contains at most one copy of each contract  $e_i$ . For any  $e_i \in M$ , we denote by  $\pi^{-1}(e_i)$  the unique element in  $\{x_i, y_i, z_i\} \cap M^*$ .

By the definitions of the preference lists  $\{P_a^*\}_{a \in W \cup F}$  in  $I^*$ , we can observe the following properties. For any agent  $a \in W \cup F$  and contracts  $e, e' \in E_a^*$ , we write  $e \succ_a^* e'$  if  $a$  prefers  $e$  to  $e'$  with respect to  $P_a^*$ . Recall that  $P_a^*$  does not contain ties, while  $P_a$  may contain.

► **Observation 7.** *For any  $e_i \in E \setminus M$  and  $e_j \in M$ , the following conditions hold.*

- *For any agent  $a \in W \cup F$ , if  $e_i, e_j \in E_a$  and  $e_i \succ_a e_j$ , then  $y_i \succ_a^* \pi^{-1}(e_j)$  holds regardless of which of  $\{x_i, y_i, z_i\}$  is  $\pi^{-1}(e_i)$ .*
- *For any worker  $w \in W$ , if  $e_i, e_j \in E_w$  and  $\pi^{-1}(e_j) \succ_w^* x_i$ , then we have either  $[\pi^{-1}(e_j) = x_j \text{ and } e_j \succeq_w e_i]$  or  $[\pi^{-1}(e_j) = y_j \text{ and } e_j \succ_w e_i]$ .*
- *For any firm  $f \in F$ , if  $e_i, e_j \in E_f$  and  $\pi^{-1}(e_j) \succ_f^* z_i$ , then we have either  $[\pi^{-1}(e_j) = z_j \text{ and } e_j \succeq_f e_i]$  or  $[\pi^{-1}(e_j) = y_j \text{ and } e_j \succ_f e_i]$ .*

First, we show the stability of  $M$  in  $I$ . For each agent  $a \in W \cup F$ , we write  $M_a^* = M^* \cap E_a^*$ , which implies that  $\pi(M_a^*) = M_a$ .

► **Lemma 8.** *The set  $M$  is a stable matching of  $I$ .*

**Proof.** Since  $M^*$  is feasible for all agents in  $I^*$ , Observation 6 implies that  $M = \pi(M^*)$  is feasible for all agents in  $I$ , i.e.,  $M$  is a matching in  $I$ .

Suppose, to the contrary, that  $M$  is not stable. Then, some contract  $e_i \in E \setminus M$  blocks  $M$ . Let  $w = \partial_W(e_i)$  and  $f = \partial_F(e_i)$ . Then,  $e_i$  is free for both  $w$  and  $f$  in  $M$ . We now show that  $y_i$  is free for both  $w$  and  $f$  in  $M^*$ , which contradicts the stability of  $M^*$ .

As  $e_i$  is free for  $w$  in  $I$ , we have (i)  $M_w + e_i \in \mathcal{I}_w$  or (ii) there exists  $e_j \in M_a$  such that  $e_i \succ_w e_j$  and  $M_a + e_i - e_j \in \mathcal{I}_w$ . Note that  $e_i \in E \setminus M$  implies  $\{x_i, y_i, z_i\} \cap M^* = \emptyset$ . In case (i), we have  $\pi(M_w^* + y_i) = M_w + e_i \in \mathcal{I}_w$ , which implies  $M_w^* + y_i \in \mathcal{I}_w^*$ ; hence,  $y_i$  is free for  $w$  in  $M^*$ . In case (ii), we have  $\pi(M_w^* + y_i - \pi^{-1}(e_j)) = M_w + e_i - e_j \in \mathcal{I}_w$ , which implies  $M_w^* + y_i - \pi^{-1}(e_j) \in \mathcal{I}_w^*$ . Furthermore, as  $e_i \succ_w e_j$ , the first statement of Observation 7 implies  $y_i \succ_w^* \pi^{-1}(e_j)$ . Thus, in each case,  $y_i$  is free for  $w$  in  $M^*$ .

Similarly, we can show that  $y_i$  is free for  $f$  in  $M^*$ . Thus,  $y_i$  blocks  $M^*$ , a contradiction. ◀

Next, we show the approximation ratio using Lemma 5. Note that  $\{E_w \mid w \in W\}$  is a partition of  $E$ , as is  $\{E_f \mid f \in F\}$ . Let  $(E, \mathcal{I}_W)$  be the direct sum of base-orderable matroids  $\{(E_w, \mathcal{I}_w) \mid w \in W\}$  and  $(E, \mathcal{I}_F)$  be the direct sum of  $\{(E_f, \mathcal{I}_f) \mid f \in F\}$ . Then, they are both base-orderable matroids on  $E$ .

By the definitions of  $\mathcal{I}_W$  and  $\mathcal{I}_F$ , for any subset  $N \subseteq E$ , we have  $N \in \mathcal{I}_W \cap \mathcal{I}_F$  if and only if  $N_a := N \cap E_a$  is feasible for each  $a \in W \cup F$ , i.e.,  $N$  is a matching. Furthermore, for any matching  $N \in \mathcal{I}_W \cup \mathcal{I}_F$  and contract  $e_i \in E \setminus N$ , which is associated with a worker  $w = \partial_W(e_i)$  (and a firm  $f = \partial_F(e_i)$ ), the condition  $N + e_i \in \mathcal{I}_W$  is equivalent to  $N_w + e_i \in \mathcal{I}_w$ . In addition, if  $N + e_i \notin \mathcal{I}_W$ , we have  $N + e_i - e_j \in \mathcal{I}_W$  if and only if  $e_j \in N_w$  and  $N_w + e_i - e_j \in \mathcal{I}_w$ . The same statements hold when  $w$  and  $W$  are replaced with  $f$  and  $F$ , respectively.

► **Lemma 9.** *The set  $M$  satisfies  $|M| \geq \frac{2}{3}|M_{\text{OPT}}|$ , where  $M_{\text{OPT}}$  is a maximum-cardinality stable matching of  $I$ .*

**Proof.** Set  $N := M_{\text{OPT}}$  for notational simplicity. Since  $M$  and  $N$  are stable matchings,  $M, N \in \mathcal{I}_W \cap \mathcal{I}_F$ . In addition,  $M + e_i \notin \mathcal{I}_W \cap \mathcal{I}_F$  for any  $e_i \in N \setminus M$  since, otherwise,  $e_i$  blocks  $M$ . Suppose, to the contrary, that  $|M| < \frac{2}{3}|N|$ . Then, by Lemma 5 and the definitions of  $\mathcal{I}_W$  and  $\mathcal{I}_F$ , there exist three contracts  $e_i, e_j, e_k$  such that  $e_i, e_k \in N \setminus M$ ,  $e_j \in M \setminus N$ , and the following conditions hold:

- $M_w + e_i \in \mathcal{I}_w$ ,
- both  $M_f + e_i - e_j$  and  $N_f - e_i + e_j$  belong to  $\mathcal{I}_f$ ,
- both  $M_{w'} - e_j + e_k$  and  $N_{w'} + e_j - e_k$  belong to  $\mathcal{I}_{w'}$ ,
- $M_{f'} + e_k \in \mathcal{I}_{f'}$ ,

where  $w = \partial_W(e_i)$ ,  $f = \partial_F(e_i) = \partial_F(e_j)$ ,  $w' = \partial_W(e_j) = \partial_W(e_k)$ ,  $f' = \partial_F(e_k)$ .

Since  $e_i \notin M$  and  $M_w + e_i \in \mathcal{I}_w$ , we have  $M_w^* + z_i \in \mathcal{I}_w^*$ ; hence,  $z_i$  is free for the worker  $w = \partial_W(z_i)$  in  $M^*$ . Then, the stability of  $M^*$  implies that  $z_i$  is not free for the firm  $f = \partial_F(z_i)$ . Since  $\pi(M_f^* + z_i - \pi^{-1}(e_j)) = M_f + e_i - e_j \in \mathcal{I}_f$  implies  $M_f^* + z_i - \pi^{-1}(e_j) \in \mathcal{I}_f^*$ , we should have  $\pi^{-1}(e_j) \succ_f^* z_i$ . Then, the third statement of Observation 7 implies that we have either  $[\pi^{-1}(e_j) = z_j$  and  $e_j \succeq_f e_i]$  or  $[\pi^{-1}(e_j) = y_j$  and  $e_j \succ_f e_i]$ .

Meanwhile, since  $e_k \notin M$  and  $M_{f'} + e_k \in \mathcal{I}_{f'}$ , we have  $M_{f'}^* + x_k \in \mathcal{I}_{f'}^*$ ; hence,  $x_k$  is free for the firm  $f' = \partial_W(x_k)$  in  $M^*$ . As  $M^*$  is stable, then  $x_k$  is not free for the worker  $w' = \partial_W(x_k)$ . Since  $\pi(M_{w'}^* + x_k - \pi^{-1}(e_j)) = M_{w'} + e_k - e_j \in \mathcal{I}_{w'}$  implies  $M_{w'}^* + x_k - \pi^{-1}(e_j) \in \mathcal{I}_{w'}^*$ , we should have  $\pi^{-1}(e_j) \succ_{w'}^* x_k$ . Then, the second statement of Observation 7 implies that we have either  $[\pi^{-1}(e_j) = x_j$  and  $e_j \succeq_{w'} e_k]$  or  $[\pi^{-1}(e_j) = y_j$  and  $e_j \succ_{w'} e_k]$ .

Because we cannot have  $\pi^{-1}(e_j) = z_j$  and  $\pi^{-1}(e_j) = x_j$  simultaneously, we must have  $\pi^{-1}(e_j) = y_j$ ,  $e_j \succ_f e_i$ , and  $e_j \succ_{w'} e_k$ . As we have  $N_f - e_i + e_j \in \mathcal{I}_f$  and  $N_{w'} + e_j - e_k \in \mathcal{I}_{w'}$ , these preference relations imply that  $e_j$  blocks  $N$ , which contradicts the stability of  $N$ . ◀

**Proof of Theorem 1.** Combining Lemmas 8 and 9, we obtain Theorem 1. ◀

## 6 Time Complexity

We explain how to implement the second step of Algorithm 1 and estimate its time complexity, which establishes Theorem 2. For this purpose, we introduce the notion of a matroid-kernel, which is a matroid generalization of a stable matching proposed by Fleiner [12, 13]. Note that it is defined not only for base-orderable matroids but for general matroids.

## 6.1 Matroid-kernels

A triple  $\mathcal{M} = (E, \mathcal{I}, \succ)$  is called an *ordered matroid* if  $(E, \mathcal{I})$  is a matroid and  $\succ$  is a strict linear order on  $E$ . For an ordered matroid  $\mathcal{M} = (E, \mathcal{I}, \succ)$  and an independent set  $S \in \mathcal{I}$ , an element  $e \in E \setminus S$  is said to be *dominated* by  $S$  in  $\mathcal{M}$  if  $S + e \notin \mathcal{I}$  and there is no element  $e' \in S$  such that  $e \succ e'$  and  $S + e - e' \in \mathcal{I}$ .

Let  $\mathcal{M}_1 = (E, \mathcal{I}_1, \succ_1)$  and  $\mathcal{M}_2 = (E, \mathcal{I}_2, \succ_2)$  be two ordered matroids on the same ground set  $E$ . Then, a set  $S \subseteq E$  is called an  $\mathcal{M}_1\mathcal{M}_2$ -kernel if  $S \in \mathcal{I}_1 \cap \mathcal{I}_2$  and any element  $e \in E \setminus S$  is dominated by  $S$  in  $\mathcal{M}_1$  or  $\mathcal{M}_2$ .

In [12], an algorithm for finding a matroid-kernel has been described using choice functions defined as follows. For an ordered matroid  $\mathcal{M} = (E, \mathcal{I}, \succ)$ , give indices of elements in  $E$  such that  $E = \{e^1, e^2, \dots, e^n\}$  and  $e^1 \succ e^2 \succ \dots \succ e^n$ . Define a function  $C_{\mathcal{M}} : 2^E \rightarrow 2^E$  by letting  $C_{\mathcal{M}}$  be the output of the following greedy algorithm for every  $S \subseteq E$ . Let  $T^0 := \emptyset$  and define  $T^\ell$  for  $\ell = 1, 2, \dots, n$  by

$$T^\ell := \begin{cases} T^{\ell-1} + e^\ell & \text{if } e^\ell \in S \text{ and } T^{\ell-1} + e^\ell \in \mathcal{I}, \\ T^{\ell-1} & \text{otherwise;} \end{cases}$$

then, let  $\mathcal{M}(S) := T^n$ .

Let  $C_{\mathcal{M}_1}, C_{\mathcal{M}_2}$  be the choice functions defined from  $\mathcal{M}_1 = (E, \mathcal{I}_1, \succ_1)$ ,  $\mathcal{M}_2 = (E, \mathcal{I}_2, \succ_2)$ , respectively. In [12, Theorem 2], Fleiner showed that an  $\mathcal{M}_1\mathcal{M}_2$ -kernel can be found using the following algorithm, which can be regarded as a generalization of the Gale–Shapley algorithm. First, set  $R \leftarrow \emptyset$ . Then, repeat the following three steps: (1)  $S \leftarrow C_{\mathcal{M}_1}(E \setminus R)$ , (2)  $T \leftarrow C_{\mathcal{M}_2}(S \cup R)$ , and (3)  $R \leftarrow (S \cup R) \setminus T$ . Stop the repetition if  $R$  is not changed at (3) and return  $T$  at that moment. In terms of the ordinary Gale–Shapley algorithm,  $R$ ,  $S$ , and  $T$  correspond to the sets of contracts that are rejected by firms thus far, proposed by workers, and accepted by firms, respectively.

► **Theorem 10** (Fleiner [12, 13]). *For any pair of ordered matroids  $\mathcal{M}_1$  and  $\mathcal{M}_2$  on the same ground set  $E$ , there exists an  $\mathcal{M}_1\mathcal{M}_2$ -kernel. One can find an  $\mathcal{M}_1\mathcal{M}_2$ -kernel in  $O(|E| \cdot \text{EO})$  time, where EO is the time required to compute  $C_{\mathcal{M}_1}(S)$  and  $C_{\mathcal{M}_2}(S)$  for any  $S \subseteq E$ .*

## 6.2 Implementation of Our Algorithm

We show that the second step of Algorithm 1 is reduced to a computation of a matroid-kernel.

For an auxiliary instance  $I^*$  defined in Section 2, note that  $\{E_w^* \mid w \in W\}$  is a partition of  $E^*$  and let  $(E^*, \mathcal{I}_W^*)$  be the direct sum of  $\{(E_w^*, \mathcal{I}_w^*)\}_{w \in W}$ . Furthermore, let  $\succ_W$  be a strict linear order on  $E^*$  that is consistent with the workers' preferences  $\{P_w^*\}_{w \in W}$  in  $I^*$ . For example, obtain  $\succ_W$  by concatenating the lists  $P_w^*$  of all workers in an arbitrary order. Then,  $\mathcal{M}_W = (E^*, \mathcal{I}_W^*, \succ_W)$  is an ordered matroid on the contract set  $E^*$ . As  $\{E_f^* \mid f \in F\}$  is also a partition of  $E^*$ , we can define an ordered matroid  $\mathcal{M}_F = (E^*, \mathcal{I}_F^*, \succ_F)$  in the same manner from  $\{(E_f^*, \mathcal{I}_f^*)\}_{f \in F}$  and  $\{P_f^*\}_{f \in F}$ .

We show that  $\mathcal{M}_W\mathcal{M}_F$ -kernels are equivalent to stable matchings of  $I$ . This has already been shown in several previous works [14, 44]. We present a proof for the completeness.

► **Lemma 11.**  *$M^* \subseteq E^*$  is a stable matching of  $I^*$  if and only if  $M^*$  is an  $\mathcal{M}_W\mathcal{M}_F$ -kernel.*

**Proof.** By the definitions of  $(E^*, \mathcal{I}_W^*)$  and  $(E^*, \mathcal{I}_F^*)$ , a set  $M^* \subseteq E^*$  is feasible for all agents in  $I^*$  if and only if  $M^* \in \mathcal{I}_W^* \cap \mathcal{I}_F^*$ . Recall that a contract  $e \in E^* \setminus M^*$  is free for the associated worker  $w := \partial_W(e)$  if  $M_w^* + e \in \mathcal{I}_w^*$  or there exists  $e' \in M_w^*$  such that  $e \succ_w^* e'$  and  $M_w^* + e - e' \in \mathcal{I}_w^*$ . By the definition of  $\mathcal{I}_W^*$ , we have  $M_w^* + e \in \mathcal{I}_w^*$  if and only if

$M^* + e \in \mathcal{I}_W^*$ . In addition, if  $M_w^* + e \notin \mathcal{I}_w^*$ , then  $M_w^* + e - e' \in \mathcal{I}_w^*$  holds for  $e' \in M_w$  if and only if  $M^* + e - e' \in \mathcal{I}_W^*$ . Because  $\succ_W$  is consistent with  $\succ_w^*$ , these imply that  $e$  is free for  $w = \partial_W(e)$  in  $M^*$  if and only if  $e$  is not dominated by  $M^*$  in  $\mathcal{M}_W$ . Similarly, we can show that  $e$  is free for the associated firm  $f := \partial_F(e)$  in  $M^*$  if and only if  $e$  is not dominated by  $M^*$  in  $\mathcal{M}_F$ . Thus, the equivalence holds.  $\blacktriangleleft$

► **Lemma 12.** *For any subset  $S^* \subseteq E^*$ , we can compute  $C_{\mathcal{M}_W}(S^*)$  and  $C_{\mathcal{M}_F}(S^*)$  in  $O(k^* \cdot |E^*|)$  time, where  $k^*$  is the maximum level of nesting of laminar families  $\mathcal{L}_a^*$  ( $a \in W \cup F$ ).*

**Proof.** We only explain the computation of  $C_{\mathcal{M}_W}(S^*)$  because that of  $C_{\mathcal{M}_F}(S^*)$  is similar.

Let  $\mathcal{L}$  be the union of  $\{\mathcal{L}_w^*\}_{w \in W}$  and define  $q : \mathcal{L} \rightarrow \mathbf{Z}_+$  by setting  $q(L) = q_w^*(L)$  for each  $w \in W$  and  $L \in \mathcal{L}_w^*$ . Then,  $\mathcal{L}$  is a laminar family on  $E^*$  and the matroid  $(E^*, \mathcal{I}_W^*)$  is defined by  $\mathcal{L}$  and  $q$ . The maximum level of nesting of  $\mathcal{L}$  is again  $k^*$ .

Referring to [4], we represent  $\mathcal{L}$  by a forest  $G$  whose node set is  $\{v_L \mid L \in \mathcal{L}\}$ . Node  $v_L$  is the parent of  $v_{L'}$  in  $G$  if  $L \subseteq L'$  and there is no  $L'' \in \mathcal{L}$  such that  $L \subsetneq L'' \subsetneq L'$ . Note that  $\mathcal{L}$  contains the set  $\{x_i, y_i, z_i\}$  for every  $e_i \in E$ , which is inclusion-wise minimal in  $\mathcal{L}$ . Therefore, the node  $v_i := v_{\{x_i, y_i, z_i\}}$  is a leaf for any  $e_i \in E$ , and any leaf has this form.

We compute the sequence  $T^0, T^1, \dots, T^{|E^*|}$  of sets in the definition of  $C_{\mathcal{M}_W}(S^*)$  as follows. For each  $v_L$ , we store a pointer to its parent, the value of  $q(L)$ , and the value of  $|T^{\ell-1} \cap L|$ . For each  $e^\ell \in E^*$ , we have  $T^{\ell-1} + e^\ell \in \mathcal{I}_W^*$  if and only if there is no ancestor node  $v_L$  of  $v_i$  with  $q(L) = |T^{\ell-1} \cap L|$ , where  $v_i$  is the leaf with  $e^\ell \in \{x_i, y_i, z_i\}$ . Then, we can check whether  $T^{\ell-1} + e^\ell \in \mathcal{I}_W^*$  in  $O(k^*)$  time by following the path of the parent pointers from  $v_i$ . When  $T^\ell = T^{\ell-1} + e^\ell$ , we update the stored values  $|T^{\ell-1} \cap L|$  to  $|T^\ell \cap L|$  for each  $L \in \mathcal{L}$  with  $e^\ell \in L$ . This is also performed in  $O(k^*)$  time by following the path of the parent pointers.  $\blacktriangleleft$

**Proof of Theorem 2.** As we have Theorem 1, what is left is to show the time complexity. The set  $E^*$  of contracts in  $I^*$  satisfies  $|E^*| = 3|E|$ . The maximum level of nesting of laminar families  $\mathcal{L}_a^*$  in  $I^*$  is  $k + 1$ . By Theorem 10 and Lemmas 11 and 12, then the second step of Algorithm 1 is computed in  $O((k + 1) \cdot |E^*|^2) = O(k \cdot |E|^2)$  time. Since the first and third steps can be performed in  $O(k \cdot |E|^2)$  time, Algorithm 1 runs in  $O(k \cdot |E|^2)$  time.  $\blacktriangleleft$

► **Remark.** Our analysis depends on the fact that the feasible set family defined by laminar constraints forms the independent set family of a base-orderable matroid. Actually, we can extend Theorem 1 to a setting where the family of feasible sets of each agent  $a \in W \cup F$  is represented by the independent set family  $\mathcal{I}_a$  of an arbitrary base-orderable matroid. To construct  $I^*$  in this case, we define  $E^*$  and  $\{P_a^*\}_{a \in W \cup F}$  as in Section 3 and define the feasible set family  $\mathcal{I}_a^*$  by  $\mathcal{I}_a^* = \{S^* \subseteq E_a^* \mid |\{x_i, y_i, z_i\} \cap S^*| \leq 1 \text{ for any } e_i \in E_a \text{ and } \pi(S^*) \in \mathcal{I}_a\}$ . We can easily show that  $(E_a^*, \mathcal{I}_a^*)$  is also a base-orderable matroid and apply the arguments in Sections 5 and 6, except Lemma 12. Given a membership oracle for each  $\mathcal{I}_a$  available, Algorithm 1 runs in  $O(\tau \cdot |E|^2)$  time in this case, where  $\tau$  is the time for an oracle call.

## 7 Strategy-Proof Approximation Mechanisms

In this section, we investigate approximation ratios for MAX-SMTI-LC attained by strategy-proof mechanisms. First, note that our setting SMTI-LC is a generalization of the stable marriage model of Gale and Shapley [16]; hence, Roth's impossibility theorem [40] implies that there is no mechanism that returns a stable matching and is strategy-proof for agents on both sides. As with many existing works on strategy-proofness in two-sided matching models, we consider one-sided strategy-proofness in the setting of many-to-one matching. Many-to-one matching models have various applications such as assignment of residents to hospitals [39, 41] and students to high schools [1–3]. In such applications, strategy-proofness for residents or students is a desirable property preventing their strategic behavior.

## 7.1 Model and Definitions

We define a setting of SMTI-OLC, which is a many-to-one variant of SMTI-LC. (Here, OLC stands for “one-sided laminar constraints”). In SMTI-OLC, each worker is assigned at most one contract and hence has no laminar constraints. An instance of SMTI-OLC is described as  $I = (W, F, E, \{P_w\}_{w \in W}, \{\mathcal{L}_f, q_f, P_f\}_{f \in F})$ . To consider strategies of workers, we slightly change the assumption on each  $P_w$ . In Section 2, it is assumed that  $P_w$  contains all contracts in  $E_w$ . Here, we allow each worker to submit a preference list  $P_w$  that is defined on any subset of  $E_w$  and regard contracts not appearing in  $P_w$  as unacceptable for  $w$ . Let  $E^\circ$  be the set of acceptable contracts, that is,  $E^\circ = \{e \in E \mid e \text{ appears in } P_w, \text{ where } w = \partial_W(e)\}$ .

A set  $M \subseteq E$  is called a *matching* if  $M \subseteq E^\circ$ ,  $|M_w| \leq 1$  for every worker  $w \in W$ , and  $M$  is feasible for every firm  $f \in F$ . For a matching  $M$ , a contract  $e \in E \setminus M$  *blocks*  $M$  if it is free for both  $\partial_W(e)$  and  $\partial_F(e)$ , where we say that  $e$  is *free* for the associated worker  $w := \partial_W(e)$  if  $e \in E^\circ$  and either  $w$  is assigned no contract in  $M$  or prefers  $e$  to the contract assigned in  $M$ . A matching  $M$  is *stable* if there is no contract that blocks  $M$ . The auxiliary instance  $I^* = (W, F, E^*, \{P_w^*\}_{w \in W}, \{\mathcal{L}_f^*, q_f^*, P_f^*\}_{f \in F})$  of  $I$  is defined similarly as in Section 3.

We remark that SMTI-OLC can be seen as a special case of SMTI-LC, although the assumption on workers’ preference lists is slightly different from that of SMTI-LC. From an SMTI-OLC instance  $I$ , define  $I^\circ = (W, F, E^\circ, \{\mathcal{L}_a^\circ, q_a^\circ, P_a^\circ\}_{a \in W \cup F})$  as follows. For each worker  $w \in W$ , set  $\mathcal{L}_w^\circ = \{E_w^\circ\}$ ,  $q_w^\circ(E_w^\circ) = 1$ , and  $P_w^\circ = P_w$ . For each firm  $f \in F$ , set  $\mathcal{L}_f^\circ = \{L \cap E^\circ \mid L \in \mathcal{L}_f\}$ ,  $q_f^\circ(L \cap E^\circ) = q_f(L)$  for each  $L \in \mathcal{L}_f$ , and let  $P_f^\circ$  be the restriction of  $P_f$  on  $E_f^\circ$  (i.e., delete the elements in  $E_f \setminus E_f^\circ$  from  $P_f$ ). Then,  $I^\circ$  is an instance of SMTI-LC in Section 2. By definition, we can observe that a subset  $M \subseteq E$  is a stable matching of  $I$  if and only if it is a stable matching of  $I^\circ$ . Therefore, we can apply Algorithm 1 to SMTI-OLC instances.

For subsets  $M, N \subseteq E$ , a worker  $w \in W$ , and a preference list  $P_w$ , we say that  $w$  *weakly prefers*  $M$  to  $N$  with respect to  $P_w$  if either (i)  $w$  is assigned a contract appearing in  $P_w$  only in  $M$  or (ii)  $w$  is assigned a contract appearing in  $P_w$  in both  $M$  and  $N$  and does not strictly prefer the one assigned in  $N$  with respect to  $P_w$ . A stable matching  $M$  of an SMTI-OLC instance  $I$  is *worker-optimal* if, for any other stable matching  $N$  of  $I$ , every worker  $w$  weakly prefers  $M$  to  $N$ .

A *mechanism* is a mapping from SMTI-OLC instances to matchings. Here, we define the *worker-strategy-proofness* of a mechanism. Let  $A$  be a mechanism. For any instance  $I$  and any worker  $w$ , let  $I'$  be an instance obtained from  $I$  by replacing  $w$ ’s list  $P_w$  with some other list  $P'_w$ . Let  $M$  and  $M'$  be the outputs of  $A$  for instances  $I$  and  $I'$ , respectively. We say that  $A$  is *worker-strategy-proof* if  $w$  weakly prefers  $M$  to  $M'$  with respect to the original list  $P_w$  regardless of the choices of  $I$ ,  $w$ , and  $P'_w$ .

## 7.2 Approximation Mechanisms

Before providing our results on SMTI-OLC, we introduce some existing results on special cases of SMTI-OLC. We first present a result on the setting without ties.

► **Lemma 13.** *In a restriction of SMTI-OLC in which all agents have strict preferences, a mechanism that returns the worker-optimal stable matching is worker-strategy-proof.*

Lemma 13 is a natural consequence of the results shown in previous works [17, 33]. For the completeness, the full version [45] provides the proof, which uses the fact that SMTI-OLC can be reduced to the model of Hatfield and Milgrom [20] if there are no ties.

Next, we introduce the results of Hamada et al. [19] on MAX-SMTI, which is a special case of MAX-SMTI-OLC in which every agent is assigned at most one contract.

► **Theorem 14** (Hamada et al. [19, Theorem 2]). *For MAX-SMTI, there is a worker-strategy-proof mechanism that returns a 2-approximate solution. On the other hand, for any  $\epsilon > 0$ , there is no worker-strategy-proof mechanism that returns a  $(2 - \epsilon)$ -approximate solution.*

► **Theorem 15** (Hamada et al. [19, Theorem 4]). *For a restriction of MAX-SMTI in which ties appear in only workers' preference lists, there is a worker-strategy-proof mechanism that returns a  $\frac{3}{2}$ -approximate solution. On the other hand, for any  $\epsilon > 0$ , there is no worker-strategy-proof mechanism that returns a  $(\frac{3}{2} - \epsilon)$ -approximate solution.*

The first statement of Theorem 14 is attained by a naive mechanism that first breaks ties in an increasing order of the indices and then finds the worker-optimal stable matching of the resultant instance. This method naturally extends to the setting of SMTI-OLC and yields the following theorem. See the full version [45] for the proof.

► **Theorem 16.** *For SMTI-OLC, there is a worker-strategy-proof mechanism that returns a stable matching  $M$  with  $|M| \geq \frac{1}{2}|M_{\text{OPT}}|$  in  $O(k \cdot |E|^2)$  time, where  $M_{\text{OPT}}$  is a maximum-cardinality stable matching and  $k$  is the maximum level of nesting of  $\mathcal{L}_f$  ( $f \in F$ ).*

Since SMTI-OLC is a generalization of SMTI, the second statement (i.e., the hardness part) of Theorem 14 immediately extends to MAX-SMTI-OLC. Therefore, for the general SMTI-OLC, there is no worker-strategy-proof mechanism with an approximation ratio better than 2.

However, in a special case in which firms' lists contain no ties, Algorithm 1 in Section 3 defines a worker-strategy-proof mechanism whose approximation ratio is  $\frac{3}{2}$ . That is, we can extend the first statement of Theorem 15 to the setting of SMTI-OLC. According to the second statement of Theorem 15, this is the best approximation ratio attained by a worker-strategy-proof mechanism.

► **Theorem 17.** *For a restriction of SMTI-OLC in which ties appear in only workers' lists, there is a worker-strategy-proof mechanism that returns a stable matching  $M$  with  $|M| \geq \frac{2}{3}|M_{\text{OPT}}|$  in  $O(k \cdot |E|^2)$  time, where  $M_{\text{OPT}}$  is a maximum-cardinality stable matching and  $k$  is the maximum level of nesting of laminar families  $\mathcal{L}_f$  ( $f \in F$ ).*

We provide a mechanism that meets the requirements in Theorem 17. Our mechanism is regarded as a possible realization of Algorithm 1. In the second step of Algorithm 1, we should choose the worker-optimal stable matching of the auxiliary instance  $I^*$ . Our mechanism is described as follows.

1. Given an instance  $I$  (in which ties appear in only workers' lists), construct  $I^*$ .
2. Find the worker-optimal stable matching  $M^*$  of  $I^*$ .
3. Let  $M = \pi(M^*)$  and return  $M$ .

In the proof of Theorem 10 (Fleiner [12, p.113]), it is shown that one can find the  $\mathcal{M}_1$ -optimal  $\mathcal{M}_1\mathcal{M}_2$ -kernel in  $O(|E| \cdot \text{EO})$  time. The arguments in Section 6 then imply that one can find the worker-optimal stable matching of  $I^*$  in  $O(k \cdot |E|^2)$  time. As we have Theorem 2, showing the strategy-proofness of the above-mentioned mechanism completes the proof of Theorem 17. To this end, we show the following lemma.

► **Lemma 18.** *Let  $I$  be an SMTI-OLC instance with  $E = \{e_i \mid i = 1, 2, \dots, n\}$  and let  $I^*$  be the auxiliary instance. If ties appear in only workers' lists in  $I$ , then the worker-optimal stable matching  $M^*$  of  $I^*$  satisfies  $M^* \cap \{z_i \mid i = 1, 2, \dots, n\} = \emptyset$ .*

**Proof.** Suppose, to the contrary, that  $z_i \in M^*$  for some index  $i$ . Then  $N := M^* - z_i + y_i$  is a matching of  $I^*$  and  $w := \partial_W(z_i) = \partial_W(y_i)$  prefers  $N$  to  $M^*$ . We intend to show that  $N$  is stable in  $I^*$ . Take any  $e \in E^* \setminus N = (E^* \setminus M^*) + z_i - y_i$ . If  $e = z_i$ , then it does not block  $N$  because  $y_i \succ_w^* z_i$ . If  $e \neq z_i$ , then the assignment of  $\partial_W(e)$  does not change in  $M^*$  and  $N$ , and hence  $e$  can block  $N$  only if  $f := \partial_F(e) = \partial_F(z_i)$  and  $z_i \succ_f^* e \succ_f^* y_i$ . This is impossible because no contract lies between  $z_i$  and  $y_i$  in  $P_f^*$  as the list  $P_f$  of the firm  $f$  is strict. Thus,  $N$  is a stable matching of  $I^*$ , which contradicts the worker-optimality of  $M^*$ . ◀

**Proof of Theorem 17.** As we have Theorem 2, what is left is to show that our mechanism is worker-strategy-proof. Let  $I = (W, F, E, \{P_w\}_{w \in W}, \{\mathcal{L}_f, q_f, P_f\}_{f \in F})$  be an instance of the setting in the statement and let  $E = \{e_i \mid i = 1, 2, \dots, n\}$ . Furthermore, let  $I'$  be obtained from  $I$  by replacing  $P_w$  with some other list  $P'_w$ . Let  $M^*$  and  $N^*$  be the worker-optimal stable matchings of the auxiliary instances defined from  $I$  and  $I'$ , respectively. Note that the two auxiliary instances have no ties and they differ only in the preference list of  $w$ . Then, Lemma 13 implies that  $w$  weakly prefers  $M^*$  to  $N^*$  with respect to  $P_w^*$ . In other words, either (i)  $w$  is assigned a contract on  $P_w^*$  only in  $M^*$ , or (ii)  $w$  is assigned a contract on  $P_w^*$  in both  $M^*$  and  $N^*$  and does not strictly prefer the one assigned in  $N^*$  w.r.t.  $P_w^*$ . By Lemma 18,  $w$  is not assigned a contract of type  $z_i$  in  $M^*$  or  $N^*$ . Then, the definition of  $P_w^*$  implies that  $w$  weakly prefers  $\pi(M^*)$  to  $\pi(N^*)$  w.r.t.  $P_w$ . Thus the mechanism is worker-strategy-proof. ◀

## Abstract

We give an  $O(k^3 \Delta n \log n \min(k, \log^2 n) \log^2(nC))$ -time algorithm for computing maximum integer flows in planar graphs with integer arc *and vertex* capacities bounded by  $C$ , and  $k$  sources and sinks. This improves by a factor of  $\max(k^2, k \log^2 n)$  over the fastest algorithm previously known for this problem [Wang, SODA 2019].

The speedup is obtained by two independent ideas. First we replace an iterative procedure of Wang that uses  $O(k)$  invocations of an  $O(k^3 n \log^3 n)$ -time algorithm for maximum flow algorithm in a planar graph with  $k$  apices [Borradaile et al., FOCS 2012, SICOMP 2017], by an alternative procedure that only makes one invocation of the algorithm of Borradaile et al. Second, we show two alternatives for computing flows in the  $k$ -apex graphs that arise in our modification of Wang's procedure faster than the algorithm of Borradaile et al. In doing so, we introduce and analyze a sequential implementation of the parallel highest-distance push-relabel algorithm of Goldberg and Tarjan [JACM 1988].

## 1 Introduction

The maximum flow problem has been extensively studied in many different settings and variations. This work concerns two related variants of the maximum flow problem in planar graphs. The first variant is the problem of computing a maximum flow in a directed planar network with integer arc *and vertex* capacities, and  $k$  sources and sinks. The second variant, which is used in algorithms for the first variant, is the problem of computing a maximum flow in a directed network that is nearly planar; there is a set of  $k$  vertices, called apices, whose removal turns the graph planar.

The problem of maximum flow in a planar graph with vertex capacities has been studied in several works since the 1990s [9, 14, 7, 2, 13]. For a more detailed survey of the history of this problem and other relevant results see [13] and references therein. Vertex capacities pose a challenge in planar graphs because the standard reduction from a flow network with vertex capacities to a flow network with only arc capacities does not preserve planarity. The problem can be solved by algorithms for maximum flow in sparse graphs (i.e., graphs with  $n$  vertices

and  $O(n)$  edges that are not necessarily planar). The fastest such algorithms currently known are an  $O(n^2/\log n)$ -time algorithm [11] for sparse graphs, and an  $O(n^{4/3+o(1)}C^{1/3})$ -time algorithm for sparse graphs with integer capacities bounded by  $C$  [8]. Until recently, there was no planarity exploiting algorithm for the case of more than a single source and a single sink. Significant progress on this problem was recently made by Wang [13]. Wang developed an  $O(k^5\Delta n \log^3 n \log^2(nC))$ -time algorithm, where  $k$  is the number of sources and sinks,  $\Delta$  is the maximum vertex degree, and  $C$  is the largest capacity of a single vertex.<sup>1</sup> This is faster than using the two algorithms for general sparse graphs mentioned above when  $k = \tilde{O}(n^{1/5}/(\Delta \log^2 C) + (nC)^{1/15}/\Delta)$ .

Wang’s algorithm uses multiple calls to an algorithm of Borradaile et al. [2] for computing a maximum flow in a  $k$ -apex graph with only arc capacities. The algorithm of Borradaile et al. [2] is based on an approach originally suggested by Hochstein and Weihe [6] for a slightly more restricted problem. In Borradaile et al.’s approach, a maximum flow in a  $k$ -apex graph with  $n$  vertices is computed by simulating the Push-Relabel algorithm of Goldberg and Tarjan [4] on a complete graph with  $k$  vertices, corresponding to the  $k$  apices of the input graph. Whenever the Push-Relabel algorithm pushes flow on an arc of the complete graph, the push operation is simulated by sending flow between the two corresponding apices in the input  $k$ -apex graph. This can be done efficiently using an  $O(n \log^3 n)$  time multiple-source multiple-sink (MSMS) maximum flow algorithm in planar graphs, which is the main result of the paper of Borradaile et al. [2]. Overall, their algorithm for maximum flow in  $k$ -apex graphs takes  $O(k^3 n \log^3 n)$  time. Flow in  $k$ -apex graphs can also be computed using the algorithms for sparse graphs mentioned above. The  $O(k^3 n \log^3 n)$ -time algorithm of Borradaile et al. is faster than these algorithms when  $k = \tilde{O}(n^{1/3}/\log^2 C + (nC)^{1/9})$ .

## 1.1 Our results and techniques

We improve the running time of Wang’s algorithm to  $O(k^3\Delta n \log n \min(k, \log^2 n) \log^2(nC))$ . This is faster than Wang’s result by a factor of  $\max(k^2, k \log^2 n)$ , extending the range of values of  $k$  for which the planarity exploiting algorithm is the fastest known algorithm for the problem to  $k = \tilde{O}(n^{1/3}/(\Delta \log^2 C) + (nC)^{1/9}/\Delta)$ . The improvement is achieved by two main ideas. At the heart of Wang’s algorithm is an iterative procedure for eliminating excess flow from vertices violating the capacity constraints. Each iteration consists of computing a circulation with some desired properties. Wang computes this circulation using  $O(k)$  calls to the algorithm of Borradaile et al. for maximum flow in  $k$ -apex graphs. We show how to compute this circulation using a constant number of invocations of the algorithm for  $k$ -apex graphs. This idea alone improves on Wang’s algorithm by a factor of  $k$ .

To further improve the running time, we modify the algorithm of Borradaile et al. for maximum flow in  $k$ -apex graphs [2]. The algorithm of Borradaile et al. uses the Push-Relabel algorithm of Goldberg and Tarjan [4]. We introduce a sequential implementation of the parallel highest-distance Push-Relabel algorithm. In this algorithm, which we call batch-highest-distance, a single operation, Bulk-Push, pushes flow on multiple arcs simultaneously, instead of just on a single arc as in Goldberg and Tarjan’s Push operation. More specifically, we simultaneously push flow on all admissible arcs whose tails have maximum height (see Section 3). This is reminiscent of parallel and distributed Push-Relabel algorithms [4, 3],

---

<sup>1</sup> In a very recent personal communication, Wang informed the authors of a subtle bug in the published version [13] of his result that led to the  $\Delta$  factor not appearing in the claimed running time. The full version of Wang’s paper (which has not been published yet) fixes the bug, and we refer to his corrected claims throughout the current work.

but our algorithm is sequential, not parallel. We prove that the total number of Bulk-Push operations performed by the batch-highest-distance algorithm is  $O(k^2)$  (this should be compared to  $O(k^3)$  Push operations for the FIFO or highest-distance Push-Relabel algorithms). We then show that, in the case of the  $k$ -apex graphs that show up in Wang's algorithm, we can implement each Bulk-Push operation using a constant number of invocations of the  $O(n \log^3 n)$ -time MSMS maximum flow algorithm for planar graphs [2]. Hence, we can find a maximum flow in such  $k$ -apex graphs in  $O(k^2 n \log^3 n)$  time, which is faster by a factor of  $k$  than the time required by the algorithm of Borradaile et al.

We also give another way to modify the algorithm of Borradaile et al. for maximum flow in  $k$ -apex graphs; the second way is better when  $k = o(\log^2 n)$ . We observe that the structure of the  $k$ -apex graphs that arise in Wang's algorithm allows us to implement each of the  $O(k^3)$  Push operations of the FIFO Push-Relabel algorithm used by Borradaile et al. in just  $O(n \log n)$  time. This is done using a procedure due to Miller and Naor [10] for the case when all sources and sinks lie on a single face.

**Roadmap.** In Section 2 we provide preliminary background and notations. Section 3 describes the sequential implementation of the parallel highest-distance Push-Relabel algorithm, and its use in an algorithm for finding maximum flow in  $k$ -apex graphs. In Section 4 we describe how to use this Push-Relabel variant to obtain an improved algorithm for computing maximum flow in planar graphs with vertex capacities.

## 2 Preliminaries

All the graphs we consider in this paper are directed. For a graph  $G$  we use  $V(G)$  and  $E(G)$  to denote the vertex set and arc set of  $G$ , respectively. For any vertex  $v \in V(G)$ , let  $\deg(v)$  denote the degree of  $v$  in  $G$ .

For a path  $P$  we denote by  $P[u, v]$  the subpath of  $P$  that starts at  $u$  and ends at  $v$ . We denote by  $P \circ Q$  the concatenation of two paths  $P, Q$  such that the first vertex of  $Q$  is the last vertex of  $P$ .

A *flow network* is a directed graph  $G$  with a capacity function  $c : V(G) \cup E(G) \rightarrow [0, \infty)$  on the vertices and arcs of  $G$ , along with two disjoint sets  $S, T \subset V(G)$  called *sources* and *sinks*, respectively. We assume without loss of generality that sources and sinks have infinite capacities, and that, for any arc  $e = (u, v) \in E(G)$ , the *reverse* arc  $(v, u)$ , denoted  $\text{rev}(e)$  is also in  $E(G)$ , and has capacity  $c(\text{rev}(e)) = 0$ .

Let  $\rho : E(G) \rightarrow [0, \infty)$ . To avoid clutter we write  $\rho(u, v)$  instead of  $\rho((u, v))$ . For each vertex  $v$  let  $\rho^{\text{in}}(v) = \sum_{(u, v) \in E(G)} \rho(u, v)$ , and  $\rho^{\text{out}}(v) = \sum_{(v, u) \in E(G)} \rho(v, u)$ . The function  $\rho$  is called a *preflow* if it satisfies the following conservation constraint: for all  $v \in V(G) \setminus (S)$ ,  $\rho^{\text{in}}(v) \geq \rho^{\text{out}}(v)$ . The *excess of a vertex  $v$  with respect to a preflow  $\rho$*  is defined by  $\text{ex}(\rho, v) = \rho^{\text{in}}(v) - \rho^{\text{out}}(v)$ . A preflow is *feasible on an arc  $e \in E(G)$*  if  $\rho(e) \leq c(e)$ . It is *feasible on a vertex  $v \in V(G)$*  if  $\rho^{\text{in}}(v) \leq c(v)$ . A preflow is said to be *feasible* if, in addition to the conservation constraint, it is feasible on all arcs and vertices. The value of a preflow  $\rho$  is defined as  $|\rho| = \sum_{s \in S} \rho^{\text{out}}(s) - \rho^{\text{in}}(s)$ . A preflow  $f$  satisfying  $\text{ex}(f, v) = 0$  for all  $v \in V(G) \setminus (S \cup T)$ , is called a *flow*. A flow whose value is 0 is called a *circulation*. A *maximum flow* is a feasible flow whose value is maximum.

► **Remark 1.** The problem of finding a maximum flow in a flow network with multiple sources and sinks can be reduced to the single-source, single-sink case by adding a super source  $s$  and super sink  $t$ , and infinite-capacity arcs  $(s, s_i)$  and  $(t_i, t)$  for every  $s_i \in S$  and  $t_i \in T$ . If the

original network is planar then this transformation adds two apices to the graph. Throughout the paper, whenever we refer to the graph  $G$ , we mean the graph  $G$  after this transformation, i.e., with a single source, the apex  $s$ , and a single sink, the apex  $t$ .

The *violation of a flow  $f$  at a vertex  $v$*  is defined by  $\text{vio}(f, v) = \max\{0, f^{\text{in}}(v) - c(v)\}$ . Thus, if  $f$  is a feasible flow then  $\text{vio}(f, v) = 0$  for all vertices  $v$ . The violation of the flow  $f$  is defined to be  $\text{vio}(f) = \max_{v \in V(G)} \text{vio}(f, v)$ .<sup>2</sup>

A preflow  $\rho$  is *acyclic* if there is no cycle  $C$  such that  $\rho(e) > 0$  for every arc  $e \in C$ . A preflow *saturates* an arc  $e$  if  $\rho(e) = c(e)$ .

The sum of two preflows  $\rho$  and  $\eta$  is defined as follows. For every arc  $e \in E(G)$ ,  $(\rho + \eta)(e) = \max\{0, \rho(e) + \eta(e) - \rho(\text{rev}(e)) - \eta(\text{rev}(e))\}$ . Multiplying the preflow  $\rho$  by some constant  $c$  to get the flow  $c\rho$  is defined as  $(c\rho)(e) = c \cdot \rho(e)$  for all  $e \in E(G)$ .

The *residual capacity*  $c_\rho(e)$  of an arc  $e$  with respect to a preflow  $\rho$  is  $c(e) - \rho(e) + \rho(\text{rev}(e))$ . The *residual graph* of a flow network  $G$  with respect to a preflow  $\rho$  is the graph  $G$  where the capacity of every arc  $e \in E(G)$  is set to  $c_\rho(e)$ . It is denoted by  $G_\rho$ . A path of  $G$  is called *augmenting* or *residual* (with respect to a preflow  $\rho$ ) if it is also a path of  $G_\rho$ .

Suppose  $G$  and  $H$  are flow networks such that every arc in  $G$  is also an arc in  $H$ . If  $f'$  is a (pre)flow in  $H$  then the *restriction* of  $f'$  to  $G$  is the (pre)flow  $f$  in  $G$  defined by  $f(e) = f'(e)$  for all  $e \in E(G)$ .

### 3 An algorithm for maximum flow in $k$ -apex graphs

In this section we introduce a sequential implementation of the parallel highest-distance Push-Relabel algorithm of Goldberg and Tarjan [4], and use it in the algorithm of Borradaile et al. [2] for maximum flow in  $k$ -apex graphs. We first give a high-level description of the Push-Relabel algorithm.

#### 3.1 The Push-Relabel algorithm [4]

Let  $H$  be a flow network (not necessarily planar) with source  $s$  and sink  $t$ , arc capacities  $c : E(H) \rightarrow \mathbb{R}$ , and no finite vertex capacities. The Push-Relabel algorithm maintains a feasible *preflow* function,  $\rho$ , on the arcs of  $H$ . A vertex  $u$  is called *active* if  $\text{ex}(\rho, u) > 0$ . The algorithm starts with a preflow that is zero on all arcs, except for the arcs leaving the source  $s$ , which are saturated. Thus, all the neighbors of  $s$  are initially active. When the algorithm terminates, no vertex is active and the preflow function is guaranteed to be a maximum flow. The algorithm also maintains a label function  $h$  (also known as distance or height function) over the vertices of  $H$ . The label function  $h : V(H) \rightarrow \mathbb{N}$  is *valid* if  $h(s) = |V(H)|$ ,  $h(t) = 0$  and  $h(u) \leq h(v) + 1$  for every residual arc  $(u, v) \in E(H_\rho)$ .

The algorithm progresses by performing two basic operations, **Push** and **Relabel**. A **Push** operation applies to an arc  $(u, v)$  if  $(u, v)$  is residual,  $\text{ex}(\rho, u) > 0$ , and  $h(u) = h(v) + 1$ . The operation moves excess flow from  $u$  to  $v$  by increasing the flow on  $e$  by  $\min\{\text{ex}(\rho, u), c(e) - \rho(e)\}$ .

The other basic operation, **Relabel**( $u$ ), assigns  $u$  the label  $h(u) = \min\{h(v) : (u, v) \in E(H_\rho)\} + 1$  and applies to  $u$  only if  $u$  is active and  $h(u)$  is not greater than the label of any neighbor of  $u$  in  $H_\rho$ . In other words, **Relabel** applies to an active vertex  $u$  only if the excess flow in  $u$  cannot be pushed out of  $u$  (because  $h(u)$  is not high enough). The algorithm performs applicable **Push** and **Relabel** operations until no vertex is active.

<sup>2</sup> We define violations only with respect to flows (rather than preflows) because we will only discuss preflows in the context of flow networks without finite vertex capacities.

To fit our purposes, we think of the algorithm as one that only maintains explicitly the excess  $\text{ex}(\rho, v)$  and residual capacity  $c_\rho(e)$  of each vertex  $v$  and arc  $e$  of  $H$ . The preflow  $\rho$  is implicit. In this view, a  $\text{Push}(u, v)$  operation decreases  $\text{ex}(\rho, u)$  and  $c_\rho(u, v)$  by  $\min\{\text{ex}(\rho, u), c_\rho(u, v)\}$  and increases  $\text{ex}(\rho, v)$  and  $c_\rho(v, u)$  by the same amount.

We reformulate Goldberg and Tarjan's correctness proof of the generic Push-Relabel algorithm to fit this view.

► **Lemma 2** ([4]). *Any algorithm that performs applicable Push and Relabel operations in any order satisfies the following properties and invariants:*

- (1)  $\text{ex}(\rho, \cdot)$  and  $c_\rho(\cdot)$  are non-negative.<sup>3</sup>
- (2) The function  $h$  is a valid labeling function.
- (3) For all  $v \in V$ , the value of  $h(v)$  never decreases, and strictly increases when  $\text{Relabel}(v)$  is called.
- (4)  $h(v) \leq 2|V(H)| - 1$  for all  $v \in V(H)$ .
- (5) Immediately after  $\text{Push}(u, v)$  is performed, either  $(u, v)$  is saturated or  $u$  is inactive.

**Proof.** Properties (1) and (5) are immediate from the definition of Push and the fact that excess and residual capacities only change during Push operations. Property (2) corresponds to Lemma 3.1 in [4], Property (3) is proved in Lemma 3.6 in [4], and Property (4) in Lemma 3.7 in [4]. ◀

► **Lemma 3** ([4, Lemma 3.3]). *Properties (1), (2) imply that there is no augmenting path from  $s$  to  $t$  at any point of the algorithm.*

► **Lemma 4** ([4, Lemma 3.8]). *Properties (3), (4) imply that the number of Relabel operations is at most  $2|V(H)| - 1$  per vertex and at most  $2|V(H)|^2$  overall.*

► **Lemma 5** ([4, Lemmas 3.9, 3.10]). *Properties (1)-(5) imply that the number of Push operations is  $O(|V(H)|^2|E(H)|)$ .*

By Lemmas 4 and 5, the algorithm terminates. Upon termination no vertex is active, so the implicit preflow  $\rho$  is in fact a feasible flow. By Lemma 3  $\rho$  is a maximum flow from  $s$  to  $t$ .

Variants of the Push-Relabel algorithm differ in the order in which applicable Push and Relabel operations are applied. Some variants, such as FIFO, highest-distance, maximal-excess, etc., guarantee faster termination than the  $O(|V(H)|^2|E(H)|)$  guarantee given above.

## 3.2 A sequential implementation of the parallel highest-distance Push-Relabel algorithm

We present a sequential implementation of the parallel highest-distance Push-Relabel algorithm, which we call Batch-Highest-Distance. This algorithm attempts to push flow on multiple edges simultaneously in an operation called Bulk-Push. In that sense, it resembles the parallel version of the highest-distance Push-Relabel algorithm. It is important to note, however, that Bulk-Push is a sequential operation and not a parallel/distributed one.

We define Bulk-Push, a batched version of the Push operation.  $\text{Bulk-Push}(U, W)$  operates on two sets of vertices,  $U$  and  $W$ . It is applicable under the following requirements:

- (i)  $\text{ex}(u) > 0$  for all  $u \in U$ .
- (ii) There exists an integer  $h$  such that  $h(u) = h$  and  $h(w) = h - 1$  for all  $u \in U$  and  $w \in W$ .
- (iii) There is a residual arc  $(u, w)$  for some  $u \in U$  and  $w \in W$ .

<sup>3</sup> This corresponds to the function  $\rho$  being a feasible preflow.

Note that in a regular Push-Relabel algorithm, conditions (i) and (ii) imply that  $\text{Push}(u, w)$  is applicable to any residual arc  $(u, w)$  with  $u \in U$  and  $w \in W$ . Condition (iii) guarantees there is at least one such arc. **Bulk-Push** pushes as much excess flow as possible from vertices in  $U$  to vertices in  $W$  so that after **Bulk-Push** the following property holds:

**(5\*)** Immediately after  $\text{Bulk-Push}(U, W)$  is called, for all  $u \in U$  and  $w \in W$ , either  $(u, w)$  is saturated or  $u$  is inactive.

We replace property (5) with the more general property (5\*) in Lemma 2 and Lemma 5. With this modification, Lemmas 2, 3, 4 and 5 apply to our sequential implementation. The proofs from [4] need no change except replacing **Push** with **Bulk-Push**. Hence, our variant terminates correctly with a maximum flow from  $s$  to  $t$ .

► **Remark.** One may think of  $\text{Bulk-Push}(U, W)$  as performing in parallel all **Push** operations on arcs whose tail is in  $U$  and whose head is in  $W$ . However, not every maximum flow with sources  $U$  and sinks  $W$  can be achieved as the sum of flows pushed by multiple **Push** operations. For example, consider the case where  $U$  consists of a single vertex  $u$ , with  $\text{ex}(u) = 2$ ,  $W = \{w_1, w_2\}$ , and the residual capacities of  $(u, w_1)$  and  $(u, w_2)$  are both 2.  $\text{Bulk-Push}(U, W)$  may push one unit of excess flow from  $u$  on each of  $(u, w_1)$  and  $(u, w_2)$ , but  $\text{Push}(u, w_i)$  would push 2 units of flow on  $(u, w_i)$ , and no flow on the other arc. Therefore, the correctness of this variant cannot be argued just by simulating **Bulk-Push** by multiple **Push** operations. Instead we chose to argue correctness by stating the generalized property (5\*).

We now discuss a concrete policy for choosing which **Bulk-Push** and **Relabel** operations to perform in the above algorithm. This policy is similar, but not identical, to the highest-distance Push-Relabel algorithm [4, 3]. As long as there is an active vertex, the algorithm repeatedly executes the following two steps, which together are called a *pulse*. Let  $h_{max}$  be the maximum label of an active vertex. That is,  $h_{max} = \max\{h(v) : \text{ex}(\rho, v) > 0\}$ . Let  $H_{max}$  be the set of all the active vertices whose height is  $h_{max}$ . In the first step of the pulse, the algorithm invokes  $\text{Bulk-Push}(H_{max}, W)$  where  $W$  is the set of all vertices  $w \in V$  such that  $h(w) = h_{max} - 1$ .<sup>4</sup> In the second step of the pulse, the algorithm applies the **Relabel** operation to all remaining active vertices in  $H_{max}$  in arbitrary order.

■ **Algorithm 1** Batch-Highest-Distance( $G, c$ ).

---

```

1: Initialize  $h(\cdot)$ ,  $c_\rho(\cdot)$  and  $\text{ex}(\cdot)$ 
2: while there exists an active vertex do
3:    $h_{max} \leftarrow \max\{h(v) : \text{ex}(\rho, v) > 0\}$ 
4:    $H_{max} \leftarrow \{v \in V(H) : \text{ex}(\rho, v) > 0, h(v) = h_{max}\}$ 
5:    $W \leftarrow \{w \in V(H) : h(w) = h_{max} - 1\}$ 
6:    $\text{Bulk-Push}(H_{max}, W)$ 
7:   Relabel all active vertices in  $H_{max}$  in arbitrary order
8: end while

```

---

► **Remark.** The crucial difference between this policy and the highest-distance Push-Relabel algorithm [4, 3] is that in the highest-distance algorithm a vertex  $u$  with height  $h_{max}$  is relabeled as soon as no more **Push** operations can be applied to  $u$ . In contrast, our variant first pushes flow from all vertices with height  $h_{max}$  and only then relabels all of them.

<sup>4</sup> Formally it may be that  $\text{Bulk-Push}(H_{max}, W)$  is not applicable because condition (iii) is not satisfied, e.g., when  $W = \emptyset$ . In such cases **Bulk-Push** does not push any flow. Condition (iii) is essential for the termination of the generic generalized algorithm, which may repeat such empty calls to **Bulk-Push** indefinitely. However, we prove in Lemma 6 that in our specific policy there are  $O(|V(H)|^2)$  pulses, regardless of the flow pushed (or not pushed) by **Bulk-Push** in each pulse.

We partition the pulses into two types according to whether any vertices are relabeled in the relabel step of the pulse. A pulse in which at least one vertex is relabeled is called *saturating*. All other pulses are called *non-saturating*.<sup>5</sup>

By Lemma 4, the total number of Relabel operations executed by the batch-highest-distance algorithm is  $O(|V(H)|^2)$ . We now prove the same bound for Bulk-Push operations.

► **Lemma 6.** *The number of pulses (and hence also the number of calls to Bulk-Push) executed by the batch-highest-distance algorithm is  $O(|V(H)|^2)$ .*

**Proof.** Note that the Relabel step of a saturating pulse consists of at least one call to Relabel which strictly increases the height of an active vertex  $v$  whose height (before the increase) was  $h_{max}$ . Hence, a saturating pulse strictly increases the value of  $h_{max}$ . The fact that the height of each vertex never decreases and is bound by  $2|V(H)|$  implies that (i) there are  $O(|V(H)|^2)$  saturating pulses, and (ii) the total increase in  $h_{max}$  over all saturating Bulk-Push operations is  $O(|V(H)|^2)$ .

As for non-saturating pulses, note that since excess flow is always pushed to a vertex with lower height, the push step of a pulse does not create excess in any vertex with height greater than or equal to  $h_{max}$ , so all vertices with height greater than  $h_{max}$  remain inactive during the pulse. By property (5\*), for every  $u \in H_{max}$  and  $w \in W$ , either  $(u, w)$  is saturated, or  $u$  is inactive. Since the pulse is non-saturating, it follows that all the vertices in  $H_{max}$  become inactive during the pulse. Hence, the value of  $h_{max}$  strictly decreases during a non-saturating pulse. Since  $h_{max} \geq 0$ , the total decrease in  $h_{max}$  is also  $O(|V(H)|^2)$ , so there are  $O(|V(H)|^2)$  non-saturating pulses. ◀

Note that we do not claim that implementing the Bulk-Push operation by applying applicable  $\text{Push}(u, w)$  operations for  $u \in U$ ,  $w \in W$  until no more such operations can be applied would result in fewer Push operations than the  $O(|V(H)|^2|E(H)|)$  bound of Lemma 5 for the generic Push-Relabel algorithm. However, in Section 4 we will show a situation where each call to Bulk-Push can be efficiently implemented using a single invocation of a multiple-source multiple-sink algorithm in a planar graph.

### 3.3 The algorithm of Borradaile et al. for $k$ -apex graphs [2]

The algorithm of Borradaile et al. [2, Section 5] uses the framework of Hochstein and Weihe [6]. Let  $H$  be a graph with a set  $V^\times$  of  $k$  apices. Denote  $V_0 = V(H) \setminus V^\times$ . The goal is to compute a maximum flow in  $H$  from a source  $s \in V(H)$  to a sink  $t \in V(H)$ . We assume that  $s$  and  $t$  are apices. This is without loss of generality since treating  $s$  and  $t$  as apices leaves the number of apices in  $O(k)$ . Let  $K^\times$  be a complete graph over  $V^\times$ . The algorithm computes a maximum flow  $\rho$  from  $s$  to  $t$  in  $H$  by simulating a maximum flow computation from  $s$  to  $t$  in  $K^\times$  using the Push-Relabel algorithm. Whenever a Push operation is performed on an arc  $(u, v)$  of  $K^\times$  it is implemented by pushing flow from  $u$  to  $v$  in the graph  $H_{uv}$ , induced by  $V_0 \cup \{u, v\}$  on the residual graph of  $H$  with respect to the flow computed so far. Note that, because no vertex of  $V_0$  is an apex of  $H$ ,  $H_{uv}$  is a 2-apex graph with apices  $u, v$ . Borradaile et al. use this fact to compute a maximum flow from  $u$  to  $v$  in  $H_{uv}$  as follows. They split  $u$  into multiple copies, each incident to a different vertex  $w$  for which  $(u, w)$  is an arc of  $H_{uv}$ . A similar process is then applied to  $v$ . Note that the resulting graph is planar. A maximum flow from  $u$  to  $v$  in  $H_{uv}$  is equivalent to a maximum flow with sources

<sup>5</sup> This is a generalization of the notions of saturating and non-saturating Push operations in [4].

the copies of  $u$  and sinks the copies of  $v$  in the resulting graph. This flow can be computed by the multiple-source multiple-sink maximum flow algorithm (the main result in [2]) in  $O(|V(H)| \log^3 |V(H)|)$  time.

The correctness of implementing the Push-Relabel algorithm on  $K^\times$  in this way was proved by Hochstein and Weihe [6] by proving essentially that the algorithm satisfies the properties in Lemma 2. Borradaile et al. used the FIFO policy of Push-Relabel, which guarantees that the number of Push operations is  $O(k^3)$ , so the overall running time of their algorithm is  $O(k^3 |V(H)| \log^3 |V(H)|)$ .

### 3.4 An algorithm for maximum flow in $k$ -apex graphs

We use the algorithm of Borradaile et al. for maximum flow in  $k$ -apex graphs from the previous section, but use our new batch-highest-distance Push-Relabel algorithm instead of the FIFO Push-Relabel algorithm to compute the maximum flow in  $K^\times$ . In order to implement the batch-highest-distance algorithm on  $K^\times$  we only need to maintain the excess  $\text{ex}(\rho, v)$  and labels  $h(v)$  of each vertex  $v \in K^\times$ , and to be able to implement Bulk-Push so that after the execution, property (5\*) is fulfilled. We do not define a flow function in  $K^\times$  nor do we explicitly maintain residual capacities of arcs of  $K^\times$ . Instead, we maintain a preflow  $\rho$  in  $H$ , and say an arc  $(u, v)$  of  $K^\times$  is residual if and only if there exists a residual path from  $u$  to  $v$  in  $H_\rho$  that is internally disjoint from the vertices of  $V^\times$ . Under this definition, there is no path of residual arcs in  $K^\times$  starting at  $s$  and ending at  $t$  if and only if there is no such path in  $H$ . Since  $K^\times$  has  $O(k)$  vertices, by Lemma 6, the algorithm performs  $O(k^2)$  pulses.

We next describe how a Bulk-Push( $U, W$ ) operation in  $K^\times$  is implemented. Let  $A = U \cup W$ . Let  $H_A$  be the graph obtained from  $H_\rho$  by deleting the vertices  $V^\times \setminus A$ . Bulk-Push( $U, W$ ) in  $K^\times$  is implemented by pushing a maximum flow in  $H_A$  with sources the vertices  $U$  and sinks the vertices  $W$ , with the additional restriction that the amount of flow leaving each vertex  $u \in U$  is at most the excess of  $u$ . The efficiency of the procedure depends on how fast we can compute the maximum flow in  $H_A$ . We denote the time to execute a single Bulk-Push operation in the graph  $H_A$  by  $T_{BP}$ . Note that  $T_{BP} = \Omega(k)$ , as it takes  $\Omega(k)$  time to construct  $H_A$  from  $H_\rho$ .

The proof of correctness is an easy adaptation of the proof of Hochstein and Weihe [6]. We cannot use their proof without change because Hochstein and Weihe considered only Push operations along a single arc of  $K^\times$  rather than the Bulk-Push operations which involves more than a single pair of vertices of  $K^\times$ .

► **Lemma 7.** *Maximum flow in  $k$ -apex graphs can be computed in  $O(k^2 \cdot T_{BP})$  time.*

**Proof.** We first show that the properties (1)-(4) in the statement of Lemma 2, and the generalized property (5\*) from Section 3.2 hold. Property (1) holds since Bulk-Push( $U, W$ ) limits the amount of flow pushed from each vertex  $u \in U$  by the excess of  $u$ . Properties (3) and (4) hold without change since Relabel is not changed.

To show property (5\*) holds, recall that an arc  $(u, w)$  of  $K^\times$  is residual if there exists, in the residual graph  $H_\rho$  with respect to the current preflow  $\rho$ , a residual path from  $u$  to  $w$  that is internally disjoint from any vertex of  $V^\times$ . With this definition it is immediate that property (5\*) holds, since our implementation of Bulk-Push( $U, W$ ) pushes a maximum flow in  $H_A$  from  $U$  that is limited by the excess flow in each vertex of  $U$ . Hence, after Bulk-Push( $U, W$ ) is executed, for every  $u \in U$  and  $w \in W$ , either there is no residual path from  $u$  to  $w$  in  $H_\rho$  that is internally disjoint from  $V^\times$ , or  $u$  is inactive.

As for property (2), since we did not change Relabel,  $h$  remains valid after calls to Relabel. It remains to show that  $h$  remains a valid labeling after Bulk-Push( $U, W$ ). Consider two vertices  $a, b \in V^\times$ . We will show that after Bulk-Push( $U, W$ ), either the arc  $(a, b)$  of  $K^\times$  is

■ **Figure 1** Illustration of property (2) in the proof of Lemma 7. A  $\text{Bulk-Push}(U, W)$  operation pushes flow along paths  $P$  and  $P'$  (dashed red paths). If  $Q$  (blue solid path) is residual after the Bulk-Push operation then the dotted black paths were residual before.

saturated (i.e., is no residual path from  $a$  to  $b$  in  $H_\rho$ ), or  $h(a) \leq h(b) + 1$ . The flow pushed (in  $H_A$ ) by the call  $\text{Bulk-Push}(U, W)$  can be decomposed into a set  $\mathcal{P}$  of flow paths, each of which starts at a vertex of  $U$  and ends at a vertex of  $W$ .

Assume that after performing  $\text{Bulk-Push}(U, W)$  there is an augmenting  $a$ -to- $b$  path,  $Q$  in  $H_\rho$ . If  $Q$  does not intersect any path  $P \in \mathcal{P}$  then  $Q$  was residual before  $\text{Bulk-Push}(U, W)$  was called, so  $h(a) \leq h(b) + 1$  because  $h$  was a valid labeling before the call. Otherwise,  $Q$  intersects some path in  $\mathcal{P}$ . Let  $c, d$  be the first and last vertices of  $Q$  that also belong to paths in  $\mathcal{P}$ . Let  $P, P' \in \mathcal{P}$  be paths such that  $c \in P$  and  $d \in P'$ . Let  $w \in W$  be the last vertex of  $P$  and let  $u \in U$  be the first vertex of  $P'$ . See Figure 1. Then, before  $\text{Bulk-Push}(U, W)$  was called,  $Q[a, c] \circ P[c, w]$  was a residual path from  $a$  to  $w$ , and  $P'[u, d] \circ Q[d, b]$  was a residual path from  $u$  to  $b$ . Since  $h$  was a valid labeling before the call, we have

$$h(u) \leq h(b) + 1 \quad \text{and} \quad h(a) \leq h(w) + 1.$$

Since  $h(u) = h(w) + 1$  it follows that

$$h(a) \leq h(w) + 1 = h(u) \leq h(b) + 1,$$

showing property (2).

We have shown that properties (1)-(4) and (5\*) hold. Hence, by Lemmas 6 and 4, the algorithm terminates after performing  $O(|V^\times|^2) = O(k^2)$  Bulk-Push and Relabel operations. Since each Relabel takes  $O(k)$  time, and each Bulk-Push takes  $\Omega(k)$  time, the total running time of the algorithm is  $O(k^2 \cdot T_{BP})$ . By Lemma 3, when the algorithm terminates there is no residual path from  $s$  to  $t$  in  $K^\times$ . By our definition of residual arcs of  $K^\times$  this implies that there is no residual path from  $s$  to  $t$  in  $H_\rho$ , so  $\rho$  is a maximum flow from  $s$  to  $t$  in  $H$ . ◀

#### 4 A faster algorithm for maximum flow with vertex capacities

In this section, we give a faster algorithm for computing a maximum flow in a directed planar graph with integer arc and vertex capacities bounded by  $C$ , parameterized by the number  $k$  of terminal vertices (sources and sinks). The fastest algorithm currently known for this problem is by Wang [13] and runs in  $O(k^5 \Delta n \text{polylog}(nC))$  time. We first sketch Wang’s algorithm, only detailing the parts that will be modified in our algorithm in Section 4.2.

## 4.1 Wang's algorithm

Wang's algorithm uses some auxiliary graphs, in which only the arcs are capacitated.

► **Definition 8** (The graph  $G^\circ$ ). *For a flow network  $G$ , the network  $G^\circ$  is obtained by the following procedure. For each vertex  $v \in V(G)$ , replace  $v$  with an undirected cycle  $C_v$  with  $d = \deg(v)$  vertices  $v_1, \dots, v_d$ .<sup>6</sup> Each arc in  $C_v$  has capacity  $c(v)/2$ . Connect each arc incident to  $v$  with a different vertex  $v_i$ , preserving the clockwise order of the arcs so that the graph remains planar.*

Recall that if  $H$  and  $G$  are two graphs such that every arc of  $G$  is also an arc of  $H$ , then the restriction of a flow  $f'$  in  $H$  to  $G$  is a flow  $f$  in  $G$  such that  $f(e) = f'(e)$  for all  $e \in E(G)$ . Thus we can speak of the restriction of a flow  $f^\circ$  in  $G^\circ$ , to a flow  $f$  in  $G$ .

Kaplan and Nussbaum [7] used the reduction from  $G$  to  $G^\circ$  to compute a maximum flow in directed planar graphs with vertex capacities and a single source and a single sink. Their algorithm computes a maximum flow  $f^\circ$  in the graph  $G^\circ$ . Let  $f$  be the restriction of  $f^\circ$  to  $G$ . Kaplan and Nussbaum then proved that, provided there is only a single source and a single sink, the values of the maximum flow in  $G^\circ$  and in  $G$  are the same and that if  $f$  is acyclic then it is a feasible maximum flow in  $G$ .

However, when dealing with multiple source and sinks this approach fails because the resulting flow  $f$  may violate vertex capacities in  $G$ . In fact, the value of the maximum flow in  $G^\circ$  may be greater than the value of the maximum flow in  $G$ . Wang proves that the set  $X$  of vertices whose capacities are violated by  $f$  (after canceling flow cycles) has size at most  $k - 2$ , and that the sum of the violations of the vertices in  $X$  is at most  $(k - 2)C$ . In order to overcome this obstacle, Wang's algorithm uses binary search to find the value  $\lambda^*$  of the maximum flow in  $G$ .

Let  $\lambda$  be the current candidate value for  $\lambda^*$ . The algorithm computes a flow  $f^\circ$  with value  $\lambda$  in the graph  $G^\circ$  (recall,  $G^\circ$  has a super source  $s$  connected to all sources, and a super sink  $t$ , connected to all sinks. Thus  $G^\circ$  has an apex set of size 2). Let  $f$  be the restriction of  $f^\circ$  to  $G$ . As long as  $\text{vio}(f) > 2k\Delta$ , the algorithm improves  $f$ . This improvement phase, which will be described shortly, is the crux of the algorithm. If  $\text{vio}(f) \leq 2k\Delta$ , then  $O(k^2\Delta)$  iterations of the classical Ford-Fulkerson algorithm suffice to get rid of all the remaining violations.

The improvement phase of the algorithm is based on finding a circulation  $g$  that cancels the violations on the infeasible vertices and does not create too much violations on other vertices. It can then be shown that adding  $1/(k\Delta) \cdot g$  to the flow  $f$  decreases  $\text{vio}(f)$  by a multiplicative factor of roughly  $1 - 1/(k\Delta)$ . After  $O(k\Delta \log(kC))$  iterations of the improvement step,  $\text{vio}(f)$  is at most  $2k\Delta$ .

In order to find the circulation  $g$  Wang defines the following auxiliary graph.

► **Definition 9** (The graph  $G^\times$ ). *Let  $f$  be a flow in  $G$ . Let  $X$  be the set of infeasible vertices. I.e., vertices  $x \in V(G)$  s.t.  $f^{\text{in}}(x) > c(x)$ . The graph  $G^\times$  is defined as follows. Starting with  $G^\circ$ , for each vertex  $x \in X$ , replace the cycle representing  $x$  with two vertices  $x^{\text{in}}$ ,  $x^{\text{out}}$  and an arc  $(x^{\text{in}}, x^{\text{out}})$  of capacity  $c(x)$ .*

*Every arc of capacity  $c$  going from a vertex  $u \notin C_x$  to a vertex in  $C_x$  becomes an arc  $(u, x^{\text{in}})$  of capacity  $c$ . Similarly, every arc of capacity  $c$  going from a vertex of  $C_x$  to a vertex  $u \notin C_x$  becomes an arc  $(x^{\text{out}}, u)$  with capacity  $c$ .*

<sup>6</sup> By undirected cycle we mean that there are directed arcs in both directions between every pair of consecutive vertices of the cycle  $C_v$ .

Since arcs of  $G^\circ$  can be identified with arcs of  $G^\times$ , the flow  $f^\circ$  can be viewed as a flow  $f^\times$  in  $G^\times$ , setting  $f^\times(x^{in}, x^{out}) = \sum_{(u, x_i) \in E(G^\circ)} f^\circ(u, x_i)$ . The flow  $f^\times$  can then be restricted to a flow in  $G$ .

Wang proves that in order to find the circulation  $g$  described above, it suffices to compute a circulation  $g^\times$  in  $G^\times$  that satisfies the following properties:

1.  $f^\times + g^\times$  is feasible in  $G^\times$ .
2. The restriction of  $f^\times + g^\times$  to  $G$  has no violations on vertices of  $X$ .
3. The restriction of  $f^\times + g^\times$  to  $G$  has at most  $(k - 2)\Delta \cdot \text{vio}(f)$  violation on any vertex in  $V(G) \setminus X$ .

The desired circulation  $g$  is the restriction of  $g^\times$  to  $G$ . If no such  $g^\times$  exists then  $g$  does not exist, which implies that  $\lambda > \lambda^*$ . Otherwise,  $\lambda \leq \lambda^*$ . The binary search for  $\lambda^*$  then continues with a different value of  $\lambda$ .

Wang essentially shows that any algorithm for finding  $g^\times$  in  $O(T)$  time, where  $T = \Omega(n)$ , yields an algorithm for maximum flow with vertex capacities in  $O(k\Delta T \log(kC) \log(nC))$  time. The additional terms stem from the  $O(k\Delta \log(kC))$  iterations of the improvement step, and the  $\log(nC)$  steps of the binary search. Wang shows how to compute  $g^\times$  in  $T = O(k^4 n \log^3 n)$  time, by eliminating the violation at each vertex of  $X$  one after the other in some auxiliary graph obtained from  $G^\times$ . Thus, the overall running time of his algorithm is  $O(k^5 \Delta n \log^3 n \log(kC) \log(nC))$ .

## 4.2 A faster algorithm for computing $g^\times$

We propose a faster way of computing the circulation  $g^\times$  by eliminating the violations in all the vertices of  $X$  in a single shot. Doing so correctly requires some care in defining the appropriate capacities in the auxiliary graph, since we only know that for each  $x \in X$ ,  $g^\times$  should eliminate at least  $\text{vio}(f, x)$  units of flow from  $x$ , but the actual amount of flow eliminated from  $x$  may have to be larger. This issue does not come up when resolving the violations one vertex at a time as was done by Wang.

Define an auxiliary graph  $H$  as follows. Starting with  $G_{f^\times}^\times$ , the residual graph of  $G^\times$  with respect to  $f^\times$ ,

- For each  $x \in X$ , set the capacity of the arc  $(x^{in}, x^{out})$  to be 0 and the capacity of  $(x^{out}, x^{in})$  to be  $c(x)$ .
- Add a super source  $s'$  and arcs  $(s', x^{in})$  with capacity  $\text{vio}(f, x)$  for every  $x \in X$ .
- Add a super sink  $t'$  and arcs  $(x^{out}, t')$  with capacity  $\text{vio}(f, x)$  for every  $x \in X$ .

Note that  $\{s, t\} \cup \bigcup_{x \in X} \{x^{in}, x^{out}\} \cup \{s', t'\}$  is an apex set of size  $O(k)$  in  $H$  (recall from Remark 1 that  $s$  and  $t$  are the super source and super sink of the original graph  $G$ ).

The circulation  $g^\times$  can be found using the following algorithm. Find a maximum flow  $h'$  from  $s'$  to  $t'$  in  $H$  using Lemma 7. Convert  $h'$  to an acyclic flow  $h$  of the same value using the algorithm of Sleator and Tarjan [12] (cf. [13, Lemma 2.5]). If  $h$  does not saturate every arc incident to  $s'$  and  $t'$ , return that the desired circulation  $g$  does not exist. Otherwise,  $h$  can be extended to the desired circulation  $g^\times$  by setting  $g^\times(x^{out}, x^{in}) = h(x^{out}, x^{in}) + \text{vio}(f, x)$  for every  $x \in X$  and  $g^\times(e) = h(e)$  for all other arcs.

The following lemma shows that any single Bulk-Push operation in the algorithm of Lemma 7 on  $H$  can be implemented by a constant number of calls to the  $O(n \log^3 n)$ -time multiple-source multiple-sink maximum flow algorithm in planar graphs of Borradaile et al. [2]. There are two challenges that need to be overcome. First, the graph  $H$  is  $O(k)$ -apex graph rather than planar. Second, the algorithm of Borradaile et al. computes a maximum flow from multiple sources to multiple sinks, not a maximum flow under the restriction that each source sends at most some given limit. This is not a problem in the case of a single

source, or a limit on just the total value of the flow, since then some of the flow pushed can be “undone”. When each of the multiple sources has a different limit, undoing the flow from one source can create residual paths from another source that did not yet reach its limit.

► **Lemma 10.** *Any single Bulk-Push operation in the execution of the algorithm of Lemma 7 on the graph  $H$  defined above can be implemented in  $O(n \log^3 n)$  time.*

**Proof.** Let  $V^\times = \{s, t\} \cup \bigcup_{x \in X} \{x^{in}, x^{out}\} \cup \{s', t'\}$  be the set of apices of  $H$ . Recall that the algorithm of Lemma 7 invokes the batch-highest-distance Push-Relabel algorithm on a complete graph  $K^\times$  over  $V^\times$ , and maintains a corresponding preflow in  $H$ . Consider a single Bulk-Push( $U, W$ ) operation from a set of apices  $U$  to a set of apices  $W$ . Let  $\rho$  denote the preflow pushed in  $H$  up to this Bulk-Push operation. Let  $A = U \cup W$ . To correctly implement Bulk-Push( $U, W$ ), we find a flow  $\rho'$  with sources  $U$  and sinks  $W$  in the graph  $H$ , which satisfies the following properties:

- (i) For every  $u \in U$ ,  $\text{ex}(\rho + \rho', u) \geq 0$ , and
- (ii) For every  $u \in U$  and  $w \in W$ , either  $\text{ex}(\rho + \rho', u) = 0$  or there is no residual path in  $H_{\rho+\rho'}$  from  $u$  to  $w$  that is internally disjoint from  $V^\times$ .

Condition (i) guarantees that  $\rho'$  does not push more flow from a vertex  $u \in U$  than the current excess of  $u$ . Condition (ii) is condition (5\*) from Section 3.2.

Let  $H''$  be the graph obtained from  $H_\rho$  by deleting the vertices  $V^\times \setminus A$ . Note that the absence of residual paths that are internally disjoint from  $V^\times$  in  $H''$  is equivalent to the absence of such paths in  $H$ . We will compute  $\rho'$  using a constant number of invocations of the  $O(n \log^3 n)$ -time multiple-source multiple-sink maximum flow algorithm in planar graphs of Borradaile et al. [2]. Instead of invoking this algorithm on  $H''$ , which is not planar, we shall invoke it on modified versions of  $H''$  which are planar.

Starting with  $H''$ , we split each vertex  $w \in W$  into  $\deg(w)$  copies. Each arc  $e$  that was incident to  $w$  before the split is now incident to a distinct copy of  $w$ , and is embedded so that it does not cross any other arc in the graph. Let  $H'$  denote the resulting graph, and let  $W'$  denote the set of vertices created as a result of splitting all the vertices of  $W$ .

The set  $W'$  replaces  $W$  as the set of sinks of the flow  $\rho'$  we need to compute. Note that  $U$  is an apex set in  $H'$ . We then build the flow  $\rho'$  gradually, by computing the following steps, each using a single invocation of the multiple-source multiple-sink maximum flow algorithm of Borradaile et al. in  $O(n \log^3 n)$  time. In what follows, when we say that the flow  $\rho'$  satisfies condition (ii) for a subset  $U'$  of  $U$  we mean that for every  $u \in U'$  and  $w \in W$ , either  $\text{ex}(\rho + \rho', u) = 0$  or there is no residual path in  $H_{\rho+\rho'}$  from  $u$  to  $w$  that is internally disjoint from  $V^\times$ .

- (1) If  $s \in U$ , starting with  $H'$ , we split  $s$  into  $\deg(s)$  copies. Each arc  $e$  that was incident to  $s$  before the split is now incident to a distinct copy of  $s$ , and is embedded so that it does not cross any other arc in the graph. We also delete all other vertices of  $U$ . We compute in the resulting graph, which is planar, a maximum flow with sources the copies of  $s$  and the sinks  $W'$ . Let  $\rho'_s$  be the flow computed. If  $|\rho'_s| > \text{ex}(\rho, s)$ , we decrease  $|\rho'_s|$  by pushing  $|\rho'_s| - \text{ex}(\rho, s)$  units of flow back from  $W'$  to the copies of  $s$ . This can be done in  $O(n)$  time in reverse topological order w.r.t.  $\rho'_s$  (cf. [2, Section 1.4]). We view  $\rho'_s$  as a flow in  $H$ , and set  $\rho' = \rho'_s$ . By construction  $\rho'$  satisfies condition (i), and satisfies condition (ii) for the subset  $\{s\}$ .
- (2) If  $t \in U$ , starting with  $H'_{\rho'}$ , we repeat step (1) with  $t$  taking the role of  $s$  to compute a flow  $\rho'_t$ . Set  $\rho' \leftarrow \rho' + \rho'_t$ . By construction of  $\rho'_t$ ,  $\rho'$  now satisfies condition (i), and satisfies condition (ii) for the subset  $U \cap \{s, t\}$ .
- (3) Let  $U^{in}$  be the set  $U \cap \{x^{in} : x \in X\}$ . If  $U^{in} \neq \emptyset$ , starting with  $H'_{\rho'}$ , we delete all the vertices of  $U$  that are not in  $U^{in}$ . Note that, since the resulting graph does not contain  $s, t, s', t'$ , nor any  $x^{out}$  for any  $x \in X$ , and since arcs incident to  $x^{in}$  only cross those

■ **Figure 2** Illustration of the auxiliary graphs used in the algorithm of Lemma 10. Only a portion of the graphs around some vertex  $x \in X$  is shown. (a) the graph  $G^\circ$ . (b) the graph  $H$ . Note that the only crossings are between arcs incident to  $x^{in}$  and arcs incident to  $x^{out}$ . (c) the graph  $H'$  in the case that  $x^{out}$  belongs to  $W$ .  $x^{out}$  is split into multiple copies, eliminating all arc crossings.

incident to  $x^{out}$ , the resulting graph is planar. For every  $x^{in} \in U^{in}$  we add a vertex  $x'$  and an arc  $(x', x^{in})$  with capacity  $\text{ex}(\rho, x^{in})$ . The resulting graph is still planar. We compute a maximum flow  $\rho'_{in}$  with sources  $\{x' : x^{in} \in U^{in}\}$  and sinks  $W'$ . We view  $\rho'_{in}$  as a flow in  $H$ , and set  $\rho' \leftarrow \rho + \rho'_{in}$ . By construction of  $\rho'_{in}$ ,  $\rho'$  now satisfies condition (i), and satisfies condition (ii) for the subset  $U \cap (\{s, t\} \cup U^{in})$ .

- (4) We repeat step (3) with  $out$  taking the role of  $in$  to compute a flow  $\rho'_{out}$ . By construction of  $\rho'_{in}$ ,  $\rho'$  now satisfies condition (i), and satisfies condition (ii) for  $U \cap (\{s, t\} \cup U^{in} \cup U^{out})$ . Since  $s'$  and  $t'$  are the source and sink of the flow computed by the Push-Relabel algorithm, they are never active vertices, so they never belong to  $U$ . Hence  $\{s, t\} \cup U^{in} \cup U^{out} \supseteq U$ , and conditions (i) and (ii) are fully satisfied by  $\rho'$ . ◀

Using Lemma 10 and Lemma 7, we get the following lemma.

▶ **Lemma 11.** *The algorithm described above finds a circulation  $g^\times$  such that*

1.  $f^\times + g^\times$  is feasible in  $G^\times$ .
  2. The restriction of  $f^\times + g^\times$  to  $G$  has no violations at vertices of  $X$ .
  3. The restriction of  $f^\times + g^\times$  to  $G$  has violation at most  $(k - 2)\Delta \cdot \text{vio}(f)$  at any vertex in  $V(G) \setminus X$ .
- in  $O(k^2 n \log^3 n)$  time if such a circulation exists.

**Proof.** We first analyze the running time. Computing the graph  $H$  can be done in  $O(n)$  time. Computing the flow  $h'$  in  $H$  using the algorithm of Lemma 7 takes  $O(k^2 \cdot T_{BP})$  time. By Lemma 10,  $T_{BP} = O(n \log^3 n)$  for the graph  $H$ . Transforming  $h'$  to an acyclic flow  $h$  using the algorithm of Sleator and Tarjan [12] takes  $O(n \log n)$  time. Finally, computing  $g^\times$  from  $h$  takes  $O(n)$  time. Hence, the total time to compute  $g^\times$  is  $O(k^2 n \log^3 n)$ .

In order to prove the correctness of the algorithm, we will first prove that there exists a feasible flow  $h$  in  $H$  that saturates every arc incident to  $s'$  and  $t'$  if and only if there exists a circulation  $g^\times$  in  $G^\times$  that satisfies conditions (1) and (2) in the statement of the lemma.

( $\Leftarrow$ ) Assume the circulation  $g^\times$  exists in  $G^\times$ . Define a flow  $h$  in  $H$  as follows. For every arc  $e \in E(H)$  not of the form  $(x^{out}, x^{in})$  set  $h(e) = g^\times(e)$ . For every  $x \in X$ , set  $h(x^{out}, x^{in}) = g^\times(x^{out}, x^{in}) - \text{vio}(f, x)$ ,  $h(s, x^{in}) = \text{vio}(f, x)$  and  $h(x^{out}, t) = \text{vio}(f, x)$ . Since the restriction of  $f^\times + g^\times$  to  $G$  has no violations on the vertices of  $x$ ,  $g^\times(x^{out}, x^{in}) \geq \text{vio}(f, x)$ , so  $h(x^{out}, x^{in}) \geq 0$  and  $h$  is a well defined flow. By definition, the flow  $h$  saturates every arc incident to  $s'$  and  $t'$ .

To show that  $h$  is feasible in  $H$  it is enough to show that  $h(x^{out}, x^{in}) \leq c(x)$  for every  $x \in X$  (on all other arcs  $h$  is feasible because  $g^\times$  is feasible in  $G_{f^\times}^\times$ ). Let  $x \in X$ . Since  $f^\times + g^\times$  is feasible in  $G^\times$ ,  $g^\times(x^{out}, x^{in}) \leq f^\times(x^{in}, x^{out})$ . Since  $h(x^{out}, x^{in}) = g^\times(x^{out}, x^{in}) - \text{vio}(f, x)$ ,  $h(x^{out}, x^{in}) \leq f^\times(x^{in}, x^{out}) - \text{vio}(f, x) = c(x)$ .

( $\Rightarrow$ ) Assume there exist a feasible flow  $h$  in  $H$  that saturates every arc incident to  $s'$  and  $t'$ , and let  $g^\times$  be the circulation obtained from  $h$  as described above. We show that  $f^\times + g^\times$  is feasible in  $G^\times$ . On all arcs  $e$  not of the form  $(x^{out}, x^{in})$ ,  $g^\times(e) = h(e)$  and the capacity of  $e$  in  $G_{f^\times}^\times$  equals the capacity of  $e$  in  $H$ . Therefore, since  $h$  is a feasible flow in  $H$ ,  $g^\times$  is feasible on  $e$  in  $G_{f^\times}^\times$ , so  $f^\times + g^\times$  is feasible on  $e$  in  $G^\times$ . We now focus on the arcs  $(x^{out}, x^{in})$  for each  $x \in X$ . Let  $e = (x^{out}, x^{in})$ . Observe that  $0 \leq h(e) \leq c(x)$ . Since  $g^\times(e) = h(e) + \text{vio}(f, x)$  we have that  $\text{vio}(f, x) \leq g^\times(e) \leq c(x) + \text{vio}(f, x) = f^\times(e)$ . Since  $(f^\times + g^\times)(x^{in}, x^{out}) = f^\times(x^{in}, x^{out}) - g^\times(x^{out}, x^{in})$ , we have  $0 \leq (f^\times + g^\times)(x^{in}, x^{out}) \leq c(x)$ , so  $f^\times + g^\times$  is feasible in  $G^\times$ .

To finish proving the ( $\Rightarrow$ ) direction, we show that the restriction of  $f^\times + g^\times$  to  $G$  has no violations on the vertices of  $X$ . By definition of  $G^\times$  and of residual graph, the only arcs in  $G_{f^\times}^\times$  that can carry flow out of  $x^{in}$  are the reverses of the arcs that carry flow into  $x$  in  $f$ , and the only arcs that can carry flow into  $x^{out}$  are the reverses of the arcs that carry flow out of  $x$  in  $f$ . We will show that  $(f + g)^{in}(x) \leq c(x)$  by considering separately the contribution of the flow on arcs of  $G$  that in  $G^\times$  are incident to  $x^{out}$ , and arcs of  $G$  that in  $G^\times$  are incident to  $x^{in}$ .

The only arc of  $f^\times$  that carries flow into  $x^{out}$  is  $(x^{in}, x^{out})$ . Thus, there is no arc  $e$  of  $G$  such that  $f^\times(e)$  carries flow into  $x^{out}$ . Since  $g^\times$  only carries flow into  $x^{out}$  along the reverses of arcs that carry flow out of  $x^{out}$  in  $f^\times$  and since for every such arc  $e'$ ,  $g^\times(e') \leq f^\times(\text{rev}(e'))$ , there is also no arc  $e$  of  $G$  such that  $(f^\times + g^\times)(e)$  carries flow into  $x^{out}$ .

The total flow that  $f^\times$  carries into  $x^{in}$  is  $c(x) + \text{vio}(f, x)$ . Let  $z$  denote the total amount of flow that  $g^\times$  carries into  $x^{in}$ . Since the only arc incident to  $x^{in}$  that carries flow in  $g^\times$  and does not belong to  $G$  is  $(x^{out}, x^{in})$ , the total amount of flow that  $g^\times$  carries into  $x^{in}$  on arcs that belong to  $G$  is  $z - g^\times(x^{out}, x^{in})$ . On the other hand,  $g^\times$  carries  $z$  units of flow out of  $x^{in}$ , and all of this flow is pushed along the reverses of arcs that carry flow into  $x^{in}$  in  $f^\times$  (and also belong to  $G$ ). Hence, the total amount of flow that  $f^\times + g^\times$  carries into  $x^{in}$  on arcs that belong to  $G$  is  $c(x) + \text{vio}(f, x) + (z - g^\times(x^{out}, x^{in})) - z$ . Therefore,

$$\begin{aligned} (f + g)^{in}(x) &= c(x) + \text{vio}(f, x) - g^\times(x^{out}, x^{in}) \\ &= c(x) + \text{vio}(f, x) - (h(x^{out}, x^{in}) + \text{vio}(f, x)) \\ &= c(x) - h(x^{out}, x^{in}) \\ &\leq c(x). \end{aligned}$$

We have thus shown that the algorithm computes a flow  $g^\times$  satisfying conditions (1) and (2) in the statement of the lemma. To see that condition (3) is also satisfied, note that the value of the flow  $h$  is  $\sum_{x \in X} \text{vio}(f, x) \leq (k-2) \cdot \text{vio}(f)$ . Since  $h$  is acyclic,  $h^{in}(v) \leq (k-2) \cdot \text{vio}(f)$  for all  $v \in H$ . Since for all  $v \in V(G) \setminus X$ ,  $f^{in}(v) \leq c(v)$ , and  $h^{in}(v) \leq \Delta(g^\times)^{in}(v)$ , it follows that the violation of  $f^\times + g^\times$  at  $v$  is at most  $(k-2)\Delta \cdot \text{vio}(f)$ .  $\blacktriangleleft$

Using the  $O(k^2 n \log^3 n)$ -time algorithm of Lemma 11 in the improvement phase of Wang's algorithm instead of using Wang's  $O(k^4 n \log^3 n)$ -time procedure for this phase results in a running time of  $O(k^3 \Delta n \text{polylog}(nC))$  for finding a maximum flow in  $G$ .

### 4.3 The case $k = o(\log^2 n)$

We now provide an algorithm that is faster for small  $k = o(\log^2 n)$ . Specifically, we describe an algorithm for computing the circulation  $g^\times$  that runs in  $O(k^3 n \log n)$  time instead of the  $O(k^2 n \log^3 n)$  time required by the algorithm of Lemma 11.

We use the same auxiliary graph  $H$  as defined above and again compute a maximum flow  $h'$  from  $s'$  to  $t'$  in  $H$ . Let  $V^\times = \{s, t\} \cup \bigcup_{x \in X} \{x^{in}, x^{out}\} \cup \{s', t'\} \cup S \cup T$  be the set of apices of  $H$  along with the original sources  $S$  and sinks  $T$  of  $G$ , and let  $K^\times$  be the complete graph on  $V^\times$ . Instead of using the batch-highest-distance Push-Relabel algorithm as in Lemma 7, we more directly follow the strategy of Borradaile et al. [2] by simulating a maximum flow computation from  $s$  to  $t$  in  $K^\times$  using the FIFO Push-Relabel algorithm. We do not wish to directly use the multiple-source multiple-sink flow algorithm of Borradaile et al. [2], because then each of the  $O(k^3)$  Push operations would take  $O(n \log^3 n)$  time.

► **Lemma 12.** *Any single (individual arc) Push operation in the graph  $H$  defined above can be implemented in  $O(n \log n)$  time.*

**Proof.** Consider a single Push( $u, v$ ) operation where  $u, v \in V^\times$ . Let  $\rho$  denote the preflow pushed in  $H$  by the FIFO Push-Relabel algorithm up to this Push operation. We find a flow  $\rho'$  with source  $u$  and sink  $v$  in the graph  $H$  such that either  $\text{ex}(\rho + \rho', u) = 0$  or  $\text{ex}(\rho + \rho', u) > 0$  and there is no residual path in  $H_{\rho+\rho'}$  from  $u$  to  $v$  that is internally disjoint from  $V^\times$ .

Let  $H'$  be the graph obtained from  $H_\rho$  by deleting vertices  $V^\times \setminus \{u, v\}$ . Instead of invoking the  $O(n \log^3 n)$ -time multiple-source multiple-sink maximum flow algorithm of Borradaile et al. [2], we will compute  $\rho'$  as follows. As before, we must consider a few different cases.

- If  $u = s$  or  $v = s$ , then  $v \in S$  or  $u \in S$ , respectively. We push up to  $\text{ex}(\rho, u)$  units of flow directly along the arc  $(u, v)$  in constant time, either saturating the arc or reducing the excess flow in  $u$  to 0. We may similarly push directly along the arc  $(u, v)$  in constant time if one of  $u$  or  $v$  is one of  $t, s',$  or  $t'$  instead.
- If  $u \in \{x_1^{in}, x_1^{out}\}$  and  $v \in \{x_2^{in}, x_2^{out}\}$  for two distinct vertices  $x_1, x_2 \in X$ , then the graph  $H'$  is planar. We add a vertex  $u'$  and an arc  $(u', u)$  with capacity  $\text{ex}(\rho, u)$  and compute the maximum flow  $\rho'$  with source  $u'$  and sink  $v$  using the single-source single-sink maximum flow algorithm in planar graphs of Borradaile and Klein [1].
- If neither of the above cases apply, then  $u, v \in \{x^{in}, x^{out}\}$  for some  $x \in X$ . If arc  $(u, v)$  has positive residual capacity, we push up to  $\text{ex}(\rho, u)$  units of flow directly along it in constant time. Similar to Step 1 in the proof of Lemma 10, starting with  $H'$ , we split  $u$  into  $\text{deg}(u)$  copies so that each arc that was incident to  $u$  is now incident to a distinct copy of  $u$ . Similarly, we split  $v$  into  $\text{deg}(v)$  copies so each arc that was incident to  $v$  is now incident to a distinct copy of  $v$ . The resulting graph is planar, and all copies of  $u$  and  $v$  lie on a common face. As mentioned by Borradaile et al. [2, p. 1280], we can then plug the linear time shortest paths in planar graphs algorithm of Henzinger et al. [5] into a divide-and-conquer procedure of Miller and Naor [10] to compute a maximum flow  $\rho'_u$  with sources the copies of  $u$  and sinks the copies of  $v$  in  $O(n \log n)$  time. Again, if the value of this flow is greater than the excess of  $u$ , we push the appropriate amount of flow back to the copies of  $u$  in  $O(n)$  time. Finally, we view  $\rho'_u$  as a flow in  $H$  to set  $\rho' = \rho'_u$ . ◀

We immediately get a variation of Lemma 11 with a running time of  $O(k^3 n \log n)$ . By using the better of the two procedures for computing  $g^\times$ , we get our main theorem.

► **Theorem 13.** *A maximum flow in an  $n$ -vertex planar flow network  $G$  with integer arc and vertex capacities bounded by  $C$  can be computed in  $O(k^3 \Delta n \log n \min(k, \log^2 n) \log(kC) \log(nC))$  time.*

## Abstract

We study the maximum-weight matching problem in the sliding-window model. In this model, we are given an adversarially ordered stream of edges of an underlying edge-weighted graph  $G(V, E)$ , and a parameter  $L$  specifying the *window size*, and we want to maintain an approximation of the maximum-weight matching of the current graph  $G(t)$ ; here  $G(t)$  is defined as the subgraph of  $G$  consisting of the edges that arrived during the time interval  $[\max(t - L, 1), t]$ , where  $t$  is the current time. The goal is to do this with  $\tilde{O}(n)$  space, where  $n$  is the number of vertices of  $G$ . We present a deterministic  $(3.5 + \varepsilon)$ -approximation algorithm for this problem, thus significantly improving the  $(6 + \varepsilon)$ -approximation algorithm due to Crouch and Stubbs [5].

We also present a generic machinery for approximating subadditive functions in the sliding-window model. A function  $f$  is called *subadditive* if for every disjoint substreams  $A, B$  of a stream  $S$  it holds that  $f(AB) \leq f(A) + f(B)$ , where  $AB$  denotes the concatenation of  $A$  and  $B$ . We show that given an  $\alpha$ -approximation algorithm for a subadditive function  $f$  in the insertion-only model we can maintain a  $(2\alpha + \varepsilon)$ -approximation of  $f$  in the sliding-window model. This improves upon recent result Krauthgamer and Reitblat [14], who obtained a  $(2\alpha^2 + \varepsilon)$ -approximation.

## 1 Introduction

A *matching* in a graph  $G(V, E)$  is a subset  $M \subseteq E$  of pairwise non-adjacent edges. Matchings play an important role in applications and they form a central concept in combinatorial and algorithmic graph theory. They have been studied extensively; there is even a book, by Lovasz and Plummer, dedicated completely to matching theory [16]. One of the most studied algorithmic problems concerning matchings is the *maximum-matching problem*. In the unweighted version, the goal is to compute a maximum-cardinality matching and in the weighted version – here every edge in the input graph has a non-negative weight – the goal is to compute a maximum-weight matching (MWM). In the classical offline setting we are given the graph  $G$  completely in advance and we have enough space to store all vertices and edges. In this setting, the fastest algorithm to compute a maximum matching is still the 30-years-old algorithm due to Micali and Vazirani [17] with running time  $O(m\sqrt{n})$ , where  $n := |V|$  and  $m := |E|$ .

In this paper, we study the maximum-weight matching problem in a streaming setting. Here we are given a stream  $S$  of edges of an underlying graph  $G(V, E)$  and we only have  $\tilde{O}(n) := O(n \cdot \text{polylog}(n))$  storage available. This means that we cannot store all edges from  $G$ , and it becomes impossible to compute a solution that is guaranteed to be optimal. The goal thus becomes to maintain a matching on the current graph whose total weight is as close to optimal as possible. In the *insertion-only model*, the current graph  $G(t)$  is the graph whose edge set consists of all edges that have arrived up to the current time  $t$ . We will be working in the *sliding-window model* [6], where we are given a window length  $L$  and the current graph  $G(t)$  consists of the last  $L$  edges from the stream. Thus, at any time  $t$  we are interested in approximating the maximum-weight matching of the edges that are within the window  $[\max(t - L, 1), t]$ .

**Our results.** We present a  $(3.5 + \varepsilon)$ -approximation for the maximum-weight matching problem in the sliding-window model. The following theorem states our main result more formally.

► **Theorem 1.** *Let  $G(V, E)$  be a graph with  $n = |V|$  vertices and let  $w : E \rightarrow \mathbb{R}^+$  be a function that assigns a weight  $w(e)$  to each edge  $e \in E$  such that the ratio of the maximum edge weight to the minimum edge weight is at most  $W$  for some  $W = n^{O(1)}$ . Then, for any given  $\varepsilon > 0$ , there exists a deterministic algorithm that maintains a  $(3.5 + \varepsilon)$ -approximate maximum-weight matching in the sliding-window model using  $\tilde{O}(n)$  space.*

A comparison of our result with the existing streaming algorithms for maximum-weight matchings is given in Table 1.

The algorithm in Theorem 1 takes the algorithm by Paz and Schwartzman [18] as a starting point. Our  $(3.5 + \varepsilon)$ -approximation is then based on two contributions: a mechanism to convert an algorithm in the insertion-only model into an algorithm in the sliding-window model, and an intricate analysis of the resulting algorithm in the case of maximum-weight matchings. The mechanism to obtain a sliding-window algorithm from an insertion-only algorithm actually works in a much more general setting, namely when we want to compute subadditive functions, defined as follows. Let  $f$  be a function that assigns a value to a data stream. Then  $f$  is called *subadditive* if for every disjoint substreams  $A, B$  of a stream  $S$  it holds that  $f(AB) \leq f(A) + f(B)$ , where  $AB$  denotes the concatenation of  $A$  and  $B$ . We say that  $f$  is *monotone* if for all  $A \subseteq B$  we have  $f(A) \leq f(B)$ . Observe that (the cost of a) maximum weight matching is a subadditive and monotone function. We prove the following result in Section 4.

► **Theorem 2.** *Let  $0 < \varepsilon \leq 1/2$  and  $\alpha \geq 1$  be two parameters. Let  $f$  be a function defined on streams that is subadditive, non-negative, and monotone. Let  $\sigma := f_{\max}/f_{\min+}$ , where  $f_{\min+} := \min\{f(X) : X \text{ is a substream of the input and } f(X) > 0\}$  and  $f_{\max} := \max\{f(X) : X \text{ is a substream of the input}\}$ . Suppose there is an algorithm in the insertion-only streaming model that  $\alpha$ -approximates  $f$  using space  $s$ . Then, there is an algorithm in the sliding-window model that maintains a  $(2\alpha + \varepsilon)$ -approximation of  $f$  using  $O(\varepsilon^{-1}s \cdot \log \sigma)$  space.*

**Previous Work.** Given the prominence of the matching problem, it is not surprising that it has already received considerable attention in the streaming setting.

In the insertion-only model, a maximal matching – a matching  $M$  such that adding any edge from  $E$  to  $M$  would violate the condition that the edges are pairwise non-adjacent – can be computed greedily using  $O(n)$  space. This immediately gives a 2-approximation for maximum-cardinality matching (MCM) [9]. If the stream is in adversarial order, obtaining an

approximation ratio better than 2 for the MCM problem is one of the most important open problems in streaming algorithms. Interestingly, Kapralov [12] showed that any streaming algorithm that achieves an approximation ratio better than  $e/(1-e) \approx 1.58$  must use  $n^{1+\Omega(\frac{1}{\log \log n})}$  storage. In the *random-order model*, where the edges from  $E$  arrive in random order, better approximation ratios than 2 have been obtained [13, 10, 7, 8, 1]. In particular, very recently, Bernstein [1] showed that we can compute a  $(\frac{3}{2} + \varepsilon)$ -approximate matching in random order streams using  $\tilde{O}(n)$  space.

Maximum-weighted matchings (MWM) have also been studied in the insertion-only model. Crouch and Stubbs [5] presented a technique that makes it possible to turn a  $c$ -approximation algorithm for the MCM problem into a  $2(1+\varepsilon)c$ -approximation algorithm for the MWM problem. A combination of this reduction and the greedy matching achieves a  $(4+\varepsilon)$ -approximation algorithm for the maximum-weight matching problem in the insertion-only model. In a breakthrough result, Paz and Schwartzman [18] developed a  $(2+\varepsilon)$ -approximation algorithm for the maximum-weight matching problem in the insertion-only model, using  $O(n \log^2 n)$  bits of space. Later, Ghaffari and Wajc [11] improved the space of Paz and Schwartzman's algorithm to  $O(n \log n)$  bits of space.

We now turn our attention to the sliding-window model. Braverman and Ostrovsky [2] introduced *smooth histograms*, a powerful framework to maintain a class of functions, called smooth function in the sliding-window model. Crouch, McGregor, and Stubbs [4] showed that the smooth-histograms technique can be applied to maintain an approximately maximal matching that achieves a  $(3+\varepsilon)$ -approximation of the maximum-cardinality matching. They also presented a 9.027-approximation algorithm for the maximum-weight matching in the sliding-window model. This can be improved using the already mentioned (more recent) technique by Crouch and Stubbs [5] to turn a  $c$ -approximation algorithm for the MCM problem into a  $2(1+\varepsilon)c$ -approximation algorithm for the MWM problem. Using this reduction and the algorithm of [4] we can achieve  $(6+\varepsilon)$ -approximation weighted matching in the sliding-window model. This reduction, which yields the best previously known result for the MWM problem in the sliding-window model, partitions the edges into weight classes and maintains a matching on the edges in each weight class. At the end of the stream, it greedily merges the matchings from largest weight class to smallest weight class. However, our algorithm is based on the algorithm by Paz and Schwartzman [18] that is explained in Section 2.

We next explain the previous work on subadditive functions in data streams. Let  $f$  be a function defined on streams, which is subadditive, non-negative, and monotone. Recently, Krauthgamer and Reitblat [14] showed that given a streaming algorithm  $\mathcal{ALG}$  that  $\alpha$ -approximates  $f$  using space  $s$ , we can develop a sliding-window algorithm that  $(2\alpha^2 + \varepsilon)$ -approximates  $f$  using space  $O(\varepsilon^{-1}s \cdot \log \sigma)$ , where  $\sigma$  is ratio of the maximum value of  $f$  to the minimum value of  $f$ . They also showed that if  $\mathcal{ALG}$  is monotone and subadditive, we can reduce the approximation factor of the sliding-window algorithm down to  $(2\alpha + \varepsilon)$ -factor. Unfortunately, it is not always easy to show a streaming algorithm is monotone and/or subadditive. In some cases, this is not in fact, the case. On the other hand, Theorem 2 shows that we can achieve  $(2\alpha + \varepsilon)$ -approximation factor independent of the monotonicity or subadditivity of the streaming algorithm  $\mathcal{ALG}$ . We should mention that there is a similar result for constrained submodular maximization in the sliding-window model due to Chen, Nguyen, and Zhang [3].

**Notation and terminology.** In this paper, we assume we are given a weighted graph  $G(V, E)$  with  $n = |V|$  vertices and a weight function  $w : E \rightarrow \mathbb{R}^+$  that assigns a non-negative weight  $w(e)$  to each edge  $e = (u, v) \in E$ , where the ratio of the maximum edge weight to the

minimum edge weight is upper-bounded by  $W = n^{O(1)}$ . We assume that the graph is simple, that is, it does not have parallel edges. We denote by  $N_G(v) = \{u \in V : \exists(u, v) \in E\}$  the set of neighbors of a vertex  $v$  in  $G$ . We drop the subscript  $G$  and write  $N(v)$  when  $G$  is clear from the context. Similarly, we denote by  $N_G(e)$  the set of edges that are neighbors of an edge  $e = (u, v)$ , that is, those edges such that one of their endpoints is in the  $\{u, v\}$ . A *matching*  $M$  of  $G$  is a set of pairwise non-adjacent edges, that is, a set where no two edges share a common vertex. The weight of the matching  $M$  is defined as  $w(M) = \sum_{e \in M} w(e)$ . A *maximum matching* of graph  $G(V, E)$  is a matching of maximum weight. Throughout the paper, when we fix a maximum-weight matching of a graph  $G$ , we denote it by  $M_{\text{opt}}(G)$ , or simply  $M_{\text{opt}}$  when  $G$  is clear from the context. We say a matching  $M$  is an  $\alpha$ -*approximate weighted matching*, for some  $\alpha > 1$ , when  $w(M) \geq (1/\alpha) \cdot w(M_{\text{opt}})$ . Finally, with a slight abuse of notation, we will often not distinguish between sets of edges and streams of edges. As an example, given a stream  $S$  of edges of an underlying graph  $G(V, E)$ , we do not distinguish between  $G(V, E)$  and  $G(V, S)$ .

## 2 Maximum-weight matching in the insertion-only model

As mentioned in the introduction, in a breakthrough paper [18], Paz and Schwartzman showed that there exists an algorithm in the insertion-only model that computes a  $(2 + \varepsilon)$ -approximate weighted matching of a graph  $G(V, E)$ . Their algorithm forms the basis of our  $(3.5 + \varepsilon)$ -approximation algorithm in the sliding-window model. In this section, we explain Paz and Schwartzman’s algorithm and we give various properties – some already proved by Ghaffari and Wajc [11], some new – that we later use.

**Overview of algorithm.** Before the stream starts, we initialize an empty stack. The streaming algorithm then processes the edges in the stream one by one. While doing so, it maintains a *potential*  $\phi(v)$  for every vertex  $v \in V$  (which is initialized to zero before the stream starts). For each arriving edge  $e = (u, v)$ , it is decided whether or not to push  $e$  on the stack based on its weight  $w(e)$  and on the potential of its endpoints. In particular, if  $w(e) \geq (1 + \varepsilon) \cdot (\phi(u) + \phi(v))$ , then  $e$  is added to the stack. When  $e$  is added to the stack, we assign a *reduced weight*  $w'(e)$  to it, defined as  $w'(e) := w(e) - (\phi(u) + \phi(v))$ ; from now on we refer to  $w(e)$  as the *original weight* of  $e$ . If  $e$  is added to the stack, we add  $w'(e)$  to the potential of its endpoints. It will be convenient to set  $w'(e) := 0$  when  $e$  is not added to the stack.

After all edges have been handled in this manner, the matching is computed greedily: we pop edges from the stack and add them to the matching  $M_{\text{alg}}(G)$  if they have no neighboring edge in  $M_{\text{alg}}(G)$ .

---

**Algorithm 1** MWM-STREAMING [18, 11].
 

---

**Streaming:**

```

1: while a new edge  $e = (u, v)$  of the stream  $S$  is revealed do
2:   if  $w(e) < (1 + \varepsilon) \cdot (\phi(u) + \phi(v))$  then  $w'(e) \leftarrow 0$ 
3:   else
4:      $w'(e) \leftarrow w(e) - (\phi(u) + \phi(v))$   $\triangleright w'(e)$  is the reduced weight of  $e$ 
5:      $\phi(u) \leftarrow \phi(u) + w'(e)$ ;  $\phi(v) \leftarrow \phi(v) + w'(e)$   $\triangleright$  update potentials
6:      $Stack.push(e)$ 

```

---

**Postprocessing:**

```

1: Let  $M_{alg}(G) \leftarrow \emptyset$  be an empty matching set.
2: while  $Stack \neq \emptyset$  do
3:    $e \leftarrow Stack.pop()$ 
4:   if  $M_{alg}(G) \cap N(e) = \emptyset$  then  $M_{alg}(G) \leftarrow M_{alg}(G) \cup \{e\}$ .
5: return  $M_{alg}(G)$ .

```

---

**Properties of the algorithm.** Let  $t_e$  be the arrival time of the edge  $e$ . Let  $P(e) := \{e' \in E : e' \in N(e) \cup \{e\} \text{ and } t_{e'} \leq t_e\}$  be the set of neighbor edges of  $e$  that arrive in the stream before  $e$  plus the edge  $e$  itself. Observe that if  $e$  is not added to the stack, then  $w(e) < (1 + \varepsilon) \cdot (\phi(u) + \phi(v))$ ; and if this happens, the reduced weight must be  $w'(e) = 0$ .

The first lemma shows that the original weight of every edge in the graph is upper-bounded by  $(1 + \varepsilon)$ -factor of the sum of the potentials that are assigned to its end-points regardless of the fact that the edge is pushed onto the stack or not. The following lemma was proved by Ghaffari and Wajc [11, Observation 3.2].

► **Lemma 3** ([11]). *After the algorithm has finished we have  $w(e) \leq (1 + \varepsilon) \cdot (\phi(v) + \phi(u))$  for each  $e = (u, v)$  in  $E$ .*

The next lemma gives a relation between the original weight  $w(e)$  of an edge  $e$  and the reduced weights  $w'(e')$  of the edges  $e' \in P(e)$ . It is a special case of Lemma 3.4 of [11], where it was stated that  $w(e) \geq \sum_{e' \in P(e)} w'(e')$ . As follows from their proof, we can only have  $w(e) > \sum_{e' \in P(e)} w'(e')$  when there are parallel edges. As we assume in this paper that  $G$  is a simple graph (i.e., does not contain any parallel edge) we state the result as follows.

► **Lemma 4** ([11]). *Suppose that the graph  $G(V, E)$  is a simple graph. Let  $e \in E$  be an edge that is added to the stack. Then  $w(e) = \sum_{e' \in P(e)} w'(e')$ .*

Lemma 4 is about edges that are added to the stack. The next lemma states a similar result for any edge  $e$ , regardless of whether it is added to the stack.

► **Lemma 5.** *For each  $e \in E$  we have  $w(e) \leq (1 + \varepsilon) \sum_{e' \in P(e)} w'(e')$ .*

**Proof.** If  $e = (u, v)$  is added to the stack, the inequality holds according to Lemma 4. Suppose that  $e$  is not added to the stack. We use  $\phi_e^-(u)$  and  $\phi_e^-(v)$  for the potential values just before the arrival of  $e$ . As  $e$  is not added to the stack, we have  $w(e) < (1 + \varepsilon) \cdot (\phi_e^-(u) + \phi_e^-(v))$ . Let  $e'$  be an edge in  $P(e) \setminus \{e\}$ . As  $G$  does not contain parallel edges,  $e'$  increases exactly one of  $\phi(u)$  or  $\phi(v)$  by  $w'(e')$ . (This also holds when  $w'(e') = 0$ .) Therefore,  $\phi_e^-(u) + \phi_e^-(v) = \sum_{e' \in P(e) \setminus \{e\}} w'(e')$ . Thus,

$$w(e) < (1 + \varepsilon) \cdot (\phi_e^-(v) + \phi_e^-(u)) = (1 + \varepsilon) \cdot \sum_{e' \in P(e) \setminus \{e\}} w'(e') \leq (1 + \varepsilon) \cdot \sum_{e' \in P(e)} w'(e') . \quad \blacktriangleleft$$

We also need Lemma 3.1 of [11], which states that the weight of the reported matching  $M_{\text{alg}}(G)$  is lower-bounded by the sum of reduced weights of all edges of the graph  $G$ , which is in fact, one half of the sum of potentials that we place on vertices. The latter is a  $(1 + \varepsilon)$ -approximation of the optimal weight  $w(M_{\text{opt}}(G))$ .

► **Lemma 6** ([11]). *Let  $M_{\text{alg}}(G)$  be the matching reported by Algorithm MWM-STREAMING. Then,*

$$w(M_{\text{alg}}(G)) \geq \sum_{e \in E} w'(e) = \frac{1}{2} \sum_{v \in V} \phi(v) \geq \frac{1}{2(1 + \varepsilon)} \cdot w(M_{\text{opt}}(G)) .$$

Suppose we have two substreams  $B$  and  $BC$ , i.e.,  $B$  is a prefix of  $BC$ . The next lemma shows that the reduced weight of an edge  $e \in B$  is the same when the algorithm is run on  $B$  as when it is run on  $BC$ . It immediately follows from the fact that  $w'(e)$  is set when  $e$  is processed, and it will not be changed afterwards.

► **Lemma 7.** *Let  $S$  be a stream of edges of an underlying simple weighted graph  $G(V, E)$ . Let  $B, C$  be two disjoint segments of the stream  $S$ . Let  $e \in B$  be an arbitrary edge in  $B$ . Let  $w'_B(e)$  and  $w'_{BC}(e)$  be the reduced weights of  $e$  when we run Algorithm MWM-STREAMING on the streams  $B$  and  $BC$ , respectively. Then,  $w'_B(e) = w'_{BC}(e)$ .*

**Making MWM-Streaming monotone.** Later, when we develop our sliding-window algorithm, we need Algorithm MWM-STREAMING to be monotone, that is, we need that the weight of the reported matching for a stream  $BC$  is at least the weight of the reported matching for  $B$ . Unfortunately, this need not be the case, because in the reporting phase the edges are popped from the stack in reverse order of their arrival and added to the matching greedily.

However, we can simply make Algorithm MWM-STREAMING monotone by maintaining the best solution over all prefixes encountered so far. More precisely, while we run the algorithm on the input stream  $S$  as usual, we maintain  $M_{\text{mon}}(S) := \arg \max\{w(M_{\text{alg}}(T)) : T \text{ is a prefix of } S\}$ . To this end, we just run the Postprocessing subroutine after each arrival on a copy of the current stack, and update  $M_{\text{mon}}(S)$  if the computed solution is better. We denote by MWM-MONOTONE this monotone version of Algorithm MWM-STREAMING.

Next, we state two useful properties of the monotone matching  $M_{\text{mon}}(S)$ .

► **Lemma 8.** *Let  $S$  be a stream of edges of an underlying simple weighted graph  $G(V, E)$ . Suppose that we have two disjoint substreams  $B$  and  $C$  of the stream  $S$ . Then,*

- **Monotonicity Property 1:**  $w(M_{\text{alg}}(B)) \leq w(M_{\text{mon}}(B)) \leq w(M_{\text{opt}}(B))$ .
- **Monotonicity Property 2:**  $w(M_{\text{mon}}(B)) \leq w(M_{\text{mon}}(BC))$ .

### 3 Maximum-weight matching in the sliding-window model

In this section, we develop our 3.5-approximation algorithm for the maximum-weight matching problem in the sliding-window model. As the first step, we next provide a generic framework for computing monotone bounded functions in the sliding-window model. Our framework is based on the *smooth-histogram techniques* developed by Braverman and Ostrovsky [2] for the sliding-window model. The smooth histogram technique was later used by Crouch, McGregor, and Stubbs [4] to develop algorithms for graph problems in the sliding-window model.

The idea behind this technique is that at any time  $t$ , we have a logarithmic number of insertion-only algorithms running in parallel, that each started at different times. As our answer at time  $t$  we then report, roughly speaking, the answer given by the “oldest”

still running algorithm; the technique ensures that this algorithm started shortly after time  $t - L$ , so that the answer is a good approximation of the actual answer. The next definition formalizes the properties we need to apply the technique. Suppose we want to approximate a function  $f$  in a sliding-window setting, and we have an algorithm  $\mathcal{ALG}$  for the insertion-only setting. The idea is that if  $A, B$  are two substreams such that  $f(ABC) \leq \alpha \cdot \mathcal{ALG}(BC)$  for any substream  $C$ , then we can  $\alpha$ -approximate  $f(ABC)$  by  $\mathcal{ALG}(BC)$ .

► **Definition 9** ( $(f, \alpha, \beta)$ -lookahead algorithm). *Let  $\beta \in (0, 1)$  and  $\alpha \in \mathbb{R}^+$  be two parameters. Let  $f$  be a real-valued monotone function defined on subsets of a ground set  $\mathcal{X}$ . Let  $S$  be a stream of items of the set  $\mathcal{X}$ . Let  $\mathcal{ALG}$  be a streaming algorithm. We say the streaming algorithm  $\mathcal{ALG}$  is an  $(f, \alpha, \beta)$ -lookahead algorithm if for any partitioning of  $S$  into three disjoint sub-streams  $A, B$ , and  $C$  with  $\mathcal{ALG}(B) \geq (1 - \beta) \cdot \mathcal{ALG}(AB)$ , we have  $f(ABC) \leq \alpha \cdot \mathcal{ALG}(BC)$ .*

The following theorem shows that if we have such a lookahead algorithm, we can develop a sliding-window algorithm for the function  $f$ . The proof of this theorem is based on the techniques developed in [4] and we give the full proof for the sake of completeness.

► **Theorem 10.** *Let  $0 < \beta < 1$  and  $\alpha \geq 1$  be two parameters. Let  $S$  be a stream of items from an underlying ground set  $\mathcal{X}$ . Let  $f$  be a monotone function defined on subsets of a ground set  $\mathcal{X}$ . Let  $\sigma := f_{\max}/f_{\min^+}$ , where  $f_{\min^+} := \min\{f(X) : X \text{ is a substream of } S \text{ and } f(X) > 0\}$  and  $f_{\max} := \max\{f(X) : X \text{ is a substream of the input}\}$ . Suppose there exists an  $(f, \alpha, \beta)$ -lookahead algorithm that uses space  $s$ . Then there exists a sliding-window algorithm that maintains an  $\alpha$ -approximation of  $f$  using  $O(\beta^{-1} \cdot s \log \sigma)$  space.*

**Proof.** We first present our algorithm SLIDINGLOOKAHEAD, which is based on the smooth histograms developed by Braverman and Ostrovsky [2] for the sliding-window model.

■ **Algorithm 2** SLIDINGLOOKAHEAD (Based on Smooth Histogram [2, 14]).

---

**Initialization:**

- 1: Let  $k \leftarrow 0$  be the number of buckets.
- 

**Streaming:**

- 1: **while** a new item  $e$  of the stream  $S$  is revealed at time  $t$  **do**
  - 2:     Create an empty bucket  $B_{k+1}$ .
  - 3:     Let  $\mathcal{ALG}_{k+1}$  be an instance of  $\mathcal{ALG}$  for the bucket  $B_{k+1}$ .
  - 4:     **for**  $i = 1, \dots, k + 1$  **do**
  - 5:         Feed  $e$  to the bucket  $B_i$ , and update its associated instance  $\mathcal{ALG}_i$ .
  - 6:     **for**  $i = 1, \dots, k - 1$  **do**
  - 7:         Let  $j > i$  be the largest index for which  $\mathcal{ALG}(B_j) \geq (1 - \beta) \cdot \mathcal{ALG}(B_i)$ .
  - 8:         Delete buckets  $B_r$  for  $i < r < j$  and their associated instances  $\mathcal{ALG}_r$ .
  - 9:     **if**  $W \subseteq B_2$  **then** Delete bucket  $B_1$  and its associated instance  $\mathcal{ALG}_1$ .
  - 10:     Let  $k$  be number of remaining buckets.
  - 11:     Renumber buckets and their associated instances.
- 

**Output:**

- 1: **if**  $W = B_1$  **then return** the solution of the  $\mathcal{ALG}_1$ , which equals  $\mathcal{ALG}(B_1)$ .
  - 2: **else return** the solution of the  $\mathcal{ALG}_2$ , which equals  $\mathcal{ALG}(B_2)$ .
-

Let  $W = [\max(t - L, 1), t]$  be the active window. With a slight abuse of notation, we will use  $W$  both for the time interval of the active window as well as for the set of items that arrive during this time interval. We consider  $k$  buckets  $B_1, \dots, B_k$  such that  $B_1 \supseteq W \supseteq B_2 \supseteq \dots \supseteq B_k$ . We later show that  $k = O(\varepsilon^{-1} \log \sigma)$ . For each bucket, we instantiate an instance of  $(f, \alpha, \beta)$ -lookahead algorithm  $\mathcal{ALG}$ . Upon arrival of a new item  $e$  at a time  $t$ , we create a new bucket  $B_{k+1}$  and add  $e$  to all buckets  $B_1, \dots, B_{k+1}$ . Next, if there exists a sequence of buckets whose values of  $\mathcal{ALG}$  are too close, we keep the bucket in this sequence that has the lowest index and delete the rest of the buckets in this sequence.

Observe that the active window  $W$  is always sandwiched between the buckets  $B_1$  and  $B_2$ . If at any time  $t$ , the active window  $W$  is covered by the bucket  $B_2$  (i.e.,  $W \subseteq B_2$ ), we then delete  $B_1$  and renumber the buckets accordingly. The output of smooth histogram is reported by the instance  $\mathcal{ALG}$  of the bucket  $B_2$ .

Next, we prove the theorem which is based on the combination of the proofs of Lemma 3 and Theorem 4 in [4]. (We should mention that the proof in [4] is for  $\alpha = 3 + \varepsilon$ , but we prove it for any  $\alpha$ .)

Let  $\mathcal{ALG}$  be a  $(f, \alpha, \beta)$ -lookahead algorithm using space  $s$ . We show that SLIDINGLOOKAHEAD maintains an  $\alpha$ -approximation of  $f$ , using  $O(\beta^{-1} \cdot s \log \sigma)$  space. First, we prove the approximation ratio. Later, we show that  $k = O(\beta^{-1} \log \sigma)$  at any time  $t$ .

Let  $W = [\max(t - L, 1), t]$  be the active window and let  $0 < \beta < 1$ . Recall that the buckets  $B_1, \dots, B_k$  satisfy  $B_1 \supseteq W \supseteq B_2 \supseteq \dots \supseteq B_k$ . If  $W = B_1$ , we return  $\mathcal{ALG}(B_1) = \mathcal{ALG}(W)$ , which satisfies  $f(W) \leq \alpha \cdot \mathcal{ALG}(B_1)$ . Now, suppose that  $W \neq B_1$ . Since we report  $\mathcal{ALG}(B_2)$ , we must show that  $f(W) \leq \alpha \cdot \mathcal{ALG}(B_2)$ . To this end, let  $t^*$  be the first time that buckets  $B_1$  and  $B_2$  became adjacent; it is the time when buckets in between  $B_1$  and  $B_2$  were removed in step 8 of the streaming phase. We denote these buckets at time  $t^*$  by  $B_1^*$  and  $B_2^*$ . So,  $\mathcal{ALG}(B_2^*) > (1 - \beta)\mathcal{ALG}(B_1^*)$ . Moreover,  $B_1 = B_1^*C$ ,  $B_2 = B_2^*C$  for the stream  $C$  consisting of the items that arrived since time  $t^*$ . Now, according to the  $(f, \alpha, \beta)$ -lookahead property of  $\mathcal{ALG}$ , we can conclude  $f(B_1) \leq \alpha \cdot \mathcal{ALG}(B_2)$ . As  $f$  is monotone, we have:

$$f(W) \leq f(B_1) \leq \alpha \cdot \mathcal{ALG}(B_2) .$$

Recall that  $k$  is the number of buckets. Next, we prove that at any time  $t$ , we have  $k = O(\beta^{-1} \log \sigma)$ . Recall that for each index  $i \in [1..k - 2]$ , we have

$$\mathcal{ALG}(B_{i+2}) < (1 - \beta) \cdot \mathcal{ALG}(B_i).$$

Since  $1/(1 - \beta) > 1 + \beta$ , we have

$$\mathcal{ALG}(B_i) > \frac{1}{1 - \beta} \cdot \mathcal{ALG}(B_{i+2}) > (1 + \beta) \cdot \mathcal{ALG}(B_{i+2}).$$

Thus,

$$\mathcal{ALG}(B_1) \geq (1 + \beta)^{\lfloor k/2 \rfloor} \cdot \mathcal{ALG}(B_k) .$$

Recall that  $\frac{f(B_1)}{f(B_k)} \leq \sigma$ . This essentially means that  $\mathcal{ALG}(B_1) \leq \sigma \alpha \cdot \mathcal{ALG}(B_k)$ . Therefore,  $k \leq O(\log_{1+\beta}(\sigma \alpha)) = O(\beta^{-1} \cdot \log \sigma)$ .  $\blacktriangleleft$

Our main result in this paper is that there exists a lookahead algorithm for the maximum weight matching problem. We state this result formally next.

► **Lemma 11.** *Let  $G(V, E)$  be a graph with  $n = |V|$  vertices and let  $w : E \rightarrow \mathbb{R}^+$  be a function that assigns a non-negative weight  $w(e)$  to each edge  $e \in E$ . Let  $0 < \varepsilon \leq \frac{1}{10}$  and  $0 < \beta \leq \frac{\varepsilon}{9}$  be two parameters. Let  $f$  be defined as the weight of a maximum weight matching of  $G$ . Then, Algorithm MWM-MONOTONE is a  $(f, (3.5 + \varepsilon), \beta)$ -lookahead algorithm. That is, for any partitioning of a stream  $S$  of edges of  $G$  into three disjoint sub-streams  $A$ ,  $B$ , and  $C$  with  $w(M_{\text{mon}}(B)) \geq (1 - \beta) \cdot w(M_{\text{mon}}(AB))$ , we have  $w(M_{\text{opt}}(ABC)) \leq (3.5 + \varepsilon) \cdot w(M_{\text{mon}}(BC))$ .*

Thus, we can use the machinery developed in Theorem 10 to obtain a  $(3.5 + \varepsilon)$ -approximate sliding-window algorithm for the maximum-weight matching.

We first define some notation and prove auxiliary tools to later prove Lemma 11.

**Notation.** Suppose we have a simple weighted graph  $G(V, E)$ , whose edges are revealed in a streaming fashion and let that stream be  $S$ . Suppose we partition the stream  $S$  into three disjoint consecutive substreams  $A$ ,  $B$ , and  $C$ . Let  $M_{\text{opt}}(ABC)$  be a fixed maximum-weight matching of  $G$ . Let  $X \in \{A, B, C, AB, BC\}$ .

- We denote by  $M_{\text{opt}}(ABC) \cap X$  those edges of the maximum-weight matching  $M_{\text{opt}}(ABC)$  that belong to the substream  $X$ .
- We denote by  $M_{\text{alg}}(X)$  the reported matching of Algorithm MWM-STREAMING if we invoke it on the input substream  $X$ .
- We let  $\phi_X(v)$  be the potential that is assigned to a vertex  $v \in V$  if we execute Algorithm MWM-STREAMING on the input substream  $X$ .
- We let  $w'_X(e)$  be the reduced weight that we assign to an edge  $e \in E$  if we execute Algorithm MWM-STREAMING on the input substream  $X$ .

A key concept in our analysis is the so-called *critical subgraph* of a graph  $G$ . We take advantage of this concept to show upper bounds for  $w(M_{\text{opt}}(ABC) \cap AB)$  and  $w(M_{\text{opt}}(ABC) \cap C)$  in Lemmas 13–16.

► **Definition 12 (Critical Subgraph).** *Consider a graph  $G$  specified by a stream  $S$  of edges. Let  $A, B, C$  be disjoint substreams of  $S$  such that  $S = ABC$ . Then, the critical subgraph of  $G$  with respect to the matching  $M_{\text{opt}}(ABC)$  and the substreams  $A, B, C$  is the subgraph  $H = (V_H, E_H)$  such that*

- $E_H := \{e \in B \mid e \text{ has two neighbors in } M_{\text{opt}}(ABC) \cap C\}$ .
- $V_H := \{v \in V \mid \exists u \in V : (u, v) \in E_H\}$ , i.e.,  $V_H$  is the set of endpoints of the edges in  $E_H$ .

**Outline of the proof of Lemma 11.** We show an upper-bound for  $w(M_{\text{opt}}(ABC))$  based on  $w(M_{\text{alg}}(AB))$  and  $w(M_{\text{alg}}(BC))$ . In particular, we show that

$$w(M_{\text{opt}}(ABC)) \leq 2(1 + \varepsilon)w(M_{\text{alg}}(AB)) + 2(1 + \varepsilon)w(M_{\text{alg}}(BC)) - \mathcal{Z} . \quad (1)$$

The slack term  $\mathcal{Z}$  shows that there might be a double counting in the above inequality. Intuitively, this makes sense as the substream  $B$  is repeated in the first and the second terms.

However, for the moment, suppose this is not the case and  $\mathcal{Z} = 0$ . Assume that  $w(M_{\text{alg}}(B)) \geq (1 - \beta) \cdot w(M_{\text{alg}}(AB))$ , that is, the sets  $A$  and  $B$  (and our algorithm) are such that  $M_{\text{alg}}(B)$  gives a good approximation of  $M_{\text{alg}}(AB)$ . Then, we have

$$\begin{aligned} w(M_{\text{opt}}(ABC)) &\leq 2 \cdot \frac{(1 + \varepsilon)}{(1 - \beta)} \cdot w(M_{\text{alg}}(B)) + 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(BC)) \\ &\leq 2 \cdot \frac{(1 + \varepsilon)}{(1 - \beta)} \cdot w(M_{\text{mon}}(B)) + 2(1 + \varepsilon) \cdot w(M_{\text{mon}}(BC)) \\ &\leq 4 \cdot (1 + O(\varepsilon)) \cdot w(M_{\text{mon}}(BC)) , \end{aligned}$$

## 73:10 Maximum-Weight Matching in Sliding Windows and Beyond

where for the second inequality we switch from Algorithm MWM-STREAMING to its monotone version which is Algorithm MWM-STREAMING-MONOTONE and the third inequality uses Monotonicity Property 2 of Lemma 8.

Observe that this result already improves upon the  $(6 + \varepsilon)$ -approximation algorithm in the sliding-window model due to Crouch and Stubbs [5]. To obtain an even better bound, we show that  $\mathcal{Z}$  is lower-bounded by a constant factor of the optimal matching of the substream  $B$ . In particular, we show that Inequality (1) holds for  $\mathcal{Z} = \frac{1}{2(1+\varepsilon)} \cdot w(M_{\text{opt}}(B))$ . Since  $w(M_{\text{opt}}(B)) \geq w(M_{\text{mon}}(B))$ , we then have

$$\begin{aligned} w(M_{\text{opt}}(ABC)) &\leq 2 \frac{(1+\varepsilon)}{(1-\beta)} w(M_{\text{mon}}(B)) + 2(1+\varepsilon)w(M_{\text{mon}}(BC)) - \frac{1}{2(1+\varepsilon)} w(M_{\text{mon}}(B)) \\ &\leq (3.5 + O(\varepsilon))w(M_{\text{mon}}(BC)) . \end{aligned}$$

**The complete proof of Lemma 11.** We find the bound on  $w(M_{\text{opt}}(ABC))$  that we claimed in Equation 1 in three steps. First in Lemma 13, we find an upper-bound on the contribution of the substream  $AB$  towards  $M_{\text{opt}}(ABC)$ . Next, we upper-bound the weight of edges of the optimal matching  $M_{\text{opt}}(ABC)$  that are in the substream  $C$ . This is done in Lemma 14. Finally, in Lemma 15 we obtain a lower-bound for the slack term  $\mathcal{Z}$  of Equation 1.

► **Lemma 13.**  $w(M_{\text{opt}}(ABC) \cap AB) \leq 2(1+\varepsilon)w(M_{\text{alg}}(AB)) - (1+\varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v)$  .

**Proof.** By definition,  $w(M_{\text{opt}}(ABC) \cap AB) = \sum_{e^* \in M_{\text{opt}}(ABC) \cap AB} w(e^*)$ . Let us consider an arbitrary edge  $e^* = (u, v) \in M_{\text{opt}}(ABC) \cap AB$ . Using Lemma 3, we have  $w(e^*) \leq (1+\varepsilon) \cdot (\phi_{AB}(u) + \phi_{AB}(v))$ . Observe that the vertices  $u$  and  $v$  cannot be in  $V_H$ . Thus, we obtain

$$w(M_{\text{opt}}(ABC) \cap AB) \leq (1+\varepsilon) \cdot \sum_{v \in V \setminus V_H} \phi_{AB}(v) = (1+\varepsilon) \cdot \sum_{v \in V} \phi_{AB}(v) - (1+\varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v) .$$

Now we use Lemma 6 that shows  $\sum_{v \in V} \phi_{AB}(v) \leq 2w(M_{\text{alg}}(AB))$ . Hence,

$$w(M_{\text{opt}}(ABC) \cap AB) \leq 2(1+\varepsilon) \cdot w(M_{\text{alg}}(AB)) - (1+\varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v) . \quad \blacktriangleleft$$

The next lemma shows that the contribution of optimal edges that are in the substream  $C$  is upper-bounded by twice the weight of the reported matching of the substream  $BC$  minus the reduced weight of edges of  $B$  that are not in the critical subgraph  $H$ .

► **Lemma 14.**  $w(M_{\text{opt}}(ABC) \cap C) \leq 2(1+\varepsilon) \cdot w(M_{\text{alg}}(BC)) - (1+\varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_B(e)$  .

**Proof.** Recall that for every edge  $e \in E$ ,  $w'_{BC}(e)$  is the reduced weight of  $e$  if we run Algorithm MWM-STREAMING on the input stream  $BC$ , where we define  $w'_{BC}(e) = 0$  if  $e \notin BC$ . To prove the lemma, we will show that

$$w(M_{\text{opt}}(ABC) \cap C) \leq 2(1+\varepsilon) \cdot \sum_{e \in BC} w'_{BC}(e) - (1+\varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_{BC}(e) . \quad (2)$$

Suppose for now that Inequality (2) is correct. According to Lemma 7, for every  $e \in B$ , we have  $w'_{BC}(e) = w'_B(e)$ . Thus,  $\sum_{e \in B \setminus E_H} w'_{BC}(e) = \sum_{e \in B \setminus E_H} w'_B(e)$ .

Next, we use Lemma 6, where we replace the graph  $G$  in that lemma with the subgraph  $G'(V, BC)$  to show that  $\sum_{e \in BC} w'_{BC}(e) \leq w(M_{\text{alg}}(BC))$ .

Putting everything together, we prove the statement of this lemma as follows:

$$\begin{aligned}
w(M_{\text{opt}}(ABC) \cap C) &\leq 2(1 + \varepsilon) \cdot \sum_{e \in BC} w'_{BC}(e) - (1 + \varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_{BC}(e) \\
&\leq 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(BC)) - (1 + \varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_{BC}(e) \\
&= 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(BC)) - (1 + \varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_B(e) .
\end{aligned}$$

It remains to prove Inequality (2). Let  $e^* \in M_{\text{opt}}(ABC) \cap C$ . We use Lemma 5, where we replace the graph  $G$  in that lemma with the subgraph  $G'(V, BC)$ . Then, Lemma 5 shows that  $w(e^*) \leq (1 + \varepsilon) \cdot \sum_{e' \in P_{BC}(e^*)} w'_{BC}(e')$ , where  $P_{BC}(e) := \{e' \in BC : e' \in N_{G'}(e) \cup \{e\} \text{ and } t_{e'} \leq t_e\}$ . (Here  $t_{e'}$  and  $t_e$  are the arrival time of edges  $e$  and  $e'$  in the substream  $BC$ .)

Hence,

$$w(M_{\text{opt}}(ABC) \cap C) = \sum_{e^* \in M_{\text{opt}}(ABC) \cap C} w(e^*) \leq (1 + \varepsilon) \sum_{e^* \in M_{\text{opt}}(ABC) \cap C} \sum_{e' \in P_{BC}(e^*)} w'_{BC}(e')$$

Consider the double summation  $\sum_{e^* \in M_{\text{opt}}(ABC) \cap C} \sum_{e' \in P_{BC}(e^*)} w'_{BC}(e')$ . Every edge  $e' \in BC$  appears in  $P_{BC}(e^*)$  for at most two edges  $e^*$ , because each endpoint of  $e'$  is incident to at most one edge from  $M_{\text{opt}}(ABC)$ . Hence, the double summation can be bounded by  $2 \cdot \sum_{e \in BC} w'_{BC}(e)$ . If, however,  $e'$  appears twice then  $e' \in E_H$ , that is,  $e'$  is part of the critical subgraph  $H$ . This means that the edges in  $B \setminus E_H$  appear at most once in the sum. Therefore,

$$w(M_{\text{opt}}(ABC) \cap C) \leq 2(1 + \varepsilon) \cdot \sum_{e \in BC} w'_{BC}(e) - (1 + \varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_{BC}(e),$$

which proves Inequality (2) and finishes the proof of the lemma.  $\blacktriangleleft$

**► Lemma 15.** *Suppose we execute Algorithm MWM-STREAMING on the substream  $AB$ . Let  $\phi_{AB}(v)$  be the potential assigned to a vertex  $v \in V_H$  at the end of this algorithm. Then,  $(1 + \varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v) \geq \sum_{e \in E_H} w'_B(e)$ .*

**Proof.** Observe that  $E_H \subseteq B \subseteq AB$ . Let us consider an arbitrary edge  $e = (u, v)$  in  $E_H$ . By applying Lemma 3 to the graph  $G'(V, AB)$  we obtain  $w(e) \leq (1 + \varepsilon)(\phi_{AB}(u) + \phi_{AB}(v))$ . Fix a maximum-weight matching  $M_{\text{opt}}(H)$  of the critical subgraph  $H(V_H, E_H)$ . Then,

$$\begin{aligned}
w(M_{\text{opt}}(H)) &= \sum_{e=(u,v) \in M_{\text{opt}}(H)} w(e) \leq \sum_{(u,v) \in M_{\text{opt}}(H)} (1 + \varepsilon)(\phi_{AB}(u) + \phi_{AB}(v)) \\
&\leq (1 + \varepsilon) \sum_{u \in V_H} \phi_{AB}(u) ,
\end{aligned}$$

where the last inequality is due to the fact that the degree of any vertex  $u \in V_H$  in the matching  $M_{\text{opt}}(H)$  is at most one. We next find a lower bound for  $w(M_{\text{opt}}(H))$ , which in turns yields a lower bound for  $(1 + \varepsilon) \sum_{u \in V_H} \phi_{AB}(v)$ .

Now, suppose we execute Algorithm MWM-STREAMING on the stream  $B$ . However, during the postprocessing phase, once we pop an edge  $e$  from the stack, we add it to the matching  $M_{\text{alg}}$  if both end-points of  $e$  are free and  $e \in E_H$ . Thus, the reported matching  $M_{\text{alg}}$  of the substream  $B$  is influenced by the edge set  $E_H$ . We denote by  $M_{\text{alg}}(B|E_H)$  the

## 73:12 Maximum-Weight Matching in Sliding Windows and Beyond

reported matching of  $B$  that is influenced by  $E_H$ . Observe that  $M_{\text{alg}}(B|E_H)$  is a matching of the critical subgraph  $H(V_H, E_H)$ . Therefore,  $w(M_{\text{alg}}(B|E_H)) \leq w(M_{\text{opt}}(H))$ . We next find a lower bound for  $w(M_{\text{alg}}(B|E_H))$ .

Consider the graph  $G'(V, B)$ . Let us fix an arbitrary edge  $e \in B$ . Recall that  $P_B(e) = \{e' \in B : e' \in N_{G'}(e) \cup \{e\} \text{ and } t_{e'} \leq t_e\}$ . (Here  $t_{e'}$  and  $t_e$  are the arrival time of edges  $e$  and  $e'$  in the substream  $B$ .) Observe that if  $e \in M_{\text{alg}}(B|E_H)$ , then  $e$  was added to the stack at some point. Using Lemma 4, we then have  $w(e) = \sum_{e' \in P_B(e)} w'_B(e')$ . Therefore,

$$\sum_{e \in M_{\text{alg}}(B|E_H)} w(e) = \sum_{e \in M_{\text{alg}}(B|E_H)} \sum_{e' \in P_B(e)} w'_B(e').$$

Now, let us consider an arbitrary edge  $e' \in E_H$ . For  $e'$  we have three cases. The first case is that  $e'$  is not in the stack, which implies  $w'_B(e') = 0$ . The second case is that  $e' \in M_{\text{alg}}(B|E_H)$ , so  $e'$  contributes to the sum  $\sum_{e \in M_{\text{alg}}(B|E_H)} w(e)$ . The third case is that  $e'$  has a neighbor  $e \in M_{\text{alg}}(B|E_H)$ , so that  $e' \in P_B(e)$ . Considering all the three cases we conclude

$$\sum_{e \in M_{\text{alg}}(B|E_H)} w(e) = \sum_{e \in M_{\text{alg}}(B|E_H)} \sum_{e' \in P_B(e)} w'_B(e') \geq \sum_{e \in E_H} w'_B(e).$$

Putting everything together, we obtain the statement of this lemma as follows:

$$(1 + \varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v) \geq w(M_{\text{opt}}(H)) \geq w(M_{\text{alg}}(B|E_H)) \geq \sum_{e \in E_H} w'_B(e) . \quad \blacktriangleleft$$

We are now finally ready to prove Inequality (1) on page 9, with  $\mathcal{Z} = \frac{1}{2(1+\varepsilon)}w(M_{\text{opt}}(B))$ .

► **Lemma 16.** *Let  $S = ABC$  be a stream of edges of an underlying weighted graph  $G(V, E)$ . Then, there exists the following upper bound for the weight of  $M_{\text{opt}}(ABC)$ :*

$$w(M_{\text{opt}}(ABC)) \leq 2(1 + \varepsilon)w(M_{\text{alg}}(AB)) + 2(1 + \varepsilon)w(M_{\text{alg}}(BC)) - \frac{1}{2(1 + \varepsilon)}w(M_{\text{opt}}(B)) .$$

**Proof.** First of all, observe that we can decompose the edges of the optimal matching  $M_{\text{opt}}(ABC)$  into the subset of edges that are in the substreams  $AB$  and  $C$ . Thus, we have

$$w(M_{\text{opt}}(ABC)) = w(M_{\text{opt}}(ABC) \cap AB) + w(M_{\text{opt}}(ABC) \cap C) .$$

Using Lemma 14 and Lemma 13, we then obtain

$$\begin{aligned} w(M_{\text{opt}}(ABC)) &\leq 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(AB)) - (1 + \varepsilon) \cdot \sum_{v \in V_H} \phi_{AB}(v) \\ &\quad + 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(BC)) - (1 + \varepsilon) \cdot \sum_{e \in B \setminus E_H} w'_B(e) . \end{aligned}$$

Next, we replace the negative term on the sum of the potentials for vertices in  $V_H$  with its lower-bound as in Lemma 15 .

$$\begin{aligned} &w(M_{\text{opt}}(ABC)) \\ &\leq 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(AB)) - \sum_{e \in E_H} w'_B(e) + 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(BC)) - (1 + \varepsilon) \sum_{e \in B \setminus E_H} w'_B(e) \\ &= 2(1 + \varepsilon) \cdot w(M_{\text{alg}}(AB)) + 2(1 + \varepsilon)w(M_{\text{alg}}(BC)) - \sum_{e \in B} w'_B(e) . \end{aligned}$$

Applying Lemma 6 to the subgraph  $G'(V, B)$  gives  $\sum_{e \in B} w'_B(e) \geq \frac{1}{2(1+\varepsilon)} \cdot w(M_{\text{opt}}(G'(V, B)))$ . Hence,

$$w(M_{\text{opt}}(ABC)) \leq 2(1+\varepsilon) \cdot w(M_{\text{alg}}(AB)) + 2(1+\varepsilon) \cdot w(M_{\text{alg}}(BC)) - \frac{1}{2(1+\varepsilon)} \cdot w(M_{\text{opt}}(B)) \quad \blacktriangleleft$$

With the help of Lemma 16 we can now prove Lemma 11.

**Proof of Lemma 11.** First of all using Lemma 16, we have the following upper-bound for the weight of  $M_{\text{opt}}(ABC)$ :

$$w(M_{\text{opt}}(ABC)) \leq 2(1+\varepsilon)w(M_{\text{alg}}(AB)) + 2(1+\varepsilon)w(M_{\text{alg}}(BC)) - \frac{1}{2(1+\varepsilon)}w(M_{\text{opt}}(B)) \quad .$$

Now, we switch from Algorithm MWM-STREAMING to its monotone version, which is Algorithm MWM-MONOTONE. Monotonicity Property 1 of Lemma 8 states that for the substream  $B$  we have  $w(M_{\text{alg}}(B)) \leq w(M_{\text{mon}}(B)) \leq w(M_{\text{opt}}(B))$ . The same bounds also hold for the substream  $AB$  and  $BC$ . Therefore,

$$\begin{aligned} w(M_{\text{opt}}(ABC)) &\leq 2(1+\varepsilon)w(M_{\text{mon}}(AB)) + 2(1+\varepsilon)w(M_{\text{mon}}(BC)) - \frac{1}{2(1+\varepsilon)}w(M_{\text{mon}}(B)) \\ &\leq \frac{2(1+\varepsilon)}{1-\beta} \cdot w(M_{\text{mon}}(B)) + 2(1+\varepsilon)w(M_{\text{mon}}(BC)) - \frac{1}{2(1+\varepsilon)}w(M_{\text{mon}}(B)) \\ &\leq 1.5(1+3\varepsilon) \cdot w(M_{\text{mon}}(B)) + 2(1+\varepsilon)w(M_{\text{mon}}(BC)) \quad , \end{aligned}$$

where for the second inequality we use the assumption of this lemma, which is

$$w(M_{\text{mon}}(B)) \geq (1-\beta) \cdot w(M_{\text{mon}}(AB)) \quad .$$

From Monotonicity Property 2 of Lemma 8, which is  $w(M_{\text{mon}}(B)) \leq w(M_{\text{mon}}(BC))$ , we now for  $\varepsilon \leq \frac{1}{10}$  conclude

$$\begin{aligned} w(M_{\text{opt}}(ABC)) &\leq 1.5(1+3\varepsilon)w(M_{\text{mon}}(B)) + 2(1+\varepsilon)w(M_{\text{mon}}(BC)) \\ &\leq (3.5+\varepsilon)w(M_{\text{mon}}(BC)) \quad . \end{aligned} \quad \blacktriangleleft$$

#### 4 Subadditive functions in the sliding-window model

In this section, we prove Theorem 2 and then we show that using this theorem, we can improve the approximation factor of quite a few submodular matching problems in the sliding-window model. We first explain the notations that we use in this section.

Let  $f$  be a function defined on streams, which is subadditive, non-negative, and monotone. Let  $\sigma := f_{\text{max}}/f_{\text{min}+}$ , where

$$f_{\text{min}+} := \min\{f(X) : X \text{ is a substream of the input and } f(X) > 0\} \quad ,$$

and

$$f_{\text{max}} := \max\{f(X) : X \text{ is a substream of the input}\}$$

Suppose we are given a streaming algorithm  $\mathcal{ALG}$  that  $\alpha$ -approximates  $f$  using space  $s$ . Very recently Krauthgamer and Reitblat [14] showed that we can use the streaming algorithm  $\mathcal{ALG}$  to develop a sliding-window algorithm that  $(2\alpha^2 + \varepsilon)$ -approximates  $f$  using space  $O(\varepsilon^{-1}s \cdot \log \sigma)$ . They also showed that if the streaming algorithm  $\mathcal{ALG}$  is monotone and subadditive, we can reduce the approximation factor of the sliding-window algorithm down to  $(2\alpha + \varepsilon)$ -factor. Unfortunately, in some cases, although  $f$  is subadditive,  $\mathcal{ALG}$  is not

subadditive, or it is not easy to show that  $\mathcal{ALG}$  is also subadditive. So, the  $(2\alpha + \varepsilon)$ -factor cannot always be a result of [14]. Nevertheless, Theorem 2 shows that we can obtain a  $(2\alpha + \varepsilon)$ -approximation algorithm in the sliding-window model, independent of the monotonicity or subadditivity of the streaming algorithm  $\mathcal{ALG}$ . Our main result in this paper is that there exists a lookahead algorithm for the maximum weight matching problem. We state this result formally next.

Next, we prove Theorem 2. To this end, in Lemma 17, we show how to transform a non-monotone algorithm  $\mathcal{ALG}$  into a monotone algorithm  $\mathcal{ALG}_{\text{mon}}$ . Later, in Lemma 18 we show that a monotone algorithm  $\mathcal{ALG}_{\text{mon}}$  that  $\alpha$ -approximates a subadditive monotone function  $f$  is in fact, a  $(f, 2\alpha + \varepsilon(\beta), \beta)$ -lookahead algorithm. Thus, we can use the machinery of Theorem 10 to develop  $(2\alpha + \varepsilon)$ -approximation sliding-window algorithms for  $f$  using the streaming algorithm  $\mathcal{ALG}_{\text{mon}}$ .

► **Lemma 17.** *Let  $f$  be a non-negative and monotone function defined on streams. Let  $\mathcal{ALG}$  be a streaming algorithm that  $\alpha$ -approximates  $f$  using space  $s$ , where  $\alpha \geq 1$ . Then, there is a monotone algorithm  $\mathcal{ALG}_{\text{mon}}$  that  $\alpha$ -approximates  $f$  using  $O(s)$  space.*

**Proof.** Let  $S$  be a stream of items of the domain  $\mathcal{X}$  of the subadditive  $f$ . In order to make the algorithm  $\mathcal{ALG}$  monotone, we store the maximum  $f$  of all prefixes of the stream  $S$ . Formally, we define  $\mathcal{ALG}_{\text{mon}}$  as follow:  $\mathcal{ALG}_{\text{mon}}(S) := \max\{\mathcal{ALG}(T) : T \text{ is a prefix of } S\}$ .

To prove the approximation factor, we show that  $\frac{1}{\alpha} \cdot f(S) \leq \mathcal{ALG}_{\text{mon}}(S) \leq f(S)$ . Observe that  $\mathcal{ALG}$  returns a  $\alpha$ -approximation of  $f(S)$ . Thus,  $\frac{1}{\alpha} \cdot f(S) \leq \mathcal{ALG}(S) \leq \mathcal{ALG}_{\text{mon}}(S)$ .

Now, it is enough to show that  $\mathcal{ALG}_{\text{mon}}(S) \leq f(S)$ . Let  $T^*$  be the prefix of  $S$  for which  $\mathcal{ALG}$  returns the maximum value among all prefixes of  $S$ . That is,  $\mathcal{ALG}_{\text{mon}}(S) = \mathcal{ALG}(T^*)$ . Since  $f$  is monotone  $f(T^*) \leq f(S)$ , we then have

$$\mathcal{ALG}_{\text{mon}}(S) = \mathcal{ALG}(T^*) \leq f(T^*) \leq f(S) . \quad \blacktriangleleft$$

► **Lemma 18.** *Let  $0 < \varepsilon \leq 1/2$ ,  $\alpha \geq 1$  and  $0 < \beta \leq \varepsilon/2\alpha$  be three parameters. Let  $f$  be a subadditive, non-negative, and monotone function defined on streams. Suppose we have a monotone streaming algorithm  $\mathcal{ALG}_{\text{mon}}$  that  $\alpha$ -approximates  $f$ . Then, Algorithm  $\mathcal{ALG}_{\text{mon}}$  is a  $(f, (2\alpha + \varepsilon), \beta)$ -lookahead algorithm. That is, for any partitioning of a stream  $S$  of items of the domain  $\mathcal{X}$  of  $f$  into three disjoint sub-streams  $A$ ,  $B$ , and  $C$  with  $\mathcal{ALG}_{\text{mon}}(B) \geq (1 - \beta) \cdot \mathcal{ALG}_{\text{mon}}(AB)$ , we have*

$$f(ABC) \leq (2\alpha + \varepsilon) \cdot \mathcal{ALG}_{\text{mon}}(BC) .$$

**Proof.** First of all since  $f$  is subadditive, we have  $f(ABC) \leq f(A) + f(BC)$ . Also, the function  $f$  is monotone, which means that  $f(A) \leq f(AB)$ . Therefore,  $f(ABC) \leq f(AB) + f(BC)$ .

Since  $\mathcal{ALG}_{\text{mon}}$  is an  $\alpha$ -approximate algorithm for  $f$ , we then have

$$f(ABC) \leq \alpha \cdot \mathcal{ALG}_{\text{mon}}(AB) + \alpha \cdot \mathcal{ALG}_{\text{mon}}(BC) .$$

We assume that  $\mathcal{ALG}_{\text{mon}}(B) \geq (1 - \beta) \cdot \mathcal{ALG}_{\text{mon}}(AB)$ . Using which, we have

$$f(ABC) \leq \frac{\alpha}{(1 - \beta)} \cdot \mathcal{ALG}_{\text{mon}}(B) + \alpha \cdot \mathcal{ALG}_{\text{mon}}(BC) .$$

Since  $\mathcal{ALG}_{\text{mon}}$  is a monotone algorithm, we have  $\mathcal{ALG}_{\text{mon}}(B) \leq \mathcal{ALG}_{\text{mon}}(BC)$ . Thus,

$$\begin{aligned} f(ABC) &\leq \frac{\alpha}{(1 - \beta)} \cdot \mathcal{ALG}_{\text{mon}}(BC) + \alpha \cdot \mathcal{ALG}_{\text{mon}}(BC) \\ &\leq \alpha(1 + 2\beta) \cdot \mathcal{ALG}_{\text{mon}}(BC) + \alpha \cdot \mathcal{ALG}_{\text{mon}}(BC) \\ &\leq (2\alpha + \varepsilon) \cdot \mathcal{ALG}_{\text{mon}}(BC) , \end{aligned}$$

by setting  $0 < \beta \leq \frac{\varepsilon}{2\alpha}$  and using the Maclaurin series  $\frac{1}{1 - \varepsilon} = 1 + \varepsilon + \varepsilon^2 + \varepsilon^3 + \dots \leq 1 + 2\varepsilon$  for  $\varepsilon \leq 1/2$ . ◀

Having Theorem 2 in hand, we can improve quite a few sliding-window algorithms that have  $(2\alpha^2 + \varepsilon)$ -approximation factor. As an example, if we have  $\alpha$ -approximation streaming algorithms for the maximum submodular matching, maximum submodular  $b$ -matching, and in general, maximum submodular rank  $p$  hypergraph  $b$ -matching, we can then use Theorem 2 to develop sliding-window algorithms for all these problems with the approximation factor of  $(2\alpha + \varepsilon)$  which significantly improves upon the best known approximation factor of  $(2\alpha^2 + \varepsilon)$  of these problems due to Krauthgamer and Reitblat [14].

As an example, we consider next the maximum submodular matching, which is defined as follows. We are given a simple graph  $G(V, E)$ . A non-negative submodular function  $w : 2^E \rightarrow \mathbb{R}^{\geq 0}$  is defined on subsets of edges. The goal is to find a matching  $M_{\text{opt}}$ , whose submodular function  $w(M_{\text{opt}})$  is maximum. We next show that the maximum submodular matching is indeed a subadditive function.

► **Lemma 19.** *Let  $w$  be a non-negative submodular function defined on subsets of edges of a simple graph  $G(V, E)$ . Then, the maximum submodular matching of  $G(V, E)$  is subadditive.*

**Proof.** Let us consider an arbitrary stream  $S$  of edges of the underlying graph  $G(V, E)$ . Suppose we partition  $S$  into two disjoint consecutive substreams  $A$  and  $B$ . Since  $w$  is non-negative, we then have  $w(M_{\text{opt}}(AB)) \leq w(M_{\text{opt}}(AB)) + w(\emptyset)$ .

Next, we use the property of submodular functions that for every two sets  $X, Y$  we have  $w(X \cup Y) + w(X \cap Y) \leq w(X) + w(Y)$ . Let  $X = M_{\text{opt}}(AB) \cap A$  and  $Y = M_{\text{opt}}(AB) \cap B$ . Since  $A$  and  $B$  are disjoint substreams, we then have  $X \cup Y = M_{\text{opt}}(AB)$  and  $w(X \cap Y) = \emptyset$ . Therefore, we have

$$w(M_{\text{opt}}(AB)) \leq w(M_{\text{opt}}(AB) \cap A) + w(M_{\text{opt}}(AB) \cap B) .$$

Finally, since  $M_{\text{opt}}(AB) \cap A$  and  $M_{\text{opt}}(AB) \cap B$  are valid matchings for  $A$  and  $B$ , respectively, then  $w(M_{\text{opt}}(AB) \cap A) \leq w(M_{\text{opt}}(A))$  and  $w(M_{\text{opt}}(AB) \cap B) \leq w(M_{\text{opt}}(B))$ . Thus, we have

$$w(M_{\text{opt}}(AB)) \leq w(M_{\text{opt}}(A)) + w(M_{\text{opt}}(B)) ,$$

as we need. ◀

For the maximum monotone submodular matching problem, Levin and Wajc [15] develop a 5.828-approximation streaming algorithm. If we plug this streaming algorithm into the generic machinery of Theorem 2, we obtain 11.656-approximation sliding-window algorithm for this problem. This significantly improves upon the 67.93-approximation factor that the result of [14] achieves.

On the other hand, for the maximum non-monotone submodular matching problem, there exists a 7.464-approximation streaming algorithm due to Levin and Wajc [15]. We use this streaming algorithm for the the generic machinery of Theorem 2 and obtain 14.9-approximation sliding-window algorithm for this problem improving the 111.4-approximation factor that the result of [14] achieves.

## Abstract

Recent works by Bravyi, Gosset and König (Science 2018), Bene Watts et al. (STOC 2019), Coudron, Stark and Vidick (QIP 2019) and Le Gall (CCC 2019) have shown unconditional separations between the computational powers of shallow (i.e., small-depth) quantum and classical circuits: quantum circuits can solve in constant depth computational problems that require logarithmic depth to solve with classical circuits. Using quantum error correction, Bravyi, Gosset, König and Tomamichel (Nature Physics 2020) further proved that a similar separation still persists even if quantum circuits are subject to local stochastic noise.

In this paper, we consider the case where *any* constant fraction of the qubits (for instance, huge blocks of qubits) may be arbitrarily corrupted at the end of the computation. We make a first step forward towards establishing a quantum advantage even in this extremely challenging setting: we show that there exists a computational problem that can be solved in constant depth by a quantum circuit but such that even solving *any* large subproblem of this problem requires logarithmic depth with bounded fan-in classical circuits. This gives another compelling evidence of the computational power of quantum shallow circuits.

In order to show our result, we consider the Graph State Sampling problem (which was also used in prior works) on expander graphs. We exploit the “robustness” of expander graphs against vertex corruption to show that a subproblem hard for small-depth classical circuits can still be extracted from the output of the corrupted quantum circuit.

## 1 Introduction

**Background.** Quantum computing was introduced in the early 1980s as a quantum mechanical model of the Turing machine that has a potential to simulate things that a classical computer could not [11, 25]. In 1994, Peter Shor developed a polynomial-time quantum algorithm for factoring integers [43], which gave an exponential speedup over the most efficient known classical algorithms for this task.

While initially realizing a physical quantum computer was thought to be extremely challenging, nowadays various types of high-fidelity processors capable of quantum algorithms have been developed [10, 24, 36, 38, 45]. These devices with noise and relatively small scale are called NISQ (Noisy Intermediate-Scale Quantum) devices [41]. For such devices, “quantum supremacy” [40] has been recently reported [6, 46].

While Shor’s algorithm and such quantum supremacy results strongly suggest that quantum computation is more powerful than classical computation, they are not mathematical proofs. While the superiority of quantum computation has been formally shown in constrained models such as query complexity [4] and communication complexity [22, 34] and considering complexity classes relative to an oracle [12, 42], almost no definite answer is known in standard computational models such as Turing machines or general circuits. Since the complexity class BQP (the class of the problems that can be solved efficiently by a quantum computer) satisfies the inclusions  $P \subseteq BPP \subseteq BQP \subseteq PSPACE$ , an unconditional separation between BPP and BQP would imply a separation between P and PSPACE, which would be a significant breakthrough. Therefore, unconditional separations between the computational powers of quantum computers and classical computers in a general setting are expected to be very hard to obtain.

However, with several assumptions from computational complexity such as non-collapse of the polynomial hierarchy or some conjectures on the hardness of the permanent, the superiority of quantum computation has been shown in the circuit model: even approximate or noisy probabilistic distributions of small depth quantum circuits are hard to simulate for classical computers [1, 2, 3, 13, 16, 17, 18, 44]. A recent breakthrough by Bravyi, Gosset and König [14] showed an *unconditional* separation between the computational powers of small-depth quantum and classical circuits: they constructed a computational problem that can be solved by quantum circuits of constant depth composed of one- and two-qubit gates acting locally on a grid and showed that any probabilistic classical circuit with bounded fan-in gates solving this problem on all inputs must have depth  $\Omega(\log n)$ , where  $n$  denotes the input size. The computational problem they use is a relation problem (i.e., for any input there are several possible outputs). Besides its theoretical importance, this separation is also important since shallow quantum circuits are likely to be easy to implement on physical devices experimentally due to their robustness to noise and decoherence.

There are several results related to this separation. Coudron, Stark and Vidick [21] and Le Gall [26] showed a similar separation in the average case setting, instead of the worst case setting considered in the original version of [14]: there exists a relation problem such that constant-depth quantum circuits can solve the relation on all inputs, but any  $O(\log n)$  depth randomized bounded fan-in classical circuits cannot solve it on *most* inputs with high probability. Bene Watts et al. [9] showed that a similar separation holds against classical circuits using unbounded fan-in gates and, considering interactive tasks, Grier and Schaeffer [28] showed even stronger classical lower bounds.

Bravyi et al. [15] additionally proved, using quantum error-correction, that a similar separation holds even if quantum circuits are corrupted by local stochastic noise (see Definition 1 below). The computational problem used in [15] is a generalized version, defined on a 3D grid, of the magic square game [35, 39], which is a nonlocal game with two cooperating players Alice and Bob who cannot communicate. The noise model is as follows.

► **Definition 1** (Definition 9 in [15]). *Consider a random  $n$ -qubit Pauli error  $E \in \{I, X, Y, Z\}^{\otimes n}$  and let  $Supp(E) \subseteq [n]$  denote its support, i.e., the subset of qubits acted on by either  $X, Y$ , or  $Z$ . For any constant  $p \in [0, 1]$ ,  $E$  is called  $p$ -local stochastic noise if*

$$\Pr[F \subseteq Supp(E)] \leq p^{|F|} \quad \text{for all } F \subseteq [n].$$

In this model, an error is given as applying a gate which is  $X, Y$  or  $Z$ . This definition assumes that when picking an arbitrary subset of qubits, the probability of all qubits are corrupted is an exponentially small function of the size of the subset. This property, which implies that a subset of size  $\Omega(\log n)$  contains with probability  $1 - 1/\text{poly}(n)$  at least one qubit that

is not corrupted, is crucial in [15] to use quantum error correction. Note that, considering interactive tasks, Grier, Ju and Schaeffer [27] showed even stronger classical lower bounds in the same noise setting.

**The Graph State Sampling problem.** Before presenting our results, let us describe in more details the computational problem introduced in [14], which is called the 2D Hidden Linear Function problem and corresponds to an extension of the Bernstein-Vazirani problem [12].

We actually describe a slightly more general computational problem that we name the “Graph State Sampling problem” and denote  $\rho(G)$ . Here  $G = (V, E)$  is a graph specifying the problem. For any graph  $G$ , the problem  $\rho(G)$  is a relation  $\rho(G) \subseteq \{0, 1\}^{|V|+|E|} \times \{0, 1\}^{|V|}$ . Given an input  $x \in \{0, 1\}^{|V|+|E|}$  for this relation problem, which we interpret as a pair  $x = (y, H)$  with  $y \in \{0, 1\}^{|V|}$  and  $H$  being a subgraph of  $G$ , we ask to output any bit string  $z \in \{0, 1\}^{|V|}$  that may appear with nonzero probability when measuring the graph state corresponding to the subgraph  $H$  in a basis determined by the bit string  $y$ . We refer to Section 5.1 for details of the definition of the problem.

The 2D Hidden Linear Function problem considered in [14] is essentially the problem  $\rho(G)$  where  $G$  is the family of 2D grid graphs. Since the graph states of subgraphs of a 2D grid can be constructed by constant-depth quantum circuits whose gates act locally on the grid graphs, the problem  $\rho(G)$  can be solved by a constant-depth quantum circuit. At the same time, Bravyi et al. [14] prove that no small-depth classical circuits can solve this problem using an argument based on the existence of quantum nonlocality in a triangle (first shown by Barrett et al. [7]). The main result in [14] can essentially be restated as follows.<sup>1</sup>

► **Theorem 2** ([14]). *There exist a constant  $\alpha > 0$  such that the following holds for all sufficiently large 2D grid graphs  $G$ :*

- (i)  $\rho(G)$  can be solved on all inputs with certainty by a constant-depth quantum circuit on  $\Theta(|G|)$  qubits composed of one- and two-qubit gates;
- (ii) no bounded-fanin classical probabilistic circuit whose depth is less than  $\alpha \log(|G|)$  can solve with high probability  $\rho(G)$  on all inputs.

**Description of our results.** In this paper we show the following result.

► **Theorem 3.** *There exist constants  $\alpha > 0$  and  $\epsilon > 0$ , and a family of graphs  $(G_i)_{i \in \mathbb{N}}$  with  $\lim_{i \rightarrow \infty} |G_i| = \infty$  such that the following holds for all sufficiently large  $i$ :*

- (i)  $\rho(G_i)$  can be solved on all inputs with certainty by a constant-depth quantum circuit on  $\Theta(|G_i|)$  qubits composed of one- and two-qubit gates;
- (ii) for any induced subgraph  $S_i$  of  $G_i$  such that  $|S_i| \geq (1 - \epsilon)|G_i|$ , no bounded-fanin classical probabilistic circuit whose depth is less than  $\alpha \log(|S_i|)$  can solve with high probability  $\rho(S_i)$  on all inputs.

Item (ii) of Theorem 3, which is proved by considering the Graph State Sampling problem over expander graphs, gives a significantly stronger hardness guarantee than in Theorem 2 and thus provides us further compelling evidence of the computational power of quantum shallow circuits.

We stress that Theorem 3 does not claim a quantum advantage for noisy shallow quantum circuits: Theorem 3 simply shows that there exists a problem that can be computed by shallow quantum circuit but such that a shallow classical circuit cannot solve *any* (large)

<sup>1</sup> In this paper, for any graph  $G$  we use the notation  $|G|$  to denote the size of the vertex set of  $G$ .

subproblem of it. We can nevertheless interpret Item (ii) as follows. A quantum circuit  $\mathcal{C}$  solving the relation  $\rho(G_i)$  has  $|G_i|$  output qubits, which are measured at the end of the computation to give the output string  $z \in \{0, 1\}^{|G_i|}$  that is a solution for the relation. Assume that an adversary chooses up to  $\epsilon|G_i|$  qubits among these  $|G_i|$  qubits and corrupts them in an arbitrary way (or, essentially equivalently, corrupts the bits of the measurement outcomes corresponding to these positions). Let  $S_i$  denote the set of qubits that are not corrupted by the adversary. Since  $\rho(S_i)$  corresponds to a subproblem<sup>2</sup> of  $\rho(G_i)$ , and since  $\mathcal{C}$  before the corruption solved the problem  $\rho(G_i)$  on all inputs, even after the corruption the part of the output of  $\mathcal{C}$  corresponding to the qubits in  $S_i$  gives a correct solution to the problem  $\rho(S_i)$ . On the other hand, Item (ii) of Theorem 3 shows that no small-depth classical circuit can solve  $\rho(S_i)$ . (Note that in Item (ii) we even allow the classical circuit to depend on  $S_i$ .)

Let us compare this model of corruption of qubits with the model of noise considered in [15]. As already mentioned, in the error model of [15] (Definition 1 above), the probability that all qubits in a given set of size  $\Theta(\log n)$ , where  $n$  denotes the total number of qubits, are corrupted by the noise is polynomially small and thus can be neglected. In comparison, Theorem 3 deals with the case where any subset of qubits of size as large as  $\Theta(n)$  can be corrupted, and shows that the quantum advantage is still preserved in this case. In this sense, our result gives a further compelling evidence of the computational power of quantum shallow circuits.

**Brief overview of our techniques and organization of the paper.** The family of graph  $(G_i)_{i \in \mathbb{N}}$  used to prove Theorem 3 is a class of expander graphs of constant degree.<sup>3</sup> Item (i) of Theorem 3 essentially follows from the fact the graph state of a bounded-degree graph can be created by a constant-depth quantum circuit composed of one- and two-qubit gates. The proof of Item (ii) of Theorem 3 exploits the “robustness” of expander graphs against corruption of vertices. More precisely, we show that even after corrupting a constant fraction of vertices, an expander graph still has a large grid minor (see Lemma 8 in Section 3). Finally, exploiting the existence of a large grid minor, we can use arguments based on quantum nonlocality (very similarly to the arguments used in prior works [14, 26]) to conclude that any classical circuit solving the Graph State Sampling problem on the expander graph requires logarithmic depth.

After giving preliminaries in Section 2, in Section 3 we present graph-theoretical results about expander graphs. In particular, we prove Lemma 8 about the existence of large grid minors in corrupted expander graphs. In Section 4, we review the result about the nonlocality of a triangle quantum graph state used in prior works. In Section 5, we define our computational problem and prove Theorem 3.

## 2 Preliminaries

**Graph theory.** All graphs considered in this paper are undirected. We write a graph as  $G = (V, E)$  where  $V$  is the vertex set and  $E$  is the edge set.  $|G|$  means the number of vertex of graph  $G$ , i.e.,  $|V|$ . The degree of a vertex is the number of edges that are incident to the vertex. We denote  $\deg(v)$  the degree of a vertex  $v$ . Given a graph  $G = (V, E)$  and any vertex set  $U \subseteq V$ , we denote  $N_G(U) = \{v \in V \setminus U : v \text{ has a neighbor in } U\}$  the external neighborhood of  $U$  in  $G$ .

<sup>2</sup> This property can immediately be derived from the formal definition of the computational problem given in Section 5.1

<sup>3</sup> For technical reasons, we actually consider a family of graphs of the form  $G \times K_2$ , where  $G$  is an expander graph of constant degree and  $K_2$  is the graph consisting of a single edge.

Let us describe the definition of graph minors. Graph  $\Gamma$  is a graph minor of graph  $G$  if it is isomorphic to a graph obtained from  $G$  by deleting edges and vertices and by contracting edges. Note that if a graph  $\Gamma$  is a minor of a subgraph  $S$  of a graph  $G$ ,  $\Gamma$  is also a minor of  $G$ . The definition is equivalent to the following definition, that if graph  $\Gamma$  is a minor of graph  $G$ , we can decompose  $G$  to connected subgraphs which connect to each other like  $\Gamma$ . We will use this definition later for explicit explanations.

► **Definition 4** (Minor, Definition 1 in [33]). *A graph  $\Gamma$  is a minor of a graph  $G$  if for every vertex  $u \in \Gamma$  there is a connected subgraph  $G_u$  of  $G$  such that all subgraphs  $G_u$  are vertex disjoint, and  $G$  contains an edge between  $G_u$  and  $G_{u'}$  whenever  $\{u, u'\}$  is an edge of  $\Gamma$ .*

Next, we will define the product of graphs  $G \times H$  of graphs  $G = (V_G, E_G)$  and  $H = (V_H, E_H)$ . The vertex set of  $G \times H$  is the Cartesian product  $V_G \times V_H$  and an edge is spanned between  $(u_G, u_H)$  and  $(v_G, v_H)$  if and only if  $u_G = v_G$  and  $\{u_H, v_H\} \in E_H$ , or  $u_H = v_H$  and  $\{u_G, v_G\} \in E_G$ . There are several ways to define graph products but we will use the definition above. In this paper, we particularly use  $G \times K_2$ , which  $K_2$  is the complete graph of two vertices. Given a graph  $G = (V, E)$ , the graph product  $G \times K_2$  is with  $2|V|$  vertices and  $2|E| + |V|$  edges.

Lastly, we refer to the Vizing's theorem, which is about edge coloring. Edge coloring is to assign colors to edges so that the edges of the same color are not incident.

► **Lemma 5** (Vizing's theorem [23]). *Every simple undirected graph can be edge colored using a number of colors that is the maximum degree or the maximum degree+1.*

**Quantum circuits.** The textbook [37] is a good reference about notations of quantum computation in our paper. We will use the Pauli  $X$ ,  $Y$  and  $Z$  gates, the Hadamard gate and the  $S$  and  $T$  gates as single qubit gates:

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, S = \begin{pmatrix} 1 & 0 \\ 0 & -i \end{pmatrix}, T = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\pi/4} \end{pmatrix},$$

where  $i$  denotes the imaginary unit of complex numbers. (Note the Phase gate  $S$  differs from the standard one in [37].) We also use the controlled Pauli  $Z$  gate (or  $CZ = |0\rangle\langle 0| \otimes I + |1\rangle\langle 1| \otimes Z$ ) as two-qubit gate.

Let us explain about quantum circuits. An  $n$ -qubit quantum circuit is initialized to  $|0^n\rangle$  and then arbitrary gates are applied to the state. We can apply gates at one time if each gate is applied to disjoint sets of qubits. The depth of a quantum circuit is  $d$  if the whole operation of circuits can be decomposed to  $U_d \dots U_2 U_1$  where each  $U_j$  is a tensor product of one- and two-qubit gates which act on disjoint sets of qubits.

Next, we describe measurements of quantum states. Mathematically, (projective) measurements are projections to some orthogonal bases. In this paper, We will use two kinds of measurements with the  $X$  basis and the  $Y$  basis. The orthogonal two states of  $X$  basis are  $\{|+\rangle, |-\rangle\}$  and the ones of  $Y$  basis are  $\left\{\frac{|0\rangle+i|1\rangle}{\sqrt{2}}, \frac{|0\rangle-i|1\rangle}{\sqrt{2}}\right\}$ . Note that the measurements of  $X$  and  $Y$  basis are equivalent to the measurements of the computational basis if we apply  $H$  and  $HS$  gates before the measurements respectively.

**Quantum graph states.** Quantum graph states are a certain type of entangled states corresponding to graphs first introduced by [30]. Let  $G = (V, E)$  be a finite simple graph. Define an associated  $|V|$  qubit graph state  $|\Phi_G\rangle$  by

$$|\Phi_G\rangle = \left( \prod_{e \in E} CZ_e \right) H^{\otimes |V|} |0^{|V|}\rangle. \quad (1)$$

The graph state  $|\Phi_G\rangle$  is a stabilizer state with stabilizer group generated by the operators  $g_v = X_v \left( \prod_{w: \{w,v\} \in E} Z_w \right)$  for all  $v \in V$ .

**Classical circuits.** A classical circuit is specified by a directed acyclic graphs. Vertices with no incoming and outgoing edges are inputs and outputs respectively and all other vertices are called gates. We must specify a function of each gate  $\{0, 1\}^k \rightarrow \{0, 1\}$  where  $k$  is the fan-in. We assume a classical probabilistic circuit receives an arbitrary binary  $x$  as an input and outputs a binary  $z$  and it also could input a random string  $r$  drawn from some arbitrary distribution. We say an input bit and an output bit are correlated iff the value of the output bit depends on the value of the input bit. For each input bit  $x_i$ , we denote the lightcone  $L_C(x_i)$  the set of output bits correlated with  $x_i$  through a classical circuit  $C$ . Likewise, the lightcone  $L_C(z_i)$  is the set of input bits correlated with an output bit  $z_i$ . In this paper, we are interested in small-depth classical circuits with bounded fan-in. We also say that a classical probabilistic circuit solves the relation  $R$  on all inputs if and only if the circuit takes any  $x \in \{0, 1\}^n$  and a random string  $r$  as input and outputs  $z \in \{0, 1\}^m$  such that  $xRz$  with high probability.

### 3 Expander graphs and their properties

Expander graphs are highly sparse but well connected graphs. Notable applications of the graphs have been found in mathematics and computer science [8, 19, 29]. Before giving the definition, we define the expansion ratio  $h(G)$  of graph  $G$ . There are several ways to define the expansion ratio, for example edge expansion, vertex expansion and spectral expansion, but these are related to each other. The way we use is called vertex expansion.

► **Definition 6** (Expansion ratio).  $h(G) = \min \left\{ \frac{|N_G(U)|}{|U|} \mid U \subset V \text{ such that } 1 \leq |U| \leq \frac{1}{2}|V| \right\}$

The definition of expander graphs we use in this paper is as follows.

► **Definition 7** (Expander graphs, Definition 3.1.8 in [31]). *A family  $(\Gamma_i)_{i \in \mathbb{N}}$  of finite non-empty connected graphs  $\Gamma_i = (V_i, E_i)$  is an expander family, if there exist constants  $d \geq 1$  and  $h > 0$ , independent of  $i$ , such that:*

- (1) *The number of vertices  $|V_i|$  “tends to infinity”, in the sense that for any  $N \geq 1$ , there are only finitely many  $i \in \mathbb{N}$  such that  $\Gamma_i$  has at most  $N$  vertices.*
- (2) *For each  $i \in \mathbb{N}$ , we have  $\max_{v \in V_i} \deg(v) \leq d$ , i.e., the maximum degree of the graphs is bounded independently of  $i$ .*
- (3) *For each  $i \in \mathbb{N}$ , the expansion constant satisfies  $h(\Gamma_i) \geq h > 0$ , i.e., it is bounded away from 0 by a constant independent of  $i$ .*

$h$  and  $d$  specify the family of expander graphs. The existence of expander graphs is by no means obvious, but it can be shown using probabilistic approaches or concrete constructions of such graphs [31]. In this paper, an expander graph denotes a graph with sufficiently large  $i$  of an expander family.

We want to prove the robustness of expander graphs to arbitrary vertex removals in terms of the size of grid minor, which is Lemma 8. We provide its proof in Appendix A.

► **Lemma 8.** *Let  $G = (V, E)$  be a expander graph. If we take a sufficiently small constant  $\epsilon > 0$ , the graph has a connected component  $C$  which contains a  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}})$  grid as a minor after up to an  $\epsilon$  fraction of  $V$  are adversarially removed.*

#### 4 Quantum nonlocality of a triangle graph state

In specific circumstances, local classical circuits cannot simulate measurement outcomes of entangled quantum states. This is called *quantum nonlocality*. In this section, we explain it occurs in a triangle graph state, as first shown in [7]. We will use this property to show the hardness of classical circuits to solve the relation problem in Section 5.

■ **Figure 1** We consider an even cycle  $\Gamma$  and three vertices  $u, v, w$  such that all pairwise distances are even.  $L, R, B$  are the region between the three vertices. Each qubit of the corresponding graph state is measured by the  $X$  or  $Y$  basis.

First, we note about properties of a graph state in a triangle shape. Let  $\Gamma$  be a triangle such that the distance between three vertices  $u, v, w$  are all even and  $|\psi_\Gamma\rangle$  be a graph state for  $\Gamma$  as in Equation (1). We define  $L, R, B$  as the vertices between  $u$  and  $v$ ,  $v$  and  $w$ ,  $u$  and  $w$ , and  $M$  as a total number of vertices in  $\Gamma$ . Also define  $L_{odd}, L_{even}, R_{odd}, R_{even}, B_{odd}, B_{even}$  as vertices of  $L, R, B$  which have odd and even distance from  $u, v, w$  respectively. The three bits  $x = x_u x_v x_w$  decide the measurement basis of  $u, v, w$  (the  $X$  basis if  $x_i = 0$  and the  $Y$  basis if  $x_i = 1$ ) and the other vertices are measured in the  $X$  basis. We denote  $\tau(x)$  possible measurement outcomes of all qubits of  $|\psi_\Gamma\rangle$  for input  $x$ , i.e.,  $\tau(x) = \{z \in \{0, 1\}^M : \langle z | H^{\otimes M} S_u^{x_u} S_v^{x_v} S_w^{x_w} | \psi_\Gamma \rangle \neq 0\}$ . We consider a relationship between input  $x$  and output  $z \in \tau(x)$ . Define the following summations:

$$z_L = \bigoplus_{i \in L_{odd}} z_i \quad z_R = \bigoplus_{i \in R_{odd}} z_i \quad z_B = \bigoplus_{i \in B_{odd}} z_i \quad z_E = \bigoplus_{i \in \{u, v, w\} \cup R_{even} \cup L_{even} \cup B_{even}} z_i.$$

▷ **Claim 9** (Claim 3 in [14]). Let  $x = x_u x_v x_w \in \{0, 1\}^3$  and suppose  $z \in \tau(x)$ . Then  $z_R \oplus z_B \oplus z_L = 0$ . Moreover, if  $x_u \oplus x_v \oplus x_w = 0$  then

$$\begin{aligned} (x_u x_v x_w = 000) \quad z_E = 0, & \quad (x_u x_v x_w = 110) \quad z_E \oplus z_L = 1, \\ (x_u x_v x_w = 101) \quad z_E \oplus z_B = 1, & \quad (x_u x_v x_w = 011) \quad z_E \oplus z_R = 1. \end{aligned}$$

The following lemma is about quantum nonlocality in graph states of triangles and similar to Lemma 3 in Section 4.1 of [14]. It shows that when we assume a classical circuit has a kind of locality, the classical circuit cannot satisfy the relation of Claim 9 as inputs and outputs.

► **Lemma 10** ([7, 14, 26]). Consider a classical circuit which takes as an input a bit string  $x = x_u x_v x_w \in \{0, 1\}^3$  and a random string  $r$ , and outputs  $z \in \{0, 1\}^M$  which are corresponding to vertices of  $\Gamma$ . Let us assume output bits in  $L$  depend on  $r$  and at most one geometrically near input bit, which is either  $x_u$  or  $x_v$ . Similarly, we assume output bits in  $R$  and  $B$  depend on  $r$  and at most one geometrically near input bit. Then, the classical circuit  $C$  cannot output  $z \in \tau(x)$  with high probability.

## 5 Proof of separation of depth between quantum and classical circuits to solve Graph State Sampling problem

In this section, we define Graph State Sampling problem and prove a separation of depth between quantum circuits and classical circuits. We consider an almost all induced subgraph  $S$  of a graph  $G \times K_2$  such that  $G$  is an expander graph. Then, we prove  $\rho(G \times K_2)$  can be solved on all inputs by a constant-depth quantum circuit on  $\Theta(|G \times K_2|)$  qubits, but  $\Omega(\log |S|)$  depth is required for any classical probabilistic circuits to solve  $\rho(S)$  on all inputs.

### 5.1 Definition of Graph State Sampling problem $\rho(G)$

In this subsection, for any graph  $G$ , we define Graph State Sampling problem  $\rho(G)$ .

The relation is defined as a subset of  $\{0, 1\}^{|V|+|E|} \times \{0, 1\}^{|V|}$  and thus consists of pairs  $(x, z)$ , where  $x \in \{0, 1\}^{|V|+|E|}$  represents the input and  $z \in \{0, 1\}^{|V|}$  represents the output. Each bit of  $x$  corresponds to a vertex or an edge. The string  $x$  decides the quantum graph state and the measurement bases: a  $CZ$  gate corresponding to edge  $e$  is applied if  $x_e = 1$ , and the qubit corresponding to a vertex  $v$  is measured in the  $X$  basis if  $x_v = 0$ , or in the  $Y$  basis if  $x_v = 1$ . The quantum state  $|\psi_x\rangle$  for each  $x$  before the measurement in the computational basis is thus:

$$|\psi_x\rangle = H^{\otimes |V|} \prod_{x_v=1} S_v \left( \prod_{x_e=1} CZ_e \right) H^{\otimes |V|} |0^{|V|}\rangle.$$

The output  $z \in \{0, 1\}^{|V|}$  of the relation is any possible outcome of the measurement of this quantum state (note that there are possibly several measurement outcomes  $z$  for each  $x$ ). Since the probability of measurement results of each binary string  $z$  is  $|\langle z | \psi_x \rangle|^2$ , the definition of  $\rho(G)$  is as follows.

► **Definition 11.** *Given a graph  $G$ ,*

$$\rho(G) = \{(x, z) | x \in \{0, 1\}^{|V|+|E|} \text{ and } z \in \{0, 1\}^{|V|} \text{ such that } |\langle z | \psi_x \rangle|^2 > 0\}.$$

### 5.2 Constant-depth quantum circuits to solve Graph State Sampling problem

The following is easily shown by Lemma 5.

► **Lemma 12.** *When the maximum degree of graph  $G = (V, E)$  is bounded by a constant,  $\rho(G)$  on all inputs can be solved with certainty by a constant-depth quantum circuit on  $\Theta(|G|)$  qubits composed of one- and two-qubit gates.*

**Proof.** The initial state  $|x\rangle \otimes |0^{|V|}\rangle$  is prepared on  $|E| + 2|V| = \Theta(|G|)$  qubits. We apply  $H^{\otimes |V|}$  to the last  $|V|$  qubits and then controlled- $CZ$  ( $CCZ$ ) gates and controlled- $S$  ( $CS$ ) gates that apply  $CZ_e$  if  $x_e = 1$  and  $S_v$  if  $x_v = 1$ . Since  $G$  is edge colorable with a constant number from Lemma 5 and  $CCZ$  gates corresponding to edges assigned the same color can be applied simultaneously (since they act on disjoint sets of qubits), the total depth of  $CCZ$  gates can be bounded by a constant.  $CS$  gates can also be applied in constant depth. We finally apply  $H^{\otimes |V|}$  to the last  $|V|$  qubits and measure these qubits in the computational basis, which gives a string  $z$  such that  $(x, z) \in \rho(G)$ .

The total depth of this circuit can be bounded by a constant. (Note that each  $CCZ$  and  $CS$  gate can be implemented in constant depth using our elementary gates [5].) We refer to Figure 2 for an illustration. ◀

■ **Figure 2** Constant-depth quantum circuit to solve  $\rho(G)$ .

### 5.3 Hardness to solve Graph State Sampling problem with shallow classical circuits

In this subsection, we prove Theorem 3, and especially the classical hardness. The impossibility argument in Section 4 assumed classical circuits had a kind of geometrical locality. The lower bounds in this section, however, do not require any geometrical locality of shallow classical circuits. The proofs are similar to the proofs of the results of Section 4.2 in [14], with the notable exception of Claim 16 and the discussion afterwards (in particular, the definition of boxes), which are specifically tailored for the expander graphs we consider.

#### 5.3.1 Good and bad vertices

To begin with, we define “good” and “bad” vertices. In a shallow classical circuit, most input bits are not correlated with many output bits. We call a vertex “bad” if the corresponding input bit are correlated with many output bits. Here is the formal definition.

► **Definition 13.** *Given a graph  $G = (V, E)$ , we consider  $\rho(G)$  and a classical probabilistic circuit  $C$  for it. Then, a vertex  $v \in V$  is good if  $L_C(x_v) = O(|V|^{\frac{1}{16}})$  and bad if  $v$  is not good.*

The following claim is similar to Claim 5 in [14].

▷ **Claim 14.** Let  $G = (V, E)$  be a graph such that the maximum degree is bounded by a constant and  $C$  be a classical probabilistic circuit for  $\rho(G)$ . Suppose the fan-in is bounded by a constant  $K$  and the depth  $d$  is less than  $\frac{\log |V|}{32 \log K}$ , the number of bad vertices is  $o(|V|)$ .

*Proof.* Since the number of correlated input bits increases by at most  $K$  times when the depth increases by 1,

$$|L_C(z_i)| \leq K^d < |V|^{\frac{1}{32}} \quad \text{for all } v \in V. \tag{2}$$

Let us consider a bipartite graph whose vertices are respective bits of  $x$  and  $z$ , and an edge is spanned if and only if  $x_i$  and  $z_j$  are correlated. Since the maximum degree of  $G$  is bounded by a constant, we have  $|x| = |V| + |E| = \Theta(|V|)$ . From Equation (2) and considering edges spanned from  $z$ , the total number of edges is limited by  $|V| \cdot |V|^{\frac{1}{32}}$ . Since bad vertices are correlated with  $\Omega(|V|^{\frac{1}{16}})$  output bits, the total number of  $x_v$  such that  $v$  is bad is  $O(|V|^{\frac{31}{32}})$  and this means the number of bad vertices is  $o(|V|)$ . ◁

#### 5.3.2 Proof of Theorem 3

Before the proof, we rewrite Theorem 3 using the notations we defined. The reason we consider the graph product  $G \times K_2$  is to take a cycle which has even length for using Lemma 10.

► **Theorem 15.** *There exist constants  $\alpha > 0$  and  $\epsilon > 0$  such that the following holds for all sufficiently large expander graphs  $G$ :*

- (i)  $\rho(G \times K_2)$  can be solved on all inputs with certainty by a constant-depth quantum circuit on  $\Theta(|G \times K_2|)$  qubits composed of one- and two-qubit gates;
- (ii) for any induced subgraph  $S$  such that  $|S| \geq (1 - \epsilon)|G \times K_2|$ , no bounded-fanin classical probabilistic circuits whose depth is less than  $\alpha \log(|S|)$  can solve  $\rho(S)$  on all inputs.

**Proof of Theorem 15.** We can take  $|G| = |V|$  arbitrary large from the property of expander graphs. Then  $|G \times K_2| = 2|G|$  and  $|S| \geq (1 - \epsilon)|G \times K_2|$  are also sufficiently large. Let us introduce some convenient notations. Given a vertex  $u \in G$ , we denote  $u'$  and  $u''$  the two corresponding vertices in  $G \times K_2$  (with no special order). Given a vertex  $v \in G \times K_2$ , we denote  $\bar{v}$  the other vertex in  $G \times K_2$  associated to the same vertex in  $G$ .

First, we prove Theorem 15 (i). We consider the Graph State Sampling problem  $\rho(G \times K_2)$ . Since the maximum degree of  $G$  is bounded by a constant  $d$ , the maximum degree of  $G \times K_2$  is bounded by  $d + 1$ . From Lemma 12,  $\rho(G \times K_2)$  can be solved with a constant-depth quantum circuit.

Next, we will prove Theorem 15 (ii), the hardness to solve  $\rho(S)$  on all inputs with shallow classical circuits. Let  $C$  be a classical probabilistic circuit to solve  $\rho(S)$  on all inputs and  $K$  be the bounded fan-in of  $C$ . In order to reach a contradiction, we assume the depth of  $C$  is less than  $\frac{\log |S|}{32 \log K}$ . Then the number of bad vertices is small, which enables us to prove the following claim.

▷ **Claim 16.**  $S$  contains an induced subgraph  $G' \times K_2$  such that all vertices are good and  $G'$  contains a  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}})$  grid as a minor.

*Proof.* From Claim 14, we know that  $S$  contains  $o(|S|)$  bad vertices. Let us remove all these bad vertices, and write  $S_{good}$  the remaining set. We further remove all vertices  $u \in S_{good}$  such that  $\bar{u} \notin S_{good}$ . The remaining set of vertices induces a graph  $H \times K_2$ , for an induced subgraph  $H$  of  $G$  such that  $|H| \geq (1 - 2\epsilon - o(1))|G|$ . From Lemma 8, when  $\epsilon$  is taken small enough, the graph  $H \times K_2$  has a connected component  $G' \times K_2$ , where  $G'$  contains a  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}})$  grid as a minor. ◁

Remember the definition of a graph minor (Definition 2 in Section 2.1). Each connected subgraph  $G_u$  in  $G'$  forming the grid (except connected subgraphs on the corners of the grid) is adjacent to the four connected subgraphs  $G_{v_1}, G_{v_2}, G_{v_3}, G_{v_4}$  where  $\{u, v_1\}, \{u, v_2\}, \{u, v_3\}$  and  $\{u, v_4\}$  are edges of the grid. For each  $G_u$ , we arbitrarily select two of these four components. Assume for instance that we selected  $G_{v_1}$  and  $G_{v_2}$ . We choose arbitrarily one vertex  $v$  in  $G_u$  adjacent to a vertex of  $G_{v_1}$ , and one vertex  $w$  in  $G_u$  adjacent to a vertex of  $G_{v_2}$ . We then arbitrarily choose one path inside  $G_u$  that connects  $v$  and  $w$  (such a path necessarily exists). We refer to Figure 3 for an illustration.

We denote  $T$  the length of one side of the grid ( $T = \Omega(|V|^{\frac{1}{4}})$ ). From each connected subgraph forming the  $T \times T$  grid of  $G'$ , we choose one vertex such that it is on a path selected in the way above (this condition of the vertices is required when adding missing segments inside boxes for Claim 18). For such a vertex  $j$ , we define  $\text{Box}(j) \subseteq G' \times K_2$  as a 2D grid of connected subgraphs of size  $\lfloor |V|^{\frac{1}{8}} \rfloor \times \lfloor |V|^{\frac{1}{8}} \rfloor$  centered at the connected subgraph which  $j'$  and  $j''$  belong to. We choose grid-shaped regions  $P, Q, R \subseteq G' \times K_2$  as shown in Figure 4.  $P$  is a upper-left region of the graph product of  $K_2$  and a  $\lfloor T/3 \rfloor \times \lfloor T/3 \rfloor$  grid of connected subgraphs cut from  $G' \times K_2$ .  $Q$  is a upper-right region and  $R$  is a bottom-left region. The following claim is similar to Claim 6 in [14].

■ **Figure 3** The path in  $G_u$  described with blue line connects  $G_{v_1}$  and  $G_{v_2}$ .

■ **Figure 4** Definition of the regions  $P, Q, R$  of  $G' \times K_2$ .

■ **Figure 5** Definition of  $\text{Box}(j)$  and a possible choice of  $p, q, r$ .

## 74:12 Quantum Advantage with Shallow Circuits Under Arbitrary Corruption

▷ **Claim 17.** For all large enough  $|V|$ , we can choose a triple of vertices  $p, q, r \in V$  such that  $p', p'' \in P, q', q'' \in Q, r', r'' \in R$  and

$$\text{Box}(p) \subseteq P, \text{Box}(q) \subseteq Q, \text{Box}(r) \subseteq R, \quad (3)$$

$$L_C(x_{p'} \cup x_{p''}) \cap \text{Box}(q) = \emptyset, L_C(x_{p'} \cup x_{p''}) \cap \text{Box}(r) = \emptyset, \quad (4)$$

$$L_C(x_{q'} \cup x_{q''}) \cap \text{Box}(p) = \emptyset, L_C(x_{q'} \cup x_{q''}) \cap \text{Box}(r) = \emptyset, \quad (5)$$

$$L_C(x_{r'} \cup x_{r''}) \cap \text{Box}(p) = \emptyset, L_C(x_{r'} \cup x_{r''}) \cap \text{Box}(q) = \emptyset. \quad (6)$$

*Proof.* One connected subgraph in the grid minor can belong to at most  $|V|^{\frac{1}{8}} \times |V|^{\frac{1}{8}} = |V|^{\frac{1}{4}}$  boxes. Since the vertices in  $G' \times K_2$  are good, a given lightcone  $L_C(x_{u'} \cup x_{u''})$  can intersect with at most  $|V|^{\frac{1}{4}} \times |L_C(x_{u'} \cup x_{u''})| = |V|^{\frac{1}{4}} \times O(|S|^{\frac{1}{16}}) = O(|V|^{\frac{5}{16}})$  boxes. The number of possibilities to choose a box in  $Q$  is  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}}) = \Omega(|V|^{\frac{1}{2}})$ . Thus if we pick boxes uniformly at random then

$$\Pr[L_C(x_{p'} \cup x_{p''}) \cap \text{Box}(q) = \emptyset] \leq O\left(\frac{|V|^{\frac{5}{16}}}{|V|^{\frac{1}{2}}}\right) < \frac{1}{6} \quad (7)$$

for large enough  $|V|$ . A similar bound applies to the five others that appear in the three equations (4, 5, 6). By the union bound, there exists at least one choice of  $p, q, r$  that satisfies all the four equations (3, 4, 5, 6). ◁

Below we consider a cycle  $\Gamma$  that is a subgraph of  $G' \times K_2$ . The following claim is similar to Claim 7 in [14].

▷ **Claim 18.** The following holds for all sufficiently large  $|V|$ . Fix some triple of vertices  $p, q, r$  satisfying the four equations (3, 4, 5, 6). Then there exists an even length cycle  $\Gamma$  containing  $p', p'', q', q'', r', r''$  such that the lightcones  $L_C(x_{p'} \cup x_{p''}), L_C(x_{q'} \cup x_{q''}), L_C(x_{r'} \cup x_{r''})$  contain no vertices of  $\Gamma$  lying outside of  $\text{Box}(p) \cup \text{Box}(q) \cup \text{Box}(r)$ .

*Proof.* Since the size of connected subgraphs of each box is  $\lfloor |V|^{\frac{1}{8}} \rfloor \times \lfloor |V|^{\frac{1}{8}} \rfloor$ , we can choose  $\lfloor |V|^{\frac{1}{8}} \rfloor$  pairwise vertex disjoint paths  $\gamma$  that connect any pair of boxes  $\text{Box}(p), \text{Box}(q), \text{Box}(r)$  (in each connected subgraph, we can always find a path which connects adjacent connected subgraphs). We refer to Figure 5 for an illustration. Let  $\gamma(a, b)$  be a path connecting  $\text{Box}(a)$  and  $\text{Box}(b)$ , where  $a \neq b \in \{p, q, r\}$ . Any triple of paths  $\gamma(p, q), \gamma(q, r), \gamma(p, r)$  can be completed to a cycle  $\Gamma$  by adding the missing segments of the cycle inside the boxes  $\text{Box}(p), \text{Box}(q), \text{Box}(r)$  because  $p, q, r$  are defined to take such a path inside each box. Since all vertices are good in  $G' \times K_2$  and each connected subgraph belongs to at most one path  $\gamma$ , we infer that  $L_C(x_{p'} \cup x_{p''})$  intersects with at most  $2 \cdot O(|S|^{\frac{1}{16}}) = O(|V|^{\frac{1}{16}})$  paths  $\gamma$ . Thus if we pick the path  $\gamma(p, q)$  uniformly at random among all  $\lfloor |V|^{\frac{1}{8}} \rfloor$  possible choices then

$$\Pr[L_C(x_{p'} \cup x_{p''}) \cap \gamma(p, q) \neq \emptyset] \leq O\left(\frac{|V|^{\frac{1}{16}}}{|V|^{\frac{1}{8}}}\right) < \frac{1}{9} \quad (8)$$

for enough large  $|V|$ . The same bound applies to eight remaining combinations of lightcones  $L_C(x_{p'} \cup x_{p''}), L_C(x_{q'} \cup x_{q''}), L_C(x_{r'} \cup x_{r''})$  and paths  $\gamma(p, q), \gamma(p, r)$ , and  $\gamma(q, r)$ . By the union bound, there exists at least one triple of paths  $\gamma(p, q), \gamma(q, r), \gamma(p, r)$  that do not intersect with  $L_C(x_{p'} \cup x_{p''}), L_C(x_{q'} \cup x_{q''}), L_C(x_{r'} \cup x_{r''})$ . When we choose  $v'$  and  $v''$  consecutively, any cycle in  $G' \times K_2$  has an even length. Since we can take the cycle in the way above, the cycle has a even length and is the desired cycle  $\Gamma$ . ◁

Let  $p, q, r$  and  $\Gamma$  be chosen as described in Claim 18. Let  $M$  be the even number of vertices of  $\Gamma$ . When we choose  $p', p'', q', q'', r', r''$  properly, the distances between  $p', q', r'$  are all even. Consider the subset of instances where

$$x_e = \begin{cases} 1 & \text{if } e \text{ is an edge of } \Gamma \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad x_v = 0 \text{ if } (v \in V \setminus \{p', q', r'\})$$

There are  $2^3 = 8$  such instances corresponding to choices of input bits  $x_{p'}, x_{q'}, x_{r'} \in \{0, 1\}$ . Let us fix inputs  $x$  of the circuit  $C$  except  $\{x_{p'}, x_{q'}, x_{r'}\}$  and consider only output bits  $z_j$  with  $j \in \Gamma$ . By the way of fixing, we obtain a classical circuit  $D$  which takes a three-bit string  $x_{p'}x_{q'}x_{r'} \in \{0, 1\}^3$  and a random string  $r$  as input and output  $z_\Gamma \in \{0, 1\}^M$ . For any input bit  $x_i \in \{x_{p'}, x_{q'}, x_{r'}\}$  we have  $L_D(x_i) \subseteq L_C(x_i)$  since any pair of input and output variables which are correlated in  $D$  are also correlated in  $C$ , by definition. Our assumption that  $C$  can solve  $\rho(S)$  on all inputs implies that  $D$  can output  $z_\Gamma \in \tau(x_{p'}x_{q'}x_{r'})$ . From Lemma 10, at least one output bit  $z_j$  such that  $j \in \Gamma$  and  $j \notin \{p', q', r'\}$  depends on the two geometrically near inputs from  $x_{p'}, x_{q'}, x_{r'}$ . By  $L_D(x_i) \subseteq L_C(x_i)$ , the same is true for the input-output dependency of  $C$ . From Claim 9, for each  $x_i$ ,  $L_C(x_i)$  only intersects with  $z_j$  such that  $j \in \text{Box}(i)$  and there is a contradiction. Therefore, the depth of any classical probabilistic circuit that has bounded fan-in  $K$  and solves  $\rho(S)$  on all inputs is not less than  $\frac{\log |S|}{32 \log K}$ . This concludes the proof of Theorem 3. ◀

## A Proof of Lemma 8

First, we introduce a notation. The range in Definition 6,  $1 \leq |U| \leq \frac{1}{2}|V|$ , may be a little arbitrary. In terms of the range where the expansion ratio is considered, we define more general expander graphs as follows.

► **Definition 19** (Definition 2.2 in [32]). *Let  $G = (V, E)$  be a graph, let  $I$  be a set of positive integers. The graph  $G$  is an  $I$ -expander if a positive constant  $h$  exists such that  $N_G(U) \geq h|U|$  for every vertex subset  $U \subset V$  satisfying  $|U| \in I$ .*

Note that this definition does not limit the maximum degree of graphs. When the graph  $G$  is an expander graph (as defined as Definition 7),  $G$  is also a  $\left[1, \frac{|V|}{2}\right]$ -expander with bounded degree.

Then, the following claim shows an expander graph still has a large connected component and it can be described using the notation of Definition 19 when a small fraction of vertices are adversarially removed.

▷ **Claim 20.** Let  $G = (V, E)$  be an expander graph. If we take a sufficiently small constant  $\epsilon > 0$ , the graph has a connected component  $C$  which has more than  $\frac{|V|}{2}$  vertices and is a  $\left[\frac{|C|}{3}, \frac{2|C|}{3}\right]$ -expander after up to an  $\epsilon$  fraction of the vertices are adversarially removed.

## 74:16 Quantum Advantage with Shallow Circuits Under Arbitrary Corruption

Proof. Let  $h$  be the expansion ratio and  $d$  be the maximum degree of the graph  $G$ . Let  $V' \subset V$  be an arbitrary subset of vertices such that  $|V'| \leq \epsilon|V|$ . Let  $C_1, \dots, C_m$  be the connected components of the left graph after  $|V'|$  vertices are adversarially removed.

To reach a contradiction, we assume every connected component is equal to or smaller than half of  $|V|$ , i.e., for all  $i$ ,  $|C_i| \leq \frac{|V|}{2}$ . From  $|V \setminus V'| + |V'| = |V|$ ,  $|V \setminus V'| = |V| - |V'| \geq (1 - \epsilon)|V|$ . Each connected component  $C_i$  has its neighbor  $N_G(C_i)$  such that  $|N_G(C_i)| \geq h|C_i|$  since  $|C_i| \leq \frac{|V|}{2}$ . A vertex can be a neighbor of at most  $d$  connected components at the same time. Therefore, by the summation of neighbors of all connected components  $C_i$ ,

$$|N_G(V \setminus V')| \geq \frac{h|V \setminus V'|}{d} \geq \frac{h}{d}(1 - \epsilon)|V|.$$

In terms of the total number of vertices,  $|V \setminus V'| + |N_G(V \setminus V')| \leq |V|$ . Then,

$$\epsilon|V| \geq |V'| = |V| - |V \setminus V'| \geq |N_G(V \setminus V')| \geq \frac{h}{d}(1 - \epsilon)|V|.$$

Thus,  $\epsilon \geq \frac{\frac{h}{d}}{1 + \frac{h}{d}}$  and this contradicts  $\epsilon$  is sufficiently small. Therefore we can pick a connected component  $C$  such that  $|C| > \frac{|V|}{2}$  from  $C_1, \dots, C_m$ .

In the graph  $C$ , we consider an arbitrary subset of vertices  $W$ , which satisfies  $\frac{|C|}{3} \leq W \leq \frac{2|C|}{3}$ . From the expander property of  $G$ ,  $|N_G(W)| \geq \frac{h|C|}{3} > \frac{h|V|}{6}$ . Since the number of removed vertices is up to  $\epsilon|V|$ ,  $|N_C(W)| > (\frac{h}{6} - \epsilon)|V|$ . If we take  $\epsilon$  smaller than  $\frac{h}{6}$ ,  $C$  is a  $\left[\frac{|C|}{3}, \frac{2|C|}{3}\right]$ -expander.  $\triangleleft$

The next claim is to show there is a relation between  $I$ -expanders of Definition 5.

▷ **Claim 21** (Lemma 2.4 in [32]). Let graph  $G = (V, E)$  be a  $\left[\frac{|V|}{3}, \frac{2|V|}{3}\right]$ -expander. Then there is a vertex subset  $Z \subset V$  such that  $|Z| < \frac{|V|}{3}$  and the graph  $G' = G[V \setminus Z]$  is a  $\left[1, \frac{|G'|}{2}\right]$ -expander.

The most significant result of minors of expander graphs is Claim 22 below. It is known that this bound ( $O(\frac{|V|}{\log(|V|)})$ ) is tight especially in terms of the size of grid minors.

▷ **Claim 22** (Corollary 8.3 in [32] and Theorem 1.1 in [20]). Let graph  $G = (V, E)$  be a  $\left[1, \frac{|V|}{2}\right]$ -expander. For any graph  $H$  with  $O(\frac{|V|}{\log(|V|)})$  vertices and edges,  $G$  contains  $H$  as a minor.

Finally, using the above claims, we can prove Lemma 8.

**Proof of Lemma 8.** From Claim 20, after the removal, the left graph has a connected component  $C$  which is a  $\left[\frac{|C|}{3}, \frac{2|C|}{3}\right]$ -expander. Using Claim 21,  $C$  contains an induced subgraph  $C'$  such that  $C'$  is a  $\left[1, \frac{|C'|}{2}\right]$ -expander and  $|C'| > \frac{2|C|}{3} > \frac{|V|}{3}$ . When  $n$  is sufficiently large,  $\frac{n}{\log(n)} \gg n^{\frac{1}{2}}$ . Therefore, from Claim 22,  $C$  contains a  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}})$  grid as a minor since the maximum degree of grid graphs is 4, which is a constant, and the number of vertices and edges of a  $\Omega(|V|^{\frac{1}{4}}) \times \Omega(|V|^{\frac{1}{4}})$  grid is  $\Omega(|V|^{\frac{1}{2}})$ .  $\blacktriangleleft$
