Contents

Preface
Stefan Szeider, Robert Ganian, and Alexandra Silva 0:xi

Conference Organization
.... 0:xiii

Invited Talks

Long Cycles in Graphs: Extremal Combinatorics Meets Parameterized Algorithms
Fedor V. Fomin, Petr A. Golovach, Danil Sagunov, and Kirill Simonov 1:1–1:4

Modern Dynamic Data Structures
Monika Henzinger 2:1–2:2

An Updated Survey of Bidding Games on Graphs
Guy Avni and Thomas A. Henzinger 3:1–3:6

Probabilistic Model Checking for Strategic Equilibria-Based Decision Making: Advances and Challenges
Marta Kwiatkowska, Gethin Norman, David Parker, Gabriel Santos, and Rui Yan 4:1–4:22

Online Bipartite Matching and Adwords
Vijay V. Vazirani 5:1–5:11

Regular Papers

Parameterized Complexity of Non-Separating and Non-Disconnecting Paths and Sets
Ankit Abhinav, Susobhan Bandopadhyay, Aritra Banik, Yasuaki Kobayashi, Shunsuke Nagano, Yota Otachi, and Saket Saurabh 6:1–6:15

Comonadic semantics for hybrid logic
Samson Abramsky and Dan Marsden 7:1–7:14

The Complexity of Periodic Energy Minimisation
Duncan Adamson, Argyrios Deligkas, Vladimir V. Gusev, and Igor Potapov 8:1–8:15

Weighted Counting of Matchings in Unbounded-Treewidth Graph Families
Antoine Amarilli and Mikaël Monet 9:1–9:15

On Upward-Planar L-Drawings of Graphs
Patrizio Angelini, Steven Chaplick, Sabine Cornelsen, and Giordano Da Lozzo ... 10:1–10:15

RAC Drawings of Graphs with Low Degree
Patrizio Angelini, Michael A. Bekos, Julia Katheder, Michael Kaufmann, and Maximilian Pfister 11:1–11:15

Polynomial Time Algorithm for ARRIVAL on Tree-Like Multigraphs
David Auger, Pierre Coucheney, and Loric Duhazé 12:1–12:14

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).
Editors: Stefan Szeider, Robert Ganian, and Alexandra Silva
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Graph Realization of Distance Sets
Amotz Bar-Noy, David Peleg, Mor Perry, and Dror Rawitz 13:1–13:14

On the Role of the High-Low Partition in Realizing a Degree Sequence by a Bipartite Graph
Amotz Bar-Noy, Toni Böhnlein, David Peleg, and Dror Rawitz 14:1–14:15

Towards a Model Theory of Ordered Logics: Expressivity and Interpolation
Bartosz Bednarczyk and Reijo Jaakkola 15:1–15:14

Algebraic Representations of Unique Bipartite Perfect Matching
Gal Beniamini 16:1–16:17

Fixed-Point Cycles and Approximate EFX Allocations
Benjamin Aram Berendsohn, Simona Boyadzhiyska, and László Kozma 17:1–17:13

Improved Lower Bound, and Proof Barrier, for Constant Depth Algebraic Circuits
C. S. Bhargav, Sagnik Dutta, and Nitin Saxena 18:1–18:16

Conflict-Free Coloring on Claw-Free Graphs and Interval Graphs
Sriram Bhyravarapu, Subrahmanyam Kalyanasundaram, and Rogers Mathew 19:1–19:14

Skolem Meets Schanuel
Yuri Bilu, Florian Luca, Joris Nieuwveld, Joël Ouaknine, David Purser, and James Worrell 20:1–20:15

Deepening the (Parameterized) Complexity Analysis of Incremental Stable Matching Problems
Niclas Boehmer, Klaus Heeger, and Rolf Niedermeier 21:1–21:15

Tree Exploration in Dual-Memory Model
Dominik Bojko, Karol Gotfryd, Dariusz R. Kowalski, and Dominik Pająk 22:1–22:16

On Vanishing Sums of Roots of Unity in Polynomial Calculus and Sum-Of-Squares
Ilario Bonacina, Nicola Galesi, and Massimo Lauria 23:1–23:15

Complete ZX-Calculi for the Stabiliser Fragment in Odd Prime Dimensions
Robert I. Booth and Titouan Carette 24:1–24:15

Extending Partial Representations of Circle Graphs in Near-Linear Time
Guido Brückner, Ignaz Rutter, and Peter Stumpf 25:1–25:14

Boundaries to Single-Agent Stability in Additively Separable Hedonic Games
Martin Bullinger 26:1–26:15

Bounded Degree Nonnegative Counting CSP
Jin-Yi Cai and Daniel P. Szabo 27:1–27:16

Continuous Rational Functions Are Deterministic Regular
Olivier Carton and Gaëtan Douéneau-Tabot 28:1–28:13

On Kernels for d-Path Vertex Cover
Radovan Červený, Pratibha Choudhary, and Ondřej Suchý 29:1–29:14

On Synthesizing Computable Skolem Functions for First Order Logic
Supratik Chakraborty and S. Akshay 30:1–30:15

Sample Compression Schemes for Balls in Graphs
Jérémie Chalopin, Victor Chepoi, Fionn Mc Inerney, Sébastien Ratel, and Yann Vaxès 31:1–31:14

On Algorithms Based on Finitely Many Homomorphism Counts
Yijia Chen, Jörg Flum, Mingjun Liu, and Zhiyang Xun 32:1–32:15

Higher-Order Quantified Boolean Satisfiability
Dmitry Chistikov, Christoph Haase, Zahra Hadizadeh, and Alessio Mansutti 33:1–33:15

On Dynamic $\alpha + 1$ Arboricity Decomposition and Out-Orientation
Aleksander B. G. Christiansen, Jacob Holm, Eva Rotenberg, and Carsten Thomassen 34:1–34:15

LO_v-Calculus: A Graphical Language for Linear Optical Quantum Circuits
Alexandre Clément, Nicolas Heurtel, Shane Mansfield, Simon Perdrix, and Benoît Valiron 35:1–35:16

Resource Optimisation of Coherently Controlled Quantum Computations with the PBS-Calculus
Alexandre Clément and Simon Perdrix 36:1–36:15

A Complexity Approach to Tree Algebras: the Polynomial Case
Thomas Colcombet and Arthur Jaquard 37:1–37:14

Enumeration Classes Defined by Circuits
Nadia Creignou, Arnaud Durand, and Heribert Vollmer 38:1–38:14

Bounding the Escape Time of a Linear Dynamical System over a Compact Semialgebraic Set
Julian D'Costa, Engel Lefaucheux, Eike Neumann, Joël Ouaknine, and James Worrell 39:1–39:14

The Pseudo-Reachability Problem for Diagonalisable Linear Dynamical Systems
Julian D'Costa, Toghrul Karimov, Rupak Majumdar, Joël Ouaknine, Mahmoud Salamati, and James Worrell 40:1–40:13

New Lower Bounds and Upper Bounds for Listing Avoidable Vertices
Mingyang Deng, Virginia Vassilevska Williams, and Ziqian Zhong 41:1–41:14

Constant-Factor Approximation Algorithm for Binary Search in Trees with Monotonic Query Times
Dariusz Dereniowski and Izajasz Wrosz 42:1–42:15

On the Identity Problem for Unitriangular Matrices of Dimension Four
Ruiwen Dong 43:1–43:14

Regular Monoidal Languages
Matthew Earnshaw and Paweł Sobociński 44:1–44:14

Oracle with $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$, but No Many-One Completeness in UP, DisjNP, and DisjCoNP
Anton Ehrmanntraut, Fabian Egidy, and Christian Glaßer 45:1–45:15

Exact Matching in Graphs of Bounded Independence Number
Nicolas El Maalouly and Raphael Steiner 46:1–46:14

CNF Encodings of Parity
Gregory Emdin, Alexander S. Kulikov, Ivan Mihajlin, and Nikita Slezkin 47:1–47:12

On the Number of Quantifiers as a Complexity Measure
Ronald Fagin, Jonathan Lenchner, Nikhil Vyas, and Ryan Williams 48:1–48:14

Non-Determinism in Lindenmayer Systems and Global Transformations
Alexandre Fernandez, Luidnel Maignan, and Antoine Spicher 49:1–49:13

A Robust Class of Languages of 2-Nested Words
Séverine Fratani, Guillaume Maurras, and Pierre-Alain Reynier 50:1–50:15

Metric Dimension Parameterized by Feedback Vertex Set and Other Structural Parameters
Esther Galby, Liana Khazaliya, Fionn Mc Inerney, Roohani Sharma, and Prafullkumar Tale 51:1–51:15

Graph Similarity Based on Matrix Norms
Timo Gervens and Martin Grohe 52:1–52:15

Approximation Algorithms for Covering Vertices by Long Paths
Mingyang Gong, Jing Fan, Guohui Lin, and Eiji Miyano 53:1–53:14

The Hamilton Compression of Highly Symmetric Graphs
Petr Gregor, Arturo Merino, and Torsten Mütze 54:1–54:14

Dispersing Obnoxious Facilities on Graphs by Rounding Distances
Tim A. Hartmann and Stefan Lendl 55:1–55:14

On the Binary and Boolean Rank of Regular Matrices
Ishay Haviv and Michal Parnas 56:1–56:14

Gaps, Ambiguity, and Establishing Complexity-Class Containments via Iterative Constant-Setting
Lane A. Hemaspaandra, Mandar Juvekar, Arian Nadjimzadah, and Patrick A. Phillips 57:1–57:15

Independent Set Reconfiguration on Directed Graphs
Takehiro Ito, Yuni Iwamasa, Yasuaki Kobayashi, Yu Nakahata, Yota Otachi, Masahiro Takahashi, and Kunihiro Wasa 58:1–58:15

Automating OBDD proofs is NP-hard
Dmitry Itsykson and Artur Riazanov 59:1–59:15

Not All Strangers Are the Same: The Impact of Tolerance in Schelling Games
Panagiotis Kanellopoulos, Maria Kyropoulou, and Alexandros A. Voudouris 60:1–60:14

On the Skolem Problem for Reversible Sequences
George Kenison 61:1–61:15

The Complexity of Computing Optimum Labelings for Temporal Connectivity
Nina Klobas, George B. Mertzios, Hendrik Molter, and Paul G. Spirakis 62:1–62:15

Beyond Value Iteration for Parity Games: Strategy Iteration with Universal Trees
Zhuan Khye Koh and Georg Loho 63:1–63:15

Countdown μ-Calculus
Jędrzej Kołodziejski and Bartek Klin 64:1–64:14

Rabbits Approximate, Cows Compute Exactly!
Balagopal Komarath, Anurag Pandey, and Nitin Saurabh 65:1–65:14

Finding 3-Swap-Optimal Independent Sets and Dominating Sets Is Hard
Christian Komusiewicz and Nils Morawietz 66:1–66:14

SAT-Based Circuit Local Improvement
Alexander S. Kulikov, Danila Pechenev, and Nikita Slezkin 67:1–67:15

Complexity of the Cluster Vertex Deletion Problem on H-Free Graphs
Hoang-Oanh Le and Van Bang Le 68:1–68:10

Reducing the Vertex Cover Number via Edge Contractions
Paloma T. Lima, Vinicius F. dos Santos, Ignasi Sau, Uéverton S. Souza, and Prafullkumar Tale 69:1–69:14

Generalized Bundled Fragments for First-Order Modal Logic
Mo Liu, Anantha Padmanabha, R. Ramanujam, and Yanjing Wang 70:1–70:14

Membership Problems in Finite Groups
Markus Lohrey, Andreas Rosowski, and Georg Zetzsche 71:1–71:16

Streaming Word Problems
Markus Lohrey and Lukas Lück 72:1–72:15

A Universal Skolem Set of Positive Lower Density
Florian Luca, Joël Ouaknine, and James Worrell 73:1–73:12

Learning Deterministic Visibly Pushdown Automata Under Accessible Stack
Jakub Michaliszyn and Jan Otop 74:1–74:16

Cohomology in Constraint Satisfaction and Structure Isomorphism
Adam Ó Conghaile 75:1–75:16

Deciding Emptiness for Constraint Automata on Strings with the Prefix and Suffix Order
Dominik Peteler and Karin Quaas 76:1–76:15

On Uniformization in the Full Binary Tree
Alexander Rabinovich 77:1–77:14

An Exact Algorithm for Knot-Free Vertex Deletion
M. S. Ramanujan, Abhishek Sahu, Saket Saurabh, and Shaily Verma 78:1–78:15

On Extended Boundary Sequences of Morphic and Sturmian Words
Michel Rigo, Manon Stipulanti, and Markus A. Whiteland 79:1–79:16

Higher-Order Causal Theories Are Models of BV-Logic
Will Simmons and Aleks Kissinger 80:1–80:14

Space-Bounded Unitary Quantum Computation with Postselection
Seiichiro Tani 81:1–81:15

Computing the Minimum Bottleneck Moving Spanning Tree
Haitao Wang and Yiming Zhao 82:1–82:15

Improved Approximation Algorithms for the Traveling Tournament Problem
Jingyang Zhao, Mingyu Xiao, and Chao Xu 83:1–83:15

Preface

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research results in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues. The first MFCS conference was organized in 1972 in Jabłonna (near Warsaw, Poland), and the conference has traditionally moved between the Czech Republic, Slovakia, and Poland. Since 2013, the conference has traveled around Europe. In 2022, MFCS celebrates its 50th anniversary in Vienna, Austria, on August 22–26.

We have an exciting program which includes 5 invited and 78 contributed talks. The invited speakers are Fedor V. Fomin (University of Bergen), Monika Henzinger (University of Vienna), Thomas Henzinger (IST Austria), Marta Kwiatkowska (University of Oxford), and Vijay Vazirani (University of California) on topics that reflect the broad scope of the conference. The latter invited talk is shared with the co-located 6th Workshop on Matching Under Preferences (MATCH-UP 2022).

The program committee of MFCS 2022 selected 78 papers out of 221 submissions, with the authors of the submitted papers representing over 35 countries. We want to express our deep gratitude to all the members of the program committee and reviewers for their extensive reports and discussions on the submissions' merits.

MFCS proceedings have been published in the Dagstuhl/LIPIcs series since 2016. We want to thank Michael Wagner and the LIPIcs team for their kind help and support. We also thank Doris Brazda and Jan Dreier and our team of student volunteers for helping with the local organization of the conference.

Long Cycles in Graphs: Extremal Combinatorics Meets Parameterized Algorithms

Abstract

We discuss recent algorithmic extensions of two classic results of extremal combinatorics about long paths in graphs. First, the theorem of Dirac from 1952 asserts that a 2-connected graph G with the minimum vertex degree $d > 1$, is either Hamiltonian or contains a cycle of length at least $2d$. Second, the theorem of Erdős-Gallai from 1959, states that a graph G with the average vertex degree $D > 1$, contains a cycle of length at least D. The proofs of these theorems are constructive, they provide polynomial-time algorithms constructing cycles of lengths $2d$ and D. We extend these algorithmic results by showing that each of the problems, to decide whether a 2-connected graph contains a cycle of length at least $2d + k$ or of a cycle of length at least $D + k$, is fixed-parameter tractable parameterized by k.

2012 ACM Subject Classification Mathematics of computing → Graph algorithms; Theory of computation → Parameterized complexity and exact algorithms

Keywords and phrases Longest path, longest cycle, fixed-parameter tractability, above guarantee parameterization, average degree, dense graph, Dirac theorem, Erdős-Gallai theorem

Category Invited Talk

Funding *Fedor V. Fomin*: The research received funding from the Research Council of Norway via the project BWCA (grant no. 314528).
Danil Sagunov: This project was supported by Leonhard Euler International Mathematical Institute in Saint Petersburg (agreement no. 075–15–2019–1620).

1 Introduction

The two fundamental theories from graph theory guarantee the existence of long cycles in dense graphs. The first theorem is Dirac's theorem from 1952.

▶ **Theorem 1** (Dirac [2, Theorem 4]). *Every n-vertex 2-connected undirected graph G with minimum vertex degree $\delta(G) \geq 2$, contains a cycle with at least $\min\{2\delta(G), n\}$ vertices.*

The second theorem from 1959 is due to Erdős and Gallai [3].

▶ **Theorem 2** (Erdős and Gallai [3]). *Every undirected graph with n vertices and more than $\frac{1}{2}(n-1)\ell$ edges ($\ell \geq 2$) contains a cycle of length at least $\ell + 1$.*

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

The proofs of both theorems are constructive, in the sense that they provide polynomial-time algorithms constructing cycles of lengths $\min\{2\delta(G), n\}$ and $\ell + 1$. This brings us to a natural and "innocent" question: is it possible to extend the algorithms provided by Theorems 1 and 2 by a "tiny" bit? For example, for an integer $k \geq 1$, *is there a polynomial time algorithm comuting a cycle of length at least $2\delta(G) + k$?* Or, *is it possible to identify in polynomial time whether a graph with $\frac{1}{2}(n-1)\ell$ edges contains a cycle of length at least $\ell + k$?*

The methods developed in the extremal Hamiltonian graph theory do not answer such questions. The combinatorial bounds in Theorems 1 and 2 are known to be sharp; that is, there exist graphs that have no cycles of length at least $\min\{2\delta(G) + 1, n\}$ or $\ell + 2$. Since the extremal graph theory studies the existence of a cycle under certain conditions, such type of questions are beyond its applicability. On the other hand, the existing methods of parameterized complexity, see e.g. [1], do not seem to be much of use here either. Such algorithms compute a cycle of length at least k in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$, which in our case is $2^{\mathcal{O}(\delta(G))} \cdot n^{\mathcal{O}(1)}$. Hence when $\delta(G)$ is, for example, at least $n^{1/100}$, these algorithms do not run in polynomial time.

We answer both questions affirmatively and in a much more general way. Our first theorem, this theorem appears in [4], implies that in polynomial time one can decide whether G contains a cycle of length at least $2\delta(G - B) + k$ for $B \subseteq V(G)$ and $k \geq 0$ as long as $k + |B| \in \mathcal{O}(\log n)$. (We denote by $G - B$ the induced subgraph of G obtained by removing vertices of B.) To state our result more precisely, we define the following problem.

Long Dirac Cycle parameterized by $k + |B|$

Input: Graph G with vertex set $B \subseteq V(G)$ and integer $k \geq 0$.
Task: Decide whether G contains a cycle of length at least $\min\{2\delta(G - B), |V(G)| - |B|\} + k$.

In the definition of Long Dirac Cycle we use the minimum of two values for the following reason. The question whether an n-vertex graph G contains a cycle of length at least $2\delta(G - B) + k$ is meaningful only for $\delta(G - B) \leq n/2$. Indeed, for $\delta(G - B) > n/2$, G does not contain a cycle of length at least $2\delta(G - B) + k > n$. However, even when $\delta(G - B) > n/2$, deciding whether G is Hamiltonian, is still very intriguing. By taking the minimum of the two values, we capture both interesting situations.

▶ **Theorem 3.** *On an n-vertex 2-connected graph G, Long Dirac Cycle is solvable in time $2^{\mathcal{O}(k+|B|)} \cdot n^{\mathcal{O}(1)}$.*

In other words, Long Dirac Cycle is fixed-parameter tractable parameterized by $k + |B|$ and the dependence on the parameters is single-exponential. This dependence is asymptotically optimal up to the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi, and Zane [6]. Solving Long Dirac Cycle in time $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ even with $B = \emptyset$ yields recognizing in time $2^{o(n)}$ whether a graph is Hamiltonian. A subexponential algorithm deciding Hamiltonicity would fail ETH. We show that solving Long Dirac Cycle in time $2^{o(|B|)} \cdot n^{\mathcal{O}(1)}$ even for $k = 1$ would contradict ETH as well. It is also NP-complete to decide whether a 2-connected graph G has a cycle of length at least $(2 + \varepsilon)\delta(G)$ for any $\varepsilon > 0$.

The 2-connectivity requirement in the statement of the theorem is important – without it Long Dirac Cycle is already NP-complete for $k = |B| = 0$. Indeed, for an n-vertex graph G construct a graph H by attaching to each vertex of G a clique of size $n/2$. Then H has a cycle of length at least $2\delta(H) \geq n$ if and only if G is Hamiltonian.

Our second theorem, that appears in [5], provides an algorithmic extension of the Erdős-Gallai theorem: A fixed-parameter tractable (FPT) algorithm with parameter k, that decides whether the circumference (the length of the longest cycle) of a graph is at least $\ell + k$. To state our result formally, we need a few definitions. For an undirected graph G with n vertices and m edges, we define $\ell_{EG}(G) = \frac{2m}{n-1}$. Then by the Erdős-Gallai theorem, G always has a cycle of length at least $\ell_{EG}(G)$ if $\ell_{EG}(G) > 2$. The parameter $\ell_{EG}(G)$ is closely related to the *average* degree of G, $\mathsf{ad}(G) = \frac{2m}{n}$. It is easy to see that for every graph G with at least two vertices, $\ell_{EG}(G) - 1 \leq \mathsf{ad}(G) < \ell_{EG}(G)$.

The *maximum average degree* $\mathsf{mad}(G)$ is the maximum value of $\mathsf{ad}(H)$ taken over all induced subgraphs H of G. Note that $\mathsf{ad}(G) \leq \mathsf{mad}(G)$ and $\mathsf{mad}(G) - \mathsf{ad}(G)$ may be arbitrary large. By Theorem 2, we have that if $\mathsf{ad}(G) \geq 2$, then G has a cycle of length at least $\mathsf{ad}(G)$ and, furthermore, if $\mathsf{mad}(G) \geq 2$, then there is a cycle of length at least $\mathsf{mad}(G)$. Based on this guarantee, we define the following problem.

Longest Cycle Above MAD

Input: A graph G on n vertices and an integer $k \geq 0$.
Task: Decide whether G contains a cycle of length at least $\mathsf{mad}(G) + k$.

Our main result is that this problem is FPT parameterized by k. More precisely, we show the following.

▶ **Theorem 4.** *Longest Cycle Above MAD can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ on 2-connected graphs.*

While Theorems 1 and 2 concern decision problems, their proofs may be adapted to produce desired cycles, if they exist. We underline this because the standard construction of a long cycle that for every $e \in E(G)$ invokes the decision algorithm on $G - e$, does not work in our case, as edge deletions decrease the average degree of a graph.

We also briefly discuss the ideas behind the proofs of both theorems that are based on an interplay between extremal combinatorics and parameterized algorithms. We develop a new graph decomposition that we call *Dirac decomposition* and then show how to use this decomposition algorithmically. Dirac decomposition is defined for a cycle C in a 2-connected graph G. Let C be a cycle of length less than $2\delta(G) + k$. Informally, the components of Dirac decomposition are connected components in $G - V(C)$. Since G is 2-connected, we can reach C by a path starting in such a component in G. One of the essential properties of Dirac decomposition is a limited number of vertices in $V(C)$ that have neighbors outside of C. In fact, we can choose two short paths P_1 and P_2 in C (and short means that their total length is of order k) such that all connections between connected components of $G - V(C)$ and C go through $V(P_1) \cup V(P_2)$. The second important property is that each connected component of $G - (V(P_1) \cup V(P_2))$ is connected with P_i in G in a very restricted way: The maximum matching size between its vertex set and the vertex set of P_i is at most one. Dirac decomposition appears to be very useful for algorithmic purposes. For a cycle C, given a Dirac decomposition for C, in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ we either solve the problem or succeed in enlarging C.

To apply Dirac decomposition, we also design a polynomial time that (except some "extremal" cases) we can either (a) enlarge the cycle C, or (b) compute a vertex cover of G of size at most $\delta(G) + 2k$, or (c) compute a Dirac decomposition. In cases (a) and (c), we can proceed iteratively. For the case (b) we need another algorithm that solves the problem in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.

1 Extended Abstract

In the past the main goal when designing data structures was to achieve optimal time per operation and optimal space. However, in recent years new applications have lead to new requirements for data structures, such as differential privacy or fairness.

In this talk I will limit myself to the first topic, namely differential privacy. Since its invention in 2006 by Dwork, McSherry, Nissim, and Smith [3] differentially private algorithms and (static) data structures have been designed for many combinatorial problems (see e.g. [5] for a book on the topic). However, very little work has been done for *dynamic* data structures. A *dynamic data structure* is a data structure that supports not only *query* operations to the stored data, but also *update* operations, such as insertions and/or deletions. In the differentially privacy research community such data structures are frequently called data structures *in the continual release* (or *continual observation*) *model.*

The problem of *binary counting* the number of 1s in a binary sequence is equivalent to a dynamic data structure that supports the *AppendBit* operation and that outputs the number of 1s in the current sequence after each *AppendBit* operation. This problem has been well-studied in the differentially private setting [4, 1, 8, 2, 7], including a version that outputs a weighted average of the bits in the sequence so far [7]. Another extension of this problem leads to the *MaxSum* and the *SumSelect* problem: Assume the input is a sequence of d-dimensional binary vectors such that the t-th vector is denoted by b_t. The goal of the *SumSelect* problem is to output the value of the coordinate i such that $i = \text{argmax}_i \sum_t b_t[i]$, the goal of *MaxSum* is to output $\max_i \sum_t b_t[i]$. These problems were studied in the continual release model in [9]: Differentially private partially *dynamic graph algorithms* were also analyzed in the continual release setting [10, 6].

We will describe the algorithm of [7] in detail and explain why it is superior to the previous solutions for binary counting under continual observation.

An Updated Survey of Bidding Games on Graphs

Guy Avni
University of Haifa, Israel

Thomas A. Henzinger
IST Austria, Austria

Abstract

A graph game is a two-player zero-sum game in which the players move a token throughout a graph to produce an infinite path, which determines the winner or payoff of the game. In *bidding games*, both players have budgets, and in each turn, we hold an "auction" (bidding) to determine which player moves the token. In this survey, we consider several bidding mechanisms and their effect on the properties of the game. Specifically, bidding games, and in particular bidding games of infinite duration, have an intriguing equivalence with *random-turn* games in which in each turn, the player who moves is chosen randomly. We summarize how minor changes in the bidding mechanism lead to unexpected differences in the equivalence with random-turn games.

1 Introduction

Games on graphs are a central class of games in formal verification [2] and have deep connections to foundations of logic [17]. They have numerous applications including reactive synthesis [16], verification [10], and reasoning about multi-agent systems [1]. Theoretically, graph games give rise to interesting and challenging problems. For example, solving parity games is a rare problem that is in NP and coNP [11], not known to be in P, and for which a quasi-polynomial algorithm was only recently discovered [8].

A graph game proceeds as follows. We place a token on one of the vertices of a graph and allow the players to move it to produce an infinite path that determines the winner or payoff of the game. Several *modes of moving* the token have been studied [2], and the most popular is *turn-based* graph games in which the players alternate turns in moving the token. We study the *bidding* mode of moving [13, 12]: players have budgets and in each turn, an "auction" (bidding) determines which player moves the token. Bidding games are a class of concurrent graph games [1]. They combine graph games with auctions, a central topic of research in algorithmic game theory (e.g., [14]).

Objectives. We stress that bidding is the mode of moving the token and it is orthogonal to the players' objectives. We consider the qualitative objectives reachability and parity, and the quantitative objective mean-payoff.

2 Bidding Mechanisms

In all the bidding mechanisms that we consider, in each turn, both players simultaneously submit bids that do not exceed their available budget, and the higher bidder "wins" the bidding and moves the token. The bidding mechanisms differ in two orthogonal properties:

1. Who pays: in *first-price* bidding only the higher bidder pays; in *all-pay* bidding both players pay their bids.
2. Where are the bids paid: in *Richman* bidding (named after David Richman), bids are paid to the opponent; in *poorman* bidding bids are paid to the "bank", thus the budget is lost.

▶ Remark 1. A well-known auction mechanism is *second-price bidding* in which the highest bidder pays the second highest bid. We point out that bidding games under first- and second-price bidding coincide, since the players in second-price bidding can follow the same optimal strategies they use in first-price bidding to guarantee the same values.

The central quantity in bidding games regards the ratio between the two players' budget, formally defined as follows.

▶ **Definition 2** (Budget ratio). *Assuming Player i's budget is B_i, for $i \in \{0, 1\}$, then Player 1's ratio is $B_1/(B_1 + B_2)$.*

Random-turn games. A *random-turn game* [15] is similar to a bidding game only that instead of bidding for moving, in each turn, we decide which player moves according to a (possibly biased) coin toss. For a bidding game $\mathcal{G}$ and $p \in [0, 1]$, we denote by $\mathsf{RT}(\mathcal{G}, p)$ the random-turn game that is obtained from $\mathcal{G}$ using a coin with bias p. Formally, random-turn games are a subclass of stochastic games [9]. To obtain a random-turn game from $\mathcal{G}$, we proceed as follows. For every vertex v in $\mathcal{G}$, we add two vertices v_{Max} and v_{Min} owned by the respective players. To simulate the coin toss at v, we add probabilistic edges from v to v_{Max} with probability p and to v_{Min} with probability $1 - p$. To simulate the choice of the player who wins the bidding, we add edges from both v_{Max} and v_{Min} to every u that is a neighbor of v in $\mathcal{G}$. The objective of $\mathsf{RT}(\mathcal{G}, p)$ coincides with the objective of $\mathcal{G}$.

3 Qualitative bidding games

The main question considered in qualitative bidding games regards the threshold budgets, which intuitively represent a necessary and sufficient initial budget ratio that suffices for winning the game. Formally,

▶ **Definition 3** (Threshold ratio). *Consider a qualitative bidding game $\mathcal{G}$ and a vertex v in $\mathcal{G}$. The* threshold ratio *in v, denoted $\mathit{Th}(v)$, is such that:*

- *If Player 1's initial ratio is strictly greater than $\mathit{Th}(v)$, he has a winning strategy from v.*
- *If Player 1's initial ratio is strictly less than $\mathit{Th}(v)$, Player 2 has a winning strategy from v.*

3.1 Reachability first-price bidding games

The focus in [13, 12] was on first-price reachability bidding games. An intriguing equivalence between reachability games with first-price Richman bidding with random-turn games, and, interestingly, only for this bidding mechanism. We formally state the result below and illustrate it in Fig. 1.

▶ **Theorem 4** ([13, 12]). *Consider a reachability bidding game with target states t_1 and t_2. Threshold ratios exist. Moreover, $\mathit{Th}(t_1) = 0$ and $\mathit{Th}(t_2) = 1$, and for any other vertex v, let v^- and v^+ be the neighbors of v such that $\mathit{Th}(v^-) \leq \mathit{Th}(v') \leq \mathit{Th}(v^+)$, for every neighbor v' of v. Then:*

- *Richman bidding: $\mathit{Th}(v) = \frac{1}{2}(\mathit{Th}(v^+) + \mathit{Th}(v^-))$ and $\mathit{Th}(v)$ coincides with the value of the vertex v in the random-turn game $RT(\mathcal{G}, 0.5)$.*
- *Poorman bidding: $\mathit{Th}(v) = \frac{\mathit{Th}(v^+)}{1-\mathit{Th}(v^-)+\mathit{Th}(v^+)}$.*

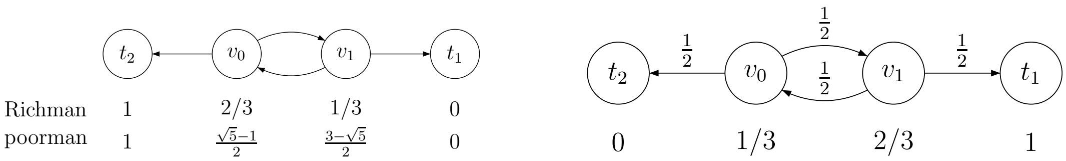

Figure 1 Left: A reachability bidding game $\mathcal{G}$ with threshold ratios, under first-price Richman and poorman bidding.
Right: The (simplified) unbiased random-turn game $\mathsf{RT}(\mathcal{G}, 0.5)$ is a Markov chain. The value of a vertex is the probability of reaching t_1. Note that under Richman bidding, for every vertex v, we have $\mathtt{Th}(\mathcal{G}, v) = 1 - val\big(\mathsf{RT}(\mathcal{G}, 0.5), v\big)$. Moreover, under poorman bidding, ratios are irrational thus such an equivalence is unlikely to exist.

3.2 Reachability all-pay bidding games

In [6], reachability games under all-pay bidding are shown to be technically much more challenging than under first-price bidding. Some positive results are shown; namely, an approximation algorithm based on discretization in games played on DAGs and results on the threshold for surely winning. Most results, however, are negative and fundamental problems, including proving that the value of the game always exists, remain open.

▶ **Theorem 5** ([6]). *Optimal strategies in reachability all-pay poorman bidding are sometimes mixed and draw bids from infinite-support distributions.*

3.3 Parity bidding games

We state a key property of parity bidding games played on strongly-connected graphs.

▶ **Theorem 6** ([4, 5, 7]). *Consider a parity game $\mathcal{G}$ played on a strongly-connected graph in which the highest parity index is odd. Under first-price Richman and poorman bidding, the threshold ratios are 0 in all the vertices; namely, Player 1 can win with any positive initial budget. Under all-pay Richman and poorman bidding, with any positive initial ratio, Player 1 has a mixed strategy that guarantees satisfying the parity objective with probability 1.*

For first-price bidding games, Theorem 6 gives rise to the following simple reduction from parity to reachability bidding games. Given a parity game $\mathcal{G}$, first reason about the bottom strongly-connected components and classify them into those that are "winning" for Player 1 and those that are “winning” for Player 2. Then, construct a reachability bidding game in which each player’s goal is to force the game to a winning bottom strongly-connected component. A similar reduction applies to all-pay bidding, however reachability games under those bidding mechanisms are not yet understood.

4 Mean-Payoff Bidding Games

In this section we consider mean-payoff games played on strongly-connected graphs. We show intricate equivalences between mean-payoff bidding games and random-turn games.

	Richman		poorman	
First-price	$\mathsf{RT}(\mathcal{G}, \frac{1}{2})$ [4]		$\mathsf{RT}(\mathcal{G}, r)$ [5]	
All-pay	Pure	Mixed	Pure	Mixed
[7]	$\mathsf{RT}(\mathcal{G}, 0)$	$\mathsf{RT}(\mathcal{G}, \frac{1}{2})$	$\mathsf{RT}(\mathcal{G}, \frac{2r-1}{r})$	$\mathsf{RT}(\mathcal{G}, \frac{3r-1}{r})$

Figure 2 Left: On top, the mean-payoff bidding game $\mathcal{G}_{\bowtie}$. The payoff of a player in $\mathcal{G}_{\bowtie}$ is the long-run ratio of the biddings won. On bottom, for $p \in [0, 1]$, the (simplified) random-turn game $\mathsf{RT}(\mathcal{G}_{\bowtie}, p)$ is a weighted Markov chain. The expected payoff in $\mathsf{RT}(\mathcal{G}_{\bowtie}, p)$ is p; we expect that a random walk stays ratio p of the time in v_{Max}.
Right: The equivalence relates the optimal payoff in a strongly-connected mean-payoff game with the expected payoff in a random-turn game, where for all-pay poorman bidding we omit the cases of $r \leq 0.5$.

Mean-payoff value. Each play of a mean-payoff game has a payoff, which is Player 1’s (Max) reward and Player 2’s (Min) cost. We illustrate the definition of the mean-payoff objective. Consider the game $\mathcal{G}_{\bowtie}$ that is depicted in the top left of Fig. 2. It models the following setting. Max and Min represent two advertisers. In each day, an auctioneer holds an auction to determine which ad shows that day. Max’s goal is to maximize the payoff, which coincides with the number of days that his ad appears in a very long time (say, a year). Alternatively, the payoff in $\mathcal{G}_{\bowtie}$ can be seen as the ratio of the biddings that Max wins in the long run. Formally, the payoff of an infinite sequence of weights $w_1, w_2, \ldots$ is $\liminf_{n \to \infty} \frac{1}{n} \sum_{1 \leq i \leq n} w_i$.

▶ **Definition 7** (Mean-payoff value in bidding games). *Consider a strongly-connected mean-payoff bidding game $\mathcal{G}$ and a budget ratio $r \in (0, 1)$. The* mean-payoff value *of $\mathcal{G}$ w.r.t. r, denoted $\mathsf{MP}(\mathcal{G}, r)$, is $c \in \mathbb{R}$ if independent of the initial vertex,*

- *when Max’s initial ratio exceeds r, he has a strategy that guarantees a payoff of $c - \varepsilon$, for every $\varepsilon > 0$, and*
- *Max cannot do better: with a ratio that exceeds $1 - r$, Min can guarantee a payoff of at most $c + \varepsilon$, for every $\varepsilon > 0$.*

Similarly, we use asMP to denote the almost-sure value, which is defined as the payoff that Max can guarantee with a mixed strategy with probability 1.

Consider a strongly-connected mean-payoff game $\mathcal{G}$ and $p \in [0, 1]$. Recall that $\mathsf{RT}(\mathcal{G}, p)$ denotes the random-turn game that is constructed from $\mathcal{G}$ in which in each turn, Max moves the token with probability p. We denote by $\mathsf{MP}(\mathsf{RT}(\mathcal{G}, p))$ the *mean-payoff value* of $\mathsf{RT}(\mathcal{G}, p)$, which is defined as the expected payoff when both players play optimally, and it is well-known to exist in stochastic games.

▶ **Theorem 8.** *Consider a strongly-connected mean-payoff game $\mathcal{G}$ and a ratio $r \in (0,1)$.*

- *First-price Richman bidding [4]: For all $r \in (0,1)$, we have $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, 0.5)\big)$.*
- *First-price poorman bidding [5]: $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, r)\big)$.*
- *All-pay Richman bidding [7]:*
  - *Under pure strategies, $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, 0)\big)$.*
  - *Under mixed strategies, $\mathit{asMP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, 0.5)\big)$.*
- *All-pay poorman bidding [7]:*
  - *Under pure strategies, if $r > 0.5$, then $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, \frac{2r-1}{r})\big)$, and if $r \leq 0.5$, then $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, 0)\big)$.*
  - *Under mixed strategies, if $r > 0.5$, then $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, \frac{3r-1}{r})\big)$, and if $r \leq 0.5$, then $\mathit{MP}(\mathcal{G}, r) = \mathit{MP}\big(\mathit{RT}(\mathcal{G}, \frac{1-r}{r})\big)$.*

In the following example, we illustrate the results stated in Theorem 8 on $\mathcal{G}_{\bowtie}$ that is depicted in Fig. 2.

▶ **Example 9.** First, let $p \in (0,1)$. The mean-payoff value of $\mathsf{RT}(\mathcal{G}_{\bowtie}, p)$ is p since intuitively, a random walk is expected to stay portion p in vertex v_{Max}.

We start with first-price bidding. Here, optimal strategies are pure (deterministic). Under Richman bidding, the initial ratio does not matter and the optimal payoff is 0.5, matching the mean-payoff value of $\mathsf{RT}(\mathcal{G}_{\bowtie}, 0.5)$. That is, for every $\varepsilon > 0$, Max can guarantee a payoff of at least 0.5 and he cannot do better even when his ratio is $1 - \varepsilon$.

The equivalence for mean-payoff Richman-bidding games can be seen as an extension of the equivalence of reachability Richman-bidding games. Since no equivalence is known for reachability poorman-bidding games, we find the equivalence for mean-payoff poorman-bidding particularly surprising. The optimal payoff Max can guarantee with a ratio of $r \in (0,1)$ in $\mathcal{G}_{\bowtie}$ is r. For example, when the initial budgets are $\langle 3, 1 \rangle$, Max's ratio is $\frac{3}{4}$, and he can guarantee a payoff arbitrarily close to $\frac{3}{4}$ (in a similar manner to Richman bidding above). This means that in the long-run, Max can win 3 times more biddings than Min. Thus, given the option to choose between first-price Richman and poorman bidding, Max prefers using first-price poorman bidding when his budget exceeds Min's budget.

We turn to illustrate the results for all-pay bidding. Again, since reachability all-pay bidding games are technically involved, we find the equivalences in mean-payoff games to be particularly good news. First, under all-pay Richman, pure (deterministic) strategies are "useless". Using mixed strategies, first-price and all-pay coincide. Specifically, using a pure strategy, Max cannot guarantee a payoff greater than 0 in $\mathcal{G}_{\bowtie}$, and he has a mixed strategy that guarantees an almost-sure payoff of 0.5. Thus, given a choice between all-pay and first-price Richman, Max would not have a preference between the two bidding mechanisms.

Surprisingly, the properties of all-pay poorman bidding are quite different. First, in contrast to all-pay Richman bidding, pure strategies are "useful" under all-pay poorman when $r > \frac{1}{2}$. For example, when $r = \frac{3}{4}$, Max can guarantee a payoff of $\frac{2}{3}$ with a pure strategy. Not too far from $\frac{3}{4}$, the optimal payoff under first-price poorman bidding. Second, when allowing mixed strategies, given the choice between all-pay and first-price poorman bidding, when $r > \frac{1}{2}$, Max prefers all-pay poorman! With a ratio of $r = \frac{3}{4}$, Max has a mixed strategy that can guarantee an almost-sure payoff of $\frac{5}{6}$; higher than the optimal payoff under first-price poorman.

Abstract

Game-theoretic concepts have been extensively studied in economics to provide insight into competitive behaviour and strategic decision making. As computing systems increasingly involve concurrently acting autonomous agents, game-theoretic approaches are becoming widespread in computer science as a faithful modelling abstraction. These techniques can be used to reason about the competitive or collaborative behaviour of multiple rational agents with distinct goals or objectives. This paper provides an overview of recent advances in developing a modelling, verification and strategy synthesis framework for concurrent stochastic games implemented in the probabilistic model checker PRISM-games. This is based on a temporal logic that supports finite- and infinite-horizon temporal properties in both a zero-sum and nonzero-sum setting, the latter using Nash and correlated equilibria with respect to two optimality criteria, social welfare and social fairness. We summarise the key concepts, logics and algorithms and the currently available tool support. Future challenges and recent progress in adapting the framework and algorithmic solutions to continuous environments and neural networks are also outlined.

1 Introduction

Game-theoretic techniques have long been a source of fundamental insights into strategic decision making for multi-agent systems. They have been widely studied in areas such as economics [27], control [43] and robotics [36]. Concurrent stochastic multi-player games (CSGs), in particular, provide a natural framework for modelling a set of interactive, rational agents operating concurrently within an uncertain or stochastic environment. They can be viewed as a collection of players (agents) with strategies for determining their actions based on the execution so far, and where the resulting evolution of the system is probabilistic.

Game-theoretic analysis is versatile, in that it can support both zero-sum and nonzero-sum (equilibria) analysis. Zero-sum properties focus on scenarios in which one player (or a coalition of players) aims to optimise some objective, while the remaining players form a coalition with the directly opposing goal. On the other hand, nonzero-sum (equilibria) properties correspond to situations where two or more players (or coalitions of players) in a CSG have distinct objectives to be maximised or minimised. In nonzero-sum properties the goals of the players (or coalitions) are not necessarily directly opposing, and therefore it may be beneficial for players to collaborate. Competitive scenarios occur in many applications, e.g., attackers and defenders in the context of computer security. Similarly, collaborative behaviour can be essential, e.g., to effectively control a multi-robot system, or for users to send data efficiently through a shared medium in a communication protocol.

Probabilistic model checking is a powerful approach to the formal analysis of systems with stochastic behaviour. It relies on the construction and analysis of a probabilistic model, guided by a formal specification of its desired behaviour in temporal logic. It is of particular benefit in the context of models, such as stochastic games, which combine nondeterministic and probabilistic behaviour. This is because the interplay between these aspects of the model can be subtle and lead to unexpected results if not carefully modelled and analysed. This is exacerbated when the system comprises multiple agents with differing objectives.

Until recently, practical applications of probabilistic model checking based on stochastic games had focused primarily on *turn-based* models [15], in which simultaneous decision making by agents is forbidden. Alternatively, model checking of *non-stochastic* games has been extensively studied, and tool support developed [5, 39]. CSGs provide a more powerful and realistic modelling formalism, but also bring considerable challenges, in terms of the higher computational complexity or undecidability for some key problems.

There has nonetheless been significant amounts of work on tackling verification problems for CSGs. A number of algorithms have been proposed for solving CSGs against formally specified zero-sum properties, e.g. [17, 18, 11]. In the case of nonzero-sum properties, [14, 25] study the existence of and the complexity of finding equilibria for stochastic games. Complexity results for finding equilibria are also considered in [9] and [23] for quantitative reachability properties and temporal logic properties, respectively. Other work concerns finding equilibria for discounted properties; we mention [49], which formulates a learning-based algorithm, and [40], which presents iterative algorithms. However these advances are mostly lacking in implementations, tool support or case studies. Tools exist for solving turn-based stochastic games [13, 16] and non-stochastic concurrent games [16, 8, 10, 55, 24, 45], with the latter class including support for computing equilibria.

At the same time, there is an increasing trend to incorporate data-driven decision making, which necessitates the incorporation on of machine learning components within autonomous systems, which are built largely using conventional, symbolic methods. Examples of such *neuro-symbolic* systems are self-driving cars whose vision function is provided via a neural network image classifier, or an aircraft controller whose collision avoidance system uses a neural network for decision support. Design automation support for such systems is lacking, yet automatic computation of equilibria aids in ensuring stable solutions.

This paper provides an overview of recent advances in developing a modelling, verification and strategy synthesis framework for concurrent stochastic games, as implemented in the PRISM-games probabilistic model checker [33]. The framework uses a temporal logic that supports a wide range of finite- and infinite-horizon properties, relating to the probability of an event's occurrence or the expected amount of reward or cost accumulated. The logic allows specification of both *zero-sum* and *nonzero-sum* properties, with the latter expressed using either *Nash equilibria* or *correlated equilibria*. For both types of equilibria, strategies are synthesised in which it is not beneficial for any player to unilaterally alter their chosen actions, but correlated equilibria also allow players to coordinate through *public signals*. Since several, varied such equilibria may exist, we also support distinct optimality criteria to select between them; we consider *social welfare*, which maximises the sum of the players utilities, and *social fairness*, which minimises the difference between the utilities.

We summarise the key concepts, logics and algorithms that underlie this framework and discuss the tool support provided by PRISM-games, including an illustrative case study of formally modelling and analysing a multi-agent communication protocols using CSGs. Future challenges and recent progress in extending the framework and algorithmic solutions to modelling of neuro-symbolic CSGs are also outlined. In contrast to the majority of prior research, the focus of this strand of work is on software tool development, applications and case studies.

2 Normal form games

We introduce the main concepts used in this paper by means of simple one-shot games known as *normal form games* (NFGs), where players make their choices at the same time. We consider both zero-sum NFGs and nonzero-sum NFGs, then define equilibria concepts for these games and summarise existing algorithms for equilibria computation.

We first require the following notation. Let $\mathit{Dist}(X)$ denote the set of probability distributions over set X. For any vector $v \in \mathbb{R}^n$, we use $v(i)$ to refer to the ith entry of the vector. For any tuple $x = (x_1, \ldots, x_n) \in X^n$, element $x' \in X$ and $i \leqslant n$, we define the tuples $x_{-i} \overset{\text{def}}{=} (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)$ and $x_{-i}[x'] \overset{\text{def}}{=} (x_1, \ldots, x_{i-1}, x', x_{i+1}, \ldots, x_n)$.

▶ **Definition 1** (Normal form game). *A (finite, n-player)* normal form game *(NFG) is a tuple* $\mathsf{N} = (N, A, u)$ *where:*

- $N = \{1, \ldots, n\}$ *is a finite set of* players*;*
- $A = A_1 \times \cdots \times A_n$ *and* A_i *is a finite set of* actions *available to player* $i \in N$*;*
- $u = (u_1, \ldots, u_n)$ *and* $u_i \colon A \to \mathbb{R}$ *is a* utility function *for player* $i \in N$.

In a normal form game N, the players choose actions simultaneously, with player $i \in N$ choosing an action from the set A_i and, assuming that each player $i \in N$ selects action a_i, player j receives the utility $u_j(a_1, \ldots, a_n)$. The *objective* of each player is to maximise their utility and their choices are governed by *strategies*, which we now define. We will also distinguish *strategy profiles*, which comprise a strategy for each player, and *correlated profiles*, which correspond to choices of the players when they are allowed to coordinate through a (probabilistic) *public signal*.

▶ **Definition 2** (Strategies, profiles and correlated profiles). *For an NFG* N*:*

- *a* strategy σ_i *for player* i *in an NFG* N *is a probability distribution over the set of actions* A_i *and we let* Σ^i_{N} *denote the set of all strategies for player* i*;*
- *a* strategy profile *(or* profile*)* $\sigma = (\sigma_1, \ldots, \sigma_n)$ *is a tuple of strategies for each player;*
- *a* correlated profile *is a tuple* (τ, ς) *comprising* $\tau \in \mathit{Dist}(D_1 \times \cdots \times D_n)$*, where* D_i *is a finite set of* signals *for player* i*, and* $\varsigma = (\varsigma_1, \ldots, \varsigma_n)$*, where* $\varsigma_i \colon D_i \to A_i$ *is a function from the signals of player* i *to the actions of player* i.

For a correlated profile (τ, ς) of N, the public signal τ is a joint distribution over signals D_i for each player i such that, if player i receives the signal $d_i \in D_i$, then it chooses action $\varsigma_i(d_i)$. We can consider any correlated profile (τ, ς) as a *joint strategy*, i.e., a distribution over $A_1 \times \cdots \times A_n$ where:

$$(\tau, \varsigma)(a_1, \ldots, a_n) = \textstyle\sum\{\tau(d_1, \ldots, d_n) \mid d_i \in D_i \wedge \varsigma(d_i) = a_i \text{ for all } i \in N\}\,.$$

Conversely, any joint strategy $\tau \in \mathit{Dist}(A_1 \times \cdots \times A_n)$ of N can be considered as a correlated profile (τ, ς), where $D_i = A_i$ and ς_i is the identity function for $i \in N$. Any profile σ of an NFG N can be mapped to an equivalent correlated profile (in which τ is the joint distribution $\sigma_1 \times \cdots \times \sigma_n$ and ς_i is the identity function). On the other hand, there are correlated profiles with no equivalent strategy profile.

Under profile σ or correlated profile (τ, ς) the expected utilities of player i are:

$$\begin{array}{rcl} u_i(\sigma) & \overset{\text{def}}{=} & \sum_{(a_1,\dots,a_n)\in A} u_i(a_1,\dots,a_n) \cdot \left(\prod_{j=1}^n \sigma_j(a_j)\right) \\ u_i(\tau,\varsigma) & \overset{\text{def}}{=} & \sum_{(d_1,\dots,d_n)\in D} \tau(d_1,\dots,d_n) \cdot u_i(\varsigma_1(d_1),\dots,\varsigma_n(d_n))\,. \end{array}$$

▶ **Example 3.** Consider the two-player NFG with available action sets $A_i = \{\mathit{heads}_i, \mathit{tails}_i\}$ for $1 \leqslant i \leqslant 2$ and a correlated profile corresponding to the joint distribution $\tau \in \mathit{Dist}(A_1 \times A_2)$, where $\tau(\mathit{heads}_1, \mathit{heads}_2) = \tau(\mathit{tails}_1, \mathit{tails}_2) = 0.5$. Under this correlated profile, the players share a fair coin and choose their action based on the outcome of the coin toss. There is no equivalent strategy profile.

2.1 Zero-sum NFGs

A *zero-sum NFG* is a two-player NFG N such that $u_1(\alpha)+u_2(\alpha) = 0$ for all $\alpha \in A$, meaning that the objectives of the players are directly opposing. Such an NFG is often called a *matrix game*, as it can be represented by a single matrix $\mathsf{Z} \in \mathbb{Q}^{l \times m}$, where $A_1 = \{a_1, \dots, a_l\}$, $A_2 = \{b_1, \dots, b_m\}$ and $z_{ij} = u_1(a_i, b_j) = -u_2(a_i, b_j)$.

We next introduce the notion of the *value* of a zero-sum NFG and recall classical results about the existence of optimal strategies.

▶ **Theorem 4** (Minimax theorem [56, 57]). *For any zero-sum NFG $\mathsf{N} = (N, A, u)$ and corresponding matrix game Z, there exists $v^\star \in \mathbb{Q}$, called the* value *of the game and denoted $\mathit{val}(\mathsf{Z})$, such that:*

- *there is a strategy $\sigma_1^\star$ for player 1, called an optimal strategy of player 1, such that under this strategy the player's expected utility is at least $v^\star$ regardless of the strategy of player 2, i.e., $\inf_{\sigma_2 \in \Sigma_{\mathsf{N}}^2} u_1(\sigma_1^\star, \sigma_2) \geqslant v^\star$;*
- *there is a strategy $\sigma_2^\star$ for player 2, called an optimal strategy of player 2, such that under this strategy the player's expected utility is at least $-v^\star$ regardless of the strategy of player 1, i.e., $\inf_{\sigma_1 \in \Sigma_{\mathsf{N}}^1} u_2(\sigma_1, \sigma_2^\star) \geqslant -v^\star$.*

The value of a matrix game $\mathsf{Z} \in \mathbb{Q}^{l \times m}$ can be found by solving a linear programming (LP) problem [56, 57].

▶ **Example 5.** Table 1 shows a classic example of a two-player zero-sum game known as *matching pennies*. Columns α and u_i represent the collective choice (profile) and player i's utility, respectively. In this example, each player has a coin for which they may choose the value to be heads or tails, i.e., $A_i = \{\mathit{heads}_i, \mathit{tails}_i\}$. If the coins match, player 1 wins the round, which is indicated by being awarded a utility of 1, while player 2 receives utility -1. If the coins do not match, then the players' utilities are negated.

Table 1 Matching pennies game in normal form.

α	$u_1(\alpha)$	$u_2(\alpha)$	α	$u_1(\alpha)$	$u_2(\alpha)$
$(\mathit{heads}_1, \mathit{heads}_2)$	1	-1	$(\mathit{tails}_1, \mathit{heads}_2)$	-1	1
$(\mathit{heads}_1, \mathit{tails}_2)$	-1	1	$(\mathit{tails}_1, \mathit{tails}_2)$	1	-1

The value for the corresponding matrix game is the solution to the following LP problem: Maximise v subject to:

$$x_1 - x_2 \geqslant v, \; x_2 - x_1 \geqslant v, \; x_1 + x_2 = 1$$

which yields the value $v^\star = 0$ with optimal strategy $\sigma_1^\star = (\frac{1}{2}, \frac{1}{2})$ for player 1 (the optimal strategy for player 2 is the same).

2.2 Nonzero-sum NFGs

The requirement for players to have directly opposing objectives is often too limiting, and it is necessary to allow distinct objectives, which cannot be modelled in a zero-sum fashion. These scenarios can be captured using the notion of *equilibria*, defined by a separate, independent objective for each agent. We now define the concepts of *Nash equilibrium* [57] and *correlated equilibrium* [6] for NFGs, which ensure stability against deviations by individual agents, improving the overall game outcomes. Since many equilibria may exist, we also introduce optimality criteria for these equilibria: *social welfare*, which is standard [46], and *social fairness*, which was first defined in [35].

Before giving the formal definitions, we first extend our notation as follows: for any profile σ and strategy $\sigma_i^\star$, the strategy tuple σ_{-i} corresponds to σ with the strategy of player i removed and $\sigma_{-i}[\sigma_i^\star]$ to the profile σ after replacing player i's strategy with $\sigma_i^\star$.

▶ **Definition 6** (Best response). *For any nonzero-sum NFG* N *and profile* σ *or correlated profile* (τ, ς) *of* N*, the* best response *moves for player* i *to* σ_{-i} *and* (τ, ς_{-i}) *are, respectively:*

- *a strategy* $\sigma_i^\star$ *for player* i *such that* $u_i(\sigma_{-i}[\sigma_i^\star]) \geqslant u_i(\sigma_{-i}[\sigma_i])$ *for all* $\sigma_i \in \Sigma^i_{\mathsf{N}}$*;*
- *a function* $\varsigma_i^\star \colon D_i \to A_i$ *for player* i *such that* $u_i(\tau, \varsigma_{-i}[\varsigma_i^\star]) \geqslant u_i(\tau, \varsigma_{-i}[\varsigma_i])$ *for all functions* $\varsigma_i \colon D_i \to A_i$*.*

▶ **Definition 7** (NE and CE). *For any nonzero-sum NFG* N*, a strategy profile* $\sigma^\star$ *is a* Nash equilibrium *(NE) and a correlated profile* $(\tau, \varsigma^\star)$ *of* N *is a* correlated equilibrium *(CE) if:*

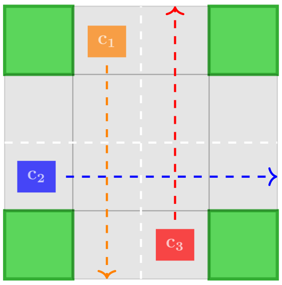
- $\sigma_i^\star$ *is a best response to* $\sigma_{-i}^\star$ *for all* $i \in N$*;*
- $\varsigma_i^\star$ *is a best response to* $(\tau, \varsigma_{-i}^\star)$ *for all* $i \in N$*;*

respectively.

Any NE of N is also a CE, while there exist CEs that cannot be represented by a strategy profile, and therefore are not NEs. For each class of equilibria, NE and CE, we introduce two optimality criteria, the first maximising *social welfare* (SW), defined as the *sum* of the utilities, and the second maximising *social fairness* (SF), which minimises the *difference* between the players' utilities. Other variants of fairness have been considered for NEs, such as in [38], where the authors seek to maximise the lowest utility among the players.

▶ **Definition 8** (SW and SF). *An equilibrium* $\sigma^\star$ *is a* social welfare *(SW) equilibrium if the sum of the utilities of the players under* $\sigma^\star$ *is maximal over all equilibria, while* $\sigma^\star$ *is a* social fair *(SF) equilibrium if the difference between the player's utilities under* $\sigma^\star$ *is minimised over all equilibria.*

We can also define the dual concept of *social cost* (SC) equilibria [34], where players try to minimise, rather than maximise, their expected utilities by considering equilibria of the game $\mathsf{N}^- = (N, A, -u)$ in which the utilities of N are negated. We remark that SC equilibria strategies are not a subset of classically defined NE or CE strategies of N.



α	$u_1(\alpha)$	$u_2(\alpha)$	$u_3(\alpha)$
(pro_1, pro_2, pro_3)	-1000	-1000	-100
(pro_1, pro_2, yld_3)	-1000	-100	-5
(pro_1, yld_2, pro_3)	5	-5	5
(pro_1, yld_2, yld_3)	5	-5	-5
(yld_1, pro_2, pro_3)	-5	-1000	-100
(yld_1, pro_2, yld_3)	-5	5	-5
(yld_1, yld_2, pro_3)	-5	-5	5
(yld_1, yld_2, yld_3)	-10	-10	-10

Figure 1 Example from [35]: Cars at an intersection and the corresponding NFG.

▶ **Example 9.** Consider the scenario from [35], based on an example from [50], where three cars meet at an intersection and want to proceed as indicated by the arrows in Figure 1. Each car can either *proceed* or *yield*. If two cars with intersecting paths proceed, then there is an accident. If an accident occurs, the car having the right of way, i.e., the other car is to its left, has a utility of −100 and the car that should yield has a utility of −1000. If a car proceeds without causing an accident, then its utility is 5 and the cars that yield have a utility of −5. If all cars yield, then, since this delays all cars, all have utility −10. The 3-player NFG is given in Figure 1. The different optimal equilibria of the NFG are:

- the SWNE and SWCE are the same: for c_2 to yield and c_1 and c_3 to proceed, with the expected utilities of the players $(5, -5, 5)$;
- the SFNE is for c_1 to yield with probability 1, c_2 to yield with probability 0.863636 and c_3 to yield with probability 0.985148, with the expected utilities of the players $(-9.254050, -9.925742, -9.318182)$;
- the SFCE gives a joint distribution where the probability of c_2 yielding and of c_1 and c_3 yielding are both 0.5 with the expected utilities of the players $(0, 0, 0)$.

Modifying u_2 such that $u_2(pro_1, pro_2, pro_3) = -4.5$ to, e.g., represent a reckless driver, the SWNE becomes for c_1 and c_3 to yield and c_2 to proceed with the expected utilities of the players $(-5, 5, -5)$, while the SWCE is still for c_2 to yield and c_1 and c_3 to proceed. The SFNE and SFCE also do not change.

Algorithms for computing equilibria in NFGs. Finding NEs in two-player NFGs is in the class of *linear complementarity* problems (LCPs). Established algorithms include the Lemke-Howson algorithm [37], which is based on the method of labelled polytopes [46], support enumeration [48] and regret minimisation [52]. In [34] a method for NE computation is developed, which reduces the problem to SMT via labelled polytopes [46] by considering the regions of the strategy profile space. This method iteratively reduces the search space of profiles as positive probability assignments are found and added as constraints on the profiles. This approach can also be used for finding both an SWNE and SFNE by computing all NEs and then selecting an optimal one.

In the case of NFGs with more than two players, the computation of NEs is more complex since, for a given support (i.e., a sub-region of the strategy profile space which fixes the set of actions chosen with nonzero probability by each player), finding NEs cannot be reduced to an LP problem. A method for such NFGs is presented in [32], based on support enumeration [48], which exhaustively examines all supports one at a time, checking whether that sub-region contains NEs. For each support, finding an SWNE can be reduced to a *nonlinear programming problem* [32]. This nonlinear programming problem can be modified to find an SFNE in each support [35].

In the case of CEs, the approach introduced in [35] is to first find a joint strategy for the players, i.e., a distribution over the action tuples, which can then be mapped to a correlated profile. For SWCEs, [35] reduces the computation to solving a LP problem which has $|A|$ variables, one for each action tuple, and $\sum_{i \in N}(|A_i|^2 - |A_i|) + |A| + 1$ constraints. For SFCEs, on the other hand, the method of [35] involves solving an optimisation problem with an additional has $|N| + 2$ variables and $3 \cdot |N|$ constraints compared to the LP problem for finding SWCEs.

3 Concurrent Stochastic Games

This section introduces *concurrent stochastic games* (CSGs) [54], in which players repeatedly make simultaneous choices over actions and the action choices cause a probabilistic update of the game state. CSGs thus provide a natural framework for modelling a set of interactive, rational agents operating concurrently within an uncertain or probabilistic environment. Compared to normal form games, they are classified as *multi-stage*, which is more convenient for specifying repeated or sequential interactions among agents. The introduction of stochasticity facilitates modelling of a wide range of important phenomena, for example uncertain behaviour due to noisy sensors or unreliable hardware in a multi-robot system, or the use of randomisation for coordination in a distributed security or networking protocol.

▶ **Definition 10** (Concurrent stochastic game). *A concurrent stochastic multi-player game (CSG) is a tuple $\mathsf{G} = (N, S, \bar{s}, A, \Delta, \delta)$ where:*

- *$N = \{1, \dots, n\}$ is a finite set of players;*
- *S is a finite set of states and $\bar{s} \in S$ is an initial state;*
- *$A = (A_1 \cup \{\bot\}) \times \cdots \times (A_n \cup \{\bot\})$ where A_i is a finite set of actions available to player $i \in N$ and $\bot$ is an idle action disjoint from the set $\cup_{i=1}^n A_i$;*
- *$\Delta \colon S \to 2^{\cup_{i=1}^n A_i}$ is an action assignment function;*
- *$\delta \colon S \times A \to \mathit{Dist}(S)$ is a probabilistic transition function.*

Given a CSG G, the set of actions available to player $i \in N$ in state $s \in S$ is given by $A_i(s) \overset{\text{def}}{=} \Delta(s) \cap A_i$. The CSG G starts in the initial state $\bar{s}$ and, if G is in the game state s, then each player $i \in N$ selects an action from its available actions in state s if this set is non-empty, and from $\{\bot\}$ otherwise. Next, supposing each player $i \in N$ chooses action a_i, the game state is updated according to the distribution $\delta(s, (a_1, \dots, a_n))$. We allow sets of players $C \subseteq N$ to form *coalitions*, and will consider the induced CSG, called the *coalition game*, with coalitions as players.

A *path* π of a CSG G is a sequence $\pi = s_0 \xrightarrow{\alpha_0} s_1 \xrightarrow{\alpha_1} \cdots$, where $s_i \in S$, $\alpha_i \in A$ and $\delta(s_i, \alpha_i)(s_{i+1}) > 0$ for all $i \geqslant 0$. We denote by $\mathit{FPaths}_{\mathsf{G},s}$ and $\mathit{IPaths}_{\mathsf{G},s}$ the sets of finite and infinite paths starting in state s of G, respectively, and drop the subscript s when considering all finite and infinite paths of G. As for NFGs, we can define *strategies* of G that resolve the choices of the players. Here, a strategy for player i is a function $\sigma_i \colon \mathit{FPaths}_{\mathsf{G}} \to \mathit{Dist}(A_i \cup \{\bot\})$ mapping finite paths to distributions over available actions, such that, if $\sigma_i(\pi)(a_i) > 0$, then $a_i \in A_i(\mathit{last}(\pi))$ where $\mathit{last}(\pi)$ is the final state of π. Furthermore, we can define strategy profiles, correlated profiles and joint strategies analogously to Section 2.

A *labelled* CSG is a tuple (G, AP, L), where G is a CSG, as in Definition 10, AP is a set of atomic propositions and $L \colon S \to 2^{AP}$ is a labelling function, specifying which atomic propositions are true in each state. We also associate CSGs with *reward structures*, which annotate states and transitions with real values. More precisely a reward structure is a pair $r = (r_A, r_S)$ consisting of an action reward function $r_A \colon S \times A \to \mathbb{R}$ and state reward function $r_S \colon S \to \mathbb{R}$. We use atomic propositions and rewards as the building blocks to specify players' utilities in a CSG, which will be described in Section 4.

Formally, the utility function or *objective* of player i in a CSG is given by a random variable $X_i \colon \mathit{IPaths}_{\mathsf{G}} \to \mathbb{R}$ over infinite paths. For a profile σ and state s, using standard techniques [31], we can construct a probability measure $\mathit{Prob}^{\sigma}_{\mathsf{G},s}$ over the paths that start in state s corresponding to σ, denoted $\mathit{IPaths}^{\sigma}_{\mathsf{G},s}$, and define the expected value $\mathbb{E}^{\sigma}_{\mathsf{G},s}(X_i)$ of player i's utility from s under σ. Similarly, we can also define such a probability measure and expected value given a correlated profile or joint strategy of G.

3.1 Zero-sum CSGs

Similarly to NFGs (see Section 2.1), *zero-sum* CSGs are two-player games that have a single utility function X for player 1, with the utility function of player 2 given by $-X$, and both players aiming to maximise the expected value of their utility. Equivalently, we can suppose that player 1 tries to maximise the expected value of X, while player 2 tries to minimise it. As for NFGs (see Theorem 4), a CSG has a *value* with respect to X if it is determined, i.e., if the maximum value that player 1 can ensure equals the minimum value that player 2 can ensure when starting from any state of the CSG. Since the CSGs we discuss in this paper are finite-state and finitely-branching, it follows that they are determined for all of the objectives that we consider [44].

Given a multi-player CSG and objective X, we can divide the players into two coalitions, $C \subseteq N$ and $N \backslash C$, and then construct a *two-player* zero-sum coalition game, in which each coalition acts as a single player, with one coalition trying to maximise the value of X and the other trying to minimise that value.

3.2 Nonzero-sum CSGs

We define *nonzero-sum* CSGs similarly to NFGs: we assume that there is a distinct and independent objective X_i for each player i (or coalitions of players). We can then define NE and CE for CSGs (see Definition 7), as well as the restricted classes of SW and SF equilibria, similarly to those for NFGs (see Definition 8). Following [34, 32], we focus on *subgame-perfect* equilibria [47], which are equilibria in *every state* of G. Furthermore, because we include infinite-horizon objectives, where the existence of NE is an open problem [7], we will in some cases use ε-NE, which do exist for any $\varepsilon > 0$ for all the infinite-horizon objectives we consider.

▶ **Definition 11** (Subgame-perfect ε-NE)**.** *For CSG G and $\varepsilon > 0$, a strategy profile $\sigma^\star$ is a* subgame-perfect ε-Nash equilibrium *for objectives $\langle X_i \rangle_{i \in N}$ if and only if $\mathbb{E}^{\sigma^\star}_{\mathsf{G},s}(X_i) \geqslant \sup_{\sigma_i \in \Sigma_i} \mathbb{E}^{\sigma^\star_{-i}[\sigma_i]}_{\mathsf{G},s}(X_i) - \varepsilon$ for all $i \in N$ and $s \in S$.*

▶ **Example 12.** As an example scenario that can be modelled as a CSG, consider a number of users trying to send packets using the slotted ALOHA protocol studied in [32, 34, 35]. If there is a collision or if sending a packet fails, a user waits for some number of slots before resending, with the wait set according to an exponential backoff scheme.

If we model this scenario as a CSG then, when a player has a packet to send, the actions available to the player correspond to either sending their packet or waiting to send the packet at some future time step. In the case when one coalition of players has an objective related to sending their packets efficiently, e.g., minimising the expected time to send their packets, and the remaining players form a second coalition and have the dual objective, we can model this scenario as a zero-sum CSG. In such a zero-sum CSG, the optimal strategy for the first coalition is to try and choose times to send that avoid collisions, while the second coalition will do the opposite and instead try and cause collisions. On the other hand, when there are more coalitions and each coalition's goal corresponds to sending their own packets efficiently, we can model this as a nonzero-sum CSG. Here we would be looking for equilibria, i.e., profiles such that no coalition could improve its objective by changing its strategy, which are also optimal, e.g., the sum of the expected times is minimal or the difference between the expected time to send for each coalition is minimal.

4 Property specifications and model checking for CSGs

Probabilistic model checking is a technique for systematically constructing a stochastic model and analysing it against a quantitative property formally specified in temporal logic. This approach can be used either to *verify* that a specification is always satisfied or to perform *strategy synthesis*, i.e., to construct a witness to the satisfaction of a property. In the context of CSGs, the latter means synthesising strategies for one or more players (or coalitions) such that the resulting behaviour of the game satisfies the specification.

To specify properties of labelled CSGs, we use the property specification language of the PRISM-games model checker [33], which is based on the logic PCTL (probabilistic computation tree logic) [26], extended with operators to specify expected reward properties [21] and the *coalition* operator $\langle\langle C\rangle\rangle$ from alternating temporal logic (ATL) [4]. The variant of this logic that just considers *zero-sum* formulae is referred to as rPATL (probabilistic alternating-time temporal logic with rewards) in [15], but here we use a further extended version that also supports *nonzero-sum* properties, using the notion of equilibria [34, 35].

▶ **Definition 13** (PRISM-games logic [34, 35]). *The syntax of the PRISM-games logic is given by the grammar:*

$$
\begin{array}{lcl}
\phi & \coloneqq & \mathtt{true} \mid \mathsf{a} \mid \neg\phi \mid \phi\wedge\phi \mid \langle\langle C\rangle\rangle\mathtt{P}_{\sim q}[\,\psi\,] \mid \langle\langle C\rangle\rangle\mathtt{R}^{r}_{\sim x}[\,\rho\,] \mid \langle\langle \mathbb{C}\rangle\rangle(\star_1,\star_2)_{\mathrm{opt}\sim x}(\theta) \\
\psi & \coloneqq & \mathtt{X}\,\phi \mid \phi\ \mathtt{U}^{\leqslant k}\ \phi \mid \phi\ \mathtt{U}\ \phi \\
\rho & \coloneqq & \mathtt{I}^{=k} \mid \mathtt{C}^{\leqslant k} \mid \mathtt{F}\ \phi \\
\theta & \coloneqq & \mathtt{P}[\,\psi\,]{+}\cdots{+}\mathtt{P}[\,\psi\,] \mid \mathtt{R}^{r}[\,\rho\,]{+}\cdots{+}\mathtt{R}^{r}[\,\rho\,]
\end{array}
$$

where a *is an atomic proposition,* $\mathbb{C} = C_1{:}\cdots{:}C_m$*,* C *and* $C_1,\dots,C_m$ *are coalitions of players such that* $C' = N\backslash C$*,* $C_i\cap C_j = \varnothing$ *for all* $1\leqslant i\neq j\leqslant m$*,* $(\star_1,\star_2)\in\{\mathrm{NE},\mathrm{CE}\}\times\{\mathrm{SW},\mathrm{SF}\}$*,* $\mathrm{opt}\in\{\min,\max\}$*,* $\sim\in\{<,\leqslant,\geqslant,>\}$*,* $q\in\mathbb{Q}\cap[0,1]$*,* $x\in\mathbb{Q}$*,* r *is a reward structure and* $k\in\mathbb{N}$*.*

The syntax distinguishes between state (ϕ), path (ψ) and reward (ρ) formulae. State formulae are evaluated over states of a CSG, while path and reward formulae are both evaluated over paths. Sums of formulae (θ) are used to specify multiple objectives for equilibria.

We omit the formal semantics, which can be found in [34, 35]. Path and reward formulae are used to express the utilities of the players, i.e., random variables over paths. For path formulae, we allow *next* ($\mathtt{X}\,\phi$), *bounded until* ($\phi\ \mathtt{U}^{\leqslant k}\ \phi$) and *unbounded until* ($\phi\ \mathtt{U}\ \phi$). We also allow the usual equivalences such as $\mathtt{F}\ \phi \equiv \mathtt{true}\ \mathtt{U}\ \phi$ (i.e., *probabilistic reachability*) and $\mathtt{F}^{\leqslant k}\ \phi \equiv \mathtt{true}\ \mathtt{U}^{\leqslant k}\ \phi$ (i.e., *bounded probabilistic reachability*). The random variable corresponding to the path formula ψ returns 1 for paths that satisfy ψ and zero otherwise. For reward formulae, we allow instantaneous (state) reward at the kth step (*instantaneous reward* $\mathtt{I}^{=k}$), reward accumulated over k steps (*bounded cumulative reward* $\mathtt{C}^{\leqslant k}$), and reward accumulated until a formula ϕ is satisfied (*expected reachability* $\mathtt{F}\ \phi$). The random variable corresponding to the reward formula ρ returns for a path the reward corresponding to ρ.

4.1 Zero-sum formulae

A state satisfies a formula $\langle\langle C\rangle\rangle\mathtt{P}_{\sim q}[\,\psi\,]$ if the coalition of players $C \subseteq N$ can ensure that the probability of the path formula ψ being satisfied is $\sim q$, regardless of the actions of the other players $(N \backslash C)$ in the game. A state satisfies a formula $\langle\langle C\rangle\rangle\mathtt{R}^{r}_{\sim x}[\,\rho\,]$ if the players in C can ensure that the expected value of the reward formula ρ for reward structure r is $\sim x$, whatever the other players do.

The model checking algorithms presented in [34] involve graph-based analysis followed by backward induction [53, 57] for exact computation of *finite-horizon properties* and value iteration [51, 12] for approximate computation of *infinite-horizon properties*. During both backward induction and value iteration for each state, at each iteration, an LP problem of size $|A|$ must be solved (corresponding to finding the value of a zero-sum one-shot game), which has complexity PTIME [30].

Strategy synthesis for the formulae $\langle\langle C\rangle\rangle\mathtt{P}_{\sim q}[\,\psi\,]$ and $\langle\langle C\rangle\rangle\mathtt{R}^{r}_{\sim x}[\,\rho\,]$ corresponds to finding optimal strategies for the players in coalition C when their objective, respectively, is maximising the probability of satisfying the formula ψ and maximising the expected value of the reward formula with respect to the reward structure r. All strategies synthesised are randomised and can be found during model checking by extracting not just the value of the zero-sum one-shot game solved in each state, but also an optimal (randomised) strategy. For infinite-horizon objectives, the synthesised strategies are memoryless, while for finite-horizon objectives, the synthesised strategies are finite-memory, with a separate distribution required for each state and each time step.

4.2 Nonzero-sum formulae

Nonzero-sum formulae allow us to reason about equilibria, for either of the types (NE or CE) and optimality criteria (SW or SF) considered here. A probabilistic formula $\langle\langle C_1{:}\cdots{:}C_m\rangle\rangle(\star_1,\star_2)_{\max\sim x}(\mathtt{P}[\,\psi_1\,]{+}\cdots{+}\mathtt{P}[\,\psi_m\,])$ is true in a state if, when the players form the coalitions $C_1,\dots,C_m$, there is a subgame-perfect equilibrium of type $\star_1$ meeting the optimality criterion $\star_2$ for which the *sum* of the values of the objectives $\mathtt{P}[\,\psi_1\,],\dots,\mathtt{P}[\,\psi_m\,]$ for the coalitions $C_1,\dots,C_m$ satisfies $\sim x$. The objective of coalition C_i is to maximise the probability of satisfying a path formula ψ_i.

For a reward formula $\langle\langle C_1{:}\cdots{:}C_m\rangle\rangle(\star_1,\star_2)_{\max\sim x}(\mathtt{R}^{r_1}[\,\rho_1\,]{+}\cdots{+}\mathtt{R}^{r_m}[\,\rho_m\,])$ the meaning is similar; however, here the objective of coalition C_i refers to a reward formula ρ_i with respect to reward structure r_i. Formulae of the form $\langle\langle C_1{:}\cdots{:}C_m\rangle\rangle(\star_1,\star_2)_{\min\sim x}(\theta)$ correspond to the dual notion of cost equilibria, which are also supported. We also allow *numerical* queries of the form $\langle\langle C_1{:}\cdots{:}C_m\rangle\rangle(\star_1,\star_2)_{\mathrm{opt}=?}(\theta)$, which return the sum of the subgame-perfect equilibrium's values of of type $\star_1$ meeting the optimality criterion $\star_2$.

Model checking algorithms, presented in [34, 32, 35], involve solving an m-player *coalition game* $\mathsf{G}^{\mathcal{C}}$, where $\mathcal{C} = \{C_1,\dots,C_m\}$ and the choices of each player i in $\mathsf{G}^{\mathcal{C}}$ correspond to the choices of the players in coalition C_i in G. If all the objectives in θ are finite-horizon, then *backward induction* [53, 57] can be applied to compute (precise) optimal equilibria values. On the other hand, if all the objectives are infinite-horizon, *value iteration* [12] can be used to approximate optimal equilibria values. When there is a combination of finite- and infinite-horizon objectives, the game under study is modified in a standard manner to make all objectives infinite-horizon.

Both backward induction and value iteration over the CSG $\mathsf{G}^{\mathcal{C}}$ work by iteratively computing new values for each state s of $\mathsf{G}^{\mathcal{C}}$. The values for each state, in each iteration, are found by computing optimal equilibria values, with respect to the criterion $\star_2$ and equilibrium type $\star_1$, of an NFG N whose utility function is derived from the outgoing transition probabilities from s in the CSG and the values computed for successor states of s in the previous iteration.

We can synthesise a strategy profile representing the appropriate type of equilibrium for the CSG by combining the optimal strategies for the equilibria generated in each individual state during solution. As for zero-sum formulae, randomisation is required and memory is needed both to keep track of both the step bound of finite-horizon objectives and the satisfaction of each player's objective.

▶ **Example 14.** We now return to the scenario from Example 12, where a number users are attempting to send packets using the slotted ALOHA protocol. The zero-sum formulae $\langle\langle \mathit{usr}_1, \ldots, \mathit{usr}_k \rangle\rangle \mathtt{R}^{\mathit{time}}_{\min=?}[\,\mathtt{F}\ \mathsf{sent}_{1\ldots k}\,]$ and $\langle\langle \mathit{usr}_1, \ldots, \mathit{usr}_k \rangle\rangle \mathtt{P}_{\max=?}[\,\mathtt{F}\ \mathsf{sent}_{1\ldots k} \wedge t \leqslant D\,]$ represent the case where the first k users form a coalition and try to minimise the expected time to send their packets or maximise the probability they send their packets within a deadline $D \in \mathbb{N}$, respectively, while the remaining users form a second coalition and try and achieve the opposite objective, i.e., maximise the expected time or minimise the probability.

On the other hand, in the nonzero-sum case, if we suppose there are m users and the objective of each user is to minimise the expected time to send their packet, this can be expressed by the nonzero-sum formula $\langle\langle \mathit{usr}_1{:}\cdots{:}\mathit{usr}_m \rangle\rangle (\star_1, \star_2)_{\min=?}(\mathtt{R}^{\mathit{time}}[\,\mathtt{F}\ \mathsf{sent}_1\,]{+}\cdots{+}\mathtt{R}^{\mathit{time}}[\,\mathtt{F}\ \mathsf{sent}_m\,])$.

5 Tool support and case studies

Tool support for the modelling and automated verification of CSGs has been implemented in PRISM-games [33], which is available from [61]. A variety of case studies have been modelled and analysed as CSGs with the tool, using both zero-sum and nonzero-sum properties. These include: a robot coordination problem [34]; futures market investors [34, 35]; medium access control [32, 34]; power control [34, 35]; a public good game [32, 35] and secret sharing [32]. The results for these case studies demonstrate: the advantages of using CSGs for modelling (for example, with respect to simpler turn-based games); that using nonzero-sum properties can yield gains for the players (or coalitions); and that the use of correlated equilibria and social fairness results may be advantageous compared to Nash equilibria and social welfare. We give a brief description of the functionality and implementation of PRISM-games and then present a representative case study: the slotted ALOHA protocol.

5.1 PRISM-games

PRISM-games [33] is an extension of the PRISM model checker, which provides support for a variety of stochastic game models, including turn-based and concurrent multi-player stochastic games, and (turn-based) timed probabilistic games.

These are all described in the PRISM-games modelling language, a stochastic extension of the Reactive Modules formalism [3]. The language facilitates the specification of systems comprising multiple components, referred to as modules, that operate in parallel, both asynchronously and synchronously through action labels. Each module has a number of finite-valued variables and a state of the system specifies the values of the variables of all modules. The behaviour of each module is defined by probabilistic guarded commands, where the guard is a predicate over the variables of the modules and the command specifies a probabilistic update of the module's variables. In a CSG model, each player constitutes a set of modules, and these therefore execute concurrently.

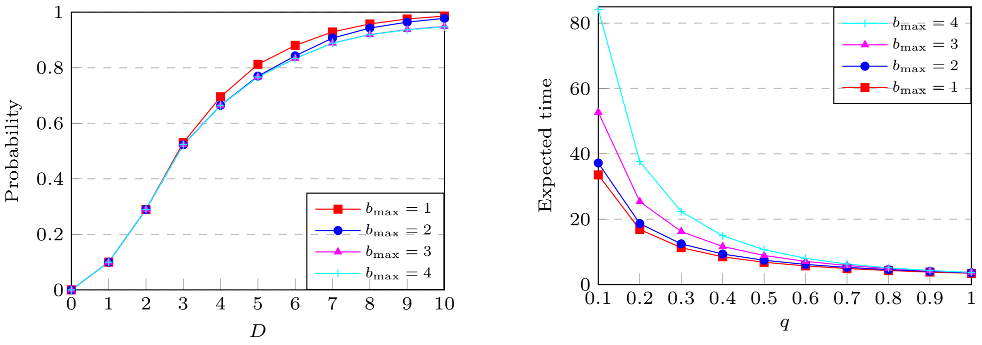


Figure 2 Results from a CSG model of the ALOHA protocol: one user maximising the probability of sending their packet before a deadline D (left); and minimising the expected time to send the packet, assuming a message transmission failure probability q (right).

PRISM-games provides a graphical user interface for designing and simulating stochastic games models, but its core functionality is to exhaustively construct a game and perform verification and strategy synthesis against a logical specification. For CSGs, the PRISM-games logic described in Definition 13 is supported, and the resulting strategies can be exported, simulated or further verified.

The implementation of CSG model checking is built within PRISM's "explicit" engine, which is based on sparse matrices and implemented in Java. Computing values (and optimal strategies) for zero-sum NFGs, needed for zero-sum formulae, is performed using the LPSolve library [41] via linear programming. The computation of SWNE or SFNE for nonzero-sum NFG, required for nonzero-sum formulae, depends on the number of players. For two players [34], labelled polytopes are used to characterise and find NE values through a reduction to SMT in both Z3 [19] and Yices [20]. If there are more than two players, the implementation [32] is based on support enumeration and uses a combination of the SMT solver Z3 [19] and the nonlinear optimisation suite Ipopt [58]. In the case of SWCE for nonzero-sum NFGs, as the problem reduces to an LP problem [35], either Gurobi [22] or the SMT solver Z3 [19] is used. Finally, for SFCE, since the problem does not reduce directly to an LP problem, only Z3 can be used.

5.2 The ALOHA case study

We now return to the slotted ALOHA protocol discussed in Examples 12 and 14 to illustrate the benefits of game-theoretic analysis with CSGs. For further details of this case study, as well as several others, see [61]. Recall that, in the slotted ALOHA protocol, a number of users are attempting to send packets on a shared medium. We assume that, in any time slot, if a single user tries to send a packet then there is a probability (q) that the packet is sent and, as more users try and send, then the probability of success decreases. If sending a packet fails, the user waits for a number of slots before resending, defined according to an exponential backoff scheme. More precisely, each user maintains a backoff counter, which it increases each time there is a failure (up to $b_{\max}$) and, if the counter equals k, randomly chooses the slots to wait from $\{0, 1, \ldots, 2^k{-}1\}$.

Zero-sum properties. We first consider the zero-sum properties $\langle\langle usr_1 \rangle\rangle \mathtt{P}_{\max=?}[\,\mathtt{F}^{\leqslant D}\mathtt{sent}_1\,]$ and $\langle\langle usr_1 \rangle\rangle \mathtt{R}^{time}_{\min=?}[\,\mathtt{F}\ \mathtt{sent}_1\,]$ from Example 14, which correspond to the first user trying to maximise the probability that their packet is sent before a deadline and trying to minimise

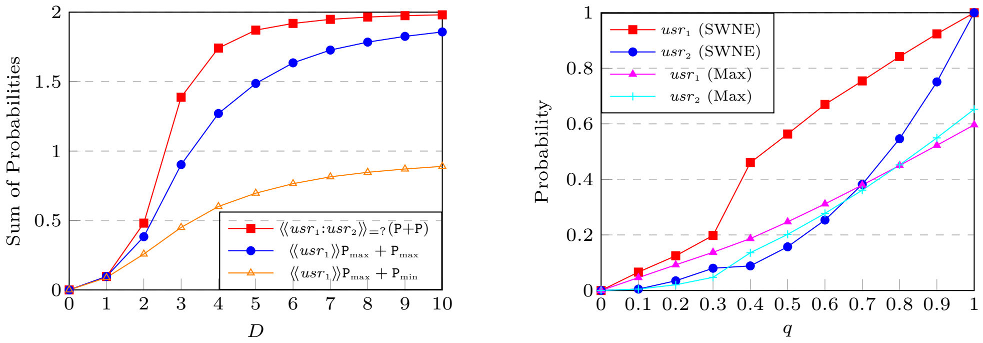

Figure 3 Results from CSG equilibria synthesis on the ALOHA protocol, maximising the probabilities of sending packets by deadline D for two coalitions (user 1, and users 2 and 3): probability sums (left) and individual probabilities (right).

the expected time to send their packet, respectively. The results for the first property when $q = 0.9$ as the deadline D varies, and for the second property as the probability q varies, are presented in Figure 2 for different values of $b_{\max}$. We see that the probability decreases and the expected time decreases as $b_{\max}$ increases; this is because, as $b_{\max}$ increases, the additional time the first user can spend in backoff outweighs the gains in reducing the chance of avoiding further collisions. By performing strategy synthesis we see that it is optimal for the first user to initially randomly decide as to when to send their packet in order to avoid collisions with the coalition of the second and third user. However, this changes to a deterministic strategy of just sending its packet when the other users have sent their packets or the deadline is getting close, and therefore waiting will mean the deadline is missed.

Benefits of equilibria. We next highlight the analysis from [34], which demonstrates the advantages of cooperation through nonzero-sum properties when using Nash equilibria (NE) and the social welfare (SW) optimality criterion, as opposed to adopting a strategy that assumes antagonistic behaviour. The first non-zero sum property we consider corresponds to the case when each user is trying to maximise the probability of sending their packet before a deadline D, with users 2 and 3 forming a coalition, represented by the formula $\langle\langle usr_1{:}usr_2{,}usr_3\rangle\rangle(\text{NE}, \text{SW})_{\max=?}(\mathtt{P}[\,\mathtt{F}\ (\mathsf{sent}_1 \wedge t{\leqslant}D)\,] + \mathtt{P}[\,\mathtt{F}\ (\mathsf{sent}_2 \wedge \mathsf{sent}_3 \wedge t{\leqslant}D)\,])$.

Figure 3 presents total values (the sum of the probabilities for user 1 and the coalition of user 2 and 3) as D varies (left) and individual values as q varies (right). By performing strategy synthesis, the analysis found that the collaboration is dependent on both D and q. In particular, if the users have more time there is a greater chance for the users to collaborate by sending in different slots, whereas, when q is large, it is unlikely users need to repeatedly send, so again can send in different slots. As Figure 3 (right) demonstrates, since the coalition has more packets to send, their probabilities are lower.

Equilibria types and optimality criteria. Finally, we report on the experiments of [35], which investigate the benefits of using different types of equilibria, i.e., *correlated* (CE) over *Nash* equilibria, and optimality criteria, i.e., *social fairness* (SF) over *social welfare* (SW). The experiments varied the number of users and considered the case when the objective of each individual user is to minimise the expected time to send their packet, which is represented by the nonzero-sum formula $\langle\langle usr_1{:}\cdots{:}usr_m\rangle\rangle(\star_1, \star_2)_{\min=?}(\mathtt{R}^{time}[\,\mathtt{F}\ \mathsf{sent}_1\,]{+}\cdots{+}\mathtt{R}^{time}[\,\mathtt{F}\ \mathsf{sent}_m\,])$.

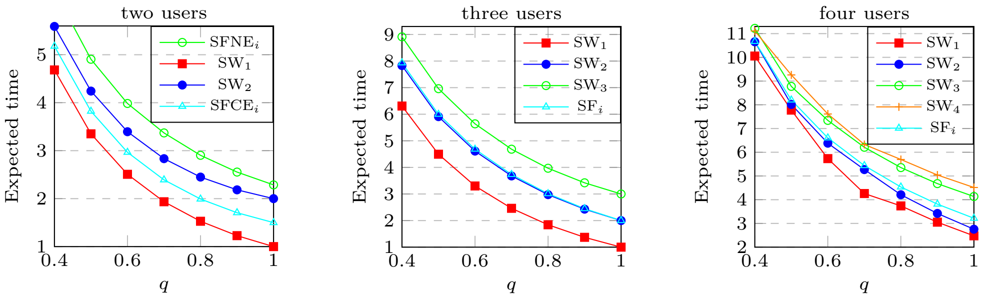

Figure 4 Results from different types of equilibria (correlated vs. Nash) and optimality criteria (social fairness vs. social welfare) for minimising the expected times for users to send packets in the ALOHA protocol., for varying numbers of users.

Synthesising optimal strategies for this specification, it was found that the cases for SWNE and SWCE coincide (although SWCE returns a joint strategy for the users, this joint strategy can be separated to form a strategy profile). This profile required one user to try and send first, and then for the remaining users to take turns to try and send afterwards. If a user fails to send, then they enter backoff and allow all remaining users to try and send before trying to send again. The reason for this is that there is no gain in a user trying to send at the same time as another user, as this will increase the probability of a collision and thus their packets not being sent, and therefore the users having to spend time in backoff.

For SFNE, which has only been implemented for the two-player case, the two users followed identical strategies, which involve randomly deciding whether to wait or transmit, unless they are the only user that has not transmitted, and then they always try to send when not in backoff. In the case of SFCE, users employed a shared probabilistic signal to coordinate which user sends next. Initially, this was a uniform choice over the users, but as time progresses the signal favoured the users with lower backoff counters as these users had fewer opportunities to send their packet previously.

Figure 4 plots the optimal values for the users, where SW$_i$ corresponds to the optimal values (expected times to send their packets) for user i for both SWNE and SWCE for the cases of two, three and four users. We see that the optimal values for the different users under SFNE and SFCE coincide, while under SWNE and SWCE they are different for each user (with the user sending first having the lowest and the user sending last the highest). Comparing the sum of the SWNE (and SWCE) values and that of the SFCE values, we see a small decrease in the sum of less than 2% of the total, whereas for SFNE there is a greater difference as the users cannot coordinate, and hence try and send at the same time.

6 Recent Developments: Neuro-symbolic CSGs

The recent encouraging advances of AI, and particularly deep learning, have resulted in computing architectures that integrate components that are synthesized from data (e.g., implemented as neural networks) with conventional, symbolic modules (e.g., controllers). Design automation support for such *neuro-symbolic* systems is, however, lacking. To this end, we have developed the model of *neuro-symbolic concurrent stochastic games* (NS-CSGs) [60, 59], which is targeted at AI-based autonomous systems, e.g., autonomous driving or aircraft controllers. NS-CSGs are a variant of (continuous-space) CSGs, in which each player is a neuro-symbolic *agent* and the agents act concurrently in a shared, continuous-state environment. As for the players of CSGs, each agent has a finite set of available actions and agents choose their actions simultaneously; however, in NS-CSGs the action choices cause the agents' local states to be updated probabilistically and the agents are endowed with a perception mechanism implemented as a neural network, through which they can observe the local states of the other agents and that of the environment and encode these observations as locally stored *percepts*. The global states of NS-CSGs comprise the state of the environment together with the local state and percept of each agent, and are therefore infinite-state, in contrast to the CSGs discussed in the rest of this paper.

▶ **Definition 15** (Neuro-symbolic concurrent stochastic game [60, 59]). *A* neuro-symbolic concurrent stochastic multi-player game *(NS-CSG)* NSC *comprises players* $(\mathsf{Ag}_i)_{i\in N}$*, for* $N = \{1,\dots,n\}$*, and an environment* E *where:*

$$\mathsf{Ag}_i = (S_i, A_i, \Delta_i, obs_i, \delta_i) \text{ for } i \in N, \quad E = (S_E, \delta_E)$$

and we have:

- $S_i = Loc_i \times Per_i$ *is a set of states for* Ag_i*, where* $Loc_i \subseteq \mathbb{R}^{b_i}$ *and* $Per_i \subseteq \mathbb{R}^{d_i}$ *are finite sets of local states and percepts, respectively;*
- $S_E \subseteq \mathbb{R}^e$ *is a closed infinite set of environment states;*
- A_i *is a nonempty finite set of actions for* Ag_i *and* $A := (A_1 \cup \{\bot\}) \times \cdots \times (A_n \cup \{\bot\})$ *is the set of* joint actions*, where* $\bot$ *is an idle action disjoint from* $\cup_{i=1}^n A_i$*;*
- $\Delta_i : S_i \to 2^{A_i}$ *is an available action function, defining the actions* Ag_i *can take in each state;*
- $obs_i : (Loc_1 \times \cdots \times Loc_n \times S_E) \to Per_i$ *is a perception function for* Ag_i*, mapping the local states of all agents and the environment to a percept of the agent, implemented via a neural network (NN) classifier;*
- $\delta_i : S_i \times A \to \mathbb{P}(Loc_i)$ *is a partial probabilistic transition function for* Ag_i *determining the distribution over the agent's local states given its current state and joint action;*
- $\delta_E : S_E \times A \to S_E$ *is a partial deterministic environment transition function determining the environment's next state given its current state and joint action.*

A (global) state for an NS-CSG NSC comprises a state $s_i = (loc_i, per_i)$ for each agent Ag_i (a pair of a local state and percept) and an environment state s_E. If an NS-CSG is in a state $s = (s_1,\dots,s_n,s_E)$, then each Ag_i simultaneously chooses one of the actions available in its state s_i (if no action is available, i.e., $\Delta_i(s_i) = \varnothing$, it picks the idle action $\bot$) yielding a joint action $\alpha = (a_1,\dots,a_n) \in A$. Next, each Ag_i updates its local state to $loc_i' \in Loc_i$, according to its probabilistic local transition function δ_i, applied to its current state (loc_i, per_i) and the joint action α. The environment updates its state to $s_E' \in S_E$ according to its local deterministic transition function δ_E, based on its state s_E and on α. Finally, each agent, based on its new local state loc_i', observes the new local states of the other agents and environment through its perception function obs_i to generate a new percept $per_i' = obs_i(loc_1',\dots,loc_n',s_E')$. Thus, the game reaches the state $s' = (s_1',\dots,s_n',s_E')$, where $s_i' = (loc_i', per_i')$ for $i \in N$. We assume that each perception function obs_i is implemented via an NN $f_i : \mathbb{R}^{b+e} \to \mathbb{P}(Per_i)$ yielding a normalised score over different percept values, where $b = \sum_{i=1}^n b_i$; however, it can be any function including other types of machine learning models. A rule is then applied that selects the percept value with the maximum score.

Formally, the semantics of an NS-CSG NSC is given by an infinite-state CSG $[\![\mathsf{NSC}]\!]$ over the product of the states of the agents and environment, which assumes a particular structure of the transition function that distinguishes between agent and environment states and uses the NN-based perception function to define which states have the same characteristics.

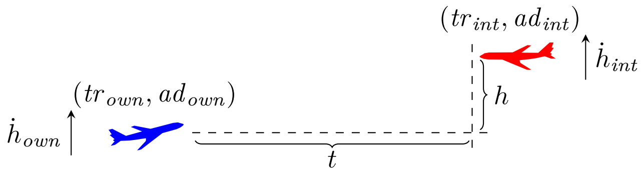

Figure 5 Geometry with trust levels and advisories for the agents of the VCAS[2] case study.

▶ **Definition 16** (Semantics of an NS-CSG). *Given an NS-CSG* NSC *consisting of n players and an environment, the semantics of* NSC *is* $[\![\mathsf{NSC}]\!] = (N, S, A, \Delta, \delta)$ *where:*

- $S = S_1 \times \cdots \times S_n \times S_E$ *is the set of (global) states, which contain both discrete and continuous elements;*
- $A = (A_1 \cup \{\bot\}) \times \cdots \times (A_n \cup \{\bot\})$*;*
- $\Delta(s_1, \ldots, s_n, s_E) = \cup_{i=1}^{n} \Delta_i(s_i)$*;*
- $\delta : (S \times ((A_1 \cup \{\bot\}) \times \cdots \times (A_n \cup \{\bot\}))) \to \mathbb{P}(S)$ *is the partial probabilistic transition function, where for states* $s = (s_1, \ldots, s_n, s_E), s' = (s'_1, \ldots, s'_n, s'_E) \in S$ *and joint action* $\alpha = (a_1, \ldots, a_n) \in A$*, if* $a_i \in \Delta_i(s_i)$ *when* $\Delta_i(s_i) \neq \varnothing$ *and* $a_i = \bot$ *otherwise, then* $\delta(s, \alpha)$ *is defined and if* $s'_i = (loc'_i, per'_i)$*,* $per'_i = obs_i(loc'_1, \ldots, loc'_n, s'_E)$ *for all* $i \in N$ *and* $s'_E = \delta_E(s_E, \alpha)$*, then*

  $$\delta(s, \alpha)(s') = \left(\textstyle\prod_{i=1}^{n} \delta_i(s_i, \alpha)(loc'_i)\right)$$

  and otherwise $\delta(s, \alpha)(s') = 0$.

To illustrate NS-CSGs, we present the VerticalCAS Collision Avoidance Scenario (VCAS[2]) [28, 29], modelled in [59], which is a variant of the one studied in [2], where the agents' trust level is modelled probabilistically to account for possible uncertainty.

▶ **Example 17.** The geometry of the VCAS[2] case study is shown in Figure 5. There are two aircraft (ownship and intruder), constituting the agents of the NS-CSG, both equipped with an NN-controlled collision avoidance system called VCAS. At each time unit (i.e., every second), VCAS issues an advisory ($ad \in \{1, \ldots, 9\}$) from which, together with the current trust level ($tr \in \{1, \ldots, 4\}$) from the previous advisory, the pilot needs to make a decision about the rate of acceleration, aimed at avoiding a near mid-air collision (NMAC) [1].

The input to the VCAS system is the tuple $(h, \dot{h}_{own}, \dot{h}_{int}, t) \in \mathbb{R}^4$ including the relative altitude h of the aircraft, the climb rate $\dot{h}_{own}$ of ownship, the climb rate $\dot{h}_{int}$ of intruder, and the time t until loss of horizontal separation between the aircraft. VCAS is implemented via nine feed-forward NNs $F = \{f_i : \mathbb{R}^4 \to \mathbb{R}^9 \mid 1 \leqslant i \leqslant 9\}$, each of which corresponds to an advisory and outputs the scores of the nine possible advisories. Each advisory will provide a set of accelerations for the agent to select from and the trust level increases probabilistically if the current advisory is compliant with the executed accelerations, and decreases otherwise. We formulate the NS-CSG with agents Ag_i for $i \in \{own, int\}$ as follows:

- the set of states for Ag_i is given by $S_i = \{1, \ldots, 4\} \times \{1, \ldots, 9\}$, where the agent state $s_i = (tr_i, ad_i) \in S_i$ has local state (trust level) tr_i and percept (advisory) ad_i;
- the set of environment states is given by $S_E = \mathbb{R}^4$, where $s_E = (h, \dot{h}_{own}, \dot{h}_{int}, t) \in S_E$ represents the relative altitude, the climb rate of the ownship, the climb rate of the intruder, and the time until loss of their horizontal separation;
- the set of actions of Ag_i is given by $A_i = \{0, \pm 3.0, \pm 7.33, \pm 9.33, \pm 9.7, \pm 11.7\}$ representing the acceleration options of Ag_i;

Table 2 Actions available for the agents of VCAS[2] for each advisory [2].

Label (ad_i)	Advisory	Description	Vertical Range (Min, Max) ft/min	Actions ft/s^2
1	COC	Clear of Conflict	$(-\infty, +\infty)$	-3, $+3$
2	DNC	Do Not Climb	$(-\infty, 0]$	-9.33, -7.33
3	DND	Do Not Descend	$[0, +\infty)$	7.33, $+9.33$
4	DES1500	Descend at least 1500 ft/min	$(-\infty, -1500]$	-9.33, -7.33
5	CL1500	Climb at least 1500 ft/min	$[+1500, +\infty)$	$+7.33$, $+9.33$
6	SDES1500	Strengthen Descend to at least 1500 ft/min	$(-\infty, -1500]$	-11.7, -9.7
7	SCL1500	Strengthen Climb to at least 1500 ft/min	$[+1500, +\infty)$	$+9.7$, $+11.7$
8	SDES2500	Strengthen Descend to at least 2500 ft/min	$(-\infty, -2500]$	-11.7, -9.7
9	SCL2500	Strengthen Climb to at least 2500 ft/min	$[+2500, +\infty)$	$+9.7$, $+11.7$

- the available action function $\Delta_i : Per_i \to A_i$ of Ag_i is independent of the local state of the agent and returns the set consisting two non-zero acceleration actions from Table 2 for a given percept and the zero acceleration action;
- the perception function $obs_i : Per_i \times S_E \to \{1, \dots, 9\}$ of Ag_i is independent of the local state of the agent and is given by the feed forward NNs F of VCAS;
- the local transition function δ_i of Ag_i updates the agent's trust level probabilistically according to its current trust level, its current advisory and its executed action;
- the environment transition function δ_E is given by $\delta_E((h, \dot{h}_{own}, \dot{h}_{int}, t), (\ddot{h}_{own}, \ddot{h}_{int})) = (h', \dot{h}'_{own}, \dot{h}'_{int}, t')$ where for time step $\Delta t = 1$:
  - $h' = h - \Delta t(\dot{h}_{own} - \dot{h}_{int}) - 0.5\Delta t^2(\ddot{h}_{own} - \ddot{h}_{int})$;
  - $\dot{h}'_{own} = \dot{h}_{own} + \ddot{h}_{own}\Delta t$;
  - $\dot{h}'_{int} = \dot{h}_{int} + \ddot{h}_{int}\Delta t$;
  - $t' = t - \Delta t$.

6.1 Zero-sum NS-CSGs

In view of the uncountable state spaces, [60] presents an approach for zero-sum *discounted infinite-horizon* cumulative rewards under the assumption of full state observability for NS-CSGs, which exploits Borel state space decomposition and identifies model restrictions to ensure determinacy, and therefore existence of a value that corresponds to a unique fixed point. Value iteration and policy iteration algorithms to compute values and synthesise optimal strategies are also derived based on formulating piecewise linear or constant representations of the value functions and strategies for NS-CSGs.

6.2 Nonzero-sum NS-CSGs

In the case of nonzero-sum NS-CSGs, [59] studies the *undiscounted, finite-horizon* equilibria synthesis problem. The use of finite-horizon objectives simplifies the analysis (note that the existence of infinite-horizon NE for CSGs is an open problem [7], and the verification of non-probabilistic infinite-horizon reachability properties for neuro-symbolic games is undecidable [2]). Both NE and CE using the SW optimality criteria are considered. The algorithms, based on backward induction and non-linear programming, compute *globally optimal* equilibria which, from a fixed initial state, are optimal over the chosen time horizon, in contrast to the local optimality of equilibria for finite-state CSGs [34, 35].

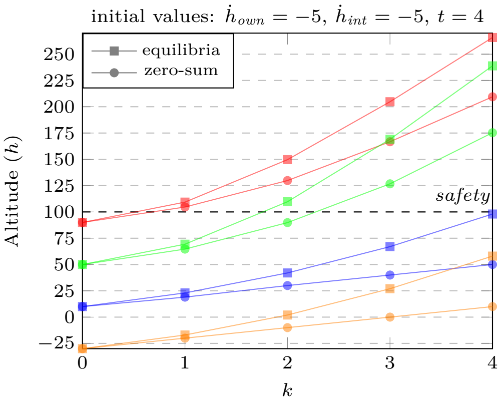

Figure 6 Relative altitude h of the two aircraft at time instants k for equilibria and zero-sum strategies for the VCAS[2] case study.

▶ **Example 18.** The NS-CSG model of the VCAS[2] system described in Example 17 is studied in [59], comparing equilibria strategies to the zero-sum strategies analysed in [2]. Figure 6 plots the relative altitude h of the two aircraft for equilibria and zero-sum strategies when maximising this value for a given time instant k, plotted for several different initial values of h. It can be seen that, with respect to the safety criterion established in [28, 2], i.e., avoiding an NMAC when two aircraft are separated by less than 100 ft vertically (dotted line) and 500 ft horizontally, equilibria strategies allow the two aircraft to reach a safe configuration within a shorter horizon, which would be missed through a zero-sum analysis.

The analysis of [59] also considers a reward structure that incorporates both the trust level and fuel consumption. Figure 7 shows the resulting equilibria strategies when both safety and trust are prioritised, using two different time horizons. When $t = 3$ initially (left), it is optimal to follow the advisories and the trust levels tr_{own} and tr_{int} of the two aircraft never decrease from their initial values of 4. However, when $t = 3$ initially (right), the optimal strategy shows a deviation from the advisory, denoted by action $a_{own} = 0$, in state s_2, resulting in tr_{own} dropping to 3 in s_3 with probability 0.9.

The experiments from [59], summarised above, and from [60] are developed using prototype tools that build upon parts of PRISM-games, but full tool support for NS-CSGs

7 Conclusions and Future Challenges

This paper has provided an overview of modelling, verification and strategy synthesis techniques that have been developed and implemented for concurrent stochastic games in the PRISM-games model checker. Through case studies, we have demonstrated the uses and advantages of zero-sum and equilibria-based reasoning in strategic decision making, highlighting Nash and correlated equlilibria in conjunction with two optimality criteria, social welfare and social fairness. We have also discussed recent trends in autonomous systems towards neural-symbolic architectures, and summarised the first steps towards developing a modelling framework to support the development of such AI-based systems. Despite some progress, many problems remain open in this area, in particular, the development of (efficient) approximate algorithms for (undiscounted infinite-horizon) temporal logic specifications where the underlying problem is undecidable even in the finite-state case [42].

Online Bipartite Matching and Adwords

Vijay V. Vazirani ✉
University of California, Irvine, CA, USA

Abstract

The purpose of this paper is to give a "textbook quality" proof of the optimal algorithm, called Ranking, for the online bipartite matching problem (OBM) and to highlight its role in matching-based market design. In particular, we discuss a generalization of OBM, called the adwords problem, which has had a significant impact in the ad auctions marketplace.

1 Introduction

The online bipartite matching problem[1] (OBM) occupies a central place not only in online algorithms but also in matching-based market design, see details in Sections 1.1 and 1.2. The purpose of this paper is to give a "textbook quality" proof[2] of the optimal algorithm, called Ranking, for this problem and to highlight its role in matching-based market design. In particular, we discuss a generalization of OBM, called the adwords problem, which has had a significant impact in the ad auctions marketplace, see Section 1.2.

Ranking achieves a competitive ratio of $\left(1 - \frac{1}{e}\right)$ [17]. Its analysis, given in [17], was considered "difficult" and it also had an error. Over the years, several researchers contributed valuable ideas to simplifying its proof, see Section 1.1 for details. The proof given in this paper is based on these ideas. Additionally, we highlight a key property used in the proof, called the *No-Surpassing Property* and simplify further its proof. This property turns out to be the bottleneck to a substantial generalization which was attempted in [21], as described below.

The adwords problem, which is called General in this paper, is a generalization of OBM. It involves matching keyword queries, as they arrive online, to advertisers; the latter have daily budget limits and they make bids for the queries. The overall goal is to maximize the total revenue. This problem is notoriously difficult and has remained largely unsolved; see Section 1.1 for marginal progress made recently. Its special case, when bids are small compared to budgets, called Small, captures a key computational issue that arises in the context of ad auctions, for instance in Google's AdWords marketplace. An optimal algorithm for Small, achieving a competitive ratio of $\left(1 - \frac{1}{e}\right)$, was first given in [19]; for the impact of this result in the marketplace, see Section 1.2.

In Open Problem Number 20 in [18], Mehta asks for a *budget-oblivious online algorithm* for Small. Such an algorithm does not know the daily budgets of advertisers; however, in a run of the algorithm, it knows when the budget of an advertiser is exhausted. However, its revenue is still compared to the optimal revenue generated by an offline algorithm with full

knowledge of the budget. Its importance lies in its use in autobidding platforms [1, 6], which manage the ad campaigns of large advertisers; they dynamically adjust bids and budgets over multiple search engines to improve performance. The greedy algorithm, which matches an arriving query to the advertiser making the highest bid, is clearly budget-oblivious; its competitive ratio is 0.5. An improved algorithm, having a competitive ratio of 0.522, was recently obtained by Udwani [20], using the idea of an LP-free analysis, which involves writing appropriate linear inequalities to compare the online algorithm with the offline optimal algorithm.

Motivated by the recent simplification of the proof of (OBM), [21] attempted to extend Ranking all the way to Small. This attempt represents a more basic approach to Small than the one used in [19] (see Section 1.1) and the hope was that it would yield an algorithm with better properties, e.g., budget-obliviousness. [21] managed to extend Ranking to an intermediate problem, called Single-Valued, thereby giving an optimal, budget-oblivious algorithm; see Section 1.1 for competing results for this problem. Under Single-Valued, each advertiser can make bids of one value only, although the value may be different for different advertisers.

The analysis of Single-Valued given in [21] involved new ideas from two domains, namely probability theory and combinatorics, with the former playing a dominant role and the latter yielding a proof of the No-Surpassing Property for Single-Valued. Equipped with these new ideas, [21] next attempted an extension from Ranking to Small. Although the more difficult, probabilistic part, of the argument did extend, a counter-example was found to the combinatorial part, showing that the No-Surpassing Property does not hold for Small.

1.1 Related Works

We start by stating simplifications to the proof of OBM. At first, [11, 4], got the ball rolling, setting the stage for the substantial simplification given in [7], using a randomized primal-dual approach. [7] introduced the idea of splitting the contribution of each matched edge into primal and dual contributions and lower-bounding each part separately. Their method for defining prices p_j of goods, using randomization, was used by subsequent papers, including this one[3].

Interestingly enough, the next simplification involved removing the scaffolding of LP-duality and casting the proof in purely probabilistic terms[4], using notions from economics to split the contribution of each matched edge into the contributions of the buyer and the seller. This elegant analysis was given by [9]. A further simplification to the proof of the No-Surpassing Property for OBM is given in the current paper.

An important generalization of OBM is online b-matching. This problem is a special case of General in which the budget of each advertiser is \$$b$ and the bids are 0/1. [16] gave a simple optimal online algorithm, called BALANCE, for this problem. BALANCE awards the next query to the interested bidder who has been matched least number of times so far. [16] showed that as b tends to infinity, the competitive ratio of BALANCE tends to $\left(1 - \frac{1}{e}\right)$.

Observe that b-matching is a special case of Small, if b is large. Indeed, the first online algorithm [19] for Small was obtained by extending BALANCE as follows: [19] first gave a simpler proof of the competitive ratio of BALANCE using the notion of a *factor-revealing*

[3] For a succinct proof of optimality of the underlying function, e^{x-1}, see Section 2.1.1 in [12].

[4] Even though there is no overt use of LP-duality in the proof of [9], it is unclear if this proof could have been obtained directly, without going the LP-duality-route.

LP [15]. Then they gave the notion of a *tradeoff-revealing LP*, which yielded an algorithm achieving a competitive ratio of $\left(1 - \frac{1}{e}\right)$. [19] also proved that this is optimal for b-matching, and hence Small, by proving that no randomized algorithm can achieve a better ratio for online b-matching; previously, [16] had shown a similar result for deterministic algorithms.

The algorithm of [19] is simple and operates as follows. The effective bid of each bidder j for a query is its bid multiplied by $(1 - e^{L_j/B_j})$, where B_j and L_j are the total budget and the leftover budget of bidder j, respectively; the query is matched to the bidder whose effective bid is highest. As a result, the algorithm of [19] needs to know the total budget of each bidder. Following [19], a second optimal online algorithm for Small was given in [5], using a primal-dual approach.

Another relevant generalization of OBM is online vertex weighted matching, in which the offline vertices have weights and the objective is to maximize the weight of the matched vertices. [2] extended Ranking to obtain an optimal online algorithm for this problem. Clearly, Single-Valued is intermediate between General and online vertex weighted matching. [2] gave an optimal online algorithm for Single-Valued by reducing it to online vertex weighted matching. This involved creating k_j copies of each advertiser j. As a result, their algorithm needs to use $\sum_{j \in A} k_j$ random numbers, where A is the set of advertisers.

We note that independent of [21], Albers and Schubert [3] had also obtained an optimal, budget-oblivious algorithm for Single-Valued; however, their technique was different and involved formulating a configuration LP and conducting a primal-dual analysis. Another advantage of the algorithms of [3] and [21], in contrast to [2], was that they need to use only $|A|$ random numbers.

For General, the greedy algorithm, which matches each query to the highest bidder, achieves a competitive ratio of 1/2. Until recently, that was the best possible. In [13] a marginally improved algorithm, with a ratio of 0.5016, was given. It is important to point out that this 60-page paper was a tour-de-force, drawing on a diverse collection of ideas – a testament to the difficulty of this problem.

In the decade following the conference version (FOCS 2005) of [19], search engine companies generously invested in research on models derived from OBM and adwords. Their motivation was two-fold: the substantial impact of [19] and the emergence of a rich collection of digital ad tools. It will be impossible to do justice to this substantial body of work, involving both algorithmic and game-theoretic ideas; for a start, see the surveys [18, 12].

1.2 Significance and Practical Impact

Google's AdWords marketplace generates multi-billion dollar revenues annually and the current annual worldwide spending on digital advertising is almost half a trillion dollars. These revenues of Google and other Internet services companies enable them to offer crucial services, such as search, email, videos, news, apps, maps etc. for free – services that have virtually transformed our lives.

We note that Small is the most relevant case of adwords for the search ads marketplace e.g., see [6]. A remarkable feature of Google, and other search engines, is the speed with which they are able to show search results, often in milliseconds. In order to show ads at the same speed, together with search results, the solution for Small needed to be minimalistic in its use of computing power, memory and communication.

The online algorithm of [19] satisfied these criteria and therefore had a substantial impact in this marketplace. Furthermore, the idea underlying their algorithm was extracted into a simple heuristic, called *bid scaling*, which uses even less computation and is widely used by search engine companies today. As mentioned above, our Conditional Algorithm for Small is even more elementary and is budget-oblivious.

It will be useful to view the AdWords marketplace in the context of a bigger revolution, namely the advent of the Internet and mobile computing, and the consequent resurgence of the area of matching-based market design. The birth of this area goes back to the seminal 1962 paper of Gale and Shapley on stable matching [10]. Over the decades, this area became known for its highly successful applications, having economic as well as sociological impact. These included matching medical interns to hospitals, students to schools in large cities, and kidney exchange.

The resurgence led to a host of highly innovative and impactful applications. Besides the AdWords marketplace, which matches queries to advertisers, these include Uber, matching drivers to riders; Upwork, matching employers to workers; and Tinder, matching people to each other, see [14] for more details.

A successful launch of such markets calls for economic and game-theoretic insights, together with algorithmic ideas. The Gale-Shapley deferred acceptance algorithm and its follow-up works provided the algorithmic backbone for the "first life" of matching-based market design. The algorithm RANKING has become the paradigm-setting algorithmic idea in the "second life" of this area. Interestingly enough, this result was obtained in the pre-Internet days, over thirty years ago.

2 Preliminaries

Online Bipartite Matching. (OBM): Let B be a set of n buyers and S a set of n goods. A bipartite graph $G = (B, S, E)$ is specified on vertex sets B and S, and edge set E, where for $i \in B$, $j \in S$, $(i, j) \in E$ if and only if buyer i *likes* good j. G is assumed to have a perfect matching and therefore each buyer can be given a unique good she likes. Graph G is revealed in the following manner. The n goods are known up-front. On the other hand, the buyers arrive one at a time, and when buyer i arrives, the edges incident at i are revealed.

We are required to design an online algorithm $\mathcal{A}$ in the following sense. At the moment a buyer i arrives, the algorithm needs to match i to one of its unmatched neighbors, if any; if all of i's neighbors are matched, i remains unmatched. The difficulty is that the algorithm does not "know" the edges incident at buyers which will arrive in the future and yet the size of the matching produced by the algorithm will be compared to the best *off-line matching*; the latter of course is a perfect matching. The formal measure for the algorithm is defined in Section 2.1.

General Adwords Problem (GENERAL): Let A be a set of m *advertisers*, also called *bidders*, and Q be a set of n *queries*. A bipartite graph $G = (Q, A, E)$ is specified on vertex sets Q and A, and edge set E, where for $i \in Q$ and $j \in A$, $(i, j) \in E$ if and only if bidder j is *interested in* query i. Each query i needs to be matched[5] to at most one bidder who is interested in it. For each edge (i, j), bidder j *knows* his bid for i, denoted by $\text{bid}(i, j) \in \mathbb{Z}_+$. Each bidder also has a *budget* $B_j \in \mathbb{Z}_+$ which satisfies $B_j \geq \text{bid}(i, j)$, for each edge (i, j) incident at j.

Graph G is revealed in the following manner. The m bidders are known up-front and the queries arrive one at a time. When query i arrives, the edges incident at i are revealed, together with the bids associated with these edges. If i gets matched to j, then the matched edge (i, j) is assigned a weight of $\text{bid}(i, j)$. The constraint on j is that the total weight of matched edges incident at it be at most B_j. The objective is to maximize the total weight of all matched edges at all bidders.

[5] Clearly, this is not a matching in the usual sense, since a bidder may be matched to several queries.

Adwords under Single-Valued Bidders (Single-Valued): Single-Valued is a special case of General in which each bidder j will make bids of a single value, $b_j \in \mathbb{Z}_+$, for the queries he is interested in. If i accepts j's bid, then i will be matched to j and the weight of this matched edge will be b_j. Corresponding to each bidder j, we are also given $k_j \in \mathbb{Z}_+$, the maximum number of times j can be matched to queries. The objective is to maximize the total weight of matched edges. Observe that the matching M found in G is a b-matching with the b-value of each query i being 1 and of advertiser j being k_j.

Adwords under Small Bids (Small): Small is a special case of General in which for each bidder j, each bid of j is small compared to its budget. Formally, we will capture this condition by imposing the following constraint. For a valid instance I of Small, define

$$\mu(I) = \max_{j \in A} \left\{ \frac{\max_{(i,j)\in E} \{\text{bid}(i,j) - 1\}}{B_j} \right\}.$$

Then we require that

$$\lim_{n(I)\to\infty} \mu(I) = 0,$$

where $n(I)$ denotes the number of queries in instance I.

2.1 The competitive ratio of online algorithms

We will define the notion of competitive ratio of a randomized online algorithm in the context of OBM.

▶ **Definition 1.** *Let $G = (B, S, E)$ be a bipartite graph as specified above. The competitive ratio of a randomized algorithm $\mathcal{A}$ for OBM is defined to be:*

$$c(\mathcal{A}) = \min_{G=(B,S,E)} \min_{\rho(B)} \frac{\mathbb{E}[\mathcal{A}(G, \rho(B))]}{n},$$

where $\mathbb{E}[\mathcal{A}(G, \rho(B))]$ is the expected size of matching produced by $\mathcal{A}$; the expectation is over the random bits used by $\mathcal{A}$. We may assume that the worst case graph and the order of arrival of buyers, given by $\rho(B)$, are chosen by an adversary who knows the algorithm. It is important to note that the algorithm is provided random bits after *the adversary makes its choices.*

▶ Remark 2. For each problem studied in this paper, we will assume that the offline matching is complete. It is easy to extend the arguments, without changing the competitive ratio, in case the offline matching is not complete. As an example, this is done for OBM in Remark 14.

3 Ranking and its Analysis

Algorithm 1 presents an optimal algorithm for OBM. Note that this algorithm picks a random permutation of goods only once. Its competitive ratio is $(1 - \frac{1}{e})$, as shown in Theorem 13. Furthermore, as shown in [17], it is an optimal online bipartite matching algorithm: no randomized algorithm can do better, up to an $o(1)$ term.

We will analyze Algorithm 2 which is equivalent to Algorithm 1 and operates as follows. Before the execution of Step (1), the adversary determines the order in which buyers will arrive, say $\rho(B)$. In Step (1), each good j is assigned a *price* $p_j = e^{w_j - 1}$, where w_j, called the *rank* of j, is picked at random from $[0, 1]$; observe that $p_j \in [\frac{1}{e}, 1]$. In Step (2), buyers

Algorithm 1 Ranking.

```
1. Initialization: Pick a random permutation, $\pi$, of the goods in $S$.

2. Online buyer arrival: When a buyer, say $i$, arrives, match her to the first
   unmatched good she likes in the order $\pi$; if none, leave $i$ unmatched.

Output the matching, $M$, found.
```

will arrive in the order $\rho(B)$, picked by the adversary, and will be matched to the cheapest available good. With probability 1 all n prices are distinct and sorting the goods by increasing prices results in a random permutation. Furthermore, since Algorithm 2 uses this sorted order only and is oblivious of the actual prices, it is equivalent to Algorithm 1. As we will see, the random variables representing actual prices are crucially important as well – in the analysis. We remark that for the generalizations of OBM studied in this paper, the prices are used not only in the analysis, but also by the algorithms.

3.1 Analysis of Ranking

We will use an *economic setting* for analyzing Algorithm 2 as follows. Each buyer i has *unit-demand* and *0/1 valuations* over the goods she likes, i.e., she accrues unit utility from each good she likes, and she wishes to get at most one of them. The latter set is precisely the set of neighbors of i in G. If on arrival of i there are several of these which are still unmatched, i will pick one having the smallest price [6]. Therefore the buyers will maximize their utility as defined below.

For analyzing this algorithm, we will define two sets of random variables, u_i for $i \in B$ and r_j, for $j \in S$. These will be called utility of buyer i and revenue of good j, respectively. Each run of Ranking defines these random variables as follows. If Ranking matches buyer i to good j, then define $u_i = 1 - p_j$ and $r_j = p_j$, where p_j is the price of good j in this run of Ranking. Clearly, p_j is also a random variable, which is defined by Step (1) of the algorithm. If i remains unmatched, define $u_i = 0$, and if j remains unmatched, define $r_j = 0$. Observe that for each good j, $p_j \in [\frac{1}{e}, 1]$ and for each buyer i, $u_i \in [0, 1 - \frac{1}{e}]$. Let M be the matching produced by Ranking and let random variable $|M|$ denote its size.

Lemma 3 pulls apart the contribution of each matched edge (i, j) into u_i and r_j. Next, we established in Lemma 11 that for each edge (i, j) in the graph, the total expected contribution of u_i and r_j is at least $1 - \frac{1}{e}$. Then, linearity of expectation allows us to reassemble the $2n$ terms in the right hand side of Lemma 3 so they are aligned with a perfect matching in G, and this yields Theorem 13.

▶ **Lemma 3.**

$$\mathbb{E}[|M|] \; = \sum_{i}^{n} \mathbb{E}\left[u_i\right] \; + \; \sum_{j}^{n} \mathbb{E}[r_j].$$

[6] As stated above, with probability 1 there are no ties.

Algorithm 2 Ranking: Economic Viewpoint.

```
1. Initialization: $\forall j \in S$:   Pick $w_j$ independently and uniformly from $[0,1]$.
   Set price  $p_j \leftarrow e^{w_j - 1}$.

2. Online buyer arrival: When a buyer, say $i$, arrives, match her to the cheapest
   unmatched good she likes; if none, leave $i$ unmatched.

Output the matching, $M$, found.
```

Proof. By definition of the random variables,

$$\mathbb{E}[|M|] = \mathbb{E}\left[\sum_{i=1}^{n} u_i + \sum_{j=1}^{n} r_j\right] = \sum_{i}^{n} \mathbb{E}[u_i] + \sum_{j}^{n} \mathbb{E}[r_j],$$

where the first equality follows from the fact that if $(i,j) \in M$ then $u_i + r_j = 1$ and the second follows from linearity of expectation. ◀

While running Algorithm 2, assume that the adversary has picked the order of arrival of buyers, say $\rho(B)$, and Step (1) has been executed. We next define several ways of executing Step (2). Let $\mathcal{R}$ denote the run of Step (2) on the entire graph G. Corresponding to each good j, let G_j denote graph G with vertex j removed. Define $\mathcal{R}_j$ to be the run of Step (2) on graph G_j.

Lemma 4 and Corollary 5 establish a relationship between the sets of available goods for a buyer i in the two runs $\mathcal{R}$ and $\mathcal{R}_j$; the latter is crucially used in the proof of Lemma 9. For ease of notation in proving these two facts, let us renumber the buyers so their order of arrival under $\rho(B)$ is $1, 2, \ldots n$. Let $T(i)$ and $T_j(i)$ denote the sets of unmatched goods at the time of arrival of buyer i (i.e., just before the buyer i gets matched) in the graphs G and G_j, in runs $\mathcal{R}$ and $\mathcal{R}_j$, respectively. Similarly, let $S(i)$ and $S_j(i)$ denote the set of unmatched goods that buyer i is incident to in G and G_j, in runs $\mathcal{R}$ and $\mathcal{R}_j$, respectively.

We have assumed that Step (1) of Algorithm 2 has already been executed and a price p_k has been assigned to each good k. With probability 1, the prices are all distinct. Let F_1 and F_2 be subsets of S containing goods k such that $p_k < p_j$ and $p_k > p_j$, respectively.

▶ **Lemma 4.** *For each i, $1 \le i \le n$, the following hold:*

1. $(T_j(i) \cap F_1) = (T(i) \cap F_1)$.
2. $(T_j(i) \cap F_2) \subseteq (T(i) \cap F_2)$.

Proof. Clearly, in both runs, $\mathcal{R}$ and $\mathcal{R}_j$, any buyer having an available good in F_1 will match to the most profitable one of these, without even considering the rest of the goods. Since $j \notin F_1$, the two runs behave in an identical manner on the set F_1, thereby proving the first statement.

The proof of the second statement is by induction on i. The base case is trivially true since $j \notin F_2$. Assume that the statement is true for $i = k$ and let us prove it for $i = k + 1$. By the first statement, we need to consider only the case that there are no available goods for the k^{th} buyer in F_1 in the runs $\mathcal{R}$ and $\mathcal{R}_j$. Assume that in run $\mathcal{R}_j$, this buyer gets matched to good l; if she remains unmatched, we will take l to be null. Clearly, l is the most profitable good she is incident to in $T_j(k)$. Therefore, the most profitable good she is incident to in run $\mathcal{R}$ is the best of l, the most profitable good in $T(k) - T_j(k)$, and j, in case it is available. In each of these cases, the induction step holds. ◀

In the corollary below, the first two statements follow from Lemma 4 and the third statement follows from the first two.

▶ **Corollary 5.** *For each i, $1 \leq i \leq n$, the following hold:*
1. $(S_j(i) \cap F_1) = (S(i) \cap F_1)$.
2. $(S_j(i) \cap F_2) \subseteq (S(i) \cap F_2)$.
3. $S_j(i) \subseteq S(i)$.

Next we define a new random variable, u_e, for each edge $e = (i, j) \in E$. This is called the *threshold* for edge e and is given in Definition 6. It is critically used in the proofs of Lemmas 9 and 11.

▶ **Definition 6.** *Let $e = (i, j) \in E$ be an arbitrary edge in G. Define random variable, u_e, called the* threshold *for edge e, to be the utility of buyer i in run $\mathcal{R}_j$. Clearly, $u_e \in [0, 1 - \frac{1}{e}]$.*

▶ **Property 7** (No-Surpassing for OBM). *Let p_j be such that the bid of j, namely $1 - p_j$, is better than the best bid that buyer i gets in run $\mathcal{R}_j$. Then, in run $\mathcal{R}$, no bid to i will surpass $1 - p_j$.*

▶ **Lemma 8.** *The No-Surpassing Property holds for OBM.*

Proof. Suppose the bid of j, namely $1 - p_j$, is better than the best bid that buyer i gets in run $\mathcal{R}_j$. If so, i gets no bid from F_1 in $\mathcal{R}_j$; observe that they are all higher than $1 - p_j$. Now, by the first part of Corollary 5, i gets no bid from F_1 in run $\mathcal{R}$ as well, i.e., in run $\mathcal{R}$, no bid to i will surpass $1 - p_j$. ◀

▶ **Lemma 9.** *Corresponding to each edge $(i, j) \in E$, the following hold.*
1. *$u_i \geq u_e$, where u_i and u_e are the utilities of buyer i in runs $\mathcal{R}$ and $\mathcal{R}_j$, respectively.*
2. *Let $z \in [0, 1 - \frac{1}{e}]$. Conditioned on $u_e = z$, if $p_j < 1 - z$, then j will definitely be matched in run $\mathcal{R}$.*

Proof.

1). By the third statement of Corollary 5, i has more options in run $\mathcal{R}$ as compared to run $\mathcal{R}_j$, and therefore $u_i \geq u_e$.

2). In run $\mathcal{R}$, if j is already matched when i arrives, there is nothing to prove. Next assume that j is not matched when i arrives. The crux of the matter is that by Lemma 8, the No-Surpassing Property holds. Therefore, in run $\mathcal{R}$, i will not have any option that is better than j and will therefore get matched to j. Since $1 - p_j > z$, $S_j(i) \cap F_1 = \emptyset$. Therefore by the first statement of Corollary 5, $S(i) \cap F_1 = \emptyset$. Since i will get no bid better than j in $\mathcal{R}$, the no-surpassing property indeed holds and i must get matched to j. ◀

▶ Remark 10. The random variable u_e is called *threshold* because of the second statement of Lemma 9. It defines a value such that whenever p_j is smaller than this value, j is definitely matched in run $\mathcal{R}$.

The intuitive reason for the next, and most crucial, lemma is the following. The smaller u_e is, the larger is the range of values for p_j, namely $[0, 1 - u_e)$, over which (i, j) will be matched and j will accrue revenue of p_j. Integrating p_j over this range, and adding $\mathbb{E}[u_i]$ to it, gives the desired bound. Crucial to this argument is the fact that p_j is independent of u_e. This follows from the fact that u_e is determined by run $\mathcal{R}_j$ on graph G_j, which does not contain vertex j.

▶ **Lemma 11.** *Corresponding to each edge $(i, j) \in E$,*

$$\mathbb{E}[u_i + r_j] \geq 1 - \frac{1}{e}.$$

Proof. By the first part of Lemma 9, $\mathbb{E}[u_i] \geq \mathbb{E}[u_e]$.

Next, we will lower bound $\mathbb{E}[r_j]$. Let $z \in [0, 1 - \frac{1}{e}]$ and let us condition on the event $u_e = z$. The critical observation is that u_e is determined by the run $\mathcal{R}_j$. This is conducted on graph G_j, which does not contain vertex j. Therefore u_e is independent of p_j.

By the second part of Lemma 9, $r_j = p_j$ whenever $p_j < 1 - z$. We will ignore the contribution to $\mathbb{E}[r_j]$ when $p_j \geq 1 - z$. Let w be s.t. $e^{w-1} = 1 - z$.

Now p_j is obtained by picking x uniformly at random from the interval $[0, 1]$ and outputting e^{x-1}. In particular, when $x \in [0, w)$, $p_j < 1 - z$. If so, by the second part of Lemma 9, j is matched and revenue is accrued in r_j, see Figure 2. Therefore,

$$\mathbb{E}[r_j \mid u_e = z] \geq \int_0^w e^{x-1}\, dx \;=\; e^{w-1} - \frac{1}{e} \;=\; 1 - \frac{1}{e} - z.$$

Let $f_{u_e}(z)$ be the probability density function of u_e; clearly, $f_{u_e}(z) = 0$ for $z \notin [0, 1 - \frac{1}{e}]$. Therefore,

$$\mathbb{E}[r_j] \;=\; \mathbb{E}[\mathbb{E}[r_j \mid u_e]] \;=\; \int_{z=0}^{1-1/e} \mathbb{E}[r_j \mid u_e = z] \cdot f_{u_e}(z) dz$$

$$\geq \int_{z=0}^{1-1/e} \left(1 - \frac{1}{e} - z\right) \cdot f_{u_e}(z) dz \;=\; 1 - \frac{1}{e} - \mathbb{E}[u_e],$$

where the first equality follows from the law of total expectation and the inequality follows from fact that we have ignored the contribution to $\mathbb{E}[r_j \mid u_e]$ when $p_j \geq 1 - z$. Hence we get

$$\mathbb{E}[u_i + r_j] = \mathbb{E}[u_i] + \mathbb{E}[r_j] \geq 1 - \frac{1}{e}.$$ ◀

▶ Remark 12. Observe that Lemma 11 is not a statement about i and j getting matched to each other, but about the utility accrued by i and the revenue accrued by j by being matched to various goods and buyers, respectively, over the randomization executed in Step (1) of Algorithm 2.

▶ **Theorem 13.** *The competitive ratio of* Ranking *is at least $1 - \frac{1}{e}$.*

Proof. Let P denote a perfect matching in G. The expected size of matching produced by Ranking is

$$\mathbb{E}\left[|M|\right] \;=\; \sum_i^n \mathbb{E}\left[u_i\right] \;+\; \sum_j^n \mathbb{E}[r_j] \;=\; \sum_{(i,j) \in P} \mathbb{E}[u_i + r_j] \;\geq\; n\left(1 - \frac{1}{e}\right),$$

where the first equality uses Lemma 3, the second follows from linearity of expectation and the inequality follows from Lemma 11 and the fact that $|P| = n$. The theorem follows. ◀

▶ Remark 14. In case G does not have a perfect matching, let P denote a maximum matching in G, of size k, say. Then summing $\mathbb{E}\left[u_i\right]$ and $\mathbb{E}[r_j]$ over the the vertices i and j matched by P, we get that the expected size of matching produced by Ranking is at least $k\left(1 - \frac{1}{e}\right)$.

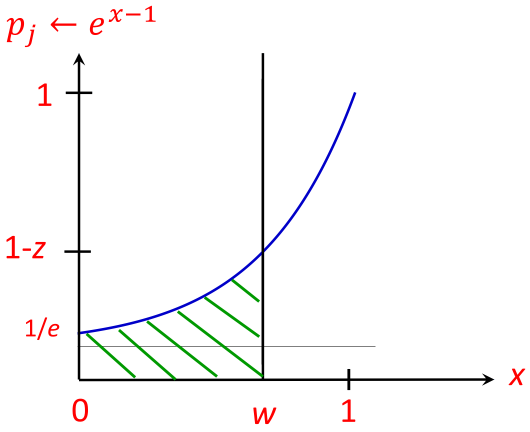

Figure 2 The shaded area is a lower bound on $\mathbb{E}[r_j \mid u_e = z]$.

Abstract

For a connected graph $G = (V, E)$ and $s, t \in V$, a non-separating s-t path is a path P between s and t such that the set of vertices of P does not separate G, that is, $G - V(P)$ is connected. An s-t path P is non-disconnecting if $G - E(P)$ is connected. The problems of finding shortest non-separating and non-disconnecting paths are both known to be NP-hard. In this paper, we consider the problems from the viewpoint of parameterized complexity. We show that the problem of finding a non-separating s-t path of length at most k is W[1]-hard parameterized by k, while the non-disconnecting counterpart is fixed-parameter tractable (FPT) parameterized by k. We also consider the shortest non-separating path problem on several classes of graphs and show that this problem is NP-hard even on bipartite graphs, split graphs, and planar graphs. As for positive results, the shortest non-separating path problem is FPT parameterized by k on planar graphs and on unit disk graphs (where no s, t is given). Further, we give a polynomial-time algorithm on chordal graphs if k is the distance of the shortest path between s and t.

1 Introduction

Lovász's path removal conjecture states the following claim: There is a function $f : \mathbb{N} \to \mathbb{N}$ such that for every $f(k)$-connected graph G and every pair of vertices u and v, G has a path P between u and v such that $G - V(P)$ is k-connected. This claim still remains open, while

some special cases have been resolved [4, 15, 17, 23]. Tutte [23] proved that $f(1) = 3$, that is, every triconnected graph satisfies that for every pair of vertices, there is a path between them whose removal results a connected graph. Kawarabayashi et al. [15] proved a weaker version of this conjecture: There is a function $f\colon \mathbb{N} \to \mathbb{N}$ such that for every $f(k)$-connected graph G and every pair of vertices u and v, G has an induced path P between u and v such that $G - E(P)$ is k-connected.

As a practical application, let us consider a network represented by an undirected graph G, and we would like to build a private channel between a specific pair of nodes s and t. For some security reasons, the path used in this channel should be dedicated to the pair s and t, and hence all other connections do not use all nodes and/or edges on this path while keeping their connections. In graph-theoretic terms, the vertices (resp. edges) of the path between s and t does not form a separator (resp. a cut) of G. Tutte's result [23] indicates that such a path always exists in triconnected graphs, but may not exist in biconnected graphs. In addition to this connectivity constraint, the path between s and t is preferred to be short due to the cost of building a private channel. Motivated by such a natural application, the following two problems are studied.

▶ **Definition 1.** *Given a connected graph G, $s, t \in V(G)$, and an integer k,* Shortest Non-Separating Path *asks whether there is a path P between s and t in G such that the length of P is at most k and $G - V(P)$ is connected. When s and t are not part of the input, and we want to find a path P of length k, such that $G - V(P)$ is connected, then we call the problem* Terminal Independent Shortest Non-Separating Path (TI-Shortest Non-Separating Path)*.*

▶ **Definition 2.** *Given a connected graph G, $s, t \in V(G)$, and an integer k, Shortest Non-Disconnecting Path asks whether there is a path P between s and t in G such that the length of P is at most k and $G - E(P)$ is connected.*

Given, the Shortest Non-Separating Path problem, a natural question arises about the complexity of the problem, when in the problem we replace the demand of P being a path with P being a connected set. Given a connected graph G, and an integer k, Smallest Non-Separating Set asks whether there is a vertex subset X of size k in G such that $G[X]$ is connected and $G - X$ is connected. Similarly, an edge counterpart can be defined as Smallest Non-Disconnecting Set. An edge set X is said to be connected if the graph $G' = (V(X), X)$ is connected. We say that a path P is *non-separating* (in G) if $G - V(P)$ is connected and is *non-disconnecting* (in G) if $G - E(P)$ is connected. Similarly, we define the notion of *non-separating* set and *non-disconnecting* set.

1.1 Our Results and Methods

We investigate the parameterized complexity of above problems and obtain following results.

1. Shortest Non-Separating Path and Smallest Non-Separating Set are W[1]-hard. These are obtained by parameterized reductions from Multicolored Clique and Clique, respectively.
2. Shortest Non-Disconnecting Path and Smallest Non-Disconnecting Set are FPT parameterized by k. These algorithms are based on matroid based tools used in parameterized complexity [11]. In particular, given a graph G, there is a well-known matroid, defined by ground set being $E(G)$ and the family of independent sets being a subsets of Y of $E(G)$, such that $G - Y$ is connected. These are called cographic matroid.

A crucial observation for the FPT algorithms for Shortest Non-Disconnecting Path and Smallest Non-Disconnecting Set is that the set of edges in a non-disconnecting path or non-disconnecting set can be seen as an independent set of a cographic matroid. By applying the representative family of matroids [11], we show that Shortest Non-Disconnecting Path and Smallest Non-Disconnecting Set can be solved in $2^{\omega k}|V|^{O(1)}$ time, where ω is the exponent of the matrix multiplication. We also show that Shortest Non-Disconnecting Path is OR-compositional, that is, there is no polynomial kernel unless coNP $\subseteq$ NP/poly.

3. To cope with the intractability of Shortest Non-Separating Path, we consider the problem on planar graphs and unit disk graphs and show that Shortest Non-Separating Path is FPT parameterized by k on planar graphs and TI-Shortest Non-Separating Path is FPT parameterized by k on unit disk graphs. The result on planar graphs can be generalized to wider classes of graphs which have the *diameter-treewidth property* [9], which are precisely apex-minor-free graphs (includes, planar and graphs of bounded genus). For, Smallest Non-Separating Set we show that it does not have polynomial kernel even on planar graphs. We also consider Shortest Non-Separating Path on several classes of graphs. We can observe that the complexity of Shortest Non-Separating Path is closely related to that of Hamiltonian Cycle (or Hamiltonian Path with specified end vertices). This observation readily proves the NP-completeness of Shortest Non-Separating Path on bipartite graphs, split graphs, and planar graphs. For chordal graphs, we devise a polynomial-time algorithm for Shortest Non-Separating Path for the case where k is the shortest path distance between s and t.

Proofs of results for Shortest Non-Separating Path and Smallest Non-Separating Set are similar and the proofs of results for Shortest Non-Disconnecting Path and Smallest Non-Disconnecting Set are similar, in this version of the paper *we only focus on* Shortest Non-Separating Path and Shortest Non-Disconnecting Path.

Related work. The shortest path problem in graphs is one of the most fundamental combinatorial optimization problems, which is studied under various settings. Indeed, our problems Shortest Non-Separating Path and Shortest Non-Disconnecting Path can be seen as variants of this problem. From the computational complexity viewpoint, Shortest Non-Separating Path is known to be NP-hard and its optimization version cannot be approximated with factor $|V|^{1-\varepsilon}$ in polynomial time for $\varepsilon > 0$ unless P = NP [24]. Shortest Non-Disconnecting Path is shown to be NP-hard on general graphs and polynomial-time solvable on chordal graphs [19].

2 Preliminaries

We use standard terminologies and known results in matroid theory and parameterized complexity theory, which are briefly discussed in this section. See [6, 21] for details.

Graphs. Let G be a graph. The vertex set and edge set of G are denoted by $V(G)$ and $E(G)$, respectively. For $v \in V(G)$, the open neighborhood of v in G is denoted by $N_G(v)$ (i.e., $N_G(v) = \{u \in V(G) : \{u,v\} \in E(G)\}$) and the closed neighborhood of v in G is denoted by $N_G[v]$ (i.e., $N_G[v] = N_G(v) \cup \{v\}$). We extend this notation to sets: $N_G(X) = \bigcup_{v \in X} N_G(v) \setminus X$ and $N_G[X] = N_G(X) \cup X$ for $X \subseteq V(G)$. For $u, v \in V(G)$, we denote by $\mathrm{dist}_G(u,v)$ the length of a shortest path between u and v in G, where the length of a path is defined as the number of edges in it. We may omit the subscript of G from these notations when no confusion arises. For $X \subseteq V(G)$, we write $G[X]$ to denote the subgraph of G induced by X. For notational convenience, we may use $G - X$ instead of $G[V(G) \setminus X]$. For $F \subseteq E$, we also use $G - F$ to represent the subgraph of G consisting all vertices of G and all edges in $E \setminus F$. For vertices u and v, a path between u and v is called a *u-v path.* A vertex is called a *pendant* if its degree is exactly 1.

Matroids and representative sets. Let E be a finite set. If $\mathcal{I} \subseteq 2^E$ satisfies the following axioms, the pair $\mathcal{M} = (E, \mathcal{I})$ is called a *matroid*: (1) $\emptyset \in \mathcal{I}$; (2) $Y \in \mathcal{I}$ implies $X \in \mathcal{I}$ for $X \subseteq Y$; and (3) for $X, Y \in \mathcal{I}$ with $|X| < |Y|$, there is $e \in Y \setminus X$ such that $X \cup \{e\} \in \mathcal{I}$. Each set in $\mathcal{I}$ is called an *independent set* of $\mathcal{M}$. From the third axiom of matroids, it is easy to observe that every (inclusion-wise) maximal independent set of $\mathcal{M}$ have the same cardinality. The *rank* of $\mathcal{M}$ is the maximum cardinality of an independent set of $\mathcal{M}$. A matroid $\mathcal{M} = (E, \mathcal{I})$ of rank n is *linear* (or *representable*) over a field $\mathbb{F}$ if there is a matrix $M \in \mathbb{F}^{n \times |E|}$ whose columns are indexed by E such that $X \in \mathcal{I}$ if and only if the set of columns indexed by X is linearly independent in M.

Let $G = (V, E)$ be a graph. A *cographic matroid* of G is a matroid $\mathcal{M}(G) = (E, \mathcal{I})$ such that $F \subseteq E$ is an independent set of $\mathcal{M}(G)$ if and only if $G - F$ is connected. Every cographic matroid is linear and its representation can be computed in polynomial time [21]. Our algorithmic result for Shortest Non-Disconnected Path is based on *representative families* due to [11].

▶ **Definition 3.** *Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid and let $\mathcal{F} \subseteq \mathcal{I}$ be a family of independent sets of $\mathcal{M}$. For an integer $q \geq 0$, we say that $\widehat{\mathcal{F}} \subseteq \mathcal{F}$ is* q-representative for $\mathcal{F}$ *if the following condition holds: For every $Y \subseteq E$ of size at most q, if there is $X \in \mathcal{F}$ with $X \cap Y = \emptyset$ such that $X \cup Y \in \mathcal{I}$, then there is $\widehat{X} \in \widehat{\mathcal{F}}$ with $\widehat{X} \cap Y = \emptyset$ such that $\widehat{X} \cup Y \in \mathcal{I}$.*

▶ **Theorem 4** ([11, 18]). *Given a linear matroid $\mathcal{M} = (E, \mathcal{I})$ of rank n that is represented as a matrix $M \in \mathbb{F}^{n \times |E|}$ for some field $\mathbb{F}$, a family $\mathcal{F} \subseteq \mathcal{I}$ of independent sets of size p, and an integer q with $p + q \leq n$, there is a deterministic algorithm computing a q-representative family $\widehat{\mathcal{F}} \subseteq \mathcal{F}$ of size $np\binom{p+q}{p}$ with*

$$O\left(|\mathcal{F}| \cdot \left(\binom{p+q}{p} p^3 n^2 + \binom{p+q}{q}^{\omega - 1} \cdot (pn)^{\omega - 1}\right)\right) + (n + |E|)^{O(1)}$$

field operations, where $\omega < 2.373$ is the exponent of the matrix multiplication.

Parameterized complexity. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a finite alphabet. A *kernelization* for L is a polynomial-time algorithm that given an instance $(I, k) \in \Sigma^* \times \mathbb{N}$, computes an "equivalent" instance $(I', k') \in \Sigma^* \times \mathbb{N}$ such that (1) $(I, k) \in L$ if and only if $(I', k') \in L$ and (2) $|I'| + k' \leq g(k)$ for some computable function g. We call (I', k') a *kernel.* If the function g is a polynomial, then the kernelization algorithm is called a *polynomial kernelization* and its output (I', k') is called a *polynomial kernel.* An *OR-composition* is an algorithm that given p instances $(I_1, k), \ldots (I_p, k) \in \Sigma^* \times \mathbb{N}$ of L, computes an instance $(I', k') \in \Sigma^* \times \mathbb{N}$ in time $(\sum_{1 \leq i \leq p} |I_i| + k)^{O(1)}$ such that (1) $(I', k') \in L$ if and only if $(I_i, k) \in L$ for some $1 \leq i \leq p$ and (2) $k' = k^{O(1)}$. For a parameterized problem L, its *unparameterized problem* is a language $L' = \{x\#1^k : (x, k) \in L\}$, where $\# \notin \Sigma$ is a blank symbol and $1 \in \Sigma$ is an arbitrary symbol.

▶ **Theorem 5** ([3]). *If a parameterized problem L admits an OR-composition and its unparameterized version is NP-complete, then L does not have a polynomial kernelization unless* $\mathrm{coNP} \subseteq \mathrm{NP/poly}$.

3 Shortest Non-Separating Path

We discuss our complexity and algorithmic results for Shortest Non-Separating Path.

3.1 Hardness on graph classes

We obverse that, in most cases, Shortest Non-Separating Path is NP-hard on classes of graphs for which Hamiltonian Path (with distinguished end vertices) is NP-hard. Let $G = (V, E)$ be a graph and $s, t \in V$ be distinct vertices of G. We add a pendant vertex p adjacent to s and denote the resulting graph by G'. Then, we have the following observation.

▶ **Observation 6.** *For every non-separating path P between s and t in G', $V(G) \setminus V(P) = \{p\}$.*

Suppose that for a class $\mathcal{C}$ of graphs,

- the problem of deciding whether given graph $G \in \mathcal{C}$ has a Hamiltonian path between specified vertices s and t in G is NP-hard and
- $G \in \mathcal{C}$ implies $G' \in \mathcal{C}$.

By Observation 6, G' has a non-separating s-t path if and only if G has a Hamiltonian path between s and t. This implies that the problem of finding a non-separating path between specified vertices is NP-hard on class $\mathcal{C}$.

▶ **Theorem 7.** *The problem of deciding if an input graph has a non-separating s-t path is NP-complete even on planar graphs, bipartite graphs, and split graphs.*

The classes of planar graphs and bipartite graphs are closed under the operation of adding a pendant. Recall that a graph G is a *split graph* if the vertex set $V(G)$ can be partitioned into a clique C and an independent set I. Thus, for the class of split graphs, we need the assumption that the pendant added is adjacent to a vertex in C.

As the problem trivially belongs to NP, it suffices to show that Hamiltonian Path (with distinguished end vertices) is NP-hard on these classes of graphs[1]. For split graphs, it is known that Hamiltonian Path is NP-hard even if the distinguished end vertices are contained in the clique C [20]. Let G be a graph and let $v \in V(G)$. We add a vertex v' that is adjacent to every vertex in $N_G(v)$, that is, v and v' are (false) twins. The resulting graph is denoted by G'. It is easy to verify that G has a Hamiltonian cycle if and only if G' has a Hamiltonian path between v and v'. The class of bipartite graphs is closed under this operation, that is, G' is bipartite. For planar graphs, G' may not be planar in general. However, Hamiltonian Cycle is NP-complete even if the input graph is planar and has a vertex of degree 2 [14]. We apply the above operation to this degree-2 vertex, and the resulting graph G' is still planar. As the problem of finding a Hamiltonian cycle is NP-hard even on bipartite graphs [20] and planar graphs [14], Theorem 7 follows.

[1] These results for bipartite graphs and planar graphs seem to be folklore but we were not able to find particular references.

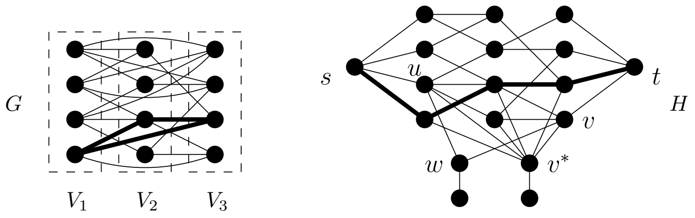

Figure 1 The left figure depicts an instance G of Multicolored Clique and the right figure depicts the graph H constructed from G. Some vertices and edges in H are not drawn in this figure for visibility. The edges of a clique C and the corresponding non-separating s-t path P are drawn as thick lines.

3.2 W[1]-hardness

Next, we show that Shortest Non-Separating Path is W[1]-hard parameterized by k. The proof is done by giving a reduction from Multicolored Clique, which is known to be W[1]-complete [10]. In Multicolored Clique, we are given a graph G with a partition $\{V_1, V_2, \dots, V_k\}$ of $V(G)$ and asked to determine whether G has a clique C such that $|V_i \cap C| = 1$ for each $1 \leq i \leq k$.

From an instance $(G, \{V_1, \dots, V_k\})$ of Multicolored Clique, we construct an instance of Shortest Non-Separating Path as follows. Without loss of generality, we assume that G contains more than k vertices. We add two vertices s and t, make s adjacent to all $v \in V_1$ and make t adjacent to all $v \in V_k$. For any pair of $u \in V_i$ and $v \in V_j$ with $|i - j| \geq 2$, we do the following. If $\{u, v\} \in E$, then we remove it. Otherwise, we add a path $P_{u,v}$ of length 2 and a pendant vertex that is adjacent to the internal vertex w of $P_{u,v}$. Finally, we add a vertex v^*, add an edge between v^* and each original vertex $v \in V(G)$, and add a pendant vertex p adjacent to v^*. The constructed graph is denoted by H. See Figure 1 for an illustration of the graph H.

▶ **Lemma 8.** *There is a clique C in G such that $|C \cap V_i| = 1$ for all $1 \leq i \leq k$ if and only if there is a non-separating s-t path of length at most $k + 1$ in H.*

Proof. Suppose first that G has a clique C with $C \cap V_i = \{v_i\}$ for all $1 \leq i \leq k$. Then, $P = \langle s, v_1, v_2, \dots, v_k, t\rangle$ is an s-t path of length $k + 1$ in H. To see the connectivity of $H - V(P)$, it suffices to show that every vertex is reachable from v^* in $H - V(P)$. By the construction of H, each vertex in $V(G) \setminus V(P)$ is adjacent to v^* in $H - V(P)$. Each vertex z in $V(H) \setminus (V(G) \cup \{v^*, p\})$ is either the internal vertex w of $P_{u,v}$ for some $u, v \in V(G)$ or the pendant vertex adjacent to w. In both cases, at least one of u and v is not contained in P as $V(P) \setminus \{s, t\}$ is a clique in G, implying that z is reachable to v^*.

Conversely, suppose that H has a non-separating s-t path P of length at most $k + 1$ in H. By the assumption that G has more than k vertices, there is a vertex of G that does not belong to P. Observe that P does not contain any internal vertex w of some $P_{u,v}$ as otherwise the pendant vertex adjacent to w becomes an isolated vertex by deleting $V(P)$, which implies $H - V(P)$ has at least two connected components. Similarly, P does not contain v^*. These facts imply that the internal vertices of P belong to $V(G)$, and we have $|V(P) \cap V_i| = 1$ for all $1 \leq i \leq k$. Let $C = V(P) \setminus \{s, t\}$. We claim that C is a clique in G. Suppose otherwise. There is a pair of vertices $u, v \in C$ that are not adjacent in G. This implies that H contains the path $P_{u,v}$. However, as P contains both u and v, the internal vertex of $P_{u,v}$ together with its pendant vertex forms a component in $H - V(P)$, yielding a contradiction that P is a non-separating path in H. ◀

Thus, we have the following theorem.

▶ **Theorem 9.** *Shortest Non-Separating Path is W[1]-hard parameterized by k.*

3.3 Graphs with the diameter-treewidth property

By Theorem 9, Shortest Non-Separating Path is unlikely to be fixed-parameter tractable on general graphs. To overcome this intractability, we focus on sparse graph classes. We first note that the algorithmic meta-theorems for FO Model Checking [12, 13] do not seem to be applicable to Shortest Non-Separating Path as we need to care about the connectivity of graphs. However, the property that vertex set X forms a non-separating s-t path can be expressed as:

$$\mathtt{conn}(V \setminus X) \wedge \mathtt{hampath}(X, s, t),$$

where $\mathtt{conn}(Y)$ and $\mathtt{hampath}(Y, s, t)$ are formulas in MSO_2 such that $\mathtt{conn}(Y)$ (resp. $\mathtt{hampath}(Y, s, t)$) is true if and only of the subgraph induced by Y is connected and (resp. the subgraph induced by Y has a Hamiltonian path between s and t). We omit the details of these formulas, which can be found in [6] for example[2]. By Courcelle's theorem [5] and its extension due to Arnborg et al. [1], we can compute a shortest non-separating s-t path in $O(f(\mathrm{tw}(G))n)$ time, where n is the number of vertices and $\mathrm{tw}(G)$ is the treewidth[3] of G. As there is an $O(\mathrm{tw}(G)^{\mathrm{tw}(G)^3}n)$-time algorithm for computing the treewidth of an input graph G [2], we have the following theorem.

▶ **Theorem 10.** *Shortest Non-Separating Path is fixed-parameter tractable parameterized by the treewidth of input graphs.*

A class $\mathcal{C}$ of graphs is *minor-closed* if every minor of a graph $G \in \mathcal{C}$ also belongs to $\mathcal{C}$. We say that $\mathcal{C}$ has the *diameter-treewidth property* if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that for every $G \in \mathcal{C}$, the treewidth of G is upper bounded by $f(\mathrm{diam}(G))$, where $\mathrm{diam}(G)$ is the diameter of G. It is well known that every planar graph G has treewidth at most $3 \cdot \mathrm{diam}(G) + 1$ [22][4], which implies that the class of planar graphs has the diameter-treewidth property. This can be generalized to more wider classes of graphs. A graph is called an *apex graph* if it has a vertex such that removing it makes the graph planar.

▶ **Theorem 11** ([7, 9]). *Let $\mathcal{C}$ be a minor-closed class of graphs. Then, $\mathcal{C}$ has the diameter-treewidth property if and only if it excludes some apex graph.*

For $C \subseteq V(G)$ that induces a connected subgraph $G[C]$, we denote by G_C the graph obtained from G by contracting $G[C]$ into a single vertex v_C and making v_C adjacent to all the vertices in $N(C)$. Since $G[C]$ is connected, vertex v_C is well-defined.

▶ **Lemma 12.** *Let $C \subseteq V(G)$ be a vertex subset such that $G[C]$ is connected. Let P be an s-t path in G with $V(P) \cap C = \emptyset$. Then, P is non-separating in G if and only if it is non-separating in G_C.*

[2] In [6], they give an MSO_2 sentence $\mathtt{hamiltonicity}$ expressing the property of having a Hamiltonian cycle, which can be easily transformed into a formula expressing $\mathtt{hampath}(X, s, t)$.

[3] We do not give the definition of treewidth and (the optimization version of) Courcelle's theorem. We refer to [6] for details.

[4] More precisely, the treewidth of a planar graph is upper bounded by $3r + 1$, where r is the radius of the graph.

Proof. Suppose first that P is non-separating in G. Let $u, v \in V(G) \setminus V(P)$ be arbitrary. As P is non-separating, there is a u-v path P' in $G - V(P)$. Let u' be the vertex of G_C such that $u' = u$ if $u \notin C$ and $u' = v_C$ if $u \in C$. Let v' be the vertex defined analogously. We show that there is a u'-v' path in $G_C - V(P)$ as well. If P' does not contain any vertex in C, then it is also a u'-v' path in G_C, and hence we are done. Suppose otherwise. Let x and y be the vertices in $V(P') \cap C$ that are closest to u and v, respectively. Note that x and y can be the end vertices of P', that is, C may contain u and v. Let $P_{u,x}$ and (resp. $P_{y,v}$) be the subpath of P' between u and x (resp. y and v). Then, the sequence of vertices obtained by concatenating $P_{u,x}$ after $P_{y,v} - \{y\}$ and replacing exactly one occurrence of a vertex in C with v_C forms a path between u' and v'. Since we choose u, v arbitrarily, there is a path between any pair of vertices in $G_C - V(P)$ as well. Hence, P is non-separating in G_C.

Conversely, suppose that P is non-separating in G_C. For $u, v \in V(G_C) \setminus V(P)$, there is a path P' in $G_C - V(P)$. Suppose that neither $u = v_C$ nor $v = v_C$. Then, we can construct a u-v path in $G - V(P)$ as follows. If $v_C \notin V(P')$, P' is also a path in $G - V(P)$ and hence we are done. Otherwise, $v_C \in V(P')$. Let P_u and P_v be the subpaths in $P' - \{v_C\}$ containing u and v, respectively. From P_u and P_v, we have a u-v path in G by connecting them with an arbitrary path in $G[C]$ between the end vertices other than u and v. Note that such a bridging path in $G[C]$ always exists since $G[C]$ is connected. Moreover, as $V(P') \cap C = \emptyset$ and $V(P) \cap C = \emptyset$, this is also a u-v path in $G - V(P)$. Suppose otherwise that either $u = v_C$ or $v = v_C$, say $u = v_C$. In this case, we can construct a path between every vertex w in C and v by concatenating P' and an arbitrary path in $G[C]$ between w and the end vertex of the subpath $P' - \{v_C\}$ other than v. Therefore, P is non-separating in G. ◀

Now, we are ready to state the main result of this subsection.

▶ **Theorem 13.** *Let $\mathcal{C}$ be a graph class excluding a fixed apex graph H as a minor. Then, Shortest Non-Separating Path on $\mathcal{C}$ is fixed-parameter tractable parameterized by k.*

Proof. Let $G \in \mathcal{C}$. We first compute $B = \{v \in V(G) : \mathrm{dist}(s, v) \le k\}$. This can be done in linear time. If $t \notin B$, then the instance (G, s, t, k) is trivially infeasible. Suppose otherwise that $t \in B$. Let C be a component in $G - B$. By definition, every non-separating s-t path P of length at most k does not contain any vertex of C. Let G' be the graph obtained from G by contracting all edges in $E(G - B)$. For each component C in $G - B$, we denote by v_C the vertex of G' corresponding to C (i.e., v_C is the vertex obtained by contracting all edges in C). Then, we have $\mathrm{diam}(G') \le 2k + 2$ as $\mathrm{diam}(G[B]) \le k$ and every vertex in $V(G') \setminus B$ is adjacent to a vertex in B. By Lemma 12, G has a non-separating s-t path of length at most k if and only if so does G'. Since $\mathcal{C}$ is minor-closed, we have $G' \in \mathcal{C}$ and hence the treewidth of G' is upper bounded by $f(2k + 2)$ for some function f. By Theorem 10, we can check whether G' has a non-separating s-t path of length at most k in $O(g(k)|V(G')|)$ time. ◀

Theorem 10 does not give precise dependence on $\mathrm{tw}(G)$ in the running time of the algorithm. In fact, given a tree decomposition of G of width $\mathrm{tw}(G)$ we can design an algorithm for Shortest Non-Separating Path running in time $2^{O(\mathrm{tw}(G))}n^{O(1)}$, using matroid based tools [11]. Further, there exists a factor-2 approximation for $\mathrm{tw}(G)$ running in time $2^{O(\mathrm{tw}(G))}n$ [16]. Combined with this we get the following result.

▶ **Theorem 14.** *There exists an algorithm for Shortest Non-Separating Path running in time $2^{O(\mathrm{tw}(G))}n^{O(1)}$.*

The proof of this result is based on the standard dynamic programming over graphs of bounded treewidth together with representative sets and will appear in the final version of the paper. Applying the result of Theorem 14 in Theorem 13, we get the following results.

▶ **Theorem 15.** *Let $\mathcal{C}$ be a graph class excluding a fixed apex graph H as a minor. Then,* Shortest Non-Separating Path *on $\mathcal{C}$ admits an algorithm with running time $2^{O(k)}n^{O(1)}$.*

3.4 TI-Shortest Non-Separating Path on Unit Disk Graphs

Given n unit disks in the plane, a unit disk graph G consists of n vertices, corresponding to each disk, and there is an edge between two vertices if and only if the corresponding unit disks intersect. For our problem, we are given a unit disk graph $G = (V, E)$ and its representation $(\mathcal{D}, C)$. Let $V = \{v_1, v_2, \cdots, v_n\}$ and for each v_i, D_i be the corresponding disk centered at c_i. Here $\mathcal{D} = \{D_i| \ 1 \le i \le n\}$ and $C = \{c_i| \ 1 \le i \le n\}$.

▶ **Reduction Rule 1.** *If G has more than two connected components then return* NO.

▶ **Lemma 16.** *Reduction Rule 1 is safe and can be implemented in polynomial time.*

Let us assume that the graph has exactly two connected components. Observe that the given instance is a YES instance if and only if at least one of the two components contains exactly k vertices. Otherwise, the instance is a NO instance. The number of components in the given graph and the number of vertices in each component can be checked in polynomial time. Thus now onward we assume that G is connected. Let us consider a $(\frac{1}{2} \times \frac{1}{2})$ square grid on the plane. Let V_S be the set of centers of the disks that are contained inside a grid cell S; more formally, $V_S = \{v_i| \ c_i \in S\}$. We also define $N(V', S)$ as the set of vertices in the cell S that are neighbors of vertices in V'. For any cell S in the grid, next, we prove that if S contains at least $k + 24$ centers then the given instance is a YES instance.

▶ **Reduction Rule 2.** *If there exists a cell S with at least $k + 24$ centers, return YES.*

▶ **Lemma 17.** *Reduction Rule 2 is safe and can be implemented in polynomial time.*

From now onwards we assume that each cell has at most $k + 23$ centers.

▶ **Theorem 18.** TI-Shortest Non-Separating Path *can be solved in time $2^{O(k \log k)}n^{O(1)}$ on unit disk graphs.*

Proof. We guess the first vertex of the path, say v_i. Let Y be the set of vertices in the circle drawn centering c_i with radius k. Observe that the vertices of the solution path P must be a subset of Y. There are at most $\mathcal{O}(k^2)$ cells inside the circle drawn centering c_i with radius k. By Reduction Rule 2, no cell contains more than $k + 23$ vertices. Thus Y contains at most $O(k^3)$ vertices. Now all we need to do is to guess a subset X of size k as potential vertices of the path P and test that indeed it forms a path and $G - X$ is connected. All this can be done in $\binom{O(k^3)}{k} \times k! \times n^{O(1)} = 2^{O(k \log k)}n^{O(1)}$ time, concluding the proof. ◀

3.5 Chordal graphs with $k = \text{dist}(s, t)$

In Section 3.1, we have seen that Shortest Non-Separating Path is NP-complete even on split graphs (and thus on more general chordal graphs as well). To overcome this intractability, we restrict ourselves to finding a non-separating s-t path of length $\text{dist}(s, t)$ on chordal graphs.

A graph G is *chordal* if it has no cycles of length at least 4 as an induced subgraph. In the following, we fix a connected chordal graph G.

▶ **Lemma 19.** *Let $S \subseteq V(G)$ be a vertex set such that $G[S]$ is connected. For $u, v \in S$, every induced u-v path P in G satisfies that $V(P) \subseteq N[S]$.*

For $u, v \in V(G)$, a set of vertices $S \subseteq V(G) \setminus \{u, v\}$ is called a *u-v separator* of G if there is no u-v path in $G - S$. An inclusion-wise minimal u-v separator of G is called a *minimal u-v separator*. A *minimal separator* of G is a minimal u-v separator for some $u, v \in G$. Dirac's well-know characterization [8] of chordal graphs states that a graph is chordal if and only if every minimal separator induces a clique.

▶ **Lemma 20.** *Let $s, t \in V(G)$ be such that $\{s, t\} \notin E(G)$. If $v \in V(G) \setminus \{s, t\}$ is an internal vertex of a shortest s-t path P, then $N[v] \setminus \{s, t\}$ is an s-t separator of G.*

Proof. Let $d = \mathrm{dist}(s, t)$. For $0 \leq i \leq d$, let

$$D_i = \{v \in V(G) : \mathrm{dist}(s, v) = i \wedge \mathrm{dist}(v, t) = d - i\}$$

and $V(P) \cap D_i = \{u_i\}$. Observe that each D_i is a clique: if $i \in \{0, d\}$, then it is a singleton; otherwise, it is a minimal s-t separator of the chordal graph $G[\bigcup_{0 \leq j \leq d} D_j]$, meaning that D_i is a clique. From this observation, we have $D_i \subseteq N[u_i] \setminus \{s, t\}$ for $0 < i < d$. Let j ($0 < j < d$) be the index such that $v = u_j$.

Suppose to the contrary that there is an induced s-t path Q such that $V(Q) \cap (N[u_j] \setminus \{s, t\}) = \emptyset$. By Lemma 19, $V(Q) \subseteq N[V(P)] = \bigcup_{0 \leq i \leq d} N[u_i]$ holds. Since Q starts in $N[u_0]$ and ends in $N[u_d]$, there are indices i and k with $0 \leq i < j < k \leq d$ such that Q consecutively visits a vertex $v_i \in N[u_i]$ and then a vertex $v_k \in N[u_k]$ in this order. Since $\mathrm{dist}(u_i, u_k) = k - i \geq 2$ and $\{v_i, v_k\} \in E$, at least one of $v_i \neq u_i$ and $v_k \neq u_k$ holds. By symmetry, we assume that $v_i \neq u_i$.

If $v_k = u_k$, then $v_i \in N(u_i) \cap N(u_k)$. In this case, we have $i = j - 1$ and $k = j + 1$ since otherwise P admits a shortcut using the subpath $\langle u_i, v_i, u_k \rangle$. This implies that $\mathrm{dist}(s, v_i) \leq \mathrm{dist}(s, u_i) + 1 = i + 1 = j$ and $\mathrm{dist}(v_i, t) \leq 1 + \mathrm{dist}(v_k, t) = 1 + \mathrm{dist}(u_k, t) = 1 + (d - k) = d - j$. Since $\mathrm{dist}(s, v_i) + \mathrm{dist}(v_i, t) \geq d$, we have $\mathrm{dist}(s, v_i) = j$ and $\mathrm{dist}(v_i, t) = d - j$. This implies that $v_i \in D_j \subseteq N[u_j] \setminus \{s, t\}$, a contradiction.

Next we consider the case $v_k \neq u_k$. Recall that we also have $v_i \neq u_i$ as an assumption. In this case, we have $k - i \leq 3$ as $\langle u_i, v_i, v_k, u_k \rangle$ is not a shortcut for P. Assume first that $k - i = 3$. By symmetry, we may assume that $i = j - 1$ and $k = j + 2$. Since $\mathrm{dist}(s, v_i) \leq \mathrm{dist}(s, u_i) + 1 = j$ and $\mathrm{dist}(v_i, t) \leq 2 + \mathrm{dist}(u_k, t) \leq 2 + (d - k) = d - j$, we have $v_i \in D_j \subseteq N[u_j] \setminus \{s, t\}$, a contradiction. Next assume that $k - i = 2$. That is, $i = j - 1$ and $k = j + 1$. Since $v_i, v_k \notin N[u_j] \setminus \{s, t\}$ and P is shortest, the vertices v_i, u_i, u_j, u_k, v_k are distinct and form a cycle of length 5. Observe that $v_i \notin \{s, t\}$ since otherwise $\langle v_i = s, v_k, u_k \rangle$ or $\langle u_i, v_i = t \rangle$ is a shortcut. Similarly, $v_k \notin \{s, t\}$. Hence, $v_i, v_k \notin N[u_j]$. Therefore, the possible chords for the cycle $\langle v_i, u_i, u_j, u_k, v_k \rangle$ are $\{u_i, v_k\}$ and $\{u_k, v_i\}$. In any combination of them, the graph has an induced cycle of length at least 4. ◀

Let d and D_i be defined as in the proof of Lemma 20, and let $D = \bigcup_{0 \leq i \leq d} D_i$. Recall that each D_i is a clique. Observe that if $|D_i| = 1$ for all $0 \leq i \leq d$, then G contains a unique shortest s-t path, and thus the problem is trivial. Otherwise, we define ℓ to be the minimum index such that $|D_\ell| > 1$ and r to be the maximum index such that $|D_r| > 1$. Since $|D_0| = |D_d| = 1$, we have $0 < \ell \leq r < d$.

Our algorithm works as follows.

1. If G contains a unique shortest s-t path P, then test if P is non-separating.
2. Otherwise, find a shortest s-t path P satisfying the following conditions.
   a. $V(P)$ does not contain a minimal a-b separator for all $a \in D_\ell$ and $b \in V \setminus D$.
   b. $V(P)$ does not contain a minimal a-b separator for all $a \in D_\ell$ and $b \in D_r$.

▶ **Lemma 21.** *The algorithm is correct.*

▶ **Lemma 22.** *The algorithm has a polynomial-time implementation.*

We do not optimize the running time of the above algorithm, and a straightforward implementation runs in time $O(n^2m)$, where $n = |V(G)|$ and $m = |E(G)|$, which might be improved with some data structure.

▶ **Theorem 23.** *There is a polynomial-time algorithm for* Shortest Non-Separating Path *on chordal graphs, given that k is equal to the shortest path distance between s and t.*

4 Shortest Non-Disconnecting Path

The goal of this section is to establish the fixed-parameter tractability and a conditional lower bound on polynomial kernelizations for Shortest Non-Disconnecting Path.

4.1 Fixed-parameter tractability

▶ **Theorem 24.** *Shortest Non-Disconnecting Path can be solved in time $2^{\omega k} n^{O(1)}$, where ω is the matrix multiplication exponent and n is the number of vertices of G.*

To prove this theorem, we give a dynamic programming algorithm with the aid of representative families of cographic matroids. Let (G, s, t, k) be an instance of Shortest Non-Disconnecting Path. For $0 \le i \le k$ and $v \in V(G)$, we define $\mathsf{dp}(i, v)$ as the family of all sets of edges F satisfying the following two conditions: (1) F is the set of edges of an s-v path of length i and (2) $G - F$ is connected. An edge set F is *legitimate* if F forms a path and $G - F$ is connected. For a family of edge sets $\mathcal{F}$ and an edge e, we define $\mathcal{F} \bowtie e := \{F \cup \{e\} : F \in \mathcal{F}\}$ and $\mathsf{leg}(\mathcal{F})$ as the subfamily of $\mathcal{F}$ consisting of all legitimate $F \in \mathcal{F}$. The following simple recurrence correctly computes $\mathsf{dp}(i, v)$.

$$\mathsf{dp}(i,v) = \begin{cases} \{\emptyset\} & i = 0 \text{ and } s = v & (3) \\ \emptyset & i = 0 \text{ and } s \neq v & (4) \\ \mathsf{leg}\left(\bigcup_{u \in N(v)} (\mathsf{dp}(i-1,u) \bowtie \{u,v\})\right) & i > 0\ . & (5) \end{cases}$$

A straightforward induction proves that $\mathsf{dp}(i, t) \neq \emptyset$ if and only if G has a non-disconnecting s-t path of length exactly i and hence it suffices to check whether $\mathsf{dp}(i, t) \neq \emptyset$ for $0 \le i \le k$. However, the running time to evaluate this recurrence is $n^{O(k)}$. To reduce the running time of this algorithm, we apply Theorem 4 to each $\mathsf{dp}(i, v)$. Now, instead of (5), we define

$$\mathsf{dp}(i,v) = \mathsf{rep}_{k-i}\left(\mathsf{leg}\left(\bigcup_{u \in N(v)} (\mathsf{dp}(i-1,u) \bowtie \{u,v\})\right)\right), \qquad (3')$$

where $\mathsf{rep}_{k-i}(\mathcal{F})$ is a $(k - i)$-representative family of $\mathcal{F}$ for the cographic matroid $\mathcal{M} = (E(G), \mathcal{I})$ defined on G. In the following, we abuse the notation of dp to denote the families of legitimate sets that are computed by the recurrence composed of (3), (4), and (3').

▶ **Lemma 25.** *The recurrence composed of (3), (4), and (3') is correct, that is, G has a non-disconnecting s-t path of length at most k if and only if $\bigcup_{0 \le i \le k} \mathsf{dp}(i, t) \neq \emptyset$.*

Proof. It suffices to show that $\mathsf{dp}(k', t) \neq \emptyset$ if G has a non-disconnecting s-t path P of length $k' \leq k$. Let $P = (v_0 = s, v_1, \dots, v_{k'} = t)$ be a non-disconnecting path in G. We assume that G has no non-disconnecting s-t path of length strictly smaller than k'. For $0 \leq i \leq k'$, we let $P_i = (v_i, v_{i+1}, \dots, v_{k'})$. In the following, we prove, by induction on i, a slightly stronger claim that there is a legitimate set $F \in \mathsf{dp}(i, v_i)$ such that $F \cup E(P_i)$ forms a non-disconnecting s-t path in G for all $0 \leq i \leq k'$. As $\mathsf{dp}(0, s) = \{\emptyset\}$ and $P_0 = P$ itself is a non-disconnecting path, we are done for $i = 0$. Suppose that $i > 0$. By the induction hypothesis, there is a legitimate $F \in \mathsf{dp}(i-1, v_{i-1})$ such that $F \cup E(P_{i-1})$ forms a non-disconnecting s-t path in G. Note that $F \cap E(P_{i-1}) = \emptyset$ as otherwise G has a non-disconnecting s-t path of length smaller than k'. Let $\mathcal{F} = \mathsf{leg}(\bigcup_{u \in N(v_i)}(\mathsf{dp}(i-1) \bowtie \{u, v_i\}))$. Since $F \cup E(P_{i-1})$ is legitimate, $F \cup \{\{v_{i-1}, v_i\}\}$ is also legitimate, implying that $\mathcal{F}$ is nonempty. Let $\widehat{\mathcal{F}} = \mathsf{rep}_{k-i}(\mathcal{F})$ be $(k-i)$-representative for $\mathcal{F}$, $X = F \cup \{\{v_{i-1}, v_i\}\}$, and let $Y = E(P_i)$. As $|Y| \leq k - i$, $X \cap Y = \emptyset$, and $X \cup Y \in \mathcal{I}$, $\widehat{\mathcal{F}}$ contains an edge set $\widehat{X}$ with $\widehat{X} \cap Y = \emptyset$ and $\widehat{X} \cup Y \in \mathcal{I}$, implying that there is $\widehat{X} \in \mathsf{dp}(i, v_i)$ such that $\widehat{X} \cup E(P_i)$ forms a non-disconnecting s-t path in G. ◀

▶ **Lemma 26.** *The recurrence can be evaluated in time $2^{\omega k} n^{O(1)} \subset 5.18^k n^{O(1)}$, where $\omega < 2.373$ is the exponent of the matrix multiplication.*

Proof. By Theorem 4, $\mathsf{dp}(i, v)$ contains at most $2^k kn$ sets for $0 \leq i \leq k$ and $v \in V(G)$ and can be computed in time $2^{\omega k} n^{O(1)}$. ◀

Thus, Theorem 24 follows.

4.2 Kernel lower bound

It is well known that a parameterized problem is fixed-parameter tractable if and only if it admits a kernel (see [6], for example). By Theorem 24, Shortest Non-Disconnecting Path admits a kernel. A next natural step next is to explore the existence of polynomial kernel for Shortest Non-Disconnecting Path. However, the following theorem conditionally rules out the possibility of polynomial kernelization. We first show the following lemma.

▶ **Lemma 27.** *Let H be a connected graph. Suppose that H has a cut vertex v. Let C be a component in $H - \{v\}$ and let $F \subseteq E(H[C \cup \{v\}])$. Then, $H - F$ is connected if and only if $H[C \cup \{v\}] - F$ is connected.*

Proof. If $H - F$ is connected, then all the vertices in $C \cup \{v\}$ are reachable from v in $H - F$ without passing through any vertex in $V(H) \setminus (\{C\} \cup \{v\})$. Thus, such vertices are reachable from v in $H[C \cup \{v\}] - F$. Conversely, suppose $H[C \cup \{v\}] - F$ is connected. Then, every vertex in C is reachable from v in $H - F$. Moreover, as F does not contain any edge outside $H[C \cup \{v\}]$, every other vertex is reachable from v in $H - F$ as well. ◀

▶ **Theorem 28.** *Unless* coNP $\subseteq$ NP/poly*, Shortest Non-Disconnecting Path does not admit a polynomial kernelization (with respect to parameter k).*

Proof. We give an OR-composition for Shortest Non-Disconnecting Path. Let $(G_1, s_1, t_1, k), \dots, (G_p, s_p, t_p, k)$ be p instances of Shortest Non-Disconnecting Path.

We assume that for $1 \leq i \leq p$, t_i is not a cut vertex in G_i. To justify this assumption, suppose that t_i is a cut vertex in G_i. Let C be the component in $G_i - \{t_i\}$ that contains s_i. By Lemma 27, for any s_i-t_i path, it is non-disconnecting in G_i if and only if so is in $G_i[C \cup \{t_i\}]$. Thus, by replacing G_i with $G_i[C]$, we can assume that t_i is not a cut vertex in G_i.

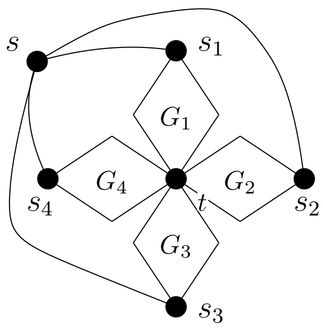

Figure 2 An illustration of the graph G obtained from $q = 4$ instances.

From the disjoint union of $G_1, \dots, G_p$, we construct a single instance (G, s, t, k') as follows. We first add a vertex s and an edge between s and s_i for each $1 \leq i \leq p$. Then, we identify all t_i's into a single vertex t. See Figure 2 for an illustration.

In the following, we may not distinguish t from t_i. Now, we claim that $(G, s, t, k+1)$ is a yes-instance if and only if (G_i, s_i, t_i, k) is a yes-instance for some i.

Consider an arbitrary s-t path in G. Observe that all edges in the path except for the one incident to s are contained in a single subgraph G_i for some $1 \leq i \leq p$ as $\{s, t\}$ separates $V(G_i) \setminus \{t_i\}$ from $V(G_j) \setminus \{t_j\}$ for $j \neq i$. Moreover, the path P forms $P = (s, s_i, v_1, \dots, v_q, t)$, meaning that the subpath $P' = (s_1, v_1, \dots, v_q, t_i)$ is an s_i-t_i path in G_i. This conversion is reversible: for any s_i-t_i path P' in G_i, the path obtained from P' by attaching s adjacent to s_i is an s-t path in G. Thus, it suffices to show that for $F \subseteq E(G_i)$, $F \cup \{\{s, s_i\}\}$ is a cut of G if and only if F is a cut of G_i. Since t is a cut vertex in $G - \{\{s, s_i\}\}$, by Lemma 27, the claim holds. ◀

We obtain the following result for the Smallest Non-Separating Set problem.

▶ **Theorem 29.** *Unless* coNP $\subseteq$ NP/poly, Smallest Non-Separating Set *does not admit a polynomial kernelization (with respect to parameter k) on planar graphs.*

Proof. We give an OR-composition for Smallest Non-Separating Set. Given t planar graphs $G_1, G_2, \cdots, G_t$ where each G_i contains n_i many vertices. We construct a new planar graph G' as follows. We create $k+2$ many copies for each planar graph G_i. For each planar graph G and a vertex $v \in V(G)$ there exists a planar embedding with v on the outer-face. Fix an arbitrary set of $k+2$ *distinct* vertices in G_i, say $v^1, v^2, \cdots, v^{k+2}$. Then, we obtain embeddings for $G_i^1, G_i^2, \cdots, G_i^{k+2}$ such that $v_i^1, v_i^2, \cdots, v_i^{k+2}$ are on the outer-face, respectively. Now add an edge between v_i^ℓ and $v_i^{\ell+1}$ for all $1 \leq \ell \leq k+1$. Also, add an edge between v_i^{k+2} and v_{i+1}^1 for all $1 \leq i \leq t-1$. That is these planar graphs are chained into a path. It is easy to see that the resulting instance G' is planar.

▷ Claim 30. G' is a YES instance if and only if at least one of the G_i is a YES instance.

Proof. We prove the forward direction first. Assume that in G', there exists a connected set X of size k in G' such that $G' - X$ is connected. Notice, deleting any vertex v_i^j from G_i^j where $j \in [k+1]$ makes the graph G' disconnected. Thus X can not contain any vertex v_i^j from G_i^j where $j \in [k+1]$. Hence, we can assume that $X \cap \{v_i^j\} = \emptyset$ in G_j for $1 \leq j \leq k+2$, i.e X is contained completely inside any one of G_i^j without containing any vertex at the outer face that shares edges with other copies of G_i. Therefore, X is of size k inside G_i^j and $G_i^j - X$ is connected. Hence, G_i is a YES instance.

Now, we prove the reverse direction. Assume that there is a graph, G_i in which there exists a connected set X of size k such that $G_i - X$ is connected. Without loss of generality, assume $X = \{v_1, v_2, \cdots, v_k\}$. Since G_i contains X, all the copies of G_i in G' also contain X. Now, we show that there exists a copy of G_i, say G_i^p in G', that does not contain any vertex of X on the outer face which shares edges with other copies of G_i. As $|X| = k$, observe that there can be at most k many different copies of G_i in G' which has a vertex of X on the outer faces which shares edges with the other copies. Hence, by pigeon hole principle, there exists at least a copy of G_i in G' which has no vertex on the outer face that shares edges with other copies. Thus, deleting X from that copy will not disconnect any G_i^a or G_j^b in the graph G'. Therefore, G' is also a YES instance. ◁

This concludes the proof. ◀

Comonadic semantics for hybrid logic

Samson Abramsky
University College London, London, UK

Dan Marsden
University of Oxford, Oxford, UK

Abstract

Hybrid logic is a widely-studied extension of basic modal logic, which corresponds to the bounded fragment of first-order logic. We study it from two novel perspectives: (1) We apply the recently introduced paradigm of comonadic semantics, which provides a new set of tools drawing on ideas from categorical semantics which can be applied to finite model theory, descriptive complexity and combinatorics. (2) We give a novel semantic characterization of hybrid logic in terms of *invariance under disjoint extensions*, a minimal form of locality. A notable feature of this result is that we give a uniform proof, valid for both the finite and infinite cases.

1 Introduction

Hybrid logic (see e.g. [8, 7]) has been widely studied as an expressive extension of basic modal logic. It is semantically natural, e.g. in the analysis of temporal reasoning [10], and since it allows an internalisation of relational semantics, it has a very well-behaved proof theory [11], without needing to resort to explicit labelling of proofs or tableaux. The corresponding fragment of first-order logic under modal translation is the *bounded fragment*, in which quantification is relativized to atomic formulas from the relational vocabulary. This fragment is important in set theory [19], and has been studied in general proof- and model-theoretic terms in [16, 15].

In the present paper we study hybrid logic with inverse modalities, which we shall refer to as hybrid temporal logic, from two novel perspectives:

- Firstly, we apply the recently introduced paradigm of *comonadic semantics* [1, 5], which gives a uniform description of a wide range of logic fragments indexed by resource parameters. These fragments play a key role in finite model theory and descriptive complexity. Examples include the Ehrenfeucht-Fraïssé comonads $\mathbb{E}_k$, which capture the quantifier-rank fragments; the pebbling comonads $\mathbb{P}_k$, which capture the finite variable fragments; and the modal comonads $\mathbb{M}_k$, which capture the modal fragments of bounded modal depth. In each case, the comonads induce a number of resource-indexed equivalences on structures, which can be shown to capture the equivalences induced by the corresponding logic fragments. Moreover, the coalgebras for these comonads can be shown to characterise important combinatorial invariants of structures. For example, in the case of $\mathbb{P}_k$, the corresponding invariant is *tree-width* [5, 1].

  The common structure exhibited by this wide range of examples has been axiomatised in a very general setting in terms of arboreal categories [4]. This provides a new set of tools drawing on ideas from categorical semantics which can be applied to finite model theory, descriptive complexity and combinatorics. Early examples of the use of these ideas can be found in [25, 13, 2, 14], and further results are emerging rapidly, see e.g. [22, 12].

In the present paper, we extend the program of comonadic semantics to hybrid logic. The comonad which captures hybrid logic is a natural restriction of a pointed version of the Ehrenfeucht-Fraïssé comonad previously introduced in [5]. This comonadic analysis nicely reveals, in a clear and conceptual way, the way in which hybrid logic sits between basic modal logic and first-order logic. We characterise the coalgebras for this comonad as tree covers of a relational structure with additional locality constraints. This enables a uniform treatment of logical equivalences, bisimulation games, and combinatorial parameters, within the axiomatic framework recently given in [4].

- Secondly, we give a novel semantic characterization of the version of hybrid logic we study, in terms of *invariance under disjoint extensions* (and various equivalent formulations). This is a minimal form of locality relative to a given base-point, and shows that hybrid logic is the maximal fragment of first-order logic retaining a local character. A notable feature of this result is that we give a uniform proof, valid for both the finite and infinite cases. In particular, we make no use of the compactness theorem, and instead use game-theoretic constructions, specifically a result we call the Workspace Lemma.

  Apart from the interest of the results pertaining to hybrid logic in themselves, we see our work here as fitting into and refining a larger picture, of an emerging landscape in which the tractability of various logic fragments is mirrored in the structural properties of the corresponding comonads. In particular, hybrid logic is undecidable, but still retains a local character. A salient property which the modal and guarded fragments have, and hybrid logic lacks, is the bisimilar companion property. This property plays a key role in the uniform proofs of the van Benthem-Rosen Theorem for these fragments [24, 3]. We mitigate the failure of this property for hybrid logic by the use of game-theoretic arguments. All of this will be explained in detail in Section 6.

After some preliminaries in Section 2, we shall introduce the hybrid comonad in Section 3, and study the coalgebras for this comonad in Section 4. In Section 5, we characterize the equivalence on structures induced by hybrid logic in terms of *spans of open pathwise embeddings* for this comonad, following the pattern established in [5] and axiomatised in [4]. Then we develop the results on the semantic characterisation of hybrid logic in Section 6.

2 Preliminaries

We shall need a few notions on posets. Given $x, y \in P$ for a poset $(P, \leq)$, we write $x \uparrow y$ if x and y are comparable in the order, i.e. $x \leq y$ or $y \leq x$. We will use finite sequences extensively; these are partially ordered by prefix, with notation $s \sqsubseteq t$ indicating that list s is a prefix of list t.

A relational vocabulary σ is a set of relation symbols R, each with a specified positive integer arity. A σ-structure $\mathfrak{A}$ is given by a set A, the universe of the structure, and for each R in σ with arity n, a relation $R^{\mathfrak{A}} \subseteq A^n$. A homomorphism $h : \mathfrak{A} \to \mathfrak{B}$ is a function $h : A \to B$ such that, for each relation symbol R of arity n in σ, for all $a_1, \ldots, a_n$ in A: $R^{\mathfrak{A}}(a_1, \ldots, a_n) \Rightarrow R^{\mathfrak{B}}(h(a_1), \ldots, h(a_n))$. We write $\mathsf{Struct}(\sigma)$ for the category of σ-structures and homomorphisms.

Since evaluation in modal logics is relative to a given world, we shall also use the pointed category $\mathsf{Struct}_\star(\sigma)$. Objects are pairs $(\mathfrak{A}, a)$, where $\mathfrak{A}$ is a σ-structure, and $a \in A$. Morphisms $h : (\mathfrak{A}, a) \to (\mathfrak{B}, b)$ are homomorphisms $h : \mathfrak{A} \to \mathfrak{B}$ such that $h(a) = b$.

A *modal vocabulary* has only relation symbols of arity ≤ 2: a set of unary predicate symbols P, which will correspond to modal propositional atoms; and a binary relation symbol E, which we think of as a *transition relation* (more traditionally referred to as an *accessibility relation*).

2.1 Hybrid Temporal Logic

The main system we shall study is Hybrid Temporal Logic (HTL). HTL formulas are built from propositional atoms p and *world variables* x, with the following syntax:

$$\varphi ::= p \mid x \mid \neg\varphi \mid \varphi \wedge \varphi' \mid \varphi \vee \varphi' \mid \Box\varphi \mid \Diamond\varphi \mid \Box^{-}\varphi \mid \Diamond^{-}\varphi \mid {\downarrow}x.\,\varphi \mid @_x\varphi.$$

We use a redundant syntax to make it more convenient to discuss fragments. The new features compared with basic modal logic, augmented with backwards modalities as is standard in temporal logic, are the world variables, which can be bound with $\downarrow$, and used to force evaluation at a given world with @. Hybrid formulae are graded by their *hybrid modal depth.* This is the usual notion of modal depth, with the adjustment that sub-formulae of the form $\Diamond x$ or $\Diamond^{-} x$, for some world variable x, are deemed to have zero depth.

The semantics of hybrid temporal logic is given by translation into first-order logic with equality over a unary modal vocabulary, with a unary predicate P for each proposition atom p, and a single transition relation E. World variables are treated as ordinary first-order variables. The translation is parameterised on a variable, corresponding to the world at which the formula is to be evaluated. We write $\psi[x/y]$ for the result of substituting x for the free occurrences of y in ψ.

$$\begin{aligned}
\mathsf{ST}_x(p) &= P(x) \\
\mathsf{ST}_x(x') &= x = x' \\
\mathsf{ST}_x(\neg\varphi) &= \neg\,\mathsf{ST}_x(\varphi) \\
\mathsf{ST}_x(\varphi \wedge \varphi') &= \mathsf{ST}_x(\varphi) \wedge \mathsf{ST}_x(\varphi') \\
\mathsf{ST}_x(\varphi \vee \varphi') &= \mathsf{ST}_x(\varphi) \vee \mathsf{ST}_x(\varphi')
\end{aligned}
\qquad
\begin{aligned}
\mathsf{ST}_x(\Box\varphi) &= \forall y.[E(x,y) \to \mathsf{ST}_y(\varphi)] \\
\mathsf{ST}_x(\Diamond\varphi) &= \exists y.[E(x,y) \wedge \mathsf{ST}_y(\varphi)] \\
\mathsf{ST}_x(\Box^{-}\varphi) &= \forall y.[E(y,x) \to \mathsf{ST}_y(\varphi)] \\
\mathsf{ST}_x(\Diamond^{-}\varphi) &= \exists y.[E(y,x) \wedge \mathsf{ST}_y(\varphi)] \\
\mathsf{ST}_x({\downarrow}x'.\varphi) &= \mathsf{ST}_x(\varphi)[x/x'] \\
\mathsf{ST}_x(@_{x'}\varphi) &= \mathsf{ST}_x(\varphi)[x'/x]
\end{aligned}$$

The obvious stipulations about renaming bound variables to avoid variable capture apply.

The target of this translation is the *bounded fragment* of first-order logic with equality, with quantifiers restricted to those of the form $\exists y.[E(x,y) \wedge \varphi]$, $\forall y.[E(x,y) \to \varphi]$, $\exists y.[E(y,x) \wedge \varphi]$, $\forall y.[E(y,x) \to \varphi]$, with $x \neq y$. Hybrid temporal logic is in fact equiexpressive with this fragment [7].

Note that $\mathsf{ST}_x(\Diamond y)$ is logically equivalent to $E(x,y)$, and similarly $\mathsf{ST}_x(\Diamond^{-} y)$ is logically equivalent to $E(y,x)$. Thus these formulas test for the presence of a transition between worlds which have already been reached, justifying our assignment of modal depth 0.

3 The hybrid comonad

We shall now introduce the hybrid comonad on $\mathsf{Struct}_\star(\sigma)$ for modal vocabularies σ, motivating it as combining features of the Ehrenfeucht-Fraïssé and modal comonads from [5].

1. We recall firstly the Ehrenfeucht-Fraïssé comonad $\mathbb{E}_k$ on $\mathsf{Struct}(\sigma)$ for an arbitrary vocabulary σ. Given a structure $\mathfrak{A}$, the universe of $\mathbb{E}_k\mathfrak{A}$ is the set of non-empty sequences of elements of A of length $\leq k$. We think of these sequences as *plays* in the Ehrenfeucht-Fraïssé game on $\mathfrak{A}$. We define the map $\varepsilon_{\mathfrak{A}} : \mathbb{E}_k A \to A$ which sends a sequence to its last element, which we think of as the current move or *focus* of the play. For a relation R of arity n, we define $R^{\mathbb{E}_k\mathfrak{A}}(s_1, \ldots, s_n)$ to hold iff $s_i {\uparrow} s_j$ for all $1 \leq i, j \leq n$, and $R^{\mathfrak{A}}(\varepsilon_{\mathfrak{A}}(s_1), \ldots, \varepsilon_{\mathfrak{A}}(s_n))$. Explicitly, for unary predicates P, $P^{\mathbb{E}_k\mathfrak{A}}(s)$ iff $P^{\mathfrak{A}}(\varepsilon_{\mathfrak{A}}(s))$, and for a binary relation R, $R^{\mathbb{E}_k\mathfrak{A}}(s,t)$ iff $s{\uparrow}t$ and $R^{\mathfrak{A}}(\varepsilon_{\mathfrak{A}}(s), \varepsilon_{\mathfrak{A}}(t))$. Thus the relations hold *along* plays as one extends another, but not between *different* (i.e. incomparable) plays.

2. This construction lifts to the pointed category $\mathsf{Struct}_\star(\sigma)$. We define the universe of $\mathbb{E}_k(\mathfrak{A}, a)$ to comprise the non-empty sequences of length $\leq k+1$ which start with a. The distinguished element is $\langle a \rangle$. The relations are lifted in exactly the same way as previously.
3. The modal comonad $\mathbb{M}_k$ over a modal vocabulary with unary predicates P corresponding to propositional atoms, and a single transition relation E, restricts the sequences in $\mathbb{E}_k(\mathfrak{A}, a)$ to those of the form $\langle a_0, \ldots a_j \rangle$, $a_0 = a$, such that for all i with $0 \leq i < j$, $E^{\mathfrak{A}}(a_i, a_{i+1})$. Thus we can only extend a sequence with an element which the previous element "sees". Moreover, the transition relation E is lifted in a correspondingly local fashion, so that a sequence is only related to its immediate extensions: $E^{\mathbb{M}_k(\mathfrak{A},a)}(s,t)$ iff $t = s\langle a' \rangle$ and $E^{\mathfrak{A}}(\varepsilon_{\mathfrak{A}}(s), \varepsilon_{\mathfrak{A}}(t))$. This is the familiar *unravelling* construction for modal structures [9].
4. The hybrid comonad $\mathbb{H}_k$ is again defined on the pointed category $\mathsf{Struct}_\star(\sigma)$. $\mathbb{H}_k(\mathfrak{A}, a)$ has as universe the subset of $\mathbb{E}_k(A, a)$ of those sequences $\langle a_0, a_1, \ldots, a_l \rangle$ such that $a_0 = a$, and for all j with $0 < j \leq l$, for some i, $0 \leq i < j$, $E^{\mathfrak{A}}(a_i, a_j)$ or $E^{\mathfrak{A}}(a_j, a_i)$. Thus we relax the locality condition of $\mathbb{M}_k$ to the condition that a sequence can only be extended with an element if it is related to *some* element which has been played previously. The σ-relations on $\mathbb{H}_k(\mathfrak{A}, a)$ are defined exactly as for $\mathbb{E}_k(\mathfrak{A}, a)$, and the distinguished element is $\langle a \rangle$, so $\mathbb{H}_k(\mathfrak{A}, a)$ is the induced substructure of $\mathbb{E}_k(\mathfrak{A}, a)$ given by this restriction of the universe. In this sense, $\mathbb{H}_k$ is closer to $\mathbb{E}_k$ than to $\mathbb{M}_k$.

To complete the specification of $\mathbb{H}_k$, we define the *coKleisli extension*: given a morphism $h : \mathbb{H}_k(\mathfrak{A}, a) \to (\mathfrak{B}, b)$, we define $h^* : \mathbb{H}_k(\mathfrak{A}, a) \to \mathbb{H}_k(\mathfrak{B}, b)$ by

$$h^*(\langle a, a_1, \ldots, a_i \rangle) = \langle h(\langle a \rangle), h(\langle a, a_1 \rangle), \ldots, h(\langle a, a_1, \ldots, a_i \rangle) \rangle.$$

We can verify that for each structure $\mathfrak{A}$, $\varepsilon_{\mathfrak{A}} : \mathbb{H}_k \mathfrak{A} \to \mathfrak{A}$ is a morphism; that for each morphism $h : \mathbb{H}_k(\mathfrak{A}, a) \to (\mathfrak{B}, b)$, $h^* : \mathbb{H}_k(\mathfrak{A}, a) \to \mathbb{H}_k(\mathfrak{B}, b)$ is a morphism; and that the following equations are satisfied, for all morphisms $h : \mathbb{H}_k(\mathfrak{A}, a) \to (\mathfrak{B}, b)$, $g : \mathbb{H}_k(\mathfrak{B}, b) \to (\mathfrak{C}, c)$:

$$\varepsilon_{\mathfrak{A}} \circ h^* = h, \qquad \varepsilon_{\mathfrak{A}}^* = \mathsf{id}_{\mathbb{H}_k \mathfrak{A}}, \qquad (g \circ h^*)^* = g^* \circ h^*,$$

This establishes the following result.

▶ **Proposition 1.** *The triple* $(\mathbb{H}_k, \varepsilon, (\cdot)^*)$ *is a comonad in Kleisli form [21].*

It is then standard [21] that $\mathbb{H}_k$ extends to a functor by $\mathbb{H}_k f = (f \circ \epsilon)^*$; that ε is a natural transformation; and that if we define the comultiplication $\delta : \mathbb{H}_k \Rightarrow \mathbb{H}_k^2$ by $\delta_{\mathfrak{A}} = \mathsf{id}^*_{\mathbb{H}_k \mathfrak{A}}$, then $(\mathbb{H}_k, \varepsilon, \delta)$ is a comonad.

3.1 *I*-morphisms and equality

Like the Ehrenfeucht-Fraïssé comonad $\mathbb{E}_k$, and unlike the modal comonad $\mathbb{M}_k$, equality is important for $\mathbb{H}_k$, as we might expect from its appearance in the translation of hybrid temporal logic into first-order logic. We shall follow the procedure introduced in [5, Section 4] to ensure that equality is properly handled in $\mathbb{E}_k$.

The issue is that elements of A may be repeated in the plays in $\mathbb{H}_k(\mathfrak{A}, a)$. In particular, this happens when there are cycles in the graph $(A, E^{\mathfrak{A}})$ which are reachable from a. We wish to view coKleisli morphisms $f : \mathbb{H}_k(\mathfrak{A}, a) \to (\mathfrak{B}, b)$ as winning strategies for Duplicator in the one-sided (or existential) Spoiler-Duplicator game from $(\mathfrak{A}, a)$ to $(\mathfrak{B}, b)$, in which Spoiler plays in $\mathfrak{A}$ and Duplicator in $\mathfrak{B}$ [18]. In order to fulfil the partial homomorphism winning condition, f must map repeated occurrences of an element $a' \in A$ in a play s in $\mathbb{H}_k(\mathfrak{A}, a)$ to the same element of B. The same issue will recur when we deal with back-and-forth games in section 5. We seek a systematic means of enforcing this requirement.

Given a relational vocabulary σ, we produce a new one $\sigma^+ = \sigma \cup \{I\}$, where I is a binary relation symbol not in σ. If we interpret $I^{(\mathfrak{A},a)}$ and $I^{(\mathfrak{B},b)}$ as the identity relations on A and B, then, following the general prescription for relation lifting in $\mathbb{E}_k(\mathfrak{A}, a)$, and hence also in $\mathbb{H}_k(\mathfrak{A}, a)$ as an induced substructure of $\mathbb{E}_k(\mathfrak{A}, a)$, we have $I^{(\mathbb{H}_k\mathfrak{A},a)}(s,t)$ iff $s{\uparrow}t$ and $\varepsilon_{\mathfrak{A}}(s) = \varepsilon_{\mathfrak{A}}(t)$. Thus a σ-morphism $f : (\mathbb{H}_k\mathfrak{A}, a) \to (\mathfrak{B}, b)$ satisfies the required condition iff it is a σ^+-morphism.

As it stands, this is an ad hoc condition: it relies on a special interpretation of the I-relation. We want our objects to live in $\mathsf{Struct}_\star(\sigma)$, but our morphisms to live in $\mathsf{Struct}_\star(\sigma^+)$. To accomplish this, we use a simple special case of the notion of *relative comonad* [6]. We can take advantage of the fact that $\mathbb{E}_k$, and hence $\mathbb{H}_k$ as a sub-comonad of $\mathbb{E}_k$, is defined uniformly in the vocabulary. Given a vocabulary σ, there is a full and faithful embedding $J : \mathsf{Struct}_\star(\sigma) \to \mathsf{Struct}_\star(\sigma^+)$ such that $I^{J(\mathfrak{A},a)}$ is the identity on A. Moreover, we have a comonad $\mathbb{E}_k^I$, which is the $\mathbb{E}_k$ construction applied to $\mathsf{Struct}_\star(\sigma^+)$. Note that this treats I like any other binary relation in the vocabulary.

We correspondingly obtain $\mathbb{H}_k^I(\mathfrak{A}, a)$ as the substructure of $\mathbb{E}_k^I(\mathfrak{A}, a)$ induced by restricting the universe to that of $\mathbb{H}_k(\mathfrak{A}, a)$. It is important to note that only the transition relation E is used to restrict the universe.

We use this data to obtain the J-relative comonad $\mathbb{H}_k^+ = \mathbb{H}_k^I \circ J$ on $\mathsf{Struct}_\star(\sigma)$. The objects of the coKleisli category for this relative comonad are those of $\mathsf{Struct}_\star(\sigma)$. CoKleisli morphisms have the form $\mathbb{H}_k^I J(\mathfrak{A}, a) \to J(\mathfrak{B}, b)$. The counit and coextension are the restrictions of those for $\mathbb{H}_k^I$ to the image of J.

3.2 CoKleisli maps, existential games, and the existential positive fragment

The standard k-round existential Ehrenfeucht-Fraïssé game from $\mathfrak{A}$ to $\mathfrak{B}$ [18, 5] is defined as follows. In each round i, Spoiler moves by choosing an element a_i from A, and Duplicator responds by choosing an element b_i from B. The winning condition for Duplicator is that the correspondence $a_i \mapsto b_i$ is a partial homomorphism from $\mathfrak{A}$ to $\mathfrak{B}$.

The k-round existential hybrid game from $(\mathfrak{A}, a)$ to $(\mathfrak{B}, b)$ is defined in exactly the same way, with two additional provisos:

- At round 0, Spoiler must play $a_0 = a$, and Duplicator must respond with $b_0 = b$.
- At round $j > 0$, Spoiler must play a move a_j such that, for some $i < j$, $E^{\mathfrak{A}}(a_i, a_j)$ or $E^{\mathfrak{A}}(a_j, a_i)$.

▶ **Proposition 2.** *There is a bijective correspondence between*

- *Winning strategies for Duplicator in the k-round existential hybrid game from $(\mathfrak{A}, a)$ to $(\mathfrak{B}, b)$*
- *CoKleisli morphisms $h : \mathbb{H}_k^+(\mathfrak{A}, a) \to J(\mathfrak{B}, b)$.*

The existential positive fragment $\mathsf{HTL}^\Diamond$ of hybrid temporal logic is defined by omitting negation and both $\Box$ and $\Box^-$ from the syntax for hybrid logic given in section 2.1. $\mathsf{HTL}_k^\Diamond$ is the fragment of $\mathsf{HTL}^\Diamond$ comprising formulas of hybrid modal depth $\leq k$.

This fragment induces a preorder on pointed structures. Define $(\mathfrak{A}, a) \Rrightarrow_k^{\mathsf{HTL}} (\mathfrak{B}, b)$ as:

$$\forall \varphi \in \mathsf{HTL}_k^\Diamond . [(\mathfrak{A}, a) \models \varphi \;\Rightarrow\; (\mathfrak{B}, b) \models \varphi].$$

Here by $(\mathfrak{A}, a) \models \varphi$ we mean $(\mathfrak{A}, a) \models \psi(x)$, where $\psi(x) = \mathsf{ST}_x(\varphi)$.

The following is a variation on standard results (see e.g. [9, 5]).

▶ **Proposition 3.** *There is a winning strategy for Duplicator in the k-round existential hybrid game from $(\mathfrak{A}, a)$ to $(\mathfrak{B}, b)$ iff $(\mathfrak{A}, a) \Rrightarrow_k^{\mathsf{HTL}} (\mathfrak{B}, b)$.*

We define another preorder on pointed structures: $(\mathfrak{A}, a) \rightarrow_k^{\mathbb{H}} (\mathfrak{B}, b)$ iff there is a coKleisli morphism $h : \mathbb{H}_k^+(\mathfrak{A}, a) \rightarrow J(\mathfrak{B}, b)$. The following is then an immediate consequence of Propositions 2 and 3.

▶ **Theorem 4.** *Let σ be a finite modal vocabulary. For all $(\mathfrak{A}, a)$, $(\mathfrak{B}, b)$ in $\mathsf{Struct}_\star(\sigma)$:*

$$(\mathfrak{A}, a) \Rrightarrow_k^{\mathsf{HTL}} (\mathfrak{B}, b) \iff (\mathfrak{A}, a) \rightarrow_k^{\mathbb{H}} (\mathfrak{B}, b).$$

4 Coalgebras

We now study coalgebras for the hybrid comonad. These will yield a natural combinatorial invariant associated with hybrid logic, and also provide a basis for the semantic characterization of the equivalence on structures induced by hybrid logic, which will be given in the following section.

A coalgebra for a comonad (G, ε, δ) is a morphism $\alpha : A \rightarrow GA$ such that $\varepsilon_A \circ \alpha = \mathsf{id}_A$ and $\delta_A \circ \alpha = G(\alpha) \circ \alpha$. Given G-coalgebras $\alpha : A \rightarrow GA$ and $\beta : B \rightarrow GB$, a coalgebra morphism from α to β is a morphism $h : A \rightarrow B$ such that $\beta \circ h = G(h) \circ \alpha$. This gives a category of coalgebras and coalgebra morphisms, denoted by $\mathbf{EM}(G)$, the *Eilenberg-Moore category* of G.

We will now analyze $\mathbf{EM}(\mathbb{H}_k)$, the category of coalgebras for the hybrid comonad on a unimodal vocabulary σ. This will lead to a natural combinatorial parameter associated with hybrid temporal logic, which is a refinement of *tree-depth* [23]. It will also provide a basis for a comonadic characterisation of bisimulation and the equivalence on structures induced by the full hybrid temporal logic, as we will see in the next section.

We will need a few more notions on posets. A chain in a poset $(P, \leq)$ is a subset $C \subseteq P$ such that, for all $x, y \in C$, $x \uparrow y$. A *forest* is a poset $(F, \leq)$ such that, for all $x \in F$, the set of predecessors $\downarrow(x) := \{y \in F \mid y \leq x\}$ is a finite chain. The height $\mathsf{ht}(F)$ of a forest F is $\sup_C |C|$, where C ranges over chains in F. Note that the height is either finite or ω. A *tree* is a forest with a least element (the root). We write the covering relation for a poset as $\prec$; thus $x \prec y$ iff $x \leq y$, $x \neq y$, and for all z, $x \leq z \leq y$ implies $z = x$ or $z = y$. Morphisms of trees are monotone maps preserving the root and the covering relation.

Given a σ-structure $\mathfrak{A}$, the *Gaifman graph* $\mathcal{G}(\mathfrak{A})$ is $(A, \frown)$, where $a \frown a'$ (a is adjacent to a') if they are distinct elements of A which both occur in a tuple of some relation $R^{\mathfrak{A}}$, R in σ.

A *tree cover* of a pointed σ-structure $(\mathfrak{A}, a)$ is a tree order $(A, \leq)$ on A with least element a, and such that if $a \frown a'$, then $a \uparrow a'$. Thus adjacent elements in the Gaifman graph must appear in the same branch of the tree. The tree cover is *generated* if for all $a' \in A$ with $a' \neq a$, for some $a'' \in A$, $a'' < a'$ and $a' \frown a''$. Tree covers of a pointed structure are neither unique, nor guaranteed to exist.

▶ **Theorem 5.** *For any pointed σ-structure $(\mathfrak{A}, a)$, and $k > 0$, there is a bijective correspondence between:*

- *$\mathbb{H}_k$-coalgebras $\alpha : (\mathfrak{A}, a) \rightarrow \mathbb{H}_k(\mathfrak{A}, a)$.*
- *Generated tree covers of $(\mathfrak{A}, a)$ of height $\leq k + 1$.*

We define the *generated tree depth* of $(\mathfrak{A}, a)$ to be the minimum height of any generated tree cover of $(\mathfrak{A}, a)$. This can be seen as a refinement of the standard notion of tree depth [23].

We define the *hybrid coalgebra number* of $(\mathfrak{A}, a)$ to be the least k such that there is an $\mathbb{H}_k$-coalgebra $\alpha : (\mathfrak{A}, a) \to \mathbb{H}_k(\mathfrak{A}, a)$. If there is no coalgebra for any k, the hybrid coalgebra number is ω. The following is an immediate consequence of Theorem 5.

▶ **Theorem 6.** *The generated tree depth of a structure $(\mathfrak{A}, a)$ coincides with its hybrid coalgebra number.*

We define a category $\mathbf{Tree}(\sigma)$ with objects $(\mathfrak{A}, a, \leq)$, where $(\mathfrak{A}, a)$ is a pointed σ-structure, and $\leq$ is a generated tree cover of $(\mathfrak{A}, a)$. Morphisms $h : (\mathfrak{A}, a, \leq) \to (\mathfrak{B}, b, \leq')$ are morphisms of pointed σ-structures which are also tree morphisms. That is, they preserve the covering relation $\prec$ in the tree order, and the root element. For each $k > 0$, there is a full subcategory $\mathbf{Tree}(\sigma)_k$ determined by those objects whose covers have height $\leq k$.

▶ **Theorem 7.** *For each $k > 0$, $\mathbf{Tree}(\sigma)_k$ is isomorphic to $\mathbf{EM}(\mathbb{H}_k)$.*

There is an evident forgetful functor $U_k : \mathbf{Tree}(\sigma)_k \to \mathsf{Struct}_\star(\sigma)$ which sends $(\mathfrak{A}, a, \leq)$ to $(\mathfrak{A}, a)$. The following is now an immediate consequence of Theorem 7.

▶ **Theorem 8.** *For each $k > 0$, U_k has a right adjoint $R_k : \mathsf{Struct}_\star(\sigma) \to \mathbf{Tree}(\sigma)_k$ given by $R_k(\mathfrak{A}, a) = (\mathbb{H}_k(\mathfrak{A}, a), \sqsubseteq)$. The comonad induced by this adjunction is $\mathbb{H}_k$. The adjunction is comonadic.*

5 Paths, open maps, and back-and-forth equivalence

The coalgebra category $\mathbf{EM}(\mathbb{H}_k)$ has a richer structure than $\mathsf{Struct}_\star(\sigma)$, articulated as $\mathbf{Tree}(\sigma)_k$ by Theorem 7. In fact, $\mathbf{Tree}(\sigma)_k$ is an *arboreal category* as defined in [4]. The axiomatic structure of an arboreal category allows us to define notions of bisimulation and games on this category, which can then be transferred to $\mathsf{Struct}_\star(\sigma)$ via the adjunction $U_k \dashv R_k$, following the general pattern laid out in [5]. This leads to a semantic characterisation of the equivalence on structures induced by hybrid logic.

To accommodate I-morphisms, as discussed in section 3.1, we work with the J-relative version of this adjunction, using $R_k^+ = R_k^I J$, where R_k^I is the instance of the adjunction for $\mathsf{Struct}_\star(\sigma^+)$.

5.1 Embeddings, paths and pathwise embeddings

A morphism e in $\mathbf{Tree}(\sigma)_k$ is an *embedding* if $U_k(e)$ is an embedding of relational structures. We write $e : T \rightarrowtail U$ to indicate that e is an embedding.

A *path* in $\mathbf{Tree}(\sigma)_k$ is an object P such that the associated tree cover is a finite linear order, so it comprises a single branch; moreover, I^P is the identity relation. We say that $e : P \rightarrowtail T$ is a *path embedding* if P is a path. A morphism $f : T \to U$ in $\mathbf{Tree}(\sigma)_k$ is a *pathwise embedding* if for any path embedding $e : P \rightarrowtail T$, $f \circ e$ is a path embedding.

5.2 Open maps

A morphism $f : T \to U$ in $\mathbf{Tree}(\sigma)_k$ is *open* if, whenever we have a commuting diagram such as 1, where P and Q are paths, there is an embedding $Q \rightarrowtail T$ such that 2 commutes.

$$\begin{tikzcd} P \arrow[r, tail] \arrow[d, tail] & Q \arrow[d, tail] \\ T \arrow[r, "f"'] & U \end{tikzcd} \qquad (1) \qquad\qquad \begin{tikzcd} P \arrow[r, tail] \arrow[d, tail] & Q \arrow[d, tail] \arrow[dl, tail] \\ T \arrow[r, "f"'] & U \end{tikzcd} \qquad (2)$$

This is often referred to as the *path-lifting property.* If we think of f as witnessing a simulation of T by U, path-lifting means that if we extend a given behaviour in U (expressed by extending the path P to Q), then we can find a matching behaviour in T to "cover" this extension. Thus it expresses an abstract form of the notion of "p-morphism" from modal logic [9], or of functional bisimulation.

5.3 Bisimulation

We can now define the *back-and-forth equivalence* $(\mathfrak{A}, a) \leftrightarrow_k^{\mathbb{H}} (\mathfrak{B}, b)$ between structures in $\mathsf{Struct}_\star(\sigma)$. This holds if there is a span of open pathwise embeddings in $\mathbf{Tree}(\sigma)_k$ $R_k^+(\mathfrak{A}, a) \leftarrow T \rightarrow R_k^+(\mathfrak{B}, b)$. Note that we are using the arboreal category $\mathbf{Tree}(\sigma)_k$ to define an equivalence on the "extensional category" $\mathsf{Struct}_\star(\sigma)$.

5.4 Games

We shall now define a *back-and-forth game* $\mathcal{G}_k((\mathfrak{A}, a), (\mathfrak{B}, b))$ played between $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$, using the comonad $\mathbb{H}_k$. Positions of the game are pairs $(s, t) \in \mathbb{H}_k(\mathfrak{A}, a) \times \mathbb{H}_k(\mathfrak{B}, b)$. The initial position is $(\langle a \rangle, \langle b \rangle)$.

We define a relation $\mathsf{W}((\mathfrak{A}, a), (\mathfrak{B}, b))$ on positions as follows. A pair (s, t) is in $\mathsf{W}((\mathfrak{A}, a), (\mathfrak{B}, b))$ iff for some path P, path embeddings $e_1 : P \rightarrowtail \mathbb{H}_k(\mathfrak{A}, a)$ and $e_2 : P \rightarrowtail \mathbb{H}_k(\mathfrak{B}, b)$, and $p \in P$, $s = e_1(p)$ and $t = e_2(p)$. The intention is that $\mathsf{W}((\mathfrak{A}, a), (\mathfrak{B}, b))$ picks out the winning positions for Duplicator.

At the start of each round of the game, the position is specified by $(s, t) \in \mathbb{H}_k(\mathfrak{A}, a) \times \mathbb{H}_k(\mathfrak{B}, b)$. The round proceeds as follows. Either Spoiler chooses some $s' \succ s$, and Duplicator must respond with $t' \succ t$, resulting in a new position (s', t'); or Spoiler chooses some $t'' \succ t$ and Duplicator must respond with $s'' \succ s$, resulting in (s'', t''). Duplicator wins the round if they are able to respond, and the new position is in $\mathsf{W}((\mathfrak{A}, a), (\mathfrak{B}, b))$.

5.5 Results

▶ **Theorem 9.** *Given $(\mathfrak{A}, a)$, $(\mathfrak{B}, b)$ in $\mathsf{Struct}_\star(\sigma)$, then $(\mathfrak{A}, a) \leftrightarrow_k^{\mathbb{H}} (\mathfrak{B}, b)$ iff Duplicator has a winning strategy for $\mathcal{G}_k((\mathfrak{A}, a), (\mathfrak{B}, b))$.*

Proof. The proof is a minor variation of that for [5, Theorem 10.1], the corresponding result for $\mathbb{E}_k$. Alternatively, this is an instance of the very general [4, Theorem 6.9]. ◀

The standard k-round Ehrenfeucht-Fraïssé game between $\mathfrak{A}$ and $\mathfrak{B}$ [20] is defined as follows. In each round i, Spoiler moves by either

- choosing an $a_i \in A$, to which Duplicator responds by choosing a $b_i \in B$; or
- choosing a $b_i \in B$, to which Duplicator responds by choosing an $a_i \in A$.

The winning condition for Duplicator is that the correspondence $a_i \mapsto b_i$ is a partial isomorphism from $\mathfrak{A}$ to $\mathfrak{B}$.

The k-round back-and-forth hybrid game between $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$ is defined in exactly the same way, with two additional provisos:

- At round 0, Spoiler must either play $a_0 = a$, to which Duplicator must respond with $b_0 = b$; or $b_0 = b$, to which Duplicator must respond with $a_0 = a$
- At round $j > 0$, if Spoiler plays a move $a_j \in A$ then, for some $i < j$, $E^{\mathfrak{A}}(a_i, a_j)$ or $E^{\mathfrak{A}}(a_j, a_i)$; while if Spoiler plays a move $b_j \in B$ then, for some $i < j$, $E^{\mathfrak{B}}(b_i, b_j)$ or $E^{\mathfrak{B}}(b_j, b_i)$.

The partial isomorphism winning condition ensures that Duplicator is subject to the same constraints.

We write HTL_k for the set of hybrid formulas of modal depth k. We define an equivalence relation on pointed structures $(\mathfrak{A}, a) \equiv_k^{\mathsf{HTL}} (\mathfrak{B}, b)$ as $\forall \varphi \in \mathsf{HTL}_k. [(\mathfrak{A}, a) \models \varphi \iff (\mathfrak{B}, b) \models \varphi]$.

▶ **Theorem 10.** *Let σ be a finite unimodal vocabulary. For all $(\mathfrak{A}, a)$, $(\mathfrak{B}, b)$ in $\mathsf{Struct}_\star(\sigma)$, the following are equivalent:*

1. $(\mathfrak{A}, a) \leftrightarrow_k^{\mathbb{H}} (\mathfrak{B}, b)$.
2. *Duplicator has a winning strategy for the k-round back-and-forth hybrid game between $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$.*
3. $(\mathfrak{A}, a) \equiv_k^{\mathsf{HTL}} (\mathfrak{B}, b)$.

6 Semantic characterization of hybrid temporal logic

We shall now prove a semantic characterisation of hybrid temporal logic in terms of invariance under disjoint extensions. A related result is already known [16, 7], however there are several novel features in our account:

- The previous results are for general (possibly infinite) structures, using tools from infinite model theory. We will give a uniform proof, which applies both to general structures, and to the finite case, which, as for the van Benthem-Rosen characterisation of basic modal logic in terms of bisimulation invariance [27, 26], is an independent result.
- Our proof follows similar lines to the uniform proof by Otto of the van Benthem-Rosen Theorem [24]. In particular, we use constructive arguments based on model comparison games, rather than model-theoretic constructions involving compactness. However, a key property used in his proof no longer holds for the hybrid fragment, so the argument has to take a different path.
- We also identify a key combinatorial lemma, implicit in [24], which we call the Workspace Lemma.
- One of the equivalent conditions in our characterization, invariance under disjoint extensions, appears to be new in this context. We can regard invariance under disjoint extensions as a minimal form of locality relative to a given basepoint. Thus this characterization shows that hybrid temporal logic defines the maximal fragment of first-order logic which retains a local character in this sense.

6.1 Comonadic aspects

Comonadic semantics have now been given for a number of important fragments of first-order logic: the quantifier rank fragments, the finite variable fragments, the modal fragment, and guarded fragments. In the landscape emerging from these constructions, some salient properties have come to the fore. These are properties which a comonad, arising from an *arboreal cover* in the sense of [4], may or may not have:

- The comonad may be *idempotent*, meaning that the comultiplication is a natural isomorphism. Idempotent comonads correspond to *coreflective subcategories*, which form the Eilenberg-Moore categories of these comonads. The modal comonads $\mathbb{M}_k$ are idempotent. The corresponding coreflective subcategories are of those modal structures which are tree-models to depth k [5].

- The comonad C may satisfy the following property: for each structure $\mathfrak{A}$, $C\mathfrak{A} \leftrightarrow^{C} \mathfrak{A}$, where $\leftrightarrow^{C}$ is the back-and-forth equivalence associated with C. We shall call this the *bisimilar companion* property. Note that an idempotent comonad, such as $\mathbb{M}_k$, will automatically have this property. The guarded comonads $\mathbb{G}_k$ from [2] are not idempotent, but have the bisimilar companion property, which is thus strictly weaker.
- Finally, the comonads $\mathbb{E}_k$ and $\mathbb{P}_k$ have neither of the above properties. Unlike the modal and guarded fragments, the quantifier rank and finite variable fragments cover the whole of first-order logic, so we call these comonads *expressive.*

Thus we have a strict hierarchy of comonads in the arboreal categories framework:

$$\text{idempotent} \Rightarrow \text{bisimilar companions} \Rightarrow \text{arboreal.}$$

This hierarchy is correlated with tractability: the modal and guarded fragments are decidable, and have the tree-model property [28, 17], while the expressive fragments do not. We can regard these observations as a small first step towards using structural properties of comonadic semantics to classify logic fragments and their expressive power. In [3], idempotence is used to give simple, general proofs of homomorphism preservation theorems for counting quantifier fragments, with an application to graded modal logic; while the bisimilar companion property is used to give a general, uniform Otto-style proof of van Benthem-Rosen theorems.

As we have already remarked, the hybrid comonads are closer to the Ehrenfeucht-Fraïssé comonads $\mathbb{E}_k$ than to the modal comonads $\mathbb{M}_k$. Indeed, the $\mathbb{H}_k$ comonads are neither idempotent, nor have the bisimilar companion property. On the tractability side, they are not decidable [7]. At the same time, they are not fully expressive for first-order logic, thus refining the above hierarchy.

Otto's proof of the van Benthem-Rosen theorem in [24] uses the bisimilar companion property. This is made explicit in the account given in [3]. Because $\mathbb{H}_k$ does not have this property, we shall use a different comonad in our invariance proof for the hybrid fragment.

Given a structure $\mathfrak{A}$, we can define a metric on A valued in the extended natural numbers $\mathbb{N} \cup \{\infty\}$, given by the path distance in the Gaifman graph $\mathcal{G}(\mathfrak{A})$ [20]. We set $d(a, b) = \infty$ if there is no path between a and b. We write $A[a; k]$ for the closed ball, centred on a, also referred to as the k-neighbourhood of a. Given $(\mathfrak{A}, a)$, we define $\mathbb{S}_k(\mathfrak{A}, a)$ to be $(\mathfrak{A}[a; k], a)$, where $\mathfrak{A}[a; k]$ is the substructure of $\mathfrak{A}$ induced by $A[a; k]$. This defines a comonad on $\mathsf{Struct}_\star(\sigma)$. The counit is the inclusion map, while coextension is the identity operation on morphisms, $h^* = h$. The fact that h is a σ-homomorphism implies that paths are preserved, so this is well defined. It is easily verified that $\mathbb{S}_k$ is an idempotent comonad. The corresponding coreflective subcategory of $\mathsf{Struct}_\star(\sigma)$ is the full subcategory of structures which are k-reachable from the initial elements. We can also define an idempotent comonad $\mathbb{S}$, where $\mathbb{S}(\mathfrak{A}, a) := \bigcup_{k \in \mathbb{N}} \mathbb{S}_k(\mathfrak{A}, a)$.

We can use this comonad to state the invariance property of interest. We say that a first-order formula $\varphi(x)$ is *invariant under generated substructures* if for all $(\mathfrak{A}, a)$ in $\mathsf{Struct}_\star(\sigma)$: $(\mathfrak{A}, a) \models \varphi \iff \mathbb{S}(\mathfrak{A}, a) \models \varphi$. It is *invariant under k-generated substructures* if for all $(\mathfrak{A}, a)$ in $\mathsf{Struct}_\star(\sigma)$: $(\mathfrak{A}, a) \models \varphi \iff \mathbb{S}_k(\mathfrak{A}, a) \models \varphi$. We use the standard disjoint union of structures, $\mathfrak{A} + \mathfrak{B}$. This is the coproduct in $\mathsf{Struct}(\sigma)$. We say that a sentence φ is *invariant under disjoint extensions* if for all $(\mathfrak{A}, a)$, $\mathfrak{B}$: $(\mathfrak{A}, a) \models \varphi \iff (\mathfrak{A} + \mathfrak{B}, a) \models \varphi$.

We can now state our main result.

▶ **Theorem 11** (Characterisation Theorem). *For any first-order formula $\varphi(x)$ with quantifier rank q, the following are equivalent:*

1. *φ is invariant under generated substructures.*
2. *φ is invariant under $q2^q$-generated substructures.*
3. *φ is invariant under disjoint extensions.*
4. *φ is equivalent to a sentence ψ of hybrid temporal logic with modal depth $\leq q2^q$.*

Note that this theorem has two versions, depending on the ambient category $\mathcal{C}$ relative to which equivalence is defined: $\forall(\mathfrak{A}, a) \in \mathcal{C}.\, (\mathfrak{A}, a) \models \varphi \iff (\mathfrak{A}, a) \models \psi$. The first version, for general models, takes $\mathcal{C} = \mathsf{Struct}_\star(\sigma)$. The second, for finite models, takes $\mathcal{C} = \mathsf{Struct}^f_\star(\sigma)$, the full subcategory of finite structures. Neither of these two versions implies the other. Following Otto [24], we aim to give a uniform proof, valid for both versions.

6.2 Proof of the Characterisation Theorem

Firstly, since any sentence can only use a finite vocabulary, we can assume without loss of generality in what follows that σ is finite. This implies that up to logical equivalence, the fragment HTL_k is finite.

Given a formula φ, we write $\mathsf{Mod}(\varphi) := \{(\mathfrak{A}, a) \mid (\mathfrak{A}, a) \models \varphi\}$. We shall use the following variation of a standard result.

▶ **Lemma 12** (Definability Lemma)**.** *For each $k > 0$ and structure $(\mathfrak{A}, a)$, there is a sentence $\theta^{(k)}_{(\mathfrak{A},\vec{a})} \in \mathsf{HTL}_k$ such that, for all $(\mathfrak{B}, b)$, $(\mathfrak{A}, a) \equiv^{\mathsf{HTL}}_k (\mathfrak{B}, \vec{b}) \iff (\mathfrak{B}, b) \models \theta^{(k)}_{(\mathfrak{A},\vec{a})}$.*

This says that $[(\mathfrak{A}, a)]_{\equiv^{\mathsf{HTL}}_k} = \mathsf{Mod}(\theta^{(k)}_{(\mathfrak{A},\vec{a})})$. Since $\equiv^{\mathsf{HTL}}_k$ has finite index, this implies that if $\mathsf{Mod}(\varphi)$ is saturated under $\equiv^{\mathsf{HTL}}_k$, φ is equivalent to a finite disjunction $\bigvee_{i=1}^n \theta^{(k)}_{(\mathfrak{A}_i,\vec{a}_i)}$, and hence to a formula in HTL_k.

The Workspace Lemma

A key step in the argument is a general result we call the Workspace Lemma. A special case of this is implicit in [24]. Note that $\equiv_q$ is elementary equivalence up to quantifier rank q.

▶ **Lemma 13** (Workspace Lemma)**.** *Given $(\mathfrak{A}, a)$ and $q > 0$, there is a structure $\mathfrak{B}$ such that $(\mathfrak{A} + \mathfrak{B}, a) \equiv_q (\mathfrak{A}[a; k] + \mathfrak{B}, a)$, where $k = 2^q$. Moreover, $|B| \leq 2q|A|$. Hence if $\mathfrak{A}$ is finite, so is $\mathfrak{B}$.*

The intuition for the workspace lemma is that the structure $\mathfrak{B}$, the *workspace*, contains enough disjoint copies of $\mathfrak{A}$ and $\mathfrak{A}[a; k]$ that Spoiler cannot tell the composite structures apart in q rounds of the Ehrenfeucht-Fraïssé game. The idea of Duplicator's strategy is that if Spoiler plays a move that is close to a previous position, in terms of distance in the Gaifman graph, Duplicator responds in the corresponding component of the other structure. If on the other hand Spoiler chooses a position that is "far away" from previously chosen positions, Duplicator responds in a fresh component of the appropriate type. The number of copies of both structures in the workspace, and the distances involved, are chosen so that everything is kept sufficiently far apart that Spoiler cannot see the difference between $\mathfrak{A} + \mathfrak{B}$ and $\mathfrak{A}[a; k] + \mathfrak{B}$. The formal argument is a delicate induction, which can be carried out at the level of generality of metric spaces.

We shall also require a few additional lemmas in our proof of the characterisation theorem. The following is immediate from the definitions.

▶ **Proposition 14.** *For each structure $(\mathfrak{A}, a)$ in $\mathsf{Struct}_\star(\sigma)$, we have $\mathbb{S}_k\mathbb{S}(\mathfrak{A}, a) = \mathbb{S}_k(\mathfrak{A}, a)$.*

The following lemma allows us to restrict our attention to generated substructures when considering HTL equivalence.

▶ **Lemma 15.** *For all $k, m > 0$, if $(\mathfrak{A}, a) \equiv^{\mathsf{HTL}}_m (\mathfrak{B}, b)$ then $\mathbb{S}_k(\mathfrak{A}, a) \equiv^{\mathsf{HTL}}_m \mathbb{S}_k(\mathfrak{B}, b)$.*

We also need the following result to strengthen HTL equivalence to first-order equivalence. We do so by lifting a Duplicator strategy for the hybrid game to one for the Ehrenfeucht-Fraïssé game, at the expense of some logical resources needed to traverse the structures step-by-step in the hybrid game.

▶ **Lemma 16.** *For all $k, q > 0$, if $\mathbb{S}_k(\mathfrak{A}, a) \equiv^{\mathsf{HTL}}_{kq} \mathbb{S}_k(\mathfrak{B}, b)$ then $\mathbb{S}_k(\mathfrak{A}, a) \equiv_q \mathbb{S}_k(\mathfrak{B}, b)$.*

Proof of the characterisation theorem

Proof of Theorem 11.

(2) ⇒ (1). Assume that φ is $\mathbb{S}_k$-invariant. Using Proposition 14, $(\mathfrak{A}, a) \models \varphi$ iff $\mathbb{S}_k(\mathfrak{A}, a) \models \varphi$ iff $\mathbb{S}_k\mathbb{S}(\mathfrak{A}, a) \models \varphi$ iff $\mathbb{S}(\mathfrak{A}, a) \models \varphi$.

(1) ⇒ (3). This follows immediately from the fact that $\mathbb{S}(\mathfrak{A} + \mathfrak{B}, a) = \mathbb{S}(\mathfrak{A}, a)$.

(3) ⇒ (4). Suppose that φ is invariant under disjoint extensions (abbreviated as IDE). Let $k = 2^q$. We shall use Lemma 12. Suppose that (i) $(\mathfrak{A}, a) \models \varphi$, and (ii) $(\mathfrak{A}, a) \equiv^{\mathsf{HTL}}_{kq} (\mathfrak{B}, b)$. We must show that $(\mathfrak{B}, b) \models \varphi$. Applying the Workspace Lemma twice, let $\mathfrak{C}$, $\mathfrak{D}$ be such that (iii) $(\mathfrak{A} + \mathfrak{C}, a) \equiv_q (\mathfrak{A}[a; k] + \mathfrak{C}, a)$ and (iv) $(\mathfrak{B} + \mathfrak{D}, b) \equiv_q (\mathfrak{B}[b; k] + \mathfrak{D}, b)$. From (ii), applying lemmas 15 and 16, we have (v) $\mathbb{S}_k(\mathfrak{A}, a) \equiv_q \mathbb{S}_k(\mathfrak{B}, b)$. Now

$$\begin{array}{rcll}
(\mathfrak{A}, a) \models \varphi & \Rightarrow & (\mathfrak{A} + \mathfrak{C}, a) \models \varphi & \mathsf{IDE} \\
& \Rightarrow & (\mathfrak{A}[a; k] + \mathfrak{C}, a) \models \varphi & (iii) \\
& \Rightarrow & \mathbb{S}_k(\mathfrak{A}, a) \models \varphi & \mathsf{IDE} \\
& \Rightarrow & \mathbb{S}_k(\mathfrak{B}, b) \models \varphi & (v) \\
& \Rightarrow & (\mathfrak{B}[b; k] + \mathfrak{D}, b) \models \varphi & \mathsf{IDE} \\
& \Rightarrow & (\mathfrak{B} + \mathfrak{D}, b) \models \varphi & (iv) \\
& \Rightarrow & (\mathfrak{B}, b) \models \varphi & \mathsf{IDE}
\end{array}$$

(4) ⇒ (2). We must show that if ψ is a formula in HTL_k, then it is invariant under k-generated substructures. This follows by a straightforward induction on syntax. ◀

▶ **Question 1.** *In his proof of the van Benthem-Rosen Theorem, Otto establishes an exponential succinctness gap between first-order logic and basic modal logic. A bisimulation-invariant first order formula of quantifier rank q has a modal equivalent of modal depth $\leq 2^q$. He shows that this is optimal. In our case, we have a gap of $q2^q$. Is this optimal for hybrid temporal logic?*

7 Further Directions

Everything which has been done for hybrid temporal logic in the present paper can be extended to the bounded fragment of first-order logic. This generalises the hybrid comonad, allowing both arbitrary relational vocabularies and constant symbols. Allowing for constants $c_1, \ldots, c_m$ involves working with the m-pointed category $\mathsf{Struct}_m(\sigma)$. This has objects $(\mathfrak{A}, \vec{a})$, where $\vec{a} = \langle a_1, \ldots, a_m \rangle \in A^m$. Morphisms $h : (\mathfrak{A}, \vec{a}) \to (\mathfrak{B}, \vec{b})$ must preserve these tuples. The intention is that $a_i = c_i^{\mathfrak{A}}$. Note that $\mathsf{Struct}_\star(\sigma) = \mathsf{Struct}_1(\sigma)$. The comonad constructions can be adapted smoothly to this setting, and the corresponding results go through without any problems.

Another variation is to consider hybrid logic without the backwards modalities $\Box^-$, $\Diamond^-$. The semantic significance of this is that directed rather than undirected reachability becomes the salient notion. The comonadic constructions can be adapted to this setting straightforwardly, but the semantic characterization results cannot be transferred directly. We leave the resolution of this issue to future work.

Abstract

The computational complexity of pairwise energy minimisation of N points in real space is a long-standing open problem. The idea of the potential intractability of the problem was supported by a lack of progress in finding efficient algorithms, even when restricted the integer grid approximation. In this paper we provide a firm answer to the problem on $\mathbb{Z}^d$ by showing that for a large class of pairwise energy functions the problem of periodic energy minimisation is NP-hard if the size of the period (known as a unit cell) is fixed, and is undecidable otherwise. We do so by introducing an abstraction of pairwise average energy minimisation as a mathematical problem, which covers many existing models. The most influential aspects of this work are showing for the first time: 1) undecidability of average pairwise energy minimisation in general 2) computational hardness for the most natural model with periodic boundary conditions, and 3) novel reductions for a large class of generic pairwise energy functions covering many physical abstractions at once. In particular, we develop a new tool of overlapping digital rhombuses to incorporate the properties of the physical force fields, and we connect it with classical tiling problems. Moreover, we illustrate the power of such reductions by incorporating more physical properties such as charge neutrality, and we show an inapproximability result for the extreme case of the 1D average energy minimisation problem.

1 Introduction

Periodic structures and models with periodic boundary conditions appear both in nature and in mathematical interpretations of physical phenomena: spin systems in Ising models [8], Buckingham–Coulomb inter-atomic potential modelling crystal structures [32], Lennard-Jones potential in inter-molecular interaction [13]. Periodic boundary conditions are often used either to define, or to approximate, a large or infinite system from a small partition, known as a *unit cell*. The series of repeating unit cells in every dimension forms a periodic structure. A unit cell can be defined as a mapping from the points within a contiguous subspace of a lattice to a finite set of "colours", an abstraction that may be used to represent anything from ions to spin states. The main advantage of this model is that the periodic structure allows the properties of the effectively infinite global structure to be determined from the finite unit cell. This advantage has led to these structures attracting a great deal of attention in mathematics, physics, biology, chemistry and computer science [1, 12, 17, 18, 19, 20].

From the perspective of the physical sciences, one of the most fundamental properties is the *potential energy* of the structure, representing the sum of pairwise attractions between ions (or spins) within the unit cell. Usually, the energy landscape is a highly non-convex function with many local minima and saddle points. The fundamental optimisation problem, associated with predicting various physical phenomena in both periodic structures and a single unit cell, is known as the *cluster problem* [34]:

> "In which way can N points be occupied (in real space) so as to minimise the sum of their interactions?"

A lack of progress with the design of efficient algorithms for solving this fundamental optimisation problem led to various hypotheses about its intractability, which has not been formally addressed due to a large number of variants and complexity of practical details regarding the problem. However, very recently the first NP-hard result was shown for closely related *removal problem*: Given a cluster of N points, can a subset of them be removed to minimise the total energy of pairwise Buckingham–Coulomb interaction [3].

This paper builds upon these previous results, showing that hardness results apply even under the more realistic *periodic boundary conditions*. In the context of crystal structure prediction, this refers to the periodic structure of the crystal, meaning that the global structure of the crystal is represented by a repeating period. Previous work [3, 11] has focused on the interaction within the unit cell, while ignoring this periodic conditions.

In this paper, we propose a more universal approach and analyse the computational complexity of the original cluster problem for a large class of pairwise energy minimisation functions under more realistic periodic boundary conditions. We introduce an abstract class of r-distance *Common Minimum Value* functions ($\mathcal{CMV}(r)$), which capture typical properties of classical force-fields of pairwise interaction (attraction, repulsion) and incorporates the variable depth r of such interaction. Then we show that the cluster problem is NP-hard if the size of the unit cell is fixed and that it is undecidable otherwise for any function in the class $\mathcal{CMV}(r)$ defined on two or three dimensional grids ($\mathbb{Z}^2$ or $\mathbb{Z}^3$). Moreover, we show that particular known classical energy-interaction functions fit to this class and inherit the results on the computational complexity. In the case of 1D grids, we design a parameterised polynomial-time algorithm to solve the fixed period pairwise energy minimisation problem. Finally, we show that under the extra physical constraint of charge-neutrality (the total sum of charges/weights associated with points in the unit cell is zero) the problem still remains undecidable for 2 and 3 dimensions, and in dimension one it cannot be approximated within any constant factor unless $P = NP$.

Crystal Structure Prediction and Computational Complexity. Predicting crystal structures by computational methods without experimental input is the Holy Grail of crystallography and material science; it has remained a noted open problem for over 30 years [24]. In general, Crystal Structure Prediction (CSP) asks to identify the periodic crystal structure from a given set of *ions* – electromagnetically charged atoms – that minimise its potential energy based on some model of interaction.

A crystal is a structure defined by a repeating period called a unit cell. Informally, the unit cell can be thought of as a three dimensional box containing *ions*, see Figure 1. Each ion belongs to a class called a *species*, determining the properties of the ion. The unit cell acts as a periodic mapping from some set of ion species to the space $\mathbb{R}^3$, or in the discrete setting to a grid such as the integer grid $\mathbb{Z}^3$. In a discrete space, the unit cell can be represented as a necklace or bracelet [4, 2]. In the most general formulations of CSP the size and shape of the unit cell are unconstrained, however bounding the size and the shape is a common restriction for many cases of CSP [12].

Crystal structure prediction can be thought of as the problem of finding the "best" configuration of ions within a three-dimensional box, but it is also important for dimension one and two, see [12]. The quality of a configuration is determined by the average pairwise interaction between each ion in the structure. The pairwise interaction in turn is determined by an energy function, taking as input the distance between ions and a set of parameters based on the ion species. A positive interaction between ions corresponds to a force pushing the ions apart, while a negative interaction indicates a force of attraction. The goal of CSP is to find a stable structure, indicated by having the minimal average pairwise interaction [23].

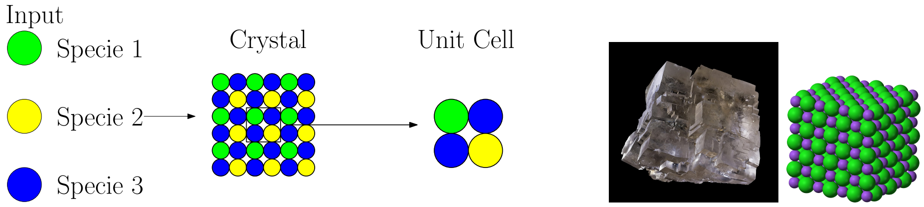

Figure 1 Left: A high level example of CSP. The input is a set of 3 species of ions (green, yellow, and blue), where each pair has an interaction computed by a given function determined by the distance and species. This set of species is transformed into a crystal structure (middle) defined by a unit cell (right). **Right:** Example of a Sodium Chloride crystal with the ionic structure. The middle and right pictures are shared under the creative commons licence.

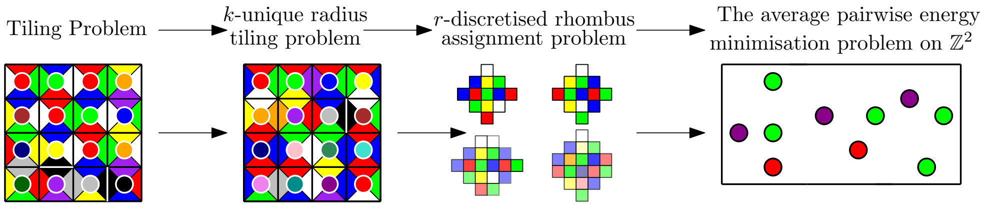
Despite countless heuristics attempts such as quasi-random sampling [27, 29], basin hoping [6, 15, 16], simulated annealing [26, 30], swarm optimisation [9, 33], and genetic algorithms [14, 22, 25] the computational complexity of the CSP problem has not been investigated [10]. The recent interdisciplinary initiative to combine chemical knowledge with state of the art computer science techniques has lead to the first formalisation of CSP as a theoretical computer science problem [3, 6].

Our Contributions. This work introduces the average pairwise energy minimisation problem on $\mathbb{Z}^d$ as a generalisation of the physically motivated models and approximation of real space using the integer grid $\mathbb{Z}^d$. This problem can be seen as a variant on the well studied class of tiling problems [5, 7]. Rather than the "hard" constraints of a tiling problem, where tiles can only be placed adjacent to each other if they fulfil a set of strict conditions, our model uses "soft" constraints, giving an energy value to the interaction between each pair of vertices in the grid based on distance and the colour of the vertices.

Our main result is showing the average pairwise energy minimisation problem on $\mathbb{Z}^d$ to be NP-hard when the size of the unit cell is fixed and is undecidable otherwise. This strengthens the argument that CSP is intractable for a fixed-size unit cell and undecidable in general.

Our proof of both intractability and undecidability come by way of a series of reductions starting with the periodic tiling problem. This series of reductions is designed to enable us to more easily encode the concept of *orientation* into the pairwise interaction constraints that the average pairwise energy minimisation problem on $\mathbb{Z}^d$ uses. In the periodic tiling problem it is necessary for all tiles to have a shared orientation in order for the undecidability results to hold, however our physically motivated models determine interaction only by the colour of the vertices, and the distance between them. To encode this property we introduce two problems: the *k-unique radius tiling problem* (defined in Section 3.1), and the r-discretised rhombus all-distinct periodic complete assignment problem (defined in Section 3.2). Figure 2 provides a sketch of this process. We strengthen our results by showing that they hold under the further constraint of *charge neutrality*, an abstraction of the physical constraint that the periods of these structures must have an equal number of positive and negative charges.



Tiling Problem

r-discretised rhombus assignment problem
The average pairwise energy minimisation problem on $\mathbb{Z}^2$

Figure 2 High level overview our series of reductions starting with the tiling problem.

2 Preliminaries

Informally, the average pairwise energy minimisation problem on $\mathbb{Z}^d$ can be thought of as the problem of determining a way of colouring the infinite grid $\mathbb{Z}^d$ with a *finite period*, while minimising the average pairwise interaction energy. The pairwise interaction energy between each pair of points on $\mathbb{Z}^d$ is determined by the colours of the points, and the distance between them. The period of a colouring is called the *unit cell*, which may equivalently be thought of as a mapping from the set of colours to the grid.

▶ **Definition 1** (Unit cell). *A* unit cell U *of size* $\vec{n} = (n_1, n_2, \ldots, n_d) \in \mathbb{N}^d$ *is a periodic mapping from the integer grid* $\mathbb{Z}^d$ *to some set of colours* $\mathcal{C}$*, defined by a colouring on the* d *dimensional grid* $n_1 \times n_2 \times \ldots \times n_d$*. Given a vector* $\vec{y} \in \mathbb{Z}^d$*,* $U(\vec{y})$ *returns the colour at position* $(y_1 \bmod n_1, y_2 \bmod n_2, \ldots, y_d \bmod n_d)$ *on the grid defining* U*.*

The number of vertices in a unit cell U of size $\vec{n}$ is denoted by $|U|$, i.e. $|U| = n_1 \cdot n_2 \cdot \ldots \cdot n_d$. Similarly $\vec{x} \in U$ is used to denote that $\vec{x}$ is a position in the finite grid defining U. Where it is clear from context, given any vector $\vec{x} \in \mathbb{Z}^d$ the colour of the vertex at position $\vec{x}$ in the grid $\mathbb{Z}^d$ coloured by U is denoted $U(\vec{x})$, giving $U(\vec{x}) = U((x_1 \bmod n_1, x_2 \bmod n_2, \ldots, x_d \bmod n_d))$.

The goal of these colourings is to minimise the *average pairwise energy per vertex* of the coloured grid. The energy between two vertices represents the force between them, with a negative energy indicating attraction and a positive energy indicating repulsion. The pairwise energy between a pair of vertices in the grid is determined by a *pairwise energy function.*

This work considers parametric pairwise energy functions f of the form $f(\overline{\theta}_{(c_i,c_j)}, r)$ where $c_i, c_j \in \mathcal{C}$ are a pair of colours, $r \in \mathbb{R}$ is a euclidean distance and $\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p$ is a vector of p parameters determined by the colours c_i and c_j. Further, this work assumes that the vector of parameters $\overline{\theta}_{(c_i,c_j)}$ are predefined for every pair of colours $c_i, c_j \in \mathcal{C}$. Each function returns a scalar real value, i.e. $f\colon \left(\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p, r \in \mathbb{R}\right) \mapsto \mathbb{R}$.

▶ **Definition 2** (Average pairwise energy per vertex). *Given a unit cell* U *of size* $\vec{n}$ *colouring the grid* $\mathbb{Z}^d$*, the* average pairwise energy per vertex *is given by:*

$$\mathrm{AE}(U) = \frac{1}{|U|} \sum_{\vec{x} \in U} \sum_{\vec{y} \in \mathbb{Z}^d} f(\overline{\theta}_{(U(\vec{x}),U(\vec{y}))}, D(\vec{x}, \vec{y}))$$

where f *is the pairwise energy function,* $D(\vec{x}, \vec{y})$ *denotes the euclidean distance between* $\vec{x}$ *and* $\vec{y}$*, and* $\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p$ *is a vector of* p *parameters.*

In this paper we assume that each energy function has a cut off distance, allowing the average pairwise energy per vertex to be compute efficiently. One further constraint that we introduce is that of *charge neutrality.* In this setting, every colour is associated with a integer charge. Given a unit cell U, the charge of $\vec{x} \in U$ is denoted $Q(U(\vec{x}))$. Note that the charge of any two points assigned the same colour are equal, i.e. if $U(\vec{x}) = U(\vec{y})$ then

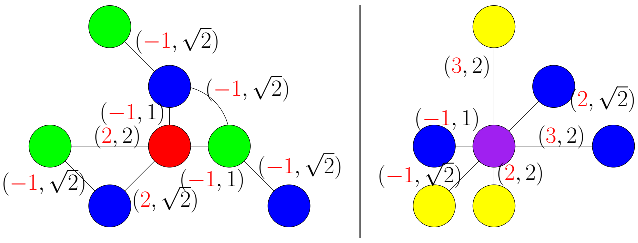

Figure 3 An overview of $\mathcal{CMV}(r)$. The energy and distance between each point is labelled as a pair (a, b) where a represents the energy and b represents the distance.

$Q(U(\vec{x})) = Q(U(\vec{y}))$ for any pair of vectors $\vec{x}, \vec{y} \in U$. A unit cell U is *charge neutral* if and only if $\sum_{\vec{x} \in U} Q(U(\vec{x})) = 0$. In general we assume that the charge neutrality constraint can be ignored, effectively assuming that the charge is 0 for every colour.

2.1 The r-Distance Common Minimal Value Class

In this paper we restrict our energy functions to the class of r-distance common minimal value functions, denoted $\mathcal{CMV}(r)$, introduced in this section. This class of functions focuses on the interactions between vertices within a distance of r of each other, for some distance $r \in \mathbb{R}$. In order to simplify reasoning on the set $\mathcal{CMV}(r)$, it is assumed that given any distance $d > r$ the value of $f(\overline{\theta}_{(c_i,c_j)}, d) = 0$ for every pair of colours $c_i, c_j \in \mathcal{C}$. Let $R(r) = \{(i,j) \in \mathbb{Z}^2 \mid \sqrt{i^2 + j^2} \leq r, (i,j) \neq (0,0)\}$ be the set of vertices on the integer grid $\mathbb{Z}^2$ within a distance of at most r of the central point $(0,0)$. Further, let $d(r) = \{\sqrt{i^2 + j^2} \mid (i,j) \in R(r)\}$ be the set of possible distances between the central vertex and any vertex in $R(r)$. As an example, $R(2) = \{(2,0), (1,1), (1,0), (1,-1), (0,2), (0,1), (0,-1), (0,-2), (-1,1), (-1,0), (-1,-1), (-2,0)\}$ and $d(r) = \{1, \sqrt{2}, 2\}$. The goal of this class is to be able to "fix" the optimal distance between pair of colours as either being some distance in $d(r)$, or as being outside of $R(r)$ – in effect penalising two colours at a distance of r or less. To this end this work uses the idea of a *common minimal value*. Informally, the common minimal value can be thought of as some negative value M such that the smallest possible interaction between any pair of vertices is M. Further, the functions in this work restrict M to appear at most once in the set of possible distance between each colour, meaning that given some pair of colours c_i and c_j, there exists at most one distance $d \in d(r)$ such that $f(\theta_{(c_i,c_j)}, d) = M$. The following definition formalises the *r-distance common minimal value class.*

▶ **Definition 3** (Common Minimal Value Functions ($\mathcal{CMV}(r)$)). *Let $\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p$ denote the vector of parameters assigned to some pair of colours $c_i, c_j \in \mathcal{C}$. The function $f(\overline{\theta}_{(c_i,c_j)}, d)$: $\mathbb{R}^{p+1} \to \mathbb{R}$ belongs to the* **class of common minimal value functions** *$\mathcal{CMV}(r)$ for $r \in \mathbb{R}$ if there exists a common minimum value $M \in \mathbb{R}$ for which the following hold:*

1. *For any two points at a distance $d > r$ and any pair of colours c_i,$c_j \in \mathcal{C}$ the value of $f(\overline{\theta}_{(c_i,c_j)}, d) = 0$;* [**Cut-off property**].
2. *For any two colours c_i,$c_j \in \mathcal{C}$ it is possible to determine a vector $\overline{\theta}_{(c_i,c_j)}$ such that the energy between any pairs of points at any distance $d \in d(r)$ is $f(\overline{\theta}_{(c_i,c_j)}, d) > M$;* [**Separation property**].
3. *For any two colours c_i,$c_j \in \mathcal{C}$ and any distance $d \in d(r)$ it is possible to determine a vector $\overline{\phi}_{(c_i,c_j)}$ such that the energy between any pair of points at distance d is $f(\overline{\phi}_{(c_i,c_j)}, d) = M$ and the energy between any pair of points at any distance $d' \in d(r), d' \neq d$ is $f(\overline{\phi}_{(c_i,c_j)}, d') > M$;* [**Optimal pairwise distance property**].

An overview of these properties is given in Figure 3. These properties are used to encode the tiling problem into the average pairwise energy minimisation problem on $\mathbb{Z}^d$. The cut-off property (Property 1) ensures that there is no interaction between vertices over a certain cut off distance, allowing these interactions to be safely ignored. The separation property (Property 2) ensures that there exists a vector of parameters such that the corresponding colours must be placed further than r apart, or suffer a small energy penalty by having an interaction greater than M. Finally the optimal pairwise distance property (Property 3) ensures that there exists a vector of parameters such that the interaction of the corresponding colours is minimised at M at exactly one distance. The goal of these conditions is to be able to force a structure on the colouring based on the relative distances between colours. This allows the structure of the tiling problem to be utilised in the setting of the average pairwise energy minimisation problem on $\mathbb{Z}^d$.

2.2 The Pairwise Energy Minimisation Problem

This section introduces our central problem, the *average pairwise energy minimisation problem on* $\mathbb{Z}^d$. In this paper we consider two versions of this problem, depending on the constraints placed on the unit cell. In the most general case, the only constraint is that the average energy of the unit cell is below some bound g. In this paper, we limit the energy functions to the class $\mathcal{CMV}(r)$. The unit cell may be constrained by having the size given as part of the input. All values are given in binary as input to our problems.

▶ **Problem 1.** *The average pairwise energy minimisation problem on* $\mathbb{Z}^d$*.*

Input: A goal energy $g \in \mathbb{Q}$, a set of colours $\mathcal{C}$, a number of dimensions $d \in \mathbb{Z}$ an energy function $f \in \mathcal{CMV}$ and a set of $|\mathcal{C}|^2$ parameters $\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p$.

Question: Does there exist a unit cell U of size $n_1 \times n_2 \times \ldots \times n_d$ for some $n_i \in \mathbb{N}^+$ where $\mathrm{AE}(U) \leq g$.

When the size of the unit cell is given as an input in the form of a vector of length d of the form $(n_1, n_2, \ldots, n_d)$, we refer to the problem as the **average pairwise energy minimisation problem on $\mathbb{Z}^d$ with a fixed period**. Here, *fixed period* refers to the size of the period being fixed as part of the input, in this case restricting the period to be of size $n_1 \times n_2 \times \ldots \times n_d$ for the given $n_1, n_2, \ldots, n_d$.

3 Undecidability for Unconstrained Period Size

We first look at the unbounded setting, where the size of the unit cell is not taken as part of the input. The main claim in this section is that Problem 1 is undecidable for any function in $\mathcal{CMV}(r)$ for $r \geq 2$. This section is split into three parts. First, we provide some background on the tiling problem that is used as the basis for this reduction. Second, we provide an auxiliary problem derived from the tiling problem to act as an intermediary step in proving the undecidablity of the average pairwise energy minimisation problem on $\mathbb{Z}^d$. Finally we prove the undecidablity of the average pairwise energy minimisation problem on $\mathbb{Z}^d$.

3.1 The Tiling Problem

In the tiling problem, we are given a set of *tiles*, square plates with a fixed orientation where each edge is coloured from some set of colours $\mathcal{C}$. The goal of a tiling problem is to completely cover the plane with tiles such that every pair of adjacent tiles is coloured the same along the shared edge. In this section, we introduce the further constraint that no two copies of the same tile may be within a distance of k or less of each other.

Before discussing the new variations of the tiling problem, let us first present some notation. The edges of the tiles are labelled *East, West, North* and *South* such that the East edge is opposite the West edge, and the South edge is opposite the North edge. More precisely, given two tiles, v at position (x_1, y_1) and u at position (x_2, y_2) respectively such that $|x_1 - x_2| \leq 1$ and $|y_1 - y_2| \leq 1$, we say that:

	$x_1 < x_2$	$x_1 = x_2$	$x_1 > x_2$
$y_1 < y_2$	v is **North-West** of u	v is **North** of u	v is **North-East** of u
$y_1 = y_2$	v is **West** of u	v is u	v is **East** of u
$y_1 > y_2$	v is **South-West** of u	v is **South** of u	v is **South-East** of u

A tile t is represented by the four edges composing it. For notation let t_e be the colour of the tile t along edge e. A tile t can be represented as $t = \{t_{East}, t_{South}, t_{West}, t_{North}\}$. A *Tile Set* is a set of tiles with the edges coloured from some set of colours $\mathcal{C}$. It is assumed the the tile set contains an infinite number of copies of each tile, allowing the complete plane to be covered with these tiles. The goal of the *Tiling problem* is to assemble copies of the tiles from a given tile set on an infinite plane ruled into squares of the size of one tile such that:

1. No tile is rotated or reflected.
2. A tile must be placed *exactly* over one square of the ruled integer plane.
3. The colour of adjacent edges must match.
4. Every square must be covered by one tile.

This problem is *solvable* for a given tile set if and only if such an assembly exists. An assembly is periodic if there exists some finite region of the plane that may be repeated so as to solve the tiling problem. The *Periodic Tiling Problem* asks if there is such a periodic assembly. Both the tiling problem and the periodic tiling problem are classical undecidable problems [5, 7]. Connections between this problem and chemistry are well established [28].

In this paper, we introduce the *k-unique radius* variant of the tiling problem to act as an intermediate problem between the general tiling problem and the average pairwise energy minimisation problem on $\mathbb{Z}^2$. The k-unique radius tiling problem is needed to help encode the notion of *orientation* into the average pairwise energy minimisation problem on $\mathbb{Z}^2$. In the tiling problem, it is integral that each tile is placed under the same orientation. This means that given two adjacent tiles, they must either touch West edge to East edge, or North edge to South edge. As our setting uses only the colours and distance between vertices to determine the pairwise energy, the concept of orientation is difficult to encode. Informally a tiling has a k-unique radius if and only if no two copies of a given tile are within a distance of at most k of each other. Let T be a tiling of $\mathbb{Z}^2$ such that $T(i, j)$ returns the tile at position (i, j). The tiling T has a k-unique radius if and only if for every $(i, j), (x, y) \in \mathbb{Z}^2$, where $D((i, j), (x, y)) \leq k$ the tile $T(i, j)$ is distinct from $T(x, y)$, i.e. $T(i, j) \neq T(x, y)$ where $D((i, j), (x, y))$ returns the distance between (i, j) and (x, y).

▶ **Problem 2.** *The periodic tiling problem with a k-unique radius.*

Input: A set of tiles, $\mathcal{T}$, and integer k
Question: Does there exist a periodic tiling of $\mathbb{Z}^2$ made from $\mathcal{T}$ such that given any tile t at position (x, y) there exists no other copy of t within a distance of k from (x, y)?

▶ **Proposition 4.** *The periodic k-unique radius tiling problem is undecidable for any $k \in \mathbb{N}$.*

Proof Sketch. The undecidability of the periodic k-unique radius tiling problem follows from the undecidability of the periodic domino problem [7]. The high level idea is to create a set of k^2 copies of each tile, labelled with $(x, y) \in [k]$. A set of additional colours are constructed such that given two tiles $t_{(x,y)}$ and $s_{(a,b)}$, $t_{(x,y)}$ can be placed adjacent to $s_{(a,b)}$ if and only if the original tiles t and s can be placed adjacently, and (a,b) is adjacent to (x,y) on the $k \times k$ toroidal grid. In one direction, any valid tiling with the original set of tiles can be transformed into a valid tiling for the new set by choosing an arbitrary origin point, and replacing the tile t at position (x,y) with the tile $t_{(x \bmod k, y \bmod k)}$. In the other direction, any tiling using the new tiles can be transformed into a tiling of the original tiles by simply replacing each tile $t_{(x,y)}$ with the tile t from the original set. ◀

▶ **Problem 3.** *The fixed period k-unique tiling problem.*

Input: A set of tiles, $\mathcal{T}$, integer k, and pair of lengths n_1, n_2.
Question: Does there exist a periodic tiling of the plane of size $n_1 \times n_2$ over $\mathcal{T}$ where every tile within a distance of k for every other tile is distinct.

▶ **Proposition 5.** *The fixed period k-unique tiling problem is NP-hard.*

Proof. Following the same arguments as in Proposition 4, the fixed period tiling problem can be reduced to the fixed period k-unique tiling problem. As the fixed period tiling problem is known to be NP-hard [5, 7, 21], the fixed period k-unique tiling problem is NP-hard. ◀

3.2 Tiling with Overlapping Digitised Rhombuses

This section covers the problem of completely covering the integer grid $\mathbb{Z}^2$ using *overlapping digitised rhombuses.* Informally, a *digitised rhombus* with radius r can be thought of as a set of mono-chromatically coloured tiles organised as a rhombus from some set of colours $\mathcal{C}$.

▶ **Definition 6** (Digitised rhombus). *A* ***digitised rhombus*** *of radius r is the mapping from the grid $\{(x,y) \in \mathbb{Z}^2 \mid |x| + |y| \leq r\}$ to a set of colours $\mathcal{C}$.*

Given a rhombus R and position $(i,j) \in \{(x,y) \in \mathbb{Z}^2 \mid |x| + |y| \leq r\}$, $R_{i,j}$ is used to denote the colour mapped by R to position (i,j), i.e. the colour of the tile at position (i,j) in the rhombus. A rhombus is *distinctly coloured* if $R_{i,j} \neq R_{l,m}$ for every pair of positions $(i,j),(l,m) \in \{(x,y) \in \mathbb{Z}^2 \mid |x| + |y| \leq r\}$ where $(i,j) \neq (l,m)$.

We use a set of rhombuses $\mathcal{R}$ analogously to the set of tiles $\mathcal{T}$ used in tiling problems. Given the integer grid $\mathbb{Z}^2$, the assignment of a rhombus R to the position $(x,y) \in \mathbb{Z}^2$ is equivalent to colouring every vertex within a radius of r of (x,y) using R. For the remainder of this section, we focus on the Manhattan distance, defined as $D((x_1,y_1),(x_2,y_2)) = |x_1 - x_2| + |y_1 - y_2|$. Given a rhombus R assigned to position $(x,y) \in \mathbb{Z}^2$, the position (x',y') at a distance of no more than r from (x,y) is coloured $R_{x'-x,y'-y}$.

The focus in this work is on *overlapping rhombuses.* Given a pair of digitised rhombuses of radius $r \in \mathbb{N}$, R and S at positions (x_1,y_1) and (x_2,y_2), R overlaps S if the Manhattan distance between R and S is no more than $2r$. The *overlap* between R and S are the set of positions that are assigned colours by both R and S. This corresponds to the set of positions $\{(a,b) \in \mathbb{Z}^2 \mid D((a,b),(x_1,y_1)) \leq r$ and $D((a,b),(x_2,y_2)) \leq r\}$. Informally, R and S properly overlap when centred at (x_1,y_1) and (x_2,y_2) if every position in the overlap is assigned the same colour by both R and S. See Figure 4 for an example.

▶ **Definition 7** (Overlapping rhombuses). *Let R and S be a pair of r-radius digitised rhombuses centred on positions (x_1,y_1) and (x_2,y_2) respectively. Rhombuses R and S* ***properly overlap*** *if and only if for every position $(i,j) \in \{(a,b) \in \mathbb{Z}^2 \mid D((a,b),(x_1,y_1)) \leq r$ and $D((a,b),(x_2,y_2)) \leq r\}$ it holds that $R_{i-x_1,j-y_1} = S_{i-x_2,j-y_2}$.*

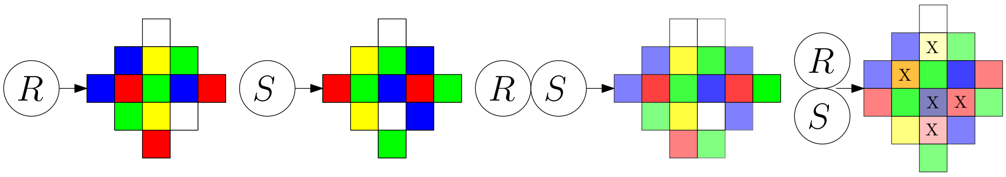

Figure 4 An example outlining how two rhombuses R and S may properly overlap (left) and when not (right). Note that X is used to denote a conflict between the two overlapping rhombuses.

Note that any two rhombuses at a distance greater than $2 \cdot r$ from each other properly overlap following Definition 7 as the set $\{(a,b) \in \mathbb{Z}^2 \mid D((a,b),(x_1,y_1)) \leq r$ and $D((a,b),(x_2,y_2)) \leq r\}$ is empty. An *assignment* of rhombuses $\mathcal{R}$ to the integer grid $\mathbb{Z}^2$ equates to a complete colouring of $\mathbb{Z}^2$ using the rhombuses in $\mathcal{R}$ as the colours. An assignment is valid if and only if a rhombus is centred on every vertex in $\mathbb{Z}^2$ and every pair of rhombuses properly overlap.

▶ **Definition 8** (Rhombus assignment). *An* ***assignment*** *A of rhombuses from the set $\mathcal{R}$ to $\mathbb{Z}^2$ is a mapping from $\mathbb{Z}^2$ to $\mathcal{R}$ such that $A : (x,y) \in \mathbb{Z}^2 \mapsto R$ for every $x,y \in \mathbb{Z}$. Let $A(x,y) : \mathbb{Z}^2 \mapsto \mathcal{R}$ return the rhombus assigned to position $(x,y) \in \mathbb{Z}^2$. An assignment A is* valid *if and only if $\forall (x_1,y_1),(x_2,y_2) \in \mathbb{Z}^2$, the rhombus $A(x_1,y_1)$ properly overlaps $A(x_2,y_2)$.*

▶ **Definition 9** (Periodic assignment). *An assignment A from $\mathbb{Z}^2$ to $\mathcal{R}$ is* ***periodic*** *if there exists a tuple $(a,b) \in \mathbb{Z}^2$ such that $A(x,y) = A(x \bmod a, y \bmod b)$ for every tuple $(x,y) \in \mathbb{Z}^2$.*

▶ **Problem 4.** *The r-discretised rhombus all-distinct periodic complete assignment problem.*

Input: A set $\mathcal{R}$ of r-radius digitised rhombuses
Question: Does there exist a valid periodic assignment of $\mathcal{R}$ to $\mathbb{Z}^2$?

▶ **Theorem 10.** *The r-discretised rhombus all-distinct periodic complete assignment problem is undecidable for any $r \geq 1$.*

Proof Sketch. This theorem is proven by transforming a set of tiles into a set of rhombuses. The set of rhombuses is constructed by taking the set of unique tilings on the grid $\{(x,y) \in \mathbb{Z}^2 \mid x^2 + y^2 \leq 1\}$, and creating a rhombus corresponding to each tiling. Each tile is represented in this model by a unique colour. ◀

The same construction as in Theorem 10 are used to derive an NP-completeness result for the fixed period r-discretised rhombus all-distinct periodic complete assignment problem. Observe that for a set of q rhombuses, and fixed period $n_1 \times n_2$, there are $q^{n_1 \cdot n_2}$ possible coverings, therefore a brute force algorithm can solve this problem in $O(q^{n_1 \cdot n_2})$-time, and therefore the problem belongs to NP. For hardness, Proposition 5 is used to establish the hardness of the fixed-period k-unique radius tiling problem, and by extension the hardness of the fixed period r-discretised rhombus all-distinct periodic complete assignment problem.

▶ **Corollary 11.** *The fixed period r-discretised rhombus all-distinct periodic complete assignment problem is NP-complete for any $r \geq 1$.*

3.3 Pairwise Energy Minimisation Problem on $\mathbb{Z}^2$ and $\mathbb{Z}^3$

With the undecidability of the r-discretised rhombus all-distinct periodic complete assignment problem established, the next step is to show how to reduce the r-discretised rhombus all-distinct periodic complete assignment problem to the average pairwise energy minimisation problem on $\mathbb{Z}^d$. In this section, the pairwise energy function is assumed to be a member of the 2-distance common minimal value class, $\mathcal{CMV}(2)$. At a high level the reduction from the r-discretised rhombus all-distinct periodic complete assignment problem is done by encoding each rhombus as a colour, then tuning the parameters of the pairwise energy function so that a valid colouring of the grid corresponds to a valid assignment of rhombuses.

The main challenge of this encoding is due to the definition of $\mathcal{CMV}(2)$. Namely, for any energy function in $\mathcal{CMV}(2)$ the pairwise energy between vertices is determined solely by the distance between vertices, colour of each vertex, and some given vector of parameters. This means that given two adjacent vertices v_i and v_j, coloured c_i and c_j respectively, the energy between v_i and v_j is the same irrespective of the relative direction of each tile.

To simplify our reduction, we introduce some additional notation. Given two vertices v_i at position (x_1, y_1) and v_j at position (x_2, y_2), v_i is said to be *directly adjacent* to v_j if $|x_1 - x_2| + |y_1 - y_2| = 1$. Similarly v_i is *diagonally adjacent* to v_j if $|x_1 - x_2| = 1$ and $|y_1 - y_2| = 1$. Finally, v_i is *peripherally adjacent* if either $|x_1 - x_2| = 2$ and $y_1 = y_2$, or $x_1 = x_2$ and $|y_1 - y_2| = 2$. Further, in Proposition 12 we assume M to be the common minimal value for all functions in $\mathcal{CMV}(r)$.

▶ **Proposition 12.** *Let $\mathcal{R}$ be a set of distinctly coloured rhombuses and let $\mathcal{C}(\mathcal{R})$ be a set of $|\mathcal{R}|$ colours such that for every rhombus $r \in \mathcal{R}$, there exists some colour $C_r \in \mathcal{C}(\mathcal{R})$. For any pairwise energy function $f \in \mathcal{CMV}(2)$, and pair of rhombuses $i, j \in \mathcal{R}$ there exists some vector of parameters $\overline{\theta}_{(c_i,c_j)}$ such that $f(\overline{\theta}_{(c_i,c_j)}, r)$ satisfies:*

1. *If i and j properly overlap when i is centred at some position directly adjacent to j then $f(\overline{\theta}_{(c_i,c_j)}, 1) = M$, and $f(\overline{\theta}_{(c_i,c_j)}, r) > M$ for any $r > 1$.*
2. *If i and j properly overlap when i is centred at some position diagonally adjacent to j then $f(\overline{\theta}_{(c_i,c_j)}, \sqrt{2}) = M$, and $f(\overline{\theta}_{(c_i,c_j)}, r) > M$ for either $r = 1$ or $r = 2$.*
3. *If i and j properly overlap when i is centred at some position peripherally adjacent to j then $f(\overline{\theta}_{(c_i,c_j)}, 2) = M$, and $f(\overline{\theta}_{(c_i,c_j)}, r) > M$ for $r < 2$.*
4. *Otherwise $f(\overline{\theta}_{(c_i,c_j)}, r) > M$ for any distance r.*

Proof. Recall that all functions in $\mathcal{CMV}(2)$ must have some vector of parameters $\overline{\theta}_{(c_i,c_j,d)} \in \mathbb{R}^p$ for every $d \in \{1, \sqrt{2}, 2\}$ such that $f(\overline{\theta}_{(c_i,c_j,d)}, d) = M$, and for every other distance distance $d' \in d(r)$ where $d' \neq d$ the value of the energy function $f(\overline{\theta}_{(c_i,c_j,d)}, d') > M$ by the optimal pairwise distance property (Property 3) of Definition 3. Therefore Conditions 1, 2, and 3 in the statement can be satisfied by choosing the appropriate vector of parameters for the distances of $1, \sqrt{2}$ and 2 respectively. Further, by the separation property (Property 2) there exists some vector of parameters $\overline{\theta}_{(c_i,c_j)} \in \mathbb{R}^p$ such that for every distance $d \in d(r)$ the energy $f(\overline{\theta}_{(c_i,c_j)}, d) > M$, satisfying Condition 4 above. ◀

Setting the parameter vectors so as to satisfy the conditions given in Proposition 12, Lemma 13 shows that a valid assignment of $\mathcal{R}$ to $\mathbb{Z}^2$ can be used to construct a valid colouring of $\mathbb{Z}^2$ using $\mathcal{C}(\mathcal{R})$. Lemma 14 shows that given such a colouring of $\mathbb{Z}^2$ using $\mathcal{C}(\mathcal{R})$, there must exist a valid assignment from $\mathbb{Z}^2$ to $\mathcal{R}$.

▶ **Lemma 13.** *Let A be a valid assignment of the set of distinctly coloured 2-radius rhombuses $\mathcal{R}$ to $\mathbb{Z}^2$ with a period of $n_1 \times n_2$. Given such an assignment there exists a periodic colouring of $\mathbb{Z}^2$ using the set of colours $\mathcal{C}(\mathcal{R})$ with an average energy per vertex of $12 \cdot M$.*

Proof Sketch. Observe that following Proposition 12 the interaction between any pair of colours within a distance of 2 is M. As A is a valid assignment of Rhombuses, the interaction between each point within a distance of at most 2 is M, giving an average energy of $12 \cdot M$. ◀

▶ **Lemma 14.** *Let U be a unit cell of size $n_1 \times n_2$ colouring $\mathbb{Z}^2$ with the colour set $\mathcal{C}(\mathcal{R})$ such that the average energy per vertex is $12 \cdot M$. Given such a unit cell there exists a valid assignment of the set of distinctly coloured 2-radius rhombuses $\mathcal{R}$ to $\mathbb{Z}^2$.*

Proof Sketch. The key observation behind this lemma is that given some vertex v at position (x, y) coloured with $c \in \mathcal{C}(\mathcal{R})$, there are exactly 4 colours $c_1, c_2, c_3, c_4 \in \mathcal{C}(\mathcal{R})$ that can be used to colour the vertices directly adjacent to v. Further, for the colour c_1 there exists exactly 1 colour that can be at a distance of 2 from a vertex coloured c_1 and a distance of 1 from a vertex coloured c. Therefore the local neighbourhood of each vertex must be coloured in such a way that the corresponding rhombuses correspond to a correct assignment. By extension, a valid colouring for the graph with an average energy per vertex of $12 \cdot M$ must correspond to a correct assignment of rhombuses to the plane $\mathbb{Z}^2$. ◀

▶ **Theorem 15.** *The average pairwise energy minimisation problem on $\mathbb{Z}^d$ is undecidable for any function in the 2-distance common minimal value class, and $d \in \{2, 3\}$.*

Proof. From Lemmas 13 and 14, there exists a valid colouring of $\mathbb{Z}^2$ with an average energy per vertex of $12M$ of $\mathcal{C}(\mathcal{R})$ if and only if there exists a valid assignment of $\mathcal{R}$ to $\mathbb{Z}^2$. As the r-discretised rhombus all-distinct periodic complete assignment problem is undecidable, the average pairwise energy minimisation problem on $\mathbb{Z}^2$ is undecidable.

To show the undecidability in 3D, consider the 3D tiling problem, where each tile is a 3D block with each face coloured. This problem is shown to be undecidable by reduction from the tiling problem. Let each block have a top and bottom face, along with the $North, West, South$ and $East$ faces. Given a set of tiles $\mathcal{T}$ a block b is constructed for each tile $t \in \mathcal{T}$ such that the colour of $North, West, South$ and $East$ faces of b match the corresponding colours of t, and the top and bottom faces of b are coloured with some universal colour c. See Figure 5 for an example. Observe that each plane of any valid tiling of these blocks on $\mathbb{Z}^3$ corresponds to a valid tiling of $\mathcal{T}$. As in the 2D setting, this problem can be restricted with the k-unique radius property. Similarly, k-unique radius tilings with 3D blocks can be converted into an all-distinct discretised rhombohedron in the same manner as the 2D case.

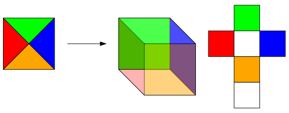

Figure 5 The transformation from a tile (left) to a 3 dimensional block (middle) and to an unfolded representation (right). The top and bottom faces are coloured with the same new colour.

An average pairwise energy minimisation problem on $\mathbb{Z}^d$ instance is constructed from these rhombohedrons in the same manner as in the 2D case. Note that an all discretised rhombohedron containing all points within a distance of 2 has 33 blocks. In this case, the average energy per vertex is $32 \cdot M$ if and only if there exists a valid tiling of $\mathbb{Z}^3$ of the original set of blocks. In one direction, if there exists such a tiling then the corresponding unit cell has an average energy per vertex of $32 \cdot M$. In the other direction, the same arguments as in the 2D case may be applied to show that any colouring with an average energy per vertex of $32 \cdot M$ corresponds to a valid tiling. ◀

Observe that the number of possible solution to the average pairwise energy minimisation problem on $\mathbb{Z}^2$ with a fixed period is at most $q^{n_1 \cdot n_2}$, where q is the number of tiles and (n_1, n_2) the size of the unit cell. Therefore, this problem is in NP. In the other direction the same arguments from Theorem 15 alongside Corollary 11 show the problem to be NP-hard.

▶ **Corollary 16.** *The fixed period average pairwise energy minimisation problem on $\mathbb{Z}^d$ is NP-complete for any function in the 2-distance common minimal value class, and $d \in \{2, 3\}$.*

4 Physically motivated pairwise energy functions

In this section, we apply the results from our abstract model to the problem of crystal structure prediction. In order to do so, we claim that the the *Buckingham-Coulomb* [32] and *Ising* [8] energy functions belong to $\mathcal{CMV}(2)$. The main results in this section, focus on *charge neutrality* in the context of the Buckingham-Coulomb potential, showing that the average pairwise energy minimisation problem on $\mathbb{Z}^d$ remains undecidable even with this restriction, and that the average pairwise energy minimisation problem on $\mathbb{Z}^d$ with a fixed period becomes hard to approximate within any positive factor in the 1D case. These results are strengthened in Section 4.2 by providing a parameterised algorithm for the average pairwise energy minimisation problem on $\mathbb{Z}$.

First, we outline the properties used by the Buckingham-Coulomb and 2-radius n-vector Ising energy functions to show that they belong to the class $\mathcal{CMV}(2)$.

The Buckingham-Coulomb Potential. The Buckingham-Coulomb energy between a pair of vertices coloured i and j at a distance of $r_{i,j}$ is given by the equation $BC(i, j, r_{i,k}) = \frac{A_{i,j}}{e^{B_{i,j} \cdot r_{i,j}}} - \frac{C_{i,j}}{r^6_{i,j}} + \frac{q_i \cdot q_j}{r_{i,j}}$ where $A_{i,j}, B_{i,j}$ and $C_{i,j}$ are a set of force field parameters, determined by the colours, q_i is the charge of colour i, and q_j is the charge of colour j. Here, we assume that rather than the integer grid, the Buckingham-Coulomb potential is performed on the set of points $\{(10 \cdot x_1, 10 \cdot x_2, \ldots, 10 \cdot x_d) \mid (x_1, x_2, \ldots, x_d) \in \mathbb{Z}^d\}$. In order to show that The Buckingham-Coulomb potential belongs to the class $\mathcal{CMV}(2)$, it is necessary to show that there exists a vector of parameters for each distance $d \in [10, \sqrt{200}, 20]$ such that (1) $BC(i, j, d) = M$, (2) $BC(i, j, d') > M$ for every $d' \in [10, \sqrt{200}, 20]$ where $d' \neq d$ and (3) there exists a vector of parameters such that $BC(i, j, d') > M$ for every $d' \in [10, \sqrt{200}, 20]$. Here $M = -1$ and the cutoff distance is set to 2. Conditions (1) and (2) are satisfied by using the faster convergence of the term $\frac{A_{i,j}}{e^{B_{i,j} \cdot r_{i,j}}}$ to 0 than the term $\frac{C_{i,j}}{r^6_{i,j}}$. Condition (3) can be satisfied by setting $A_{i,j}$ to a sufficiently large value, while setting $C_{i,j}$ to 0.

The 2-Radius n-Vector Ising Model. The second energy function we look at is a generalisation of the n-vector Ising model [31]. In the n-vector Ising model, each colour $c \in \mathcal{C}$ corresponds to a unit vector $\vec{c}$. Given a pair of adjacent vertices v and u, coloured c_v and c_u respectively, the energy between v and u is given by the dot product of the vectors, $\vec{c}_v \cdot \vec{c}_u$. In the 2-radius n-vector Ising model, each colour corresponds to a triple of n-length unit vectors. For notation, let $c[i]$ be the i^{th} vector in the triple corresponding to colour c. Given a pair of vertices v and u, coloured c_v and c_u respectively, the energy between v and u is given by $c_v[i] \cdot c_u[i]$ where i is 1 if v and u are at a distance of 1, 2 if v and u are at a distance of $\sqrt{2}$ or 3 if v and u are at a distance of 2. The value of each vector is chosen such that the product of any pair of vertices at distance d is either M, where M is some minimum value, or 0.

▷ Claim 17. The **Buckingham-Coulomb potential** and **2-radius n-vector Ising model** belong to $\mathcal{CMV}(2)$.

4.1 Charge Neutrality

In this section we focus on charge neutrality constraint. Recall that the charge of each colour, denoted $Q(c)$ is an integer value, and that a unit cell is charge neutral if $\sum_{\vec{x} \in U} Q(U(\vec{x})) = 0$.

▶ **Corollary 18.** *The Charge-Neutral average pairwise energy minimisation problem on $\mathbb{Z}^d$ with non-zero charges is undecidable for the Buckingham-Coulomb Potential for $d \in \{2, 3\}$.*

Theorem 19 compliments the proof of NP-hardness from Corollary 16 by showing that the charge-neutral fixed period pairwise energy minimisation problem is NP hard both to solve and to approximate within any constant factor for the Buckingham-Coulomb potential in 1D.

▶ **Theorem 19.** *The charge-neutral fixed period pairwise energy minimisation problem in 1D for the Buckingham-Coulomb potential can not be approximated within any constant factor in polynomial time unless $P = NP$.*

Proof Sketch. This theorem is proven via a reduction from the k-independent set problem. The high level idea is to construct a colour for each vertex in the input graph with a positive charge of $+1$, and a single negative ion of charge $-k$. The energy function is determined such that the interaction between any two colours representing adjacent vertices in the input graph is arbitrarily high, while the pairwise interaction between the positive and negative ions set to -1. This ensures that a valid solution to the charge-neutral fixed period pairwise energy minimisation problem can only be found if there exists an independent set. ◀

4.2 A Parameterised Algorithm for the 1D Setting

In this section we compliment the hardness results by providing a parameterised algorithm for solving the average pairwise energy minimisation problem on $\mathbb{Z}^d$ in 1D. Our algorithm provides solution in $O(n^3 \cdot q^{3 \cdot d})$ where n is the size of the unit cell, q is the number colours, and d is the cut off distance.

Construction. Given an instance of the fixed period pairwise energy minimisation problem for the 1D grid with length n, and set of colours $\mathcal{C}$, a graph G is constructed. Let $\mathcal{V}(d, \mathcal{C}) = \{(x_1, x_2, \dots, x_{d+1}) \mid x_1, x_2, \dots, x_{d+1} \in \mathcal{C}\}$. For notation given $l \in \mathcal{V}(d, \mathcal{C})$, l_i is used to denote the colour of the i^{th} position of l, i.e. given $l = (1, 2, 1, 2)$, $l_2 = 2$ while $l_3 = 1$. For every $i \in [n]$ and $l \in \mathcal{V}(d, \mathcal{C})$ the vertex $v_{i,l}$ is constructed and added to the set V of vertices. Given a pair vertices $v_{i,l}, v_{j,k} \in V$, the edge $v_{i,l}, v_{j,k}$ is added to the set of edges E if and only if $i + 1 = j$ and $l_2, l_3, \dots, l_{d+1} = k_1, k_2, \dots, k_d$. The weight of $(v_{i,l}, v_{j,k})$, denoted $w(v_{i,l}, v_{j,k})$, equals to $\sum_{i=1}^{d} f(i, \overline{\theta}_{(k_1, k_{i+1})})$. This means that each edge $(v_{i,l}, v_{j,k})$ corresponds to the pairwise interaction energy between k_1 and each subsequent vertex in k. In order to account for the energy from the first vector, an additional set of q^{d+1} vertices labelled v_l for every $l \in \mathcal{V}(d, \mathcal{C})$. The vertex v_l has only a single edge connecting it to $v_{1,l}$, weighted as before. Hence by constructing a path of length n starting at some vertex v_l and ending at the vertex $v_{n,l}$ the weight of the path with correspond to the total pairwise energy of the corresponding unit cell. Thus by finding such a path with minimum energy the solution to the fixed period pairwise energy minimisation problem may be found. Using the above construction, the solution to the fixed period pairwise energy minimisation problem instance is found by determining the shortest path from each vertex of the form v_l to the vertex $v_{n,l}$ for every $l \in \mathcal{V}(d, \mathcal{C})$. Note that this graph can be constructed in $O(((n+1) \cdot q^{d+1})^2)$ time for any energy function that can be computed in constant time, by simply constructing the full set of $(n+1) \cdot q^{d+1}$ vertices (corresponding to each position in the grid and list of d colours), and computing the energy between them using the energy function.

▶ **Theorem 20.** *There exists an algorithm to solve the fixed period pairwise energy minimisation problem in $O(n^3 \cdot q^{3 \cdot (d+1)})$ time for any function in $\mathcal{CMV}(d)$.*

Proof. Using the construction above, the solution to the corresponding fixed period pairwise energy minimisation problem instance can be found by using an efficient algorithm for solving the all pairs shortest path problem. Note the graph can be constructed in $O(((n+1) \cdot q^{d+1})^2) \approx O(n^2 \cdot q^{2(d+1)})$ time, assuming that the energy function can be evaluated in constant time. Using the Floyd–Warshall algorithm, the paths may be found in $O(|V|^3)$ time. Note that the number of vertices equals $(n+1) \cdot q^{d+1}$ giving a total complexity of $O\left((n+1)^3 \cdot q^{3\cdot(d+1)}\right) \approx O\left(n^3 \cdot q^{3\cdot(d+1)}\right)$. ◀

Abstract

We consider a weighted counting problem on matchings, denoted PrMatching($\mathcal{G}$), on an arbitrary fixed graph family $\mathcal{G}$. The input consists of a graph $G \in \mathcal{G}$ and of rational probabilities of existence on every edge of G, assuming independence. The output is the probability of obtaining a *matching* of G in the resulting distribution, i.e., a set of edges that are pairwise disjoint. It is known that, if $\mathcal{G}$ has bounded *treewidth*, then PrMatching($\mathcal{G}$) can be solved in polynomial time. In this paper we show that, under some assumptions, bounded treewidth in fact *characterizes* the tractable graph families for this problem. More precisely, we show intractability for all graph families $\mathcal{G}$ satisfying the following *treewidth-constructibility* requirement: given an integer k in unary, we can construct in polynomial time a graph $G \in \mathcal{G}$ with treewidth at least k. Our hardness result is then the following: for *any* treewidth-constructible graph family $\mathcal{G}$, the problem PrMatching($\mathcal{G}$) is intractable. This generalizes known hardness results for weighted matching counting under some restrictions that do not bound treewidth, e.g., being planar, 3-regular, or bipartite; it also answers a question left open in [1]. We also obtain a similar lower bound for the weighted counting of edge covers.

1 Introduction

Many complexity results on computational problems rely on a study of fundamental graph patterns such as independent sets, vertex covers, edge covers, matchings, cliques, etc. In this paper we specifically study *counting problems* for such patterns, and for the most part focus on counting the *matchings*: given an input graph G, we wish to count how many edge subsets of G are a matching, i.e., each vertex has at most one incident edge.

Our goal is to address an apparent gap between the existing intractability and tractability results for counting matchings and similar patterns. On the one hand, counting the matchings is known to be #P-hard, and hardness is known even when the input graph is restricted in certain ways, e.g., being planar, being 3-regular, or being bipartite [18, 14, 27, 26]. On

the other hand, some restrictions can make the problem tractable, e.g., imposing that the input graphs have *bounded treewidth* [5, 1], because matchings can be described in monadic second-order logic. But this does not settle the complexity of the problem; could there be other restrictions on graphs that makes it tractable to count matchings or other patterns?

This paper answers this question in the negative, for a *weighted* version of counting problems: we show that, at least for matchings and edge covers, and under a technical assumption on the graph family, the weighted counting problem is intractable if we do not bound the treewidth of the input graphs. Thus, treewidth is the right parameter to ensure tractability. Our weighted counting problems are of the following form: we fix a graph family $\mathcal{G}$ (e.g., 3-regular graphs, graphs of treewidth $\leqslant 2$), we are given as input a graph G of $\mathcal{G}$ along with an independent probability of existence for each edge, and the goal is to compute the probability in this distribution of the subsets of edges of G which have a certain property, e.g., they are a matching, they are an edge cover. Note that the class $\mathcal{G}$ restricts the shape of the graphs, but the edge probabilities are arbitrary – and indeed there are known tractability results when we restrict the graphs and probabilities to be symmetric [6]. Our paper shows the hardness of these problems when $\mathcal{G}$ is not of bounded treewidth; the specific technical assumption on $\mathcal{G}$ is that one can effectively construct graphs of $\mathcal{G}$ having arbitrarily high treewidth, i.e., the *treewidth-constructible* requirement from [1] (cf. Definition 2.2):

▶ **Result 1.** *Let $\mathcal{G}$ be an arbitrary family of graphs which is treewidth-constructible. Then the problem, given a graph $G = (V, E)$ of $\mathcal{G}$ and rational probability values $\pi(e)$ for every edge of G, of computing the probability of a matching in G under π, is #P-hard under ZPP reductions.*

We obtain an analogous result for edge covers. Thus, as bounded-treewidth makes the problems tractable, our results imply that treewidth characterizes the tractable graph families for these problems – for weighted counting, and assuming treewidth-constructibility. We leave open the complexity of unweighted counting, and of weighted counting on graph families that have unbounded treewidth but satisfy weaker requirements than treewidth-constructibility, e.g., being strongly unbounded poly-logarithmically [16, 13].

The paper is devoted to showing Result 1. Because of the page limit, the full proofs are deferred to the full version [4]. At a high level, we use the standard technique of reducing from the #P-hard problem of counting matchings on a 3-regular planar graph G [26], using the randomized polynomial-time grid minor extraction result of [10] as in [1]. However, the big technical challenge is to reduce the counting of matchings of G to the problem of computing the probability of a matching on the arbitrary subdivision G' of G that we extract. For this, we use the classical interpolation method, where we design a linear equation system relating the matchings to the result of polynomially many oracle calls on G', with different probability assignments; and we argue that the matrix is invertible. After the preliminaries (Section 2), we present this proof, first in the case where G' is a 6-subdivision of G (Section 3), and then when it is a n-subdivision, i.e., when all edges are subdivided to the same length n (Section 4). These special cases already pose some difficulties, most of which are solved by adapting techniques by Dalvi and Suciu [12]; e.g., to show invertibility, we study the Jacobian determinant of the mapping associating edge probabilities to the probability of matchings on paths with fixed endpoints, and we borrow a technique from [12] to effectively construct suitable rational edge probabilities.

The main novelties of this work are in Section 5, where we extend the proof to the general case: G' is a subdivision of G, and different edges of G may be subdivided in G' to different lengths. To obtain the equation system, we show that we can assign probabilities on short paths so that they "behave" like long paths. Proving this stand-alone *emulation result*

(Proposition 5.2) was the main technical obstacle; the proof is by solving a system of equations involving the Fibonacci sequence. It also introduces further complications, e.g., dealing with numerical error (because the resulting probabilities are irrational), and distinguishing even-length and odd-length subdivisions. After concluding the proof of Result 1 in Section 5, we adapt it in Section 6 to edge covers.

Related work. Our work follows a line of results that show the intractability of some problems on any "sufficiently constructible" unbounded-treewidth graph family. Kreutzer and Tazari [16] (see also [13]) show that there are formulas in an expressive formalism (MSO_2) that are intractable to check on any subgraph-closed unbounded treewidth graph family that is closed under taking subgraphs and satisfies a requirement of being *strongly unbounded poly-logarithmically*. This was extended in [1] to the weighted counting problem, this time for a query in first-order logic, with a different hardness notion (#P-hardness under randomized reductions), and under the stronger requirement of treewidth-constructibility. Our focus here is to show that the hardness of weighted counting already holds for natural and well-studied graph properties, e.g., "being a matching"; this was left as an open problem in [1].

For such weak patterns, lower bounds were shown in [1] and [3] on the *size of tractable representations*: for any graph G of bounded degree having treewidth k, any so-called *d-SDNNF* circuit representing the matchings (or edge covers) of G must have exponential size in k. However, this does not imply that the problems are intractable, as some tractable counting algorithms do not work via such circuit representations (e.g., the one in [12]). Thus, our hardness result does not follow from this size bound, but rather complements it.

The necessity of bounded treewidth has also been studied for graphical models [9] and Bayesian networks [17]. Specifically, [17] shows the intractability of inference in a Bayesian network as a function of the treewidth (but without otherwise restricting the class of network), and [9] restricts the shape of the graphical model but allows arbitrary "potential functions" (whereas we assume independence across edges). There are also necessity results on treewidth for the problem of *counting the homomorphisms* between two structures in the CSP context [11]; but this has no clear relationship to our problems, where we do (weighted) *counting of the substructures* that have a certain form (e.g., are matchings).

Note that, unlike our problem of weighted counting of matchings, the problem of *finding* a matching of maximal weight in a weighted graph is tractable on arbitrary graphs, using Edmond's blossom algorithm [21].

2 Preliminaries

We write $\mathbb{N}^+$ for $\mathbb{N}\setminus\{0\}$, and for $n \in \mathbb{N}^+$ we write $[n]$ the set $\{0, \ldots, n-1\}$. We write $\mathbb{R}$ the real numbers and $\mathbb{Q}$ the rational numbers. Recall that *decimal fractions* are rational numbers that can be written as a fraction $a/10^k$ of an integer a and a power of ten 10^k.

Reductions and complexity classes. Recall that #P is the class of counting problems that count the number of accepting paths of a nondeterministic polynomial-time Turing machine. A problem P_1 is #P-*hard* if every problem P_2 of #P reduces to P_1 in polynomial time; following Valiant [19, 20], we use here the notion of *Turing reductions*, i.e., P_2 can be solved in polynomial time with an oracle for P_1. We specifically study what we call #P*-hardness under zero-error probabilistic polynomial-time (ZPP) reductions*. To define these, we define a *randomized algorithm* as an algorithm that has access to an additional random tape. We say that a decision problem is in *ZPP* if there is a randomized algorithm that (always) runs in polynomial time on the input instance, and returns the correct answer on the instance (i.e., accepting or rejecting) with some constant probability, and otherwise returns a special failure value. The probabilities are taken over the draws of the contents of the random tape. The exact value of the acceptance probability is not important, because we can make it exponentially small by simply repeating the algorithm polynomially many times. Going beyond decision problems, a *ZPP algorithm* is a randomized algorithm that runs in polynomial time but may return a special failure value with some constant probability. A *ZPP (Turing) reduction* from a problem P_1 to a problem P_2 is then a ZPP algorithm having access to an oracle for P_2 that takes an instance of problem P_1, runs in polynomial time, returns the correct output (for P_1) with some constant probability, and returns the special failure value otherwise. Again, the failure probability can be made arbitrarily small by invoking the reduction multiple times. A problem P_2 is then said to be *#P-hard under ZPP reductions* if any #P-hard problem P_1 has a ZPP reduction to it. We will implicitly rely on the fact that we can show #P-hardness under ZPP reductions by reducing in ZPP from any problem which is #P-hard (under Turing reductions); see the full version [4] for details.

Graphs and problem studied. A finite undirected *graph* $G = (V, E)$ consists of a finite set V of *vertices* (or *nodes*) and of a set E of *edges* of the form $\{x, y\}$ for $x, y \in V$ with $x \neq y$. A *graph family* $\mathcal{F}$ is a (possibly infinite) set of graphs. For $v \in V$, we write $\mathcal{E}_G(v)$ for the set of edges that are incident to v. Recall that a *matching* of G is a set of edges $M \subseteq E$ that do not share any vertices, i.e., for every $e, e' \in M$ with $e \neq e'$ we have $e \cap e' = \emptyset$; or equivalently, we have $|\{\mathcal{E}_G(v) \cap M\}| \leqslant 1$ for all $v \in V$. For a graph family $\mathcal{F}$, we write #Matching($\mathcal{F}$) the problem of counting the matchings for graphs in $\mathcal{F}$: the input is a graph $G \in \mathcal{F}$, and the output is the number of matchings of G, written #Matching(G).

We study a weighted version of #Matching, defined on *probabilistic graphs.* A *probabilistic graph* is a pair (G, π) where $G = (V, E)$ is a graph and $\pi \colon E \to [0, 1]$ maps every edge e of H to a probability value $\pi(e)$. The probabilistic graph (G, π) defines a probability distribution on the set of subsets E' of E, where each edge $e \in E$ is in E' with probability $\pi(e)$, assuming independence across edges. Formally, the probability of each subset E' is:

$$\Pr_{G,\pi}(E') := \prod_{e \in E'} \pi(e) \times \prod_{e \in E \setminus E'} (1 - \pi(e)).$$

Given a probabilistic graph (G, π), the *probability of a matching in G under pi*, denoted $\Pr_{\text{matching}}(G, \pi)$, is the probability of obtaining a matching in the distribution. Formally:

$$\Pr_{\text{matching}}(G, \pi) \ := \sum_{\text{matching } M \text{ of } G} \Pr_{G,\pi}(M). \tag{1}$$

In particular, if π maps every edge to the probability 1/2, then we have $\Pr_{\text{matching}}(G, \pi) = \#\text{Matching}(G)/2^{|E|}$. For a graph family $\mathcal{F}$, we will study the problem PrMatching($\mathcal{F}$) of computing the probability of a matching: the input is a probabilistic graph (G, π) where $G \in \mathcal{F}$ and π is an arbitrary function with rational probability values, and the output is $\Pr_{\text{matching}}(G, \pi)$. Note that $\mathcal{F}$ only specifies the graph G and not the probabilities π, in particular π can give probability 0 to edges, which amounts to removing them.

Treewidth and topological minors. Treewidth is a parameter mapping any graph G to a number $\text{tw}(G)$ intuitively describing how far G is from being a tree. We omit the formal definition of treewidth (see [25]), as we only rely on the following *extraction result*: given any *planar graph H of maximum degree* 3, and a graph G of *sufficiently high* treewidth, it is possible (in randomized polynomial time) to find H as a *topological minor* of G. We now define this.

The *degree* of a node v in $H = (V_H, E_H)$ is simply $|\mathcal{E}_G(v)|$. We say that H is 3-*regular* if every vertex has degree 3, and call H *planar* if it can be drawn on the plane without edge crossings, in the usual sense [24]. Given H and $\eta\colon E_H \to \mathbb{N}^+$, the *$\eta$-subdivision of H*, written $\mathrm{Sub}(H, \eta)$, is the graph obtained from H by replacing every edge $e = \{x, y\}$ by a path of length $\eta(e)$, whose end vertices are identified with x and y, all intermediate vertices being fresh across all edges. We abuse notation and write $\mathrm{Sub}(H, i)$ for $i \in \mathbb{N}_+$ to mean $\mathrm{Sub}(H, \eta_i)$ for η_i the constant-i function. Note that $\mathrm{Sub}(H, 1) = H$. A *subgraph* of a graph $G = (V_G, E_G)$ is a graph (V'_G, E'_G) where $E'_G \subseteq E_G$ and $V'_G \subseteq V_G$ such that $e \subseteq V'_G$ for each edge $e \in E'_G$. The graph $H = (V_H, E_H)$ is a *topological minor* of the graph $G = (V_G, E_G)$ if there is a function $\eta\colon E_H \to \mathbb{N}^+$ such that there is an isomorphism f from the subdivision $\mathrm{Sub}(H, \eta) = (V'_H, E'_H)$ to some subgraph $G' = (V'_G, E'_G)$ of G, i.e., a bijection $f\colon V'_H \to V'_G$ such that for every $x, y \in V'_H$ we have $\{x, y\} \in E'_H$ if and only if $\{f(x), f(y)\} \in E'_G$.

We can now state the extraction result that we use, which follows from the work of Chekuri and Chuzhoy [10]:

▶ **Theorem 2.1** (Direct consequence of [10], see, e.g., [1], Lemma 4.4)**.** *There exists $c \in \mathbb{N}$ and a ZPP algorithm*[1] *that, given as input a planar graph $H = (V_H, E_H)$ of maximum degree 3 and another graph G with $\mathrm{tw}(G) \geqslant |V_H|^c$, computes a subgraph G' of G, a function $\eta : V_H \to \mathbb{N}^+$, and an isomorphism from Sub(H, η) to G' (witnessing that H is a topological minor of G).*

Our intractability result will apply to graph families where large treewidth graphs can be efficiently found, which we formalize as *treewidth-constructibility* like in [1]:

▶ **Definition 2.2.** *A graph family $\mathcal{F}$ is* treewidth-constructible *if there is a polynomial-time algorithm that, given an integer k written in unary*[2]*, outputs a graph $G \in \mathcal{F}$ with $\mathrm{tw}(G) \geqslant k$.*

Kronecker products and Vandermonde matrices. To simplify notation, we will work with matrices indexed with arbitrary finite sets (not necessarily ordered). Given two finite sets I, J of same cardinality, we write $\mathbb{R}^{I,\,J}$ (resp., $\mathbb{Q}^{I,\,J}$) the set of matrices with real values (resp., rational values) whose rows are indexed by I and columns by J. When $\boldsymbol{A} \in \mathbb{R}^{I,\,J}$ and $(i, j) \in I \times J$, we write $a_{i,j}$ the corresponding entry. We recall that the inverse of an invertible matrix M with entries in $\mathbb{Q}$ also has entries in $\mathbb{Q}$ and can be computed in polynomial time in the encoding size of M.

Given two matrices $\boldsymbol{A} \in \mathbb{R}^{I,\,J}$ and $\boldsymbol{B} \in \mathbb{R}^{K,\,L}$, the *Kronecker product of $\boldsymbol{A}$ and $\boldsymbol{B}$*, denoted $\boldsymbol{A} \otimes \boldsymbol{B}$, is the matrix $\boldsymbol{C} \in \mathbb{R}^{I\times K,\,J\times L}$ defined by $c_{(i,k),(j,l)} := a_{i,j} \times b_{k,l}$ for $(i, j, k, l) \in I \times J \times K \times L$. Recall that $\boldsymbol{A} \otimes \boldsymbol{B}$ is invertible if and only if both $\boldsymbol{A}$ and $\boldsymbol{B}$ are. For $n \in \mathbb{N}^+$ and $(p_0, \ldots, p_{n-1}) \in \mathbb{R}^n$, we denote by $\mathcal{V}(p_0, \ldots, p_{n-1})$ the *Vandermonde matrix with coefficients* $(p_0, \ldots, p_{n-1})$, i.e., the matrix in $\mathbb{R}^{[n],[n]}$ whose (i, j)-th entry is p_i^j. Recall that this matrix is invertible if and only if the $p_0, \ldots, p_{n-1}$ are pairwise distinct.

[1] The randomized algorithm from [10] is indeed a ZPP algorithm because the output that it returns (namely, a prospective embedding of a grid as a topological minor of the input graph) can be verified in (deterministic) polynomial time. Hence, we can always detect when the algorithm has failed, and then return the special failure value.

[2] Note that the existence of such an algorithm for k written in unary would be implied by the same claim but with k given in binary. In other words, the existence of an algorithm for k given in unary is a weaker requirement. This is simply because, given an integer in unary, we can convert it in PTIME to an integer in binary.

3 Proof When Every Subdivision Has Length 6

Towards showing our main result (Result 1), we first show in this section a much simpler result: counting the matchings of a graph G reduces to counting the probability of a matching on the graph where each edge is subdivided into a path of length 6. We use similar techniques to previous work, in particular Greenhill [14] and Dalvi and Suciu [12], but present them in detail because we will adapt them in the rest of the paper. Formally, in this section, we show:

▶ **Proposition 3.1.** *For any graph family $\mathcal{F}$, the problem #Matching($\mathcal{F}$) reduces in polynomial time to PrMatching($\mathcal{G}$) where $\mathcal{G} = \{Sub(H, 6) \mid H \in \mathcal{F}\}$.*

Let $H = (V, E)$ be a graph in $\mathcal{F}$ for which we wish to count the number of matchings, with $m := |E|$. Let us start by fixing for the remainder of this section an arbitrary orientation $\overrightarrow{H}$ of H obtained by choosing some orientation of the edges, i.e., $\overrightarrow{H} = (V, \overrightarrow{E})$ is a *directed* graph where for every edge $\{x, y\} \in E$ we add exactly one of (x, y) or (y, x) in $\overrightarrow{E}$. The high-level idea of the reduction is then the following. First, using $\overrightarrow{H}$, we define some sets S_τ, based on 4-tuples $\tau \in [m + 1]^4$, such that the number of matchings of H can be computed from the cardinalities $|S_\tau|$. Second, we argue that these cardinalities can be connected to the results of oracle calls for the PrMatching problem by a system of linear equations. Third, we argue that the matrix of this system can be made invertible. We now detail these three steps.

Step 1: Defining the sets S_τ and linking them to matchings. We define a *selection function* of the graph H as a function μ that maps each vertex $x \in V$ to at most one incident edge, i.e., to a subset of $\mathcal{E}_H(x)$ of size at most one. We will partition the set of selection functions by counting the number of edges of each *type* that each selection function has, as defined next. Given a selection function μ, consider each edge $e = (x, y)$ of $\overrightarrow{H}$. The edge e can have one of four types: letting b be 1 if $\mu(x)$ selects e (i.e., $\mu(x) = \{\{x, y\}\}$) and 0 otherwise (i.e., $\{x, y\} \notin \mu(x)$), and letting b' be 1 if $\mu(y)$ selects e and 0 otherwise, we say that *e has type bb' with respect to (w.r.t.) μ*. We now define the sets S_τ as follows.

▶ **Definition 3.2.** *For a 4-tuple $\tau \in [m + 1]^4$, indexed in binary, let $S_\tau \subseteq S$ be the set of the selection functions μ such that, for all $b, b' \in \{0, 1\}$, precisely $\tau_{bb'}$ edges have type bb' w.r.t. μ.*

Observe that S_τ is empty unless $\tau_{00} + \tau_{01} + \tau_{10} + \tau_{11} = m$. We can then easily connect the cardinalities $|S_\tau|$ to the number of matchings of H as follows (see the full version [4]):

▶ **Fact 3.3.** *We have that #Matching(H) $= \sum_{\substack{\tau \in [m+1]^4 \\ \tau_{01} = \tau_{10} = 0}} |S_\tau|$.*

Step 2: Recovering the $|S_\tau|$ from oracle calls. We now explain how to use the oracle for PrMatching($\mathcal{G}$) to compute in polynomial time all the values $|S_\tau|$, allowing us to conclude via Fact 3.3. We will invoke the oracle on $(m + 1)^4$ probabilistic graphs, denoted $H_6(\kappa)$ for $\kappa \in [m + 1]^4$, as defined next. To this end, let us consider $(m + 1)^4$ 4-tuples of probability values, written $\rho_\kappa = (\rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11}) \in [0, 1]^4$ for $\kappa \in [m + 1]^4$; the precise choice of these values will be explained in Step 3. For $\kappa \in [m + 1]^4$, we then define $H_6(\kappa)$ to be the probabilistic graph (H_6, π_κ) where $H_6 := \text{Sub}(H, 6)$ is the 6-subdivision of H and the probabilities π_κ are defined as follows. For every directed edge (x, y) of $\overrightarrow{H}$, the subdivision H_6 contains an (undirected) path between x and y, and we define π_κ on this path as follows:

$$x \overset{1/2}{\rule{1cm}{0.4pt}} v_1 \overset{\rho_{\kappa,00}}{\rule{1cm}{0.4pt}} v_2 \overset{\rho_{\kappa,01}}{\rule{1cm}{0.4pt}} v_3 \overset{\rho_{\kappa,10}}{\rule{1cm}{0.4pt}} v_4 \overset{\rho_{\kappa,11}}{\rule{1cm}{0.4pt}} v_5 \overset{1/2}{\rule{1cm}{0.4pt}} y$$

We now introduce some notation for the probability of matchings in paths of length 4. We write $\Pi_4(\rho_\kappa)$ the probability of having a matching in the 4-edge path with successive probabilities $\rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11}$. The value can be explicitly computed as a polynomial in the values $\rho_{\kappa,bb'}$, e.g., using Equation (1). Accordingly, we will also use Π_4 as a polynomial with real variables, i.e., $\Pi_4(\chi)$ for a 4-tuple χ of real values (which may not be in $[0,1]$). We also define variants of these definitions that account for the two surrounding edges, i.e., those with probability 1/2: for $b, b' \in \{0,1\}$, write $\Pi_4^{bb'}(\rho_\kappa)$ to denote the probability of having a matching in the same 4-edge path but when adding an edge incident to the first vertex with probability 1 if $b = 1$, and adding an edge incident to the last vertex with probability 1 if $b' = 1$. Equivalently, $\Pi_4^{bb'}(\rho_\kappa)$ is the probability of obtaining a matching where we further require if $b = 1$ that the edge with probability $\rho_{\kappa,00}$ is *not* taken, and if $b' = 1$ that the edge with probability $\rho_{\kappa,11}$ is *not* taken. The values $\Pi_4^{bb'}(\rho_\kappa)$ are also explicitly computable as polynomials, and again we also see $\Pi_4^{bb'}$ as a polynomial with real variables. To simplify notation, for $b, b' \in \{0,1\}$ and $\kappa \in [m+1]^4$ let us write $\Lambda_{\kappa,bb'} := \Pi_4^{bb'}(\rho_\kappa)$.

We then show that the probability of a matching in the subdivided graph H_6 can be obtained by first summing over the possible edge type cardinalities τ, and then regrouping the edges of the same type by noticing that the matchings corresponding to the selection functions in the set S_τ all have the same probability. Namely, we show (see the full version [4]):

▶ **Fact 3.4.** *For each $\kappa \in [m+1]^4$, we have:*

$$2^{2m} \times \Pr_{matching}(H_6(\kappa)) \;=\; \sum_{\tau \in [m+1]^4} |S_\tau| \times (\Lambda_{\kappa,00})^{\tau_{00}} \times (\Lambda_{\kappa,01})^{\tau_{01}} \times (\Lambda_{\kappa,10})^{\tau_{10}} \times (\Lambda_{\kappa,11})^{\tau_{11}}.$$

Now, let us write $c_\kappa := \Pr_{\text{matching}}(H_6(\kappa))$ the value returned by the oracle call on $H_6(\kappa)$, and let $\boldsymbol{C}$ be the vector of these oracle answers. Let $\boldsymbol{S}$ be the vector $|S_\tau|$ of the values that we wish to compute. Both these vectors are indexed by $[m+1]^4$. Observe that the equation above defines a system of linear equations $\boldsymbol{V}\boldsymbol{S} = \boldsymbol{C}$ with $\boldsymbol{V} \in \mathbb{R}^{[m+1]^4,[m+1]^4}$ defined by

$$v_{\kappa,\tau} \;:=\; 2^{-2m} \times (\Lambda_{\kappa,00})^{\tau_{00}} \times (\Lambda_{\kappa,01})^{\tau_{01}} \times (\Lambda_{\kappa,10})^{\tau_{10}} \times (\Lambda_{\kappa,11})^{\tau_{11}}.$$

Therefore, if we can choose 4-tuples of probability values ρ_κ that make $\boldsymbol{V}$ invertible, we would be able to recover all $|S_\tau|$ values from the oracle answers $\boldsymbol{C}$, from which we could compute the number of matchings of H using Fact 3.3. This is what we do next.

Step 3: Making $\boldsymbol{V}$ invertible. We now explain how to choose in polynomial time $(m+1)^4$ 4-tuples ρ_κ of rational probability values, for $\kappa \in [m+1]^4$, such that $\boldsymbol{V}$ is invertible. To this end, consider the matrix $\boldsymbol{U}$ defined like $\boldsymbol{V}$ except that each 4-tuple ρ_κ is replaced by a 4-tuple of variables $\chi_\kappa = (\chi_{\kappa,00}, \chi_{\kappa,01}, \chi_{\kappa,10}, \chi_{\kappa,11})$. Each cell $m_{\kappa,\tau}$ of $\boldsymbol{U}$ is then a polynomial P_τ in the 4 variables $\chi_{\kappa,bb'}$ for $b, b' \in \{0,1\}$; in particular, note that the polynomial only depends on the column τ, whereas the variables $\chi_{\kappa,bb'}$ only depend on the row κ. We can then find suitable values ρ_κ using a technique introduced by Dalvi and Suciu [12] (see the full version [4]):

▶ **Proposition 3.5** (From Proposition 8.44 of [12]). *Fix $k \in \mathbb{N}$, let $(x_i)_{i \in I}$ be k-tuples of real variables indexed by a finite set I, let $(P_j)_{j \in J}$ be polynomials in k variables indexed by a finite set J, and consider the matrix $\boldsymbol{M}$ indexed by $I \times J$ such that $m_{i,j} = P_j(x_i)$ for all $(i,j) \in I \times J$. Assume that* $\det(\boldsymbol{M})$ *is not the null polynomial. There is an algorithm that runs in polynomial time in $\boldsymbol{M}$ and finds $|I|$ k-tuples of decimal fractions $(a_i)_{i \in I}$ with values in $[0,1]$ such that the matrix obtained by substituting each x_i by a_i in $\boldsymbol{M}$ is invertible.*

If $\det(\boldsymbol{U})$ is not the null polynomial, we can invoke this result with $k = 4$ and $I = J = [m+1]^4$ on the matrix $\boldsymbol{U}$, which gives us in polynomial time the desired rational probability values ρ_κ (namely, the a_i from the proposition) and concludes the proof of Proposition 3.1.

Hence, the only remaining point is to argue that $\det(\boldsymbol{U})$ is not the null polynomial (in the χ_κ). To this end, let us study the mapping $\xi : \mathbb{R}^4 \to \mathbb{R}^4$, defined as follows, with χ denoting a 4-tuple of real variables: $\xi(\chi) := \big(\Pi_4^{00}(\chi), \Pi_4^{01}(\chi), \Pi_4^{10}(\chi), \Pi_4^{11}(\chi)\big)$. For a 4-tuple of reals ρ, we call the mapping ξ *invertible* around point ρ if there is $\epsilon > 0$ such that the *ϵ-neighborhood around* $\xi(\rho)$, i.e., the set $\{\alpha \in \mathbb{R}^4 \mid |\alpha_{bb'} - \xi(\rho)_{bb'}| \leqslant \epsilon \text{ for each } b, b' \in \{0,1\}\}$, is included in the image of ξ. We conclude by showing two claims:

▶ **Fact 3.6.** *The mapping ξ is invertible around some point.*

Proof. By the inverse function theorem [23], if the *Jacobian determinant* of ξ at a point is not null, then ξ is invertible around that point. Recall that the Jacobian determinant of ξ is the determinant of the *Jacobian matrix* of ξ, which is the 4×4 matrix $\boldsymbol{J}_\xi$ whose entry at cell $((b_1, b_2), (b'_1, b'_2))$ is $\frac{\partial \Lambda_{\chi, b_1 b_2}}{\partial \chi_{b'_1 b'_2}}$. We explicitly compute $\det(\boldsymbol{J})$ with the help of SageMath, showing that it is not the null polynomial (see the full version [4]). ◀

▶ **Fact 3.7.** *If ξ is invertible around some point ρ, then* $\det(\boldsymbol{U})$ *is not the null polynomial.*

Proof. The invertibility of ξ around ρ implies that there exist, for each $b, b' \in \{0,1\}$, a set of $m+1$ distinct values $\Psi_{bb'} := \{\psi_{bb',0}, \ldots, \psi_{bb',m-1}\}$ such that the Cartesian product $\Psi := \bigtimes_{b,b' \in \{0,1\}} \Psi_{bb'}$ is included in the ϵ-neighborhood of $\xi(\rho)$. Let us index the $(m+1)^4$ 4-tuples of Ψ as ψ_κ for $\kappa \in [m+1]^4$, i.e., $\psi_\kappa = (\psi_{00,\kappa_{00}}, \psi_{01,\kappa_{01}}, \psi_{10,\kappa_{10}}, \psi_{11,\kappa_{11}})$. Using invertibility, let α_κ be a preimage of each ψ_κ, i.e., $\xi(\alpha_\kappa) = \psi_\kappa$ for all $\kappa \in [m+1]^4$. But then observe that, for this choice of χ_κ (i.e., substituting the χ_κ by the α_κ), each cell $u_{\kappa,\tau}$ of the matrix $\boldsymbol{U}$ becomes:

$$u_{\kappa,\tau} = 2^{-2m} \times (\psi_{00,\kappa_{00}})^{\tau_{00}} \times (\psi_{01,\kappa_{01}})^{\tau_{01}} \times (\psi_{10,\kappa_{10}})^{\tau_{10}} \times (\psi_{11,\kappa_{11}})^{\tau_{11}}.$$

Thus, $\boldsymbol{U}$ is the Kronecker product of four Vandermonde matrices $\boldsymbol{U}_{bb'}$ for $b, b' \in \{0,1\}$, where $\boldsymbol{U}_{bb'}$ is $\mathcal{V}(\psi_{bb',0}, \ldots, \psi_{bb',m-1})$. As the $\Psi_{bb'}$ consist of pairwise distinct values, these Vandermonde matrices are invertible, and their Kronecker product $\boldsymbol{U}$ also is. ◀

4 Proof When All Subdivisions Have the Same Length $\geqslant 7$

We now prove a variant of Proposition 3.1 where all edges of the initial graph are subdivided the same number of times (at least 7). Given a graph H and integer $K > 0$, we write G_K to mean $\mathrm{Sub}(H, K)$. In this section we show:

▶ **Proposition 4.1.** *Fix an integer $K \geqslant 7$. Then, for any graph family $\mathcal{F}$, the problem #Matching($\mathcal{F}$) reduces in polynomial time to PrMatching($\mathcal{G}$), where $\mathcal{G} = \{H_K \mid H \in \mathcal{F}\}$.*

To prove this, we follow the same strategy as for Proposition 3.1. The first step – the definition of the S_τ – is strictly identical; for m the number of edges of H, we fix again an orientation $\vec{H}$ of H, and denote S_τ for $\tau \in [m+1]^4$ the $(m+1)^4$ sets of selection functions defined from $\vec{H}$ as in Definition 3.2. In particular, Fact 3.3 still holds. Now, we will again construct $(m+1)^4$ probabilistic graphs, denoted $H_K(\kappa)$ for $\kappa \in [m+1]^4$, such that, letting $c_\kappa := \mathrm{Pr}_{\mathrm{matching}}(H_K(\kappa))$, the $|S_\tau|$ and the c_κ form a linear system of equations $\boldsymbol{VS} = \boldsymbol{C}$. We will then again use the Jacobian technique to argue that the determinant of this matrix is not the null polynomial, and complete the proof using Proposition 3.5 to compute in polynomial time rational values that make $\boldsymbol{V}$ have rational entries and be invertible. The difference with Section 3 is in the construction of the probabilistic graphs $H_K(\kappa)$, and in the Jacobian determinant. Before we start, we need to extend the notation from Section 3.

Probabilistic path graphs. For $n \in \mathbb{N}^+$ we denote by P_n the *path of length* n, i.e., $P_n = (\{v_0, \ldots, v_n\}, E)$ where $E = \{\{v_i, v_{i+1}\} \mid 0 \leqslant i \leqslant n-1\}$. For $\rho \in [0,1]^n$, we let $P_n(\rho)$ be the probabilistic graph where each edge $\{v_i, v_{i+1}\}$ of P_n has probability ρ_i. We write $\Pi_n(\rho)$ the probability of a matching in $P_n(\rho)$. For $b, b' \in \{0,1\}$, we write $\Pi_n^{bb'}(\rho)$ to denote $\Pi_{n+2}(b, \rho, b')$, i.e., the probability of a matching in $P_n(\rho)$ where we add an edge to the left if $b = 1$ and add an edge to the right if $b' = 1$. In particular $\Pi_n^{00}(\rho) = \Pi_n(\rho)$. We call the quadruple of values $\Pi_n^{bb'}(\rho)$ for $b, b' \in \{0,1\}$ the *behavior* of the path $P_n(\rho)$. Each $\Pi_n^{bb'}(\rho)$ is a polynomial in the probabilities ρ, and thus we also see $\Pi_n^{bb'}$ as a polynomial with real variables as in Section 3. We will use the following two lemmas. The first one expresses the behavior of the concatenation of two paths as a function of the behavior of each path (see the full version [4]):

▶ **Lemma 4.2.** *Let $n, n' \in \mathbb{N}^+$ and $\rho \in [0,1]^n$, $\rho' \in [0,1]^{n'}$ be tuples of probability values. Then, for every $b, b' \in \{0,1\}$, we have:*

$$\Pi_{n+n'}^{bb'}(\rho, \rho') \;=\; (\Pi_n^{b0}(\rho) \times \Pi_{n'}^{1b'}(\rho')) + (\Pi_n^{b1}(\rho) \times \Pi_{n'}^{0b'}(\rho')) - (\Pi_n^{b1}(\rho) \times \Pi_{n'}^{1b'}(\rho')).$$

The second lemma expresses the values $\Pi_n^{bb'}(1/2, \ldots, 1/2)$ in terms of the *Fibonacci sequence*. Recall that this is the integer sequence defined by $f_0 := 0$, $f_1 := 1$, and $f_n := f_{n-1} + f_{n-2}$ for all $n \in \mathbb{N}^+$, and that this sequence satisfies *Cassini's identity* [22], which says that $f_n^2 = f_{n+1} f_{n-1} + (-1)^{n+1}$ for every $n \in \mathbb{N}^+$. We have (see the full version [4]):

▶ **Lemma 4.3.** *For all $n \in \mathbb{N}^+$, $b, b' \in \{0,1\}$, we have $\Pi_n^{bb'}(1/2, \ldots, 1/2) = \frac{f_{n+2-b-b'}}{2^n}$.*

Proving Proposition 4.1. Let us now build the graphs $H_K(\kappa)$. As before, consider $(m+1)^4$ 4-tuples of probability values $\rho_\kappa = (\rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11})$ for $\kappa \in [m+1]^4$, to be chosen later. Each graph $H_K(\kappa)$ has H_K as its underlying graph, and for every directed edge $(x, y) \in \overrightarrow{H}$, we set the probabilities on the corresponding undirected path in H_K as follows:

$$x \overset{1/2}{\rule{2em}{0.4pt}} v_1 \overset{\rho_{\kappa,00}}{\rule{2em}{0.4pt}} v_2 \overset{\rho_{\kappa,01}}{\rule{2em}{0.4pt}} v_3 \overset{\rho_{\kappa,10}}{\rule{2em}{0.4pt}} v_4 \overset{\rho_{\kappa,11}}{\rule{2em}{0.4pt}} v_5 \overset{1/2}{\rule{2em}{0.4pt}} v_6 \overset{1/2}{\rule{2em}{0.4pt}} \cdots \overset{1/2}{\rule{2em}{0.4pt}} v_{K-1} \overset{1/2}{\rule{2em}{0.4pt}} y$$

Note that this is like in Section 3, but giving probability $1/2$ to the $N := K - 6$ extra edges on the path. For $b, b' \in \{0,1\}$ we write again $\Lambda_{\kappa,bb'} := \Pi_4^{bb'}(\rho_\kappa)$ the behavior of the 4-path with probabilities ρ_κ, and we define the behavior $\Upsilon_{\kappa,bb'} := \Pi_{K-2}^{bb'}(\rho_\kappa, 1/2, \ldots, 1/2)$ of the path depicted above without the first and last edges. Note that with Lemma 4.2 and Lemma 4.3, we can then express the $\Upsilon_{\kappa,bb'}$ as a function of the $\Lambda_{\kappa,bb'}$ and of the Fibonacci numbers:

▶ **Fact 4.4.** *We have $\Upsilon_{\kappa,bb'} = 2^{-N} \times (\Lambda_{\kappa,b0} \times f_{N+1-b'} + \Lambda_{\kappa,b1} \times f_{N-b'})$ for $b, b' \in \{0,1\}$.*

Studying the graphs $H_K(\kappa)$, by the same reasoning as for Fact 3.4, we can easily show:

$$2^{2m} \times \Pr_{\text{matching}}(H_K(\kappa)) \;=\; \sum_{\tau \in [m+1]^4} |S_\tau| \times (\Upsilon_{\kappa,00})^{\tau_{00}} \times (\Upsilon_{\kappa,01})^{\tau_{01}} \times (\Upsilon_{\kappa,10})^{\tau_{10}} \times (\Upsilon_{\kappa,11})^{\tau_{11}}. \quad (2)$$

This is again a system of linear equations $\boldsymbol{VS} = \boldsymbol{C}$ with $\boldsymbol{V} \in \mathbb{R}^{[m+1]^4, [m+1]^4}$, where $v_{\kappa,\tau} := 2^{-2m} \times (\Upsilon_{\kappa,00})^{\tau_{00}} \times (\Upsilon_{\kappa,01})^{\tau_{01}} \times (\Upsilon_{\kappa,10})^{\tau_{10}} \times (\Upsilon_{\kappa,11})^{\tau_{11}}$. To show that we can compute in polynomial time 4-tuples of rational probability values ρ_κ for $\kappa \in [m+1]^4$ that make $\boldsymbol{V}$ have rational entries and be invertible, we reason as in Section 3. Specifically, we study the Jacobian determinant of the mapping $\xi_N : \chi \mapsto (\Pi_{K-2}^{00}(\chi, 1/2, \ldots, 1/2),\ \Pi_{K-2}^{01}(\chi, 1/2, \ldots, 1/2),$

$\Pi^{10}_{K-2}(\chi, 1/2, \ldots, 1/2)$, $\Pi^{11}_{K-2}(\chi, 1/2, \ldots, 1/2))$, where χ is a 4-tuple of real variables. We show that this determinant is not the null polynomial. To do this, starting from the Jacobian $\boldsymbol{J}_\xi$ of Section 3, using Fact 4.4 and Cassini's identity, and using the fact that the determinant is multilinear and alternating, we obtain (see the full version [4]):

▶ **Fact 4.5.** *We have:* $\det(\boldsymbol{J}_{\xi_N}) = 2^{-4N} \times \det(\boldsymbol{J}_\xi)$.

Hence, $\det(\boldsymbol{J}_{\xi_N})$ is not the null polynomial and, as in Section 3, we can use Proposition 3.5 to complete the proof of Proposition 4.1 (see the full version [4]).

5 Proof for Arbitrary Subdivisions

In this section we finally prove our main result (Result 1), which we re-state here:

▶ **Theorem 5.1.** *Let $\mathcal{G}$ be an arbitrary family of graphs which is treewidth-constructible. Then PrMatching($\mathcal{G}$) is #P-hard under ZPP reductions.*

We will reduce from the problem of counting matchings in 3-regular planar graphs of, which is #P-hard[3] by [26]. Our reduction will be similar to that of Section 4, with the major issue that the various edges of the input graph can now be subdivided to different lengths.

The proof consists of five steps. In step 1, we show a general result allowing us to assign probabilities to a path of length 4 so as to "emulate" the behavior of any long path of *even* length. We then revisit the proof of the previous section. Step 2 extracts the input graph H from the treewidth-constructible family. Step 3 relates the number of matchings of H to cardinalities similar to those of the previous section, but taking the parities of the subdivisions into account. Step 4 then explains how to conclude using emulation. Last, step 5 works around the issue that the probabilities of Step 1 could be irrational, by explaining how we can conclude with sufficiently precise approximations. We now detail these steps.

Step 1: Emulating long even paths. We start by presenting the main technical tool, namely, how to emulate long paths of even length by paths of length 4.

▶ **Proposition 5.2** (Emulation result). *There exist closed-form expressions, denoted $p(i), q(i)$, $r(i), s(i)$, such that for every even integer $i \geqslant 4$ the following hold:*

(A) *the expressions evaluate to well-defined probability values, i.e., we have* $0 \leqslant p(i), q(i), r(i), s(i) \leqslant 1$*; and*

(B) *the path of length 4 with probabilities $p(i), q(i), r(i), s(i)$ behaves like a path of length i with probabilities $1/2$, i.e., $\Pi^{bb'}_4(p(i), q(i), r(i), s(i)) = \Pi^{bb'}_i(1/2, \ldots, 1/2)$ for all $b, b' \in \{0, 1\}$.*

Further, each of these expressions is of the form $\frac{P \pm \sqrt{Q}}{R}$ where P, Q, R are polynomials in the Fibonacci numbers f_{i-1} and f_{i-2} and in 2^{-i}, with rational coefficients.

Proof sketch. The result is simple to state, but we did not find an elegant way to show it. Our proof consists of four steps: (i) rewriting condition (B) into a simpler equivalent system of equations (using Lemma 4.3), (ii) proving that any solution of that system must be in $(0, 1)^4$, (iii) exhibiting closed-form expressions that satisfy the system, found with the help of SageMath; and (iv) verifying that these expressions are well-defined. See the full version [4]. ◀

[3] Note that, in holographic literature, graphs may be multigraphs (i.e., can have multiple edges between two nodes) – see [15]. However, inspecting the proof of [26], we see that the graphs are in fact simple.

▶ Remark 5.3. As $\Pi_i^{bb'}(1/2,\ldots,1/2)$ is symmetric, one would expect the closed-form expressions to satisfy $p(i) = s(i)$ and $q(i) = r(i)$. However, surprisingly, numerical evaluation (already for $i = 6$) shows that our solution does not have this property.

▶ Remark 5.4. It is necessary to require that i is even, as otherwise Proposition 5.2 demonstrably does not hold. In fact, we can prove that, more generally, the behavior of a probabilistic path inherently depends on the parity of its length (see the full version [4]). This is why we will distinguish even-length and odd-length subdivisions in the sequel.

Step 2: Choosing the graph in $\mathcal{G}$. Let $H = (V, E)$ be the input to the reduction, i.e., the 3-regular planar graph for which we want to compute $\#\text{Matching}(H)$, and let $m := |E|$. We first build the graph $H_{10} = \text{Sub}(H, 10)$, writing $H_{10} = (V_{10}, E_{10})$ and we compute $k := |V_{10}|^c$ where c is the constant from Theorem 2.1. Notice that H_{10} is a planar graph of maximum degree 3, and that the size of k in unary is polynomial in (the encoding size of) H. Intuitively, this initial subdivision in 10 will ensure that we have enough room for our probabilistic gadgets. Now, we use the treewidth-constructibility of $\mathcal{G}$ to build in polynomial time a graph $G = (V_G, E_G) \in \mathcal{G}$ such that $\text{tw}(G) \geqslant k$, and using Theorem 2.1 we compute in ZPP a subgraph G' of G with a subdivision $\eta_{10} : E_{10} \to \mathbb{N}^+$ of H_{10} and an isomorphism from $\text{Sub}(H_{10}, \eta_{10})$ to G'. This gives us a subdivision $\eta : E \to \mathbb{N}^+$ of H and an isomorphism f from $\text{Sub}(H, \eta)$ to G', with the initial subdivision ensuring that $\eta(e) \geqslant 10$ for each $e \in E$.

Step 3: Defining the new sets $S_{\tau,\tau'}$ and linking them to matchings. As before, fix an orientation $\overrightarrow{H}$ of H. We call an edge e of H *even* if $\eta(e)$ is even, and *odd* otherwise. For $\tau, \tau' \in [m+1]^4$, both indexed in binary, we define $S_{\tau,\tau'}$ to be the set of selection functions μ of H such that, for $b, b' \in \{0,1\}$, precisely $\tau_{bb'}$ even edges e of H have type bb' w.r.t. μ, and precisely $\tau'_{bb'}$ odd edges e of H have type bb' w.r.t. μ. Then, as in Section 3, we have:

$$\#\text{Matching}(H) = \sum_{\substack{\tau,\tau' \in [m+1]^4 \\ \tau_{01}=\tau_{10}=\tau'_{01}=\tau'_{10}=0}} |S_{\tau,\tau'}|. \tag{3}$$

Step 4: Describing the probabilistic graphs and obtaining the system. To complete the definition of the reduction, let us build the $(m+1)^8$ probabilistic graphs on which we want to invoke the oracle, denoted $G(\kappa, \kappa')$ for $\kappa, \kappa' \in [m+1]^4$. Let $K := \max_{\substack{e \in E \\ \eta(e) \text{ is even}}} (\eta(e))$ and $K' := \max_{\substack{e \in E \\ \eta(e) \text{ is odd}}} (\eta(e))$ and $N := K - 6$ and $N' := K' - 6$. The underlying graph of $G(\kappa, \kappa')$ is G, every edge $e \in E_G$ that is not in G' is assigned probability zero, and we explain next what is the probability associated to the edges that are in G'. Consider $2 \times (m+1)^4$ 4-tuples of probability values $\rho_\kappa = (\rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11})$ and $\rho'_\kappa = (\rho'_{\kappa',00}, \rho'_{\kappa',01}, \rho'_{\kappa',10}, \rho'_{\kappa',11})$ for $\kappa, \kappa' \in [m+1]^4$, to be chosen later. For every directed edge $(x, y) \in \overrightarrow{H}$, let $\gamma := \eta(\{x, y\})$ be the length to which it is subdivided in G'. Letting $f(x), v_1, \ldots, v_{\gamma-1}, f(y)$ be the corresponding path in G', we set the probabilities of the γ edges along that path as follows:

- If γ is even (illustrated in Figure 1):
  - $1/2, \rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11}$ for the first 5 edges,
  - $p(N - \gamma + 10), q(N - \gamma + 10), r(N - \gamma + 10), s(N - \gamma + 10)$ for the next four edges,
  - $1/2$ for the remaining $\gamma - 9$ edges.
- If γ is odd:
  - $1/2, \rho'_{\kappa',00}, \rho'_{\kappa',01}, \rho'_{\kappa',10}, \rho'_{\kappa',11}$ for the first 5 edges,
  - $p(N' - \gamma + 10), q(N' - \gamma + 10), r(N' - \gamma + 10), s(N' - \gamma + 10)$ for the next four edges,
  - $1/2$ for the remaining $\gamma - 9$ edges.

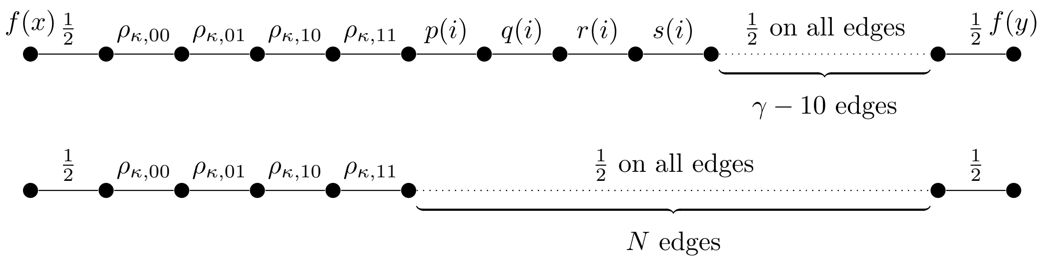

Figure 1 The upper path depicts how we set the probabilities along a path $f(x), v_1, \ldots, v_{\gamma-1}, f(y)$ corresponding to an edge $(x, y) \in \overrightarrow{H}$ such that $\gamma := \eta(\{x, y\})$ is even. We write $i := N - \gamma + 10$. By Lemma 4.2 and Proposition 5.2, this path has exactly the same behavior as the lower path.

We know that $N - \gamma + 10$ (resp., $N' - \gamma + 10$) is an even integer when γ is even (resp., when γ is odd); and it is $\geqslant 4$ by definition of K (resp., of K'). Thus, using Proposition 5.2 and then Lemma 4.2, we know that the path that we defined behaves exactly like the path $P_K(1/2, \rho_{\kappa,00}, \rho_{\kappa,01}, \rho_{\kappa,10}, \rho_{\kappa,11}, 1/2, \ldots, 1/2)$ if γ is even, and exactly like the path $P_{K'}(1/2, \rho'_{\kappa',00}, \rho'_{\kappa',01}, \rho'_{\kappa',10}, \rho'_{\kappa',11}, 1/2, \ldots, 1/2)$ if γ is odd (see again Figure 1).

We have now managed to ensure that all paths for even edges (resp., for odd edges) behave as if they had been subdivided to length K (resp., to length K'). We continue the proof as in the previous section, except that we distinguish odd and even edges. Specifically, for $b, b' \in \{0, 1\}$, we write as in the previous section $\Upsilon_{\kappa,bb'} := \Pi^{bb'}_{K-2}(\rho_\kappa, 1/2, \ldots, 1/2)$ and $\Upsilon'_{\kappa',bb'} := \Pi^{bb'}_{K'-2}(\rho'_{\kappa'}, 1/2, \ldots, 1/2)$. Using the same reasoning as for Equation 2, we obtain:

$$2^{2m} \times \Pr_{\text{matching}}(G(\kappa, \kappa')) = \sum_{\tau,\tau' \in [m+1]^4} |S_{\tau,\tau'}| \times (\Upsilon_{\kappa,00})^{\tau_{00}} \times (\Upsilon_{\kappa,01})^{\tau_{01}} \times (\Upsilon_{\kappa,10})^{\tau_{10}} \times (\Upsilon_{\kappa,11})^{\tau_{11}}$$
$$\times (\Upsilon'_{\kappa',00})^{\tau'_{00}} \times (\Upsilon'_{\kappa',01})^{\tau'_{01}} \times (\Upsilon'_{\kappa',10})^{\tau'_{10}} \times (\Upsilon'_{\kappa',11})^{\tau'_{11}}, \qquad (4)$$

i.e., we obtain a system of linear equations $\mathbf{\Gamma S} = \boldsymbol{C}$ with $\boldsymbol{S}$ the vector of the desired values $|S_{\tau,\tau'}|$, with $\boldsymbol{C}$ the vector of the oracle answers $\Pr_{\text{matching}}(G(\kappa, \kappa'))$, and with $\mathbf{\Gamma} \in \mathbb{R}^{[m+1]^8, [m+1]^8}$, whose entries are given according to the above equation. But notice that we have $\mathbf{\Gamma} = \boldsymbol{V} \otimes \boldsymbol{V}'$, with $v_{\kappa,\tau} := 2^{-m} \times (\Upsilon_{\kappa,00})^{\tau_{00}} \times (\Upsilon_{\kappa,01})^{\tau_{01}} \times (\Upsilon_{\kappa,10})^{\tau_{10}} \times (\Upsilon_{\kappa,11})^{\tau_{11}}$ and $v'_{\kappa',\tau'} := 2^{-m} \times (\Upsilon'_{\kappa',00})^{\tau'_{00}} \times (\Upsilon'_{\kappa',01})^{\tau'_{01}} \times (\Upsilon'_{\kappa',10})^{\tau'_{10}} \times (\Upsilon'_{\kappa',11})^{\tau'_{11}}$. Since $\boldsymbol{V}$ and $\boldsymbol{V}'$ share no variables and are identical up to renaming variables, to argue that there exist 4-tuples of probabilistic values ρ_κ and $\rho'_{\kappa'}$ for $\kappa, \kappa' \in [m+1]^4$ that make $\mathbf{\Gamma}$ invertible, it is enough to know that the Jacobian determinant of the mapping ξ_N is not identically null, as we showed in the previous section (Fact 4.5). Thus, we can again use Proposition 3.5 to compute in polynomial time $2 \times (m+1)^4$ 4-tuples of rational probability values ρ_κ and $\rho'_{\kappa'}$ such that the matrices $\boldsymbol{V}$ and $\boldsymbol{V}'$, hence $\mathbf{\Gamma}$, are invertible (see the full version [4]). By Equation 4, $\mathbf{\Gamma}$ has rational entries, and its inverse $\mathbf{\Gamma}^{-1}$ also does and is computable in polynomial time.

Step 5: Using decimal fractions approximations. The last issue is that we cannot really obtain $\boldsymbol{C}$ via oracle calls, because the graphs $G(\kappa, \kappa')$ may have irrational edge probabilities, namely, the $p(i), q(i), r(i), s(i)$. We now argue that we can still recover the $\boldsymbol{C}$, so that we can compute $\boldsymbol{S} = \mathbf{\Gamma}^{-1}\boldsymbol{C}$ and conclude. To do this, we first observe that $\boldsymbol{C}$ is in fact a vector of decimal fractions, as the graphs $G(\kappa, \kappa')$ emulate a graph where the probabilities are decimal fractions; further, we can bound the number of decimal places of its values to $[m \times (\max(N, N') + 10)] \times z$, with z the maximal number of decimal places of a decimal fraction in $\rho_\kappa, \rho'_\kappa$ Second, we show how to compute decimal fraction *approximations* $\widehat{p(i)}, \widehat{q(i)}, \widehat{r(i)}, \widehat{s(i)}$

of the $p(i), q(i), r(i), s(i)$, in polynomial time in the desired number of places, using the form that they have according to Proposition 5.2. Third, we argue that when invoking the oracles on the graphs where we replace $p(i), q(i), r(i), s(i)$ by $\widehat{p(i)}, \widehat{q(i)}, \widehat{r(i)}, \widehat{s(i)}$, then the error on the answer is bounded as a function of that of the approximations, so that we can recover $\boldsymbol{C}$ exactly if the approximations were sufficiently precise. See the full version [4] for detailed proofs.

6 Result for Edge Covers

Having shown Result 1, we now explain how to adapt its proof to obtain our analogous results for edge covers. We only sketch the argument, and refer to the full version [4] for more details. Recall that an *edge cover* of a graph $G = (V, E)$ is a set of edges $S \subseteq E$ such that $V = \bigcup_{e \in S} e$. Given a probabilistic graph (G, π), we define $\mathrm{Pr}_{\mathrm{edgeCover}}(G, \pi)$ to be the sum of the probabilities of all edge covers in the probability distribution induced by π, and define $\mathrm{PrEdgeCover}(\mathcal{F})$ for a graph family $\mathcal{F}$ to be the corresponding computational problem. We first note that, in this context, the strict analogue of Result 1 does not hold. Indeed, take some treewidth-constructible graph family $\mathcal{G}$, and consider the graph family $\mathcal{G}'$ obtained from $\mathcal{G}$ as follows: for every graph $G \in \mathcal{G}$, we add to $\mathcal{G}'$ the graph that is obtained from G by attaching a dangling edge with a fresh vertex to every node of G. The family $\mathcal{G}'$ is still treewidth-constructible, but $\mathrm{PrEdgeCover}(\mathcal{G}')$ is now tractable as it is easy to see that the edge covers of a graph in $\mathcal{G}'$ are precisely the edge subsets where all dangling edges are kept.

To avoid this, let us assume that $\mathcal{G}$ is closed under taking subgraphs, i.e., if $G \in \mathcal{G}$ and G' is a subgraph of G, then $G' \in \mathcal{G}$. We then have:

▶ **Theorem 6.1.** *Let $\mathcal{G}$ be an arbitrary family of graphs which is treewidth-constructible and closed under taking subgraphs. Then PrEdgeCover($\mathcal{G}$) is #P-hard under ZPP reductions.*

This is proved like Result 1, with the following modifications. We reduce from counting edge covers (instead of matchings) on 3-regular planar graphs: this is hard by [8], even on simple graphs [2, Appendix D]. We now define a selection function μ to map each vertex $x \in V$ to *at least* one incident edge, and we define the types and the sets $S_{\tau,\tau'}$ as before, via an arbitrary orientation of the graph H. We obtain the number of edge covers of H from the quantities $|S_{\tau,\tau'}|$ exactly as in Equation 3. We redefine $\Pi_n^{bb'}(\rho)$ to be the probability of an edge cover in a path of length n with probabilities ρ on the edges and with endpoint constraints given by b, b' as before. Lemma 4.3 then becomes $\Pi_n^{bb'}(1/2, \ldots, 1/2) = \frac{f_{n+b+b'}}{2^n}$, i.e., the role of b, b' is "reversed". Analogous versions of Lemma 4.2 and of Proposition 5.2 still hold, so the relevant Jacobian determinants are still non-identically null. We take the graph $G \in \mathcal{G}$ again via the topological minor extraction result, but this time directly extracting $\mathrm{Sub}(H, \eta) \in \mathcal{G}$ as $\mathcal{G}$ is subgraph-closed. The rest of the proof is identical.

We point out that the situation is different for *perfect* matchings. Indeed, using a weighted variant of the FKT algorithm [7, Chapter 4], the weighted counting of perfect matchings is polynomial-time over the class of planar graphs, which is treewidth-constructible.

We conclude by leaving open two directions for future work. The first one would be to obtain the same kind of lower bounds when the probabilities annotate the *nodes* instead of the edges, that is, studying the corresponding weighted counting problems for, e.g., independent sets, vertex covers, or cliques. We believe that the corresponding result should hold and do not expect any surprises. The second question would be to show our hardness results in the *unweighted* case, e.g., unweighted counting of matchings, assuming that the graph family is subgraph-closed. This appears to be much more challenging, as our current proof crucially relies on the ability to use arbitrary probability values.

Abstract

In an *upward-planar L-drawing* of a directed acyclic graph (DAG) each edge e is represented as a polyline composed of a vertical segment with its lowest endpoint at the tail of e and of a horizontal segment ending at the head of e. Distinct edges may overlap, but not cross. Recently, upward-planar L-drawings have been studied for st-graphs, i.e., planar DAGs with a single source s and a single sink t containing an edge directed from s to t. It is known that a *plane st-graph*, i.e., an embedded st-graph in which the edge (s, t) is incident to the outer face, admits an upward-planar L-drawing if and only if it admits a bitonic st-ordering, which can be tested in linear time.

We study upward-planar L-drawings of DAGs that are not necessarily st-graphs. On the combinatorial side, we show that a plane DAG admits an upward-planar L-drawing if and only if it is a subgraph of a plane st-graph admitting a bitonic st-ordering. This allows us to show that not every tree with a fixed bimodal embedding admits an upward-planar L-drawing. Moreover, we prove that any acyclic cactus with a single source (or a single sink) admits an upward-planar L-drawing, which respects a given outerplanar embedding if there are no transitive edges. On the algorithmic side, we consider DAGs with a single source (or a single sink). We give linear-time testing algorithms for these DAGs in two cases: (i) when the drawing must respect a prescribed embedding and (ii) when no restriction is given on the embedding, but the DAG is biconnected and series-parallel.

1 Introduction

In order to visualize hierarchies, directed acyclic graphs (DAGs) are often drawn in such such a way that the geometric representation of the edges reflects their direction. To this aim *upward drawings* have been introduced, i.e., drawings in which edges are monotonically increasing curves in the y-direction. Sugiyama et al. [21] provided a general framework for drawing DAGs upward. To support readability, it is desirable to avoid edge crossings [20, 23]. However, not every planar DAG admits an *upward-planar drawing*, i.e., an upward drawing in which no two edges intersect except in common endpoints. A necessary condition is that the corresponding embedding is *bimodal*, i.e., all incoming edges are consecutive in the cyclic sequence of edges around any vertex. Di Battista and Tamassia [12] showed that a

DAG is upward-planar if and only if it is a subgraph of a *planar st-graph*, i.e., a planar DAG with a single source and a single sink that are connected by an edge. Based on this characterization, it can be decided in near-linear time whether a DAG admits an upward-planar drawing respecting a given planar embedding [5, 8]. However, it is NP-complete to decide whether a DAG admits an upward-planar drawing when no fixed embedding is given [16]. For special cases, upward-planarity testing in the variable embedding setting can be performed in polynomial time: e.g. if the DAG has only one source [6, 9, 19], or if the underlying undirected graph is series-parallel [14]. Furthermore, parameterized algorithms for upward-planarity testing exist with respect to the number of sources or the treewidth of the input DAG [11].

Every upward-planar DAG admits a straight-line upward-planar drawing [12], however such a drawing may require exponential area [13]. Gronemann introduced bitonic st-orderings for DAGs [17]. A plane st-graph that admits a bitonic st-ordering also admits an upward-planar drawing in quadratic area. It can be tested in linear time whether a plane st-graph admits a bitonic st-ordering [17], and whether a planar st-graph admits a planar embedding that allows for a bitonic st-ordering [1, 10]. By subdividing some transitive edges once, every plane st-graph can be extended such that it admits a bitonic st-ordering. Moreover, the minimum number of edges that have to be subdivided can be determined in linear time, both, in the variable [1] and the fixed embedding setting [17].

In an *L-drawing* of a directed graph [4] each edge e is represented as a polyline composed of a vertical segment incident to the tail of e and a horizontal segment incident to the head of e. In a *planar L-drawing*, distinct edges may overlap, but not cross. See Fig. 1b for an example. The problem of testing for the existence of a planar L-drawing of a directed graph is NP-complete [10]. On the other hand, every upward-planar DAG admits a planar L-drawing [3]. A planar L-drawing is *upward* if the lowest end vertex of the vertical segment of an edge e is the tail of e (see Fig. 1c). A planar st-graph admits an upward-planar L-drawing if and only it admits a bitonic st-ordering [10].

Our Contribution. We characterize in Theorem 2 the plane DAGs admitting an upward-planar L-drawing as the subgraphs of plane st-graphs admitting a bitonic st-ordering. We first apply this characterization to prove that there are trees with a fixed bimodal embedding that do not admit an upward-planar L-drawing (Theorem 3). Moreover, the characterization allows to test in linear time whether any DAG with a single source or a single sink admits an upward-planar L-drawing preserving a given embedding (Theorem 5).

We further show that every single-source acyclic cactus admits an upward-planar L-drawing by directly computing the x- and y-coordinates as post- and pre-order numbers, respectively, in a DFS-traversal (Theorem 4). The respective result holds for single-sink acyclic cacti. Finally, we use a dynamic-programming approach combined with a matching algorithm for regular expressions to decide in linear time whether a DAG with a single source or a single sink has an embedding admitting an upward-planar L-drawing if it is biconnected and series-parallel (Theorem 7). Observe that a plane st-graph does not necessarily admit an upward-planar L-drawing if the respective graph with reversed edges does. This justifies studying single-source and -sink graphs independently. Full details for proofs of statements marked with ($\star$) can be found in the full version of the paper [2].

2 Preliminaries

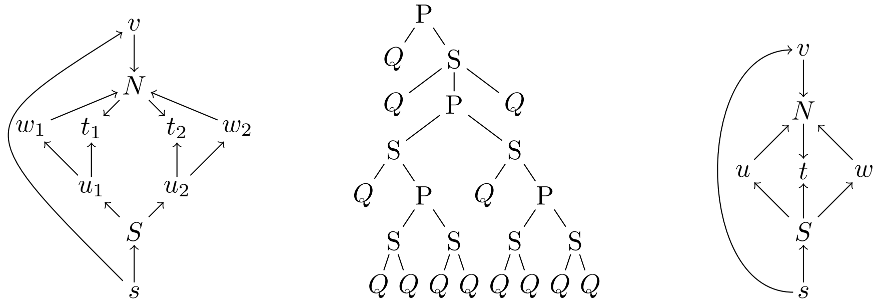
For standard graph theoretic notations and definitions we refer the reader to [22].

Digraphs. A *directed graph (digraph)* $G = (V, E)$ is a pair consisting of a finite set V of *vertices* and a set E of edges containing ordered pairs of distinct vertices. A vertex of a digraph is a *source* if it is only incident to outgoing edges and a *sink* if it is only incident to incoming edges. A *walk* is a sequence of vertices such that any two consecutive vertices in the sequence are adjacent. A *path* is a walk with distinct vertices. In this work we assume that all graphs are *connected*, i.e., that there is always a path between any two vertices. A *cycle* is a walk with distinct vertices except for the first and the last vertex which must be equal. A *directed path* (*directed cycle*) is a path (cycle) where for any vertex v and its successor u in the path (cycle) there is an edge directed from u to v. In the following, we only consider *acyclic digraphs (DAGs)*, i.e., digraphs that do not contain directed cycles. A DAG is a *tree* if it is connected and contains no cycles. It is a *cactus* if it is connected and each edge is contained in at most one cycle.

Drawings. In a *drawing (node-link diagram)* of a digraph vertices are drawn as points in the plane and edges are drawn as simple curves between their end vertices. A drawing of a DAG is *planar* if no two edges intersect except in common endpoints. A planar drawing splits the plane into connected regions – called *faces*. A *planar embedding* of a DAG is the counter-clockwise cyclic order of the edges around each vertex according to a planar drawing. A *plane* DAG is a DAG with a fixed planar embedding and a fixed unbounded face.

The *rotation* of an orthogonal polygonal chain, possibly with overlapping edges, is defined as follows: We start with rotation zero. If the curve bends to the left, i.e., if there is a convex angle to the left of the curve, then we add $\pi/2$ to the rotation. If the curve bends to the right, i.e., if there is a concave angle to the left of the curve, then we subtract $\pi/2$ from the rotation. Moreover, if the curve has a 2π angle to the left, we handle this as two concave angles and if there is a 0 angle to the left, we handle this as two convex angles. The rotation of a simple polygon – with possible overlaps of consecutive edges – traversed in counterclockwise direction is 2π.

Single-source series-parallel DAGs. Series-parallel digraphs are digraphs with two distinguished vertices, called *poles*, and can be defined recursively as follows: A single edge is a series-parallel digraph. Given k series-parallel digraphs $G_1, \ldots, G_k$ (*components*), with poles v_i, u_i, $i = 1, \ldots, k$, a series-parallel digraph G with poles v and u can be obtained in two



(a) DAG not upward-planar. **(b)** Decomposition-tree. **(c)** Embedding not upward-planar.

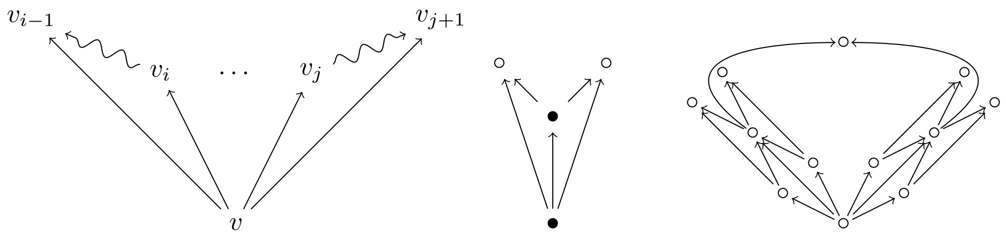
Figure 2 a) A bimodal single-source series-parallel DAG that is not upward-planar b) with its decomposition-tree. c) A single-source series-parallel DAG with an embedding that is not upward-planar. However, the DAG with a different embedding is upward-planar.

ways: by merging $v_1, \ldots, v_k$ and $u_1, \ldots, u_k$, respectively, into the new poles v and u (*parallel composition*), or by merging the vertices u_i and v_{i+1}, $i = 1, \ldots, k-1$, and setting $u = u_1$ and $v = v_k$ (*series composition*). The recursive construction of a series-parallel digraph is represented in a decomposition-tree T. We refer to the vertices of T as *nodes*. The leaves (vertices of degree one) of the decomposition-tree are labeled Q and represent the edges. The other nodes (*inner nodes*) are labeled P for parallel composition or S for series composition. No two adjacent nodes of T have the same label. Fig. 2b shows the decomposition-tree of the graph in Fig. 2a. Let μ be a node of T. We denote by $T(\mu)$ the subtree rooted at μ and by $G(\mu)$ the subgraph of G corresponding to $T(\mu)$, i.e., the subgraph of G formed by the edges corresponding to the leaves of $T(\mu)$. The vertices of $G(\mu)$ that are different from its poles are called *internal.* Given an arbitrary biconnected digraph G, it can be determined in linear time whether it is series-parallel, and a decomposition-tree of G can be computed also in linear time [18]. Moreover, rooting a decomposition-tree of a biconnected series-parallel digraph G at an arbitrary inner node yields again a decomposition-tree of G.

In the following, we assume that G is a series-parallel DAG with a single source (sink) s. If G has more than one edge, we root the decomposition-tree T at the inner node incident to the Q-node corresponding to an edge incident to s. This implies that for any node μ of T no internal vertex of $G(\mu)$ can be a source (sink) of $G(\mu)$ and at least one of the poles of $G(\mu)$ is a source (sink) of $G(\mu)$.

It follows from [6] that every single-source series-parallel DAG is upward-planar if each vertex is incident to at most one incoming or at most one outgoing edge. However, even in that case, not every bimodal embedding is already upward-planar, see Fig. 2c. Moreover, not every single-source series-parallel DAG is upward-planar, even if it admits a bimodal embedding, see Fig. 2a. The reason for that is a P-node μ with two children μ_1 and μ_2 such that a pole N of $G(\mu)$ is incident to an incoming edge in $G - G(\mu)$, and to both incoming and outgoing edges in both, $G(\mu_1)$ and $G(\mu_2)$. Bimodal single-source series-parallel DAGs without this property are always upward-planar [2].

Given an upward-planar drawing of G with distinct y-coordinates for the vertices, we call the pole of $G(\mu)$ with lower y-coordinate the *South pole* of $G(\mu)$ and the other pole the *North pole* of $G(\mu)$. Observe that the South (North) pole of G is the unique source (sink) s. If μ is a P-node with children $\mu_1, \ldots, \mu_\ell$, then the South pole of $G(\mu_i)$, $i = 1, \ldots, \ell$ is the South pole of $G(\mu)$. Finally, if μ is an S-node with children $\mu_1, \ldots, \mu_\ell$, then observe



(a) Valley.

(b) Fixed.

(c) Variable.

Figure 3 (a) Forbidden configuration for bitonic *st*-orderings. (b+c) Single-source series-parallel plane DAG that does not admit an upward-planar L-drawing since it contains a valley, in case (c) in any upward-planar embedding.

that at most one among the components $G(\mu_i)$, $i = 1, \dots, \ell$ can have more than one source (sink) – otherwise G would have more than one source (sink). The South (North) pole of all other components is their unique source (sink).

Bitonic st-ordering. A *planar st-graph* is a planar DAG with a single source s, a single sink t, and an edge (s,t). An *st-ordering* of a planar st-graph is an enumeration π of the vertices with distinct integers, such that $\pi(u) < \pi(v)$ for every edge (u,v). A *plane st-graph* is a planar st-graph with a planar embedding in which the edge (s,t) is incident to the outer face. Every plane st-graph admits an upward-planar drawing [12].

For each vertex v of a plane st-graph, we consider the ordered list $S(v) = \langle v_1, v_2, \dots, v_k \rangle$ of the successors of v as they appear from left to right in an upward-planar drawing. An st-ordering of a plane st-graph is *bitonic*, if there is a vertex v_h in $S(v) = \langle v_1, v_2, \dots, v_k \rangle$ such that $\pi(v_i) < \pi(v_{i+1})$, $i = 1, \dots, h-1$, and $\pi(v_i) > \pi(v_{i+1})$, $i = h, \dots, k-1$. We say that the successor list $S(v) = \langle v_1, v_2, \dots, v_k \rangle$ of a vertex v contains a *valley* if there are $1 < i \leq j < k$ such that there are both, a directed v_i-v_{i-1}-path and a directed v_j-v_{j+1}-path in G. See Fig. 3. Gronemann [17] characterized the plane st-graphs that admit a bitonic st-ordering as follows.

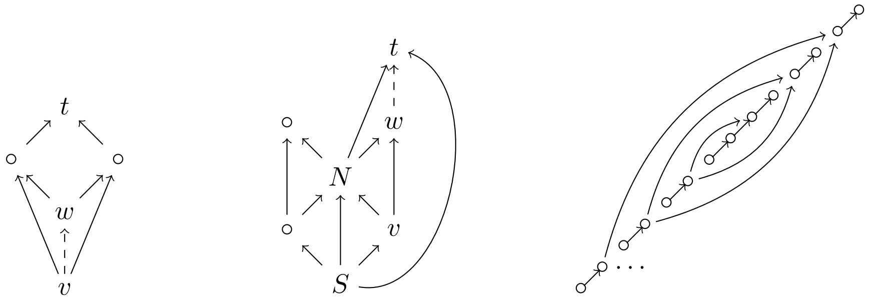
▶ **Theorem 1** ([17]). *A plane st-graph admits a bitonic st-ordering if and only if the successor list of no vertex contains a valley.*

3 Upward-Planar L-Drawings – A Characterization

A plane st-graph admits an upward-planar L-drawing if and only it admits a bitonic st-ordering [10]. We extend this result to general plane DAGs and discuss some consequences.

▶ **Theorem 2.** *A plane DAG admits an upward-planar L-drawing if and only if it can be augmented to a plane st-graph that admits an upward-planar L-drawing, i.e., a plane st-graph that admits a bitonic st-ordering.*

Proof. Let G be a plane DAG. Clearly, if an augmentation of G admits an upward-planar L-drawing, then so does G. Let now an upward-planar drawing of G be given. Add a directed triangle with a new source s, a new sink t, and a new vertex x enclosing the drawing of G. As long as there is a vertex v of G that is not incident to an incoming or outgoing edge, shoot a ray from v to the top or the right, respectively, until it hits another edge and follow the segment to the incident vertex – recall that one end of any segment is a vertex and one end is a bend. The orientation of the added edge is implied by the L-drawing. The result is an upward-planar L-drawing of a digraph with the single source s and the single sink t. ◀



(a) Single sink. **(b)** Single source. **(c)** Family of trees.

Figure 4 DAGs that do not admit an upward-planar L-drawing even though they do not contain a valley. Dashed edges indicate augmentations and are not part of the DAG.

Observe that every series-parallel st-graph admits a bitonic st-ordering [1, 10] and, thus, an upward-planar L-drawing. This is no longer true for upward-planar series-parallel DAGs with several sources or several sinks. Figs. 3b and 3c show examples of two single-source upward-planar series-parallel DAGs that contain a valley. There are even upward-planar series-parallel DAGs with a single source or a single sink that do not admit an upward-planar L-drawing, even though the successor list of no vertex contains a valley.

Consider the DAG G in Fig. 4a (without the dashed edge). G has a unique upward-planar embedding. Since no vertex has more than two successors there cannot be a valley. Assume G admits a planar L-drawing. By Theorem 2 there should be an extension of G to a plane st-graph G' that admits a bitonic st-ordering. But the internal source w can only be eliminated by adding the edge (v, w). Thus w is a successor of v in G'. Hence, the successor list of v in G' contains a valley. By Theorem 1, G' is not bitonic, a contradiction.

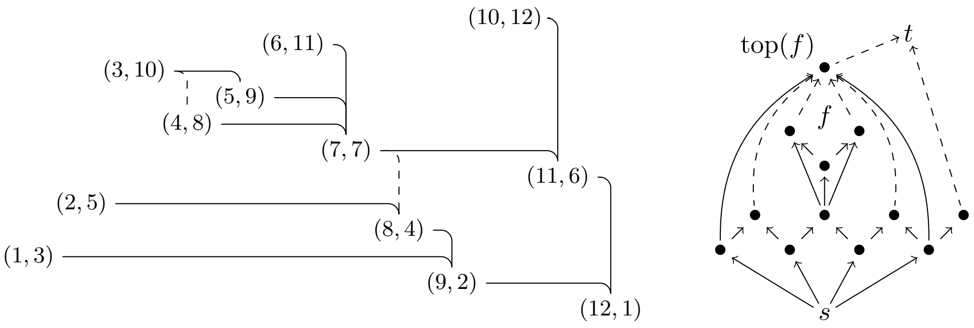
Now consider the DAG G in Fig. 4b (without the dashed edge). G has two symmetric upward-planar embeddings: with the curved edge to the right or the left of the remainder of the DAG. We may assume that the curved edge is to the right. But then an augmentation to a plane st-graph G' must contain the dashed edge, which completes a valley at the single source and its three rightmost outgoing edges. By Theorem 1, G' is not bitonic, a contradiction.

A planar L-drawing is *upward-leftward* [10] if all edges are upward and point to the left.

▶ **Theorem 3** (Trees). *Every directed tree admits an upward-leftward planar L-drawing, but not every tree with a fixed bimodal embedding admits an upward-planar L-drawing.*

Proof. If the embedding is not fixed, we can construct an upward-planar L-drawing of the input tree by removing one leaf v and its incident edge e, drawing the smaller directed tree inductively, and inserting the removed leaf into this upward-leftward planar L-drawing. To this end let u be the unique neighbor of v. We embed e as the first incoming or outgoing edge of u, respectively, in counterclockwise direction, and draw v slightly to the right and below u, if e is an incoming edge of u, or slightly to the left and above u, if e is an outgoing edge of v. This guarantees that the resulting L-drawing is upward-leftward and planar.

When the embedding is fixed, we consider a family of plane trees T_k, $k \geq 1$, proposed by Frati [15, Fig. 4a], that have $2k$ vertices and require an exponential area $\Omega(2^{k/2})$ in any embedding-preserving straight-line upward-planar drawing; see Fig. 4c. We claim that, for sufficiently large k, the tree T_k does not admit an upward-planar L-drawing. Suppose, for a contradiction, that it admits one. By Theorem 2, we can augment this drawing to an upward-planar L-drawing of a plane st-graph G with $n = 2k + 3$ vertices. This implies that G admits a bitonic st-ordering [10]. Hence, G (and thus T_k) admits a straight-line upward-planar drawing in quadratic area $(2n - 2) \times (n - 1)$ [17], a contradiction. ◀



(a) Cactus with post- and pre-order numbers as coordinates. **(b)** Augmentation.

Figure 5 (a) Single-source acyclic cactus. The dashed edges are the last edges on a left path cycles. (b) A new sink t and the dashed edges augment a plane single-source DAG to a plane st-graph.

4 Single-Source or -Sink DAGs with Fixed Embedding

In the fixed embedding scenario, we first prove that every single-source or -sink acyclic cactus with no transitive edge admits an upward-planar L-drawing and then give a linear-time algorithm to test whether a single-source or -sink DAG admits an upward-planar L-drawing.

▶ **Theorem 4** (Plane Single-Source or Single-Sink Cacti). *Every acyclic cactus G with a single source or single sink admits an upward-leftward outerplanar L-drawing. Moreover, if there are no transitive edges (e.g., if G is a tree) then such a drawing can be constructed so to maintain a given outerplanar embedding.*

Proof. We first consider the case that G has a single source s. Observe that then each biconnected component C of G (which is either an edge or a cycle) has a single source, namely the cut-vertex of G that separates it from the part of the DAG containing s. This implies that C also has a single sink (although G may have multiple sinks, belonging to different biconnected components). In particular, if C is a cycle, it consists of a *left* path P_ℓ and a *right* path P_r between its single source and single sink. By flipping the cycle C – maintaining outerplanarity – we can ensure that P_ℓ contains more than one edge. Note that this flipping is only performed if there are transitive edges. Consider the tree T that results from G by removing the last edge of every left path.

We perform a depth-first search on T starting from s where the edges around a vertex are traversed in clockwise order. We enumerate each vertex twice, once when we first meet it (DFS-number or *preorder* number) and once when we finally backtrack from it (*postorder* number). To also obtain that each edge points to the left, backtracking has to be altered from the usual DFS: Before backtracking on a left path P_ℓ of a cycle C, we directly jump to the single source s_C of C and continue the DFS from there, following the right path P_r of C. Only once we have backtracked from the single sink t_C of C, we give each vertex on P_ℓ, excluding s_C, a postorder number and then we continue backtracking on P_r. See Fig. 5a.

Let the y-coordinate of a vertex be its preorder number and let the x-coordinate be its thus constructed postorder number. Since each vertex has a larger preorder- and a lower postorder-number than its parent, the drawing is upward-leftward. In [2] we prove that it is also planar and preserves the embedding, which was updated only in the presence of transitive edges.

Now consider the case that G has a single sink. Flip the embedding, i.e., reverse the linear order of the incoming (outgoing) edges around each vertex. Reverse the orientation of the edges, construct the drawing of the resulting single-source DAG, rotate it by 90 degrees in counter-clockwise direction, and mirror it horizontally. This yields the desired drawing. ◀

General DAGs. Two consecutive incident edges of a vertex form an *angle*. A *large angle* in an upward-planar straight-line drawing is an angle greater than π between two consecutive edges incident to a source or a sink, respectively. An *upward-planar embedding* of an upward-planar DAG is a planar embedding with the assignment of large angles according to a straight-line upward-planar drawing. For single-source or single-sink DAGs, respectively, a planar embedding and a fixed outer face already determine an upward-planar embedding [6].

An angle is a *source-switch* or a *sink-switch*, respectively, if the two edges are both outgoing or both incoming edges of the common end vertex. Observe that the number $A(f)$ of source-switches in a face f equals the number of sink-switches in f. Bertolazzi et al. [5] proved that in biconnected upward-planar DAGs, the number $L(f)$ of large angles in a face f is $A(f) - 1$, if f is an inner face, and $A(f) + 1$, otherwise, and mentioned in the conclusion that this result could be extended to simply connected graphs. An explicit proof for single-source or -sink DAGs can be found in [2].

▶ **Theorem 5.** *Given an upward-plane single-source or single-sink DAG, it can be tested in linear time whether it admits an upward-planar L-drawing.*

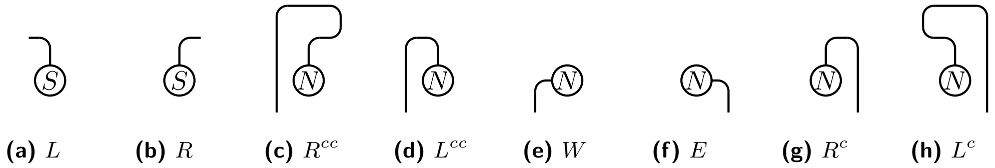
In the following, we prove the theorem for a DAG G with a single source s; the single-sink case is discussed in [2]. In an upward-planar straight-line drawing of G, the only large angle at a source-switch is the angle at s in the outer face. Thus, in the outer face all angles at sink-switches are large and in an inner face f all but one angle at sink-switches are large. For an inner face f, let $\text{top}(f)$ be the sink-switch of f without large angle. See Fig. 5b.

▶ **Lemma 6.** *Let G be a single source upward-planar DAG with a fixed upward-planar embedding, let f be an inner face, and let v be a sink with a large angle in f. Every plane st-graph extending G contains a directed v-$top(f)$-path.*

Proof. Consider a planar st-graph extending G. In this graph there must be an outgoing edge e of v towards the interior of f. Let w be the head of e. Follow a path from w on the boundary of f upward until a sink-switch v' is met. If this sink-switch is $\text{top}(f)$, we are done. Otherwise continue recursively by considering an outgoing edge e' of v' toward the interior of f. Eventually this process terminates when $\text{top}(f)$ is reached. ◀

Proof of Theorem 5, single-source case. Let G be an upward-planar single-source DAG with a fixed upward-planar embedding. Let G' be the DAG that results from G by adding in each inner face f edges from all sinks with a large angle in f to $\text{top}(f)$ and by adding a new sink t together with edges from all sink-switches on the outer face. We will show that G admits an upward-planar L-drawing if and only if G' does. This implies the statement, since testing whether G' admits a bitonic st-ordering can be performed in linear time [17].

Clearly, if $G' \supseteq G$ admits an upward-planar L-drawing, then so does G. In order to prove the other direction, suppose that G has an upward-planar L-drawing. In order to prove that G' admits an upward-planar L-drawing, we show that it is a planar st-graph that admits a bitonic st-ordering [10]. To show this, we argue that G' is acyclic, has a single source and a single sink, and the successor list of no vertex contains a valley by Theorem 1.



(a) L **(b)** R **(c)** R^{cc} **(d)** L^{cc} **(e)** W **(f)** E **(g)** R^{c} **(h)** L^{c}

Figure 6 The different types of a path between the poles. (a,b) South types; (c-h) North types.

Namely, the edges to the new sink t cannot be contained in any directed cycle. Furthermore, by Theorem 2, there is an augmentation G'' of G such that (a) G'' is a planar st-graph and such that (b) G'' admits an upward-planar L-drawing. By Lemma 6, the edges added into inner faces of G either belong to G'' or are transitive edges in G''. Thus, G' is acyclic.

Since G' does not have more sources than G, there is only one source in G'. Each sink has a large angle in some face. Thus, in G' each vertex other than t has at least one outgoing edge. Therefore, G' is a planar st-graph.

Assume now that there is a face f with a sink w such that the edge $(w,\text{top}(f))$ would be part of a valley at a vertex v in G', i.e., assume there are successors $v_{i-1}, v_i, v_j, v_{j+1}$ of v from left to right (with possibly $v_i = v_j$) such that there is both, a directed v_i-v_{i-1}-path and a directed v_j-v_{j+1}-path. Since the out-degree of w in G' is one, it follows that $w \neq v$. Thus, $(w,\text{top}(f))$ could only be part of the v_i-v_{i-1}-path or the v_j-v_{j+1}-path. But then, by Lemma 6, there would be such a path in any augmentation of G to a planar st-graph. Finally, the edges incident to t cannot be involved in any valley, since all the tails have out-degree 1. Thus, G' contains no valleys. ◀

5 Single-Source or -Sink Series-Parallel DAGs with Variable Embedding

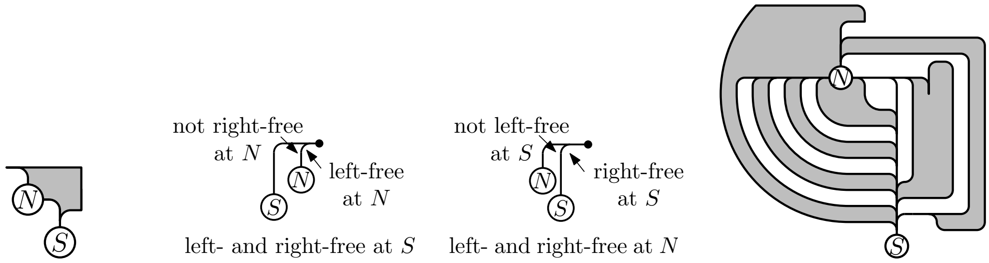
The goal of this section is to prove the following theorem.

▶ **Theorem 7.** *It can be tested in linear time whether a DAG with a single source or a single sink admits an upward-planar L-drawing if it is biconnected and series-parallel.*

In the following we assume that G is a biconnected series-parallel DAG.

Single Source. We follow a dynamic-programming approach inspired by Binucci et al. [7] and Chaplick et al. [11]. We define feasible types that combinatorially describe the "shapes" attainable in an upward-planar L-drawing of each component. We show that these types are sufficient to determine the possible types of a graph obtained with a parallel or series composition, and show how to compute them efficiently. The types depend on the choice of the South pole as the bottommost pole (if it is not uniquely determined by the structure of the graph, e.g., if one of them is the unique source), and on the type of the leftmost S-N-path P_L and the rightmost S-N-path P_R between the South-pole S and the North-pole N. Observe that P_L and P_R do not have to be directed paths.

More precisely, the type of an S-N-path P is defined as follows: There are two *South-types* depending on the edge incident to S: L (outgoing edge bending to the *left*; Fig. 6a) and R (outgoing edge bending to the *right*; Fig. 6b). For the last edge incident to the North pole N we have in addition the types for the incoming edges: W (incoming edge entering from the left – *West*; Fig. 6e) and E (incoming edge entering from the right – *East*; Fig. 6f). For the types R and L we further distinguish whether P passes to the left of N (R^{cc}/L^{cc}; Figs. 6c and 6d) or to the right of N (R^{c}/L^{c}; Figs. 6g and 6h): Let h be the horizontal line



(a) $\langle (E,L),(L^c,R)\rangle$ **(b)** $\langle (R^{cc},R),(R^{cc},R)\rangle$ **(c)** $\langle (R^c,R),(R^c,R)\rangle$ **(d)** Parallel composition.

Figure 7 (a–c) Illustrations for types of a component. (d) A parallel composition of eight components of the following types: $\langle (R^{cc},L),(W,L)\rangle$, $\langle (W,L),(W,L)\rangle$, $\langle (W,L),(W,L)\rangle$, $\langle (W,L),(E,L)\rangle$, $\langle (E,L),(E,L)\rangle$ single edge, $\langle (E,R),(E,R)\rangle$ not left-free at N, $\langle (R^c,R),(R^c,R)\rangle$. The result is of type $\langle (R^{cc},L),(R^c,R)\rangle$.

through N. We say that P *passes to the left (right)* of N if the last edge of P (from S to N) that intersects h does so to the left (right) of N. Thus, there are six *North-types* for a path between the poles: $R^{cc}, L^{cc}, W, E, R^c, L^c$. The superscripts c and cc stand for clockwise and counter-clockwise, respectively, to denote the rotation of a path that passes to the left (right) of N, when walking from N to S. This is justified in the next lemma and depicted e.g., in Fig. 7a, where the right S-N-path has type L^c, since (walking from N to S) it first bends to the left and then passes to the right of N by rotating clockwise.

▶ **Lemma 8** (⋆). *Let G be a series-parallel DAG with no internal sources. Let an upward-planar L-drawing of G be given where the poles S and N are incident to the outer face and S is below N. Let P be a not necessarily directed S-N-path. Let P' be the polygonal chain obtained from P by adding a vertical segment pointing from N downward. The rotation of P' is*

- *π if the type of P at N is in $\{E, L^c, R^c\}$.*
- *$-\pi$ if the type of P at N is in $\{L^{cc}, R^{cc}, W\}$.*

We say that the *type of a path between the poles* is (X, x), if X is the North-type and x is the South-type of the path, e.g., the type of a path that bends right at the South-pole, passes to the right of the North-pole and ends in an edge that leaves the North-pole bending to the left is (L^c, R), see P_R in Fig. 7a. For two North-types X and Y, we say $X < Y$ if X is before Y in the ordering $[R^{cc}L^{cc}WER^cL^c]$. The South-types are ordered $L < R$. For two types (X, x) and (Y, y) we say that $(X, x) \leq (Y, y)$ if $X \leq Y$ and $x \leq y$, and $(X, x) < (Y, y)$ if $(X, x) \leq (Y, y)$ and $X < Y$ or $x < y$.

The *type of a component* is determined by eight entries, whether the component is a single edge or not, the choice of the bottommost pole (South pole), the type of P_L, the type of P_R, and additionally four FREE-*flags*: For each pole, two flags *left-free* and *right-free* indicating whether the bend on P_L and P_R, respectively, on the edge incident to the pole is *free* on the left or the right, respectively: More precisely, let P be an S-N-path and let e be an edge of P incident to a pole X. We say that e is *free* on the right (left) at X if e bends to the right (left) – walking from S to N – or if the bend on e is not contained in an edge not incident to X. See Figs. 7b and 7c. We denote a type by $\langle (X, x), (Y, y)\rangle$ where (X, x) is the type of P_L and (Y, y) is the type of P_R without explicitly mentioning the flags or the choice of the South pole. Observe that $Y < L^c$ if $X = R^{cc}$ and $\langle (X, x), (Y, y)\rangle$ is the type of a component. Fig. 7d illustrates how components of different types can be composed in parallel.

▶ **Lemma 9** (Parallel Composition (⋆)). *A component C of type $\langle (X, x), (Y, y)\rangle$ with the given four* FREE-*flags can be obtained as a parallel composition of components $C_1, \ldots, C_\ell$ of type $\langle (X_1, x_1), (Y_1, y_1)\rangle, \ldots, \langle (X_\ell, x_\ell), (Y_\ell, y_\ell)\rangle$ from left to right at the South pole if and only if*

- $X_1 = X$, $Y_\ell = Y$, $x_1 = x$, $y_\ell = y$,
- *C is left(right)-free at the North- and South-pole, respectively, if and only if C_1 (C_ℓ) is,*
- *$Y_i \le X_i$ and*
  - *C_i is right-free if $Y_i = X_{i+1} \in \{R^{cc}, E, R^c\}$*
  - *C_{i+1} is left-free if $Y_i = X_{i+1} \in \{L^{cc}, W, L^c\}$*
  - *C_i is right-free or C_{i+1} is left-free if $Y_i \in \{L^{cc}, L^c\}$ and $X_{i+1} \in \{R^{cc}, R^c\}$ or vice versa.*
- - *$y_i = x_{i+1} = L$ and C_i is right-free, or*
  - *$y_i = x_{i+1} = R$ and C_{i+1} is left-free, or*
  - *$y_i = L$ and $x_{i+1} = R$ and C_i is right-free or C_{i+1} is left-free.*
- *and single edges are the first among the components with a boundary path of type (W, R) and the last among the components with a boundary path of type (E, L).*

Sketch of Proof. Since the necessity of the conditions is evident, we shortly sketch how to prove sufficiency. By construction, we ensure that the angle between two incoming edges is 0 or π and the angle between an incoming and an outgoing edge is $\pi/2$ or $3\pi/2$. It remains to show the following three conditions [10]: (i) The sum of the angles at a vertex is 2π, (ii) the rotation at any inner face is 2π, (iii) and the *bend-or-end property* is fulfilled, i.e., there is an assignment that assigns each edge to one of its end vertices with the following property. Let e_1 and e_2 be two incident edges that are consecutive in the cyclic order and attached to the same side of the common end vertex v. Let f be the face/angle between e_1 and e_2. Then at least one among e_1 and e_2 is assigned to v and its bend leaves a concave angle in f. ◀

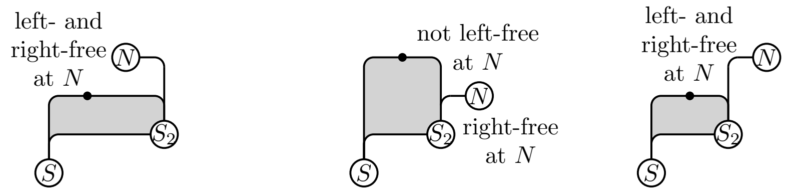
Lemma 9 yields a strict order of the possible types from left to right that can be composed in parallel. Moreover, let σ be a sequence of types of components from left to right that can be composed in parallel and let τ be a type in σ. Then Lemma 9 implies that τ appears exactly once in σ or the leftmost path and the rightmost path have both the same type in τ and all four free-flags are positive. In that case the type τ might occur arbitrarily many times and all appearances are consecutive. Thus, σ can be expressed as a *simple regular expression* on an alphabet $\mathcal{T}$, i.e., a sequence ρ of elements in $\mathcal{T} \cup \{^\star\}$ such that * does not occur as the first symbol of ρ and there are no two consecutive * in ρ. A sequence s of elements in $\mathcal{T}$ is *represented* by a simple regular expression ρ if it can be obtained from ρ by either removing the symbol preceding a * or by repeating it arbitrarily many times.

Observe that the elements in the simple regular expression ρ representing σ are distinct, thus, the length of ρ is linear in the number of types, i.e., constant. In particular, to obtain a linear-time algorithm to enumerate the attainable types of a series-parallel DAG obtained via a parallel composition, it suffices to establish the following algorithmic lemma.

▶ **Lemma 10** (Simple Regular Expression Matching ($\star$))**.** *Let $\mathcal{T}$ be a constant-size alphabet (set of types), and ρ be a constant-length simple regular expression over $\mathcal{T}$. For a collection $\mathcal{C}$ of items where each $C \in \mathcal{C}$ has a set $\mathcal{T}(C) \subseteq \mathcal{T}$, one can test in $\mathcal{O}(|\mathcal{C}|)$ time, if there is a selection of a type from each $\mathcal{T}(C)$, $C \in \mathcal{C}$ that can be ordered to obtain a sequence represented by ρ.*

▶ **Corollary 11.** *The types of a parallel composition can be computed in time linear in the number of its children.*

In order to understand how the type of a series composition is determined from the types of the children, let us first have a look at an easy example: Assume that G_1 and G_2 consist both of a single edge e_1 and e_2, respectively, and that the type of both is (W, R). Assume further that G is obtained by merging the North poles N_1 and N_2 of G_1 and G_2, respectively.



(a) G_1 has type L^{cc}, G_2 type L.

(b) G_1 has type L^{cc}, G_2 type R at S_2.

Figure 8 Different free-flags in the case that the North pole is merged with the South pole.

There are two ways how this can be done, namely e_1 can be attached to $N_1 = N_2$ before e_2 or after it in the counterclockwise order starting from R^{cc} and ending at L^c. In the first case the North type of G is R^{cc}, in the second case it is R^c. Moreover, in the first case G is left-free but not right-free at the North-pole, while in the second case it is right-free but not left-free at the South-pole. See Figs. 7b and 7c.

▶ **Lemma 12** (Series Composition). *Let G_1 and G_2 be two series-parallel DAGs with no internal source that admit an upward-planar L-drawing of a certain type $\langle(X_1, x_1), (Y_1, y_1)\rangle$ and $\langle(X_2, x_2), (Y_2, y_2)\rangle$, respectively, with the poles on the outer face. Let G be the DAG obtained by a series combination of G_1 and G_2 such that the common pole of G_1 and G_2 is not a source in both, G_1 and G_2. Then the possible types of G in an upward-planar L-drawing maintaining the types of G_1 and G_2 can be determined in constant time.*

Proof. Let S_i and N_i, respectively, be the South and North pole of G_i, $i = 1, 2$. We may assume that S_1 is the South pole of G and, thus, N_1 is the common pole of G_1 and G_2.

First suppose that $N_1 = S_2$, i.e., that N_2 is the North pole of G. It follows that N_1 cannot be a source of G_1. Then G admits an upward-planar L-drawing if and only if $x_2 = L$ and $X_1 \neq R^{cc}$ or $y_2 = R$ and $Y_1 \neq L^c$, and the respective FREE-conditions are fulfilled at $N_1 = S_2$. The South-type of G is the South type of G_1. The North-type of G is the North-type of G_2 except for the FREE-flags, which might have to be updated if the next-to-last edge on the leftmost or rightmost path, respectively, is already contained in G_1 and is an outgoing edge of N_1. This might yield different North-types concerning the flags. See Fig. 8.

Now suppose that $N_1 = N_2$. Then G admits an upward-planar L-drawing if and only if G_1 can be embedded before G_2, i.e., $Y_1 \leq X_2$ and $X_1 < Y_2$, and not ($X_1 = R^{cc}$ and $Y_2 = L^c$) or G_2 can be embedded before G_1, i.e., $Y_2 \leq X_1$ and $X_2 < Y_1$, and not ($X_2 = R^{cc}$ and $Y_1 = L^c$) and the respective FREE-conditions are fulfilled at $N_1 = N_2$. If $X_1 = Y_1 = X_2 = Y_2 \in \{E, W\}$ then both conditions are fulfilled which might give rise to two upward-planar L-drawings with distinct labels by adding G_2 before or after G_1 at the common pole. The FREE-flags might have to be updated if the second edge on the leftmost or rightmost path, respectively, is already contained in G_2 or if the next-to-last edge on the leftmost or rightmost path, respectively, is already contained in G_1 and the type of G_1 at N_1 equals the respective type of G_2 at N_2. Except for the flags, the South-type of G is the South type of G_1 and the North type of G_2 yields the North type of G except for the specifications c or cc: First observe that both, the leftmost path and the rightmost path, either have both type c or both type cc. Otherwise, G_1 would be contained in an inner face of G_2. The North type of both paths is indexed c if G_2 is embedded before G_1. Otherwise, the North type is indexed cc. Regarding the time complexity, observe that our computation of the set of possible types of G does not depend on the size of G_1 and G_2, but only on the number of types in their admissible sets. Since these sets have constant size and the above conditions on the types of G_1 and G_2 can be tested in constant time, we thus output the desired set in constant time. ◀

▶ **Lemma 13.** *The types of a series composition can be computed in time linear in the number of its children.*

Proof. Let $C_1, \dots, C_\ell$ be the components of a series component C and let $\mathcal{T}(C_i)$, $i = 1, \dots, \ell$ be the set of possible types of C_i. For $k = 1, \dots, \ell$, we inductively compute the set $\mathcal{T}_i$ of possible types of the series combination C^k of $C_1, \dots, C_k$, where $\mathcal{T}_1 = \mathcal{T}(C_1)$. To compute $\mathcal{T}_k$ for some $k = 2, \dots, \ell$, we combine all possible combinations of a type in $\mathcal{T}_{k-1}$ and a type in $\mathcal{T}(C_k)$ and, applying Lemma 12, we check in constant time which types (if any) they would yield for C^k. Since the number types is constant each step can be done in constant time. ◀

Single Sink. For the case that G has a single sink, the algorithmic principles are the same as in the single-source case. The main difference is the type of an N-S-path P in a component C, where S and N are the South- and North-pole of C. The North pole of a component is always a sink and the North-type of P is W or E in this order from left to right. The South-type is one among $E^c, W^c, L, R, E^{cc}, W^{cc}$ in this order from left to right (according to the outgoing edges at N), depending on whether the last edge of P (traversed from N to S) is an incoming edge entering from the left (W) or the right (E), or an outgoing edge bending to the left (L) or the right (R), and whether the last edge of P leaving the half-space above the horizontal line through S does so to the right of S (cc) or the left of S (c).

The type consists again of the choice of the topmost pole (North pole), the type of the leftmost N-S-path, the type of the rightmost N-S-path, the four FREE-flags – which are defined the same way as in the single source case – and the information whether the component is a single edge or not.

6 Conclusion and Future Work

We have shown how to decide in linear time whether a plane single-source or -sink DAG admits an upward-planar L-drawing. A natural extension of this work would be to consider plane DAGs with multiple sinks and sources, the complexity of which is open. In the variable embedding setting, we have presented a linear-time testing algorithm for single-source or -sink series-parallel DAGs. Some next directions are to consider general single-source or -sink DAGs or general series-parallel DAGs. We remark that the complexity of testing for the existence of upward-planar L-drawings in general also remains open.

Abstract

Motivated by cognitive experiments providing evidence that large crossing-angles do not impair the readability of a graph drawing, RAC (Right Angle Crossing) drawings were introduced to address the problem of producing readable representations of non-planar graphs by supporting the optimal case in which all crossings form 90° angles.

In this work, we make progress on the problem of finding RAC drawings of graphs of low degree. In this context, a long-standing open question asks whether all degree-3 graphs admit straight-line RAC drawings. This question has been positively answered for the Hamiltonian degree-3 graphs. We improve on this result by extending to the class of 3-edge-colorable degree-3 graphs. When each edge is allowed to have one bend, we prove that degree-4 graphs admit such RAC drawings, a result which was previously known only for degree-3 graphs. Finally, we show that 7-edge-colorable degree-7 graphs admit RAC drawings with two bends per edge. This improves over the previous result on degree-6 graphs.

1 Introduction

In the literature, there is a wealth of approaches to draw planar graphs. Early results date back to Fáry's theorem [22], which guarantees the existence of a planar straight-line drawing for every planar graph; see also [9, 30, 31, 33, 34]. Over the years, several breakthrough results have been proposed, e.g., de Fraysseix, Pach and Pollack [11] in the late 80's devised a linear-time algorithm [10] that additionally guarantees the obtained drawings to be on an integer grid of quadratic size (thus making high-precision arithmetics of previous approaches unnecessary). Planar graph drawings have also been extensively studied in the presence of bends. Here, a fundamental result is by Tamassia [32] in the context of *orthogonal* graph drawings, i.e., drawings in which edges are axis-aligned polylines. In his seminal paper, Tamassia suggested an approach, called *topology-shape-metrics*, to minimize the number of bends of degree-4 plane graphs using flows. For a complete introduction, see [12].

When the input graph is non-planar, however, the available approaches that yield aesthetically pleasing drawings are significantly fewer. The main obstacle here is that the presence of edge-crossings negatively affects the drawing's quality [28] and, on the other hand,

their minimization turns out to be a computationally difficult problem [23]. In an attempt to overcome these issues, a decade ago, Huang et al. [26] made a crucial observation that gave rise to a new line of research (currently recognized under the term "beyond planarity" [25]): edge crossings do not negatively affect the quality of the drawing too much (and hence the human's ability to read and interpret it), if the angles formed at the crossing points are large. Thus, the focus moved naturally to non-planar graphs and their properties, when different restrictions on the type of edge-crossings are imposed; see [19] for an overview.

Among the many different classes of graphs studied as part of this emerging line of research, one of the most studied ones is the class of *right-angle-crossing graphs* (or *RAC graphs*, for short); see [14] for a survey. These graphs were introduced by Didimo, Eades and Liotta [15, 17] back in 2009 as those admitting straight-line drawings in which the angles formed at the crossings are all 90°. Most notably, these graphs are optimal in terms of the crossing angles, which makes them more readable according to the observation by Huang et al. [26]; moreover, RAC drawings form a natural generalization of orthogonal graph drawings [32], as any crossing between two axis-aligned polylines trivially yields 90° angles.

In the same work [15, 17], Didimo, Eades and Liotta proved that every n-vertex RAC graph is sparse, as it can contain at most $4n - 10$ edges, while in a follow-up work [16] they observed that not all degree-4 graphs are RAC. This gives rise to the following question which has also been independently posed in several subsequent works (see e.g., [3], [18, Problem 6], [14, Problem 9.5], [19, Problem 8]) and arguably forms the most intriguing open problem in the area, as it remains unanswered since more than one decade.

▶ **Question 1.** *Does every graph with degree at most 3 admit a straight-line RAC drawing?*

The most relevant result that is known stems from the related problem of simultaneously embedding two or more graphs on the Euclidean plane, such that the crossings between different graphs form 90° angles. In this setting, Argyriou et al. [4] showed that a cycle and a matching always admit such an embedding, which implies that every *Hamiltonian* degree-3 graph is RAC.

Finally, note that recognizing RAC graphs is hard in the existential theory of the reals [29], which also implies that RAC drawings may require double-exponential area, in contrast to the quadratic area requirement for planar graphs [11].

RAC graphs have also been studied by relaxing the requirement that the edges are straight-line segments, giving rise to the class of k*-bend* RAC graphs (see, e.g, [1, 6, 7, 8, 13]), i.e., those admitting drawings with at most k bends per edge and crossings at 90° angles. It is known that every degree-3 graph is 1-bend RAC and every degree-6 graph is 2-bend RAC [3]. While the flexibility guaranteed by the presence of one or two bends on each edge is not enough to obtain a RAC drawing for every graph (in fact, 1- and 2-bend RAC graphs with n vertices have at most $5.5n - O(1)$ and $72n - O(1)$ edges, respectively [1, 6]), it is known that every graph is 3-bend RAC [13] and fits on a grid of cubic size [21].

Our contribution. We provide several improvements to the state of the art concerning RAC graphs with low degree. In particular, we make an important step towards answering Question 1 by proving that 3-edge-colorable degree-3 graphs are RAC (Theorem 3). This result applies to Hamiltonian 3-regular graphs, to bipartite 3-regular graphs and, with some minor modifications to our approach, to all Hamiltonian degree-3 graphs, thus extending the result in [4]. As a further step towards answering Question 1, we prove that bridgeless 3-regular graphs with oddness at most 2 are RAC (Theorem 8). If their oddness is k, we provide an algorithm to construct a 1-bend RAC drawing where at most k edges have a bend(Theorem 9).

We then focus on RAC drawings with one or two bends per edge. Namely, we prove that all degree-4 graphs admit 1-bend RAC drawings and all 7-edge-colorable degree-7 graphs admit 2-bend RAC drawings (Theorems 10 and 12), which form non-trivial improvements over the state of the art, as the existence of such drawings was previously known only for degree-3 and degree-6 graphs [3]. Due to space constraints, proofs of statements marked with $(*)$ can be found in [2].

2 Preliminaries

Let $G = (V, E)$ be a graph. W.l.o.g. we assume that G is connected, as otherwise we apply our drawing algorithms to each component of G separately. G is called *degree-k* if the maximum degree of G is k. G is called *k-regular* if the degree of each vertex of G is exactly k. A 2-factor of an undirected graph $G = (V, E)$ is a spanning subgraph of G consisting of vertex disjoint cycles. Let F be a 2-factor of G and let $\prec$ be a total order of the vertices such that the vertices of each cycle $C \in F$ appear consecutive in $\prec$ according to some traversal of C. In other words, every two vertices that are adjacent in C are consecutive in $\prec$ except for two particular vertices, which are the first and the last vertices of C in $\prec$. We call the edge between these two vertices the *closing edge* of C. By definition, $\prec$ also induces a total order of the cycles of F. Let $\{u, v\}$ be an edge in $E \setminus F$ and let C and C' be the cycles of F that contain u and v, respectively. If $C = C'$, then $\{u, v\}$ is a *chord* of C. Otherwise, $C \neq C'$. If $u \prec v$, $\{u, v\}$ is called a *forward edge* of u and a *backward edge* of v. The following theorem provides a tool to partition the edges of a bounded degree graph into 2-factors [27].

▶ **Theorem 2** (Eades, Symvonis, Whitesides [20]). *Let $G = (V, E)$ be an n-vertex undirected graph of degree Δ and let $d = \lceil \Delta/2 \rceil$. Then, there exists a directed multi-graph $G' = (V, E')$ with the following properties:*

1. *each vertex of G' has indegree d and outdegree d;*
2. *G is a subgraph of the underlying undirected graph of G'; and*
3. *the edges of G' can be partitioned into d edge-disjoint directed 2-factors.*

Furthermore, the directed graph G' and the d 2-factors can be computed in $\mathcal{O}(\Delta^2 n)$ time.

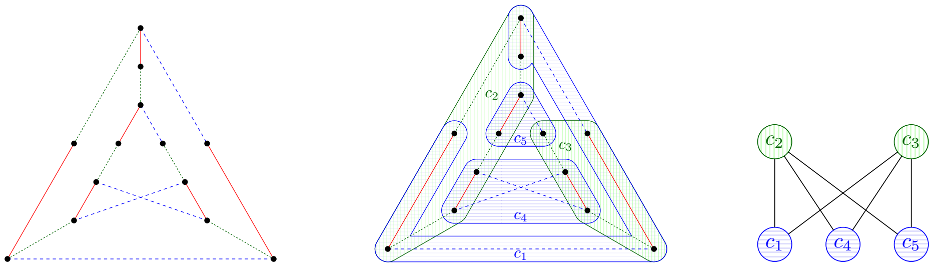
Let Γ be a polyline drawing of G such that the vertices and edge-bends lie on grid points. The area of Γ is determined by the smallest enclosing rectangle. Let $\{u, v\}$ be an edge in Γ. We say that $\{u, v\}$ is using an *orthogonal port* at u if the edge-segment s_u of $\{u, v\}$ that is incident to u is either horizontal or vertical; otherwise it is using an *oblique port* at u. We denote the orthogonal ports at u by N, E, S and W, if s_u is above, to the right, below or to the left of u, respectively. If no edge is using a specific orthogonal port, we say that this port is *free*.

3 RAC drawings of 3-edge-colorable degree-3 graphs

In this section, we prove that 3-edge-colorable degree-3 graphs admit RAC drawings of quadratic area, which can be computed in linear time assuming that the edge coloring is given (testing the existence of such a coloring is NP-complete even for 3-regular graphs [24]).

▶ **Theorem 3.** *Given a 3-edge-colorable degree-3 graph G with n vertices and a 3-edge-coloring of G, it is possible to compute in $O(n)$ time a RAC drawing of G with $O(n^2)$ area.*

We assume w.l.o.g. that G does not contain degree-1 vertices, as otherwise we can replace each such vertex with a 3-cycle while maintaining the 3-edge-colorability of the graph and without asymptotically increasing the size of the graph. Since G is 3-edge-colorable, it can be



(a) G **(b)** $c_1, \dots, c_5$ **(c)** $\mathcal{H}$

Figure 1 (a) A non-planar, non-Hamiltonian, 3-edge-colorable degree-3 example graph G. The matching M_1 is drawn with blue dashed lines, M_2 with red solid lines and M_3 with green dotted lines. (b) The components c_1, c_2 and c_3 of the subgraph H_y induced by $M_1 \cup M_2$ (shaded in blue) and the components c_4 and c_5 of H_x induced by $M_2 \cup M_3$ (shaded in green). (c) The auxiliary graph $\mathcal{H}$ in which the components of H_y and H_x sharing at least one vertex are connected by an edge. In this example, the BFS traversal of the components of $\mathcal{H}$ is c_1, c_2, c_3, c_4, c_5.

decomposed into three matchings M_1, M_2 and M_3. In the produced RAC drawing, the edges in M_1 will be drawn horizontal, those in M_3 vertical, while those in M_2 will be crossing-free, not maintaining a particular slope. Let H_y and H_x be two subgraphs of G induced by $M_1 \cup M_2$ and $M_2 \cup M_3$, respectively. Since every vertex of G has at least two incident edges, which belong to different matchings, each of H_y and H_x spans all vertices of G. Further, any connected component in H_y or H_x is either a path or an even-length cycle, as both H_y and H_x are degree-2 graphs alternating between edges of different matchings.

We define an auxiliary bipartite graph $\mathcal{H}$, whose first (second) part has a vertex for each connected component in H_y (H_x), and there is an edge between two vertices if and only if the corresponding components share at least one vertex; see Fig. 1.

▶ **Property 4.** *The auxiliary graph $\mathcal{H}$ is connected.*

Proof. Suppose for a contradiction that $\mathcal{H}$ is not connected. Let v_c and $v_{c'}$ be two vertices of $\mathcal{H}$ that are in different connected components of $\mathcal{H}$. By definition of $\mathcal{H}$, v_c and $v_{c'}$ correspond to connected components c and c', respectively, of H_y or H_x. W.l.o.g. assume that c belongs to H_y. Let u_0 and u_k be two vertices of G that belong to c and c', respectively. Since G is connected, there is a path $P = (u_0, u_1, u_2, \dots u_k)$ between u_0 and u_k in G, such that no two consecutive edges in P belong to the same matching. Let (u_i, u_{i+1}) be the first edge of P from u_0 to u_k that belongs to M_3, which exists since $c \neq c'$. By construction, this implies that u_i belongs to c and to another component c^* of H_x. By definition of $\mathcal{H}$, v_c and v_{c^*} are connected in $\mathcal{H}$, where v_{c^*} is the corresponding vertex of c^* in $\mathcal{H}$. Repeating this argument until u_k is reached yields a path in $\mathcal{H}$ from v_c to $v_{c'}$, a contradiction. ◀

We now define two total orders $\prec_y$ and $\prec_x$ of the vertices of G, which will then be used to assign their y- and x-coordinates, respectively, in the final RAC drawing of G. Since we seek to draw the edges of M_1 (M_3) horizontal (vertical), we require that the endvertices of any edge in M_1 (M_3) are consecutive in $\prec_y$ ($\prec_x$, respectively). Moreover, for the edges of M_2, we guarantee some properties that will allow us to draw them without crossings.

To construct $\prec_y$ and $\prec_x$, we process the components of H_y and H_x according to a certain BFS traversal of $\mathcal{H}$ and for each visited component of H_y (H_x), we append all its vertices to $\prec_y$ ($\prec_x$) in a certain order.

To select the first vertex of the BFS traversal of H, we consider a vertex u of G belonging to two components c and c' of H_y and H_x, respectively, such that u is the endpoint of c if c is a path; if c is a cycle, we do not impose any constraints on the choice of u. We refer to vertex u as the *origin vertex* of G. Also, let v_c and $v_{c'}$ be the vertices of $\mathcal{H}$ corresponding to c and c', respectively. By definition of $\mathcal{H}$, v_c and $v_{c'}$ are adjacent in $\mathcal{H}$. We start our BFS traversal of $\mathcal{H}$ at v_c and then we move to $v_{c'}$ in the second step (note that this choice is not needed for the definition of $\prec_y$ and $\prec_x$, but it guarantees a structural property that will be useful later). From this point on, we continue the BFS traversal to the remaining vertices of $\mathcal{H}$ without further restrictions. In the following, we describe how to process the components of H_y and H_x in order to guarantee an important property (see Property 5)

Let c be the component of H_y or H_x corresponding to the currently visited vertex in the traversal of $\mathcal{H}$. Since $\mathcal{H}$ is bipartite, no other component of H_y (H_x) shares a vertex with c, if c belongs to H_y (H_x). Hence, no vertex of c already appears in $\prec_y$ ($\prec_x$).

If c is a path, then we append the vertices of c to $\prec_y$ or $\prec_x$ in the natural order defined by a walk from one of its endvertices to the other. Note that if c is the first component in the BFS traversal of $\mathcal{H}$, one of these endvertices is by definition the origin vertex of G, which we choose to start the walk. Hence, in the following we focus on the case that c is a cycle. In this case, the vertices of c will also be appended to $\prec_y$ or $\prec_x$ in the natural order defined by some specific walk of c, such that the so-called *closing edge* connecting the first and the last vertex of c in this order belongs to M_2. Note that an edge might be closing in both orders $\prec_y$ and $\prec_x$.

Suppose first that $c \in H_y$. If c is the first component in the BFS traversal of $\mathcal{H}$, then we append the vertices of c to $\prec_y$ in the order that they appear in the cyclic walk of c starting from the origin vertex of G and following the edge of M_1 incident to it. Otherwise, let v be the first vertex of c in $\prec_x$, which is well defined since there is at least one vertex of c that is part of $\prec_x$, namely, the one that is shared with its parent. We append the vertices of c to $\prec_y$ in the order that they appear in the cyclic walk of c starting from v and following the edge of M_1 incident to v. Hence, v is the first vertex of c in both $\prec_y$ and $\prec_x$. In both cases, it follows that the closing edge of c belongs to M_2.

Suppose now that $c \in H_x$, which implies that c is not the first component in the BFS traversal of $\mathcal{H}$. Let v be the first vertex of c in $\prec_y$, which is again well defined since there is at least one vertex of c that is part of $\prec_y$. We append the vertices of c to $\prec_x$ in the inverse order that they appear in the cyclic walk of c starting from v and following the edge (v, w) of M_3 incident to v (or equivalently, in the order they appear in the cyclic walk of c starting from the neighbor of v different from w and ending at v). Hence, v is the first vertex of c in $\prec_y$ and the last vertex of c in $\prec_x$. Also in this case, the closing edge of c belongs to M_2. See Fig. 2 for an illustration. Note that the closing edge of a component c is contained inside the parent component of c is the BFS traversal. Moreover, by construction, the following property holds.

▶ **Property 5.** *The endvertices of any edge in M_1 (M_3) are consecutive in $\prec_y$ ($\prec_x$). The endvertices of any edge in M_2 are consecutive in $\prec_y$ ($\prec_x$) unless this edge is a closing edge in a component of H_y (of H_x).*

Computing the vertex coordinates. We use $\prec_y$ and $\prec_x$ to specify the y- and the x-coordinates of the vertices, respectively. To do so, we iterate through $\prec_y$ and set the y-coordinate of its first vertex to 1. Let v be the next vertex in the iteration and let u be its predecessor in $\prec_y$. Assume that the y-coordinate of u is i. If $(u, v) \in M_1$, we set the same y-coordinate i to v. Otherwise, either u and v belong to two different components of H_y or $(u, v) \in M_2$ and we set the y-coordinate $i + 1$ to v. Similarly, we iterate through $\prec_x$ and set the x-coordinate of its first vertex to 1. Let v be the next vertex in the iteration and let u be its predecessor in $\prec_x$. Assume that the x-coordinate of u is i. If $(u, v) \in M_3$, we set

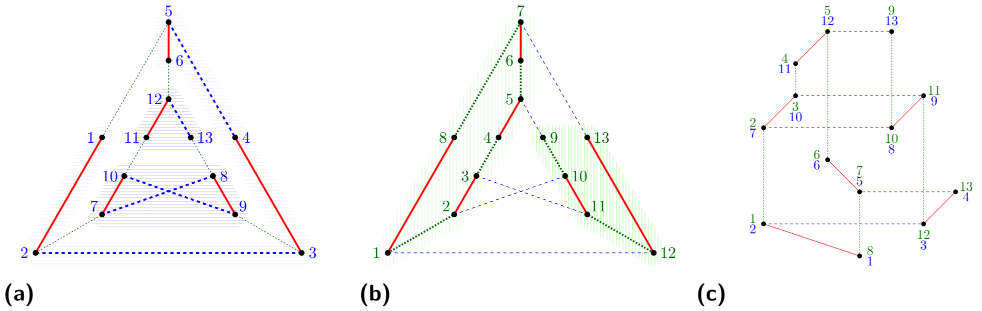


Figure 2 The total orders (a) $\prec_y$ for H_y that consists of the blue and red edges, and (b) $\prec_x$ for H_x that consists of the green and red edges. The final drawing of G is shown in (c).

the x-coordinate of v to i. Otherwise, either u and v belong to two different components of H_x or $(u, v) \in M_2$ and we set the x-coordinate $i + 1$ to v. Hence, no two vertices share the same x- and y-coordinates. We next show that the computed vertex coordinates induce a straight-line RAC drawing Γ of G with the possible exception of the edge of M_2 incident to the origin vertex of G, since this edge would be a closing edge for both c and c' and hence by Property 5 its endpoints would be consecutive in neither $\prec_y$ nor $\prec_x$. If this edge exists, we denote it by e^*, while the graph $G \setminus e^*$ and its drawing in Γ are denoted by G^* and Γ^*, respectively.

▶ **Lemma 6.** *Let e be an edge of G^*. Then, e is drawn horizontally in Γ^* if $e \in M_1$; vertically in Γ^* if $e \in M_3$ and crossing-free in Γ^* if $e \in M_2$.*

Proof. If $e \in M_1$ or $e \in M_3$, the statement follows from Property 5 and the computed vertex coordinates. Hence, let $e = (u, v)$ be an edge of M_2 and let $c_y \in H_y$ and $c_x \in H_x$ be the two components of $\mathcal{H}$ containing e. Suppose to the contrary that there is an edge $e' = (u', v')$ crossing e. If $e' \in M_1$, then both u' and v' belong to the same component $c'_y \in H_y$. If $c'_y \neq c_y$, then e' cannot cross e as the vertices of c_y and c'_y span different intervals of y-coordinates, hence e' belongs to c_y. Similarly, if $e' \in M_3$, then e' belongs to c_x. Finally, if $e' \in M_2$, then u' and v' belong to the same component in both H_y and H_x; thus e' belongs to both c_y and c_x.

1. Edge e is a closing edge for neither c_y nor c_x: The vertices u and v are consecutive in both $\prec_y$ and $\prec_x$ by Property 5. Hence, both their x- and y-coordinate differ by exactly one by construction. Since all vertices have integer coordinates, no horizontal or vertical edge is crossing e, hence $e' \in M_2$. Observe that since the y- (the x-) coordinate of the vertices in c_y (in c_x) are non-decreasing along the walk defining its order in $\prec_y$ (in $\prec_x$), no crossing between e and e' can occur if e' is not a closing edge of c_y or c_x, which will be covered in the next cases (by swapping the roles of e and e').
2. Edge e is a closing edge for c_y but not for c_x: Note that c_y is not the first component in the BFS traversal, since the closing edge of this component is e^*. Further, u and v are consecutive in $\prec_x$, but not in $\prec_y$. We assume that u directly precedes v in $\prec_x$, which implies that u is the first vertex of c_y in $\prec_y$, while v is the last. It follows that their x-coordinates differ by exactly one, hence e' cannot belong to M_3. If e' belongs to M_1, then one of u' or v', say u', has x-coordinate smaller or equal to the one of u. Since u and v are consecutive in $\prec_x$, we have necessarily that u' precedes u in $\prec_x$, which is a contradiction to the choice of u since both u' and v' belong to c_y. In fact, u was chosen as the starting point of the walk, when considering c_y, as the first vertex of c_y in $\prec_x$, hence $e' \in M_2$. Since both endpoints of e' belong to both c_y and c_x, then one of u' or v',

say u', has x-coordinate smaller or equal to the one of u. Since u and v are consecutive in $\prec_x$, we have necessarily that $u' \prec_x u$, which is a contradiction to the choice of u since both u' and v' belong to c_y.

3. Edge e is a closing edge for c_x but not for c_y: This case is analogous to the previous one.
4. Edge e is a closing edge for both c_y and c_x: Observe that neither c_y nor c_x is the first component in the BFS traversal of $\mathcal{H}$, since e^* is the closing edge of this component, which is not part of G^*. Recall that by definition, the vertices v_{c_y} and v_{c_x} corresponding to c_y and c_x in $\mathcal{H}$ are adjacent. Assume that c_y is visited before c_x in the BFS traversal; the other case is symmetric. By our construction rule, when considering c_y, we started the walk from the vertex u that is the first vertex of c_y in $\prec_x$, which means u also belongs to a component c'_x of H_x. Since c_y is a cycle, u is incident to an edge in M_2, which then also belongs to c'_x. Clearly, the edge of M_2 incident to u is the closing edge of c_y and contained in c'_x, which implies that the edge does not belong to c_x, hence this case does not occur in G^*. ◀

By the last case of Lemma 6, it follows that if the edge e^* exists, then it is the only closing edge of two components, which is summarized in the following corollary.

▶ **Corollary 7.** *There is at most one edge in M_2 that is a closing edge for two components.*

We now describe how to add the edge e^* to Γ^* if such an edge exists to obtain the final drawing Γ. Let u and v be the endvertices of e^* with u being the origin vertex of G. By construction, u and v are in the first two components c and c' of the BFS traversal of $\mathcal{H}$. Since u is the first vertex in $\prec_y$, its y-coordinate is 1, i.e., u is the bottommost vertex of Γ^*. Also, since u is the first vertex of c' in $\prec_y$, it is incident to the closing edge of c' and c by definition, in particular, this edge is e^*. Note that this implies that the x-coordinate of v is 1, so v is the leftmost vertex of Γ^* and the first vertex in $\prec_x$. This ensures that v can be moved to the left and u to the bottom in order to draw the edge e^* crossing-free. In particular, moving v by n units to the left and u by n units to the bottom we can guarantee that e^* does not intersect the first quadrant $\mathbb{R}^2_+$, while by construction any other edge (not incident to u or v) lies in $\mathbb{R}^2_+$. Since e^* is the only edge of M_2 incident to u and v, it remains to consider the edges of M_1 and M_3 incident to u or v. Observe that the edge of M_1 incident to v remains horizontal, while the edge of M_3 incident to u remains vertical. Finally, the edge of M_1 incident to u is crossing free in Γ^*, since there is no vertex below it, hence it remains crossing-free after moving u to the bottom. Similarly, the edge of M_3 incident to v is crossing free in Γ^*, since there is not vertex to the left of it, hence it remains crossing-free after moving v to the left. Together with Lemma 6 we obtain that Γ is a RAC drawing of G. We complete the proof of Theorem 3 by discussing the time complexity and the required area. We construct the components of H_y and H_x based on the given edges-coloring using BFS in $\mathcal{O}(n)$ time. To define $\prec_y$ and $\prec_x$, we choose the origin vertex u and the components c and c' for the start of the BFS of $\mathcal{H}$ in linear time. We then traverse every edge of G at most twice. Hence, this step takes $\mathcal{O}(n)$ time in total. Assigning the vertex coordinates, by first iterating through $\prec_y$ and $\prec_x$ and then possibly moving the end-vertices of e^*, clearly takes $\mathcal{O}(n)$ time again, hence the drawing can be computed in linear time.

For the area, we observe that the initial x- and y-coordinates for all the vertices range between 1 and n. Since we possibly move the origin vertex u and its M_2 neighbor v by n units each, the drawing area is at most $2n \times 2n$.

We conclude this section by mentioning two results that form generalizations of our approach of Theorem 3. In this regard, we need the notion of oddness of a bridgeless 3-regular graph, which is defined as the minimum number of odd cycles in any possible 2-factor of it. Theorem 8 is limited to oddness-2, while Theorem 9 provides an upper bound on the number of edges requiring one bend that is linear in the oddness; their proofs are in [2].

▶ **Theorem 8.** **(*)** *Every bridgeless* 3*-regular graph with oddness* 2 *admits a RAC drawing in quadratic area which can be computed in subquadratic time.*

▶ **Theorem 9.** **(*)** *Every bridgeless* 3*-regular graph with oddness* $k \geq 2$ *admits a* 1*-bend RAC drawing in quadratic area where at most* k *edges require one bend.*

4 1-Bend RAC Drawings of Degree-4 graphs

In this section, we focus on degree-4 graphs and show that they admit 1-bend RAC drawings.

▶ **Theorem 10.** *Given a degree-*4 *graph* G *with* n *vertices, it is possible to compute in* $O(n)$ *time a* 1*-bend RAC drawing of* G *with* $O(n^2)$ *area.*

Proof. By Theorem 2, we augment G into a directed 4-regular multigraph G' with edge disjoint 2-factors F_1 and F_2. Let G_s be the graph obtained from G' as follows. For each vertex u of G' with incident edges $(a_1, u), (u, b_1) \in F_1$ and $(a_2, u), (u, b_2) \in F_2$, we add two vertices u_s and u_t to G_s that are incident to the following five edges: u_s is incident to the two incoming edges of u, namely, (a_1, u_s) and (a_2, u_s), while u_t is incident to (u_t, b_1) and (u_t, b_2). Finally, we add the edge (u_s, u_t) to G_s, which we call *split-edge*.

By construction, G_s is 3-regular and 3-edge colorable, since each vertex of it is incident to one edge of F_1, one edge of F_2 and one split-edge. By applying the algorithm of Theorem 3 to G_s, we obtain a RAC drawing Γ_s of G_s, such that the matching M_2 in the algorithm is the one consisting of all the split-edges. To obtain a 1-bend drawing for G', it remains to merge the vertices u_s and u_t for every vertex u in G'. We place u at the position of u_s in Γ_s. We draw each outgoing edge (u, x) of u as a polyline with a bend placed close to the position of u_t in Γ_s (the specific position will be discussed later), which implies that the two segments are close to the edges (u_s, u_t) and (u_t, x) in Γ_s, respectively. This guarantees that any edge has exactly one bend, as any edge is outgoing for exactly one of its endvertices.

We next discuss how we place the bends for the outgoing edges of u. Since each split-edge belongs to M_2, it is drawn in Γ_s either as the diagonal of a 1 × 1 grid box or as a closing edge. Also, since the outgoing edges of u are in M_1 and M_3, they are drawn as horizontal and vertical line-segments.

Assume first that the split-edge of u is the diagonal of a 1 × 1 grid box; see Fig. 3a. If the outgoing edge (u_t, x) belongs to M_1, then we place the bend of (u, x) either half a unit to the right of u_t if x is to the right of u_t in Γ_s, or half a unit to its left otherwise. Symmetrically, if (u_t, x) belongs to M_3, we place the bend half a unit either above or below u_t.

Assume now that the split-edge of u is a closing edge in exactly one of H_y or H_x, say w.l.o.g. of a cycle c in H_x, i.e., it spans the whole x-interval of c. By construction, the outgoing edge of (u_t, x) that belongs to M_3 is a vertical line-segment attached above u, as either u_t or u_s are the first vertex of c in $\prec_y$; in the latter case, u_t is the second vertex of c in $\prec_y$ by construction. If the edge (u_t, x) belongs to M_3, we place the bend exactly at the computed position of u_t. If (u_t, x) belongs to M_1, we place it either half a unit to the right of u_t if x is to the right of u_t in Γ_s, or half a unit to its left otherwise; see Fig. 3b.

Assume last that the split-edge of u is the closing edge e for a H_y and a H_x cycle, which is unique by Corollary 7. As discussed for the analogous case in Section 3 (see the discussion following Corollary 7), one of u_s and u_t, say w.l.o.g. u_s, is the leftmost, while the other u_t is the bottommost vertex in Γ_s. For the placement of the bends, we slightly deviate from our approach above. Let (u_t, x) and (u_t, y) be the two edges of M_1 and M_3 incident to u_t in G_s. Then, it is not difficult to find two grid points b_x and b_y sufficiently below the positions of x and y in Γ_s, such that (u, x) and (u, y)

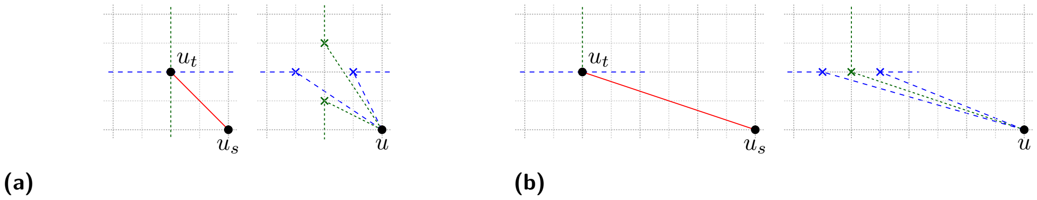

Figure 3 Illustration on how to place the bends in the proof of Theorem 10. To merge the vertices u_s and u_t of a vertex u in G', u is placed at the position of u_s. The bends of the outgoing edges at u are placed close to the position of u_t in the drawing depending on their orientation.

drawn by bending at b_x and b_y do not cross. Since no two bends overlap, no new crossings are introduced and the slopes of the segments involved in crossings are not modified, the obtained drawing Γ' is a 1-bend RAC drawing for G' (and thus for G).

Regarding the time complexity, we observe that we can apply Theorem 2 and the split-operation in $\mathcal{O}(n)$ time. The split operation immediately yields a valid 3-coloring of the edges, hence we can apply the algorithm of Theorem 3 to obtain Γ_s in $\mathcal{O}(n)$ time. Finally, contracting the edges can clearly be done in $\mathcal{O}(n)$ time, as it requires a constant number of operations per edge. For the area, we observe that in order to place the bends, we have to introduce new grid-points, but we at most double the number of points in any dimension, hence we still maintain the asymptotic quadratic area guaranteed by Theorem 3. ◀

The following theorem, whose proof is in [2], provides an alternative construction which additionally guarantees a linear number of edges drawn as straight-line segments.

▶ **Theorem 11.** **(*)** *Given a degree-4 graph G with n vertices and m edges, it is possible to compute in $O(n)$ time a 1-bend RAC drawing of G with $O(n^2)$ area where at least $\frac{m}{8}$ edges are drawn as straight-line segments.*

5 RAC drawings of 7-edge-colorable degree-7 graphs

We prove that 7-edge-colorable degree-7 graphs admit 2-bend RAC drawings by proving the following slightly stronger statement.

▶ **Theorem 12.** *Given a degree-7 graph G decomposed into a degree-6 graph H and a matching M, it is possible to compute in $O(n)$ time a 2-bend RAC drawing of G with $O(n^2)$ area.*

Since H is a degree-6 graph, it admits a decomposition into three disjoint (directed) 2-factors F_1, F_2 and F_3 after applying Theorem 2 and (possibly) augmenting H to a 6-regular (multi)-graph. To distinguish between directed and undirected edges, we write $\{u, v\}$ to denote an undirected edge between u and v, while (u, v) denotes a directed edge from u to v. In the following, we will define two total orders $\prec_x$ and $\prec_y$, which will define the x- and y-coordinates of the vertices of G, respectively. We define $\prec_y$ such that the vertices of each cycle in F_1 will be consecutive in $\prec_y$. Initially, for any cycle of F_1, the specific internal order of its vertices in $\prec_y$ is specified by one of the two traversals of it; however, we note here that this choice may be refined later in order to guarantee an additional property (described in Lemma 13). The definition of $\prec_x$ is more involved and will also be discussed later. Theorem 2 guarantees that the edges of F_2 (F_3) are oriented such that any vertex has at most one incoming and one outgoing edge in F_2 (F_3). Once $\prec_y$ and $\prec_x$ are computed, each vertex u of G will be mapped to point $(8i, 8j)$ of the Euclidean plane provided that u is the i-th vertex in $\prec_x$ and the j-th vertex in $\prec_y$. Each vertex u is associated with a closed box $B(u)$ centered at u of size 8×8. We aim at computing a drawing of G in which

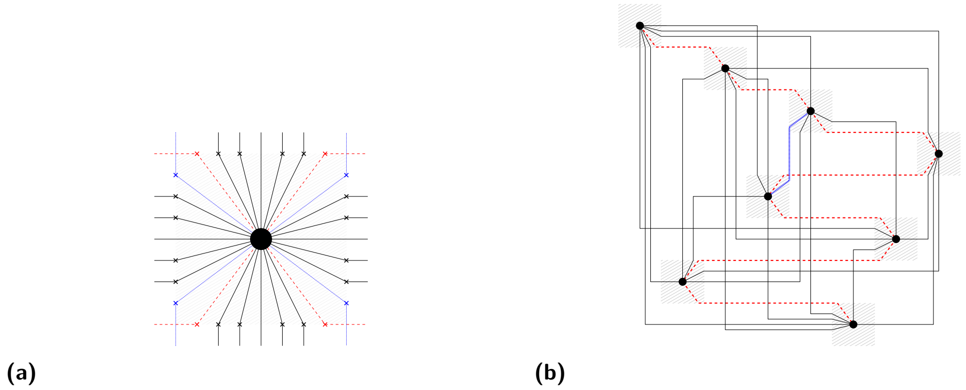

Figure 4 Edge routing in the 8×8 box $B(u)$ of a vertex u (a). Red dashed (blue dotted) ports are reserved for horizontal (vertical) type-2 edges. A 2-bend RAC drawing of K_8 is shown in (b). In this drawing, red dashed edges are horizontal type-2, while the blue dotted one is vertical type-2.

(i) no two boxes overlap, and
(ii) the edges are drawn with two bends each so that only the edge-segments that are incident to u are contained in the interior of $B(u)$, while all the other edge-segments are either vertical or horizontal.

This guarantees that the resulting drawing is 2-bend RAC; see Fig. 4b.

In the final drawing, all edges will be drawn with exactly three segments, out of which either one or two are *oblique*, i.e., they are neither horizontal nor vertical. It follows from (ii) that the bend point between an oblique segment and a vertical (horizontal) segment lies on a horizontal (vertical) side of the box containing the oblique segment. During the algorithm, we will classify the edges as *type*-1 or *type*-2. Type-1 edges will be drawn with one oblique segment, while type-2 edges with two oblique segments. In particular, for a type-1 edge (u, v), we further have that the oblique segment is incident to v, which implies that (u, v) occupies an orthogonal port at u. On the other hand, a type-2 edge (u, v) requires that $B(u)$ and $B(v)$ are *aligned* in y (in x), i.e., there exists a horizontal (vertical) line that is partially contained in both $B(u)$ and $B(v)$, in order to draw the middle segment of (u, v) horizontally (vertically). By construction, this is equivalent to having u and v consecutive in $\prec_y$ ($\prec_x$). These alignments guarantee that if we partition the edges of F_1 into $\bar{F_1}$ and $\hat{F_1}$ containing the closing and non-closing ones, respectively, then it is possible to draw $\hat{F_1}$ as a horizontal type-2 edge (independent of the x-coordinate of its endvertices), as its endvertices are consecutive in $\prec_y$ by construction. Thus, we can put our focus on edges in $\bar{F_1} \cup F_2 \cup F_3$, which we initially classify as type-1 edges (by orienting each edge (u, v) of $\bar{F_1}$ from u to v if $u \prec_y v$). We refine $\prec_y$ using the concept of *critical vertices*. Namely, for a vertex u of G, the direct successors of u in $\bar{F_1} \cup F_2 \cup F_3$ are the critical vertices of u, which are denoted by $c(u)$. Based on the relative position of u to its critical vertices in $\prec_y$, we label u as (α, β), if α vertices $t_1, \dots, t_\alpha$ of $c(u)$ are after u in $\prec_y$ and β vertices $b_1, \dots, b_\beta$ before. We refer to $t_1, \dots, t_\alpha$ ($b_1, \dots, b_\beta$) as the *upper* (*lower*) *critical neighbors* of u. An edge connecting u to an upper (lower) critical neighbor is called *upper critical* (*lower critical*, respectively). More general, the upper and lower critical edges of u are its *critical edges*.

Note that $2 \leq \alpha + \beta \leq 3$ as any vertex has exactly one outgoing edge in F_2 and F_3 and at most one in $\bar{F_1}$, that is, the number of upper and lower critical neighbors of vertex u ranges between 2 and 3. It follows that the label of each vertex of H is in $\{(0, 2), (1, 1), (2, 0), (1, 2), (2, 1), (3, 0)\}$; refer to these labels as the *feasible labels* of the vertex.

Observe that a $(3,0)$-, $(2,1)$- or $(1,2)$-label implies that the vertex is incident to a closing edge of F_1 (hence, each cycle in F_1 has at most one such vertex, which is its first one in $\prec_y$). This step will complete the definition of $\prec_y$.

▶ **Lemma 13.** **(*)** *For each cycle c of F_1, there is an internal ordering of its vertices followed by a possible reorientation of one edge in $F_2 \cup F_3$, such that in the resulting $\prec_y$*

(a) *every vertex of c has a feasible label,*
(b) *no vertex of c has label $(3,0)$, and*
(c) *if there exists a $(1,2)$-labeled vertex in c, then its (only) upper critical neighbor belongs to c.*

Now that $\prec_y$ is completely defined, we orient any edge $(u,v) \in M$ from u to v if and only if $u \prec_y v$. In this case, we further add v as a critical vertex of u. This implies that some vertices can have one more critical upper neighbor, which then gives rise to the new following labels, which we call *tags* for distinguishing: $\{[3,1],[3,0],[2,2],[2,1],[2,0],[1,2],[1,1],[0,2]\}$. In this context, Lemma 13 guarantees the following property.

▶ **Property 14.** *Any cycle c of F_1 has at most one vertex with tag $[\alpha,\beta]$ such that $\alpha+\beta=4$.*

Next, we compute the final drawing satisfying Properties (i) and (ii) by performing two iterations over the vertices of G in reverse $\prec_y$ order. In the first, we specify the final position of each vertex of G in $\prec_x$ and classify its incident edges while maintaining the following Invariant 15. In the second one, we exploit the computed $\prec_x$ to draw all edges of G.

▶ **Invariant 15.** *The endvertices of each vertical type-2 edge are consecutive in $\prec_x$. Further, any vertex is incident to at most one vertical type-2 edge.*

The second part of Invariant 15 implies that the vertical type-2 edges form a set of independent edges. In this regard, we say that a vertex u is a *partner* of a vertex v in G if and only if u and v are connected with an edge in this set.

In the first iteration, we assume that we have processed the first i vertices $v_n,\dots,v_{n-i+1}$ of G in reverse $\prec_y$ order and we have added these vertices to $\prec_x$ together with a classification of their incident edges satisfying Invariant 15. We determine the position of v_{n-i} in $\prec_x$ based on the $\prec_x$ position of its upper critical neighbors. The incident edges of v_{n-i} are classified based on a case analysis on its tag $[\alpha,\beta]$. Recall that unless otherwise specified, every edge is a type-1 edge.

1. The tag of v_{n-i} is $[3,1]$ or $[3,0]$: Let a, b and c be the upper critical neighbors of v_{n-i}, which implies that they were processed before v_{n-i} by the algorithm and are already part of $\prec_x$. W.l.o.g. assume that $a \prec_x b \prec_x c$. By Invariant 15, vertex b is the partner of at most one already processed vertex b', which is consecutive with b in $\prec_x$. If b' exists and $b' \prec_x b$, then we add v_{n-i} immediately after b in $\prec_x$. Symmetrically, if b' exists and $b \prec_x b'$, then we add v_{n-i} immediately before b in $\prec_x$. Otherwise, we add v_{n-i} immediately before b in $\prec_x$. This guarantees that v_{n-i} is placed between a and c in $\prec_x$ and that Invariant 15 is satisfied, since none of the upper critical edges incident to v_{n-i} was classified as a type-2 edge.
2. The tag of v_{n-i} is $[2,1]$,$[2,0]$, $[1,2]$, $[1,1]$ or $[0,2]$: By appending v_{n-i} to $\prec_x$, we maintain Invariant 15, since none of the upper critical edges incident to v_{n-i} was classified as type-2.
3. The tag of v_{n-i} is $[2,2]$: Let a and b be the upper critical neighbors of v_{n-i}, which implies that they were processed before v_{n-i} by the algorithm and are already part of $\prec_x$. W.l.o.g.

assume that $(v_{n-i}, a) \in M$. We classify the edge (v_{n-i}, b) as a vertical type-2 edge and we add v_{n-i} immediately before b in $\prec_x$. To show that Invariant 15 is maintained by this operation it is sufficient to show that b was not incident to a vertical type-2 edge before. Suppose for a contradiction that there is a vertex b' in $\{v_n, \dots, v_{n-i+1}\}$, such that (b, b') or (b', b) is a type-2 edge. As seen in the previous cases, this implies that b or b' has tag $[2, 2]$, respectively. Since in the $[2, 2]$ case the edge classified as type-2 is the one not in M and since any vertex that has tag $[2, 2]$ has label $(1, 2)$, by Lemma 13 it follows that vertical type-2 edges are chords of a cycle. Hence, b or b' would lie in the same cycle as v_{n-i}, which is a contradiction to Property 14, thus Invariant 15 holds.

Orders $\prec_x$ and $\prec_y$ define the placement of the vertices. By iterating over the vertices, we describe how to draw the edges to complete the drawing such that Properties (i) and (ii) are satisfied. We distinguish cases based on the tag of the current vertex v_i.

1. The tag of v_i is $[3, 1]$ or $[3, 0]$: Let $\{a, b, c\}$ be the upper critical neighbors of v_i. The construction of $\prec_x$ ensures that not all of $\{a, b, c\}$ precede or follow v_i in $\prec_x$, w.l.o.g. we can assume that $a \prec_x b, v_i \prec_x c$. Then, we assign the W-port at v_i to (v_i, a), the N-port at v_i to (v_i, b) and the E-port at v_i to (v_i, c). If v_i has a lower critical neighbor, we assign the S-port at v_i for the edge connecting v_i to it.
2. The tag of v_i is $[2, 1]$ or $[2, 0]$: Let $\{a, b\}$ be the upper critical neighbors of v_i. We assign the N-port at v_i to (v_i, a). Note that v_i was appended to $\prec_x$ during its construction. If $b \prec_x v_i$, we assign the W-port at v_i to (v_i, b). Otherwise, we assign the E-port at v_i to (v_i, b). The S-port is assigned to the lower critical edge of v_i, if present.
3. The tag of v_i is $[1, 2]$ or $[0, 2]$: This case is symmetric to the one above by exchanging the roles of upper and lower critical neighbors and N- and S-ports.
4. The tag of v_i is $[1, 1]$: Let a be the upper critical neighbor and b the lower critical neighbor of v_i. Then we assign the N-port to the edge (v_i, a) and the S-port to (v_i, b).
5. The tag of v_i is $[2, 2]$: Let $\{a, b\}$ and $\{c, d\}$ be the upper and lower critical neighbors of v_i. W.l.o.g. let $(v_i, a) \in M$. By Invariant 15 and construction, the edge (v_i, b) is a type-2 edge. The N- and S-ports at v_i are assigned to the edges (v_i, a) and (v_i, c). If $d \prec_x v_i$, we assign the W-port at v_i to (v_i, d). Otherwise, we assign the E-port at v_i to (v_i, d).

We describe how to place the bends of the edges on each side of the box $B(u)$ of an arbitrary vertex u based on the type of the edge that is incident to u, refer to Fig. 4a. We focus on the bottom side of $B(u)$. Let (x_u, y_u) be the position of u that is defined by $\prec_x$ and $\prec_y$. Recall that the box $B(u)$ has size 8×8. Let $e = \{u, v\}$ be an edge incident to u. If e is a horizontal type-2 edge, then we place its bend at $(x_u - 3, y_u - 4)$, if $v \prec_x u$, otherwise we have $u \prec_x v$ and we place the bend at $(x_u + 3, y_u - 4)$. If e is a type-1 edge that uses the S-port of u, then segment of e incident to u passes through point $(x_u, y_u - 4)$. If e is a type-1 edge oriented from v to u such that $v \prec_y u$ and e uses either the W-port or the E-port of v, then we place the bend at $(x_u + i, y_u - 4)$ with $i \in \{-2, -1, 1, 2\}$. Since any vertex has at most four incoming type-1 edges after applying Lemma 13, we can place the bends so that no two overlap. No other edge crosses the bottom side of $B(u)$. The description for the other sides can be obtained by rotating this scheme; for the left and the right side the type-2 edges are the vertical ones.

We now describe how to draw each edge $e = (u, v)$ of G based on the relative position of u and v in $\prec_x$ and $\prec_y$ and the type of e. Refer to Fig. 4b. Suppose first that e is a type-2 edge. If e is a horizontal type-2 edge, then u and v are consecutive in $\prec_y$ and $B(u)$ and $B(v)$ are aligned in y-coordinate, in particular, there is a horizontal line that contains the top side of one box and the bottom side of the other, hence it passes through the two assigned bend-points, which implies that the middle segment is horizontal. Similarly, if e is a vertical type-2 edge, then u and v are consecutive in $\prec_x$ by Invariant 15. Hence, the assigned points for the bends define a vertical middle segment. Suppose now that e is a type-1 edge. The case analysis for the second iteration over the vertices guarantees that for any relative position of v to u, we assigned an appropriate orthogonal port at u which allows to find a point on the first segment, such that the orthogonal middle-segment of the edge e (that is perpendicular to the first) can reach the assigned bend point on the boundary of $B(v)$.

We argue that the constructed drawing is indeed 2-bend RAC as follows. By construction, every edge consists of three segments and no bend overlaps with an edge or with another bend. Each vertical (horizontal) line either crosses only one box or contains the side of exactly two boxes, whose corresponding vertices are consecutive in $\prec_x$ ($\prec_y$). This implies that if a vertical (horizontal) segment of an edge shares a point with the interior of a box, then this box correspond to one of its endvertices. Further, any oblique segment is fully contained inside the box of its endvertex, hence crossings can only happen between a vertical and a horizontal segment which implies that the drawing is RAC.

To complete the proof of Theorem 12, we discuss the time complexity and the required area. We apply Theorem 2 to $G \setminus M$ to obtain F_1, F_2, F_3 in $\mathcal{O}(n)$ time. Computing the labels clearly takes $\mathcal{O}(n)$ time. For each cycle of F_1, the ordering of its internal vertices in Lemma 13 can be done in time linear in the size of the cycle by computing for each vertex the number of forward and backward edges, and of chords. Computing the tags takes $\mathcal{O}(n)$ time. In each of the following two iterations, we perform a constant number of operations per vertex. Hence we can conclude that the drawing can be computed in $\mathcal{O}(n)$ time. For the area, we can observe that the size of the grid defined by the boxes is $8n \times 8n$ and by construction, any vertex and any bend point is placed on a point on the grid.

▶ **Corollary 16.** *Given a 7-edge-colorable degree-7 graph with n vertices and a 7-edge-coloring of it, it is possible to compute in $O(n)$ time a 2-bend RAC drawing of it with $O(n^2)$ area.*

6 Conclusions and Open Problems

We significantly extended the previous work on RAC drawings for low-degree graphs in all reasonable settings derived by restricting the number of bends per edge to 0, 1, and 2. The following open problems are naturally raised by our work.

- Are all 4-edge-colorable degree-3 graphs RAC (refer to Question 1)?
- Are all degree-5 graphs 1-bend RAC? What about degree-6 graphs?
- Is it possible to extend Theorem 12 to all (i.e., not 7-edge-colorable) degree-7 graphs or even to (subclasses of) graphs of higher degree, e.g. Hamiltonian degree-8 graphs?
- While recognizing graphs that admit a (straight-line) RAC drawing is NP-hard [5], the complexity of the recognition problem in the 1- and 2-bend setting is still unknown.

Abstract

A *rotor walk* in a directed graph can be thought of as a deterministic version of a Markov Chain, where a pebble moves from vertex to vertex following a simple rule until a terminal vertex, or sink, has been reached. The *ARRIVAL problem*, as defined by Dohrau et al. [8], consists in determining which sink will be reached. While the walk itself can take an exponential number of steps, this problem belongs to the complexity class NP ∩ co-NP without being known to be in P. In this work, we define a class of directed graphs, namely *tree-like multigraphs*, which are multigraphs having the global shape of an undirected tree. We prove that in this class, ARRIVAL can be solved in almost linear time, while the number of steps of a rotor walk can still be exponential. Then, we give an application of this result to solve some deterministic analogs of stochastic models (e.g., Markovian decision processes, Stochastic Games).

1 Introduction

The *rotor routing*, or *rotor walk model*, has been studied under different names: *eulerian walkers* [17, 16] and *patrolling algorithm* [19]. It shares many properties with a more algebraic focused model: *abelian sandpiles* [4, 15]. We can cite [12] and [15] as general introductions to this cellular automaton.

Let us explain briefly how a rotor walk works. Consider a directed graph and for each vertex v, if v has k outgoing arcs, number these arcs from 1 to k. Then, we place a pebble on a starting vertex and proceed to the walk. On the initial vertex, the pebble moves to the next vertex according to arc 1. It does the same on the second vertex and so on. But the second time that a vertex is reached, the pebble will move according to arc 2, and so on until arc k has been used, and then we start again with arc 1.

In this work, we fix a set of vertices that we call sinks and stop the walking process when a sink is reached. The problem of determining, for a starting configuration (numbering) of arcs and an initial vertex, which sink will be reached first is the ARRIVAL problem. It

is defined in [8] together with a proof that the problem belongs to the complexity class NP ∩ co-NP, but it is not known to be in P. It has then been shown in [10] that the problem is in the smaller complexity class UP ∩ co-UP, and a subexponential algorithm has been proposed in [11], based on computing a Tarski fixed point. This algorithm is even polynomial if the graph is almost acyclic (in a certain sense). A direct application of the rotor-routing automaton is that several structural properties of Markov chains can be approximated or bounded by rotor walks see [6, 7, 9]. It seems natural to extend these results to one and two player variants and define rotor analogs for *Markov decision processes* and *stochastic games* [18]. It is proved in [18] that deciding if a player can ensure some value is NP-complete for the one-player version and PSPACE-complete for the two-player version.

Contributions and Organization of the Paper

We define the class of *tree-like multigraphs*, and prove that while the number of steps needed to complete a rotor walk can still be exponential, the tree-like structure helps to efficiently solve ARRIVAL in linear time. We also extend our results to one-player and two-player variants. It is to be noted that tree-like multigraphs are not almost acyclic in the sense of [11], thus their algorithm does not run in polynomial time in our case.

In Section 2, we first give some standard definitions for multigraphs and proceed to define rotor walks in this context, together with different rotor-routing notions (*exit pattern, cycle pushing*, etc.). Next, in Section 3, we define tree-like multigraphs and our main tool to study ARRIVAL on these graphs, namely the *return flow.* Then, in Section 4, we sketch a polynomial algorithm that solves ARRIVAL and finally we show that this algorithm can be used to efficiently solve both the one and two player case.

The following table summarizes our results (bold), i.e. time complexity of computing the sink (or the optimal sink, for one-player and two-player) reached by a particle starting on a particular vertex in a graph $G = (V, A)$. Results on simple tree-like multigraphs depicted here and quickly presented in this paper are detailed in our extended version [1]. The first column states the complexity of the natural algorithm to solve these problems, namely simulating the *rotor walk.*

	Rotor Walk	0 player	1 player	2 players
General digraph	*exponential*	NP ∩ coNP	NP-complete	PSPACE-complete
Tree-like multigraph	**exponential**	$\boldsymbol{O(\lvert A\rvert)^\dagger}$	$\boldsymbol{O(\lvert A\rvert)}$	$\boldsymbol{O(\lvert A\rvert)}$
Simple Tree-like multigraph	$\boldsymbol{O(\lvert V\rvert^2)}$	$\boldsymbol{O(\lvert V\rvert)^\dagger}$	$\boldsymbol{O(\lvert V\rvert)^\dagger}$	$\boldsymbol{O(\lvert V\rvert)^\dagger}$

The † indicates the cases where we can solve the problem for all vertices of the graph at the same time with this complexity. Note that all proofs that do not appear directly in the document are detailed in our extended version [1].

2 Basic Definitions

2.1 Directed Multigraphs

In this paper, unless stated otherwise, we always consider a directed multigraph $G = (V, \mathcal{A}, h, t)$ where V is a finite set of *vertices*, $\mathcal{A}$ is a finite set of *arcs*, and h (for *head*) and t (for *tail*) are two maps from $\mathcal{A}$ to V defining incidence between arcs and vertices. For sake of clarity, we only consider graphs without arcs of the form $h(a) = t(a)$ (i.e. loops). All our complexity results would remain true if we authorized them. Note that multigraphs can have multiple arcs with the same head and tail. Let $u \in V$ be a vertex, we denote by $\mathcal{A}^+(u)$ (resp. $\mathcal{A}^-(u)$) the subset of arcs $a \in \mathcal{A}$ with tail u (resp. with head u).

Let $\Gamma^+(u)$ (resp. $\Gamma^-(u)$) be the subset of vertices $v \in V$ such that there is an arc $a \in \mathcal{A}$ with $h(a) = v$ and $t(a) = u$ (resp.$h(a) = u$ and $t(a) = v$). A graph such that for all $u \in V$ we have $|\mathcal{A}^+(u)| = |\Gamma^+(u)|$ is called *simple.* A vertex u for which $|\Gamma^+(u) \cup \Gamma^-(u)| = 1$ is called a *leaf.*

2.2 Rotor Routing Mechanics

Rotor Graphs

Let $G = (V, \mathcal{A}, h, t)$ be a multigraph.

▶ **Definition 1** (Rotor Order). *We define a* rotor order *at $u \in V$ as an operator denoted by θ_u such that:*

- $\theta_u : \mathcal{A}^+(u) \to \mathcal{A}^+(u)$
- *for all $a \in \mathcal{A}^+(u)$, the orbit $\{a, \theta_u(a), \theta_u^2(a), ..., \theta_u^{|\mathcal{A}^+(u)|-1}(a)\}$ of arc a under θ_u is equal to $\mathcal{A}^+(u)$, where $\theta_u^k(a)$ is the composition of θ_u applied to arc a exactly k times.*

Observe that each arc of $\mathcal{A}^+(u)$ appears exactly once in any orbit of θ_u. Now, we will integrate the operator θ_u to our graph structure as follows.

▶ **Definition 2** (Rotor Graph). *A* rotor graph *G is a (multi)graph G together with:*

- *a partition $V = V_0 \cup S_0$ of vertices, where $S_0 \neq \emptyset$ is a particular set of vertices called sinks, and V_0 is the rest of the vertices;*
- *a rotor order θ_u at each $u \in V_0$.*

In this document, unless stated otherwise, all the graphs we consider are rotor graphs with $G = (V_0, S_0, \mathcal{A}, h, t, \theta)$.

▶ **Definition 3** (Rotor Configuration). *A* rotor configuration *(or simply configuration) of a rotor graph G is a mapping ρ from V_0 to $\mathcal{A}$ such that $\rho(u) \in \mathcal{A}^+(u)$ for all $u \in V_0$. We denote by $\mathcal{C}(G)$ the set of all rotor configurations on the rotor graph G.*

What will be called a *particle* in the remaining of this paper is a pebble which will move from one vertex to another; hence the position of the particle is characterized by a single vertex. This movement, called rotor walk, follows specific rules that we detail after.

▶ **Definition 4** (Rotor-particle configuration). *A* rotor-particle configuration *is a couple (ρ, u) where ρ is a rotor configuration and $u \in V$ denotes the position of a particle.*

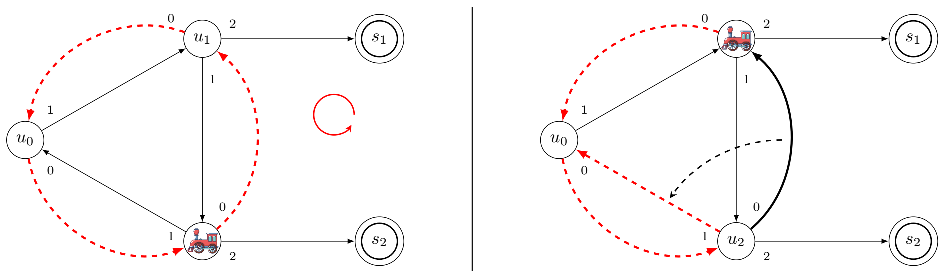
Rotor Walk

▶ **Definition 5.** *Let us define two mappings on $\mathcal{C}(G) \times V_0$:*

- **turn***, with values in $\mathcal{C}(G)$, is defined by* **turn**$(\rho, u) = \rho'$ *where ρ' is equal to ρ except at u where $\rho'(u) = \theta_u(\rho(u))$.*
- **move***, with values in V, is defined by* **move**$(\rho, u) = h(\rho(u))$.

By composing those mappings, we are now ready to define the *routing of a particle* which is a single step of a rotor walk.

▶ **Definition 6** (Routing of a Particle). *The* ***routing*** *of a particle (illustrated in Figure 1) from a rotor-particle configuration (ρ, u) is a mapping:* **routing** $: \mathcal{C}(G) \times V_0 \longrightarrow \mathcal{C}(G) \times V$ *defined by* **routing**$(\rho, u) = (\rho', v)$*, with $\rho' =$* **turn**(ρ, u) *and $v =$* **move**(ρ, u)*. This can be viewed as the particle first travelling through $\rho(u)$ and then $\rho(u)$ is replaced by $\theta_u(\rho(u))$.*



(a) Let ρ be the rotor configuration depicted by the red arcs in dashes.

(b) The red rotor configuration in dashes is obtained by processing the operation: $\mathbf{routing}(\rho, u_2)$.

Figure 1 A rotor-routing where the particle is depicted by a train and starts on u_2. The sink-vertices are s_1 and s_2. The red arcs in dashes represent the current rotor configuration. The rotor orders on the different vertices are anticlockwise, i.e. they are: θ_{u_0}:(u_0,u_2),(u_0,u_1); θ_{u_1}: (u_1,u_0),(u_1,u_2),(u_1,s_1); θ_{u_2}: (u_2,u_1),(u_2,u_0),(u_2,s_2). These orders are also depicted by the numbers around each vertex.

▶ Remark 7. Our routing rule (move, then turn) is slightly different than the one defined in [17] which is mostly used in the literature (turn, then move) but is more convenient to study ARRIVAL. The two rules are equivalent up to applying **turn** mapping on all vertices.

A rotor-routing is in fact a single step of a rotor walk.

▶ **Definition 8** (Rotor Walk). *A* rotor walk *is a (finite or infinite) sequence of rotor-particle configurations* $(\rho_i, u_i)_{i\geq 0}$*, which is recursively defined by* $(\rho_{i+1}, u_{i+1}) = \mathbf{routing}(\rho_i, u_i)$ *as long as* $u_i \in V_0$*.*

One can check that the sequence of vertices in the rotor walk starting from the rotor-particle configuration depicted on Figure 1(b) until a sink is reached is $u_1, u_0, u_2, u_0, u_1, u_2, s_2$.

Routing to Sinks

Now that we have defined our version of rotor-walk, we proceed to the corresponding version of the problem *ARRIVAL* similar to the one stated in [8].

▶ **Definition 9** (Maximal Rotor Walk). *A maximal rotor walk is a rotor walk such that in the case where it is finite, the last vertex must be a sink vertex* $s \in S_0 = V \setminus V_0$*.*

▶ **Definition 10** (Stopping Rotor Graph). *If, for any vertex* $u \in V$*, there exists a directed path from* u *to a sink* $s \in S_0$*, the graph is said to be* stopping.

The next lemma is a classical result on rotor walks (cf Lemma 16 in [12]).

▶ **Lemma 11** (Finite number of steps). *If* G *is stopping then any rotor walk in* G *is finite.*

The main objective of our work is to study the sink that will be reached by a maximal rotor walk from a rotor-particle configuration, if the rotor walk is finite.

▶ **Definition 12** (Exit Sink). *Let* $u \in V$*, let* ρ *be a configuration, if the maximal rotor walk starting from* (ρ, u) *is finite in* G*, then the sink reached by such a rotor walk is denoted by* $\mathbf{S}_G(\rho, u)$ *and called* exit sink *of* u *for the rotor configuration* ρ *in* G*.*

▶ **Definition 13** (Exit Pattern). *For a rotor configuration* ρ *on a stopping rotor graph* G*, the* exit pattern *is the mapping that associates to each vertex* $u \in V$*, its exit sink* $\mathbf{S}_G(\rho, u)$*.*

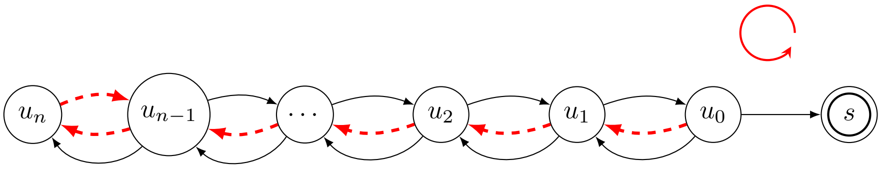


Figure 2 Family of path-like multigraphs where maximal routing can take an exponential number of steps in the number of vertices, here equal to $n+2$. The interior vertices (u_0 to u_{n-1}) have two arcs going left and one going right. Routing a particle from u_0 to sink s with the initial configuration ρ drawn with red arcs in dashes takes a non-polynomial time considering the anticlockwise rotor ordering on each vertex, depicted by the curved arc in red. One can check that the number of times a particle starting from u_0 will travel from u_i to u_{i+1} before reaching s is 2^{i+1}.

2.3 ARRIVAL and Complexity Issues

With our notations, ARRIVAL (see [8]) can be expressed as the following decision problem:

In a stopping rotor graph G,
given (ρ, u) and $s \in S_0$
does $\mathbf{S}_G(\rho, u) = s$?

This problem belongs to NP ∩ co-NP for simple graphs as shown in [8], but there is still no polynomial algorithm known to solve it. The case of eulerian simple graphs can be solved in time $O(|V+\mathcal{A}|^3)$, since a finite maximal rotor walk from (ρ, v) ends in at most $O(|V+\mathcal{A}|^3)$ routings (see [19]).

In the case of multigraphs, ARRIVAL still belongs to NP ∩ co-NP, since the polynomial certificate used for simple graphs in [8] remains valid. Our goal in this paper is to solve the problem in polynomial time for a particular class of multigraphs. Despite that, even for a path multigraph, the routing can be exponential, as shown on Figure 2.

2.4 Cycle Pushing

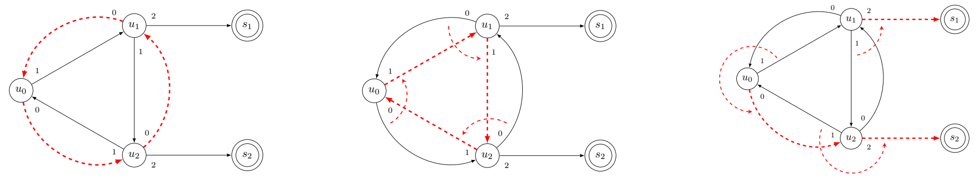
In order to speed-up the rotor walk process, a simple tool to avoid computing every step of the walk is the use of *cycle pushing*. We keep the terminology of *cycle pushing* used in [12] – even if what is called a cycle in this terminology is usually called a directed cycle or circuit in graph theory.

▶ **Definition 14** (Cycle *Pushing*). *Let ρ be a rotor configuration on G containing a directed cycle $C = (u_1, u_2, u_3, ..., u_k)$. We call* cycle push *the operation on ρ that leads to a configuration ρ' such that:*
- *for all $u_i \in C$, $\rho'(u_i) = \theta_{u_i}(\rho(u_i))$;*
- $\forall u \in V_0 \setminus C, \rho'(u) = \rho(u)$

*i.e. we process a **turn** on all $u_i \in C$.*

Note that a cycle push on a cycle C can also be computed by putting a particle on a vertex u of C and routing the particle until it comes back to u for the first time. Hence, cycle pushing is in a sense a shortcut on the rotor walk process, so in a manner similar to Lemma 11 it follows that in a stopping rotor graph, any sequence of cycle pushes is finite. This is a well known result in rotor walk studies (see [15]). It implies that, by processing a long enough sequence of successive cycle pushes, the resulting configuration contains no directed cycles. Such a sequence of cycle pushes is called *maximal.*

The two following results can be found in [12].



(a) Red Rotor Configuration ρ in dashes with rotor order on each vertex described by increasing numbers.

(b) The red configuration in dashes is obtained from a Cycle Push on the cycle $\{(u_0,u_2),(u_2,u_1),(u_1,u_0)\}$.

(c) Destination Forest (depicted by red arcs in dashes) computed by two successive cycle pushes on ρ.

Figure 3 Computation of the Destination Forest by successive cycle pushing.

▶ **Lemma 15** (Exit Pattern conservation for Cycle Push). *If G is a stopping rotor graph, for any rotor configuration ρ and configuration ρ' obtained from ρ by a cycle push, the exit pattern for ρ and ρ' is the same.*

▶ **Lemma 16** (Commutativity of Cycle Push). *In a stopping rotor graph, any maximal sequence of cycle pushes starting from a given rotor configuration ρ leads to the same acyclic configuration ρ' (ρ' does not contain a cycle).*

▶ **Definition 17** (Destination Forest). *We call the configuration obtained by a maximal cycle push sequence on ρ the* Destination Forest *of ρ, denoted by $D(\rho)$.*

The destination forest has a simple interpretation in terms of rotor walks: start a rotor walk by putting a particle on any vertex of a stopping graph G; consider a vertex $u \in V_0$; if the particle ever reaches u, it will leave u by arc $D(\rho)(u)$ on the last time it enters u.

In an acyclic configuration like $D(\rho)$, finding the exit pattern is simple, precisely:

▶ **Lemma 18** (Path to a sink). *If there is a directed path between $u \in V$ and $s \in S_0$ in ρ then $\mathbf{S}_G(\rho, u) = s$. It follows that from $D(\rho)$ one can compute the exit pattern of ρ in time complexity $O(|\mathcal{A}|)$.*

This gives us a new approach, since computing the exit pattern of a configuration ρ can be done by computing its Destination Forest $D(\rho)$. Note that by doing this we are solving a problem harder than ARRIVAL because we compute the exit sink of all vertices simultaneously.

▶ Remark 19. The strategy consisting in pushing cycles until the Destination Forest is reached can take an exponential number of steps. This is the case in the example drawn in Figure 2.

3 Tree-Like Multigraphs: Return Flow Definition

3.1 Tree-Like Multigraphs

To a directed multigraph $G = (V, \mathcal{A}, h, t)$ we associate:

- A simple directed graph $\hat{G} = (V, \hat{\mathcal{A}})$ such that, for $u, v \in V$ there is an arc from u to v in $\hat{G}$ if there is at least one arc $a \in \mathcal{A}$ with $t(a) = u$ and $h(a) = v$. Please note that even if there are multiple arcs a that satisfy this property, there is only one arc with tail u and head v in $\hat{\mathcal{A}}$. As it is unique, an arc from u to v in $\hat{\mathcal{A}}$ will simply be denoted by (u, v).
- A simple undirected graph $\overline{G} = (V, E)$ such that, for $u, v \in V$ there is an edge between u and v in $\overline{G}$ if and only if there is at least one arc $a \in \mathcal{A}$ such that $t(a) = u$ and $h(a) = v$ or $h(a) = u$ and $t(a) = v$.

▶ **Definition 20** (Tree-Like Rotor Multigraph and Tree-Like Multigraph). *A rotor multigraph $G = (V_0, S_0, \mathcal{A}, h, t, \theta)$ is tree-like if $\overline{G}$ is a tree and its set of leaves contains S_0. In that case, we say that $G = (V, \mathcal{A}, h, t)$ is a* tree-like multigraph.

Without loss of generality, in order to avoid some complexity in the notation and proofs, we will only study stopping tree-like rotor multigraphs.

▶ **Definition 21** (Sink Component). *A sink component is a strongly connected component in G that does not contain a sink vertex and such that there is no arc leaving the component.*

Note that all sink components can be computed in linear time.

▶ **Lemma 22** (Lemma 36 in [1]). *Consider a configuration ρ on a (not necessarily stopping) tree-like rotor multigraph $G = (V_0, S_0, \mathcal{A}, h, t, \theta)$. Consider a configuration ρ' on the* stopping *tree-like rotor multigraph $G' = (V_0', S_0', \mathcal{A}', h, t, \theta)$ where G' is obtained from G by replacing each sink component by a unique sink, and where $\rho'(u) = \rho(u)$ for each $u \in V_0'$. For any $u \in V$, finding the exit sink of u (if any) or the sink component reached by u in G for the configuration ρ can be directly determined by solving ARRIVAL for the configuration ρ' in G'.*

Note that, after replacing sink components by sinks, the multigraph G' may no longer be a tree-like multigraph but a forest-like multigraph. However we can split the study of ARRIVAL in each tree-like component of this forest since a particle cannot travel between those trees in a rotor walk.

3.2 Return Flows

Let us consider the simple example depicted on Figure 4 to motivate the introduction of (u, v)-subtrees and return flows, which is our main tool. In this figure, consider the routing of a particle starting at u:

- the particle moves from u to v_1, and stays for a while in the subtree T_1 – where it either reaches a sink or comes back to u. Suppose it comes back to u. Then:
- the particle moves from u to v_3, and either reaches a sink in T_3 or comes back to u. Suppose it comes back to u once again;
- the rotor walk goes on, in T_3, then in $T_2, T_1, T_1, T_3, \ldots$
- until finally the particle ends in a sink in one of the subtrees, say T_2.

Now consider only the relative movement that the particle had in T_2: it went from u into T_2 and back to u a number of times, before it ended in a sink. If we were to replace T_1 and T_3 by single arc leading back automatically to u, the relative movement in T_2 would have been exactly the same. The return flow will be a quantity that counts exactly the ability of each subtree to bounce back the particle to u. During the process described above, every time the particle enters a subtree and comes back to u, we can think of it as consuming a single unit of return flow in this subtree. The first time that a particle enters a subtree that has exactly one unit of return flow left, then the particle must end in a sink of that subtree.

▶ **Definition 23** ((u, v)-subtree). *Let $(u, v) \in \hat{\mathcal{A}}$. The (u, v)-subtree $T_{(u,v)}$ is a sub(multi)graph of G:*

- *whose vertices are all the vertices of the connected component of $\bar{G} \setminus \{u\}$ that contains v, together with u;*
- *whose arcs are all the arcs of G that link the vertices above, excepted in u where we remove all arcs of $\mathcal{A}^+(u)$ but a single arc a with head v. Such an arc a always exists because $(u, v) \in \hat{\mathcal{A}}$;*
- *whose rotor orders are unchanged except at u where $\theta_u(a) = a$.*

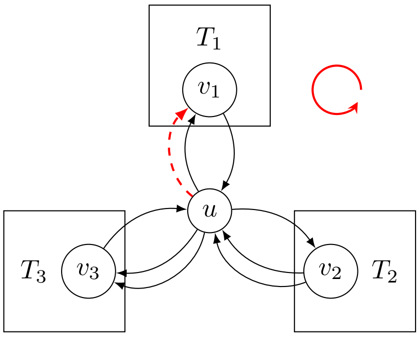


Figure 4 We sketch a stopping tree-like rotor multigraph as follows: a vertex u, its neighbours v_1, v_2, v_3 (that might be sinks), respectively belonging to T_1, T_2, T_3, the three connected components of $\bar{G} \setminus \{u\}$. In particular, we have $\hat{\mathcal{A}}^+(u) = \{(u, v_1); (u, v_2); (u, v_3)\}$. We consider the rotor configuration in red on u and θ_u is the anticlockwise order on the arcs of $\mathcal{A}^+(u)$.

Such a subtree is a (not necessarily stopping) tree-like rotor multigraph. A rotor configuration ρ in G can be thought of as a rotor configuration ρ' in $T_{(u,v)}$ by defining that $\rho'(u) = a$ and $\rho'(w) = \rho(w)$ for all $w \in T_{(u,v)}$.

We define a notion of *flow* for a particular starting vertex.

▶ **Definition 24** (Flow of (u, v))**.** *We define the* flow *on arc $(u, v) \in \hat{\mathcal{A}}$ for configuration ρ, denoted by $F_\rho(u, v)$, the number of times (possibly infinite) that an arc with tail u and head v is visited during the maximal rotor walk of a particle starting from the rotor-particle configuration (ρ, u). We denote by $F_\rho(u)$ the flow vector of (u, v) for every $v \in \Gamma^+(u)$.*

▶ **Definition 25** (Return flow)**.** *The* return flow *of arc $(u, v) \in \hat{\mathcal{A}}$ for configuration ρ, denoted by $r_\rho(u, v)$, is the flow on (u, v) in the (u, v)-subtree $T_{(u,v)}$.*

By definition of return flow, if $u \in S_0$, then $r_\rho(u, v) = 0$, and if $v \in S_0$, or if $(v, u) \notin \hat{\mathcal{A}}$ then $r_\rho(u, v) = 1$. Remark also that, even if the tree-like multigraph is stopping, it is not necessarily the case of any (u, v)-subtree: this is for instance the case of a leaf v which is not a sink such that $(u, v) \in \hat{\mathcal{A}}$. Finiteness of the return flow characterizes the subtrees that are stopping as stated in Lemma 26.

▶ **Lemma 26** (Lemma 40 in [1])**.** *Given a stopping tree-like multigraph G and an arc $(u, v) \in \hat{\mathcal{A}}$, the (u, v)-subtree $T_{(u,v)}$ is stopping if and only if for any rotor configuration on G, the return flow of (u, v) is finite.*

We give a bound on the maximal value of the return flow in a multigraph as it will be used to express our complexity results later.

▶ **Lemma 27** (Return flow bound, Lemma 41 in [1])**.** *Return flows can be written in at most $O(|\mathcal{A}|)$ bits.*

Return flows and flows are linked by the following result:

▶ **Lemma 28** (Lemma 42 in [1])**.** *Given a stopping tree-like rotor multigraph G, consider $u \in V_0$ and suppose that $h(D(\rho)(u)) = v$. Then:*

- *$F_\rho(u, v) = r_\rho(u, v)$;*
- *for all $w \in \Gamma^+(u) \setminus \{v\}$, $\quad F_\rho(u, w) < r_\rho(u, w)$;*
- *for all $w \in \Gamma^+(u) \cap \Gamma^-(u) \setminus \{v\}, r_\rho(w, u) = F_\rho(u, w) + 1$.*

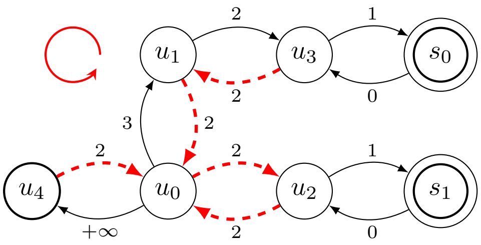

Figure 5 Examples of return flows in a simple graph. The rotor configuration is depicted by red arcs in dashes, with $S_0 = \{s_0, s_1\}$, and θ_{u_i} is the anticlockwise order on every vertex. We write the return flow of all arcs of $\hat{\mathcal{A}}$ next to their corresponding arc in $\mathcal{A}$. As a tutorial example, we detail the computation of $r_\rho(u_1, u_0)$ and $r_\rho(u_0, u_1)$. In the (u_1, u_0)-subtree, the particle will visit the following sequence of vertices $u_1, u_0, u_2, u_0, u_1, u_0, u_4, u_0, u_2, s_1$, where it crosses (u_1, u_0) twice, thus $r_\rho(u_1, u_0) = 2$. For the (u_0, u_1)-subtree, the sequence of vertices visited by the particle is $u_0, u_1, u_0, u_1, u_3, u_1, u_0, u_1, u_3, s_0$ hence $r_\rho(u_0, u_1) = 3$.

Thus, to compute $D(\rho)(u)$, we need to compute the flow of all arcs (u, w) with $w \in \Gamma^+(u)$ and compare it to $r_\rho(u, w)$. Theorem 29 gives the time complexity of such operation where $c(a, b)$ is the time complexity to divide an integer a by an integer b.

▶ **Theorem 29** (Theorem 43 in [1]). *For any vertex $u \in V_0$, given the return flows of all arcs $(u, v) \in \hat{\mathcal{A}}$ with $v \in \Gamma^+(u)$, one can compute $D(\rho)(u)$ and the flow on each arc (u, v) in time $O(|\Gamma^+(u)| \cdot c(r_{\max}, |\mathcal{A}^+(u)|))$ with r_{max} being the maximum (finite) value of $r_\rho(u, v)$ for all $v \in \Gamma^+(u)$.*

But in the case of simple graphs, we can improve this computation (see Lemma 30).

▶ **Lemma 30** (Lemma 61 in [1]). *If the graph is simple, $D(\rho)(u)$ is the first arc with respect to order θ_u, starting at $\rho(u)$, among all arcs of $\mathcal{A}^+(u)$ with minimal return flow. The flow on all arcs $(u, v) \in \hat{\mathcal{A}}$ can be computed in time $O(|\Gamma^+(u)|)$.*

4 ARRIVAL for Tree-Like Multigraphs

In this section we show that, for a given configuration ρ, we can compute the Destination Forest $D(\rho)$ in time complexity $O(|\mathcal{A}| \cdot c(r_{\max}, |\mathcal{A}|))$, hence solve the ARRIVAL problem for every vertex at the same time. To achieve this, we recursively compute return flows for all arcs in $\hat{\mathcal{A}}$ and then use these flows to compute the destination forest.

▶ **Theorem 31** (Complete Destination Algorithm, Theorem 47 in [1]). *The configuration $D(\rho)$ can be computed in time $O(|\mathcal{A}|)$ for a stopping tree-like rotor multigraph in a model where arithmetic operations can be made in constant time, or alternatively in $O(|\mathcal{A}| \cdot c(r_{\max}, |\mathcal{A}|))$ on a Turing Machine.*

Sketch of the Proof. Consider an arbitrary vertex x. We proceed with a Breadth-First Search (BFS) to compute an order such that all necessary return flows are already computed when we use Theorem 29. The algorithm is split into two phases:

1. Computation of the return flows of arcs directed from x towards leaves, starting from the arcs closest to the leaves and recursively coming back to x, using Theorem 29.
2. Computation of the return flows of all remaining arcs, starting from the arcs closest to x and recursively coming back to the leaves. We use Theorem 29 only twice for each vertex u to compute the return flows of all arcs (u, v) with (u, v) being directed from the leaves towards x.

All in all, we use Theorem 29 three times for each vertex, hence the time complexity is $O(\sum_{u \in V} (|\hat{\mathcal{A}}^+(u)| \cdot c(r_{\max}, |\mathcal{A}|)))$ which amounts to $O(|\mathcal{A}| \cdot c(r_{\max}, |\mathcal{A}|))$. ◀

We showed in Lemma 27 that return flows could be written in at most $O(|\mathcal{A}|)$ bits which gives an upper bound for $c(r_{\max}, |\mathcal{A}|)$ of $k|\mathcal{A}|\log(|\mathcal{A}|)$ for some constant $k > 0$. It is proved in [14] that the multiplication of two n bits integers can be done in time $O(n \log(n))$ and as the complexity of the division is equivalent to the complexity of multiplication (see [5]), the bound follows. Thus the complexity of our algorithm is $O(|\mathcal{A}|^2 \log(|\mathcal{A}|))$ in this context.

Simple Graph

In the case of simple graphs, this algorithm has a better complexity as we can use Lemma 30 instead of Theorem 29. Nevertheless, the algorithm remains the same and the complexity sums up to $O(|A|)$ which is also $O(|V|)$ as the graph is simple (details can be found in Theorem 63 in [1]).

5 One and Two player Variants

Problem ARRIVAL can be seen as a zero-player game where the winning condition is that the particle reaches a particular sink (or set of sinks). The one and two players variants of ARRIVAL (i.e. deterministic analogs of *Markov decision processes* and *Stochastic games*) we address in this section are inspired from [18], but differ by the choice of the set of strategies (see the discussion hereafter).

We specifically consider a game with a single player that controls a subset of vertices $V_{\mathcal{MAX}}$ of V_0. Given a rotor configuration on the rest of the vertices of V_0, a starting vertex and a set of targets among the sinks, his goal is to wisely choose the initial rotor configuration of the vertices he controls (his strategy) such that the particle reaches one of the targets.

Our definition of the way a player controls his vertices is somewhat different from the one in the seminal paper [18], where a strategy consists in choosing an outgoing-arc each time the particle is on a vertex controlled by the player. In this sense the set of strategies that we allow (which seems to us a very natural extension of the zero player case) is a finite subset of the version from [18] and could seem easier, but the latter can in fact be solved by some slight modifications of our algorithm. Moreover, the proof of NP-completeness from [18] is still valid in our case, despite the fact that we reduce the number of available strategies.

▶ **Definition 32** (Partial Configuration). *Let V' be a subset of V_0, a* partial rotor configuration *on V' is a mapping ρ' from V' to $\mathcal{A}$ such that $\rho'(u) \in \mathcal{A}^+(u)$ for all $u \in V'$.*

Given the disjoint sets of vertices V_r, $V_{\mathcal{MAX}}$ and S_0, a one-player rotor game (resp. one-player tree-like rotor game) is defined by $(V_r, V_{\mathcal{MAX}}, S_0, \mathcal{A}, h, t, \theta, \mathrm{val}, \rho)$ where:

- $(V_0, S_0, \mathcal{A}, h, t, \theta)$ is a rotor graph (resp. tree-like rotor graph) with $V_0 = V_r \cup V_{\mathcal{MAX}}$;
- val is a map from S_0 to $\{0, 1\}$ defining the target sinks (sinks of value 1);
- ρ is a partial configuration on V_r, i.e. on the vertices not controlled by the player.

The tree-like rotor game is *stopping* if and only if the induced rotor graph $(V_0, S_0, \mathcal{A}, h, t, \theta)$ is stopping. The player is called $\mathcal{MAX}$, and a *strategy* for $\mathcal{MAX}$ is a partial rotor configuration on $V_{\mathcal{MAX}}$. We denote by $\Sigma_{\mathcal{MAX}}$ the finite set of strategies for this player.

Consider a partial rotor configuration ρ on V_r together with strategy σ and denote by (ρ, σ) the rotor configuration where we apply the partial configuration ρ or σ depending on whether the vertex is in V_r or $V_{\mathcal{MAX}}$. The *value of the game* for strategy σ and starting

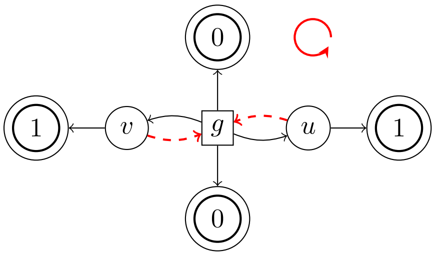

Figure 6 Simple graph where the optimal strategy depends on the starting vertex u_0, with $V_{\mathcal{MAX}} = \{g\}$, with $u, v \in V_0$ and with all other vertices being sinks. As in previous examples, the starting configuration is depicted by red arcs in dashes, and the rotor order on all vertices is an anticlockwise order on their outgoing arcs. In the case $u_0 = v$, the only optimal strategy is $\sigma(g) = (g, v)$ and the game has value 1. In the case $u_0 = u$, the only optimal strategy is $\sigma(g) = (g, u)$ and the game has value 1.

vertex u_0 is denoted by $\mathrm{val}_\sigma(u_0)$ and is equal to $\mathrm{val}(s)$ where s is the sink reached by a maximal rotor walk from the rotor particle configuration $((\rho, \sigma), u_0)$ if any, and 0 otherwise. As in the zero-player framework, up to computing strongly connected components that do not contain sinks and replacing each of them with a sink of value 0, we can suppose that the tree-like rotor game is stopping. In the following, all rotor games we consider are tree-like and stopping unless stated otherwise.

When u_0 is fixed, the maximal value of $\mathrm{val}_\sigma(u_0)$ over strategies $\sigma \in \Sigma_{\mathcal{MAX}}$ is called the *optimal value* of the game with starting vertex u_0 and is denoted by $\mathrm{val}^*(u_0)$. Any strategy $\sigma \in \Sigma_{\mathcal{MAX}}$ such that $\mathrm{val}_\sigma(u_0) = \mathrm{val}^*(u_0)$ is called an *optimal strategy* for the game starting in u_0. Observe that optimal strategies may depend on the choice of u_0 (see Figure 6).

The one-player ARRIVAL problem consists in computing the optimal value of a given starting vertex in a one-player rotor game.

Recall that in the tree-like rotor graph, $T_{(u,v)}$ denotes the (u, v)-subtree. We extend this notation to denote the one-player, not necessarily stopping, game played on the (u, v)-subtree where we restrict $V_{\mathcal{MAX}}$ and V_r to the subtree. For this game, we only consider the case where the starting vertex is u.

▶ **Definition 33** (Value under strategy). *Let (u, v) be an arc of $\hat{\mathcal{A}}$. For a strategy σ on the (u, v)-subtree, we denote by $val_\sigma(u, v)$ (resp. $val^*(u, v)$) the value of the game under strategy σ (resp. under an optimal strategy) in $T_{(u,v)}$. This is called the value (resp. the optimal value) of arc (u, v) for strategy σ.*

▶ **Definition 34** (Optimal return flow r^*). *Let (u, v) be an arc of $\hat{\mathcal{A}}$. If $val^*(u, v) = 0$, then $r^*(u, v)$ is defined as the maximum of $r_\sigma(u, v)$ over all strategies σ on $T_{(u,v)}$, otherwise it is the minimum of $r_{\sigma^*}(u, v)$ among* optimal *strategies σ^* on $T_{(u,v)}$.*

Lemma 35 connects the value $\mathrm{val}_\sigma(u)$ with the value of the last outgoing arc of vertex u while processing a maximal rotor walk from the rotor-particle configuration $((\rho, \sigma), u)$.

▶ **Lemma 35.** *Let a be an arc of $\mathcal{A}^+(u)$ such that $D(\rho, \sigma)(u) = a$ with $h(a) = v$. We have $val_\sigma(u) = val_\sigma(u, v)$.*

To recursively compute an optimal strategy, we need a stronger notion of optimality, namely a *subtree optimal strategy.*

▶ **Definition 36** (Subtree optimal strategy). *A strategy σ^* is* subtree optimal *at u_0 if it is optimal at u_0 and, moreover, $val_{\sigma^*}(u, v) = val^*(u, v)$ and $r_{\sigma^*}(u, v) = r^*(u, v)$ for every (u, v)-subtree such that (u, v) is directed from u_0 towards the leaves.*

Instead of recursively computing only the return flow as in the zero-player game, we now propagate both the optimal value and the optimal return flow to construct a subtree optimal strategy (details in the proof of Theorem 54 in [1]) and give an equivalent of Theorem 31 for the one-player game.

▶ **Theorem 37** (Computation of $\mathrm{val}^*(u_0)$, Theorem 54 in [1])**.** *The optimal value $val^*(u_0)$ can be computed in the same time complexity as the computation of $D(\rho)$ in the zero-player game (see Theorem 31).*

Some remarks are in order here. (i) The algorithm used to compute $\mathrm{val}^*(u_0)$ (Algorithm 3 in [1]) provides the optimal value of u_0 as well as a subtree optimal strategy at u_0 for every decisional vertex. A tutorial example is given in [1] (Figure 11). (ii) This algorithm can also be adapted to compute optimal values for games with more general type of strategies, particularly those in [18]. (iii) In the case of a simple graph, one can compute $\mathrm{val}^*(u_0)$ for every vertex u_0 with the same time complexity as in Theorem 37 as detailed in our extended version [1]. (iv) If we consider a game with integer values on the sinks, one can use a dichotomic process to solve it in $\log(|S|)$ steps where a step consists in solving a binary game.

Two-player Game

In the two-player game, each player controls the initial configuration on disjoint sets of vertices, and the second player wants to minimize the value of the game. In a general graph, there may not exist an equilibrium in pure strategies (see Figure 7 where we define a game equivalent to *matching pennies*). However, in the case of tree-like rotor multigraphs, we can show that there always is an equilibrium in pure strategies and compute it (see [1]). As in the one-player case, if we consider integer values, we can simply proceed using a dichotomy technique.

Conclusion and Future Work

Concerning ARRIVAL, one remaining fundamental question is to determine whether there exists a polynomial algorithm to solve the zero-player game. Similarly, problems such as *simple stochastic games, parity games* and *mean-payoff games* are also in NP ∩ co-NP, and there are no polynomial algorithm known to solve them (see [13]). For those different problems, considering subclasses of graphs where we can find polynomial algorithms is a fruitful approach (see [2] and [3]). This paper is a first step in this direction.

Thus, we would like to study more general classes of graphs. To begin with, even graphs that are well-studied in terms of the *sandpile group* such that ladders or grids remain now an open problem for ARRIVAL. The problem of finding the destination of multiple particles at the same time is also an important open problem in nearly all cases – we solve it for the (simple) path graph in our extended version (see [1]).

Now that the Tree-like multigraph case is settled, it seems natural to try and extend these results to classes of graphs with bounded width (e.g. treewidth, pathwidth, etc.). However, this extension is not direct and requires further work. If we were to replace a single node by a bag of nodes, defining an analog of the rotor ordering, the routine and return flows is much more complicated since a particle can enter and leave the bag in different ways. We need to compute and store all the exit arcs for all entering arcs in the bag for every rotor configuration, and combine these informations for neighbouring bags in order to find locally the destination forest. We intend to finish this work in a near future.

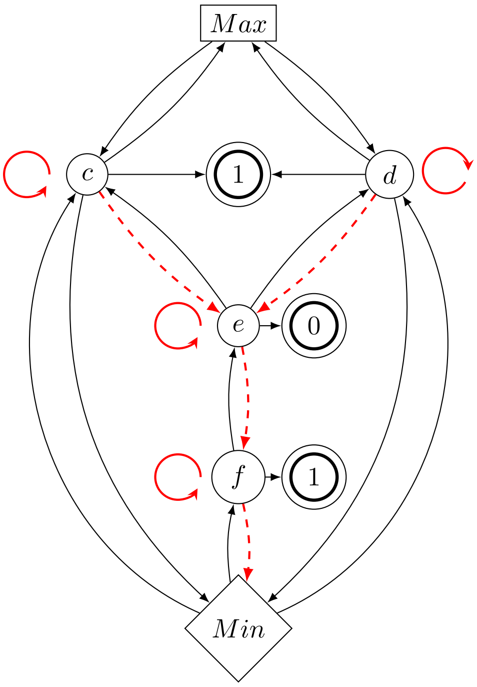

Figure 7 This example is a simple undirected graph where each edge is replaced by two arcs. We have $V_{\mathcal{MAX}} = \{Max\}$, $V_{\mathcal{MIN}} = \{Min\}$ and $V_0 = \{c, d, e, f\}$ and S_0 is the rest of the vertices with their value written inside them. The particle starts on the vertex Max. In this game, the only optimal strategy for $\mathcal{MAX}$ when the strategy for $\mathcal{MIN}$ is the arc (Min, x) with $x \in \{c, d\}$ is (Max, x). On the other hand the only optimal strategy for $\mathcal{MIN}$ when the strategy for $\mathcal{MAX}$ is the arc (Max, c) (resp. (Max, d)) is (Min, d) (resp. (Min, c)). The situation is like the classical matching pennies game where one player tries to match the strategy of the opponent whereas the other player has the opposite objective. It is known that such game does not admit a Nash equilibrium in pure strategies.

Abstract

The Distance Realization problem is defined as follows. Given an $n \times n$ matrix D of nonnegative integers, interpreted as inter-vertex distances, find an n-vertex weighted or unweighted graph G realizing D, i.e., whose inter-vertex distances satisfy $dist_G(i,j) = D_{i,j}$ for every $1 \le i < j \le n$, or decide that no such realizing graph exists. The problem was studied for general weighted and unweighted graphs, as well as for cases where the realizing graph is restricted to a specific family of graphs (e.g., trees or bipartite graphs). An extension of Distance Realization that was studied in the past is where each entry in the matrix D may contain a *range* of consecutive permissible values. We refer to this extension as Range Distance Realization (or Range-DR). Restricting each range to at most k values yields the problem k-Range Distance Realization (or k-Range-DR). The current paper introduces a new extension of Distance Realization, in which each entry $D_{i,j}$ of the matrix may contain an arbitrary set of acceptable values for the distance between i and j, for every $1 \le i < j \le n$. We refer to this extension as Set Distance Realization (Set-DR), and to the restricted problem where each entry may contain at most k values as k-Set Distance Realization (or k-Set-DR).

We first show that 2-Range-DR is NP-hard for unweighted graphs (implying the same for 2-Set-DR). Next we prove that 2-Set-DR is NP-hard for unweighted and weighted trees. We then explore Set-DR where the realization is restricted to the families of stars, paths, or cycles. For the weighted case, our positive results are that for each of these families there exists a polynomial time algorithm for 2-Set-DR. On the hardness side, we prove that 6-Set-DR is NP-hard for stars and 5-Set-DR is NP-hard for paths and cycles. For the unweighted case, our results are the same, except for the case of unweighted stars, for which k-Set-DR is polynomially solvable for any k.

1 Introduction

Background. *Network realization* problems are fundamental graph-algorithmic questions in which one is asked to construct a network conforming to some predefined requirements. Given a *specification* (or *information profile*) that consists of constraints on some network parameters, such as the vertex degrees, distances, or connectivity, one is required to construct a network conforming to the given specification, i.e., satisfying the requirements, or to determine that no such network exists. The motivation for network realization problems stems from both "exploratory" contexts where one attempts to reconstruct an *existing* network of unknown structure based on the outcomes of experimental measurements, and engineering contexts related to network design.

In the Distance Realization problem, the given profile is an $n \times n$ matrix D such that each entry $D_{i,j} \in \mathbb{N} \cup \{\infty\}$, for $1 \leq i < j \leq n$, and $D_{i,i} = \{0\}$, for every $1 \leq i \leq n$. We view $D_{i,j}$ as specifying the required distance between the vertices i and j in the network. A graph $G = (V, E)$ is a *realization* of D if $dist_G(i,j) = D_{i,j}$, for every $1 \leq i < j \leq n$, where $dist_G(i,j)$ denotes the distance between i and j in G. Generally, we may be interested in two types of realizing graphs. In unweighted Distance Realization it is assumed that each edge of the realizing graph is of length 1. In weighted Distance Realization the edges of the realizing graph may have any positive integral lengths.

Observe that an unweighted realizing graph is fully determined by D: the edge (i,j) exists in the graph if and only if $D_{i,j} = 1$. It follows that there is only one graph G_D that may serve as a candidate realizing graph. This was observed by Hakimi and Yau [12], who provided a characterization for distance realization by unweighted graphs, implying also a polynomial-time algorithm for unweighted Distance Realization. Notice also that in the case where the realization is required to be a specific graph H, one can solve unweighted Distance Realization by deciding whether H and G_D are isomorphic. This Graph Isomorphism problem is computationally easy when H belongs to certain graph types, such as stars, paths, and cycles, and therefore the problem of distance realization by such graphs can be solved in polynomial time.

Hakimi and Yau [12] also studied weighted Distance Realization. They proved that the necessary and sufficient condition for the realizability of a given martix D is that D is a metric. Furthermore, they gave a polynomial-time algorithm that computes a realization for any given metric distance matrix. More specifically, their algorithm constructs a minimum-edge realizing graph whose edges are necessary in every realization of D.

Patrinos and Hakimi [14] considered the case where weights can be negative. They showed that any symmetric matrix (with zero diagonal) is a distance matrix of some graph G. They gave necessary and sufficient conditions for realizing such a matrix by a tree, and they showed that if a tree realization exists it is unique. Distance Realization in *weighted trees* was considered in [2], which presented a characterization for realizability. For unweighted trees, there is a straightforward realization algorithm, based on the algorithm of [12] for general unweighted graphs, and on the fact that the realization, if exists, is unique. Distance realization restricted to bipartite graphs was studied in [4], where it was observed that it is sufficient to check the unique realization in the unweighted case or the minimal realization in the weighted case.

A natural extension of Distance Realization is when each entry in the distance matrix may contain a *range* of consecutive values instead of a single value. Range specifications may arise, for example, when D reflects the properties of an unknown network, and its values are obtained by imprecise measurements, or alternatively, when D represents a design specification for a planned network in a setting where distance constraints are not rigid and allow some flexibility. Formally, we are given two values $D^-_{i,j}$ and $D^+_{i,j}$ for every i, j and the realizing G must satisfy $D^-_{i,j} \leq dist_G(i,j) \leq D^+_{i,j}$. We refer to this extended version of the problem as Range Distance Realization (or Range-DR).

Tamura et al. [18] obtained necessary and sufficient conditions for the realizability of a range distance matrix by weighted graphs, generalizing the result of [12] from precise to range specifications. A polynomial-time algorithm for weighted Range-DR was given in [15]. The unweighted version of Range-DR was shown to be NP-hard in [4], where it was also shown that if the realizing graph is required to be a tree, then both the unweighted and weighted versions of Range-DR are NP-hard.

Realization with Distance Sets. In this paper we introduce a novel extension of Range Distance Realization, called Set Distance Realization (Set-DR). Instead of a *range*, we assume that each entry $D_{i,j}$ in the distance matrix specifies a *set* of acceptable values for the distance between i and j, for every $1 \le i < j \le n$. More formally, consider an $n \times n$ matrix D, such that each entry $D_{i,j} \subseteq \mathbb{N} \cup \{\infty\}$, for $1 \le i < j \le n$, is a non-empty set, and $D_{i,i} = \{0\}$, for every $1 \le i \le n$. We view $D_{i,j}$ as specifying a list of acceptable values of the distance between i and j, where i and j are vertices in some network. A graph $G = (V, E)$ is a *realization* of the D if $dist_G(i, j) \in D_{i,j}$, for every $1 \le i < j \le n$.

One of the main questions studied in this paper involves the effect of limiting the number of values in each entry of the matrix D. This question is equally interesting for Set-DR and Range-DR. Given an integer k, we say that the matrix D is a k*-set* distance matrix if $|D_{i,j}| \le k$ for every $1 \le i < j \le n$. A distance matrix D is a k*-range* distance matrix, if $D_{i,j}$ is a range that contains at most k consecutive values for every $1 \le i < j \le n$. A 1-set distance profile is called *precise*. Restricting the Set Distance Realization problem to k-set distance matrices yields the problem k-Set Distance Realization (or k-Set-DR). Similarly, restricting the Range Distance Realization problem to k-range distance matrices yields the problem k-Range Distance Realization (or k-Range-DR).

Henceforth, we assume that entry $D_{i,j}$ in a 2-set distance matrix D consists of two integers, $D_{i,j} = \left\{d^0_{i,j}, d^1_{i,j}\right\}$, which need not be distinct.

Our Results. In this paper we study the computational complexity of k-Set-DR and k-Range-DR, as a function of k, in various graph families.

Inspecting the proof given in [4] for the hardness results for Range-DR by trees and unweighted graphs reveals that 3-Range-DR is already NP-hard over these graph families, implying that 3-Set-DR is NP-hard as well. We modify the reductions from [4] to show that already 2-Range-DR is NP-hard for general unweighted graphs, where precise realization is known to be polynomial [12]. For general weighted graphs, it is known that Range-DR is computationally easy [15]. We note that the algorithm from [15] does not work for Set-DR, since it relies on the continuity of the given ranges. In fact, Set-DR for general weighted graphs remains an open problem. We show that both unweighted 2-Set-DR and weighted 2-Set-DR are NP-hard for trees. Thus, we obtain a dichotomy between 2-set distance realization and precise realization for trees, since precise realization is known to be solvable in polynomial time [12, 2].

Next, we show that 2-Set-DR is polynomial time solvable for stars, paths, and cycles. Our realization algorithms are based on a reduction to the 2-SAT problem (satisfiability of a 2-CNF formula), which can be solved in linear time [10]. The idea is to use one vertex i_0 as a point of reference for all other vertices. Thus, a Boolean variable b_j is associated with each vertex j and determines which of the two values of $D_{i_0,j}$ should be used. The 2-CNF formula is constructed according to the rest of the entries of D. Applying this approach for stars is rather straightforward, but it becomes more complicated for paths, and especially for cycles. In addition, we prove that there exists a polynomial time algorithm for k-Set-DR on unweighted stars, for any k. For weighted stars, we present a polynomial time realization algorithm for Range-DR when the range values are polynomially bounded. This algorithm is based on a reduction to the feasibility problem of linear integer programs with at most two variables per constraint, which can be solved efficiently [5].

On the hardness side, we show that Set-DR is NP-hard for weighted stars already with 6-set distance profiles. We obtain slightly tighter results for paths and cycles, for which both unweighted Set-DR and weighted Set-DR are already NP-hard already with 5-set

distance profiles. Our hardness results are based on reductions from the 3-colorability problem. However, the reductions are not similar. Specifically, in the case of weighted stars, the possible colors of a vertex are encoded in the distance matrix by possible edge weights, while in the case of weighted and unweighted paths, the colors are encoded by vertices and their location on the path. The hardness result for 5-Set-DR on the cycle is obtained by a reduction from 5-Set-DR on the path.

Tables 1 and 2 summarize our results.

Related Work. An optimization variant of Distance Realization problem was introduced in [12]. In this problem, a distance matrix D is given over a set S of n vertices, and the goal is to find a graph G including S, with possibly *auxiliary* vertices, that realizes the given distance matrix for S. Necessary and sufficient conditions are given for a matrix to be realizable by a weighted or an unweighted graph. It is shown in [9] that an optimal realization can have at most n^4 vertices, and therefore, there is a finite (but exponential) time algorithm to find an optimal realization. In [1] it is shown that finding optimal realizations of distance matrices with integral entries is NP-complete, and evidence to the difficulties in approximating the optimal realization is provided in [6]. Over the years, various heuristics for optimal realizations were considered [13, 16, 17, 19]. Since optimal realization seems hard even to approximate, special cases and other variations have been studied [6, 11].

[1] This result requires that the entries of D are polynomially bounded.

Special attention has been given to the optimal distance realization problem where the realizing graph is a tree. In [12], a procedure is given for finding a tree realization of D if exists. It is also shown therein that a tree realization, if exists, is unique and is the optimum realization of D. Necessary and sufficient conditions for a distance matrix to be realizable by a tree were given in several papers [3, 8, 17]. Finally, an $O(n^2)$ time algorithm for optimal tree-realization is described in [7].

2 Realizations by Trees and Unweighted Graphs

In this section we consider unweighted realizations in general graphs and both unweighted and weighted realizations in trees.

2.1 Realizations by Unweighted Graphs

For general graphs, recall that the range realization problem in weighted graphs and the precise realization problem in unweighted graphs both have a polynomial time algorithm. We provide an NP-hardness result for Range-DR by unweighted graphs, even for 2-range distance profiles.

▶ **Theorem 1.** *2-Range-DR is NP-hard in unweighted graphs.*

Proof. We prove the theorem using a reduction from the 3-coloring problem.

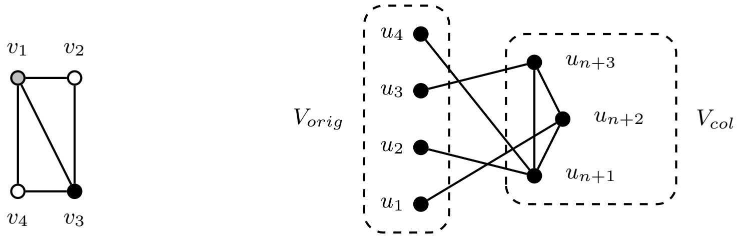
Consider an instance G of the 3-coloring problem. We construct a 2-range distance matrix D for $n+3$ vertices, i.e., for the vertex set $\{u_1, \ldots, u_{n+3}\}$. Intuitively, we think of the first n vertices, $V_{orig} = \{u_1, \ldots, u_n\}$, as representing the *original* vertices of the given graph G, and of additional 3 vertices of D, $V_{col} = \{u_{n+1}, u_{n+2}, u_{n+3}\}$, as representing the three *colors*. Let

$$D_{i,j} = \begin{cases} \{1\} & i = n+1, \ldots, n+3, \quad j = n+1, \ldots, n+3, \\ \{1,2\} & i = 1, \ldots, n, \quad j = n+1, \ldots, n+3, \\ \{2,3\} & 1 \le i < j \le n, \quad (v_i, v_j) \notin E(G), \\ \{3\} & 1 \le i < j \le n, \quad (v_i, v_j) \in E(G). \end{cases}$$

We now prove that the input G is 3-colorable if and only if D is realizable by an unweighted graph. (See Figure 1 for an illustration.)

Suppose G is 3-colorable. Let $\chi : V(G) \mapsto \{1, \ldots, 3\}$ be the coloring function. For the matrix D defined from G, construct a realizing graph $\mathcal{G}$ as follows. Start with a triangle containing the color vertices $u_{n+1}, u_{n+2}, u_{n+3}$. Connect each original vertex u_i to the color vertex $u_{n+\chi(i)}$. It is easy to verify that $\mathcal{G}$ realizes D (see Figure 1b for an example).

Suppose there exists an unweighted graph $\mathcal{G}$ which realizes the matrix D. Consider two original vertices u_i and u_j. Since $1 \notin D_{i,j}$, it follows that u_i and u_j are not connected by an edge. Therefore, every original vertex u_i must be connected to at least one of the color vertices. Define a coloring function for G as follows. For every original vertex u_i, let $n+c$ be some color vertex connected to u_i, and let $\chi(v_i) = c$. Since $1, 2 \notin D_{i,j}$, if two vertices v_i and v_j are connected by an edge in G, then their distance in $\mathcal{G}$ must be at least 3. This ensures that none of the color vertices are connected to both u_i and u_j (as this would make their distance 2). It follows that if $(v_i, v_j) \in E(G)$, then v_i and v_j are assigned different colors. ◀



(a) A 3-colorable graph. **(b)** A realization of D.

Figure 1 An example of the reduction in the proofs of Theorem 1 for $n = 4$. White, gray, and black correspond to nodes $n + 1$, $n + 2$, and $n + 3$, respectively.

2.2 Tree Realizations

Next, we show that distance realization in unweighted or weighted trees is hard even for 2-set distance profiles. The reduction we use is almost identical to a reduction from [4] that (implicitly) shows hardness for 3-range distance profiles. The proof is ommited for lack of space.

▶ **Theorem 2.** *2-Set-DR is NP-hard for both unweighted trees and weighted trees.*

3 Star Realizations

In this section we study Set-DR in stars. We show that there exists a polynomial time algorithm that solves weighted 2-Set-DR in stars. On the other hand, we show that 5-Set-DR on weighted stars is NP-hard. Furthermore, we present a polynomial time algorithm that solves k-Range-DR on weighted stars, for any k, provided that matrix entries are polynomially bounded.

To put these results in context, it may be useful to observe that the *unweighted* case in stars is easier: unweighted k-Set-DR in stars can be solved in polynomial time for any k.

3.1 2-Set-DR on Stars is Easy

We show that the 2-Set-DR problem in stars can be solved efficiently.

▶ **Theorem 3.** *There exists a polynomial time algorithm for 2-Set-DR on stars.*

Proof. Assume that i is the center of the star. It follows that the weight of any edge (i, j), for $j \neq i$ can be either $d^0_{i,j}$ or $d^1_{i,j}$. Define a Boolean variable x_j, where $x_j = \text{FALSE}$, if the weight of the edge (i, j) is $d^0_{i,j}$, and $x_j = \text{TRUE}$, if the weight of the edge (i, j) is $d^1_{i,j}$. The rest of the entries of D are used to create a 2-CNF formula that is satisfiable if and only if there exists a star realization of D in which i is the center.

Consider two vertices $j, k \neq i$. Since there are two possible weights for the edges (i, j) and (i, k), it follows that there are four possible distances from j to k:

1. $d^0_{i,j} + d^0_{i,k}$,
2. $d^0_{i,j} + d^1_{i,k}$,
3. $d^1_{i,j} + d^0_{i,k}$, and
4. $d^1_{i,j} + d^1_{i,k}$.

For each one of the above four options, check whether it equals $d^0_{j,k}$ or $d^1_{j,k}$. This induces a truth table on the variable x_j and x_k that can be represented by at most two 2-CNF clauses.[2] Doing this for all pairs of vertices creates a 2-CNF formula that contains at most $O(n^2)$ clauses by concatenating all the above mentioned clauses.

Suppose that there exists a star realization P of D with i as a center. This induces an assignment to the variables Boolean variables that satisfies the 2-CNF formula. On the other hand, assume that the 2-CNF formula that is obtained by assuming that i is the center is satisfiable. A satisfying assignment induces a star, which complies with the profile.

Since there are n candidates for the center vertex, we need to run the above process n times. It follows that the total running time of the algorithm is $O(n^3)$. ◀

We remark that the running time for unweighted case can be improved to $O(n^2)$.

▶ **Theorem 4.** *There exists a polynomial time algorithm for k-SET-DR on unweighted stars, for any k.*

Proof. Since all distances in an unweighted star are either 1 or 2, one may assume that $D_{i,j} \subseteq \{1, 2\}$, for every $i \neq j$. The theorem follows due to Theorem 3. ◀

3.2 6-Set-DR on Weighted Stars is Hard

We show that the star realization problem is NP-hard even on 6-set distance profiles.

▶ **Theorem 5.** *6-SET-DR is NP-hard in weighted stars.*

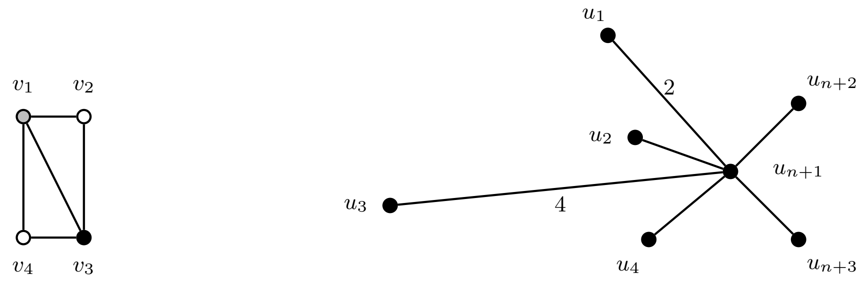
Proof. We prove the lemma using a reduction from the 3-COLORING problem.

Consider a graph G, where $V(G) = \{v_1, \ldots, v_n\}$. We construct a distance matrix D on $n + 3$ vertices, denoted by $\{u_1, \ldots, u_{n+3}\}$. Informally, the distance matrix is defined to force u_{n+1} to be the center of the star while u_{n+2} and u_{n+3} must be two of the leaves whose distance from the center is 1. The rest of the vertices, $u_1, \ldots, u_n$ that are associated with the n vertices $v_1, \ldots, v_n$ of G, are leaves whose distance from the center is either 1, 2, or 4. The idea is that distance 2^c is associated with the color c (0, 1, or 2). Finally, the distances between these n leaves is defined to guarantee that the two endpoints of any edge of G are associated with different colors, if a realization exists. More formally, the 6-set distance matrix D is defined as follows for any two indices $1 \leq k < \ell \leq n + 3$:

$$D_{k,\ell} = \begin{cases} \{3,5,6\} & k, \ell \leq n, (v_k, v_\ell) \in E(G), \\ \{2,3,4,5,6,8\} & k, \ell \leq n, (v_k, v_\ell) \notin E(G), \\ \{1,2,4\} & k \leq n, \ell = n+1, \\ \{2,3,5\} & k \leq n, \ell = n+2, n+3, \\ \{1\} & k = n+1, \ell = n+2, n+3, \\ \{2\} & k = n+2, \ell = n+3 \ . \end{cases}$$

We show that G is 3-colorable if and only if D is realizable by weighted star.

[2] For example, let $D_{i,j} = \{2, 3\}$, $D_{i,k} = \{3, 4\}$, and $D_{j,k} = \{5, 7\}$. There are two possible weight assignments: either $w(i, j) = d^0_{i,j}$ and $w(i, k) = d^0_{i,k}$ or $w(i, j) = d^1_{i,j}$ and $w(i, k) = d^1_{i,k}$ This can be represented by the clause $(\neg x_j \vee \neg x_k) \wedge (x_j \vee x_k)$.



(a) A 3-colorable graph. **(b)** A realization of D.

Figure 2 An example of the reduction in the proof of Theorem 5 for $n = 4$. White, gray, and black correspond to the weights of the edges of the star. Edges without a label are of weight 1.

Assume that G is 3-colorable and $\chi : V \mapsto \{0, 1, 2\}$ is a 3-coloring of G. We describe a star realization S. First, let u_{n+1} be the center of the star. Vertices u_{n+2} and u_{n+3} are leaves such that $w(u_{n+1}, w_{n+2}) = w(u_{n+1}, w_{n+2}) = 1$. Next, for every $i \in \{1, \dots, n\}$, if $\chi(v_i) = c$, then $w(u_{n+1}, u_i) = 2^{\chi(v_i)}$. It is straightforward to verify that S realizes D. In particular, we observe that the first requirement of D is satisfied, since χ is a 3-coloring.

For the other direction, suppose that S is a star realization of D. First, notice that the above distance matrix makes sure that $u_{n+2}, u_{n+1}, u_{n+3}$ form a path with two edges of weight 1. Hence, u_{n+1} must be the center of the star. We define a coloring χ of $V(G)$ according to the weights of the edges to the center: $\chi(v_i) = \log_2 w(u_{n+1}, u_i)$. χ is a proper 3-coloring, since the first requirement of D ensures that $w(u_{n+1}, u_i) \neq w(u_{n+1}, u_j)$ if $(v_i, v_j) \in E$. This is because $2 = 1 + 1$, $4 = 2 + 2$, and $8 = 4 + 4$ are not members of $\{3, 5, 6\}$ which are the possible distances between u_i and u_j. (See Figure 2.) ◀

3.3 Range-DR on Weighted Stars

In [4] it was shown that there exists a polynomial time algorithm that solves the Range-DR problem on a given fixed weighted tree, assuming that non-integral edges weights are allowed. Let D be a range distance matrix, where $D_{ij} = \left\{D^-_{ij}, \dots, D^+_{ij}\right\}$. Also, let $T = (V, E_T)$ be a known tree, and let $P_{k,\ell} = (k = i_0, i_1, \dots, i_{t_{k,\ell}} = \ell)$ be the unique path from vertex k to vertex ℓ in T. For each edge $(i, j) \in E_T$, let $w_{i,j}$ be the variable that denotes the weight of this edge. Consider the following linear program:

$$\sum_{j=0}^{j=t_{k,\ell}-1} w_{i_j,i_{j+1}} \geq D^-_{k,\ell} \qquad \forall P_{k,\ell}$$

$$\sum_{j=0}^{j=t_{k,\ell}-1} w_{i_j,i_{j+1}} \leq D^+_{k,\ell} \qquad \forall P_{k,\ell}$$

The algorithm from [4] finds a realization by obtaining a feasible solution to the above program.

As mentioned above this approach may obtain a realization with non-integral edge weights and distances. Moreover, it may be the case that there exists a realization with non-integral edge weights, while a realization with integral edge lengths does not exist. For example, consider the following distance matrix:

$$D = \begin{pmatrix} \{0\} & \{3\} & \{3\} & \{1,2\} \\ \{3\} & \{0\} & \{3\} & \{1,2\} \\ \{3\} & \{3\} & \{0\} & \{1,2\} \\ \{1,2\} & \{1,2\} & \{1,2\} & \{0\} \end{pmatrix}$$

D admits no star realization with integral weights, but if one allows edge lengths and distances of 1.5, then a realization exists (where vertex v_4 is the center, and all edge weights are 1.5).

We show that the realization problem with integral edge weights is solvable on stars, assuming that the entries of D are polynomially bounded.

▶ **Theorem 6.** *Assume that the entries of D are polynomially bounded. Then there exists a polynomial time algorithm for* RANGE-DR *on weighted stars.*

Proof. Fix the center of the star, and consider the above LP. Since all paths are of length one or two, the resulting integer linear program contains at most two variables per inequality. Since we require integral weights, we add the following integrality constraints: $w_i \in \mathbb{N}$, for every i. The feasibility problem of integer programs with at most two variables per constraint is solvable in $O(mU)$, where m is the number of constraints and U is the range of the variables [5]. In this case $U = \max_{i,j}(D_{ij})$. ◀

Notice that the above mentioned NP-hardness for 6-SET-DR applies to profiles in which each entry is composed of at most 6 constants, which means that it is polynomially bounded.

4 Path Realizations

In this section we study the realization of distance profiles by paths. We first show that if each entry of the distance matrix consists of at most two different values then a realization by a path (if exists) can be found by a polynomial time algorithm. On the other hand, we show that SET-DR on paths is NP-hard, even on 5-set distance profiles. Both results hold both for weighted and unweighted paths.

4.1 Algorithm for 2-Set-DR on Paths

A path P realizes the 2-set distance profile D if either $dist_P(i,j) = d^1_{i,j}$ or $dist_P(i,j) = d^2_{i,j}$ holds for every i and j.

We show that 2-SET-DR on weighted paths can be solved by a reduction to 2-CNF satisfiability, which can be solved in $O(m)$ time [10], where m is the number of clauses.

▶ **Theorem 7.** *There exists a polynomial time algorithm for 2-*SET*-DR on weighted paths.*

Proof. Assume that the weighted path is embedded on the real line where the vertices are located at integers and the distance between any two vertices is their distance on the line. Furthermore, assume that the leftmost vertex is vertex i and it is located at 0.

Any realization of D in which i is the left-most node, implies that vertex $j \neq i$ is located either at $d^0_{i,j}$ or at $d^1_{i,j}$. Define a Boolean variable x_j, where $x_j =$ FALSE represents that j is located at $d^0_{i,j}$ and $x_j =$ TRUE represents that j is located at $d^1_{i,j}$. The rest of the entries of D will create a 2-CNF formula that is satisfiable if and only if there exists a realization of D on the path in which i is the left-most vertex.

Consider the possible placements of two vertices $j, k \neq i$. Since each one of them has two possible placements, it follows that there are four possible placements of j and k:

1. j at $d^0_{i,j}$ and k at $d^0_{i,k}$,
2. j at $d^0_{i,j}$ and k at $d^1_{i,k}$,
3. j at $d^1_{i,j}$ and k at $d^0_{i,k}$, and
4. j at $d^1_{i,j}$ and k at $d^1_{i,k}$.

For each one of the above four options, check whether it complies with $d^0_{j,k}$ or with $d^1_{j,k}$. This induces a truth table on the variable x_j and x_k that can be represented by at most two 2-CNF clauses. Doing this for all pairs of vertices creates a 2-CNF formula that contains at most $O(n^2)$ clauses by concatenating all the above mentioned clauses.

If there exists a path realization P of the profile, then embed it on the real line such that the left-most vertex i of P is located at 0. Then, consider the formula that we get by assuming that i is the left-most vertex of P, and assign values to the Boolean variables according to the distances from i. Since P realizes the profile, the 2-CNF formula must be satisfied. On the other hand, assume that the 2-CNF formula that is obtained by assuming that i is placed on 0 is satisfiable. A satisfying assignment induces a placement of the vertices on the real line, and this implies a realization of the profile.

Since there are n candidates for the left-most vertex we need to run the above process n times. It follows that the total running time of the algorithm is $O(n^3)$. ◀

The same proof works for the unweighted case. One only need to notice that in this case all the distances are integers in the range $\{1, \ldots, n-1\}$ and therefore the placement of the vertices is a bijection from $\{1, \ldots, n\}$ to $\{0, \ldots, n-1\}$.

▶ **Theorem 8.** *There exists a polynomial time algorithm for 2-Set-DR on unweighted paths.*

4.2 Hardness Result

Range-DR in weighted paths was shown to be NP-hard in [4] using a reduction from the Linear Arrangement problem. This result also applies to unweighted paths. It is important to note that the reduction constructs a matrix with unlimited ranges.

We start the section with an alternative and simpler proof that also requires unlimited ranges.

▶ **Theorem 9.** *Range-DR is NP-hard in both weighted and unweighted paths.*

Proof. We prove the theorem using a reduction from Hamiltonian Path. Given a graph G, construct the following distance matrix:

$$D_{i,j} = \begin{cases} \{1, \ldots, n-1\} & (v_i, v_j) \in E(G) \ , \\ \{2, \ldots, n-1\} & (v_i, v_j) \notin E(G) \ . \end{cases}$$

If G has a Hamiltonian path, then this path induces a realization of D. On the other hand, a realization of D corresponds to a Hamiltonian path in G. ◀

Next we show that the Set-DR problem on paths is NP-hard even on 5-set distance profiles.

▶ **Theorem 10.** *5-Set-DR is NP-hard in unweighted and weighted paths.*

Proof. We prove the lemma using a reduction from the 3-coloring problem.

Consider a graph G, where $V(G) = \{v_1, \ldots, v_n\}$. We construct a distance matrix D on $3n+2$ vertices, denoted $\{u_0, \ldots, u_{3n+1}\}$. Intuitively, the vertices u_{3i-2}, u_{3i-1} and u_{3i} represent vertex v_i in the original graph, and the location of u_{3i-2} encoded the color of v_i.

The vertices u_0 and u_{3n+1} are the end-points of the path, and they serve as preference points. More formally, for every x, we define $\bar{x} \triangleq \lceil x/3 \rceil$. The matrix is defined as follows for any two indices $0 \le k < \ell \le 3n+1$:

$$D_{k,\ell} = \begin{cases} \{3n+1\} & k=0, \ell=3n+1, \\ \{3\bar{\ell}-2, 3\bar{\ell}-1, 3\bar{\ell}\} & k=0, \bar{\ell} \in \{1,\dots,n\}, \\ \{3n-3\bar{k}+1, 3n-3\bar{k}+2, 3n-3\bar{k}+3\} & \bar{k} \in \{1,\dots,n\}, \ell = 3n+1, \\ \{1,2\} & \bar{k} = \bar{\ell}, \\ \{3(\bar{\ell}-\bar{k})+\Delta : \Delta \in \{-2,-1,0,1,2\}\} & \bar{k} < \bar{\ell}, \\ & k \bmod 3 \neq 1 \text{ or } \ell \bmod 3 \neq 1 \\ & \text{ or } (v_{\bar{k}}, v_{\bar{\ell}}) \notin E(G), \\ \{3(\bar{\ell}-\bar{k})+\Delta : \Delta \in \{-2,-1,1,2\}\} & \bar{k} < \bar{\ell}, \\ & k, \ell \bmod 3 = 1, (v_{\bar{k}}, v_{\bar{\ell}}) \in E(G) . \end{cases}$$

Observe that D is a 5-set distance matrix. Also, notice that only the last requirement is not a range, and it consists of a union of two ranges of size 2.

We show that G is 3-colorable if and only if D is realizable using an unweighted path.

Assume that G is 3-colorable and $\chi : V \mapsto \{0,1,2\}$ is a 3-coloring of G. We describe a path realization as a placement of the vertices on integral points from 0 to $3n+1$. First, u_0 is placed on 0 and u_{3n+1} is placed on $3n+1$. Next, for every $i \in \{1,\dots,n\}$, if $\chi(v_i) = c$, then u_{3i-2} is placed at location $3i-2+c$. The vertices u_{3i-1} and u_{3i} are placed at the two remaining free locations from $\{3i-2, 3i-1, 3i\}$. It is straightforward to verify that P realizes D. We observe that the last requirement of D is satisfied, since χ is a 3-coloring. See example in Figure 3.

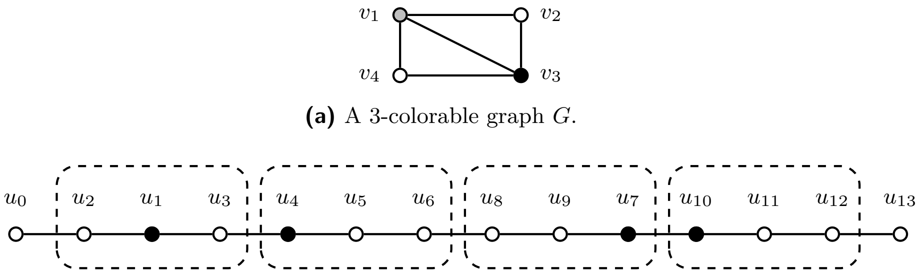
Now suppose that P is a path realization of D. First, notice that the above distance matrix makes sure that the distance between u_0 and u_{3n+1} must be $3n+1$. Moreover, all the other distances are strictly less than $3n+1$. Hence, if a path realization exists, then we may assume without loss of generality that u_0 is placed on 0 and u_{3n+1} is placed on $3n+1$. In the weighted case, it follows that all other vertices are located at $\{1,\dots,3n\}$, which means that all edges are of unit length. Since the distances between u_{3i-2}, u_{3i-1} and u_{3i} are 1 or 2, for every $i \in \{1,\dots,n\}$, these three nodes are forced to appear as a sub-path of P consisting of two edges. Moreover, the required distances from u_0 and u_{3n+1} forces u_{3i-2}, u_{3i-1} and u_{3i} to be assigned to the three consecutive positions $3i-2, 3i-1, 3i$ on the path. We define a coloring χ according to the positions of $\{u_{3i-2} : i \in \{1,\dots,n\}\}$. More specifically, $\chi(v_i) = c$ if u_{3i-2} is located at $3i-2+c$. χ is a 3-coloring, since the last requirement of D ensures that $\chi(v_i) \neq \chi(v_j)$ if $(v_i, v_j) \in E$. ◀

The above proof implies an even stronger result, that we will need in the sequel for the hardness of 5-Set-DR in cycles.

▶ **Theorem 11.** *5-Set-DR is NP-hard in unweighted and weighted paths, even when the required end-points of the path are given in the input.*

5 Cycle Realizations

As was the case with the path, we first show that for 2-set distance profiles a realization by a cycle, if exists, can be found with a polynomial time algorithm. On the other hand, we show that the Set-DR problem on cycles is NP-hard even on 5-set distance profiles, by a reduction from the path realization problem.



(a) A 3-colorable graph G.

(b) A realization of D.

Figure 3 An example of the reduction in the proof of Theorem 10. White, gray, and black are colors 0, 1, and 2, respectively. The location of full nodes correspond to the chosen colors.

5.1 Realization of 2-set distance Profiles by Cycles

A cycle C realizes the 2-set distance profile D if either $dist_C(i,j) = d^1_{i,j}$ or $dist_C(i,j) = d^2_{i,j}$ holds for every i and j.

The proofs of theorems 12 and 13 are omitted due to the page restriction.

▶ **Theorem 12.** *There exists a polynomial time algorithm for 2-Set-DR on unweighted cycles.*

▶ **Theorem 13.** *There exists a polynomial time algorithm for 2-Set-DR on weighted cycles.*

5.2 Hardness Result

We start the section with a hardness proof that requires unlimited ranges.

▶ **Theorem 14.** *Range-DR is NP-hard in both weighted and unweighted cycles.*

Proof. We prove the theorem using a reduction from Hamiltonian Cycle. Given a graph G, construct the following distance matrix:

$$D_{i,j} = \begin{cases} \{1, \dots, \lfloor \frac{n}{2} \rfloor\} & (v_i, v_j) \in E(G) \ , \\ \{2, \dots, \lfloor \frac{n}{2} \rfloor\} & (v_i, v_j) \notin E(G) \ . \end{cases}$$

If G has a Hamiltonian cycle, then this cycle induces a realization of D. On the other hand, a realization of D corresponds to a Hamiltonian cycle in G. ◀

Next we show that Set-DR on cycles is NP-hard even on 5-set distance profiles using reductions from the problem on paths, where the required end-points of the paths are given in the input.

▶ **Theorem 15.** *5-Set-DR is NP-hard in unweighted and weighted cycles.*

Proof. We use a reduction from the Set-DR in unweighted paths, where D is a 5-set distance matrix and the required end-points of the path are given in the input, which was shown to be NP-hard in Theorem 11.

Intuitively, we add $3n$ vertices $n+1, \dots, 4n$, unit weight edges between i and $i+1$, for $i \in \{n, \dots, 4n-1\}$, and the unit weight edge $(4n, 1)$. Formally, given a matrix $D \in \mathbb{N}^{n \times n}$ we construct a matrix $D' \in \mathbb{N}^{4n \times 4n}$ as follows:

$$D'_{k,\ell} = \begin{cases} D_{k,\ell} & 1 \le k, \ell \le n, \\ \min\{(\ell - k), (4n - \ell + k)\} & n < k < \ell \le 4n, \\ \{\min\{(\ell - \delta - 1), (4n + 1 - \ell + \delta)\} : \delta \in D_{k,1}\} & 1 \le k \le n, n < \ell \le 4n, \end{cases}$$

Note that we assume without loss of generality that $\delta \in D_{k,1}$ if and only if $n - 1 - \delta \in D_{k,n}$.

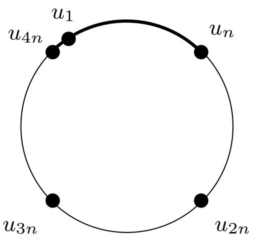


Figure 4 Depiction of the reduction in the proof of Theorem 15, from path realization to cycle realization. The thick line between u_1 and u_n corresponds to the location of the original vertices.

Suppose that D is realizable. In this case, D' is realizable by using a cycle of total length $4n$, where the vertices $u_1, \ldots, u_n$ are placed at positions $1, .., n$ as they are placed in the path realization. Vertex u_i, for $i > n$ is placed at i. (See Figure 4.)

On the other hand, assume that D' is realizable, and assume that u_1 and u_n are placed at locations 1 and n on the cycle. It follows that u_i is located at i, for every $i > n$. In this case, D can be realized by the arc from 1 to n. ◀

6 Summary and Open Problems

This paper introduces the parametric Set Distance Realization (Set-DR) problem, which is an extension of the Range Distance Realization (Range-DR) problem. We study the computational complexity of k-Set-DR and k-Range-DR, as a function of k, in various graph families.

Several questions remain open, including the following.

- Range-DR in weighted general graphs can be solved in polynomial time, but the status of Set-DR is currently unclear.
- For trees, 3-Range-DR and 2-Set-DR are NP-hard, but the status of the 2-Range-DR problem remains unsettled.
- For stars, the hardness of the k-Set-DR problem is unsettled for $k = 3, 4, 5$.
- For paths and cycles the k-Set-DR problem is unsettled for $k = 3, 4$.
- The status of Range-DR for paths and cycles is an open problem.

Abstract

We consider the problem of characterizing degree sequences that can be realized by a bipartite graph. If a partition of the sequence into the two sides of the bipartite graph is given as part of the input, then a complete characterization has been established over 60 years ago. However, the general question, in which a partition and a realizing graph need to be determined, is still open. We investigate the role of an important class of special partitions, called *High-Low partitions*, which separate the degrees of a sequence into two groups, the high degrees and the low degrees. We show that when the High-Low partition exists and satisfies some natural properties, analysing the High-Low partition resolves the bigraphic realization problem. For sequences that are known to be not realizable by a bipartite graph or that are undecided, we provide approximate realizations based on the High-Low partition.

1 Introduction

1.1 Background and Motivation

Graphic degree sequences are among the most well-researched objects in the domain of graph realizations, studied extensively for over 60 years. A sequence $d = (d_1, \ldots, d_n)$ of non-negative integers is said to be a *graphic degree sequence* if there exists an n-vertex simple graph G such that $\deg(G) = d$, where $\deg(G)$ denotes the sequence of vertex degrees of G. The *graphic degree realization (GDR)* problem requires, given a sequence d, to decide whether d is graphic, and if so, to construct a graph G realizing it. Erdös and Gallai [18] gave a complete characterization for graphic degree sequences. However, their method does not provide a realizing graph. Havel and Hakimi [21, 24] gave an algorithm that, given a sequence d, generates a realizing graph, or proves that the sequence is not graphic, in time $\mathcal{O}(\sum_i d_i)$ which is optimal.

In this paper we consider the natural variant of the graphic degree realization problem, referred to as the *bigraphic degree realization (BDR)* problem, where the realizing graph is required to be bipartite. A sequence admitting a bipartite realizing graph is called a *bigraphic degree sequence*. This problem was mentioned in [33] as an open problem over 40 years ago, but we are unaware of any attempt to solve it.

The literature does contain, however, a sizeable amount of research on the simpler variant, hereafter referred to as the *given partition* version of the bigraphic degree realization problem, BDR^P, where the partition of d is given as part of the input. More explicitly, the input consists of a *partition*, namely, *two* sequences $a = (a_1, \ldots, a_p)$ and $b = (b_1, \ldots, b_q)$, and the question is to decide whether there exists a bipartite graph $G = (A, B, E)$ such that $|A| = p$, $|B| = q$, and the sequences of degrees of the vertices of A and B are equal to a and b, respectively. We refer to such a pair (a, b) as a *bigraphic degree partition.*

Interestingly, the history of bigraphic degree partitions is as ancient as that of graphic degree sequences. In 1957, Gale and Ryser [19, 35] gave a well-known complete characterization, known as the Gale-Ryser conditions, for a pair of sequences (a, b) to be a bigraphic degree partition. These conditions imply also a polynomial time decision algorithm for BDR^P (by applying a variant of the Havel-Hakimi construction procedure).

Given the Gale-Ryser characterization, the fact that the well-known PARTITION problem is pseudo-polynomial (cf. [9, 16]) would appear to suggest a plausible approach for attacking the (plain) bigraphic degree realization problem BDR, by searching for a bigraphic degree partition for the given sequence d. This approach makes sense because $d_1 < n$ is a necessary condition for a sequence d to be graphic (or bigraphic), and for such d, finding one of the partitions (if one exists) is achievable in polynomial time. However, this approach encounters several immediate obstacles. First, it is possible that some partitions of d are bigraphic while other partitions are not[1]. Second, there may be exponentially many different partitions for a given sequence[2]. Other approaches may be attempted, based on the special structure required by a bigraphic degree partition. So far, however, the bigraphic degree realization remains unresolved: There is no characterization for the class of bigraphic degree sequences, and it is unknown whether the BDR problem is NP-complete.

Towards attacking the bigraphic degree realization problem we study a specific and significant type of partitions that separate the degrees of a sequence by their size, i.e., into two blocks, a block of high degrees and a block of low ones. We refer to such partitions as *High-Low partitions.* These partitions represent an extreme approach, striving to maximize the difference between the degrees on the two sides of the partition. (An opposite extreme approach would be to try to make the two sides as *similar* as possible; we study the role of such partitions, referred to as *equal* partitions, in [8].) High-Low partitions are thus interesting in their own right, and can also be viewed as bipartite counterparts of other partition types considered in the literature, such as *core-periphery* partitions, which commonly occur in social networks, see [3, 4, 5, 11, 34, 46].

1.2 Our Contribution

Our key observation concerning the role of High-Low partitions is that there are special instances where deciding the realizability of the High-Low partition resolves also the BDR problem, i.e., decides whether the given sequence is bigraphic or not (and if so, provides an *exact* realization). Moreover, when the BDR problem is decided in the negative or is unsolved, we are able to generate *approximate* realizations for the given sequence based on its High-Low partition.

[1] Consider the sequence $(6, 6, 4, 4, 2, 2, 2, 2, 2, 2)$ which has three partitions: *(i.)* $(6, 6, 4)(4, 2, 2, 2, 2, 2, 2)$, *(ii.)* $(6, 4, 2, 2, 2)(6, 4, 2, 2, 2)$, and *(iii.)* $(6, 6, 2, 2)(4, 4, 2, 2, 2, 2)$. However, only the last partition is bigraphic.

[2] Consider the sequence $d = (n, n, n-1, n-1, \ldots, 2, 2, 1, 1)$ of length $2n$, for n divisible by 4. Split d into subsequences $B_j = (x, x, x+1, x+1, x+2, x+2, x+3, x+3)$, for $x = 4(j-1)+1$, noting that each B_j has three partitions: *(i.)* $(x, x+1, x+2, x+3)(x, x+1, x+2, x+3)$, *(ii.)* $(x, x, x+3, x+3)(x+1, x+1, x+2, x+2)$, and *(iii.)* $(x+1, x+1, x+2, x+2)(x, x, x+3, x+3)$. This yields $3^{n/4}$ different partitions for d.

Apart from being easier to generate, approximate realizations are desirable for several other reasons. In many applications it is required to design a network given some partial specifications, and returning that there is no suitable network (even provably) is not satisfactory. Additionally, specifications often rely on imprecise data making exact realizations unattractive. Bar-Noy et al. [6] survey different applications and types of approximate network realizations. Our approximate realizations are either

(i) bipartite *multigraphs* (namely, graphs that allow *parallel edges*) with low *maximum* multiplicity of parallel edges or

(ii) *super-realizations* which are bipartite (plain) graphs where a subset of the vertices adheres to the given degree sequence and with a small number of additional vertices and edges.

The *High-Low partition* of a non-increasing sequence $d = (d_1, \ldots, d_n)$ has the form $H = (d_1, \ldots, d_k)$ and $L = (d_{k+1}, \ldots, d_n)$ for some k. The partition (H, L) is *balanced* if $\sum_{i=1}^{k} d_i = \sum_{i=k+1}^{n} d_i$. Clearly, a bigraphic degree partition is necessarily balanced.

Well-behaved High-Low Partition. It turns out that for High-Low partitions, the first Gale-Ryser conditions are of paramount significance. These conditions stipulate that the largest degree on each side must not exceed the number of vertices on the other side (or formally, $d_1 \leq n - k$ and $d_{k+1} \leq k$). We refer to a balanced High-Low partition (H, L) that satisfies the first Gale-Ryser conditions as a *well-behaved* High-Low partition.

Being well-behaved does not, in itself, ensure that the partition is bigraphic[3]. It does, however, enable us to resolve the BDR problem: as we show in Section 3 that the BDR problem is solvable for a non-increasing sequence d that admits a well-behaved High-Low partition (H, L). Specifically, when d admits a well-behaved High-Low partition (H, L), it suffices to test the entire collection of Gale-Ryser conditions on (H, L). If all the conditions are met, then (H, L) is a bigraphic degree partition, hence d is a bigraphic degree sequence. If, on the other hand, one or more of the Gale-Ryser conditions is violated for (H, L), then *every* partition of d must violate one Gale-Ryser condition and d has *no* bigraphic degree partition. It follows that d itself is not a bigraphic degree sequence. On the positive side, we show in Section 4 that even in case a well-behaved High-Low partition fails to be bigraphic, it is still what we call 2-*bigraphic*, namely, it has a realizing bipartite *multigraph* whose maximum edge multiplicity is 2.

Multigraph Realizations. Next, we look at sequences that have a balanced High-Low partition that is *not* well-behaved, i.e., the first Gale-Ryser conditions are violated. Based on the High-Low partition we provide approximate realizations by bipartite *multigraphs* (without loops) measuring their quality by the maximum multiplicity of edges. We consider this notion for general graphs and bipartite graphs. Let r, t be positive integers. A sequence d of non-negative integers is said to be r-graphic if there exists a multigraph G such that $\deg(G) = d$ and the maximum multiplicity of an edge in G is at most r. Similarly, a partition (a, b) is t-bigraphic if there exists a bipartite multigraph $G(A, B, E)$ such that the maximum multiplicity of an edge in G is at most t and the sequences of degrees of the vertices of A and B are equal to a and b, respectively.

[3] Consider the sequence $((6m)^m, (2m)^{5m+1}, 1^{2m})$ (superscripts denote multiplicities of degrees) which has a well-behaved High-Low partition $H = ((6m)^m, (2m)^{m+1})$, $L = ((2m)^{4m}, 1^{2m})$, but it is not bigraphic.

In Section 4, we show that the balanced High-Low partition (H, L) of an r-graphic sequence is t-bigraphic where $t = \max\{t(d), 2r\}$ and $t(d)$ is a parameter indicating the extent to which (H, L) violates the first Gale-Ryser conditions.

Super-Graph Realizations. In Section 5, we deal with sequences where the High-Low partition is not balanced, and study the *High-Low near-partition* obtained by taking $H = \{d_1, \ldots, d_k\}$ and $L = \{d_{k+1}, \ldots, d_n\}$ for the smallest k such that $\sum_{i=1}^{k} d_i \geq \sum_{i=k+1}^{n} d_i$. For sequences where (H, L) satisfies the first Gale-Ryser conditions (called *quasi-well-behaved*), we come close to resolving its realizability status: Either we provide a bipartite super-realization, i.e., a bipartite graph G where $\deg(G) = d'$, and d is a subsequence of d' such that $|d'| - |d| \leq 2(d_k - 1)$ or we decide that d is not bigraphic.

Finally, in Section 6 we show how to combine the results on the two different types of (single-criterion) approximate realizations to yield bi-criterion approximate realizations, i.e., realizations by bipartite super-multigraphs.

1.3 Related Work

Next to characterizing graphic degree sequences, several related questions were considered: Given a degree sequence, find all the (non-isomorphic) graphs that realize it, count all its (non-isomorphic) realizing graphs, and uniformly sample a random realization. These questions are well-studied, cf. [13, 18, 21, 24, 26, 37, 39, 40, 44, 45], and have important applications in network design, randomized algorithms, social networks [10, 15, 17, 29] and chemical networks [38]. Miller [30] recapitulates reduced criteria for a sequence to be graphic. For surveys on graphic sequences, see [41, 42, 43].

Extensive literature exists on finding realizations having certain properties. A degree sequence is *potentially* P-graphic if it has a realization with property P where P is some graph theoretic property. Rao [33] surveys results (see references therein) on several properties including k-edge/k-vertex connected, hamiltonian and tournament. Characterizing potentially bipartite sequences, i.e., the BDR problem, is mentioned as an open problem.

Additional results include a characterization for trees (cf. [20]). The existing results on *planar* graphs are restricted to k*-sequences*, in which the difference between $\max d_i$ and $\min d_i$ is at most k, for $k = 0, 1, 2$ [1, 36]. Degree sequences of *split* graphs (see [23]), *threshold* graphs (see [22]), *matrogenic* graphs (see [28]) and *difference* graphs (see [22]) are fully characterized. Moreover, Degree sequences of *chordal*, *interval*, and *perfect* graphs were studied in [12].

Realizations by multigraphs were considered by Owens and Trent [32] showing how to realize degree sequences with minimum total number of parallel edges or loops (see [31, 27] for improved algorithms). Interestingly, computing a realization with maximum total number of parallel edges is known to be NP-hard, see [25].

2 Preliminaries and Definitions

Let $G = (V, E)$ be a multigraph without loops. Denote by $E_G(v, w)$ the multiset of edges connecting $v, w \in V$. The *maximum multiplicity* of G is $\mathsf{MaxMult}(G) = \max_{(v,w)\in E}(|E_G(v, w)|)$.

2.1 Degree Sequences of Graphs and Multigraphs

Let $d = (d_1, d_2, \ldots, d_n)$ be a sequence of nonnegative integers in nonincreasing order. The *volume* of d is $\sum d = \sum_{i=1}^{n} d_i$. We call a sequence with even volume a *degree sequence*.

We present the characterization of Erdös and Gallai [18] for graphic degree sequences.

▶ **Theorem 1** (Erdös-Gallai [18]). *A degree sequence $d = (d_1, d_2, \dots, d_n)$ is graphic if and only if, for $\ell = 1, \dots, n$,*

$$\sum_{i=1}^{\ell} d_i \le \ell(\ell-1) + \sum_{i=\ell+1}^{n} \min\{\ell, d_i\}. \tag{1}$$

We refer to Equation (1) as the *ℓ-th Erdös-Gallai inequality* EG_ℓ. The Erdös-Gallai characterization allows us to check if a sequence is graphic or not in polynomial time.

A degree sequence d is *r-graphic*, for a positive integer r, if there is a multigraph G such that $\deg(G) = d$ and $\mathsf{MaxMult}(G) \le r$. The Erdös-Gallai inequalities were extended to characterize r-graphic sequences.

▶ **Theorem 2** (Chungphaisan [14]). *Let r be a positive integer. The degree sequence $d = (d_1, d_2, \dots, d_n)$ is r-graphic if and only if, for $\ell = 1, \dots, n$,*

$$\sum_{i=1}^{\ell} d_i \le r\ell(\ell-1) + \sum_{i=\ell+1}^{n} \min\{r\ell, d_i\}, \tag{2}$$

Note that, for a given sequence d, the minimum r such that d is r-graphic can be determined in polynomial time.

2.2 Degree Sequences of Bipartite Graphs and Multigraphs

Let d be a degree sequence for which $\sum d = 2m$ for some integer m. A *block* of d is a subsequence a such that $\sum a = m$. Define $B(d) := \{a \subset d \mid \sum a = m\}$ as the set of all blocks of sequence d. For each $a \in B(d)$ there is a disjoint $b \in B(d)$ that completes it to form a partition of d (so that merging them in sorted order yields d). We call such a pair $a, b \in B(d)$ a *(balanced) partition* of d since $\sum a = \sum b$. Denote the set of all degree partitions of d by $\mathsf{BP}(d) = \{\{a, b\} \mid a, b \in B(d),\ d \setminus a = b\}$.

The Gale-Ryser theorem characterizes bigraphic degree partitions.

▶ **Theorem 3** (Gale-Ryser [19, 35]). *Let d be a degree sequence and partition $(a, b) \in \mathsf{BP}(d)$ where $a = (a_1, a_2, \dots, a_p)$ and $b = (b_1, b_2, \dots, b_q)$. The partition (a, b) is bigraphic if and only if*

$$\sum_{i=1}^{\ell} a_i \le \sum_{i=1}^{q} \min\{\ell, b_i\}, \tag{3}$$

for $\ell = 1, \dots, p$.

We refer to Equation (3) as the *ℓ-th Gale-Ryser inequality* GR^L_ℓ on the left. By symmetry, the partition (a, b) is bigraphic if and only if $\sum_{i=1}^{\ell} b_i \le \sum_{i=1}^{p} \min\{\ell, a_i\}$, for $\ell = 1, \dots, q$. We refer to this equation as the *ℓ-th Gale-Ryser inequality* GR^R_ℓ on the right.

Let t be a positive integer. A degree sequence d is t-bigraphic if d has a partition $(a, b) \in \mathsf{BP}(d)$ such that there is a bipartite multigraph $G = (A, B, E)$ such that $\mathsf{MaxMult}(G) \le t$, $|A| = |a|$, $|B| = |b|$, and the sequences of degrees of the vertices of A and B are equal to a and b, respectively. We also say that partition (a, b) is t-bigraphic. Miller [30] cites the following result of Berge characterizing t-bigraphic partitions.

▶ **Theorem 4** (Berge [30]). *Consider a positive integer t, a degree sequence d and a partition $(a,b) \in BP(d)$ where $a = (a_1,\dots,a_p)$ and $b = (b_1,\dots,b_q)$. The partition (a,b) is t-bigraphic if and only if*

$$\sum_{i=1}^{\ell} a_i \le \sum_{i=1}^{q} \min\{\ell t, b_i\}, \tag{4}$$

for $\ell = 1,\dots,p$.

2.3 Ferrers Diagrams, Conjugate Sequences and Majorization

Ferrers diagrams (cf. [2]) are instrumental in illustrating integer sequences and partitions graphically (see Figure 1).

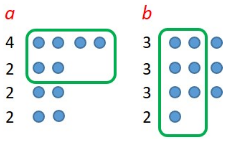

Figure 1 The Ferrers diagram of the partition $a = (4,2,2,2)$ and $b = (3,3,3,1)$.

Conjugate sequences provide us with a convenient alternative way to represent the Gale-Ryser conditions. The *prefix-sum* of a sequence d up to index i is $\sum(d[i]) = \sum_{j=1}^{i} d_j$. Let the sequences a,b have the same length, i.e., $p = q$. (If two sequences are not of the same length, the shorter sequence can be padded with 0's.) Given a degree sequence d, its *conjugate* sequence $\widetilde{d} = (\widetilde{d}_1, \widetilde{d}_2, \dots, \widetilde{d}_{d_1})$ is defined by $\widetilde{d}_k = |\{i \mid d_i \ge k\}|$.

The duality between $\sum a[i]$ and $\sum \widetilde{b}[i]$ is captured graphically in the Ferrers diagram: a_i is the i-th row on the left, and $\widetilde{b}_i$ is the i-th column on the right. Consequently, $\sum a[i]$ is the sum of the first i rows on the left, whereas $\sum \widetilde{b}[i]$ is the sum of the first i columns on the right. (In the figure, the green ovals capture $\sum a[2]$ and $\sum \widetilde{b}[2]$.)

Majorization is a partial order on degree sequences: *a majorizes b* ($b \trianglelefteq a$) if and only if $\sum(b[i]) \le \sum(a[i])$ for every $i \in [1,q]$.

Observe that if $a \trianglerighteq b$, then $\widetilde{b} \trianglerighteq \widetilde{a}$. The Gale-Ryser theorem can now be reformulated using majorization and conjugates, noting that $\sum_{i=1}^{q} \min\{\ell, b_i\} = \sum_{i=1}^{\ell} \widetilde{b}_i$.

▶ **Theorem 5** (Gale-Ryser [19, 35], conjugate representation). *Let d be a degree sequence and $(a,b) \in BP(d)$. The partition (a,b) is bigraphic if and only if $a \trianglelefteq \widetilde{b}$.*

Furthermore, a graphic description of the ℓ-th Gale-Ryser condition on the left is that the sum of the first ℓ *rows* on the left Ferrers diagram (representing a), must be no greater than the sum of the first ℓ *columns* on the right Ferrers diagram (representing b). (The sequence is bigraphic if and only if these conditions hold for every $\ell \le p$.) As the sequences a and b (or equivalently their Ferrers diagrams) can switch sides, it is clear that the Gale-Ryser conditions are symmetric, i.e., $a \trianglelefteq \widetilde{b}$ if and only if $b \trianglelefteq \widetilde{a}$.

3 Well-Behaved High-Low Partitions

In this section, we study sequences that have a well-behaved High-Low partition. Let $d = (d_1,\dots,d_n)$ be a degree sequence with a High-Low partition $HL(d) = (H,L)$ where $H = (d_1,\dots,d_k)$ and $L = (d_{k+1},\dots,d_n)$, for some positive integer $k < n$. We assume that $d_1 \le n-k$ and that $d_{k+1} \le k$, i.e., (H,L) is well-behaved.

In the following, we suppose that (H, L) is not bigraphic implying that at least one Gale-Ryser condition on H and L, respectively, is not satisfied. Let x be the index of the first violated Gale-Ryser condition on L, i.e., such that $\sum(L[i]) \leq \sum(\widetilde{H}[i])$, for $i < x$, and

$$\sum(L[x]) > \sum(\widetilde{H}[x]). \tag{5}$$

▶ **Observation 6.** *For a well-behaved $HL(d) = (H, L)$, $d_k < x$.*

Proof. For $i \leq d_k$, we have that $\sum(\widetilde{H}[i]) = i \cdot k$, and $\sum(L[i]) \leq i \cdot d_{k+1}$ (see Figure 2). Since (H, L) is well-behaved, $d_{k+1} \leq k$, and it follows that $\sum(L[i]) \leq \sum(\widetilde{H}[i])$, hence the ith Gale-Ryser condition on L holds, for $i \leq d_k$. Consequently, $x > d_k$. ◀

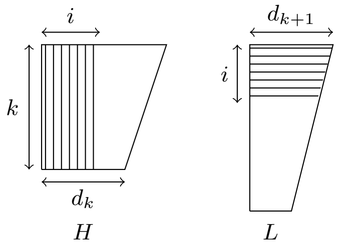

Figure 2 $\sum \tilde{H}[i]$ vs. $\sum L[i]$.

▶ **Observation 7.** *For a well-behaved $HL(d) = (H, L)$, $x > k$.*

Proof. If $d_k \geq k$, then the claim follows from Observation 6. Now suppose $d_k < k$. We need to show that $\sum(\widetilde{H}[j]) \geq \sum(L[j])$ for every $d_k < j \leq k$. This follows because

$$\sum(\widetilde{H}[j]) \geq \sum(\widetilde{H}[d_k]) = k \cdot d_k \geq k \cdot d_{k+1} \geq \sum(L[k]) \geq \sum(L[j]).$$ ◀

Our main goal is to prove the following result.

▶ **Theorem 8.** *Consider a degree sequence d with a well-behaved High-Low partition $HL(d) = (H, L)$. If (H, L) is not bigraphic, then d is not bigraphic (i.e., no partition of d is bigraphic).*

First, we prove a weaker statement. For some other partition $(A, B) \in \mathtt{BP}(d)$, define

$$H^m = H \setminus A, \qquad L^m = L \setminus B, \qquad H^s = H \cap A, \text{ and } \qquad L^s = L \cap B.$$

Moreover, we denote $h = |H^m|$ and $\ell = |L^m|$. Hence, the partition (A, B) can be viewed as obtained from (H, L) by *moving* a subset H^m from the left to the right, and a subset L^m from the right to the left. The subsets H^s and L^s *stay* on their respective sides. Note that, keeping A and B sorted in nonincreasing order, the elements of H^m appear at the beginning of B and the elements of L^m appear at the end of A. Figure 3 illustrates this transformation.

For an index i and an ordered set of integers S, denote the first i elements of S by $S[i]$. Moreover, we use $\sum(S) = \sum_{z \in S} z$ to denote the sum of elements in S. In line with our previous definition, $\sum(S[i])$ is the prefix-sum of S up to index i.

▶ **Definition 9.** *Call the partition (A, B)* benign *if L^m contains at most h of the top x elements of L, i.e., $|L[x] \cap L^m| \leq h$ or equivalently $|L[x] \setminus L^m| \geq x - h$.*

▶ **Lemma 10.** *Consider a degree sequence d with well-behaved High-Low partition $HL(d) = (H, L)$. If (H, L) is not bigraphic, then no benign partition of d is bigraphic.*

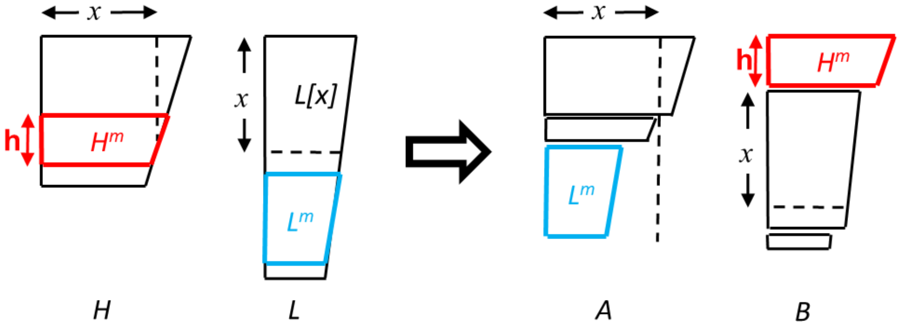

Figure 3 Illustration of the transformation from (H, L) to (A, B). Partition (A, B) is benign since $L[x] \cap L^m$ is empty.

Proof. Let d and $HL(d) = (H, L)$ be as in the lemma, and let (A, B) be some benign partition of d. To show the lemma, we show that $\sum(B[x]) > \sum(\widetilde{A}[x])$ holds, i.e., the partition (A, B) violates GR^R_x. First, verify that

$$\sum(B[x]) = \sum(H^m) + \sum(L^s[x-h]),$$

and that

$$\sum(\widetilde{A}[x]) = \sum(L^m) + \sum(\widetilde{H^s}[x]) \tag{6}$$

since $x > d_{k+1}$ by Observation 6. We need to show that $\sum(L^s[x-h]) > \sum(\widetilde{H^s}[x])$ since $\sum(H^m) = \sum(L^m)$. By Equation (5), it follows that

$$\sum(L[x]) - \sum(L^s[x-h]) + \sum(L^s[x-h]) > \sum(\widetilde{H}[x]) = \sum(\widetilde{H^s}[x]) + \sum(\widetilde{H^m}[x]).$$

To finish the proof, we argue that $\sum(\widetilde{H^m}[x]) \geq \sum(L[x]) - \sum(L^s[x-h])$. Since (A, B) is benign, $L^s[x-h]$ contains at least $x - h$ rows of $L[x]$, or equivalently $L[x] \setminus L^s[x-h]$ are at most h rows of L. It follows that

$$\sum(L[x]) - \sum(L^s[x-h]) \leq h \cdot d_k \leq \sum(\widetilde{H^m}[x])$$

where the last inequality holds due to Observation 6. ◀

Using the symmetry of the Gale-Ryser conditions we prove the following corollary. We introduce another notation, $s = |L[x] \cap L^m|$.

▶ **Corollary 11.** *Consider a degree sequence d with well-behaved High-Low partition $HL(d) = (H, L)$. If (H, L) is not bigraphic, then no partition of d where $x - s \leq k - h$ is bigraphic.*

Proof. The result is obtained from switching the definitions of the moving and staying parts. Partition (B, A) can be viewed as obtained from (H, L) by moving H^s from H to L and L^s from L to H. Note that $|H^s| = k - h$ and $|L^s \cap L[x]| = x - s$. The condition $x - s \leq k - h$ implies that (B, A) is benign, and the corollary follows with Lemma 10. ◀

Another benign case is when the largest element of H^m or H^s is smaller or equal to x. Denote $\lambda = \min\{\max\{H^m\}, \max\{H^s\}\}$.

▶ **Lemma 12.** *Consider a degree sequence d with well-behaved High-Low partition $HL(d) = (H, L)$. If (H, L) is not bigraphic, then no partition of d where $\lambda \leq x$ is bigraphic.*

Proof. Consider d and (H, L) as in the lemma. First, we verify the claim for $\lambda = \max\{H^m\}$. To that end, let (A, B) be a partition of d such that $\max\{H^m\} \leq x$. To prove the claim, we show that $\sum(B[x]) > \sum(\widetilde{A}[x])$ holds. With Equations (5) and (6) it follows that

$$\sum(L[x]) > \sum(\widetilde{H}[x]) = \sum(\widetilde{H^s}[x]) + \sum(\widetilde{H^m}[x]) \overset{(\star)}{=} \sum(\widetilde{H^s}[x]) + \sum(H^m) = \sum(\widetilde{A}[x]),$$

where $(\star)$ holds since $\max\{H^m\} \leq x$. Because (H, L) is a High-Low partition, B majorizes L and, in particular, $\sum(B[x]) \geq \sum(L[x]) > \sum(\widetilde{A}[x])$ holds.

With the arguments used to prove Corollary 11, the claim also holds in case $\lambda = \max\{H^s\}$, and the lemma follows. ◀

Now we are ready to prove Theorem 8.

Proof of Theorem 8. Consider d and $HL(d) = (H, L)$ as in the lemma, and let (A, B) be some partition of d. Towards a contradiction suppose that (A, B) is bigraphic. It follows that

(a) $\sum(B[x]) \leq \sum(\widetilde{A}[x])$,
(b) $\sum(A[x]) \leq \sum(\widetilde{B}[x])$,
(c) $\lambda \leq \sum(B[1]) \leq \sum(\widetilde{A}[1]) = k - h + \ell$,
(d) $\lambda \leq \sum(A[1]) \leq \sum(\widetilde{B}[1]) = n - k + h - \ell$,
(e) $x < \lambda$,
(f) $s > h$, and
(g) $s < x - k + h$.

Equations (a), (b), (c), (d) are Gale-Ryser conditions (see Theorem 3), and the upper bounds on λ hold by definition. As (A, B) is bigraphic, Equation (e) is implied by Lemma 12. Moreover, Equations (f) and (g) are implied by Lemma 10 and Corollary 11, respectively.

Recall that Equation (5) reads

$$\sum(L[x]) > \sum(\widetilde{H}[x]) = \sum(\widetilde{H^s}[x]) + \sum(\widetilde{H^m}[x]).$$

Note that (d) and (e) imply $x < \lambda \leq n - k + h - \ell = |B|$ (i.e., $B[x]$ is a proper subset of B). With Equation (a) we have that

$$\sum(\widetilde{H^s}[x]) + \sum(L^m) = \sum(\widetilde{A}[x]) \geq \sum(B[x]) = \sum(L^s[x-h]) + \sum(H^m).$$

Since $\sum(L^m) = \sum(H^m)$ we get a lower bound on $\sum(\widetilde{H^s}[x])$:

$$\sum(\widetilde{H^s}[x]) \geq \sum(L^s[x-h]). \tag{7}$$

Note that (c) and (e) imply $x < \lambda \leq k - h + \ell = |A|$ (i.e., $A[x]$ is a proper subset of A). Since $k - h < x$ and $d_{k+1} < x$, it follows from Observations 6 and 7 that

$$\sum(L^s) + \sum(\widetilde{H^m}[x]) = \sum(\widetilde{B}[x]) \geq \sum(A[x]) = \sum(H^s) + \sum(L^m[x-k+h]).$$

Since $\sum(L^s) = \sum(H^s)$ we get a lower bound on $\sum(\widetilde{H^m}[x])$:

$$\sum(\widetilde{H^m}[x]) \geq \sum(L^m[x-k+h]). \tag{8}$$

Equation (5) together with Equations (7) and (8) yields

$$\sum(L[x]) > \sum(L^s[x-h]) + \sum(L^m[x-k+h]).$$

Observe that $L^s[x-h]$ contains $L[x] \setminus L^m$ as $s > h$. Since $s < x - k + h$, $L^m[x-k+h]$ contains $L[x] \cap L^m$. It follows that $\sum(L^s[x-h]) \cup \sum(L^m[x-k+h])$ contains $L[x]$, and so

$$\sum(L^s[x-h]) + \sum(L^m[x-k+h]) \geq \sum(L[x])$$

holds contradicting the previous equation. Consequently, (A, B) cannot be bigraphic. ◀

Theorem 8 implies that the bigraphic realizability status can be fully resolved for a degree sequence with a well-behaved High-Low partition.

▶ **Theorem 13.** *Let d be a degree sequence with a well-behaved High-Low partition. It can be decided in polynomial time whether d is bigraphic or not. If d happens to be bigraphic, a bipartite graph realizing d can be computed in polynomial time.*

Proof. Let d be as in the theorem. Computing the High-Low partition $HL(d) = (H, L)$ is straight forward. Using the Gale-Ryser theorem (Theorem 3), we decide if (H, L) is bigraphic or not, and due to Theorem 8 if d is bigraphic or not. If (H, L) is bigraphic, a bipartite graph realizing d can be computed by applying the Havel-Hakimi algorithm to one side of the partition (see [7] for details). All steps are performed in polynomial time. ◀

4 Realizations by Bipartite Multigraphs

Our goal is to provide realizations based on multigraphs without loops where the maximum multiplicity of parallel edges is used to measure their quality. We examine degree sequences that have a balanced High-Low partition but are not necessarily bigraphic. Let r be a positive integer. In the following, we consider an r-graphic degree sequence d with High-Low partition $HL(d) = (H, L)$ where $H = (d_1, \ldots, d_k)$ and $L = (d_{k+1}, \ldots, d_n)$, for some integer $k \in [1, n-1]$. We do not assume that d is well-behaved, and quantify the violation of the first Gale-Ryser conditions with the following definitions. Let

$$t_H(d) = \left\lceil \frac{d_1}{n-k} \right\rceil \qquad \text{and} \qquad t_L(d) = \left\lceil \frac{d_{k+1}}{k} \right\rceil ,$$

and define $t(d) = \max\{t_H(d), t_L(d)\}$. (Note that sequence d has a well-behaved High-Low partition if $t(d) = 1$.) First, we observe that $t_H(d)$ is bounded for r-graphic sequences.

▶ **Lemma 14.** *Let d be an r-graphic degree sequence with High-Low partition $HL(d) = (H, L)$. Then, $t_H(d) \leq 2r$.*

Proof. Let d be as in the lemma with $H = (d_1, \ldots, d_k)$ and $L = (d_{k+1}, \ldots, d_n)$. Since (H, L) is a High-Low partition, we have that $k \leq n-k$. Moreover, $d_1 \leq r(n-1)$ as d is r-graphic. It follows that

$$t_H(d) = \left\lceil \frac{d_1}{n-k} \right\rceil \leq \left\lceil \frac{r(n-1)}{n-k} \right\rceil \leq \left\lceil \frac{r(k+n-k)}{n-k} \right\rceil \leq 2r. \qquad ◀$$

The main result of this section is the next theorem. Its proof is omitted in the conference version of the paper.

▶ **Theorem 15.** *Let d be an r-graphic degree sequence with High-Low partition $HL(d) = (H, L)$ and let $t = \max\{t(d), 2r\}$. Then, (H, L) is t-bigraphic.*

We remark that the conclusion of Theorem 15 does not hold if the degree sequence d is not r-graphic. To see this, consider the non-graphic sequence $d = ((9m)^{m-1}, 6m+1, (3m)^{3m-1}, 1^1)$ for some positive integer m. (We use superscripts to denote the multiplicities of degrees.) Verify that d has a High-Low partition (H, L) where $H = ((9m)^{m-1}, 6m+1)$ and $L = ((3m)^{3m-1}, 1^1)$. We have $t_H(d) = t_L(d) = 3$, but the conditions of Theorem 4 for 3-bigraphic degree sequences are violated. Specifically, the condition for index $m-1$ requires $9m(m-1) \leq (3m-1) \cdot 3 \cdot (m-1) + 1$, which is false.

We complement Theorem 15 by providing an existential lower bound.

▶ **Lemma 16.** *There are degree sequences d with High-Low partition $HL(d)$ such that $t(d) > 1$, and d is not t'-bigraphic for any $t' < t(d)$.*

Proof. Let t be a positive integer, and let p be some prime number. Set $x \geq t(p+1)$ such that p is not a prime factor of x, and consider the sequence $d = (x^{p+2}, p^x)$. Verify that sequence d has a High-Low partition $HL(d) = (H, L)$ with blocks $H = (x^{p+1})$ and $L = (x, p^x)$. By the choice of x and p, d does not have other partitions. We have that $t(d) = t_L(d) \geq t$. It follows that d is not t'-bigraphic for any $t' \leq t$. ◀

For graphic degree sequences, we get the following result.

▶ **Corollary 17.** *Let d be a graphic degree sequence with High-Low partition $HL(d) = (H, L)$ and $t = t(d)$.*

(i) *If $t = 1$, then (H, L) is 2-bigraphic.*
(ii) *If $t > 1$, then (H, L) is t-bigraphic.*

If there is a well-behaved High-Low partition, Theorem 8 implies the following result.

▶ **Corollary 18.** *Let d be a graphic degree sequence with well-behaved High-Low partition $HL(d) = (H, L)$. Then, either*

(i) *(H, L) is bigraphic, or*
(ii) *d is not bigraphic and (H, L) is 2-bigraphic.*

Combinatorial Bounds. In the last part of this section, we show bounds on $t_L(d)$ and $t_H(d)$ in case the degree sequence d is r-graphic or bigraphic. The proofs of the following two theorems are omitted in the conference version of the paper.

We start with r-graphic degree sequences. Lemma 14 provides a bound on $t_H(d)$. The next theorem establishes a bound on $t_L(d)$.

▶ **Theorem 19.** *Let d be an r-graphic sequence with High-Low partition $HL(d) = (H, L)$. Then,*

$$t_L(d) \leq \left\lceil \frac{r(k+1)}{2} \right\rceil.$$

We note that the bound of Theorem 19 is tight and that for graphic sequences, $t_L(d) < t_H(d)$ as well as $t_H(d) < t_L(d)$ can occur. To see this, consider the following two examples.

(1) The graphic sequence $d = (6, 3, 3, 3, 3, 3, 3)$ has exactly one (High-Low) partition (H, L) with blocks $H = (6, 3, 3)$ and $L = (3, 3, 3, 3)$. Verify that $t_L(d) = 2$ and $t_H(d) = 1$.
(2) The degree sequence $d' = ((\frac{k(k+1)}{2})^{k+1}, 1^{\frac{k(k+1)}{2}(k-1)})$, for a positive integer k, is graphic (to see this, observe that $\sum d'$ is even, and that the $(k+1)$th-EG inequality holds; for such a block sequence this is sufficient, see, e.g., [30]). The $(k+1)$th-EG inequality reads $(k(k+1)/2) \cdot (k+1) \leq k(k+1) + (k(k+1)/2) \cdot (k-1)$, which trivially holds. Moreover, $HL(d') = (H', L')$ where $H' = ((\frac{k(k+1)}{2})^k)$ and $L' = ((\frac{k(k+1)}{2}), 1^{\frac{k(k+1)}{2}(k-1)})$. Hence, $|H'| = k$ and $d_{k+1} = \frac{k(k+1)}{2}$.

The next result improves the bounds on $t_L(d)$ and $t_H(d)$ for bigraphic degree sequences.

▶ **Theorem 20.** *Let d be a bigraphic sequence with High-Low partition $HL(d)$. Then,*

$$t_H(d) \leq 1, \quad \textit{and} \qquad t_L(d) \leq \left\lceil \frac{k+2+1/k}{4} \right\rceil.$$

5 Realizations by Bipartite Super-Graphs

We next focus on the situation when the given sequence does not admit a balanced High-Low partition (with $\sum H = \sum L$). In this case, we consider the *High-Low near-partition (HLnP)* (H, L) of d, obtained by taking $H = \{d_1, \ldots, d_k\}$ and $L = \{d_{k+1}, \ldots, d_n\}$ for the smallest k such that $\sum H \geq \sum L$ (i.e., $\sum H - d_k < \sum L + d_k$).

Define the *imbalance gap* of the sequence d to be $IG(d) = \sum H - \sum L$. Rearranging the above two inequalities, we get the following.

▶ **Observation 21.** $0 \leq IG(d) < 2d_k$.

In the remainder of this section we assume that $IG(d) > 0$. We refer to such sequences d as *High-Low-imbalanced*. We call the High-Low near-partition (H, L) *quasi-well-behaved* if it satisfies the first Gale-Ryser condition on both sides.

The main result of this section is that when the given sequence d is High-Low-imbalanced but enjoys a quasi-well-behaved High-Low near-partition, it is possible to come close to resolving its realizability status, in the sense that there is a poly-time algorithm that either decides that d is not bigraphic, or constructs a bipartite super-realization for d with a small number of new vertices and edges. We use the operator $\circ$ to merge two sequences.

▶ **Definition 22.** *A bipartite (n', m') super-realization of an n-integer sequence d, for $n' > n$ and $m' > \sum d$, is a bipartite graph $G(A, B, E)$ such that $|A \cup B| = n + n'$, $|E| = \sum d + m'$, and $deg(A \cup B) = d \circ d'$ for some sequence d' of n' integers.*

Our algorithm hinges on the idea of completing a High-Low near-partition of a given imbalanced sequence d into a (balanced) High-Low partition of a larger sequence in a suitable way. Consider a family D of quasi-well-behaved n-integer nonincreasing sequences. A mapping $\varphi : D \mapsto D'$ is said to be a *valid completion mapping* for D if for every $d \in D$ such that $HLnP(d) = (H, L)$ and $k = |H|$, the generated n'-integer sequence $d' = \varphi(d)$ satisfies the following properties.

(P1) $(H, L \circ d')$ is a well-behaved High-Low partition of $d \circ d'$.

(P2) If d is bigraphic then $d \circ d'$ is bigraphic as well.

The generated sequence $d' = \varphi(d)$ is referred to as the *valid completion* of d.

We now describe a generic Algorithm $A(d, d')$ that, given a High-Low-imbalanced n-integer nonincreasing sequence d with $IG(d) = t$ and a valid completion d' of p integers for d, generates a bipartite (p, t) super-realization for d. The algorithm operates as follows.

1. Construct the High-Low near-partition $HLnP(d) = (H, L)$ for the given sequence d.
2. Let $t \leftarrow IG(d) = \sum H - \sum L$.
3. Set $L' \leftarrow L \circ d'$ (sorted in nonincreasing order).
4. Test all Gale-Ryser conditions on (H, L').
5. If (H, L') is bigraphic, then construct and return a realizing bipartite graph G' for it.
6. Otherwise (* (H, L') is not bigraphic *) return "d is not bigraphic".

▶ **Lemma 23.** *Consider a sequence d and let d' be a valid completion for d. If Algorithm $A(d, d')$ returns a graph G' (Step 5), then it is a bipartite (p, t) super-realization for d. If the algorithm returns a negative response (Step 6), then d is indeed not bigraphic.*

Proof. The first claim follows immediately by the definition of p and t and the fact that G' is a bipartite realization of (H, L').

To prove the second claim, suppose (H, L') is non-bigraphic. As d' is a valid completion of d, property (P1) implies that (H, L') is a well-behaved High-Low partition of $d \circ d'$. It follows from Theorem 8 that $d \circ d'$ is also non-bigraphic. This, in turn, implies by property (P2) that d is not bigraphic. ◀

▶ **Lemma 24.** *Consider a quasi-well-behaved n-integer nonincreasing sequence d with $t = IG(d)$. The sequence $d' = (1^t)$ is a valid completion for d.*

Proof. To see that (P1) holds, observe that

(1) $(H, L \circ d')$ is a High-Low partition of $d \circ d'$ because the elements of d' are no greater than the elements of H.

(2) it is balanced because $\sum H = \sum(L \circ d')$ by the choice of t.

(3) it satisfies the first Gale-Ryser condition on the left since (H, L) is quasi-well-behaved, so $d_1 \leq n - k \leq n + t - k$.

(4) it satisfies the first Gale-Ryser condition on the right since d_{k+1} satisfies $d_{k+1} \leq k$ by the fact that (H, L) is quasi-well-behaved, and $d'_1 = 1 \leq k$, so $\max(L \circ d') \leq k$.

To see that (P2) holds, suppose d is bigraphic, and let G be a bipartite graph realizing it. Noting that $IG(d)$ must be even (as it is the difference of two integers whose sum is even), let M be a matching consisting of $t/2$ edges. Then $G \cup M$ is a bipartite realization of $d \circ d'$. ◀

We conclude the following.

▶ **Theorem 25.** *Consider a quasi-well-behaved n-integer nonincreasing sequence d and let $d' = (1^{IG(d)})$. Then Algorithm $A(d, d')$, in poly-time, either yields a bipartite $(IG(d), IG(d))$ super-realization for d or decides that d is not bigraphic.*

Our goal is to find a poly-time algorithm that constructs a bipartite super-realization for d with less new vertices. We continue this analysis in the journal version of the paper.

6 Realizations by Super-Multigraphs

We consider super-multigraph realizations based on the High-Low near-partition. Together, Theorems 15 and 25 imply the following.

▶ **Corollary 26.** *Let d be an r-graphic sequence, $d' = d \circ 1^{IG(d)}$, and $t = \max\{2r, t(d')\}$. Then, there is a t-bipartite $(IG(d), IG(d))$ super-realization for d.*

If d is quasi-well-behaved and graphic, we apply Corollary 18 yielding the following.

▶ **Corollary 27.** *Consider a quasi-well-behaved and graphic sequence d and let $d' = (1^{IG(d)})$. Either d is undecided and Algorithm $A(d, d')$ yields in poly-time a bipartite $(IG(d), IG(d))$ super-realization for d, or d is not bigraphic and has a 2-bipartite $(IG(d), IG(d))$ super-realization.*

Towards a Model Theory of Ordered Logics: Expressivity and Interpolation

Bartosz Bednarczyk

Computational Logic Group, Technische Universität Dresden, Germany

Reijo Jaakkola

Tampere University, Finland

Abstract

We consider the family of guarded and unguarded ordered logics, that constitute a recently rediscovered family of decidable fragments of first-order logic (FO), in which the order of quantification of variables coincides with the order in which those variables appear as arguments of predicates. While the complexities of their satisfiability problems are now well-established, their model theory, however, is poorly understood. Our paper aims to provide some insight into it.

We start by providing suitable notions of bisimulation for ordered logics. We next employ bisimulations to compare the relative expressive power of ordered logics, and to characterise our logics as bisimulation-invariant fragments of FO à la van Benthem.

Afterwards, we study the Craig Interpolation Property (CIP). We refute yet another claim from the infamous work by Purdy, by showing that the fluted and forward fragments do not enjoy CIP. We complement this result by showing that the ordered fragment and the guarded ordered logics enjoy CIP. These positive results rely on novel and quite intricate model constructions, which take full advantage of the "forwardness" of our logics.

1 Introduction

An ongoing research in computational logic has lead to discovery of new decidable fragments of first-order logics (FO) that extend modal and description logics. The main ideas that were proposed in the past involve: restricting the number of variables [8], relativised quantification [1, 26], restricted use of negation [24], relativised negation [3], one-dimensionality and uniformity [11], separateness [25] and ordered quantification [12, 22]. To compare aforementioned logics, the authors of [1, Section 4.7] proposed a list of desirable meta-properties of logic, which can serve as a yardstick to measure how "nice" a given logic is. We expect a logic L to

(A) be decidable and have the *Finite Model Property* (FMP),

(B) satisfy the Craig Interpolation Property (CIP), *i.e.* for any L-formulae φ, ψ such that $\varphi \models \psi$ there should be an L-formulae χ, called an *interpolant*, that uses only symbols appearing in the common vocabulary of φ and ψ, so that $\varphi \models \chi \models \psi$ holds,

(C) and to satisfy the analog of Łoś-Tarski Preservation Theorem (ŁTPT), *i.e.* any L-formula φ preserved under substructures should be equivalent to some universal L-formula.

It turned out that FO^2 and GF, example logics based on restricted number of variables and relativised quantification, are not "nice" as they do not enjoy CIP [17, Examples 1–2]. In contrast, UNFO and GNFO, the logics based on relativised negation, fulfil the properties (A)–(C), consult: [24, 2, 6]. For one-dimensionality, separateness and ordered quantification we have partial results only.

In this paper we take a closer look at logics enjoying ordered quantification, which have been receiving increasing attention recently [20, 4, 15]. Their syntax can be informally explained as follows. We first require that all variables appearing in formulae are additionally indexed by the quantifier depth and then impose a certain restriction on such numbers in variable sequences in atoms. Assuming that $\alpha(\overline{x})$ is in the scope of the n-th quantifier (but not the $(n+1)$-th), in the fluted fragment $\mathsf{L}_{\mathsf{suf}}$ of Quine [22] (resp. in the ordered fragment $\mathsf{L}_{\mathsf{pre}}$ by Herzig [12][1]) the tuple $\overline{x}$ is required to be a suffix (resp. a prefix) of the sequence $x_1, x_2, \ldots, x_n$. The forward fragment $\mathsf{L}_{\mathsf{inf}}$ [4] is more liberal and allows infixes in place of suffixes or prefixes. An example formula $\varphi \in (\mathsf{L}_{\mathsf{suf}} \cap \mathsf{L}_{\mathsf{inf}}) \setminus \mathsf{L}_{\mathsf{pre}}$ is given below:

1. No student admires every professor.

$$\forall x_1\ (\mathrm{student}(x_1) \to \neg\forall x_2\ (\mathrm{professor}(x_2) \to \mathrm{admires}(x_1, x_2)))$$

2. No lecturer introduces any professor to every student.

$$\forall x_1\ \mathrm{lecturer}(x_1) \to \neg\exists x_2\ [\mathrm{professor}(x_2) \land \forall x_3\ (\mathrm{student}(x_3) \to \mathrm{introduce}(x_1, x_2, x_3))]$$

Next, we provide a few coexamples, *i.e.* formulae that, as stated, do not belong to any of $\mathsf{L}_{\mathsf{inf}}, \mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{suf}}$. The blue colour indicates a mismatch in the variable ordering.

1. The relation isPartOf is transitive.

$$\forall x_1\ \forall x_2\ \forall x_3\ \mathrm{isPartOf}(x_1, x_2) \land \mathrm{isPartOf}(x_2, x_3) \to \mathrm{isPartOf}(\underline{x_1, x_3})$$

2. A narcissist is a person who loves himself.

$$\forall x_1\ \mathrm{narcissist}(x_1) \to \mathrm{person}(x_1) \land \mathrm{loves}(\underline{x_1, x_1})$$

3. The binary relation hasChild is the inverse of the hasParent relation.

$$\forall x_1\ \forall x_2\ \mathrm{hasParent}(x_1, x_2) \leftrightarrow \mathrm{hasParent}(\underline{x_2, x_1})$$

All of $\mathsf{L}_{\mathsf{inf}}, \mathsf{L}_{\mathsf{suf}}, \mathsf{L}_{\mathsf{pre}}$ are decidable and have the Finite Model Property. Their satisfiability problem is, respectively, Tower-complete for $\mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L}_{\mathsf{suf}}$, and PSpace-complete for $\mathsf{L}_{\mathsf{pre}}$. Somehow unexpectedly, the Tower-completeness of $\mathsf{L}_{\mathsf{suf}}$ was established only recently by Pratt-Hartmann et al. [20], after pointing out a mistake in the proof of the exponential-size model of $\mathsf{L}_{\mathsf{suf}}$ by Purdy [21] and disproving Purdy's claim of NExpTime-completeness of $\mathsf{L}_{\mathsf{suf}}$. The model theory of $\mathsf{L}_{\mathsf{inf}}, \mathsf{L}_{\mathsf{suf}}$, and $\mathsf{L}_{\mathsf{pre}}$ is, however, poorly understood. The only results that we are aware of are Purdy's claims that $\mathsf{L}_{\mathsf{suf}}$ has CIP [21, Thm. 14] and ŁTPT [21, Corr. 17]. But in the light of previously discovered errors, one should treat Purdy's paper with caution.

[1] Strictly speaking, the syntax of $\mathsf{L}_{\mathsf{pre}}$ is slightly more liberal than the original syntax of the ordered fragment as defined by Herzig, since the syntax of $\mathsf{L}_{\mathsf{pre}}$ allows requantifying variables.

1.1 Our results

This paper kick-starts a project of understanding the model theory of *ordered logics*, by which we mean the logics $\mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{suf}}$, and $\mathsf{L}_{\mathsf{inf}}$ as well as their intersections with the guarded fragment GF [1], focusing on the problems mentioned in the introduction.

In Section 3, we design a suitable notion of bisimulations and compare the relative expressive power of ordered logics. Our proofs employ standard model-theoretic constructions like the Compactness Theorem and ω-saturated structures. Next, we investigate CIP in Section 4, which is the main technical contribution of the paper. First, we focus on interpolation for the fluted and the forward fragments. We show that, surprisingly, $\mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L}_{\mathsf{suf}}$ do not enjoy CIP, refuting yet another claim from the infamous work of Purdy [21, Thm. 14]. Fortunately, other members of the family of ordered logics enjoy CIP, as shown in Sections 4.2–4.3. We stress here that standard techniques for proving CIP, *e.g.* those based on zig-zag products [19, 14, 2, 16], do not seem to work in our case.[2] This forces us to take a different route: we construct models explicitly by specifying types of tuples.

We believe that our proof methods, which are based on novel and intricate model-theoretic constructions, are very general. In particular, we believe that our CIP proof for guarded ordered logics can serve as a useful meta-technique (or even a heuristic) for (dis)proving CIP for fragments of GF. For instance, the proof can be adopted to fragments with CIP, deriving existing results (*e.g.* for the 2-variable GF [14] or the uniform one-dimensional GF [16]) and its failure gives hints why a certain fragment may not have CIP (*e.g.* in the case of full GF).

2 Preliminaries

Henceforth, we employ standard terminology from (finite and classical) model theory [18, 13]. All the logics considered here will be fragments of the first-order logic (FO) over purely-relational equality-free vocabularies, under the usual syntax and semantics.

We fix a countably infinite set of variables $\{x_i \mid i \in \mathbb{N}\}$ and throughout this paper all the formulas use only variables from this set. With $\mathsf{sig}(\varphi)$ we denote the set of relational symbols appearing in φ. We use $\mathsf{ar}(\mathrm{R})$ to denote the arity of R. For a logic L and a signature σ we use $\mathsf{L}[\sigma]$ in place of $\{\varphi \in \mathsf{L} \mid \mathsf{sig}(\varphi) \subseteq \sigma\}$. The k-variable fragment of L (*i.e.* employing only the variables $x_1, x_2, \ldots, x_k$) is denoted L^k. We write $\varphi(\overline{x})$ to indicate that all free variables from φ are members of $\overline{x}$. If $\overline{x}$ contains precisely the free variables of φ, then we will emphasise this separately. Given a structure $\mathfrak{A}$ and $B \subseteq A$, we will use $\mathfrak{A} \restriction B$ to denote the *substructure* of $\mathfrak{A}$ that B induces.

Tuples and subsequences. An n-tuple is a tuple with n elements. The 0-tuple is denoted with ϵ. We use $\overline{x}_{i\ldots j}$ to denote the $(j{-}i{+}1)$-tuple $x_i, x_{i+1}, \ldots, x_j$. We say that $\overline{x}_{i\ldots j}$ is an infix of a tuple $\overline{x}_{k\ldots l}$ if $k \leq i \leq j \leq l$ holds. If, in addition, $k = i$ (resp. $j = l$) we say that $\overline{x}_{i\ldots j}$ is a prefix (resp. suffix) of $\overline{x}_{k\ldots l}$. We use the word *affix* as a place-holder for the words *pre*fix, *suf*fix or *inf*ix. For a set S, we write $\overline{x} \sqsubseteq S$ iff $x_i \in S$ for all indices $1 \leq i \leq |\overline{x}|$, where $|\overline{x}|$ denotes the length of $\overline{x}$. A tuple $\overline{\mathrm{a}} \sqsubseteq A$ is *σ-live* in $\mathfrak{A}$ if $|\overline{\mathrm{a}}| \leq 1$ or $\overline{\mathrm{a}} \in \mathrm{R}^{\mathfrak{A}}$ for some $\mathrm{R} \in \sigma$.

Logics. We next introduce the logics $\mathsf{L}_{\mathsf{affix}} \in \{\mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{suf}}, \mathsf{L}_{\mathsf{inf}}\}$. We start from $\mathsf{L}_{\mathsf{suf}}$, which for technical reasons we need to define separately from $\mathsf{L}_{\mathsf{pre}}$ and $\mathsf{L}_{\mathsf{inf}}$. For every $n \in \mathbb{N}$, we define the set $\mathsf{L}_{\mathsf{suf}}(n)$ as follows:

[2] For logics that are closed under negation on the level of formulas, zig-zag constructions seem to work only if the logics are *one-dimensional* and *uniform*, see [16] for more details. None of our logics are one-dimensional nor uniform.

- an atom $\alpha(\overline{x})$ is in $\mathsf{L}_{\mathsf{suf}}(n)$ if $\overline{x}$ is a suffix of $\overline{x}_{1\ldots n}$,
- $\mathsf{L}_{\mathsf{suf}}(n)$ is closed under Boolean connectives $\wedge, \vee, \neg, \rightarrow$,
- if φ is in $\mathsf{L}_{\mathsf{suf}}(n{+}1)$ then $\exists x_{n+1}\ \varphi$ and $\forall x_{n+1}\ \varphi$ are in $\mathsf{L}_{\mathsf{suf}}(n)$.

We put $\mathsf{L}_{\mathsf{suf}} := \mathsf{L}_{\mathsf{suf}}(0)$, which is exclusively composed of sentences.

To define the fragments $\mathsf{L} \in \{\mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{inf}}\}$, for every $n \in \mathbb{N}$ we define the set of $\mathsf{L}(n)$ as follows:

- an atom $\alpha(\overline{x})$ is in $\mathsf{L}_{\mathsf{pre}}(n)$ if $\overline{x}$ is a prefix of $\overline{x}_{1\ldots n}$ and in $\mathsf{L}_{\mathsf{inf}}(n)$ if $\overline{x}$ is an infix of $\overline{x}_{1\ldots n}$.
- if $\varphi \in \mathsf{L}(n_1)$ and $\psi \in \mathsf{L}(n_2)$, then for all $n \geq \max\{n_1, n_2\}$ we have that $\neg\varphi, (\varphi \vee \psi), (\varphi \wedge \psi), (\varphi \rightarrow \psi)$ are in $\mathsf{L}(n)$.
- if φ is in $\mathsf{L}(n{+}1)$ then $\exists x_{n+1}\ \varphi$ and $\forall x_{n+1}\ \varphi$ are in $\mathsf{L}(n)$.

We set $\mathsf{L} := \mathsf{L}(0)$, which is exclusively composed of sentences. We stress that in contrast to $\mathsf{L}_{\mathsf{suf}}$, the logics $\mathsf{L} \in \{\mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{inf}}\}$ allow us to requantify variables. We recommend the reader to employ the above definition to show that $\forall x_1 \forall x_2 \forall x_3 (\mathrm{R}(x_1 x_2 x_3) \rightarrow (\mathrm{A}(x_1) \wedge \exists x_2 \exists x_3 \mathrm{S}(x_1 x_2 x_3))) \in \mathsf{L}_{\mathsf{inf}}$.

Notice that if $\varphi(\overline{x}) \in \mathsf{L}_{\mathsf{affix}}(n)$, where $\overline{x}$ lists all the free variables of φ in order (with respect to their indices), then $\overline{x}$ is an affix of the tuple $\overline{x}_{1\ldots n}$. The logics $\mathsf{L}_{\mathsf{pre}}, \mathsf{L}_{\mathsf{suf}}$, and $\mathsf{L}_{\mathsf{inf}}$ were studied under the names of ordered [12], fluted [22], and forward [4] fragments. The *guarded* counterparts $\mathsf{G}_{\mathsf{affix}}$ of $\mathsf{L}_{\mathsf{affix}}$, are defined as the intersection of $\mathsf{L}_{\mathsf{affix}}$ and the guarded fragment GF [1], *i.e.* by imposing that blocks of quantifiers are relativised by atoms (recalled below). Abusing notation, we speak about all these logics collectively as *ordered logics.*

For reader's convenience we recall that GF is the smallest fragment of FO such that:

- Every atomic formula is in GF;
- GF is closed under boolean connectives $\wedge, \vee, \neg, \rightarrow$;
- If $\varphi(\overline{x}, \overline{y})$ is in GF and $\alpha(\overline{x}, \overline{y})$ is an atom containing all free variables of φ then both $\forall \overline{y}\ (\alpha(\overline{x}, \overline{y}) \rightarrow \varphi(\overline{x}, \overline{y}))$ and $\exists \overline{y}\ (\alpha(\overline{x}, \overline{y}) \wedge \varphi(\overline{x}, \overline{y}))$ are in GF;
- If $\varphi(x)$ has only a single free-variable x, then $\forall x\ \varphi$ and $\exists x\ \varphi$ are in GF.

The atoms α, appearing in the 3rd item of the above definition is called a *guard.*

For a finite signature σ and $n \in \mathbb{N}$, a (σ, n)*-affix-type* is a conjunction of atoms with n free variables $\overline{x}_{1\ldots n}$, in which for every $\mathrm{R} \in \sigma$ and every affix $\overline{x}_{l\ldots k}$ of $\overline{x}_{1\ldots n}$, of length $\mathsf{ar}(\mathrm{R})$, exactly one of $\mathrm{R}(\overline{x}_{l\ldots k})$, $\neg\mathrm{R}(\overline{x}_{l\ldots k})$ appears as a conjunct. For a σ-structure $\mathfrak{A}$ and a tuple $\bar{\mathrm{a}} \mathrel{\overline{\in}} A$ with $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{affix}}[\sigma]}(\bar{\mathrm{a}})$ we denote the *unique* $(\sigma, |\bar{\mathrm{a}}|)$-affix-type realised by $\bar{\mathrm{a}}$ in $\mathfrak{A}$.

2.1 Model Checking

Before jumping into the main part of the paper, we would like to point out some results on the combined complexity of model checking problems of ordered logics, since these seem to be missing from the literature. In what follows we will employ the *matrix encoding of structure*, that is a standard encoding in finite model theory [18, p. 88]. Given a $\{\mathrm{R}_1, \ldots, \mathrm{R}_m\}$-structure $\mathfrak{A}$ with a linearly-ordered domain A, by its *matrix encoding* we mean a binary string $\mathrm{menc}(\mathfrak{A}) := 0^n 1 \mathrm{menc}(\mathrm{R}_1) \ldots \mathrm{menc}(\mathrm{R}_m)$, where $\mathrm{menc}(\mathrm{R}_i)$ is a binary sequence of length $|A|^{\mathsf{ar}(\mathrm{R}_i)}$, in which the j-th bit is 1 iff the j-th tuple in the lexicographic ordering of $|A|^{\mathsf{ar}(\mathrm{R}_i)}$ belongs to $\mathrm{R}_i^{\mathfrak{A}}$.

The following theorem collects our complexity results. We have not tried to optimise the upper bounds for $\mathsf{G}_{\mathsf{pre}}$ and $\mathsf{L}_{\mathsf{pre}}$: it is quite possible that they can be improved further.

▶ **Theorem 1.** *Under the matrix encoding of structures, the combined complexity of the model-checking problem for a logic* L *is*

1. *decidable in* PTime *for* $\mathsf{G}_{\mathsf{pre}}$ *and* $\mathsf{L}_{\mathsf{pre}}$*,*
2. PTime*-complete for* $\mathsf{L} \in \{\mathsf{G}_{\mathsf{suf}}, \mathsf{G}_{\mathsf{inf}}, \mathsf{L}_{\mathsf{suf}}\}$*, and*
3. PSpace*-complete for* $\mathsf{L} = \mathsf{L}_{\mathsf{inf}}$*.*

Proof. The upper bound for $\mathsf{G}_{\mathsf{pre}}$ follows from the second item while the upper bound for $\mathsf{L}_{\mathsf{pre}}$ is proved in [5, App. A.1]. For the second item, the lower bound follows for all of the logics from the fact that they embed standard modal logic, for which the combined complexity is PTime-complete [10, Cor. 3.1.7]. For $\mathsf{G}_{\mathsf{suf}}$ and $\mathsf{G}_{\mathsf{inf}}$ matching upper bounds follow from the fact that the combined complexity of the guarded fragment is PTime-complete, while for $\mathsf{L}_{\mathsf{suf}}$ the matching upper bound is proved in [5, App. A.1]. Finally, for the third item, the upper bound follows from the fact that the combined complexity of FO is PSpace-complete [7], while the matching lower bound follows from the fact that $\mathsf{L}_{\mathsf{inf}}$ contains monadic FO, for which the combined complexity of model-checking is PSpace-complete [18, p. 99]. ◀

The matrix encoding is not the only natural way of encoding models. Another option would be to use the *list/database encoding* of models, where one essentially encodes relations by listing the tuples that they contain, as opposed to describing their adjacency matrices. It is easy to see that, if there is no bound on the arities of the relation symbols, then the list encoding of a model can be exponentially more succinct than its matrix encoding. Our proofs for the upper bounds of $\mathsf{L}_{\mathsf{pre}}$ and $\mathsf{L}_{\mathsf{suf}}$ are heavily dependent on the fact that we are using the matrix encoding of models, and hence it is conceivable that the complexities are higher if we are using list encoding.[3] We leave the related investigations as a very interesting future research direction.

3 Expressive power

We study the relative expressive power of ordered logics with a suitable notion of bisimulations.

▶ **Definition 2.** *A non-empty set* $\mathcal{Z} \subseteq \bigcup_{n<\omega}(A^n \times B^n)$ *is a* $\mathsf{L}_{\mathsf{affix}}[\sigma]$-bisimulation *between pointed structures* $\mathfrak{A}, \bar{\mathrm{a}}$ *and* $\mathfrak{B}, \bar{\mathrm{b}}$*, where* $|\bar{\mathrm{a}}| = |\bar{\mathrm{b}}|$*, if and only if* $(\bar{\mathrm{a}}, \bar{\mathrm{b}}) \in \mathcal{Z}$ *and for all* $(\bar{\mathrm{c}}, \bar{\mathrm{d}}) \in \mathcal{Z}$ *the following conditions hold:*

(atomic harmony) $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{affix}}[\sigma]}(\bar{\mathrm{c}}) = \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{affix}}[\sigma]}(\bar{\mathrm{d}})$.

(forth) *For a (possibly empty) affix* $\bar{\mathrm{c}}_{i\ldots j}$ *of* $\bar{\mathrm{c}}$ *and* $\mathrm{e} \in A$ *there is* $\mathrm{f} \in B$ *s.t.* $(\bar{\mathrm{c}}_{i\ldots j}\mathrm{e}, \bar{\mathrm{d}}_{i\ldots j}\mathrm{f}) \in \mathcal{Z}$.

(back) *For a (possibly empty) affix* $\bar{\mathrm{d}}_{i\ldots j}$ *of* $\bar{\mathrm{d}}$ *and* $\mathrm{f} \in B$ *there is* $\mathrm{e} \in A$ *s.t.* $(\bar{\mathrm{c}}_{i\ldots j}\mathrm{d}, \bar{\mathrm{d}}_{i\ldots j}\mathrm{f}) \in \mathcal{Z}$.

For $\mathsf{G}_{\mathsf{affix}}$, we replace the conditions (forth), (back) by their guarded counterparts:

(gforth) For a (possibly empty) affix $\bar{\mathrm{c}}_{i\ldots j}$ of $\bar{\mathrm{c}}$ and a σ-live tuple $\bar{\mathrm{e}}$ in $\mathfrak{A}$ such that $\bar{\mathrm{c}}_{i\ldots j} = \bar{\mathrm{e}}_{1\ldots j-i+1}$ there is a σ-live tuple $\bar{\mathrm{f}}$ with $\bar{\mathrm{d}}_{i\ldots j} = \bar{\mathrm{f}}_{1\ldots j-i+1}$ and $(\bar{\mathrm{e}}, \bar{\mathrm{f}}) \in \mathcal{Z}$,

(gback) For a (possibly empty) affix $\bar{\mathrm{d}}_{i\ldots j}$ of $\bar{\mathrm{d}}$ and a σ-live tuple $\bar{\mathrm{f}}$ in $\mathfrak{B}$ such that $\bar{\mathrm{d}}_{i\ldots j} = \bar{\mathrm{f}}_{1\ldots j-i+1}$ there is a σ-live tuple $\bar{\mathrm{e}}$ with $\bar{\mathrm{c}}_{i\ldots j} = \bar{\mathrm{e}}_{1\ldots j-i+1}$ and $(\bar{\mathrm{e}}, \bar{\mathrm{f}}) \in \mathcal{Z}$,

For a logic L and a finite signature σ, we write $\mathfrak{A} \equiv_{\mathsf{L}[\sigma]} \mathfrak{B}$ if $\mathfrak{A}$ and $\mathfrak{B}$ satisfy the same $\mathsf{L}[\sigma]$-sentences, and we write $\mathfrak{A} \sim_{\mathsf{L}[\sigma]} \mathfrak{B}$ if there is an $\mathsf{L}[\sigma]$-bisimulation between $\mathfrak{A}$ and $\mathfrak{B}$. If $|\bar{\mathrm{a}}| = |\bar{\mathrm{b}}|$, we use $\mathfrak{A}, \bar{\mathrm{a}} \equiv_{\mathsf{L}[\sigma]} \mathfrak{B}, \bar{\mathrm{b}}$ to denote that for every (possibly empty) affix $\bar{\mathrm{a}}_{i\ldots j}$ of $\bar{\mathrm{a}}$ and $\varphi(\bar{x}_{i\ldots j}) \in \mathsf{L}[\sigma]$, where $\bar{x}_{i\ldots j}$ is an affix of $(x_1, \ldots, x_n)$, we have that $\mathfrak{A} \models \varphi(\bar{\mathrm{a}}_{i\ldots j})$ if and only if $\mathfrak{B} \models \varphi(\bar{\mathrm{b}}_{i\ldots j})$. For the next lemma consult [5, App. B.1]

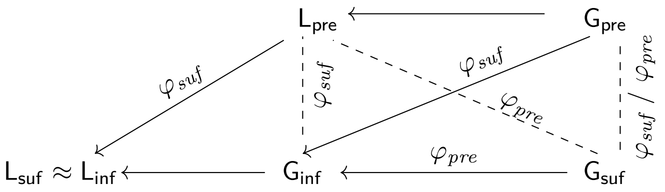
▶ **Lemma 3.** *Let* $\mathsf{L} \in \{\mathsf{L}_{\mathsf{affix}}, \mathsf{G}_{\mathsf{affix}}\}$*. Then* $\mathfrak{A}, \bar{\mathrm{a}} \sim_{\mathsf{L}[\sigma]} \mathfrak{B}, \bar{\mathrm{b}}$ *implies* $\mathfrak{A}, \bar{\mathrm{a}} \equiv_{\mathsf{L}[\sigma]} \mathfrak{B}, \bar{\mathrm{b}}$*. The converse holds over* ω*-saturated* $\mathfrak{A}$ *and* $\mathfrak{B}$*.*

[3] They can not decrease, because a list encoding of a model can always be constructed efficiently from its matrix encoding.

A logic L_2 is *at least as expressive as* a logic L_1 (written $\mathsf{L}_1 \preceq \mathsf{L}_2$) if for all $\varphi \in \mathsf{L}_1$ there is a $\psi \in \mathsf{L}_2$ such that $\varphi \equiv \psi$. We write $\mathsf{L}_1 \approx \mathsf{L}_2$ iff $\mathsf{L}_1 \preceq \mathsf{L}_2$ and $\mathsf{L}_2 \preceq \mathsf{L}_1$. In case $\mathsf{L}_1 \not\preceq \mathsf{L}_2$ and $\mathsf{L}_2 \not\preceq \mathsf{L}_1$ we call L_1 and L_2 incomparable. Lastly, $\mathsf{L}_1 \prec \mathsf{L}_2$ denotes that L_2 is *strictly more expressive* than L_1, *i.e.* $\mathsf{L}_1 \preceq \mathsf{L}_2$ and $\mathsf{L}_1 \not\approx \mathsf{L}_2$. Note that, by definition, all the considered fragments L satisfy $\mathsf{L} \preceq \mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L} \prec \mathsf{FO}$ (every such L is decidable). Moreover, $\mathsf{G}_{\mathsf{affix}} \prec \mathsf{L}_{\mathsf{affix}}$ is a consequence of $\forall x_1 \forall x_2 \mathrm{R}(x_1, x_2)$ not being $\mathsf{GF}[\{\mathrm{R}\}]$-definable (which is well-known and follows from the fact that GF has the tree-model property). Our results are as follows:

▶ **Theorem 4.** *(a)* $\mathsf{L}_{\mathsf{pre}} \prec \mathsf{L}_{\mathsf{suf}} \approx \mathsf{L}_{\mathsf{inf}} \prec \mathsf{FO}$*, (b)* $\mathsf{G}_{\mathsf{affix}} \prec \mathsf{L}_{\mathsf{affix}}$ *for all affixes, (c)* $\mathsf{G}_{\mathsf{suf}} \prec \mathsf{G}_{\mathsf{inf}}$*, (d)* $\mathsf{G}_{\mathsf{pre}} \prec \mathsf{G}_{\mathsf{inf}}$*, and (e) otherwise the logics are incomparable.*

Proof. Full proofs are in [5, App. B.2]. The relationships between different logics with separating examples (omitting trivial examples due to guardedness) are depicted below. With φ_{pre} we denote the formula $\forall x_1 x_2 x_3\ \mathrm{R}(x_1 x_2 x_3) \rightarrow \mathrm{S}(x_1 x_2)$, while φ_{suf} denotes $\forall x_1 x_2 x_3\ \mathrm{R}(x_1 x_2 x_3) \rightarrow \mathrm{T}(x_2 x_3)$. Solid (resp. dashed) arrows from L_1 to L_2 denote that $\mathsf{L}_1 \prec \mathsf{L}_2$ holds (resp. that the logics are incomparable).



$\mathsf{L}_{\mathsf{pre}}$
$\mathsf{G}_{\mathsf{pre}}$
φ_{suf}
φ_{suf}
φ_{suf}
φ_{pre}
φ_{suf} / φ_{pre}
φ_{pre}
$\mathsf{L}_{\mathsf{suf}} \approx \mathsf{L}_{\mathsf{inf}}$
$\mathsf{G}_{\mathsf{inf}}$
$\mathsf{G}_{\mathsf{suf}}$

The equi-expressivity of $\mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L}_{\mathsf{suf}}$ is an easy observation: we turn each maximally nested subformulae into DNF and push the atoms violating the definition of $\mathsf{L}_{\mathsf{affix}}$ outside. ◀

Knowing the relative expressive power of our logics, we would like to characterise them as bisimulation-invariant fragments of FO, as was done with other decidable logics, see *e.g.* [9]. Given a formula $\varphi(\overline{x}) \in \mathsf{L}$, we say that it is $\sim_{\mathsf{L}}$-invariant iff for all $\mathfrak{A}, \overline{\mathrm{a}} \sim_{\mathsf{L}}^{\mathsf{sig}(\varphi)} \mathfrak{B}, \overline{\mathrm{b}}$ we have $\mathfrak{A} \models \varphi(\overline{\mathrm{a}}) \Leftrightarrow \mathfrak{B} \models \varphi(\overline{\mathrm{b}})$. L is $\sim_{\mathsf{L}}$-invariant iff all its formulae are $\sim_{\mathsf{L}}$-invariant. We will next show that $\mathsf{L}_{\mathsf{affix}}$ (resp. $\mathsf{G}_{\mathsf{affix}}$) are exactly the $\sim_{\mathsf{L}_{\mathsf{affix}}}$- (resp. $\sim_{\mathsf{G}_{\mathsf{affix}}}$-) invariant fragments of FO. This confirms that our notion of bisimulation is the right one.

▶ **Theorem 5.** *Let* $\mathsf{L} \in \{\mathsf{L}_{\mathsf{affix}}, \mathsf{G}_{\mathsf{affix}}\}$ *and let* $\varphi(\overline{x})$ *be a* $\sim_{\mathsf{L}}$*-invariant* FO *formula. Then there exists a formula* $\psi(\overline{x})$ *in* L *which is equivalent with* $\varphi(\overline{x})$*.*

Proof. We follow standard proof methods, see *e.g.* [2, Thm. 3.2]. Suppose $\varphi(x_1, \ldots, x_n) \in \mathsf{FO}$ is $\sim_{\mathsf{L}}$-invariant, where $\overline{x} = (x_1, \ldots, x_n)$ enumerates precisely the set of free variables of φ. The case when φ is unsatisfiable φ is trivial, thus assume otherwise. Consider the set $\Gamma := \{\chi(\overline{x}_{i\ldots j}) \in \mathsf{L} \mid \varphi(\overline{x}) \models \chi(\overline{x}_{i\ldots j})\}$. Clearly $\varphi(\overline{x}) \models \Gamma$. Since FO is compact, it suffices to show that $\Gamma \models \varphi(\overline{x})$. Let $\mathfrak{A}$ be a structure and $\overline{\mathrm{a}} \in A^n$ so that $\mathfrak{A} \models \chi(\overline{\mathrm{a}}_{i\ldots j})$, for every $\chi(\overline{x}_{i\ldots j}) \in \Gamma$. Next, consider the set $\Sigma := \{\chi(\overline{x}_{i\ldots j}) \in \mathsf{L} \mid \mathfrak{A} \models \chi(\overline{\mathrm{a}}_{i\ldots j})\}$. Again, by compactness of FO we can show that $\Sigma \cup \{\varphi\}$ is consistent. Take a structure $\mathfrak{B}$ and $\overline{\mathrm{b}} \in B^n$ so that $\mathfrak{B} \models \varphi(\overline{\mathrm{b}})$ and $\mathfrak{B} \models \chi(\overline{\mathrm{b}}_{i\ldots j})$, for every $\chi(\overline{x}_{i\ldots j}) \in \Sigma$. Observe that by construction $\mathfrak{A}, \overline{\mathrm{a}} \equiv_{\mathsf{L}} \mathfrak{B}, \overline{\mathrm{b}}$. Replacing $\mathfrak{A}$ and $\mathfrak{B}$ with their ω-saturated elementary extensions $\hat{\mathfrak{A}}$ and $\hat{\mathfrak{B}}$, we know by Lemma 3 that $\hat{\mathfrak{A}}, \overline{\mathrm{a}} \sim_{\mathsf{L}} \hat{\mathfrak{B}}, \overline{\mathrm{b}}$. Chasing the resulting diagram we get $\mathfrak{A} \models \varphi(\overline{\mathrm{a}})$. ◀

4 Craig Interpolation

Recall that the Craig Interpolation Property (CIP) for a logic L states that if $\varphi(\overline{x}) \models \psi(\overline{x})$ holds (with φ and ψ having the same free variables), then there is a $\chi(\overline{x}) \in \mathsf{L}[\mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)]$ (an L-*interpolant*) such that $\varphi(\overline{x}) \models \chi(\overline{x})$ and $\chi(\overline{x}) \models \psi(\overline{x})$ hold. We always assume that both φ and ψ are satisfiable, otherwise we can take $\bot$ as a trivial interpolant.

To reason about interpolants we employ the notion of *joint consistency* [23]. We say that L-formulae $\varphi(\overline{x}_{1\ldots n})$ and $\psi(\overline{x}_{1\ldots n})$ (having exactly $\overline{x}_{1\ldots n}$ free) are *jointly-*$\mathsf{L}[\tau]$*-consistent* (or just *jointly consistent* in case $\tau := \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$ and L are known from the context), if there are structures $\mathfrak{A} \models \varphi(\overline{\mathrm{a}})$ and $\mathfrak{B} \models \psi(\overline{\mathrm{b}})$ such that $\mathfrak{A}, \overline{\mathrm{a}} \sim_{\mathsf{L}[\tau]} \mathfrak{B}, \overline{\mathrm{b}}$. The next lemma is classic and links joint consistency and interpolation: see [5, App. C.1].

▶ **Lemma 6.** *Let* $\mathsf{L} \subseteq \mathsf{FO}$*, and let* $\varphi(\overline{x}), \psi(\overline{x}) \in \mathsf{L}$ *with* $\tau := \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$*. Then* $\varphi(\overline{x})$ *and* $\neg\psi(\overline{x})$ *are jointly consistent iff there is no* $\mathsf{L}[\tau]$*-interpolant for* $\varphi(\overline{x}) \models \psi(\overline{x})$*.*

We simplify the reasoning about ordered logics by employing suitable normal forms. We say that a formula $\varphi(\overline{x})$ from[4] $\mathsf{L}_{\mathsf{pre}}$ (resp. from $\mathsf{G}_{\mathsf{affix}}$) is in *normal form* if it has the shape:
(NForm-$\mathsf{L}_{\mathsf{pre}}$) $\mathrm{H}(\overline{x}) \wedge \bigwedge_{i=1}^{s} \forall\overline{x}_{1\ldots\ell_i}(\alpha_i \rightarrow \exists x_{\ell_i+1}\beta_i) \wedge \bigwedge_{j=1}^{t} \forall\overline{x}_{1\ldots\ell_j}(\alpha_j \rightarrow \forall x_{\ell_j+1}\beta_j)$,
(NForm-$\mathsf{G}_{\mathsf{affix}}$) $\mathrm{H}(\overline{x}) \wedge \bigwedge_{i=1}^{s} \forall\overline{x}_{1\ldots\ell_i}(\mathrm{R}_i(\overline{x}_{1\ldots\ell_i}) \rightarrow \exists\overline{x}_{\ell_i+1\ldots\ell_i+k_i}(\mathrm{S}_i(\overline{x}_{1\ldots\ell_i+k_i}) \wedge \psi_i(\overline{x}_{1\ldots\ell_i+k_i}))) \wedge \bigwedge_{j=1}^{t} \forall\overline{x}_{1\ldots\ell_j}(\mathrm{R}_j(\overline{x}_{1\ldots\ell_j}) \rightarrow \psi_j(\overline{x}_{1\ldots\ell_j}) \rightarrow \forall\overline{x}_{\ell_j+1\ldots\ell'_j}(\mathrm{T}_j(\overline{x}_{1\ldots\ell'_j}) \rightarrow \psi'_j(\overline{x}_{1\ldots\ell'_j})))$,
where $\alpha_i, \alpha_j, \beta_i$ and β_j are quantifier-free $\mathsf{L}_{\mathsf{pre}}$-formulae, $\mathrm{R}_i, \mathrm{R}_j$, T_j and H are relational symbols, and ψ_i, ψ_j and ψ'_j are $\mathsf{G}_{\mathsf{affix}}$-formulae. The symbol H is called the *head* of $\varphi(\overline{x})$. We will often speak about *existential/universal requirements* of a formula, meaning the appropriate subformulae with the maximal quantifier prefix $\forall^*\exists^*$ and $\forall^*$. In aforementioned normal forms we implicitly allow various parameters to be zero, *e.g.* in subformulae of the form $\forall\overline{x}_{1\ldots\ell_i}(\alpha_i \rightarrow \exists x_{\ell_i+1}\beta_i)$ we allow $\ell_i = 0$, and we agree that the result is $\exists x_{\ell_i+1}\beta_i$.

The following lemma can be shown using standard renaming techniques, in complete analogy to [4, 15], with a minor (but technically tedious) modification in the case of $\mathsf{G}_{\mathsf{suf}}$, see [5, App. C.2].

▶ **Lemma 7.** *Let* $\mathsf{L} \in \{\mathsf{L}_{\mathsf{pre}}, \mathsf{G}_{\mathsf{affix}}\}$*, and take* $\varphi(\overline{x}), \psi(\overline{x}) \in \mathsf{L}$*. Suppose that there are models* $\mathfrak{A}$ *and* $\mathfrak{B}$ *such that* $\mathfrak{A} \models \varphi(\overline{\mathrm{a}})$*,* $\mathfrak{B} \models \psi(\overline{\mathrm{b}})$ *and* $\mathfrak{A}, \overline{\mathrm{a}} \sim_{\mathsf{L}[\tau]} \mathfrak{B}, \overline{\mathrm{b}}$*, where* $\tau = \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$*. Then there exist formulae* $\varphi'(\overline{x}), \psi'(\overline{x}) \in \mathsf{L}$ *in normal form and extensions* $\mathfrak{A}'$ *and* $\mathfrak{B}'$ *of* $\mathfrak{A}$ *and* $\mathfrak{B}$ *respectively, such that (i)* $\varphi'(\overline{x})$ *and* $\psi'(\overline{x})$ *have the same head* H*, (ii)* $\mathsf{sig}(\varphi') \cap \mathsf{sig}(\psi') = \tau \cup \{\mathrm{H}\}$*, (iii)* $\varphi'(\overline{x}) \models \varphi(\overline{x})$ *and* $\psi'(\overline{x}) \models \psi(\overline{x})$*, and (iii)* $(\mathfrak{A}', \overline{\mathrm{a}}) \sim_{\mathsf{L}[\tau\cup\{\mathrm{H}\}]} (\mathfrak{B}', \overline{\mathrm{b}})$ *holds.*

The following lemma is a useful tool when dealing with interpolation, allowing us to switch our attention to a certain satisfiability problem. Its proof is routine, consult [5, App. C.3].

▶ **Lemma 8.** *Let* $\mathsf{L} \in \{\mathsf{L}_{\mathsf{pre}}, \mathsf{G}_{\mathsf{affix}}\}$*. If for any jointly-consistent* L*-formulae* $\varphi(\overline{x}), \psi(\overline{x})$ *in normal forms from Lemma 7 with the same head, there is* $\mathfrak{U} \models \varphi(\overline{x}) \wedge \psi(\overline{x})$*, then* L *has CIP.*

4.1 Disproving CIP in $\mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L}_{\mathsf{suf}}$

We start our investigation of CIP for $\mathsf{L}_{\mathsf{affix}}$ and $\mathsf{G}_{\mathsf{affix}}$ by further discrediting the infamous work of Purdy [21]. We prove, in stark contrast to [21, Thm. 14], that $\mathsf{L}_{\mathsf{suf}}$ does not have CIP.

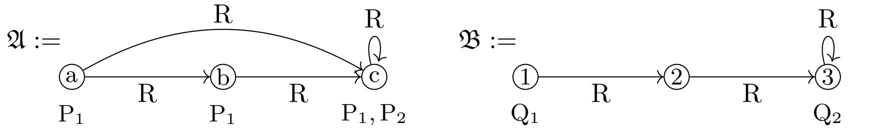
▶ **Theorem 9.** $\mathsf{L}_{\mathsf{inf}}$ *and* $\mathsf{L}_{\mathsf{suf}}$ *do not have CIP. More specifically, there are* $\mathsf{L}^2_{\mathsf{suf}}$*-sentences* φ, ψ *with* $\varphi \models \psi$ *but without any* $\mathsf{L}_{\mathsf{inf}}[\mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)]$*-interpolant.*

Proof. Consider the following $\mathsf{L}^3_{\mathsf{inf}}$-sentences φ and ψ, presented respectively below:

$$\forall\overline{x}_{1\ldots3}[(\mathrm{R}(x_1,x_2) \wedge \mathrm{R}(x_2,x_3)) \rightarrow (\mathrm{P}_1(x_1) \wedge \mathrm{P}_2(x_3))] \;\wedge\; \forall x_1\forall x_2[(\mathrm{P}_1(x_1) \wedge \mathrm{P}_2(x_2)) \rightarrow \mathrm{R}(x_1,x_2)]$$
$$\exists\overline{x}_{1\ldots3}[\mathrm{R}(x_1,x_2) \wedge \mathrm{R}(x_2,x_3) \wedge \mathrm{Q}_1(x_1) \wedge \mathrm{Q}_2(x_3)] \;\wedge\; \forall x_1\forall x_2[(\mathrm{Q}_1(x_1) \wedge \mathrm{Q}_2(x_2)) \rightarrow \neg\mathrm{R}(x_1,x_2)],$$

[4] To avoid notational glitter we will be a bit careless when dealing with formulae with free-variables.

with $\mathfrak{A} \models \varphi$ iff $(\mathrm{R}^{\mathfrak{A}} \circ \mathrm{R}^{\mathfrak{A}}) \subseteq \mathrm{P}_1^{\mathfrak{A}} \times \mathrm{P}_2^{\mathfrak{A}}$ and $\mathrm{P}_1^{\mathfrak{A}} \times \mathrm{P}_2^{\mathfrak{A}} \subseteq \mathrm{R}^{\mathfrak{A}}$, and $\mathfrak{B} \models \psi$ iff $\mathrm{Q}_1^{\mathfrak{B}} \times \mathrm{Q}_2^{\mathfrak{B}} \subseteq B^2 \setminus \mathrm{R}^{\mathfrak{B}}$ and there are $(\mathrm{a}, \mathrm{b}), (\mathrm{b}, \mathrm{c}) \in \mathrm{R}^{\mathfrak{B}}$ with $\mathrm{a} \in \mathrm{Q}_1^{\mathfrak{B}}$ and $\mathrm{c} \in \mathrm{Q}_2^{\mathfrak{B}}$. Observe that $\varphi \models \neg\psi$, since φ entails transitivity of R, while ψ entails that this is not the case. But φ and ψ are jointly-$\mathsf{L}_{\mathsf{inf}}[\{\mathrm{R}\}]$-consistent (it suffices to take $\mathfrak{A}$ and $\mathfrak{B}$ depicted below, *cf.* [5, App. C.5].



Hence, by Lemma 6 there is no $\mathsf{L}_{\mathsf{inf}}[\{\mathrm{R}\}]$-interpolant for $\varphi \models \neg\psi$. By slightly obfuscating φ and ψ (*i.e.* by shifting quantifiers and introducing a unary symbol to get rid of the third variable) we can make our counterexample formulae to be in $\mathsf{L}^2_{\mathsf{suf}}$; consult [5, App. C.6]. ◀

We left open the question whether $\mathsf{L}_{\mathsf{suf}}$ and $\mathsf{L}_{\mathsf{inf}}$ have the *Projective Beth Definability Property* (PBDP). We conjuncture that the answer is *no*, but we haven't found a suitable example yet.

4.2 Restoring CIP in $\mathsf{L}_{\mathsf{pre}}$

Even though $\mathsf{L}_{\mathsf{suf}}$ and $\mathsf{L}_{\mathsf{inf}}$ fail to have CIP, it turns out that $\mathsf{L}_{\mathsf{pre}}$ still has it. To prove interpolation for $\mathsf{L}_{\mathsf{pre}}$, we are going to construct a model for two jointly consistent $\mathsf{L}_{\mathsf{pre}}$ formulae $\varphi(\overline{x})$ and $\psi(\overline{x})$. However, rather than modifying existing amalgamation-based arguments used, for instance, in [19, 14, 2], we will construct our model explicitly by specifying prefix-types for tuples. We feel that our approach, which is more direct in nature than other arguments found in the literature, could potentially be useful also in other contexts.

Take $\varphi(\overline{x})$ and $\psi(\overline{x})$ in normal form (NForm-$\mathsf{L}_{\mathsf{pre}}$) satisfying the premise of Lemma 8. Hence, there are structures $\mathfrak{A}$ and $\mathfrak{B}$ and tuples $\overline{\mathrm{a}} \in A^k$ and $\overline{\mathrm{b}} \in B^k$ such that that $\mathfrak{A} \models \varphi(\overline{\mathrm{a}}), \mathfrak{B} \models \psi(\overline{\mathrm{b}})$ and $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{L}_{\mathsf{pre}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$, where $\sigma := \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$. Let $\tau := \mathsf{sig}(\varphi) \cup \mathsf{sig}(\psi)$.

We will define a sequence of τ-structures $\mathfrak{U}_1 \leq \ldots \leq \mathfrak{U}_M := \mathfrak{U}$, where $M = \max\{\mathsf{ar}(\mathrm{R}) \mid \mathrm{R} \in \tau\}$, satisfying the following inductive assumptions: (i) $U_i = \mathbb{N}$, (ii) the interpretation of symbols from τ of arity $> i$ is empty, and (iii) for any i-tuple $\overline{\mathrm{c}}$ in $\mathfrak{U}_i$ there are i-tuples $\overline{\mathrm{d}}$ in $\mathfrak{A}$ and $\overline{\mathrm{e}}$ in $\mathfrak{B}$ so that $(\mathfrak{A}, \overline{\mathrm{d}}) \sim_{\mathsf{L}_{\mathsf{pre}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{e}})$ and $\mathsf{tp}_{\mathfrak{U}_i}^{\mathsf{L}_{\mathsf{pre}}[\tau]}(\overline{\mathrm{c}}) = \mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{d}}) \cup \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\psi)]}(\overline{\mathrm{e}})$ hold. The last condition guarantees that no tuple $\overline{\mathrm{c}}$ of $\mathfrak{U}_i$ violates the universal requirements of φ and ψ, since otherwise the corresponding tuple would violate them, contradicting modelhood of $\mathfrak{A}$ or $\mathfrak{B}$.[5]

For the inductive base, take $\mathfrak{U}_1$ with domain $\mathbb{N}$ and empty interpretation of symbols from τ. Our goal is to realise each $(\mathsf{sig}(\varphi), 1)$-prefix-type, which is realised in $\mathfrak{A}$ and $\mathfrak{B}$, in $\mathfrak{U}_1$ in a careful way, suggested by the inductive assumption. Let t be a $(\mathsf{sig}(\varphi), 1)$-prefix type realised in $\mathfrak{A}$ and let $\mathrm{c} \in A$ be some element witnessing it. Since $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{L}_{\mathsf{pre}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$ holds, there exists an element d of $\mathfrak{B}$ so that $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\sigma]}(\mathrm{c}) = \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{pre}}[\sigma]}(\mathrm{d})$. Now we will assign the $(\tau, 1)$-prefix-type $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\varphi)]}(\mathrm{c}) \cup \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\psi)]}(\mathrm{d})$ to some element e of $\mathfrak{U}_1$, for which we have not yet assigned a $(\tau, 1)$-prefix-type. For the remaining elements of $\mathfrak{U}_1$, having no $(\tau, 1)$-prefix-type assigned, we assign any of the previously realised types.

[5] We note that this claim no longer holds if $\mathsf{L}_{\mathsf{pre}}$ is replaced by either $\mathsf{L}_{\mathsf{suf}}$ or $\mathsf{L}_{\mathsf{affix}}$, which is why the forthcoming construction does not work for these logics.

Suppose then that $\mathfrak{U}_k$ is defined. To define $\mathfrak{U}_{k+1}$, we will start by providing witnesses for the existential requirements of φ and ψ; since the two cases are rather analogous, we will restrict our attention to the former case. Consider an existential requirement $\varphi_i^{\exists}$ of $\varphi(\overline{x})$ and let $\overline{\mathrm{e}} \in U_k^k$ be a k-tuple so that $\mathfrak{U} \models \alpha_i(\overline{\mathrm{e}})$. By construction, there exists a tuple $\overline{\mathrm{a}} \in A^k$ witnessing $\mathsf{tp}_{\mathfrak{U}_k}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{e}}) = \mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{a}})$. Since $\mathfrak{A} \models \varphi_i^{\exists}$, there exists an element $\mathrm{c} \in A$ so that $\mathfrak{A} \models \beta_i(\overline{\mathrm{a}}, \mathrm{c})$. Due to $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{L}_{\mathsf{pre}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$, we know that there exists an element $\mathrm{d} \in B$ satisfying $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\sigma]}(\overline{\mathrm{a}}, \mathrm{c}) = \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{pre}}[\sigma]}(\overline{\mathrm{b}}, \mathrm{d})$. Now we pick an element $f \in U$ for which we have not yet assigned a $(\tau, k{+}1)$-prefix-type for the tuple $(\overline{\mathrm{e}}, \mathrm{f})$ (recall that the domain of our model is $\mathbb{N}$, so such an element always exists). We assign the following $(\tau, k{+}1)$-prefix-type to the tuple $(\overline{\mathrm{e}}, \mathrm{f})$: $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\varphi)]}((\overline{\mathrm{a}}, \mathrm{c})) \cup \mathsf{tp}_{\mathfrak{B}}^{\mathsf{L}_{\mathsf{pre}}[\mathsf{sig}(\psi)]}((\overline{\mathrm{b}}, \mathrm{d}))$. Note that the assigned $(\tau, k{+}1)$-prefix-type is consistent with the (τ, k)-prefix-type that we assigned to $\overline{\mathrm{e}}$. Having assigned witnesses to relevant existential requirements of $\varphi(\overline{x})$ and $\psi(\overline{x})$, there are still $(k{+}1)$-tuples of elements of $\mathfrak{U}$ for which we have not yet assigned a $(\tau, k{+}1)$-prefix-type. For those tuples we will assign any $(\tau, k{+}1)$-prefix-type that we have already assigned to some other $(k{+}1)$-tuple of elements of $\mathfrak{U}_{k+1}$. This completes the construction of $\mathfrak{U}_{k+1}$.

By construction, it is clear that there exists a tuple $\overline{\mathrm{e}}$ of elements of $\mathfrak{U}$ so that $\overline{\mathrm{e}} \in \mathrm{H}^{\mathfrak{U}}$; in particular, $\mathfrak{U} \models \varphi(\overline{\mathrm{e}}) \wedge \psi(\overline{\mathrm{e}})$ holds. Thus, by Lemma 8 we conclude:

▶ **Theorem 10.** $\mathsf{L}_{\mathsf{pre}}$ *enjoys the Craig Interpolation Property.*

4.3 Restoring CIP in guarded logics

Finally we turn our attention to the logics $\mathsf{G}_{\mathsf{affix}}$ and present the main contribution of the paper. It will be convenient to employ suitable tree-like models. Intuitively, HATs [4] are just trees in which relations connect elements but only in a level-by-level ascending order; see Figure 1. HAHs are collections of HATs.

▶ **Definition 11.** *A structure* $\mathfrak{T}$ *is a* higher-arity tree *(HAT) if its domain is a prefix-closed subset of sequences from* $\mathbb{N}^*$ *and for all relation symbols* R *we have that* $(d_1, \ldots, d_k) = \overline{\mathrm{d}} \in \mathrm{R}^{\mathfrak{T}}$ *implies that for each index* $i < k$ *there exists a number* n_i *such that* $\mathrm{d}_{i+1} = \mathrm{d}_i \cdot n_i$*, where* $\mathrm{d}_i \cdot n_i$ *means that the element* n_i *is appended to the sequence* d_i*. A structure* $\mathfrak{H}$ *is a* higher-arity hedge *(HAH) if* $\mathfrak{H}$ *becomes a HAT if extended by a single element* ε*.*

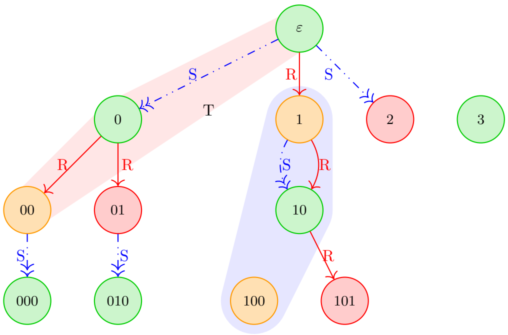


Figure 1 An example HAT $\mathfrak{T}$. All relations go down lvl-by-lvl. The red area means $(\varepsilon, 0, 00) \in \mathrm{T}^{\mathfrak{T}}$.

By a subtree of a HAT $\mathfrak{T}$ rooted at an element d we mean a substructure of $\mathfrak{T}$ with the domain composed of all elements of the form dw for a possibly empty word w. Note that such a subtree is also a HAT after an obvious renaming.

We are going to employ the following lemma, stating that for our purposes we can focus on tree-like models only. Its proof relies on the suitable notion of unravelling, see [5, App. C.4].

▶ **Lemma 12.** *Let a logic* L *be any of* $\mathsf{G}_{\mathsf{affix}}$*,* φ, ψ *be* L*-formulae and* $\sigma := \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$ *containing the predicate* H*. Assume that models* $\mathfrak{A} \models \varphi(\overline{\mathrm{a}}), \mathfrak{B} \models \psi(\overline{\mathrm{b}})$ *are given such that* $\overline{\mathrm{a}} \in \mathrm{H}^{\mathfrak{A}}, \overline{\mathrm{b}} \in \mathrm{H}^{\mathfrak{B}}$ *and* $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$ *hold. Then there are HAH models* $\mathfrak{T}_{\mathfrak{A}} \models \varphi(\overline{\mathrm{c}}), \mathfrak{T}_{\mathfrak{B}} \models \psi(\overline{\mathrm{d}})$ *satisfying* $\overline{\mathrm{c}} \in \mathrm{H}^{\mathfrak{T}_{\mathfrak{A}}}, \overline{\mathrm{d}} \in \mathrm{H}^{\mathfrak{T}_{\mathfrak{B}}}$ *and* $(\mathfrak{T}_{\mathfrak{A}}, \overline{\mathrm{c}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{T}_{\mathfrak{B}}, \overline{\mathrm{d}})$*.*

Take $\varphi(\overline{x})$, $\psi(\overline{x})$ in form (NForm-$\mathsf{G}_{\mathsf{affix}}$) with the same head, satisfying the premise of Lemma 8. We have structures $\mathfrak{A}$ and $\mathfrak{B}$ and tuples $\overline{\mathrm{a}} \in A^k$ and $\overline{\mathrm{b}} \in B^k$ so that $\mathfrak{A} \models \varphi(\overline{\mathrm{a}}), \mathfrak{B} \models \psi(\overline{\mathrm{b}})$ and $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$, where $\sigma := \mathsf{sig}(\varphi) \cap \mathsf{sig}(\psi)$ and $\tau := \mathsf{sig}(\varphi) \cup \mathsf{sig}(\psi)$. Using Lemma 12 we can assume that $\mathfrak{A}$ and $\mathfrak{B}$ are τ-HAHs. As done before, we aim at constructing a τ-structure being a model of both φ and ψ. To do this, we will construct a growing sequence of τ-HAHs $\mathfrak{U}_0 := \mathfrak{A} \leq \mathfrak{U}_1 \leq \ldots \leq \mathfrak{U}_n \leq \ldots$, whose limit $\mathfrak{U}$ will be a model of $\varphi \wedge \psi$. For simplicity, let us employ the following naming scheme. A tuple $\overline{\mathrm{d}}$ from $\mathfrak{U}_n$ ($\overline{\mathrm{d}} \sqsubseteq U_n$) is called (a) *n-fresh* if $\overline{\mathrm{d}} \sqsubseteq U_{n-1}$ and *n-aged* otherwise, (b) *maximal* if its not an affix of any different σ-live tuple.

A high-level idea of the construction of the sequence $\mathfrak{U}_i$, obfuscated by many challenging technical details, is as follows. Starting from $\mathfrak{A}$ we inductively "complete" types of all σ-live tuples to become proper τ-live tuples. This will help, if done carefully and in a bisimilarity-preserving way, the structure $\mathfrak{U}_i$ to fulfil the universal constraints of φ and ψ, but may introduce tuples without witnesses for the existential constraints. Hence, after each "completion" phase, we will "repair" the obtained structure by "copying" some substructures of $\mathfrak{A}$ and $\mathfrak{B}$ and "gluing" them on existing witness-lacking tuples (providing the required witnesses).

During the construction we will make sure that for every n-aged $\mathsf{sig}(\varphi)$-live (resp. $\mathsf{sig}(\psi)$-live) k-tuple in $\mathfrak{U}$, there exists a k-tuple in $\mathfrak{A}$ (resp. in $\mathfrak{B}$) having equal $(\mathsf{sig}(\varphi), k)$-affix-type (resp. $(\mathsf{sig}(\psi), k)$-affix-type). This will be controlled by means of partial *witness functions* $\mathsf{wit}_{\mathfrak{A}} : U_n \to A, \mathsf{wit}_{\mathfrak{B}} : U_n \to B$, intuitively pinpointing from where a tuple in $\mathfrak{U}$ originated from. To make the construction work, the witness function will fulfil several technical criteria, that are listed below. Conditions (a) and (b) speak about the compatibility of types between a tuple and its witness tuple; this guarantees that no tuple from $\mathfrak{U}_n$ violate the universal requirements of φ and ψ. Conditions (c)–(d) guarantees the satisfaction of the existential requirements of φ and ψ (condition (c) takes care of "local" requirements while (d) handles the "global" ones). Formally, for every n-aged $\overline{\mathrm{c}}$ from $\mathfrak{U}_n$ we have that:

(a) If $\overline{\mathrm{c}}$ is σ-live then both $\overline{\mathrm{d}} := \mathsf{wit}_{\mathfrak{A}}(\overline{\mathrm{c}})$ and $\overline{\mathrm{e}} := \mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{c}})$ are defined, $(\mathfrak{A}, \overline{\mathrm{d}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{e}})$ holds and $\mathsf{tp}_{\mathfrak{U}_n}^{\mathsf{G}_{\mathsf{affix}}[\tau]}(\overline{\mathrm{c}})$ is equal to $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{d}}) \cup \mathsf{tp}_{\mathfrak{B}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\psi)]}(\overline{\mathrm{e}})$.

(b) If $\overline{\mathrm{c}}$ is not σ-live but is $\mathsf{sig}(\varphi)$-live (resp. $\mathsf{sig}(\psi)$-live), then $\overline{\mathrm{d}} := \mathsf{wit}_{\mathfrak{A}}(\overline{\mathrm{c}})$ (resp. $\overline{\mathrm{d}} := \mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{c}})$) is defined, and $\mathsf{tp}_{\mathfrak{U}_n}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{c}})$ is equal to $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{d}})$ (resp. $\mathsf{tp}_{\mathfrak{B}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\psi)]}(\overline{\mathrm{d}})$).

(c) if $\overline{\mathrm{c}}$ is $\mathsf{sig}(\varphi)$-live (resp. $\mathsf{sig}(\psi)$-live), then for every existential requirement $\lambda := \mathrm{R}_i(\overline{x}_{1\ldots\ell_i}) \to \exists \overline{x}_{\ell_i\ldots\ell_i+k_i}(\mathrm{S}_i(\overline{x}_{1\ldots\ell_i+k_i}) \wedge \theta_i(\overline{x}_{1\ldots\ell_i+k_i}))$ from φ (resp. from ψ) with $\overline{\mathrm{c}}$ satisfying the premise of λ, there is a tuple $\overline{\mathrm{d}}$ in $\mathfrak{U}_n$ so that $\overline{\mathrm{c}}\overline{\mathrm{d}}$ satisfies the conclusion of λ.

(d) For every $\mathsf{sig}(\varphi)$-live (resp. $\mathsf{sig}(\psi)$-live) tuple $\overline{\mathrm{d}}$ from $\mathfrak{A}$ (resp. from $\mathfrak{B}$) there is a tuple $\overline{\mathrm{e}}$ in $\mathfrak{U}_1$ such that $\mathsf{tp}_{\mathfrak{U}_n}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{e}}) = \mathsf{tp}_{\mathfrak{A}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{d}})$ (resp. $\mathsf{tp}_{\mathfrak{U}_n}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\overline{\mathrm{e}}) = \mathsf{tp}_{\mathfrak{B}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\psi)]}(\overline{\mathrm{d}})$).

While the following property is not necessary to guarantee that the limit $\mathfrak{U}$ is a model of $\varphi \wedge \psi$, it plays an important technical role in the construction:

(e) If $\overline{\mathrm{d}}$ is an n-fresh σ-live tuple such that either $\mathsf{wit}_{\mathfrak{A}}(\overline{\mathrm{d}})$ or $\mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}})$ is undefined, then for every prefix $\overline{\mathrm{d}}_{1\ldots k}$ of $\overline{\mathrm{d}}$ that is contained in U_{n-1}, meaning that $\overline{\mathrm{d}}_{1\ldots k} \sqsubseteq U_{n-1}$, there exists an n-aged σ-live tuple $\overline{\mathrm{c}}$ which contains $\overline{\mathrm{d}}_{1\ldots k}$ as its affix.

Using conditions (a)–(d) it follows that $\mathfrak{U} \models \varphi \wedge \psi$, allowing us to conclude (by Lemma 8):

▶ **Theorem 13.** $\mathsf{G}_{\mathsf{inf}}, \mathsf{G}_{\mathsf{suf}}$ *and* $\mathsf{G}_{\mathsf{pre}}$ *enjoy the Craig Interpolation Property.*

We will now move on to the construction of $\mathfrak{U}$, described below. We start from the crucial, aforementioned notions of *completions* and *repairs*. Intuitively the *completion* just "completes a type of a tuple" in a bisimulation-preserving way, taking all symbols of τ into account. *Repair* simply "plugs in" certain subtrees from $\mathfrak{A}$ or $\mathfrak{B}$ into $\mathfrak{U}$, providing missing witnesses.

▶ **Definition 14** (completion). *Let $(\mathfrak{T}, \bar{\mathrm{d}})$ be a pointed τ-HAH, where $\bar{\mathrm{d}}$ is σ-live with $\mathsf{wit}_{\mathfrak{A}}, \mathsf{wit}_{\mathfrak{B}}$ defined. The* $\bar{\mathrm{d}}$-completion *of $\mathfrak{T}$ is obtained from $\mathfrak{T}$ by redefining interpretation of symbols from τ in a min. way so that $\mathsf{tp}_{\mathfrak{T}}^{\mathsf{G}_{\mathsf{affix}}[\tau]}(\bar{\mathrm{d}})$ equals $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\varphi)]}(\mathsf{wit}_{\mathfrak{A}}(\bar{\mathrm{d}})) \cup \mathsf{tp}_{\mathfrak{B}}^{\mathsf{G}_{\mathsf{affix}}[\mathsf{sig}(\psi)]}(\mathsf{wit}_{\mathfrak{B}}(\bar{\mathrm{d}}))$.*

▶ **Definition 15** (repair). *Let $(\mathfrak{T}, \bar{\mathrm{c}})$ be a pointed τ-HAH with only $\bar{\mathrm{d}} := \mathsf{wit}_{\mathfrak{A}}(\bar{\mathrm{c}})$ defined, where $\bar{\mathrm{c}}$ is σ-live in $\mathfrak{T}$. Suppose also that there is a tuple $\bar{\mathrm{e}}$ in $\mathfrak{B}$ such that $(\mathfrak{A}, \bar{\mathrm{d}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \bar{\mathrm{e}})$ holds. The* $(\mathfrak{B}, \bar{\mathrm{e}})$-repair *of $\bar{\mathrm{c}}$ is a τ-HAH $\mathfrak{T}'$ obtained from $\mathfrak{T}$ in the following five steps:*

1. *Let $\mathfrak{B}_0$ be the subtree of $\mathfrak{B}$ rooted at the first element of $\bar{\mathrm{e}}$.*
2. *Take $\mathfrak{T}'$ to be the union of $\mathfrak{T}$ and $\mathfrak{B}_0$ without $\bar{\mathrm{e}}$.*
3. *$\mathfrak{T}'$ will contain $\mathfrak{T}$ as a substructure.*
4. *By identifying $\bar{\mathrm{c}}$ with $\bar{\mathrm{e}}$, we interpret the relation symbols for tuples of elements of $\mathfrak{T}' \restriction B_0$ in such a way that the resulting substructure of $\mathfrak{T}'$ is isomorphic with $\mathfrak{B}_0$.*
5. *We set $\mathsf{wit}_{\mathfrak{B}}$ on freshly added elements to be the identity on $\mathfrak{B}_0$.*

The substructure $\mathfrak{T}' \restriction (B_0 \cup \bar{\mathrm{c}})$ is called a $\bar{\mathrm{c}}$-component *of $\mathfrak{T}'$. $\mathfrak{T}'$ becomes a HAH after a routine renaming. We define* $(\mathfrak{A}, \bar{\mathrm{d}})$-repair *of $\bar{\mathrm{c}}$ analogously.*

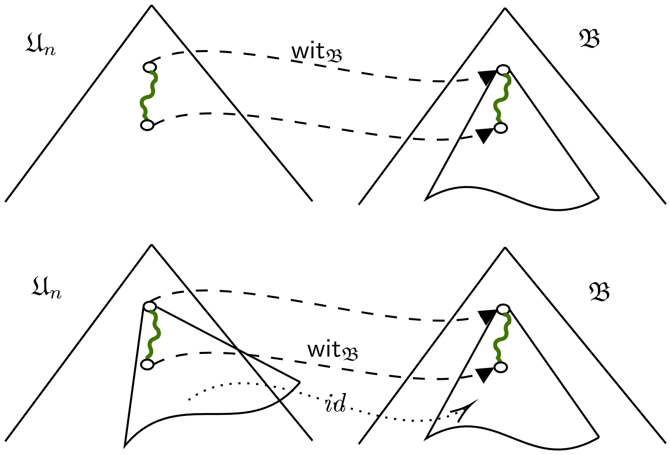

Figure 2 An example structure $\mathfrak{U}_n$ before and after we performed a "$\mathfrak{B}$"-repair.

We proceed with the base of induction, setting first $\mathfrak{U}_0$ to be $\mathfrak{A}$. It will be four-fold.

Base case: Step I. We set up $\mathsf{wit}_{\mathfrak{A}}$ and $\mathsf{wit}_{\mathfrak{B}}$ functions. For $\mathsf{wit}_{\mathfrak{A}}$ we will simply take the identity function. To define $\mathsf{wit}_{\mathfrak{B}}$, we intuitively proceed by traversing $\mathfrak{U}_0$ from top to bottom. More precisely, let $L_0^{\mathfrak{A}}$ denote the set of all maximal σ-live tuples in $\mathfrak{U}_0$. Letting $<_{lex}$ denote the lexicographic ordering of $\mathbb{N}^*$, we construct a well-founded linear ordering $\prec$ on $L_0^{\mathfrak{A}}$ as follows: $\bar{\mathrm{c}} \prec \bar{\mathrm{d}}$ iff there is an $i \leq \min\{|\bar{\mathrm{c}}|, |\bar{\mathrm{d}}|\}$ such that $\mathrm{c}_i <_{lex} \mathrm{d}_i$ and $\mathrm{c}_j = \mathrm{d}_j$ for every $j <_{lex} i$ (note that if there is no such i, then the tuples are equal due to maximality). One can show that $\bar{\mathrm{c}} \prec \bar{\mathrm{d}}$ implies that (♡): if $\bar{\mathrm{c}}$ and $\bar{\mathrm{d}}$ share some elements, then there exists i, j and k such that $\bar{\mathrm{c}}_{i \ldots j} = \bar{\mathrm{d}}_{1 \ldots k}$ and none of the elements d_ℓ, for $\ell > k$, occur in $\bar{\mathrm{c}}$. To prove this, one needs to simply show that if d_k occurs in $\bar{\mathrm{c}}$, then $(\mathrm{d}_1, \ldots, \mathrm{d}_k)$ is an affix of $\bar{\mathrm{c}}$ (the proof goes via careful inspection of the definition of HAHs, *cf.* [5, App. C.7]).

We define $\mathsf{wit}_{\mathfrak{B}}$ inductively w.r.t $\prec$. Consider a maximal σ-live tuple $\overline{\mathrm{d}}$ and suppose that we have defined $\mathsf{wit}_{\mathfrak{B}}$ for all the σ-live tuples $\overline{\mathrm{c}} \prec \overline{\mathrm{d}}$. There are two cases to consider.

- There exists a tuple $\overline{\mathrm{c}} \prec \overline{\mathrm{d}}$ sharing at least one element with $\overline{\mathrm{d}}$. By ($\heartsuit$), for every such tuple $\overline{\mathrm{c}}$ there are i, j and k so that $\overline{\mathrm{c}}_{i \ldots j} = \overline{\mathrm{d}}_{1 \ldots k}$ and none of the elements d_ℓ, for $\ell > k$, occur in $\overline{\mathrm{c}}$. Let $\overline{\mathrm{c}}$ be the tuple for which the corresponding value k is the largest. Since $\overline{\mathrm{c}}$ is σ-live, by induction hypothesis there exists some $\overline{\mathrm{e}} \sqsubseteq B$ such that $(\mathfrak{A}, \overline{\mathrm{c}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{e}})$ holds. Thus there exists some $\overline{\mathrm{f}} \sqsubseteq B$ such that $\overline{\mathrm{f}}_{i \ldots j} = \overline{\mathrm{e}}_{i \ldots j}$ and $(\mathfrak{A}, \overline{\mathrm{d}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{f}})$. We now extend $\mathsf{wit}_{\mathfrak{B}}$ in such a way that $\mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}}) = \overline{\mathrm{f}}$.
- Otherwise $\overline{\mathrm{c}}$ and $\overline{\mathrm{d}}$ do not share any elements. Since $\overline{\mathrm{d}}$ is σ-live and $(\mathfrak{A}, \overline{\mathrm{a}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{b}})$, there exists some $\overline{\mathrm{e}} \sqsubseteq B$ such that $(\mathfrak{A}, \overline{\mathrm{d}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \overline{\mathrm{e}})$. We then simply extend $\mathsf{wit}_{\mathfrak{B}}$ in such a way that $\mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}}) = \overline{\mathrm{e}}$.

The resulting mapping $\mathsf{wit}_{\mathfrak{B}}$. This finishes Step I.

Base case: Step II. We next complete types of all fresh (= all in this case) σ-live tuples of $\mathfrak{U}_0$. Take any maximal σ-live tuple $\overline{\mathrm{d}}$ from $\mathfrak{U}_0$ and perform the $\overline{\mathrm{d}}$-completion of $\mathfrak{U}_0$. It is easy to see that this process is conflict-free in the following sense: there is no tuple $\overline{\mathrm{c}}$ and $R \in \mathsf{sig}(\psi)$ so that we end up specifying both $\overline{\mathrm{c}} \in \mathrm{R}^{\mathfrak{U}_0}$ and $\overline{\mathrm{c}} \notin \mathrm{R}^{\mathfrak{U}_0}$. First, if two maximal σ-live tuples $\overline{\mathrm{d}}$ and $\overline{\mathrm{e}}$ have affixes $\overline{\mathrm{d}}_{i \ldots j}$ and $\overline{\mathrm{e}}_{k \ldots \ell}$ such that $\overline{\mathrm{d}}_{i \ldots j} = \overline{\mathrm{e}}_{k \ldots \ell}$, then we know that $\mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}}_{i \ldots j}) = \mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{e}}_{k \ldots \ell})$, and thus there are no conflicts in the "intersections" of σ-live tuples. Second, by construction $\mathsf{tp}_{\mathfrak{A}}^{\mathsf{G}_{\mathsf{affix}}[\sigma]}(\overline{\mathrm{d}}) = \mathsf{tp}_{\mathfrak{B}}^{\mathsf{G}_{\mathsf{affix}}[\sigma]}(\mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}}))$ holds for all maximal σ-live tuple $\overline{\mathrm{d}}$, and hence the σ-infix-types that we assigned to σ-live tuples are indeed types, *i.e.* they are consistent. Thus our process is conflict-free.

Note that our structure satisfies now conditions (a) and (b).

Base case: Step III. We finish the base case by providing witnesses for fresh $\mathsf{sig}(\psi)$-tuples via repairs. Recall that $L_0^{\mathfrak{A}}$ denotes the set of all maximal σ-live tuples in $\mathfrak{U}_0^{\mathfrak{A}}$. For each $\overline{\mathrm{d}} \in L_0^{\mathfrak{A}}$ we perform the $(\mathfrak{B}, \mathsf{wit}_{\mathfrak{B}}(\overline{\mathrm{d}}))$-repair of $\overline{\mathrm{d}}$; the resulting structure will be taken to be $\mathfrak{U}_1$. Note that now every $\mathsf{sig}(\psi)$-live tuple in $\mathfrak{U}_1$ has its witnesses for the existential requirements, but there may be new $\mathsf{sig}(\varphi)$-live tuples without them. Moreover, $\mathsf{wit}_{\mathfrak{B}}$ is defined for all freshly added elements, but $\mathsf{wit}_{\mathfrak{A}}$ is not. Furthermore, we note that $\mathfrak{U}_1$ now satisfies condition (e), since all the 1-fresh live tuples for which $\mathsf{wit}_{\mathfrak{A}}$ is not defined are present in the subtrees that we attached to $\mathfrak{U}_0$ during the repair, which is done only at (maximal) σ-live tuples.

Base case: Step IV. It could be the case that the structure $\mathfrak{U}_1$ produced in the previous step violates (d), due to the lack of realisation of a certain type from $\mathfrak{B}$. Thus, as an extra precaution, unique to the base case, we add a disjoint copy of $\mathfrak{B}$ to $\mathfrak{U}_1$ and define $\mathsf{wit}_{\mathfrak{B}}$ for it to be the identity. Note that now (d) will be satisfied in any extension of $\mathfrak{U}_1$.

Inductive step. The inductive step is analogous to Steps I-III from the base case, hence we keep its description short. Assume that $\mathfrak{U}_n$ is defined and that in the previous step of the construction we employed $\mathfrak{B}$-repairs (the case of $\mathfrak{A}$-repairs is symmetric). Given a component $\mathfrak{C}$ that was created during such a repair, we let $L_n^{\mathfrak{C}}$ denote the set of all maximal n-fresh σ-live tuples in $\mathfrak{C}$. Since $\mathfrak{C}$ is essentially a HAT (up to renaming), we can again define a well-founded linear order $\prec$ on $L_n^{\mathfrak{C}}$ in the same way as we did in the base case for $L_0^{\mathfrak{A}}$. As in the base case, we then define missing values of $\mathsf{wit}_{\mathfrak{A}}$ for elements of $\mathfrak{C}$ inductively w.r.t $\prec$.

Observe that some of the tuples in $L_n^{\mathfrak{C}}$ might contain a proper prefix of elements of U_{n-1}. In the case of $\mathsf{G}_{\mathsf{suf}}$ these tuples do not cause any problems to us, because suffix-types do not impose any constraints on proper prefixes. In the cases of $\mathsf{G}_{\mathsf{pre}}$ and $\mathsf{G}_{\mathsf{inf}}$ we handle these tuples by using the fact that $\mathfrak{U}_n$ satisfies condition (e) as follows. Let $\bar{\mathrm{d}} \in L_n^{\mathfrak{C}}$ be such a tuple and let k be the largest index so that $\bar{\mathrm{d}}_{1\ldots k} \sqsubseteq U_{n-1}$. Using condition (e), we know that there exists a σ-live n-aged tuple $\bar{\mathrm{c}}$ so that $\bar{\mathrm{c}}_{i\ldots j} = \bar{\mathrm{d}}_{1\ldots k}$, for some i and j. Employing condition (a), we know that $\bar{\mathrm{e}} := \mathsf{wit}_{\mathfrak{A}}(\bar{\mathrm{c}})$, $\bar{\mathrm{f}} := \mathsf{wit}_{\mathfrak{B}}(\bar{\mathrm{c}})$ and $\bar{\mathrm{h}} := \mathsf{wit}_{\mathfrak{B}}(\bar{\mathrm{d}})$ are defined and that $(\mathfrak{A}, \bar{\mathrm{e}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \bar{\mathrm{f}})$. Thus there exists a σ-live tuple $\bar{\mathrm{g}} \sqsubseteq A$ such that $\bar{\mathrm{f}}_{i\ldots j} = \bar{\mathrm{g}}_{i\ldots j}$ and $(\mathfrak{A}, \bar{\mathrm{g}}) \sim_{\mathsf{G}_{\mathsf{affix}}[\sigma]} (\mathfrak{B}, \bar{\mathrm{h}})$. We now extend $\mathsf{wit}_{\mathfrak{A}}$ in such a way that $\mathsf{wit}_{\mathfrak{A}}(\bar{\mathrm{d}}) = \bar{\mathrm{g}}$.

The above procedure is repeated for all components $\mathfrak{C}$ that were introduced during the previous repair. Having defined $\mathsf{wit}_{\mathfrak{A}}$ for all the elements, we perform a completion that works for exactly the same reasons as described before. Finally, letting L_n denote the set of all maximal n-fresh σ-live tuples, we perform repair of every tuple in L_n, which results in a model that we select as $\mathfrak{U}_{n+1}$. We stress that every $\mathsf{sig}(\varphi)$-live tuple in $\mathfrak{U}_{n+1}$ has its witnesses for the existential requirements, but there can now be new $\mathsf{sig}(\psi)$-live tuples without them. We also emphasise that $\mathsf{wit}_{\mathfrak{A}}$ is defined for all the new elements but $\mathsf{wit}_{\mathfrak{B}}$ might not be. This concludes the inductive step and hence, also the construction of $\mathfrak{U}$ and the proof of Theorem 13.

▶ Remark 16. The presented model construction is quite generic. Indeed, the only part of the construction which is really specific to $\mathsf{G}_{\mathsf{affix}}$ is the first step of the construction, namely the part where we define inductively the values of witness functions. We expect that the presented technique can be easily adapted to other logics, especially to other fragments of the guarded fragments. For instance, we believe that our technique can be adjusted, *e.g.* to the case of the two-variable GF from [14] as well as to the uniform one-dimensional GF from [16].

5 Conclusions

In this paper kick-started a project of understanding the model theory of the family of guarded and unguarded ordered logics. We first investigated the relative expressive power of ordered logics by means of suitable bisimulations. Afterwards, we proceed with the Craig Interpolation Property (CIP) showing that (i) the fluted and the forward fragments do not enjoy CIP, (ii) while the other logics that we consider enjoy it. The fact that the fluted fragment does not posses CIP was quite unexpected in the light of already existing claims for the contrary [21, Thm. 14]. For the other logics we proposed a novel model-theoretic "complete-and-repair" method of creating a model out of two bisimilar forest-like structures.

There are several interesting future work directions.

1. One example is to investigate the Łoś-Tarski Preservation Theorem as well as other preservation theorems. While we think that we already have a working construction for guarded ordered logics, the status of ŁTPT holding for $\mathsf{L}_{\mathsf{pre}}$, $\mathsf{L}_{\mathsf{suf}}$, and $\mathsf{L}_{\mathsf{inf}}$ is not clear.[6]
2. Another work direction is to take a look at on effective interpolation, similarly to what has been proposed in [6] as well as on the interpolant existence problem for $\mathsf{L}_{\mathsf{inf}}$ and $\mathsf{L}_{\mathsf{suf}}$, as done in [17]. Preliminary results were obtained. It is also interesting whether the guarded ordered logics enjoy stronger versions of interpolations, *e.g.* Lyndon's interpolation or Otto's interpolation. We are quite optimistic about it.
3. What is the complexity of the model checking problem for ordered logics, if we use list encoding to encode our structures?

[6] Purdy provides a "proof" in [21] that $\mathsf{L}_{\mathsf{suf}}$ has ŁTPT. However, his "proof" is sketchy and lacks sufficient mathematical arguments required to verify its correctness. In the light of our discovery of yet another false claim from [21], we believe that it is safe to assume that ŁTPT for $\mathsf{L}_{\mathsf{suf}}$ *is open.*

We are also actively working on the finitary versions of van Benthem theorem for the forward guarded fragment as well as the Lindström-style characterisation theorems. This is an ongoing work of Benno Fünfstück, a master student at TU Dresden, under the supervision of B. Bednarczyk.

Algebraic Representations of Unique Bipartite Perfect Matching

Gal Beniamini ✉
The Hebrew University of Jerusalem, Israel

Abstract

We obtain complete characterizations of the Unique Bipartite Perfect Matching function, and of its Boolean dual, using multilinear polynomials over the reals. Building on previous results [2, 3], we show that, surprisingly, the dual description is *sparse* and has *low* ℓ_1*-norm* – only exponential in $\Theta(n \log n)$, and this result extends even to other families of matching-related functions. Our approach relies on the Möbius numbers in the matching-covered lattice, and a key ingredient in our proof is Möbius' inversion formula.

These polynomial representations yield complexity-theoretic results. For instance, we show that unique bipartite matching is *evasive* for classical decision trees, and *nearly evasive* even for generalized query models. We also obtain a tight $\Theta(n \log n)$ bound on the log-rank of the associated two-party communication task.

1 Introduction

A perfect matching in a graph is a subset of edges spanning the graph, no two of which are incident to the same vertex. In this paper we consider the *decision problem* of unique bipartite matching: the input is a balanced bipartite graph over $2n$ vertices, and the goal is to determine whether the graph contains a *unique* perfect matching. This problem can be naturally cast as a Boolean function.

▶ **Definition.** *The unique bipartite perfect matching function* $\mathrm{UBPM_n} : \{0,1\}^{n^2} \to \{0,1\}$ *is*

$$\mathrm{UBPM_n}(x_{1,1}, \dots, x_{n,n}) = \begin{cases} 1 & \{(i,j) : x_{i,j} = 1\} \text{ has a unique perfect matching} \\ 0 & \text{otherwise.} \end{cases}$$

The complexity of $\mathrm{UBPM_n}$ is closely related to that of $\mathrm{BPM_n}$ – the problem in which we drop the uniqueness condition and simply ask whether a bipartite graph *contains* a perfect matching. Both $\mathrm{BPM_n}$ and $\mathrm{UBPM_n}$ are known to lie in **P**, due to a classical result by Edmonds [9]. However, despite their close connection, not all known algorithmic results extend from one problem to another. For instance, $\mathrm{UBPM_n}$ was shown by Kozen, Vazirani and Vazirani to be in **NC** [19] (see also [14]), and no such result is known for $\mathrm{BPM_n}$. Lovász showed that $\mathrm{BPM_n}$ is in **RNC** [21], and the current best-known *deterministic* parallel algorithm is due to Fenner, Gurjar and Thierauf [10], placing the problem in **Quasi-NC**. Determining the membership of bipartite perfect matching in **NC** remains one of the main open problems in parallelizability.

Our main results in this paper are the complete characterizations of both $\mathrm{UBPM_n}$ and its dual function, by means of polynomials. These characterizations leverage a deep connection to the polynomial representations of $\mathrm{BPM_n}$, obtained in [3, 2], and it is our hope that they can be used to further our understanding of the connection between the two. To present our results we require some notation. We say that a bipartite graph is *matching-covered* if every edge of the graph participates in some perfect matching. For a graph G we denote its *cyclomatic number*, a topological quantity, by $\chi(G) = e(G) - v(G) + c(G)$. The set of all perfect matchings of G is denoted $\mathrm{PM}(G)$, and the cardinality of this set is denoted $\mathrm{per}(G)$ (the permanent of G). Under these notations, our first theorem is the following closed-form description of the *unique* real multilinear polynomial representing $\mathrm{UBPM_n}$.

▶ **Theorem 1** (The Unique Bipartite Perfect Matching Polynomial).

$$\mathrm{UBPM_n}(x_{1,1}, \dots, x_{n,n}) = \sum_{G \subseteq K_{n,n}} c_G \prod_{(i,j) \in E(G)} x_{i,j}$$

where

$$c_G = \begin{cases} (-1)^{\chi(G)} \,\mathrm{per}(G) & G \textit{ is matching-covered} \\ 0 & \textit{otherwise.} \end{cases}$$

The polynomial appearing in Theorem 1 bears a striking resemblance to the representation of $\mathrm{BPM_n}$, the only difference being the multiplicative $\mathrm{per}(G)$ appearing in each term of $\mathrm{UBPM_n}$. This is a direct result of the connection between the two functions and the *matching-covered lattice*, hereafter $\mathcal{L}_n$, which is formed by all matching-covered graphs of order $2n$, ordered with respect to the subgraph relation. Billera and Sarangarajan [5] proved that $\mathcal{L}_n$ is isomorphic to the face lattice of the Birkhoff Polytope $\mathbf{B}_n$. Consequently, this combinatorial lattice is Eulerian, and its Möbius function is particularly well-behaved – a fact which we rely on indirectly throughout this paper. In [3], it was shown that $\mathrm{BPM_n}$ is intimately related to the matching-covered lattice: every such graph corresponds to a monomial, and their coefficients are given by Möbius numbers. Our proof of Theorem 1 extends this connection by leveraging Möbius Inversion Formula, and in fact allows us to derive the polynomial representation for *any* indicator function over $\mathcal{L}_n$ (including, for instance, $\mathrm{BPM_n}$), while also simplifying somewhat parts of the original proof.

Theorem 1 yields information-theoretic lower bounds. For example, $\mathrm{UBPM_n}$ has full total degree and is thus *evasive*, i.e., any decision tree computing it must have full depth, n^2. Unlike its analogue $\mathrm{BPM_n}$, which is a *monotone* bipartite graph property and thus known to be evasive [17], the *unique* perfect matching function is *not monotone*, and for such functions evasiveness is not guaranteed (see e.g. [23]). We also obtain lower bounds against generalized families of decision trees, whose internal nodes are labeled by arbitrary parity functions (XOR-DT), or conjunctions (AND-DT), over subsets of the inputs bits.

▶ **Corollary.** *For classical, parity, and conjunction trees, the following lower bounds hold:*

$$\mathrm{D}(\mathrm{UBPM_n}) = n^2, \quad \mathrm{D}^{\mathrm{XOR}}(\mathrm{UBPM_n}) \geq \left(\tfrac{1}{2} - o(1)\right) n^2 \quad \textit{and} \quad \mathrm{D}^{\mathrm{AND}}(\mathrm{UBPM_n}) \geq (\log_3 2) n^2 - o(1).$$

In the second part of this paper we consider the Boolean dual function $\mathrm{UBPM_n^\star}$, which is obtained by flipping all the input and output bits (or formally, $\mathrm{UBPM_n^\star}(x_{1,1}, \dots, x_{n,n}) = 1 - \mathrm{UBPM_n}(1 - x_{1,1}, \dots, 1 - x_{n,n})$). By construction, this is the indicator over all bipartite graphs whose *complement* does *not* contain a unique perfect matching. Our second result is a complete characterization of $\mathrm{UBPM_n^\star}$ as a real multilinear polynomial. This description relies *heavily* on the that of $\mathrm{BPM_n^\star}$ – which is the dual of the bipartite perfect matching function $\mathrm{BPM_n}$. The polynomial representation of the latter dual was obtained in a series of papers [3, 2], and is omitted here for brevity.

▶ **Theorem 2** (The Dual Polynomial of Unique Bipartite Perfect Matching)**.**

$$\mathrm{UBPM}_{\mathrm{n}}^{\star}(x_{1,1},\dots,x_{n,n}) = \sum_{G\subseteq K_{n,n}} c_G^{\star} \prod_{(i,j)\in E(G)} x_{i,j}$$

where

$$c_G^{\star} = \mathrm{per}(G)\cdot a_G^{\star} + \sum_{M\notin \mathrm{PM}(G)} (-1)^{|E(M)\setminus E(G)|}\cdot a_{G\cup M}^{\star}$$

and $a_G^{\star}$ *denotes the coefficient of* G *in* $\mathrm{BPM}_{\mathrm{n}}^{\star}$.

Theorem 2 expresses the coefficient of every graph G as an alternating sum over coefficients of $\mathrm{BPM}_{\mathrm{n}}^{\star}$, corresponding exactly to those graphs formed by adjoining a single perfect matching to G. This suffices in order to *inherit* the main structural result of [2] regarding $\mathrm{BPM}_{\mathrm{n}}^{\star}$: the ℓ_1-norm of $\mathrm{UBPM}_{\mathrm{n}}^{\star}$, i.e., the norm of the coefficient vector of the representing polynomial, is *very small* – only exponential in $\Theta(n\log n)$, and this is tight.

▶ **Corollary.** *The dual polynomial is sparse and its coefficients are small. Explicitly,*

$$\log\|\mathrm{UBPM}_{\mathrm{n}}^{\star}\|_1 = \Theta(n\log n).$$

The low norm of the dual yields algorithmic results for the unique-bipartite-matching problem, and for related matching problems. For instance, through the approximation scheme of [2, 29], it allows one to obtain a low-degree polynomial *approximation* of the unique bipartite matching function over the hypercube (i.e., "approximate degree"), which holds even for *exponentially small* error. The same ℓ_1-norm bound also directly extends to the spectral norm of $\mathrm{UBPM}_{\mathrm{n}}$,[1] which is a well-studied quantity in analysis of Boolean functions.

Finally, we consider the two-party deterministic communication complexity of unique bipartite matching. The input is a graph $G \subseteq K_{n,n}$, whose edges are distributed among two parties according to *any arbitrary* and *fixed* partition. The sparse polynomial representation of $\mathrm{UBPM}_{\mathrm{n}}^{\star}$ allows us to deduce that the log-rank of the communication matrix, for *any* of the above communication tasks, is bounded by only $\mathcal{O}(n\log n)$, and we prove that this is tight.[2] We remark that, while we show that unique matching has low log-rank, not much is known regarding its *deterministic communication complexity*. For the monotone variant $\mathrm{BPM}_{\mathrm{n}}$, known algorithms (e.g. [15]) can be translated into protocols using only $\widetilde{\mathcal{O}}(n^{3/2})$ bits [25]. However, it is currently not known how to convert algorithms for $\mathrm{UBPM}_{\mathrm{n}}$ (such as [11, 12]), into protocols using even $\mathcal{O}(n^{2-\varepsilon})$ bits, for any $\varepsilon > 0$. Determining the deterministic communication complexity of $\mathrm{UBPM}_{\mathrm{n}}$ is thus left as an open problem.

2 Preliminaries and Notation

2.1 Boolean Functions and Polynomials

Every Boolean function $f : \{0,1\}^n \to \{0,1\}$ can be *uniquely* represented by a multilinear polynomial $p \in \mathbb{R}[x_1,\dots,x_n]$ (see e.g. [27]), where f and p agree on all Boolean inputs $\{0,1\}^n$. The family of subsets corresponding to monomials in this polynomial representation

[1] The spectra of any function and its dual are identical up to sign, and the $\{0,1\}$-polynomial ℓ_1-norm is always trivially at least as large as the $\{\pm 1\}$-representation ("Fourier") ℓ_1-norm.

[2] In fact, our results hold even for a certain $\wedge$-*lifted* and dualised version of this problem.

(i.e., whose coefficient does not vanish) is denoted by $\mathrm{mon}(f)$. The cardinality of $\mathrm{mon}(f)$ is known as the *sparsity* of f, and the maximal cardinality of any $S \in \mathrm{mon}(f)$ is known as the *total degree* of f, hereafter $\deg(f)$. The ℓ_1-norm of f is the norm of its representing polynomial's coefficient vector, namely:

$$\|f\|_1 \overset{\mathrm{def}}{=} \left\|(a_S)_{S\subseteq[n]}\right\|_1, \text{ where } f \text{ is } \{0,1\}\text{-represented by } p(x_1,\ldots,x_n) = \sum_{S\subseteq[n]} a_S \prod_{i\in S} x_i.$$

Given a Boolean function $f : \{0,1\}^n \to \{0,1\}$, it is often useful to consider the transformation in which we *invert* all the input and output bits. This process produces a new Boolean function $f^\star$, known as the Boolean dual.

▶ **Definition 3.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. The* ***Boolean dual*** *of f is the function $f^\star : \{0,1\}^n \to \{0,1\}$ where the symbols 0 are 1 are interchanged. Formally,*

$$\forall x \in \{0,1\}^n : \; f^\star(x_1,\ldots,x_n) = 1 - f(1-x_1,\ldots,1-x_n).$$

The polynomial representations of a Boolean function f and its dual $f^\star$ can differ substantially (for example $\mathrm{AND_n}^\star = \mathrm{OR_n}$, and while the former is represented by a single monomial, the latter consists of $2^n - 1$ monomials). However, since f and $f^\star$ are obtained by affine transformations of one another, they share many properties. For example, their Fourier spectra are identical [27], up to sign. Moreover, they have the same approximate degree [2] for any error ε, and the ranks of their associated communication matrices (see proceeding subsections) are identical up to an additive constant (of 1).

2.2 Graphs

We use the standard notation for quantities relating to graphs. In particular, the sets of vertices, edges and connected components of a graph are denoted by $V(G)$, $E(G)$ and $C(G)$, and their cardinalities are denoted $v(G)$, $e(G)$ and $c(G)$, respectively. A less common measure appearing in this paper is the cyclomatic number $\chi(G)$, a topological quantity.

▶ **Definition 4.** *Let G be a graph. The* ***cyclomatic number*** *of G is defined by:*

$$\chi(G) = e(G) - v(G) + c(G).$$

A *matching* in a graph $G \subseteq K_{n,n}$ is a collection of edges sharing no vertices, and said matchings are called *perfect* if they contain exactly n edges (i.e., every vertex in the graph is incident to precisely one edge in the matching). The set of *all* perfect matchings denoted by $\mathrm{PM}(G)$. For any graph $G \subseteq K_{n,n}$, we define the *permanent* $\mathrm{per}(G)$ and the *determinant* $\det(G)$ as the application of these two functions to the biadjacency matrix of G, noting that $\mathrm{per}(G)$ counts the number of perfect matchings in G.

Perfect matchings and the graphs formed by unions thereof play a central role in this paper. A graph $G \subseteq K_{n,n}$ is called **matching-covered** if and only if every edge of G participates in some perfect matching. Matching-covered graphs have interesting combinatorial properties. For example, this is precisely the family of all graphs admitting a bipartite ear decomposition (similar to the ear decomposition of 2-edge-connected graphs). This family had previously appeared extensively in the literature, and in particular had been studied at length by Lovász and Plummer [28], and by Hetyei [13]. Hereafter, we denote the set of all such graphs by

$$\mathrm{MC_n} = \Big\{G \subseteq K_{n,n} : G \text{ is matching-covered}\Big\}.$$

All graphs in this paper are *balanced bipartite graphs*, over the fixed vertex set of the complete bipartite graph $K_{n,n}$. Consequently, we use the notation $G \subseteq H$ to indicate inclusion over the edges, and similarly $G \cup H$ is the graph whose edges are $E(G) \cup E(H)$. Lastly, many of the Boolean functions appearing in this paper are defined over subgraphs of $K_{n,n}$, where every input bit is associated with a single edge. For such functions, the notation $f(G)$, where $G \subseteq K_{n,n}$, corresponds to this mapping.

2.3 Communication Complexity

In this paper we consider the *two-party deterministic communication model.* For a comprehensive textbook on the topic, we refer the reader to [20]. The **deterministic communication complexity** of f, hereafter $\mathrm{D}^{\mathrm{CC}}(f)$, is the *least number of bits communicated by a protocol computing f, on the worst-case input.* Any (*unpartitioned*) Boolean function $f : \{0,1\}^n \to \{0,1\}$ naturally gives rise to a *family* of associated two-party communication tasks: one corresponding to each possible partition of the input bits between the two parties. The **deterministic communication complexity of a Boolean function** is then defined as follows.

▶ **Definition 5.** *The deterministic communication complexity of $f : \{0,1\}^n \to \{0,1\}$ is defined*

$$\mathrm{D}^{\mathrm{CC}}(f) \overset{def}{=} \max_{S \sqcup \bar{S} = [n]} \mathrm{D}^{\mathrm{CC}}\left(f_S(x,y)\right)$$

where $\mathrm{D}^{\mathrm{CC}}\left(f_S(x,y)\right)$ is the deterministic communication complexity of the two-party Boolean function $f_S(x,y) : \{0,1\}^{|S|} \times \{0,1\}^{|\bar{S}|} \to \{0,1\}$, representing f under the partition $S \sqcup \bar{S}$.

For any two-party Boolean function, let us also define the following two useful objects.

▶ **Definition 6.** *Let $f : \{0,1\}^m \times \{0,1\}^n \to \{0,1\}$. The **communication matrix** of f is*

$$M_f \in \mathbb{R}^{\{0,1\}^m \times \{0,1\}^n}, \text{ where } \forall (x,y) \in \{0,1\}^m \times \{0,1\}^n : \ M_f(x,y) = f(x,y).$$

▶ **Definition 7.** *Let $f : \{0,1\}^m \times \{0,1\}^n \to \{0,1\}$ be a two-party function. We say that $S \subseteq \{0,1\}^m \times \{0,1\}^n$ is a **fooling set** for f if and only if:*

$$S \subseteq f^{-1}(1), \text{ and } \forall (x_1,y_1) \neq (x_2,y_2) \in S : \ \{(x_1,y_2),(x_2,y_1)\} \cap f^{-1}(0) \neq \emptyset.$$

The log of the rank of M_f *over the reals* (sometimes referred to as the "log-rank of f") is intimately related to the communication complexity of f. A classical theorem due to Mehlhorn and Schmidt [24] states that $\mathrm{D}^{\mathrm{CC}}(f) \geq \log_2 \operatorname{rank} M_f$, and these two quantities are famously conjectured to be polynomially related [22]. As for the fooling set, it is well known that $\mathrm{D}^{\mathrm{CC}}(f) \geq \log_2 \operatorname{fs}(f)$ for any two-party function f [20], where $\operatorname{fs}(f)$ is the maximum size of a fooling set. This bound was extended by Dietzfelbinger, Hromkovič and Schnitger [8], who showed that in fact $\log \operatorname{fs}(f) \leq 2 \log \operatorname{rank} f + 2$.

2.4 Posets, Lattices and Möbius Functions

Partially ordered sets (hereafter, **posets**) are defined by a tuple $\mathscr{P} = (P, \leq)$, where P is the element set, and $\leq$ is the order relation (which is reflexive, antisymmetric and transitive). For any two elements $x, y \in P$, the notation $[x,y] \overset{\text{def}}{=} \{z \in P : x \leq z \leq y\}$ denotes the *interval* from x to y. A *combinatorial lattice* is a poset satisfying two additional conditions: every two elements have a least upper bound (a “join”), and a greatest lower bound (a “meet”). The *face lattice of a polytope* is a combinatorial lattice whose elements correspond to the faces of a polytope, ordered by the subset relation. Such a lattice is *bounded* – it has a unique bottom element (the empty face $\hat{0}$), and a unique top element (the polytope itself), and it is also *graded*, meaning that the length of all maximal chains between any two elements x, y are identical (in other words, the elements can be *ranked*).

Partially ordered sets come equipped with an important function known as the **Möbius function**. The Möbius function of a poset is the inverse, with respect to convolution, of its zeta function $\zeta(x,y) = \mathbb{1}\{x < y\}$. For information on incidence algebra and the Möbius function, we refer the reader to [30].

▶ **Definition 8** (Möbius Function for Posets). *Let $\mathcal{P} = (P, \leq)$ be a finite poset. The Möbius function $\mu_{\mathcal{P}} : P \times P \to \mathbb{R}$ of $\mathcal{P}$ is defined*

$$\forall x \in P: \ \mu_{\mathcal{P}}(x,x) = 1, \quad \forall x, y \in P, \ y < x: \ \mu_{\mathcal{P}}(y,x) = -\sum_{y \leq z < x} \mu_{\mathcal{P}}(y,z).$$

The Möbius Inversion Formula allows one to relate two functions defined on a poset $\mathcal{P}$, where one function is a downwards closed sum of another, by means of the Möbius function. This can be seen as a generalization of its number-theoretic analogue (as indeed the Möbius function of number theory arises in this manner from the *divisibility poset*).

▶ **Theorem 9** (Möbius Inversion Formula, see [30]). *Let $\mathcal{P} = (P, \leq)$ be a finite poset and let $f, h : P \to \mathbb{F}$ be two functions, where $\mathbb{F}$ is a field. Then:*

$$\forall x \in P: \ h(x) = \sum_{y \leq x} f(y) \quad \iff \quad \forall x \in P: \ f(x) = \sum_{y \leq x} h(y)\mu_{\mathcal{P}}(y,x).$$

3 The Unique Perfect Matching Polynomial

Our main object of study is the unique bipartite matching function.

▶ **Definition 10.** *The Unique Bipartite Perfect Matching function is defined*

$$\mathrm{UBPM_n}(x_{1,1}, \ldots, x_{n,n}) = \begin{cases} 1 & \{(i,j) : x_{i,j} = 1\} \subseteq K_{n,n} \textit{ has a unique P.M.} \\ 0 & \textit{otherwise.} \end{cases}$$

The unique multilinear representation of $\mathrm{UBPM_n}$ is characterized in the following Theorem.

▶ **Theorem 1.** *The unique polynomial* $\mathrm{UBPM_n} : \{0,1\}^{n^2} \to \{0,1\}$ *is given by*

$$\mathrm{UBPM_n}\left(x_{1,1}, \ldots, x_{n,n}\right) = \sum_{G \in \mathrm{MC_n}} (-1)^{\chi(G)} \ \mathrm{per}(G) \prod_{(i,j) \in E(G)} x_{i,j}.$$

Proof. The proof is centered around the combinatorial *lattice of matching-covered graphs*,

$$\mathcal{L}_n = \left(\mathrm{MC_n} \cup \{\hat{0}\}, \subseteq\right), \text{ where } \hat{0} \text{ is the graph with } 2n \text{ isolated vertices}$$

where the order relation for this lattice is *containment over the edge set*, i.e., $G \supseteq H \iff E(G) \supseteq E(H)$. Let us consider the following two functions $f : \mathcal{L}_n \to \{0,1\}$ and $h : \mathcal{L}_n \to \mathbb{Z}$ on the lattice, which are the restrictions of $\mathrm{UBPM_n}$ and of the Permanent function, respectively:

$$\forall G \in \left(\mathrm{MC_n} \cup \{\hat{0}\}\right): \ f(G) = \mathrm{UBPM_n}(G) = \begin{cases} 1 & G \in PM(K_{n,n}) \\ 0 & \text{otherwise} \end{cases}$$

$$h(G) = \mathrm{per}(G) = \#\text{Perfect Matchings in } G.$$

These two functions are intimately related. Indeed, for any element G of the lattice, one can compute $h(G)$ by taking the sum $f(H)$ over all H in the downwards closed interval $[\hat{0}, G]$. Therefore, by an application of Möbius' Inversion Formula (Theorem 9) to the matching-covered lattice, we obtain:

$$\forall G \in \mathcal{L}_n: \; h(G) = \sum_{G \supseteq H \in \mathcal{L}_n} f(H) \iff \forall G \in \mathcal{L}_n: \; f(G) = \sum_{G \supseteq H \in \mathcal{L}_n} \mu(H, G) h(H)$$

where $\mu : \mathcal{L}_n \to \mathbb{Z}$ is the Möbius function of the lattice $\mathcal{L}_n$. A well known result due to Billera and Sarangarajan [5] states that $\mathcal{L}_n$ is isomorphic to the *face lattice* of the Birkhoff Polytope B_n, which is the convex hull of all $n \times n$ permutation matrices. Consequently, $\mathcal{L}_n$ is an Eulerian lattice – and its Möbius function μ is can be directly computed (see e.g. [30]), as follows:

$$\forall G, H \in \mathcal{L}_n, \; H \subseteq G: \quad \mu(H, G) = (-1)^{\operatorname{rank}(G) - \operatorname{rank}(H)}$$

where $\operatorname{rank}(x)$ denotes the maximal length of a chain from $\hat{0}$ to x (equivalently, $\operatorname{rank}(x) = dim(f_x) + 1$, where f_x is the face of B_n corresponding to the lattice element x). In [3] it was shown that the rank of every graph G in the matching-covered lattice is exactly $\chi(G) + 1$, where $\chi(G) = e(G) - v(G) + c(G)$ is the cyclomatic number, a topological quantity. Recalling our prior application of Möbius inversion, we obtain the following set of identities (note that the bottom element can be omitted, as $\operatorname{per}(\hat{0})$ is zero):

$$\forall G \in \mathcal{L}_n: \; (-1)^{\chi(G)} \sum_{G \supseteq H \in \mathrm{MC_n}} (-1)^{\chi(H)} \operatorname{per}(H) = \begin{cases} 1 & G \in \mathrm{PM}(K_{n,n}) \\ 0 & \text{otherwise.} \end{cases}$$

To conclude the proof, let us consider the following real multilinear polynomial, wherein we assign weight $(-1)^{\chi_G} \operatorname{per}(G)$ to every matching-covered graph:

$$p(x_{1,1}, \dots, x_{n,n}) = \sum_{G \in \mathrm{MC_n}} (-1)^{\chi(G)} \operatorname{per}(G) \prod_{(i,j) \in E(G)} x_{i,j}.$$

Let $G \subseteq K_{n,n}$ and observe that, by construction:

$$p(G) = \sum_{H \in \mathrm{MC_n}} (-1)^{\chi(H)} \operatorname{per}(H) \cdot \mathbb{1}\{E(H) \subseteq E(G)\} = \sum_{G \supseteq H \in \mathrm{MC_n}} (-1)^{\chi(H)} \operatorname{per}(H).$$

It remains to show that p "agrees" with $\mathrm{UBPM_n}$ on all inputs. It is not hard to see that it suffices to show this claim only for matching-covered graphs, since given any $G \subseteq K_{n,n}$ which is *not* matching-covered, one may consider the graph G' formed by the union of all perfect matching in G (in other words, the maximal matching-covered graph contained in G). By construction, we have $p(G') = p(G)$, and by definition, $\mathrm{UBPM_n}(G) = \mathrm{UBPM_n}(G')$ – thus, hereafter we consider only inputs $G \in \mathrm{MC_n}$. First, let us check the two trivial cases; the empty graph, and a single matching:

$$p(\hat{0}) = 0, \text{ and } p(M) = (-1)^{\chi(M)} = (-1)^{n-2n+n} = 1 \quad \forall M \in PM(K_{n,n}).$$

Finally, for any matching-covered graph G containing *more than a single matching*, i.e. $G \in \mathrm{MC_n}$ such that $G \notin PM(K_{n,n})$, it holds that:

$$p(G) = \sum_{G \supseteq H \in \mathrm{MC_n}} (-1)^{\chi(H)} \operatorname{per}(H) = 0$$

where the last equality follows from the identities obtained through Möbius' Inversion Formula. Thus, $p(x_{1,1}, \dots, x_{n,n})$ agrees with $\mathrm{UBPM_n}$ everywhere, and is its *unique* representation. ◀

3.1 Indicators on the Matching-Covered Lattice

We remark that the proof of Theorem 1 readily extends, through the same analysis using Möbius inversion, to any arbitrary *indicator function* over the matching-covered lattice. For any set $S \subseteq \mathrm{MC_n}$, let $I_S : \{0,1\}^{n^2} \to \{0,1\}$ be the Boolean function

$$\forall G \subseteq K_{n,n} : \ I_S(G) = \mathbb{1}\left\{ H \in S \text{ where } H = \bigcup_{M \in \mathrm{PM}(G)} M \right\}.$$

Then, the multilinear polynomial representing I_S is given by

$$I_S(x_{1,1}, \ldots, x_{n,n}) = \sum_{G \in \mathrm{MC_n}} \left((-1)^{\chi(G)} \sum_{H \in [\hat{0}, G] \cap S} (-1)^{\chi(H)+1} \right) \prod_{(i,j) \in E(G)} x_{i,j}.$$

3.2 Evasiveness and Generalized Decision Trees

The characterization of $\mathrm{UBPM_n}$ as a multilinear polynomial can be used to derive several complexity-theoretic corollaries. Firstly, this polynomial has *full total degree over* $\mathbb{R}$ and thus (see e.g. [6]):

▶ **Corollary 11.** $\mathrm{UBPM_n}$ *is evasive, i.e., any decision computing it has full depth,* n^2.

Let us remark that, contrary to its counterpart $\mathrm{BPM_n}$ which is a *monotone* bipartite graph property and thus known to be evasive [31], the *unique* matching function is *not monotone* and for such functions evasiveness is not guaranteed (see [23] for one such example). Theorem 1 can be also used to derive strong bounds (near evasiveness) versus larger classes of decision trees, for example trees whose internal nodes are labeled by arbitrary conjunctions of the input bits (hereafter AND-DT), and by arbitrary parity functions (XOR-DT). It is known [3] that the depth of any AND-DT computing a Boolean function f is at least $\log_3 |\mathrm{mon}(f)|$. Applying this to $\mathrm{UBPM_n}$ and recalling that asymptotically almost all balanced bipartite graphs are matching-covered ([3]), we have:

▶ **Corollary 12.** *Any* AND-DT *computing* $\mathrm{UBPM_n}$ *has depth at least* $(\log_3 2) \cdot n^2 - o_n(1)$.

As for parity decision trees, it is well known that the depth of any such tree is bounded by the total degree of its unique representing polynomial, over $\mathbb{F}_2$ (see [27, 3]). Noting that $\mathrm{per}(G) \equiv \det(G) \pmod 2$, we may write the $\mathbb{F}_2$-polynomial representation of $\mathrm{UBPM_n}$ as follows

$$\mathrm{UBPM_n}\,(x_{1,1}, \ldots, x_{n,n}) = \sum_{\substack{G \in \mathrm{MC_n} \\ \det(G) \equiv 1 \pmod 2}} \ \prod_{(i,j) \in E(G)} x_{i,j}.$$

Clearly this polynomial does not have full degree for any $n > 1$, as $\mathrm{per}(K_{n,n})$ is $n! \equiv 0 \pmod 2$[3]. Nevertheless, we claim that its $\mathbb{F}_2$-degree is at most a constant factor away from full. Observe that its monomials constitute precisely of all graphs that are both matching-covered, and whose biadjacency matrices are invertible over $\mathbb{F}_2$, i.e., are elements of the group $\mathrm{GL}_n(\mathbb{F}_2)$. However, asymptotically almost all graphs are matching-covered, and by a standard counting argument, the order of $\mathrm{GL}_n(\mathbb{F}_2)$ satisfies

[3] It is well known ([27]) that for any function $f : \{0,1\}^n \to \{0,1\}$, $\deg_2(f) = n \iff |f^{-1}(1)| \equiv 1 \pmod 2$. Therefore we obtain that the number of graphs $G \subseteq K_{n,n}$ containing a *unique perfect matching* is even, for any $n > 1$.

$$\Pr_{A\sim M_n(\mathbb{F}_2)}[A \in \mathrm{GL}_n(\mathbb{F}_2)] = \left(\tfrac{1}{2};\tfrac{1}{2}\right)_\infty \pm o_n(1)$$

where $\left(\frac{1}{2};\frac{1}{2}\right)_\infty \approx 0.28878$ is a Pochhammer symbol. Thus by a standard Chernoff argument, there exists a matching-covered graph with odd determinant and at least $\frac{1}{2}n^2 - o_n(1)$ edges.

▶ **Corollary 13.** $\mathrm{D}^{\mathrm{XOR}}(\mathrm{UBPM_n}) \geq \deg_2(\mathrm{UBPM_n}) \geq \left(\frac{1}{2} - o_n(1)\right) n^2$

4 The Dual Polynomial

In this section we consider the Boolean dual function (Definition 3) of $\mathrm{UBPM_n}$.

▶ **Definition 14.** *The function* $\mathrm{UBPM}^\star_\mathrm{n} : \{0,1\}^{n^2} \to \{0,1\}$ *is defined*

$$\mathrm{UBPM}^\star_\mathrm{n}(x_{1,1},\ldots,x_{n,n}) = \begin{cases} 1 & \left\{(i,j) : x_{i,j} = 0\right\} \subseteq K_{n,n} \textit{ does } \underline{\textit{not}} \textit{ have a unique P.M.} \\ 0 & \textit{otherwise.}\end{cases}$$

In what follows, we provide a full characterization of polynomial representing $\mathrm{UBPM}^\star_\mathrm{n}$. This description relies heavily on the that of another dual function – $\mathrm{BPM}^\star_\mathrm{n}$ – which is the dual of the bipartite perfect matching function $\mathrm{BPM_n}$ (which is defined identically to $\mathrm{UBPM_n}$, but without the *uniqueness* condition). The polynomial representation of $\mathrm{BPM}^\star_\mathrm{n}$ was obtained in a series of papers [3, 2]. Its monomials correspond to a family of graphs called "*totally ordered graphs*", and their coefficients are can be computed through a normal-form block decomposition of the aforementioned graphs. The full details are presented in [2], and are omitted here for brevity. In what follows, it suffices for us to denote

$$\mathrm{BPM}^\star_\mathrm{n}(x_{1,1},\ldots,x_{n,n}) = \sum_{G\subseteq K_{n,n}} a^\star_G \prod_{(i,j)\in E(G)} x_{i,j}.$$

Under this notation, our characterization of $\mathrm{UBPM}^\star_\mathrm{n}$ is the following.

▶ **Theorem 2.** *The unique polynomial representation of* $\mathrm{UBPM}^\star_\mathrm{n} : \{0,1\}^{n^2} \to \{0,1\}$ *is*

$$\mathrm{UBPM}^\star_\mathrm{n}(x_{1,1},\ldots,x_{n,n}) = \sum_{G\subseteq K_{n,n}} c^\star_G \prod_{(i,j)\in E(G)} x_{i,j}$$

where for every $G \subseteq K_{n,n}$ *we have:*

$$c^\star_G = \mathrm{per}(G)\cdot a^\star_G + \sum_{M\notin \mathrm{PM}(G)} (-1)^{|E(M)\setminus E(G)|}\cdot a^\star_{G\cup M}.$$

Proof. The polynomial representing $\mathrm{UBPM}^\star_\mathrm{n}$ can be expressed using $\mathrm{UBPM_n}$, via duality:

$$\mathrm{UBPM}^\star_\mathrm{n}(x_{1,1},\ldots,x_{n,n}) = 1 - \mathrm{UBPM_n}(1-x_{1,1},\ldots,1-x_{n,n}).$$

Substituting the characterization of Theorem 1 and expanding, we deduce that the coefficient of every graph $G \subseteq K_{n,n}$ in $\mathrm{UBPM_n}$ is:

$$c^\star_G = (-1)^{e(G)+1} \sum_{G\subseteq H\in \mathrm{MC_n}} (-1)^{\chi(H)}\,\mathrm{per}(H).$$

Writing $\mathrm{per}(H) = \sum_{M\in\mathrm{PM}(K_{n,n})} \mathbb{1}\{M \subseteq H\}$ and exchanging order of summation,

$$c^\star_G = (-1)^{e(G)+1} \sum_{M\in\mathrm{PM}(K_{n,n})} \sum_{G\subseteq H\in \mathrm{MC_n}} (-1)^{\chi(H)} \mathbb{1}\{M\subseteq H\}.$$

There are two possible cases in the above summation over all perfect matchings; either the matching is present in G, or it is not. Clearly every matching-covered graph containing G also contains any matching of G, so in the former case we get a contribution of $(-1)^{e(G)+1}\operatorname{per}(G)\cdot\sum_{G\subseteq H\in\mathrm{MC_n}}(-1)^{\chi(H)}$. As for the latter case, observe that for every $M\notin\mathrm{PM}(G)$, the set of matching-covered graphs containing G and M is exactly all matching-covered graphs containing $G\cup M$. Finally, we recall [3] that the coefficient of any graph $G\subseteq K_{n,n}$ in $\mathrm{BPM_n^\star}$ is given by:

$$a_G^\star=(-1)^{e(G)+1}\sum_{G\subseteq H\in\mathrm{MC_n}}(-1)^{\chi(H)}.$$

Putting the two together and simplifying, we obtain:

$$c_G^\star=\operatorname{per}(G)\cdot a_G^\star+\sum_{M\notin\mathrm{PM}(G)}(-1)^{|E(M)\setminus E(G)|}\cdot a_{G\cup M}^\star.$$ ◀

4.1 Corollary: The ℓ_1-norm of $\mathrm{UBPM_n^\star}$

One immediately corollary of Theorem 2 is the following fact: the multilinear polynomial representing $\mathrm{UBPM_n^\star}$ has *very low ℓ_1-norm* – i.e., it has few monomials, and the coefficient of every such monomial is not too large. A similar bound had previous been attained for $\mathrm{BPM_n^\star}$ in [2], which we heavily rely on for our proof.

▶ **Corollary 15.** *The ℓ_1-norm of $\mathrm{UBPM_n^\star}$ is bounded only by $\log_2\|\mathrm{UBPM_n^\star}\|_1=\Theta(n\log n)$.*

Proof. For the upper bound, we rely heavily on Theorem 2 and on the ℓ_1-norm of $\mathrm{BPM_n^\star}$ obtained in [2]. In the latter, it was shown that every coefficient in $\mathrm{BPM_n^\star}$ has magnitude at most 2^{2n}, and thus using the characterization of Theorem 2, the coefficient of any graph G satisfies

$$\log_2|c_G^\star|\le\log_2\left(\operatorname{per}(G)\cdot 2^{2n}+(n!-\operatorname{per}(G))\cdot 2^{2n}\right)\le n\log_2 n+n\log_2(4/e)+\Theta(\log n).$$

It remains to bound the *sparsity* of $\mathrm{UBPM_n^\star}$. To this end, consider the graphs whose coefficients do not vanish in $\mathrm{BPM_n^\star}$, and let us take a "ball" around every such graph $G\in\operatorname{mon}(\mathrm{BPM_n^\star})$, as follows:

$$B(G)=\Big\{H\subseteq K_{n,n}:\exists M\in\mathrm{PM}(K_{n,n})\text{ such that }E(H)\cup E(M)=E(G)\Big\}.$$

From Theorem 1 it follows that for every graph G, the coefficient $c_G^\star$ *does not vanish* only if either $G\in\operatorname{mon}(\mathrm{BPM_n^\star})$ or there exists some $H\in\operatorname{mon}(\mathrm{BPM_n^\star})$ such that $G\in B(H)$. However, each of the aforementioned balls is relatively small (in fact, can be bounded by $|B(G)|\le 2^n\cdot n!$), thus by the union bound:

$$|\operatorname{mon}(\mathrm{UBPM_n^\star})|\le|\operatorname{mon}(\mathrm{BPM_n^\star})|\,(1+2^n\cdot n!)=2^{\Theta(n\log n)}$$

where the last equality follows from the bound $\log_2|\operatorname{mon}(\mathrm{BPM_n^\star})|\le 2n\log_2 n+\mathcal{O}(n)$, obtained in [3]. This concludes the proof of the upper bound. The lower bound now follows directly from Theorem 1, as it suffices to observe that the coefficient of the complete bipartite graph is $\pm\operatorname{per}(K_{n,n})=\pm(n!)$. ◀

5 The Communication Rank of Unique Bipartite Matching

5.1 Rank and Polynomial Representation

The log-rank of a Boolean function is very closely related to its representation as a multilinear polynomial. This relationship is made very evident in the case of certain "lifted" functions: given a Boolean function $f : \{0,1\}^n \to \{0,1\}$, one can define the following pair of functions $f_\wedge, f_\oplus : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, where

$$\forall x, y \in \{0,1\}^n : f_\wedge(x,y) = f(x \wedge y), \text{ and } f_\oplus(x,y) = f(x \oplus y).$$

It is well known [18, 4] that the rank of the communication matrices $M_{f_\wedge}$ and $M_{f_\oplus}$ is *exactly characterized* by the *sparsity* (i.e., number of monomials) of the polynomials representing f in the $\{0,1\}$-basis and the $\{\pm 1\}$-basis (the Fourier basis), respectively. In other words,

$$\begin{aligned}\operatorname{rank}(M_{f_\wedge}) &= \#\{\text{monomials in } \{0,1\}\text{-polynomial representing } f\}\\ \operatorname{rank}(M_{f_\oplus}) &= \#\{\text{monomials in } \{-1,1\}\text{-polynomial representing } f\}.\end{aligned}$$

The polynomial representation of a Boolean function f over the $\{0,1\}$-basis, or that of its dual $f^\star$, can also be used to derive communication rank upper bounds for non-lifted functions. The following lemma gives such a bound for the communication task of f, under *any* input partition.

▶ **Lemma 16.** *Let $f : \{0,1\}^n \to \{0,1\}$. Then, for every partition $S \sqcup \bar{S} = [n]$ we have:*

$$\operatorname{rank}(M_{f^{S\sqcup\bar{S}}}) \le \min\left\{ |\operatorname{mon}(f)|, |\operatorname{mon}(f^\star)| + 1 \right\}.$$

Proof. Let $S \sqcup \bar{S} = [n]$ be some input partition, and let M and M' be the communication matrices of f and $f^\star$ under this partition, respectively. By definition of Boolean duality, we have $M = J - M_\pi M' M_\sigma$ where $J = \mathbb{1} \otimes \mathbb{1}$ is the all-ones matrix, and M_π, M_σ are the permutation matrices for

$$\forall x \subseteq S : \ \pi(x) = S \setminus x, \quad \forall y \subseteq \bar{S} : \ \sigma(y) = \bar{S} \setminus y$$

therefore $|\operatorname{rank}(M) - \operatorname{rank}(M')| \le 1$, and it suffices to bound the rank of M'. However, we now observe that the polynomial representing f naturally induces a $|\operatorname{mon}(f)|$-rank decomposition of M (and likewise $f^\star$ for M'), as per [26], by considering the following sum of rank-1 matrices:

$$\forall T \in \operatorname{mon}(f), \text{ add the rank-1 matrix } a_T \cdot (\mathbb{1}_X \otimes \mathbb{1}_Y)$$

where a_T is the coefficient of T in f, and

$$X = \left\{ x : (T \cap S) \subseteq x \subseteq S \right\}, \quad Y = \left\{ y : \left(T \cap \bar{S}\right) \subseteq y \subseteq \bar{S} \right\}. \qquad ◀$$

5.2 The Rank of Unique Bipartite Matching

The log-rank of the unique bipartite matching function, ranging over all input partitions, is exactly characterized in the following Theorem.

▶ **Theorem 17.** *The log-rank of unique bipartite perfect matching is*

$$\max_{E \sqcup \bar{E} = E(K_{n,n})} \log \operatorname{rank}(M_{\mathrm{UBPM}_n^{E\sqcup\bar{E}}}) = \Theta(n \log n)$$

where $\mathrm{UBPM}_n^{E\sqcup\bar{E}}$ *is the two-party function whose input is partitioned according to* $E \sqcup \bar{E}$.

Proof. To obtain the lower bound, we must first fix a particular input partition. Assume without loss of generality that $n = 2m$ and let us partition the left and right vertices into two sets, $L = A \sqcup B$, $R = C \sqcup D$, where $A = \{a_1, \dots, a_m\}$, $B = \{b_1, \dots, b_m\}$, $C = \{c_1, \dots, c_m\}$ and $D = \{d_1, \dots, d_m\}$. Hereafter we consider the input partition wherein Alice receives all the edges incident to the left vertices A and Bob receives all the edges incident to the left vertices B. To prove our lower bound, we shall construct a *fooling set* (Definition 7). Let us introduce some notation: for every permutation $\pi \in S_m$ and two sets $X, Y \in \{A, B, C, D\}$, the notation $\pi(X, Y)$ refers to the matching from X to Y using the permutation π. Formally,

$$\forall X, Y \in \{A, B, C, D\} : \forall \pi \in S_m : \ \pi(X, Y) \overset{\text{def}}{=} \Big\{ \{x_i, y_{\pi(i)}\} : i \in [m] \} \Big\}.$$

Under this notation, we claim that

$$S = \Big\{ \big(\mathrm{id}(A, C) \ \sqcup \ \pi(A, D), \ \ \mathrm{id}(B, D) \ \sqcup \ \{\{b_{\pi(i)}, c_j\} : 1 \le i < j \le m\}\big) \ : \ \pi \in S_m \Big\}$$

is a fooling set for $\mathrm{UBPM}_n^{K_{A,R} \sqcup K_{B,R}}$, where $\mathrm{id} \in S_m$ is the identity element.

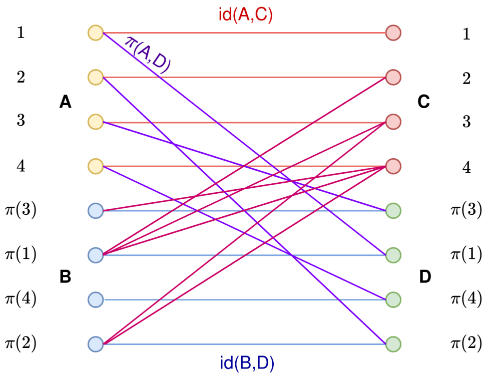

Figure 1 A graph G in the fooling set S, for $m = 4$ and $\pi = (2413)$.

$\underline{\{x \sqcup y : (x, y) \in S\} \subseteq \mathrm{UBPM}_n^{-1}(1)}$: Let $\pi \in S_m$ and consider $G \subseteq K_{n,n}$ where:

$$E(G) = \mathrm{id}(A, C) \ \sqcup \ \pi(A, D) \ \sqcup \ \mathrm{id}(B, D) \ \sqcup \ \big\{\{b_{\pi(i)}, c_j\}\big\}_{i<j}.$$

Clearly G has the identity perfect matching, whereby A is matched to C and B to D. Let us denote this matching by M. To show that M is *unique*, it suffices to show that there exists no M-alternating cycle in G. By construction, the vertices in any such cycle must alternate between $C - A - D - B$ (since the only edges joining $A \leftrightarrow C$ and $B \leftrightarrow D$ are those in the matching M). Thus, for any $i \in [m]$, an M-alternating path starting with c_i must be of the form:

$$c_i \sim a_i \sim d_{\pi(i)} \sim b_{\pi(i)} \sim c_j \sim \dots$$

where $j > i$. However, observe that $b_{\pi(m)}$ is not adjacent to any vertex in C, so any such path will eventually (after at most m passes through B) terminate at $b_{\pi(m)}$, without looping back to c_i. Therefore there exists no M-alternating cycle, and M is indeed unique.

$\underline{\forall (x_1, y_1), (x_2, y_2) \in S : \ (x_1 \sqcup y_2) \in \mathrm{UBPM_n}^{-1}(0)}$: Let $\pi, \sigma \in S_m$ where $\pi \ne \sigma$, and let G be the graph:

$$E(G) = \mathrm{id}(A, C) \ \sqcup \ \pi(A, D) \ \sqcup \ \mathrm{id}(B, D) \ \sqcup \ \big\{\{b_{\sigma(i)}, c_j\}\big\}_{i<j}.$$

Once again, clearly G has the identity matching M, whereby A is matched to C and B to D. To show that M is not unique, it suffices to exhibit an alternating cycle. Recall that $\sigma \neq \pi$ and therefore $\sigma^{-1} \circ \pi \neq \mathrm{id}$, and in particular, there exists some $i \in [m]$ such that $\sigma^{-1}(\pi(i)) < i$. By construction, the following M-alternating cycle is present in G:

$$c_i \sim a_i \sim d_{\pi(i)} \sim b_{\pi(i)} = b_{\sigma(\sigma^{-1}(\pi(i)))} \sim c_i.$$

Therefore, S is a fooling set for $\mathrm{UBPM_n}$ under the aforementioned input partition. To conclude the lower bound, we recall the following Theorem, due to Dietzfelbinger, Hromkovič and Schnitger [8]:

▶ **Theorem 18** ([8]). *$\forall f : \{0,1\}^m \times \{0,1\}^n \to \{0,1\}$ we have $\log_2 \mathrm{fs}(f) \leq 2\left(\log_2 \mathrm{rank}\, M_f + 1\right)$.*

Therefore, we have:

$$\log_2 \mathrm{rank}\left(M_{\mathrm{UBPM}_n^{K_{A,R} \sqcup K_{B,R}}}\right) \geq \tfrac{1}{2}\log_2 |S| - 1 = \tfrac{1}{4} n \log_2 n - \Theta(n)$$

concluding the lower bound. As for the upper bound, it follows directly from Lemma 16, and from the characterization of Theorem 2 (see Corollary 15). ◀

A The Approximate Degree of $\mathrm{UBPM_n}$

The ε-approximate degree $\widetilde{\deg}_\epsilon(f)$, of a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is the *least* degree of a real multilinear polynomial *approximating* f pointwise over $\{0,1\}^n$, with error at most ε. Formally,

▶ **Definition 19.** *Let $f : \{0,1\}^n \to \{0,1\}$ and let $0 < \varepsilon < \frac{1}{2}$. The ε-approximate degree of f, $\widetilde{\deg}_\epsilon(f)$, is the least degree of a real multilinear polynomial $p \in \mathbb{R}[x_1, \dots, x_n]$ such that:*

$$\forall x \in \{0,1\}^n : \ |f(x) - p(x)| \leq \varepsilon.$$

If $\varepsilon = {}^1\!/_3$, then we omit the subscript in the above notation, and instead write $\widetilde{\deg}(f)$.

Approximate degree is a well-studied complexity measure. For a comprehensive survey on the topic, we refer the reader to [7]. With regards to Theorem 2, we make the following observation: every Boolean function whose polynomial representation, or that of its dual, have low ℓ_1-norm – can be efficiently *approximated* in the ℓ_∞-norm by a low-degree polynomial. Firstly, it is not hard to see that for any Boolean function $f:\{0,1\}^n \to \{0,1\}$ and any $\varepsilon > 0$, the ε-approximate degree of f is identical to that of its dual $f^\star$. This follows since $f^\star$ can be obtained through an *affine transformation* of f, which cannot increase the degree, and the same transformation can similarly be applied to any approximating polynomial of f (and the converse follows since $(f^\star)^\star = f$). The second component of the approximation scheme is the following lemma.

▶ **Lemma 20** ([2], similar to [29]). *Let $f:\{0,1\}^n \to \{0,1\}$ be a Boolean function, and let $p \in \mathbb{R}[x_1,\dots,x_n]$ be its representing polynomial, where $\|p\|_1 \in [3, 2^n]$. Then:*

$$\forall \, \|p\|_1^{-1} \le \varepsilon \le \frac{1}{3} : \quad \widetilde{\deg}_\epsilon(f) = \mathcal{O}\left(\sqrt{n \log \|p\|_1}\right).$$

The proof of Lemma 20 follows from the following simple approximation scheme: replace every *monomial* (of sufficiently large degree) with a polynomial that approximates it pointwise, to some sufficiently small error (depending only on the ℓ_1-norm of the representing polynomial). The full details of this scheme appeared previously in [2, 29]. Combining Lemma 20 with the ℓ_1-bound of Corollary 15, we obtain:

▶ **Corollary 21.** *For any $n > 1$, and $2^{-n\log n} \le \varepsilon \le \frac{1}{3}$, we have:*

$$\widetilde{\deg}_\epsilon(\mathrm{UBPM_n}) = \mathcal{O}(n^{3/2}\sqrt{\log n}).$$

B Families of Matching Functions having Low Dual ℓ_1-Norm

The main algorithmic result in this paper is the low ℓ_1-norm of the dual function of $\mathrm{UBPM_n}$, from which we deduce *upper bounds*, for instance on the communication rank and the approximate degree. In [2], a similar bound had been obtained for the dual of the perfect matching function, $\mathrm{BPM_n}$. These norm bounds and their corollaries extend to a wide range of *matching-related functions*, some of which are detailed below.

Functions Obtained by Restrictions

Consider any two Boolean functions f and g, such that g is obtained by a *restriction* of f (i.e., by fixing some of the inputs bits of f). As restrictions cannot increase the norm, it clearly holds that $\|g\|_1 \le \|f\|_1$ and $\|g^\star\|_1 \le \|f^\star\|_1$. Several intrinsically interesting matching-functions can be cast in this way. One notable example is the bipartite k-matching function, which is the indicator over all graphs $G \subseteq K_{n,n}$ containing a matching of size k.

$$\mathrm{BM_{n,k}}(x_{1,1},\dots,x_{n,n}) = \begin{cases} 1 & \{(i,j) : x_{i,j} = 1\} \subseteq K_{n,n} \text{ has a } k\text{-matching} \\ 0 & \text{otherwise.} \end{cases}$$

This function is obtained by a restriction of BPM_{2n-k}, as follows. Label the vertices of $K_{2n-k,2n-k}$ by

$$L = A \sqcup V, \text{ where } A = \{a_1,\dots,a_n\}, V = \{v_1,\dots,v_{n-k}\}$$
$$R = B \sqcup U, \text{ where } B = \{b_1,\dots,b_n\}, U = \{u_1,\dots,u_{n-k}\}.$$

Given any input $G \subseteq K_{n,n}$ to $\mathrm{BM}_{\mathrm{n,k}}$, the edges of G are encoded via the edges joining A and B, and moreover we fix two additional bicliques $K_{A,U}$, $K_{V,B}$. The resulting graph contains a bipartite perfect matching if and only if G contains a k-matching, and thus

▶ **Corollary.** *For every $0 < k \le n$, we have* $\log \left\|\mathrm{BM}^{\star}_{\mathrm{n,k}}\right\|_1 = \mathcal{O}(n \log n)$.

This norm bound is tight whenever $k = \alpha n$, for any *constant* $0 < \alpha < 1$, as are (up to log-factors) the bounds on the approximate degree and on the log-rank.

▶ **Corollary.** *Let $\alpha \in (0,1)$ be a constant. Then for every $n > 1$ and $2^{-n \log n} \le \varepsilon \le \frac{1}{3}$, we have:*

$$\log \left\|\mathrm{BM}^{\star}_{n,\alpha n}\right\|_1 = \Theta(n \log n), \quad \widetilde{\deg}_{\epsilon}\left(\mathrm{BM}_{n,\alpha n}\right) = \widetilde{\Theta}(n^{3/2}), \quad \textit{and} \ \log \operatorname{rank}\left(\mathrm{BM}_{n,\alpha n}\right) = \widetilde{\Theta}(n).$$

The aforementioned approximate degree lower bound follows using the method of *Spectral Sensitivity* – a complexity measure due to Aaronson, Ben-David, Kothari, Rao and Tal [1], based on Huang's proof of the sensitivity conjecture [16]. [1] proved that the approximate degree of any total function f is bounded below by the spectral radius of its *sensitivity graph* (i.e., the f-cut of the hypercube). As this graph is bipartite, its spectrum is symmetric, and it therefore suffices (by Cauchy interlacing) to obtain a lower bound on the spectral radius of any vertex induced subgraph of the sensitivity graph [2].

For $\mathrm{BM}_{\mathrm{n,k}}$ this construction is straightforward – consider the induced graph whose left vertices are all $(k-1)$-matchings, and right vertices are all k-matchings. This produces a biregular subgraph of the sensitivity graphs of $\mathrm{BM}_{\mathrm{n,k}}$, with left degrees $(n-k+1)^2$ and right degrees k. As it is well known that the spectral radius of a biregular graph is $\sqrt{d_L d_R}$ (where d_L and d_R are the left and right degrees, respectively), this concludes the bound on the spectral sensitivity of $\mathrm{BM}_{\mathrm{n,k}}$, and by extension, its approximate degree[4]. This lower bound on $\widetilde{\deg}\left(\mathrm{BM}_{\mathrm{n,k}}\right)$ now implies the ℓ_1-norm lower bound, through Lemma 20.

As for the log-rank lower bound, it follows by a simple fooling set argument, under the same input partition used in Theorem 17. Let $L = A \sqcup B$ be the left vertices corresponding to the input partition, where $|A| = |B| = n/2$, and let A' and B' be the first $k/2$ vertices of A and B, respectively. Let C be the first $k = \alpha n$ right vertices. Then, under the notation of Theorem 17,

$$S = \left\{ \left(\mathrm{id}(A', S), \mathrm{id}(B', \bar{S})\right) \ : \ S \subseteq C, \ \bar{S} = C \setminus S, \ |S| = |\bar{S}| = \tfrac{k}{2} \right\}$$

is a fooling set for $\mathrm{BM}_{n,\alpha n}$, where the indices of S and $\bar{S}$ correspond to a *fixed* ordering on C. Any pair (x,y) contains a k-matching, but for any mismatching pair belonging to sets $S_1 \neq S_2 \subseteq C$, we have that $S_1 \cap S_2 \neq \emptyset$ and thus the maximum matching is of size $|S_1 \cup S_2| < k$. By construction, this fooling set is of size

$$\log_2 |S| = \log_2 \binom{k}{k/2} = k - o(1)$$

and the log-rank bound now follows from Theorem 18.[5]

[4] We remark that the same construction also trivially extends to $\mathrm{UBM}_{\mathrm{n,k}}$; the *unique* k-matching function.

[5] For the *unique* bipartite k-matching function $\mathrm{UBM}_{\mathrm{n,k}}$ one can obtain a slightly stronger log-rank bound by repeating the construction of Theorem 17 with k-matchings rather than perfect matchings, and by adding $n-k$ isolated vertices. This yields a log-rank bound of $\log_2\left(k/2!\right) = \Theta(k \log k)$.

Formulas over Low-Norm Functions

Given any two nontrivial Boolean functions f and g, the norms of their conjunction, disjunction, and negation are at-most multiplicative in their respective norms, and the same holds for their duals. Therefore, the dual of any short De Morgan formula whose atoms are Boolean functions of low dual ℓ_1-norm, will similarly inherit the low-norm property. Several matching functions can be represented in this way, and thus have low dual norm. For example

$$\mathrm{MaxMatch}_{\mathrm{n,k}}(x_{1,1},\ldots,x_{n,n}) = \begin{cases} 1 & \text{The maximum matching of } \left\{(i,j) : x_{i,j}=1\right\} \text{ is of size } k \\ 0 & \text{otherwise} \end{cases}$$

can be constructed as $\mathrm{MaxMatch}_{\mathrm{n,k}} = \mathrm{BM}_{\mathrm{n,k}} \wedge\neg\, \mathrm{BM}_{n,k+1}$.

Fixed-Point Cycles and Approximate EFX Allocations

Abstract

We study edge-labelings of the complete bidirected graph $\overleftrightarrow{K}_n$ with *functions* that map the set $[d] = \{1, \ldots, d\}$ to itself. We call a directed cycle in $\overleftrightarrow{K}_n$ a *fixed-point cycle* if composing the labels of its edges in order results in a map that has a fixed point, and we say that a labeling is *fixed-point-free* if no fixed-point cycle exists. For a given d, we ask for the largest value of n, denoted $R_f(d)$, for which there exists a fixed-point-free labeling of $\overleftrightarrow{K}_n$. Determining $R_f(d)$ for all $d > 0$ is a natural Ramsey-type question, generalizing some well-studied zero-sum problems in extremal combinatorics. The problem was recently introduced by Chaudhury, Garg, Mehlhorn, Mehta, and Misra [EC 2021], who proved that $d \leq R_f(d) \leq d^4 + d$ and showed that the problem has close connections to *EFX allocations*, a central problem of fair allocation in social choice theory.

In this paper we show the improved bound $R_f(d) \leq d^{2+o(1)}$, yielding an efficient $(1 - \varepsilon)$-EFX allocation with n agents and $O((n/\varepsilon)^{0.67})$ unallocated goods; this improves the bound of $O((n/\varepsilon)^{0.8})$ of Chaudhury, Garg, Mehlhorn, Mehta, and Misra.

Additionally, we prove the stronger upper bound $2d - 2$, in the case where all edge-labels are *permutations*. A very special case of this problem, that of finding *zero-sum cycles* in digraphs whose edges are labeled with elements of $\mathbb{Z}_d$, was recently considered by Alon and Krivelevich [JGT 2021] and by Mészáros and Steiner [EJC 2021]. Our result improves the bounds obtained by these authors and extends them to labelings with elements of an arbitrary (not necessarily commutative) group, while also simplifying the proof.

1 Introduction

Let $\overleftrightarrow{K}_n$ denote the complete bidirected graph on n vertices, that is, $\overleftrightarrow{K}_n$ has directed edges (u, v) and (v, u) for every pair u, v of distinct vertices. For an integer $d > 0$, a *d-labeling*, or simply *labeling*, ℓ of $\overleftrightarrow{K}_n$ is an assignment of a function $\ell_e \colon [d] \to [d]$ to each edge e of $\overleftrightarrow{K}_n$, where $[d] = \{1, \ldots, d\}$.

Let C be a simple cycle of $\overset{\leftrightarrow}{K}_n$ with edges $e_1, \ldots, e_k$ (appearing in this order), where each edge e_i is labeled with a function f_i, for $i \in [k]$. We say that C is a *fixed-point cycle* if the function $f = f_1 \circ f_2 \circ \cdots \circ f_k = f_k(f_{k-1}(\cdots f_1(x) \cdots))$ has a fixed point, i.e., $f(x) = x$ for some $x \in [d]$. Observe that cyclically permuting the edges along C does not affect the existence of a fixed point.

Let $R_f(d)$ be the largest value n such that a d-labeling of $\overset{\leftrightarrow}{K}_n$ with no fixed-point cycle exists. Although not obvious a priori, the finiteness of $R_f(d)$ for all d can be seen through a simple reduction to Ramsey's theorem. In light of the known exponential bounds on multicolor Ramsey numbers [13, 20, 23], the bound obtained in this way is *doubly exponential* in d (see [12] for details).

A lower bound of $R_f(d) \geq d$ can be obtained through the following construction (found independently by various authors in different contexts). Say $V(\overset{\leftrightarrow}{K}_d) = [d]$, and label all edges (i, j) such that $i < j$ with the function $x \mapsto x$ and all other edges with the function $x \mapsto x + 1 \pmod{d}$. The avoidance of fixed-point cycles follows from the observation that every cycle contains at least one and at most $d - 1$ edges of the form (i, j) with $i > j$.

The question of determining $R_f(d)$ was recently raised by Chaudhury, Garg, Mehlhorn, Mehta, and Misra [12] in a slightly different, but equivalent form they call the *rainbow cycle problem.* They proved the upper bound $R_f(d) \leq d^4 + d$.

The motivation in [12] for introducing this problem comes from an application to *discrete fair division.* In particular, through an elegant and surprising connection, they showed that *polynomial* upper bounds on $R_f(d)$ yield nontrivial guarantees for the quality of allocations in a certain natural setting with a strong fairness condition.

EFX allocations

In economics and computational social choice theory, the *discrete fair division* problem asks to distribute a set of m indivisible goods among n agents in a *fair* way. The problem has a long history (see for example [22]) and different notions of fairness have been extensively studied, leading to a rich set of algorithmic and hardness results (e.g., see [8] or [9] and the references therein for an overview and precise definitions).

As simple examples show, complete *envy-freeness* cannot, in general, be achieved. One of the most compelling relaxations of this notion is *envy-freeness up to any good* (EFX). Informally, EFX means that no agent should prefer the goods received by any other agent to their own, if an arbitrary single good is removed from the other's set. The existence of EFX allocations is considered one of the central open questions of contemporary social choice theory (e.g., see [6, 9, 10, 12, 19]), and thus, various relaxations of it have been proposed. In particular, it is desirable to show that an EFX allocation exists (and can be efficiently computed) when (i) a certain global number t of goods are left unallocated, and (ii) envy-freeness is required to hold when every agent scales the values of others' goods by a factor of $1 - \varepsilon$ for some $0 \leq \varepsilon < 1$. Such an allocation is called $(1 - \varepsilon)$*-EFX with t unallocated goods.* It is desirable to minimize both t and ε, with the original EFX question requiring $t = \varepsilon = 0$.

Very recently, Chaudhury, Garg, Mehlhorn, Mehta, and Misra [12] introduced a correspondence between approximate EFX allocations and the fixed-point cycle problem described above (in their terminology, the *rainbow cycle problem*). Suppressing constant factors, the connection can be summarized as follows.

▶ **Theorem 1** (Theorem 4 in [12]). *For all $\varepsilon \in (0, 1/2]$, if $R_f(d) \in O(d^c)$ for some $c \geq 1$, then there exists a $(1 - \varepsilon)$-EFX allocation with $O((n/\varepsilon)^{\frac{c}{1+c}})$ unallocated goods, where n is the number of agents.*

Moreover, if the upper bound on $R_f(d)$ is *constructive* (i.e., a fixed-point cycle can be found in time polynomial in the number n of vertices whenever n exceeds the given bound on $R_f(d)$), then the claimed allocation can also be found in polynomial time. The result of $R_f(d) \leq d^4 + d$ from [12] is constructive; together with Theorem 1 it thus implies an efficient algorithm for computing an approximate EFX allocation with $O((n/\varepsilon)^{0.8})$ unallocated goods, the first guarantee of this kind with a *sublinear* (in n) number of unallocated goods.

Rainbow cycles

As remarked in [12], the question of determining $R_f(d)$ is in itself a natural question of extremal graph theory, independently of its application to EFX allocations.

Chaudhury, Garg, Mehlhorn, Mehta, and Misra formulated the problem in a slightly different, but essentially equivalent, way as follows. Given an n-partite digraph with each part having *at most* d vertices, a *rainbow cycle* is a cycle that visits each part *at most once*. The task is to determine the largest $n = n(d)$ for which such a digraph can avoid rainbow cycles, with the requirement that each vertex in part i has an incoming edge from at least one vertex in part j, for all distinct $i, j \in [n]$.

Note that we may assume that there is an extremal example containing *exactly* d vertices in each part. Indeed, if $\vec{G}$ is an extremal example and some part has fewer than d vertices, let v be any vertex from that part; then add the necessary number of new vertices, making them all "clones" of v, that is, every new vertex has the same in- and out-neighborhood as v. Then the newly obtained digraph has a rainbow cycle if and only if $\vec{G}$ does. Further, we may assume that each vertex v of $\vec{G}$ has *exactly* one incoming edge from every part other than its own. With these observations, the equivalence between the rainbow cycle problem and the fixed-point cycle problem is evident: we can view the bipartite digraph containing the edges from a part V_i to another part V_j as the mapping given by $y \mapsto x$, where $(x, y) \in E(V_i, V_j)$.

Our main result improves the upper bound of Chaudhury, Garg, Mehlhorn, Mehta, and Misra.

▶ **Theorem 2.** *For all $d > 0$ we have $R_f(d) \leq d^{2+o(1)}$.*

Similarly to the previous result, our bound is constructive. Combining Theorem 2 with Theorem 1 thus yields the following result about EFX allocations.

▶ **Corollary 3.** *For all $\varepsilon \in (0, 1/2]$, there exists an efficient $(1-\varepsilon)$-EFX allocation with $O((n/\varepsilon)^{0.67})$ unallocated goods.*

Zero-sum problems in extremal combinatorics

The problem of determining $R_f(d)$ can be cast as a generalization of some classical zero-sum problems in extremal combinatorics (this is somewhat less apparent in the original multipartite formulation of the problem). Zero-sum problems have received substantial attention and form a well-defined subfield of combinatorics, with an algebraic flavour. Perhaps the earliest result in this area is the Erdős-Ginzburg-Ziv theorem [14] which states that every collection of $2m - 1$ integers contains m integers whose sum modulo m is zero (see [3] for multiple proofs and extensions). Zero-sum problems *in graphs* typically ask, given an edge- or vertex-weighted graph, whether a certain substructure exists with zero total weight (modulo some fixed integer). Well-studied cases include complete graphs, cycles, stars, and trees (e.g., see [2, 5, 7, 11, 15, 21] for surveys and representative results).

More recently, for a given positive integer d, Alon and Krivelevich [4] asked for the maximum integer n such that the edges of the complete bidirected graph $\overleftrightarrow{K}_n$ can be labeled with integers so that there is no zero-sum cycle modulo d. In the following, we denote this quantity by $n = R_i(d)$. Alon and Krivelevich showed through an elegant probabilistic argument that $R_i(d) \in O(d \log d)$, with an improvement to $R_i(d) \in O(d)$ when d is prime. The application considered in [4] is finding cycles of length divisible by d in minors of complete graphs. It is easy to see this question as a special case of our fixed-point cycle problem: simply replace every edge-label k by the function $x \mapsto x + k \pmod{d}$. Zero-sum cycles in the original labeling are then in bijection with fixed-point cycles in our new labeling, and thus $R_i(d) \leq R_f(d)$.

Recently, Mészáros and Steiner [17] improved the result of Alon and Krivelevich, showing $R_i(d) \leq 8d - 1$, with further improvements for prime d. In fact, Mészáros and Steiner generalized the result, allowing the labels to come from an arbitrary commutative group of order d. The proof of the main result in [17] can be seen as an extension of an incremental construction of [4], combined with an intricate inductive argument that makes use of group-theoretic results.

We improve these results and show an upper bound of $R_i(d) \leq 2d - 2$ through somewhat similar, but arguably simpler arguments. Our result extends to arbitrary groups (not necessarily commutative). In fact, we prove the result in the more general setting of fixed-point cycles, when the edge-labels are restricted to *permutations* of $[d]$. The permutation case subsumes the integer case, since the functions $x \mapsto x + k \pmod{d}$ in the above reduction are permutations. Denoting the corresponding quantity by $R_p(d)$, we thus have $R_i(d) \leq R_p(d) \leq R_f(d)$, and (omitting the easy case $R_i(1) = R_p(1) = R_f(1) = 1$), prove the following.

▶ **Theorem 4.** *For all $d \geq 2$, we have $R_p(d) \leq 2d - 2$.*

By the above discussion, Theorem 4 implies that $R_i(d) \leq 2d - 2$. In fact, the following more general result holds.

▶ **Corollary 5.** *Let ℓ be a labeling of $\overleftrightarrow{K}_{2d-1}$ with elements of a (not necessarily abelian) group $(G, \cdot)$ of order d. Then there is a cycle whose labels multiply to the identity $1 \in G$.*

To our knowledge, the question of permutation labels has not been considered before. We see it as a natural problem of intermediate generality; it facilitates a simple proof for the integer case, allowing to sidestep the group-theoretic tools used in previous proofs.

In the case of permutation labels, it is natural to ask whether we can guarantee, instead of a fixed-point cycle, the existence of an *identity-cycle.* Indeed, Corollary 5 implies, as a very special case, that if $n \geq 2d! - 1$ and the edges of $\overleftrightarrow{K}_n$ are labeled with permutations of $[d]$, then there is a cycle whose labels compose to $\mathbf{1}_d$. The bound of $2d! - 1$ may appear rather loose, and one may wonder if a condition similar to that of Theorem 4, or at least one with polynomial dependence on d, would be sufficient. The following lower bound rules out this possibility.

▶ **Lemma 6.** *There exists a fixed $d_0 > 0$ such that for all $d \geq d_0$ and some $n \geq e^{\sqrt{d \ln d}}$, there is a labeling of $\overleftrightarrow{K}_n$ with permutations of $[d]$ such that there is no cycle whose labels compose to $\mathbf{1}_d$.*

Open questions

Closing the gap between the lower and upper bounds remains an interesting challenge for all three considered quantities ($R_f(d)$, $R_p(d)$, and $R_i(d)$). The lower bound construction with d vertices discussed earlier can be adapted to all three settings, and it remains a plausible conjecture that $R_i(d) = R_p(d) = R_f(d) = d$. This is easily verified [12] for $d \leq 3$ in the case of $R_f(d)$ (and hence for $R_p(d)$), and was verified via SAT-solvers [17] for $d \leq 6$ in the case of $R_i(d)$. Showing $R_f(d) \in O(d)$ would yield, via Theorem 1, an approximate EFX allocation with $O(\sqrt{n/\varepsilon})$ unallocated goods.

A further natural question is whether other classical zero-sum results from extremal combinatorics can be extended to the fixed-point setting.

Organization of the paper

In § 2 we introduce some useful terminology. In § 3 we prove Theorem 4, Corollary 5, and Lemma 6 and in § 4 we prove Theorem 2.

Independent work

Independently and concurrently to our work, Akrami, Chaudhury, Garg, Mehlhorn, and Mehta [1] also obtained the upper bound $R_p(d) \leq 2d - 2$, and an improved upper bound $R_f(d) \in O(d^2)$.

2 Preliminaries

Let $\overset{\leftrightarrow}{K}_n$ be given together with a labeling ℓ that assigns functions $[d] \to [d]$ to the edges. By *path* or *cycle* we always mean a *simple* path or cycle, and for a path P, we denote by $V(P)$ its set of vertices. All *edges* in this paper are directed, and an edge (u, v) is alternatively denoted by $u \to v$.

When we say that the edge $u \to v$ *maps* x to y, we mean that the function ℓ_{uv} assigned to $u \to v$ maps x to y. Similarly, a path (or cycle) $u_1 \to \cdots \to u_k$ maps x to y if, given the label f_i on $u_i \to u_{i+1}$ for each $i \in [k-1]$, we have $(f_1 \circ \cdots \circ f_{k-1})(x) = y$. For consistency, a path with only one vertex is said to map every value to itself.

We write $v{:}i$ for a pair of a vertex $v \in V(\overset{\leftrightarrow}{K}_n)$ and a value $i \in [d]$. By $u{:}x \xrightarrow{\ell} v{:}y$ (or simply $u{:}x \to v{:}y$ when the labeling ℓ is clear from the context) we denote the fact that the edge $u \to v$ maps x to y.

Let $W = (v_1{:}i_1, v_2{:}i_2, \ldots, v_k{:}i_k)$ be a sequence of vertex-value pairs with $v_j{:}i_j \to v_{j+1}{:}i_{j+1}$ for each $j \in [k-1]$. We call W a *valued walk* in $(\overset{\leftrightarrow}{K}_n, \ell)$. If $v_1 = v_k$, then W is a *valued circuit*. If all vertices in W are distinct, then W is a *valued path*. A valued circuit in which all vertices but the last are distinct is a *valued cycle*.

Finally, let $u, v, w \in V(\overset{\leftrightarrow}{K}_n)$ and $x, y \in [d]$. We say that w *routes* $u{:}x$ *to* $v{:}y$ if $u{:}x \to w{:}z \to v{:}y$ for some $z \in [d]$.

3 Permutation labels

In this section we prove our main result for permutation labels.

▶ **Theorem 4.** *For all $d \geq 2$, we have $R_p(d) \leq 2d - 2$.*

First, we introduce a useful tool, generalizing a technique used in [4, 17] to the fixed-point cycle setting.

Let ℓ be a labeling of $\overset{\leftrightarrow}{K}_n$ that assigns to every edge e a permutation $\ell_e \colon [d] \to [d]$. Consider an edge $u \to v$ of $\overset{\leftrightarrow}{K}_n$ with label ℓ_{uv}. Let $(g_i)_i$ and $(h_i)_i$ denote the labels of the incoming and outgoing edges at v, respectively. A *shifting at* $u \to v$ changes the labeling ℓ by replacing each g_i by $g_i \circ {\ell_{uv}}^{-1}$ and each h_i by $\ell_{uv} \circ h_i$. In particular, the label of $u \to v$ becomes the identity permutation $\mathbf{1}_d$. Let ℓ' be the resulting labeling. Observe that mappings along cycles remain unchanged, in particular $(\overset{\leftrightarrow}{K}_n, \ell')$ has a fixed-point cycle if and only if $(\overset{\leftrightarrow}{K}_n, \ell)$ does.

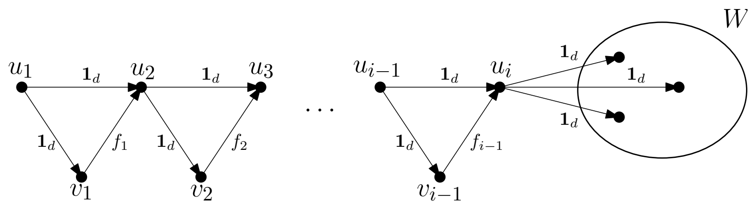

Figure 1 Illustration of the proof of Theorem 4.

Proof of Theorem 4. We start with the case $d = 2$. Suppose there is a permutation 2-labeling ℓ of $\overleftrightarrow{K}_3$ without a fixed-point cycle. The two possible labels are $\mathbf{1}_2$ and the function $\overline{\mathbf{1}}_2$ that maps $1 \mapsto 2$ and $2 \mapsto 1$. For each pair of vertices u, v the labels ℓ_{uv} and ℓ_{vu} must be distinct, otherwise we have a fixed-point cycle $u \to v \to u$. This means that the number of edges labeled $\overline{\mathbf{1}}_2$ in ℓ is precisely 3. Now consider two directed 3-cycles in $\overleftrightarrow{K}_3$ that form a partition of the edges. One of these cycles has to contain an even number of edges labeled $\overline{\mathbf{1}}_2$. Clearly, that cycle maps each value to itself, a contradiction. Thus, $R_p(2) \leq 2$.

Consider now the case $d \geq 3$; let $n \geq 2d - 1$, and let ℓ be an arbitrary permutation d-labeling of $\overleftrightarrow{K}_n$. We show that a fixed-point cycle exists.

We construct a "chain" consisting of vertices $u_1, \dots, u_j$ and $v_1, \dots, v_{j-1}$ (for some $j \leq d$) and transform the labeling so that each edge of the form $u_i \to u_{i+1}$ or $u_i \to v_i$ is labeled $\mathbf{1}_d$. By *step* i we mean either the edge $u_i \to u_{i+1}$ or the path $u_i \to v_i \to u_{i+1}$. Let $S_i \subseteq [d]$ denote the set of possible values to which 1 can be mapped along some path that concatenates steps $1, \dots, i-1$. Observe that if $S_i = [d]$ then we are done, since $u_i \to u_1$ maps some $x \in [d]$ to 1, and adding this edge to the path from u_1 to u_i that maps 1 to x yields a fixed-point cycle.

We construct the chain step-by-step (see Figure 1), ensuring that $|S_i| \geq i$ for all i. If we reach $|S_i| = d$, then we are done, having used at most $2d - 1$ vertices.

Pick vertex $u_1 \in V(\overleftrightarrow{K}_n)$ arbitrarily. The condition is then trivially satisfied.

Assume now that we have identified vertices $u_1, \dots, u_i$ and $v_1, \dots, v_{i-1}$ of the chain. Let $W \subseteq V(\overleftrightarrow{K}_n)$ denote the set of vertices *not used* yet, and shift at all edges $u_i \to u$ for $u \in W$. Observe that no label along the chain is affected. Now consider all edges *between* vertices in W. There are two possible cases.

Case 1: If some edge $v \to u$ (for $u, v \in W$) maps some element $x \in S_i$ to some element $y \notin S_i$, then extend the chain with $u_{i+1} = u$ and $v_i = v$. The set of reachable values becomes $S_{i+1} \supseteq S_i \cup \{y\}$, establishing the claim for the next step.

Case 2: All edges within W map S_i to S_i, and consequently $[d] \setminus S_i$ to $[d] \setminus S_i$. Since the chain has used up $2i - 1 \leq 2|S_i| - 1$ vertices, the digraph induced by W has at least $2d - 1 - (2|S_i| - 1) \geq 2\,|[d] \setminus S_i|$ vertices. If $i \leq d - 2$, then $|[d] \setminus S_i| \geq 2$, and we can argue inductively that the digraph induced by W has a fixed-point cycle. If $i = d - 1$, then $|[d] \setminus S_i| = 1$ and $|W| \geq 2$, so we trivially have a fixed-point cycle. ◀

We next show the extension of the result to the case of labels from an arbitrary (not necessarily abelian) group.

▶ **Corollary 5.** *Let ℓ be a labeling of $\overleftrightarrow{K}_{2d-1}$ with elements of a (not necessarily abelian) group $(G, \cdot)$ of order d. Then there is a cycle whose labels multiply to the identity $1 \in G$.*

Proof. Let ℓ be a labeling that assigns elements of the group $(G, \cdot)$ of order d to edges of $\overleftrightarrow{K}_{2d-1}$. Construct a labeling ℓ' of $\overleftrightarrow{K}_{2d-1}$, assigning the function $x \mapsto x \cdot k$ to every edge with label k in ℓ. By Theorem 4, ℓ' has a fixed-point cycle. Suppose its labels are $f_1, \dots, f_t$, where $f_i(x) = x \cdot k_i$ for all $i \in [t]$. Then $(f_1 \circ \cdots \circ f_t)(x) = x$ for some $x \in G$, which implies that $k_1 \cdot \cdots \cdot k_t = 1 \in G$. ◀

Finally, we prove that to guarantee a cycle whose labels compose to the identity permutation, we need a *super-polynomial* number of vertices.

▶ **Lemma 6.** *There exists a fixed $d_0 > 0$ such that for all $d \geq d_0$ and some $n \geq e^{\sqrt{d \ln d}}$, there is a labeling of $\overleftrightarrow{K}_n$ with permutations of $[d]$ such that there is no cycle whose labels compose to $\mathbf{1}_d$.*

Proof. For given $d > 0$, let $n = n(d)$ denote the *maximum order* of a permutation of $[d]$, that is, n is the largest integer for which there exists a permutation $\pi\colon [d] \to [d]$ such that $\pi^n = \mathbf{1}_d$ but $\pi^k \neq \mathbf{1}_d$ for all $1 \leq k < n$. The function $n(d)$ is *Landau's function*, and it is well known [16, 18] that $n(d) = e^{(1+o(1))\sqrt{d \ln d}}$. (One can obtain high-order permutations by combining cycles of different prime lengths.)

The construction is now similar to the one used earlier. Let $\pi\colon [d] \to [d]$ be a permutation of order n, let $V(\overleftrightarrow{K}_n) = [n]$, and label all edges (i, j) such that $i < j$ with $\mathbf{1}_d$ and all other edges with π. Since every cycle contains at least one and at most $n - 1$ edges of the form (i, j) with $i > j$, composing the labels along a cycle cannot yield $\mathbf{1}_d$. ◀

4 General function labels

Before proving our main theorem, we first present a weaker result, in order to introduce some techniques that will be used later. The result already improves the bound from [12], while using a similar argument.

▶ **Lemma 7.** *For all $d > 0$ we have $R_f(d) \leq d^3 - d^2 + d$.*

Proof. Suppose that $n \geq d^3 - d^2 + d + 1$, and let ℓ be an arbitrary d-labeling of $\overleftrightarrow{K}_n$. We show that a fixed-point cycle exists. For that, we proceed algorithmically.

Partition $V(\overleftrightarrow{K}_n)$ arbitrarily into two parts $V = \{v_1, \ldots, v_d\}$ and $U = \{u_1, \ldots, u_{d^3-d^2+1}\}$, and consider all vertices of U initially *unmarked*.

In the preprocessing phase, for each triplet $(i, x, y) \in [d-1] \times [d]^2$ in turn, check whether there exists an unmarked vertex $u \in U$ that routes $v_i{:}x$ to $v_{i+1}{:}y$. If yes, then *mark* u, and say that u is *responsible* for the triplet (i, x, y).

Observe that as we mark at most $(d-1)d^2$ vertices of U, we have at least one unmarked vertex remaining in U after the preprocessing phase. Let $c \in U$ be such a vertex. Consider now the walk that alternates between visiting c and visiting the vertices of V in order, giving rise to the valued walk $W = (c{:}c_0, v_1{:}x_1, c{:}c_1, v_2{:}x_2, \ldots, v_d{:}x_d, c{:}c_d)$, where $x_i, c_i \in [d]$ for all $i \in [d]$ and $c_0 = 1$. Since $|\{c_0, \ldots, c_d\}| \leq d$, there must be some i, j such that $0 \leq i < j \leq d$ and $c_i = c_j$, yielding the valued fixed-point *circuit* $C = (c{:}c_i, v_{i+1}{:}x_{i+1}, \ldots, v_j{:}x_j, c{:}c_j)$.

It remains to transform C into a cycle. For all k such that $i < k < j$ replace the subpath $v_k \to c \to v_{k+1}$ in C by $v_k \to c' \to v_{k+1}$, where $c' \in U$ is the *unique* marked vertex that is responsible for the triplet (k, x_k, x_{k+1}). Such a vertex must exist in U, for otherwise c itself would have been chosen as responsible for this triplet in the preprocessing phase. We have removed all occurrences of c in C but the first and last, and we have not changed the mappings of values; thus we obtain a fixed-point cycle. An efficient algorithm for finding this cycle is implicit in the proof. ◀

Next, we introduce a transformation that will be useful in the main proof.

Compression

Given a d-labeling ℓ of $\overleftrightarrow{K}_n$, define the *imageset* of a vertex v as $\mathrm{im}(v) = \{y \mid u{:}x \xrightarrow{\ell} v{:}y,$ for some $u, x\}$. In words, $\mathrm{im}(v)$ is the subset of values in $[d]$ that can be mapped to by edges to v.

We say that v is *k-compressed* if $|\mathrm{im}(v)| \leq k$. Observe that all vertices are trivially d-compressed, and the existence of a 1-compressed vertex would immediately yield a fixed-point cycle. Indeed, if v is 1-compressed, then the cycle $v \to u \to v$ maps the unique element in $\mathrm{im}(v)$ to itself for any $u \in V(\overleftrightarrow{K}_n)$.

We now describe the compression operation, illustrated in Figure 2. Let w be a k-compressed vertex for some $k \geq 2$ and $w' \in V(\overleftrightarrow{K}_n) \setminus \{w\}$. Suppose there exist two paths P_1 and P_2 from w to w', together with two distinct values $i_1, i_2 \in \mathrm{im}(w)$ and $j \in [d]$ such that P_1 maps i_1 to j and P_2 maps i_2 to j. Note that the sets of interior vertices of P_1 and P_2 do not need to be disjoint and that either of the paths may consist of a single edge.

Define the function $f\colon [d] \to [d]$ as follows: let $f(i_2) = j$; for all $x \in \mathrm{im}(w) \setminus \{i_2\}$, let $f(x) = y$, where P_1 maps x to y; for all $x \in [d] \setminus \mathrm{im}(w)$, choose $f(x)$ arbitrarily. Now, delete all vertices of P_1 and P_2, and add a new vertex $w^\star$ with edges to and from all remaining vertices. For all $v \in V(\overleftrightarrow{K}_n) \setminus (V(P_1) \cup V(P_2))$, if the edge $v \to w$ had the label g, then the edge $v \to w^\star$ gets the label $g \circ f$, and if an edge $w' \to u$ had the label h, then the edge $w^\star \to u$ gets the label h. The labels of edges not involving $w^\star$ remain unchanged.

We refer to this operation as *compressing P_1 and P_2 to $w^\star$*. Suppose we are left with n' vertices and observe that $n - n' \leq |V(P_1)| + |V(P_2)| - 3$, since P_1 and P_2 have common endpoints. Let ℓ' denote the resulting labeling of $\overleftrightarrow{K}_{n'}$. We prove two crucial properties.

▶ **Lemma 8.** *Suppose that P_1 and P_2 (with starting vertex w) are compressed to $w^\star$ in the way described above, resulting in a labeling ℓ' of $\overleftrightarrow{K}_{n'}$.*

(i) *If w is k-compressed in $(\overleftrightarrow{K}_n, \ell)$, then $w^\star$ is $(k-1)$-compressed in $(\overleftrightarrow{K}_{n'}, \ell')$.*

(ii) *If $(\overleftrightarrow{K}_{n'}, \ell')$ has a fixed-point cycle, then $(\overleftrightarrow{K}_n, \ell)$ has a fixed-point cycle.*

Proof.

(i) Let $S \subseteq [d]$ denote the set of values to which values in $\mathrm{im}(w) \setminus \{i_2\}$ are mapped by P_1. Clearly $|S| \leq |\mathrm{im}(w)| - 1 \leq k - 1$. Since P_2 maps i_2 to j and $j \in S$ by construction (as P_1 maps i_1 to j), every edge $v \to w^\star$ maps all values in $[d]$ to S and thus $|\mathrm{im}(w^\star)| \leq |\mathrm{im}(w)| - 1$.

(ii) If a fixed-point cycle in $(\overleftrightarrow{K}_{n'}, \ell')$ avoids $w^\star$, then it also exists in $(\overleftrightarrow{K}_n, \ell)$. Otherwise, suppose a cycle in $(\overleftrightarrow{K}_{n'}, \ell')$ contains the segment $v{:}x \to w^\star{:}y \to u{:}z$. Then, in $(\overleftrightarrow{K}_n, \ell)$, the edge $v \to w$ maps x to some value in $\mathrm{im}(w)$ that is mapped by P_1 or P_2 to $w'{:}y$, and $w' \to u$ maps y to z. Replacing $w^\star$ by P_1 or P_2 thus gives a fixed-point cycle in $(\overleftrightarrow{K}_n, \ell)$. Given a fixed-point cycle in $(\overleftrightarrow{K}_{n'}, \ell')$, a fixed-point cycle in $(\overleftrightarrow{K}_n, \ell)$ can be reconstructed (i.e., the compression can be undone) efficiently, with minor bookkeeping.

In the remainder of the section we prove our main theorem.

▶ **Theorem 2.** *For all $d > 0$ we have $R_f(d) \leq d^{2+o(1)}$.*

The high-level strategy is similar to the one used in the proof of Lemma 7. The main difference is that, instead of trying to build a cycle using a sequence of d designated vertices $(v_1, \ldots, v_d)$ and a well-chosen center-vertex (c), we pick a sequence of *far fewer* designated vertices, and use the structure imposed upon them by a special compressed vertex. We may fail to find a fixed-point cycle (or even a circuit) with any candidate center. In that case, however, we make progress by *compressing* the special vertex further. After repeating the

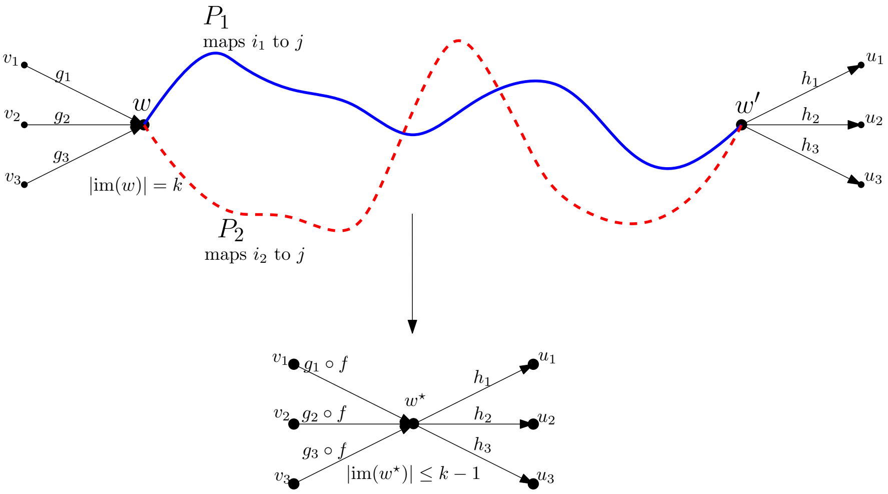

Figure 2 Compressing P_1 and P_2 to $w^\star$.

process sufficiently many times, we will have created a large number of highly compressed vertices. The mappings between these vertices are sufficiently restricted that we can find a fixed-point cycle in the digraph induced by them, through a *recursive application* of the same procedure.

The following lemma describes the key *win-win* step of the procedure: we either find a fixed-point cycle, or identify two paths that allow the compression of a vertex.

▶ **Lemma 9.** *Let $k \geq 2$, $n \geq 4d\lceil \frac{d}{k} \rceil^2 + 2\lceil \frac{d}{k} \rceil + 2$, and $w \in V(\overleftrightarrow{K}_n)$ be a k-compressed vertex. Then either $(\overleftrightarrow{K}_n, \ell)$ has a fixed-point cycle, or there exist a vertex $u \in V(\overleftrightarrow{K}_n) \setminus \{w\}$, values $i_1, i_2 \in \mathrm{im}(w)$ with $i_1 \neq i_2$ and $x \in [d]$, and two paths on at most $4\lceil \frac{d}{k} \rceil + 2$ vertices each from $w{:}i_1$ and $w{:}i_2$ to $u{:}x$.*

Proof. Let $q = 2\lceil \frac{d}{k} \rceil + 1$ and arbitrarily fix a q-subset $V \subseteq V(\overleftrightarrow{K}_n) \setminus \{w\}$. Write $V = \{v_1, v_2, \ldots, v_q\}$ and $U = V(\overleftrightarrow{K}_n) \setminus (V \cup \{w\})$. Notice that $|U| \geq 4d\lceil \frac{d}{k} \rceil^2$.

Call a vertex $c \in U$ *valid* for (i, x, y), where $i \in [q-1]$ and $x, y \in [d]$, if c routes $v_i{:}x$ to $v_{i+1}{:}y$ and there are at least $q-1$ vertices in U that route $v_i{:}x$ to $v_{i+1}{:}y$ (including c). Let k_c denote the number of triples (i, x, y) for which c is *not* valid. Double-counting yields

$$\sum_{c \in U} k_c \leq (q-1) \cdot d^2 \cdot (q-2) < 4d^2 \left\lceil \frac{d}{k} \right\rceil^2.$$

Thus, by the pigeonhole principle, there exists a $c \in U$ with $k_c < \frac{4d^2\lceil \frac{d}{k} \rceil^2}{|U|} \leq d$. Fix such a c.

Recall that $|\mathrm{im}(w)| = k$ and assume without loss of generality that $\mathrm{im}(w) = [k]$. For each $i \in [k]$, we construct a (valued) walk W_i that starts with $v_1{:}\ell_{wv_1}(i)$ and visits $v_2, \ldots, v_q$ in that order, possibly taking a detour through c at every step.

Fix $i \in [k]$. We describe the construction of W_i by iteratively constructing prefixes W_i^j that start with v_1 and end with v_j. First, let $W_i^1 = v_1{:}x_1$, where $x_1 = \ell_{wv_1}(i)$.

For $1 < j \leq q$, suppose that W_i^{j-1} ends with $v_{j-1}{:}x_{j-1}$, and consider the values y_j, x_j reached in the valued path $v_{j-1}{:}x_{j-1} \to c{:}y_j \to v_j{:}x_j$. If c is valid for $(j-1, x_{j-1}, x_j)$, then let $W_i^j = W_i^{j-1} \to c{:}y_j \to v_j{:}x_j$. Otherwise, let $W_i^j = W_i^{j-1} \to v_j{:}x'_j$ for the appropriate x'_j. Finally, let $W_i = W_i^q$. Note that W_i contains at most $2q-1$ vertices (including up to $q-1$ occurrences of c).

Observe that in the process of constructing $W_1, \dots, W_k$, we make $(q-1) \cdot k \geq 2d$ steps in total, where each step either adds c to the current walk, or finds that c is not valid for some triple $(j-1, x_{j-1}, x_j)$.

We claim that some vertex-value pair occurs at least twice in all the valued walks $W_1, W_2, \dots, W_k$. Suppose not. Then, in particular, c occurs at most d times. Moreover, the triples $(j-1, x_{j-1}, x_j)$ for which c is not valid that we encounter in the construction of the walks must be pairwise distinct (if $(j-1, x_{j-1}, x_j)$ occurs twice in this way, then two distinct paths must contain $v_{j-1}{:}x_{j-1}$). This means that we encounter such triples at most k_c times in total. The total number of steps is then at most $d + k_c < 2d$, contradicting our earlier observation. This proves the claim.

First, consider the case where some $v{:}x$ occurs in *two different walks* W_{i_1}, W_{i_2}. Define W'_{i_1} and W'_{i_2} by removing all vertices after v from W_{i_1} and W_{i_2}, respectively. We turn W'_{i_1} and W'_{i_2} into (simple) paths as follows. Suppose c occurs more than once in W'_{i_1}. Suppose W'_{i_1} contains the segment $v_i{:}x_i \to c{:}y_i \to v_{i+1}{:}x_{i+1}$. If this is not the first occurrence of c, then we simply replace c by some vertex $c' \in U \setminus \{c\}$ that routes $v_i{:}x_i$ to $v_{i+1}{:}x_{i+1}$ and has not been used in this way before. Note that we do this at most $q-2$ times (once for each occurrence of c in W'_{i_1} except for the first one), and there are at least $q-2$ such vertices in $U \setminus \{c\}$ by construction, so the operation is well-defined. We proceed the same way for W'_{i_2} (recall that the paths needed for the compression operation need not be internally disjoint). Call the resulting (simple) paths W''_{i_1} and W''_{i_2}, respectively. Then $w{:}i_1 \to W''_{i_1}$ and $w{:}i_2 \to W''_{i_2}$ are the desired paths of at most $2q \leq 4\lceil \frac{d}{k} \rceil + 2$ vertices, and we are done.

Second, suppose that some $v{:}x$ occurs twice *in a single walk* $W = W_i$. Then $v = c$, since each v_i occurs only once in W. We now find a sub-walk of W that has a fixed point. Remove all vertices before the first occurrence of $c{:}x$ and all vertices after the second occurrence of $c{:}x$, and call the resulting valued walk W'. Clearly, W' is a fixed-point walk and contains at most $q-1$ occurrences of c (counting both start and end individually). Then, similarly as in the first case, transform W' into a simple cycle by replacing all occurrences of c, except at the start/end, by suitable vertices (at most $q-3$ of them) in $U \setminus \{c\}$. The result is a fixed-point cycle. ◀

We prove Theorem 2 via the following recurrence.

▶ **Lemma 10.** *For all $d \geq 2^9$, we have $R_f(d) < 5d^2 + 9d \log_2 d \cdot (R_f(\lfloor \sqrt{d} \rfloor) + 1)$.*

Proof. Set $n = 5d^2 + 9d \log_2 d \cdot (R_f(\lfloor \sqrt{d} \rfloor) + 1)$ and consider an arbitrary labeling ℓ of $\overset{\leftrightarrow}{K}_n$. We show that $(\overset{\leftrightarrow}{K}_n, \ell)$ contains a fixed-point cycle. We again proceed algorithmically. Our strategy is to perform transformations on $\overset{\leftrightarrow}{K}_n$ and ℓ, such as to compress vertices using Lemma 9. We say that a $\lfloor \sqrt{d} \rfloor$-compressed vertex is *fully compressed*.

We first observe that if we have more than $R_f(\lfloor \sqrt{d} \rfloor)$ fully compressed vertices, then we are done. Indeed, consider the subdigraph induced by the set F of vertices that are fully compressed. For all $u, v \in F$, restrict each function ℓ_{uv} to an arbitrary subset of $[d]$ of size $\lfloor \sqrt{d} \rfloor$ containing $\mathrm{im}(u)$. Applying an arbitrary bijection from each such set to $[\lfloor \sqrt{d} \rfloor]$, transform the restricted labeling into a valid $\lfloor \sqrt{d} \rfloor$-labeling on the subdigraph induced by F without creating new fixed-point cycles. Then, if $|F| > R_f(\lfloor \sqrt{d} \rfloor)$, we can recursively find a fixed-point cycle in the induced subdigraph, from which we can recover a fixed-point cycle in $(\overset{\leftrightarrow}{K}_n, \ell)$.

Now we explain how we obtain the required number of fully compressed vertices. Let T be an arbitrary set of $R_f(\lfloor \sqrt{d} \rfloor) + 1$ vertices which are to be compressed and let S be the remaining set of vertices of $\overset{\leftrightarrow}{K}_n$. At each step, let $w \in T$ be any vertex that is *not* fully compressed; say w is k-compressed. Apply Lemma 9 to w and the subdigraph induced by $\{w\} \cup S$. If we find a fixed-point cycle, then we are immediately done by Lemma 8.

Otherwise, we find two paths P_1 and P_2 starting at w that we can compress into a single $(k-1)$-compressed vertex $w^\star$. Now set $T = T \setminus \{w\} \cup \{w^\star\}$ and $S = S \setminus (V(P_1) \cup V(P_2))$. Note that the size of S reduces by at most $8\lceil \frac{d}{k} \rceil + 1 \leq 8\frac{d}{k} + 9$.

We need to ensure that we always have enough vertices to apply Lemma 9. First we count the number of vertices that get removed from S throughout the process. Note that, for each k such that $\lfloor \sqrt{d} \rfloor + 1 \leq k \leq d$, we transform a k-compressed vertex of T into a $(k-1)$-compressed vertex of T at most $R_f(\lfloor \sqrt{d} \rfloor) + 1$ times, and every time we perform such an operation, we remove at most $8\frac{d}{k} + 9$ vertices from S. Thus, the number of vertices we remove throughout the process is at most

$$\begin{aligned}
(R_f(\lfloor \sqrt{d} \rfloor) + 1) \sum_{k=\lfloor \sqrt{d} \rfloor + 1}^{d} \left(8\frac{d}{k} + 9\right) &\leq (R_f(\lfloor \sqrt{d} \rfloor) + 1)\,(8d \log_2 d + 9d - 1) \\
&\leq (R_f(\lfloor \sqrt{d} \rfloor) + 1)(9d \log_2 d - 1),
\end{aligned}$$

where the first inequality uses the fact that $\sum_{k=1}^{d} 1/k \leq \log_2 d$, and the second inequality uses our assumption $\log_2 d \geq 9$.

Also accounting for the $R_f(\lfloor \sqrt{d} \rfloor) + 1$ vertices in T, it follows that the final set S has at least $5d^2$ remaining vertices, which is enough to ensure that we can apply Lemma 9. Indeed, the number of additional vertices needed to apply Lemma 9 is

$$\begin{aligned}
4d\left\lceil \frac{d}{k} \right\rceil^2 + 2\left\lceil \frac{d}{k} \right\rceil + 1 &\leq 4d(\sqrt{d}+1)^2 + 2(\sqrt{d}+1) + 1 \\
&\leq 5d^2,
\end{aligned}$$

since we always have $k \geq \lfloor \sqrt{d} \rfloor + 1 \geq \sqrt{d}$, and $d \geq 16$. Thus, the process terminates successfully, leaving us with the set T of $R_f(\lfloor \sqrt{d} \rfloor) + 1$ fully compressed vertices, using which we find a fixed-point cycle, as discussed above. ◀

Finally, we show that the above recurrence solves to $R_f(d) \in \mathcal{O}(d^2 \cdot 2^{(\log_2 \log_2 d)^2})$, thus implying Theorem 2.

▶ **Lemma 11.** *For all $d \geq 4$, we have $R_f(d) \leq 16 \cdot d^2 \cdot 2^{(\log_2 \log_2 d)^2}$.*

Proof. If $d < 2^{20}$, the claim follows by Lemma 7, since $16 \cdot d^2 \cdot 2^{(\log_2 \log_2 d)^2} \geq d^3 - d^2 + d$ for all $d < 2^{20}$. Assume therefore that $d \geq 2^{20}$. Denoting $C = 16$ we have:

$$\begin{aligned}
R_f(d) &\leq 5d^2 + 9d \log_2 d \cdot (R_f(\lfloor \sqrt{d} \rfloor) + 1) && \text{(from Lemma 10)} \\
&\leq 5d^2 + 9d \log_2 d \cdot \left(C \cdot (\lfloor \sqrt{d} \rfloor)^2 \cdot 2^{(\log_2 \log_2 \lfloor \sqrt{d} \rfloor)^2} + 1\right) && \text{(by induction)} \\
&\leq 5d^2 + 9d \log_2 d \cdot \left(C \cdot d \cdot 2^{(\log_2 \log_2 \sqrt{d})^2} + 1\right) && \text{(using } \lfloor \sqrt{d} \rfloor \leq \sqrt{d}\text{)} \\
&\leq 6d^2 + 9C \cdot d^2 \log_2 d \cdot 2^{(\log_2 \log_2 \sqrt{d})^2} && \text{(using } 9 \log_2 d \leq d, \text{ for } d \geq 52\text{)} \\
&\leq 10C \cdot d^2 \log_2 d \cdot 2^{(\log_2 \log_2 \sqrt{d})^2} && \text{(using } d \geq 2^6\text{)} \\
&= 10C \cdot d^2 \log_2 d \cdot 2^{((\log_2 \log_2 d)-1)^2} \\
&= 10C \cdot d^2 \cdot 2^{((\log_2 \log_2 d)-1)^2 + \log_2 \log_2 d} \\
&= C \cdot d^2 \cdot 2^{(\log_2 \log_2 d)^2} \cdot \left(10 \cdot 2^{1 - \log_2 \log_2 d}\right) \\
&= C \cdot d^2 \cdot 2^{(\log_2 \log_2 d)^2} \cdot (20/\log_2 d) \\
&\leq C \cdot d^2 \cdot 2^{(\log_2 \log_2 d)^2}. && \text{(using } d \geq 2^{20}\text{)}
\end{aligned}$$

This concludes the proof. ◀

Note that the constant factor 16 in Lemma 11 can be significantly reduced through a more careful optimization, but we have avoided this, preferring a simpler presentation.

Improved Lower Bound, and Proof Barrier, for Constant Depth Algebraic Circuits

Abstract

We show that any product-depth Δ algebraic circuit for the Iterated Matrix Multiplication Polynomial $\mathrm{IMM}_{n,d}$ (when $d = O(\log n/\log\log n)$) must be of size at least $n^{\Omega\left(d^{1/(\varphi^2)^\Delta}\right)}$ where $\varphi = 1.618\ldots$ is the golden ratio. This improves the recent breakthrough result of Limaye, Srinivasan and Tavenas (FOCS'21) who showed a super polynomial lower bound of the form $n^{\Omega\left(d^{1/4^\Delta}\right)}$ for constant-depth circuits.

One crucial idea of the (LST21) result was to use set-multilinear polynomials where each of the sets in the underlying partition of the variables could be of different sizes. By picking the set sizes more carefully (depending on the depth we are working with), we first show that any product-depth Δ *set-multilinear* circuit for $\mathrm{IMM}_{n,d}$ (when $d = O(\log n)$) needs size at least $n^{\Omega\left(d^{1/\varphi^\Delta}\right)}$. This improves the $n^{\Omega\left(d^{1/2^\Delta}\right)}$ lower bound of (LST21). We then use their Hardness Escalation technique to lift this to general circuits.

We also show that our lower bound cannot be improved significantly using these same techniques. For the *specific* two set sizes used in (LST21), they showed that their lower bound cannot be improved. We show that for any $d^{o(1)}$ set sizes (out of maximum possible d), the scope for improving our lower bound is minuscule: there exists a set-multilinear circuit that has product-depth Δ and size almost matching our lower bound such that the value of the measure used to prove the lower bound is maximum for this circuit. This results in a barrier to further improvement using the same measure.

1 Introduction

An *Arithmetic Circuit* is a natural model to compute multivariate polynomials over a field $\mathbb{F}$. It is a layered *directed acyclic graph* with leaves labelled by variables $x_1, \ldots, x_n$ or elements from $\mathbb{F}$. The internal nodes are alternating layers of either addition $(+)$ or multiplication $(\times)$ gates. The circuit computes a polynomial in $\mathbb{F}[x_1, \ldots, x_n]$ in the natural way: the $+$ gates compute arbitrary $\mathbb{F}$-linear combination of their inputs and the $\times$ gates compute the product.

Some associated *complexity measures* are of particular importance. The *size* of the circuit is the total number of nodes (edges) in the graph. The *depth* of the circuit is the number of layers in the circuit. By *product-depth*, we mean the number of layers of multiplication gates (depth is roughly twice the product-depth). *Arithmetic Formulas* are a subclass of circuits whose underlying graph is a *tree*. For general survey of the field of Algebraic Complexity Theory, see [3, 30, 21].

Valiant [34], in a very influential work defined the classes VP and VNP which can be considered the arithmetic analogues of P and NP. Much like in the Boolean world, the question of whether VP and VNP are the same is one of the central open problems of algebraic complexity theory. Though the best known lower bounds for general arithmetic circuits [2] ($\Omega(n \log n)$) and formulas [10] ($\Omega(n^2)$) fall far short of the super polynomial lower bounds that we hope to prove, there have been many super polynomial lower bounds known for various restricted classes [22, 23, 24]. See [4, 26] for excellent surveys of lower bounds.

One of the most interesting restrictions is that of bounding the *depth* of circuits and formulas. When the depth is a constant, circuits and formulas are equivalent up to polynomial blow up in their size and hence we use them interchangeably in this paper. Unlike the Boolean world though, a very curious phenomenon of *depth reduction* occurs in arithmetic circuits [35, 1, 16, 31, 8] which essentially says that depth 3 and depth 4 circuits are almost as powerful as general ones. Formally, any degree d polynomial f that has a size s circuit can also be computed by a depth 4 *homogeneous* circuit or a depth 3 (possibly non homogeneous) circuit of size $s^{O(\sqrt{d})}$. Hence proving an $n^{\omega(\sqrt{d})}$ lower bound on these special circuits is enough to separate VP from VNP. The extreme importance of bounded depth circuits has led to a large body of work proving lower bounds for these models and their variants [28, 29, 25, 11, 7, 13, 17, 6, 18, 14, 12, 15, 9].

The LST breakthrough. Recently in a remarkable work, Limaye, Srinivasan and Tavenas [20] proved the first superpolynomial lower bound for general constant depth circuits. More precisely, they showed that the Iterated Matrix Multiplication polynomial $\mathrm{IMM}_{n,d}$ (where $d = o(\log n)$) has no product-depth Δ circuits of size $n^{d^{\exp(-O(\Delta))}}$. The polynomial $\mathrm{IMM}_{n,d}$ is defined on $N = dn^2$ variables. The variables are partitioned into d sets $X_1, \ldots, X_d$ of n^2 variables each (viewed as $n \times n$ matrices). The polynomial is defined as the $(1,1)$-th entry of the matrix product $X_1 X_2 \cdots X_d$. All monomials of the polynomial are of the same degree and so $\mathrm{IMM}_{n,d}$ is *homogeneous.* As the the individual degree of any variable is at most 1, it is also *multilinear.* Moreover, every monomial has exactly one variable from each of the sets $X_1, \ldots, X_d$. Hence the polynomial is also *set-multilinear.* For any $\Delta \leq \log d$, $\mathrm{IMM}_{n,d}$ has a set-multilinear circuit of product-depth Δ and size $n^{O(d^{1/\Delta})}$. There are no significantly better upper bounds known even if we allow general circuits. It makes sense to conjecture that this upper bound is tight (see [5] for limitations to improvement in special cases).

The lower bound of [20] proceeds by first transforming size s, product-depth Δ, general algebraic circuits computing a set-multilinear polynomial of degree d to *set-multilinear* algebraic circuits of product-depth 2Δ and size $\mathrm{poly}(s)d^{O(d)}$ (which is not huge if d is small). Hence lower bounds on bounded depth set-multilinear circuits translate to bounded depth general circuit lower bounds albeit with some loss. Finally, considering set-multilinear circuits with variables partitioned into sets of *different sizes* and crucially using this discrepancy of set sizes helps in obtaining strong set-multilinear lower bounds.

Our Results. In this work, we improve the lower bound for IMM against constant depth circuits. We also exhibit barriers to improving the bound further using these techniques, which is of importance as this is the only known approach to achieve super polynomial lower bounds for general low depth circuits.

For the rest of this paper, let $\mu(\Delta) = 1/(F(\Delta) - 1)$ where $F(n) = \Theta(\varphi^n)$ is the n-th Fibonacci number (starting with $F(0) = 1$, $F(1) = 2$) and $\varphi = (1 + \sqrt{5})/2 = 1.618\ldots$ is the golden ratio.

▶ **Theorem 1** (General circuit lower bound)**.** *Fix a field* $\mathbb{F}$ *of characteristic* 0 *or characteristic* $> d$*. Let* N, d, Δ *be such that* $d = o(\log N/\log\log N)$*. Then, any product-depth* Δ *circuit computing* $\mathrm{IMM}_{n,d}$ *on* $N = dn^2$ *variables must have size at least* $N^{\Omega\left(d^{\mu(2\Delta)}/\Delta\right)}$*.*

▶ Remark. Theorem 1 improves on the lower bound of $N^{\Omega\left(d^{1/(2^{2\Delta}-1)}/\Delta\right)}$ of [20] since $F(2\Delta) = \Theta(\varphi^{2\Delta}) \ll 2^{2\Delta}$.

To prove Theorem 1, we use the hardness escalation given by (Lemma 6) which allows for a way to convert general circuits to set-multilinear ones without too much size blow up, provided the degree is small. The actual lower bound is proved on set-multilinear circuits.

▶ **Theorem 2** (Set-multilinear circuit lower bound)**.** *Let* $d \leq (\log n)/4$*. Any product-depth* Δ *set-multilinear circuit computing* $\mathrm{IMM}_{n,d}$ *must have size at least* $n^{\Omega\left(d^{\mu(\Delta)}/\Delta\right)}$*.*

▶ Remark. This is an improvement over the $n^{\Omega\left(d^{1/(2^{\Delta}-1)}/\Delta\right)}$ bound of [20, Lemma 15]. Also, the result holds over any field $\mathbb{F}$. The restriction on the characteristic in Theorem 1 comes from the conversion to set-multilinear circuits. The difference between $\mu(2\Delta)$ in Theorem 1 and $\mu(\Delta)$ in Theorem 2 is also due to the doubling of product-depth during this conversion.

In a recent work [32], Limaye, Srinivasan and Tavenas proved a product-depth Δ *set-multilinear* formula lower bound of $(\log n)^{\Omega(\Delta d^{1/\Delta})}$ for $\mathrm{IMM}_{n,d}$. There is no restriction of degree, but in the small degree regime, the bound is much weaker than [20] and cannot be used for escalation. Improving on it, Kush and Saraf [19] showed a lower bound of $n^{\Omega(n^{1/\Delta}/\Delta)}$ for the size of product-depth Δ set-multilinear formulas computing an n^2-variate, degree n polynomial in VNP from the family of Nisan-Wigderson design-based polynomials. Unlike both [32] and [19], we are interested in the low degree regime where set-multilinear lower bounds can be lifted, and our bounds will be for IMM (a polynomial in VP), making these works incomparable to ours. We now prove Theorem 1 à la [20, Corollary 4]:

Proof of Theorem 1. From Lemma 6 and Theorem 2, for a circuit of product-depth Δ and size s computing $\mathrm{IMM}_{n,d}$ we get that $d^{O(d)}\mathrm{poly}(s) \geq N^{\Omega\left(d^{\mu(2\Delta)}/2\Delta\right)}$. Since $d = O(\log N/\log\log N)$, it follows that $d^{O(d)} = N^{O(1)}$. Therefore, $\mathrm{poly}(s) \geq N^{\Omega\left(d^{\mu(2\Delta)}/2\Delta\right)}/d^{O(d)}$ $\geq N^{\Omega\left(d^{\mu(2\Delta)}/4\Delta\right)}$ implying the required lower bound on s and thus, also Theorem 1. ◀

▶ Remark. Theorem 1 also holds when $d = o(\log N)$ and $\Delta \leq 1/4 \log_\phi \log d$. This is because the above bound on Δ implies that $d^{\mu(2\Delta)}/\Delta \geq d^{\Omega(1/\varphi^{2\Delta})}/\Delta \geq d^{\Omega(1/\sqrt{\log d})}/\log\log d \geq \log d$. Using this inequality together with the assumption $d = o(\log N)$, we get $d^{O(d)} = 2^{O(d\log d)} \leq 2^{o(\log N \cdot d^{\mu(2\Delta)}/\Delta)} = N^{o(d^{\mu(2\Delta)}/\Delta)}$ whence we can proceed similarly to the proof of Theorem 1.

The hard polynomial for which we prove set-multilinear lower bound is actually a word polynomial (Definition 4) which is a set-multilinear restriction of IMM (Lemma 5). Hence the lower bound gets translated to $\mathrm{IMM}_{n,d}$. These word polynomials are set-multilinear with respect to $(X_1, \ldots, X_d)$ where each of the X_is could potentially be of different sizes.

For the two specific set sizes considered in [20], they also exhibit polynomials that match their lower bound. It still leaves open the question whether we can improve the lower bound if we choose some other set sizes. In Theorem 2, by choosing two set sizes that are distinctly different from the ones in [20], we show that it is indeed possible to improve their lower bound. It might then seem plausible, that using many more set sizes could improve the lower bound further. We show that this is false for most cases. Suppose there are γ different set sizes among the X_is. We show that there are set-multilinear polynomials which can be computed by product-depth Δ circuits having size roughly comparable to the size lower bound of Theorem 2, provided γ is not too large. Formally,

▶ **Theorem 3** (Barrier). *Let $s_1, \dots, s_\gamma$ be positive integers. Fix sets $X_1, \dots, X_d$ where for all i, $|X_i| \in \{s_1, \dots, s_\gamma\}$. For any fixed positive integer Δ, there exist polynomials P_Δ and Q_Δ that are set-multilinear with respect to $X_1, \dots, X_d$ such that P_Δ can be computed by product-depth Δ circuits of size $n^{O\left(\Delta\gamma d^{\mu(\Delta)}\right)}$ and Q_Δ can be computed by product-depth Δ circuits of size $n^{O\left(\Delta d^{\mu(\Delta-1)}+\gamma\right)}$. Moreover, both P_Δ and Q_Δ maximise the measure used to prove lower bounds.*

▶ Remark. The two different polynomials with slightly different sizes will imply barriers to improving the lower bound in different regimes of γ. Suppose Δ is small (say $\Delta = O(1)$). When $\gamma = O(1)$, the size of P_Δ matches our lower bound, essentially implying its tightness. When γ is $d^{o(1)}$, the size of Q_Δ is only slightly larger than the lower bound (note $\mu(\Delta-1)$ vs $\mu(\Delta)$). Hence even using multiple set sizes, the scope for improvement is tiny.

In an almost parallel work [33], Limaye, Srinivasan and Tavenas show similar barrier results. They simplify the proof framework of [20] and give a characterization of the lower bounds that can be proved via this technique using a combinatorial property which they term *Tree Bias*. Their result works for any d set sizes but the upper bound they obtain is weaker. More precisely, for any partition $(X_1, \dots, X_d)$ of the input variables they exhibit a set-multilinear polynomial that can be computed by product-depth Δ set-multilinear circuits of size $n^{d^{1/\Delta^{\Omega(\log \Delta)}}}$ while simultaneously maximising the measure. These barrier results (Theorem 3 and results of [33]) suggest that new measures might be necessary to improve the lower bounds.

2 Preliminaries

For any positive integer n, we denote by $F(n)$ the n-th Fibonacci number with $F(0) = 1$, $F(1) = 2$ and $F(n) = F(n-1) + F(n-2)$. The nearest integer to any real number r is denoted by $\lfloor r \rceil$. We follow the notation of [20] as much as possible for better readability.

We consider words that are tuples $(w_1, \dots, w_d)$ of length d where $2^{|w_i|}$ are integers. These words define the actual set sizes of the set-multilinear polynomials we will be working with. Given a word w, let $\overline{X}(w)$ denote the tuple of sets of variables $(X_1(w), \dots, X_d(w))$ where the size of each $X_i(w)$ is $2^{|w_i|}$. We denote the space of set-multilinear polynomials over $\overline{X}(w)$ by $\mathbb{F}_{sm}[\overline{X}(w)]$.

For a word w and any subset $S \subseteq [d]$, the sum of elements of w indexed by S is denoted by $w_S = \sum_{i \in S} w_i$. If for all $t \le d$, $|w_{[t]}| \le b$, then we call w b-unbiased. Denote by $w_{|S}$ the sub-word indexed by S. The positive and negative indices of w are denoted $\mathcal{P}_w = \{i \mid w_i \ge 0\}$ and $\mathcal{N}_w = \{i \mid w_i < 0\}$ respectively with the corresponding collections $\{X_i(w)\}_{i \in \mathcal{P}_w}$ and $\{X_i(w)\}_{i \in \mathcal{N}_w}$ being the positive and negative variable sets. We denote by $\mathcal{M}_w^{\mathcal{P}}$ (resp. $\mathcal{M}_w^{\mathcal{N}}$) the set of all set-multilinear monomials over the positive (resp. negative) variable sets.

The *partial derivative matrix* $\mathcal{M}_w(f)$ has rows indexed by $\mathcal{M}_w^{\mathcal{P}}$ and columns by $\mathcal{M}_w^{\mathcal{N}}$. The entry corresponding to row $m_+ \in \mathcal{M}_w^{\mathcal{P}}$ and $m_- \in \mathcal{M}_w^{\mathcal{N}}$ is the coefficient of the monomial $m_+ m_-$ in f. The complexity measure we use is the *relative rank*, same as [20]:

$$\mathrm{relrk}_w(f) := \frac{\mathrm{rank}(\mathcal{M}_w(f))}{\sqrt{|\mathcal{M}_w^{\mathcal{P}}| \cdot |\mathcal{M}_w^{\mathcal{N}}|}} = \frac{\mathrm{rank}(\mathcal{M}_w(f))}{2^{\frac{1}{2}\sum_{i \in [d]} |w_i|}} \le 1 \; .$$

The following properties of relrk_w will be useful (see [20] for the proofs).

1. (Imbalance) For any $f \in \mathbb{F}_{sm}[\overline{X}(w)]$, $\mathrm{relrk}_w(f) \leq 2^{-|w_{[d]}|/2}$.
2. (Sub-additivity) For any $f, g \in \mathbb{F}_{sm}[\overline{X}(w)]$, $\mathrm{relrk}_w(f+g) \leq \mathrm{relrk}_w(f) + \mathrm{relrk}_w(g)$.
3. (Multiplicativity) Suppose $f = f_1 f_2 \cdots f_t$ where $f_i \in \mathbb{F}_{sm}[\overline{X}(w_{|S_i})]$ and $(S_1, \ldots, S_t)$ is a partition of $[d]$. Then, $\mathrm{relrk}_w(f) = \mathrm{relrk}_w(f_1 f_2 \cdots f_t) = \prod_{i\in[t]} \mathrm{relrk}_{w_{|S_i}}(f_i)$.

We now define the hard polynomials we prove lower bounds for. For any monomial $m \in \mathbb{F}_{sm}[\overline{X}(w)]$, let $m_+ \in \mathcal{M}_w^{\mathcal{P}}$ and $m_- \in \mathcal{M}_w^{\mathcal{N}}$ be its "positive" and "negative" parts. As $|X_i| = 2^{|w_i|}$, the variables of X_i can be indexed using boolean strings of length $|w_i|$. This gives a way to associate a boolean string with any monomial. Let $\sigma(m_+)$ and $\sigma(m_-)$ be the strings associated with m_+ and m_- respectively. We write $\sigma(m_+) \sim \sigma(m_-)$ if one is a prefix of the other.

▶ **Definition 4** ([20, Word polynomials]). *Let w be any word. The polynomial P_w is defined as the sum of all monomials $m \in \mathbb{F}_{sm}[\overline{X}(w)]$ such that $\sigma(m_+) \sim \sigma(m_-)$.*

The matrices $M_w(P_w)$ have full rank (equal to either the number of rows or columns, whichever is smaller) and hence $\mathrm{relrk}_w(P_w) = 2^{-|w_{[d]}|/2}$. We also note (without proof) that these polynomials can be obtained as *set-multilinear* restrictions of $\mathrm{IMM}_{n,d}$.

▶ **Lemma 5** ([20, Lemma 8]). *Let w be any b-unbiased word. If there is a set-multilinear circuit computing $\mathrm{IMM}_{2^b,d}$ of size s and product-depth Δ, then there is also a set-multilinear circuit of size s and product-depth Δ computing the polynomial $P_w \in \mathbb{F}_{sm}[\overline{X}(w)]$. Moreover, $\mathrm{relrk}_w(P_w) \geq 2^{-b/2}$.*

We also state the set-multilinearization lemma alluded to before.

▶ **Lemma 6** ([20, Proposition 9]). *Let s, N, d, Δ be growing parameters with $s \geq Nd$. If C is a circuit of size at most s and product-depth at most Δ computing a set-multilinear polynomial P over the sets of variables $(X_1, \ldots, X_d)$ (with $|X_i| \leq N$), then there is a* set-multilinear circuit *$\tilde{C}$ of size $d^{O(d)}\mathrm{poly}(s)$ and product-depth at most 2Δ computing P.*

3 Proof outline

From the discussion in Section 1 and Lemmas 5 and 6, in order to prove general circuit lower bounds, it suffices to prove that there is a high rank word polynomial that needs large set-multilinear formulas. For a word (and hence set sizes) of our choice, we show that relrk_w is small for set-multilinear formulas of a certain size.

Let k be an integer close to $\log_2 n$. In [20], the authors choose the positive entries of the word w to be an integer close to $k/\sqrt{2}$ and the negative entries to be $-k$. Evidently, these entries are independent of the product-depth Δ. In this paper, we take the positive entries to be $(1 - p/q)k$ and the negative entries to be $-k$ where p and q are suitable integers dependent on Δ. This *depth-dependent* construction of the word enables us to improve the lower bound. We demonstrate the high level proof strategy of the lower bound for the case of product-depth 3.

Proof overview of Theorem 2 for $\Delta = 3$. Define $G(i) = 1/\mu(i) = F(i) - 1$ for all i and let $\lambda = \lfloor d^{1/G(3)} \rfloor$. Consider a set-multilinear forumula C of product-depth 3 and let v be a gate in it. Suppose that the subformula $C^{(v)}$ rooted at v has product-depth $\delta \leq 3$, size s and degree $\geq \lambda^{G(\delta)}/2$. We will prove that $\mathrm{relrk}_w(C^{(v)}) \leq s2^{-k\lambda/48}$ by induction on δ. This will give us the desired upper bound of the form $s2^{-k\lambda/48} = sn^{-\Omega(d^{\mu(3)})}$ on the relative rank of the whole formula when v is taken to be the output gate. Write $C^{(v)} = C_1 + \cdots + C_t$ where each C_i is a subformula of size s_i rooted at a product gate. Because of the subadditivity of relrk_w, it suffices to show that $\mathrm{relrk}_w(C_i) \leq s_i 2^{-k\lambda/48}$ for all i.

Base case. If $\delta = 1$, then C_i is a product of linear forms. Thus, it has rank 1 and hence low relative rank.

Induction step. $\delta \in \{2, 3\}$. Write $C_i = C_{i,1} \dots C_{i,t_i}$ where each $C_{i,j}$ is a subformula of product-depth $\delta - 1$. If any $C_{i,j}$ has degree $\geq \lambda^{G(\delta-1)}/2$, then by induction hypothesis, the relative rank of $C_{i,j}$ and hence C_i will have the desired upper bound and we are done.

Otherwise each $C_{i,j}$ has degree $D_{ij} < \lambda^{G(\delta-1)}/2$. As the formula is set-multilinear, there is a collection of variable-sets $(X_l)_{l\in S_j}$ with respect to which $C_{i,j}$ is set-multilinear. For $j \in [t_i]$, let a_{ij} be the number of positive indices in S_j i.e. the number of positive sets in the collection $(X_l)_{l\in S_j}$. Then the number of negative indices is $(D_{ij} - a_{ij})$.

We consider two cases: if $a_{ij} \leq D_{ij}/3$, then $w_{S_j} \leq (D_{ij}/3) \cdot (1 - p/q)k + (2D_{ij}/3) \cdot (-k) \leq -D_{ij}k/3$. Otherwise $a_{ij} > D_{ij}/3$ and if we can prove that $|w_{S_j}| \geq a_{ij}k/(4\lambda^{G(\delta)-1})$, then in both of the above cases, we would have $|w_{S_j}| \geq D_{ij}k/(12\lambda^{G(\delta)-1})$. By the multiplicativity and imbalance property of relrk_w, it would follow that $\mathrm{relrk}_w(C_i) \leq 2^{\sum_{j=1}^{t_i} -\frac{1}{2}|w_{S_j}|} \leq 2^{-k\lambda/48}$ and we would be done. Thus, we now only have to show that $|w_{S_j}| \geq a_{ij}k/(4\lambda^{G(\delta)-1})$. We have

$$|w_{S_j}| = |a_{ij}(1 - p/q) - (D_{ij} - a_{ij})|\, k \ .$$

Notice that $|w_{S_j}|/k$ is the distance of $a_{ij}p/q$ from some integer, so it must be at least the minimum of $\{a_{ij}p/q\}$ and $1 - \{a_{ij}p/q\}$ where $\{.\}$ denotes the fractional part. The number $a_{ij}p/q$ being rational, has a fractional part $\zeta = (a_{ij}p \bmod q)/q$ and hence it comes down to solving the following system of inequalities:

$$\min(\zeta,\ 1 - \zeta) \geq a_{ij}/(4\lambda^{G(\delta)-1}) \text{ for } \delta \in \{2,3\} \text{ when } a_{ij} \leq D_{ij} < \lambda^{G(\delta-1)}/2 \ .$$

Assign $p = \lambda$, $q = \lambda^2 + 1$. The $\delta = 2$ case is clearly satisfied as $(a_{ij}\lambda \mod (\lambda^2 + 1)) = a_{ij}\lambda$ when $0 \leq a_{ij} \leq \lambda/2$.

Consider the case of $\delta = 3$ and $a_{ij} < \lambda^2/2$. Write $a_{ij} = y_1\lambda + y_0$ for integers $y_1 = \lfloor a_{ij}/\lambda \rfloor < \lambda/2$ and $y_0 \leq \lambda - 1$. Thus, $a_{ij}\lambda \equiv -y_1 + y_0\lambda \mod (\lambda^2 + 1)$. Through some case analysis, one can show that $\min\Big(|y_0\lambda - y_1|,\ \lambda^2 + 1 - |y_0\lambda - y_1|\Big) \geq y_1$ which immediately implies the inequality for the $\delta = 3$ case as $y_1 = \lfloor a_{ij}/\lambda \rfloor \geq a_{ij}/(2\lambda)$.

We can attempt to extend this proof technique to product-depth 4 as follows:
We would similarly want to express a_{ij} as $a_{ij} = y_2\lambda^2 + y_1\lambda + y_0$ for integers $y_2 = \lfloor a_{ij}/\lambda^2 \rfloor, y_0 \leq \lambda - 1$ and $y_1 \leq \lambda - 1$. Ideally, we would want that for some $q \approx \lambda^4$,

$$p\lambda^2 \equiv 1 \bmod q,\ p\lambda \equiv -\lambda^2 \bmod q \text{ and } p \equiv \lambda^3 \bmod q$$

so that $a_{ij}p \equiv y_2 - y_1\lambda^2 + y_0\lambda^3 \bmod q$ and then we can carry out a similar analysis as in the $\Delta = 3$ case. But this is not possible since multiplying the second congruence equation by λ gives $p\lambda^2 \equiv -\lambda^3 \bmod q$, which contradicts the first congruence equation. So we decide to express a_{ij} as $a_{ij} = y_2b_2 + y_1b_1 + y_0b_0$ where b_2, b_1, b_0 are close to $\lambda^2, \lambda, 1$ respectively, instead of being precisely equal to these powers of λ. Then we choose $c_2 \approx 1, c_1 \approx -\lambda^2, c_0 \approx \lambda^3$ and we assign values to p and q such that

$$pb_2 \equiv c_2 \bmod q,\ pb_1 \equiv c_1 \bmod q \text{ and } pb_0 \equiv c_0 \bmod q.$$

It is easy to verify that all these conditions are satisfied if we define

$$b_0 = 1, b_1 = \lambda, b_2 = b_1(\lambda - 1) + b_0; \qquad c_2 = 1, c_1 = -\lambda^2, c_0 = c_2 - c_1(\lambda - 1);$$
$$p = c_0 \text{ and } q = pb_1 - c_1.$$

This inspired our construction of the sequences $\{b_m\}$ and $\{c_m\}$ for general product-depth Δ.

Proof overview of Theorem 3. As mentioned before, we would like to find a family of polynomials for which our lower bound is tight. All the same, we want to maintain high relative rank of these polynomials. If we are able to achieve this and find the appropriate small sized formulas for the said polynomials, we will have that the lower bound cannot be improved using the relative rank measure.

The polynomial P we define will be a close variant of the word polynomials from before. This will ensure that the partial derivative matrix has the maximum possible rank for a matrix of its dimension. From the Imbalance property, the relative rank we obtain is $2^{-|w_{[d]}|/2}$ where we have ensured that $w_{[d]}$ is small. We want to construct the formula F for P such that it has a nice inductive structure. That is, we want the polynomials computed by the subformulas of F to also have high relative rank. This will help us construct a formula from its sub formulas while maintaining high relative rank.

Suppose a subformula F' of F is set multilinear with respect to a subtuple $\mathcal{T}$ of the sets of variables $\overline{X}(w)$. Let these sets in $\mathcal{T}$ be indexed by a set $S_{\mathcal{T}} \subseteq [d]$. As we would like high relative rank of F', the Imbalance property again suggests that $|w_{S_{\mathcal{T}}}|$ be small. And we desire this of every subformula, their subformulas, and so on. So roughly, we want a way to partition our intial index set $[d]$ into some number of index sets $S_1, \dots, S_r$ such that each $|w_{S_i}|$ is small. Suppose we are then able to create subformulas of rank $2^{-|w_{S_i}|/2}$. It turns out that we will have to add roughly $2^{\sum_i |w_{S_i}|}$ many of them to get a polynomial of high relative rank. So to control the size of the formula, we would like $\sum_i |w_{S_i}|$ to be small as well.

In their Depth Hierarchy section, [20] use Dirichlet's approximation principle [27] to pick these nice index sets $\{S_i\}$. Their procedure only works for the particular two variable-set sizes they choose. We extend this to any two set sizes in Claim 13. Interestingly, we do not use Dirichlet to pick the index sets but rather to obtain a lower bound on the size of the sets that we do eventually pick. We think of picking sets as an investment process: when we pick a set S, we buy the $|S|$ elements in it for a cost of $|w_S|$. Hence the cost per element is $|w_S|/|S|$. At each product-depth, we are only allowed to pick sets of size under a certain threshold and we pick the ones with the lowest cost per element. It turns out that this lowest cost decreases exponentially as the depth increases and helps us build a small formula. The decrease is captured by the Fibonacci numbers and is the reason why they emerge in our lower bound and upper bound.

Making these ideas precise requires extensive notation and we postpone further discussion to Section 5.

4 The lower bound: Proof of Theorem 2

In this section we prove the set-multilinear lower bound of Theorem 2.

Fix the product-depth Δ for which we want to prove the lower bound. Define $G(i) := F(i) - 1$ for all i and $\lambda = \lfloor d^{1/G(\Delta)} \rfloor$. We can assume that $\lambda \geq 3$ because otherwise $d^{\mu(\Delta)} < 3$ and in that case, the lower bound is trivial. The lower bound we aim to prove is $n^{\Omega(d^{1/G(\Delta)})}$. We first define the sequences $\{b_m\}$ and $\{c_m\}$ mentioned in the proof overview:

Let $r_m := \lambda^{G(m+1)-G(m)} - 1$ for $0 \leq m \leq \Delta - 2$.

Define

$$b_0 := 1, \quad b_1 := \lambda \text{ and } b_m := b_{m-2} + r_{m-1} b_{m-1} \text{ for } 2 \leq m \leq \Delta - 2\ .$$

Define

$$c_{\Delta-2} := (-1)^{\Delta-2}, \qquad c_{\Delta-3} := (-1)^{\Delta-3} \lambda^{G(\Delta-1)-G(\Delta-2)} \text{ and}$$
$$c_m := (-1)^m (|c_{m+2}| + r_{m+1}|c_{m+1}|) \text{ for } \Delta - 4 \geq m \geq 0\ .$$

Note that the sign parity of c_m is $(-1)^m$ for all m.
Thus, $c_{m-2} = (-1)^{m-2}(|c_m| + r_{m-1}|c_{m-1}|) = c_m - r_{m-1}c_{m-1}$ which implies

$$c_m = c_{m-2} + r_{m-1}c_{m-1} \text{ for } 2 \leq m \leq \Delta - 2\ .$$

It can be shown (see the full version for the proof) that each b_m is close to $\lambda^{G(m)}$ and each $|c_m|$ is close to $\lambda^{G(\Delta-1)-G(m+1)}$:

$$\frac{\lambda^{G(m)}}{2} \leq b_m \leq \lambda^{G(m)} \quad \text{and} \quad \frac{\lambda^{G(\Delta-1)-G(m+1)}}{2} \leq |c_m| \leq \lambda^{G(\Delta-1)-G(m+1)} \quad \text{for all } m. \tag{1}$$

Define

$$p := c_0 \text{ and } q := pb_1 - c_1 = c_0(r_0+1) - c_1\ .$$

By defining the integers p and q this way, we have ensured that $pb_0 \equiv c_0 \bmod q$ and $pb_1 \equiv c_1 \bmod q$. Hence from the relations $b_m = b_{m-2}+r_{m-1}b_{m-1}$ and $c_m = c_{m-2}+r_{m-1}c_{m-1}$, it inductively follows that

$$pb_m \equiv c_m \bmod q \qquad \text{for } 0 \leq m \leq \Delta - 2\ . \tag{2}$$

Constructing the word. Define $\alpha = 1 - p/q$. As $\dfrac{p}{q} \leq \dfrac{c_0}{c_0(r_0+1)} = 1/\lambda$, we have $\alpha \geq 1/2$. Since $q = c_0\lambda - c_1$, it implies that

$$q \leq |c_0|\lambda + |c_1| \leq 2\lambda^{G(\Delta-1)} \leq d < \lfloor \log_2 n \rfloor / 2$$

where the second inequality follows from the upper bound on each $|c_m|$ in (1). Therefore, there exists a multiple of q in the interval $\left[\frac{\lfloor \log_2 n \rfloor}{2}, \lfloor \log_2 n \rfloor\right]$. Let k be this multiple of q. Then αk is an integer. We can construct a word w over the alphabet $\{\alpha k, -k\}$ such that w is k-unbiased. This can be done using induction: if $|w_{[i]}| \leq 0$, set $w_{i+1} = \alpha k$, otherwise set $w_{i+1} = -k$.

With these definitions in place, we are ready to prove Theorem 2. Assume the following lemma:

▶ **Lemma 7.** *Let $\delta \leq \Delta$ be an integer and α, k be as defined above. Let w be any word of length d over the alphabet $\{\alpha k, -k\}$. Then any set-multilinear formula C of product-depth δ, degree $D \geq \lambda^{G(\delta)}/8$ and size at most s satisfies*

$$\mathrm{relrk}_w(C) \leq s2^{-k\lambda/256}.$$

Proof of Theorem 2. By lemma 5, there exists a set-multilinear projection P_w of $\mathrm{IMM}_{2^k,d}$ such that $\mathrm{relrk}_w(P_w) \geq 2^{-k}$. If there is a set-multilinear circuit of size s and product-depth Δ computing $\mathrm{IMM}_{n,d}$, then we can expand it to a set-multilinear formula of size at most $s^{2\Delta}$ which computes the same polynomial. Hence we will also have a set-multilinear formula of size at most $s^{2\Delta}$ computing P_w. As $d \geq \lambda^{G(\Delta)}/8$, taking the particular case of $\delta = \Delta$ in Lemma 7, we obtain $\mathrm{relrk}_w(P_w) \leq s^{2\Delta}2^{-k\lambda/256}$. This gives the desired lower bound

$$s^{2\Delta} \geq 2^{-k}2^{k\lambda/256} \geq \left(\frac{n}{4}\right)^{\frac{d^{1/G(\Delta)}}{512}}/n = n^{\Omega(d^{\mu(\Delta)})}. \qquad \blacktriangleleft$$

Proof of Lemma 7. We proceed by induction on δ. We can write $C = C_1 + \cdots + C_t$ where each C_i is a subformula of size s_i rooted at a product gate. Because of the subadditivity of relrk_w, it suffices to show that

$$\mathrm{relrk}_w(C_i) \leq s_i 2^{-k\lambda/256} \qquad \text{for all } i.$$

Base case. C has product-depth $\delta = 1$ and degree $D \geq \lambda/8$.
Then C_i is a product of linear forms. If L is linear form on some variable set $X(w_j)$, then $\mathrm{relrk}_w(L) \leq 2^{-|w_j|/2} \leq 2^{-k/4}$. Therefore by the multiplicativity of relrk_w,

$$\mathrm{relrk}_w(C_i) \leq 2^{-kD/4} \leq 2^{-k\lambda/32}\ .$$

Induction hypothesis. Assume that the lemma is true for all product-depths $\leq \delta - 1$.

Induction step. Let C be a formula of product-depth δ and degree $D \geq \lambda^{G(\delta)}/8$.
We can write $C_i = C_{i,1} \ldots C_{i,t_i}$ where each $C_{i,j}$ is a subformula of product-depth $\delta - 1$.
If C_i has a factor, say $C_{i,1}$, of degree $\geq \lambda^{G(\delta-1)}/8$, then by induction hypothesis,

$$\mathrm{relrk}_w(C_i) \leq \mathrm{relrk}_w(C_{i,1}) \leq s_i 2^{-k\lambda/256}\ .$$

Otherwise every factor of C_i has degree $< \lambda^{G(\delta-1)}/8$. Let $C_i = C_{i,1} \ldots C_{i,t_i}$ where each $C_{i,j}$ has degree $D_{ij} < \lambda^{G(\delta-1)}/8$. If C_i is set-multilinear with respect to $(X_l)_{l\in S}$, then let $(S_1, \ldots, S_{t_i})$ be the partition of S such that each $C_{i,j}$ is set-multilinear with respect to $(X_l)_{l\in S_j}$.
For $j \in [t_i]$, let a_{ij} be the number of positive indices in S_j. We have two cases: If $a_{ij} \leq D_{ij}/2$, then

$$w_{S_j} \leq \frac{D_{ij}}{2} \cdot \alpha k + \frac{D_{ij}}{2} \cdot (-k) = -\frac{D_{ij}p}{2q}k \leq -\frac{D_{ij}k}{4\lambda}$$

where the last inequality follows from $\frac{p}{q} \geq \frac{c_0}{2c_0(r_0+1)} = \frac{1}{2\lambda}$. The other case is $a_{ij} > D_{ij}/2$. If we can prove that $|w_{S_j}| \geq a_{ij}k/(8\lambda^{G(\delta)-1})$, then in both of the above cases, we would have $|w_{S_j}| \geq D_{ij}k/(16\lambda^{G(\delta)-1})$. By the multiplicativity and imbalance property of relrk_w and the assumption $D \geq \lambda^{G(\delta)}/8$, it would follow that

$$\mathrm{relrk}_w(C_i) \leq \prod_{j=1}^{t_i} 2^{-\frac{1}{2}|w_{S_j}|} \leq 2^{-\sum_{j=1}^{t_i} D_{ij}k/(32\lambda^{G(\delta)-1})} = 2^{-Dk/(32\lambda^{G(\delta)-1})} \leq 2^{-k\lambda/256}$$

and we would be done. Thus, we now only have to show that $|w_{S_j}| \geq a_{ij}k/(8\lambda^{G(\delta)-1})$.

$$\begin{aligned} |w_{S_j}| &= |a_{ij} \cdot \alpha k + (D_{ij} - a_{ij}) \cdot (-k)| = \left|a_{ij}\frac{p}{q} - (2a_{ij} - D_{ij})\right| k && \text{as } \alpha = 1 - p/q \\ &\geq \left|\frac{a_{ij}p}{q} - \left\lfloor \frac{a_{ij}p}{q} \right\rceil\right| k && \text{where } \lfloor . \rceil \text{ denotes the nearest integer.} \end{aligned}$$

The fractional part of $\dfrac{a_{ij}p}{q}$ is $\dfrac{a_{ij}p \bmod q}{q}$. Hence in order to prove that $|w_{S_j}| \geq a_{ij}k/(8\lambda^{G(\delta)-1})$, it is enough to verify that the following inequality is satisfied:

$$\min\left(\frac{a_{ij}p \bmod q}{q}, 1-\frac{a_{ij}p \bmod q}{q}\right) \geq \frac{a_{ij}}{8\lambda^{G(\delta)-1}} \tag{3}$$

Showing that the p, q we defined satisfy the inequality (3). We will first find what we call the base $(b_0, \dots, b_{\Delta-2})$ representation of the number a_{ij}. For $0 \leq m \leq \Delta-2$, inductively define y_m to be the integer quotient when $\left(a_{ij} - \sum\limits_{m'=m+1}^{\Delta-2} b_{m'}y_{m'}\right)$ is divided by b_m. Then we can express a_{ij} as $a_{ij} = \sum\limits_{m=0}^{\Delta-2} b_m y_m$. Since $b_m \geq \lambda^{G(m)}/2$ for all m and $a_{ij} \leq D_{ij} < \lambda^{G(\delta-1)}/8$, we have the following bounds on the values of y_m:

$$y_m = 0 \text{ for } m \geq \delta-1, \tag{4}$$

$$y_{\delta-2} = \left\lfloor \frac{a_{ij}}{b_{\delta-2}} \right\rfloor < \frac{\frac{\lambda^{G(\delta-1)}}{8}}{\frac{\lambda^{G(\delta-2)}}{2}} \leq \frac{\lambda^{G(\delta-1)-G(\delta-2)}-1}{2} = \frac{r_{\delta-2}}{2}, \tag{5}$$

$$y_m \leq \left\lfloor \frac{b_{m+1}-1}{b_m} \right\rfloor = r_m \text{ for } m < \delta-2\ . \tag{6}$$

By (2), $a_{ij}p \equiv \sum\limits_{m=0}^{\Delta-2} c_m y_m \bmod q$. Therefore,

$$\min\left(\frac{a_{ij}p \bmod q}{q}, 1-\frac{a_{ij}p \bmod q}{q}\right) = \min\left(\left|\sum_{m=0}^{\Delta-2} c_m y_m\right|/q,\ 1-\left|\sum_{m=0}^{\Delta-2} c_m y_m\right|/q\right) \tag{7}$$

if $\left|\sum_{m=0}^{\Delta-2} c_m y_m\right|/q \leq 1$, which is true by the following claim (see the full version for the proof):

▷ Claim 8. If $0 \leq y_m \leq r_m$ for all m, then $\left|\sum\limits_{m=0}^{\Delta-2} c_m y_m\right| < q - c_0$.

Now let f be the highest index such that $y_f \geq 1$ (by (4), $f \leq \delta-2$) and e be the smallest index such that $y_e \geq 1$. Then $\left|\sum_{m=0}^{\Delta-2} c_m y_m\right| = \left|\sum_{m=e}^{f} c_m y_m\right|$. We need two more claims whose proofs can be found in the full version.

▷ Claim 9. Let y_m be non-negative integers such that $y_e \geq 1$. Then $\left|\sum_{m=e}^{f} c_m y_m\right| \geq \min\Big(|c_f y_f|, |c_{f-1}| - |c_f y_f|\Big)$.

▷ Claim 10. Let $\{y_m\}_{m=0}^{\delta-2}$ be a sequence of non-negative integers. Let $f \leq \delta-2$ be the highest index such that $y_f \geq 1$. If $y_{\delta-2} = \lfloor \frac{a_{ij}}{b_{\delta-2}} \rfloor \leq r_{\delta-2}/2$ and $0 \leq y_m \leq r_m$ for all $m \leq \delta-2$, then $\min\Big(|c_f y_f|, |c_{f-1}| - |c_f y_f|\Big) \geq |c_{\delta-2}a_{ij}/(2b_{\delta-2})|$.

If $\delta = 2$, then $f = 0$ by (4). Thus $q - \left|\sum_{m=e}^{f} c_m y_m\right| > c_0 r_0 - |c_0 y_0| > c_0 r_0/2 > |c_f y_f|$ where the last two inequalities follow from (5).

Otherwise $\delta > 2$. By Claim 8, $q - \left|\sum_{m=e}^{f} c_m y_m\right| > c_0$. From the definition of the sequence $\{c_m\}$, we have $c_0 \geq |c_f r_f| \geq |c_f y_f|$ when $f > 0$. But when $f = 0$, it follows that $y_{\delta-2} = 0$ implying $a_{ij} < b_{\delta-2}$. This further implies $c_0 \geq |c_{\delta-2}| \geq |c_{\delta-2} a_{ij}/b_{\delta-2}|$.

From the analysis of the two cases above and by Claims 9 and 10, we get that

$$\min\left(\left|\sum_{m=e}^{f} c_m y_m\right|,\ q - \left|\sum_{m=e}^{f} c_m y_m\right|\right)/q \geq \left|\frac{c_{\delta-2} a_{ij}}{2 b_{\delta-2} q}\right|.$$

The bounds on each b_m and $|c_m|$ given in (1) imply the following:

$$|c_{\delta-2}| \geq \lambda^{G(\Delta-1)-G(\delta-1)}/2, \quad b_{\delta-2} \leq \lambda^{G(\delta-2)}, \quad q \leq |c_0|\lambda + |c_1| \leq 2\lambda^{G(\Delta-1)}\ .$$

Hence $\min\left(\left|\sum_{m=e}^{f} c_m y_m\right|/q,\ 1 - \left|\sum_{m=e}^{f} c_m y_m\right|/q\right) \geq \frac{a_{ij}}{8\lambda^{G(\delta-1)+G(\delta-2)}} = \frac{a_{ij}}{8\lambda^{G(\delta)-1}}$ which together with (7) implies (3). ◀

5 Limitations on improving the bounds: Proof of Theorem 3

We will show here that the techniques of [20] cannot hope to prove much stronger lower bounds. We do this by constructing polynomials for which the lower bound we proved earlier is tight. We begin by showing this in the case of two different set sizes. We can normalize with respect to the bigger set size to assume that the weights are $-k$ and αk ($\alpha \in [0,1]$) without loss of generality. Clearly, $k \leq \log n$.

▶ **Lemma 11.** *Let n, d, Δ be such that $d \leq n$. For any $\alpha \in [0,1]$ let $w \in \{-k, \alpha k\}^d$ be a word. There is a polynomial $P_\Delta \in \mathbb{F}_{sm}[\overline{X}(w)]$ which is computable by a set-multilinear formula of product-depth at most Δ, size at most $n^{O(\Delta d^{\mu(\Delta)})}$ and has the maximum possible relative rank.*

▶ Remark. We can replace αk with $\lfloor \alpha k \rfloor$ and assume that the weights in w are integers. It can be shown that this will not change the arguments in any significant way (see Claim 21 in the full version).

We will need the extensive notation from [20]. We restate it here.

Notation.

- As in Section 2 and from the remark above, we assume $|X(w_i)| = 2^{|w_i|}$ and that the variables are indexed by binary strings $\{0,1\}^{|w_i|}$.
- Given any subset $S \subseteq [d]$, we denote by $S_+ = \{i \in S \mid w_i > 0\}$ the positive indices of S and similarly by S_-, the negative indices.
- We let $K = \sum_{i\in[d]} |w_i|$, $k_+ = \sum_{i\in S_+} |w_i|$ and $k_- = \sum_{i\in S_-} |w_i|$. We say S is $\mathcal{P}$-heavy if $k_+ \geq k_-$ and $\mathcal{N}$-heavy otherwise.
- Setting $I = [K]$, we partition the set $I = I_1 \cup \cdots \cup I_d$ where I_j is an interval of length $|w_j|$ that starts at $\sum_{i<j} |w_j| + 1$. Given a $T \subseteq [d]$, we let $I(T) = \bigcup_{j\in T} I_j$.
- Let $m = m_+ m_- \in \mathcal{M}_w^S$ be any monomial. The boolean string $\sigma(m_+)$ associated with the positive monomial (as defined in Section 2) can be thought of as a labelling of the elements of $I(S_+)$ in the natural way - $\sigma(m_+) : I(S_+) \to \{0,1\}$. Similarly for $\sigma(m_-)$.

Given a set S, we define a sequence of polynomials that we will later show to have small size set multilinear formulas but large rank.

Fix $J_+ \subseteq I(S_+)$ and $J_- \subseteq I(S_-)$ such that $|J_+| = |J_-| = \min\{k_+, k_-\}$. Let π be a bijection from J_+ to J_-. Such a tuple (S, J_+, J_-, π) is called valid. Fix a valid (S, J_+, J_-, π).

A string $\tau \in \{0,1\}^{|k_+ - k_-|}$ defines a map $I(S_+) \setminus J_+ \to \{0,1\}$ if S is $\mathcal{P}$-heavy and a map $I(S_-) \setminus J_- \to \{0,1\}$ if S is $\mathcal{N}$-heavy.

The polynomial $P_{(S,J_+,J_-,\pi,\tau)}$ is the sum of all monomials m such that

1. $\sigma(m_+)(j) = \sigma(m_-)(\pi(j))$ for all $j \in J_+$, and
2. $\sigma(m_+)(j) = \tau(j)$ for all $j \in I(S_+) \setminus J_+$ if S is $\mathcal{P}$-heavy or $\sigma(m_-)(j) = \tau(j)$ for all $j \in I(S_-) \setminus J_-$ if S is $\mathcal{N}$-heavy.

As observed in [20], these polynomials have maximum possible relative rank and other properties that help in building formulas for them inductively (precise statements in the full version).

To proceed, we introduce a few notions that help make the ideas in the proof overview above precise. Fix Δ as in Lemma 11. We define the *fractional cost* fc. Set $\mathrm{fc}(0) = 1$ and

$$\mathrm{fc}(\delta) \coloneqq \min_{q < d^{\mu(\Delta)}/\mathrm{fc}(\delta-1)} |q\alpha - \lfloor q\alpha \rceil|/q \qquad \text{for } 1 \leq \delta \leq \Delta - 1.$$

The quantity $|q\alpha - \lfloor q\alpha \rceil|$ is the distance to the nearest integer from $q\alpha$. For $1 \leq \delta \leq \Delta - 1$, we denote by p_δ the (least) value of q for which the above expression attains the minimum. We also denote by $n_\delta \coloneqq \lfloor p_\delta \alpha \rceil$ the nearest integer to $p_\delta \alpha$. Finally, we set $p_\Delta \coloneqq |\mathcal{P}_w|$ (total number of positive sets) and $n_\Delta \coloneqq |\mathcal{N}_w|$ (total number of negative sets).

We state (without proof) a few properties of the terms defined above and point the reader to the full version for details.

(C1) (Exponential decline) The fractional cost falls exponentially with depth i.e., $\mathrm{fc}(\delta) \leq 1/(d^{\mu(\Delta)})^{F(\delta+1)-2}$ for $1 \leq \delta \leq \Delta - 1$. This exponential decline causes $\mathrm{fc}(\Delta - 1)$ to be very small: $\mathrm{fc}(\Delta - 1) \leq 2d^{\mu(\Delta)}/p_\Delta$.

(C2) (Monotonicity) Let $\Delta' \leq \Delta - 1$ be the smallest integer for which $\mathrm{fc}(\Delta') \leq 2d^{\mu(\Delta)}/p_\Delta$ holds (such a Δ' exists from the second part of (C1)). Redefine $p_{\Delta'+1} \coloneqq p_\Delta$ and $n_{\Delta'+1} \coloneqq n_\Delta$. We have that $p_{\delta-1} \leq p_\delta$ and $n_{\delta-1} \leq n_\delta$ for all $\delta \leq \Delta' + 1$.

With the notation in place, we can now state the following central claim that constructs the polynomial needed for Lemma 11:

▷ Claim 12. Let Δ, Δ' be as fixed above and $S \subseteq [d]$ be such that $|w_S| \leq k$. Then, there exist J_+, J_-, π such that (S, J_+, J_-, π) is valid and for any integer $\delta \leq \Delta' + 1$ and for all $\tau \in \{0,1\}^{|k_+ - k_-|}$, the polynomial $P_{(S,J_+,J_-,\pi,\tau)}$ can be computed by a set-multilinear formula of product-depth δ and size at most $|S|^\delta 2^{5k\delta d^{\mu(\Delta)}}$.

We finish the proof of Lemma 11 assuming the above claim:

Proof of Lemma 11. As $w_{[d]} \leq k$, applying Claim 12 to $S = [d]$ and $\delta = \Delta' + 1$, gives a polynomial $P_{\Delta'+1} \in \mathbb{F}_{sm}[\overline{X}(w)]$ with $\mathrm{relrk}_w(P_{\Delta'+1}) = 2^{-|w_{[d]}|/2}$. The polynomial $P_{\Delta'+1}$ is computable by a set-multilinear formula of product-depth at most Δ of size at most $d^\Delta 2^{10k\Delta d^{\mu(\Delta)}} \leq n^{O\left(\Delta d^{\mu(\Delta)}\right)}$, since $\Delta' + 1 \leq \Delta$ by definition. ◀

The following claim is the main technical result that helps in proving Claim 12. It is in the same spirit as [20, Claim 28], but we show the existence of a better partition with a more careful analysis. Our analysis holds for any $\alpha \in [0,1]$.

▷ Claim 13. Fix $\delta \leq \Delta' + 1$. Let $S \subseteq [d]$ with $|w_S| \leq k$ such that $|S_+| \leq p_\delta$ and $|S_-| \leq n_\delta$. Then there exists a partition of S as $S_1 \cup S_2 \cup \ldots S_r$ where the following conditions hold:

1. $|S_{i,+}| \leq p_{\delta-1}$ and $|S_{i,-}| \leq n_{\delta-1}$
2. $\sum_{i=1}^{r} |w_{S_i}| \leq 5kd^{\mu(\Delta)}$
3. $|w_{S_i}| \leq k$ for all $i \in [r]$

Proof of Claim 13. As long as possible, pick sets S_i with $|S_{i,+}| = p_{\delta-1}$ positive indices and $|S_{i,-}| = n_{\delta-1}$ negative indices. For all such sets picked, we have

$$|w_{S_i}| = \left|\sum\nolimits_{j\in S_i} w_j\right| = k \cdot |p_{\delta-1}\alpha - n_{\delta-1}| = k \cdot |p_{\delta-1}\alpha - n_{\delta-1}| \leq k \ . \tag{8}$$

Suppose the sets chosen after the procedure are $S_1, \ldots, S_m$, where $m = \min\left\{\left\lfloor\frac{|S_+|}{p_{\delta-1}}\right\rfloor, \left\lfloor\frac{|S_-|}{n_{\delta-1}}\right\rfloor\right\}$ and we are left with the set S'. Since we cannot pick the sets any more, we must have that $|S'_+| < p_{\delta-1}$ or $|S'_-| < n_{\delta-1}$ (or both). We analyze one case, others being analogous.

Say $m = \left\lfloor\frac{|S_+|}{p_{\delta-1}}\right\rfloor$ (i.e. $|S'_+| < p_{\delta-1}$). Also suppose $|S'_-| > n_{\delta-1}$. We pick a set S_{m+1} with $|S'_+|$ positive indices and $p \leq (|S_-| - m \cdot n_{\delta-1})$ negative indices such that

$$|w_{S_{m+1}}| = k\left|\alpha|S'_+| - p\right| = k\left|\alpha(|S_+| - m \cdot p_{\delta-1}) - p\right| \leq k. \tag{9}$$

Note that we can always choose $\alpha|S'_+| - 1 \leq p \leq \alpha|S'_+| + 1$ to satisfy the desired constraints. This follows from observing that $|p_{\delta-1}\alpha - n_{\delta-1}| \leq 1$ which gives $p_{\delta-1}\alpha - 1 \leq n_{\delta-1} \leq p_{\delta-1}\alpha + 1$. Now use the fact that $|S'_-| > n_{\delta-1}$.

The remaining set $T = S' \setminus S_{m+1}$ has only negative values which we split into singletons $S_{m+2}, \ldots, S_r$ (there are $(|S_-| - mn_{\delta-1} - p)$ of these sets). As these are singletons, for $m + 2 \leq j \leq r$ we trivially have $|w_{S_j}| \leq k$.

We also note that since $(|S_-| - m \cdot n_{\delta-1} - p)$ is positive, it is equal to $|m \cdot n_{\delta-1} + p - |S_-||$, which can be rewritten as $|(\alpha|S_+| - |S_-|) - (m(p_{\delta-1}\alpha - n_{\delta-1})) - (\alpha(|S_+| - m \cdot p_{\delta-1}) - p)|$. Using the triangle inequality, we can upper bound this quantity by the sum of $|\alpha|S_+| - |S_-||$, $|m(p_{\delta-1}\alpha - n_{\delta-1})|$ and $|\alpha(|S_+| - mp_{\delta-1}) - p|$. The first term is less than 1 since $|w_S| \leq k$ and the last term is less than 1 from (9). Putting it all together, we have

$$(|S_-| - m \cdot n_{\delta-1} - p) \leq |m(p_{\delta-1}\alpha - n_{\delta-1})| + 2. \tag{10}$$

Finally,

$$\begin{aligned}
\sum_{i=1}^{r} |w_{S_i}| &= \sum_{i=1}^{m} |w_{S_i}| + |w_{S_{m+1}}| + \sum_{i=m+2}^{r} |w_{S_i}| \\
&\leq km|p_{\delta-1}\alpha - n_{\delta-1}| + k + k(|S_-| - m \cdot n_{\delta-1} - p) \\
&\leq km|p_{\delta-1}\alpha - n_{\delta-1}| + k + k\,|m(p_{\delta-1}\alpha - n_{\delta-1})| + 2k \qquad \text{(using (10))} \\
&\leq k\left(2\left\lfloor\frac{|S_+|}{p_{\delta-1}}\right\rfloor |p_{\delta-1}\alpha - n_{\delta-1}| + 3\right) \leq k\left(2|S_+|\frac{|p_{\delta-1}\alpha - n_{\delta-1}|}{p_{\delta-1}} + 3\right) \\
&\leq k\left(2p_\delta \cdot \mathrm{fc}(\delta-1) + 3\right) \qquad \text{(By definition of fc)} \\
&\leq 5kd^{\mu(\Delta)}
\end{aligned}$$

where the last inequality is true because $\mathrm{fc}(\delta - 1) \leq 2d^{\mu(\Delta)}/p_\delta$ holds for $\delta \leq \Delta'$ by the definition of fc and p_δ; it also holds for $\delta = \Delta' + 1$ by the definition of Δ'. ◁

Armed with all this, the proof of Claim 12 becomes quite similar to the proof of Claim 27 in [20] (we refer the reader to the full version for details).

Handling more than two weights. To handle the case when there are multiple weights, we partition the index set $[d]$ into sets $\{S_i\}$ such that the sub-word indexed by each S_i contains at most two distinct weights (details in the full version). We can assume without loss of generality that all entries of w are integers as before.

▶ **Lemma 14.** *Let $w \in \{\alpha_1, \ldots, \alpha_\gamma\}^d$ ($|\alpha_i| \leq k$ for all i) be a word with $\gamma \leq d$ different weights and $|w_{[d]}| \leq k$. Then, the index set $[d]$ can be partitioned as $S_1 \cup \ldots \cup S_\eta$ with $\eta \leq 6\gamma$ such that for all $i \in [\eta]$, the sub-word $w_{|S_i}$ has at most two distinct weights and $|w_{S_i}| \leq k$.*

We can now use Claim 12 to construct polynomials with small set-multilinear formula size but large rank, even when the number of distinct set sizes is not two.

▷ Claim 15. Let $S \subseteq [d]$ and let $w \in \{\alpha_1, \ldots, \alpha_\gamma\}^d$ ($|\alpha_i| \leq k$ for all i) be a word with $\gamma \leq d$ different weights and $|w_S| \leq k$. Then, there exist $(J_+, J_-, \pi), (J'_+, J'_-, \pi')$ such that (S, J_+, J_-, π) and (S, J'_+, J'_-, π') are valid. For any fixed integer Δ and for all $\tau \in \{0,1\}^{|k_+ - k_-|}$, the polynomial $P_{(S,J_+,J_-,\pi,\tau)}$ can be computed by a set-multilinear formula of product-depth Δ and size at most $|S|^\Delta 2^{30k\gamma\Delta d^{\mu(\Delta)}}$ while the polynomial $P_{(S,J'_+,J'_-,\pi',\tau)}$ can be computed by a set-multilinear formula of product-depth Δ and size at most $|S|^\Delta 2^{5k\Delta d^{\mu(\Delta-1)}+6\gamma k}$.

The proof of Claim 15 is quite similar to that of Claim 12 and we prove it in the full version. Assuming the claim, we can finally prove Theorem 3:

Proof of Theorem 3. As $w_{[d]} \leq k$, applying Claim 15 to $S = [d]$, gives polynomials $P_\Delta, Q_\Delta \in \mathbb{F}_{sm}[\overline{X}(w)]$ with relative rank $\mathrm{relrk}_w(P_\Delta) = \mathrm{relrk}_w(Q_\Delta) = 2^{-|w_{[d]}|/2}$ (using the fact that this class of polynomials has maximum possible relative rank).

The polynomial P_Δ has product-depth Δ set-multilinear formula of size at most

$$d^\Delta 2^{30k\gamma\Delta d^{\mu(\Delta)}} \leq n^{O\left(\gamma\Delta d^{\mu(\Delta)}\right)}.$$

The polynomial Q_Δ has product-depth Δ set-multilinear formula of size at most

$$d^\Delta 2^{5k\Delta d^{\mu(\Delta-1)}+6\gamma k} \leq n^{O\left(\Delta d^{\mu(\Delta-1)}+\gamma\right)}.$$ ◀

Abstract

A *Conflict-Free Open Neighborhood coloring*, abbreviated CFON* coloring, of a graph $G = (V, E)$ using k colors is an assignment of colors from a set of k colors to a subset of vertices of $V(G)$ such that every vertex sees some color exactly once in its open neighborhood. The minimum k for which G has a CFON* coloring using k colors is called the *CFON* chromatic number* of G, denoted by $\chi^*_{ON}(G)$. The analogous notion for closed neighborhood is called CFCN* coloring and the analogous parameter is denoted by $\chi^*_{CN}(G)$. The problem of deciding whether a given graph admits a CFON* (or CFCN*) coloring that uses k colors is NP-complete. Below, we describe briefly the main results of this paper.

- For $k \geq 3$, we show that if G is a $K_{1,k}$-free graph then $\chi^*_{ON}(G)= O(k^2 \log \Delta)$, where Δ denotes the maximum degree of G. Dębski and Przybyło in [J. Graph Theory, 2021] had shown that if G is a line graph, then $\chi^*_{CN}(G)= O(\log \Delta)$. As an open question, they had asked if their result could be extended to claw-free ($K_{1,3}$-free) graphs, which are a superclass of line graphs. Since it is known that the CFCN* chromatic number of a graph is at most twice its CFON* chromatic number, our result positively answers the open question posed by Dębski and Przybyło.
- We show that if the minimum degree of any vertex in G is $\Omega(\frac{\Delta}{\log^{\epsilon} \Delta})$ for some $\epsilon \geq 0$, then $\chi^*_{ON}(G)= O(\log^{1+\epsilon} \Delta)$. This is a generalization of the result given by Dębski and Przybyło in the same paper where they showed that if the minimum degree of any vertex in G is $\Omega(\Delta)$, then $\chi^*_{ON}(G)= O(\log \Delta)$.
- We give a polynomial time algorithm to compute $\chi^*_{ON}(G)$ for interval graphs G. This answers in positive the open question posed by Reddy [Theoretical Comp. Science, 2018] to determine whether the CFON* chromatic number can be computed in polynomial time on interval graphs.
- We explore biconvex graphs, a subclass of bipartite graphs and give a polynomial time algorithm to compute their CFON* chromatic number. This is interesting as Abel et al. [SIDMA, 2018] had shown that it is NP-complete to decide whether a planar bipartite graph G has $\chi^*_{ON}(G) = k$ where $k \in \{1, 2, 3\}$.

1 Introduction

A *Conflict-Free Open Neighborhood coloring*, abbreviated CFON* coloring, of a graph $G = (V, E)$ using k colors is an assignment of colors from a set of k colors to a subset of vertices of $V(G)$ such that every vertex sees some color exactly once in its open neighborhood. The minimum k for which G has a CFON* coloring using k colors is called the *CFON* chromatic number* of G, denoted by $\chi^*_{ON}(G)$.[1] The analogous notion for closed neighborhood is called CFCN* coloring and the analogous parameter is denoted by $\chi^*_{CN}(G)$. It is known (see for instance, Equation 1.3 from [26]) that if G has no isolated vertices, then $\chi^*_{CN}(G)$ is at most twice $\chi^*_{ON}(G)$. Given a graph G and integer $k > 0$, the *CFON* coloring problem* is the problem of determining if $\chi^*_{ON}(G) \leq k$. The CFON* variant is considered to be harder than the CFCN* variant, see for instance, remarks in [22, 26].

The notion of conflict-free coloring was introduced by Even, Lotker, Ron and Smorodinsky in 2004, motivated by the frequency assignment problem in wireless communication [14]. The conflict-free coloring problem on graphs was introduced and first studied by Cheilaris [8] and Pach and Tardos [26]. Conflict-free coloring has found applications in the area of sensor networks [17, 25] and coding theory [23]. Since its introduction, the problem has been extensively studied, see for instance [1, 3, 5, 6, 8, 18, 19, 26, 28]. The decision version of the CFON* coloring problem and many of its variants are known to be NP-complete [1, 18]. In [18], Gargano and Rescigno showed that the optimization version of the CFON* coloring problem is hard to approximate within a factor of $n^{1/2-\epsilon}$, unless $\mathsf{P} = \mathsf{NP}$. Fekete and Keldenich [15] and Hoffmann et al. [21] studied a conflict-free variant of the chromatic Art Gallery Problem, which is about guarding a simple polygon P using a finite set of colored point guards such that each point $p \in P$ sees at least one guard whose color is distinct from all the other guards visible from p.

The conflict-free coloring problem has been studied on several graph classes like planar graphs, split graphs, geometric intersection graphs like interval graphs, unit disk intersection graphs and unit square intersection graphs, graphs of bounded degree, block graphs, etc. [1, 4, 6, 9, 16, 22, 26, 27]. The problem has been studied from parameterized complexity perspective. The problem is fixed-parameter tractable when parameterized by tree-width, neighborhood diversity, distance to cluster, or the combined parameters clique-width and the number of colors [2, 4, 6, 18, 27].

1.1 Our Contribution and Discussion

Below, we discuss the main results of this paper.

The complete bipartite graph $K_{1,3}$ is known as a *claw*. If a graph does not contain a claw as an induced subgraph, then it is called a *claw-free graph*. The *claw number* of a graph G is the largest integer k such that G contains an induced $K_{1,k}$. Dębski and Przybyło [10] showed that if G is a line graph with maximum degree Δ, then $\chi^*_{CN}(G)= O(\log \Delta)$. This bound is tight up to constants. Line graphs are a subclass of claw-free graphs. In [10], it was asked whether the above result can be extended to claw-free graphs. We do this by

[1] It is also known by the name "partial conflict-free chromatic number" as only a subset of vertices are assigned colors. The "(full) conflict-free chromatic number" of a graph, which requires assigning colors to all the vertices, is at most one more than its partial conflict-free chromatic number. We use the notations $\chi^*_{ON}(G)$ and $\chi^*_{CN}(G)$ to be consistent with our other papers on related topics. In our other papers, we use $\chi_{ON}(G)$ and $\chi_{CN}(G)$ to refer to the versions of the problem that require all the vertices to be assigned a color.

proving a more general result. We show that if G is $K_{1,k}$-free with maximum degree Δ, then $\chi^*_{ON}(G)= O(k^2 \log \Delta)$. Since $\chi^*_{CN}(G) \leq 2\chi^*_{ON}(G)$, we have $\chi^*_{CN}(G)= O(k^2 \log \Delta)$ as well. This result is presented in Section 3.2.

What is the maximum number of colors required to CFON* color a graph whose maximum degree is Δ? It can be seen that the graph obtained by subdividing every edge of a complete graph requires $\Delta + 1$ colors. It is known that for a graph G with maximum degree Δ, $\chi^*_{ON}(G)$ is at most $\Delta + 1$ [26]. Pach and Tardos [26] showed that if the minimum degree of any vertex in G is $\Omega(\log \Delta)$, then $\chi^*_{ON}(G)= O(\log^2 \Delta)$. In this direction, Dębski and Przybyło [10] showed that if the minimum degree of any vertex in G is $\Omega(\Delta)$, then the previous upper bound can be improved to show $\chi^*_{ON}(G)= O(\log \Delta)$. We extend the proof idea of [10] to generalize their result. We show that if the minimum degree of any vertex in G is $\Omega(\frac{\Delta}{\log^{\epsilon} \Delta})$ for some $\epsilon \geq 0$, then $\chi^*_{ON}(G)= O(\log^{1+\epsilon} \Delta)$. This result is presented in Section 3.3. A natural open question we have here is, can we get a stronger upper bound for the CFON* chromatic number of a graph with minimum degree $\omega(1)$? When the minimum degree is $o(\log \Delta)$, the only upper bound known is $O(\Delta)$ mentioned above due to [26]. In this situation our first result does give a better (than $O(\Delta)$) upper bound for CFON* chromatic number, if the claw number of the graph under consideration is $o\left(\sqrt{\frac{\Delta}{\log \Delta}}\right)$.

For an interval graph G, it has been shown that [4, 27] $\chi^*_{ON}(G) \leq 3$. It was shown in [4] that there exists an interval graph that requires 3 colors, making the above bound tight. It was asked in [27] if there is a polynomial time algorithm that given an interval graph G, computes $\chi^*_{ON}(G)$. We answer this in the affirmative and give polynomial time characterization algorithms for interval graphs G that decide if $\chi^*_{ON}(G) \in \{1, 2, 3\}$. These results are presented in Section 4.

For a bipartite graph G, it is easy to see that $\chi^*_{CN}(G) \leq 2$. On the contrary, there exist bipartite graphs G, for which $\chi^*_{ON}(G) = \Theta(\sqrt{n})$. It is NP-complete [1] to decide if a planar bipartite graph is CFON* colorable using k colors, where $k \in \{1, 2, 3\}$. We study the problem on some subclasses of bipartite graphs that include chain graphs, biconvex bipartite graphs, and bipartite permutation graphs. We show that three colors are sufficient to CFON* color a biconvex bipartite graph and give characterization algorithms to decide the CFON* chromatic number. The results are presented in Section 5.

2 Preliminaries

Throughout the paper, we consider simple undirected graphs. We denote the vertex set and the edge set of a graph $G = (V, E)$, by $V(G)$ and $E(G)$. For standard graph notations, we refer to the graph theory book by R. Diestel [11]. For a vertex $v \in G$, its *open neighborhood*, denoted by $N_G(v)$, is the set of neighbors of v in G. The *closed neighborhood* of v, denoted by $N_G[v]$, is $N_G(v) \cup \{v\}$. We use log to denote the logarithm to the base 2, and ln to denote the natural logarithm. Proofs of the results marked with ($\star$) are omitted due to space constraints.

3 Improved bounds for $\chi^*_{ON}(G)$ for graphs with bounded claw number

The graph $K_{1,k}$ is the complete bipartite graph on $k+1$ vertices with one vertex in one part and the remaining k vertices in the other part.

▶ **Definition 1** (Claw number). *The* claw number *of a graph G is the smallest k such that G is $K_{1,k+1}$-free. In other words, it is the largest k such that G contains an induced $K_{1,k}$.*

The complete bipartite graph $K_{1,3}$ is called a *claw*. A graph is called a *claw-free graph* if it does not contain a claw as an induced subgraph.

In this section, we prove two results: (i) an improved bound for $\chi^*_{ON}(G)$ in terms of the claw number and maximum degree of G, and (ii) an improved bound for $\chi^*_{ON}(G)$ for graphs with high minimum degree. We begin by stating a couple of results from probability theory which will be useful.

▶ **Lemma 2** (*The Local Lemma*, [13]). *Let $A_1, \ldots, A_n$ be events in an arbitrary probability space. Suppose that each event A_i is mutually independent of a set of all the other events A_j but at most d, and that $Pr[A_i] \leq p$ for all $i \in [n]$. If $4pd \leq 1$, then $Pr[\cap_{i=1}^{n} \overline{A_i}] > 0$.*

▶ **Theorem 3** (Chernoff Bound, Corollary 4.6 in [24]). *Let $X_1, \ldots, X_n$ be independent Poisson trials such that $Pr[X_i] = p_i$. Let $X = \sum_{i=1}^{n} X_i$ and $\mu = E[X]$. For $0 < \delta < 1$, $Pr[|X - \mu| \geq \delta\mu] \leq 2e^{-\mu\delta^2/3}$.*

3.1 Auxiliary lemmas

In this subsection, we state some auxiliary lemmas on conflict-free chromatic number of graphs and hypergraphs having certain structural characteristics that will be used to prove the main theorems in Sections 3.2 and 3.3. Before we begin, let us define the conflict-free chromatic number of a hypergraph.

▶ **Definition 4.** *Given a hypergraph $\mathcal{H} = (V, \mathcal{E})$, a coloring $c : V \rightarrow [r]$ is a* conflict-free coloring *of $\mathcal{H}$ if for every hyperedge $E \in \mathcal{E}$, there is a vertex in E that receives a color under c that is distinct from the colors received by all the other vertices in E. The minimum r such that $c : V \rightarrow [r]$ is a conflict-free coloring of $\mathcal{H}$ is called the* conflict-free chromatic number *of $\mathcal{H}$. This is denoted by $\chi_{CF}(\mathcal{H})$.*

The following theorem on conflict-free coloring of hypergraphs is from [26]. The degree of a vertex in a hypergraph is the number of hyperedges it is part of.

▶ **Theorem 5** (Theorem 1.1(b) in [26]). *Let $\mathcal{H}$ be a hypergraph and let Δ be the maximum degree of any vertex in $\mathcal{H}$. Then, $\chi_{CF}(\mathcal{H}) \leq \Delta + 1$.*

We prove an upper bound for the conflict-free chromatic number of a "near uniform hypergraph" in Lemma 6 below.

▶ **Lemma 6.** *Let $\mathcal{H} = (V, \mathcal{E})$ be a hypergraph where (i) every hyperedge intersects with at most Γ other hyperedges, and (ii) for every hyperedge $E \in \mathcal{E}$, $r \leq |E| \leq \ell r$, where $\ell \geq 1$ is some integer and $r \geq 2\log(4\Gamma)$. Then, $\chi_{CF}(\mathcal{H}) \leq e\ell r$, where e is the base of natural logarithm.*

Proof. For each vertex in V, assign a color that is chosen independently and uniformly at random from a set of $e\ell r$ colors. We will first show that the probability of this coloring being bad for an edge is small, and then use Local Lemma to show the existence of conflict-free coloring for $\mathcal{H}$ using at most $e\ell r$ colors.

Consider a hyperedge $E \in \mathcal{E}$ with $m := |E|$. By assumption, we have $r \leq m \leq \ell r$. Let A_E denote the bad event that E is colored with $\leq |E|/2$ colors. Note that if A_E does not occur, then E is colored with $> |E|/2$ colors, hence there is at least one color that appears exactly once in E.

$$\begin{aligned}
Pr[A_E] &\leq \binom{e\ell r}{m/2}\left(\frac{m/2}{e\ell r}\right)^m \\
&\leq \left(\frac{e^2\ell r}{m/2}\right)^{m/2}\left(\frac{m/2}{e\ell r}\right)^m \qquad \text{(since } \binom{n}{k} \leq \left(\frac{en}{k}\right)^k\text{)} \\
&= \frac{(m/2)^{m/2}}{(\ell r)^{m/2}} \quad = \quad \left(\frac{m}{2\ell r}\right)^{m/2} \\
&\leq (1/2)^{m/2} \quad \leq \quad \frac{1}{4\Gamma}.
\end{aligned}$$

Here the penultimate inequality follows since $m \leq \ell r$, and the last inequality follows since $m \geq 2\log(4\Gamma)$.

We apply the Local Lemma (Lemma 2) on the events A_E for all hyperedges $E \in \mathcal{E}$. Since each hyperedge intersects with at most Γ other hyperedges, and $4 \cdot \frac{1}{4\Gamma} \cdot \Gamma \leq 1$, we get $Pr[\cap_{E\in\mathcal{E}}(\overline{A}_E)] > 0$. That is, there is a conflict free coloring of $\mathcal{H}$ that uses at most $e\ell r$ colors. This completes the proof of the lemma. ◀

Lemmas 7 and 8 prove upper bounds for $\chi^*_{ON}(G)$ when G satisfies certain degree restrictions.

▶ **Lemma 7.** *Let G be a graph with (i) $V(G) = X \uplus Y$, $X, Y \neq \emptyset$, (ii) every vertex in G has at most d_X neighbors in X, (iii) every vertex in Y has at least one neighbor in X, and (iv) every vertex in X has at most d_Y neighbors in Y. Then, there is a coloring of vertices of X with $d_X d_Y + d_X - d_Y + 1$ colors such that every vertex in Y sees some color exactly once among its neighbors in X.*

Proof. For each vertex $y \in Y$, we arbitrarily choose one of its neighbors in X. Let us call this neighbor $f(y)$. For each $y \in Y$, contract the edges $\{y, f(y)\}$ to obtain a resulting graph G_X. Note that the vertex set of G_X is $V(G_X) = X$. The maximum degree of a vertex in the new graph G_X is at most $(d_X - 1)d_Y + d_X$. Thus, we can do a proper coloring (such that no pair of adjacent vertices receive the same color) of G_X using $d_X d_Y + d_X - d_Y + 1$ colors. We note that this coloring of the vertices of X satisfies our requirement: in the original graph G, for each $y \in Y$, the neighbor $f(y)$ is colored distinctly from all the other neighbors of y in X. ◀

▶ **Lemma 8.** *Let G be a graph with (i) $V(G) = X \uplus Y$, $X, Y \neq \emptyset$, (ii) every vertex in Y has at most t_X neighbors in X, and (iii) every vertex in X has at least one neighbor in Y. Then, there is a coloring of the vertices of Y using at most $(t_X + 1)$ colors such that every vertex in X sees some color exactly once among its neighbors in Y.*

Proof. For every vertex $v \in X$, let $N^Y_G(v)$ denote the set $N_G(v) \cap Y$, i.e., the neighbors of v in Y in the graph G. Since every vertex in X has at least one neighbor in Y, we have, $|N^Y_G(v)| \geq 1$. We construct a hypergraph $\mathcal{H} = (V, \mathcal{E})$ from G as described below. We have (i) $V = Y$, and (ii) $\mathcal{E} = \{N^Y_G(v) \ : \ v \in X\}$. Since every vertex in Y has at most t_X neighbors in X in the graph G, the maximum degree of a vertex in the hypergraph $\mathcal{H}$ (that is, the maximum number of hyperedges a vertex in $\mathcal{H}$ is part of) is at most t_X. From Theorem 5, we have $\chi_{CF}(\mathcal{H}) \leq t_X + 1$. Observe that in this coloring of the vertices of Y using at most $(t_X + 1)$ colors, every vertex in X sees some color exactly once among its neighbors in Y. ◀

The following lemma, which will be used in the proof of Theorem 12, shows that given a graph with high minimum degree there exists a subset of vertices that, for every vertex, intersects its neighborhood at a small number of vertices.

▶ **Lemma 9.** *Let Δ denote the maximum degree of a graph G. It is given that every vertex in G has degree at least $\frac{c\Delta}{\log^{\epsilon}\Delta}$ for some $\epsilon \geq 0$ and c is a constant. Then, there exists $A \subseteq V(G)$ such that for every vertex $v \in V(G)$,*

$$75\log(2\Delta) < |N_G(v) \cap A| < \frac{125}{c}\log^{1+\epsilon}(2\Delta).$$

Proof. We construct a random subset A of $V(G)$ as described below. Each $v \in V(G)$ is independently chosen into A with probability $\frac{100\log^{1+\epsilon}(2\Delta)}{c\Delta}$. For a vertex $v \in V(G)$, let X_v be a random variable that denotes $|N_G(v) \cap A|$. Then, $\mu_v := E[X_v] = \frac{100\log^{1+\epsilon}(2\Delta)}{c\Delta}d_G(v) \geq 100\log(2\Delta)$. Since $d_G(v) \leq \Delta$, we also have $\mu_v \leq \frac{100\log^{1+\epsilon}(2\Delta)}{c}$. Let B_v denote the event that $|X_v - \mu_v| \geq \frac{\mu_v}{4}$. Applying Theorem 3 with $\delta = 1/4$, we get $Pr[B_v] = Pr[|X_v - \mu_v| \geq \frac{\mu_v}{4}] \leq 2e^{-\frac{\mu_v}{48}} \leq 2e^{-\frac{100\log(2\Delta)}{48}} = 2e^{-\frac{100\ln(2\Delta)}{48\ln 2}} < \frac{2}{(2\Delta)^3}$. The event B_v is mutually independent of all but those events B_u where $N_G(u) \cap N_G(v) \neq \emptyset$. Hence, every event B_v is mutually independent of all but at most Δ^2 other events. Applying Lemma 2 with $p = Pr[B_v] \leq \frac{2}{(2\Delta)^3}$ and $d = \Delta^2$, we have $4 \cdot \frac{2}{(2\Delta)^3} \cdot \Delta^2 \leq 1$. Thus, there is a non-zero probability that none of the events B_v occur. In other words, for every v, it is possible to have $\frac{3}{4}\mu_v < X_v < \frac{5}{4}\mu_v$. Using the upper and lower bounds of μ_v we computed above, we can say that there exists an A such that, for every v, $75\log(2\Delta) < |N_G(v) \cap A| < \frac{125}{c}\log^{1+\epsilon}(2\Delta)$. ◀

3.2 Graphs with bounded claw number

▶ **Theorem 10.** *Let G be a $K_{1,k}$-free graph with maximum degree Δ having no isolated vertices. Then, $\chi^*_{ON}(G) = O(k^2\log\Delta)$.*

Proof. Consider a proper coloring (such that no pair of adjacent vertices receive the same color) of G, $h : V(G) \to [\Delta+1]$, using $\Delta+1$ colors. Let $C_1, C_2, \ldots, C_{\Delta+1}$ be the color classes given by this coloring G. That is, $V(G) = C_1 \uplus C_2 \uplus \cdots \uplus C_{\Delta+1}$ is the partitioning of the vertex set of G given by the coloring, where each C_i is an independent set. We may assume that the coloring h satisfies the following property: for every $1 < i \leq \Delta+1$, every vertex v in C_i has at least one neighbor in every C_j, where $1 \leq j < i$ (otherwise, we can move v to a color class C_j, $j < i$, in which it has no neighbors without compromising on the "properness" of the coloring). Since G is $K_{1,k}$-free, we have the following observation.

▶ **Observation 11.** *For every $i \in [\Delta+1]$, a vertex in G has at most $k-1$ neighbors in C_i.*

Let $r = 2\log(4\Delta^2)$. We partition the vertex set of G into three parts, namely V_1, V_2, and V_3 as described below. We have $V_1 := C_1$. If $\Delta > r$, then $V_2 := C_2 \uplus C_3 \uplus \cdots \uplus C_{r+1}$ and $V_3 := C_{r+2} \uplus C_{r+3} \uplus \cdots \uplus C_{\Delta+1}$. Otherwise, $V_2 := C_2 \uplus C_3 \uplus \cdots \uplus C_{\Delta+1}$ and $V_3 := \emptyset$.

The rest of the proof is about constructing a coloring $f : V(G) \to \mathbb{N} \times \mathbb{N}$ that is a CFON* coloring of G. Let $N_1 = \{1, 2, \ldots, r_1\}$, $N_2 = \{r_1+1, r_1+2, \ldots, r_1+r_2\}$, and $N_3 = \{r_1+r_2+1, r_1+r_2+2, \ldots, r_1+r_2+r_3\}$, where $|N_1| = r_1 = (k-1)(k-2)r + k$, $|N_2| = r_2 = e(k-1)r$, and $|N_3| = r_3 = k$. We define three colorings f_1, f_2, and f_3 below.

We begin by describing the coloring $f_1 : V_1 \to N_1$. Let $G[V_1 \cup V_2]$ be the subgraph of G induced on $V_1 \cup V_2$. From Observation 11, every vertex in $G[V_1 \cup V_2]$ has at most $k-1$ neighbors in $V_1 = C_1$. Every vertex in V_2 has at least one neighbor in V_1 due to the property of our coloring h. From Observation 11, we can also say that every vertex in V_1 has at most

$r(k-1)$ neighbors in V_2. Applying Lemma 7 on $G[V_1 \cup V_2]$ with $X = V_1$, $Y = V_2$, $d_X = k-1$ and $d_Y = r(k-1)$, we can say that there is a coloring $f_1 : V_1 \to N_1$ of the vertices of V_1 with $(k-1)(k-2)r + k$ colors such that every vertex in V_2 sees some color exactly once among its neighbors in V_1.

We now describe the coloring $f_2 : V_2 \to N_2$. If $V_3 = \emptyset$, then, $\forall v \in V_2$, $f_2(v) = r_1 + 1$. Suppose $V_3 \neq \emptyset$. For a vertex v in G, let $N_G^{V_2}(v)$ denote the set of neighbors of v in V_2 in the graph G. We construct a hypergraph $\mathcal{H}_2 = (V_2, \mathcal{E}_2)$ as follows. We have $\mathcal{E}_2 = \{N_G^{V_2}(v) \ : \ v \in V_3\}$. Consider an arbitrary hyperedge $E \in \mathcal{E}_2$. In the graph G, since every vertex in V_3 has at least one neighbor in every color class C_i, $2 \leq i \leq r+1$, $|E| \geq r$. Using Observation 11, we can say that $|E| \leq (k-1)r$. As $|N_G^{V_2}(v)| \leq N_G(v) \leq \Delta, \forall v \in V(G)$, we have $|E| \leq \Delta$. This also implies that E intersects with at most Δ^2 other hyperedges in $\mathcal{E}_2$. Applying Lemma 6 with $\ell = (k-1)$ and $\Gamma = \Delta^2$, we have $\chi_{CF}(\mathcal{H}_2) \leq e(k-1)r$. Thus, there is a coloring $f_2 : V_2 \to N_2$ of the vertices V_2 such that every vertex in V_3 sees some color exactly once among its neighbors in V_2.

Finally, we describe the coloring $f_3 : V_2 \cup V_3 \to N_3$. From Observation 11, every vertex in $V_2 \cup V_3$ has at most $k-1$ neighbors in $V_1 = C_1$. Since there are no isolated vertices in G, every vertex in V_1 has at least one neighbor in $V_2 \cup V_3$. Applying Lemma 8 with $X = V_1$, $Y = V_2 \cup V_3$, and $t_X = k-1$, we get a coloring $f_3 : V_2 \cup V_3 \to N_3$ of the vertices of $V_2 \cup V_3$ using at most k colors such that every vertex in V_1 sees some color exactly once among its neighbors in $V_2 \cup V_3$.

We are now ready to define the coloring f.

$$f(v) = \begin{cases} (1, f_1(v)), \text{ if } v \in V_1 \\ (f_2(v), f_3(v)), \text{ if } v \in V_2 \\ (1, f_3(v)), \text{ if } v \in V_3. \end{cases}$$

We now argue that f is indeed a CFON* coloring of G. Consider a vertex $v \in V(G)$. If $v \in V_3$, v sees some color exactly once among its neighbors in V_2 under the coloring f_2. Let u be that neighbor of v in V_2 and $f_2(u)$ be that color that appears exactly once in the neighborhood of v in V_2. Since the codomains of f_1, f_2, and f_3 are pairwise disjoint sets, v does not see the same color among its neighbors in V_1 or in V_2. Further, since $f(u) = (f_2(u), f_3(u))$, the final coloring f only refines the color classes of V_2 given by f_2. Thus, the color $(f_2(u), f_3(u))$ appears exactly once among the neighbors of v in G. The cases when $v \in V_1$ and $v \in V_2$ also follow using similar arguments.

The coloring f uses at most $|N_1| + |N_2||N_3| + |N_3| = (k-1)(k-2)r + k + e(k-1)kr + k$ colors. Since $r = O(\log \Delta)$, this implies that $\chi_{CF}^{ON}(G) = O(k^2 \log \Delta)$. ◀

3.3 Graphs with high minimum degree

When a graph G has high minimum degree, the following theorem gives improved upper bounds for $\chi_{ON}^*(G)$ in terms of its maximum degree.

▶ **Theorem 12.** *Let G be a graph with maximum degree Δ. It is given that every vertex in G has degree at least $\frac{c\Delta}{\log^{\epsilon} \Delta}$ for some $\epsilon \geq 0$ and c is a constant. Then, $\chi_{ON}^*(G) = O(\log^{1+\epsilon} \Delta)$.*

Proof. Apply Lemma 9 to find an $A \subseteq V(G)$ such that for every $v \in V(G)$, $75 \log(2\Delta) < |N_G(v) \cap A| < \frac{125}{c} \log^{1+\epsilon}(2\Delta)$. Construct a hypergraph $\mathcal{H} = (A, \mathcal{E})$ where $\mathcal{E} = \{N_G(v) \cap A \ : \ v \in V(G)\}$. Every $E \in \mathcal{E}$ satisfies $2\log(4\Delta^2) < 75 \log(2\Delta) < |E| < \frac{125}{c} \log^{1+\epsilon}(2\Delta)$. Applying Lemma 6 with $r = 75 \log(2\Delta)$ and $\ell = \frac{5}{3c} \log^{\epsilon}(2\Delta)$, we get $\chi_{CF}(\mathcal{H}) \leq \frac{340}{c} \log^{1+\epsilon}(2\Delta)$. It is easy to see that this conflict-free coloring of $\mathcal{H}$ is indeed a CFON* coloring for G. ◀

4 Interval graphs

In this section, we show that the problem of determining the CFON* chromatic number of a given interval graph is polynomial time solvable. It was shown in [4, 27] that, for an interval graph G, $\chi^*_{ON}(G) \leq 3$ and that there exists an interval graph that requires three colors. The complexity of the problem on interval graphs was posed as an open question in the above papers. We show that CFON* coloring is polynomial time solvable. That is, given an interval graph G, in polynomial time we decide whether $\chi^*_{ON}(G)$ is 1, 2 or 3. We state it formally below.

▶ **Theorem 13.** *Given an interval graph G, there is a polynomial time algorithm that determines $\chi^*_{ON}(G)$.*

▶ Remark 14 (Notation). In the introduction, we defined CFON* coloring to be an assignment of colors to a *subset* of the vertices. For the sake of convenience, we will use the color 0 to denote uncolored vertices. That is, we will use an assignment $f : V(G) \rightarrow \{0, 1, 2\}$, to denote a coloring that assigns the colors 1 and 2 to some vertices. The vertices that are assigned 0 by f are the "uncolored" vertices. The "color" 0 cannot serve as a unique color in the neighborhood of any vertex.

▶ **Definition 15** (Interval Graphs). *A graph $G = (V, E)$ is called an* interval graph *if there exists a set of intervals on the real line such that the following holds: (i) there is a bijection between the intervals and the vertices and (ii) there exists an edge between two vertices if and only if the corresponding intervals intersect.*

The main ingredient of the algorithm is the use of *multi-chain ordering* property on interval graphs. Before defining the multi-chain ordering property, we look at some prerequisites.

▶ **Definition 16** (Chain Graph [12]). *A bipartite graph $G = (A, B)$ is a* chain graph *if and only if for any two vertices $u, v \in A$, either $N(u) \subseteq N(v)$ or $N(v) \subseteq N(u)$. If G is a chain graph, it follows that for any two vertices $u, v \in B$, either $N(u) \subseteq N(v)$ or $N(v) \subseteq N(u)$.*

As a consequence, we can order the vertices in B in the decreasing order of the degrees. We can break ties arbitrarily. If $b_1 \in B$ appears before $b_2 \in B$ in the ordering, then it follows that $N(b_2) \subseteq N(b_1)$.

▶ **Definition 17** (Multi-chain Ordering [7, 12]). *Given a connected graph $G = (V, E)$, we arbitrarily choose a vertex as $v_0 \in V(G)$ and construct distance layers $L_0, L_1, \ldots, L_p$ from v_0. The layer L_i, where $i \in [p]$, represents the set of vertices that are at a distance i from v_0. Note that p here denotes the largest integer such that L_p is non-empty.*

We say that these layers form a multi-chain ordering *of G if for every two consecutive layers L_i and L_{i+1}, where $i \in \{0, 1, \ldots, p-1\}$, we have that the vertices in L_i and L_{i+1}, and the edges connecting these layers form a chain graph.*

▶ **Theorem 18** (Theorem 2.5 of [12]). *All connected interval graphs admit multi-chain orderings.*

We give a characterization of interval graphs that require one color and two colors in polynomial time in Theorem 21 and Theorem 23 respectively. Given an interval graph G, the algorithms decide if G is CFON* colorable using one color or two colors. If G is not CFON* colorable using one color or two colors, we conclude that G is CFON* colorable using three colors (since it is known that for an interval graph G, $\chi^*_{ON}(G) \leq 3$). One of the key ideas used in Theorem 23 (to decide if G can be CFON* colored using two nonzero colors) is sort of a bootstrapping idea. After narrowing down the possibilities, we need to test if a given subgraph can be colored using the colors $\{0, 1\}$ so as to obtain a CFON* coloring. To solve this, we use Theorem 21.

Before we proceed to the main theorems of this section, we observe the following on a graph G that admits multi-chain ordering.

▶ **Observation 19.** *If G admits a multi-chain ordering, then every distance layer L_i, for $0 \leq i < p$ contains a vertex v such that $N(v) \supseteq L_{i+1}$.*

Proof. Consider a multi-chain ordering of G, starting with an arbitrary vertex. For any two consecutive distance layers L_i and L_{i+1}, it can be seen that each vertex in L_{i+1} has a neighbor in L_i. This, together with the fact that L_i and L_{i+1} form a chain graph, imply that there is a vertex $v \in L_i$ such that $N(v) \supseteq L_{i+1}$. ◀

▶ **Observation 20.** *In any CFON* coloring of G that uses one color, at most one vertex in each L_i is assigned the color 1.*

Proof. Consider a layer L_i of the graph. As per Observation 19, there is a $v \in L_i$ such that $N(v) \supseteq L_{i+1}$. If two vertices in L_{i+1} are colored 1, then the vertex $v \in L_i$ does not have a uniquely colored neighbor. Hence in all the layers $L_1, L_2, \ldots$ up to the last layer L_p, we have that at most one vertex is assigned the color 1. Since L_0 has only one vertex, the statement is trivially true for L_0. ◀

▶ **Theorem 21.** *Given an interval graph $G = (V, E)$, we can decide in $O(n^5)$ time if $\chi^*_{ON}(G) = 1$.*

Proof. Let $L_0, L_1, \ldots, L_p$ be the distance layers of G constructed from an arbitrarily chosen vertex v_0, satisfying the multi-chain ordering. If there is a CFON* coloring that uses 1 color, then from Observation 20, at most one vertex in each layer is assigned the color 1. There are two possibilities for a layer L_i: either it has no vertices colored 1, or it has exactly one vertex that is colored 1. In the former case, there is a unique coloring for L_i when none of the vertices in L_i are assigned the color 1. In the latter case, we have $|L_i|$ many colorings (for L_i) where each coloring has exactly one vertex with color 1 (and the rest are assigned 0). In total, we have at most $|L_i| + 1$ colorings for each L_i. We call all such colorings *valid*.

The task is to find if there is a sequence of colorings assigned to each layer of G such that we have a CFON* coloring. Notice that the vertices in L_i can possibly have neighbors in the layers L_{i-1}, L_i, and L_{i+1}. The question of deciding whether the vertices in L_i have a uniquely colored neighbor entirely depends on the colorings assigned to these three layers. We say that colorings assigned to three consective layers are *good* if the vertices in the central layer have uniquely colored neighbors. We use a dynamic programming based approach to verify the existence of a CFON* coloring for G.

We now construct a layered companion hypergraph $\mathcal{G} = (V', \mathcal{E})$ with vertices in $p + 1$ layers. Each layer T_i of $\mathcal{G}$ corresponds to the layer L_i of G where $i \in [p] \cup \{0\}$. Each vertex in layer T_i of $\mathcal{G}$ corresponds to a valid coloring of vertices in L_i of G. Hence the number of vertices in each layer T_i of $\mathcal{G}$ is equal to $|L_i| + 1$. We now explain how the hyperedges $\mathcal{E}$ of $\mathcal{G}$ are determined.

For $1 \leq i \leq p-1$, the vertices $x \in T_{i-1}$, $y \in T_i$, $z \in T_{i+1}$ form a hyperedge $\{x, y, z\}$ if the corresponding colorings, when assigned to L_{i-1}, L_i and L_{i+1} respectively, ensures that every vertex in L_i has a uniquely colored neighbor. We also have hyperedges $\{y, z\}$, where $y \in T_0$ and $z \in T_1$ are colorings such that when y and z are assigned to L_0 and L_1 respectively, the vertex in L_0 sees a uniquely colored neighbor. Similarly, we have hyperedges $\{x, y\}$, where $x \in T_{p-1}$ and $z \in T_p$ are colorings such that when x and y are assigned to L_{p-1} and L_p respectively, all the vertices in L_p see a uniquely colored neighbor.

Since the number of valid colorings is $|L_i| + 1$ for the layer L_i, the total number of valid colorings across all layers is at most $2n$. The total number of potential hyperedges to check is at most $O(n^3)$. Once we fix valid colorings x_{i-1}, x_i, x_{i+1} for L_{i-1}, L_i, L_{i+1} respectively, we can check in $O(|L_i| \cdot n) \leq O(n^2)$ time if $\{x_{i-1}, x_i, x_{i+1}\} \in \mathcal{E}$. Hence we need $O(n^5)$ time to construct $\mathcal{G}$.

To obtain a CFON* coloring for G, we need to construct a sequence of colorings $x_0 \in T_0$, $x_1 \in T_1, \ldots, x_p \in T_p$ such that $\{x_0, x_1\} \in \mathcal{E}$, $\{x_{i-1}, x_i, x_{i+1}\} \in \mathcal{E}$ for all $1 \leq i \leq p-1$, and finally $\{x_{p-1}, x_p\} \in \mathcal{E}$. For this, we use Lemma 22, stated and proved below. Since each $|T_i| = |L_i| + 1 \leq n + 1$, and number of layers is at most n, this takes at most $O(n^4)$ time. The construction of $\mathcal{G}$ takes $O(n^5)$ time and dominates the running time. ◀

▶ **Lemma 22.** *Suppose there is a layered hypergraph $\mathcal{G} = (V', \mathcal{E})$ with layers $T_0, T_1, T_2, \ldots, T_p$, where $|T_i| \leq \alpha$, for $0 \leq i \leq p$ and $p \leq \beta$. Suppose further that all the hyperedges in $\mathcal{E}$ contain one vertex each from three consecutive layers, or contain one vertex each from T_0 and T_1, or contain one vertex each from T_{p-1} and T_p. We can determine if there exists a sequence $x_0 \in T_0$, $x_1 \in T_1, \ldots, x_p \in T_p$ such that $\{x_0, x_1\} \in \mathcal{E}$, $\{x_{i-1}, x_i, x_{i+1}\} \in \mathcal{E}$ for all $1 \leq i \leq p-1$, and finally $\{x_{p-1}, x_p\} \in \mathcal{E}$ in $O(\alpha^3\beta)$ time.*

Proof. We start with the vertices in T_0. For each vertex $x_1 \in T_1$, we store a list of predecessors x_0 such that $\{x_0, x_1\} \in \mathcal{E}$. For $1 \leq i \leq p-1$, we do the following at each vertex $x_i \in T_i$. We look at the list of predecessors stored. If x_{i-1} is a listed predecessor of x_i, then we search for all the hyperedges $\{x_{i-1}, x_i, z\}$, where $z \in T_{i+1}$. If we find such a hyperedge $\{x_{i-1}, x_i, x_{i+1}\} \in \mathcal{E}$, then we store x_i as a predecessor in the list at x_{i+1}. Finally, for each $x_p \in T_p$, we check if there is a listed predecessor $z \in T_{p-1}$ of x_p such that $\{z, x_p\} \in \mathcal{E}$. If there is any such $x_p \in T_p$ for which this holds, then there exists a sequence as desired in the statement of the lemma.

Note that the general step involves going through a list of size at most α at each vertex x_i. For each listed predecessor x_{i-1}, there are potentially at most α hyperedges of the form $\{x_{i-1}, x_i, z\}$ to check, where $z \in T_{i+1}$. We need to do this for all the vertices (at most α of them) of T_i. This gives a time complexity of $O(\alpha^3)$ at the i-th layer. Since there are β layers, the total running time is $O(\alpha^3\beta)$. ◀

We now proceed to the next result that decides in polynomial time whether $\chi_{ON}(G) = 2$.

▶ **Theorem 23** ($\star$)**.** *Given an interval graph G, we can decide in $O(n^{20})$ time if $\chi_{ON}(G) = 2$.*

Sketch of Proof. The idea of this proof is similar to the proof of Theorem 21. For a layer $|L_i|$, we had $|L_i| + 1$ colorings to consider in Theorem 21. Unlike in Theorem 21, we have more colorings to consider since the vertices can get the colors $\{0, 1, 2\}$. We have the following types of colorings in each layer L_i:

Type 1: All the vertices in L_i are assigned the color 0. There is only one coloring of L_i of this type.

Type 2: Exactly one vertex is assigned the color 1 or 2 while the rest are assigned the color 0. The number of colorings is $2|L_i|$.

Type 3: Both the colors 1 and 2 appear exactly once and the rest are assigned the color 0. The number of colorings is $|L_i|(|L_i| - 1) \leq |L_i|^2$.

Type 4: One of the colors 1 or 2 appears at least twice while the other color appears exactly once. The remaining vertices are assigned the color 0.

Type 5: One of the colors 1 or 2 appears at least twice and all the other vertices are assigned the color 0.

Due to space constraints, the full proof is omitted. We describe a proof sketch highlighting the key ideas in the proof below.

- The above 5 types are exhaustive. We cannot have a "Type 6" coloring in L_{i+1} where there are at least two vertices with color 1 and at least two vertices with color 2. This is because Observation 19 implies the existence of a vertex $v \in L_i$ such that $N(v) \supseteq L_{i+1}$. This implies that v does not have a uniquely colored neighbor for such a coloring of L_{i+1}.
- The number of colorings of Types 1, 2, 3 are polynomial in $|L_i|$ while the number of colorings of Types 4 and 5 are exponential in $|L_i|$. Since we cannot consider an exponential number of colorings, we consider a polynomial subset of Type 4 and Type 5 colorings which are representatives of all possible Type 4 and Type 5 colorings.
- Given a Type 4 or Type 5 coloring, the key point is that it is enough to fix the colors of a few vertices that we will refer to as "left-important" and "right-important" vertices. This allows us to restrict the focus onto a reduced number of representative colorings.
- Because of the flexibility offered by the representative colorings, there are some cases where we have to explore further in order to decide if the graph is CFON* colorable using colors from $\{0, 1, 2\}$. This reduces to the problem of testing whether a given subgraph is CFON* colorable using colors from $\{0, 1\}$. We use Theorem 21 (with some minor changes) to accomplish this. This is the last, but critical step that we need to complete the proof. ◀

Using Theorems 21 and 23, we can now infer Theorem 13.

▶ Remark 24. Recently, the work of Gonzalez and Mann [20] (done simultaneously and independently from ours) on mim-width showed that the CFON* coloring problem is polynomial-time solvable on graph classes for which a branch decomposition of constant mim-width can be computed in polynomial time. This includes the class of interval graphs. We note that our work gives a more explicit algorithm without having to go through the machinery of mim-width. We also note that the mim-width algorithm, as presented in [20], requires a running time in excess of $\Omega(n^{300})$. Hence our algorithm is better in this regard as well.

5 Subclasses of Bipartite Graphs

It is known that there exist bipartite graphs G for which $\chi^*_{ON}(G) = \Theta(\sqrt{n})$, where n is the number of vertices of G. Abel et al. [1] showed that it is NP-complete to decide if k colors are sufficient to CFON* color a planar bipartite graph even when $k \in \{1, 2, 3\}$. This implies that CFON* coloring is NP-hard on bipartite graphs as well. In this section, we study CFON* coloring on some subclasses of bipartite graphs namely biconvex graphs and bipartite permutation graphs. We show that CFON* coloring is polynomial time solvable on these classes.

We first define biconvex graphs, followed Lemma 26 by a bound on the CFON* chromatic number. The proof of Lemma 26 is omitted.

▶ **Definition 25** (Biconvex Graph). *We say that an ordering σ of X in a bipartite graph $B = (X, Y, E)$ satisfies the* adjacency property *if for every vertex $y \in Y$, the neighborhood $N(y)$ is a set of vertices that are consecutive in the ordering σ of X. A bipartite graph (X, Y, E) is* biconvex *if there are orderings of X (with respect to Y) and Y (with respect to X) that fulfill the adjacency property.*

▶ **Lemma 26** (⋆). *If G is a biconvex graph, then $\chi^*_{ON}(G) \leq 3$.*

▶ **Theorem 27.** *The problem of determining the CFON* chromatic number of a given biconvex graph is solvable in polynomial time.*

Proof. Given a biconvex graph G, we show that $\chi^*_{ON}(G) \leq 3$. We use the fact that every induced subgraph of a biconvex graph admits multi-chain ordering [7, 12]. Let $G = (V, E)$ be a biconvex graph and let $V_0, V_1, \dots, V_q$ be a partition of vertices $V(G)$ respecting the multi-chain ordering conditions. Similar to interval graphs, we now characterize graphs that require one color and two colors. Note that the algorithms in Theorems 21 and 23 work for biconvex graphs too as the proof is based on the multi-chain ordering property and biconvex bipartite graphs admit multi-chain ordering property. In fact, the proof is a bit simpler because of the fact that each V_i is an independent set and we do not need to take care of the edges within a part V_i, as in the case of interval graphs. ◀

The class of bipartite permutation graphs [7] are a subclass of biconvex, and also admit multi-chain ordering property. Hence it follows from Theorem 27 that the problem is polynomial time solvable on bipartite permutation graphs.

▶ **Corollary 28.** *The problem of determining the CFON* chromatic number of a given bipartite permutation graph is solvable in polynomial time.*

6 Conclusion

In this paper, we study CFON* coloring on claw-free graphs, interval graphs and biconvex graphs.

We first show that if G is a $K_{1,k}$-free graph with maximum degree Δ, then $\chi^*_{ON}(G) = O(k^2 \log \Delta)$. We then show that if the minimum degree of G is $\Omega(\frac{\Delta}{\log^\epsilon \Delta})$ for some $\epsilon \geq 0$, then $\chi^*_{ON}(G) = O(\log^{1+\epsilon} \Delta)$. The tightness of these bounds is a natural open question.

We show that CFON* coloring is polynomial time solvable on interval graphs and biconvex graphs, critically using the fact that they admit multi-chain ordering property. Using a similar approach, it can be shown that the full coloring variant of the problem (i.e., CFON coloring) is polynomial time solvable on these graph classes. It is known that CFON* coloring is NP-hard on planar bipartite graphs and there exist bipartite graphs on n vertices that requires $\Theta(\sqrt{n})$ colors. It may be of interest to study the problem on other subclasses of bipartite graphs, such as convex bipartite graphs, chordal bipartite graphs and tree-convex bipartite graphs.

Abstract

The celebrated Skolem-Mahler-Lech Theorem states that the set of zeros of a linear recurrence sequence is the union of a finite set and finitely many arithmetic progressions. The corresponding computational question, the Skolem Problem, asks to determine whether a given linear recurrence sequence has a zero term. Although the Skolem-Mahler-Lech Theorem is almost 90 years old, decidability of the Skolem Problem remains open. The main contribution of this paper is an algorithm to solve the Skolem Problem for simple linear recurrence sequences (those with simple characteristic roots). Whenever the algorithm terminates, it produces a stand-alone certificate that its output is correct – a set of zeros together with a collection of witnesses that no further zeros exist. We give a proof that the algorithm always terminates assuming two classical number-theoretic conjectures: the Skolem Conjecture (also known as the Exponential Local-Global Principle) and the p-adic Schanuel Conjecture. Preliminary experiments with an implementation of this algorithm within the tool Skolem point to the practical applicability of this method.

1 Introduction

1.1 The Skolem Problem

A (rational) linear recurrence sequence (LRS) $\boldsymbol{u} = \langle u_n \rangle_{n=0}^{\infty}$ is a sequence of rational numbers satisfying the equation

$$u_{n+d} = c_1 u_{n+d-1} + \cdots + c_{d-1} u_{n+1} + c_d u_n \qquad (1)$$

for all $n \in \mathbb{N}$, where the coefficients $c_1, \ldots, c_d$ are rational numbers and $c_d \neq 0$. We say that the above recurrence has *order d*. We moreover say that an LRS is *simple* if the characteristic polynomial of its minimal-order recurrence has simple roots.

The celebrated theorem of Skolem, Mahler, and Lech (see [15]) describes the structure of the set $\{n \in \mathbb{N} : u_n = 0\}$ of zero terms of an LRS as follows:

▶ **Theorem 1.** *Given a linear recurrence sequence $\boldsymbol{u} = \langle u_n \rangle_{n=0}^{\infty}$, the set of zero terms is a union of finitely many arithmetic progressions, together with a finite set.*

The statement of Theorem 1 can be refined by considering the notion of *non-degeneracy* of an LRS. An LRS is non-degenerate if in its minimal recurrence the quotient of no two distinct roots of the characteristic polynomial is a root of unity. A given LRS can be effectively decomposed as an interleaving of finitely many non-degenerate sequences, some of which may be identically zero. The core of the Skolem-Mahler-Lech Theorem is the fact that a non-zero non-degenerate linear recurrence sequence has finitely many zero terms. Unfortunately, all known proofs of this last assertion are ineffective: it is not known how to compute the finite set of zeros of a given non-degenerate linear recurrence sequence. It is readily seen that the existence of a procedure to do so is equivalent to the existence of a procedure to decide whether an arbitrary given LRS has a zero term. The problem of deciding whether an LRS has a zero term is variously known as the Skolem Problem or the Skolem-Pisot Problem.

Decidability of the Skolem Problem is known only for certain special cases, based on the relative order of the absolute values of the characteristic roots. Say that a characteristic root λ is *dominant* if its absolute value is maximal among all the characteristic roots. Decidability is known in case there are at most 3 dominant characteristic roots, and also for recurrences of order at most 4 [26, 34]. However for LRS of order 5 it is not currently known how to decide the Skolem Problem.

The Skolem Problem, along with closely related questions such as the Positivity Problem, is intimately connected to various fundamental topics in program analysis and automated verification, such as the termination and model checking of simple while loops [3, 18, 27] or the algorithmic analysis of stochastic systems [1, 2, 5, 13, 28]. It also appears in a variety of other contexts, such as formal power series [29, 33] and control theory [9, 16]. The Skolem Problem is often used as a reference to establish hardness of other open decision problems; in addition to some of the previously cited papers, the articles [4, 14], for example, specifically invoke hardness of the Skolem Problem for simple LRS of order 5. Thus far, the only known complexity bound for the Skolem Problem is NP-hardness [10].

1.2 The Skolem Conjecture and the Bi-Skolem Problem

The notion of linear recurrence equally well makes sense for a bi-infinite sequence $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$ of rational numbers: one defines $\boldsymbol{u}$ to be a *linear recurrent bi-sequence (LRBS)* if it satisfies the recurrence (1) for all $n \in \mathbb{Z}$. Note that every LRS $\boldsymbol{u}$ extends uniquely to an LRBS satisfying the same recurrence (one obtains such an extension by "running the recurrence backwards"). The notions of simplicity and non-degeneracy carry over in the obvious way to LRBS. We remark also that the Skolem-Mahler-Lech Theorem remains valid for LRBS – a non-degenerate LRBS has finitely many zeros. The analog of the Skolem Problem for LRBS is the *Bi-Skolem Problem*, which asks, for a given LRBS $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$, whether there exists $n \in \mathbb{Z}$ with $u_n = 0$.

A major motivation to consider the Bi-Skolem Problem is the existence of the *Exponential Local-Global Principle*, a conjecture introduced by Thoralf Skolem in 1937 [32]. To formulate the conjecture we first make some observations about the value set of an LRBS. Given a non-zero integer b, let $\mathbb{Z}[\frac{1}{b}]$ be the subring of $\mathbb{Q}$ obtained by adjoining $\frac{1}{b}$ to $\mathbb{Z}$. We note that every rational LRBS takes values in $\mathbb{Z}[\frac{1}{b}]$ for some b. Indeed, if $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$ satisfies recurrence (1) and $\mathbb{Z}[\frac{1}{b}]$ contains the coefficients $c_1, \ldots, c_d$, the reciprocal c_d^{-1} of the last coefficient, and the initial terms $u_0, \ldots, u_{d-1}$, then by running the recurrence forwards and backwards from the initial terms we see that $u_n \in \mathbb{Z}[\frac{1}{b}]$ for all $n \in \mathbb{Z}$.

▶ **Skolem Conjecture.** *Let $\boldsymbol{u}$ be a simple rational LRBS taking values in the ring $\mathbb{Z}[\frac{1}{b}]$ for some integer b. Then $\boldsymbol{u}$ has no zero iff, for some integer $m \geq 2$ with $\gcd(b, m) = 1$, we have that $u_n \not\equiv 0 \bmod m$ for all $n \in \mathbb{Z}$.*

In other words, the Skolem Conjecture asserts that if a simple LRBS fails to have a zero, then this is witnessed modulo m for some m. The truth of this conjecture immediately entails the existence of an algorithm to solve the Bi-Skolem Problem for simple LRBS: simply search in parallel either for a zero of the LRBS, or for a number m substantiating the absence of zeros. If the Skolem Conjecture holds, then the search must necessarily eventually terminate.

There exists a substantial body of literature on the Skolem Conjecture, including proofs of a variety of special cases. In particular, the Skolem Conjecture has been shown to hold for simple LRBS of order 2 [6], and for certain families of LRBS of order 3 [30, 31]. In a different but related vein, Bertók and Hajdu have shown that, in some sense, the Skolem Conjecture is valid in "almost all" instances [7, 8].

1.3 Main Results

It is immediate that the Bi-Skolem Problem reduces to the Skolem Problem: an LRBS $\langle u_n \rangle_{n=-\infty}^{\infty}$ has a zero term if and only if at least one of the one-way infinite sequences $\langle u_n \rangle_{n=0}^{\infty}$ and $\langle u_{-n} \rangle_{n=0}^{\infty}$, both of which are LRS, has a zero term. However it is open whether there is a reduction in the other direction (equivalently, it is open whether an oracle for the Bi-Skolem Problem can be used to determine *all* the zeros of a non-degenerate LRBS). Indeed, an oracle for the Bi-Skolem Problem would appear to be of little utility in deciding the Skolem Problem for an LRS whose bi-completion happens to harbour a zero at a negative index. It is likewise not known (in spite of the similar nomenclature) whether the truth of the Skolem Conjecture implies decidability of the Skolem Problem.

Our first main result is as follows:

▶ **Theorem 2.** *The Skolem Problem reduces to the Bi-Skolem Problem subject to the weak p-adic Schanuel Conjecture.*

Schanuel's Conjecture [21, Pages 30-31] is a unifying conjecture in transcendental number theory that plays a key role in the study of the exponential function over both the real and complex numbers. In particular, a celebrated paper of Macintyre and Wilkie [23] obtains decidability of the first-order theory of the structure $(\mathbb{R}; <, \cdot, +, \exp)$ assuming Schanuel's Conjecture over $\mathbb{R}$. A p-adic version of the Schanuel Conjecture, referring to the exponential function on the ring $\mathbb{Z}_p$ of p-adic integers, was formulated in [12]. This conjecture was shown in [24] to imply decidability of the first-order theory of the structure $(\mathbb{Z}_p; <, \cdot, +, \exp)$.

Since the reduction in Theorem 2 specialises to simple LRBS we obtain:

▶ **Theorem 3.** *The Skolem Problem for simple LRS is decidable subject to the weak p-adic Schanuel Conjecture and the Skolem Conjecture.*

The proof of Theorem 3 gives an algorithm that computes the set of zeros of a non-degenerate simple LRBS. The algorithm moreover produces an unconditional certificate that its output is correct, i.e., that all zeros have been found. This certificate consists of a partition of the input LRBS into finitely many subsequences such that each subsequence contains at most one zero. For a subsequence with no zero, the algorithm finds an integer m such that the subsequence is non-zero modulo m; for a subsequence with a zero, the algorithm provides a prime p such that p divides the non-zero terms a well-described (upper-bounded) number of times. The conjectural aspect of Theorem 3 solely concerns the proof that the algorithm terminates on all input sequences.

We have implemented our algorithm within the Skolem tool,[1] which enumerates the set of zeros of a given non-degenerate simple LRS, and produces an independent (conjecture-free) certificate that all zeros have been found. Preliminary experiments, which we present in Section 5, point to the practical applicability of our algorithm.

1.4 Related Work

The decidability of the Skolem Problem is generally considered to have been open since the early 1930s, as the p-adic techniques underpinning the Skolem-Mahler-Lech Theorem were well understood already at the time not to be effective. As noted earlier, a breakthrough establishing decidability at order 4 occurred in the mid-1980s [26, 34], making key use of Baker's Theorem on linear forms in logarithms of algebraic numbers. Very recently, we have shown that the Skolem Problem is decidable at order 5 assuming only the Skolem Conjecture; and in the same paper we also obtained unconditional decidability for reversible LRS[2] of order 7 or less [22]. A minor contribution of the present paper is to improve on the former result by establishing a Turing reduction from the Skolem Problem at order 5 to the Bi-Skolem Problem for simple LRBS of order 5; this is the content of Theorem 12.

2 Technical Background

2.1 Computation in Number Fields

A number field $\mathbb{K}$ is a finite-degree extension of $\mathbb{Q}$. For computational purposes, such a field can be represented in the form $\mathbb{Q}[X]/(g(X))$, where $g(X)$ is the minimal polynomial of a primitive element of $\mathbb{K}$. With such a representation it is straightforward to do arithmetic in $\mathbb{K}$, including solving systems of linear equations with coefficients in $\mathbb{K}$. Moreover, given a polynomial $f(X) \in \mathbb{Q}[X]$, one can compute a representation in the above form of the splitting field $\mathbb{K}$ of f over $\mathbb{Q}$, together with representations of the roots of f as elements of $\mathbb{K}$ [20].

In addition to basic arithmetic and linear algebra in $\mathbb{K}$, we wish to determine whether some given elements $\lambda_1, \dots, \lambda_s \in \mathbb{K}$ are multiplicatively independent and, if not, to exhibit $a_1, \dots, a_s \in \mathbb{Z}$ such that $\lambda_1^{a_1} \cdots \lambda_s^{a_s} = 1$. For this we can use the following result, which shows that if such a multiplicative relation exists then there exists one in which the exponents $a_1, \dots, a_s$ have absolute value at most B for some bound B computable from the height of the λ_i and the degree of the number field $\mathbb{K}$.

[1] Skolem can be experimented with online at `https://skolem.mpi-sws.org/`.

[2] An integer LRS is *reversible* if its completion as an LRBS only takes on integer values.

▶ **Theorem 4** (Masser [25]). *Let $\mathbb{K}$ be a number field of degree D over $\mathbb{Q}$. For $s \geq 1$ let $\lambda_1, \ldots, \lambda_s$ be non-zero elements of $\mathbb{K}$ having absolute logarithmic Weil height at most h over $\mathbb{Q}$. Then the group of multiplicative relations*

$$L = \{(k_1, \ldots, k_s) \in \mathbb{Z}^s : \lambda_1^{k_1} \cdots \lambda_s^{k_s} = 1\} \tag{2}$$

is generated (as an additive subgroup of $\mathbb{Z}^s$) by a collection of vectors all of whose entries have absolute value at most $(csh)^{s-1}D^{s-1}\dfrac{(\log(D+2))^{3s-3}}{(\log\log(D+2))^{3s-4}}$, for some absolute constant c.

2.2 p-adic Numbers

Let p be a prime. Define the *p-adic valuation* $v_p : \mathbb{Q} \to \mathbb{Z} \cup \{\infty\}$ by $v_p(0) = \infty$ and $v_p\left(p^\nu \cdot \frac{a}{b}\right) = \nu$ for all $a, b \in \mathbb{Z} \setminus \{0\}$ such that $\gcd(ab, p) = 1$. In other words, $v_p(x)$ gives the exponent of p as a divisor of $x \in \mathbb{Q}$. The map v_p determines an absolute value $|\cdot|_p$ on $\mathbb{Q}$, where $|x|_p := p^{-v_p(x)}$ (with the convention that $|0|_p = p^{-\infty} = 0$). Due to the fact that $v_p(a+b) \geq \min(v_p(a), v_p(b))$, we have the strong triangle equality: $|a+b|_p \leq \max(|a|_p, |b|_p)$ for all $a, b \in \mathbb{Q}$. In other words, $|\cdot|_p$ is a *non-Archimedean* absolute value. The field $\mathbb{Q}_p$ of *p-adic numbers* is the completion of $\mathbb{Q}$ with respect to $|\cdot|_p$. The absolute value $|\cdot|_p$ extends to a non-Archimedean absolute value on $\mathbb{Q}_p$. The ring of *p-adic integers* is $\mathbb{Z}_p := \{x \in \mathbb{Q}_p : |x|_p \leq 1\}$. The ring $\mathbb{Z}_p$ contains a unique maximal ideal $p\mathbb{Z}_p$, with the quotient $\mathbb{Z}_p/p\mathbb{Z}_p$ being isomorphic to $\mathbb{F}_p$ (the finite field with p elements). When we refer to elements of $\mathbb{Z}_p$ modulo p we refer to their image under this quotient map.

Given a sequence of numbers $\langle a_n \rangle_{n=0}^\infty$ in $\mathbb{Z}_p$, the infinite sum $\sum_{n=0}^\infty a_n$ converges to an element of $\mathbb{Z}_p$ if and only if $|a_n|_p \to 0$ (equivalently, $v_p(a_n) \to \infty$) as $n \to \infty$. It follows that given a sequence $\langle a_n \rangle_{n=0}^\infty$ in $\mathbb{Z}_p$ with $|a_n|_p \to 0$, the corresponding power series $f(X) = \sum_{j=0}^\infty a_j X^j$ defines a function $f : \mathbb{Z}_p \to \mathbb{Z}_p$.

Consider a monic polynomial $g(X) \in \mathbb{Z}[X]$ with non-zero discriminant $\Delta(g)$. Let p be a prime that does not divide $\Delta(g)$. Denote by $\overline{g}(X) \in \mathbb{F}_p[X]$ the polynomial obtained from g by replacing each coefficient with its residue modulo p. It is well known that a sufficient condition for g to split completely over $\mathbb{Z}_p$ is that $\overline{g}$ split over $\mathbb{F}_p$. Indeed, in this situation one can use Hensel's Lemma [17, Theorem 3.4.1] to "lift" each of the roots of $\overline{g}$ in $\mathbb{F}_p$ to a distinct root in $\mathbb{Z}_p$. Moreover, by the Chebotarev density theorem [19] there are infinitely many primes p for which $\overline{g}$ splits over $\mathbb{F}_p$. Hence there are infinitely many primes p such that g splits over $\mathbb{Z}_p$. Note that the last statement holds even without the assumption that $\Delta(g) \neq 0$, since $g \in \mathbb{Z}[X]$ splits over $\mathbb{Z}_p$ whenever $\frac{g}{\gcd(g,g')} \in \mathbb{Z}[X]$ splits over $\mathbb{Z}_p$ (and the latter has non-zero discriminant).

Let p be an odd prime.[3] The *p-adic exponential* is defined as $\exp(x) = \displaystyle\sum_{k=0}^\infty \frac{x^k}{k!}$, which converges for all $x \in p\mathbb{Z}_p$. The *p-adic logarithm* is defined as $\log(x) = \displaystyle\sum_{k=0}^\infty (-1)^{k+1}\frac{(x-1)^k}{k}$, which converges for all $x \in 1 + p\mathbb{Z}_p$. For $x, y \in p\mathbb{Z}_p$ we have $\exp(x+y) = \exp(x)\exp(y)$ and for $x, y \in 1 + p\mathbb{Z}_p$ we have $\log(xy) = \log(x) + \log(y)$. Indeed we have that exp and log yield mutually inverse isomorphisms between the additive group $p\mathbb{Z}_p$ and multiplicative group $1 + p\mathbb{Z}_p$.

[3] We omit the prime $p = 2$ to avoid special cases in the facts below.

Schanuel's Conjecture for the complex numbers is a powerful unifying principle in transcendence theory. We will need the following p-adic version of the weak form of Schanuel's Conjecture, which can be found, e.g., as [12, Conjecture 3.10].

▶ **Conjecture 5** (Weak p-adic Schanuel Conjecture)**.** *Let $\alpha_1, \dots, \alpha_s \in 1+p\mathbb{Z}_p$ be algebraic over $\mathbb{Q}$ and such that $\log \alpha_1, \dots, \log \alpha_s$ are linearly independent over $\mathbb{Q}$. Then $\log \alpha_1, \dots, \log \alpha_s$ are algebraically independent over $\mathbb{Q}$, i.e., for every non-zero polynomial $P \in \mathbb{Q}_p[X_1, \dots, X_s]$ whose coefficients are algebraic over $\mathbb{Q}$, we have that $P(\log \alpha_1, \dots, \log \alpha_s) \neq 0$.*

A known special case of Conjecture 5 is the following result of Brumer [11], which is a p-adic analog of Baker's Theorem on linear independence of logarithms of algebraic numbers.

▶ **Theorem 6.** *Let $\alpha_1, \dots, \alpha_s \in 1+p\mathbb{Z}_p$ be algebraic over $\mathbb{Q}$ and such that $\log \alpha_1, \dots, \log \alpha_s$ are linearly independent over $\mathbb{Q}$. Then $\beta_0 + \beta_1 \log \alpha_1 + \cdots + \beta_s \log \alpha_s \neq 0$ for all $\beta_0, \dots, \beta_s \in \mathbb{Q}_p$ that are algebraic over $\mathbb{Q}$ and not all zero.*

3 p-adic Power-Series Representation of LRBS

Let $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$ be an LRBS of rational numbers satisfying the linear recurrence

$$u_{n+d} = c_1 u_{n-d-1} + \cdots + c_d u_n \quad (n \in \mathbb{Z}),$$

where $c_d \neq 0$. For the purposes of computing the zeros of $\boldsymbol{u}$ we can assume without loss of generality that the coefficients $c_1, \dots, c_d$ of the recurrence are integers. (It is easy to see that for any integer ℓ such that $\ell c_i \in \mathbb{Z}$ for $i \in \{1, \dots, d\}$, the scaled sequence $\langle \ell^n u_n \rangle_{n=-\infty}^{\infty}$ satisfies an integer recurrence.) Write $g(X) := X^d - c_1 X^{d-1} - \cdots - c_d$ for the *characteristic polynomial* of the recurrence and let

$$A := \begin{pmatrix} c_1 & \cdots & c_{d-1} & c_d \\ 1 & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & 1 & 0 \end{pmatrix}, \quad \alpha := \begin{pmatrix} 0 & \cdots & 0 & 1 \end{pmatrix}, \quad \text{and} \quad \beta := \begin{pmatrix} u_{d-1} \\ \vdots \\ u_1 \\ u_0 \end{pmatrix}.$$

We now have the matrix-exponential representation $u_n = \alpha A^n \beta$ for all $n \in \mathbb{Z}$. (Here A is known as the *companion matrix* of the recurrence.)

The key tool in our approach – which also underlies the proof of the Skolem-Mahler-Lech Theorem – is the representation of the LRBS $\boldsymbol{u}$ in terms of a power series $f(X) = \sum_{j=0}^{\infty} a_j X^j$ with coefficients in $\mathbb{Z}_p$. In defining f we work with an odd prime p such that (i) p does not divide the constant term c_d of the recurrence; (ii) p does not divide the discriminant $\Delta\left(\frac{g}{\gcd(g,g')}\right)$; (iii) the characteristic polynomial g splits over $\mathbb{Z}_p$. As explained in Section 2.2, there are infinitely many such primes. Moreover, for a particular prime p that does not divide $\Delta\left(\frac{g}{\gcd(g,g')}\right)$, we can easily verify whether g splits over $\mathbb{Z}_p$, since this is equivalent to $\frac{g}{\gcd(g,g')}$ splitting over $\mathbb{F}_p$.

Write $\lambda_1, \dots, \lambda_s \in \mathbb{Z}_p$ for the distinct roots of g. Let $\mathbb{K}$ be the subfield of $\mathbb{Q}_p$ generated by $\lambda_1, \dots, \lambda_s$. Then $\mathbb{K}$ is a number field and thus we can compute symbolically in $\mathbb{K}$ as described in Section 2.1. It is well known that the sequence $\boldsymbol{u}$ admits an exponential-polynomial representation

$$u_n = \sum_{i=1}^{s} Q_i(n) \lambda_i^n \quad (n \in \mathbb{Z}), \tag{3}$$

where $Q_i \in \mathbb{K}[X]$ has degree strictly less than the multiplicity of λ_i as a root of g. The coefficients of each polynomial Q_i can be computed as the unique solution of the system of linear equations that arises by substituting $n = 0, \dots, d-1$ in Equation (3) (where, recall, d is the order of the recurrence).

The companion matrix has determinant $\det(A) = \pm c_d$, which is non-zero modulo p; hence A is invertible modulo p. Let L be the least positive integer such that $A^L \equiv I \bmod p$. Being an eigenvalue of A^L, $\lambda_i^L \equiv 1 \bmod p$ for all $i \in \{1, \dots, s\}$ and hence the p-adic logarithm $\log \lambda_i^L$ is defined for all $i \in \{1, \dots, s\}$. We thus obtain the following representation of the subsequence $\langle u_{Ln} \rangle_{n=-\infty}^{\infty}$ in terms of the p-adic exponential and logarithm functions:

$$u_{Ln} = \sum_{i=1}^{s} Q_i(Ln)\lambda_i^{Ln} = \sum_{i=1}^{s} Q_i(Ln)\exp(n \log \lambda_i^L)\,.$$

Now consider the power series $f(X) = \sum_{j=0}^{\infty} a_j X^j$ such that

$$f(x) := \sum_{i=1}^{s} Q_i(Lx)\exp(x \log \lambda_i^L) \tag{4}$$

for all $x \in \mathbb{Z}_p$. Then we have $u_{Ln} = f(n)$ for all $n \in \mathbb{Z}$. Moreover, since $a_j = \frac{1}{j!} f^{(j)}(0)$, by taking derivatives in (4) we obtain the following expression for the coefficients of f:

$$a_j = \frac{1}{j!} \sum_{i=1}^{s} \sum_{k=0}^{j} \binom{j}{k} L^k Q_i^{(k)}(0) \left(\log \lambda_i^L\right)^{j-k}\,. \tag{5}$$

In the remainder of this section we recall an alternative formula for the coefficients of f as p-adically convergent sums of rational numbers. This provides a simple method to compute $v_p(a_j)$ that avoids computing p-adic approximations of the characteristic roots, as would be needed if we were to directly use (5).

Recall that we have $A^L \equiv I \mod p$. Let us say that $A^L = I + pB$ for some integer matrix B. Then we have:

$$\begin{aligned}
u_{Ln} &= \alpha A^{Ln} \beta \\
&= \alpha (I + pB)^n \beta \\
&= \sum_{k=0}^{n} \binom{n}{k} p^k \alpha B^k \beta \\
&= \sum_{k=0}^{n} \frac{n(n-1)\dots(n-k+1)}{k!} p^k \alpha B^k \beta \\
&= \sum_{k=0}^{\infty} \frac{n(n-1)\dots(n-k+1)}{k!} p^k \alpha B^k \beta \\
&= \sum_{k=0}^{\infty} \sum_{j=0}^{\infty} c_{k,j} n^j \frac{p^k}{k!} \quad \text{for certain } c_{k,j} \in \mathbb{Z} \text{ with } c_{k,j} = 0 \text{ for } j > k \\
&= \sum_{j=0}^{\infty} \sum_{k=j}^{\infty} c_{k,j} n^j \frac{p^k}{k!}\,.
\end{aligned}$$

It remains to see why one can reverse the order of summation in the last line above and why the resulting sums converge in $\mathbb{Z}_p$. For this we can apply [17, Proposition 4.1.4], for which we require that the summand $c_{k,j} n^j \frac{p^k}{k!}$ converge to 0 as $j \to \infty$ and converge to 0 uniformly in j as $k \to \infty$. But this precondition follows from the fact that $v_p(k!) < \frac{k}{p-1}$, from which we have $v_p\left(c_{k,j} n^j \frac{p^k}{k!}\right) \geq \frac{(p-2)k}{p-1}$ for all $k \geq j$.

Now consider the power series $\widetilde{f}(X) := \sum_{j=0}^{\infty} b_j X^j$ where

$$b_j := \sum_{k=j}^{\infty} c_{k,j} \frac{p^k}{k!} \in \mathbb{Z}_p \,. \tag{6}$$

By the above considerations we have that $v_p(b_j) \geq \frac{(p-2)j}{p-1}$ and hence $\widetilde{f}$ converges on $\mathbb{Z}_p$ and satisfies $\widetilde{f}(n) = u_{Ln}$ for all $n \in \mathbb{Z}$. In particular, the power series f and $\widetilde{f}$ agree on $\mathbb{Z}$ and hence (e.g., by [17, Proposition 4.4.3]) are identical, i.e., $a_j = b_j$ for all $j \in \mathbb{N}$. Thus we can use Equation (6) to exactly compute $v_p(a_j)$ for any j such that $a_j \neq 0$.

4 Computing all the Zeros of an LRBS

In this section we show, assuming the weak p-adic Schanuel Conjecture, that the set of all zeros of a non-degenerate LRBS is computable using an oracle for the Bi-Skolem Problem. In particular, this gives a Turing reduction of the Skolem Problem to the Bi-Skolem Problem.

▶ **Proposition 7.** *Let $f : \mathbb{Z}_p \to \mathbb{Z}_p$ be given by a convergent p-adic power series $f(X) = \sum_{k=0}^{\infty} a_k X^k$, with coefficients in $\mathbb{Z}_p$. Suppose that ℓ is a positive integer such that $a_0 = \cdots = a_{\ell-1} = 0$ and $a_\ell \neq 0$. Then, writing $\nu := v_p(a_\ell)$, we have $f(p^{\nu+1}x) \neq 0$ for all non-zero $x \in \mathbb{Z}_p$.*

Proof. Let $x \in \mathbb{Z}_p$ be non-zero. For every $m > \ell$ we have

$$\begin{aligned} v_p(a_\ell(p^{\nu+1}x)^\ell) &= \nu + \ell(\nu+1) + v_p(x^\ell) \\ &< m(\nu+1) + v_p(x^m) \quad (\text{since } \ell < m \text{ and } x \neq 0) \\ &\leq v_p(a_m(p^{\nu+1}x)^m) \,. \end{aligned}$$

It follows that for all $m \geq \ell$,

$$v_p\left(\sum_{k=0}^{m} a_k (p^{\nu+1}x)^k\right) = v_p(a_\ell(p^{\nu+1}x)^\ell) \,.$$

Letting m tend to infinity, we have $v_p(f(p^{\nu+1}x)) = v_p(a_\ell(p^{\nu+1}x)^\ell) < \infty$ and we conclude that $f(p^{\nu+1}x) \neq 0$. ◀

▶ **Proposition 8.** *Let $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$ be a non-zero LRBS consisting of rational numbers. Assuming the weak p-adic Schanuel Conjecture, one can compute a positive integer M such that $u_{Mn} \neq 0$ for all $n \in \mathbb{Z} \setminus \{0\}$.*

Proof. As explained in Section 3, there exists a prime p and a positive integer L such that $u_{Ln} = f(n)$ for all $n \in \mathbb{Z}$, for the p-adic power series $f(X) = \sum_{j=0}^{\infty} a_j X^j$ whose coefficients are given by the formula (4). Recall that in this formula the λ_i are the characteristic roots of $\boldsymbol{u}$ and the Q_i are the coefficients appearing in the exponential polynomial formula (3).

Pick a maximal multiplicatively independent subset of characteristic roots. Without loss of generality we can write this set as $\{\lambda_1, \ldots, \lambda_t\}$ for some $t \leq s$. As discussed in Section 2, given the characteristic polynomial of the recurrence, we can compute such a set, as well as integers m_i and $n_{i,j}$ for $i \in \{1, \ldots, s\}$ and $j \in \{1, \ldots, t\}$, where the m_i are non-zero, such that for all $i \in \{1, \ldots, s\}$ we have

$$\lambda_i^{m_i} = \lambda_1^{n_{i,1}} \cdots \lambda_t^{n_{i,t}} \,.$$

Raising the left- and right-hand sides in the above equation to the power L and then taking (p-adic) logarithms, we get that

$$\log \lambda_i^L = \frac{n_{i,1}}{m_i} \log \lambda_1^L + \cdots + \frac{n_{i,t}}{m_i} \log \lambda_t^L$$

for all $i \in \{1, \ldots, s\}$. In other words, for all $i \in \{1, \ldots, s\}$ we have that $\log \lambda_i^L = \ell_i(\log \lambda_1^L, \ldots, \log \lambda_t^L)$ for an effectively computable linear form $\ell_i(X_1, \ldots, X_t)$ with rational coefficients.

For $j \in \mathbb{N}$, define $F_j \in \mathbb{K}[X_1, \ldots, X_t]$ by

$$F_j(X_1, \ldots, X_t) := \frac{1}{j!} \sum_{i=1}^{s} \sum_{k=0}^{j} \binom{j}{k} L^k Q_i^{(k)}(0) \ell_i(X_1, \ldots, X_t)^{j-k} .$$

Then by Equation (5) we have

$$a_j = F_j \left(\log \lambda_1^L, \ldots, \log \lambda_t^L\right) . \tag{7}$$

We claim that $a_j \neq 0$ if F_j is not identically zero. Since the coefficients of F_j are algebraic over $\mathbb{Q}$ and the set $\{\log \lambda_1, \ldots, \log \lambda_t\}$ is linearly independent over $\mathbb{Q}$, the claim follows immediately from Equation 7 and the weak p-adic Schanuel Conjecture (Conjecture 5).

We can now use the following procedure to compute a positive integer M such that $u_{Mn} \neq 0$ for all $n \in \mathbb{Z}$:

1. Successively compute the polynomials $F_0, F_1, \ldots$.
2. Let j_0 be the least index j such that F_j is not identically zero. Compute $\nu := v_p(a_{j_0})$ using the series (6). The weak p-adic Schanuel Conjecture implies that $a_{j_0} \neq 0$ and hence the computation of $v_p(a_{j_0})$ terminates.
3. Set $M := Lp^{\nu+1}$. Applying Proposition 7, we have $u_{Mn} \neq 0$ for all non-zero integers n.

Note that j_0 is well defined in Line 2, since if all the a_j were zero, then $\boldsymbol{u}$ would be the identically zero sequence, contradicting our initial assumption. ◀

A couple of remarks about the proof of Proposition 8 are in order.

▶ Remark 9. Observe that the p-adic Schanuel Conjecture is only required for termination of the procedure described at the end of the proof. If the procedure terminates then it is certain that a_{j_0} is the first non-zero coefficient of the power series (6) and hence the outputted value of M is guaranteed to be such that $u_{Mn} \neq 0$ for all non-zero integers n.

▶ Remark 10. Examining the expression (5) and noting that $Q_i^{(k)}(0) = 0$ for $k > \deg(Q_i)$, we see that the sequence $\langle j! a_j \rangle_{j=0}^{\infty}$ is given by an exponential polynomial corresponding to a (non-rational) LRS of order d and hence at least one of $a_0, a_1, \ldots, a_{d-1}$ is non-zero. This means that the index j_0 in Line 2 of the above procedure is at most $d - 1$.

▶ **Theorem 11.** *Assuming the weak p-adic Schanuel Conjecture, there is a Turing reduction from the Skolem Problem to the Bi-Skolem Problem.*

Proof. We present a recursive procedure that uses an oracle for the Bi-Skolem Problem to compute all the zeros of a non-degenerate LRBS that is not identically zero.

Given a non-degenerate LRBS $\boldsymbol{u} = \langle u_n \rangle_{n=-\infty}^{\infty}$, we use the oracle for the Bi-Skolem Problem to determine whether there exists $n \in \mathbb{Z}$ with $u_n = 0$. If the oracle outputs that no such n exists then the procedure terminates. Otherwise one searches for $n_0 \in \mathbb{Z}$ such that $u_{n_0} = 0$; clearly the search is guaranteed to terminate. Having found n_0, by reindexing the sequence $\boldsymbol{u}$ we can suppose that $n_0 = 0$. Now we use Proposition 8 to compute a positive integer M such that $u_{Mn} \neq 0$ for all $n \neq 0$. We then divide the sequence $\boldsymbol{u}$ into M subsequences $\boldsymbol{u}^{(0)}, \dots, \boldsymbol{u}^{(M-1)}$, where for $j \in \{0, \dots, M-1\}$, the j-th subsequence is given by $u_n^{(j)} = u_{Mn+j}$ for all $n \in \mathbb{Z}$. We know that $n = 0$ is the only zero of $\boldsymbol{u}^{(0)}$. We now recursively call the procedure to find all zeros of the remaining subsequences $\boldsymbol{u}^{(1)}, \dots, \boldsymbol{u}^{(M-1)}$. Observe that the computation must terminate since each recursive call involves discovering a new zero of the original sequence $\boldsymbol{u}$, and by the version of the Skolem-Mahler-Lech Theorem for LRBS, there are only finitely many such zeros. ◀

If we restrict to recurrences of order at most 5 then we obtain an unconditional version of Theorem 11.

▶ **Theorem 12.** *There is a Turing reduction from the Skolem Problem for LRS of order at most* 5 *to the Bi-Skolem Problem for simple LRBS of order at most* 5.

Proof. As summarised in Appendix A, the Skolem Problem can be decided for all LRS $\langle u_n \rangle_{n=0}^{\infty}$ of order at most 5 except those that (after scaling) have a closed form $u_n = \sum_{i=1}^{5} \alpha_i \lambda_i^n$ satisfying the following three conditions, where $\lambda_1, \dots, \lambda_5$ are algebraic integers that generate a number field $\mathbb{K} := \mathbb{Q}(\lambda_1, \dots, \lambda_5)$:

1. $\alpha_1 \neq -\alpha_3$;
2. $\lambda_1 \lambda_2 = \lambda_3 \lambda_4$;
3. there is a prime ideal $\mathfrak{p}$ in $\mathcal{O}_{\mathbb{K}}$ that divides λ_1 and λ_3 but not $\lambda_2, \lambda_4, \lambda_5$.

The theorem at hand is proven using the procedure described in the proof of Theorem 11, which uses as a subroutine the procedure described in Proposition 8. To avoid relying on the weak p-adic Schanuel Conjecture, it suffices to give an unconditional proof of the termination of the latter procedure when invoked on LRBS whose closed-form representation satisfies the above three conditions. In other words, we must show (unconditionally) that for such LRBS one can compute a positive integer M such that $u_{Mn} \neq 0$ for all $n \in \mathbb{Z} \setminus \{0\}$.

Let p be a prime satisfying Conditions (i)–(iii) listed in Section 3. In particular, we have an embedding of $\mathbb{K}$ into $\mathbb{Q}_p$. Recall from Section 3 that there exists a positive integer L such that $u_{Ln} = f(n)$ for a p-adic power series $f(X) = \sum_{j=0}^{\infty} a_j X^j$ such that $a_1 = \sum_{i=1}^{5} \alpha_i \log \lambda_i^L$. The termination of the procedure described in the proof of Proposition 8 will be assured if $a_1 \neq 0$. We claim that for an LRBS satisfying the above three conditions, one has $a_1 = \sum_{i=1}^{5} \alpha_i \log \lambda_i^L \neq 0$.

To prove the claim, suppose for a contradiction that $\sum_{i=1}^{5} \alpha_i \log \lambda_i^L = 0$. Raising to the L-th power and then taking logarithms in Condition 2 above, we also have $\log \lambda_1^L + \log \lambda_2^L - \log \lambda_3^L - \log \lambda_4^L = 0$. Combining the two previous equations to cancel $\log \lambda_1^L$ we have

$$(\alpha_2 - \alpha_1) \log \lambda_2^L + (\alpha_3 + \alpha_1) \log \lambda_3^L + (\alpha_4 + \alpha_1) \log \lambda_4^L + \alpha_5 \log \lambda_5^L = 0 \,. \tag{8}$$

From Condition 1 ($\alpha_1 \neq -\alpha_3$), we have that the coefficient of $\log \lambda_3^L$ in Equation (8) is non-zero. Applying Theorem 6, possibly several times, we eventually obtain an equation $\sum_{i=2}^{5} \beta_i \log \lambda_i^L = 0$ such that the β_i are integers and $\beta_3 \neq 0$. Equivalently, we have a multiplicative relation among the characteristic roots that involves λ_3 but not λ_1. But this contradicts Condition 3 and the proof is concluded. ◀

▶ **Theorem 13.** *The Skolem Problem for simple LRS is decidable assuming the Skolem Conjecture and the weak p-adic Schanuel Conjecture. The Skolem Problem for LRS of order at most 5 is decidable assuming the Skolem Conjecture.*

▶ Remark 14. Given that the Skolem Conjecture remains open in general, it is worth remarking that the proof of Theorem 13 sustains the following more general formulation: Consider a class $\mathcal{C}$ of simple LRBS that is closed under taking subsequences and under translations. If the Skolem Conjecture holds for $\mathcal{C}$ then, assuming the weak p-adic Schanuel Conjecture, the Skolem Problem is decidable over LRS in $\mathcal{C}$.

5 The Skolem Tool

We have implemented our algorithm in the Skolem tool, which finds all zeros (at both positive and negative indices) for simple integer LRS, and produces independent certificates guaranteeing that there are no further zeros. Even though we do not have complexity bounds, Skolem can efficiently handle many interesting examples, including several from the literature for which no proof technique was previously known to apply. Our tool is available online at `https://skolem.mpi-sws.org` and includes several built-in examples.

The implementation is written in Python, using the SageMath computer-algebra extension. This allows for the efficient and exact manipulation of mathematical objects, including elements of $\mathbb{Z}_p$. Python handles integers of arbitrary sizes seamlessly, making it especially suitable for our purposes, since even small examples can give rise to very large numbers within the inner workings of our algorithm.

▶ **Example 15.** Consider the LRS from [22, Example 2.4]:

$$u_{n+5} = 9u_{n+4} - 10u_{n+3} + 522u_{n+2} - 4745u_{n+1} + 4225u_n$$

with initial terms (for $n = 0, 1, 2, 3, 4$) of $\langle -30, -27, 0, 469, 1762\rangle$. It is shown in [22] to have a unique zero at index 2 by being non-zero modulo 12625 at all indices larger than 2. The Skolem tool establishes this in a simpler way: after finding $u_2 = 0$, the tool calculates that there are no zeros in $\langle u_{2+14n}\rangle_{n=-\infty}^{\infty}$ for $n \neq 0$. Then the tool computes that $\langle u_{k+14n}\rangle_{n=-\infty}^{\infty}$ is non-zero modulo 29 for each even $k \neq 2$, and non-zero modulo 2 for each odd k (where $0 \leq k \leq 13$). Observe that the computed modulo classes, and thus the resulting certificate, is much smaller than those arising from 12625 as used in [22].

▶ **Example 16.** Consider the LRS from [22, Example 2.5]:

$$u_{n+6} = 6u_{n+5} - 26u_{n+4} + 66u_{n+3} - 130u_{n+2} + 150u_{n+1} - 125u_n$$

with initial terms (for $n = 0, 1, 2, 3, 4, 5$) of $\langle 0, 3, 11, -12, -125, -177\rangle$, which was established at the time of writing to lie beyond the reach of existing known techniques. The Skolem tool is able to show using the methods developed in the present paper that there are indeed no further zeros (other than $u_0 = 0$).

▶ **Example 17.** Consider the reversible order-8 LRS from [22, Example 3.5]:

$$u_{n+8} = 6u_{n+7} - 25u_{n+6} + 66u_{n+5} - 120u_{n+4} + 150u_{n+3} - 89u_{n+2} + 18u_{n+1} - u_n$$

with initial terms (for $n = 0, \ldots, 7$) of $\langle 0, 0, -48, -120, 0, 520, 624, -2016\rangle$, which likewise was established at the time to lie beyond the reach of existing techniques. Skolem shows that there are no zeros other than those lying at indices 0, 1, and 4.

Table 1 Table showing the distribution of outcomes by order. The line between orders 6 and 7 shows the boundary beyond which more than 50% of runs timeout. The second experiment shows the timeout rate when the timeout is increased to $60s \cdot \textit{order}$ (“degenerate” and “not-simple” counts omitted as the distribution is similar to the 60s timeout experiment and unaffected by the timeout).

	Timeout of 60 seconds						Timeout of $60 \cdot \textit{order}$ seconds

5.1 Testing

The Skolem tool was tested on a suite of random LRS, with the order taken uniformly between 2 and 10 and the coefficients taken uniformly at random between -20 and 20. Tests were run for 48 hours using a 60-second timeout[4], generating 82367 test instances.[5]

The results are presented in Tables 1 and 2. In particular, from order 7 onwards the tool is unable to handle more than half of the instances within one minute, with the timeout percentage jumping significantly from order 6. Both degenerate and non-simple LRS instances are very sparse, and as expected the higher the order the fewer such instances were randomly produced.

The experiments were re-run using a timeout of $60 \cdot \textit{order}$ seconds (i.e., ranging from 2–10 minutes) in order to determine whether the 60-second timeout was too strict. The timeout percentage does decrease, but the overall pattern shows that the vast majority of LRS of order 7 and above could not be handled to completion before the timeout.

Table 2 presents statistical information. In the main experiment the average time is below 9 seconds for order-6 examples that succeed within 60 seconds. However, the decrease from order-8 onwards is explained by there being significantly fewer examples succeeding within 60 seconds. On average there are very few zeros (as can be expected) and those that do occur are almost always those occurring within the initial terms (the largest zero is nearly always at index less than the order).

The average maximum jump step used (i.e., M such that $\langle u_{Mn} \rangle$ has no zeros for $n \neq 0$ and $u_0 = 0$) is observed on average to grow with the order (except at order 10 with only 25 successful samples).

[4] Testing was conducted using SageMath 9.5 in Docker on a Dell PowerEdge M620 blade equipped with 2× 3.3 GHz Intel Xeon E5-2667 v2 (2×8 cores, 32 with hyper-threading) and 256GB ram. Testing was restricted to 16 parallel threads (50% of the computer’s resources) for institutional reasons.

[5] 7 instances were discarded: 6 happened to be the zero sequence, one resulted in an exception (outside of the main tool code) which was later fixed.

Table 2 Table listing statistical information for successful runs, by order. Line between orders 6 and 7 shows the boundary beyond which more than 50% of runs timeout, resulting in skewed analysis for the subsequent rows. For the second experiment, with timeout of $60 \cdot \mathit{order}$ seconds, only the mean time is shown as there are fewer data points.

Order	mean time (seconds)	mean count of zeros	max count of zeros	mean max zero	max zero index	mean tree depth	mean max jump	mean time (seconds) $60s \cdot \mathit{order}$
2	0.03	0.06	1	0.63	6	1.06	5.11	0.03

A Hard Cases of the Skolem Problem at Order 5

As explained in [22], the Skolem Problem is known to be decidable for all LRS of order at most 5 except for those sequences $\boldsymbol{u} = \langle u_n \rangle_{n=0}^{\infty}$ having an exponential-polynomial representation

$$u_n = \alpha_1 \lambda_1^n + \overline{\alpha_1}\overline{\lambda_1}^n + \alpha_2 \lambda_2^n + \overline{\alpha_2}\overline{\lambda_2}^n + \alpha_3 \lambda_3^n \tag{9}$$

such that $\alpha_1, \alpha_2, \alpha_3, \lambda_1, \lambda_2, \lambda_3 \in \overline{\mathbb{Q}}$ satisfy $|\lambda_1| = |\lambda_2| > |\lambda_3|$ and $\lambda_1, \lambda_2, \lambda_3$ are not all units. It is further shown in [22] that by scaling sequences of this form we can assume that there exists a prime ideal $\mathfrak{p}$ in the ring of integers of the number field generated by $\lambda_1, \overline{\lambda_1}, \lambda_2, \overline{\lambda_2}, \lambda_3$ such that $\mathfrak{p}$ divides λ_1 and λ_2, but not $\overline{\lambda_1}, \overline{\lambda_2}$ and λ_3.

Here we make the further observation that for non-degenerate LRS of the form (9), under the assumption that $|\alpha_1| = |\alpha_2|$, there is a computable upper bound on n such that $u_n = 0$.

By scaling we can assume without loss of generality that $|\lambda_1| = |\lambda_2| = 1$ and $|\alpha_1| = |\alpha_2| = 1$. Thus we can write $\lambda_1 = e^{i\theta_1}$ and $\lambda_2 = e^{i\theta_2}$ for $\theta_1, \theta_2 \in [0, 2\pi)$ and we can put $\alpha_1 = e^{i\phi_1}$ and $\alpha_2 = e^{i\phi_2}$ for $\phi_1, \phi_2 \in [0, 2\pi)$. Then we have

$$\begin{aligned} u_n &= \alpha_1\lambda_1^n + \overline{\alpha_1}\overline{\lambda_1}^n + \alpha_2\lambda_2^n + \overline{\alpha_2}\overline{\lambda_2}^n + \alpha_3\lambda_3^n \\ &= 2\cos(n\theta_1 + \phi_1) + 2\cos(n\theta_2 + \phi_2) + \alpha_3\lambda_3^n \\ &= 4\left(\cos\left(\frac{n(\theta_1+\theta_2)+\phi_1+\phi_2}{2}\right)\cos\left(\frac{n(\theta_1-\theta_2)+\phi_1-\phi_2}{2}\right)\right) + \alpha_3\lambda_3^n\,. \end{aligned}$$

By non-degeneracy of $\boldsymbol{u}$, the terms $\cos\left(\frac{n(\theta_1+\theta_2)+\phi_1+\phi_2}{2}\right)$ and $\cos\left(\frac{n(\theta_1-\theta_2)+\phi_1-\phi_2}{2}\right)$ are respectively zero for at most one value of $n \in \mathbb{N}$. Furthermore, using Baker's Theorem on linear forms in logarithms (see [26, 34] for details), each of these terms has a lower bound (when non-zero) of the form $\frac{c}{n^d}$ for explicitly computable constants c and d. Since $|\lambda_3| < 1$ it follows that $u_n \neq 0$ for all $n \geq n_0$ for some effective threshold n_0.

Deepening the (Parameterized) Complexity Analysis of Incremental Stable Matching Problems

Abstract

When computing stable matchings, it is usually assumed that the preferences of the agents in the matching market are fixed. However, in many realistic scenarios, preferences change over time. Consequently, an initially stable matching may become unstable. Then, a natural goal is to find a matching which is stable with respect to the modified preferences and as close as possible to the initial one. For Stable Marriage/Roommates, this problem was formally defined as Incremental Stable Marriage/Roommates by Bredereck et al. [AAAI '20]. As they showed that Incremental Stable Roommates and Incremental Stable Marriage with Ties are NP-hard, we focus on the parameterized complexity of these problems. We answer two open questions of Bredereck et al. [AAAI '20]: We show that Incremental Stable Roommates is W[1]-hard parameterized by the number of changes in the preferences, yet admits an intricate XP-algorithm, and we show that Incremental Stable Marriage with Ties is W[1]-hard parameterized by the number of ties. Furthermore, we analyze the influence of the degree of "similarity" between the agents' preference lists, identifying several polynomial-time solvable and fixed-parameter tractable cases, but also proving that Incremental Stable Roommates and Incremental Stable Marriage with Ties parameterized by the number of different preference lists are W[1]-hard.

1 Introduction

Efficiently adapting solutions to changing inputs is a core issue in modern algorithmics [3, 6, 9, 16, 27]. In particular, in *incremental* combinatorial problems, roughly speaking, the goal is to build new solutions incrementally while adapting to changes in the input. Typically, one wants to avoid (if possible) too radical changes in the solution relative to perhaps moderate changes in the input. The corresponding study of incremental algorithms attracted research on numerous problems and scenarios [24], including among many others shortest path computation [40], flow computation [31], clustering problems [9, 35], and graph coloring [28].

In this paper, we study the problem of adapting stable matchings under preferences to change. Consider for instance the following two scenarios: First, as reported by Feigenbaum et al. [18], school seats in public schools are centrally assigned in New York. Ahead of the

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

start of the new year, all interested students are asked to submit their preferences over public schools. Then, a stable matching of students to public schools is computed and transmitted. However, in the past, shortly before the start of the new year typically around 10% of students changed their preferences and decided to attend a private school instead, leaving the initially implemented matching unstable and triggering lengthy decentralized ad hoc updates. Second, consider the assignment of freshmen to double bedrooms in college accommodation. After the orientation weeks, it is quite likely that students got to know each other (and in particular their roommates) better and thus their initially uninformed preferences changed, making the matching unstable.

In our work, we focus on the problem of finding a stable matching after the "change" that is as close as possible to a given initially stable matching. The closeness condition here is due to the fact that in most applications reassignments come at some cost which we want to minimize (e.g., in the above New York example, reassigning students might make it necessary for the family to reallocate within the city). We build upon the work of Bredereck et al. [7], who performed a first systematic study of incremental versions of stable matching problems, and the recent (partially empirical) follow-up work by Boehmer et al. [5], who proved among others that different types of changes are "equivalent" to each other. The central focus of our studies lies on the Stable Roommates (SR) problem: given a set of agents with each agent having preferences over other agents, the task is to find a stable matching, i.e., a matching so that there are no two agents preferring each other to their assigned partner. We also consider a famous special case of SR, namely Stable Marriage (SM), where the set of agents is partitioned into two sets, and each agent may only be matched to an agent from the other set. Formally, in the incremental versions of SR and SM, called Incremental Stable Roommates (ISR) and Incremental Stable Marriage (ISM), we are given two preference profiles containing the preferences of each agent before and after the "change" and a matching that is stable in the preference profile before the change. Then, the task is to find a matching that is stable after the change and as close as possible to the given matching, i.e., has a minimum symmetric difference to it.

Related Work. Bredereck et al. [7] formally introduced Incremental Stable Marriage [with ties] (ISM/[ISM-T]) and Incremental Stable Roommates [with ties] (ISR/[ISR-T]). They showed that ISM without ties (in the preference lists) is solvable in polynomial time by a simple reduction to finding a stable matching maximizing the weight of the included agent pairs (which is solvable in polynomial time [17]). In contrast to this, ISR is NP-complete [12, Theorem 4.2], yet admits an FPT-algorithm for the parameter k, that is, the maximum allowed size of the symmetric difference between the two matchings [7]. With ties, Bredereck et al. [7] showed that ISM-T and ISR-T are NP-complete and W[1]-hard for k even if the two preference profiles only differ in a single swap in some agent's preference list. As ISR-T can be considered as a generalization of ISM-T, their results motivate us to focus on the NP-hard ISR and ISM-T problems (which are somewhat incomparable problems). Recently, Boehmer et al. [5] followed up on the work of Bredereck et al. [7], proving that different types of changes such as deleting agents or performing swaps of adjacent agents in some preference list are "equivalent". Moreover, they introduced incremental variants of further stable matching problems and performed empirical studies.

More broadly considered, matching problems involving preferences in the presence of change are of high current interest in several application domains. Many such works fall into the category of "dynamic matchings" [1, 2, 14, 15, 34]. However, different from our work, there the focus is typically on adapting classic stability notions to dynamic settings while we rather aim for "reestablishing" (classic) stability at minimal change cost.

Table 1 Overview of our main results where each row contains results for one parameterization. Note that ISM is polynomial-time solvable as proven by Bredereck et al. [7].

	ISR	ISM-T
$\lvert\mathcal{P}_1 \oplus \mathcal{P}_2\rvert$	W[1]-h. (Th. 1) & XP (Th. 2)	NP-h. for $\lvert\mathcal{P}_1 \oplus \mathcal{P}_2\rvert = 1$ (Th. 5)
#ties+k	FPT wrt. k (Th. 1 in [7])	W[1]-h. even if $\lvert\mathcal{P}_1 \oplus \mathcal{P}_2\rvert = 1$ (Th. 5) XP (even for parameter #agents with ties) (Pr. 6)
#outliers	FPT (Th. 10)	?
#master lists	W[1]-h. even for complete preferences (Th. 11/12)	

Closer to our work, there are several papers on adapting a given matching to change (while minimizing the number of reassignments): First, Gajulapalli et al. [20] designed a polynomial-time (and incentive-compatible) algorithm for an incremental variant of the many-to-one version of Stable Marriage (known as Hospital Residents) where new agents are added. Second, Feigenbaum et al. [18] considered an incremental variant of Hospital Residents where some agents may leave the system. They designed a "fair", Pareto-efficient, and strategy-proof algorithm for finding a matching before and after the change. Both these works are closest related to the polynomial-time solvable ISM problem, which we do not study. Third, Bhattacharya et al. [3] studied one-to-one matching markets where agents are added and deleted over time and for some agents the set of acceptable partners may change. Their focus is on updating the matching in each step such that the number of reassignments is small while maintaining a small unpopularity factor. So in contrast to our work, they do not maintain that the matching is stable but (close to) popular.

Also motivated by temporally evolving preferences, several papers study the robustness of stable matchings subject to changing preferences [4, 11, 21, 22, 23, 36]. By selecting a robust initial stable matching, one can increase the odds that it remains stable after some changes.

Our Contributions. Focusing on the two NP-hard problems ISR and ISM-T, we significantly extend the work of Bredereck et al. [7] on incremental stable matchings, particularly answering their two main open questions. Moreover, we strengthen several of their results. In addition, we analyze the impact of the degree of "similarity" between the agents' preference lists. Doing so, from a conceptual perspective, we complement work of Meeks and Rastegari [38]. They studied the influence of the number of agent types on the computational complexity of stable matching problems (two agents are of the same type if they have the same preferences and all other agents are indifferent between them). By way of contrast, we consider the smaller so far unstudied parameter "number of different preference lists".

Next, we present a brief summary of the structure of the paper (for each section marking the main studied problem(s)) and our main contributions (see Table 1 for an overview):

Section 3 (ISR). Motivated by the observation that ISM-T is NP-hard even if just one swap has been performed, Bredereck et al. [7] asked for the parameterized complexity of ISR with respect to the difference $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ between the two given preference profiles. We design and analyze an involved algorithm solving ISR in polynomial time if $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ is constant (in other words, this is an XP-algorithm). Our algorithm relies on the observation that if we know how certain agents are matched in the matching to be constructed and we adapt the given matching accordingly, then we can find an optimal solution by propagating these changes through the matching until a new stable matching is reached; a general approach that might be of independent interest. We complement this result by proving that ISR parameterized by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ is W[1]-hard.

Section 4 (ISM-T). Bredereck et al. [7] considered the total number of ties to be a promising parameter to potentially achieve fixed-parameter tractability results. We prove that this is not the case as ISM-T is W[1]-hard with respect to k *plus* the total number of ties even if $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$. Notably, this result strengthens the W[1]-hardness with respect to k for $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$ of Bredereck et al. [7] for ISM-T, while presenting a fundamentally different yet less technical proof. On the positive side, we devise an XP-algorithm for the number of agents with at least one tie in their preferences.

Section 5 (ISR; ISM-T). We study different cases where the agents have "similar" preferences. For instance, we consider the case where all but s agents have the same preference list (we call these s agents *outliers*), or the case where each agent has one out of only p different *master preference lists*. We devise an algorithm that enumerates all stable matchings in an SR instance in FPT time with respect to s, implying an FPT algorithm for ISR parameterized by s. In contrast to this and to a simple FPT algorithm for the number of agent types [5], we prove that ISR and ISM-T are W[1]-hard with respect to the number p of different preference lists.

2 Preliminaries

The input of Stable Roommates with Ties (SR-T) is a set $A = \{a_1, \dots, a_{2n}\}$ of agents. Each agent $a \in A$ has a subset $\mathrm{Ac}(a) \subseteq A \setminus \{a\}$ of agents it *accepts* and a preference relation $\succsim_a$ which is a weak order over the agents $\mathrm{Ac}(a)$. Without loss of generality, we assume that acceptance is symmetric, i.e., for two agents $a, a' \in A$, $a' \in \mathrm{Ac}(a)$ implies $a \in \mathrm{Ac}(a')$. We collect the preferences of all agents in a *preference profile* $\mathcal{P}$. For two agents $a', a'' \in \mathrm{Ac}(a)$, agent a *weakly prefers* a' to a'' if $a' \succsim_a a''$. If a weakly prefers a' to a'' but does not weakly prefer a'' to a', then a *strictly prefers* a' to a'', and we write $a' \succ_a a''$. If a weakly but not strictly prefers a' to a'', then a is *indifferent* between a' and a'' and we write $a' \sim_a a''$; in other words, a' and a'' are *tied*. If a strictly prefers a' to a'' or $a' = a''$ holds, then we write $a' \succeq_a a''$. We say that an agent a has strict preferences, which we denote as $\succ_a$, if $\succsim_a$ is a strict order, and, in this case, we use the terms "strictly prefer" and "prefer" interchangeably. For two preference relations $\succsim$ and $\succsim'$ defined over the same set, the swap distance between $\succsim$ and $\succsim'$ is the number of agent pairs that are ordered differently by the two relations, i.e., $|\{(a,b) : a \succ b \wedge b \succsim' a\}| + |\{(a,b) : a \sim b \wedge \neg(a \sim' b)\}|$; for two preference relations over different sets, we define the swap distance to be infinite. For two preference profiles $\mathcal{P}_1$ and $\mathcal{P}_2$ containing the preferences of the same agents, $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ denotes the total swap distance between the two preference relations of an agent summed over all agents.[1]

A *matching* M is a set of pairs $\{a, a'\}$ with $a \neq a' \in A$, $a \in \mathrm{Ac}(a')$, and $a' \in \mathrm{Ac}(a)$, where each agent appears in at most one pair. In a matching M, an agent a is *matched* if a is part of one pair from M; otherwise, a is *unmatched*. A *perfect matching* is a matching in which all agents are matched. For a matching M and an agent $a \in A$, we denote by $M(a)$ the partner of a in M, i.e., $M(a) = a'$ if $\{a, a'\} \in M$ and $M(a) := \square$ if a is unmatched in M. All agents $a \in A$ strictly prefer any agent from $\mathrm{Ac}(a)$ to being unmatched, i.e., $a' \succ_a \square$ for all $a \in A$ and $a' \in \mathrm{Ac}(a)$.

[1] Notably, by the equivalence theorem of Boehmer et al. [5, Theorem 1], all our results (except for Theorem 5 where the constant $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ increases by a small number) still hold if $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ instead denotes the number of agents whose preferences changed, the number of deleted agents (i.e., the number of agents with empty preferences in $\mathcal{P}_2$ and non-empty preferences in $\mathcal{P}_1$), or the number of added agents (i.e., the number of agents with empty preferences in $\mathcal{P}_1$ and non-empty preferences in $\mathcal{P}_2$).

Two agents $a \neq a' \in A$ *block* a matching M if a and a' accept each other and strictly prefer each other to their partners in M, i.e., $a \in \mathrm{Ac}(a')$, $a' \in \mathrm{Ac}(a)$, $a' \succ_a M(a)$, and $a \succ_{a'} M(a')$. A matching M is *stable* if it is not blocked by any agent pair.[2] An agent pair $\{a, a'\}$ is called a *stable pair* if there is a stable matching M with $\{a, a'\} \in M$. For two matchings M and M', we denote by $M \triangle M'$ the set of pairs that appear only in M or only in M', i.e., $M \triangle M' = \{\{a, a'\} \mid (\{a, a'\} \in M \wedge \{a, a'\} \notin M') \vee (\{a, a'\} \notin M \wedge \{a, a'\} \in M')\}$. The incremental variant of Stable Roommates [with Ties] is defined as follows.

> Incremental Stable Roommates [with Ties] (ISR/[ISR-T])
> **Input:** A set A of agents, two preference profiles $\mathcal{P}_1$ and $\mathcal{P}_2$ containing the strict [weak] preferences of all agents, a stable matching M_1 in $\mathcal{P}_1$, and an integer k.
> **Question:** Is there a matching M_2 that is stable in $\mathcal{P}_2$ such that $|M_1 \triangle M_2| \leq k$?

We also consider the incremental variant of Stable Marriage. Instances of Stable Marriage are instances of Stable Roommates where the set of agents is partitioned into two sets U and W such that agents from one of the sets only accept agents from the other set, i.e., $\mathrm{Ac}(m) \subseteq W$ for all $m \in U$ and $\mathrm{Ac}(w) \subseteq U$ for all $w \in W$. Following traditional conventions, we refer to the agents from U as men and to the agents from W as women. All definitions from above still analogously apply to Stable Marriage. Thus, in Incremental Stable Marriage [with Ties] (ISM/[ISM-T]), we are given a set $A = U \cup W$ of agents and two preference profiles $\mathcal{P}_1$ and $\mathcal{P}_2$ containing the strict [weak] preferences of all agents, where each $m \in U$ accepts only agents from W and the other way round.

Lastly, in Stable Roommates, the preferences of an agent $a \in A$ are *complete* if $\mathrm{Ac}(a) = A \setminus \{a\}$. In Stable Marriage, the preferences of an agent $a \in U \cup W$ are *complete* if $\mathrm{Ac}(a) = W$ for $a \in U$ or if $\mathrm{Ac}(a) = U$ for $a \in W$. If the preferences of an agent are not complete, then they are *incomplete*.

We defer the proofs (or their completions) of all results marked by $(\star)$ to a full version.

3 Incremental Stable Roommates Parameterized by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$

Bredereck et al. [7] showed that ISR-T and ISM-T are NP-hard even if $\mathcal{P}_1$ and $\mathcal{P}_2$ differ only by a single swap. While Bredereck et al. showed that ISR (without ties) is NP-hard, they asked whether it is fixed-parameter tractable parameterized by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$. We show that ISR is W[1]-hard with respect to $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ (Section 3.1), yet admits an intricate polynomial-time algorithm for constant $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ (Section 3.2), thus still clearly distinguishing it from the case with ties.

3.1 W[1]-Hardness

This section is devoted to proving that ISR with respect to $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ is W[1]-hard:

▶ **Theorem 1** $(\star)$. *ISR parameterized by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$ is W[1]-hard.*

To prove the theorem, we reduce from the W[1]-hard Multicolored Clique problem parameterized by the solution size ℓ [39]. In Multicolored Clique, we are given an ℓ-partite graph $G = (V^1 \cup V^2 \cup \dots \cup V^\ell, E)$ and the question is whether there is a clique X

[2] This definition of stability in the presence of ties is the by far most frequently studied variant known as *weak stability*. *Strong stability* and *super stability* are the two most popular alternatives. Notably, ISM-T (as defined later) becomes polynomial-time solvable for both strong and super stability, as for these two stability notions a stable matching maximizing a given weight function on all pairs of agents can be found in polynomial time [19, 32, 33].

of size ℓ in G with $X \cap V^c \neq \emptyset$ for all $c \in [\ell]$. To simplify notation, we assume that $V^c = \{v_1^c, \ldots, v_\nu^c\}$ for all $c \in [\ell]$ and that the given graph G is r-regular for some $r \in \mathbb{N}$. We refer to the elements of $[\ell]$ as *colors* and say that a vertex v has color $c \in [\ell]$ if $v \in V^c$. The structure of the reduction is as follows. For each color $c \in [\ell]$, there is a vertex-selection gadget, encoding which vertex from V^c is part of the multicolored clique. Furthermore, there is one edge gadget for each edge. Unless both endpoints of an edge are selected by the corresponding vertex-selection gadgets, the matching M_2 selected in the edge gadget contributes to the difference $M_1 \triangle M_2$ between M_1 and M_2. We set k (that is, the upper bound on $|M_1 \triangle M_2|$) such that at least $\binom{\ell}{2}$ edges need to have both endpoints in the selected set of vertices, implying that the selected set of vertices forms a clique.

Vertex-Selection Gadget. For each color $c \in [\ell]$, we add a vertex selection gadget. For each vertex $v_i^c \in V^c$, we add one 4-cycle consisting of agents $a_{i,1}^c$, $a_{i,2}^c$, $a_{i,3}^c$, and $a_{i,4}^c$. Further, in $\mathcal{P}_2$, two agents s^c and $\bar{s}^c$ are "added" to the gadget (more formally, s^c and $\bar{s}^c$ are matched to dummy agents t^c and $\bar{t}^c$ in all stable matching in $\mathcal{P}_1$ but cannot be matched to t^c and $\bar{t}^c$ in a stable matching in $\mathcal{P}_2$). We construct the vertex-selection gadget such that the agents s^c and $\bar{s}^c$ have to be matched to agents from the same 4-cycle in a stable matching in $\mathcal{P}_2$. This encodes the selection of the vertex corresponding to this 4-cycle to be part of the multicolored clique. Lastly, we add a second 4-cycle consisting of agents $\bar{a}_{i,1}^c$, $\bar{a}_{i,2}^c$, $\bar{a}_{i,3}^c$, and $\bar{a}_{i,4}^c$ for each vertex $v_i^c \in V^c$ to achieve that $M_1 \triangle M_2$ contains the same number of pairs from the vertex-selection gadget, independent of which vertex is selected to be part of the clique.

Apart from agents s^c and $\bar{s}^c$, all agents from the vertex-selection gadget only find agents from the gadget acceptable, while s^c and $\bar{s}^c$ also find agent $a_{e,1}$ (this agent will be introduced in the next paragraph "Edge Gadget") for each edge e incident to a vertex from V^c acceptable. For $v_i^c \in V^c$, let $A_{\delta(v_i^c),1}$ denote the set of agents $a_{e,1}$ such that e is an edge incident to v_i^c, i.e., $A_{\delta(v_i^c),1} := \{a_{e,1} \mid e \in E \wedge e \cap v_i^c \neq \emptyset\}$, and let $[A_{\delta(v_i^c),1}]$ denote an arbitrary strict order of $A_{\delta(v_i^c),1}$. For all $c \in [\ell]$ and $i \in [n]$, each vertex-selection gadget contains the following agents with the indicated preferences in $\mathcal{P}_1$:

$$
\begin{aligned}
&s^c : t^c \succ a_{1,1}^c \succ \bar{a}_{1,1}^c \succ [A_{\delta(v_1^c),1}] \succ a_{2,1}^c \succ \bar{a}_{2,1}^c \succ [A_{\delta(v_2^c),1}] \succ \cdots \succ a_{n,1}^c \\
&\quad \succ \bar{a}_{n,1}^c \succ [A_{\delta(v_1^n),1}] \\
&\bar{s}^c : \bar{t}^c \succ a_{n,4}^c \succ \bar{a}_{n,4}^c \succ [A_{\delta(v_n^c),1}] \succ a_{n-1,4}^c \succ \bar{a}_{n-1,4}^c \succ [A_{\delta(v_{n-1}^c),1}] \succ \cdots \succ a_{1,4}^c \\
&\quad \succ \bar{a}_{1,4}^c \succ [A_{\delta(v_1^c),1}]
\end{aligned}
$$

$$
t^c : s^c \succ u^c, \qquad \bar{t}^c : \bar{s}^c \succ \bar{u}^c, \qquad u^c : t^c, \qquad \bar{u}^c : \bar{t}^c
$$

$$
\begin{aligned}
&a_{i,1}^c : a_{i,2}^c \succ s^c \succ a_{i,4}^c, \quad a_{i,2}^c : a_{i,3}^c \succ a_{i,1}^c, \quad a_{i,3}^c : a_{i,4}^c \succ a_{i,2}^c, \quad a_{i,4}^c : a_{i,1}^c \succ \bar{s}^c \succ a_{i,3}^c \\
&\bar{a}_{i,1}^c : \bar{a}_{i,2}^c \succ s^c \succ \bar{a}_{i,4}^c, \quad \bar{a}_{i,2}^c : \bar{a}_{i,3}^c \succ \bar{a}_{i,1}^c, \quad \bar{a}_{i,3}^c : \bar{a}_{i,4}^c \succ \bar{a}_{i,2}^c, \quad \bar{a}_{i,4}^c : \bar{a}_{i,1}^c \succ \bar{s}^c \succ \bar{a}_{i,3}^c
\end{aligned}
$$

In $\mathcal{P}_2$, only the preferences of agents t^c and $t^{\bar{c}}$ change to $u^c \succ s^c$, respectively, $\bar{u}^c \succ \bar{s}^c$. See Figure 1 for an example. Notably, in each of the added 4-cycles, there exist two matchings of the four agents that are stable within the cycle in both $\mathcal{P}_1$ and $\mathcal{P}_2$ (i.e., $\{\{a_{i,1}^c, a_{i,2}^c\}, \{a_{i,3}^c, a_{i,4}^c\}\}$ or $\{\{a_{i,1}^c, a_{i,4}^c\}, \{a_{i,2}^c, a_{i,3}^c\}\}$ and $\{\{\bar{a}_{i,1}^c, \bar{a}_{i,2}^c\}, \{\bar{a}_{i,3}^c, \bar{a}_{i,4}^c\}\}$ or $\{\{\bar{a}_{i,1}^c, \bar{a}_{i,4}^c\}, \{\bar{a}_{i,2}^c, \bar{a}_{i,3}^c\}\}$ for $c \in [\ell]$ and $i \in [\nu]$). Matching M_1 contains for the 4-cycles consisting of agents $\{a_{i,t}^c \mid t \in [4]\}$ the edges $\{a_{i,1}^c, a_{i,2}^c\}$ and $\{a_{i,3}^c, a_{i,4}^c\}$ and for the 4-cycles consisting of agents $\{\bar{a}_{i,t}^c \mid t \in [4]\}$ the edges $\{\bar{a}_{i,1}^c, \bar{a}_{i,4}^c\}$ and $\{\bar{a}_{i,2}^c, \bar{a}_{i,3}^c\}$.

Edge Gadget. For each edge $e = \{v_i^c, v_j^{\hat{c}}\}$, we add an edge gadget. This gadget consists of a 4-cycle with agents $a_{e,1}$, $a_{e,2}$, $a_{e,3}$, and $a_{e,4}$, admitting two different matchings that are stable *within* the gadget in both $\mathcal{P}_1$ and $\mathcal{P}_2$. The matching M_1 contains $\{a_{e,1}, a_{e,4}\}$ and $\{a_{e,3}, a_{e,2}\}$

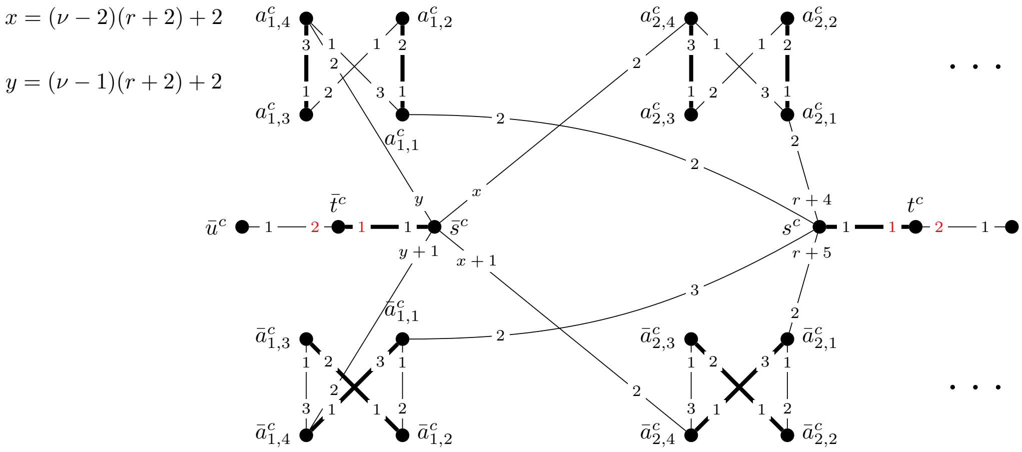

Figure 1 An example for the vertex-selection gadget from Theorem 1. For an edge between two agents a and a', the number x closer to agent a means that a ranks a' at position x, i.e., there are $x-1$ agents which a prefers to a'. For example, the preferences of $a^c_{1,4}$ are $a^c_{1,1} \succ \bar{s}^c \succ a^c_{1,3}$. The depicted preferences are those in $\mathcal{P}_1$. The preferences in $\mathcal{P}_2$ arise from swapping the red numbers. The matching M_1 is marked in bold.

in this 4-cycle and remains stable in M_2 if all of s^c, $\bar{s}^c$, $s^{\hat{c}}$, and $\bar{s}^{\hat{c}}$ are matched at least as good as the respective agents corresponding to v^c_i and $v^{\hat{c}}_j$. This notably only happens if the vertex-selection gadgets of V^c and $V^{\hat{c}}$ "select" the endpoints of e. Otherwise, the agents in this component need to be matched as $\{a_{e,1}, a_{e,2}\}$ and $\{a_{e,3}, a_{e,4}\}$ in M_2, thereby contributing four pairs to $M_1 \triangle M_2$. For each $e = \{v^c_i, v^{\hat{c}}_j\} \in E$, the agent's preferences are as follows:

$$a_{e,1} : a_{e,2} \succ s^c \succ \bar{s}^c \succ s^{\hat{c}} \succ \bar{s}^{\hat{c}} \succ a_{e,4}, \qquad a_{e,2} : a_{e,3} \succ a_{e,1},$$
$$a_{e,3} : a_{e,4} \succ a_{e,2}, \qquad a_{e,4} : a_{e,1} \succ a_{e,3}.$$

The Reduction. To complete the description of the parameterized reduction, we set $M_1 := \{\{s^c, t^c\}, \{\bar{s}^c, \bar{t}^c\} \mid c \in [\ell]\} \cup \{\{a^c_{i,1}, a^c_{i,2}\}, \{a^c_{i,3}, a^c_{i,4}\}, \{\bar{a}^c_{i,1}, \bar{a}^c_{i,4}\}, \{\bar{a}^c_{i,3}, \bar{a}^c_{i,2}\} \mid c \in [\ell], i \in [\nu]\} \cup \{\{a_{e,1}, a_{e,4}\}, \{a_{e,3}, a_{e,2}\} \mid e \in E\}$ and $k := \ell \cdot (4\nu + 5) + 4(|E| - \binom{\ell}{2})$.

For the correctness of the reduction one can show that in M_2 for each $c \in [\ell]$ there is some $i^* \in [\nu]$ such that the matching M_2 contains pairs $\{s^c, a^c_{i^*,1}\}$, $\{\bar{s}^c, a^c_{i^*,4}\}$ (this corresponds to selecting vertex $v^c_{i^*}$ for color c). Then, the only agents $a_{e,1}$ for an edge $e \in E$ incident to some vertex from V^c that both s^c and $\bar{s}^c$ do not prefer to their partner in M_2 are those in $A_{\delta(v^c_{i^*}),1}$. This implies that for all edges $e = \{v^c_i, v^{\hat{c}}_j\}$ with both endpoints selected we can match $a_{e,1}$ worse than s^c, $\bar{s}^c$, $s^{\hat{c}}$, and $\bar{s}^{\hat{c}}$. Thus, we can select $\{a_{e,1}, a_{e,4}\}, \{a_{e,2}, a_{e,3}\}$ as in M_1 in the respective edge gadget. In contrast, for all other edges we have to select the other matching in the edge gadget. To upper-bound the overall symmetric difference, one needs to further prove that for all $j < i^*$, matching M_2 contains $\{\{\bar{a}^c_{j,1}, \bar{a}^c_{j,2}\}, \{\bar{a}^c_{j,3}, \bar{a}^c_{j,4}\}\}$, and that for all $j > i^*$, matching M_2 contains $\{\{a^c_{j,1}, a^c_{j,4}\}, \{a^c_{j,2}, a^c_{j,3}\}\}$. Thus, independent of the selected vertex, each vertex-selection gadget contributes $4\nu + 5$ pairs to $M_1 \triangle M_2$.

3.2 XP-Algorithm

Complementing the above W[1]-hardness result, we now sketch an intricate XP-algorithm for ISR parameterized by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$, resulting in the following theorem:

▶ **Theorem 2** (⋆). *ISR can be solved in $\mathcal{O}(2^{4|\mathcal{P}_1 \oplus \mathcal{P}_2|} \cdot n^{5|\mathcal{P}_1 \oplus \mathcal{P}_2|+3})$ time.*

Our algorithm works in two phases: In the initialization phase, we make some guesses how the stable matching M_2 looks like and accordingly change the original stable matching M_1. These changes and guesses then impose certain constraints how good/bad some agents must be matched in M_2. Subsequently, in the propagation phase, we locally resolve blocking pairs caused by the initial changes by "propagating" these constraints through the instance until a new stable matching is reached. This matching is then guaranteed to be as close as possible to the original stable matching. We believe that our technique to propagate changes through a matching is also of independent interest and might find applications elsewhere. In the following, we sketch the main ingredients of our algorithm. We say that we *update a matching M to contain a pair $e = \{a, b\}$* if we delete all pairs containing a or b from M and add pair e to M.

Initialization Phase (First Part of Description). Our algorithm maintains a matching M. At the beginning, we set $M := M_1$. Before we change M, we make some guesses on how the output matching M_2 shall look like. These guesses are responsible for the exponential part of the running time (the rest of our algorithm runs in polynomial time). The guesses result in some changes to M and, for some agents $a \in A$, in a "best case" and "worst case" to which partner a can be matched in M_2. Consequently, we will store in $\mathrm{bc}(a)$ the *best case* how a may be matched in M_2, i.e., the most-preferred (by a in $\mathcal{P}_2$) agent b for which we cannot exclude that a is matched to b in a stable matching in $\mathcal{P}_2$ respecting the guesses. Similarly, $\mathrm{wc}(a)$ stores the *worst case* to which a can be matched. We initialize $\mathrm{bc}(a) = \mathrm{wc}(a) = \perp$ for all $a \in A$, encoding that we do not know a best or worst case yet.

To be more specific, among others, in the initialization phase we guess for each agent $a \in A$ with modified preferences as well as for $M_1(a)$ how they are matched in M_2 and update M to include the guessed pairs. Moreover, as an unmatched agent a shall always have $\mathrm{bc}(a) \neq \perp$ or $\mathrm{wc}(a) \neq \perp$, we guess for all agents a that became unmatched by this whether they prefer $M_1(a)$ to $M_2(a)$ (in which case we set $\mathrm{bc}(a) := M_1(a)$) or $M_2(a)$ to $M_1(a)$ (in which case we set $\mathrm{wc}(a) := M_1(a)$). Our algorithm also makes further guesses in the initialization phase. However, in order to understand the purpose of these additional guesses, it is helpful to first understand the propagation phase in some detail. Thus, we postpone the description of the additional guesses to the end of this section.

Propagation Phase. After the initialization phase, blocking pairs for the current matching M force the algorithm to further change M and force a propagation of best and worst cases through the instance until a stable matching is reached. As our updates to M are in some sense "minimally invasive" and exhaustive, once M is stable in $\mathcal{P}_2$, it is guaranteed to be the stable matching in $\mathcal{P}_2$ which is closest to M_1 among all matchings respecting the initial guesses. At the core of the technique lies the simple observation that in an SR instance for each stable pair $\{c, d\}$ and each stable matching N not including $\{c, d\}$ exactly one of c and d prefers the other to its partner in N:

▶ **Lemma 3** ([26, Lemma 4.3.9]). *Let N be a stable matching and $e = \{c, d\} \notin N$ be a stable pair in an SR instance. Then either $N(c) \succ_c d$ and $c \succ_d N(d)$ or $d \succ_c N(c)$ and $N(d) \succ_d c$.*

From this we can draw conclusions in the following spirit: Assuming that for a stable pair $\{c, d\}$ in $\mathcal{P}_2$ we have that $\mathrm{wc}(c) \succ_c d$, i.e., c is matched better than d in M_2, it follows from Lemma 3 that d is matched worse than c in M_2, implying that we can safely set $\mathrm{bc}(d) = c$.

Algorithm 1 Simplified propagation step performed for a pair $\{a, b\}$ of two matched agents blocking M with $\mathrm{bc}(b) = M(b)$ or for an unmatched agent a with $\mathrm{wc}(a) \neq \bot$.

```
1: if a is unmatched then Let $e = \{a, c\}$ be the stable pair in $\mathcal{P}_2$ such that $c \succ_a^{\mathcal{P}_2} \mathrm{wc}(a)$
   and $\mathrm{bc}(c) \succ_c^{\mathcal{P}_2} a$ (or $\mathrm{bc}(c) = \bot$) and $c$ is worst-ranked by $a$ among all such pairs.
2: else Let $e = \{a, c\}$ be the stable pair in $\mathcal{P}_2$ such that $c \succ_a^{\mathcal{P}_2} M(a)$ and $\mathrm{bc}(c) \succ_c^{\mathcal{P}_2} a$ (or
   $\mathrm{bc}(c) = \bot$) and $c$ is worst-ranked by $a$ among all such pairs.
3: if no such pair exists then Reject this guess.
4: else Update $M$ such that it contains $e$, set $\mathrm{wc}(a) := c$ and $\mathrm{bc}(c) := a$.
5:     if $M(a) \neq \square$ then $\mathrm{bc}(M(a)) := a$.
6:     if $M(c) \neq \square$ then $\mathrm{wc}(M(c)) := c$.
```

In the following, we will now explain simplified versions of some parts of the propagation phase, while leaving out others (in fact, for the full algorithm and proof of correctness an extensive analysis is needed; see our full version).

Assume for a moment that the current matching M is perfect and that there is a blocking pair for M in $\mathcal{P}_2$ (see Algorithm 1 for a pseudocode-description of the following procedure). Because M_1 is stable in $\mathcal{P}_1$, all pairs that currently block M_1 either involve an agent with changed preferences or resulted from previous changes made to M. Using this, one can show that at least one of the two agents from a blocking pair $\{a, b\}$, say b, will have $a \succ_b \mathrm{bc}(b) = M(b)$. Thus, we know that b is matched worse than a in any stable matching in $\mathcal{P}_2$ respecting our current guesses. Accordingly, for $\{a, b\}$ not to block M_2, agent a has to be matched to b or better and, in particular, better than $M(a)$ in the solution. As a consequence, we update the worst case of a to be the next agent c which a prefers to $M(a)$ such that $\{a, c\}$ is a stable pair in $\mathcal{P}_2$, i.e., we set $\mathrm{wc}(a) := c$ (see Line 4). This change is then further propagated through the instance. Note that from Lemma 3 it follows that if $\{a', a''\}$ is a stable pair in $\mathcal{P}_2$ and agent a'' is the worst possible partner of a' in a stable matching in $\mathcal{P}_2$ (or a' prefers its worst possible partner to a''), then agent a'' cannot be matched better than agent a' in a stable matching in $\mathcal{P}_2$. Thus, by setting $\mathrm{wc}(a') := a''$ we also get $\mathrm{bc}(a'') := a'$. Consequently, applying this to our previous update $\mathrm{wc}(a) = c$, we can also set $\mathrm{bc}(c) := a$ (see Line 4). Moreover, recall that a prefers c to a's current partner $M(a)$ in M. Thus, assuming that in a stable matching M^* in $\mathcal{P}_2$ one of a and $M(a)$ prefers the other to its partner in M^* and the other prefers its partner in M^*, we can use the same argument again and set $\mathrm{bc}(M(a)) := a$ (see Line 5; we will discuss in the last paragraph in this section why this assumption can be made). For the update in Line 6 a similar reasoning applies.

So far we assumed that all agents are matched (which indeed needs to be the case for M_2 because we can delete all agents not matched by M_2 in a preprocessing step). Using this, whenever there is an unmatched agent a, one can show that it cannot be matched to $\mathrm{bc}(a)$ or $\mathrm{wc}(a)$. Thus, if $\mathrm{wc}(a) \neq \bot$, then we match a to the next-better agent c before $\mathrm{wc}(a)$ in its preferences such that $\{a, c\}$ is a stable pair in $\mathcal{P}_2$ and set $\mathrm{wc}(a) = c$. Subsequently, we propagate this change as in the above described case of a blocking pair (see Algorithm 1). Otherwise, we have $\mathrm{bc}(a) \neq \bot$ and we match a to the next-worse agent b after $\mathrm{bc}(a)$ in the preferences of a such that $\{a, b\}$ is a stable pair in $\mathcal{P}_2$. Here, a slightly more complicated subsequent propagation step is needed (as described in our full version).

Repeating these steps, i.e., matching so far unmatched agents and resolving blocking pairs, eventually either results in a conflict (i.e., an agent preferring its worst case to its best case, or changing a pair which we guessed to be part of M_2) or in a stable matching. In the first case, we conclude that no stable matching obeying our guesses exists, while in the latter case, we found a stable matching obeying the guesses and minimizing the symmetric difference to M_1 among all such matchings. The reason for the optimality of this matching is that every matching obeying our initial guesses has to obey the best and worst cases at the termination of the algorithm, and the computed matching M contains all pairs from M_1 which comply with the best and worst cases.

Initialization Phase (Second Part of Description). In addition to the guesses described above, the algorithm guesses the set F of pairs from M_1 for which both endpoints prefer M_2 to M_1. Similarly, the algorithm guesses the set H of pairs from M_2 for which both endpoints prefer M_1 to M_2. Notably, one can prove that the cardinality of both F and H can be upper-bounded by $|\mathcal{P}_1 \oplus \mathcal{P}_2|$, ensuring XP-running time. The reason why we need to guess the set F is that pairs $\{a, b\}$ from M_1 may not be stable pairs in $\mathcal{P}_2$. In this case, a preferring $M(a)$ to b does not imply that b prefers a to $M(b)$. Thus, if we would treat the pairs from F as "normal" pairs, we would propagate an incorrect worst case in Line 5. Note that all pairs from $M \setminus M_1$ are stable pairs in $\mathcal{P}_2$, as we only add pairs that are stable over time (see Line 4). The reason why we need to guess the set H is more subtle but also due to fact that pairs from H might cause problems for our propagation step (see our full version). To incorporate our guesses, for each $\{a, b\} \in F$, we delete $\{a, b\}$ from M and set $\text{wc}(a) = b$ and $\text{wc}(b) = a$, while for each $\{a, b\} \in H$ we update M to include H. We remark that from the proof of Theorem 1 it follows that ISR is NP-complete even if we know for each agent a whose preferences changed as well as $M_1(a)$ how they are matched in M_2 and the set of pairs $F \subseteq M_1$ for which both endpoints prefer M_2 to M_1. This indicates that guessing the set H might be necessary for an XP-algorithm.

4 Incremental Stable Marriage with Ties Parameterized by the Number of Ties

Bredereck et al. [7] raised the question how the total number of ties influences the computational complexity of ISM-T. Note that the number of ties in a preference relation is the number of equivalence classes of the relation containing more than one agent. For instance the preference relation $a \sim b \sim c \succ d \sim e \succ f$ contains two ties, where the first tie has size three and the second tie has size two. In this section, following a fundamentally different and significantly simpler path than Bredereck et al., we show that their W[1]-hardness result for ISM-T parameterized by k for $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$ still holds if we parameterize by k *plus* the number of ties. To prove this, we introduce a natural extension of ISM called Incremental Stable Marriage with Forced Edges (ISMFE). ISMFE differs from ISM in that as part of the input we are additionally given a subset $Q \subseteq M_1$ of the initial matching, and the question is whether there is a stable matching M_2 for the changed preferences with $|M_1 \triangle M_2| \leq k$ containing all pairs from Q, i.e., $Q \subseteq M_2$.

We first show that ISMFE with ties is intractable even if $|Q| = 1$ by reducing from a W[1]-hard local search problem related to finding a perfect stable matching with ties [37]:

▶ **Proposition 4** ($\star$). *ISMFE with ties parameterized by k and the summed number of ties in $\mathcal{P}_1$ and $\mathcal{P}_2$ is W[1]-hard, even if $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$ and $|Q| = 1$ and only women have ties in their preferences.*

Second, we reduce ISMFE with ties to ISM-T. The general idea of this parameterized reduction is to replace a forced pair $\{m, w\} \in Q$ by a gadget consisting of $6(k + 1)$ agents. In M_1, we match the agents from the gadget in a way such that if m and w are matched differently in M_2, then, compared to M_1, the matching in the whole gadget needs to be changed, thereby exceeding the given budget k. This reduction implies:

▶ **Theorem 5** (⋆)**.** *ISM-T parameterized by k and the summed number of ties in $\mathcal{P}_1$ and $\mathcal{P}_2$ is W[1]-hard, even if $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$ and only women have ties in their preferences.*

We remark that our reduction also implies the W[1]-hardness of ISM-T parameterized by k if each tie has size at most two and $|\mathcal{P}_1 \oplus \mathcal{P}_2| = 1$.

On the algorithmic side, parameterized by the number of agents with at least one tie in their preferences in $\mathcal{P}_2$, ISM-T lies in XP. The idea of our algorithm is to first guess the partners of all agents in M_2 with a tie in their preferences in $\mathcal{P}_2$ and subsequently reduce the problem to an instance of Weighted Stable Marriage, which is polynomial-time solvable [17]. Note that parameterizing by the summed size of all ties results in fixed-parameter tractability, as we can iterate over all possibilities of breaking the ties and subsequently apply the algorithm for ISM.

▶ **Proposition 6** (⋆)**.** *ISM-T parameterized by the number of agents with at least one tie in their preferences in $\mathcal{P}_2$ lies in XP. ISM-T parameterized by the summed size of all ties in $\mathcal{P}_2$ is fixed-parameter tractable.*

5 Master Lists

After having shown in the previous section that ISM-T and ISR mostly remain intractable even if we restrict several problem-specific parameters, in this section we analyze the influence of the structure of the preference profiles by considering what happens if the agents' preferences are similar to each other. The arguably most popular approach in this direction is to assume that there exists a single central order (called master list) and that all agents derive their preferences from this order. This approach has already been applied to different stable matching problems in the quest for making them tractable [8, 13, 29, 30]. Specifically, we analyze in Section 5.1 the case where the preferences of all agents follow a single master list, in Section 5.2 the case where all but few agents have the same preference list, and in Section 5.3 the case where each agent has one of few different preference lists (which generalizes the setting considered in Section 5.2).

5.1 One Master List

In an instance of Stable Marriage/Roommates with agent set A, we say that the preferences of agent $a \in A$ can be *derived* from some preference list $\succsim^*$ over agents A if the preferences of a are $\succsim^*$ restricted to $\mathrm{Ac}(a)$. If the preferences of all agents in $\mathcal{P}_2$ can be derived from the same strict preference list (which is typically called *master list*), then there is a unique stable matching in $\mathcal{P}_2$ which iteratively matches the so-far unmatched top-ranked agent in the master list to the highest ranked agent it accepts:

▶ **Observation 7.** *If all preferences in $\mathcal{P}_2$ can be derived from the same strict preference list, then ISR can be solved in linear time.*

This raises the question what happens when the master list is not a strict but a weak order. If the preferences of the agents may be incomplete, then reducing from the NP-hard Weakly Stable Pair problem (the question is whether there is a stable matching in an SM-T/SR-T instance containing a given pair [29, Lemma 3.4]), one can show that even assuming that all preferences are derived from a weak master list is not sufficient to make ISM-T or ISR-T polynomial-time solvable.

▶ **Observation 8** (⋆)**.** *ISM-T and ISR-T are NP-hard even if all preferences in $\mathcal{P}_1$ and $\mathcal{P}_2$ can be derived from the same weak preference list.*

In contrast to this, if we assume that the preferences of agents in $\mathcal{P}_2$ are complete and derived from a weak master list, then we can solve ISM-T and ISR-T in polynomial time. While for ISM-T this follows from a characterization of stable matchings in such instances as the perfect matchings in a bipartite graph due to Irving et al. [29, Lemma 4.3], for ISR-T this characterization does not directly carry over. Thus, we need a new algorithm: Assume that the master list consists of q ties (possibly containing just one agent) and let $A_i \subseteq A$ be the set of agents from the ith tie for $i \in [q]$. Distinguishing between several cases, we build the matching M_2 by dealing for increasing $i \in [q]$ with each tie separately while greedily maximizing the overlap of the so-far constructed matching with M_1. Our algorithm exploits the observation that in a stable matching, for $i \in [q]$, all agents from A_i are matched to agents from A_i except if (i) $|\bigcup_{j \in [i-1]} A_j|$ is odd in which case one agent from A_i is matched to an agent from A_{i-1}, or (ii) if $|\bigcup_{j \in [i]} A_j|$ is odd in which case one agent from A_i is matched to an agent from A_{i+1}.

▶ **Proposition 9** (⋆). *If the preferences of agents in $\mathcal{P}_2$ are complete and derived from a weak master list, then ISM-T/ISR-T can be solved in polynomial time.*

5.2 Few Outliers

Next, we consider the case that almost all agents derive their complete preferences from a single strict preference list (we will call these agents *followers*), while the remaining agents (we will call those agents *outliers*) have arbitrary preferences. ISR is fixed-parameter tractable with respect to the number of outliers, as we show that all stable matchings in a Stable Roommates instance can be enumerated in FPT time with respect to this parameter:

▶ **Theorem 10** (⋆). *Given a Stable Roommates instance $(A, \mathcal{P})$ and a partitioning $F \uplus S$ of the agents A such that all agents from F have complete preferences that can be derived from the same strict preference list, one can enumerate all stable matchings in $(A, \mathcal{P})$ in $\mathcal{O}(n^2 \cdot |S|^{|S|})$ time. Consequently, ISR is solvable in $\mathcal{O}(n^2 \cdot |S|^{|S|})$ time, where $|S|$ is the number of outliers in $\mathcal{P}_2$.*

If the master list may contains ties, then enumerating stable matchings becomes a lot more complicated, as here we have much more flexibility on how the agents are matched. Thus, we leave it open whether there exists a similar fixed-parameter tractability result for a weak master list (both in the roommates and marriage setting).

5.3 Few Master Lists

Motivated by the positive result from Section 5.2, in this section we consider the smaller parameter “number of different preference lists”. Recall that Observation 7 states that if the preference lists of all agents are derived from a strict master list in a Stable Roommates instance, then there exists only one stable matching (even if the preferences of the agents may be incomplete). This raises the question what happens if there exist “few” master lists and each agent derives its preferences from one of the lists. To the best of our knowledge, the parameter “number of master lists” has not been considered before. However, it nicely complements (and lower-bounds) the parameter “number of agent types” as studied by Meeks and Rastegari [38]. Two agents are of the same type if they have the same preferences and all other agents are indifferent between them. Notably, Boehmer et al. [5, Proposition 5] proved that ISM-T is fixed-parameter tractable with respect to the number of agent types. Their algorithm also works for ISR-T.

If the preferences of agents are incomplete, then as proven in Observation 8, ISM-T is already NP-hard for just one weak master list. Moreover, note that a reduction of Cseh and Manlove [12, Theorem 4.2] implies that ISR with incomplete preferences is NP-hard even if the preferences of each agent are derived from one of two weak preference lists. Consequently, in this subsection we focus on the case with complete preferences.

In contrast to the two fixed-parameter tractability results for the number of outliers (Theorem 10) and the number of agent types [5], we show that parameterized by the number p of master lists, ISR is W[1]-hard even if the preferences of agents are complete:

▶ **Theorem 11** (⋆). *ISR is W[1]-hard parameterized by the minimum number p such that in $\mathcal{P}_2$ the preferences of each agent can be derived from one of p strict preference lists, even if in $\mathcal{P}_1$ as well as in $\mathcal{P}_2$ all agents have complete preferences.*

Containment of this problem in XP is an intriguing open question; in other words, is there a polynomial-time algorithm if the number of master lists is constant?

Recalling that ISM-T is polynomial-time solvable if agents have complete preferences derived from one weak master list (Proposition 9), we now ask the same question for ISM-T. Using a similar but slightly more involved reduction than for Theorem 11, we show that this problem is W[1]-hard with respect to the number of master lists.

▶ **Theorem 12** (⋆). *ISM-T is W[1]-hard parameterized by the minimum number p such that in $\mathcal{P}_2$ the preferences of each agent can be derived from one of p weakly ordered preference lists, even if in $\mathcal{P}_1$ as well as in $\mathcal{P}_2$ all agents have complete preferences.*

Again, it remains open whether ISM-T for a constant number of master lists is polynomial-time solvable or NP-hard.

6 Conclusion

Among others, answering two open questions of Bredereck et al. [7], we have contributed to the study of the computational complexity of adapting stable matchings to changing preferences. From a broader algorithmic perspective, in particular, the “propagation” technique from our XP-algorithm for the number of swaps, and the study of the number of different preference lists/master lists as a new parameter together with the needed involved constructions for the two respective hardness proofs could be of interest.

There are several possibilities for future work. As direct open questions, for the parameterization by the number of outliers, we do not know whether ISM-T or ISR-T are fixed-parameter tractable. Moreover, it remains open whether ISR or ISM-T with complete preferences is polynomial-time solvable for a constant number of master lists.

Finally, it would also be interesting to analyze a variation of ISR or ISM where the matching in $\mathcal{P}_1$ is not given, i.e., we have to find two matchings M_1 and M_2 with $|M_1 \triangle M_2| \leq k$ such that M_1 is stable in $\mathcal{P}_1$ and M_2 is stable in $\mathcal{P}_2$. Notably, this is a special case of a multistage [16, 25] variant of stable matching problems and Chen et al. [10] already proved that this problem is NP-hard for $k = 0$ in the bipartite case.

Abstract

We study the problem of online tree exploration by a deterministic mobile agent. Our main objective is to establish what features of the model of the mobile agent and the environment allow linear exploration time. We study agents that, upon entering a node, do not receive as input the edge via which they entered. In such model, deterministic memoryless exploration is infeasible, hence the agent needs to be allowed to use some memory. The memory can be located at the agent or at each node. The existing lower bounds show that if the memory is either only at the agent or only at the nodes, then the exploration needs superlinear time. We show that tree exploration in dual-memory model, with constant memory at the agent and logarithmic in the degree at each node is possible in linear time when one of the two additional features is present: fixed initial state of the memory at each node (so called clean memory) or a single movable token. We present two algorithms working in linear time for arbitrary trees in these two models. On the other hand, in our lower bound we show that if the agent has a single bit of memory and one bit is present at each node, then the exploration may require quadratic time even on paths, if the initial memory at nodes could be set arbitrarily (so called dirty memory). This shows that having clean node memory or a token allows linear time exploration of trees in the dual-memory model, but having neither of those features may lead to quadratic exploration time even on a simple path.

1 Introduction

Consider a mobile entity deployed inside an undirected graph with the objective to visit all its nodes without any a priori knowledge of the topology or size of the graph. This problem, called a graph exploration, is among the basic problems investigated in the context of a mobile agent in a graph [1, 10, 24, 26, 33] and has applications to robot navigation [35] and searching the World Wide Web [7]. In this paper we focus on tree exploration by a deterministic agent. Clearly, to explore the whole tree of n nodes, any agent needs time $\Omega(n)$. A question arises:

"What are the minimum agent capabilities required to complete the tree exploration in linear time?" Many practical applications may not allow the agent to easily backtrack its moves due to technical, security or privacy reasons. Thus, in this work we assume that the agent, upon entering a node, does ***not*** receive any information about the edge via which it entered.

We consider three components of the input to the agent: memory at the agent, memory at each node, and movable tokens (cf. e.g. [4, 3, 10, 11]). A deterministic agent given some input always chooses the same outgoing edge. Hence at a node of degree d needs at least d different inputs in order to be able to choose all of d outgoing edges. Thus in order to ensure the sufficient number of possible inputs, the number of possible values of the memory and possible present or absent states of the tokens, must exceed d. Hence, the sum of the memory at the agent, memory at the node and the number of tokens must be at least $\lceil \log d_v \rceil$ bits, for any node of degree d_v, where log denotes base-2 logarithm (cf. [34, Observation 1.1]).

In many applications, mobile agents are meant to be small, simple and inexpensive devices or software, cf. [11, 24]. These restrictions limit the size of the memory with which they can be equipped. Thus it is crucial to analyse the performance of the agent equipped with the minimum size of the memory. In this paper we assume the asymptotically minimum necessary memory size of $O(\log d_v)$, where only a constant number of bits is stored at the agent and logarithmic number (in the degree) at each node.

We consider two additional features of the model, namely – clean memory or a single token, and we show that each of these assumptions alone allows linear-time tree exploration. We also prove that when both features are absent, then the linear time exploration with small memory may be impossible even on a simple path.

2 Model

The agent is located in an initially unknown tree $T = (V, E)$ with $n = |V|$ nodes, where n is not known to the agent. The agent can traverse one of the edges incident to its current location within a single step, in order to visit a neighbouring node at its other end. The nodes of the tree are unlabelled, however in order for the agent to locally distinguish the edges outgoing from its current position, we assume that the tree is port-labelled. This means that at each node v with some degree d_v, its outgoing edges are uniquely labelled with numbers from $\{1, 2, \ldots, d_v\}$. Throughout the paper we assume that the port labels are assigned by an adversary that knows the algorithm used by the agent in advance and wants to maximize the exploration time.

Memory. The agent is endowed with some number of memory bits (called *agent memory* or *internal memory*), which it can access and modify. In our results, we assume that the agent has $O(1)$ bits of memory.

Each node $v \in V$ contains some number of memory bits as well, which can be modified by the agent when visiting that node. We will call these bits *node memory* or *local memory*. We assume that node v contains $\Theta(\log d_v)$ bits of memory. Hence, each node is capable of storing a constant number of pointers to its neighbours in the tree.

General Exploration Algorithm. Upon entering a node v, the agent a receives, as input, its current state s_a, the state s_v of the current node v, the number tok_v of tokens at v, the number tok_a of tokens at the agent and the degree d_v of the current node. It outputs its new state s'_a, new state s'_v of node v, new state $\text{tok}'_a, \text{tok}'_v$ of the tokens at the agent/node, respectively, and port p_{out} via which it exits node v; hence, the algorithm defines a transition:

$$(s_a, s_v, \mathrm{tok}_a, \mathrm{tok}_v, d_v) \to (s'_a, s'_v, \mathrm{tok}'_a, \mathrm{tok}'_v, p_{\mathrm{out}}),$$

that must satisfy $\mathrm{tok}_a + \mathrm{tok}_v = \mathrm{tok}'_a + \mathrm{tok}'_v$. In models without the tokens, the state transition of the algorithm can be simplified to:

$$(s_a, s_v, d_v) \to (s'_a, s'_v, p_{\mathrm{out}})$$

Starting state. We assume that for a given deterministic algorithm, there is one starting state s of the agent (obtained from the agent memory), in which the agent is at the beginning of (any execution of) the algorithm. The agent can also use this state later (it can transition to s in subsequent steps of the algorithm). The starting location of the agent is chosen by an adversary accordingly to agent's algorithm (to maximize the agent's exploration time).

Our models. In this paper we study the following three models:

In CleanMem, there is a fixed state $\hat{s}$ and each node v is initially in the state $s_v = \hat{s}$, regardless of the degree of the vertex. In this model the agent does not have access to any tokens.

In DirtyMem, the memory at the nodes is in arbitrary initial states, which are chosen by an adversary. In this model the agent does not have access to any tokens.

In Token, the agent is initially equipped with a single token. If the agent holds a token, it can drop it at a node upon visiting that node. When visiting a node, the agent receives as input whether the current node already contains a token. In this case the agent additionally outputs whether it decides to pick up the token, i.e., deduct from tok_v and add to tok_a. Clearly, since the agent has only one token, then after dropping it at some node, it needs to pick it up before dropping it again at some other node. In this model we assume that the initial state of the memory at each node is chosen by an adversary (like in DirtyMem model).

3 Our results

Upper bounds. While a lot of the existing literature focuses on feasibility of exploration, we show that it is possible to complete the tree exploration in the minimum possible linear time using (asymptotically) minimal memory. We show two algorithms in models CleanMem and Token, exploring arbitrary unknown trees in the optimal time $O(n)$ if constant memory is located at the agent and logarithmic memory is located at each node. Our results show that in the context of tree exploration in dual-memory model, the assumption about clean memory (fixed initial state of node memory) can be "traded" for a token.

It is worth noting that in both our algorithms, the agent returns to the starting position and terminates after completing the exploration, which is a harder task than a perpetual exploration. If the memory is only at the agent, exploration of trees with stop at the starting node requires $\Omega(\log n)$ bits of memory [14]; if the agent is only required to terminate at any node then still a superconstant $\Omega(\log \log \log n)$ memory is required [14]; while exploration without stop is feasible using $O(\log \Delta)$ agent memory [14] (where Δ is the maximum degree of a node). All these results assume that the agent could receive the port number via which it entered the current node, while our algorithms operate without this information.

Lower bound. To explore a path with a single bit of memory and with arbitrary initial state at each node (note that $\log d_v = 1$ for internal nodes on the path), one can employ the Rotor-Router algorithm and achieve exploration time of $O(n^2)$ [41] (there is no need for agent memory), which is time and memory optimal in the model with only node memory [34].

We want to verify the hypothesis that dual-memory allows to achieve linear time of exploration of trees. In our lower bound we analyse path exploration with one bit at each node and additional one bit of memory at the agent. We prove that in this setting, in DirtyMem model an exploration of the path requires $\Omega(n^2)$ steps in the worst case. Interestingly, since time $O(n^2)$ in already achievable with only a single bit at each node (and no memory at the agent), our lower bound shows that adding a single bit at the agent does not reduce the exploration time significantly.

3.1 Previous and related work

Only node memory. One approach for exploration using only node memory is Rotor-Router [41]. It is a simple strategy, where upon successive visits to each node, the agent is traversing the outgoing edges in a round-robin fashion. Its exploration time is $\Theta(mD)$ for any graph with m edges and diameter D [2, 41]. It is easy to see that this algorithm can be implemented in port-labelled graphs with zero bits of memory at the agent and only $\lceil \log d_v \rceil$ bits of memory at each node v with degree d_v (note that this is the minimum possible amount of memory for any correct exploration algorithm using only memory at the nodes). Allowing even unbounded memory at each node still leads to $\Omega(n^3)$ time for some graphs, and $\Omega(n^2)$ time for paths [34]. These lower bounds hold even if the initial state of the memory at each node is clean (i.e., each node starts in some fixed state $\hat{s}$ like in CleanMem model). Hence, only node memory is insufficient for subquadratic time exploration of trees.

Only agent memory. When the agent is not allowed to interact with the environment, then such agent, when exploring regular graphs, does not acquire any new information during exploration. Hence such an algorithm is practically a sequence of port numbers that can be defined prior to the exploration process. In the model with agent memory, the agent is endowed with some number of bits of memory that the agent can access and modify at any step. Thus for the case of the path, the lower bound (for unlimited agent memory) can be infered from a lower bound $\Omega(n^{1.51})$ for Universal Traversal Sequences (UTS) [9]. If this number of bits is logarithmic in n (otherwise, the exploration is infeasible [14]), then in this model it is possible to implement UTS (the agent only remembers the position in the sequence). The best known upper bound is $O(n^3)$ [1] and the best known constructive upper bound is $O(n^{4.03})$ [31]. Memory $\Theta(D \log \Delta)$ is sufficient and sometimes required to explore any graph with maximum degree Δ [24]. For directed graphs, memory $\Omega(n \log \Delta)$ at the agent is sometimes required to explore any graph with maximum outdegree Δ, while memory $O(n\Delta \log \Delta)$ is always sufficient [23].

Finite state automata. An agent equipped with only constant number of bits of persistent memory can be regarded as a finite state automaton (see e.g. [8, 24, 25]). Movements of such agent, typically modelled as a finite Moore or Mealy automaton, are completely determined by a state transition function $f(s, p, d_v) = (s', p')$, where s, s' are the agent's states and p, p' are the ports through which the agent enters and leaves the node v. A finite state automaton cannot explore an arbitrary graph in the setting, where the nodes have no unique labels [39]. Fraigniaud et al. [24] showed that for any $\Delta \geqslant 3$ and any finite state agent with k states, one can construct a planar graph with maximum degree Δ and at most $k + 1$ nodes, that cannot be explored by the agent. It is, however, possible in this model to explore (without stop) the trees, assuming that the finite state agent has access to the incoming port number (cf. [14]).

Two types of memory. Sudo et al. [40] consider exploration of general graphs with two types of memory, where both memories may have arbitrary initial states. They show that $O(\log n)$ bits at the agent and at each node allows exploration in time $O(m + nD)$. Cohen et al. [8] studied the problem of exploring an arbitrary graph by a finite state automaton, which is capable of assigning $O(1)$-bit labels to the nodes. They proposed an algorithm, that – assuming the agent knows the incoming port numbers – dynamically labels the nodes with three different labels and explores (with stop) an arbitrary graph in time $O(mD)$ (if the graph can be labelled offline, both the preprocessing stage and the exploration take $O(m)$ steps). They also show that with 1-bit labels and $O(\log \Delta)$ bits of agent memory it is possible to explore (with stop) all bounded-degree graphs of maximum degree Δ in time $O(\Delta^{10}m)$.

Tokens. Deterministic, directed graph exploration in polynomial time using tokens has been considered in [3], where it was shown that a single token is sufficient if the agent has an upper bound on the number of vertices n and $\Theta(\log \log n)$ tokens are sufficient and necessary otherwise. In [4] the authors proposed a probabilistic polynomial time algorithm that allows two cooperating agents without the knowledge of n to explore any strongly connected directed graph. They also proved that for a single agent with $O(1)$ tokens this is not possible in polynomial time in n with high probability. Using one pebble, the exploration with stop requires an agent with $\Omega(\log n)$ bits of memory [25]. The same space bound remains true for perpetual exploration [24]. Disser et al. [15] show that for a single agent with $O(1)$ memory, to explore any undirected anonymous graph (i.e. with unlabelled vertices and port-labelled edges) with n vertices, $\Theta(\log \log n)$ distinguishable pebbles are necessary and sufficient. They proposed an algorithm based on universal exploration sequences (UXS, cf. [30, 38]), which runs in polynomial time and the agent terminates after returning to the starting vertex with all pebbles. For the lower bound they show that an agent with $O((\log n)^{1-\varepsilon})$ bits of memory (for any constant $\varepsilon > 0$) needs $\Omega(\log \log n)$ pebbles to explore all undirected graphs.

Randomized and collaborative exploration. Although we focus on deterministic graph exploration by a single agent, there is a vast body of literature on randomized exploration techniques, see e.g. [1, 12, 18, 19]. A classical and well-studied processes are random walks, where the agent in each step moves to a neighbour chosen uniformly at random (or does not move with some constant probability). Exploration using this method takes expected time $\Omega(n \log n)$ [20] and $O(n^3)$ [21], where for each of these bounds there exists a graph class for which it is tight. Randomness alone cannot ensure linear time of tree exploration, since expected time $\Omega(n^2)$ is required even for paths [32]. However approaches using memory at the agent [28], local information on explored neighbours [5], or local information on degrees [36] have shown that there are many methods to speedup random walks. Finally, to achieve fast exploration, usage of multiple agents is possible, cf. [12, 13, 15, 16, 17, 22, 27, 29, 37].

4 Upper bounds

4.1 Exploration in CleanMem model

To simplify descriptions, let us denote the starting position of the agent as Root. In this section we show an algorithm exploring any tree in $O(n)$ steps using $O(1)$ bits of memory at the agent and $O(\log d_v)$ bits of memory at each node v of degree d_v in CleanMem model. The memory at each node is organized as follows. It contains two port pointers (of $\lceil \log d_v \rceil$ bits each):

- v.parent – at some point of the execution, contains the port number leading to Root,
- v.last – points to the last port taken by the agent during the exploration

and two flags (of 1 bit):

- v.root – indicates whether the node is Root of the exploration,
- v.visited – indicates whether the node has already been visited.

At each node, the initial state of last pointers is 1, initial state of parent is NULL and initial state of each flag is False. The agent's memory contains one variable State that can take one of five possible values: Initial, Roam, Down, Up, Terminated.

For simplicity of the pseudocode we use a flag *parentSet*, which controls if parent is correctly set. This flag does not need to be stored because it is set and accessed in the same round. It is possible to write a more complicated pseudocode without this variable.

In our pseudocode, we use a procedure MOVE(p), in which the agent traverses an edge labelled with port p from its current location. When the agent changes its state to Terminated, it does not make any further moves.

Algorithm's description. For the purpose of the analysis, assume that tree T is rooted at the initial position of the agent (the Root). The main challenge in designing an exploration algorithm in this model is that the agent located at some node v may not know which port leads to the parent of v. Indeed, if the agent knew which port leads to its parent, it could perform a DFS traversal. In Algorithm 1 the agent would traverse the edges corresponding to outgoing ports in order $1, 2, 3, \ldots, d_v$ (skipping the port leading to its parent) and take the edge to its parent after completing the exploration of the subtrees rooted at its current position. Note that it is possible to mark, which outgoing ports have already been traversed by the agent using only a single pointer at each node hence 0 bits at the agent and $\lceil \log d_v \rceil$ bits at each node allow for linear time exploration in this case.

Since in our model, the agent does not know, which port leads to the parent, we need a second pointer parent at each node. To set it correctly, we first observe that in the model CleanMem, using flag visited, it is possible to mark the nodes that have already been visited. Notice that when the agent traverses some edge outgoing from v in the tree for the first time and enters to a node that has already been visited, then this node is certainly the parent of v. We can utilize this observation to establish correctly v.parent pointer using state Down. When entering to a node in this state, we know that the previously taken edge (port number of this edge is stored in v.last) leads to the parent of v. Our algorithm also ensures, that after entering a subtree rooted at v, the agent leaves it once, and the next time it enters this subtree it correctly sets v.parent and in subsequent steps it visits all the nodes of the subtree. Finally, having correctly set pointers parent at all the nodes, allows the agent to efficiently return to the starting node after completing the exploration and flag root allows the agent to terminate the algorithm at the starting node.

▶ **Theorem 1.** *Algorithm 1 explores any tree and terminates at the starting node in $O(n)$ steps in CleanMem model.*

Proof. First note that the algorithm marks the starting node with flag root (line 2). The algorithm never returns to state Initial, hence only this node will be marked with the root flag. The only line, where the agent terminates the algorithm is line 14 hence the agent can only terminate in the starting node. We need to show that the agent will terminate in every tree and before the termination it will visit all the vertices and the time of the exploration will be $O(n)$. Let us denote the starting node as Root and for any node v different from Root, will call the single neighbour of v that is closer to Root as the parent of v.

Algorithm 1 Tree exploration in CleanMem model.

```
   // Agent is at some node $v$ and the outgoing ports are $\{1, 2, \ldots, d_v\}$
1  if $State = Initial$ then
2      $v$.root ← True, State ← Roam, $v$.visited ← True;
3      MOVE($v$.last);
4  else
5      if $State = Down$ then
6          $v$.parent ← $v$.last, State ← Roam;     // mark edge as leading to parent
7          $v.parentSet$ ← True;
8      else
9          $v.parentSet$ ← False
10     if (($State = Roam$ and $d_v = 1$) or $State = Up$ or $v.parentSet = True$) and
        $v.root = False$ and $v.last = d_v$ and $v.parent \neq NULL$ then
11         State ← Up;                  // exploration of this subtree completed
12         MOVE($v$.parent) ;                             // return to the parent
13     else if $State = Up$ and $v.root = True$ and $v.last = d_v$ then
14         State ← Terminated;       // exploration of the whole tree completed
15     else
16         if $State = Roam$ and $v.visited = True$ and $v.parentSet = False$ then
17             State ← Down;
18         else if $State = Up$ then
19             State ← Roam, $v$.last ← $v$.last + 1;
20         else
21             if  $v.visited = True$ then  $v$.last ← $v$.last + 1;
22             else  $v$.visited ← True;
23         MOVE($v$.last);
```

We will show the following claim using induction over the structure of the tree.

▷ Claim 2. Assume that the agent enters to some previously unvisited subtree rooted at v with n_v vertices for the first time in state Roam in step t_s. Then the agent:

C.1 returns to the parent of v for the first time in state Roam (denote by $t_r > t_s$ the step number of the first return from v to its parent),
C.2 goes back to v in the state Down at step $t_r + 1$,
C.3 returns to the parent of v for the second time in state Up (denote by $t_f > t_r + 1$ the step number of the second return from v to its parent),
C.4 visits all the vertices of this subtree and spends $O(n_v)$ steps within time interval $[t_s, t_f]$.

Proof. We will first show it for all the leaves. Then, assuming that the claim holds for all the subtrees rooted at the children of some node v, we will show it for v. To show this claim for any leaf l, consider the agent entering in state Roam to l. Upon the first visit to l, the agent sets the flag l.visited to True and leaves (without changing the state of the agent) with port 1. This proves C.1. In the next step, at the parent of l, a state changes to Down and the agent uses the same port as during the last time in parent of l. Therefore the agent moves back to l (C.2) and sets l.parent ← 1 (line 6). Then the agent changes its state to Up and moves to the parent (lines 11–12). This shows C.3. Node l was visited twice within the considered time steps, which shows C.4. This completes the proof of the claim for all the leaves.

Now, consider any internal node v of the tree (with $d_v > 1$) and assume that the claim holds for all its children. When the agent enters to v for the first time, it sets the flag $v.\mathsf{visited}$ to `True` and moves to its neighbour w (while being in state Roam) via port 1.

Case 1: w is the parent of v. This immediately shows C.1. If the parent of v is not Root, then it has the degree at least 2, hence the agent will evaluate the if-statement in line 10 to `False`. Thus the agent will execute line 16 and change its state to Down. The agent uses the same port as during the previous visit of w, therefore the agent goes back to v (C.2), hence it will correctly set the pointer $v.\mathsf{parent}$ (it will point to the parent of v), which shows C.3.

Case 2: w is a child of v. In this case we enter to a child of v. We have by the inductive assumption (C.1), that the agent will return from w to v in state Roam. Since the agent enters to v in state Roam, then the value of *parentSet* is `False` and the agent executes line 16, transitions to state Down and then line 23 it takes the same edge as during the last visit to v, hence it moves back to node w (C.2). By C.3 we get that the next time the agent will traverses the edge from w to v, it will be in state Up. Then the agent increments pointer $v.\mathsf{last}$ (line 19) and moves to the next neighbour of v (line 23).

Thus the agent either finds the parent or explores the whole subtree rooted at one of its children w in $O(n_w)$ steps (by the inductive assumption C.4). An analogous analysis holds for ports $2, 3, \ldots, d_v$. When the agent returns from the neighbour connected to v via the last port d_v, it is either in state Up or Down (the second case happens if the edge leading from v to its parent has port number d_v). In both cases it executes lines 11 and 12 and leaves to its parent (the pointer to parent is established since the agent had traversed each outgoing edge, hence it moved to its parent and correctly set the parent pointer).

By this way, the agent visits all the subtrees rooted at v's children $w_1, w_2, \ldots, w_{d_v-1}$ (or up to w_{d_v} if $v = \mathsf{Root}$). Hence, the total number of steps for a node $v \neq \mathsf{Root}$ is $O\left(\sum_{i=1}^{d_v-1} n_{w_i}\right) = O(n_v)$ and $v = \mathsf{Root}$ it is $O\left(\sum_{i=1}^{d_v} n_{w_i}\right) = O(n)$. ◁

To complete the proof of Theorem 1 we need to analyse the actions of the agent at Root. Consider the actions of the agent at Root when the Root.last pointer takes values $i = 1, 2, \ldots, d_{\mathsf{Root}}$. Let v_i be the neighbour of Root pointed by port number i at Root. Observe that the agent at Root behaves similarly as in all the other internal nodes (only exception is that the agent will never enter Root in state Down, because by Claim 2 the agent can enter to it only in states Roam or Up, since the Root has no parent). By Claim 2, the agent visits the whole subtrees rooted at these nodes in time proportional to the number of nodes in these subtrees. When the agent returns from node $v_{d_{\mathsf{Root}}}$ in state Up then the algorithm terminates (line 14). The total runtime is proportional to the total number of nodes in the tree. ◀

4.2 Exploration in Token model

Algorithm's description. In Algorithm 2, the agent has a single token, which can be DROP*ped*, TAKE*n* and MOVE*d* (i.e., carried by the agent across an edge of the graph). Moreover, the agent is always in one state from set $\{\mathsf{Initial}, \mathsf{Roam}, \mathsf{RR}, \mathsf{Down}, \mathsf{Up}, \mathsf{Terminated}\}$. Our algorithm ensures, that in states Roam and RR the agent does not hold the token and in the remaining states, it does. In these four states the agent can eventually DROP it. Each node v has degree denoted by d_v, which is part of the input to the agent, when entering to a node. Moreover, the memory at each node v is organized into three variables: $v.\mathsf{last}$ and $v.\mathsf{parent}$ of size $\lceil \log d_v \rceil$ and a flag $v.\mathsf{root} \in \{\mathtt{True}, \mathtt{False}\}$ to mark the Root. We assume that in all vertices, variables last, parent and root have initially any admissible value (if not, then the agent would easily notice it and change such a value). Moreover, when the agent is entering to a node, it can see whether the node contains the token or not.

We would like to perform a similar exploration as in CleanMem model – we will use pointers last and parent as in Algorithm 1. However, the difficulty in this model is that these pointers may have arbitrary initial values. Especially, if the initial value of parent is incorrect, Algorithm 1 may fall into an infinite loop. Hence in this section we propose a new Algorithm 2 that handles dirty memory using a single token. In this algorithm the agent maintains an invariant that the node with the token, and all the nodes on the path from the token's location to the Root are guaranteed to have correctly set parent pointers. To explore new nodes, the agent performs a Rotor-Router (shortly RR) traversal, starting from node v with the token to its neighbour w (by the invariant, the agent chooses w as one of its children, not its parent). During this traversal, the agent is resetting the parent pointers at each node (and cleaning the root flags). The agent is using last as the pointer for the purpose of RR algorithm. The agent does **not** have to reset last as the RR requires no special initialization. Moreover, by the properties of RR the agent does not traverse the same edge twice in the same direction before returning to the starting node. Since the agent starts in the node with the token, it can notice that it completed a traversal. During this traversal each edge is used at most twice (once in each direction). Moreover, each node visited during this traversal has cleaned memory (pointer parent points to NULL and root is set to False). After returning to the node with the token, pointer v.last points at w and w.last points at v. Hence it is possible to traverse this edge and correctly set pointer w.parent maintaining the invariant. After moving the token down, the agent starts the RR procedure again. Since the agent is not cleaning the pointer last, the RR will use different edges than during the previous traversal. Using this we show in the proof of Theorem 2 that our algorithm traverses every edge at most 6 times.

Preliminaries. Let us introduce some notation: a variable Token associated with a vertex currently occupied by the agent, which is 1, when the agent meets the token and 0 otherwise. If Token $= 1$, then the agent can TAKE the token and the agent with the token can DROP it. Let Path(v) denote a set of all vertices, which are on the shortest path from Root to v, excluding Root. Let T_v denote the subtree of T rooted at v, i.e., $(w \in T_v) \equiv (w = v \vee v \in \mathsf{Path}(w))$. Let $T_{v,p}$ denote a subtree of T_v, rooted at a node connected by edge labelled by outport p at vertex v, i.e. if p leads from v to w (where $v \in \mathsf{Path}(w)$), then $T_{v,p} = T_w$ (we do not define such a tree when p directs towards Root). We say that the action is performed away from Root (downwards), if it starts in v and ends in T_v. Otherwise the action is towards Root (upwards). Let Tok(t) and Ag(t) be the positions of the token and the agent, respectively, at the end of the moment t. Let Act(t) be the action performed during the t-th step. Let the variable v.visited(t) $\in \{0, 1\}$ indicate whether v was visited by Algorithm 2 until the moment t. Note that this variable is not stored at the nodes and this notation is only for the analysis.

Additionally, we consider two substates of RR, depending on the value of the Token variable. Substate RR_0 is state RR, if variable Token $= 0$ at the node to which the agent entered in the considered step. Similarly RR_1 indicates that the agent enters in state RR to a node with Token $= 1$. Note that this distinction is only for the purpose of the analysis, and it does not influence the definition of the algorithm. In our analysis, we will call Initial, Roam, RR_0, RR_1, Down, Up, Terminated *actions* as these states (and substates) correspond to different commands executed by the agent (see the pseudocode of Algorithm 2).

Algorithm 2 Tree exploration in Token model.

```
// Agent is at some node $v$ and the outgoing ports are $\{1, 2, \ldots, d_v\}$
if $State = Initial$ then
    Clean(), $v$.last ← 1, DROP;
    // mark the root for termination
    $v$.root ← True;
    State ← Roam;
else if $State = RR$ and $Token = 1$ then
    // substate RR$_1$
    TAKE, State ← Down;
else if $State = RR$ and $Token = 0$ then
    // substate RR$_0$
    Clean();
    Progress() ;        // increment last
else if $State = Down$ then
    DROP, $v$.parent ← $v$.last;
    Progress();
    State ← Roam;
    IfUp() ;     // check if in a leaf
else if $State = Up$ then
    DROP, Progress();
    State ← Roam;
    if $v.last = 1$ and $v.root = True$ then
        State ← Terminated;
    IfUp();
else    // State = Roam
    Clean(), State ← RR;
if $State \neq Terminated$ then
    MOVE($v$.last);

Procedure Clean()
    $v$.root ← False, $v$.parent ← NULL;

Procedure Progress()
    $v$.last ← ($v$.last mod $d_v$) + 1;

Procedure IfUp()
    if $v.parent = v.last$ then
        TAKE, State ← Up;
```

We assume that Initial action is performed at time step 0. Let Root denote the initial position of the agent. Let v.last(t) and v.parent(t) denote, respectively, the values of v.last and v.parent pointers at the end of the moment t. If v is the starting point of the t-th step, then we say that v.last(t) is the outport related to t-th moment. Moreover, v.last($\cdot$) cannot be changed until the node v will be visited for the next time. Each MOVE(v.last) involves traversing an edge outgoing from the current position of the agent via the port indicated by the current value of variable last at the current position.

Properties of the algorithm. Let us define the following set of properties P(t) (the k-th property at moment t is denoted as $P.k(t)$; in this definition we denote Ag(t) $= w$) that describe the structure of the walk and the interactions with the memory at the nodes by an agent performing Algorithm 2.

P.1 During t-th step:
  a. If Down or Roam is performed, the move of the agent is away from Root (downwards).
  b. If Up or RR$_1$ is performed, the move of the agent is towards Root (upwards).

P.2 $w \in T_{\mathsf{Tok}(t)}$.

P.3 If w is visited for the first time at step t (Act(t) $\in$ {Initial, Roam, RR$_0$}), then it is also cleaned, which means that w.parent is set to NULL and w.root is set to False.

P.4 For every $v \in$ Path(Tok(t)), v.parent(t) $\neq$ NULL.

P.5 If w.visited($t-1$) $= 1$ and w.parent($t-1$) $\neq$ NULL, then Act(t) $\notin$ {Roam, RR$_0$}.

P.6 If w.visited(t) $= 1$ and w.parent(t) $\neq$ NULL, then w.parent(t) points towards Root.

P.7 If the state at the end of t-th moment is Up, then T_w is explored.

P.8 If $t > 0$, then for every $x \leq$ Root.last($t-1$), $T_{\mathsf{Root},x}$ is explored before t-th moment.

P.9 If w.parent(t) = NULL, then there do not exist $s_1 < s_2 < t$ such that w.last(s_1) = w.last$(t) \neq w$.last(s_2), where w.parent(s_1) = NULL (w.last$(\cdot)$ cannot be changed to the same value two times before w.parent$(\cdot)$ was established).

P.10 There do not exist $s_1 < s_2 < t$ such that w.last(s_1) = w.last$(t) \neq w$.last(s_2) and w.parent$(s_1) \neq$ NULL (w.last$(\cdot)$ cannot be changed to the same value two times after w.parent$(\cdot)$ was established).

▶ **Lemma 3.** *At time* 0*, Initial phase of Algorithm 2 guarantees* P(0)*.*

▶ **Lemma 4.** *If Algorithm 2 satisfies* P(s) *for all* $s \leq t$*, then it also fulfills* P$(t+1)$*.*

All the omitted proofs from this section are deferred to the full version of the paper [6].

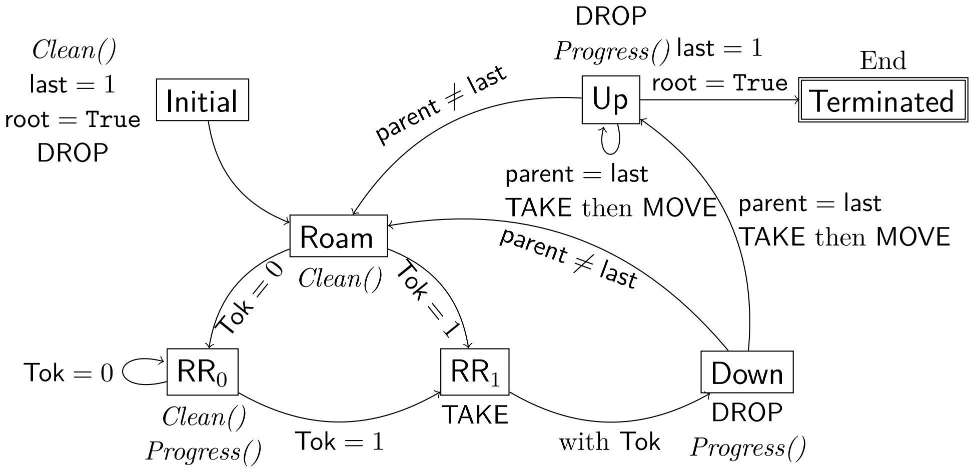

Figure 1 Illustration of actions and state transitions in Algorithm 2.

We will use properties P(t) to show correctness and time complexity of our Algorithm 2.

▶ **Theorem 5.** *Algorithm 2 explores any tree and terminates at the starting node in at most* $6(n-1)$ *steps in the Token model.*

Proof. Using Lemmas 3 and 4, we get that Algorithm 2 satisfies P(t) for each step t. First of all, from P.3, all visited vertices are cleaned upon the first visits.

Consider some vertex v and its arbitrary outport p. If $v \neq$ Root, then from P.9 and P.10, p may be used two times instantly after the incrementation of v.last$(\cdot)$ (once when v.parent$(\cdot)$ = NULL and once when v.parent$(\cdot) \neq$ NULL). Realize that, when v = Root, then from P.2 and the fact, that any vertex with the token cannot be cleaned by RR$_0$ and Roam moves, we claim that Root.parent$(\cdot)$ will always be NULL. By P.9, p may be used once instantly after the incrementation of Root.last$(\cdot)$. Moreover, regardless of the choice of p, it may be used also after Roam or RR$_1$ action without a change of v.last$(\cdot)$.

Case 1. Assume that Act(t) = RR$_1$ is taken via port p. From P.1(t) and P.2(t), p directs upwards towards the token. Then Act$(t+1)$ = Down is performed downwards (from P.1$(t+1)$) via the same edge as p (but with the opposite direction) and changes the position of the token to Tok$(t+1) = v$ and establishes v.parent$(t+1) \leftarrow p$. By P.1, p cannot be used during Roam action. Realize that if $p = v$.last$(s-1)$ for some moment $s > t$ and Act(s) = RR$_1$, then Tok$(s-1)$ is one step towards Root from v (from P.1(s)). Since the token can be moved only during Up and Down actions, then there exists a moment s' such that $t < s' < s$ and $\mathsf{Act}(s') = \mathsf{Up}$ changes the position of the token from v to $\mathsf{Tok}(s)$. However then $\mathsf{Tok}(s).\mathsf{last}(s) \neq \mathsf{Tok}(s).\mathsf{last}(s-1)$ ($\mathsf{Tok}(s)$ is not a leaf) and by P.10, P.6 and P.4, it cannot be changed back since $\mathsf{parent}(\mathsf{Tok}(s)) \neq \mathsf{NULL}$.

Case 2. Assume that $\mathsf{Act}(t) = \mathsf{Roam}$ is taken from node $v = \mathsf{Tok}(t-1)$ via port p (downwards, by P.1(t)). The first action after time t, which leads to the token, is always RR_1. However, as showed before, after RR_1 action there is an instant Down action, which moves the token via p to some vertex w and sets $w.\mathsf{parent} \neq \mathsf{NULL}$. Hence by P.5, Roam action cannot be performed via p once again. By P.1, p cannot be used during RR_1 action.

Our considerations show that each outport can be used at most 3 times. Since each tree of size n has $2(n-1)$ outports, Algorithm 2 terminates after at most $6(n-1)$ moves.

It remains to show that all vertices are then explored. Realize that Algorithm 2 terminates in $(t+1)$-st moment only when the agent is in $\mathsf{Tok}(t)$, $\mathsf{Tok}(t).\mathsf{last}(t) = 1$, $\mathsf{Tok}(t).\mathsf{root} = \mathtt{True}$ and the state is Up at the end of t-th moment. From P.3, we know that the first visit in some v sets root flag to $\mathtt{True}$ in Root and to $\mathtt{False}$ in all other nodes, and this flag does not change (Roam and RR_0 do not clean the vertices with the token, so by P.2, Root cannot be cleaned by these moves). Hence the termination entails $\mathsf{Tok}(t) = \mathsf{Root}$. Since $\mathsf{Root}.\mathsf{parent}(t) = \mathsf{NULL}$, then from P.9 we know that each port p in Root will be set by $\mathsf{Root}.\mathsf{last}(\cdot)$ only once (since the first moment) and P.8 means that each subtree $T_{\mathsf{Root},p}$ for $p \in \{1, \dots, d_{\mathsf{Root}}\}$ were explored before returning to Root, hence the exploration of T_{Root} was completed. ◀

5 Lower bound

In this section we analyse the exploration of paths with one bit of memory at each node and one bit at the agent. We show that in this setting, in the $\mathsf{DirtyMem}$ model, the exploration of the path sometimes requires $\Omega(n^2)$ steps.

Notation. In the following lower bound on the path, we will focus on the actions of the algorithm performed in vertices with degree 2. In such vertices, there are four possible inputs to the algorithm $S = \{(0,0),(0,1),(1,0),(1,1)\}$, where in a pair (a, v), a denotes a bit on the agent and v is a bit saved on the vertex. Let us denote the sets of agent and vertex states by As and Vs, respectively. We also use elements from Ps $= \{0,1\}$ to denote ports in vertices of degree 2. Moreover, a shorthand notation $\overline{b}$ indicates the inverted value of a bit. For example, if $a = 0$, then $\overline{a} = 1$ and vice versa. The goal of this section is to prove:

▶ **Theorem 6.** *Every deterministic algorithm that can explore any path in the* $\mathsf{DirtyMem}$ *model with one bit at the agent and one bit at each node requires time* $\Omega(n^2)$ *to explore some worst-case path with* n *nodes.*

Assume, for a contradiction, that there exists algorithm $\mathcal{A}$, which explores every path in $o(n^2)$ steps. Without loss of generality, we may assume that the adversary always sets the agent in the middle point of the path. For algorithm $\mathcal{A}$, for every $s \in S$, by $A(s)$, $V(s)$, $P(s)$ we denote, respectively, the returned agent state, vertex state and the chosen outport in each vertex with degree 2. Moreover, let $R_3(s) := (A(s), V(s), P(s))$ and $R_2(s) := (A(s), V(s))$. We will show that $\mathcal{A}$ either falls into an infinite loop or performs no faster than Rotor-Router.

The proof of Theorem 6 is divided into several parts. In the first one, we provide several properties of potential algorithms $\mathcal{A}$ that can eventually explore the path in $o(n^2)$ time. These properties are used in the second part, where we prove that the agent does not change its internal state every time, however it has to change the state of the vertex in each step. Further, we check two algorithms (called X and Y), which turn out to explore the path even slower than the Rotor-Router algorithm. The analysis of those two algorithms is quite challenging. Next we show that if three states of $\mathcal{A}$ return the same outport, then either it falls into an infinite loop or explores the path in $\Omega(n^2)$ steps. In the latter part we consider the rest of amenable algorithms, which can either be reduced to previous counterexamples or fall into an infinite loop. A big part of the proof is technical and due to space limitations it is moved to the full version of the paper [6]. Nevertheless, in here we present two parts of the proof to let the reader feel the flavour of high-level ideas and utilized techniques.

▶ **Fact 7.** $(\forall\, a \in \mathrm{As})(\exists\, v \in \mathrm{Vs})\ A(a, v) = \overline{a}$.

Proof. Assume that $(\exists\, a \in \mathrm{As})(\forall\, v \in \mathrm{Vs})\ A(a, v) = a$. If a is the initial state of the agent, then the agent will never change its state before reaching an endpoint of the path. Hence, the time to reach the endpoint cannot be faster than Rotor-Router algorithm, hence the adversary can initialize ports in such a way that the endpoint will be reached after $\Omega(n^2)$ steps. If $\overline{a}$ is the starting state, then either the agent state never changes which reduces to the previous case or $A(\overline{a}, w) = a$ for some $w \in \mathrm{Vs}$. Then, the adversary sets w as the initial state of the starting vertex and after the fist step the state of the agent changes to a and by the same argument as in the first case, the algorithm requires $\Omega(n^2)$ steps. ◀

▶ **Fact 8.** $(\forall\, a \in \mathrm{As})(\forall\, v \in \mathrm{Vs})\ R_2(a, v) \neq (a, v)$.

Proof. We will show that otherwise algorithm $\mathcal{A}$ falls into an infinite loop for some initial state of the path. Assume that $R_3(a, v) = (a, v, p)$ for some $a \in \mathrm{As}$, $v \in \mathrm{Vs}$, $p \in \mathrm{Ps}$. Then if a is the starting agent state, the agent falls into an infinite loop on the left gadget from Figure 2 (double circle denotes the starting position of the agent and a above the node indicates its initial state). If $\overline{a}$ is the starting state, then by Fact 7, $(\exists\, w \in \mathrm{Vs})\ A(\overline{a}, w) = a$. Let $q = P(\overline{a}, w)$ and note that the agent falls into an infinite loop in the right gadget at Figure 2. ◀

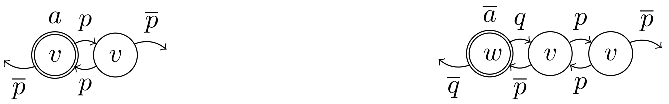

Figure 2 Two looping gadgets for an algorithm with $R_2(a, v) = (a, v)$.

Independently of the above facts, let us consider the foregoing **Algorithm Q** and more complicated gadgets, which force the agent to fall into an infinite loop (see Figure 3).

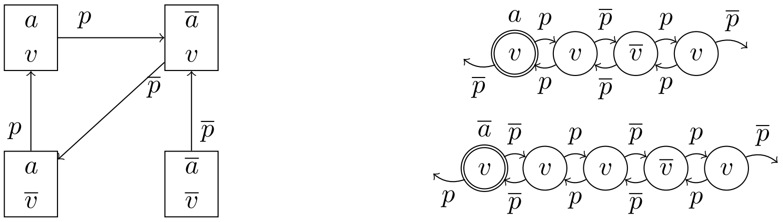

Figure 3 Definition of Algorithm Q (left) and gadgets on which it falls into an infinite loop.

6 Conclusions and open problems

One conclusion from our paper is that certain assumptions of the model of mobile agents can be exchanged. We showed, that in the context of linear time tree exploration, the assumption of clean memory at the nodes can be exchanged for a single token or the knowledge of the incoming port. The paper leaves a number of promising open directions. We showed that token and clean memory allow for linear time exploration of trees, however, we have not ruled out the possibility that linear time exploration of trees is feasible without both these assumptions. Our lower bound suggests that memory $\omega(1)$ at the agent is probably necessary in DirtyMem model. Another open direction would be to consider different graph classes, or perhaps directed graphs. Finally, a very interesting future direction is to study dual-memory exploration with team of multiple mobile agents. Such approach could lead to even smaller exploration time, however, dividing the work between the agents in such models is very challenging since the graph is initially unknown.

Abstract

Vanishing sums of roots of unity can be seen as a natural generalization of knapsack from Boolean variables to variables taking values over the roots of unity. We show that these sums are hard to prove for polynomial calculus and for sum-of-squares, both in terms of degree and size.

2012 ACM Subject Classification Theory of computation → Proof complexity; Computing methodologies → Representation of polynomials

Keywords and phrases polynomial calculus, sum-of-squares, roots of unity, knapsack

1 Introduction

Statements from combinatorics, constraint satisfaction problems (CSP), arithmetic circuit design, and algebra itself can be formalized either as statements about polynomial equalities (and inequalities), or via propositional logic. The approach based on propositional logic is amenable to *state-of-the-art* algorithms for satisfiability (SAT), usually variations of *Conflict-Driven-Clause-Learning* SAT solvers (CDCL), see for instance [28, 29, 3]. These solvers are surprisingly efficient, but their reasoning is ultimately based on the *resolution* proof system. On problems coming from algebra, CDCL solvers do not exploit the algebraic aspects of the problem, and therefore are typically unable to solve them. Switching to algebra allows to leverage on tools as Hilbert's Nullstellensatz and Gröbner basis computation in order to solve systems of polynomial equations [10], or semidefinite programming to solve systems of polynomial inequalities [30, 25]. These algebraic tools have been successful in practice for instance to solve κ-COLORING [11, 12, 13] and the verification of arithmetic multiplier circuits [22, 21, 23]. κ-COLORING, and in general CSP problems over finite domains of size κ, are naturally encoded using κ-valued variables. In particular, the algebraic tools for κ-COLORING use the *Fourier encoding*, which represents values via complex variables z subjected to the constraint $z^\kappa = 1$ and hence such that

$$z \in \{1, \zeta, \zeta^2, \ldots, \zeta^{\kappa-1}\} ,$$

where ζ is a primitive κth root of unity. A κ-valued variable z can be alternatively represented as a collection of indicator Boolean variables $x_1, \ldots, x_\kappa$ equipped with the additional constraint $x_1 + \cdots + x_\kappa = 1$.

Picking the right encoding is essential to leverage the algebraic structure of the problem. Even simple changes, for instance adding new variables to represent Boolean negations may already give significant speedups both in theory and in practice [14, 20].

In this paper, following a general approach from proof complexity, we show that algorithms leveraging Hilbert's Nullstellensatz or Gröbner basis computations cannot prove efficiently the unsatisfiability of some natural sets of polynomials equations over the Fourier variables.

The proof systems we consider are *polynomial calculus* and *sum-of-squares*. Polynomial calculus is a well studied proof system that captures Hilbert's Nullstellensatz and Gröbner basis computations. It is a system that certifies the unsatisfiability of sets of polynomial equations. It has been studied for polynomials over different fields or rings and, in particular, also for polynomials over the complex numbers $\mathbb{C}$, see for instance [7]. Given polynomials $p_1, \ldots, p_m$ with coefficients in a field $\mathbb{F}$, a refutation of $\{p_1 = 0, \ldots, p_m = 0\}$ in *polynomial calculus over* $\mathbb{F}$, denoted as $\mathsf{PC}_{\mathbb{F}}$, is a sequence of polynomials $p_1, \ldots, p_s$ over $\mathbb{F}$ such that $p_s = 1$ and each $p_{m+1}, \ldots, p_s$ is either (1) $r \cdot p_k$ for some polynomial r with coeffcients in $\mathbb{F}$ and some $k < i$; or (2) a linear combination $\alpha p_j + \beta p_k$ for $j, k < i$ and $\alpha, \beta \in \mathbb{F}$.

Regarding sum-of-squares, it is a systems to certify the unsatisfiability of sets of polynomial equations *and inequalities* over $\mathbb{R}$. A sum-of-squares $\mathsf{SoS}_{\mathbb{R}}$ refutation of the set of contraints $\{p = 0 \ : \ p \in P\} \cup \{h \geq 0 \ : \ h \in H\}$ is an identity of the form

$$-1 = \sum_{p \in P} q_p \cdot p + \sum_{h \in H} q_h \cdot h + \sum_{s \in S} s^2 \ ,$$

where the s, q_p, q_h are polynomials over $\mathbb{R}$ and moreover the q_hs are sums of squared polynomials. In presence of Boolean or $\{\pm 1\}$-valued variables, $\mathsf{SoS}_{\mathbb{R}}$ p-simulates $\mathsf{PC}_{\mathbb{R}}$ [4, 34].

In this paper, we introduce a generalization of sum-of-squares with polynomials over $\mathbb{C}$, $\mathsf{SoS}_{\mathbb{C}}$ (see Section 2 for the formal definition). Since $\mathbb{C}$ is not an ordered field, this generalization of sum-of-squares to $\mathbb{C}$ can only be used to certify the unsatisfiability of sets of polynomial *equations*. For sets of polynomial equations over $\mathbb{R}$ and in the presence of Boolean variables, $\mathsf{SoS}_{\mathbb{C}}$ coincides with the usual notion of sum-of-squares over $\mathbb{R}$, but the generalization is necessary to deal with Fourier variables or to reason about polynomials over $\mathbb{C}$. In presence of Fourier variables, $\mathsf{SoS}_{\mathbb{C}}$ p-simulates $\mathsf{PC}_{\mathbb{C}}$, see Section 2 for more details.

PC and SoS can be used to solve computational problems once they are encoded as sets of polynomials equations. It is customary to discuss sets of polynomial equations simply as sets of polynomials. We adopt this custom and we say that a set of polynomials over $\mathbb{C}$ is *satisfiable* when it has a common zero $\boldsymbol{\alpha} \in \mathbb{C}^n$. The most naïve algebraic encoding is to use variables ranging over $\{0, 1\}$ to represent the truth values of variables. This Boolean nature of a variable x is enforced via the polynomial $x^2 - x$. With this encoding then, for example, the satisfiability of a propositional clause $x \vee \neg y \vee z$ can be encoded as the satisfiability of the set of polynomials $\{(1 - x)y(1 - z), \ x^2 - x, \ y^2 - y, \ z^2 - z\}$. Truth values of variables are sometimes also encoded in the Fourier basis $\{\pm 1\}$ and, as we already mentioned, for some CSPs it is convenient to use κ-valued variables using the κth roots of unity.

Finding deductions in PC/SoS may be hard, and in general there are important proxy measures to estimate such hardness: the maximum *degree* of the polynomials involved in the deductions, and the number of monomials involved in the whole proof when polynomials are written explicitly as sums of monomials (*size*). The degree is a very rough measure of the proof search space, the size is a lower bound on the time required to produce the proof.

Studying size and degree complexity in algebraic systems over Fourier encodings is particularly relevant to understand how to leverage to proof complexity techniques like the *Smolensky's method* in circuit complexity [33]. He proved exponential lower bounds to compute the MOD_p function by bounded-depth circuits using the unbounded gates in $\{\wedge, \vee, \mathrm{MOD}_q\}$, for p and q relatively prime, employing a reduction to low-degree polynomials over $\mathrm{GF}(q)$ approximating such circuits. In proof complexity, it is a long-standing problem to obtain lower bounds for proof systems over bounded-depth formulas with modular gates.

Non-trivial degree lower bounds for Fourier encodings were first obtained for the Nullstellensatz proof system and PC by Grigoriev in [18] and Buss *et al.* in [7] for the Tseitin principle over p-valued variables (instead of the usual $\{0,1\}$) and the so-called MOD_p principles [7].

For $\mathsf{PC}/\mathsf{SoS}_{\mathbb{R}}$ over Boolean variables we know degree and size lower bounds for the encodings of several computational problems, see for instance [2, 17, 31, 32, 35]. For the size lower bounds in PC and $\mathsf{SoS}_{\mathbb{R}}$ this is essentially due to degree-size tradeoffs: if a set of polynomials *over Boolean variables* has no refutation in $\mathsf{PC}/\mathsf{SoS}_{\mathbb{R}}$ of degree at most D, then it has no refutation containing less than $2^{\Omega\left(\frac{(D-d)^2}{n}\right)}$ monomials, see [1, 19].

No such degree-size relation holds for polynomials over the Fourier variables. For instance, it is well-known that Tseitin contradictions over the Boolean variables $\{0,1\}$ require an exponential number of monomials to be refuted in PC, while PC can refute them with a linear number of monomials if the encoding uses the variables $\{\pm 1\}$, see [7].

To the best of our knowledge, the first size lower bounds in $\mathsf{PC}/\mathsf{SoS}_{\mathbb{R}}$ for polynomials with $\{\pm 1\}$ variables are proved by [34] for the pigeonhole principle and random 11-CNFs. Moreover that work provides a technique to turn strong degree lower bounds in that framework into strong size lower bounds for the same polynomials composed with some carefully constructed gadgets. We extend this latter approach to get size lower bound under the Fourier encoding of κ-valued variables, and we apply it to a generalization of KNAPSACK for these variables.

The classical KNAPSACK problem corresponds to the set of polynomials

$$\left\{ \sum_{i=1}^{n} c_i x_i - r \ , \quad x_1^2 - x_1, \ldots, x_n^2 - x_n \right\} , \tag{1}$$

where $r, c_1, \ldots, c_n \in \mathbb{C}$. For KNAPSACK are known linear degree lower bounds in PC, see [19, Theorem 5.1], and, when all the c_is are 1 and $r \in \mathbb{R}$, degree lower bounds in $\mathsf{SoS}_{\mathbb{R}}$ of the form $\min\{2\lfloor \min\{r, n-r\}\rfloor + 3, n\}$, see [17]. Size lower bounds are also implied by the respective size-degree tradeoffs [19, 1].

Sums of roots of unity. We consider the problem of when a sum of n variables with values in the κth roots of unity can be equal to some value $r \in \mathbb{C}$, that is the satisfiability of

$$\mathsf{SRU}_n^{\kappa,r} := \left\{ \sum_{i\in[n]} z_i - r, \ z_1^{\kappa} - 1, \ldots, z_n^{\kappa} - 1 \right\} . \tag{2}$$

Linear relations of the form $\sum_{i=1}^{n} c_i \zeta_i = 0$, where c_i are complex numbers and ζ_i are roots of unity, arise naturally in several contexts [9], and have been extensively studied in the literature, see for instance [16, 15]. When κ divides n, $\kappa \mid n$, it is easy to see that $\mathsf{SRU}_n^{\kappa,0}$ is satisfiable, because the κth roots of unity sum to zero.

When κ is a power of a prime number p, this is indeed the only possibility, that is $\mathsf{SRU}_n^{\kappa,0}$ is satisfiable over $\mathbb{C}$ if and only if $p \mid n$. (For the simple proof of this fact see the full version.) For the general case of $\kappa \in \mathbb{N}$, Lam and Leung [24] characterize exactly the set of natural numbers n such that $\mathsf{SRU}_n^{\kappa,0}$ is satisfiable. As a corollary of their results, if κ is not a power of a prime then, there exists a $n_0(\kappa)$ s.t. for every $n \geq n_0(\kappa)$ the set of polynomials $\mathsf{SRU}_n^{\kappa,0}$ is satisfiable.

Our results. In this paper we show the hardness to certify in PC and $\mathsf{SoS}_{\mathbb{C}}$ the unsatisfiability of $\mathsf{SRU}_n^{\kappa,0}$ when κ is a prime and does not divide n. For simplicity, we leave the discussion for the case when κ is a power of a prime for the journal version. Our main results regarding $\mathsf{PC}/\mathsf{SoS}_{\mathbb{C}}$ informally say that $\mathsf{SoS}_{\mathbb{C}}$ and $\mathsf{PC}_{\mathbb{C}}$ cannot capture divisibility arguments.

A linear degree lower bound for $\mathsf{SRU}_n^{2,0}$ follows immediately, via a linear transformation, from the known degree lower bound for KNAPSACK in SoS, since the Grigoriev's lower bound in [17] can easily extended to $\mathsf{SoS}_{\mathbb{C}}$. In this paper we generalize this result proving degree and size lower bounds in $\mathsf{SoS}_{\mathbb{C}}$ for $\mathsf{SRU}_n^{\kappa,r}$ for κ an odd prime.

▶ **Theorem 1** (Degree lower bound for $\mathsf{SRU}_n^{\kappa,r}$). *Let $n, d \in \mathbb{N}$, κ be a prime, $r \in \mathbb{C}$. Let r be written as $r_1 + \zeta r_2$, where $r_1, r_2 \in \mathbb{R}$ and ζ is some κth primitive root of unity. If*

$$\kappa d \leq \min\{r_1 + r_2 + (\kappa - 1)n + \kappa,\ n - r_1 - r_2 + \kappa\}\ ,$$

then there are no $\mathsf{SoS}_{\mathbb{C}}$-refutations of $\mathsf{SRU}_n^{\kappa,r}$ of degree at most d. In particular, $\mathsf{SRU}_n^{\kappa,0}$ requires refutations of degree $\Omega\left(\frac{n}{\kappa}\right)$ in $\mathsf{SoS}_{\mathbb{C}}$.

From the set of polynomials in $\mathsf{SRU}_n^{2,r}$ we can easily infer the polynomials in $\mathsf{SRU}_n^{\kappa,0}$, via a linear transformation and a weakening. This is enough to prove degree lower bounds for $\mathsf{SRU}_n^{\kappa,0}$ in $\mathsf{PC}_{\mathbb{C}}$ since, Impagliazzo, Pudlák, and Sgall [19, Theorem 5.1] proved a linear degree lower bound for KNAPSACK and therefore $\mathsf{SRU}_n^{2,r}$ for any r. This is not the case for $\mathsf{SoS}_{\mathbb{C}}$: $\mathsf{SRU}_n^{2,r}$ is refutable in small degree and size in $\mathsf{SoS}_{\mathbb{C}}$ if $r \in \mathbb{C} \setminus \mathbb{R}$, see Example 4. In other words, in $\mathsf{SoS}_{\mathbb{C}}$, unlike the case of PC, it is not possible to reduce the hardness of $\mathsf{SRU}_n^{\kappa,0}$, for $\kappa > 2$ to KNAPSACK.

To prove the degree lower bound in $\mathsf{SoS}_{\mathbb{C}}$ for $\mathsf{SRU}_n^{\kappa,r}$ (Theorem 1) first we construct a candidate pseudo-expectation for $\mathsf{SRU}_n^{\kappa,r}$ based on the symmetries of the set of polynomials. Then we prove its correctness, following the approach by Blekherman [5, 6] as presented in [27, Theorem B.11] but generalized to $\mathsf{SoS}_{\mathbb{C}}$. Due to page limitations we only show in Section 4 how to use the generalization of Blekherman's theorem (Theorem 13) to prove Theorem 1.

We also prove a size lower bound for $\mathsf{SRU}_n^{\kappa,0}$ in $\mathsf{SoS}_{\mathbb{C}}$. We lift degree lower bounds to size lower bounds generalizing to κ-valued Fourier variables the lifting approach due to Sokolov [34], originally designed for real valued polynomials and $\{\pm 1\}$-variables.

▶ **Theorem 2** (Size lower bound for $\mathsf{SRU}_n^{\kappa,0}$). *Let κ be a prime and $n \in \mathbb{N}$, if $n \gg \kappa$ then the set of polynomials $\mathsf{SRU}_n^{\kappa,0}$ has no refutation in $\mathsf{SoS}_{\mathbb{C}}$ within monomial size $2^{o(n)}$.*

Theorem 2, for $\kappa = 2$, follows easily from the techniques of Sokolov [34] and Grigoriev's degree lower bound for KNAPSACK [17]. For $\kappa > 2$ it requires some non-trivial extension of the lifting technique from [34]. That is, the composition of polynomials with appropriate gadgets (see Definition 6). Our generalization of the lifting from [34] is Theorem 7 in Section 3.

Theorem 1 and Theorem 2 also hold for $\mathsf{PC}_{\mathbb{C}}$, since $\mathsf{SoS}_{\mathbb{C}}$ simulates $\mathsf{PC}_{\mathbb{C}}$.

Structure of the paper. In the next section, we give the necessary preliminaries on roots of unity and the formal definition of $\mathsf{SoS}_{\mathbb{C}}$. In Section 3 we layout the proof of a way to lift degree lower bounds to size lower bounds in $\mathsf{SoS}_{\mathbb{C}}$ for sets of polynomials over the Fourier variables (Theorem 7) and we show how to prove Theorem 2 from Theorem 1 and Theorem 7. The proof of Theorem 1 is in Section 4.

2 Preliminaries

Given $n, k \in \mathbb{N}$, let $[n] := \{1, \dots, n\}$, and if k divides n we write $k \mid n$. For $a \in \mathbb{R}$ and $b \in \mathbb{N}$, let $\binom{a}{0} := 1$ and $\binom{a}{b} := \frac{a(a-1)\dots(a-b+1)}{b!}$ for $b \geq 1$. **Boldface** symbols indicate vectors, and $\boldsymbol{x}$ denotes a vector with n elements $(x_1, \dots, x_n)$. We denote with $\boldsymbol{x}$ Boolean variables, with $\boldsymbol{z}$ κ-valued variables and with $\boldsymbol{y}$ generic variables or auxiliary variables. Given a set of polynomials $P \subseteq \mathbb{C}[\boldsymbol{y}]$, $\langle P \rangle$ denotes the ideal generated by P in $\mathbb{C}[\boldsymbol{y}]$. Let $\underline{i}$ be the imaginary unit in $\mathbb{C}$, i.e. $\underline{i}^2 = -1$.

Roots of unity. For a positive integer κ, a *κth root of unity* is a root of the polynomial $z^\kappa - 1$. All the roots of unity except 1 are also roots of the polynomial $1 + z + \cdots + z^{\kappa-1}$, indeed $z^\kappa - 1 = (z-1) \cdot (1 + z + \cdots + z^{\kappa-1})$. A κth root of unity ζ is called *primitive* if $\zeta^t \neq 1$ for all $1 \leq t < \kappa$. If this is the case the κth roots of unity are indeed $1, \zeta, \zeta^2, \dots, \zeta^{\kappa-1}$. Some of the results of this paper hold for roots of unity in generic fields but, for sake of clarity, we only consider roots of unity in $\mathbb{C}$. Notice that the complex conjugate of ζ^t is $\zeta^{\kappa-t}$. For concreteness, we denote as ζ a specific primitive κth root of unity, for instance $\mathrm{e}^{2\pi\underline{i}/\kappa}$, and as Ω_κ the set $\{1, \zeta, \zeta^2, \dots, \zeta^{\kappa-1}\}$. We often denote as ω a generic element in Ω_κ.

SoS over the complex numbers. The key concept at the core of the sum-of-squares proof system is that squares of real valued polynomials are always positive. For a complex valued polynomial $p \in \mathbb{C}[\boldsymbol{y}]$ we use that $p \cdot p^* \geq 0$, where p^* is the function that maps the assignment $\boldsymbol{\alpha}$ to the complex conjugate of the value $p(\boldsymbol{\alpha})$. We need a polynomial representation of function p^* that we call *formal conjugate* of p. To have such polynomial, in general, we would need to use a twin formal variable to represent x^* for any original variable x. Furthermore we would need to add to the proof system various axioms to relate x and x^*. In this work we focus on $\mathsf{SoS}_\mathbb{C}$ under the Boolean and Fourier encodings, hence we can represent formal conjugates as polynomials without any additional axiom or variable. For a Boolean variable $x \in \{0, 1\}$ we have that x^* is x itself. For a Fourier variable z raised to an integer power $0 \leq t < \kappa$, the function $(z^t)^*$ is $z^{\kappa-t}$. Then the operator * extends homomorphically on sums and products, and it is equal to the usual complex conjugate on complex number. We are now ready to define the sum-of-squares proof system over complex number.

▶ **Definition 3** (Sum-of-Squares over $\mathbb{C}$, $\mathsf{SoS}_\mathbb{C}$)**.** *Fix an integer $\kappa \geq 2$. Consider a set of polynomials $P \subseteq \mathbb{C}[\boldsymbol{x}, \boldsymbol{z}]$ where P contains $z^\kappa - 1$ and for each variable z, and contains $x^2 - x$ for each variable x. A* refutation of P in $\mathsf{SoS}_\mathbb{C}$ *is an equality of the form*

$$-1 = \sum_{p \in P} q_p \cdot p + \sum_{s \in S} s \cdot s^* \ ,$$

where the $s \in S$ and q_p for $p \in P$ are in $\mathbb{C}[\boldsymbol{x}, \boldsymbol{z}]$ and each s^* is the formal conjugate of s.

The degree *of the refutation is* $\max\{\deg(q_p) + \deg(p), \deg(s \cdot s^*) \ : \ p \in P, \ s \in S\}$*. The* size *of the refutation is the total number of monomials occurring with non-zero coefficients among polynomials $\{q_p, p \ : \ p \in P\} \cup \{s, s^* \ : \ s \in S\}$.*

Notice that, for polynomials $p, q \in \mathbb{R}[\boldsymbol{x}, \boldsymbol{z}]$, $(p + \underline{i}q)(p - \underline{i}q) = p^2 + q^2$. Therefore for $P \subseteq \mathbb{R}[\boldsymbol{x}]$ and containing $x_i^2 - x_i$ for every $i \in [n]$, the notion of $\mathsf{SoS}_\mathbb{C}$ and $\mathsf{SoS}_\mathbb{R}$ coincide.

By Hilbert's Nullstellensatz, $\mathsf{SoS}_\mathbb{C}$ is complete: for every unsatisfiable set of polynomials P there is a $\mathsf{SoS}_\mathbb{C}$-refutation. Conversely, only unsatisfiable sets of polynomials have $\mathsf{SoS}_\mathbb{C}$ refutations: for any assignment $\boldsymbol{\alpha}$ of a polynomial s, polynomial $s \cdot s^*$ evaluates to $|s(\boldsymbol{\alpha})|^2$ which is a non-negative real number.

▶ **Example 4.** The set of polynomials $\{\sum_{j\in[n]} x_j - \underline{i},\ x_1^2 - x_1, \dots,\ x_n^2 - x_n\}$ has a simple $\mathsf{SoS}_{\mathbb{C}}$ refutation:

$$-1 = -(\sum_{j\in[n]} x_j - \underline{i})(\sum_{j\in[n]} x_j + \underline{i}) + (\sum_{j\in[n]} x_j)^2 \ .$$

Via similar algebraic equalities it is not hard to see that $\mathsf{SoS}_{\mathbb{C}}$ can refute easily the set of polynomials corresponding to KNAPSACK in eq. (1) when $r \in \mathbb{C} \setminus \mathbb{R}$ and all c_is are real. By a simple modification of [4, Lemma 3.1] and [34], we also have that, in presence of the axioms $y_i^\kappa - 1$, $\mathsf{SoS}_{\mathbb{C}}$ simulates $\mathsf{PC}_{\mathbb{C}}$, that is $\mathsf{PC}_{\mathbb{C}}$ refutations can be converted to $\mathsf{SoS}_{\mathbb{C}}$ refutations with just a polynomial increase in size.[1] Impagliazzo, Pudlák, and Sgall in [19, Theorem 5.1] prove that the set of polynomials in eq. (1) is hard for $\mathsf{PC}_{\mathbb{C}}$, hence $\mathsf{SoS}_{\mathbb{C}}$ is strictly stronger than $\mathsf{PC}_{\mathbb{C}}$.

3 Size lower bounds in Sum-of-Squares

In this section we prove the size lower bound for $\mathsf{SRU}_n^{\kappa,0}$ in $\mathsf{SoS}_{\mathbb{C}}$ from the the corresponding degree lower bound. That is we show how to prove Theorem 2 from Theorem 1. On a very high level, this is done *composing* the polynomials in $\mathsf{SRU}_n^{\kappa,r}$ with some polynomials $\boldsymbol{g}$, obtaining then some new set of polynomials $\mathsf{SRU}_n^{\kappa,r} \circ \boldsymbol{g}$, and then via a lifting theorem showing how degree lower bounds on $\mathsf{SRU}_n^{\kappa,r}$ imply size lower bounds on $\mathsf{SRU}_n^{\kappa,r} \circ \boldsymbol{g}$.

▶ **Definition 5** (composition of polynomials). *Let $\boldsymbol{x}, \boldsymbol{y}_1, \dots \boldsymbol{y}_n$ be tuples of distinct variables where $\boldsymbol{y}_j = (y_{j1}, \dots, y_{j\ell_j})$. Given a polynomial $p \in \mathbb{C}[\boldsymbol{x}]$ and $\boldsymbol{g} = (g_1 \dots, g_n)$ with $g_j \in \mathbb{C}[\boldsymbol{y}_j]$ we denote by $p \circ \boldsymbol{g}$ the polynomial obtained substituting each instance of the variable x_j in p with the polynomial $g_j(\boldsymbol{y}_j)$ and then expanding the obtained algebraic expression as a sum of monomials in the new variables. The polynomial $p \circ \boldsymbol{g}$ then belongs to the ring $\mathbb{C}[\boldsymbol{y}_1, \dots, \boldsymbol{y}_n]$.*

Similarly, for a set of polynomials $P \subset \mathbb{C}[\boldsymbol{x}]$ we denote as $P \circ \boldsymbol{g}$ the set of polynomials $\{p \circ \boldsymbol{g} \ : \ p \in P\}$.

We are only interested in composing polynomials with $\boldsymbol{g}$ when $\boldsymbol{g}$ has some good properties. Those are a generalization of the notion of *compliant gadgets* from [34, Definition 2.1].

▶ **Definition 6** (compliant polynomial). *A polynomial $g \in \mathbb{C}[y_1, \dots, y_\ell]$ is* compliant *if it is symmetric and there exists a function $h : \Omega_\kappa \to \Omega_\kappa^\ell$ such that*

1. *$g \circ h = \mathbf{id}$, i.e. for all $b \in \Omega_\kappa$, $g(h(b)) = b$;*
2. *for each $b \in \Omega_\kappa$, the first κ coordinates of $h(b)$ list all the elements of Ω_κ; and*
3. *$\prod_{\omega\in\Omega_\kappa} h(\omega)$ is a constant function.*

We say that $\boldsymbol{g} = (g_1 \dots, g_n)$ with $g_j \in \mathbb{C}[\boldsymbol{y}_j]$ is compliant *when each g_j is compliant.*

The original definition of [34, Definition 2.1] focuses on real polynomials and sets of values $\{0, 1\}$ and $\{\pm 1\}$, while ours focuses on complex polynomials and the set of κth roots of unity.

The size lower bound on $\mathsf{SRU}_n^{\kappa,0}$ in $\mathsf{SoS}_{\mathbb{C}}$ follows from the following general result.

▶ **Theorem 7.** *Let P a finite set of polynomials of degree at most d_0 in $\mathbb{C}[\boldsymbol{x}]$ containing the polynomials $x_i^\kappa - 1$ for each $i \in [n]$. Let $\boldsymbol{g}$ be a tuple of compliant polynomials with $g_i \in \mathbb{C}[y_{i1}, \dots, y_{i\ell_i}]$. If P requires degree D to be refuted in $\mathsf{SoS}_{\mathbb{C}}$, then*

$$P \circ \boldsymbol{g} \cup \{y_{ij}^\kappa - 1 \ : \ i \in [n],\ j \in [\ell_i]\}$$

requires monomial size at least $\exp(\frac{(D-d_0)^2}{8\ell^\kappa(\kappa-1)n})$ to be refuted in $\mathsf{SoS}_{\mathbb{C}}$, where $\ell = \max_{i\in[n]} \ell_i$.

[1] The main difference with [4, Lemma 3.1] and [34] is to consider polynomials $s \cdot s^*$ instead of squares s^2 and then to use the algebraic equality $(p+q)(p+q)^* + (p-q)(p-q)^* = 2pp^* + 2qq^*$ instead of the one for the reals $(p+q)^2 + (p-q)^2 = 2p^2 + 2q^2$.

This result is a generalization of [34, Theorem 4.2]. Before seeing how to prove this result let us see how to apply it to prove a size lower bound for $\mathsf{SRU}_n^{\kappa,0}$, that is Theorem 2, restated below for convenience of the reader.

▶ **Theorem 2** (Size lower bound for $\mathsf{SRU}_n^{\kappa,0}$). *Let κ be a prime and $n \in \mathbb{N}$, if $n \gg \kappa$ then the set of polynomials $\mathsf{SRU}_n^{\kappa,0}$ has no refutation in $\mathsf{SoS}_{\mathbb{C}}$ within monomial size $2^{o(n)}$.*

Proof. Let $n = (2\kappa + 1)n' + b$ with $b \in \{0, \dots, 2\kappa\}$. Let $\ell_1 = \cdots = \ell_b = 2\kappa + 2$ and $\ell_{b+1} = \cdots = \ell_{n'} = 2\kappa + 1$. Consider the tuple $\boldsymbol{g} = (g_1, \dots, g_{n'})$ where $g_i \in \mathbb{C}[y_{i1}, \dots, y_{i\ell_i}]$ is the polynomial

$$g_i(y_{i1}, \dots, y_{i\ell_i}) := \frac{1}{\kappa}\Big(\sum_{j \in [\ell_i]} y_{ij} - (\ell_i - 2\kappa)\Big) .$$

We have that $\mathsf{SRU}_n^{\kappa,0}$ after renaming of variables is a subset of

$$\mathsf{SRU}_{n'}^{\kappa,r} \circ \boldsymbol{g} \cup \{y_{ij}^{\kappa} - 1 \ :\ i \in [n'],\ j \in [\ell_i]\} \tag{3}$$

with $r = -\frac{n'+b}{\kappa}$. By Theorem 1, there are no $\mathsf{SoS}_{\mathbb{C}}$ refutations of $\mathsf{SRU}_{n'}^{\kappa,r}$ in degree $\frac{n'}{\kappa}$. Each g_i is compliant. Indeed, the polynomial g_i is symmetric and we can take as $h_i : \Omega_\kappa \to \Omega_\kappa^{\ell_i}$ the function mapping

$$h_i : \omega \mapsto (1, \zeta, \zeta^2, \dots, \zeta^{\kappa-1}, \underbrace{1, 1, \dots, 1}_{\ell_i - 2\kappa}, \underbrace{\omega, \omega, \dots, \omega}_{\kappa}) ,$$

where ζ is a primitive κth root of unity in $\mathbb{C}$. Clearly, $g \circ h$ is the identity and

$$\prod_{\omega \in \Omega_\kappa} h_i(\omega) = \zeta^{\kappa(\kappa-1)/2}\omega^{\kappa} = \zeta^{\kappa(\kappa-1)/2}$$

since ω is a κth root of unity. By Theorem 7, the set of polynomials (3) requires $\mathsf{SoS}_{\mathbb{C}}$ refutations of monomial size at least $\exp\big(\frac{(\frac{n'}{\kappa} - \kappa)^2}{8\ell^{\kappa}(\kappa-1)n'}\big) = 2^{\Omega(n)}$ if $n \gg \kappa$. Therefore $\mathsf{SRU}_n^{\kappa,0}$ requires refutations size $2^{\Omega(n)}$, too. ◀

We conclude this section with a proof sketch of Theorem 7. The overall structure of the argument is that typical for size-degree trade-offs and can be found for instance in [8, 34, 1]. The idea is to show, on one side, that there exists a relatively long sequence of restrictions such that the restricted polynomials have small degree refutations (Theorem 8) and that each individual restriction can only make the degree decrease a little (Lemma 9). Those two facts will imply that the sequence of restrictions must be very long and this will imply the size-degree trade-off.

The *reduced degree* of a refutation in $\mathsf{SoS}_{\mathbb{C}}$ of a set of polynomials P containing the polynomials $x_j^{\kappa} - 1$ is the degree of the refutation where we do not take in account the degrees of the polynomials q_p where p is $x_j^{\kappa} - 1$ (see Definition 3).

Next theorem is the first ingredient for the proof of Theorem 7. It is a generalization of [34, Theorem 4.1] and its proof, an adaptation of the argument given in [34], is in the full version.

▶ **Theorem 8.** *Let P be finite a set of polynomials of degree d_0 in $\mathbb{C}[\boldsymbol{x}]$ containing the polynomials $x_j^{\kappa} - 1$ for each $j \in [n]$. Let $\boldsymbol{g}$ be a tuple of compliant polynomials with $g_i \in \mathbb{C}[y_{i1}, \dots, y_{i\ell_i}]$ and $\omega_1, \omega_2, \dots, \omega_m \in \Omega_\kappa$. If there is a $\mathsf{SoS}_{\mathbb{C}}$ refutation of $P \circ \boldsymbol{g} \cup \{y_{ij}^{\kappa} - 1 \ :\ i \in [n],\ j \in [\ell_i]\}$ of size s then there exists a sequence of variables $x_{i_1}, \dots, x_{i_m}$ with $m \geq \ell^{\kappa} n \ln(s)/D$ such that*

1. *$\ell = \max_i \ell_i$;*
2. *the choice of x_{i_t} only depends on $\omega_1, \dots, \omega_{t-1}$;*
3. *there is a $\mathsf{SoS}_{\mathbb{C}}$ refutation of $P\restriction_{x_{i_1}=\omega_1,\dots,x_{i_m}=\omega_m}$ of reduced degree at most $D + d_0$.*

The second ingredient for the proof of Theorem 7 is the following lemma.

▶ **Lemma 9.** *Let P be a finite set of polynomials in $\mathbb{C}[\boldsymbol{x}]$ containing the polynomials $x_j^\kappa - 1$ for each $j \in [n]$. Suppose any $\mathsf{SoS}_{\mathbb{C}}$ refutation of P has reduced degree at least D. Then, for any variable x_j there is $\omega \in \Omega_\kappa$ such that $\mathsf{SoS}_{\mathbb{C}}$ refutations of $P\restriction_{x_j=\omega}$ must have reduced degree at least $D - 2\kappa + 2$.*

Proof. (sketch) For sake of contradiction, suppose there exists some variable x such that for every $\omega \in \Omega_\kappa$, $P\restriction_{x=\omega}$ has a refutation of reduced degree $D - 2\kappa + 1$. For every $\ell \in \mathbb{N}$, $x^\ell - \omega^\ell$ is a multiple of $x - \omega$. Therefore, for every $p \in P$, the polynomial $p - p\restriction_{x=\omega}$ belongs to the ideal generated by $x - \omega$. This means that we can transform refutations of $P\restriction_{x=\omega}$ into refutations of $P \cup \{x - \omega\}$ without increasing the degree. Hence, there are refutations of $P \cup \{x - \omega\}$ of reduced degree $D - 2\kappa + 1$ for every $\omega \in \Omega_\kappa$.

Let π_ω be a refutation of $P \cup \{x - \omega\}$ of reduced degree $D - 2\kappa + 1$. Let $q_\omega(x) = \prod_{\omega' \neq \omega}(x - \omega')$.

It is easy to see that multiplying π_ω by the polynomial $q_\omega q_\omega^*$ we get a derivation of $-q_\omega q_\omega^*$ from P. This new derivation has reduced degree $D-2\kappa+1+2(\kappa-1) = D-1$. Now we can take a linear combination (with *non-negative real* coefficients) of the previous derivations to get the derivation of -1. More precisely we need numbers $\alpha_\omega \geq 0$ such that $\sum_{\omega\in\Omega_\kappa} \alpha_\omega q_\omega q_\omega^* - 1 \in \langle x^\kappa - 1\rangle$. Setting $\alpha_\omega = 1/q_\omega(\omega)q_\omega(\omega)^*$ we get that that $\sum_{\omega\in\Omega_\kappa} \alpha_\omega q_\omega q_\omega^* - 1$ is zero for all $\omega \in \Omega_\kappa$ and therefore in the ideal $\langle x^\kappa - 1\rangle$. This finally gives a $\mathsf{SoS}_{\mathbb{C}}$ refutation of P in degree $D - 1$, contradicting the assumption on P. ◀

Proof of Theorem 7. Let s be the smallest size of a $\mathsf{SoS}_{\mathbb{C}}$ refutation of the set of polynomials $P \circ \boldsymbol{g} \cup \{y_{ij}^\kappa - 1 : \ i \in [n],\ j \in [\ell_i]\}$. We alternate applications of Theorem 8 to pick x_{i_t} with applications of Lemma 9 to pick ω_t, and in the end we have a sequence of variables/values $x_{i_1} = \omega_1, \dots, x_{i_m} = \omega_m$. By these choices, the restricted set of polynomials $P\restriction_{x_{i_1}=\omega_1,\dots,x_{i_m}=\omega_m}$ requires refutations of reduced degree at least $D - 2\kappa m + 2m$. By Theorem 8, we can set $m = \ell^k n \ln(s)/D'$ for some $D' > 0$ and get a refutation of reduced degree at most $D' + d_0$. Hence, $D' + d_0 \geq D - 2m(\kappa - 1)$ and we get that $\ln(s) \geq \frac{D'(D-D'-d_0)}{2\ell^k n(\kappa-1)}$. The largest value is attained for $D' = (D - d_0)/2$ and we get $\ln(s) \geq \frac{(D-d_0)^2}{8\ell^k n(\kappa-1)}$. ◀

4 Degree lower bounds in $\mathsf{SoS}_{\mathbb{C}}$

In this section we prove Theorem 1, restated here for convenience of the reader.

▶ **Theorem 1** (Degree lower bound for $\mathsf{SRU}_n^{\kappa,r}$). *Let $n, d \in \mathbb{N}$, κ be a prime, $r \in \mathbb{C}$. Let r be written as $r_1 + \zeta r_2$, where $r_1, r_2 \in \mathbb{R}$ and ζ is some κth primitive root of unity. If*

$$\kappa d \leq \min\{r_1 + r_2 + (\kappa - 1)n + \kappa,\ n - r_1 - r_2 + \kappa\}\ ,$$

then there are no $\mathsf{SoS}_{\mathbb{C}}$-refutations of $\mathsf{SRU}_n^{\kappa,r}$ of degree at most d. In particular, $\mathsf{SRU}_n^{\kappa,0}$ requires refutations of degree $\Omega\left(\frac{n}{\kappa}\right)$ in $\mathsf{SoS}_{\mathbb{C}}$.

It is convenient to consider the following Boolean encoding of the sums of roots of unity,

$$\mathsf{bool\text{-}SRU}_n^{\kappa,r} := \left\{ \sum_{i\in[n]} \Big(\sum_{j\in[\kappa]} \zeta^{j-1} x_{ij} \Big) - r,\ x_{ij}^2 - x_{ij},\ \sum_{j\in[\kappa]} x_{ij} - 1\ :\ i \in [n], j \in [\kappa] \right\}\ . \quad (4)$$

The set of equations $\mathsf{SRU}_n^{\kappa,r}$ uses variables taking values in $\{1,\zeta,\zeta^2,\dots,\zeta^{\kappa-1}\}$, the encoding in eq. (4) uses indicator variables to select the appropriate power of ζ. It is easy to see that the degree needed to refute $\mathsf{SRU}_n^{\kappa,r}$ in $\mathsf{PC}_{\mathbb{C}}/\mathsf{SoS}_{\mathbb{C}}$ is at least the degree needed to refute $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$ in $\mathsf{PC}_{\mathbb{C}}/\mathsf{SoS}_{\mathbb{C}}$. Hence, it is enough to show the degree lower bound for $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$. To show this we construct a degree-d *pseudo-expectation* for $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$, i.e., a linear operator $\tilde{\mathbb{E}}:\mathbb{C}[\boldsymbol{x}]\to\mathbb{C}$ such that

- $\tilde{\mathbb{E}}(1)=1$,
- $\tilde{\mathbb{E}}(mp)=0$, for every $p\in\mathsf{bool\text{-}SRU}_n^{\kappa,r}$ and m monomial such that $\deg(p)+\deg(m)\le d$,
- $\tilde{\mathbb{E}}(s\cdot s^*)\in\mathbb{R}_{\ge 0}$, for every polynomial s s.t. $\deg(s\cdot s^*)\le d$.

It is easy to see that the existence of a degree-d pseudo-expectation for a set of polynomials P implies that P cannot be refuted in degree-d $\mathsf{SoS}_{\mathbb{C}}$. The construction of an appropriate pseudo-expectation $\tilde{\mathbb{E}}$ for $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$ is the goal of this section.

Some notation. In this section we consider fixed $r\in\mathbb{C}$ and $r_1,r_2\in\mathbb{R}$ such that $r=r_1+\zeta r_2$. Let $\boldsymbol{e}_j$ be the vector of dimension κ with the jth entry 1 and all other entries 0. For $j\in[\kappa]$, let $\boldsymbol{x}^{(j)}:=(x_{1j},\dots,x_{nj})$. That is, $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$ is a set of polynomials in $\mathbb{C}[\boldsymbol{x}^{(1)},\dots,\boldsymbol{x}^{(\kappa)}]$. Given a tuple of sets $\boldsymbol{I}=(I_1,\dots,I_\kappa)$, where $I_j\subseteq[n]$, let $X_{\boldsymbol{I}}:=\prod_{j\in[\kappa]}\prod_{i\in I_j}x_{ij}$. With $\|\cdot\|$ we always denote the 1-norm. So $\|\boldsymbol{x}^{(j)}\|$ denotes the polynomial $\sum_{i\in[n]}x_{ij}$.

A potential satisfying assignment of $\mathsf{bool\text{-}SRU}_n^{\kappa,r}$ consists of $\boldsymbol{\gamma}=(\gamma_1,\dots,\gamma_\kappa)$, the allocation of the n roots of unity in the directions $\zeta^0,\dots,\zeta^{\kappa-1}$. The sum $\sum_{j\in[\kappa]}\zeta^{j-1}\gamma_j$ must be equal to the target value $r=r_1+\zeta r_2$, so we spread uniformly $n-r_1-r_2$ among the γ_js, and then add r_1 and r_2 to γ_1 and γ_2 respectively. This leads to the definitions

$$\begin{cases}\gamma_1=\frac{n-r_1-r_2}{\kappa}+r_1\ ,\\ \gamma_2=\frac{n-r_1-r_2}{\kappa}+r_2\ ,\\ \gamma_j=\frac{n-r_1-r_2}{\kappa}\quad\text{for } j\ge 3\ .\end{cases}\tag{5}$$

Observe that $\|\boldsymbol{\gamma}\|=n$. For ease of notation let $\hat{\gamma}=\frac{n-r_1-r_2}{\kappa}$ and $r_3=\dots=r_\kappa=0$. Therefore, we can write $\gamma_j=\hat{\gamma}+r_j$ for each $j\in[\kappa]$.

Given $\boldsymbol{I}=(I_1,\dots,I_\kappa)$ with $I_j\subseteq[n]$, and variables $\boldsymbol{v}=(v_1,\dots,v_\kappa)$, let $S(X_{\boldsymbol{I}})$ be the polynomial in the variables $\boldsymbol{v}$ defined by

$$S(X_{\boldsymbol{I}}):=\begin{cases}\dfrac{(n-|\bigcup_{j\in[\kappa]}I_j|)!}{n!}\displaystyle\prod_{j\in[\kappa]}\prod_{\ell=0}^{|I_j|-1}(v_j-\ell) & \text{if the sets in } \boldsymbol{I} \text{ are pair-wise disjoint}\ ,\\ 0 & \text{otherwise}\ .\end{cases}\tag{6}$$

By linearity, extend $S(\cdot)$ to all polynomials. That is, given $p=\sum_{\boldsymbol{I}}\alpha_{\boldsymbol{I}}X_{\boldsymbol{I}}$ with $\alpha_{\boldsymbol{I}}\in\mathbb{C}$, let $S(p):=\sum_{\boldsymbol{I}}\alpha_{\boldsymbol{I}}S(X_{\boldsymbol{I}})$. We define

$$\tilde{\mathbb{E}}(p):=S(p)(\boldsymbol{\gamma})$$

and we show that $\tilde{\mathbb{E}}$ is a pseudo-expectation for $\mathsf{bool\text{-}Kn}_n^{\kappa,r}$.

Let $\mathbb{B}$ be the ideal $\langle x_{ij}^2-x_{ij},\ x_{ij}x_{ij'}:i\in[n],\ j,j'\in[\kappa],\ j\ne j'\rangle$. Given polynomials $p,q\in\mathbb{C}[\boldsymbol{x}^{(1)},\dots,\boldsymbol{x}^{(\kappa)}]$, we use the notation $p\equiv q$ to denote that $p-q\in\mathbb{B}$.

▶ **Lemma 10.** *If $p\equiv q$ then $\tilde{\mathbb{E}}(p)=\tilde{\mathbb{E}}(q)$.*

Proof. By definition $p\equiv q$ means there exists a polynomial $s\in\mathbb{B}$ such that $p=q+s$. By construction, $\tilde{\mathbb{E}}$ maps to 0 every polynomial in $\mathbb{B}$, in particular $\tilde{\mathbb{E}}(s)=0$. By the linearity of $\tilde{\mathbb{E}}$, then $\tilde{\mathbb{E}}(p)=\tilde{\mathbb{E}}(q)$. ◀

From the definition of $\tilde{\mathbb{E}}$, it follows easily that the lifts of the polynomials in $\textsf{bool-SRU}_n^{\kappa,r}$ are mapped to 0 by $\tilde{\mathbb{E}}$.

▶ **Theorem 11.** *For every $\boldsymbol{I} = (I_1, \dots, I_\kappa)$ with $I_j \subseteq [n]$ and $i \in [n]$, and every $p \in \textsf{bool-SRU}_n^{\kappa,r}$, $\tilde{\mathbb{E}}(X_{\boldsymbol{I}} p) = 0$.*

Proof. The fact that $\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(x_{ij}^2 - x_{ij})) = 0$ is immediate by the definition of $\tilde{\mathbb{E}}$.

Given $\boldsymbol{a} = (a_1, \dots, a_\kappa) \in [n]^\kappa$, let $E_{\boldsymbol{a}} := \frac{(n-\|\boldsymbol{a}\|)!}{n!} \prod_{j\in[\kappa]} \prod_{\ell=0}^{a_j-1} (\gamma_j - \ell)$. Notice that for every $j \in [\kappa]$, $E_{\boldsymbol{a}+\boldsymbol{e}_j} = E_{\boldsymbol{a}} \frac{\gamma_j - a_j}{n - \|\boldsymbol{a}\|}$. If the sets I_j are not pair-wise disjoint then, by definition, the pseudo-expectation is already 0, so it is enough to consider the case when the I_js are pair-wise disjoint.

Let $\boldsymbol{t} = (t_1, \dots, t_\kappa)$ where $t_j = |I_j|$. To show that $\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(\sum_{j\in[\kappa]} x_{ij} - 1)) = 0$ we have two cases. If $i \in \bigcup_{j\in[\kappa]} I_j$, then

$$\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(\sum_{j\in[\kappa]} x_{ij} - 1)) = E_{\boldsymbol{t}} - E_{\boldsymbol{t}} = 0 \ .$$

If $i \notin \bigcup_{j\in[\kappa]} I_j$, then

$$\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(\sum_{j\in[\kappa]} x_{ij} - 1)) = \sum_{j\in[\kappa]} E_{\boldsymbol{t}+\boldsymbol{e}_j} - E_{\boldsymbol{t}} = E_{\boldsymbol{t}} \cdot \left(\sum_{j\in[\kappa]} \frac{\gamma_j - t_j}{n - \|\boldsymbol{t}\|} - 1 \right) = E_{\boldsymbol{t}} \cdot \left(\frac{\|\boldsymbol{\gamma}\| - \|\boldsymbol{t}\|}{n - \|\boldsymbol{t}\|} - 1 \right) = 0 \ ,$$

since $\|\boldsymbol{\gamma}\| = n$.
Finally we prove that $\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(\sum_{j\in[\kappa]} \zeta^{j-1} \|\boldsymbol{x}^{(j)}\| - r_1 - \zeta r_2)) = 0$:

$$\begin{aligned}
\tilde{\mathbb{E}}(X_{\boldsymbol{I}}(\sum_{j\in[\kappa]} \zeta^{j-1} \|\boldsymbol{x}^{(j)}\| - r_1 - \zeta r_2)) &= E_{\boldsymbol{t}} \sum_{j\in[\kappa]} \zeta^{j-1} t_j + \sum_{i \notin \bigcup_{j\in[\kappa]} I_j} (\sum_{j\in[\kappa]} \zeta^{j-1} E_{\boldsymbol{t}+\boldsymbol{e}_j}) - (r_1 + \zeta r_2) E_{\boldsymbol{t}} \\
&= E_{\boldsymbol{t}} \sum_{j\in[\kappa]} \zeta^{j-1} t_j + (n - \|\boldsymbol{t}\|) \sum_{j\in[\kappa]} \zeta^{j-1} E_{\boldsymbol{t}+\boldsymbol{e}_j} - (r_1 + \zeta r_2) E_{\boldsymbol{t}} \\
&= E_{\boldsymbol{t}} \sum_{j\in[\kappa]} \zeta^{j-1} t_j + E_{\boldsymbol{t}} \sum_{j\in[\kappa]} \zeta^{j-1} (\gamma_j - t_j) - (r_1 + \zeta r_2) E_{\boldsymbol{t}} \\
&= E_{\boldsymbol{t}} \cdot \left(\sum_{j\in[\kappa]} \zeta^{j-1} t_j + \sum_{j\in[\kappa]} \zeta^{j-1} (\gamma_j - t_j) - (r_1 + \zeta r_2) \right) \\
&= E_{\boldsymbol{t}} \cdot \left(\sum_{j\in[\kappa]} \zeta^{j-1} \gamma_j - (r_1 + \zeta r_2) \right) \\
&= E_{\boldsymbol{t}} \cdot \left(\sum_{j\in[\kappa]} \zeta^{j-1} \hat{\gamma} + \sum_{j\in[\kappa]} \zeta^{j-1} r_j - (r_1 + \zeta r_2) \right) \\
&= 0 \ ,
\end{aligned}$$

since $\gamma_j = \hat{\gamma} + r_j$, $r_j = 0$ for $j > 2$, and $\sum_{j\in[k]} \zeta^{j-1} = 0$. ◀

This result, together with Theorem 12 below, implies that $\tilde{\mathbb{E}}$ is a degree-d pseudo-expectation for $\textsf{bool-SRU}_n^{\kappa,r}$, and therefore a degree-d lower bound for the refutations of $\textsf{bool-SRU}_n^{\kappa,r}$ and $\textsf{SRU}_n^{\kappa,r}$ in $\textsf{SoS}_{\mathbb{C}}$, i.e. Theorem 1. The idea is to use to Blekherman's approach in [27, Appendix B,C]. Let us recall first some useful notation.

Let $\mathfrak{S}_n$ be the symmetric group of n elements. For a set $J \subseteq [n]$ and a permutation $\sigma \in \mathfrak{S}_n$, let $\sigma J := \{\sigma(j) \,:\, j \in J\}$. Consider variables $\boldsymbol{y} = (y_1, \dots, y_n)$. For a set $J \subseteq [n]$ let $Y_J := \prod_{j \in J} y_j$. Given a polynomial $p \in \mathbb{C}[\boldsymbol{y}]$, that is $p(\boldsymbol{y}) = \sum_{J \subseteq [n]} p_J Y_J$, with $p_J \in \mathbb{C}$, let

$$\sigma p(\boldsymbol{y}) := \sum_J p_J Y_{\sigma J} \ .$$

Then define the *symmetrization* of p as the polynomial $\mathrm{Sym}(p) \in \mathbb{C}[\boldsymbol{y}]$ given by

$$\mathrm{Sym}(p)(\boldsymbol{y}) := \frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} \sigma p(\boldsymbol{y}) \ .$$

▶ **Theorem 12.** *For every polynomial $p \in \mathbb{C}[\boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(\kappa)}]$ of degree at most d, if*

$$-(\kappa - 1)n + \kappa d - \kappa \le r_1 + r_2 \le n - \kappa d + \kappa \ ,$$

then $\tilde{\mathbb{E}}(p \cdot p^*) \ge 0$ where p^* is the formal conjugate of p.

Proof. Let $\boldsymbol{\gamma}$ be defined as in eq. (5), and recall $\hat{\gamma} = \frac{n - r_1 - r_2}{\kappa}$. Recall that the polynomial $S(X_{\boldsymbol{I}})$ when evaluated on $\boldsymbol{\gamma}$ is exactly $\tilde{\mathbb{E}}(X_{\boldsymbol{I}})$, see the comment after eq. (6). We have that

$$\begin{aligned}
\tilde{\mathbb{E}}(p \cdot p^*) &= S(p \cdot p^*)(\boldsymbol{\gamma}) && \text{[by the definition of } \tilde{\mathbb{E}}] \\
&= S(p \cdot p^*)(r_1 + \hat{\gamma}, r_2 + \hat{\gamma}, \dots, r_\kappa + \hat{\gamma}) && \text{[by the definition of } \boldsymbol{\gamma}] \\
&= \mathrm{Sym}(p\restriction_\rho \cdot p\restriction^*_\rho)(\hat{\gamma} \boldsymbol{e}_1) && \text{[by Theorem 14 below]} \\
&= \sum_{j=0}^{d} p_{d-j}(\hat{\gamma}) \cdot p^*_{d-j}(\hat{\gamma}) \prod_{i=0}^{j-1} (\hat{\gamma} - i)(n - \hat{\gamma} - i) \ , && \text{[by Theorem 13 below]}
\end{aligned}$$

where ρ is the substitution given by $\rho(x_{ij}) := y_i + \frac{r_j}{n}$ (recall that $r_3 = \cdots = r_\kappa = 0$). Now, $p_{d-j}(\hat{\gamma}) \cdot p^*_{d-j}(\hat{\gamma})$ is always real and non-negative since it is the module of the complex number $p_{d-j}(\hat{\gamma})$, hence to enforce the non-negativity of $\tilde{\mathbb{E}}(p \cdot p^*)$ it is enough to argue that $\prod_{i=0}^{j-1} (\hat{\gamma} - i)(n - \hat{\gamma} - i) \ge 0$. This is true if $\hat{\gamma} - d + 1 \ge 0$ and $n - \hat{\gamma} - d + 1 \ge 0$. I.e. if

$$-(\kappa - 1)n + \kappa d - \kappa \le r_1 + r_2 \le n - \kappa d + \kappa \ . \qquad ◀$$

▶ **Theorem 13** (adaptation of [27, Theorem B.11])**.** *Given variables $\boldsymbol{y} = (y_1, \dots, y_n)$ and $p, q \in \mathbb{C}[\boldsymbol{y}]$ with degree at most $d \le n/2$,*

$$\mathrm{Sym}(p \cdot p^*)(\boldsymbol{y}) \equiv \sum_{j=0}^{d} p_{d-j}(\|\boldsymbol{y}\|) \cdot p^*_{d-j}(\|\boldsymbol{y}\|) \prod_{i=0}^{j-1} (\|\boldsymbol{y}\| - i)(n - \|\boldsymbol{y}\| - i) \ ,$$

where p_{d-j} is a univariate polynomial with coefficients in $\mathbb{C}$, p^*_{d-j} is the formal conjugate of p_{d-j} and the degree of both polynomials is at most $(d - j)/2$.

This result is provable using exactly the same argument of Blekherman in [27, Theorem B.11], adapted to complex numbers.

▶ **Theorem 14.** *Given $p \in \mathbb{C}[\boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(\kappa)}]$,*

$$S(p)(r_1 + \|\boldsymbol{y}\|, r_2 + \|\boldsymbol{y}\|, r_3 + \|\boldsymbol{y}\|, \dots, r_\kappa + \|\boldsymbol{y}\|) \equiv \mathrm{Sym}(p\restriction_\rho)(\boldsymbol{y}) \ ,$$

where ρ is the substitution given by $\rho(x_{ij}) := y_i + \frac{r_j}{n}$ (recall that $r_3 = \cdots = r_\kappa = 0$).

Proof. Given a vector of variables $\boldsymbol{y} = (y_1, \dots, y_m)$, let $\binom{\|\boldsymbol{y}\|}{t}$ be the polynomial

$$\binom{\|\boldsymbol{y}\|}{t} := \frac{\|\boldsymbol{y}\|(\|\boldsymbol{y}\| - 1) \cdots (\|\boldsymbol{y}\| - t + 1)}{t!} .$$

It holds that $\binom{\|\boldsymbol{y}\|}{t} \equiv \sum_{\substack{I \subseteq [n] \\ |I|=t}} Y_I$. (A proof of this fact is in the full version.) This immediately implies that

$$\prod_{j \in [\kappa]} \binom{\|\boldsymbol{x}^{(j)}\|}{t_j} \equiv \sum_{\substack{\boldsymbol{I}=(I_1,\dots,I_\kappa),\ I_j \subseteq [n] \\ |I_j|=t_j}} X_{\boldsymbol{I}} . \tag{7}$$

For a vector of sets $\boldsymbol{I} = (I_1, \dots, I_\kappa)$ and a permutation $\sigma \in \mathfrak{S}_n$, let $\sigma\boldsymbol{I} := (\sigma I_1, \dots, \sigma I_\kappa)$. Given a polynomial $p = \sum_{\boldsymbol{I}} p_{\boldsymbol{I}} X_{\boldsymbol{I}}$ in $\mathbb{C}[\boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(\kappa)}]$ and a permutation $\sigma \in \mathfrak{S}_n$ let

$$\sigma p := \sum_{\boldsymbol{I}} p_{\boldsymbol{I}} X_{\sigma\boldsymbol{I}} .$$

Now, for any polynomial $p \in \mathbb{C}[\boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(\kappa)}]$

$$\frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} \sigma p \equiv S(p)(\|\boldsymbol{x}^{(1)}\|, \dots, \|\boldsymbol{x}^{(\kappa)}\|) . \tag{8}$$

To see this equivalence, by linearity, it is enough to show that for every $\boldsymbol{I}$ with $I_j \subseteq [n]$

$$\frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} X_{\sigma\boldsymbol{I}} \equiv S(X_{\boldsymbol{I}})(\|\boldsymbol{x}^{(1)}\|, \dots, \|\boldsymbol{x}^{(\kappa)}\|) .$$

If the sets in $\boldsymbol{I}$ are not pair-wise disjoint it is immediate to see that $\frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} X_{\sigma\boldsymbol{I}} \in \mathbb{B}$, and therefore $\frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} X_{\sigma\boldsymbol{I}} \equiv 0$. Suppose then $\boldsymbol{I} = (I_1, \dots, I_\kappa)$ and the sets I_j are pair-wise disjoint. Let $t_j = |I_j|$, then

$$\begin{aligned}
\frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} X_{\sigma\boldsymbol{I}} &= \frac{(n - \|\boldsymbol{t}\|)! \prod_{j \in [\kappa]} t_j!}{n!} \cdot \sum_{\substack{\boldsymbol{S}=(S_1,\dots,S_\kappa) \\ \text{pair-wise disj.} \\ |S_j|=t_j}} X_{\boldsymbol{S}} \\
&\equiv \frac{(n - \|\boldsymbol{t}\|)! \prod_{j \in [\kappa]} t_j!}{n!} \cdot \sum_{\substack{\boldsymbol{S}=(S_1,\dots,S_\kappa) \\ |S_j|=t_j}} X_{\boldsymbol{S}} \\
&\equiv \frac{(n - \|\boldsymbol{t}\|)!}{n!} \prod_{j \in [\kappa]} t_j! \cdot \prod_{j \in [\kappa]} \binom{\|\boldsymbol{x}^{(j)}\|}{t_j} \qquad (9) \\
&= S(X_{\boldsymbol{I}})(\|\boldsymbol{x}^{(1)}\|, \dots, \|\boldsymbol{x}^{(\kappa)}\|) ,
\end{aligned}$$

where the equality in eq. (9) follows from eq. (7).

To conclude, it is then enough to observe that the statement we want to prove follows from eq. (8) restricting both sides of the equality by ρ. To prove this we use that $\sigma X_{\boldsymbol{I}}\restriction_\rho = \sigma(X_{\boldsymbol{I}}\restriction_\rho)$. ◀

5 Conclusions

The study of algebraic proof systems under Fourier encoding is still at its infancy. There are many natural questions about its size efficiency. We understand reasonably well the strength relation between resolution and PC in the Boolean encoding. Sokolov [34] stresses that we do not even know yet whether PC with $\{\pm 1\}$ simulates resolution or not.

We mentioned already that the study of κ-COLORING of graphs is a very natural application of PC with Fourier encoding. There are some degree lower bounds in literature [26], but size lower bounds are still unknown. Understanding size would allow to understand larger classes of algebraic algorithms for this problem.

Abstract

We introduce a family of ZX-calculi which axiomatise the stabiliser fragment of quantum theory in odd prime dimensions. These calculi recover many of the nice features of the qubit ZX-calculus which were lost in previous proposals for higher-dimensional systems. We then prove that these calculi are complete, i.e. provide a set of rewrite rules which can be used to prove any equality of stabiliser quantum operations. Adding a discard construction, we obtain a calculus complete for mixed state stabiliser quantum mechanics in odd prime dimensions, and this furthermore gives a complete axiomatisation for the related diagrammatic language for affine co-isotropic relations.

1 Introduction

The ZX-calculus is a powerful yet intuitive graphical language for reasoning about quantum computing, or, more generally, about operations on quantum systems [23, 46]. It allows one to represent such quantum operations pictorially, and comes equipped with a set of rules which, in principle, make it possible to derive any equality between those pictures [3, 38, 42]. It has now had several applications in quantum information processing, from MBQC [32, 5] through quantum error correction codes [31, 29, 20, 33]. More recently, it has been used to obtain state-of-the-art optimisation techniques for quantum circuits [39, 28, 30] and faster classical simulation algorithms for general quantum computations [40].

Despite its origins in categorical quantum mechanics and the diagrammatic language for finite-dimensional linear spaces [1, 22, 23] the literature on the ZX-calculus has been concerned almost exclusively with small-dimensional quantum systems, and even then mostly with the case of two-dimensional quantum systems, or qubits. The qubit ZX-calculus is remarkable in its simple treatment of stabiliser quantum mechanics, along with the fact that any diagram can be treated purely graph-theoretically, without concern to its overall layout, and without losing its quantum-mechanical interpretation. Those proposals that go beyond qubits lose many of these nice features, and are significantly more complicated than the qubit case [43, 51, 9, 50, 49]. In particular, they eschew the prised “Only Connectivity Matters” (OCM) meta-rule, often cited as one of the key features in the qubit case. In these calculi, which can represent any linear map between the corresponding Hilbert spaces, it is also not necessarily obvious (at least, to us) how to pick out and work with the stabiliser fragment.

Stabiliser quantum mechanics is a simple yet particularly important fragment of quantum theory. While much less powerful than the full fragment – it can be efficiently classically simulated, even in odd prime dimensions [27] – it has seen significant study [34, 36] and forms the basis for a number of key methods in quantum information theory [35]. Operationally, it can be described as the fragment of quantum mechanics which is obtained if one allows only state preparation and measurement in the computational basis, and unitary operations from the *Clifford groups* [35]. In the qubit case, the stabiliser fragment of the ZX-calculus was proved complete in [3] while ignoring global scalars, and extended to include scalars in [4]. A simplified calculus further reducing the set of axioms of the calculus was presented in [6].

In this article, we present a simple family of ZX-calculi which are complete for stabiliser quantum mechanics in odd prime dimensions, and which recover as many of the nice features of the qubit calculus as possible. In odd prime dimensions, stabiliser quantum mechanics can be given a particularly nice graphical presentation, owing to the group-theory underlying the corresponding Clifford groups [41, 2, 27]. We then give this calculus a set of rewrite rules that is complete, i.e. rich enough to derive any equality of stabiliser quantum operations. In particular, it is a design priority to recover OCM, and to make explicit the stabiliser fragment and its group-theoretical underpinnings. Adding a discard construction [18], we obtain a universal and complete calculus for mixed state stabiliser quantum mechanics in odd prime dimensions. By previous work [26], this gives a complete axiomatisation for the related diagrammatic language for affine co-isotropic relations, while still maintaining OCM.

Although we do not do so here, these calculi can naturally be extended to represent much larger fragments of quantum theory, up to the entire theory in odd prime dimensions [51]. However, finding a complete axiomatisation for such calculi will presumably be a much more complicated task, and we leave this for future work.

All proofs and additional appendices are available in the full version of the paper [14].

2 Stabiliser quantum mechanics in odd prime dimensions

Throughout this paper, p denotes an arbitrary odd prime, and $\mathbb{Z}_p = \mathbb{Z}/p\mathbb{Z}$ the ring of integers with arithmetic modulo p. We also put $\omega := e^{i\frac{2\pi}{p}}$, and let $\mathbb{Z}_p^*$ be the group of units of $\mathbb{Z}_p$. Since p is prime, $\mathbb{Z}_p$ is a field and $\mathbb{Z}_p^* = \mathbb{Z}_p \setminus \{0\}$ as a set. We also have need of the following definition:

$$\chi_p(x) = \begin{cases} 1 & \text{if} \quad \text{there is no } y \in \mathbb{Z}_p \text{ s.t. } x = y^2; \\ 0 & \text{otherwise;} \end{cases} \tag{1}$$

which is just the characteristic function of the complement of the set of squares in $\mathbb{Z}_p$.

The Hilbert space of a qupit [35, 52] is $\mathcal{H} = \text{span}\{|m\rangle \mid m \in \mathbb{Z}_p\} \cong \mathbb{C}^p$, and we write $U(\mathcal{H})$ the group of unitary operators acting on $\mathcal{H}$. We have the following standard operators on $\mathcal{H}$, also known as the *clock* and *shift* operators: $Z\,|m\rangle := \omega^m\,|m\rangle$ and $X\,|m\rangle := |m+1\rangle$ for any $m \in \mathbb{Z}_p$. In particular, note that $ZX = \omega XZ$.

We call any operator of the form $\omega^k X^a Z^b$ for $k, a, b \in \mathbb{Z}_p$ a *Pauli operator*. We say a Pauli operator is *trivial* if it is proportional to the identity. The collection of all Pauli operators is denoted $\mathscr{P}_1$ and called the *Pauli group*. For $n \in \mathbb{N}^*$, the *generalised Pauli group* is $\mathscr{P}_n := \bigotimes_{k=1}^n \mathscr{P}_1$.

Of particular importance to us are the *(generalised) Clifford groups*. These are defined, for each $n \in \mathbb{N}^*$, as the normaliser of $\mathscr{P}_n$ in $U(\mathcal{H}^{\otimes n})$: C is a Clifford operator if for any $P \in \mathscr{P}_n$, $CPC^\dagger \in \mathscr{P}_n$. It is clear that that every Pauli operator is Clifford, but there are non-Pauli Clifford operators. An important example is the *Fourier* gate: $F\,|m\rangle = \frac{1}{\sqrt{d}} \sum_{n\in\mathbb{Z}_p} \omega^{mn}\,|n\rangle$

which is such that $FXF^\dagger = Z$ and $FZF^\dagger = X^{-1}$. We also need the *phase* gate: $S\,|m\rangle = \omega^{2^{-1}m(m+1)}\,|m\rangle$ such that $SXS^\dagger = \omega XZ$ and $SZS^\dagger = Z$. Yet another important example is the *controlled-phase* gate, which acts on $\mathcal{H}\otimes\mathcal{H}$, $E\,|m\rangle\,|n\rangle \coloneqq \omega^{mn}\,|m\rangle\,|n\rangle$. It is important to emphasise a key difference between the qupit and the qubit case: when $p \neq 2$, none of these operators are self-inverse. In fact, if Q is a Pauli and I the identity operator on $\mathcal{H}$, we have $Q^p = I$, $E^p = I \otimes I$ and $F^4 = I$.

As a side note, these equations imply that both X and Z, and in fact every Pauli, have spectrum $\{\omega^k \mid k \in \mathbb{Z}_p\}$. As a result, we denote $|k : Q\rangle$ the eigenvector of a given Pauli Q associated with eigenvalue ω^k, and furthermore use the notation $|k,\ldots,k : Q\rangle = \bigotimes_{k=1}^n |k : Q\rangle$. It follows from the definition of Z that we can identify $|k : Z\rangle = |k\rangle$.

Now, for any $\alpha \in [0, 2\pi)$, the operator $e^{i\alpha}I$ is Clifford. However, we want to construct calculi with a finite axiomatisation. As a result, the diagrams in the calculus are countable and this makes it impossible for us to represent all such phases $e^{i\alpha}$. Unfortunately, finding a group of phases that behaves well diagrammatically is somewhat inconvenient, and involves some elementary number theory. This is why, for an odd prime p, we consider the group of phases generated by the composition of the previously defined Clifford gates. Explicitly, it is given by:

if $p \equiv 1 \mod 4$, $\mathbb{P}_p \coloneqq \{(-1)^s\omega^t \mid s,t \in \mathbb{Z}\}$

if $p \equiv 3 \mod 4$, $\mathbb{P}_p \coloneqq \{i^s\omega^t \mid s,t \in \mathbb{Z}\}$

This of course covers all cases since p is odd. Then, we restrict our attention to the *reduced* Clifford group, $\mathscr{C}_n = \{\lambda C \mid \lambda \in \mathbb{P}_p, C \in U(\mathcal{H}^{\otimes n})$ is Clifford and special unitary$\}$. We call $\mathscr{C}_1^{\otimes n}$ the *local Clifford group* on n qupits. It is clear from these examples that $\mathscr{C}_n$ is strictly larger than $\mathscr{C}_1^{\otimes n}$, but it turns out to not be that much larger:

▶ **Proposition 1** ([21, 41]). *The reduced Clifford group $\mathscr{C}_n$ is generated by the gate-set $\{F_j, S_j, E_{j,k} \mid j,k = 1,\ldots,n\}$.*

Stabiliser quantum mechanics can be operationally described as the fragment of quantum mechanics in which the only operations allowed are initialisations and measurements in the eigenbases of Pauli operators, and unitary operations from the generalised Clifford groups. As before, we restrict our attention to the fragment of stabiliser quantum mechanics where only unitary operations from the reduced Clifford group are allowed. Scalars are then taken from the monoid $\mathbb{G}_p \coloneqq \{0, \sqrt{p^r}\lambda \mid r \in \mathbb{Z}, \lambda \in \mathbb{P}_p\}$. Little is lost for the description of quantum algorithms, since we can always simplify by a global phase to make the Clifford generators special unitary. Thus, we can embed any stabiliser circuit into the calculus, and then calculate the relative phases of different branches of a computation without restriction.

▶ **Definition 2.** *The symmetric monoidal category* Stab_p *has as objects $\mathbb{C}^{pn}$ for each $n \in \mathbb{N}$, and morphisms generated by:*

- $\mathbb{C} \to \mathbb{C}^p : \lambda \mapsto \lambda\,|0\rangle$;
- $\mathbb{C}^{pn} \to \mathbb{C}^{pn} : |\psi\rangle \mapsto U\,|\psi\rangle$ *for any* $U \in \mathscr{C}_n$;
- $\mathbb{C}^p \to \mathbb{C} : |\psi\rangle \mapsto \langle 0|\psi\rangle$.

The monoidal product is given by the usual tensor product of linear spaces.

It is clear that Stab_p is a subcategory of the category FLin of finite dimensional $\mathbb{C}$-linear spaces; it is also a PROP.

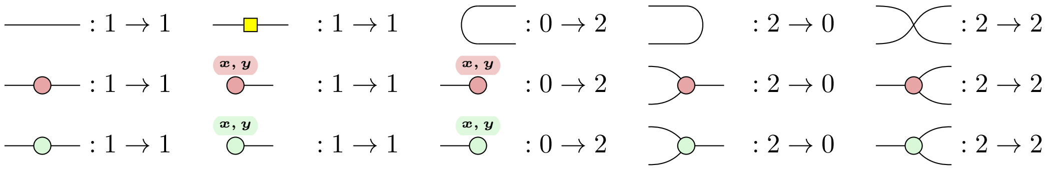
3 A ZX-calculus for odd prime dimensions

In this section, we present our family of ZX-calculi, with one for each odd prime. Relying on some of the group theoretical properties of the qupit Clifford groups, we can give a relatively simple presentation of the calculi, which avoids the need to explicitly consider rotations in p-dimensional space, significantly simplifing the presentation compared to previous work [43]. These calculi are also constructed in order to satisfy the property of *flexsymmetry*, proposed in [15, 16], and which allows one to recover the OCM meta-rule. OCM is an intuitively desirable feature for the design of a graphical language; anecdotally, it greatly simplifies the human manipulation of diagrams, including in the proofs of this paper. More formally, it means that the equational theory can be formalised in terms of double pushout rewriting over graphs rather than over hypergraphs as is necessary in the more general theory [11, 10, 12].

Another key concern is the issue of completeness, which we begin to address in this article. Outside of qubits [38, 42, 47], there has so far been a complete axiomatisation only for the stabiliser fragment in dimension $p = 3$ [48]. We present an axiomatisation which is complete for the stabiliser fragment for any odd prime p, and leave the general case for future work.

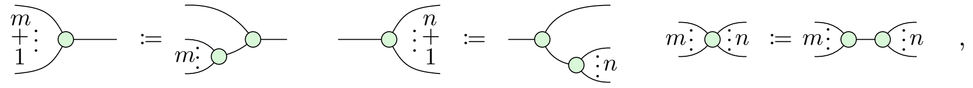
3.1 Generators

For any odd prime p, consider the symmetric monoidal category $\mathsf{ZX}_p^{\mathrm{Stab}}$ with objects $\mathbb{N}$ and morphisms generated by:



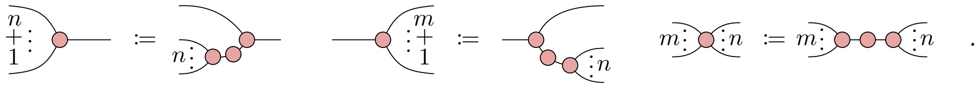
where $x, y \in \mathbb{Z}_p$. We also introduce a generator $\star : 0 \to 0$ to simplify the calculus; it will correspond to a scalar whose representation in terms of the other generators depends non-trivially on the dimension p. Morphisms are composed by connecting output wires to input wires, and the monoidal product is given on objects by $n \otimes m = n + m$ and on morphisms by vertical juxtaposition of diagrams.

We extend this elementary notation with a first piece of syntactic sugar, which is standard for the ZX-calculus family: *green spiders* are defined inductively, for any $m, n \in \mathbb{N}$, by



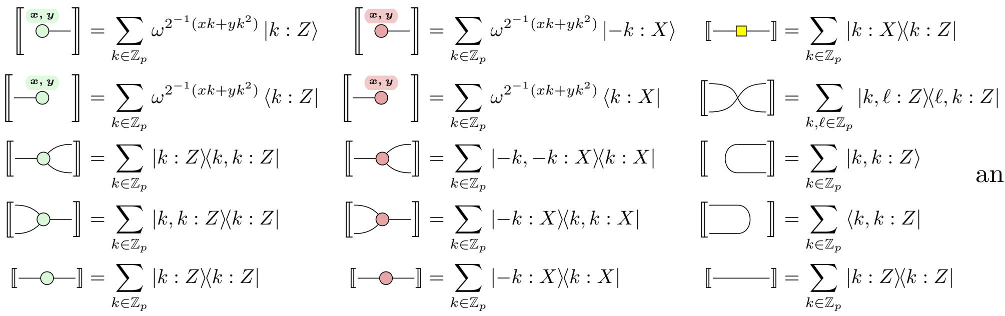
and it is clear that these have types $m + 1 \to 1$, $1 \to n + 1$ and $m \to n$ respectively.

Red spiders are defined analogously to ZH-calculus harvestmen:



Labelled spiders are given by: 
3.2 Standard interpretation and universality

The standard interpretation of a $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram is a symmetric monoidal functor $[\![-]\!]$: $\mathsf{ZX}_p^{\mathrm{Stab}} \to \mathsf{FLin}$ (the category of finite-dimensional complex Hilbert spaces). It is defined on objects as $[\![m]\!] := \mathbb{C}^{p \times m}$, and on the generators of the morphisms as:



$$= \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} |k:Z\rangle \qquad = \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} |-k:X\rangle \qquad = \sum_{k\in\mathbb{Z}_p} |k:X\rangle\langle k:Z|$$

$$= \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} \langle k:Z| \qquad = \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} \langle k:X| \qquad = \sum_{k,\ell\in\mathbb{Z}_p} |k,\ell:Z\rangle\langle \ell,k:Z|$$

$$= \sum_{k\in\mathbb{Z}_p} |k:Z\rangle\langle k,k:Z| \qquad = \sum_{k\in\mathbb{Z}_p} |-k,-k:X\rangle\langle k:X| \qquad = \sum_{k\in\mathbb{Z}_p} |k,k:Z\rangle$$

and

$$= \sum_{k\in\mathbb{Z}_p} |k,k:Z\rangle\langle k:Z| \qquad = \sum_{k\in\mathbb{Z}_p} |-k:X\rangle\langle k,k:X| \qquad = \sum_{k\in\mathbb{Z}_p} \langle k,k:Z|$$

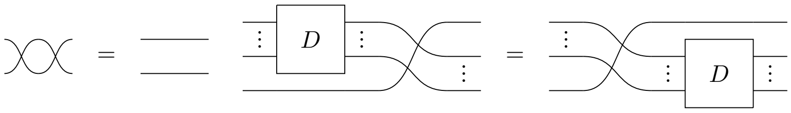
$$= \sum_{k\in\mathbb{Z}_p} |k:Z\rangle\langle k:Z| \qquad = \sum_{k\in\mathbb{Z}_p} |-k:X\rangle\langle k:X| \qquad = \sum_{k\in\mathbb{Z}_p} |k:Z\rangle\langle k:Z|$$

$[\![\star]\!] = -1$. Then, by the functoriality of the standard interpretation, we deduce that  $= \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} |k:Z\rangle^{\otimes n} \langle k:Z|^{\otimes m}$ and  $= \sum_{k\in\mathbb{Z}_p} \omega^{2^{-1}(xk+yk^2)} |-k:X\rangle^{\otimes n} \langle k:X|^{\otimes m}$.

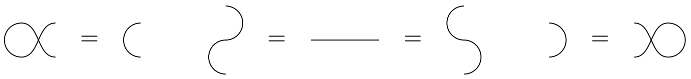
▶ **Theorem 3** (Universality). *The standard interpretation $[\![-]\!]$ is universal for the qupit stabiliser fragment, i.e. for any stabiliser operation $C : \mathbb{C}^{pm} \to \mathbb{C}^{pn}$ there is a diagram $D \in \mathsf{ZX}_p^{\mathrm{Stab}}$ such that $[\![D]\!] = C$. Put formally, the co-restriction of $[\![-]\!]$ to Stab_p is full.*

3.3 Axiomatisation

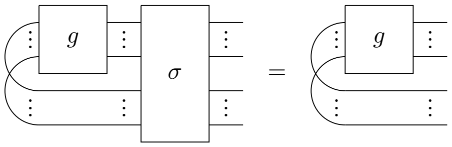
We now begin to introduce rewrite rules with which to perform a purely diagrammatic reasoning. By doing so we are in fact describing a PROP by generators and relations [7], thus the swap is required to verify the following properties:



Note that the last equation is required to hold for any diagram $D : n \to m$. This property states that our diagrams form a symmetric monoidal category. Furthermore, we want this category to be self-dual compact-closed, hence the cup and cap must verify:



Furthermore, as long as the connectivity of the diagram remains the same, vertices can be freely moved around without changing the standard interpretation of the diagram. This is a consequence of the fact that we require our generators to be *flexsymmetric*, as shown in [15]. This amounts to imposing that all generators except the swap verify:



where $\sigma : n+m \to n+m$ stands for any permutation of the wires involving swap maps. We will consider all the previous rules as being purely structural and will not explicitly state their use. Using these rules, we can in fact deduce that both the green and red spiders (and

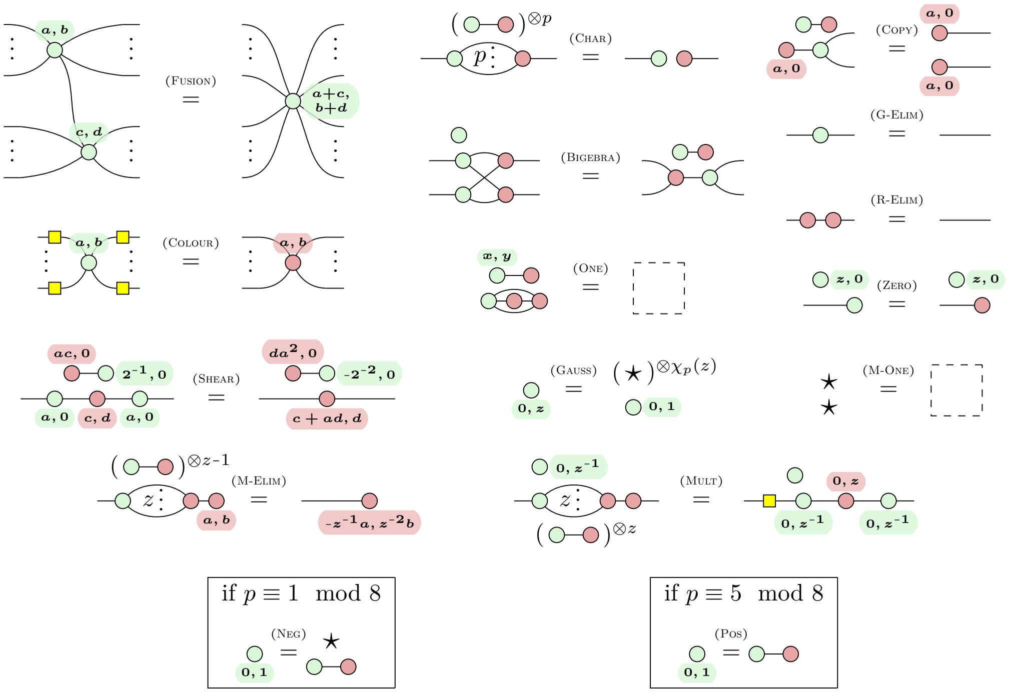


Figure 1 A presentation of the equational theory zx_p, which is sound and complete for the stabiliser fragment. The equations hold for any $a, b, c, d \in \mathbb{Z}_p$ and $z \in \mathbb{Z}_p^*$. χ_p is the characteristic function of the complement of the set of squares in $\mathbb{Z}_p$, defined in equation (1).

their labelled varieties) are themselves flexsymmetric. This means that the language follows the OCM meta-rule, and we can formally treat any $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram as a graph[1] whose vertices are the spiders, and whose edges are labelled by the $1 \to 1$ generators of the language.[2]

Figure 1 presents the remainder of the equational theory zx_p, which as we shall see axiomatises the stabiliser fragment of quantum mechanics in the qupit ZX-calculus. Firstly though, we must be sure that all of these rules are sound for the standard interpretation, i.e. it should not be possible to derive an equality of diagrams whose quantum mechanical interpretations are different.

▶ **Theorem 4** (Soundness). *The equational theory* zx_p *is sound for* $[\![-]\!]$, *i.e., for any* $A, B \in \mathsf{ZX}_p^{\mathrm{Stab}}$, $\mathrm{zx}_p \vdash A = B$ *implies* $[\![A]\!] = [\![B]\!]$. *Put formally,* $[\![-]\!]$ *factors through the projection* $\mathsf{ZX}_p^{\mathrm{Stab}} \to \mathsf{ZX}_p^{\mathrm{Stab}}/\mathrm{zx}_p$.

This set of rewriting rule also turns out to be also complete:

▶ **Theorem 5** (Completeness). *The equational theory* zx_p *is complete for* $[\![-]\!]$, *i.e., for any* $A, B \in \mathsf{ZX}_p^{\mathrm{Stab}}$, $[\![A]\!] = [\![B]\!]$ *implies* $\mathrm{zx}_p \vdash A = B$.

The proof of Theorem 5 will be the object of the following sections.

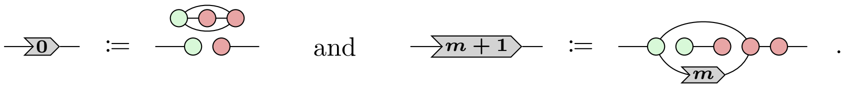
[1] Note that the graphs in question must be allowed to have loops and parallel edges, so are perhaps better called *pseudographs* or *multigraphs*.

[2] There is a small ambiguity: $1 \to 1$ spiders can be treated as either edges or vertices. When considering diagrams, it matters little which, since any given graph is always to be understood as one of the many equivalent $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagrams constructed formally out of the generators. Any computer implementation of the calculus will have to carefully resolve this ambiguity in its internal representation.

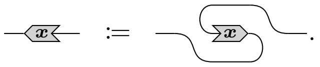
3.4 Syntactic sugar for multi-edges

Before we move into the proof of completeness, we introduce some syntactic sugar to the language. Given axiom (Char), in $\mathsf{ZX}_p^{\mathrm{Stab}}$, unlike the qubit case, spiders of opposite colours can be connected by more that one edge, and these multi-edges cannot be simplified. We therefore add some syntactic sugar to represent such multi-edges. These constructions add no expressiveness to the language, and are simply used to reduce the size of some recurring diagrams. They are shamelessly stolen from previous work [13, 53, 17, 19], and we use them to obtain a particularly nice representation of qupit graph states [54]. Graph states a central role in our proof of completeness, as they have in previous completeness results of the stabiliser fragments for dimensions 2 and 3 [3, 30, 48]. In particular, these constructions permit a nice presentation of how graph states evolve under local Clifford operations.

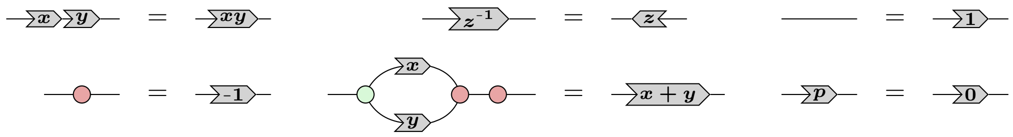
Firstly, we extend $\mathsf{ZX}_p^{\mathrm{Stab}}$ by *multipliers*, which are defined inductively by:



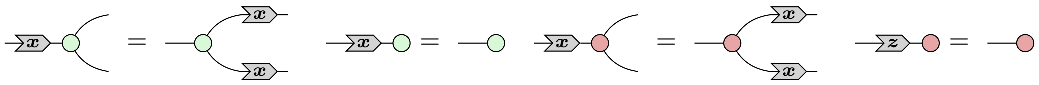
Explicitly, then, for $x \in \mathbb{Z}_p^*$, 
We also define inverted multipliers, using the standard notation for graphical languages based on symmetric monoidal categories:



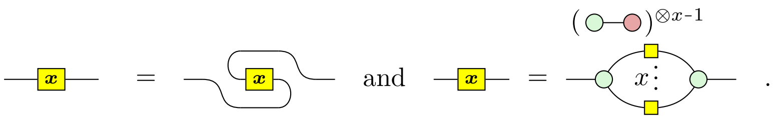
▶ **Proposition 6.** *Multipliers verify the following equations under* zx_p*: for any* $x, y \in \mathbb{Z}_p$ *and* $z \in \mathbb{Z}_p^*$*,*



which amounts to saying that the multipliers form a presentation of the field $\mathbb{Z}_p$*. They also verify the following useful copy and elimination identities:*

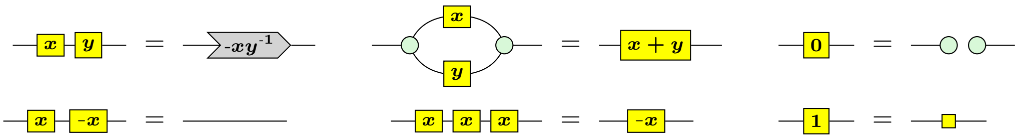


We can also unambiguously define *Fourier boxes*:  since . Fourier boxes exactly match the labelled "Hadamard" boxes introduced for the qutrit case [45] when $p = 3$. Owing to the flexsymmetry of the language, we have that for any $x \in \mathbb{Z}_p$,



(2)

▶ **Proposition 7.** zx_p *proves the following equations:*



(3)

4 Completeness

We now have all the necessary tools to show that our equational theory is complete. The structure of our proof is similar to the one used to show the completeness in the qubit case [3]. However, if the overall scheme is very similar, each step separately can involve different approaches more suited to the qupit situation. The plan is as follows. We identify a family of scalars, called *elementary scalars*, which correspond to those which appear when applying the rewrites of zx_p. We first show the completeness up to non-zero elementary scalars, which allows us to work with simpler diagrams without taking care of all the invertible scalars appearing along the way. Then, we show the completeness for elementary scalars independently, leading to a general proof of completeness. The proof of completeness up to non-zero elementary scalars goes something like this:

1. Take two diagrams with the same interpretation.
2. Put them into a simplified form, called the *GS+LC* form in [3].
3. Define the notion of simplified GS+LC form for a pair of diagrams in which some vertices are marked. Then show that in a simplified GS+LC pair if a vertex is marked on one side, it must also be marked on the other side, else the two diagrams cannot have the same interpretation.
4. Show that two diagram forming an rGS+LC pair such that their marked vertices matches and having the same interpretation are equal modulo the equational theory.

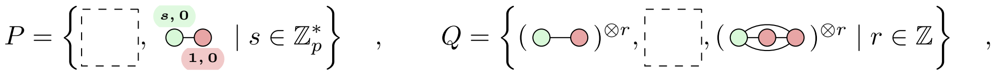
4.1 Elementary scalars

The following is standard from categorical quantum mechanics:

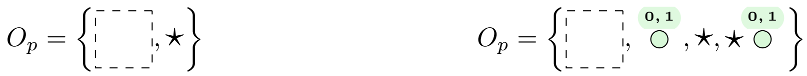
▶ **Lemma 8.** *If $A, B \in \mathsf{ZX}_p^{\mathrm{Stab}}[0,0]$, then $[\![A \otimes B]\!] = [\![A]\!] \cdot [\![B]\!] = [\![A \circ B]\!]$, where $\cdot$ is the usual multiplication on $\mathbb{C}$ restricted to the monoid $\mathbb{G}$.*

Now, as when we were defining the group of phases $\mathbb{P}_p$, the set of normal forms for phases must depend on the prime p in question:

▶ **Definition 9.** *An* elementary scalar *is a diagram $A \in \mathsf{ZX}_p^{\mathrm{Stab}}[0,0]$ which is a tensor product of diagrams from the collection $O_p \cup P \cup Q$: where*



if $p \equiv 1 \mod 4$, *if $p \equiv 3 \mod 4$,*



If $A, B \in \mathsf{ZX}_p^{\mathrm{Stab}}$, we say that A and B are equal up to an elementary scalar *if there is an elementary scalar C such that $A = B \otimes C$. In that case, we write $A \simeq B$.*

Comparing with the definition of $\mathbb{G}$, the interpretation of the elements of P correspond to powers of ω, the elements of Q to (possible negative) powers of $\sqrt{p}$, and the elements of O_p to powers of -1 or i depending on the value of p. This remark will naturally lead to the normal for for scalars in a few sections.

Now, as written, equality up to an elementary scalar might seem like a relation that is not symmetric and therefore not an equivalence relation.

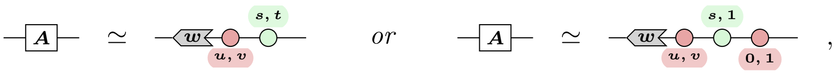
▶ **Proposition 10.** *Every elementary scalar $C \in \mathsf{ZX}_p^{\mathrm{Stab}}[0,0]$ has a multiplicative inverse, i.e. an elementary scalar $C^{-1} \in \mathsf{ZX}_p^{\mathrm{Stab}}[0,0]$ such that $C \otimes C^{-1} = C \circ C^{-1} =$* *.*

In light of this fact, if $A \simeq B$, there is an elementary scalar C such that $A = B \otimes C$, and then $B = B \otimes C \otimes C^{-1} = A \otimes C^{-1}$, so that $B \simeq A$.

▶ **Proposition 11.** *Every equation in zx_p can be loosened to equality up to an elementary scalar by erasing every part of the LHS and RHS diagrams which is disconnected from the inputs and outputs.*

Probably the most important case of equality up to elementary scalars is the completeness of the single-qupit Clifford groups, on which the entire proof of completeness of the calculus rests. The fragment of $\mathsf{ZX}_p^{\mathrm{Stab}}$ which corresponds to $\mathscr{C}_1$ is that generated by the $1 \to 1$ diagrams: , ,  and . We call any such diagram a *single-qupit Clifford diagram* or $\mathscr{C}_1$-diagram.

▶ **Proposition 12.** *If $A \in \mathsf{ZX}_p^{\mathrm{Stab}}[0,0]$ is a single-qupit Clifford diagram, then zx_p proves that*

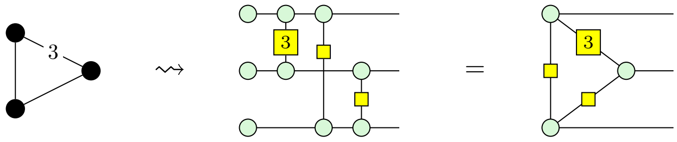


(4)

for some $s, t, u, v \in \mathbb{Z}_p$ and $w \in \mathbb{Z}_p^*$. Furthermore, this form is unique.

4.2 Relating stabiliser diagrams to graphs

The completeness proof begins by relating every diagram to simpler one in the form of a graph state diagram. Graph states are defined as usual – diagrammatically, we have an embedding of graphs given (informally) by:



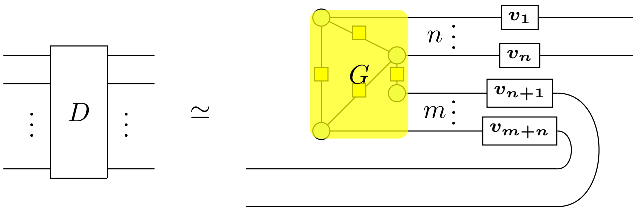
(5)

More specifically, we want to relate the diagram to the following form:

▶ **Definition 13** ([3, 48])**.** *A* GS+LC diagram *is a $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram which consists of a graph state diagram with arbitrary single-qupit Clifford operations applied to each output. These associated Clifford operations are called* vertex operators.

▶ **Proposition 14.** *Every $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram $0 \to n$ can be rewritten, up to elementary scalars, to GS+LC form under zx_p.*

In other words, zx_p proves that, for any stabiliser $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram $D : m \to n$, there is a graph G on $m+n$ vertices and a set $(v_k)_{k=1}^{m+n}$ of $\mathscr{C}_1$-diagrams such that



(6)

and we need only consider the question of whether zx_p can prove the equality of two GS+LC diagrams.

4.3 Completeness modulo elementary scalars

Now, as a first step, we show that zx_p can normalise any pair of diagrams with equal interpretations, up to elementary scalars. In particular, as was shown in the previous section, we can relax zx_p to reason about equality up to elementary scalars by simply ignoring the scalar part of each rule, and make free use of the "scalarless" equational theory. We will take care of the resulting scalars in the next section.

This part of the completeness proof follows the general ideas of [3]. The first step on the way to completeness is to note that, considering a diagram in GS+LC form, where the vertex operators have been normalised, we can obtain a yet more reduced diagram by absorbing as much as possible of the vertex operators into local scalings and local complementations. We then obtain the following form for the vertex operators:

▶ **Definition 15** ([3]). *A $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram is in* reduced *GS+LC (or rGS+LC) form if it is in GS+LC form, and furthermore:*

1. *All vertex operators belong to the following set:* $R = \Bigg\{$ 
$\Bigg|\, s, t \in \mathbb{Z}_p \Bigg\}$.
2. *Two adjacent vertices do not have vertex operators that both include red spiders.*

▶ **Proposition 16.** *If $D \in \mathsf{ZX}_p^{\mathrm{Stab}}$ is a Clifford diagram, then there is a diagram $G \in \mathsf{ZX}_p^{\mathrm{Stab}}$ in rGS+LC form such that $\mathrm{zx}_p \vdash D \simeq G$.*

Then, given two diagrams with equal interpretations, taking them both to rGS+LC makes the task of comparing the diagrams considerably easier. In particular, we can guarantee that the corresponding vertex operators in each diagram always have matching forms:

▶ **Definition 17** ([3]). *A pair of rGS+LC of the same type (i.e. whose graphs have the same vertex set V) is said to be* simplified *if there is no pair of vertices $q, p \in V$ such that q has a red vertex operator in the first diagram but not the second, q has a red vertex operator in the second diagram but not the first, and q and p are adjacent in at least one of the diagrams.*

▶ **Proposition 18.** *Any pair A, B of rGS+LC diagrams of the same type (i.e. on the same vertex set) can be simplified.*

For the sake of clarity, we shall say that a vertex operator (or equivalently, the vertex itself) is *marked* if it contains a red spider (i.e. it belongs to the right-hand form of definition 15). Then, two diagrams with the same interpretation can always be rewriten so that the marked vertices match:

▶ **Proposition 19.** *Let $C, D \in \mathsf{ZX}_p^{\mathrm{Stab}}$ be a simplified pair in rGS+LC form, then $[\![C]\!] = [\![D]\!]$ only if the marked vertices in C and D are the same.*

We have enough control over the pair of diagrams to finish the completeness proof:

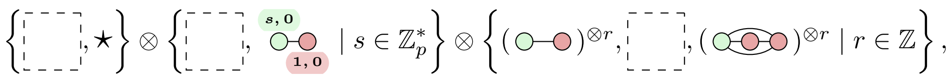
▶ **Theorem 20.** zx_p *is complete for $[\![-]\!]$, i.e. if for any pair of diagrams $A, B \in \mathsf{ZX}_p^{\mathrm{Stab}}[0, n]$ with $n \neq 0$, $[\![A]\!] = [\![B]\!]$, then $\mathrm{zx}_p \vdash A \simeq B$.*

4.4 Completeness of the scalar fragment

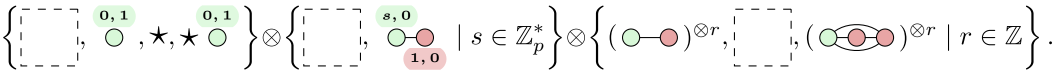
Finally, we are ready to leap-frog off of the previous section into the full completeness (including scalars). First, we need to find a normal form for diagrams which evaluate to 0. In fact, we need pick one normal form for each type $m \to n$:

▶ **Proposition 21.** *The zero scalar "destroys" diagrams: for any $m, n \in \mathbb{N}$ and $D \in \mathsf{ZX}_p^{\mathrm{Stab}}[m,n]$,* 
We take the RHS diagram to be the "zero" diagram of type $m \to n$.

A scalar diagram is in *normal form* if it is either the zero scalar, or it belongs to the set



when $p \equiv 1 \mod 4$, or to the set



when $p \equiv 3 \mod 4$. It is straightforward to see, by evaluating $[\![-]\!]$ on each element, that these sets contain exactly one diagram for each scalar in $\mathbb{G}_p \setminus \{0\}$ (and the zero scalar  corresponds to $0 \in \mathbb{G}_p$).

▶ **Theorem 22.** zx_p *proves any scalar diagram equal to a scalar in normal form (depending on the congruence of p modulo 4), or to the zero scalar*  .

The completeness for the whole stabiliser fragment follows immediately, combining theorems 20 and 22:

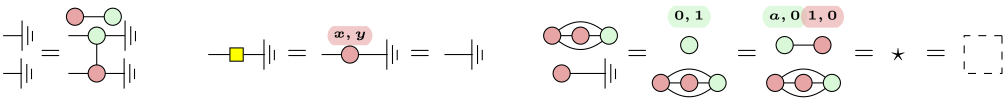
▶ **Theorem 23.** *The equational theory* zx_p *is complete for* Stab_p*, i.e. for any* $\mathsf{ZX}_p^{\mathrm{Stab}}$*-diagrams A and B, if $[\![A]\!] = [\![B]\!]$, then $\mathrm{zx}_p \vdash A = B$.*

5 Mixed states and co-isotropic relations

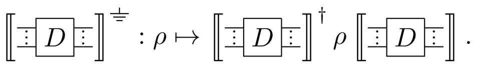
In this last section we use the work of [18] to extend our completeness result to the mixed-state case. We then unravel the connection to the Lagrangian relation investigated in [26].

5.1 A complete graphical language for CPM(Stab_p)

We now extend our completeness result form Stab_p to CPM(Stab_p), the category of completely positive maps corresponding to mixed state stabiliser quantum mechanics, see [44, 23] for a formal definition. We will rely on the discard construction of [18] to define a graphical language $(\mathsf{ZX}_p^{\mathrm{Stab}})^{\bar{\bar{\pm}}}$. It consists in adding to the equational theory one generator, the discard $\bar{\bar{\pm}} : 1 \to 0$ and equations stating that this generator erases all isometries. In Stab_p, the isometries are generated by a small family of diagrams, the equations to add are then:



A new interpretation $[\![\_]\!] : \mathsf{ZX}_p^{\mathrm{Stab}\bar{\bar{\pm}}} \to \mathrm{CPM}(\mathsf{Stab}_p)$ is defined as  $: \rho \mapsto \mathrm{Tr}(\rho)$ for the ground and for all $\mathsf{ZX}_p^{\mathrm{Stab}}$-diagram $D : n \to m$:



Corollary 22 of [18] provides a sufficient condition for the previous construction to extend to a universal and complete graphical language for Stab_p into a universal complete graphical language for $\mathrm{CPM}(\mathsf{Stab}_p)$. This condition is for Stab_p to have *enough isometries* in the sense of [18], By similar arguments as is the qubit case, we can show that Stab_2 indeed has enough isometries and then it follows that:

▶ **Theorem 24.** $(\mathsf{ZX}_p^{\mathrm{Stab}})^{\doteqdot}$ *is universal and complete for* $\mathrm{CPM}(\mathsf{Stab}_p)$.

5.2 Co-isotropic relations

It has been shown in [26, 25, 24] that $\mathrm{CPM}(\mathsf{Stab}_p)$ is equivalent to the category of affine co-isotropic relations up to scalars. More formally, we endow $\mathbb{Z}_p^2$ with the symplectic form: $\omega\left(\begin{bmatrix}a\\b\end{bmatrix},\begin{bmatrix}c\\d\end{bmatrix}\right) = ad - bc$, and $\mathbb{Z}_p^{2m} = \bigoplus_m \mathbb{Z}_p^2$ with the direct sum symplectic form.

▶ **Definition 25.** *The symmetric monoidal category* $\mathsf{AffCoIsoRel}_{\mathbb{Z}_p}$ *has as objects* $\mathbb{N}$*, and as morphisms, relations* $R : \mathbb{Z}_p^{2m} \to \mathbb{Z}_p^{2n}$ *such that* R *viewed as a subset of* $\mathbb{Z}_p^m \times \mathbb{Z}_p^n$ *is an affine co-isotropic subspace thereof.*

Since [26] works in the scalarless ZX-calculus, we need to add one extra axiom, which suffices to eliminate all remaining (non-zero) scalars in Stab_p: we impose the rule (Mod) that $p = 1$. Diagrammatically, this amounts to quotienting $(\mathsf{ZX}_p^{\mathrm{Stab}})^{\doteqdot}$ by the rule:  $=$.

Then we can give an interpretation $[-]$ of $(\mathsf{ZX}_p^{\mathrm{Stab}})^{\doteqdot}$ making it universal and complete for $\mathsf{AffCoIsoRel}_{\mathbb{Z}_p}$, and which is defined uniquely by the commutative diagram:

$$\begin{tikzcd}
(\mathsf{ZX}_p^{\mathrm{Stab}})^{\doteqdot} \arrow[r, dashed, "{[-]}"] \arrow[d, "{[\![-]\!]}"'] & \mathsf{AffCoIsoRel}_{\mathbb{Z}_p} \arrow[d, leftrightarrow] \\
\mathrm{CPM}(\mathsf{Stab}_p) \arrow[r, two heads] & \mathrm{CPM}(\mathsf{Stab}_p)/(\textsc{Mod})
\end{tikzcd}$$

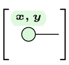
Explicitly, it is given by the identity on objects, $[m] = m$, and is defined on morphisms by: for $x, y \in \mathbb{Z}_p$ and $z \in \mathbb{Z}_p^*$,

$$= \left\{\left(\bigoplus_{k=1}^m \begin{bmatrix}a\\b_k\end{bmatrix}, \bigoplus_{k=1}^n \begin{bmatrix}-a\\-c_k\end{bmatrix}\right) \,\middle|\, a, b_k, c_k \in \mathbb{Z}_p \quad \text{and} \quad \sum_k b_k = \sum_k c_k\right\}$$

$$= \left\{\left(\bigoplus_{k=1}^m \begin{bmatrix}a_k\\c\end{bmatrix}, \bigoplus_{k=1}^n \begin{bmatrix}b_k\\c\end{bmatrix}\right) \,\middle|\, a, b_k, c_k \in \mathbb{Z}_p \quad \text{and} \quad \sum_k a_k = \sum_k b_k\right\}$$

$$= \left\{\left(\bullet, \begin{bmatrix}-1 & 0\\-y & -1\end{bmatrix}\begin{bmatrix}v\\0\end{bmatrix} + \begin{bmatrix}-x\\0\end{bmatrix}\right) \,\middle|\, v \in \mathbb{Z}_p\right\}$$

$$= \left\{\left(\mathbf{v}, \begin{bmatrix}0 & -1\\1 & 0\end{bmatrix}\mathbf{v}\right) \,\middle|\, \mathbf{v} \in \mathbb{Z}_p^2\right\}$$



$$= \left\{\left(\bullet, \begin{bmatrix}1 & -y\\0 & 1\end{bmatrix}\begin{bmatrix}0\\v\end{bmatrix} + \begin{bmatrix}0\\x\end{bmatrix}\right) \,\middle|\, v \in \mathbb{Z}_p\right\}$$

$$= \left\{\left(\mathbf{v}, \begin{bmatrix}z & 0\\0 & z^{-1}\end{bmatrix}\mathbf{v}\right) \,\middle|\, \mathbf{v} \in \mathbb{Z}_p^2\right\}$$

Note that all of these are actually affine *Lagrangian* relations. The only generator which has a co-isotropic but not Lagrangian semantics is the discard map:  $= \{(\mathbf{v}, \bullet) \mid \mathbf{v} \in \mathbb{Z}_p^2\}$.

As pointed out in [7, 8, 26], the related category of affine Lagrangian relations over the field $\mathbb{R}[x,y]/(xy-1)$ can be used to represent a fragment of electrical circuits. We expect that the axiomatisation of figure 1 can be adapted to that setting, but leave this for a future article.

6 Conclusion

We have constructed a ZX-calculus which captures the stabiliser fragment in odd prime dimensions, whilst retaining many of the “nice” features of the qubit ZX-calculus. Of course, there are a few obvious questions that we leave for future work.

First amongst these is the question of whether a fully universal calculus can be obtained from the ideas we used here. The spiders we have used here labelled with elements $a, b \in \mathbb{Z}_p \times \mathbb{Z}_p$ and which can be interpreted as polynomials $x \mapsto ax + bx^2$ which parametrise the phases of the spider. Adding one additional term of degree 3 is already sufficient to obtain a universal calculus in prime dimensions (strictly) greater than 3 [37]. In fact, one might as well add all higher order of polynomials (mod p) since access to such higher degrees will hopefully prove useful in finding commutation relations for the resulting spiders.

Secondly, it remains to be seen how to formulate a universal ZX-calculus for non-prime dimensions, even for just the stabiliser fragment. For this, the methods in this article are clearly inadequate: for example local scaling is no longer an invertible operation and thus certainly not in the Clifford group.

Finally, the set of axioms we provide here is probably not minimal. It would be nice to see if a simplified version can be obtained, as was done in [6] for the qubit case.

Extending Partial Representations of Circle Graphs in Near-Linear Time

Guido Brückner

Peter Stumpf
University of Passau, Germany

Abstract

The *partial representation extension problem* generalizes the recognition problem for geometric intersection graphs. The input consists of a graph G, a subgraph $H \subseteq G$ and a representation $\mathcal{H}$ of H. The question is whether G admits a representation $\mathcal{G}$ whose restriction to H is $\mathcal{H}$. We study this question for *circle graphs*, which are intersection graphs of chords of a circle. Their representations are called *chord diagrams*.

We show that for a graph with n vertices and m edges the partial representation extension problem can be solved in $O((n+m)\alpha(n+m))$ time, where α is the inverse Ackermann function. This improves over an $O(n^3)$-time algorithm by Chaplick, Fulek and Klavík [2019]. The main technical contributions are a canonical way of orienting chord diagrams and a novel compact representation of the set of all canonically oriented chord diagrams that represent a given circle graph G, which is of independent interest.

1 Introduction

Geometric intersection representations of graphs are an important concept that establishes a strong connection between geometry, combinatorics and graph theory. In an intersection representation of a graph $G = (V, E)$ each vertex $v \in V$ is represented by a geometric object $R(v)$ whose intersections encode the edges of G, i.e., $\{u, v\} \in E$ if and only if $R(u)$ and $R(v)$ intersect. Different classes of graphs can be obtained by restricting the types of geometric objects used for the representation. For example *interval graphs* are intersection representations of intervals of the real line, *string graphs* are intersection graphs of curves in the plane and *circle graphs* are intersection graphs of chords of a circle; see Figure 1.

For a fixed class $\mathcal{C}$ of intersection graphs a natural question is the *recognition problem*, which asks whether a given graph G belongs to $\mathcal{C}$. For circle graphs the recognition problem has been studied for a long time, and has culminated in an algorithm with running time $O((n + m)\alpha(n + m))$ [10, 13], where n and m denote the number of vertices and edges of the input graph, respectively, and α denotes the slowly growing inverse of the Ackermann function. There is also an $O(n^2)$ time algorithm which is faster for very dense graphs [24].

A generalization of the basic recognition problem has attracted considerable attention: the *partial representation extension problem* [19, 1, 23, 2, 9, 18, 17, 21]. In this problem, the input consists of a triplet $(G, H, \mathcal{R}')$, where G is a graph, $H \subseteq G$ is an induced subgraph

of G, and $\mathcal{R}'$ is an intersection representation of H. The question is whether there exists a representation $\mathcal{R}$ of G that *extends* $\mathcal{R}'$, i.e., its restriction to H coincides with $\mathcal{R}'$. Following the notation of Chaplick, Fulek and Klavík [4], for a class $\mathcal{C}$ of intersection graphs, we denote the partial representation extension problem for $\mathcal{C}$ by RepExt($\mathcal{C}$).

Related Work

The recognition problem can be solved efficiently for a wide range of classes of intersection graphs. The partial representation extension problem was introduced by Klavík et al. [20], who gave an efficient algorithm for RepExt($\mathcal{I}$), where $\mathcal{I}$ denotes the class of interval graphs, which they improved to linear running time in their full version [19]. Angelini et al. [1] give a linear-time algorithm for planar topological graph drawings and Patrignani shows NP-hardness for planar straight-line drawings [23]. Recently, the problem has also been considered for simple topological and 1-planar drawings [2, 9]. In the meantime efficient algorithms are known for proper and unit interval graphs [18], permutation graphs and function graphs [17], as well as for trapezoid graphs [21]. Concerning the class Circle of circle graphs, Chaplick et al. [4] gave the first efficient algorithm for RepExt(Circle) with running time $O(n^3)$.

For other forms of representation, there are compact descriptions of all representations of a graph G, e.g., SPQR-trees [22, 8] for planar graphs and modular decomposition trees [11] for comparability graphs. Both descriptions express a representation of G by choosing representations for small graphs that are associated to the nodes of a tree in such a way that a bijection is obtained between the representations of G and the choices for the small graphs. For circle graphs, Cunningham and Edmonds introduced split-trees [7] that decompose a graph along its splits into smaller graphs from which G is assembled in a tree structure. Gioan and Paul [12] described split-trees using graph-labeled trees. Gioan et al. [13] observed that all possible chord diagrams of G can be obtained by choosing a chord diagram for each of the small graphs associated to the nodes of the split-tree of G and combining them suitably with each other.

Contribution and Outline

However, besides the choices of the chord diagrams, there are choices to be made when combining those diagrams, which Gioan et al. [13] express by basically directing the individual chords. These choices allow to obtain the same chord diagram starting with a different set of directed chord diagrams for the nodes of the split-tree; see Figure 2. We strengthen this connection by generalizing the concept of split-trees and introducing a canonical orientation of chord diagrams. In particular, for the canonical split-trees of Cunningham and Edmonds,

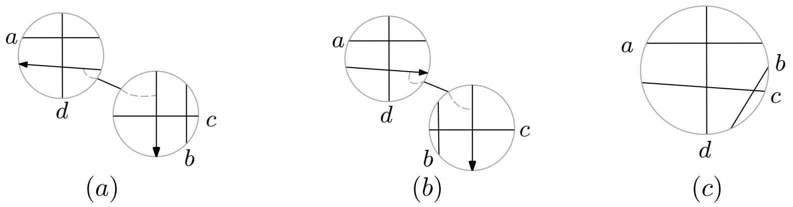

Figure 2 (a), (b) split-trees with different associated chord diagrams, only the relevant orientations are shown (c) the chord diagram resulting from the join for (a) and (b).

we establish a situation analogous to SPQR-trees or modular decomposition trees: the canonically oriented chord diagrams of G correspond bijectively to choices of canonically oriented chord diagrams for the nodes of the canonical split-tree.

In the $O(n^3)$-time algorithm of Chaplick et al. [4] for RepExt(Circle), they characterize all viable chord diagrams and solve the problem recursively, creating a decomposition that appears to be similar to the decomposition in our representation. To illustrate the usefulness of our representation, we improve over this result by showing how to extend partial chord diagrams in near-linear time $O((n+m)\alpha(n+m))$. This answers open questions of Chaplick et al. [4] and Kalisz et al. [16] who specifically ask whether such a representation of all chord diagrams exists and whether it can be used to solve RepExt(Circle) faster. We note that, given the data structure computed by the fastest known recognition algorithm by Gioan et al. [13], our algorithm runs in linear time.

We introduce notation and preliminary definitions in Section 2. In Section 3 we develop the compact description of representations. Section 4 shows how these results can be used to obtain an almost-linear time algorithm for RepExt(Circle). Lemmas and theorems marked with ($\star$) are proven in the full version.

2 Preliminaries

In this section we introduce important concepts that we use throughout the paper. In particular, we recall the concepts of circle graphs and chord diagrams, and we introduce a way to canonically orient them. Moreover, we also recall the notion of splits and split decompositions, which are a classic tool in circle graph recognition algorithms.

Circle Graphs and Chord Diagrams

An *(undirected) chord diagram* D consists of a set C of *chords* of the unit circle, i.e., undirected straight-line segments that connect pairwise distinct points on the unit circle. A chord diagram D naturally defines an intersection graph $G(D) = (C, E)$ of its chords, where $\{c, c'\} \in E$ if and only if the chords c and c' intersect in D, i.e., if and only if their endpoints alternate around the unit circle. A graph G is a *circle graph* if it is an intersection graph of the chords of a chord diagram.

While chord diagrams are geometric objects, we are mostly interested in their combinatorial structure, i.e., we identify chord diagrams with the same order of chord ends on the circle. To break certain symmetries we usually consider *oriented* chord diagrams, which additionally have a chord end as a *starting point*. Then an oriented chord diagram D can be encoded as the word over the set of chords C obtained by starting at the starting point and walking around the unit circle in clockwise direction and recording the encountered chords. For $c \in C$, we refer to the first end of c that we encounter with $\mathring{c}$ and to the second end with

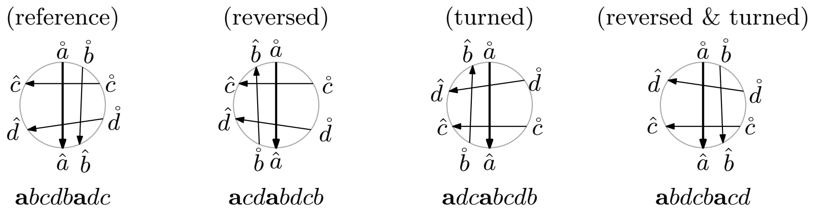

Figure 3 The turn and rev operation on a chord diagram with reference chord a.

$\hat{c}$. We consider the chord c as directed from $\mathring{c}$ to $\hat{c}$ in the geometric interpretation; see Figure 3 (reference). Unless mentioned otherwise, chord diagrams are always considered oriented and they are usually treated as their encodings.

We call the chord with the starting point the *reference chord* of D. We never change the reference chord. In the following, we consider changes that can be applied to every chord diagram without changing the represented graph or the reference chord. For a word w we write w^{rev} for the word obtained by reading w backwards. The *reverse* of a chord diagram $a\rho a\sigma$ is $\text{rev}(a\rho a\sigma) = a\sigma^{\text{rev}}a\rho^{\text{rev}}$. Geometrically, this corresponds to mirroring the chord diagram at the reference chord a; see Figure 3 (reversed). The *turn* of a chord diagram $a\rho a\sigma$ is $\text{turn}(a\rho a\sigma) = a\sigma a\rho$. Geometrically, this corresponds to choosing $\hat{a}$ as the new starting point. In a sense, this turns the chord diagram by 180 degrees; see Figure 3 (turned). Note that $\text{turn}(\text{turn}(a\rho a\sigma)) = a\rho a\sigma$, $\text{rev}(\text{rev}(a\rho a\sigma)) = a\rho a\sigma$ and $\text{turn}(\text{rev}(a\rho a\sigma)) = \text{turn}(a\sigma^{\text{rev}}a\rho^{\text{rev}})) = a\rho^{\text{rev}}a\sigma^{\text{rev}} = \text{rev}(a\sigma a\rho) = \text{rev}(\text{turn}(a\rho a\sigma))$, i.e., turn and rev are selfinverse and commute.

Splits and Split-Trees

Let $G = (V, E)$ be a graph. Consider a bipartition (X, Y) of V with $\emptyset \subsetneq X, Y \subsetneq V$ and let $B_X \subseteq X$ denote the subset of vertices of X that are adjacent to a vertex in Y and let $B_Y \subseteq Y$ denote the subset of vertices of Y that are adjacent to a vertex in X. The bipartition (X, Y) is called a *split* if all possible edges between B_X and B_Y exist in G, i.e., $\{\{x, y\} \mid x \in B_X, y \in B_Y\} \subseteq E$. Then (B_X, B_Y) is called the *split boundary*; see Figure 1. Observe that if X and Y are not connected, then B_X, B_Y are empty. A split (X, Y) is *trivial* if one of its sides consists of a single vertex. Following Courcelle [5], we call a split (X, Y) *good* if it does not overlap any other split, in the sense that for any other split (W, Z) at least one of $X \cap W$, $X \cap Z$, $Y \cap W$, $Y \cap Z$ is empty. A graph is *prime* if all its splits are trivial, and it is *degenerate* if every bipartition of the vertices yields a split. It is well known that the connected degenerate graphs are precisely cliques and stars [6].

Next, we define *split-trees*, introduced by Cunningham and Edmonds [7] as decomposition trees. We use the graph-labeled tree description of Gioan and Paul [12]. However we consider graph-labeled trees that correspond to general decompositions in the sense of Cunningham and Edmonds, while Gioan and Paul used the term split-tree for a unique structure which we later define as the canonical split-tree. To avoid confusion with the vertices and edges of our graphs, we refer to the vertices and edges of split-trees as nodes and arcs, respectively. A *split-tree* T is a tree where each inner node μ has a *skeleton graph* $\text{skel}(\mu)$ and a bijection corr_μ from $V(\text{skel}(\mu))$ to the nodes of T adjacent to μ; see Figure 4. Given an inner node μ and a neighbor ν of μ, we often need to refer to the vertex v of $\text{skel}(\mu)$ that represents ν. For convenience, we define $v_\mu(\nu)$ as the vertex v of $\text{skel}(\mu)$ with $\text{corr}_\mu(v) = \nu$.

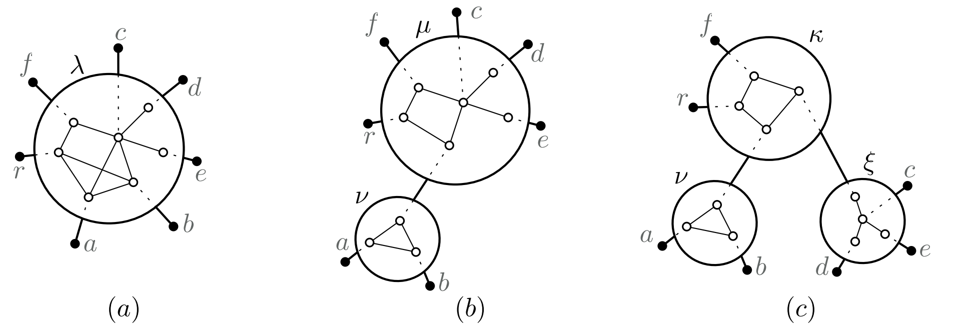

Figure 4 Split-trees of the graph from Figure 1a. (a) shows the base case, in (b) the node λ from (a) is decomposed into μ and ν along the split $(\{a,b\},\{c,d,e,r,f\})$. In (c) the node μ from (b) is further decomposed along the split that has $\{c,d,e\}$ on one side.

We define split-trees inductively. Let $G=(V,E)$ be a graph. In the base case; see Figure 4a, a split-tree T of G consists of one inner node λ and one leaf for each vertex $v \in V$ that is adjacent to λ. We identify the leaves of T with the vertices in V. Define the skeleton of λ as $\text{skel}(\lambda)=G$. For every vertex $v \in V(\text{skel}(\lambda))$, we define $\text{corr}_\lambda(v)$ as the leaf node v of T.

We can further decompose such a split-tree. Let λ be an inner node and let (X,Y) be a non-trivial split of $\text{skel}(\lambda)$. Let G_X denote the graph obtained from $\text{skel}(\lambda)$ by contracting Y into a single vertex y. Symmetrically, let G_Y denote the graph obtained from $\text{skel}(\lambda)$ by contracting X into a single vertex x. Then λ can be split into two nodes μ, ν connected by an arc $\{\mu,\nu\}$; see Figure 4b. Define $\text{skel}(\mu)=G_X$ and $\text{skel}(\nu)=G_Y$. Observe that y in G_X represents the graph G_Y and x in G_Y represents the graph G_X. We define $\text{corr}_\mu(y)=\nu$ and $\text{corr}_\nu(x)=\mu$. For any vertex $v \in V(\text{skel}(\lambda))$ we replace the arc $\{\lambda,\text{corr}_\lambda(v)\}$ with $\{\mu,\text{corr}_\lambda(v)\}$ if $v \in X$ or $\{\nu,\text{corr}_\lambda(v)\}$ if $v \in Y$. Finally, for each inner node κ adjacent to λ consider the unique vertex $v \in \text{skel}(\kappa)$ with $\text{corr}_\kappa(v)=\lambda$. We redefine $\text{corr}_\kappa(v)=\mu$ if $v_\lambda(\kappa) \in X$ and $\text{corr}_\kappa(v)=\nu$ if $v_\lambda(\kappa) \in Y$. Observe that the result is still a tree and corr_ξ is well defined for each inner node ξ. Hence, the inner nodes may be decomposed again. The split-trees of G are the split-trees that can be obtained in this way.

The inverse of a decomposition is a *join*. Let G_1, G_2 be two (vertex-disjoint) graphs with $v_2 \in G_1$, $v_1 \in G_2$. Then we define their *join at* v_2,v_1 as the graph obtained from $G_1 \cup G_2$ by connecting all neighbors of v_2 in G_1 with all neighbors of v_1 in G_2 and removing the vertices v_1, v_2. We denote the resulting graph by $G_1 \oplus_{v_2,v_1} G_2=(V,E)$. For a split-tree T with an arc $\{\mu,\nu\}$ let $b=v_\mu(\nu)$, $a=v_\nu(\mu)$. The nodes μ, ν can be joined into a single node λ with $\text{skel}(\lambda)=\text{skel}(\mu) \oplus_{b,a} \text{skel}(\nu)$. Moreover, for any inner node κ adjacent to μ or ν and the unique vertex $v \in V(\text{skel}(\kappa))$ with $\text{corr}_\kappa(v) \in \{\mu,\nu\}$ we redefine $\text{corr}_\kappa(v)=\lambda$.

Let T denote a split-tree and let $\{\mu,\nu\}$ be an arc of T. Removing $\{\mu,\nu\}$ separates T into two trees T_μ and T_ν where T_μ contains the node μ and T_ν contains the node ν. Let $L(T_\mu) \subseteq V$ denote the set of leaves of T_μ. By construction of the split-tree $(L(T_\mu),L(T_\nu))$ is a split of G, which is induced by the arc $\{\mu,\nu\}$. For example, the blue split from Figure 1a is represented by the arc $\{\kappa,\xi\}$ in Figure 4c. Let (A,B) be a non-trivial split of $\text{skel}(\mu)$. This split induces a split (L_A,L_B) of G with $L_A=\bigcup_{v\in A} L(T_{\text{corr}_\mu(v)})$ and $L_B=\bigcup_{v\in B} L(T_{\text{corr}_\mu(v)})$. An example of this is the red split from Figure 1b that is represented by a non-trivial split inside node ξ of Figure 4c. We call an inner node of a split-tree *degenerate* and *prime*, if its skeleton graph is degenerate and prime, respectively. Observe that in the split-tree in Figure 4c, the node κ is prime, and ν, ξ are degenerate.

In a *good-split-tree* every inner arc $\{\mu, \nu\}$ of T induces a good split. For a connected graph G, a *canonical split-tree* is a good-split-tree such that no skeleton has a non-trivial good split, no inner arc induces a trivial split, and any two arcs induce different splits. A canonical split-tree is obtained by decomposing G (in arbitrary order) along all its good splits. This is possible since the good splits form a laminar set. The resulting canonical split-tree is denoted by $\mathrm{ST}(G)$. It was first defined by Cunningham and Edmonds [7]. We use the graph-labeled-tree description by Gioan and Paul [12]. It is unique, and nodes have connected skeletons that are either prime or degenerate. Moreover, if two adjacent nodes μ, ν are both degenerate, then either one of them is a star and one is a clique, or they are both stars and the vertices $v_\mu(\nu)$ and $v_\nu(\mu)$ are either both leaves or both the star centers of their respective skeletons. By the following useful property, $\mathrm{ST}(G)$ represents all splits of G.

▶ **Proposition 1** ([6],[14, Theorem 2.18])**.** *A partition (A, B) of the vertex set of a connected graph G is a split of G if and only if it is induced by an arc of $\mathrm{ST}(G)$ or by a non-trivial split of a (skeleton of a) degenerate node of $\mathrm{ST}(G)$.*

3 Compact Representation of all Chord Diagrams

Let $G = (V, E)$ be a circle graph. In Section 3.1 we establish a correspondence between the chord diagrams of G and assignments of chord diagrams to the inner nodes of a split-tree of G. For canonical split-trees, this correspondence turns out to be a bijection. We further show that both directions of this bijection can be computed in linear time. In Section 3.2 we describe the possible choices for the chord diagrams for nodes of a canonical split-tree of G. Altogether, this gives the claimed compact representation for connected circle graphs.

3.1 Configurations of Split-Trees

Let $G = (V, E)$ be a circle graph, let $r \in V$ be the reference chord of G and let T be a split-tree of G. We root T at r and direct all arcs away from the root. For each inner node ν of T, we define the reference chord r_ν as the chord $v_\nu(\mu)$ associated with the parent μ of ν. A *configuration* c of T is a mapping that assigns to each inner node μ of T a chord diagram $c(\mu)$ of $\mathrm{skel}(\mu)$ with reference chord r_μ; see Figure 5. We also refer to $c(\mu)$ as the *configuration of* μ. Recall that a split decomposition can be used to split a node λ of T into two nodes μ, ν connected by a (directed) arc (μ, ν). In the reverse direction, a join composition can be used to join two nodes μ, ν connected by an arc (μ, ν) into a single node λ. The join operation extends to configurations.

The configurations of μ and ν induce a unique configuration of λ as follows. Let $v = v_\mu(\nu)$ and let $c(\nu) = r_\nu \rho r_\nu \sigma$. The induced configuration $c(\lambda) = c(\mu) \oplus_{v, r_\nu} c(\nu)$ of λ is obtained from $c(\mu)$ by replacing $\mathring{v}$ with ρ and $\hat{v}$ with σ. See Figure 5b. The order of multiple joins affects neither the resulting split-tree nor the resulting configuration. For a configuration c of a split-tree T we denote by $\mathcal{D}(c)$ the chord diagram obtained by joining the configurations of all inner nodes of T. For connected graphs, the two joined chord diagrams $c(\mu)$, $c(\nu)$ are fully determined by their join $c'(\lambda)$ since the four combined words ρ, σ, μ, ν are fully determined by $c'(\lambda)$. This implies that two different configurations yield two different chord diagrams.

If G is connected, a diagram D can be decomposed along a split (A, B) only if the endpoints of the chords in A and B appear suitably in D. We say that D *respects* the split (A, B) if D decomposes into two words over A and two words over B that alternate. Formally, this means we have $D = \rho_1 \sigma_1 \rho_2 \sigma_2 \rho_3$ where $\rho_2, (\rho_3 \rho_1)$ and σ_1, σ_2 are words over A and B.

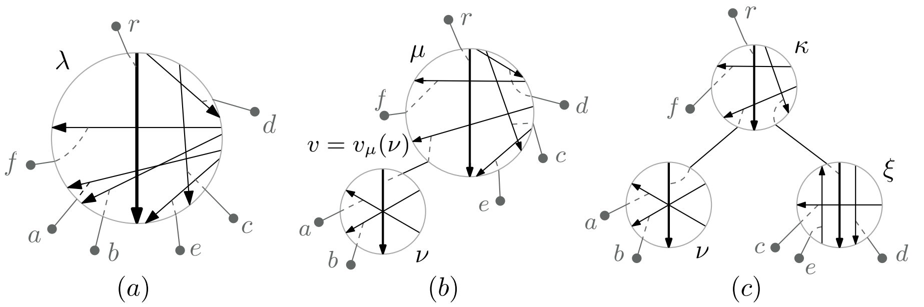

Figure 5 (a), (b), (c) show configurations of the corresponding split-trees in Figure 4 that yield the same chord diagram. We have $c'(\lambda) = rdcdf\mathbf{ba}ecer\mathbf{ba}f = rdcdf\mathbf{v}ecer\mathbf{v}f \oplus_{v,r_\nu} r_\nu bar_\nu ba = c(\mu) \oplus_{v,r_\nu} c(\nu)$, where $v = v_\mu(\nu)$.

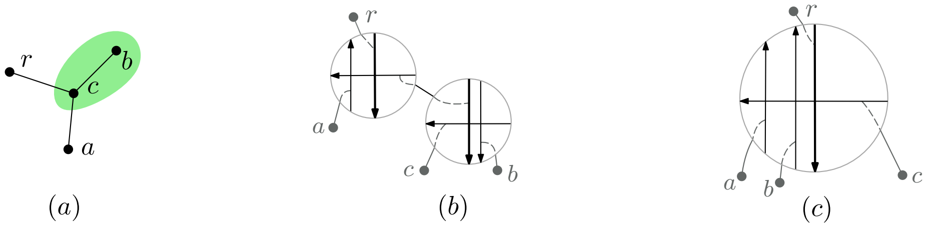

Figure 6 (a) A star G with a non-good split ({r,a},{b,c}). (b) A split-tree T of G with an arc corresponding to the bad split in (a). (c) A chord diagram of G that is not represented by T.

We show that a chord diagram can be recursively decomposed along several splits if it respects each of them. This yields the following lemma.

▶ **Lemma 2** ($\star$). *Let G be a (not necessarily connected) circle graph and let T be a split-tree of G rooted at some reference chord r. Then the mapping $\mathcal{D}$ that maps configurations of T to chord diagrams of G is surjective on the set of chord diagrams of G with reference chord r that respect all splits induced by arcs of T.*

Note that, for any configuration c of T, the chord diagram $\mathcal{D}(c)$ respects all splits induced by arcs of T. Since it is known that a chord diagram D of a connected circle graph G respects all good splits of G [5, Proposition 9], we conclude the following.

▶ **Theorem 3.** *Let T be a good-split-tree of a connected circle graph G rooted at some reference chord $r \in V(G)$. Then the mapping $\mathcal{D}$ that maps configurations of T to chord diagrams of G with reference chord r is a bijection.*

We can translate between configuration and chord diagram in linear time, which allows us to use this result algorithmically. Note that in the following theorem the split-trees are not required to be good-split-trees, which means there may be chord diagrams for their graph that they do not represent; see Figure 6. This will be useful when dealing with RepExt(Circle).

▶ **Theorem 4.** *Let T be a split-tree of a connected circle graph G rooted at some reference chord $r \in V(G)$. Then the mapping $\mathcal{D}$ can be computed in linear time. Conversely, given a chord diagram D of G with reference chord r, it can be tested in linear time whether there exists a configuration c of T with $\mathcal{D}(c) = D$. If it exists, the configuration c can also be computed in linear time.*

Proof. We store chord diagrams as circular doubly linked lists of endpoints of chords in clockwise order. We assume that each chord endpoint is equipped with a pointer to the corresponding vertex and each vertex has pointers to the two endpoints of its chord.

Let c be a configuration of T. We first store for each chord u in a chord diagram which of its ends is $\mathring{u}$. We then process the tree T in bottom-up order. If c contains only a single inner node, then the configuration of this node is the desired diagram $\mathcal{D}(c)$. Otherwise let μ be an inner node of T whose children are all leaves and let ν be its parent. Let T' be the split tree obtained by replacing in T the node μ together with all its leaves by a single leaf v and let c' be the configuration of T' that coincides with c for all nodes of T'. Clearly, c' and T' can be computed from c and T in $O(1)$ time. We now recursively compute $\mathcal{D}(c')$ in time linear in the size of T'. To obtain $\mathcal{D}(c)$, we replace in $\mathcal{D}(c')$ the endpoints $\mathring{v}, \hat{v}$ of v by the sequences π, σ, respectively, where $c(\mu) = r\pi r\sigma$ and r is the reference chord of μ. Since we maintain the order of the endpoints in doubly linked lists, this can be done in $O(1)$ time. Therefore we only spend $O(1)$ time per node of T.

Conversely assume that D is a chord diagram of G with reference chord r. We again process the tree T in bottom-up order. As before, if T contains only a single inner node μ then $c(\mu) = D$ is the desired configuration. Otherwise let μ be an inner node whose children are all leaves. We denote the set of leaves of μ by L. Note that $(L, V \setminus L)$ is a split of G. Let T' be the tree obtained from T by replacing μ and its leaves by a single leaf v. Using simple flags, we can decide for an endpoint of a chord of D in constant time whether it belongs to a vertex of L and if so, whether it has already been processed. We now treat the endpoints of the vertices in L one by one. For the first endpoint e we obtain in this way, we scan to the left and right in the doubly linked list of D starting at e. In this way we determine a maximal sublist $[e_1, e_2]$ of D (containing all endpoints that lie clockwise between the first and last points e_1, e_2 of that list) with $e \in [e_1, e_2]$ such that all elements of $[e_1, e_2]$ belong to vertices of L. We mark all endpoints that we encounter in this way as processed. We then scan further the leaves of L. We do find another endpoint f that is not yet processed since G is connected. We similarly determine a sublist $[f_1, f_2]$ around f so that all endpoints that lie clockwise between f_1, f_2 belong to vertices of L and the predecessor of f_1 and the successor of f_2 do not. If there is an unprocessed endpoint left, this means D does not respect split $(L, V \setminus L)$ and we can reject. Hence, assume no unprocessed endpoint remains.

We thus have partitioned the endpoints of the chords of L into two disjoint sublists $[e_1, e_2]$ and $[f_1, f_2]$ of D. Then let D' be the diagram obtained from D by replacing the sublists $[e_1, e_2]$, $[f_1, f_2]$ each with v. We recursively compute a configuration c' of T' with $\mathcal{D}(c') = D'$ where for each chord u the end $\mathring{u}$ is stored. If this succeeds, we obtain the desired configuration c as follows. For each inner node $\nu \neq \mu$ we set $c(\nu) = c'(\nu)$. Since we know from each predecessor and successor u of $\mathring{v}$, $\hat{v}$ whether it is $\mathring{u}$, we can set $c(\mu) = r[e_1, e_2]r[f_1, f_2]$ or $c(\mu) = r[f_1, f_2]r[e_1, e_2]$ accordingly, where r is the reference chord of $\operatorname{skel}(\mu)$. By construction it is $\mathcal{D}(c) = D$. Note that any other choice of $c(\mu)$ or $\mathcal{D}(c_{|T-\mu})$ results in a chord diagram different from D, since $[e_1, e_2]$ and $[f_1, f_2]$ are non-empty and separated by chords not in L. We can then first iterate through the list of $[e_1, e_2]$, $[f_1, f_2]$ that replaces $\mathring{v}$ and then other one to store each endpoint $\mathring{u}$.

The time spent to compute T', D' as well to modify c' into c is proportional to $|L|$. Therefore the algorithm runs in linear time. ◀

3.2 Configurations of Canonical Split-Trees

In a chord diagram D of a degenerate circle graph G, i.e., of a clique or a star, one half of D determines the other half. More precisely, we can describe a chord diagram of a connected degenerate circle graph $G = (V, E)$ with reference chord $r \in V$ with a cyclic permutation of V

using the following mapping $\phi_{G,r}$ to chord diagrams of G with reference chord r. If G is a clique, we set $\phi_{G,r}(r\rho) = r\rho r\rho$. If G is a star with center x, we set $\phi_{G,r}(x\rho\sigma) = \rho^{\text{rev}} x\rho\sigma x\sigma^{\text{rev}}$ where ρ ends with r or is empty if $x = r$.

▶ **Lemma 5** (⋆). *For a clique or a star $G = (V, E)$ with $r \in V$ the map $\phi_{G,r}$ is a bijection.*

Bouchet [3] showed that the undirected chord diagram of a connected prime circle graph is unique up to reversal. We can additionally choose the orientation of the reference chord. As a shorthand, we set $\text{tr} = \{\text{id}, \text{turn}, \text{rev}, \text{turn}(\text{rev})\}$ and for any chord diagram D we set $\text{tr}(D) = \{D, \text{turn}(D), \text{rev}(D), \text{turn}(\text{rev}(D))\}$. Note that we can have $|\text{tr}(D)| < 4$, e.g., for cliques we have $\text{turn}(D) = D$.

▶ **Lemma 6** (⋆). *Let G be a connected prime circle graph, $r \in V(G)$, and D a chord diagram with reference chord r. Then $|\text{tr}(D)| = 4$ and $\text{tr}(D)$ is the set of chord diagrams of G with reference chord r.*

By combining Theorem 3 with Lemmas 5, 6 we obtain the claimed compact representation of all chord diagrams of a connected circle graph G.

▶ **Theorem 7.** *Let G be a connected circle graph and let T be the canonical split-tree of G with reference chord $r \in V(G)$. Let each prime node μ be equipped with a chord diagram of $\text{skel}(\mu)$ with reference chord r_μ. There is a bijection between the chord diagrams of G with reference chord r and the choices of (i) applying an operation $\tau_\mu \in \text{tr}$ to each prime node μ and (ii) choosing a cyclic permutation of $V(\text{skel}(\mu))$ for each degenerate node μ.*

4 Partial Representation Extension

In this section, we solve RepExt(Circle) for a given circle graph $G = (V, E)$ and a chord diagram D_H of an induced subgraph $H \subseteq G$ in near-linear time. The idea is the following. Assume G is connected and let T be the canonical split-tree of G. By Theorem 3, all chord diagrams of G are represented by T. We project T and its configurations in a sense on H and obtain an enriched split-tree T_H of H. We show that T_H describes exactly the chord diagrams of H that can be extended to G. This means we just need to check whether T_H describes the given chord diagram D_H.

If G is disconnected and there is a connected component C with two predrawn chord ends a, b, and a distinct connected component C' with two predrawn chord ends c, d in D_H such that a, b and c, d alternate in D_H, then there is no extension of D_H to G since C, C' need to cross each other (even though the crossing chords might not be predrawn). Chaplick et al. [4] argue that otherwise an extension exists if and only if each connected component of G admits an extension. Testing this requirement as well as combining representation extensions of the different components can be done in linear time. Hence, we assume in the following that G is connected. Note that H may still be disconnected.

We start with a canonical split-tree T of G rooted at a reference chord $r \in V(H)$, which by Theorem 3 represents all chord diagrams of G. For a chord diagram D of G let $D|_H$ denote the chord diagram for H induced by D (i.e., the chords of H are placed as in D with the same starting point). Let T_H be the subtree of T whose leaves are the vertices of H and whose inner nodes are the inner nodes of T that lie on a path from r to some leaf in $V(H)$. For each inner node of T_H, we define $\text{skel}_{T_H}(\mu)$ as the subgraph of $\text{skel}_T(\mu)$ induced by the vertices $v_\mu(V(T_H))$, i.e., we keep exactly those chords that represent nodes that lead to at least one vertex of H (see Figure 7). Finally, we suppress nodes with K_2 as skeleton in T_H

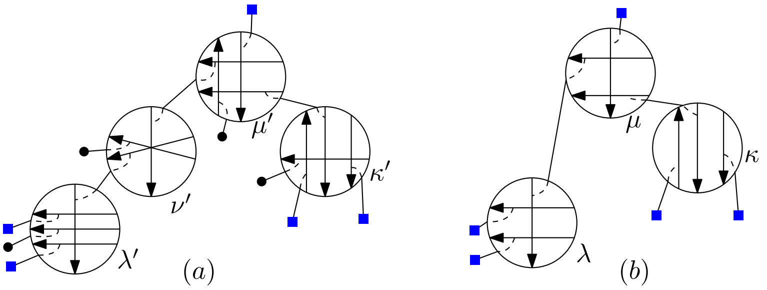

Figure 7 (a) Configuration of a canonical split-tree T. Leaves in $V(H)$ are blue squares. (b) split-tree T_H with the corresponding configuration. Node μ is degenerate in T_H while μ' is prime in T. $\mathrm{skel}(\kappa)$ is an isolated set while $\mathrm{skel}(\kappa')$ is a star.

by (iteratively) joining them with one of their neighbors. Note that T_H is a split-tree of H rooted at r, and each inner node μ of T_H stems from exactly one inner node μ' of T. We call T_H the *projection of T onto H*.

Let now c be a configuration of T. We define its *projection* c_H by setting $c_H(\mu) = c(\mu')|_{\mathrm{skel}_{T_H}(\mu)}$ for each node μ of T_H, i.e., it is the restriction of the chord diagram $c(\mu')$ to $\mathrm{skel}_{T_H}(\mu)$. Observe that the reference chord is not removed, and therefore $c_H(\mu)$ has the same reference chord as $c(\mu')$, i.e., c_H is a configuration of T_H. The following lemma shows that the projection $(T, c) \mapsto (T_H, c_H)$ commutes with all relevant operations.

▶ **Lemma 8.** *We have (i) $\mathcal{D}(c)|_H = \mathcal{D}(c_H)$ and (ii) for every inner node μ of T_H,* $\mathrm{turn}(c_H(\mu)) = \mathrm{turn}(c(\mu'))|_{\mathrm{skel}_{T_H}(\mu)}$ *and* $\mathrm{rev}(c_H(\mu)) = \mathrm{rev}(c(\mu'))|_{\mathrm{skel}_{T_H}(\mu)}$.

Proof. For Property (i) observe that it suffices to show that joining two diagrams commutes with the projection to a subgraph H. It then follows that $\mathcal{D}(c)|_H$, where the join is projected to H, is the same as $\mathcal{D}(c_H)$, where the skeletons are projected before the join, coincide.

More formally, let H_1, H_2 be two induced subgraphs of graphs G_1, G_2, respectively, and let $H = H_1 \oplus_{v_2,v_1} H_2$ and $G = G_1 \oplus_{v_2,v_1} G_2$. We show that for any chord diagrams D_1, D_2 of G_1, G_2, respectively, it is $(D_1 \oplus_{v_2,v_1} D_2)|_H = D_1|_{H_1} \oplus_{v_2,v_1} D_2|_{H_2}$. To see this, let $D_1 = \alpha v_2 \beta v_2 \gamma$ and $D_2 = v_1 \rho v_1 \sigma$ and let $\alpha', \beta', \gamma', \rho', \sigma'$ be the words obtained from $\alpha, \beta, \gamma, \rho, \sigma$ by removing all symbols for chords that are not in $V(H)$. Then we have $(D_1 \oplus_{v_2,v_1} D_2)|_H = (\alpha\rho\beta\sigma\gamma)|_H = \alpha'\rho'\beta'\sigma'\gamma'$. On the other hand, it is $D_1|_{H_1} \oplus_{v_2,v_1} D_2|_{H_2} = \alpha' v_2 \beta' v_2 \gamma' \oplus_{v_2,v_1} v_1 \rho' v_1 \sigma' = \alpha'\rho'\beta'\sigma'\gamma'$.

For Property (ii), let H be an induced subgraph of G. Let $D = r\rho r\sigma$ be a chord diagram for G with reference chord r and let ρ', σ' be the restrictions of ρ, σ to H, respectively. Then $\mathrm{turn}(D)|_H = \mathrm{turn}(r\rho r\sigma)|_H = (r\sigma r\rho)|_H = r\sigma' r\rho' = \mathrm{turn}(r\rho' r\sigma') = \mathrm{turn}((r\rho r\sigma)|_H) = \mathrm{turn}(D|_H)$ and $\mathrm{rev}(D)|_H = \mathrm{rev}(r\rho r\sigma)|_H = (r\sigma^{\mathrm{rev}} r\rho^{\mathrm{rev}})|_H = r\sigma^{\mathrm{rev}} r\rho^{\mathrm{rev}}|_H = r\sigma'^{\mathrm{rev}} r\rho'^{\mathrm{rev}} = \mathrm{rev}(r\rho' r\sigma') = \mathrm{rev}(D|_H)$. ◀

Let D_H be a chord diagram of H. By Theorem 3 there exists a chord diagram of G that extends D_H if and only if there exists a configuration c of T with $\mathcal{D}(c)|_H = D_H$. By Lemma 8(i) this holds if and only if there exists a configuration c of T whose projection c_H satisfies $\mathcal{D}(c_H) = \mathcal{D}(c)|_H = D_H$. We aim to find such a configuration c. To do this, we make use of the property from Lemma 8(ii) as follows. Let c' be an arbitrary configuration of T. By Theorem 7, the configuration c is obtained from c' by (i) choosing a configuration for each degenerate node of T and (ii) by choosing for each prime node μ one of the diagrams $c(\mu) \in \mathrm{tr}(c'(\mu))$. Note that induced subgraphs of cliques are themselves cliques and an induced subgraph of a star is either a star or an independent set. In the latter case

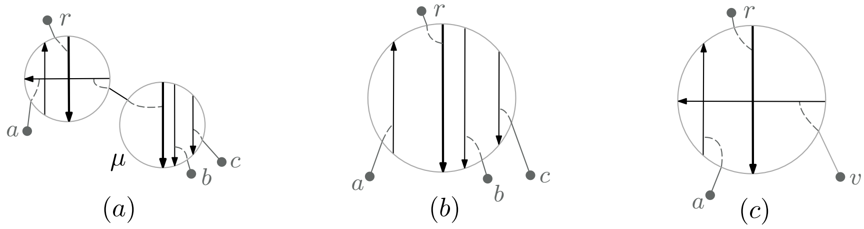

Figure 8 (a) a restricted split-tree for a graph H (b) a chord diagram D_H for H where the chord ends of the leaves of μ are contiguous. (c) the chord diagram we wish to create from D_H by replacing b,c by v. Note that the position of $\hat{v}$ is not neighboring the position of any leaf of μ in (b).

an induced chord diagram has the form $\rho^{\mathrm{rev}}\rho\sigma\sigma^{\mathrm{rev}}$ where the center of the original star has one end between ρ^{rev} and ρ and one end between σ and σ^{rev}. By Lemma 8(ii) it follows that c_H is obtained from c'_H by (i) arbitrarily choosing a configuration for each node of T_H that stems from a degenerate node of T and is connected, (ii) choosing a configuration of the form $\rho^{\mathrm{rev}}\rho\sigma\sigma^{\mathrm{rev}}$ for each node of T_H that stems from a degenerate node of T and is an independent set and (iii) by choosing for each node μ of T_H that stems from a prime node in T one of the diagrams $c_H(\mu) \in \mathrm{tr}(c'_H(\mu))$.

We condense these rules as follows. We label the nodes of T_H as degenerate if they stem from a degenerate node in T and as prime if they stem from a prime node of T. We call two configuration c_H, c'_H of T_H *equivalent* if $c_H(\mu) \in \mathrm{tr}(c'_H(\mu))$ for each prime-labeled node, and for each degenerate-labeled node ν where $\mathrm{skel}(\nu)$ is an independent set, $c_H(\nu)$ is of the form $\rho^{\mathrm{rev}}\rho\sigma\sigma^{\mathrm{rev}}$. We call (T_H, c'_H) *the restricted split-tree of H with respect to G* and say that (T_H, c'_H) *represents* a diagram D_H of H if $D_H = \mathcal{D}(c_H)$ for some configuration c_H that is equivalent to c'_H. By the above observations, D_H can be extended to a diagram of G if and only if D_H is represented by (T_H, c'_H), where c'_H is the projection of a configuration of T.

If H is connected, this condition can be tested in linear time by computing the unique configuration c_H of T_H with $\mathcal{D}(c_H) = D_H$ using Theorem 4 and then checking whether it is equivalent to c'_H. If H is not connected, we use the following lemma to test whether (T_H, c'_H) represents D_H and to obtain a corresponding configuration c_H of T_H in that case.

▶ **Lemma 9** ($\star$). *Let (T_H, c'_H) be a restricted split-tree of a graph H with respect to a connected graph G and let D_H be a chord diagram of H with the root r of T_H as reference chord. It can be tested in linear time whether (T_H, c'_H) represents D_H. If so, a corresponding configuration c_H can also be computed in linear time.*

Sketch of proof. We use a bottom-up approach as in the proof of Theorem 4 to find c_H. Recall that in the proof of Theorem 4, we iteratively processed an inner node μ with only leaves as children and searched for subwords of D_H that correspond to a chord diagram D_μ of $\mathrm{skel}(\mu)$ to check whether D_μ can be part of a configuration and then replace these subwords with a chord that represents μ as a leave for the remaining split-tree. To find these subwords we started at arbitrary leaves of μ to find contiguous sublists of such leaves in D_H. However, if H is not connected, it can happen that when processing a node μ, all its leaves are contiguous in D_H; see Figure 8. For example, this happens if μ is a leftmost leaf of a star node in T that lost its center in T_H (something similar can happen in prime-labeled nodes). In this case the first found sublist $[e_1, e_2]$ of leaves of μ already contains all leaves of μ and we do not find a second sublist $[f_1, f_2]$. This means that we have no pointer to the correct place in the new chord diagram D' for the second end of the leaf chord v that replaces μ. We thus allow D_H to be a relaxed chord diagram where for some chords only one end is fixed. We then use the characterization of inner nodes of restricted split-trees to compute configurations for those nodes that match the given relaxed chord diagrams.

For example, if μ is a labeled degenerate and $\mathrm{skel}(\mu)$ is a star with center x, we start at an end of x in D_H and traverse simultaneously in both directions until all ends are traversed (except possibly the second end of x). At each end of a chord v with no second end, insert that second end where the other traversal is at that moment. When a chord with two ends is reached, wait in front of that chord until the other traversal also reaches that chord and then skip that chord in both traversals. If the traversals wait at different chords we reject. In that case D_H induces the subword $xaabb$ (or some cyclic shifted version of that word) which cannot be realized by a star with center x. If x has a second end, the traversals meet and end there. Otherwise, add the second end of x where the traversals meet. Thereby, all chords for leaves intersect x and no other intersection occurs. By construction we obtain a chord diagram $c_H(\mu)$ that realizes D_H.

Note that both ends of v can be neighbors in $\mathcal{D}(c_H|_{T_H-\mu})$. Then, moving the end $\hat{r}$ of the reference chord in $c_H(\mu)$ does not change $\mathcal{D}(c_H)$ and c_H is no longer required to be unique. ◀

▶ **Theorem 10.** *Given $T = \mathrm{ST}(G)$ and a chord diagram D of G, RepExt(Circle) can be solved in linear time. In the positive case a representation of G that extends the given diagram D_H of H can be computed in the same running time.*

Proof. From D we compute in linear time a configuration c' of T with $\mathcal{D}(c') = D$ using Theorem 4. From T and c', we compute in linear time the projection to the restricted split-tree (T_H, c'_H) of H. With Lemma 9, we test whether it represents the given diagram D_H of H and obtain a configuration c_H equivalent to c'_H with $\mathcal{D}(c_H) = D_H$. We now define a configuration c of T as follows. For each prime-labeled node μ of T_H, we define $c(\mu') = \tau(c'(\mu'))$ where $\tau \in \mathrm{tr}$ such that $c_H(\mu) = \tau(c'_H(\mu))$. For each degenerate-labeled node μ of T_H, we choose a configuration as follows. If $\mathrm{skel}_H(\mu)$ is connected we can extend $c'(\mu)$ arbitrarily. For a precise argument, we have by Lemma 5, $c_H(\mu) = \phi_{\mathrm{skel}_H(\mu),r}(\sigma)$ for some cyclic permutation σ of $V(\mathrm{skel}_{T_H}(\mu))$. We create a permutation σ' of $V(\mathrm{skel}_T(\mu))$ by appending the elements of $V(\mathrm{skel}_T(\mu')) \setminus V(\mathrm{skel}_{T_H}(\mu))$ to σ in an arbitrary order. We then set $c(\mu') = \phi_{H,r}(\sigma')$. If $\mathrm{skel}_{T_H}(\mu)$ is not connected, then $\mathrm{skel}_T(\mu')$ is a star where the reference chord $r_{\mu'}$ is not the center x and $\mathrm{skel}_{T_H}(\mu)$ does not contain x. In that case $c_H(\mu)$ is of the form $c_H(\mu) = \rho^{\mathrm{rev}}\rho\sigma\sigma^{\mathrm{rev}}$ and we have to insert the other chords in parallel, such that x can intersect all chords. Then set $c(\mu') = \rho^{\mathrm{rev}}x\rho\sigma\alpha x\alpha^{\mathrm{rev}}$, where α are the elements of $V(\mathrm{skel}_T(\mu)) \setminus V(\mathrm{skel}_{T_H}(\mu)) \setminus \{x\}$. Finally, for each node μ' of T that is not contained in T_H, we set $c(\mu') = c'(\mu')$. By construction, we have that c_H is the projection of c, and therefore $\mathcal{D}(c)|_H = \mathcal{D}(c_H) = D_H$, i.e., $\mathcal{D}(c)$ is the desired representation of G. Clearly the amount of work per skeleton is linear, and therefore the overall running time is linear. ◀

Theorem 10 assumes that $\mathrm{ST}(G)$ and a chord diagram of G are available. If not, we can compute them in $O((n+m)\alpha(n+m))$ time [13, 14].

▶ **Corollary 11.** *RepExt(Circle) can be solved in $O((n+m)\alpha(n+m))$ time.*

5 Conclusion

We have developed a data structure that compactly represents all chord diagrams for a connected circle graph. As an application, we have shown how to solve the partial representation extension problem for circle graphs in almost linear time, improving over the $O(n^3)$ algorithm of Chaplick et al. [4]. Using a reduction of Chaplick et al. this also solves the extension problem for permutation graphs in near linear time, improving over two different $O(n^3)$ algorithms [4], [17]. Our data structure may also be useful when seeking restricted chord diagrams that satisfy additional constraints. For example, we believe that it is possible to significantly simplify the circular-arc graph recognition of Hsu et al. [15].

Boundaries to Single-Agent Stability in Additively Separable Hedonic Games

Martin Bullinger
Technical University of Munich, Germany

Abstract

Coalition formation considers the question of how to partition a set of agents into coalitions with respect to their preferences. Additively separable hedonic games (ASHGs) are a dominant model where cardinal single-agent values are aggregated into preferences by taking sums. Output partitions are typically measured by means of stability, and we follow this approach by considering stability based on single-agent movements (to join other coalitions), where a coalition is defined as stable if there exists no beneficial single-agent deviation. Permissible deviations should always lead to an improvement for the deviator, but they may also be constrained by demanding the consent of agents involved in the deviations, i.e., by agents in the abandoned or welcoming coalition. Most of the existing research focuses on the unanimous consent of one or both of these coalitions, but more recent research relaxes this to majority-based consent. Our contribution is twofold. First, we settle the computational complexity of the existence of contractually Nash-stable partitions, where deviations are constrained by the unanimous consent of the abandoned coalition. This resolves the complexity of the last classical stability notion for ASHGs. Second, we identify clear boundaries to the tractability of stable partitions under majority-based stability concepts by proving elaborate hardness results for restricted classes of ASHGs. Slight further restrictions lead to positive results.

1 Introduction

Coalition formation is a vibrant topic in multi-agent systems at the intersection of theoretical computer science and economic theory. Given a set of agents, e.g., humans or machines, the central concern is to determine a coalition structure, or partition, of the agents into subsets, or so-called coalitions. Agents have preferences over coalition structures, and therefore coalition formation naturally generalizes the matching problem under preferences [22]. As in the special case of matchings, a common assumption is that externalities outside one's own coalition play no role, i.e., agents are only concerned about the coalition they are part of. This assumption leads to the popular framework of hedonic games [18].

In contrast to matchings, the number of coalitions an agent can be part of is not polynomially bounded in coalition formation, and therefore, a lot of effort has been put into identifying reasonable and succinct classes of hedonic games (see, e.g., [2, 5, 8, 20]). In many such classes, agents extract cardinal preferences from a weighted and possibly directed graph by some aggregation method. Probably the most natural and thoroughly researched way to aggregate preferences is by taking the sum of the weights of edges towards agents in one's own coalition. This leads to the concept of additively separable hedonic games (ASHGs) [8]. This paper continues to investigate this class of hedonic games.

The desirability of an output, i.e., of a coalition structure, is frequently measured with respect to stability, which captures the prospect of agents maintaining their coalitions. A coalition structure is stable if no single agent or group of agents has an incentive to deviate by leaving their coalitions and joining other coalitions or forming new coalitions. Depending on the requirements that deviators need to meet, one can define various specific stability notions. In this paper, we focus on stability based on single-agent deviations. This means that a deviation consists of a single agent that abandons her current coalition to join another existing coalition or to form a new coalition of her own.

In this case, a reasonable minimum requirement is that a deviating agent should improve her coalition. If no such deviation is possible, then a coalition structure is said to be Nash-stable. However, this leads to an immensely strong stability concept because the deviation is only constrained weakly. As a consequence, Nash-stable outcomes hardly ever exist. For instance, consider a game with two agents x and y where x prefers to form a coalition with y over staying alone, whereas y prefers to stay alone. Then, x always has an incentive to join y whenever she is in a coalition of her own, whereas y would always leave x. Such run-and-chase situations occur in most classes of hedonic games.[1]

Therefore, various weakenings of Nash stability have been proposed. These restrict the possible deviations by adding further requirements on other agents involved in the deviation. Typically, two types of constraints are considered, namely the demanding of some kind of consent from the abandoned or the welcoming coalition. Most of the research has focused on the unanimous consent of these coalitions. This leads to the concepts of contractual Nash stability and individual stability where all agents in the abandoned or welcoming coalition have to approve the deviation. Still, unanimous consent of involved coalitions is a strong requirement. Hence, a reasonable compromise is to merely demand partial consent. Therefore, we also study stability where deviations are constrained by the approval of a majority vote of the abandoned or welcoming coalition.

1.1 Contribution

Our contribution is twofold. First, we settle the complexity of the existence problem of contractually Nash-stable coalition structures. Despite knowing for quite long that No-instances, i.e., additively separable hedonic games which do not admit a contractually Nash-stable coalition structure, exist [28], detailed computational investigations of single-agent stability during the last decade have left this problem open [10, 29]. Hence, we complete the picture of the complexity of unanimity-based single-agent stability concepts in ASHGs.

Second, we investigate majority-based stability concepts. We will show that, even under significant weight restrictions, stable coalition structures need not exist and we can leverage No-instances to obtain computational intractabilities. This complements very recent results by Brandt et al. [10] and resolves problems left open by this work. In particular, we completely pinpoint the complexity of majority-based stability notions in friends-and-enemies games and appreciation-of-friends games.

These results are in line with the repeatedly observed theme in hedonic games research that the existence of counterexamples is the key to computational intractabilities (see, e.g., [3, 10, 11, 16, 29]).[2] On the other hand, we demonstrate that the observed intractabilities lie at the computational boundary by carving out further weak restrictions that lead to the existence and efficient computability of stable states.

[1] Notably, Nash-stable coalition structures always exist in ASHGs if the input graph is symmetric [8], and in a generalization of this class of games called subset-neutral hedonic games [27].

[2] A notable exception is provided by Bullinger and Kober [13] who identify a class of hedonic games where partitions in the core always exist, but are still hard to compute.

1.2 Related Work

The study of hedonic games was initiated by Drèze and Greenberg [18] but was only popularized two decades later by Banerjee et al. [6], Cechlárová and Romero-Medina [15], and Bogomolnaia and Jackson [8]. Aziz and Savani [4] review many important concepts in their survey. Two important research questions concern the design of reasonable computationally manageable subclasses of hedonic games and the detailed investigation of their computational properties. The former has led to a broad landscape of game representations. Some of these representations [5, 20] are ordinal and fully expressive, i.e., they can, in principle, express every preference relation over coalitions. Still, representing certain preference relations requires exponential space. These representations are contrasted by cardinal representations based on weighted graphs [2, 8, 26], which are not fully expressive but only require polynomial space (except when weights are artificially large). Apart from the already discussed additively separable hedonic games, important aggregation methods consider the average of weights leading to the classes fractional hedonic games [2] and modified fractional hedonic games [26]. Additively separable hedonic games have important subclasses where the focus lies in distinguishing friends and enemies, and therefore only two different weights are present in the underlying graph [16].

The computational properties of hedonic games have been extensively studied and we focus on literature related to additively separable hedonic games. Various versions of stability have been investigated [1, 3, 10, 16, 29, 21]. The closest to our work are the detailed studies of single-agent stability by Sung and Dimitrov [29] and Brandt et al. [10]. Gairing and Savani [21] settle the complexity of single-agent stability for symmetric input graphs. Majority-based stability has only received little attention thus far [10, 21]. Apart from stability, other desirable axioms concern efficiency and fairness. Aziz et al. [3] cover a wide range of axioms, whereas Elkind et al. [19] and Bullinger [12] focus on Pareto optimality, and Brandt and Bullinger [9] investigate popularity, an axiom combining ideas from stability and efficiency which is also related to certain majority-based stability notions [10]. Finally, a recent trend in the research on coalition formation is to complement the static view of existence problems by considering dynamics based on stability concepts (see, e.g., [7, 10, 11, 14, 23]).

2 Preliminaries

In this section, we formally introduce hedonic games and our considered stability concepts.

2.1 Hedonic Games

Let $N = [n]$ be a set of $n \in \mathbb{N}$ agents, where we define $[n] = \{1, \dots, n\}$. The output of a coalition formation problem is a coalition structure, that is, a partition of the agents into different disjoint coalitions according to their preferences. A *partition* of N is a subset $\pi \subseteq 2^N$ such that $\bigcup_{C\in\pi} C = N$, and for every pair $C, D \in \pi$, it holds that $C = D$ or $C \cap D = \emptyset$. An element of a partition is called a *coalition* and, given a partition π, the unique coalition containing agent i is denoted by $\pi(i)$. We refer to the partition π given by $\pi(i) = \{i\}$ for every agent $i \in N$ as the *singleton partition*, and to $\pi = \{N\}$ as the *grand coalition*.

Let $\mathcal{N}_i$ denote all possible coalitions containing agent i, i.e., $\mathcal{N}_i = \{C \subseteq N : i \in C\}$. A *hedonic game* is a tuple $(N, \succsim)$, where N is an agent set and $\succsim = (\succsim_i)_{i\in N}$ is a tuple of weak orders $\succsim_i$ over $\mathcal{N}_i$ representing the preferences of the respective agent i. Hence, as mentioned before, agents express preferences only over the coalitions of which they are part without considering externalities. The strict part of an order $\succsim_i$ is denoted by $\succ_i$, i.e., $C \succ_i D$ if and only if $C \succsim_i D$ and not $D \succsim_i C$.

Additively separable hedonic games assume that every agent is equipped with a cardinal utility function that is aggregated by taking the sum of single-agent values. Formally, following [8], an *additively separable hedonic game* (ASHG) (N, v) consists of an agent set N and a tuple $v = (v_i)_{i \in N}$ of utility functions $v_i \colon N \to \mathbb{R}$ such that $\pi \succsim_i \pi'$ if and only if $\sum_{j \in \pi(i)} v_i(j) \geq \sum_{j \in \pi'(i)} v_i(j)$. Clearly, ASHGs are a subclass of hedonic games. When we specify ASHG utilities, we neglect, without loss of generality, $v_i(i)$ because the preferences do not depend on it and we implicitly assume that it is set to an appropriate constant if an ASHG has to fit into a certain subclass of games.

Every ASHG can be naturally represented by a complete directed graph $G = (N, E)$ with weight $v_i(j)$ on arc (i, j). There are various subclasses of ASHGs that allow a natural interpretation in terms of friends and enemies. An agent $j \in N$ is called a *friend* (or *enemy*) of agent $i \in N$ if $v_i(j) > 0$ (or $v_i(j) < 0$). An ASHG is called a *friends-and-enemies game* (FEG) if $v_i(j) \in \{-1, 1\}$ for every pair of agents $i, j \in N$ [10]. Further, following [16], an ASHG is called an *appreciation-of-friends game* (AFG) (or an *aversion-to-enemies game* (AEG)) if $v_i(j) \in \{-1, n\}$ (or $v_i(j) \in \{-n, 1\}$). In such games, agents seek to maximize their number of friends while minimizing their number of enemies, where these goals have a different priority in each case. Based on the friendship of agents, we define the *friendship relation* (or *enemy relation*) as the subset $R \subseteq N \times N$ where $(i, j) \in R$ if and only if $v_i(j) > 0$ (or $v_i(j) < 0$).

2.2 Single-Agent Stability

We want to study stability under single agents' incentives to perform deviations. A *single-agent deviation* performed by agent i transforms a partition π into a partition π' where $\pi(i) \neq \pi'(i)$ and, for all agents $j \neq i$,

$$\pi'(j) = \begin{cases} \pi(j) \setminus \{i\} & \text{if } j \in \pi(i), \\ \pi(j) \cup \{i\} & \text{if } j \in \pi'(i), \text{ and} \\ \pi(j) & \text{otherwise.} \end{cases}$$

We write $\pi \xrightarrow{i} \pi'$ to denote a single-agent deviation performed by agent i transforming partition π to partition π'.

We consider myopic agents whose rationale is to only engage in a deviation if it immediately makes them better off. A *Nash deviation* is a single-agent deviation performed by agent i making her better off, i.e., $\pi'(i) \succ_i \pi(i)$. Any partition in which no Nash deviation is possible is said to be *Nash-stable* (NS).

Following [10], we introduce consent-based stability concepts via favor sets. Let $C \subseteq N$ be a coalition and $i \in N$ an agent. The *favor-in set* of C with respect to i is the set of agents in C (excluding i) that strictly favor having i inside C rather than outside, i.e., $F_{\text{in}}(C, i) = \{j \in C \setminus \{i\} \colon C \cup \{i\} \succ_j C \setminus \{i\}\}$. The *favor-out set* of C with respect to i is the set of agents in C (excluding i) that strictly favor having i outside C rather than inside, i.e., $F_{\text{out}}(C, i) = \{j \in C \setminus \{i\} \colon C \setminus \{i\} \succ_j C \cup \{i\}\}$.

An *individual deviation* (or *contractual deviation*) is a Nash deviation $\pi \xrightarrow{i} \pi'$ such that $F_{\text{out}}(\pi'(i), i) = \emptyset$ (or $F_{\text{in}}(\pi(i), i) = \emptyset$). Then, a partition is said to be *individually stable* (IS) or *contractually Nash-stable* (CNS) if it allows for no individual or contractual deviation, respectively. A related weakening of both stability concepts is contractual individual stability (CIS), based on deviations that are both individual and contractual deviations [8, 17].

Finally, we define hybrid stability concepts according to [10] where the consent of the abandoned or welcoming coalition is decided by a majority vote. A Nash deviation $\pi \xrightarrow{i} \pi'$ is

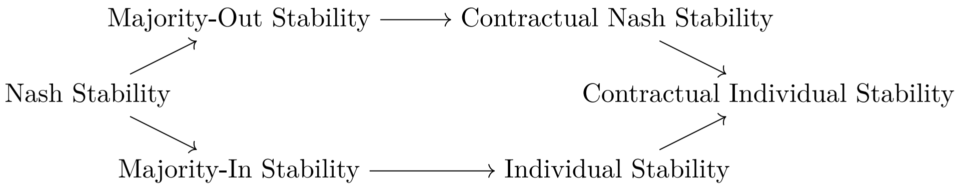

Figure 1 Logical relationships between stability notions. An arrow from concept S to concept S' indicates that if a partition satisfies S, it also satisfies S'. Conversely, this means that every S' deviation is also an S deviation.

called a *majority-in deviation* (or *majority-out deviation*) if $|F_{\text{in}}(\pi'(i), i)| \geq |F_{\text{out}}(\pi'(i), i)|$ (or $|F_{\text{out}}(\pi(i), i)| \geq |F_{\text{in}}(\pi(i), i)|$). Similar to before, a partition is said to be *majority-in stable* (MIS) or *majority-out stable* (MOS) if it allows for no majority-in or majority-out deviation, respectively. The concepts MIS and MOS are special cases of the voting-based stability notions by Gairing and Savani [21] for a threshold of 1/2. Brandt et al. [10] also consider stability concepts that require voting-based consent by both the abandoned and welcoming coalition, similar to CIS.

For a stability concept $S \in \{\text{NS}, \text{IS}, \text{CNS}, \text{MIS}, \text{MOS}\}$, we denote the deviation corresponding to S as *S deviation*, e.g., CNS deviation for a contractual deviation. A taxonomy of our related solution concepts is provided in Figure 1.

3 Contractual Nash Stability

Our first result settles the computational complexity of contractual Nash stability in ASHGs. All of our reductions in this and the subsequent sections are from the NP-complete problem Exact3Cover (E3C) [25]. An instance of E3C consists of a tuple (R, S), where R is a ground set together with a set S of 3-element subsets of R. A Yes-instance is an instance such that there exists a subset $S' \subseteq S$ that partitions R.

Before giving the complete proof, we briefly describe the key ideas. Given an instance (R, S) of E3C, the reduced instance consists of three types of gadgets. First, every element in R is represented by a subgame that does not contain a CNS partition. In principle, any such game can be used for a reduction, and we use the game identified by Sung and Dimitrov [28]. Moreover, we have further auxiliary gadgets that also consist of the same No-instance. The number of these auxiliary gadgets is equal to the number of sets in S that would remain after removing an exact cover of R, i.e., there are $|S| - |R|/3$ such gadgets. By design, the agents in the subgames corresponding to No-instances have to form coalitions with agents outside of their subgame in every CNS partition. The only agents that can achieve this are agents in gadgets corresponding to elements in S. A gadget corresponding to an element $s \in S$ can either prevent non-stability caused by exactly one auxiliary gadget, or by the three gadgets corresponding to the elements $r \in R$ with $r \in s$. Hence, the only possibility to deal with all No-instances simultaneously is if there exists an exact cover of R by sets in S. Then, the gadgets corresponding to elements in R can be dealt with by the cover and there are just enough elements in S to additionally deal with the other auxiliary gadgets.

▶ **Theorem 1.** *Deciding whether an ASHG contains a CNS partition is NP-complete.*

Proof. We provide a reduction from E3C. Let (R, S) be an instance of E3C and set $a = |S| - |R|/3$ (this is the number of additional sets in S if removing some exact cover). Without

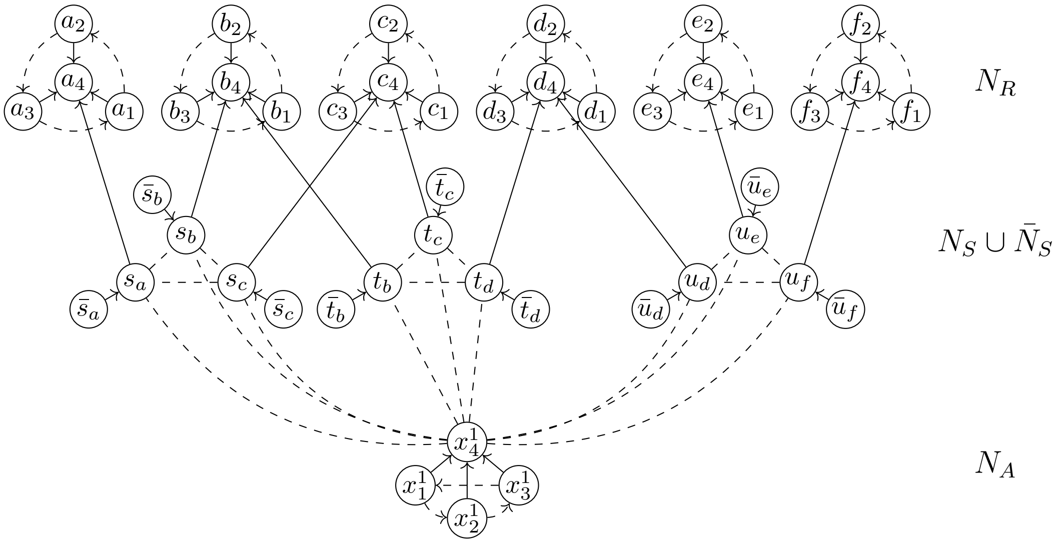

Figure 2 Schematic of the reduction from the proof of Theorem 1. We depict the reduced instance for the instance (R, S) of E3C where $R = \{a, b, c, d, e, f\}$, and $S = \{s, t, u\}$, with $s = \{a, b, c\}$, $t = \{b, c, d\}$, and $u = \{d, e, f\}$. Fully drawn edges mean a positive utility, which is usually 1 except between agents of the types $\bar{s}_r$ and s_r, where $v_{\bar{s}_r}(s_r) = 3$. Dashed edges represent a utility of 0. For agents in $\bar{N}_S$, only the single positive utility is displayed. Other omitted edges represent a negative utility of -4.

loss of generality, $a \geq 0$. We define an ASHG (N, v) as follows. Let $N = N_R \cup N_S \cup \bar{N}_S \cup N_A$ where

- $N_R = \cup_{r \in R} N_r$ with $N_r = \{r_i : i \in [4]\}$ for $r \in R$,
- $N_S = \cup_{s \in S} N_s$ with $N_s = \{s_r : r \in s\}$ for $s \in S$,
- $\bar{N}_S = \cup_{s \in S} \bar{N}_s$ with $\bar{N}_s = \{\bar{s}_r : r \in s\}$ for $s \in S$, and
- $N_A = \cup_{1 \leq j \leq a} N^j$ with $N^j = \{x_i^j : i \in [4]\}$ for $1 \leq j \leq a$.

We define valuations v as follows:

- For each $r \in R$, $i \in [3]$: $v_{r_i}(r_4) = 1$.
- For each $r \in R$, $(i, j) \in (1, 2), (2, 3), (3, 1)$: $v_{r_i}(r_j) = 0$.
- For each $1 \leq j \leq a$, $i \in [3]$: $v_{x_i^j}(x_4^j) = 1$.
- For each $1 \leq j \leq a$, $(i, k) \in (1, 2), (2, 3), (3, 1)$: $v_{x_i^j}(x_k^j) = 0$.
- For each $s \in S$, $r \in s$: $v_{s_r}(r_4) = 1$.
- For each $s \in S$, $r \in s$, $1 \leq j \leq a$: $v_{s_r}(x_4^j) = v_{x_4^j}(s_r) = 0$.
- For each $s \in S$, $r, r' \in s$: $v_{s_r}(s_{r'}) = 0$.
- For each $s \in S$, $r, r' \in s$, $r \neq r'$, $z \in (N_S \cup N_A) \setminus N_s$: $v_{\bar{s}_r}(s_r) = 3$, $v_{\bar{s}_r}(s_{r'}) = -2$, and $v_{\bar{s}_r}(z) = 0$.
- All other valuations are -4.

An illustration of the game is given in Figure 2. The agents in N_R in the reduced instance form gadgets consisting of a subgame without CNS partition for every element in R. The agents in N_A constitute further such gadgets. The agents in N_S consist of triangles for every set in S and are the only agents who can bind agents in the gadgets in any CNS partition. Finally, agents in $\bar{N}_S$ avoid having agents in N_S in separate coalitions to bind agents in N_A.

We claim that (R, S) is a Yes-instance if and only if (N, v) contains a CNS partition. Suppose first that $S' \subseteq S$ partitions R. Consider any bijection $\phi\colon S \setminus S' \to [a]$. Define a partition π by taking the union of the following coalitions:

- For every $r \in R, i \in [3]$, form $\{r_i\}$.
- For $s \in S', r \in s$, form $\{s_r, r_4\}$.
- For $s \in S \setminus S'$, form $\{s_r : r \in s\} \cup \{x_4^{\phi(s)}\}$.
- For $s \in S, r \in s$, form $\{\bar{s}_r\}$.
- For $1 \leq j \leq a, i \in [3]$, form $\{x_i^j\}$.

We claim that π is CNS. We will show that no agent can perform a deviation.

- For $r \in R$, $i \in [3]$, it holds that $v_{r_i}(\pi) = 0$ and joining any other coalition results in a negative utility. In particular, $v_{r_i}(\pi(r_4) \cup \{r_i\}) = -3$.
- For $r \in R$, r_4 is not allowed to leave her coalition.
- For $s \in S'$, $r \in s$, it holds that $v_{s_r}(\pi) = 1$ and joining any other coalition results in a negative utility. The agent s_r is in a most preferred coalition.
- For $s \in S \setminus S'$, $r \in s$, it holds that $v_{s_r}(\pi) = 0$ and joining any other coalition results in a negative utility. In particular, $v_{s_r}(\pi(r_4) \cup \{s_r\}) = -3$.
- For $s \in S'$, $r \in s$, the agent $\bar{s}_r$ obtains a non-positive utility by joining any other coalition. In particular, $v_{\bar{s}_r}(\pi(s_r) \cup \{\bar{s}_r\}) = -1$.
- For $s \in S \setminus S'$, $r \in s$, the agent $\bar{s}_r$ obtains a non-positive utility by joining any other coalition. In particular, $v_{\bar{s}_r}(\pi(s_r) \cup \{\bar{s}_r\}) = -1$.
- For $1 \leq j \leq a$, $i \in [3]$, it holds that $v_{x_i^j}(\pi) = 0$ and joining any other coalition results in a negative utility. In particular, $v_{x_i^j}(\pi(x_4^j) \cup \{x_i^j\}) = -11$.
- For $1 \leq j \leq a$, x_4^j is in a best possible coalition (achieving utility 0).

Conversely, assume that (N, v) contains a CNS partition π. Define $S' = \{s \in S \colon \pi(s_r) \cap N_R \neq \emptyset$ for some $r \in s\}$. We will show first that S' covers all elements in R and then show that $|S'| = |R|/3$.

Let $r \in R$. Then, for all $i \in [3]$, $\pi(r_i) \subseteq N_r$. This follows because there is no agent who favors r_i in her coalition. Therefore, she would leave any coalition with an agent outside N_r to receive non-negative utility in a singleton coalition. Further, if there is no $s \in S$ with $r \in s$ such that $r_4 \in \pi(r_s)$, then $\pi(r_4) \subseteq N_r$. Indeed, if r_4 forms any coalition except a singleton coalition, she will receive negative utility, and then there must exist an agent who favors her in the coalition. Consequently, if $r_4 \notin \pi(r_s)$ for all $s \in S$ with $r \in s$, then r_4 is in a singleton coalition, or there exists $i \in [3]$ with $r_4 \in \pi(r_i)$, for which we already know that $\pi(r_i) \subseteq N_r$.

Assume now that $\pi(r_4) \subseteq N_r$. For $i, i' \in [3]$, $r_i \notin \pi(r_{i'})$ because then one of them would receive a negative utility and could perform a CNS deviation to form a singleton coalition. If $\{r_4\} \in \pi$, then r_1 would deviate to join her. Hence, there exists exactly one $i \in [3]$ with $\{r_i, r_4\} \in \pi$. Suppose without loss of generality that $\{r_1, r_4\} \in \pi$. But then, r_3 would perform a CNS deviation to join them, a contradiction. We can conclude that there exists $s \in S$ with $r \in s$ such that $r_4 \in \pi(r_s)$. Hence, $s \in S'$ and we have shown that S' covers R.

To bound the cardinality of S', we will show that, for every $1 \leq j \leq a$, there exists $s \in S \setminus S'$ with $N_s \subseteq \pi(x_4^j)$. Let therefore $1 \leq j \leq a$ and let $C = \pi(x_4^j)$. Similar to the considerations about agents in N_r, we know that $\pi(x_i^j) \subseteq X^j$ for $i \in [3]$, and that it cannot happen that $C \subseteq X^j$, and therefore $C \cap X^j = \{x_4^j\}$. In particular, there must be an agent $y \in N \setminus X^j$ with $y \in C$. Since no agent in C favors x_4^j to be in her coalition, we know that $v_{x_4^j}(\pi) \geq 0$ and therefore $C \subseteq \{x_4^j\} \cup N_S$. Let $s \in S$ and $r \in s$ with $s_r \in C$. As we already know that $\bar{s}_r \notin C$, it must hold that $N_s \subseteq C$ to prevent her from joining. It follows that $s \notin S'$. Since $\pi(x_4^j) \cap \pi(x_4^{j'}) = \emptyset$ for $1 \leq j' \leq a$ with $j' \neq j$, we find an injective mapping $\phi\colon [a] \to S \setminus S'$ such that, for every $1 \leq j \leq a$, $N_{\phi(j)} \subseteq \pi(x_4^j)$. Consequently, $|S'| \leq |S| - |\phi([a])| \leq |S| - a = |R|/3$. Hence, S' covers all elements from R with (at most) $|R|/3$ sets and therefore is an exact cover. ◀

The reduction in the previous proof only uses a very limited number of different weights, namely the weights in the set $\{1, 0, -2, -4\}$, where the weight -4 may be replaced by an arbitrary smaller weight. By contrast, CNS partitions always exist if the utility functions of an ASHG assume at most one nonpositive value, and can be computed efficiently in this case [10, Theorem 4]. This encompasses for instance FEGs, AFGs, and AEGs. Hence, the hardness result is close to the boundary of computational feasibility.

4 Appreciation-of-Friends Games

In this section, we consider appreciation-of-friends games. Typically, these games behave well with respect to stability. In particular, IS, CNS, and MIS partitions always exist and can be computed efficiently, while it is only known that NS leads to non-existence and computational hardness among single-agent stability concepts [10, 16]. By contrast, we show in our next result that MOS partitions need not exist in AFGs. In other words, despite their conceptual complementarity, the stability concepts MOS and MIS lead to very different behavior in a natural class of ASHGs. The constructed game has a sparse friendship relation in the sense that almost all agents only have a single friend. After discussing the counterexample, we show how requiring slightly more sparsity yields a positive result. Due to space restrictions, some proofs are omitted or sketched.

▶ **Proposition 2.** *There exists an AFG without an MOS partition.*

Proof. We define the game formally. An illustration is given in Figure 3. Let $N = \{z\} \cup \bigcup_{x\in\{a,b,c\}} N_x$, where $N_x = \{x_i \colon i \in [5]\}$ for $x \in \{a, b, c\}$. In the whole proof, we read indices modulo 5, mapping to the respective representative in [5]. The utilities are given as:

- For all $i \in [5], x \in \{a, b, c\}\colon v_{x_i}(x_{i+1}) = n$.
- For all $x \in \{a, b, c\}\colon v_{x_1}(z) = n$.
- All other valuations are -1.

The AFG consists of 3 cycles with 5 agents each, together with a special agent that is liked by a fixed agent of each cycle and has no friends herself. The key insight to understanding why there exists no MOS partition is that agents of type x_1 where $x \in \{a, b, c\}$ have conflicting candidate coalitions in a potential MOS partition. Either, they want to be with z (a coalition that has to be small because z prefers to stay alone) or they want to be with x_2 which requires a rather large coalition containing their cycle.

Before going through the proof that this game has no MOS partition, it is instructional to verify that, for cycles of 5 agents, the unique MOS partition is the grand coalition, i.e., the unique MOS partition of the game restricted to N_x is $\{N_x\}$, where $x \in \{a, b, c\}$. This is a key idea of the construction and is implicitly shown in Case 2 of the proof for $x = b$.

Assume for contradiction that the defined AFG admits an MOS partition π. To derive a contradiction, we perform a case distinction over the coalition sizes of z.

Case 1. $|\pi(z)| = 1$.

In this case, it holds that $\pi(z) = \{z\}$. Then, $\pi(a_1) \in \{\{a_1, a_2\}, \{a_1, a_5\}\}$. Indeed, if $\pi(a_1) \neq \{a_1, a_2\}$, then a_1 has an NS deviation to join z, and is allowed to perform it unless $\pi(a_1) = \{a_1, a_5\}$. We may therefore assume that $\{a_i, a_{i+1}\} \in \pi$ for some $i \in \{1, 5\}$.

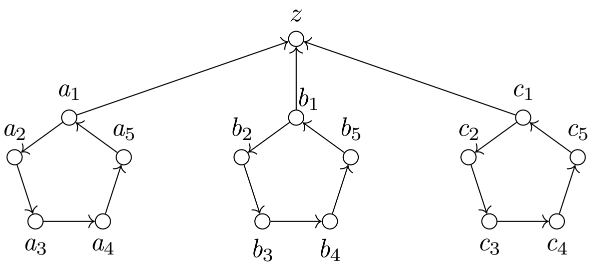

Figure 3 AFG without an MOS partition. The depicted (directed) edges represent friends, i.e., a utility of n, whereas missing edges represent a utility of -1.

Then, $\pi(a_{i-1}) = \{a_{i-1}, a_{i-2}\} =: C$. Otherwise, a_{i-1} can perform an MOS deviation to join $\{a_i, a_{i+1}\}$. But then a_{i+2} can perform an MOS deviation to join C. This is a contradiction and concludes the case that $|\pi(z)| = 1$.

Case 2. $|\pi(z)| > 1$.

Let $F := \{a_1, b_1, c_1\}$, i.e., the set of agents that have z as a friend. Note that z can perform an NS deviation to be a singleton. Hence, as π is MOS, $|F \cap \pi(v)| \geq |\pi(z)|/2$. In particular, there exists an $x \in \{a, b, c\}$ with $\pi(z) \cap N_x = \{x_1\}$. We may assume without loss of generality that $\pi(z) \cap N_a = \{a_1\}$. Then, $\pi(a_5) = \{a_4, a_5\}$. Otherwise, a_5 has an MOS deviation to join $\pi(z)$. Similarly, $\pi(a_3) = \{a_2, a_3\}$ (because of the potential deviation of a_3 who would like to join $\{a_4, a_5\}$). Now, note that $v_{a_1}(\{a_1, a_2, a_3\}) = n - 1$. We can conclude that $|\pi(z)| \leq 3$ as a_1 would join $\{a_2, a_3\}$ by an MOS deviation, otherwise. Hence, we find $x \in \{b, c\}$ with $N_x \cap \pi(z) = \emptyset$. Assume without loss of generality that $x = b$ has this property.

Assume first that $\pi(b_1) = \{b_1, b_5\}$. Then, $\pi(b_4) = \{b_3, b_4\}$. Otherwise, b_4 has an MOS deviation to join $\{b_1, b_5\}$. But then b_2 has an MOS deviation to join $\{b_3, b_4\}$, a contradiction. Hence, $\pi(b_1) \neq \{b_1, b_5\}$. Note that we have now excluded the only case where b_1 is not allowed to perform an NS deviation. In all other cases, no majority of agents prefers her to stay in the coalition. We can conclude that $b_2 \in \pi(b_1)$ because otherwise, b_1 can perform an MOS deviation to join $\pi(z)$. If $b_5 \notin \pi(b_1)$, then $\pi(b_5) = \{b_4, b_5\}$ (to prevent a potential deviation by b_5). But then b_3 has an MOS deviation to join them. Hence, $b_5 \in \pi(b_1)$. Similarly, if $b_4 \notin \pi(b_1)$, then $\pi(b_4) = \{b_3, b_4\}$ and b_2 has an MOS deviation to join $\{b_3, b_4\}$ (which is permissible because $b_5 \in \pi(b_1)$). Hence $\{b_1, b_2, b_4, b_5\} \subseteq \pi(b_1)$, and therefore even $N_b \subseteq \pi(b_1)$. Hence, b_1 has an MOS deviation to join $\pi(v)$ (recall that $|\pi(v)| \leq 3$). This is the final contradiction, and we can conclude that π is not MOS. ◀

Note that most agents in the previous example have at most 1 friend (only three agents have 2 friends). By contrast, if every agent has at most one friend, MOS partitions are guaranteed to exist. This is interesting because it covers in particular directed cycles, which cause problems for Nash stability. The constructive proof of the following proposition can be directly converted into a polynomial-time algorithm.

▶ **Proposition 3.** *Every AFG where every agent has at most one friend admits an MOS partition.*

Proof. We prove the statement by induction over n. Clearly, the grand coalition is MOS for $n = 1$. Now, assume that (N, v) is an AFG with $n \geq 2$ such that every agent has at most one friend. Consider the underlying directed graph $G = (N, A)$ where $(x, y) \in A$ if and only if $v_x(y) > 0$, i.e., y is a friend of x. By assumption, G has a maximum out-degree of 1, hence it can be decomposed into directed cycles and a directed acyclic graph.

Assume first that there exists $C \subseteq N$ such that C induces a directed cycle in G. We call an agent y *reachable* by agent x if there exists a directed path in G from x to y. Let $c \in C$ and define $R = \{x \in N \colon c \text{ reachable by } x\}$. Note that $C \subseteq R$ and that R is identical to the set of agents that can reach *any* agent in C. By induction, there exists an MOS partition π' of the subgame of (N, v) induced by $N \setminus R$ that is MOS. Define $\pi = \pi' \cup \{R\}$. We claim that π is MOS. Let $x \in N \setminus R$. By our assumptions on π', there exists no MOS deviation of x to join $\pi(y)$ for $y \in N \setminus R$. In particular, if x is allowed to perform a deviation, then x must have a non-negative utility (otherwise, she can form a singleton coalition contradicting that π' is MOS). So her only potential deviations are to a coalition where she has a friend. Note that x has no friend in R. Indeed, if y was a friend of x in R, then c is reachable for x in G through the concatenation of (x, y) and the path from y to c. Hence, x has no MOS deviation. Now, let $x \in R$. Then, $v_x(\pi) > 0$ because she forms a coalition with her unique friend. By assumption, x has no friend in any other coalition. Therefore, x has no MOS deviation either.

We may therefore assume that G is a directed acyclic graph. Hence, there exists an agent $x \in N$ with in-degree 0. If x has no friend, let $T = \{x\}$. If x has a friend y, we claim that there exists an agent w such that (i) w is the friend of at least one agent and (ii) every agent that has w as a friend has in-degree 0, i.e., such agents are not the friend of any agent. We provide a simple linear-time algorithm that finds such an agent. We will maintain a tentative agent w that will continuously fulfill (i) and update w until this agent also fulfills (ii). Start with $w = y$. Note that this agent w fulfills (i) because y is a friend of x. If w is the friend of some agent z that is herself the friend of some other agent, update $w = z$. For the finiteness (and efficient computability) of this procedure, consider a topological order σ of the agents N in the directed acyclic graph G [24], i.e., a function $\sigma \colon N \to [n]$ such that $\sigma(a) < \sigma(b)$ whenever $(a, b) \in A$. Note that if w is replaced by the agent z in the procedure, then $\sigma(z) < \sigma(w)$. Hence, w is replaced at most n times, and our procedure finds the desired agent w after a linear number of steps. Now, define $T = \{a \in N \colon w \text{ reachable by } a\}$, i.e., T contains precisely w and all agents that have w as a friend.

We are ready to find the MOS partition. By induction, we find a partition π' that is MOS for the subgame induced by $N \setminus T$. Consider $\pi = \pi' \cup \{T\}$. Then, $a \in T \setminus \{w\}$ has no incentive to deviate, because she has no friend in any other coalition and has w as a friend. Also, w is not allowed to perform a deviation, because the non-empty set of agents $T \setminus \{w\}$ unanimously prevents that. Possible deviations by agents in $N \setminus T$ can be excluded as in the first part of the proof because these agents have no friend in T. Together, we have completed the induction step and found an MOS partition. ◀

On the other hand, it is NP-complete to decide whether an AFG contains an MOS partition. For a proof, we use the game constructed in Proposition 2 as a gadget in a greater game. The difficulty is to preserve bad properties about the existence of MOS partitions because the larger game might allow for new possibilities to create coalitions with the agents in the counterexample.

▶ **Theorem 4.** *Deciding whether an AFG contains an MOS partition is NP-complete.*

5 Friends-and-Enemies Games

Friends-and-enemies games always contain efficiently computable stable coalition structures with respect to the unanimity-based stability concepts IS and CNS [10]. In this section, we will see that the transition to majority-based consent crosses the boundary of tractability.

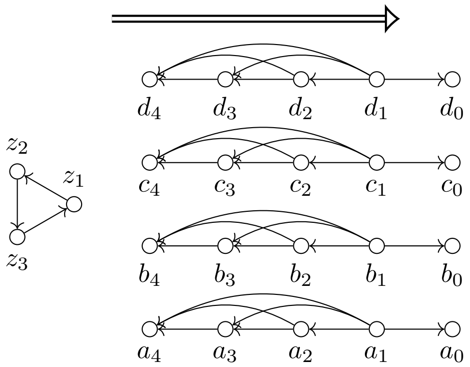

Figure 4 FEG without an MOS partition. The depicted (directed) edges represent friends. The double arrow means that every agent to the left of the tail of the arrow has every agent below the arrow as a friend.

The closeness to this boundary is also emphasized by the fact that it is surprisingly difficult to even construct No-instances for MOS and MIS, i.e., FEGs which do not contain an MOS or MIS partition, respectively. Indeed, the smallest such games that we can construct are games with 23 and 183 agents, respectively. We will start by considering MOS.

▶ **Proposition 5.** *There exists an FEG without an MOS partition.*

Proof sketch. We only give a brief overview of the instance by means of the illustration in Figure 4. The FEG consists of a triangle of agents together with 4 sets of agents whose friendship relation is complete and transitive, together with one additional agent each that gives a temptation for the agent of the transitive substructures with the most friends.

An important reason for the non-existence of MOS partitions is that there is a high incentive for the transitive structures to form coalitions. This gives incentive to agents z_i to join them. If z_1, z_2, and z_3 are in disjoint coalitions, then they would chase each other according to their cyclic structure. If they are all in the same coalition, then agents x_0 for $x \in \{a, b, c, d\}$ prevent the complete transitive structures to be part of this coalition and other transitive structures are more attractive. ◀

In the previous proof, it is particularly useful to establish disjoint coalitions of groups of agents who dislike each other. On the other hand, if we make the further assumption that one agent from every pair of agents likes the other agent, then this does not work anymore and the grand coalition is MOS. This condition essentially means completeness of the friendship relation.[3] Note that this proposition is not true for other stability concepts such as NS or even IS.

▶ **Proposition 6.** *The grand coalition is MOS in every FEG with complete friendship relation.*

Proof. Let (N, v) be an FEG with complete friendship relation, and let π be the grand coalition. We claim that π is MOS. Suppose that there is an agent $x \in N$ who can perform an NS deviation to form a singleton.

[3] Technically, the friendship relation may not be reflexive, but we can set $v_i(i) = 1$ for all $i \in N$ in an FEG to formally achieve completeness.

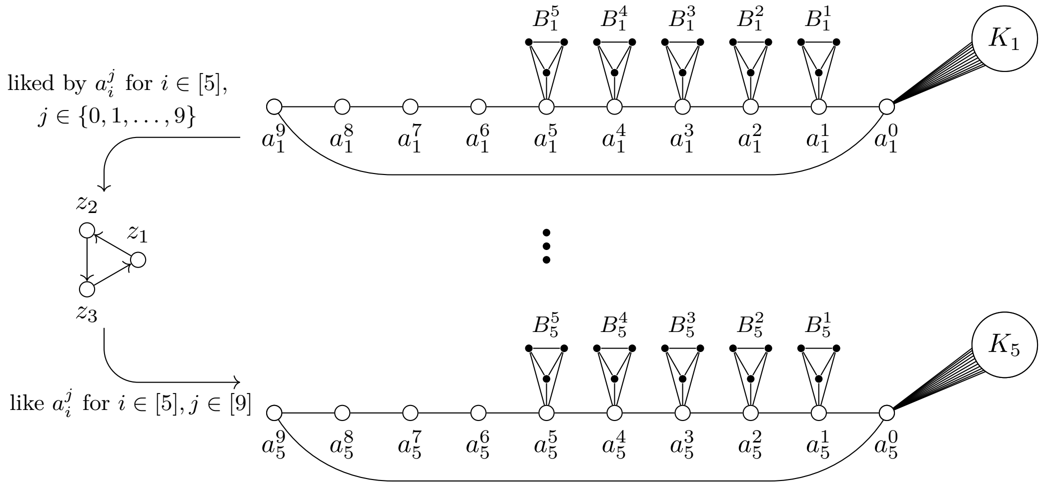

Figure 5 FEG without an MIS partition. The depicted edges represent friends. Undirected edges represent mutual friendship. For $i \in [5]$, some of the edges of agents in A_i are omitted. In fact, these agents form cliques. Also, each K_i represents a clique of 11 agents.

Then, $v_x(N) < 0$ and therefore $|\{y \in N \setminus \{x\} : v_x(y) = -1\}| > \{y \in N \setminus \{x\} : v_x(y) = 1\}|$. Hence,

$$\begin{aligned} |F_{\text{in}}(N, x)| &\geq |\{y \in N \setminus \{x\} : v_x(y) = -1\}| \\ &> |\{y \in N \setminus \{x\} : v_x(y) = 1\}| \\ &\geq |F_{\text{out}}(N, x)|. \end{aligned}$$

In the first inequality, we use that x is a friend of all of her enemies. In the final inequality, we use that x can only be an enemy of her friends. Hence, x is not allowed to perform an MOS deviation. ◀

Still, the non-existence of MOS partitions in FEGs shown in Proposition 5 can be leveraged to prove an intractability result. Interestingly, in contrast to the proofs of Theorem 1 and Theorem 4, the next theorem merely uses the existence of an FEG without an MOS partition to design a gadget and does not exploit the specific structure of a known counterexample.

▶ **Theorem 7.** *Deciding whether an FEG contains an MOS partition is NP-complete.*

In our next result, we construct an FEG without an MIS partition. Despite a lot of structure, the game is quite large encompassing 183 agents.

▶ **Proposition 8.** *There exists an FEG without an MIS partition.*

Proof sketch. We illustrate the example with the aid of Figure 5 and briefly discuss some key features. Again, the central element is a directed cycle of three agents. These agents are connected to five copies of the same gadget. This gadget consists of a main clique $\{a_i^0, \ldots, a_i^9\}$ of 10 mutual friends and further cliques that cause certain temptations for agents in the main clique. Cliques are linked by agents that have an incentive to be part of two cliques, which are part of disjoint coalitions. Since it is possible to balance all diametric temptations, the instance does not admit an MIS partition. ◀

Similar to Proposition 6, it is easy to see that the singleton partition is MIS in every FEG with complete enemy relation. Indeed, then an agent either has no incentive to join another agent, or the other agent will deny her consent. Hence, MIS can also prevent typical run-and-chase games which do not admit NS partitions. We are ready to prove hardness of deciding on the existence of MIS partitions in FEGs.

▶ **Theorem 9.** *Deciding whether an FEG contains an MIS partition is NP-complete.*

6 Discussion and Conclusion

We have investigated single-agent stability in additively separable hedonic games. Our main results determine strong boundaries to the efficient computability of stable partitions. Table 1 provides a complete picture of the computational complexity of all considered stability notions and subclasses of ASHGs, where our results close all remaining open problems. First, we resolve the computational complexity of computing CNS partitions, which considers the last open unanimity-based stability notion in unrestricted ASHGs. The derived hardness result stands in contrast to positive results when considering appropriate subclasses such as FEGs, AEGs, or AFGs [10]. Second, our intractability concerning AFGs stands in contrast to known positive results for all other consent-based stability notions, and can also be circumvented by considering AFGs with a sparse friendship relation. Finally, we provide sophisticated hardness proofs for majority-based stability concepts in FEGs. These turn into computational feasibilities when transitioning to unanimity-based stability, or under further assumptions to the structure of the friendship graph.

A key step of all hardness results in restricted classes of ASHGs was to construct the first No-instances, that is, games that do not admit stable partitions for the respective stability notion. This is no trivial task as can be seen from the complexity of the constructed games. Once No-instances are found, we can leverage them as gadgets of hardness reductions, which is a typical approach for complexity results about hedonic games. We have provided both reductions where the explicit structure of the determined No-instances is used as well as reductions where the mere existence of No-instances is sufficient and used as a black box.

Our results complete the picture of the computational complexity for all considered stability notions and game classes. Still, majority-based stability notions deserve further attention because they offer a natural degree of consent to perform deviations. Their thorough investigation in other classes of hedonic games might lead to intriguing discoveries.

Table 1 Overview of the computational complexity of single-agent stability concepts in different classes of ASHGs. The NP-completeness results concern deciding on the existence of a stable partition. Membership in Function-P means that the search problem of constructing a stable partition can be solved in polynomial time.

ASHG	Unrestricted	Friends-and-enemies games	Appreciation-of-friends games
NS	NP-complete [29]	NP-complete [10]	NP-complete [10]
IS	NP-complete [29]	Function-P [10]	Function-P [16]
CNS	NP-complete (Th. 1)	Function-P [10]	Function-P [10]
MIS	NP-complete [10]	NP-complete (Th. 9)	Function-P [10]
MOS	NP-complete [10]	NP-complete (Th. 7)	NP-complete (Th. 4)

Bounded Degree Nonnegative Counting CSP

Abstract

Constraint satisfaction problems (CSP) encompass an enormous variety of computational problems. In particular, all partition functions from statistical physics, such as spin systems, are special cases of counting CSP (#CSP). We prove a complete complexity classification for every counting problem in #CSP with nonnegative valued constraint functions that is valid when every variable occurs a bounded number of times in all constraints. We show that, depending on the set of constraint functions $\mathcal{F}$, every problem in the complexity class #CSP($\mathcal{F}$) defined by $\mathcal{F}$ is *either* polynomial time computable for all instances without the bounded occurrence restriction, *or* is #P-hard even when restricted to bounded degree input instances. The constant bound in the degree depends on $\mathcal{F}$. The dichotomy criterion on $\mathcal{F}$ is decidable. As a second contribution, we prove a slightly modified but more streamlined decision procedure (from [15]) for tractability. This enables us to fully classify a family of *directed* weighted graph homomorphism problems. This family contains both P-time tractable problems and #P-hard problems. To our best knowledge, this is the first family of such problems explicitly classified that are not *acyclic*, thereby the Lovász-goodness criterion of Dyer-Goldberg-Paterson [24] cannot be applied.

1 Introduction

Constraint Satisfaction Problems (CSPs) have been a subject of immense interest due to their wide applicability and intrinsic elegance. In particular, counting CSPs, or #CSPs, have been an active subject in computational counting complexity [18, 19, 10, 9, 22, 7, 15, 13], including their approximate solutions [28, 30, 20, 42, 41]. Roughly speaking, an (unweighted) constraint satisfaction problem deals with the following scenario, where there is a set of variables, each taking values over some finite domain D, and a set of constraints, each applied on an (ordered) subsequence of these variables. The #CSP problem on an instance asks how many assignments there are of these variables that satisfy all of the given constraints.

Applications of CSP problems are wide-ranging and varied. They range from within computer science to physical sciences such as physics, chemistry, engineering, even music [52, 1, 38, 47]. Within computer science, belief propagation has been a popular research topic in AI, which are ultimately based on some forms of partition function evaluations [5, 39, 40, 46, 29, 48, 51]. The term partition function, which we define formally later, arises from statistical physics, where one can see special cases of (weighted) counting CSPs in the

form of spin systems such as the Ising and Potts models, e.g. [25]. As is the case in physical sciences as well as in applications within computer science, the instances of counting CSP problems that occur in practice are often with the additional restriction that variables occur a bounded number of times.

To define (unweighted) #CSP problems formally, let D be a finite domain set, Γ be a set of constraint relations Θ_i, where each Θ_i is a relation on D of arity $r_i = r(\Theta_i) \geq 1$. An instance of #CSP(Γ) is then defined by a set X of n variables over D, and a list of constraints Θ from Γ, and for each constraint Θ in the list a sequence of $r(\Theta)$ variables from X that the constraint is applied to. This defines an n-ary relation R in D^n on the input variables where an assignment $(x_1, \ldots, x_n) \in D^n$ is in R iff all constraints are satisfied. For any fixed Γ, the counting CSP problem #CSP(Γ) consists of all input instances using constraint relations from Γ. The computational problem is to compute the size of R given an arbitrary input instance, where the (worst case) computational complexity is measured in terms of size n of the set of variables and the size of the list of constraints. For a finite (fixed) Γ, this can be simplified to just n, up to a polynomial factor. A complexity dichotomy theorem can classify, depending on Γ, the problem #CSP(Γ) as either computable in polynomial time (P-time), or #P-complete, with no intermediate cases. Typically, the set Γ is a fixed finite set, which defines the #CSP problem – this Γ is the name of the problem. However, in most dichotomy theorems one can allow infinite sets, where in the P-time computable case we assume the specification of the constraints in the instances counts toward the input size, and in the #P-complete case there is a finite subset $\Gamma_0 \subseteq \Gamma$ such that #CSP(Γ_0) is #P-hard.

For example, if we let $D = \{0, 1\}$ and $\Gamma = \{\mathrm{OR}_k | k \geq 1\} \cup \{\neq_2\}$, where OR_k is the k-ary OR function, and $\neq_2$ the binary disequality function, then the problem #CSP(Γ) is equivalent to #SAT, the counting Boolean satisfiability problem.

This formulation can be generalized to the weighted setting. In the most general case, the constraint functions can take real or complex values. In this paper we only consider #CSP defined by nonnegatively weighted constraint functions. This means that we replace the constraint language Γ by a set of constraint functions $\mathcal{F}$, where each $f_i \in \mathcal{F}$ has some arity $r_i \geq 1$ and maps D^{r_i} to nonnegative algebraic reals, denoted as $\mathbb{R}_+$.[1] Any given instance I defines a function $F_I : D^n \to \mathbb{R}_+$, such that on each assignment of variables, F_I takes the value the product over the constraint functions in I evaluated on the assignment. The solution to this instance I of #CSP($\mathcal{F}$) is then

$$Z_{\mathcal{F}}(I) = \sum_{(x_1, \ldots, x_n) \in D^n} F_I(x_1, \ldots, x_n). \tag{1}$$

This sum-of-products expression in (1) is called the partition function for an instance of #CSP, with the terminology coming from statistical physics [3]. When all functions in $\mathcal{F}$ are 0-1 valued, then the product is also 0-1 valued and is equivalent to the logical AND, and the partition function counts the number of satisfying assignments. Thus this $Z_{\mathcal{F}}(I)$ generalizes the unweighted case when $\mathcal{F}$ is a set of constraint relations Γ.

As a special case of #CSP, a q-state spin system is a problem on a domain $[q]$ with the constraint language having only a single binary constraint defined by the $q \times q$ interaction matrix A. An instance to this problem is a graph $G = (V, E)$, where the vertices (sites) are considered to be variables (spins) and the edges (bonds) correspond to the interactions between these vertices. The famous Ising model with parameter λ has domain size $q = 2$,

[1] Restricting to algebraic numbers is standard in this research area because we wish to state our results in the Turing machine model for strict bit complexity. See [14].

and is defined by its interaction matrix $A^{\lambda}_{\text{Ising}} = \begin{bmatrix} \lambda & 1 \\ 1 & \lambda \end{bmatrix}$ (see Figure 1b). The Potts model (Figure 1d) and Widom-Rowlinson model (Figure 1c) on 3 states are defined by the following interaction matrices respectively,

$$A^{\lambda}_{\text{3Potts}} = \begin{bmatrix} \lambda & 1 & 1 \\ 1 & \lambda & 1 \\ 1 & 1 & \lambda \end{bmatrix} \quad \text{and} \quad A_{\text{WR}} = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix}.$$

Familiar problems in computer science can also be expressed in this model; e.g., independent set (IS) is defined by $A_{\text{IS}} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$ (Figure 1a).

Bulatov [9] proved a sweeping complexity dichotomy for unweighted #CSPs in, which used deep results from universal algebra. His dichotomy theorem states that #CSP(Γ) is solvable in polynomial time if Γ satisfies a condition called congruence singularity; it is #P-complete otherwise. Dyer and Richerby [22] gave another proof of this dichotomy using a new P-time tractability criterion, which they proved to be equivalent to congruence singularity.

A nonnegative matrix is block-rank-1 if it becomes a block-diagonal matrix after a permutation of its rows and a permutation of its columns separately, such that all blocks are rank 1 except for possibly one all-zero block. (Here the blocks in the block-diagonal form of the matrix need not be square matrices.) For example, the following matrix (where blank entries are 0's)

$$\begin{bmatrix}
A_{0,0} & & A_{0,2} & & & & & \\
A_{1,0} & & A_{1,2} & & & & & \\
& & & & A_{2,4} & & A_{2,6} & \\
& & & & A_{3,4} & & A_{3,6} & \\
& A_{4,1} & & A_{4,3} & & & & \\
& A_{5,1} & & A_{5,3} & & & & \\
& & & & & A_{6,5} & & A_{6,7} \\
& & & & & A_{7,5} & & A_{7,7}
\end{bmatrix} \tag{2}$$

is block-rank-1 if each nonzero rectangle of the form $\begin{bmatrix} A_{i,j} & A_{i,j'} \\ A_{i',j} & A_{i',j'} \end{bmatrix}$ has rank 1.

For unweighted #CSP, the Dyer-Richerby condition in [22] for polynomial time tractability in the dichotomy theorem is *Strong Balance*. Let $d = |D|$ be the domain size. We say a constraint language Γ is *Strongly Balanced* if every n-ary relation R defined by an instance of #CSP(Γ) satisfies the following condition:

For any $a, b \geq 1$ and $c \geq 0$ with $a + b + c \leq n$, the following $d^a \times d^b$ matrix M is block-rank-1:

$$M(\boldsymbol{u}, \boldsymbol{v}) = \left|\{\boldsymbol{w} \in D^c : \exists \boldsymbol{z} \in D^{n-c-b-a} \text{ s.t. } (\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}, \boldsymbol{z}) \in R\}\right| .$$

(If $a + b + c = n$, then the quantified statement "$\exists \boldsymbol{z} \in D^{n-c-b-a}$ such that $(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}, \boldsymbol{z}) \in R$" simply means that $(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}) \in R$.)

If we are dealing with $\mathcal{F}$ rather than Γ, and if $\mathcal{F}$ is not a set of 0-1 valued functions, then the existential quantified statement "$\exists \boldsymbol{z}$" has no meaning. It turns out that there are several equivalent notions of *Balance*, which when $\mathcal{F}$ is restricted to a set of 0-1 valued functions (i.e. when $\mathcal{F}$ can be identified with a constraint language Γ) are all equivalent to the notion of Strong Balance; see Lemma 9.4 in [15]. These notions of Balance do not use existential quantifiers (see Definition 2 in Section 2). These notions are central to the #CSP dichotomies for #CSP($\mathcal{F}$) for nonnegative valued $\mathcal{F}$.

The study of #CSPs is closely related to that of counting graph homomorphisms [35, 27, 4, 36]. For two graphs G and H, a graph homomorphism from G to H is a mapping $f : V(G) \to V(H)$ that preserves vertex adjacency. In other words, if $e = \{u, v\} \in E(G)$ then $e' = \{f(u), f(v)\} \in E(H)$, for all edges e in G. The question of interest in counting complexity is the number of graph homomorphisms from one graph to another, which can also be represented by a partition function. If we let A be the $m \times m$ adjacency 0-1 matrix of the graph H, then the number of homomorphisms from G to H can be represented as a sum-of-products partition function as follows,

$$Z_A(G) = \sum_{f:V(G)\to[m]} \prod_{\{u,v\}\in E(G)} A_{f(u),f(v)}.$$

Partition functions of graph homomorphism can represent important physical spin systems such as the Ising, Potts, or Widom-Rowlinson models, as well as many other well known problems in computer science.

Counting graph homomorphisms is a special case of #CSP. In fact, the vertex-edge incidence graph of G defines an input to a #CSP problem, where vertices $V(G)$ are variables and edges $E(G)$ are (applications of binary) constraints, and the constraint language consists of a single binary relation represented by the adjacency matrix A defining the graph homomorphism problem $G \mapsto Z_A(G)$. Just as in #CSPs, the counting graph homomorphism function $Z_A(G)$ can be generalized from the 0-1 unweighted case to the weighted case where A is a real or complex matrix. It is symmetric for an undirected graph H, in which case we also only consider undirected G; for directed graph homomorphisms, A need not be symmetric.

The first dichotomy on counting graph homomorphisms was due to Dyer and Greenhill [21] for undirected graphs. They showed that there is a simple criterion such that if A satisfies the criterion then $G \mapsto Z_A(G)$ is computable in P-time, otherwise it is #P-complete. In fact they proved that if A does not satisfy the criterion then the problem of evaluating $Z_A(G)$ remains #P-complete even when restricted to graphs G with bounded degree Δ, for some Δ depending on A. Computing $G \mapsto Z_A(G)$ when restricted to graphs G with bounded degree Δ is called $\text{EVAL}^{(\Delta)}(A)$. The Dyer-Greenhill dichotomy was extended to the nonnegatively weighted case by Bulatov and Grohe in [8]. This dichotomy was then referenced throughout the field, as many other discoveries, including the results on #CSPs, ended up applying it. However, the hardness part of the proof of the Bulatov-Grohe dichotomy theorem required input graphs that have unbounded degrees. When restricted to bounded degree graphs, the worst case complexity of the Bulatov-Grohe dichotomy was left open for 15 years, until it was finally resolved by Govorov, Cai, and Dyer in [26] for graph homomorphisms with nonnegative weights, and continued by Cai and Govorov in [16] for complex weights. Most problems in statistical physics [6, 11, 31] use bounded degree graphs, and also most of the approximation algorithms work on bounded degree graphs [2, 23, 32, 33, 37, 43, 44, 45, 49]. Over the Boolean domain where variables take 0-1 values, it is known that the #CSP dichotomy for complex valued constraint functions holds for input instances where each variable occurs at most three times [17].

It has been an open problem to extend the general domain #CSP dichotomies to include the bounded degree case, i.e. where each variable occurs a bounded number of times. It was open even for the 0-1 unweighted case. For the nonnegative cases, this would be the analogous Govorov-Cai-Dyer extension [26] of the Bulatov-Grohe dichotomy for graph homomorphism, but apply to a much broader class of problems, as graph homomorphism is the special case of $\#\mathrm{CSP}(\mathcal{F})$ where $\mathcal{F}$ consists of a single binary function.

In this paper we prove such a dichotomy for bounded degree nonnegative #CSPs. For any finite domain D, any finite set of nonnegative constraint functions $\mathcal{F}$ on D, and any integer $\Delta \geq 0$, we define $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ to be the #CSP problem, where the input consists of n variables $x_1, \ldots, x_n$ over D and a sequence of constraint functions $f_1, \ldots, f_m \in \mathcal{F}$ each applied to a subsequence of the n variables, where each variable x_i appears no more than Δ times among $f_1, \ldots, f_m$. Note that in general, a function $f \in \mathcal{F}$ may occur multiple times among $f_1, \ldots, f_m$. We take $n + m$ as the input size. We prove that the same dichotomy criterion in [15] applies to the bounded degree case: if the P-time tractability criterion is not satisfied, then $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ remains #P-hard for some $\Delta > 0$. The dichotomy criterion of [15] will be explained in more detail after we introduce some more definitions in Section 2. These notions are further explicated in Theorem 4, and a more technical statement of Theorem 1 is given in Theorem 6.

▶ **Theorem 1.** *For any finite domain D and any nonnegatively weighted constraint functions $\mathcal{F}$ on D, if $\mathcal{F}$ satisfies the tractability criterion in [15], then $\#\mathrm{CSP}(\mathcal{F})$ is P-time computable; otherwise, $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ is #P-hard [2] for some $\Delta > 0$.*

For any fixed finite set $\mathcal{F}$ of constraint functions, the arities of $f \in \mathcal{F}$ are bounded. Viewing any instance as a bipartite graph, with the variables $x_1, \ldots, x_n$ on one side and constraints $f_1, \ldots, f_m \in \mathcal{F}$ on the other, with an edge between x_i and f_j if x_i is an input to the function f_j, we can see that the condition for a #CSP instance to be bounded degree corresponds exactly to this bipartite graph having bounded degree.

Our second contribution in this paper is a slightly modified but more streamlined decision procedure (compared to that of [15]) for polynomial time tractability. This enables us to fully classify a family of *directed* weighted graph homomorphism problems. This family contains both P-time tractable problems and #P-hard problems. To our best knowledge, this is the first family of such problems explicitly classified that are not *acyclic*, thereby the Lovász-goodness criterion of Dyer-Goldberg-Paterson [24] cannot be applied.

2 Balance

Several variants of the *Balance* condition have been used in the study of counting constraint satisfaction problems. In addition to the *Strong Balance* condition [22], the following conditions have been introduced in [15]. Recall that $d = |D|$ denotes the domain size.

[2] The problem $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ is also no harder than #P under a polynomial-time Turing reduction for any $\mathcal{F}$. The statement for Theorem 1 does not state #P-complete only for the technical reason that by definition functions in #P take nonnegative integer values while the partition function in (1) need not.

▶ **Definition 2** (Various notions of Balance). *We have the following notions:*

1. *(Balance) We say $\mathcal{F}$ is* Balanced *if for any $n \geq 2$, any $a \geq 1$ and $b \geq 1$ with $a + b \leq n$, and any instance I of #CSP($\mathcal{F}$) which defines an n-ary function $F_I(x_1, \dots, x_n)$ over D^n, the following $d^a \times d^b$ matrix M_I is block-rank-1: The rows and columns of M_I are indexed by tuples $\boldsymbol{u} \in D^a$ and $\boldsymbol{v} \in D^b$ respectively, and*

$$M_I(\boldsymbol{u}, \boldsymbol{v}) = \sum_{\boldsymbol{w} \in D^{n-a-b}} F_I(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}),$$

for all $\boldsymbol{u} \in D^a, \boldsymbol{v} \in D^b$. If $a + b = n$ then the sum $\sum_{\boldsymbol{w} \in D^{n-a-b}} F_I(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w})$ is simply $F_I(\boldsymbol{u}, \boldsymbol{v})$.

2. *(Weak Balance) We say $\mathcal{F}$ is* Weakly Balanced *if the definition for Balance holds for $b = 1$.*
3. *(Primitive Balance) We say $\mathcal{F}$ is* Primitively Balanced *if the definition for Balance holds for $a = b = 1$.*

While these three notions may seem to have varying strengths, all three are in fact equivalent by combining the proof in [15] and [34]. See Theorem 4 below. We need the following definition.

▶ **Definition 3** (Strong Rectangularity). *We say a matrix M is* Rectangular *if after a row permutation and a column permutation it is a block diagonal matrix where all diagonal blocks have no zero entries, except possibly one all zero block. We say a constraint language Γ over D is* Strongly Rectangular *if for any input instance I of #CSP(Γ) which defines an n-ary relation R_I over D^n and for any a and b such that $1 \leq a < b \leq n$, the following $|D|^a \times |D|^{b-a}$ matrix M is rectangular: The rows of M are indexed by $\boldsymbol{u} \in D^a$, the columns of M are indexed by $\boldsymbol{v} \in D^{b-a}$, and*

$$M(\boldsymbol{u}, \boldsymbol{v}) = \left|\{\boldsymbol{w} \in D^{n-b} : (\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{w}) \in R_I\}\right|.$$

▶ **Theorem 4.** *The notions of Balance, Weak Balance, and Primitive Balance are equivalent, and can be taken as the P-time tractability criterion of the dichotomy in [15].*

Proof. For any $\mathcal{F}$ of nonnegative valued constraint functions, Cai, Chen and Lu proved in [15] that (1) if $\mathcal{F}$ is Balanced then it is Weakly Balanced and that the support constraint language of $\mathcal{F}$ satisfies Strong Rectangularity, and (2) the latter two conditions imply that #CSP($\mathcal{F}$) is P-time computable. Here the support constraint language of $\mathcal{F}$ is obtained by taking the support set of each function in $\mathcal{F}$. On the other hand they also proved that if $\mathcal{F}$ is not Balanced then #CSP($\mathcal{F}$) is #P-hard. Thus their dichotomy criterion is that $\mathcal{F}$ is Balanced. They also proved in [15] that Primitive Balance implies Weak Balance. Lin and Wang proved in [34] that Weak Balance implies Balance, thus unifying all three notions. ◀

3 Bounded Degree #CSPs

▶ **Lemma 5.** *Let M be a nonnegative matrix. If M is not block-rank-1 then neither is MM^T.*

Proof. If every two rows of M are either proportional or their nonzero entries are on disjoint subsets of columns, then M would be block-rank-1. Thus there are rows M_i and M_j, such that they are linearly independent, and the subsets of columns where their nonzero entries occur intersect. Being nonnegative, the latter condition implies that they are not orthogonal. So by the Cauchy-Schwarz inequality we have

$$0 < (M_i \cdot M_j)^2 < (M_i \cdot M_i)(M_j \cdot M_j).$$

Letting $A = MM^T$ we find four nonzero elements $A_{i,i}, A_{i,j} = A_{j,i}$, and $A_{j,j}$ satisfying $A_{i,i}A_{j,j} > A_{i,j}^2 > 0$, so A is not block-rank-1. ◀

We can now prove our main result, i.e., if a nonnegative constraint set $\mathcal{F}$ does not satisfy the Balance condition, then $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ is #P-hard for some $\Delta > 0$.

▶ **Theorem 6.** *If $\mathcal{F}$ is Primitively Balanced, then the problem $\#\mathrm{CSP}(\mathcal{F})$ without degree restriction is computable in polynomial time, otherwise $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$ is #P-hard for some $\Delta > 0$.*

Proof. We only need to prove the hardness part. Let $\mathcal{F}$ be a finite set of nonnegatively weighted constraint functions that is not Primitively Balanced. Then for some instance I on n variables, the $|D| \times |D|$ matrix M defined by

$$M(x_1, x_2) = \sum_{(x_3,\ldots,x_n)\in D^{n-2}} F_I(x_1, x_2, x_3, \ldots, x_n)$$

is not block-rank 1. If we let $A = MM^T$, then A is symmetric, nonnegative, and not block-rank 1 by Lemma 5. This A defines a graph homomorphism problem. We know from [26] that the bounded degree nonnegative graph homomorphism problem $\mathrm{EVAL}^{(\Delta)}(A)$ is #P-hard for some $\Delta > 0$, where the constant Δ depends on A. Here we show a reduction $\mathrm{EVAL}^{(\Delta)}(A) \le_P \#\mathrm{CSP}^{(\Delta')}(\mathcal{F})$, for some $\Delta' > 0$, thereby showing that $\#\mathrm{CSP}^{(\Delta')}(\mathcal{F})$ is #P-hard for some $\Delta' > 0$.

To show that, consider graphs G with maximum degree at most Δ as input instances of $\mathrm{EVAL}^{(\Delta)}(A)$. We can compute the value $Z_A(G)$ by expressing it as the partition function $Z_{\mathcal{F}}(I(G))$ for some instance $I(G)$ of polynomial size in $\#\mathrm{CSP}^{(\Delta')}(\mathcal{F})$. We will use the instance I that defines the matrix M as having constant size, as it does not depend on G. We construct $I(G)$, an input to $\#\mathrm{CSP}(\mathcal{F})$, with the additional property that every variable occurs at most Δ' times, such that $Z_{\mathcal{F}}(I(G)) = Z_A(G)$, as follows.

We note that each entry in A is a dot product of two row vectors in M, and every entry of M is a sum over $|D|^{n-2}$ evaluations of F_I.

We will define a (binary) gadget, which is an instance of $\#\mathrm{CSP}(\mathcal{F})$ of bounded size, with two specially labelled variables called x^* and x^{**}. Copies of this gadget will be used in the construction of (global) $\#\mathrm{CSP}(\mathcal{F})$ instances. A (binary) gadget may have other variables, but in the global $\#\mathrm{CSP}(\mathcal{F})$ instances all constraints applied to the variables other than x^* and x^{**} in each copy are from within the gadget. We define $I(G)$ by replacing every edge in G by a copy of this gadget. Formally, the construction is as follows, where the gadget simulates the edge weights in A in the #CSP setting.

1. Define a variable x_v over D for every $v \in V(G)$.
2. For each $e = uv \in E(G)$ we add $2n-3$ variables y_e, $\boldsymbol{z}_e = (z_{e,3}, \ldots, z_{e,n})$, and $\boldsymbol{z}'_e = (z'_{e,3}, \ldots, z'_{e,n})$ over the same domain D. We then apply two copies of I as constraints, one copy over the variables $(x_u, y_e, \boldsymbol{z}_e)$ and another over $(x_v, y_e, \boldsymbol{z}'_e)$. There are no other constraints applied on the variables y_e, $\boldsymbol{z}_e$ and $\boldsymbol{z}'_e$.

Thus one copy of the binary gadget is used to replace each edge $uv \in E(G)$, with the two specially labelled variables x^* and x^{**} identified with x_u and x_v. This gadget defines the following constraint function with input variables x_u and x_v taking values in D,

$$\begin{aligned}
&\sum_{y_e\in D}\left(\sum_{\boldsymbol{z}_e\in D^{n-2}} F_I(x_u, y_e, \boldsymbol{z}_e) \sum_{\boldsymbol{z}'_e\in D^{n-2}} F_I(x_v, y_e, \boldsymbol{z}'_e)\right)\\
&= \sum_{y_e\in D} M_I(x_u, y_e) M_I(x_v, y_e)\\
&= (MM^T)(x_u, x_v)\\
&= A(x_u, x_v).
\end{aligned}$$

Therefore the gadget defines the edge constraint function represented by the matrix A, which is exactly the edge weights in $Z_A(G)$.

Since G has bounded degrees, and I also has constant size, $I(G)$ also has bounded degrees. The variables y_e are "local" to each edge $e \in E(G)$ in the sense that there are no other constraints on them except in the definition of the gadget for this edge e, which has constant size. The same is true for $\boldsymbol{z}_e$ and $\boldsymbol{z}'_e$.

Also, the size of $I(G)$ is linear in the size of G, so this is a polynomial time reduction. That $Z_{\mathcal{F}}(I(G)) = Z_A(G)$ follows from the fact that A is the edge constraint function by our construction. ◀

The constant Δ in Theorem 1 depends on $\mathcal{F}$. In [21], Dyer and Greenhill conjectured that a universal constant $\Delta = 3$ suffices for $\mathrm{EVAL}^{(\Delta)}(A)$ where A is a 0-1 symmetric matrix. This is still open. It is open whether a universal constant Δ, or a constant that only depends on the domain size $|D|$, may suffice for even the 0-1 case, for both $\mathrm{EVAL}^{(\Delta)}(A)$ and $\#\mathrm{CSP}^{(\Delta)}(\mathcal{F})$. In [17] it is known that the constant 3 suffices for the Boolean domain. Xia [50] proved that a universal Δ *does not* exist for $\mathrm{EVAL}^{(\Delta)}(A)$ for complex symmetric matrices A, assuming #P does not collapse to P.

4 Effective Dichotomy and a Family of Directed GH

The condition of Balance (Definition 2) in the dichotomy refers to all instances I of $\#\mathrm{CSP}(\mathcal{F})$, which is an infinitary statement. Thus it is not immediate that the tractability condition in Theorem 6 is decidable. However the condition is the same as the one in [15] for the unbounded degree case, and in that paper a decision procedure is given. Here we give a slight modification of the same decision procedure for the dichotomy in Theorem 6. This form is more symmetric and allows us to apply the procedure more effectively.

▶ **Theorem 7.** *The polynomial-time tractability condition of balance in Theorem 6 can be tested by the following two conditions. Measured in the size of D and $\mathcal{F}$, this shows that the decision problem for testing balance is in* NP*.*

(A) *There is a Mal'tsev polymorphism $\varphi : D^3 \to D$ for (the support of) every function in $\mathcal{F}$. This means that φ preserves all relations defined as the support of some function in $\mathcal{F}$ (this is called a polymorphism), and satisfies $\varphi(a,a,b) = \varphi(b,a,a) = b$ for all $a, b \in D$ (Mal'tsev property). The existence of such a mapping φ is equivalent to Strong Rectangularity.*

(B) *For all $\alpha \neq \beta, \kappa \neq \lambda \in D$ there is a bijection $\pi : D^6 \to D^6$ satisfying the following three properties:*

1. $\pi((\alpha,\alpha,\alpha,\beta,\beta,\beta)) = (\alpha,\alpha,\alpha,\beta,\beta,\beta)$.
2. $\pi((\kappa,\lambda,\kappa,\lambda,\kappa,\lambda)) = (\lambda,\kappa,\lambda,\kappa,\lambda,\kappa)$.
3. *Any function $f \in \mathcal{F}$ with arity r is invariant under π, that is, for any sequence $(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_r)$ of length r of 6-tuples where $\boldsymbol{y}_i = (y_{i,1}, \ldots, y_{i,6}) \in D^6$ for $1 \le i \le r$, the following holds:*

$$\prod_{j \in [6]} f(y_{1,j}, \ldots, y_{r,j}) = \prod_{j \in [6]} f(\pi(\boldsymbol{y}_1)_j, \ldots, \pi(\boldsymbol{y}_r)_j). \tag{3}$$

The only difference in the statement of this decision criterion compared to the one stated in [15] is a more symmetric expression for condition *B2* of (B). We omit the proof here as it closely follows the proof in [15][3] However, this more symmetric form makes the criterion

[3] Alternatively, one can apply a perm $\pi = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 1 & 3 & 2 & 4 & 6 & 5 \end{pmatrix}$ which is an automorphism of the relational structure $(\mathfrak{D}, \mathfrak{F})$, the 6th power of $\#\mathrm{CSP}(\mathcal{F})$, to derive this form of the decision criterion from

more easily applicable. We demonstrate this by proving new tractable and intractable cases of directed graph homomorphisms that were previously unknown. The tractability or intractability of these problems were decidable in principle by previous methods; however, the decision procedure of the previous method was in practice too complicated to be useful.

Dyer, Goldberg and Paterson in [24] proved a decidable complexity dichotomy for (unweighted) directed graph homomorphisms that is restricted to directed *acyclic* graphs. Their polynomial-time tractability criterion is an interesting condition of being *layered* and *Lovász-good* for directed acyclic graphs. They state in [24] that "An interesting feature of the dichotomy, which is absent from previously-known dichotomy results, is that there is a rich supply of tractable graphs H with complex structure". Going beyond directed *acyclic* graphs, as it is done with Theorem 6 and 7, is expected to yield even more polynomial-time tractable problems. However, up until now we don't have any interesting concrete examples. (Part of the reason is probably that testing for the tractability criterion, while decidable, is not a simple matter; see below.) The dichotomy theorem in this paper applies more generally without the *acyclicity* restriction. We now give a family of non-acyclic directed graph homomorphism problems that we can completely classify using our tractability criterion in Theorem 7. To our best knowledge, this is the first such explicit family that can be classified, going beyond the Lovász-goodness criterion [24].

To start, if we take all nonzero $A_{i,j} = 1$ in equation (2), we get a binary relation that defines a polynomial-time tractable problem. This represents an adjacency matrix of a directed graph H illustrated in Figure 2. In fact, we can give an infinite family of tractable #CSP based on a weighted binary constraint function given in equation (4). These problems were considered in [12], where it was shown that, while the complexity of the #CSP defined by these relations is provably decidable, the decision criterion was yet too complicated, therefore for what values of $A_{i,j}$ in equation (2) the problem it defines is tractable for #CSP was not resolved.

We will show that a nonnegative binary constraint function given in the form of equation (2) with positive entries $A_{i,j}$ defines a tractable #CSP iff the constraint function is a positive multiple of the function in equation (4)

$$A = \begin{bmatrix} 1 & & v & & & & & \\ u & & uv & & & & & \\ & & & & y & & yv & \\ & & & & yu & & yuv & \\ & x & & xv & & & & \\ & xu & & xuv & & & & \\ & & & & & z & & zv \\ & & & & & zu & & zuv \end{bmatrix} \tag{4}$$

for some positive reals u, v, x, y, z, with the condition that $z = xy$.

The #CSP problem it defines is on a domain of size 8 and has a constraint function set $\mathcal{F}$ consisting of a single binary (but not symmetric) constraint function given by the matrix in (4). The directed graph defined by the support of the function is not acyclic.

We first prove the relation in (4) for any positive u, v, x, y and $z = xy$ defines a tractable problem. After that we prove the reverse direction.

To apply Theorem 7, we treat $D = \{0, \ldots, 7\}$ as a vector space $(\mathrm{GF}[2])^3$ of size 8, represented by three bit strings $\{0,1\}^3$. Then we can take the Mal'tsev polymorphism $\varphi : D^3 \to D$ where $\varphi(x, y, z) = x - y + z$. (Here $-$ is the same as $+$ in $\mathrm{GF}[2^3]$.) It is Mal'tsev because $\varphi(a, a, b) = \varphi(b, a, a) = b$ for all $a, b \in D$. The directed edge relation given by the matrix (2) (by setting all 16 nonzero entries $A_{i,j} = 1$) is given symbolically as follows:

$$A_{i,j} = 1 \text{ where } i = i_1 i_2 i_3, j = j_1 j_2 j_3 \in D \iff j_1 = i_2 \text{ and } j_3 = i_1. \tag{5}$$

the form proved in [15]. For detailed definitions of $(\mathfrak{D}, \mathfrak{F})$ and automorphism of relational structures see page 2190 in [15].

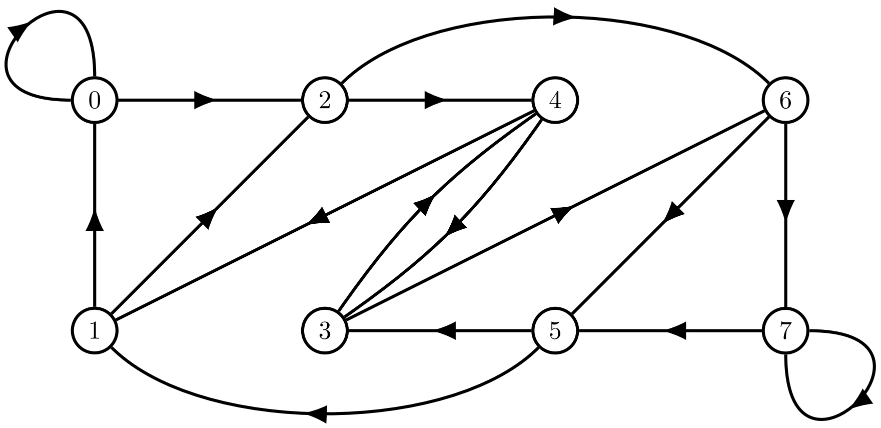

Figure 2 A tractable binary relation represented by a directed graph. The adjacency matrix is given in equation (4).

One can easily check that φ is a polymorphism, i.e. for any (x,x'), (y,y') and (z,z'), if $A_{x,x'} = A_{y,y'} = A_{z,z'} = 1$ then $A_{\varphi(x,y,z),\varphi(x',y',z')} = 1$.

For the second requirement (B), there are $|D|^6! = 262144! > 10^{1306590}$ bijections from D^6 to D^6, so it is infeasible to enumerate them. However the following map π works.

Let $M : \{0,1\}^6 \to \{0,1\}^6$ be the bijection that swaps (010101) and (101010) and acts as the identity on the rest. In particular, M preserves the Hamming weight. Let M_i be the ith output bit of M, and let $x_1, x_2, \ldots, x_6 \in D$ where each x_i consists of three bits $x_i = a_i b_i c_i \in \{0,1\}^3$.

We write $\boldsymbol{x} = (x_1, \ldots, x_6) = (a_1b_1c_1, \ldots, a_6b_6c_6) \in D^6$. We will also represent $\boldsymbol{x}$ bitwise using $\boldsymbol{a} = (a_1, \ldots, a_6) \in \{0,1\}^6$, $\boldsymbol{b} = (b_1, \ldots, b_6) \in \{0,1\}^6$, and $\boldsymbol{c} = (c_1, \ldots, c_6) \in \{0,1\}^6$, and write $\boldsymbol{x} = \boldsymbol{abc}$.

Then we define

$$\begin{aligned} \pi(\boldsymbol{x}) &= \pi(x_1, x_2, \ldots, x_6) = \pi(a_1b_1c_1, a_2b_2c_2, \ldots, a_6b_6c_6) \\ &= (M_1(\boldsymbol{a})M_1(\boldsymbol{b})M_1(\boldsymbol{c}),\ M_2(\boldsymbol{a})M_2(\boldsymbol{b})M_2(\boldsymbol{c}),\ \ldots,\ M_6(\boldsymbol{a})M_6(\boldsymbol{b})M_6(\boldsymbol{c})) \end{aligned}$$

▷ Claim 8. The mapping $\pi : D^6 \to D^6$ satisfies properties B1, B2, and B3 of (B) in Theorem 7 for all $\alpha \neq \beta, \kappa \neq \lambda \in D$. [4]

Proof Sketch. Property B1 holds by construction, because M fixes pointwise 0^6, 1^6, $0^3 1^3$, $1^3 0^3$. It satisfies property B2 because in addition it swaps (010101) and (101010).

For property B3, equation (3) is expressed as (more details are given below)

$$u^{\sum c_i} v^{\sum d_i} x^{\sum a_i} y^{\sum b_i} \left(\frac{z}{xy}\right)^{\sum a_i b_i} = u^{\sum M_i(\boldsymbol{c})} v^{\sum M_i(\boldsymbol{d})} x^{\sum M_i(\boldsymbol{a})} y^{\sum M_i(\boldsymbol{b})} \left(\frac{z}{xy}\right)^{\sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})} \tag{6}$$

[4] In Theorem 7 the mapping π may depend on $\alpha \neq \beta, \kappa \neq \lambda \in D$, but the π in Claim 8 is in fact the same for all $\alpha, \beta, \kappa, \lambda$.

where all sums (as well as those below) range from $i = 1$ to 6. Because M preserves Hamming weight, we get $\sum_{i=1}^{6} a_i = \sum_{i=1}^{6} M_i(\boldsymbol{a})$, and similarly for $\boldsymbol{b}, \boldsymbol{c}, \boldsymbol{d}$, and since $z = xy$, this equation holds. ◀

We now investigate *all* possible tractable cases of A in (2) with positive entries $A_{i,j}$. By the necessary condition of Balance applied to the binary function A itself, all relevant four 2×2 blocks must be of rank 1, in order to be tractable, i.e., it takes the form in (4) with some positive u, v, x, y and z, up to a global positive factor. We prove that, up to a global positive factor, a nonnegative matrix A in (2) with the given support structure defines a tractable partition function $Z_{\mathcal{F}}(\cdot)$ where $\mathcal{F} = \{A\}$ iff A has the form in (4) for some positive reals u, v, x, y and $z = xy$; otherwise $Z_{\mathcal{F}}(\cdot)$ is #P-hard.

This #CSP problem has $\mathcal{F}$ consisting of a single binary (nonsymmetric) constraint function defined by the matrix A. By its support structure and the Mal'tsev polymorphism we already satisfied condition (A) of Theorem 7. So, the problem is tractable if and only if for all $\alpha \neq \beta, \kappa \neq \lambda \in D$, there is a bijection $\pi : D^6 \to D^6$ that satisfies the following three properties:

1. $\pi((\alpha, \alpha, \alpha, \beta, \beta, \beta)) = (\alpha, \alpha, \alpha, \beta, \beta, \beta)$.
2. $\pi((\kappa, \lambda, \kappa, \lambda, \kappa, \lambda)) = (\lambda, \kappa, \lambda, \kappa, \lambda, \kappa)$.
3. For the binary function represented by the matrix A, and any 6-tuples $\boldsymbol{x}, \boldsymbol{y} \in D^6$, where $\boldsymbol{x} = (x_1, \ldots, x_6)$ and $\boldsymbol{y} = (y_1, \ldots, y_6)$, we have the following invariance under π,

$$\prod_{i \in [6]} A_{x_i, y_i} = \prod_{i \in [6]} A_{\pi(\boldsymbol{x})_i, \pi(\boldsymbol{y})_i}. \tag{7}$$

Suppose there is a bijection $\pi : D^6 \to D^6$ that satisfies these properties. Let $\pi(x_1, \ldots, x_6) = (\pi_1(x_1, \ldots, x_6), \ldots, \pi_6(x_1, \ldots, x_6))$, where $\pi_i : D^6 \to D$, and $\pi_i(x_1, \ldots, x_6)$ is the ith output entry in D of π. Denote the three bits of $\pi_i(x_1, \ldots, x_6)$ as $f_i(x_1, \ldots, x_6)$, $g_i(x_1, \ldots, x_6)$, and $h_i(x_1, \ldots, x_6)$. To satisfy property 3, we need each π_i to preserve the edge relation 5, i.e., preserve the support set. Since π is a bijection, if we verify that a nonzero LHS of (7) implies a nonzero RHS of (7), we will also have proved that it maps a zero LHS to a zero RHS; thus it preserves the support set. So, consider arbitrary

$$\boldsymbol{x} = (x_1, \ldots x_6) = (a_1 b_1 c_1, \ldots, a_6 b_6 c_6) \in D^6, \quad \boldsymbol{y} = (y_1, \ldots, y_6) = (b_1 d_1 a_1, \ldots, b_6 d_6 a_6) \in D^6.$$

This is a generic pair of tuples such that $A_{x_i, y_i} \neq 0$, for $1 \leq i \leq 6$. We need $A_{\pi_i(\boldsymbol{x}), \pi_i(\boldsymbol{y})} \neq 0$ for each i. As before we will also represent $\boldsymbol{x}$ bitwise using $\boldsymbol{a} = (a_1, \ldots, a_6) \in \{0,1\}^6$, $\boldsymbol{b} = (b_1, \ldots, b_6) \in \{0,1\}^6$, $\boldsymbol{c} = (c_1, \ldots, c_6) \in \{0,1\}^6$ and $\boldsymbol{d} = (d_1, \ldots, d_6) \in \{0,1\}^6$, and write $\boldsymbol{x} = \boldsymbol{abc}$ and $\boldsymbol{y} = \boldsymbol{bda}$.

Therefore, by the edge relation, we have $f_i(\boldsymbol{abc}) = h_i(\boldsymbol{bda})$. Hence f_i is independent of the third part of the input $\boldsymbol{c}$. Also, $g_i(\boldsymbol{abc}) = f_i(\boldsymbol{bda})$, so f_i is also independent of the second part of the input, and therefore is in fact a function on the first part of the input only. Thus there is a function $f_i' : \{0,1\}^6 \to \{0,1\}$, such that $f_i(\boldsymbol{abc}) = f_i'(\boldsymbol{a})$. Then, from $f_i'(\boldsymbol{a}) = h_i(\boldsymbol{bda})$, we know that h_i is actually a function of its third part of the input only. From $g_i(\boldsymbol{abc}) = f_i'(\boldsymbol{b})$, we know that g_i is a function of its second part of the input only. Thus, there are functions $g_i', h_i' : \{0,1\}^6 \to \{0,1\}$, such that $g_i(\boldsymbol{abc}) = g_i'(\boldsymbol{b})$ and $h_i(\boldsymbol{abc}) = h_i'(\boldsymbol{c})$. Putting these together, we see $f_i'(\boldsymbol{a}) = g_i'(\boldsymbol{a}) = h_i'(\boldsymbol{a})$. Since $\boldsymbol{a} \in \{0,1\}^6$ is arbitrary, we get $f_i' = g_i' = h_i'$. We now rename these as $M_i := f_i' = g_i' = h_i'$. In other words, $\pi : D^6 \to D^6$ has the form $\pi = (\pi_1, \pi_2, \ldots, \pi_6)$ where $\pi_i(\boldsymbol{abc}) = M_i(\boldsymbol{a}) M_i(\boldsymbol{b}) M_i(\boldsymbol{c})$. We will name the mapping $M = (M_1, M_2, \ldots, M_6) : \{0,1\}^6 \to \{0,1\}^6$ with M_i being its ith bit output. Since π is a bijection, so must be M.

Now we pick $\alpha = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \beta = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \kappa = \begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}, \lambda = \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix} \in D$. (We write them as column vectors to visually aid the readers.) Then clearly $\alpha \neq \beta, \kappa \neq \lambda$. We have $(\alpha, \alpha, \alpha, \beta, \beta, \beta) = \begin{bmatrix} 0\,0\,0\,1\,1\,1 \\ 1\,1\,1\,0\,0\,0 \\ 0\,0\,0\,0\,0\,0 \end{bmatrix}$. For any π defined by a bijection M as above, it satisfies property 1. above iff M pointwise fixes 000000, 000111 and 111000. We also have $(\kappa, \lambda, \kappa, \lambda, \kappa, \lambda) = \begin{bmatrix} 1\,0\,1\,0\,1\,0 \\ 0\,1\,0\,1\,0\,1 \\ 1\,1\,1\,1\,1\,1 \end{bmatrix}$, and $(\lambda, \kappa, \lambda, \kappa, \lambda, \kappa) = \begin{bmatrix} 0\,1\,0\,1\,0\,1 \\ 1\,0\,1\,0\,1\,0 \\ 1\,1\,1\,1\,1\,1 \end{bmatrix}$. Hence π satisfies property 2. above iff M fixes 111111 and swaps 010101 with 101010. Below we assume M is a bijection that satisfies these properties.

It is easy to verify that for any bijection $M : \{0,1\}^6 \to \{0,1\}^6$, the mapping π defined above preserves the support (defined by nonzero values of the LHS in (7)). Since M is a bijection, in the following we only need to verify that (7) holds for any nonzero LHS of (7) (as any zero LHS automatically has a zero RHS).

Now we show that equation (7) in property 3 is the same as (6).

To see that, take any nonzero of the LHS in (7) with $\boldsymbol{x} = \boldsymbol{abc}$ and $\boldsymbol{y} = \boldsymbol{bda}$, then the LHS is evaluated as

$$\begin{aligned} & \prod_{i \in [6]} (u^{c_i} v^{d_i})^{(1-a_i)(1-b_i)} (y u^{c_i} v^{d_i})^{(1-a_i)b_i} (x u^{c_i} v^{d_i})^{a_i(1-b_i)} (z u^{c_i} v^{d_i})^{a_i b_i} \\ = & \prod_{i \in [6]} u^{c_i} v^{d_i} x^{a_i} y^{b_i} \left(\frac{z}{xy}\right)^{a_i b_i} \\ = & \; u^{\sum c_i} v^{\sum d_i} x^{\sum a_i} y^{\sum b_i} \left(\frac{z}{xy}\right)^{\sum a_i b_i} \end{aligned}$$

The expression for the RHS is nearly identical, with $M_i(\boldsymbol{a})$ substituting a_i, and so on.

Now it is clear that if $z = xy$, then the partition function $Z_{\mathcal{F}}(\cdot)$ is tractable, witnessed by any π defined by a bijection on $\{0,1\}^6$ that preserves Hamming weight, pointwise fixes 000000, 111111, 000111, 111000, and swaps 010101 and 101010.

Next, assume $z \neq xy$. We can multiply both sides of (6) over all 2^6 possible $\boldsymbol{c}$ and all 2^6 possible possible $\boldsymbol{d}$, and using the fact that M is a bijection, to get

$$\begin{aligned} & u^{6 \cdot 2^{11}} v^{6 \cdot 2^{11}} x^{2^{12} \sum a_i} y^{2^{12} \sum b_i} \left(\frac{z}{xy}\right)^{2^{12} \sum a_i b_i} = \\ & \quad u^{6 \cdot 2^{11}} v^{6 \cdot 2^{11}} x^{2^{12} \sum M_i(\boldsymbol{a})} y^{2^{12} \sum M_i(\boldsymbol{b})} \left(\frac{z}{xy}\right)^{2^{12} \sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})}, \end{aligned}$$

which is equivalent to

$$x^{\sum a_i} y^{\sum b_i} \left(\frac{z}{xy}\right)^{\sum a_i b_i} = x^{\sum M_i(\boldsymbol{a})} y^{\sum M_i(\boldsymbol{b})} \left(\frac{z}{xy}\right)^{\sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})}. \tag{8}$$

Then multiplying over all 2^6 possible 6-tuples $\boldsymbol{b}$,

$$x^{2^6 \sum a_i} y^{6 \cdot 2^{11}} \left(\frac{z}{xy}\right)^{2^5 \sum a_i} = x^{2^6 \sum M_i(\boldsymbol{a})} y^{6 \cdot 2^{11}} \left(\frac{z}{xy}\right)^{2^5 \sum M_i(\boldsymbol{a})},$$

we get $\left(\frac{xz}{y}\right)^{\sum a_i} = \left(\frac{xz}{y}\right)^{\sum M_i(\boldsymbol{a})}$.

Suppose $xz \neq y$, it follows that $\sum_{i=1}^{6} a_i = \sum_{i=1}^{6} M_i(\boldsymbol{a})$ for any $\boldsymbol{a}$, i.e., M preserves Hamming weight. Then it follows from (6) that

$$\left(\frac{z}{xy}\right)^{\sum a_i b_i} = \left(\frac{z}{xy}\right)^{\sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})}.$$

But if we take $\boldsymbol{a} = 000111$ and $\boldsymbol{b} = 010101$, we have $M(\boldsymbol{a}) = \boldsymbol{a}$ and $M(\boldsymbol{b}) = 101010$. Then $\sum_{i=1}^{6} a_i b_i = 2$, but $\sum_{i=1}^{6} M_i(\boldsymbol{a}) M_i(\boldsymbol{b}) = 1$. This is a contradiction to (6), since $z \neq xy$. Hence we conclude that the partition function $Z_{\mathcal{F}}(\cdot)$ is #P-hard.

Next, suppose that $xz = y$, then (8) is simplified to

$$x^{\sum a_i} y^{\sum b_i} x^{-2\sum a_i b_i} = x^{\sum M_i(\boldsymbol{a})} y^{\sum M_i(\boldsymbol{b})} x^{-2\sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})}. \tag{9}$$

Multiplying over all possible $\boldsymbol{a}$, this becomes

$$x^{2^5} y^{2^6 \sum b_i} x^{-2\cdot 2^5 \sum b_i} = x^{2^5} y^{2^6 \sum M_i(\boldsymbol{b})} x^{-2\cdot 2^5 \sum M_i(\boldsymbol{b})}.$$

This simplifies to

$$\left(\frac{y}{x}\right)^{\sum b_i} = \left(\frac{y}{x}\right)^{\sum M_i(\boldsymbol{b})}.$$

If $x \neq y$, M preserves weight and we are done by the same argument as for when $xz \neq y$.

Otherwise if $x = y$, (9) becomes

$$x^{\sum a_i + \sum b_i - 2\sum a_i b_i} = x^{\sum M_i(\boldsymbol{a}) + \sum M_i(\boldsymbol{b}) - 2\sum M_i(\boldsymbol{a}) M_i(\boldsymbol{b})}.$$

This is equivalent to

$$x^{\frac{1}{2} - \frac{1}{2}\sum (2a_i - 1)(2b_i - 1)} = x^{\frac{1}{2} - \frac{1}{2}\sum (2M_i(\boldsymbol{a}) - 1)(2M_i(\boldsymbol{b}) - 1)},$$

which can be written as

$$x^{\sum a_i' b_i'} = x^{\sum M_i(\boldsymbol{a})' M_i(\boldsymbol{b})'}$$

where $a_i' = 2a_i - 1 \in \{-1, 1\}$, and similarly for b_i', and $M_i(\boldsymbol{a})'$, $M_i(\boldsymbol{b})'$. We can fix the same $\boldsymbol{a}$ and $\boldsymbol{b}$ as above, and this gives $\boldsymbol{a}' = (-1, -1, -1, 1, 1, 1)$ and $\boldsymbol{b}' = (-1, 1, -1, 1, -1, 1)$. Then we get $2 = \sum_{i=1}^{6} a_i' b_i' \neq \sum_{i=1}^{6} M_i(\boldsymbol{a})' M_i(\boldsymbol{b})' = -2$. Thus we must have $x = 1$, and then $y = 1$ and $z = 1$, which contradicts $z \neq xy$. We have proved that if $z \neq xy$ the partition function $Z_{\mathcal{F}}(\cdot)$ is #P-hard.

Continuous Rational Functions Are Deterministic Regular

Abstract

A word-to-word function is rational if it can be realized by a non-deterministic one-way transducer. Over finite words, it is a classical result that any rational function is regular, i.e. it can be computed by a deterministic two-way transducer, or equivalently, by a deterministic streaming string transducer (a one-way automaton which manipulates string registers).

This result no longer holds for infinite words, since a non-deterministic one-way transducer can guess, and check along its run, properties such as infinitely many occurrences of some pattern, which is impossible for a deterministic machine. In this paper, we identify the class of rational functions over infinite words which are also computable by a deterministic two-way transducer. It coincides with the class of rational functions which are continuous, and this property can thus be decided. This solves an open question raised in a previous paper of Dave et al.

2012 ACM Subject Classification Theory of computation → Transducers

Keywords and phrases infinite words, rational functions, determinization, continuity, streaming string transducers, two-way transducers

1 Introduction

Transducers are finite-state machines obtained by adding outputs to finite automata. They are very useful in a lot of areas like coding, computer arithmetic, language processing or program analysis, and more generally in data stream processing. In this paper, we study transducers which compute partial functions. They are either deterministic, or non-deterministic but unambiguous (they have at most one accepting run on a given input).

Over finite words, a deterministic two-way transducer (2-dT) consists of a deterministic two-way automaton which can produce outputs. Such machines realize the class of *regular functions*, which is often considered as one of the functional counterparts of regular languages. It coincides with the class of functions definable by monadic second-order transductions [7], or copyless deterministic streaming string transducers (dSST), which is a model of one-way automata manipulating string registers [1]. On the other hand, the model of non-deterministic one-way transducers (1-nT) describe the well-known class of *rational functions*. It is well known that any rational function is regular, but the converse does not hold.

Infinite words. The class of *regular functions over infinite words* was defined in [2] using monadic second-order transductions. It coincides with the class of functions realized by 2-dT with ω-regular lookahead, or by copyless dSST with some Müller conditions. However, the use of ω-regular lookaheads (or Müller conditions for dSST) is necessary to capture the expressive power of monadic second-order logic on infinite words, in order to check properties such as infinitely many occurrences of some pattern. Similarly, the model of 1-nT with Büchi acceptance conditions defines the subclass of *rational functions over infinite words*.

Even if regular and rational functions give very natural frameworks for specification (due to their connections with logic), not all these functions can effectively be computed by a deterministic machine without lookaheads. It turns out that the regular functions which can be computed by a deterministic Turing machine (doing an infinite computation on its infinite input) are exactly those which are continuous for the Cantor topology [5]. Furthermore continuity can be decided, which was has been known for rational functions since [10].

The authors of [5] conjecture that any continuous rational (or even regular) function can in fact be computed by a 2-dT (without lookahead), instead of a Turing machine. A partial answer was obtained in [8], whose results imply that 2-dT can be built for a subclass of rational functions defined by 1-nT where some forms of non-determinism are prohibited. Their proof is based on game-theoretic techniques.

Contributions. This paper shows that any continuous rational function over infinite words can be extended to a function which is computable by a 2-dT (without lookaheads). Since the converse also holds, this result completely characterizes rational functions which can be computed by 2-dTs, up to an extension of the domain. Furthermore, this property is decidable and our construction of a 2-dT is effective.

This result is tight, in the sense that two-way moves cannot be avoided. Indeed, one-way deterministic transducers (describing the class of *sequential functions*) cannot realize all continuous rational functions, even when only considering total functions (contrary to what happens for the subclass of rational functions studied in [8]).

In order to establish this theorem, we first study the expressive power of 2-dT over infinite words. We introduce the class of *deterministic regular functions* as the class of functions computed by 2-dT (as opposed to the regular functions, which are not entirely deterministic since they use lookaheads to guess the future). Following the aforementioned equivalences between two-way and register transducers, we prove that deterministic rational functions are exactly the functions which are realized by copyless dSST (without Müller conditions). Hence our problem is reduced to showing that any continuous rational function can be realized by a copyless dSST. Building a copyless dSST is also relevant for practical applications, since it corresponds to a streaming algorithm over infinite strings.

Then we introduce various new concepts in order to transform a 1-nT computing a continuous function into a dSST. This determinization procedure is rather involved. The main difficulty is that even if the 1-nT is unambiguous, it might not check its guesses after reading only a finite number of letters. In other words, a given input can label several infinite runs, even if only one of them is accepting. However, a deterministic machine can never determine which run is the accepting one, since it requires to check whether a property occurs infinitely often. This intuition motivates our key definition of *compatible sets* among the states of a 1-nT. Such sets are the sets of states which have a “common infinite future”. The restriction of 1-nT considered in [8] leads to compatible sets which are always singletons (hence their condition defines a natural special case). We show that when the function computed by the 1-nT is continuous, the outputs produced along finite runs which end in a compatible set enjoy several combinatorial properties.

We finally describe how to build a dSST which realizes the continuous function given by a 1-nT. Its construction is is rather complex, and it crucially relies on the aforementioned properties of compatible sets. These sets are manipulated by the dSST in an original tree-like fashion. To the knowledge of the authors, this construction of this dSST is completely new (in particular, it is not based on the constructions of [5] nor of [8]).

Outline. We recall in Section 2 the definitions of rational functions and one-way transducers. In Section 3, we present the new class of deterministic regular functions and give the various transducer models which capture it. Our main result which relates continuous rational and deterministic regular functions is given in Section 4. The proof is sketched in sections 4 and 5.

2 Rational functions

Letters A, B denote alphabets, i.e. finite sets of letters. The set A^* (resp. A^+, A^ω) denotes the set of finite words (resp. non-empty finite words, infinite words) over the alphabet A. If $u \in A^* \cup A^\omega$, we let $|u| \in \mathbb{N} \cup \{\infty\}$ be its length. For $a \in A$, $|u|_a$ denotes the number of a in u. For $1 \leqslant i \leqslant |u|$, $u[i] \in A$ is the i-th letter of u. If $1 \leqslant i \leqslant j \leqslant |u|$, $u[i{:}j]$ stands for $u[i]u[i{+}1] \cdots$ until j. We write $w[i{:}]$ for $u[i{:}|u|]$. If $j > |u|$ we let $u[i{:}j] := u[i{:}|u|]$. If $j < i$ we let $u[i{:}j] := \varepsilon$. We write $u \sqsubseteq v$ (resp. $u \sqsubset v$) when u is a (resp. strict) prefix of v. Given two words u, v, we let $u \wedge v$ be their longest common prefix. We say that u, v are *mutual prefixes* if $u \sqsubseteq v$ or $v \sqsubseteq u$. In this case we let $u \vee v$ be the longest of them. A function f between two sets S, T is denoted by $f : S \to T$. If f is a *partial function* (i.e. possibly with non-total domain), it is denoted $f : S \rightharpoonup T$. Its domain is denoted $\mathsf{Dom}(f)$.

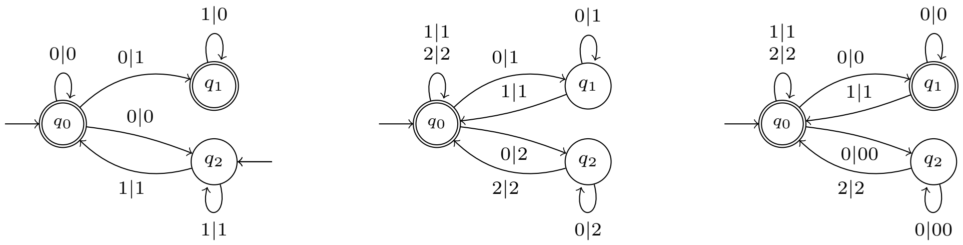
▶ **Definition 2.1.** *A* one-way non-deterministic transducer (1-nT) $\mathcal{T} = (A, B, Q, I, F, \Delta, \lambda)$ *is:*

- *a finite input (respectively output) alphabet A (respectively B);*
- *a finite set of states Q with $I \subseteq Q$ initial and $F \subseteq Q$ final;*
- *a transition relation $\Delta \subseteq Q \times A \times Q$;*
- *an output function $\lambda : \Delta \to B^*$ (defined for each transition).*

We write $q \xrightarrow{a|\alpha} q'$ whenever $(q, a, q') \in \Delta$ and $\lambda(q, a, q') = \alpha$. A *run* labelled by some $x \in A^* \cup A^\omega$ is a sequence of consecutive transitions $\rho := q_0 \xrightarrow{x[1]|\alpha_1} q_1 \xrightarrow{x[2]|\alpha_2} q_2 \cdots$. The *output* of ρ is the word $\alpha_1\alpha_2 \cdots \in A^* \cup A^\omega$. If $x \in A^\omega$, we also write $q_0 \xrightarrow{x|\alpha_1\alpha_2\cdots} \infty$ to denote an infinite run starting in q_0. The run ρ is *initial* if $q_0 \in I$, *final* if $x \in A^\omega$ and $q_i \in F$ infinitely often (Büchi condition), and *accepting* if both initial and final. $\mathcal{T}$ computes the *relation* $\{(x, y) : y \in B^\omega$ is output along an accepting run on $x\}$. It is *functional* if this relation is a (partial) function. In this case, $\mathcal{T}$ can be transformed in an equivalent *unambiguous* 1-nT (a transducer which has at most one accepting run on each $x \in A^\omega$) [3, Corollary 3]. A function $f : A^\omega \rightharpoonup B^\omega$ is said to be *rational* if it can be computed by a (unambiguous) 1-nT.

▶ **Example 2.2.** In Figure 2, we describe 1-nTs which compute the following functions:

- $\mathsf{normalize} : \{0,1\}^\omega \rightharpoonup \{0,1\}^\omega$ mapping $x \mapsto x$ if $|x|_0 = \infty$ and $u01^\omega \mapsto u10^\omega$ if $u \in \{0,1\}^*$;
- $\mathsf{replace} : \{0,1,2\}^\omega \rightharpoonup \{1,2\}^\omega$ with $\mathsf{Dom}(\mathsf{replace}) = \{x : |x|_1 = \infty$ or $|x|_2 = \infty\}$ and mapping $0^{n_1}a_1 0^{n_2}a_2 \cdots \mapsto {a_1}^{n_1+1}{a_2}^{n_2+1} \cdots$ if $a_i \in \{1,2\}$, $n_i \in \mathbb{N}$;
- $\mathsf{double} : \{0,1,2\}^\omega \to \{0,1,2\}^\omega$ mapping $0^{n_1}a_1 0^{n_2}a_2 \cdots \mapsto 0^{a_1 n_1}a_1 0^{a_2 n_2}a_2 \cdots$ and $0^{n_1}a_1 \cdots 0^{n_m}a_m 0^\omega \mapsto 0^{a_1 n_1}a_1 \cdots 0^{a_m n_m}a_m 0^\omega$ (if finitely many 1 or 2).



(a) 1-nT computing normalize. **(b)** 1-nT computing replace. **(c)** 1-nT computing double.

Figure 2 Unambiguous, clean and trim 1-nTs computing the functions of Example 2.2.

▶ Remark 2.3. The functions mentioned in Example 2.2 are not *sequential*, i.e. they cannot be computed by deterministic one-way transducers (i.e. deterministic 1-nTs).

A 1-nT is *trim* if any state is both accessible and co-accessible, or equivalently if it occurs in some accepting run. It is *clean* if the production along any accepting run is infinite.

▶ **Lemma 2.4.** *A trim* 1-nT *is clean if and only if for all $q \in F$, the existence of a cycle $q \xrightarrow{u|\alpha} q$ for $u \in A^+$ implies $\alpha \neq \varepsilon$. Given an unambiguous* 1-nT*, one can build an equivalent unambiguous, clean and trim* 1-nT*.*

3 Deterministic regular functions

We now introduce the new class of *deterministic regular* functions, which are computed by *deterministic two-way transducers*. Contrary to 1-nTs, such machines cannot test ω-regular properties of their input. Hence they describe continuous (and computable) functions.

▶ **Definition 3.1.** *A* deterministic two-way transducer (2-dT) $\mathcal{T} = (A, B, Q, q_0, \delta, \lambda)$ *is:*

- *an input alphabet A and an output alphabet B;*
- *a finite set of states Q with an initial state $q_0 \in Q$;*
- *a transition function $\delta : Q \times (A \uplus \{\vdash\}) \rightharpoonup Q \times \{\triangleleft, \triangleright\}$;*
- *an output function $\lambda : Q \times (A \uplus \{\vdash\}) \rightharpoonup B^*$ with same domain as δ.*

If the input is $x \in A^\omega$, then $\mathcal{T}$ is given as input the word $\vdash x$. The symbol $\vdash$ is used to mark the beginning of the input. We denote by $x[0] := \vdash$. A *configuration* over $\vdash x$ is a tuple (q, i) where $q \in Q$ is the current state and $i \geqslant 0$ is the current position of the reading head. The *transition relation* $\rightarrow$ is defined as follows. Given a configuration (q, i), let $(q', \star) := \delta(q, w[i])$. Then $(q, i) \rightarrow (q', i')$ whenever either $\star = \triangleleft$ and $i' = i - 1$ (move left), or $\star = \triangleright$ and $i' = i + 1$ (move right). A *run* is a (finite or infinite) sequence of configurations $(q_1, i_1) \rightarrow (q_2, i_2) \rightarrow \cdots$. An *accepting* run is an infinite run which starts in $(q_0, 0)$ and such that $i_n \rightarrow \infty$ when $n \rightarrow \infty$ (otherwise the transducer repeats the same loop).

The partial function $f : A^\omega \rightharpoonup B^\omega$ computed by $\mathcal{T}$ is defined as follows. Let $x \in A^\omega$ be such that there exists a (unique) accepting run $(q_0^x, i_0^x) \rightarrow (q_1^x, i_1^x) \rightarrow \cdots$ labelled by x. Let $y := \prod_{j=1}^{\infty} \lambda(q_j^x, w[i_j^x]) \in B^* \cup B^\omega$ be the concatenation of the outputs produced along this run. If $y \in B^\omega$, we define $f(x) := y$. Otherwise $f(x)$ is undefined.

▶ **Example 3.2.** The function replace from Example 2.2 can be computed by 2-dT. For each $i \geqslant 1$, this 2-dT crosses the block 0^{n_i} to determines a_i, and then crosses the block once more and outputs ${a_i}^{n_i+1}$. The function double can be computed using similar ideas. However, an important difference is that the 2-dT must output the block 0^{n_i} when it crosses it for the first time, in order to ensure that the production over 0^ω is 0^ω.

There exists deterministic regular functions which are not rational, for instance the function which reverses (mirror image) a prefix of its input.

Over finite words, it is known that two-way transducers are equivalent to copyless streaming string transducers [1]. Over infinite words, a similar equivalence holds between two-way transducers with lookahead and copyless streaming string transducers with Müller output conditions [2]. These models define the class of *regular functions* over infinite words. However, lookaheads enable two-way transducers to check ω-regular properties of their input (and thus non-computable behaviors). Hence our deterministic regular functions form a strict subclass of these regular functions over infinite words.

We now introduce a model of streaming string transducer to describe deterministic regular functions, in the spirit of the aforementioned results. In our setting, it consists of a one-way deterministic automaton with a finite set $\mathfrak{R}$ of registers that store words from B^*. We use a distinguished register $\mathfrak{out}$ to store the output produced when reading an infinite word. The registers are modified using *substitutions*, i.e. mappings $\mathfrak{R} \to (B \uplus \mathfrak{R})^*$. We denote by $\mathcal{S}^B_{\mathfrak{R}}$ the set of these substitutions. They can be extended morphically from $(B \uplus \mathfrak{R})^*$ to $(B \uplus \mathfrak{R})^*$ by preserving the elements of B. They can be composed (see Example 3.3).

▶ **Example 3.3.** Let $\mathfrak{R} = \{\mathfrak{r}, \mathfrak{s}\}$ and $B = \{b\}$. Consider $\sigma_1 := \mathfrak{r} \mapsto b, \mathfrak{s} \mapsto b\mathfrak{r}\mathfrak{s}b$ and $s_2 := \mathfrak{r} \mapsto \mathfrak{r}b, \mathfrak{s} \mapsto \mathfrak{r}\mathfrak{s}$, then $\sigma_1 \circ \sigma_2(\mathfrak{r}) = s_1(\mathfrak{r}b) = bb$ and $\sigma_1 \circ \sigma_2(\mathfrak{s}) = \sigma_1(\mathfrak{r}\mathfrak{s}) = bb\mathfrak{r}\mathfrak{s}b$.

▶ **Definition 3.4.** *A* deterministic streaming string transducer (dSST) *is:*

- *a finite input (resp. output) alphabet A (resp. B);*
- *a finite set of states Q with $q_0 \in Q$ initial;*
- *a transition function $\delta : Q \times A \rightharpoonup Q$;*
- *a finite set of registers $\mathfrak{R}$ with a distinguished output register $\mathfrak{out} \in \mathfrak{R}$;*
- *an update function $\lambda : Q \times A \rightharpoonup \mathcal{S}^B_{\mathfrak{R}}$ such that for all $(q, a) \in \mathsf{Dom}(\lambda) = \mathsf{Dom}(\delta)$:*
  - *$\lambda(q, a)(\mathfrak{out}) = \mathfrak{out} \cdots$;*
  - *there is no other occurence of $\mathfrak{out}$ in $\{\lambda(q, a)(\mathfrak{r}) : \mathfrak{r} \in \mathfrak{R}\}$.*

We denote it $\mathcal{T} = (A, B, Q, q_0, \delta, \mathfrak{R}, \mathfrak{out}, \lambda)$.

This machine defines a function $f : A^* \rightharpoonup B^*$ as follows. For $i \geqslant 0$ let $q^x_i := \delta(q_0, x[1{:}i])$ (when defined). For $i \geqslant 1$, we let $\lambda^x_i := \lambda(q^x_{i-1}, x[i])$ (when defined) and $\lambda^x_0(\mathfrak{r}) = \varepsilon$ for all $\mathfrak{r} \in \mathfrak{R}$. For $i \geqslant 0$, define the substitution $[\![\cdot]\!]^x_i := \lambda^x_0 \circ \cdots \circ \lambda^x_i$. By construction we get $[\![\mathfrak{out}]\!]^x_i \sqsubseteq [\![\mathfrak{out}]\!]^x_{i+1}$ (when defined). If $[\![\mathfrak{out}]\!]^x_i$ is defined for all $i \geqslant 0$ and $|[\![\mathfrak{out}]\!]^x_i| \to +\infty$, we let $f(x) := \bigvee_i [\![\mathfrak{out}]\!]^x_i$ (it denotes the unique infinite word y such that $[\![\mathfrak{out}]\!]^x_i \sqsubseteq y$ for all $i \geqslant 0$). Otherwise $f(x)$ is undefined.

We say that a substitution $\sigma \in \mathcal{S}^B_{\mathfrak{R}}$ is *copyless* (resp. K-bounded) if for all $\mathfrak{r} \in \mathfrak{R}$, $\mathfrak{r}$ occurs at most once in $\{\sigma(\mathfrak{s}) : \mathfrak{s} \in \mathfrak{R}\}$ (resp. for all $\mathfrak{r}, \mathfrak{s} \in \mathfrak{R}$, $\mathfrak{r}$ occurs at most K times in $\sigma(\mathfrak{s})$).

▶ **Definition 3.5** (Copy restrictions). *We say that a* dSST $\mathcal{T} = (A, B, Q, q_0, \delta, \mathfrak{R}, \mathfrak{out}, \lambda)$ *is* copyless *(resp.* K-bounded*) if for all $x \in A^\omega$ and $i \leqslant j$ such that $\lambda^x_i \circ \cdots \circ \lambda^x_j$ is defined, this substitution is copyless (resp. K-bounded).*

▶ **Example 3.6.** The function replace from Example 2.2 can be computed by a copyless dSST. For all $i \geqslant 1$, it crosses the block 0^{n_i} and computes 1^{n_i} and 2^{n_i} in two registers. Once it sees a_i it adds in $\mathfrak{out}$ the register storing ${a_i}^{n_i}$. The function double can be computed using similar ideas. However, an important difference is that the dSST must directly output the block 0^{n_i} while crossing it, in order to ensure that the production over 0^ω is 0^ω.

The proof of the next result is quite involved, but it is largely inspired by the techniques used for regular functions over finite or infinite words (see e.g. [4, 6]).

▶ **Theorem 3.7.** *The following machines compute the same class of functions $A^\omega \rightharpoonup B^\omega$:*
1. *deterministic two-way transducers* (2-dT)*;*
2. *K-bounded deterministic streaming string transducers* (*K-bounded* dSST)*;*
3. *copyless deterministic streaming string transducers* (*copyless* dSST)*.*

Furthermore, all the conversions are effective.

▶ Remark 3.8. Even if this result is a variant of existing results over finite or infinite words, it requires a proof on its own. Indeed, the authors are not aware of a direct proof which would enable to deduce it from the existing similar results.

Let us now describe the domains of deterministic regular functions. We say that a language is *Büchi deterministic* if it is accepted by a deterministic Büchi automaton [9].

▶ **Proposition 3.9.** *If f is deterministic regular, then* $\mathsf{Dom}(f)$ *is Büchi deterministic.*

We finally give a closure property of deterministic regular functions under pre-composition.

▶ **Definition 3.10.** *A* restricted 1-nT *is a* 1-nT *whose states all are final.*

The semantics of a restricted 1-nT $\mathcal{N} = (A, B, Q, I, \Delta, \lambda)$ is defined so that it *always* computes a function $f : A^\omega \rightharpoonup B^\omega$. The domain $\mathsf{Dom}(f)$ is the set of $x \in A^\omega$ such that $\mathcal{N}$ has a unique accepting run labelled by x, and such that the output along this unique run is infinite. In this case, we let $f(x)$ be the output of along this run. Intuitively, such a transducer expresses the ability to make non-deterministic guesses, as long as these guesses can be verified after reading a finite number of letters (i.e. there are no two possible infinite runs).

▶ **Theorem 3.11.** *Given a restricted* 1-nT *computing a function $f : A^\omega \rightharpoonup B^\omega$ and a deterministic regular function $g : B^\omega \rightharpoonup C^\omega$, $g \circ f$ is (effectively) deterministic regular.*

4 Continuous rational functions are deterministic regular

We now state the main result of this paper, which shows that a rational function can be extended to a deterministic regular function. Using an extension of the original function is necessary since not all ω-regular languages are Büchi deterministic (see Proposition 3.9). Note that Theorem 4.2 is in fact an equivalence, in the sense that a rational function which can be extended to a deterministic regular function is obviously continuous.

We recall that a function $f : A^\omega \rightharpoonup B^\omega$ is *continuous* if and only if for all $x \in \mathsf{Dom}(f)$ and $n \geqslant 0$, there exists $p \geqslant 0$ such that $\forall y \in \mathsf{Dom}(f)$, $|x \wedge y| \geqslant p \Rightarrow |f(x) \wedge f(y)| \geqslant n$.

▶ **Example 4.1.** The functions replace and double are continuous, but normalize is not.

▶ **Theorem 4.2.** *Given a continuous rational function $f : A^\omega \rightharpoonup B^\omega$, one can build a deterministic regular function f' which extends f (i.e. for all $x \in \mathsf{Dom}(f)$, $f(x) = f'(x)$).*

To prove Theorem 4.2, it is enough by theorems 3.7 and 3.11 to show that f' can be computed as a composition of a restricted 1-nT and a K-bounded dSST (see Subsection 4.2, the construction will in fact give a 1-bounded transducer).

4.1 Properties of continuous rational functions

We first describe some structural properties of 1-nT computing continuous functions. In this subsection, we let $\mathcal{T} = (A, B, Q, I, F, \Delta, \lambda)$ be an unambiguous, clean and trim 1-nT computing a continuous function $f : A^\omega \rightharpoonup B^\omega$. It is well known that $\mathcal{T}$ verifies Lemma 4.3. This property is in fact equivalent to the continuity of f (see e.g. [10] or [5]).

▶ **Lemma 4.3.** *For all $q_1, q_2 \in I$, $q_1' \in F$, $q_2' \in Q$, $u \in A^*$, $u' \in A^+$, $\alpha_1, \alpha_1', \alpha_2, \alpha_2' \in B^*$ such that $q_i \xrightarrow{u|\alpha_i} q_i' \xrightarrow{u'|\alpha_i'} q_i'$ for $i \in \{1, 2\}$ we have (note that $\alpha_1' \neq \varepsilon$ since $\mathcal{T}$ is clean):*

- *if $\alpha_2' \neq \varepsilon$, then $\alpha_1 {\alpha_1'}^\omega = \alpha_2 {\alpha_2'}^\omega$;*
- *if $\alpha_2' = \varepsilon$, $x \in A^\omega$, $\beta \in B^\omega$ and $q_2' \xrightarrow{x|\beta} \infty$ is final, then $\alpha_1 {\alpha_1'}^\omega = \alpha_2 \beta$.*

Empty cycles $q \xrightarrow{u|\varepsilon} q$ for $q \notin F$ cannot be avoided in a 1-nT. However, we shall see in Lemma 4.4 that such cycles can be avoided if the function is continuous. Formally, we say that the clean $\mathcal{T}$ is *productive* if the hypotheses of Lemma 4.3 imply $\alpha_2' \neq \varepsilon$.

▶ **Lemma 4.4.** *Given $\mathcal{T}$, one can build an equivalent unambiguous, trim and productive* 1-nT.

Compatible sets and steps. We now introduce the key notion of a *compatible set* which is a set of states having a "common future" and such that one of the future runs is accepting.

▶ **Definition 4.5** (Compatible set). *We say that a set of states $C \subseteq Q$ is* compatible *whenever there exists $x \in A^\omega$ and infinite runs ρ_q for each $q \in C$ labelled by x such that:*

- *$\forall q \in C$, ρ_q starts from q;*
- *$\exists q \in C$ such that ρ_q is final.*

Let Comp be the set of compatible sets. If $S \subseteq Q$, let $\mathsf{Comp}(S)$ be the set $2^S \cap \mathsf{Comp}$.

▶ **Definition 4.6** (Pre-step). *We say that C, u, D is a* pre-step *if $C, D \in \mathsf{Comp}$, $u \in A^*$ and for all $q \in D$, there exists a unique state $\mathsf{pre}^u_{C,D}(q) \in C$ such that $\mathsf{pre}^u_{C,D}(q) \xrightarrow{u} q$.*

Note that for all $D' \in \mathsf{Comp}(D)$, we have $\mathsf{pre}^u_{C,D}(D') \in \mathsf{Comp}$.

▶ **Definition 4.7** (Step). *We say that a pre-step C, u, D is a* step *if $\mathsf{pre}^u_{C,D}$ is surjective.*

Given $q \in D$, let $\mathsf{prod}^u_{C,D}(q)$ be the output $\alpha \in B^*$ produced along the run $\mathsf{pre}^u_{C,D}(q) \xrightarrow{u|\alpha} q$. We say that a (pre-)step is *initial* whenever $C \subseteq I$. We first claim that the productions along the runs of an initial step are mutual prefixes. Lemma 4.3 is crucial here.

▶ **Lemma 4.8.** *Let J, u, C be an initial step. Then $\mathsf{prod}^u_{J,C}(q)$ for $q \in C$ are mutual prefixes.*

▶ **Example 4.9.** In Figure 2b, if a step is initial, it is of the form $\{q_0\}, u, \{q_i\}$ for some $i \in \{0, 1, 2\}$. In Figure 2c, $\{q_0\}, 0^n, \{q_1, q_2\}$ is an initial step for all $n \geqslant 0$.

▶ **Definition 4.10** (Common, advance). *Let J, u, C be an initial step. We define:*

- *the* common *$\mathsf{com}^u_{J,C} \in B^*$ as the longest common prefix $\bigwedge_{q \in C} \mathsf{prod}^u_{J,C}(q)$;*
- *for all $q \in C$, its* advance *$\mathsf{adv}^u_{J,C}(q) \in B^*$ as $(\mathsf{com}^u_{J,C})^{-1}\, \mathsf{prod}^u_{J,C}(q)$;*
- *the* maximal advance *$\mathsf{max}\text{-}\mathsf{adv}^u_{J,C}$ as the longest advance, i.e. $\bigvee_{q \in C} \mathsf{adv}^u_{J,C}(q)$.*

Definition 4.10 makes sense by Lemma 4.8, and furthermore $\mathsf{prod}^u_{J,C}(q) = \mathsf{com}^u_{J,C}\, \mathsf{adv}^u_{J,C}(q)$ for all $q \in C$. Now let $M := \max_{q,q' \in Q, a \in A} |\lambda(q, a, q')|$ and $\Omega := M|Q|^{|Q|}$. We say that a compatible set C is *separable* if there exists an initial step which ends in C, and such that the lengths of the productions along two of its runs differ of at least Ω.

▶ **Definition 4.11** (Separable set). *Let $C \in \mathsf{Comp}$, we say that C is* separable *if there exists an initial step J, u, C and $p, q \in C$ such that $\big||\mathsf{adv}^u_{J,C}(p)| - |\mathsf{adv}^u_{J,C}(q)|\big| > \Omega$.*

▶ Remark 4.12. In other words, it means that $|\mathsf{max}\text{-}\mathsf{adv}^u_{J,C}| > \Omega$.

It is easy to see (by a pumping argument) that one can decide if a set is separable. We now show that the productions along the initial steps which end in a separable set are forced to "iterate" some value θ if the step is pursued. The following lemma is the key ingredient for showing that a rational function is deterministic regular (see Section 4).

▶ **Lemma 4.13** (Looping futures). *Let $C \in \mathsf{Comp}$ be separable and J, u, C be an initial step (not necessarily the one which makes C separable). There exists $\tau, \theta \in B^*$ with $|\tau| \leqslant 3\Omega$, and $|\theta| = \Omega!$ which can be uniquely determined from C and $\mathsf{adv}^u_{J,C}(q)$ for $q \in C$, such that:*

- $\tau \sqsubseteq \mathsf{max\text{-}adv}^u_{J,C} \sqsubseteq \tau\theta^\omega$;
- *for all step C, v, D and $q \in D$, $\mathsf{prod}^v_{C,D}(q) \sqsubseteq (\mathsf{adv}^u_{J,C}(p))^{-1}\tau\theta^\omega$ with $p := \mathsf{pre}^v_{C,D}(q)$.*

▶ Remark 4.14. Since $\mathsf{adv}^u_{J,C}(p) \sqsubseteq \mathsf{max\text{-}adv}^u_{J,C} \sqsubseteq \tau\theta^\omega$, the second item makes sense.

▶ **Example 4.15.** In Figure 2c, the compatible set $C := \{q_1, q_2\}$ is separable. For all step C, v, D we have $D = C$ thus $v = 0^n$, $\mathsf{prod}^{0^n}_{C,D}(q_1) = 0^n$ and $\mathsf{prod}^{0^n}_{C,D}(q_2) = 0^{2n}$.

4.2 Composition of a restricted 1-nT and a 1-bounded dSST

In the rest of this paper, we let $\mathcal{T} = (A, B, Q, I, F, \Delta, \lambda)$ be an unambiguous, productive and trim 1-nT computing a continuous $f : A^\omega \rightharpoonup B^\omega$. Our goal is to rewrite f as the composition of a restricted 1-nT and a 1-bounded dSST. We first build the restricted 1-nT, which computes an over-approximation of the accepting run of $\mathcal{T}$ in terms of compatible sets.

▶ **Lemma 4.16.** *One can build a restricted 1-nT $\mathcal{N}$ computing $g : A^\omega \rightharpoonup (\mathsf{Comp} \uplus A)^\omega$ such that $\mathsf{Dom}(f) \subseteq \mathsf{Dom}(g)$, and for all $x \in \mathsf{Dom}(g)$, $g(x) = C_0 x[1] C_1 x[2] C_2 \cdots$ where:*

- *$C_0 \subseteq I$ and for all $i \geqslant 0$, $C_i, x[i{+}1], C_{i+1}$ is a pre-step;*
- *if $x \in \mathsf{Dom}(f)$ then $\forall i \geqslant 0$, $q^x_i \in C_i$, where $q^x_0 \xrightarrow{x[1]} q^x_1 \xrightarrow{x[2]} \cdots$ is the accepting run of $\mathcal{T}$.*

Given $x \in \mathsf{Dom}(f)$, we denote by $C^x_0, C^x_1, \ldots$ the sequence of compatible sets produced by $\mathcal{N}$ in Lemma 4.16. We now describe a 1-bounded dSST $\mathcal{S}$ which, when given as input $g(x) \in (\mathsf{Comp} \uplus A)^\omega$ for $x \in \mathsf{Dom}(f)$, outputs $f(x)$ (this description is continued in Section 5).

Tree of compatibles. Given $C \in \mathsf{Comp}$, we define $\mathsf{tree}(C)$ as a finite set of words over $\mathsf{Comp}(C)$, which describes the decreasing chains for $\subset$. It can be identified with the set of all root-to-node paths of a tree labelled by elements of $\mathsf{Comp}(C)$, as shown in Example 4.18.

▶ **Definition 4.17** (Tree of compatibles). *Given $C \in \mathsf{Comp}$, we denote by $\mathsf{tree}(C)$ the set of words $\pi = C_1 \cdots C_n \in (\mathsf{Comp}(C))^+$ such that $C_1 = C$ and for all $1 \leqslant i \leqslant n{-}1$, $C_i \supset C_{i+1}$.*

▶ **Example 4.18.** If $C = \{1,2,3\}$ and $\mathsf{Comp}(C) = \{\{1,2,3\},\{1,2\},\{2,3\},\{1\},\{2\},\{3\}\}$, then we have $\mathsf{tree}(C) = \{\{1,2,3\}\{1,2\}\{1\}, \{1,2,3\}\{1,2\}\{2\}, \{1,2,3\}\{2,3\}\{2\}, \{1,2,3\}\{2,3\}\{3\}, \{1,2,3\}\{1\}, \{1,2,3\}\{2\}, \{1,2,3\}\{3\}\}$. Its view as a tree is depicted in Figure 3.

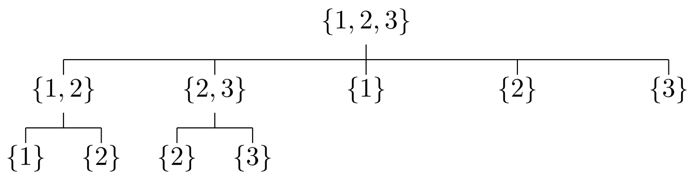


Figure 3 The tree of compatibles obtained from Example 4.18.

Information stored. The states of the dSST $\mathcal{S}$ are partitioned in two categories: the sets of the *separable mode* and the sets of of the *non-separable mode*. A configuration of the dSST $\mathcal{S}$ will always keep track of the following information:

- the content of a register $\mathfrak{out}$;
- two sets $\mathsf{J}, \mathsf{C} \in \mathsf{Comp}$ and a function $\mathsf{pre} : \mathsf{C} \to \mathsf{J}$ (stored in the state);
- a function $\mathsf{lag} : \mathsf{C} \to B^*$ such that $|\mathsf{lag}(q)| \leqslant 3\Omega$ for all $q \in \mathsf{C}$ (stored in the state).

Furthermore, when $\mathcal{S}$ is in a state of the separable mode, it will additionally store:

- a value $\theta \in B^*$ with $|\theta| = \Omega!$ (stored in the state);
- for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$ (note that $C_1 = \mathsf{C}$ by definition of $\mathsf{tree}(\mathsf{C})$):
  - a function $\mathsf{nb}_\pi : C_n \to [0{:}4]$ (stored in the state);
  - the content of a register $\mathfrak{out}_\pi$. For $\pi = \mathsf{C}$, we identify the register $\mathfrak{out}_\mathsf{C}$ with $\mathfrak{out}$;
- a function $\mathsf{last} : \mathsf{C} \to B^*$ such that $|\mathsf{last}(q)| < \Omega!$ forall $q \in \mathsf{C}$ (stored in the state).

If a configuration of $\mathcal{S}$ is clearly fixed, we abuse notations and denote by $\mathfrak{out}_\pi$ (resp. nb_π, lag, etc.) the value contained in register $\mathfrak{out}_\pi$ (resp. stored in the state) in this configuration. In a given configuration of $\mathcal{S}$, we say that $\pi \in \mathsf{tree}(\mathsf{C})$ is *close* if for all $\pi \sqsubset \pi' \in \mathsf{tree}(\mathsf{C})$, we have $\mathsf{nb}_{\pi'} = 0$ and $\mathfrak{out}_{\pi'} = \varepsilon$ (intuitively, the subtree rooted in π stores empty informations).

Invariants. The main idea for building $\mathcal{S}$ it the following. If C_i^x is a non-separable set, then the productions along the initial runs which end in C_i^x are mutual prefixes (by Lemma 4.8) which only differ from a bounded information. Hence the common part com of these runs is stored to $\mathfrak{out}$, and the adv are stored in the lag. If C_i^x becomes separable, then these runs still produce mutual prefixes, but two of them can differ by a large information. However by Lemma 4.13, they iterate some value θ. Hence the only relevant information is the number of θ which were produced along these runs. Formally, our construction ensures that the following invariants hold when $\mathcal{S}$ has just read $C_0^x x[1] C_1^x \cdots x[i] C_i^x$ for $i \geqslant 0$:

1. $\mathsf{C} = C_i^x$;
2. $\mathsf{J}, x[1{:}i], \mathsf{C}$ is an initial step and $\mathsf{pre} = \mathsf{pre}_{\mathsf{J},\mathsf{C}}$
3. if C is not separable, then $\mathcal{S}$ is in non-separable mode and:
   a. $\mathfrak{out} = \mathsf{com}_{\mathsf{J},\mathsf{C}}^{x[1:i]}$;
   b. $\mathsf{lag}(q) = \mathsf{adv}_{\mathsf{J},\mathsf{C}}^{x[1:i]}(q)$ for all $q \in \mathsf{C}$.
4. if C is separable, then $\mathcal{S}$ is in separable mode and:
   a. the $\mathsf{lag}(q)$ for $q \in Q$ are mutual prefixes, and so $\mathsf{max\text{-}lag} := \bigvee_{q \in C} \mathsf{lag}(q)$ is defined. Furthermore, there exists $q \in \mathsf{C}$ such that $\mathsf{lag}(q) = \varepsilon$. We say that some $q \in \mathsf{C}$ is *lagging* if and only if $\mathsf{lag}(q) \sqsubset \mathsf{max\text{-}lag}$ (strict prefix), otherwise it is *not lagging*;
   b. if $\pi \in \mathsf{tree}(\mathsf{C})$ is such that $\pi \neq \mathsf{C}$ (i.e. $\mathfrak{out}_\pi \neq \mathfrak{out}$), then $\mathfrak{out}_\pi \in \theta^*$;
   c. for all $q \in \mathsf{C}$, $\mathsf{last}(q) \sqsubseteq \theta^\omega$ (if furthermore $|\mathsf{last}(q)| < \Omega!$, then $\mathsf{last}(q) \sqsubset \theta$);
   d. if q is lagging, then $\mathsf{last}(q) = \varepsilon$ and for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$ such that $q \in C_n$, we have $\mathsf{nb}_\pi(q) = 0$ and, if $\pi \neq \mathsf{C}$, $\mathfrak{out}_\pi = \varepsilon$;
   e. for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$, for $1 \leqslant i \leqslant n$ define $\pi_i := C_1 \cdots C_i$. If $C_n = \{q\}$, then:
      - $\mathsf{prod}_{\mathsf{J},\mathsf{C}}^{x[1:i]}(q) = \mathfrak{out}\ \mathsf{lag}(q)$ if q is lagging;
      - $\mathsf{prod}_{\mathsf{J},\mathsf{C}}^{x[1:i]}(q) = \mathfrak{out}\ \mathsf{max\text{-}lag}\ \theta^{\mathsf{nb}_{\pi_1}(q)} \left(\prod_{i=2}^{n} \mathfrak{out}_{\pi_i}\, \theta^{\mathsf{nb}_{\pi_i}(q)}\right) \mathsf{last}(q)$ if q is not lagging.
   f. for all future steps C, u, D and for all $q \in D$, $\mathsf{prod}_{\mathsf{J},D}^{x[1:i]u}(q) \sqsubseteq \mathfrak{out}\ \mathsf{max\text{-}lag}\ \theta^\omega$;
   g. for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$ not close, let $J_n := \mathsf{pre}_{\mathsf{J},\mathsf{C}}^{x[1:i]}(C_n) \subseteq \mathsf{J}$. Then $J_n, x[1{:}i], C_n$ is an initial step, which can be decomposed as an initial step $J_n, x[1{:}j], E$ and a step $E, x[j{+}1{:}i], C_n$ such that $|\mathsf{max\text{-}adv}_{J_n,E}^{x[1:j]}| \geqslant 4\Omega!$.

5 Description of the 1-bounded dSST for Subsection 4.2

In this section, we finally describe how the dSST $\mathcal{S}$ can preserve the invariants of Subsection 4.2, while being 1-bounded and outputting $f(x)$ when $x \in \mathsf{Dom}(f)$.

Let us first deal with the initialization of $\mathcal{S}$. When reading the first letter C_0^x of $g(x)$, $\mathcal{S}$ stores $\mathsf{J} \leftarrow C_0^x$, $\mathsf{C} \leftarrow C_0^x$ and $\mathsf{lag}(q) \leftarrow \varepsilon$ for all $q \in C_0^x$. This is enough if C_0^x is not separable. Otherwise, we let θ be given by Lemma 4.13 (applied to the initial simulation $C_0^x, \varepsilon, C_0^x$), $\mathsf{nb}_\pi(q) \leftarrow 0$ and $\mathfrak{out}_\pi \leftarrow \varepsilon$ for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(C_0^x)$ and all $q \in C_n$.

▷ Claim 5.1. Invariants 1 to 4 (with $i = 0$) hold after this operation.

Assume now that the invariants hold for some $x \in \mathsf{Dom}(f)$ and $i \geqslant 0$. We describe how $\mathcal{S}$ updates its information when it reads $x[i{+}1]C_{i+1}^x$. Let $a := x[i{+}1]$.

5.1 If C_i^x was not separable

In this case $\mathcal{S}$ was in the non-separable mode. We update $\mathsf{pre} \leftarrow \mathsf{pre} \circ \mathsf{pre}^a_{C_i^x, C_{i+1}^x}$, $\mathsf{C} \leftarrow C_{i+1}^x$ and $\mathsf{J} \leftarrow \mathsf{pre}(\mathsf{C})$. Since C_i^x, a, C_{i+1}^x was a pre-step, then $\mathsf{J}, x[1{:}i{+}1], \mathsf{C}$ is an initial step. For all $q \in C_{i+1}^x$, let $\delta_q := \mathsf{lag}(\mathsf{pre}^a_{C_i^x, C_{i+1}^x}(q))\, \mathsf{prod}^a_{C_i^x, C_{i+1}^x}(q)$. Now let $c := \bigwedge_{q \in Q} \delta_q$, we update $\mathfrak{out} \leftarrow \mathfrak{out}\, c$ and define $\alpha_q := c^{-1}\delta_q$ for all $q \in \mathsf{C}$. It is easy to see that:

▷ Claim 5.2. $\mathfrak{out} = \mathsf{com}_{\mathsf{J},\mathsf{C}}^{x[1:i+1]}$ and $\alpha_q = \mathsf{adv}_{\mathsf{J},\mathsf{C}}^{x[1:i+1]}(q)$ for all $q \in \mathsf{C}$.

Finally we discuss two cases depending on the separability of $\mathsf{C} = C_{i+1}^x$:

- if C is not separable, then $\mathcal{S}$ stays in non-separable mode and it updates $\mathsf{lag}(q) \leftarrow \alpha_q$ for all $q \in \mathsf{C}$ (note that $|\alpha_q| \leqslant \Omega \leqslant 3\Omega$). We easily see that invariants 1, 2 and 3 hold.
- if C is separable, $\mathcal{S}$ goes to separable mode. By applying Lemma 4.13 to $\mathsf{J}, x[1{:}i{+}1], \mathsf{C}$ we get $\tau \in B^*$ with $k := |\tau| \leqslant 3\Omega$. We update $\mathsf{lag}(q) \leftarrow \alpha_q[1{:}k]$ and $\mathsf{last}(q) \leftarrow \alpha_q[k{+}1{:}]$ for all $q \in \mathsf{C}$. The θ is given by Lemma 4.13, and we let $\mathsf{nb}_\pi(q) \leftarrow 0$ and $\mathfrak{out}_\pi \leftarrow \varepsilon$ for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$ (except for $\mathfrak{out}_\pi = \mathfrak{out}$ when $\pi = \mathsf{C} = C_{i+1}^x$) and all $q \in C_n$.

  ▶ **Lemma 5.3.** *Invariants 1, 2 and 4 hold in $i{+}1$ after this operation. Furthermore $|\theta| = \Omega!$, $|\mathsf{lag}(q)| \leqslant 3\Omega$ for all $q \in \mathsf{C}$, and for all $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$, $\mathsf{nb}_\pi = 0$.*

  Note that we may have $|\mathsf{last}(q)| \geqslant \Omega!$. In order to reduce their sizes, we apply the tool detailed in Subsection 5.2 (it will push the $\mathsf{last}(q)$ into the $\mathsf{nb}_\pi(q)$ and $\mathfrak{out}_\pi$).

5.2 Toolbox: reducing the size of $\mathsf{last}(q)$

In this subsection, we assume that $\mathcal{S}$ is in its separable mode and that invariants 2 and 4 hold in some $i \geqslant 0$. Furthermore, we suppose that $|\theta| = \Omega!$, $|\mathsf{lag}(q)| \leqslant 3\Omega$ for all $q \in \mathsf{C}$, and for all $C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$, $\mathsf{nb}_{C_1 \cdots C_n} : C_n \to [0{:}4]$. However last may be longer than it should.

From invariant 4c, there exists $n : \mathsf{C} \to \mathbb{N}$ such that $\mathsf{last}(q) = \theta^{n(q)}\delta_q$ with $\delta_q \sqsubset \theta$ for all $q \in \mathsf{C}$. We update $\mathsf{last}(q) \leftarrow \delta_q$ and $\mathsf{nb}_\mathsf{C}(q) \leftarrow \mathsf{nb}_\mathsf{C}(q) + n(q)$ for all $q \in \mathsf{C}$. Now, we have $|\mathsf{last}(q)| < \Omega!$ and $\mathsf{nb}_\pi(q) \leqslant 4$ when $\pi \neq \mathsf{C}$.

In order to reduce the value nb_C, we apply the function **down**(C) of Algorithm 1 which adds some θ in the $\mathfrak{out}_\pi$. Let us describe its base case informally. If $\mathsf{nb}_\mathsf{C}(q) > 0$ for all $q \in \mathsf{C}$, then no state is lagging by invariant 4d. Thus $\mathsf{lag}(q) = \mathsf{max\text{-}lag}$ for all $q \in \mathsf{C}$, and so $\mathsf{max\text{-}lag} = \varepsilon$ by invariant 4a. With the notations of invariant 4e (note that $\pi_1 = \mathsf{C}$), we get $\mathsf{prod}^{\mathsf{J},\mathsf{C}}_{x[1:i]}(q) = \mathfrak{out}\ \theta^{\mathsf{nb}_{\pi_1}(q)} \left(\prod_{i=2}^n \mathfrak{out}_{\pi_i}\, \theta^{\mathsf{nb}_{\pi_i}(q)}\right) \mathsf{last}(q)$ for all $q \in \mathsf{C}$. Thus we can produce in $\mathfrak{out}$ the value $\theta^m := \bigwedge_{q \in \mathsf{C}} \theta^{\mathsf{nb}_\mathsf{C}(q)}$ (i.e. $m \leftarrow \min_{q \in \mathsf{C}} \mathsf{nb}_\mathsf{C}(q)$) and remove m to each $\mathsf{nb}_\mathsf{C}(q)$.

Algorithm 1 Sending down values in $\mathsf{tree}(\mathsf{C})$.

```
Function down($\pi$)
    $C_1 \cdots C_n \leftarrow \pi$;
    /* 1.  Add the common part of the buffers to the local output      */
    $m \leftarrow \min_{q \in C_n} \mathsf{nb}_\pi(q)$;
    $\mathfrak{out}_\pi \leftarrow \mathfrak{out}_\pi\, \theta^m$;
    $\mathsf{nb}_\pi(q) \leftarrow \mathsf{nb}_\pi(q) - m$  for all  $q \in C'$;
    /* 2.  Check if some buffers $\mathsf{nb}_\pi(q)$ are still more than $4$      */
    for $q \in C_n$ do
        if $\mathsf{nb}_\pi(q) > 4$ then
            for $C' \in \mathsf{Comp}(C_n)$ such that $C' \neq C_n$ and $q \in C'$ do
                $\mathsf{nb}_{\pi C'}(q) \leftarrow \mathsf{nb}_{\pi C'}(q) + (\mathsf{nb}_\pi(q) - 4)$;
            end
            $\mathsf{nb}_\pi(q) \leftarrow 4$;
        end
    end
    /* 3.  Recursive calls                                              */
    for $C' \in \mathsf{Comp}(C_n)$ with $C' \neq C_n$ do
        down($\pi C'$);
    end
```

▶ **Lemma 5.4.** *Algorithm 1 is well defined. After the operation described in this subsection, invariants 2 and 4 hold, and furthermore we have* $|\theta| = \Omega!$, $|\mathsf{lag}(q)| \leqslant 3\Omega$ *and* $|\mathsf{last}(q)| < \Omega!$ *for all* $q \in \mathsf{C}$, *and for all* $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$, $\mathsf{nb}_\pi : C_n \to [0{:}4]$.

5.3 If C_i^x was separable

If C_i^x is separable, then $\mathcal{S}$ was in the separable mode by invariant 4. We first explain in Subsubsection 5.3.1 how to perform the update when C, a, C_{i+1}^x is a step (it corresponds to the "easy case" thanks to invariant 4f which deals with future steps). Then, we explain in Subsubsection 5.3.2 how the other case can be reduced to the first one, after a preprocessing which selects a subset $C' \subseteq \mathsf{C}$ such that C', a, C_{i+1}^x is a step.

5.3.1 Updating when C, a, C_{i+1}^x is a step

In the current subsubsection we assume that invariants 2 and 4 hold, that $\mathsf{C} \subsetneq C_i^x$ is separable, and that C, a, C_{i+1}^x is a step. We show how to update the information stored by $\mathcal{S}$ in accordance with this step. Note that C_{i+1}^x is necessarily separable.

Since C will be modified, so will be $\mathsf{tree}(\mathsf{C})$, hence we begin with several register updates. For $\pi = D_1 \cdots D_n \in \mathsf{tree}(C_{i+1}^x)$, we define $C_i := \mathsf{pre}^a_{\mathsf{C}, C_{i+1}^x}(D_i)$ for $1 \leqslant i \leqslant n$. Since we had a step then $C_1 = \mathsf{C}$, $C_i \in \mathsf{Comp}(\mathsf{C})$ and $C_1 \supseteq \cdots \supseteq C_n$. But we may not have $C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$ due to possible equalities. Let $1 = i_1 < \cdots < i_m \leqslant n$ be such that $C_{i_1} = \cdots = C_{i_2 - 1} \supset C_{i_2}$ and so on until $C_{i_m - 1} \supset C_{i_m} = \cdots = C_n$. Then $\rho := C_{i_1} \cdots C_{i_m} \in \mathsf{tree}(\mathsf{C})$ and:

- if $i_m = n$, we let $\mathsf{nb}_\pi \leftarrow \mathsf{nb}_\rho \circ \mathsf{pre}^a_{\mathsf{C}, C_{i+1}^x}$ and $\mathfrak{out}_\pi \leftarrow \mathfrak{out}_\rho$;
- if $i_m < n$, we let $\mathsf{nb}_\pi \leftarrow 0$ and $\mathfrak{out}_\pi \leftarrow \varepsilon$.

For all $q \in C_{i+1}^x$, let $k_q := |\mathsf{lag}(\mathsf{pre}^a_{\mathsf{C}, C_{i+1}^x}(q))^{-1}\, \mathsf{max\text{-}lag}\,|$ and:

- $\mathsf{lag}(q) \leftarrow \mathsf{lag}(\mathsf{pre}^a_{\mathsf{C}, C_{i+1}^x}(q))(\mathsf{prod}^a_{\mathsf{C}, C_{i+1}^x}(q)[1{:}k_q])$ (note that $\mathsf{max\text{-}lag}$ remains unchanged);
- $\mathsf{last}(q) \leftarrow \mathsf{last}(\mathsf{pre}^a_{\mathsf{C}, C_{i+1}^x}(q))(\mathsf{prod}^a_{\mathsf{C}, C_{i+1}^x}(q)[k_q{+}1{:}])$.

Now let $c := \bigwedge_{q \in \mathsf{C}} \mathsf{lag}(q)$. We update $\mathsf{lag}(q) \leftarrow c^{-1}\,\mathsf{lag}(q)$ for all $q \in \mathsf{C}$ (therefore $\mathsf{max\text{-}lag}$ becomes $c^{-1}\,\mathsf{max\text{-}lag}$), $\mathfrak{out} \leftarrow \mathfrak{out}\ \ c$, $\mathsf{C} \leftarrow C^x_{i+1}$ and finally $\mathsf{pre} \leftarrow \mathsf{pre} \circ \mathsf{pre}^a_{\mathsf{C},C^x_{i+1}}$.

▶ **Lemma 5.5.** *After the operation described in this subsection, invariants 1, 2 and 4 hold, and* $|\theta| = \Omega!$, $|\,\mathsf{lag}(q)| \leqslant \Omega$ *for all* $q \in \mathsf{C}$, *and* $\mathsf{nb}_\pi : C_n \to [0{:}4]$ *for all* $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$.

However, we may have $|\,\mathsf{last}(q)| \geqslant \Omega!$. Thus we finally apply Subsection 5.2 once more.

5.3.2 Preprocessing when C, a, C^x_{i+1} is not a step

In the current subsubsection we assume that invariants 1, 2 and 4 hold in $i \geqslant 0$, that $\mathsf{C} = C^x_i$ is separable, and that C^x_i, a, C^x_{i+1} is *not* a step. Then let $C' := \mathsf{pre}^a_{C^x_i,C^x_{i+1}}(C^x_{i+1}) \subset \mathsf{C}$ (an equality would give a step) and $\pi := \mathsf{C}\,C' \in \mathsf{tree}(C)$. Two cases can occur.

If π is close. In this case, we have for all $\pi \sqsubset \pi' \in \mathsf{tree}(\mathsf{C})$ that $\mathsf{nb}_{\pi'} = 0$ and $\mathfrak{out}_{\pi'} = \varepsilon$. Therefore by invariant 4e we can describe the productions for all $q \in C'$ as follows:

- $\mathsf{prod}^{\mathsf{J},\mathsf{C}}_{x[1:i]}(q) = \mathfrak{out}\ \ \mathsf{lag}(q)$ if q is lagging;
- $\mathsf{prod}^{\mathsf{J},\mathsf{C}}_{x[1:i]}(q) = \mathfrak{out}\ \ \mathsf{max\text{-}lag}\ \ \mathfrak{out}_{\mathsf{C}\,C'}\ \ \theta^{\mathsf{nb}_\mathsf{C}(q)+\mathsf{nb}_{\mathsf{C}\,C'}(q)}\ \ \mathsf{last}(q)$ if q is not lagging.

Now two cases are possible, depending on whether there is a lagging state in C' or not:

- if there exists $q' \in C'$ which is lagging, then we must have $\mathfrak{out}_{\mathsf{C}\,C'} = \varepsilon$ by invariant 4d. For all $q \in C'$ let $\delta_q := \mathsf{lag}(q)\theta^{\mathsf{nb}_\mathsf{C}(q)+\mathsf{nb}_{\mathsf{C}\,C'}(q)}\ \ \mathsf{last}(q)$ and let $c := \bigwedge_{q \in C'} \delta_q$. Then we update $\mathfrak{out} \leftarrow \mathfrak{out}\ \ c$ and define $\alpha_q := c^{-1}\delta_q$ for all $q \in C'$;
- if each $q \in C'$ is not lagging, we define $\delta_q := \theta^{\mathsf{nb}_\mathsf{C}(q)+\mathsf{nb}_{\mathsf{C}\,C'}(q)}\,\mathsf{last}(q)$ and $c := \bigwedge_{q \in C'} \delta_q$. Then we update $\mathfrak{out} \leftarrow \mathfrak{out}\ \ \mathsf{max\text{-}lag}\ \ \mathfrak{out}_{\mathsf{C}\,C'}\ \ c$ and define $\alpha_q := c^{-1}\delta_q$ for all $q \in C'$;

We finally update $\mathsf{J} \leftarrow \mathsf{pre}(C')$, $\mathsf{C} \leftarrow C'$ and $\mathsf{pre} \leftarrow \mathsf{pre}|_{C'}$. It is easy to see that $\mathsf{J}, x[1{:}i], \mathsf{C}$ is a step and furthermore that we have computed com and adv.

▷ Claim 5.6. $\mathfrak{out} = \mathsf{com}^{x[1:i+1]}_{\mathsf{J},\mathsf{C}}$ and $\alpha_q = \mathsf{adv}^{x[1:i+1]}_{\mathsf{J},\mathsf{C}}(q)$ for all $q \in \mathsf{C}$.

This result exactly corresponds to Claim 5.2 from Subsection 5.1 (replace $i{+}1$ by i). Thus, to conclude, we just need to apply the operations described after Claim 5.2.

If π is not close. Let $c := \bigwedge_{q \in C'} \mathsf{lag}(q)$, we update $\mathfrak{out} \leftarrow \mathfrak{out}\ \ c\ \ \mathfrak{out}_{\mathsf{C}\,C'}$ and for all $q \in C'$, $\mathsf{lag}(q) \leftarrow c^{-1}\,\mathsf{lag}(q)$ and $\mathsf{last}(q) \leftarrow \theta^{\mathsf{nb}_\mathsf{C}(q)}\,\mathsf{last}(q)$. Then, we update $\mathsf{nb}_{C'\pi} \leftarrow \mathsf{nb}_{\mathsf{C}\,C'\pi}$ and $\mathfrak{out}_{C'\pi} \leftarrow \mathfrak{out}_{\mathsf{C}\,C'\pi}$ for all $\pi \in (C')^{-1}\,\mathsf{tree}(C')$ (except for $\pi = \varepsilon$, in which case we have already updated $\mathfrak{out}_{C'} = \mathfrak{out}$ before). We finally update $\mathsf{J} \leftarrow \mathsf{pre}(C')$, $\mathsf{C} \leftarrow C'$ and $\mathsf{pre} \leftarrow \mathsf{pre}|_{C'}$.

▶ **Lemma 5.7.** *After the operation described in this subsection, invariants 2 and 4 hold, and* $|\theta| = \Omega!$, $|\,\mathsf{lag}(q)| \leqslant \Omega$ *for all* $q \in \mathsf{C}$, *and* $\mathsf{nb}_\pi : C_n \to [0{:}4]$ *for all* $\pi = C_1 \cdots C_n \in \mathsf{tree}(\mathsf{C})$. *Furthermore* C *is separable.*

▶ Remark 5.8. Contrary to the former cases, the main difficulty here is to show the preservation of invariant 4f. For this we essentially rely on invariant 4g and show that θ is still suitable.

Again, we may have $|\,\mathsf{last}(q)| \geqslant \Omega!$. Thus we finally apply Subsection 5.2 once more.

5.4 Boundedness and productivity of the construction

We first claim that $\mathcal{S}$ is a 1-bounded dSST, by construction.

▶ **Lemma 5.9.** *The* dSST $\mathcal{S}$ *is* 1*-bounded.*

It follows from invariants 1, 2 and 4e that for all $x \in \mathsf{Dom}(f)$, $\mathfrak{out}$ is always a prefix of $f(x)$ when $\mathcal{S}$ reads $g(x)$. To conclude the construction of $\mathcal{S}$, it remains to see that $\mathfrak{out}$ tends to an infinite word. The key ideas for showing Lemma 5.10 is to use the fact that $\mathcal{T}$ is productive, and that Algorithm 1 can only empty a buffer $\mathsf{nb}_{\mathsf{C}}(q)$ if it outputs a word.

▶ **Lemma 5.10.** *If $x \in \mathsf{Dom}(f)$, then $|\mathfrak{out}| \to \infty$ when $\mathcal{S}$ reads $g(x)$.*

6 Outlook

This paper provides a solution to an open problem. From a practical point of view, it allows to build a copyless streaming algorithm from a rational specification whenever it is possible (it is impossible when the rational function is not continuous). We conjecture that the techniques introduced in this paper can be extended to show that any continuous *regular* function is deterministic regular. Furthermore, they may also be used to study the rational or regular functions which are uniformly continuous for the Cantor topology, and capture them with a specific transducer model (another open problem of [5]).

Abstract

In this paper we study the kernelization of the d-Path Vertex Cover (d-PVC) problem. Given a graph G, the problem requires finding whether there exists a set of at most k vertices whose removal from G results in a graph that does not contain a path (not necessarily induced) with d vertices. It is known that d-PVC is NP-complete for $d \geq 2$. Since the problem generalizes to d-Hitting Set, it is known to admit a kernel with $\mathcal{O}(dk^d)$ edges. We improve on this by giving better kernels. Specifically, we give kernels with $\mathcal{O}(k^2)$ vertices and edges for the cases when $d = 4$ and $d = 5$. Further, we give a kernel with $\mathcal{O}(k^4 d^{2d+9})$ vertices and edges for general d.

1 Introduction

Vertex deletion problems have been studied extensively in graph theory. These problems require finding a subset of vertices whose deletion results in a graph that belongs to some desired class of graphs. One such problem is path covering. Given a graph $G = (V, E)$, the d-Path Vertex Cover problem (d-PVC) asks to compute a subset $S \subseteq V$ of vertices such that the graph resulting from removal of S does not contain a path on d vertices. Here the path need not necessarily be induced. The problem was first introduced by Brešar et al. [1]. It is known to be NP-complete for any $d \geq 2$ due to the meta-theorem of Lewis and Yannakakis [21]. The 2-PVC problem is the same as the well known Vertex Cover problem. The 3-PVC problem is also known as Maximum Dissociation Set or Bounded Degree-One Deletion. The d-PVC problem is motivated by the field of designing secure wireless communication protocols [22] or in route planning and speeding up of shortest path queries [18].

With respect to exact algorithms, several efficient (better than brute force enumeration) algorithms are known for 2-PVC and 3-PVC. In particular, 2-PVC (Vertex Cover) can be solved in $\mathcal{O}(1.1996^n)$ time and polynomial space due to Xiao and Nagamochi [33], while 3-PVC can be solved in $\mathcal{O}(1.4613^n)$ time and polynomial space due to Chang et al. [6] or in $\mathcal{O}(1.3659^n)$ time and exponential space due to Xiao and Kou [31].

From the approximation point of view, it is known due to Brešar et al. [1] that d-PVC, for $d > 2$, cannot be r-approximated within a factor of $r = 1.3606$ in polynomial time, unless P=NP. A greedy d-approximation algorithm for d-PVC can be employed by repeatedly finding a d-path and putting its vertices into the solution. Due to Fomin et al. [17], we can find an arbitrary d-path in $\mathcal{O}(2.619^d dn \log n)$ time, and therefore the approximation algorithm runs in $\mathcal{O}(n^2 \log n)$ time in the size of the input. While the algorithms of Zehavi [34] and Tsur [25], with running times $\mathcal{O}^*(2.597^d)$ and $\mathcal{O}^*(2.554^d)$,[1] respectively, can be faster for large d, their running time factor polynomial in input size is much worse than $\mathcal{O}(n \log n)$. Lee [20] gave a $\mathcal{O}(\log d)$-approximation algorithm which runs in $\mathcal{O}^*(2^{\mathcal{O}(d^3 \log d)})$ time. For 3-PVC a 2-approximation algorithm was given by Tu and Zhou [30] and for 4-PVC a 3-approximation algorithm is known due to Camby et al. [2].

When parameterized by the size of the solution k, d-PVC is directly solvable by a trivial FPT algorithm for d-Hitting Set, that runs in $\mathcal{O}^*(d^k)$ time. However, since d-PVC is a restricted case of d-Hitting Set, it is known due to Fomin et al. [15] that for $d \geq 4$ d-PVC can be solved in $\mathcal{O}^*((d - 0.9245)^k)$ time and for $d \geq 6$ algorithms with even better running times are known due to Fernau [14]. Namely the running times are $\mathcal{O}^*((d - 1 + c_d)^k)$, where c_d is a small positive constant which monotonically approaches 0 as d goes to ∞. There has been considerable study for the case when d is a small constant. For the 2-PVC (Vertex Cover) problem, current best known algorithm due to Chen, Kanj, and Xia [7] runs in time $\mathcal{O}^*(1.2738^k)$. For 3-PVC, the current best known algorithm due to Tsur [27] runs in $\mathcal{O}^*(1.713^k)$ time. For the 4-PVC problem, Tsur [28] gave the current best algorithm that runs in $\mathcal{O}^*(2.619^k)$ time. In previous work [3, 4], a subset of authors developed an $\mathcal{O}^*(4^k)$ algorithm for 5-PVC. For $d = 5$, 6, and 7 Tsur [26] claimed algorithms for d-PVC with running times $\mathcal{O}^*(3.945^k)$, $\mathcal{O}^*(4.947^k)$, and $\mathcal{O}^*(5.951^k)$, respectively. A subset of authors used a computer to generate even faster algorithms for $3 \leq d \leq 8$ [5].

In this paper, we are interested in kernels for the d-PVC problem. Since an instance of d-PVC can be formulated as an instance of d-Hitting Set, by using the results of Fafianie and Kratsch [13] we immediately get a kernel for d-PVC with at most $d(k+1)^d$ vertices and at most $(d-1)(k+1)^d$ edges by keeping only the vertices and edges that are contained in the corresponding sets of the reduced d-Hitting Set instance.

Regarding the lower bounds for kernels of d-PVC, Dell and Melkebeek [10] have shown that for Vertex Cover it is not possible to achieve a kernel with $\mathcal{O}(k^{2-\varepsilon})$ edges unless coNP is in NP/poly (which would imply a collapse of the polynomial hierarchy). This result extends to d-PVC for any $d \geq 2$. Therefore, kernels with $\mathcal{O}(k^2)$ edges for d-PVC are the best we can hope for.

The current best kernels known are a kernel for Vertex Cover with $2k - c \log k$ vertices for any fixed constant c due to Lampis [19] and a kernel with $5k$ vertices for 3-PVC due to Xiao and Kou [32]. No specific kernels are known for d-PVC with $d \geq 4$, except for those inherited from d-Hitting Set.

Dell and Marx [9] recently studied kernels for the related d-Path Packing problem, which also inspired our work.

[1] The $\mathcal{O}^*()$ notation suppresses all factors polynomial in the input size.

Our contribution

We give kernels with $\mathcal{O}(k^2)$ edges for 4-PVC and 5-PVC (asymptotically optimal, unless coNP $\subseteq$ NP/poly). Furthermore, for the general case, we give a kernel for d-PVC for any $d \geq 6$ with $\mathcal{O}(k^4 d^{2d+9})$ edges.

2 Preliminaries

We use the notations related to parameterized complexity as described by Cygan et al. [8]. We consider simple and undirected graphs unless otherwise stated. For a graph G, we use $V(G)$ to denote the vertex set of G and $E(G)$ to denote the edge set of G. By $G[X]$ we denote the subgraph of G induced by vertices of $X \subseteq V(G)$. By $N(v)$ we denote the set of neighbors of $v \in V(G)$ in G. Analogically, $N(X) = \bigcup_{x \in X} N(x) \setminus X$ denotes the set of neighbors of vertices in $X \subseteq V(G)$. The degree of vertex v is denoted by $\deg(v) = |N(v)|$. For simplicity, we write $G \setminus v$ for $v \in V(G)$ and $G \setminus X$ for $X \subseteq V(G)$ as shorthands for $G[V(G) \setminus \{v\}]$ and $G[V(G) \setminus X]$, respectively.

A *d-path* (also denoted by P_d), denoted as an ordered d-tuple $(p_1, p_2, \ldots, p_d)$, is a path on d vertices $\{p_1, p_2, \ldots, p_d\}$. A *$d$-path free* graph is a graph that does not contain a d-path as a subgraph (the d-path needs not to be induced). The *length* of a path P is the number of edges in P, in particular, the length of a d-path P_d is $d-1$.

The d-PATH VERTEX COVER problem is formally defined as follows:

d-PATH VERTEX COVER, d-PVC	
INPUT:	A graph $G = (V, E)$, a non-negative integer k.
OUTPUT:	A set $S \subseteq V$, such that $\lvert S \rvert \leq k$ and $G \setminus S$ is a P_d-free graph.

A d-path packing $\mathcal{P}$ of size l in a graph G is a collection of l vertex disjoint d-paths in the graph G. We use $V(\mathcal{P})$ to denote the union of the vertex sets of the d-paths in the packing $\mathcal{P}$. For rest of the graph theory notations we refer to Diestel [11].

For a positive integer i, we will use $[i]$ to denote the set $\{1, 2, \ldots, i\}$.

▶ **Proposition 1** ($\star$). *For a given graph G and an integer k, there is an algorithm which either correctly answers whether G has a d-path vertex cover of size at most k, or finds an inclusion-wise maximal d-path packing $\mathcal{P}$ of size at most k in $\mathcal{O}(2.619^d dkn \log n)$ time.*

3 General Reduction Rules

Let us start with reduction rules that apply to d-PVC for most values of d. Assume that we are working with an instance $(G = (V, E), k)$ of d-PVC for some $d \geq 4$. We start with a reduction rule whose correctness is immediate.

▶ **Reduction Rule 1.** *If there is a connected component C in G which does not contain a P_d, then remove C.*

The next rule allows us to get rid of multiple degree-one vertices adjacent to a single vertex.

▶ **Reduction Rule 2** ($\star$). *Let there be three distinct vertices $v, x, y \in V$ such that $N(x) = N(y) = \{v\}$. We reduce the instance by deleting the vertex x.*

4 High Degree Reduction Rule for 4-PVC and 5-PVC

In this section, we are going to introduce the reduction rules which are applicable to both 4-PVC and 5-PVC instances. We assume that we are working with a d-PVC instance $(G = (V, E), k)$ for $d \in \{4, 5\}$ which is reduced by exhaustively employing Reduction Rule 2.

Our aim is to show that the degree of each vertex can be reduced to linear in the parameter. First assume that there is a large matching in the neighborhood of some vertex v. We call a matching $\mathcal{M}$ in G *adjacent* to vertex v, if it is a matching in $G \setminus v$ and for each edge $\{a_i, b_i\} \in \mathcal{M}$ at least one of its vertices, say a_i, is adjacent to v in G.

▶ **Reduction Rule 3** (⋆). *If v is a vertex and $\mathcal{M}$ a matching adjacent to v of size $|\mathcal{M}| \geq k+2$, then delete v and decrease k by* 1.

To exhaustively apply Reduction Rule 3, we need to find for each $v \in V$ a largest matching adjacent to v. This can be done as follows. Let $A = N(v)$ and $B = N(A) \setminus \{v\}$. Let G_v be the graph obtained from $G[A \cup B]$ by removing edges with both endpoints in B. It is easy to observe, that each matching adjacent to v is also a matching in G_v and vice-versa. Hence, it suffices to find a largest matching in G_v, which can done in polynomial time [12].

Therefore, we further assume that the instance is reduced with respect to Reduction Rule 3. We fix a vertex v and find a largest matching $\mathcal{M}$ adjacent to it by the above algorithm. Let M be the set of vertices covered by matching $\mathcal{M}$ and $m = |\mathcal{M}|$. Since the instance is reduced, we know that $m \leq k + 1$. Let $X = N(v) \setminus M$. We refer the reader to the Figure 1 for overview of our setting.

▶ **Observation 2** (⋆). *For each $x \in X$ we have $N(x) \setminus \{v\} \subseteq M$.*

▶ **Observation 3** (⋆). *No two distinct vertices $x, y \in X$ are connected to the opposite endpoints of a single edge $\{a_i, b_i\}$ in $\mathcal{M}$.*

▶ **Observation 4** (⋆). *If there is a vertex $x \in X$ such that for some edge $\{a_i, b_i\}$ in the matching $\mathcal{M}$ we have that $\{a_i, b_i\} \subseteq N(x)$, then $N(\{a_i, b_i\}) \cap X = \{x\}$.*

We now partition the set X into three sets. Let X_2 be the set of vertices such that for each $x \in X_2$ we have some edge $\{a_i, b_i\}$ in the matching $\mathcal{M}$ such that $\{a_i, b_i\} \subseteq N(x)$. Let X_0 be the vertices such that for each $x \in X_0$ we have that $N(x) = \{v\}$. Note, that X_0 contains at most one vertex due to Reduction Rule 2 being exhaustively applied. Lastly, let $X_1 = X \setminus (X_2 \cup X_0)$ be the rest of the vertices in X. See Figure 1 for an illustration of the sets X_2, X_0, and X_1.

▶ **Observation 5** (⋆). *If the vertex v has degree at least $(d + 2)(k + 1) + 1$, then $|X_1| \geq (d - 1)(k + 1)$.*

Now we focus on the edges between X_1 and M. By Observation 3, for each edge $\{a_i, b_i\}$ in $\mathcal{M}$ we have that the vertices in X_1 may be adjacent to at most one vertex of such edge, i.e. $|\{a_i, b_i\} \cap N(X_1)| \leq 1$. Letting $M_1 = M \cap N(X_1)$ we have $|M_1| \leq k + 1$.

We are now ready to employ the Expansion Lemma. We use the version of Fomin et al. [16], which is a generalization of the original results by Prieto [23, Corollary 8.1] and Thomassé [24, Theorem 2.3].

▶ **Definition 6.** *Let G be a bipartite graph with vertex bipartition (A, B). A set of edges $Q \subseteq E(G)$ is called a q-expansion, $q \geq 1$, of A into B if every vertex of A is incident with exactly q edges of Q, and Q saturates exactly $q|A|$ vertices in B.*

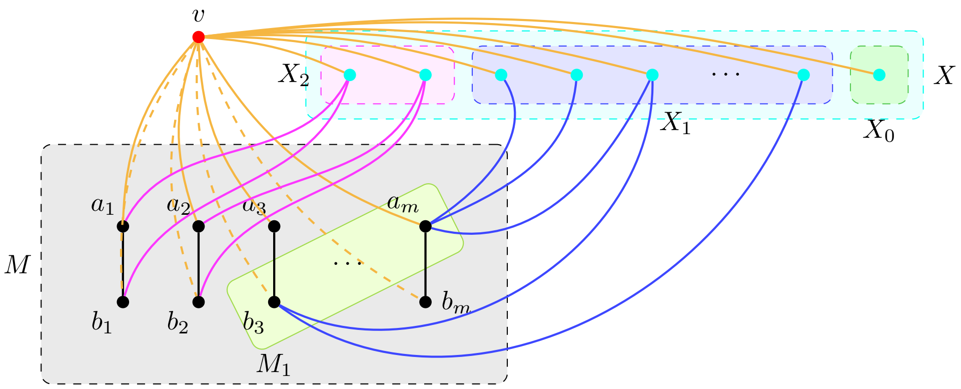

Figure 1 An overview of the definitions of sets X_0, X_1, X_2, and M_1.

▶ **Lemma 7** (Expansion Lemma; Fomin et al. [16]). *Let q be a positive integer, and G be a bipartite graph with bipartition (A, B) such that $|B| \geq q|A|$, and there are no isolated vertices in B. Then, there exists nonempty $A' \subseteq A$ and $B' \subseteq B$ such that A' has a q-expansion into B' and $N(B') \subseteq A'$. Moreover, the sets A', B' and the q-expansion can be found in polynomial time.*

▶ **Observation 8** ($\star$). *There exist non-empty subsets $M' \subseteq M_1$ and $X' \subseteq X_1$ such that there is a $(d-1)$-expansion Q' from M' into X' and $N(X') \subseteq M' \cup \{v\}$.*

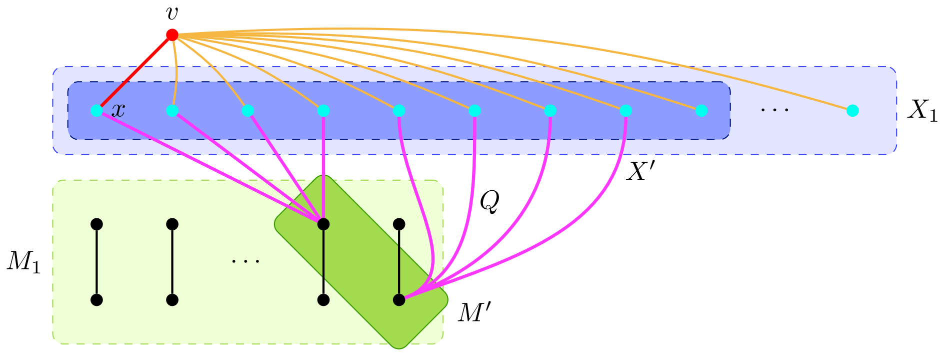

Figure 2 A graphical interpretation of applying the Expansion Lemma to our setting.

We refer the reader to Figure 2 for a graphical interpretation of the situation guaranteed by Observation 8. Now, let us focus on the sets M' and X' and the way they are connected with vertex v. We are going to show that some edge between v and X' is now redundant.

▶ **Reduction Rule 4.** *Let v be a vertex of degree at least $(d+2)(k+1)+1$. Let $\mathcal{M}$ be a largest matching adjacent to v and M be the set of vertices covered by $\mathcal{M}$. Let $X_1 \subseteq N(v) \setminus M$ be the set of vertices x with $N(x) \cap M \neq \emptyset$ and $|N(x) \cap \{a_i, b_i\}| \leq 1$ for each $\{a_i, b_i\} \in \mathcal{M}$. Let $M_1 = M \cap N(X_1)$. Let the non-empty subsets $M' \subseteq M_1$ and $X' \subseteq X_1$ be the sets with the $(d-1)$-expansion Q from M' into X' and such that $N(X') \subseteq M' \cup \{v\}$. Let $x \in X'$. Reduce the instance by deleting the edge $\{x, v\}$.*

Proof of Correctness. Let $(G = (V, E), k)$ be the original instance and $(G' = (V, E'), k)$ the reduced one. For each vertex $m \in M'$ let Q_m be the set of vertices of X' incident to m in the $(d-1)$-expansion Q. Since G' is a subgraph of G, if S is a solution for G, then S is also a solution for G'. Hence we will concetrate on the other direction.

Suppose that S' is a solution for the reduced instance. If it is also a solution for the original one, then we are done. Suppose it is not, i.e., there is a P_d in $G \setminus S'$. This P_d contains the edge $\{x, v\}$, otherwise it would be also present in $G' \setminus S'$. Therefore $v \notin S'$ and $x \notin S'$.

There are three ways how solution S' can interact with M' and X' that we need to address.

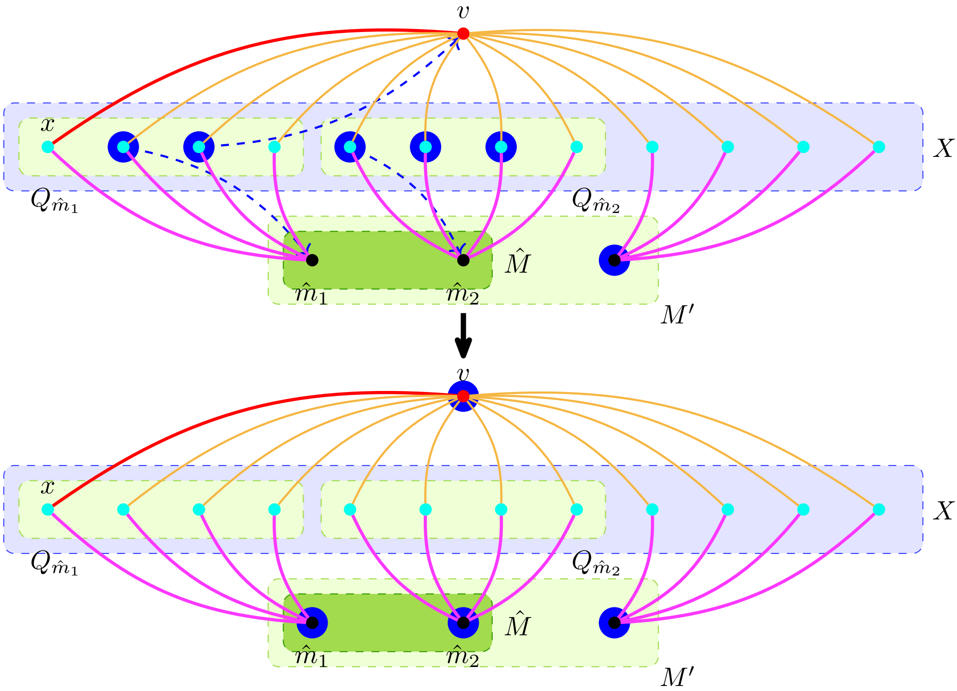

Figure 3 Illustration of the first part of the proof of correctness of Reduction Rule 4.

Firstly, suppose that $M' \nsubseteq S'$ and let $\widehat{M} = M' \setminus S'$. See Figure 3 for an illustration. We have that for each vertex $\widehat{m} \in \widehat{M}$ it must be that $|Q_{\widehat{m}} \cap S'| \geq 2$. Indeed, if this is not the case, there would be a P_d in $G' \setminus S'$ which uses the $(d-2)$ vertices of $Q_{\widehat{m}}$ not in S' and the vertices $\widehat{m}$ and v. Consider a set $S = (S' \cup \widehat{M} \cup \{v\}) \setminus \bigcup_{\widehat{m} \in \widehat{M}} Q_{\widehat{m}}$. Observe, that any P_d which uses some vertex from X' must contain at least one of the vertices in M' or v, because $N(X') \subseteq M' \cup \{v\}$. Therefore the set S is a solution for the reduced graph G' as it contains both M' and v. The set S is also a solution for G as it contains v and therefore covers any P_d which might use the deleted edge $\{x, v\}$. Finally, $|S| \leq |S'|$, because for each $\widehat{m}$ that we add into S, we remove at least two vertices of $Q_{\widehat{m}}$ from S and therefore we have that $|\widehat{M} \cup \{v\}| \leq 2|\widehat{M}| \leq |\bigcup_{\widehat{m} \in \widehat{M}} Q_{\widehat{m}}|$.

Secondly, assume that $M' \subseteq S'$ and there is some $x' \in X'$ such that $x' \in S'$. We construct the set $S = (S' \setminus X') \cup \{v\}$. Again, observe that S' is a solution for G' because any P_d which uses some vertex from X' must contain at least one of the vertices in M' or v and both are fully contained in S. We also have that S is a solution for G, again, as it contains v and therefore covers any P_d which might use the deleted edge $\{x, v\}$. Finally, $|S| \leq |S'|$, because we have the assumption that there is some $x' \in X'$ and $x' \in S'$.

Lastly, assume that $M' \subseteq S'$ and $X' \cap S' = \emptyset$. In this case, the P_d that we found in $G \setminus S'$ must be of the form $P = (x, v, u_3, \ldots, u_d)$ and $u_3, \ldots, u_d \notin (M' \cup X')$. The existence of such P_d also gives us that $v, u_3, \ldots, u_d \notin S'$. Let x' be an arbitrary vertex of $X' \setminus \{x\}$ (note that $|X'| \geq (d-1)|M'| \geq 3$). Then the P_d of the form $P' = (x', v, u_3, \ldots, u_d)$ can be found in both G and G', which contradicts the fact that S' is a solution in G'.

To sum up, we have shown that when we delete the edge $\{x, v\}$ from G, then for any solution S' for G' which is not also a solution for G, we can always find a new solution S, $|S| \leq |S'|$ which is a solution for both G' and G. ◀

As the application of the rule only requires finding a largest matching adjacent to v, classifying the vertices of $N(v)$, and finding a $(d-1)$-expansion and these tasks can be done in polynomial time, the rule can be applied in polynomial time.

5 4-PVC Kernel with Quadratic Number of Edges

Let $(G = (V, E), k)$ be an instance reduced by exhaustively employing Reduction Rules 1–4. Then the maximum degree in G is at most $(d + 2)(k + 1) = 6k + 6$. Furthermore, assume that the algorithm of Proposition 1 actually returned an inclusion-wise maximal packing $\mathcal{P}$ in G with at most k 4-paths instead of answering immediately. Let $P = V(\mathcal{P})$, and let $A = V \setminus P$. There are at most $4k$ vertices in P. Each connected component in $G[A]$ is a 4-path free graph, otherwise we would be able to increase the size of the packing $\mathcal{P}$. Since the instance is reduced with respect to Reduction Rule 1, each connected component in $G[A]$ is connected to P by at least one edge.

To show that an instance reduced with respect to all the above rules has a quadratic number of edges, it suffices to count separately the number of edges incident on P and the number of edges in $G[A]$. Since the maximum degree in G is at most $6k + 6$ and there are at most $4k$ vertices in P, there are at most $4k \cdot (6k + 6) = 24k^2 + 24k$ edges incident on P.

To count the edges in $G[A]$, we first observe that a connected 4-path free graph is either a triangle, or a star (possibly degenerate, i.e., with at most 3 vertices). Here a *q-star* is a graph with vertices $\{c, l_1, \ldots, l_q\}$, $q \geq 0$ and edges $\{\{c, l_i\} \mid i \in \{1, \ldots, q\}\}$. Vertex c is called *a center*, vertices $\{l_1, \ldots, l_q\}$ are called *leaves*. The term *star* will be used for a q-star with an arbitrary number of leaves. Note that, a graph with a single vertex is a 0-star, a graph with two vertices and a single edge is a 1-star, and a 3-path is a 2-star. A *triangle* is a cycle on three vertices.

Secondly, as the instance is reduced with respect to Reduction Rule 1, each connected component in $G[A]$ is connected to P by at least one edge. Therefore, there are at most $24k^2 + 24k$ connected components in $G[A]$, as there are only that many edges going from P to A. Next, we provide an observation about stars in $G[A]$.

▶ **Observation 9** (⋆). *For each q-star $(c, l_1, l_2, \ldots, l_q)$ in $G[A]$, there are at most two vertices in the q-star which are not connected to P by any edge in G, one possibly being the center c and the other possibly being a leaf l_i of the star.*

▶ **Observation 10** (⋆). *There are at most $72k^2 + 72k$ edges in $G[A]$.*

We conclude this section with the final statement about our kernel.

▶ **Theorem 11** (⋆). *4-Path Vertex Cover admits a kernel with $96k^2 + 96k$ edges, where k is the size of the solution.*

6 5-PVC Kernel with Quadratic Number of Edges

The idea is completely analogous to the previous section. We employ the following characterization.

A *star with a triangle* is formed by connecting two leaves of a star with an edge. A *bi-star* is formed by connecting the centers of two stars with an edge.

▶ **Lemma 12** (Červený and Suchý [3, Lemma 4]). *A connected 5-path free graph is either a graph on at most 4 vertices, a star with a triangle, or a bi-star.*

We conclude this section with the final statement about our kernel.

▶ **Theorem 13** ($\star$). *5-Path Vertex Cover admits a kernel with* $245k^2 + 245k$ *edges, where* k *is the size of the solution.*

7 d-PVC Kernel with $\mathcal{O}(k^4 d^{2d+9})$ Edges

In this section, we give a kernelization algorithm for d-PVC with $d \geq 6$.

An intuition behind the approach. The kernelization algorithm marks some vertices and edges, which it wants to keep, and throws away the rest. Essentially, the kernelization creates a subgraph $\widehat{G}$ of the input graph G. For correctness of the algorithm, we want to show that if there is a d-path P in G which misses some set of vertices S (a prospective solution), then we will also find some d-path P' in $\widehat{G}$, which also misses the set S.

We begin by finding a maximal packing $\mathcal{M}$ in G and we keep in $\widehat{G}$ all vertices M of the packing and all edges between them. Now, on one hand, if the path P would be completely contained in M, then trivially the path appears also in $\widehat{G}$. On the other hand, the path P cannot be completely outside of M. Thus, the path P crosses between M and outside of M at least once. This corresponds to vertices of M being connected by a path of prescribed length outside of M. We later formalize this as a "request".

To get more structure, we leverage the behavior of DFS trees of the connected components outside of M. With the DFS trees we identify vertices, which are "crucial" for the requests, and we further split the requests into "sub-requests" according to the "crucial" vertices.

The algorithm is inspired by Dell and Marx [9]. However, while the considered problems have similarities, many ideas are not translatable. In particular, they could afford to consider all "sub-requests" and keep $\Omega(k)$ vertices for each without affecting their bound (cf. [9, p. 23]). We had to be more careful in which "sub-requests" we consider and we need to employ Lemma 15 (below) to only keep $d^{\mathcal{O}(d)}$ vertices and edges for each such "sub-request" to achieve our precise bound. Also, to achieve the edge bound, we need to keep track of the purpose for which the individual vertices were marked, which makes it hard to split the algorithm into small self-contained steps.

Formal definitions. More formally, assume that we are given an instance $(G = (V, E), k)$ of d-PVC. We start by running the algorithm of Proposition 1 on the instance. If it answers directly, then we are done. Otherwise it returns a maximal packing $\mathcal{M}$ in G. Let M be the vertices of the packing $\mathcal{M}$. Recall that $|M| \leq dk$.

Let $G' = G \setminus M$, i.e., G' is the graph outside the packing $\mathcal{M}$. Label the connected components of G' as $G'_1, G'_2, \ldots, G'_t$. For each component G'_i pick an arbitrary vertex $r_i \in G'_i$ and compute a *depth-first search* tree T_i of G'_i rooted at r_i. Note that $V(T_i) = V(G'_i)$. Let $\mathcal{F}$ denote the forest consisting of all the trees $T_i, i \in [t]$. Note that $V(\mathcal{F}) = V(G')$.

For a rooted forest F and its vertex $v \in V(F)$, $\mathit{sub}(v)$ denotes the set of vertices of a maximal subtree of F rooted at v and $\mathit{anc}(v)$ the set of ancestors of v in F, i.e., $\mathit{anc}(v) = \{u \mid u \in V(F), v \in \mathit{sub}(u)\}$. Note that $v \in \mathit{anc}(v)$.

We provide the following observations regarding the DFS trees T_i and the forest $\mathcal{F}$.

▶ **Observation 14** ($\star$).

(a) *Each $y \in V(\mathcal{F})$ has at most $d-1$ ancestors.*

(b) *For two vertices $u, v \in V(\mathcal{F})$ which are not in ancestor-descendant relation, we have $sub(u) \cap sub(v) = \emptyset$ and $\{u, v\} \notin E(G)$.*

(c) *If C is a connected subgraph of G', then there is a vertex $w \in V(C)$ such that $V(C) \subseteq sub(w)$.*

A triple (f, l, X) is *an X-request*, if $l \in \{1, \dots, d-1\}$, $X \subseteq V(G)$, and either $f = \{u, v\} \subseteq X$, $u \neq v$, or $f = \{x\} \subseteq X$. For an X-request (f, l, X) and $H \subseteq V(G)$, we use $\mathcal{P}^H_{f,l}$ to denote the set of paths P of length l in $G[H \cup f]$ such that each $x \in f$ is an endpoint of P. In particular, if $f = \{u, v\}$, $u \neq v$, then u and v are the endpoints of P and if $f = \{x\}$, then one endpoint of P is x and the other can be any vertex of H. A set $H \subseteq V(G)$ is said to *satisfy an X-request* (f, l, X) if $\mathcal{P}^H_{f,l} \neq \emptyset$.

An M-request (f, l, M) will be simply denoted as $\varrho(f, l)$ and called *a request*.

In the next paragraphs we cover the notion of the "crucial" vertices mentioned in the earlier intuition. Roughly speaking, a vertex of F is "crucial" if the set of its descendants (vertices of its subtree) satisfies some request.

For each request $\varrho(f, l)$ we define the set $Y_{f,l} \subseteq V(\mathcal{F})$ as the set of all vertices $v \in V(\mathcal{F})$ such that $sub(v)$ satisfies the request $\varrho(f, l)$. Note that if $v \in Y_{f,l}$, then also $w \in Y_{f,l}$ for every $w \in anc(v)$, since $sub(w) \supseteq sub(v)$. Thus, if $Y_{f,l} \cap V(G'_i) \neq \emptyset$ for some i, then in particular $r_i \in Y_{f,l}$ and $Y_{f,l}$ induces a connected subtree of T_i. The request $\varrho(f, l)$ is *resolved* if the subforest $\mathcal{F}[Y_{f,l}]$ has at least $k + d + 1$ leaves.

Recall, that in the intuition we examined some d-path P in G. The resolved request basically ensures that there are at least $k + d + 1$ disjoint paths in G which satisfy said request. The idea is that the prospective solution may compromise at most k of these paths and the other parts of P may compromise at most d of these paths. As we will keep exactly $k + d + 1$ of these disjoint paths in $\widehat{G}$, we can be sure, that at least one of them will always be usable to reroute some part of P which will help us to find the desired path P' in $\widehat{G}$.

Now, we focus on the unresolved requests. Let $\mathcal{R}^*$ be the set of all requests $\varrho(f, l)$ which are *not* resolved and let $\mathcal{Y} = \bigcup_{\varrho(f,l) \in \mathcal{R}^*} Y_{f,l}$.

We are now getting to the notion of sub-requests. These have either one endpoint in M and the other in $\mathcal{Y}$, or both endpoints in $\mathcal{Y}$, or only one prescribed endpoint, which is in $\mathcal{Y}$. Note that if the two endpoint are in $\mathcal{Y}$, then, by Observation 14, either one of the endpoints is an ancestor of the other, or there is no path connecting them outside $(M \cup \mathcal{Y})$.

An $(M \cup \mathcal{Y})$-request $(g, j, M \cup \mathcal{Y})$ will be simply denoted as $\sigma(g, j)$ and called *a sub-request* if there exists $y \in \mathcal{Y}$ such that $y \in g$ and $g \subseteq M \cup anc(y)$. In particular, either $g = \{y\}$ or one of the vertices in g is y and the other vertex is in $M \cup anc(y)$.

Even though we will not formally define a *resolved sub-request*, later we will actually show that the sub-request is "resolved" if there are at least $2d$ paths satisfying it.

Description of the algorithm. We are now ready to describe the kernelization algorithm. As we mentioned earlier, the algorithm first marks some vertices and edges, which it wants to keep, and it deletes the rest of the graph. Therefore, the core of the algorithm is the marking procedure. In our case, the main procedure is called **Mark** which in turn uses a procedure called **Mark 2**. These procedures are described in Algorithm 1 and Algorithm 2, respectively.

Let us now give an insight into how the procedures **Mark** and **Mark 2** were constructed. We will start with **Mark**.

Algorithm 1 Marking procedure **Mark**.

```
1  Let $M$, $\mathcal{F}$, and $\mathcal{Y}$ be as in the text.
2  Mark all the vertices and edges in $G[M \cup \mathcal{Y}]$.
3  foreach resolved request $\varrho(f, l)$ do
4      Pick arbitrary $k + d + 1$ leaves $h_1, h_2, \ldots, h_{k+d+1}$ of $\mathcal{F}[Y_{f,l}]$.
5      foreach leaf $h_i$ do
6          Pick an arbitrary path $P$ from $\mathcal{P}_{f,l}^{sub(h_i)}$.
7          Mark the vertices and edges of $P$.
8  foreach $y \in \mathcal{Y}$ do
9      foreach sub-request $\sigma(g, j)$ such that $g \subseteq M \cup anc(y)$ and $g \not\subseteq M$ do
10         Let $C_1, C_2, \ldots, C_{q'}$ be the vertex sets of the connected components of
           $G \setminus (M \cup \mathcal{Y})$ such that for all $i \in [q']$, $N(C_i) \cap \mathcal{Y} \subseteq anc(y)$ and $C_i$ satisfies
           $\sigma(g, j)$.
11         if $q' \geq 2d$ then
12             foreach $i \in [2d]$ do
13                 Pick an arbitrary path $P \in \mathcal{P}_{g,j}^{C_i}$.
14                 Mark the vertices and edges of $P$.
15         else
16             foreach $i \in [q']$ do
17                 Run the marking procedure Mark 2 on $\Big(\sigma(g, j), C_i, \emptyset\Big)$.
```

Algorithm 2 Marking procedure **Mark 2**$\Big(\sigma(g, j), C_i, W\Big)$.

```
1  if $|W| \leq 2d$ and $\mathcal{P}_{g,j}^{C_i \setminus W} \neq \emptyset$ then
2      Let $P \in \mathcal{P}_{g,j}^{C_i \setminus W}$.
3      Mark all the edges and vertices of $P$.
4      foreach $v \in V(P) \setminus g$ do
5          $W' = W \cup \{v\}$
6          Call Mark 2 on $\Big(\sigma(g, j), C_i, W'\Big)$
```

The lines 3–7 deal with the resolved requests. Essentially, by preserving $k + d + 1$ corresponding paths for the request $\varrho(f, l)$, we retain all the necessary structure such that we do not create any new solutions in the reduced instance.

In the two following `for`-cycles, we first pick a vertex y of $\mathcal{Y}$. This fixes the set of ancestors $anc(y)$, i.e., it fixes the set of vertices on the path from y to the root of its tree in $\mathcal{F}$. And, for this particular y, we then pick a sub-request $\sigma(g, j)$ which lives on this fixed set $anc(y)$ and M. This allows us to look only at some components of $G \setminus (M \cup \mathcal{Y})$ and actually makes it possible for us to bound their number. The bounding happens on lines 11–14 and we can also say that the sub-request $\sigma(g, j)$ is resolved when the number of components is at least $2d$. The bound $2d$ follows from Lemma 15, which will be stated later. For a resolved sub-request we proceed similarly to resolved request. Namely, we preserve one corresponding path in each of some $2d$ of the components.

If the number of components is not large, the lines 15–17 run the second marking procedure **Mark 2** on each of these components and the aim is to bound their size.

Now, recall again, that in the intuition we examined some d-path P in G and some prospective solution S. The purpose of the marking procedure **Mark 2** is to brute-force all the possible ways of how the path P and solution S may compromise the paths which satisfy the sub-request $\sigma(g,j)$ and which are contained in the component C_i. The procedure works recursively, starts with the empty set of "compromising" vertices W and it always picks a path which was not yet compromised, marks it (so that it remains in $\widehat{G}$), and tries to compromise its vertices one by one. By doing it like this, we ensure, that all the important parts of C_i remain in $\widehat{G}$ no matter what parts of C_i were compromised.

And the main trick is that we can stop the recursion of **Mark 2** once the number of "compromising" vertices reaches $2d$. This number $2d$ again follows from Lemma 15.

Now, the kernelization can be formally summarized as follows. Run the marking procedure **Mark** on the instance (G,k). The marking results in two subsets $\widehat{V} \subseteq V(G)$ and $\widehat{E} \subseteq E(G)$ corresponding to marked vertices and edges by **Mark**. Reduce the instance (G,k) to the instance $(\widehat{G},k)$ where $\widehat{G} = (\widehat{V},\widehat{E})$.

With that we conclude the intuition and we continue with the formal proof of correctness. First, we state the crucial Lemma 15, then the main body of the proof follows in Lemma 16, and we finish with the proof of the size of the kernel in Lemma 17.

Lemma 15 roughly states that any reasonable solution only contains at most d vertices among each set of components considered on line 10 of Algorithm 1.

▶ **Lemma 15.** *Let (G,k) be an instance of d-PVC. Let $\widehat{G} = (\widehat{V},\widehat{E})$ be a subgraph of G such that $\widehat{V}$ and $\widehat{E}$ are the result of running the marking procedure **Mark** on (G,k). Let S' be a solution for the instance $(\widehat{G},k)$ of d-PVC. Let $y \in \mathcal{Y}$ and let $C_1, C_2, \dots, C_c$ be the vertex sets of the connected components of $\widehat{G} \setminus (M \cup \mathcal{Y})$ such that $N(C_i) \cap \mathcal{Y} \subseteq anc(y)$ for $i \in [c]$. Then $\widehat{S} = (S' \setminus \bigcup_{i\in[c]} C_i) \cup anc(y)$ is a solution for $\widehat{G}$.*

Proof. If $\widehat{S}$ is a solution for $(\widehat{G},k)$, we are done. Suppose to the contrary that it is not. Then there is a d-path P in $\widehat{G} \setminus \widehat{S}$. Assume that P is selected such that it contains the least number of vertices which are in S' i.e., $|V(P) \cap S'|$ is minimized among all d-paths in $\widehat{G} \setminus \widehat{S}$. As $S' \setminus \widehat{S} \subseteq \bigcup_{i\in[c]} C_i$, path P must contain at least one vertex from at least one set $C_i \cap S'$, because otherwise P would also be in $\widehat{G} \setminus S'$, which is a contradiction with S' being a solution for $(\widehat{G},k)$. Further, since $N(C_i) \subseteq (M \cup \mathcal{Y})$, $N(C_i) \cap \mathcal{Y} \subseteq anc(y)$, and $anc(y) \subseteq \widehat{S}$ by assumption, we have $N(C_i) \setminus \widehat{S} \subseteq M$. Therefore $P \cap M \neq \emptyset$, as otherwise the path P would be contained in C_i, which is a contradiction with $\mathcal{M}$ being a maximal packing of d-paths.

We split the path P into segments according to the vertices of M, i.e., a *segment* of P is a sub-path $(v_1, v_2, \dots, v_s)$ of P such that $v_2, v_3, \dots, v_{s-1} \in V(G) \setminus M$ and either $\{v_1, v_s\} \subseteq M$ (an inner segment), or one of v_1, v_s is in M, while the other is an endpoint of P (an outer segment). The argument is the same in both cases.

Let $P' = (v_1, v_2, \dots, v_s)$ be the segment of P which uses some vertex from $C_i \cap S'$. Observe, that the segment P' corresponds to request $\varrho(f,l) = \varrho(V(P') \cap M, s-1)$ as $2 \leq s \leq d$ and $|V(P') \cap M| \in \{1,2\}$. In particular, $V(P') \setminus M$ satisfies $\varrho(f,l)$.

We also know that $V(P') \cap \mathcal{Y} = \emptyset$, because $N(C_i) \setminus \widehat{S} \subseteq M$. With that we argue that the request $\varrho(f,l)$ must be resolved. Indeed, suppose it is not. By Observation 14(c) there is a vertex v in $V(P') \cap C_i$ such that that $V(P') \cap C_i \subseteq sub(v)$. But that implies that $sub(v)$ satisfies the request $\varrho(f,l)$ and, therefore, vertex v should have been included in $Y_{f,l}$ and, consequently, v should have been included in $\mathcal{Y}$, which is a contradiction with $V(P') \cap \mathcal{Y} = \emptyset$.

Now, as the request $\varrho(f,l)$ is resolved, the marking procedure **Mark** picked $k+d+1$ leaves $h_1, h_2, \dots, h_{k+d+1}$ from $\mathcal{F}[Y_{f,l}]$ and for each such leaf h_i it marked the vertices and edges of some path $P_i \in \mathcal{P}_{f,l}^{sub(h_i)}$. Therefore, these paths $P_1, P_2, \dots, P_{k+d+1}$ remained in $\widehat{G}$. Further, at least one of these paths is untouched by the vertices of S' and the vertices of P as $|S'| \leq k$ and $|V(P)| \leq d$, respectively. Let this one untouched path be P_i. Observe, that we can swap the segment P' with the path P_i in P to obtain a d-path P^*. But then the path P^* contains strictly fewer vertices which are in S' than P, which is a contradiction with the choice of P. ◀

Now we can prove the correctness of the algorithm.

▶ **Lemma 16** (⋆). *Let (G,k) be an instance of d-PVC. Let $\widehat{G} = (\widehat{V}, \widehat{E})$ be a subgraph of G such that $\widehat{V}$ and $\widehat{E}$ are obtained by running the marking procedure* ***Mark*** *on (G,k). Then, (G,k) is a YES instance if and only if $(\widehat{G},k)$ is a YES instance.*

Proof sketch. For the "if" direction we pick a solution S' to $\widehat{G}$ such that any application of Lemma 15 would increase its size. If S' was not a solution to G, then as in Lemma 15, we pick a special d-path P witnessing that, but this time with the least number of unmarked edges in G. Then we again split P into segments according to M and, in case the corresponding request was not resolved, further into sub-segments according to $\mathcal{Y}$. We always pick a (sub-)segment with at least one unmarked edge and we show that we can swap the (sub-)segment with some other suitable fully marked sub-path to obtain a contradiction with the choice of P. ◀

The following lemma shows the bound on the size of the kernel.

▶ **Lemma 17** (⋆). *Let (G,k) be an instance of d-PVC. Let $\widehat{G} = (\widehat{V}, \widehat{E})$ be a subgraph of G such that $\widehat{V}$ and $\widehat{E}$ are obtained by running the marking procedure* ***Mark*** *on (G,k). Then, $|\widehat{V}| = \mathcal{O}(k^4 d^{2d+9})$ and $|\widehat{E}| = \mathcal{O}(k^4 d^{2d+9})$.*

We summarize the result in the following theorem.

▶ **Theorem 18.** *d-Path Vertex Cover admits a kernel with $\mathcal{O}(k^4 d^{2d+9})$ vertices and edges, where k is the size of the solution.*

Proof. As the marking procedures **Mark** and **Mark 2** can by implemented in polynomial time, the theorem directly follows from Lemmas 16 and 17. ◀

8 Conclusion

We presented kernels with $\mathcal{O}(k^2)$ edges for 4-PVC and 5-PVC and with $\mathcal{O}(k^4 d^{2d+9})$ edges for d-PVC for any $d \geq 6$. An obvious open question is whether there is a kernel with $\mathcal{O}(k^2)$ edges for every $d \geq 6$.

Furthermore, the size of our kernel depends on d by a factor of $d^{\mathcal{O}(d)}$. We believe that this could be improved to $2^{\mathcal{O}(d)}$ with the use of representative sets. However, improving this to a factor polynomial in d would imply coNP $\subseteq$ NP/poly. As observed by Dell and Marx [9], running such a kernel with $k = 0$ would give a polynomial kernel for the d-Path problem, which would have the above mentioned implications.

Next, for 2-PVC and 3-PVC, there are kernels with linear number of vertices [19, 32]. Hence, another open question is whether such a kernel can be obtained also for say 4-PVC. Further interesting open questions can be found in the recent survey of Tu [29].

On Synthesizing Computable Skolem Functions for First Order Logic

Supratik Chakraborty

S. Akshay
Department of Computer Science and Engineering, IIT Bombay, India

Abstract

Skolem functions play a central role in the study of first order logic, both from theoretical and practical perspectives. While every Skolemized formula in first-order logic makes use of Skolem constants and/or functions, not all such Skolem constants and/or functions admit effectively computable interpretations. Indeed, the question of whether there exists an effectively computable interpretation of a Skolem function, and if so, how to automatically synthesize it, is fundamental to their use in several applications, such as planning, strategy synthesis, program synthesis etc.

In this paper, we investigate the computability of Skolem functions and their automated synthesis in the full generality of first order logic. We first show a strong negative result, that even under mild assumptions on the vocabulary, it is impossible to obtain computable interpretations of Skolem functions. We then show a positive result, providing a precise characterization of first-order theories that admit effective interpretations of Skolem functions, and also present algorithms to automatically synthesize such interpretations. We discuss applications of our characterization as well as complexity bounds for Skolem functions (interpreted as Turing machines).

1 Introduction

The history of Skolem functions can be traced back to 1920, when the Norwegian mathematician, Thoralf Albert Skolem, gave a simplified proof of a landmark result in logic, now known as the *Löwenheim-Skolem* theorem. Skolem's proof made use of a key observation: *For every first order logic formula $\exists y\, \varphi(x, y)$, the choice of y that makes $\varphi(x, y)$ true (if at all) depends on x in general. This dependence can be thought of as implicitly defining a function that gives the "correct" value of y for every value of x. If F_y denotes a fresh unary function symbol, the second order sentence $\exists F_y\, \forall x\, \big(\exists y\, \varphi(x, y) \Rightarrow \varphi(x, F_y(x))\big)$ formalizes this idea.* Since the implication trivially holds in the other direction too, the second order sentence $\exists F_y\, \forall x\, \big(\exists y\, \varphi(x, y) \Leftrightarrow \varphi(x, F_y(x))\big)$ is valid.

Let $\xi_1 \equiv \exists y\, \varphi(x, y)$ and $\xi_2 \equiv \varphi(x, F_y(x))$. The fresh function symbol F_y introduced in transforming ξ_1 to ξ_2 is called a *Skolem function*. Skolem functions play an extremely important role in logic – both from theoretical and applied perspectives. While it suffices in some contexts to simply know that a Skolem function F_y exists, in other contexts, we require an effective procedure to compute $F_y(x)$ for every value of x. This motivates us to ask if Skolem functions are always computable, and whenever they are, can we algorithmically generate a halting Turing machine that computes the function? Note that we are concerned with computability at two levels here: (i) computability of the Skolem function itself, and (ii) computability of a halting Turing machine that computes the Skolem function. For clarity of

exposition, we call the Turing machine referred to in (ii) above a *computable interpretation of Skolem function*, and the problem of generating it algorithmically the *synthesis problem for Skolem functions.*

The synthesis problem for Skolem functions has been studied in detail in the propositional setting, specifically for quantified Boolean formulas (QBF) with a $\forall^*\exists^*$ quantifier prefix [17, 16, 12, 18, 13, 22, 27, 5, 23, 3, 1, 21, 4, 14, 24]. Surprisingly, a similar in-depth investigation in the context of general first order logic appears lacking in the literature, despite several potential applications, viz. automatic program synthesis and repair [26, 19, 28]. Some notable works in the context of specific theories include those of Kuncak et al [19] (for linear rational arithmetic), Spielman et al [25] (unbounded bit-vector theory), Preiner et al [20] (bit-vector theory) etc. in which terms that serve as interpretations of Skolem functions in specific theories are synthesized. In [17], Jiang presented a partial approach for quantifier elimination in general first-order theories by relying on the availability of functions that can be conditionally expressed by a finite set of terms. Unfortunately, such finite conditional decomposition may not always be possible (as acknowledged in [17]), even when a computable interpretation of the Skolem function exists. The problem of quantifier-free constraint solving, i.e. finding assignments of free variables that render a quantifier-free formula `true`, has been investigated in depth for several theories, viz. propositional logic, theory of arrays, linear rational arithmetic, real algebraic numbers, Presburger arithmetic, regular languages of finite strings etc. If the theory also admits effective quantifier elimination, this yields an algorithm for synthesizing computable interpretations of Skolem functions. However, not all first order theories admit effective quantifier elimination, e.g. Presburger arithmetic (without divisibility predicates) or the theory of evaluated trees [10] does not. We show that for some such theories, computable interpretations of Skolem functions can be synthesized algorithmically.

Our main contributions are to ask and answer the following questions:

- Does there always exist computable interpretations of Skolem functions for a first order formula interpreted over a structure? We answer this question strongly in the negative by showing that uncomputable interpretations cannot be avoided even with one binary predicate and one existential quantifier in the formula.
- We next ask if it is possible to algorithmically decide whether computable interpretations exist for all Skolem functions, given a formula and a structure over which it is interpreted. We answer this question in the negative.
- Next, we ask if it is possible to characterize the class of structures such that effectively computable interpretations of Skolem functions can be algorithmically synthesized for all formulas interpreted over a structure in the class. We answer this by showing that decidability of the elementary diagram of a structure serves as the required necessary and sufficient condition. Using this result, we show that several important first-order theories admit synthesis of effectively computable Skolem functions, while others do not.
- For structures satisfying the condition in the above characterization, we present lower and upper complexity bounds for effectively computable interpretations of Skolem functions.
- Finally, we distinguish between synthesizing Skolem functions as halting Turing machines vs terms in the underlying logic and show that the latter is a strictly weaker notion.

Our results reveal a highly a nuanced picture of the computability landscape for synthesizing interpretations of Skolem functions in first-order logic. We hope that this work will be a starting point towards further research into the design of practical algorithms (whenever possible) to synthesize Skolem functions for various first order theories. Proofs that are missing due to lack of space can be found in the full version at [2].

2 Preliminaries

Since every Turing machine with tape alphabet $\{0,1\}$ can be encoded as a natural number (we use $\mathbb{N}$ for naturals), and since every finite string over $\{0,1\}^*$ can be encoded as a natural number, we often speak of Turing machine i, denoted TM_i, running on input string j, where $i, j \in \mathbb{N}$.

We use x, y, z, etc., possibly with subscripts, to denote first order variables, $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$, etc., possibly with subscripts, to denote sequences of first order variables. We use φ, ξ, α, possibly with subscripts, to denote formulas. For a sequence $\mathbf{X}_i$, $|\mathbf{X}_i|$ denotes the count of variables in $\mathbf{X}_i$, and $x_{i,1}, \ldots x_{i,|\mathbf{X}_i|}$ denotes the variables. A *vocabulary* $\mathcal{V}$, is a set of function and/or predicate symbols, along with their respective arities. Constants are function symbols with arity 0. We assume that $\mathcal{V}$ *has finitely many predicate and function symbols, except possibly for countably infinitely many constant symbols.* We also assume that *a special binary predicate "$=$" (equality) is present in every vocabulary.*

We consider first order logic formulas over vocabulary $\mathcal{V}$, also called $\mathcal{V}$*-formulas.* The notion of *bound* and *free* variables is standard, $\mathcal{V}$-formulas without free variables are $\mathcal{V}$-*sentences.* A $\mathcal{V}$*-term* is either a variable or $f(t_1, \ldots t_k)$, where f is a k-ary function symbol in $\mathcal{V}$ and $t_1, \ldots t_k$ are $\mathcal{V}$-terms. When $\mathcal{V}$ is implicit from the context, we omit it. A *ground term* (resp. *ground formula*) is a term (resp. formula) without any variables. For x, a free variable in ξ, t a term in which all variables (if any) are free in ξ, $\xi[x \mapsto t]$ denotes the formula obtained by *substituting t for x in ξ*, i.e., replacing every free occurrence of x in ξ with t.

A $\mathcal{V}$*-structure* $\mathfrak{M}$ consists of a *universe* $U^{\mathfrak{M}}$ of elements and an interpretation of every predicate and function symbol in $\mathcal{V}$ over $U^{\mathfrak{M}}$. The interpretation of the special predicate "$=$" is always the identity relation, and we write $t_1 = t_2$ instead of $=(t_1, t_2)$ for notational convenience. We denote the interpretation of a predicate symbol P (resp. function symbol f) in $\mathfrak{M}$ as $P^{\mathfrak{M}}$ (resp. $f^{\mathfrak{M}}$). In general, an interpretation of a predicate or function symbol may be well-defined but not computable. We say a $\mathcal{V}$-structure $\mathfrak{M}$ is *computable* if $U^{\mathfrak{M}}$ is countable and if $P^{\mathfrak{M}}$ (resp. $f^{\mathfrak{M}}$) is computable for all predicate symbol P (resp. function symbol f) in $\mathcal{V}$. In other words, there exists a halting Turing machine for computing the interpretations $P^{\mathfrak{M}}$ (resp. $f^{\mathfrak{M}}$). *Throughout this paper, we assume that all $\mathcal{V}$-structures are computable.* This is motivated by practical applications of Skolem functions; additionally, non-computable $\mathcal{V}$-structures may make it difficult (even impossible) to obtain computable interpretations of Skolem functions in most cases. A computable $\mathcal{V}$ structure can be finitely represented, e.g. by using a single bit to encode whether the universe is finite or countably infinite, and by giving a natural number encoding of each Turing machine that computes an interpretation of a predicate or function symbol. If there are countably infinite constant symbols, we assume that interpretations of all of them can be collectively encoded by a single Turing machine that computes a mapping from $\mathbb{N}$ (index of constant symbol) to $\mathbb{N}$ (index of element in universe). If a $\mathcal{V}$-formula $\xi(\mathbf{Z})$ evaluates to true when interpreted over $\mathfrak{M}$ and with $\mathbf{Z}$ set to $\sigma \in \left(U^{\mathfrak{M}}\right)^{|\mathbf{Z}|}$, we say that $\mathfrak{M}$ is a *model* of $\xi(\sigma)$ and denote it by $\mathfrak{M} \models \xi(\sigma)$. An *expansion* of a vocabulary $\mathcal{V}$ is a vocabulary $\mathcal{V}'$ such that $\mathcal{V} \subseteq \mathcal{V}'$. Given a $\mathcal{V}$-structure $\mathfrak{M}$ and a $\mathcal{V}'$-structure $\mathfrak{M}'$, where $\mathcal{V}'$ is an expansion of $\mathcal{V}$, $\mathfrak{M}'$ is an *expansion* of $\mathfrak{M}$ if (i) $U^{\mathfrak{M}'} = U^{\mathfrak{M}}$, and (ii) all predicate/function symbols in $\mathcal{V}$ are interpreted identically in $\mathfrak{M}$ and $\mathfrak{M}'$.

For a quantifier $Q \in \{\exists, \forall\}$ and sequence of variables $\mathbf{X}_i = (x_{i,1}, \ldots x_{i,|\mathbf{X}_i|})$, we use $Q\mathbf{X}_i$ to denote the block of quantifiers $Qx_{i,1} \ldots Qx_{i,|\mathbf{X}_i|}$. Every first order logic formula can be effectively transformed to a semantically equivalent *prenex normal form*, in which all quantifiers appear to the left of the quantifier-free part of the formula. Henceforth, we assume all first order formulas are in prenex normal form, unless stated otherwise. Let $\xi(\mathbf{Z}) \equiv \forall \mathbf{X}_1 \exists \mathbf{Y}_1 \cdots \forall \mathbf{X}_q \exists \mathbf{Y}_q\, \varphi(\mathbf{Z}, \mathbf{X}_1, \mathbf{Y}_1, \ldots \mathbf{X}_q, \mathbf{Y}_q)$ be such a formula, where $\mathbf{Z}$ is a sequence of free variables, and φ is quantifier-free. We say that $\forall \mathbf{X}_1 \exists \mathbf{Y}_1 \cdots \forall \mathbf{X}_q \exists \mathbf{Y}_q$ is the *quantifier prefix* of the formula, and it has q $\forall^* \exists^*$ blocks. The quantifier-free part, i.e. φ, is called the *matrix* of the formula. Note that in case the leading (leftmost) quantifier in ξ is existential, $\mathbf{X}_1$ may be considered to be an empty sequence, and similarly, if the trailing (rightmost) quantifier in ξ is universal. Every variable $y_{i,j}$ that is existentially quantified in the quantifier prefix is called an an *existential variable* in ξ. The notion of *universal variables* is analogously defined. The quantifier prefix imposes a total order on the quantified variables in ξ. We say that a variable u is *to the left* (resp. *right*) of variable v in the quantifier prefix iff Qu appears to the left (resp. right) of $Q'v$ in the quantifier prefix, where $Q, Q' \in \{\exists, \forall\}$.

Skolemization. Given a formula ξ in prenex normal form, *Skolemization* refers to the process of transforming ξ to a new formula $\xi^\star$ via the following steps: (i) for every existential variable $y_{i,j}$, substitute $F_{y_{i,j}}(\mathbf{Z}, \mathbf{X}_1, \ldots \mathbf{X}_i)$ for $y_{i,j}$ in φ, where $F_{y_{i,j}}$ is a new function symbol of arity $|\mathbf{Z}| + \sum_{j=1}^{i} |\mathbf{X}_j|$, and (ii) remove all existential quantifiers from the quantifier prefix of ξ. The functions $F_{y_{i,j}}$ introduced above are called *Skolem functions.* In case ξ has no free variables and the leading quantifier is existential, the Skolem functions for variables in the leftmost existential quantifier block have no arguments (i.e. they are nullary functions). Such functions are also called *Skolem constants.* The sentence $\xi^\star$ is said to be in *Skolem normal form* if the matrix of $\xi^\star$ is in conjunctive normal form. The key guarantee of Skolemization is as follows: for every existential variable $y_{i,j}$, let $\xi^\star_{y_{i,j}}$ denote the formula obtained by Skolemizing all existential variables to the left of $y_{i,j}$ in the quantifier prefix. Formally, $\xi^\star_{y_{i,j}}$ is obtained by (i) substituting the Skolem function $F_{y_{k,l}}$ for every existential variable $y_{k,l}$ to the left of $y_{i,j}$ in the quantifier prefix, and (ii) removing all quantifiers to the left of and including $\exists y_{i,j}$ from the quantifier prefix. Note that $\xi^\star_{y_{i,j}}$ has free variables in $\mathbf{Z}, \mathbf{X}_1, \ldots \mathbf{X}_i, y_{i,j}$. Skolemization guarantees that for every $\mathcal{V}$-structure $\mathfrak{M}$ over which ξ is interpreted, there always exists an expansion $\mathfrak{M}^\star$ of $\mathfrak{M}$ that provides an interpretation of $F_{y_{i,j}}$ for all existential variables $y_{i,j}$ such that the following holds for every $i \in \{1, \ldots q\}$ and $j \in \{1, \ldots |\mathbf{Y}_i|\}$:

$$\forall \mathbf{Z} \forall \mathbf{X}_1 \ldots \forall \mathbf{X}_i \left(\exists y_{i,j}\, \xi^\star_{y_{i,j}} \;\Leftrightarrow\; \xi^\star_{y_{i,j}}[y_{i,j} \mapsto F_{y_{i,j}}(\mathbf{Z}, \mathbf{X}_1, \ldots \mathbf{X}_i)]\right) \tag{1}$$

▶ **Example 1.** Consider $\xi(z) \equiv \exists y \forall x \exists u \forall v \exists w\, \varphi(z, x, y, u, v, w)$. Skolemizing gives $\xi^\star \equiv \forall x \forall v\, \varphi(z, x, F_y(z), F_u(z, x), v, F_w(z, x, v))$, where $F_y(z), F_u(z, x)$ and $F_w(z, x, v)$ are Skolem functions for y, u and w respectively. Using the notation introduced above, we have

- $\xi^\star_y(z, y) \;\equiv\; \forall x \exists u \forall v \exists w\, \varphi(z, x, y, u, v, w)$
- $\xi^\star_u(z, x, u) \;\equiv\; \forall v \exists w\, \varphi(z, x, F_y(z), u, v, w)$
- $\xi^\star_w(z, x, v, w) \;\equiv\; \varphi(z, x, F_y(z), F_u(z, x), v, w)$

By virtue of Skolemization, we know that for every structure $\mathfrak{M}$ over which ξ is interpreted, there exists an expansion $\mathfrak{M}^\star$ that interprets F_y, F_u and F_w such that the following hold.

- $\forall z \big(\exists y\, \xi^\star_y(z, y) \Leftrightarrow \xi^\star_y[y \mapsto F_y(z)]\big)$
- $\forall z \forall x \left(\exists u\, \xi^\star_u(z, x, u) \Leftrightarrow \xi^\star_u[u \mapsto F_u(z, x)]\right)$
- $\forall z \forall x \forall v \left(\exists w \xi^\star_w(z, x, v, w) \Leftrightarrow \xi^\star_w[w \mapsto F_w(z, x, v)]\right)$

Let $\mathcal{V}^\star$ be the expansion of $\mathcal{V}$ obtained by adding all Skolem function and constant symbols in $\xi^\star$ to $\mathcal{V}$. In general, a $\mathcal{V}$-structure $\mathfrak{M}$ over which $\xi(\mathbf{Z})$ is interpreted can be expanded to a $\mathcal{V}^\star$-structure by adding interpretations of Skolem functions for all existential variables in $\xi(\mathbf{Z})$. However, not every such expansion of $\mathfrak{M}$ may model the sentence (1) above for every existential variable $y_{i,j}$. Skolemization guarantees that there exists at least one "correct" expansion $\mathfrak{M}^\star$ of $\mathfrak{M}$ that does so. We call the interpretation of Skolem functions in such a "correct" expansion as an *$\mathfrak{M}$-interpretation* of the Skolem functions. There may be multiple "correct" expansions of $\mathfrak{M}$, and hence multiple $\mathfrak{M}$-interpretations of Skolem functions. Skolemization guarantees the existence of at least one $\mathfrak{M}$-interpretation of all Skolem functions/constants; however, it doesn't tell us whether these are computable interpretations, and if so, can we algorithmically synthesize the interpretation as a halting Turing machine? These are two central questions that concern us in this paper.

Sometimes, given a $\mathcal{V}$-formulas ξ, we can find an $\mathfrak{M}$-interpretation of Skolem functions that works in the same way for all computable structures $\mathfrak{M}$ over which ξ is interpreted (modulo differences in interpreting predicates and functions). Formally, suppose there exists a halting Turing machine M_ξ with access to oracles that compute the interpretations of predicates and functions in $\mathfrak{M}$, and suppose M_ξ computes an $\mathfrak{M}$-interpretation of Skolem functions for all existential variables in ξ, and for all $\mathcal{V}$-structures $\mathfrak{M}$. Then, we say that ξ admits a *uniform representation* of $\mathfrak{M}$-interpretations of Skolem functions.

Model theory. We use $\mathcal{V}(\mathfrak{M})$ to denote the expansion of $\mathcal{V}$ obtained by adding a fresh constant symbol c_e for every element $e \in U^{\mathfrak{M}}$, if not already present in $\mathcal{V}$. Clearly, if $U^{\mathfrak{M}}$ and $\mathcal{V}$ are countable, so is $\mathcal{V}(\mathfrak{M})$. We use $\mathfrak{M}_C$ to denote the expansion of $\mathfrak{M}$ to a $\mathcal{V}(\mathfrak{M})$-structure that interprets the additional constants in $\mathcal{V}(\mathfrak{M})$ in the natural way, i.e. c_e is interpreted to have the value e, for all $e \in U^{\mathfrak{M}}$. The *elementary diagram* of $\mathfrak{M}$, denoted $\mathcal{ED}(\mathfrak{M})$, is the set of all $\mathcal{V}(\mathfrak{M})$-sentences ξ such that $\mathfrak{M}_C \models \xi$. The *diagram* of $\mathfrak{M}$, denoted $\mathcal{D}(\mathfrak{M})$, is the set of all literals in $\mathcal{ED}(\mathfrak{M})$, i.e. the set of all atomic ground formulas that hold in $\mathfrak{M}_C$. Clearly, $\mathcal{D}(\mathfrak{M}) \subseteq \mathcal{ED}(\mathfrak{M})$. A set Γ of $\mathcal{V}$-sentences is called a *$\mathcal{V}$-theory* if it is consistent, i.e. there exists a $\mathcal{V}$-structure that serves as a model for every sentence in Γ. Given a $\mathcal{V}$-structure $\mathfrak{M}$, the set of all first order $\mathcal{V}$-sentences ξ such that $\mathfrak{M} \models \xi$ is called the *theory of* $\mathfrak{M}$, denoted $Th(\mathfrak{M})$. Note that both $\mathcal{ED}(\mathfrak{M})$ and $\mathcal{D}(\mathfrak{M})$ are $\mathcal{V}$-theories, and $\mathcal{ED}(\mathfrak{M}) = Th(\mathfrak{M}_C)$, where $Th(\mathfrak{M}_C)$ is the $\mathcal{V}(\mathfrak{M})$-theory of $\mathfrak{M}_C$. We say that a $\mathcal{V}$-theory Γ is *decidable* iff there exists a Turing machine that takes as input an arbitrary $\mathcal{V}$-sentence ξ and always halts and correctly reports whether $\xi \in \Gamma$ or not. If $\mathfrak{M}$ is a computable structure, it follows immediately that $\mathcal{D}(\mathfrak{M})$ is a decidable theory, but $\mathcal{ED}(\mathfrak{M})$ is not necessarily so.

A $\mathcal{V}$-theory Γ is said to admit *quantifier elimination* if for every $\mathcal{V}$-formula $\xi(\mathbf{Z})$ with free variables $\mathbf{Z}$, there exists a semantically equivalent quantifier-free $\mathcal{V}$-formula $\xi^\#(\mathbf{Z})$ such that the sentence $\forall \mathbf{Z}\,\big(\xi(\mathbf{Z}) \Leftrightarrow \xi^\#(\mathbf{Z})\big)$ is in Γ. If, in addition, there exists a Turing machine that takes an arbitrary $\mathcal{V}$-formula (ξ) as input and computes its quantifier-eliminated form ($\xi^\#$) and halts, we say that Γ admits *effective quantifier elimination*[1]. For a $\mathcal{V}$-structure $\mathfrak{M}$, we say that $Th(\mathfrak{M})$ admits *effective constraint solving* if there exists a Turing machine that takes a $\mathcal{V}$-formula $\xi(\mathbf{Z})$ with free variables $\mathbf{Z}$ as input and halts after reporting one of two things: (i) a $|\mathbf{Z}|$-tuple σ of elements from $U^{\mathfrak{M}}$ such that $\mathfrak{M} \models \xi(\sigma)$, or (ii) no such $|\mathbf{Z}|$-tuple of elements from $U^{\mathfrak{M}}$ exists. Note that the formula $\xi(\mathbf{Z})$ may have quantifiers in general. In case the above Turing machine exists only if $\xi(\mathbf{Z})$ is quantifier-free, we say that $Th(\mathfrak{M})$ admits *effective quantifier-free constraint solving.* Clearly, if $Th(M)$ admits effective quantifier elimination and effective quantifier-free constraint solving, then it also admits effective constraint solving.

[1] There is a technique, popularly called "Morleyization", that trivially makes a theory admit effective quantifier elimination by expanding the vocabulary to include a separate predicate symbol for each $\mathcal{V}$-formula. For purposes of this paper, we disallow expansion of the vocabulary (and hence "Morleyization") during effective quantifier elimination.

3 An illustrative example

Consider the vocabulary $\mathcal{V} = \{P, c, d\}$, where P is a binary predicate symbol, and c and d are constants, and the first-order $\mathcal{V}$-sentence $\xi \equiv \forall x \exists y P(x,y) \wedge \big(P(x,c) \vee P(x,d)\big)$. We will use $\varphi(x,y)$ to denote the matrix of the above formula, i.e. $P(x,y) \wedge \big(P(x,c) \vee P(x,d)\big)$. On Skolemizing ξ we get $\xi^\star \equiv \forall x \varphi(x, F_y(x))$, where F_y is a fresh unary Skolem function symbol. Let $\mathfrak{M}$ be a computable $\mathcal{V}$-structure. We now ask if there exists an algorithm $\mathcal{A}^{[F]}$ that serves as a computable interpretation of $F_y : U^{\mathfrak{M}} \to U^{\mathfrak{M}}$. A careful examination of ξ and $\xi^\star$ reveals that such an algorithm indeed exists. Specifically, the algorithm (represented informally as an imperative "program" for ease of understanding) "**input**(x)**; if** $\mathtt{P}^{\mathfrak{M}}(\mathtt{x}, \mathtt{c}^{\mathfrak{M}})$ **then return** $c^{\mathfrak{M}}$ **else return** $d^{\mathfrak{M}}$" takes as input $x \in U^{\mathfrak{M}}$ and returns either $c^{\mathfrak{M}}$ or $d^{\mathfrak{M}}$ depending on whether $P^{\mathfrak{M}}(x, c^{\mathfrak{M}})$ evaluates to true or false. If we let this algorithm interpret F_y in the expansion $\mathfrak{M}^\star$ of $\mathfrak{M}$, then it is not hard to see that we indeed have $\mathfrak{M}^\star \models \forall x \big(\exists y \varphi(x,y) \Leftrightarrow \varphi(x, F_y(x)\big)$.

However, is this always possible? Consider the $\mathcal{V}$-formula $\alpha \equiv \forall x \exists y\, P(x,y)$ instead of ξ, whose Skolemized version is $\alpha^\star \equiv \forall x\, P(x, F_y(x))$. As we show in Section 5, it is impossible to obtain a computable $\mathfrak{M}$-interpretation of the Skolem function $F_y(x)$ in this case for all $\mathcal{V}$-structures $\mathfrak{M}$.

There are several observations that one can now make. Clearly, algorithm $\mathcal{A}^{[F]}$ described above is specific to the formula ξ; a different formula would have required a different algorithm to be designed for its Skolem function(s). Interestingly, algorithm $\mathcal{A}^{[F]}$ also requires access to the interpretations of c, d and P in the $\mathcal{V}$-structure $\mathfrak{M}$ on which ξ is interpreted. Since we are given an effectively computable interpretation of P in $\mathfrak{M}$, there exists an algorithm $\mathcal{A}^{[P]}$ to compute $P^{\mathfrak{M}}$. Algorithm $\mathcal{A}^{[F]}$ effectively uses $\mathcal{A}^{[P]}$ as a sub-routine to compute the value of $F_y(x)$ for every $x \in U^{\mathfrak{M}}$. Note that if the interpretation of P (in perhaps a different $\mathcal{V}$-structure $\mathfrak{M}'$) was not effectively computable, the "program" above would not serve as an effectively computable interpretation of F_y. This underlines the importance of effectively computable structures in the synthesis of Skolem functions.

It is easy to see that "**input(x); if** $\mathtt{P}^{\mathfrak{M}}(\mathtt{x}, \mathtt{c}^{\mathfrak{M}})$ **then return** $c^{\mathfrak{M}}$ **else return** $d^{\mathfrak{M}}$" *uniformly* serves as a computable interpretation of F_y in every computable $\mathcal{V}$-structure $\mathfrak{M}$ over which ξ is interpreted. Regardless of the actual structure $\mathfrak{M}$, a computable $\mathfrak{M}$-interpretation of F_y is obtained by invoking algorithms to compute interpretations of P, c, d in $\mathfrak{M}$ as sub-routines. Thus we get a uniform representation of an $\mathfrak{M}$-interpretation of F_y.

Finally, the interpretation of Skolem function F discussed above is represented as an algorithm, and not as a $\mathcal{V}$-term. Is it possible to obtain a $\mathcal{V}$-term that uniformly represents an $\mathfrak{M}$-interpretation of F_y in this case? To answer this, first observe that there are only two terms, viz. c and d, that can be formed using $\mathcal{V}$. If one of these terms serves as a uniform $\mathfrak{M}$-interpretation of F_y, choose a structure $\mathfrak{M}$ as follows: $U^{\mathfrak{M}} = \{a_0, a_1\}, c^{\mathfrak{M}} = a_0, d^{\mathfrak{M}} = a_1, P^{\mathfrak{M}}(a_0, a_0) = P^{\mathfrak{M}}(a_1, a_1) = \mathsf{false}$ and $P^{\mathfrak{M}}(a_0, a_1) = P^{\mathfrak{M}}(a_1, a_0) = \mathsf{true}$. Clearly $\mathfrak{M} \models \forall x \exists y \varphi(x,y)$. However, with $F_y(x) = c$ (or $F_y(x) = d$), we have $MM^\star \not\models \forall x \big(\exists y \varphi(x,y) \;\Leftrightarrow\; \varphi(x, F(x))\big)$. Thus even when an effectively computable interpretation of a Skolem function exists, it may not be representable as a term over $\mathcal{V}$.

4 Problem statement

We now formulate the primary questions that we wish to address in this paper.

1. Given a vocabulary $\mathcal{V}$, a $\mathcal{V}$-formula $\xi(\mathbf{Z})$ in prenex normal form and a computable $\mathcal{V}$-structure $\mathfrak{M}$, the SkolemExist problem asks if there exists a *computable* $\mathfrak{M}$-interpretation of Skolem functions for all existential variables in ξ. We have already seen in Section 3 that there are positive instances of SkolemExist. We ask if there are negative instances as well, i.e. there is no computable $\mathfrak{M}$-interpretation of Skolem functions.

2. Next, we ask if SkolemExist is decidable.
3. We then consider special cases where either the formula $\xi(\mathbf{Z})$ or structure $\mathfrak{M}$ is fixed, and ask if it is possible to characterize the class of problems where the SkolemExist problem has a positive answer.
4. In cases where the SkolemExist problem has a positive answer, we ask the following:
   a. Does there exist an algorithm to synthesize computable $\mathfrak{M}$-interpretations of Skolem functions? We call this problem SkolemSynthesis and consider two variants of it, where either (i) $\mathcal{V}$ and $\xi(\mathbf{Z})$ are fixed and $\mathfrak{M}$ is the input of SkolemSynthesis, or (ii) $\mathcal{V}$ and $\mathfrak{M}$ is fixed and ξ is the input of SkolemSynthesis.
   b. Is it possible to obtain finite uniform representations of $\mathfrak{M}$-interpretations of Skolem functions, and if so, can we obtain these as $\mathcal{V}$-terms?
   c. In case SkolemExist has a positive answer, can we give bounds on the worst-case running time of computable $\mathfrak{M}$-interpretations of Skolem functions?

Note that SkolemSynthesis is not meaningful in cases where SkolemExist has a negative answer. Hence, we don't try to answer SkolemSynthesis in negative instances of SkolemExist. Moreover, all the above problems except the last one is trivial if the universe $U^{\mathfrak{M}}$ is finite. Therefore, we focus mostly on structures with countably infinite universe.

5 Hardness of SkolemExist and SkolemSynthesis

We have already seen a positive instance (i.e. problem instance with positive answer) of SkolemExist in Section 3. The following lemma shows that SkolemExist always has a positive answer if all Skolem functions are Skolem constants. In the following, we use $(\mathcal{V}, \mathfrak{M}, \xi)$ to denote an instance of SkolemExist, where $\mathcal{V}$ is a vocabulary, $\mathfrak{M}$ is a computable $\mathcal{V}$-structure and ξ is a $\mathcal{V}$-formula.

▶ **Lemma 2.** *For every vocabulary $\mathcal{V}$, every computable $\mathcal{V}$-structure $\mathfrak{M}$ and every $\mathcal{V}$-sentence $\exists \mathbf{Y}\, \varphi(\mathbf{Y})$, where φ is a quantifier-free $\mathcal{V}$-formula with free variables in $\mathbf{Y}$, the instance $(\mathcal{V}, \mathfrak{M}, \xi)$ of SkolemExist has a positive answer.*

However, there are negative instances of SkolemExist, even with a restricted vocabulary.

▶ **Theorem 3.** *There exists a negative instance of SkolemExist where the vocabulary has a single binary predicate.*

Now that we know there are positive and negative instances of SkolemExist, we ask if SkolemExist is decidable. Unfortunately, we obtain a negative answer in general.

▶ **Theorem 4.** *SkolemExist is undecidable.*

Proof. We prove this theorem by contradiction. Suppose, if possible, there exists a halting Turing machine M that takes as inputs a vocabulary $\mathcal{V}$, a $\mathcal{V}$-formula $\xi(\mathbf{Z})$ and a computable $\mathcal{V}$-structure $\mathfrak{M}$, and decides if there exists a computable $\mathfrak{M}$-interpretation of Skolem functions for all existential variables in $\xi(\mathbf{Z})$. We show below that we can use M to effectively decide if an arbitrary Turing machine, say TM_i, halts on the empty tape.

Consider $\mathcal{V} = \{Q, a\}$, where Q is a binary predicate symbol and a is a constant symbol. For each $i \in \mathbb{N}$, define $\mathfrak{M}_i$ to be a $\mathcal{V}$-structure such that $\mathbf{U}^{\mathfrak{M}_i} = \mathbb{N}$, $a^{\mathfrak{M}_i} = i$ and $Q^{\mathfrak{M}_i}(u, v) = \mathsf{true}$ for $u, v \in \mathbb{N}$ iff the Turing machine TM_u halts on the empty tape within v steps. It is easy to see that each $\mathfrak{M}_j$ is a computable $\mathcal{V}$-structure. We also define the $\mathcal{V}$-sentence $\xi \equiv \exists s \forall u \exists x \left(\left(Q(a, s) \wedge (x = u)\right) \vee \left(\neg Q(a, u) \wedge Q(u, x)\right)\right)$. Skolemizing this formula gives $\xi^\star \equiv \forall u \left(\left(Q(a, c_s) \wedge (F_x(u) = u)\right) \vee \left(\neg Q(a, u) \wedge Q(u, F_x(u))\right)\right)$, where c_s is a Skolem constant for s, and F_x is a Skolem function for x. From the guarantee of Skolemization, the following must hold:

- $\exists s \forall u \exists x \left(\left(Q(a,s) \wedge (x = u)\right) \vee \left(\neg Q(a,u) \wedge Q(u,x)\right)\right) \Leftrightarrow \forall u \exists x \left(\left(Q(a,c_s) \wedge (x = u)\right) \vee \left(\neg Q(a,u) \wedge Q(u,x)\right)\right)$
- $\forall u \big(\exists x \left(\left(Q(a,c_s) \wedge (x = u)\right) \vee \left(\neg Q(a,u) \wedge Q(u,x)\right)\right) \Leftrightarrow \left(\left(Q(a,c_s) \wedge (F_x(u) = u)\right) \vee \left(\neg Q(a,u) \wedge Q(u,F_x(u))\right)\right)\big)$

We now consider two cases.

- Suppose TM_i halts on the empty tape after $p \in \mathbb{N}$ steps. Then $\mathfrak{M}_i \models Q(a,p)$. In this case, by choosing the $c_s^{\mathfrak{M}_i} = p$ and by choosing $F_x^{\mathfrak{M}_i}(u) = u$ for all $u \in \mathbb{N}$, both the above guarantees of Skolemization are easily seen to hold. Clearly, the Skolem functions have computable interpretations in this case.
- If TM_i doesn't halt on the empty tape, then $\mathfrak{M}_i \models \forall u\, \neg Q(a,u)$. In this case, we choose an arbitary value, say 0, for s. However, for the guarantee of Skolemization to hold, we must have the following: for every $u \in \mathbb{N}$, if $\exists x Q(u,x)$ holds (i.e. TM_u halts on the empty tape), then $Q(u, F_x^{\mathfrak{M}_i}(u))$ must also hold (i.e. TM_u must also halt in $F_x^{\mathfrak{M}_i}(u)$ steps). Clearly, such an interpretation $F_x^{\mathfrak{M}_i}$ is not computable, as otherwise it can be used to decide the halting problem.

The above reasoning shows that there exist computable $\mathfrak{M}_i$-interpretations of all Skolem functions of existential variables in ξ iff TM_i halts on empty tape. Thus, if we feed the instance $(\mathcal{V}, \mathfrak{M}_i, \xi)$ as input to the supposed Turing machine M that decides SkolemExist, we can decide if TM_i halts on the empty tape, for every $i \in \mathbb{N}$. This gives a decision procedure for the halting problem on the empty tape – an impossibility! ◀

It is easy to see that the proof of Theorem 4 can be repeated with $\xi \equiv \forall u \exists s \exists x \left(\left(Q(a,s) \wedge (x = u)\right) \vee \left(\neg Q(a,u) \wedge Q(u,x)\right)\right)$ as well. This gives the following interesting result.

▶ **Theorem 5.** *If the vocabulary contains a binary predicate and a constant, SkolemExist is undecidable for the quantifier prefix classes $\exists\forall\exists$ and $\forall\exists\exists$. However it is decidable for the class $\exists^+\forall^*$.*

The second part of the above Theorem follows from an easy generalization of the proof of Lemma 2. This leaves only the case of $\forall\exists$ quantifier prefix, for which the decidability of SkolemExist remains open. We consider the case of the vocabulary having only monadic predicates later in Theorem 7.

The above negative results motivate us to consider special cases of SkolemExist and SkolemSynthesis, where either the $\mathcal{V}$-formula $\xi(\mathbf{Z})$ or the $\mathcal{V}$-structure $\mathfrak{M}$ is fixed.

Fixing the formula. The proof of Theorem 4 is quite damning: even if we allow the possibility of a potentially different algorithm, say $A_{\mathcal{V},\xi}$, for deciding SkolemExist for each combination of $\mathcal{V}$ and ξ, we cannot hope to have an algorithm $A_{\mathcal{V},\xi}$ for every $(\mathcal{V}, \xi)$ pair. This is because in the proof of Theorem 4, we had indeed kept the vocabulary and formula fixed. This leaves only a few questions to be investigated if we fix the vocabulary and formula. If we consider $\mathcal{V}$ and ξ as fixed, the $\mathcal{V}$-structure $\mathfrak{M}$ is the only input to our problems of interest. The following theorem shows that SkolemSynthesis cannot be answered positively in this case even under fairly strong conditions.

Recall from Lemma 2 that SkolemExist has a positive answer if all Skolem functions are Skolem constants. Hence, by choosing ξ to be a $\mathcal{V}$-sentence with only existential quantifiers, we are guaranteed that all problem instances are positive instances of SkolemExist.

▶ **Theorem 6.** *There exists a vocabulary $\mathcal{V}$, a $\mathcal{V}$-sentence ξ and a family of $\mathcal{V}$-structures $\mathcal{F} = \{\mathfrak{M}_i \mid i \in \mathbb{N}\}$, such that $(\mathcal{V}, \mathfrak{M}_i, \xi)$ is a positive instance of SkolemExist for all $i \in \mathbb{N}$, yet there is no uniform representation of $\mathfrak{M}_i$-interpretations of the Skolem constants. Additionally, the SkolemSynthesis problem has a negative answer for the class of problem instances $\{(\mathcal{V}, \xi, \mathfrak{M}_i) \mid i \in \mathbb{N}\}$.*

It is interesting to ask now if there is a characterization of $\mathcal{V}$-formulas, such that for each $\mathcal{V}$-formula satisfying this characterization, the SkolemExist and SkolemSynthesis problems have positive answers for all $\mathcal{V}$-structures. The proof of Theorem 3 tells us that we must disallow binary predicates and $\forall\exists$ blocks in the quantifier prefix, which severely restricts the vocabulary and formulas. What happens if we allow a relational vocabulary with only monadic predicates (Löwenheim class with equality) [9]?

▶ **Theorem 7.** *Let the vocabulary $\mathcal{V}$ contain only monadic predicates and equality. Then SkolemExist has a positive answer, but not so for SkolemSynthesis.*

Proof. With k monadic predicates, the universe can be partitioned into 2^k equivalence classes based on predicate valuations. By an argument (based on Ehrenfeucht-Fraisse games) similar to that used to prove small-model property of Löwenheim class (see [9]), if a prenex formula ξ has quantifier rank r, the range of each Skolem function can be restricted to $\leq r.2^k$ elements. Using an argument similar to that in proof of Lemma 2, there exists a TM that enumerates the required set, say S, of $\leq r.2^k$ elements. Since elements of an equivalence class can only be distinguished using $=$, for each Skolem function of arity p, we must search for its correct interpretation over all $S^p \rightarrow S$ mappings. Since there are finitely many such mappings, we can enumerate the TMs computing these mappings, and one of them must effectively serve as the correct interpretation for the Skolem function under consideration. Since ξ has finitely many existential variables, it follows that there exists computable interpretations of all Skolem functions in ξ.

To see why SkolemSynthesis has a negative answer in general even with one monadic predicate P and one existential quantifier, consider $\mathcal{V} = \{P\}$, $\xi \equiv \exists x P(x)$, and a structure $\mathfrak{M}_i$ having universe $\mathbb{N}$ and $P^{\mathfrak{M}_i}(x) =$ true iff TM_i halts on empty tape within x steps. If there exists an algorithm to synthesize computable M_i-interpretations of the Skolem constant for x in ξ, we can use it to decide if TM_i halts on empty tape – an impossibility! Thus, we must disallow even monadic predicates if we want to characterize V-formulas that admit positive answer to SkolemSynthesis for all $\mathcal{V}$-structures. ◀

Fixing the structure. We now fix the structure $\mathfrak{M}$ (and vocabulary $\mathcal{V}$) and take the formula ξ as the only input of our problems of interest. Since the structure $\mathfrak{M}$ is fixed, we use the notation $\mathcal{U}$ for $U^{\mathfrak{M}}$ henceforth. Theorem 3 already shows that even when the structure is fixed, the SkolemExist problem has a negative instance. However, the $\mathcal{V}$-structure used in that proof may appear hand-crafted. This leads us to ask if there is a "natural" vocabulary $\mathcal{V}$ and $\mathcal{V}$-structure $\mathfrak{M}$, such that SkolemExist has a negative instance when considering $\mathcal{V}$-formulas. It turns out that this is indeed the case, and we show it by appealing to the classical Matiyasevich-Robinson-Davis-Putnam (MRDP) theorem [11].

▶ **Proposition 8.** *Skolem functions for the first order theory of natural numbers over the vocabulary $\{\times, +, 0, 1\}$ do not admit computable interpretations.*

Finally, in the setting of a fixed $\mathcal{V}$-structure $\mathfrak{M}$, even if SkolemExist is answered in the positive for all $\mathcal{V}$-formulas in a class Ξ, the SkolemSynthesis problem may have a negative answer for the class of problem instances $\{(\mathcal{V}, \mathfrak{M}, \xi) \mid \xi \in \Xi\}$.

▶ **Theorem 9.** *There exists a vocabulary $\mathcal{V}$, a $\mathcal{V}$-structure $\mathfrak{M}$ and a class of $\mathcal{V}$-sentences $\Xi = \{\xi_i \mid i \in \mathbb{N}\}$ s.t., $(\mathcal{V}, \mathfrak{M}, \xi)$ is a positive instance of SkolemExist for all $\xi_i \in \Xi$, yet SkolemSynthesis has a negative answer for the class of instances $\{(\mathcal{V}, \mathfrak{M}, \xi_i) \mid i \in \mathbb{N}\}$.*

6 Necessary & sufficient condition for synthesizing Skolem functions

Given these strong negative results is there hope for proving existence and synthesizability of computable interpretations for Skolem functions. Indeed, there do exist many natural theories where computable interpretations of Skolem functions exist and can indeed be synthesized, e.g., Boolean case, Presburger arithmetic etc. So, what determines when a $\mathcal{V}$-theory admits effective synthesis of computable interpretations of Skolem functions for all $\mathcal{V}$-formulas? Our first positive result is a surprising characterization of a *necessary and sufficient* condition for algorithmic synthesis of computable interpretations of Skolem functions.

▶ **Theorem 10.** *Let $\mathfrak{M}$ be a computable $\mathcal{V}$-structure for vocabulary $\mathcal{V}$. The* SkolemSynthesis *problem for $\mathcal{V}$-formulas, i.e. for problem instances $\{(\mathcal{V}, \mathfrak{M}, \xi) \mid \xi$ is a $\mathcal{V}$-formula$\}$, has a positive answer iff $\mathcal{ED}(\mathfrak{M})$ is decidable.*

Proof. ($\Longleftarrow$) Let $\xi(\mathbf{Z})$ be a $\mathcal{V}$-formula with free variables $\mathbf{Z}$, where $\xi(\mathbf{Z}) \equiv \forall \mathbf{X}_1 \exists \mathbf{Y}_1 \ldots \forall \mathbf{X}_n \exists \mathbf{Y}_n$
$\xi_n(\mathbf{Z}, \mathbf{X}_1, \mathbf{Y}_1, \ldots, \mathbf{X}_n, \mathbf{Y}_n)$, where $\mathbf{X}_1, \ldots, \mathbf{X}_n$ are n sequences of universally quantified variables, $\mathbf{Y}_1, \ldots \mathbf{Y}_n$ are sequences of existentially quantified variables, $\mathbf{Z}$ is a sequence of free variables and ξ_n is quantifier-free. We will show that there is an algorithm, that for every $i \in \{1, \ldots, n\}$, takes as input a $(|\mathbf{Z}|+|\mathbf{X}_1|+\ldots+|\mathbf{X}_i|)$ tuple of values from the universe $\mathcal{U}$, say, $\mu \in \mathcal{U}^{|\mathbf{Z}|}, \sigma_1 \in \mathcal{U}^{|\mathbf{X}_1|}, \ldots, \sigma_i \in \mathcal{U}^{|\mathbf{X}_i|}$ and halts after computing a $(|\mathbf{Y}_1|+\ldots+|\mathbf{Y}_i|)$-dimensional vector of values, $\mathbf{F}_1(\mu, \sigma_1) \in \mathcal{U}^{|Y_1|}, \ldots \mathbf{F}_i(\mu, \sigma_1, \ldots \sigma_i) \in \mathcal{U}^{|\mathbf{Y}_i|}$ where for each $1 \leq j \leq i$, $\mathbf{F}_j$ is a $|\mathbf{Y}_j|$-dimensional vector of Skolem functions, each of arity $|\mathbf{Z}| + |\mathbf{X}_1| + \ldots + |\mathbf{X}_j|$.

The proof is by induction on i. For $i = 1$, let $\xi(\mathbf{Z}) \equiv \forall \mathbf{X}_1 \exists \mathbf{Y}_1\, \xi_1(\mathbf{Z}, \mathbf{X}_1, \mathbf{Y}_1)$, where ξ_1 has one less number of quantifier alternations than ξ. On Skolemizing, we get $\xi^\star(\mathbf{Z}) \equiv \forall \mathbf{X}_1\, \xi_1(\mathbf{Z}, \mathbf{X}_1, \mathbf{F}_1(\mathbf{Z}, \mathbf{X}_1))$, where $\mathbf{F}_1$ is a $|\mathbf{Y}_1|$-dimensional vector of Skolem functions each of arity $|\mathbf{Z}| + |\mathbf{X}_1|$. We now design a Turing machine (or algorithm) M_1 that takes any $|\mathbf{Z}|+|\mathbf{X}_1|$-tuple of elements from $\mathcal{U}$, say (μ, σ_1), as input and halts after computing $\mathbf{F}_1(\mu, \sigma_1)$:

(a) It first determines if $\exists \mathbf{Y}_1\, \xi_1(\mu, \sigma_1, \mathbf{Y}_1)$ holds, using the decision procedure for $\mathcal{ED}(\mathfrak{M})$.

(b) If the answer to the above question is "Yes", the machine M_1 recursively enumerates $|\mathbf{Y}_1|$-tuples of elements of $\mathcal{U}$, and for each tuple ν thus enumerated, it checks if $\xi_1(\mu, \sigma_1, \nu)$ evaluates to true. Again the decidability of $\mathcal{ED}(\mathfrak{M})$ ensures that this check can also be effectively done. The machine M_1 outputs the first (in recursive enumeration order) element of $\mathcal{U}^{|\mathbf{Y}_1|}$, for which $\xi_1(\mu, \sigma_1, \nu)$ is true as $\mathbf{F}_1(\mu, \sigma_1)$, and halts.

(c) If the answer is "No", i.e. there is no $\nu \in \mathcal{U}^{|\mathbf{Y}_1|}$ s.t. $\xi_1(\mu, \sigma_1, \nu)$ is true, M_1 outputs the first (in recursive enumeration order) tuple of $\mathcal{U}^{|\mathbf{Y}_1|}$ as $\mathbf{F}_1(\mu, \sigma_1)$, and halts.

It is easy to verify that the vector of functions $\mathbf{F}_1$ computed by M_1 satisfies $\forall \mathbf{X}_1 \big(\exists \mathbf{Y}_1\, \xi_1(\mathbf{Z}, \mathbf{X}_1, \mathbf{Y}_1) \Leftrightarrow \xi_1(\mathbf{Z}, \mathbf{X}_1, \mathbf{F}_1(\mathbf{Z}, \mathbf{X}_1))\big)$ for every valuation of the free variables $\mathbf{Z}$ in $\mathcal{U}^{|\mathbf{Z}|}$, i.e., we have a (correct) $\mathfrak{M}$-interpretation of Skolem function $\mathbf{F}_1$. This completes the base case for $i = 1$.

For the general case of $i \geq 1$, we write $\xi(\mathbf{Z})$ as $\forall \mathbf{X}_1 \exists \mathbf{Y}_1 \ldots \forall \mathbf{X}_i \exists \mathbf{Y}_i \xi_i(\mathbf{Z}, \mathbf{X}_1, \mathbf{Y}_1, \ldots \mathbf{X}_i, \mathbf{Y}_i)$, where ξ_i is a formula with i less $\forall^*\exists^*$ blocks than ξ. By induction hypothesis, we know that there exists a Turing machine M_i that takes as input any values for free variables $\mathbf{Z}$ and universally quantified variables $\mathbf{X}_1, \ldots \mathbf{X}_i$ and outputs values for $\mathbf{Y}_1, \ldots \mathbf{Y}_i$ so that they correspond to outputs of (correct) $\mathfrak{M}$-interpretations of vectors of Skolem functions $\mathbf{F}_1, \ldots \mathbf{F}_i$.

We need to show the existence of a computable interpretation of the vector of Skolem functions $\mathbf{F}_{i+1}$ for $\mathbf{Y}_{i+1}$. Thus, we are given a $(|\mathbf{Z}| + |\mathbf{X}_1| + \ldots + |\mathbf{X}_i| + |\mathbf{X}_{i+1}|)$-tuple of values from $\mathcal{U}$, and we need to show how to define a Turing machine M_{i+1} that takes this vector as input and halts after computing values of vectors of Skolem functions $\mathbf{F}_1(\mu, \sigma_1), \ldots \mathbf{F}_{i+1}(\mu, \sigma_1, \ldots \sigma_i, \sigma_{i+1})$. Let $(\mu, \sigma_1, \ldots, \sigma_i, \sigma_{i+1})$ be the given set of input values. The Turing machine M_{i+1} first simulates M_i on input $(\mu, \sigma_1, \ldots, \sigma_i)$. This returns i vectors of values $\nu_1 = \mathbf{F}_1(\mu, \sigma_1) \in \mathcal{U}^{|Y_1|}, \ldots \nu_i = \mathbf{F}_i(\mu, \sigma_1, \ldots \sigma_i) \in \mathcal{U}^{|Y_i|}$ such that each of $\mathbf{F}_1, \ldots, \mathbf{F}_i$ is a Skolem function vector. Plugging in all these values in ξ_i gives a sentence $\hat{\xi}_i = \xi_i[\mathbf{Z} \mapsto \mu, \mathbf{X}_1 \mapsto \sigma_1, \mathbf{Y}_1 \mapsto \nu_1, \ldots, \mathbf{X}_i \mapsto \sigma_i, \mathbf{Y}_i \mapsto \nu_i]$. Observe that $\hat{\xi}_i \equiv \forall \mathbf{X}_{i+1} \exists \mathbf{Y}_{i+1} \hat{\xi}_{i+1}(\mathbf{X}_{i+1}, \mathbf{Y}_{i+1})$ for some formula $\hat{\xi}_{i+1}(\mathbf{X}_{i+1}, \mathbf{Y}_{i+1})$. We can then apply the same argument as in the base case above and conclude.

Note that the values of $\mathbf{Z}, \mathbf{X}_1, \ldots \mathbf{X}_n$ used above were arbitrary tuples from $\mathcal{U}^{|\mathbf{Z}|}$, $\mathcal{U}^{|\mathbf{X}_1|}, \ldots \mathcal{U}^{|\mathbf{X}_n|}$. Hence lifting the notation introduced in sentence (1) of Section 2 to talk about vector of variables $\mathbf{Y}_{i+1}$ instead of single variables $y_{i,j}$, we conclude that the vector of functions $\mathbf{F}_{i+1}$ computed by Turing machine M_{i+1} satisfies $\forall \mathbf{Z} \forall \mathbf{X}_1 \ldots \forall \mathbf{X}_{i+1}$ $\big(\exists \mathbf{Y}_{i+1} \xi^{\star}_{\mathbf{Y}_{i+1}} \Leftrightarrow \xi^{\star}_{\mathbf{Y}_{i+1}}[\mathbf{Y}_{i+1} \mapsto \mathbf{F}_{i+1}(\mathbf{Z}, \mathbf{X}_1, \ldots \mathbf{X}_{i+1})]\big)$. Thus, $\mathbf{F}_{i+1}$ gives a (correct) $\mathfrak{M}$-interpretation of a vector of Skolem functions for $\mathbf{Y}_{i+1}$, which completes the proof.

($\Rightarrow$) In the other direction, we will show that if there exists a halting Turing machine, say M, that synthesizes computable $\mathfrak{M}$-interpretations of Skolem functions for all existential variables in all $\mathcal{V}$-formulas, then $\mathcal{ED}(\mathfrak{M})$ must be decidable. We assume that there are at least two elements in $\mathcal{U}$; let's call them d_1, d_2. To show that $\mathcal{ED}(\mathfrak{M})$ is decidable, we need to show a decision procedure for the $\mathcal{V}(\mathfrak{M})$-theory of $\mathfrak{M}_C$. Consider any $\mathcal{V}(\mathfrak{M})$-sentence φ. This sentence may have finitely many constants that are not in $\mathcal{V}$. Let us say $c_1, \ldots c_k$ are these constants, for some non-negative integer k. We introduce k fresh variables $y_1, \ldots y_k$ and define φ' to be the formula obtained by taking φ and replacing each occurrence of the constant c_i by variable y_i respectively. Note that φ' is a $\mathcal{V}$-formula. We introduce 3 more fresh variables x, z_1, z_2 and consider the sentence $\psi \equiv \forall y_1 \ldots \forall y_k \forall z_1 \forall z_2 \exists x \big(((x = z_1) \wedge \varphi') \vee ((x = z_2) \wedge \neg \varphi')\big)$. We can easily rewrite this formula in prenex normal form, but doing so still leaves x as the leftmost existentially quantified variable. We now feed this prenex normal form of ψ as the input to Turing machine M (that synthesizes computable interpretations of Skolem functions for all existential variables in all $\mathcal{V}$-formulas). Let the computable interpretation of the Skolem function for x, as output by M, be the Turing machine M_x. Therefore, M_x takes as inputs values of $y_1, \ldots y_k, z_1, z_2$ (as these are the only universally quantified variables to the left of x in the quantifier prefix) and it always halts after computing a value for x. Now we run the Turing machine M_x with the inputs: c_i as the value for y_i for $i \in \{1, \ldots k\}$, d_1 as the value for z_1 and d_2 as the value for z_2. Let the value computed by M_x with these inputs be t. We then check if $t = d_1$. If yes, we conclude that $\mathfrak{M}_C \models \varphi$, else $\mathfrak{M}_C \not\models \varphi$. Thus, we have a decision procedure for $\mathcal{V}(\mathfrak{M})$-theory of $\mathfrak{M}_C$, i.e., $\mathcal{ED}(\mathfrak{M})$ is decidable. ◀

The construction in the first part of the above proof shows that there exists a Turing machine that runs in time polynomial in the length of ξ and in the length of a decision procedure for $\mathcal{ED}(\mathfrak{M})$, and generates a computable interpretation (i.e. code for a halting Turing machine) that computes $\mathfrak{M}$-interpretations of all Skolem functions in ξ. Further, since a positive answer to SkolemSynthesis implies a positive answer to SkolemExist, Theorem 10 also gives a sufficient condition for SkolemExist to have a positive answer.

7 Applications and complexity

We now look at some consequences of the above characterization. We first ask if we can algorithmically synthesize computable interpretations of Skolem functions in some well-known theories in first-order logic. We start with a lemma.

▶ **Lemma 11.** *Let $\mathfrak{M}$ be a computable $\mathcal{V}$-structure with universe $\mathcal{U}$. Suppose for every element $e \in \mathcal{U}$, there exists an effectively computable uni-variate $\mathcal{V}$-formula $\alpha_e(x)$ such that $\alpha_e(x)$ is* true *iff $x = e$. Then $Th(\mathfrak{M})$ is decidable iff $\mathcal{ED}(\mathfrak{M})$ is decidable.*

One may wonder if decidability of $Th(\mathfrak{M})$ automatically implies decidability of $\mathcal{ED}(\mathfrak{M})$. However, this is not true in general (see [2] for more details), emphasizing the need for Lemma 11. From Lemma 11 and Theorem 10 we now have,

▶ **Corollary 12.** *For the following theories, both SkolemExist and SkolemSynthesis have positive answers, and we can effectively synthesize computable $\mathfrak{M}$-interpretations for Skolem functions for a $\mathcal{V}$-formula: 1. Presburger arithmetic; 2. Linear rational arithmetic (LRA); 3. Theory of real algebraic numbers; 4. Theory of dense linear orders without endpoints.*

For the theory of natural numbers with addition, multiplication and order, we have seen in Proposition 8 that SkolemExist has a negative answer, which of course implies that SkolemSynthesis cannot have a positive answer. Using Lemma 11 and Theorem 10 we get a direct proof for the latter fact. To see this note that the premise of Lemma 11 holds for this theory as for Presburger arithmetic. Hence, $\mathcal{ED}(\mathfrak{M})$ is decidable iff $Th(\mathfrak{M})$ is decidable. But we know from the MRDP theorem [11] that the latter is indeed undecidable. Thus, from Theorem 10, we obtain that SkolemSynthesis has negative instances in this theory.

We remark that the above discussion can also be seen as an alternate proof of the fact that the elementary diagram is undecidable, since Theorem 10 is a characterization.

Complexity bounds on $\mathfrak{M}$-interpretations. When it applies, the proof of Theorem 10 gives us a construction of a Turing machine M that takes a formula ξ as input and outputs a computable $\mathfrak{M}$-interpretation (i.e. code for another Turing machine, say M') of Skolem functions for all existential variables in ξ. What bounds can we give on the worst case running time of M' (Problem 4.c in Section 4)? We start with a lower bound that follows from the second part of the proof of Theorem 10.

▶ **Theorem 13.** *Let $\mathfrak{M}$ be a computable $\mathcal{V}$-structure with a decidable $\mathcal{ED}(\mathfrak{M})$. The worst case running time of any computable $\mathfrak{M}$-interpretation of Skolem functions for a $\mathcal{V}$-formula is at least as much as that of a decision procedure for $\mathcal{ED}(\mathfrak{M})$.*

This shows for instance that for Presburger arithmetic, there exists formulas for which any computable $\mathfrak{M}$-interpretation of Skolem functions will take at least (alternating) double exponential time [8, 15] Next, for upper bounds, the computable $\mathfrak{M}$-interpretation of Skolem functions, as detailed in the proof of Theorem 10, relies on enumeration. Hence, it does not help in giving complexity upper bounds. However, if a theory admits effective constraint solving (see Sec. 2 for a definition), then we can do better.

▶ **Theorem 14.** *Let $\mathfrak{M}$ be a $\mathcal{V}$-structure such that $\mathcal{ED}(\mathfrak{M})$ is decidable. Suppose $\mathcal{ED}(\mathfrak{M})$ admits effective constraint solving with worst-case time complexity $T(n)$ and the solution is represented as a tuple of domain elements requiring at most $S(n)$ bits. Then we can synthesize $\mathfrak{M}$-interpretations of Skolem functions for $\mathcal{V}$-formulas of size n, such that the running time and output size of the $\mathfrak{M}$-interpretations are bounded by recursive functions of $T(n)$ and $S(n)$.*

As an example, if $S(n)$ is linear, i.e., $S(n) \leq C.n$ for a constant $C > 0$, then we get $time(n) \leq k.T(k.(\max\{C, 1\})^k.n)$ and $size(n) \leq k.(\max\{C, 1\})^k.n$. Finally, one way to obtain an algorithm for effective constraint solving is by using effective quantifier elimination repeatedly and then using quantifier-free constraint solving. Thus, we could further bound the complexity as functions of the complexity for effective quantifier elimination and that of quantifier-free constraint solving. This can be applied, for example, for LRA, theory of reals etc. Significantly, there are first-order theories that do not admit effective quantifier elimination but admit effective constraint solving, e.g., theory of evaluated trees [10]. In such cases, we can still use our approach to synthesize Skolem functions.

8 Expressing Skolem functions as terms

Whenever Skolem functions are computable, one can further ask: *Can Skolem functions be represented as terms?* Notice that in the Boolean setting, the notions of terms, functions and formulas are often conflated (as noted by Jiang [17] as well). Note that there are theories without any terms, for which Skolem functions can still be synthesized as halting Turing machines. For instance, the theory of (countable) dense linear order without endpoints does not admit any terms. Yet, from Corollary 12, we know that we can effectively synthesize computable Skolem functions for this theory. In fact, we can show a stronger result, viz, even when the theory admits terms, we may not be able to interpret a Skolem function as a term. To see this, consider the Presburger formula: $\forall y \forall z \exists x(((x = y) \vee (x = z)) \wedge ((x \geq y) \wedge (x \geq z)))$. The unique Skolem function for x is $\max(y, z)$, which can be written as an imperative program as: "**input(y,z); if** y $\geq$ z **then return** y **else return** z". This is a uniform representation (see Sec. 2) of a computable $\mathfrak{M}$-interpretation of the Skolem function for x. However, this function cannot be written as a term in Presburger arithmetic. Indeed, any term of y, z that uses only $+$, 0, 1 must be linear, while max is a non-linear function. Thus, we have

▶ **Proposition 15.** *There exist first order theories for which Skolem functions can be effectively computed, but they cannot be expressed as terms.*

As described in [17], if Skolem functions in a first order theory can be represented using a *finite set of conditional terms* (like in the case of $\max(y, z)$ above), the theory admits effective quantifier elimination. However, we already have first order theories, e.g. the theory of evaluated trees, that don't admit quantifier elimination, but admit effective synthesis of computable interpretations of Skolem functions. In such cases, Skolem functions can't be represented as a finite set of conditional terms either.

Note that there is a related notion of deskolemization in proof theory (see e.g., [6], [7]) in which proofs of Skolemized formulas are related to the proofs of corresponding formulas without Skolem functions. However, this does not necessarily yield computable interpretations of Skolem functions as terms.

9 Conclusion

The study of algorithmic computation of Skolem functions is highly nuanced. We explored what it means for Skolem functions for first order logic to be computable and synthesizable. Defining computable interpretations of Skolem functions as Turing machines, we showed that they may not always exist and checking if they exist is undecidable in general. However, when we fix a computable structure, we gave a precise characterization of when they exist and show several applications for specific theories. While we have made some preliminary progress regarding complexity issues, the question of synthesizing succinct interpretations is still open as is the question of when Skolem functions can be represented as terms in the logic. We hope that the theoretical framework set up here will lead to research towards implementable synthesis of Skolem functions for first order logic.

Abstract

One of the open problems in machine learning is whether any set-family of VC-dimension d admits a sample compression scheme of size $O(d)$. In this paper, we study this problem for balls in graphs. For balls of arbitrary radius r, we design proper sample compression schemes of size 4 for interval graphs, of size 6 for trees of cycles, and of size 22 for cube-free median graphs. We also design approximate sample compression schemes of size 2 for balls of δ-hyperbolic graphs.

1 Introduction

Sample compression schemes were introduced by Littlestone and Warmuth [22], and have been vastly studied in the literature due to their importance in computational machine learning. Roughly, a sample compression scheme consists of a compressor α and a reconstructor β, and the aim is to compress data as much as possible, such that data coherent with the original data can be reconstructed from the compressed data. For balls in graphs, sample compression schemes of size k can be defined as follows. Given a ball $B = B_r(x)$ of a graph $G = (V, E)$, a realizable sample for B is a signed subset $X = (X^+, X^-)$ of V such that X^+ is included in B, and X^- is disjoint from B. Given a realizable sample X, X is compressed to a subsample $\alpha(X) \subseteq X$ of size at most k. The reconstructor β takes $\alpha(X)$ as an input and returns $\beta(\alpha(X))$, a subset B' of vertices of G that is consistent with X, *i.e.*, X^+ is included in B', and X^- is disjoint from B'. If B' is always a ball of G, then the compression scheme is proper. If $X^+ = B$ and $X^- = V \setminus B$, then $\beta(\alpha(X))$ must coincide with B. Note that a proper sample compression scheme of size k for the family of all balls of G yields a sample compression scheme of size k for any subfamily of balls (*e.g.*, for balls of a fixed radius r), but this scheme is no longer proper. Sample compression schemes are labeled if β knows the labels of the elements of $\alpha(X)$, and are unlabeled otherwise (abbreviated LSCS and USCS, resp.). The Vapnik-Chervonenkis dimension (VC-dimension) of a set system was introduced by Vapnik and Chervonenkis [27] as a complexity measure of set systems. VC-dimension is central in PAC-learning, and is important in combinatorics and discrete geometry. Floyd and Warmuth [17] asked whether any set-family of VC-dimension d has a sample compression scheme of size $O(d)$. This remains one of the oldest open problems in machine learning.

In this paper, we consider the family of balls in graphs, which is as general as the sample compression conjecture. Indeed, the sample compression conjecture for set families in general is equivalent to the same conjecture restricted to the family of balls of radius 1 on split graphs in which samples only contain vertices in the clique, and the centers of the unit balls are in the stable set. Balls in graphs also constitute an important topic in graph theory, and moreover, their VC-dimension has often been considered in the literature (see, *e.g.*, [4, 7, 10, 16, 26]).

The VC-dimension of the balls of radius r of a graph not containing K_{n+1} as a minor is at most n [10]. This result was extended to arbitrary balls in [7]. Hence, the VC-dimension of balls of planar graphs is at most 4 (2 for trees and 3 for trees of cycles), and the VC-dimension of balls of a chordal graph G is at most its clique number $\omega(G)$. The VC-dimension of balls of interval graphs was shown to be at most 2 in [16]. Finally, the VC-dimension of balls of cube-free median graphs is unknown, but we can prove that it is at least 4.

Our results. In this paper, we design proper sample compression schemes of small size for the family of balls of a graph G. We investigate this problem for different graph classes. For trees of cycles, we exhibit proper LSCS of size 6 for all balls. Then, we design proper LSCS of size 22 for all balls of cube-free median graphs. We also construct proper LSCS of size 4 for all balls of interval graphs. Finally, we define (ρ, μ)-approximate proper sample compression schemes, and design $(2\delta, 3\delta)$-approximate LSCS of size 2 for δ-hyperbolic graphs.

Related work. Floyd and Warmuth [17] proved that, for any concept class of VC-dimension d, any LSCS has size at least $\frac{d}{5}$, and that, for some maximum classes of VC-dimension d, they have size at least d. Pálvölgyi and Tardos [25] proved that some concept classes of VC-dimension 2 do not admit USCS of size at most 2. On the positive side, it was shown by Moran and Yehudayoff [24] that LSCS of size $O(2^d)$ exist (their schemes are not proper). For particular concept classes, better results are known. Floyd and Warmuth [17] designed LSCS of size d for regions in arrangements of central hyperplanes in $\mathbb{R}^d$. Ben-David and Litman [5] obtained USCS of size d for regions in arrangements of affine hyperplanes in $\mathbb{R}^d$. Helmbold, Sloan, and Warmuth [19] (implicitly) constructed USCS of size d for intersection-closed concept classes. Moran and Warmuth [23] designed proper LSCS of size d for ample classes. Chalopin et al. [9] designed USCS of size d for maximum families. They also combinatorially characterized USCS for ample classes via the existence of *unique sink orientations* of their graphs. However, the existence of such orientations is open. Chepoi, Knauer, and Philibert [12] extended the result of [23], and designed proper LSCS of size d for concept classes defined by Complexes of Oriented Matroids (COMs). COMs were introduced in [3] as a natural common generalization of ample classes and Oriented Matroids [6].

2 Definitions

Concept classes and sample compression schemes. Let V be a non-empty finite set. Let $\mathcal{C} \subseteq 2^V$ be a family of subsets (also called a *concept class*) of V. The *VC-dimension* VC-dim$(\mathcal{C})$ of $\mathcal{C}$ is the size of a largest set $Y \subseteq V$ *shattered* by $\mathcal{C}$, *i.e.*, such that $\{C \cap Y : C \in \mathcal{C}\} = 2^Y$. In machine learning, a *(labeled) sample* is a set $X = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, where $x_i \in V$ and $y_i \in \{-1, +1\}$. To X is associated the unlabeled sample $\underline{X} = \{x_1, \ldots, x_m\}$. A sample X is *realizable by a concept* C if $y_i = +1$ if $x_i \in C$, and $y_i = -1$ if $x_i \notin C$. A sample X is *realizable by a concept class* $\mathcal{C}$ if X is realizable by some $C \in \mathcal{C}$.

We adopt the language of sign maps and sign vectors from [6]. Let $\mathcal{L}$ be a *set of sign vectors*, *i.e.*, maps from V to $\{\pm1, 0\} := \{-1, 0, +1\}$. The elements of $\mathcal{L}$ are also called *covectors*. For $X \in \mathcal{L}$, let $X^+ := \{v \in V : X_v = +1\}$ and $X^- := \{v \in V : X_v = -1\}$. $\underline{X} = X^- \cup X^+$ is called the *support* of X, and its complement $X^0 := V \setminus \underline{X} = \{v \in V : X_v = 0\}$ the *zero set* of X. Since $X^0 = V \setminus (X^- \cup X^+)$, we will view any sample X as $X^- \cup X^+$. Let $\preceq$ be the product ordering on $\{\pm1, 0\}^V$ relative to the ordering of signs with $0 \preceq -1$ and $0 \preceq +1$. Any concept class $\mathcal{C} \subseteq 2^V$ can be viewed as a set of sign vectors of $\{\pm1\}^V$: for any $C \in \mathcal{C}$ we consider the sign vector $X(C)$, where $X_v(C) = +1$ if $v \in C$ and $X_v(C) = -1$ if $v \notin C$. For simplicity, we will consider $\mathcal{C}$ as a family of sets and as a set of $\{\pm1\}$-vectors. We now define sample compression schemes. This way of presenting them seems novel. From the definition, it follows that a sample X is just a $\{\pm1, 0\}$-sign vector. Given a concept class $\mathcal{C} \subseteq 2^V$ and $C \in \mathcal{C}$, the set of samples realizable by C consists of all covectors $X \in \{\pm1, 0\}^V$ such that $X \preceq C$. We denote by $\downarrow \mathcal{C}$ the set of all samples realizable by $\mathcal{C}$.

A *proper labeled sample compression scheme* (*proper LSCS*) of size k for a concept class $\mathcal{C} \subseteq \{\pm1\}^V$ is defined by a *compressor* $\alpha : \{\pm1, 0\}^V \to \{\pm1, 0\}^V$ and a *reconstructor* $\beta : \{\pm1, 0\}^V \to \mathcal{C}$ such that, for any realizable sample $X \in \downarrow \mathcal{C}$, $\alpha(X) \preceq X \preceq \beta(\alpha(X))$ and $|\underline{\alpha}(X)| \leq k$, where $\preceq$ is the order between sign vectors defined above, and $\underline{\alpha}(X)$ is the support of the subsample of the sign vector X. Hence, $\alpha(X)$ is a signed vector with a support of size at most k such that $\alpha(X) \preceq X$, and $\beta(\alpha(X))$ is a concept C of $\mathcal{C}$ viewed as a sign vector. It suffices to define the map α only on $\downarrow \mathcal{C}$, and the map β only on $\mathrm{Im}(\alpha) := \alpha(\downarrow \mathcal{C})$. The condition $X \preceq \beta(\alpha(X))$ is equivalent to the condition $\beta(\alpha(X))|\underline{X} = X$, which means that the restriction of the concept $\beta(\alpha(X))$ to the support of X coincides with the sign vector X. *Proper unlabeled sample compression schemes* (*proper USCS*) are defined analogously, only that $\alpha(X)$ is not a signed vector, but a subset of size at most k of the support of X. For graphs, any preprocessing on the input graph G, such as a labeling or an embedding of G, is permitted and known to both the compressor and the reconstructor. As in, *e.g.*, [22, 24], information, like representing the support as a vector with coordinates, is also permitted, and when we use such information, we refer to α and β as vectors rather than maps. Lastly, in our schemes, the reconstructor returns the empty set when $X^+ = \varnothing$, and thus, one may consider that our schemes are not proper. We note that in all of the LSCS for the family of balls of arbitrary radius we exhibit in this paper, we could simply choose an ordering on the vertices of the graph $G = (V, E)$, and put into $\alpha(X)$ a single vertex $z \in X^-$ such that its successor z' in the ordering does not belong to X^-. Then, the reconstructor returns a ball $B_0(z')$ that does not intersect $X = X^-$ by the choice of z. However, to avoid additional complications for such degenerate cases, we make use of the empty set.

Graphs. Every graph $G = (V, E)$ in this paper is simple and connected. The *distance* $d(u, v) := d_G(u, v)$ between two vertices u and v of a graph G is the length of a (u, v)-shortest path. The *interval* $I(u, v)$ is the set of vertices contained in (u, v)-shortest paths. A set S is *gated* if, for any vertex $x \in V$, there is a vertex $x' \in S$ (the *gate* of x, with $x' = x$ if $x \in S$) such that $x' \in I(x, y)$ for any $y \in S$. A *median* of a triplet u, v, w is any vertex in $I(u, v) \cap I(v, w) \cap I(w, u)$. A graph G is *median* [1] if any triplet of vertices u, v, w has a unique median. For any vertex $x \in V$ and any integer $r \geq 0$, the *ball of radius r centered at x* is the set $B_r(x) := \{v \in V : d(v, x) \leq r\}$. The unit ball $B_1(x)$ is usually denoted by $N[x]$ and called the *closed neighborhood of x*. The *sphere* of radius r centered at x is the set $S_r(x) = \{z \in V : d(z, x) = r\}$. Let also $\mathrm{cB}_r(u) = V \setminus B_r(u)$. Two balls $B_{r_1}(x)$ and $B_{r_2}(y)$ are *distinct* if $B_{r_1}(x)$ and $B_{r_2}(y)$ are distinct as sets. We denote by $\mathcal{B}(G)$ the set of all distinct balls of G, and by $\mathcal{B}_r(G)$ the set of all distinct balls of radius r of G. For a subset $Y \subseteq V$, we call $\mathrm{diam}(Y) = \max\{d(u, v) : u, v \in Y\}$ the *diameter* of Y, and we call any pair $u, v \in Y$ such that $d(u, v) = \mathrm{diam}(Y)$ a *diametral pair* of Y.

3 Trees of cycles

A *tree of cycles* (or *cactus*) is a graph in which each *block* (2-connected component) is a cycle or an edge. We can design proper labeled (unlabeled, resp.) sample compression schemes of size 2 for balls of (metric, resp.) trees, and balls of radius r of trees [8]. Indeed, for balls in metric trees, $\alpha(X)$ is generally a diametral pair u, v of X^+ and we return the ball of radius $d(u, v)/2$ centered at the middle point of the (u, v)-shortest path. This does not work for balls of radius r in trees, for which we cleverly encode a center.

We now describe the main result of this section: a proper labeled sample compression scheme of size 6 for balls of trees of cycles. Let G be a tree of cycles. For a vertex v of G that is not a cut vertex, let $C(v)$ be the unique cycle containing v. If v is a cut vertex or a degree-one vertex, then set $C(v) = \{v\}$. Let $T(G)$ be the tree whose vertices are the cut vertices and the blocks of G, and where a cut vertex v is adjacent to a block B of G if and only if $v \in B$. For any two vertices u, v of G, let $C(u, v)$ denote the union of all cycles and/or edges on the unique path of $T(G)$ between $C(u)$ and $C(v)$. Note that $C(u, v)$ is a path of cycles, and that $C(u, v)$ is gated. Let X be a realizable sample for $\mathcal{B}(G)$, and $\{u^+, v^+\}$ a diametral pair of X^+. The next lemma shows that the center of a ball realizing X can always be found in $C(u^+, v^+)$.

▶ **Lemma 1.** *Let $B_r(x)$ be a ball realizing X, x' be the gate of x in $C(u^+, v^+)$, and $r' = r - d(x, x')$. Then, the ball $B_{r'}(x')$ also realizes X.*

In what follows, let $B_r(x)$ be a ball realizing X with x in $C(u^+, v^+)$ (it exists by Lemma 1). Let C be a cycle of $C(u^+, v^+)$ containing x. The main idea is to encode a region of $C(u^+, v^+)$ where the center x of $B_r(x)$ is located (this region may be C), the center, and the radius of $B_r(x)$ by a few vertices of X. The diametral pair $\{u^+, v^+\}$ is in $\alpha(X)$. If X contains a vertex $w \neq u^+, v^+$ whose gate in $C(u^+, v^+)$ is in C, then C is easily detected by including w in $\alpha(X)$. In this case, it remains to find the position of x in C and to compute the radius r. This is done by using 2 or 3 vertices of X. Otherwise, if the gates in $C(u^+, v^+)$ of all vertices $w \in X \setminus \{u^+, v^+\}$ are outside C, then we show that $B_r(x)$ is determined by 4 vertices in X.

The partitioning of X. For a vertex $y \in C(u^+, v^+)$, set $r_y := \max\{d(y, u^+), d(y, v^+)\}$ and $r^*_y := \max\{d(y, w) : w \in X^+\}$. Clearly, $B_{r^*_y}(y)$ is the smallest ball centered at y containing X^+. For any vertex z of G, we denote by z' its gate in $C(u^+, v^+)$. Let u^* and v^* be the gates of u^+ and v^+ in C. We partition X and X^- as follows. Let X_u (X^-_u, resp.) consist of all $w \in X$ ($w \in X^-$, resp.) whose gate w' in $C(u^+, v^+)$ belongs to $C(u^+, u^*)$. The sets X_v and X^-_v are defined analogously. Let X_C (X^-_C, resp.) consist of all the vertices $w \in X$ ($w \in X^-$, resp.) whose gates w' in $C(u^+, v^+)$ belong to the cycle C. Note that some of these sets can be empty and that $X^-_u \subseteq X_u$, $X^-_v \subseteq X_v$, and $X^-_C \subseteq X_C$. Let u_0 be the cut vertex of $C(u^+, v^+)$ farthest from u^*, and such that, for any vertex $w \in X_u$, its gate $w' \in C(u^+, v^+)$ is not in $C(u_0, u^*)$. Analogously, we define the cut vertex v_0 with respect to v^* and X_v. If $u^* = u^+$ ($v^* = v^+$, resp.), then set $u_0 = u^* = u^+$ ($v_0 = v^* = v^+$, resp.).

First, suppose that $X_C = \varnothing$. Let w_1 be a vertex of X_u closest to u_0, and z_1 a vertex of X^-_u closest to x. Note that w_1 always exists as u^+ is in X_u, and that z_1 exists if and only if X^-_u is non-empty. Similarly, we define the vertices w_2 and z_2 with respect to X_v and X^-_v. See Fig. 1 for an illustration. The next lemmas show how to compute $B_r(x)$ in this case.

▶ **Lemma 2.** *For $y \in C(u_0, v_0)$, if there exists a vertex $w \in X^+ \setminus B_{r_y}(y)$, then $w' \in C(y)$. Consequently, if $X_C = \varnothing$, then, for any $y \in C(u_0, v_0)$, we have $X^+ \subset B_{r_y}(y)$ and $r_y = r^*_y$.*

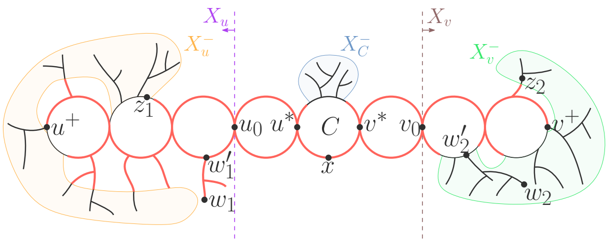

Figure 1 The vertices and sets used in the proper labeled sample compression scheme for trees of cycles. The ball $B_r(x)$ is represented in red. The cycles outside $C(u^+, v^+)$ are represented as paths.

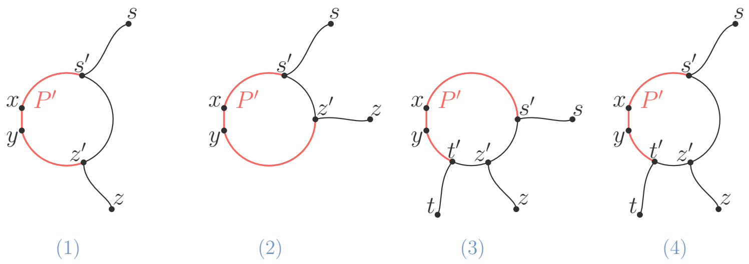
▶ **Lemma 3.** *If $X^- \neq \varnothing$ and $X_C = \varnothing$, then $B_{r_y^*}(y) \cap X^- = \varnothing$ for any vertex $y \in C(u_0, v_0)$ such that $B_{r_y^*}(y) \cap \{z_1, z_2\} = \varnothing$.*

Now, suppose that $X_C \neq \varnothing$. By the definition of r_x^*, $B_{r_x^*}(x)$ also realizes X. Let w be a vertex of X whose gate w' in $C(u^+, v^+)$ is in C. If, for every $y \in C$, $B_{r_y^*}(y)$ realizes X, then $B_{r_{w'}^*}(w')$ realizes X, and, in this case, let $s \in X^+$ be such that $d(w', s) = r_{w'}^*$. Otherwise, we can find two adjacent vertices x and y of C such that $B_{r_x^*}(x)$ realizes X, but $B_{r_y^*}(y)$ does not. This implies that there is a vertex $z \in X^-$ with $z \in B_{r_y^*}(y) \setminus B_{r_x^*}(x)$. In this case, let $s, t \in X^+$ be such that $r_y^* = d(y, s)$ and $r_x^* = d(x, t)$, with $t = s$ whenever $r_y^* = r_x^* + 1$. Let s', t', and z' be the respective gates of s, t, and z in C. If $s = t$ ($s \neq t$, resp.), then let P' be the path of C between s' and z' (t', resp.) containing the edge xy. See Fig. 2 for an illustration.

▶ **Lemma 4.** *For adjacent vertices $x, y \in C$, and the corresponding vertices $z \in X^-$ and $s \in X^+$, one of the following conditions holds:*
(1) *$r_y^* = r_x^* + 1$, $d(x, z) = d(y, z) + 1$, and $d(x, s) = d(y, s) - 1$;*
(2) *$r_y^* = r_x^* + 1$, $d(x, z) = d(y, z)$, and $d(x, s) = d(y, s) - 1$;*
(3) *$r_y^* = r_x^*$, $d(x, z) = d(y, z) + 1$, and $d(x, s) = d(y, s)$;*
(4) *$r_y^* = r_x^*$, $d(x, z) = d(y, z) + 1$, and $d(x, s) = d(y, s) - 1$.*

Without the knowledge of r_x^* and r_y^*, the relationships between $d(x, z)$ and $d(y, z)$, and between $d(x, s)$ and $d(y, s)$ do not allow us to distinguish between the cases (1) and (4). This can be done by additionally using the vertex $t \in X^+$ defined above. Indeed, in Case (1) we have $t = s$, while in Case (4) we have $t \neq s$ and $d(x, t) = d(y, t) + 1$. We continue with the following simple lemma for paths (where, for each edge xy in the path, x is to the left of y):

▶ **Lemma 5.** *Let Q be a graph which is a path with end-vertices $a \neq b$, and let d' be its distance function. Then, Q contains a unique edge $x_0 y_0$ such that $d'(x_0, b) - d'(x_0, a) \in \{1, 2\}$.*



(1) (2) (3) (4)

Figure 2 Definition and positioning of s, t, and z in the four cases of Lemma 4.

We use Lemma 5 to find adjacent vertices x_0 and y_0 of C and an integer r_x^* that satisfy a condition of Lemma 4. Let P' be the path between z' and s' (or between s' and t') containing the edge xy as defined above. Let P be the path of G obtained by joining the shortest (s', s)- and (z, z')-paths ((s, s')- and (t', t)-paths, resp.) to P'. Let d' be the distance function on P.

▶ **Lemma 6.** *Let P be the (s,z)-path or (s,t)-path of G defined above. Let x_0y_0 be the unique edge of P satisfying the conclusion of Lemma 5. Then, $x_0 = x$ and $y_0 = y$. Moreover,*

(1) *if P is an (s,z)-path, $d'(x_0,z) = d(x_0,z)$, and $d'(y_0,s) = d(y_0,s)$, then $r^*_x = d(y_0,s) - 1$;*

(2) *if P is an (s,z)-path, $d'(x_0,z) = d(x_0,z) + 1$, and $d'(y_0,s) = d(y_0,s)$, then $r^*_x = d(y_0,s) - 1$;*

(3) *if P is an (s,z)-path, $d'(x_0,z) = d(x_0,z)$, and $d'(y_0,s) = d(y_0,s) + 1$, then $r^*_x = d(y_0,s)$;*

(4) *if P is an (s,t)-path, then $r^*_x = d(x_0,t)$.*

The compressor $\alpha(X)$. The compressor $\alpha(X)$ is a vector with six coordinates, which are grouped into three pairs: $\alpha(X) := (\alpha_1(X), \alpha_2(X), \alpha_3(X))$. The pair $\alpha_1(X) \subseteq X^+$ is a diametral pair (u^+, v^+) of X^+, $\alpha_2(X)$ is used to specify the region of $C(u^+, v^+)$ where the center of the target ball is located, and the pair $\alpha_3(X)$ is used to compute the radius of this ball. We use the symbol $*$ to indicate that the respective coordinate of $\alpha(X)$ is empty.

We continue with the definitions of $\alpha_2(X)$ and $\alpha_3(X)$. First, suppose that $X_C = \varnothing$, *i.e.*, $X_u \cup X_v = X$ and $X^-_u \cup X^-_v = X^-$. Then, set $\alpha_2(X) := (w_1, w_2)$ and $\alpha_3(X) := (z_1, z_2)$. Now, suppose that $X_C \neq \varnothing$. Let w be a vertex of X whose gate w' in $C(u^+, v^+)$ belongs to C. If $B_{r^*_x}(x)$ realizes X for any vertex x of C, then set $\alpha_2(X) := (w, *)$ and $\alpha_3(X) := (s, *)$, where $s \in X^+$ is such that $d(w', s) = r^*_{w'}$. Otherwise, we pick an edge xy of C such that $B_{r^*_x}(x)$ realizes X and $B_{r^*_y}(y)$ does not realize X. Let s', t', and z' be the respective gates in C of the vertices s, t, and z as defined previously. If $s = t$, then the path P is defined by the vertices s and z, and set $\alpha_3(X) := (s, z)$. Otherwise, the path P is defined by the vertices s and t, and set $\alpha_3(X) := (s, t)$. Moreover, set $\alpha_2(X) := (*, w)$ if the edge xy belongs to the path from s' to z' (from s' to t', resp.) in the clockwise traversal of C, and $\alpha_2(X) := (w, *)$ otherwise. Formally, the compressor function α is defined in the following way:

(C1) if $X^- = \varnothing$, set $\alpha_1(X) = \alpha_2(X) = \alpha_3(X) := (*, *)$;

(C2) otherwise, if $|X^+| = 0$, set $\alpha_1(X) = \alpha_2(X) := (*, *)$ and $\alpha_3(X) := (z, *)$, where z is an arbitrary vertex of X^-;

(C3) otherwise, if $X^+ = \{u\}$, set $\alpha_1(X) := (u, *)$, $\alpha_2(X) := (*, *)$, and $\alpha_3(X) := (z, *)$, where z is an arbitrary vertex of X^-;

(C4) otherwise, if $|X^+| \geq 2$ and $X_C = \varnothing$, set $\alpha_1(X) := (u^+, v^+)$, $\alpha_2(X) := (w_1, w_2)$, and

- **(C4i)** if the vertex z_2 does not exist, then set $\alpha_3(X) := (z_1, *)$;
- **(C4ii)** if the vertex z_1 does not exist, then set $\alpha_3(X) := (*, z_2)$;
- **(C4iii)** if the vertices z_1 and z_2 exist, set $\alpha_3(X) := (z_1, z_2)$;

(C5) otherwise ($|X^+| \geq 2$ and $X_C \neq \varnothing$), and

- **(C5i)** if, for any vertex $y \in C$, the ball $B_{r^*_y}(y)$ realizes X, then set $\alpha_1(X) := (u^+, v^+)$, $\alpha_2(X) := (w, *)$, and $\alpha_3(X) := (s, *)$, where $s \in X^+$ is such that $d(w', s) = r^*_{w'}$;
- **(C5ii)** otherwise, if s and z are given, and the edge xy belongs to the clockwise (s', z')-path of C, then set $\alpha_2(X) := (*, w)$ and $\alpha_3(X) := (s, z)$;
- **(C5iii)** otherwise, if s and z are given, and the edge xy belongs to the counterclockwise (s', z')-path of C, then set $\alpha_2(X) := (w, *)$ and $\alpha_3(X) := (s, z)$;
- **(C5iv)** otherwise, if s and t are given, and the edge xy belongs to the clockwise (s', t')-path of C, then set $\alpha_2(X) := (*, w)$ and $\alpha_3(X) := (s, t)$;
- **(C5v)** otherwise, if s and t are given, and the edge xy belongs to the counterclockwise (s', t')-path of C, then set $\alpha_2(X) := (w, *)$ and $\alpha_3(X) := (s, t)$.

The reconstructor $\beta(X)$. Let Y be a vector on six coordinates grouped into three pairs Y_1, Y_2, and Y_3. If $Y_1 = (y_1, y_2)$, then, for any vertex t of G, we denote by t' its gate in $C(y_1, y_2)$. For any vertex y of $C(y_1, y_2)$, we also set $r_y := \max\{d(y, y_1), d(y, y_2)\}$. The reconstructor β takes Y and returns a ball $B_r(y)$ of G defined in the following way:

(R1) if $Y = ((*, *), (*, *), (*, *))$, then $\beta(Y)$ is any ball that contains the vertex set of G;

(R2) if $Y = ((*, *), (*, *), (y_5, *))$, then $\beta(Y)$ is the empty set;

(R3) if $Y = ((y_1, *), (*, *), (y_5, *))$, then $\beta(Y)$ is the ball $B_0(y_1)$;

(R4) if $Y_1 = (y_1, y_2)$ and $Y_2 = (y_3, y_4)$, then let u_0 be the cut vertex of $C(y'_3)$ between y'_3 and y_2, and v_0 be the cut vertex of $C(y'_4)$ between y'_4 and y_1. Then, $\beta(Y)$ is any ball $B_{r_y}(y)$ centered at $y \in C(u_0, v_0)$ such that $B_{r_y}(y)$ contains no vertex of Y_3.

(R5i) if $Y = ((y_1, y_2), (y_3, *), (y_5, *))$, then $\beta(Y)$ is the ball $B_r(y'_3)$ of radius $r = d(y'_3, y_5)$;

(R5ii) if $Y = ((y_1, y_2), (*, y_4), (y_5, y_6))$ and $(y_5, y_6) \in X^+ \times X^-$, let xy be the edge of the (y'_5, y'_6)-path in the clockwise traversal of the cycle $C(y'_4)$ such that $|d'(x, y_6) - d'(x, y_5)| \in \{1, 2\}$ and y is closer to y_6 than x is. Let $\beta(Y)$ be the ball $B_r(x)$, where $r = d(y, y_5)$ if $d'(y, y_5) = d(y, y_5) + 1$, and $r = d(y, y_5) - 1$ otherwise;

(R5iii) if $Y = ((y_1, y_2), (y_3, *), (y_5, y_6))$ and $(y_5, y_6) \in X^+ \times X^-$, let xy be the edge of the (y'_5, y'_6)-path in the counterclockwise traversal of $C(y'_3)$ such that $|d'(x, y_6) - d'(x, y_5)| \in \{1, 2\}$ and y is closer to y_6 than x is. Let $\beta(Y)$ be the ball $B_r(x)$, where $r = d(y, y_5)$ if $d'(y, y_5) = d(y, y_5) + 1$, and $r = d(y, y_5) - 1$ otherwise;

(R5iv) if $Y = ((y_1, y_2), (*, y_4), (y_5, y_6))$ and $(y_5, y_6) \in X^+ \times X^+$, let xy be the edge of the (y'_5, y'_6)-path in the clockwise traversal of the cycle $C(y'_4)$ such that $|d'(x, y_6) - d'(x, y_5)| \in \{1, 2\}$ and y is closer to y_6 than x is. Let $\beta(Y)$ be the ball $B_r(x)$, where $r = d(x, y_6)$;

(R5v) if $Y = ((y_1, y_2), (y_3, *), (y_5, y_6))$ and $(y_5, y_6) \in X^+ \times X^+$, let xy be the edge of the (y'_5, y'_6)-path in the counterclockwise traversal of the cycle $C(y'_3)$ such that $|d'(x, y_6) - d'(x, y_5)| \in \{1, 2\}$ and y is closer to y_6 than x is. Let $\beta(Y)$ be the ball $B_r(x)$, where $r = d(x, y_6)$;

▶ **Proposition 7.** *For any tree of cycles G, the pair (α, β) of vectors defines a proper labeled sample compression scheme of size 6 for $\mathcal{B}(G)$.*

Proof. Let X be a realizable sample for $\mathcal{B}$, $Y = \alpha(X)$, and $B_r(x^*) = \beta(Y)$. We prove case by case that the ball $B_r(x^*)$ realizes the sample X. One can easily see that the cases (Rk) and their subcases in the definition of β correspond to the cases (Ck) and their subcases in the definition of α: namely, the vector Y in Case (Rk) has the same specified coordinates as the vector $\alpha(X)$ in Case (Ck). We consider only the Case (R4), the other cases being similar. Then, $Y_1 = (y_1, y_2)$ and $Y_2 = (y_3, y_4)$. Since $Y = \alpha(X)$, the sample X satisfies the conditions of Case (C4), *i.e.*, $|X^+| \geq 2$ and $X_C = \varnothing$. Therefore, $Y_1 = (y_1, y_2) = (u^+, v^+) = \alpha_1(X), Y_2 = (y_3, y_4) = (w_1, w_2) = \alpha_2(X)$, and Y_3 (containing one or two vertices) coincides with $\alpha_3(X)$ (containing one or two vertices z_1, z_2 as in subcases (C4i)–(C4iii)). The ball $B_{r_y}(y)$ returned by Case (R4) is centered at $y \in C(u_0, v_0)$, contains Y_1, and is disjoint from Y_3. Since the target ball $B_r(x)$ has its center on $C(u_0, v_0)$ and is compatible with $X \supseteq Y_1 \cup Y_3$, the ball $B_{r_y}(y)$ is well-defined. By Lemma 2, $B_{r_y}(y)$ contains X^+. By Lemma 3, $B_{r_y}(y)$ is disjoint from X^-. Thus, $B_{r_y}(y)$ is compatible with X. ◀

▶ Remark 8. The most technically involved case of the previous result is the case $X_C \neq \varnothing$. In fact, this case corresponds to proper labeled sample compression schemes in *spiders*, *i.e.*, in graphs consisting of a single cycle C and paths of different lengths emanating from this cycle. Due to this case, $\alpha(X)$ in our result is not a signed map but a signed vector of size 6. Thus, in this case, we need extra information compared to the initial definition of proper labeled sample compression schemes. The VC-dimension of the family of balls in a spider and in a tree of cycles is 3. We wonder *whether the family of balls in spiders admits a proper labeled sample compression scheme without any information that is of (a) size* 3 *or (b) constant size.*

4 Cube-free median graphs

The *dimension* $\dim(G)$ of a median graph G is the largest dimension of a hypercube of G. A *cube-free median graph* is a median graph of dimension 2, *i.e.*, a median graph not containing 3-cubes as isometric subgraphs. For references about median graphs, see [1]. For cube-free median graphs, see [2, 11, 13, 14]. We use the fact that intervals of median graphs are gated. We describe a proper LSCS of size 22 for balls of cube-free median graphs.

Let G be a cube-free median graph. Let X be a realizable sample for $\mathcal{B}(G)$, and $\{u^+, v^+\}$ a diametral pair of X^+. The next lemma shows that the center of a ball realizing X can always be found in $I(u^+, v^+)$ (this result does not hold for all median graphs):

▶ **Lemma 9.** *If x' is the gate of x in the interval $I(u^+, v^+)$, and $r' = r - d(x, x')$, then X is a realizable sample for $B_{r'}(x')$, i.e., $X^+ \subseteq B_{r'}(x')$ and $X^- \cap B_{r'}(x') = \varnothing$.*

By [14], $I(u^+, v^+)$ of a cube-free median graph has an isometric embedding in the square grid $\mathbb{Z}^2$. We denote by (z_a, z_b) the coordinates in $\mathbb{Z}^2$ of a vertex $z \in I(u, v)$. We consider isometric embeddings of $I(u, v)$ in $\mathbb{Z}^2$ for which $u = (0, 0)$ and $v = (v_a, v_b)$ with $v_a \geq 0$ and $v_b \geq 0$. We fix a canonical isometric embedding, which can be used both by the compressor and the reconstructor. Finally, we use the same notation for the vertices and their images under the embedding, and we denote by $\mathbf{I}$ the interval $I(u^+, v^+)$ embedded in $\mathbb{Z}^2$. As usual, for a vertex $z \in V$, we denote by z' its gate in the interval $I(u^+, v^+)$.

The compressor $\alpha(X)$. The compressor $\alpha(X)$ is a vector with 22 coordinates grouped into four parts $\alpha(X) := (\alpha_1(X), \alpha_2(X), \alpha_3(X), \alpha_4(X))$. The part $\alpha_1(X) \subseteq X^+$ consists of a diametral pair (u^+, v^+) of X^+. The part $\alpha_2(X) \subseteq X$ has size 4, and is used to specify a region $\mathbf{R} \subseteq \mathbf{I} = I(u^+, v^+)$ such that the gates in $I(u^+, v^+)$ of all the vertices of X are located outside or on the boundary of $\mathbf{R}$. Moreover, $\mathbf{R}$ contains the center x of the target ball $B_r(x)$. The parts $\alpha_3(X) \subseteq X^+$ and $\alpha_4(X) \subseteq X^-$ each have size 8 and are used to locate the center and the radius of a ball $B_{r''}(y)$ realizing X. Now, we formally define $\alpha_i(X)$, $i = 1, ..., 4$. Let $X_1 := \{w \in X : w'_b \geq x_b\}$, $X_2 := \{w \in X : w'_a \geq x_a\}$, $X_3 := \{w \in X : w'_b \leq x_b\}$, and $X_4 := \{w \in X : w'_a \leq x_a\}$. Since $I(u^+, v^+)$ is gated, $X = \cup_{i=1}^4 X_i$. Denote by X'_i, $i = 1, ..., 4$, the gates of the vertices of X_i in $I(u^+, v^+)$. Set $\alpha_2(X) := (w_1, w_2, w_3, w_4) \in X^4$, where:

- w_1 is a vertex of X_1 whose gate w'_1 has the smallest ordinate among the vertices of X'_1;
- w_2 is a vertex of X_2 whose gate w'_2 has the smallest abscissa among the vertices of X'_2;
- w_3 is a vertex of X_3 whose gate w'_3 has the largest ordinate among the vertices of X'_3;
- w_4 is a vertex of X_4 whose gate w'_4 has the largest abscissa among the vertices of X'_4;

For a vertex $w = (w_a, w_b) \in \mathbb{Z}^2$, we consider the four coordinate halfplanes $\mathbf{H}_{\leq w_a} := \{t : t_a \leq w_a\}$, $\mathbf{H}_{\geq w_a}$,$\mathbf{H}_{\leq w_b}$, and $\mathbf{H}_{\geq w_b}$. Let $\mathbf{R}$ be the set of vertices of $\mathbf{I}$ that belong to the intersection of the halfplanes $\mathbf{H}_1 := \mathbf{H}_{\leq w_{1b}}$, $\mathbf{H}_2 := \mathbf{H}_{\leq w_{2a}}$, $\mathbf{H}_3 := \mathbf{H}_{\geq w_{3b}}$, and $\mathbf{H}_4 := \mathbf{H}_{\geq w_{4a}}$. If a vertex w_i does not exist, then the corresponding halfplane $\mathbf{H}_i$ is not defined. From the definition, the inside of $\mathbf{R}$ does not contain gates of vertices of X. We denote by $\mathbf{S}_i$, $i = 1, ..., 4$, the intersection of $\mathbf{I}$ with the closure of the complementary halfspace of $\mathbf{H}_i$. We call $\mathbf{S}_i$, $i = 1, ...4$, a *strip of* $\mathbf{I}$. Consequently, the interval $\mathbf{I}$ is covered by the region $\mathbf{R}$, two *horizontal* strips $\mathbf{S}_1$ and $\mathbf{S}_3$, and two *vertical* strips $\mathbf{S}_2$ and $\mathbf{S}_4$. Using this notation, we can redefine X_i as the

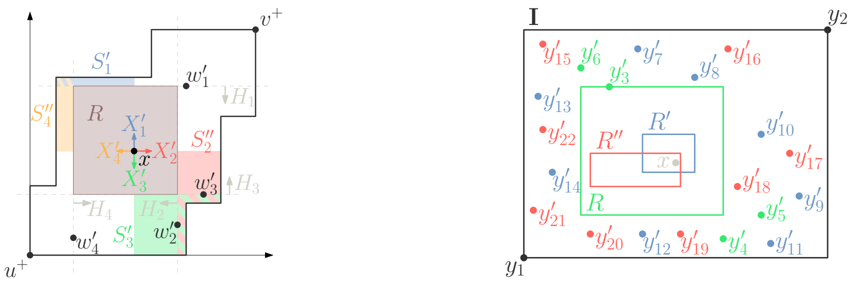


Figure 3 On the left, the region $\mathbf{R}$ and the halfstrips $\mathbf{S}'_1(x)$, $\mathbf{S}''_2(x)$, $\mathbf{S}'_3(x)$, and $\mathbf{S}''_4(x)$. On the right, the regions $\mathbf{R}$, $\mathbf{R}'$, and $\mathbf{R}''$ computed from $\alpha(X)$. Steps 1-4 of the reconstruction correspond to the black, green, blue, and red parts of the figure. The target center x is given in gray.

sets of all the vertices of X whose gate in $\mathbf{I}$ belongs to the strip $\mathbf{S}_i$. Consequently, $X'_i \subseteq \mathbf{S}_i$. Furthermore, for a vertex $z \in \mathbb{Z}^2$, each strip $\mathbf{S}_i$ is partitioned into two strips $\mathbf{S}'_i(z)$ and $\mathbf{S}''_i(z)$ by the vertical or horizontal line passing via z. The labeling of the strips is done in the clockwise order around z, see Fig. 3 (left). Let $\alpha_3(X) := (s_1, t_1, s_2, t_2, s_3, t_3, s_4, t_4)$, where

- s_1 is a vertex of X^+ furthest from x, whose gate s'_1 belongs to $\mathbf{S}'_1(x)$, and t_1 is a vertex of X^+ such that its gate t'_1 belongs to $\mathbf{S}''_1(x)$ and the abscissa of t'_1 is closest to x_a;
- s_2 is a vertex of X^+ furthest from x, whose gate s'_2 belongs to $\mathbf{S}''_2(x)$, and t_2 is a vertex of X^+ such that its gate t'_2 belongs to $\mathbf{S}'_2(x)$ and the ordinate of t'_2 is closest to x_b;
- s_3 is a vertex of X^+ furthest from x, whose gate s'_3 belongs to $\mathbf{S}'_3(x)$, and t_3 is a vertex of X^+ such that its gate t'_3 belongs to $\mathbf{S}''_3(x)$ and the abscissa of t'_3 is closest to x_a;
- s_4 is a vertex of X^+ furthest from x, whose gate s'_4 belongs to $\mathbf{S}''_4(x)$, and t_4 is a vertex of X^+ such that its gate t'_4 belongs to $\mathbf{S}'_4(x)$ and the ordinate of t'_4 is closest to x_b.

Let $\alpha_4(X) := (p_1, q_1, p_2, q_2, p_3, q_3, p_4, q_4)$, where p_i is a vertex of X^- closest to x, whose gate p'_i belongs to $\mathbf{S}'_i(x)$, and q_i is a vertex of X^- closest to x, whose gate q'_i belongs to $\mathbf{S}''_i(x)$. If any of the vertices of the four groups is not defined, then its corresponding coordinate in $\alpha(X)$ is set to $*$.

The reconstructor $\beta(Y)$. Let Y be a vector of 22 coordinates corresponding to a realizable sample and grouped into four parts $Y_1 := (y_1, y_2)$, $Y_2 := (y_3, y_4, y_5, y_6)$, $Y_3 := (y_7, y_8, y_9, y_{10}, y_{11}, y_{12}, y_{13}, y_{14})$, and $Y_4 := (y_{15}, y_{16}, y_{17}, y_{18}, y_{19}, y_{20}, y_{21}, y_{22})$. The reconstructor $\beta(Y)$ returns a ball $B_{r''}(y)$ by performing the following steps (see Fig. 3 (right)):

1. Using Y_1, canonically isometrically embed $I(y_1, y_2)$ into $\mathbb{Z}^2$ as $\mathbf{I}$.
2. Using Y_2, compute the gates y'_i of y_i in $\mathbf{I}$ and compute the region $\mathbf{R}$ as the intersection of the halfplanes $\mathbf{H}_{\leq y_{1b}}$, $\mathbf{H}_{\leq y_{2a}}$, $\mathbf{H}_{\geq y_{3b}}$, and $\mathbf{H}_{\geq y_{4a}}$ with $\mathbf{I}$.
3. Using Y_3, compute the set $\mathbf{R}' \subseteq \mathbf{R}$ of all $y = (y_a, y_b) \in \mathbf{R}$ such that the gates $y'_7, y'_8, y'_9, y'_{10}, y'_{11}, y'_{12}, y'_{13}, y'_{14}$ belong to $\mathbf{S}'_1(y)$, $\mathbf{S}''_1(y)$, $\mathbf{S}''_2(y)$, $\mathbf{S}'_2(y)$, $\mathbf{S}'_3(y)$, $\mathbf{S}''_3(y)$, $\mathbf{S}''_4(y)$, $\mathbf{S}'_4(y)$, resp. For each $y \in \mathbf{R}'$, let r'_y be the *smallest* radius such that $Y_1 \cup Y_3 \subseteq B_{r'_y}(y)$.
4. Using Y_4, compute the region $\mathbf{R}'' \subseteq \mathbf{R}$ consisting of all the vertices $y \in \mathbf{R}$ such that the gates $y'_{15}, y'_{16}, \ldots, y'_{21}, y'_{22}$ belong to the strips $\mathbf{S}'_1(y)$, $\mathbf{S}''_1(y)$, …, $\mathbf{S}'_4(y)$, $\mathbf{S}''_4(y)$, respectively. For each $y \in \mathbf{R}''$, let r''_y be the *largest* radius such that $B_{r''_y}(y) \cap Y_4 = \varnothing$.
5. Let $\mathbf{R}_0 := \{y \in \mathbf{R}' \cap \mathbf{R}'' : r''_y \geq r'_y\}$ and return as $\beta(Y)$ any ball $B_{r''_y}(y)$ with $y \in \mathbf{R}_0$.

▶ **Proposition 10.** *For any cube-free median graph G, the pair (α, β) of vectors defines a proper labeled sample compression scheme of size 22 for $\mathcal{B} = \mathcal{B}(G)$.*

5 Interval Graphs

For any interval graph $G = (V, E)$, we construct proper LSCS of size 4 for $\mathcal{B}(G)$ and $\mathcal{B}_r(G)$. We consider a representation of G by a set of segments $J_v, v \in V$ of $\mathbb{R}$ with pairwise distinct ends. For any $u \in V$, we denote by $J_u = [s_u, e_u]$ its segment, where s_u is the start of J_u, and e_u is the end of J_u, *i.e.*, $s_u \le e_u$. We use the following property of interval graphs:

▶ **Lemma 11.** *If $u, v \in B_r(x)$, $s_u, s_z < s_v$, and $e_u < e_v, e_z$, then $z \in B_r(x)$.*

Proof. Since $s_z < s_v$ and $e_u < e_z$, if J_u and J_v intersect, then J_z covers the segment $[s_v, e_u]$, and otherwise, J_z intersects $[e_u, s_v]$. Let P be a path obtained from a shortest (x, u)-path of G by removing u, and Q be a path obtained from a shortest (x, v)-path by removing v. The union J_S of all segments of $S := P \cup \{x\} \cup Q$ intersects J_u and J_v. If J_u and J_v intersect, then J_z covers $[s_v, e_u]$, and thus, intersects J_S. Otherwise, J_S covers $[e_u, s_v]$, and J_z intersects $[e_u, s_v]$. In both cases, J_z and J_S intersect, whence a segment of S intersects J_z. Since all segments of S are at distance at most $r - 1$ from x, $z \in B_r(x)$. ◀

Let X be a realizable sample for $\mathcal{B}(G)$. A *farthest pair* of X^+ is a pair $\{u^+, v^+\}$ such that u^+ is the vertex in X^+ whose interval J_{u^+} ends farthest to the left, and v^+ is the vertex in X^+ whose interval J_{v^+} begins farthest to the right, *i.e.*, for any $w \in X^+$, we have $e_{u^+} < e_w$ and $s_w < s_{v^+}$. If $u^+ \ne v^+$, then $[e_{u^+}, s_{v^+}] \cap J_w \ne \varnothing$ for any $w \in X^+$. If $u^+ = v^+$, then $J_{u^+} \subseteq J_w$ for any $w \in X^+$. A vertex p^- of X^- is a *left-bounder* if there is a ball $B_r(x)$ realizing X such that $e_{p^-} < s_x$ and, for all $p \in X^-$ with $e_p < s_x$, it holds that $e_p \le e_{p^-}$. Analogously, a vertex q^- of X^- is a *right-bounder* if there is a ball $B_r(x)$ realizing X such that $e_x < s_{q^-}$ and, for all $q \in X^-$ with $e_x < s_q$, it holds that $s_{q^-} \le s_q$. If p^- is a left-bounder and q^- is a right-bounder, then $\{p^-, q^-\}$ is a *bounding pair* of X^-. The farthest pair $\{u^+, v^+\}$ of X^+ and the bounding pair $\{p^-, q^-\}$ of X^- have the following properties:

▶ **Lemma 12.** *If $u^+, v^+ \in B_r(x)$ and $r > 0$, then $X^+ \subseteq B_r(x)$.*

Proof. Pick any $w \in X^+ \setminus \{u^+, v^+\}$. By the definition of u^+ and v^+, we have $s_w < s_{v^+}$ and $e_{u^+} < e_w$. If $u^+ \ne v^+$, then $s_{u^+} < s_{v^+}$ and $e_{u^+} < e_{v^+}$, and so, $s_{u^+}, s_w < s_{v^+}$ and $e_{u^+} < e_{v^+}, e_w$. By Lemma 11, $w \in B_r(x)$. Now, let $u^+ = v^+$. Then, $J_{u^+} \subset J_w$, and thus, any segment intersecting J_{u^+} also intersects J_w. Consequently, w is included in any ball of G of radius $r > 0$ containing u^+, and, in particular, $w \in B_r(x)$. ◀

▶ **Lemma 13.** *If $e_{p^-} < s_x$ and $p^- \notin B_r(x)$, then, for all $z \in X^-$ with $e_z < e_{p^-}$, $z \notin B_r(x)$. Also, if $e_x < s_{q^-}$ and $q^- \notin B_r(x)$, then, for all $w \in X^-$ with $s_{q^-} < s_w$, $w \notin B_r(x)$.*

Proof. For the first statement, towards a contradiction, suppose that $e_{p^-} < s_x$ and $p^- \notin B_r(x)$, but there exists $z \in X^-$ such that $e_z < e_{p^-}$ and $z \in B_r(x)$. Then, $s_z, s_{p^-} < s_x$ since $s_z \le e_z < e_{p^-} < s_x$, and $e_z < e_x, e_{p^-}$ as $e_z < e_{p^-} < s_x \le e_x$. By Lemma 11, $p^- \in B_r(x)$, a contradiction. For the second statement, suppose by way of contradiction that $e_x < s_{q^-}$ and $q^- \notin B_r(x)$, but there exists $w \in X^-$ such that $s_{q^-} < s_w$ and $w \in B_r(x)$. Then, $s_x, s_{q^-} < s_w$ since $s_x \le e_x < s_{q^-} < s_w$, and $e_x < e_w, e_{q^-}$ as $e_x < s_{q^-} < s_w \le e_w$. By Lemma 11, $q^- \in B_r(x)$, a contradiction. ◀

The compressor $\alpha(X)$ of X is a vector with four coordinates grouped into two pairs: $\alpha(X) := (\alpha_1(X), \alpha_2(X))$. The pair $\alpha_1(X)$ is a farthest pair $\{u^+, v^+\}$ of X^+ and the pair $\alpha_2(X)$ is a bounding pair $\{p^-, q^-\}$ of X^-. We use the symbol $*$ to indicate that the respective coordinate of $\alpha(X)$ is empty. We define $\alpha(X)$ as follows:

(C1) if $X^+ = \varnothing$, then set $\alpha_1(X) = \alpha_2(X) := (*, *)$;
(C2) if $X^+ = \{x\}$, then set $\alpha_1(X) := (x, *)$ and $\alpha_2(X) := (*, *)$;
(C3) if $|X^+| \geq 2$, then set $\alpha_1(X) := (u^+, v^+)$ if $u^+ \neq v^+$ and $\alpha_1(X) := (*, v^+)$ if $u^+ = v^+$;
 (C3i) if $X^- = \varnothing$, then set $\alpha_2(X) := (*, *)$;
 (C3ii) if there exists a bounding pair of X^-, then set $\alpha_2(X) := (p^-, q^-)$;
 (C3iii) if there exists a left-bounder, but not a right-bounder of X^-, then set $\alpha_2(X) := (p^-, *)$;
 (C3iv) if there exists a right-bounder, but not a left-bounder vertex of X^-, then set $\alpha_2(X) := (*, q^-)$.

The reconstructor β takes any signed vector Y on four coordinates grouped into two pairs Y_1 and Y_2 from $\mathrm{Im}(\alpha)$, and returns a ball $\beta(Y)$ defined as follows:
(R1) if $Y_1 = Y_2 = (*, *)$, then $\beta(Y)$ is the empty ball;
(R2) if $Y_1 = (y_1, *)$ and $Y_2 = (*, *)$, then $\beta(Y)$ is the ball of radius 0 centered at y_1;
(R3) if $Y_1 = (y_1, y_2)$ or $Y_1 = (*, y_2)$, then $\beta(Y)$ is any ball $B_r(x)$ of radius $r \geq 1$ containing Y_1, not intersecting Y_2, and such that:
 (R3i) if $Y_2 = (*, *)$, then no condition;
 (R3ii) if $Y_2 = (y_3, y_4)$, then $e_{y_3} < s_x$ and $e_x < s_{y_4}$;
 (R3iii) if $Y_2 = (y_3, *)$, then $e_{y_3} < s_x$;
 (R3iv) if $Y_2 = (*, y_4)$, then $e_x < s_{y_4}$.

Now, let X be a realizable sample for $\mathcal{B}_r(G)$. If $|X^+| \geq 2$ or $r \geq 1$, then we define α and β as above, since, in these cases, we do not specify the radius of the ball realizing X in α, nor the radius of the ball returned by β. So, we can exhibit a proper LSCS of size 4 for $\mathcal{B}_r(G)$ if we can deal with the case $|X^+| \leq 1$. The only difference is that if $|X^+| \leq 1$, then we set $\alpha_2(X)$ as in Case (C3), but we set $\alpha_1(X) := (*, *)$ when $X^+ = \varnothing$, and $\alpha_1(X) := (*, x)$ when $X^+ = \{x\}$. Now, let $r = 0$. If $|X^+| = 0$ and there is a ball $B_0(y)$ such that $y \notin X^-$ and $e_y < e_z$ for any $z \in V, z \neq y$, then $\alpha(X) := ((*, *), (*, *))$. Otherwise, if $|X^+| = 0$, there is a ball $B_0(y)$ such that $y \notin X^-$, $w' \in X^-$, $e_{w'} < e_y$, and, for all $w \in V$ with $e_w < e_y$, we have $e_w \leq e_{w'}$. In this case, $\alpha(X) := ((*, *), (w', *))$. If $X^+ = \{x\}$, set $\alpha(X) := ((x, *), (*, *))$. Given any signed vector Y on four coordinates, β returns a ball $\beta(Y)$ defined as follows. If $Y = ((*, *), (*, *))$, then $\beta(Y)$ is the ball $B_0(x)$ such that $e_x < e_z$ for any $z \in V \setminus \{x\}$. If $Y = ((*, *), (y_3, *))$, then $\beta(Y)$ is the ball $B_0(x)$ such that $e_{y_3} < e_x$, and, for all $w \in V$ with $e_w < e_x$, it holds that $e_w \leq e_{y_3}$. Lastly, if $Y = ((x, *), (*, *))$, then $\beta(Y)$ is the ball $B_0(x)$.

▶ **Proposition 14.** *For any interval graph $G = (V, E)$, the pair (α, β) of vectors defines a proper labeled sample compression scheme of size 4 for $\mathcal{B}(G)$ and $\mathcal{B}_r(G)$.*

Proof. Let X be a realizable sample for $\mathcal{B}(G)$ (the case of $\mathcal{B}_r(G)$ is similar), $Y = \alpha(X)$, and $B_r(x) = \beta(Y)$. The cases (Rk) and their subcases in the definition of β correspond to the cases (Ck) and their subcases in the definition of α. The correctness is trivial if $k = 1, 2$. Now, let $k = 3$. Since Y_1 always contains a farthest pair of X^+ and the returned ball $B_r(x)$ contains Y_1 and $r \geq 1$, by Lemma 12, $X^+ \subseteq B_r(x)$. Furthermore, in Case (C3), any ball realizing X must have a radius $r \geq 1$ since $|X^+| \geq 2$. Now, we prove that $X^- \cap B_r(x) = \varnothing$. This is trivial in subcase (R3i) since $X^- = \varnothing$. In the remaining subcases of (R3), $X^- \cap B_r(x) = \varnothing$ follows from the definition of the corresponding subcase of case (C3) and Lemma 13. ◀

6 Hyperbolic graphs

A (ρ,μ)*-approximate proper labeled sample compression scheme of size* k for the family of balls $\mathcal{B}(G)$ of a graph G compresses any realizable sample X to a subsample $\alpha(X)$ of support of size k, such that $\beta(\alpha(X))$ is a ball $B_r(x)$ such that $X^+ \subseteq B_{r+\rho}(x)$ and $X^- \cap B_{r-\mu}(x) = \varnothing$. Let (V,d) be a metric space and $w \in V$. Let $\delta \geq 0$. A metric space (X,d) is δ*-hyperbolic* [18] if, for any four points u,v,x,y of X, the two larger of the sums $d(u,v)+d(x,y)$, $d(u,x)+d(v,y)$, and $d(u,y)+d(v,x)$, differ by at most $2\delta \geq 0$. Next, we show that δ-hyperbolic graphs admit a $(2\delta,3\delta)$-approximate labeled sample compression scheme of size 2.

An interval $I(u,v)$ of a graph is ν*-thin* if $d(x,y) \leq \nu$ for any two points $x,y \in I(u,v)$ with $d(u,x)=d(u,y)$ and $d(v,x)=d(v,y)$. Intervals of δ-hyperbolic graphs are 2δ-thin. A metric space (X,d) is *injective* if, whenever X is isometric to a subspace Z of a metric space (Y,d'), there is a map $f: Y \to Z$ such that $f(z)=z$ for any $z \in Z$ and $d'(f(x),f(y)) \leq d'(x,y)$ for any $x,y \in Y$. By a construction of Isbell [20] (rediscovered by Dress [15]), any metric space (V,d) has an *injective hull* $E(V)$, *i.e.*, the smallest injective metric space into which (V,d) isometrically embeds. Lang [21] proved that the injective hull of a δ-hyperbolic space is δ-hyperbolic. It was shown in [15] that the injective hull $T := T(u,v,y,w)$ of a metric space on 4 points u,v,y,w is a rectangle $R := R(u',v',y',w')$ with four attached tips uu',vv',yy',ww' (one or several tips may reduce to a single point or R may reduce to a segment or a single point). The smallest side of R is exactly the hyperbolicity of the quadruplet u,v,y,w.

Let X be a realizable sample of $\mathcal{B}(G)$ and $\{u^+,v^+\}$ be a diametral pair of X^+. Let $B_{r^*}(y)$ be a ball of smallest radius such that $X^+ \subseteq B_{r^*}(y)$ and $X^- \cap B_{r^*}(y) = \varnothing$. We set $\alpha(X) := \varnothing$ if $X^+ = \varnothing$, $\alpha(X) := X^+$ if $|X^+| = 1$, and $\alpha(X) := \{u^+,v^+\}$ if $|X^+| \geq 2$. Given a subset Y of size at most 2, the reconstructor returns $\beta(Y) = \varnothing$ if $Y = \varnothing$, $\beta(Y) = B_0(y)$ if $Y = \{y\}$, and $\beta(Y) = B_{d(y_1,y_2)/2}(x)$ if $Y = \{y_1,y_2\}$, where x is the middle of a (y_1,y_2)-geodesic.

▶ **Proposition 15.** *For any δ-hyperbolic graph $G=(V,E)$, the pair (α,β) defines a $(2\delta,3\delta)$-approximate proper labeled sample compression scheme of size 2 for $\mathcal{B}(G)$.*

Proof. We first show that $X^+ \subseteq B_{r+2\delta}(x)$, where $r = d(u^+,v^+)/2$ and x is a middle of a (u^+,v^+)-geodesic. Pick any $w \in X^+$. Since u^+,v^+ is a diametral pair of X^+, $d(u^+,w) \leq 2r$ and $d(v^+,w) \leq 2r$. We also have $d(u^+,v^+) = 2r$ and $d(x,u^+) = d(x,v^+) = r$. Thus, the three distance sums have the form $d(u^+,w)+d(x,v^+) \leq 3r$, $d(v^+,w)+d(x,u^+) \leq 3r$, and $d(u^+,v^+)+d(x,w) = 2r+d(x,w)$. By the definition of δ-hyperbolicity, we conclude that either $d(x,w) \leq r$ (if $d(u^+,v^+)+d(x,w)$ is at most $3r$) or $d(x,w) \leq r+2\delta$ (if $d(u^+,v^+)+d(x,w)$ is the largest sum). Hence, $w \in B_{r+2\delta}(x)$. We now show that $X^- \cap B_{r-3\delta}(x) = \varnothing$. Pick $w \in X^-$ and consider the injective hull T of the points $\{u^+,v^+,y,w\}$. T is a rectangle R with four tips (see Fig. 4) and is a subspace of the injective hull $E(V)$. Since $w \in X^-$, $w \notin B_{r^*}(y)$. Since $u^+,v^+ \in B_{r^*}(y)$, we deduce that $d(y,w) > d(y,u^+)$ and $d(y,w) > d(y,v^+)$. Let x' be a point of $I(u^+,v^+) \cap T$ such that $d(u^+,x') = d(u^+,x) = r$ and $d(v^+,x') = d(v^+,x) = r$. Since the injective hull T is δ-hyperbolic, its intervals are 2δ-thin, and thus, $d(x,x') \leq 2\delta$.

Case 1. u^+, v^+, y, and w are as in Fig. 4(1). First, suppose that x' belongs to the tip between u^+ and u' or to the segment between u' and v'. Since y' and w' belong to a common geodesic from y to w and from y to v^+, and since $v^+ \in B_{r^*}(y)$ and $w \notin B_{r^*}(y)$, we deduce that $d(w,w') > d(w',v^+) \geq d(v',v^+)$. Consequently, $d(v',w) > d(v',v^+)$. If x' is located on the tip between u^+ and u' or on the segment between u' and v', then, since $r = d(x',v^+) = d(x',v') + d(v',v^+)$ and $d(x',w) = d(x',v') + d(v',w)$, we obtain that $w \notin B_r(x')$. Since $d(x,x') \leq 2\delta$, $w \notin B_{r-2\delta}(x)$. If x' belongs to the tip between v' and v^+, then $r = d(x',v^+) \leq d(v',v^+) \leq d(v',w)$, whence $w \notin B_r(x')$ and $w \notin B_{r-2\delta}(x)$.

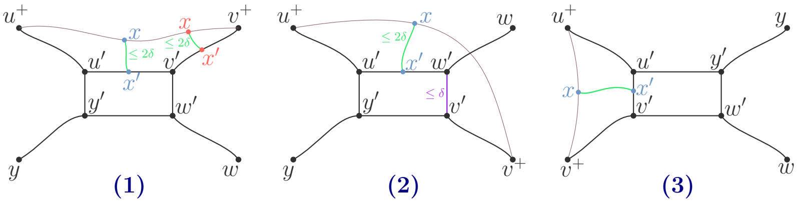

Figure 4 Cases 1-3 of Proposition 15.

Case 2. u^+ and v^+, and y and w are opposite in T as in Fig. 4(2). Consider x' to be on the boundary of T containing the vertices u', w', and v'. Since $v^+ \in B_{r^*}(y)$ and $w \notin B_{r^*}(y)$, then $d(v', w') + d(w', w) > d(v', v^+)$. Note also that $d(v', w') \le \delta$, and thus, $d(w, v') > d(v', v^+) - \delta$. Independently of the location of x' on the boundary of T, $w \notin B_{r-\delta}(x')$. Thus, $w \notin B_{r-3\delta}(x)$.

Case 3. u^+, v^+, y, and w are as in Fig. 4(3). Since w' belongs to a geodesic between y and w and between y and v^+, and $w \notin B_{r^*}(y), v^+ \notin B_{r^*}(y)$, we deduce that $d(w', w) > d(w', v') + d(v', v^+) \ge d(v', v^+)$. Independently of the location of x', we obtain that $w \notin B_{r-2\delta}(x)$. ◀

7 Perspectives

A direction of interest is to design proper sample compression schemes for balls of radius r in trees of cycles or cube-free median graphs. Designing sample compression schemes of size $O(d)$ for balls in general median graphs G of dimension d is also open, as well as whether the VC-dimension of $\mathcal{B}(G)$ is $O(d)$ or not. For general median graphs, it no longer holds that the interval between a diametral pair of X^+ contains a center of a ball realizing X. However, one can show that X^+ contains $2d$ vertices whose convex hull contains such a center. This convex hull can be d-dimensional and it is unclear how to encode the center in this region.

Other open questions are to design proper sample compression schemes of constant size for balls of planar graphs and of size $O(\omega(G))$ for balls of a chordal graph G. In [8], we showed that the former is possible for balls of radius 1, and that the latter is possible for split graphs. Finding proper sample compression schemes of size $O(\omega(G))$ for $\mathcal{B}(G)$ is also interesting for other classes of graphs from metric graph theory: bridged graphs (generalizing chordal graphs) and Helly graphs; for their definitions and characterizations, see [1].

Abstract

It is well known [16] that up to isomorphism a graph G is determined by the homomorphism counts $\hom(F, G)$, i.e., by the number of homomorphisms from F to G where F ranges over all graphs. Moreover, it suffices that F ranges over the graphs with at most as many vertices as G. Thus, in principle, we can answer any query concerning G with only accessing the $\hom(\cdot, G)$'s instead of G itself. In this paper, we deal with queries for which there is a *hom algorithm*, i.e., there are *finitely many* graphs $F_1, \dots, F_k$ such that for any graph G whether it is a YES-instance of the query is already determined by the vector $\overrightarrow{\hom}_{F_1,\dots,F_k}(G) := (\hom(F_1, G), \dots, \hom(F_k, G))$.

We observe that planarity of graphs and 3-colorability of graphs, properties expressible in monadic second-order logic, have no hom algorithm. On the other hand, queries expressible as a Boolean combination of universal sentences in first-order logic FO have a hom algorithm. Even though it is not easy to find FO definable queries without a hom algorithm, we succeed to show this for the non-existence of an isolated vertex, a property expressible by the FO sentence $\forall x \exists y Exy$, somehow the "simplest" graph property not definable by a Boolean combination of universal sentences. These results provide a characterization of the prefix classes of first-order logic with the property that each query definable by a sentence of the prefix class has a hom algorithm.

For *adaptive* hom algorithms, i.e., algorithms that might access a $\hom(F_{i+1}, G)$ with F_{i+1} depending on $\hom(F_j, G)$ for $1 \le j \le i$ we show that *three* homomorphism counts $\hom(\cdot, G)$ are sufficient and in general necessary to determine the (isomorphism type of) G. In particular, by three adaptive queries we can answer any question on G. Moreover, adaptively accessing two $\hom(\cdot, G)$'s is already enough to detect an isolated vertex.

In 1993 Chaudhuri and Vardi [6] showed the analogue of the Lovász Isomorphism Theorem for the right homomorphism vector of a graph G, i.e, the vector of values $\hom(G, F)$ where F ranges over all graphs characterizes the isomorphism type of G. We study to what extent our results carry over to the right homomorphism vector.

1 Introduction

In [16], one of the first papers on graph homomorphisms, Lovász proved that graphs G and H are isomorphic if and only if for all graphs F the number $\hom(F, G)$ of homomorphisms from F to G is equal to the number $\hom(F, H)$ of homomorphisms from F to H. Recently, this result has attracted a lot of attention in various contexts, e.g., algorithms and complexity [3, 9], machine learning [2, 14], and logic [1, 15]. Among others, it provides a powerful reduction of problems concerning graph structures to questions on the number of homomorphisms.

Lovász' result says that the infinite vector $\overrightarrow{\hom}(G) := (\hom(F, G))_{F \text{ a graph}}$ determines the graph G up to isomorphism. For a class C of graphs set $\overrightarrow{\hom}_{\mathsf{C}}(G) := (\hom(F, G))_{F\in\mathsf{C}}$. Using Lovász' *Cancellation Law* [17] (see Theorem 7.9) it is easy to see that for some classes C, including the class of 3-colorable graphs and the class of graphs that can be mapped homomorphically to an odd cycle, $\overrightarrow{\hom}_{\mathsf{C}}(G)$ already determines G up to isomorphisms. A further example: the class of 2-degenerate graphs has this property [12]. For other natural classes of graphs, $\overrightarrow{\hom}_{\mathsf{C}}(G)$ does not have the full power of distinguishing non-isomorphic graphs but characterizes interesting graph properties (e.g., see [10]).

We turn to results more relevant for the algorithmic problems we are interested in. Actually Lovász' proof shows that in order to determine the isomorphism type of G it is sufficient to consider the homomorphism counts $\hom(F, G)$ for the graphs F with at most as many vertices as G. As a consequence, given an oracle to $\overrightarrow{\hom}(G)$, we might answer any query by first recovering G and then computing the query on G. However, such a naive algorithm requires *exponentially* many entries in $\overrightarrow{\hom}(G)$, i.e., $\hom(F, G)$ for all isomorphism types of graphs F with at most as many vertices as G, rendering any practical implementation beyond reach.

There are queries that can be answered very easily using $\overrightarrow{\hom}(G)$, e.g., to decide whether G has a clique of size k, all we need to know is $\hom(K_k, G)$ where K_k is the complete graph on k vertices. So ideally, one would hope that to answer a query on G it suffices to access $\overrightarrow{\hom}(G)$ for finitely many fixed graphs independent of G.

The question of using $\overrightarrow{\hom}(G)$ to answer queries algorithmically has been raised before. In [9] Curticapean et al. observed that counting (induced) subgraphs isomorphic to a fixed graph F can be reduced to computing appropriate linear combinations of subvectors of $\overrightarrow{\hom}(G)$. Thereby they introduced the so-called graph motif parameters. Using this framework, they were able to design some algorithms faster than the known ones to count various specific subgraphs and induced subgraphs. These results can be understood as answering counting queries using $\hom(\cdot, G)$'s. More explicitly, Grohe [15] asked whether it is possible to answer any C^{k+1}-query in *polynomial time* by accessing $\hom(F, G)$ for graphs F of tree-width bounded by k. Here, C^{k+1} denotes counting first-order logic with $k+1$ variables [5]. Observe that without the polynomial time constraint such an algorithm exists because graphs G and H cannot be distinguished by C^{k+1} if and only if $\hom(F, G) = \hom(F, H)$ for finitely many graphs F of tree-width bounded by k [12] (see also [10]).

Our contributions

In this paper we study what Boolean queries (equivalently, graph properties) can be answered using a constant number of homomorphism counts. More precisely, let C be a class of graphs closed under isomorphism. We ask: are there graphs $F_1, \dots, F_k$ such that for any graph G whether $G \in \mathsf{C}$ can be decided knowing $\overrightarrow{\hom}_{F_1,\dots,F_k}(G) := (\hom(F_1, G), \dots, \hom(F_k, G))$.

In Section 4 we observe that this is the case if C can be defined by a sentence of first-order logic (FO) that is a Boolean combination of *universal* sentences. For $d \geq 1$ this includes the class of graphs of maximum degree d, of tree-depth [7] exactly d, and the class of graphs of

SC-depth [8] exactly d (but also the classes where we replace "exactly d" by "at most d"). On the negative side, in Section 6 we show that for any $k \geq 1$ and any $F_1, \dots, F_k$ there are graphs G and H such that

- $\overrightarrow{\text{hom}}_{F_1,\dots,F_k}(G) = \overrightarrow{\text{hom}}_{F_1,\dots,F_k}(H)$ and G contains an isolated vertex but H does not.

That is, any $\overrightarrow{\text{hom}}_{F_1,\dots,F_k}(G)$ is not sufficient to detect the existence of an isolated vertex in G. This is our technically most challenging result; it requires non-trivial arguments using linear algebra. We introduce some of the tools and construction methods needed in this proof already in Section 5, thereby showing the corresponding result for the class of planar graphs and the class of 3-colorable graphs.

A graph G has no isolated vertex if it satisfies the FO-sentence $\forall x \exists y Exy$. Thus we know for what quantifier-prefix classes of FO-sentences all queries definable by a sentence of the class can be answered by $\overrightarrow{\text{hom}}_{F_1,\dots,F_k}(G)$ for some $F_1, \dots, F_k$ *independent* of G.

Answering a query using $\overrightarrow{\text{hom}}_{F_1,\dots,F_k}(\cdot)$ can be phrased as an algorithm checking this query with *non-adaptive* access to $\overrightarrow{\text{hom}}(G)$ on entries $F_1, \dots, F_k$. It is also very natural to allow access to $\overrightarrow{\text{hom}}(G)$ to be *adaptive*. Informally, on input G an *adaptive hom algorithm* still queries some $\text{hom}(F_1, G), \dots, \text{hom}(F_k, G)$, but for $i = 0, \dots, k-1$ the choice of F_{i+1} might depend on $\text{hom}(F_1, G), \dots, \text{hom}(F_i, G)$ (see Definition 7.2 for a precise description). It turns out that adaptive hom algorithms are extremely powerful. In Section 7 we first present an adaptive hom algorithm with *two* accesses to $\overrightarrow{\text{hom}}(G)$ that can decide whether G has no isolated vertices. Even more, the algorithm is able to compute the number of vertices of G of degree k for each $k \geq 0$. So in particular, it can decide whether G is regular. Furthermore, in Section 7 we provide an adaptive hom algorithm that queries *three* entries in $\overrightarrow{\text{hom}}(G)$ and determines (the isomorphism type of) G. Hence, it can answer any question on G. The downside of this algorithm is its superpolynomial running time, while all the aforementioned hom algorithms run in polynomial time (when provided with access to $\text{hom}(G)$). For graph classes that are relevant in applications it is a challenging task to study whether there is an algorithm where the size of the corresponding F's are polynomial in the size of G. We conjecture that there is no polynomial time algorithm that can reconstruct a graph G only accessing $\overrightarrow{\text{hom}}(G)$ (even without the requirement of a constant number of accesses).

Results in [1] may be interpreted as saying that often proper subvectors of the right homomorphism vector $\overleftarrow{\text{hom}}(G) := (\text{hom}(G, F))_{F \text{ a graph}}$ of a graph G are not so expressive as the corresponding subvectors of the (left) homomorphism vector. For our topic, the finite subvectors, in Section 8 we prove that our two "positive results" on hom algorithms (namely, Theorem 4.4 on Boolean combinations of universal sentences and Theorem 7.4 on the power of 3 adaptive hom algorithms) fail for the finite right subvectors. Even when the result is the same (e.g., there is no right hom algorithm showing the non-existence of isolated vertices) the proof and its complexity can be quite different.

Due to space limitations for some proofs we refer to the full version of the paper.

2 Preliminaries

We denote by $\mathbb{N}$ the set of natural numbers greater than or equal to 0. For $n \in \mathbb{N}$ let $[n] := \{1, 2, \dots, n\}$.

For graphs we use the notation $G = (V(G), E(G))$ common in graph theory. Here $V(G)$ is the nonempty set of vertices of G and $E(G)$ is the set of edges. We only consider finite, simple, and undirected graphs and briefly speak of graphs. To express that there is an edge connecting the vertices u and v of the graph G, we use (depending on the context) one of the notations $uv \in E(G)$ and $\{u, v\} \in E(G)$. For graphs G and H with disjoint vertex sets we denote by $G \mathbin{\dot\cup} H$ the *disjoint union of G and H*, i.e., the graph with vertex set $V(G) \cup V(H)$ and edge set $E(G) \cup E(H)$. If the vertex sets are not disjoint, we tacitly pass to isomorphic copies with disjoint vertex sets. Similarly, $\dot\bigcup_{i \in I} G_i$ denotes the disjoint union of the graphs G_i with $i \in I$. For a graph G and $\ell \geq 1$ we denote by ℓG the disjoint union of ℓ copies of G.

For $n \geq 1$ we denote by K_n a clique with n vertices, by P_n a path of n vertices, and by C_n a cycle of n vertices.

For graphs G and H by $G \cong H$ we express that G and H are isomorphic. All classes of graphs considered in this paper are closed under isomorphism.

▶ **Definition 2.1.** Let G and H be graphs and $f : V(G) \to V(H)$. The function f is a *homomorphism* if $uv \in E(G)$ implies $f(u)f(v) \in E(H)$ for all $u, v \in V(G)$. It is an *embedding* (or *monomorphism*) if f is a homomorphism that is one-to-one. We call f an *epimorphism* if f is a homomorphism, the range of f is $V(H)$, and for every $u'v' \in E(H)$ there are $u, v \in V(G)$ such that $uv \in E(G)$ and $f(u) = u'$, $f(v) = v'$. We get the definitions of *strong homomorphism*, *strong embedding*, and *strong epimorphism* by additionally requiring in the previous definitions that $(uv \in E(G) \iff f(u)f(v) \in E(H))$ for all $u, v \in V(G)$.

We denote by $\textsc{Hom}(G, H)$ the set of homomorphisms from G to H, thus $\hom(G, H) := |\textsc{Hom}(G, H)|$ is the number of homomorphisms from G to H. Similarly, we define $s\text{-}\textsc{Hom}(G, H)$ and $\text{s-hom}(G, H)$ for strong homomorphisms and use corresponding notations for the other notions of morphisms. Finally, $\textsc{Aut}(G)$ and $\text{aut}(G)$ denote the set of automorphisms of G and their number, respectively.

The equalities (1) and (2) are easy to verify and will often be used tacitly. For graphs F_1, F_2, and G and $\text{xyz} \in \{\hom, \text{emb}\}$,

$$\hom(F_1 \mathbin{\dot\cup} F_2, G) = \hom(F_1, G) \cdot \hom(F_2, G), \tag{1}$$

$$\text{if } G \text{ is connected, then } \text{xyz}(G, F_1 \mathbin{\dot\cup} F_2) = \text{xyz}(G, F_1) + \text{xyz}(G, F_2). \tag{2}$$

Once and for all we fix an enumeration

$$F_1^0, F_2^0, F_3^0, \dots \tag{3}$$

of graphs such that each graph is isomorphic to exactly one graph in the list and such that $i \leq j$ implies $F_i^0 \leq F_j^0$. Here for graphs F and G by $F \leq G$ we mean that

$$|V(F)| < |V(G)| \;\text{ or }\; (|V(F)| = |V(G)| \text{ and } |E(F)| \leq |E(G)|).$$

In particular, F_1^0 is a graph whose vertex set is a singleton. We repeatedly use:

▶ **Theorem 2.2** (Lovász Isomorphism Theorem [16]). *Let G and H be graphs. If $\hom(F, G) = \hom(F, H)$ for all graphs F with $|V(F)| \leq \min\{|V(G)|, |V(H)|\}$, then G and H are isomorphic, i.e., the finite vector $\hom(F, G))_{F \text{ a graph with } |V(F)| \leq |V(G)|}$ determines G up to isomorphism.*

3 Algorithms accessing morphism counts

For what classes C of graphs is there a finite set F of graphs such that the membership of any graph G in C is determined by the values $\hom(F, G)$ where F ranges over F? This question leads to the following definition.

▶ **Definition 3.1.** Let C be a class of graphs. *A hom algorithm for* C *(with a constant number of non-adaptive accesses to homomorphism counts)* consists of a $k \geq 1$, graphs $F_1, \ldots, F_k$, and an $X \subseteq \mathbb{N}^k$ such that for all G,

$$G \in \mathsf{C} \iff (\hom(F_1, G), \ldots, \hom(F_k, G)) \in X.$$

We then say that the *hom algorithm decides* C. Analogously we define the notions of *emb algorithm*, *s-hom algorithm*, and *s-emb algorithm.*

Often we use the following fact, whose proof is immediate: A class C can be decided by a hom algorithm if and only if there is a finite set $\mathsf{F} = \{F_1, \ldots, F_k\}$ of graphs such that for all G and H (recall that $\overrightarrow{\hom}_{\mathsf{F}}(G) = (\hom(F_1, G), \ldots, \hom(F_k, G))$),

$$\overrightarrow{\hom}_{\mathsf{F}}(G) = \overrightarrow{\hom}_{\mathsf{F}}(H) \text{ implies } (G \in \mathsf{C} \iff H \in \mathsf{C}).$$

▶ **Remark 3.2.** If the set X in Definition 3.1 is decidable, then we easily extract an actual algorithm for C with an oracle to $\overrightarrow{\hom}(G)$. However the previous equivalence only holds for arbitrary X. Nevertheless, all our positive results have decidable X's. We use the current definition to ease presentation, and also to make our negative result, namely Theorem 6.1, stronger. Let C have a hom algorithm as in Definition 3.1. Then the set X can be chosen to be decidable if and only if C is decidable.

▶ **Examples 3.3.**

(a) By taking $k = 1$, a graph F whose vertex set is a singleton, and an arbitrary set $X \subseteq \mathbb{N}$, we get a hom algorithm for the class of graphs whose number of vertices is in X. In particular, for an undecidable X we get an undecidable class of graphs with a hom algorithm.

(b) Theorem 2.2 shows that every class that only contains finitely many graphs up to isomorphism can be decided by a hom algorithm.

(c) By passing from $k \geq 1$, $F_1, \ldots, F_k$, and $X \subseteq \mathbb{N}^k$ to $k \geq 1$, $F_1, \ldots, F_k$, and $\mathbb{N}^k \setminus X$, we see that with every class C also the class $\mathsf{C}^{\text{comp}} := \{G \mid G \notin \mathsf{C}\}$ has a hom algorithm.

By Definition 3.1 we have four types of algorithms (hom, emb, s-hom, s-emb). The following proposition shows that a class has an algorithm of one type if and only if it has an algorithm of any other type. This allows us to speak of a *query algorithm accessing morphism counts* (or *query algorithm* for short) if in the given context it is irrelevant to what type we refer.

▶ **Proposition 3.4.** *For a class* C *of graphs the following five statements are equivalent.*

(a) *There is a hom algorithm for* C.

(b) *There is an emb algorithm for* C.

(c) *There is an s-hom algorithm for* C.

(d) *There is an s-emb algorithm* C.

(e) *There is a hom algorithm for* C^c*, the class of graphs that are complements of graphs in* C *(the complement of a graph* G *is the graph* $G^c = \big(V(G), \{uv \mid u \neq v \text{ and } uv \notin E(G)\}\big)$.

The equivalence (a) ⇔ (b) and (c) ⇔ (d) are well known (e.g., see the proof of the Lovász Isomorphism Theorem in [15]). It uses the fact that every $h \in \textsc{Hom}(F, G)$ can be written as $h = f \circ g$, where for some graph F' we have $g \in \textsc{Epi}(F, F')$ and $f \in \textsc{Emb}(F', G)$. Clearly, $F' \leq F$ (as otherwise $\textsc{Epi}(F, F') = \emptyset$). Hence.

$$\hom(F, G) = \sum_{F' \leq F} \frac{1}{\operatorname{aut}(F')} \cdot \operatorname{epi}(F, F') \cdot \operatorname{emb}(F', G), \tag{4}$$

where the sum ranges over all isomorphism types of graphs F' with $F' \leq F$ and the corresponding equation for s-hom and s-emb.

As in the literature we did not find a proof of the equivalence (a) ⇔ (c), the main tool in our proof of Theorem 4.4, we present proofs of the equivalences (a) ⇔ (c) and its consequence (a) ⇔ (e) in the full version of the paper.

▶ **Remark 3.5.** The proof of the equivalences of (a) to (e) show: If for C we have a query algorithm of one type based on graphs $F_1, \dots, F_k$ and $m := \max\{|V(F_i)| \mid i \in [k]\}$, then for any other type we can compute finitely many graphs, all with at most m vertices, that are the graphs of a query algorithm for C of this other type.

4 FO-definable classes with query algorithms

We start by showing that every class of graphs that excludes a finite set of graphs as induced subgraphs has a query algorithm. Of course, the complement and the union of such classes again have such an algorithm. In terms of first-order logic this means that every class axiomatizable by a Boolean combination of universal sentences has a query algorithm.

For a finite set F of graphs we define the class $\textsc{Forb}(\mathsf{F})$ by

$$\textsc{Forb}(\mathsf{F}) := \big\{G \bigm| G \text{ has no induced subgraph isomorphic to a graph in } \mathsf{F}\big\}.$$

We say that *a class* C *of graphs is definable by a set of forbidden induced subgraphs* if there is a finite set F with $\mathsf{C} = \textsc{Forb}(\mathsf{F})$.

Examples of classes definable by a set of forbidden induced subgraphs are classes of bounded vertex cover number (attributed to Lovász), of bounded tree-depth [11], or even of bounded shrub-depth [13]. All these classes have a query algorithm:

▶ **Lemma 4.1.** *Every class of graphs definable by a set of forbidden induced subgraphs can be decided by a query algorithm.*

Proof. If $\mathsf{C} = \textsc{Forb}(\emptyset)$, we set $k = 1$, let F be an arbitrary graph, and take $X := \mathbb{N}$. Assume now that $\mathsf{C} = \textsc{Forb}(\mathsf{F})$ with $\mathsf{F} = \{F_1, \dots, F_k\}$ and $k \geq 1$. Then, for $X = \{(0, 0, \dots, 0)\} \subseteq \mathbb{N}^k$,

$$G \in \mathsf{C} \quad \iff \quad \big(\text{s-emb}(F_1, G), \dots, \text{s-emb}(F_k, G)\big) \in X.$$

Hence, k, $F_1, \dots, F_k$, and X constitute an s-emb algorithm for C. ◀

The following lemma shows that the universe of classes with query algorithms is closed under the Boolean operations. Part (a) was already mentioned as Examples 3.3 (c). We omit the straightforward proof.

▶ **Lemma 4.2.**

(a) *If* C *has a query algorithm, then so does* $\{G \mid G \notin \mathsf{C}\}$.

(b) *If* C *and* C' *have query algorithms, then* $\mathsf{C} \cap \mathsf{C}'$ *and* $\mathsf{C} \cup \mathsf{C}'$ *have query algorithms.*

Recall that *formulas* φ of *first-order logic* FO for graphs are built up from *atomic formulas* $x = y$ and Exy (where x, y are variables) using the Boolean connectives $\neg$, $\wedge$, and $\vee$ and the universal $\forall$ and existential $\exists$ quantifiers. A *sentence* is a formula without free variables (i.e., all variables of φ are in the scope of a corresponding quantifier). If φ is a sentence, we denote by $\mathsf{C}(\varphi)$ the class of graphs that are models of φ.

An FO-formula is *universal* if it is built up from atomic and negated atomic formulas by means of the connectives $\wedge$ and $\vee$ and the universal quantifier $\forall$. If in this definition we replace the universal quantifier by the existential one, we get the definition of an *existential formula*. The following result is well known (e.g., see [18]).

▶ **Lemma 4.3.** *Let* C *be a class of graphs. Then* C *is the class of graphs definable by a universal sentence if and only if* C *is definable by a set of forbidden induced subgraphs.*

By Lemma 4.1 – Lemma 4.3 we get:

▶ **Theorem 4.4.** *If the* FO*-sentence* φ *is a Boolean combination of universal sentences, then there is a query algorithm for* $\mathsf{C}(\varphi)$*.*

▶ **Remark 4.5.** The class $\mathsf{C}(3)$ of 3-regular graphs (each vertex has exactly 3 neighbors) is an example of a class decidable by a query algorithm, definable in FO but not by a Boolean combination of universal sentences. Indeed, using the following steps we get a query algorithm deciding whether a graph G belongs to $\mathsf{C}(3)$.

- We check whether $G \in \mathsf{C}(\leq 3)$, i.e., whether each vertex has at most 3 neighbors. Note that $\mathsf{C}(\leq 3)$ is definable by a universal sentence. Hence there is a hom algorithm for $\mathsf{C}(\leq 3)$, say consisting of $k \geq 1$, $F_1, \dots, F_k$, and $X_{\leq 3}$ $(\subseteq \mathbb{N}^k)$.
- We query $\hom(K_1, G)$ in order to get $n := |V(G)|$.
- We query $\hom(P_2, G)$, i.e., the number of homomorphisms from the path P_2 of two vertices to G. Then, G is 3-regular if and only if $\hom(P_2, G) = 3 \cdot n$.

Hence, we have a hom algorithm for $\mathsf{C}(3)$ consisting of $k+2$, $F_1, \dots, F_k, K_1, P_2$, and X where X consists of all tuples $(n_1, \dots, n_k, n, 3n)$ with $(n_1, \dots, n_k) \in X_{\leq 3}$ and $n \geq 1$.

The class $\mathsf{C}(3)$ is definable in FO by

$$\forall x \forall y_1 \dots \forall y_4 \exists z_1 \dots \exists z_3 \Big(\neg\big(\bigwedge_{1 \leq i < j \leq 4} y_i \neq y_j \wedge \bigwedge_{i \in [4]} Exy_i \big) \wedge \big(\bigwedge_{1 \leq i < j \leq 3} z_i \neq z_j \wedge \bigwedge_{j \in [3]} Exz_j \big) \Big).$$

If it would be definable by a Boolean combination of universal sentences, then it would be also definable by a sentence φ of the form $\varphi = \exists x_1 \dots \exists x_m \forall y_1 \dots \forall y_\ell \psi$ with $m, \ell \in \mathbb{N}$ and with quantifier-free ψ. Let G be a graph with more than $m+1$ vertices that is the disjoint union of copies of the clique K_4. Of course, G is 3-regular. Hence, G is a model of φ. In particular, there are vertices $u_1, \dots, u_m$ that satisfy in G the formula $\forall y_1 \dots \forall y_\ell \psi(x_1, \dots, x_m)$ if we interpret x_1 by u_1, …, x_m by u_m. Choose a vertex $u \in V(G) \setminus \{u_1, \dots, u_m\}$. Then, $G \setminus u$, the graph induced by G on $V(G) \setminus \{u\}$, is still a model of φ but not 3-regular.

By the previous remark the question arises whether every class $\mathsf{C}(\varphi)$ for an FO-sentence φ of the form$\forall x_1 \dots \forall x_m \exists y_1 \dots \exists y_\ell \psi$ with quantifier free ψ can be decided by a query algorithm. We will see that already for the simple formula $\forall x \exists y Exy$ of this type, the class $\mathsf{C}(\forall x \exists y Exy)$, i.e., the class of graphs not containing isolated vertices, has no query algorithm.

5 Planarity and 3-colorability

As just mentioned we want to show that no query algorithm detects the existence of an isolated vertex. In this section we prove the corresponding result for planarity, where some easy tools and construction methods relevant in the much more involved proof for isolated vertices are used. Essentially by a similar proof one can show the same result for 3-colorability. Note that the class of planar graphs and the class of 3-colorable graphs are definable in monadic second-order logic but not in first-order logic.

By the following lemma a class has no query algorithm if there is no emb algorithm for this class that only uses *connected graphs*:

▶ **Lemma 5.1.** *Let* C *be a class of graphs. Assume that for every finite set* K' *of connected graphs there are graphs* G *and* H *such that (a) and (b) hold.*

(a) *$G \in \mathsf{C}$ and $H \notin \mathsf{C}$.*

(b) *For all $F' \in \mathsf{K}'$ we have $\mathrm{emb}(F', G) = \mathrm{emb}(F', H)$.*

Then there is no hom algorithm for C, i.e., for every finite set K of graphs there are graphs G and H such that (c) and (d) hold

(c) *$G \in \mathsf{C}$ and $H \notin \mathsf{C}$.*

(d) *For all $F \in \mathsf{K}$ we have $\mathrm{hom}(F, G) = \mathrm{hom}(F, H)$.*

Proof. By (1), $\mathrm{hom}(F^1 \dot\cup F^2, F^3) = \mathrm{hom}(F^1, F^3) \cdot \mathrm{hom}(F^2, F^3)$ holds for arbitrary graphs F^1, F^2, F^3. Thus, if the class of connected components of graphs in a finite set K satisfies (d) for some G and H, then K satisfies (d), too. Hence, we can assume that the graphs in K are connected. Let $n := \max\{|V(F)| \mid F \in \mathsf{K}\}$ and $\mathsf{K}' := \{F_i^0 \mid i \geq 1, |V(F_i^0)| \leq n, F_i^0 \text{ connected}\}$. By assumption we know that there are graphs G and H such that (a) and (b) hold for K'. Now we recall (4), i.e.,

$$\mathrm{hom}(F, G) = \sum_{F' \leq F} \frac{1}{\mathrm{aut}(F')} \cdot \mathrm{epi}(F, F') \cdot \mathrm{emb}(F', G).$$

If F is connected, then $\mathrm{epi}(F, F') > 0$ implies that F' is connected, too. That is, the values $\mathrm{hom}(F, G)$ for $F \in \mathsf{K}$ are determined by the values of $\mathrm{emb}(F', G)$ for $F' \in \mathsf{K}'$. Therefore, (d) holds by (b). ◀

▶ **Theorem 5.2.** *The class P of planar graphs and the class $\mathsf{C}(3\text{-}col)$ of 3-colorable graphs have no query algorithm.*

Proof. Here we only present the proof for P. For a contradiction, by Lemma 5.1 we can assume that there is an emb algorithm for P that uses the finite set F of connected graphs. By induction on $n := |\mathsf{F}|$, we show that this cannot be the case. Let $|\mathsf{F}| = 1$, i.e., $\mathsf{F} = \{F\}$ for some connected F. Set $k := |V(F)| + 4$. Clearly, $K_k \notin \mathsf{P}$ and both, $\mathrm{emb}(F, F)$ and $\mathrm{emb}(F, K_k)$, are nonzero. If F is planar, we set (recall that for a graph G and $p \in \mathbb{N}$ by pG we denote the disjoint union of p copies of G),

$$G := \mathrm{emb}(F, K_k)F \quad \text{and} \quad H := \mathrm{emb}(F, F)K_k$$

By (2), $\mathrm{emb}(F, G) = \mathrm{emb}(F, K_k) \cdot \mathrm{emb}(F, F) = \mathrm{hom}(F, H)$ and $G \in \mathsf{P}$, $H \notin \mathsf{P}$, a contradiction. If F is not planar, we set $G := K_1$ and take as H a topological minor of K_k in which every edge in K_k is subdivided into $1 + |(V(F)|$ edges. Then $H \notin \mathsf{P}$ but $\mathrm{emb}(F, G) = 0 = \mathrm{emb}(F, H)$, again a contradiction.

Now assume $|\mathsf{F}| \geq 2$. If F contains no planar graphs, we essentially can proceed as in the preceding case. So assume that F contains a planar graph. Choose a "minimal" (w.r.t. $\leq$) planar graph $F \in \mathsf{F}$ and set $\mathsf{F}' := \mathsf{F} \setminus \{F\}$. By minimality, $\mathrm{emb}(F', F) = 0$ for all planar $F' \in \mathsf{F}'$. As there is no embedding from a non-planar graph to a planar graph, we have $\mathrm{emb}(F', F) = 0$ for all $F' \in \mathsf{F}'$. By induction hypothesis, there are G_0 and H_0 satisfying the desired properties with respect to F'. If $\mathrm{emb}(F, G_0) = \mathrm{emb}(F, H_0)$, then we can simply take $G := G_0$ and $H := H_0$. Otherwise, assume first that $\mathrm{emb}(F, G_0) < \mathrm{emb}(F, H_0)$. We set

$$G := \mathrm{aut}(F)G_0 \dot\cup (\mathrm{emb}(F, H_0) - \mathrm{emb}(F, G_0))F \quad \text{and} \quad H := \mathrm{aut}(F)H_0.$$

Hence, $G \in \mathsf{P}$, $H \notin \mathsf{P}$, and $\mathrm{emb}(F, G) = \mathrm{emb}(F, H)$ (by (2)). In case $\mathrm{emb}(F, G_0) > \mathrm{emb}(F, H_0)$ we argue similarly. ◀

6 No query algorithm detects isolated vertices

▶ **Theorem 6.1.** *The class $\mathsf{C}(\forall x\exists y Exy)$ of graphs without isolated vertices has no query algorithm.*

In the proof given in the full version of the paper we use some tools already used in the preceding section:

- By Lemma 5.1 it suffices to show that $\mathsf{C}(\forall x\exists y Exy)$ has no emb algorithm that only uses connected graphs.
- If C is one of the classes P or $\mathsf{C}(\forall x\exists y Exy)$, then the disjoint union $\dot{\bigcup}_{i\in I} G_i$ of a family $(G_i)_{i\in I}$ of graphs is in C if and only if each G_i is in C.
- By (2), for graphs F_1 and F_2, $p, q \geq 1$, and a connected graph G, we have

  $$\mathrm{emb}(G, pF_1 \mathbin{\dot\cup} qF_2) = p\,\mathrm{emb}(G, F_1) + q\,\mathrm{emb}(G, F_2),$$

  i.e., $\mathrm{emb}(G, pF_1 \mathbin{\dot\cup} qF_2)$ is a linear combination of $\mathrm{emb}(G, F_1)$ and $\mathrm{emb}(G, F_2)$.

Furthermore note:

- Let G be a connected graph with more than one vertex. If the graph F' is obtained from the graph F by adding a set of isolated vertices, then $\mathrm{emb}(G, F') = \mathrm{emb}(G, F)$.

Recall that in (3) we fixed the enumeration $F_1^0, F_2^0, \ldots$ of graphs that contains a copy of every isomorphism type and respects the relation $\leq$. Here we let $H_1, H_2, \ldots$ be the subsequence of $F_1^0, F_2^0, \ldots$ consisting of the connected graphs.

For $i \geq 1$ let $\alpha_i := (\mathrm{emb}(H_i, H_j))_{j\geq 1}$ be the vector containing the emb-values of H_i for connected graphs. We sketch the idea underlying the proof of Theorem 6.1. The central idea can be vaguely expressed by saying that for each $n \geq 1$ there is an $r_n \in \mathbb{N}$ such that appropriate "subvectors" of length r_n of r_n-many of the $\alpha_1, \ldots, \alpha_n$ are linearly independent vectors of the vector space $\mathbb{Q}^{r_n}$ and hence, a basis of $\mathbb{Q}^{r_n}$. In particular, every further vector of $\mathbb{Q}^{r_n}$ is a linear combination of these vectors. Furthermore, r_n tends to infinity when n increases.

For an arbitrary emb algorithm with connected graphs we must show the existence of graphs G and H, one with isolated vertices the other one without, that cannot be distinguished by this emb algorithm. We use the tools mentioned above to construct such graphs using the knowledge about the linear independence or linear dependence of some tuples of vectors obtained in the first steps of the proof.

7 Adaptive hom algorithms

For $r \geq 1$ let S_r denote the star of r vertices, i.e., a graph that consists of a vertex of degree $r-1$ (the center of the star) and $r-1$ vertices of degree 1, all neighbors of the center. For a vertex u of a graph we denote by $\deg(u)$ its degree. Note that $\deg(u) = 0$ means that u is isolated. The proof in the full paper of the following result is built on the well-known equality (see e.g., [4, 15]) obtained by looking at the value of the center of a star under a homomorphism: $\mathrm{hom}(S_r, G) = \sum_{v\in V(G)} \deg(v)^{r-1}$.

▶ **Proposition 7.1.** *Let G be a graph and $d_i := |\{u \in V(G) \mid \deg(u) = i\}|$ for $i \geq 0$. If $n := |V(G)|$, then $\mathrm{hom}(S_{n\cdot\log n}, G)$ determines $d_0, \ldots, d_{n-1}$.*

In Section 6 we showed that there is no query algorithm that decides whether a graph G is in $\mathsf{C}(\forall x\exists y Exy)$, i.e., whether $d_0 = 0$ for G. However, Proposition 7.1 shows that for a graph G with n vertices this can be decided by querying $\mathrm{hom}(S_{n\cdot\log n}, G)$. Thus, we have an algorithm for $\mathsf{C}(\forall x\exists y Exy)$ consisting of two homomorphism counts:

- query $n := \hom(F^0_1, G)$ $(= |V(G)|)$,
- query $\hom(S_{n \cdot \log n}, G)$.

That is, the selection of the graph for the second homomorphism count, in our case $S_{n\cdot \log n}$, depends on the answer to the first query. This leads to the notion of adaptive hom algorithm. Recall that $F^0_1, F^0_2, \dots$ is an enumeration of all graphs (up to isomorphism) respecting $\leq$.

▶ **Definition 7.2.** Let C be a class of graphs and $k \geq 1$. A *k adaptive hom algorithm for* C consists of a function $g : \{\emptyset\} \cup \bigcup_{i \in [k-1]} \mathbb{N}^i \to \mathbb{N}$ and a subset X of $\mathbb{N}^k$ such that for all G,

$$G \in \mathsf{C} \iff (n_1, \dots, n_k) \in X,$$

where $n_1 := \hom(F^0_{g(\emptyset)}, G)$, $n_2 := \hom(F^0_{g(n_1)}, G)$, $\dots$, $n_k := \hom(F^0_{g(n_1,n_2,\dots,n_{k-1})}, G)$. We then say that C *can be decided by a k adaptive hom algorithm.*

The main result of this section:

▶ **Theorem 7.3.** *Every class C can be decided by a 3 adaptive hom algorithm.*

To get this result we show:

▶ **Theorem 7.4.** *For $n \geq 1$ there exist graphs F_1 $(= F_1(n))$ and F_2 $(= F_2(n))$ such that for all graphs G and H with n vertices,*

$$\hom(F_1, G) = \hom(F_1, H) \quad \textit{and} \quad \hom(F_2, G) = \hom(F_2, H) \quad \textit{imply} \quad G \cong H.$$

In fact, by this result for any class C of graphs, we get the 3 adaptive hom algorithm that for a graph G queries

- $\hom(F^0_1, G)$; set $n := \hom(F^0_1, G)$
- $\hom(F_1(n), G)$ and $\hom(F_2(n), G)$

(where $F_1(n)$ and $F_2(n)$ are the graphs of Theorem 7.4) and has as set X the set

$$X := \{(n, \hom(F_1(n), H), \hom(F_2(n), H)) \mid n \geq 1,\ H \in \mathsf{C}, \text{ and } |V(H)| = n\}.$$

▶ **Corollary 7.5.** *For graphs G and H, if $n_0 := \hom(F^0_1, G) = \hom(F^0_1, H)$, $\hom(F_1(n_0), G) = \hom(F_1(n_0), H)$, and $\hom(F_2(n_0), G) = \hom(F_2(n_0), H)$, then $G \cong H$.*

Hence, by "3 adaptive hom counts" we can characterize the isomorphism type of any graph. It is not possible to do this by two queries, more precisely (for a proof see the full paper):

▶ **Theorem 7.6.** *There is no $s_0 \in \mathbb{N}$ such that for some function $g : \mathbb{N} \to \mathbb{N}$ and all graphs G and H, if $n_0 := \hom(F^0_{s_0}, G) = \hom(F^0_{s_0}, H)$ and $\hom(F^0_{g(n_0)}, G) = \hom(F^0_{g(n_0)}, H)$, then $G \cong H$.*

We turn to a proof of Theorem 7.4. An important tool will be the following lemma.

▶ **Lemma 7.7.** *Let $n \geq 1$ and K be a finite set of graphs. We can construct a graph F_{K} such that for all G and H with exactly n vertices we have $\hom(F_{\mathsf{K}}, G) = \hom(F_{\mathsf{K}}, H)$ if and only if G and H satisfy at least one of the conditions (a) and (b).*

(a) *There exist $F, F' \in \mathsf{K}$ such that $\hom(F, G) = 0$ and $\hom(F', H) = 0$.*

(b) *For all $F \in \mathsf{K}$, $\hom(F, G) = \hom(F, H)$.*

Proof. The idea of the construction is best seen by assuming $\mathsf{K} = \{F_1, F_2\}$ (iterating the following process one gets the general case). We set $r := n^{|V(F_1)|}$. As $|V(G)| = n$, we know that $\hom(F_1, G) \le r$. We set $F_{\mathsf{K}} := F_1 \dot\cup rF_2$. By (1) for every graph F,

$$\hom(F_{\mathsf{K}}, F) = \hom(F_1, F) \cdot \hom(F_2, F)^r. \tag{5}$$

Hence, if (a) or (b) hold, then $\hom(F_{\mathsf{K}}, G) = \hom(F_{\mathsf{K}}, H)$. Conversely, assume $z := \hom(F_{\mathsf{K}}, G) = \hom(F_{\mathsf{K}}, H)$. If $z = 0$, then (a) must hold by (5). If $z = 1$, then $\hom(F_i, G) = \hom(F_i, H) = 1$ for $i \in [2]$ and (b) holds. Otherwise, $z \ge 2$. Let $F := G$ or $F := H$ and set $x := \hom(F_1, F)$ and $y := \hom(F_2, F)$. Let p be a prime number with $p|z$ (i.e., p divides z). Choose the maximum k such that $p^k|z$. Write k in the form $k = \ell \cdot r + m$ with $0 \le m < r$. As $z = x \cdot y^r$ and $x \le r$, the factor p^m appears in x and the factor p^ℓ in y. This determines x and y; they do not depend on the $F \in \{G, H\}$ chosen. ◀

If the alternative (b) holds, we can replace in a hom algorithm the set K of graphs by the single graph F_{K}. The previous lemma doesn't help too much if the alternative (a) holds. To overcome this alternative essentially we consider the bipartite graphs and the non-bipartite graphs separately. For this purpose we recall the definition and some simple facts on bipartite graphs.

A graph G is *bipartite* if there is a partition $V(G) = X \dot\cup Y$ such that each edge has one end in X and one end in Y. The next lemma contains some simple facts on bipartite graphs.

▶ **Lemma 7.8.** *Let G be a graph. Then:*

(a) *G is bipartite $\iff$ $\hom(G, P_2) \ne 0$.*

(b) *If G is connected and bipartite, then $\hom(G, P_2) = 2$.*

(c) *G is bipartite $\iff$ $\hom(G, H) \ne 0$ for all graphs H with at least one edge.*

(d) *G is bipartite $\iff$ G does not contain a cycle of odd length.*

(e) *If G is bipartite and F is not, then $\hom(F, G) = 0$.*

(f) *If G is bipartite, then G is determined (up to isomorphism) by the values $\hom(F, G)$ for the bipartite graphs F with $F \le G$ (by the Lovász Isomorphism Theorem and part (e)).*

For graphs G and H the *product $G \times H$ of G and H* is the graph with $V(G \times H) := \{(u, v) \mid u \in V(G),\ v \in V(H)\}$ and $E(G \times H) := \{\{(u, v), (u', v')\} \mid \{u, u'\} \in E(G) \text{ and } \{v, v'\} \in E(H)\}$. One easily verifies that for any graph H,

$$\hom(F, G \times H) = \hom(F, G) \cdot \hom(F, H). \tag{6}$$

Besides the simple facts on bipartite graphs mentioned above, we also need a deep result:

▶ **Theorem 7.9** (Lovász Cancellation Law [17]). *A graph H is not bipartite if and only if $F \times H \cong G \times H$ implies $F \cong G$ for all graphs F and G.*

The following lemma contains a further step for the proof of Theorem 7.4.

▶ **Lemma 7.10.** *Let $n \ge 2$ and t be the smallest natural number with $n \le 2t$. We set (recall that C_m denotes a cycle of length m)*

$$\mathsf{K}_t := \{F \mid \hom(F, C_{2t+1}) > 0 \textit{ and } |V(F)| \le (2t+1)^2\}. \tag{7}$$

For graphs G and H with $|V(G)| = |V(H)| = n$, if $\hom(F, G) = \hom(F, H)$ for all $F \in \mathsf{K}_t$, then $G \cong H$.

Proof. Assume $G \ncong H$. By Lemma 7.8 (d), C_{2t+1} is not bipartite. Thus, by the Lovász Cancellation Law $G \times C_{2t+1} \ncong H \times C_{2t+1}$ As $G \times C_{2t+1}$ has $n \cdot (2t+1)$ vertices, by the Lovász Isomorphism Theorem (see Theorem 2.2) there is a graph F with $|V(F)| \leq n \cdot (2t+1) \leq (2t+1)^2$ such that

$$\hom(F, G \times C_{2t+1}) \neq \hom(F, H \times C_{2t+1}). \tag{8}$$

If F is not in K_t, then $\hom(F, C_{2t+1}) = 0$ and thus by (6) we get a contradiction to (8). Hence, $F \in \mathsf{K}_t$ and so by assumption, $\hom(F, G) = \hom(F, H)$. However, this contradicts (8) (use again (6)). ◀

Proof of Theorem 7.4. The case $n = 1$ is trivial. Assume $n \geq 2$. Let again t be the smallest natural number with $n \leq 2t$ and K_t be defined by (7). For the class K_{bip} of bipartite graphs in K_t let F_1 be the graph constructed in Lemma 7.7 for K_{bip} (i.e., $F_1 = F_{\mathsf{K}_{\text{bip}}}$). As the disjoint union of bipartite graphs is bipartite, the proof of Lemma 7.7 shows that F_1 is bipartite. Let F_2 be the graph constructed in Lemma 7.7 for the class $\mathsf{K}_t \setminus \mathsf{K}_{\text{bip}}$. We show that for graphs G and H with $|V(G)| = |V(H)| = n$,

$$\hom(F_i, G) = \hom(F_i, H) \text{ for } i \in [2] \text{ implies } G \cong H.$$

If G and H both have no edge, then clearly $G \cong H$. If, say G has an edge but $E(H) = \emptyset$, then, as F_1 is bipartite, $\hom(F_1, G) \neq 0 = \hom(F_1, H)$ by Lemma 7.8 (c) and $E(F_1) \neq \emptyset$. Hence we can assume that both graphs contain at least one edge. For a contradiction assume that $\hom(F_i, G) = \hom(F_i, H)$ for $i \in [2]$ and that $G \ncong H$. Then, by Lemma 7.10 there is a graph $F_0 \in \mathsf{K}_t$ with

$$\hom(F_0, G) \neq \hom(F_0, H). \tag{9}$$

Assume first that $F_0 \in \mathsf{K}_{\text{bip}}$. As G and H contain at least one edge, by Lemma 7.8 (c)

$$\hom(F, G) > 0 \quad \text{and} \quad \hom(F, H) > 0,$$

for every bipartite graph F. In particular, this holds for all graphs F in K_{bip}. Thus, $\hom(F_1, G) = \hom(F_1, H)$ implies the second case in Lemma 7.7, i.e., for every $F \in \mathsf{K}_{\text{bip}}$,

$$\hom(F, G) = \hom(F, H).$$

In particular, this holds for $F = F_0$ contradicting (9).

Thus $F_0 \in \mathsf{K}_t \setminus \mathsf{K}_{\text{bip}}$. Then $\hom(F_0, F) = 0$ for all bipartite graphs F $\big($by Lemma 7.8 (e)$\big)$. Hence, by (9) at least one of G and H must be non-bipartite. By $\hom(F_2, G) = \hom(F_2, H)$, Lemma 7.7, and (9) there exist graphs F^G and F^H in $\mathsf{K}_t \setminus \mathsf{K}_{\text{bip}}$ with

$$\hom(F^G, G) = \hom(F^H, H) = 0.$$

W.l.o.g. suppose that G is not bipartite and thus contains an odd cycle, say of length ℓ. Since $\ell \leq n \leq 2t+1$, we have $\hom(C_{2t+1}, C_\ell) > 0$. In fact, one easily verifies that $\hom(C_k, C_m) > 0$ for odd m and k with $m < k$. As $F^G \in \mathsf{K}_t$, $\hom(F^G, C_{2t+1}) > 0$. Therefore, $\hom(F^G, C_\ell) > 0$, which implies $\hom(F^G, G) > 0$, a contradiction. ◀

8 Right hom algorithms

In 1993 Chaudhuri and Vardi [6] (see also [1]) showed the analogue of the Lovász Isomorphism Theorem for the right homomorphism vector of a graph G. More precisely, the vector of values $\hom(G, F)$, where F ranges over all graphs, characterizes the isomorphism type of G. In this section we will see that our main "positive" results on hom algorithms fail for right hom algorithms (see Proposition 8.2) and that various results that survive use a completely different proof technique. Note that a graph G is 3-colorable if $\hom(G, K_3) > 0$ in contrast to Theorem 5.2.

▶ **Definition 8.1.** A class C of graphs can be *decided by a right hom algorithm* if and only if there is a $k \geq 1$ and graphs $F_1, \ldots, F_k$ such that for all graphs G and H,

$$\hom(G, F_1) = \hom(G, F_k), \ldots, \hom(G, F_k) = \hom(G, F_k) \text{ imply } (G \in \mathsf{C} \iff H \in \mathsf{C}),$$

or equivalently, if in addition to $F_1, \ldots, F_k$ there is a set $X \subseteq \mathbb{N}^k$ such that for any graph G, $\big(G \in \mathsf{C} \iff (\hom(G, F_1), \ldots, \hom(G, F_k)) \in X\big)$.

Again one can show that C is decidable if and only if as X can be chosen a decidable set.

It should be clear how we define k *adaptive right hom algorithms* for a class C of graphs.

The failure in the "right world" of the "positive" results Theorem 4.4 and Theorem 7.3 is shown by (it should be clear how we define k *adaptive right hom algorithms* for a class C of graphs):

▶ **Proposition 8.2.** *let $k \geq 1$. The class $\mathsf{K}(3)$ of graphs containing a clique of size 3 (expressible by the existential sentence $\exists x \exists y \exists z(Exy \wedge Eyz \wedge Exz)$) cannot be decided by a k adaptive right hom algorithm (and hence not by a right hom algorithm).*

Proof. For a graph G we denote by $\chi(G)$ the chromatic number of G, i.e., the least s such that G is s-colorable. Clearly, $\big(m < \chi(G) \iff \hom(G, K_m) = 0\big)$ for the clique K_m with m elements, and hence, for every graph F,

$$\text{if } |V(F)| < \chi(G), \text{ then } \hom(G, F) = 0. \tag{10}$$

For a contradiction, assume that g and X (compare Definition 7.2) witness the existence of a k adaptive right hom algorithm for C. Then set

$$n_1 := g(\emptyset),\ n_2 := g(0),\ n_3 := g(0,0), \ldots, n_k := g(\underbrace{0, \ldots, 0}_{k-1 \text{ times}}).$$

Let $s > 3$ be bigger than any of the $|V(F^0_{n_i})|$'s. According to [19] there is a $G_0 \notin \mathsf{K}(3)$ such that $\chi(G_0) = s$. Thus by (10), we have $\hom(G_0, F^0_{n_1}) = 0, \ldots, \hom(G_0, F^0_{n_k}) = 0$ and hence, $(0, 0, \ldots, 0) \notin X$. However, $K_s \in \mathsf{K}(3)$ and $\hom(K_s, F^0_{n_1}) = 0, \ldots, \hom(K_s, F^0_{n_k}) = 0$, thus $(0, 0, \ldots, 0) \in X$, a contradiction. ◀

Note that Theorem 10 in [1] cannot be applied to show (directly) the existence of an FO-sentence φ with no right hom algorithm. To apply this theorem to such a φ we should have for all graphs G and H, $(G \models \varphi \iff H \models \varphi)$ implies $|V(G)| = |V(H)|$. One easily verifies that this condition is not satisfied by any FO-sentence φ.

We mention a positive result on right hom algorithms (proven in the full version of the paper).

▶ **Theorem 8.3.** *Every class* C *of graphs with the property that there is a bound on the number of edges of graphs in* C *has a right hom algorithm.*

Finally we remark that some results with nontrivial proofs for hom algorithms are trivial for right hom algorithms. For example, the following simple proof shows that there is no right hom algorithm for the class $\mathsf{C}(\forall x \exists y Exy)$ of graphs with no isolated vertices.

Let $F_1, \dots, F_k$ be any finite set of graphs and set $m := 1 + \max\{|V(F_i)| \mid i \in [k]\}$. Then, $\hom(K_m, F_i) = 0 = \hom(K_m \dot\cup K_1)$ for every $i \in [k]$. Thus there is no right hom algorithm that detects an isolated vertex.

Abstract

The Boolean satisfiability problem plays a central role in computational complexity and is often used as a starting point for showing NP lower bounds. Generalisations such as Succinct SAT, where a Boolean formula is succinctly represented as a Boolean circuit, have been studied in the literature in order to lift the Boolean satisfiability problem to higher complexity classes such as NEXP. While, in theory, iterating this approach yields complete problems for k-NEXP for all $k > 0$, using such iterations of Succinct SAT is at best tedious when it comes to proving lower bounds.

The main contribution of this paper is to show that the Boolean satisfiability problem has another canonical generalisation in terms of higher-order Boolean functions that is arguably more suitable for showing lower bounds beyond NP. We introduce a family of problems HOSAT(k, d), $k \geq 0$, $d \geq 1$, in which variables are interpreted as Boolean functions of order at most k and there are d quantifier alternations between functions of order exactly k. We show that the unbounded HOSAT problem is TOWER-complete, and that HOSAT(k, d) is complete for the weak k-EXP hierarchy with d alternations for fixed $k, d \geq 1$ and d odd.

We illustrate the usefulness of HOSAT by characterising the complexity of weak Presburger arithmetic, the first-order theory of the integers with addition and equality but without order. It has been a long-standing open problem whether weak Presburger arithmetic has the same complexity as standard Presburger arithmetic. We answer this question affirmatively, even for the negation-free fragment and the Horn fragment of weak Presburger arithmetic.

1 Introduction

The Boolean satisfiability problem (SAT) plays a central role in computational complexity. It was the first problem shown to be NP-complete [8] and has ever since been used a countless number of times to show NP lower bounds for numerous combinatorial problems, a prime example being Karp's list of twenty-one NP-complete problems [17]. What makes SAT stand

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

out is its simplicity: describing an instance of SAT does not require tapes and automata as in the case of Turing machines, and neither grids nor dominoes like in tiling problems; it also does not require the introduction of graphs and their properties as in, e.g., graph colouring problems. To obtain a reduction from SAT, it suffices to show how to encode assignments to Boolean variables and how to model connectives. Unfortunately, this simplicity does not transfer over to higher complexity classes.

Succinct representations have been used as a technical tool to lift NP-complete problems to exponential classes [27, 20, 2, 32]. The idea is that the main object of interest is succinctly encoded by a Boolean circuit. For instance, a Boolean formula represented as a DAG whose vertices are labelled by a type (e.g., a Boolean connective or constant value) and a unique integer index can be encoded by a Boolean circuit with outputs. Given a binary encoding of an index, this circuit returns the type of the node with that index and, if present, the indices of its two predecessor nodes. Succinct variants of P- or NP-complete problems become EXP- or NEXP-complete, e.g., the Succinct Circuit Value problem and the Succinct SAT Problem are respectively EXP- and NEXP-complete [26]. In theory, this approach can be iterated indefinitely, and, e.g., the problem of deciding whether a propositional formula encoded by a Boolean circuit that is itself encoded by a Boolean circuit evaluates to true is a "canonical" 2-EXP-complete problem. One does not need too much imagination to see that these iterated succinct problems become unbearable for showing lower bounds.

This loss of simplicity for higher complexity classes compared to classical SAT is at odds with other canonical problems, such as the halting problem for a (non)deterministic Turing machine running in time $f(n)$ on an input of length n, or the problem of tiling a grid of size $f(n) \times f(n)$. Here, the function f can be chosen appropriately in order to obtain hard problems for many complexity classes such as k-EXP and k-NEXP [26]. The same picture emerges in the presence of alternation: whereas QBF [12, Chapter 7.4] elegantly extends SAT to the whole polynomial hierarchy [33], no simple extension of SAT has been defined to capture every level of the weak k-EXP hierarchies, for any $k \geq 1$ (cf. [15]). Again, this is in contrast with Turing machines and tiling problems: both admit extensions to deal with alternation in the context of complexity classes above NP [4, 5, 23].

The main contribution of this paper is to identify a canonical generalisation of SAT, called HOSAT, that gives complete problems for all weak k-EXP hierarchies and that shares the simplicity of classical SAT. Instead of Boolean variables, the building blocks of HOSAT are *function applications*. The functions considered are higher-order Boolean function f of order k, i.e., functions that take as input higher-order functions of order $k-1$ and return a Boolean value, and Boolean values themselves are functions of order zero. HOSAT closes function applications under Boolean connectives as well as quantification.

The development of HOSAT is a result of an attempt of the authors to settle the open problem of the computational complexity of *weak Presburger arithmetic*, the first-order theory of the integers with addition and equality, but without an order predicate (which is provably not definable in this theory). This less expressive theory is in fact the "original" arithmetic theory studied by Presburger in his seminal paper [28], see also [7], and it has been an open problem whether it is computationally as hard as what is nowadays commonly understood as Presburger arithmetic; see, e.g., [6]. The lower bound for Presburger arithmetic given by Berman [3] reduces from an alternating Turing machine running in doubly exponential time with a linear number of alternations. This reduction glosses over some technical details, which is unproblematic in the presence of the sufficient expressive power that the order predicate provides, but becomes problematic for weak Presburger arithmetic. Giving a clean reduction from HOSAT enables us to settle the complexity of weak Presburger arithmetic and to show that it has indeed the same complexity as Presburger arithmetic with the order predicate. We hope that HOSAT will be as beneficial as it was for us for other researchers for proving their lower bounds, in particular since the question of finding canonical complete problems for weak k-EXP hierarchies frequently comes up; see, e.g., [31, 21].

2 Preliminaries

We write $\mathbb{Z}$, $\mathbb{N}$ and $\mathbb{N}_+$ to denote the set of integers, natural numbers including zero, and natural numbers without zero, respectively. Unless otherwise stated, we assume integers to be encoded in binary. Given $l, u \in \mathbb{N}$, we define $[l, u] := \{l, l+1, \dots, u\}$, $[l, u) := [l, u-1]$ and $[u] := [0, u)$. The cardinality of a finite set A is denoted by $\#A$. For $k, n \in \mathbb{N}$, we write $\exp_2^k(n)$ for the tetration function inductively defined as $\exp_2^0(n) := n$ and $\exp_2^k(n) := 2^{\exp_2^{k-1}(n)}$. Intuitively, $\exp_2^k(n)$ is a tower of exponentials of height k, base 2, and top-most exponent n.

We recall complexity classes based on the notion of alternating Turing machines [5]. The class $\Sigma_d^{k\text{-EXP}}$ contains all problems that can be decided by an alternating Turing machine running in time $\exp_2^k(f(n))$ on an input of length n, where $f : \mathbb{N} \to \mathbb{N}$ is some polynomial that does not depend on the input, and starting in an existential state and making at most $d-1$ alternations on every computation path. By definition, $\Sigma_1^{k\text{-EXP}} = k\text{-NEXP}$. The *weak* k-EXP *hierarchy* is defined as $\bigcup_{d \geq 0} \Sigma_d^{k\text{-EXP}}$; for $k = 1$ see [15].

Given functions $a, s, t \colon \mathbb{N} \to \mathbb{N}$, the class $\mathrm{STA}(s(n), t(n), a(n))$ contains all problems that can be decided by an alternating Turing machine in time $t(n)$ using space $s(n)$ making at most $a(n)$ alternations on every computation path, where n is the length of the input. We use $*$ to indicate an unbounded availability of a certain resource. For instance, the polynomial hierarchy can be characterized as $\bigcup_{d \in \mathbb{N}} \mathrm{STA}(*, n^{O(1)}, d)$, and the d-th level of the weak k-EXP hierarchy $\Sigma_d^{k\,\text{EXP}}$ corresponds to $\mathrm{STA}(*, \exp_2^k(n^{O(1)}), d)$. The STA complexity measure was introduced by Berman [3] to show the following result.

▶ **Theorem 1** ([3]). *Presburger arithmetic is complete for* $\mathrm{STA}(*, 2^{2^{n^{O(1)}}}, O(n))$.

A function $f : \mathbb{N} \to \mathbb{N}$ is said to be *elementary* if there is a $k \in \mathbb{N}$ such that $f(n) < \exp_2^k(n)$ for all $n \in \mathbb{N}$. The (non-elementary) class TOWER [29] contains all problems decidable by a Turing machine in time $\exp_2^{g(n)}(f(n))$ for some fixed polynomial f and elementary function g, on inputs of length n. We have $\cup_{k \geq 1} k\text{-EXP} \subsetneq \text{TOWER}$, as TOWER contains problems decidable in time $\exp_2^n(1)$.

3 The higher-order quantified satisfiability problem

We introduce the *higher-order quantified satisfiability problem*, a problem whose instances form a hierarchy $(\mathrm{HOSAT}(k, d))_{k,d}$ of problems that characterise every complexity class $\Sigma_d^{k\text{-EXP}}$.

We write $\mathbb{B}$ to denote the Boolean domain $\{0, 1\}$. We often treat $\mathbb{B}$ as the set of the two nullary Boolean functions $() \to \{0\}$ and $() \to \{1\}$. Fix $n \in \mathbb{N}_+$ and let $\mathbb{B}_{0,n} := \mathbb{B}$. Given $k \geq 1$, we write $\mathbb{B}_{k,n}$ for the set of all functions with domain $(\mathbb{B}_{k-1,n})^n$ and codomain $\mathbb{B}$. For instance, $\mathbb{B}_{1,n}$ is the set of all n-ary Boolean functions $f \colon \{0,1\}^n \to \{0,1\}$, whereas $\mathbb{B}_{2,n}$ is the set of all n-ary second-order Boolean functions $f \colon (\{0,1\}^n \to \{0,1\})^n \to \{0,1\}$. For $k \geq 1$, the number of functions in $\mathbb{B}_{k,n}$ satisfies the recurrence relation $\#(\mathbb{B}_{k,n}) = 2^{\#(\mathbb{B}_{k-1,n})^n}$, and therefore $\exp_2^{k+1}(n) \leq \#\mathbb{B}_{k,n} \leq \exp_2^{k+1}((k+1) \cdot n)$. We refer to the indices k and n as the *order* and the *arity* of $\mathbb{B}_{k,n}$, respectively. Both n and k are written in unary.

We discuss the encoding $enc(f)$ of Boolean functions as bit-strings over $\{0, 1\}$, which we often treat as the binary number from $\mathbb{N}$ represented by the bit-string, with least significant digit first. For $b \in \mathbb{B}$, $enc(b) := b$. Functions $f \in \mathbb{B}_{1,n}$ can be encoded as a string of length

2^n over $\mathbb{B}$, whose i-th position encodes the truth value of f on the tuple $(b_1,\dots,b_n) \in \mathbb{B}^n$ such that $b_1 \cdots b_n$ is the binary encoding of i, with least significant digit first. For $k > 1$, functions $f \in \mathbb{B}_{k,n}$ can be encoded as a string over $\mathbb{B}$ whose i-th position encodes the truth value of f on input $(g_1,\dots,g_n) \in (\mathbb{B}_{k-1,n})^n$ such that the concatenation $\mathit{enc}(g_1)\cdots\mathit{enc}(g_n)$ of the encodings of $g_1,\dots,g_n$ is a binary encoding of i, with least significant digit first. The length $|f|$ of a function f from $\mathbb{B}_{k,n}$ is defined as the length of $\mathit{enc}(f)$. Therefore, $|b| = 1$ for all $b \in \mathbb{B}$, and for every $f \in \mathbb{B}_{k,n}$ with $k \geq 1$, we have $|f| = (\#(\mathbb{B}_{k-1,n}))^n \geq (\exp_2^k(n))^n$.

A *quantifier-free generalised Boolean formula* is a formula from the following grammar

$$\Phi ::= \top \mid f(g_1,\dots,g_n) \mid \neg\Phi \mid \Phi \wedge \Phi$$

where $f(g_1,\dots,g_n)$ is said to be a *function application*, and each f, $g_1,\dots,g_n$ are *function symbols* taken from an infinite alphabet Σ. Each function symbol in Σ is implicitly endowed with a type $\mathbb{B}_{k,n}$, with $k,n \in \mathbb{N}$. A (quantifier-free) generalised Boolean formula is said to be *well-formed* whenever every function application is consistent with the type of the function symbol, i.e., a function application $f(g_1,\dots,g_n)$ requires f to be of arity n, if $f \in \mathbb{B}$ then $n = 0$, and otherwise $f \in \mathbb{B}_{k,n}$ for some $k \geq 1$ and every g_i with $i \in [1,n]$ belongs to $\mathbb{B}_{k-1,n}$.

Given a vector-variable of function symbols $\boldsymbol{f} = (f_1,\dots,f_m)$ of type $\mathbb{B}_{k,n}$, we write $\exists \boldsymbol{f} \colon \mathbb{B}_{k,n}$ as a shorthand for the *existential quantifier block* $\exists f_1 \colon \mathbb{B}_{k,n} \ \dots\ \exists f_m \colon \mathbb{B}_{k,n}$; the *universal quantifier block* $\forall \boldsymbol{f} \colon \mathbb{B}_{k,n}$ stands for $\forall f_1 \colon \mathbb{B}_{k,n} \ \dots\ \forall f_m \colon \mathbb{B}_{k,n}$. The set of all *generalised Boolean formulae of order* 0 and alternation depth d is the set of all formulae $\exists \boldsymbol{b}_1 \colon \mathbb{B}\ \forall \boldsymbol{b}_2 \colon \mathbb{B}\ \dots\ \exists \boldsymbol{b}_d \colon \mathbb{B}\,.\,\Phi$, where Φ is a quantifier-free generalised Boolean formula. *Generalised Boolean formulae of order* $k \geq 1$ and alternation depth d are formulae

$$\exists \boldsymbol{f}_1 \colon \mathbb{B}_{k,n}\ \forall \boldsymbol{f}_2 \colon \mathbb{B}_{k,n}\ \dots\ \exists \boldsymbol{f}_d \colon \mathbb{B}_{k,n}\,.\,\Phi,$$

where the arity n is arbitrary and Φ is a generalised Boolean formula of order $k-1$, arbitrary alternation depth, and same arity n. The semantics of generalised Boolean formulae is as expected, e.g., $\exists f \colon \mathbb{B}_{k,n}\ \Psi$ states that there is a function $f \in \mathbb{B}_{k,n}$ that makes Ψ true. We write $\Phi \equiv \Psi$ to denote that Φ and Ψ are *equivalent*.

The size $|\Phi|$ of a generalised Boolean formula Φ is the number of symbols required to write it down, where "$\colon \mathbb{B}_{k,n}$" is a lexeme that decorates the function symbols, providing their type, and should not be confused with the actual set $\mathbb{B}_{k,n}$. We write $\mathrm{fv}(\Phi)$ for the set of *free* function symbols of Φ, i.e., the set of those function symbols that do not appear in the scope of a quantifier. A *sentence* is a well-formed generalised Boolean formula Φ where all function symbols are quantified, i.e. $\mathrm{fv}(\Phi) = \emptyset$. We sometimes write $\Phi(f_1,\dots,f_m)$ or $\Phi(\boldsymbol{f})$, with $\boldsymbol{f} = (f_1,\dots,f_m)$, for a formula Φ with $\mathrm{fv}(\Phi) = \{f_1,\dots,f_m\}$. Given function symbols $g_1,\dots,g_m$ and a formula $\Phi(f_1,\dots,f_m)$, we write $\Phi(g_1,\dots,g_m)$ for the formula obtained from Φ by replacing each f_i with g_i.

Generalised Boolean formulae are formulae in prenex normal form in which the type $\mathbb{B}_{k,n}$ of Boolean functions of the quantifier prefix weakly decreases with respect to k. For presentational convenience, throughout the remainder of the paper we relax these constraints and consider formulae that are not in prenex formal form. This is done w.l.o.g., as standard ways of efficiently translating formulae in prenex normal form also work for generalised Boolean formulae. Moreover, we use standard Boolean connectives $\vee$, $\rightarrow$ and $\leftrightarrow$, and $\bot$.

Let k and d in $\mathbb{N}_+$. We introduce the problem $\mathrm{HOSAT}(k,d)$:

$\mathrm{HOSAT}(k,d)$: d-ALTERNATING SATISFIABILITY PROBLEM OF ORDER k

INPUT: A sentence Φ of order k and alternation depth d.
QUESTION: Is Φ valid?

We define $\mathrm{HOSAT}(k,*) := \bigcup_{d \in \mathbb{N}_+} \mathrm{HOSAT}(k,d)$, i.e., the problem of deciding the validity of a sentence of order k and arbitrary alternation depth; and $\mathrm{HOSAT} := \bigcup_{k \in \mathbb{N}_+} \mathrm{HOSAT}(k,*)$.

▶ **Theorem 2.** *(I)* $\mathrm{HOSAT}(k,d)$ *is complete for* $\Sigma_d^{k\text{-EXP}}$ *for odd* d.
(II) $\mathrm{HOSAT}(k,*)$ *is complete for* $\mathrm{STA}(*, \exp_2^k(n^{O(1)}), O(n))$.

To keep the presentation simple, we only formulate the result for odd d. The reduction we use to show the lower bound of Theorem 2(I) is uniform for all $k \geq 1$. By uniform polynomial time reduction [29], this implies that HOSAT is TOWER-complete.

Related work. In view of the fact that HOSAT is a natural generalisation of SAT, it comes with no surprise that some of its instances have previously been defined and have found diverse application in the past. In [1], Babai, Fortnow and Lund relied on $\mathrm{HOSAT}(1,1)$ (called *Oracle-3-satisfiability* in the paper) to show that NEXP $\subseteq$ MIP, where MIP is the class of all languages with multiple-prover interactive proof systems. In [19], Lohrey relied on $\mathrm{HOSAT}(1,d)$ (called $\mathrm{QO}\Sigma_d$-SAT in the paper) to show Σ_d^{EXP}-hardness of model checking Σ_d-MSO sentences over hierarchical graph unfoldings. These works already hint at how considering Boolean functions instead of succinct circuits is already beneficial, in terms of directness of the reductions, for NEXP-hard problems.

Above Σ_d^{EXP}, closely related is the work of Statman on the typed λ-calculus. In [30], he considers the λ-calculus with single ground type $\mathbf{0}$, no constants, only power types ($\to$) and β-conversion, and shows that checking whether two λ-terms of the calculus reduce to the same normal form is non-elementary recursive (in fact, it shows that the problem is TOWER-complete). The proof of TOWER-hardness follows thanks to a Church encoding of the basic language of set theory denoted by Statman with Ω. The variables in formulae from Ω are associated with a number type from $\mathbb{N}$. A variable of type n ranges over $\mathcal{D}_n$ where $\mathcal{D}_0 := \{\mathbf{0}, \mathbf{1}\}$, with $\mathbf{0}$ and $\mathbf{1}$ constants, and $\mathcal{D}_{n+1}$ is the powerset of $\mathcal{D}_n$. Formulae of Ω are obtained by taking the closure under Boolean connectives and quantification of membership queries of the form $\mathbf{0} \in x$, $\mathbf{1} \in x$ and $y \in z$, where x is of type 1 and y and z are of types n and $n+1$, respectively, for some $n \in \mathbb{N}$. While HOSAT and the satisfiability of formulae from Ω are essentially the same problem, the logic Ω is not suitable to capture any of the levels of the weak k-EXP hierarchies. To see this, fix $k \geq 1$ and let $\Omega(k)$ be the subset of the formulae in Ω having variables of type at most k. Differently from $\mathrm{HOSAT}(k,*)$, the satisfiability problem of $\Omega(k)$ can be shown to be in PSPACE (more precisely, it is equivalent to QBF) since the sets $\mathcal{D}_j$ with $j \leq k$ are now fixed a priori. Here, the reason why $\mathrm{HOSAT}(k,*)$ is instead k-NEXP-hard is because the sets $\mathbb{B}_{j,n}$ with $j \leq k$ still have some degree of freedom given by the unbounded number of choices for $n \in \mathbb{N}$.

According to [30], TOWER-completeness of the satisfiability problem of Ω was announced by Meyer in [24, Theorem 1(7)] as part of a forthcoming paper coauthored with Fischer. To the best of our knowledge, the latter paper was never published. To resolve this issue, in [22] Mairson gives a revision of [30] that provides a standalone proof of the TOWER-hardness of Ω and a simplification to the aforementioned Church encoding.

4 The complexity of $\mathrm{HOSAT}(k,d)$

We prove Theorem 2(I). The proof of the $\Sigma_d^{k\text{-EXP}}$ upper bound is quite simple: given a sentence $\exists \boldsymbol{f}_1 \colon \mathbb{B}_{k,n}\ \forall \boldsymbol{f}_2 \colon \mathbb{B}_{k,n} \cdots \exists \boldsymbol{f}_d \colon \mathbb{B}_{k,n} \,.\, \Phi$, where Φ is a generalised Boolean formula of order $k-1$ and arbitrary alternation depth, an alternating Turing machine running in k-EXP time and performing d alternations implements the following recursive procedure.

1. Guess functions from $\mathbb{B}_{k,n}$ for each of the function symbols in the vectors $\boldsymbol{f}_1, \dots, \boldsymbol{f}_d$, alternating between existential and universal states according to the quantifier prefix.
2. Recursively on Φ, if $\Phi = \exists f \colon \mathbb{B}_{j,n}\ \Psi$ (resp. $\Phi = \forall f \colon \mathbb{B}_{j,n}\ \Psi$) with $j < k$ then check whether some (resp. each) function of order j satisfies Φ when assigned to f; if Φ is quantifier-free, then check whether it is satisfied under the current assignment of function symbols.

Since k-exponential time is available, the second step can be performed deterministically by iterating through all function in $\mathbb{B}_{j,n}$, thus without introducing further alternation.

The $\Sigma_d^{k\text{-EXP}}$ lower bound of $\mathrm{HOSAT}(k,d)$ is shown by reducing from the *d-alternating multi-tiling problem of order k* (in short, $\mathrm{AMTP}(k,d)$) considered in [10]. A *multi-tiling system* $\mathcal{S}$ is a tuple $(\mathcal{T}, \mathcal{T}_0, \mathcal{T}_{\mathrm{acc}}, \mathcal{H}, \mathcal{V}, \mathcal{M}, m)$ such that $\mathcal{T}$ is a finite set of *tile types*, $\mathcal{T}_0, \mathcal{T}_{\mathrm{acc}} \subseteq \mathcal{T}$ are sets of *initial* and *accepting* tiles, respectively, $\mathcal{H}, \mathcal{V}, \mathcal{M} \subseteq \mathcal{T} \times \mathcal{T}$ represent the *horizontal*, *vertical* and *multi-tiling* matching relations, respectively, and $m \in \mathbb{N}_+$ is a number written in unary. We write $|\mathcal{S}|$ for the number of symbols required to encode $\mathcal{S}$.

Fix $k \in \mathbb{N}_+$, and let $\mathrm{grid}(k,m)$ be the two-dimensional grid $[\exp_2^k(m)] \times [\exp_2^k(m)]$, where we recall that $[u] := [0,u)$. Each $(h,v) \in \mathrm{grid}(k,m)$ is said to be a *position* of the grid, comprised of a *horizontal position* h and a *vertical position* v. Let $d \in \mathbb{N}$ odd (so that the innermost quantifier of the $\mathrm{AMTP}(k,d)$ problem we are about to formalise is existential). A *d-level $\mathcal{S}$-tiling* for $\mathrm{grid}(k,m)$ is a tuple $(\mathfrak{f}_1, \mathfrak{f}_2, \mathfrak{f}_3, \dots, \mathfrak{f}_d)$ such that for all $\ell \in [1,d]$:

maps: $\mathfrak{f}_\ell \colon \mathrm{grid}(k,m) \to \mathcal{T}$ assigns a tile type to each position of $\mathrm{grid}(k,m)$;
hori: $(\mathfrak{f}_\ell(i,j), \mathfrak{f}_\ell(i,j+1)) \in \mathcal{H}$ for every $j \in [\exp_2^k(m)-1]$ and $i \in [\exp_2^k(m)]$;
vert: $(\mathfrak{f}_\ell(i,j), \mathfrak{f}_\ell(i+1,j)) \in \mathcal{V}$ for every $i \in [\exp_2^k(m)-1]$ and $j \in [\exp_2^k(m)]$;
multi: if $\ell < d$, then $(\mathfrak{f}_\ell(i,j), \mathfrak{f}_{\ell+1}(i,j)) \in \mathcal{M}$ for every $i,j \in [\exp_2^k(m)]$; and
accept: $\mathfrak{f}_d(\exp_2^k(m)-1, j) \in \mathcal{T}_{\mathrm{acc}}$, for some $j \in [\exp_2^k(m)]$.

The *initial row* $I(\mathfrak{f})$ of a map $\mathfrak{f} \colon \mathrm{grid}(k,m) \to \mathcal{T}$ is the word $\mathfrak{f}(0,0)\mathfrak{f}(0,1)\dots\mathfrak{f}(0,\exp_2^k(m)-1)$.

$\mathrm{AMTP}(k,d)$: d-ALTERNATING MULTI-TILING PROBLEM OF ORDER k

INPUT: A multi-tiling system $\mathcal{S} = (\mathcal{T}, \mathcal{T}_0, \mathcal{T}_{\mathrm{acc}}, \mathcal{H}, \mathcal{V}, \mathcal{M}, m)$.
QUESTION: Is it true that there is $w_1 \in (\mathcal{T}_0)^{\exp_2^k(m)}$ such that for all $w_2 \in (\mathcal{T}_0)^{\exp_2^k(m)}$ there is $\cdots$ there is $w_d \in (\mathcal{T}_0)^{\exp_2^k(m)}$ such that $\mathrm{grid}(k,m)$ has a d-level tiling $(\mathfrak{f}_1, \dots, \mathfrak{f}_d)$ where $I(\mathfrak{f}_\ell) = w_\ell$ for all $\ell \in [1,d]$?

▶ **Proposition 3** ([10]). *The problem* $\mathrm{AMTP}(k,d)$ *is complete for* $\Sigma_d^{k\text{-EXP}}$. *When d is given as part of the input instead of being fixed, the problem is* $\mathrm{STA}(*, \exp_2^k(n^{O(1)}), O(n))$*-complete.*

The $\mathrm{AMTP}(k,d)$ problem arose from [4], in which the case $k = 1$ and d not fixed is shown to be $\mathrm{STA}(*, 2^{n^{O(1)}}, O(n))$-complete. See [25, Appendix E.7] or [23] for self-contained proofs.

In the remaining part of this section, we describe a reduction from $\mathrm{AMTP}(k,d)$ to $\mathrm{HOSAT}(k,d)$. First, we introduce a family of generalised Boolean formulae that allows us to compare the bit-strings $\mathit{enc}(f)$ and $\mathit{enc}(g)$ of two functions f and g in $\mathbb{B}_{k,n}$, with $n,k \in \mathbb{N}$. Subsequently, we define formulae to encode the tiling conditions (maps)–(accept) as well as the alternation on elements of $(\mathcal{T}_0)^{\exp_2^k(m)}$ required by the $\mathrm{AMTP}(k,d)$ problem. We remind the reader that, w.l.o.g., we define generalised Boolean formulae without constraining them to be in prenex normal form, though we need to keep track of the quantifier alternation for function symbols of type k.

Comparing bit-strings. We define formulae $\mathrm{eq}_k(f,g)$, $\mathrm{less}_k(f,g)$ and $\mathrm{succ}_k(f,g)$ stating that $\mathit{enc}(f) = \mathit{enc}(g)$, $\mathit{enc}(f) < \mathit{enc}(g)$ and $\mathit{enc}(f)+1 = \mathit{enc}(g)$, respectively, and $(h_1, \dots, h_n) <_k (h_1', \dots, h_n')$, with all h_i and h_i' in $\mathbb{B}_{k,n}$, which checks if the concatenation $\mathit{enc}(h_1)\cdots\mathit{enc}(h_n)$ encodes a number smaller than $\mathit{enc}(h_1')\cdots\mathit{enc}(h_n')$. The formula $\mathrm{eq}_k(f,g)$ is defined as:

$$\mathrm{eq}_k(f,g) := \forall h_1, \dots, h_n \colon \mathbb{B}_{k-1,n}.f(h_1, \dots, h_n) \leftrightarrow g(h_1, \dots, h_n).$$

The formulae $\mathrm{less}_k(f,g)$ and $(h_1,\dots,h_n) <_k (h'_1,\dots,h'_n)$ have a mutually recursive definition: $\mathrm{less}_{k+1}(f,g)$ is defined using $(h_1,\dots,h_n) <_k (h'_1,\dots,h'_n)$, which in turn requires $\mathrm{less}_k(f,g)$. First, we define the base case $(h_1,\dots,h_n) <_0 (h'_1,\dots,h'_n)$, with each h_i and h'_i in $\mathbb{B} = \{0,1\}$:

$$(h_1,\dots,h_n) <_0 (h'_1,\dots,h'_n) := \bigvee_{i=1}^{n} \neg h_i \wedge h'_i \wedge \bigwedge_{j=i+1}^{n} (h'_j \leftrightarrow h_j).$$

Intuitively, this formula forces $\mathit{enc}(h_1)\dots\mathit{enc}(h_n) < \mathit{enc}(h'_1)\dots\mathit{enc}(h'_n)$ by requiring that there is a bit $i \in [1,n]$ that is set to 0 in $\mathit{enc}(h_1)\dots\mathit{enc}(h_n)$, set to 1 in $\mathit{enc}(h'_1)\dots\mathit{enc}(h'_n)$, and the binary representations of $\mathit{enc}(h'_1)\dots\mathit{enc}(h'_n)$ and $\mathit{enc}(h_1)\dots\mathit{enc}(h_n)$ coincide on all bits $j > i$. This is indeed the characterisation of $<$ on binary numbers in least significant digit first encoding. The same idea is used to define the formula $\mathrm{less}_k(f,g)$. Inductively, assume that the formula $(h_1,\dots,h_n) <_k (h'_1,\dots,h'_n)$ was defined. We use it to define $\mathrm{less}_{k+1}(f,g)$:

$$\mathrm{less}_{k+1}(f,g) := \exists \boldsymbol{h} \colon \mathbb{B}_{k,n} \,.\, \neg f(\boldsymbol{h}) \wedge g(\boldsymbol{h}) \ \wedge \forall \boldsymbol{h'} \colon \mathbb{B}_{k,n} \,.\, \boldsymbol{h} <_k \boldsymbol{h'} \to (f(\boldsymbol{h'}) \leftrightarrow g(\boldsymbol{h'})),$$

where $\boldsymbol{h} = (h_1,\dots,h_n)$ and $\boldsymbol{h'} = (h'_1,\dots,h'_n)$.

To complete the definitions of $\mathrm{less}_k(f,g)$ and $(h_1,\dots,h_n) <_k (h'_1,\dots,h'_n)$, what is left is to define $(h_1,\dots,h_n) <_{k+1} (h'_1,\dots,h'_n)$ using less_{k+1}. We need to respect the equivalence $(h_1,\dots,h_n) <_{k+1} (h'_1,\dots,h'_n) \equiv \bigvee_{i=1}^{n} \mathrm{less}_{k+1}(h_i,h'_i) \wedge \bigwedge_{j=i+1}^{n} \mathrm{eq}_{k+1}(h_j,h'_j)$. However, we cannot define $(h_1,\dots,h_n) <_{k+1} (h'_1,\dots,h'_n)$ as the formula in the right hand side of this equivalence, as this formula uses n occurrences of less_k and would thus lead to both less_k and $(h_1,\dots,h_n) <_k (h'_1,\dots,h'_n)$ being of size exponential in k. To solve this issue and obtain formulae of polynomial size, we rely on a variant of a trick used by Fisher and Rabin in [11], based on the equivalence $\Phi(a) \vee \Phi(b) \equiv \exists c : \Phi(c) \wedge (c = a \vee c = b)$:

$$\begin{aligned}&(h_1,\dots,h_n) <_{k+1} (h'_1,\dots,h'_n) \ := \\ &\quad \exists a,b \colon \mathbb{B}_{k+1,n} \,.\, \mathrm{less}_{k+1}(a,b) \wedge \bigvee_{i=1}^{n} \mathrm{eq}_{k+1}(a,h_i) \wedge \mathrm{eq}_{k+1}(b,h'_i) \wedge \bigwedge_{j=i+1}^{n} \mathrm{eq}_{k+1}(h_j,h'_j).\end{aligned}$$

▶ **Lemma 4.** *Let $f,g \in \mathbb{B}_{k,n}$. Then, $\mathrm{less}_k(f,g)$ iff $\mathit{enc}(f){<}\mathit{enc}(g)$; and $|\mathrm{less}_k(f,g)| \le O(n^3k)$.*

The definition of $\mathrm{succ}_k(f,g)$ follows a similar characterisation of successor for binary numbers: we have $a + 1 = b$ whenever (1) there is a bit i that is set to 0 in a and to 1 in b, (2) the binary representations of a and b coincide on every bit $j > i$ (exactly as in the case of $<$) and moreover (3) every bit $j < i$ is set to 1 in a and it is set to 0 in b. For instance, in least significant digit first encoding, $(1111001)_2 + 1 = (0000101)_2$. We have:

$$\begin{aligned}\mathrm{succ}_{k+1}(f,g) := \exists \boldsymbol{h} \colon \mathbb{B}_{k,n} \,.\, \neg f(\boldsymbol{h}) \wedge g(\boldsymbol{h}) \ \wedge \forall \boldsymbol{h'} \colon \mathbb{B}_{k,n} \,.& \\ \big(\boldsymbol{h} <_k \boldsymbol{h'} \to (f(\boldsymbol{h'}) \leftrightarrow g(\boldsymbol{h'}))\big) \wedge \big(\boldsymbol{h'} <_k \boldsymbol{h} \to f(\boldsymbol{h'}) \wedge \neg g(\boldsymbol{h'})\big),&\end{aligned}$$

where $\boldsymbol{h} = (h_1,\dots,h_n)$ and $\boldsymbol{h'} = (h'_1,\dots,h'_n)$.

▶ **Lemma 5.** *For $f,g \in \mathbb{B}_{k,n}$, $\mathrm{succ}_k(f,g)$ iff $\mathit{enc}(f) + 1 = \mathit{enc}(g)$; and $|\mathrm{succ}_k(f,g)| \le O(n^3k)$.*

From $\mathbf{AMTP}(k,d)$ to $\mathbf{HOSAT}(k,d)$. We are ready to prove the lower bounds of Theorem 2. For $k = 1$, the Σ_d^{EXP}-hardness of $\mathrm{HOSAT}(1,d)$ was already established by Lohrey in [19, Proposition 33] via a reduction from Turing machines. Therefore, we consider $k \ge 2$ (our proof can nonetheless be adapted to the case $k = 1$). Let $\mathcal{S} = (\mathcal{T}, \mathcal{T}_0, \mathcal{T}_{\mathrm{acc}}, \mathcal{H}, \mathcal{V}, \mathcal{M}, m)$ be a multi-tiling system. We assume $\mathcal{T} = [1,r]$ for some $r \in \mathbb{N}_+$ (thus $\mathcal{H}, \mathcal{V}, \mathcal{M} \subseteq [1,r] \times [1,r]$).

Let $n := 2 + \#\mathcal{T} + m$. We write $\bot_k$ for the function in $\mathbb{B}_{k,n}$ such that $\mathit{enc}(\bot_k) = 0$, i.e. $\bot_k$ is the only solution f of the formula $\mathrm{bot}_k(f) := \forall g_1,\dots,g_n \colon \mathbb{B}_{k-1,n} \,.\, \neg f(g_1,\dots,g_n)$. Similarly, we write $\top_k$ for the function in $\mathbb{B}_{k,n}$ with maximal encoding, that is the only solution f to the formula $\mathrm{top}_k(f) := \forall g_1,\dots,g_n \colon \mathbb{B}_{k-1,n} \,.\, f(g_1,\dots,g_n)$. The first step of the reduction consists of encoding the d functions of a d-level $\mathcal{S}$-tiling $(\mathfrak{f}_1,\dots,\mathfrak{f}_d)$. We encode each of these functions using a function $f \in \mathbb{B}_{k,n}$ satisfying the following two properties:

1: If $f(h,v,t_1,\dots,t_r,u_1,\dots,u_m) = 1$ then $enc(h)$ and $enc(v)$ belong to $[\exp_2^k(m)]$, each t_i belongs to $\{\bot_{k-1},\top_{k-1}\}$ and every u_j is $\bot_{k-1}$.

2: Given $h,v \in \mathbb{B}_{k-1,n}$, if $enc(h), enc(v) \in [\exp_2^k(m)]$ then there is exactly one tuple $\boldsymbol{t} = (t_1,\dots,t_r)$ such that $f(h,v,\boldsymbol{t},u_1,\dots,u_m) = 1$; and exactly one among $t_1,\dots,t_r$ is $\top_{k-1}$.

Here, the inputs h and v are used to represent horizontal and vertical positions in the grid, the inputs $t_1,\dots,t_r$ are used to encode the tiles, and the inputs $u_1,\dots,u_m$ are only required to makes sure we have enough inputs to encode the fact that h and v belong to $[\exp_2^k(m)]$ (see the formula ok_1 below). Together, Properties (1) and (2) characterise the condition (maps) of the $\mathcal{S}$-tiling (we add the other tiling conditions later). To capture Property 1 above, notice first that h and v should be taken from a space of exactly $\exp_2^k(m)$ functions. As $\#(\mathbb{B}_{k-1,n}) \geq \exp_2^k(m)$, this obliges us to introduce a formula $\mathrm{ok}_k(g)$ characterising the fact that a function $g \in \mathbb{B}_{k,n}$ is such that $enc(g) \in [\exp_2^{k+1}(m)]$. We have

$$\begin{aligned}\mathrm{ok}_1(g) &:= \forall h_1,\dots,h_n \colon \mathbb{B} \,.\, g(h_1,\dots,h_n) \to \textstyle\bigwedge_{i=m+1}^n \neg h_i\\ \mathrm{ok}_{k+1}(g) &:= \forall h_1,\dots h_n \colon \mathbb{B}_{k,n} \,.\, g(h_1,\dots,h_n) \to (\mathrm{ok}_k(h_1) \wedge \textstyle\bigwedge_{i=2}^n \mathrm{bot}_k(h_i)).\end{aligned}$$

Intuitively, for $k \geq 1$ the formula $\mathrm{ok}_k(g)$ holds whenever for all inputs $(h_1,\dots,h_n)$ and $j := enc(h_1)\cdots enc(h_n)$, if the j-th bit of $enc(g)$ is set to 1 then $j \in [\exp_2^k(m)]$. This means that $enc(g)$ corresponds to a binary number with $\exp_2^k(m)$ bits, i.e. $enc(g) \in [\exp_2^{k+1}(m)]$.

In all the formulae below, we let $\boldsymbol{t} = (t_1,\dots,t_r)$, $\boldsymbol{u} = (u_1,\dots,u_m)$ and $\boldsymbol{t'} = (t'_1,\dots,t'_r)$. We define the formula $\mathrm{mapsOne}_k(f)$ stating that $f \in \mathbb{B}_{k,n}$ satisfies Property 1:

$$\begin{aligned}\mathrm{mapsOne}_k(f) :=& \forall h,v,\boldsymbol{t},\boldsymbol{u} \colon \mathbb{B}_{k-1,n} \,.\, f(h,v,\boldsymbol{t},\boldsymbol{u}) \to \mathrm{ok}_{k-1}(h) \wedge \mathrm{ok}_{k-1}(v) \wedge\\ &\textstyle\bigwedge_{i=1}^r(\mathrm{top}_{k-1}(t_i) \vee \mathrm{bot}_{k-1}(t_i)) \wedge \bigwedge_{j=1}^m \mathrm{bot}_{k-1}(u_j).\end{aligned}$$

Suppose that $f \in \mathbb{B}_{k,n}$ satisfies $\mathrm{mapsOne}_k(f)$. In a similar fashion, one defines a formula $\mathrm{mapsTwo}_k(f)$ stating that f satisfies Property 2 of the encoding:

$$\begin{aligned}&\mathrm{mapsTwo}_k(f) := \forall h,v \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{ok}_{k-1}(h) \wedge \mathrm{ok}_{k-1}(v) \to \exists \boldsymbol{t},\boldsymbol{u} \colon \mathbb{B}_{k-1,n} \,.\, f(h,v,\boldsymbol{t},\boldsymbol{u}) \wedge\\ &\textstyle\bigvee_{i=1}^r(\mathrm{top}_{k-1}(t_i) \wedge \bigwedge_{\substack{j=1\\ j\neq i}}^r \mathrm{bot}_{k-1}(t_j)) \wedge \forall \boldsymbol{t'} \colon \mathbb{B}_{k-1,n} \,.\, f(h,v,\boldsymbol{t'},\boldsymbol{u}) \to \bigwedge_{i=1}^r \mathrm{eq}_{k-1}(t_i,t'_i).\end{aligned}$$

We define $\mathrm{maps}_k(f) := \mathrm{mapsOne}_k(f) \wedge \mathrm{mapsTwo}_k(f)$, and move to the remaining tiling conditions. The conditions (hori) and (vert) can be defined with the help of the formula succ_k. Below, we present the definition of the formula $\mathrm{hori}_k(f)$ that encodes the condition (hori):

$$\begin{aligned}\mathrm{hori}_k(f) := \forall h,v,v' \colon \mathbb{B}_{k-1,n} \,.\, &\mathrm{ok}_{k-1}(h) \wedge \mathrm{ok}_{k-1}(v) \wedge \mathrm{ok}_{k-1}(v') \wedge \mathrm{succ}_{k-1}(v,v')\\ &\to \textstyle\bigvee_{(i,j)\in\mathcal{H}} f(h,v,\underline{i}) \wedge f(h,v',\underline{j}),\end{aligned}$$

where $f(h,v,\underline{i})$ is a shortcut for $\exists \boldsymbol{t},\boldsymbol{u} \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{top}_{k-1}(t_i) \wedge f(h,v,\boldsymbol{t},\boldsymbol{u})$, i.e. a formula stating that the tile $i \in \mathcal{T}$ is assigned to the position $(enc(h), enc(v))$ of the grid, under the hypothesis that f satisfies $\mathrm{maps}_k(f)$. The definition of the formula $\mathrm{vert}_k(f)$ encoding the condition (vert) is defined analogously. For the condition (multi), let f and g be two functions of $\mathbb{B}_{k,n}$ satisfying maps_k. We define:

$$\mathrm{multi}_k(f,g) := \forall h,v \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{ok}_{k-1}(h) \wedge \mathrm{ok}_{k-1}(v) \to \textstyle\bigvee_{(i,j)\in\mathcal{M}} f(h,v,\underline{i}) \wedge g(h,v,\underline{j}).$$

Lastly, we define the formula $\mathrm{acc}_k(f)$ corresponding to the condition (accept):

$$\begin{aligned}\mathrm{acc}_k(f) := \exists h, v \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{ok}_{k-1}(h) \land \mathrm{ok}_{k-1}(v) \land \big(\textstyle\bigvee_{i \in \mathcal{T}_{\mathrm{acc}}} f(h, v, \underline{i})\big) \land \\ \forall h' \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{less}_{k-1}(h, h') \to \neg \mathrm{ok}_{k-1}(h').\end{aligned}$$

Here, the subformula $\forall h' \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{less}_{k-1}(h, h') \to \neg \mathrm{ok}_{k-1}(h')$ forces $enc(h) = \exp_2^2(m) - 1$.

To complete the reduction, what is left is to encode the quantifier prefix "$\exists w_1 \in (\mathcal{T}_0)^{\exp_2^k(m)}$ $\forall w_2 \in (\mathcal{T}_0)^{\exp_2^k(m)}$ $\dots$ $\exists w_d \in (\mathcal{T}_0)^{\exp_2^k(m)}$" of the $\mathrm{AMTP}(k, d)$ problem. To this end, we introduce two formulae $\mathrm{row}_k(f)$ and $\mathrm{rowCp}_k(f, g)$. The former states that $f \in \mathbb{B}_{k,n}$ satisfies maps_k, and whenever $f(h, v, \boldsymbol{t}, \boldsymbol{u})$ holds the only t_i equal to $\top_{k-1}$ is such that $i \in \mathcal{T}_0$:

$$\mathrm{row}_k(f) := \mathrm{maps}_k(f) \land \forall h, v, \boldsymbol{t}, \boldsymbol{u} : \mathbb{B}_{k-1,n} \,.\, f(h, v, \boldsymbol{t}, \boldsymbol{u}) \to \textstyle\bigvee_{i \in \mathcal{T}_0} \mathrm{top}_k(t_i).$$

We use this formula to quantify on the initial row $I(\mathfrak{f})$ of a $\mathcal{S}$-tiling function $\mathfrak{f}$, forgetting about the information stored by f elsewhere. This is done thanks to the formula $\mathrm{rowCp}_k(f, g)$, which given $f, g \in \mathbb{B}_{k,n}$ satisfying maps_k, states that f and g agree on the first row:

$$\mathrm{rowCp}_k(f, g) := \exists h \colon \mathbb{B}_{k-1,n} \,.\, \mathrm{bot}_{k-1}(h) \land \forall v, \boldsymbol{t}, \boldsymbol{u} \colon \mathbb{B}_{k-1,n} \,.\, f(h, v, \boldsymbol{t}, \boldsymbol{u}) \leftrightarrow g(h, v, \boldsymbol{t}, \boldsymbol{u}),$$

The quantifier prefix of $\mathrm{AMTP}(k, d)$ is encoded in $\mathrm{HOSAT}(k, d)$ by first quantifying over functions $w_1, \dots, w_d \in \mathbb{B}_{k,n}$ satisfying row_k, appropriately alternating between existential and universal quantification, and then existentially quantifying over functions $f_1, \dots, f_d \in \mathbb{B}_{k,n}$ that encode the $\mathcal{S}$-tiling functions $(\mathfrak{f}_1, \dots, \mathfrak{f}_d)$. The formula $\mathrm{rowCp}_k(f_i, w_i)$ is used to "copy" the first row of w_i in f_i. This leads to the formula $\mathrm{amtp}_k(\mathcal{S})$:

$$\begin{aligned}&\exists w_1 \colon \mathbb{B}_{k,n} \,.\, \mathrm{row}_k(w_1) \land \\ &\quad \forall w_2 \colon \mathbb{B}_{k,n} \,.\, \mathrm{row}_k(w_2) \to \\ &\quad\quad \dots \\ &\quad\quad\quad \exists w_d \colon \mathbb{B}_{k,n} \,.\, \mathrm{row}_k(w_d) \land \\ &\quad\quad\quad\quad \exists f_1, \dots, f_d \colon \mathbb{B}_{k,n} \,.\, \textstyle\bigwedge_{i=1}^{d} (\mathrm{maps}_k(f_i) \land \mathrm{rowCp}_k(f_i, w_i) \land \mathrm{hori}_k(f_i) \land \mathrm{vert}_k(f_i)) \\ &\quad\quad\quad\quad\quad\quad \land \textstyle\bigwedge_{i=1}^{d-1} \mathrm{multi}_k(f_i, f_{i+1}) \land \mathrm{acc}_k(f_d).\end{aligned}$$

▶ **Proposition 6.** *Let $d \in \mathbb{N}_+$ and $k \geq 2$. The formula $\mathrm{amtp}_k(\mathcal{S})$ is valid if and only if $\mathrm{AMTP}(k, d)$ accepts on input $\mathcal{S}$. Moreover, the formula $\mathrm{amtp}_k(\mathcal{S})$ has size $O(d \cdot k \cdot |\mathcal{S}|^4)$.*

Notice that $\mathrm{amtp}_k(\mathcal{S})$ is a generalised Boolean formula of order k and alternation depth d, since bringing it into prenex normal form yields a formula of the form $\exists w_1 \colon \mathbb{B}_{k,n} \, \forall w_2 \colon \mathbb{B}_{k,n} \dots$ $\exists w_d, f_1, \dots, f_d \colon \mathbb{B}_{k,n} \,.\, \Phi$, where Φ is a generalised Boolean formula of order $k - 1$ and size in $O(d \cdot k \cdot |\mathcal{S}|^4)$. By Proposition 3 (first part), this completes the proof of Theorem 2(I). Theorem 2(II) is proven analogously, by simply treating d as part of the input instead of being fixed. The upper bound follows the same strategy as the case of $\mathrm{HOSAT}(k, d)$, and the lower bound follows form Proposition 6 together with the second part of Proposition 3.

5 Weak Presburger arithmetic is as hard as Presburger arithmetic

In this section, we illustrate the usefulness of the higher order satisfiability problem by employing it to derive a $\mathrm{STA}(*, \exp_2^2(n^{O(1)}), O(n))$ lower bound for the weak fragment of Presburger arithmetic (*Weak PA*), hence showing that this logic matches the complexity of (standard) Presburger arithmetic. Weak PA is the first-order theory of the structure $\langle \mathbb{Z}, (c)_{c \in \mathbb{Z}}, +, = \rangle$, where $(c)_{c \in \mathbb{Z}}$ are constant symbols interpreted as their homographic integer, the binary function symbol $+$ is interpreted as addition on $\mathbb{Z}$ and the binary relation $=$ is interpreted as equality on $\mathbb{Z}$. Subsequently, linear Terms $t, t', \dots$ are of the form $a_1x_1 + \dots + a_dx_d + c$, where d is arbitrary, $a_1, \dots, a_d, c \in \mathbb{Z}$, and $x_1, \dots, x_d$ are first-order variables interpreted over $\mathbb{Z}$. Formulae of Weak PA close equalities between linear terms $t = t'$ under Boolean connectives $\neg$, $\wedge$, $\vee$, etc., and first-order quantifiers $\exists x$ and $\forall x$. For example, given $m \in \mathbb{N}_+$ and linear terms t, t', the *modulo constraint* $t \equiv_m t'$ stating that t is congruent to t' modulo m is characterised by the Weak PA formula $\exists x \,.\, t - t' = x \cdot m$, where x is a variable not appearing in t or t'.

Surprisingly, our lower bound holds for the following two fragments of Weak PA:

- The *positive fragment* that forbids negation, allowing formulae from the grammar
$$\Phi ::= a_1x_1 + \dots + a_dx_d = c \mid \Phi \wedge \Phi \mid \Phi \vee \Phi \mid \exists x \,.\, \Phi \mid \forall x \,.\, \Phi.$$
- The *Horn fragment*, in which formulae are of the form $\exists \boldsymbol{x}_1 \forall \boldsymbol{x}_2 \dots \exists \boldsymbol{x}_m \,.\, \bigwedge_{i \in I}(\Phi_i \to \Psi_i)$, where $\boldsymbol{x}_1, \dots, \boldsymbol{x}_m$ are vectors of variables, and each Φ_i and Ψ_i is a system of equalities, that is a conjunction of equalities between linear terms.

▶ **Theorem 7.** *The positive and Horn fragments of Weak PA are* $\mathrm{STA}(*, 2^{2^{n^{O(1)}}}, O(n))$*-hard.*

To prove this theorem we provide a reduction from $\mathrm{HOSAT}(2, *)$ to the validity problem for the positive fragment of Weak PA, and a translation from Weak PA to its Horn fragment. The reduction defines arithmetic with multiplication on doubly exponential finite segments of integers, such as $[2^{2^n}]$, and, in a more restricted way, one exponential higher. Here we strengthen Berman's lower bound argument for standard PA [3] (see also [18, Lecture 22]), which relies on the order predicate throughout.

Encoding second-order Boolean functions in Weak PA. Let $n \in \mathbb{N}_+$ be encoded in unary. In a nutshell, the main difficulty in the reduction from $\mathrm{HOSAT}(2, *)$ is to understand how to encode the functions in $\mathbb{B}_{1,n}$ and $\mathbb{B}_{2,n}$ using integer numbers, as well as translating the function applications $f(g_1, \dots, g_n)$. For the set $\mathbb{B}_{1,n}$, we rely on the encoding $\mathit{enc}(.)$ defined in Section 3 that maps every function $f \in \mathbb{B}_{1,n}$ into the number $\mathit{enc}(f) \in [2^{2^n}]$ written in binary. To encode functions in $\mathbb{B}_{2,n}$, we borrow ideas from [13, 14]. We say that $z \in \mathbb{Z}$ *encodes some function in* $\mathbb{B}_{2,n}$ if and only if for every $i \in [2^{n2^n}]$ and all prime numbers $p, q \in [i^3, (i+1)^3)$, $z \equiv_p 0$ or $z \equiv_p 1$, and $z \equiv_p 0$ if and only if $z \equiv_q 0$. Furthermore, we say that $z \in \mathbb{Z}$ *(precisely) encodes the function* $f \in \mathbb{B}_{2,n}$ if and only if z encodes some function in $\mathbb{B}_{2,n}$ and moreover for every $\boldsymbol{g} = (g_0, \dots, g_{n-1}) \in (\mathbb{B}_{1,n})^n$ and $b \in \{0, 1\}$,

$$f(\boldsymbol{g}) = b \quad \text{if and only if} \quad z \equiv_p b \text{ for a prime } p \in [\beta(\boldsymbol{g})^3, (\beta(\boldsymbol{g}) + 1)^3),$$

where $\beta : (\mathbb{B}_{1,n})^n \to [0, 2^{n2^n})$ is the bijection $\beta(g_0, \dots, g_{n-1}) := \sum_{j=0}^{n-1} \mathit{enc}(g_j) \cdot 2^{j \cdot 2^n}$. The fact that any function in $\mathbb{B}_{2,n}$ is encoded by some $z \in \mathbb{Z}$ follows from the Chinese remainder theorem together with Ingham's theorem [16], a theorem ensuring that for i sufficiently large, $[i^3, (i+1)^3)$ contains at least one prime. As in, e.g., [13, 14], to simplify the presentation we apply Ingham's theorem as if it was known to be true for all $i \in \mathbb{N}$. An alternative would be to use an analogous result on primes between fixed powers that holds for all i [9], or to add constant offsets throughout.

From $\mathrm{HOSAT}(2, *)$ to the positive fragment of Weak PA. We formalise the translation τ that, given a formula from $\mathrm{HOSAT}(2, *)$ returns an equivalent formula in the positive fragment of Weak PA. We divide the translation into three parts, depending on whether we are dealing with a generalised Boolean formula of order 0, 1 or 2. The translation τ is homomorphic for

formula	semantics	formula	semantics
$\varphi_n(x,z)$	$x = 2^{2^n} \cdot z$	$\mathrm{intdiv}_n(x,y,q,r)$	$x = q \cdot y + r$, $y \in [2^{2^n}]$, $r \in [y]$

Figure 1 Auxiliary formulae required to reduce HOSAT$(2,*)$ to positive Weak PA.

binary Boolean connectives: $\tau(\Phi \wedge \Psi) := \tau(\Phi) \wedge \tau(\Psi)$ and $\tau(\Phi \vee \Psi) := \tau(\Phi) \vee \tau(\Psi)$. Without loss of generality we assume that negations occurring in the quantifier-free part of generalised Boolean formulae only appear in front of function applications (recall that we see Boolean values as 0-ary functions). A *(function application) literal* is either a function application $f(g_1, \dots, g_\ell)$ or its negation $\neg f(g_1, \dots, g_\ell)$.

Formulae of order 0. We translate $\exists f \colon \mathbb{B}$, $\forall f \colon \mathbb{B}$ and literals f and $\neg f$, with f of type $\mathbb{B}$. Let $\mathbb{B}(x) := x = 0 \vee x = 1$, i.e. the formula stating $x \in \mathbb{B}$. Clearly, $\tau(f) := f = 1$ and $\tau(\neg f) := f = 0$. The quantifiers $\exists f \colon \mathbb{B}$ and $\forall f \colon \mathbb{B}$ are translated as follows:

$$\tau(\exists f \colon \mathbb{B}\ \Phi) := \exists f \,.\, \mathbb{B}(f) \wedge \tau(\Phi), \qquad \tau(\forall f \colon \mathbb{B}\ \Phi) := \forall f' \exists f \,.\, f \equiv_2 f' \wedge \mathbb{B}(f) \wedge \tau(\Phi).$$

A few words on the translation of $\forall f \colon \mathbb{B}$. We cannot translate the universal quantifier $\forall f \colon \mathbb{B}\ \Phi$ as $\forall f \,.\, \mathbb{B}(f) \to \tau(\Phi)$, i.e. relying on the $\exists$-$\forall$ duality, as $\mathbb{B}(f) \to \tau(\Phi)$ is not in the positive fragment of Weak PA. Our definition circumvents this problem by relying on the equivalence $\forall x \,.\, x \in [0,\ell] \to \Phi(x, \boldsymbol{z}) \quad \equiv \quad \forall x' \exists x \,.\, x' \equiv_{\ell+1} x \wedge x \in [0,\ell] \wedge \Phi(x, \boldsymbol{z})$.

Formulae of order 1. We treat quantifiers $\exists f \colon \mathbb{B}_{1,n}$, $\forall f \colon \mathbb{B}_{1,n}$ and literals $f(g_1, \dots, g_n)$ and $\neg f(g_1, \dots, g_n)$, where f is of type $\mathbb{B}_{1,n}$ and each g_i is of type $\mathbb{B}$. To achieve this we rely on the auxiliary formulae formally specified in Figure 1 and defined below ($\psi_{k,n}(x)$, $\mathrm{notprime}_n(p)$ and $x =_n y^3$ are defined later as only used for formulae of order 2). The formulae φ_n, mult_n, I_n and intdiv_n are an adaptation of the homonymous formulae provided by Kozen in [18, Lecture 22] in the context of linear real arithmetic. For instance, the formula $\varphi_n(x,z)$ is inductively defined in [18, p. 147] as follows:

$$\varphi_0(x,z) := x = 2z, \qquad \varphi_{n+1}(x,z) := \exists y \forall a, b \,.\, (a = x \wedge b = y) \vee (a = y \wedge b = z) \to \varphi_n(a,b).$$

The inductive case of $\varphi_{n+1}(x,z)$ is defined relying on the trick of Fisher and Rabin [11] we already encountered in Section 3, used here to obtain a linear size formula equivalent to $\exists y : \varphi_n(x,y) \wedge \varphi_n(y,z)$. As it stands $\varphi_{n+1}(x,z)$ is not in the positive fragment of Weak PA. We rely on modulo constraints to resolve this issue, redefining $\varphi_{n+1}(x,z)$ as follows:

$$\varphi_{n+1}(x,z) := \exists y \forall i \exists a, b \,.\, \big((i \equiv_2 0 \wedge a = x \wedge b = y) \vee (i \equiv_2 1 \wedge a = x \wedge b = y)\big) \wedge \varphi_n(a,b)\,.$$

The definitions of $\mathrm{mult}_n(x,y,z)$, $I_n(x)$ and $\mathrm{intdiv}_n(x,y,q,r)$ require similar adaptations w.r.t. [18, p. 148f], which are omitted due to space constraints. The formulae quot_n and rem_n are simple shortcuts of intdiv_n, e.g., $\mathrm{quot}_n(x,y,q) := \exists r\, \mathrm{intdiv}_n(x,y,q,r)$.

Finally, $\mathrm{power}_n(y,j)$ is intuitively defined by bit-blasting j into n bits $j_0, \dots, j_{n-1}$, so that $j = \sum_{i=0}^{n-1} j_i \cdot 2^i$, and forcing $y = 2^j = \prod\{\exp_2^2(i) : i \in [n] \text{ and } j_i = 1\}$ to hold:

$$\begin{aligned}\mathrm{power}_n(y,j) := \exists (j_0, y_0, z_0), \dots, (j_{n-1}, y_{n-1}, z_{n-1}) \,.\, j = \textstyle\sum_{i=0}^{n-1} j_i \cdot 2^i \ \wedge z_0 = y_0 \wedge y = z_{n-1} \\ \wedge \textstyle\bigwedge_{i=1}^{n-1} \big(\mathrm{mult}_n(z_i, z_{i-1}, y_i) \wedge \big((j_i = 0 \wedge y_i = 1) \vee (j_i = 1 \wedge \varphi_i(y_i, 1))\big)\big).\end{aligned}$$

The subformula $z_0 = y_0 \land y = z_{n-1} \land \bigwedge_{i=1}^{n-1} \mathrm{mult}_n(z_i, z_{i-1}, y_i)$ computes $y = \prod_{i=0}^{n-1} y_i$. We are ready to translate the generalised Boolean formula of order 1. Recall that we encode a function f in $\mathbb{B}_{1,n}$ with the number $\mathit{enc}(f) \in [2^{2^n}]$, and we have $f(g_0, \dots, g_{n-1}) = 1$ if and only if the jth bit of $\mathit{enc}(f)$ is 1, where $j = \sum_{i=1}^{n-1} g_i \cdot 2^i$. With this in mind, the case for existential quantifiers closely follows the definition for formulae of order 0: $\tau(\exists f\colon \mathbb{B}_{1,n}\ \Phi) := \exists f \,.\, I_n(f) \land \tau(\Phi)$. The case of universal quantifiers is more involved: whereas for the case of formulae of order 0 we resorted to reasoning modulo 2, we now reason modulo 2^{2^n}. We can bind 2^{2^n} to a variable ℓ with the formula $\varphi_n(\ell, 1)$. For $m \in \mathbb{Z}$ and $r \in [2^{2^n}]$, we can then check if $m \equiv_\ell r$ holds using the formula $\mathrm{rem}_{n+1}(m, \ell, r)$. Note that we use rem_{n+1} instead of rem_n, as ℓ belongs to the set $[2^{2^{n+1}}] \setminus [2^{2^n}]$. Here is the translation:

$$\tau(\forall f\colon \mathbb{B}_{1,n}\ \Phi) := \forall f' \exists f, \ell \,.\, \varphi_n(\ell, 1) \land \mathrm{rem}_{n+1}(f', \ell, f) \land \tau(\Phi).$$

For the function application literal $f(g_0, \dots, g_{n-1})$, where each g_i is mapped through τ into a homonymous Boolean variable according to the translation of formulae of order 0, we consider the number $j = \sum_{i=0}^{n-1} g_i \cdot 2^i$ and check that the jth bit of $\mathit{enc}(f)$ is set to 1 by verifying that the quotient of the division $f/2^j$ is odd. As a formula:

$$\tau(f(g_0, \dots, g_{n-1})) := \exists j, y, q \,.\, j = \textstyle\sum_{i=0}^{n-1} g_i \cdot 2^i \land \mathrm{power}_n(y, j) \land \mathrm{quot}_n(f, y, q) \land q \equiv_2 1.$$

We treat the literal $\neg f(g_0, \dots, g_{n-1})$ in a similar way, by checking whether $f/2^j$ is even. So, $\tau(\neg f(g_0, \dots, g_{n-1}))$ is obtained from $\tau(f(g_0, \dots, g_{n-1}))$ by replacing $q \equiv_2 1$ with $q \equiv_2 0$.

Formulae of order 2. To complete the definition of τ, we now show how to handle quantifiers $\exists f : \mathbb{B}_{2,n}$ and $\forall f : \mathbb{B}_{2,n}$, and function application literals $f(g_1, \dots, g_n)$ and $\neg f(g_1, \dots, g_n)$, where f is of type $\mathbb{B}_{2,n}$ and every g_i is of type $\mathbb{B}_{1,n}$. As explained at the beginning of the section, functions in $\mathbb{B}_{2,n}$ are encoded as integers $z \in \mathbb{Z}$ having the property that for every $i \in [2^{n2^n}]$ and all prime numbers $p, q \in [i^3, (i+1)^3)$, $z \equiv_p 0$ or $z \equiv_p 1$, and $z \equiv_p 0$ if and only if $z \equiv_q 0$. Below, we aim at defining the formula $\mathrm{enc}_n^2(z)$ stating that z encodes some function in $\mathbb{B}_{2,n}$. We start by defining the formula $\mathrm{notprime}_n(p)$ from Figure 1:

$$\mathrm{notprime}_n(p) := I_n(p) \land \exists d \,.\, I_n(d) \land I_n(d-2) \land I_n(p-d-1) \land \mathrm{rem}_n(p, d, 0).$$

Informally, $\mathrm{notprime}_n(p)$ states that p is not a prime number by finding a divisor $d \in [2, p-1]$. Notice that if we assume $p, d \in [2^{2^n}]$ then $I_n(d-2) \equiv d \geq 2$ and $I_n(p-d-1) \equiv d < p$.

Two further comments on the definition of encoding for functions in $\mathbb{B}_{2,n}$ given above: first, observe that this definition requires the construction of numbers $(i+1)^3$ with $i \in [2^{n2^n}]$. Since $(2^{n2^n} + 1)^3 < 2^{2^{2(n+1)}}$, all these numbers satisfy the formula $I_{2(n+1)}(x)$. This explains the contribution of $\mathrm{notprime}_{2(n+1)}$ and similar formulae in the forthcoming definition of $\mathrm{enc}_n^2(z)$. Second, the encoding requires to iterate over all $i \in [2^{n2^n}]$. As in the definition of τ for the case $\forall f : \mathbb{B}_{1,n}$, this is done by binding 2^{n2^n} to a variable ℓ and then considering all numbers in $[\ell]$ by relying on the formula $\mathrm{rem}_{2(n+1)}$. To characterise 2^{n2^n} we use the following formula that, given $k \in \mathbb{N}_+$ in unary, is satisfied whenever $x = 2^{k2^n}$:

$$\psi_{k,n}(x) := \exists z_1, \dots, z_k \,.\, z_k = 1 \land \varphi_k(x, z_1) \land \textstyle\bigwedge_{i=1}^{k-1} \varphi_n(z_i, z_{i+1}).$$

We define $x =_n y^3 := \exists z \,.\, \mathrm{mult}_{2(n+1)}(z, y, y) \land \mathrm{mult}_{2(n+1)}(x, z, y)$ and the formula $\mathrm{enc}_n^2(z)$:

$$\begin{aligned}
\mathrm{enc}_n^2(z) := {} & \forall i' \exists i, \ell, a, b \ .\ \psi_{n,n}(\ell) \land \mathrm{rem}_{2(n+1)}(i', \ell, i) \land a =_n i^3 \land b =_n (i+1)^3 \land \\
& \quad \forall p', q' \exists \ell', p, q \ .\ \varphi_{2(n+1)}(\ell', 1) \land \mathrm{rem}_{2n+3}(p', \ell', p) \land \mathrm{rem}_{2n+3}(q', \ell', q) \land \\
& \quad \Big(\textstyle\bigvee_{r \in \{p,q\}} \big(I_{2(n+1)}(a - r - 1) \lor I_{2(n+1)}(r - b) \lor \mathrm{notprime}_{2(n+1)}(r) \big) \\
& \quad\quad \lor \textstyle\bigvee_{s \in \{0,1\}} \big(\mathrm{rem}_{2(n+1)}(z, p, s) \land \mathrm{rem}_{2(n+1)}(z, q, s) \big) \Big).
\end{aligned}$$

Let us dissect this formula line by line. The first line iterates through all $i \in [\ell] = [2^{n2^n}]$, binding a and b to i^3 and $(i{+}1)^3$ respectively. The second line iterates through all $p, q \in [\ell'] = [2^{2^{2(n+1)}}]$. Following the definition of our encoding of functions in $\mathbb{B}_{2,n}$, we check that

- one among p and q lies outside $[a, b)$ or is not prime (third line of the formula), or
- $z \equiv_p 0$ or $z \equiv_p 1$, and $z \equiv_p 0$ if and only if $z \equiv_q 0$ (fourth line of the formula).

▶ **Lemma 8.** *A number $z \in \mathbb{Z}$ satisfies $\mathrm{enc}_n^2(z)$ iff z encodes some function in $\mathbb{B}_{2,n}$.*

We can now define τ for $\exists$ quantifiers: $\tau(\exists f\colon \mathbb{B}_{2,n}\ \Phi) := \exists f : \mathrm{enc}_n^2(f) \wedge \tau(\Phi)$. For universal quantifiers we reason dually and define a positive Weak PA formula $\mathrm{notenc}_n^2(z)$ stating that z does not encode any function in $\mathbb{B}_{2,n}$. Defining this formula requires a positive Weak PA formula to test for the primality of $p \in [2^{2^n}]$:

$$\mathrm{prime}_n(p) := I_n(p) \wedge \forall z \exists d, r \,.\, \mathrm{rem}_n(z, p, d) \wedge \big(d = 0 \vee d = 1 \vee \big(\mathrm{rem}_n(p, d, r) \wedge I_n(r - 1)\big)\big).$$

Afterwards, $\mathrm{notenc}_n^2(z)$ is defined by slightly revisiting $\mathrm{enc}_n^2(z)$:

$$\begin{aligned}\mathrm{notenc}_n^2(z) := \exists i, \ell, a, b, p, q \,.\, &\psi_{n,n}(\ell) \wedge I_{2(n+1)}(\ell - i - 1) \wedge a =_n i^3 \wedge b =_n (i+1)^3 \wedge \\ &\textstyle\bigwedge_{r \in \{p,q\}} \big(I_{2(n+1)}(r - a) \wedge I_{2(n+1)}(b - r - 1) \wedge \mathrm{prime}_{2(n+1)}(r)\big) \wedge \\ &\exists s, t \,.\, \mathrm{rem}_{2(n+1)}(z, p, s) \wedge \mathrm{rem}_{2(n+1)}(z, p, t) \wedge (I_{2(n+1)}(s - 2) \vee s \equiv_2 t + 1).\end{aligned}$$

We define the translation for universal quantifiers as $\tau(\forall f\colon \mathbb{B}_{2,n}\ \Phi) := \forall f : \mathrm{notenc}_n^2(f) \vee \tau(\Phi)$.

Let $\boldsymbol{g} = (g_0, \dots, g_{n-1})$. What is left is to treat the literals $f(\boldsymbol{g})$ and $\neg f(\boldsymbol{g})$. Once more, recall that every g_i is a function in $\mathbb{B}_{1,n}$, and thus it is translated through τ into a homonymous integer variable that is constrained to be in $[2^{2^n}]$. Suppose that z encodes the function f. To check whether $f(\boldsymbol{g})$ holds (resp. does not hold), we must check whether $z \equiv_p 1$ (resp. $z \equiv_p 0$) for some prime number p in the interval $[i^3, (i+1)^3)$ with $i := \sum_{j=0}^{n-1} g_j \cdot 2^{j \cdot 2^n}$. Formally, given $d \in \{0, 1\}$ and $i \in [2^{n2^n}]$, we define the macro $z[i] =_n d$ to check this property:

$$\begin{aligned}z[i] =_n d \ := \ \exists a, b, p \,.\ a =_n i^3 \wedge b =_n (i+1)^3 \wedge \mathrm{prime}_{2(n+1)}(p) \wedge \\ I_{2(n+1)}(p - a) \wedge I_{2(n+1)}(b - p - 1) \wedge \mathrm{rem}_{2(n+1)}(z, p, d).\end{aligned}$$

It then suffices to compute i from $\boldsymbol{g} = (g_0, \dots, g_{n-1})$, with the following formula

$$\gamma_n(i, \boldsymbol{g}) := \exists x_0, y_0, \dots, x_{n-1}, y_{n-1} \,.\, i = \textstyle\sum_{j=0}^{n-1} x_j \ \wedge \bigwedge_{j=0}^{n-1} \big(\psi_{j,n}(y_j) \wedge \mathrm{mult}_{2(n+1)}(x_j, y_j, g_j)\big),$$

leading to the following translations for the literals $f(\boldsymbol{g})$ and $\neg f(\boldsymbol{g})$:

$$\tau(f(\boldsymbol{g})) := \exists i \,.\, \gamma_n(i, \boldsymbol{g}) \wedge f[i] =_n 1, \qquad \tau(\neg f(\boldsymbol{g})) := \exists i \,.\, \gamma_n(i, \boldsymbol{g}) \wedge f[i] =_n 0.$$

The correctness of the translation τ is provided by the following proposition, shown by structural induction on the generalised Boolean formula Φ.

▶ **Proposition 9.** *A generalised Boolean formula Φ of order 2 is valid if and only if so is $\tau(\Phi)$. The size of $\tau(\Phi)$ is polynomial in the size of Φ.*

Horn Weak PA = Weak PA. To complete the proof of Theorem 7, we need to show that Weak PA reduces to its Horn fragment. Briefly, this is done with standard formula manipulations and by relying on the equivalences below (notice the similarities to the trick used to define φ_n):

$$\Phi \wedge \Psi \ \equiv \ \forall x \,.\, (x \equiv_2 0 \to \Phi) \wedge (x \equiv_2 1 \to \Psi), \qquad \Phi \vee \Psi \ \equiv \ \exists x \,.\, (x \equiv_2 0 \to \Phi) \wedge (x \equiv_2 1 \to \Psi);$$

where the variable x above does not occur in Φ nor in Ψ.

Abstract

A graph has arboricity α if its edges can be partitioned into α forests. The dynamic arboricity decomposition problem is to update a partitioning of the graph's edges into forests, as a graph undergoes insertions and deletions of edges. We present an algorithm for maintaining partitioning into $\alpha + 1$ forests, provided the arboricity of the dynamic graph never exceeds α. Our algorithm has an update time of $\tilde{O}(n^{3/4})$ when α is at most polylogarithmic in n.

Similarly, the dynamic bounded out-orientation problem is to orient the edges of the graph such that the out-degree of each vertex is at all times bounded. For this problem, we give an algorithm that orients the edges such that the out-degree is at all times bounded by $\alpha + 1$, with an update time of $\tilde{O}(n^{5/7})$, when α is at most polylogarithmic in n. Here, the choice of $\alpha + 1$ should be viewed in the light of the well-known lower bound by Brodal and Fagerberg which establishes that, for general graphs, maintaining only α out-edges would require linear update time.

However, the lower bound by Brodal and Fagerberg is non-planar. In this paper, we give a lower bound showing that even for planar graphs, linear update time is needed in order to maintain an explicit three-out-orientation. For planar graphs, we show that the dynamic four forest decomposition and four-out-orientations, can be updated in $\tilde{O}(n^{1/2})$ time.

1 Introduction

Dynamic graphs have been the subject of much study. Here one is typically interested in maintaining some property of or information about the graph, as edges of the graph are inserted and deleted. Sometimes one studies more restricted classes of graphs with more structure

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

in the hopes of improving algorithmic performance. The existence of efficient algorithms for testing planarity of a fully-dynamic graph [17, 24] motivates efforts to dynamically maintain well-known properties of planar graphs, such as e.g. bounded out-degree orientations and colourings.

The *arboricity* of a graph G is the smallest number α such that α forests can cover the edges of G. Planar graphs have arboricity at most 3. If a forest is rooted arbitrarily, and all of the edges in the forest are oriented towards the roots, then every vertex has out-degree 1. In particular, this implies that the edges of a planar graph resp. graphs of arboricity α can be oriented such that no vertex has out-degree more than 3 resp. α . We call an orientation of a graph such that no vertex has more than k out-edges a *k-bounded out-orientation.* Since there exists planar graphs on n vertices with more than $2n$ edges, it follows that there exists planar graphs for which a 3-bounded out-orientation is the lowest out-orientation possible.

In light of the above, we ask the question: can one efficiently maintain a 3-bounded out-orientation of a dynamic planar graph? Here the aim is to be more efficient than the fastest static algorithm – running in linear time – as one could construct a dynamic algorithm by statically recomputing a new solution after every update.

It turns out that it is not possible to improve upon this; at least not if we want to maintain an *explicit* orientation. Here, one has to store the orientation of every edge in memory opposed to an *implicit* orientation, where one is allowed to compute the orientation of an edge at query-time. More precisely we show that any algorithm maintaining an explicit 3-bounded out-orientation of a dynamic planar graph must spend $\Omega(n)$ update time, even amortised. For the broader class of graphs with bounded arboricity, Brodal & Fagerberg [9] showed that any algorithm maintaining an explicit α-bounded out-orientation must spend $\Omega(n)$ update time, even amortised. However for $\alpha = 3$ their example is far from planar. Our lower bound shows that the same bounds indeed hold for planar graphs.

In light of this negative result, it is natural to ask if one can do better if a little slack on the number of out-edges is allowed. We show that this is indeed the case, as we provide an algorithm maintaining a 4-bounded out-orientation of a dynamic planar graph with $\tilde{O}(\sqrt{n})$ amortised update time. In fact, this generalises to maintaining an $(\alpha + 1)$-bounded out-orientation of a dynamic graph whose arboricity never exceeds α through-out the entire update sequence. Here the algorithm has an amortised update-time of $\tilde{O}(n^{5/7})$. Here $\tilde{O}$ hides α and $\log n$ factors, so one should think of $\alpha = O(1)$.

An *arboricity decomposition* of a graph is a decomposition of the graph's edges into forests. We show how to dynamically maintain a 4-arboricity decomposition of a dynamic planar graph with $\tilde{O}(\sqrt{n})$ amortised update time. This also generalises to graphs of bounded degree α: here we present an algorithm maintaining an $(\alpha + 1)$ arboricity decomposition with an amortised update-time of $\tilde{O}(n^{3/4})$.

The presented algorithms all follow the same idea: we show how to update the out-orientation or arboricity decomposition in such a way that 1) every update only uses very little of the extra slack provided by having one more out-edge or one more forest available and 2) the update time scales with the amount of extra slack used. Combining these two properties allow us to truncate the update algorithm if it runs for too long and instead statically recompute an optimal solution.

1.1 Results

We consider dynamic graphs on n vertices undergoing a sequence of updates such that the arboricity of the graph at all times is bounded by α. We refer to such a sequence of updates as an α preserving sequence of updates.

We show the following theorem for maintaining an $\alpha + 1$ out-orientation.

▶ **Theorem 1.** *Given an initially empty dynamic graph undergoing an arboricity α preserving sequence of updates and a static black box algorithm that computes an α-bounded out-degree orientation of a graph with n vertices and arboricity α in time $S(\alpha, n)$, the algorithm will maintain an $(\alpha + 1)$-bounded out-degree orientation with an amortised insertion time of $O(\sqrt{\alpha \cdot S(\alpha, n)})$, and a worst-case deletion time of $O(1)$.*

Specifying a black box algorithm gives the following corollary:

▶ **Corollary 2.** *Given an initially empty dynamic planar graph undergoing edge insertions and deletions, there is an algorithm that maintains a 4-bounded out-degree orientation with an amortised insertion time of $O(\sqrt{n})$, and a worst-case deletion time of $O(\log n)$.*

Proof. Chrobak & Eppstein gave a linear-time algorithm for computing a 3-bounded out-degree orientation in planar graphs [12]. Now applying Theorem 1 yields the result. ◀

For bounded arboricity graphs, applying the fastest static algorithm [31] gives an amortised update time of $\tilde{O}(n^{5/7})$. We show the following theorem for maintaining an $\alpha + 1$ arboricity decomposition:

▶ **Theorem 3.** *Given an initially empty dynamic graph undergoing an arboricity α preserving sequence of updates and a static black box algorithm that computes an α arboricity decompostion of a graph with n vertices and arboricity α in time $S(\alpha, n)$, the algorithm will maintain an $(\alpha + 1)$ arboricity decomposition with an amortised insertion time of $O(\alpha\sqrt{S(\alpha, n)} \log n)$, and a worst-case deletion time of $O(\log n)$.*

Specifying black box algorithms gives the following corollaries:

▶ **Corollary 4.** *Given an initially empty dynamic planar graph undergoing edge insertions and deletions, then there exists an algorithm maintaining a 4-arboricity decomposition with an amortised insertion time of $O(\sqrt{n} \log n)$, and a worst-case deletion cost of $O(\log n)$.*

Proof. Chrobak & Eppstein also showed how to compute a 3-forest partition in linear time in planar graphs [12]. ◀

For bounded arboricity graphs, applying the fastest static algorithm [18, 19] gives an amortised update time of $\tilde{O}(n^{3/4})$. Finally, we show a lower bound for maintaining explicit 3-bounded out-orientations in dynamic planar graphs:

▶ **Theorem 5.** *Let $\mathcal{A}$ be an algorithm explicitly maintaining a 3-bounded out-degree orientation of an n-vertex planar graph under insertion and deletion of edges. Then there exists a sequence of updates taking $\Omega(n)$ amortised time per update.*

Note that some results rely on ideas similar to those that appeared in the master's thesis by A. B. G. Christiansen [10].

1.2 Related Work

Dynamic Planar Graphs. Dynamic planar graphs have been studied both in the incremental (edge-insertion only) [13, 25, 35, 38] and fully-dynamic (insertion/deletion) setting [16, 17, 20, 24, 26].

Table 1 Overview of dynamic algorithms for maintaining out-orientations. This table is inspired by a similar table in [11].

He et al. [22]	$O(\alpha\sqrt{\log n})$	$O(\sqrt{\log n})$ am.	yes
Berglin & Brodal [5]	$O(\alpha + \log n)$	$O(\log n)$	no
Henzinger et al. [23]	40α	$O(\log^2 n)$ am.	no
Kowalik [29]	$O(\alpha \log n)$	$O(1)$ am.	yes
Christiansen & Rotenberg [11]	$\alpha + 2$	$\tilde{O}(\log^3 (n)))$	yes
New (Thm. 1)	$\alpha + 1$	$\tilde{O}(n^{5/7})$	yes

Bounded Out-Orientations. For the more general class of graphs with bounded arboricity, the out-orientation problem is well studied – both from a dynamic view-point [9, 27, 37, 29, 5] and a static view-point [18, 34, 6, 1]. For dynamic arboricity-bounded graphs, Brodal & Fagerberg gave an algorithm maintaining a $2(\alpha + 1)$-bounded out-orientation with amortised $O(\alpha + \log n)$ update time. There also exists an algorithm [11] for maintaining an $(\alpha + 2)$-bounded out-orientation with worst-case update time in $O(\text{poly}(\log n, \alpha))$.See Table 1 for an overview.

From a static view-point, the fastest algorithms have running time $\tilde{O}(m^{10/7})$ [31] and $\tilde{O}(m\sqrt{n})$ [30]. Furthermore, Kowalik [28] also gave an algorithm computing a $(\alpha + 1)$ out-orientation in $\tilde{O}(m)$ time. Specialising to the planar case, where the graphs are assumed to be planar at all times, the lowest out-degree one can get in the dynamic setting while still achieving sublinear update time becomes 5 with update time in $O(\text{poly}(\log n))$. In the static case, Chrobak & Eppstein showed how to compute a 3 out-orientation in linear time [12].

Arboricity Decompositions. There has been a lot of work dedicated to computing an arboricity decomposition [18, 19, 14, 34]. The state-of-the-art for computing exact arboricity decompositions run in $\tilde{O}(m^{3/2})$ time [18, 19]. There also exists approximation algorithms. There is a 2-approximation algorithm [3, 15] as well as an algorithm for computing an $\alpha + 2$ arboricity decomposition in near-linear time [7]. From the dynamic side, Bannerjee et al. [4] give a dynamic algorithm for maintaining the current arboricity. The algorithm has a near-linear update time. They also provide a lower bound of $\Omega(\log n)$ for dynamically maintaining arboricity. Henzinger et al. [23] provide a dynamic algorithm for maintaining a $2\alpha'$ arboricity decomposition, given access to any black box dynamic α' out-degree orientation algorithm. Combining this technique with the results from Table 1 yields different trade-offs. Finally there also exists an algorithm maintaining an $(\alpha + 2)$ arboricity decomposition with $O(\text{poly}(\log(n), \alpha))$ update-time [11].

Specialising to the planar case, the last of the algorithms above yields a sublinear update time dynamic algorithm for computing a 5 arboricity decomposition. In the static case, Chrobak & Eppstein also showed how to compute a 3-forest partition in linear time [12].

1.3 Paper Outline

In Section 2 we recall preliminaries. Section 3 is dedicated to Theorem 1. In Section 4 we show Theorem 3. Finally in Section 5, we prove Theorem 5.

2 Preliminaries & Notation

We follow standard graph-terminology. We say that a graph $G = (V, E)$ is *k-degenerate* if every subgraph of G has a vertex of degree at most k. If the edges of G receives an orientation, we let the *out-edges* of a vertex v be the edges oriented away from v. The *out-degree* of v is then the number of out-edges incident to v.

Nash-Williams showed the following density formula for graphs of arboricity α:

▶ **Theorem 6** ([33, 32]). *Let G be a graph with no loops. Then*

$$\alpha(G) = \left\lceil \max_{J \subset G, |V(J)| \geq 2} \frac{|E(J)|}{|V(J)| - 1} \right\rceil$$

A plane graph is a planar graph together with an embedding into the plane such that no edges cross. For plane graphs we have the usual notion of faces. A *triangulation* is a maximal planar subgraph (wrt. the edges). If the triangulation is equipped with an embedding, we call it a *plane triangulation.* For planar graphs, we have the following well-known theorem:

▶ **Theorem 7** (Euler's Theorem). *If G is a connected plane graph with n vertices, m edges and f faces, then $n - m + f = 2$. In particular, if G is a planar triangulation, then $m = 3n - 6$.*

3 Low Out-orientations

In this section, we present a dynamic algorithm that maintains an $(\alpha + 1)$-bounded out-degree orientation. Suppose we are given an initially empty dynamic graph G on n vertices undergoing an arboricity α preserving sequence of updates. Then the algorithm has an update time of $\tilde{O}(\sqrt{S(\alpha, n)})$ provided that it is given access to a black box static algorithm for computing an α-bounded out-degree orientation in $O(S(\alpha, n))$ time.

The idea behind the algorithm is the following: suppose we are given a graph G, an edge $e = uv \in G$ and an $\alpha + 1$ orientation of $G - e$. Then we can extend the orientation of $G - e$ to an $\alpha + 1$ orientation of G in the following way. Find a minimal oriented path P beginning at u that ends at a vertex w with out-degree at most α. We will refer to such a path as an *augmenting path.* After finding P, we reorient all edges along the path. Finally, we make uv an out-edge of u. This yields an $\alpha + 1$ orientation of G since the only vertex to have its out-degree increased is w, and w was specifically chosen to have out-degree $< \alpha + 1$.

In order to find P, we look for w by doing a breadth-first-search (BFS) beginning from u. In Lemma 8, we show that such a BFS always succeeds and that it takes time proportional to the number of vertices visited. Finally, we show that if the BFS visits too many vertices, we have witnessed enough updates to be able to truncate the search and recompute an α orientation.

The Algorithm. Whenever an edge is deleted, we can simply delete it in the graph, so we focus on insertions. Suppose $e = uv$ is inserted. Either u has out-degree $< \alpha + 1$ and $P = u$ is an augmenting path or u has out-degree $\alpha + 1$ in which case, we push u's neighbours to a queue Q and mark them as visited. Now we can recursively visit vertices in Q by pushing the un-visited neighbours of vertices with degree $\alpha + 1$ to Q, and terminating with an augmenting path if we locate a vertex with out-degree $< \alpha + 1$. In the end of the update algorithm, we mark all visited vertices as un-visited. The search for P has the following properties:

▶ **Lemma 8.** *Suppose that $G - uv$ is given an $(\alpha + 1)$-bounded out-degree orientation, and we begin a search from u. Then after visiting t vertices the following holds:*

1. *If no vertex with out-degree $< \alpha + 1$ has been visited, then Q is not empty.*
2. *The algorithm has spent $O(\alpha \cdot t)$-time.*

Proof. We begin by showing that 1) holds. Suppose for contradiction that the algorithm has visited all vertices pushed to Q without finding a vertex with out-degree $< \alpha + 1$. Let J be the set of visited vertices. Since the algorithm pushes all new out-neighbours of a vertex v to Q, when visiting v, it must be the case that all out-edges of vertices in J go to other vertices in J. Since the algorithm did not find a vertex with out-degree $< \alpha + 1$, all vertices of J have out-degree $\alpha + 1$, and as a result, there must be at least $(\alpha + 1)|J|$ edges between vertices in J. But then, $\frac{|E(J)|}{|J|-1} = \frac{(\alpha+1)|J|}{|J|-1} > \alpha + 1 > \alpha$, contradicting Theorem 6.

Now, we show that 2) also holds. After visiting t vertices, the algorithm has traversed every out-edge out of the visited vertices when pushing new out-neighbours to Q. The time needed to perform these steps is $O(1)$ per visited vertex and $O(1)$ per out-edge leaving a visited vertex. Since every visited vertex has out-degree $\alpha + 1$ by assumption, the total time spent in the search is $O(\alpha \cdot t)$. ◀

▶ Remark 9. Lemma 2 in [9] implies that P has length $O(\alpha \log(n))$.

Now we make the following observation:

▶ **Observation 10.** *Inserting an edge e into G increases the number of vertices with out-degree $\alpha + 1$ by at most one.*

Proof. The only vertex that has its out-degree increased during an insertion is the final vertex of the augmenting path. ◀

In particular this means that if we visit t vertices when searching for P, then we must have witnessed at least t insertions, since the last time we statically re-computed an α-bounded out-orientation. As such, we arrive at Theorem 1 (restated below for convenience):

▶ **Theorem 11** (Theorem 1). *Given an initially empty dynamic graph undergoing an arboricity α preserving sequence of updates and a static black box algorithm that computes an α-bounded out-degree orientation of a graph with n vertices and arboricity α in time $S(\alpha, n)$, the algorithm will maintain an $(\alpha+1)$-bounded out-degree orientation with an amortised insertion time of $O(\sqrt{\alpha \cdot S(\alpha, n)})$, and a worst-case deletion time of $O(1)$.*

Proof. The algorithm clearly maintains an $(\alpha + 1)$-bounded out-degree orientation. All that remains is to analyse the amortised cost of running the black box algorithm. To this end, say a vertex is *bad*, if it has out-degree $\alpha + 1$. Suppose that we have witnessed i insertions since the last time that the static black-box algorithm was run, and suppose furthermore that inserting e_{i+1} causes the insertion search to visit $\sqrt{S(\alpha, n)/\alpha}$ bad vertices. Then Observation 10 implies that $i \geq \sqrt{S(\alpha, n)/\alpha}$, and so setting aside $O(\sqrt{\alpha \cdot S(\alpha, n)})$ credit for each insertion, ensures that at least $O(S(\alpha, n))$ credit is stored, when the black box algorithm is run. Furthermore, by Lemma 8 each truncated search spends no more than $O(\alpha \cdot \sqrt{S(\alpha, n)/\alpha})$-time, yielding a total amortised insertion time in $O(\sqrt{\alpha \cdot S(\alpha, n)})$, as claimed. To delete an edge, we may remove it from the graph in constant time (assuming that we are given a pointer to the edge as part of the query). ◀

4 Low Arboricity Decompositions

In this section, we present a dynamic algorithm that maintains an $(\alpha + 1)$-arboricity decomposition. The setup is the same as in the previous section: we assume that we are given an initially empty dynamic graph G on n vertices undergoing an arboricity α preserving sequence of updates. The algorithm has an update time of $\tilde{O}(\sqrt{S(\alpha, n)})$ provided that it is given access to a black box static algorithm for computing an α-arboricity decomposition in $O(S(\alpha, n))$ time.

The idea behind this algorithm is the same as in the previous section. We give an algorithm based on a search procedure with slow update time, and arrive at the final algorithm via truncation of the search. The main difficulty of turning the algorithm from the previous section into an algorithm maintaining an arboricity decomposition is that it is not clear how to direct a search to obtain a sequence of forest alterations that allows one to accommodate the insertion of an edge.

We will now present how to accommodate the edge insertion using techniques that are inspired by [18] and [21]. To this end, suppose we are given a graph G, an edge $e = uv \in G$ and an $\alpha + 1$ arboricity decomposition of $G - e$. We are then interested in extending this to an $\alpha + 1$ arboricity decomposition of G. If e cannot be added to forest F_i, it is because u and v are connected by a path T_i^1 in F_i. If this is the case for all i, then we must move one of the edges in T_j^1 for some j to be able to put e into F_j. If this is not possible for any j, it is because all vertices on T_j^1 sit in the same tree in all forests. So for all j we can let T_j^2 be the smallest tree in F_j spanning the vertices $\bigcup_{i=1}^{\alpha+1} V(T_i^1)$. Continuing like this yields trees T_i^r (see Figure 1). We cannot continue this construction indefinitely since we cannot partition G's edges into $\alpha + 1$ spanning trees without contradicting the fact that G has arboricity α. Hence, there must exist a largest k for which T_j^k has no movable edges for all choices of j. For an edge $e' \neq e$, we let the *rank* $r(e')$ of e' be the smallest r such that $e' \in T_i^r$ for some i that we denote $t(e')$. We set $r(e) = 0$. Furthermore, we define $T^r = \bigcup_i T_i^r$. Similar to [18, 21], we can now define an *augmenting sequence* of edges that we can move between forests to accommodate an insertion of e:

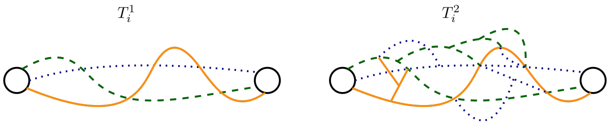

Figure 1 An illustration of the first two layers of the forests. The forests are represented by different colours.

▶ **Definition 12.** *Suppose G is a graph, $e_0 \in E(G)$ an edge in G, and that we are given an $\alpha + 1$ arboricity decomposition $F_1, \ldots, F_{\alpha+1}$ of $G - e_0$. Then an augmenting sequence of edges is a sequence of edges $e_0, e_1, \ldots, e_k$ satisfying the following conditions:*

1. *For all $i \geq 0$, the rank of e_i satisfies $r(e_i) \leq i$.*
2. *For all $i \geq 1$, if $e_{i-1} = xy$, then x and y sit in different trees in $F_{t(e_i)} - e_i$.*
3. *There exists some $j \neq k$ such that $F_j \cup e_k$ is a forest.*

Given such a sequence of edges $e_1, \ldots, e_k$, we can extend the arboricity decomposition of $G - e$ to contain e. Indeed, we move e_k from $F_{t(k)}$ to F_j. Now $e_1, \ldots, e_{k-1}$ is an augmenting sequence. Eventually, e can be inserted into $F_{t(e_1)}$.

We shall search for an augmenting sequence differently than in [18]. Here, when visiting an edge e' belonging to forest F_i, for $j \neq i$ they en-queue the entire fundamental cycle in $F_j \cup e_i$. However, this cycle could possibly have length $\Omega(n)$. Instead, we visit the paths blocking e' one edge at time, only en-queuing the visited edge. This ensures that at all times, the time spent searching for an augmenting sequence is proportional to the number of vertices that we have processed. This property is key in ensuring that we can afford to truncate our search and run a static algorithm, if we do not identify an augmenting sequence fast.

The algorithm. Similar to the previous section, we first describe a slow, search–based algorithm, and then we obtain a faster algorithm via truncation. We accommodate edge deletions by simply deleting the edge from the dynamic forest data structure, it resides in. To handle an insertion of an edge $e = uv$, we construct a short augmenting sequence as follows. Beginning with e, we process an edge by trying to insert it into all forests. If this is not possible, u and v must be connected by a path in F_i for all i. For each i, beginning with $i = 1$, we then try to move every edge on this path in F_i. If we fail to do so, it means that there is no augmenting sequence ending with an edge in $T^1 = \bigcup_i T_i^1$. Now we search for an augmenting sequence ending with an edge in T^2. If we fail to locate such an augmenting sequence, we try to find one ending with an edge in T^3 and so on. To do so for T^r, having already tried all edges in T^{r-1}, we try to move all edges blocking an edge in T^{r-1} i.e. we try to move edges blocking the previously explored edges. When we try to move such an edge, but fail to do so, it is because the endpoints of these edges are connected by blocking paths in all forests. Conceptually we would like to push these blocking paths to a queue as we encounter them, in order to remember them. This is relevant, since we might have to visit them later to try to locate an augmenting sequence. However, these paths might have length $\Omega(n)$, and, similar to the last section, we would like the time spent during a search to depend on the number of visited vertices. Hence, in practice, we traverse the blocking paths one by one. Whenever we visit an edge f on a blocking path in a forest F_j, we try to move it to another forest. If this is not possible, we push f to a queue Q, store that f is blocking e by saving a value $b(f) = e$, and mark both endpoints of f as visited in F_j. Now we can always recover the edges on the paths blocking f one-by-one using standard dynamic forest data-structures. When we are done trying to move edges from the previous set of blocking paths, we recursively try to move the un-processed edges blocking $e' = \texttt{pop}(Q)$. Note that whenever a blocking path reaches a previously visited edge, we terminate that blocking path and push no further edges of it to Q. The nature of the search ensures that the blocking paths form trees in each forest, and therefore no blocking edge is left unvisited by this early termination. Indeed, one of the endpoints of the blocking path was already in the tree, and so as soon as the path connects to this tree we can be certain that the rest of the edges on the path have been processed. If we encounter an edge g that we can move to a new forest, we extract an augmenting sequence by moving the edge and then recursively moving the edge it was blocking. We have the following claim:

▷ Claim 13. Let e and g be as above. We have that $e = b^{r(g)}(g), \ldots, b(b(g)), b(g), g$ is an augmenting sequence, where $b^k(g)$ is the edge obtained by following the blocked edge k steps back.

Proof. Observe that we process all edges of rank i before processing any edges of rank $i + 1$. In particular, we only visit edges of rank $i + 1$ when processing edges of rank i. Therefore, for all processed edges h, we have that $r(b(h)) = r(h) - 1$. Hence, $b^{r(g)}(g) = e$, as e is the only edge of rank 0. It is now easy to verify that the conditions of Definition 12 hold. ◁

By storing each vertex in a data structure for maintaining dynamic forests for instance top-trees [2] or link-cut trees [36], we can determine whether a blocking path exists, and if it does, we can traverse it spending $O(\log n)$ time to find the path and $O(1)$ time per visited edge on the path. Thus the search satisfy the following properties:

▶ **Lemma 14.** *Suppose that we have an $\alpha + 1$ arboricity decomposition of $G - uv$, and we begin a search to extend it to an $\alpha + 1$ arboricity decomposition of G. Then after visiting t vertices the following holds:*

1. *If no moveable edge has been located, then Q is not empty.*
2. *The algorithm has spent $O(\alpha^2 \cdot t \cdot \log n)$-time.*

Proof.

1. Let E denote the set of edges, visited by the algorithm. Every time we unsuccessfully try to move an edge $e = xy$, we conceptually push all edges on the unique x to y path in F_i to Q for all i. Thus, the blocking paths necessarily form trees in each forest. In particular, this means that if Q is empty, the graph formed by all the visited edges, $J = G[E]$, will be a tree if restricted to F_i for all i. Indeed, suppose it is not true, and that the restriction of J to F_j is not a tree. Then we must have visited some first edge leaving the component, containing u, of the restriction of J to F_j for which we did not explore a blocking path in F_j, contradicting the fact that Q is empty. This means, in particular, that $|E(J)| \geq (\alpha + 1)(|V(J)| - 1)$, and hence J contradicts Theorem 6, as in the proof of Lemma 8.
2. Since the algorithm has visited t vertices, it cannot have visited more than $\alpha \cdot t$ edges. Otherwise, the t visited vertices form a subgraph with a density contradicting Theorem 6. Each time the algorithm visits an edge, it spends only $O(\alpha \log n)$-time. Indeed, it takes $O(\alpha \log n)$-time to check if the edge can be moved and $O(1)$-time to push it to Q. Finally, we can update pointers to the blocked edge with only $O(1)$ overhead per visit. Since the algorithm has visited no more than $\alpha \cdot t$ edges, 2) follows. ◀

Furthermore, we make the following observations:

▶ **Observation 15.** *If the search phase is unsuccessful after visiting t vertices, then every vertex visited by the algorithm during the search phase must belong to the same tree in every forest F_i. In particular, this means that $|E(F_{\alpha+1})| \geq t - 1$.*

Proof. We prove the observation by contraposition. Suppose that we initially tried to insert uv. If at some point we try to move an edge $e = xy \in F_j$ with endpoints belonging to different trees in F_k, $k \neq j$, then e could be moved to F_k rendering the search phase successful. In particular, this means that if $u \in T \subset F_i$ and there is some other vertex w in a different tree T' in F_i that we also visit, then at some point, we must have tried to move an edge e' with only one endpoint in T. But then e' could have been moved to F_i, contradicting the fact that the search was unsuccessful. ◀

▶ **Observation 16.** *Augmenting along an augmenting sequence $e_0, e_1, \ldots, e_k$ increases the size of the forest that e_k is moved to by one. All other forests remain the same size.*

Proof. We prove the statement by induction on k. The induction basis is clear, so we move to the induction step. After moving e_k from $F_{t(e_k)}$ to some forest F_i, the size of F_i is increased by one, the size of $F_{t(e_k)}$ is decreased by one, and all other forests have the same size. Now $e_0, e_1, \ldots, e_{k-1}$ is an augmenting sequence, so we can apply induction on it. This sequence increases the size of $F_{t(e_k)}$ by exactly one, and all other forests remain the same size. Hence, we arrive at the statement. ◀

Since a deletion never increases the size of a forest, the two above observations together imply that choosing the truncation $t = \sqrt{\frac{S(\alpha,n)}{\alpha^2}} + 1$ means that we witness at least $\sqrt{\frac{S(\alpha,n)}{\alpha^2}}$ insertions between any two runs of the static black box algorithm. Since we can extend the black box algorithm to maintain the dynamic forests using only $O(\log n)$ overhead per operation, the total time needed for each run is in $O(S(\alpha, n) \log n)$. Combining this with Lemma 14, we find that setting aside $O(\alpha\sqrt{S(\alpha, n)} \log n)$ per insertion yields a total amortised update time in $O(\alpha\sqrt{S(\alpha, n)} \log n)$. Hence:

▶ **Theorem 17** (Identical to Theorem 3). *Given an initially empty dynamic graph undergoing an arboricity α preserving sequence of updates and a static black box algorithm that computes an α arboricity decompostion of a graph with n vertices and arboricity α in time $S(\alpha, n)$, the algorithm will maintain an $(\alpha + 1)$ arboricity decomposition with an amortised insertion time of $O(\alpha\sqrt{S(\alpha, n)}\log n)$, and a worst-case deletion time of $O(\log n)$.*

5 Dynamic 3-Out Orientations in planar graphs

In this section, we show that any dynamic algorithm maintaining a 3-bounded out-orientation of a dynamic planar graph can be forced to spend $\Omega(n)$ update time. The idea is to first consider a different problem: let G be a plane triangulation. Then G has an outer face xyz. Every vertex incident to the outer face is an *outer* vertex. All vertices that are not outer vertices are *inner* vertices. A 3-orientation of G is then an orientation of all edges incident to inner vertices such that all inner vertices have out-degree 3. Given a plane triangulation, we have the notion of a *diagonal flip*: a diagonal flip is the action of removing an edge xy incident on faces xyz and vxy and replacing it with the edge vz (see Figure 2). note that such a flip is only possible, if the edge vz does not already exist. The *flip distance* between two undirected graphs is then the minimum number of diagonal flips needed to go from one one graph to the other. We show that any algorithm explicitly maintaining a 3-orientation of a dynamic plane triangulation under diagonal flips of inner edges, can be made to spend linear update time. This is done by constructing two planar graphs of constant flip distance, but with unique 3-orientations differing on $\Omega(n)$ edges. By slightly generalising and by considering a graph containing multiple copies of this construction, we arrive at the explicit lower bound for maintaining 3-orientations in dynamic planar graphs.

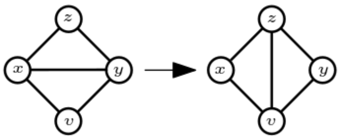

Figure 2 A diagonal flip.

3-Orientations. Brehm [8] showed that a plane triangulation has a unique 3-orientation if and only if it is *stacked* which is equivalent to being 3-degenerate. In fact this can be slightly generalised - and we will use this slight generalisation later on, when dealing with graphs where no embedding is specified. The proof of the generalisation is similar, so we only provide a sketch:

▶ **Lemma 18.** *Let G be a planar triangulation with a 3-bounded out-degree orientation O. Let x, y, z form a triangle in G, and let H be a component of $G - \{x, y, z\}$, such that the out-degree $d^+_G(v) = 3$ for all $v \in H$. Then the restriction of any 3-bounded out-degree orientation of G to all edges incident to H is unique if and only if $G[V(H) \cup \{x, y, z\}]$ is 3-degenerate.*

Proof (Sketch). A counting argument shows that all edges between H and x, y, z are oriented away from H. Indeed, $G[H \cup \{x, y, z\}]$ is planar and so contains at most $3(|H| + 3) - 6$ edges. 3 of these go between x, y, z, so the remaining $3|H|$ edges must be out-edges of vertices in H.

Next, we show that the restriction of any 3-bounded out-degree orientation O to H is unique iff it is acyclic. Indeed, suppose it is not acyclic. Then it has a directed cycle. Reversing the orientation along this cycle creates a new 3-bounded out-degree orientation with a different restriction. The other direction is as follows: suppose that there exists an orientation for which the restriction to H is acyclic, but that this restriction is not unique. Comparing two such restrictions gives an edge which is oriented differently in the two orientations. Now, since every point has out-degree 3 an endpoint cannot be incident to only one such edge, so there is a new edge - oriented differently by the two orientations - that one can follow. Continuing like this eventually gives you a directed cycle in H as, by above, one never reaches x, y, z. This is a contradiction.

The Lemma then follows by noting that having an acyclic 3-bounded out-degree orientation is equivalent to being 3-degenerate. Indeed, beginning at an arbitrary vertex in H and following incoming edges backwards ensures that one ends up in a source in H. This source has degree at most 3. We can remove this vertex and apply induction to see that any subgraph not containing this vertex also has a vertex of degree at most 3. The other direction follows, since the 3-degeneracy implies that in any non-empty subgraph $S \subset H$ one can always find a vertex $v \in S$ of degree 3 in $G[S \cup \{x, y, z\}]$. Beginning from H one can remove such a vertex and orient its incident edges so that it becomes a source. Continuing like this never creates cycles and therefore yields an acyclic 3-bounded out-degree orientation. ◀

As noted earlier, we give the lower bound by first considering explicit 3-orientations in plane graphs. We have the following lemma:

▶ **Lemma 19.** *Let $\mathcal{A}$ be an algorithm explicitly maintaining a 3-orientation of an n-vertex plane triangulation under diagonal flips. Then the flip operation can be made to spend $\Omega(n)$ update time, even when considering amortised complexity.*

Proof. Consider the following plane triangulation containing a path $s_1, s_2, \ldots, s_k$ of length $k = n - 5 = \Omega(n)$ (see Figure 3). The plane triangulation is 3-degenerate, and hence by Lemma 18, it has a unique 3-orientation: By diagonal flipping the edge uv and subsequently the edge s_1x, one gets a new plane triangulation. It is again 3-degenerate, and hence by Lemma 18 it has a unique 3-orientation. (see Figure 4). By diagonally flipping the same edges in the opposite order, one reclaims the original graph. The new 3-orientation has $\Omega(n)$ edges oriented differently compared to the original 3-orientation, but it only requires a constant number of diagonal flips to go between the two graphs. Hence, a constant number of flips forces $\mathcal{A}$ to change the orientation of $\Omega(n)$ edges, and thus, the update time for the diagonal flip operation must be $\Omega(n)$, even amortised, as one can force this update sequence as many times as desired. ◀

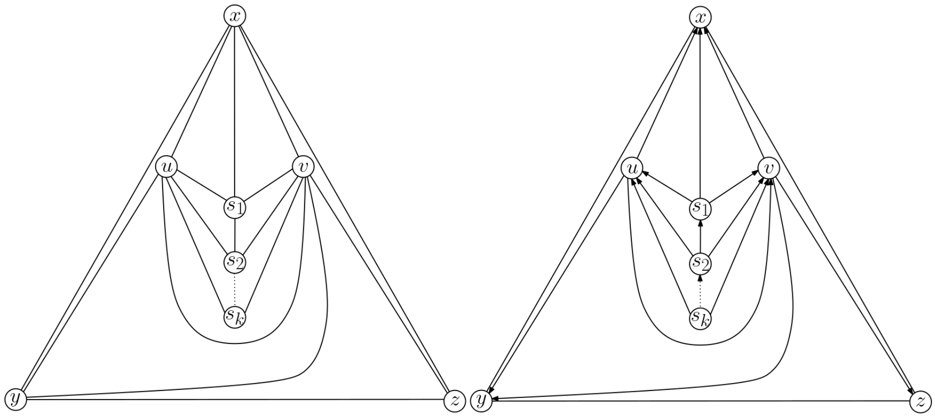

Figure 3 The plane triangulation along with its unique 3-orientation.

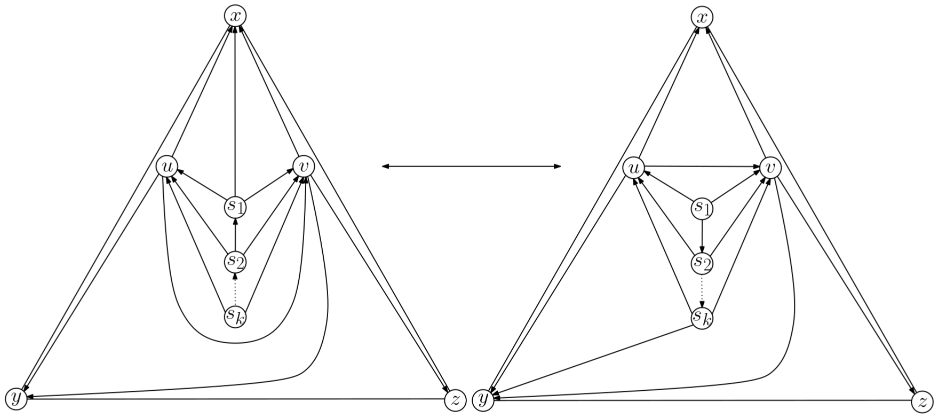

Figure 4 Going between two unique 3-orientations.

3-Bounded Out-Orientations. The goal now is to extend this lower bound to 3-bounded out-degree orientations of planar graphs under insertion/deletion of edges. There are only three things to consider before doing such an extension. Firstly, now we support the operations insertion/deletion of edges and not the diagonal flip. This is however a non-issue since a diagonal flip can be simulated by first deleting the edge and then inserting the other diagonal. Secondly, we now consider 3-bounded out-degree orientations and so outer vertices also have out-edges, and not all inner vertices are required to have out-degree 3. Lastly, the lower bound should apply not only to plane graphs where an embedding is chosen, but also to planar graphs. We deal with the last two points by using at least 13 copies of the graph from above. Then, in at least one of the copies, all inner vertices must have out-degree 3 - both before and after a sequence of updates. Hence, we can do the aforementioned updates in all 13 copies, and this will then ensure that at least one copy has to behave as in Lemma 19. Now, we show Theorem 5:

▶ **Theorem 20** (Identical to Theorem 5). *Let $\mathcal{A}$ be an algorithm explicitly maintaining a 3-bounded out-degree orientation of an n-vertex planar graph under insertion and deletion of edges. Then there exists a sequence of updates taking $\Omega(n)$ amortised time per update.*

Proof. Create a planar graph G by placing 13 copies of the graph P from the proof of Lemma 19 in the plane, and triangulating the outside arbitrarily. Let $n = |V(G)|$. For each copy P_i of P, we let the set I_i resp. O_i be the set of vertices that are inner resp. outer vertices of P_i, if P_i is embedded as in Lemma 19. In particular, for a specific copy of P, say P_i, the corresponding set I_i has size $|I_i| = \frac{n}{13} - 3 = \Omega(n)$. Since G is a plane triangulation, it follows from Euler's Theorem that $|E(G)| = 3n - 6$. This implies that at most 6 vertices of G can have out-degree strictly less than 3. Hence, in at least 7 of the 13 copies of P, every vertex in I has out-degree 3. Since the O vertices of each of these specific copies of P form a triangle, it follows from Lemma 18 that the edges incident to I must have the same orientation as in the plane embedding in Lemma 19 and that this orientation is unique.

Now, we simulate the flip sequence used in Lemma 19 in each copy. Doing this in all 13 copies only requires 26 insertions and 26 deletions in total. After these alterations, it is still the case that in at least 7 of the 13 copies of P every vertex in I has out-degree 3. Furthermore, since the O vertices of each of these specific copies of P form a triangle, it follows from Lemma 18 that the edges incident to I must have the same orientation as in the altered plane embedding in Lemma 19 and that this orientation is unique. At least one copy P_i of P has out-degree 3 at every vertex in I_i in both the orientation before and in the orientation after the update sequence. Consequentially, $\mathcal{A}$ must have reoriented at least $|I_i| - 3 = \Omega(n)$ edges during the update sequence. The update sequence consists of only a constant number of updates, and it can be reversed by first deleting uv and re-inserting it across the opposite diagonal in each copy, and then doing the same for $s_k y$ in every copy of P. Each reversal of the update sequence, requires only a constant number of updates, but forces $\mathcal{A}$ to change at least $\Omega(n)$ edge-orientations. It follows that there exists a sequence of updates taking $\Omega(n)$ amortised time per update. ◀

6 Conclusion

We have shown how to dynamically maintain 4-bounded out-orientations and 4-arboricity decompositions with sublinear update time. We extended these algorithms to compute $\alpha + 1$-bounded out-orientations and arboricity decompositions in α-arboricity bounded dynamic graphs. Finally, we also showed that maintaining a 3-bounded out-orientation of a planar graph explicitly, must take $\Omega(n)$ update time, even amortised. This extends the explicit lower bound of Brodal & Fagerberg to the planar case.

It would be interesting to see, if one can maintain $\alpha + 1$ out-edges or forests in sub-polynomial time. Results of Brodal & Fagerberg [9] and Harris et al. [21] show that the problems of maintaining $\alpha + 1$ out-edges resp. forests have $O(\alpha \log n)$ recourse – how close to this worst-case recourse can one get the update times?

Abstract

We introduce the $\mathrm{LO_v}$-calculus, a graphical language for reasoning about linear optical quantum circuits with so-called vacuum state auxiliary inputs. We present the axiomatics of the language and prove its soundness and completeness: two $\mathrm{LO_v}$-circuits represent the same quantum process if and only if one can be transformed into the other with the rules of the $\mathrm{LO_v}$-calculus. We give a confluent and terminating rewrite system to rewrite any polarisation-preserving $\mathrm{LO_v}$-circuit into a unique triangular normal form, inspired by the universal decomposition of Reck *et al.* (1994) for linear optical quantum circuits.

1 Introduction

Quantum computing and information processing promise a variety of advantages over their classical analogues, from the potential for computational speedups (e.g. [33, 51]) to enhanced security and communication (e.g. [7, 28]). By encoding information into the states of physical systems that are quantum rather than classical, one can then process that information by

evolving and manipulating the systems according to the laws of quantum mechanics. This opens up the possibility of exploiting non-classical behaviours available to quantum systems in order to process information in radically new and potentially advantageous ways.

The development of quantum technologies has proceeded at pace over the past number of years, with a variety of different physical supports for quantum information being pursued. These include matter-based systems like superconducting circuits, cold atoms, and trapped ions, as well as light-based systems, in which information is encoded in photons. Among these, photons have a privileged role in the sense that regardless of hardware choice it will eventually be necessary to network quantum processors, and (as the only sensible support for communicating quantum information) some quantum information will need to be treated photonically. Yet, in their own right, photons also offer viable approaches to quantum computation in the noisy intermediate-scale [40] and large-scale fault-tolerant [6] regimes.

The standard unit of quantum information is the quantum bit or qubit, and photons allow for a rich variety of ways to encode qubits. However it is also interesting to note that treating photons as informational units in their own right can be advantageous. A good example is BosonSampling, originally proposed by Aaronson and Arkhipov [1], a computational task that is $\#P$-hard but which can be efficiently solved by interacting photons in an idealised generic linear-optical circuit in which no qubit encoding need be imposed. At present, along with Random Circuit Sampling [2, 9], this provides one of the two main routes to experimental demonstrations of quantum computational advantage [3, 55, 53, 54], in which quantum devices have been claimed to outperform classical capabilities for specific tasks.

The usual semantics for quantum computation stemming from quantum mechanics is based on unitary matrices (or unitary operators in general) over Hilbert spaces. Although this faithfully models the extensional behaviour of a computation, it fails to address several key aspects that are of interest when considering the design and implementation of quantum algorithms. A first limitation is the intensional description of the computation: an algorithm or quantum computation in general consists of modular components that are composed and combined in specific way, and one wants to keep track of this information. One therefore needs a *language* for coding these. The other important aspect is the need to specify and verify the said code. Indeed, classically simulating a quantum process is a task that is exponentially costly in the size of the system, while running code on physical devices is expensive. If some limited testing techniques are available on quantum systems [29, 43], it is however highly desirable to be able to reason and prove the desired properties of the code upstream, and rely on *formal methods*. If text-based high-level languages oriented towards formal methods have successfully been proposed in the literature [32, 8, 37], we aim in this paper to explore a lower-level, graphical language, making contact with photonic hardware.

Graphical languages for quantum computation have a long history: since Feyman diagrams [30], graphical languages for representing (low-level) quantum processes have been considered as an answer to the limitations of plain unitary matrices. Quantum circuits – the quantum equivalent to classical, boolean circuits – are an obvious candidate for a graphical language, and indeed, several lines of research took them as their main object of study [32, 22, 46, 13]. Quantum circuits in particular form a natural medium for describing the execution flow of a computation. The main problem with the model of quantum circuits is the lack of a satisfactory equational presentation. If several attempts have been made for various subsets [20, 19, 36, 45], none of them provides a complete presentation.

A recent proposal responding to the shortfalls of quantum circuits as a model is the ZX-calculus [21], which, along with its variants [11, 4, 12], have proved to be particularly useful for reasoning about qubit quantum mechanics, for applications such as quantum circuit optimisation [25, 5], verification [26, 31, 35] and representation e.g. for MBQC patterns [27] or error-correction [27, 23]. However, while ZX-calculus is versatile and provides a welcomed formal semantics for quantum computation, it remains at an abstract level.

There is therefore a clear interest in developing a graphical language for quantum photonic processes, especially linear quantum optics, which is closer to photonic hardware and laboratory operations that are easily implementable in bulk optics, fibres, or in integrated photonic circuits. This would provide a more formal counterpart to software frameworks that have been proposed for defining and classically simulating such processes to the extent that it is tractable [39, 34]. The need for such a formal language is also evidenced, for example, by the appeal to diagrams to concisely illustrate equivalent unitaries in recent work in the physics literature [48]. Following on the trend for graphical quantum languages, the PBS-calculus [16, 10, 17] has been proposed as a first step towards an alternative to ZX dedicated to linear quantum optical computation (LOQC). The PBS-calculus makes it possible to reason on a small subset of linear optical components only acting on the polarisation of a photon. While it is enough to describe and analyse non causally-ordered computations, it falls short at expressing other aspects of LOQC typically considered in the physics community, such as the phase. Note that a recent, independent work[1] establishes some connections between the ZX-calculus and the photon preserving fragment of linear optics with multiple photons [24].

Our goal here is to take a more bottom-up approach and to propose a new language which formalises the kinds of diagrammatics that are currently in use in the physics community. In practice this can find many uses including for the design, optimisation, verification, error-correction, and systematic study of linear optical quantum circuits for quantum information.

Contributions. Our main contributions are the following.

- A graphical language for LOQC featuring most of the physical apparatuses used in the physics literature. The language comes equipped with an equational theory that is sound and complete with respect to the standard semantics of LOQC.
- A strongly normalising and globally confluent rewrite system and normal form for the polarisation-preserving fragment, for which we recover the Reck *et al.* [49] decomposition as normal form (modulo 0-angled beam splitters and 0-angled phase shifters) with a novel proof of its uniqueness.

Finally, and maybe more importantly, our language makes it possible to formalise and reason within a common framework on various presentations of LOQC stemming from parallel research paths. Our semantics not only allow us to recover, extend and improve on some key results in LOQC such as the universal decompositions of Reck *et al.* [49] and Clements *et al.* [18], but it also gives a unifying language for the different formalisms from the literature. Furthermore, this result paves the way towards the design of complete equational theories for quantum circuits [14].

Plan of the paper. The article is structured as follows. In Section 2, we present the syntax and the semantics of the LO_v-calculus. The equational theory and its soundness are given in Section 3. In Section 4 we present the strongly normalising and globally confluent rewrite system. This allows us to prove the completeness of the LO_v-calculus in Section 5. Finally, we conclude in Section 6. More complete proofs can be found in the appendix of the technical report [15].

[1] The preprint version of [24] has been upladed to arXiv a few days after the one of the present paper [15].

2 Linear Optical Quantum Circuits

A linear optical quantum computation [42, 41] (LOQC) consists of spatial modes through which photons pass – which may be physically instantiated by optical fibers, waveguides in integrated circuits, or simply by paths in free space (bulk optics) – and operations that act on the spatial and polarisation degrees of freedom of the photons, including in particular *beam splitters* (), *polarising beam splitters* (), *phase shifters* ( ), *wave plates* ( ), *pola-negations* () and finally the *vacuum state sources* and *detectors* (and). Their action and the semantics are described in Section 2.2.

2.1 Syntax

In order to formalise linear optical quantum circuits, we use the formalism of PROPs [44]. A PRO is a strict monoidal category whose monoid of objects is freely generated by a single X: the objects are all of the form $X \oplus ... \oplus X$,[2] and simply denoted by n, the number of occurrences of X. PROs are typically represented graphically as circuits: each copy of X is represented by a wire and morphisms by boxes on wires, so that $\oplus$ is represented vertically and morphism composition "$\circ$" is represented horizontally. For instance, D_1 and D_2 represented as  and  can be horizontally composed as $D_2 \circ D_1$, represented by  , and vertically composed as $D_1 \oplus D_2$, represented by  . A PROP is the symmetric monoidal analogue of PRO, so it is equipped with a swap .

▶ **Definition 1.** **LO$_v$** *is the PROP of* LO$_v$*-circuits generated by*

 $: 0 \to 1$  $: 1 \to 0$  $: 1 \to 1$  $: 1 \to 1$

 $: 2 \to 2$  $: 2 \to 2$

where $\theta, \varphi \in \mathbb{R}$. When the parameters θ and φ are omitted we take them to be equal to $\pi/4$. We write  *as a shortcut notation for*  *. The tensor of the monoidal structure is denoted with $\oplus$, and the identity, swap and empty circuit (unit of $\oplus$) are denoted as follows:*  $: 1 \to 1$,  $: 2 \to 2$, $: 0 \to 0$.

▶ **Example 2.** An example of a linear optical quantum circuit using all of the connectives presented in Definition 1 is shown in Figure 2.

[2] Here we denote the monoidal product as $\oplus$ rather than $\otimes$ in order to better correspond to the semantics of LO$_v$-circuits (see Section 2.2).

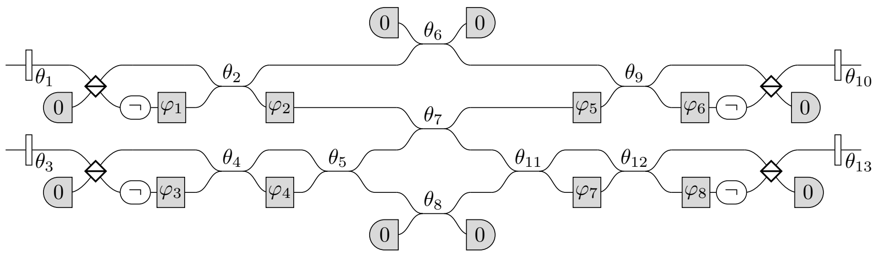

Figure 2 LO$_\text{v}$-circuit implementing a variational quantum eigensolver [47], an algorithm with applications including calculation of ground-state energies in quantum chemistry.

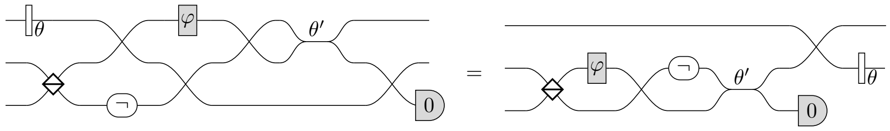

Figure 3 Two equivalent representations of the same LO$_\text{v}$-circuit.

▶ Remark 3. The axioms of PROPs guarantee that linear optical quantum circuits are defined up to deformations: Figure 3 shows two equivalent circuits under the equations of PROPs.

Among the generators, the beam splitters and phase shifters are known to preserve the polarisation of the photons, as a consequence, we define a *polarisation-preserving* sub-PRO of LO$_\text{v}$ as follows.

▶ **Definition 4. LO$_\text{PP}$** *is the PRO of* polarisation-preserving circuits *generated by beam splitters*  *and phase shifters* *.*

Notice that we define polarisation-preserving circuits as a PRO rather than a PROP, thus they do not include swaps.

2.2 Single-Photon Semantics

We will characterise photons by their spatial and polarisation modes. Spatial modes refer to position, and polarisation can be horizontal (H) or vertical (V). Note that the quantum formalism admits (normalised complex) superpositions of both spatial and polarisation modes. For any $n \in \mathbb{N}$, let $M_n = \{\mathrm{V}, \mathrm{H}\} \times [n]$, where $[n] = \{0, \dots n-1\}$, be the set of states (spatial and polarisation modes). The elements of M_n are denoted c_p with $c \in \{\mathrm{V}, \mathrm{H}\}$ and $p \in [n]$. The state space of a single photon is $\mathbb{C}^{M_n} = span(|\mathrm{V}_i\rangle, |\mathrm{H}_i\rangle \mid i \in [n])$. Notice that $\mathbb{C}^{M_0} = \mathbb{C}^{\emptyset} = \{0\}$ is the Hilbert space of dimension 0. For instance, on 2 spatial modes (i.e. 2 wires), there are four possible basis states: $\mathrm{H}_0, \mathrm{H}_1, \mathrm{V}_0, \mathrm{V}_1$. Indeed, a photon can be on one of the two wires, while in the horizontal or vertical polarisation. The state space is then a 4-dimensional Hilbert space. The semantics of a LO$_\text{v}$-circuit is defined as follows.

▶ **Definition 5.** *For any* LO$_\text{v}$*-circuit* $D : n \to m$*, let* $[\![D]\!] : \mathbb{C}^{M_n} \to \mathbb{C}^{M_m}$ *be the linear map inductively defined by Table 1*[3]*, and by* $[\![D_2 \circ D_1]\!] = [\![D_2]\!] \circ [\![D_1]\!]$, $[\![D_1 \oplus D_2]\!] = [\![D_1]\!] \oplus [\![D_2]\!]$*, where for all* $f \in \mathbb{C}^{M_n} \to \mathbb{C}^{M_m}$ *and* $g \in \mathbb{C}^{M_{n'}} \to \mathbb{C}^{M_{m'}}$, $(f \oplus g)(|c_k\rangle) = f(|c_k\rangle)$ *if* $k < n$ *and* $S_{m,m'}(g(|c_{k-n}\rangle))$ *if* $k \geq n$*, with* $S_{m,m'} : \mathbb{C}^{M_{m'}} \to \mathbb{C}^{M_{m+m'}} = |c_k\rangle \mapsto |c_{k+m}\rangle$ *a shift of the positions by* m*.*

[3] There are many possible conventions for beam splitters. We have chosen this one as it is a symmetric

Table 1 Semantics of LO$_\mathrm{v}$-circuits.

 $= 0$  $= 0$  $= 0$

 $= |c_p\rangle \mapsto \cos(\theta)|c_p\rangle + i\sin(\theta)|c_{1-p}\rangle$

 $= \begin{cases}|\mathrm{V}_0\rangle \mapsto \cos(\theta)|\mathrm{V}_0\rangle + i\sin(\theta)|\mathrm{H}_0\rangle\\ |\mathrm{H}_0\rangle \mapsto \cos(\theta)|\mathrm{H}_0\rangle + i\sin(\theta)|\mathrm{V}_0\rangle\end{cases}$

 $= |c_0\rangle \mapsto e^{i\varphi}|c_0\rangle$

 $= \begin{cases}|\mathrm{V}_p\rangle \mapsto |\mathrm{V}_p\rangle\\ |\mathrm{H}_p\rangle \mapsto |\mathrm{H}_{1-p}\rangle\end{cases}$

 $= |c_p\rangle \mapsto |c_{1-p}\rangle$

 $= |c_0\rangle \mapsto |c_0\rangle$

▶ **Example 6.** The negation inverts polarisation:  : $|\mathrm{V}_0\rangle \mapsto |\mathrm{H}_0\rangle$ and $|\mathrm{H}_0\rangle \mapsto |\mathrm{V}_0\rangle$.

▶ Remark 7. The semantics of the circuits is sound with respect to the axioms of PROPs. In other words two circuits that are equal up to deformation have the same semantics. More formally, $[\![.]\!] : \mathbf{LO_v} \to (\mathbf{Hilb}, \oplus, 0)$ is a monoidal functor where **Hilb** is the category of state spaces $\mathbb{C}^{M_n}$ and linear maps.

▶ Remark 8. All the generators of the LO$_\mathrm{v}$-circuits are photon preserving, even the vacuum state sources () and detectors (). Indeed the vacuum state source produces no photons, whereas the semantics of the detector corresponds to a postselection on the case where no photons are detected.

▶ **Definition 9.** *For any* LO$_\mathrm{PP}$*-circuit* $D : n \to n$*, we define* $[\![D]\!]_\mathrm{pp} : \mathbb{C}^n \to \mathbb{C}^n$ *as the unique linear map such that* $[\![.]\!] \circ \iota = \iota \circ [\![.]\!]_\mathrm{pp}$ *where* $\iota : \mathbb{C}^n \to \mathbb{C}^{M_n} = |k\rangle \mapsto |\mathrm{H}_k\rangle$.

For instance  $= \begin{pmatrix}\cos(\theta) & i\sin(\theta)\\ i\sin(\theta) & \cos(\theta)\end{pmatrix}$.

Polarisation-preserving circuits are universal for unitary transformations, this is a direct consequence of the result of Reck *et al.* [49]. Unitary transformations can actually be uniquely represented by LO$_\mathrm{PP}$-circuits, as illustrated by the following two cases on 2 and 3 modes, the general case being proved in Section 4.

▶ **Lemma 10.** *For any unitary* 2×2 *matrix* U*, there exist unique* $\beta_1, \alpha_1 \in [0, \pi)$ *and* $\beta_2, \beta_3 \in [0, 2\pi)$ *such that*  $= U$*, and* $\alpha_1 \in \{0, \frac{\pi}{2}\} \Rightarrow \beta_1 = 0$.

Proof. The proof is given in [15]. ◀

▶ **Lemma 11.** *For any unitary* 3×3 *matrix* U*, there exist unique angles* $\alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2, \beta_3 \in [0, \pi)$ *and* $\beta_4, \beta_5, \beta_6 \in [0, 2\pi)$ *such that*  $= U$ *where* $\forall i \in \{1, 2, 3\}, \alpha_i \in \{0, \frac{\pi}{2}\} \Rightarrow \beta_i = 0$*, and where* $\alpha_2 = 0 \Rightarrow \alpha_1 = 0$.

Proof. The existence of such a canonical form is shown in [49]. The uniqueness can then be derived by analysing the possible cases (See [15]). ◀

operation with good composition properties. The convention for the wave plate has been chosen for similar reasons.

$\mathrm{LO_v}$-circuits are more expressive than $\mathrm{LO_{PP}}$-ones, they not only act on the polarisation but the use of detectors and sources allow the representation of non-unitary evolutions: For any $\mathrm{LO_v}$-circuit $D : n \to m$, $[\![D]\!]$ is sub-unitary[4]. $\mathrm{LO_v}$-circuits are actually universal for sub-unitary transformations:

▶ **Theorem 12** (Universality of $\mathrm{LO_v}$). *For every sub-unitary map $U : \mathbb{C}^{M_n} \to \mathbb{C}^{M_m}$ (i.e. such that $U^\dagger U \sqsubseteq I$) there exists a diagram $D : n \to m$ s.t. $[\![D]\!] = U$.*

Proof. The proof given in [15] relies on the normal forms developed in Section 5. ◀

3 Equational Theory

Two distinct $\mathrm{LO_v}$-circuits may represent the same quantum evolution: for instance, composing two negations is equivalent to the identity. In order to characterise equivalences of $\mathrm{LO_v}$-circuits, we introduce a set of equations, shown in Figure 4. They capture basic properties of $\mathrm{LO_v}$-circuits, such as: detectors and sources essentially absorbing the other generators (Equations (9) to (12)); parameters forming a monoid (Equations (1) and (2)); and various commutation properties (Equations (15), (16)). Notice that there are two equations acting on 3 modes: Equation (6) and Equation (18). Equation (6) is a variant of the Yang-Baxter Equation [38], whereas Equation (18) is a property of decompositions into Euler angles. Indeed, in 3-dimensional space, the two sides of this equation correspond to two distinct decompositions in elementary rotations.

▶ **Definition 13** ($\mathrm{LO_v}$-calculus). *Two $\mathrm{LO_v}$-circuits D_1, D_2 are equivalent according to the rules of the* $\mathrm{LO_v}$-calculus, *denoted $\mathrm{LO_v} \vdash D_1 = D_2$, if one can transform D_1 into D_2 using the equations given in Figure 4. More precisely, $\mathrm{LO_v} \vdash \cdot = \cdot$ is defined as the smallest congruence which satisfies the equations of Figure 4 in addition to the axioms of PROP.*

▶ **Proposition 14** (Soundness). *For any two $\mathrm{LO_v}$-circuits D_1 and D_2, if $\mathrm{LO_v} \vdash D_1 = D_2$ then $[\![D_1]\!] = [\![D_2]\!]$.*

Proof. Since semantic equality is a congruence it suffices to check that for every equation of Figure 4 both sides have the same semantics, which follows from Definition 5 and Lemma 11. ◀

▶ **Proposition 15.** *The rules of the $\mathrm{LO_v}$-calculus imply that the parameters are 2π-periodic, i.e. for any $\theta, \varphi \in \mathbb{R}$:*

Proof. The proof is given in [15]. ◀

We now state one of our main results: the completeness of the $\mathrm{LO_v}$-calculus.

▶ **Theorem 16** (Completeness). *For any two $\mathrm{LO_v}$-circuits D_1 and D_2, if $[\![D_1]\!] = [\![D_2]\!]$ then $\mathrm{LO_v} \vdash D_1 = D_2$.*

The proof of Theorem 16 is given in Section 5. As a step towards proving the theorem, we first consider the fragment of the $\mathrm{LO_{PP}}$-circuits.

[4] U is sub-unitary (see for instance [50]) iff $U^\dagger U \sqsubseteq I$, where $\sqsubseteq$ is the Löwner partial order, i.e. $I - U^\dagger U$ is a positive semi-definite.

Figure 4 Axioms of the LO$_v$-calculus. The equations are valid for arbitrary parameters $\varphi, \varphi_i, \theta, \theta_i \in \mathbb{R}$. In Equation (18), the angles on the left-hand side can take any value while the right-hand side is given by Lemma 11 (where U is the $[\![.]\!]_{\text{pp}}$-semantics of the left-hand side of the equation).

4 Polarisation-Preserving Circuits

This section gives a universal normal form for any LO$_{\text{PP}}$-circuit. We prove the uniqueness of that form by introducing a strongly normalising and confluent polarisation-preserving rewrite system: PPRS.

▶ **Definition 17.** *The rewrite system* PPRS *is defined on* LO$_{\text{PP}}$*-circuits with the rules of Figure 5.*

▶ **Lemma 18.** *If D_1 rewrites to D_2 using the* PPRS *rewrite system then* LO$_v \vdash D_1 = D_2$.

Proof. The proof is given in [15]. ◀

▶ **Theorem 19.** *The rewrite system* PPRS *is strongly normalising.*

Proof. The proof is done by defining a lexicographic order on six distinct values: numbers of beam splitters of various angle ranges, count of specific patterns, numbers and positions of phase shifters. The order is shown to be decreasing with respect to the rewrite rules of PPRS. The complete proof is given in [15]. ◀

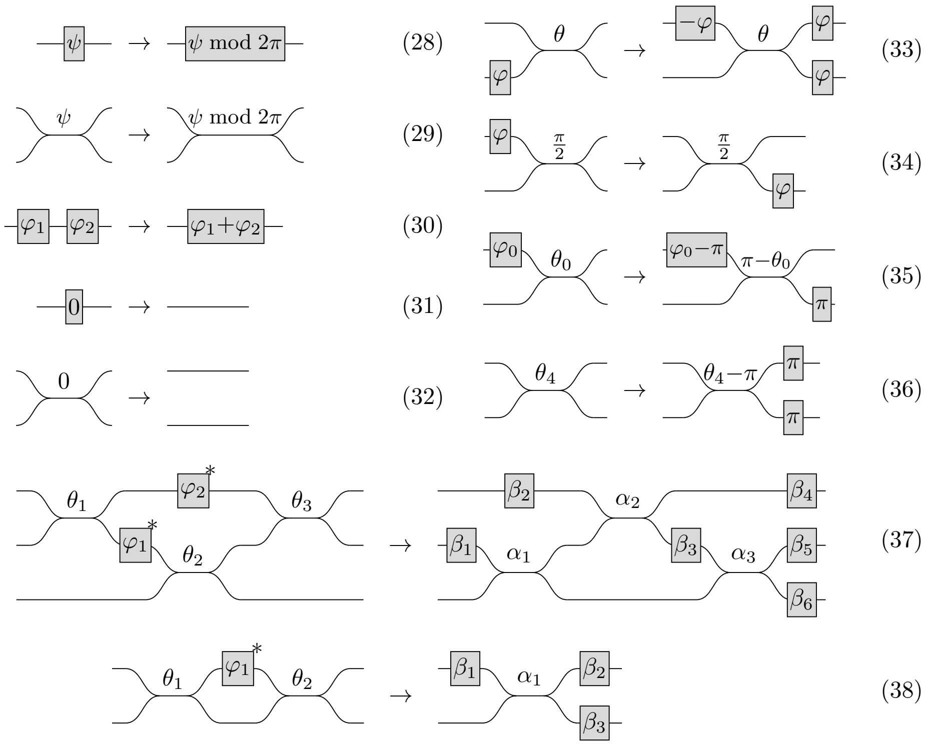

Figure 5 Rewriting rules of PPRS. $\psi \in \mathbb{R} \setminus [0, 2\pi)$, $\varphi, \varphi_1, \varphi_2 \in (0, 2\pi)$, $\varphi_0, \theta_4 \in [\pi, 2\pi)$, $\theta, \theta_0, \theta_1, \theta_2, \theta_3 \in (0, \pi)$, and $\theta_0 \neq \frac{\pi}{2}$. $-\boxed{\varphi}^{*}-$ denotes either $-\boxed{\varphi}-$ or ———. In Rules (37) and (38), the angles on the left-hand side can take any value while the right-hand side is given by Lemma 11 and Lemma 10 respectively.

As PPRS is terminating, we can therefore derive the existence of normal forms. The next step is to show that these normal forms are unique: this is derived from Theorem 20.

▶ **Theorem 20.** PPRS *is globally confluent.*

Proof. PPRS is locally confluent. Indeed, one can show by case analysis that the non-trivial peaks all use at most three wires. Each peak can be closed since for any polarisation-preserving LO$_\text{v}$-circuit of size $n \in \{1, 2, 3\}$, PPRS terminates to a specific unique normal form: when $n = 1$, a simple phase-shift; when $n = 2$, the form shown in Lemma 10; when $n = 3$, the form shown in Lemma 11. See [15] for details. Finally, using Theorem 19, global confluence is deduced from Newman's lemma [52]. ◀

▶ **Definition 21.** *A* PPRS triangular normal form *is a circuit with a triangular shape similar to Figure 1a, but with all* 0*-angled generators replaced with identities and with additional conditions on the angles, as described in Figure 6.*

Figure 7 shows an example: the figure on the left is the “full” circuit with 0-angled beam splitters while on the right is the corresponding PPRS triangular normal form.

▶ **Lemma 22.** *Any irreducible* LO$_\text{PP}$*-circuit is a PPRS triangular normal form.*

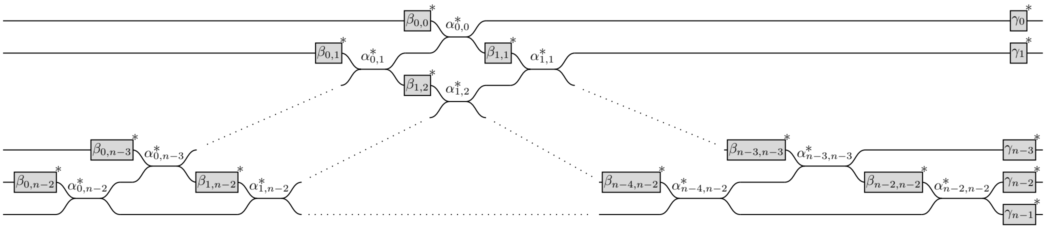

Figure 6 General scheme of a PPRS triangular normal form. The stars mean that any phase shifter or beam splitter with angle 0 is replaced by the identity. The conditions on the angles are the following: $\alpha_{i,j}, \beta_{i,j} \in [0,\pi)$; $\gamma_i \in [0,2\pi)$; $\alpha_{i,j} = 0 \Rightarrow \forall j' > j, \alpha_{i,j'} = 0$; $\alpha_{i,j} \in \{0, \frac{\pi}{2}\} \Rightarrow \beta_{i,j} = 0$.

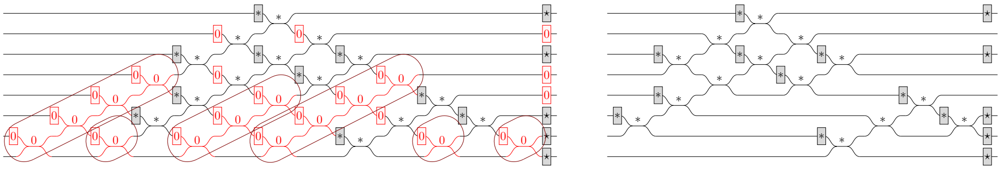

Figure 7 An example of a PPRS triangular normal form. In the figure on the left, the beam splitters and phase shifters with angle 0 in the corresponding triangular form are shown in red. In the figure on the right, they are replaced with identities.

Proof. This property can be proven by induction. First, we lay out the properties of any irreducible circuit that can be directly deduced from the PPRS rules of Figure 5. Then, we give two more properties characterising the PPRS triangular normal forms. By induction, we prove that any irreducible circuit respects those two properties, so that any irreducible circuit is a PPRS triangular normal form. See [15] for more details. ◀

▶ **Theorem 23.** *Any* LO$_{\text{PP}}$*-circuit, with the rules of* PPRS*, converges to a unique* PPRS *triangular normal form.*

Proof. PPRS is globally confluent and terminating: normal forms are unique. From Lemma 22, PPRS triangular normal forms are the only irreducible forms. Therefore, any polarisation-preserving circuit terminates to such a unique normal form. ◀

▶ Remark 24. In particular by using Equation (18) and by adding 0-angled beam splitters if necessary, one can turn any circuit in PPRS triangular normal form into a circuit in the rectangular form of [18] shown in Figure 1b. A schematic example of such a transformation is shown in [15].

We can now prove the completeness of the polarisation-preserving fragment.

▶ **Theorem 25.** *For any* LO$_{\text{PP}}$*-circuits* C_1,C_2 *such that* $[\![C_1]\!]_{\text{pp}} = [\![C_2]\!]_{\text{pp}}$*, their normal forms are equal, i.e.* $N_1 = N_2$*, where* N_1 *(resp.* N_2*) is the unique normal form of* C_1 *(resp.* C_2*) given by Theorem 23.*

Proof. As the rewrite system preserves the semantics, it is sufficient to prove that $[\![N_1]\!]_{\text{pp}} = [\![N_2]\!]_{\text{pp}} \Rightarrow N_1 = N_2$. First, we can show by induction that $[\![N]\!]_{\text{pp}} = [\![I_n]\!]_{\text{pp}} \Rightarrow N = I_n$. Indeed, to have the semantics as the identity, we can show the upper beam splitter and phase shifters are necessarily 0-angled. The proof follows from induction, details are given in [15]. Let P be an inverse circuit of N_1 and N_2, that is, a polarisation-preserving circuit such that $[\![P]\!]_{\text{pp}} = [\![N_1]\!]_{\text{pp}}^{-1}$. The existence of such a circuit follows from [49]. As $[\![N_1P]\!]_{\text{pp}} = [\![PN_2]\!]_{\text{pp}} = [\![I_n]\!]_{\text{pp}}$, the term N_1PN_2 can both be reduced to N_1 (by reducing PN_2 first) and N_2 (by reducing N_1P first). By Theorem 23, $N_1 = N_2$. ◀

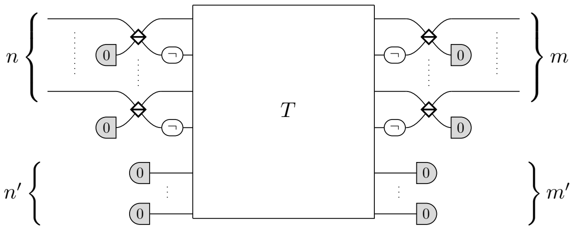

Figure 8 Shape of a circuit in normal form as of Definition 27.

▶ **Proposition 26** (Universality and uniqueness in the polarisation-preserving fragment)**.** *For any unitary* $U\colon \mathbb{C}^n \to \mathbb{C}^n$*, there exists a unique circuit* T *in* PPRS *triangular normal form such that* $[\![T]\!]_{\mathrm{pp}} = U$*.*

Proof. This follows directly from [49], Theorems 23 and 25 and the fact that all PPRS triangular normal forms are irreducible. ◀

5 Completeness of the $\mathrm{LO_v}$-Calculus

To prove the completeness of the $\mathrm{LO_v}$-Calculus (Theorem 16), we introduce the following notion of normal form.

▶ **Definition 27** (Normal form)**.** *A circuit in normal form* $N : n \to m$ *is a circuit of the form shown in Figure 8, where* T *is a PPRS triangular normal form (Definition 21). If* $n' = m' = 0$*, then* N *is said to be in* pure normal form.

▶ **Lemma 28** (Uniqueness of the pure normal form)**.** *If two circuits* N_1 *and* N_2 *in pure normal form are such that* $[\![N_1]\!] = [\![N_2]\!]$*, then* $N_1 = N_2$*.*

Proof. Let T_1 (resp. T_2) be the $\mathrm{LO_{PP}}$-circuit associated with N_1 (resp N_2) as in Figure 8. Notice that $[\![T_i]\!]_{\mathrm{pp}} \circ \mu = \mu \circ [\![N_i]\!]$ where $\mu : \mathbb{C}^{M_n} \to \mathbb{C}^{2n}$ is the isomorphism $|\mathrm{V}_k\rangle \mapsto |2k\rangle$ and $|\mathrm{H}_k\rangle \mapsto |2k+1\rangle$. Thus $[\![N_1]\!] = [\![N_2]\!]$ implies $[\![T_1]\!]_{\mathrm{pp}} = [\![T_2]\!]_{\mathrm{pp}}$ so that the result follows from Theorem 23. ◀

▶ **Lemma 29.** *For any circuit* D *without vacuum state sources or detectors there exists a circuit in pure normal form* N *such that* $\mathrm{LO_v} \vdash D = N$*.*

Proof. The proof is given in [15]. ◀

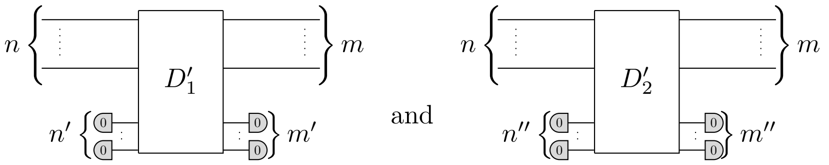
Completeness for circuits without vacuum state sources or detectors follows directly from Lemmas 28 and 29:

▶ **Proposition 30.** *Given any two circuits* D_1 *and* D_2 *without any* (0)– *or* –(0)*, if* $[\![D_1]\!] = [\![D_2]\!]$ *then* $\mathrm{LO_v} \vdash D_1 = D_2$*.*

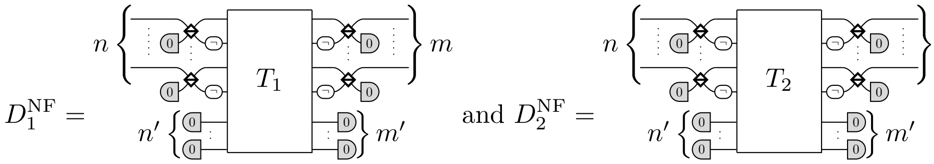
Proof. By Lemma 29, there exist two circuits in pure normal form N_1 and N_2 such that $\mathrm{LO_v} \vdash D_1 = N_1$ and $\mathrm{LO_v} \vdash D_2 = N_2$. By Proposition 14, one has $[\![N_1]\!] = [\![D_1]\!] = [\![D_2]\!] = [\![N_2]\!]$, so that by Lemma 28, $N_1 = N_2$. The result follows by transitivity. ◀

Proof of Theorem 16

We now have the required material to to finish the proof of Theorem 16. Let $D_1, D_2 : n \to m$ be any two LO$_\text{v}$-circuits such that $[\![D_1]\!] = [\![D_2]\!]$. By deformation, we can write them as



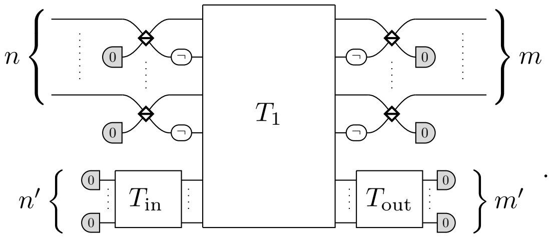
where D_1', D_2' do not contain (0)— or —(0). Up to using Equation (8), we can assume that $n'' = n'$. Since circuits without vacuum state sources and detectors necessarily have the same number of input wires as of output wires, this implies that $m'' = m'$. By Lemma 29, we can put D_1' and D_2' in pure normal form. Then by using Equations (9)–(14), we get two circuits in normal form



with T_1 and T_2 in PPRS triangular normal form.

$[\![D_1]\!] = [\![D_2]\!]$ implies that $\pi \circ [\![T_1]\!]_{\text{pp}} \circ \iota = \pi \circ [\![T_2]\!]_{\text{pp}} \circ \iota$ where $\iota : \mathbb{C}^{2n} \to \mathbb{C}^{2n+n'}$ is the injection $|k\rangle \mapsto |k\rangle$ and $\pi : \mathbb{C}^{2m+m'} \to \mathbb{C}^{2m}$ is the projector s.t. $\pi|k\rangle = |k\rangle$ when $k < 2m$ and $\pi|k\rangle = 0$ otherwise. Thus there exists two unitaries Q, Q' s.t. $[\![T_2]\!]_{\text{pp}} = (I \oplus Q') \circ [\![T_1]\!]_{\text{pp}} \circ (I \oplus Q)$ (see [15]).

By Proposition 26, there exist two circuits T_{in} and T_{out} in PPRS triangular normal form such that $[\![T_{\text{in}}]\!]_{\text{pp}} = Q$ and $[\![T_{\text{out}}]\!]_{\text{pp}} = Q'$. Using the equational theory we can then make T_{in} and T_{out} appear, turning D_1^{NF} into



Since by construction, the middle part has the same single-photon semantics as T_2, by Proposition 30 we can transform it into T_2 using the axioms of the LO$_\text{v}$-calculus, which means transforming D_1^{NF} into D_2^{NF}. The result follows by transitivity. ◀

6 Conclusion

In this paper, we presented the LO$_\text{v}$-calculus, a graphical language for LOQC capturing most of the components typically considered in the physics community for linear optical quantum circuits. The language comes equipped with a sound and complete semantics, and we discussed how it provides a unifying framework for many of the existing approaches in the literature. We explained how several existing results can be ported in the LO$_\text{v}$ framework.

An obvious direction for future work is to extend the language to allow for sources and detectors of a non-zero number of photons. A more exploratory research avenue is to add support for features such as squeezed states or continuous variables.

Abstract

Coherent control of quantum computations can be used to improve some quantum protocols and algorithms. For instance, the complexity of implementing the permutation of some given unitary transformations can be strictly decreased by allowing coherent control, rather than using the standard quantum circuit model. In this paper, we address the problem of optimising the resources of coherently controlled quantum computations. We refine the PBS-calculus, a graphical language for coherent control which is inspired by quantum optics. In order to obtain a more resource-sensitive language, it manipulates abstract gates – that can be interpreted as queries to an oracle – and more importantly, it avoids the representation of useless wires by allowing unsaturated polarising beam splitters. Technically the language forms a coloured PROP. The language is equipped with an equational theory that we show to be sound, complete, and minimal.

Regarding resource optimisation, we introduce an efficient procedure to minimise the number of oracle queries of a given diagram. We also consider the problem of minimising both the number of oracle queries and the number of polarising beam splitters. We show that this optimisation problem is NP-hard in general, but introduce an efficient heuristic that produces optimal diagrams when at most one query to each oracle is required.

1 Introduction

Most models of quantum computation (like quantum circuits) and most quantum programming languages are based on the *quantum data/classical control* paradigm. In other words, based on a set of quantum primitives (e.g. unitary transformations, quantum measurements), the way these primitives are applied on a register of qubits is either fixed or classically controlled.

However, quantum mechanics offers more general control of operations: for instance in quantum optics it is easy to control the trajectory of a system, like a photon, based on its polarisation using a *polarising beam splitter*. One can then position distinct quantum primit-

Figure 1 [*Left*] Coherently controlled quantum computation for solving the commuting problem. Only two queries are used: one query to U and one query to V. [*Right*] Optimal circuit for solving the commuting problem, where the 3-qubit gate is a control-swap. Notice that three queries are necessary in the quantum circuit model.

ives on the distinct trajectories. Since the polarisation of a photon can be in superposition, it achieves some form of quantum control, called coherent control: the quantum primitives are applied in superposition depending on the state of another quantum system. Coherent control is not only a subject of interest for foundations of quantum mechanics [21, 26, 33], it also leads to advantages in solving computational problems [18, 4, 14, 27] and in designing more efficient protocols [19, 9, 1, 17, 20].

Indeed, some problems can be solved more efficiently by using coherent control rather than the usual quantum circuits. This separation has been proved in a multi-oracle model where the measure of complexity is the number of queries to (a single or several distinct) oracles, which are generally unitary maps. The simplest example is the following problem [9]: given two oracles U and V with the promise that they are either commuting or anti-commuting, decide whether U and V are commuting or not. This problem can be solved using the so-called quantum switch [10] which can be implemented using only two queries by means of coherent control, whereas solving this problem requires at least 3 queries (e.g. two queries to U and one query to V) in the quantum circuit model (see Figure 1).

In this paper, we address the problem of optimising resources of coherently controlled quantum computations. To do so, we first refine the framework of the PBS-calculus – a graphical language for coherently controlled quantum computation – to make it more resource-sensitive. Then, we consider the problem of optimising the number of queries, and also the number of polarising beam splitters, of a given coherently controlled quantum computation, described as a PBS-diagram.

PBS-calculus. The PBS-calculus is a graphical language that has been introduced [12] to represent and reason about quantum computations involving coherent control of quantum operations. Inspired by quantum optics [11], the polarising beam splitter (PBS for short), denoted  is at the heart of the language: when a photon enters the PBS, say from the top left, it is reflected (and hence outputted on the top right) if its polarisation is vertical; or transmitted (and hence outputted on the bottom right) if its polarisation is horizontal. If the polarisation is a superposition of vertical and horizontal, the photon is outputted in a superposition of two positions. As a consequence, the trajectory of a particle, say a photon, will depend on its polarisation. The second main ingredient of the PBS-calculus are the gates, denoted $-\boxed{U}-$ which applies some transformation U on a data register. Notice that the gates never act on the polarisation of the particle.

PBS-diagrams, which form a traced symmetric monoidal category (more precisely a traced prop [24]), are equipped with an equational theory that allows one to transform a diagram. The equational theory has been proved to be sound, complete, and minimal [12].

Notice that a PBS-diagram may have some useless wires, like in the example of the "half quantum switch", see Figure 2 (left). We refine the PBS-calculus in order to allow one to remove these useless wires, leading to unsaturated PBS (or 3-leg PBS) like  or .

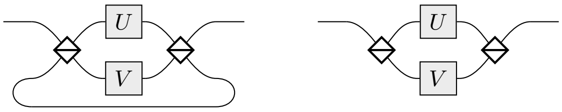

Figure 2 A coherent control of U and V, also called a half quantum switch: when the initial polarisation is vertical ($\mathbf{V}$), U is applied on the data register, when the polarisation is horizontal ($\mathbf{H}$), V is applied. Whatever the polarisation is, the particle always goes out of the top port of the second beam splitter. On the right-hand side the diagram is made of beam splitters with a missing leg, whereas on the left-hand side standard beam splitters are used, and a useless trace is added.

To avoid ill-formed diagrams like , a typing discipline is necessary. To this end, we use the framework of coloured props: each wire has 3 possible colours: black, red and blue which can be interpreted as follows: a photon going through a blue (resp. red) wire must have a horizontal (resp. vertical) polarisation.

The introduction of unsaturated polarising beam splitters requires to revisit the equational theory of the PBS-calculus. The heart of the refined equational theory is the axiomatisation of the 3-leg polarising beam splitters, together with some additional equations which govern how 4-leg polarising beam splitters can be decomposed into 3-leg ones. To show the completeness of the refined equational theory, we introduce normal forms and show that any diagram can be put in normal form. Finally, we also show the minimality of the equational theory by proving that none of the equations can be derived from the other ones.

Resource Optimisation. The PBS-calculus, thanks to its refined equational theory, provides a way to detect and remove dead-code in a diagram. We exploit this property to address the crucial question of resource optimisation. We introduce a specific form of diagrams that minimises the number of gates, more precisely the number of queries to oracles, with an appropriate modelisation of oracles. We provide an efficient procedure to transform any diagram into this specific form. We then focus on the problem of optimising both the number of queries and the number of polarising beam splitters. We refine the previous procedure, leading to an efficient heuristic. We show that the produced diagrams are optimal when every oracle is queried at most once, but might not be optimal in general. We actually show that the general optimisation problem is NP-hard using a reduction from the *maximum Eulerian cycle decomposition problem* [8].

Related work. Several languages have been designed to represent coherently controlled quantum computation: some of them are extensions of quantum circuits, and other diagrammatic languages [30, 5, 31, 29]; others are based on abstract programming languages [2, 32, 16, 15, 6]. While there are numerous works on resource-optimisation of quantum computation, in particular for quantum circuits [23, 3, 25], there was, up to our knowledge, no procedure for resource optimisation of coherently controlled quantum computation.

All omitted proofs can be found in the preprint version of the paper [13].

2 Coloured PBS-diagrams

We use the formalism of traced coloured props (i.e. small traced symmetric strict monoidal categories whose objects are freely spanned by the elements of a set of colours) to represent coherently controlled quantum computations. We are going to use the “colours” $\mathbf{v}$, $\mathbf{h}$, $\top$, to denote respectively vertical, horizontal or possibly both polarisations.

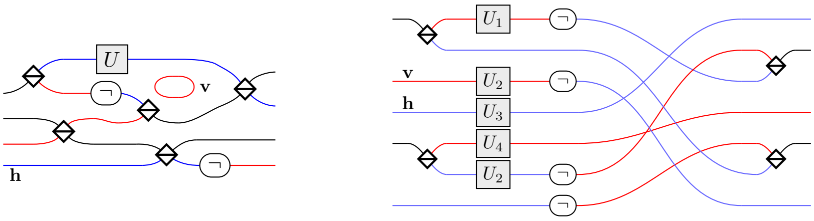

Figure 3 (*Left*) An example of diagram of type $\top \oplus \top \oplus \mathbf{v} \oplus \mathbf{h} \to \top \oplus \mathbf{h} \oplus \top \oplus \mathbf{v}$. (*Right*) An example of a diagram of type $\top \oplus \mathbf{v} \oplus \mathbf{h} \oplus \top \oplus \mathbf{h} \to \mathbf{h} \oplus \top \oplus \mathbf{v} \oplus \top \oplus \mathbf{h}$, in a particular form that we will call *normal form* (see Definition 15).

▶ **Definition 1.** *Given a monoid* M*, let* $\mathbf{Diag}^{\mathsf{M}}$ *be the traced coloured prop with colours* $\{\mathbf{v}, \mathbf{h}, \top\}$ *freely generated by the following generators, for any* $U \in \mathsf{M}$*:*

	: $\top \oplus \top \to \top \oplus \top$			: $\top \oplus \mathbf{v} \to \mathbf{v} \oplus \top$			: $\top \to \mathbf{h} \oplus \mathbf{v}$
	: $\mathbf{h} \oplus \top \to \mathbf{h} \oplus \top$			: $\mathbf{v} \oplus \top \to \top \oplus \mathbf{v}$			: $\mathbf{v} \oplus \mathbf{h} \to \top$
	: $\top \oplus \mathbf{h} \to \top \oplus \mathbf{h}$			: $\top \to \mathbf{v} \oplus \mathbf{h}$			: $\mathbf{h} \oplus \mathbf{v} \to \top$
	: $\top \to \top$			: $\mathbf{v} \to \mathbf{h}$			: $\mathbf{h} \to \mathbf{v}$
	: $\top \to \top$			: $\mathbf{v} \to \mathbf{v}$			: $\mathbf{h} \to \mathbf{h}$

The morphisms of $\mathbf{Diag}^{\mathsf{M}}$ are called M-diagrams or simply diagrams when M is irrelevant or clear from the context. Intuitively, the diagrams are inductively obtained by composition of the generators from Definition 1 using the sequential composition $D_2 \circ D_1$, the parallel composition $D_3 \oplus D_4$, and the trace $Tr_d(D)$ which are respectively depicted as follows:    . Notice that these compositions should type-check, i.e. $D_1 : a \to b$, $D_2 : b \to c$ and $D : a \oplus d \to b \oplus d$ with $d \in \{\top, \mathbf{v}, \mathbf{h}\}$. The axioms of the traced coloured prop guarantee that the diagrams are defined up to deformation: two diagrams whose graphical representations are isomorphic are equal.

Regarding notations, we use actual colours for wires: blue for $\mathbf{h}$-wires, red for $\mathbf{v}$-wires, and black for $\top$-wires. We also add labels on the wires, which are omitted when clear from the context, so that there is no loss of information in the case of a colour-blind reader or black and white printing. Two examples of diagrams are given in Figure 3.

Unless specified, the unit of M is denoted I and its composition is $\cdot$ which will be generally omitted (VU rather than $V \cdot U$). The main two examples of monoids we consider in the rest of the paper are:

- The monoid $\mathcal{U}(\mathcal{H})$ of isometries of a Hilbert space $\mathcal{H}$ with the usual composition. When $\mathcal{H}$ is of finite dimension, the elements of $\mathcal{U}(\mathcal{H})$ are unitary maps. With a slight abuse of notations, the corresponding traced coloured prop of diagrams is denoted $\mathbf{Diag}^{\mathcal{H}}$.
- The free monoid $\mathcal{G}^*$ on some set $\mathcal{G}$. The gates, when the monoid is freely generated, can be interpreted as queries to oracles (each element of $\mathcal{G}$ corresponds to an oracle): the gates implement a priori arbitrary operations with no particular structures. We use the term *abstract diagram* when the underlying monoid is freely generated. Notice that the free monoid case can also be seen as an extension of the *bare diagrams* [7] whose gates are labelled with *names*.

3 Semantics

The input of a diagram is a single particle, which has a polarisation, a position and a data register. A basis state for the polarisation is either vertical or horizontal, and a basis state for the position is an integer which corresponds to the wire on which the particle is located. The type of a diagram restricts the possible input/output configurations: if $D : \mathbf{v} \oplus \top \to \mathbf{h} \oplus \mathbf{h} \oplus \mathbf{v}$ then the possible input (resp. output) configurations are the following polarisation-position pairs: $\{(\mathbf{V}, 0), (\mathbf{V}, 1), (\mathbf{H}, 1)\}$ (resp. $\{(\mathbf{H}, 0), (\mathbf{H}, 1), (\mathbf{V}, 2)\}$). More generally for any object a, let $[a]$ be the set of possible configurations, and $|a|$ be its size, inductively defined as follows: $|I| = 0$, $|a \oplus \top| = |a \oplus \mathbf{v}| = |a \oplus \mathbf{h}| = |a| + 1$, and $[I] = \emptyset$, $[a \oplus \mathbf{v}] = [a] \cup \{(\mathbf{V}, |a|)\}$, $[a \oplus \mathbf{h}] = [a] \cup \{(\mathbf{H}, |a|)\}$ and $[a \oplus \top] = [a] \cup \{(\mathbf{V}, |a|), (\mathbf{H}, |a|)\}$.

The semantics of a M-diagram $D : a \to b$ is a map $[a] \to [b] \times \mathsf{M}$ which associates with an input configuration (c, p), an output configuration (c', p') and a side effect $U_k \ldots U_1 \in \mathsf{M}$ which represents the action applied on a data register of the particle. Thus the semantics of a diagram can be formulated as follows:

▶ **Definition 2.** *Given an M-diagram $D : a \to b$, let $\llbracket D \rrbracket : [a] \to [b] \times \mathsf{M}$ be inductively defined as: $\forall D_1 : a \to b, D_2 : b \to d, D_3 : d \to e, D_4 : a \oplus f \to b \oplus f$, where $f \in \{\top, \mathbf{v}, \mathbf{h}\}$:*

$\llbracket$  $\rrbracket = \begin{cases} (\mathbf{V}, 0) \mapsto ((\mathbf{V}, 0), I) \\ (\mathbf{H}, 0) \mapsto ((\mathbf{H}, 1), I) \end{cases}$

$\llbracket$  $\rrbracket = \begin{cases} (\mathbf{V}, 0) \mapsto ((\mathbf{V}, 1), I) \\ (\mathbf{H}, 0) \mapsto ((\mathbf{H}, 0), I) \end{cases}$

$\llbracket$  $\rrbracket = \begin{cases} (\mathbf{V}, 0) \mapsto ((\mathbf{V}, 0), I) \\ (\mathbf{H}, 1) \mapsto ((\mathbf{H}, 0), I) \end{cases}$

$\llbracket$  $\rrbracket = \begin{cases} (\mathbf{V}, 1) \mapsto ((\mathbf{V}, 0), I) \\ (\mathbf{H}, 0) \mapsto ((\mathbf{H}, 0), I) \end{cases}$

$\llbracket$ 
$\rrbracket = (c, p) \mapsto \begin{cases} ((c, p), I) & \text{if } c = \mathbf{V} \\ ((c, 1 - p), I) & \text{if } c = \mathbf{H} \end{cases}$

$\llbracket$ 
$\rrbracket = (c, p) \mapsto ((c, 1 - p), I)$

$\llbracket$ 
$\rrbracket = (c, 0) \mapsto ((c, 0), I)$

$\llbracket$ 
$\rrbracket = \begin{cases} (\mathbf{V}, 0) \mapsto ((\mathbf{H}, 0), I) \\ (\mathbf{H}, 0) \mapsto ((\mathbf{V}, 0), I) \end{cases}$

$\llbracket$ 
$\rrbracket = (c, 0) \mapsto ((c, 0), U)$

$$\llbracket D_1 \oplus D_3 \rrbracket = (c, p) \mapsto \begin{cases} \llbracket D_1 \rrbracket (c, p) & \textit{if } p < |a| \\ S_a(\llbracket D_3 \rrbracket (c, p - |a|)) & \textit{otherwise} \end{cases} \qquad \llbracket D_2 \circ D_1 \rrbracket = \llbracket D_2 \rrbracket \circ \llbracket D_1 \rrbracket$$

$$\llbracket Tr_f(D_4) \rrbracket = (c, p) \mapsto \begin{cases} \llbracket D_4 \rrbracket (c, p) \quad \textit{if } \pi_{pos}(\llbracket D_4 \rrbracket (c, p)) < |b| \\ \llbracket D_4 \rrbracket \circ S_{a-b}(\llbracket D_4 \rrbracket (c, p)) \\ \qquad \textit{if } \pi_{pos}(\llbracket D_4 \rrbracket \circ S_{a-b}(\llbracket D_4 \rrbracket (c, p))) < |b| \leq \pi_{pos}(\llbracket D_4 \rrbracket (c, p)) \\ \llbracket D_4 \rrbracket \circ S_{a-b}(\llbracket D_4 \rrbracket \circ S_{a-b}(\llbracket D_4 \rrbracket (c, p))) \quad \textit{otherwise} \end{cases}$$

where the composition is: $g \circ f(c, p) = ((c'', p''), U'U)$ with $f(c, p) = ((c', p'), U)$ and $g(c', p') = ((c'', p''), U')$; $\pi_{pos} : [a] \times \mathsf{M} \to \mathbb{N} = ((c, p), U) \mapsto p$ is the projector on the position, and $S_a : [b] \times \mathsf{M} \to [a \oplus b] \times \mathsf{M} = ((c, p), U) \mapsto ((c, p + |a|), U)$ and $S_{a-b} : [b] \times \mathsf{M} \to [a] \times \mathsf{M} = ((c, p), U) \mapsto ((c, p + |a| - |b|), U)$ shift the position.

Given $D : a \to b$ and $(c, p) \in [a]$, we denote respectively by $c^D_{c,p}$, $p^D_{c,p}$ and $U^D_{c,p}$ the polarisation, the position and the element of M, such that $\llbracket D \rrbracket (c, p) = ((c^D_{c,p}, p^D_{c,p}), U^D_{c,p})$. In the case where M is the free monoid $\mathcal{G}^*$, its elements can be seen as words, so we will use the notation $w^D_{c,p}$ instead of $U^D_{c,p}$.

Notice that the semantics of the trace is not defined as a fixed point but as a finite number of unfoldings. Indeed, like for PBS-diagrams, one can show that any wire of a diagram is used at most twice, each time with a distinct polarisation.

▶ **Proposition 3.** $[\![.]\!]$ *is well defined, i.e. the axioms of the traced coloured prop are sound and the semantics of the trace is well defined.*

3.1 Quantum semantics

Any diagram whose underlying monoid consists of linear maps, admits a *quantum semantics* defined as follows:

▶ **Definition 4** (Quantum semantics). *Given a monoid* M *of linear maps (with the standard composition) on a complex vector space* $\mathcal{V}$*, for any* M*-diagram* $D : a \to b$ *the quantum semantics of* D *is the linear map* $V_D : \mathbb{C}^{[a]} \otimes \mathcal{V} \to \mathbb{C}^{[b]} \otimes \mathcal{V} = |c,p\rangle \otimes |\phi\rangle \mapsto \left|c^D_{c,p}, p^D_{c,p}\right\rangle \otimes U^D_{c,p}\,|\phi\rangle$.

The diagrams in $\mathbf{Diag}^{\mathcal{H}}$ are valid by construction, in the sense that their semantics are valid quantum evolutions:

▶ **Proposition 5.** *For any* $D \in \mathbf{Diag}^{\mathcal{H}}$*,* $V_D : \mathbb{C}^{[a]} \otimes \mathcal{H} \to \mathbb{C}^{[b]} \otimes \mathcal{H}$ *is an isometry.*

Note that $[\![D]\!] = [\![D']\!]$ implies $V_D = V_{D'}$; the converse is true if and only if $0 \notin \mathsf{M}$:

▶ **Proposition 6.** *Given a monoid* M *of complex linear maps, we have* $\forall D, D', [\![D]\!] = [\![D']\!] \Leftrightarrow V_D = V_{D'}$*, if and only if* $0 \notin \mathsf{M}$.

In particular, two diagrams in $\mathbf{Diag}^{\mathcal{H}}$ have the same action semantics if and only if they have the same quantum semantics.

3.2 Interpretation

Given a monoid homomorphism $\gamma : \mathsf{M} \to \mathsf{M}'$, one can transform any M-diagram into a M'-diagram straightforwardly, by applying γ on each gate of the diagram:

▶ **Definition 7.** *Given a* M*-diagram* $D : a \to b$ *and a monoid homomorphism* $\gamma\colon \mathsf{M} \to \mathsf{M}'$*, we define its* γ*-interpretation* $\gamma(D) : a \to b$ *as the* M'*-diagram obtained by applying* γ *to each gate of* D*. It is defined inductively as:* $\gamma(\overset{a}{-}\boxed{U}- : a \to a) = \overset{a}{-}\boxed{\gamma(U)}- : a \to a$*, for any other generator* g*,* $\gamma(g) = g$*,* $\gamma(D_2 \circ D_1) = \gamma(D_2) \circ \gamma(D_1)$*,* $\gamma(D_1 \oplus D_2) = \gamma(D_1) \oplus \gamma(D_2)$*, and* $\gamma(Tr_e(D)) = Tr_e(\gamma(D))$.

▶ **Proposition 8.** *Any* M*-diagram is the interpretation of an abstract diagram.*

It is easy to see that the action of monoid homomorphisms on diagrams is well-behaved with respect to the semantics:

▶ **Proposition 9.** *Given any* M*-diagram* $D : a \to b$ *and any monoid homomorphism* $\gamma\colon \mathsf{M} \to \mathsf{M}'$*, for any configuration* $(c,p) \in [a]$*, if* $[\![D]\!]\,(c,p) = ((c',p'),U)$ *then* $[\![\gamma(D)]\!]\,(c,p) = ((c',p'),\gamma(U))$.

As a consequence, given two abstract diagrams $D_1, D_2 \in \mathbf{Diag}^{\mathcal{G}^*}$, if $[\![D_1]\!] = [\![D_2]\!]$ then for any homomorphism $\gamma : \mathcal{G}^* \to \mathsf{M}$, $[\![\gamma(D_1)]\!] = [\![\gamma(D_2)]\!]$. The converse is not true in general. Notice that in the framework of graphical languages an equation holds in graphical languages for traced symmetric (resp. dagger compact closed) monoidal categories if and only if it holds in finite-dimensional vector (resp. Hilbert) spaces [22, 28]. We prove a similar result by showing that interpreting abstract diagrams using 2-dimensional Hilbert spaces is enough to completely characterise their semantics:

▶ **Proposition 10.** *Given a Hilbert space $\mathcal{H}$ of dimension at least 2 and a set $\mathcal{G}$, $\forall D_1, D_2 \in$ $\mathbf{Diag}^{\mathcal{G}^*}$, there exists a monoid homomorphism $\gamma\colon \mathcal{G}^* \to \mathcal{U}(\mathcal{H})$ s.t. $[\![D_1]\!] = [\![D_2]\!] \Leftrightarrow [\![\gamma(D_1)]\!] =$ $[\![\gamma(D_2)]\!]$.*

A stronger result, where the homomorphism γ is independent of the diagrams, is also true, assuming the axiom of choice:

▶ **Proposition 11.** *Given a Hilbert space $\mathcal{H}$ of dimension at least 2, and a set $\mathcal{G}$ of cardinality at most the cardinality of $\mathcal{U}(\mathcal{H})$, there exists a monoid homomorphism $\gamma\colon \mathcal{G}^* \to \mathcal{U}(\mathcal{H})$ s.t. $\forall D_1, D_2 \in \mathbf{Diag}^{\mathcal{G}^*}$, $[\![D_1]\!] = [\![D_2]\!] \Leftrightarrow [\![\gamma(D_1)]\!] = [\![\gamma(D_2)]\!]$.*

▶ Remark 12. Notice that the cardinality of $\mathcal{U}(\mathcal{H})$ is $\max(2^{\aleph_0}, 2^{\dim(\mathcal{H})})$ (where $2^{\aleph_0}$ is the cardinality of $\mathbb{R}$).

4 Equational theory

In this section, we introduce an equational theory which allows one to transform any M-diagram into an equivalent one. Indeed, all the equations we present in this section preserve the semantics of the diagrams (see Proposition 14).

These equations are summarised in Figure 4. They form what we call the CPBS-calculus:

▶ **Definition 13** (CPBS-calculus)**.** *Two* M*-diagrams D_1, D_2 are equivalent according to the rules of the* CPBS*-calculus, denoted* CPBS $\vdash D_1 = D_2$*, if one can transform D_1 into D_2 using the equations given in Figure 4. More precisely,* CPBS $\vdash \cdot = \cdot$ *is defined as the smallest congruence which satisfies equations of Figure 4 in addition to the axioms of coloured traced prop.*

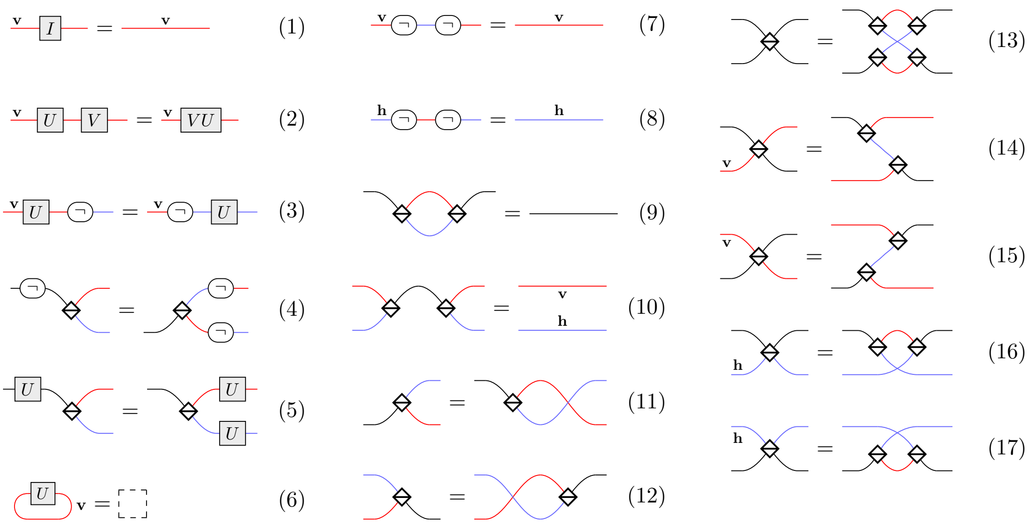

Figure 4 Axioms of the CPBS-calculus. $U, V \in$ M. Equations (1) and (2) reflect the monoid structure of M; Equations (3) to (5) show how the three generators commute; Equation (6) means that a disconnected diagram (with no inputs/outputs) can be removed; Equations (7) to (10) witness the fact that the negation and the 3-leg PBS are invertible; Equations (11) and (12) are essentially topological rules; Equations (13) to (17) show how 4-leg PBS can be decomposed into 3-leg PBS. Notice in particular that the other rules do not use 4-leg PBS, as a consequence one could define the language using 3-leg PBS only and see the 4-leg PBS as syntactic sugar.

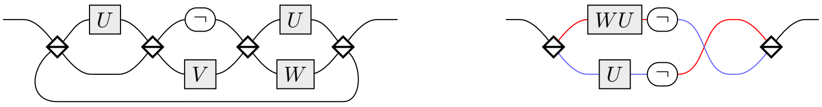

Figure 5 An example of a CPBS-diagram (*left*) and its equivalent diagram in normal form (*right*).

Notice that the CPBS-calculus subsumes the PBS-calculus: the fragment of monochromatic (black) $\mathcal{H}$-diagrams of the CPBS-calculus coincides with the set of PBS-diagrams, moreover, for any two PBS-diagrams D_1, D_2, PBS $\vdash D_1 = D_2$ if and only if CPBS $\vdash D_1 = D_2$.

▶ **Proposition 14** (Soundness). *For any two* M*-diagrams D_1 and D_2, if* CPBS $\vdash D_1 = D_2$ *then* $[\![D_1]\!] = [\![D_2]\!]$.

We introduce normal forms, that will be useful to prove that the equational theory is complete, and will also play a role in optimising the number of gates in a diagram in Section 5.

▶ **Definition 15.** *A diagram is said to be in* normal form *if it is of the form $M \circ P \circ F \circ G \circ S$, where:*

- *S is of the form $b_1 \oplus \cdots \oplus b_n$, where each b_i is either* $\overset{\mathbf{v}}{—}$, $\overset{\mathbf{h}}{—}$ *or* - *G is of the form $g_1 \oplus \cdots \oplus g_k$, where each g_i is either* $\overset{\mathbf{v}}{—}$, $\overset{\mathbf{h}}{—}$, *or* $\overset{\mathbf{v}}{—}\boxed{U_i}—$ *or* $\overset{\mathbf{h}}{—}\boxed{U_i}—$ *with $U_i \neq I$*
- *F is of the form $n_1 \oplus \cdots \oplus n_k$, where each n_i is either* $\overset{\mathbf{v}}{—}$, $\overset{\mathbf{h}}{—}$, $\overset{\mathbf{v}}{—}\boxed{\neg}—$ *or* $\overset{\mathbf{h}}{—}\boxed{\neg}—$
- *P is a permutation of the wires, that is, a trace-free diagram in which all generators are identity wires or swaps*
- *M is of the form $w_1 \oplus \cdots \oplus w_m$, where each w_i is either* $\overset{\mathbf{v}}{—}$, $\overset{\mathbf{h}}{—}$ *or*  .

For example, the diagram shown in Figure 3 (right) is in normal form.

▶ **Theorem 16.** *For any* M*-diagram D, there exists a* M*-diagram in normal form N such that* CPBS $\vdash D = N$.

Note that the structure of the normal form as well as the proof of Theorem 16 use in an essential way the removal of useless wires made possible by the use of colours, and in particular Equation (10), which has no equivalent in the monochromatic PBS-calculus of [12]. An example of CPBS-diagram and its normal form are given in Figure 5.

Now we use the normal form to prove the completeness of the CPBS-calculus:

▶ **Lemma 17** (Uniqueness of the normal form). *For any two diagrams in normal form N and N', if $[\![N]\!] = [\![N']\!]$ then $N = N'$.*

▶ **Theorem 18** (Completeness). *Given any two* M*-diagrams D_1 and D_2, if $[\![D_1]\!] = [\![D_2]\!]$ then* CPBS $\vdash D_1 = D_2$.

Finally, each equation of Figure 4 is necessary for the completeness:

▶ **Theorem 19** (Minimality). *None of the equations of Figure 4 is a consequence of the others.*

5 Resource optimisation

We show in this section that the equational theory of the CPBS-calculus can be used for resource optimisation.

5.1 Minimising the number of oracle queries

We consider the problem of minimising the number of oracle queries: given a set $\mathcal{G}$ of (distinct) oracles and a $\mathcal{G}^*$-diagram D, the objective is to find a diagram D' equivalent to D (i.e. $[\![D]\!] = [\![D']\!]$) such that D' is using a minimal number of queries to each oracle. Since there are several oracles, the definition of the optimal diagrams should be made precise.

First, we define the number of queries to a given oracle:

▶ **Definition 20.** *Given a $\mathcal{G}^*$-diagram D, for any $U \in \mathcal{G}$, let $\#_U(D)$ be the number of queries to U in D, inductively defined as follows: $\#_U(\overset{a}{-}\boxed{w}-) = |w|_U$, $\#_U(g) = 0$ for all the other generators, and $\#_U(D_1 \oplus D_2) = \#_U(D_2 \circ D_1) = \#_U(D_1) + \#_U(D_2)$, $\#_U(Tr_a(D)) = \#_U(D)$, where $|w|_U$ is the number of occurrences of U in the word $w \in \mathcal{G}^*$.*

We can now define a query-optimal diagram as follows:

▶ **Definition 21.** *A $\mathcal{G}^*$-diagram D is query-optimal if $\forall D' \in \mathbf{Diag}^{\mathcal{G}^*}$, $\forall U \in \mathcal{G}$, $[\![D]\!] = [\![D']\!]$ implies $\#_U(D) \leq \#_U(D')$.*

Notice that given a diagram, it is not a priori guaranteed that there exists an equivalent diagram which is query-optimal, if for instance, all the diagrams which minimise the number of queries to some oracle U do not minimise the number of queries to another oracle V. We actually show (Proposition 23) that any diagram can be turned into a query-optimal one. To this end, we first need a lower-bound on the number of queries to a given oracle:

▶ **Proposition 22** (Lowerbound)**.** *For any $\mathcal{G}^*$-diagram $D : a \to b$ and any $U \in \mathcal{G}$, $\#_U(D) \geq \left\lceil \sum_{(c,p)\in X} \frac{|w^D_{c,p}|_U}{2} \right\rceil$ where $w^D_{c,p} \in \mathcal{G}^*$ is such that $[\![D]\!]\,(c,p) = (c', p', w^D_{c,p})$.*

Notice that Proposition 22 provides a lower bound on the minimal number of queries to U one can reach in optimising a diagram since the right-hand side of the inequality only depends on the semantics of the diagram.

We are now ready to introduce an optimisation procedure that transforms any diagram into an equivalent query-optimal one:

Query optimisation procedure of a $\mathcal{G}^*$-diagram D.

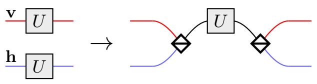
1. Transform D into its normal form D_{NF}. A recursive procedure for doing this can easily be deduced from the proof of Theorem 16.
2. Split all gates into elementary gates (that is, gates whose label is a single letter), using the following variants of Equation (2), which are consequences of the equations of Figure 4 (see [13]): $\forall U \in \mathcal{G}$, $\forall w \in \mathcal{G}^*$, $w \neq I$:

(18)

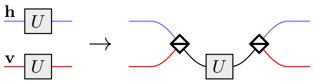
(19)

(20)

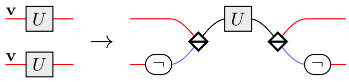
3. As long as the diagram contains two nonblack gates with the same label, merge them. To do so, deform the diagram to put one over the other, and apply one of the following equations, which are also consequences of the equations of Figure 4 :



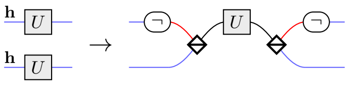
(21)



(22)



(23)



(24)

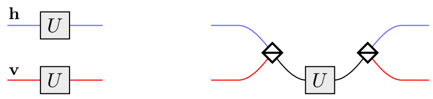


Figure 6 Two equivalent diagrams: the diagram on the left is optimal in terms of number of polarising beam splitters, the diagram on the right is optimal in terms of queries. Notice there is no equivalent diagram with no polarising beam splitter and at most a single query.

An example of query-optimised diagram is given in Figure 8. The query-optimisation procedure transforms any diagram into an equivalent query-optimal one:

▶ **Proposition 23.** *The diagram D_0 output by the query optimisation procedure is query-optimal: for any U and any D' s.t. $[\![D']\!] = [\![D_0]\!]$, one has $\#_U(D_0) \leq \#_U(D')$.*

Notice that the query-optimisation procedure is efficient: one can naturally define the size $|D|$ of a diagram $D \in \mathbf{Diag}^{\mathcal{G}^*}$ as follows: $|\overset{a}{-}\boxed{w}-| = |w|$, $|g| = 1$ for all the other generators, and $|D_1 \oplus D_2| = |D_2 \circ D_1| = |D_1| + |D_2|$, $|Tr_a(D)| = |D| + 1$. Step 1 of the procedure, which consists in putting the diagram in normal form, can be done using a number of elementary equations of Figure 4 which is quadratic in the size of the diagram, the other two steps being linear. Notice that here we only count the number of basic equations, but it requires also some diagrammatic transformations, which can be handled efficiently using appropriate data structures.

5.2 Optimising both queries and PBS

We refine the resource optimisation of a diagram by considering not only the number of queries but also the number of instructions, and in particular the number of polarising beam splitters. Notice that the number of beam splitters and the number of queries cannot be minimised independently, in the sense that there might not exist a diagram that is both query-optimal and PBS-optimal (see such an example in Figure 6). As the implementation of an oracle is a priori more expensive than the implementation of a single PBS, we optimise the number of queries and then the number of PBS in this order, i.e. the measure of complexity is the lexicographic order number of queries, number of polarising beam splitters.

▶ **Definition 24.** *A diagram D is query-PBS-optimal if D is query-optimal and for any query-optimal diagram D' equivalent to D (i.e. $[\![D]\!] = [\![D']\!]$), $\#_{\mathrm{PBS}}(D) \leq \#_{\mathrm{PBS}}(D')$, where $\#_{\mathrm{PBS}}(D)$ be the number of PBS of D.*

We introduce an efficient heuristic, called *PGT procedure* that, when applied on a query-optimal diagram D_0, preserves the number of queries. Moreover, the produced diagram, called in PGT form (see Figure 7), is query-PBS-optimal when there is at most one query to each oracle:

▶ **Theorem 25.** *Any query-optimal diagram in PGT form that does not contain two queries to the same oracle (i.e. $\forall U \in \mathcal{G}, \#_U(D) \leq 1$) is query-PBS-optimal.*

The procedure relies on equations of Figure 4, together with easy to derive variants of these equations. The procedure, with all steps detailed, more pictures and explicit statement of the variants of the equations, is given in the preprint version of the paper [13].

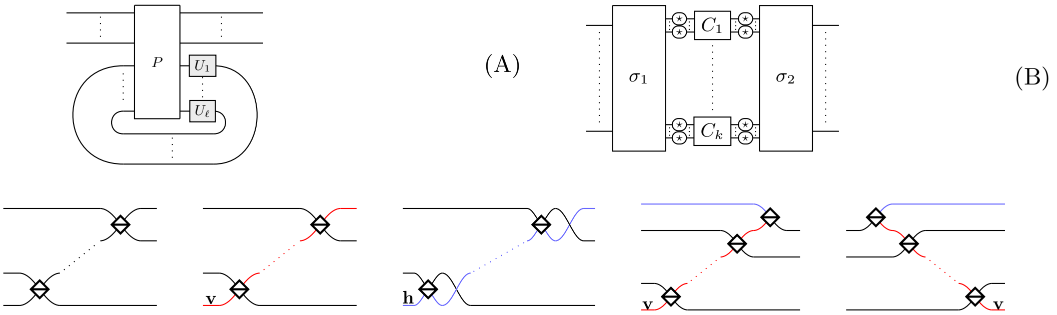

Figure 7 Schematic description of a diagram in PGT form (for Permutation, Gates and Traces). A diagram is in PGT form if it is of the form (A), with P of the form (B), and the C_i of the forms depicted on the second line.  denotes either or  with $a \in \{\mathbf{v}, \mathbf{h}\}$, and σ_1, σ_2 are permutations of the wires.

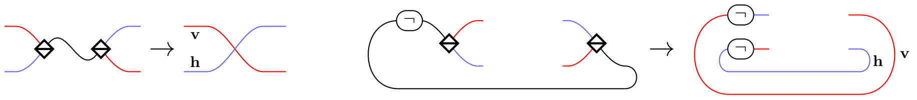
PGT procedure. Given a query optimal diagram D_0:

0. During all the procedure, every time there are two consecutive negations, we remove them using Equation (7), (8) or their all-black version.

1. Deform the gate-optimal diagram D_0 to put it in the form (A) with P gate-free. The goal of the following steps is to put P in stair form.

2. Split all PBS of the form  into combinations of , ,  and , using Equations (13) to (17).

3. As long as there are two PBS connected by a black wire, with possibly a black negation on this wire, push the possibly remaining negation out using Equation (4), and cancel the PBS together using Equation (10) and its variants. For example:



When there are not two such PBS anymore, all black wires are connected to at least one side of P (possibly through negations), and the PBS are connected together with red and blue wires with possibly negations on them.

4. Remove all isolated loops. Note that since D_0 is query-optimal, there cannot be loops containing gates at this point.

5. Deform P to put it in the form (B) with the C_i of the form  and σ_1 and σ_2 being wire permutations, where  is either or  with $a \in \{\mathbf{v}, \mathbf{h}\}$,  is either  or  and  is either  or .

6. Remove the negations in the middle of the C_i by pushing them to the bottom by means of variants of Equation (4).

7. Transform each C_i, which is now, up to deformation, a ladder of PBS without negations, into one of the five kinds of stairs depicted in Figure 7, depending on its type. To do so, deform it and apply Equations (11) and (12) appropriately, and repeatedly apply the appropriate equation among (14), (15), (16), and a variant of (13). This gives us D_1.

An example of diagram produced by the PGT procedure is given in Figure 8.

Since the PGT procedure consists in putting a subdiagram of D_0 in stair form (except Step 1 which is just deformation and does not change the number of PBS), this procedure does not increase the number of PBS in D_0:

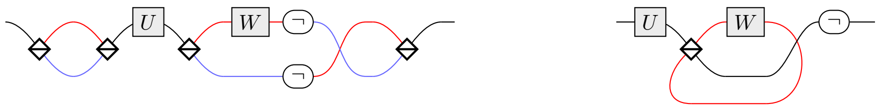


Figure 8 The diagram on the left is the obtained by applying the query-optimisation procedure on the example of Figure 5. The diagram on the right is (up to deformation) obtained by applying the PGT procedure to the diagram on the left. Notice that this diagram is both query- and PBS-optimal.

▶ **Proposition 26.** *The diagram D_1 output by the PGT procedure contains at most as many PBS as the initial diagram D_0.*

This also implies that given any diagram D, there exists an equivalent query-PBS-optimal diagram in PGT form. Indeed, by Proposition 23, there exist query-optimal diagrams equivalent to D, and among these diagrams, some of them have minimal number of PBS and are therefore query-PBS-optimal. Finally, applying the PGT procedure to one of these diagrams gives us an equivalent diagram in PGT form, which, since the PGT procedure does not change the gates or increase the number of PBS, is still query-PBS-optimal.

Applying the PGT procedure after the query optimisation procedure produces an interesting heuristic: the output diagram is necessarily query-optimal and can even be query-PBS-optimal when it does not contain two queries to the same oracle.

Notice that, like the query optimisation procedure, the PGT procedure is efficient, i.e. it can be done using a number of elementary graphical transformations (those of Figure 4) which is linear in the size of the diagram. Moreover, it also requires some diagrammatic transformations, which can be handled using appropriate data structures, leading to a quadratic algorithm.

5.3 Hardness

We show in this section that the query-PBS optimisation problem is actually NP-hard.

▶ **Theorem 27.** *The problem of, given an abstract diagram, finding an equivalent query-PBS-optimal diagram, is NP-hard.*

The proof, given in [13], is based on a reduction from the maximum Eulerian cycle decomposition problem (MAX-ECD) which is known to be NP-hard [8]. The MAX-ECD problem consists, given a graph, in finding a partition of its set of edges into the maximum number of cycles. Intuitively, the reduction goes as follows: given an Eulerian graph $G = (V = \{v_0, \dots v_{n-1}\}, E)$, let σ be a permutation of the vertices of the graph s.t. $\forall i, (v_i, \sigma(v_i)) \in E$ (such a σ exists since G is Eulerian), we construct a V^*-diagram D such that the number of occurrences of each v_i in D is half its degree in G; and such that $\forall i$, $[\![D]\!]\,(\mathbf{V}, i) = ((\mathbf{V}, i), v_i)$ and $[\![D]\!]\,(\mathbf{H}, i) = ((\mathbf{H}, i), \sigma(v_i))$. Roughly speaking, we show that the edge-partitions of G into cycles correspond to the possible implementations of D, and that a partition with a maximal number of cycles leads to an implementation with a minimal number of PBS.

In the following, we explore a few variants of the problem, which remain NP-hard.

First, query-PBS optimisation is still hard when restricted to negation-free diagrams:

▶ **Corollary 28.** *The problem of, given a negation-free abstract diagram, finding an equivalent diagram which is query-PBS-optimal among negation-free diagrams, is NP-hard.*

Additionally, it is also hard, in a query-optimal diagram, to optimise the gates and the negations together by, respectively, defining a cost function (at least in the case where the negation cost is not less than the PBS), prioritising the negations over the PBS, and prioritising the PBS over the negations. Note that the NP-hardness is clear in the third case since the considered problem is a refinement of the query-PBS-optimisation problem addressed in Theorem 27.

▶ **Corollary 29.** *For any $\alpha \geq 1$, the problem of, given an abstract diagram D, finding an equivalent query-optimal diagram D' such that $\#_{\text{PBS}}(D') + \alpha\#_{\neg}(D')$ is minimal, is NP-hard, where $\#_{\neg}(D)$ is the number of negations in D.*

▶ **Corollary 30.** *The problem of, given an abstract diagram D, finding an equivalent query-¬-PBS-optimal*[1] *diagram is NP-hard.*

6 Discussions and Future Work

The power and limits of quantum coherent control is an intriguing question. Maybe surprisingly, we have proved that coherently controlled quantum computations, when expressed in the PBS-calculus, can be efficiently optimised: any PBS-diagram can be transformed in polynomial time into a diagram that is optimal in terms of oracle queries. We have refined the procedure to also decrease the number of polarising beam splitters. It leads to an optimal diagram when each oracle is queried only once, but the corresponding optimisation problem is NP-hard in general. We leave to future work an experimental evaluation of the PGT procedure when each oracle is not necessarily queried only once.

To perform the resource optimisation, we have introduced a few add-ons to the framework of the PBS-calculus. First, we have refined the syntax in order to allow the representation of unsaturated (or 3-leg) polarising beam splitters. They are essential ingredients for resource optimisation, as they provide a way to decompose a diagram into elementary components and then remove the useless ones. However, notice that one can perform resource optimisation of vanilla PBS-diagrams, using the refined one only as an intermediate language. Indeed, given a vanilla PBS-diagram (where all wires are black), one can apply the optimisation procedures described in this paper. The resulting optimised PBS-diagram may contain some unsaturated PBS, but all these 3-leg PBS can be saturated by adding useless traces and then one can make the diagram monochromatic. The resulting vanilla PBS-diagram keeps the same number of queries and PBS.

We have also generalised the gates of the diagrams, by considering arbitrary monoids. This is a natural abstraction that allows one to consider various examples and in particular the one of the free monoid which is appropriate to model the oracle queries. The query complexity is a convenient model to prove lower bounds, but note that the optimisation procedures described in this paper can be applied with any arbitrary monoid (for instance using Proposition 8). However, there is no guarantee of minimality with an arbitrary monoid.

Another direction of research is to consider resource optimisation in a more expressive language for quantum control. Indeed, the polarisation of a particle can only be flipped within a PBS-diagram. The PBS-calculus is well suited for most applications of coherent control in quantum computing, by allowing the description of superpositions of classical controls (in particular superposition of causal orders) since the input particle can be in any superposition of polarisations. However, it would be interesting to develop resource optimisation techniques for quantum computation involving arbitrary quantum control.

[1] A diagram is query-¬-PBS-optimal if it is optimal according to the lexicographic order: the number of queries then the number of negations and finally the number of polarising beam splitters.

A Complexity Approach to Tree Algebras: the Polynomial Case

Thomas Colcombet

Arthur Jaquard
Université Paris Cité, CNRS, IRIF, F-75013, Paris, France

Abstract

In this paper, we consider infinitely sorted tree algebras recognising regular language of finite trees. We pursue their analysis under the angle of their asymptotic complexity, i.e. the asymptotic size of the sorts as a function of the number of variables involved.

Our main result establishes an equivalence between the languages recognised by algebras of polynomial complexity and the languages that can be described by nominal word automata that parse linearisation of the trees. On the way, we show that for such algebras, having polynomial complexity corresponds to having uniformly boundedly many orbits under permutation of the variables, or having a notion of bounded support (in a sense similar to the one in nominal sets).

We also show that being recognisable by an algebra of polynomial complexity is a decidable property for a regular language of trees.

1 Introduction

Among the many different approaches to language theory, the algebraic one focalises toward the understanding of the expressive power of regular languages based on the properties of algebraic recognizers. The first work in this direction [11] characterized star-free languages, and initiated a very fruitful branch of research. While algebraic theories for word languages (both finite and inifinite) are already well developed, the corresponding picture remains incomplete for e.g. languages of trees (both finite or infinite) or graphs. Finding an effective characterization of the regular languages of trees definable in first order logic remains for instance a long standing open problem.

When designing algebras for tree languages or graph languages, one is naturally inclined to consider infinitely sorted algebras. The case of tree algebras (such as preclones, ω-hyperclones, operads [8, 1]) is typical: plugging a subtree into another one requires a mechanism for identifying the leaf/leaves in which the substitution has to be performed. Notions such as variables, hole types, or colors are used for that. Another example is the one of graphs (HR- and VR- algebras [7]) in which basic operations (a) glue graphs together using a set of colors (sometimes called ports) for identifying the glue-points, or (b) add all possible edges between vertices of fixed given colors. In these examples, the algebras are naturally sliced into infinitely many sorts based on the number of variables/hole types/colors that are used simultaneously.

However, a technical difficulty arises immediately when using such algebras. Even when all sorts are finite (what we call a finite algebra), these algebras are not really finite due to the infinite number of sorts. This forbids, for instance, to explicitely describe the whole algebra in a finite way, which is of course a problem for designing algorithms. This hurdle to handle infinitely sorted algebras can, arguably, be seen as one of the causes of the many years that it took before having a good definition of an algebra for infinite trees [2], or the time that it took before it was possible to characterize logically the expressiveness of recognizable properties of graphs under bounded tree-width hypothesis [4].

Complexity of algebras. To cope with this difficulty, the notion of complexity for infinitely sorted algebras was introduced in [5]. In each of the above cases, the sorts are naturally indexed by a natural number parameter: the number of variables, or hole types, or colors. Hence an algebra $\mathcal{A}$ would have a carrier of the form

$$(A_n)_{n\in\mathbb{N}}$$

together with suitable operations that depend on the particular algebra type. Such an algebra is called finite if all the A_n are finite and, in this case, the complexity map $c_{\mathcal{A}}\colon \mathbb{N} \to \mathbb{N}$ of the algebra is defined as:

$$c_{\mathcal{A}}(n) = |A_n| \ , \qquad \text{for all } n \in \mathbb{N}.$$

This approach gives rises to the classification of finite algebras depending on the asymptotic growth of $c_{\mathcal{A}}$: algebras can have bounded complexity, polynomial complexity, etc. It is then possible to study the expressive power of algebras in a prescribed complexity class.

In all of the mentioned examples of algebras, there is a natural operation that performs a renaming of the variables/hole types/colors. This renaming is parameterized by a bijection over variables/hole types/colors, and this permutation acts on the corresponding sort. Thus, there is an action of the symmetric group over n elements, $\mathbf{Sym}(n)$ over A_n. The orbit-complexity map $c^\circ\colon \mathbb{N} \to \mathbb{N}$ is then naturally defined as:

$$c^\circ_{\mathcal{A}}(n) = |A_n/\mathbf{Sym}(n)| \ , \qquad \text{for all } n \in \mathbb{N}.$$

The notions of bounded orbit-complexity, polynomial orbit-complexity, etc. are then defined accordingly.

Along with the definitions of complexity and orbit-complexity, a precise description of the languages recognized by tree algebras of bounded complexity was given in [5][1]. In this article we endeavor to study tree algebras of polynomial complexity.

Tree algebras. The notion of tree algebra that we presented above is a bit unpractical, because the variables/hole types/colors are unnamed (we will simply call them variables from now on). We instead consider tree algebras with a carrier of the form

$$(A_X)_{X \text{ finite set of variables}}$$

for which the notions of complexity and orbit-complexity can be easily adapted. Given a finite X, a tree is then seen as an element of A_X whenever all the variables on the leaves of the tree are in X. This notion of tree algebras may have different flavors:

[1] Let us emphasize that the algebras used in [5] are different, since all variables are furthermore required to appear at least once. This apparently inocuous modification has consequences on the results.

- *Unrestrained tree algebras* in which there is no additional constraint, as in this paper.
- *Affine tree algebras*: all variables must appear on at most one leaf of the tree [2].
- *Relevant tree algebras*: all variables must appear on at least one leaf of the tree [5].
- *Linear tree algebras*: all variables must appear on exactly one leaf of the tree [8, 9].

We could also consider variants in which the variables are ordered. For instance, starting from linear tree algebras and adding the condition that, when read from left to right, the variables are monotone, corresponds to preclones [8]. The expressive power of relevant tree algebras of bounded complexity was precisely described in [5].

Contributions of the article. In this article, we study unrestrained tree algebras (or simply tree algebras from now on) of polynomial complexity.

We introduce a way to encode finite trees into data words, and thus to encode languages of trees into languages of data words (we say that the language of trees is described by the language of data words).

We then establish that tree algebras of polynomial complexity and of bounded orbit-complexity have the same expressive power, thus answering a question from [5] (for unrestrained tree algebras). Moreover, the languages that they recognize are exactly those described by regular languages over our data alphabet (in which the notion of regular language is defined using orbit-finite nominal automata [10, 3], a mild generalization of register automata that fit nicely into our algebraic setting).

Our main result is the following Theorem 1. It states the above described equivalences, and add a third item that will be formalised in the body of the paper.

▶ **Theorem 1.** *For a regular language of finite trees, the following properties are equivalent:*

1. *Being recognized by a finite tree algebra of polynomial complexity.*
2. *Being recognized by a finite tree algebra of bounded orbit complexity.*
3. *Being recognized by a finite tree algebra that has a bounded and stable system of supports.*
4. *Being described by a coding automaton.*

Our second theorem, Theorem 22, establishes the decidability of this class.

Structure of the paper. In Section 2, we recall some classical definitions, and introduce the notion of algebras. In Section 3, we explain our encoding of trees into data words, and prove Proposition 16 corresponding to the implication from Item 4 to Items 1 and 2 of Theorem 1. In Section 4, we look in detail at the properties of tree algebras of polynomial complexity and bounded orbit-complexity. Doing this, we prove Propositions 19 and 20, that correspond to proving implications from Items 1 and 2 to Item 3, and from Item 3 to Item 4 of Theorem 1. We also address the decidability question an prove Theorem 22. Section 5 concludes.

2 Definitions

We denote by $\mathbb{N}$ the set of all non-negative integers. Given $n \in \mathbb{N}$, we write $[n] = \{0, 1, ..., n-1\}$. The symmetric group (resp. alternating group) of a set X is denoted $\mathbf{Sym}(X)$ (resp. $\mathbf{Alt}(X)$). We fix a finite *ranked alphabet* Σ; the *arity* of a *symbol* $a \in \Sigma$ is denoted $\mathrm{ar}(a)$. It is a *constant* if $\mathrm{ar}(a) = 0$, and is *unary* if $\mathrm{ar}(a) = 1$. For $k \in \mathbb{N}$, we set $\Sigma_k = \{a \in \Sigma \mid \mathrm{ar}(a) = k\}$. A^* is the set of finite words over A, and $A^+ = A^* \setminus \{\varepsilon\}$.

2.1 Trees

In this section, we introduce notions and notations for trees.

We fix a countable set of *variables* $\mathcal{V}$. Given a finite set of variables X, a Σ, X-tree is, informally, a tree in which nodes are labelled by elements of Σ and leaves also possibly by variables of X. Formally, a *Σ, X-tree* is a partial map $t \colon \mathbb{N}^* \to \Sigma \uplus X$ such that $\mathrm{dom}(t)$ is non-empty and prefix-closed, and furthermore, for every $u \in \mathrm{dom}(t)$ there exists $n \in \mathbb{N}$ such that $\{i \mid ui \in \mathrm{dom}(t)\} = [n]$, and

- either $t(u) \in \Sigma_n$ (*symbol node*), or
- $t(u) \in X$ and $n = 0$ (*variable node*). Note that a variable node is always a leaf.

$\Sigma, \emptyset$-trees are simply called *Σ-trees.* The elements in $\mathrm{dom}(t)$ are called *nodes.* The prefix relation over nodes is called the *ancestor relation.* The node ε is called the *root* of the tree. The tree t is *finite* if it has finitely many nodes. A *branch* of a tree t is a maximal set of nodes ordered under the ancestor relation. Let $\mathrm{Trees}(\Sigma, X)$ bet the set of finite Σ, X-trees, for every finite set of variables X.

▶ Remark 2. Note that Σ, X-trees are also Σ, Y-trees whenever $X \subseteq Y$. This is in contrast with [5] in which all variables were assumed to appear at least once.

Building trees. We introduce now some operations on trees. See Fig. 1.

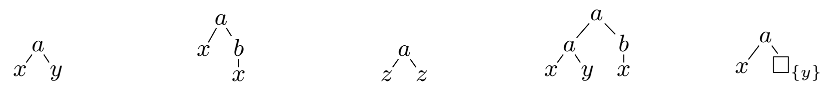
- ε_x, where x is a variable, denotes the $\Sigma, \{x\}$-tree consisting of a single root node labelled x.
- $a(x_0, \dots, x_{n-1})$, for $x_0, \dots, x_{n-1}$ variables and $a \in \Sigma_n$, denotes the $\Sigma, \{x_0, \dots, x_{n-1}\}$-tree consisting of a root labelled a, and children $0, \dots, n-1$ labelled with variables $x_0, \dots, x_{n-1}$ respectively.
- $s \cdot_x t$, for two trees $s \in \mathrm{Trees}(\Sigma, X)$, $t \in \mathrm{Trees}(\Sigma, Y)$ and a variable $x \in \mathcal{V}$, is the $\Sigma, (X \setminus \{x\}) \cup Y$-tree s in which t is substituted for every occurrence of the variable x, which may not be present in s at all.
- $\widetilde{\sigma}(t)$, for a tree $t \in \mathrm{Trees}(\Sigma, X)$ and a map $\sigma \colon X \to Y$, is the Σ, Y-tree obtained as t in which variable $\sigma(x)$ has been substituted to x for every $x \in X$. Note that $\widetilde{\sigma} \circ \widetilde{\tau} = \widetilde{\sigma \circ \tau}$.
- $t[x_0 \leftarrow t_0, \dots, x_{n-1} \leftarrow t_{n-1}]$ denotes the tree of sort $X \setminus \{x_0, \dots, x_{n-1}\} \cup \bigcup_i Y_i$ obtained from t by simultaneously substituting the tree t_i for the variable x_i for every $i \in [n]$, where t is a tree of sort X, $x_0, \dots, x_{n-1} \in \mathcal{V}$, and $t_0, \dots, t_{n-1}$ are trees of sort Y_i for every $i \in [n]$. Note that this operation is equivalent to a combination of the previous ones.
- $a(t_0, ..., t_{n-1})$, for $a \in \Sigma_n$, denotes the tree of root a and children $t_0, \dots, t_{n-1}$ at respective positions $0, \dots, n-1$. Again, this operation is equivalent to a combination of the previous ones.

▶ **Example 3.** Throughout this paper, we use the map $\mathrm{create}_x^X : X \to X \cup \{x\}$, acting as the identity, in which X is a finite set of variables and $x \in \mathcal{V}$. $\widetilde{\mathrm{create}_x^X}$ is thus a mapping from $\mathrm{Trees}(\Sigma, X)$ to $\mathrm{Trees}(\Sigma, X \cup \{x\})$ that maps every tree to itself. Most of the time, we will simply write $\mathrm{create}_x(t)$ when X is clear from the context.

▶ **Lemma 4.** *All finite trees can be obtained from the trees of the form ε_x and $a(x_0, \dots, x_{n-1})$ using the operations "$\cdot$".*

Expressions denoting finite trees. For X a finite set of variables, a *tree-expression of sort X (over the alphabet Σ)* is an expression built inductively as follows:

- ε_x is a tree-expression of sort $\{x\}$ for every variable x,
- $a(x_0, \dots, x_{n-1})$ is a tree-expression of sort $\{x_0, \dots, x_{n-1}\}$ for every symbol $a \in \Sigma_n$,



$t = a(x, y)$ $t \cdot_y b(x)$ $\tilde{\sigma}(t)$ $t[x \leftarrow t, y \leftarrow b(x)]$ $a(x, \square_{\{y\}})$

Figure 1 Trees and contexts with their notations. Here $\sigma(x) = \sigma(y) = z$.

- $S \cdot_x T$ is a tree-expression of sort $X \setminus \{x\} \cup Y$ for all tree-expressions S of sort X, all tree-expressions T of sort Y, and all variables $x \in \mathcal{V}$ (*substitution*),
- $\tilde{\sigma}(T)$ is a tree-expression of sort Y for all tree-expressions T of sort X, and map $\sigma \colon X \to Y$ (*renaming*). Note that σ needs not be bijective here.

For a tree-expression T of sort X, $[\![T]\!]$ denotes its evaluation into a finite Σ, X-tree using the operations of substitution and renaming.

Contexts. We define now contexts, which are terms with a specific leaf called the hole. Since we work in a multi-sorted algebra, the hole itself has a sort. Essentially, to a hole of sort X will be substituted a term of sort X. Formally, for fixed finite set of variables Y, a *context of sort X with hole of sort Y* (or simply a context) is defined inductively as a tree expression of sort X, using the extra construction $\square_Y$ (the *hole of sort* Y) which is a context of sort Y with hole of sort Y. This new construction must appear exactly once in a context.

For C a context of sort X with hole of sort Y, $[\![C]\!] \colon \mathrm{Trees}(\Sigma, Y) \to \mathrm{Trees}(\Sigma, X)$ is the function which to a tree of sort Y t associates the tree of sort X obtained by evaluating the operations as above, interpreting $\square_Y$ as t.

2.2 Finite tree algebras

Our notion of tree algebra is the natural notion associated to finite trees equipped with the above operations. We give here a more formal definition, though the detail of identities is more for reference. What matters is that it is defined such that the free algebra coincides with finite trees. A *tree algebra* $\mathcal{A}$ consists of an infinite collection of carrier sets A_X indexed by finite sets of variables X, together with operations:

- $\varepsilon_x^{\mathcal{A}} \in A_{\{x\}}$ for every variable x,
- $a(x_0, \ldots, x_{n-1})^{\mathcal{A}} \in A_{\{x_0, \ldots, x_{n-1}\}}$ for all $a \in \Sigma_n$ and variables $x_0, \ldots, x_{n-1}$,
- $\cdot_x^{\mathcal{A}} \colon A_X \times A_Y \to A_{X \setminus \{x\} \cup Y}$ for all finite sets of variables X, Y and $x \in \mathcal{V}$,
- $\sigma^{\mathcal{A}} \colon A_X \to A_Y$ for every renaming $\sigma \colon X \to Y$,

that satisfy the expected identities, i.e. the ones guaranteeing that several ways to describe the same tree yield the same evaluation in the algebra. Formally, for all s, t, u that belong to A_X, A_Y, A_Z respectively,

- $\varepsilon_x \cdot_x t = t$ for every $x \in \mathcal{V}$,
- $t \cdot_x \varepsilon_x = t$ for every $x \in Y$,
- $(s \cdot_x^{\mathcal{A}} t) \cdot_y^{\mathcal{A}} u = s \cdot_x^{\mathcal{A}} (t \cdot_y^{\mathcal{A}} u)$ for all $x \in X$ and $y \in X \setminus Y$ (horizontal associativity), and
- $(s \cdot_x^{\mathcal{A}} t) \cdot_y^{\mathcal{A}} u = s \cdot_x^{\mathcal{A}} (t \cdot_y^{\mathcal{A}} u)$ for all $x \in X$ and $y \in Y \setminus X \cup \{x\}$ (vertical associativity),

for all s, t that belong to A_X, A_Y, $x \in X$ and renaming $\sigma \colon X \to Y$,

- $\sigma^{\mathcal{A}}(s \cdot_x^{\mathcal{A}} t) = \sigma^{\mathcal{A}}(s) \cdot_x^{\mathcal{A}} t$ if $\sigma^{-1}(\sigma(x)) = \{x\}$ and $\sigma(y) = y$ for every $y \in X \cap Y \setminus \{x\}$,
- $\sigma^{\mathcal{A}}(s \cdot_x^{\mathcal{A}} t) = s \cdot_x \sigma^{\mathcal{A}}(t)$ if $\sigma(y) = y$ for every $y \in X \cap Y \setminus \{x\}$,

for all maps $\sigma \colon X \to Y$ and $\tau \colon Y \to Z$, $(\tau \circ \sigma)^{\mathcal{A}} = \tau^{\mathcal{A}} \circ \sigma^{\mathcal{A}}$, and for all maps $\sigma \colon \{x_0, \ldots x_{n-1}\} \to Y$ and $a \in \Sigma_n$, $\sigma^{\mathcal{A}}(a(x_0, \ldots, x_{n-1})^{\mathcal{A}}) = a(\sigma(x_0), \ldots, \sigma(x_{n-1}))^{\mathcal{A}}$. In practice, we shall not explicitly use these identities, and simply write two elements of the algebra equal as soon as they obviously come from expressions denoting the same trees. A tree algebra is *finite* if the A_X's are all finite.

A *morphism of tree algebras* from $\mathcal{A}$ to $\mathcal{B}$ is a family of maps $\alpha_X\colon A_X \to B_X$ for every finite sets of variables X which preserves all operations, i.e. $\alpha_Y(\sigma^{\mathcal{A}}(s)) = \sigma^{\mathcal{B}}(\alpha_X(s))$ for every map $\sigma\colon X \to Y$, $\alpha(a(x_0,\dots,x_{n-1})^{\mathcal{A}}) = a(x_0,\dots,x_{n-1})^{\mathcal{B}}$, and $\alpha_{X\setminus\{x\}\cup Y}(s \cdot_x^{\mathcal{A}} t) = \alpha_X(s) \cdot_x^{\mathcal{B}} \alpha_Y(t)$ for all $s \in A_X$, $t \in A_Y$ and $x \in \mathcal{V}$.

The $\mathrm{Trees}(\Sigma, X)$ sets equipped with the operations of substitution and renaming form a tree algebra (it is the free tree algebra generated by $\emptyset$). For $\mathcal{A}$ a tree algebra, its associated *evaluation morphism* is the unique morphism from $\mathrm{Trees}(\Sigma)$ to $\mathcal{A}$.

A *congruence* $\sim$ over a tree algebra $\mathcal{A}$ is a family $\sim$ of equivalence relations over the A_X's (each denoted $\sim$) such that, for any $a \sim b \in A_X$, $c \sim d \in A_Y$, $y \in Y$ and $\sigma\colon X \to Y$: $c \cdot_y a \sim c \cdot_y b$; $c \cdot_y a \sim d \cdot_y a$ and $\widetilde{\sigma}(a) \sim \widetilde{\sigma}(b)$. From such a congruence, one can define the *quotient algebra* $\mathcal{A}/\sim$ in the natural way.

2.3 Languages and syntactic algebras

A *language of finite* Σ*-trees* L is a set of Σ-trees. It is *recognized by* a tree algebra $\mathcal{A}$ if there is a set $P \subseteq A_\emptyset$ such that $L = \alpha^{-1}(P)$ in which α is the evaluation morphism of $\mathcal{A}$.

The *syntactic congruence* $\sim_L$ *of a language* L of finite Σ-trees is defined in the following way $s \sim_L t$ for s, t finite Σ-trees if, for every context C, $[\![C]\!](s) \in L$ if and only if $[\![C]\!](t) \in L$. It is easy to prove that $\sim_L$ is indeed a congruence. The quotient algebra $\mathrm{Trees}(\Sigma)/_{\sim_L}$ is called the *syntactic algebra* of L, and this algebra recognizes L.

▶ **Example 5.** The language of all finite trees in which the symbol a appears on the leftmost branch has for syntactic tree algebra the algebra with sorts $A_X = \{\bot, \top\} \uplus X$ for every finite set of variables X. Let t be a Σ, X-tree, we define α as follows: $\alpha_X(t) = \top$ if there is an a on the leftmost branch of t, $\alpha_X(t) = x$ if the leftmost branch of t ends with an x but contains no a, and $\alpha_X(t) = \bot$ otherwise. The operations of the algebra are defined so that α becomes the evaluation morphism.

2.4 Complexity

Following [5], we define the notion of complexity and of orbit-complexity of a tree algebra $\mathcal{A}$.

Complexity. We start by highlighting the fact that any bijection σ between finite sets of variables X and Y induces a bijection $\widetilde{\sigma}$ between A_X and A_Y. As such, it is meaningful to define the *complexity map* of the algebra $c_{\mathcal{A}}\colon \mathbb{N} \to \mathbb{N}$ as follows:

$$c_{\mathcal{A}}(|X|) = |A_X| \ , \qquad \text{for every finite set of variables } X.$$

A tree algebra $\mathcal{A}$ has *bounded complexity* if $c_{\mathcal{A}}$ is bounded. It has *polynomial complexity* if there is a polynomial P such that $c_{\mathcal{A}}(n) \leqslant P(n)$ for every $n \in \mathbb{N}$.

Orbit-complexity. Similarly, we define the *orbit-complexity map* $c^{\circ}_{\mathcal{A}}\colon \mathbb{N} \to \mathbb{N}$ as:

$$c^{\circ}_{\mathcal{A}}(|X|) = |A_X/\mathbf{Sym}(X)| \ , \qquad \text{for every finite set of variables } X,$$

in which $A_X/\mathbf{Sym}(X)$ is the set of all orbits of A_X under the action of $\mathbf{Sym}(X)$. A tree algebra $\mathcal{A}$ has *bounded orbit-complexity* if $c^{\circ}_{\mathcal{A}}$ is bounded.

▶ **Example 6.** The tree algebra $\mathcal{A}$ from Example 5 has polynomial complexity and bounded orbit-complexity: $c_{\mathcal{A}}(n) = n + 2$ and $c^{\circ}_{\mathcal{A}}(n) = 3$ for every $n \in \mathbb{N}$.

To check whether a language of trees is recognized by an algebra with a prescribed complexity, one only needs to look at its syntactic algebra.

▶ **Lemma 7.** *If L is a language of Σ-trees recognized by a tree algebra $\mathcal{B}$, then its syntactic tree algebra $\mathcal{A}$ has lower complexity:*

$$c_{\mathcal{A}}(n) \leqslant c_{\mathcal{B}}(n) \quad \textit{and} \quad c^{\circ}_{\mathcal{A}}(n) \leqslant c^{\circ}_{\mathcal{B}}(n)\ ,\ \textit{for all } n \in \mathbb{N}.$$

2.5 Tree automata

A *tree automaton* $\mathcal{B} = (Q, I, (\delta_a)_{a\in\Sigma})$ over Σ has a finite set Q of *states*, a set of *accepting states* $I \subseteq Q$ and a *transition relation* $\delta_a \subseteq Q \times Q^{\mathrm{ar}(a)}$ for every symbol $a \in \Sigma$. A *run of* $\mathcal{B}$ over a finite tree t is a mapping $\rho\colon \mathrm{dom}(t) \to Q$ such that, for any vertex $u \in \mathrm{dom}(t)$ with $t(u) = a \in \Sigma$, $(\rho(u), (\rho(u0), ..., \rho(u(\mathrm{ar}(a) - 1)))) \in \delta_a$. A run is *accepting* if $\rho(\varepsilon) \in I$. A language L of finite trees is called *regular* if it is recognized by a tree automaton $\mathcal{B}$, meaning the trees in L are exactly those for which there is an accepting run in $\mathcal{B}$.

Example 8 below shows the translation from tree automata to tree algebra.

▶ **Example 8** (Automaton algebra)**.** Consider a regular language L of finite trees recognized by the tree automaton $\mathcal{B} = (Q, q_0, (\delta_a)_{a\in\Sigma})$. Consider some finite set of variables X. An *X-run profile* is a tuple $\tau \in Q \times \mathcal{P}(Q)^X$. For a Σ, X-tree t, $\tau = (p, (U_x)_{x\in X})$ is a *run profile over* t if there exists a run ρ of the automaton over Q such that $\rho(\varepsilon) = p$ and for every variables $x \in X$, U_x is the set of states assumed by ρ at leaves labelled x. We define a tree algebra $\mathcal{A}$ that has as elements of sort X sets of X-run profiles. The definition of the operations is natural, and is such that the image of a Σ, X-tree t under the evaluation morphism yields the set of run profiles over t. It naturally recognizes the language L.

Note that this definition yields an algebra of doubly exponential complexity (and hence, this is an upper bound for regular languages). Of course, in practice, one can restrict the algebra to the reachable elements, and this may dramatically reduce the complexity.

The converse translation is also true (it is for instance proved for preclones in [8]), yielding the following result.

▶ **Proposition 9.** *A finite tree language is regular if and only if it is recognized by a finite algebra. Moreover, every regular tree language is recognized by an algebra of doubly exponential complexity.*

2.6 Group actions and orbit-finite sets

To conclude this list of definitions, we recall some notions on group actions.

Group actions. A (left) group action of a group G on a set X is given by a function $\cdot\colon G \times X \to X$ such that $e \cdot x = x$ and $\sigma \cdot (\tau x) = (\sigma\tau) \cdot x$ for all $x \in X$ and $\sigma, \tau \in G$, where e is the neutral element of G. A set X equipped with such an action is called a *G-set.*

Orbits. For every x in a G-set X, the set $G \cdot x = \{\sigma \cdot x \mid \sigma \in G\}$ is called the *orbit* of x. A G-set is partitioned by the orbits of its elements, and it is said to be *orbit-finite* whenever it has only a finite number of different orbits.

Equivariant subsets and relations. Given a G-set X, a subset Y of X is *equivariant* if $\sigma \cdot Y = Y$ for every $\sigma \in G$. Accordingly, a relation $R \subseteq X \times Y$ between G-sets X and Y is equivariant if it is an equivariant subset of the G-set $X \times Y$ equipped with the point-wise action of G. In particular, a function $f\colon X \to Y$ is equivariant exactly when $f(\sigma \cdot x) = \sigma \cdot f(x)$ for all $x \in X$ and $\sigma \in G$.

Support and nominal sets. From now on, we will only be looking at the group $G = \mathbf{Sym}(\mathcal{V})$. Consider then a $\mathbf{Sym}(\mathcal{V})$-set X. A set $S \subseteq \mathcal{V}$ *supports* an element $x \in X$ if $\sigma \cdot x = x$ for every $\sigma \in \mathbf{Sym}(\mathcal{V} \setminus S)$, where $\mathbf{Sym}(\mathcal{V} \setminus S)$ is seen as a subgroup of $\mathbf{Sym}(V)$. A $\mathbf{Sym}(V)$-set is called a *nominal* set if all of its elements are supported by a finite set.

Given an element $x \in X$ that is finitely supported, it admits a least support. The *least support* of an element x from a nominal set X will be denoted $\mathrm{supp}(x)$.

Whenever A and B are $\mathbf{Sym}(\mathcal{V})$-sets, the set of all functions from A to B may be equipped with the action that maps $f\colon A \to B$ to $\sigma \cdot f$ defined for every $a \in A$ by $(\sigma \cdot f)(a) = \sigma \cdot f(\sigma^{-1} \cdot a)$. When seen in this way as a $\mathbf{Sym}(\mathcal{V})$-set, a function $f\colon A \to B$ is supported by $X \subseteq \mathcal{V}$ whenever $f(\sigma \cdot x) = \sigma \cdot f(x)$ for every $\sigma \in \mathbf{Sym}(\mathcal{V} \setminus X)$.

3 Nominal word automata for tree languages

We start our presentation by showing how nominal word automata can be used to describe regular languages of finite trees. To this end, we first explain in Section 3.1, how to encode trees into data words. In Section 3.2, we exploit this to interpret data languages as tree languages, using the notion of coding automata. In Section 3.3 we establish Proposition 16 stating that languages of trees that are described by coding automata are recognized by tree algebras of polynomial complexity and bounded orbit complexity (thus proving the implication from Item 4 to Items 1 and 2 of Theorem 1).

3.1 Coding languages

In this section, we show how to encode finite trees into data words.

Coding alphabet. We begin by defining the nominal alphabet used for this encoding:

- Let $C_{\mathcal{V}}$ be the set of elements $[x]$ for $x \in \mathcal{V}$.
- Let $C_{\mathcal{V},\Sigma}$ be the set of elements $[\cdot_x a(x_0, ..., x_{n-1})]$ for $a \in \Sigma_n$ and $x, x_0, ..., x_{n-1} \in \mathcal{V}$.
- Let $C = C_{\mathcal{V}} \uplus C_{\mathcal{V},\Sigma}$. It is called the *coding alphabet.*

The coding alphabet is naturally made into a $\mathbf{Sym}(V)$-set, by defining, for every $\sigma \in \mathbf{Sym}(\mathcal{V})$, $\sigma[x] = [\sigma(x)]$ and $\sigma[\cdot_x a(x_0, ..., x_{n-1})] = [\cdot_{\sigma(x)} a(\sigma(x_0), ..., \sigma(x_{n-1}))]$ for all $[x]$ and $[\cdot_x a(x_0, ..., x_{n-1})]$ in the coding alphabet. It is obviously both orbit-finite and nominal.

Tree coding. A *coding* is a word in $\mathrm{Codings} = C_{\mathcal{V}} C_{\mathcal{V},\Sigma}{}^*$. We shall describe now how codings can be evaluated to trees. This is natural since, forgetting the bracket notation, codings can be seen as tree expressions. The *evaluation* $T(c)$ of a coding c is defined as follows: $T([x]) = x$, where $[x] \in C_{\mathcal{V}}$ and $T(c[\cdot_x a(x_0, ..., x_{n-1})]) = \mathrm{create}_x(T(c)) \cdot_x a(x_0, ..., x_{n-1})$, where c is a tree coding and $[\cdot_x a(x_0, ..., x_{n-1})] \in C_{\mathcal{V},\Sigma}$.

▶ **Example 10.** According to the definition of evaluation, $T([x][\cdot_x a(x, y)]) = x \cdot_x a(x, y) = a(x, y)$. Similarly, $T([x][\cdot_x a(x, y)][\cdot_x c][\cdot_x d]) = ((x \cdot_x a(x, y)) \cdot_x c) \cdot_y d = a(c, d)$.

We will be particularly interested in codings c that evaluate to trees without variables (meaning $T(c) \in \text{Trees}(\Sigma, \emptyset)$). Let $\text{Codings}_\emptyset$ be the set of these codings that evaluate to variable-less trees.

Describing languages of trees. A language of codings K is said to *describe* a language L of trees without free variables if, for every coding $c \in \text{Codings}_\emptyset$, $c \in K$ if and only if $T(c) \in L$. The crucial point in this definition is that the language K may also contain codings that do not evaluate to a tree without free variables.

▶ **Example 11.** Let L be a language of trees without free variables, and let K be the language of all codings that evaluate to trees in L. Then both K and $K' = K \cup \{[x][\cdot_x a(x, y)]\}$ describe L. That is because $[x][\cdot_x a(x, y)] \notin \text{Codings}_\emptyset$.

However, not all languages of codings describe tree languages.

▶ **Example 12.** Let $\Sigma = \Sigma_0 \cup \Sigma_2$ with $\Sigma_0 = \{c\}$ and $\Sigma_2 = \{a, b\}$, and consider the language K of codings in which the third letter is $[\cdot_x c]$ for any choice of $x \in \mathcal{V}$.

Let $c = [x][\cdot_x a(x, y)][\cdot_y c][\cdot_x a(y, y)][\cdot_y c]$ and $c' = [x][\cdot_x a(x, y)][\cdot_x a(y, y)][\cdot_y c]$, then c is in K but not c'. Note however that $T(c) = T(c') = a(a(c, c), c)$, and thus K does not describe a language of trees.

3.2 Coding automata

Let us now look at acceptance of coding languages by automata. We start by recalling the notion of nominal automata [10], which is used to recognize data languages over orbit-finite nominal alphabets.

Nominal automaton. A *deterministic G-automaton* is given by

- an orbit-finite G-set A (the alphabet),
- a G-set Q (the states),
- an empty supported $q_0 \in Q$ called the *initial state*,
- an equivariant subset $F \subseteq Q$ of *final states*,
- and an equivariant function $\delta \colon Q \times A \to Q$ called the *transition function*.

Acceptance of a word $w \in A^*$ is then defined in the standard way. A deterministic G-automaton is called *orbit-finite* whenever Q is. It is called *nominal* when $G = \mathbf{Sym}(V)$ and when A and Q are both nominal sets. In this paper, we only consider *orbit-finite nominal automata.*

Coding automata. An orbit-finite nominal automaton $\mathcal{A}$ over the coding alphabet is called a *coding automaton* if it recognizes a language that describes a tree language. We also assume that there is no transition toward the initial state. The *tree language described* by a coding automaton is the language L of trees without free variables described by the language K recognized by $\mathcal{A}$. In other words, it is the language

$$L = \{T(c) \mid c \in \text{Codings}_\emptyset,\ \mathcal{A} \text{ accepts } c\} .$$

▶ **Example 13.** Let $\Sigma = \Sigma_0 \cup \Sigma_2$ with $\Sigma_0 = \{c\}$ and $\Sigma_2 = \{a, b\}$, and consider the language L of trees such that the total number of nodes labelled a appearing on the leftmost branch and the rightmost branch is even. We give a coding automaton that describes L. Its set of states is $Q = \{q_0\} \uplus \{\varepsilon(x) \mid x \in \mathcal{V}\} \uplus \{i(x, y) \mid i \in [2], x, y \in \mathcal{V} \cup \{*\}\}$, and the action of $\mathbf{Sym}(V)$ on Q is the one naturally obtained by permuting the variables. Its transitions are defined in the natural way so that:

- q_0 is the initial state,
- $\varepsilon(x)$ is reached from q_0 by reading $[x]$,
- $\delta(q_0, c) = i(x, y)$, in which i is the total number of nodes labelled a on the leftmost and rightmost branches of t modulo 2, and x (resp. y) is the variable on the leaf of the leftmost (resp. rightmost) branch ($*$ if there is no such variable), for $t = T(c)$.

Setting the only accepting state to be $0(*, *)$, this automaton describes L.

A coding automaton is thus a device that takes as input a top-down description of a tree (a coding), and that decides its belonging to a language while remembering only boundedly many variables. Intuitively, such a device can only remember what happens along boundedly many branches. The subtlety of the model is that it must always yield the same result for a given tree, nonwithstanding the actual coding that was provided.

Minimization. Coding automata can be minimized, in the sense that a coding automaton can be effectively turned into another one that describes the same tree language and is minimal. This property turns out to be key to prove Theorem 1. The construction, though similar to the classical one for minimizing nominal automata recognizing a word language, is not the same. One subtlety is that in our case, there are states in the automaton that may accept both codings in $\mathrm{Codings}_\emptyset$ and codings outside of $\mathrm{Codings}_\emptyset$. Standard constructions are not able to cope with such a phenomenon.

We start by defining the *Myhill-Nerode relation* (or *congruence*) of a tree language L over codings by $c \equiv_L c'$, for codings c, c', when

$$T(cv) \in L \Leftrightarrow T(c'v) \in L \quad \text{for all } v \in {C_{\mathcal{V},\Sigma}}^* \text{ such that } cv \in \mathrm{Codings}_\emptyset \text{ and } c'v \in \mathrm{Codings}_\emptyset \ .$$

Note here that the trees coded by c and c' may have a different set of free variables. This is the only subtlety in the proof of the following expected statement.

▶ **Lemma 14.** *The Myhill-Nerode relation of a tree language L is an equivariant congruence in the sense that it is an equivalence and $cv \equiv_L c'v$ for all codings c, c' such that $c \equiv_L c'$, and every $v \in {C_{\mathcal{V},\Sigma}}^*$.*

It is now standard (see e.g. [10]) to define the *minimal automaton* $\mathrm{Min}_L = (Q, q_0, F, \delta)$ of a tree language L as follows:

- $Q = \{q_0\} \uplus \mathrm{Codings}/_{\equiv_L}$, in which q_0 is the (fresh) initial state,
- $F = \{[c]_{\equiv_L} \mid [c]_{\equiv_L} \subseteq L\}$,
- the transition function δ is given by $\delta(q_0, [x]) = [\,[x]\,]_{\equiv_L}$ and $\delta([c]_{\equiv_L}, v) = [cv]_{\equiv_L}$,

where $[c]_{\equiv_L}$ is the $\equiv_L$-class of $c \in \mathrm{Codings}$.

▶ **Lemma 15.** *For L a a tree language described by a coding automaton,* Min_L *is effectively a coding automaton which describes L.*

3.3 From coding automata to tree algebras

Our next result is Proposition 16 below, which corresponds to the implication from Item 4 to Items 1 and 2 of Theorem 1.

▶ **Proposition 16.** *Every tree language L described by a coding automaton is also recognized by a tree algebra that has both polynomial complexity and bounded orbit-complexity.*

This is proved by transforming the minimal automaton $\mathrm{Min}_L = (Q, q_0, F, \delta)$ that describes a language L, into a tree algebra $\mathcal{A}$ that recognizes the same language and has both polynomial complexity and bounded orbit-complexity. We only outline this construction, which is similar to the monoid of transitions of a word automaton.

Let Q_- be $Q \setminus \{q_0\}$. Given a state $q \in Q_-$, a variable x and a tree t possibly with free variables, we define:

$$\delta_t(q, x) := \delta(q, v)$$

in which $v \in C_{\mathcal{V},\Sigma}{}^*$ is such that $T([x]v) = t$ and does not contain a letter of the form $[\cdot_y a(z_0, ..., z_{\mathrm{ar}(a)-1})]$ in which $y \in \mathrm{supp}(q) \setminus \{x\}$. This definition is shown to be meaningful, in the sense that it does not depend on the choice of v.

The elements of $\mathcal{A}$ are then defined to be the δ_t's, and the operations of the algebra are defined so that the image of a tree t under the evaluation morphism is δ_t. This algebra recognizes L and we show, this is the difficult part of the proof, that it has both polynomial complexity and bounded orbit-complexity.

4 Tree algebras

We now tackle the study of tree algebras of polynomial complexity and bounded orbit-complexity, and prove the remaining implications of Theorem 1. We first define in Section 4.1 the notion of system of supports of a tree algebra that appears in Theorem 1. In Section 4.2, we make use of this notion to prove Theorem 1. Finally we state Theorem 22, our decidability result, in Section 4.3.

4.1 Syntactic tree algebras and systems of supports

We start this section by defining systems of supports of a tree algebra. We then prove Lemma 17 which states that a syntactic tree algebra always has a minimal system of supports, and that it is stable (this property is mentionned in Item 3 of Theorem 1). Finally, we prove Proposition 19, corresponding to implications from Items 1 and 2 to Item 3 in Theorem 1.

System of supports. We now introduce the notion of system of supports. It is a way to transport the notion of support from $\mathbf{Sym}(V)$-sets to tree algebras, which are a collection of $\mathbf{Sym}(X)$-sets for X finite.

For every finite set of variables X, a subset S_a of X is a *support* of $a \in A_X$ if $\sigma(a) = a$ for every $\sigma \in \mathbf{Sym}(X \setminus S_a)$. A *system of supports* for an algebra $\mathcal{A}$ is a family $(S_a)_{a\in\mathcal{A}}$ such that S_a is a support of a for all finite X and $a \in A_X$.

Stability. The notion of system of supports is however lacking to describe properties of tree algebras, as there is no relation between the supports of the different elements, we introduce different notions of stability to cope with this issue.

We define the following properties for a system of supports $(S_a)_{a\in\mathcal{A}}$:

- Being *stable under renamings* if $S_{\sigma(a)} \subseteq \sigma(S_a)$ for $a \in A_X$, X finite, and renaming σ.
- Being *stable under internal substitutions* if $S_{a\cdot_x b} \subseteq (S_a \setminus \{x\}) \cup S_b$ for all $a \in A_X$, $x \in S_a$ and $b \in A_Y$, for finite X and Y.
- Being *stable under external substitutions* $S_{a\cdot_x b} \subseteq S_a$ for all $a \in A_X$, $x \in X \setminus S_a$ and all $b \in A_Y$, for finite X and Y.

- Being *stable under substitutions* if it is both stable under internal and external substitutions.

Finally, a system of supports is *stable* if it is both stable under renamings and substitutions, and it is *bounded* if there is a bound K such that $|S_a| \leq K$ for every $a \in \mathcal{A}$.

Our main result concerning systems of supports, Lemma 17, states the existence of a canonical support for syntactic tree algebras. Moreover, this system of supports $(S_a)_{a\in\mathcal{A}}$ is *minimal*, meaning that $S_a \subseteq T_a$, for every $a \in \mathcal{A}$ and every $(T_a)_{a\in\mathcal{A}}$ with the same stability properties.

▶ **Lemma 17.** *Let $\mathcal{A}$ be a syntactic tree algebra. Then $\mathcal{A}$ has a minimal stable system of supports.*

The proof of this result is lengthy and relies on the fact that a Σ, X-tree t can be seen as a Σ, Y-tree for all $X \subseteq Y$, allowing one to use standard techniques from nominal set theory. The system of supports introduced in Lemma 17 is the *canonical system of supports* of $\mathcal{A}$.

▶ **Example 18.** We once again take a look at the tree algebra introduced in Example 5. Its canonical system of supports is given, for all finite X, by:

$$S_\top = S_\bot = \emptyset \ , \qquad S_x = \{x\} \text{ for all } x \in X \ .$$

We now establish Proposition 19 below, corresponding to implications from Item 1 to Item 3 and from Item 2 to Item 3 of Theorem 1. According to Lemma 7, it is enough to prove the results for syntactic tree algebras, meaning we only need to prove that the canonical system of supports is bounded.

▶ **Proposition 19.** *Let $\mathcal{A}$ be a finite syntactic tree algebra that has either polynomial complexity or bounded orbit complexity. Then $\mathcal{A}$ has a bounded and stable system of supports.*

4.2 From tree algebras to coding automata

Our next result is Proposition 20 below, corresponding to implication from Item 3 to Item 4 of Theorem 1.

▶ **Proposition 20.** *Let L be recognized by a finite tree algebra with a bounded and stable system of supports. Then there is a coding automaton that describes L.*

The following Lemma 21 shows that we only need to consider syntactic tree algebras.

▶ **Lemma 21.** *Let L be a language of trees. If L is recognized by a tree algebra that has a bounded and stable system of supports, then the syntactic tree algebra of L can also be equipped with such a system of supports.*

From tree algebra to coding automata. Fix a language of trees L, let $\mathcal{A}$ be its syntactic tree algebra, and let $(S_a)_{a\in\mathcal{A}}$ be its canonical system of supports, which is bounded (by say K) and stable. In order to prove Proposition 20, we extract from $\mathcal{A}$ a coding automaton $\text{Auto}_\mathcal{A}$ that describes L. Intuitively, because $(S_a)_{a\in\mathcal{A}}$ is stable and bounded, $\mathcal{A}$ is uniquely determined by the A_X's for $|X| \leq K$. This is used to defined an appropriate automaton, whose set of states is orbit-finite.

This concludes the proof of Proposition 20 and thus the proof of Theorem 1.

4.3 Decidability

Our last result is the following.

▶ **Theorem 22.** *There is an algorithm which, given a regular tree language, decides whether it is recognizable by a tree algebra of polynomial complexity.*

The proof informally consists in constructing the expected coding automaton, dropping when possible the variables that are irrelevant for deciding the membership to the language (in the sense that, whatever tree is plugged in it, it does not change the membership to the language). The crucial point is to prove that a bounded number of variables suffices. Regular cost functions over finite trees provide a straightforward technique for solving this boundedness question [6].

5 Conclusion

We analyzed the expressive power of unrestrained tree algebras of polynomial complexity. Theorem 1 shows a link between combinatorial properties (being recognized by tree algebras of polynomial complexity, or of bounded orbit-complexity) and an algebraic one (being described by a coding automaton). Doing so, it gives a crisp description of the expressive power of this class of tree algebras, which we also proved to be decidable.

Other types of tree algebras. This theory is easily ported to affine tree algebras, for which we get the same equivalence and decidability results. In the case of relevant and linear tree algebras, however, the breaking point is the existence of a canonical system of supports. At the cost of a much more technical proof, it remains possible to prove the equivalence of Items 1, 3, and 4 in Theorem 1. We conjecture Theorem 1 to still hold.

Future work. A natural extension to this work is to study the expressive power of tree algebras of exponential complexity, which we conjecture to be the same as the one of tree algebras of polynomial orbit-complexity. Such tree algebras are much more expressive than those studied in this article. It is for instance easy to check that both of these classes subsume the one of languages recognized by top-down deterministic tree automata.

Abstract

We refine the complexity landscape for enumeration problems by introducing very low classes defined by using Boolean circuits as enumerators. We locate well-known enumeration problems, e.g., from graph theory, Gray code enumeration, and propositional satisfiability in our classes. In this way we obtain a framework to distinguish between the complexity of different problems known to be in **DelayP**, for which a formal way of comparison was not possible to this day.

1 Introduction

In computational complexity theory, most often decision problems are studied that ask for the existence of a solution to some problem instance, e.g., a satisfying assignment of a given propositional formula. In contrast, enumeration problems ask for a list of all solutions, e.g., all satisfying assignments. In many application areas these are the more "natural" kind of problems – let us just mention database queries, web search, diagnosis, data mining, bioinformatics, etc.

The notion of *tractability* for enumeration problems requires a new approach, simply because there may be a large number of solutions, exponential in the input size. Widely studied is the class **DelayP** ("polynomial delay"), containing all enumeration problems where, for a given instance x, (i) the time to compute the first solution, (ii) the time between producing any two consecutive solutions, and (iii) the time to detect that no further solution exists, are all polynomially bounded in the length of x. Also the class **IncP** ("incremental polynomial time"), where we allow the time to produce the next solution and to signal that no further solution exists to grow by a polynomial bounded in the size of the input *plus* the number of already computed solutions. These classes were introduced in 1988 in [14], and since then, an immense number of membership results have been obtained. Recently, also intractable enumeration problems have received some attention. Reducibilities, a completeness notion and a hierarchy of intractable enumeration problems, analogous to the well-known polynomial hierarchy, were defined and studied in [9].

In this paper we will look for notions of tractability for enumeration stricter than the above two. More specifically, we will introduce a refinement of the existing classes based on the computation model of Boolean circuits. The main new class in our framework is the class $\mathbf{Del}\cdot\mathbf{AC}^0$. An enumeration problem belongs to this class if there is a family of $\mathbf{AC}^0$ circuits, i.e., a family of Boolean circuits of constant depth and polynomial size with unbounded fan-in gates, that (i) given the input computes the first solution, (ii) given input

and a solution computes the next solution (in any fixed order of solutions), and (iii) given input and the last solution, signals that no further solution exists. Still using $\mathbf{AC}^0$ circuits we then consider extended classes by allowing

- precomputation of different complexity (typically, polynomial time precomputation) and/or
- memory to be passed on from the computation of one solution to the next (from a constant to a polynomial number of bits)

By this, we obtain a hierarchy of classes within **DelayP/IncP** shown in Fig. 1.

The main motivation behind our work is the wish to be able to compare the complexity of different tractable enumeration problems by classifying them in a fine hierarchy within **DelayP**, and to obtain lower bounds for enumeration tasks. From different application areas such as graph problems, Gray code enumeration and satisfiability, we identify natural problems, all belonging to **DelayP**, some of which can be enumerated in $\mathbf{Del}\cdot\mathbf{AC}^0$, some cannot, but allowing precomputation or a certain number of bits of auxiliary memory they can. We would like to mention in particular the maybe algorithmically most interesting contribution of our paper, the case of enumeration for satisfiability of 2-CNF (Krom) formulas. While it is known that counting satisfying assignments for formulas from this fragment of propositional logic is #**P**-complete [18], we exhibit a $\mathbf{Del}_\mathbf{P}\cdot\mathbf{AC}^0$ algorithm (i.e. $\mathbf{Del}\cdot\mathbf{AC}^0$ with polynomial time precomputation but no memory), for enumeration, thus placing the problem in one of the lowest class in our framework. This means that surprisingly satisfying assignments of Krom formulas can be enumerated very efficiently (only $\mathbf{AC}^0$ is needed to produce the next solution) after a polynomial time precomputation before producing the first solution.

Building on well-known lower bounds (in particular for the parity function [12, 1]) we prove (unconditional) separations among (some of) our classes and strict containment in **DelayP**, and building on well-known completeness results we obtain conditional separations, leading to the inclusions and non-inclusions depicted in Fig. 1.

Another refinement of **DelayP** that has received considerable attention in the past, in particular in the database community, is the class $\mathbf{CD}\circ\mathbf{lin}$ of problems that can be enumerated on RAMs with constant delay after linear time preprocessing [11] (see also the surveys [16, 10]). A consequence of the widely believed assumption that Boolean matrix multiplication cannot be computed in time linear in the number m of non-zero entries of the matrices A, B and AB (the so called BMM conjecture, see e.g. [5]), is that enumerating the one-entries in AB is not in $\mathbf{CD}\circ\mathbf{lin}$ [3], but we will see that it is in $\mathbf{Del}\cdot\mathbf{AC}^0$. On the other hand, the familiar lower bound for parity [1, 12] easily leads to an enumeration problem not in $\mathbf{Del}\cdot\mathbf{AC}^0$ but in $\mathbf{CD}\circ\mathbf{lin}$; hence we see that $\mathbf{CD}\circ\mathbf{lin}$ and $\mathbf{Del}\cdot\mathbf{AC}^0$ are incomparable classes; thus our approach provides a novel way to refine polynomial delay (see Section 3.3).

This paper is organized as follows. After some preliminaries, we introduce our new classes in Sect. 3. In Sect. 4 we present a number of upper and lower bounds for example enumeration problems from graph theory, Gray code enumeration and propositional satisfiability. Depending whether we allow or disallow precomputation steps, we obtain further conditional or unconditional separation results between classes in Sect. 5. Finally we conclude with a number of open problems.

Because of space limitations, some of our proofs are only sketched or even omitted here; full proofs will appear in the final version of this paper.

2 Preliminaries

Since our main computational model will be Boolean circuits, we fix the alphabet $\Sigma = \{0, 1\}$, and use this alphabet to encode graphs, formulas, etc., as usual. Any reasonable encoding will do for all of our results.

Let $R \subseteq \Sigma^* \times \Sigma^*$ be a computable predicate. We say that R is polynomially balanced, if there is a polynomial p such that for all pairs $(x, y) \in R$, we have $|y| \leq p(|x|)$. Now we define the enumeration problem associated to R as follows.

Enum·R
Input: $x \in \Sigma^*$
Output: an enumeration of elements in $\mathrm{Sol}_R(x) = \{y : R(x, y)\}$

We require that R is computable but do not make any complexity assumptions on R. In the enumeration context, it is sometimes stipulated that R is polynomial-time checkable, i.e., membership of (x, y) in R is decidable in time polynomial in the length of the pair [17, 6]. Generally, we do not require this, but we will come back to this point later.

We assume basic familiarity of the reader with the model of Boolean circuits, see, e.g., [20, 7]. We use $\mathbf{AC}^0$ to denote the class languages that can be decided by uniform families of Boolean circuits of polynomial size and constant depth with gates of unbounded fan-in. The class of functions computed by such circuit families is denoted by $\mathbf{FAC}^0$, and for simplicity often again by $\mathbf{AC}^0$. The notation for the corresponding class of languages/functions defined by uniform families of circuits of polynomial size and logarithmic depth with gates of bounded fan-in is $\mathbf{NC}^1$.

The actual type of uniformity used is of no importance for the results of the present paper. However, for concreteness, all circuit classes in this paper are assumed to be uniform using the "standard" uniformity condition, i. e., DLOGTIME-uniformity/$\mathrm{U_E}$-uniformity [4]; the interested reader may also consult the textbook [20].

3 Delay Classes with Circuit Generators

In this section we present the formal definition of our new enumeration classes. As we already said, we will restrict our definition to usual delay classes; classes with incremental delay can be defined analogously, however, we will see that our delay-classes with memory in a sense reflect incremental classes in the circuit model.

The main idea is that the generation of a *next* solution will be done by a circuit from a family; in the examples and lower and upper bounds in the upcoming sections, these families are usually of low complexity like $\mathbf{AC}^0$ or $\mathbf{NC}^1$. The generator will receive the original input word plus the previous solution. Parameters in the definition will be first the complexity of any precomputation before the first solution is output, and second the amount of information passed from the generation of one solution to the next.

3.1 Delay Classes with no Memory

For a family $\mathcal{C} = (C_n)_{n\in\mathbb{N}}$ of Boolean circuits, circuit C_i will be the circuit in the family with i input gates. When the length of the circuit input is clear from the context, we will usually simply write $C_{|\cdot|}$ to refer to the circuit with appropriate number of input gates. In the subsequent definitions we use $\mathcal{K}$ to denote a complexity classes defined by families of Boolean circuits obeying certain complexity restrictions. Examples are the above mentioned cases $\mathcal{K} = \mathbf{AC}^0$ or $\mathcal{K} = \mathbf{NC}^1$, but any circuit complexity class will do. Our definitions make sense both for uniform and for non-uniform classes.

▶ **Definition 1** ($\mathcal{K}$-delay). *Let R be a polynomially balanced predicate. The enumeration problem* Enum$\cdot R$ *is in* $\mathbf{Del}\cdot\mathcal{K}$ *if there exists a family of $\mathcal{K}$-circuits $\mathcal{C} = (C_n)_{n\in\mathbb{N}}$ such that, for all inputs x, there is an enumeration $y_1, ..., y_k$ of $\mathrm{Sol}_R(x)$ and:*

- $C_{|\cdot|}(x) = y_1 \in \mathrm{Sol}_R(x)$,
- *for all $i < k$:* $C_{|\cdot|}(x, y_i) = y_{i+1} \in \mathrm{Sol}_R(x)$
- $C_{|\cdot|}(x, y_k) = y_k$

Note that by the last requirement, the circuit family signals there is no further solution if the input solution is given again as output. Moreover, we point out that, in the definition above, if x is an input and $y \in \mathrm{Sol}_R(x)$, then $C_{|x|+|y|}$ produces a $z \in \mathrm{Sol}_R(x)$. However, if $y \notin \mathrm{Sol}_R(x)$, nothing is specified about the output z.

Next we consider classes where a precomputation before outputting the first solution is allowed. The ressource bounds of the precomputation are specified by an arbitrary complexity class.

▶ **Definition 2** ($\mathcal{K}$-delay with T-precomputation). *Let R be a polynomially balanced predicate and T be a complexity class. The enumeration problem* Enum$\cdot R$ *is in* $\mathbf{Del}_T\cdot\mathcal{K}$ *if there exists an algorithm M working with resource T and a family of $\mathcal{K}$-circuits $\mathcal{C} = (C_n)_{n\in\mathbb{N}}$ such that, for all input x there is an enumeration $y_1, ..., y_k$ of $\mathrm{Sol}_R(x)$ and:*

- *M computes some value x^*, i.e., $M(x) = x^*$*
- $C_{|\cdot|}(x^*) = y_1 \in \mathrm{Sol}_R(x)$,
- *for all $i < k$:* $C_{|\cdot|}(x^*, y_i) = y_{i+1} \in \mathrm{Sol}_R(x)$
- $C_{|\cdot|}(x^*, y_k) = y_k$

3.2 Delay Classes with Memory

Extending the above model, we now allow each circuit to produce slightly more than the next solution. These additional information is then passed as extra input to the computation of the next solution, in other words, it can serve as an auxiliary memory.

▶ **Definition 3** ($\mathcal{K}$-delay with auxiliary memory). *Let R be a polynomially balanced predicate. The enumeration problem* Enum$\cdot R$ *is in* $\mathbf{Del}^*\cdot\mathcal{K}$ *if there exist two families of $\mathcal{K}$-circuits $\mathcal{C} = (C_n)_{n\in\mathbb{N}}$, $\mathcal{D} = (D_n)_{n\in\mathbb{N}}$ such that, for all input x there is an enumeration $y_1, ..., y_k$ of $\mathrm{Sol}_R(x)$ and:*

- $C_{|\cdot|}(x) = y_1^*$ *and* $D_{|\cdot|}(y_1^*) = y_1 \in \mathrm{Sol}_R(x)$,
- *for all $i < k$:* $C_{|\cdot|}(x, y_i^*) = y_{i+1}^*$ *and* $D_{|\cdot|}(y_{i+1}^*) = y_{i+1} \in \mathrm{Sol}_R(x)$,
- $C_{|\cdot|}(x, y_k^*) = y_k^*$,
- *for $1 \leq i \leq k$, y_i is a prefix of y_i^*; i. e., the information y_i^* passed on to the next round consists of the previous solution y_i plus any additional information.*

When there exists a polynomial $p \in \mathbb{N}[x]$ such that $|y_i^*| \leq p(|x|)$, for all $i \leq k$, the class is called $\mathbf{Del}^{\mathrm{P}}\cdot\mathcal{K}$*, $\mathcal{K}$-*delay with polynomial auxiliary memory. *When there exists a constant $c \in \mathbb{N}$ such that $|y_i^*| \leq |y_i| + c$, for all $i \leq k$, the class is called* $\mathbf{Del}^{\mathrm{c}}\cdot\mathcal{K}$*, $\mathcal{K}$-*delay with constant auxiliary memory.

The idea is that the y_i^* will contain the previous solution plus the additional memory. Hence the superscript “c” indicates a bounded auxiliary memory size.

By abuse of expression, we will sometimes say that a problem in some of these classes above can be enumerated with a delay in $\mathcal{K}$ or with a $\mathcal{K}$-delay. When there is no restriction on memory i.e. when considering the class $\mathbf{Del}_T^*\cdot\mathcal{K}$, an incremental enumeration mechanism can be used. Indeed, the memory can then store all solutions produced so far which results in an increase of the expressive power.

Also in the case of memory, we allow possibly precomputation before the first output is made:

▶ **Definition 4** ($\mathcal{K}$-delay with T-precomputation and auxiliary memory)**.** *Let R be a polynomially balanced predicate and T be a complexity class. The enumeration problem* Enum·R *is in* $\mathbf{Del}^*_T{\cdot}\mathcal{K}$ *if there exists an algorithm M working with resource T and two families of $\mathcal{K}$-circuits $\mathcal{C} = (C_n)_{n\in\mathbb{N}}$, $\mathcal{D} = (D_n)_{n\in\mathbb{N}}$ such that, for all input x there is an enumeration $y_1, ..., y_k$ of* $\mathrm{Sol}_R(x)$ *and:*

- *M computes some value x^*, i.e., $M(x) = x^*$,*
- *$C_{|\cdot|}(x^*) = y^*_1$ and $D_{|\cdot|}(y^*_1) = y_1 \in \mathrm{Sol}_R(x)$,*
- *for all $i < k$: $C_{|\cdot|}(x^*, y^*_i) = y^*_{i+1}$ and $D_{|\cdot|}(y^*_{i+1}) = y_{i+1} \in \mathrm{Sol}_R(x)$,*
- *$C_{|\cdot|}(x^*, y^*_k) = y^*_k$,*
- *for $1 \le i \le k$, y_i is a prefix of y^*_i.*

When there exists a polynomial $p \in \mathbb{N}[x]$ such that $|y^*_i| \le p(|x|)$, for all $i \le k$, the class is called $\mathbf{Del}^{\mathrm{P}}_T{\cdot}\mathcal{K}$, $\mathcal{K}$-delay with T-precomputation and polynomial auxiliary memory*. When there exists a constant $c \in \mathbb{N}$ such that $|y^*_i| \le |y_i| + c$, for all $i \le k$, the class is called $\mathbf{Del}^{\mathrm{c}}_T{\cdot}\mathcal{K}$,* $\mathcal{K}$-delay with T-precomputation and constant auxiliary memory*.*

3.3 Relation to Known Enumeration Classes

All classes we consider in this paper are subclasses of the well-known classes **DelayP** or **IncP**, resp., even if we allow our circuit to be of arbitrary depth (but polynomial size).

▶ **Theorem 5.** *If $\mathcal{K}, T \subseteq \mathbf{P}$, then $\mathbf{Del}^{\mathrm{P}}_T{\cdot}\mathcal{K} \subseteq \mathbf{DelayP}$ and $\mathbf{Del}^*_T{\cdot}\mathcal{K} \subseteq \mathbf{IncP}$.*

Let us briefly clarify the relation between our classes and the class **CD∘lin** of enumeration problems that have a constant delay on a RAM after linear-time precomputation. This class was introduced in [11].

The algorithmic problem, given a graph, to enumerate all pairs of vertices that are connected by a path of length 2 has only a polynomial number of solutions and is trivially in $\mathbf{Del}{\cdot}\mathbf{AC}^0$. Since it is essentially the same as Boolean matrix multiplication, it is not in **CD∘lin**, assuming the beforementioned BMM hypothesis.

On the other hand, note that the enumeration problem Enum-Parity, given as input a sequence of bits with the solution set consisting only of one solution, the parity of the input, is not in $\mathbf{Del}{\cdot}\mathbf{AC}^0$, since the parity function is not in $\mathbf{AC}^0$ [12, 1]. However, since Parity can be computed in linear time, Enum-Parity is trivially in **CD∘lin**.

As we will show in detail in the full version of this paper, the computation of a constant number of time steps of a RAM can be simulated by $\mathbf{AC}^0$ circuits. Hence if we add linear precomputation and polynomial memory to save the configuration of the RAM, we obtain an upper bound for **CD∘lin**. To summarize:

▶ **Theorem 6.** *Assuming the BMM hypothesis, the classes $\mathbf{Del}{\cdot}\mathbf{AC}^0$ and **CD∘lin** are incomparable, and* $\mathbf{CD{\circ}lin} \subsetneq \mathbf{Del}^{\mathrm{P}}_{lin}{\cdot}\mathbf{AC}^0$.

4 Examples

In this section we show that many natural problems, ranging from graph problems, enumeration of Gray codes and satisfiability problems lie in our circuit classes.

4.1 Graph Problems

We first consider the enumeration problem associated with the notion of reachability in a graph.

Enum-Reach
Input: a graph $G = (V, E)$, $s \in V$
Output: an enumeration of vertices reachable from s

▶ **Theorem 7.** Enum-Reach $\in \mathbf{Del}^{\mathrm{P}} \cdot \mathbf{AC}^0$

Proof. At each step multiplication of Boolean matrices gives the set of vertices which are reachable from s with one more step. This can be done in $\mathbf{AC}^0$. The polynomial memory is used to remember all vertices that have been encountered to far. Observe that in each step, more vertices are being produced, until we reach convergence. ◀

Let us now turn to the enumeration of all transversals (i. e., vertex-sets intersecting every edge), not only the minimal ones.

Enum-Transversal
Input: A hypergraph $H = (V, \mathcal{E})$
Output: an enumeration of all transversals of H

▶ **Theorem 8.** Enum-Transversal $\in \mathbf{Del} \cdot \mathbf{AC}^0$.

Proof. Let $\mathcal{E}$ be a set of hyperedges over a set of n vertices. Every binary word $y = y_1 \cdots y_n \in \{0,1\}^n$ can be interpreted as a subset of vertices. We propose an algorithm that enumerates each of these words that corresponds to a transversal of H in lexicographical order with the convention $1 < 0$. The algorithm is as follows:

- As a first step output $1 \ldots 1$, the trivial solution.
- Let H be the input and y be the last output solution.
  - For each prefix $y_1 \ldots y_i$ of y with $y_i = 1$ and $i \leq n$ consider the word of length n, $z^i = y_1 \ldots y_{i-1} 01 \ldots 1$.
  - Check whether at least one of these words z^i is a transversal of H.
  - If yes select the one with the longest common prefix with y, that is the transversal z^i with the largest i and output it as the next solution.
  - Else stop.

First we prove that the algorithm is correct. The transversal that is the successor of y in our lexicographical order (where $1 < 0$), if it exists, has a common prefix with y, then a bit flipped from 1 to 0, and finally is completed by 1's only. Indeed, a successor of y necessarily starts this way, and by monotonicity the first extension of such a prefix into a solution is the one completed by 1's only. As a consequence our algorithm explores all possible candidates and select the next transversal in the lexicographical order.

Now let us prove that this is an $\mathbf{AC}^0$-delay enumeration algorithm that does not require memory. The main observation is that one can check with an $\mathbf{AC}^0$ circuit whether a binary word corresponds to transversal of H. Now, for each i we can use a sub-circuit, which on input (H, y) checks whether $y_i = 1$ and if yes whether z^i is a transversal of H. This circuit can output $(z^i, 1)$ if both tests are positive, and $(y_i, 0)$ otherwise. All these sub-circuits can be wired in parallel. Finally it suffices to use a selector to output z^i with the largest i for which $(z^i, 1)$ is output at the previous step. Such a selector can be implemented by an $\mathbf{AC}^0$ circuit. ◀

It is then easy to show (in a similar way) that enumeration of all dominating sets of a graph can be done in $\mathbf{Del}{\cdot}\mathbf{AC}^0$.

4.2 Gray Code

Given $n \in \mathbb{N}$, a Gray n-code is a ranked list of elements of Σ^n such that between two successive words x, y there exists only one bit such that $x_i \neq y_i$. Since we deal with Boolean circuits, we have to fix $\Sigma = \{0,1\}$, but Gray codes are defined for arbitrary alphabets.

The binary reflected Gray code of length n, denoted G^n, is made of 2^n words: $G^n = [G^n_0, G^n_1, \ldots, G^n_{2^n-1}]$. It is defined recursively as follows: $G^1 = [0,1]$ and, for $n \geq 1$

$$G^n = [0G_0^{n-1}, 0G_1^{n-1}, \ldots, 0G_{2^{n-1}-1}^{n-1}, 1G_{2^{n-1}-1}^{n-1}, \ldots, 1G_1^{n-1}, 1G_0^{n-1}].$$

As an example let us consider the list of pairs $(rank, word)$ for $n = 4$: $(0, 0000)$, $(1, 0001)$, $(2, 0011)$, $(3, 0010)$, $(4, 0110)$, $(5, 0111)$, $(6, 0101)$, $(7, 0100)$, $(8, 1100)$, $(9, 1101)$, $(10, 1111)$, $(11, 1110)$, $(12, 1010)$, $(13, 1011)$, $(14, 1001)$, $(15, 1000)$.

Given n and $r < 2^n$, let $b_{n-1} \cdots b_1 b_0$ be the binary decomposition of r and $G^n_r = a_{n-1} \cdots a_1 a_0 \in \Sigma^n$ be the rth word in the binary reflected code of length n. It is well-known that, for all $j = 0, ..., n-1$,

$$b_j = \sum_{i=j}^{n-1} a_i \bmod 2 \text{ and } a_j = (b_j + b_{j+1}) \bmod 2.$$

Hence computing the rank of a word in the binary reflected code amounts to be able to compute parity. On the other side, computing the word from its rank can easily be done by a circuit.

While it is trivial to enumerate all words of length n in arbitrary or lexicographic order, this is not so clear for Gray code order. Also, given a rank or a first word, to enumerate all words of higher Gray code rank (in arbitrary order) are interesting computational problems.

Enum-Gray-Rank
Input: a binary word r of length n interpreted as an integer in $[0, 2^n[$
Output: an enumeration of words of G^n that are of rank at least r.

Enum-Gray-Word
Input: a word x of length n
Output: an enumeration of words of G^n, that are of rank at least the rank of x.

It turns out that for those problems where the order of solutions is not important, a very efficient enumeration is possible:

▶ **Theorem 9.** *Let n be an integer*

1. *Given 1^n, enumerating all words of length n even in lexicographic ordering is in* $\mathbf{Del}{\cdot}\mathbf{AC}^0$
2. Enum-Gray-Rank $\in \mathbf{Del}{\cdot}\mathbf{AC}^0$
3. Enum-Gray-Word $\in \mathbf{Del}{\cdot}\mathbf{AC}^0$

We next turn to those versions of the above problems, where we require that solutions are given one after the other in Gray code order. For each of them, the computational complexity is provably higher than in the above cases.

▶ **Theorem 10.** *Given 1^n, enumerating all words of length n in a Gray code order is in* $\mathbf{Del}^{\mathrm{c}}{\cdot}\mathbf{AC}^0 \setminus \mathbf{Del}_{\mathbf{P}}{\cdot}\mathbf{AC}^0$

Proof. A classical method to enumerate gray code of length n is the following [15].

- Step 0 : produce the word $0 \cdots 0$ of length n.
- Step $2k+1$: switch the bit at position 0.
- Step $2k+2$: find minimal position i where there is a 1 and switch bit at position $i+1$.

This method can be turned into an $\mathbf{AC}^0$-delay enumeration without precomputation using one bit of memory (to keep trace if the step is an even or odd one all along the computation). This proves the membership in $\mathbf{Del}^{\mathrm{c}} \cdot \mathbf{AC}^0$.

For the lower bound, suppose $\mathcal{C} = (C_n)_{n \in \mathbb{N}}$ is an $\mathbf{AC}^0$ circuit family enumerating the Gray code of length n after polynomial time precomputation produced by machine M. We will describe how to use $\mathcal{C}$ to construct an $\mathbf{AC}^0$-family computing the parity function, contradicting the lower bound given by [1, 12].

Given is an arbitrary word $w = w_{n-1} \ldots w_0$ of length n, and we want to compute its parity $\left(\sum_{i=0}^{n-1} w_i\right) \bmod 2$. Let $x^* = M(1^n)$. Then, w will appear as a solution somewhere in the enumeration defined by $\mathcal{C}$. Let w' be the next words after w. There exists r such that $G_r^n = w$ and $G_{r+1}^n = w'$. By comparing w and w', one can decide which transformation step has been applied to w to obtain w' and thus if r is odd or even. Note that the parity of w is 1 if and only if r is odd. Hence, one can compute parity by a constant depth circuit operating as follows:

```
Input $w$:
    $n := |w|$;
    $x^* := M(1^n)$;
    $w' := C_{|\cdot|}(x^*, w)$;
    if last bits of $w$ and $w'$ differ then $v := 1$ else $v := 0$;
    output $v$.
```

Note that the computation of x^* does not depend on w but only on the length of w; hence x^* can be hardwired into the circuit family, which, since M runs in polynomial time, will then be P-uniform. But we know from [12, 1] that parity cannot even be computed by non-uniform $\mathbf{AC}^0$ circuit families. ◀

We also consider the problem of enumerating all words starting not from the first one but at a given position, but now in Gray code order. Surprisingly this time the complexity will depend on how the starting point is given, by rank or by word.

Enum-Gray-Rank$_{ord}$
Input: A binary word r of length n interpreted as an integer in $[0, 2^n[$
Output: an enumeration of words of G^n in increasing number of ranks starting from rank r.

Enum-Gray-Word$_{ord}$
Input: A word x of length n
Output: an enumeration of words of G^n in Gray code order that are of rank at least the rank of x.

▶ **Theorem 11.** 1. Enum-Gray-Rank$_{ord} \in \mathbf{Del}^{\mathrm{c}} \cdot \mathbf{AC}^0 \setminus \mathbf{Del}_{\mathbf{P}} \cdot \mathbf{AC}^0$.
2. Enum-Gray-Word$_{ord}$ *is in the class* $\mathbf{Del}^{\mathrm{c}}_{\mathbf{P}} \cdot \mathbf{AC}^0$*, but neither in* $\mathbf{Del}_{\mathbf{P}} \cdot \mathbf{AC}^0$ *nor* $\mathbf{Del}^{\mathrm{c}} \cdot \mathbf{AC}^0$.

4.3 Satisfiability Problems

Deciding the satisfiability of a CNF-formula is well-known to be $\mathbf{NP}$-complete. Nevertheless the problem becomes tractable for some restricted classes of formulas. For such classes we investigate the existence of an $\mathbf{AC}^0$-delay enumeration algorithm. First we consider monotone formulas.

Enum-Monotone-Sat
Input: A set of positive (resp. negative) clauses Γ over a set of variables V
Output: an enumeration of all assignments over V that satisfy Γ

The following positive result is an immediate corollary of Theorem 8.

▶ **Theorem 12.** Enum-Monotone-Sat $\in \mathbf{Del}\cdot\mathbf{AC}^0$.

If we allow polynomial precomputation, then we obtain an $\mathbf{AC}^0$-delay enumeration algorithm for a class of CNF-formulas, referred to as IHS in the literature (for Implicative Hitting Sets, see [8]), which is larger than the monotone class. A formula in this class consists of monotone clauses (either all positive or all negative) together with implicative clauses.

Enum-IHS-Sat
Input: A set of clauses $\mathcal{C}$ over a set of variables V, with $\mathcal{C} = \mathcal{M} \cup \mathcal{B}$, where $\mathcal{M}$ is a set of positive clauses (resp. negative clauses) and $\mathcal{B}$ a set of clauses of the form $(\neg x)$ or $(x \vee \neg x')$ (resp. of of the form (x) or $(x \vee \neg x')$)
Output: an enumeration of all assignments over V that satisfy Γ

▶ **Theorem 13.** Enum-IHS-Sat $\in \mathbf{Del_P}\cdot\mathbf{AC}^0 \setminus \mathbf{Del}^*\cdot\mathbf{AC}^0$.

Proof sketch. Observe that contrary to the monotone case 1....1 is not a trivial solution. Indeed a negative unary clause $(\neg x)$ in $\mathcal{B}$ forces x to be assigned 0, and this truth value can be propagated to other variables by the implicative clauses of the form $(x \vee \neg x')$. For this reason as a precomputation step, for each variable x we compute $\mathrm{tc}(x)$ the set of all variables that have to be set to 0 in any assignment satisfying Γ in which x is assigned 0. With this information we can use an algorithm that enumerates all truth assignments satisfying Γ in lexicographical order very similar to the one used for enumerating the transversals of a graph (see the proof of Theorem 8).

For the lower bound, consider the st-connectivity problem: given a directed graph $G = (V, A)$ with two distinguished vertices s and t, decide whether there exists a path from s to t. From G, s and t we build an instance of Enum-IHS-Sat as follows. We consider a set a clauses $\mathcal{C} = \mathcal{P} \cup \mathcal{B}$, where $\mathcal{P} = \{(s \vee t)\}$ and $\mathcal{B} = \{(\neg s)\} \cup \{(x \vee \neg y) \mid (x, y) \in A\}$. This is an $\mathbf{AC}^0$-reduction.

Observe that there exists a path from s to t if and only if Γ is unsatisfiable. Suppose that Enum-IHS-Sat $\in \mathbf{Del}\cdot\mathbf{AC}^0$, this means in particular that outputting a first assignment satisfying Γ or deciding there is none is in $\mathbf{AC}^0$. Thus the above reduction shows that st-connectivity is in $\mathbf{AC}^0$, thus contradicting the fact that st-connectivity is known not to be in $\mathbf{AC}^0$ (see [12, 1]). ◀

Surprisingly the enumeration method used so far for satisfiability problems presenting a kind of monotonicity can be used for the enumeration of all assignments satisfying a Krom set of clauses (i.e., a 2-CNF formula) as soon as the literals are considered in an appropriate order.

▶ **Theorem 14.** Enum-Krom-Sat $\in \mathbf{Del_P}\cdot\mathbf{AC}^0 \setminus \mathbf{Del}^*\cdot\mathbf{AC}^0$.

Proof sketch. The proof builds on the algorithm in [2] that decides whether a set of Krom clauses is satisfiable in linear time.

Let Γ be a set of 2-clauses over a set of n variables V. We perform the following precomputation steps:

- Build the associated implication graph, i.e., the directed graph G whose set of vertices is the set of literals $V \cup \{\bar{v} : v \in V\}$. For any 2-clause $(l \vee l')$ in Γ there are two arcs $\bar{l} \to l'$ and $\bar{l'} \to l$ in G.

- For each literal l compute $\text{tc}(l)$ the set of vertices that are reachable from l in G.
- Compute the set of strongly connected components of G. If no contradiction is detected, that is if no strongly connected component contains both a variable x and its negation, then contract each strongly connected component into one vertex. The result of this operation is a DAG, which, by abuse of notation, we also call G.
- Compute a topological ordering of the vertices of G.
- In searching through this topological ordering, build an ordered sequence M of n literals corresponding to the first occurrences of each variable.

If the set of clauses is satisfiable, one can enumerate the satisfying assignments given as truth assignments on M in lexicographic order. The enumeration process is similar in spirit as the one developed in the preceding theorem.

For the lower bound, the proof given in Theorem 13 applies. ◀

We next turn to the special case where clauses are XOR-clauses, i.e., clauses in which the usual "or" connective is replaced by the exclusive-or connective, $\oplus$. Such a clause can be seen as a linear equation over the two elements field $\mathbb{F}_2$.

Enum-XOR-Sat
Input: A set of XOR-clauses Γ over a set of variables V
Output: an enumeration of all assignments over V that satisfy Γ

If we allow a polynomial precomputation step, then we obtain an $\mathbf{AC}^0$-delay enumeration algorithm for this problem that uses constant memory. Interestingly this algorithm relies on the efficient enumeration of binary words in a Gray code order that we have seen in the previous section and contrary to the satisfiability problems studied so far does not provide an enumeration in lexicographic order.

▶ **Theorem 15.** Enum-XOR-Sat $\in \mathbf{Del}^{\mathrm{c}}_{\mathbf{P}}\cdot\mathbf{AC}^0 \setminus \mathbf{Del}^*\cdot\mathbf{AC}^0$.

Proof sketch. Observe that a set of XOR-clauses Γ over a set of variables $V = \{x_1, \ldots x_n\}$ can be seen as a linear system over V on the two elements field $\mathbb{F}_2$. As a consequence enumerating all assignments over V that satisfy Γ comes down to enumerating all solutions of the corresponding linear system.

As a precomputation step we apply Gaussian elimination in order to obtain an equivalent triangular system. If the system has no solution, we indicate this as required by Definition 1. Otherwise we can suppose that the linear system is of rank $n-k$ for some $0 \leq k \leq n-1$, and without loss of generality that $x_1, \ldots, x_k$ are free variables, whose assignment determines the assignment of all other variables in the triangular system. We then compute a first solution s_0 corresponding to $x_1, \ldots, x_k$ assigned $0 \ldots 0$. Next, for each $i = 1, \ldots, k$ compute the solution s_i corresponding to all variables in $x_1, , \ldots x_k$ assigned 0 except x_i which is assigned 1. Compute then the influence list of x_i, $L(x_i) = \{j \mid k+1 \leq j \leq n, s_0(x_j) \neq s_i(x_j)\}$. The influence list of x_i gives the bits that will be changed when going from a solution to another one in flipping only the bit x_i in the prefix corresponding to the free variables. Observe that this list does not depend on the solution (s_0 in the definition) we start from.

With this precomputation we start our enumeration procedure, which uses the enumeration of binary prefixes of length k in a Gray code order as a subprocedure. ◀

5 Separations of Delay Classes

In the previous results we already presented a few lower bounds, but now we will systematically strive to separate the studied classes.

As long as no precomputation is allowed, we are able to separate all delay classes – with the exception of the class with unbounded auxiliary memory. With precomputation, the situation seems to be more complicated. We obtain only a conditional separation of the class with constant memory from the one without memory at all.

5.1 Unconditional Separations for Classes without Precomputation

▶ **Theorem 16.** $\mathbf{Del}\cdot\mathbf{AC}^0 \subsetneq \mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0$

Proof. Let $x \in \{0,1\}^*$, $|x| = n \in \mathbb{N}^*$, $x = x_1 \dots x_n$. We denote by $m = \lceil \log n \rceil + 1$. Let R_L be defined for all $x \in \{0,1\}^*$ as the union of the two following sets A and B:

- $A = \{\, y \in \{0,1\}^* \big| |y| = m, y \neq 0^m, y \neq 1^m \,\}$
- $B = \{\, 1^m \}$ if x has an even number of ones, else $B = \{\, 0^m \}$.

We denote by $z_1, ..., z_t$ an enumeration of elements of A. Clearly, $|R_L(x)| = t + 1$ and $t \geq n$. To show that $R_L \in \mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0$, we use the enumeration of elements of A (which is easy) and one additional memory bit that is transferred from one step to the other to compute Parity. Indeed, we build families of circuits (C_n) and (D_n) according to Definition 3 as follows.

- First $C_{|\cdot|}(x)$ computes $y_1^* = z_1 b^1$ where $b^1 = x_1$, and $D_{|\cdot|}(y_1^*) = z_1$.
- For $1 < i \leq t$, the circuit $C_{|\cdot|}(x, y_{i-1}^*)$ computes y_i^*, where $y_i^* = z_i b^i$ with $b^i = b^{i-1} \oplus x_i$ if $i \leq n$, and $b^i = b^{i-1}$ else, and $D_{|\cdot|}(y_i^*) = z_i$.
- After t steps, the memory bit b^t contains a 0 if and only if the number of ones in x is even. According to this, we either output 1^m or 0^m as last solution.

Note that the size of the solutions is m, the size of the memory words above is $m + 1$, hence we need constant amount of additional memory. The circuit families (C_n) and (D_n) are obviously DLOGTIME-uniform.

Suppose now that $R_L \in \mathbf{Del}\cdot\mathbf{AC}^0$ and let (C_n) be the associated family of enumeration circuits. We construct a circuit family as follows: We compute in parallel all $C_{|\cdot|}(x)$ and $C_{|\cdot|}(x, z_i)$ for $1 \leq i \leq t$. In this way, we will obtain among other solutions either 0^m or 1^m. We accept in the first case. Note that the z_i are the same for all inputs x of the same length. Thus, we obtain an $\mathbf{AC}^0$ circuit family for parity, contradicting [12, 1]. ◀

By extending the above approach, one can prove the following separation:

▶ **Theorem 17.** $\mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0 \subsetneq \mathbf{Del}^{\mathrm{P}}\cdot\mathbf{AC}^0$

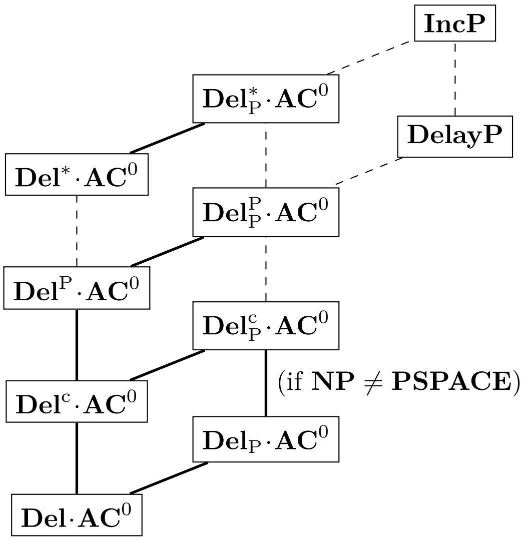
The parity problem can be seen as an enumeration problem: given x, one output the unique solution 1 if the number of ones in x is even. One outputs 0 if it is odd. Since as a function problem, parity can not be in $\mathbf{Del}^{\mathrm{P}}\cdot\mathbf{AC}^0$ (the fact there is only one solution makes memory useless). It is obviously in **DelayP**. This implies that $\mathbf{Del}^{\mathrm{P}}\cdot\mathbf{AC}^0 \subsetneq \mathbf{DelayP}$. Putting all the previous results together, we conclude:

▶ **Corollary 18.** $\mathbf{Del}\cdot\mathbf{AC}^0 \subsetneq \mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0 \subsetneq \mathbf{Del}^{\mathrm{P}}\cdot\mathbf{AC}^0 \subsetneq \mathbf{DelayP}$.

5.2 Conditional Separation for Classes with Precomputation

If precomputation is allowed, the separation proofs of the previous subsection no longer work; in fact we do not know if the corresponding separations hold. However, under reasonable complexity-theoretic assumptions we can at least separate the classes $\mathbf{Del}_{\mathbf{P}}\cdot\mathbf{AC}^0$ and $\mathbf{Del}^{\mathrm{c}}_{\mathbf{P}}\cdot\mathbf{AC}^0$. Note that in Theorem 10 we already proved a separation of just these two classes, but this concerns only the special case of ordered enumeration, and does not say anything about the general case. We find it interesting that the proof of the result below relies on a characterization of the class **PSPACE** in terms of regular leaf-languages or *serializable computation* [13, 19].

▶ **Theorem 19.** *If* $\mathbf{NP} \neq \mathbf{PSPACE}$*, then* $\mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0 \setminus \mathbf{Del}_{\mathbf{P}}\cdot\mathbf{AC}^0 \neq \emptyset$.



$\mathbf{IncP}$
$\mathbf{Del}^*_{\mathrm{P}}\cdot\mathbf{AC}^0$
$\mathbf{DelayP}$
$\mathbf{Del}^*\cdot\mathbf{AC}^0$
$\mathbf{Del}^{\mathrm{P}}_{\mathrm{P}}\cdot\mathbf{AC}^0$
$\mathbf{Del}^{\mathrm{P}}\cdot\mathbf{AC}^0$
$\mathbf{Del}^{\mathrm{c}}_{\mathrm{P}}\cdot\mathbf{AC}^0$
(if $\mathbf{NP} \neq \mathbf{PSPACE}$)
$\mathbf{Del}^{\mathrm{c}}\cdot\mathbf{AC}^0$
$\mathbf{Del}_{\mathrm{P}}\cdot\mathbf{AC}^0$
$\mathbf{Del}\cdot\mathbf{AC}^0$

Figure 1 Diagram of the classes. Bold lines denote strict inclusions.

6 Conclusion

The obtained inclusion relations among the classes we introduced are summarized in Fig. 1. We noted earlier that in our context, enumeration problems are defined without a complexity assumption concerning the underlying relation. We should remark that quite often, a polynomial-time upper bound is required, see [17, 6]. All of our results, with the exception of the conditional separations in Sect. 5 also hold under the stricter definition; however, the relation R_L used in the lower bounds in Subsect. 5.2 is based on a **PSPACE**-complete set and therefore, to check whether $y \in R_L(x)$ requires polynomial space w.r.t. the length of x. It would be nice to be able to base these separations on polynomial-time checkable relations, or even better, to separate the classes unconditionally, but this remains open. Moreover, some further inclusions in Fig. 1 are still not known to be strict.

In Subsect. 4.3, we proved that, for several fragments of propositional logic, among them the Krom and the affine fragments, the enumeration of satisfiable assignments is in the class $\mathbf{Del}_{\mathbf{P}}\cdot\mathbf{AC}^0$. This means satisfiable assignments can be enumerated very efficiently, i. e., by an $\mathbf{AC}^0$-circuit family, after some precomputation, which is also efficiently doable (in polynomial time). For another important and very natural fragment of propositional logic, namely the Horn fragment, a **DelayP**-algorithm is known, but it is not at all clear how polynomial-time precomputation can be of any help to produce more than one solution. Since Horn-Sat is **P**-complete, we conclude that Enum-Horn-Sat $\notin \mathbf{Del}^*\cdot\mathbf{AC}^0$, and we conjecture that it is not in $\mathbf{Del}_{\mathbf{P}}\cdot\mathbf{AC}^0$. In fact, we do not see any reasonable better bound than the known **DelayP**.

Abstract

We study the Escape Problem for discrete-time linear dynamical systems over compact semialgebraic sets. We establish a uniform upper bound on the number of iterations it takes for every orbit of a rational matrix to escape a compact semialgebraic set defined over rational data. Our bound is doubly exponential in the ambient dimension, singly exponential in the degrees of the polynomials used to define the semialgebraic set, and singly exponential in the bitsize of the coefficients of these polynomials and the bitsize of the matrix entries. We show that our bound is tight by providing a matching lower bound.

1 Introduction

An *invariant set* of a dynamical system is a set K such that every trajectory that starts in K remains in K. Dually, an *escape set* K is one such that every trajectory that starts in K eventually leaves K (either temporarily or permanently). While it is usually straightforward to establish that a given set K is invariant, it can be challenging to decide whether it is an escape set. Indeed, while the former problem amounts to showing that K is closed under the transition function, the latter potentially involves considering entire orbits. In particular, even in case K has a finite escape time (the maximum number of steps for an orbit to escape the set), it can be highly non-trivial to establish an explicit upper bound on the escape time.

In this paper we focus on escape sets for (discrete-time) linear dynamical systems. Given a rational matrix $A \in \mathbb{Q}^{n\times n}$ we say that $K \subseteq \mathbb{R}^n$ is an escape set for A if for all points $x \in K$, there exists $t \in \mathbb{N}$ such that $A^t x \notin K$. The *compact escape problem (CEP)* asks to decide whether a given compact semialgebraic set K is an escape set for a given matrix A.

Decidability of CEP was shown in [18] and its computational complexity was characterised in [9] as being interreducible with the decision problem for a certain fragment of the theory of real closed fields.

The present paper focusses exclusively on positive instances (A, K) of CEP, that is, we assume that we are given a compact semialgebraic escape set for a linear dynamical system. In this situation it turns out, due to compactness of K, that there exists a finite time T such that for all $x \in K$ there exists $t \leq T$ with $A^t x \notin K$. The least such T is called the *escape time* of (A, K). Our main result (Theorem 1, shown below) gives an explicit upper bound on the escape time of (A, K) as a function of the length of the description of the matrix A and semialgebraic set K. In general, it is recognised that bounded liveness is a more useful property than mere liveness. Theorem 1 can be used to establish bounded liveness of several kinds of systems. For example, the result gives an upper bound on the termination time of a single-path linear loop with compact guard (cf. [22, 5]); it also gives a bound on the number of steps to remain in a particular control location of a hybrid system before a given (compact) state invariant becomes false, forcing a transition.

We next introduce some terminology to formalise our main contribution. We say that a semialgebraic set S has complexity at most (n, d, τ) if it can be expressed by a boolean combination of polynomial equations and inequalities $P(x_1, \ldots, x_n) \bowtie 0$ with $\bowtie \in \{\leq, =\}$, involving polynomials $P \in \mathbb{Z}[x_1, \ldots, x_n]$ in at most n variables of total degree at most d with integer coefficients bounded in bitsize by τ. Our main result is as follows:

► **Theorem 1.** *There exists an integer function* $\mathrm{CompactEscape}(n, d, \tau) \in 2^{(d\tau)^{n^{O(1)}}}$ *with the following property. If $K \subseteq \mathbb{R}^n$ is a compact semialgebraic set of complexity at most (n, d, τ) that is an escape set for a matrix $A \in \mathbb{Q}^{n \times n}$ with entries of bitsize at most τ, then the escape time of K is bounded by* $\mathrm{CompactEscape}(n, d, \tau)$.

As explained in the proof sketch below, Theorem 1 relies on the availability of certain quantitative bounds within semialgebraic geometry and number theory, particularly concerning quantifier elimination and Diophantine approximation. The latter results are crucial to handling the case in which the matrix A has complex eigenvalues of absolute value one.

Note that the upper bound on the escape time in Theorem 1 is singly exponential in the degrees and the bitsize of the coefficients of the polynomials used to define K and the bitsize of the coefficients of A. It is doubly exponential in the dimension. In Section 8 we provide two examples, one where A is an isometry and another in which all eigenvalues of A have absolute value strictly greater than one, that yield a corresponding lower bound of this form. It is moreover straightforward to give examples of non-compact escape sets for which the escape time is infinite.

Proof Overview. Let us now give a high-level overview of the proof of Theorem 1. As in the statement of the theorem, let $K \subseteq \mathbb{R}^n$ be a compact semialgebraic set of complexity at most (n, d, τ) and let $A \in \mathbb{Q}^{n \times n}$ be a matrix with entries of bitsize bounded by τ, and such that for all $x \in K$ there exists $t \in \mathbb{N}$ such that $A^t x \notin K$.

To facilitate the analysis of the dynamical behaviour of A we first transform our system into real Jordan normal form. A theorem of Cai [6] ensures that this step does not significantly increase the complexity of the system.

The dynamics of A naturally decomposes into a rotational part, corresponding to eigenvalues of modulus one, and an expansive or contractive part, corresponding to eigenvalues of absolute value different from 1 and to generalised eigenvalues of arbitrary moduli. Accordingly, the ambient space $\mathbb{R}^n$ decomposes into two subspaces V_{rec} and $V_{\text{non-rec}}$, such that A

exhibits rotational behaviour on V_{rec} and expansive or contractive behaviour on $V_{\text{non-rec}}$. We start by considering the special cases where either $V_{\text{rec}} = 0$ or $V_{\text{non-rec}} = 0$, so that only one of the two types of behaviours occurs.

First, assume that A has no complex eigenvalues of modulus 1. Since every trajectory under A escapes K we have in particular that $0 \notin K$. A theorem due to Jeronimo, Perrucci and Tsigaridas [15] shows that K is bounded away from zero by a function of the form $2^{-(d\tau)^{n^{O(1)}}}$ and a theorem due to Vorobjov [23] establishes an upper bound on the absolute value of every coordinate of every point in K of the form $2^{(d\tau)^{n^{O(1)}}}$. Furthermore, thanks to a result of Mignotte [17], we can bound the eigenvalues of A away from 1 by a function of the form $2^{\tau^{n^{O(1)}}}$. This yields a doubly exponential bound on how long it takes for A to leave the set K (either by converging to 0 or by converging to infinity in some eigenspace).

Now assume that all eigenvalues of A have modulus 1. This case is handled through a combination of two bounds. For the first bound we start by noting that for every $x \in K$ the closure of the orbit $\overline{\mathcal{O}_A(x)}$ is a compact semialgebraic set that is not entirely contained within K. In fact we show that for all $x \in K$ there exists a point $y \in \overline{\mathcal{O}_A(x)}$ whose distance to K is at least $2^{-(d\tau)^{n^{O(1)}}}$. This bound is achieved by applying [15, Theorem 1] to a suitable polynomial on an auxiliary semialgebraic set, which is constructed using quantifier elimination. The singly exponential bounds obtained in [14, 20] are crucial for this step to work. The second step of the argument combines Baker's theorem on linear forms in logarithms with a quantitative version of Kronecker's theorem on simultaneous Diophantine approximation to obtain a bound of the form $N_P \in 2^{(\tau P)^{n^{O(1)}}}$ such that for all positive integers P every point $z \in \overline{\mathcal{O}_A(x)}$ is within 2^{-P} of a point of the form $A^t x$ with $0 \leq t \leq N_P$. Combining the two bounds described above, we obtain a doubly exponential bound on the escape time.

In the presence of both types of behaviour, the analysis of each case becomes more involved. We select a parameter $\varepsilon > 0$ and partition K into three sets: $K_{\text{rec}} = K \cap V_{\text{rec}}$, $K_{\geq\varepsilon}$, and $K_{<\varepsilon}$. The matrix A exhibits purely rotational behaviour on K_{rec}. Intuitively, on $K_{\geq\varepsilon}$ the expansive or contractive behaviour of A dominates the overall dynamics, while on $K_{<\varepsilon}$ the rotational behaviour dominates the overall dynamics. We establish in Lemma 14 a bound N_{rec} such that for each initial point $x \in V_{\text{rec}}$, one of its first N_{rec} iterates is bounded away from K. In Lemma 15 we establish a bound $N_{\geq\varepsilon}$ such that every $x \in K_{\geq\varepsilon}$ either escapes or enters $K_{<\varepsilon} \cup K_{\text{rec}}$ within at most $N_{\geq\varepsilon}$ iterations. Finally, in Section 7, we establish a bound on how often the system can switch from a state where rotational behaviour dominates to one where expansive or non-expansive behaviour does and vice versa. We use this to combine the two bounds to an overall bound on the escape time, proving Theorem 1.

Main Contributions. While decidability of CEP was already established in [18], the proof given there was non-effective, combining two unbounded searches. To obtain a uniform quantitative bound on the escape time, the argument given in [18] needs to be refined and extended in two significant ways:

Firstly, one needs to establish non-trivial quantitative refinements of the techniques used in the decidability proof: to bound the escape time for purely expanding or retracting systems, we need to combine the sharp effective bounds on compact semialgebraic sets from real algebraic geometry established in [23, 15] with Mignotte's root separation bound [17]. The case of purely rotational systems requires an original combination of a quantitative version of Kronecker's theorem on simultaneous Diophantine approximation [12] and a quantitative version of Baker's theorem on linear forms in logarithms [1]. All of these techniques were completely absent from the decidability proof.

Secondly, to establish mere decidability of the problem, it was possible to study the possible behaviours of the system – rotating, expanding, or retracting – in isolation. For example, if the set K contains a point which has a non-zero component in an eigenspace of A for an eigenvalue whose modulus is strictly greater than one, then the system must eventually escape. However, no uniform bound on the escape time may be derived in this situation, for the component is allowed to be arbitrarily close to zero. Therefore, as outlined above, it is necessary in our proof to subdivide K into pieces where rotational, retractive, and expansive behaviour can be present simultaneously. The interaction of the three behaviours significantly increases the difficulty of the analysis and requires completely new ideas.

2 Mathematical Tools

We use the following singly exponential quantifier elimination result given in [2]. For a historical overview on this type of result see [2, Chapter 14, Bibliographical Notes].

▶ **Theorem 2** ([2, Theorem 14.16]). *Let $S \subseteq \mathbb{R}^{k+n_1+\cdots+n_\ell}$ be a semialgebraic set of complexity at most $(k + n_1 + n_2 + \cdots + n_\ell, d, \tau)$. Let $Q_1, \ldots, Q_\ell \in \{\exists, \forall\}$ be a sequence of alternating quantifiers. Consider the set $S' \subseteq \mathbb{R}^k$ of all $(x_1, \ldots, x_k) \in \mathbb{R}^k$ satisfying the first-order formula*

$$(Q_1(x_{1,1}, \ldots, x_{1,n_1})) \ldots (Q_\ell(x_{\ell,1}, \ldots, x_{\ell,n_\ell})) . \\ ((x_1, \ldots, x_k, x_{1,1}, \ldots, x_{1,n_1}, \ldots, x_{\ell,1}, \ldots, x_{\ell,n_\ell}) \in S)$$

Then S' is a semialgebraic set of complexity at most $(k, d^{O(n_1\cdot\dots\cdot n_\ell)}, \tau d^{O(n_1\cdot\dots\cdot n_\ell\cdot k)})$.

The next theorem is due to Vorobjov [23]. See also [13, Lemma 9] and [3, Theorem 4].

▶ **Theorem 3.** *There exists an integer function* $\operatorname{Bound}(n, d, \tau) \in 2^{\tau d^{O(n)}}$ *with the following property:*

Let K be a compact semialgebraic set of complexity at most (n, d, τ). Then K is contained in a ball centred at the origin of radius at most $\operatorname{Bound}(n, d, \tau)$.

A closely related result, due to [15], yields a lower bound on the minimum of a polynomial over a compact semialgebraic set, provided the minimum is non-zero. The result in [15] mentions explicit constants, which is more than we need.

▶ **Theorem 4** ([15, Theorem 1]). *There exists an integer function* $\operatorname{LowerBound}(n, d, \tau) \in 2^{(\tau d)^{n^{O(1)}}}$ *such that the following holds true:*

Let $P \in \mathbb{Q}[x_1, \ldots, x_n]$ be a polynomial of degree at most d, whose coefficients have bitsize at most τ. Let K be a compact semialgebraic set of complexity at most (n, d, τ). If $\min_{x\in K} P(x) > 0$ *then* $\min_{x\in K} P(x) > 1/\operatorname{LowerBound}$.

With the help of Theorem 2, Theorem 4 can be generalised to yield a lower bound on the distance of two disjoint compact semialgebraic sets. A very similar result is proved in [21] under more general assumptions. Unfortunately, the complexity bound stated there is not sufficiently fine-grained for our purpose, since the author do not distinguish the dimension of a set from the other complexity parameters.

▶ **Lemma 5.** *There exists an integer function* $\operatorname{Sep}(n, d, \tau) \in 2^{(\tau d)^{n^{O(1)}}}$ *with the following property:*

Let K and L be compact semialgebraic sets of complexity at most (n, d, τ). Assume that every $x \in K$ has positive euclidean distance to L. Then $\inf_{x\in K} d(x, L) > 1/\operatorname{Sep}(n, d, \tau)$.

Proof. See [10, Appendix E]. ◀

We require a version of Kronecker's theorem on simultaneous Diophantine approximation. See [19, Corollary 3.1] for a proof.

▶ **Theorem 6.** *Let $(\lambda_1, \ldots, \lambda_m)$ be complex algebraic numbers of modulus 1. Consider the free Abelian group*
