$$L = \{(n_1, \ldots, n_m) \in \mathbb{Z}^m \mid \lambda_1^{n_1} \cdot \cdots \cdot \lambda_m^{n_m} = 1\}.$$

Let $(\beta_1, \ldots, \beta_s)$ be a basis of L. Let $\mathbb{T}^m = \{(z_1, \ldots, z_m) \in \mathbb{C}^m \mid |z_j| = 1\}$ denote the complex unit m-torus. Then the closure of the set $\left\{(\lambda_1^k, \ldots, \lambda_m^k) \in \mathbb{T}^m \mid k \in \mathbb{N}\right\}$ is the set $S = \left\{(z_1, \ldots, z_m) \in \mathbb{T}^m \mid \forall j \leq s.(z_1, \ldots, z_m)^{\beta_j} = 1\right\}$.

Moreover, for all $\varepsilon > 0$ and all $(z_1, \ldots, z_m) \in S$ there exist infinitely many indexes k such that $|\lambda_j^k - z_j| < \varepsilon$ for $j = 1, \ldots, m$.

Moreover, the integer multiplicative relations between given complex algebraic numbers in the unit circle can be elicited in polynomial space. For a proof see [7, 16]. We assume the standard encoding of algebraic numbers, see [8] for details.

▶ **Theorem 7.** *Let $(\lambda_1, \ldots, \lambda_m)$ be complex algebraic numbers of modulus 1. Consider the free Abelian group*

$$L = \{(n_1, \ldots, n_m) \in \mathbb{Z}^m \mid \lambda_1^{n_1} \cdot \cdots \cdot \lambda_m^{n_m}\}.$$

Then one can compute in polynomial space a basis $(\beta_1, \ldots, \beta_s) \in (\mathbb{Z}^m)^s$ for L. Moreover, the integer entries of the basis elements β_j are bounded polynomially in the size of the encodings of $\lambda_1, \ldots, \lambda_m$ and singly exponentially in m.

We need to be able to bound away the modulus of eigenvalues that fall outside the unit circle away from 1. This is achieved by combining a classic result due to Mignotte [17] on the separation of algebraic numbers with a bound on the height of the resultant of two polynomials, proved in [4, Theorem 10].

▶ **Lemma 8.** *Let λ be a complex algebraic number whose minimal polynomial has degree at most d and coefficients bounded in bitsize by τ. Assume that $|\lambda| \neq 1$. Then we have $||\lambda| - 1| > 2^{-(\tau d)^{O(1)}}$.*

Proof. See [10, Appendix C]. ◀

3 Preliminaries

3.1 Converting the matrix to real Jordan normal form

To obtain a bound on the escape time it will be important to work with instances of the Escape Problem in real Jordan normal form. In the following, let $\mathbb{A}$ denote the field of algebraic numbers. We establish the following reduction to this case:

▶ **Lemma 9.** *Let (K, A) be an instance of the Compact Escape Problem. Assume that K is given by a formula involving s polynomial equations and equalities $P \bowtie 0$ where $P \in \mathbb{Z}[x_1, \ldots, x_n]$ is a polynomial in n variables of degree at most d whose coefficients are bounded in bitsize by τ.*

Let $\gamma_1, \ldots, \gamma_m \in \mathbb{R}$ denote the real and imaginary parts of the eigenvalues of A. Let δ be a bound on the degrees of $\gamma_1, \ldots, \gamma_m$.

Then there exists an equivalent instance (J, K') of the Compact Escape Problem where $J \in \mathbb{A}^{(n+m)\times(n+m)}$ is in real Jordan normal form and K' is given by a formula involving at most $s + 3m$ polynomial equations and equalities $P \bowtie 0$ where $P \in \mathbb{Z}[x_1, \dots, x_{n+m}]$ is a polynomial in $n + m$ variables of degree at most $\delta \cdot d$ whose coefficients are bounded in bitsize by $\tau + d(\log(2n) + \log(\delta + 1) + \sigma)$, where σ depends polynomially on n and the bitsize of the entries of A.

Proof. See [10, Appendix B]. ◀

3.2 Decomposing K

Let $K \subseteq \mathbb{R}^n$ be a compact semialgebraic set. Let $A \in \mathbb{R}^{n\times n}$ be a matrix in real Jordan normal form,

$$A = \begin{pmatrix} J_1 & & \\ & \ddots & \\ & & J_m \end{pmatrix}.$$

Here, each J_i is a real Jordan block of the form

$$J_i = \begin{pmatrix} \Lambda_i & I_i & & \\ & \ddots & \ddots & \\ & & \Lambda_i & I_i \\ & & & \Lambda_i \end{pmatrix},$$

where $\Lambda_{i,1}$ is either a real number or a 2×2 real matrix of the form $\begin{pmatrix} a_i & -b_i \\ b_i & a_i \end{pmatrix}$ and, accordingly, I_i is either the real number 1 or the 2×2 identity matrix. The elements Λ_i correspond to real or complex eigenvalues $\lambda_i \in \mathbb{C}$ of A. By slight abuse of language we call $|\lambda_i|$ the modulus of Λ_i. By further slight abuse of language we define the "eigenspace" of Λ_i as the one- or two-dimensional space spanned by the vectors that correspond to the first entry of the Jordan block J_i. The "generalised eigenspaces" for Λ_i are defined analogously.

Write $\mathbb{R}^n$ as the direct sum of two spaces $\mathbb{R}^n = V_{\text{rec}} \oplus V_{\text{non-rec}}$ where V_{rec} is the direct sum of the eigenspaces for eigenvalues of modulus 1, and $V_{\text{non-rec}}$ is the direct sum of the eigenspaces and generalised eigenspaces for eigenvalues of modulus $\neq 1$ and the generalised eigenspaces for eigenvalues of modulus 1. By convention, if A has no eigenvalues of modulus 1 we let $V_{\text{rec}} = 0$. Similarly, if A has only eigenvalues of modulus 1 and no generalised eigenvalues we let $V_{\text{non-rec}} = 0$. Thus, we decompose the state space $\mathbb{R}^n$ into a part V_{rec} on which A exhibits purely rotational behaviour, and a part $V_{\text{non-rec}}$ where A is additionally expansive or contractive.

We will work with several different norms throughout this paper. In addition to the familiar ℓ^2 and ℓ^∞ norms we introduce a third norm, depending on the matrix A, that combines features of the two. It facilitates block-wise arguments while ensuring that the restriction of A to V_{rec} is an isometry.

Write $\mathbb{R}^n$ as a direct sum $\mathbb{R}^n = V_1 \oplus \cdots \oplus V_s \oplus W_1 \oplus \cdots \oplus W_t$, where $V_1, \dots, V_s$ correspond to the Jordan blocks of A associated with real eigenvalues and $W_1, \dots, W_t$ correspond to the Jordan blocks of A associated with non-real eigenvalues. Let $\pi_{W_j} : \mathbb{R}^n \to W_j$ and $\pi_{V_j} : \mathbb{R}^n \to V_j$ denote the orthogonal projections onto W_j and V_j respectively.

For a vector $x \in V_i$, let $\|x\|_J^{V_i} = \|x\|_\infty$. For a vector $x = (x_1, y_1, \dots, x_k, y_k) \in W_i$, let

$$\|x\|_J^{W_i} = \max_{j=1,\dots,k} \left(\sqrt{x_j^2 + y_j^2}\right).$$

For a vector $x \in \mathbb{R}^n$, let

$$\|x\|_J = \max\left\{ \max_{j=1,\dots,s} \left\|\pi_{V_j}(x)\right\|_J^{V_j}, \max_{j=1,\dots,t} \left\|\pi_{W_j}(x)\right\|_J^{W_j} \right\}.$$

Call $\|x\|_J$ the Jordan norm of x. Observe that $\|x\|_J$ depends on the choice of the V_i's and W_i's. The Jordan norm compares to the ℓ^2- and ℓ^∞- norms as follows:

$$n^{-1/2}\|x\|_J \leq n^{-1/2}\|x\|_2 \leq \|x\|_\infty \leq \|x\|_J \leq \|x\|_2 \leq n^{1/2}\|x\|_\infty \leq n^{1/2}\|x\|_J .$$

Let $\varepsilon > 0$. Consider the ball $B_J(0,\varepsilon) \subseteq \mathbb{R}^n$ about 0 with respect to the distance induced by the $\|\cdot\|_J$-norm. We partition K into three sets:

$$\begin{aligned} &K_{\text{rec}} = K \cap V_{\text{rec}} \\ &K_{<\varepsilon} = K \cap (V_{\text{rec}} \oplus ((V_{\text{non-rec}} \cap B_J(0,\varepsilon)) \setminus \{0\})) \\ &K_{\geq\varepsilon} = K \cap (V_{\text{rec}} \oplus (V_{\text{non-rec}} \setminus B_J(0,\varepsilon))) \end{aligned}$$

4 A quantitative version of Kronecker's theorem for complex algebraic numbers

Our central tool for bounding the escape time in the recurrent case is a quantitative version of Kronecker's theorem for complex algebraic numbers.

Let $(\lambda_1,\dots,\lambda_m)$ be complex algebraic numbers of modulus 1. Our goal is to find for all $\varepsilon > 0$ a bound N such that for all $(\alpha_1,\dots,\alpha_m) \in \mathbb{T}^m$ contained in the closure of the sequence $(\lambda_1^t,\dots,\lambda_m^t)_{t\in\mathbb{N}}$ there exists $t \leq N$ such that $|\lambda_j^t - \alpha_j| < \varepsilon$ for all $j = 1,\dots,m$.

We first consider the case where the λ_j's do not admit any integer multiplicative relations. In this case we can employ the following quantitative version of the continuous formulation of Kronecker's theorem, proved in [12]:

▶ **Theorem 10** ([12, Theorem 4.1]). *Let $\varphi_1,\dots,\varphi_N$ and $\zeta_1,\dots,\zeta_N$ be real numbers. Let $\varepsilon_1,\dots,\varepsilon_N$ be positive real numbers with $\varepsilon_j < 1/2$ for all j. Let $M_j = \left\lceil \frac{1}{\varepsilon_j}\log\frac{N}{\varepsilon_j}\right\rceil$. Let $\varphi = (\varphi_1,\dots,\varphi_N)$. Let $\delta = \min\left\{|\varphi\cdot m| \mid m \in \mathbb{Z}^N, |m_j| < M_j, m \neq 0\right\}$. Assume that $\delta > 0$. Then in any interval I of length $T \geq 4/\delta$ there is a real number t such that $\|\varphi_j t - \zeta_j\| < \varepsilon_j$, where $\|\cdot\|$ denotes distance to the nearest integer.*

Intuitively, the number δ in Theorem 10 is a quantitative measure of the linear independence of the φ_j's, as it bounds away from zero all integer linear combinations of the φ_j's with suitably bounded coefficients. In our case we consider the numbers $\varphi_j = \log\lambda_j$. For our purpose we need to obtain a bound on t, and thus a bound on δ, in terms of the algebraic complexity of the numbers $\lambda_1,\dots,\lambda_m$. This is achieved by invoking a quantitative version of Baker's theorem on linear forms in logarithms due to Baker and Wüstholz [1]. Recall that any algebraic number μ is the root of a unique irreducible polynomial p_μ with pairwise coprime integer coefficients. The *height* of an algebraic number μ is the maximum of the absolute values of the coefficients of p_μ. The *degree* of μ is the degree of p_μ. Recall that a field E is called an *extension* of a field F if E contains F as a subfield. The *degree* of a field extension $E \supseteq F$ is the dimension of E as an F-vector space.

▶ **Theorem 11.** *Let $\mu_1, \ldots, \mu_N$ be algebraic numbers, none of which is equal to 0 or 1. Let*

$$L(z_1, \ldots, z_N) = b_1 z_1 + \cdots + b_N z_N$$

be a linear form with rational integer coefficients $b_1, \ldots, b_N$. Let B be an upper bound on the absolute values of the b_j's. For $j = 1, \ldots, N$, let $A_j \geq \exp(1)$ be a bound on the height of μ_j. Let d be the degree of the field extension $\mathbb{Q}(\mu_1, \dot{;}\mu_N)$ generated by $\mu_1, \ldots, \mu_N$ over $\mathbb{Q}$. Fix a determination of the complex logarithm $\log$. Let $\Lambda = L(\log \mu_1, \ldots, \log \mu_N)$. If $\Lambda \neq 0$ then

$$\log |\Lambda| > -(16Nd)^{2(N+2)} \log A_1 \cdot \cdots \cdot \log A_N \log B.$$

Finally, in the case where the λ_j's admit integer multiplicative relations, we employ Theorem 7 to bound their complexity. We arrive at the following result:

▶ **Theorem 12.** *Let $(\lambda_1, \ldots, \lambda_m)$ be complex algebraic numbers of modulus 1. Assume that the numbers $2\pi i, \log \lambda_1, \ldots, \log \lambda_s$ are linearly independent over the rationals, where $0 \leq s \leq m$. Let d be the degree of the field extension $\mathbb{Q}(\lambda_1, \ldots, \lambda_s)$. Let $A_1, \ldots, A_s \geq \exp(1)$ be upper bounds on the heights of $\lambda_1, \ldots, \lambda_s$. Let $\ell \in \mathbb{N}$, and $\varepsilon_{s+1}, \ldots, \varepsilon_m \in \mathbb{Z}^s$ be such that*

$$\lambda_j^\ell = (\lambda_1, \ldots, \lambda_s)^{\varepsilon_j}$$

for all $j = s+1, \ldots, m$. By convention, if $s = 0$ the right-hand side of the above equation is to be taken equal to 1.

Let

$$L = \max \left\{ \ell, \sum_{k=1}^{s} |\varepsilon_{s+1,k}|, \ldots, \sum_{k=1}^{s} |\varepsilon_{m,k}| \right\}.$$

Let $\alpha_1, \ldots, \alpha_m \in \mathbb{T}^m$ be such that any rational linear relation between the numbers $2\pi i, \log \lambda_1, \ldots, \log \lambda_m$ is also satisfied by the numbers $2\pi i, \log \alpha_1, \ldots, \log \alpha_m$. Let $\varepsilon > 0$. Then there exists a positive integer

$$t \leq 8\pi\ell \left(\tfrac{2\pi L}{\varepsilon}\right)^s \left(2s \tfrac{2\pi L}{\varepsilon} \left\lceil \tfrac{4\pi L}{\varepsilon} \log \tfrac{4\pi s L}{\varepsilon} \right\rceil\right)^{(16(s+1)d)^{2(s+3)} \log A_1 \cdot \cdots \cdot \log A_s} + \ell$$

such that $\left|\lambda_j^t - \alpha_j\right| < \varepsilon$ for $j = 1, \ldots, m$.

Proof. An outline of the proof is sketched above. See [10, Appendix D] for a full proof. ◀

For the purpose of bounding the escape time, the following coarse bound suffices:

▶ **Corollary 13.** *There exists an integer function $\mathrm{Kron}(n, \tau, P) \in 2^{(\tau P)^{n^{O(1)}}}$, such that the following holds true:*

Let $\lambda_1, \ldots, \lambda_n$ be algebraic numbers of modulus 1. Assume that the degree of each λ_j is bounded by n. Let τ be a bound on the bitsize of the coefficients of the minimal polynomials of the λ_j's. Let P be a positive integer. Let $\alpha_1, \ldots, \alpha_n$ be complex numbers which are contained in the closure of the sequence $(\lambda_1^t, \ldots, \lambda_n^t)_{t \in \mathbb{N}}$. Then there exists a $t \leq \mathrm{Kron}(n, \tau, P)$ such that $|\alpha_j - \lambda_j^t| < 2^{-P}$ for all $j \in \{1, \ldots, n\}$.

Proof. By Kronecker's theorem, any integer multiplicative relation between the λ_j's is also satisfied by the α_j's. Theorem 12 hence yields a bound on t such that $|\alpha_j - \lambda_j^t| < 2^{-P}$ holds for all $j \in \{1, \ldots, n\}$.

This bound is given in terms of quantities s, d, ℓ, $\varepsilon_{s+1}, \ldots, \varepsilon_m \in \mathbb{Z}^s$, $A_1, \ldots, A_s$, and L. It remains to show that these quantities can be chosen to be suitably bounded in terms of n and τ.

Proposition 26 in [10, Appendix D], which is mainly based on Theorem 7, shows that numbers ℓ and $\varepsilon_1, \dots, \varepsilon_m$ can be computed in polynomial space. In particular, the absolute size of L and ℓ is of the form $2^{(n\tau)^{O(1)}}$. The numbers $\log A_i$ are bounded by τ by assumption. We have $s \leq m \leq n$ by definition. Finally, we have assumed that each λ_j has degree at most n. It follows that the degree d of the field extension $\mathbb{Q}(\lambda_1, \dots, \lambda_s)$ is bounded by n^n. The result follows from Theorem 12. ◀

5 The recurrent eigenspace

The next lemma establishes as a special case an escape bound for all initial values $x \in K_{\mathrm{rec}}$. In order to combine the recurrent and the non-recurrent case we need a stronger result, however. Thus, we establish not only a bound on the escape time for all initial values $x \in K_{\mathrm{rec}}$, but a bound N such that every $x \in V_{\mathrm{rec}}$ – not just in K_{rec} – has distance at least $1/N$ – not just positive distance – from K. Further, note that Lemma 14 is still applicable in the special cases where $K_{\mathrm{rec}} = \emptyset$ or $V_{\mathrm{rec}} = 0$.

▶ **Lemma 14.** *There exists an integer function* $\mathrm{Rec}(n, d, \tau) \in 2^{(\tau d)^{n^{O(1)}}}$ *with the following property:*

Let $A \in \mathbb{A}^{n \times n}$ *be a matrix in real Jordan normal form with algebraic entries. Assume that the minimal polynomial of* A *has rational coefficients whose bitsize is bounded by* τ*. Let* $K \subseteq \mathbb{R}^n$ *be a compact semialgebraic set of complexity at most* (n, d, τ)*. If every point* $x \in K_{\mathrm{rec}}$ *escapes* K *under iterations of* A *then for all* $x \in V_{\mathrm{rec}}$ *there exists* $t \leq \mathrm{Rec}(n, d, \tau)$ *such that*

$$\mathrm{dist}_{\ell^2}(A^t x, K) > \frac{\sqrt{n}}{\mathrm{Rec}(n, d, \tau)}.$$

Proof. The full proof is given in [10, Appendix F]. We only sketch an outline here.

We first prove the result for initial points $x \in K_{\mathrm{rec}}$. For these points, the closure of the orbit $\overline{\mathcal{O}_A(x)}$ of x under A is a compact semialgebraic set. We employ Corollary 13 to obtain for all $\varepsilon > 0$ a doubly exponential bound N such that for all $x \in K_{\mathrm{rec}}$ and all $y \in \overline{\mathcal{O}_A(x)}$ there exists $t \leq N$ such that $\|A^t x - y\|_2 < \varepsilon$. We then use Theorem 4 to obtain a uniform at most doubly exponentially small lower bound on the quantity

$$\inf_{x \in K_{\mathrm{rec}}} \sup_{y \in \overline{\mathcal{O}_A(x)}} \inf_{z \in K} \|y - z\|_2^2 .$$

In order to apply this theorem we construct an auxiliary semialgebraic set, whose complexity is controlled by Theorem 2. Combining these two steps, we obtain a function Rec_0 that satisfies the statement of the lemma for all initial points $x \in K_{\mathrm{rec}}$.

Finally, we extend the result to all initial points $x \in V_{\mathrm{rec}}$. The special case where $K_{\mathrm{rec}} = \emptyset$ is treated using Theorem 4.

In the case where K_{rec} is non-empty we obtain from Lemma 5 that every $x \in V_{\mathrm{rec}}$ which is doubly exponentially close to K with a sufficiently large constant in the third exponent is already doubly exponentially close to K_{rec}, with a slightly smaller constant in the third exponent. Now, any point that is sufficiently far away from K trivially satisfies the claim. By the preceding discussion, points $x \in V_{\mathrm{rec}}$ that are sufficiently close to K are already sufficiently close to K_{rec}, so that there exists an escaping orbit $\overline{\mathcal{O}_A(x')}$ with $x' \in K_{\mathrm{rec}}$ which is close to the orbit of x since A is an isometry on V_{rec}. This allows us to reduce the result to the already established result for initial values in K_{rec}. ◀

6 The non-recurrent eigenspace

The next lemma concerns the subset $K_{\geq\varepsilon}$ of K containing the points in K that are bounded away from V_{rec} by some $\varepsilon > 0$.

For any such point, there exist coordinates (or pairs of coordinates if the corresponding eigenvalues are not real) whose contribution to the Jordan norm is greater than ε. Moreover, the contribution to the Jordan norm of these coordinates does not stay constant under applications of A. If the contribution to the norm of at least one such coordinate is increasing under applications of A, the orbit will eventually leave K, since K is compact. Moreover, Theorem 3 yields an upper bound on the escape time.

Coordinates whose contribution to the norm is decreasing under applications of A will, after sufficiently many iterations, contribute less than ε. We establish a uniform upper bound on the number of iterations required to ensure this for all such coordinates. Combining this with the previous bound, we obtain a number N such that after at most N applications of A, every $x \in K_{\geq\varepsilon}$ has either escaped K, entered $K_{<\varepsilon} \cup K_{\text{rec}}$, or it remains in $K_{\geq\varepsilon}$ because it has a component whose contribution to the norm was initially smaller than ε, but grew beyond ε under iteration of A. In the last case, the point will grow in norm beyond the bound established in Theorem 3 and thus escape K after a further N applications of A. This yields a uniform bound on the number of iterations that are required for any point $x \in K_{\geq\varepsilon}$ to either leave K entirely or move into $K_{<\varepsilon} \cup K_{\text{rec}}$.

The overall structure of this proof closely follows the one given in [11], where the assumptions allow the authors to restrict the discussion to real eigenvalues.

▶ **Lemma 15.** *There exists an integer function* $\text{NonRec}(n, d, \tau, P) \in 2^{(d\tau P)^{n^{O(1)}}}$ *with the following property:*

Let K be a compact semialgebraic set of complexity at most (n, d, τ). Let $A \in \mathbb{A}^{n\times n}$ be a matrix in real Jordan normal form. Assume that the characteristic polynomial of A has rational coefficients whose bitsize is bounded by τ. Let P be a positive integer.

Then for all $x \in K_{\geq 2^{-P}}$ there exists $t \leq \text{NonRec}(n, d, \tau, P)$ such that $A^t x \notin K_{\geq 2^{-P}}$.

Proof. See [10, Appendix G] for details. ◀

7 Proof of Theorem 1

In the previous two sections, we successively showed how to establish a bound on the escape time for an instance (A, K) when the orbit remains in the recurrent eigenspace and how the orbit behaves when it starts away from the recurrent eigenspace. In this section, we show how to combine both results in order to establish an escape bound for any starting point in K. This will thus prove Theorem 1.

Let (A_0, K_0) be an instance of the compact escape problem, where $K_0 \subseteq \mathbb{R}^n$ is a compact semialgebraic set of complexity at most (n_0, d_0, τ_0) and $A_0 \in \mathbb{Q}^{n\times n}$ is a square matrix with rational entries whose bitsize is bounded by τ_0. Assume that every point $x \in K_0$ escapes K_0 under iterations of A_0.

Apply Lemma 9 to convert the instance (A_0, K_0) into an equivalent instance (A, K) such that $A \in \mathbb{A}^{n\times n}$ is in real Jordan normal form. Then the set K has complexity at most (n, d, τ), were $n = 2n_0$, $d = n_0 d_0$, and $\tau = (n_0\tau_0 d_0)^{C_\tau}$ for some absolute constant C_τ. By construction, the characteristic polynomial of A has rational coefficients of bitsize at most τ.

Let Rec be the function from Lemma 14. Let $\varepsilon = \frac{1}{\text{Rec}(n,d,\tau)}$ and $N_{\text{rec}} = \text{Rec}(n, d, \tau)$. Let $x \in K$. If $x \in K_{\text{rec}}$ then x escapes within N_{rec} steps. Suppose that $x \in K_{<\varepsilon}$.

Then there are two possibilities:

1. We have $A^t x \notin K_{\geq\varepsilon}$ for all $t \leq N_{\text{rec}}$.
2. We have $A^t x \in K_{\geq\varepsilon}$ for at least one $t \leq N_{\text{rec}}$.

In the first case, the orbit of x remains close to V_{rec} for long enough that we can rely on Lemma 14. Indeed, let x_0 denote the orthogonal projection of x onto V_{rec}. Let $t \leq N_{\text{rec}}$ be such that $\text{dist}_{\ell^2}(A^t x_0, K) > \sqrt{n}\varepsilon$. Since $A^t x \notin K_{\geq\varepsilon}$, we have $\|A^t x - A^t x_0\|_J < \varepsilon$, so that $\|A^t x - A^t x_0\|_2 < \sqrt{n}\varepsilon$. Let $y \in K$. Then

$$\left\|A^t x - y\right\|_2 \geq \left\|A^t x_0 - y\right\|_2 - \left\|A^t x - A^t x_0\right\|_2 > \sqrt{n}\varepsilon - \sqrt{n}\varepsilon = 0.$$

Thus, x escapes K under iterations of A.

In the second case, let t_1 be such that $A^{t_1} x \in K_{\geq\varepsilon}$. Let NonRec be the function from Lemma 15. Let $N_{\geq\varepsilon} = \text{NonRec}(n, d, \tau, \lceil\log(1/\varepsilon)\rceil)$. By Lemma 15 there exists $t_2 \leq N_{\geq\varepsilon}$ such that $A^{t_2} A^{t_1} x$ is contained either in $K_{<\varepsilon} \cup K_{\text{rec}}$ or in the complement of K. In the latter case we are done. In the former case we apply the initial case distinction: either for all $t \leq N_{\text{rec}}$ we have $A^t A^{t_2} A^{t_1} x \notin K_{\geq\varepsilon}$ or we have $A^{t_3} A^{t_2} A^{t_1} x \in K_{\geq\varepsilon}$ for at least one $t_3 \leq N_{\text{rec}}$. Once again, in the first case, the point has escaped. By repeating this reasoning, we construct a (finite or infinite) sequence $t_1, t_2, \dots$ such that $t_i \leq N_{\text{rec}}$ if i is odd and $t_i \leq N_{\geq\varepsilon}$ if i is even and

$$A^{t_s} \cdot \dots \cdot A^{t_1} x \in \begin{cases} K_{<\varepsilon} \cup K_{\text{rec}} & \text{if } s \text{ is even,} \\ K_{\geq\varepsilon} & \text{if } s \text{ is odd.} \end{cases}$$

We claim that the sequence $t_1, t_2, \dots$ is finite and contains at most n^3 elements.

Consider a real Jordan block of A of size $m \leq n$ associated to the eigenvalue Λ. Denote by x_J the orthogonal projection of x onto the dimensions associated with this block.

Assume first that Λ is a real eigenvalue (as opposed to a 2×2 block representing a complex eigenvalue). If $\Lambda = 0$, then clearly $\left\|J^k x_J\right\|_J$ is monotonically decreasing. Thus, assume in the sequel that $\Lambda \neq 0$.

Let $j \in \{1, \dots, m\}$. The $m - j + 1$'th component of the vector $J^k x_J$, viewed as a function of t, is an exponential polynomial $E_j(t) = \Lambda^t P(t)$, where $P \in \mathbb{R}[z]$ is a real polynomial of degree $j - 1$. Consider the real function

$$(E_j(\cdot))^2 \colon \mathbb{R} \to \mathbb{R},\ (E_j(t))^2 = |\Lambda|^{2t} |P(t)|^2.$$

This function is differentiable in t with derivative

$$\tfrac{d}{dt}(E_j(t))^2 = \Lambda^{2t} \left(\log(\Lambda^2)(P(t)^2) + 2P(t)P'(t)\right).$$

This derivative vanishes if and only if the factor $\left(\log(\Lambda^2)(P(t)^2) + 2P(t)P'(t)\right)$ vanishes. This factor is a polynomial of degree $2j - 2$, so that it has at most $2j - 2$ real zeroes. It follows that there exist numbers $t_{j,1}, \dots, t_{j,m_j}$ with $m_j \leq 2j - 2$ such that the function $(E_j(t))^2 - \varepsilon^2$ does not change its sign in any of the open intervals

$$(0, t_{j,1}), (t_{j,1}, t_{j,2}), \dots, (t_{j,m_j-1}, t_{j,m_j}), (t_{j,m_j}, +\infty).$$

Thus, the norm $\|J^t x_J\|_J$ changes from smaller than ε to bigger than ε at most

$$\sum_{j=1}^{m}(2j - 2) = 2\sum_{j=1}^{m} j - 2m = (m+1)m - 2m = m^2 - m$$

times.

The case where Λ represents a complex eigenvalue λ is similar. However, we now consider the evolution of the two coordinates corresponding to one Λ-block simultaneously.

For $j \in \{1, \dots, m\}$, write $E_j(t)$ for the $m-j+1$'th component of the vector $J^t x_J$, viewed as a function of t. We have for all $j \in \{1, \dots, m/2\}$ that the function

$$F_j(t) = (E_{2j}(t))^2 + (E_{2j-1}(t))^2$$

is an exponential polynomial $F_j(t) = |\lambda|^t P_j(t)$, where $P_j \in \mathbb{R}[z]$ is a real polynomial of degree $j-1$. Therefore, exactly as in case where Λ is a real eigenvalue, the derivative of F_j vanishes at most $2j-2$ times. From which we can deduce that the norm $\|J^t x_J\|_J$ crosses the ε-threshold at most $m^2 - m$ times.

Estimating generously, we have at most n Jordan blocks of size at most n, each of which crosses the ε-threshold at most $n^2 - n$ times. In total, we cross the threshold at most $n^3 - n^2$ times. The total escape bound is hence $n^3 \max\{N_{\mathrm{rec}}, N_{\geq\varepsilon}\}$. By the same argument, the same escape bound holds true when the initial point x lies in $K_{\geq\varepsilon}$.

Substituting the constants N_{rec}, $N_{\geq\varepsilon}$, n, d, and τ with their definitions, we obtain the upper bound

$$\begin{aligned}&\mathrm{CompactEscape}(n_0, d_0, \tau_0) = \\ &\quad (2n_0)^3 \max\Big\{ \mathrm{Rec}\left(2n_0, n_0 d_0, (n_0 d_0 \tau_0)^{C_\tau}\right), \\ &\qquad\qquad \mathrm{NonRec}\left(2n_0, n_0 d_0, (n_0 d_0 \tau_0)^{C_\tau}, \log\left\lceil \mathrm{Rec}\left(2n_0, n_0 d_0, (n_0 d_0 \tau_0)^{C_\tau}\right)\right\rceil\right) \Big\}.\end{aligned}$$

One easily verifies that $\mathrm{CompactEscape}(n, d, \tau) \in 2^{(d\tau)^{n^{O(1)}}}$ as claimed.

8 A matching lower bound on escape time

In Theorem 1 we established a uniform upper bound on the escape time for all positive instances of the Compact Escape Problem. Our bound is doubly exponential in the ambient dimension and singly exponential in the rest of the data. We will now show that this bound cannot be significantly improved by showing that a doubly exponential bound cannot be avoided even for purely rotational systems. A second example displaying a doubly exponential lower bound is presented in [10, Appendix H].

▶ **Example 16.** For $(n, d, \tau) \in \mathbb{N}^3$, let $K_{(n,d,\tau)} \subseteq \mathbb{R}^{n+2}$ be the set of all points $(x, y, u_1, \dots, u_n)$ satisfying the (in)equalities: $x^2 + y^2 = 1, u_1 = 2^{-\tau}$, $(x-1)^2 + y^2 \geq u_n$ and for $1 \leq i \leq n-1$, $u_{i+1} = (u_i)^d$.

Hence, $K_{(n,d,\tau)} = \left(S^1 \setminus B\left((1,0), 2^{-\tau d^{n-1}}\right)\right) \times \left\{\left(2^{-\tau}, 2^{-\tau d}, \dots, 2^{-\tau d^{n-1}}\right)\right\}$, where $S^1 \subseteq \mathbb{R}^2$ is the unit circle. Let $a = \frac{3}{5}$, $b = \frac{4}{5}$. Let

$$A_{(n,d,\tau)} = \begin{pmatrix} a & -b & 0 \\ b & a & 0 \\ 0 & 0 & I_n \end{pmatrix}$$

where I_n is the $n \times n$- identity matrix. It is easy to see that the complex number $\frac{3}{5} + i\frac{4}{5}$ has modulus 1 and is not a root of unity. It follows from Dirichlet's theorem on simultaneous Diophantine approximation that the orbit of A is equal to $S^1 \times \left\{\left(2^{-\tau}, 2^{-\tau d}, \dots, 2^{-\tau d^{n-1}}\right)\right\}$, so that every initial point escapes under A.

We claim that there exists a point $x \in K_{(n,d,\tau)}$ that requires $2^{\tau d^{n-1}}$ steps to escape. Indeed, let $x_0 \in K_{(n,d,\tau)}$ be an arbitrary initial point. Consider the orbit $x_t = A^t x_0$. Let $N < 2^{\tau d^{n-1}}$. By the pigeonhole principle, the finite set of points $x_0, \dots, x_N$ contains at least one consecutive pair of points x_i, x_j on the circle such that the points x_i and x_j are joined by an arc of the circle of length strictly greater than $2/N$. It follows that we can ensure that none of the points $x_1, \dots, x_N$ is outside of $K_{(n,d,\tau)}$ by applying a suitable planar rotation to all points. Since all planar rotations commute, there exists for each angle θ an initial point $x_\theta \in S^1 \times \left\{\left(2^{-\tau}, 2^{-\tau d}, \ldots, 2^{-\tau d^{n-1}}\right)\right\}$, such that the orbit of x_θ under A is equal to the orbit of x_0 under A rotated by θ. This proves the claim.

Abstract

We study fundamental reachability problems on pseudo-orbits of linear dynamical systems. Pseudo-orbits can be viewed as a model of computation with limited precision and pseudo-reachability can be thought of as a robust version of classical reachability. Using an approach based on *o*-minimality of $\mathbb{R}_{\exp}$ we prove decidability of the discrete-time pseudo-reachability problem with arbitrary semialgebraic targets for diagonalisable linear dynamical systems. We also show that our method can be used to reduce the continuous-time pseudo-reachability problem to the (classical) time-bounded reachability problem, which is known to be conditionally decidable.

1 Introduction

A *discrete-time linear dynamical system* (LDS) is given by an update matrix $M \in \mathbb{Q}^{d\times d}$ and a starting point $s \in \mathbb{Q}^d$. An LDS describes a system whose state contains d rational numbers and evolves linearly. The *orbit* of such a system is the infinite sequence $\langle s, Ms, M^2s, \ldots\rangle$ of points in $\mathbb{Q}^d$. Orbits of LDS arise in many areas of computer science and mathematics, including verification of linear loops [10], automata theory [3], and the theory of linear recurrence sequences [17].

A fundamental problem about LDS is the question of deciding, given a system $\langle M, s\rangle$ and a semialgebraic target set $S \subseteq \mathbb{R}^d$, whether there exists $n \in \mathbb{N}$ such that $M^n s \in S$. This problem is known as the *reachability problem for LDS* and has been studied extensively over the last few decades. In their seminal work, Kannan and Lipton showed that the point-to-point reachability problem, i.e., the case in which S is a singleton, is decidable in polynomial time. At the same time they observed that the case in which S is a $(d-1)$-dimensional subspace of $\mathbb{R}^d$ (i.e. a hyperplane) is equivalent to the famous *Skolem problem* whose decidability remains open to this day. The Skolem problem asks, given a linear recurrence sequence defined by a recurrence relation $u_{n+d} = a_1 u_n + \ldots + a_d u_{n+d-1}$ and initial values $u_0, \ldots, u_{d-1}$, to decide whether there exists n such that $u_n = 0$. In addition to this Skolem-hardness, the difficulty of settling the reachability problem was further demonstrated by the results of [16], which show that solving the reachability problem with halfspace targets, known as the *positivity problem*, would entail major mathematical breakthroughs in the field of Diophantine approximation.

The reachability problem is defined with reference to the exact dynamics of an LDS. Since computational systems typically operate with finite precision, it is natural to consider an alternate notion of reachability involving so-called *pseudo-orbits.* The notion of pseudo-orbit is an important conceptual tool in dynamical systems that was studied by Anosov [2], Bowen [4], and Conley [6], and was used by the latter to prove what is sometimes called the fundamental theorem of dynamical systems. Given an LDS $\langle M, s\rangle$, a sequence $\langle x_n \mid n \in \mathbb{N}\rangle$ is an *ϵ-pseudo-orbit* of s under M if $x_0 = s$ and $\|Mx_n - x_{n+1}\| < \epsilon$ for all $n \in \mathbb{N}$. In other words, in a pseudo-orbit one considers an enlarged transition relation that is obtained by considering the dynamical system up to precision ϵ. Given $\epsilon > 0$, a set S is said to be *ϵ-pseudo-reachable* if there exists an ϵ-pseudo-orbit $\langle x_0 = s, x_1, x_2, \ldots\rangle$ of s under M that reaches S. We further say that S is *pseudo-reachable* if S is ϵ-pseudo-reachable for every $\epsilon > 0$. If a set S of error states is not pseudo-reachable then we can consider the system as being safe if implemented with sufficient precision, while if S is pseudo-reachable, it means that no finite amount of precision suffices to make the system reliably safe.

Recently, D'Costa et al. [7] considered the pseudo-reachability problem and, somewhat surprisingly, showed decidability in cases where S is a point (the pseudo-orbit problem), a hyperplane (the pseudo-Skolem problem) or a halfspace (the pseudo-positivity problem). Their proof of the first result relies on an exact characterisation of ϵ-pseudo-orbits. Their solution to the latter two problems, however, depends heavily on the fact that a hyperplane (a halfspace) can be defined using a single equality (inequality), an approach which unfortunately cannot be generalised to arbitrary semialgebraic targets. **In this work, we develop a novel logical approach to show the decidability of the pseudo-reachability problem for diagonalisable systems with arbitrary semialgebraic targets.**

1.1 High-level proof sketch of our approach

Our solution to the diagonalisable pseudo-reachability problem can be summarised as follows. Let $\widetilde{\mathcal{O}}_\epsilon(n)$ denote the set of all points that are reachable exactly at time n via an ϵ-pseudo-orbit. The pseudo-reachability problem then consists in checking whether the sentence $\Phi := \forall\epsilon.\, \exists n \in \mathbb{N} : \widetilde{\mathcal{O}}_\epsilon(n) \cap S \neq \emptyset$ is true. In this form, Φ is not amenable to application of logical methods as it involves both integer and real-valued variables, in addition to exponentiation with a complex base (coming from non-real eigenvalues of M). We therefore first move to the continuous domain and construct an abstraction $\mathcal{A}_\epsilon(t)$ for $t \in \mathbb{R}^{\geq 0}$ that is definable in $\mathbb{R}_{\exp}$ such that $\mathcal{A}_\epsilon(n) \supseteq \widetilde{\mathcal{O}}_\epsilon(n)$ for all $n \in \mathbb{N}$. We then investigate the values of ϵ and t that make $\Psi(\epsilon, t) := \mathcal{A}_\epsilon(t) \cap S \neq \emptyset$ true. We show that by the o-minimality of $\mathbb{R}_{\exp}$, either for every $\epsilon > 0$ there exists T such that for all $t > T$, $\Psi(\epsilon, t)$ holds, or the pseudo-reachability problem is equivalent to a finite-horizon reachability problem that is easily solvable. In the former case, it follows that for every $\epsilon > 0$, $\Psi(\epsilon, n)$ holds for all sufficiently large integer values n, thus establishing a bridge back to the discrete setting. We conclude by showing that in this case, S is pseudo-reachable. Intuitively, the idea is to use the universal quantification over ϵ to argue that if S can be reached using an $\epsilon/2$-abstraction at all but finitely many time steps, then it can be reached by an ϵ-pseudo-orbit, in fact at infinitely many possible time steps. The importance of the universal quantification is also illustrated by the following hardness result. For any fixed $\epsilon > 0$, it is decidable whether $\exists n \in \mathbb{N} : \mathcal{A}_\epsilon(n) \cap S \neq \emptyset$ holds, whereas the ϵ-pseudo-reachability problem of determining whether $\exists n \in \mathbb{N} : \widetilde{\mathcal{O}}_\epsilon(n) \cap S \neq \emptyset$ holds is hard with respect to (a hard subclass of) the Skolem problem, as shown in Section 4.

The approach outlined above can be adapted to solve a few other related problems about linear dynamical systems. An example would be the *robust reachability problem* recently considered by Akshay et al. in [1]: given an LDS $\langle M, s\rangle$ and a semialgebraic target S, decide whether for all $\epsilon > 0$ there exists a point s' in the ϵ-neighbourhood of s whose orbit reaches S. This problem can be thought of as a modification of the pseudo-reachability problem where only one perturbation is allowed at the very beginning. Due to this simplification, we are able to show, in the full version of this paper, full decidability (that is, without the restriction to diagonalisable systems) of the robust reachability problem. Finally, as the first step of our solution is to translate the problem into the continuous domain, the continuous versions of both the pseudo-reachability problem (Section 5) and the robust reachability problem (discussed in the full version) can be handled using the same approach, arguably more naturally. For the former, because we proceed by reducing the pseudo-reachability problem to bounded-time reachability problem, the decidability result assumes Schanuel's conjecture.

2 Mathematical tools

We write $B(c, r)$ for the closed ℓ_2-ball of radius r centred around $c \in \mathbb{R}^d$ and $\mathbf{0} \in \mathbb{R}^d$ for the d-dimensional zero vector. We denote by $\mathbb{T} \subseteq \mathbb{C}$ the unit circle in the complex plane and by $||x||$ the ℓ_2-norm of a vector $x \in \mathbb{R}^d$.

2.1 First-order logic

We denote by $\mathbb{R}_0$ the (structure of) real numbers with addition and multiplication, by $\mathbb{R}_{\exp}$ the real numbers with addition, multiplication and (unbounded) exponentiation and by $\mathbb{R}_{\exp,\cos\restriction[0,T]}$ the real numbers with exponentiation and bounded (in input, by some $T > 0$) trigonometric functions. By the Tarski-Seidenberg theorem, the theory of $\mathbb{R}_0$ admits effective quantifier elimination and is therefore decidable. The theories of $\mathbb{R}_{\exp}$ and $\mathbb{R}_{\exp,\cos\restriction[0,T]}$ are known to be decidable subject to Schanuel's conjecture (see, e.g., [11]) in transcendental number theory [13, 19]. However $\mathbb{R}_{\exp,\cos\restriction[0,T]}$ (and hence $\mathbb{R}_{\exp}$ and $\mathbb{R}_0$) are unconditionally known to be o-minimal [18]. That is, any subset of $\mathbb{R}$ definable using arithmetic operations, real exponentiation and bounded trigonometric functions is a finite union of intervals. In particular, any subset of $\mathbb{R}^{\geq 0}$ definable in this way is either bounded or contains all sufficiently large real numbers. For the discrete-time problems considered in this paper we will only need to work with $\mathbb{R}_{\exp}$. We will need $\mathbb{R}_{\exp,\cos\restriction[0,T]}$ only when considering the classical bounded-time reachability problem for continuous-time linear dynamical systems.

A *semialgebraic* set is a subset of $\mathbb{R}^d$ definable (without parameters) in $\mathbb{R}_0$. We say that a function $\varphi : \mathbb{R}^l \to \mathbb{R}^m$ is semialgebraic if its graph is a semialgebraic subset of $\mathbb{R}^{l+m}$. Intuitively, semialgebraic functions are exactly the functions that can be specified using arithmetic and logical operations over the real numbers.

2.2 Kronecker's theorem and its applications

The analysis of problems about linear dynamical systems often reduces to that of the orbit $\langle \Gamma^n \mid n \in \mathbb{N} \rangle$ where $\Gamma^n = (\gamma_1^n, \ldots, \gamma_k^n)$ for $\gamma_1, \ldots, \gamma_k \in \mathbb{T}$. Let $\mathcal{T} = \mathrm{cl}(\{\Gamma^n : n \in \mathbb{N}\})$ be the topological closure of this discrete orbit. The set $\mathcal{T}$ is semialgebraic and well-understood with the help of Kronecker's theorem in simultaneous Diophantine approximation [9].

▶ **Theorem 1** (Kronecker). *Let $\theta_1, \ldots, \theta_k, \varphi_1, \ldots, \varphi_k \in \mathbb{R}$ be such that for any $a_1, \ldots, a_k \in \mathbb{Z}$,*

$$\sum_{i=1}^{k} a_i \theta_i \in \mathbb{Z} \Rightarrow \sum_{i=1}^{k} a_i \varphi_i \in \mathbb{Z}.$$

For any $\epsilon > 0$ there exist infinitely many $n \in \mathbb{N}$ such that $\{n\theta_i - \varphi_i\} < \epsilon$ for all $1 \leq i \leq k$, where $\{x\}$ denotes the distance from $x \in \mathbb{R}$ to the nearest integer.

To apply this theorem to our situation, let

$$\mathcal{T} = \{(z_1, \ldots, z_k) : \forall a_1, \ldots, a_k \in \mathbb{Z} : \gamma_1^{a_1} \cdots \gamma_k^{a_k} = 1 \Rightarrow z_1^{a_1} \cdots z_k^{a_k} = 1\}.$$

For $z = (z_1, \ldots, z_k) \in \mathcal{T}$, by considering $\theta_i = \frac{\arg(\gamma_i)}{2\pi}$ and $\varphi_i = \frac{\arg(z_i)}{2\pi}$ for $1 \leq i \leq k$ we can deduce that for each $\epsilon > 0$ there exists n such that $||z - \Gamma^n|| < \epsilon$ and hence the orbit $\langle \Gamma^n \mid n \in \mathbb{N} \rangle$ is dense in $\mathcal{T}$. On the other hand, using Masser's deep results [14] about multiplicative relations between algebraic numbers one can compute, in polynomial time, a finite basis for $\{(a_1, \ldots, a_k) \in \mathbb{Z}^k : \gamma_1^{a_1} \cdots \gamma_k^{a_k} = 1\}$. Hence $\mathcal{T}$ is closed, semialgebraic and effectively computable. It then follows that $\mathcal{T} = \mathrm{cl}(\{\Gamma^n : n \in \mathbb{N}\})$.

We will also need the following lemma which is a consequence of the effective computability of $\mathcal{T} = \mathrm{cl}(\{\Gamma^n : n \in \mathbb{N}\})$ as a semialgebraic set.

▶ **Lemma 2.** *Let $R = \mathrm{diag}(\Lambda_1, \ldots, \Lambda_k) \in \mathbb{R}^{2k \times 2k}$ be a block diagonal matrix where Λ_i is an algebraic rotation matrix for $1 \leq i \leq k$. The closure of the set $\{R^n x : n \in \mathbb{N}\}$, for x with algebraic entries, is semialgebraic and effectively computable.*

The proof follows immediately from diagonalising R^n and observing that all eigenvalues of R are algebraic numbers in $\mathbb{T}$.

3 Decidability for discrete-time diagonalisable systems

In this section we prove our main result: the decidability of the pseudo-reachability problem for discrete-time diagonalisable *affine dynamical systems*, which are a generalisation of LDS. The reason we consider affine systems is that the well-known homogenisation trick (increasing the dimension by one and adding a coordinate that is always equal to 1) used for reducing the classical reachability problem for affine systems to the reachability problem for LDS doesn't work for the pseudo-reachability problem: when perturbations are allowed, one cannot force a coordinate to remain constant. Hence affine systems require separate treatment.

▶ **Problem 3** (pseudo-reachability). *Let $M \in \mathbb{Q}^{L \times L}$ be an update matrix, $s \in \mathbb{Q}^L$ be a starting point, $b \in \mathbb{Q}^L$ be an affine term and $S \subseteq \mathbb{R}^L$ be a semialgebraic target set. A sequence $\langle x_0 = s, x_1, x_2 \ldots \rangle$ is an ϵ-pseudo-orbit of s if $||Mx_n + b - x_{n+1}|| \leq \epsilon$ for all n. The pseudo-reachability problem asks: given M, b, s and S, decide whether for each $\epsilon > 0$ there exists an ϵ-pseudo-orbit of s that reaches the set S.*

Let $\widetilde{\mathcal{O}}_\epsilon(n)$ denote the set of all points that are reachable via an ϵ-pseudo-orbit of s under the map $x \mapsto Mx + b$ at time n. Since $\widetilde{\mathcal{O}}_\epsilon(0) = \{s\}$ and $\widetilde{\mathcal{O}}_\epsilon(n+1) = M\widetilde{\mathcal{O}}_\epsilon(n) + b + \epsilon B(\mathbf{0}, 1)$, by induction we can show that $\widetilde{\mathcal{O}}_\epsilon(n) = M^n s + \sum_{i=0}^{n-1} M^i b + \epsilon \sum_{i=0}^{n-1} M^i B(\mathbf{0}, 1)$. The pseudo-reachability problem is then equivalent to determining the truth of $\forall\epsilon.\, \exists n : \widetilde{\mathcal{O}}_\epsilon(n) \cap S \neq \emptyset$. Here $B(\mathbf{0}, 1)$ can be viewed as a set of "control inputs", and the pseudo-reachability problem can be viewed as the problem of determining whether S can be reached using arbitrarily small control inputs. The next lemma shows that we can in fact, choose any reasonable control set.

▶ **Lemma 4** (Invariance under change of the control set). *Let $\mathcal{B} \subseteq \mathbb{R}^L$ be a bounded set containing an open ball around the origin.*

1. *The pseudo-reachability problem as defined above is equivalent to the problem of determining whether*

$$\forall\epsilon.\, \exists n : (M^n s + \sum_{i=0}^{n-1} M^i b + \epsilon \sum_{i=0}^{n-1} M^i \mathcal{B}) \cap S \neq \emptyset.$$

2. *We may assume the matrix M is in real Jordan form.*

Proof. Since $\mathcal{B}$ is assumed to be bounded and to contain an open neighbourhood around the origin, there must exist constants C_1, C_2 such that $C_1 B(\mathbf{0}, 1) \subseteq \mathcal{B} \subseteq C_2 B(\mathbf{0}, 1)$. Hence

$$C_1 \epsilon \sum_{i=0}^{n-1} M^i B(\mathbf{0}, 1) \subseteq \epsilon \sum_{i=0}^{n-1} M^i \mathcal{B} \subseteq C_2 \epsilon \sum_{i=0}^{n-1} M^i B(\mathbf{0}, 1).$$

The proof of (1) then follows from the fact that ϵ is universally quantified: one can simulate (i) an ϵ-pseudo-orbit with control set $\mathcal{B}$ using a $C_2\epsilon$-pseudo-orbit with control set $B(\mathbf{0}, 1)$ and (ii) an ϵ-pseudo-orbit with control set $B(\mathbf{0}, 1)$ using a ϵ/C_1-pseudo-orbit with control set $\mathcal{B}$. Proof of (2) follows from observing that multiplying $B(\mathbf{0}, 1)$ by an invertible change of basis matrix results in a bounded control set containing a neighbourhood around $\mathbf{0}$. ◀

Observe that the change of the control set described above is not applicable when ϵ is fixed, as in the ϵ-pseudo-reachability problem discussed in Section 4.

3.1 A closed form for $\widetilde{\mathcal{O}}_\epsilon(n)$

We now use Lemma 4 to choose a control set that results in $\widetilde{\mathcal{O}}_\epsilon(n)$ with a convenient first-order closed form: observe that the naïve formulation above involves the term $\sum_{i=0}^{n-1} M^i B(\mathbf{0}, 1)$ which is not "first-order".

Assume M is diagonalisable and in real Jordan form: $M = \operatorname{diag}(\Lambda_1, \ldots, \Lambda_k, \rho_{k+1}, \ldots, \rho_d)$. That is, M consists of d block, the first k of which have dimension 2×2 and a pair of non-real conjugate eigenvalues, whereas the remaining blocks are 1×1 and real. Write ρ_j for the spectral radius of the jth block. We can factor M into a "scaling" and a "rotation" as $M = DR$ where $D = \operatorname{diag}(\rho_1, \rho_1, \ldots, \rho_k, \rho_k, \rho_{k+1}, \rho_{k+2}, \ldots, \rho_d)$ is diagonal and R is a block-diagonal matrix that consists of blocks that are either 2×2 rotation matrices or 1×1 and equal to $[\pm 1]$. Hereafter we will be using the convenient "rotation-invariant" control set

$$\mathcal{B} = \prod_{j=1}^{k} B((0,0), 1) \times \prod_{j=k+1}^{d} [-1, 1] = \prod_{j=1}^{d} B(\mathbf{0}, 1)$$

where $B((0,0),1)$ is the unit disc. Observe that $\mathcal{B}$ is a product of ℓ_2-balls that matches the block structure of M. It follows that $R\mathcal{B} = \mathcal{B}$ and hence

$$\widetilde{\mathcal{O}}_\epsilon(n) = D^n R^n s + \sum_{i=0}^{n-1} M^i b + \epsilon \sum_{i=0}^{n-1} D^i R^i \mathcal{B} = D^n R^n s + \sum_{i=0}^{n-1} M^i b + \epsilon\mathcal{B}(n)$$

where $\mathcal{B}(n) = \sum_{i=0}^{n-1} D^i \mathcal{B}$. We then have

$$\mathcal{B}(n) = \sum_{i=0}^{n-1} D^i \prod_{j=1}^{d} B(\mathbf{0},1) = \sum_{i=0}^{n-1}\prod_{j=1}^{d} B(\mathbf{0},\rho_j^i) = \prod_{j=0}^{d} B(\mathbf{0},\sum_{i=0}^{n-1}\rho_j^i).$$

Geometrically, the idea is that a 2×2 or a 1×1 block of D maps an origin-centred disc (which corresponds to a symmetric interval in 1D) to an origin-centred disc, and a set-sum of such discs is again an origin-centred disc. Note that our ability to reason in this way crucially depends on the fact that M is diagonalisable. Finally, since $\sum_{i=0}^{n-1} \rho_j^i$ is either $\frac{\rho_j^n - 1}{\rho_j - 1}$ or $n\rho_j$, we can write $\mathcal{B}(n) = \{z : \varphi(z, n, \rho_1^n, \ldots, \rho_d^n)\}$, where φ is a semialgebraic predicate.

We can apply the blockwise summation technique, distinguishing between the cases where the spectral radius of the block is 1 or different from 1, to the term $\sum_{i=0}^{n-1} M^i b$ to obtain the closed form $\sum_{i=0}^{n-1} M^i b = D^n R^n x' + cn + d$, where x', c and d only depend on M and b. We then fold s and x' into a new, fictive starting point x to obtain the final closed form

$$\widetilde{\mathcal{O}}_\epsilon(n) = D^n R^n x + cn + d + \epsilon\mathcal{B}(n).$$

In order to solve the pseudo-reachability problem, we henceforth consider the problem of determining the truth of the sentence $\forall\epsilon > 0.\, \exists n : (D^n R^n x + cn + d + \epsilon\mathcal{B}(n)) \cap S \neq 0$, where all the input vectors and matrices have real algebraic entries.

3.2 Passing to the abstraction

The expression for $\widetilde{\mathcal{O}}_\epsilon(n)$ contains the term $D^n R^n x$, which is the last obstacle to obtaining an expression which we can attack using known results about theories of real numbers. To address this issue we resort to abstracting $\widetilde{\mathcal{O}}_\epsilon(n)$. Let

$$\mathcal{T} := \mathrm{cl}\left(\{R^n x : n \in \mathbb{N}\}\right) \text{ and } \mathcal{A}_\epsilon(n) := D^n\mathcal{T} + cn + d + \epsilon\mathcal{B}(n)$$

where $\mathcal{T}$ is the closure of the orbit of x under R, and is semialgebraic and effectively computable by the discussion in Subsection 2.2. Moreover, recall that by Kronecker's theorem for every $z \in \mathcal{T}$ and $\epsilon > 0$ there exist infinitely many integers $0 < n_1 < n_2 < \ldots$ such that $||R^{n_i}x - z|| < \epsilon$ for all i.

Here $\mathcal{A}_\epsilon(n)$ acts as an abstraction of $\widetilde{\mathcal{O}}_\epsilon(n)$. In particular, for all $\epsilon > 0$ and $n \in \mathbb{N}$ we have $\mathcal{A}_\epsilon(n) \supseteq \widetilde{\mathcal{O}}_\epsilon(n)$. Observe that $\mathcal{A}_\epsilon(n) = \{z : \varphi(z, \epsilon, n, \rho_1^n, \ldots, \rho_d^n)\}$ for a semialgebraic predicate φ. Viewing $\mathcal{A}_\epsilon(n)$ as a proxy for $\widetilde{\mathcal{O}}_\epsilon(n)$, we arrive at the following dichotomy.

▶ **Lemma 5.** *Either*

1. *for every $\epsilon > 0$ there exists N_ϵ such that for all $n > N_\epsilon$, $\mathcal{A}_\epsilon(n)$ intersects S, or*
2. *there exist N and $\epsilon > 0$, both effectively computable, such that $\mathcal{A}_\epsilon(n)$ does not intersect S for all $n > N$.*

Moreover, it can be effectively determined which case holds.

Proof. First we show that the dichotomy holds, putting the issues of effectiveness aside. Let

$$\Phi(\epsilon, n) = \bigvee_{\alpha \in A} \bigwedge_{\beta \in B} p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$$

be a quantifier-free formula equivalent to $\mathcal{A}_\epsilon(n) \cap S \neq \emptyset$. Such $\Phi(\epsilon, n)$ must exist because $\mathcal{A}_\epsilon(n)$ is semialgebraic with parameters from $\{\epsilon, n, \rho_1^n, \ldots, \rho_d^n\}$ and by the Tarski-Seidenberg theorem, each such set can be described using a quantifier-free formula of the form given above. Suppose Case 1 does not hold. Then there exists a particular $\epsilon > 0$ such that $\Phi(\epsilon, n)$ does not hold for arbitrarily large n. Treating n as a continuous parameter, consider the set $\{n \in \mathbb{R}_{\geq 0} : \Phi(\epsilon, n) \text{ does not hold}\}$. By o-minimality of $\mathbb{R}_{\text{exp}}$ this set is a finite union of intervals and and by the assumption that Case 1 does not hold, it contains arbitrarily large integers. Hence it must contain all integers in (N, ∞) for some $N \in \mathbb{N}$. That is, for all $n > N$ the formula $\Phi(\epsilon, n)$ does not hold.

Effectiveness. We now address the issues of effectiveness. Consider the formula

$$\Psi(\epsilon) = \exists N_\epsilon . \forall n > N_\epsilon : \Phi(\epsilon, n).$$

We show that $\Psi(\epsilon)$ is equivalent to a formula $\psi(\epsilon)$ in the language of $\mathbb{R}_0$. To determine which case holds it then remains to determine the truth value of the sentence $\forall \epsilon : \psi(\epsilon)$.

By the o-minimality argument above, given $\epsilon > 0$, each $p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$ either holds for finitely many integer values of n or holds for all sufficiently large integer values n. By elementary considerations it follows that $\Psi(\epsilon)$ is equivalent to

$$\bigvee_{\alpha \in A} \bigwedge_{\beta \in B} \exists N_\epsilon . \forall n > N_\epsilon : p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0.$$

Hence it suffices to show how to construct a formula $\psi(\epsilon)$ in the language of $\mathbb{R}_0$ that is equivalent to $\exists N_\epsilon . \forall n > N_\epsilon : p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$. For each $\epsilon > 0$, the formula first tests if $p_{\alpha,\beta}(\epsilon)$ (as a polynomial in $d+1$ remaining variables) is identically zero. If yes, then $\varphi(\epsilon)$ is true or false depending only on $\bowtie_{\alpha,\beta}$. Otherwise, write $p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) = \sum_{i=1}^k q_i(\epsilon, n) R_i^n$ where $q_i(\epsilon)$ is not identically zero for all i and $R_1 > \cdots > R_k > 0$ are real algebraic numbers of the form $\rho_1^{p_1} \cdots \rho_d^{p_d}$ for $p_1, \ldots, p_d \in \mathbb{N}$. Since $|q_1(\epsilon, n) R_1^n| > \left|\sum_{i=2}^k q_i(\epsilon, n) R_i^n\right|$ for sufficiently large n, whether $p_{\alpha,\beta}(\epsilon, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$ holds for sufficiently large n depends only on $q_1(\epsilon, n)$. Hence we can choose $\psi(\epsilon)$ to be $\lim_{n \to \infty} q_1(\epsilon) \bowtie_{\alpha,\beta} 0$, which amounts to a sign condition on the coefficients of $q_1(\epsilon, n)$.

Computing N. Finally, we show that in Case 2, the value N can be effectively computed. To this end, by repeatedly trying smaller and smaller values of ϵ first compute a rational $e > 0$ such that $\Psi(e)$ (equivalently, $\psi(e)$) does not hold. To be able to compute N it then suffices to compute, for a particular (α, β), a value $N_{\alpha,\beta}$ such that $p_{\alpha,\beta}(e, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$ does not hold for all $n > N_{\alpha,\beta}$, assuming that it does not hold for sufficiently large n. We can then take N to be the maximum of $N_{\alpha,\beta}$ over $(\alpha, \beta) \in A \times B$.

To compute $N_{\alpha,\beta}$, consider $p := p_{\alpha,\beta}(e)$. Assuming it is not identically zero (otherwise we can choose $N_{\alpha,\beta}$ to be any positive integer), write $p(n, \rho_1^n, \ldots, \rho_d^n) = \sum_{i=1}^k q_i(n) R_i^n$ where q_i is not identically zero for all i and $R_1 > \cdots > R_k > 0$ are real algebraic. Since $p_{\alpha,\beta}(e, n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$ and hence $p(n, \rho_1^n, \ldots, \rho_d^n) \bowtie_{\alpha,\beta} 0$ do not hold for sufficiently large n, it must be the case that $q_1(n) \bowtie_{\alpha,\beta} 0$ does not hold for sufficiently large n. Hence it remains to choose $N_{\alpha,\beta}$ large enough so that for all $n > N_{\alpha,\beta}$, $|q_1(n) R_1^n|$ dominates $\left|\sum_{i=2}^k q_i(n) R_i^n\right|$. ◀

3.3 From the abstraction back to ϵ-pseudo-orbits

In this section we consider the relationship between the two cases of Lemma 5 and our original pseudo-reachability problem. We start with Case 2. Observe that $\mathcal{O}_\epsilon(n) \subseteq \mathcal{A}_\epsilon(n)$ for every $n \in \mathbb{N}$ and $\epsilon > 0$. Therefore, when Case 2 holds, for any $n > N$ and $\epsilon > 0$ the target set cannot be reached by $\mathcal{O}_\epsilon$. It remains to check pseudo-reachability at time steps $n \leq N$. We claim that S is pseudo-reachable if and only

$$\forall \epsilon. \exists n \leq N : (M^n x + cn + d + \epsilon \mathcal{B}(n)) \cap S \neq \emptyset.$$

Let $\overline{S}$ denote the topological closure of S. We show that the statement above is equivalent to $\exists n \leq N : M^n x + cn + d \in \overline{S}$. Observe that if for all $n \leq N$ the point $M^n x + cn + d$ is not in $\overline{S}$, then by compactness the smallest distance from $\{M^n x + cn + d \mid n \leq N\}$ to $\overline{S}$ is positive and hence for sufficiently small ϵ the target S cannot be ϵ-pseudo-reached within the first N steps. Conversely, if $M^n x + cn + d \in \overline{S}$ for some $n \leq N$, then because $\mathcal{B}(n)$ is full dimensional and contains $\mathbf{0}$ in its interior, it follows that $(M^n x + cn + d + \epsilon \mathcal{B}(n)) \cap S \neq \emptyset$ for all $\epsilon > 0$. Therefore, in Case 2 pseudo-reachability can be decided by simply checking if $\{M^n x + cn + d \mid n \leq N\}$ reaches $\overline{S}$.

Next we will show that S is pseudo-reachable if Case 1 holds. Given $z \in \mathcal{T}$, we define a "localisation" of the abstraction at the point z as $\mathcal{A}_\epsilon(n)(z) := D^n z + cn + d + \epsilon \mathcal{B}(n)$. Observe that $\mathcal{A}_\epsilon(n) = \{\mathcal{A}_\epsilon(n)(z) : z \in \mathcal{T}\}$. This definition of a localisation will allow us to select a "concrete trajectory" from the set of all possible (abstract) trajectories.

Fix $\epsilon > 0$ and let $T_n := \{z \in \mathcal{T} : \mathcal{A}_\epsilon(n)(z)$ intersects $S\}$. The next lemma implies that the sequence T_n must tend towards a limiting shape; i.e. it cannot "jump around" forever.

▶ **Lemma 6.** *Let $T_n = \{z : \varphi(z, n, \rho_1^n, \dots, \rho_d^n)\}$, where φ is a semialgebraic predicate and $\rho_1, \dots, \rho_d$ are real algebraic, be a family of non-empty sets contained in a compact set $\mathcal{T}$. There exists a non-empty limiting set $L \subseteq \mathcal{T}$ to which the sequence T_n converges as $n \to \infty$, in the following sense.*

a *For every $\epsilon > 0$, there exists N such that for all $n > N$, $T_n \subseteq L + B(\mathbf{0}, \epsilon)$.*

b *For all $z \in L$ and $\epsilon > 0$ there exists N such that for all $n > N$, $z + B(\mathbf{0}, \epsilon)$ intersects T_n.*

Proof. Write $\varphi(z, n, \rho_1^n, \dots, \rho_d^n) = \bigvee_{\alpha \in A} \bigwedge_{\beta \in B} p_{\alpha,\beta}(z, n, \rho_1^n, \dots, \rho_d^n) \bowtie_{\alpha,\beta} 0$. We can define the sequence $\langle T_t \mid t \in \mathbb{R} \rangle$ as $T_t = \{z : \varphi(z, t, \rho_1^t, \dots, \rho_d^t)\}$. Let $L = \{x : \liminf d(x, T_t) = 0\}$ where $d(x, T_t)$ denotes the shortest Euclidean distance from x to a point in T_t.

We prove the first claim by contradiction. Suppose there exists $\epsilon > 0$ such that at infinitely many unbounded time steps $t_1 < t_2 < \dots$ there are points $z_1, z_2, \dots$ such that $z_i \in T_i$ but $z_i \notin L + B(\mathbf{0}, \epsilon)$. Then the sequence z_i must have an accumulation point z in $\mathcal{T} \setminus L$. But z will also satisfy $\liminf d(z, T_t) = 0$ and hence $z \in L$, a contradiction.

We prove the second claim using o-minimality of $\mathbb{R}_{\exp}$. Fix $z \in L$ and $\epsilon > 0$ and consider the set $Z = \{t \in \mathbb{R} : z + B(\mathbf{0}, \epsilon)$ intersects $T_t\}$. The set Z is o-minimal, and since $z \in L$, it is unbounded from above. Hence it must contain an interval of the form (N, ∞), which implies the desired result. ◀

One can also show that the set L described above is in fact semialgebraic, but this is not necessary for our arguments. We are now ready to show that S is pseudo-reachable if Case 1 of Lemma 5 holds.

▶ **Lemma 7.** *If for every $\epsilon > 0$ there exists N_ϵ such that for all $n > N_\epsilon$, $\mathcal{A}_\epsilon(n)$ intersects S then S is pseudo-reachable.*

The main idea of the proof is to use the assumption that $\mathcal{A}_{\epsilon/2}(n)$ intersects S for sufficiently large n to construct an ϵ-pseudo-orbit that hits S. Intuitively, in order to simulate $\mathcal{A}_{\epsilon/2}(n)$ using an ϵ-pseudo-orbit, $\epsilon/2$ of the total control allowance is used to replicate the effect of the control inputs (of size at most $\epsilon/2$, corresponding to the $\frac{\epsilon}{2}\mathcal{B}(n)$ term in the definition of $\mathcal{A}_{\epsilon/2}(n)$) and the remaining $\epsilon/2$ is used to compensate for the abstraction from the starting point a to the set $\mathcal{T}$. In fact, we do not know if one can deduce that S is ϵ-pseudo-reachable from knowing that $\mathcal{A}_{\epsilon}(n)$ intersects S for sufficiently large n. This illustrates the reason why the pseudo-reachability problem is easier than the ϵ-pseudo-reachability problem; see Section 4 for a more concrete argument.

Proof. Fix $\epsilon > 0$. We show how to construct an ϵ-pseudo-orbit that hits S. Consider $\mathcal{A}_{\epsilon/2}(n)$. By assumption, there exists N_1 such that for all $n > N_1$, $\mathcal{A}_{\epsilon/2}(n)$ intersects S. We now investigate which localisations of the abstraction are responsible for intersecting S. Apply Lemma 6 to the sequence of sets $T_n = \{z \in \mathcal{T} : \mathcal{A}_{\epsilon/2}(n)(z) \text{ intersects } S\}$ to obtain their "limit" L. Fix any $p \in L$.

Let ϵ' be small enough so that $\epsilon' D^n \mathcal{B} \subseteq \frac{\epsilon}{2}\mathcal{B}(n)$ for all $n > 0$. Intuitively, such ϵ' must exist because $D^n\mathcal{B}$ and $D^{n-1}\mathcal{B}$ only differ by at most a constant factor that only depends on the magnitudes $\rho_1, \dots, \rho_d$ of eigenvalues of M, and we have that $D^{n-1}\mathcal{B} \subseteq \sum_{i=0}^{n-1} D^i\mathcal{B} = \mathcal{B}(n)$. By Lemma 6 (b), there exists $N > N_1$ such that for all $n > N$, $p + B(\mathbf{0}, \epsilon'/2)$ intersects T_n. That is, for all $n > N$ there exists $p_n \in \mathcal{T}$ such that $||p - p_n|| < \epsilon'/2$ and $p_n \in T_n$. Equivalently,

$$||p - p_n|| < \epsilon'/2 \text{ and } \mathcal{A}_{\epsilon/2}(n)(p_n) \text{ intersects } S.$$

By Kronecker's theorem there must exist $m > N$ such that $||R^m x - p|| < \epsilon'/2$. Hence we have $||R^m x - p_m|| < \epsilon'$ which implies $R^m x - p_m \in \epsilon'\mathcal{B}$ and hence $D^m(R^m x - p_m) \in \epsilon' D^m\mathcal{B}$. Since by construction of ϵ' we have $\epsilon' D^m \mathcal{B} \subseteq \frac{\epsilon}{2}\mathcal{B}(m)$, it follows that $D^m(R^m x - p_m) \in \frac{\epsilon}{2}\mathcal{B}(m)$ and hence $D^m p_m \in D^m R^m x + \frac{\epsilon}{2}\mathcal{B}(m)$. Therefore,

$$\widetilde{\mathcal{O}}_{\epsilon}(m) = (D^m R^m x + \frac{\epsilon}{2}\mathcal{B}(m)) + cm + d + \frac{\epsilon}{2}\mathcal{B}(m) \supseteq D^m p_m + cm + d + \frac{\epsilon}{2}\mathcal{B}(m) = \mathcal{A}_{\epsilon/2}(m)(p_m).$$

Since $\mathcal{A}_{\epsilon/2}(m)(p_m)$ intersects S, it then follows that $\widetilde{\mathcal{O}}_{\epsilon}(m)$ too must intersect S. ◀

3.4 The algorithm

To summarise, the analysis above gives us the following algorithm for determining if S is pseudo-reachable, i.e. if $\forall \epsilon > 0 . \exists n : \widetilde{\mathcal{O}}_{\epsilon}(n) \cap S \neq \emptyset$. Let $\varphi(n, \epsilon)$ be a quantifier-free formula in $\mathbb{R}_{\exp}$ defining the abstraction $\mathcal{A}_{\epsilon}(n)$. First determine, using the algorithm described in the proof of Lemma 5, whether Case 1 or Case 2 holds. If the former holds, then conclude that S is pseudo-reachable. If Case 2 holds, then compute the value of N effectively and check if there exists $n < N$ such that $(M^n x + cn + d) \cap \overline{S} \neq \emptyset$.

4 Skolem-hardness of the ϵ-pseudo-reachability problem

In this section we consider the ϵ-pseudo-reachability problem for discrete diagonalisable systems: given diagonalisable M, starting point s, a target set S and $\epsilon > 0$, decide whether there exists n such that $M^n s + \sum_{k=0}^{n-1} M^k B(\mathbf{0}, \epsilon) \cap S \neq 0$. This problem is also known as the reachability problem for linear time-invariant systems [8] with the control set $B(\mathbf{0}, \epsilon)$. We will reduce a hard subclass of the Skolem problem to our ϵ-pseudo-reachability problem.

The Skolem problem is not known to be decidable for orders $d \geq 5$, even for diagonalisable recurrences. The largest class of sequences for which decidability is known is the MSTV (Mignotte-Shorey-Tijdeman-Vereschagin) class, which consists of all linear recurrence sequences over integers that (i) have at most three dominant roots with respect to the usual (Archimedean) absolute or (ii) have at most two dominant roots with respect to a p-adic absolute value [12]. We consider the Skolem problem for integer sequences whose roots $\rho, \lambda_1, \ldots, \lambda_d$ satisfy $\rho = |\lambda_1| = \cdots = |\lambda_d|$. This class of sequences contains infinitely many instances that are not in the MSTV class and hence is a hard subclass of the Skolem problem.

Recall that any linear recurrence sequence can be written as $u_n = c^\top M^n s$ where M is the companion matrix of u_n whose eigenvalues are the roots of u_n. Let u_n be a diagonalisable sequence that belongs to the hard subclass described above, i.e. $u_n = c^\top M^n s$ where $M = \operatorname{diag}(\Lambda_1, \ldots, \Lambda_d, \rho)$ and Λ_i is a 2×2 real Jordan block with $\rho(\Lambda_i) = \rho$ for $1 \leq i \leq d$. We reduce the problem "does u_n have a zero?" to an ϵ-pseudo-reachability problem.

Consider the sequence $v_n = u_n^2$. Observe that $v_n = \sum_{i=1}^{L} c_i \Gamma_i^n s_i + C r^n$ where

- $r = \rho^2$,
- Γ_i is a 2×2 real Jordan block with $\rho(\Gamma_i) = r$ for $1 \leq i \leq L$,
- $c_i, s_i \in \mathbb{R}^2$ for $1 \leq i \leq L$, and
- $C > 0$.

The first two statements follow from the fact that the eigenvalues of v_n are products of eigenvalues of u_n. That $C > 0$ can be deduced as follows. Consider $w_n = \sum_{i=1}^{L} c_i \Gamma_i^n s_i$. It only has non-real roots and hence by [15] is infinitely often positive and negative. Hence if C is not positive, then $v_n < 0$ for infinitely many n, which contradicts the fact that $v_n \geq 0$.

Next observe that u_n has a zero iff there exists n such that $v_n \leq 0$. Since we are interested only in the sign of v_n, by scaling v_n by $C(2r)^n$ if necessary we assume that $r \in (0, 1)$ and $C = 1$. We will construct an instance of the ϵ-pseudo-reachability problem that is positive if and only if there exists n such that $v_n \leq 0$.

Define

- $A = \operatorname{diag}(\Gamma_1, \ldots, \Gamma_L)$,
- $s = (s_1, \ldots, s_L)$ and $c = (c_1, \ldots, c_L)$,
- $\epsilon = \frac{1-r}{||c||}$, and
- $H = \{z : c^\top \cdot z + 1 \leq 0\}$.

Observe that H is ϵ-pseudo-reachable if and only if $A^n s + \sum_{i=0}^{n-1} A^i B(\mathbf{0}, \epsilon) \cap H \neq 0$ for some n. Since $A^i B(\mathbf{0}, \epsilon) = B(\mathbf{0}, r^i \epsilon)$, we have $\sum_{i=0}^{n-1} A^i B(\mathbf{0}, \epsilon) = B(\mathbf{0}, \frac{1-r^n}{1-r}\epsilon) \coloneqq \mathcal{B}(n)$ and

$$H \text{ is } \epsilon\text{-pseudo-reachable} \iff \min_{z \in \mathcal{B}(n)} c \cdot (A^n s + z) + 1 \text{ is} \leq 0 \text{ for some } n.$$

We will show that in fact $\min_{z \in \mathcal{B}(n)} c \cdot (A^n s + z) + 1 = v_n$, which will conclude the proof.

$$\begin{aligned}
\min_{z \in \mathcal{B}(n)} c \cdot (A^n s + z) + 1 &= \sum_{i=1}^{L} c_i \Gamma_i^n s_i + 1 + \min_{z \in \mathcal{B}(n)} c \cdot z \\
&= \sum_{i=1}^{L} c_i \Gamma_i^n s_i + 1 - ||c|| \frac{1 - r^n}{1 - r} \epsilon \\
&= \sum_{i=1}^{L} c_i \Gamma_i^n s_i + r^n \\
&= v_n.
\end{aligned}$$

5 The continuous-time pseudo-reachability problem

In this section we show that the approach we described in Section 3 for deciding the discrete-time pseudo-reachability problem for diagonalisable systems also works in the continuous setting with one important difference: to handle Case 2 of the dichotomy lemma (exactly the same as Lemma 5) we need to solve the *bounded-time reachability problem for continuous-time affine dynamical systems*, which is only known to be decidable assuming Schanuel's conjecture [5]. For detailed proofs see the full version of the paper.

Let $M = \operatorname{diag}(\Lambda_1, \dots, \Lambda_k, \rho_{k+1}, \dots, \rho_d) \in (\mathbb{R} \cap \overline{\mathbb{Q}})^{L \times L}$ be a diagonalisable matrix in real Jordan form, $s \in \mathbb{Q}^L$ be a starting point, $b \in \mathbb{Q}^L$ be an affine term and $S \subseteq \mathbb{R}^L$ be a semialgebraic target set. The trajectory of the system (in the absence of additional control inputs) is given by

$$x(t) = e^{Mt}s + \int_0^t e^{Mh} b \, dh.$$

Intuitively, while in the discrete setting control inputs are applied after each unit of time and thus are represented by a sequence $\langle d_n \mid n \in \mathbb{N} \rangle$, in the continuous setting they are represented by a continuous function $\Delta : \mathbb{R}_{\geq 0} \to \mathbb{R}^L$. Hence an ϵ-pseudo-orbit is defined as a trajectory

$$x(t) = e^{Mt}s + \int_0^t e^{Mh} b \; dh + \int_0^t e^{Mh} \Delta(t-h) \, dh.$$

for some control signal $\Delta : \mathbb{R}_{\geq 0} \to \mathbb{R}^L$ satisfying $||\Delta_\epsilon(t)|| \leq \epsilon$ for all $t \geq 0$. The pseudo-reachability problem is then defined in the same way as before: decide whether for every $\epsilon > 0$ there exists an ϵ-pseudo-orbit that reaches S.

Let $\mathcal{B}$ be the same control set as defined in Subsection 3.1. For $1 \leq j \leq k$, let $r_j = \operatorname{Re}(\lambda_j)$ and $\omega_j = \operatorname{Im}(\lambda_j)$ where λ_j is a non-real eigenvalue of the block Λ_j. For $k < j \leq d$ let $r_j = \rho_j$ and $\omega_j = 0$. By using essentially the same arguments as in Subsection 3.1, we can show that the pseudo-reachability problem is equivalent to determining the truth of

$$\forall \epsilon > 0. \, \exists t : (e^{Mt}x + ct + d + \epsilon\mathcal{B}(t)) \cap S \neq \emptyset$$

where x, c, d are L-dimensional vectors and $\mathcal{B}(t) = \{z : \varphi(z, t, e^{r_1 t}, \dots, e^{r_d t})\}$ for semialgebraic predicate φ. We denote the term $e^{Mt}x + ct + d + \epsilon\mathcal{B}(t)$ by $\widetilde{\mathcal{O}}_\epsilon(n)$.

To define a convenient abstraction, we again write $e^{Mt} = D(t)R(t)$ where $D(t) := \operatorname{diag}(e^{r_1 t}, e^{r_1 t}, \dots, e^{r_k t}, e^{r_k t}, e^{r_{k+1} t}, e^{r_{k+2} t}, \dots, e^{r_{k+d} t})$ is diagonal and $R(t)$ is a block diagonal matrix whose blocks are rotation matrices of the form $\begin{bmatrix} \cos(\omega_j t) & -\sin(\omega_i t) \\ \sin(\omega_j t) & \cos(\omega_j t) \end{bmatrix}$ for $1 \leq j \leq k$ and are of the form $\Omega_i = \begin{bmatrix} 1 \end{bmatrix}$ for $k + 1 \leq j \leq d$. Just as in the discrete case, we next define

$$\mathcal{T} := \operatorname{cl}(\{R(t)x : t \in \mathbb{R}_{\geq 0}\}) \text{ and } \mathcal{A}_\epsilon(t) := D(t)\mathcal{T} + ct + d + \epsilon\mathcal{B}(t),$$

where $\mathcal{T}$ is again semialgebraic and effectively computable [5] and $\mathcal{A}_\epsilon$ acts as an abstraction of $\widetilde{\mathcal{O}}_\epsilon(t)$. In particular, for all $\epsilon > 0$ and $t \in \mathbb{R}_{\geq 0}$, we have $\widetilde{\mathcal{O}}_\epsilon(t) \subseteq \mathcal{A}_\epsilon(t)$. Moreover, observe that $\mathcal{A}_\epsilon(t) = \varphi(t, e^{r_1 t}, \dots, e^{r_d t})$ for a semialgebraic function φ, which is the most important property we need. In the full verision, using the same approach based on o-minimality we show the following.

▶ **Theorem 8.** *The continuous-time pseudo-reachability problem reduces to the bounded-time reachability problem for continuous-time affine dynamical systems.*

Intuitively, the dichotomy lemma (Lemma 5) holds verbatim for the continuous systems, and in Case 1 again S is always pseudo-reachable. It then remains to handle Case 2. Since bounded-time reachability problem for continuous-time affine dynamical systems can be encoded in $\mathbb{R}_{\exp,\cos\restriction[0,T]}$, we have the following (conditional) decidability result.

▶ **Corollary 9.** *Continuous-time pseudo-reachability problem for diagonalisable affine dynamical systems is decidable subject to Schanuel's conjecture.*

6 Discussion

The main technical result of our paper is that it is decidable whether

$$\forall \epsilon > 0. \exists n : (M^n x + f(n) + \epsilon\mathcal{B}(n)) \cap S \neq 0$$

where M is a diagonalisable matrix with algebraic entries, x is an algebraic starting point, f is a semialgebraic function, S is a semialgebraic target and $\mathcal{B}(n) = \varphi(n, \rho_1^n, \dots, \rho_d^n)$ for $\rho_1, \dots, \rho_d \in \mathbb{R} \cap \overline{\mathbb{Q}}$ and a semialgebraic function φ. We used this result to show decidability of the discrete-time pseudo-reachability problem for diagonalisable systems in the following way. We first observed that the pseudo-reachability problem can be cast as the problem of determining whether $\forall \epsilon > 0. \exists n : \widetilde{\mathcal{O}}_\epsilon(n) \cap S \neq \emptyset$, where $\widetilde{\mathcal{O}}_\epsilon(n)$ is the set of all points that are reachable exactly at the time n via an ϵ-pseudo-orbit. After choosing $\mathcal{B}$ as the most convenient control set (see Lemma 4 and Subsection 3.1), we then showed that $\widetilde{\mathcal{O}}_\epsilon(n)$ can be written as $M^n x + f(n) + \epsilon\mathcal{B}(n)$.

The reason we are unable to show decidability for non-diagonalisable systems in this fashion is that we are unable to write $\widetilde{\mathcal{O}}_\epsilon(n)$ as $M^n x + f(n) + \epsilon\mathcal{B}(n)$. For example, already for the Jordan block $M = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$, and in general already for blocks with a single repeated real eigenvalue, we do not know whether it is even possible to eliminate the summation $\sum_{i=0}^{n-1} M^i B$ and express $\widetilde{\mathcal{O}}_\epsilon(n) = M^n x + \epsilon \sum_{i=0}^{n-1} M^i B$, where B is any full dimensional shape containing $\mathbf{0}$ in its interior, in the required fashion.

Our approach, however, can be used to solve, in full generality, the robust reachability problem of [1]: given M, x and S, decide whether $\forall \epsilon > 0 : \exists n : (M^n x + \epsilon M^n B(\mathbf{0}, 1)) \cap S \neq \emptyset$. Intuitively, the reason is that in this version there is no summation of the form $\sum_{i=0}^{n-1} M^i B$. Detailed proofs (for both the discrete-time and the continuous-time versions) can be found in the full version. For diagonalisable systems in particular, decidability of the robust reachability problem is almost immediate. First, one can again show that the problem is equivalent to determining whether $\forall \epsilon > 0 : \exists n : (M^n x + \epsilon M^n \mathcal{B}) \cap S \neq \emptyset$. It then remains to observe that $M^n \mathcal{B} = \varphi(n, \rho_1^n, \dots, \rho_d^n)$ for a semialgebraic predicate φ and apply the technical result described above.

Abstract

We consider the problem of listing all avoidable vertices in a given n vertex graph. A vertex is avoidable if every pair of its neighbors is connected by a path whose internal vertices are not neighbors of the vertex or the vertex itself. Recently, Papadopolous and Zisis showed that one can list all avoidable vertices in $O(n^{\omega+1})$ time, where $\omega < 2.373$ is the square matrix multiplication exponent, and conjectured that a faster algorithm is not possible.

In this paper we show that under the 3-OV Hypothesis, and thus the Strong Exponential Time Hypothesis, $n^{3-o(1)}$ time is needed to list all avoidable vertices, and thus the current best algorithm is conditionally optimal if $\omega = 2$. We then show that if $\omega > 2$, one can obtain an improved algorithm that for the current value of ω runs in $O(n^{3.32})$ time. We also show that our conditional lower bound is actually higher and supercubic, under a natural High Dimensional 3-OV hypothesis, implying that for our current knowledge of rectangular matrix multiplication, the avoidable vertex listing problem likely requires $\Omega(n^{3.25})$ time. We obtain further algorithmic improvements for sparse graphs and bounded degree graphs.

1 Introduction

The notion of an "avoidable" vertex in a graph has been studied since the 1970s in the context of minimal elimination orderings for Gaussian elimination [24, 26], though the name "avoidable" was first used by Beisegel et al. [9]. A vertex is avoidable if and only if a minimal elimination ordering can start from it.

In Gaussian elimination of sparse matrices, one iteratively selects a pivot, and then eliminates its row from the rest of the matrix, potentially creating new nonzero entries: i.e. fill-in. One seeks to find a good elimination ordering to minimize the fill-in, as the fill-in determines both the running time and the necessary storage. An iterative approach from the 1970s by [24, 26] was to pick an avoidable vertex (in a graph corresponding to the current sparse matrix), use it as a pivot, and repeat.

A single avoidable vertex always exists and can be found in linear time in the size of the matrix as shown by Beisegel, Chudnovsky, Gurvich, Milanic and Servatius [9]. By repeating n times (for an $n \times n$ matrix), one can complete the Gaussian elimination in $O(n^3)$ time; cubic time can be necessary, as the fill-in can make an originally sparse matrix into a dense one very quickly (though for some matrices this approach can still work well).

A natural question is, can one still use the minimal elimination orderings approach from the 1970s to find a minimal elimination ordering and hopefully perform Gaussian elimination in truly subcubic time $O(n^{3-\varepsilon})$ for $\varepsilon > 0$, without using the heavy Strassen-like techniques that achieve the fastest matrix multiplication algorithms nowadays [28, 12, 6]?

The hope here is that instead of iteratively finding a new pivot n times, we can compute several pivots in batch faster and then use them in the Gaussian elimination process. As a first step, one would ask whether one can find all the (at most n) possible avoidable vertices in an n-node graph in truly subcubic time? Finding n avoidable vertices as the matrix graph changes due to fill-in, can intuitively be more complicated.

This motivates studying the problem of listing all avoidable vertices in a graph. Beisegel et al. [9] present further motivations for studying avoidable vertices, including faster clique algorithms in certain classes of graphs. Beisegel et al. [9] showed that every graph on at least two vertices contains at least two avoidable vertices that are at distance the diameter of the graph, and that two avoidable vertices can be found in linear time. They provided extensions for avoidable edges, and also used their results for avoidable vertices to provide fast algorithms for maximum weight clique detection in special classes of graphs.

While the algorithm of [9] can find an avoidable vertex in linear time, the authors only mention a very slow algorithm for finding the set of all avoidable vertices of a graph. Recently, Papadopolous and Zisis [25] provide algorithms for computing all avoidable vertices of an n vertex, m edge graph, running in time $O(\min\{n^{\omega+1}, n^2+m^2\})$, where $\omega < 2.37286$ is the exponent of square matrix multiplication [6].

A simpler definition than the one based on minimal elimination orderings is that v is avoidable if every two neighbors of v, are connected by a path that has no internal vertices that are v or neighbors of v. As [9] put it, if vertices represent people, then any two neighbors of an avoidable person v can communicate a secret without any direct acquaintances of v learning the secret.

A special case of avoidable vertices are *simplicial vertices*. A vertex is simplicial if its neighborhood is a clique. Simplicial vertices are very well studied in graph theory. For example, in the 1960s Dirac [17] showed that every chordal graph contains a simplicial vertex.

Kloks, Kratsch and Müller [20] showed how to list all simplicial vertices in an n-node graph in $O(n^\omega)$ time. It has been open for over 20 years whether a faster algorithm exists. (Spinrad [27] explicitly states finding such an algorithm as an open problem.) In the preliminaries we give a simple proof that the $O(n^\omega)$ time algorithm of [20] is optimal for *listing* all simplicial vertices, unless triangles can be found faster. It still remains open whether finding a single simplicial vertex can be done faster.

Papadopoulos and Zisis [25] state that they do not believe that the running times of their algorithms for listing avoidable vertices can be improved without resolving the open problem for simplicial vertices. In this paper we show that it is actually *possible* to improve the avoidable vertex listing running time slightly, and further provide fine-grained hardness reductions that point to concrete hurdles that need to be overcome to further improve the running time.

1.1 Our results

We provide new algorithms and fine-grained lower bounds for listing all avoidable vertices.

1.1.1 Fine-grained lower bounds

In Section 3, we provide a tight connection between Avoidable Vertex Listing and one of the central problems in fine-grained complexity, 3-Orthogonal Vectors.

In the k-Orthogonal Vectors problem (k-OV), one is given k sets of n Boolean Vectors each $S_1, \ldots, S_k \subseteq \{0,1\}^d$ in d dimensions, and one wants to determine whether there exist $a_1 \in S_1, \ldots, a_k \in S_k$ so that $\sum_{c=1}^{d} \prod_{i=1}^{k} a_i[c] = 0$, i.e. that $a_1, \ldots, a_k$ are orthogonal.

The k-OV Hypothesis of Fine-Grained Complexity (see e.g. [31]) states that there is no $O(n^{k-\varepsilon})$ time algorithm with $\varepsilon > 0$ that solves size n instances of k-OV when $d = \text{poly}\log(n)$, in the word-RAM model of computation with $O(\log n)$ bit words.

For any integer $k \geq 2$, the k-OV Hypothesis follows from the popular Strong Exponential Time Hypothesis (SETH) as shown by Williams [33]. The k-OV Hypothesis is even more believable than SETH, as even if SETH fails, the k-OV Hypothesis might still be true. SETH and the k-OV Hypothesis have been shown to imply a large variety of tight conditional lower bounds (see the survey [31] for some results). 3-OV in particular implies such bounds for graph diameter approximation [8, 23, 16, 14], various dynamic problems [1] and more.

Our first theorem is:

▶ **Theorem 1.** *Under the 3-OV Hypothesis, listing all avoidable vertices in an n vertex graph requires $n^{3-o(1)}$ time in the word-RAM model of computation with $O(\log n)$ bit words.*

One can think of this as a negative result. It gives a concrete limitation to using minimal elimination orderings to obtain a general truly subcubic time algorithm for Gaussian elimination.

The $O(n^{\omega+1})$ time algorithm of [25] would run in $O(n^3)$ time if $\omega = 2$ (as some believe). Thus, if $\omega = 2$, their algorithm would be optimal, under SETH and the 3-OV Hypothesis.

Nevertheless, ω might not be 2. Indeed, there has been quite a bit of work (e.g. [7, 10, 5, 4]) that shows that the known techniques for matrix multiplication cannot achieve $\omega = 2$. Can we have a conditional lower bound in terms of ω?

Here, we notice that the reduction used to prove Theorem 1 can also be used to tightly reduce to Avoidable Vertex Listing the 3-OV problem for vectors of dimension n, rather than polylogarithmic in n, which the standard 3-OV Hypothesis is about.

While 3-OV in polylogarithmic dimensions has a simple $n^{3+o(1)}$ time algorithm (compute the inner product of every triple of vectors), the fastest known algorithm for 3-OV in n dimensions is essentially the same as that for 4-clique [18]. It runs in $O(n^{\omega(1,2,1)})$ time where $\omega(1, 2, 1)$ is the exponent of multiplying an n by n^2 matrix by an n^2 by n matrix (see the preliminaries). The current best bound on this exponent is $\omega(1, 2, 1) < 3.251640$ [22].

We formulate the High Dimensional 3-OV Hypothesis that states that 3-OV for n vectors in n dimensions requires $n^{\omega(1,2,1)-o(1)}$ time on the word RAM with $O(\log n)$ bit words. This Hypothesis is the natural extension of the High Dimensional 2-OV Hypothesis used in prior work (e.g. [13]).

We then extend Theorem 1:

▶ **Corollary 2.** *Under the High Dimensional 3-OV Hypothesis, listing all avoidable vertices in an n vertex graph requires $n^{\omega(1,2,1)-o(1)}$ time on the word RAM with $O(\log n)$ bit words.*

Thus, with the current bounds on ω and $\omega(1, 2, 1)$, the algorithm of [25] runs in $O(n^{3.373})$, while our conditional lower bound is $n^{3.251-o(1)}$. This gap motivates the question:

In the case when $\omega > 2$, is there an algorithm for listing all avoidable vertices that runs faster than $O(n^{\omega+1})$? Can one achieve a running time closer to $O(n^{\omega(1,2,1)})$?

1.1.2 Faster Algorithms

Utilizing rectangular matrix multiplication techniques, in Section 4-7 we develop a method for listing all avoidable vertices with a running time strictly between $O(n^{\omega+1})$ and $O(n^{\omega(1,2,1)})$.

▶ **Theorem 3.** *All avoidable vertices in an m-edge, n-vertex graph can be listed in time*

$$O\left(\min\{m^{1.7}n^{0.2} + mn^{1+o(1)}, m^{0.977}n^{1.4+o(1)}, n^{3.32}\}\right).$$

In particular, in dense graphs the above running time is $O(n^{3.32})$ which is faster than $O(n^{\omega+1})$ for the current value of $\omega < 2.373$. In fact, for any value of ω greater than 2, our algorithm would run faster than in $O(n^{\omega+1})$ time, as rectangular matrix multiplication can always give us some savings. Our algorithm runs even faster in sparse graphs. Finally, we also address the case of bounded degree graphs in Appendix B and obtain improved running times for that case as well.

2 Preliminaries

Let $G = (V_G, E_G)$ be an undirected, unweighted graph. For a vertex $v \in V$, we use $N_G(v)$ to denote the neighborhood of v. For $X \subset V_G$, we define $G(X)$ to be the induced subgraph of X, namely the graph with vertex set X and edge set $\{uv|u, v \in X\} \cap E_G$, and define $G\backslash X$ to be $G(V_G\backslash X)$. We call u, v connected in a graph if there is a path connecting them. The connected components of a graph V are the maximal subsets of V_G such that any two vertices in the subset are connected. When G is clear from the context, we omit G as a subscript.

Avoidable Vertex Listing
Input: $G = (V_G, E_G)$
Task: Call a vertex $v \in V_G$ avoidable if for any $a \neq b \in N_G(v)$, there exists a path from a to b not containing v and any other neighbor of v ("avoiding" v and neighbors). Find all avoidable vertices.

Throughout the paper, unless otherwise noted, we denote $n = |V_G|$ and $m = |E_G|$, where G is the current graph.

There is an alternative definition which defines v as avoidable if and only if for any $x \neq y \in N(v)$, there exists $T \subseteq V_G$ where $\{v, x, y\} \subseteq T$ and $G(T)$ is a single simple cycle (e.g. [9]). We can see both definitions are equivalent by taking T as the shortest valid path from a to b in the first definition.

A vertex v in G is *simplicial* if for every pair of vertices $x, y \in N(v)$, (x, y) is an edge.

▶ **Proposition 4** ([20]). All simplicial vertices of an n node graph can be listed in $O(n^\omega)$ time.

Proof. The following simple $O(n^\omega)$ time algorithm lists all simplicial vertices of G: Define A as the $n \times n$ adjacency matrix of G, where $A[i,j] = 1$ if (i,j) is an edge of G, and $A[i,j] = 0$ otherwise. Let B be the $n \times n$ matrix with $B[i,j] = 1$ if $i \neq j$ and (i,j) is not an edge of G; let $B[i,j] = 0$ otherwise. Compute the matrix product $C = ABA$ in $O(n^\omega)$ time. For a vertex i, $C[i,i]$ is nonzero iff there exist distinct neighbors j, k of i for which (j,k) is not an edge. Thus $C[i,i] = 0$ if and only if i is a simplicial vertex. Thus by going through the diagonal of C, we can in additional $O(n)$ time list all simplicial vertices of G. ◀

It is not hard to show that listing all simplicial vertices is at least as hard as Triangle detection. This means that the problem probably needs $n^{\omega-o(1)}$ time, unless one can detect triangles faster. Moreover via [32], we get that there is a truly subcubic time combinatorial fine-grained reduction from Boolean Matrix Multiplication to listing all simplicial vertices. Thus any subcubic algorithm for the problem likely requires matrix multiplication.

▶ **Proposition 5.** If one can list all simplicial vertices of a graph in $T(n)$ time, then one can detect a triangle in an n node graph in $O(T(n))$ time.

Proof. Let $G = (V, E)$ be a graph in which we want to find a triangle. Create a new graph G' as follows. Every $v \in V$ has two copies v_1 and v_2 in G'. Let V_1 and V_2 be the sets of vertices with the corresponding subscripts. For every edge (u, v) of G, add edges (u_1, v_2) and (u_2, v_1) in G'. Finally, for every non-edge (x, y) of G where $x \neq y$, add an edge (x_2, y_2) to G'.

Suppose v_1 is a simplicial vertex of G'. All neighbors of v_1 are in V_2, and the only way for v_1 to be simplicial is if in G no pair of its neighbors has an edge between them, i.e. v_1 does not appear in a triangle. On the other hand, any vertex that is not simplicial must have a pair of neighbors in G that are connected by an edge. Thus, if we can list all simplicial vertices, we can determine if a vertex of V_1 is not in the list, and that will tell us whether G has a triangle. ◀

The 3-OV problem (see e.g. [31]) is defined as follows[1].

3-OV
Input: Three sets of Boolean vectors $A, B, C \subseteq \{0,1\}^d$ where $|A| = |B| = |C| = n$
Task: decide whether there are $a \in A, b \in B, c \in C$ so that their generalized inner product is 0, i.e. $\sum_{i=1}^{d} a_i b_i c_i = 0$.

The 3-OV Hypothesis (see e.g. [31]), states that in the word-RAM model with $O(\log n)$ bit words, 3-OV requires $n^{3-o(1)}$ even if d is polylogarithmic.

A now well-known result that follows from the seminal work of Williams [33] is that the 3-OV Hypothesis follows from the Strong Exponential Time Hypothesis (SETH) of Impagliazzo, Paturi, Zane and Calabro [11, 19].

In the high dimensional version of 3-OV, when the dimension d can be large, the fastest algorithm for the problem is no longer cubic. In particular, when $d = O(n)$, the fastest known algorithm runs in $O(n^{\omega(1,2,1)}) \leq O(n^{3.252})$ time. The running time $O(n^{\omega(1,2,1)})$ is a bit faster than $O(n^{\omega+1})$ as long as $\omega > 2$, and is $O(n^3)$ if $\omega = 2$.

We give the folklore algorithm here for completeness.

▶ **Proposition 6** (Folklore). 3-OV on vectors of dimension $d = O(n)$ can be solved in $O(n^{\omega(1,2,1)})$ time.

Proof. Let A and B be the given sets of d-dimensional vectors. Without loss of generality, assume that $d = n$. Create an $n^2 \times n$ matrix Boolean D such that for $a \in A, b \in B$, $i \in [n]$, we have $D[(a,b), i] = 1$ if and only if $a_i = b_i = 1$. Let C' be the $n \times n$ matrix which for $i \in [n], c \in C$, $C'[i, c] = 1$ if and only if $c_i = 1$. Then $DC'[(a,b), c]$ contains a 0 if and only if the generalized inner product of a, b, c is 0. ◀

Prior work (see e.g. [13, 3]) conjectured that the high dimensional variant (when $d = O(n)$) of 2-OV requires $n^{\omega-o(1)}$ time. A natural extension of this assumption is that the matrix multiplication based running time for 3-OV is best possible.

▶ **Definition 7.** *The High Dimensional 3-OV Hypothesis states that in the word-RAM model with $O(\log n)$ bit words, 3-OV in n dimensions requires $n^{\omega(1,2,1)-o(1)}$ time.*

Our hypothesis above is also related to a popular hypothesis (e.g. [15, 31]) that the best known running time for 4-Clique is best possible. The best known algorithm for 4-Clique by [20] is analogous to the best known algorithm for high-dimensional 3-OV above, and it is natural to conjecture that if this algorithm is best for 4-Clique, it could also be best for 3-OV.

[1] An equivalent definition has as an input a single set of vectors and we want to find a triple of orthogonal vectors in the set.

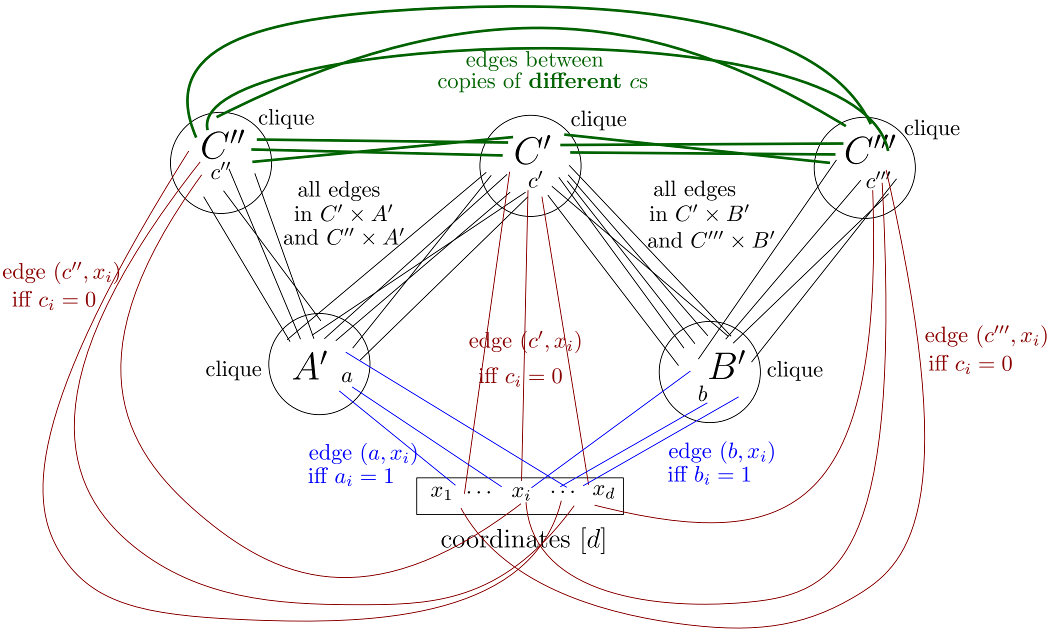

Figure 1 A depiction of the construction from 3-OV to Avoidable Vertex Listing.

3 Conditional Lower Bound

In this section, we derive a conditional lower bound for the problem based on 3-OV-hardness. We show that an instance of 3-OV of size n can be reduced to the Avoidable Vertex Listing problem in a graph of $O(n)$ vertices. Therefore Avoidable Vertex Listing requires $\Omega(n^{3-o(1)})$ time, under the 3-OV Hypothesis and the Strong Exponential Time Hypothesis.

Construction

Let an instance $A, B, C \subseteq \{0,1\}^d$ of 3-OV be given. We create a graph G from it as follows. The construction is depicted in figure 1.

For every vector $a \in A$, we create a node a' in G. Denote by A' the set of nodes formed by all such a's. Similarly, for every vector $b \in B$, we create a node b' in G, forming a set of nodes B', and for every vector $c \in C$, we create a node c', forming a set of nodes C'.

We make each of A', B', C' into a clique by adding an edge between every pair of nodes in it. Also, we add edges between each node of C' and every node in $A' \cup B'$.

We add d "coordinate nodes" $x_1, \ldots, x_d$, corresponding to each coordinate. For each $a \in A$ and $i \in [d]$, add an edge (a', x_i) if $a_i = 1$. Similarly, for each $b \in B$ and $i \in [d]$, add an edge (b', x_i) if $b_i = 1$. For each $c \in C$ and $i \in [d]$, we add an edge (c', x_i) if $c_i = 0$. Notice we treat C differently from A and B: we add edges for C if the corresponding bit is not set but we add edges for A, B if the bit is set.

For each $c \in C$, we add two more new nodes c'' and c''', forming sets C'' and C''' respectively. We add edges from each c'' to all of A', and edges from each c''' to all of B'. We add edges from both c'' and c''' to all x_i for which $c_i = 0$. For every $p \neq q \in C$, we add edges $(p', q'), (p', q''), (p', q'''), (p'', q''), (p'', q'''), (p''', q''')$. In other words, we connect all pairs of nodes in $C' \cup C'' \cup C'''$ corresponding to different vectors in C.

Proof of Correctness

We now prove the correctness of our construction. Specifically, for every $c' \in C'$ corresponding to vector $c \in C$, we will show that c' is not avoidable in G if and only if there exists $a \in A, b \in B$ such that $a \cdot b \cdot c = 0$.

Take some $c' \in C'$. Let X_c be the set of coordinate nodes x_i for which $c_i = 0$.

First, consider a pair of the neighbors of c' that is not in $A' \times B'$. We'll show such a pair is connected without visiting c' and other neighbors of c'. Since a neighbor of c' can either fall in A', B', X_c or $C' \cup C'' \cup C'''$, there are several cases:

- If the pair contains a vertex $a' \in A'$, let it be (a', t). When $t \in A' \cup C' \cup C''$, there is a direct edge between t and a'. When $t \in C'''$, we must have $t = e'''$ with $e \neq c$. Thus there is a path from a' to c'' (which is not a neighbor of c') to t. When $t \in X_c$, there is also a path from a' to c'' (which is not a neighbor of c') to t.
- Similarly, if the pair of neighbors contains a vertex $b' \in B'$, the pair is also connected.
- If the pair of neighbors (e, f) are in $X_c \cup C' \cup C'' \cup C'''$, then these nodes are not copies of c', so they have a path through $c'' \in C''$.

Thus every pair of neighbors of c' except for those in $A' \times B'$ has either an edge between them or a path through non-neighbors of c'.

Consider now some $a' \in A', b' \in B'$. If there is a path from a' to b' through non-neighbors of c', then this path can only go through x_i such that $c_i = 1$. The path cannot go through c'' or c''' as those nodes only have neighbors that are also neighbors of c'. Hence the only possible paths from a' to b' through non-neighbors of c' are of the form a' to x_i to b' where $a_i = b_i = 1 = c_i$. Thus, there is a neighbor pair of c' that is not connected when c' and its neighbors are removed if and only if there are $a \in A, b \in B$ so that $a \cdot b \cdot c = 0$.

Proof of Theorem 1, Corollary 2. Any algorithm for Avoidable Vertex Listing can solve High Dimensional 3-OV in roughly the same time: we convert the given instance to the aforementioned graph (which takes $O(n^2 + nd)$ time), run Avoidable Vertex Listing on the graph, and check if there is any non-avoidable c'. The converted graph has $O(n + d)$ vertices. Thus, if avoidable vertices for n-node graphs could be listed in $O(n^\alpha)$ time, so does n dimensional 3-OV. ◀

4 Basic Algorithm

In this section, we present a basic algorithm for Avoidable Vertex Listing, which performs a series of Boolean matrix multiplications. The approach is similar to the method of Papadopolous and Zisis [25].

Let $G = (V, E)$ be a given graph, an instance of Avoidable Vertex Listing.

For each $v \in G$, we check if v is avoidable in two steps. We first find all the connected components $C(v)$ in $G \backslash \{v\} \backslash N_G(v)$. Then for every $x \neq y \in N(v)$, we check if there exists $a \in N(x), b \in N(y)$ such that a, b are in the same connected component in $G \backslash \{v\} \backslash N_G(v)$.

The first step takes $O(nm)$ time via e.g., breadth-first search. For the second step, we can set a matrix A with entries labeled $N(v) \times C(v)$, where $A[i, j] = 1$ iff $N(i) \cap j \neq \emptyset$. Then it suffices to check if $A \times A^T$ (where $\times$ corresponds to Boolean matrix multiplication) has a zero outside of its diagonal. Calculating matrix multiplication directly takes $O(n^\omega)$ time per vertex, thus we can solve the problem in $O(n^{\omega+1})$ time.

With a more careful analysis, we can show the above algorithm is in fact of $O(mn^{\omega-1})$ time. For each vertex v, we need to do a matrix multiplication of size $(\deg v, n) \times (n, \deg v)$, which can be done in $O((\deg v)^\omega (n/\deg v)) = O(n(\deg v)^{\omega-1})$ time. Notice that $\sum_{v \in V} \deg v = 2m$, by convexity of function $x^{\omega-1}$, the total time complexity $O(\sum_{v \in V} n(\deg v)^{\omega-1}) \leq O((m/n)n^\omega) = O(mn^{\omega-1})$ - minimized when $2m/n$ vertices each have degree n.

For sparse graphs, we can do even better. Notice that every entry in A corresponds to an edge in G, so there are only $O(m)$ non-zero entries in A. We can use sparse matrix multiplication [34] to perform the multiplication, taking $\widetilde{O}((\deg v)^{1.2}m^{0.7} + (n \deg v)^{1+o(1)})$ time[2]. By convexity, the function is maximized when $\deg v \in \{0, n\}$, so $\widetilde{O}(\sum_v((\deg v)^{1.2}m^{0.7} + (n \deg v)^{1+o(1)})) = \widetilde{O}((m/n)(n^{1.2}m^{0.7} + (n^2)^{1+o(1)})) = \widetilde{O}(m^{1.7}n^{0.2} + mn^{1+o(1)})$, which works better when m is small.

5 Algorithm for Dense Graphs and High Degree Vertices

We first show how to handle dense graphs and high degree vertices. We achieve this by dividing paths into short and long paths, and utilizing rectangular matrix multiplication.

Let the set of vertices we consider be $V_h \subseteq V$. For every $v \in V_h$ and $p, q \in N(v)$, we call a path from p to q passing no other neighbours of v *short* if its length $\leq \ell$ where ℓ is a parameter to be set, or *long* if its length $> \ell$. We treat short paths and long paths separately.

5.1 Short paths

On short paths, for every $l \leq \ell$, we want to compute for every $v \in V_h$, $p, q \in V$, if there is a path from p to q in G that has at most l edges and does not use any internal nodes that are neighbors of v or v itself. Let $X_v^l(p, q) = 1$ if so and $X_v^l(p, q) = 0$ otherwise. Notice here we do not require $p, q \in N(v)$.

We compute this matrix incrementally. Let A be the adjacency matrix of G and suppose we have calculated X_v^{l-1}. For some $X_v^l(p, q) = 1$, consider the last node r in the corresponding path from p to q, we must have $X_v^{l-1}(p, r) = 1$, $A(r, q) = 1, r \notin N(v) \cup \{v\}$, and vice versa.

Therefore, we can construct a $(n \cdot |V_h|) \times n$ matrix C where

$$C[(v, p), r] = 1 \text{ if } X_v^{l-1}(p, r) = 1 \text{ and } r \notin N(v) \cup \{v\}, \text{ and } C[(v, p), r] = 0 \text{ otherwise,}$$

then $X_v^l(p, q) = 1$ if and only if $(C \times A)[(v, p), q] \neq 0$.

Thus X_v^l can be computed from X_v^{l-1} in $O(M(n|V_h|, n, n))$[3] time with rectangular matrix multiplication (e.g. [22]). The computation of X_v^ℓ would thus take overall time $O(\ell M(n|V_h|, n, n))$.

5.2 Long paths

For $p, q \in V$ and $v \in V_h$, suppose that there is a path from p to q with at least ℓ edges that does not use internal vertices that are v or neighbors of v. Let $P_v(p, q)$ be such a path.

We randomly sample a set of vertices $S \subseteq V$ of size $10n/\ell \log n$. We claim that S "splits" every $P_v(p, q)$ into pieces of length $\leq \ell$ with high probability. (This lemma is well-known and widely used. We include it for completeness.)

▶ **Lemma 8.** *Suppose the path is of nodes $t_0, t_1, \cdots, t_m$ where $t_0 = p$, $t_m = q$, $m \geq \ell$. For every i, call $t_i, t_{i+1}, \cdots, t_{i+\ell-1}$ an ℓ-length segment. For a randomly sampled $S \subseteq V$ where $|S| = \lceil 10n/\ell \log n \rceil$, every ℓ-length segment of the path contains an element from S with probability $\geq 1 - n^{-9}$.*

[2] $\widetilde{O}$ hides logarithmic factors. Our matrix multiplication is rectangular with size $(\deg v, n, \deg v)$, but the original proof also holds for this case.

[3] $M(a, b, c)$ is the time complexity of multiplying (possibly rectangular) matrices of size $a \times b$ and $b \times c$.

Proof. For any ℓ elements, the probability that none of them lies in S is $\binom{n-\ell}{|S|}/\binom{n}{|S|} = \prod_{i=0}^{|S|-1} \frac{n-\ell-i}{n-i} \leq (1-\frac{\ell}{n})^{|S|} \leq (1-\frac{\ell}{n})^{n/\ell \cdot 10 \log n} \leq n^{-10}$. The result then follows from a union bound. ◀

By the lemma, with high probability S splits each $P_v(p,q)$ into consecutive pieces of length at most ℓ: the first is from p to some $s_1 \in S$, then a piece from s_1 to some $s_2 \in S$, …, a piece from some $s_{t-1} \in S$ to $s_t \in S$, and finally a piece from s_t to q. Since we have computed for every pair of vertices whether there is a path of length at most ℓ between them not using neighbors of v, we can use this information to compute the full paths as follows.

For every $v \in V_h$, we build a graph G_v whose vertices are the nodes S' of S that are not v or neighbors of v, and there is an edge in G_v between a and b if $X_v^\ell(a,b) = 1$ (i.e. there is a path of length at most ℓ avoiding the neighbors of v and v). We compute the transitive closure of G_v. Since G_v is undirected, this can be done in time $\widetilde{O}(n^2/\ell^2)$ for each v.

Let T_v be the transitive closure matrix, compute $Y_v = X_v^\ell[\cdot, S'] \times T_v \times X_v^\ell[S', \cdot]$ which accounts for the first and the final piece in the path. By the above argument, this will tell us for every pair of nodes if there is a path between them avoiding the neighbors of v with high probability.

The running time of this over all v is $\widetilde{O}(|V_h| \cdot M(n, n/\ell, n))$, where $M(r,s,t)$ is the time to multiply an $r \times s$ by an $s \times t$ matrix.

5.3 Overall runtime on dense graphs

Combining the two algorithms, the final running time would be

$$\widetilde{O}(\ell M(n|V_h|, n, n) + |V_h| \cdot M(n, n/\ell, n)).$$

Take $V_h = V$, we immediately get an algorithm for dense graphs. Let $\ell = n^a$,

$$\widetilde{O}(\ell M(n|V_h|, n, n) + |V_h| \cdot M(n, n/\ell, n)) = \widetilde{O}(n^{\max(\omega(1,2,1)+a, 1+\omega(1,1,1-a))})$$

Using bounds from [22], let $a = 0.0682157$, we have $\omega(1,1,1-a) < 2.319856$, $\max(\omega(1,2,1)+a, 1+\omega(1,1,1-a)) < 3.319856$, so the running time exponent of our algorithm is < 3.320, slightly better than $\omega + 1 \approx 3.373$. As long as $\omega > 2$, this algorithm will benefit from rectangular matrix multiplication and have a complexity of $O(n^{\omega-\varepsilon})$ for some $\varepsilon > 0$.

6 Algorithm for Low Degree Vertices

The result in the previous section works well for dense graphs or high degree vertices. One simple improvement is to combine the previous algorithm with sparse matrix multiplication as in Section 4. In the following, we show we can actually do a bit better by a carefully designed counting method.

We call a vertex "low-degree" if it has degree $\leq d$. Let the set of low-degree vertices be $V_l \subseteq V$. Again for every $v \in V_l$ and $p, q \in N(v)$, we call a path from p to q passing no other neighbours of v or v short or long depending on whether its length is $\leq L$.

For long paths, we calculate connected components of $G_v = G \backslash \{v\} \backslash N_G(v)$ for each $v \in V_l$ and perform the matrix multiplication as in Section 4, but here we can keep only connected components with size $\geq L$, since otherwise the shortest path will have length $\leq L$ and a short path could instead be considered. As there are at most n/L such components, we only need to perform matrix multiplications of size $(\deg(v), n/L, \deg(v))$, in time $M(\deg(v), n/L, \deg(v))$.

Now we show how to handle the short paths. We count the number of short avoiding paths (not necessarily simple) modulo some random prime p and check if it equals to zero. Since the number of paths of a given length $< n$ is $\leq n^n$, it has no more than n different prime factors $\geq n$. We randomly sample p as a prime in (n^5, n^6), by prime number theorem there are $\Omega(n^{5.99})$ primes within the range, so with probability $\geq 1 - O(n^{-4.99})$, if the number of paths is non-zero, it would remain non-zero modulo p. Since we need to check whether the number of paths is zero at most n^3 times, by union bound, all the checks would be correct with high probability.

For each $i \in [1, L]$ and each $u, v \in G$, we compute the number of paths (not necessarily simple) from u to v using exactly i steps, modulo p. This could be done by matrix multiplication in time $\widetilde{O}(Ln^\omega)$.

For a vertex v with neighbors $v_1, v_2, \cdots, v_s$, let $v_0 = v$. Construct the following matrices F_i where

$$F_i[x, y] = \text{number of paths from } v_x \text{ to } v_y \text{ with length } i \text{ without visiting other } v\text{'s} \pmod p$$

To compute F, let G_i be the matrix where

$$G_i[x, y] = \text{the number of paths from } v_x \text{ to } v_y \text{ with length } i \pmod p$$

G's can be directly retrieved from the computed matrices. For an invalid path that visits neighbors of v or v midways (which are the paths counted in G but not in F), we consider the number of steps j took before the first such visit, and the contribution will be $F_j G_{i-j}$. Therefore we have $F_i \equiv G_i - \sum_{1 \leq j < i} F_j G_{i-j} \pmod p$.

To compute $F_1, F_2, \cdots, F_L$ from $G_1, G_2, \cdots, G_L$, we can use the standard divide-and-conquer technique (see e.g. [30]). To compute $F_l, F_{l+1}, \cdots, F_r$, let $m = \lfloor (l + r)/2 \rfloor$, we first recursively compute $F_l, F_{l+1}, \cdots, F_m$, then calculate the contribution of $F_l, F_{l+1}, \cdots, F_m$ to $F_{m+1}, F_{m+2}, \cdots, F_r$, then recursively compute $F_{m+1}, F_{m+2}, \cdots, F_r$.

To calculate the contribution, for every $i \in [m + 1, r]$, we need to calculate $\sum_{j=l}^{m} F_j G_{i-j}$. By introducing variable x, the problem can be formulated as a polynomial multiplication:

$$\begin{aligned}\sum_{j=l}^{m} F_j G_{i-j} &= \sum_{j=0}^{m-l} F_{j+l} G_{i-l-j} \\ &= [x^{i-l}] \left(\sum_{j=0}^{m-l} F_{j+l} x^j \right) \left(\sum_{j=0}^{r-l} G_j x^j \right)^{4}\end{aligned}$$

Therefore we can let $F' = \sum_{j=0}^{m-l} F_{j+l} x^j$, $G' = \sum_{j=0}^{r-l} G_j x^j$, compute their matrix product modulo p, extract coefficients of x to get the contributions. Entries in these matrices are polynomials in $F_p[x]$ with degree $O(r - l)$, and operations on such polynomials can be done in $\widetilde{O}(r - l)$ time via Fast Fourier Transform (e.g. [2]). Each divide-and-conquer process takes $\widetilde{O}((r - l)s^\omega)$ time and computing $F_1, F_2, \cdots, F_L$ takes $\widetilde{O}(Ls^\omega)$ time in total.

Combining the algorithm for short and long paths, we now have an algorithm that takes $\widetilde{O}(Ln^\omega)$ time for pre-computation and spends $\widetilde{O}(M(\deg(v), n/L, \deg(v)) + L \deg(v)^\omega)$ time for each vertex $v \in V_L$.

[3] $[x^c]$ extracts coefficient of x^c in a polynomial $p(x)$.

7 Final Algorithm

Finally, we combine the ideas in Section 5 and Section 6. We set a parameter d, use the algorithm in Section 5 to treat vertices with degree $> d$ and use the algorithm in Section 6 to treat vertices with degree $\le d$.

The number of vertices with degree $> d$ is $O(m/d)$, so the combined complexity would be

$$\widetilde{O}(\ell M(nm/d,n,n)+(m/d)\cdot M(n,n/\ell,n)+Ln^{\omega}+\sum_{\deg(v)\le d}(M(\deg(v),n/L,\deg(v))+L\deg(v)^{\omega})).$$

By convexity, it would be maximized when $\deg(v)\in\{0,d\}$ for low-degree vertices. The final complexity would then be

$$\widetilde{O}(\ell M(nm/d,n,n)+Ln^{\omega}+(m/d)(M(n,n/\ell,n)+M(d,n/L,d)+Ld^{\omega})).$$

Optimizing with respect to d,ℓ,L, we find the complexity to be $O(m^{0.977}n^{1.4+o(1)})$ (Appendix A).

Combining the algorithms discussed in Section 4, Section 5, Section 7, we arrive at the following theorem.

▶ **Theorem 9.** *Avoidable Vertex Listing can be solved in time*

$$O(\min\{m^{1.7}n^{0.2}+mn^{1+o(1)},m^{0.977}n^{1.4+o(1)},n^{3.32}\}).$$

8 Conclusion

In this paper, we present a new fine-grained reduction from 3OV to Avoidable Vertex Listing, providing essentially cubic and even supercubic (if $\omega > 2$) conditional hardness for the problem. We also present new improved algorithms for the problem, combining techniques such as rectangular matrix multiplication, sparse matrix multiplication, the principle of inclusion-exclusion and counting.

As analyzed in Section 4, the algorithm by Papadopoulos and Zisis [25] solves Avoidable Vertex Listing in $O(mn^{\omega-1})$ time, and our algorithm improves upon this bound when $\omega > 2$. When $\omega = 2$, that algorithm runs in $O(mn)$ time, and by our 3OV lower bound, this running time is conditionally optimal when $m = \Omega(n^2)$. An interesting problem would be, when $m = o(n^2)$ and $\omega = 2$, can we do better than $\Omega(nm)$? While we can break this bound in regular or random graphs[4] (Appendix B), it remains open for more general graphs.

A Missing Calculation in Section 7

Suppose $m = n^\alpha$ $(\alpha \in [1,2])$, let

$$\begin{cases} d = n^{0.015122\alpha^2 - 0.07237\alpha + 1.056742} \\ \ell = n^{-0.0364\alpha^2 + 0.17612\alpha - 0.138437} \\ L = \ell^{0.180156}. \end{cases}$$

When $t \in [1,2]$, $\omega(1,1,t) < 0.0625t^2 + 0.697t + 1.614$ (this can be verified by bounds in [22], [21] and convexity). Let $f(t) = 0.0625t^2 + 0.697t + 1.614$.

$$\begin{aligned}\ell M(nm/d,n,n) &= n^{-0.0364\alpha^2+0.17612\alpha-0.138437} M(n^{-0.015122\alpha^2+1.07237\alpha-0.056742},n,n)\\ &= O(n^{-0.0364\alpha^2+0.17612\alpha-0.138437+\omega(1,1,-0.015122\alpha^2+1.07237\alpha-0.056742)})\\ &= O(n^{-0.0364\alpha^2+0.17612\alpha-0.138437+f(-0.015122\alpha^2+1.07237\alpha-0.056742)})\\ &= O(n^{0.977\alpha+1.4})\end{aligned}$$

The last step can be proved by calculating the extrema of the function $-0.0364\alpha^2+0.17612\alpha-0.138437+f(-0.015122\alpha^2+1.07237\alpha-0.056742)-(0.977\alpha+1.4)$, which stays negative in $[1,2]$.

Similarly we can verify the following by computing the extrema of functions:

$$Ln^\omega = n^{0.180156(-0.0364\alpha^2+0.17612\alpha-0.138437)+\omega} = O(n^{0.977\alpha+1.4})$$

$$\begin{aligned}(m/d)M(n,n/\ell,n) =&O(n^{\alpha-\log_n d+\omega(1,1,\log_n(n/\ell))})\\ =&O(n^{\alpha-\log_n d+f(1-\log_n \ell)})\\ =&O(n^{0.977\alpha+1.4})\end{aligned}$$

$$\begin{aligned}(m/d)M(d,n/L,d) =&O(n^{\alpha-\log_n d+\log_n d\cdot\omega(1,1,\log_n(n/L)/\log_n d)})\\ =&O(n^{\alpha-\log_n d+\log_n d\cdot f((1-\log_n L)/\log_n d)})\\ =&O(n^{0.977\alpha+1.4})\end{aligned}$$

$$(m/d)Ld^\omega = O(n^{\alpha-\log_n d+\log_n L+\omega\log_n d}) = O(n^{0.977\alpha+1.4})$$

Thus the whole complexity is bounded by $O(n^{0.977\alpha+1.4}) = O(m^{0.977}n^{1.4+o(1)})$.

B An $\widetilde{O}(nd^3)$ Time Algorithm for Bounded Degree Graphs

Suppose every vertex in the graph G has degree not exceeding d, we provide a simple algorithm listing all avoidable vertices of G in $\widetilde{O}(nd^3)$ time.

We maintain a fully-dynamic graph connectivity oracle X supporting addition and removal of edges [29]. In the beginning, we add all edges in G to X.

For each vertex v, to judge if v is avoidable, we remove all edges adjacent to v or neighbors of v in X. Then we enumerate every two neighbors of v: p and q. Assume p and q is not directly connected, we add all edges adjacent to p and q, but not to v or neighbors of v, to X, and in X check if p and q is now connected. After checking we remove these edges and consider the next pair. After considering each vertex v we add back initially removed edges.

In this way, for each vertex $O(d^3)$ edge modifications (enumerating neighboring pairs and their adjacent edges) to X will be performed, thus taking $\widetilde{O}(nd^3)$ time in total.

Constant-Factor Approximation Algorithm for Binary Search in Trees with Monotonic Query Times

Abstract

We consider a generalization of binary search in linear orders to the domain of weighted trees. The goal is to design an adaptive search strategy whose aim is to locate an unknown target vertex of a given tree. Each query to a vertex v incurs a non-negative cost $\omega(v)$ (that can be interpreted as the duration of the query) and returns a feedback that either v is the target or the edge incident to v is given that is on the path towards the target. The goal of the algorithm is to find a strategy that minimizes the worst-case total cost. We propose a constant-factor approximation algorithm for trees with a monotonic cost function. Such function is defined as follows: there exists a vertex r such that for any two vertices u, v on any path connecting r with a leaf it holds that if u is closer to r than v, then $\omega(u) \geq \omega(v)$. The best known approximation algorithm for general weight functions has the ratio of $\mathcal{O}(\sqrt{\log n})$ [Dereniowski et al. ICALP 2017] and it remains as a challenging open question whether constant-factor approximation is achievable in such case. This gives our first motivation towards considering monotonic cost functions and the second one lies in the potential applications.

1 Introduction

We study a natural generalization of the classical binary search problem, where the algorithm is asked to locate a specific element in a sorted array of keys with as few comparisons as possible [20]. We generalize the binary search in two dimensions. Instead of arrays, we consider trees, with the keys represented as vertices of the tree. Additionally, we allow the cost of comparisons to vary across the vertices of the tree. As a result, instead of minimizing the worst-case number of queries, our objective is to minimize the worst-case total cost of the search. This problem has been introduced for trees in [26] and for general graphs in [15]. There are two characteristics of such search algorithms: the computational complexity of calculating a search strategy and the worst-case cost called the *query complexity*.

As a fundamental problem in computer science, binary search in trees and graphs has numerous practical applications in data management systems or scheduling of parallel processes (through graph coloring), machine learning, and other fields. We discuss the relevant practical problems later on in more detail.

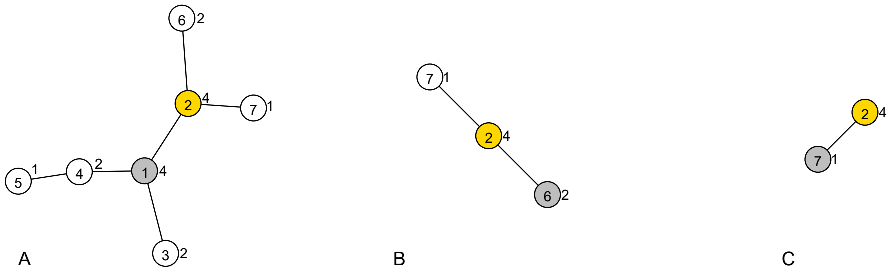

Figure 1 Binary search on weighted trees. The input tree A contains a target vertex (2), whose position is unknown to the algorithm. A series of queries is performed to the vertices 1, 6, and 7, which incurs a cost equal to 4, 2 and 1, for each query respectively. As a result of the subsequent queries, subtrees B and C are generated that consist of all vertices that may still contain the target, given the information revealed by previous queries.

1.1 Problem statement

An a priori unknown target vertex t in a known input tree $T = (V, E, \omega)$, with a query cost function $\omega\colon V(T) \to \mathbb{R}_+$, should be located by an algorithm via a series of queries. Each query selects a vertex v and as an answer receives information that either v is the target (which completes the search), or otherwise it is given an edge $\{v, u\}$ such that u lies on a path between v and t. (Note that in the case of a tree the path is unique but for general graphs, any of the shortest paths is provided, see [15].) The answer is generated at the cost of $\omega(v)$ and we want to design an algorithm that finds the target with the minimum cost in the worst case. More precisely, once the target has been returned by the algorithm, the cost of the search equals the sum of the costs of all queries that have been asked, and the performance of the algorithm is the maximum search cost taken over all vertices as potential targets. One might think about this search process that with each query the search is narrowed to a subtree of T that can still contain the target. The process is *adaptive* in the sense that the choice of the subsequent elements to be queried depends on the locations and answers of the previous queries. Also, we consider only *deterministic* algorithms, where given a fixed sequence of queries performed so far (and the information obtained), the algorithm selects always the same element as the next query for a given tree. E.g., the optimal algorithm for the classic binary search problem on paths that always queries the median element is adaptive and deterministic. It can be equivalently stated that the algorithm calculates a *strategy* for the given input tree, which encodes the queries to be performed for each potential target.

1.2 Related work and earlier techniques

While in this work we analyze queries that ask questions about vertices of a tree (vertex query model), an edge query model has been also studied. In the latter, the answer to each queried edge $e \in E(G)$ returns one of the two subgraphs in $G \setminus \{e\}$ which contains the target. The two search models are basically equivalent for paths, but in general, a query to a vertex with a high degree reveals more information than a query to an incident edge. For example, to locate the target in a star, one query is sufficient in the vertex model, while in the edge model all edges need to be queried in the worst case. The binary search can be further generalized to general graphs, where the answer to a vertex (or edge) query returns directional information with respect to the *shortest* path to the target [15].

It should be noted that other optimization criteria can be considered (e.g., the average search cost), as well as noisy search models where the response to a query can be incorrect with a certain probability.

For paths, a natural dynamic programming approach obtains an optimal algorithm for the weighted version of the problem, which runs in $\mathcal{O}(n^3)$ time and $\mathcal{O}(n^2)$ space [19]. The cubic time can be improved by exploiting a monotonic structure of search costs of the sub-intervals, which yields an $\mathcal{O}(n^2)$ time solution [5], for any assignment of the query costs. A linear time $(2 + \epsilon + o(1))$-approximation algorithm has been presented in [21], where the approach is based on a trade-off between querying the vertices with small costs and maintaining a balanced decision tree.

For unweighted trees, optimal search strategies can be computed in linear time by calculating vertex rankings of the input tree [23, 26], which is a type of graph coloring, where on a path between any two vertices with the same color there must be a vertex with a color of a higher value [17, 18]. Once the ranking is calculated, the search strategy is obtained by always querying the vertex with the highest color, considering the set of vertices that can still contain the target. Tree rankings have been studied as an independent line of research leading to the discovery of several algorithms, including linear time algorithms [22, 28].

For weighted trees, the binary search problem becomes NP-complete [12]. A quasi polynomial-time approximation scheme was obtained through a dynamic programming approach [8]. The QPTAS is then recursively applied to carefully selected subtrees of the input tree, which results in a polynomial-time algorithm with an approximation ratio of $\mathcal{O}(\sqrt{\log n})$.

The binary search problem has been extended to general graphs in [13, 15], where a function Φ is defined over the vertex set of the graph that can still contain the search target, given the responses to the queries performed so far. The Φ is defined in such a way that for each considered vertex it encodes the sum of distances to all other considered vertices. In each step, the vertex that minimizes Φ is selected as the next query, and the search space is reduced to the vertices consistent with the query response, i.e., the vertices with a shortest path from the queried vertex containing the edge returned by the query. The algorithm uses at most $\log_2 n$ queries to find arbitrary vertex in a graph with a uniform cost of queries. A further study of using graph median for queries can be found in [11].

In the context of practical applications, a related search model has been used to characterize the confidentiality of searching information in databases of genetics information [16].

1.3 Our contribution

An open question has been posed several times about whether a constant-factor approximation algorithm exists for arbitrary weight functions, see e.g. [2, 4, 5]. The main motivation of this work is to address this question by finding a natural input instance for which a constant-factor approximation is achievable. We define this instance as follows: we allow an input tree to have arbitrary structure but the weight function is assumed to be monotonic:

▶ **Definition 1.** *Given a tree $T = (V, E, \omega)$, we say that a cost function ω is* monotonic *if there exists a vertex $r \in V$ such that for any $u, v \in V$, if v lies on the path between r and u in T, then $\omega(u) \leq \omega(v)$.*

Our primary contribution is in providing a constant-factor approximation algorithm for the binary search problem in this subclass of trees with non-uniform weights. Our solution shows how a method developed for the problem with uniform costs [26] can be leveraged for the monotonic case. Our main result is the following.

▶ **Theorem 2.** *There exists an 8-approximate adaptive search algorithm for the search problem in weighted trees with monotonic cost functions. The algorithm runs in linear time.*

The organization of the remaining parts of the paper is as follows. Section 1.4 describes the motivation for our work, based on practical applications of the studied search model and several use cases of the monotonic structure of the cost function. Section 2 introduces our notation and essential concepts commonly used in the related body of research. Section 3 presents the class of decision trees (structured decision trees) that we restrict ourselves to when building the solution for the search problem. Section 4 introduces further concepts, which are needed to formulate our algorithm in the subsequent Section 5 and to prove the approximation factor in Section 6. Section 7 concludes the paper, where we suggest potential directions for future research.

1.4 Motivation and applications

Graphs form a natural abstraction for processes in many domains. Large graphs are becoming common in data management and processing systems [27]. Compared to data structures without order over its elements, it is known that maintaining at least a partial order improves the performance of fundamental operations like search, update or insert in terms of the number of comparisons needed [20]. At the same time, creating optimal strategies for searching in structures with a partial order, can be inherently hard [12]. We conclude that efficient approximation algorithms for searching in large graphs are important for the advancement of systems focused on large graph analysis.

The classic binary search and its generalizations is a basic problem in computer science that occurs in numerous practical problems. The binary search problem posed as a graph ranking problem can be used to model parallel Cholesky factorization of matrices [9], scheduling of parallel database queries [10], and VLSI layouts [29]. The binary search model for graphs has been used to build a general framework for interactive learning of classifiers, rankings, or clusterings [14].

A monotonic structure of the comparisons cost occurs naturally when considering data access times in computer systems, e.g., due to memory hierarchies of modern processors, characteristics of the storage devices, or distributed nature of data management systems. In the literature on the binary search problem, a Hierarchical Memory Model of computation has been studied [1], in which the memory access time is monotonic with respect to the location of a data element in the array. Another work was devoted to modeling the problem of text retrieval from magnetic or optical disks, where a cost model was such that the cost of a query was monotonic from the location of the previous query performed in the search process [24]. We also mention an application of tree domains in automated bug search in computer code [3]. In such a case naturally occurs a possibility that the tree to be searched has the monotonicity property. In particular, each query represents performing an automatic test that determines whether the part of the code that corresponds to the subtree under the tested vertex has an error. Thus, the vertices that are closer to the root represent larger parts of the code and thus may require more or longer lasting tests.

2 Preliminaries

The set of vertices of a tree T is denoted by $V(T)$. Given a tree $T=(V,E,w)$ and a connected subset of vertices $V' \subseteq V(T)$, we denote by $T[V']$ the induced subtree of T consisting of all vertices from V'. For a rooted T, we denote the root of T by $r(T)$, while for any $v \in V(T)$, T_v denotes the subtree of T rooted at v and consisting of v and all its descendants. For any two intervals $I, I' \in \{[a,b) \colon 0 \leq a < b\}$ we write $I > I'$ when $i > i'$ for each $i \in I$ and $i' \in I'$.

The *sequence of queries* is defined as a sequence of vertices queried by a search strategy $\mathcal{A}$ for a target t and is denoted by $\mathcal{Q}_{\mathcal{A}}(T,t)$. The vertex queried by $\mathcal{A}$ in the i-th step is denoted by $\mathcal{Q}_{\mathcal{A},i}(T,t)$. Given a search strategy for T, one can easily generate a search strategy for any subtree T' by simply discarding the queries to the vertices outside of T'. A useful way of encoding search strategies is by using decision trees.

▶ **Definition 3.** *We define a* decision tree *for $T=(V,E,w)$ generated by a search strategy $\mathcal{A}$ as a rooted tree $\mathcal{T}=(\mathcal{V},\mathcal{E})$, where $\mathcal{V}=V(T)$. The root of $\mathcal{T}$ is the first vertex queried by $\mathcal{A}$. For any $v\in\mathcal{V}$, v has a child v' if and only if v' is queried by $\mathcal{A}$ right after v for some choice of the target. Each $v\in\mathcal{V}$ corresponds to a subset $\mathcal{T}(v)\subset V(T)$ which contains all vertices that can still contain the target when $\mathcal{A}$ queries v.*

It can be seen that the root r of any decision tree corresponds to $\mathcal{T}(r)=V(T)$ and the leaves correspond to single vertices in $V(T)$.

Lemma 4 shows a property of the decision trees with respect to the positions of vertices that belong to some connected component of the input tree.

▶ **Lemma 4.** *Let $\mathcal{T}$ be a decision tree for T. If T' is a subtree of T, then there exists a vertex $u\in V(T')$, such that for every $v\in V(T')$ it holds $v\in V(\mathcal{T}_u)$.*

Proof. We traverse the decision tree $\mathcal{T}$ starting at the root of $\mathcal{T}$ and following a path to some leaf. If $r(\mathcal{T})\in V(T')$, then the lemma follows. Otherwise, consider children v_i of $r(\mathcal{T})$. Because in T there is only one edge incident to $r(\mathcal{T})$ that lies on a path to all vertices of T', all vertices of T' belong to exactly one subtree $\mathcal{T}_{v_i}$. We continue the traversal in $\mathcal{T}_{v_i}$ and set u as the first visited vertex in this process that belongs to T'. ◀

We now formally define the cost of a search process, which is the property the algorithm is trying to minimize. In terms of the search strategy $\mathcal{A}$ for an input tree $T=(V,E,\omega)$, the sum of costs of all queries performed when finding a target $t\in V(T)$ is denoted by $COST(\mathcal{A},t)$, while the *cost* of $\mathcal{A}$ is defined as $COST(\mathcal{A})=\max_{t\in V} COST(\mathcal{A},t)$.

Sometimes in our analysis, we will take one decision tree and measure its cost with different query times, i.e., for different weights. This approach will allow us to artificially increase the cost of some queries in the decision tree, which we formalize as follows. Let $\mathcal{T}$ be a decision tree for $T=(V,E,\omega)$ and ω' an arbitrary cost function defined on $V(T)$, potentially a different one than ω. We denote by $COST(\mathcal{T},\omega')$ the *cost of the decision tree according to the cost function* ω':

$$COST(\mathcal{T},\omega')=\max\{\sum_{v\in P}\omega'(v)\mid P \text{ is a path from the root to a leaf in } \mathcal{T}\}.$$

The *cost* of $\mathcal{T}$ is then $COST(\mathcal{T},\omega)$ and we shorten it to $COST(\mathcal{T})$. (Note that one may equivalently define the cost of $\mathcal{T}$ by taking $COST(\mathcal{T})=COST(\mathcal{A})$ where $\mathcal{T}$ is generated by $\mathcal{A}$.) The minimum cost that is achievable for T is denoted by

$$OPT(T)=\min\{COST(\mathcal{T})\mid \mathcal{T} \text{ is a decision tree for } T\}.$$

We say that $\mathcal{T}$ *is optimal* if and only if $COST(\mathcal{T})=OPT(T)$.

We will use the following simple folklore lemma whose proof is given for completeness. Lemma 5 has been previously formulated in [5] in the context of a slightly different problem of edge search in weighted trees.

▶ **Lemma 5.** *If $\mathcal{T}$ is a decision tree for T, then for any subtree T' of T there exists a decision tree $\mathcal{T}'$, such that $COST(\mathcal{T}')\leq COST(\mathcal{T})$.*

Proof. We first apply Lemma 4 and reduce $\mathcal{T}$ to its subtree rooted at $u \in V(T')$. Then, we sequentially remove from $\mathcal{T}_u$ all nodes that do not belong to T'. For every removed node v, consider all subtrees rooted at the children of v in the current decision tree. When removing v we also remove all subtrees that do not contain any vertex from T' but we connect the roots of all other subtrees (note that there will be only one such subtree) directly under the parent of v. Hence, the reduced tree is still a decision tree. What is more, all paths from the root to a leaf in the obtained decision tree result from corresponding paths from $\mathcal{T}$ by removing zero or more nodes, which upperbounds the cost of $\mathcal{T}'$ by the cost of $\mathcal{T}$. ◀

We say that a cost function ω is *rounded* if the values taken by ω are powers of two (for any $v \in V(T)$, $\omega(v) = 2^k$ for some $k \in \mathbb{N}$). We also say that T' is the *rounding* of T if it is obtained from T by rounding the cost function to the closest, greater power of two. We obtain that $OPT(T') \leq 2\,OPT(T)$ because $\omega' \leq 2\omega$. On the other hand, Lemma 6 shows how large is the overhead from applying an optimal decision tree for the input with a rounded cost function to search through the input tree with the original weights.

▶ **Lemma 6.** *Let $T' = (V, E, \omega')$ be the rounding of $T = (V, E, \omega)$. Let $\mathcal{T}$ and $\mathcal{T}'$ be optimal decision trees respectively for T and T'. We have:*

$$COST(\mathcal{T}', \omega) \leq 2\,COST(\mathcal{T}) = 2OPT(T).$$

Proof. We have $COST(\mathcal{T}', \omega) \leq COST(\mathcal{T}', \omega') \leq COST(\mathcal{T}, \omega') \leq 2COST(\mathcal{T}, \omega)$. The first inequality holds because $\omega \leq \omega'$. The second inequality holds because $\mathcal{T}'$ is optimal for T'. The last inequality holds because $\omega' \leq 2\omega$. ◀

3 Structured decision trees

For a rooted tree $T = (V, E, \omega)$ with a monotonic ω, we assume that the root is selected as in Definition 1, that is informally speaking, while traversing any path from the root to a leaf, the weights of visited vertices are non-increasing. From now on we assume that the input tree is rooted. We define a *layer* of a tree T as a subgraph L of T such that all vertices in $V(L)$ have the same cost, $\omega(u) = \omega(v)$ for any $u, v \in V(L)$. A connected component of L is called a *layer component*. We also denote by $\omega(L)$ the cost of querying a vertex that belongs to L, i.e., $\omega(L) = \omega(v)$ for any $v \in V(L)$.

The *upper border* of layer L is the set of roots of its layer components. The subset of $V(L)$ consisting of vertices that have at least one child that belongs to a different layer is called the *lower border* of L. We will also say that a layer component L' is *directly below* a layer component L if and only if $r(L')$ has a parent in L. The *top* layer component is the one that contains the root of T and a *bottom* layer component is any L such that there is no component directly below L. We note that we will apply the above terms to a rounded ω.

▶ **Definition 7.** *Let T be a tree with a monotonic cost function and $\mathcal{T}$ a decision tree for T. Consider a layer component L of T. Let $v = r(L)$. We say that $\mathcal{T}$ is* structured *with respect to L if for every vertex $u \in V(T_v)$, it holds that $u \in V(\mathcal{T}_v)$. We say that a decision tree $\mathcal{T}$ for T is* structured *if and only if $\mathcal{T}$ is structured with respect to all layer components of T.*

Informally speaking, in a structured $\mathcal{T}$ we require that each vertex in the entire subtree T_v is below v in $\mathcal{T}$. This is one of the central ideas in our work for the following reason. While performing bottom-up processing of (an unweighted) T in [26] (and also other works e.g. [22]) each vertex v encodes which steps are already used for queries of the vertices from T_v. In our case, that is in a weighted T, we need to encode intervals and the technical problem with that is that they have different durations while moving upwards from one layer component to the next. Thus, some intervals that are free to perform queries while moving to a parent of v may be too short due to the weights in the next layer component. To deal with that, we make $v = r(L)$ also the root of $\mathcal{T}_v$. In this way only one interval, i.e., the one assigned to v needs to be taken into account while moving upwards.

Our method requires the decision tree to be structured only when processing the internal components of T. By not enforcing structuring with respect to the top layer component, a potential additive cost of a single query can be avoided. See the *Process Component* procedure (Line 9, Algorithm 2). However, this optimization does not change the worst-case cost of the strategy. In result, the decision tree generated by our algorithm is not structured in general, and although $r(\mathcal{T})$, the first vertex queried by the strategy, always belongs to the top layer component of T, we may have that $r(\mathcal{T}) \neq r(T)$, while in a structured decision tree we always have $r(\mathcal{T}) = r(T)$, because $\mathcal{T}$ is structured with respect to the top layer component of T.

It turns out in our analysis that considering only structured decision trees introduces an overall multiplicative cost of 2 to the performance of the algorithm:

▶ **Lemma 8.** *Let $T = (V, E, \omega)$ be a tree with a monotonic and rounded cost function. There exists a structured decision tree $\mathcal{T}'$ for T, such that $COST(\mathcal{T}') \leq 2\,OPT(T)$.*

Proof. Let $\mathcal{T}$ be any decision tree for T. Since $\mathcal{T}$ is selected arbitrarily, it is enough to prove that $COST(\mathcal{T}') \leq 2\,COST(\mathcal{T})$.

In order to construct the structured decision tree, we traverse $\mathcal{T}$ in a breadth-first fashion starting at the root of $\mathcal{T}$. The $\mathcal{T}'$ is constructed in the process.

By Lemma 4, for an arbitrary layer component L of T, there exists a vertex $u' \in V(L)$ such that all vertices from L belong to $\mathcal{T}_{u'}$. Among all vertices of L, u' is visited first during the traversal.

Consider an arbitrary node u being accessed during the traversal. Let L be the layer component such that $u \in L$. If $\mathcal{T}$ is structured with respect to L we continue with the next node. Otherwise (which for a specific L will happen only once, when $u = u'$, as argued in the last paragraph of the proof), we modify $\mathcal{T}$ by performing the following steps.

Let $v = r(L)$. We want to replace the subtree $\mathcal{T}_u$ with a subtree consisting of the same nodes but rooted at v. Consider a subtree T' of the input T, which can still contain the target when the search process is about to query u according to $\mathcal{T}$. E.g., $V(T') = V(\mathcal{T}_u)$. Let v has k neighbors in T'. We attach under v the decision trees created with Lemma 5 for the k components obtained by removing v from T'. Lemma 5 shows that the cost of any of the k decision trees is not greater than $COST(\mathcal{T}_u)$. Accounting for the cost of v, structuring L increases $COST(\mathcal{T})$ no more than $\omega(L)$. Consider an arbitrary path P from root to a leaf in $\mathcal{T}$. For every node $u \in P$ that triggers structuring (informally, u is u' for some L) an additional node from L is inserted in P. Thus, in the worst case, the weighted length of arbitrary P increases 2 times when transforming $\mathcal{T}$ into structured $\mathcal{T}'$.

By starting the breadth-first traversal at the root of $\mathcal{T}$, structuring with regards to one layer component does not make $\mathcal{T}$ not structured with regards to any of the previously structured layer components. ◀

By combining Lemmas 6 and 8 one obtains Corollary 9, which relates the cost of an optimal decision tree for an input T with the cost of a structured decision tree obtained through the analysis of the rounding of T.

▶ **Corollary 9.** *For any tree T with a monotonic cost function there exists a structured decision tree with rounded weights, whose cost is at most $4 \cdot OPT(T)$.*

4 Bottom-up tree processing

Our method extends the ranking-based method for searching in trees with uniform costs of queries [26, 28]. The state-of-the-art algorithm calculates a function $f\colon V(T) \to \mathbb{N}$ called a *strategy function* (also called in the literature a *ranking* [22, 28], or tree-depth [25]). The strategy function is such that for each pair of distinct vertices $v_1, v_2 \in V(T)$, if $f(v_1) = f(v_2)$, then each path connecting v_1 and v_2 has a vertex v_3 such that $f(v_3) > f(v_1)$. One property of the strategy function is that it encodes the (reversed) order of the queries. E.g., in any sequence of queries, a vertex with a higher value of f is always queried before those with lower values of the strategy function. Thus, the maximal value of f over the vertices of a tree is the worst-case number of queries necessary to search the tree. In order to express the variable costs of queries we extend the strategy function into an *extended strategy function* (see also [7]).

▶ **Definition 10.** *A function $f\colon V(T) \to \{[a,b)\colon 0 \leq a < b\}$, where $|[a,b)| \geq \omega(v)$ for each $v \in V(T)$, is an* extended strategy function *if for each pair of distinct vertices $v_1, v_2 \in V(T)$, if $f(v_1) \cap f(v_2) \neq \emptyset$, then the path connecting v_1 and v_2 has a v_3 such that $f(v_3) > f(v_1) \cup f(v_2)$. The length of an interval assigned to a vertex v encodes the cost corresponding to querying v.*

Keeping in mind that the cost function is the time needed to perform a query, the values of an extended strategy function indicate the time periods in which the respective vertices will be queried. Note that, e.g., due to the rounding, the time periods will be longer than the query durations and this is easily resolved either by introducing idle times or by following the actual query durations while performing a search based on a strategy produced by our algorithm.

We say that $u \in V(T)$ is *visible from* $v \in V(T)$ if on the path from v to u there is no vertex x such that $f(x) > f(u)$, where f is a strategy function defined on $V(T)$. If u is visible from v we also say that the value $f(u)$ is visible from v. The sequence of values visible from v in descending order is called a *visibility sequence* for v.

In our approach, informally speaking, we will partition the rounding of the input tree into several subtrees (the layer components) and for each of them, we will use the algorithm from [26]. To clearly describe the initialization required prior to triggering the leveraged subroutine, and also for completeness, we recall a *vertex extension operator* used in [26] for calculating a strategy function. Let f be a strategy function defined on all vertices below $v \in V(T)$. Let v_i, $1 \leq i \leq k$, be the children of v. The vertex extension operator attributes v with $f(v)$, based on the visibility sequences $S(v_i)$ of the children according to the following procedure. Consider a set M with values that belong to at least two distinct visibility sequences $S(v_i)$. Let m be the maximum value in M if $M \neq \emptyset$ or -1 otherwise. The $f(v)$ is set to the lowest integer greater than m that does not belong to any $S(v_i)$. The following lemma characterizes the vertex extension operator.

▶ **Lemma 11** ([26]). *Given the visibility sequences assigned to the children of $v \in V(T)$, the* vertex extension operator *assigns to v a visibility sequence that is lexicographically minimal (the vertex extension operator is minimizing). Moreover, (lexicographically) increasing the visibility sequence of a child of v does not decrease the visibility sequence calculated for v (the vertex extension operator is monotone).*

In our approach, we restrict ourselves to extended strategy functions which generate decision trees that are structured (see Definition 7).

▶ **Definition 12.** *We say that an extended strategy function f, defined on the vertices of a tree T with monotonic cost function, is* structured *if for any layer component L, $f(u) > f(v)$ for each $v \in V(T_u)$, where $u = r(L)$.*

It follows that a structured extended strategy function represents a structured decision tree.

As mentioned earlier, we will process each layer component L with the vertex extension operator but in order to do it correctly, we need to initialize appropriately the roots of the layer components below L. For that, we define the following operators. Let f be an extended strategy function defined on the vertices of T_v, where v is the root of a layer component L'. The *structuring operator* assigns to v the minimal interval so that f is a structured extended strategy function on T_v. (We note that in our algorithm v will have some interval assigned when the structuring operator is applied to v. Hence, the application will assign the new required interval.) The *cost scaling operator* aligns the interval attributed to v: if $f(v) = [a, b)$ and L is the layer component directly above L', the cost scaling operator assigns v a new interval $[\omega(L)\lceil\frac{b}{\omega(L)}\rceil - \omega(L), \omega(L)\lceil\frac{b}{\omega(L)}\rceil)$. We will say that the interval $f(v)$ is *aligned to* $\omega(L)$ after this modification. Informally speaking, this is done so that the children of the leaves in L have intervals whose endpoints are multiples of $\omega(L)$ so that they become "compatible" with the allowed placements for intervals of the vertices from L. Yet in other words, this allows us to translate the intervals of the children of the leaves in L into integers that can be treated during bottom-up processing of L in a uniform way.

▶ **Observation 13.** *Let a layer component L' be directly below a layer component L in $T = (V, E, \omega)$. If $r(L')$ is assigned an interval $[a, b)$, whose endpoints are consecutive multiples of $\omega(L')$ (i.e. $a = k\omega(L')$ and $b = (k+1)\omega(L')$ for some integer k), then the cost scaling operator assigns to $r(L')$ an interval $[a', b')$ such that $b' \leq b + \omega(L) - \omega(L')$.*

Proof. Consider a layer component L of $T = (V, E, \omega)$ and a structured extended strategy function f defined on the vertices below L. The cost scaling operator selects b' as the smallest multiple of $\omega(L)$ that is greater or equal than b. Since $a' = b' - \omega(L)$, we have that $a' < b$. On the other hand, because $b - a = \omega(L')$, a is the highest multiple of $\omega(L')$ that is less than b. Subsequently, because $w(L)$ is divisible by $w(L')$, we obtain that $a' \leq a$. What follows, $a' + \omega(L') \leq b$, and finally $b' \leq b + \omega(L) - \omega(L')$. ◀

5 Algorithm

We propose an algorithm *Structured Tree Search* (Algorithm 1). The algorithm starts with a pre-processing pass, which transforms the input tree to its rounding and selects a root arbitrarily from the set of vertices with the highest cost o query (cf. Definition 1). An extended strategy function f is then calculated during a bottom-up traversal over the layer components of the tree by applying the *Process Component* procedure (Algorithm 2). Hence, the extended strategy function for the vertices of a layer component L is calculated only after it is already defined for all vertices below the component. Moreover, since we use a structured f, only its values assigned to the roots of the layer components below L are important when calculating f for the vertices of L.

Given a layer component L, the procedure *Process Component* iterates over the vertices of L in a depth-first, postorder fashion. Suppose that a structured extended strategy function f is defined on all vertices below L and that f is aligned to $\omega(L)$ at all roots of layer components directly below L. To calculate f for the vertices of L, we first calculate the strategy function f' for each vertex of L and then obtain f from f' using the formula: $f(u) = [f'(u)\omega(L), (f'(u) + 1)\omega(L))$, where $u \in V(L)$. (Recall that this is a conversion

Algorithm 1 Structured Tree Search.

```
Let $T$ be an input tree with a monotonic cost function, for which the extended strategy
function $f$ is calculated.
$T \leftarrow$ the rounding of $T$
for each layer component $L$ in bottom-up fashion do
    ProcessComponent($L, f$)
end for
return $f$
```

that takes us from the integer-valued strategy function f' to the interval-valued extended strategy function.) To provide an applicable input for the vertex extension operator at the leaves of L, for each child $u \in V(L')$ of such leaf, we calculate the integer $f'(u) = \frac{b}{\omega(L')}$ that is derived from the extended strategy function at u, i.e. from $f(u) = [a, b)$. Note that since our decision trees are structured, the visibility sequence corresponding to each root of a layer component below L (which includes u) consists of only one value, the one that equals the strategy function at the root. What follows, deriving the value of f' only for the roots of the layer components directly below L is sufficient to create a valid input for the vertex extension operator. In other words, we make these preparations to use the operator and the corresponding method from [26]. Once each vertex $v \in V(L)$ obtains the corresponding extended strategy function $f(v)$, we apply for the root of L the structuring operator followed by the cost scaling operator. This will close the entire “cycle” of processing one layer component.

Algorithm 2 Calculates extended strategy function f for vertices of a layer component L.

```
procedure ProcessComponent($L$, $f$)
    for each root $v$ of a layer component directly below $L$ do
        $f'(v) \leftarrow \frac{b}{\omega(L)}$, where $b$ is the right endpoint of the interval $f(v)$
    end for
    for each $u \in V(L)$ in a postorder fashion do
        Obtain $f'(u)$ by applying the vertex extension operator to $v$
        $f(u) \leftarrow$ the interval derived from $f'(u)$, see Section 4
    end for
    if the root $v$ of $L$ is not the root of $T$ then
        Update $f(v)$ by applying the structuring operator to $v$
        Update $f(v)$ by applying the cost scaling operator to $v$
    end if
end procedure
```

6 Analysis

Lemma 14 characterizes the interval of the extended strategy function that the *Process Component* procedure assigns to the root of a layer component.

▶ **Lemma 14.** *Consider a layer component L of $T = (V, E, \omega)$ and a structured extended strategy function f defined on the vertices below L. Let the intervals of f assigned to the roots of the layer components directly below L be aligned to $\omega(L)$. Suppose that the values of f over $V(L)$ are obtained by a call to procedure* ProcessComponent(L,f). *We have that f is a structured extended strategy function on $V(T_{r(L)})$, and the lowest possible interval I, such that $I > f(u)$, for each u below $r(L)$, is assigned to $r(L)$.*

Proof. Due to the alignment of f at the roots of the components directly below L, the strategy function f' derived from f for these roots is consistent with the query costs in L. That is, the construction of f' done at the beginning of the procedure gives an integer-valued strategy function. Since f is structured, among all vertices below L, the extension operator correctly needs to consider only the values of f' at the roots of components directly below L.

By Lemma 11, the visibility sequence calculated for the root of L is (lexicographically) minimized among all possible valid assignments of f'. Hence in particular, the value of $\max\{f'(v) \mid v \in V(T_{r(L)})\}$ is minimized. It follows that if there exists such an optimal assignment of f' that is structured, then this f' is calculated by the procedure is structured and consequently the f obtained from f' is minimal and structured. If there exists no optimal assignments of f' over $V(L)$ that is structured, the structuring operator modifies f and assigns to $r(L)$ the lowest interval that is greater than $f(u)$ for any u below $r(L)$. ◀

What follows from Lemma 14 and Observation 13 is that given an extended strategy function f fixed below a layer component L, Algorithm 1 extends f to the vertices of L in such a way that the interval assigned to $r(L)$ is not higher than the optimal interval (assuming that f is fixed below L) incremented by an additive factor $\omega(L') - \omega(L)$, where L' is a layer component directly above L. If L is the top component, the structuring transform is not applied and the additional cost is not incurred.

We now formulate a technical Lemma 15 that helps analyze the strategy generated by Algorithm 1.

▶ **Lemma 15.** *Let $T = (V, E, \omega)$ be a tree with a monotonic and rounded cost function. We denote by f_{opt} an optimal structured extended strategy function on $V(T)$. Let L be a layer component of T with k layer components L_j, $1 \leq j \leq k$, directly below L. Let $v_j = r(L_j), 1 \leq j \leq k$. We define f' as a function defined on $V(T)$ such that for all vertices below any v_j, f' is equal to f_{opt}, while for the vertices v_j and above, f' is equal to $f_{opt} + \omega(L)$. It holds that f' is a structured extended strategy function on $V(T)$.*

Proof. We first show that f' is an extended strategy function. We need to show that for any pair $x, y \in V(T)$, $x \neq y$, if $f'(x) = f'(y)$, then there is a vertex $z \in V(T)$ separating x, y such that $f'(z) > f'(x)$. (See Definition 10.)

We analyze the following cases with respect to the locations of the vertices x and y. In all cases we assume that $x \neq y$, $f'(x) = f'(y)$, and z is the vertex separating x and y according to f'.

- $x \in V(L_i)$, $y \in V(L_j)$ and $i = j$.
  Let $v = r(L_i)$. Because f_{opt} is structured, f' is also structured within the subtree T_v, since it assigns v a higher interval than f_{opt} and f' is otherwise identical to f_{opt}. What follows, because f' is structured and we assumed $f'(x) = f'(y)$, we have that $x \neq v$ and $y \neq v$.
  Consider the f_{opt} as defined on all vertices of L_i. Because $x, y \in V(L_i)$, we have $z \in V(L_i)$. If $z \neq v$, then $f'(z) = f_{opt}(z) > f_{opt}(x) = f'(x)$, where the last equation holds because $x \neq v$. If $z = v$, we also have $f'(z) > f'(x)$, because f' is structured in T_v.
- $x \in V(L_i)$, $y \in V(L_j)$ and $i \neq j$.
  Because f' is structured in L_i, we have $z = r(L_i)$.
- Both x and y belong to $V(L)$.
  Because f_{opt} is an extended strategy function in L, there is a $z \in V(L)$ such that $f_{opt}(z) > f_{opt}(x)$. Then, by adding $\omega(L)$ to both sides of the inequality one obtains $f'(z) > f'(x)$.

- $x \in V(L_i)$ for some i and $y \in V(L)$.
  If $x \neq r(L_i)$ then $z = r(L_i)$, because f' is structured in L_i.
  Otherwise, both x and y are in the subtree $T[V(L) \cup \{x\}]$. Recall that in this subtree f' is derived from f_{opt} by adding a constant offset, which gives an extended strategy function.

To show that f' is structured in the remaining cases, we observe that for all vertices above L, f' is derived from the structured f_{opt} by shifting the assigned intervals by a positive offset, which does not change the structural property of the layer components' roots. ◀

▶ **Lemma 16.** *The cost of the decision tree generated by Algorithm 1 is at most 2 times greater than the cost of an optimal structured decision tree.*

Proof. The proof is by induction, bottom-up over the layer components of the input tree. Take a tree $T = (V, E, \omega)$ with a monotonic and rounded cost function. We denote by $c(i), 1 \leq i \leq l$, the query cost to a vertex in the $i - th$ layer, where the layers are ordered according to their cost of query and l is the number of layers in T. Let f_{opt} be an optimal (structured) extended strategy function and f_{alg} be the extended strategy function generated by Algorithm 1. We denote by $z(v)$ the cost of querying the parent of v or the cost of v itself if there is no vertex above v, i.e. when v is the root of T.

We want to prove the following induction claim. For any layer component L it holds $f_{alg}(v) \leq f_{opt}(v) + z(v)$, where $v = r(L)$.

The cost of the decision tree generated by f_{alg} is equal to the supremum of $f_{alg}(r(T))$. Since the cost of a single query to the top layer is not more than the cost of an optimal structured decision tree, the lemma follows from the induction claim applied to the top layer component.

Let L be a bottom layer component. Based on Lemma 14 we know that by applying the vertex extension and structuring operators, Algorithm 1 generates an optimal structured assignment of the extended strategy function to the vertices of L. In a case where L is also the top component (which is the trivial case of T being a single layer component) we have f_{alg} is optimal and the induction claim holds. Otherwise, the cost scaling operator extends the interval assigned to $r(L)$, increasing the cost of L by (at most) an additive factor of $c(2) - c(1)$ over the optimal cost. Since the added factor is less than $z(r(L))$, the induction claim holds for the bottom layer component L.

Let L be a layer component from the i-th layer, with k layer components L_j, $1 \leq j \leq k$, directly below L. We denote the roots of the layer components L_j by v_j. Consider a strategy function f' which is defined as in Lemma 15, that is for all vertices below any v_j, f' is equal to f_{opt}, while for vertices v_j and all vertices above, f' is equal to $f_{opt} + \omega(L)$. Lemma 15 implies that f' is a structured extended strategy function on $V(T)$.

From the induction hypothesis we have that for any v_j, $f_{alg}(v_j) \leq f_{opt}(v_j) + z(v_j) = f_{opt}(v_j) + \omega(L)$. According to Lemma 14 and Observation 13, Algorithm 1 assigns intervals to the vertices of L such that the interval assigned to the root of L is the lowest possible (when L is the top component), or the lowest possible interval incremented by a positive offset of $\omega(L') - \omega(L)$, where L' is the layer component directly above L. If we sum up the additive increments due to cost scaling in all layer components below L, we obtain $\sum_{i<l} c(i) < c(l) = z(v)$ (recall that $c(i)$'s are powers of 2). Thus, $f_{alg}(v) \leq f_{opt}(v) + z(v)$. ◀

By combining Lemmas 6, 8, and 16 we obtain that Algorithm 1 generates a solution for the binary search problem with a cost at most 8 times greater than that of an optimal solution. We note that Algorithm 1 maintains the main structure of the linear time algorithm from [26] (a single bottom-up pass over vertices of the tree.) Our method extends the state-of-the-art algorithm by adding a fixed number of $\mathcal{O}(1)$ steps, computed when visiting vertices during the bottom-up traversal. See the *Process Component* procedure, Algorithm 2. What follows, Algorithm 1 also runs in linear time. This proves Theorem 2.

7 Conclusions

We recall a related tree search problem, called *edge search*, in which one performs queries on edges: each reply provides information which endpoint of the queried edge is closer to the target [3]. One can similarly define a monotonic cost function $\omega\colon E(T) \to \mathbb{R}_+$ for the edge search by requiring that there exists a choice for the root r so that for any two edges $\{x, y\}$ and $\{y, z\}$, if x is closer to r than y, then $\omega(\{x, y\}) \geq \omega(\{y, z\})$.

Interestingly, the edge search problem is NP-complete for monotonic weight function which follows from [6], although the authors do not obtain this fact directly. More precisely, the reduction in [6] constructs a spider in which each leg has three edges with weights $2a, a$, and $\Theta(an)$ (listing them by following from the root to the leaf). Denote by e the latter edge incident to a leaf. It is not hard to see that e can be replaced by a star on $\Theta(n)$ edges, each of weight at most a, thus getting an instance with a monotonic cost function and the same search cost.

It turns out that the problem we study in this work is more general in the class of weighted trees – see the corresponding reduction in [8]. This reduction however does not preserve the property of monotonicity. In other words, a conversion from an instance of the edge search with a monotonic cost function produces an instance of the vertex search with a non-monotonic cost function. Thus, the fact that the edge search is NP-complete for weighted trees pointed above does not imply hardness in our case. We do believe that the argument of hardness cannot be easily obtained in a similar way as for the edge search in [6] and we leave as an open question whether the vertex search problem studied in this work is NP-complete in case of monotonic cost functions.

Also, we repeat the previously mentioned interesting and challenging open question whether a constant-factor approximation is possible for the vertex search in trees with general weight functions.

On the Identity Problem for Unitriangular Matrices of Dimension Four

Ruiwen Dong ✉
Department of Computer Science, University of Oxford, UK

Abstract

We show that the Identity Problem is decidable in polynomial time for finitely generated sub-semigroups of the group $\mathsf{UT}(4, \mathbb{Z})$ of 4×4 unitriangular integer matrices. As a byproduct of our proof, we also show the polynomial-time decidability of several subset reachability problems in $\mathsf{UT}(4, \mathbb{Z})$.

1 Introduction

Among the most prominent algorithmic problems for matrix semigroups are the *Identity Problem* and the *Membership Problem*. For the Membership Problem, the input is a finite set of square matrices $A_1, \ldots, A_k$ and a target matrix A. The problem is to decide whether A lies in the semigroup generated by $A_1, \ldots, A_k$. The Identity Problem is the Membership Problem restricted to the case where A is the identity matrix. These two problems are closely related to each other, and, as shown in many circumstances, studying the Identity Problem is usually the first step in studying the Membership Problem.

For general matrices, the Membership Problem is undecidable by a classical result of Markov [10]. Indeed, it is one of the earliest undecidability results on algorithmic problems in matrix semigroups. Most variants of the problem remain undecidable in low dimension. For example, the *Mortality Problem*, which is the Membership Problem in which the target matrix is 0, is undecidable in dimension three [12]. In dimension four, the Membership Problem is undecidable for matrices in $\mathrm{SL}(4, \mathbb{Z})$ (see [11]), while the Identity Problem is undecidable for the set of 4×4 integer matrices $\mathcal{M}_{4\times4}(\mathbb{Z})$ (see [2]).

However, there has also been steady progress on the decidability side. The Membership Problem is shown to be decidable for $\mathrm{GL}(2, \mathbb{Z})$ in [4]. This decidability result is then extended to 2×2 integer matrices with nonzero determinant [13], and to 2×2 integer matrices with determinants equal to 0 and ±1 [14]. It remains an intricate open problem whether the Membership Problem or the Identity Problem is decidable for $\mathrm{SL}(3, \mathbb{Z})$.

Recently, there has been more progress on closing the decidability gap by restricting consideration to the class of unitriangular matrices. It has long been known that the *Group Membership Problem* is decidable for $\mathsf{UT}(n, \mathbb{Z})$, the group of unitriangular integer matrices of dimension n. The Group Membership Problem asks to decide whether a matrix A lies in the *group* generated by given matrices $A_1, \ldots, A_k$. In fact, it is decidable for all finitely generated solvable matrix groups [8]. Later, Babai et al. [1] showed that the Group Membership Problem for *commuting matrices* can be computed in polynomial time (note that commuting matrices are simultaneously upper-triangularizable). However, there are significant differences between the group case and the semigroup case. In fact, for large enough n, the *Knapsack Problem* for $\mathsf{UT}(n, \mathbb{Z})$ is undecidable [7]. Given matrices $A_1, \ldots, A_k$

and A, the Knapsack Problem asks to decide whether there exist natural numbers $e_1, \dots, e_k$ such that $A_1^{e_1} \cdots A_k^{e_k} = A$. From the undecidability of the Knapsack Problem, one can deduce the undecidability of the semigroup Membership Problem for $\mathsf{UT}(n, \mathbb{Z})$ for large enough n [9].

Nevertheless, there have been some positive decidability results. The Identity Problem has been shown to be decidable for the group of 3×3 unitriangular integer matrices $\mathsf{UT}(3, \mathbb{Z})$ and the Heisenberg groups H_{2n+1} in [6]. Shortly after, the decidability result was extended to the Membership Problem [5]. Ko et al. left open the problem whether the Identity Problem in $\mathsf{UT}(n, \mathbb{Z})$ is decidable for $n \geq 4$, as well as finding the smallest n for which the Membership Problem for $\mathsf{UT}(n, \mathbb{Z})$ becomes undecidable.

The main result of this paper is that the Identity Problem is decidable in polynomial time for $\mathsf{UT}(4, \mathbb{Z})$. This further narrows the gap between decidability and undecidability and can be regarded as a first step towards the Membership Problem for $\mathsf{UT}(4, \mathbb{Z})$. The foundation of our method is the arguments developed in [5] for the Membership Problem of $\mathsf{UT}(3, \mathbb{Z})$. However, in order to pass from dimension three to four, we need to introduce additional methods from convex geometry, linear programming and even use the aid of computational algebraic geometry software. The proof for $\mathsf{UT}(3, \mathbb{Z})$ heavily relies on the fact that the subgroup generated by commutators of matrices from a given subset of $\{A_1, \dots, A_k\} \subset \mathsf{UT}(3, \mathbb{Z})$ is isomorphic to a subgroup of $\mathbb{Z}$. This is no longer the case for $\mathsf{UT}(4, \mathbb{Z})$. However, $\mathsf{UT}(4, \mathbb{Z})$ is still metabelian [15], and its derived subgroup is isomorphic to $\mathbb{Z}^3$. Given a finite set $\mathcal{G} \subseteq \mathsf{UT}(4, \mathbb{Z})$, we construct elements in $\langle \mathcal{G} \rangle$ that fall inside the derived subgroup of $\mathsf{UT}(4, \mathbb{Z})$. These elements then generate a cone in $\mathbb{Z}^3$ under the isomorphism between the derived subgroup and $\mathbb{Z}^3$. The possible shapes of this cone will determine the Identity Problem.

There is strong evidence that the new techniques introduced in this paper can help tackle the Identity Problem for $\mathsf{UT}(n, \mathbb{Z})$ with $n \geq 5$.

2 Preliminaries

Denote by $\mathsf{UT}(4, \mathbb{Z})$ the group of upper triangular integer matrices with ones on the diagonal:

$$\mathsf{UT}(4, \mathbb{Z}) \coloneqq \left\{ \begin{pmatrix} 1 & a & d & f \\ 0 & 1 & b & e \\ 0 & 0 & 1 & c \\ 0 & 0 & 0 & 1 \end{pmatrix} \middle| a, b, c, d, e, f \in \mathbb{Z} \right\}.$$

Denote its normal subgroups

$$\mathsf{U}_1 \coloneqq \left\{ \begin{pmatrix} 1 & 0 & d & f \\ 0 & 1 & 0 & e \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \middle| d, e, f \in \mathbb{Z} \right\}, \quad \mathsf{U}_2 \coloneqq \left\{ \begin{pmatrix} 1 & 0 & 0 & f \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \middle| f \in \mathbb{Z} \right\}$$

in the lower central series: $\mathsf{UT}(4, \mathbb{Z}) \trianglerighteq \mathsf{U}_1 = [\mathsf{UT}(4, \mathbb{Z}), \mathsf{UT}(4, \mathbb{Z})] \trianglerighteq \mathsf{U}_2 = [\mathsf{UT}(4, \mathbb{Z}), \mathsf{U}_1]$ (see [15, Chapter 5]). In particular, U_1 and U_2 are respectively the derived subgroup and the centre of $\mathsf{UT}(4, \mathbb{Z})$. For convenience, we introduce the following notations:

$$UT(a, b, c; d, e, f) \coloneqq \begin{pmatrix} 1 & a & d & f \\ 0 & 1 & b & e \\ 0 & 0 & 1 & c \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad U_1(d, e, f) \coloneqq UT(0, 0, 0; d, e, f).$$

There are surjective group homomorphisms $\varphi_0 \colon \mathsf{UT}(4, \mathbb{Z}) \to \mathbb{Z}^3$ defined by

$$\varphi_0(UT(a, b, c; d, e, f)) = (a, b, c),$$

with $\ker(\varphi_0) = \mathsf{U}_1$, and $\varphi_1 \colon \mathsf{U}_1 \to \mathbb{Z}^2$,

$$\varphi_1(U_1(d,e,f)) = (d,e),$$

with $\ker(\varphi_1) = \mathsf{U}_2$. Moreover, U_1 is itself abelian, with a natural isomorphism $\tau \colon \mathsf{U}_1 \xrightarrow{\sim} \mathbb{Z}^3$:

$$\tau(U_1(d,e,f)) = (d,e,f).$$

Denote by τ_d the projection $U_1(d,e,f) \mapsto d$, τ_e the projection $U_1(d,e,f) \mapsto e$, and τ_f the projection $U_1(d,e,f) \mapsto f$. Then, $\varphi_1 = (\tau_d, \tau_e)$ and $\tau = (\tau_d, \tau_e, \tau_f)$.

Finally, define the subgroup of $\mathsf{UT}(4,\mathbb{Z})$:

$$\mathsf{U}_{10} \coloneqq \{U_1(0,e,f) \mid e,f \in \mathbb{Z}\} \trianglelefteq \mathsf{U}_1.$$

For a finite set of matrices $\mathcal{G} = \{A_1, \dots, A_k\}$, denote by $\langle \mathcal{G} \rangle$ the semigroup generated by $\mathcal{G}$. In this paper, we are concerned with the following problems.

▶ **Definition 1.** Let G be a monoid of matrices, and H a subset of G.

(i) The *Identity Problem* in G asks, given a finite set of matrices $\mathcal{G}$ in G, whether $I \in \langle \mathcal{G} \rangle$. If this is the case, we say that the identity matrix is *reachable.*

(ii) The *H-Reachability Problem* in G asks, given a finite set of matrices $\mathcal{G}$ in G, whether $H \cap \langle \mathcal{G} \rangle \neq \emptyset$. If this is the case, we say that H is *reachable.*

The main result of this paper is that the Identity Problem in $\mathsf{UT}(4,\mathbb{Z})$ is decidable in polynomial time, with respect to the number of bits required to encode all the entries of the matrices in $\mathcal{G}$ (each matrix $UT(a,b,c,d,e,f)$ is encoded by the entries a,b,c,d,e,f).

It turns out that the three problems: Identity Problem, U_2-Reachability and U_{10}-Reachability are interconnected and it is more convenient to devise algorithms that decide them simultaneously. A trivial observation is that, because $I \in \mathsf{U}_2 \subset \mathsf{U}_{10}$, a positive instance of the Identity Problem is also a positive instance of U_2-Reachability; and a positive instance of U_2-Reachability is also a positive instance of U_{10}-Reachability.

The following definitions will be used throughout this paper.

▶ **Definition 2** (String, product and Parikh vector)**.** Let $\mathcal{G} = \{A_1, \dots, A_k\}$ be a fixed set of matrices in $\mathsf{UT}(4,\mathbb{Z})$. A *string* of $\mathcal{G}$ is an expression $B_1 B_2 \cdots B_m$ such that $B_i \in \mathcal{G}, i = 1, \dots, m$. The *product* of a string $B_1 B_2 \cdots B_m$ is the matrix $P \in \mathsf{UT}(4,\mathbb{Z})$ such that $P = B_1 B_2 \cdots B_m$. The *Parikh vector* of a string $B_1 B_2 \cdots B_m$ is the vector $\boldsymbol{\ell} = (\ell_1, \dots, \ell_k) \in \mathbb{Z}_{\geq 0}$ where

$$\ell_j = \operatorname{card}(\{i \mid B_i = A_j\}), j = 1, \dots, k.$$

When $\mathcal{G}$ is clear from the context, we simply use the term “string” instead of “string of $\mathcal{G}$”.

For an integer $n \geq 1$, the *Heisenberg group* of dimension $2n+1$ is the group H_{2n+1} of $(n+2) \times (n+2)$ integer matrices of the form $H = \begin{pmatrix} 1 & \boldsymbol{a} & c \\ 0 & I_n & \boldsymbol{b}^\top \\ 0 & 0 & 1 \end{pmatrix}$, where $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{Z}^n$, $c \in \mathbb{Z}$.

The following result comes from [6] and [5].

▶ **Lemma 3** ([5, Theorem 7])**.** *The Identity Problem and the Membership Problem in* H_{2n+1} *are decidable for all* $n \geq 1$.

3 Identity problem, U_2- and U_{10}-Reachability in $\mathsf{UT}(4,\mathbb{Z})$

In this section, we construct algorithms that decide the Identity Problem, U_2-Reachability and U_{10}-Reachability in $\mathsf{UT}(4,\mathbb{Z})$.

3.1 Overview of decision strategy

For any set of vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_l \in \mathbb{R}^n$, denote by

$$\langle \boldsymbol{v}_1, \ldots, \boldsymbol{v}_l \rangle_{\mathbb{R}_{\geq 0}} \coloneqq \left\{ \sum_{i=1}^{l} r_i \boldsymbol{v}_i \,\middle|\, r_i \in \mathbb{R}_{\geq 0}, i = 1, \ldots, l \right\}$$

the $\mathbb{R}_{\geq 0}$-cone generated by $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_l$, and by $\langle \boldsymbol{v}_1, \ldots, \boldsymbol{v}_l \rangle_{\mathbb{R}}$ the $\mathbb{R}$-vector space spanned by $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_l$.

Let $\mathcal{G} = \{A_1, \ldots, A_k\}$ be a set of matrices in $\mathsf{UT}(4, \mathbb{Z})$, for which we want to decide the Identity Problem, U_2-Reachability and U_{10}-Reachability. Define the $\mathbb{R}_{\geq 0}$-cone

$$\mathcal{C} \coloneqq \langle \varphi_0(A_1), \ldots, \varphi_0(A_k) \rangle_{\mathbb{R}_{\geq 0}}, \tag{1}$$

and denote by $\mathcal{C}^{lin}$ its lineality space, i.e. the largest linear subspace (by inclusion) contained in $\mathcal{C}$. In particular, $\mathcal{C}^{lin} = \mathcal{C} \cap -\mathcal{C}$. A basis of $\mathcal{C}^{lin}$ can be effectively computed in polynomial time [16]. For any matrix $A_i \in \mathcal{G}$, the projection $\varphi_0(A_i)$ can be either in $\mathcal{C}^{lin}$ or in $\mathcal{C} \setminus \mathcal{C}^{lin}$. However, in order to reach U_1, which contains the identity matrix, U_2 and U_{10}, one can only use matrices A_i with $\varphi_0(A_i) \in \mathcal{C}^{lin}$. This is formally stated by the following proposition.

▶ **Proposition 4.** *If the product of a string $B_1 \cdots B_m$ is in U_1, then every $B_j, j = 1, \ldots m$, must be in the set $\{A_i \in \mathcal{G} \mid \varphi_0(A_i) \in \mathcal{C}^{lin}\}$.*

Proof. Suppose on the contrary that some B_j satisfies $\varphi_0(B_j) \in \mathcal{C} \setminus \mathcal{C}^{lin}$.

Since φ_0 is a group homomorphism, we have

$$B_1 \cdots B_m \in \mathsf{U}_1 \iff \varphi_0(B_1 \cdots B_m) = \mathbf{0} \iff \sum_{i=1}^{m} \varphi_0(B_i) = \mathbf{0}.$$

Therefore, $-\varphi_0(B_j) = \sum_{i \neq j} \varphi_0(B_i) \in \mathcal{C}$.

Hence, the linear subspace $\varphi_0(B_j)\mathbb{R} = \langle \varphi_0(B_j), -\varphi_0(B_j) \rangle_{\mathbb{R}_{\geq 0}}$ is contained in $\mathcal{C}$. This yields $\varphi_0(B_j)\mathbb{R} \subseteq \mathcal{C}^{lin}$, a contradiction to $\varphi_0(B_j) \in \mathcal{C} \setminus \mathcal{C}^{lin}$. ◀

The overall strategy for constructing our algorithm is to use induction on $\text{card}(\mathcal{G})$. If $\text{card}(\mathcal{G}) = 0$, then the answers to the Identity Problem, U_2-Reachability and U_{10}-Reachability are all negative. Suppose now that we have an algorithm that decides all three problems for every set of at most $k - 1$ matrices, we will construct an algorithm that decides them for a set of k matrices $\mathcal{G} = \{A_1, \ldots, A_k\}$. By Proposition 4, if some matrix A_i satisfies $\varphi_0(A_i) \in \mathcal{C} \setminus \mathcal{C}^{lin}$, then we can discard it without changing the answer to the Identity Problem or $\mathsf{U}_2, \mathsf{U}_{10}$-Reachability. This decreases the number of elements in $\mathcal{G}$, and an algorithm is available by the induction hypothesis on $\text{card}(\mathcal{G})$. Hence, we can suppose that every $A_i \in \mathcal{G}$ satisfies $\varphi_0(A_i) \in \mathcal{C}^{lin}$, so $\mathcal{C} = \mathcal{C}^{lin}$ is a linear space.

Since $\varphi_0(A_i) \in \mathbb{Z}^3$, $\mathcal{C}$ is a linear subspace of $\mathbb{R}^3$. We identify cases according to the dimension of $\mathcal{C}$, with each of the following four subsections treating the case of dimension 3, 1, 0, 2. The pseudocode of the decision procedure for the Identity Problem is given here as a reference point for the detailed case analysis. The decision procedures for U_2-reachability and U_{10}-reachability follow similar patterns and their pseudocode is given in the appendix of the full version of this paper. Note that the decision procedure for the Identity Problem invokes the decision procedure for U_2-reachability as a subroutine. Similarly, the decision procedure for U_2-reachability will invoke the decision procedure for U_{10}-reachability as a subroutine.

Algorithm 1 IdentityProblem(): deciding the Identity Problem for a subset of $\mathsf{UT}(4,\mathbb{Z})$.

```
Input: A set $\mathcal{G} = \{A_1, \dots, A_k\}$ of matrices in $\mathsf{UT}(4,\mathbb{Z})$.
Output: True or False.

Step 1: Compute the cone $\mathcal{C}$ and its lineality space $\mathcal{C}^{lin}$. For $i = 1, \dots, k$, if some
        $\varphi_0(A_i)$ is not in $\mathcal{C}^{lin}$, return IdentityProblem($\mathcal{G} \setminus \{A_i\}$).
Step 2: a. If $\dim(\mathcal{C}) = 3$, return True.
        b. If $\dim(\mathcal{C}) = 1$, return True if the condition in Proposition 15(i) is satisfied,
           otherwise return False.
        c. If $\dim(\mathcal{C}) = 0$, return True if $\tau(A_i), i = 1, \dots, m$ generate a semigroup
           containing $\mathbf{0}$, otherwise return False.
        d. If $\dim(\mathcal{C}) = 2$, compute a non-zero vector $(p, q, r) \in \mathbb{Q}^3$ orthogonal to $\mathcal{C}$.
             i. If $p = 0$, but $q, r$ are not zero, or $r = 0$, but $q, p$ are not zero.
                Compute $L_0$, if $\mathrm{supp}(L_0) = \{1, \dots, k\}$, return True, otherwise return
                IdentityProblem($\{A_i \mid i \in \mathrm{supp}(L_0)\}$).
            ii. If $p = r = 0$, problem reduces to Identity Problem in $\mathrm{H}_5$.
           iii. If $p = q = 0, r \neq 0$ or $r = q = 0, p \neq 0$, compute $A'_i$ as in (9). Return
                U2Reachability($A'_1, \dots, A'_k$) (see full version of paper).
```

We now give an overview of the motivation behind classifying cases according to the dimension of $\mathcal{C}$. As a convention, we always use $A_i, i = 1, \dots, k$ to denote elements of the fixed generating set $\mathcal{G}$, and Greek letters to denote their entries, i.e. $A_i = UT(\alpha_i, \beta_i, \kappa_i; \delta_i, \epsilon_i, \phi_i)$. We use $B_i, i = 1, \dots, m$ to denote arbitrary elements in $\langle \mathcal{G} \rangle$ (when appearing in *strings*, they are elements in $\mathcal{G}$), and Latin letters to denote their entries, i.e. $B_i = UT(a_i, b_i, c_i, d_i, e_i, f_i)$. The variables B_i can depend on the context.

First of all, we need some results on the structure of products in $\mathsf{UT}(4,\mathbb{Z})$. For a positive integer m, denote by S_m the permutation group of the set $\{1, \dots, m\}$. Throughout this paper, given some matrices $B_1, \dots, B_m \in \langle \mathcal{G} \rangle$, we will often be computing the product of strings of the form $B^t_{\sigma(1)} \cdots B^t_{\sigma(m)}$, where $\sigma \in \mathrm{S}_m$ and $t \in \mathbb{Z}_{\geq 0}$. The overall idea is to find various strings $B^t_{\sigma(1)} \cdots B^t_{\sigma(m)}$ whose product is in $\mathsf{U}_1 \overset{\tau}{\cong} \mathbb{Z}^3$, then use them to generate an abelian semigroup containing the identity matrix. Let us define the following important values and abbreviations that will be used throughout this paper. These complicated formulas are related to the *logarithm* of the matrices B_i, and readers can for the time being ignore their exact form and treat them as black boxes.

▶ **Notation 5.** Given a series of matrices $B_1, \dots, B_m$ where $B_i = UT(a_i, b_i, c_i; d_i, e_i, f_i), i = 1, \dots, m$, we introduce the following notation:

(i) For $\sigma \in \mathrm{S}_m, t \in \mathbb{Z}_{\geq 0}$,

$$B(\sigma, t) \coloneqq B^t_{\sigma(1)} \cdots B^t_{\sigma(m)}. \tag{2}$$

(ii) For $\sigma \in \mathrm{S}_m$,

$$D_\sigma \coloneqq \sum_{i<j} a_{\sigma(i)} b_{\sigma(j)} + \frac{1}{2} \sum_{i=1}^{m} a_i b_i, \quad E_\sigma \coloneqq \sum_{i<j} b_{\sigma(i)} c_{\sigma(j)} + \frac{1}{2} \sum_{i=1}^{m} b_i c_i,$$

$$F_\sigma \coloneqq \sum_{i<j<k} a_{\sigma(i)} b_{\sigma(j)} c_{\sigma(k)} + \frac{1}{2} \sum_{i<j} (a_{\sigma(i)} b_{\sigma(i)} c_{\sigma(j)} + a_{\sigma(i)} b_{\sigma(j)} c_{\sigma(j)}) + \frac{1}{6} \sum_{i=1}^{m} a_i b_i c_i,$$

$$G_\sigma \coloneqq \sum_{i<j}(a_{\sigma(i)}e_{\sigma(j)} + d_{\sigma(i)}c_{\sigma(j)} - \frac{1}{2}a_{\sigma(i)}b_{\sigma(j)}c_{\sigma(j)} - \frac{1}{2}a_{\sigma(i)}b_{\sigma(i)}c_{\sigma(j)}) + \frac{1}{2}\sum_{i=1}^{m}(a_ie_i + d_ic_i - a_ib_ic_i). \quad (3)$$

(iii) For $i = 1, \dots, m$,

$$D_i \coloneqq d_i - \frac{1}{2}a_ib_i, \quad E_i \coloneqq e_i - \frac{1}{2}b_ic_i, \quad F_i \coloneqq f_i - \frac{1}{2}(a_ie_i + d_ic_i) + \frac{1}{3}a_ib_ic_i. \quad (4)$$

The following proposition gives an exact expression for $B(\sigma, t)$. Because of the heavily computational nature of most of our propositions, their proofs are given in the appendix of the full version of this paper.

▶ **Proposition 6.** *Let $B_i = UT(a_i, b_i, c_i; d_i, e_i, f_i), i = 1, \dots, m$, $\sigma \in \mathrm{S}_m, t \in \mathbb{Z}_{\geq 0}$, then*

$$B(\sigma, t) = UT\left(t\sum_{i=1}^{m} a_i, t\sum_{i=1}^{m} b_i, t\sum_{i=1}^{m} c_i; \right. \left. t^2D_\sigma + t\sum_{i=1}^{m} D_i, t^2E_\sigma + t\sum_{i=1}^{m} E_i, t^3F_\sigma + t^2G_\sigma + t\sum_{i=1}^{m} F_i\right). \quad (5)$$

Notice that $B(\sigma, t) \in \mathsf{U}_1$ if and only if $\sum_{i=1}^{m} a_i = \sum_{i=1}^{m} b_i = \sum_{i=1}^{m} c_i = 0$, a condition that does not depend on the value of t.

Proposition 6 shows that, if $B(\sigma, t)$ is in U_1, then as $t \to \infty$, the asymptotic behaviour of $\tau(B(\sigma, t))$ approaches the vector $(t^2D_\sigma, t^2E_\sigma, t^3F_\sigma)$, provided that $D_\sigma, E_\sigma, F_\sigma$ do not vanish. Therefore, the hope is that, as t, σ vary, the vectors $(t^2D_\sigma, t^2E_\sigma, t^3F_\sigma)$ can generate $\mathbb{R}^3$ as an $\mathbb{R}_{\geq 0}$-cone, barring a few degenerate cases. If these degenerate cases do not happen, then the different vectors $\tau(B(\sigma, t))$ will also generate $\mathbb{R}^3$ as an $\mathbb{R}_{\geq 0}$-cone. In particular, the identity element in $\mathbb{R}^3$ can be generated by $\tau(B(\sigma, t))$ as an additive semigroup, giving a positive answer to the Identity Problem. For the degenerate cases, they will be treated individually. As it will turn out, there are only two types of degeneracy (which may occur simultaneously):

(i) $F_\sigma = 0$ for all σ.

(ii) For some $p, r \in \mathbb{Q}$, possibly zero, we have $pD_\sigma = rE_\sigma$ for all σ.

When (i) occurs, the asymptotic behaviour of $\tau(B(\sigma, t))$ approaches the vector $(t^2D_\sigma, t^2E_\sigma, t^2G_\sigma)$, since G_σ is the second most dominant term after F_σ. This situation reminds us of the Identity Problem for H_3, and can be solved in a similar way. When (ii) occurs, the vectors $(t^2D_\sigma, t^2E_\sigma, t^3F_\sigma)$ are constrained to a strict linear subspace of $\mathbb{R}^3$. Hence, in order to describe the $\mathbb{R}_{\geq 0}$-cone generated by the vectors $\tau(B(\sigma, t))$, one needs to consider the sub-dominant terms as well, i.e. the terms $t\sum_{i=1}^{m} D_i, t\sum_{i=1}^{m} E_i$.

The rest of this paper aims to formalize this idea. We first exhibit a series of lemmas that characterise these degenerate cases. Our first lemma shows that, supposing $B(\sigma, t) \in \mathsf{U}_1$, then degenerate case (ii) happens if and only if $\langle \varphi_0(B_1), \dots, \varphi_0(B_m)\rangle_{\mathbb{R}}$ is degenerate (i.e. of dimension at most 2).

▶ **Lemma 7.** *Given $p, r \in \mathbb{R}$ and $m \geq 2$. Suppose $\sum_{i=1}^{m} a_i = \sum_{i=1}^{m} b_i = \sum_{i=1}^{m} c_i = 0$. The two following statements are equivalent:*

(i) *For all $\sigma \in \mathrm{S}_m$, $pD_\sigma = rE_\sigma$.*

(ii) *Either $b_i = 0$ for all $i = 1, \dots, m$, or there exist $q \in \mathbb{R}$, such that $pa_i + qb_i + rc_i = 0$ for all $i = 1, \dots, m$.*

The next lemma shows that if $B(\sigma,t) \in \mathsf{U}_1$, then by "inverting" σ, we get a permutation σ' such that (D_σ, E_σ) and $(D_{\sigma'}, E_{\sigma'})$ are opposites of one another.

▶ **Lemma 8.** *Suppose $\sum_{i=1}^m a_i = \sum_{i=1}^m b_i = \sum_{i=1}^m c_i = 0$, $m \geq 2$. For every $\sigma \in \mathrm{S}_m$, there exists $\sigma' \in \mathrm{S}_m$, such that $(D_{\sigma'}, E_{\sigma'}) = -(D_\sigma, E_\sigma)$.*

We then show that, if $B(\sigma,t) \in \mathsf{U}_1$, then the value of F_σ for different $\sigma \in \mathrm{S}_m$ sums up to zero:

▶ **Lemma 9.** *Suppose $\sum_{i=1}^m a_i = \sum_{i=1}^m b_i = \sum_{i=1}^m c_i = 0$, where $m \geq 3$. Then we have $\sum_{\sigma \in \mathrm{S}_m} F_\sigma = 0$.*

The last lemma characterizes situations where the aforementioned degenerate case (i) happens. Its proof relies on the aid of a computational algebraic geometry software due to the complexity of the expressions F_σ.

▶ **Lemma 10.** *Let $m = 4$. Suppose $\sum_{i=1}^4 a_i = \sum_{i=1}^4 b_i = \sum_{i=1}^4 c_i = 0$. Then, $F_\sigma = 0$ for all $\sigma \in \mathrm{S}_4$, if and only if at least one of the following four conditions holds:*

(i) $a_1 = a_2 = a_3 = a_4 = 0$.

(ii) $b_1 = b_2 = b_3 = b_4 = 0$.

(iii) $c_1 = c_2 = c_3 = c_4 = 0$.

(iv) $\operatorname{rank} \begin{pmatrix} a_1 & a_2 & a_3 & a_4 \\ b_1 & b_2 & b_3 & b_4 \\ c_1 & c_2 & c_3 & c_4 \end{pmatrix} \leq 1$.

A common idea of Lemma 7 and Lemma 10 is that the degeneracy of $(D_\sigma, E_\sigma, F_\sigma)$ is related to the degeneracy of $\varphi_0(B_1), \ldots, \varphi_0(B_m)$. Hence, it is natural to consider the degeneracy of the vectors $\varphi_0(A_i), i = 1, \ldots, k$, where $A_i \in \mathcal{G}$ are the elements of the generating set. This degeneracy is described by the dimension of the linear space $\mathcal{C}$ discussed at the beginning of the section. This justifies the classification according to $\dim(\mathcal{C})$. We now begin the case analysis.

3.2 $\mathcal{C}$ has dimension 3

The main idea of this case is that, for a well chosen set of matrices $B_1, B_2, B_3, B_4 \in \langle \mathcal{G} \rangle$, the vectors $(D_\sigma, E_\sigma, F_\sigma), \sigma \in \mathrm{S}_4$, are not degenerate and the asymptotic behaviour of $\tau(B(\sigma,t))$ approaches the vector $(t^2 D_\sigma, t^2 E_\sigma, t^3 F_\sigma)$, leading to a positive answer to the Identity Problem.

Let $B_1, B_2, B_3, B_4 \in \langle \mathcal{G} \rangle$ with $B_i = UT(a_i, b_i, c_i; d_i, e_i, f_i), i = 1, \ldots, 4$ be such that

$$\sum_{i=1}^{4} \varphi_0(B_i) = 0 \tag{6}$$

and

$$\langle \varphi_0(B_1), \varphi_0(B_2), \varphi_0(B_3), \varphi_0(B_4) \rangle_{\mathbb{R}_{\geq 0}} = \mathcal{C} = \mathbb{R}^3. \tag{7}$$

Equation (6) shows that $B(\sigma,t) \in \mathsf{U}_1$ for all $\sigma \in \mathrm{S}_4, t \in \mathbb{Z}_{\geq 0}$.

The following lemma shows that the d,e-coordinates of different $\tau(B(\sigma,t))$ generate $\mathbb{R}^2$ as an $\mathbb{R}_{\geq 0}$-cone.

▶ **Lemma 11.** *Assuming (6) and (7), we have $\langle \{\varphi_1(B(\sigma,t)) \mid \sigma \in \mathrm{S}_4, t \in \mathbb{Z}\} \rangle_{\mathbb{R}_{\geq 0}} = \mathbb{R}^2$.*

Proof. First, we claim that $\langle\{(D_\sigma, E_\sigma) \mid \sigma \in \mathrm{S}_4\}\rangle_{\mathbb{R}} = \mathbb{R}^2$.

In fact, suppose to the contrary that $\langle\{(D_\sigma, E_\sigma) \mid \sigma \in \mathrm{S}_4\}\rangle_{\mathbb{R}}$ has dimension at most 1. Then there exist $p, r \in \mathbb{R}$, not both zero, such that for all $\sigma \in \mathrm{S}_4$, $pD_\sigma = rE_\sigma$. By Lemma 7, this means that either $b_i = 0$ for all i or there exists some $q \in \mathbb{R}$ such that $pa_i + qb_i + rc_i = 0$ for all i. In both cases, the $\mathbb{R}$-linear subspace spanned by $\varphi_0(B_1), \varphi_0(B_2), \varphi_0(B_3), \varphi_0(B_4)$ has dimension at most 2, contradicting Equation (7). This proves the claim. Hence, there exist $\sigma_1, \sigma_2 \in \mathrm{S}_4$ such that $(D_{\sigma_1}, E_{\sigma_1})$ and $(D_{\sigma_2}, E_{\sigma_2})$ span $\mathbb{R}^2$ as an $\mathbb{R}$-linear space.

Next, by Lemma 8, there exist $\sigma_1', \sigma_2' \in \mathrm{S}_4$ such that $(D_{\sigma_1'}, E_{\sigma_1'}) = -(D_{\sigma_1}, E_{\sigma_1})$ and $(D_{\sigma_2'}, E_{\sigma_2'}) = -(D_{\sigma_2}, E_{\sigma_2})$. It follows that $(D_{\sigma_1}, E_{\sigma_1}), (D_{\sigma_2}, E_{\sigma_2}), (D_{\sigma_1'}, E_{\sigma_1'}), (D_{\sigma_2'}, E_{\sigma_2'})$ generate $\mathbb{R}^2$ as an $\mathbb{R}_{\geq 0}$-cone, and all four vectors are non-zero.

Finally, consider the products $B(\sigma, t)$ with $\sigma \in \{\sigma_1, \sigma_2, \sigma_1', \sigma_2'\}$. By Proposition 6, when $t \to +\infty$, we have $\varphi_1(B(\sigma, t)) = (D_\sigma, E_\sigma)t^2 + O(t)$. Therefore, when t is large enough, the angle between $\varphi_1(B(\sigma, t))$ and (D_σ, E_σ) tends to zero, for all $\sigma \in \{\sigma_1, \sigma_2, \sigma_1', \sigma_2'\}$. Hence, for large enough t, $\varphi_1(B(\sigma_1, t)), \varphi_1(B(\sigma_2, t)), \varphi_1(B(\sigma_1', t)), \varphi_1(B(\sigma_2', t))$ generate $\mathbb{R}^2$ as an $\mathbb{R}_{\geq 0}$-cone. This proves the Lemma. ◀

The next proposition shows that as σ, t vary, the vectors $\tau(B(\sigma, t))$ generate $\mathbb{R}^3$ as an $\mathbb{R}_{\geq 0}$-cone.

▶ **Proposition 12.** *Assuming* (6) *and* (7)*, we have* $\langle\{\tau(B(\sigma, t)) \mid \sigma \in \mathrm{S}_4, t \in \mathbb{Z}\}\rangle_{\mathbb{R}_{\geq 0}} = \mathbb{R}^3$.

Proof. First, note that all $B(\sigma, t)$ have integer coefficients. By Lemma 11, there exist elements $P_1, P_2, P_3 \in \langle\{B(\sigma, t) \mid \sigma \in \mathrm{S}_4, t \in \mathbb{Z}\}\rangle$ such that $\varphi_1(P_i), i = 1, 2, 3$ generate $\mathbb{R}^2$ as an $\mathbb{R}_{\geq 0}$-cone (see Figure 1 for an illustration.).

Next, the idea is to find two additional matrices $P_+, P_- \in \{B(\sigma, t) \mid \sigma \in \mathrm{S}_4, t \in \mathbb{Z}\}$, whose images under τ are relatively close to the f-axis in $\mathbb{R}^3$. By Lemmas 9 and 10, there exist $\sigma_+, \sigma_- \in \mathrm{S}_4$ such that $F_{\sigma_+} > 0, F_{\sigma_-} < 0$. Indeed, by condition (7), none of the four conditions of Lemma 10 hold. Thus there exists $\sigma \in \mathrm{S}_4$ such that $F_\sigma \neq 0$. Then Lemma 9 shows we can find σ_+ and σ_- such that $F_{\sigma_+} > 0$ and $F_{\sigma_-} < 0$.

By Proposition 6, when $t \to +\infty$, we have $\tau_f(B(\sigma_+, t)) = F_{\sigma_+}t^3 + O(t^2)$ and $\tau_f(B(\sigma_-, t)) = F_{\sigma_-}t^3 + O(t^2)$, whereas $\tau_d(B(\sigma_\pm, t)) = O(t^2)$ and $\tau_e(B(\sigma_\pm, t)) = O(t^2)$. Therefore, when t is large enough, the angle between $\tau(B(\sigma_+, t))$ and $(0, 0, 1)$ tends to zero, as well as the angle between $\tau(B(\sigma_-, t))$ and $(0, 0, -1)$.

Finally, we claim that there exists t such that $\tau(P_1), \tau(P_2), \tau(P_3), \tau(B(\sigma_+, t)), \tau(B(\sigma_-, t))$ generate $\mathbb{R}^3$ as an $\mathbb{R}_{\geq 0}$-cone. See Figure 1 for an illustration. To justify this claim, suppose to the contrary that for every t, the $\mathbb{R}_{\geq 0}$-cone spanned by the five vectors $\tau(P_1), \tau(P_2), \tau(P_3)$, $\tau(B(\sigma_+, t))$, $\tau(B(\sigma_-, t))$ is a proper subset of $\mathbb{R}^3$. In other words, if we denote by $\langle \cdot, \cdot \rangle$ the canonical inner product of $\mathbb{R}^3$, then there exists a vector $\boldsymbol{v}_t$ with norm 1, such that $\langle \boldsymbol{v}_t, \tau(P_i)\rangle \geq 0, i = 1, 2, 3$ and $\langle \boldsymbol{v}_t, \tau(B(\sigma_\pm, t))\rangle \geq 0$. For example, we can take $\boldsymbol{v}_t$ to be any normalized vector in the dual of the cone generated by these five vectors ([3, Chapter 2.6]). By the compactness of the unit sphere, $\{\boldsymbol{v}_t\}_{t \in \mathbb{N}}$ has a limit point $\boldsymbol{v}$. We have $\langle \boldsymbol{v}, \tau(P_i)\rangle \geq 0, i = 1, 2, 3$, so $\boldsymbol{v}$ is not orthogonal to the f-axis, otherwise $\tau(P_i), i = 1, 2, 3$ would all be on the same side of a hyperplane passing through the f-axis, contradicting the fact that their d, e-coordinates generate $\mathbb{R}^2$ as an $\mathbb{R}_{\geq 0}$-cone. Hence, $\langle \boldsymbol{v}, (0, 0, 1)\rangle \neq 0$. Without loss of generality, suppose $\langle \boldsymbol{v}, (0, 0, 1)\rangle < 0$. When $t \to \infty$, the angle between $(0, 0, 1)$ and $\tau(B(\sigma_+, t))$ tends to zero. Therefore, for all large enough t, we have $\langle \boldsymbol{v}, \tau(B(\sigma_+, t))\rangle < 0$. Since $\boldsymbol{v}$ is a limit point of $\{\boldsymbol{v}_t\}_{t \in \mathbb{N}}$, there exists a large enough t such that $\langle \boldsymbol{v}_t, \tau(B(\sigma_+, t))\rangle < 0$. This contradicts the fact that $\langle \boldsymbol{v}_t, \tau(B(\sigma_+, t))\rangle \geq 0$ for all t. ◀

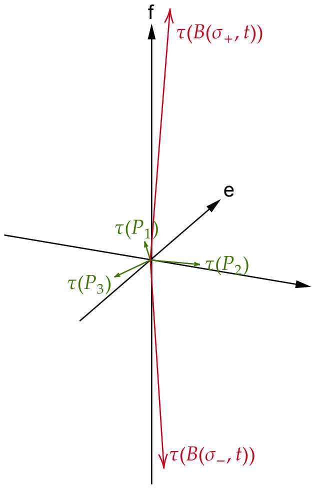

Figure 1 Illustration of the five vectors constructed in Proposition 12.

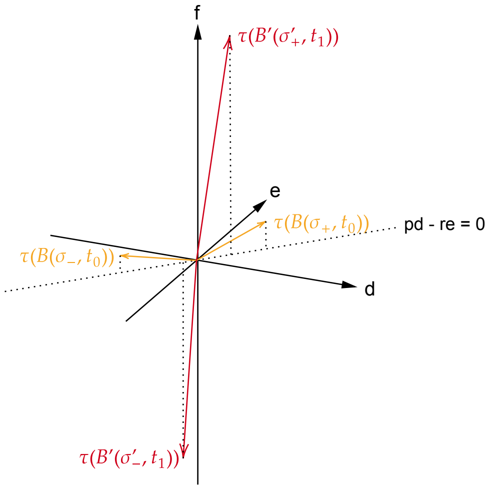

Figure 2 Illustration of the four vectors constructed in Proposition 19.

▶ **Corollary 13.** *When $\mathcal{C}$ has dimension 3, the identity matrix is reachable (and hence also* U_2 *and* U_{10}*).*

Proof. By Proposition 12, one can find $Q_1, Q_2, Q_3, Q_4 \in \langle\mathcal{G}\rangle \cap \mathsf{U}_1$ such that $\tau(Q_i), i = 1, \ldots, 4$ generate $\mathbb{R}^3$ as an $\mathbb{R}_{\geq 0}$-cone. In particular, $-\tau(Q_1) \in \langle \tau(Q_1), \tau(Q_2), \tau(Q_3), \tau(Q_4)\rangle_{\mathbb{R}_{\geq 0}}$. So there exist $x_i \in \mathbb{R}_{\geq 0}, i = 1, \ldots, 4$, not all zero, such that $\sum_{i=1}^4 x_i \tau(Q_i) = \mathbf{0}$. Since $\tau(Q_i), i = 1, \ldots, 4$ have integer entries, one can suppose $x_i \in \mathbb{Z}_{\geq 0}$. Hence, $\tau(\prod_{i=1}^4 Q_i^{x_i}) = \sum_{i=1}^4 x_i \tau(Q_i) = \mathbf{0}$, which yields $I = \prod_{i=1}^4 Q_i^{x_i} \in \langle\mathcal{G}\rangle$. ◀

3.3 $\mathcal{C}$ has dimension 1

Next, we consider the case where $\dim \mathcal{C} = 1$. The main idea of this case is that if the product of a string $B_1 \cdots B_m$ is in U_1, then all $D_\sigma, E_\sigma, F_\sigma$ vanish, so $\tau(B(\sigma, t))$ is determined by some linear terms as well as by G_σ. Recall that we write $A_i = UT(\alpha_i, \beta_i, \kappa_i; \delta_i, \epsilon_i, \phi_i)$, $i = 1, \ldots, k$. Similar to notation (4), we define the following quantities for convenience:

$$\Delta_i \coloneqq \delta_i - \frac{1}{2}\alpha_i\beta_i, \quad \mathcal{E}_i \coloneqq \epsilon_i - \frac{1}{2}\beta_i\kappa_i, \quad \Phi_i \coloneqq \alpha_i\beta_i\kappa_i - \frac{1}{2}(\alpha_i\epsilon_i + \delta_i\kappa_i) + \frac{1}{3}\phi_i. \tag{8}$$

Since $\mathcal{C}$ has dimension 1, there exist $\alpha, \beta, \kappa \in \mathbb{Z}$ such that $\varphi_0(A_i) = (\alpha, \beta, \kappa) \cdot \rho_i$ for $\rho_i \in \mathbb{Z}, i = 1, \ldots, k$.

▶ **Proposition 14.** *Suppose $\varphi_0(A_i) = (\alpha, \beta, \kappa) \cdot \rho_i$ for $\rho_i \in \mathbb{Z}, i = 1, \ldots, k$. Let $\boldsymbol{\ell} = (\ell_1, \ldots, \ell_k)$ be the Parikh vector of a string $B_1 \cdots B_m$, with the product $P = B_1 \cdots B_m$. Then*

(i) *$P \in \mathsf{U}_{10}$ if and only if $\sum_{i=1}^k \ell_i\rho_i = 0$ and $\sum_{i=1}^k \ell_i\Delta_i = 0$.*

(ii) *$P \in \mathsf{U}_2$ if and only if $\sum_{i=1}^k \ell_i\rho_i = 0, \sum_{i=1}^k \ell_i\Delta_i = 0$ and $\sum_{i=1}^k \ell_i\mathcal{E}_i = 0$.*

The immediate consequence of Proposition 14 is that U_2-Reachability and U_{10}-Reachability are decidable using linear programming (LP). For example, U_{10}-Reachability has a positive answer if and only if the LP instance $\sum_{i=1}^k \ell_i\rho_i = 0$, $\sum_{i=1}^k \ell_i\Delta_i = 0$, $\ell_i \geq 0, i = 1, \ldots, k$, has a non-zero *integer* solution $(\ell_1, \ldots, \ell_k)$. However, because all the equations and inequalities in the LP instance are *homogeneous*, the LP instance has a non-zero *integer* solution if and only if it has a non-zero *rational* solution. Furthermore, the total bit length of $\rho_i, \Delta_i, \mathcal{E}_i$ is linear with respect to the encoding size of $\mathcal{G}$. Therefore, the existence of a non-zero rational solution is decidable in polynomial time. In particular, for $i = 1, \dots, k$, one can decide whether this LP instance has a rational solution $(\ell_1, \dots, \ell_k)$ with $\ell_i = 1$. Then, the LP instance has a non-zero rational solution if and only if it has a rational solution with $\ell_i = 1$ for some i. The decision procedure for U_2-Reachability is similar.

Next, we consider the Identity Problem. Define the set

$$\Lambda \coloneqq \left\{ (\ell_1, \dots, \ell_k) \in \mathbb{Z}_{\geq 0}^k \,\middle|\, \sum_{i=1}^k \ell_i \rho_i = \sum_{i=1}^k \ell_i \Delta_i = \sum_{i=1}^k \ell_i \mathcal{E}_i = 0 \right\}.$$

By Proposition 14, the product of a string is in U_2 if and only if its Parikh vector is in Λ. It is easy to see that Λ is additively closed, meaning $\Lambda + \Lambda \subseteq \Lambda$. Define the *support* of a Parikh vector $\boldsymbol{\ell} = (\ell_1, \dots, \ell_k)$ to be $\operatorname{supp}(\boldsymbol{\ell}) = \{i \mid \ell_i \neq 0\}$, and the support of the set Λ to be

$$\operatorname{supp}(\Lambda) \coloneqq \bigcup_{\boldsymbol{\ell} \in \Lambda} \operatorname{supp}(\boldsymbol{\ell}) = \{i \mid \exists (\ell_1, \dots, \ell_k) \in \Lambda, \ell_i \neq 0\}.$$

For $i = 1, \dots, k$, we have $i \in \operatorname{supp}(\Lambda)$ if and only if the LP instance $\sum_{i=1}^k \ell_i \rho_i = \sum_{i=1}^k \ell_i \Delta_i = \sum_{i=1}^k \ell_i \mathcal{E}_i = 0$, $\ell_i > 0$ and $\ell_j \geq 0, j \neq i$ has an *integer* solution. Again, by homogeneity, this is decidable in polynomial time by deciding the existence of a *rational* solution. Hence, $\operatorname{supp}(\Lambda)$ is computable in polynomial time by deciding whether $i \in \operatorname{supp}(\Lambda)$ for all $i = 1, \dots, k$.

If $\operatorname{supp}(\Lambda) \neq \{1, \dots, k\}$, we can discard the elements $A_i \in \mathcal{G}$ with $i \notin \operatorname{supp}(\Lambda)$, then $\operatorname{card}(\mathcal{G})$ decreases and we are done by the induction hypothesis. Hence, we only need to consider the case where $\operatorname{supp}(\Lambda) = \{1, \dots, k\}$. The following proposition answers the Identity Problem in this case. Again, the homogeneity yields a polynomial time deciding procedure.

▶ **Proposition 15.** *Suppose* $\varphi_0(A_i) = (\alpha, \beta, \kappa) \cdot \rho_i$ *for* $\rho_i \in \mathbb{Z}, i = 1, \dots, k$, *and* $\operatorname{supp}(\Lambda) = \{1, \dots, k\}$. *Define the values* $\Gamma_i = \alpha \epsilon_i - \kappa \delta_i, i = 1, \dots, k$. *Then*

- **(i)** *When* $\rho_i \Gamma_j = \rho_j \Gamma_i$ *for all* $i, j \in \{1, \dots, k\}$, *the identity matrix is reachable if and only if the set* $\{(\ell_1, \dots, \ell_k) \in \Lambda \mid \sum_{i=1}^k \ell_i \Phi_i = 0\}$ *is not equal to* $\{\mathbf{0}\}$.
- **(ii)** *When* $\rho_i \Gamma_j \neq \rho_j \Gamma_i$ *for some* $i, j \in \{1, \dots, k\}$, *the identity matrix is reachable.*

3.4 $\mathcal{C}$ has dimension 0

In this case, $\varphi_0(A_i) = \mathbf{0}$ for all i, so $\mathcal{G} \subset \mathsf{U}_1$. Since $\mathsf{U}_1 \overset{\tau}{\cong} \mathbb{Z}^3$, the Identity Problem and U_2, U_{10}-Reachability are decidable using linear programming. For example, deciding the Identity Problem amounts to deciding whether the LP instance $\sum_{i=1}^k \ell_i \cdot \tau(A_i) = \mathbf{0}$, $\ell_i \geq 0, i = 1, \dots, k$ has a non-zero integer solution. As before, by the homogeneity of the LP instance, this is decidable in polynomial time by considering solutions in $\mathbb{Q}$.

3.5 $\mathcal{C}$ has dimension 2

Suppose now that there exist $p, q, r \in \mathbb{Z}$, not all zero, such that $p\alpha_i + q\beta_i + r\kappa_i = 0, i = 1, \dots, k$. Consider the following cases on the values of p, q, r.

3.5.1 Case 1: there is at most one zero among p, q, r

The main difficulty of this case is as follows. By Lemma 7, (D_σ, E_σ) is constrained to the one dimensional subspace $\{(d, e) \mid pd - re = 0\} \subset \mathbb{R}^2$. Therefore, in order to decide whether the vectors $\tau(B(\sigma, t))$ can generate the neutral element, one needs to take into account their linear terms, i.e. $(\sum_{i=1}^m D_i, \sum_{i=1}^m E_i)$ as well. Define the additively closed set:

$$L \coloneqq \left\{ (\ell_1, \dots, \ell_k) \in \mathbb{Z}_{\geq 0}^k \,\middle|\, \sum_{i=1}^k \ell_i \varphi_0(A_i) = 0 \right\}.$$

The product P of a string $B_1 \cdots B_m$ is in U_1 if and only if its Parikh vector is in L.

▶ **Lemma 16.** *When $\mathcal{C} = \mathcal{C}^{lin}$, we have* $\operatorname{supp}(L) = \{1, \dots, k\}$.

We continue to adopt the notations from (8) for $\Delta_i, \mathcal{E}_i$. Consider the subset of L:

$$L_0 := \left\{ (\ell_1, \dots, \ell_k) \in L \,\middle|\, p \sum_{i=1}^{k} \ell_i \Delta_i - r \sum_{i=1}^{k} \ell_i \mathcal{E}_i = 0 \right\}.$$

L_0 can be described as the set of Parikh vectors whose corresponding strings have linear terms falling on the line $pd - re = 0$. Again, L_0 is additively closed. The main idea is that the quadratic term of $\varphi_1(B(\sigma, t))$ falls on the line $pd - re = 0$, therefore, if $P \in \mathsf{U}_2, \varphi_1(B(\sigma, t)) = 0$, then its linear term must also fall on the line $pd - re = 0$. This leads to the following lemma.

▶ **Lemma 17.** *Suppose* $\dim \mathcal{C} = 2$*. If the product P of a string $B_1 \cdots B_m$ is in U_2, then its Parikh vector $\boldsymbol{\ell}$ is in L_0.*

The following proposition gives a solution to the U_{10}-Reachability problem.

▶ **Proposition 18.** *Suppose* $\dim \mathcal{C} = 2$ *and at most one of p, q, r is zero.*

(i) *When $r \neq 0$, U_{10} is reachable.*

(ii) *When $r = 0, p \neq 0$, U_{10} is reachable if and only if L_0 is not equal to $\{\mathbf{0}\}$.*

In particular, whether L_0 equals $\{\mathbf{0}\}$ is decidable by linear programming, (again, by homogeneity, one can solve the linear programming instance in $\mathbb{Q}$). Hence, U_{10}-Reachability is decidable. We then treat the Identity Problem and U_2-Reachability. Consider the support of L_0. As before, $\operatorname{supp}(L_0) = \{i \mid \exists (\ell_1, \dots, \ell_k) \in L_0, \ell_i \neq 0\}$ is computable using linear programming. By Lemma 17, in order to reach U_2 (or the identity matrix), we can only use matrices with index in $\operatorname{supp}(L_0)$. By discarding matrices and using the induction hypothesis on $\operatorname{card}(\mathcal{G})$, we only need to consider the case where $\operatorname{supp}(L_0) = \{1, \dots, k\}$. The following proposition gives a positive answer to the Identity Problem and U_2-Reachability in this case.

▶ **Proposition 19.** *Suppose* $\dim \mathcal{C} = 2$ *and at most one of p, q, r is zero. If* $\operatorname{supp}(L_0) = \{1, \dots, k\}$*, then the identity matrix is reachable. (In particular, U_2 is reachable.)*

Sketch of proof. Similarly to Proposition 12, we construct four elements in $\mathsf{U}_1 \cap \langle \mathcal{G} \rangle$ whose images under τ generate the two-dimensional linear subspace $\{(d, e, f) \in \mathbb{R}^3 \mid pd - re = 0\}$ as an $\mathbb{R}_{\geq 0}$-cone (see Figure 2 for an illustration). Consequently, the $\mathbb{Z}_{\geq 0}$-cone that they generate is two-dimensional lattice in $\{(d, e, f) \in \mathbb{Z}^3 \mid pd - re = 0\}$, which contains the neutral element. ◀

3.5.2 Case 2: $p = r = 0$

In this case, $\mathcal{G} \subset \mathrm{H}_5$, so the Identity Problem is decidable by Lemma 3. U_2 and U_{10}-Reachability reduce to the Identity Problem in $\mathbb{Z}^4$ and $\mathbb{Z}^3$, respectively, which are decidable in polynomial time using linear programming. Here, we claim an additional complexity result that strengthens Lemma 3, which is crucial for a polynomial complexity algorithm for $\mathsf{UT}(4, \mathbb{Z})$.

▶ **Proposition 20.** *For a fixed n, the Identity Problem in H_{2n+1} is decidable in polynomial time.*

3.5.3 Case 3: $p = q = 0$, $r \neq 0$ or $r = q = 0$, $p \neq 0$

The main technique in this case is a reduction from the Identity Problem to U_2-Reachability, from U_2-Reachability to U_{10}-Reachability, and from U_{10}-Reachability to linear programming or to the Identity Problem in H_3. If $p = q = 0$, $r \neq 0$, then $\kappa_i = 0, i = 1, \dots, k$. If $r = q = 0$, $p \neq 0$, then $\alpha_i = 0, i = 1, \dots, k$. Define the following matrices in H_3:

$$H_i \coloneqq \begin{pmatrix} 1 & \alpha_i & \delta_i \\ 0 & 1 & \beta_i \\ 0 & 0 & 1 \end{pmatrix}, \quad i = 1, \dots, k.$$

The following proposition along with Proposition 20 provides a solution to U_{10}-Reachability.

▶ **Proposition 21.**

(i) *When $\kappa_i = 0, i = 1, \dots, k$, U_{10}-Reachability for $A_1, \dots, A_k$ is equivalent to the Identity Problem for $H_1, \dots, H_k$.*

(ii) *When $\alpha_i = 0, i = 1, \dots, k$, U_{10} is reachable for $A_1, \dots, A_k$ if and only if $\sum_{i=1}^{k} \ell_i \delta_i = \sum_{i=1}^{k} \ell_i \beta_i = \sum_{i=1}^{k} \ell_i \kappa_i = 0$ has a non-zero integer solution $(\ell_1, \dots, \ell_k) \in \mathbb{Z}_{\geq 0}^{k}$.*

Next, consider the Identity Problem and U_2-Reachability. By symmetry, we can suppose $p = q = 0$, $r \neq 0$, so $\kappa_i = 0, i = 1, \dots, k$. Define

$$A'_i \coloneqq UT(\beta_i, \alpha_i, \epsilon_i; \delta_i, \phi_i, 0), i = 1, \dots, k, \tag{9}$$

the following proposition reduces the Identity Problem and U_2-Reachability for $A_1, \dots, A_k$ to reachability problems for $A'_1, \dots, A'_k$:

▶ **Proposition 22.** *Suppose $\kappa_i = 0, i = 1, \dots, k$.*

(i) *The Identity Problem for $A_1, \dots, A_k$ is equivalent to U_2-Reachability for $A'_1, \dots, A'_k$.*

(ii) *U_2-Reachability for $A_1, \dots, A_k$ is equivalent to U_{10}-Reachability for $A'_1, \dots, A'_k$.*

Together with the previous Subsections 3.2 - 3.5.2, we have completely reduced the Identity Problem for $\mathcal{G}$ to either the problem for a set of smaller cardinality, or to U_2-reachability of another set. We have also reduced U_2-reachability for $\mathcal{G}$ to either a problem for a set of smaller cardinality, or to U_{10}-reachability of another set. By Proposition 21 and the previous subsections, U_{10}-reachability is decidable. Hence, we have now exhausted all the possible cases for the dimension of $\mathcal{C}$, and we conclude that the Identity Problem, U_2-Reachability and U_{10}-Reachability in $\mathsf{UT}(4, \mathbb{Z})$ are decidable.

4 Complexity analysis and concluding remarks

In this paper, we have shown that the Identity Problem for $\mathsf{UT}(4, \mathbb{Z})$ is decidable. A brief analysis of our algorithm shows that it terminates in polynomial time. In fact, we can first show that the algorithm for U_{10}-Reachability terminates in polynomial time. Starting with $k = \mathrm{card}(\mathcal{G})$ matrices, we need to solve at most $O(k)$ linear equations, $O(k)$ homogeneous linear programming instances and one Identity Problem in H_3 before either $\mathrm{card}(\mathcal{G})$ decreases or a conclusion on U_{10}-Reachability is reached. All these problems have $O(k)$ inputs which are of polynomial size with respect to the coefficients of the matrices in $\mathcal{G}$, and are known to have polynomial complexity. Furthermore, the number $\mathrm{card}(\mathcal{G})$ decreases at most k times. Hence, the total complexity of our algorithm for U_{10}-reachability is polynomial with respect to the input $\mathcal{G}$. Then, using the same method, we can show that the algorithm for U_2-Reachability terminates in polynomial time: since after polynomial time, either $\mathrm{card}(\mathcal{G})$

decreases, or the problem is reduced to U_{10}-Reachability, or a conclusion on U_2-Reachability is reached. At last, we can show that the algorithm for the Identity Problem terminates in polynomial time: after polynomial time, either $\mathrm{card}(\mathcal{G})$ decreases, or the problem is reduced to U_2-Reachability or the Identity Problem in H_5, or a conclusion on the Identity Problem is reached. (In particular, the polynomial complexity of the Identity Problem in H_5 is a new result of our paper, see Proposition 20.)

It is likely that our method can be adapted to study the Identity Problem for other metabelian matrix groups, for instance the direct product H_3^n. There is also evidence that the arguments in this paper can be strengthened to tackle the Identity Problem for $\mathsf{UT}(n, \mathbb{Z})$ with $n \geq 5$, even though $\mathsf{UT}(5, \mathbb{Z})$ ceases to be metabelian. In fact, one can push the convex geometry arguments down the derived series of $\mathsf{UT}(n, \mathbb{Z})$, even when the series has length greater than two. Another natural follow-up question is the Membership Problem for $\mathsf{UT}(4, \mathbb{Z})$. An interesting idea would be to adapt the Register Automata method introduced in [5] for passing from the Identity Problem to the Membership Problem.

Abstract

We introduce regular languages of morphisms in free monoidal categories, with their associated grammars and automata. These subsume the classical theory of regular languages of words and trees, but also open up a much wider class of languages over string diagrams. We use the algebra of monoidal categories to investigate the properties of regular monoidal languages, and provide sufficient conditions for their recognizability by deterministic monoidal automata.

1 Introduction

Classical formal language theory has been extended to various kinds of algebraic structures, such as infinite words, rational sequences, trees, countable linear orders, graphs of bounded tree width, etc. In recent years, the essential unity of the field has been better understood [1, 16]. Such structures can often be seen as algebras for monads on the category of sets, and sufficient conditions exist [1] for formal language theory to extend to their algebras.

In this paper, we make a first step into a programme of extending language theory to higher-dimensional algebraic structures. Here we make the step from monoids to 2-monoids, better known as monoidal categories.

We introduce a categorial framework for reasoning about languages of morphisms in strict monoidal categories – including their associated grammars and automata. We show how these include classical and tree automata, but also open up a wilder world of string diagram languages. By investigating the morphisms in monoidal categories from the perspective of language theory, this work contributes to research into the computational manipulation of string diagrams, and so their usage in industrial strength applications. Omitted proofs can be found in the full version [6].

2 Related work

Bossut [2] studied rational languages of planar acyclic graphs and proved a Kleene theorem for a class of such languages. Bossut's graph languages feature initial and final states, whereas our languages consist of scalar morphisms, which more neatly generalizes the theory of regular string and tree languages. Bossut introduces a notion of automaton for these languages, but these lack a state machine denotation – being more similar to our grammars.

In [10], Heindel recasts Bossut's approach using monoidal categories. Unfortunately the purported Myhill-Nerode result was incorrect, due to a flawed definition of syntactic congruence. We rectify this in Section 5, but a Myhill-Nerode type theorem remains open.

Zamdzhiev [18] introduced context-free languages of string diagrams using the string graph representation of string diagrams and the machinery of context-free graph grammars. In contrast, our approach does not require an intermediate representation of string diagrams as graphs: we work directly with morphisms in monoidal categories. This allows us to use the algebra of monoidal categories to reason about properties of monoidal languages.

Winfree et al. [13] use DNA self-assembly to simulate cellular automata and Wang tile models of computation. The kinds of two-dimensional languages obtained in this way can be seen quite naturally as regular monoidal languages, as illustrated in Example 12.

Walters' note [17] on regular and context-free grammars served as a starting point for our definition of regular monoidal grammar. Rosenthal [12], developing some of the ideas of Walters, defined automata as relational presheaves, which is similar in spirit to our functorial definition of monoidal automata. The framework of Colcombet and Petrişan [5] considering automata as functors is also close in spirit to our definition of monoidal automata. However, all of these papers are directed towards questions involving classical one-dimensional languages, rather than languages of diagrams as in the present paper.

Fahrenberg et al. [7] investigated languages of higher-dimensonal automata, a well-established model of concurrency. We might expect that the investigations of the present paper correspond to a detailed study of a particular low-dimensional case of such languages, but the precise correspondence between these notions is unclear.

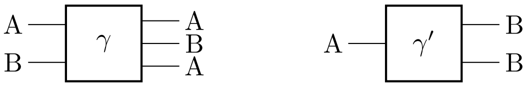
3 Regular monoidal grammars and regular monoidal languages

A *monoidal grammar* is a finite specification for the construction of string diagrams: i.e. morphisms in free monoidal categories (more specifically, free pros). We introduce *regular monoidal grammars*, an analogue of classical (right-) regular grammars, and their equivalent representation as non-deterministic *monoidal automata*. We begin by recalling the notion of monoidal graph and how they present free monoidal categories.

3.1 Monoidal graphs and free pros

▶ **Definition 1.** *A monoidal graph $\mathcal{G}$ consists of sets $E_{\mathcal{G}}, V_{\mathcal{G}}$ and functions $dom, cod : E_{\mathcal{G}} \rightrightarrows V_{\mathcal{G}}^*$ where $V_{\mathcal{G}}^*$ is the underlying set of the free monoid. The elements of $E_{\mathcal{G}}$ are called* generators*, and for a generator $\gamma \in E_{\mathcal{G}}$, $dom(\gamma), cod(\gamma)$ are the domain, codomain (resp.) types of γ.*

Diagrammatically, a monoidal graph can be pictured as a collection of boxes, labelled by elements of $E_{\mathcal{G}}$ with wires entering on the left and exiting on the right, labelled by types given by the functions dom, cod. For example, the following depicts the monoidal graph $\mathcal{G}$ with $E_{\mathcal{G}} = \{\gamma, \gamma'\}, V_{\mathcal{G}} = \{A, B\}, dom(\gamma) = AB, cod(\gamma) = ABA, dom(\gamma') = A, cod(\gamma') = BB$:



Given that we are interested in finite state machines over finite alphabets, we shall work exclusively with finite monoidal graphs, i.e. those in which $E_{\mathcal{G}}$ and $V_{\mathcal{G}}$ are both finite sets.

▶ **Definition 2.** *A morphism $\Psi : \mathcal{G}' \to \mathcal{G}$ of monoidal graphs is a pair of functions $V_\Psi : V_{\mathcal{G}} \to V_{\mathcal{G}'}, E_\Psi : E_{\mathcal{G}} \to E_{\mathcal{G}'}$ such that $dom \fatsemi V_\Psi^* = E_\Psi \fatsemi dom$ and $cod \fatsemi V_\Psi^* = E_\Psi \fatsemi cod$.*

Monoidal graphs and their morphisms form a category $\mathsf{MonGraph}$. Recall that a (coloured) pro is a strict monoidal category whose monoid of objects is free (on the set of "colours"). There is a category Pro with objects pros and morphisms strict monoidal functors whose action on objects is determined by a function between their sets of colours. We call these *pro morphisms*. (Coloured) props are pros that are also *symmetric* (strict) monoidal categories.

Pros (and props) are monadic over monoidal graphs: the forgetful functor $\mathcal{U} : \mathsf{Pro} \to \mathsf{MonGraph}$ has a left adjoint $\mathcal{F} : \mathsf{MonGraph} \to \mathsf{Pro}$, and Pro is equivalent to the category of algebras for the induced monad on $\mathsf{MonGraph}$ (see [8, §2.3]). $\mathcal{F}$ sends a monoidal graph $\mathcal{G}$ to a pro $\mathcal{F}\mathcal{G}$ whose set of objects is $V_{\mathcal{G}}^*$ and whose morphisms are *string diagrams* (see [15]).

3.2 Monoidal languages and regular monoidal grammars

Classically, a language over an alphabet Σ is a subset of the free monoid Σ^*. A *monoidal language* is defined similarly, replacing free monoids with free pros over a *monoidal alphabet*:

▶ **Definition 3.** *A monoidal alphabet Γ is a finite monoidal graph where V_Γ is a singleton.*

For a generator γ of a monoidal alphabet, we refer to $dom(\gamma), cod(\gamma)$ as the arity, coarity (resp.) of γ, writing $ar(\gamma)$, $coar(\gamma)$. Such generators are drawn with "untyped" wires.

▶ **Definition 4.** *A monoidal language L over a monoidal alphabet Γ is a subset $L \subseteq \mathcal{F}\Gamma(0,0)$ of morphisms with arity and coarity 0 in the free pro generated by Γ.*

▶ Remark 5. The restriction to arity and coarity zero (i.e. *scalar*) morphisms may appear arbitrary. However, we will see in Section 4 that this captures and explains the classical definitions of finite-state automata over words and trees. It also leads to more concise definitions in our theory.

Regular monoidal grammars specify monoidal languages that are an analogue of classical regular languages. They can be obtained by taking Walters' [17] definition of regular language and replacing the adjunction between reflexive graphs and categories with that between monoidal graphs and pros. As shown in Section 4, they include the classical definitions of regular tree and word languages as grammars over monoidal alphabets of a particular shape.

▶ **Definition 6.** *A regular monoidal grammar is a morphism of finite monoidal graphs $\Psi : \mathcal{M} \to \Gamma$ where Γ is a monoidal alphabet.*

Intuitively, a regular monoidal grammar is a labelling of the edges of $\mathcal{M}$ by generators in Γ. Indeed, the vertex function $V_\Psi : V_{\mathcal{M}} \to \{\bullet\}$ is unique, so the grammar is determined by its edge function $E_\Psi : E_{\mathcal{M}} \to E_\Gamma$, sending edges to their labels. In Section 3.4 we show that this data determines a transition system with states words $w \in V_{\mathcal{M}}^*$.

▶ Remark 7. Every regular monoidal grammar determines a pro morphism between free pros, $\mathcal{F}\Psi : \mathcal{F}\mathcal{M} \to \mathcal{F}\Gamma$, which we may also refer to as a regular monoidal grammar.

For any string diagram $s \in \mathcal{F}\Gamma$ over an alphabet Γ, we can think of the set of string diagrams $\mathcal{F}\Psi^{-1}(s)$ as a set of possible "parsings" of that diagram.

▶ Remark 8. We represent regular monoidal grammars diagrammatically by drawing the monoidal graph $\mathcal{M}$ as above, but labelling each box $e \in E_{\mathcal{M}}$ with $E_{\Psi}(e)$. The resulting diagram is not in general a diagram of a monoidal graph, since it may contain boxes with the same label but different domain or codomain types. Examples are given below.

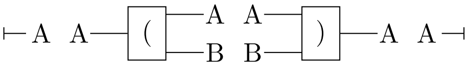
3.3 Regular monoidal languages

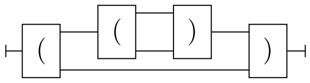
A regular monoidal grammar determines a monoidal language as follows:

▶ **Definition 9.** *Given a regular monoidal grammar $\Psi : \mathcal{M} \to \Gamma$, the image under $\mathcal{F}\Psi$ of the endo-hom-set of the monoidal unit ε in $\mathcal{F}\mathcal{M}$ is a monoidal language $\mathcal{F}\Psi[\mathcal{F}\mathcal{M}(\varepsilon, \varepsilon)] \subseteq \mathcal{F}\Gamma(0, 0)$.*

We call the class of languages determined by regular monoidal grammars the *regular monoidal languages*. We shall see that they are precisely the languages accepted by *non-deterministic monoidal automata* (Section 3.4). The basic idea is that a "word" is a scalar string diagram, i.e. one with no "dangling wires". The language of a monoidal grammar then consists of those scalar string diagrams that can be given a parsing. Parsings can be visually explained using the graphical notation for grammars (Remark 8). A morphism in the language defined by a grammar is any string diagram that can be built using the "typed" building blocks, such that there are no dangling wires, and then erasing the types on the wires. The following examples of regular monoidal grammars illustrate this idea:

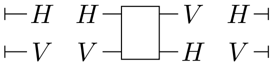
▶ **Example 10** (Balanced parentheses)**.** Recall that the Dyck language, the language of balanced parentheses, is a paradigmatic example of a non-regular word language. However, we can recognize balanced parentheses using the regular monoidal grammar shown below left. An example of a morphism in the language defined by this grammar is shown on the right.

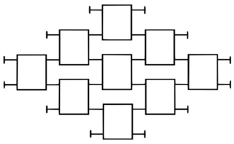




This illustrates how regular monoidal grammars permit unbounded concurrency. Here, as one scans from left to right, the (unbounded) size of the internal boundary of a string diagram keeps track of the number of open left parentheses.

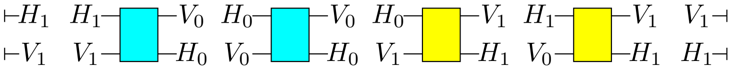
▶ **Example 11** (Brick walls)**.** A variant on the "brick wall" language introduced by [2] is given by the following grammar (left below). An example of a morphism in the language defined by this grammar is shown on the right.

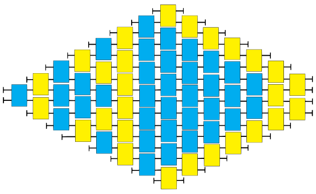




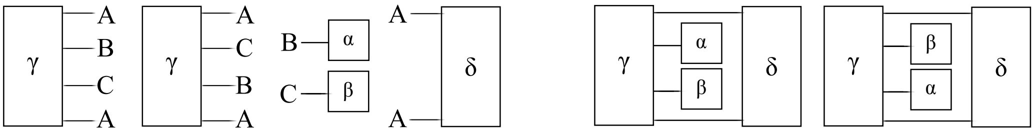
In Section 3.5 we will see how this language of "brick walls" allows us to construct the following example as an intersection of two languages:

▶ **Example 12** (Sierpiński gasket)**.** In [13], self-assembly of DNA tiles was used to realize the behaviour of a cellular automaton that computes the Sierpiński gasket fractal, based on the computation of the XOR gate. [13] implicitly depicts a monoidal grammar, and so Sierpiński gaskets of arbitrary iteration depth (e.g. right below) are in fact the monoidal language over this grammar (left below, where we use colours for the alphabet):





▶ **Example 13.** We define a grammar (left below) that will serve as a running counterexample in Section 7, as it defines a language that cannot be deterministically recognized. The connected string diagrams in this language are exactly two (right below).



▶ Remark 14. If the monoidal graph $\mathcal{M}$ has no edges whose domain is ε and no edges whose codomain is ε, a regular monoidal grammar $\Psi : \mathcal{M} \to \Gamma$ will define a language containing only the identity on the monoidal unit, i.e. the empty string diagram (denoted). In fact, *every* monoidal language contains the empty string diagram.

3.4 Non-deterministic monoidal automata

Recall that a non-deterministic finite automaton (NFA) is given by a finite set Q of states, an initial state $i \in Q$, a set of final states $F \subseteq Q$, and for each $a \in \Sigma$, a function $Q \xrightarrow{\Delta_a} \mathcal{P}(Q)$. Non-deterministic *monoidal automata* do not have initial and final states; string diagrams are simply accepted or rejected depending on their shape. In Section 4, we will see that initial and final states derive from this definition, when the alphabet is of a particular form.

▶ **Definition 15.** *A non-deterministic monoidal automaton $\Delta = (Q, \Delta_\Gamma)$ over a monoidal alphabet Γ is given by a finite set Q, together with a set of transition functions indexed by generators $\Delta_\Gamma = \{Q^{ar(\gamma)} \xrightarrow{\Delta_\gamma} \mathcal{P}(Q^{coar(\gamma)})\}_{\gamma \in E_\Gamma}$.*

For classical NFAs, the assignment $a \mapsto \Delta_a$ extends uniquely to a functor $\Sigma^* \to \mathsf{Rel}$, the inductive extension of the transition structure from letters to words. We define the inductive extension of monoidal automata from generators to string diagrams. First recall the definition of the endomorphism pro of an object in a monoidal category:

▶ **Definition 16.** *Let $\mathcal{C}$ be a monoidal category, and Q an object of $\mathcal{C}$. The endomorphism pro of Q, $\mathcal{C}_Q$, has natural numbers as objects, hom-sets $\mathcal{C}_Q(n,m) := \mathcal{C}(Q^n, Q^m)$, composition and identities as in $\mathcal{C}$. The monoidal product is addition on objects, and as in $\mathcal{C}$ on morphisms.*

The codomains of our inductive extension will be endomorphism pros of finite sets Q in Rel, considered as the Kleisli category of the powerset monad $\mathcal{P}$. Since $\mathcal{P}$ is a commutative monad (with respect to the cartesian product of sets, with $\mathcal{P}X \times \mathcal{P}Y \to \mathcal{P}(X \times Y)$ given by the product of subsets), the following lemma gives us the monoidal structure on Rel:

▶ **Lemma 17** ([11], Corollary 4.3). *Let T be a commutative monad on a symmetric monoidal category $\mathcal{C}$. Then the Kleisli category $\mathsf{Kl}(T)$ has a canonical monoidal structure, which is given on objects by the monoidal product in $\mathcal{C}$, and on morphisms $f : X \to TA, g : Y \to TB$ by $X \otimes Y \xrightarrow{f \otimes g} TA \otimes TB \xrightarrow{\nabla} T(A \otimes B)$, where ∇ is given by the commutativity of T.*

▶ Remark 18. The maybe monad $(-)_\perp$ is also commutative, so its Kleisli category, equivalent to the category Par of sets and partial functions, also has a canonical monoidal structure, and for each set Q there is an endomorphism pro Par_Q. We will come back to Par_Q in Section 6.

Now we can define the inductive extension of a non-deterministic monoidal automaton:

▶ **Observation 19.** *The assignment of generators to transition functions $\gamma \mapsto \Delta_\gamma$ in Definition 15 determines a morphism of monoidal graphs $\Gamma \to |\mathsf{Rel}_Q|$. Such morphisms are in bijection with pro morphisms $\Delta : \mathcal{F}\Gamma \to \mathsf{Rel}_Q$. We will also refer to the inductive extension Δ as a non-deterministic monoidal automaton, and sometimes write Δ_α for the relation $\Delta(\alpha : n \to m)$.*

A scalar string diagram is mapped to one of the two possible nullary relations $\{\bullet\} \to \mathcal{P}(\{\bullet\})$, which represent accepting or rejecting computations, and thus can be used to define the language of the automaton:

▶ **Definition 20.** *Let $\Delta : \mathcal{F}\Gamma \to \mathit{Rel}_Q$ be a non-deterministic monoidal automaton. Then the monoidal language accepted by Δ is $\mathcal{L}(\Delta) := \{\alpha \in \mathcal{F}\Gamma(0,0) \mid \Delta_\alpha(\bullet) = \{\bullet\}\}$.*

There is an evident correspondence between regular monoidal grammars and non-deterministic monoidal automata. The graphical representation of a grammar makes this most clear: it can also be thought of as the "transition graph" of a non-deterministic monoidal automaton. More explicitly we have:

▶ **Proposition 21.** *Given a regular monoidal grammar $\Psi : \mathcal{M} \to \Gamma$, define a monoidal automaton with $Q = V_\mathcal{M}$, $w(\Delta_\gamma)w' \iff \exists \sigma \in E_\Psi^{-1}(\gamma)$ such that $dom(\sigma) = w, cod(\sigma) = w'$. Conversely given a monoidal automaton (Q, Δ_Γ), define a regular monoidal grammar with $V_\mathcal{M} = Q$ and take an edge $w \to w'$ over $\gamma \iff w(\Delta_\gamma)w'$. This correspondence of grammars and automata preserves the recognized language.*

▶ Remark 22. In automata theory it is often convenient to consider automata with ε-transitions, or word-labelled transitions more generally. As monoidal grammars, these correspond to arbitrary functors $\mathcal{F}\mathcal{M} \to \mathcal{F}\Gamma$, that is (by the adjunction $\mathcal{U} \dashv \mathcal{F}$), to morphisms of finite monoidal graphs $\mathcal{M} \to \mathcal{U}\mathcal{F}\Gamma$. The corresponding generalization of monoidal automata requires considering Rel_Q as a monoidal 2-category with 2-cells the inclusions. Identity on objects, strict monoidal lax 2-functors $\mathcal{F}\Gamma \to \mathsf{Rel}_Q$ (where $\mathcal{F}\Gamma$ is considered as equipped with identity 2-cells), then give the refined notion of monoidal automaton. Such a lax 2-functor need no longer send the identity on n wires to the identity relation on Q^n, but merely to a relation that includes the identity; this corresponds to allowing silent transitions. Similarly, *lax* preservation of composition corresponds to allowing "term-labelled" transitions.

3.5 Closure properties of regular monoidal languages

We record some closure properties of regular monoidal languages.

▶ **Lemma 23** (Closure under union)**.** *Let L and L' be regular monoidal languages over Γ. Then $L \cup L'$ is a regular monoidal language over Γ.*

▶ **Lemma 24** (Closure under intersection)**.** *Let L and L' be regular monoidal languages over Γ. Then $L \cap L'$ is a regular monoidal language over Γ.*

▶ Remark 25. The Sierpiński gasket language (Example 12) is the intersection of the brick wall language (Example 11) and an "XOR gate" language: this explains the origin of the states in the grammar shown in Example 12.

▶ **Lemma 26** (Closure under monoidal product and factors)**.** *Let L be a regular monoidal language. Then $\alpha, \beta \in L \iff \alpha \otimes \beta \in L$.*

▶ **Lemma 27** (Closure under images of alphabets)**.** *Let L a be regular monoidal language over Γ, and $\Gamma \xrightarrow{h} \Gamma'$ be a morphism of monoidal alphabets. Then $(\mathcal{F}h)L$ is a regular monoidal language over Γ'.*

▶ **Lemma 28** (Closure under preimages of alphabets)**.** *Let L a regular monoidal language over Γ, and $\Gamma' \xrightarrow{h} \Gamma$ be a morphism of monoidal alphabets. Then the inverse image of L, $(\mathcal{F}h)^{-1}(L)$ is a regular monoidal language over Γ'.*

Closure under complement is often held to be an important criterion for what should count as a *recognizable* language. Indeed, for the abstract monadic second order logic introduced in [1], it is a *theorem* that the class of recognizable languages relative to a monad on Set is closed under complement. However, given that every monoidal language contains the empty string diagram, we obviously have that:

▶ **Observation 29.** *Regular monoidal languages are not closed under complement.*

This suggests that there is no obvious account of regular monoidal languages in terms of monadic second order logic. On the other hand, there is no reason we should expect even the general account of monadic second order logic given in [1] to extend to monoidal categories, since these are not algebras for a monad on Set. Moreover, taking inspiration from classical examples in Section 4, one could also refine what is meant by complement, for instance focussing on the set of non-empty connected scalar diagrams – see below for more details.

4 Regular word and tree languages as regular monoidal languages

Classical non-deterministic finite-state automata and tree automata can be seen as non-deterministic monoidal automata over alphabets of a particular shape.

To make the correspondence precise, in the following we restrict monoidal languages to their *connected* string diagrams. Strictly speaking, the language of a monoidal automaton always contains only the empty diagram or is countably infinite, because if α is accepted by the automaton, so are arbitrary finite monoidal products $\alpha \otimes \cdots \otimes \alpha$. However, it is of course possible for a monoidal language to consist of a finite number of connected string diagrams.

From another perspective, without restricting to connected components, we can say that the monoidal automata corresponding to finite-state and tree automata have the power of an unbounded number of such classical automata running in parallel.

4.1 Finite-state automata

▶ **Definition 30.** *A word monoidal alphabet is a monoidal alphabet having only generators of arity and coarity 1,* $-\boxed{\sigma}-$ *, along with a single "start" generator* $\vdash\!-$ *of arity 0 and coarity 1, and "end" generator* $-\!\dashv$ *of arity 1 and coarity 0.*

▶ **Observation 31.** *Non-deterministic monoidal automata over word monoidal alphabets correspond to classical NFAs.*

Let an NFA $A = (Q, \Sigma, \Delta, i, F)$ be given. We build a monoidal automaton as follows. Form the monoidal alphabet Σ' by starting with generators $\vdash\!-$, $-\!\dashv$ and adding generators $-\boxed{\sigma}-$ for each $\sigma \in \Sigma$. For each $-\boxed{\sigma}-$, take the transition function $\Delta_\sigma := \Delta(\sigma, -) : Q \to \mathcal{P}(Q)$. For $-\!\dashv$ take the transition function $Q \to \mathcal{P}(Q^0)$ to be the characteristic function of $F \subseteq Q$, sending elements of F to $\{\bullet\}$ and to $\varnothing$ otherwise, and for $\vdash\!-$ take the function $Q^0 \to \mathcal{P}(Q)$ to pick out the singleton $\{i\}$. This defines a monoidal automaton $A' := (Q, \Delta'_{\Sigma'})$, and a simple induction shows that $\mathcal{L}(A) = \mathcal{L}(A')$, if one restricts to connected string diagrams.

Conversely, the data of a monoidal automaton over a word monoidal alphabet corresponds to the data of an NFA, the only difference being that the transition function associated to $\vdash\!-$ picks out a *set* of initial states $\{\bullet\} \to \mathcal{P}(Q)$. We can always "normalize" such an automaton into an equivalent NFA with one initial state (see [14, §2.3.1]). This shows how NFA initial and final states are captured by this particular shape of monoidal alphabet.

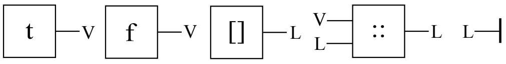
4.2 Tree automata

Recall that non-deterministic finite tree automata come in two flavours, bottom-up and top-down, depending on whether they process a tree starting at the leaves or at the root, respectively. A non-deterministic bottom-up finite tree automaton is given by a finite set of states Q, a "ranked" alphabet $(\Sigma, r : \Sigma \to \mathbb{N})$, a set of final states $F \subseteq Q$, and for each $\sigma \in \Sigma$ a transition function $\Delta_\sigma : Q^{r(\sigma)} \to \mathcal{P}(Q)$. A non-deterministic top-down tree automaton, instead, has a set of initial states $I \subseteq Q$ and transition functions $\Delta_\sigma : Q \to \mathcal{P}(Q^{r(\sigma)})$. We can recover these as non-deterministic monoidal automata over *tree monoidal alphabets*:

▶ **Definition 32.** *A top-down tree monoidal alphabet is a monoidal alphabet having only generators of arity 1 (and arbitrary coarities $\geqslant 0$),*  *, along with a single "root" generator* $\vdash\!\!-$ *. Analogously, a bottom-up tree monoidal alphabet is a monoidal alphabet having only generators of coarity 1 (and arbitrary arities $\geqslant 0$),*  *, along with a single "root" generator* $-\!\!\dashv$ *.*

▶ **Observation 33.** *Bottom-up tree automata are exactly non-deterministic monoidal automata over bottom-up tree monoidal alphabets, and likewise for top-down tree automata.*

The idea is similar to that sketched above for NFAs. For example, consider the following graph of a monoidal automaton over a bottom-up tree monoidal alphabet, recognizing trees corresponding to terms of the inductive type of lists of boolean values (a list may be empty, [], or be a boolean value "consed" onto a list via ::).

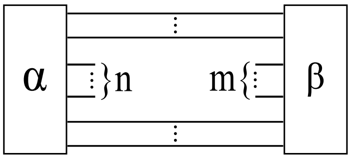


Intuitively, the connected scalar string diagrams determined by this language are trees, with leaves on the left, and the root on the right. Monoidal automata over top-down tree monoidal alphabets have a similar form, but are mirrored horizontally, and thus morphisms in the language have the root on the left, and leaves on the right, and monoidal automata read the morphism starting at the root.

5 The syntactic pro of a monoidal language

In this section we introduce the *syntactic congruence* on monoidal languages and the corresponding *syntactic pro*, by analogy with the syntactic congruence on classical regular languages and their associated syntactic monoid. In Section 7.2 we will give an algebraic property of the syntactic pro sufficient for the language to be deterministically recognizable.

▶ **Definition 34.** *A context of capacity (n, m), where $n, m \geqslant 0$, is a scalar string diagram with a hole – as illustrated below – with zero or more additional wires exiting the first box and entering the second (indicated by ellipses).*



Given a context of capacity (n, m), we can fill the hole with a string diagram $\alpha : n \to m$. Write $C[\alpha]$ for the resulting string diagram. Note that the empty diagram is a context, the empty context. Contexts allow us to define contextual equivalence of string diagrams:

▶ **Definition 35** (Syntactic congruence)**.** *Given a monoidal language $L \subseteq \mathcal{F}\Gamma(0,0)$ we define its syntactic congruence $\equiv_L$ as follows. Let α, β be morphisms in $\mathcal{F}\Gamma(n,m)$. Then $\alpha \equiv_L \beta$ whenever $C[\alpha] \in L \iff C[\beta] \in L$, for all contexts C of capacity (n,m).*

▶ **Definition 36.** *The syntactic pro of a monoidal language L is the quotient pro $\mathcal{F}\Gamma/{\equiv_L}$. The quotient functor $S_L : \mathcal{F}\Gamma \to \mathcal{F}\Gamma/{\equiv_L}$ is the syntactic morphism of L. For more details, see the full version [6].*

▶ Remark 37. The syntactic congruences for classical regular languages of words and trees are also special cases of this congruence over word and tree monoidal alphabets.

▶ **Lemma 38.** *L is the inverse image along the syntactic morphism of the equivalence class of the empty diagram.*

Proof. Let $\alpha \in L$. Then $\alpha \equiv_L \boxed{}$, since the empty diagram is in every language and if C is a context of capacity $(0,0)$ distinguishing α and $\boxed{}$, then we have a contradiction by Lemma 26. So $\alpha \in S_L^{-1}(\left[\boxed{}\right])$, and conversely. ◀

In the terminology of algebraic language theory, we say that the syntactic morphism *recognizes* L. A full investigation of algebraic recognizability of monoidal languages is a topic for future work. For now, we record the following lemma which is needed for Theorem 59:

▶ **Lemma 39.** *If a monoidal language L is regular, then its syntactic pro $\mathcal{F}\Gamma/{\equiv_L}$ is locally finite (i.e. has finite hom-sets).*

Proof. It suffices to exhibit a full pro morphism into $\mathcal{F}\Gamma/{\equiv_L}$ from a locally finite pro. Let L be a regular monoidal language recognized by $\Delta : \mathcal{F}\Gamma \to \mathsf{Rel}_Q$. Δ induces a congruence $\sim$ on $\mathcal{F}\Gamma$ defined by $\alpha \sim \beta \iff \Delta(\alpha) = \Delta(\beta)$, which implies that $\mathcal{F}\Gamma/{\sim}$ is locally finite, since Rel_Q is locally finite. Define the pro morphism $\mathcal{F}\Gamma/{\sim} \to \mathcal{F}\Gamma/{\equiv_L}$ to be identity on objects and $[\alpha]_\sim \mapsto [\alpha]_{\equiv_L}$ on morphisms. This is well-defined since if $\alpha \sim \beta$ and $C[\alpha] \in L$ for some context C, then by functoriality $C[\beta] \in L$. Clearly it is full, so $\mathcal{F}\Gamma/{\equiv_L}$ is locally finite. ◀

6 Deterministic monoidal automata

Classically, the expressive equivalence of deterministic and non-deterministic finite-state automata for string languages is well known, but already for trees, top-down deterministic tree automata are less expressive than bottom-up deterministic tree automata. Therefore we cannot expect to determinize non-deterministic monoidal automata. However, we have already seen monoidal languages that are deterministically recognizable (Examples 10, 11, 12, interpreted as the transition relations of monoidal automata, are functional relations). Here we introduce deterministic monoidal automata and show that their languages enjoy the property of *causal closure*. In Section 7 we consider the question of determinizability.

▶ **Definition 40.** *A deterministic monoidal automaton $\delta = (Q, \delta_\Gamma)$ over a monoidal alphabet Γ is given by a finite set Q, together with transition functions $\delta_\Gamma = \{Q^{ar(\gamma)} \xrightarrow{\delta_\gamma} Q_\perp^{coar(\gamma)}\}_{\gamma \in \Gamma}$.*

Recall the definition of the pro Par_Q from Remark 18. Then as in Observation 19, such assignments $\gamma \mapsto \delta_\gamma$ uniquely extend to pro morphisms $\delta : \mathcal{F}\Gamma \to \mathsf{Par}_Q$, and we will also refer to such pro morphisms as deterministic monoidal automata. δ maps scalar string diagrams to one of the two functions $Q^0 \to Q_\perp^0$, and we use this to define the language of the automaton:

▶ **Definition 41.** *Let $\delta : \mathcal{F}\Gamma \to \mathsf{Par}_Q$ be a deterministic monoidal automaton. Then the language accepted by δ is $\mathcal{L}(\delta) := \{\alpha \in \mathcal{F}\Gamma(0,0) \mid \delta_\alpha(\bullet) = \bullet\}$.*

We give a necessary condition for a monoidal language to be recognized by a deterministic monoidal automaton. The idea is to generalize the characterization of top-down deterministically recognizable tree languages as those that are closed under the operation of splitting a tree language into the set of possible paths through the trees, and reconstituting trees by grafting compatible paths [9]. For string diagrams, we call the analogue of paths through a tree the *causal histories* of a diagram (Definition 46).

First, we briefly recall the machinery of (cartesian) *restriction categories* [3], that will be necessary in the following. Restriction categories are an abstraction of the category of partial functions, and provide us with a diagrammatic calculus for reasoning about determinization of monoidal languages.

▶ **Definition 42** ([4]). *A cartesian restriction prop is a prop in which every object is equipped with a commutative comonoid structure (with the counit depicted by ─● , comultiplication by ─●< , and symmetry by ⨯) that is coherent, and for which the comultiplication is natural (for more details, see the full version [6]).*

▶ **Definition 43.** *The free cartesian restriction prop on a monoidal graph $\mathcal{M}$, denoted $\mathcal{F}_{\downarrow}\mathcal{M}$ is given by taking the free prop on the monoidal graph $\mathcal{M}$ extended with a comultiplication and counit generator for every object in $V_{\mathcal{M}}$, and quotienting the morphisms by the structural equations of cartesian restriction categories (for more details, see the full version [6]).*

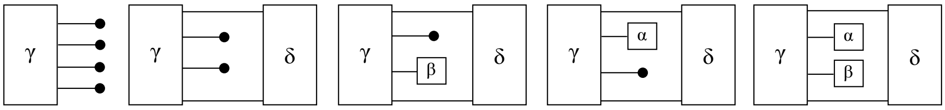
▶ Remark 44. Par is the paradigmatic example of a cartesian restriction category, with ─● on X given by the relation $X \to \{\bullet, \bot\}$ sending every element to •, and ─●< given by the diagonal relation. Par_Q inherits this structure and so is a cartesian restriction prop. Therefore deterministic monoidal automata (Q, δ_Γ) also have inductive extensions to morphisms of cartesian restriction props, $\overline{\delta} : \mathcal{F}_{\downarrow}\Gamma \to \mathsf{Par}_Q$, and these have a obvious notion of associated language, defined similarly to Definition 41. These are related by the following lemma, which follows from the universal properties of $\mathcal{F}\Gamma$ and $\mathcal{F}_{\downarrow}\Gamma$:

▶ **Lemma 45.** *If (Q, δ_Γ) is a deterministic monoidal automaton, then δ factors through $\overline{\delta}$ as $\delta = \mathcal{H}_\Gamma \,\mathring{,}\, \overline{\delta}$, where $\mathcal{H}_\Gamma : \mathcal{F}\Gamma \to \mathcal{F}_{\downarrow}\Gamma$ sends morphisms to their equivalence class in $\mathcal{F}_{\downarrow}\Gamma$.*

Recall that any restriction category is poset-enriched: $f \leqslant g$ if f is "less defined" than g, i.e. if f coincides with g on f's domain of definition. For the hom-set from the monoidal unit to itself, we have $f \leqslant g \iff f \otimes g = f$. Now we can define causal histories:

▶ **Definition 46.** *Let γ be a string diagram in $\mathcal{F}\Gamma(0,0)$. We call a string diagram h in $\mathcal{F}_{\downarrow}\Gamma(0,0)$ a causal history of γ if $\mathcal{H}_\Gamma(\gamma) \leqslant h$ in $\mathcal{F}_{\downarrow}\Gamma(0,0)$. Let $L \subseteq \mathcal{F}\Gamma(0,0)$ be a regular monoidal language. The set of causal histories of L, denoted $ch(L)$, is defined to be $\mathcal{H}_\Gamma(L)^{\uparrow}$, the upwards closure of $\mathcal{H}_\Gamma(L)$ in the poset $\mathcal{F}_{\downarrow}\Gamma(0,0)$.*

A causal history represents the possible causal influence of parts of a diagram on generators appearing "later" in the diagram. For example, the following five string diagrams are causal histories of the rightmost string diagram below (every diagram is a causal history of itself), taken from the language introduced in Example 13:

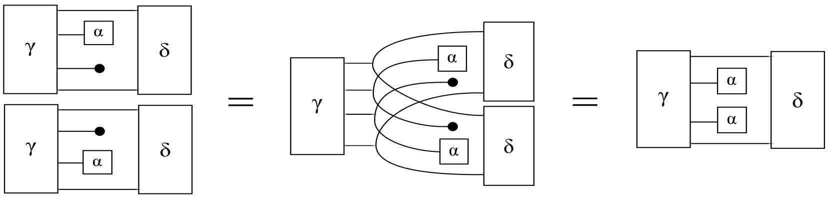


▶ **Lemma 47.** *Let $M = (Q, \delta_\Gamma)$ be a deterministic monoidal automaton, with functors $\delta : \mathcal{F}\Gamma \to \mathsf{Par}_Q$, $\overline{\delta} : \mathcal{F}_{\downarrow}\Gamma \to \mathsf{Par}_Q$. Then if δ accepts γ, $\overline{\delta}$ accepts all causal histories of γ.*

Proof. Since $\delta = \mathcal{H}_\Gamma \mathbin{⨟} \overline{\delta}$, if δ accepts γ, then $\overline{\delta}$ accepts $\mathcal{H}_\Gamma(\gamma)$. Let h be a causal history of γ. Then $\overline{\delta}(\mathcal{H}_\Gamma(\gamma)) = \overline{\delta}(h \otimes \mathcal{H}_\Gamma(\gamma)) = \overline{\delta}(h) \otimes \overline{\delta}(\mathcal{H}_\Gamma(\gamma))$. But then $\overline{\delta}$ accepts h by Lemma 26. ◀

▶ **Definition 48** (Causal closure of a language). *Let L be a monoidal language over a monoidal alphabet Γ. Let $\bigotimes ch(L)$ denote the closure of the set of causal histories of L under monoidal product. Then the causal closure of L is $\mathcal{H}_\Gamma^{-1} \bigotimes ch(L)$. A monoidal language is causally closed if it is equal to its causal closure.*

To illustrate causal closure, consider the following figure, which shows part of the derivation of a morphism in the causal closure of the language of Example 13:



The leftmost diagram depicts the monoidal product of two causal histories determined by the counterexample language. By the equational theory of cartesian restriction categories (see the full version [6]), this is equal to the string diagrams in the center and on the right, where we first apply the naturality of $-\!\!\bullet\!\!\!<$ (for γ), then unitality (twice), then naturality of $-\!\!\bullet\!\!\!<$ (for δ). The rightmost form of the diagram exhibits this morphism as being in the image of $\mathcal{H}_\Gamma$, and its preimage under $\mathcal{H}_\Gamma$ is the same diagram in $\mathcal{F}\Gamma$. Since this diagram is not in the original language, the language is not causally closed.

▶ **Theorem 49.** *If a monoidal language is recognized by a deterministic monoidal automaton, then it is causally closed.*

Proof. Let L be recognized by a deterministic monoidal automaton $\delta : \mathcal{F}\Gamma \to \mathsf{Par}_Q$. We have $\delta = \mathcal{H}_\Gamma \mathbin{⨟} \overline{\delta}$ and from Lemma 47 that $\overline{\delta}$ accepts causal histories of morphisms in L. Since languages are closed under monoidal product (Lemma 26), then by definition of the causal closure, δ must accept everything in the causal closure of L. ◀

7 Deterministically recognizable monoidal languages

Non-deterministic finite state automata for words and bottom-up trees can be determinized via the well known powerset construction. However, top-down tree automata cannot be determinized in general [9, §2.11], so general monoidal automata also cannot be determinized (Observation 33). However, there are interesting examples of deterministically recognizable monoidal languages that are not tree languages, such as the monoidal Dyck language (Example 10) and Sierpiński gaskets (Example 12), and it is an intriguing theoretical challenge to characterize such languages.

In Section 7.1 we study a class of determinizable automata called *convex* automata. In Section 7.2 we give a sufficient condition for a language to be deterministically recognizable.

7.1 Convex automata and the powerset construction

The classical powerset construction is given conceptually by composition with the functor $\mathsf{Rel} \to \mathsf{Set}$, right adjoint to the inclusion $\mathsf{Set} \hookrightarrow \mathsf{Rel}$. As remarked above, we cannot hope to obtain an analogue of this functor for monoidal automata. Thus we describe a suitable subcategory of Rel_Q for which determinization is functorial, that of convex relations.

▶ **Definition 50.** *A relation $\Delta : Q^n \to \mathcal{P}(Q^m)$ is convex if there is a morphism Δ^* such that the following square commutes:*

$$\begin{tikzcd}
(\mathcal{P}Q)^n \arrow[r, "\Delta^*"] \arrow[d, "\nabla"'] & (\mathcal{P}Q)^m \arrow[d, "\nabla"] \\
\mathcal{P}(Q^n) \arrow[r, "\Delta^{\#}"] & \mathcal{P}(Q^m)
\end{tikzcd}$$

where $\Delta^{\#}$ is the Kleisli lift of Δ, and ∇ is the monoidal multiplication given by the commutativity of the powerset monad.

▶ **Observation 51.** *If Δ is convex, the morphism Δ^* is unique, since ∇ is a monomorphism.*

▶ **Example 52.** The relation $\Delta_\gamma : Q^0 \to \mathcal{P}(Q^4)$ induced by the grammar in Example 13 is not convex, since (A, B, B, A) and (A, C, C, A), which we can think of as "convex combinations" of the other state vectors, are not included in the image of the relation.

▶ **Lemma 53.** *Convex relations determine a sub-pro $\mathsf{CRel}_Q \hookrightarrow \mathsf{Rel}_Q$.*

▶ **Definition 54.** *An automaton $\Delta : \mathcal{F}\Gamma \to \mathsf{Rel}_Q$ is convex if it factors through CRel_Q.*

The following lemma gives the powerset construction on convex automata. We use the non-empty powerset $\mathcal{P}^+$ to avoid duplication of failure state ($\varnothing$ in Rel_Q, but $\perp$ in $\mathsf{Par}_{\mathcal{P}^+(Q)}$):

▶ **Lemma 55.** *For each set Q there is a morphism of pros $\mathcal{D}_Q : \mathsf{CRel}_Q \to \mathsf{Par}_{\mathcal{P}^+(Q)}$ which is identity on objects and acts as follows on morphisms:*

$$\Delta_\alpha : Q^n \to \mathcal{P}(Q^m)$$
$$\downarrow$$
$$\mathcal{P}^+(Q)^n \xrightarrow{\eta^n} (\perp\mathcal{P}^+(Q))^n \xrightarrow{\cong} \mathcal{P}(Q)^n \xrightarrow{\Delta^*_\alpha} \mathcal{P}(Q)^m \xrightarrow{\cong} (\perp\mathcal{P}^+(Q))^m \xrightarrow{\nabla} \perp\mathcal{P}^+(Q)^m$$

where $\perp$ is the maybe monad, η is the unit of this monad, and ∇ is its monoidal multiplication with respect to the cartesian product.

Determinization of a convex automaton $\Delta : \mathcal{F}\Gamma \to \mathsf{CRel}_Q$ is now just given by post-composition with the functor $\mathcal{D}_Q$. We show that this preserves the language:

▶ **Theorem 56.** *Determinization of convex automata preserves the accepted language: let $\Delta : \mathcal{F}\Gamma \to \mathsf{CRel}_Q$ be a convex automaton, then $\mathcal{L}(\Delta) = \mathcal{L}(\Delta \,⨟\, \mathcal{D}_Q)$.*

Proof. Let $\alpha \in \mathcal{L}(\Delta)$, i.e. $\Delta_\alpha(\bullet) = \{\bullet\}$. Then we must have $\Delta^*_\alpha(\bullet) = \bullet$, and so $(\Delta \,⨟\, \mathcal{D}_Q)_\alpha(\bullet) = \bullet$. Conversely let $\alpha \in \mathcal{L}_\mathcal{D}(\Delta \,⨟\, \mathcal{D}_Q)$, i.e. $(\Delta \,⨟\, \mathcal{D}_Q)_\alpha(\bullet) = \bullet$. Then we must have that $\Delta^*_\alpha(\bullet) = \bullet$, and so $\Delta_\alpha(\bullet) = \{\bullet\}$, that is $\alpha \in \mathcal{L}(\Delta)$. ◀

▶ **Example 57.** Non-deterministic monoidal automata over word monoidal alphabets (Definition 30) are convex: for a relation $\Delta : Q \to \mathcal{P}(Q)$, Δ^* is given by the Kleisli extension of Δ. This reflects the well known determinizability of classical finite-state automata.

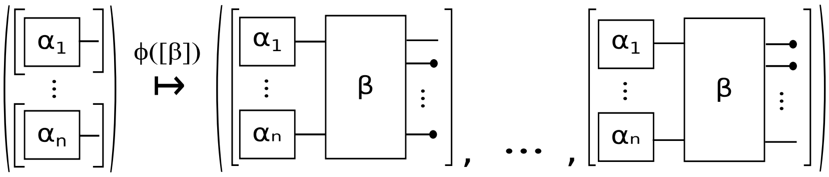
▶ **Example 58.** Similarly, non-deterministic monoidal automata over bottom-up tree monoidal alphabets (Definition 32) are convex, with $\Delta^* := \nabla \,⨟\, \Delta^{\#}$. For top-down tree monoidal alphabets, the general obstruction to convexity (and thus determinizability) is seen as the non-existence of a left inverse of ∇.

7.2 A sufficient condition for deterministic recognizability

▶ **Theorem 59.** *If the syntactic pro of a regular monoidal language has the structure of a cartesian restriction prop, then the language is recognizable by a deterministic monoidal automaton.*

Proof. Let L be a monoidal language such that $\mathcal{F}\Gamma/{\equiv_L}$ has a cartesian restriction prop structure. We exhibit a pro morphism $\mathcal{F}\Gamma/{\equiv_L} \xrightarrow{\phi} \mathsf{Par}_Q$ such that $\mathcal{F}\Gamma \xrightarrow{S_L} \mathcal{F}\Gamma/{\equiv_L} \xrightarrow{\phi} \mathsf{Par}_Q$ is a deterministic monoidal automaton accepting exactly L.

Let $Q := \mathcal{F}\Gamma/{\equiv_L}(0,1)$. By Lemma 39, this is a finite set. For $m > 0$ and $[\beta] \in \mathcal{F}\Gamma/{\equiv_L}(n,m)$, define $\phi([\beta]) : n \to m$ to be the following map from $Q^n \to Q^m_\perp$:



When $m = 0$ (i.e. $[\beta]$ has coarity 0), let $\phi([\beta])([\alpha_1], ..., [\alpha_n]) = \bullet$, if $[(\alpha_1 \otimes ... \otimes \alpha_n) \mathbin{⨟} \beta] =$ [⬚], and $\phi([\beta])([\alpha_1], ..., [\alpha_n]) = \perp$ otherwise. The proof that this defines a morphism of pros is an exercise in diagrammatic reasoning using the equational theory of cartesian restriction categories, see the full version [6]. To see that this automaton accepts exactly L, let $\alpha \in \mathcal{L}(S_L \mathbin{⨟} \phi)$, then by definition we must have $S_L(\alpha) =$ [⬚], and so $\alpha \in L$ (by Lemma 38). Conversely let $\alpha \in L$, then $S_L(\alpha) =$ [⬚] and by definition ϕ ([⬚]) $(\bullet) = \bullet$, so $\alpha \in \mathcal{L}(S_L \mathbin{⨟} \phi)$. Therefore $S_L \mathbin{⨟} \phi$ is a deterministic monoidal automaton recognizing L. ◀

▶ **Example 60.** A simple example is the language L of "bones" over the monoidal alphabet $\Gamma = \{$ ▫–, –▫ $\}$, having one connected component: ▫—▫ . The syntactic pro $\mathcal{F}\Gamma/{\equiv_L}$ has a cartesian restriction prop structure, with the counit –• given by the equivalence class [–▫], comultiplication  by , and symmetry by . It is clear that $\mathcal{F}\Gamma/{\equiv_L}(0,1)$ has one equivalence class, [–▫], which becomes the state of the monoidal automaton. The construction above then gives the obvious transition functions required for each generator.

8 Conclusion and future work

The most immediate open question is to determine necessary and sufficient conditions for determinizability: causal closure is a promising candidate. Furthermore we would like to understand the relation between convexity and Theorem 59. Classical topics in the theory of regular languages such as a Myhill-Nerode theorem are also ripe for future investigation. We also plan to investigate further applications of regular monoidal languages in computer science, for example representing trace languages and look-ahead parsing.

Just as our definition of regular monoidal grammar was obtained from Walters' definition of regular grammar by replacing the adjunction $\mathsf{Cat} \to \mathsf{Graph}$ with the adjunction $\mathsf{Pro} \to \mathsf{MonGraph}$, we might consider other adjunctions and their corresponding notion of grammar. In the first instance, our theory should smoothly generalize to languages in free props, but perhaps also other (higher) categorical structures.

We plan to investigate a notion of context-free monoidal language, using a similar algebraic approach to this paper. One candidate for the algebra of such languages, inspired again by [17], are (monoidal) multicategories of n-hole contexts (in the sense of Definition 34).

Oracle with $\mathsf{P} = \mathsf{NP} \cap \mathsf{coNP}$, but No Many-One Completeness in UP, DisjNP, and DisjCoNP

Abstract

We construct an oracle relative to which $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$, but there are no many-one complete sets in UP, no many-one complete disjoint NP-pairs, and no many-one complete disjoint coNP-pairs.

This contributes to a research program initiated by Pudlák [33], which studies incompleteness in the finite domain and which mentions the construction of such oracles as open problem. The oracle shows that $\mathsf{NP} \cap \mathsf{coNP}$ is indispensable in the list of hypotheses studied by Pudlák. Hence one should consider stronger hypotheses, in order to find a universal one.

1 Introduction

Questions of the existence of complete sets in promise classes have a long history. They turned out to be difficult and remained open. Consider the following examples, where the questions are expressed as hypotheses.

$\mathsf{NP} \cap \mathsf{coNP}$: $\mathrm{NP} \cap \mathrm{coNP}$ does not contain many-one complete sets [23]
UP : UP does not contain many-one complete sets [22]
CON : p-optimal proof systems for TAUT do not exist [26]
SAT : p-optimal proof systems for SAT do not exist [15]
TFNP : TFNP does not contain many-one complete problems [27]
DisjNP : DisjNP does not contain many-one complete pairs [34]
$\mathsf{DisjCoNP}$: DisjCoNP does not contain many-one complete pairs [28, 32]

So far, the following implications are known: $\mathsf{DisjNP} \Rightarrow \mathsf{CON}$ [34], $\mathsf{UP} \Rightarrow \mathsf{CON}$ [25], $\mathsf{DisjCoNP} \Rightarrow \mathsf{TFNP}$ [33], $\mathsf{TFNP} \Rightarrow \mathsf{SAT}$ [5, 33], and $\mathsf{NP} \cap \mathsf{coNP} \Rightarrow \mathsf{CON} \lor \mathsf{SAT}$ [25]. This raises the question of whether further implications are provable with the currently available means. Thanks to a work by Pudlák [33], this question recently gained momentum. In fact, Pudlák's interest goes beyond: He initiated a research program to find a general principle from which the remaining hypotheses follow as special cases. This is motivated by the study of incompleteness in the finite domain, since these hypotheses can either be expressed as the non-existence of complete elements in promise classes or as statements about the unprovability of sentences of some specific form in weak theories.

Pudlák [33] states as open problem to construct oracles that show that the relativized conjectures are different or show that they are equivalent. Such oracles have been constructed by Verbitskii [38], Glaßer et al. [18], Khaniki [24], Dose [10, 11, 9], and Dose and Glaßer [12]. The restriction to relativizable proofs arises from the following idea: We consider the mentioned hypotheses as conjectures, hence we expect that they are equivalent. In this situation we are not primarily concerned with the question of whether two hypotheses are equivalent, but rather whether their equivalence can be *recognized* with the currently available means. An accepted formalization of this is the notion of relativizable proofs.

Our Contribution. We construct an oracle relative to which the following holds: UP, DisjNP, $\mathsf{DisjCoNP}$, but $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$, which implies $\neg\mathsf{NP} \cap \mathsf{coNP}$. Hence there is no relativizable proof for $\mathsf{NP}\cap\mathsf{coNP}$, even if we simultaneously assume all remaining hypotheses we mentioned so far. This demonstrates that $\mathsf{NP} \cap \mathsf{coNP}$ is indispensable in the list of currently viewed hypotheses and suggests to broaden the focus and include stronger statements.

Pudlák [33] ranks $\mathsf{NP} \cap \mathsf{coNP}$ as a plausible conjecture that is apparently incomparable with CON and TFNP. Our oracle supports this estimation, as it rules out relativizable proofs for "$\mathsf{CON} \Rightarrow \mathsf{NP} \cap \mathsf{coNP}$" and "$\mathsf{TFNP} \Rightarrow \mathsf{NP} \cap \mathsf{coNP}$." By Dose [10, 11], the same holds for the converse implications. Overall, we recognize a strong independence between $\mathsf{NP} \cap \mathsf{coNP}$ and all remaining hypotheses:

(i) There does not exist a relativizable proof for $\mathsf{NP} \cap \mathsf{coNP}$, even if we simultaneously assume all remaining hypotheses.

(ii) There exists a relativizable proof for the implication $\mathsf{NP} \cap \mathsf{coNP} \Rightarrow \mathsf{CON} \vee \mathsf{SAT}$ [25]. But there does not exist a relativizable proof showing that $\mathsf{NP} \cap \mathsf{coNP}$ implies one of the remaining hypotheses [10, 11].

Our oracle combines several separations with the collapse $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$. This leads to conclusions on the independence of the statement $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$ from typical assumptions. For instance, the oracle shows that $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$ cannot be proved by relativizing means, even under the strong but likely assumption $\mathsf{UP} \wedge \mathsf{DisjNP} \wedge \mathsf{DisjCoNP}$.

Further characteristics of our oracle are, for example, $\mathrm{NE} \neq \mathrm{coNE}$, $\mathrm{NPMV} \not\subseteq_c \mathrm{NPSV}$, and the shrinking and separation properties do not hold for NP and coNP. Corollary 10 presents a list of additional properties.

Open Questions. Currently, for almost every pair A, B of hypotheses, we either know a relativizable proof for the implication $\mathsf{A} \Rightarrow \mathsf{B}$, or we know an oracle relative to which $\mathsf{A} \wedge \neg\mathsf{B}$. Only three cases are left: (1) $\mathsf{UP} \overset{?}{\Rightarrow} \mathsf{DisjNP}$, (2) $\mathsf{TFNP} \overset{?}{\Rightarrow} \mathsf{DisjCoNP}$, and (3) $\mathsf{SAT} \overset{?}{\Rightarrow} \mathsf{TFNP}$. This leads to the following task for future research: Prove these implications or construct oracles relative to which they do not hold.

Background on Connections Between Promise Classes and Proof Systems. Informally, promise classes are complexity classes that are characterized by machines that satisfy certain properties. Usually, these properties are hard or even impossible to validate. Thus, when working with an element of a promise class, one has to trust the *promise* that the respective machine has said property. We are mainly interested in the following well-studied promise classes: The class of disjoint NP-pairs $\mathrm{DisjNP} = \{(A, B) \mid A, B \in \mathrm{NP}, A \cap B = \emptyset\}$ [35, 21], the class of disjoint coNP-pairs DisjCoNP [14, 15] (defined respectively), the class of sets accepted by nondeterministic polynomial-time machines with at most one accepting computation path UP [37], the class $\mathrm{NP} \cap \mathrm{coNP}$ [13], and the class of all total polynomial search problems TFNP [27]. As an example, the machines characterizing UP promise that on every input,

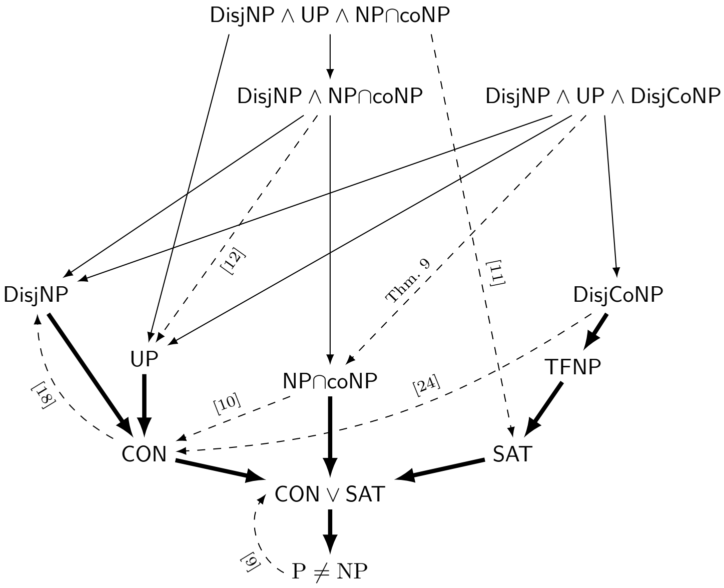

Figure 1 Solid arrows mean implications. All implications occurring in the figure have relativizable proofs. (The only nontrivial ones are DisjNP ⇒ CON [34], UP ⇒ CON [25, Cor. 4.1], DisjCoNP ⇒ TFNP ⇒ SAT [33, Prop. 5.6][5, Thm. 25][33, Prop. 5.10].) Implications between the conjectures originally considered by Pudlák (i.e., not the conjunctions) are highlighted bold. A dashed arrow from one conjecture A to another conjecture B means that there is an oracle X against the implication A ⇒ B, meaning that A ∧ ¬B holds relative to X.

they either reject on all computation paths, or accept on exactly one computation path. Furthermore, we are interested in proof systems defined by Cook and Reckhow [8], especially optimal and p-optimal proof systems for the set of satisfiable formulas SAT, for the set of tautologies TAUT.

The connections between propositional proof systems and promise classes have been studied intensively. Krajícek and Pudlák [26] linked propositional proof systems (and thus the hypothesis CON) to standard complexity classes by proving that NE = coNE implies the existence of optimal propositional proof systems and E = NE implies the existence of p-optimal propositional proof systems. These results were subsequently improved by Köbler, Messner, and Torán [25].

Glaßer, Selman, and Sengupta [17] give several characterizations of DisjNP. Some characterizations use different notions of reducibility while others use the existence of $\leq_{\mathrm{m}}^{\mathrm{p}}$-complete functions in NPSV and the uniform enumerability of disjoint NP-pairs. Glaßer, Selman, and Zhang [19, 20] connect propositional proof systems to disjoint NP-pairs. They prove that the degree structure of DisjNP and of all canonical disjoint pairs of propositional proof systems is the same. Beyersdorff [1, 2, 3, 4] and Beyersdorff and Sadowkski [6] investigate further connections between disjoint NP-pairs and propositional proof systems.

Pudlák [30, 31, 33] draws connections between the finite consistency problem, proof systems, and promise classes like DisjNP and TFNP. Moreover, he asks for oracles that separate hypotheses regarding proof systems and promise classes. Several oracles have been constructed since Pudlák formulated his research questions. Concerning the listed hypotheses, Figure 1 summarizes all known (relativizing) implications and implications that do not hold relative to some oracle.

The paper is organized as follows: Section 2 defines the complexity classes mentioned above and presents our notations. Section 3 contains the oracle construction: the first part defines the construction, the second part proves that it is well-defined, and the last part shows the claimed properties.

2 Preliminaries

Basic Notation. Throughout this paper, let Σ be the alphabet $\{0,1\}$. The set Σ^* denotes the set of finite words over Σ. The set Σ^ω denotes the set of ω-infinite words, i.e., the ω-infinite sequences of characters from Σ. Let $\Sigma^{\leq n} := \{w \in \Sigma^* \mid |w| \leq n\}$. For a word $w \in \Sigma^* \cup \Sigma^\omega$, we denote with $w(i)$ the i-th character of w for $0 \leq i < |w| \leq \omega$. We write $v \sqsubseteq w$ when v is a prefix of w, that is, $|v| \leq |w|$ and $v(i) = w(i)$ for all $0 \leq i < |v|$. Accordingly, $v \sqsubsetneq w$ when $v \sqsubseteq w$ and $v \neq w$. The empty word is denoted by ε. For a finite set $A \subseteq \Sigma^*$, we define $\ell(A) := \sum_{w \in A} |w|$.

Let $\mathbb{N}$ denote the set of non-negative integers, and $\mathbb{N}^+$ the set of positive integers. We say that two sets X and Y *agree on set* Z when $X \cap Z = Y \cap Z$.

The finite words Σ^* can be linearly ordered by their quasi-lexicographic (i.e., "shortlex") order $\prec_{\text{lex}}$, uniquely defined by requiring $0 \prec_{\text{lex}} 1$. Under this definition, there is a unique order-isomorphism between $(\Sigma^*, \prec_{\text{lex}})$ and $(\mathbb{N}, <)$, which induces a polynomial-time computable, polynomial-time invertible bijection between Σ^* and $\mathbb{N}$. Hence, we can transfer the notations, relations, and operations for Σ^* to $\mathbb{N}$ and vice versa. In particular, $|n|$ denotes the length of the word represented by $n \in \mathbb{N}$. By definition of $\prec_{\text{lex}}$, whenever $a \leq b$, then $|a| \leq |b|$. We eliminate the ambiguity of the expressions 0^i and 1^i by always interpreting them over Σ^i. Moreover, $<$ denotes both the less-than relation for natural numbers and the quasi-lexicographic order $\prec_{\text{lex}}$ for finite words. Similarly for $\leq$ and $\preceq_{\text{lex}}$. From the properties of order-isomorphism, this is compatible with the above identification of words and numbers.

Complexity Classes. We understand P (resp., NP) as the usual complexity class of languages decidable by a deterministic (resp., nondeterministic) polynomial-time Turing machine. The class FP refers to the class of total functions that can be computed by a deterministic polynomial-time Turing transducer [29]. Valiant [37] defined UP as the set of all languages that can be recognized by a nondeterministic polynomial-time machine that, on every input, accepts on at most one computation path. For a complexity class $\mathcal{C}$ we define $\text{co}\mathcal{C} := \{\overline{A} \mid A \in \mathcal{C}\}$ as the complementary complexity class of $\mathcal{C}$. Between sets of words, we employ the usual *polynomial-time many-one reducibility*: $A \leq_{\text{m}}^{\text{p}} B$ if there exists an $f \in \text{FP}$ such that $x \in A \Leftrightarrow f(x) \in B$. The usual notion of $\leq_{\text{m}}^{\text{p}}$-completeness and -hardness follows.

A *disjoint* NP*-pair* is a pair (A, B) of disjoint sets in NP. Selman [35] and Grollmann and Selman [21] defined the class DisjNP as the set of disjoint NP-pairs. The classes DisjCoNP [14, 15], DisjUP, and DisjCoUP are defined similarly. Between two pairs, we employ the following related notion of reducibility [34, 18]: Let (A, B) and (C, D) be two disjoint pairs. We say that (A, B) is *polynomial-time many-one reducible to* (C, D), denoted by $(A, B) \leq_{\text{m}}^{\text{pp}} (C, D)$, if there is a function $h \in \text{FP}$ such that $h(A) \subseteq C$ and $h(B) \subseteq D$. The terms $\leq_{\text{m}}^{\text{pp}}$-completeness and -hardness also follow directly from this definition of reduction.

Proof Systems. We use the notion of proof systems for sets by Cook and Reckhow [8]: A function $f \in \text{FP}$ is called a *proof system for* $\text{img}(f)$. Specifically, a proof system f for TAUT is a *propositional* proof system. We say that a proof system g is *(p-)simulated* by a proof system f, denoted by $f \leq g$ (resp., $f \leq^{\text{p}} g$), if there exists a total function π (resp.,

$\pi \in \mathrm{FP}$) and a polynomial p such that $|\pi(x)| \leq p(|x|)$ and $f(\pi(x)) = g(x)$ for all x. We call a proof system f *(p-)optimal* for the set $\mathrm{img}(f)$, if $g \leq f$ (resp., $g \leq^{\mathrm{p}} f$) for all $g \in \mathrm{FP}$ with $\mathrm{img}(g) = \mathrm{img}(f)$.

Relativizations. We can relativize each complexity and function class to some oracle O, by equipping all machines corresponding to the respective class with oracle access to O. That is, e.g., $\mathrm{UP}^O := \{L(M^O) \mid M$ is a nondeterministic polynomial-time oracle Turing machine, and for all inputs x, $M^O(x)$ accepts on at most one path$\}$. The classes P^O, NP^O and so on are defined similarly. We can also relativize our notions of reducibility by using functions from FP^O instead of FP. In other words, we allow the reduction functions to access the oracle in relativized instances. This results in polynomial-time many-one reducibilities relative to an oracle O, which we denote as $\leq_{\mathrm{m}}^{\mathrm{p},O}$ for sets and $\leq_{\mathrm{m}}^{\mathrm{pp},O}$ for pairs of disjoint sets. In the same way, we can relativize (p-)simulation of proof systems to some oracle O, and denote the relativized simulation as $\leq^O$ resp. $\leq^{\mathrm{p},O}$. When it is clear from context that some statements refer to the relativized ones relative to some fixed oracle O, we sometimes omit the indication of O in the superscripts.

We define $p_i(n) := n^i + i$. Let $\{M_i\}_{i\in\mathbb{N}}$ and $\{F_i\}_{i\in\mathbb{N}}$ be, respectively, standard enumerations of nondeterministic polynomial-time (oracle) Turing machines resp. deterministic polynomial-time (oracle) Turing transducers, having the property that runtime of M_i, F_i is bounded by p_i relative to any oracle. Note that $\{L(M_i^O) \mid i \in \mathbb{N}\} = \mathrm{NP}^O$, $\{F_i^O \mid i \in \mathbb{N}\} = \mathrm{FP}^O$.

Specific Notation Used in our Oracle Construction. We now take on the notations proposed by Dose and Glaßer [12] designed for the construction of oracles. The domain of definition, image, and support for partial function $t\colon A \to \mathbb{N}$ are defined as $\mathrm{dom}(t) := \{x \in A \mid t(x)$ defined$\}$, $\mathrm{img}(t) := \{t(x) \mid x \in A, t(x)$ defined$\}$, $\mathrm{supp}(t) := \{x \in A \mid t(x)$ defined and $t(x) > 0\}$. We say that t is *injective on its support* if, for any $a, b \in \mathrm{supp}(t)$, $t(a) = t(b)$ implies $a = b$. If t is not defined at point x, then $t \cup \{x \mapsto y\}$ denotes the extension t' of t that at x has value y and satisfies $\mathrm{dom}(t') = \mathrm{dom}(t) \cup \{x\}$.

For a set A, we denote with $A(x)$ the characteristic function at point x, i.e., $A(x)$ is 1 if $x \in A$, and 0 otherwise. We can identify an oracle $A \subseteq \mathbb{N}$ with its characteristic ω-word $A(0)A(1)A(2)\cdots$ over Σ^ω. In this way, $A(i)$ denotes both the characteristic function at point i and the i-th character of its characteristic word. Similarly, for a finite word $w \in \Sigma^*$, we also understand w as the set $\{i \mid w(i) = 1\}$ and, e.g., we write $A = w \cup B$ where A and B are sets. (However, we understand $|w|$ as the length of the word w, and not the cardinality of set $\{i \mid w(i) = 1\}$.) Thus, a finite word w describes an oracle which is partially defined, i.e., only defined for natural numbers (or equivalently words) $x < |w|$. Being able to interpret a word w as a set and partial oracle is very useful for the oracle construction. In most construction steps we decide the membership of the smallest undefined word of a partial oracle w, which is simply $|w|$. This gives access to very concise notation.

In particular, for oracle machines M, the notation $M^w(x)$ refers to $M^{\{i \mid w(i)=1\}}(x)$ (that is, oracle queries that w is not defined for are negatively answered). This also allows us to define the following notion: we say that $M^w(x)$ is *definite* if all queries on all computation paths are $< |w|$ (or equivalently: $w(q)$ is defined for all queries q on all computation paths); we say that $M^w(x)$ *definitely accepts* (resp., *definitely rejects*) if $M^w(x)$ is definite and accepts (resp., rejects). Intuitively, the term definite describes computations that do not change when extending the respective oracle, because the queries are too short. This allows the following observation:

▶ **Observation 1.**

(i) *When $M^w(x)$ is a definite computation, and $v \sqsupseteq w$, then $M^v(x)$ is definite. Computation $M^v(x)$ accepts if and only if $M^w(x)$ accepts.*

(ii) *When w is defined for all words of length $p_i(|x|)$, then $M_i^w(x)$ is definite.*

(iii) *When $M^w(x)$ accepts on some computation path with set of oracle queries Q, and w, v agree on Q, then $M^v(x)$ accepts on the same computation path and with the same set of oracle queries Q.*

For an oracle w, a transducer F, and a machine M, we occasionally understand the notation $M^w(F^w(x))$ as the single computation of the machine $M \circ F$ on input x relative to w. Consequently, we say that $M^w(F^w(x))$ definitely accepts (resp., rejects) when $M \circ F$ definitely accepts (resp., rejects) input x relative to w.

In our oracle construction, we want to injectively reserve and assign countably infinitely many *levels* n, that are, words of same length n, for a countably infinite family of witness languages, with increasingly large gaps. For this, let $e(0) := 2$, $e(i) := 2^{e(i-1)}$. There is a polynomial-time computable, polynomial-time invertible injective function f, mapping $(m, h) \in \mathbb{N} \times \mathbb{N}$ to $\mathbb{N}$. Now define $H_m := \{e(f(m, h)) \mid h \in \mathbb{N}\}$ as the set of levels reserved for witness language m. This definition ensures

▶ **Observation 2.**

(i) *The set H_m is countably infinite, a subset of the even numbers, and all $H_0, H_1, \ldots$ are pairwise disjoint.*

(ii) *The sequence $\min H_0, \min H_1, \ldots$ is unbounded.*

(iii) *When $n \in H_m$, then $n < n' < 2^n$ implies $n' \notin H_0, H_1, \ldots$.*

(iv) *Every set $H_m \in \mathrm{P}$ for all $m \in \mathbb{N}$.*

3 Oracle Construction

We are primarily interested in an oracle O with the property that relative to that oracle, UP, DisjNP, DisjCoNP, and ¬NP ∩ coNP hold, but our construction yields the following slightly stronger statements:

(i) NP ∩ coNP = P (implying ¬NP ∩ coNP).

(ii) DisjNP does not contain $\leq_{\mathrm{m}}^{\mathrm{pp}}$-hard pairs for DisjUP (implying DisjNP).

(iii) UP does not contain $\leq_{\mathrm{m}}^{\mathrm{p}}$-complete languages (i.e., UP).

(iv) DisjCoNP does not contain $\leq_{\mathrm{m}}^{\mathrm{pp}}$-hard pairs for DisjCoUP (implying DisjCoNP).

Given a (possibly partial) oracle O and $m \in \mathbb{N}$, we define the following witness languages:

$$A_m^O := \{0^n \mid n \in H_m, \text{there exists } x \in \Sigma^n \text{ such that } x \in O \text{ and } x \text{ ends with } 0\}$$
$$B_m^O := \{0^n \mid n \in H_m, \text{there exists } x \in \Sigma^n \text{ such that } x \in O \text{ and } x \text{ ends with } 1\}$$
$$C_m^O := \{0^n \mid n \in H_m, \text{there exists } x \in \Sigma^n \text{ such that } x \in O\}$$
$$D_m^O := \{0^n \mid n \in H_m, \text{for all } x \in \Sigma^n, x \in O \rightarrow x \text{ ends with } 0\}$$
$$E_m^O := \{0^n \mid n \in H_m, \text{for all } x \in \Sigma^n, x \in O \rightarrow x \text{ ends with } 1\}$$

Their purpose is to be a “witness” that an element of DisjNP (resp., UP, DisjCoNP) is not complete by admitting no reduction to this element. This only works if the witness languages themselves belong to the respective classes. The following observation shows how the membership of the witness languages to the respective classes depends on the oracle.

▶ **Observation 3.**

(i) *If for all $n \in H_m$, $|O \cap \Sigma^n| \leq 1$, then (A_m^O, B_m^O) is in* DisjUP^O*, and C_m^O is in* UP^O.

(ii) *If for all $n \in H_m$, $O \cap \Sigma^n$ contains at least one word but not two words with the same parity, (i.e., there exists $\alpha \in \Sigma^{n-1}0$, $\beta \in \Sigma^{n-1}1$ such that the set $O \cap \Sigma^n$ is equal to $\{\alpha\}$ or $\{\beta\}$ or $\{\alpha, \beta\}$), then (D_m^O, E_m^O) is in* $\mathrm{DisjCoUP}^O$.

Preview of the Construction. The construction is quite technical, since the oracle has to satisfy several properties which simultaneously demand structure (i.e., property (i)) and freedom (i.e., properties (ii), (iii) and (iv)) during the construction. This leads to several dependencies and special cases that need to be addressed, mostly by combinatorial arguments and various extensions of the oracle constructed so far. To keep track of the progress of the construction, it is divided into tasks corresponding to the desired properties (i)–(iv). Each task contributes to the goal of satisfying its corresponding property.

1. Work towards $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP}$: For all $a \neq b$, the construction tries to achieve that M_a, M_b do not accept complementary. (*Accepting complementary* should mean that for each input x, precisely one of $M_a(x), M_b(x)$ accepts and the other rejects.) If this is not possible, (M_a, M_b) inherently accept complementary, and thus $L(M_a) \in \mathrm{NP} \cap \mathrm{coNP}$. Then, we start to *encode* into the oracle, whether M_a accepts some inputs or not. Thus, the final oracle will contain the encodings for almost all inputs, thus allowing to recover the accepting behavior of M_a and hence to decide $L(M_i)$ in P using oracle queries.
2. Work towards (ii), which implies DisjNP: For all $i \neq j$, the construction tries to achieve that M_i, M_j both accept some input x, hence $x \in L(M_i) \cap L(M_j)$ and $(L(M_i), L(M_j)) \notin \mathrm{DisjNP}$. If this is not possible, (M_i, M_j) inherently is a disjoint NP-pair. In this case, we fix some m, make sure that (A_m, B_m) is a disjoint UP-pair and diagonalize against every transducer F_r, so that F_r does not realize the reduction $(A_m, B_m) \leq_{\mathrm{m}}^{\mathrm{pp}} (L(M_i), L(M_j))$. This is achieved by, (i) for all $n \in H_m$, insert at most one word of length n into O (and thus $(A_m, B_m) \in \mathrm{DisjUP}$), and (ii) for every r there is an $n \in H_m$ such that $0^n \in A_m$ but $M_i(F_r(0^n))$ rejects (or analogously $0^n \in B_m$ but $M_j(F_r(0^n))$ rejects).
3. Work towards (iii), i.e., UP: Try to make M_i accept on two separate paths. If this is not possible, then $L(M_i)$ inherently is a UP-language. In this case, we fix some m, make sure that C_m is a language in UP and diagonalize against every transducer F_r so that F_r does not realize the reduction $C_m \leq_{\mathrm{m}}^{\mathrm{p}} L(M_i)$. This is achieved by, (i) for all $n \in H_m$, insert at most one word of length n into O (and thus $C_m \in \mathrm{UP}$), and (ii) for every r there is an $n \in H_m$ such that $0^n \in C_m$ if and only if $M_i(F_r(0^n))$ rejects.
4. Work towards (iv), which implies DisjCoNP: Try to achieve that M_i, M_j both reject some input x, hence $x \in \overline{L(M_i)} \cap \overline{L(M_j)}$ and $(L(M_i), L(M_j)) \notin \mathrm{DisjNP}$. If this is not possible, (M_i, M_j) inherently is a disjoint coNP-pair. In this case, we fix some m, make sure that (D_m, E_m) is a disjoint coUP-pair and diagonalize against every transducer F_r, so that F_r does not realize the reduction $(D_m, E_m) \leq_{\mathrm{m}}^{\mathrm{pp}} (L(M_i), L(M_j))$. This is achieved by, (i) for all $n \in H_m$, insert at least one word of length n into O but not two words with same parity (and thus $(D_m, E_m) \in \mathrm{DisjCoUP}$), and (ii) for every r there is an $n \in H_m$ such that $0^n \in D_m$ but $M_i(F_r(0^n))$ accepts (or analogously $0^n \in E_m$ but $M_j(F_r(0^n))$ accepts).

To these requirements, we assign the following symbols representing tasks: $\tau_{a,b}^1$, $\tau_{i,j}^2$, $\tau_{i,j,r}^2$, τ_i^3, $\tau_{i,r}^3$, $\tau_{i,j}^4$, $\tau_{i,j,r}^4$ for all $a, b, i, j, r \in \mathbb{N}, i \neq j$, $a \neq b$. The symbol $\tau_{a,b}^1$ represents the coding or the destruction of $\mathrm{NP} \cap \mathrm{coNP}$-pairs. The symbol $\tau_{i,j}^2$ represents the destruction of a disjoint NP-pair, $\tau_{i,j,r}^2$ the diagonalization of that pair against transducer F_r. Analogously for UP and $\tau_i^3, \tau_{i,r}^3$. Analogously for DisjCoNP and $\tau_{i,j}^4, \tau_{i,j,r}^4$.

For the coding, we injectively define the code word $c(a,b,x) := 0^a10^b10^l10^p1x$ with $p = p_a(|x|) + p_b(|x|)$, $l \in \mathbb{N}$ minimal such that $l \geq 7/8|c(a,b,x)|$ and $c(a,b,x)$ has odd length. By this, a code word contains the word x as information and is padded to sufficient length. We call any word of the form $c(\cdot,\cdot,\cdot)$ a *code word.* This ensures the following properties:

▷ Claim 4. For all $a, b \in \mathbb{N}$, $x \in \Sigma^*$, the following holds:

(i) $|c(a,b,x)| \notin H_m$ for any m.

(ii) For fixed a, b, the function $x \mapsto c(a,b,x)$ is polynomial-time computable, and polynomial-time invertible with respect to $|x|$.

(iii) Relative to any oracle, the running times of $M_a(x)$ and $M_b(x)$ are both bounded by $< |c(a,b,x)|/8$.

(iv) For every partial oracle $w \in \Sigma^*$, if $c(a,b,x) \leq |w|$, then $M_a^w(x)$ and $M_b^w(x)$ are definite.

During the construction we successively add requirements that we maintain. To keep track of these requirements, we use a partial function t belonging to some set $\mathcal{T}$, which we define below. In particular, the partial function t maps some of the above task symbols to $\mathbb{N}$. In fact, these requirements determine to a large extent how tasks are treated and are mainly responsible that the oracle satisfies the desired properties. To add a requirement in the construction, we can extend the function t.

Define $\mathcal{T}$ as the set of all partial functions t mapping $\tau^1_{a,b}$, $\tau^2_{i,j}$, τ^3_i, $\tau^4_{i,j}$, $i \neq j$, $a \neq b$ to $\mathbb{N}$, and $\mathrm{dom}(t)$ is finite, and t is injective on its support.

To now link the maintenance of the requirements with the oracle construction, we introduce the notion of *validity.* A partial oracle $w \in \Sigma^*$ is called *t-valid* for $t \in \mathcal{T}$ if it satisfies the following properties:

V1 If $t(\tau^1_{a,b}) = 0$, then there exists an x such that $M_a^w(x)$, $M_b^w(x)$ both definitely accept or both definitely reject.
(Meaning: if $t(\tau^1_{a,b}) = 0$, then for every extension of the oracle, M_a, M_b do not accept complementary.)

V2 If $0 < t(\tau^1_{a,b}) \leq c(a,b,x) < |w|$, then $M_a^w(x)$ is definite. Additionally, the computation $M_a^w(x)$ accepts when $c(a,b,x) \in w$, and rejects when $c(a,b,x) \notin w$. When the above conditions are met by $c(a,b,x)$ we sometimes refer to these code words as *mandatory* code words with respect to some t-valid partial oracle w. Note that when the previous conditions are not met ($\tau^1_{a,b} \notin \mathrm{dom}(t)$ or $t(\tau^1_{a,b}) = 0$ or $t(\tau^1_{a,b}) > c(a,b,x)$) then the code word $c(a,b,x)$ may be a member of oracle w, independent of M_a, M_b.
(Meaning: if $t(\tau^1_{a,b}) > 0$, then from $t(\tau^1_{a,b})$ on, we encode $L(M_a)$ into the oracle. That is, $L(M_a^O) = (\{x \mid c(a,b,x) \in O\} \cup \text{some finite set}) \in \mathrm{P}^O$.)

V3 If $t(\tau^2_{i,j}) = 0$, then there exists an x such that $M_i^w(x)$, $M_j^w(x)$ both definitely accept.
(Meaning: if $t(\tau^2_{i,j}) = 0$, then for every extension of the oracle, $(L(M_i), L(M_j)) \notin \mathrm{DisjNP}$.)

V4 If $t(\tau^2_{i,j}) = m > 0$, then for every $n \in H_m$ it holds that $|\Sigma^n \cap w| \leq 1$.
(Meaning: if $t(\tau^2_{i,j}) = m > 0$, then ensure that $(A_m, B_m) \in \mathrm{DisjUP}$ relative to the final oracle.)

V5 If $t(\tau^3_i) = 0$, then there exists an x such that $M_i^w(x)$ is definite and accepts on two different paths.
(Meaning: if $t(\tau^3_i) = 0$, then for every extension of the oracle, $L(M_i) \notin \mathrm{UP}$.)

V6 If $t(\tau^3_i) = m > 0$, then for every $n \in H_m$ it holds that $|\Sigma^n \cap w| \leq 1$.
(Meaning: if $t(\tau^3_i) = m > 0$, then ensure that $C_m \in \mathrm{UP}$ relative to the final oracle.)

V7 If $t(\tau^4_{i,j}) = 0$, then there exists an x such that $M_i^w(x)$, $M_j^w(x)$ both definitely reject.
(Meaning: if $t(\tau^4_{i,j}) = 0$, then for every extension of the oracle, $(\overline{L(M_i)}, \overline{L(M_j)}) \notin \mathrm{DisjCoNP}$.)

V8 If $t(\tau^4_{i,j}) = m > 0$, then for every $n \in H_m$ it holds that all words in $\Sigma^n \cap w$ have pairwise different parity. If additionally w is defined for all words of length n, then $|\Sigma^n \cap w| > 0$. (Meaning: if $t(\tau^4_{i,j}) = m > 0$, then ensure that $(D_m, E_m) \in \mathrm{DisjCoUP}$ relative to the final oracle.)

Intuitively, a t-valid oracle is a possibly partial oracle which has the desired properties (i)–(iv) "partially satisfied". This notion of validness helps in the oracle construction, since our oracle is defined inductively, the induction step deals with a partial oracle and therefore t-validity fits great as part of an induction hypothesis which states that the partial oracle is constructed properly so far. Observe that V4, V6, V8 do not (pairwise) contradict each other, since t is injective on its support and all $H_1, H_2, \dots$ are pairwise disjoint, by Observation 2(i). Also observe that V2 and V4 (resp., V2 and V6, V2 and V8) do not contradict each other, as $c(\cdot,\cdot,\cdot)$ has odd length, but all n in all H_m are even by Observation 2(i).

Oracle Construction. Let T be a countable enumeration of

$$\begin{aligned}\{\tau^1_{a,b} \mid a, b \in \mathbb{N}, a \neq b\} \cup \{\tau^2_{i,j} \mid i, j \in \mathbb{N}, i \neq j\} &\cup \{\tau^2_{i,j,r} \mid i, j, r \in \mathbb{N}, i \neq j\}\\ \cup \{\tau^3_i \mid i \in \mathbb{N}\} \qquad\qquad &\cup \{\tau^3_{i,r} \mid i, r \in \mathbb{N}\}\\ \cup \{\tau^4_{i,j} \mid i, j \in \mathbb{N}, i \neq j\} &\cup \{\tau^4_{i,j,r} \mid i, j, r \in \mathbb{N}, i \neq j\}\end{aligned}$$

with the property that $\tau^2_{i,j}$ appears earlier than $\tau^2_{i,j,r}$, τ^3_i appears earlier than $\tau^3_{i,r}$, $\tau^4_{i,j}$ earlier than $\tau^4_{i,j,r}$.

We inductively define an infinite sequence $\{(w_s, t_s)\}_{s \in \mathbb{N}}$, where the s-th term of the sequence is a pair (w_s, t_s) of a partial oracle and a function in $\mathcal{T}$. We call the s-th term the *stage* s. We ensure that for all $s \in \mathbb{N}$, w_s is a t_s-valid partial oracle.

In each stage, we treat the smallest task in the order specified by T, and after treating a task we remove it and possibly other higher tasks from T. In the next stage, we continue with the next task not already removed from T. (In every stage, there always exists a task not already removed, as we never remove *all* remaining tasks from T in any stage.)

We start with the nowhere defined function $t_0 \in \mathcal{T}$ and the t_0-valid oracle $w_0 := \varepsilon$ as 0-th stage. Then we begin treating the tasks.

Thus, for stage $s > 0$, we have that $w_0, w_1, \dots, w_{s-1}$ and $t_0, t_1, \dots, t_{s-1}$ are defined. With this, we define the s-th stage (w_s, t_s) such that (a) $w_{s-1} \sqsubsetneq w_s$, and $t_s \in \mathcal{T}$ is a (not necessarily strict) extension of t_{s-1}, and (b) w_s is t_s-valid, and (c) the earliest task τ still in T is treated and removed in some way.

So for each task we strictly extend the oracle and are allowed to add more requirements, by extending the valid function, that have to be maintained in the further construction. Finally, we choose $O := \bigcup_{i \in \mathbb{N}} w_i$. (Note that O is totally defined since in each step we strictly extend the oracle.) Also, every task in T is assigned some stage s where it was treated (or removed from T).

We now define stage $s > 0$, which starts with some $t_{s-1} \in \mathcal{T}$ and a t_{s-1}-valid oracle w_{s-1} and treats the first task that still is in T choosing an extension $t_s \in \mathcal{T}$ of t_{s-1} and a t_s-valid $w_s \sqsupsetneq w_{s-1}$. Let us recall that each task is immediately deleted from T after it is treated. There are seven cases depending on the form of the task that is treated in stage s:

- Task $\tau^1_{a,b}$: Let $t' := t_{s-1} \cup \{\tau^1_{a,b} \mapsto 0\}$. If there exists a t'-valid $v \sqsupsetneq w_{s-1}$, then assign $t_s := t'$ and let $w_s := v$.

  Otherwise, let $t_s := t_{s-1} \cup \{\tau^1_{a,b} \mapsto n\}$ with $n \in \mathbb{N}^+$ sufficiently large such that $n > |w_s|, \max \mathrm{img}(t_{s-1})$. Thus t_s is injective on its support, and w_{s-1} is t_s-valid. Let $w_s := w_{s-1}y$ with $y \in \{0, 1\}$ such that w_s is t_s-valid. Lemma 5 shows that such y does indeed exist.

(Meaning: try to ensure that M_a, M_b do not accept complementary, cf. V1. If that is impossible, require that from now on the computations of M_a are encoded into the oracle, cf. V2.)

- Task $\tau^2_{i,j}$: Let $t' := t_{s-1} \cup \{\tau^2_{i,j} \mapsto 0\}$. If there exists t'-valid $v \sqsupsetneq w_{s-1}$, then assign $t_s := t'$ and $w_s := v$. Besides task $\tau^2_{i,j}$, also remove all tasks $\tau^2_{i,j,0}, \tau^2_{i,j,1}, \dots$ from T.

  Otherwise, let $t_s := t_{s-1} \cup \{\tau^2_{i,j} \mapsto m\}$ with $m \in \mathbb{N}^+$ sufficiently large such that $m \notin \mathrm{img}(t_{s-1})$ and that w_{s-1} defines no word of length $\min H_m$. Thus t_s is injective on its support, and w_{s-1} is t_s-valid. Let $w_s := w_{s-1}y$ with $y \in \{0, 1\}$ such that w_s is t_s-valid. Again, Lemma 5 shows that such y does indeed exist.

  (Meaning: try to ensure that M_i, M_j do not accept disjointly, cf. V3. If that is impossible, choose a sufficiently large “fresh” m and require for the further construction that $(A_m, B_m) \in$ DisjUP (cf. V4). The treatment of the tasks $\tau^2_{i,j,0}, \tau^2_{i,j,1}, \dots$ defined below makes sure that (A_m, B_m) cannot be reduced to $(L(M_i), L(M_j))$.)
- Task τ^3_i: Defined symmetrically to task $\tau^2_{i,j}$. Let $t' := t_{s-1} \cup \{\tau^3_i \mapsto 0\}$. If there exists t'-valid $v \sqsupsetneq w_{s-1}$, then assign $t_s := t'$ and $w_s := v$. Besides task τ^3_i, also remove all tasks $\tau^3_{i,0}, \tau^3_{i,1}, \dots$ from T.

  Otherwise, let $t_s := t_{s-1} \cup \{\tau^3_i \mapsto m\}$ with $m \in \mathbb{N}^+$ sufficiently large such that $m \notin \mathrm{img}(t_{s-1})$ and that w_{s-1} defines no word of length $\min H_m$. Thus t_s is injective on its support, and w_{s-1} is t_s-valid. Let $w_s := w_{s-1}y$ with $y \in \{0, 1\}$ such that w_s is t_s-valid. Again, Lemma 5 shows that such y does indeed exist.

  (Meaning: try to ensure that M_i does accept on two different paths, cf. V5. If that is impossible, choose a sufficiently large “fresh” m and require for the further construction that $C_m \in$ UP (cf. V6). The treatment of the tasks $\tau^3_{i,0}, \tau^3_{i,1}, \dots$ defined below makes sure that C_m cannot be reduced to $L(M_i)$.)
- Task $\tau^4_{i,j}$: Defined symmetrically to task $\tau^2_{i,j}$. (Meaning: try to ensure that M_i, M_j do not reject disjointly, cf. V7. If that is impossible, choose a sufficiently large “fresh” m and require for the further construction that $(D_m, E_m) \in$ DisjCoUP (cf. V8). The treatment of the tasks $\tau^4_{i,j,0}, \tau^4_{i,j,1}, \dots$ defined below makes sure that (D_m, E_m) cannot be reduced to $(\overline{L(M_i)}, \overline{L(M_j)})$.)
- Task $\tau^2_{i,j,r}$: We have $t_{s-1}(\tau^2_{i,j}) = m \in \mathbb{N}^+$. Let $t_s := t_{s-1}$ and choose a t_s-valid $w_s \sqsupsetneq w_{s-1}$ such that there is some $n \in \mathbb{N}$ and at least one of the following holds:
  - $0^n \in A^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_i(F^{w_s}_r(0^n))$ definitely rejects.
  - $0^n \in B^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_j(F^{w_s}_r(0^n))$ definitely rejects.

  In Theorem 6 we show that such w_s does exist.

  (Meaning: ensure that F_r does not reduce (A_m, B_m) to $(L(M_i), L(M_j))$.)
- Task $\tau^3_{i,r}$: We have $t_{s-1}(\tau^3_i) = m \in \mathbb{N}^+$. Let $t_s := t_{s-1}$ and choose a t_s-valid $w_s \sqsupsetneq w_{s-1}$ such that there is some $n \in \mathbb{N}$ and at least one of the following holds:
  - $0^n \in C^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_i(F^{w_s}_r(0^n))$ definitely rejects.
  - $0^n \notin C^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_i(F^{w_s}_r(0^n))$ definitely accepts.

  In Theorem 7 we show that such w_s does exist.

  (Meaning: ensure that F_r does not reduce C_m to $L(M_i)$.)
- Task $\tau^4_{i,j,r}$: Defined symmetrically to $\tau^2_{i,j,r}$. Choose a t_s-valid $w_s \sqsupsetneq w_{s-1}$ such that for some $n \in \mathbb{N}$, one of the two holds:
  - $0^n \in D^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_i(F^{w_s}_r(0^n))$ definitely accepts.
  - $0^n \in E^v_m$ for all $v \sqsupseteq w_s$ and $M^{w_s}_j(F^{w_s}_r(0^n))$ definitely accepts.

  In Theorem 8 we show that such w_s does exist.

  (Meaning: ensure that F_r does not reduce (D_m, E_m) to $(\overline{L(M_i)}, \overline{L(M_j)})$.)

Observe that t_s is always defined to be in $\mathcal{T}$. Remember that the treated task is immediately deleted from T. This completes the definition of stage s, and thus, the entire sequence $\{(w_s, t_s)\}_{s \in \mathbb{N}}$. We now show that this construction is indeed possible. The proofs of the theorems/lemma announced in the definition are either roughly sketched or omitted. For detailed proofs, we refer to the full version of the paper. It is not difficult to see that a valid oracle can be extended by one bit such that it remains valid:

▶ **Lemma 5.** *Let $s \in \mathbb{N}$, $(w_0, t_0), \dots, (w_s, t_s)$ defined, and let $w \in \Sigma^*$ be a t_s-valid oracle with $w \sqsupseteq w_s$, and $z := |w|$. (Think of z as the next word we need to decide its membership to the oracle, i.e., $z \notin w0$ or $z \in w1$.) Then there exists $y \in \{0, 1\}$ such that wy is t_s-valid. Specifically:*

(i) *If $z = c(a, b, x)$ and $0 < t_s(\tau^1_{a,b}) \leq z$, then $w1$ is t_s-valid if $M^w_a(x)$ accepts (or when $M^w_b(x)$ rejects), and $w0$ is t_s-valid if $M^w_a(x)$ rejects (or when $M^w_b(x)$ accepts).*
(Meaning: if we are at a position of some mandatory code word, add the word as appropriate for the NP ∩ coNP*-pair.)*

(ii) *If there exists $\tau = \tau^2_{i,j}$ or $\tau = \tau^3_i$ with $m = t_s(\tau) > 0$ and $n \in H_m$ such that $|z| = n$, $w \cap \Sigma^n \neq \emptyset$, then $w0$ is t_s-valid.*
(Meaning: if we are on a level n belonging to a DisjUP*-pair or a* UP*-language, ensure that there is no more than one word on that level.)*

(iii) *If there exists $\tau^4_{i,j}$, $m = t_s(\tau^4_{i,j}) > 0$ and $n \in H_m$ such that $|z| = n$ and there is some other word $x \in w \cap \Sigma^n$ with same parity as z, then $w0$ is t_s-valid. (Meaning: if we are on a level n belonging to a* DisjCoUP*-pair, ensure that on that level, there are no two words with the same parity.)*

(iv) *If there exists $\tau^4_{i,j}$, $m = t_s(\tau^4_{i,j}) > 0$ and $n \in H_m$ such that $|z| = n$, $|z + 1| > n$, $w \cap \Sigma^n = \emptyset$, then $w1$ is t_s-valid.*
(Meaning: if we finalize level n belonging to a DisjCoUP *witness pair, ensure that there is at least one word on that level.)*

(v) *In all other cases, $w0$ and $w1$ are t_s-valid.*

Lemma 5 shows that the construction is possible for the tasks $\tau^1_{a,b}$, $\tau^2_{i,j}$, τ^3_i and $\tau^4_{i,j}$. Now we show that the construction is possible for $\tau^2_{i,j,r}$, $\tau^3_{i,r}$ and $\tau^4_{i,j,r}$, respectively. We first consider task $\tau^2_{i,j,r}$.

▶ **Theorem 6.** *Let $s \in \mathbb{N}^+$, $(w_0, t_0), \dots, (w_{s-1}, t_{s-1})$ defined. Consider task $\tau^2_{i,j,r}$.*

Suppose that $t_s = t_{s-1}$, $t_s(\tau^2_{i,j}) = m > 0$. Then there exists a t_s-valid $w \sqsupsetneq w_{s-1}$ and $n \in \mathbb{N}$ such that one of the two holds:

(i) *$0^n \in A^v_m$ for all $v \sqsupseteq w$ and $M^w_i(F^w_r(0^n))$ definitely rejects.*

(ii) *$0^n \in B^v_m$ for all $v \sqsupseteq w$ and $M^w_j(F^w_r(0^n))$ definitely rejects.*

Proof sketch. We prove the Theorem by contradiction. Let $\hat{s} < s$ be the stage that treated $\tau^2_{i,j}$ with $t_{\hat{s}} = t_{\hat{s}-1} \cup \{\tau^2_{i,j} \mapsto m\}$ and $m > 0$. We construct a suitable alternative oracle $u' \sqsupsetneq w_{\hat{s}-1}$, which is valid with respect to $t' := t_{\hat{s}-1} \cup \{\tau^2_{i,j} \mapsto 0\}$. Then, by definition, we obtain that u' is one possible t'-valid extension of $w_{\hat{s}-1}$ in stage $\hat{s}$, hence $t_{\hat{s}} = t'$ and $t_{\hat{s}}(\tau^2_{i,j}) = 0$, contradicting $t_s(\tau^2_{i,j}) = m > 0$ in the hypothesis of this Theorem 6.

Assume that (i) and (ii) do not hold. Fix some sufficiently large $n \in H_m$. This is some level that belongs to the witness NP-pair (A_m, B_m). For every $\xi \in \Sigma^n$, one can provisionally keep extending w_{s-1} bitwise with Lemma 5 while inserting precisely the word ξ into level n. Continue extending until a sufficiently long but fixed length n' such that $M_i(F_r(0^n))$ and $M_j(F_r(0^n))$ are definite (relative to any oracle), and call the resulting oracle u_ξ. By construction, this oracle is t_s-valid. By assumption, when $\alpha \in \Sigma^{n-1}0$, then $M_i(F_r(0^n))$ accepts relative to u_α, and when $\beta \in \Sigma^{n-1}1$, then $M_j(F_r(0^n))$ accepts relative to u_β.

We want to maintain these accepting computations relative to an oracle containing, in level n, exactly one $\alpha \in \Sigma^{n-1}0$ and one $\beta \in \Sigma^{n-1}1$. The accepting behavior for any such computation, say $M_i(F_r(0^n))$ relative to u_α, depends on the oracle queries posed on that path. However, this computation might also query certain mandatory code words $c(a, b, x)$, whose memberships depend on further, shorter queries of computations $M_a(x)$, $M_b(x)$. Continuing this recursively, we obtain a set of queries Q_α^+ the original computation $M_i(F_r(0^n))$ transitively depends on.

Similarly, for each $\beta \in \Sigma^{n-1}1$ we can define a set of queries Q_β^+ an accepting path of the computation $M_j(F_r(0^n))$ relative to u_β depends on. One can verify that Q_α^+ and Q_β^+ only have polynomially many elements.

The crucial idea that completes the proof is to find suitable $\alpha \in \Sigma^{n-1}0$ and $\beta \in \Sigma^{n-1}1$ such that u_α and u_β agree on the set $Q_\alpha^+ \cap Q_\beta^+$. Such a pair of words α and β exists; we skip here the combinatorial argument, but intuitively this assertion holds from the fact that there are exponentially many choices for α, β but for each choice, Q_α^+ and Q_β^+ create only polynomially many dependencies. With this property, it is possible to construct a $t_{\hat{s}-1}$-valid oracle $u' \sqsupsetneq w_{s-1}$ such that $\alpha, \beta \in u'$ holds, u' and u_α agree on Q_α^+, and symmetric u' and u_β agree on Q_β^+. By assumption and Observation 1(iii), this means that *both* $M_i(F_r(0^n))$ and $M_j(F_r(0^n))$ definitely accept relative to u'. Thus u' is also t'-valid, as desired. ◀

With only slight modifications, one can give the same Theorem concerning tasks $\tau_{i,r}^3$. We omit the specific details.

▶ **Theorem 7.** *Let $s \in \mathbb{N}^+$, $(w_0, t_0), \ldots, (w_{s-1}, t_{s-1})$ defined. Consider task $\tau_{i,r}^3$.*

Suppose that $t_s = t_{s-1}$, $t_s(\tau_i^3) = m > 0$. Then there exists a t_s-valid $w \sqsupsetneq w_{s-1}$ and $n \in \mathbb{N}$ such that one of the following holds:

(i) *$0^n \in C_m^v$ for all $v \sqsupseteq w$ and $M_i^w(F_r^w(0^n))$ definitely rejects.*

(ii) *$0^n \notin C_m^v$ for all $v \sqsupseteq w$ and $M_i^w(F_r^w(0^n))$ definitely accepts.*

Lastly, handling task $\tau_{i,j,r}^4$ is also possible. For this we use techniques similar to previous theorems. In this setting, it is in fact possible to explicitly construct a suitable extension for the task. Due to many additional technical details required, we omit the proof of this theorem and refer to the full version of the paper.

▶ **Theorem 8.** *Let $s \in \mathbb{N}^+$, (w_{s-1}, t_{s-1}) defined. Consider task $\tau_{i,j,r}^4$.*

Suppose that $t_s = t_{s-1}$, $t_s(\tau_{i,j}^4) = m > 0$. Then there exists a t_s-valid $w \sqsupsetneq w_{s-1}$ and $n \in \mathbb{N}$ such that one of the following holds:

(i) *$0^n \in D_m^v$ for all $v \sqsupseteq w$ and $M_i^w(F_r^w(0^n))$ definitely accepts.*

(ii) *$0^n \in E_m^v$ for all $v \sqsupseteq w$ and $M_j^w(F_r^w(0^n))$ definitely accepts.*

We have now completed the proofs showing that the oracle construction can be performed as desired. The following theorem confirms the desired properties of $O := \bigcup_{i \in \mathbb{N}} w_i$. Remember that $|w_0| < |w_1| < \ldots$ is unbounded, hence for any z there is a sufficiently large s such that $|w_s| > z$. Also remember that w_s is t_s-valid for all $s \in \mathbb{N}$. Using these facts and the properties V1–V8 of t_s-valid oracles, one can easily state the following result for the final oracle.

▶ **Theorem 9.** *Relative to $O = \bigcup_{i \in \mathbb{N}} w_i$, the following holds:*

(i) $\mathrm{NP} \cap \mathrm{coNP} = \mathrm{P}$*, which implies* $\neg\mathsf{NP} \cap \mathsf{coNP}$.

(ii) *No pair in* DisjNP *is* $\leq_{\mathrm{m}}^{\mathrm{pp}}$*-hard for* DisjUP*, which implies* DisjNP.

(iii) *No language in* UP *is* $\leq_{\mathrm{m}}^{\mathrm{p}}$*-complete for* UP*, i.e.,* UP.

(iv) *No pair in* DisjCoNP *is* $\leq_{\mathrm{m}}^{\mathrm{pp}}$*-hard for* DisjCoUP*, which implies* $\mathsf{DisjCoNP}$.

From Theorem 9 and known relativizable results, we obtain the following additional properties that hold relative to the oracle. See, e.g., the work of Fenner et al. [15] for a definition of the mentioned function classes $\mathrm{NPSV}, \mathrm{NPbV}, \mathrm{NP}k\mathrm{V}, \mathrm{NPMV}$ and their total variants $\mathrm{NPSV_t}, \mathrm{NPbV_t}, \mathrm{NP}k\mathrm{V_t}, \mathrm{NPMV_t}$. Here, NEE means $\mathrm{NTIME}\left(2^{O(2^n)}\right)$.

▶ **Corollary 10.** *The following holds relative to the oracle O constructed in this section.*

(i) $\mathrm{P} = \mathrm{NP} \cap \mathrm{coNP} \subsetneq \mathrm{UP} \subsetneq \mathrm{NP}$
(ii) UP, NP, NE, *and* NEE *are not closed under complement.*
(iii) $\mathrm{UP} \not\subseteq \mathrm{coNP}$
(iv) $\mathrm{NEE} \cap \mathrm{TALLY} \not\subseteq \mathrm{coNEE}$
(v) $\mathrm{NPSV_t} \subseteq \mathrm{PF}$
(vi) $\mathrm{NPbV_t} \not\subseteq_c \mathrm{NPSV_t}$
(vii) $\mathrm{NP}k\mathrm{V_t} \not\subseteq_c \mathrm{NPSV_t}$ *for all $k \geq 2$*
(viii) $\mathrm{NPMV_t} \not\subseteq_c \mathrm{NPSV_t}$
(ix) $\mathrm{NPMV} \not\subseteq_c \mathrm{NPSV}$
(x) $\mathrm{TFNP} \not\subseteq_c \mathrm{PF}$
(xi) $\mathrm{NP} \cap \mathrm{coNP}$ *has $\leq_\mathrm{m}^\mathrm{p}$-complete sets, i.e.,* $\neg\mathsf{NP} \cap \mathsf{coNP}$.
(xii) UP *has no $\leq_\mathrm{m}^\mathrm{p}$-complete sets, i.e.,* UP.
(xiii) DisjNP *has no $\leq_\mathrm{m}^\mathrm{pp}$-complete pairs, i.e.,* DisjNP.
(xiv) DisjCoNP *has no $\leq_\mathrm{m}^\mathrm{pp}$-complete pairs, i.e.,* $\mathsf{DisjCoNP}$.
(xv) *No pair in* DisjNP *is $\leq_\mathrm{m}^\mathrm{pp}$-hard for* DisjUP.
(xvi) *No pair in* DisjCoNP *is $\leq_\mathrm{m}^\mathrm{pp}$-hard for* DisjCoUP.
(xvii) *There are no p-optimal proof systems for* TAUT, *i.e.,* CON.
(xviii) *There are no optimal proof systems for* TAUT.
(xix) *There are no p-optimal proof systems for* SAT, *i.e.,* SAT.
(xx) TFNP *has no $\leq_\mathrm{m}^\mathrm{p}$-complete problems, i.e.,* TFNP.
(xxi) $\mathrm{NPMV_t}$ *has no $\leq_\mathrm{m}^\mathrm{p}$-complete functions.*
(xxii) NP *and* coNP *do not have the shrinking property. [7, 16]*
(xxiii) NP *and* coNP *do not have the separation property. [16]*
(xxiv) DisjNP *and* DisjCoNP *contain* P*-inseparable pairs.*

Exact Matching in Graphs of Bounded Independence Number

Nicolas El Maalouly

Raphael Steiner
Department of Computer Science, ETH Zürich, Switzerland

Abstract

In the *Exact Matching Problem* (EM), we are given a graph equipped with a fixed coloring of its edges with two colors (red and blue), as well as a positive integer k. The task is then to decide whether the given graph contains a perfect matching exactly k of whose edges have color red. EM generalizes several important algorithmic problems such as *perfect matching* and restricted minimum weight spanning tree problems.

When introducing the problem in 1982, Papadimitriou and Yannakakis conjectured EM to be **NP**-complete. Later however, Mulmuley et al. presented a randomized polynomial time algorithm for EM, which puts EM in **RP**. Given that to decide whether or not **RP**=**P** represents a big open challenge in complexity theory, this makes it unlikely for EM to be **NP**-complete, and in fact indicates the possibility of a *deterministic* polynomial time algorithm. EM remains one of the few natural combinatorial problems in **RP** which are not known to be contained in **P**, making it an interesting instance for testing the hypothesis **RP**=**P**.

Despite EM being quite well-known, attempts to devise deterministic polynomial algorithms have remained illusive during the last 40 years and progress has been lacking even for very restrictive classes of input graphs. In this paper we push the frontier of positive results forward by proving that EM can be solved in deterministic polynomial time for input graphs of bounded independence number, and for bipartite input graphs of bounded bipartite independence number. This generalizes previous positive results for complete (bipartite) graphs which were the only known results for EM on dense graphs.

1 Introduction

The problem of deciding whether a given graph contains a perfect matching, as well as the related problem of computing a maximum (minimum) weight perfect matching in a given graph are amongst the foundational problems in algorithmic graph theory and beyond, and the fact that they can be solved in polynomial time [4] is an integral part of many efficient algorithms in theoretical computer science.

In 1982, Papadimitriou and Yannakakis [17] studied a decision problem related to perfect matchings in edge-colored graphs as follows: Given as input a graph G whose edges come with a given fixed two-edge coloring (say, with colors red and blue), then the task is to decide whether for a given integer k there exists a perfect matching M of G such that exactly k of the edges in M are red. Clearly, in the special case when all edges are colored red and $k = \frac{n}{2}$,

this problem is simply to decide whether there exists a perfect matching in a given graph. For a heterogeneous coloring of the edges, however, the difficulty of the problem seems to change quite dramatically (see below).

The original motivation of Papadimitriou and Yannakakis [17] to study the above problem, which from now on will be called *Exact Matching* and abbreviated by EM, was their investigation of *restricted minimum weight spanning tree problems*. In the usual minimum weight spanning tree problem, we are given a graph with non-negative edge-weights and seek to find a spanning tree minimizing the total edge-weight, and this is well-known to be solvable in polynomial time using for instance Kruskal's algorithm [12]. Papadimitriou and Yannakakis considered what happens if we restrict the shape of the spanning trees allowed in the output, and obtained several results. For instance, the problem is easily seen to be **NP**-hard if the considered spanning trees are constrained to be paths, by a reduction from the Hamiltonian Path problem, but it is polynomial-time solvable if the tree shapes are restricted to stars or 2-stars. While for many classes of trees, Papadimitriou and Yannakakis [17] classified the complexity of the above problem, some cases remained unsettled. In particular, they proved that the restricted minimum weight spanning tree problem for so-called *double* 2-*stars* is equivalent to EM, and left it as an open problem to decide its computational complexity. In fact, they stated the conjecture that EM is **NP**-complete. Up until today, neither has this conjecture been confirmed, nor is it known whether EM can be solved in polynomial time by a deterministic algorithm. Yet, there have been some interesting results and developments regarding the problem in the past, which we summarize in the following.

Only few years after the introduction of the problem, in a breakthrough result Mulmuley, Vazirani and Vazirani [16] developed their so-called *isolation lemma*, and demonstrated its power by using it to prove that EM can be solved by a randomized polynomial time algorithm, i.e. it is contained in **RP**. This makes it unlikely to be **NP**-hard. In fact, deciding whether **RP**=**P** remains one of the big challenges in complexity theory. This means that problems such as EM, for which we know containment in **RP** but are not aware of deterministic polynomial time algorithms, are interesting candidates for testing the hypothesis **RP**=**P**. Indeed, due to this, EM is cited in several papers as an open problem. This includes recent breakthrough papers such as the seminal work on the parallel computation complexity of the matching problem [19], works on planarizing gadgets for perfect matchings [8], works on more general constrained matching problems [1, 14, 15, 18] and on multicriteria optimization problems [7] among others. Even though EM has caught the attention of many researchers from different areas, there seems to be a substantial lack of progress on the problem even when restricted to very special subclasses of input graphs as we will see next. This highlights the surprising difficulty of the problem given how simple it may seem at first glance.

Previous results for EM on restricted classes of graphs. It may surprise some readers that EM is even non-trivial if the input graphs are complete or complete bipartite graphs: In fact, at least four different articles have appeared on resolving these two special cases of EM [10, 20, 6, 9], which are now known to be solvable in deterministic polynomial time. Another positive result follows from the existence of Pfaffian orientations and their analogues on planar graphs and $K_{3,3}$-minor free graphs [21], EM is solvable in polynomial time on these classes via a derandomization of the techniques used in [16]. Considering a generalization of Pfaffian orientations, it was further proved in [5] that EM can be solved in polynomial time for graphs embeddable on a surface of bounded genus. Finally, from the well-known meta-theorem of Courcelle [2], one easily obtains that EM can be efficiently solved on classes of bounded tree-width.

Our contribution. In this paper, we generalize the known positive results for EM on very dense graphs such as complete and complete bipartite graphs to graphs of independence number at most α and to bipartite graphs of bipartite independence number at most β, for all fixed integers $\alpha, \beta \geq 1$. The *independence number* of a graph G is defined as the largest number α such that G contains an *independent set* of size α. The *bipartite independence number* of a bipartite graph G equipped with a bipartition of its vertices is defined as the largest number β such that G contains a *balanced independent set* of size 2β, i.e., an independent set using exactly β vertices from both color classes.

▶ **Theorem 1.** *There is a deterministic algorithm for EM on graphs of independence number α running in time $n^{O(f(\alpha))}$, for $f(\alpha) = 2^{O(\alpha)}$.*

▶ **Theorem 2.** *There is a deterministic algorithm for EM on bipartite graphs of bipartite independence number β running in time $n^{O(f(\beta))}$, for $f(\beta) = 2^{O(\beta)}$.*

The special cases $\alpha = 1$ and $\beta = 1$ of the above results correspond exactly to the previously studied cases of complete and complete bipartite graphs. We emphasize that even though bounding the independence number might seem like a big restriction on the input graphs, already for $\alpha = 2, \beta = 2$ our results cover rich and complicated classes of graphs, for instance every complement of a triangle-free graph belongs to the class of independence number at most 2, and every bipartite complement of a C_4-free bipartite graph belongs to the class of bipartite independence number at most 2.

Another interesting observation in support of the above is the following: So far, for all classes of graphs on which EM was known to be solvable in polynomial time (including planar graphs, $K_{3,3}$-minor-free graphs, graphs of bounded genus, complete and complete bipartite graphs), the number of perfect matchings was also known to be countable in polynomial time (cf. [11, 13, 5, 21]), and one may wonder about whether tractability of EM aligns with the tractability of corresponding counting problems for perfect matchings. However, even for graphs of independence number 2 we are not aware that polynomial schemes for counting perfect matchings exist, and in fact conjecture that this problem is computationally hard, therefore putting our result into nice contrast with previous positive results on EM.

▶ **Conjecture 3.** *The problem of counting perfect matchings in input graphs of independence number 2 is $\#\boldsymbol{P}$-complete.*

Organization of the paper. The remainder of this paper is organized as follows: In Section 2 we present the basic definitions and conventions we use throughout the paper. In Section 3 we prove Theorem 1, i.e., showing the existence of an XP algorithm parameterized by the independence number of the graph. In Section 4 we consider the bipartite graphs case and prove Theorem 2. In Section 5 we discuss distance-d independence number parameterizations and in Section 6 we conclude the paper and provide some open problems.

2 Preliminaries

Due to space restrictions, proofs of statements marked $\star$ have been deferred to the appendix. All graphs considered are simple. For a graph $G = (V, E)$ we let $n = |V(G)|$, i.e. the number of vertices in G. Given an instance of EM and a perfect matching[1] (abbreviated PM) M, we

[1] A perfect matching of a graph is a matching (i.e., an independent edge set) in which every vertex of the graph is incident to exactly one edge of the matching.

define edge weights as follows: blue edges get weight 0, matching red edges get weight -1 and non-matching red edges get weight $+1$. For G' a subgraph[2] of G, we define $R(G')$ (resp. $B(G')$) to be the set of red (resp. blue) edges in G', $r(G') := |R(G')|$ and $w_M(G')$ to be the sum of the weights of edges in G'. For ease of notation, we will use $w(G')$ for $w_M(G')$ and will make the matching explicit whenever it is not M.

Whenever we consider a set of cycles or paths, it is always assumed that they are vertex disjoint and alternating with respect to the current matching M (unless specified otherwise). Define an x-path to be an alternating path of weight x. Undirected cycles are considered to have an arbitrary orientation. For a cycle C and $u, v \in C$, $C[u, v]$ is defined as the path from u to v along C (in the fixed but arbitrarily chosen orientation). For simplicity, a cycle is also considered to be a path i.e. a closed path (its starting vertex is chosen arbitrarily). $Ram(r, s)$ refers to the Ramsey number, i.e. every graph on $Ram(r, s)$ vertices contains either a clique of size r or an independent set of size s. For simplicity we will use the following upper bound $Ram(s + 1, s + 1) < 4^s$ [3]. For two sets of edges M and M', $M\Delta M'$ refers to the symmetric difference between the two sets (i.e. the edges that appear in exactly one of the two sets). Note that if M and M' are two PMs, then $M\Delta M'$ forms a set of cycles (each alternating with respect to both matchings) and will be use as such. Also note that with the above defined edge weights we have $r(M') = r(M) + w(M\Delta M')$.

3 Bounded Independence Number Graphs

The algorithm relies on a 2 phase process. The first phase is an algorithm that outputs a PM M with $|k - r(M)|$ bounded (by a function of α), i.e. with a number of red edges that only differs from k by a function of α. This algorithm is also of independent interest since it provides a solution that is close to optimal (for small independence number) while its running time is polynomial and independent of the independence number.

▶ **Theorem 4.** *Given a "Yes" instance of EM, there exists a deterministic polynomial time algorithm that outputs a PM M with $k - 2 \cdot 4^\alpha \leq r(M) \leq k$.*

▶ Remark. Note that a standalone proof of Theorem 4 can be made quite simple but would require additional notions and definitions. Our main focus however, is on the proof of Theorem 1, so the proof structure is tailored towards that end and the proof of Theorem 4 will come as result along the way.

The second phase is an algorithm that outputs a solution matching with a running time that depends on the size of the smallest color class in a symmetric difference between a given matching and a solution matching. It is also of independent interest as it can be more generally useful for the study of other parameterizations of EM as well as other matching problems with color constraints.

▶ **Proposition 5.** *Let M and M' be two PMs in G s.t. $|B(M\Delta M')| \leq L$ or $|R(M\Delta M')| \leq L$. Then there exists a deterministic algorithm running in time $n^{O(L)}$ such that given M it outputs a PM M'' with $r(M'') = r(M')$.*

Proof. Suppose w.l.o.g. $|R(M\Delta M')| \leq L$ (the other case is similar by swapping the colors). Guess $R(M\Delta M')$ in time $n^{O(L)}$ by trying all possibilities (the rest of the algorithm should succeed for at least one such possibility). Compute $R(M') = R(M)\Delta R(M\Delta M')$.

[2] Note that the subgraph can also be a set of edges or cycles.

Remove the edges $R(M')$ and their endpoints from the graph as well as all remaining red edges. Compute a PM M_1 on the rest of the graph (such a PM must exist since $M' \backslash R(M')$ is one such example) and let $M'' := M_1 \cup R(M')$. Observe that M'' is a PM with $r(M'') = |R(M'')| = |R(M')| = r(M')$. ◀

For this phase to run in polynomial time for bounded independence number, we need to show that there exists a PM M^* with exactly k red edges, where $M \Delta M^*$ (M being the PM we get after the first phase) has a bounded (by a function of α) number of edges of some color class. The main technical challenge is to show that for this to be the case it is sufficient to have $|k - r(M)|$ bounded (which is guaranteed by the first phase). The rest of this section is devoted to this proof. Along the way we will also prove Theorem 4. Before going into the technical details, we give a quick overview.

3.1 Proof Overview

In order to apply Proposition 5, we will consider the solution matching M^* which minimizes the number of edges in $M \Delta M^*$ (M being the PM we get after the first phase) and aim to show that it contains a bounded number of edges of some color class. Towards this end, we want to show that if the set of alternating cycles $M \Delta M^*$ contains a large number of edges from both color classes, then there be must another set of alternating cycles $\mathcal{C}$ with the same total weight as $M \Delta M^*$, but containing strictly less edges. This contradicts the minimality of $M \Delta M^*$ since $M \Delta \mathcal{C}$ is also a solution matching with $|E(M \Delta (M \Delta \mathcal{C}))| = |E(\mathcal{C})| < |E(M \Delta M^*)|$. In other words, we want to show that unless one color class in $M \Delta M^*$ is bounded, we can reduce the size of one or more of the cycles in $M \Delta M^*$ while keeping the total weight unchanged.

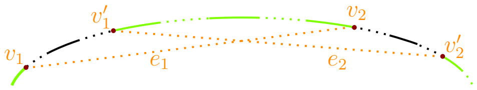

Figure 1 A skip formed by two non-matching edges e_1 and e_2 (in orange). Matching edges are represented by full lines and non-matching edges by dotted lines. The paths removed by the skip are depicted in black.

Skips. The main tool we use to show the existence of smaller alternating cycles is something we call a skip (see Figure 1). At a high level, a skip is simply a pair of edges that creates a new alternating cycle C' by replacing two paths of an alternating cycle C. If those paths have total length more than 2 then $|C'| < |C|$. This means that if a solution matching M^{**} exists, such that $M \Delta M^{**}$ is the same as $M \Delta M^*$ but with C replaced by C', it would contradict the minimality of $M \Delta M^*$. For M^{**} to be a solution matching, we also need $w(C) = w(C')$ so that M^{**} also has k red edges. For this reason we look for skips that do not change the total weight (we call them 0 skips). It can happen however, that even though no 0 skip exists, a collection of skips exists, that can be used independently, and their total weight change is zero (we call them 0 skip sets). Also observe that these skips can come from different cycles of $M \Delta M^*$ and still be used to reduce its total number of edges (i.e. we can modify multiple cycles in $M \Delta M^*$ simultaneously to preserve the total weight change). So by taking $M \Delta M^*$ to be minimal (in terms of total number of edges), we are guaranteed that no such skip sets can exist.

Skips from Paths. To show the existence of skips (which will lead to the desired contradiction), we rely on Ramsey theory to show that if we take a large enough (with respect to α) collection of disjoint paths on an alternating cycle, starting and ending with non-matching edges, then they must form skips. Now if these paths have certain desired weights, then we could make sure that we get a 0 skip set as desired.

Paths from Edge Pairs. To prove the existence of paths of desired weight, we analyze the cycles in $M \Delta M^*$ by looking at their edge pairs, i.e. pairs of consecutive matching and non-matching edges. These edge pairs can have 3 configurations from which we can extract the paths. (1) Consecutive same sign pairs (sign here refers to the weight of the pair), (2) consecutive different sign pairs and (3) consecutive 0 pairs. We show that we can extract paths of the desired properties from all of these configurations, and the types of skips we get is dependent on the weights of the cycles and the sizes of their color classes.

Bounding the Cycle Weights. Next, we show that if $M \Delta M^*$ is minimal, all of its cycles have bounded weight. This is mainly achieved by showing that cycles of large weight must have skips that reduce their weight. This changes the total weight of $M \Delta M^*$ however, and must be compensated for either by skips on a cycle of opposite sign weight, or by removing some of the cycles in $M \Delta M^*$.

Bounding one color class. After bounding the weights of the cycles in $M \Delta M^*$ (by a function of α), we will also bound their number given that their total weight is bounded. With these properties (bounded cycle weights and number of cycles), we can show that if $M \Delta M^*$ has enough edges from both colors, then at least one of its cycles contains enough positive skips and one of its cycles contains enough negative skips, together forming a 0 skip set, i.e. $M \Delta M^*$ is not minimal. So choosing $M \Delta M^*$ minimal implies a bound on the size of one of its color classes.

3.2 Detailed Proof

Skips. We start by formally defining a skip and its properties.

▶ **Definition 6.** *Let C be an alternating cycle. A skip S is a set of two non-matching edges $e_1 := (v_1, v_2)$ and $e_2 := (v_1', v_2')$ with $e_1, e_2 \notin C$ and $v_1, v_1', v_2, v_2' \in C$ (appearing in this order along C) s.t. $C' = e_1 \cup e_2 \cup (C \setminus C[v_1, v_1'] \cup C[v_2, v_2'])$ is an alternating cycle, $|C| - |C'| > 0$ and $|w(S)| \leq 4$ where $w(S) := w(C') - w(C)$ is called the weight of the skip.*

Note that we require a skip to have weight at most 4. This is mainly to simplify the analysis since it is enough to only consider such skips.

If $P \subseteq C$ is a path and $C[v_1, v_2'] \subseteq P$, then we say that P contains the skip S. We say using S to mean replacing C by C'. If $C \in M \Delta M'$ for some PM M', then by using S we also modify M' accordingly (i.e. s.t. $M \Delta M'$ now contains C' instead of C). Observe that a positive skip (where positive refers to the weight of the skip) increases the cycle weight, a negative skip decreases it and a 0 skip does not change the cycle weight. Using a skip always results in a cycle of smaller cardinality. Two skips $\{(v_1, v_2), (v_1', v_2')\}$ and $\{(u_1, u_2), (u_1', u_2')\}$ are called disjoint if they are contained in disjoint paths along the cycle. Note that two disjoint skips can be used independently.

▶ **Definition 7.** *Let $\mathcal{C}$ be a set of alternating cycles. A 0 skip set is a set of disjoint skips on cycles of $\mathcal{C}$ s.t. the total weight of the skips is 0.*

Observe that finding a skip with some desired properties can be done in polynomial time by trying all possible combinations of 2 edges, every time checking if the edges form a skip with the desired properties (i.e. checking if the resulting cycle C' is alternating, has strictly less edges then C and the weight change is as desired, which can all be done in polynomial time).

Skips from Paths. Next, we show that if a cycle contains a lot of disjoint paths then it must contain a skip that replaces 2 of these paths by its 2 edges.

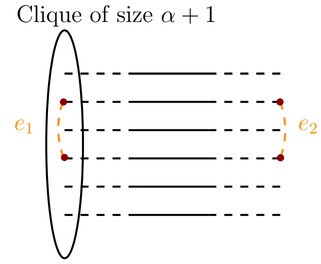

Figure 2 A subset of $\mathcal{P}$ of size $\alpha + 1$ whose starting vertices form a clique.

▶ **Lemma 8.** *Let P be an alternating path containing a set $\mathcal{P}$ of disjoint paths, each of length at least 3 and starting and ending at non-matching edges, of size $|\mathcal{P}| \geq 4^{\alpha}$. Then P contains a skip. If all paths in $\mathcal{P}$ have the same weight x, then if x is one of the following values, we get the following types of skips:*

- $x = 2$: *negative skip.*
- $x = 1$: *negative or 0 skip.*
- $x = 0$: *positive or 0 skip.*
- $x = -1$: *positive skip.*

Proof. The set of starting vertices of the paths in $\mathcal{P}$ must contain a clique Q of size $\alpha + 1$ since $|\mathcal{P}| > Ram(\alpha + 1, \alpha + 1)$ (and the independence number of the graph is α). Let $\mathcal{P}'$ be the set of paths from $\mathcal{P}$ starting with vertices in Q and Q' their set of ending vertices. Since $|Q'| = \alpha + 1$, there must be an edge connecting two of its vertices, call it e_2. Let P_1 and P_2 be the two paths in $\mathcal{P}'$ connected by e_2. Let e_1 be the edge connecting the starting vertices of P_1 and P_2 (which must exist since Q is a clique). Note that e_1 and e_2 must be non-matching edges since they are chords of the alternating cycle C so their endpoints are matched to edges of C. Now observe that e_1 and e_2 form a skip S (see Figure 2) and $w(S) = w(e_1) + w(e_2) - w(P_1) - w(P_2)$. Finally, suppose P_1 and P_2 have weight x and note that $w(e_1), w(e_2) \in \{0, 1\}$ since they are non-matching edges. We get $-2x \leq w(S) \leq 2 - 2x$ thus proving the lemma. ◀

The above lemma only shows the existence of a skip of a certain sign, and does not guarantee the existence of 0 skips, i.e. skips that do not change the cycle weight. The next lemma shows that if there are enough disjoint positive and negative skips we can still obtain a 0 skip set (i.e. we can still reduce the cardinality of $M \Delta M'$ without changing its weight).

▶ **Lemma 9** (⋆). *Let $\mathcal{S}$ be a collection of disjoint skips. If $\mathcal{S}$ contains at least 4 positive skips and at least 4 negative skips (all mutually disjoint), then $\mathcal{S}$ must contain a 0 skip set.*

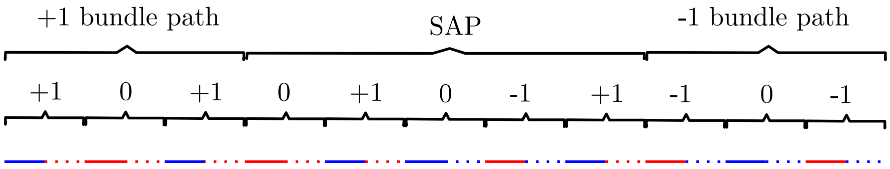

Figure 3 An example of an alternating path containing a $+1$ bundle, a -1 bundle and an SAP. Matching edges are represented by full lines and non-matching edges by dotted lines. The colors of the edges correspond to their color in the graph.

Edge Pairs. For a given alternating cycle, our goal is to find paths of some desired weight in order to apply Lemma 8. To make finding these paths easier, we look at pairs of edges. Each pair consists of two consecutive edges (the first a matching-edge and the second a non-matching edge). We label the pairs according to their weight (see in Figure 3 the label above each pair of edges).

▶ **Definition 10.** *A $+1$ pair (resp. -1 pair and 0 pair) is a pair of consecutive edges (the first a matching-edge and the second a non-matching edge) along an alternating cycle such that their weight sums to 1 (resp. -1 and 0).*

Two $+1$ (resp. -1) pairs are called consecutive if there is an alternating path between them on the cycle which only contains 0 pairs.

▶ **Definition 11.** *A $+1$ (resp. -1) bundle is a pair of edge-disjoint consecutive $+1$ (resp. -1) pairs. The path starting at the first pair and ending at the second one (including both pairs) is referred to as the bundle path (see Figure 3 for an example of such bundles).*

Note that a $+1$ (resp. -1) bundle path has weight $+2$ (resp. -2). Two bundles are called disjoint if their bundle paths are edge disjoint.

▶ **Definition 12.** *A Sign Alternating Path (SAP) is an alternating path P formed by edge pairs, such that it does not contain any bundles (see Figure 3 for an example of such path).*

Note that for an SAP P, $|w(P)| \leq 1$.

Paths from Edge Pairs. Our goal is to bound the number of edges from some color class in $M\Delta M^*$, when the latter is chosen to contain a minimum number of edges. To this end, we aim to show that a large number of edges of both color classes implies the existence of a 0 skip set (which would contradict the minimality of $M\Delta M^*$). By Lemma 9 it suffices to show the existence of many positive and negative skips which in turn can be a result of many paths of certain weight (by Lemma 8).

In the next two lemmas, we first show that a large number of edges of some color class implies the existence of either many bundles, a long SAP or many 0-paths starting with an edge of that color class. Then we show that all of these structures result in paths of the desired weights.

▶ **Lemma 13** ($\star$). *Let P be an alternating path containing at least $10t^3$ blue (resp. red) edges. Then one of the following properties must hold:*
(a) *P contains at least t disjoint bundles.*
(b) *P contains an SAP with at least t non-zero pairs.*
(c) *P contains at least t edge-disjoint 0-paths of length at least 4 starting with a blue (resp. red) matching edge.*

▶ **Lemma 14** (⋆). *A path P, satisfying one of the following properties, must contain t disjoint paths each of length at least 3, starting and ending with non-matching edges and having specific weights that depend on the satisfied property:*

(a) *P contains t disjoint $+1$ bundles: paths of weight $+2$.*
(b) *P contains t disjoint -1 bundles: paths of weight -1.*
(c) *P contains t edge-disjoint 0-paths of length at least 4 starting with a red matching edge: paths of weight $+1$.*
(d) *P contains t edge-disjoint 0-paths of length at least 4 starting with a blue matching edge: paths of weight 0.*
(e) *P contains an SAP with at least $2t+1$ non-zero pairs: paths of weight $+1$.*
(f) *P contains an SAP with at least $2t+1$ non-zero pairs: paths of weight 0.*

While the above lemmas would be enough to show the existence of many skips whenever $M\Delta M^*$ contains many edges from both color classes, these skips can still be of the same sign (e.g. all positive) which is not enough to use Lemma 9. We will later show that this cannot happen if the cycles in $M\Delta M^*$ have bounded weight.

Bounding Cycle Weights. In this part, we will deal with cycles of unbounded weight. We start by showing that a large cycle weight implies the existence of many skips that can be used to reduce it.

▶ **Lemma 15** (⋆). *Let P be an alternating path with $w(P) \geq 2t \cdot 4^{\alpha}$ (resp. $w(P) \leq -2t \cdot 4^{\alpha}$), then P contains at least t disjoint negative (resp. positive) skips.*

The above lemma also allows for simple proof of Theorem 4.

Proof of Theorem 4. Let M_1 be a PM containing a minimum number of red edges and M_2 a PM with a maximum number of red edges (should be at least k). Note that M_1 (resp. M_2) can be computed in polynomial time by simply using a maximum weight perfect matching algorithm with -1 (resp. $+1$) weights assigned to red edges and 0 weights assigned to blue edges.

Now as long as $r(M_1) \leq k - 2 \cdot 4^{\alpha}$ and $r(M_2) > k$ we will apply the following procedure (otherwise we output $M := M_1$): Let $C \in M_1\Delta M_2$ with $w(C) > 0$ (such a cycle must exist since $r(M_1) < r(M_2)$). If $w(C) \leq 2 \cdot 4^{\alpha}$ then we replace M_1 by $M_1\Delta C$ and iterate (note that $r(M_1) < r(M_1\Delta C) \leq k$). Otherwise, by Lemma 15, C contains a negative skip. We find it in polynomial time and use it to reduce the cycle weight, and iterate the whole procedure (note that $r(M_2)$ decreases). If at any point $r(M_2)$ drops below k, we simply output $M := M_2$. In all cases $w(M_1\Delta M_2)$ decreases after every iteration. So there can be at most n iterations (since the PMs have at most $n/2$ edges each, so $w(M_1\Delta M_2) \leq n$ and we only iterate as long as it is bigger than 0), each running in polynomial time. ◀

▶ Remark. Note that the proof only relies on Lemma 15 which in turn only relies on Lemma 8 and the part of Lemma 14 that deals with bundles. Most of the previously defined notions are not needed for this standalone result.

From Lemma 15 we get that if $M\Delta M^*$ contains both a positive cycle of unbounded weight and a negative cycle of unbounded weight, we can find a 0 skip set using Lemma 9. It could be the case however, that we have only one of the two, say a positive cycle of unbounded weight (with respect to α), and many negative weight cycles (which would be required if $|w(M\Delta M^*)|$ is bounded, which is guaranteed by the first phase of the algorithm). In this case we can get many negative skips from the positive weight cycle of unbounded weight but we are not guaranteed to find positive skips, so we need another way to compensate for the total weight change. Notice that this can be achieved by removing negative cycles from $M\Delta M^*$. So we will combine the use of negative skips with the removal of some of the negative cycles in order to get a zero total weight change. We call this a 0 skip-cycle set.

▶ **Definition 16.** *Let $\mathcal{C}$ be a set of alternating cycles. A 0 skip-cycle set is a set of disjoint skips on cycles of $\mathcal{C}$ and/or cycles from $\mathcal{C}$, s.t. the total weight of the skips minus the total weight of the cycles is 0.*

We say that we use a skip-cycle set $\mathcal{S}$ to mean that we use all skips in $\mathcal{S}$ and remove all cycles in $\mathcal{S}$ from $\mathcal{C}$. Note that a 0 skip set is a 0 skip-cycle set. Also a cycle $C \in M\Delta M^*$ with $w(C) = 0$ is a 0 skip-cycle set. The following lemma shows that if a set of alternating cycles has bounded weight but one of its cycles has an unbounded weight then it must contain a 0 skip-cycle set.

▶ **Lemma 17** ($\star$). *Let $t \geq 8 \cdot 4^{\alpha}$ and $t' = 4t^2$. Let $\mathcal{C}$ be a set of alternating cycles and $C \in \mathcal{C}$ s.t. $|w(\mathcal{C})| \leq t'$ and $|w(C)| \geq 2t'$, then $\mathcal{C}$ contains a 0 skip-cycle set.*

Bounding one color class. So far we have shown that we can bound the weight of the cycles in $M\Delta M^*$ (if $M\Delta M^*$ is minimal). What we want to show next is that if $M\Delta M^*$ contains many blue (resp. red) edges and all of its cycles have bounded weight, then it also contains many positive (resp. negative) skips. This way we show that having many edges of both color classes results in a 0 skip set.

First we deal with the case when the number of cycles in $M\Delta M^*$ is unbounded. The following lemma shows that if the number of cycles is large enough compared to their individual and total weights, then there must be a subset of them of 0 total weight (i.e., a 0 skip-cycle set).

▶ **Lemma 18** ($\star$). *Let $t \geq 3$. Let $\mathcal{C}$ be a set of alternating cycles s.t. $|w(\mathcal{C})| \leq t$, $|w(C)| \leq 2t$ for all $C \in \mathcal{C}$ and $|\mathcal{C}| \geq 10t^3$, then $\mathcal{C}$ contains a 0 skip-cycle set.*

Now we deal with the case when the number of cycles in $M\Delta M^*$ is bounded. In this case, for the number of edges of some color class to be unbounded, it has to be unbounded on at least one of the cycles. Lemma 21 deals with this case by first using Lemma 13 to show the existence of many bundles, many 0-paths starting with a red edge and many 0-paths starting with a blue edge, or a long SAP. In the latter two cases, we can prove the existence of both positive and negative skips resulting in a 0 skip set. In the case of bundles however, we need to have both many $+1$ and many -1 bundles for this to work. In Lemma 19 we show that if the weight of an alternating cycle is bounded, then the difference between the number of $+1$ and -1 bundles is also bounded. This in turn allows us to prove that the existence of many bundles results in a 0 skip set as well (see Lemma 20).

▶ **Lemma 19** ($\star$). *Let C be a cycle with $|w(C)| \leq l$. If C contains $3t + l$ disjoint -1 (resp. $+1$) bundles, then C also contains at least t disjoint $+1$ (resp. -1) bundles.*

▶ **Lemma 20** ($\star$). *Let $t \geq 8 \cdot 4^{\alpha}$. Let C be a cycle with $|w(C)| \leq 2t$. If C contains more than $10t$ disjoint bundles then it must contain a 0 skip set.*

▶ **Lemma 21** ($\star$). *Let $t \geq 8 \cdot 4^{\alpha}$. Let $\mathcal{C}$ be a collection of cycles s.t. $|\mathcal{C}| \leq 10t^3$, $|w(C)| \leq 2t$ for all $C \in \mathcal{C}$ and $\mathcal{C}$ contains at least $1000t^6$ blue edges and $1000t^6$ red edges, then $\mathcal{C}$ contains a 0 skip set.*

Proof of Theorem 1. Use the algorithm of Theorem 4 to get a matching M s.t. $k - 2 \cdot 4^{\alpha} \leq r(M) \leq k$. Let M^* be a PM with k red edges that minimizes $|E(M \Delta M^*)|$. Consider the set of cycles $M \Delta M^*$. Observe that it cannot contain a 0 skip-cycle set (by minimality of its number of edges) and $|w(M \Delta M^*)| \leq |k - r(M)| \leq 2 \cdot 4^{\alpha}$. Let $t = 256 \cdot 4^{2\alpha}$ (so t is large enough to apply all the previous lemmas). If some cycle $C \in M \Delta M^*$ has $|w(C)| \geq 2t$, by Lemma 17 we get a 0 skip-cycle set. So we consider the case when all cycles $C \in M \Delta M^*$ have $|w(C)| < 2t$. If $M \Delta M^*$ contains at least $10t^3$ cycles, by Lemma 18 we get a 0 skip set. So we consider the case when $|M \Delta M^*| \leq 10t^3$. By Lemma 21, since $M \Delta M^*$ does not contain a 0 skip set, it must contain at most $f(\alpha)$ edges of some color class (for $f(\alpha) = 1000 \cdot (256 \cdot 4^{2\alpha})^6 = 2^{O(\alpha)}$). By Proposition 5 we can find a PM with exactly k red edges in $n^{O(f(\alpha))}$ time if one exists. ◀

4 Bipartite Graphs

In this section, we consider Bipartite graphs, which contain very large independent sets ($\geq n/2$). For this reason, we instead parameterize by the bipartite independence number β. Note that for the proof of Theorem 1 the only time we used the bounded independence number is in the proof of Lemma 8. So we need an analogue of it that works for bounded bipartite independence number, which will be given in Lemma 23. We will also need a new notion of a skip that better fits the bipartite case. We call it a biskip (see Definition 22 and Figure 4). We will also rely on an orientation of the edges of the graph defined as follows. Given a bipartite graph G with bipartition (A, B) and a matching M, we transform G into a directed graph G_M by orienting every matching edge from A to B and every non-matching edge from B to A.

▶ **Definition 22.** *Let C be a directed alternating cycle. A biskip S is a set of 2 arcs $a_1 := (v_1, v_2)$ and $a_2 := (v_1', v_2')$ with $a_1, a_2 \notin C$ and $v_1, v_2', v_1', v_2 \in C$ (appearing in this order along C) s.t. $C_1 := C[v_2, v_1] \cup a_1$ and $C_2 := C[v_2', v_1'] \cup a_2$ are vertex disjoint alternating cycles, $|C| - |C_1| - |C_2| > 0$ and $|w(S)| \leq 4$ where $w(S) := w(C_1) + w(C_2) - w(C)$ is called the weight of the biskip.*

If $P \subseteq C$ is a path and $C[v_1, v_2] \subseteq P$, then we say that P contains the biskip S. We say using S to mean replacing C by C_1 and C_2. If $C \in M \Delta M'$ for some PM M', then by using S we also modify M' accordingly (i.e. s.t. $M \Delta M'$ now contains C_1 and C_2 instead of C). Two skips $\{(v_1, v_2), (v_1', v_2')\}$ and $\{(u_1, u_2), (u_1', u_2')\}$ are called disjoint if they are contained in disjoint paths.

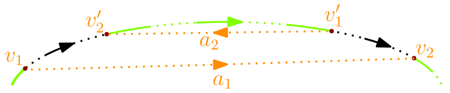

Figure 4 A biskip formed by two non-matching arcs a_1 and a_2 (in orange). Matching edges are represented by full lines and non-matching edges by dotted lines. The paths removed by the biskip are depicted in black.

▶ Remark. Note that the biskip could have been defined with one arc instead of two (since in this case one arc is enough to shorten an alternating cycle), which would have made the definition simpler. Definition 22 is however, very similar to the definition of the skip (see Definition 6) and this in turn allows us to prove Theorem 2 in an analogous way to Theorem 1 instead of requiring a completely different proof.

▶ **Lemma 23.** *Let $P \subseteq G_M$ be a directed alternating path containing a set $\mathcal{P}$ of disjoint directed paths, each of length at least 3 and starting and ending at a non-matching edge, s.t. $|\mathcal{P}| \geq 4^{2\beta+2}$. Then P contains a biskip. If all paths in $\mathcal{P}$ have the same weight x, then if x is one of the following values, we get the following types of biskips:*

- *$x = 2$: negative biskip.*
- *$x = 1$: negative or 0 biskip.*
- *$x = 0$: positive or 0 biskip.*
- *$x = -1$: positive biskip.*

Proof. Consider the graph G_C defined as follows: $V(G_C) = \mathcal{P}$, there is an edge between two vertices if their corresponding paths have an arc that goes from the start vertex of the first path to the end vertex of the second.

▷ Claim. G_C has independence number bounded by $2\beta + 1$.

Proof. Take any subset Q of vertices of G_C of size $2\beta + 2$. Let Q_1 be $\beta + 1$ consecutive (along C) vertices of Q and Q_2 the rest. Let V_1 be the set of start vertices of the paths corresponding to Q_1 in G_M and V_2 be the set of end vertices of the paths corresponding to Q_2 in G_M. Observe that $V_1 \cup V_2$ is a balanced set of size $2\beta + 2$, so there must be an arc connecting two of its vertices. Observe that the arc must be going from V_1 to V_2 since it corresponds to a non-matching edge. So G_C contains an edge corresponding to this arc, i.e. Q is not an independent set. ◁

G_C must contain a clique Q of size $2\beta + 2$ since $|V(G_C)| = |\mathcal{P}| \geq \mathit{Ram}(2\beta + 2, 2\beta + 2)$. Let Q_1 be $\beta + 1$ consecutive (along C) vertices of Q and Q_2 the rest. Let V_1 be the set of end vertices of the paths corresponding to Q_1 in G_M and V_2 be the set of start vertices of the paths corresponding to Q_2 in G_M. Observe that $V_1 \cup V_2$ is a balanced set of size $2\beta + 2$, so there must be an arc (call it a_1) connecting two of its vertices. Observe that the arc must be going from V_2 to V_1 since it corresponds to a non-matching edge. Let P_1 and P_2 be the paths corresponding to its start and end vertices. P_1 and P_2 must be connected by an edge in Q, let a_2 be the corresponding arc in G_M. So a_2 connects the start of P_1 to the end of P_2 and a_1 connects the start of P_2 to the end of P_1. Observe that a_1 and a_2 form a biskip S and $w(S) = w(a_1) + w(a_2) - w(P_1) - w(P_2)$. Let $x = w(P_1) = w(P_2)$ (x depends on the type of paths considered) and note that $w(e_1), w(e_2) \in \{0, 1\}$. We get $-2x \leq w(S) \leq 2 - 2x$ thus proving the lemma. ◀

The rest of the proof of Theorem 2 follows the same structure as that of Theorem 1 while using biskips instead of skips. Due to lack of space we will defer all the details to the appendix where we will restate all the definitions and lemmas that need to be adapted.

5 Distance-d Independence Number

In this section we show that the algorithms developed for small independence number graphs cannot be generalized to distance-d independence number, for $d > 2$, unless they can be used to solve EM on any graph. A distance-d independent set is a set of vertices at pairwise distance at least d (i.e. the shortest path between any two of them contains at least d edges) and the distance-d independence number is the size of the largest such set. Note that for $d = 2$ we get the normal independence number. Let $\alpha_d(G)$ be the distance-d independence number of a graph G.

▶ **Theorem 24.** *EM can be reduced to EM on graphs with $\alpha_d(G) = 1$, for any $d > 2$, in deterministic polynomial time.*

Proof. Given a graph $G = (V, E)$ we construct another graph $G' = (V', E')$ by adding two new vertices u and v s.t. $V' = V \cup \{u, v\}$ and $E' := E \cup (u, v) \cup \{(u, x) : x \in V\}$. All edges in E keep their colors while new edges get color blue. Observe that any PM on G' must contain (u, v) since it is the only edge connected to v, so by removing this edge from the PM we get a PM for G. Also note that G' has distance-d independence number of 1, for any $d > 2$, since any two vertices are connected to u, i.e. have distance 2. Now if there exists a PM M with exactly k red edges in G', we know that $M\backslash(u, v)$ is a PM with exactly k red edges in G. ◀

A similar theorem applies for bipartite graphs. Note that here we do not need to consider balanced independent sets (a similar result holds if we do).

▶ **Theorem 25.** *EM on bipartite graphs can be reduced to EM on bipartite graphs with $\alpha_d(G) = 2$, for any $d > 2$, in deterministic polynomial time.*

Proof. Given a bipartite graph $G = (U, V, E)$ we construct another bipartite graph $G' = (U', V', E')$ s.t. $U' = U \cup \{u, u'\}$, $V' = V \cup \{v, v'\}$ and $E' := E \cup \{(u, x) : x \in V'\} \cup \{(v, x) : x \in U'\}$. All edges in E keep their colors while new edges get color blue. Observe that any PM on G' must contain (u, v') and (v, u') since they are the only edges connected to u' and v', so by removing these edges from the PM we get a PM for G. Also note that G' has distance-d independence number of 2, for any $d \geq 2$, since it can contain at most one vertex from each of U' and V' (any two vertices of U' are connected to v, and any two vertices of V' are connected to u). Now if there exists a PM M with exactly k red edges in G', we know that $M\backslash((u, v') \cup (v, u'))$ is a PM with exactly k red edges in G. ◀

6 Conclusion and Open Problems

In this paper we initiated the study of the parameterized complexity of EM by showing that it can be solved in deterministic polynomial time on graphs of bounded independence number and bipartite graphs of bounded bipartite independence number (i.e. we developed XP algorithms). This is an important step towards finding the right complexity class of the problem in general graphs as it generalizes the only previously known results on dense graph classes which were restricted to complete (bipartite) graphs.

A natural next step would be to design corresponding FPT-algorithms in which the exponent in the running time is independent of the independence number. Another future direction would be to study the parameterized complexity of EM for other graph parameters. As we showed, parameterizing by higher distance independence numbers does not provide any additional structure, so it would be interesting to find other parameters that could yield non-trivial structure. Finally, it would be interesting to prove our conjecture on the hardness of counting PMs in graphs of independence number 2 or to find deterministic polynomial time algorithms for EM that work on graph classes for which counting PMs is #**P**-hard.

Abstract

The minimum number of clauses in a CNF representation of the parity function $x_1 \oplus x_2 \oplus \cdots \oplus x_n$ is 2^{n-1}. One can obtain a more compact CNF encoding by using non-deterministic variables (also known as guess or auxiliary variables). In this paper, we prove the following lower bounds, that almost match known upper bounds, on the number m of clauses and the maximum width k of clauses: 1) if there are at most s auxiliary variables, then $m \geq \Omega\left(2^{n/(s+1)}/n\right)$ and $k \geq n/(s+1)$; 2) the minimum number of clauses is at least $3n$. We derive the first two bounds from the Satisfiability Coding Lemma due to Paturi, Pudlák, and Zane using a tight connection between CNF encodings and depth-3 circuits. In particular, we show that lower bounds on the size of a CNF encoding of a Boolean function imply depth-3 circuit lower bounds for this function.

1 Overview

1.1 Motivation

A popular approach for solving a difficult combinatorial problem in practice is to encode it in conjunctive normal form (CNF) and to invoke a SAT-solver. There are two main reasons why this approach works well for many hard problems: the state-of-the-art SAT-solvers are extremely efficient and many combinatorial problems are expressed naturally in CNF. At the same time, a CNF encoding is not unique and one usually determines a good encoding empirically. Moreover, there is no such thing as the best encoding of a given problem as it also depends on a SAT-solver at hand. Prestwich [10] gives an overview of various ways to translate problems into CNF and discusses their desirable properties, both from theoretical and practical points of view.

Already for such simple functions as the parity function $x_1 \oplus x_2 \oplus \cdots \oplus x_n$, it is not immediate how to encode them in CNF (to make it efficiently handled by SAT-solvers). Parity function is used frequently in cryptography (hash functions, stream ciphers, etc.). It is known that the minimum number of clauses in a CNF computing parity is 2^{n-1}. This becomes impractical quickly as n grows. A standard way to reduce the size of an encoding is by using non-deterministic variables (also known as guess or auxiliary variables). Namely, one introduces s non-deterministic variables $y_1, \dots, y_s$ and partitions the set of input variables into $s+1$ blocks of size at most $\lceil n/(s+1) \rceil$: $\{x_1, x_2, \dots, x_n\} = X_1 \sqcup X_2 \sqcup \dots \sqcup X_{s+1}$. Then, one writes down the following $s+1$ parity functions in CNF:

$$\left(y_1 = \bigoplus_{x \in X_1} x\right), \left(y_2 = y_1 \oplus \bigoplus_{x \in X_2} x\right), \dots,$$
$$\left(y_s = y_{s-1} \oplus \bigoplus_{x \in X_s} x\right), \left(1 = y_s \oplus \bigoplus_{x \in X_{s+1}} x\right). \quad (1)$$

The value for the parameter s is usually determined experimentally. For example, Prestwich [9] reports that taking $s = 10$ gives the best results when solving the minimal disagreement parity learning problem using local search based SAT-solvers.

The simple construction above implies several upper bounds on the number m of clauses, the number s of non-deterministic variables, and the width k of clauses:

Limited non-determinism: using s non-deterministic variables, one can encode parity either as a CNF with at most

$$m \le (s+1)2^{\lceil n/(s+1) \rceil + 2 - 1} \le 4(s+1)2^{n/(s+1)}$$

clauses or as a k-CNF, where

$$k = 2 + \lceil n/(s+1) \rceil \le 3 + n/(s+1)\,.$$

Unlimited non-determinism: one can encode parity as a CNF with at most $4n$ clauses (to do this, use $s = n-1$ non-deterministic variables; then, each of n functions in (1) can be written in CNF using at most four clauses).

1.2 Results

In this paper, we show that the upper bounds mentioned above are essentially optimal.

▶ **Theorem 1.** *Let F be a CNF-encoding of PAR_n with m clauses, s non-deterministic variables, and maximum clause width k.*

1. *The parameters s and m cannot be too small simultaneously:*

$$m \ge \Omega\left(\frac{s+1}{n} \cdot 2^{n/(s+1)}\right). \quad (2)$$

2. *The parameters s and k cannot be too small simultaneously:*

$$k \ge n/(s+1)\,. \quad (3)$$

3. *The parameter m cannot be too small:*

$$m \ge 3n - 9\,. \quad (4)$$

1.3 Techniques

We derive a lower bound $m \ge \Omega((s+1)2^{n/(s+1)}/n)$ from the Satisfiability Coding Lemma due to Paturi, Pudlák, and Zane [8]. This lemma allows to prove a $2^{\sqrt{n}}$ lower bound on the size of depth-3 circuits computing the parity function. Interestingly, the lower bound $m \ge \Omega((s+1)2^{n/(s+1)}/n)$ implies a lower bound $2^{\Omega(\sqrt{n})}$ almost immediately, though it is not clear whether a converse implication can be easily proved.

To prove a lower bound $m \ge 3n - 9$, we analyze carefully the structure of a CNF encoding.

1.4 Related work

Many results for various computational models with limited non-determinism are surveyed by Goldsmith, Levy, and Mundhenk [2]. An overview of known approaches for CNF encodings is given by Prestwich [10]. Two recent results that are close to the results of this paper are the following. Morizumi [7] proved that non-deterministic inputs do not help in the model of Boolean circuits over the U_2 basis (the set of all binary functions except for the binary parity and its complement) for computing the parity function: with and without non-deterministic inputs, the minimum size of a circuit computing parity is $3(n-1)$. Kucera, Savický, Vorel [5] prove almost tight bounds on the size of CNF encodings of the at-most-one Boolean function ($[x_1+\dots+x_n \le 1]$). Sinz [11] proves a linear lower bound on the size of CNF encodings of the at-most-k Boolean function.

2 General setting

2.1 Computing Boolean functions by CNFs

For a Boolean function $f(x_1,\dots,x_n)\colon \{0,1\}^n \to \{0,1\}$, we say that a CNF $F(x_1,\dots,x_n)$ *computes* f if $f \equiv F$, that is, for all $x_1,\dots,x_n \in \{0,1\}$, $f(x_1,\dots,x_n) = F(x_1,\dots,x_n)$. We treat a CNF as a set of clauses and by the *size* of a CNF we mean its number of clauses. It is well known that for every function f, there exists a CNF computing it. One way to construct such a CNF is the following: for every input $x \in \{0,1\}^n$ such that $f(x)=0$, populate a CNF with a clause of length n that is falsified by x.

This method does not guarantee that the produced CNF has the minimal number of clauses: this would be too good to be true as the problem of finding a CNF of minimum size for a given Boolean function (specified by its truth table) is NP-complete as proved by Masek [6] (see also [1] and references herein). For example, for a function $f(x_1,x_2)=x_1$ the method produces a CNF $(\overline{x_1} \lor x_2) \land (\overline{x_1} \lor \overline{x_2})$ whereas the function x_1 is already in CNF format.

2.2 Parity

It is well known that for many functions, the minimum size of a CNF is exponential. The canonical example is the parity function $\mathrm{PAR}_n(x_1,\dots,x_n) = x_1 \oplus \dots \oplus x_n$. The property of PAR_n that prevents it from being computable by short CNF's is its high *sensitivity*: by flipping *any* bit in *any* input $x \in \{0,1\}^n$, one flips the value of $\mathrm{PAR}_n(x)$.

▶ **Lemma 2.** *The minimum size of a CNF computing* PAR_n *has size* 2^{n-1}.

Proof. An upper bound follows from the method above by noting that $|\mathrm{PAR}_n^{-1}(0)| = 2^{n-1}$.

A lower bound is based on the fact that any clause of a CNF F computing PAR_n must contain all variables $x_1,\dots,x_n$. Indeed, if a clause $C \in F$ did not depend on x_i, one could find an input $x \in \{0,1\}^n$ that falsifies C (hence, $F(x) = \mathrm{PAR}_n(x) = 0$) and remains to be falsifying even after flipping x_i. As any clause of F has exactly n variables, it rejects exactly one $x \in \{0,1\}^n$. Hence, F must contain at least $|\mathrm{PAR}_n^{-1}(0)| = 2^{n-1}$ clauses. ◀

2.3 Encoding Boolean functions by CNFs

We say that a CNF F *encodes* a Boolean function $f(x_1,\dots,x_n)$ if the following two conditions hold.

1. In addition to the input bits $x_1, \dots, x_n$, F also depends on s bits $y_1, \dots, y_s$ called *guess inputs* or *non-deterministic inputs*.
2. For every $x \in \{0,1\}^n$, $f(x) = 1$ iff there exists $y \in \{0,1\}^s$ such that $F(x,y) = 1$. In other words, for every $x \in \{0,1\}^n$,

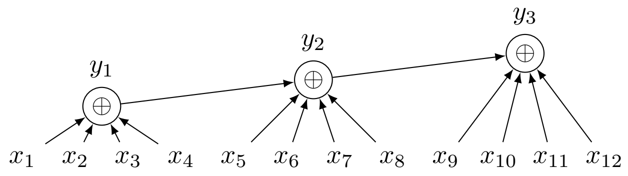
$$f(x) = \bigvee_{y \in \{0,1\}^s} F(x,y)\,. \tag{5}$$

Such representations of Boolean functions are widely used in practice when one translates a problem to SAT. For example, the following CNF encodes PAR$_4$:

$$(x_1 \vee x_2 \vee \overline{y_1}) \wedge (x_1 \vee \overline{x_2} \vee y_1) \wedge (\overline{x_1} \vee x_2 \vee y_1) \wedge (\overline{x_1} \vee \overline{x_2} \vee \overline{y_1}) \wedge (y_1 \vee x_3 \vee \overline{y_2}) \wedge \\ (y_1 \vee \overline{x_3} \vee y_2) \wedge (\overline{y_1} \vee x_3 \vee y_2) \wedge (\overline{y_1} \vee \overline{x_3} \vee \overline{y_2}) \wedge (\overline{x_4} \vee y_2) \wedge (x_4 \vee \overline{y_2})\,. \tag{6}$$

2.4 Boolean Circuits and Tseitin Transformation

A natural way to get a CNF encoding of a Boolean function f is to take a circuit computing f and apply Tseitin transformation [12]. We describe this transformation using a toy example. The following circuit computes PAR$_{12}$ with three gates. It has 12 inputs, 3 gates (one of which is an output gate), and has depth 3.

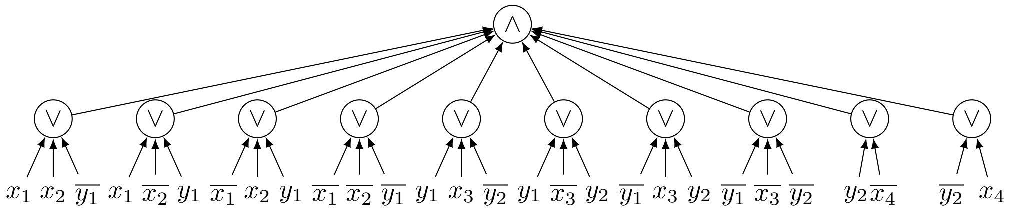


y_1
y_2
y_3
$\oplus$
$\oplus$
$\oplus$
x_1 x_2 x_3 x_4 x_5 x_6 x_7 x_8 x_9 x_{10} x_{11} x_{12}

$$y_1 = x_1 \oplus x_2 \oplus x_3 \oplus x_4$$
$$y_2 = y_1 \oplus x_5 \oplus x_6 \oplus x_7 \oplus x_8$$
$$y_3 = y_2 \oplus x_9 \oplus x_{10} \oplus x_{11} \oplus x_{12}$$

To the right of the circuit, we show the functions computed by each gate. One can translate each line into CNF. Adding a clause (y_3) to the resulting CNF gives a CNF encoding of the function computed by the circuit. In fact, the CNF (1) can be obtained this way (after propagating the value of the output gate).

A CNF can be viewed as a depth-2 circuit where the output gate is an AND, all other gates are ORs, and the inputs are variables and their negations. For example, the following circuit corresponds to a CNF (6). Such depth-2 circuits are also denoted as AND $\circ$ OR circuits.



$\wedge$
$\vee$ $\vee$ $\vee$ $\vee$ $\vee$ $\vee$ $\vee$ $\vee$ $\vee$ $\vee$
x_1 x_2 $\overline{y_1}$ x_1 $\overline{x_2}$ y_1 $\overline{x_1}$ x_2 y_1 $\overline{x_1}$ $\overline{x_2}$ $\overline{y_1}$ y_1 x_3 $\overline{y_2}$ y_1 $\overline{x_3}$ y_2 $\overline{y_1}$ x_3 y_2 $\overline{y_1}$ $\overline{x_3}$ $\overline{y_2}$ y_2 $\overline{x_4}$ $\overline{y_2}$ x_4

2.5 Depth-3 circuits

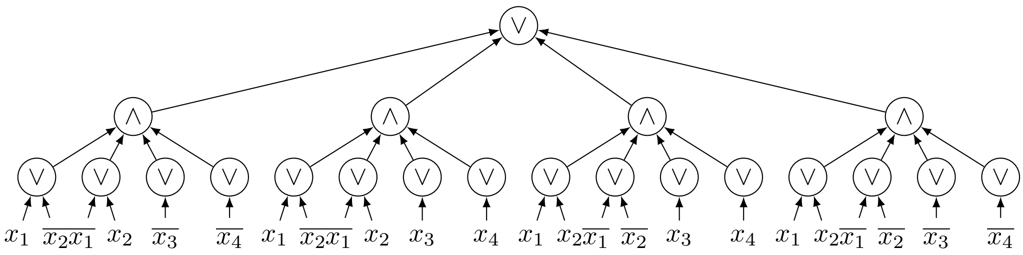
Depth-3 circuits is a natural generalization of CNFs: a Σ_3-*circuit* is simply an OR of CNFs. In a circuit, these CNFs are allowed to share clauses. A Σ_3-*formula* is a Σ_3-circuit whose CNFs do not share clauses (in other words, it is a circuit where the out-degree of every gate is equal to one).

On the one hand, this computation model is still simple enough. On the other hand, proving lower bounds against this model is much harder: getting a $2^{\omega(n)}$ lower bound for an explicit function (say, from NP or E^{NP}) is a major challenge. Proving a lower bound $2^{\omega(n/\log\log n)}$ would resolve another open question, through Valiant's depth reduction [13]: proving a superlinear lower bound on the size of logarithmic depth circuits. We refer the reader to Jukna's book [4, Chapter 11] for an exposition of known results for depth-3 circuits. For the parity function, the best known lower bound on depth-3 circuits is $\Omega(2^{\sqrt{n}})$ [8]. If one additionally requires that a circuit is a formula, i.e., that every gate has out-degree at most 1, then the best lower bound is $\Omega(2^{2\sqrt{n}})$ [3]. Both lower bounds are tight up to polynomial factors.

Equation (5) shows a tight connection between CNF encodings and depth-3 circuits of type $\mathrm{OR} \circ \mathrm{AND} \circ \mathrm{OR}$. Namely, let $F(x_1, \dots, x_n, y_1, \dots, y_s) = \{C_1, \dots, C_m\}$ be a CNF encoding of a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$. Then, $f(x) = \vee_{y \in \{0,1\}^s} F(x, y)$. By assigning y's in all 2^s ways, one gets an Σ_3-formula that computes f:

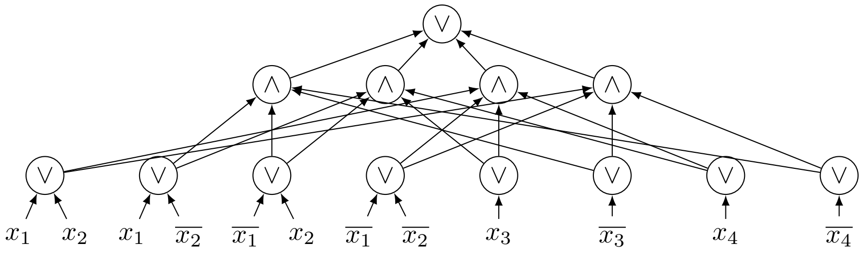
$$f(x) = \bigvee_{j \in [2^s]} F_j(x)\,, \tag{7}$$

where each F_j is a CNF. We call this an *expansion* of F. For example, an expansion of a CNF (6) looks as follows. It is an OR of four CNFs.



x_1 $\overline{x_2}$ $\overline{x_1}$ x_2 $\overline{x_3}$ $\overline{x_4}$ x_1 $\overline{x_2}$ $\overline{x_1}$ x_2 x_3 x_4 x_1 x_2 $\overline{x_1}$ $\overline{x_2}$ x_3 x_4 x_1 x_2 $\overline{x_1}$ $\overline{x_2}$ $\overline{x_3}$ $\overline{x_4}$

An expansion is a formula: it is an OR of CNFs, every gate has out-degree one. One can also get a *circuit-expansion*: in this case, gates are allowed to have out-degree more than one; alternatively, CNFs are allowed to share clauses. For example, this is a circuit-expansion of (6).



x_1 x_2 x_1 $\overline{x_2}$ $\overline{x_1}$ x_2 $\overline{x_1}$ $\overline{x_2}$ x_3 $\overline{x_3}$ x_4 $\overline{x_4}$

Below, we show that CNF encodings and depth-3 circuits can be easily transformed one into the other. It will prove convenient to define the size of a circuit as its number of gates *excluding* the output gate. This way, the size of a CNF formula equals its number of clauses (a CNF is a depth-2 formula). By a $\Sigma_3(t, r)$-circuit we denote a Σ_3-circuit having at most t ANDs on the second layer and at most r ORs on the third layer (hence, its size is at most $t + r$).

▶ **Lemma 3.** *Let $F(x_1, \dots, x_n, y_1, \dots, y_s)$ be a CNF encoding of size m of a function $f\colon \{0,1\}^n \to \{0,1\}$. Then, f can be computed by a $\Sigma_3(2^s, m \cdot 2^s)$-formula and by a $\Sigma_3(2^s, m)$-circuit.*

Proof. Let $F = \{C_1, \dots, C_m\}$. To expand F as $\bigvee_{j \in [2^s]} F_j$, we go through all 2^s assignments to non-deterministic variables $y_1, \dots, y_s$. Under any such assignment, each clause C_i is either satisfied or becomes a clause $C'_i \subseteq C_i$ resulting from C_i by removing all its non-deterministic variables. Thus, for each $j \in [2^s]$, $F_j \subseteq \{C'_1, \dots, C'_m\}$. The corresponding Σ_3-formula contains at most $2^s + m2^s$ gates: there are 2^s gates for F_j's, each F_j contains no more than m clauses. The corresponding Σ_3-circuit contains no more than $2^s + m$ gates: there are 2^s gates for F_j's and m gates for $C'_1, \dots, C'_m$ (each F_j selects which of these m clauses to contain). ◀

Interestingly, the upper bounds on depth-3 circuits resulting from this simple transformation cannot be substantially improved. Indeed, by plugging in a CNF encoding of PAR_n with $s = \sqrt{n}$ and $m = O(\sqrt{n}2^{\sqrt{n}})$ (see (1)), one gets a Σ_3-formula and a Σ_3-circuit of size $2^{2\sqrt{n}}$ and $2^{\sqrt{n}}$, respectively, up to polynomial factors. As discussed above, these bounds are known to be optimal.

Below, we show a converse transformation.

▶ **Lemma 4.** *Let C be a $\Sigma_3(t, r)$-formula (circuit) computing a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$. Then, f can be encoded as a CNF with $\lceil \log t \rceil$ non-deterministic variables of size r ($2rt$, respectively).*

Proof. Let $C = F_1 \vee \dots \vee F_t$ be a Σ_3-formula (hence, $r = \mathrm{size}(F_1) + \dots + \mathrm{size}(F_t)$). Introduce $s = \lceil \log t \rceil$ non-deterministic variables $y_1, \dots, y_s$. Then, for every assignment to $y_1, \dots, y_s$, take the corresponding CNF F_i ($1 \le i \le 2^s$ is the unique integer corresponding to this assignment) and add y_i's with the corresponding signs to every clause of F_i. Call the resulting CNF F'_i. Then, $F = F'_1 \wedge \dots \wedge F'_{2^s}$ encodes f and F has at most r clauses.

If C is a Σ_3-circuit, we need to create a separate copy of every gate corresponding to a clause in each of 2^s CNFs. Hence, the size of the resulting CNF encoding is at most $r2^s \le 2rt$. ◀

Finally, we show that proving strong lower bounds on the size of CNF encodings is not easier than proving strong lower bounds on the size of depth-3 circuits. Let C be a $\Sigma_3(t, r)$-formula computing PAR_n. Lemma 4 guarantees that PAR_n can be encoded as a CNF of size r with $\lceil \log t \rceil$ non-deterministic variables. Then, by the inequality (2),

$$\mathrm{size}(C) = t + r \ge t + \Omega\left(\frac{1}{n} \cdot 2^{\frac{n}{\log t + 2}}\right) \ge \frac{1}{n}\left(t + \Omega\left(2^{\frac{n}{\log t + 2}}\right)\right) \ge \Omega\left(\frac{2^{\sqrt{n}}}{n}\right) .$$

Similarly, if C is a $\Sigma_3(t, r)$-circuit, Lemma 4 guarantees that PAR_n can be encoded as a CNF of size $2rt$ with $\lceil \log t \rceil$ non-deterministic variables. Then,

$$\mathrm{size}(C) = t + r \ge t + \Omega\left(\frac{1}{2tn} \cdot 2^{\frac{n}{\log t + 2}}\right) \ge \Omega\left(\frac{2^{\sqrt{n/2}}}{n}\right) .$$

3 Lower bounds for CNF encodings of parity

In this section, we prove Theorem 1. The essential property of the parity function used in the proof is its high sensitivity (every satisfying assignment is isolated): for any $i \in [n]$ and any $x, x' \in \{0,1\}^n$ that differ in the i-th position only, $\mathrm{PAR}(x) \neq \mathrm{PAR}(x')$. This means that if a CNF F computes PAR and $F(x) = 1$, then F must contain a clause that is satisfied by x_i only. Following [8], we call such a clause *critical* with respect to (x, i). This notion extends to CNF encodings in a natural way. Namely, let $F(x, y)$ be a CNF encoding of PAR. Then, for any (x, y) such that $F(x, y) = 1$ and any $i \in [n]$, F contains a clause that becomes falsified if one flips the bit x_i. We call it critical w.r.t. (x, y, i).

3.1 Limited non-determinism

To prove a lower bound $m \geq \Omega((s+1)2^{n/(s+1)}/n)$, we adapt a proof of the $\Omega(n^{1/4}2^{\sqrt{n}})$ lower bound for depth-3 circuits computing PAR_n by Paturi, Pudlák, and Zane [8]. Let $F(x_1, \ldots, x_n)$ be a CNF. For every isolated satisfying assignment $x \in \{0,1\}^n$ of F and every $i \in [n]$, fix a shortest critical clause w.r.t. (x, i) and denote it by $C_{F,x,i}$. Then, for an isolated satisfying assignment x, define its weight w.r.t. F as

$$w_F(x) = \sum_{i=1}^{n} \frac{1}{|C_{F,x,i}|} \,.$$

▶ **Lemma 5** (Lemma 5 in [8]). *For any μ, F has at most $2^{n-\mu}$ isolated satisfying assignments of weight at least μ.*

Proof of (2), $m \geq \Omega\left(\frac{s+1}{n} \cdot 2^{n/(s+1)}\right)$**.** Let $F(x_1, \ldots, x_n, y_1, \ldots, y_s)$ be a CNF encoding of size m of PAR_n. Consider its expansion:

$$\mathrm{PAR}_n(x) = \bigvee_{j \in [2^s]} F_j(x) \,.$$

We extend the definitions of $C_{F,x,i}$ and $w(x)$ to CNFs with non-deterministic variables as follows. Let $x \in \mathrm{PAR}_n^{-1}(1)$ and let $j \in [2^s]$ be the smallest index such that $F_j(x) = 1$. For $i \in [n]$, let $C'_{F,x,i} = C_{F_j,x,i}$ (that is, we simply take the first F_j that is satisfied by x and take its critical clause w.r.t. (x, i)). Then, the weight $w'_F(x)$ of x w.r.t. to F is defined simply as $w_{F_j}(x)$. Clearly,

$$w'_F(x) = \sum_{i \in [n]} \frac{1}{|C'_{(F,x,i)}|} \,.$$

For $l \in [n]$, let also $N_{l,F}(x) = |\{i \in [n] \colon |C'_{F,x,i}| = l\}|$ be the number of critical clauses (w.r.t. x) of length l. Clearly,

$$w'_F(x) = \sum_{l \in [n]} \frac{N_{l,F}(x)}{l} \,. \tag{8}$$

For a parameter $0 < \varepsilon < 1$ to be chosen later, split $\mathrm{PAR}_n^{-1}(1)$ into light and heavy parts:

$$H = \{x \in \mathrm{PAR}_n^{-1}(1) \colon w'_F(x) \geq s + 1 + \varepsilon\} \,,$$
$$L = \{x \in \mathrm{PAR}_n^{-1}(1) \colon w'_F(x) < s + 1 + \varepsilon\} \,.$$

We claim that

$$|H| \leq 2^s \cdot 2^{n-s-1-\varepsilon} \,.$$

Indeed, for every $x \in H$, $w'_F(x) = w_{F_j}(x)$ for some $j \in [2^s]$, and by Lemma 5, F_j cannot accept more than $2^{n-s-1-\varepsilon}$ isolated solutions of weight at least $s + 1 + \varepsilon$. Since $|H| + |L| = |\mathrm{PAR}_n^{-1}(1)| = 2^{n-1}$, we conclude that

$$|L| = 2^{n-1} - |H| \geq (1 - 2^{-\varepsilon})2^{n-1} \,. \tag{9}$$

Let $F = \{C_1, \dots, C_m\}$. For every $k \in [m]$, let $C'_k \subseteq C_k$ be the clause C_k with all non-deterministic variables removed. Hence, for every $j \in [2^s]$, $F_j \subseteq \{C'_1, \dots, C'_m\}$. For $l \in [n]$, let $m_l = |\{k \in [m] \colon |C'_k| = l\}|$ be the number of such clauses of length l. Consider a clause C'_k and let $l = |C'_k|$. Then, there are at most $l2^{n-l}$ pairs (x, i), where $x \in \mathrm{PAR}^{-1}(1)$ and $i \in [n]$, such that $C'_{F,x,i} = C'_k$: there are at most l choices for i, fixing i fixes the values of all l literals in C'_k (all of them are equal to zero except for the i-th one), and there are no more than 2^{n-l} choices for the other bits of x. Recall that $N_{l,F}(x)$ is the number of critical clauses w.r.t. x of length l. Thus, we arrive at the following inequality:

$$m_l \cdot l \cdot 2^{n-l} \geq \sum_{x \in \mathrm{PAR}^{-1}(1)} N_{F,l}(x) \geq \sum_{x \in L} N_{F,l}(x) \,.$$

Then,

$$m = \sum_{l \in [n]} m_l \geq \sum_{l \in [n]} \frac{\sum_{x \in L} N_{F,l}(x)}{l2^{n-l}} = \sum_{x \in L} \sum_{l \in [n]} \frac{N_{F,l}(x)}{l2^{n-l}} = \sum_{x \in L} n2^{-n} \sum_{l \in [n]} \frac{N_{F,l}(x)}{n} \cdot \frac{2^l}{l} \,. \tag{10}$$

To estimate the last sum, let

$$T(x) = \sum_{l \in [n]} \frac{N_{F,l}(x)}{n} \cdot \frac{2^l}{l} = \sum_{l \in [n]} \frac{N_{F,l}(x)}{n} \cdot g(l) \,,$$

where $g(l) = \frac{2^l}{l}$. Since $g(l)$ is convex (for $l > 0$) and $\sum_{l \in [n]} \frac{N_{F,l}(x)}{n} = 1$, Jensen's inequality gives

$$T(x) \geq g\left(\sum_{l \in [n]} \frac{N_{F,l}(x)}{n} \cdot l \right) \,. \tag{11}$$

Further, Sedrakyan's inequality[1] (combined with (8) and $\sum_{l \in [n]} N_{F,l}(x) = n$) gives

$$\sum_{l \in [n]} l N_{F,l}(x) = \sum_{l \in [n]} \frac{N^2_{F,l}(x)}{N_{F,l}(x)/l} \geq \frac{\left(\sum_{l \in [n]} N_{F,l}(x)\right)^2}{\sum_{l \in [n]} N_{F,l}(x)/l} = \frac{n^2}{w'_F(x)} \,. \tag{12}$$

Since $g(l)$ is monotonically increasing for $l \geq 1/\ln 2$ and $w'_F(x) < s + 1 + \varepsilon$ for every $x \in L$, combining (11) and (12), we get

$$T(x) \geq g\left(\frac{n}{w'_F(x)}\right) \geq g\left(\frac{n}{s+1+\varepsilon}\right) \,, \tag{13}$$

for $s \leq n \ln 2 - 1 - \varepsilon$. (If $s > n \ln 2 - 1 - \varepsilon$, then the lower bound $m \geq \Omega(2^{n/(s+1)}/n)$ is trivial.)

[1] Sedrakyan's inequality is a special case of Cauchy–Schwarz inequality: for all $a_1, \dots, a_n \in \mathbb{R}$ and $b_1, \dots, b_n \in \mathbb{R}_{>0}$, $\sum_{i=1}^n a_i^2/b_i \geq \left(\sum_{i=1}^n a_i\right)^2 / \sum_{i=1}^n b_i$.

Thus,

$$\begin{aligned}
m &\geq \sum_{x \in L} n2^{-n}T(x) \geq && \text{(10 and 13)}\\
&\geq \sum_{x \in L} n2^{-n} g\left(\frac{n}{s+1+\varepsilon}\right) = && \text{(definition of } g\text{)}\\
&= |L|2^{-n}2^{\frac{n}{s+1+\varepsilon}}(s+1+\varepsilon) \geq && \text{(9)}\\
&\geq \left(\frac{1}{2} - \frac{1}{2^{\varepsilon+1}}\right)(s+1+\varepsilon)2^{\frac{n}{s+1+\varepsilon}} = && \text{(rewriting)}\\
&= \left(\frac{1}{2} - \frac{1}{2^{\varepsilon+1}}\right)(s+1+\varepsilon)2^{\frac{n}{s+1}}2^{\frac{-n\varepsilon}{(s+1)(s+1+\varepsilon)}} .
\end{aligned}$$

Set $\varepsilon = 1/n$. Then,

$$\left(\frac{1}{2} - \frac{1}{2^{\frac{1}{n}+1}}\right) = \Theta\left(\frac{1}{n}\right) .$$

Also,

$$\frac{1}{2} \leq 2^{\frac{-1}{(s+1)(s+1+1/n)}} \leq 1 ,$$

as $2^{-1/x}$ is increasing for $x > 0$. This finally gives a lower bound

$$m \geq \Omega\left(\frac{s+1}{n} \cdot 2^{\frac{n}{s+1}}\right) .$$ ◀

3.2 Width of clauses

To prove the lower bound $k \geq n/(s+1)$, we use the following corollary of the Satisfiability Coding Lemma.

▶ **Lemma 6** (Lemma 2 in [8]). *Any k-CNF $F(x_1, \ldots, x_n)$ has at most $2^{n-n/k}$ isolated satisfying assignments.*

Proof of (3), $k \geq n/(s+1)$**.** Consider a k-CNF $F(x_1, \ldots, x_n, y_1, \ldots, y_s)$ that encodes PAR_n. Expand F to an OR of 2^s k-CNFs:

$$\mathrm{PAR}_n(x) = \bigvee_{j \in [2^s]} F_j(x) .$$

By Lemma 6, each F_j accepts at most $2^{n-n/k}$ isolated solutions. Hence,

$$2^s \geq \frac{2^{n-1}}{2^{n-n/k}} = 2^{n/k-1}$$

and thus, $k \geq n/(s+1)$. ◀

3.3 Unlimited non-determinism

In this section, we prove the lower bound $m \geq 3n - 9$.

Proof of (4), $m \geq 3n - 9$. We use induction on n. The base case $n \leq 3$ is clear. To prove the induction step, assume that $n > 3$ and consider a CNF encoding $F(x_1, \ldots, x_n, y_1, \ldots, y_s)$ of PAR_n with the minimum number of clauses. Below, we show that one can find k deterministic variables (where $k = 1$ or $k = 2$) such that assigning appropriately chosen constants to them reduces the number of clauses by at least $3k$, respectively. The resulting function computes PAR_{n-k} or its negation. It is not difficult to see that the minimum number of clauses in encodings of PAR and its negation are equal (by flipping the signs of all occurrences of any deterministic variable in a CNF encoding of PAR, one gets a CNF encoding of the negation of PAR, and vice versa). Hence, one can proceed by induction and conclude that F contains at least $3(n-k) - 9 + 3k = 3n - 9$ clauses.

To find the required k deterministic variables, we go through a number of cases. In the analysis below, by a d-literal we mean a literal that appears exactly d times in F, a d^+-literal appears at least d times. A (d_1, d_2)-literal occurs d_1 times positively and d_2 times negatively. Other types of literals are defined similarly. We treat a clause as a set of literals (that do not contain a literal together with its negation) and a CNF formula as a set of clauses.

Note that for all $i \in [s]$, y_i must be a $(2^+, 2^+)$-literal. Indeed, if y_i (or $\overline{y_i}$) is a 0-literal, one can assign $y_i \leftarrow 0$ ($y_1 \leftarrow 1$, respectively). It is not difficult to see that the resulting formula still encodes PAR. If y_i is a $(1, t)$-literal, one can eliminate it using resolution: for all pairs of clauses $C_0, C_1 \in F$ such that $\overline{y_i} \in C_0$ and $y_i \in C_1$, add a clause $C_0 \cup C_1 \setminus \{y_i, \overline{y_i}\}$ (if this clause contains a pair of complementary literals, ignore it); then, remove all clauses containing y_i or $\overline{y_i}$. The resulting formula still encodes PAR_n, but has a smaller number of clauses than F (we remove $1 + t$ clauses and add at most t clauses).

In the case analysis below, by l_i we denote a literal that corresponds to a deterministic variable x_i or its negation $\overline{x_i}$.

1. *F contains a 3^+-literal l_i.* Assigning $l_i \leftarrow 1$ eliminates at least three clauses from F.
2. *F contains a 1-literal l_i.* Let $l_i \in C \in F$ be a clause containing l_i. C cannot contain other deterministic variables: if $l_i, l_j \in C$ (for $i \neq j \in [n]$), consider $x \in \{0,1\}^n$ such that $\mathrm{PAR}_n(x) = 1$ and $l_i = l_j = 1$ (such x exists since $n > 3$), and its extension $y \in \{0,1\}^s$ such that $F(x, y) = 1$; then, F does not contain a critical clause w.r.t. (x, y, i). Clearly, C cannot be a unit clause, hence it must contain a non-deterministic variable y_j. Consider $x \in \{0,1\}^n$, such that $\mathrm{PAR}_n(x) = 1$ and $l_i = 1$, and its extension $y \in \{0,1\}^s$ such that $F(x, y) = 1$. If $y_j = 1$, then F does not contain a critical clause w.r.t. (x, y, i). Thus, for every $(x, y) \in \{0,1\}^{n+s}$ such that $F(x, y) = 1$ and $l_i = 1$, it holds that $y_j = 0$. This observation allows us to proceed as follows: first assign $l_i \leftarrow 1$, then assign $y_j \leftarrow 0$. The former assignment satisfies the clause C, the latter one satisfies all the clauses containing $\overline{y_j}$. Thus, at least three clauses are removed.
3. *For all $i \in [n]$, x_i is a $(2, 2)$-literal.* If there is no clause in F containing at least two deterministic variables, then F contains at least $4n$ clauses and there is nothing to prove. Let $l_i, l_j \in C_1 \in F$, where $i \neq j$, be a clause containing two deterministic variables and let $l_i \in C_2 \in F$ and $l_j \in C_3 \in F$ be the two clauses containing other occurrences of l_i and l_j ($C_1 \neq C_2$ and $C_1 \neq C_3$, but it can be the case that $C_2 = C_3$).

   Assume that C_2 contains another deterministic variable: $l_k \in C_2$, where $k \neq i, j$. Consider $x \in \{0,1\}^n$, such that $\mathrm{PAR}_n(x) = 1$ and $l_i = l_j = l_k = 1$ (such x exists since $n > 3$), and its extension $y \in \{0,1\}^s$ such that $F(x, y) = 1$. Then, F does not contain a critical clause w.r.t. (x, y, i): C_1 is satisfied by l_j, C_2 is satisfied by l_k. For the same reason, C_2 cannot contain the literal l_j. Similarly, C_3 cannot contain other deterministic variables and the literal l_i. (At the same time, it is not excluded that $\overline{l_j} \in C_2$ or $\overline{l_i} \in C_3$.) Hence, $C_2 \neq C_3$. Note that each of C_2 and C_3 must contain at least one non-deterministic variable: otherwise, it would be possible to falsify F by assigning l_i and l_j.

a. *At least one of C_2 and C_3 contains a single non-deterministic variable.* Assume that it is C_2:

$$\{l_i, y_1\} \subseteq C_2 \subseteq \{l_i, \overline{l_j}, y_1\}\,.$$

Assign $l_j \leftarrow 1$. This eliminates two clauses: C_1 and C_3 are satisfied. Also, under this substitution, $C_2 = \{l_i, y_1\}$ and l_i is a 1-literal. We claim that in any satisfying assignment of the resulting formula F', $l_i = \overline{y_1}$. Indeed, if (x, y) satisfies F' and $l_i = y_1$, then $l_i = y_1 = 1$ (otherwise C_2 is falsified). But then there is no critical clause in F' w.r.t. (x, y, i). Since in every satisfying assignment $l_i = \overline{y_1}$, we can replace every occurrence of y_1 ($\overline{y_1}$) by $\overline{l_i}$ (y_1, respectively). This, in particular, satisfies the clause C_2.

b. *Both C_2 and C_3 contain at least two non-deterministic variables:*

$$\{l_i,\ l_j\} \subseteq C_1, \quad \{l_i,\ y_1,\ y_2\} \subseteq C_2, \quad \{l_j,\ y_3,\ y_4\} \subseteq C_3\,.$$

Here, y_1 and y_2 are different variables, y_3 and y_4 are also different, though it is not excluded that some of y_1 and y_2 coincide with some of y_3 and y_4. Let $Y \subseteq \{y_1, \ldots, y_s\}$ be non-deterministic variables appearing in C_2 or C_3.

Recall that for every $(x, y) \in \{0,1\}^{n+s}$ such that $F(x, y) = 1$ and $l_i = l_j = 1$, it holds that $y = 0$ for all $y \in Y$. This means that if a variable $y \in Y$ appears in both C_2 and C_3, then it has the same sign in both clauses. Consider two subcases.

i. $Y = \{y_1, y_2\}$:

$$\{l_i,\ l_j\} \subseteq C_1, \quad \{l_i,\ y_1,\ y_2\} \subseteq C_2, \quad \{l_j,\ y_1,\ y_2\} \subseteq C_3\,.$$

Assume that $\overline{y_1} \notin C_1$. Assign $l_i \leftarrow 1$, $l_j \leftarrow 1$. Then, assigning $y_1 \leftarrow 0$ eliminates at least two clauses. Let us show that there remains a clause that contains $\overline{y_2}$. Consider $x \in \mathrm{PAR}_n^{-1}(1)$, such that $l_i = l_j = 1$, and its extension $y \in \{0,1\}^s$, such $F(x, y) = 1$. We know that y_1 and y_2 must be equal to 0. However, flipping the value of y_2 results in a satisfying assignment. Thus, it remains to analyze the following case:

$$\{l_i,\ l_j, \overline{y_1}, \overline{y_2}\} \subseteq C_1, \quad \{l_i,\ y_1,\ y_2\} \subseteq C_2, \quad \{l_j,\ y_1,\ y_2\} \subseteq C_3\,.$$

Assume that $\overline{l_j} \notin C_2$ and $\overline{l_i} \notin C_1$. Assign $l_i \leftarrow 1$, then assign $y_1 \leftarrow 0$ and $y_2 \leftarrow 0$. Under this assignment, $C_3 = \{l_j\}$ (recall that C_3 cannot contain other deterministic variables, see Case 3). This would mean that $l_j = 1$ in every satisfying assignment of the resulting CNF formula which cannot be the case for a CNF encoding of parity. Thus, we may assume that either $\overline{l_j} \in C_2$ or $\overline{l_i} \in C_1$. Without loss of generality, assume that $\overline{l_j} \in C_2$.

Let us show that for every $(x, y) \in \{0,1\}^{n+s}$, such that $F(x, y) = 1$ and $l_i = 1$, it holds that $l_j \neq y_1$ and $l_j \neq y_2$. Indeed, if there is $(x, y) \in \{0,1\}^{n+s}$ such that $F(x, y) = 1$ and $l_i = l_j = 1$, then y_1 and y_2 must be equal to 0. If there is $(x, y) \in \{0,1\}^{n+s}$, such that $F(x, y) = 1, l_i = 1, l_j = 0$, then y_1 and y_2 must be equal to 0, otherwise F does not contain a critical clause w.r.t. (x, y, i). Thus, assigning $l_i \leftarrow 1$ eliminates two clauses (C_1 and C_2). We then replace y_1 and y_2 with $\overline{l_j}$ and delete the clause C_3.

ii. $|Y| \geq 3, \{y_1, y_2, y_3\} \subseteq Y$:

$$\{l_i,\ l_j\} \subseteq C_1, \quad \{l_i,\ y_1,\ y_2\} \subseteq C_2, \quad \{l_j,\ y_1,\ y_3\} \subseteq C_3\,.$$

Assigning $l_i \leftarrow 1, l_j \leftarrow 1$ eliminates C_1, C_2, C_3. Assigning $y_1 \leftarrow 0$ eliminates at least one more clause (y_1 appears positively at least two times, but it may appear in C_1). There must be a clause with $\overline{y_2}$ (otherwise we could assign $y_2 \leftarrow 1$). Assigning $y_2 \leftarrow 0$ eliminates at least one more clause. Similarly, assigning $y_3 \leftarrow 1$ eliminates another clause. In total, we eliminate at least six clauses. ◀

Abstract

In 1981, Neil Immerman described a two-player game, which he called the "separability game" [15], that captures the number of quantifiers needed to describe a property in first-order logic. Immerman's paper laid the groundwork for studying the number of quantifiers needed to express properties in first-order logic, but the game seemed to be too complicated to study, and the arguments of the paper almost exclusively used quantifier rank as a lower bound on the total number of quantifiers. However, last year Fagin, Lenchner, Regan and Vyas [10] rediscovered the game, provided some tools for analyzing them, and showed how to utilize them to characterize the number of quantifiers needed to express linear orders of different sizes. In this paper, we push forward in the study of number of quantifiers as a bona fide complexity measure by establishing several new results. First we carefully distinguish minimum number of quantifiers from the more usual descriptive complexity measures, minimum quantifier rank and minimum number of variables. Then, for each positive integer k, we give an explicit example of a property of finite structures (in particular, of finite graphs) that can be expressed with a sentence of quantifier rank k, but where the same property needs $2^{\Omega(k^2)}$ quantifiers to be expressed. We next give the precise number of quantifiers needed to distinguish two rooted trees of different depths. Finally, we give a new upper bound on the number of quantifiers needed to express s-t connectivity, improving the previous known bound by a constant factor.

1 Introduction

In 1981 Neil Immerman described a two-player combinatorial game, which he called the "separability game" [15], that captures the number of quantifiers needed to describe a property in first-order logic (henceforth FOL). In that paper Immerman remarked,

> "Little is known about how to play the separability game. We leave it here as a jumping off point for further research. We urge others to study it, hoping that the separability game may become a viable tool for ascertaining some of the lower bounds which are 'well believed' but have so far escaped proof."

Immerman's paper laid the groundwork for studying the number of quantifiers needed to express properties in FOL, but alas, the game seemed too complicated to study and the paper used the surrogate measure of quantifier rank, which provides a lower bound on the number of quantifiers, to make its arguments. One of the reasons for the difficulty of directly analyzing the number of quantifiers is that the separability game is played on a pair $(\mathcal{A}, \mathcal{B})$ of *sets* of structures, rather than on a pair of structures as in a conventional Ehrenfeucht-Fraïssé game. However, last year Fagin, Lenchner, Regan and Vyas [10] rediscovered the games, provided some tools for analyzing them, and showed how to utilize them to characterize the number of quantifiers needed to express linear orders of different sizes. In this paper, we push forward in the study of number of quantifiers as a bona fide complexity measure by establishing several new results, using these rediscovered games as an important, though not exclusive, tool. Although Immerman called his game the "separability game," we keep to the more evocative "multi-structural game," as coined in [10].

Given a property P definable in FOL, let $\mathit{Quants}(P)$ denote the minimum number of quantifiers over all FO sentences that express P. **This paper exclusively considers expressibility in FOL.** $\mathit{Quants}(P)$ is related to two more widely studied descriptive complexity measures, the minimum quantifier rank needed to express P, and the minimum number of variables needed to express P. The quantifier rank of an FO sentence σ is typically denoted by $qr(\sigma)$. We shall denote the *minimum* quantifier rank over *all* FO sentences describing the property P by $\mathit{Rank}(P)$, and denote the minimum number of variables needed to describe P by $Vars(P)$. When referring to a specific sentence σ, we shall denote the analogs of $\mathit{Quants}()$ and $Vars()$ by $\mathit{quants}(\sigma)$ and $\mathit{vars}(\sigma)$. (That is, $\mathit{quants}(\sigma), vars(\sigma)$ and $qr(\sigma)$ refer to the number of quantifiers, variables and quantifier rank of the particular sentence σ.) On the other hand, $\mathit{Quants}(P), Vars(P)$ and $\mathit{Rank}(P)$ refer to the minimum values of these quantities among all expressions describing P. Possibly there is one sentence establishing $\mathit{Quants}(P)$, another establishing $Vars(P)$, and a third establishing $\mathit{Rank}(P)$. We investigate the *extremal* behavior of $\mathit{Quants}(P)$, via studying concrete properties P for which $\mathit{Quants}(P)$ behaves differently from the other measures.

First of all, for every property P, since every variable in a sentence describing P is bound to a quantifier, and quantifiers can only be bound to a single variable, it must be that $Vars(P) \leq \mathit{Quants}(P)$. The following simple proposition observes that $Vars(P)$ is also upper bounded by $\mathit{Rank}(P)$.

▶ **Proposition 1.** *For every property P: $Vars(P) \leq \mathit{Rank}(P)$.*

A proof is in [11, Prop. 1]. Since clearly $\mathit{Rank}(P) \leq \mathit{Quants}(P)$, we have:

$$Vars(P) \leq \mathit{Rank}(P) \leq \mathit{Quants}(P). \tag{1}$$

Furthermore, it follows from Immerman [16, Prop. 6.15] that $\mathit{Quants}(P)$ and $\mathit{Rank}(P)$ can both be arbitrarily larger than $Vars(P)$. When the property P is *s-t* connectivity up to path length k, Immerman shows that $Vars(P) \leq 3$, yet $\mathit{Rank}(P) \geq \log_2(k)$.

Summary of Results

From equation (1), we see that the number of quantifiers needed to express a property is lower-bounded by the minimum quantifier rank and number of variables. How much larger can $\mathit{Quants}(P)$ be, compared to the other two measures? It is known (see [8]) that there *exists* a fixed vocabulary V and an infinite sequence $P_1, P_2, \ldots$ of properties such that P_k is a property of finite structures with vocabulary V such that $\mathit{Rank}(P_k) \leq k$, yet $\mathit{Quants}(P_k)$ is not an elementary function of k. However, the existence of such P_k are proved via counting arguments. We provide an *explicitly computable* sequence of properties $\{P_k\}$ with a high growth rate in terms of the number of quantifiers required. (By "explicitly computable", we mean that there is an algorithm A such that, given a positive integer k, the algorithm A prints a FO sentence σ_k with quantifier rank k defining the property P_k, in time polynomial in the length of σ_k.)

▶ **Theorem** (Theorem 4, Section 2). *There is an explicitly computable sequence of properties $\{P_k\}$ such that for all k we have $Rank(P_k) \leq k$, yet $Quants(P_k) \geq 2^{\Omega(k^2)}$.*

Next, we give an example of a setting in which one can completely nail down the number of quantifiers that are necessary and sufficient for expressing a property. Building on Fagin *et al.* [10], which gives results on the number of quantifiers needed to distinguish linear orders of different sizes, we study the number of quantifiers needed to distinguish rooted trees of different depths.

Let $t(r)$ be the maximum d such that there is a formula with r quantifiers that can distinguish rooted trees of depth d (or larger) from rooted trees of depth less than d. Reasoning about the relevant multi-structural games, we can completely characterize $t(r)$, as follows.

▶ **Theorem** (Theorem 14, Section 3). *For all $r \geq 1$ we have*

$$t(2r) = \frac{7 \cdot 4^r}{18} + \frac{4r}{3} - \frac{8}{9}, \qquad t(2r+1) = \frac{8 \cdot 4^r}{9} + \frac{4r}{3} - \frac{8}{9}.$$

It follows from the above theorem that we can distinguish (rooted) trees of depth at most d from trees of depth greater than d using only $\Theta(\log d)$ quantifiers, and we can in fact pin down the *exact* depth that can be distinguished with r quantifiers. This illustrates the power of multi-structural games, and gives hope that more complex problems may admit an exact number-of-quantifiers characterization.

Next, we consider the question of how many quantifiers are needed to express that two nodes s and t are connected by a path of length at most n, in directed (or undirected) graphs. In our notation, we wish to determine $Quants(P)$ where P is the property of s-t connectivity via a path of length at most n. Considering the significance of s-t connectivity in both descriptive complexity and computational complexity, we believe this is a basic question that deserves a clean answer. It follows from the work of Stockmeyer and Meyer that s-t connectivity up to path length n can be expressed with $3\log_2(n) + O(1)$ quantifiers. As mentioned earlier, s-t connectivity is well-known to require quantifier rank at least $\log_2(n) - O(1)$. We manage to reduce the number of quantifiers necessary for s-t connectivity.

▶ **Theorem** (Theorem 15, Section 4). *The number of quantifiers needed to express s-t connectivity is at most $3\log_3(n) + O(1) \approx 1.893\log_2(n) + O(1)$.*

The remainder of this manuscript proceeds as follows. In the next subsection we describe multi-structural games and compare them to Ehrenfeucht-Fraïssé games. In the subsection that follows we review related work in complexity. We then prove the theorems mentioned above. In Section 2 we prove Theorem 4. In Section 3 we prove Theorem 14. In Section 4 we prove Theorem 15. In Section 5, we give final comments and suggestions for future research.

1.1 Multi-Structural Games

The standard Ehrenfeucht-Fraïssé game (henceforth E-F game) is played by "Spoiler" and "Duplicator" on a pair (A, B) of structures over the same FO vocabulary V, for a specified number r of *rounds*. If V contains constant symbols $\lambda_1, ..., \lambda_k$, then designated ("constant") elements c_i of A, and c'_i of B, must be associated with each λ_i. In each round, Spoiler chooses an element from A or from B, and Duplicator replies by choosing an element from the other structure. In this way, they determine sequences of elements $a_1, \ldots, a_r, c_1, \ldots, c_k$ of A and $b_1, \ldots, b_r, c'_1, \ldots, c'_k$ of B, which in turn define substructures A' of A and B' of B. Duplicator wins if the function given by $f(a_i) = b_i$ for $i = 1, \ldots, r$, and $f(c_j) = c'_j$ for $j = 1, \ldots, k$, is an isomorphism of A' and B'. Otherwise, Spoiler wins.

The equivalence theorem for E-F games [9, 12] characterizes the minimum *quantifier rank* of a sentence ϕ over V that is true for A but false for B. The quantifier rank $qr(\phi)$ is defined as zero for a quantifier-free sentence ϕ, and inductively:

$$\begin{aligned} qr(\neg\phi) &= qr(\phi), \\ qr(\phi \vee \psi) &= qr(\phi \wedge \psi) = \max\{qr(\phi), qr(\psi)\}, \\ qr(\forall x\phi) &= qr(\exists x\phi) = qr(\phi) + 1. \end{aligned}$$

▶ **Theorem 2** ([9, 12], Equivalence Theorem for E-F Games)**.** *Spoiler wins the r-round E-F game on (A, B) if and only if there is a sentence ϕ of quantifier rank at most r such that $A \models \phi$ while $B \models \neg\phi$.*

In this paper we make use of a variant of E-F games, which have come to be called *multi-structural games* [10]. Multi-structural games (henceforth M-S games) make Duplicator more powerful and can be used to characterize the *number* of quantifiers, rather than the quantifier *rank*. In an M-S game there are again two players, Spoiler and Duplicator, and there is a fixed number r of rounds. Instead of being played on a pair (A, B) of structures with the same vocabulary (as in an E-F game), the M-S game is played on a pair $(\mathcal{A}, \mathcal{B})$ of *sets of structures*, all with the same vocabulary. For k with $0 \leq k \leq r$, by a *labeled structure* after k rounds, we mean a structure along with a labeling of which elements were selected from it in each of the first k rounds. Let $\mathcal{A}_0 = \mathcal{A}$ and $\mathcal{B}_0 = \mathcal{B}$. Thus, $\mathcal{A}_0$ represents the labeled structures from $\mathcal{A}$ after 0 rounds, and similarly for $\mathcal{B}_0$ – in other words nothing is yet labelled except for constants. If $1 \leq k < r$, let $\mathcal{A}_k$ be the labeled structures originating from $\mathcal{A}$ after k rounds, and similarly for $\mathcal{B}_k$. In round $k+1$, Spoiler either chooses an element from each member of $\mathcal{A}_k$, thereby creating $\mathcal{A}_{k+1}$, or chooses an element from each member of $\mathcal{B}_k$, thereby creating $\mathcal{B}_{k+1}$. Duplicator responds as follows. Suppose that Spoiler chose an element from each member of $\mathcal{A}_k$, thereby creating $\mathcal{A}_{k+1}$. Duplicator can then make multiple copies of each labeled structure of $\mathcal{B}_k$, and choose an element from each copy, thereby creating $\mathcal{B}_{k+1}$. Similarly, if Spoiler chose an element from each member of $\mathcal{B}_k$, thereby creating $\mathcal{B}_{k+1}$, Duplicator can then make multiple copies of each labeled structure of $\mathcal{A}_k$, and choose an element from each copy, thereby creating $\mathcal{A}_{k+1}$. Duplicator wins if there is some labeled structure A in $\mathcal{A}_r$ and some labeled structure B in $\mathcal{B}_r$ where the labelings give a partial isomorphism. Otherwise, Spoiler wins.

In discussing M-S games we sometimes think of the play of the game by a given player, in a given round, as taking place on one of two "sides", the $\mathcal{A}$ side or the $\mathcal{B}$ side, corresponding to where the given player plays from on that round.

Note that on each of Duplicator's moves, Duplicator can make "every possible choice", via the multiple copies. Making every possible choice creates what we call the *oblivious strategy.* Indeed, Duplicator has a winning strategy if and only if the oblivious strategy is a winning strategy.

The following equivalence theorem, proved in [15, 10], is the analog of Theorem 2 for E-F games.

▶ **Theorem 3** ([15, 10], Equivalence Theorem for Multi-Structural Games)**.** *Spoiler wins the r-round M-S game on $(\mathcal{A}, \mathcal{B})$ if and only if there is a sentence ϕ with at most r quantifiers such that $A \models \phi$ for every $A \in \mathcal{A}$ while $B \models \neg\phi$ for every $B \in \mathcal{B}$.*

In [10] the authors provide a simple example of a property P of a directed graph that requires 3 quantifiers but which can be expressed with a sentence of quantifier rank 2. P is the property of having a vertex with both an in-edge and an out-edge. P can be expressed via the sentence $\sigma = \exists x(\exists y E(x,y) \wedge \exists y E(y,x))$, where $E(,)$ denotes the directed edge relation. In [10] it is shown that while Spoiler wins a 2-round E-F game on the two graphs A and B in Figure 1, Duplicator wins the analogous 2-round M-S game starting with these two graphs.

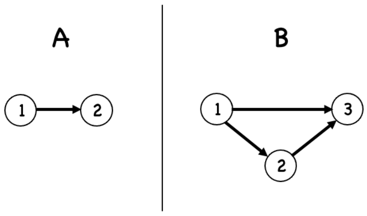

Figure 1 The graph B, on the right, contains a vertex with both an in-edge and an out-edge, while the graph A, on the left, does not.

Hence, by Theorem 3, the property P is not expressible with just 2 quantifiers.

1.2 Related Work in Complexity

Trees are a much studied data structure in complexity theory and logic. It is well known that it is impossible, in FOL, to express that a graph with no further relations is a tree [18, Proposition 3.20]. We note, however, that given a partial ordering on the nodes of a graph, it is easy to express in FOL the property that the partial ordering gives rise to a tree. The relevant sentence expresses that there is a root (i.e., a greatest element) from which all other nodes descend, and if a node x has nodes y and z as distinct ancestors then one of y and z must have the other as its own ancestor. Hence the needed sentence is the conjunction of the following two sentences:

$$\exists x \forall y (y \neq x \rightarrow y < x),$$
$$\forall x \forall y \forall z ((x < y \wedge x < z \wedge y \neq z) \rightarrow (y < z \vee z < y)).$$

There are also interesting models of computation and logics based on trees. See, for example, the literature on Finite Tree Automata [7] and Computational Tree Logic [6].

We now discuss s-t connectivity. In this paragraph only, n denotes the number of nodes in the graph and k the number of edges in a shortest path from s to t. The s-t connectivity problem has been studied extensively in both logic [1, 16] and complexity theory. Most complexity studies of this problem have focused on space and time complexity. Directed s-t connectivity is known to be NL-complete (see for example Theorem 16.2 in [19]), while undirected s-t connectivity is known to be in L [20]. Savitch [22] proved that s-t connectivity can be solved in $O(\log^2(n))$ space and $n^{\log_2(n)(1+O(1))}$ time. Recent work of Kush and Rossman [17] has shown that the *randomized* AC^0 formula complexity of s-t connectivity is at most size $n^{0.49\log_2(k)+O(1)}$, a slight improvement. Barnes, Buss, Ruzzo and Schieber [2] gave an algorithm running in both sublinear space and polynomial time for s-t connectivity. Gopalan, Lipton, and Meka [13] presented randomized algorithms for solving s-t connectivity with non-trivial time-space tradeoffs. The s-t connectivity problem has also been studied from the perspective of circuit and formula depth. For the weaker model of AC^0 formulas an $n^{\Omega(\log(k))}$ size lower bound is known to hold unconditionally [4, 5, 21].

There is also a natural and well-known correspondence with the number of quantifiers in FOL and circuit complexity, in particular with the circuit class AC^0 (constant-depth circuits comprised of NOT gates along with unbounded fan-in OR and AND gates). For example, Barrington, Immerman, and Straubing [3] proved that uniform$_{\mathsf{FO}}$-$\mathsf{AC}^0 = \mathsf{FO}[<, \mathrm{BIT}]$, thus characterizing the problems solvable in uniform AC^0 by those expressible in FOL with ordering and a BIT relation.

More generally it is known that uniform$_{\mathsf{FO}}$-$\mathsf{AC}[t(n)] = \mathsf{FO}[<, \mathrm{BIT}][t(n)]$ ([16], Theorem 5.22), i.e., FO formulas over ordering and BIT relations, defined via constant-sized blocks that are "iterated" for $O(t(n))$ times, are equivalent in expressibility with AC circuits of depth $O(t(n))$. (See [11, Appendix C] for a more detailed statement.) Generally speaking, the number of quantifiers of FOL sentences (with a regular form) roughly corresponds to the *depth* of a (highly uniform) AC^0 circuit deciding the truth or falsity of the given sentence. Thus the number of quantifiers can be seen as a proxy for "uniform circuit depth".

2 Difference in Magnitude: Quantifier Rank vs. Number of Quantifiers

Let V be a vocabulary with at least one relation symbol with arity at least 2. It is known [8] that the number of inequivalent sentences in vocabulary V with quantifier rank k is not an elementary function of k (that is, grows faster than any tower of exponents). Since the number of sentences in vocabulary V with k quantifiers is at most only double exponential in k (e.g., a function that grows like $2^{2^{p(k)}}$ for some polynomial $p(k)$ – see [11, Appendix A] for a proof), it follows by a counting argument that for each positive integer k, there is a property P of finite structures with vocabulary V that can be expressed by a sentence of quantifier rank k, but where the number of quantifiers needed to express P is not an elementary function of k. However, to our knowledge, up to now no *explicit* examples have been given of a property P where the quantifier rank of a sentence to express P is k, but where the number of quantifiers needed to express the property P is at least exponential in k. In the proof of the following theorem, we give such an explicit example.

Let $f_V(k)$ be the number of structures with k nodes up to isomorphism in vocabulary V (such as the number of non-isomorphic graphs with k nodes). Note that in the case of graphs (a single binary relation symbol), $f_V(k)$ is asymptotic to $(2^{k^2})/k!$ [14], and Stirling's formula implies that $f_V(k) = 2^{\Omega(k^2)}$). We have the following theorem.

▶ **Theorem 4.** *Assume that the vocabulary V contains at least one relation symbol with arity at least 2. There is an algorithm such that given a positive integer k, the algorithm produces a FO sentence σ of quantifier rank k where the minimum number of quantifiers needed to express σ in FOL is $kf_V(k-1)$, which grows like $2^{\Omega(k^2)}$, and where the algorithm runs in time polynomial in the length of σ.*

Proof. For simplicity, let us assume that the vocabulary V consists of a single binary relation symbol, so that we are dealing with graphs. It is straightforward to modify the proof to deal with an arbitrary vocabulary with at least one relation symbol of arity at least 2. Let us write f for f_V. Let $C_1, \ldots, C_{f(k-1)}$ be the $f(k-1)$ distinct graphs up to isomorphism with $k-1$ nodes. For each j with $1 \leq j \leq f(k-1)$, derive the graph D_j that is obtained from C_j by adding one new node with a single edge to every node in C_j. Thus, D_j has k nodes. D_j uniquely determines C_j, since C_j is obtained from D_j by removing a node a that has a single edge to every remaining node; even if there were two such nodes a, the result would be the same. Therefore, there are $f(k-1)$ distinct graphs D_j. We now give our sentence σ. Let σ_j be the sentence $\exists x_1 \cdots \exists x_k \tau_j(x_1, \ldots, x_k)$, which expresses that there is a graph with a subgraph isomorphic to D_j. Then the sentence σ is the conjunction of the sentences σ_j for $1 \leq j \leq f(k-1)$. Since the sentence σ is of length $2^{\Omega(k^2)}$, it is not hard to verify that this sentence can be generated by an algorithm running in polynomial time in the length of the sentence (there is enough time to do all of the isomorphism tests by a naive algorithm).

The sentence σ has quantifier rank k. As written, this sentence has $kf(k-1)$ quantifiers. Let A be the disjoint union of $D_1, \ldots, D_{f(k-1)}$. If p is a point in A, define B_p to be the result of deleting the point p from A. Let $\mathcal{A}$ consist only of A, and let $\mathcal{B}$ consist of the graphs B_p for each p in A. If p is in the connected component D_j of A, then B_p does not have a subgraph isomorphic to D_j. Hence, no member of $\mathcal{B}$ satisfies σ. Since the single member A of $\mathcal{A}$ satisfies σ, and since no member of $\mathcal{B}$ satisfies σ, we can make use of M-S games played on $\mathcal{A}$ and $\mathcal{B}$ to find the number of quantifiers needed to express σ.

Assume that we have labeled copies of A and the various B_p's after i rounds of an M-S game played on $\mathcal{A}$ and $\mathcal{B}$. The labelling tells us which points have been selected in each of the first i rounds. Let us say that a labeled copy of A and a labeled copy of B_p are *in harmony* after i rounds if the following holds. For each m with $1 \leq m \leq i$, if a is the point labeled m in A, and b is the point labeled m in B_p, then $a = b$. In particular, if the labeled copies of A and B_p are in harmony, then there is a partial isomorphism between the labeled copies of A and B_p.

Let Duplicator have the following strategy. Assume first that in round i, Spoiler selects in $\mathcal{A}$, and selects a point a from a labeled member A of $\mathcal{A}$. Then Duplicator (by making extra copies of labeled graphs in $\mathcal{B}$ as needed) does the following for each labeled B_p in $\mathcal{B}$. If $a \neq p$, and if the labeled copies of A and B_p before round i are in harmony, then Duplicator selects a in B_p, which maintains the harmony. If $a = p$, or if the labeled A and B_p before round i are not in harmony, then Duplicator makes an arbitrary move in B_p.

Assume now that in round i, Spoiler selects in $\mathcal{B}$. When Spoiler selects the point b from a labeled copy of B_p, then for each labeled A from $\mathcal{A}$, if the labeled copy of A is in harmony with the labeled copy of B_p before round i, then Duplicator selects b in A, and thereby maintains the harmony. We shall show shortly (Property * below) that in every round, each labeled member of $\mathcal{A}$ is in harmony with a labeled member of $\mathcal{B}$, so in the case we are now considering where Spoiler selects in $\mathcal{B}$, Duplicator does select a point in round i in each labeled member of $\mathcal{A}$.

We prove the following by induction on rounds:

Property *: If A is a labeled graph in $\mathcal{A}$ and if point p in A was not selected in the first i rounds, then there is a labeled copy of B_p that is in harmony with A after i rounds.

Property * holds after 0 rounds (with no points selected). Assume that Property * holds after i rounds; we shall show that it holds after $i+1$ rounds. There are two cases, depending on whether Spoiler moves in $\mathcal{A}$ or in $\mathcal{B}$ in round $i+1$. Assume first that Spoiler moves in $\mathcal{A}$ in round $i+1$. Assume that point p was not selected in A after $i+1$ rounds. By inductive assumption, there are labeled versions of A and B_p that are in harmony after i rounds. So by Duplicator's strategy, labeled versions of of A and B_p are in harmony after $i+1$ rounds. Now assume that Spoiler moves in $\mathcal{B}$ in round i+1. For each labeled graph A in $\mathcal{A}$, if a labeled B_p is in harmony with the labeled A after i rounds, then by Duplicator's strategy, the harmony continues between the labeled A and B_p after $i+1$ rounds. So Property * continues to hold after $i+1$ rounds. This completes the proof of Property *.

After $(kf(k-1))-1$ rounds, pick an arbitrary labeled graph A in $\mathcal{A}$. Since at most $(kf(k-1))-1$ points have been selected after $(kf(k-1))-1$ rounds, and since A contains $kf(k-1)$ points (because it is the disjoint union of $f(k-1)$ graphs each with k points), there is some point p that was not selected in A in the first $(kf(k))-1$ rounds. Therefore, by Property *, a labeled version of A and of B_p are in harmony after $(kf(k))-1$ rounds, and hence there is a partial isomorphism between the labeled A and B_p. So Duplicator wins the $(kf(k-1))-1$ round M-S game! Therefore, by Theorem 3, the number of quantifiers needed to express σ is more than $(kf(k-1))-1$. Since σ has $kf(k-1)$ quantifiers it follows that the minimum number of quantifiers need to express σ is exactly $kf(k-1)$. ◀

3 Rooted Trees

Our aim in this section is to establish the minimum number of quantifiers needed to distinguish rooted trees of depth at least k from those of depth less than k using first-order formulas, given a partial ordering on the vertices induced by the structure of the rooted tree. Figure 2 gives an example of a tree where we designate x as the root node. We define the depth of such a tree to be the maximum number of nodes in a path from the root to a leaf, where all segments in the path are directed from parent to child. Although it is more customary to denote the depth of a tree in terms of the number of *edges* along such a path, we keep to the above definition because we will often run into the special case of linear orders, which we view as trees in the natural way, and linear orders are characterized by their size (number of nodes) and we would like the size of a liner order to correspond to the depth of the associated tree. Let us denote the tree rooted at x by T_x. We make the arbitrary choice that the node x is the *largest* element in the induced partial order, so that for two nodes α, β of T_x, we have $\alpha > \beta$ if and only if there is a path $(x_1, ..., x_n)$ in T_x with $\alpha = x_1$ and $\beta = x_n$ such that x_i is a parent of x_{i+1} for $1 \leq i \leq n-1$. Thus, for example, in Figure 2, $x > q$ and $z > s$, etc.

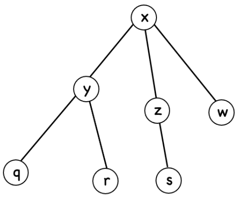

Figure 2 A rooted tree with designated root node x and depth 3.

The problem of distinguishing the depth of a rooted tree via a first-order formula with a minimum number of quantifiers is similar to the analogous problem for linear orders of different sizes, since a rooted tree has depth k or greater if and only if it has a leaf node, above which there is linear order of size at least $k-1$.

Our strategy will be to characterize a tree of depth d recursively as a graph containing a vertex v which has a subtree of depth k that includes v and everything below it, and a linear order of length $d-k$ comprising the vertices above v, where k is chosen to minimize the total number of quantifiers. We then show that this is the minimum quantifier way to characterize a tree of each given depth.

The following result is classic and key to establishing a number of fundamental inexpressibility results in FOL [18]. It is typically obtained by appeal to Theorem 2.

▶ **Theorem 5** ([18], Theorem 3.6). *Let $f(r) = 2^r - 1$. In an r-round E-F game played on two linear orders of different sizes, Duplicator wins if and only if the size of the smaller linear order is at least $f(r)$.*

Analogs of Theorem 5 are proven for M-S games in [10]. The following definition and theorems are from that paper.

▶ **Definition 6** ([10]). *Define the function $g : \mathbb{N} \to \mathbb{N}$ such that $g(r)$ is the maximum number k such that there is a formula with r quantifiers that can distinguish linear orders of size k or larger from linear orders of size less than k.*

▶ **Theorem 7** ([10]). *The function g takes on the following values: $g(1) = 1, g(2) = 2, g(3) = 4, g(4) = 10$, and for $r > 4$,*

$$g(r) = \begin{cases} 2g(r-1) & \text{if } r \text{ is even,} \\ 2g(r-1)+1 & \text{if } r \text{ is odd.} \end{cases}$$

▶ **Theorem 8** ([10]). *In an r-round M-S game played on two linear orders of different sizes Duplicator has a winning strategy if and only if the size of the smaller linear order is at least $g(r)$.*

For given positive integers r and k, we want to know if there exist sentences with r quantifiers that distinguish rooted trees of depth k or larger from rooted trees of depth smaller than k. For $k = r$, one such sentence is

$$\exists x_1 \cdots \exists x_r \bigwedge_{1 \leq i < r} (x_i < x_{i+1}), \tag{2}$$

which distinguishes rooted trees of depth r or larger from rooted trees of depth less than r. Here, if T_x is a rooted tree of depth exactly r then x_1 would be a deepest child. Since there are only finitely many inequivalent formulas in up to r variables that include the relations $<$ and $=$ and at most r quantifiers, there is some maximum such k, which we shall designate by $t(r)$. With $\mathbb{N} = \{1, 2, ...\}$, we restate this definition of t formally as follows. Note that no meaningful sentence about trees can be constructed with a single quantifier, so the definition begins at $r = 2$.

▶ **Definition 9.** *Define the function $t : \{2, 3, ...\} \to \mathbb{N}$ such that $t(r)$ is the maximum number z such that there is a formula with r quantifiers that can distinguish rooted trees of depth z or larger from rooted trees of depth less than z.*

By (2) above, $t(r) \geq r$ for $r \geq 2$. For an M-S game of r rounds on rooted trees of sizes $t(r)$ or larger on one side, and $t(r) - 1$ or smaller on the other side, by the Equivalence Theorem, Spoiler will have a winning strategy.

Since linear orders are perfectly good rooted trees, we have the following:

▶ **Observation 10.** *For all r we have $t(r) \leq g(r)$.*

Simple arguments establishing that $t(2) = 2$, and $t(3) = 4$, stemming from Observation 10, are given in [11, Sec. 3.1]. An analysis establishing $t(4) = 8$ is given in [11, Sec. 3.2]. Except for one paragraph, we shall not need that analysis, nor the particular result, though the reader may have an easier time understanding the rather intricate inductive argument that follows by first reading the analysis of this case.

In the proof of Theorem 7 [10], the authors provide explicit sentences that distinguish linear orders of size $g(r)$ or greater from those of size less than $g(r)$. From the proof of their Theorem 1.6, it can be seen that the distinguishing sentences Φ_r, for $r > 4$ take the form:

$$\Phi_r = \begin{cases} \exists x_1 \forall x_2 \cdots \forall x_{r-1} \exists x_r \phi_r & \text{for } r \text{ odd,} \\ \forall x_1 \exists x_2 \cdots \forall x_{r-1} \exists x_r \phi_r & \text{for } r \text{ even,} \end{cases}$$

where ϕ_r is quantifier-free. For odd r, the formula Φ_r says that there exists a point x_1, with a least linear order of size at least $\lfloor \frac{r}{2} \rfloor$ to both sides of x_1. For even r, the formula Φ_r says that for all x_1, there exists a linear order of at least size $\frac{r}{2}$ to one side or the other of x_1.

Let us denote by $t_\forall(r)$ the maximum number k such that rooted trees of depth k and above can be distinguished from rooted trees of depth less than k using prenex formulas with r quantifiers beginning with a universal quantifier. Equivalently, $t_\forall(r) = k$ is the largest depth of a rooted tree such that Spoiler has a winning strategy on r-round M-S games played on rooted trees of depth k or greater versus those of depth less than k when his first move is constrained to be on the tree of lesser depth. Analogously, when considering linear orders, let $g_\forall(r)$ and $g_\exists(r)$ denote, respectively, the maximum number k such that linear orders of size k and above can be distinguished from linear orders of size less than k using prenex formulas with r quantifiers beginning, respectively, with a universal or existential quantifier.

▶ **Lemma 11.** *For $r > 1$, one has $t_\forall(r) = t(r-1) + 1$.*

A proof of this very simple lemma is given in [11, Proof of Lemma 18].

▶ **Lemma 12.** *For $r \geq 2$, the following hold:*

$$g_\exists(2r) = 2g_\forall(2r-1) + 1, \tag{3}$$

$$g_\forall(2r+1) = 2g_\exists(2r). \tag{4}$$

Further, there are expressions establishing the $g_\exists$ relations having prenex signatures $\exists\forall\cdots\exists\forall\exists\exists$ with $r-1$ iterations of the $\exists\forall$ pair and then a final $\exists\exists$, while there are expressions establishing the $g_\forall$ relations having prenex signatures $\forall\exists\cdots\forall\exists\exists$ with r iterations of the $\forall\exists$ pair and then a final $\exists$.

A proof of this lemma is given in [11, Proof of Lemma 19].

▶ **Theorem 13.** *For $r \geq 2$, the following holds:*

$$t(r) = g_\forall(r-1) + t_\forall(r-1) + 1 = g_\forall(r-1) + t(r-2) + 2. \tag{5}$$

If r is odd, then $g_\forall(r-1) = g(r-1)$ so for r odd we have:

$$t(r) = g(r-1) + t_\forall(r-1) + 1 = g(r-1) + t(r-2) + 2. \tag{6}$$

A proof of this theorem is given in [11, Proof of Theorem 20].

We can combine the previous results to prove the following explicit expression for $t()$ [11, Proof of Theorem 21].

▶ **Theorem 14.** *For all $r \geq 1$ we have*

$$t(2r) = \frac{7 \cdot 4^r}{18} + \frac{4r}{3} - \frac{8}{9}, \qquad t(2r+1) = \frac{8 \cdot 4^r}{9} + \frac{4r}{3} - \frac{8}{9}.$$

A table comparing the values of f, g and t for $2 \leq r \leq 10$ is given in [11, Section 3.4].

4 s-t Connectivity

In this section we explore the number of quantifiers needed to express either directed or undirected s-t connectivity (henceforth STCON) in FOL with the binary edge relation E, as a function of the number n of edges in a shortest path between the distinguished nodes s and

t. STCON, also known as *reachability* between labelled nodes s and t, refers to the property of graphs that labelled nodes s and t are connected. STCON(n) denotes the property that s and t are connected by a path of length at most n edges.

In [11, Appendix B], we show how to describe STCON(n) using $2\log_2(n)+O(1)$ quantifiers. The following theorem generalizes that construction, to improve the number of quantifiers to $3\log_3(n)+O(1)$. A similar argument shows that $K\log_K(n)+O(1)$ quantifiers can be used for any positive integer K, although this quantity is minimized for $K=3$.

▶ **Theorem 15.** *STCON(n) can be expressed with* $3\log_3(n)+O(1)$ *quantifiers.*

Proof. We shall use Υ_i to denote sentences with i quantifiers, and τ_j to denote quantifier-free expressions, where the subscript j denotes the path length characterized by τ_j.

We start with the following simple expression stating that s and t are connected and $d(s,t)\leq 3$, where $d(s,t)$ denotes the length of the shortest path from s to t:

$$\Upsilon_2 = \exists x_1 \exists x_2 (\tau_3 \vee \tau_2 \vee \tau_1), \tag{7}$$

where:

$$\tau_3 \quad = \quad E(s,x_1) \wedge E(x_1,x_2) \wedge E(x_2,t), \tag{8}$$
$$\tau_2 \quad = \quad E(s,x_1) \wedge E(x_1,t), \tag{9}$$
$$\tau_1 \quad = \quad E(s,t). \tag{10}$$

We now iteratively add three quantifiers at each stage and slot two nodes between each of the previously established nodes, as in Figure 3.

Figure 3 An illustration of slotting two nodes between each of the pre-established nodes s, x_1, x_2 and t in order to express a distance 9, $s-t$ path, using 5 quantifiers as in expressions (11) and (12).

We express that there is a path of length at most 9 from s to t, using 5 quantifiers as follows:

$$\Upsilon_5 = \exists x_1 \exists x_2 \forall x_3 \exists x_4 \exists x_5 (\tau_9 \vee \tau_8 \vee \cdots \vee \tau_1). \tag{11}$$

In this case, we just show τ_9. The simplifications required to get from τ_8 down to τ_4 are analogous to those for getting from τ_3 down to τ_1, but where we apply (8) – (10) separately to each of (12) – (14).

$$\tau_9 = \quad ((x_3 = s) \rightarrow E(s,x_4) \wedge E(x_4,x_5) \wedge E(x_5,x_1)) \;\; \wedge \tag{12}$$
$$((x_3 = t) \rightarrow E(x_1,x_4) \wedge E(x_4,x_5) \wedge E(x_5,x_2)) \;\; \wedge \tag{13}$$
$$((x_3 \neq s \wedge x_3 \neq t) \rightarrow E(x_2,x_4) \wedge E(x_4,x_5) \wedge E(x_5,t)). \tag{14}$$

Using 8 quantifiers, we can slot two new nodes between each node established in the prior step, as depicted in Figure 4. The associated logical expression is

$$\Upsilon_8 = \exists x_1 \exists x_2 \forall x_3 \exists x_4 \exists x_5 \forall x_6 \exists x_7 \exists x_8 (\tau_{27} \vee \tau_{26} \vee \cdots \vee \tau_1), \text{ and} \tag{15}$$

$$\tau_{27} = ((x_3 = s \wedge x_6 = s) \rightarrow E(s,x_7) \wedge E(x_7,x_8) \wedge E(x_8,x_4)) \;\; \wedge \tag{16}$$
$$((x_3 = s \wedge x_6 = t) \rightarrow E(x_4,x_7) \wedge E(x_7,x_8) \wedge E(x_8,x_5)) \;\; \wedge \tag{17}$$
$$((x_3 = s \wedge (x_6 \neq s \wedge x_6 \neq t)) \rightarrow E(x_5,x_7) \wedge E(x_7,x_8) \wedge E(x_8,x_1)) \;\; \wedge \tag{18}$$
$$\ldots \tag{19}$$
$$(((x_3 \neq s \wedge x_3 \neq t) \wedge (x_6 \neq s \wedge x_6 \neq t)) \rightarrow E(x_5,x_7) \wedge E(x_7,x_8) \wedge E(x_8,t)). \tag{20}$$

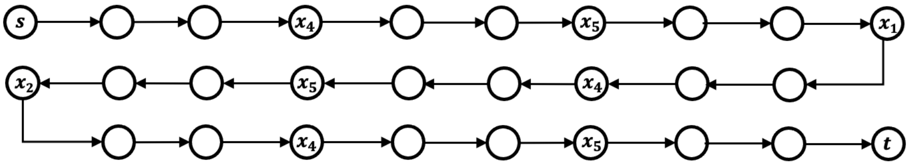

Figure 4 Slotting two nodes between each of the pre-established nodes s, x_1, x_2, x_4, x_5, and t in order to express a distance 27, $s-t$ path, using 8 quantifiers as in expressions (15) and (16)-(20).

The expression τ_{27} will have the two "pivot points" around the universally quantified variables x_3 and x_6 and so have $3^2 = 9$ antecedent conditions corresponding to the possible ways the universally quantified variables x_3 and x_6 can each take the values s, t or neither s nor t. The right hand side of each equality condition describes how to fill in the edges in Figure 4 with two new vertices (utilizing the two newest existentially quantified variables, x_7 and x_8) and three new edges.

In this way we obtain sentences with $3n-1$ quantifiers that can express STCON instances of path length up to 3^n. Thus, when n is a power of 3, we can express STCON instances of length n with $3\log_3(n) - 1 \approx 1.893\log_2(n) - 1$ quantifiers, and when n is *not* a power of 3, with $\lfloor 3\log_3(n) + 2 \rfloor$ quantifiers. The theorem therefore follows. ◀

A Remark on Lower Bounds on Quantifier Rank and hence on Number of Quantifiers

Lower bounds on the number of quantifiers for s-t connectivity follow readily from the literature. The well-known proof that connectivity is not expressible in FOL ([16, Prop. 6.15] or [18, Corollary 3.19]) can be used to establish that s-t connectivity with path length n is not expressible as a formula of quantifier rank $\log_2(n) - c$ for some constant c.

▶ **Theorem 16** (Immerman, Proposition 6.15 [16]). *There exists a constant c such that s-t connectivity to path length n is not expressible as a formula of quantifier rank $\log_2(n) - c$.*

Since the quantifier rank is a lower bound on the number of quantifiers, the previous theorem immediately implies a lower bound on the number of quantifiers as well. While we have shown that STCON(n) can be expressed with $3\log_3(n) + O(1)$ quantifiers, we note that the minimum quantifier *rank* of STCON(n) is well-known to be lower.

▶ **Theorem 17** ([18]). *s-t connectivity to path length n can be expressed with a formula of quantifier rank $\log_2(n) + O(1)$.*

5 Final Comments and Future Directions

Although progress on M-S games did not come until 40 years after their initial discovery in [15], the results of this paper show that these games are quite amenable to analysis, and the more detailed information they give about the requisite quantifier structure has the potential to yield many new and interesting insights.

Theorem 4 tells us that the number of quantifiers can be more than exponentially larger than the quantifier rank. This shows that the number of quantifiers is a more refined measure than the quantifier rank, and gives an interesting and natural measure of the complexity of a FO formula. It would be interesting to find explicit examples where the quantifier rank is k, but where the required number of quantifiers grows even faster than in our example in the proof of Theorem 4. Ideally, we would even like to find explicit examples where the required number of quantifiers is non-elementary in k.

We have extended the results on the number of quantifiers needed to distinguish linear orders of different sizes [10] to distinguish rooted trees of different depths. Can this line of attack be carried further to incorporate other structures, say to other structures with induced partial orderings such as finite lattices?

The most immediate question arising from our work is whether one can improve the known upper or lower bounds on the number of quantifiers needed to express s-t connectivity. In particular, what is the smallest constant $c \geq 1$ such that s-t connectivity (up to path length n) is expressible using $c \log_2(n)$ quantifiers? Our Theorem 15 shows that $\mathit{Quants}(\text{STCON}(n))$ is at most $3\log_3(n) + O(1) \approx 1.893 \log_2(n) + O(1)$. The well-known lower bound of $\mathit{Rank}(\text{STCON}(n)) \geq \log_2(n) - O(1)$ (cited as Theorem 16) yields the only lower bound we know on $\mathit{Quants}(\text{STCON}(n))$, but we also know the upper bound $\mathit{Rank}(\text{STCON}(n)) \leq \log_2(n) + O(1)$ (cited as Theorem 17). As these upper and lower bounds for the quantifier rank of $\text{STCON}(n)$ essentially match, in order to improve the lower bound on $\mathit{Quants}(\text{STCON}(n))$ further (by a multiplicative constant), we *cannot* rely on a rank lower bound: we will have to resort to other methods, such as M-S games.

Another question is whether we can find other problems with even larger quantifier number lower bounds than logarithmic ones. Let us stress that substantially larger lower bounds on the number of quantifiers would have major implications for circuit complexity lower bounds. For example, by the standard way of expressing uniform circuit complexity classes in FOL [16], a property (over the $<$ relation) that requires $\log^{\alpha(n)}(n)$ quantifiers, where $\alpha(n)$ is an unbounded function of n, would imply a lower bound for uniform$_{\mathsf{FO}}$-NC. See [11, Appendix C] for an exact statement.

Another interesting direction to push this research is to extend the notion of multi-structural games to 2nd-order logic, FOL with counting, or to fixed point logic.

Abstract

Global transformations provide a categorical framework for capturing synchronous rewriting systems, generalizing cellular automata to dynamical systems over dynamic spaces. Originally developed for addressing deterministic dynamical systems, the presented work raises the question of non-determinism. While a usual approach is to develop a general non-deterministic setting where deterministic systems can be retrieved as a specific case, we show here that by choosing the right parametrization, global transformations can already be used to handle non-determinism. Context-free Lindenmayer systems, already shown to be captured by global transformation in the deterministic case, are used to illustrate the approach. From this concrete example, the formal obstructions are exhibited, leading to a solution involving a 2-categorical monad and its associated Kleisli construction.

1 Introduction

Global transformations (GT) has been introduced in [12] as a precise formal description of dynamical systems defined over a space which is also dynamic while being still synchronous. This synchronicity property makes GT apart from the main stream of the literature on graph transformations and graph rewriting systems. They however share with this literature the fact that they are very generically defined using category theory in order not to be tied to a specific kind of space. For instance, GT can be used with directed or undirected graphs, labeled or not, hypergraphs, abstract cell complexes.

In order to present the framework to a public not familiar with category theory, the well known deterministic Lindenmayer systems have been presented in terms of GT in [4]. In this paper, we return to Lindenmayer systems, not as a pedagogical exercise but to explore non-determinism in GT in the simplest possible concrete setting.

A usual approach for studying non-determinism from a deterministic object consists in generalizing the deterministic object into a non-deterministic one and then to show that the original deterministic case is a degenerate case of the new non-deterministic setting. We rather seek to demonstrate that non-determinism is already encompassed as a particular case of the current definition of GT. This is in complete analogy with dynamical systems. Indeed, the general definition of dynamical systems is in terms of sets of states and evolution functions. Non-deterministic dynamical systems are *particular* dynamical systems where

the sets happen to be powersets of an underlying set of real states. This quest emerged from the necessity to talk about non-deterministic, probabilistic and quantum systems, with the intuition that it should not be very different to what happens for dynamical systems. It is not obvious at first that this is possible, because GT are mainly about the notion of (dynamic) locality, but non-deterministic, probabilistic and quantum systems all exhibit somewhat non-local features of correlation and entanglement.

At this point, it is not possible to say much without properly defining the terms that we use. So we dig into the formal definitions of the main objects in Section 2. This will allow us to show that a naive approach of this quest, based on powersets, does not work as explored in Section 3. In Section 4, we circumvent the obstruction in the most natural way and go to an intuitive solution that does not look as a dynamical system, because the transformation does not go from a set to itself but from a set to a bigger set. Section 5 comes back on the relation between dynamical system and non-deterministic system in terms of monad and Kleisli category. This well-known categorical point of view on dynamical systems leads us to consider a 2-monad and its Kleisli 2-category, linking together the previous attempts with this setting as a coherent whole, and providing a positive answer to our quest.

2 Preliminaries

The following notations are used along the paper. Formal language operations are written as follows. For a given alphabet Σ, Σ^* is the set of finite words on Σ, and ε is the empty word. The length of a word $u \in \Sigma^*$ is written $|u|$ and its ith letter, for $0 \leq i < |u|$, is written u_i. The concatenation of two words $u, v \in \Sigma^*$ is written $u \cdot v$. Concatenation of sets $U, V \subseteq \Sigma^*$ is written $U \cdot V$ and is defined by $\{u \cdot v \mid u \in U, v \in V\}$. For a given set U, the powerset of U is written $\mathrm{P}(U)$. The cartesian product of a family of sets $\{U_i\}_{i\in I}$ is written $\prod_{i\in I} U_i$, and the projection on component i for an element x of that product is written $x(i)$.

The reader is assumed familiar with basic notions of category theory. The colimit of a given diagram D is written $\mathrm{Colim}(D)$. The notation F/x stands for the comma category F over x where x is an object of some category and F is a functor into that category. The first projection is then written $\mathrm{Proj}[F/x]$. The restriction of a category $\mathbf{C}$ to the full subcategory with objects $S \subset \mathbf{C}$ is written $\mathbf{C} \upharpoonright S$. The restriction of a functor F to a subcategory $\mathbf{C}$ of its domain is written $F \upharpoonright \mathbf{C}$ as well.

2.1 Global Transformations

A global transform is a *synchronous* rewriting rule system. This is made possible by considering inclusions between rules in order to make explicit how overlapping applications of rules should be handle, similarly to the notion of amalgamation in classical graph transformation [2, 1]. Asking the coherence of the rule inclusions means exactly to ask them to form categories and functors, leading to the following definitions.

▶ **Definition 1** (rule systems and global transformations). *A* rule system *T on a category $\mathbf{C}$ is a tuple $\langle \mathbf{\Gamma}_T, \mathrm{L}_T, \mathrm{R}_T\rangle$ where $\mathbf{\Gamma}_T$ is a category whose objects and morphism are called* rules *and* rule inclusions*, $\mathrm{L}_T : \mathbf{\Gamma}_T \to \mathbf{C}$ is a full embedding functor called the* l.h.s. functor*, and $\mathrm{R}_T : \mathbf{\Gamma}_T \to \mathbf{C}$ is a functor called the* r.h.s. functor*. A rule system is a* global transformation *when the functor:*

$$T(-) = \mathrm{Colim}(\mathrm{R}_T \circ \mathrm{Proj}[\mathrm{L}_T/-]) \tag{1}$$

abusively also denoted T, is well-defined. The subscript T is omitted when this does not lead to any confusion.

This definition is a simplified version of alternative definitions found in [12, 5] but is enough for the present study. This definition makes GT T into a (pointwise) left Kan extensions of R_T along L_T, *i.e.*, a pair $\langle T, \eta : \mathrm{R}_T \Longrightarrow T \circ \mathrm{L}_T\rangle$ such that any other pair $\langle K, \rho : \mathrm{R}_T \Longrightarrow K \circ \mathrm{L}_T\rangle$ factorizes through η by a unique $\lambda : T \Longrightarrow K$ as in the following diagram. The natural transformation η is the identity, *i.e.*, $T \circ \mathrm{L}_T = \mathrm{R}_T$.

$$\begin{tikzcd}
\mathbf{C} \arrow[rrd, "T"] \arrow[rrd, bend left, "K"] \arrow[rd, phantom, "\lambda\Uparrow"] & & \\
\mathbf{\Gamma} \arrow[u, "\mathrm{L}_T"] \arrow[rr, "\mathrm{R}_T"'] \arrow[r, phantom, "\rho\Uparrow\ \ \eta\Uparrow"] & & \mathbf{C}
\end{tikzcd}$$

For more information on GT, one can consult [12, 4, 5, 7] but the specific case considered below might be enough to exemplify the relation between synchronous rewriting systems and left Kan extensions as explored by GT.

2.2 Non-Deterministic Lindenmayer Systems

Lindenmayer systems are a variant of formal grammars for specifying languages through a mechanism of parallel string rewriting [13, 10]. The present study focuses on Lindenmayer systems without context, where a word u on an alphabet Σ is synchronously rewritten by mapping each individual letter to a word (deterministic case) or set of words (non-deterministic case).

▶ **Definition 2.** *A* non-deterministic Lindenmayer system *on an alphabet Σ is given by a function $\delta : \Sigma \to \mathrm{P}(\Sigma^*)$ and produces the function on words $\Delta : \Sigma^* \to \mathrm{P}(\Sigma^*)$:*

$$\Delta(u) = \{v_0 \cdot \ldots \cdot v_{|u|-1} \mid (v_0, \ldots, v_{|u|-1}) \in \delta(u_0) \times \ldots \times \delta(u_{|u|-1})\} \tag{2}$$

and the dynamical system $\overline{\Delta} : \mathrm{P}(\Sigma^*) \to \mathrm{P}(\Sigma^*)$:

$$\overline{\Delta}(U) = \bigcup_{u \in U} \Delta(u). \tag{3}$$

▶ **Example 3.** Consider the alphabet $\Sigma = \{\mathtt{a}, \mathtt{b}\}$ with function δ defined by $\delta(\mathtt{a}) = \{\mathtt{a}, \mathtt{ab}\}$ and $\delta(\mathtt{b}) = \{\varepsilon, \mathtt{b}\}$. In this system, each a may potentially produce a new b on its right, and each b remains or vanishes. The behavior on the word ab is given by $\Delta(\mathtt{ab}) = \{\mathtt{a}\cdot\varepsilon, \mathtt{ab}\cdot\varepsilon, \mathtt{a}\cdot\mathtt{b}, \mathtt{ab}\cdot\mathtt{b}\} = \{\mathtt{a}, \mathtt{ab}, \mathtt{abb}\}$. Notice that ab is produced in two different ways.

In [4], deterministic Lindenmayer systems (without and with context) are presented as GT. This encoding relies on the category $\mathbf{W}$ of finite words that also plays a crucial role in this study. Let us fix the symbol Σ for the alphabet.

▶ **Definition 4.** *Let $\mathbf{W}$ be the category having Σ^* as set of objects, and*

$$\mathbf{W}(u, v) := \{\, p \in \{0, \ldots, |v| - |u|\} \mid u_i = v_{p+i}\ \forall i \in \{0, \ldots, |u| - 1\}\,\}$$

as set of arrows from any $u \in \Sigma^*$ to any $v \in \Sigma^*$. We write $p : u \to v$ for $p \in \mathbf{W}(u, v)$. The composite $q \circ p : u \to w$ of any two arrows $q : v \to w$ and $p : u \to v$ is given by $q + p$, 0 being the identity arrow of any $u \in \Sigma^*$.

Category $\mathbf{W}$ records the many places words appear in each other which is the relevant notion of *locality* for Lindenmayer systems. Indeed, the concatenations involved in Equation (2) correspond to colimits in $\mathbf{W}$, as stated by the following theorem, and is the basic ingredient of the expression of deterministic Lindenmayer systems as GT.

▶ **Theorem 5** (from [4]). *For any two words u, v, the word $u \cdot v$ is the colimit in $\mathbf{W}$ of the diagram:*

$$\begin{tikzcd}
u & & v & & & u \cdot v & \\
& \varepsilon \arrow[ul, "|u|"] \arrow[ur, "0"'] & & \text{with components} \quad u \arrow[urr, "0"] & & & v \arrow[ul, "|u|"'] \; . \\
& & & & & \varepsilon \arrow[ull, "|u|"] \arrow[ur, "0"'] \arrow[uu, "|u|"'] &
\end{tikzcd}$$

▶ **Example 6.** Let us illustrate the construction of [4] with a simple example. Consider the deterministic Lindenmayer system defined on $\Sigma = \{\mathtt{a}, \mathtt{b}\}$ by $\delta(\mathtt{a}) = \{\mathtt{ab}\}$ and $\delta(b) = \{\mathtt{a}\}$. The associated GT $T = \langle \mathbf{\Gamma}, \mathrm{L}, \mathrm{R} \rangle$ is completely determined by the following diagrams presenting respectively the category of rules $\mathbf{\Gamma}$ as a full subcategory of $\mathbf{W}$ with inclusion functor L, and the image of $\mathbf{\Gamma}$ by R:

$$\begin{tikzcd}
\mathtt{a} & \varepsilon \arrow[l, bend right, "1"'] \arrow[l, bend left, "0"] \arrow[r, bend left, "1"] \arrow[r, bend right, "0"'] & \mathtt{b} & {} \arrow[r, mapsto, "\mathrm{R}"] & {} & \mathtt{ab} & \varepsilon \arrow[l, bend right, "2"'] \arrow[l, bend left, "0"] \arrow[r, bend left, "1"] \arrow[r, bend right, "0"'] & \mathtt{a}
\end{tikzcd}$$

The computation of $T(ab)$ as defined by Equation (1) is pictured by the following diagrams:

$$\begin{tikzcd}
& \mathtt{ab} & & & & & & \mathtt{ab} \cdot \mathtt{a} & \\
\mathtt{a} \arrow[ur, "0"] & & \mathtt{b} \arrow[ul, "1"'] & \mathtt{ab} & & \mathtt{a} & \mathtt{ab} \arrow[ur, "0"] & & \mathtt{a} \arrow[ul, "2"'] \\
& \varepsilon \arrow[ul, "1"] \arrow[ur, "0"'] \arrow[uu, "1"'] & & & \varepsilon \arrow[ul, "2"] \arrow[ur, "0"'] & & & \varepsilon \arrow[ul, "2"] \arrow[ur, "0"'] \arrow[uu, "2"'] &
\end{tikzcd}$$

On the left, the diagram illustrates the information provided by the comma category $\mathrm{L}/\mathtt{ab}$. It corresponds to the pattern matching of the rules l.h.s. in the input word $\mathtt{ab}$. On the middle, the diagram $\mathrm{R} \circ \mathrm{Proj}[\mathrm{L}/\mathtt{ab}]$ is represented. On the right, the application of Theorem 5 for computing the colimit requested by $T(\mathtt{ab})$ constructs the expected result $\mathtt{aba}$.

3 The Challenge of Powersets

Let us recall the goal and make it more precise in light of the formal definitions. We already know from [4] that deterministic Lindenmayer systems are GT, and now we want to establish that non-deterministic Lindenmayer systems are also GT, without any extension of the framework. This means that we want to provide a rule system (Definition 1) based on δ such that $\overline{\Delta}$ (Definition 2) is obtained by the colimit formula of Equation (1). This implies in particular that we need to design the appropriate category, say $\mathbf{PW}$, with a calibrated notion of arrows to capture what we can informally call *non-deterministic locality.* The first idea that comes to mind is to take $\mathrm{P}(\Sigma^*)$ as set of objects for $\mathbf{PW}$ so that an object represents a set of possibilities. It remains to define arrows of $\mathbf{PW}$. However, it will cause difficulties as we are now going to see.

To make this more concrete, let us take the simple example of $\Sigma = \{\mathtt{a}, \mathtt{b}\}$, $\delta(\mathtt{a}) = \{\mathtt{a}, \mathtt{b}\}$ and $\delta(\mathtt{b}) = \{\varepsilon\}$. First, notice that $\Delta(\varepsilon) = \{\varepsilon\}$. Second, on the input $\mathtt{aa}$, it produces the behavior $\Delta(\mathtt{aa}) = \{\mathtt{aa}, \mathtt{ab}, \mathtt{ba}, \mathtt{bb}\}$ corresponding to the four possibilities combining the possible evolutions of each $\mathtt{a}$. Using the lessons learned in the deterministic case as illustrated in Example 6, we make the educated guess that the involved diagram should be of the form:

$$\begin{tikzcd}
\{\mathtt{a},\mathtt{b}\} & & \{\mathtt{a},\mathtt{b}\} \\
& \{\varepsilon\} \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] &
\end{tikzcd}$$

to produce the colimit

$$\begin{tikzcd}
& \{\mathtt{aa},\mathtt{ab},\mathtt{ba},\mathtt{bb}\} & \\
\{\mathtt{a},\mathtt{b}\} \arrow[ur, "\eta_1"] & & \{\mathtt{a},\mathtt{b}\} \arrow[ul, "\eta_2"'] \\
& \{\varepsilon\} \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] \arrow[uu, "\eta_3"'] &
\end{tikzcd}$$.

The diagram contains $\{\varepsilon\}$ for the matched ε between the two $\mathtt{a}$ in $\mathtt{aa}$, and two times $\{\mathtt{a},\mathtt{b}\}$ for each occurrence of $\mathtt{a}$. The arrows in the diagram indicate that the empty words at the end of the words in the left object need to correspond to the empty words at the beginning of the words in the right object as in Theorem 5. The expected colimit results in the concatenation $\{\mathtt{aa},\mathtt{ab},\mathtt{ba},\mathtt{bb}\}$. Based on these assumptions, we know that:

- the arrow "end" of $\mathbf{PW}$ should be based on arrows $1 : \varepsilon \to \mathtt{a}$ and $1 : \varepsilon \to \mathtt{b}$ of $\mathbf{W}$,
- the arrow "beg" of $\mathbf{PW}$ should be based on arrows $0 : \varepsilon \to \mathtt{a}$ and $0 : \varepsilon \to \mathtt{b}$ of $\mathbf{W}$,
- the arrow η_1 should be based on $0 : \mathtt{a} \to \mathtt{aa}$, $0 : \mathtt{a} \to \mathtt{ab}$, $0 : \mathtt{b} \to \mathtt{ba}$, and $0 : \mathtt{b} \to \mathtt{bb}$,
- the arrow η_2 should be based on $1 : \mathtt{a} \to \mathtt{aa}$, $1 : \mathtt{b} \to \mathtt{ab}$, $1 : \mathtt{a} \to \mathtt{ba}$, and $1 : \mathtt{b} \to \mathtt{bb}$,
- the arrow η_3 should be based on $1 : \varepsilon \to \mathtt{aa}$, $1 : \varepsilon \to \mathtt{ab}$, $1 : \varepsilon \to \mathtt{ba}$, and $1 : \varepsilon \to \mathtt{bb}$.

A natural choice for designing the arrows of $\mathbf{PW}$ is then to gather of these arrows of $\mathbf{W}$ into sets of arrows, leading to the following definition.

▶ **Definition 7.** *Let $\mathbf{PW}$ be the category having $\mathrm{P}(\Sigma^*)$ as set of objects, and*

$$\mathbf{PW}(U, V) := \mathrm{P}(\{\, p : u \to v \in \mathbf{W} \mid u \in U, v \in V \,\})$$

as set of arrows from any $U \in \mathrm{P}(\Sigma^*)$ to any $V \in \mathrm{P}(\Sigma^*)$. As usual, we write $P : U \to V$ for $P \in \mathbf{PW}(U, V)$. The composite $Q \circ P : U \to W$ of any two arrows $P : U \to V$ and $Q : V \to W$ is given by $\{p + q : u \to w \mid p : u \to v \in P, q : v \to w \in Q\}$, $\{0 : u \to u \mid u \in U\}$ being the identity arrow of any $U \in \Sigma^*$.

Notice that for any $P \in \mathbf{PW}(U, V)$, P does not contain integers but arrows of $\mathbf{W}$ with their domain and codomain. To avoid any confusion, we always write $p : u \to v \in P$ for elements of P.

▶ **Example 8.** With this category, the previous example works as expected if we take our previous list of constraints to define end, beg, η_1, η_2, and η_3 as sets of arrows: end $= \{1 : \varepsilon \to \mathtt{a}, 1 : \varepsilon \to \mathtt{b}\}$, beg $= \{0 : \varepsilon \to \mathtt{a}, 0 : \varepsilon \to \mathtt{b}\}$, $\eta_1 = \{0 : \mathtt{a} \to \mathtt{aa}, 0 : \mathtt{a} \to \mathtt{ab}, 0 : \mathtt{b} \to \mathtt{ba}, 0 : \mathtt{b} \to \mathtt{bb}\}$, and so on so forth. To see this, consider another cocone to some object $U \in \mathbf{PW}$ with components $\rho_1 : \{\mathtt{a},\mathtt{b}\} \to U$, $\rho_2 : \{\mathtt{a},\mathtt{b}\} \to U$, $\rho_3 : \{\varepsilon\} \to U$. We aim at showing that there is a unique arrow $\mu : \{\mathtt{aa},\mathtt{ab},\mathtt{ba},\mathtt{bb}\} \to U$ such that $\rho_i = \mu \circ \eta_i$ for $i \in \{1, 2, 3\}$.

First notice that ρ_1, ρ_2, and ρ_3 are bijectively related. Indeed, by definition of the composition in $\mathbf{PW}$ and by commutativity of the cocone, each $f_1 : l_1 \to u \in \rho_1$ compose with the unique appropriate arrow $1 : \varepsilon \to l_1$ of "end" to give a bijectively corresponding arrow in $f_1 + 1 : \varepsilon \to u \in \rho_3$. Surjectivity holds by the definition of the composition. Injectivity stands on the fact that an occurrence of $\mathtt{a}$ and an occurrence of $\mathtt{b}$ in a given word (here u) cannot be at the same position. Therefore, given $f_1 + 1 : \varepsilon \to u \in \rho_3$, there is a unique letter l_1 such that $f_1 : l_1 \to u \in \rho_1$. Similarly, there is also such a bijection mapping each $f_2 : l_2 \to u \in \rho_2$ to $f_2 : \varepsilon \to u \in \rho_3$. Consequently, the mediating μ has to contain exactly arrows with domain the concatenation of source letters l_i of two bijectively related arrows $f_1 : l_1 \to u \in \rho_1$ and $f_2 : l_2 \to u \in \rho_2$, and with codomain u. Formally μ has to be $\{f_1 : l_1 \cdot l_2 \to u \mid f_1 : l_1 \to u \in \rho_1$ and corresponding $f_1 + 1 : l_2 \to u \in \rho_2\}$.

The fact that this mediating commutes appropriately comes directly from the fact that $\mu \circ \eta_1 = \{f_1 : l_1 \to u \mid 0 : l_1 \to l_1 \cdot l_2 \in \eta_1, f_1 : l_1 \cdot l_2 \to u \in \mu\}$ which turns to be ρ_1. Commutations for ρ_2 and ρ_3 hold as well. Finally, μ is unique by construction.

While the previous example works, the proof uses explicitly the properties specific to the example. In the general case, the construction fails as shown by the following example.

▶ **Example 9.** We consider a different non-deterministic Lindenmayer system where $\Sigma = \{\mathtt{a}\}$ and $\delta(\mathtt{a}) = \{\mathtt{a}, \mathtt{aa}\}$. This produces the behavior $\Delta(\mathtt{aa}) = \{\mathtt{aa}, \mathtt{aaa}, \mathtt{aaaa}\}$. Notice in particular that the concatenations $\mathtt{a} \cdot \mathtt{aa}$ and $\mathtt{aa} \cdot \mathtt{a}$ give the same word $\mathtt{aaa}$ in $\Delta(\mathtt{aa})$. Following the same construction as presented in Example 8, we consider the following colimit:

$$\begin{tikzcd}
 & \{\mathtt{aa}, \mathtt{aaa}, \mathtt{aaaa}\} & \\
\{\mathtt{a}, \mathtt{aa}\} \arrow[ur, "\eta_1"] & & \{\mathtt{a}, \mathtt{aa}\} \arrow[ul, "\eta_2"'] \\
 & \{\varepsilon\} \arrow[uu, "\eta_3"'] \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] &
\end{tikzcd}$$

where

- $\eta_1 = \{0 : \mathtt{a} \to \mathtt{aa}, 0 : \mathtt{a} \to \mathtt{aaa}, 0 : \mathtt{aa} \to \mathtt{aaa}, 0 : \mathtt{aa} \to \mathtt{aaaa}\}$,
- $\eta_2 = \{1 : \mathtt{a} \to \mathtt{aa}, 1 : \mathtt{aa} \to \mathtt{aaa}, 2 : \mathtt{a} \to \mathtt{aaa}, 2 : \mathtt{aa} \to \mathtt{aaaa}\}$, and
- $\eta_3 = \{1 : \varepsilon \to \mathtt{aa}, 1 : \varepsilon \to \mathtt{aaa}, 2 : \varepsilon \to \mathtt{aaa}, 2 : \varepsilon \to \mathtt{aaaa}\}$.

To see that this cocone is *not* a colimit, consider the cocone to $\{\mathtt{aaa}\}$ having components $\rho_1 = \{0 : \mathtt{a} \to \mathtt{aaa}\}$, $\rho_2 = \{1 : \mathtt{aa} \to \mathtt{aaa}\}$, and $\rho_3 = \{1 : \varepsilon \to \mathtt{aaa}\}$. The only possible mediating is $\mu = \{0 : \mathtt{aaa}, \mathtt{aaa}\}$ but it fails to respect the required commutation property. Indeed, $\mu \circ \eta_1 = \{0 : \mathtt{a} \to \mathtt{aaa}, 0 : \mathtt{aa} \to \mathtt{aaa}\}$ which definitively differs from ρ_1.

So the first and simplest intuitive idea does not work and we have not designed the appropriate category. In particular, the construction fails since it is not able to distinguish the different ways for generating a given output (case $\mathtt{aaa}$ in Example 9). We then deduce that an appropriate category, if it exists, needs to keep track of this information. Moreover, notice that in Equation (1), the arrows of the category are not only used for constructing the result as a colimit, but also to decompose an input U into a coma category L_T/U and produce the diagram by the formula $\mathrm{R} \circ \mathrm{Proj}[\mathrm{L}_T/U]$. So the previous discussion has only addressed one side of the problem.

4 From Sets to Indexed Families

There are plenty of other possible definitions for designing arrows of **PW** and the research space to get the right one is pretty large. However, having considered several attempts of definitions, we come to the following working hypothesis.

▶ **Conjecture 10.** *There is no category with set of objects* $\mathrm{P}(\Sigma^*)$ *and an appropriate choice of arrows* $\mathrm{beg}_U, \mathrm{end}_U : \{\varepsilon\} \to U$ *producing concatenation as a colimit.*

Irrespectively of the validity of that conjecture, we choose to circumvent directly the problem that occurred in the previous example and to jump to other aspects of the program. As previously evoked, the obstruction was that $\mathtt{a} \cdot \mathtt{aa}$ and $\mathtt{aa} \cdot \mathtt{a}$ merged into a single word $\mathtt{aaa}$, so that the mediating arrow could not specify whether it needed this word as a result of the first concatenation or of the second one. To keep track of that information, we simply allow for a word to appear many times and we take families of words instead of sets of words. Taking this path of least resistance, we obtain the following category where an arrow from a source family of words to a target family of words, picks a unique word from the source for each word in the target. This additional "unique source word" property is respected by all the arrows considered up to now. Taking the view that an arrow $p : u \to v$ in $\mathbf{W}$ selects a subword of v, this constraint says that an arrow to a family of words similarly selects a subword for each member of that family.

▶ **Definition 11.** *For any $\mathbf{C} \in \mathbf{Cat}$, $\mathbb{O}\mathbf{C} \in \mathbf{Cat}$ has pairs $(I : \mathrm{Set}, U \in \mathbf{C}^I)$ as objects and*

$$\mathbb{O}\mathbf{C}((I,U),(J,V)) := \{\, (P : J \to I, P' : \prod_{j \in J} \mathbf{C}(U_{P(j)}, V_j))\,\}$$

as set of arrows from any $(I,U) \in \mathbb{O}\mathbf{C}$ to any $(J,V) \in \mathbb{O}\mathbf{C}$. As usual, we write $(P,P') : (I,U) \to (J,V)$ for $(P,P') \in \mathbb{O}\mathbf{C}((I,U),(J,V))$. The composite $(Q,Q') \circ (P,P') : (I,U) \to (K,W)$ of any two arrows $(P,P') : (I,U) \to (J,V)$ and $(Q,Q') : (J,V) \to (K,W)$ is given by the pair $(R : K \to I, R' : \prod_{k \in K} \mathbf{C}(U_{R(k)}, W_k))$ where :

$$R(k) = P(Q(k)) \text{ and } R'(k) = Q'(k) \circ P'(Q(k)) : U_{P(Q(k))} \to V_{Q(k)} \to W_k \in \mathbf{C}.$$

The identity arrow of any (I,U) is (P,P') where $P(i) = i$ and $P'(i) = \mathrm{id}_{P(i)} : P(i) \to P(i)$.

One may have recognised in this definition the construction for non-determinism of [11]. It happens to be the free cartesian completion of $\mathbf{C}$, the dual of $\mathrm{Fam}(\mathbf{C})$ construction for free coproduct completion [9, 3, 14], i.e. $\mathbb{O}\mathbf{C} = \mathrm{Fam}(\mathbf{C}^{\mathrm{op}})^{\mathrm{op}}$.

It is not hard to see that each object of this category has many isomorphic objects of bijective index set, so that the particular index set used is irrelevant. The real information contained in an equivalence class of isomorphic objects is the number of times each word occurs. Here, we allow this cardinality to be arbitrary. The issue of cardinality is a detail at this point, and we do not bother commenting on this issue before the conclusion. In the meantime, one can freely add the word *finite* anywhere one feels it is needed.

At this time, some notations are required to handle families and some relevant elements of $\mathbb{O}\mathbf{W}$. Given an arbitrary set U, we write $\overline{U}$ for the corresponding family containing each elements of U exactly once and given by the pair (U, id_U). Also, for any $(I,U) \in \mathbb{O}\mathbf{W}$, we consider the appropriate arrows $\mathrm{beg}_{(I,U)}, \mathrm{end}_{(I,U)} : \overline{\{\varepsilon\}} \to (I,U)$ identifying the occurrences of the empty words respectively at the beginning and at the end of the words of the family (I,U), and which are given by $\mathrm{beg}_{(I,U)} = ([i \mapsto \varepsilon], [i \mapsto (0 : \varepsilon \to U_i)])$ and $\mathrm{end}_{(I,U)} = ([i \mapsto \varepsilon], [i \mapsto (|U_i| : \varepsilon \to U_i)])$. We make use here of the notation $[x \mapsto f(x)]$ to specify succinctly an anonymous function; domains and codomains can always be retrieved from the context.

With the category $\mathbb{O}\mathbf{W}$ and these beginning and ending arrows, we obtain concatenation as wanted and in a very similar way to concatenation in $\mathbf{W}$ with Theorem 5.

▶ **Proposition 12.** *For any two families $(I,U),(J,V) \in \mathbb{O}\mathbf{W}$, a colimit of the diagram*

$$\begin{tikzcd}
(I,U) & & (J,V) \\
& \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}_{(I,U)}"] \arrow[ur, "\mathrm{beg}_{(I,U)}"'] &
\end{tikzcd}$$

is given by the cocone

$$\begin{tikzcd}
& (I \times J, (i,j) \mapsto U_i \cdot V_j) & \\
(I,U) \arrow[ur, "\eta_1"'] & & (J,V) \arrow[ul, "\eta_2"] \\
& \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}_{(I,U)}"] \arrow[ur, "\mathrm{beg}_{(I,U)}"'] \arrow[uu, "\eta_3"'] &
\end{tikzcd}$$

where

- $\eta_1 = ([(i,j) \mapsto i], [(i,j) \mapsto (0 : U_i \to U_i \cdot V_j)])$,
- $\eta_2 = ([(i,j) \mapsto j], [(i,j) \mapsto (|U_i| : V_j \to U_i \cdot V_j)])$, *and*
- $\eta_3 = ([(i,j) \mapsto \varepsilon], [(i,j) \mapsto (|U_i| : \varepsilon \to U_i \cdot V_j)])$.

Proof. Indeed, consider another cocone to some (K, W) with components, $(P, P') : (I, U) \to (K, W)$, $(Q, Q') : (J, V) \to (K, W)$, and $(R, R') : \overline{\{\varepsilon\}} \to (K, W)$. The mediating arrow is given by $([k \mapsto (P(k), Q(k))], [k \mapsto P'(k) : U_{P(k)} \cdot V_{Q(k)} \to W_k])$. Notice that this mediating follows the exact same definition as the one exhibited in Example 8. ◀

It is now time to summarize what we have just achieved. We took a diagram shape that allowed to obtain *deterministic* Lindenmayer systems as GT by encoding concatenation as colimit. Then, we changed the objects and arrows in this diagram to obtain what we can informally call *non-deterministic concatenation*. But the diagram shape itself arises from the *deterministic* decomposition of a single input word (see [4]). In other words, the pattern matching is not considered in $\mathbb{O}\mathbf{W}$ but in $\mathbf{W}$. So for now, we only have the following.

▶ **Definition 13.** *For any non-deterministic Lindenmayer system* $(\Sigma, \delta : \Sigma \to \mathrm{P}(\Sigma^*))$*, we write* $\mathbf{D} : \mathbf{W} \to \mathbb{O}\mathbf{W}$ *for the functor mapping words* $u \in \mathbf{W}$ *to* $\mathbf{D}(u) = (I, V)$ *where*

$$I := \delta(u_0) \times \ldots \times \delta(u_{|u|-1}) \text{ and } V_{(v_0,\ldots,v_{|u|-1})} := v_0 \cdot \ldots \cdot v_{|u|-1}$$

and arrows $p : u' \to u$ *to* $\mathbf{D}(p) = (P, P')$ *where*

$$P((v_0, \ldots, v_{|u|-1})) := (v_p, \ldots, v_{p+|u'|-1}) \text{ and}$$

$$P'((v_0, \ldots, v_{|u|-1})) := |v_0| + \ldots + |v_{p-1}| : v_p \cdot \ldots \cdot v_{p+|u'|-1} \to v_0 \cdot \ldots \cdot v_{|u|-1}.$$

The functor $\mathbf{D}$ is a categorical counterpart of $\Delta : \Sigma^* \to \mathrm{P}(\Sigma^*)$ of Definition 2 but with families making sure that we keep the multiple instances of each word. Indeed, for $\mathbf{D}(u) = (I, U)$, each index $(v_0, \ldots, v_{|u|-1}) \in I$ corresponds to a choice of a word v_i among the possibilities provided by $\delta(u_i)$, for each letter u_i of u. For such a choice, the associated resulting word $V_{(v_0,\ldots,v_{|u|-1})}$ is simply given by the concatenation of the v_i. The definition of $\mathbf{D}(p)$ expresses the monotony of Δ. The monotony can be illustrated as follows. Consider $u = \alpha_1 \cdot u' \cdot \alpha_2$ with $|\alpha_1| = p$. Taking $v' \in \Delta(u')$, $\gamma_1 \in \Delta(\alpha_1)$, and $\gamma_2 \in \Delta(\alpha_2)$, we have $v = \gamma_1 \cdot v' \cdot \gamma_2 \in \Delta(u)$. So we have an arrow $|\gamma_1| : v' \to v$. As a family of arrows, $\mathbf{D}(p)$ gathers all of these arrows. In the formula of Definition 13, we have $\alpha_1 = u_0 \ldots u_{p-1}$, $u' = u_p \ldots u_{p+|u'|-1}$, $\gamma_1 = v_0 \cdot \ldots \cdot v_{p-1}$, and $v' = v_p \cdot \ldots \cdot v_{p+|u'|-1}$.

Exactly as Δ is generated from its sole behavior on letters given by δ as stated by Definition 2, we will see that the functor $\mathbf{D}$ is generated from its restriction to the letters and ε. We start by defining the categorical counterpart $\mathbf{d}$ of δ.

▶ **Definition 14.** *For any non-deterministic Lindenmayer system* $(\Sigma, \delta : \Sigma \to \mathrm{P}\Sigma^*)$*, we write* $\mathbf{d} : \mathbf{W} \restriction \Sigma \cup \{\varepsilon\} \to \mathbb{O}\mathbf{W}$ *for the functor from the full subcategory* $\mathbf{W} \restriction \Sigma \cup \{\varepsilon\}$ *of* $\mathbf{W}$ *to* $\mathbb{O}\mathbf{W}$ *defined as* $\mathbf{d} = \mathbf{D} \restriction (\mathbf{W} \restriction \Sigma \cup \{\varepsilon\})$*.*

The functor $\mathbf{d}$ is entirely characterized in terms of arrows beg and end.

▶ **Lemma 15.** *For any* $a \in \Sigma$*, we have* $\mathbf{d}(0 : \varepsilon \to a) = \mathrm{beg}_{\mathbf{d}(a)}$ *and* $\mathbf{d}(1 : \varepsilon \to a) = \mathrm{end}_{\mathbf{d}(a)}$*.*

Proof. Consider $0 : \varepsilon \to a$. By Defs 14 and 13, $\mathbf{d}(\varepsilon) = \mathbf{D}(\varepsilon) = (\{\varepsilon\}, [\varepsilon \mapsto \varepsilon]) = \overline{\{\varepsilon\}}$, and $\mathbf{d}(a) = \mathbf{D}(a) = (\delta(a), [i \mapsto i])$. By the same definitions, $\mathbf{d}(0 : \varepsilon \to a) = \mathbf{D}(0 : \varepsilon \to a) = (P, P')$ with $P(i) = \varepsilon$ and $P'(i) = |\varepsilon| : \varepsilon \to i$ where i ranges over $\delta(a)$. Clearly, $\mathbf{d}(0 : \varepsilon \to a) = \mathrm{beg}_{(\delta(a),[i \mapsto i])} = \mathrm{beg}_{\mathbf{d}(a)}$ as expected. We get $\mathbf{d}(1 : \varepsilon \to a) = \mathrm{end}_{\mathbf{d}(a)}$ similarly. ◀

We can now establish that $\mathbf{D}$ is obtained as an extension of $\mathbf{d}$ thereby providing a categorical counterpart of Definition 2.

▶ **Proposition 16.** *$\mathbf{D}$ is a pointwise left Kan extension of $\mathbf{d}$ along the inclusion functor $\iota : \mathbf{W} \restriction \Sigma \cup \{\varepsilon\} \to \mathbf{W}$ as in the following diagram where η is the identity.*

$$\begin{tikzcd}
\mathbf{W} \arrow[drr, "\mathbf{D}"] & & \\
\mathbf{W} \restriction \Sigma \cup \{\varepsilon\} \arrow[u, hook, "\iota"] \arrow[rr, "\mathbf{d}"'] & {} \arrow[u, phantom, "\eta\Uparrow"] & \mathbb{O}\{\mathbf{W}\}
\end{tikzcd}$$

Proof. Using the explicit definition of pointwise left Kan extensions in terms of colimit, we are left to show that $\mathbf{D}(-) = \mathrm{Colim}(\mathbf{d} \circ \mathrm{Proj}[\iota/-])$. In [4], it is already proved that the diagram $\mathrm{Proj}[\iota/u]$ has the following zigzag shape:

$$\begin{tikzcd}
& u_0 & & u_1 & & \cdots & & u_{|u|-1} & \\
\varepsilon \arrow[ur, "0"'] & & \varepsilon \arrow[ul, "1"] \arrow[ur, "0"'] & & \varepsilon \arrow[ul, "1"] \arrow[ur, "0"'] & & \varepsilon \arrow[ul, "1"] \arrow[ur, "0"'] & & \varepsilon \arrow[ul, "1"]
\end{tikzcd}$$

Using Lemma 15, the diagram $\mathbf{d} \circ \mathrm{Proj}[\iota/u]$ is:

$$\begin{tikzcd}
& (\delta(u_0), [i \mapsto i]) & & (\delta(u_1), [i \mapsto i]) & & \cdots & & (\delta(u_{|u|-1}), [i \mapsto i]) & \\
\overline{\{\varepsilon\}} \arrow[ur, "\mathrm{beg}"'] & & \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] & & \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] & & \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}"] \arrow[ur, "\mathrm{beg}"'] & & \overline{\{\varepsilon\}} \arrow[ul, "\mathrm{end}"]
\end{tikzcd} .$$

Iteratively using Prop. 12 on this finite sequence, the colimit of this diagram is clearly the non-deterministic concatenation of the $(\delta(u_k), [i \mapsto i])$, $0 \leq k < |u|$, which is also the definition of $\mathbf{D}(u)$ as given in Def. 13. To prove that η is the identity, it is enough to consider the particular case of the previous reasoning with $|u| \leq 1$ that shows that $(\mathbf{D} \circ \iota)(u) = \mathbf{d}(u)$.

Given some $p : u' \to u$, for proving that $\mathbf{D}(p) = \mathrm{Colim}(\mathbf{d} \circ \mathrm{Proj}[\iota/p])$ we remark that $\mathbf{D}(p)$ has to be a mediating arrow. By unicity of the mediating arrow, it remains to show that $\mathbf{D}(p)$ obeys the requested commutations of mediating arrows, which is straightforward. ◀

So far, for a non-deterministic Lindenmayer system (Σ, δ), we have $\mathbf{d}$ as a categorical counterpart of δ, which gives rise by left Kan extension to $\mathbf{D}$, the categorical counterpart of Δ. However, we still do not have a dynamical system, since the domain and codomain of $\mathbf{D} : \mathbf{W} \to \mathbb{O}\mathbf{W}$ are not strictly the same. In other words, we now want a left Kan extension counterpart of $\overline{\Delta} : \mathrm{P}(\Sigma^*) \to \mathrm{P}(\Sigma^*)$ of Definition 2, say $\overline{\mathbf{D}} : \mathbb{O}\mathbf{W} \to \mathbb{O}\mathbf{W}$. Clearly, we already know the expected definition of $\overline{\mathbf{D}}$ since we want to apply independently $\mathbf{D}$ on each element of a family (I, U) and to flatten the results altogether.

▶ **Definition 17.** *Let $\overline{\mathbf{D}} : \mathbb{O}\mathbf{W} \to \mathbb{O}\mathbf{W}$ be the functor defined as*

$$\overline{\mathbf{D}}((I,U)) = \left(\bigcup_{i \in I} (\{i\} \times J_i) \, , \, [(i,j) \mapsto (V_i)_j] \right) \ \textit{where } (J_i, V_i) = \mathbf{D}(U_i),$$

and $\overline{\mathbf{D}}((P,P') : (I',U') \to (I,U)) = (Q,Q')$ such that, for each $(i,j) \in \bigcup_{i \in I} (\{i\} \times J_i)$:

$$Q((i,j)) = (P(i), R_i(j)) \ \textit{and } Q'((i,j)) = R'_i(j) \ \textit{where } (R_i, R'_i) = \mathbf{D}(P'(i)).$$

Obtaining $\overline{\mathbf{D}}$ as a Kan extension consists in embedding $\mathbf{W}$ into $\mathbb{O}\mathbf{W}$, then extending along this embedding. The notation $\overline{U}$ that we have introduced earlier can be turned into a *singleton functor* for defining this embedding.

▶ **Definition 18.** *For any category $\mathbf{C}$, the singleton functor $\mathrm{sing}_{\mathbf{C}} : \mathbf{C} \to \mathbb{O}\mathbf{C}$ is defined as*

$$\mathrm{sing}_{\mathbf{C}}(x) = \overline{\{x\}} \text{ and } \mathrm{sing}_{\mathbf{C}}(f : x \to y) = ([y \to x], [y \mapsto (f : x \to y)]).$$

Unfortunately, the program stops here since $\overline{\mathbf{D}}$ fails to be the extension of $\mathbf{d}$ along $\mathrm{sing}_{\mathbf{W}} \circ \iota : \mathbf{W} \restriction \Sigma \cup \{\varepsilon\} \to \mathbf{W} \hookrightarrow \mathbb{O}\mathbf{W}$. In fact, the arrows of $\mathbb{O}\mathbf{W}$ are not well-suited for decomposing a family of words in the appropriate way for the expected concatenation. For instance, consider the family in inputs $\overline{\{\mathtt{aa}, \mathtt{bb}\}}$. The comma category $\mathrm{sing}_{\mathbf{W}} \circ \iota/\overline{\{\mathtt{aa}, \mathtt{bb}\}}$ fails to identify the occurrences of $\mathtt{a}$ in this family. Indeed, an arrow from $\overline{\{\mathtt{a}\}}$ to $\overline{\{\mathtt{aa}, \mathtt{bb}\}}$ requires to identify an occurrence of $\mathtt{a}$ in $\mathtt{bb}$ but there is none. So there is no arrow between those two families and the diagram $\mathbf{d} \circ \mathrm{Proj}[\mathrm{sing}_{\mathbf{W}} \circ \iota/\overline{\{\mathtt{a}, \mathtt{b}\}}]$ of Equation (1) contains only ε's and does not exhibit the expected zigzag shape.

5 The Kleisli 2-Category of the 2-Monad of Families

As explained in Section 1, we propose to solve the last issue by placing oneself in a 2-categorical context. Since this solution can seem more elaborate than necessary, let us make precise why this transition to 2-categories is conceptually natural with respect to our goal.

Let us develop the relation between dynamical systems and their non-deterministic counterparts. At a general level of description, dynamical systems can be defined once we have a collection of objects to model the states, and a way to specify endo-functions on these objects to model the dynamics. For instance, in the category of sets and functions, the states are modeled as a set and the dynamics as a function; the usual case of (deterministic) dynamical systems is captured. But in the category of topological spaces and continuous functions, states are modeled as a topological space and the dynamics by a continuous function, allowing to handle the so-called topological dynamical systems. Similarly, in the category of sets and relations, states are modeled as a set and the dynamics by a relation. This last case is particularly interesting for our concern since it is the place to deal with non-deterministic dynamical systems. Formally this latter category is equivalently described as the *Kleisli category* of the so-called *powerset monad*. This is based on the fact that $R \subseteq X \times Y$ is equivalently a function $f : X \to \mathrm{P}(Y)$, that singletons allow any set X to be seen as included in $\mathrm{P}(X)$, and that unions allow any sets of sets in $\mathrm{P}(\mathrm{P}(X))$ to be simplified in a simple set of $\mathrm{P}(X)$. The two lessons we learn here are that (1) dynamical systems are parametrized by the nature of the objects and the arrows they rely on, and that (2) the parametrization for the non-determinitic counterpart is based on the powerset monad.

We now proceed to apply the same scheme for the GT. The difference with dynamical systems is that GT are not defined with two layers (an object for the states and an arrow for the dynamics) but with three layers: categories, functors and natural transformations as it can be seen in the pointwise left Kan extension diagram of Section 2.1. So they are parametrized by a 2-category. For instance, the simple GT as defined in Definition 1 are parametrized by **Cat**, the 2-category of categories. Following the second lesson on non-deterministic dynamical systems, for the particular case of non-deterministic GT, we propose this 2-category parameter to be set to the Kleisli 2-category induced by the 2-monad of families.

We already have all the ingredients of a 2-monad on **Cat** as we now proceed to show. Firstly, the construction $\mathbb{O}\mathbf{C}$ of Definition 11 can be extended to act on functors and natural transformations and yields a 2-functor $\mathbb{O} : \mathbf{Cat} \to \mathbf{Cat}$.

▶ **Definition 19.** *For any functor $F : \mathbf{C} \to \mathbf{C}'$, the functor $\mathbb{O}F : \mathbb{O}\mathbf{C} \to \mathbb{O}\mathbf{C}'$ is defined as $\mathbb{O}F((I, U)) = (I, F \circ U)$, and $\mathbb{O}F((P, P') : (I, U) \to (J, V)) = (P, F \circ P')$. For any natural transformation $\alpha : F \Longrightarrow G : \mathbf{C} \to \mathbf{C}'$, the natural transformation $\mathbb{O}\alpha : \mathbb{O}F \Longrightarrow \mathbb{O}G : \mathbb{O}\mathbf{C} \to \mathbb{O}\mathbf{C}'$ has components $(\mathbb{O}\alpha)_{(I,U)} = ([i \mapsto i], [i \mapsto \alpha_{U_i}]) : (I, F \circ U) \to (I, G \circ U)$.*

To make the 2-functor $\mathbb{O}$ into a 2-monad, we need to consider the obvious pairs of operations, the first one, $\mathrm{sing}_{\mathbf{C}} : \mathbf{C} \to \mathbb{O}\mathbf{C}$, lifting an object of a category $\mathbf{C}$ to a singleton family of $\mathbb{O}\mathbf{C}$, and the second one, $\mu_{\mathbf{C}} : \mathbb{O}\mathbb{O}\mathbf{C} \to \mathbb{O}\mathbf{C}$, flattening a family of families of objects into a simple family of objects. Notice that this last construction has already been encountered in Definition 17 of $\overline{\mathbf{D}}$, whose role of flattening has also been underlined above. In particular, the function $\overline{\mathbf{D}}$ is in fact obtained as $\mu_{\mathbf{W}} \circ \mathbb{O}\mathbf{D}$ from Definition 13. The two operations form indeed a 2-monad.

▶ **Proposition 20.** *Operations* $\mathrm{sing}\_$ *and* $\mu\_$ *make* $\mathbb{O} : \mathbf{Cat} \to \mathbf{Cat}$ *into a 2-monad, i.e., all instances of the following diagrams weakly commute.*

$$\begin{tikzcd}
\mathbb{O}\mathbb{O}\mathbb{O}\mathbf{C} \arrow[r, "\mathbb{O}\mu_{\mathbf{C}}"] \arrow[d, "\mu_{\mathbb{O}\mathbf{C}}"'] & \mathbb{O}\mathbb{O}\mathbf{C} \arrow[d, "\mu_{\mathbf{C}}"] \\
\mathbb{O}\mathbb{O}\mathbf{C} \arrow[r, "\mu_{\mathbf{C}}"'] \arrow[ur, phantom, "\overset{\sim}{\Nearrow}"] & \mathbb{O}\mathbf{C}
\end{tikzcd}
\qquad
\begin{tikzcd}
\mathbb{O}\mathbb{O}\mathbf{C} \arrow[dr, "\mu_{\mathbf{C}}"'] & \mathbb{O}\mathbf{C} \arrow[l, "\mathrm{sing}_{\mathbb{O}\mathbf{C}}"'] \arrow[r, "\mathbb{O}(\mathrm{sing}_{\mathbf{C}})"] \arrow[d, "\mathrm{id}_{\mathbb{O}\mathbf{C}}"] \arrow[dl, phantom, "\overset{\sim}{\Longrightarrow}", near start] \arrow[dr, phantom, "\overset{\sim}{\Longleftarrow}", near start] & \mathbb{O}\mathbb{O}\mathbf{C} \arrow[dl, "\mu_{\mathbf{C}}"] \\
& \mathbb{O}\mathbf{C} &
\end{tikzcd}$$

Proof. For the first square, and given an object $(I, U) \in \mathbb{O}\mathbb{O}\mathbb{O}\mathbf{C}$, the top-right path leads to index set of the form $(i, (j, k))$ for the object in $\mathbb{O}\mathbf{C}$ while the left-bottom path leads to the form $((i, j), k)$, hence the weak commutation. For the triangles on the right, an object $(I, U) \in \mathbb{O}\mathbf{C}$ sees each index $i \in I$ transformed into $((I, U), i) \in \{(I, U)\} \times I$ by the left path and into $(i, U_i) \in \{(i, U_i) \mid i \in I\}$ by the right path. ◀

In order to ease the reading of elements of the Kleisli weak 2-category, let us introduce some notations. We write $\widetilde{F} : \mathbf{C} \mathrel{-\!\!\circ\!\!\rightarrow} \mathbf{D}$ to represent a functor $F : \mathbf{C} \to \mathbb{O}\mathbf{D}$ of the Kleisli weak 2-category. A 2-arrow $\widetilde{\eta} : \widetilde{F} \mathrel{=\!\!\circ\!\!\Rightarrow} \widetilde{G}$ stands simply for a natural transformation $\eta : F \Longrightarrow G$. The composition of arrows in the Kleisli weak 2-category, written $\widetilde{G} \circ \widetilde{F} : \mathbf{C} \mathrel{-\!\!\circ\!\!\rightarrow} \mathbf{D} \mathrel{-\!\!\circ\!\!\rightarrow} \mathbf{E}$, is the functor $\mu_{\mathbf{E}} \circ \mathbb{O}G \circ F : \mathbf{C} \to \mathbb{O}\mathbf{D} \to \mathbb{O}\mathbb{O}\mathbf{E} \to \mathbb{O}\mathbf{E}$.

We finally reach our initial goal as we are now able to show that the diagram of Prop. 16 is in fact a summary of a GT in the Kleisli weak 2-category induced by the 2-monad $\mathbb{O}$. More accurately, considering the GT diagram of the rule system $\langle \mathbf{W} \restriction \Sigma \cup \{\varepsilon\}, \widetilde{\mathrm{sing}_{\mathbf{W}} \circ \iota}, \widetilde{\mathbf{d}} \rangle$ is completely equivalent to considering the diagram of Prop. 16, achieving the fact that the initial non-determinitic Lindenmayer system is indeed a GT. Moreover, this works for any non-deterministic rule system $\langle \mathbf{\Gamma}, \widetilde{\mathrm{sing}_{\mathbf{C}} \circ \mathrm{L}}, \widetilde{\mathrm{R}} \rangle$ on any category $\mathbf{C}$. Notice the particular form of the l.h.s. functor defined using $\mathrm{L} : \Gamma \to \mathbf{C}$ which is still required to be a full embedding.

▶ **Theorem 21.** *Let* $\widetilde{T} = \langle \mathbf{\Gamma}_T, \widetilde{\mathrm{sing}_{\mathbf{C}} \circ \mathrm{L}_T}, \widetilde{\mathrm{R}_T} \rangle$ *be a rule system in the Kleisli weak 2-category induced by the 2-monad* $\mathbb{O}$. $\widetilde{T}$ *is a GT iff* T *is the left Kan extension of* R_T *along* L_T *in the 2-category* $\mathbf{Cat}$.

Proof. The rule system being a GT, we have a pair $\langle \widetilde{T}, \widetilde{\eta} : \widetilde{\mathrm{R}_T} \Longrightarrow \widetilde{T} \circ \widetilde{\mathrm{sing}_{\mathbf{C}} \circ \mathrm{L}_T} \rangle$ which is a left Kan extension in the Kleisli 2-category and takes the following diagrammatic form for any other pair $\langle \widetilde{K}, \widetilde{\rho} : \widetilde{\mathrm{R}_T} \Longrightarrow \widetilde{K} \circ \widetilde{\mathrm{sing}_{\mathbf{C}} \circ \mathrm{L}_T} \rangle$:

$$\begin{tikzcd}[column sep=huge]
\mathbf{C} \arrow[rrd, bend left, "\widetilde{K}"] \arrow[rrd, "\widetilde{T}"'] & \widetilde{\lambda} \Uparrow & \\
\mathbf{\Gamma} \arrow[u, "\widetilde{\mathrm{sing}_{\mathbf{C}} \circ \mathrm{L}_T}"] \arrow[rr, "\widetilde{\mathrm{R}_T}"'] & \widetilde{\rho} \Uparrow \quad \widetilde{\eta} \Uparrow & \mathbf{C}
\end{tikzcd}$$

This diagram corresponds by definition to the diagram in **Cat** on the left below. By naturality of sing and Prop. 20, it (weakly) simplifies into the expected diagram, on the right below.

$$\begin{tikzcd}
\mathbb{O}\mathbf{C} \arrow[rrd, "\mathbb{O}T"] \arrow[rrd, bend left, "\mathbb{O}K"] \arrow[rrd, phantom, near start, "\Uparrow \mathbb{O}\lambda \Uparrow"] & & \\
\mathbf{C} \arrow[u, "\mathrm{sing}_{\mathbf{C}}"] \arrow[rr, phantom, "\rho \Uparrow \quad \eta \Uparrow"] & & \mathbb{O}\mathbb{O}\mathbf{C} \arrow[d, "\mu_{\mathbf{C}}"] \\
\mathbf{\Gamma} \arrow[u, "\mathrm{L}_T"] \arrow[rr, "\mathrm{R}_T"'] & & \mathbb{O}\mathbf{C}
\end{tikzcd}
\qquad
\begin{tikzcd}
\mathbf{C} \arrow[rrd, "T"] \arrow[rrd, bend left, "K"] \arrow[rrd, phantom, near start, "\lambda \Uparrow"] & & \\
\mathbf{\Gamma} \arrow[u, "\mathrm{L}_T"] \arrow[rr, "\mathrm{R}_T"'] \arrow[rr, phantom, shift left=3, "\rho \Uparrow \quad \eta \Uparrow"] & & \mathbb{O}\mathbf{C}
\end{tikzcd}$$

◀

6 Final Discussion

This journey started with the general goal of going toward non-deterministic, probabilistic and quantum GT. Starting with the first concrete step of capturing non-deterministic Lindenmayer systems as GT, we guessed some constructions based on the deterministic case. The result of these guesses did not have the precise form of a GT in the 2-category of categories, functors and natural transformations. But we showed they correspond in fact to a GT in another (weak) 2-category. The latter is induced by Kleisli's construction on a particular (weak) 2-monad that we made explicit. This is to be expected since the same architecture happens for non-deterministic dynamical systems. Indeed, they are also dynamical systems in another category, with the latter being induced by a monad. All in all, we ended with a general solution for mixing non-determinism with locality as described in the global transformation framework.

Along the way, we mentioned a few technicalities on which we now come back. The first one is the Conjecture 10 on which we want to add a comment. If it is wrong, then families can be simplified into sets. But in this case, there should be a relation between the family-based solution just presented and this new set-based solution. But thinking of this relation as a functor from families to sets reinforce us in the belief that the conjecture is true.

The second technicality is about the size of the families considered, which is related to the size issues for the "2-category of categories". For most practical purpose, it is possible to restrict oneself to finite families. In this case, a small category $\mathbf{C}$ leads to a small category $\mathbb{O}\mathbf{C}$. In this case, the 2-functor $\mathbb{O}$ is indeed an endomorphism of the 2-category of *small* categories. Dropping the finiteness constraint though, one then considers a 2-functor $\mathbb{O}\mathbf{C}$ from *small* categories to *large* categories. This is however perfectly fine, since this describes a so-called *relative pseudomonad* with an associate Kleisli's construction, as defined in [8].

In [6], one can find a direct account of the 2-category described here in terms of 2-monad. In particular, the *open* functors and *open* natural transformations are introduced using presheaves and proved to form a weak 2-category. More precisely, an open functor F from a category $\mathbf{C}$ to a category $\mathbf{D}$ is the data of a presheaf on $\mathbf{C}$ together with a functor from the category of elements of that presheaf to $\mathbf{D}$. An interesting feature of this presheaf presentation is that it allows to speak directly about special properties arising from the association of locality and non-determinism. For instance, correlations and intrications correspond to obstructions of the presheaf to be a sheaf. The formal definition in [6] can be made easier to manipulate by the use of discrete fibrations instead of categories of elements through the so-called Grothendieck construction, and doing so presents this bicategory as a particular bicategory of spans. Moreover, this bicategory is a sub-bicategory of the bicategory of profunctors (*a.k.a.* distributors). Notice that the many presentations of this bicategory are strongly related to the many possible presentations one can have of the notion of "relation": powerset monad (as in this paper), spans, and characteristic functions of the relation.

Abstract

Regular nested word languages (a.k.a. visibly pushdown languages) strictly extend regular word languages, while preserving their main closure and decidability properties. Previous works have shown that considering languages of 2-nested words, *i.e.* words enriched with two matchings (a.k.a. 2-visibly pushdown languages), is not as successful: the corresponding model of automata is not closed under determinization. In this work, inspired by homomorphic representations of indexed languages, we identify a subclass of 2-nested words, which we call 2-wave words. This class strictly extends the class of nested words, while preserving its main properties. More precisely, we prove closure under determinization of the corresponding automaton model, we provide a logical characterization of the recognized languages, and show that the corresponding graphs have bounded treewidth. As a consequence, we derive important closure and decidability properties. Last, we show that the word projections of the languages we define belong to the class of linear indexed languages.

1 Introduction

The class of regular languages constitutes a cornerstone of theoretical computer science, thanks to its numerous closure and decidability properties. A long line of research studied extensions of this class, while preserving its robustness. Context free languages (CFL for short) constitute a very important class: they admit multiple presentations, by means of pushdown automata, context-free grammars and more, and have led to numerous applications. Unfortunately, CFL do not satisfy several important properties enjoyed by regular languages. More precisely, the corresponding automaton model, namely pushdown automata, does not admit determinization. In addition, the class of CFL is not closed under intersection nor complement, and universality, inclusion and equivalence are undecidable properties.

A simple way to patch this is by considering as input the word together with the inherent matching relation, resulting in what is known as a *nested word* [3]. Indeed, as soon as a word belongs to a CFL, one can identify a matching relation on (some of) the positions of the word, whatever the presentation of the CFL. For instance, if the CFL is given as a pushdown automaton, then this relation associates push/pop positions. Another way to define the matching relation is to use an alternative presentation of CFL given in [16], which refines the Chomsky-Schützenberger theorem. Following this work, one can show that a language L is a CFL iff there exists a regular language R, a Dyck language D_2 over two pairs of brackets, and two homomorphisms h (h is non-erasing), g such that $L = h(g^{-1}(D_2) \cap R)$. This alternative presentation also leads to a natural matching relation, induced by D_2. The model of *nested* *word automata* naturally extends finite-state automata by allowing to label edges of the matching relation with states (often called hierarchical). This model accepts the so-called class of *regular nested word languages*, allowing to recover most of the nice properties of regular languages. More precisely, nested word automata can always be determinized. The class of regular nested word languages is closed under all the boolean operations, admits an equivalent presentation by means of logic (monadic-second order logic with a binary predicate corresponding to the matching relation), and expected decidability properties (emptiness, universality, inclusion and equivalence). It is worth noticing that another way to present this class is by splitting the alphabet into call/return/internal symbols. This leads to so-called *visibly pushdown languages* [2], and the associated model of visibly pushdown automata.

Several works tried to extend the class of regular nested word languages while preserving its closure and decidability properties. In particular, a focus has been put on words with multiple matching relations. In [19], the authors consider multiple stacks with a semantical restriction of push/pop operations known as k phases. That way, they obtain decidability of the emptiness problem. However, their model of automata cannot be determinized. In [6], the authors consider visibly pushdown automata with multiple stacks, with an ordering on stacks, and prove the closure under complement of their model. Their proof does not rely on the determinization of the model: indeed, as shown in [19], this class cannot be determinized in general. This corrects a previous result published in [5], which states that the general class of 2-stack visibly pushdown automata is closed under complementation, which does not hold, as shown in [4]. The crux in their proof was the use of determinization of 2-stack visibly pushdown automata. In [4], Bollig studies 2-stack visibly pushdown automata in their unrestricted form. He proves the equivalence with the existential fragment of monadic second-order logic, but that quantifier alternation leads to an infinite hierarchy in this setting. As a corollary, the resulting class of languages is not closed under complementation. Another restriction, known as scope-bounded pushdown languages, has been introduced in [20, 21], for which the authors manage to prove that the automaton model can be determinized.

The previous survey of related works shows the difficulty in identifying a class of 2-nested words for which the corresponding automaton model can be determinized. As a consequence, the decidability results presented in these papers require ad-hoc involved proofs. Graphs of bounded treewidth constitute an alternative approach for obtaining decidability properties. Indeed, in [13], the authors show that most of the previous classes with good decidability properties actually correspond to graphs of bounded treewidth, for which MSO decidability follows from [7, 17]. Yet, determinization of nested word automata is the keystone of the nice properties of this model, and thus constitutes a highly desirable feature. In the present work, taking inspiration in indexed languages, we identify a class of 2-nested words for which automata can be determinized. Our class is incomparable with those of [19], [6] and [20, 21]. Intuitively, between two matched positions of the first matching, they bound the number of switches between matchings, while we do not. In addition, the proof of determinizability of [20, 21] is different from ours, as their proof is a kind of superviser that uses determinization of [3] as a subroutine, while ours generalizes the construction of [3] to two nestings.

Indexed languages [1] correspond to the level 2 of the infinite hierarchy of higher-order languages [14]. With numerous applications in computational linguistics, they have been much studied during the seventies and the eighties [15, 8, 9]. Homomorphic characterizations of CFL that we presented before have been extended to (linear) indexed languages in several works, including [22, 10]. One of them (see [10]) shows that L is an indexed language iff there exists a regular language R, two Dyck languages D_2 and D_k over two and k pairs of brackets respectively, and two homomorphisms h, g such that $L = h(g^{-1}(D_2) \cap R \cap D_k)$, with some additional conditions on g. This presentation allows to associate with a word $w \in L$ two matchings, induced by D_2 and D_k, which interact in a very particular way. Graphically speaking, this interaction yields kinds of *waves* (see Figure 1). When restricted to linear indexed languages, the length of these waves is upper bounded by 2, yielding the structure of 2-waves that will be of interest to us in this paper. All these notions will be formally presented in the paper. We also refer the reader to Section 7, in which we explore the relationship between our work and (linear) indexed languages.

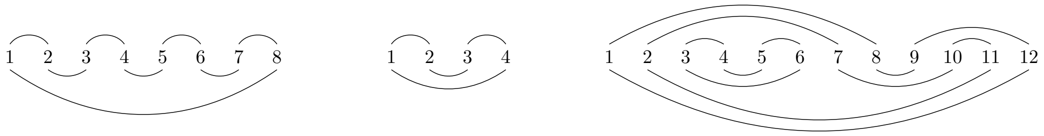

Figure 1 A 4-wave (left), a 2-wave (middle), and a combination of 2-waves (right).

In this paper, we consider 2-nested words whose matchings satisfy the structural restriction of 2-waves; we call them 2-wave words. The main result of this paper is to show that 2-nested word automata are closed under determinization on the class of 2-wave words. While determinization of nested word automata extends the well-known powerset construction with a reference state, our construction is more involved in order to be able to reconcile the labels of the different arches, and we give a detailed proof of correction. This allows us to prove the equivalence of automata with monadic-second order logic on 2-wave words, as well as with its existential fragment. This contrasts with results of [4] which show that on 2-nested words, quantifier alternation yields an infinite hierarchy. We also prove that the graphs associated with 2-wave words are MSO-definable, and have bounded treewidth. As a consequence, we obtain the following decidability results for the class of 2-wave words: satisfiability of MSO, emptiness of automata (in polynomial time), universality, inclusion and equivalence of automata (in exponential time).

In Section 2, we introduce the definitions of matchings and nested words, and provide a grammar for 2-wave words. In Section 3, we introduce the automaton model, and present in Section 4 the main result of the paper: the closure under determinization over 2-wave words. Applications to logic and decidability are presented in Sections 5 and 6. Last, a discussion on relations with (linear) indexed languages is given in Section 7.

2 Words and matchings

Words and relations. For any positive integer n, $[n] = \{1, \ldots, n\}$ is the set of all positive integers ranging from 1 to n. When referencing a position in a word, integers might be called *positions* or *index*. Σ denotes a finite alphabet. The empty word is denoted ϵ, and the set of finite words on Σ is denoted Σ^*. The length of $w \in \Sigma^*$ is denoted $|w|$. Given a non-empty word $w \in \Sigma^*$, its positions are numbered from 1 to $|w|$. We say that u is a *factor* of w if there exist two words x, y such that $w = xuy$. Given an interval $I \subseteq [|w|]$, we denote by $w_{|I}$ the factor of w corresponding to positions in I. Unless specified otherwise, words and automata introduced in this paper are defined on Σ.

▶ **Definition 1.** *A* matching relation *of length* $n \geq 0$ *is a binary relation* M *on* $[n]$ *such that:*
1. *if* $M(i, j)$ *then* $i < j$*, i.e.* M *is compatible with the natural order on integers*
2. *if* $M(i, j)$ *and* $M(k, l)$ *then* $\{i, j\} \cap \{k, l\} \neq \emptyset \implies i = k \wedge j = l$*, i.e. any integer is related at most once by the matching*
3. *if* $M(i, j)$ *and* $M(k, l)$ *then* $i < k < j \implies l < j$ *i.e. a matching is non-crossing.*

Since a matching is an injective functional relation, we will often use functional notations: $M(i) = j$ or $M^{-1}(j) = i$ rather than $M(i, j)$. If $M(i, j)$, we call i a *call* position, j a *return* position and if $k \in [n]$ is neither a call nor a return position we call it an *internal* position.

If I is a subset of $[n]$ we denote by I^c the subset of call positions of I, and by I^r the subset of return positions and I^{int} the subset of internal position. We say that I is *without pending arch* (wpa) if it has no pending call nor pending return, *i.e.* $M(I^c) \cup M^{-1}(I^r) \subseteq I$. Note that this definition holds when I is an interval, but even for an arbitrary subset of $[n]$. In particular, we say a pair (I_1, I_2) of intervals is without pending arch if $I_1 \cup I_2$ is. In this case, we may also say that (I_1, I_2) is a pair of *matched intervals.*

(2-)Nested words. We first recall the classical definition of nested words:

▶ **Definition 2.** *A* nested word *on* Σ *is a pair* $\omega = (w, M)$ *where* $w \in \Sigma^*$ *and* M *is a matching of length* $|w|$*. We write* $\mathsf{NW}(\Sigma)$ *the set of nested words on* Σ*, and* $\mathsf{NWL}(\Sigma)$ *the set of languages of nested words.*

Words equipped with two matchings are called 2-nested words:

▶ **Definition 3.** *A* 2-nested word *on* Σ *is a triple* $\omega = (w, M_1, M_2)$ *where* $w \in \Sigma^*$ *and* M_1*,* M_2 *are matchings of length* $|w|$*. We write* $\mathsf{2NW}(\Sigma)$ *for the set of 2-nested words on* Σ*, and* $\mathsf{2NWL}(\Sigma)$ *for the set of languages of 2-nested words.*

▶ **Example 4.** An example of a nested word (resp. two examples of 2-nested words) is depicted on the left (resp. on the middle and right) of Figure 2. For 2-nested words, the matching M_1 is depicted above, while matching M_2 is depicted below.

Given a 2-nested word $\omega = (w, M_1, M_2)$ and an interval $I \subseteq [|w|]$ which is wpa w.r.t. both M_1 and M_2, we denote by $\omega_{|I}$ the 2-nested word consisting of $w_{|I}$ and of the two matchings M_1' and M_2' obtained from M_1 and M_2 by restricting them to I, and then shifting them to the interval $[|I|]$. It is routine to verify that if ω is a 2-nested word, then so is $\omega_{|I}$.

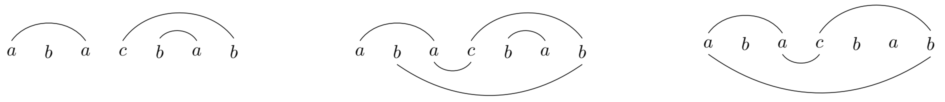

Figure 2 A nested word (left) and two 2-nested words (middle and right).

2-Waves and 2-wave words. In the sequel, we introduce the restriction of 2-nested words on which we will focus. Intuitively, wave structures are graphs obtained from the two matchings consisting of cycles alternating M_1-arches and M_2-arches whose shape evokes waves.

▶ **Definition 5.** *Let* n *be an integer, and* (M_1, M_2) *be a pair of matching relations of length* n*. A sequence of* 4 *integers* $1 \leq i_1 < i_2 < i_3 < i_4 \leq n$ *is a* 2-wave *if the following holds:*

- $M_1(i_1, i_2)$ *and* $M_1(i_3, i_4)$ *(top arches),*
- $M_2(i_2, i_3)$ *(bottom arch), and* $M_2(i_1, i_4)$ *(support arch)*

A pair (M_1, M_2) *is a* 2-wave structure *if any arch in* $M_1 \cup M_2$ *belongs to a 2-wave.*

▶ Remark 6. One could allow 2-wave structures to admit 1-waves, *i.e.* pairs of indices (i_1, i_2) with $i_1 < i_2$, $M_1(i_1, i_2)$ and $M_2(i_1, i_2)$. All our results would also hold for this generalization. However, in order to simplify the presentation of the paper, we do not consider them in this extended abstract.

▶ **Definition 7.** *A* 2*-wave word is a* 2*-nested word* $\omega = (w, M_1, M_2)$ *such that* (M_1, M_2) *is a* 2*-wave structure. We denote by* $\mathsf{WW}_2(\Sigma)$ *the set of* 2*-wave words over the alphabet* Σ.

▶ **Example 8.** Examples of waves are given on Figure 1. Let us consider the 2-nested words depicted on Figure 2. The one on the middle is not a 2-wave word (the upper arch $(5, 6)$ does not belong to a 2-wave), while the one on the right is.

Grammar. In order to proceed with structural induction, we present an inductive presentation of 2-wave words based on multiple context-free grammars (MCFG for short [18]). To this end, we turn to 2-visibly pushdown languages: the alphabet Σ is duplicated into five copies Σ^c_c, Σ^c_r, Σ^r_c, Σ^r_r and $\Sigma^{\text{int}}_{\text{int}}$, whose disjoint is denoted $\tilde{\Sigma}$. This way, the two matchings are encoded in the types of the symbols: the upper index is for the first and the lower index for the second matching relation. More formally, given $\omega \in \mathsf{WW}_2(\Sigma)$, we denote by $\tilde{\omega} \in \tilde{\Sigma}^*$ its visibly pushdown version.

In MCFG, non-terminals allow to express tuples of words. We present a grammar with two non-terminals W and H which represent respectively words (denoted $w \in \tilde{\Sigma}^*$), and pairs of words (denoted $(x, y) \in \tilde{\Sigma}^* \times \tilde{\Sigma}^*$). The grammar is defined by the following rules:

$$\begin{array}{lcl} \mathsf{W} \ni w & ::= & \epsilon \mid i \mid w_1 w_2 \mid x w y \\ \mathsf{H} \ni (x, y) & ::= & (\epsilon, \epsilon) \mid (x_1 x_2, y_2 y_1) \mid (w_1 x w_1', w_2 y w_2') \mid (axb, cyd) \end{array}$$

where $i \in \Sigma^{\text{int}}_{\text{int}}$ and $(a, b, c, d) \in \Sigma^c_c \times \Sigma^r_c \times \Sigma^c_r \times \Sigma^r_r$.

▶ **Lemma 9.** $L(\mathsf{W}) = \{\tilde{\omega} \in \tilde{\Sigma}^* \mid \omega \in \mathsf{WW}_2(\Sigma)\}$

Proof sketch. We give some hints on how to show the right to left implication. Let $\omega = (w, M_1, M_2) \in \mathsf{WW}_2(\Sigma)$. We show, by induction on $n \leq |w|$, the following properties:

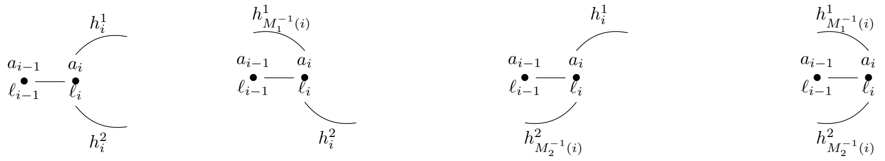
- Let $I \subseteq [|w|]$ such that $|I| = n$ and I is wpa, then $\tilde{\omega}_{|I} \in L(\mathsf{W})$.
- Let $I_1, I_2 \subseteq [|w|]$ such that $|I_1| + |I_2| = n$ and (I_1, I_2) is wpa, then $(\tilde{\omega}_{|I_1}, \tilde{\omega}_{|I_2}) \in L(\mathsf{H})$.

The proof decomposes the 2-wave, by distinguishing cases according to the structure of the two matchings. One can then verify that in all cases, one can produce the words using one of the rules of the grammar. ◀

3 2-Nested Word Automata

Nested word automata have been introduced in [3] as an extension of finite-state automata intended to recognize nested words. They label arches of the matching relation with so-called *hierarchical* states: if the position corresponds to a call (resp. a return), then the automaton "outputs" (resp. "receives") the hierarchical state used to label the arch, hence we place it after the input letter (resp. before). This corresponds to push/pop operations performed by a (visibly) pushdown automaton. The extension of this model to multiple matchings is natural, and has already been considered in [4, 6]: with two matchings, automata label edges of both matchings with hierarchical states.

We first introduce some notations. Let us assume that two matching relations M_1, M_2 of length n are given. Then, each index $i \in [n]$ can be labelled in 9 different ways depending on it's call, return and internal status with regard to matchings M_1 and M_2. We say that a position i is a *call-return* if it is a call w.r.t. M_1, and a return w.r.t. M_2. We extend this convention to other possible types of positions (*call-call*, *return-call*, *call-internal*. . .). Let $I \subseteq [n]$ and $x, y \in \{c, r, \text{int}\}$. Following our graphical representation of 2-nested words, in which M_1 is depicted above the word, and M_2 is depicted below, we denote by I^x_y the subset



$(\ell_{i-1}, a_i, h_i^1, h_i^2, \ell_i) \in \Delta_c^c$ $(\ell_{i-1}, h^1_{M_1^{-1}(i)}, a_i, h_i^2, \ell_i) \in \Delta_c^r$ $(\ell_{i-1}, h^2_{M_2^{-1}(i)}, a_i, h_i^1, \ell_i) \in \Delta_r^c$ $(\ell_{i-1}, h^1_{M_1^{-1}(i)}, h^2_{M_2^{-1}(i)}, a_i, \ell_i) \in \Delta_r^r$

Figure 3 Examples of transition steps.

of I with x status on M_1, and y status on M_2. For instance, given a position $i \in I$, we have $i \in I_r^c$ if i is a call w.r.t. M_1 and a return w.r.t. M_2. We also introduce the following shortcuts: for $x \in \{c, r\}$, $I^x = I_c^x \cup I_r^x \cup I_{\text{int}}^x$ and $I_x = I_x^c \cup I_x^r \cup I_x^{\text{int}}$. For instance, I^c (resp. I_c) denotes the set of positions in I which are a call w.r.t. M_1 (resp. M_2).

▶ **Definition 10.** *A* 2-nested word automaton *is a tuple $A = (Q, Q_0, Q_f, P, \Sigma, \Delta)$ where :*

- *Q is a finite set of states and $Q_0, Q_f \subseteq Q$ are respectively the initial and final states*
- *P is a set of hierarchical states*
- *$\Delta = (\Delta_y^x)_{x,y \in \{c,r,int\}}$ is a set of transitions : $\Delta_y^x \subseteq Q \times P^{\mathsf{in}_{x,y}} \times \Sigma \times P^{\mathsf{out}_{x,y}} \times Q$, where $\mathsf{in}_{x,y}$ (resp. $\mathsf{out}_{x,y}$) is the number of r (resp. c) in $\{x, y\}$. For instance, $\mathsf{in}_{c,r} = \mathsf{in}_{r,c} = 1$ and $\mathsf{out}_{c,c} = 2$.*

▶ Remark 11. In the previous definition, elements in $P^{\mathsf{in}_{x,y}}$ correspond to hierarchical states that label closing arches, which can be interpreted as popped symbols, while elements in $P^{\mathsf{out}_{x,y}}$ correspond to hierarchical states that label opening arches, which can be interpreted as pushed symbols. Elements of Q are called *linear* states, as they follow the edges of the linear order, in contrast to hierarchical states.

▶ **Definition 12** (Run/Language of a 2NWA). *Let $\omega = (a_1 \dots a_n, M_1, M_2) \in \mathsf{2NW}$ and A be a* 2NWA*. Let $\ell = (\ell_i)_{i \in [\![0,n]\!]}$ be a sequence of states, $h^1 = (h_i^1)_{i \in [n]^c}$ and $h^2 = (h_i^2)_{i \in [n]_c}$ be two sequences of elements of P. For all $i \in [n]$, we write $run_i^A(\omega, \ell, h^1, h^2)$ if one of the following cases holds: (the first four cases are illustrated on Figure 3)*

- **call-call:** *$i \in [n]_c^c$, and $(\ell_{i-1}, a_i, h_i^1, h_i^2, \ell_i) \in \Delta_c^c$*
- **return-call:** *$i \in [n]_c^r$, and $(\ell_{i-1}, h^1_{M_1^{-1}(i)}, a_i, h_i^2, \ell_i) \in \Delta_c^r$*
- **call-return:** *$i \in [n]_r^c$, and $(\ell_{i-1}, h^2_{M_2^{-1}(i)}, a_i, h_i^1, \ell_i) \in \Delta_r^c$*
- **return-return:** *$i \in [n]_r^r$, and $(\ell_{i-1}, h^1_{M_1^{-1}(i)}, h^2_{M_2^{-1}(i)}, a_i, \ell_i) \in \Delta_r^r$*
- **call-internal:** *$i \in [n]_{int}^c$, and $(\ell_{i-1}, a_i, h_i^1, \ell_i) \in \Delta_{int}^c$*
- **internal-call:** *$i \in [n]_c^{int}$, and $(\ell_{i-1}, a_i, h_i^2, \ell_i) \in \Delta_c^{int}$*
- **return-internal:** *$i \in [n]_{int}^r$, and $(\ell_{i-1}, h^1_{M_1^{-1}(i)}, a_i, \ell_i) \in \Delta_{int}^r$*
- **internal-return:** *$i \in [n]_r^{int}$, and $(\ell_{i-1}, h^2_{M_2^{-1}(i)}, a_i, \ell_i) \in \Delta_r^{int}$*
- **internal-internal:** *$i \in [n]_{int}^{int}$, and $(\ell_{i-1}, a_i, \ell_i) \in \Delta_{int}^{int}$*

If for all $i \in [n]$, $run_i^A(\omega, \ell, h^1, h^2)$ holds, the triple (ℓ, h^1, h^2) is said to be a run *of A* over *ω; it is an* accepting run *if $\ell_0 \in Q_0$ and $\ell_n \in Q_f$.*

We will write $q \xrightarrow[A]{\omega} q'$ when there exists a triple (ℓ, h^1, h^2) which is a run of A on ω, and whose first (resp. last) element of ℓ is equal to q (resp. q'). If we denote by n the length of ω, and if $I \subseteq [n]$ is an interval wpa, then we write $q \xrightarrow[A]{\omega, I} q'$ as a shortcut for $q \xrightarrow[A]{\omega_{|I}} q'$.

A 2-nested word is accepted by *A if it admits an accepting run. The set of all 2-nested words accepted by A is denoted $L(A)$, and a language of 2-nested words is called* regular *if it is accepted by a 2-nested word automaton. In the sequel, we will also be interested in restricting the language of a* 2NWA *to 2-wave words. Hence, we denote by $L_{\mathsf{WW}_2}(A)$ the set of 2-wave words accepted by A,* i.e. *$L(A) \cap \mathsf{WW}_2(\Sigma)$.*

▶ **Example 13.** Let $A_{ex} = (Q, Q_0, Q_f, P, \{a, b, c, d\}, \Delta)$, with $Q = \{q_a, q_b, q_c, q_d\}$, $Q_0 = \{q_a\}$, $Q_f = \{q_d\}$, $P = Q$ and Δ defined as follows (we only give non-empty transition sets):

$\Delta_c^c = \{(q_a, a, q_a, q_a, q_a)\}$
$\Delta_c^r = \{(q_x, q_a, b, q_b, q_b) \mid x \in \{a, b\}\}$
$\Delta_r^c = \{(q_x, q_b, c, q_c, q_c) \mid x \in \{b, c\}\}$
$\Delta_r^r = \{(q_x, q_c, q_a, d, q_d) \mid x \in \{c, d\}\}$

Figure 4 A run of A_{ex} over ω_2.

We illustrate the semantics of 2NWA by giving on Figure 4 a graphical representation of a run of A_{ex} on the 2NW $\omega_2 = (a^2b^2c^2d^2, M_1, M_2)$, with M_1, M_2 depicted on Figure 4. We let the reader check that the projection of $L(A_{ex})$ on Σ^* is equal to $\{a^nb^nc^nd^n \mid n \geq 1\}$, hence not context-free.

▶ **Definition 14** (deterministic 2NWA). *A 2NWA is deterministic iff $Q_0 = \{q_0\}$ and for all $x, y \in \{c, r, int\}$, Δ_y^x induces a function $Q \times P^{\mathsf{in}_{x,y}} \times \Sigma \to P^{\mathsf{out}_{x,y}} \times Q$.*

▶ **Example 15.** The automaton A_{ex} considered in Example 13 is deterministic.

Normal form. To ease further constructions, we present a normal form for 2NWA that requires the hierarchical state of an arch to be equal to the target linear state of its call index. More formally, we say that a 2NWA is in weakly-hierarchical post form (post form for short) if $P = Q$ and for all $x, y \in \{c, r, \text{int}\}$, $\Delta_y^x \subseteq \bigcup_{q \in Q} Q \times Q^{\mathsf{in}_{x,y}} \times \Sigma \times \{q\}^{\mathsf{out}_{x,y}} \times \{q\}$. As a consequence, transitions of an automaton in post form can be simplified: $\Delta_y^x \subseteq Q \times Q^{\mathsf{in}_{x,y}} \times \Sigma \times Q$.

It is worth observing that in a 2NWA in post form, a run is completely characterized by the linear states. Hence, we can omit the hierarchical states in the formula run_i^A, and we can say that a sequence of (linear) states ℓ is a run of A on a 2-nested word ω.

▶ **Example 16.** The automaton A_{ex} considered in Example 13 is in post form.

▶ **Lemma 17.** *Given a* 2NWA $A = (Q, Q_0, Q_f, \Sigma, P, \Delta)$, *we can build a* 2NWA $A' = (Q', q_0', Q_f', \Sigma, Q', \Delta')$ *which is in weakly-hierarchical post form and such that $L(A) = L(A')$.*

Closure properties. Applying classical automata constructions to 2NWA, one can prove the following closure properties of regular 2NWL.

▶ **Proposition 18** (See also [4]). *Regular* 2NWL *are closed under union, intersection, and direct and reciprocal image by a non erasing alphabetic morphism.*

4 Determinization of 2NWA over 2-wave words

▶ **Theorem 19.** 2NWA *are determinizable on the subclass of 2-wave words,* i.e., *given a* 2NWA A, *we can build a deterministic* 2NWA A' *such that $L_{\mathsf{WW}_2}(A) = L_{\mathsf{WW}_2}(A')$.*

Thanks to Lemma 17, we start from a 2NWA in post normal form $A = (Q, Q_0, Q_f, \Delta)$. This normal form will allow to lighten the presentation, as less arguments are needed to write the transitions and the runs. We will describe the construction of a deterministic 2NWA A' (not in post normal form), which accepts the same language of 2-wave words.

Introduction to the construction. The determinization of finite-state automata, known as the powerset construction, registers all the states reachable by a run of A, which in the sequel are named *current* states. The determinization procedure of [3] for nested word automata requires the recording of two states. In addition to the current state, they also store the state labelling the call of the arch covering the current position. This state is named *reference* state. Intuitively, it stores where we come from, and will be used when closing the arch to reconcile the global run with what happened below this arch.

In our setting, as we consider a pair of matchings (M_1, M_2) instead of a single one, we need to store triples of states, composed of two reference states (one for M_1 and one for M_2), and one current state. Hence, states of A' will be sets of such triples of states.

The very particular shape of 2-wave words, and in particular the fact that the support arch and the top arches do end up at the same return-return position, ensure that we can gather the information collected along these two paths to compute, in a deterministic fashion, the set of possible current states.

However, when trying to address the setting of 2-wave words, we face another difficulty related to reference states. Indeed, the computations we will perform on each arch of the 2-wave word are somehow disconnected. In order to be sure that they can be reconciled, we will enrich the reference state of the second top arch of the 2-wave with the state of the bottom arch and that of the first top arch. This allows us to check whether the reference associated with the second top arch is *compatible* with that chosen for the first top arch.

Construction. We will define the deterministic 2NWA $A' = (Q', \{q'_0\}, Q'_f, P', \delta)$ in the following way. We first introduce the reference states for M_1 and M_2: [1]

$$\begin{array}{lll} \overline{\mathcal{R}}^1 & := Q & \text{the reference for positions at the surface of the first top arch} \\ \overline{\mathcal{R}}^2 & := Q^3 & \text{the reference for positions at the surface of the second top arch} \\ \underline{\mathcal{R}} & := Q & \text{the reference for } M_2 \end{array}$$

We denote by $\overline{\mathcal{R}}$ the union $\overline{\mathcal{R}}^1 \cup \overline{\mathcal{R}}^2$. This allows us to define:

$$\begin{array}{llll} Q' & := 2^{\overline{\mathcal{R}}^1 \times \underline{\mathcal{R}} \times Q} \cup 2^{\overline{\mathcal{R}}^2 \times \underline{\mathcal{R}} \times Q} & q'_0 & := \{(q_0, q_0, q_0);\ q_0 \in Q_0\} \\ Q'_f & := \{S \in Q';\ S \cap Q \times Q \times Q_f \neq \emptyset\} & P' & := (Q' \times \Sigma) \cup (Q' \times \Sigma)^2 \end{array}$$

The transition function δ for A' is defined as follows, by distinguishing cases according to the nature of the symbol. The construction is illustrated on Figure 5. In order to ease the writing, the arguments of the formula are not explicitly written.

- $\delta_{\text{int}}(S, \alpha) := \{(\overline{r}, \underline{r}, q');\ \exists q\ (\overline{r}, \underline{r}, q) \in S \wedge (q, \alpha, q') \in \Delta_{\text{int}}\}$
- $\delta_c^c(S_1, \alpha_1) := (S'_1, (S_1, \alpha_1), (S_1, \alpha_1))$ where

$$S'_1 := \{(q'_1, q'_1, q'_1);\ \exists \overline{r}_1, \underline{r}_0, q_1\ \phi_1\}$$
$$\phi_1 := (\overline{r}_1, \underline{r}_0, q_1) \in S_1 \wedge (q_1, \alpha_1, q'_1) \in \Delta_c^c.$$

[1] Observe that the reference state for the second top arch is a triple of states, as explained before.

- $\delta_c^r(S_2,(S_1,\alpha_1),\alpha_2) := (S_2',(S_1,\alpha_1,S_2,\alpha_2))$ where

$$S_2' := \{(\overline{r}_1,q_2',q_2');\ \exists \underline{r}_0,\underline{r}_2,q_1,q_1',q_2\ \phi_2\}$$
$$\phi_2 := \phi_1 \wedge (q_1',\underline{r}_2,q_2) \in S_2 \wedge (q_2,q_1',\alpha_2,q_2') \in \Delta_c^r$$

- $\delta_r^c(S_3,(S_1,\alpha_1,S_2,\alpha_2),\alpha_3) := (S_3',(S_2,\alpha_2,S_3,\alpha_3))$ where [2]

$$S_3' := \{(q_1'q_2'q_3',\underline{r}_2,q_3');\ \exists \overline{r}_1,\overline{r}_3,\underline{r}_0,q_1,q_2,q_3\ \phi_3\}$$
$$\phi_3 := \phi_2 \wedge \overline{r}_1 \preceq \overline{r}_3 \wedge (\overline{r}_3,q_2',q_3) \in S_3 \wedge (q_3,q_2',\alpha_3,q_3') \in \Delta_r^c$$

- $\delta_r^r(S_4,(S_2,\alpha_2,S_3,\alpha_3),(S_1,\alpha_1),\alpha_4) := S_4'$ where

$$S_4' := \{(\overline{r}_3,\underline{r}_0,q_4');\ \exists \overline{r}_1,\underline{r}_2,q_1,q_1',q_2,q_2',q_3,q_3',q_4\ \phi_4\}$$
$$\phi_4 := \phi_3 \wedge (q_1'q_2'q_3',q_1',q_4) \in S_4 \wedge (q_4,q_3',q_1',\alpha_4,q_4') \in \Delta_r^r$$

▶ Remark 20. Formulas $(\phi_j)_{j\in[4]}$ are not quantified at all, hence all their variables are free. Their objective is to link parameters extracted from the triplets of states of A'.

Proof of correctness. We fix a 2-wave word $\omega = (w, M_1, M_2)$, with $w = a_1 \dots a_n$. The following proposition states that on an interval without pending arch, runs of A' exactly capture possible runs of A, while keeping track of the reference states, as explained before.

▶ **Proposition 21.** *Let $[\![s,f]\!] \subseteq [n]$ be wpa, and $S,S' \in Q'$ such that $S \xrightarrow[A']{\omega,[\![s,f]\!]} S'$, then:*

$$\forall \overline{r} \in \overline{\mathcal{R}},\ \underline{r} \in \underline{\mathcal{R}},\ q' \in Q,\ \left((\overline{r},\underline{r},q') \in S' \iff \exists q \in Q\ (\overline{r},\underline{r},q) \in S \wedge q \xrightarrow[A]{\omega,[\![s,f]\!]} q'\right)$$

Before sketching the proof of this proposition, we fix some notations. Let $[\![s,f]\!] \subseteq [n]$ be an interval wpa, and $S,S' \in Q'$ such that $S \xrightarrow[A']{\omega,[\![s,f]\!]} S'$. Observe that as A' is deterministic,

[2] $\preceq$ denotes the prefix partial order on strings.

it has a unique run on the 2-wave word ω restricted to $[\![s,f]\!]$. We let $(L_i)_{i\in[\![s-1,f]\!]}$ denote the (linear) states of this run. In particular, we have $L_{s-1} = S$ and $L_f = S'$. As A' is deterministic, hierarchical states are completely determined from linear ones.

In order to prove Proposition 21, we separate the direct from the indirect case. For the indirect case, it is easy to show by induction that any run of A on ω (restricted to $[\![s,f]\!]$) will appear in the run of A' on ω (restricted to $[\![s,f]\!]$). This only requires to define carefully the corresponding reference states.

▶ **Lemma 22.** *Let $\ell = (\ell_i)_{i\in[\![s-1,f]\!]}$ be a run of A on ω (restricted to $[\![s,f]\!]$) such that $\ell_{s-1} = q$, $\ell_f = q'$ and $(\overline{r},\underline{r},q) \in S = L_{s-1}$. Then we can define reference mappings $\overline{R}$ and $\underline{R}$ from $[\![s-1,f]\!]$ to $\overline{\mathcal{R}}$ and $\underline{\mathcal{R}}$ respectively, such that $\overline{R}(f) = \overline{r}$, $\underline{R}(f) = \underline{r}$, and for all $i \in [\![s-1,f]\!]$, $(\overline{R}(i),\underline{R}(i),\ell_i) \in L_i$.*

The direct implication will be proven by induction on $[\![s,f]\!]$. More precisely, we rely on the grammar allowing to describe all 2-wave words given in Section 2. We use a slight abuse of notation here, as the grammar is based on the visibly pushdown presentation, while we work here with 2-nested words, but we believe the correspondence is without ambiguity. The three first cases of the grammar (internal, empty word, and concatenation of 2-wave words) are easy. The last case decomposes the 2-wave word ω as $\omega = x\omega' y$, with (x,y) being a pair of "matched" words, *i.e.* given by the non-terminal H. Intuitively, the grammar gives a decomposition of the wpa interval associated with ω into a wpa interval corresponding to ω', and a pair of matched intervals corresponding to (x,y). Hence, this requires to study pairs of matched intervals, *i.e.* a pair of intervals which is without pending arch. To this end, we introduce a notation for a "partial" run on a pair of matched intervals:

▶ **Definition 23.** *Let $(I_1 = [\![i_1,j_1]\!], I_2 = [\![i_2,j_2]\!])$ be a pair of matched intervals w.r.t. ω. Let q_1,q_2,q_1',q_2' be four states. We let $J = I_1 \cup I_2 \cup \{i_1-1, i_2-1\}$. We write $q_1,q_2 \xrightarrow[A]{\omega,I_1,I_2} q_1',q_2'$ if there exists $(\ell_i)_{i\in J}$ such that $\forall i \in J$, $run_i^A(\omega,\ell)$ and $\forall k \in [2]$, $q_k = \ell_{i_k-1}$ and $q_k' = \ell_{j_k}$*

We are now ready to state the following lemma:

▶ **Lemma 24.** *Let (i_1,i_2,i_3,i_4) be a 2-wave such that $i_1 \in [\![s,f]\!]$ and $(\overline{r}_3,\underline{r}_0,q_4') \in L_{i_4}$. For any $\overline{r}_1,\underline{r}_2,q_1,q_1',q_2,q_2',q_3,q_3',q_4$ satisfying ψ_4 we have $q_1,q_3 \xrightarrow[A]{\omega,[\![i_1,i_2]\!],[\![i_3,i_4]\!]} q_2',q_4'$.*

Lemma 24 confirms the intuition that a 2-wave is an encapsulation in its sort: any q_1, q_2' and q_3 yielded by $(\overline{r}_3,\underline{r}_0,q_4') \in L_{i_4}$ via the construction of L_{i_4} (e.g. via ψ_4) define with q_4' a run of A on ω on the subset of positions given by $[\![i_1,i_2]\!]$ and $[\![i_3,i_4]\!]$.

We explain how to conclude the proof of Proposition 21. Starting from the 2-wave word ω, we obtained a decomposition $\omega = x\omega' y$, with (x,y) being a pair of "matched" words produced by H. We can show in addition that extremal positions of x and y exactly correspond to a 2-wave, in the sense of the premises of Lemma 24. Combining it with the induction hypothesis (direct implication of Proposition 21) applied on ω', we can exhibit the expected run in A.

Proof of Theorem 19. First, observe that by construction, A' is deterministic and complete. Let $\omega \in \mathsf{WW}_2(\Sigma)$. As A' is deterministic and complete, it has a unique run on ω starting from q_0'. Let $(L_i)_{i\in[\![0,n]\!]}$ be this run, with $L_0 = q_0'$. We proceed by equivalence:

$$\begin{aligned}\omega \in L(A') \iff L_n \in Q_f' \iff L_n \cap Q \times Q \times Q_f \neq \emptyset \iff \exists(\overline{r},\underline{r},q_f) \in L_n\ q_f \in Q_f \\ \iff \exists q_0, q_f \in Q_f\ (\overline{r},\underline{r},q_0) \in q_0' \text{ and } q_0 \xrightarrow[A]{\omega} q_f \iff \omega \in L(A).\end{aligned}$$

◀

Closure under complementation. It is proved in [19] that regular 2NWL are not closed under complementation, since they are not determinizable. The definition of 2NWL they use is sightly different from ours because the two matchings do not share positions, but the same negative result can be shown for our definition. For example, there is no deterministic automaton recognizing the language $\{(a^{n+m}b^m a^n b^m a^n, \{(i, i+2(n+m)) \mid 1 \leq i \leq n+m\}, \{(i, i+n+m) \mid 1 \leq i \leq n+m\}) \mid n, m \geq 0\}$. However, thanks to our determinization result for regular WW_2 languages, we get:

▶ **Proposition 25.** *Regular languages of* 2*-wave words are closed under complementation.*

5 Logical characterization

We show that languages of 2-wave words definable in monadic second order logic (MSO) are exactly regular languages of 2-wave words. Let us fix $\mathcal{V} = \mathcal{V}_1 \cup \mathcal{V}_2$, $\mathcal{V}_1$ is the set of first order variables (whose elements will be written using lower-cases) and $\mathcal{V}_2$ is the set of second order variables (whose elements will be written using upper-cases).

The monadic second-order logic of 2-nested words (MSO$(\Sigma, <, M_1, M_2)$) is given by

$$\phi := Q_a(x) \mid x < y \mid X(x) \mid M_i(x, y) \mid \neg\phi \mid \phi \wedge \phi \mid \exists x\ \phi \mid \exists X\ \phi$$

where $a \in \Sigma$, $x, y \in \mathcal{V}_1$, $X \in \mathcal{V}_2$, $i \in \{1, 2\}$.

The semantics is defined over 2-nested words in a natural way. The first-order variables are interpreted over positions of the nested word, while set variables are interpreted over sets of positions; $Q_a(x)$ holds if the symbol at the position interpreted for x is a, $x < y$ holds if the position interpreted for x is lesser than the position interpreted for y, and $M_i(x, y)$ holds if the positions interpreted for x and y are related by a nesting edge of matching M_i.

Let us define some fragments of MSO$(\Sigma, <, M_1, M_2)$. The set FO$(\Sigma, <, M_1, M_2)$ of first order (FO) formulas is the set of all formulas in MSO$(<, M_1, M_2)$ that do not contain any second-order quantifier. Furthermore, the set EMSO$(\Sigma, <, M_1, M_2)$ of existential MSO (EMSO) formulas consists of all formulas of the form $\exists X_1 \ldots \exists X_n \phi$, with $\phi \in$ FO$(\Sigma, <, M_1, M_2)$. If $\mathcal{L}$ is a logic (MSO, EMSO or FO), and ϕ is a closed formula in $\mathcal{L}(\Sigma, <, M_1, M_2)$, the *language defined by* ϕ, denoted $L(\phi)$ is the set of all 2-nested words that are a model for ϕ, and $L_{\mathsf{WW}_2}(\phi)$ is the set of all 2-wave words that are a model for ϕ, that is, $L_{\mathsf{WW}_2}(\phi) = L(\phi) \cap \mathsf{WW}_2(\Sigma)$.

In [4], Bollig shows the equivalence between automata and EMSO for the whole class of 2-nested words. However, he shows that quantifier alternation yields an infinite hierarchy. In our setting, this hierarchy collapses, and we obtain the equivalence between MSO and EMSO. The following characterization extends that given in [3] for regular nested word languages. Its proof follows classical lines, and relies on Propositions 18 and 25.

▶ **Theorem 26.** *A language of* 2*-wave words is definable in EMSO iff it is definable in MSO iff it is regular.*

6 Decision problems

The analysis we did so far of 2NWA over 2-wave words allows to establish the following decidability results:

▶ **Theorem 27.** *Let A and B be two* 2NWA *over* Σ*. The following holds:*

- *Determining whether* $L_{\mathsf{WW}_2}(A) = \emptyset$ *can be decided in polynomial time.*
- *Determining whether* $L_{\mathsf{WW}_2}(A) = \mathsf{WW}_2(\Sigma)$ *can be decided in exponential time.*
- *Determining whether* $L_{\mathsf{WW}_2}(A) \subseteq L_{\mathsf{WW}_2}(B)$ *(resp.* $L_{\mathsf{WW}_2}(A) = L_{\mathsf{WW}_2}(B)$*) can both be decided in exponential time.*

Proof sketch. The first result follows from the grammar presented in Section 2 that produces all 2-wave words. More precisely, we maintain a set W of pairs of states (for non-terminal W) and a set H of quadruplets of states (for non-terminal H). Intuitively, $(p, q) \in W$ means that there exists a 2-wave word ω and a run $p \xrightarrow[A]{\omega} q$. We initialize them with identity relations and saturate them using the rules of the grammar, and corresponding transitions of A. The other results are direct consequences from closure under complement using the determinization procedure, with the observation that the latter has exponential complexity. ◀

On the treewidth of 2-wave words. Any 2NW $\omega = (w, M_1, M_2)$ of length n can be seen as a graph whose set of vertices is $[n]$ and set of edges is $M_1 \cup M_2 \cup \{(i, i+1)\}_{i \in [n-1]}$, then an alternative approach to decidability is by using Courcelle's Theorem on graphs of bounded treewidth. Indeed, using the grammar presented in Section 2 for 2-wave words (Lemma 9), we show:

▶ **Lemma 28.** *For all $\omega \in \mathsf{WW}_2(\Sigma)$, ω has treewidth at most* 11.

In addition, it is easy to verify that the class of 2-wave words can be expressed in MSO. As a consequence, we obtain using [7, 17]:

▶ **Proposition 29.** *Given a formula $\phi \in MSO(<, M_1, M_2)$, checking whether there exists $\omega \in \mathsf{WW}_2(\Sigma)$ that satisfies ϕ is decidable.*

7 Relation to indexed languages

Let $\mathcal{L}$ be a logic (FO, EMO, or MSO), we denote by $\exists\text{Match}\mathcal{L}(\Sigma, <, M)$ the class of all word languages $L = \{u \in \Sigma^* \mid \exists M (u, M) \in L_M\}$ such that L_M is definable in $\mathcal{L}(\Sigma, <, M)$. Similarly, we denote by $\exists\mathsf{WW}_2\mathcal{L}(\Sigma, <, M_1, M_2)$ the class of languages $L = \{u \in \Sigma^* \mid \exists (u, M_1, M_2) \in L_{\mathsf{WW}_2}(\phi)\}$ for $\phi \in \mathcal{L}(\Sigma, <, M_1, M_2)$.

It is proved in [12] that CFL $= \exists\text{Match FO}(\Sigma, <, M) = \exists\text{Match MSO}(\Sigma, <, M)$. A key of the proof is the fact that CF grammars can be put in Greibach double normal form. Then each production has the form $X \to aub$, and the derivation tree of a word can be encoded by matching letters delimiting each production.

Consider now indexed grammars that generate Indexed Languages (IL). They are CF grammars where each non-terminal symbol carries a pushdown stack (often denoted X^ω where X is the non terminal and ω the stack). Grammars contain *push productions* of the form $X \to Y^p$ saying that any X^ω can be rewritten $Y^{p\omega}$; *pop productions* of the form $X^p \to Y$ saying that any $X^{p\omega}$ can be rewritten Y^ω and *copy productions* of the form $X \to YZ$ saying that any X^ω can be rewritten $Y^\omega Z^\omega$.

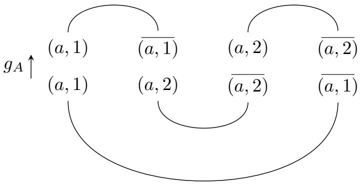
The derivation tree of a word can be encoded using two matching relations: one delimiting productions (corresponding to M_2), and one for the stack moves (corresponding to M_1). The nested structure thus obtained is a wave structure, where each wave follows a pushed symbol amongst the different copies. In particular, a 2-wave corresponds to a symbol which has been popped but has never been copied. Indexed grammars which never process copies are called *linear indexed grammars* and generate *linear indexed languages* (LIL). In such grammars, copy productions have the form $X \to X^\bullet Y$ or $X \to XY^\bullet$ where $\bullet$ marks the symbol on which the stack is transmitted.

The next Proposition establishes a formal connection between regular languages of 2-wave words and linear indexed languages:

▶ **Proposition 30.** *Languages in $\exists\mathsf{WW}_2 MSO(\Sigma, <, M_1, M_2)$ are linear indexed languages.*

Proof sketch. We use the homomorphic characterization of linear indexed languages given in [22]. We denote by $\mathcal{D}_A$ the Dyck language over alphabet A with inverse letters in $\bar{A} = \{\bar{a} \mid a \in A\}$. Then, a language L is linear indexed iff there exists an alphabet A, a regular language R and a morphism h such that $L = h(R \cap \mathcal{D}_{\Gamma_A} \cap g_A^{-1}(\mathcal{D}_{\Gamma_A}))$, where: $A_i = \{(a, i) \mid a \in A\}$, for $i = 1, 2$, $\Gamma_A = A_1 \cup A_2$ and g_A is the morphism defined by

$$g_A : \begin{array}{ll} (a,1) \mapsto (a,1) & \overline{(a,1)} \mapsto \overline{(a,2)} \\ (a,2) \mapsto \overline{(a,1)} & \overline{(a,2)} \mapsto (a,2) \end{array}$$



Remark that from a given a word u in $\mathcal{D}_{\Gamma_A} \cap g_A^{-1}(\mathcal{D}_{\Gamma_A})$, we can construct a 2NW (u, M_1, M_2) where arches in M_2 correspond to $\mathcal{D}_{\Gamma_A}$, and M_1 to $g_A^{-1}(\mathcal{D}_{\Gamma_A})$.

The proof is then similar to that of Chomsky-Schützenberger Theorem applied to pushdown automata: the regular language R encodes runs on linear states, $\mathcal{D}_{\Gamma_A}$ and $g_A^{-1}(\mathcal{D}_{\Gamma_A})$ ensure the consistency of hierarchical states and h projects the run on its word. ◀

However, we don't know if the equality holds, mainly because we don't know if linear indexed languages can be put in a Greibach double normal like form.

We can also ask whether the logical characterization of CFL extends to indexed languages. The appropriate structure seems to be 2NW whose edges form *waves* of unbounded length. Intuitively, a k-wave generalizes a 2-wave as follows: it consists of $2k$ indices in increasing order, with k top arches, $k-1$ bottom arches, and an additional support arch. An example of a 4-wave is depicted on Figure 1. This yields the notion of k-wave word (WW_k), and that of wave word (WW), which is simply the union of WW_k over k. As an example, the 2-nested word depicted on Figure 6 is in WW_4. So, the question is: does $\mathsf{IL} = \exists\mathsf{WWFO}(\Sigma, <, M_1, M_2) = \exists\mathsf{WWMSO}(\Sigma, <, M_1, M_2)$ hold? Proposition 31 provides an element of response, and we think that $\mathsf{IL} \neq \exists\mathsf{WWFO}(\Sigma, <, M_1, M_2)$.

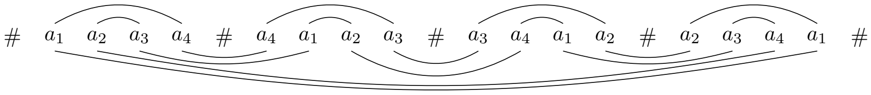


Figure 6 Example of a word in L and its associated wave structure.

▶ **Proposition 31.** *There exists a language which is not an indexed language but being* $\exists\mathsf{WW}$*EMSO*$(\Sigma, <, M_1, M_2)$*-definable.*

Proof sketch. Consider $\Sigma = A \cup \{\#\}$ for any alphabet A, and the set L of all words of the form $\#u_1\#u_2\# \dots u_n\#$, for $n \geq 1$, such that for all $i \in [1, n-1]$, $u_i \in A^n$, and if $u_i = a_1 \dots a_n$, then $u_{i+1} = a_n a_1 \dots a_{n-1}$. Using the Shrinking Lemma given in [11] for indexed languages, it can easily be proved that L is not an indexed language. In addition, one can write an EMSO-formula defining 2-wave words $(\#u_1\#u_2\# \dots u_n\#, M_1, M_2)$ such that (M_1, M_2) forms $n/2$ embedded n-waves (see an example on Figure 6). ◀

8 Conclusion

A natural perspective of this work consists in studying its extension to k-wave words. We believe that the determinization property should hold for this class too. This will require to improve our arguments, as the present proof seems intricate to be adapted to k-waves.

For unbounded waves, automata are not determinizable: Bollig proved in [4] that regular 2NWL are not closed under complementation, and are then not determinizable. His proof uses the encoding of grids in 2NWL, and can thus be adapted to (unbounded) wave words.

Another perspective consists in characterizing the subclass of indexed languages capturing languages $\exists\mathsf{WW}L$, when L is a regular WW_2 language, and determine if $\exists\mathsf{WW}L$ is still indexed when L is a regular WW_k language, for $k > 2$.

Abstract

For a graph G, a subset $S \subseteq V(G)$ is called a *resolving set* if for any two vertices $u, v \in V(G)$, there exists a vertex $w \in S$ such that $d(w,u) \neq d(w,v)$. The Metric Dimension problem takes as input a graph G and a positive integer k, and asks whether there exists a resolving set of size at most k. This problem was introduced in the 1970s and is known to be NP-hard [GT 61 in Garey and Johnson's book]. In the realm of parameterized complexity, Hartung and Nichterlein [CCC 2013] proved that the problem is W[2]-hard when parameterized by the natural parameter k. They also observed that it is FPT when parameterized by the vertex cover number and asked about its complexity under *smaller* parameters, in particular the feedback vertex set number. We answer this question by proving that Metric Dimension is W[1]-hard when parameterized by the feedback vertex set number. This also improves the result of Bonnet and Purohit [IPEC 2019] which states that the problem is W[1]-hard parameterized by the treewidth. Regarding the parameterization by the vertex cover number, we prove that Metric Dimension does not admit a polynomial kernel under this parameterization unless NP $\subseteq$ coNP/*poly*. We observe that a similar result holds when the parameter is the distance to clique. On the positive side, we show that Metric Dimension is FPT when parameterized by either the distance to cluster or the distance to co-cluster, both of which are smaller parameters than the vertex cover number.

1 Introduction

Problems dealing with distinguishing the vertices of a graph have attracted a lot of attention over the years, with the metric dimension problem being a classic one that has been vastly studied since its introduction in the 1970s by Slater [31], and independently by Harary and Melter [22]. Formally, given a graph G and an integer $k \geq 1$, the Metric Dimension problem asks whether there exists a subset $S \subseteq V(G)$ of vertices of G of size at most k such that, for any two vertices $u, v \in V(G)$, there exists a vertex $w \in S$ such that $d(w, u) \neq d(w, v)$. If such a subset $S \subseteq V(G)$ exists, it is called a *resolving set*. The size of a smallest resolving set of a graph G is the *metric dimension* of G, and is denoted by $MD(G)$.

There are many variants and problems associated to the metric dimension, with *identifying codes* [27], *adaptive identifying codes* [4], and *locating dominating sets* [32] asking for the vertices to be distinguished by their neighborhoods in the subset chosen. Other variants of note are the *k-metric dimension*, where each pair of vertices must be resolved by k vertices in $S \subseteq V(G)$ instead of just one [15], and the *truncated metric dimension*, where the distance metric is the minimum of the distance in the graph and some integer k [34]. Along similar lines, in the *centroidal dimension* problem, each vertex must be distinguished by its relative distances to the vertices in $S \subseteq V(G)$ [17]. The metric dimension has also been considered in digraphs, with Bensmail et al. [6] providing a summary of the related work in this area. Interestingly, there are many game-theoretic variants of the metric dimension, such as *sequential metric dimension* [5], the *localization game* [9, 24], and the *centroidal localization game* [8]. The metric dimension and its variants have been studied for both their theoretical interest and their numerous applications such as in network verification [2], fault-detection in networks [36], pattern recognition and image processing [30], graph isomorphism testing [1], chemistry [11, 26], and genomics [35]. For more on these variants and others, see [28] for the latest survey.

Much of the related work around the metric dimension problem focuses on its computational complexity. Metric Dimension was first shown to be NP-complete in general graphs in [19]. Later, it was also shown to be NP-complete in split graphs, bipartite graphs, co-bipartite graphs, and line graphs of bipartite graphs in [14], in bounded-degree planar graphs [12], and interval and permutation graphs of diameter 2 [18]. On the positive side, there are linear-time algorithms for Metric Dimension in trees [31], cographs [14], and cactus block graphs [25], and a polynomial-time algorithm for outerplanar graphs [12].

Since the problem is NP-hard even for very restricted cases, it is natural to ask for ways to confront this hardness. In this direction, the parameterized complexity paradigm allows for a more refined analysis of the problem's complexity. In this setting, we associate each instance I with a parameter ℓ, and are interested in an algorithm with running time $f(\ell) \cdot |I|^{\mathcal{O}(1)}$ for some computable function f. Parameterized problems that admit such an algorithm are called fixed parameter tractable (FPT) with respect to the parameter under consideration. On the other hand, under standard complexity assumptions, parameterized problems that are hard for the complexity class W[1] or W[2] do not admit such fixed-parameter algorithms. A parameter may originate from the formulation of the problem itself (called natural parameters) or it can be a property of the input graph (called structural parameters).

Hartung and Nichterlein [23] proved that Metric Dimension is W[2]-hard when parameterized by the natural parameter, the solution size k, even when the input graph is bipartite and has maximum degree 3. This motivated the study of the parameterized complexity of the problem under structural parameterizations. It was observed in [23] that the problem admits a simple FPT algorithm when parameterized by the vertex cover number. It took a considerable amount of work and/or meta-results to prove that there are FPT algorithms parameterized by the max leaf number [13], the modular width or treelength plus the maximum degree [3], and the treedepth [20]. In [14], they gave an XP algorithm parameterized by the feedback edge set number. Only recently, it was shown that Metric Dimension is W[1]-hard parameterized by the treewidth [7], answering an open question mentioned in [3, 12, 13]. This result was improved upon since, with it being shown that Metric Dimension is even NP-hard in graphs of treewidth 24 [29]. For more on the metric dimension, see [33] for a recent survey.

Our contributions. In this paper, we continue the analysis of structural parameterizations of Metric Dimension. See the Hasse diagram in Figure 1 for a summary of known results and our contributions. As mentioned before, it is known that Metric Dimension is W[1]-hard parameterized by the treewidth [7]. There are two natural directions to improve this result. One direction was to show that Metric Dimension is para-NP-hard parameterized by the treewidth, which was proven in [29]. Another direction is to prove that Metric Dimension is W[1]-hard for a higher parameter than treewidth, *i.e.*, one for which the treewidth is upper bounded by a function of it. A parameter fitting this profile is the feedback vertex set number since the treewidth of a graph G is upper bounded by the feedback vertex set number of G plus one. Moreover, the complexity of Metric Dimension parameterized by the feedback vertex set number is left as an open problem in [23], the seminal paper on the parameterized complexity of Metric Dimension. We take this direction and answer this open question of [23] by proving that Metric Dimension is W[1]-hard parameterized by the feedback vertex set number (see Sec. 2). We then revisit the complexity of the problem when parameterized by the vertex cover number. Recall that the problem is known to admit an FPT algorithm, and hence, a *kernel*, under this parameterization. We prove that, however, Metric Dimension does not admit a polynomial kernel unless $\mathsf{NP} \subseteq \mathsf{coNP}/poly$ when parameterized by the vertex cover number (see Sec. 3)[1]. On the positive side, we then show that Metric Dimension is FPT for the structural parameters the distance to cluster and the distance to co-cluster both of which are smaller parameters than the vertex cover number (see Sec. 4). Note that the FPT algorithm for the distance to cluster parameter implies an FPT algorithm for the distance to clique parameter. With a slight modification of the reduction in Sec. 3, we establish the problem does not admit a polynomial kernel, under the same assumption, when the parameter is the distance to clique.

In this extended abstract, we omit the standard terminology and some formal proofs (which are marked with $\star$) due to space constraints and present them in the full version on arXiv. Recall that any two vertices $u, v \in V(G)$ are *true twins* if $N[u] = N[v]$, and are *false twins* if $N(u) = N(v)$. A subset of vertices $S \subseteq V(G)$ *resolves* a pair of vertices $u, v \in V(G)$ if there exists a vertex $w \in S$ such that $d(w, u) \neq d(w, v)$. A vertex $u \in V(G)$ is *distinguished* by a subset of vertices $S \subseteq V(G)$ if, for any $v \in V(G) \setminus \{u\}$, there exists a vertex $w \in S$ such that $d(w, u) \neq d(w, v)$. We end this section with the following simple observation.

▶ **Observation 1.** *Let G be a graph. Then, for any (true or false) twins $u, v \in V(G)$ and any resolving set S of G, $S \cap \{u, v\} \neq \emptyset$.*

[1] After this paper was short-listed for the proceedings of MFCS 2022, Florent Foucaud informed us of the paper of Gutin et al. [21], which contains a slightly stronger result.

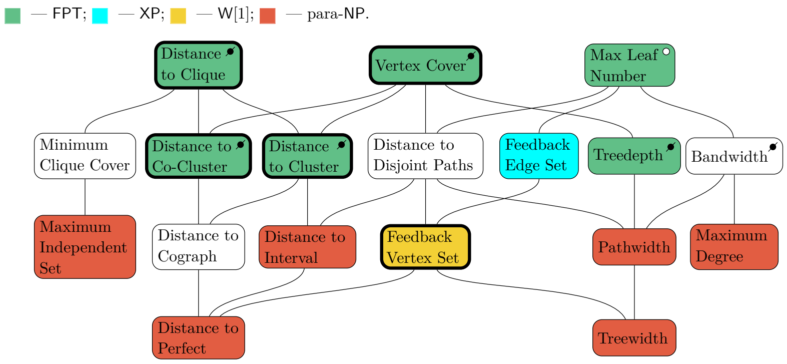

Figure 1 Hasse diagram of graph parameters and associated results for Metric Dimension. An edge indicates that the lower parameter is upper bounded by a function of the higher one. Colors correspond to the known hardness with respect to the highlighted parameter. The parameters for which the hardness remains an open question are not colored. The crossed bold circle in the upper-right corner means that Metric Dimension does not admit a polynomial kernel when parameterized by the marked parameter unless NP ⊆ coNP/*poly*; the white one if a polynomial kernel exists. The bold borders highlight parameters that are covered in this paper. Also see Footnote 1.

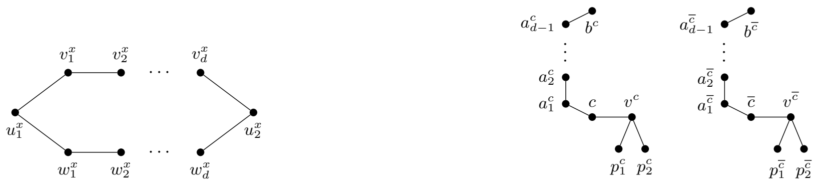
2 The Feedback Vertex Set Number

In this section, we prove that Metric Dimension is W[1]-hard parameterized by the feedback vertex set number. To prove this, we reduce from the NAE-Integer-3-Sat problem defined as follows. An instance of this problem consists of a set X of variables, a set C of clauses, and an integer d. Each variable takes a value in $\{1, \dots, d\}$, and clauses are of the form $(x \le a_x, y \le a_y, z \le a_z)$, where $a_x, a_y, a_z \in \{1, \dots, d\}$. A clause is satisfied if not all three inequalities are true and not all are false. The goal is to find an assignment of the variables that satisfies all given clauses. This problem was shown to be W[1]-hard parameterized by the number of variables [10].

▶ **Theorem 2.** Metric Dimension *is* W[1]*-hard parameterized by the feedback vertex set number.*

Proof. We reduce from NAE-Integer-3-Sat: given an instance (X, C, d) of this problem, we construct an instance (G, k) of Metric Dimension as follows. For each variable $x \in X$, we introduce a cycle G_x of length $2d + 2$ which has two distinguished *anchor vertices* u^x_1 and u^x_2 as depicted in Figure 2a; for convenience, we may also refer to u^x_1 as v^x_0 or w^x_0, and to u^x_2 as v^x_{d+1} or w^x_{d+1}. For each clause $c = (x \le a_x, y \le a_y, z \le a_z)$, we introduce the gadget G_c depicted in Figure 2b consisting of two vertex-disjoint copies H_c and $H_{\bar{c}}$ of the same graph. More precisely, for $\ell \in \{c, \bar{c}\}$, H_ℓ consists of a $K_{1,3}$ on the vertex set $\{\ell, v^\ell, p^\ell_1, p^\ell_2\}$, where v^ℓ has degree three, and a path P_{b^ℓ} of length d connects ℓ to b^ℓ. The subgraph of G_c induced by $\{\ell, v^\ell, p^\ell_1, p^\ell_2 \mid \ell \in \{c, \bar{c}\}\}$ is referred to as the *core of* G_c.

We further connect G_c to G_x, G_y, and G_z as follows. For every $t \in \{x, y, z\}$, we connect b^c to u^t_1 by a path $P^{t,c}_1$ of length $4d - a_t$, and v^c to u^t_2 by a path $P^{t,c}_2$ of length $4d + a_t - 1$. Furthermore, letting $w^{t,c}$ be the neighbor of v^c on $P^{t,c}_2$, we attach a copy $W^{t,c}$ of $K_{1,3}$ to $w^{t,c}$ by identifying $w^{t,c}$ with one of the leaves; we denote by $t^{t,c}_1$ and $t^{t,c}_2$ the two remaining leaves and refer to $W^{t,c}$ as a *pendant claw*. Similarly, for every $t \in \{x, y, z\}$, we connect $b^{\bar{c}}$ to u^t_2 by a path $P^{t,\bar{c}}_2$ of length $3d + a_t$, and $v^{\bar{c}}$ to u^t_1 by a path $P^{t,\bar{c}}_1$ of length $5d - a_t$. Furthermore, letting $w^{t,\bar{c}}$ be the neighbor of $v^{\bar{c}}$ on $P^{t,\bar{c}}_1$, we attach a copy $W^{t,\bar{c}}$ of $K_{1,3}$ to $w^{t,\bar{c}}$ by identifying $w^{t,\bar{c}}$ with one of the leaves; we denote by $t^{t,\bar{c}}_1$ and $t^{t,\bar{c}}_2$ the two remaining



(a) The variable gadget G_x.

(b) The clause gadget G_c is the disjoint union of H_c (left) and $H_{\bar{c}}$ (right).

Figure 2 The gadgets in the proof of Theorem 2.

leaves and refer to $W^{t,\bar{c}}$ as a *pendant claw*. Finally, we introduce a path $P = t_1pt_2$ which we connect to the clause gadgets as follows. For every clause $c \in C$ and $\ell \in \{c, \bar{c}\}$, we connect p to v^ℓ by a path P_ℓ of length $2d$. Furthermore, letting w^ℓ be the neighbor of p on P_ℓ, we attach a copy W^ℓ of $K_{1,3}$ to w^ℓ by identifying w^ℓ with one of the leaves; we denote by t_1^ℓ and t_2^ℓ the two remaining leaves and refer to W^ℓ as a *pendant claw*. This concludes the construction of G (see Figure 3).

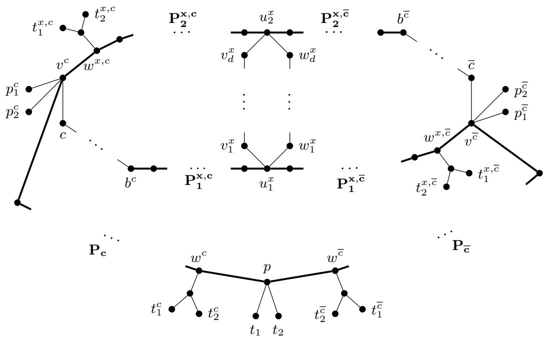


Figure 3 An illustration of the reduction in the proof of Theorem 2.

We set $k = |X| + 10|C| + 1$. Observe that the feedback vertex set number of G is at most $2|X| + 1$: indeed, removing $\{p\} \cup \{u_1^x, u_2^x \mid x \in X\}$ from G results in a graph without cycles. We next show that the instance (X, C, d) is satisfiable if and only if (G, k) is a Yes-instance for Metric Dimension. To this end, we first prove the following.

▷ Claim 3 (⋆). For any two distinct $s, t \in \{c, \bar{c} \mid c \in C\}$ and any two distinct variables $x, y \in X$, the following hold.

(i) The shortest path from H_s to H_t contains P_s and P_t as subpaths and has length $4d$.

(ii) $d(V(G_x), V(G_y)) \geq 6d$.

(iii) If x appears in the clause corresponding to s, then $d(V(G_x), V(H_s)) \geq 3d$.

(iv) If x does not appear in the clause corresponding to s, then any shortest path from G_x to H_s contains P_s as a subpath and has length at least $8d$.

▷ Claim 4 (⋆). For every clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$ and every $t \in \{x, y, z\}$, the following hold.

(i) For every $i \in \{0, \dots, d+1\}$, if $i \leq a_t$, then the shortest path from v_i^t to c contains $P_1^{t,c}$ as a subpath and has length $5d + i - a_t$. Otherwise, the shortest path from v_i^t to c contains $P_2^{t,c}$ as a subpath and has length $5d + 1 + a_t - i$.

(ii) For every $i \in \{0, \dots, d+1\}$, if $i \leq a_t - 1$, then the shortest path from v_i^t to v^c contains $P_1^{t,c}$ as a subpath and has length $5d + 1 + i - a_t$. Otherwise, the shortest path from v_i^t to v^c contains $P_2^{t,c}$ as a subpath and has length $5d + a_t - i$.

(iii) For every $i \in \{0, \ldots, d+1\}$, if $i \leq a_t - 2$, then the shortest path from v_i^t to $t_1^{t,c}$ contains $P_1^{t,c}$ as a subpath and has length $5d + 4 + i - a_t$. Otherwise, the shortest path from v_i^t to $t_1^{t,c}$ contains $P_2^{t,c}[u_2^t, w^{t,c}]$ as a subpath and has length $5d + 1 + a_t - i$.

▷ Claim 5 (⋆). For every clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$ and every $t \in \{x, y, z\}$, the following hold.

(i) For every $i \in \{0, \ldots, d+1\}$, if $i \leq a_t$, then the shortest path from v_i^t to $\overline{c}$ contains $P_1^{t,\overline{c}}$ as a subpath and has length $5d + 1 + i - a_t$. Otherwise, the shortest path from v_i^t to $\overline{c}$ contains $P_2^{t,\overline{c}}$ as a subpath and has length $5d + 1 + a_t - i$.

(ii) For every $i \in \{0, \ldots, d+1\}$, if $i \leq a_t + 1$, then the shortest path from v_i^t to $v^{\overline{c}}$ contains $P_1^{t,\overline{c}}$ as a subpath and has length $5d + i - a_t$. Otherwise, the shortest path from v_i^t to $v^{\overline{c}}$ contains $P_2^{t,\overline{c}}$ as a subpath and has length $5d + 2 + a_t - i$.

(iii) For every $i \in \{0, \ldots, d+1\}$, if $i \leq a_t + 2$, then the shortest path from v_i^t to $t_1^{t,\overline{c}}$ contains $P_1^{t,\overline{c}}[u_1^t, w^{t,\overline{c}}]$ as a subpath and has length $5d + 1 + i - a_t$. Otherwise, the shortest path from v_i^t to $t_1^{t,\overline{c}}$ contains $P_2^{t,\overline{c}}$ as a subpath and has length $5d + 5 + a_t - i$.

Assume first that (X, C, d) is satisfiable and let $\phi : X \to \{1, \ldots, d\}$ be an assignment of the variables satisfying every clause in C. We construct a resolving set S of G as follows. First, we add t_1 to S. For every variable $x \in X$, we add $v_{\phi(x)}^x$ to S. Finally, for every clause $c \in C$, we add $p_1^c, p_1^{\overline{c}}, t_1^c, t_1^{\overline{c}}$ to S and further add, for every variable t appearing in c, $t_1^{t,c}, t_1^{t,\overline{c}}$ to S. Note that $|S| = k$ and that every vertex of S is distinguished by itself. Let us show that S is indeed a resolving set of G. To this end, consider two distinct vertices $u, v \in V(G)$. We distinguish the following cases to show that there exists $w \in S$ such that $d(w, u) \neq d(w, v)$.

Case 1. *At least one of u and v belongs to a pendant claw.* W.l.o.g., assume first that $u \in V(W^\ell)$, where $\ell \in \{c, \overline{c} \mid c \in C\}$. If $v \in V(G) \setminus V(W^\ell)$, then $d(t_1^\ell, v) > 2 \geq d(t_1^\ell, u)$. Suppose therefore that $v \in V(W^\ell)$ as well. If $\{u, v\} \neq \{w^\ell, t_2^\ell\}$, then $d(t_1^\ell, u) \neq d(t_1^\ell, v)$. If $\{u, v\} = \{w^\ell, t_2^\ell\}$, then $d(t_1, w^\ell) = 2 < 4 = d(t_1, t_2^\ell)$. Second, assume that $u \in V(W^{t,\ell})$, where $\ell \in \{c, \overline{c}\}$ for some clause $c \in C$ and t is a variable appearing in clause c. If $v \in V(G) \setminus V(W^{t,\ell})$, then $d(t_1^{t,\ell}, v) > 2 \geq d(t_1^{t,\ell}, u)$. Suppose therefore that $v \in V(W^{t,\ell})$ as well. If $\{u, v\} \neq \{w^{t,\ell}, t_2^{t,\ell}\}$, then $d(t_1^{t,\ell}, u) \neq d(t_1^{t,\ell}, v)$. If $\{u, v\} = \{w^{t,\ell}, t_2^{t,\ell}\}$, then $d(p_1^\ell, w^{t,\ell}) = 2 < 4 = d(p_1^\ell, t_2^{t,\ell})$.

Case 2. *At least one of u and v belongs to the core of a clause gadget.* Assume, w.l.o.g., that $u \in \{\ell, v^\ell, p_1^\ell, p_2^\ell\}$, where $\ell \in \{c, \overline{c}\}$ for some clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$. If v is not a neighbor of v^ℓ, then $d(p_1^\ell, v) > 2 \geq d(p_1^\ell, u)$. If v is the neighbor of v^ℓ on the path P_ℓ, then $d(t_1, v) = d < d(t_1, u)$. Also, $v = w^{t,\ell}$ was covered by the previous case. So, consider $v \in \{\ell, v^\ell, p_1^\ell, p_2^\ell\}$. If $\{u, v\} \neq \{\ell, p_2^\ell\}$, then clearly $d(p_1^\ell, u) \neq d(p_1^\ell, v)$. Assume therefore that $\{u, v\} = \{\ell, p_2^\ell\}$. Since ϕ satisfies c, there exist $t, f \in \{x, y, z\}$ such that $\phi(t) \leq a_t$ and $\phi(f) > a_f$. Then, either $\phi(t) < a_t$, in which case, by Claim 4(i) and (ii),

$$d(v_{\phi(t)}^t, c) = 5d + \phi(t) - a_t < 5d + \phi(t) - a_t + 2 = d(v_{\phi(t)}^t, v^c) + 1 = d(v_{\phi(t)}^t, p_2^c),$$

or $\phi(t) = a_t$, in which case, by Claim 4(i) and (ii),

$$d(v_{\phi(t)}^t, c) = 5d < 5d + 1 = d(v_{\phi(t)}^t, v^c) + 1 = d(v_{\phi(t)}^t, p_2^c).$$

Similarly, either $\phi(f) = a_f + 1$, in which case, by Claim 5(i) and (ii),

$$d(v_{\phi(f)}^f, \overline{c}) = 5d < 5d + 2 = d(v_{\phi(f)}^f, v^{\overline{c}}) + 1 = d(v_{\phi(f)}^f, p_2^{\overline{c}}),$$

or $\phi(f) > a_f + 1$, in which case, by Claim 5(i) and (ii),

$$d(v_{\phi(f)}^f, \overline{c}) = 5d + 1 + a_f - \phi(f) < 5d + 3 + a_f - \phi(f) = d(v_{\phi(f)}^f, v^{\overline{c}}) + 1 = d(v_{\phi(f)}^f, p_2^{\overline{c}}).$$

In all cases, we conclude that there exists $w \in S$ such that $d(w, \ell) \neq d(w, p_2^\ell)$.

Case 3. *At least one of u and v belongs to a variable gadget.* Assume, w.l.o.g., that $u \in V(G_x)$ for some variable $x \in X$. By the previous cases, we may assume that v does not belong to the core of a clause gadget or a pendant claw. If $v \in V(G_y)$ for some variable $y \neq x$, then by Claim 3(ii),

$$d(v^x_{\phi(x)}, u) \leq d+1 < 6d \leq d(V(G_x), V(G_y)) \leq d(v^x_{\phi(x)}, v).$$

Now, suppose that $v \in V(G_x)$ as well. If $\{u, v\} = \{v^x_i, w^x_i\}$ for some $i \in [d]$, then

$$d(v^x_{\phi(x)}, v^x_i) = |\phi(x) - i| < d(v^x_{\phi(x)}, w^x_i) = \min\{\phi(x) + i, 2d + 2 - \phi(x) - i\}.$$

Suppose next that $u = v^x_i$ and $v = v^x_j$ for two distinct $i, j \in \{0, \ldots, d+1\}$, say $i < j$, w.l.o.g. Consider a clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$ containing x. If $j < a_x$, then by Claim 4(ii),

$$d(p^c_1, v^x_i) = d(v^c, v^x_i) + 1 = 5d + 2 + i - a_x < 5d + 2 + j - a_x = d(v^c, v^x_j) + 1 = d(p^c_1, v^x_j).$$

Now, suppose that $i < a_x \leq j$. Then, by Claim 4(ii),

$$d(p^c_1, v^x_i) - d(p^c_1, v^x_j) = 5d + 2 + i - a_x - (5d + a_x - j + 1) = i + j + 1 - 2a_x.$$

Thus, if $i + j + 1 - 2a_x \neq 0$, then $d(p^c_1, v^x_i) \neq d(p^c_1, v^x_j)$. Now, if $i + j + 1 - 2a_x = 0$, then either $j = a_x$ and $i = a_x - 1$, in which case, by Claim 4(iii),

$$d(t^{x,c}_1, v^x_i) = 5d + 2 > 5d + 1 = d(t^{x,c}_1, v^x_j),$$

or $j > a_x$ and $i < a_x - 1$, in which case, by Claim 4(iii),

$$d(t^{x,c}_1, v^x_j) = 5d + 1 + a_x - j = 5d + 2 + i - a_x < 5d + 4 + i - a_x = d(t^{x,c}_1, v^x_i).$$

Finally, if $a_x \leq i < j$, then by Claim 4(ii),

$$d(p^c_1, v^x_j) = 5d + 1 + a_x - j < 5d + 1 + a_x - i = d(p^c_1, v^x_i).$$

Since for any $t \in V(G) \setminus V(G_x)$ and $k \in [d]$, $d(t, v^x_k) = d(t, w^x_k)$, we conclude similarly if either $u = v^x_i$ and $v = w^x_j$, or $u = w^x_i$ and $v = w^x_j$ for two distinct $i, j \in \{0, \ldots, d+1\}$. Assume, henceforth, that $v \notin \bigcup_{x \in X} V(G_x)$. If v does not belong to a path connecting G_x to some clause gadget, then

$$d(v^x_{\phi(x)}, v) \geq \min_{c \in C} d(V(G_x), V(G_c)) \geq 3d > d + 1 \geq d(v^x_{\phi(x)}, u)$$

by Claim 3(iii) and (iv). Suppose therefore that $v \in V(P^{x,\ell}_i)$, where $i \in \{1, 2\}$ and $\ell \in \{c, \bar{c}\}$ for some clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$ containing x. W.l.o.g., let us assume that $u = v^x_j$ where $j \in \{0, \ldots, d+1\}$.
Assume first that $\ell = c$ and $i = 1$. Let $P^{x,c}_1 = z_0 \ldots z_{4d-a_x}$, where $z_0 = b^c$ and $z_{4d-a_x} = u^x_1$. Let $v = z_k$, where $k \in [4d - a_x - 1]$. If $j \leq a_x - 1$, then by Claim 4(ii), the shortest path from p^c_1 to v^x_j contains $P^{x,c}_1$ as a subpath, which implies in particular that $d(p^c_1, v) < d(p^c_1, u)$. Suppose therefore that $j \geq a_x$. Then, by Claim 4(ii),

$$d(p^c_1, u) - d(p^c_1, v) = 5d + 1 + a_x - j - (d + k + 2).$$

Thus, if $5d + 1 + a_x - j - (d + k + 2) \neq 0$, then $d(p^c_1, u) \neq d(p^c_1, v)$. Now, if $5d + 1 + a_x - j - (d + k + 2) = 0$, then by Claim 4(iii),

$$d(t^{x,c}_1, u) = 5d + 1 + a_x - j = d + k + 2 < d + k + 4 = d(t^{x,c}_1, v).$$

Second, assume that $\ell = c$ and $i = 2$. Let $P_2^{x,c} = z_0 \dots z_{4d+a_x-1}$, where $z_0 = v^c$ and $z_{4d+a_x-1} = u_2^x$. Let $v = z_k$, where $k \in [4d + a_x - 2]$ (note that since v does not belong to the core of a clause gadget or a pendant claw by assumption, in fact $k \geq 2$). If $j \geq a_x$, then by Claim 4(ii), the shortest path from p_1^c to u contains $P_2^{x,c}$ as a subpath, which implies in particular that $d(p_1^c, v) < d(p_1^c, u)$. Otherwise, $j \leq a_x - 1$, in which case

$$d(p_1^c, u) - d(p_1^c, v) = 5d + 2 + j - a_x - (k + 1).$$

Thus, if $5d+2+j-a_x-(k+1) \neq 0$, then $d(p_1^c, u) \neq d(p_1^c, v)$. Now, if $5d+2+j-a_x-(k+1) = 0$, then $j < a_x - 1$ since $k < 5d$, and so, by Claim 4(iii),

$$d(t_1^{x,c}, u) = 5d + 4 + j - a_x = k + 3 > k + 1 = d(t_1^{x,c}, v).$$

Third, assume that $\ell = \overline{c}$ and $i = 1$. Let $P_1^{x,\overline{c}} = z_0 \dots z_{5d-a_x}$, where $z_0 = v^{\overline{c}}$ and $z_{5d-a_x} = u_1^x$. Let $v = z_k$, where $k \in [5d - a_x - 1]$ (note that since v does not belong to the core of a clause gadget or a pendant claw by assumption, in fact $k \geq 2$). If $j \leq a_x + 1$, then by Claim 5(ii), the shortest path from $p_1^{\overline{c}}$ to v_j^x contains $P_1^{x,\overline{c}}$ as a subpath which implies in particular that $d(p_1^{\overline{c}}, v) < d(p_1^{\overline{c}}, u)$. Suppose therefore that $j \geq a_x + 2$. Then, by Claim 5(ii),

$$d(p_1^{\overline{c}}, v_j^x) - d(p_1^{\overline{c}}, z_k) = 5d + 3 + a_x - j - (k + 1).$$

Thus, if $5d + 3 + a_x - j - (k + 1) \neq 0$, then $d(p_1^{\overline{c}}, v_j^x) \neq d(p_1^{\overline{c}}, z_k)$. Now, if $5d + 3 + a_x - j - (k + 1) = 0$, then $j > a_x + 2$ since $k < 5d$, and so, by Claim 5(iii),

$$d(t_1^{x,\overline{c}}, v_j^x) = 5d + 5 + a_x - j = k + 3 > k + 1 = d(t_1^{x,\overline{c}}, z_k).$$

Assume finally that $\ell = \overline{c}$ and $i = 2$. Let $P_2^{x,\overline{c}} = z_0 \dots z_{3d+a_x}$, where $z_0 = b^{\overline{c}}$ and $z_{3d+a_x} = u_2^x$. Let $v = z_k$, where $k \in [3d + a_x - 1]$. If $j \geq a_x + 2$, then by Claim 5(ii), the shortest path from $p_1^{\overline{c}}$ to u contains $P_2^{x,\overline{c}}$ as a subpath, which implies in particular that $d(p_1^{\overline{c}}, v) < d(p_1^{\overline{c}}, u)$. Suppose therefore that $j \leq a_x + 1$. Then, by Claim 5(ii),

$$d(p_1^{\overline{c}}, v_j^x) - d(p_1^{\overline{c}}, z_k) = 5d + 1 + j - a_x - (d + k + 2).$$

Thus, if $5d + 1 + j - a_x - (d + k + 2) \neq 0$, then $d(p_1^{\overline{c}}, v_j^x) \neq d(p_1^{\overline{c}}, z_k)$. Now, if $5d + 1 + j - a_x - (d + k + 2) = 0$, then $j < a_x + 1$ since $k < 4d$, and so, by Claim 5(iii),

$$d(t_1^{x,\overline{c}}, v_j^x) = 5d + 1 + j - a_x = d + k + 2 < d + k + 4 = d(t_1^{x,\overline{c}}, z_k).$$

In all the subcases, we conclude that there exists $w \in S$ such that $d(w, u) \neq d(w, v)$.

Case 4. *None of the above.* First, note that p is distinguished by S since it is the unique vertex of G at distance 1 from t_1. Second, t_2 is distinguished by S since it is the unique vertex of G at distance 2 from t_1 and distance 4 from t_1^c and $t_1^{\overline{c}}$ for all $c \in C$. Thus, in this last case, we can assume that both u and v belong either to paths connecting gadgets or to some path P_{b^ℓ}, where $\ell \in \{c, \overline{c} \mid c \in C\}$. Assume first that $u \in V(P_\ell)$ for some $\ell \in \{c, \overline{c} \mid c \in C\}$. If $v \in V(P_\ell)$ as well, then surely $d(t_1, u) \neq d(t_1, v)$. If $v \in V(P_q)$ for some $q \in \{c, \overline{c} \mid c \in C\}$ different from ℓ, then $d(p_1^\ell, u) < d(p_1^\ell, v)$ since the unique shortest path from p_1^ℓ to v contains P_ℓ as a subpath. Finally, if there exists $q \in \{c, \overline{c} \mid c \in C\}$ such that v belongs to P_{b_q} or to some path connecting H_q to a variable gadget, then $d(t_1, v) > d(t_1, v^q) \geq d(t_1, u)$.

Second, assume that $u \in V(P_i^{x,\ell})$, where $i \in [2]$ and $\ell \in \{c, \overline{c}\}$ for some clause c containing variable x. Note that by the previous paragraph, we may assume that $v \notin \bigcup_{q \in C} V(P_q) \cup V(P_{\overline{q}})$. Suppose first that $v \in V(P_j^{y,q})$, where $j \in [2]$ and $q \in \{c', \overline{c}'\}$ for some clause c' containing variable y. Note that $d(t_1^\ell, u) = d(t_1, u)$. So, if $q \neq \ell$, then either $d(t_1, u) \neq d(t_1, v)$, or

$$d(t_1^\ell, v) - d(t_1^\ell, u) = d(t_1^\ell, p) + d(t_1, v) - 1 - d(t_1^\ell, u) = d(t_1, v) + 2 - d(t_1, u) = 2.$$

Thus, assume that $q = \ell$. Suppose first that $x = y$. If $i = j$, then surely $d(p_1^\ell, u) \neq d(p_1^\ell, v)$. Otherwise, assume, w.l.o.g., that u belongs to the path containing $w^{x,\ell}$. Note that $d(t_1^{x,\ell}, u) = d(p_1^\ell, u)$. Then, either $d(p_1^\ell, u) \neq d(p_1^\ell, v)$, or

$$d(t_1^{x,\ell}, v) - d(t_1^{x,\ell}, u) = d(t_1^{x,\ell}, v^\ell) + d(p_1^\ell, v) - 1 - d(t_1^{x,\ell}, u) = d(p_1^\ell, v) + 2 - d(p_1^\ell, u) = 2.$$

Second, suppose that $x \neq y$. If u belongs to the path containing $w^{x,\ell}$, then we argue as previously. By symmetry, we may also assume that v does not belong to the path containing $w^{y,\ell}$. This implies, in particular, that $i = j$ and b^ℓ is the endpoint in H_ℓ of both $P_i^{x,\ell}$ and $P_j^{y,\ell}$. Thus, $d(v_{\phi(x)}^x, u) \leq d(v_{\phi(x)}^x, u_i^x) + d(u_i^x, b^\ell) \leq d + 4d$. First, note that if a shortest path P from $v_{\phi(x)}^x$ to v contains $P_i^{x,\ell}$ as a subpath, then since $u \in V(P_i^{x,\ell})$, it follows that $d(v_{\phi(x)}^x, u) < d(v_{\phi(x)}^x, v)$. Hence, we may assume that P contains a vertex in G_y or both v^ℓ and b^ℓ. By Claim 3(ii), if P contains a vertex in G_y, then

$$d(v_{\phi(x)}^x, v) > d(V(G_x), V(G_y)) \geq 6d > 5d \geq d(v_{\phi(x)}^x, u).$$

Otherwise, P contains v^ℓ and b^ℓ, and so, letting $t \in [2] \setminus \{i\}$, we get that

$$\mathsf{lgt}(P) \geq d(v_{\phi(x)}^x, u_t^x) + d(u_t^x, v^\ell) + d(v^\ell, b^\ell) + d(b^\ell, v) \geq 1 + 4d + d + 1 > 5d \geq d(v_{\phi(x)}^x, u).$$

Suppose finally that $u \in V(P_{b^\ell})$ for some $\ell \in \{c, \overline{c} \mid c \in C\}$. By the two previous paragraphs, we may assume that $v \in V(P_{b^q})$ for some $q \in \{c, \overline{c} \mid c \in C\}$. If $q = \ell$, then surely $d(p_1^\ell, u) \neq d(p_1^\ell, v)$. Otherwise, by Claim 3(i),

$$d(p_1^\ell, v) \geq d(V(H_\ell), V(H_q)) = 4d > d + 1 \geq d(p_1^\ell, u), \text{ which concludes case 4.}$$

By the above case analysis, we infer that, for any $u, v \in V(G)$, there exists $w \in S$ such that $d(w, u) \neq d(w, v)$, that is, S is a resolving set of G. Since $|S| = k$, it follows that (G, k) is a YES-instance for METRIC DIMENSION.

Conversely, assume that (G, k) is a YES-instance for METRIC DIMENSION and let S be a resolving set of size at most k. By Observation 1, for any clause $c \in C$ and any variable $x \in X$ appearing in c,

$$|S \cap \{p_1^c, p_2^c\}| \geq 1,\ |S \cap \{p_1^{\overline{c}}, p_2^{\overline{c}}\}| \geq 1,\ |S \cap \{t_1^c, t_2^c\}| \geq 1, \text{ and } |S \cap \{t_1^{\overline{c}}, t_2^{\overline{c}}\}| \geq 1. \quad (1)$$

$$|S \cap \{t_1^{x,c}, t_2^{x,c}\}| \geq 1 \text{ and } |S \cap \{t_1^{x,\overline{c}}, t_2^{x,\overline{c}}\}| \geq 1. \quad (2)$$

$$|S \cap \{t_1, t_2\}| \geq 1. \quad (3)$$

Consider now a variable x. Since any path from a vertex in $V(G) \setminus V(G_x)$ to a vertex in $\{v_i^x, w_i^x \mid i \in [d]\}$ contains u_1^x or u_2^x, and, for any $i \in [d]$ and $u \in \{u_1^x, u_2^x\}$, $d(u, v_i^x) = d(u, w_i^x)$, no vertex in $V(G) \setminus \{v_i^x, w_i^x \mid i \in [d]\}$ can resolve v_i^x and w_i^x for any $i \in [d]$. It follows that

$$|S \cap \{v_i^x, w_i^x \mid i \in [d]\}| \geq 1. \tag{4}$$

Now, note that S has size at most $k = |X| + 10|C| + 1$, and so, equality must in fact hold in every inequality of Equations (1)–(4). W.l.o.g., let us assume that $t_1 \in S$ and that, for every clause $c \in C$ and variable $x \in X$ appearing in c, we have that $p_1^c, p_1^{\overline{c}}, t_1^c, t_1^{\overline{c}}, t_1^{x,c}, t_1^{x,\overline{c}} \in S$.

For every variable $x \in X$, assume, w.l.o.g., that $S \cap \{v_i^x, w_i^x \mid i \in [d]\} = S \cap \{v_i^x \mid i \in [d]\}$, and let $i_x \in [d]$ be the index of the vertex in $S \cap \{v_i^x \mid i \in [d]\}$. We contend that the assignment which sets each variable x to i_x satisfies every clause in C. Indeed, consider a clause $c = (x \leq a_x, y \leq a_y, z \leq a_z)$. We first aim to show that, for every $w \in S \setminus \{V(G_x) \cup V(G_y) \cup V(G_z)\}$ and $\ell \in \{c, \overline{c}\}$, $d(w, \ell) = d(w, p_2^\ell)$. Note that it suffices to show that any shortest path from $w \in S \setminus \{V(G_x) \cup V(G_y) \cup V(G_z)\}$ to $\ell \in \{c, \overline{c}\}$ contains v^ℓ, as then $d(w, \ell) = d(w, v^\ell) + 1 = d(w, p_2^\ell)$. Now, if $w \in V(G_t)$ for some $t \in \{c', \overline{c'} \mid c' \in C\}$ different from ℓ, then this readily follows from Claim 3(i); and if $w \in V(G_t)$ for some $t \in X \setminus \{x, y, z\}$, then this readily follows from Claim 3(iv). If $w = t_1^{r,q}$ for some $r \in X$ and $q \in \{c', \overline{c'} \mid c' \in C\}$, then $d(t_1^{r,q}, \ell) = d(t_1^{r,q}, v^q) + d(v_q, \ell)$, and so, by Claim 3(i), any path from w to ℓ contains v^ℓ. Finally, if $w \in \{t_1^{c'}, t_1^{\overline{c}'} \mid c' \in C\}$, then clearly any shortest path from w to ℓ contains v^ℓ.

Since S is a resolving set, it follows that, for every clause $c \in C$, there exist $t, f \in \{x, y, z\}$ such that $d(v_{i_t}^t, c) \neq d(v_{i_t}^t, p_2^c)$ and $d(v_{i_f}^f, \overline{c}) \neq d(v_{i_f}^f, p_2^{\overline{c}})$. Now, by Claim 4(i) and (ii), if $i_t > a_t$, then $d(v_{i_t}^t, c) = 5d + 1 + a_t - i_t = d(v_{i_t}^t, v^c) + 1 = d(v_{i_t}^t, p_2^c)$, a contradiction to our assumption. Therefore, $i_t \leq a_t$. Similarly, if $i_f \leq a_f$, then by Claim 5(i) and (ii), $d(v_{i_f}^f, \overline{c}) = 5d + 1 + i_f - a_f = d(v_{i_f}^f, v^{\overline{c}}) + 1 = d(v_{i_f}^f, p_2^{\overline{c}})$, a contradiction to our assumption. Therefore, $i_f > a_f$, and so, the assignment constructed indeed satisfies every clause in C. ◀

3 The Vertex Cover Number and the Distance to clique

In this section, we prove that Metric Dimension parameterized by either the vertex cover number or the distance to clique does not admit a polynomial kernel unless NP $\subseteq$ coNP$/poly$. Both reductions are similar ones from the SAT problem, in which we are given a conjunctive normal form (CNF) formula ϕ on n variables and m clauses, and we are asked whether there exists an assignment of either true or false to each of the variables, such that ϕ is true (satisfied). SAT is known to not admit a polynomial kernel unless NP $\subseteq$ coNP$/poly$ [16]. We first prove that Metric Dimension parameterized by the vertex cover number does not admit a polynomial kernel unless NP $\subseteq$ coNP$/poly$, with the same result for distance to clique to follow after from a small modification to this reduction.

▶ **Theorem 6.** Metric Dimension *parameterized by the vertex cover number does not admit a polynomial kernel unless* NP $\subseteq$ coNP$/poly$.

Proof. ($\star$) By a reduction from SAT, we prove that Metric Dimension parameterized by the vertex cover number does not admit a polynomial kernel unless NP $\subseteq$ coNP$/poly$. Let ϕ be an instance of SAT, *i.e.*, a SAT formula on n variables $x_1, \ldots, x_n$ and m clauses $C_1, \ldots, C_m$. Since any SAT formula on n variables trivially has at most $3^n - 1$ unique clauses, we may assume that $m \leq 3^n - 1$.

From ϕ, we construct an instance (G, k) of Metric Dimension as follows. For each $i \in [n]$, construct a cycle $(t_i a_i^1 b_i^1 f_i b_i^2 a_i^2 t_i)$ on 6 vertices, and let $I_i := \{a_i^1, a_i^2, b_i^1, b_i^2\}$. Construct a path $g^1 g g^2$ on 3 vertices and, for each $i \in [n]$, make both f_i and t_i adjacent to g. For each $j \in [m]$, add a pair of vertices c_j^1 and c_j^2, and let $C_j := \{c_j^1, c_j^2\}$. For each $j \in [m]$, make c_j^2 adjacent to both f_i and t_i for each $i \in [n]$. For each $j \in [m]$ and each $i \in [n]$, if $x_i = \texttt{True}$ does not satisfy the clause $\mathcal{C}_j$ in ϕ, then make c_j^1 adjacent to t_i, and if $x_i = \texttt{False}$ does not satisfy $\mathcal{C}_j$, then make c_j^1 adjacent to f_i. Let $\alpha = \lceil n \cdot \log_2 3 \rceil$, and, for each $\ell \in [\alpha]$, construct a path $z_\ell^1 z_\ell z_\ell^2$ on 3 vertices. For each $j \in [m]$, consider the binary representation $\text{bin}(j)$ of j, and connect both c_j^1 and c_j^2 with z_ℓ if $\text{bin}(j)[\ell] = 1$, where $[\ell]$ is the ℓ^{th} bit of j in its binary representation from right to left. Finally, construct a clique on the vertices $z_1, \ldots, z_\alpha, g$. This completes the construction of G (see Figure 4).

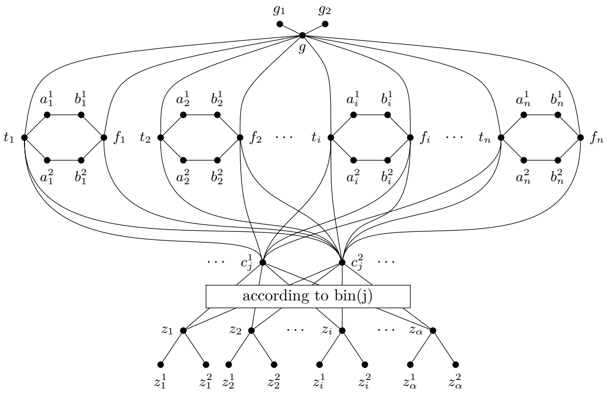

Figure 4 Illustration of the graph G constructed in the proof of Theorem 6. The vertices $z_1, \ldots, z_\alpha, g$ are in a clique that is not drawn. In this particular case, ϕ has a clause $(\overline{x_1} \vee x_2 \vee \overline{x_n})$.

To simplify notation for the proof, let $I := I_1 \cup \cdots \cup I_n$. Set $k = n + \alpha + 1$. Note that the vertex cover number of G is at most $4n + \alpha + 1$ since $\{g\} \cup \{a_i^1, a_i^2, t_i, f_i, z_\ell \mid i \in [n], \ell \in [\alpha]\}$ is a vertex cover of G. We now show that the instance ϕ is satisfiable if and only if (G, k) is a Yes-instance for Metric Dimension. We just sketch the proof from here. To prove that if ϕ is satisfiable, then (G, k) is a Yes-instance for Metric Dimension, we build a resolving set R of G of size k as follows. First, put the vertices of $\{g_1, z_1^1, \ldots, z_1^1\}$ in R. Then, for all $i \in [n]$, if, according to the satisfying truth value assignment of ϕ, $x_i = \texttt{True}$ ($x_i = \texttt{False}$, resp.), then add a_i^1 (b_i^1, resp.) to R. Clearly, $|R| = k$, and it is not difficult to check that R is a resolving set of G.

Now, we prove that if (G, k) is a Yes-instance for Metric Dimension, then ϕ is satisfiable. For any resolving set R of G, one can show that since $|R| \leq n + \alpha + 1$, then $|R \cap \{g^1, g^2\}| = 1$, $|R \cap \{z_\ell^1, z_\ell^2\}| = 1$ for all $\ell \in [\alpha]$, and $|R \cap I_i| = 1$ for all $i \in [n]$. W.l.o.g., assume that $\{g^1, z_1^1, \ldots, z_\alpha^1\} \subset R$. Consider $j \in [m]$. It can be shown that no vertex in $\{g^1, z_1^1, \ldots, z_\alpha^1\}$ can resolve the two vertices of C_j, and thus, there must exist $w \in R \cap I$ such that $d(w, c_j^1) \neq d(w, c_j^2)$. Since for every $i \in [n]$ such that x_i does not appear in the clause C_j, $d(u, c_j^1) = d(u, c_j^2)$ for every $u \in I_i$, there must exist $i \in [n]$ such that x_i appears in the clause C_j and $w \in R \cap I_i$. In particular, c_j^1 must be non-adjacent to one of t_i and f_i. Now, if c_j^1 is non-adjacent to t_i, then c_j^1 is adjacent to f_i, and so, $w \in \{a_i^1, a_i^2\}$, as otherwise $d(w, c_j^1) = d(w, c_j^2)$. Symmetrically, if c_j^1 is non-adjacent to f_i, then c_j^1 is adjacent to t_i, and so, $w \in \{b_i^1, b_i^2\}$, as otherwise $d(w, c_j^1) = d(w, c_j^2)$. So, the truth assignment obtained by setting a variable x_i to $\texttt{True}$ if $R \cap I_i \subseteq \{a_i^1, a_i^2\}$, and to $\texttt{False}$ otherwise, satisfies ϕ. ◀

By making the vertices of $\{C_j \mid j \in [m]\}$ into a clique in the construction of G in the proof of Theorem 6, observe that the distance to clique of the resulting graph is at most $6n + 3\alpha + 3$, and that none of the distances described in the proof change. Then, from the proof of Theorem 6 for this modified G, we obtain the following:

▶ **Theorem 7.** Metric Dimension *parameterized by the distance to clique does not admit a polynomial kernel unless* NP $\subseteq$ coNP/*poly.*

4 The Distance to Cluster and the Distance to co-cluster

In this section, we prove that Metric Dimension is FPT parameterized by either the distance to cluster or the distance to co-cluster. In fact, we show that the problem admits an exponential kernel parameterized by the distance to cluster (or co-cluster). Since the main ideas for these two parameters are the same, we focus on the distance to cluster parameter. Applying Reduction Rule 2 for false twins (instead of true twins) and defining equivalence classes over the independent sets (instead of cliques) for Reduction Rule 3, we get the similar result for the distance to co-cluster. Recall that, for a graph G, the *distance to cluster* of G is the minimum number of vertices of G that need to be deleted so that the resulting graph is a *cluster graph*, *i.e.*, a disjoint union of cliques.

▶ **Theorem 8.** Metric Dimension *is* FPT *parameterized by the distance to cluster.*

Proof. Let (G, k) be an instance of Metric Dimension and let $X \subseteq V(G)$ be such that $G - X$ is a disjoint union of cliques. To obtain a kernel for the problem, we present a set of reduction rules. The safeness of the following reduction rule is trivial.

▶ **Reduction Rule 1.** *If $V(G) \neq \emptyset$ and $k \leq 0$, then return a trivial* No*-instance.*

▶ **Reduction Rule 2.** *If there exist $u, v, w \in V(G)$ such that u, v, w are true (or false) twins, then remove u from G and decrease k by one.*

▷ Claim 9 (⋆). Reduction Rule 2 is safe.

We assume, henceforth, that Reduction Rule 2 has been exhaustively applied to (G, k). This implies, in particular, that for every clique C of $G - X$, there are at most two vertices in C with the same neighborhood in X. Since the number of distinct neighborhoods in X is at most $2^{|X|}$, each clique in $G - X$ has order at most $2^{|X|+1}$. We now aim to bound the number of cliques in $G - X$. To this end, we define a notion of *equivalence classes* over the set of cliques of $G - X$. It will easily be seen that the number of equivalence classes is at most $2^{2^{|X|+1}}$. The number of cliques in each equivalence class will then be bounded by using Reduction Rule 3.

For every clique C of $G - X$, the *signature* $\texttt{sign}(C)$ of C is the *multiset* containing the neighborhoods in X of each vertex of C, that is, $\texttt{sign}(C) = \{N(u) \cap X : u \in C\}$. For any two cliques C_1, C_2 of $G - X$, we say that C_1 and C_2 are *identical*, which we denote by $C_1 \sim C_2$, if and only if $\texttt{sign}(C_1) = \texttt{sign}(C_2)$. It is not difficult to see that $\sim$ is in fact an equivalence relation with at most $2^{2^{|X|+1}}$ equivalence classes: indeed, since the number of distinct neighborhoods in X is at most $2^{|X|}$, and at most two vertices of each clique have the same neighborhood in X, the number of distinct signatures is at most $2^{2^{|X|+1}}$. Consider now an equivalence class $\mathcal{C}$ of $\sim$. Note that since the signature of a clique is a multiset, the number of vertices in each $C \in \mathcal{C}$ is equal to $|\texttt{sign}(C)|$. For any $C_1, C_2 \in \mathcal{C}$, we say that two vertices $u \in C_1$ and $v \in C_2$ are *clones* if $N(u) \cap X = N(v) \cap X$ (in particular, if $C_1 = C_2$ and $u \neq v$, then u, v are true twins). For any $C_1, C_2 \in \mathcal{C}$ and any $u \in C_1$, we denote by $c(u, C_2)$

the set of clones of u in C_2 (note that $|c(u, C_2)| \leq 2$). Now observe that, for any two cliques $C_1, C_2 \in \mathcal{C}$, the number of pairs of true twins in C_1 and C_2 is the same: we let $t(\mathcal{C})$ be the number of pairs of true twins in each clique of $\mathcal{C}$. We highlight that there are exactly $2t(\mathcal{C})$ vertices in each clique of $\mathcal{C}$ that have true twins. The following claim for clones is the analog of Observation 1 for twins.

▷ Claim 10 (⋆). Let C_1 and C_2 be two cliques of an equivalence class $\mathcal{C}$ of $\sim$. Let $u \in C_1$ and $v \in C_2$ be clones. Then, for any $w \in V(G) \setminus (V(C_1) \cup V(C_2))$, $d(u, w) = d(v, w)$, and so, for any resolving set S of G, $S \cap (V(C_1) \cup V(C_2)) \neq \emptyset$.

It follows from the above claim that, for any equivalence class $\mathcal{C}$ of $\sim$ and any resolving set S, S contains at least $|\mathcal{C}| - 1$ vertices in $V(\mathcal{C}) := \bigcup_{C \in \mathcal{C}} V(C)$. We now present an upper bound on the size of $S \cap V(\mathcal{C})$ when $|\mathcal{C}| \geq |X| + 2$.

▷ Claim 11 (⋆). For every equivalence class $\mathcal{C}$ of $\sim$, if $|\mathcal{C}| \geq |X| + 2$, then, for any minimum resolving set S of G, $|S \cap V(\mathcal{C})| \leq |X| + |\mathcal{C}| \cdot \max\{1, t(\mathcal{C})\}$.

Let $\mathcal{C}$ be an equivalence class of $\sim$, and let S be a resolving set of G. For every $i \geq 0$, we denote by $\mathcal{C}^S_{=i}$ ($\mathcal{C}^S_{\geq i}$, resp.) the set of cliques $C \in \mathcal{C}$ such that $|S \cap V(C)| = i$ ($|S \cap V(C)| \geq i$).

▷ Claim 12 (⋆). Let $\mathcal{C}$ be an equivalence class of $\sim$ such that $|\mathcal{C}| \geq |X| + 2$. Then, for any minimum resolving set S of G, the following hold:

(i) if $t(\mathcal{C}) = 0$, then $|\mathcal{C}^S_{=0}| \leq 1$ and $|\mathcal{C}^S_{\geq 2}| \leq |X| + 1$;
(ii) if $t(\mathcal{C}) \neq 0$, then $|\mathcal{C}^S_{\geq t(\mathcal{C})+1}| \leq |X| + 1$.

The above claim states that if some equivalence class $\mathcal{C}$ of $\sim$ contains at least $|X| + 3$ cliques, then, for any minimum resolving set S of G, if $t(\mathcal{C}) = 0$, then $\mathcal{C}^S_{=1} \neq \emptyset$, and otherwise, $\mathcal{C}^S_{=t(\mathcal{C})} \neq \emptyset$. The following reduction rule is based on this claim.

▶ **Reduction Rule 3.** *If there exists an equivalence class $\mathcal{C}$ of $\sim$ such that $|\mathcal{C}| \geq 2^{|X|+2} + |X| + 2$, then remove a clique $C \in \mathcal{C}$ from G and reduce k by* $\max\{1, t(\mathcal{C})\}$.

▷ Claim 13 (⋆). Reduction Rule 3 is safe.

Now observe that once Reduction Rule 3 has been exhaustively applied to (G, k), each equivalence class of $\sim$ contains at most $2^{|X|+2} + |X| + 1$ cliques. Since there are at most $2^{2^{|X|+1}}$ equivalence classes and each clique of $G - X$ has size at most $2^{|X|+1}$, we conclude that G contains at most $2^{2^{|X|+1}} \cdot (2^{|X|+2} + |X| + 1) \cdot 2^{|X|+1} + |X|$ vertices. ◀

5 Conclusion

As the Metric Dimension problem is W[2]-hard when parameterized by the solution size [23], the next natural step is to understand its parameterized complexity under structural parameterizations. We continued this line of research, following in the steps of [3, 13, 20], and more recently [7, 29]. Our most technical result is a proof that the Metric Dimension problem is W[1]-hard when parameterized by the feedback vertex set number of the graph. We thereby improved the result by Bonnet and Purohit [7] that states the problem is W[1]-hard when parameterized by the treewidth, and answered an open question in [23]. It is easy to see that the problem admits an FPT algorithm when parameterized by the larger parameter, the vertex cover number of the graph. On the positive side, we proved that the problem admits FPT algorithms when parameterized by the distance to cluster and the distance to co-cluster, which are smaller parameters than the vertex cover number.

Although this work advances the understanding of structural parameterizations of Metric Dimension, it falls short of completing the picture (see Figure 1). We find it hard to extend the positive results to the parameters like the minimum clique cover, the distance to disjoint paths, feedback edge set, and the bandwidth. It would be interesting to find FPT algorithms or prove that such algorithms are highly unlikely to exist for these parameters. The FPT algorithm parameterized by the treedepth in [20] relies on the meta-result. Is it possible to get an FPT algorithm whose running time is a single or double exponent in the treedepth? It would also be interesting to investigate the problem parameterized by the distance to cograph. Recall that the problem is polynomial-time solvable in cographs [14].

Bonnet and Purohit [7] conjectured that the problem is W[1]-hard even when parameterized by the treewidth plus the solution size. Towards resolving this conjecture, an interesting question would be to investigate whether the problem admits an FPT algorithm when parameterized by the feedback vertex set number plus the solution size. Note that even an XP algorithm parameterized by the feedback vertex set number is not apparent.

Graph Similarity Based on Matrix Norms

Abstract

Quantifying the similarity between two graphs is a fundamental algorithmic problem at the heart of many data analysis tasks for graph-based data. In this paper, we study the computational complexity of a family of similarity measures based on quantifying the mismatch between the two graphs, that is, the "symmetric difference" of the graphs under an optimal alignment of the vertices. An important example is similarity based on graph edit distance. While edit distance calculates the "global" mismatch, that is, the number of edges in the symmetric difference, our main focus is on "local" measures calculating the maximum mismatch per vertex.

Mathematically, our similarity measures are best expressed in terms of the adjacency matrices: the mismatch between graphs is expressed as the difference of their adjacency matrices (under an optimal alignment), and we measure it by applying some matrix norm. Roughly speaking, global measures like graph edit distance correspond to entrywise matrix norms like the Frobenius norm and local measures correspond to operator norms like the spectral norm.

We prove a number of strong NP-hardness and inapproximability results even for very restricted graph classes such as bounded-degree trees.

1 Introduction

Graphs are basic models ubiquitous in science and engineering. They are used to describe a diverse range of objects and processes from chemical compounds to social interactions. To understand and classify graph models, we need to compare graphs. Since data and models are not always guaranteed to be exact, it is essential to understand what makes two graphs similar or dissimilar, and to be able to compute similarity efficiently. There are many different approaches to similarity, for example, based on edit-distance (e.g. [3,6,27]), spectral similarity (e.g. [16,29,30]), optimal transport (e.g. [5,23,25]), or behavioral equivalence (e.g. [28,31]). This is only natural, because the choice of a "good" similarity measure will usually depend on the application. While graph similarity has received considerable attention in application areas such as computer vision (see, for example, [7,9]) and network science (see, for example, [8]), theoretical computer scientists have not explored similarity systematically; only specific "special cases" such as isomorphism [14] and bisimilarity [28] have been studied to great depth. Yet it seems worthwhile to develop a *theory of graph similarity* that compares different similarity measures, determines their algorithmic and semantic properties, and thus gives us a better understanding of their suitability for various kinds of applications. We see our paper as one contribution to such a theory.

Maybe the simplest graph similarity measure is based on graph edit distance: the *edit distance* between graphs G, H (for simplicity of the same order) is the minimum number of edges that need to be added and deleted from G to obtain a graph ismorphic to H.

In this paper, we study the computational complexity of a natural class of similarity measures that generalize the similarity derived from edit distance of graphs. In general, we view similarity as proximity with respect to some metric. A common way of converting a graph metric d into a similarity measure s is to let $s(G, H) := \exp(-\beta \cdot d(G, H))$ for some constant $\beta > 0$. For our considerations the transformation between distance and similarity is irrelevant, so we focus directly on the metrics. In terms of computational complexity, computing similarity tends to be a hard algorithmic problem. It is known that computing edit distance, exactly or approximately, is NP-hard [3, 13, 18, 27] even on very restricted graph classes. In fact, the problem is closely related to the quadratic assignment problem [22, 26], which is notorious for being a very hard combinatorial optimization problem also for practical, heuristic approaches. Within the spectrum of similarities, the "limit" case of graph isomorphism shows that overall the complexity of graph similarity is far from trivial.

The metrics we study in this paper are based on minimizing the mismatch between two graphs. For graphs G, H with the same vertex set V, we define their *mismatch graph* $G - H$ to be the graph with vertex set V and edge set $E(G) \triangle E(H)$, the symmetric difference between the edge sets of the graphs. We assign *signs* to edges of the mismatch graph to indicate which graph they come from, say, a positive sign to the edges in $E(G) \setminus E(H)$ and a negative sign to the edges in $E(H) \setminus E(G)$. To quantify the mismatch between our graphs we introduce a *mismatch norm* μ on signed graphs that satisfies a few basic axioms such as subadditivity as well as invariance under permutations and under flipping the signs of all edges. Now for graphs G, H, not necessarily with the same vertex set, but for simplicity of the same order,[1] we define the distance $\mathrm{dist}_\mu(G, H)$ to be the minimum of $\mu(G^\pi - H)$, where π ranges over all bijective mappings from $V(G)$ to $V(H)$ and G^π is the image of G under π.

The simplest mismatch norm μ_{ed} just counts the number of edges of the mismatch graph $G - H$, ignoring their signs. Then the associated distance $\mathrm{dist}_{\mathrm{ed}}(G, H)$ is the edit distance between G and H. (Note that we write $\mathrm{dist}_{\mathrm{ed}}$ instead of the clunky $\mathrm{dist}_{\mu_{\mathrm{ed}}}$; we will do the same for other mismatch norms discussed here.) Another simple yet interesting mismatch norm is μ_{deg} measuring the maximum degree of the mismatch graph, again ignoring the signs of the edges. Then $\mathrm{dist}_{\mathrm{deg}}(G, H)$ measures how well we can align the two graphs in order to minimize the "local mismatch" at every node. Hence an alignment where at every vertex there is a mismatch of one edge yields a smaller $\mathrm{dist}_{\mathrm{deg}}$ than an alignment that is perfect at all nodes expect one, where it has a mismatch of, say, $n/2$, where n is the number of vertices. For edit distance it is the other way round. Depending on the application, one or the other may be preferable. Another well-known graph metric that can be described via the mismatch graph is Lovász's *cut distance* (see [19, Chapter 8] and Section 3 of this paper). And, last but not least, for the mismatch norm μ_{iso} defined to be 0 if the mismatch graph has no edges and 1 otherwise, $\mathrm{dist}_{\mathrm{iso}}(G, H)$ is 0 if G and H are isomorphic, and 1 otherwise, so computing the distance between two graphs amounts to deciding if they are isomorphic.

Mathematically, the framework of mismatch norms and the associated distances is best described in terms of the adjacency matrices of the graphs; the adjacency matrix A_{G-H} of the mismatch graph (viewed as a matrix with entries $0, +1, -1$ displaying the signs of the

[1] A general definition that also applies to graphs of distinct order can be found in Section 3, but for the hardness results we prove in this paper we can safely restrict our attention to graphs of the same order; this only makes the results stronger.

edges) is just the difference $A_G - A_H$. Then mismatch norms essentially are just matrix norms applied to to A_{G-H}. It turns out that "global norms" such as edit distance and direct generalizations correspond to entrywise matrix norms (obtained by applying a vector norm to the flattened matrix), and "local norms" such as μ_{deg} correspond to operator matrix norms (see Section 3). Cut distance corresponds to the cut norm of matrices. Instead of adjacency matrices, we can also consider the Laplacian matrices, exploiting that $L_{G-H} = L_G - L_H$, and obtain another interesting family of graph distances.

For every mismatch norm μ, we are interested in the problem $\textsc{Dist}_\mu$ of computing $\text{dist}_\mu(G, H)$ for two given graphs G, H. Note that this is a minimization problem where the feasible solutions are the bijective mappings between the vertex sets of the two graphs. It turns out that the problem is hard for most mismatch norms μ, in particular almost all the natural choices discussed above. The single exception is μ_{iso} related to the graph isomorphism problem. Furthermore, the hardness results usually hold even if the input graphs are restricted to be very simple, for example trees or bounded degree graphs. For edit distance and the related distance based on entrywise matrix norms this was already known [3, 13]. Our focus in this paper is on operator norms. We prove a number of hardness results for different graph classes. One of the strongest ones is the following (see Theorem 19). Here $\textsc{Dist}_p$ denotes the distance measure derived from the ℓ_p-operator norm.

▶ **Theorem 1.** *For $1 \leq p \leq \infty$ there is a constant $c > 1$ such that, unless* $\mathsf{P} = \mathsf{NP}$*, $\textsc{Dist}_p$ has no factor-c approximation algorithm even if the input graphs are restricted to be trees of bounded degree.*

For details and additional results, we refer to Section 4 and 5.

Initially we aimed for a general hardness result that applies to all mismatch norms satisfying some additional natural conditions. However, we found that the hardness proofs, while following the same general strategies, usually have some intricacies exploiting special properties of the specific norms. Furthermore, for cut distance, none of these strategies seemed to work. Nevertheless, we were able to give a hardness proof for cut distance (Theorem 23) that is simply based on the hardness of computing the cut norm of the matrix [1]. This is remarkable in so far as usually the hard part of computing the distance is to find an optimal alignment π, whereas computing $\mu(G^\pi - H)$ is usually easy. For cut norm, it is even hard to compute $\mu(G^\pi - H)$ for a fixed alignment π.

Related Work

Graph similarity has mostly been studied in specific application areas, most importantly computer vision, data mining, and machine learning (see the references above). Of course not all similarity measures are based on mismatch. For example, metrics derived from vector embedding or graph kernels in machine learning (see [17]) provide a completely different approach (see [12] for a broader discussion). Of interest compared to our work (specifically for the ℓ_2-operator norm a.k.a. spectral norm) is the spectral approach proposed by Kolla, Koutis, Madan, and Sinop [16]. Intuitively, instead of the "difference" of two graphs that is described by our mismatch graphs, their approach is based on taking a "quotient".

The complexity of similarity, or "approximate graph isomorphism", or "robust graph isomorphism" has been studied in [2, 3, 13, 15, 16, 18, 27], mostly based on graph edit distance and small variations. Operator norms have not been considered in this context.

2 Preliminaries

We denote the class of real numbers by $\mathbb{R}$ and the nonnegative and positive reals by $\mathbb{R}_{\geq 0}, \mathbb{R}_{>0}$, respectively. By $\mathbb{N}, \mathbb{N}_{>0}$ we denote the sets of nonnegative resp. positive integers. For every $n \in \mathbb{N}_{>0}$ we let $[n] := \{1, \ldots, n\}$.

We will consider matrices with real entries and with rows and columns indexed by arbitrary finite sets. Formally, for finite sets V, W, a $V \times W$ matrix is a function $A\colon V \times W \to \mathbb{R}$. A standard $m \times n$-matrix is just an $[m] \times [n]$-matrix. We denote the set of all $V \times W$ matrices by $\mathbb{R}^{V \times W}$, and we denote the entries of a matrix A by A_{vw}.

For a square matrix $A \in \mathbb{R}^{V \times V}$ and injective mapping $\pi : V \to W$, we let A^π be the $V^\pi \times V^\pi$-matrix with entries $A_{v^\pi w^\pi} := A_{vw}$. Note that we apply the mapping π from the right and denote the image of v under π by v^π. If $\rho : W \to X$ is another mapping, we denote the composition of π and ρ by $\pi\rho$. We typically use this notation for mappings between matrices and between graphs.

We use a standard graph theoretic notation. We denote the vertex set of a graph G by $V(G)$ and the edge set by $E(G)$. Graphs are finite, simple, and undirected, that is, $E(G) \subseteq \binom{V(G)}{2}$. We denote edges by vw instead of $\{v, w\}$. The *order* of a graph is $|G| := |V(G)|$. The *adjacency matrix* $A_G \in \{0,1\}^{V(G) \times V(G)}$ is defined in the usual way. We denote the class of all graphs by $\mathcal{G}$.

Let G be a graph with vertex set $V := V(G)$. For a mapping $\pi : V \to W$ we let G^π be the graph with vertex set $\{v^\pi \mid v \in V\}$ and edge set $\{v^\pi w^\pi \mid vw \in E(G) \text{ with } v^\pi \neq w^\pi\}$. Then $A_{G^\pi} = A_G^\pi$ if π is injective.

For graphs G, H, we denote the set of all injective mappings $\pi : V(G) \to V(H)$ by $\mathrm{Inj}(G, H)$. Graphs G and H are *isomorphic* (we write $G \cong H$) if there is an $\pi \in \mathrm{Inj}(G, H)$ such that $G^\pi = H$. We think of the mappings in $\mathrm{Inj}(G, H)$, in particular if $|G| = |H|$ and they are bijective, as *alignments* between the graphs. Intuitively, to measure the distance between two graphs, we will align them in an optimal way to minimize the mismatch.

3 Graph Metrics Based on Mismatches

A *graph metric* is a function $\delta : \mathcal{G} \times \mathcal{G} \to \mathbb{R}_{\geq 0}$ such that
(GM0) $\delta(G, H) = \delta(G', H')$ for all G, G', H, H' such that $G \cong G'$ and $H \cong H'$;
(GM1) $\delta(G, G) = 0$ for all G;
(GM2) $\delta(G, H) = \delta(H, G)$ for all G, H;
(GM3) $\delta(F, H) \leq \delta(F, G) + \delta(G, H)$ for all F, G, H.
Note that we do not require $\delta(G, H) > 0$ for all $G \neq H$, not even for $G \not\cong H$, so strictly speaking this is just a *pseudometric*. We are interested in the complexity of the following problem:

DIST$_\delta$

Instance: Graphs G, H, $p, q \in \mathbb{N}_{>0}$
Problem: Decide if $\delta(G, H) \geq \frac{p}{q}$

A *signed graph* is a weighted graph with edge weights $-1, +1$, and for every edge e of a signed graph we denote its *sign* by $\mathrm{sg}(e)$. For a signed graph Δ, we let $E_+(\Delta) := \{e \in E(\Delta) \mid \mathrm{sg}(e) = +1\}$ and $E_-(\Delta) := \{e \in E(\Delta) \mid \mathrm{sg}(e) = -1\}$. *Isomorphisms* of signed graphs must preserve signs. A signed graph Δ is a subgraph of a signed graph Γ (we write $\Delta \subseteq \Gamma$) if $V(\Delta) \subseteq V(\Gamma)$, $E_+(\Delta) \subseteq E_+(\Gamma)$, and $E_-(\Delta) \subseteq E_-(\Gamma)$. We denote the class of all signed graphs by $\mathcal{S}$.

For every $\Delta \in \mathcal{S}$, we let $-\Delta$ be the signed graph obtained from Δ by flipping the signs of all edges. We define the *sum* of $\Delta, \Gamma \in \mathcal{S}$ to be the signed graph $\Delta+\Gamma$ with vertex set $V(\Delta+\Gamma) = V(\Delta) \cup V(\Gamma)$ and signed edge sets $E_+(\Delta+\Gamma) = \big(E_+(\Delta) \cup E_+(\Gamma)\big) \setminus \big(E_-(\Delta) \cup E_-(\Gamma)\big)$ and $E_-(\Delta+\Gamma) = \big(E_-(\Delta) \cup E_-(\Gamma)\big) \setminus \big(E_+(\Delta) \cup E_+(\Gamma)\big)$. The adjacency matrix A_Δ of a signed graph Δ displays the signs of the edges, so $A_\Delta \in \{0, 1, -1\}^{V(\Delta)\times V(\Delta)}$ with $(A_\Delta)_{vw} = \mathrm{sg}(vw)$ if $vw \in E(\Delta)$ and $(A_\Delta)_{vw} = 0$ otherwise. Note that $A_{-\Delta} = -A_\Delta$ for all $\Delta \in \mathcal{S}$ and $A_{\Delta+\Gamma} = A_\Delta + A_\Gamma$ for all $\Delta, \Gamma \in \mathcal{S}$ with $V(\Delta) = V(\Gamma)$ and $E_+(\Delta) \cap E_+(\Gamma) = \emptyset$ and $E_-(\Delta) \cap E_-(\Gamma) = \emptyset$.

The *mismatch graph* of two graphs G, H is the signed graph $G - H$ with vertex set $V(G - H) \coloneqq V(G) \cup V(H)$ and signed edge set $E_+(G - H) \coloneqq E(G) \setminus E(H)$, $E_-(G - H) \coloneqq E(H) \setminus E(G)$. Note that if $V(G) = V(H)$ then for the adjacency matrices we have $A_{G-H} = A_G - A_H$. Observe that every signed graph Δ is the mismatch graph of the graphs $\Delta_+ \coloneqq (V(\Delta), E_+(\Delta))$ and $\Delta_- \coloneqq (V(\Delta), E_-(\Delta))$.

A *mismatch norm* is a function $\mu : \mathcal{S} \to \mathbb{R}_{\geq 0}$ satisfying the following conditions:

(MN0) $\mu(\Delta) = \mu(\Gamma)$ for all $\Delta, \Gamma \in \mathcal{S}$ such that $\Delta \cong \Gamma$;

(MN1) $\mu(\Delta) = 0$ for all $\Delta \in \mathcal{S}$ with $E(\Delta) = \emptyset$;

(MN2) $\mu(\Delta) = \mu(-\Delta)$ for all Δ;

(MN3) $\mu(\Delta+\Gamma) \leq \mu(\Delta)+\mu(\Gamma)$ for all $\Delta, \Gamma \in \mathcal{S}$ with $V(\Delta) = V(\Gamma)$ and $E_+(\Delta) \cap E_+(\Gamma) = \emptyset$ and $E_-(\Delta) \cap E_-(\Gamma) = \emptyset$.

(MN4) $\mu(\Delta) = \mu(\Gamma)$ for all $\Delta, \Gamma \in \mathcal{S}$ with $E_+(\Delta) = E_+(\Gamma)$ and $E_-(\Delta) = E_-(\Gamma)$;

For every mismatch norm μ, we define $\mathrm{dist}_\mu : \mathcal{G} \times \mathcal{G} \to \mathbb{R}_{\geq 0}$ by

$$\mathrm{dist}_\mu(G, H) \coloneqq \begin{cases} \min_{\pi \in \mathrm{Inj}(G,H)} \mu(G^\pi - H) & \text{if } |G| \leq |H|, \\ \min_{\pi \in \mathrm{Inj}(H,G)} \mu(G - H^\pi) & \text{if } |H| < |G|. \end{cases}$$

We write $\textsc{Dist}_\mu$ instead of $\textsc{Dist}_{\mathrm{dist}_\mu}$ to denote the algorithmic problem of computing dist_μ for two graphs G, H.

▶ **Lemma 2.** *For every mismatch norm μ the function* dist_μ *is a graph metric.*

Proof. Conditions (GM0), (GM1), (GM2) follow from (MN0), (MN1), (MN2), respectively. To prove (GM3), let F, G, H be graphs. Padding the graphs with isolated vertices, by (MM4) we may assume that $|F| = |G| = |H|$. By (MN0) we may further assume that $V(F) = V(G) = V(H) \coloneqq V$. Choose $\pi, \rho \in \mathrm{Inj}(V, V)$ such that $\mathrm{dist}_\mu(F, G) = \mu(F^\pi - G)$ and $\mathrm{dist}_\mu(G, H) = \mu(G^\rho - H)$.

Then by (MN0) we have

$$\mu(F^{\pi\rho} - G^\rho) = \mu\big((F^\pi - G)^\rho\big) = \mu(F^\pi - G) = \mathrm{dist}_\mu(F, G).$$

Now consider the two mismatch graphs $\Delta \coloneqq F^{\pi\rho} - G^\rho$ and $\Gamma \coloneqq G^\rho - H$. We have $E_+(\Delta) = E(F^{\pi\rho}) \setminus E(G^\rho)$ and $E_+(\Gamma) = E(G^\rho) \setminus E(H)$. Thus $E_+(\Delta) \cap E(G^\rho) = \emptyset$ and $E_+(\Gamma) \subseteq E(G^\rho)$, which implies $E_+(\Delta) \cap E_+(\Gamma) = \emptyset$. Similarly, $E_-(\Delta) \cap E_-(\Gamma) = \emptyset$. Moreover, $\Delta + \Gamma = F^{\pi\rho} - H$, because

$$A_{\Delta+\Gamma} = A_\Delta + A_\Gamma = (A_F^{\pi\rho} - A_G^\rho) + (A_G^\rho - A_H) = A_F^{\pi\rho} - A_H = A_{F^{\pi\rho}-H}.$$

Thus by (MN3),

$$\mathrm{dist}_\mu(F, H) \leq \mu(F^{\pi\rho} - H) = \mu(\Delta + \Gamma) \leq \mu(\Delta) + \mu(\Gamma) = \mathrm{dist}_\mu(F, G) + \mathrm{dist}_\mu(G, H).$$

This proves (GM3). ◀

▶ Remark 3. None of the five conditions (MN0)–(MN4) on a mismatch norm μ can be dropped if we want to guarantee that dist_μ is a graph metric, but of course we could replace them by other conditions. While (MN0)–(MN3) are very natural and directly correspond to conditions (GM0)–(GM3) for graph metrics, condition (MN4) is may be less so. We chose (MN4) as the simplest condition that allows us to compare graphs of different sizes.

Having said this, it is worth noting that (MN0), (MN1) and (MN3) imply (MN4) for graphs Δ, Γ with $|\Delta| = |\Gamma|$. For graphs Δ, Γ with $|\Delta| < |\Gamma|$ they only imply $\mu(\Delta) \geq \mu(\Gamma)$. Thus as long as we only compare graphs of the same order, (MN4) is not needed. In particular, since our hardness results always apply to graphs of the same order, (MN4) is inessential for the rest of the paper.

However, it is possible to replace (MN4) by other natural conditions. For example, Lovász's metric based on a scaled cut norm [20] does not satisfy (MN4) and instead uses a blowup of graphs to a common size to compare graphs of different sizes.

Let us now consider a few examples of mismatch norms.

▶ **Example 4** (Isomorphism). The mapping $\iota := \mathcal{S} \to \mathbb{R}_{\geq 0}$ defined by $\iota(\Delta) := 0$ if $E(\Delta) = \emptyset$ and $\iota(\Delta) := 1$ otherwise is a mismatch norm. Under the metric dist_ι, all nonisomorphic graphs have distance 1 (and isomorphic graphs have distance 0, as they have under all graph metrics).

▶ **Example 5** (Matrix Norms). Recall that a matrix (pseudo) norm $\|\cdot\|$ associates with every matrix A (say, with real entries) an nonnegative real $\|A\|$ in such a way that $\|N\| = 0$ for matrices N with only 0-entries, $\|aA\| = |a| \cdot \|A\|$ for all matrices A and reals $a \in \mathbb{R}$, and $\|A + B\| \leq \|A\| + \|B\|$ for all matrices A, B of the same dimensions.

Actually, we are only interested in square matrices here. We call a matrix norm $\|\cdot\|$ *permutation invariant* if for all $A \in \mathbb{R}^{V\times V}$ and all bijective $\pi : V \to V$ we have $\|A\| = \|A^\pi\|$. It is easy to see that for every permutation invariant matrix norm $\|\cdot\|$, the mapping $\mu_{\|\cdot\|} : \mathcal{S} \to \mathbb{R}_{\geq 0}$ defined by $\mu_{\|\cdot\|}(\Delta) := \|A_\Delta\|$ satisfies (MN0)–(MN3).

We call a permutation invariant matrix norm $\|\cdot\|$ *paddable* if it is invariant under extending matrices by zero entries, that is, $\|A\| = \|A'\|$ for all $A \in \mathbb{R}^{V\times V}$, $A' \in \mathbb{R}^{V'\times V'}$ such that $V' \supseteq V$, $A_{vw} = A'_{vw}$ for all $v, w \in V$, and $A'_{vw} = 0$ if $v \in V' \setminus V$ or $w \in V' \setminus V$. A paddable matrix norm also satisfies (MN4).

The following common matrix norms are paddable (and thus by definition also invariant). Let $1 \leq p \leq \infty$ and $A \in \mathbb{R}^{V\times V}$.

1. *Entrywise p-norm:* $\|A\|_{(p)} := \Big(\sum_{v,w\in V} |A_{vw}|^p\Big)^{\frac{1}{p}}$. The best-known special case is the *Frobenius norm* $\|\cdot\|_F := \|\cdot\|_{(2)}$.
2. *ℓ_p-operator norm:* $\|A\|_p := \sup_{\boldsymbol{x}\in\mathbb{R}^V\setminus\{\boldsymbol{0}\}} \frac{\|A\boldsymbol{x}\|_p}{\|\boldsymbol{x}\|_p}$, where the vector p-norm is defined by $\|\boldsymbol{a}\|_p := \big(\sum_{v\in V} a_v^p\big)^{\frac{1}{p}}$. In particular, $\|A\|_2$ is known as the *spectral norm.*
3. *Absolute ℓ_p-operator norm:* $\|A\|_{|p|} := \|\operatorname{abs}(A)\|_p$, where abs takes entrywise absolute values. For the mismatch norm, taking entrywise absolute values means that we ignore the signs of the edges.
4. *Cut norm:* $\|A\|_\square := \max_{S,T\subseteq V} \Big|\sum_{v\in S,w\in T} A_{vw}\Big|$.

▶ **Example 6** (Laplacian Matrices). Recall that the *Laplacian matrix* of a weighted graph G with vertex set $V := V(G)$ is the $V \times V$ matrix L_G with off-diagonal entries $(L_G)_{vw}$ being the negative weight of the edge $vw \in E(G)$ if there is such an edge and 0 otherwise and diagonal entries $(L_G)_{vv}$ being the sum of the weights of all edges incident with v. For an unweighted graph we have $L_G = D_G - A_G$, where D_G is the diagonal matrix with the vertex degrees as diagonal entries.

Observe that for a signed graph $\Delta = G - H$ we have $L_\Delta = L_G - L_H$.

It is easy to see that for every paddable matrix norm $\|\cdot\|$, the function $\mu^L_{\|\cdot\|} : \mathcal{S} \to \mathbb{R}_{\geq 0}$ defined by $\mu^L_{\|\cdot\|}(\Delta) := \|L_\Delta\|$ is a mismatch norm.

Clearly, $\textsc{Dist}_\mu$ is not a hard problem for every mismatch norm. For example, $\textsc{Dist}_\nu$ is trivial for the trivial mismatch norm ν defined by $\nu(\Delta) := 0$ for all Δ, and $\textsc{Dist}_\iota$ for ι from Example 4 is equivalent to the graph isomorphism problem and hence in quasipolynomial time [4].

However, for most natural matrix norms the associated graph distance problem is NP-hard. In particular, for every $p \in \mathbb{R}_{>0}$, this holds for the metric $\mathrm{dist}_{(p)}$ based on the entrywise p-norm $\|\cdot\|_{(p)}$.

▶ **Theorem 7** ([13]). *For $p \in \mathbb{R}_{>0}$, $\textsc{Dist}_{(p)}$ is NP-hard even if restricted to trees or bounded-degree graphs.*

The proof in [13] is only given for the Frobenius norm, that is, $\textsc{Dist}_{(2)}$, but it actually applies to all p. In the rest of the paper, we study the complexity of $\textsc{Dist}_p$, $\textsc{Dist}_{|p|}$ and $\textsc{Dist}_\square$.

4 Complexity for Operator Norms

In this section we investigate the complexity of $\textsc{Dist}_p$ and $\textsc{Dist}_{|p|}$ for $1 \leq p \leq \infty$. However, as $\mu_{|p|}$ would only be a special case within the upcoming proofs, we omit to mention it explicitly. We also omit to specify the possible values for p.

Given graphs G and H, an alignment from G to H, and a node $v \in V(G)$ we refer to the nodes whose adjacency is not preserved by π as the *π-mismatches of v*. If π is clear from the context we might omit it. We call $G^\pi - H$ the *mismatch graph of π*.

For all ℓ_p-operator norms the value of $\mu_p(G^\pi - H)$ strongly depends on the maximum degree in the mismatch graph of π. We capture this property with the following definition.

▶ **Definition 8.** *Let G, H be graphs of the same order and π an alignment from G to H. The* π-mismatch count (π-MC) *of a node $v \in V(G)$ is defined as:*

$$\mathrm{MC}(v, \pi) := |\{w \in V(G) \mid w \textit{ is a } \pi\textit{-mismatch of } v\}|\,.$$

We use MC for nodes in H analogously. The *maximum mismatch count* (π-MMC) of π is defined as:

$$\mathrm{MMC}(\pi) := \max_{v \in V(G)} \mathrm{MC}(v, \pi).$$

Again we might drop the π if it is clear from the context. Note that the MMC corresponds to the maximum degree in the mismatch graph and that we use a slightly abbreviated notation in which we assume the graphs are given by the alignment.

The ℓ_1-operator norm and the ℓ_∞-operator norm measure exactly the maximum mismatch count. Due to the relation between the ℓ_p-operator norms we can derive an upper bound for μ_p. The proof of Lemma 9 can be found in the full version [11].

▶ **Lemma 9.** *Let G, H be graphs of the same order and π an alignment from G to H. Then*

$$\mu_1(G^\pi - H) = \mu_\infty(G^\pi - H) = \mathrm{MMC}(\pi),$$
$$\mu_p(G^\pi - H) \leq \mathrm{MMC}(\pi).$$

Next, we observe that μ_p is fully determined by the connected component of the mismatch graph with the highest mismatch norm. The proof of Lemma 10 can be found in the full version [11].

▶ **Lemma 10.** *Let G, H be graphs of the same order, π an alignment from G to H, and $\mathcal{C}$ the set of all connected components in $G^\pi - H$. Then*

$$\mu_p(G^\pi - H) = \max_{C \in \mathcal{C}} \mu_p(C).$$

For the sake of readability, we introduce a function as abbreviation for our upcoming bounds.

▶ **Definition 11.** *For all $1 \leq p \leq \infty$ we define the function* bound_p *as follows:*

$$\mathrm{bound}_p(c) \coloneqq \max\left(c^{1/p}, c^{1-1/p}\right).$$

In particular, $\mathrm{bound}_2(c) = \sqrt{c}$. Now we derive our lower bound. The proof of Lemma 12 can be found in the full version [11].

▶ **Lemma 12.** *Let G, H be graphs of the same order, π an alignment from G to H, and $v \in V(G)$.*
If v has at least c mismatches, then

$$\mu_p(G^\pi - H) \geq \mathrm{bound}_p(c).$$

If $G^\pi - H$ is a star, then

$$\mu_p(G^\pi - H) = \mathrm{bound}_p(\mathrm{MMC}(\pi)).$$

While μ_1 and μ_∞ simply measure the MMC, μ_2 also considers the connectedness of the mismatches around the node with the highest MC. As Lemma 9 and Lemma 12 tell us, μ_2 ranges between the $\sqrt{\mathrm{MMC}}$ and the MMC. In fact, the lower bound is tight for stars and the upper bound is tight for regular graphs. This is intuitive as these are the extreme cases in which no mismatch can be removed/added without decreasing/increasing the MMC, respectively. Other ℓ_p-operator norms interpolate between μ_2 and μ_1 / μ_∞ in terms of how much they value the connectedness within the mismatch component of the node with the highest MC.

The lower bound for $\mu_p(G^\pi - H)$ gives us lower bound for $\mathrm{dist}_p(G, H)$.

▶ **Lemma 13.** *Let G, H be graphs of the same order and π an alignment from G to H. If all alignments from G to H have a node with at least c mismatches, then*

$$\mathrm{dist}_p(G, H) \geq \mathrm{bound}_p(c).$$

Proof. This follows directly from the first claim of Lemma 12. ◀

The following upper bound might seem to have very restrictive conditions but is actually used in several hardness proofs.

▶ **Lemma 14.** *Let G, H be graphs of the same order and π an alignment from G to H. If the mismatch graph of π consists only of stars, then*

$$\mathrm{dist}_p(G, H) \ \leq \mu_p(G^\pi - H) \ = \mathrm{bound}_p(\mathrm{MMC}(\pi)).$$

Proof. This follows directly from Lemma 10 and the second claim of Lemma 12. ◀

The last tool we need to prove the hardness is that we can distinguish two alignments by their MMC as long as the mismatch graph of the alignment with the lower MMC consists only of stars. The proof of Lemma 15 can be found in the full version [11].

▶ **Lemma 15.** *For all $c, d \in \mathbb{N}$ with $c < d$ it holds that* $\mathrm{bound}_p(c) < \mathrm{bound}_p(d)$.

The graph isomorphism problem becomes solvable in polynomial time if restricted to graphs of bounded degree [21]. In contrast to this, $\textsc{Dist}_F$ is NP-hard even under this restriction [13]. We show that the same applies to $\textsc{Dist}_p$.

The reduction in the hardness proof works for any mismatch norm which can, said intuitively, distinguish the mismatch norm of the 1-regular graph of order n from any other n-nodes mismatch graph in which every node has at least one -1 edge but at least one node has an additional -1 edge and $+1$ edge. In particular, the construction also works for $\textsc{Dist}_{(p)}$. However, it does not work for the cut-distance, for which we independently prove the hardness in Section 6.

▶ **Theorem 16.** $\textsc{Dist}_p$ *and* $\textsc{Dist}_{|p|}$ *are* NP*-hard for* $1 \leq p \leq \infty$ *even if both graphs have bounded degree.*

Proof. The proof is done by reduction from the NP-hard Hamiltonian Cycle problem in 3-regular graphs ($\textsc{Ham-Cycle}$) [10]. Given a 3-regular graph G of order n as an instance of $\textsc{Ham-Cycle}$, the reduction uses the n-nodes cycle C_n and G as inputs for $\textsc{Dist}_p$. We claim G has a Hamiltonian cycle if and only if $\mathrm{dist}_p(C_n, G) \leq \mathrm{bound}_p(1)$.

Assume that G has a Hamiltonian cycle. Then there exists a bijection $\pi : V(C_n) \to V(G)$ that aligns the cycle C_n perfectly with the Hamiltonian cycle in G. Each node in G has three neighbors, two of which are matched correctly by π as they are part of the Hamiltonian cycle. Hence, each node has a π-mismatch count of 1 and obviously the MMC of π is 1 as well. According to Lemma 14, we get $\mathrm{dist}_p(C_n, G) \leq \mathrm{bound}_p(1)$.

Conversely, assume that G has no Hamiltonian cycle. Then, for any alignment π' from C_n to G, there exists at least one edge vw in C_n that is not mapped to an edge in G. Hence, only one of the three edges incident to $\pi'(v)$ in G can be matched correctly. In total, v has at least one mismatch from C_n to G and two mismatches from G to C_n, which implies $\mathrm{MC}(v, \pi') \geq 3$. Using Lemma 13, we get $\mathrm{dist}_p(C_n, G) \geq \mathrm{bound}_p(3)$. And then $\mathrm{dist}_p(C_n, G) > \mathrm{bound}_p(1)$ according to Lemma 15. ◀

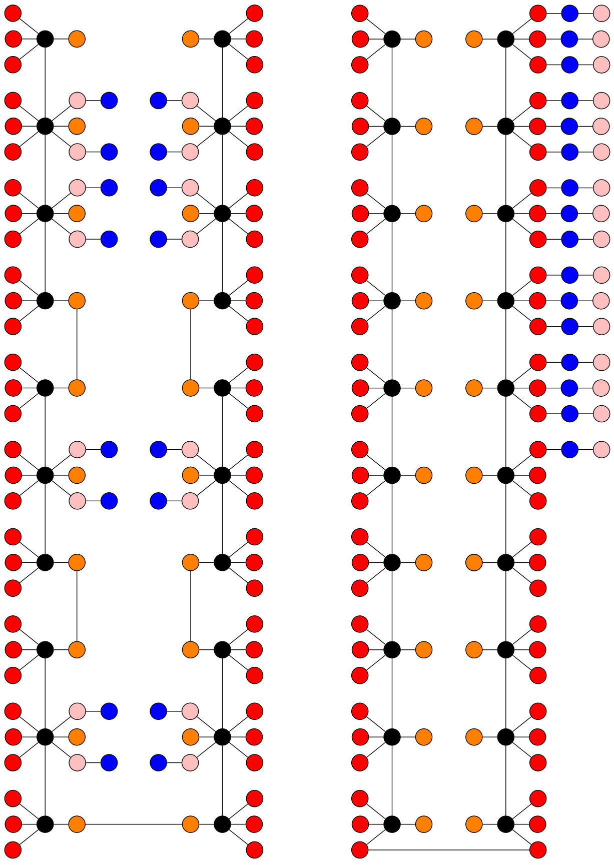
Next, we modify the construction to get an even stronger NP-hardness result. The proof can be found in the full version [11].

▶ **Theorem 17.** $\textsc{Dist}_p$ *and* $\textsc{Dist}_{|p|}$ *are* NP*-hard for* $1 \leq p \leq \infty$ *even if restricted to a path and a graph of maximum degree* 3*.*

Similar to bounded degree input graphs, restricting graph isomorphism to trees allows it to be solved in polynomial time [24] but $\textsc{Dist}_F$ is NP-hard for trees [13]. We show that $\textsc{Dist}_p$ remains NP-hard for trees even when applying the bounded degree restriction simultaneously.

▶ **Theorem 18.** $\textsc{Dist}_p$ *and* $\textsc{Dist}_{|p|}$ *are* NP*-hard for* $1 \leq p \leq \infty$ *even if restricted to bounded-degree trees.*

Proof. The proof is done by reduction from the NP-hard $\textsc{Three-Partition}$ problem [10] that is defined as follows. Given the integers A and $a_1, \ldots, a_{3m}$ in unary representation, such that $\sum_{i=1}^{3m} a_i = mA$ and $A/4 < a_i < A/2$ for $1 \leq i \leq 3m$, decide whether there exists a



(a) T_1.

(b) T_2.

Figure 1 Example of the construction in the proof of Theorem 18 where m=2, A=10, a_1=a_2=4 and a_3=a_4=a_5=a_6=3. Best viewed in color.

partition of $a_1, \ldots, a_{3m}$ into m groups of size 3 such that the elements in each group sum up to exactly A. For technical reasons, we restrict the reduction to $A \geq 8$. However, the ignored cases are trivial. Precisely, for $A \in \{6, 7\}$ the answer is always YES and for $A \in [5]$ there exist no valid instances.

Given an instance of Three-Partition with $A \geq 8$, we construct two trees T_1 and T_2 such that the given instance has answer YES, if and only if $\text{dist}_p(T_1, T_2) \leq \text{bound}_p(2)$. Figure 1 shows an example of T_1 and T_2 for $m = 2$ and $A = 10$. For illustrative reasons we assign each node a color during the construction. The colors are used in the example and we will refer to certain nodes by their color later in the proof. However, they do not restrict the possible alignments in any way.

Initialize T_1 as the disjoint union of paths $p_1^1, \ldots, p_{3m}^1$ such that p_i^1 has a_i black nodes; initialize T_2 as the disjoint union of paths $p_1^2, \ldots, p_m^2$ consisting of A black nodes each. In the following we refer to one endpoint of p_i^k as $e_1(p_i^k)$ and the other endpoint as $e_2(p_i^k)$. We attach three new red leaves and one new orange leaf to each black node in both T_1 and T_2. Next we modify the graphs into trees by connecting the paths. For $1 \leq i \leq 3m - 1$ we add an edge between the orange leaf adjacent to $e_1(p_i^1)$ and the orange leaf adjacent to $e_2(p_{i+1}^1)$. For $1 \leq i \leq m - 1$ we add an edge between one of the red leaves adjacent to $e_1(p_i^2)$ and one of the red leaves adjacent to $e_2(p_{i+1}^2)$.

Next we attach two new pink leaves to each inner (non-endpoint) path node in T_1 and attach a new blue leaf to each pink node. Then we add the same number of blue nodes to T_2 and connect each blue node to one of the red nodes with degree 1. Finally, we attach a new pink leaf to each blue node. Note that both T_1 and T_2 are trees with bounded degree. Precisely, the highest degree in T_1 is 8 and 6 in T_2 independent of the problem instance.

Intuitively, the construction ensures that every inner path node has already 2 mismatches just because of the degree difference. If there is no partition, at least one path in T_1 cannot be mapped contiguously into a path in T_2 which raises the MC of some inner path node to at least 3. Simultaneously, the construction ensures that there is an alignment for which the mismatch graph consists only of stars with maximum degree 2 if there is an alignment.

The formal continuation of this proof can be found in the full version [11]. ◀

5 Approximability for Operator Norms

In this section we investigate the approximability of $\textsc{Dist}_p$ and $\textsc{Dist}_{|p|}$ for $1 \leq p \leq \infty$. Again, we omit specifying the possible values for p and mentioning $\textsc{Dist}_{|p|}$ explicitly as the proofs work the same for it. We consider the following two possibilities to measure the error of an approximation algorithm for a minimization problem. An algorithm $\mathcal{A}$ has *multiplicative error* $\alpha > 1$, if for any instance $\mathcal{I}$ of the problem with an optimum $\mathrm{OPT}(\mathcal{I})$, $\mathcal{A}$ outputs a solution with value $\mathcal{A}(\mathcal{I})$ such that $\mathrm{OPT}(\mathcal{I}) \leq \mathcal{A}(\mathcal{I}) \leq \alpha\mathrm{OPT}(\mathcal{I})$. In this case we call $\mathcal{A}$ an *α-approximation algorithm*. An algorithm $\mathcal{B}$ has *additive error* $\varepsilon > 0$, if $\mathrm{OPT}(\mathcal{I}) \leq \mathcal{B}(\mathcal{I}) \leq \mathrm{OPT}(\mathcal{I}) + \varepsilon$ for any instance $\mathcal{I}$.

Approximating $\textsc{Dist}_p$ with multiplicative error is at least as hard as the graph isomorphism problem (GI) since such an approximation algorithm $\mathcal{A}$ could be used to decide GI considering that $\mathcal{A}(G, H) = 0$ if and only if G is isomorphic to H.

Furthermore, we can deduce thresholds under which the α-approximation is NP-hard using the gap between the decision values of the reduction in each hardness proof from Section 4.

▶ **Theorem 19.** *For $1 \leq p \leq \infty$ and any $\varepsilon > 0$, unless $\mathsf{P} = \mathsf{NP}$, there is no polynomial time approximation algorithm for $\textsc{Dist}_p$ or $\textsc{Dist}_{|p|}$ with a multiplicative error guarantee of*

1. $\mathrm{bound}_p(3) - \varepsilon$*, even if both input graphs have bounded degree,*
2. $\mathrm{bound}_p(2) - \varepsilon$*, even if one input graph is a path and the other one has bounded degree,*
3. $\frac{\mathrm{bound}_p(3)}{\mathrm{bound}_p(2)} - \varepsilon$*, even if both input graphs are trees with bounded degree.*

Proof. We recall the proof of Theorem 16. If G has a Hamiltonian cycle, then $\mathrm{dist}_p(C_n, G) \leq \mathrm{bound}_p(1) = 1$. Otherwise $\mathrm{dist}_p(C_n, G) \geq \mathrm{bound}_p(3)$. Assume there is a polynomial time approximation algorithm $\mathcal{A}$ with a multiplicative error guarantee of $\mathrm{bound}_p(3) - \varepsilon$ for $\varepsilon > 0$. Then we can distinguish the two cases by checking whether $\mathcal{A}(C_n, G) < \mathrm{bound}_p(3)$ and therefore decide $\textsc{Ham-Cycle}$ on 3-regular graphs in polynomial time. The same argument can be used for the other bounds using the proofs of Theorem 17 and Theorem 18, respectively. ◀

In particular, this implies that there is no polynomial time approximation scheme (PTAS) for $\textsc{Dist}_p$ or $\textsc{Dist}_{|p|}$ under the respective restrictions.

Next we show the additive approximation hardness by scaling up the gap between the two decision values of the reduction in the proof of Theorem 16. For this we replace each edge with a colored gadget and then modify the graph so that an optimal alignment has to be color-preserving. The proof of Theorem 20 can be found in the full version [11].

▶ **Theorem 20.** *For $1 \leq p \leq \infty$ there is no polynomial time approximation algorithm for $\textsc{Dist}_p$ with any constant additive error guarantee unless $\mathsf{P} = \mathsf{NP}$.*

However, the approximation of $\textsc{Dist}_p$ becomes trivial once we restrict the input to graphs of bounded degree, although $\textsc{Dist}_p$ stays NP-hard under this restriction. The proof of Theorem 21 can be found in the full version [11].

▶ **Theorem 21.** *For $1 \leq p \leq \infty$, if one graph has maximum degree d, then there is a polynomial time approximation algorithm for $\textsc{Dist}_p$ and $\textsc{Dist}_{|p|}$ with*

1. *a constant additive error guarantee $2d$,*
2. *a constant multiplicative error guarantee $1 + 2d$.*

6 Complexity for Cut Norm

Finally, we show the hardness for $\textsc{Dist}_\square$ which corresponds to the cut distance $\hat{\delta}_\square$ (see [19, Chapter 8]. For any signed graph G and $V \subseteq V(G)$ the induced subgraph $G[V]$ is the signed graph with vertex set V, $E_+(G[V]) = \{vw \in E_+(G) \mid v, w \in V)\}$, and $E_-(G[V]) = \{vw \in E_-(G) \mid v, w \in V)\}$.

▶ **Lemma 22.** *Let Δ be a signed graph and $W \subseteq V(\Delta)$. Then $\mu_\square(\Delta) \geq \mu_\square(\Delta[W])$.*

Proof. Let $V := V(\Delta)$, $A := A_\Delta$, $B := A_{\Delta[W]}$ and $S', T' := \operatorname{argmax}_{S,T \subseteq W} \left|\sum_{v \in S, w \in T} B_{vw}\right|$. Then

$$\|\Delta[W]\|_\square = \left|\sum_{v \in S', w \in T'} B_{vw}\right| = \left|\sum_{v \in S', w \in T'} A_{vw}\right| \leq \max_{S,T \subseteq V} \left|\sum_{v \in S, w \in T} A_{vw}\right| = \|\Delta\|_\square . \qquad ◀$$

Our hardness proof for $\textsc{Dist}_\square$ is based on the hardness of computing the cut norm. Intuitively, the construction enforces a specific alignment by modifying the nodes degrees.

▶ **Theorem 23.** *The problem $\textsc{Dist}_\square$ is NP-hard.*

Proof. The proof is done by reduction from the NP-hard $\textsc{Max-Cut}$ problem on unweighted graphs [10]. First, we recall how Alan and Naor [1] construct a matrix A for any graph G so that $\|A\|_\square = MAXCUT(G)$. Orient G in an arbitrary manner, let $V(G) = \{v_1, v_2, \ldots, v_n\}$ and $E(G) = \{e_1, e_2, \ldots, e_m\}$. Then A is the $2m \times n$ matrix defined as follows. For each $1 \leq i \leq m$, if e_i is oriented from v_j to v_k, then $A_{2i-1,j} = A_{2i,k} = 1$ and $A_{2i-1,k} = A_{2i,j} = -1$. The rest of the entries in A are all 0.

Next, we observe that the matrix

$$B = \begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}$$

has the property $\|B\|_\square = 2\,\|A\|_\square = 2 \cdot MAXCUT(G)$ since the cut norm is invariant under transposition and the two submatrices A, A^T have no common rows or columns in B.

We interpret B as the adjacency matrix of a signed graph Δ' and construct the two unsigned graphs $F' := (V(\Delta), E_+(\Delta))$, $H' := (V(\Delta), E_-(\Delta))$. Then $\mu_\square(F' - H') = \mu_\square(\Delta') = \|B\|_\square = 2 \cdot MAXCUT(G)$. Next, we modify F', H' into the graphs F, H by adding $i \cdot \left(\left\lceil \frac{n^2}{4} \right\rceil + n\right)$ leaves to node v_i for $1 \leq i \leq n$. The reduction follows from the claim that $\operatorname{dist}_\square(F, H) = 2 \cdot MAXCUT(G)$, which we prove in the following.

Let π be an alignment that maps v_i to v_i for $1 \leq i \leq n$ and each leaf in F to a leaf in H so that its adjacency is preserved; let Δ be the mismatch graph of π. Then $E(\Delta) = E(\Delta')$ and therefore $\mu_\square(F^\pi - H) = 2 \cdot MAXCUT(G)$. We conclude $\operatorname{dist}_\square(F, H) \leq 2 \cdot MAXCUT(G)$.

It remains to show that no alignment can lead to a lower mismatch norm. First, let σ be any alignment that maps v_i to v_i for $1 \leq i \leq n$; let Λ be the mismatch graph of σ. Then $\Lambda[\{v_1, \ldots, v_n\}] = \Delta'$ and we get $\mu_\square(\Lambda) \geq 2 \cdot \mathit{MAXCUT}(G)$ from Lemma 22.

Conversely, let ρ be any alignment that maps v_i to v_j for $i \neq j$ and $i, j \leq n$; let Γ be the mismatch graph of ρ. The number of leaves adjacent to v_i in F and to v_j in H differs at least by $\left\lceil \frac{n^2}{4} \right\rceil + n$. Without restriction we can assume there are at least $l := \left\lceil \frac{n^2}{4} \right\rceil$ leaves $w_1, \ldots, w_l$ adjacent to v_i in F that are mismatched by ρ. Let $S := \{v_i^\rho, w_1^\rho, \ldots, w_l^\rho\}$. Then $\Gamma[S]$ has exactly l edges all of which have the same sign. It is easy to see that $\mu_\square(\Gamma[S]) = 2l$ which implies $\mu_\square(\Gamma) \geq 2l$ according to Lemma 22. We chose l so that $2l \geq \frac{n^2}{2} \geq 2 \cdot \mathit{MAXCUT}(G)$. After considering all alignments, we get $\operatorname{dist}_\square(F, G) \geq 2 \cdot \mathit{MAXCUT}(G)$. This proves our claim and therefore concludes the reduction. ◀

7 Concluding Remarks

We study the computational complexity of a class of graph metrics based on mismatch norms, or equivalently, matrix norms applied to the difference of the adjacency matrices of the input graphs under an optimal alignment between the vertex sets. We find that computing the distance between graphs under these metrics (at least for the standard, natural matrix norms) is NP-hard, often already on simple input graphs such as trees. This was essentially known for entrywise matrix norms. We prove it for operator norms and also for the cut norm.

We leave it open to find (natural) general conditions on a mismatch norm such that the corresponding distance problem becomes hard. Maybe more importantly, we leave it open to find meaningful tractable relaxations of the distance measures.

Measuring similarity via mismatch norms is only one approach. There are several other, fundamentally different ways to measure similarity. We are convinced that graph similarity deserves a systematic and general theory that compares the different approaches and studies their semantic as well as algorithmic properties. Our paper is one contribution to such a theory.

Abstract

Given a graph, the general problem to cover the maximum number of vertices by a collection of vertex-disjoint long paths seemingly escapes from the literature. A path containing at least k vertices is considered long. When $k \leq 3$, the problem is polynomial time solvable; when k is the total number of vertices, the problem reduces to the Hamiltonian path problem, which is NP-complete. For a fixed $k \geq 4$, the problem is NP-hard and the best known approximation algorithm for the weighted set packing problem implies a k-approximation algorithm. To the best of our knowledge, there is no approximation algorithm directly designed for the general problem; when $k = 4$, the problem admits a 4-approximation algorithm which was presented recently. We propose the first $(0.4394k + O(1))$-approximation algorithm for the general problem and an improved 2-approximation algorithm when $k = 4$. Both algorithms are based on local improvement, and their performance analyses are done via amortization.

1 Introduction

Path Cover (PC) is one of the most well-known NP-hard optimization problems in algorithmic graph theory [11], in which given a simple undirected graph $G = (V, E)$ one wishes to find a minimum collection of vertex-disjoint paths that cover all the vertices, that is, every vertex of V is on one of the paths. It has numerous applications from the real life, such as transportation networks, communication networks and networking security. In particular, it includes the Hamiltonian path problem [11] as a special case, which asks for the existence of a single path covering all the vertices.

The Hamiltonian path problem is NP-complete; therefore, the PC problem cannot be approximated within ratio 2 if P $\neq$ NP. In fact, to the best of our knowledge, there is no $o(|V|)$-approximation algorithm for the PC problem. In the literature, several alternative

objective functions have been proposed and studied [3, 1, 18, 2, 19, 4, 12, 5]. For example, Berman and Karpinski [3] tried to maximize the number of edges on the paths in a path cover, which is equal to $|V|$ minus the number of paths, and proposed a 7/6-approximation algorithm. Chen et al. [4, 5] showed that finding a path cover with the minimum total number of order-1 and order-2 paths (where the order of a path is the number of vertices on the path; i.e., singletons and edges) can be done in polynomial time, but it is NP-hard to find a path cover with the minimum number of paths of order at most ℓ when $\ell \geq 3$.

Recently, Kobayashi et al. [15] generalized the problem studied by Chen et al. [4, 5] to assign a weight representing its profit or cost to each order-ℓ path, with the goal of finding a path cover of the maximum weight or the minimum weight, respectively. For instance, when the weight $f(\ell)$ of an order-ℓ path is $f(\ell) = 1$ for any $\ell \leq k$ and $f(\ell) = 0$ for any $\ell \geq k + 1$, where k is a fixed integer, the *minimization* problem reduces to the problem studied by Chen et al. [4, 5]; when $f(\ell)$ is $f(\ell) = 1$ for any $\ell \leq k$ and $f(\ell) = +\infty$ for any $\ell \geq k + 1$, the *minimization* problem is the so-called k-path partition problem [20, 16, 8, 7, 9, 6]; when $f(\ell)$ is $f(\ell) = 0$ for any $\ell \leq |V| - 1$ but $f(|V|) \neq 0$, the *maximization* problem reduces to the Hamiltonian path problem.

Given an integer $k \geq 4$, in the special case where $f(\ell) = 0$ for any $\ell < k$ but $f(\ell) = \ell$ for any $\ell \geq k$, the *maximization* problem can be re-phrased as to find a set of vertex-disjoint paths of order at least k to cover the most vertices, denoted as MaxP^{k+}PC. The MaxP^{4+}PC problem (i.e., $k = 4$) is complementary to finding a path cover with the minimum number of paths of order at most 3 [4, 5], and thus it is NP-hard. Kobayashi et al. [15] presented a 4-approximation algorithm for MaxP^{4+}PC by greedily adding an order-4 path or extending an existing path to the longest possible.

For a fixed integer $k \geq 4$, the MaxP^{k+}PC problem is NP-hard too [15]; to the best of our knowledge there is no approximation algorithm designed directly for it. Nevertheless, the MaxP^{k+}PC problem can be cast as a special case of the Maximum Weighted $(2k - 1)$-Set Packing problem [11], by constructing a set of ℓ vertices when they are traceable (that is, they can be formed into a path) in the given graph and assigning its weight ℓ, for every $\ell = k, k + 1, \ldots, 2k - 1$. (This upper bound $2k - 1$ will become clear in the next section.) The Maximum Weighted $(2k - 1)$-Set Packing problem is APX-complete [13] and the best known approximation guarantee is $k - \frac{1}{63{,}700{,}992} + \epsilon$ for any $\epsilon > 0$ [17].

In this paper, we study the MaxP^{k+}PC problem from the approximation algorithm perspective. The problem and its close variants have many motivating real-life applications in various areas such as various (communication, routing, transportation, optical etc.) network design [14]. For example, when a local government plans to upgrade its subway infrastructures, the given map of rail tracks is to be decomposed into multiple disjoint lines of stations, each of which will be taken care of by a team of workers. Besides being disjoint so that while some lines are under construction the other lines can function properly, each line is expected long enough for the team to work on continuously during a shift without wasting time and efforts to move themselves and materials from one point to another. Viewing the map as a graph, the goal of planning is to find a collection of vertex-disjoint long paths to cover the most vertices (and of course, possibly under some other real traffic constraints).

We contribute two approximation algorithms for the MaxP^{k+}PC problem, the first of which is a $(0.4394k + O(1))$-approximation algorithm for any fixed integer $k \geq 4$, denoted as Approx1. We note that Approx1 is the first approximation algorithm directly designed for the MaxP^{k+}PC problem, and it is a local improvement algorithm that iteratively applies one of the three operations, addition, replacement and double-replacement, each takes $O(|V|^k)$ time and covers at least one more vertex. While the addition and the replacement operations have appeared in the 4-approximation algorithm for the MaxP^{4+}PC problem [15], the double-replacement operation is novel and it replaces one existing path in the current path collection with two new paths. At termination, that is, when none of the local improvement operations is applicable, we show by an amortization scheme that each path P in the computed solution is attributed with at most $\rho(k)n(P)$ vertices covered in an optimal solution, where $n(P)$ denotes the order of the path P and $\rho(k) \leq 0.4394k + 0.6576$ for any $k \geq 4$.

The second $O(n^8)$-time algorithm, denoted as Approx2, is for the MaxP^{4+}PC problem. Besides the three operations in Approx1, we design two additional operations, re-cover and look-ahead. The re-cover operation aims to increase the number of 4-paths in the solution, and the look-ahead operation covers at least one more vertex by trying multiple paths equivalent to an existing path in the current solution in order to execute a replacement operation. With these two more local improvement operations, we design a refined amortization scheme to show that, on average, each vertex covered in the computed solution is attributed with at most two vertices covered in an optimal solution. That is, Approx2 is a 2-approximation algorithm for the MaxP^{4+}PC problem. We also show a lower bound of $\frac{16}{9}$ on the worst-case performance ratio of Approx2.

The rest of the paper is organized as follows. In Section 2, we introduce the basic notations and definitions. Section 3 is devoted to the MaxP^{k+}PC problem, where we present the Approx1 algorithm and its performance analysis. In Section 4, we present the Approx2 algorithm for the MaxP^{4+}PC problem, and outline the performance analysis. Due to space limit, while we provide most part of the performance analyses for both algorithms here to convince the readers, some technical details are left out to the full version of the paper. We conclude the paper in the last section with some possible future work.

2 Preliminaries

For a fixed integer $k \geq 4$, in the MaxP^{k+}PC problem, we are given a simple undirected graph and want to find a collection of vertex-disjoint paths of order at least k to cover the maximum number of vertices.

We consider simple undirected graphs in this paper and we fix a graph G for discussion. Let $V(G)$ and $E(G)$ denote its vertex set and edge set in the graph G, respectively. We simplify $V(G)$ and $E(G)$ as V and E, respectively, when the underlying graph is clear from the context. We use $n(G)$ to denote the *order* of G, that is, $n = |V|$ is the number of vertices in the graph. A subgraph S of G is a graph such that $V(S) \subseteq V(G)$ and $E(S) \subseteq E(G)$; and likewise, $n(S) = |V(S)|$ denotes its order. Given a subset of vertices $R \subseteq V$, the subgraph of G *induced* on R is denoted as $G[R]$, of which the vertex set is R and the edge set contains all the edges of E each connecting two vertices of R. A (simple) path P in G is a subgraph of which the vertices can be ordered into $(v_1, v_2, \ldots, v_{n(P)})$ such that $E(P) = \{\{v_i, v_{i+1}\}, i = 1, 2, \ldots, n(P) - 1\}$. A path of order ℓ is called an *ℓ-path* (also often called a *length-$(\ell - 1)$ path* in the literature).

In this paper we are most interested in paths of order at least 4. In the sequel, given an ℓ-path P with $\ell \geq 4$, we let u_j denote the vertex of P at distance j from one ending vertex of P, for $0 \leq j \leq \lceil \frac{\ell}{2} \rceil - 1$, and v_j denote the vertex of P at distance j from the other ending vertex, for $0 \leq j \leq \lfloor \frac{\ell}{2} \rfloor - 1$. When ℓ is odd, then the center vertex of the path is $u_{\frac{\ell-1}{2}}$. This way, a $(2s + 1)$-path is represented as u_0-u_1-$\cdots$-u_{s-1}-u_s-v_{s-1}-$\cdots$-v_1-v_0, and a $(2s)$-path is represented as u_0-u_1-$\cdots$-u_{s-1}-v_{s-1}-$\cdots$–v_1-v_0. Though the path is undirected and the vertex naming is often arbitrary, sometimes we will pick a particular endpoint of the path to be the vertex u_0.

Given another path Q, let $Q - P$ denote the subgraph of Q by removing those vertices in $V(P)$, and the edges of $E(Q)$ incident at them, from Q. Clearly, if $V(P) \cap V(Q) = \emptyset$, then $Q - P = Q$; otherwise, $Q - P$ is a collection of sub-paths of Q each has at least one endpoint that is adjacent to some vertex on P through an edge of $E(Q)$. For a collection $\mathcal{P}$ of vertex-disjoint paths, it is also a subgraph of G, with its vertex set $V(\mathcal{P}) = \cup_{P\in\mathcal{P}} V(P)$ and edge set $E(\mathcal{P}) = \cup_{P\in\mathcal{P}} E(P)$. We similarly define $Q - \mathcal{P}$ to be the collection of sub-paths of Q after removing those vertices in $V(\mathcal{P})$ from $V(Q)$, together with the edges of $E(Q)$ incident at them. Furthermore, for another collection $\mathcal{Q}$ of vertex-disjoint paths, we can define $\mathcal{Q} - \mathcal{P}$ analogously, that is, $\mathcal{Q} - \mathcal{P}$ is the collection of sub-paths of the paths in $\mathcal{Q}$ after removing those vertices in $V(\mathcal{P})$ from $V(\mathcal{Q})$, together with the edges of $E(\mathcal{Q})$ incident at them.

▶ **Definition 1** (Associatedness). *Given two collections $\mathcal{P}$ and $\mathcal{Q}$ of vertex-disjoint paths, if a path S of $\mathcal{Q} - \mathcal{P}$ has an endpoint that is adjacent to a vertex v in $V(\mathcal{P}) \cap V(\mathcal{Q})$ in $\mathcal{Q}$, then we say S is* associated *with v.*

One sees that a path S of $\mathcal{Q} - \mathcal{P}$ can be associated with zero to two vertices in $V(\mathcal{P}) \cap V(\mathcal{Q})$, and conversely, a vertex of $V(\mathcal{P}) \cap V(\mathcal{Q})$ can be associated with zero to two paths in $\mathcal{Q} - \mathcal{P}$.

If the paths of the collection $\mathcal{P}$ all have order at least k, then the vertices of $V(\mathcal{P})$ are said *covered* by the paths of $\mathcal{P}$, or simply by $\mathcal{P}$. Let $R = V - V(\mathcal{P})$. For any vertex $v \in V(\mathcal{P})$, *an extension* $e(v)$ at the vertex v is a path in the subgraph $G[R]$ of G induced on R which has an endpoint adjacent to v in G. Note that there could be many extensions at v, and we use $n(v) = \max_{e(v)} n(e(v))$ to denote the order of the longest extensions at the vertex v.

▶ **Lemma 2.** *Given two collections $\mathcal{P}$ and $\mathcal{Q}$ of vertex-disjoint paths in the graph G, for every vertex $v \in V(\mathcal{P})$, any path of $\mathcal{Q} - \mathcal{P}$ associated with v has order at most $n(v)$.*

Proof. The lemma holds since $\mathcal{Q} - \mathcal{P}$ is a subgraph of the induced subgraph $G[V - V(\mathcal{P})]$, that is, every path of $\mathcal{Q} - \mathcal{P}$ is a path in $G[V - V(\mathcal{P})]$, and the associatedness (see Definition 1) is a special adjacency through an edge of $E(\mathcal{Q})$. ◀

Our goal is to compute a collection of vertex-disjoint paths of order at least k, such that it covers the most vertices. In our local improvement algorithms below, we start with the empty collection $\mathcal{P} = \emptyset$ to iteratively expand $V(\mathcal{P})$ through one of a few operations, to be defined later. Notice that for an ℓ-path with $\ell \ge 2k$, one can break it into a k-path and an $(\ell - k)$-path by deleting an edge. Since they cover the same vertices, we assume without loss of generality hereafter that any collection $\mathcal{P}$ inside our algorithms contains vertex-disjoint paths of order in between k and $2k - 1$, inclusive.

3 A $(0.4394k + 0.6576)$-approximation algorithm for MaxP^{k+}PC

For a given integer $k \ge 4$, the best known approximation algorithm for the Maximum Weighted $(2k - 1)$-Set Packing problem leads to an $O(n^{2k-1})$-time $(k - \frac{1}{63{,}700{,}992} + \epsilon)$-approximation algorithm for the MaxP^{k+}PC problem, for any $\epsilon > 0$ [17]. In this section, we define three local improvement operations for our algorithm for the MaxP^{k+}PC problem, denoted as Approx1. We show later that its time complexity is $O(n^{k+1})$ and its approximation ratio is at most $0.4394k + 0.6576$.

For the current path collection $\mathcal{P}$, if there is a path covering k-vertices outside of $V(\mathcal{P})$, then the following operation adds the k-path into $\mathcal{P}$.

▶ **Operation 3.** *For a k-path P in the induced subgraph $G[V - V(\mathcal{P})]$, the* Add(P) *operation adds P to $\mathcal{P}$.*

Since finding a k-path in the induced subgraph $G[V - V(\mathcal{P})]$, for any $\mathcal{P}$, can be done in $O(n^k)$ time, determining whether or not an addition operation is applicable, and if so then applying it, can be done in $O(n^k)$ time too. Such an operation increases $|V(\mathcal{P})|$ by k.

Recall that a path $P \in \mathcal{P}$ is represented as u_0-u_1-$\cdots$-v_1-v_0. Though it is undirected, we may regard u_0 the *head* vertex of the path and v_0 the *tail* vertex for convenience. The next operation seeks to extend a path of $\mathcal{P}$ by replacing a prefix (or a suffix) with a longer one.

▶ **Operation 4.** *For a path $P \in \mathcal{P}$ such that there is an index t and an extension $e(u_t)$ with $n(e(u_t)) \geq t+1$ (an extension $e(v_t)$ with $n(e(v_t)) \geq t+1$, respectively), the* Rep(P) *operation replaces the prefix u_0-u_1-$\cdots$-u_{t-1} of P by $e(u_t)$ (the suffix v_{t-1}-$\cdots$-v_1-v_0 of P by $e(v_t)$, respectively).*

Similarly, one sees that finding an extension $e(u_t)$ (of order at most $k-1$, or otherwise an Add operation is applicable) in the induced subgraph $G[V - V(\mathcal{P})]$, for any vertex $u_t \in P \in \mathcal{P}$, can be done in $O(n^{k-1})$ time. Therefore, determining whether or not a prefix or a suffix replacement operation is applicable, and if so then applying it, can be done in $O(n^k)$ time. Note that such an operation increases $|V(\mathcal{P})|$ by at least 1.

The third operation tries to use a prefix and a non-overlapping suffix of a path in $\mathcal{P}$ to grow them into two separate paths of order at least k.

▶ **Operation 5.** *For a path $P \in \mathcal{P}$ such that*

(i) *there are two indices t and j with $j \geq t+1$ and two vertex-disjoint extensions $e(u_t)$ and $e(u_j)$ with $n(e(u_t)) \geq k-(t+1)$ and $n(e(u_j)) \geq k-(n(P)-j)$, the* DoubleRep$(P)$ *operation replaces P by two new paths $P_1 = u_0$-u_1-$\cdots$-u_t-$e(u_t)$ and $P_2 = e(u_j)$-u_j-$\cdots$-v_1-v_0;*

(ii) *or there are two indices t and j and two vertex-disjoint extensions $e(u_t)$ and $e(v_j)$ with $n(e(u_t)) \geq k-(t+1)$ and $n(e(v_j)) \geq k-(j+1)$, the* DoubleRep(P) *operation replaces P by two new paths $P_1 = u_0$-u_1-$\cdots$-u_t-$e(u_t)$ and $P_2 = e(v_j)$-v_j-$\cdots$-v_1-v_0.*

Note that finding an extension $e(u_t)$ (of order at most t, or otherwise a Rep operation is applicable) can be limited to those indices $t \geq \frac{k-1}{2}$. Furthermore, we only need to find an extension $e(u_t)$ of order at most $\frac{k-1}{2}$ (equal to $\frac{k-1}{2}$ only if $t = \frac{k-1}{2}$). For the same reason, we only need to find an extension $e(v_j)$ of order at most $\frac{k-1}{2}$ for those indices $j \geq \frac{k-1}{2}$ (equal to $\frac{k-1}{2}$ only if $j = \frac{k-1}{2}$). Since $k \leq n(P) \leq 2k-1$ for any $P \in \mathcal{P}$, we only need to find an extension $e(u_j)$ of order at most $\frac{k-1}{2}$ too (equal to $\frac{k-1}{2}$ only if $j = \frac{n(P)-1}{2}$ and $n(P) = k$). In summary, finding the two vertex-disjoint extensions $e(u_t)$ and $e(u_j)$, or $e(u_t)$ and $e(v_j)$, in the induced subgraph $G[V - V(\mathcal{P})]$ can be done in $O(n^{k-1})$ time (in $\Theta(n^{k-1})$ for at most 2 pairs of t and j). It follows that determining whether or not a double replacement operation is applicable, and if so then applying it, can be done in $O(n^k)$ time. Also, such an operation increases $|V(\mathcal{P})|$ by at least 1 as the total number of vertices covered by the two new paths P_1 and P_2 is at least $2k$. We summarize the above observations on the three operations into the following lemma.

▶ **Lemma 6.** *Given a collection $\mathcal{P}$ of vertex-disjoint paths of order in between k and $2k-1$, determining whether or not one of the three operations* Add, Rep *and* DoubleRep *is applicable, and if so then applying it, can be done in $O(n^k)$ time. Each operation increases $|V(\mathcal{P})|$ by at least 1.*

Given a graph $G = (V, E)$, our approximation algorithm for the MaxP^{k+}PC problem, denoted as Approx1, is iterative. It starts with the empty collection $\mathcal{P} = \emptyset$; in each iteration, it determines whether any one of the three operations Add, Rep and DoubleRep is applicable, and if so then it applies the operation to update $\mathcal{P}$. During the entire process, $\mathcal{P}$ is maintained to be a collection of vertex-disjoint paths of order in between k and $2k-1$. The algorithm terminates if none of the three operations is applicable for the current $\mathcal{P}$, and returns it as the solution. A simple high level description of the algorithm Approx1 is given in Algorithm 1. From Lemma 6, we see that each operation improves the collection $\mathcal{P}$ to cover at least one more vertex. Therefore, the overall running time of Approx1 is in $O(n^{k+1})$.

Algorithm 1 Approx1 (high level description).

```
Input: A graph $G = (V, E)$;
1. initialize $\mathcal{P} = \emptyset$;
2. while (one of the operations Add, Rep, DoubleRep is applicable)
   2.1 apply the operation to update $\mathcal{P}$;
   2.2 break any path of order $2k$ or above into two paths, one of which is a $k$-path;
3. return the final $\mathcal{P}$.
```

Below we fix $\mathcal{P}$ to denote the collection of paths returned by our algorithm Approx1. The next three lemmas summarize the structural properties of $\mathcal{P}$, which are useful in the performance analysis.

▶ **Lemma 7.** *For any path Q of order at least k in the graph G, $V(Q) \cap V(\mathcal{P}) \neq \emptyset$.*

Proof. The lemma holds due to the termination condition of the algorithm Approx1, since otherwise an Add operation is applicable. ◀

▶ **Lemma 8.** *For any path $P \in \mathcal{P}$, $n(u_j) \le j$ and $n(v_j) \le j$ for any index j.*

Proof. The lemma holds due to the termination condition of the algorithm Approx1, since otherwise a Rep operation is applicable. ◀

▶ **Lemma 9.** *Suppose there is a vertex u_t on a path $P \in \mathcal{P}$ and an extension $e(u_t)$ with $n(e(u_t)) \ge k - t - 1$. Then,*

(i) *for any vertex u_j with $j \ge t + 1$, $j \le k - 2$ and every extension $e(u_j)$ vertex-disjoint to $e(u_t)$ has order $n(e(u_j)) \le k - j - 2$;*

(ii) *for any index j, every extension $e(v_j)$ vertex-disjoint to $e(u_t)$ has order $n(e(v_j)) \le k - j - 2$.*

Proof. The lemma holds due to the termination condition of the algorithm Approx1.

First, for any vertex u_j with $j \ge t + 1$, an extension $e(u_j)$ vertex-disjoint to $e(u_t)$ has order $n(e(u_j)) \le k - (n(P) - j) - 1$ since otherwise a DoubleRep operation is applicable. Using the fact that $n(P) \ge 2j + 1$, $n(e(u_j)) \le k - j - 2$. Then by $k - j - 2 \ge 0$, we have $j \le k - 2$.

Next, similarly, for any index j, a vertex-disjoint extension $e(v_j)$ to $e(u_t)$ has order $n(e(v_j)) \le k - j - 2$ since otherwise a DoubleRep operation is applicable. ◀

We next examine the performance of the algorithm Approx1. We fix $\mathcal{Q}$ to denote an optimal collection of vertex-disjoint paths of order at least k that covers the most vertices. We apply an amortization scheme to *assign* the vertices of $V(\mathcal{Q})$ to the vertices of $V(\mathcal{P}) \cap V(\mathcal{Q})$. We will show that, using the structural properties of $\mathcal{P}$ in Lemmas 7–9, the average number of vertices *received* by a vertex of $V(\mathcal{P})$ is upper bounded by $\rho(k)$, which is the approximation ratio of Approx1.

In the amortization scheme, we assign the vertices of $V(\mathcal{Q})$ to the vertices of $V(\mathcal{P}) \cap V(\mathcal{Q})$ as follows: Firstly, assign each vertex of $V(\mathcal{Q}) \cap V(\mathcal{P})$ to itself. Next, recall that $\mathcal{Q} - \mathcal{P}$ is the collection of sub-paths of the paths of $\mathcal{Q}$ after removing those vertices in $V(\mathcal{Q}) \cap V(\mathcal{P})$. By Lemma 7, each path S of $\mathcal{Q} - \mathcal{P}$ is associated with one or two vertices in $V(\mathcal{Q}) \cap V(\mathcal{P})$. If the path S is associated with only one vertex v of $V(\mathcal{Q}) \cap V(\mathcal{P})$, then all the vertices on S are assigned to the vertex v. If the path S is associated with two vertices v_1 and v_2 of $V(\mathcal{Q}) \cap V(\mathcal{P})$, then a half of the vertices on S are assigned to each of the two vertices v_1 and v_2. One sees that in the amortization scheme, all the vertices of $V(\mathcal{Q})$ are assigned to the vertices of $V(\mathcal{P}) \cap V(\mathcal{Q})$; conversely, each vertex of $V(\mathcal{P}) \cap V(\mathcal{Q})$ receives itself, plus some fraction of or all the vertices on one or two paths of $\mathcal{Q} - \mathcal{P}$. (We remark that the vertices of $V(\mathcal{P}) - V(\mathcal{Q})$, if any, receive nothing.)

▶ **Lemma 10.** *For any vertex u_j on a path $P \in \mathcal{P}$ with $j \le k-2$, if $n(u_j) \le k-j-2$, then u_j receives at most $\frac{3}{2}\min\{j, k-j-2\}+1$ vertices.*

Proof. By Lemma 8, we have $n(u_j) \le j$. Therefore, $n(u_j) \le \min\{j, k-j-2\}$. By Lemma 2, any path of $\mathcal{Q} - \mathcal{P}$ associated with u_j contains at most $\min\{j, k-j-2\}$ vertices.

If there is at most one path of $\mathcal{Q} - \mathcal{P}$ associated with u_j, then the lemma is proved.

Consider the remaining case where there are two paths of $\mathcal{Q} - \mathcal{P}$ associated with u_j. Since $2\min\{j, k-j-2\}+1 \le j + (k-j-2)+1 = k-1$, while the path $Q \in \mathcal{Q}$ containing the vertex u_j has order at least k, we conclude that one of these two paths of $\mathcal{Q} - \mathcal{P}$ is associated with another vertex of $V(\mathcal{Q}) \cap V(\mathcal{P})$. It follows from the amortization scheme that u_j receives at most $\frac{3}{2}\min\{j, k-j-2\}+1$ vertices. ◀

▶ **Lemma 11.** *Suppose s is an integer such that $\lfloor \frac{k}{2} \rfloor - 1 \le s \le k-2$. Then we have*

$$\sum_{j=1}^{s} \min\{j, k-j-2\} = ks + \frac{3}{2}k - \frac{1}{4}k^2 - \frac{5}{2}s - \frac{1}{2}s^2 - 2 - \frac{1}{4}(k \bmod 2),$$

where mod *is the modulo operation.*

Proof. The formula can be directly validated by distinguishing the two cases where k is even or odd, and using the fact that $\min\{j, k-j-2\} = j$ if and only if $j \le \lfloor \frac{k}{2} \rfloor - 1$. ◀

▶ **Theorem 12.** *The algorithm* Approx1 *is an $O(|V|^{k+1})$-time $\rho(k)$-approximation algorithm for the* MaxP^{k+}PC *problem, where $k \ge 4$ and*

$$\rho(k) = \begin{cases} \frac{3k+1}{2} - \frac{1}{4}\sqrt{18k^2-3}, & \text{if } k \text{ is odd;} \\ \frac{3k+1}{2} - \frac{1}{4}\sqrt{18k^2-21}, & \text{if } k \text{ is even.} \end{cases}$$

Proof. Recall that all the vertices of $V(\mathcal{Q})$ are assigned to the vertices of $V(\mathcal{Q}) \cap V(\mathcal{P})$, through our amortization scheme. Below we estimate for any path $P \in \mathcal{P}$ the total number of vertices received by the vertices of $V(P) \cap V(\mathcal{Q})$, denoted as $r(P)$, and we will show that $\frac{r(P)}{n(P)} \le \rho(k)$.

We fix a path $P \in \mathcal{P}$ for discussion. If it exists, we let t denote the smallest index j such that the vertex u_j on the path P is associated with a path $e(u_j)$ of $\mathcal{Q} - \mathcal{P}$ with order $n(e(u_j)) \ge k-j-1$. Note that if necessary we may rename the vertices on P, so that the non-existence of t implies any path of $\mathcal{Q} - \mathcal{P}$ associated with the vertex u_j or v_j has order at most $k-j-2$, for any index j. Furthermore, by Lemma 9, if t exists, then any path of $\mathcal{Q} - \mathcal{P}$, except $e(u_t)$, associated with the vertex u_j or v_j has order at most $k-j-2$, for any index $j \ne t$. We remark that $e(u_t)$ could be associated with another vertex on the path P. When $n(P) = 2k-1$, t exists and $t = k-1$.

We distinguish three cases for $n(P)$ based on its parity and on whether it reaches the maximum value $2k-1$. Due to space limit, below we only discuss the first case in detail.

Case 1. $n(P) = 2s+1$ where $\frac{k-1}{2} \le s \le k-2$.

Since $s \ge \frac{k-1}{2}$, we have $\min\{s, k-s-2\} = k-s-2$. If the index t does not exist, that is, any path of $\mathcal{Q}-\mathcal{P}$ associated with the vertex u_j or v_j has order at most $k-j-2$, for any index j, then by Lemma 10 each of the vertices u_j and v_j receives at most $\frac{3}{2}\min\{j, k-j-2\}+1$ vertices. Hence we have

$$\begin{aligned}
r(P) &\le 2\sum_{j=0}^{s-1}\left(\frac{3}{2}\min\{j,k-j-2\}+1\right)+\frac{3}{2}\min\{s,k-s-2\}+1\\
&= 3\sum_{j=0}^{s}\min\{j,k-j-2\}-\frac{3}{2}\min\{s,k-s-2\}+(2s+1)\\
&\le 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4. && (1)
\end{aligned}$$

If the index t exists, then by Lemmas 8 and 2, $n(e(u_t)) \le t$ and thus the vertex u_t receives at most $2t+1$ vertices. Note that if $e(u_t)$ is associated with another vertex on the path P, then we count all the vertices of $e(u_t)$ towards u_t but none to the other vertex (that is, we could overestimate $r(P)$). It follows from Lemma 10, the above Eq. (1), $t \le s$, and $s \ge \frac{k-1}{2}$ that

$$\begin{aligned}
r(P) &\le 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4-\left(\frac{3}{2}\min\{t,k-t-2\}+1\right)+(2t+1)\\
&= 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4+\left(2t-\frac{3}{2}\min\{t,k-t-2\}\right)\\
&= 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4+\max\left\{\frac{1}{2}t,\frac{7}{2}t-\frac{3}{2}k+3\right\}\\
&\le 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4+\max\left\{\frac{1}{2}s,\frac{7}{2}s-\frac{3}{2}k+3\right\}\\
&= 3\sum_{j=1}^{s}\min\{j,k-j-2\}-\frac{3}{2}k+\frac{7}{2}s+4+\left(\frac{7}{2}s-\frac{3}{2}k+3\right)\\
&= 3\sum_{j=1}^{s}\min\{j,k-j-2\}-3k+7s+7. && (2)
\end{aligned}$$

Combining Eqs. (1, 2), and by Lemma 11, in Case 1 we always have

$$r(P) \le 3\sum_{j=1}^{s}\min\{j,k-j-2\}-3k+7s+7 = 3ks+\frac{3}{2}k-\frac{3}{4}k^2-\frac{1}{2}s-\frac{3}{2}s^2+1-\frac{3}{4}(k \bmod 2).$$

Therefore, using $n(P) = 2s+1$ we have

$$\frac{r(P)}{n(P)} \le \begin{cases} \frac{3k+1}{2}-\frac{3}{8}(2s+1)-\frac{6k^2-1}{8(2s+1)} \le \frac{3k+1}{2}-\frac{1}{4}\sqrt{18k^2-3}, & \text{if } k \text{ is odd;}\\ \frac{3k+1}{2}-\frac{3}{8}(2s+1)-\frac{6k^2-7}{8(2s+1)} \le \frac{3k+1}{2}-\frac{1}{4}\sqrt{18k^2-21}, & \text{if } k \text{ is even,}\end{cases}$$

where the upper bound $\rho(k)$ is achieved when $n(P) \approx \sqrt{2}k$.

Case 2 where $n(P) = 2k - 1$ and Case 3 where $n(P) = 2s$ with $\frac{k}{2} \le s \le k - 1$ are discussed similarly, and the estimated upper bounds on $\frac{r(P)}{n(P)}$ are slightly less than the above $\rho(k)$. Therefore, they together prove that the worst-case performance ratio of the algorithm Approx1 is at most $\rho(k)$, for any $k \ge 4$. Note that $\rho(k) \le \frac{3k+1}{2} - \frac{1}{4}\sqrt{18k^2 - 21} \le 0.4394k + 0.6576$. ◀

4 A 2-approximation algorithm for MaxP^{4+}PC

One sees that the algorithm Approx1 is an $O(n^5)$-time 2.4150-approximation algorithm for the MaxP^{4+}PC problem, which improves the previous best $O(n^5)$-time 4-approximation algorithm proposed in [15] and $O(n^7)$-time $(4 - \frac{1}{63{,}700{,}992} + \epsilon)$-approximation algorithm implied by [17]. In the amortized analysis for Approx1, when a path of $\mathcal{Q} - \mathcal{P}$ is associated with two vertices of $V(\mathcal{Q}) \cap V(\mathcal{P})$, one half of the vertices on this path is assigned to each of these two vertices. We will show that when $k = 4$, that is, for the MaxP^{4+}PC problem, the assignment can be done slightly better by observing where these two vertices are on the paths of $\mathcal{P}$ and then assigning vertices accordingly. To this purpose, we will need to refine the algorithm using two more local improvement operations, besides the three Add, Rep and DoubleRep operations. We denote our algorithm for the MaxP^{4+}PC problem as Approx2.

We again use $\mathcal{P}$ to denote the path collection computed by Approx2. Since Approx2 employs the three Add, Rep and DoubleRep operations, all of which are not applicable at termination, the structural properties stated in Lemmas 7–9 continue to hold, and we summarize them specifically using $k = 4$.

▶ **Lemma 13.** *For any path $P \in \mathcal{P}$,*

(1) $4 \le n(P) \le 7$;
(2) $n(u_j) \le j$ *and* $n(v_j) \le j$*, for any valid index* j;
(3) *if* $n(P) = 6$, $n(u_2) > 0$ *and* $n(v_2) > 0$*, then both* u_2 *and* v_2 *are adjacent to a unique vertex in* $V - V(\mathcal{P})$*, and hence they have common extensions;*
(4) *if* $n(P) = 7$*, then* $n(u_2) = n(v_2) = 0$.

We also fix $\mathcal{Q}$ to denote an optimal collection of vertex-disjoint paths of order at least 4 that covers the most vertices. Using Lemma 13, we may attach a longest possible extension in $\mathcal{Q} - \mathcal{P}$ to every vertex of a path of $\mathcal{P}$, giving rise to the *worst cases* illustrated in Figure 1, with respect to the order of the path. Since a vertex of a path $P \in \mathcal{P}$ can be associated with up to two paths in $\mathcal{Q} - \mathcal{P}$, the worst-case performance ratio of the algorithm Approx2 is at most $\max\{\frac{17}{7}, \frac{14}{6}, \frac{13}{5}, \frac{8}{4}\} = 2.6$. Our next two local improvement operations are designed to deal with three of the four worst cases where the path orders are $5, 6$ and 7. Afterwards, we will show by an amortization scheme that the average number of vertices assigned to a vertex of $V(\mathcal{P})$ is at most 2.

Since the average number of vertices assigned to a vertex on a 4-path in $\mathcal{P}$ is already at most 2, the first operation is employed to construct more 4-paths in $V(\mathcal{P})$, whenever possible.

▶ **Operation 14.** *For any two paths P and P' in $\mathcal{P}$ of order at least 5 such that their vertices are covered exactly by a set of paths in G of order at least 4 and of which at least one path has order 4, the* Re-cover(P, P') *operation replaces P and P' by this set of paths.*

In other words, the Re-cover(P, P') operation removes the two paths P and P' from $\mathcal{P}$, and then uses the set of paths to re-cover the same vertices. Since there are $O(n^2)$ possible pairs of paths P and P' in $\mathcal{P}$, and by $|V(P) \cup V(P')| \le 14$ the existence of a set of paths re-covering $V(P) \cup V(P')$ can be checked in $O(1)$ time, we conclude that determining whether

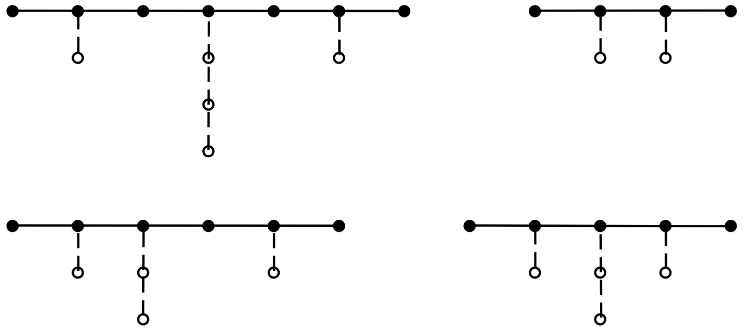

Figure 1 The worst case of a path $P \in \mathcal{P}$ with respect to its order, where a vertex on the path P is attached with a longest possible extension in $\mathcal{Q} - \mathcal{P}$, with its edges dashed. The edges on the path P are solid and the vertices are shown filled, while the vertices on the extensions are unfilled.

or not a Re-cover operation is applicable, and if so then applying it, can be done in $O(n^2)$ time. Note that such an operation does not change $|V(\mathcal{P})|$, but it increases the number of 4-paths by at least 1. For example, if $n(P) = 5$ and $n(P') = 7$, and we use u'_j's and v'_j's to label the vertices on P', then a Re-cover operation is applicable when u_0 is adjacent to any one of u'_0, u'_2, v'_2, v'_0 (resulting in three 4-paths); or if $n(P) = n(P') = 6$, then a Re-cover operation is applicable when u_0 is adjacent to any one of u'_0, u'_1, v'_1, v'_0 (resulting in three 4-paths).

▶ **Operation 15.** *For a path $P \in \mathcal{P}$ such that there is an index $t \in \{2, 3\}$ and an extension $e(u_t)$ with $n(e(u_t)) = t$,*

- **(i)** *if replacing P by the path $e(u_t)$-u_t-$\cdots$-v_1-v_0 enables a Rep operation, then the* Look-ahead(P) *operation first replaces P by $e(u_t)$-u_t-$\cdots$-v_1-v_0 and next executes the Rep operation;*
- **(ii)** *if $n(P) = 6$ and one of v_0 and v_2 is adjacent to a vertex w, such that w is on $e(u_2)$ or on u_0-u_1 or on another path of $\mathcal{P}$ but at distance at most 1 from one end, then the* Look-ahead(P) *operation first replaces P by the path u_0-u_1-u_2-$e(u_2)$ and next uses v_0-v_1-v_2 as an extension $e(w)$ to execute a Rep operation.*

In some sense, the Look-ahead(P) operation looks one step ahead to see whether or not using the extension $e(u_t)$ in various ways would help cover more vertices. Recall that we can rename the vertices on a path of $\mathcal{P}$, if necessary, and thus the above definition of a Look-ahead operation applies to the vertex v_2 symmetrically, if there is an extension $e(v_2)$ with $n(e(v_2)) = 2$. Also, when u_t is the center vertex of the path P (i.e., $n(P) = 5, 7$), one should also examine replacing P by the path u_0-u_1-$\cdots$-u_t-$e(u_t)$.

When the first case of a Look-ahead operation applies, its internal Rep operation must involve at least two of the t vertices $u_0, u_1, \ldots, u_{t-1}$[2] because otherwise an Add or a Rep operation would be applicable before this Look-ahead operation. Since there are $O(n^3)$ possible extensions at the vertex u_t, it follows from Lemma 6 that determining whether or not the first case of a Look-ahead operation is applicable, and if so then applying it, can be done in $O(n^6)$ time. Note that such an operation increases $|V(\mathcal{P})|$ by at least 1.

[2] First, at least one of these t vertices $u_0, u_1, \ldots, u_{t-1}$, say u, should be on the extension used in the internal Rep operation; then the extension extends to the/a vertex adjacent to u.

When the second case of a Look-ahead operation applies, we see that after the replacement (which reduces $|V(\mathcal{P})|$ by 1), the vertex w is always on a path of $\mathcal{P}$ at distance at most 1 from one end; and thus the succeeding Rep operation increases $|V(\mathcal{P})|$ by at least 2. The net effect is that such a Look-ahead operation increases $|V(\mathcal{P})|$ by at least 1. Since there are $O(n^2)$ possible extensions at the vertex u_2, determining whether or not the second case of a Look-ahead operation is applicable, and if so then applying it, can be done in $O(n^4)$ time.

We summarize the above observations on the two new operations into the following lemma.

▶ **Lemma 16.** *Given a collection $\mathcal{P}$ of vertex-disjoint paths of order in between 4 and 7, determining whether or not one of the two operations* Re-cover *and* Look-ahead *is applicable, and if so then applying it, can be done in $O(n^6)$ time. Each operation either increases $|V(\mathcal{P})|$ by at least 1, or keeps $|V(\mathcal{P})|$ unchanged and increases the number of 4-paths by at least 1.*

We are now ready to present the algorithm Approx2 for the MaxP^{4+}PC problem, which in fact is very similar to Approx1. It starts with the empty collection $\mathcal{P} = \emptyset$; in each iteration, it determines in order whether any one of the five operations Add, Rep, DoubleRep, Re-cover, and Look-ahead is applicable, and if so then it applies the operation to update $\mathcal{P}$. During the entire process, $\mathcal{P}$ is maintained to be a collection of vertex-disjoint paths of order in between 4 and 7. The algorithm terminates if none of the five operations is applicable for the current $\mathcal{P}$, and returns it as the solution. A simple high level description of the algorithm Approx2 is given in Algorithm 2. From Lemmas 6 and 16, the overall running time of Approx2 is in $O(n^8)$. Next we show that the worst-case performance ratio of Approx2 is at most 2, and thus its higher running time is paid off. The performance analysis is done through a similar but more careful amortization scheme.

Algorithm 2 Approx2 (high level description).

```
Input: A graph $G = (V, E)$;
1. initialize $\mathcal{P} = \emptyset$;
2. while (one of Add, Rep, DoubleRep, Re-cover and Look-ahead is applicable)
   2.1 apply the operation to update $\mathcal{P}$;
3. return the final $\mathcal{P}$.
```

The amortization scheme assigns the vertices of $V(\mathcal{Q})$ to the vertices of $V(\mathcal{P}) \cap V(\mathcal{Q})$. Firstly, each vertex of $V(\mathcal{Q}) \cap V(\mathcal{P})$ is assigned to itself. Next, recall that $\mathcal{Q} - \mathcal{P}$ is the collection of sub-paths of the paths of $\mathcal{Q}$ after removing those vertices in $V(\mathcal{Q}) \cap V(\mathcal{P})$. By Lemma 7, each path S of $\mathcal{Q} - \mathcal{P}$ is associated with one or two vertices in $V(\mathcal{Q}) \cap V(\mathcal{P})$.

When the path S of $\mathcal{Q} - \mathcal{P}$ is associated with two vertices v and v' of $V(\mathcal{Q}) \cap V(\mathcal{P})$, a half of all the vertices on S are assigned to each of v and v', except the *first* special case below. In this *first* special case, $n(S) = 1$, $v = u_1$ (or $v = v_1$, respectively) and $v' = u'_3$ on some paths $P, P' \in \mathcal{P}$ with $n(P) \geq 5$ and $n(P') = 7$, respectively; then the whole vertex on S is assigned to u'_3 (that is, none is assigned to u_1, or v_1, respectively).

When the path S of $\mathcal{Q} - \mathcal{P}$ is associated with only one vertex v of $V(\mathcal{Q}) \cap V(\mathcal{P})$, all the vertices on S are assigned to the vertex v, except the *second* and the *third* special cases below where $n(S) = 1$ and $v = u_1$ (or $v = v_1$, respectively) on a path $P \in \mathcal{P}$ with $n(P) \geq 5$. In the *second* special case, S-u_1-$[r]$-u'_3 is a subpath of some path $Q \in \mathcal{Q}$, where u'_3 is the center vertex of some 7-path $P' \in \mathcal{P}$, and $[r]$ means the vertex r might not exist but if it exists then it is not the center vertex of any 7-path in $\mathcal{P}$; in this case, a half of the vertex on S

is assigned to each of u_1 and u'_3.[3] In the *third* special case, S-u_1-u'_2 is a subpath of some path $Q \in \mathcal{Q}$, where $u'_2 \neq u_2$ is on some path $P' \in \mathcal{P}$ of order 5 or 6; in this case, a half of the vertex on S is assigned to each of u_1 and u'_2.

One sees that in the amortization scheme, all the vertices of $V(\mathcal{Q})$ are assigned to the vertices of $V(\mathcal{P}) \cap V(\mathcal{Q})$; conversely, each vertex of $V(\mathcal{P}) \cap V(\mathcal{Q})$ receives itself, plus some or all the vertices on its associated paths of $\mathcal{Q} - \mathcal{P}$, and some u_2, v_2 vertices on 5-/6-paths and some u_3 vertices on 7-paths could receive some additional vertices not on their associated paths, through the three special cases. (We remark that a vertex and its received vertices are on the same path in $\mathcal{Q}$, and that the vertices of $V(\mathcal{P}) - V(\mathcal{Q})$ receive nothing.)

The following lemma presents the joint effect of the above amortization scheme, of which the proof is omitted due to space limit.

▶ **Lemma 17.**

1. *For any path $P \in \mathcal{P}$, each of the vertices u_0 and v_0 receives at most 1 vertex; each of the vertices u_1 and v_1 receives at most $\frac{5}{2}$ vertices; when $n(P) = 7$, each of the vertices u_2 and v_2 receives at most 1 vertex.*
2. *For any 5-path $P \in \mathcal{P}$, if the vertex u_2 receives more than 3 vertices, then each of the vertices u_1 and v_1 receives at most $\frac{3}{2}$ vertices.*
3. *For any 6-path $P \in \mathcal{P}$, if the vertices u_2 and v_2 together receive more than 5 vertices, then the total number of vertices received by all the vertices of P is at most 12.*
4. *For any 7-path $P \in \mathcal{P}$, if the vertex u_3 receives more than 5 vertices, then the vertices u_0 and u_1 (v_0 and v_1, respectively) together receive at most $\frac{5}{2}$ vertices.*

▶ **Theorem 18.** *The algorithm* Approx2 *is an $O(|V|^8)$-time 2-approximation algorithm for the* MaxP^{4+}PC *problem, and $\frac{16}{9}$ is a lower bound on its performance ratio.*

Proof. Similar to the proof of Theorem 12, we will show that $\frac{r(P)}{n(P)} \le 2$ for any path $P \in \mathcal{P}$, where $r(P)$ denotes the total number of vertices received by all the vertices on P through the amortization scheme. We do this by differentiating the path order $n(P)$, which is in between 4 and 7.

Case 1. $n(P) = 4$. By Lemma 17.1, we have $r(P) \le 1 + \frac{5}{2} + \frac{5}{2} + 1 = 7$. It follows that $\frac{r(P)}{n(P)} \le \frac{7}{4}$.

Case 2. $n(P) = 5$. If the vertex u_2 receives at most 3 vertices, then by Lemma 17.1, we have $r(P) \le 3 + 7 = 10$. Otherwise, u_2 receives at most 5 vertices, and by Lemma 17.2 each of u_1 and v_1 receives at most $\frac{3}{2}$ vertices. It follows again by Lemma 17.1 that $r(P) \le 5 + 5 = 10$. That is, either way we have $r(P) \le 10$ and thus $\frac{r(P)}{n(P)} \le 2$.

Case 3. $n(P) = 6$. If the vertices u_2 and v_2 together receive at most 5 vertices, then by Lemma 17.1, we have $r(P) \le 5 + 7 = 12$. Otherwise, by Lemma 17.3 we have $r(P) \le 12$. That is, either way we have $r(P) \le 12$ and thus $\frac{r(P)}{n(P)} \le 2$.

Case 4. $n(P) = 7$. If the vertex u_3 receives at most 5 vertices, then by Lemma 17.1, we have $r(P) \le 5 + 2 + 7 = 14$. Otherwise, u_3 receives at most 7 vertices, and by Lemma 17.4 the vertices u_0 and u_1 (v_0 and v_1, respectively) together receive at most $\frac{5}{2}$ vertices. It follows again by Lemma 17.1 that $r(P) \le 7 + 2 + 5 = 14$. That is, either way we have $r(P) \le 14$ and thus $\frac{r(P)}{n(P)} \le 2$.

This proves that Approx2 is a 2-approximation algorithm.

[3] In the second special case, if r exists and $r \notin V(\mathcal{P})$, then it falls into the first special case and, as a result, the vertex u_1 receives only $\frac{1}{2}$ vertex and the vertex u'_3 receives $\frac{3}{2}$ vertices.

One might wonder whether the performance analysis can be done better. Though we are not able to show the tightness of the performance ratio 2, we give below a graph to show that $\frac{16}{9}$ is a lower bound.

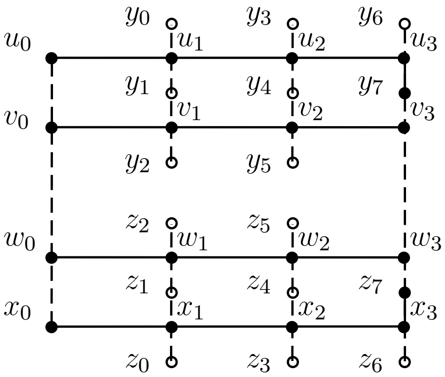

Figure 2 A graph of order 32 to show that the performance ratio of the algorithm APPROX2 is lower bounded by $\frac{16}{9}$. All the edges in the graph are shown, either solid or dashed. The 18 filled vertices are covered by the collection of two 5-paths and two 4-paths computed by APPROX2, and the edges on these paths are shown solid; the edges on an optimal collection of paths, which covers all the vertices, are shown dashed.

The graph displayed in Figure 2 contains 32 vertices. An optimal solution covers all the vertices, and its paths are (vertical) u_0-v_0-w_0-x_0, y_0-u_1-y_1-v_1-y_2, z_0-x_1-z_1-w_1-z_2, y_3-u_2-y_4-v_2-y_5, z_3-x_2-z_4-w_2-z_5, y_6-u_3-y_7-v_3, and w_3-z_7-x_3-z_6. Assuming the algorithm APPROX2 adds four 4-paths (horizontal) u_0-u_1-u_2-u_3, v_0-v_1-v_2-v_3, w_0-w_1-w_2-w_3, x_0-x_1-x_2-x_3, and then extends the first and the last to u_0-u_1-u_2-u_3-y_7, x_0-x_1-x_2-x_3-z_7. Then none of the five operations can be applied to improve the solution, which covers a total of 18 vertices only. That is, the algorithm APPROX2 only achieves a performance ratio of $\frac{16}{9}$ on the graph. ◀

5 Conclusion

In this paper, we studied the general vertex covering problem MAXP^{k+}PC, where $k \geq 4$, to find a collection of vertex-disjoint paths of order at least k to cover the most vertices in the input graph. The problem seemingly escapes from the literature, but it admits a k-approximation algorithm by reducing to the weighted $(2k-1)$-set packing problem [17]. We proposed the first direct $(0.4394k + O(1))$-approximation algorithm and an improved 2-approximation algorithm when $k = 4$. Both algorithms are local improvement based on a few operations, and we proved their approximation ratios via amortized analyses.

We suspect our amortized analyses are tight, and it would be interesting to either show the tightness or improve the analyses. For designing improved approximation algorithms, one can look into whether the two new operations in APPROX2 for $k = 4$ can be helpful for $k \geq 5$; other different ideas might also work, for example, one can investigate whether or not a maximum path-cycle cover [10] can be taken advantage of.

On the other hand, we haven't addressed whether or not the MAXP^{k+}PC problem, for a fixed $k \geq 4$, is APX-hard, and if it is so, then it is worthwhile to show some non-trivial lower bounds on the approximation ratio, even only for $k = 4$.

Abstract

We say that a Hamilton cycle $C = (x_1, \ldots, x_n)$ in a graph G is k-symmetric, if the mapping $x_i \mapsto x_{i+n/k}$ for all $i = 1, \ldots, n$, where indices are considered modulo n, is an automorphism of G. In other words, if we lay out the vertices $x_1, \ldots, x_n$ equidistantly on a circle and draw the edges of G as straight lines, then the drawing of G has k-fold rotational symmetry, i.e., all information about the graph is compressed into a $360°/k$ wedge of the drawing. We refer to the maximum k for which there exists a k-symmetric Hamilton cycle in G as the *Hamilton compression of* G. We investigate the Hamilton compression of four different families of vertex-transitive graphs, namely hypercubes, Johnson graphs, permutahedra and Cayley graphs of abelian groups. In several cases we determine their Hamilton compression exactly, and in other cases we provide close lower and upper bounds. The cycles we construct have a much higher compression than several classical Gray codes known from the literature. Our constructions also yield Gray codes for bitstrings, combinations and permutations that have few tracks and/or that are balanced.

1 Introduction

A *Hamilton cycle* in a graph is a cycle that visits every vertex of the graph exactly once. This concept is named after the Irish mathematician and astronomer Sir William Rowan Hamilton (1805–1865), who invented the Icosian game, in which the objective is to find a Hamilton cycle along the edges of the dodecahedron. Figure 1 shows the dodecahedron with a Hamilton cycle on the circumference. Hamilton cycles have been studied intensively from

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

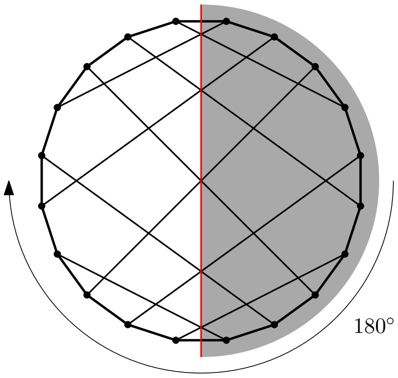

Figure 1 The dodecahedron with a 2-symmetric Hamilton cycle.

various different angles, such as graph theory (necessary/sufficient conditions, packing and covering etc. [11, 12, 13, 18]), optimization (shortest tours, approximation [2]), algorithms (complexity [10], exhaustive generation [22, 25]) and algebra (Cayley graphs [5, 19, 24, 28]). In this work we introduce a new graph parameter that quantifies how symmetric a Hamilton cycle in a graph can be. For example, the cycle in the dodecahedron shown in Figure 1 is 2-symmetric, as the drawing has 2-fold (i.e., $360°/2 = 180°$) rotational symmetry.

1.1 Hamilton cycles with rotational symmetry

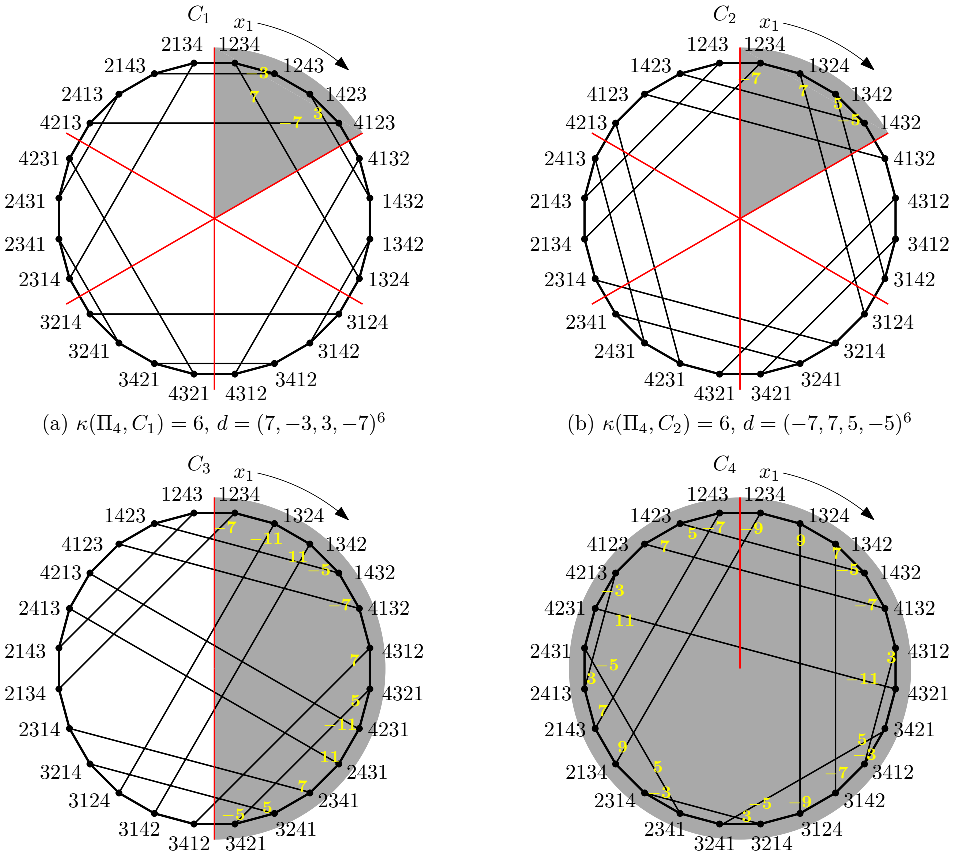
Formally, let $G = (V, E)$ be a graph with n vertices. We say that a Hamilton cycle $C = (x_1, \ldots, x_n)$ is *k-symmetric* if the mapping $f : V \to V$ defined by $x_i \mapsto x_{i+n/k}$ for all $i = 1, \ldots, n$, where indices are considered modulo n, is an automorphism of G. I.e., we have

$$C = P, f(P), f^2(P), \ldots, f^{k-1}(P) \quad \text{for the path} \quad P := (x_1, \ldots, x_{n/k}). \tag{1}$$

The idea is that the entire cycle C can be reconstructed from the path P, which contains only a $1/k$-fraction of all vertices, by repeatedly applying the automorphism f to it. In other words, if we lay out the vertices $x_1, \ldots, x_n$ equidistantly on a circle, and draw edges of G as straight lines, then we obtain a drawing of G with k-fold rotational symmetry, i.e., f is a rotation by $360°/k$; see Figure 2. We refer to the maximum k for which the Hamilton cycle C of G is k-symmetric as the *compression factor of* C, and we denote it by $\kappa(G, C)$.

1.2 Connection to LCF notation

There is yet another interesting interpretation of the compression factor in terms of the LCF notation of a graph, named after its inventors Lederberg, Coxeter and Frucht (see [9]). The idea is to describe a 3-regular Hamiltonian graph (such as the dodecahedron) concisely by considering one of its Hamilton cycles $C = (x_1, \ldots, x_n)$. Each vertex x_i has the neighbors x_{i-1} and x_{i+1} (modulo n) in the graph, plus a third neighbor x_j, which is $d_i := j - i$ (modulo n) steps away from x_i along the cycle. The *LCF sequence* of G is the sequence $d = (d_1, \ldots, d_n)$, where each d_i is chosen so that $-n/2 < d_i \leq n/2$. Clearly, we also have $d_i \notin \{-1, 0, +1\}$. Note that if C is k-symmetric, then the LCF sequence d of G is k-periodic, i.e., it has the form $d = (d_1, \ldots, d_{n/k})^k$, where the k in the exponent denotes k-fold repetition; see Figure 2. While LCF notation is only defined for 3-regular graphs, we can easily extend it to arbitrary graphs with a Hamilton cycle $C = (x_1, \ldots, x_n)$, by considering a sequence of sets $D = (D_1, \ldots, D_n)$, where D_i is the set of distances to all neighbors of x_i on the cycle except x_{i-1} and x_{i+1}; see Figure 3 (a)+(d). As before, if C is k-symmetric, then the corresponding sequence D is k-periodic, i.e., it has the form $D = (D_1, \ldots, D_{n/k})^k$. Frucht [9] writes:



(a) $\kappa(\Pi_4, C_1) = 6$, $d = (7, -3, 3, -7)^6$

(b) $\kappa(\Pi_4, C_2) = 6$, $d = (-7, 7, 5, -5)^6$

(c) $\kappa(\Pi_4, C_3) = 2$,
$d = (-7, -11, 11, -5, -7, 7, 5, -11, 11, 7, 5, -5)^2$

(d) $\kappa(\Pi_4, C_4) = 1$,
$d = (-9, 9, 7, -5, -7, 3, -11, 5, -3, -7, -9, 3,$
$-5, 5, -3, 9, 7, 3, -5, 11, -3, 7, 5, -7)$

Figure 2 Hamilton cycles $C_1, \ldots, C_4$ in the 4-permutahedron Π_4 with different LCF sequences and compression factors.

> "What happens with the LCF notation if we replace one hamiltonian circuit by another one? The answer is: nearly everything can happen! Indeed the LCF notation for a graph can remain unaltered or it can change completely [...] In such cases we should choose of course the shortest of the existing LCF notations."

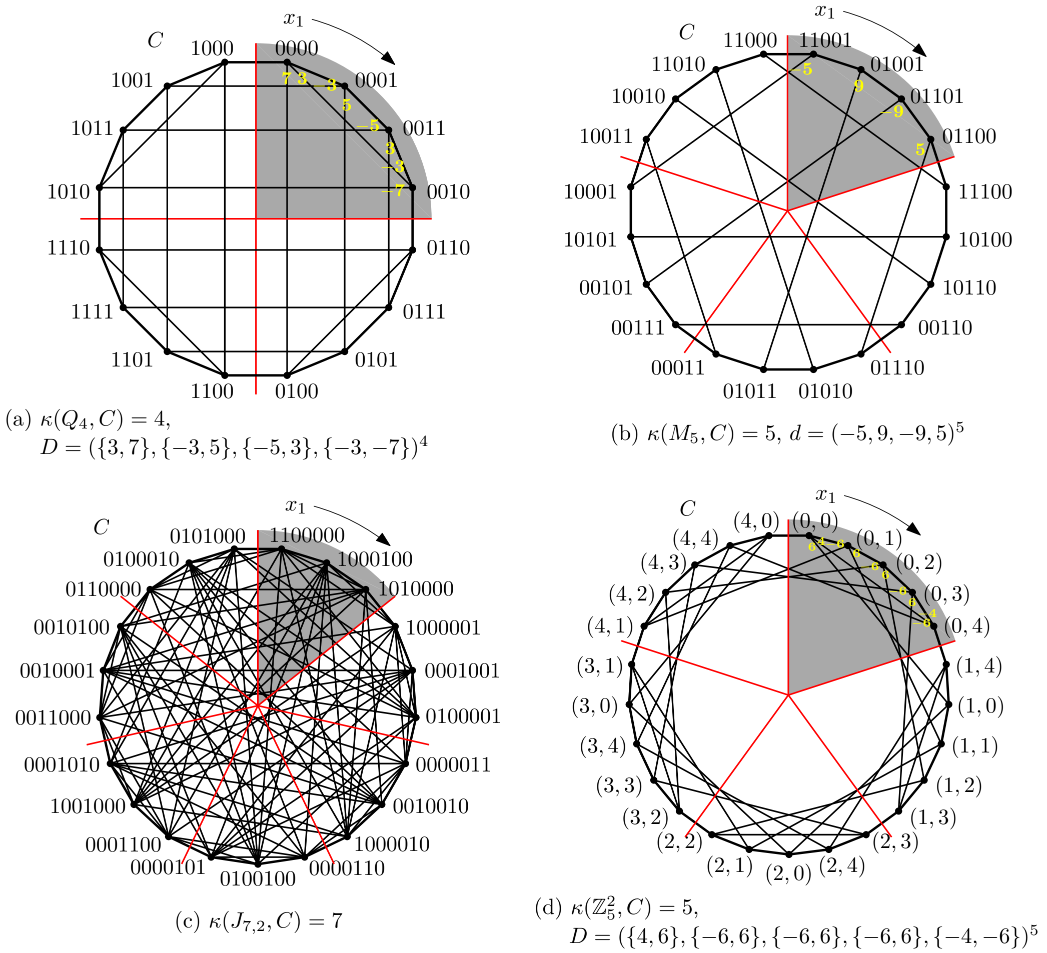
This observation is illustrated in Figure 2, which shows four different Hamilton cycles of the same graph G that have different LCF sequences and compression factors.

1.3 Hamilton compression

Frucht's suggestion is to search for a Hamilton cycle C in G whose compression factor $\kappa(G, C)$ is as large as possible. Formally, for any graph G we define

$$\kappa(G) := \max \big\{\kappa(G, C) \mid C \text{ is a Hamilton cycle in } G\big\}, \tag{2}$$

and we refer to this quantity as the *Hamilton compression of* G. If G has no Hamilton cycle, then we define $\kappa(G) := 0$. While the maximization in (2) is simply over all Hamilton cycles in G, and the automorphisms arise as possible rotations of those cycles, this definition is somewhat impractical to work with. In our arguments, we rather consider all automorphisms



(a) $\kappa(Q_4, C) = 4$,
$D = (\{3, 7\}, \{-3, 5\}, \{-5, 3\}, \{-3, -7\})^4$

(b) $\kappa(M_5, C) = 5$, $d = (-5, 9, -9, 5)^5$

(c) $\kappa(J_{7,2}, C) = 7$

(d) $\kappa(\mathbb{Z}_5^2, C) = 5$,
$D = (\{4, 6\}, \{-6, 6\}, \{-6, 6\}, \{-6, 6\}, \{-4, -6\})^5$

Figure 3 Symmetric Hamilton cycles in the (a) 4-cube; (b) middle levels of the 5-cube; (c) Johnson graph $J_{7,2}$; (d) abelian Cayley graph $(\mathbb{Z}_5^2, \{(0, 1), (1, 0)\})$.

of G, and then search for a Hamilton cycle that is k-symmetric under the chosen automorphism. Specifically, proving a lower bound of $\kappa(G) \geq k$ amounts to finding an automorphism f of G and a k-symmetric Hamilton cycle under f. To prove an upper bound of $\kappa(G) < k$, we need to argue that there is no k-symmetric Hamilton cycle in G, for any choice of f.

By what we said in the beginning, the quantity $\kappa(G)$ can be seen as a measure for the nicest (i.e., most symmetric) way of drawing the graph G on a circle. Thus, our paper contains many illustrations that convey the aesthetic appeal of this problem.

1.4 Easy observations and bounds

We collect a few basic observations about the quantity $\kappa(G)$. Trivially, we have $0 \leq \kappa(G) \leq n$, where n is the number of vertices of G. The upper bound n can be improved to

$$\kappa(G) \leq \max_{f \in \mathrm{Aut}(G)} \mathrm{ord}(f), \tag{3}$$

where $\mathrm{Aut}(G)$ is the automorphism group of G, and $\mathrm{ord}(f)$ is the order of f. An immediate consequence of (1) is that all orbits of the automorphism f must have the same size n/k, and the path $P = (x_1, \ldots, x_{n/k})$ visits every orbit exactly once. This can be used to improve (3) further by restricting the maximization to automorphisms from $\mathrm{Aut}(G)$ whose orbits all have the same size. Furthermore, as k must divide n, we obtain that $\kappa(G) \in \{0, 1, n\}$ for prime n.

Clearly, every Hamilton cycle of a graph G is 1-symmetric, by taking the identity mapping $f = \mathrm{id}$ as automorphism. Consequently, we have $\kappa(G) \geq 1$ for any Hamiltonian graph. On the other hand, if G is Hamiltonian and highly symmetric, i.e., if it has a rich automorphism group, then intuitively G should have a large value of $\kappa(G)$, i.e., it should admit highly symmetric Hamilton cycles. For example, for the cycle C_n on n vertices and the complete graph K_n on n vertices we have $\kappa(C_n) = \kappa(K_n) = n$. More generally, note that $\kappa(G) = n$ if and only if G is a special circulant graph, namely the vertices of G can be labeled with $1, \ldots, n$ such that vertex i is adjacent to all vertices $j = i + d$ (modulo n) with $d \in L$, where L is a fixed list with $1 \in L$. Note that general circulant graphs do not require that $1 \in L$, but the aforementioned characterization requires this assumption.

2 Our results

Vertex-transitive graphs are a prime example of highly symmetric graphs. A graph is *vertex-transitive* if for any two vertices there is an automorphism that maps the first vertex to the second one. In other words, the automorphism group of the graph acts transitively on the vertices. In this paper we investigate the Hamilton compression $\kappa(G)$ of four families of vertex-transitive graphs G, namely hypercubes, Johnson graphs, permutahedra, and Cayley graphs of abelian groups. In the following definitions the letter n denotes a graph parameter and not the number of vertices of the graph as in Section 1. The *n-dimensional hypercube* Q_n, or *n-cube* for short, has as vertices all bitstrings of length n, and an edge between any two strings that differ in a single bit; see Figure 3 (a). The *Johnson graph* $J_{n,m}$ has as vertices all bitstrings of length n with fixed Hamming weight m, and an edge between any two strings that differ in a transposition of a 0 and 1; see Figure 3 (c). The *n-permutahedron* Π_n, has as vertices all permutations of $[n] := \{1, \ldots, n\}$, and an edge between any two permutations that differ in an adjacent transposition, i.e., a swap of two neighboring entries of the permutations in one-line notation; see Figure 2. For a group Γ and generating set $S \subseteq \Gamma$, the Cayley graph $G(\Gamma, S)$ has Γ as its vertex set and undirected edges $\{x, y\}$ for all $x, y \in \Gamma$ and $s \in S$ with $y = xs$; see Figure 3 (d). Note that the hypercube is isomorphic to a Cayley graph of the abelian group $\mathbb{Z}_2^n$.

Hamilton cycles with various additional properties in the aforementioned families of graphs have been the subject of a long line of previous research under the name of *combinatorial Gray codes* [22, 25]. We will see that some classical constructions of such cycles have a non-trivial small compression factor, and we construct cycles with much higher compression factor that we show to be optimal or near-optimal. Along the way, many interesting number-theoretic and algebraic phenomena arise. Due to space constraints, in this extended abstract we only mention our main results, while all proofs can be found in the preprint [15].

2.1 Hypercubes

One of the classical constructions of a Hamilton cycle in Q_n is the well-known *binary reflected Gray code (BRGC)* [14]. This cycle in Q_n is defined inductively by $\Gamma_0 := \varepsilon$ and $\Gamma_n := 0\Gamma_{n-1}, 1\overleftarrow{\Gamma}_{n-1}$ for all $n \geq 1$, where ε is the empty sequence and $\overleftarrow{\Gamma}_{n-1}$ denotes the reversal of the sequence Γ_{n-1}. In words, the cycle Γ_n is obtained by concatenating the vertices of Γ_{n-1} prefixed by 0 with the vertices of Γ_{n-1} in reverse order prefixed by 1. The cycle Γ_n is shown in Figure 3 (a) and Figure 4 (a) for $n = 4$ and $n = 8$, and these drawings have 4-fold rotational symmetry.

▶ **Proposition 1.** *The BRGC Γ_n has compression $\kappa(Q_n, \Gamma_n) = 4$ for $n \geq 2$.*

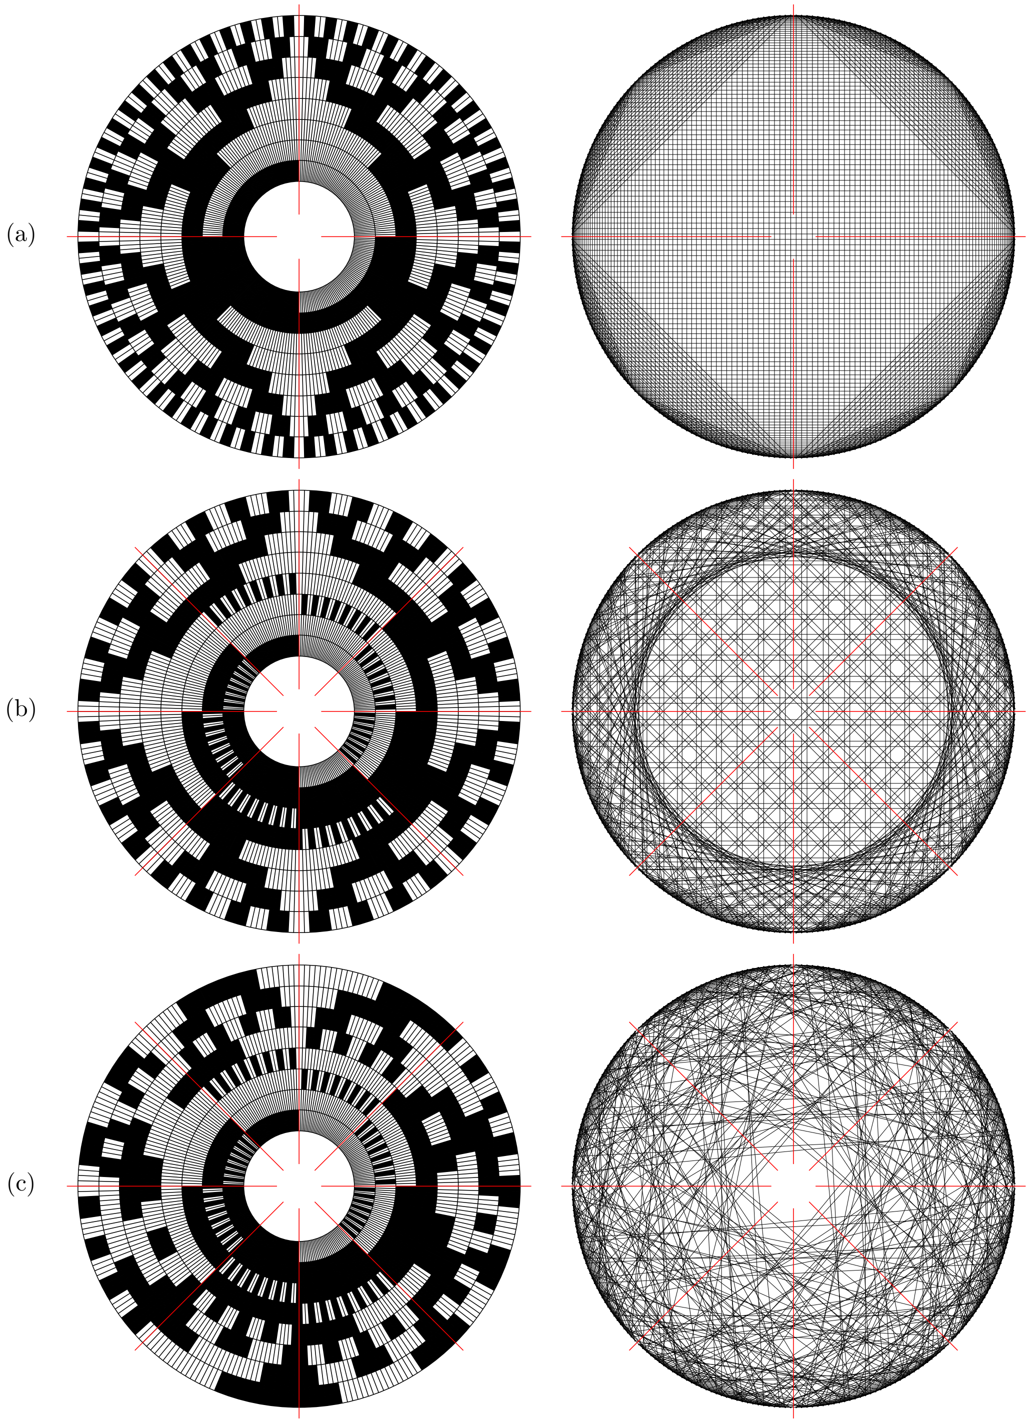


Figure 4 Symmetric Hamilton cycles in Q_8. Cycles are on the left (0=white, 1=black), with the first and last bit on the inner and outer track, respectively. The full graph Q_8 is on the right, with vertices arranged in cycle order and edges drawn as straight lines. (a) Binary reflected Gray code Γ_8 with compression 4; (b) Hamilton cycle with compression 8 from Theorem 2; (c) 2-track Hamilton cycle with compression 8 from Theorem 8.

We improve upon this by constructing new Hamilton cycles in Q_n that have optimal linear Hamilton compression; see Figure 4 (b).

▶ **Theorem 2.** *We have* $\kappa(Q_2) = 4$ *and* $\kappa(Q_n) = 2^{\lceil \log_2 n \rceil}$ *for all* $n \geq 3$.

Note that $n \leq \kappa(Q_n) < 2n$ for $n \geq 2$, in particular $\kappa(Q_n) = \Theta(n)$, i.e., the optimal compression grows linearly with n.

2.2 Johnson graphs and relatives

Our definition of Hamilton compression is inspired by a variant of the well-known middle levels problem raised by Knuth in Problem 56 in Section 7.2.1.3 of his book [17]. Let M_{2n+1} denote the subgraph of Q_{2n+1} induced by all bitstrings with Hamming weight n or $n+1$. In other words, M_{2n+1} is the subgraph of the cover graph of the Boolean lattice of dimension $2n+1$ induced by the middle two levels. There is a natural automorphism of M_{2n+1} all of whose orbits have the same size, namely cyclic left-shift of the bitstrings by one position. Knuth asked whether M_{2n+1} admits a $(2n+1)$-symmetric Hamilton cycle

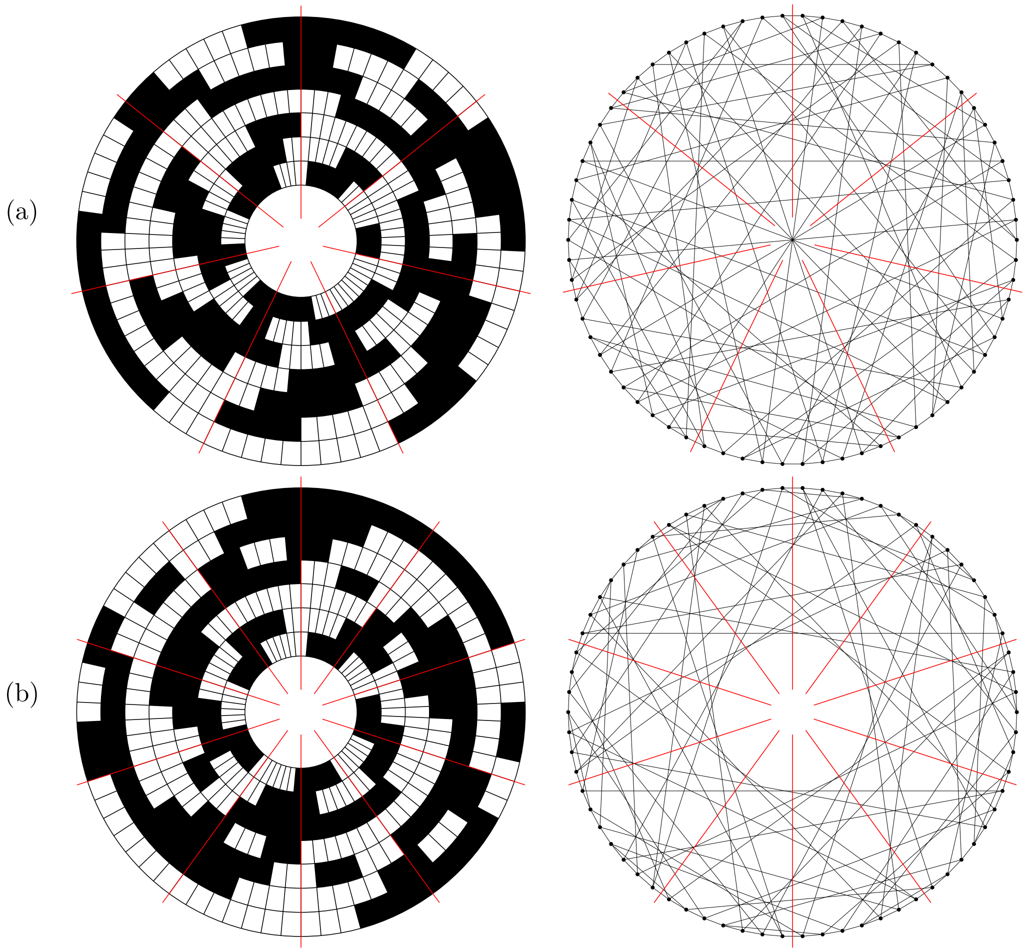

Figure 5 Symmetric Hamilton cycles in the middle levels graph M_7: (a) A solution to Knuth's problem with compression 7 for f being cyclic left-shift; (b) Hamilton cycle with compression 10 for f being left-shift of the last 5 bits and complementation of all bits.

under this automorphism, and he rated this the hardest open problem in his book, with a difficulty rating of 49/50. Such cycles are shown in Figure 3 (b) and Figure 5 (a) for the graphs M_5 and M_7, respectively. Knuth's problem was answered affirmatively in full generality in [21], which establishes the lower bound $\kappa(M_{2n+1}) \geq 2n+1$. We show that this is at most a factor of 2 away from optimality.

▶ **Theorem 3.** *For all $n \geq 1$ we have $2n+1 \leq \kappa(M_{2n+1}) \leq 2(2n+1)$.*

Interestingly, it seems that both bounds in Theorem 3 can be improved. For example, for $n=3$ we can take the automorphism f of M_7 defined by $x_1 \cdots x_7 \mapsto \overline{x_1 x_2 x_4 x_5 x_6 x_7 x_3}$, which fixes the first two bits, cyclically left-shifts the remaining five bits by one position, and then complements all bits. A 10-symmetric Hamilton cycle under this f is shown in Figure 5 (b), whereas the lower and upper bounds are 7 and 14, respectively. In fact, computer experiments show that $\kappa(M_7) = 10$.

For the Johnson graphs $J_{n,m}$, we obtain the following exact results and bounds. Part (i) and (ii) of the theorem are illustrated in Figure 6 (a) and (b), respectively.

▶ **Theorem 4.** *The Hamilton compression of the Johnson graph $J_{n,m}$, where $n > m > 0$, has the following properties:*

(i) *If n and m are coprime, we have $\kappa(J_{n,m}) = n$.*
(ii) *If n and m are not coprime and $n \neq 2m$, we have $n/2 < \max\{m, n-m\} < \kappa(J_{n,m}) \leq n$.*
(iii) *If n and m are not coprime and $n = 2m$, we have $n/2 < \kappa(J_{n,m}) \leq 2n$.*
(iv) *For any $\varepsilon > 0$ there is an n_0 such that for all $n > n_0$ with $n \neq 2m$ we have $(1-\varepsilon)n \leq \kappa(J_{n,m}) \leq n$. In particular, we have $\kappa(J_{n,m}) = (1-o(1))n$ for $n \neq 2m$.*

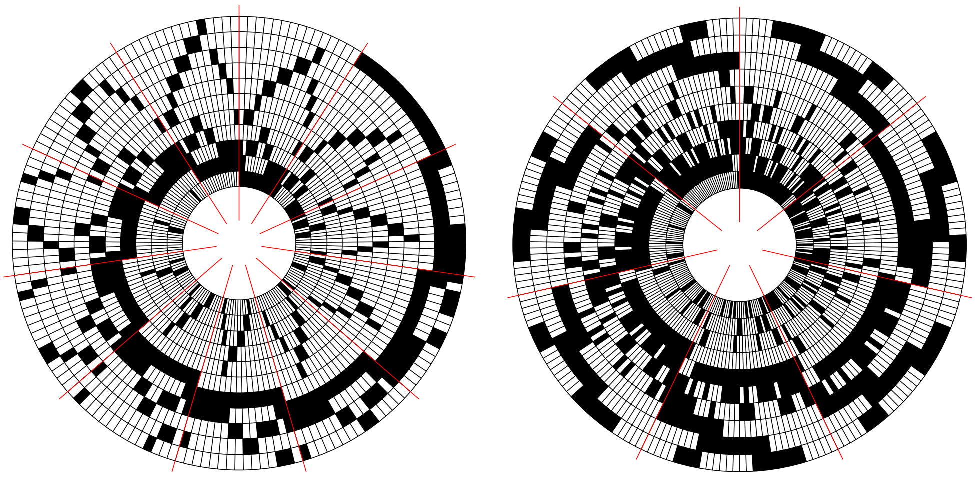

Figure 6 Symmetric Hamilton cycles in Johnson graphs: (a) Balanced 1-track Hamilton cycle in $J_{11,3}$ with compression $n = 11$; the automorphism left-shifts all n bits; (b) 4-track Hamilton cycle in $J_{10,4}$ with compression $q = 7$; the automorphism left-shifts the first q bits.

2.3 Permutahedra

Another classical Gray code is produced by the *Steinhaus-Johnson-Trotter (SJT) algorithm*, which generates permutations by adjacent transpositions. This algorithm computes a Hamilton cycle in Π_n, which can be described inductively as follows: $\Lambda_1 := 1$ and for all

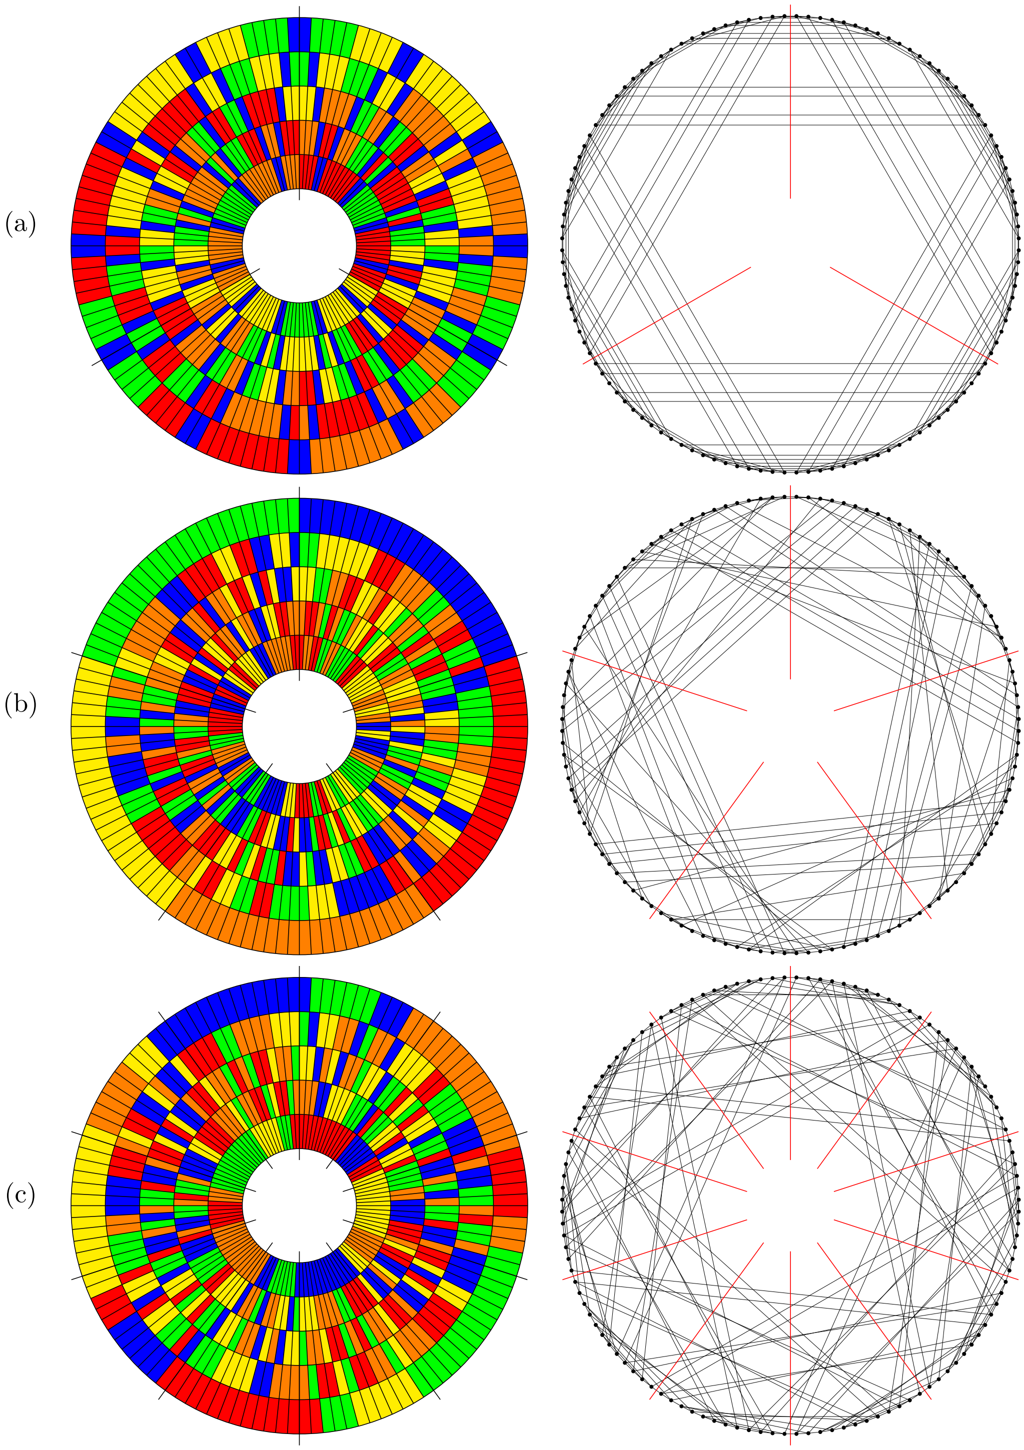

Figure 7 Symmetric Hamilton cycles in Π_5 (1=red, 2=orange, 3=yellow, 4=green, 5=blue): (a) Steinhaus-Johnson-Trotter cycle Λ_5 with compression 3; (b) Cycle with compression 5; (c) Cycle with optimal compression 10.

$n \geq 2$ the cycle Λ_n is obtained from Λ_{n-1} by replacing each permutation of length $n-1$ by the n permutations given by inserting n in every possible position, alternatingly from right to left or vice versa. The cycle Λ_n is shown in Figure 2 (a) and Figure 7 (a) for $n = 4$ and $n = 5$, respectively, and these drawings have 6-fold or 3-fold rotational symmetry.

▶ **Proposition 5.** *The SJT cycle Λ_n has compression $\kappa(\Pi_n, \Lambda_n) = 6$ for $n = 3, 4$ and $\kappa(\Pi_n, \Lambda_n) = 3$ for $n \geq 5$.*

We improve upon this by constructing new Hamilton cycles in Π_n that have mildly exponential Hamilton compression; see Figure 7 (b)+(c). Specifically, the growth of the optimum compression is determined by *Landau's function* $\lambda(n)$, which is defined as the maximum order of an element in the symmetric group S_n.

▶ **Theorem 6.** *We have $\kappa(\Pi_n) = \Theta(\lambda(n)) = e^{(1+o(1))\sqrt{n \ln n}}$.*

The lower and upper bounds in the proof of Theorem 6 differ at most by a factor of 2 for every $n \geq 3$. Moreover, we achieve the optimal compression in infinitely many cases, in particular for the following values of $n \leq 100$: $n = 3, 4, 5, 15, 22, 46, 49, 51, 52, 53, 55, 68, 69, 72, 73, 74, 75, 80, 82, 85, 87, 88, 89, 91, 92, 93, 96, 97, 99, 100$.

2.4 Abelian Cayley graphs

A classical folklore result asserts that every Cayley graph of an abelian group has a Hamilton cycle. The Chen-Quimpo theorem [4] asserts that in fact much stronger Hamiltonicity properties hold. It is thus natural to ask whether Cayley graphs of abelian groups have highly symmetric Hamilton cycles.

▶ **Theorem 7.** *Let Γ be an abelian group.*

(i) *If $|\Gamma|$ is a product of distinct odd primes, then for the canonical generating set $S \subseteq \Gamma$, the Cayley graph $G = G(\Gamma, S)$ has compression $\kappa(G) = 1$.*

(ii) *If $|\Gamma| \geq 3$ is even or divisible by a square greater than 1, then for any generating set $S \subseteq \Gamma$, the Cayley graph $G = G(\Gamma, S)$ has compression $\kappa(G) \geq 2$.*

In particular, toroidal grids $\mathbb{Z}_p \times \mathbb{Z}_q$ for distinct odd primes p, q have only compression 1. The canonical generating set of a finite abelian group Γ is the set of unit vectors in the decomposition of Γ as a product of cyclic groups given by the structure theorem of finite abelian groups.

3 Related problems

We proceed to discuss some applications of our results to closely related problems.

3.1 Lovász' conjecture

A well-known question of Lovász' [20] asks whether there are infinitely many vertex-transitive graphs that do not admit a Hamilton cycle. So far only five such graphs are known, namely K_2, the Petersen graph, the Coxeter graph, and the graphs obtained from the latter two by replacing every vertex by a triangle. Vertex-transitive graphs have a lot of automorphisms, and we may take the quantity $\kappa(G)$ as a measure of how strongly G is Hamiltonian. In particular, Lovász' question may be rephrased as 'Are there infinitely many vertex-transitive graphs G with $\kappa(G) = 0$?' More generally, we may ask: 'Are there infinitely many vertex-transitive graphs G with $\kappa(G) = k$, for each fixed integer k?' A particularly relevant subclass

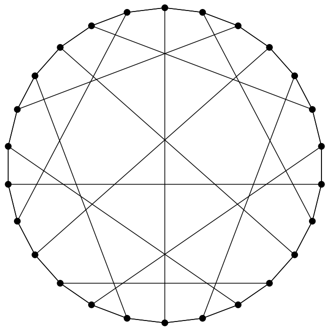

Figure 8 One of the smallest vertex-transitive non-Cayley graphs G with $\kappa(G) = 1$.

of vertex-transitive graphs are Cayley graphs, so we may ask the same question about Cayley graphs. From our results mentioned in Section 2.4 we obtain an infinite family of Cayley graphs G with $\kappa(G) = 1$. Computer experiments show that the smallest vertex-transitive non-Cayley graphs G with $\kappa(G) = 1$ have 26 vertices, and one of them is shown in Figure 8.

The path P in (1) is a Hamilton path in the quotient graph G/f obtained by collapsing each orbit of f into a single vertex. The idea of constructing a Hamilton cycle in G by constructing a Hamilton cycle in the much smaller graph G/f that is then "lifted" to the full graph is well known in the literature, and has been used to solve some special cases of Lovász' problem affirmatively; see e.g. [1, 6, 19, 21, 27]. It is particularly useful for computer searches, as it reduces the search space dramatically.

3.2 *t*-track and balanced Gray codes

We say that a sequence C of strings of length n consists of t *tracks* if in the $|C| \times n$ matrix corresponding to C there are t columns such that every other column is a cyclically shifted copy of one of these columns. This property is relevant for applications, as it saves hardware when implementing Gray-coded rotary encoders. Instead of using n tracks and n reading heads aligned at the same angle (each reading one track), one can use only t tracks, and place some of the n reading heads at appropriately rotated positions.

Hiltgen, Paterson, and Brandestini [16] showed that the length of any 1-track cycle in Q_n must be a multiple of $2n$. In particular, such a cycle cannot be a Hamilton cycle unless n is a power of 2. For the case $n = 2^r$, $r \geq 3$, Etzion and Paterson [7] showed that there is 1-track cycle of length $2^n - 2n$, and Schwartz and Etzion [26] subsequently showed that the length $2^n - 2n$ is best possible. Taken together, these results show that there is no 1-track Hamilton cycle in Q_n for any $n \geq 3$. We complement this negative result by constructing a 2-track Hamilton cycle in Q_n, for every n that is a sum of two powers of 2; see Figure 4 (c).

▶ **Theorem 8.** *For every $n = 2^r$ and $m = 2^s$, where $r \geq 2$ and $r \geq s \geq 0$, there is a $2n$-symmetric Hamilton cycle in Q_{n+m} that has 2 tracks.*

More generally, we obtain t-track Hamilton cycles in Q_n for every n that is a sum of $t \geq 2$ powers of 2. In particular, every dimension n admits a Hamilton cycle with at most logarithmically many tracks.

▶ **Theorem 9.** *For every $n = 2^r$ and $(m_1, \ldots, m_{t-1}) = (2^{s_1}, \ldots, 2^{s_{t-1}})$, where $r, t \geq 2$ and $r \geq s_1 \geq \cdots \geq s_{t-1} \geq 0$, there is a $2n$-symmetric Hamilton cycle in $Q_{n+m_1+\cdots+m_{t-1}}$ that has t tracks.*

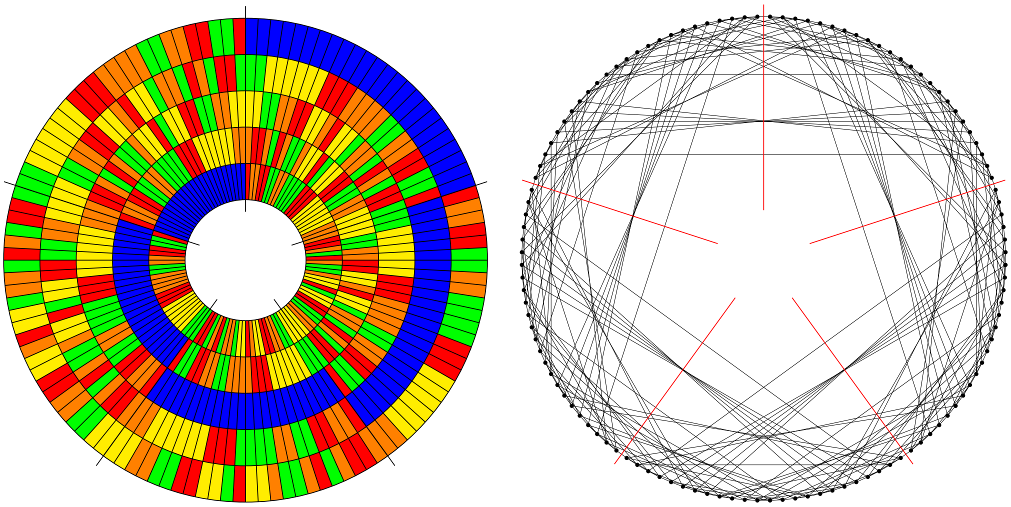

Figure 9 Balanced 1-track Hamilton cycle in Π_5^+ with compression 5 from Theorem 11 (cyclically adjacent transpositions).

From our construction in the Johnson graph $J_{n,m}$ when n and m are coprime, we obtain 1-track Hamilton cycles that are also *balanced*, i.e., each bit is flipped equally often (cf. [3, 8]); see Figure 6 (a).

▶ **Theorem 10.** *Let $n > m > 0$ be such that n and m are coprime. Then $J_{n,m}$ has an n-symmetric Hamilton cycle that has 1 track and is balanced, i.e., each bit is flipped equally often ($\binom{n}{m}/n$ many times).*

We write Π_n^+ for the graph obtained from the permutahedron Π_n by adding edges that correspond to transpositions of the first and last entry of a permutation, i.e., we allow cyclically adjacent transpositions. The next theorem is illustrated in Figure 9.

▶ **Theorem 11.** *For every odd $n \geq 3$ there is an n-symmetric Hamilton cycle in Π_n^+ that has 1 track and is balanced, i.e., each of the n transpositions is used equally often ($(n-1)!$ many times).*

4 Open questions

The Hamilton compression $\kappa(G)$ is a newly introduced graph parameter, so many natural follow-up questions arise. We conclude this paper by listing several of these problems.

- Can the Gray codes constructed in this paper be computed efficiently? While our proofs translate straightforwardly into algorithms whose running time is polynomial in the size of the graph, a more ambitious goal are algorithms whose running time per generated vertex is polynomial in the length of the vertex labels (bitstrings, permutations, etc.).
- What is the Hamilton compression of the middle levels graph (recall Theorem 3)?
- For any integer $n \geq 1$, the odd graph O_n has as vertices all bitstrings of length $2n+1$ with Hamming weight n, and an edge between any two strings that have no 1s in common. Odd graphs O_n, $n \geq 3$, were shown to have a Hamilton cycle in [23], so $\kappa(O_n) \geq 1$. We can use cyclic shifts as the automorphism, and it is easy to see that $\kappa(O_n) \leq 2n+1$. We conjecture that $\kappa(O_n) = 2n+1$ for all $n \geq 4$, which we confirmed for $n = 4$.

- In view of Section 2.4, the main open question here is whether the Cayley graph $G = G(\Gamma, S)$, where Γ is an abelian group such that $|\Gamma|$ is a product of distinct odd primes and S is a non-canonical set of generators, has $\kappa(G)$ equal to 1 or exceeding 1.
- What is the Hamilton compression of the associahedron, which has as automorphism group the dihedral group of a regular n-gon? For $n = 5, 6, 7, 8$ we determined the values $5, 2, 7, 2$ by computer, and we suspect that the primality of n plays a role.
- Instead of asking about the largest number $k = \kappa(G)$ such that $\mathrm{Aut}(G, C)$ (automorphisms of G that preserve C) contains the cyclic subgroup of order k for some Hamilton cycle C in G, we may ask for the dihedral subgroup of the largest order, which would allow not only for rotations of the drawings but also reflections.
- Is there a 1-track Hamilton cycle in Π_n (recall Theorem 11)? Equivalently, can all $n!$ permutations be listed by adjacent transpositions so that every column is a cyclic shift of every other column?
- Is there a balanced Hamilton cycle in Π_n? Equivalently, can all $n!$ permutations be listed using each of the $n - 1$ adjacent transpositions equally often? Alternatively, what about using each of the $\binom{n}{2}$ transpositions equally often (see [8])? For $n = 5$, we found orderings satisfying the constraints of both questions.

Dispersing Obnoxious Facilities on Graphs by Rounding Distances

Tim A. Hartmann
Department of Computer Science, RWTH Aachen University, Germany

Stefan Lendl
Department of Operations and Information Systems, University of Graz, Austria

Abstract

We continue the study of δ-dispersion, a continuous facility location problem on a graph where all edges have unit length and where the facilities may also be positioned in the interior of the edges. The goal is to position as many facilities as possible subject to the condition that every two facilities have distance at least δ from each other.

Our main technical contribution is an efficient procedure to "round-up" distance δ. It transforms a δ-dispersed set S into a $\delta^\star$-dispersed set $S^\star$ of same size where distance $\delta^\star$ is a potentially slightly larger rational $\frac{a}{b}$ with a numerator a upper bounded by the longest (not-induced) path in the input graph.

Based on this rounding procedure and connections to the distance-d independent set problem we derive a number of algorithmic results. When parameterized by treewidth, the problem is in XP. When parameterized by treedepth the problem is FPT and has a matching lower bound on its time complexity under ETH. Moreover, we can also settle the parameterized complexity with the solution size as parameter using our rounding technique: δ-Dispersion is FPT for every $\delta \leq 2$ and W[1]-hard for every $\delta > 2$.

Further, we show that δ-dispersion is NP-complete for every fixed irrational distance δ, which was left open in a previous work.

1 Introduction

We study the algorithmic behavior of a continuous dispersion problem. Consider an undirected graph G, whose edges have unit length. Let $P(G)$ be the continuum set of points on all the edges and vertices. For two points $p, q \in P(G)$, we denote by $d(p, q)$ the length of a shortest path containing p and q in the underlying metric space. A subset $S \subseteq P(G)$ is *δ-dispersed* for some positive real number δ, if every distinct points $p, q \in S$ have distance at least $d(p, q) \geq \delta$. Our goal is, for a given graph G and a positive real number δ, to compute a maximum cardinality subset $S \subseteq P(G)$ that is δ-dispersed. We denote by δ-*disp*(G) the maximum size of a δ-dispersed set of G. The decision problem Dispersion asks for a δ-dispersed set of size at least k, where additionally integer $k \geq 0$ is part of the input. When δ is fixed and not part of the input, we refer to the problem as δ-Dispersion.

1.1 Known and Related Results

The area of obnoxious facility location goes back to seminal articles of Goldman & Dearing [6] and Church & Garfinkel [3]. The area includes a wide variety of objectives and models. For example, purely geometric variants have been studied by Abravaya & Segal [1], Ben-Moshe, Katz & Segal [2], and Katz, Kedem & Segal [14]. Recently, van Ee studied the approximability of a generalized covering problem in a metric space that also involves dispersion constraints [19]. Another direction is a graph-theoretic model, where every edge of the given graph G is rectifiable and has some individual length. Tamir discusses the complexity and approximability of several optimization problems. For example, when G is a tree, then a δ-dispersed set can be computed in polynomial time [18]. Another task is to place a single obnoxious facility in a network while maximizing, for example, the smallest distance from the facility to certain clients, as studied by Segal [16].

In a previous work, the complexity of Dispersion was studied for every rational distance δ. When δ is a rational number with numerator 1 or 2, the problem is polynomial time solvable, while it is NP-complete for all other rational values of δ [7, 8]. The complexity when δ is irrational was left as an open problem.

A closely related facility location problem is δ-covering. The objective is to place as few locations as possible on $P(G)$ subject to the condition that any point in $P(G)$ is in distance at most δ to a placed location. This problem is polynomial time solvable whenever δ is a unit fraction, while it is NP-hard for all non unit fractions δ [10]. Furthermore, the parameterized complexity with the parameter solution size k is studied. δ-covering is fixed parameter tractable when $\delta < \frac{3}{2}$, while for $\delta \geq \frac{3}{2}$ the problem is W[2]-complete [10]. Tamir [17] showed that for δ-covering only certain distances δ are of interest. For every amount of points p the distance $\max\{\delta^\star : |\delta^\star\text{-cover}(G)| = p\}$ is of the form $\frac{L'}{2p'}$ where $p' \in \{1, \ldots, p\}$ and L' is roughly at most twice the length of a non-induced path in G.

1.2 Our Contribution

Our main technical contribution is an efficient and constructive rounding procedure. Given a δ-dispersed set S for some distance value $\delta > 0$, it transforms S into a $\delta^\star$-dispersed set $S^\star$ of equal size with a slightly larger well-behaving distance value $\delta^\star \geq \delta$. The new distance $\delta^\star$ is a rational $\frac{a}{b}$ with small numerator a. More precisely, the numerator is upper bounded by the length of the longest (not-induced) path L, hence upper bounded asymptotically by the number of vertices n of the input graph (see Section 5).

Our second technical contribution relates the optimal solution for distance δ and $\frac{\delta}{\delta+1}$ for $\delta \leq 3$. A δ-dispersed set translates to a $\frac{\delta}{\delta+1}$-dispersed set by placing one more point on every edge, and vice versa by removing one point (see Section 3).

Further we explore a connection of Dispersion and an independent set problem (see Section 4). The combination of that connection with our technical contributions yields several algorithmic results for Dispersion (see Section 6 and Section 7):

- Dispersion is NP-hard even for chordal graphs of diameter 4.
- Dispersion is FPT for the graph parameter treedepth $\mathsf{td}(G)$ with a run time matching a lower bound under ETH. We complement this result by showing that δ-Dispersion is W[1]-hard for the slightly more general graph parameter pathwidth $\mathsf{pw}(G)$, even for the combined parameter $\mathsf{pw}(G) + k$. Similarly, δ-Dispersion is W[1]-hard for the graph parameter $\mathsf{fvs}(G)$, the minimum size of a feedback vertex set.
- Dispersion is XP for the parameter treewidth $\mathsf{tw}(G)$, with a running time of $(2L)^{\mathsf{tw}(G)} n^{\mathcal{O}(1)}$, where n is the number of vertices and L is an upper bound on the length

of the longest path in G. We complement this result by the more general lower bound of $n^{o(\mathsf{tw}(G)+\sqrt{k})}$, assuming ETH. It implies the lower bound of $L^{o(\mathsf{tw}(G)+\sqrt{k})}$ since $L \leq n$. Note that a mere lower bound of $L^{o(\mathsf{tw}(G)+\sqrt{k})}$ would not exclude an $n^{o(\mathsf{tw}(G))}$-algorithm.

In addition, we completely resolve the complexity of δ-dispersion, by showing NP-hardness for irrational δ (see Section 8). We also study the parameterized complexity when parameterized by the solution size k. The problem is W[1]-hard when $\delta > 2$, and FPT otherwise. Thus, there is a sharp threshold at $\delta = 2$ where the complexity jumps from FPT to W[1]-hard (see Section 9).

We mark statements whose proof can be found in the full version of the paper (see [9]) with "($\star$)".

2 Preliminaries

We use the word *vertex* in the graph-theoretic sense, while we use the word *point* to denote the elements of the geometric structure $P(G)$. As an input for δ-dispersion, we consider graphs G that are undirected, connected, and without loops and isolated vertices.

For an edge $\{u, v\} \in E(G)$ and a real number $\lambda \in [0, 1]$, let $p(u, v, \lambda) \in P(G)$ be the point on edge $\{u, v\}$ that has distance λ from u. Note that $p(u, v, 0) = u$, $p(u, v, 1) = v$ and $p(u, v, \lambda) = p(v, u, 1 - \lambda)$. Further, we use $d(p, q)$ for the length of a shortest path between points $p, q \in P(G)$.

For a subset of vertices $V' \subseteq V(G)$ or a subset of edges $E' \subseteq E(G)$, we denote by $G[V']$ and $G[E']$ the subgraph induced by V' and E', respectively. The neighborhood of a vertex u is $N(u) := \{v \in V(G) \mid \{u, v\} \in E(G)\}$. We use n as the number of vertices of G, when G is clear from the context.

For a graph G and integer $c \geq 1$, let the *c-subdivision of G* be the graph G where every edge is replaced by a path of length c.

▶ **Lemma 1** ([8])**.** *Let G be a graph, let $c \geq 1$ be an integer, and let G' be the c-subdivision of G. Then δ-disp$(G) = (c\delta)$-disp(G').*

For integers a and b, we denote the rational number $\frac{a}{b}$ as *b-simple.* A set $S \subseteq P(G)$ is b-simple, if for every point $p(u, v, \lambda)$ in S the edge position λ is *b-simple.*

▶ **Lemma 2** ([8])**.** *Let $\delta = \frac{a}{b}$ with integers a and b, and let G be a graph. Then, there exists an optimal δ-dispersed set $S^\star$ that is $2b$-simple.*

For an introduction into parameterized algorithms, we refer to [4]. We study of the complexity of Dispersion with the natural parameter solution size k, as well as its dependency on structural measures on the input graph. Besides treewidth $\mathsf{tw}(G)$ and pathwidth $\mathsf{pw}(G)$, we also study the parameters "feedback vertex set size" $\mathsf{fvs}(G)$ and treedepth $\mathsf{td}(G)$.

A graph has a feedback vertex set $W \subseteq V(G)$ if G after removing W contains no cycle. The "feedback vertex set size" is the size of a smallest feedback vertex set of G.

The treedepth of a connected graph G can be defined as follows. If G is disconnected, it is the maximum treedepth of its components; If G consists of a single vertex, then $\mathsf{td}(G) = 1$; And else it is one plus the minimum over all $u \in V(G)$ of the treedepth of G without vertex u.

We provide lower bounds for the time-complexity assuming the Exponential Time Hypothesis (ETH): There is no $2^{o(N)}$-time algorithm for 3-SAT with N variables and $\mathcal{O}(N)$ clauses [11]. For more details on ETH, we refer to [4].

3 Translating δ-Dispersion

There is an intriguing relation of the optimal solution for distance δ and $\frac{\delta}{2\delta+1}$ for the similar problem δ-covering [10]. We may analogously expect that an optimal solution for δ-dispersion translates to an optimal solution for $\frac{\delta}{\delta+1}$-dispersion; i.e., that an optimal δ-dispersed set corresponds to an optimal $\frac{\delta}{\delta+1}$-dispersed set of the same size plus one extra point for every edge.

This is not true for $\delta = 3+\varepsilon$ for any $\varepsilon > 0$: Consider a triangle, where a $(3+\varepsilon)$-dispersed set S contains at most one point p. Since $\frac{\delta}{\delta+1} > \frac{3}{4}$, a $\frac{\delta}{\delta+1}$-dispersed set however contains at most $3 < |S| + 3$ points.

Causing trouble is a non-trivial closed walk containing p of length less than δ. The translating lemma may only apply to a variation of dispersion that is sensitive to such walks, a variant which we call *auto-dispersion.* A δ-dispersed set $S \subseteq P(G)$ is δ*-auto-dispersed* if additionally for every point $p \in S$ there is no walk from p to p of length $< \delta$ that is locally-injective. A walk is *locally-injective* if, when interpreted as a continuous mapping $f : [0,1] \to P(G)$ from $f(0) = p$ to $f(1) = p$, has for every pre-image $c \in (0,1)$ a positive range $\varepsilon > 0$ such that f restricted to the interval $(c-\varepsilon, c+\varepsilon)$ is injective.

▶ **Lemma 3.** ($\star$) *Let G be a graph and $\delta > 0$. Then δ-auto-disp$(G) = \frac{\delta}{\delta+1}$-auto-disp$(G) + |E(G)|$.*

Fortunately, this translation lemma is still useful for ordinary δ-dispersion. We have δ-auto-disp$(G) = \delta$-disp(G) for $\delta \leq 3$, since there is no such locally-injective walk of length < 3. The threshold of 3 is tight according to the above example with graph K_3.

▶ **Corollary 4.** *Let G be a graph and $\delta \in (0,3]$. Then δ-disp$(G) = \frac{\delta}{\delta+1}$-disp$(G) + |E(G)|$.*

4 Dispersion and Independent Set

To solve Dispersion we can borrow from algorithmic results from a generalized independent set problem. A classical independent set is a set of *vertices* where each two elements have to be at least 2 apart from each other (when we consider that the edges have unit length). In a 2-dispersed set also each two elements need to be at least 2 apart from each other, though the set contains a set of *points* of the graph.

To generalize the independent set problem, we may ask that the vertices are not 2 apart but some integer d apart from each other. Such a generalization for independent set is called a *distance-d independent* set or *d-scattered set.* They have been studied by Eto et al. [5] and Katsikarelis et al. [13].

Let $\alpha_d(G)$ be the maximum size of a distance-d independent set, for a graph G and integer d. We relate δ-dispersion to α_d. We consider the *c-subdivision of a graph G*, denoted as G_c, which is the graph G where every edge is replaced by a path of length c, for some integer $c \geq 1$.

▶ **Lemma 5.** *Consider integers a, b and a $2b$-subdivision G_{2b} of a graph G. Then $\frac{a}{b}$-disp$(G) = \alpha_{2a}(G_{2b})$.*

Proof. Consider the b-subdivision G_b of G. Then G_{2b} is a 2-subdivision of G_b. We know that $\frac{a}{b}$-disp$(G) = 2a$-disp(G_{2b}) from Lemma 1. Hence it remains to show $2a$-disp$(G_{2b}) = \alpha_{2a}(G_{2b})$.

Clearly, a distance-$2a$ independent set $I \subseteq V(G)$ is also a $2a$-dispersed set. For the reverse direction, assume there is a $2a$-dispersed set I_{2a} of G_{2b}. Then I_{2a} corresponds to an a-dispersed set I of G_b of same size, according to Lemma 1. Since a is integer, we may assume that S contains only half-integral points, hence points with edge position from $\{0, \frac{1}{2}, 1\}$, according to Lemma 2. Let G_{2b} result from G_b by replacing each edge $\{u, v\}$ by a path $uw_{u,v}v$. Then let $I \subseteq V(G_{2b})$ consist of vertex $u \in V(G)$ with a point in S and every $w_{u,v}$ for every point $p(u, v, \frac{1}{2}) \in S$. Then I is a distance-$2a$ independent set of G_{2b} of size $|I| = |S|$. ◀

Thus to solve Dispersion for $\delta = \frac{a}{b}$ we can use algorithms for distance-d independent set. For rationals $\frac{a}{b}$ with small values of a and b this possibly leads to efficient algorithms. For example, a distance-d independent set on graphs width treewidth $\mathsf{tw}(G)$ (and a given tree decomposition) can be found in time $d^{\mathsf{tw}(G)} n^{\mathcal{O}(1)}$, see [13]. "Simply" subdivide the edges of the input graph sufficiently often, which does not increase the treewidth of the considered graph. To find a $\frac{a}{b}$-dispersed set in a graph G, we can search for distance $2a$ independent set the $2b$-subdivision of G.

▶ **Corollary 6.** *There is an algorithm that, given a rational distance $\frac{a}{b} > 0$ and a graph G, a tree decomposition of width $\mathsf{tw}(G)$, computes a maximum $\frac{a}{b}$-dispersed set S in time $(2a)^{\mathsf{tw}(G)}(bn)^{\mathcal{O}(1)}$.*

However, in general this constitutes a possibly exponential increase of the input size. While in the input of $\frac{a}{b}$-dispersion encodes a and b in binary, the subdivided graph essentially encodes b in unary. Further, if δ is irrational, we do not have a suitable subdivision at all.

5 Rounding the Distance

For a given graph G and distance δ, we state a rational $\delta^\star \geq \delta$ such that δ-disp(G) = $\delta^\star$-disp(G). Our proof is constructive. We give a procedure that efficiently transforms a δ-dispersed set into a $\delta^\star$-dispersed set. The guaranteed rational $\delta^\star$ has a numerator bounded by the longest path in G (or just n as an upper bound thereof). It is independent of the precise structure of the given graph.

To give some intuition: Generally there is some leeway for δ. For example, in a star $K_{1,k}$, $k \geq 1$ for every $\delta \in (1, 2]$ the optimal solution puts a point on every leaf yielding a δ-dispersed set of size k. Hence for instance $\frac{3}{2}$-disp$(K_{1,k})$ = 2-disp$(K_{1,k})$. However, for $\delta > 2$ only one point can be placed, such that 2-disp$(K_{1,k}) \neq (2 + \varepsilon)$-disp$(K_{1,k})$ for every $\varepsilon > 0$.

So what $\delta^\star$ can be guaranteed such that δ-disp(G) = $\delta^\star$-disp(G)? An illustrative example is a path of length 6. Then $\frac{15}{11}$-disp$(G) = 5 = \frac{3}{2}$-disp(G). For $\delta = \frac{15}{11}$ tightly packing 5 points allows to have a space of size $\frac{6}{11}$ at either end of the path, not enough to place another point. However, placing 5 points in distance $\delta = \frac{3}{2}$ allows no leeway; δ is (already) a divisor of 6, the length of the considered path. Distance $\delta^\star$ relies on L, the length of the longest (not-induced) path in G. We have to take into account that δ might divide any path of length $\leq L$. Our $\delta^\star$ is the smallest rational $\frac{a^\star}{b^\star}$ where the numerator $a^\star \leq 2L$. In other words, the inverse of $\delta^\star$ is the next smaller rational number of the inverse of δ in the Farey sequence of order $2L$.

▶ **Theorem 7.** *Let $\delta \in \mathbb{R}^+$. Let L be an upper bound on the length of paths in G. Let $\delta^\star = \frac{a^\star}{b^\star} \geq \delta$ minimal with $a^\star \leq 2L$ and $b^\star \in \mathbb{N}$. Then δ-disp(G) = $\delta^\star$-disp(G).*

Clearly, a $\delta^\star$-dispersed set $S^\star$, is also δ-dispersed, since $\delta^\star \geq \delta$. We have to show the reverse direction. Consider a δ-dispersed set S (of size $|S| \geq 2$) of a connected graph G that is not $\delta^\star$-dispersed, hence δ is irrational or is equal to $\frac{a}{b}$ for some co-prime a, b with $a > 2L$.

In the following we develop our rounding procedure that shows the reverse direction. Our presentation aims to be accessible by starting from the core algorithmic idea from which we unravel all involved technical concepts piece by piece. The detailed proofs are placed in the appendix.

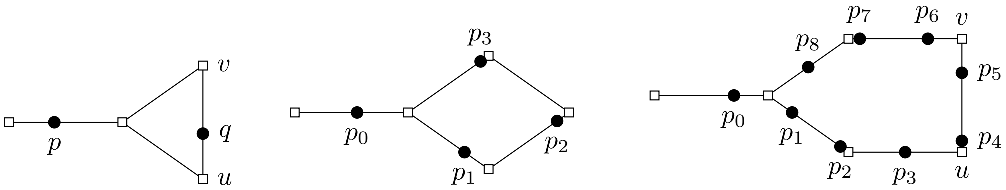

Figure 1 (left) Consider critical points $\{p,q\}$ (points depicted as black dots; vertices as white squares). If we move q away from p by $\varepsilon \geq 0$, their distance increases by ε until q reaches the half-integral point $p(u,v,\frac{1}{2})$. (middle) Let $\{p_i,p_{i-1}\}$ be critical for $i \geq 1$. Consider moving $p_i, i \geq 1$ by $i\varepsilon$ away from p_{i-1}. Once p_2 becomes half-integral, points $\{p_3,p_0\}$ become also critical, hence we cannot continue to move points in the same way. This happens when a point in S becomes half-integral or … (right) … a point half-way between two points in S becomes half-integral, as in this example between p_4,p_5. We say p_4,p_5 *witness* the *pivot* $p(u,v,\frac{1}{2})$.

5.1 Overview

Our rounding procedure repeatedly applies a pushing algorithm to the current point set S. We show that each such step strictly decreases a polynomially bounded potential $\Phi : P(G) \to \mathbb{N}$.

▶ **Theorem 8.** *Suppose that there is an algorithm, that given a δ-dispersed set S with $\delta < \delta^\star$ computes an $\varepsilon > 0$ and a $(\delta+\varepsilon)$-dispersed set S_ε of size $|S_\varepsilon| = |S|$ that satisfies $\Phi(S) > \Phi(S_\varepsilon)$ for some polynomially bounded potential $\Phi : P(G) \to \mathbb{N}$. Then Theorem 7 follows.*

Proof. Let S be a δ-dispersed set. Apply the assumed algorithm to obtain a $\varepsilon > 0$ and a $(\delta+\varepsilon)$-dispersed set S_ε of size $|S_\varepsilon| = |S|$. If $\delta = \delta^\star$, we reached our goal. Else we apply the assumed algorithm again. Since the potential $\Phi : P(G) \to \mathbb{N}$ decreases for S_ε compared to S and Φ is polynomially bounded, we have to reach $\delta^\star$ in polynomial many steps. ◀

In the remainder of this section we will develop such an algorithm. It pushes the points of point set S away from each other such that their pairwise distance increases from "at least δ" to "at least $\delta+\varepsilon$". We choose $\varepsilon \geq 0$ as large as possible limited by some events. Either we already reach $\delta+\varepsilon = \delta^\star$, hence we reached our goal, or at least one of three events occurs. We will specify these events in the course of this section. These events mean that one pushing step, i.e., one step for Theorem 8 terminated. All the following preparations for such a pushing step start anew.

We make sure that our potential $\Phi : P(G) \to \mathbb{N}$ decreases when an event occurs. Each of the three events has a corresponding partial potential $\Phi_1(S)$, $\Phi_2(S)$ and $\Phi_3(S)$. They define the overall potential as $\Phi(S) := \Phi_1(S) + \Phi_2(S) + \Phi_3(S)$. Each part never increases. Whenever event i occurs, $\Phi_i(S)$ strictly decreases.

We denote a pair of points $\{p,q\}$ from our given point set S as δ-*critical*, if they have distance exactly δ. Hence the critical pairs of points are exactly those that we need to push away from each other. At the same time we make sure that, once $\{p,q\}$ are δ-critical, they never turn uncritical again, i.e., they are $(\delta+\varepsilon)$-critical in the next step. An uncritical pair of points $\{p,q\}$ might become critical, hence we have to take care of $\{p,q\}$ in future steps. This constitutes our first event. The corresponding partial potential is $\Phi_1(S)$, the number of uncritical pairs of points $\{p,q\}$.

(Event 1) A δ-uncritical pair of points $\{p,q\}$ becomes $(\delta+\varepsilon)$-critical.

$$\Phi_1(S) \;:=\; \left|\left\{\{p,q\} \in \tbinom{S}{2} \mid \{p,q\} \text{ are not } \delta\text{-critical}\right\}\right| \;\leq\; |S|^2$$

5.2 Coordination of Movement

We need to coordinate the movement of all critical pairs of points. To this end, we will fix some set of *root points* R. Our movement will be locally prescribed for sequences of points $p_0, p_1, \ldots, p_s$ that originate in $p_0 \in R$ and where each $\{p_0, p_1\}, \ldots, \{p_{s-1}, p_s\}$ is critical. The overall movement will be uniquely defined by movement defined for these sequences.

For now, consider such a sequence of points $p_0, p_1, p_2, \ldots$. Our idea is to do not move p_0, to move p_1 by distance ε away from p_0, point p_2 by distance 2ε away from p_1 and so on. We have to stop pushing in this way as soon as one of the points, say p_i, becomes half-integral, i.e., p_i is moved onto a vertex or the midpoint of an edge. See Figure 1 for examples. This constitutes the second event.

(Event 2) A non-half-integral $p \in S$ becomes half-integral.

$$\Phi_2(S) \;\coloneqq\; \big|\{p \in S \mid p \text{ is not half-integral}\}\big| \;\le\; |S|.$$

The next pushing step will choose p_i as one of the root point R and will move the points away from p_i instead of p_0. Very similarly, we stop when a point $r \in P(G)$ that is "half-way" between two points p_i, p_{i-1} becomes half-integral. Formally, we denote such a point r as an (S, δ)-*pivot*, or simply a pivot, if it is half-integral and there is a (critical) pair of points $\{p, q\} \in \binom{S}{2}$, the witnesses, that have equal distances to r, which means $d(p, r) = d(q, r) = \frac{\delta}{2}$. Let $\mathsf{pivots}(S, \delta)$ be the set of (S, δ)-pivots, and let $W(S, \delta) \subseteq \binom{S}{2}$ be the family of pairs of points from S, that witness some (S, δ)-pivot. This leads to the third and final event.

(Event 3) A non-pivot point $r \in P(G)$ becomes a pivot.

$$\Phi_3(S) \;\coloneqq\; \big|\{r \in P(G) \mid r \text{ is half-integral}\} \setminus \mathsf{pivots}(S, \delta)\big| \;\le\; |V(G)|^2.$$

Hence a root point R may not only be a point $p \in S$ but also come from the set of pivots. We will later properly define R as a superset of half-integral points $p_i \in S$ and the (S, δ)-pivots.

We use an *auxiliary graph* G_S for the current δ-dispersed set S. Its vertex set is $S \cup \mathsf{pivots}(S, \delta)$. Essentially we make all pairs of critical $\{p, q\}$ adjacent unless they witness a pivot; If they do witness a pivot, we make them adjacent to the pivot:

- For $\{p, q\} \in W(S, \delta)$ and for every pivot $r \in \mathsf{pivots}(S, \delta)$ they witness, add edges $\{p, r\}, \{r, q\}$; and
- for every critical pair of points $\{p, q\} \in \binom{S}{2} \setminus W(S, \delta)$ add edge $\{p, q\}$.

Note that, for every edge $\{r, p\}$ with $r \in \mathsf{pivots}(S, \delta)$, there is at least one other edge $\{r, q\}$ such that p, q witness r as a pivot.

Now we define the sequence of points which serve as the structure to state the movement. A path $P = (p_0, p_1, \ldots, p_s)$ in the auxiliary graph G_S of length $s \ge 1$ is a *spine* if $p_1, \ldots, p_s$ are not half-integral. Note that any sub-sequence $(p_0, \ldots, p_i)$ for $1 \le i \le s$ is also a spine.

5.3 Velocities

We assign velocities vel_P to the points $p_0, \ldots, p_s$ of a spine P that specify their movement speed. The point p_i for $i \in \{1, \ldots, s\}$ is moved by $\mathsf{vel}(p_i)\varepsilon$. Thus setting $\mathsf{vel}(p_1) = 1$ makes the δ-critical $\{p_0, p_1\}$ become $(\delta + \varepsilon)$-critical, as desired. Setting $\mathsf{vel}(p_i) = i$ for $i \ge 1$, however, can make consecutive points $\{p_{i-1}, p_i\}$ uncritical. Figure 2 provides an example. To see this, fix some shortest p_{i-1}, p_i-path P_i and some shortest p_i, p_{i+1}-path P_{i+1}. The paths P_i and P_{i+1} can have a trivial intersection of only $\{p_i\}$ or their intersection may contain more than one point. We denote this bit of information as $\mathsf{flip}_P(p_i) \in \{-1, 1\}$. We set $\mathsf{flip}_P(p_i) = 1$

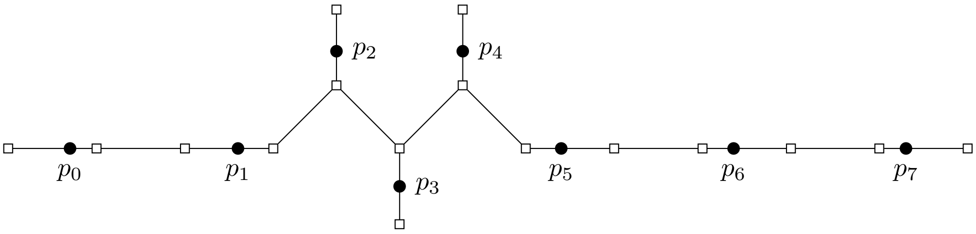

Figure 2 A spine $P = (p_0, \dots, p_7)$. The shortest path between p_0, p_1 and the shortest path between p_1, p_2 have the trivial intersection of $\{p_1\}$, hence $\mathsf{flip}_P(p_1) = 1$. In turn, the shortest path between p_1, p_2 and the shortest path between p_2, p_3 have a non-trivial intersection, hence $\mathsf{flip}_P(p_1) = -1$. Also $\mathsf{flip}_P(p_3) = \mathsf{flip}_P(p_4) = -1$ while the other values are positive. Consequently $(\mathsf{sgn}_P(p_1), \dots, \mathsf{sgn}_P(p_7)) = (1, 1, -1, 1, -1, -1, -1)$. Thus $(\mathsf{vel}_P(p_1), \dots, \mathsf{vel}_P(p_7)) = (1, 2, 1, 2, 1, 0, -1)$. In particular, $\mathsf{sgn}_P(p_5)$ is negative such that it is moved towards p_4. In turn, $\mathsf{sgn}_P(p_7)$ and $\mathsf{vel}_P(p_7)$ are negative such that p_7 has a net movement away from p_0. Under this movement all $\{p_0, p_1\}, \dots, \{p_6, p_7\}$ remain critical.

if and only if the path P_i and P_{i-1} have a trivial intersection. (The definition of flip_P is independent on the exact considered shortest paths and we will define it properly in the next subsection.)

The easy case is when P_i and P_{i+1} have a trivial intersection, i.e., $\mathsf{flip}_P(p_i) = 1$. Then we increase the velocity of the next point p_{i+1}. The first time we encounter the other case, that $\mathsf{flip}_P(p_i) = -1$, we decrease the velocity of the next point p_{i+1}. Further we move p_{i+1} *towards* and not away of p_i. Hence we also specify a sgn of the velocity that records whether a point p_{i+1} is pushed towards or away from its predecessor p_i. All these changes are relative to whether the movement of predecessor p_i is away from p_{i-1}, i.e., whether $\mathsf{sgn}(p_i)$ is positive. For example, the second time we encounter a point p_j with $\mathsf{flip}_P(p_j) = -1$, point p_{j+1} is again moved away from its predecessor.

This leads to the following definition of vel_P and sgn_P for a spine P. We define its half-integral *velocities* $\mathsf{vel}_P : \{p_0, \dots, p_s\} \to \{\frac{z}{2} \mid z \in \mathbb{Z}\}$ depending on *signs* $\mathsf{sgn}_P : \{p_1, \dots, p_s\} \to \{-1, 1\}$, which in turn depend on flip_P. We may drop the subscript P, if it is clear from the context. Let $\mathsf{vel}(p_0) = 0$. Let $\mathsf{vel}(p_1) = \frac{1}{2}$, if $p_0 \in \mathsf{pivots}(S, \delta)$, and let $\mathsf{vel}(p_1) = 1$, if $p_0 \in S$. For $i \geq 1$, let

$$\mathsf{vel}(p_{i+1}) \;\coloneqq\; \mathsf{vel}(p_i) + \mathsf{sgn}(p_{i+1}).$$

Thus $\mathsf{sgn} \in \{-1, 1\}$ indicates whether the velocity increases or decreases. The current sgn is unchanged unless flip is negative. Let $\mathsf{sgn}(p_1) = 1$. For $2 \leq i \leq s$, let

$$\mathsf{sgn}(p_i) \;\coloneqq\; \mathsf{flip}(p_{i-1})\,\mathsf{sgn}(p_{i-1}) \;=\; \prod_{0<j<i} \mathsf{flip}(p_j).$$

The movement step of a point p_i in a spine $P = (p_0, \dots, p_i)$ is now as follows. We push the point p_i by the (possibly negative) distance $\mathsf{sgn}_P(p_i)\,\mathsf{vel}_P(p_i)\varepsilon$ away from its predecessor p_{i-1}. In other words, the point $p_i = p(u, v, \lambda)$ is replaced by the point $p(u, v, \lambda + \mathsf{sgn}_P(p_i)\,\mathsf{vel}_P(p_i)\varepsilon)$ assuming that vertex u compared to v is in some sense closer to the predecessor point p_{i-1}. We make this notion formal in the next subsection.

5.4 Directions

We formalize the notion the direction of a point p towards another point q. The *direction* $\mathsf{dir}(p \to q) \in \{u, v\}$ for distinct points $p = p(u, v, \lambda) \in P(G)$ and $q \in P(G)$ is defined as follows:

- For points $p = p(u, v, \lambda_p)$ and $q = p(u, v, \lambda_q)$ on a common edge $\{u, v\} \in E(G)$ with $\lambda_p < \lambda_q$, let $\mathsf{dir}(p \to q) = v$. Let $\overline{\mathsf{dir}}(p \to q) = u$.
- For points $p = p(u_p, v_p, \lambda_p)$ and $q = p(u_q, v_q, \lambda_q)$ on distinct edges $\{u_p, v_p\} \neq \{u_q, v_q\}$, let $\mathsf{dir}(p \to q)$ be the unique vertex of $\{u_p, v_p\}$ that is contained in *every* shortest path between p and q, if such a vertex exists. If $\mathsf{dir}(p \to q)$ is defined, let $\overline{\mathsf{dir}}(p \to q)$ be the unique vertex in $\{u_p, v_p\} \setminus \{\mathsf{dir}(p \to q)\}$.

▶ **Lemma 9.** ($\star$) *For distinct points $p, q \in V(G_S)$, $\mathsf{dir}(p \to q)$ is well-defined, unless p is half-integral.*

Hence we can properly define $\mathsf{flip}(p_i)$ of a point p_i of a spine $(p_0, \ldots, p_s)$ with $1 \leq i \leq s-1$, since p_i with $i \geq 1$ is non-half-integral. Let

$$\mathsf{flip}(p_i) := \begin{cases} 1, & \mathsf{dir}(p_i \to p_{i-1}) \neq \mathsf{dir}(p_i \to p_{i+1}), \\ -1, & \text{else.} \end{cases}$$

Further, for a non-half-integral point $p = p(u, v, \lambda)$ we have $\{u, v\} = \{\mathsf{dir}(p \to q), \overline{\mathsf{dir}}(p \to q)\}$. By symmetry assume that $\overline{\mathsf{dir}}(p \to q) = u$. We can equivalently specify point p as $p(\overline{\mathsf{dir}}(p \to q), \mathsf{dir}(p \to q), \lambda)$. Conveniently, we may write $p = p(\cdot, \overline{\mathsf{dir}}(p \to q), \lambda)$ since the missing entry is clear from the context. Doing so, the edge position λ measures a part of the length of any shortest p, q-path, specifically the part using the edge of p (assuming q is on another edge).

Now we can also properly define one pushing step for a point p_i of a spine $P = (p_0, \ldots, p_s)$ and for $\varepsilon > 0$. Let λ_i be such that $p_i = p(\cdot, \overline{\mathsf{dir}}(p_i \to p_{i-1}), \lambda_i)$. Then the new point is

$$(p_i)_{P,\varepsilon} := p\big(\cdot,\ \overline{\mathsf{dir}}(p_i \to p_{i-1}),\ \lambda_i + \mathsf{sgn}_P(p_i)\,\mathsf{vel}_P(p_i)\varepsilon\big).$$

▶ **Lemma 10.** ($\star$) *For a spine $P = (p_0, \ldots, p_s)$ and $i \in \{0, \ldots, s-1\}$, points $(p_i)_{P,\varepsilon}, (p_{i+1})_{P,\varepsilon}$ are $(\delta + \varepsilon)$-critical for the maximal $\varepsilon \leq \delta^\star - \delta$ that is limited by the Events 1,2,3.*

5.5 Root Points

We formally define the set of root points R. Let R_0 be the set of half-integral points in G_S. There may be some components of the auxiliary graph G_S without a point in R_0. Let R result from R_0 by adding exactly one point from every component that has no point in R_0.

We consider only spines $P = (p_0, \ldots, p_i)$ where $p_0 \in R$. Clearly every point G_S is part of at least one spine and hence has some movement prescribed. We also claim that the prescribed movement is uniquely defined. In other words, there are no spines $P = (p_0, \ldots, p_i)$ and $Q = (q_0, \ldots, q_j)$ with $p_0, q_0 \in R$ that terminate at the same point $p_i = q_j$ and contradict in their prescribed movement for $p_i = q_j$.

▶ **Lemma 11.** ($\star$) *Let $\delta < \delta^\star$. Consider spines $P = (p_0, \ldots, p_i)$ and $Q = (q_0, \ldots, q_j)$ with $p_0, q_0 \in R$ and $p_i = q_j$. Then (1) $\mathsf{vel}_P(p_i) = \mathsf{vel}_Q(q_j)$; and (2) $\overline{\mathsf{dir}}(p_i \to p_{i-1}) = \overline{\mathsf{dir}}(q_j \to q_{j-1})$ if and only if $\mathsf{sgn}_P(p_i) = \mathsf{sgn}_Q(q_j)$.*

Therefore we can uniquely define the moved version of a point p as $p_\varepsilon := (p)_{P,\varepsilon}$ where we may choose P to be an arbitrary spine starting in R and containing p. This defines the set of pushed points $S_\varepsilon := \{\, p_\varepsilon \mid p \in S \,\}$.

For the proof of Lemma 11, we use that $\delta^\star = \frac{a^\star}{b^\star} \geq \delta$ is minimal with $a^\star \leq 2L$. Since spines P, Q meet at the point $p_i = q_j$ their roots p_0, q_0 must be from the same component in the auxiliary graph G_S; in other words p_0, q_0 are both half-integral or are the same point.

Our proof by contradiction considers these two options and whether P, Q reach p_i and q_j from the same vertex relatively to if they agree on the sgn of $p_i = q_j$. An example is that $p_0 = q_0$ and P, Q reach $p_i = q_j$ from the same vertex (formally with $\overline{\mathsf{dir}}(p_i \to p_{i-1}) \neq \overline{\mathsf{dir}}(q_j \to q_{j-1})$) while they agree on the sgn (formally $\mathsf{sgn}_P(p_i) = \mathsf{sgn}_Q(q_j)$). Then we can glue P and Q together forming a walk starting in $p_0 = q_0$ and returning to $p_0 = q_0$. This walk then has half-integral length at most $2L$ but is made up of hops of length δ. That implies the contradiction that already $\delta = \delta^\star$.

5.6 Summery

With the previous observations we can assemble the algorithm for Theorem 8. Our potential counts how many elements can still trigger Events 1,2,3. That is

$$\Phi(S) \;:=\; \Phi_1(S) + \Phi_2(S) + \Phi_3(S) \;\leq\; 2|S|^2 + |V(G)|^2.$$

We define $\varepsilon^\star \geq 0$ as the maximal $\varepsilon \leq \delta^\star - \delta$ limited by the Events 1,2,3. We claim that $\varepsilon^\star \geq 0$ is defined. This is due to that the above events depend on continuous functions in ε, which are the distance of p_ε to its closest half-integral point, and the distance between points p_ε and q_ε for $p, q \in S$.

To show termination, we prove that no such element can trigger its according event more than once. Lemma 10 already implies that a δ-critical pair of points $\{p, q\}$ stays $(\delta + \varepsilon^\star)$-critical. It remains to show the following monotonicities:

▶ **Lemma 12.** ($\star$) *Let S be a δ-dispersed set for $\delta < \delta^\star$ and $\varepsilon^\star$ defined as above. Then:*

- (1) *$S_{\varepsilon^\star}$ is a $(\delta + \varepsilon^\star)$-dispersed set of size $|S|$.*
- (2) *If $\{p, q\} \in \binom{S}{2}$ is δ-critical, then $\{p_{\varepsilon^\star}, q_{\varepsilon^\star}\}$ is $(\delta + \varepsilon^\star)$-critical.*
- (3) *If $r \in \mathsf{pivots}(S, \delta)$, then $r \in \mathsf{pivots}(S_{\varepsilon^\star}, \delta + \varepsilon^\star)$.*

Now we have all the tools to show Theorem 8. Determine $\varepsilon^\star$ and the $(\delta + \varepsilon^\star)$-dispersed set $S_{\varepsilon^\star}$ as defined before. The resulting set $S_{\varepsilon^\star}$ is a $(\delta + \varepsilon^\star)$-dispersed set of the same size, according to Lemma 12. If $\delta + \varepsilon^\star = \delta^\star$ then $S_{\varepsilon^\star}$ is already the desired $\delta^\star$-dispersed set. Else one of the Events 1,2,3 occurred. We observe that the potential strictly decreases, that is $\Phi(S_{\varepsilon^\star}) < \Phi(S)$. Because of the monotonicities of Lemma 10 and Lemma 12 the partial potentials Φ_1, Φ_2 and Φ_3 do not increase. If Event 1 occurs then Φ_1 strictly decreases. If Event 2 occurs then Φ_2 strictly decreases. If Event 3 occurs then Φ_3 strictly decreases. All in all at least one part strictly decreases and so does Φ. This completes the proof of Theorem 8 and hence of Theorem 7.

6 Algorithmic Implications

Based on the rounding procedure from Section 5, the translation result from Section 3 and connections to distance-d independent set we derive a number of algorithmic results.

▶ **Theorem 13.** *There is an algorithm that, given distance $\delta \geq 0$, a graph G, a tree decomposition and an upper bound $L \in \mathbb{N}$ on the length of the longest path in G, computes a maximum δ-dispersed set S in time $(2L)^{\mathsf{tw}(G)} n^{\mathcal{O}(1)}$.*

Proof. According to Theorem 7, we may consider the rounded up distance, that is a rational $\frac{a}{b} \geq \delta$ with $a \leq 2L$, instead of δ. Notice that $\frac{a}{b}$ is polynomial time computable. As long as $\frac{a}{b} \leq \frac{3}{4}$, we may repeatedly apply Corollary 4 such that eventually we obtain that $\frac{3}{4}b < a \leq 2L$. Let G_{2b} be a $2b$-subdivision of G. Observe that $\mathsf{tw}(G) = \mathsf{tw}(G_{2b})$ and the number of vertices increases only by a factor of $\mathcal{O}(n^2L)$. According to Lemma 5 $\frac{a}{b}$-disp$(G) = \alpha_{2a}(G_{2b})$. Thus, to answer the original δ-Dispersion-instance we may find a maximum distance-$2a$ independent set in G_{2b}, which is possible in time $(2a)^{\mathsf{tw}(G)}n^{\mathcal{O}(1)}$, according to [12]. ◀

This result immediately yields parameterized complexity results for the parameters treedepth and treewidth. Regarding the treewidth, note that n is an upper bound on L. Thus the above algorithm is an XP-algorithm for the parameter treewidth. When a treewidth decomposition is given, Dispersion can be solved in time $2n^{\mathsf{tw}(G)}n^{\mathcal{O}(1)}$.

▶ **Corollary 14.** *Dispersion can be solved in time $2n^{\mathsf{tw}(G)}n^{\mathcal{O}(1)}$, assuming a tree decomposition is given.*

Similarly we obtain an FPT algorithm for treedepth $\mathsf{td}(G)$ of the input graph. The treedepth $\mathsf{td}(G)$ implies a bound on L, which is $L \leq 2^{\mathsf{td}(G)}$. Since also $\mathsf{td}(G) \geq \mathsf{tw}(G)$, we obtain an $2^{\mathcal{O}(\mathsf{td}(G)^2)}n^{\mathcal{O}(1)}$-time algorithm, assuming a treedepth decomposition is given.

▶ **Corollary 15.** *Dispersion can be solved in time $2^{\mathcal{O}(\mathsf{td}(G)^2)}n^{\mathcal{O}(1)}$, assuming a treedepth decomposition is given.*

7 Parameterized Hardness Results

We complement the positive results by hardness results. These results borrow ideas from hardness-reductions for the similar problem Distance Independent Set (DIS), see Section 4.

A natural generalization of treedepth is the maximum diameter of graph G, which is the maximum distance between any vertices $u, v \in V(G)$ (since we only consider connected graphs G). We show NP-hardness for graphs of any diameter ≥ 3 even for chordal graphs by a reduction from Independent Set, similarly as NP-hardness for DIS is shown by Eto et al. [5]. Our reduction also shows W[1]-hardness with respect to the solution size k.

▶ **Lemma 16.** ($\star$) *For every $\delta > 3$, δ-Dispersion is NP-complete and W[1]-hard with parameter solution size, even for connected chordal graphs of diameter $\leq \lceil\delta\rceil$.*

Another direct generalization of treedepth is pathwidth of the input graph G. We show W[1]-hardness even for the combined parameters pathwidth and solution size $\mathsf{pw}(G) + k$. With the same reduction also W[1]-hardness for the combined parameters "feedback vertex set size" $\mathsf{fvs}(G)$ and solution size k follows. We can essentially use the same reduction as used by Katsikarelis et al. to show W[1]-hardness of DIS when parameterized by $\mathsf{fvs}(G) + k$ by reducing from Multi-Colored-Independent-Set [12].

▶ **Theorem 17.** ($\star$) *Dispersion is W[1]-hard parameterized by $\mathsf{pw}(G)+k$. Further, there is no $n^{o(\sqrt{\mathsf{pw}(G)}+\sqrt{k})}$-time algorithm unless ETH fails. Dispersion is W[1]-hard parameterized by $\mathsf{fvs}(G) + k$. Further, there is no $n^{o(\mathsf{fvs}(G)+\sqrt{k})}$-time algorithm unless ETH fails.*

Since $\mathsf{fvs}(G)$ is a linear upper bound for the treewidth of G, we also obtain: Dispersion is W[1]-hard parameterized by $\mathsf{tw}(G) + k$. Further, there is no $n^{o(\mathsf{tw}(G)+\sqrt{k})}$-time algorithm unless ETH fails. Similarly as in [12] we obtain a lower bound for treedepth.

▶ **Theorem 18.** ($\star$) *Assuming ETH, there is no $2^{o(\mathsf{td}(G)^2)}$-time algorithm for Dispersion.*

8 NP-hardness for Irrational Distance

We show NP-hardness of δ-Dispersion for every irrational distance $\delta > 0$. Thus together with earlier results [8] the complexity for every real $\delta > 0$ is resolved: For rational distance $\delta = \frac{a}{b}$ where $a \in \{1, 2\}$ the problem is polynomial time solvable, while it is NP-complete for every other distance $\delta > 0$.

▶ **Theorem 19.** *For every irrational $\delta > 0$, δ-Dispersion is NP-complete.*

The key step is a reduction from Independent Set which shows NP-hardness not only for a single distance δ but for the whole interval $\delta \in (2, 3]$.

Construction. Given a graph G and integer $k \in \mathbb{N}$, we construct an input for δ-Dispersion consisting of a graph G' and integer $k' = k$ as follows. For every vertex $u \in V(G)$ introduce vertices u_1, u_2 and edge $\{u_1, u_2\}$. For every edge $\{u, v\} \in E(G)$ introduce edges $\{u_i, v_j\}$ for every $i, j \in \{1, 2\}$.

▶ **Lemma 20.** *For every $\delta \in (2, 3]$, δ-Dispersion is NP-hard and W[1]-hard when parameterized by solution size.*

Proof. Clearly, this construction is polynomial time computable. Further, the reduction is parameter preserving such that W[1]-hardness of Independent Set implies W[1]-hardness of Dispersion, assuming correctness of the reduction.

Hence, it remains to show the correctness, that G has an independent set of size k if and only if G' has a δ-dispersed set of size k.

($\Rightarrow$) Let $I \subseteq V(G)$ be an independent set of graph G. We define $S := \{p(u_1, u_2, \frac{1}{2}) \mid u \in I\} \subseteq P(G)$, which has size $|S| = |I|$. We claim that S is δ-dispersed in G' for $\delta \in (2, 3]$. Since any vertices $u, v \in V(G)$ have distance at least 2 in G, their corresponding points $p(u_1, u_2, \frac{1}{2})$ and $p(v_1, v_2, \frac{1}{2})$ have distance at least 3 in $P(G)$. Thus they are δ-dispersed for $\delta \in (2, 3]$.

($\Leftarrow$) Let $S \subseteq P(G)$ be a δ-dispersed set for some $\delta \in (2, 3]$. We define the *ball* B_u for $u \in V(G)$ as the points in $P(G)$ with distance at most $\frac{1}{2}$ to u_1 or u_2, which is $B_u := \{p(u_i, v, \lambda) \mid i \in \{1, 2\}, \{u_i, v\} \in E(G'), \lambda \in [0, \frac{1}{2}]\}$. Every ball B_u for $u \in V(G)$ contains at most one point from S since points $p, q \in B_u$ can be at most $2 < \delta$ apart. Every union $B_u \cup B_v$ for adjacent $\{u, v\} \in E(G)$ contains at most one point from S since points $p, q \in B_u \cup B_v$ can also be at most $2 < \delta$ apart.

Now we define an independent set $I \subseteq V(G)$. Add vertex $u \in V(G)$ for every point $p \in S \cap B_u$ except when $p \in B_u \cap B_v$ for some $v \in P(G)$. If $p \in S \cap B_u \cap B_v$, add either the point u or v to I. Then $|I| = |S|$ since the union of B_u for $u \in V(G)$ is the whole point space $P(G)$. Further, no adjacent vertices u, v are in I since $B_u \cup B_v$ contain at most one point from S. Thus $I \subseteq V(G)$ is an independent set of size $|S|$. ◀

Because $\delta \le 3$ we may apply Lemma 3 to obtain NP-hardness for δ in the interval $(\frac{2}{2x+1}, \frac{3}{3x+1}]$ for every integer $x \ge 0$. Applying Lemma 1 yields NP-hardness for δ in the interval $(\frac{2c}{2x+1}, \frac{3c}{3x+1}]$ for every integer $c \ge 1$.

Now, consider any irrational distance $\delta > 0$. Consider $F := \{c\delta^{-1} - \lfloor c\delta^{-1} \rfloor \mid c \ge 1\}$, the set of fractional parts of multiples of δ^{-1}. Since δ^{-1} is irrational, F is a dense subset of the interval $[0, 1]$. Let integer $c \ge 1$ be such that $\frac{1}{3} \le c\delta^{-1} - \lfloor c\delta^{-1} \rfloor < \frac{1}{2}$. Thus there is a non-negative x such that $x + \frac{1}{3} \le c\delta^{-1} < x + \frac{1}{2}$. This implies that $\frac{2c}{2x+1} < \delta \le \frac{3c}{3x+1}$ and hence NP-hardness for δ-dispersion. This finishes the proof of Theorem 19.

9 Parameter Solution Size

δ-Dispersion parameterized by the solution size k is W[1]-hard when $\delta > 2$: When $\delta \in (2, 3]$ Lemma 20 shows W[1]-hardness, while for $\delta > 3$ Lemma 16 implies W[1]-hardness even when the input graph is chordal. It remains to consider $\delta \leq 2$. Observe that for $\delta \leq 2$, every graph G satisfies $\delta\text{-disp}(G) \geq \nu(G)$ [8], where $\nu(G)$ is the maximum matching size of G. Thus, a win-win situation occurs. Determine $\nu(G)$ in polynomial time. If $k \leq \nu(G)$, we may immediately answer "yes". Otherwise $k > \nu(G) \geq \frac{\mathsf{vc}(G)}{2}$, where $\mathsf{vc}(G)$ is the minimum size of a vertex cover in G. The size of a vertex cover upper bounds the treedepth. A treedepth decomposition of size $\mathsf{td}(G)$ is computable in FPT-time [15]. Thus we may apply the FPT algorithm for parameter treedepth from Theorem 13.

▶ **Theorem 21.** *δ-Dispersion parameterized by solution size k is FPT if $\delta \leq 2$; and $W[1]$-hard if $\delta > 2$.*

On the Binary and Boolean Rank of Regular Matrices

Abstract

A $0,1$ matrix is said to be regular if all of its rows and columns have the same number of ones. We prove that for infinitely many integers k, there exists a square regular $0,1$ matrix with binary rank k, such that the Boolean rank of its complement is $k^{\widetilde{\Omega}(\log k)}$. Equivalently, the ones in the matrix can be partitioned into k combinatorial rectangles, whereas the number of rectangles needed for any cover of its zeros is $k^{\widetilde{\Omega}(\log k)}$. This settles, in a strong form, a question of Pullman (Linear Algebra Appl., 1988) and a conjecture of Hefner, Henson, Lundgren, and Maybee (Congr. Numer., 1990). The result can be viewed as a regular analogue of a recent result of Balodis, Ben-David, Göös, Jain, and Kothari (FOCS, 2021), motivated by the clique vs. independent set problem in communication complexity and by the (disproved) Alon-Saks-Seymour conjecture in graph theory. As an application of the produced regular matrices, we obtain regular counterexamples to the Alon-Saks-Seymour conjecture and prove that for infinitely many integers k, there exists a regular graph with biclique partition number k and chromatic number $k^{\widetilde{\Omega}(\log k)}$.

1 Introduction

For a $0,1$ matrix M of dimensions $n \times m$, consider the following three notions of rank.

- The (standard) *rank* of M over $\mathbb{R}$, denoted by $\mathrm{rank}_{\mathbb{R}}(M)$, is the minimal k for which there exist real matrices A and B of dimensions $n \times k$ and $k \times m$ respectively, such that $M = A \cdot B$ where the operations are over $\mathbb{R}$.
- The *binary rank* of M, denoted by $\mathrm{rank}_{\mathrm{bin}}(M)$, is the minimal k for which there exist $0,1$ matrices A and B of dimensions $n \times k$ and $k \times m$ respectively, such that $M = A \cdot B$ where the operations are over $\mathbb{R}$. Equivalently, $\mathrm{rank}_{\mathrm{bin}}(M)$ is the smallest number of monochromatic combinatorial rectangles in a *partition* of the ones in M.
- The *Boolean rank* of M, denoted by $\mathrm{rank}_{\mathbb{B}}(M)$, is the minimal k for which there exist $0,1$ matrices A and B of dimensions $n \times k$ and $k \times m$ respectively, such that $M = A \cdot B$ where the operations are under Boolean arithmetic (namely, $0+x = x+0 = x$, $1+1 = 1 \cdot 1 = 1$, and $x \cdot 0 = 0 \cdot x = 0$). Equivalently, $\mathrm{rank}_{\mathbb{B}}(M)$ is the smallest number of monochromatic combinatorial rectangles in a *cover* of the ones in M.

Note that every $0,1$ matrix M satisfies $\mathrm{rank}_{\mathrm{bin}}(M) \geq \mathrm{rank}_{\mathbb{R}}(M)$ and $\mathrm{rank}_{\mathrm{bin}}(M) \geq \mathrm{rank}_{\mathbb{B}}(M)$.

The above notions of rank play a central role in the area of communication complexity, introduced in 1979 by Yao [31]. In the communication problem associated with a $0,1$ matrix M of dimensions $n \times m$, one player holds a row index $i \in [n]$ and another player holds a column index $j \in [m]$, and their goal is to decide whether $M_{i,j} = 1$ while minimizing the worst-case number of communicated bits. For the deterministic setting, the well-known log-rank conjecture of Lovász and Saks [24] suggests that the communication complexity of the problem is polynomially related to $\log_2 \text{rank}_{\mathbb{R}}(M)$ (see, e.g., [25]). For the non-deterministic setting, it is not difficult to see that the minimum number of bits that should be communicated is precisely $\lceil \log_2 \text{rank}_{\mathbb{B}}(M) \rceil$. For the *unambiguous* non-deterministic setting, where each input is required to have at most one accepting computation, the minimum number of bits that should be communicated is precisely $\lceil \log_2 \text{rank}_{\text{bin}}(M) \rceil$.

For a $0,1$ matrix M, let $\overline{M}$ denote the complement matrix obtained from M by replacing the ones by zeros and the zeros by ones. A result of Yannakakis [30] implies that every $0,1$ matrix M with $\text{rank}_{\text{bin}}(M) = k$ satisfies

$$\text{rank}_{\mathbb{B}}(\overline{M}) \leq \text{rank}_{\text{bin}}(\overline{M}) \leq k^{O(\log k)}. \tag{1}$$

The challenge of determining the largest possible value of $\text{rank}_{\mathbb{B}}(\overline{M})$ for a $0,1$ matrix M with $\text{rank}_{\text{bin}}(M) = k$ has attracted intensive attention in the literature, mostly with the equivalent formulation of the clique vs. independent set problem introduced in [30] (see [20, Chapter 4.4]). The first non-trivial bound was given by Huang and Sudakov [19] who provided, building on a construction of Razborov [28], a family of such matrices M satisfying $\text{rank}_{\mathbb{B}}(\overline{M}) \geq \Omega(k^{6/5})$ (see [11] for extended constructions). The constant $6/5$ in the exponent was improved to $3/2$ by Amano [1] and then to 2 by Shigeta and Amano [29]. The first super-polynomial separation was obtained by Göös [13], who provided a family of such matrices M satisfying $\text{rank}_{\mathbb{B}}(\overline{M}) \geq k^{\Omega(\log^{0.128} k)}$. This was then improved in a work of Ben-David, Hatami, and Tal [3] to $\text{rank}_{\mathbb{B}}(\overline{M}) \geq k^{\Omega(\log^{0.22} k)}$. In a recent breakthrough, it was shown by Balodis, Ben-David, Göös, Jain, and Kothari [2] that the bound can be further improved to $\text{rank}_{\mathbb{B}}(\overline{M}) \geq k^{\widetilde{\Omega}(\log k)}$, which matches the upper bound in (1) up to $\log \log k$ factors hidden in the $\widetilde{\Omega}$ notation. Note that the result of [2] strengthens an earlier result of Göös, Pitassi, and Watson [15], who provided a near optimal separation between the binary rank of a $0,1$ matrix and the deterministic communication complexity of the problem associated with it.

Interestingly, the above problem is closely related to a graph-theoretic problem proposed by Alon, Saks, and Seymour in 1991 (see [21]). For a graph G, let $\chi(G)$ denote its chromatic number, and let $\text{bp}(G)$ denote its biclique partition number, that is, the smallest number of edge-disjoint bicliques (i.e., complete bipartite graphs) needed for a partition of the edge set of G. A classic result of Graham and Pollak [16] asserts that the complete graph K_n on n vertices satisfies $\text{bp}(K_n) = n - 1$. Inspired by this result, Alon, Saks, and Seymour conjectured that every graph G satisfies $\text{bp}(G) \geq \chi(G) - 1$. The conjecture was disproved by Huang and Sudakov in [19], where it was shown that for infinitely many integers k there exists a graph G satisfying $\text{bp}(G) = k$ and $\chi(G) \geq \Omega(k^{6/5})$. These graphs were used there to derive the aforementioned separation between $\text{rank}_{\text{bin}}(M)$ and $\text{rank}_{\mathbb{B}}(\overline{M})$ for $0,1$ matrices M (see [19, Section 4]). In a work of Bousquet, Lagoutte, and Thomassé [6], the two problems were shown to be essentially equivalent, allowing the authors of [2] to derive, for infinitely many integers k, the existence of a graph G satisfying $\text{bp}(G) = k$ and $\chi(G) \geq k^{\widetilde{\Omega}(\log k)}$. As in the matrix setting, the gap is optimal up to $\log \log k$ factors in the exponent.

A $0,1$ matrix M is said to be *d-regular* if every row and every column in M has precisely d ones. In 1986, Brualdi, Manber, and Ross [7] proved that for every d-regular $0,1$ matrix M of dimensions $n \times n$ where $0 < d < n$, the rank of M over the reals is equal to that of its complement, that is, $\text{rank}_{\mathbb{R}}(M) = \text{rank}_{\mathbb{R}}(\overline{M})$. Following their work, Pullman [27] asked in 1988 whether every such matrix M satisfies $\text{rank}_{\text{bin}}(M) = \text{rank}_{\text{bin}}(\overline{M})$. In 1990, Hefner, Henson, Lundgren, and Maybee [18] conjectured that the answer to this question is negative (see [18, Conjecture 3.2]). The question was asked again in 1995 in a survey by Monson, Pullman, and Rees [26] (see [26, Open problem 7.1]).[1] Note that for the Boolean rank, such a statement does not hold in general. For example, the 1-regular identity matrix I_n satisfies $\text{rank}_{\mathbb{B}}(I_n) = n$ and yet $\text{rank}_{\mathbb{B}}(\overline{I_n}) = (1 + o(1)) \cdot \log_2 n$ (see [12]).

1.1 Our Contribution

The current work aims to determine the largest possible gap between the binary rank of *regular* 0, 1 matrices and the Boolean rank of their complement. Our main result is the following.

▶ **Theorem 1.** *For infinitely many integers k, there exists a square regular 0, 1 matrix M satisfying $\text{rank}_{\text{bin}}(M) = k$ and $\text{rank}_{\mathbb{B}}(\overline{M}) \geq k^{\widetilde{\Omega}(\log k)}$.*

Theorem 1 can be viewed as a regular analogue of the aforementioned result of Balodis et al. [2], showing that their near optimal separation between $\text{rank}_{\text{bin}}(M)$ and $\text{rank}_{\mathbb{B}}(\overline{M})$ can also be attained by regular matrices M. Since every 0, 1 matrix M satisfies $\text{rank}_{\text{bin}}(\overline{M}) \geq \text{rank}_{\mathbb{B}}(\overline{M})$, Theorem 1 settles, in a strong form, the question of Pullman asked in [27, 26] (and the variants of the question mentioned there) and confirms the conjecture of Hefner et al. [18]. We remark that regular matrices M with $\text{rank}_{\mathbb{B}}(\overline{M})$ larger than $\text{rank}_{\text{bin}}(M)$ can also be derived from [19] (see Section 1.2 for details). While these matrices are sufficient to answer the original question of [27, 26], they only achieve a polynomial gap between the quantities.

The proof of Theorem 1 relies on a modification of the construction of [2] to the regular setting. It involves an extension of the query-to-communication lifting theorem in non-deterministic communication complexity proved by Göös, Lovett, Meka, Watson, and Zuckerman [14], as well as a two-source extractor studied by Bouda, Pivoluska, and Plesch [4] and by Kothari, Meka, and Raghavendra [22]. For an overview of the proof, see Section 1.2.

As alluded to before, matrices M with $\text{rank}_{\text{bin}}(M)$ much smaller than $\text{rank}_{\mathbb{B}}(\overline{M})$ are known to imply graphs G with $\text{bp}(G)$ much smaller than $\chi(G)$, and thus yield counterexamples to the Alon-Saks-Seymour conjecture (see [6]). Although the conjecture is false in general, it is of interest to identify classes of graphs that satisfy a polynomial version of the conjecture. In particular, it was asked in [2] whether the chromatic number of perfect graphs is polynomially upper bounded in terms of their biclique partition number (see [30] for a related question; see also [23, 5, 10]). As an application of Theorem 1, we show that this is not the case for the class of regular graphs. Namely, we show that the near optimal separation achieved in [2] between the biclique partition number and the chromatic number can also be attained by regular graphs.

▶ **Theorem 2.** *For infinitely many integers k, there exists a simple regular graph G satisfying $\text{bp}(G) = k$ and $\chi(G) \geq k^{\widetilde{\Omega}(\log k)}$.*

1.2 Overview of Proofs

Our goal is to obtain regular 0, 1 matrices M for which the binary rank of M is much smaller than the Boolean rank of $\overline{M}$. We first observe that a polynomial gap between the two quantities, for a regular matrix, can be derived from a construction of Huang and

[1] The question of [27, 18, 26] was originally formulated using the notion of *non-negative integer rank*, which coincides with the binary rank for 0, 1 matrices (see, e.g., [17, Lemma 2.1]).

Sudakov [19]. Indeed, it can be verified that the (simple) graphs G given in [19], which satisfy $\mathrm{bp}(G) = k$ and $\chi(G) \geq \Omega(k^{6/5})$, are regular, hence their adjacency matrices are regular as well. The following simple claim implies that these adjacency matrices achieve a polynomial gap between the binary rank and the Boolean rank of the complement.

▷ Claim 3. For every simple graph G, the adjacency matrix M of G satisfies that $\mathrm{rank_{bin}}(M) \leq 2 \cdot \mathrm{bp}(G)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M}) \geq \chi(G)$.

Proof. For a simple graph G on the vertex set $[n]$, put $k = \mathrm{bp}(G)$, and consider the k bipartitions $(A_1, B_1), \ldots, (A_k, B_k)$ of the k edge-disjoint bicliques that form a partition of the edge set of G. Observe that for every $i \in [k]$, the sets $A_i \times B_i$ and $B_i \times A_i$ form combinatorial rectangles of ones in the adjacency matrix M of G, and that these $2k$ rectangles form a partition of the ones in M, hence $\mathrm{rank_{bin}}(M) \leq 2 \cdot k$.

Next, put $m = \mathrm{rank}_{\mathbb{B}}(\overline{M})$, and let $A_1 \times B_1, \ldots, A_m \times B_m$ be m combinatorial rectangles that form a cover of the ones in $\overline{M}$, i.e., the zeros in M. For every $i \in [m]$, let C_i denote the set of elements $j \in [n]$ satisfying $(j, j) \in A_i \times B_i$. Since G is simple, the elements on the diagonal of M are all zeros, hence the sets C_i for $i \in [m]$ cover all vertices of G. Since $A_i \times B_i$ is a rectangle of zeros in M, it also follows that C_i is an independent set in G. This implies that $m \geq \chi(G)$, and we are done. ◁

The matrices M that are known to achieve super-polynomial separations between $\mathrm{rank_{bin}}(M)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M})$, however, are apparently far from being regular [13, 3, 2]. Their constructions rely on a powerful technique, known as *query-to-communication lifting*, that enables to deduce separation results in communication complexity from separation results in the more approachable area of query complexity. The proofs of the separation results of [13, 3, 2] involve two main steps, as described below.

In the first step, one provides a family of Boolean functions $f : \{0,1\}^n \to \{0,1\}$ with a large gap between two certain measures of Boolean functions, namely, the unambiguous 1-certificate complexity of f and the 0-certificate complexity of f (see Section 2.3). These measures can be viewed as query complexity analogues of the binary rank of a matrix and the Boolean rank of its complement. It is shown in [2] that the gap between the two measures can be nearly quadratic.

In the second step, the separation is "lifted" from query complexity to communication complexity. This is done by considering, for some gadget function $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$, the communication problem in which two players get inputs from $\{0,1\}^{\ell \cdot n}$ and aim to determine the value of the composed function $f \circ g^n : \{0,1\}^{\ell \cdot n} \times \{0,1\}^{\ell \cdot n} \to \{0,1\}$, defined by $(f \circ g^n)(x, y) = f(g(x_1, y_1), g(x_2, y_2), \ldots, g(x_n, y_n))$ for all $x, y \in \{0,1\}^{\ell \cdot n}$. Here, the vectors $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$ are viewed as concatenations of n blocks of size ℓ. Query-to-communication lifting results typically show that for some gadget g, a gap between certain query complexity measures of f implies a gap between the suitable communication complexity measures of the composed function $f \circ g^n$. For the non-deterministic setting, it is shown in [14] that if the gadget g is the inner product function on vectors of length $\ell = \Theta(\log n)$, then a gap between the unambiguous 1-certificate complexity and the 0-certificate complexity for f implies a gap between the unambiguous non-deterministic communication complexity and the co-non-deterministic communication complexity for $f \circ g^n$ (see also [13, Appendix A]). The analysis uses the fact that the inner product function forms a two-source extractor, as shown by Chor and Goldreich [9].

Let M denote the matrix associated with the communication problem of $f \circ g^n$ for the function f constructed in [2] and the inner product function g. The lifting result of [14] implies that M attains a near optimal separation between $\mathrm{rank_{bin}}(M)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M})$. However, it can be seen that the matrix M is not regular at all. For example, the row and the column of M that correspond to the all-zero vector consist of only ones or only zeros, depending on the value of f on the all-zero vector.

We turn to describe how we obtain regular matrices M with a similar gap between $\mathrm{rank}_{\mathrm{bin}}(M)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M})$. We first observe that to construct a regular matrix M, it suffices to replace the inner product function in the above construction by a different gadget function g. Specifically, it turns out that if g is unbiased in a strong sense, namely, it is unbiased even while fixing one of its two inputs, then the matrix M associated with $f \circ g^n$ is regular for any function f (see Section 4.1). Hence, to obtain the desired separation on regular matrices, we provide an extension of the query-to-communication lifting theorem of [14] which allows the gadget function g to be not only the inner product function but any low-discrepancy function. We note that such an extension was speculated already in [14, Remark 1] and was actually established for the deterministic and probabilistic settings in a recent work of Chattopadhyay, Filmus, Koroth, Meir, and Pitassi [8]. Building on the approach of [14] and on tools supplied in [8], we prove that such an extension holds for the non-deterministic setting as well (for a precise statement, see Theorem 7). We proceed by showing that a slight variant g of the inner product function, studied in [4] and in [22], is unbiased in the required sense and has low discrepancy. Then, to prove Theorem 1, we apply our generalized query-to-communication lifting theorem to the family of functions f provided in [2] with this gadget g.

Let us mention that our generalized lifting theorem is not essential for the proof of Theorem 1. It turns out that the matrix M obtained using the aforementioned gadget function g has a sub-matrix that corresponds to a composition with the standard inner product function, hence the lower bound on $\mathrm{rank}_{\mathbb{B}}(\overline{M})$ can also be derived from the lifting result of [14]. Yet, the generality of our lifting theorem can be used to obtain a separation between $\mathrm{rank}_{\mathrm{bin}}(M)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M})$ using various other gadget functions, and we believe that it might find additional applications.

We finally use the regular matrices given in Theorem 1 to provide regular counterexamples for the Alon-Saks-Seymour conjecture and to prove Theorem 2. It is shown in [6] that a matrix M with $\mathrm{rank}_{\mathrm{bin}}(M)$ much smaller than $\mathrm{rank}_{\mathbb{B}}(\overline{M})$ can be transformed into a graph G with $\mathrm{bp}(G)$ much smaller than $\chi(G)$. This transformation, however, does not preserve the regularity. In fact, a natural attempt to produce a regular graph G from a regular matrix M using the approach of [6] results in a graph that is not even simple (because it has loops). Moreover, certain steps of the argument of [6] identify subgraphs of this graph G with a biclique partition number much smaller than the chromatic number, but those subgraphs are not necessarily regular even if G is. We overcome these difficulties by combining the approach of [6] with a couple of additional ideas, and show that any square regular matrix M with a large gap between $\mathrm{rank}_{\mathrm{bin}}(M)$ and $\mathrm{rank}_{\mathbb{B}}(\overline{M})$ can be transformed into a simple regular graph G with a similar gap between $\mathrm{bp}(G)$ and $\chi(G)$ (see Theorem 12).

1.3 Outline

The rest of the paper is organized as follows. In Section 2, we collect several definitions and results needed throughout the paper. In Section 3, we present our generalized query-to-communication lifting theorem in non-deterministic communication complexity. Its proof can be found in the full version of the paper. In Section 4, we present and analyze a certain gadget function, and combine it with the lifting theorem to prove Theorem 1. Finally, in Section 5, we obtain regular graphs that form counterexamples to the Alon-Saks-Seymour conjecture and confirm Theorem 2.

2 Preliminaries

2.1 Non-deterministic Communication Complexity

Let Λ be a finite set, and let $F : \Lambda \times \Lambda \to \{0,1\}$ be a function. In the communication problem associated with F, one player holds an input $x \in \Lambda$ and another player holds an input $y \in \Lambda$, and their goal is to decide whether $F(x,y) = 1$ by a communication protocol that minimizes the worst-case number of communicated bits. The $0,1$ matrix M associated with the function F is the matrix whose rows and columns are indexed by Λ, defined by $M_{x,y} = F(x,y)$ for all $x, y \in \Lambda$. Consider the following three non-deterministic communication complexity measures of a function F.

- The *non-deterministic communication complexity* of F, denoted by $\mathsf{NP}^{\mathsf{cc}}(F)$, is the smallest possible number of communicated bits in a non-deterministic communication protocol for F, that is, a protocol satisfying that $F(x,y) = 1$ if and only if there exists an accepting computation on (x,y). It holds that $\mathsf{NP}^{\mathsf{cc}}(F) = \lceil \log_2 \mathrm{rank}_{\mathbb{B}}(M) \rceil$.
- The *co-non-deterministic communication complexity* of F, denoted by $\mathsf{coNP}^{\mathsf{cc}}(F)$, is the non-deterministic communication complexity of the negation $\neg F$ of F, defined by $(\neg F)(x,y) = 1 - F(x,y)$ for all $x, y \in \Lambda$. It thus holds that $\mathsf{coNP}^{\mathsf{cc}}(F) = \lceil \log_2 \mathrm{rank}_{\mathbb{B}}(\overline{M}) \rceil$.
- A non-deterministic protocol is called *unambiguous* if it satisfies that each input has at most one accepting computation. The smallest possible number of communicated bits in such a protocol for F is referred to as the *unambiguous non-deterministic communication complexity* of F and is denoted by $\mathsf{UP}^{\mathsf{cc}}(F)$. It holds that $\mathsf{UP}^{\mathsf{cc}}(F) = \lceil \log_2 \mathrm{rank}_{\mathrm{bin}}(M) \rceil$.

2.2 Composed Functions

For integers n and ℓ, let $f : \{0,1\}^n \to \{0,1\}$ and $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ be two functions. The function $g^n : \{0,1\}^{\ell \cdot n} \times \{0,1\}^{\ell \cdot n} \to \{0,1\}^n$ is defined by

$$g^n(x,y) = (g(x_1,y_1), g(x_2,y_2), \ldots, g(x_n,y_n))$$

for all $x, y \in \{0,1\}^{\ell \cdot n}$, where the vectors $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$ are viewed as concatenations of n blocks of size ℓ. The *composed function* $f \circ g^n : \{0,1\}^{\ell \cdot n} \times \{0,1\}^{\ell \cdot n} \to \{0,1\}$ is defined by $(f \circ g^n)(x,y) = f(g^n(x,y))$. For a set $I \subseteq [n]$ and a vector $x \in \{0,1\}^{\ell \cdot n}$, we let $x_I \in \{0,1\}^{\ell \cdot |I|}$ denote the projection of x to the blocks whose indices are in I. Note that when $I = \{i\}$ for some $i \in [n]$, we have $x_i = x_I$. For vectors $x, y \in \{0,1\}^{\ell \cdot n}$, we let $g^I(x_I, y_I)$ denote the projection of $g^n(x,y)$ to the indices of I.

2.3 Certificate Complexity

An n-variate k-*DNF* formula φ is a Boolean formula on n variables that can be written as a disjunction $\varphi = c_1 \vee \cdots \vee c_m$, where every c_i is a conjunction of at most k literals. The formula φ is said to be *unambiguous* if for every input $x \in \{0,1\}^n$ there is at most one $i \in [m]$ that satisfies $c_i(x) = 1$. For a Boolean function $f : \{0,1\}^n \to \{0,1\}$, consider the following query complexity measures.

- The 1-*certificate complexity* of f, denoted by $\mathsf{C}_1(f)$, is the smallest integer k for which f can be written as a k-DNF formula.
- The 0-*certificate complexity* of f, denoted by $\mathsf{C}_0(f)$, is $\mathsf{C}_1(\neg f)$, where $\neg f$ is the negation of f. Equivalently, $\mathsf{C}_0(f)$ is the smallest integer k for which f can be written as a k-CNF formula.
- The *unambiguous* 1-*certificate complexity* of f, denoted by $\mathsf{UC}_1(f)$, is the smallest integer k for which f can be written as an unambiguous k-DNF formula.

We need the following result that was proved in [2].

▶ **Theorem 4** ([2]). *For infinitely many integers r, there exists a Boolean function $f : \{0,1\}^n \to \{0,1\}$ satisfying $\mathsf{UC}_1(f) = r$ and $\mathsf{C}_0(f) \geq \widetilde{\Omega}(r^2)$ where $r = n^{\Omega(1)}$.*

2.4 Discrepancy

▶ **Definition 5** (Discrepancy). *Let Λ be a finite set, let $g : \Lambda \times \Lambda \to \{0,1\}$ be a function, and let X, Y be independent random variables that are uniformly distributed over Λ. The* discrepancy *of g with respect to a combinatorial rectangle $R \subseteq \Lambda \times \Lambda$ is denoted by $\mathrm{disc}_R(g)$ and is defined by*

$$\mathrm{disc}_R(g) = \Big|\Pr\left[g(X,Y) = 0 \text{ and } (X,Y) \in R\right] - \Pr\left[g(X,Y) = 1 \text{ and } (X,Y) \in R\right]\Big|.$$

The discrepancy *of g, denoted by $\mathrm{disc}(g)$, is defined as the maximum of $\mathrm{disc}_R(g)$ over all combinatorial rectangles $R \subseteq \Lambda \times \Lambda$.*

3 Lifting from Certificate to Communication Complexity

In this section, we present our extension of the query-to-communication lifting theorem in non-deterministic communication complexity to general low-discrepancy functions. We start with a simple upper bound on the unambiguous non-deterministic communication complexity of a composed function.

▶ **Lemma 6.** *For all functions $f : \{0,1\}^n \to \{0,1\}$ and $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$, it holds that $\mathsf{UP}^{\mathsf{cc}}(f \circ g^n) \leq O\big(\mathsf{UC}_1(f) \cdot \max(\log_2 n, \ell)\big)$.*

Proof. Put $k = \mathsf{UC}_1(f)$. Then, the function f can be written as an unambiguous n-variate k-DNF formula $\varphi = c_1 \vee \cdots \vee c_m$ where $m \leq (2n)^k$. Consider the following non-deterministic protocol for the communication problem associated with the function $f \circ g^n$. Let $x, y \in \{0,1\}^{\ell \cdot n}$ be the inputs of the players. The first player selects non-deterministically an index $i \in [m]$ and sends it to the other player. Let $I \subseteq [n]$ denote the set of indices of the variables that appear in the clause c_i, and note that $|I| \leq k$. Then, the first player sends the projection x_I of x to the blocks of I, and similarly, the second player sends the projection y_I of y to the blocks of I. The players accept if and only if $c_i(g^I(x_I, y_I)) = 1$.

Observe that $(f \circ g^n)(x,y) = 1$ if and only if the protocol has an accepting computation on the inputs x, y. Observe further that the fact that φ is unambiguous implies that the protocol is unambiguous as well. Finally, the number of bits communicated by the protocol is $O(\log_2 m + k \cdot \ell) \leq O\big(k \cdot \max(\log_2 n, \ell)\big)$, completing the proof. ◀

We turn to state a lower bound on the co-non-deterministic communication complexity of composed functions $f \circ g^n$ for low-discrepancy functions g. Its proof can be found in the full version of the paper.

▶ **Theorem 7.** *For every $\eta > 0$ there exists $c > 0$ for which the following holds. Let ℓ and n be integers such that $\ell \geq c \cdot \log_2 n$, and let $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ be a function satisfying $\mathrm{disc}(g) \leq 2^{-\eta \cdot \ell}$. Then, for every function $f : \{0,1\}^n \to \{0,1\}$, it holds that*

$$\mathsf{coNP}^{\mathsf{cc}}(f \circ g^n) \geq \Omega\big(\eta \cdot \mathsf{C}_0(f) \cdot \ell\big).$$

4 The Binary and Boolean Rank of Regular Matrices

In what follows we consider the notion of strongly unbiased functions and show that compositions with such functions are associated with regular matrices. We then present a strongly unbiased function and analyze its discrepancy. Equipped with this function, we apply the lifting theorem from the previous section to prove Theorem 1.

4.1 Strongly Unbiased Functions

Consider the following definition.

▶ **Definition 8.** *Let ℓ be an integer. We call a function $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$* strongly unbiased *if for every vector $x \in \{0,1\}^\ell$, the number of vectors $y \in \{0,1\}^\ell$ satisfying $g(x,y) = 1$ is $2^{\ell-1}$, and for every vector $y \in \{0,1\}^\ell$, the number of vectors $x \in \{0,1\}^\ell$ satisfying $g(x,y) = 1$ is $2^{\ell-1}$. Equivalently, g is strongly unbiased if the matrix associated with g is $2^{\ell-1}$-regular.*

The following lemma shows that compositions with strongly unbiased functions are associated with regular matrices.

▶ **Lemma 9.** *For all functions $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ and $f : \{0,1\}^n \to \{0,1\}$, if g is strongly unbiased then the matrix associated with the composed function $f \circ g^n$ is regular.*

Proof. Let $g : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ be a strongly unbiased function, let $f : \{0,1\}^n \to \{0,1\}$ be a function, and let M be the matrix of dimensions $2^{\ell \cdot n} \times 2^{\ell \cdot n}$ associated with the composed function $f \circ g^n$. Since g is strongly unbiased, it follows that for every vector $x \in \{0,1\}^{\ell \cdot n}$ and for every vector $a \in \{0,1\}^n$, precisely 2^{-n} fraction of the vectors $y \in \{0,1\}^{\ell \cdot n}$ satisfy $g^n(x,y) = a$. This implies that the row of the matrix M that corresponds to a vector $x \in \{0,1\}^{\ell \cdot n}$ consists of the evaluations of the function f on all vectors $a \in \{0,1\}^n$, where each such evaluation appears exactly $2^{-n} \cdot 2^{\ell \cdot n} = 2^{(\ell-1)n}$ times. In particular, the number of ones in this row is $2^{(\ell-1)n} \cdot |f^{-1}(1)|$. Since this number is independent of x, it follows that this is the number of ones in each row of the matrix M. By symmetry, this is also the number of ones in each column of M, implying that the matrix M is regular. ◀

4.2 The Gadget Function

For an integer $\ell \geq 1$, define the function $g_\ell : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ by

$$g_\ell(x,y) = x_1 + y_1 + \sum_{i=2}^{\ell} x_i \cdot y_i \pmod 2$$

for all $x, y \in \{0,1\}^\ell$. We first observe that g_ℓ is strongly unbiased.

▶ **Lemma 10.** *For every integer $\ell \geq 1$, the function g_ℓ is strongly unbiased.*

Proof. Consider the function g_ℓ for an integer $\ell \geq 1$. By definition, for every $x \in \{0,1\}^\ell$, it holds that for every $y' \in \{0,1\}^{\ell-1}$ exactly one of the two vectors $y \in \{0,1\}^\ell$ with suffix y' satisfies $g(x,y) = 1$. This implies that for every $x \in \{0,1\}^\ell$ precisely $2^{\ell-1}$ of the vectors $y \in \{0,1\}^\ell$ satisfy $g(x,y) = 1$. By symmetry, we also have that for every $y \in \{0,1\}^\ell$ precisely $2^{\ell-1}$ of the vectors $x \in \{0,1\}^\ell$ satisfy $g(x,y) = 1$, so we are done. ◀

The following lemma claims that the functions g_ℓ have low discrepancy. We note that this can be directly derived from a bound on the discrepancy of the inner product function. Yet, we present in the full version of the paper a bound with a somewhat better multiplicative constant, borrowing an argument of Bouda, Pivoluska, and Plesch [4].

▶ **Lemma 11.** *For every integer $\ell \geq 1$, the discrepancy of the function g_ℓ satisfies*

$$\mathrm{disc}(g_\ell) \leq 2^{-(\ell+1)/2}.$$

4.3 Proof of Theorem 1

We are ready to put everything together and to complete the proof of Theorem 1.

Proof of Theorem 1. By Theorem 4, for infinitely many integers r, there exists a Boolean function $f : \{0,1\}^n \to \{0,1\}$ satisfying $\mathsf{UC}_1(f) = r$ and $\mathsf{C}_0(f) \geq \widetilde{\Omega}(r^2)$ where $r = n^{\Omega(1)}$. For an integer ℓ, consider the function $g_\ell : \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}$ defined in Section 4.2. By Lemma 11, it holds that $\mathrm{disc}(g_\ell) \leq 2^{-\eta \cdot \ell}$ for $\eta = 1/2$. Theorem 7 yields that there exists a constant c, such that for $\ell = \lceil c \cdot \log_2 n \rceil$, the composed function $f \circ g_\ell^n$ satisfies

$$\mathsf{coNP}^{\mathsf{cc}}(f \circ g_\ell^n) \geq \Omega(\mathsf{C}_0(f) \cdot \ell) \geq \widetilde{\Omega}(r^2). \tag{2}$$

By Lemma 6, it further holds that

$$\mathsf{UP}^{\mathsf{cc}}(f \circ g_\ell^n) \leq O(\mathsf{UC}_1(f) \cdot \ell) \leq \widetilde{O}(r), \tag{3}$$

where for the second inequality we have used our choice of ℓ and the fact that $r = n^{\Omega(1)}$.

To complete the proof, let M be the square $2^{\ell \cdot n} \times 2^{\ell \cdot n}$ matrix associated with the composed function $f \circ g_\ell^n$. By Lemma 10, the function g_ℓ is strongly unbiased, hence by Lemma 9, the matrix M is regular. Recalling that $\mathsf{UP}^{\mathsf{cc}}(f \circ g_\ell^n) = \lceil \log_2 \mathrm{rank}_{\mathrm{bin}}(M) \rceil$, it follows from (3) that $\mathrm{rank}_{\mathrm{bin}}(M) \leq 2^{\widetilde{O}(r)}$. Put $k = \mathrm{rank}_{\mathrm{bin}}(M)$, and combine (2) with the fact that $\mathsf{coNP}^{\mathsf{cc}}(f \circ g_\ell^n) = \lceil \log_2 \mathrm{rank}_{\mathbb{B}}(\overline{M}) \rceil$ to obtain that $\mathrm{rank}_{\mathbb{B}}(\overline{M}) \geq 2^{\widetilde{\Omega}(r^2)} \geq k^{\widetilde{\Omega}(\log k)}$. ◀

5 The Alon-Saks-Seymour Conjecture and Regular Graphs

In this section, we prove the following theorem.

▶ **Theorem 12.** *For every square regular $0,1$ matrix M, there exists a simple regular graph G satisfying $\mathrm{bp}(G) \leq 33 \cdot \mathrm{rank}_{\mathrm{bin}}(M)^2$ and $\chi(G) \geq \mathrm{rank}_{\mathbb{B}}(\overline{M})^{1/3}$.*

Applying Theorem 12 to the matrices given by Theorem 1 yields regular graphs that form counterexamples to the Alon-Saks-Seymour conjecture with a near optimal gap between the biclique partition number and the chromatic number. This confirms Theorem 2.

5.1 Biclique Covering

We start with some definitions that will be used throughout the proof of Theorem 12. All graphs considered here are undirected. They do not contain parallel edges but they may have loops. As usual, a graph is said to be *simple* if it contains no loops and no parallel edges. For a graph $G = (V, E)$, a *biclique of* G is a complete bipartite subgraph of G, that is, a pair (A, B) of sets $A, B \subseteq V$ where every vertex of A is adjacent in G to every vertex of B. For adjacent vertices x, y of G such that $x \in A$ and $y \in B$, we say that the biclique (A, B) covers the oriented edge (x, y). Note that although the edges of G are undirected, a biclique of G covers edges of G with some orientation.

For an integer t, a *t-biclique covering* of G is a collection of bicliques of G that cover every edge of G at least once and at most t times. The minimum size of such a covering is called the *t-biclique covering number of* G and is denoted by $\mathrm{bp}_t(G)$. For $t = 1$, a 1-biclique covering is also called a *biclique partition*, and we write $\mathrm{bp}(G) = \mathrm{bp}_1(G)$.

We need the following result of Bousquet, Lagoutte, and Thomassé [6].

▷ Claim 13 ([6, Claim 28]). Let $H = (V, E)$ be a simple graph, and let $\mathcal{C}$ be a t-biclique covering of size k of H. Let $E' \subseteq E$ be the set of edges of H that are covered by $\mathcal{C}$ exactly t times. Then, the graph $H' = (V, E')$ satisfies $\mathrm{bp}(H') \leq (2k)^t$.

5.2 From Regular Matrices to Regular Graphs

We are ready to prove Theorem 12.

Proof of Theorem 12. Let M be an $n \times n$ regular $0, 1$ matrix, and let d denote the number of ones in each row and each column of M. Put $k = \mathrm{rank}_{\mathrm{bin}}(M)$ and $m = \mathrm{rank}_{\mathbb{B}}(\overline{M})$.

We first define a graph $H = (V, E)$ on the vertex set $V = [n] \times [n]$ in which every two (not necessarily distinct) vertices $(i_1, j_1), (i_2, j_2) \in V$ are adjacent if $M_{i_1,j_2} = 1$ or $M_{i_2,j_1} = 1$. Define $V_0 = \{(i, j) \in V \mid M_{i,j} = 0\}$ and $V_1 = \{(i, j) \in V \mid M_{i,j} = 1\}$. Note that $V = V_0 \cup V_1$, and notice that the vertices of H that have loops are precisely the vertices of V_1.

Let $H_0 = H[V_0]$ denote the subgraph of H induced on the vertices of V_0. Clearly, H_0 is a simple graph. The following lemma relates its chromatic number to the Boolean rank of $\overline{M}$.

▶ **Lemma 14.** *The graph H_0 satisfies $\chi(H_0) \geq m$.*

Proof. Put $r = \chi(H_0)$. Then, there exists a partition of V_0 into r independent sets $I_1, \ldots, I_r$ of H_0. For each $t \in [r]$, let A_t be the set of elements $i \in [n]$ for which there exists some $j \in [n]$ such that $(i, j) \in I_t$, and let B_t be the set of elements $j \in [n]$ for which there exists some $i \in [n]$ such that $(i, j) \in I_t$. Since I_t is an independent set in H_0, it follows that every pair $(i, j) \in A_t \times B_t$ satisfies $M_{i,j} = 0$. This implies that $A_t \times B_t$ is a combinatorial rectangle of zeros in the matrix M. Since the r given independent sets cover the entire set V_0, it follows that for every pair $(i, j) \in V_0$ there exists some $t \in [r]$ such that $(i, j) \in I_t$, and this t satisfies $(i, j) \in A_t \times B_t$. This shows that the rectangles $A_t \times B_t$ with $t \in [r]$ form a cover of the zeros of M, hence $r \geq \mathrm{rank}_{\mathbb{B}}(\overline{M}) = m$, as required. ◀

The next lemma provides a 2-biclique covering of H.

▶ **Lemma 15.** *There exists a 2-biclique covering $\mathcal{C}$ of H such that*

1. $|\mathcal{C}| = k$,
2. *for every adjacent distinct vertices $(i_1, j_1), (i_2, j_2)$ of H, if both $M_{i_1,j_2} = 1$ and $M_{i_2,j_1} = 1$ hold, then the edge that connects them is covered by $\mathcal{C}$ twice in the two opposite orientations, and if only one of them holds, then it is covered by $\mathcal{C}$ once, and*
3. *every loop of H is covered by $\mathcal{C}$ once.*

Proof. By $k = \mathrm{rank}_{\mathrm{bin}}(M)$, there exists a collection of k combinatorial rectangles $A_t \times B_t$ of ones, $t \in [k]$, that forms a partition of the ones of the matrix M. We define $\mathcal{C}$ as the collection of all bicliques of the form $C_t = (A_t \times [n], [n] \times B_t)$ for $t \in [k]$.

Let $(i_1, j_1), (i_2, j_2)$ be two (not necessarily distinct) vertices of H. If $M_{i_1,j_2} = 1$ then there exists a unique $t \in [k]$ such that $(i_1, j_2) \in A_t \times B_t$. This implies that the oriented edge $((i_1, j_1), (i_2, j_2))$ is covered by the biclique C_t and is not covered by any other biclique of $\mathcal{C}$. If, however, it holds that $M_{i_1,j_2} = 0$, then no $t \in [k]$ satisfies $(i_1, j_2) \in A_t \times B_t$, hence the oriented edge $((i_1, j_1), (i_2, j_2))$ is not covered by any biclique of $\mathcal{C}$.

We turn to show that $\mathcal{C}$ is a 2-biclique covering of H that satisfies the assertion of the lemma. By definition, we have $|\mathcal{C}| = k$, as required for Item 1. Let $(i_1, j_1), (i_2, j_2)$ be two distinct vertices of H. If the vertices are adjacent then $M_{i_1,j_2} = 1$ or $M_{i_2,j_1} = 1$. The above discussion implies that if both the conditions hold then the edge that connects them is covered twice in the two opposite orientations, whereas if only one of the conditions holds, then the edge is covered once, as required for Item 2. For a vertex (i, j) that has a loop, it holds that $M_{i,j} = 1$, hence the oriented edge $((i, j), (i, j))$ is covered once by $\mathcal{C}$, as required for Item 3. On the other hand, if the vertices $(i_1, j_1), (i_2, j_2)$ are not adjacent then $M_{i_1,j_2} = 0$ and $M_{i_2,j_1} = 0$, hence no oriented edge between them is covered by $\mathcal{C}$. It thus follows that $\mathcal{C}$ is a 2-biclique covering of H, and we are done. ◀

Let $\mathcal{C}$ be the 2-biclique covering of H given by Lemma 15. Consider the two subgraphs of H_0 defined by $H_0^{(1)} = (V_0, E_1)$ and $H_0^{(2)} = (V_0, E_2)$, where E_t is the set of edges of H_0 that are covered by $\mathcal{C}$ exactly t times for $t \in [2]$. Since the edge set of H_0 is $E_1 \cup E_2$, it follows that

$$\chi(H_0) \leq \chi(H_0^{(1)}) \cdot \chi(H_0^{(2)}). \tag{4}$$

To obtain the desired simple regular graph, we proceed by considering the following two cases according to the chromatic number of $H_0^{(2)}$.

Case 1. Suppose first that $\chi(H_0^{(2)}) \geq m^{1/3}$. Let $\mathcal{C}'$ be the collection of bicliques of H obtained from $\mathcal{C}$ by replacing every biclique $(A, B) \in \mathcal{C}$ by the three bicliques $(A \cap B, A \cap B)$, $(A \cap B, B \setminus A)$, and $(A \setminus B, B)$, where bicliques with an empty part can be avoided. Observe that these three bicliques cover precisely the same edges covered by (A, B) with the same multiplicities and orientations. Therefore, $\mathcal{C}'$ is a 2-biclique covering of H of size $|\mathcal{C}'| \leq 3k$ which satisfies Items 2 and 3 of Lemma 15. It further satisfies that each of its bicliques has either equal or disjoint parts. We let $\mathcal{C}'' \subseteq \mathcal{C}'$ denote the collection of bicliques of $\mathcal{C}'$ with equal parts. It clearly holds that $|\mathcal{C}''| \leq k$ and $|\mathcal{C}' \setminus \mathcal{C}''| \leq 2k$.

Every biclique of $\mathcal{C}''$ has the form (A, A) for some set $A \subseteq V$. For every $x \in A$, it covers a loop of x as an oriented edge (x, x), and for every distinct $x, y \in A$, it covers the edge that connects x and y in the two opposite orientations, namely, as (x, y) and as (y, x). This implies that all the vertices that appear in the bicliques of $\mathcal{C}''$ have loops in H and thus belong to V_1. Since the parts of the bicliques of $\mathcal{C}' \setminus \mathcal{C}''$ are disjoint, it follows that the bicliques of $\mathcal{C}''$ cover all the loops of H. Since $\mathcal{C}'$ is a 2-biclique covering of H that covers the loops once, it follows that no edge is covered by both $\mathcal{C}''$ and $\mathcal{C}' \setminus \mathcal{C}''$.

Let F be the graph obtained from H by removing the edges of the bicliques of $\mathcal{C}''$. Since the bicliques of $\mathcal{C}''$ cover all the loops of H, it follows that the graph F is simple. The collection $\mathcal{C}' \setminus \mathcal{C}''$ forms a 2-biclique covering of F, hence $\mathrm{bp}_2(F) \leq 2k$. Let $F^{(2)}$ denote the subgraph of F on V that includes all the edges that are covered by $\mathcal{C}' \setminus \mathcal{C}''$ twice. Since the bicliques of $\mathcal{C}''$ involve only vertices of V_1, it follows that $F^{(2)}$ has an induced subgraph isomorphic to $H_0^{(2)}$, implying that $\chi(F^{(2)}) \geq \chi(H_0^{(2)}) \geq m^{1/3}$.

Now, let G be the graph that contains two disjoint copies of $F^{(2)}$, with additional edges between the two copies according to the bicliques of $\mathcal{C}''$. More precisely, G is the graph on the vertex set $V \times [2]$ in which two vertices (x, b) and (y, b) for $b \in [2]$ are adjacent if x and y are adjacent in $F^{(2)}$, and two vertices $(x, 1)$ and $(y, 2)$ are adjacent if (x, y) is an oriented edge covered by the bicliques of $\mathcal{C}''$. The graph G is simple, because $F^{(2)}$ is simple and because no oriented edge is covered twice by $\mathcal{C}''$. We claim that G satisfies the assertion of the theorem.

Firstly, G has an induced subgraph isomorphic to $F^{(2)}$, hence it follows that $\chi(G) \geq \chi(F^{(2)}) \geq m^{1/3}$.

Secondly, we claim that $\mathrm{bp}(G) \leq 33 \cdot k^2$. To see this, use Claim 13 and $\mathrm{bp}_2(F) \leq 2k$ to obtain that $\mathrm{bp}(F^{(2)}) \leq (4k)^2$, that is, at most $(4k)^2$ bicliques are needed for a partition of the edges of each copy of $F^{(2)}$ in G. Consider further the bicliques $(A \times \{1\}, A \times \{2\})$ for $(A, A) \in \mathcal{C}''$, which form a partition with size at most k of the edges of G between the vertices of $V \times \{1\}$ and those of $V \times \{2\}$. It follows that $\mathrm{bp}(G) \leq 2 \cdot (4k)^2 + k \leq 33 \cdot k^2$.

Finally, we claim that G is regular with degree d^2. To see this, consider an arbitrary vertex $(i_1, j_1, b) \in V \times [2]$ in G. This vertex is adjacent to the vertices (i_2, j_2, b) for which the pairs (i_1, j_1) and (i_2, j_2) are adjacent in H and the edge that connects them is covered twice by $\mathcal{C}' \setminus \mathcal{C}''$. It is further adjacent to the vertices (i_2, j_2, b') with $b' \neq b$ for which the pairs (i_1, j_1) and (i_2, j_2) are adjacent in H and the edge that connects them is covered by $\mathcal{C}''$ (twice if they are distinct, and once otherwise). Since $\mathcal{C}'$ satisfies Items 2 and 3 of Lemma 15, it follows that the degree of (i_1, j_1, b) in G is precisely the number of pairs $(i_2, j_2) \in V$ satisfying $M_{i_1,j_2} = 1$ and $M_{i_2,j_1} = 1$. By the d-regularity of M, the latter is equal to d^2, so we are done.

Case 2. Suppose next that $\chi(H_0^{(2)}) < m^{1/3}$. We start by proving that there exists an independent set $S \subseteq V_0$ in the graph $H_0^{(2)}$ for which

$$\chi(H_0^{(1)}[S]) \geq m^{1/3}. \tag{5}$$

Indeed, the assumption implies that there exists a proper coloring of $H_0^{(2)}$ with fewer than $m^{1/3}$ colors. If the induced subgraph of $H_0^{(1)}$ on every color class of this coloring has chromatic number smaller than $m^{1/3}$, then one can obtain a proper coloring of $H_0^{(1)}$ whose number of colors is smaller than $m^{1/3} \cdot m^{1/3} = m^{2/3}$, which implies using (4) that $\chi(H_0) < m^{2/3} \cdot m^{1/3} = m$, in contradiction to Lemma 14. This implies that some color class $S \subseteq V_0$ of the coloring of $H_0^{(2)}$ satisfies (5).

Now, consider the 3-partite graph G' whose vertex set consists of three copies of V that are connected by three copies of the bicliques of $\mathcal{C}$ oriented in a cyclic manner. More precisely, the vertex set of G' is $V \times [3]$ and its edges are those of the bicliques $(A \times \{1\}, B \times \{2\})$, $(A \times \{2\}, B \times \{3\})$, and $(A \times \{3\}, B \times \{1\})$ for all $(A, B) \in \mathcal{C}$. By Lemma 15, no oriented edge of the bicliques of $\mathcal{C}$ is covered twice. It thus follows that G' is a simple graph and that each of its edges is covered by the above bicliques exactly once. By $|\mathcal{C}| = k$, it follows that $\mathrm{bp}(G') \leq 3k$. Further, Items 2 and 3 of Lemma 15 imply that the degree of every vertex $(i_1, j_1, b) \in V \times [3]$ of G' is precisely the sum of the number of pairs $(i_2, j_2) \in V$ satisfying $M_{i_1,j_2} = 1$ and the number of pairs $(i_2, j_2) \in V$ satisfying $M_{i_2,j_1} = 1$. Since the matrix M is d-regular, it follows that the graph G' is regular with degree $2nd$.

We next define a graph G as follows. The graph G is obtained from G' by removing all the edges whose both endpoints are in $S \times [3]$ and by adding the edges of the induced subgraph $H[S]$ of H on S to each of the three copies of S in G (i.e., $S \times \{b\}$ for $b \in [3]$). Since G' is a simple graph, using the fact that S is a subset of V_0, it follows that G is a simple graph as well. We claim that G satisfies the assertion of the theorem.

Firstly, since S is an independent set in $H_0^{(2)}$, the subgraph of G induced on every copy of S is isomorphic to $H_0^{(1)}[S]$. It thus follows from (5) that $\chi(G) \geq \chi(H_0^{(1)}[S]) \geq m^{1/3}$.

Secondly, we claim that $\mathrm{bp}(G) \leq 9k$. To see this, recall that $\mathrm{bp}(G') \leq 3k$, and consider some biclique partition with size at most $3k$ of the edges of G'. Replace each biclique $(A \times \{b\}, B \times \{b'\})$ of this partition, where $b \neq b'$, by the two bicliques

$$((A \setminus S) \times \{b\}, B \times \{b'\}) \ \text{ and } \ ((A \cap S) \times \{b\}, (B \setminus S) \times \{b'\}).$$

This gives us a biclique partition with size at most $6k$ of all the edges of G' but those spanned by the vertices of $S \times [3]$. It remains to cover the edges of the three copies of $H[S]$ in G. Since S is an independent set in $H_0^{(2)}$, each edge of $H[S]$ is covered by $\mathcal{C}$ exactly once, so by restricting the bicliques of $\mathcal{C}$ to the vertices of S, we get a biclique partition of $H[S]$ with size at most k. This gives us a biclique partition with size at most k of the edges of $G[V \times \{b\}]$ for each $b \in [3]$, implying that $\mathrm{bp}(G) \leq 6k + 3k = 9k$.

Finally, we claim that G is regular. To see this, recall that G' is regular and that G is obtained from G' by replacing the edges between the different copies of S by the corresponding edges inside the copies of S. Since those edges are covered exactly once by $\mathcal{C}$, this does not change the degrees of the vertices, yielding that the graph G is regular as well, and we are done. ◀

Abstract

Cai and Hemachandra used iterative constant-setting to prove that Few $\subseteq \oplus$P (and thus that FewP $\subseteq \oplus$P). In this paper, we note that there is a tension between the nondeterministic ambiguity of the class one is seeking to capture, and the density (or, to be more precise, the needed "nongappy"-ness) of the easy-to-find "targets" used in iterative constant-setting. In particular, we show that even less restrictive gap-size upper bounds regarding the targets allow one to capture ambiguity-limited classes. Through a flexible, metatheorem-based approach, we do so for a wide range of classes including the logarithmic-ambiguity version of Valiant's unambiguous nondeterminism class UP. Our work lowers the bar for what advances regarding the existence of infinite, P-printable sets of primes would suffice to show that restricted counting classes based on the primes have the power to accept superconstant-ambiguity analogues of UP. As an application of our work, we prove that the Lenstra–Pomerance–Wagstaff Conjecture implies that all $\mathcal{O}(\log\log n)$-ambiguity NP sets are in the restricted counting class $\mathrm{RC}_{\mathrm{PRIMES}}$.

1 Introduction

We show that every NP set of low ambiguity belongs to broad collections of restricted counting classes.

We now describe the two types of complexity classes just mentioned. For any set $S \subseteq \mathbb{N}^+$, the restricted counting class RC_S [7] is defined by $\mathrm{RC}_S = \{L \mid (\exists f \in \#\mathrm{P})(\forall x \in \Sigma^*)[(x \notin L \implies f(x) = 0) \wedge (x \in L \implies f(x) \in S)]\}$. That is, a set L is in RC_S exactly if there is a nondeterministic polynomial-time Turing machine (NPTM) that on each string not in L has zero accepting paths and on each string in L has a number of accepting paths that belongs to the set S. For example, though this is an extreme case, NP $= \mathrm{RC}_{\mathbb{N}^+}$.

In the 1970s, Valiant started the study of ambiguity-limited versions of NP by introducing the class UP [36], unambiguous polynomial time, which in the above notation is simply $\mathrm{RC}_{\{1\}}$. (The ambiguity (limit) of an NPTM refers to an upper bound on how many *accepting*

paths it has as a function of the input's length. An NP language falls within a given level of ambiguity if it is accepted by some NPTM that happens to satisfy that ambiguity limit.) More generally, for each function $f : \mathbb{N} \to \mathbb{N}^+$ or $f : \mathbb{N} \to \mathbb{R}^{\geq 1}$, $\mathrm{UP}_{\leq f(n)}$ denotes the class of languages L for which there is an NPTM N such that, for each x, if $x \notin L$ then N on input x has no accepting paths, and if $x \in L$ then $1 \leq \#\mathrm{acc}_N(x) \leq \lfloor f(|x|) \rfloor$ (where $\#\mathrm{acc}_N(x)$ denotes the number of accepting computation paths of N on input x). (Since, for all N and x, $\#\mathrm{acc}_N(x) \in \mathbb{N}$, the class $\mathrm{UP}_{\leq f(n)}$ just defined would be unchanged if $\lfloor f(|x|) \rfloor$ were replaced by $f(|x|)$.) Ambiguity-limited nondeterministic classes whose ambiguity limits range from completely unambiguous ($\mathrm{UP}_{\leq 1}$, i.e., UP) to polynomial ambiguity (Allender and Rubinstein's class FewP [3]) have been defined and studied.

In this paper, we show that many ambiguity-limited counting classes – including ones based on types of logarithmic ambiguity, loglog ambiguity, logloglog ambiguity, and loglogloglog ambiguity – are contained in various collections of restricted counting classes. We do so primarily through two general theorems (Theorems 4.7 and 4.12) that help make clear how, as the size of the "holes" allowed in the sets underpinning the restricted counting classes becomes smaller (i.e., as the sets become more "nongappy"), one can handle more ambiguity. Table 1 summarizes our results about the containment of ambiguity-limited counting classes in restricted counting classes.

Only for polynomial ambiguity was a result of this sort previously known. In particular, Beigel, Gill, and Hertrampf [5], strengthening Cai and Hemachandra's result $\mathrm{FewP} \subseteq \oplus\mathrm{P}$ [13], proved that $\mathrm{FewP} \subseteq \mathrm{RC}_{\{1,3,5,\ldots\}}$, and Borchert, Hemaspaandra, and Rothe [7] noted that $\mathrm{FewP} \subseteq \mathrm{RC}_T$ for each nonempty set $T \subseteq \mathbb{N}^+$ that has an easily presented (formally, P-printable [25], whose definition will be given in Section 2) subset V that is $(n+\mathcal{O}(1))$-nongappy (i.e., for some k the set V never has more than k adjacent, empty lengths; that is, for each collection of $k+1$ adjacent lengths, V will always contain at least one string whose length is one of those $k+1$ lengths).

Our proof approach in the present paper connects somewhat interestingly to the history just mentioned. We will describe in Section 4 the approach that we will call *the iterative constant-setting technique*. However, briefly put, that refers to a process of sequentially setting a series of constants – first c_0, then c_1, then c_2, ..., and then c_m – in such a way that, for each $0 \leq j \leq m$, the summation $\sum_{0 \leq \ell \leq j} c_\ell \binom{j}{\ell}$ falls in a certain "yes" or "no" target set, as required by the needs of the setting. For RC_S classes, the "no" target set will be $\{0\}$ and the "yes" target set will be S. In this paper, we will typically put sets into restricted counting classes by building Turing machines that guess (for each $0 \leq \ell \leq j$) cardinality-ℓ sets of accepting paths of another NPTM and then amplify each such successful accepting-path-set guess by – via splitting/cloning of the path – creating from it c_ℓ accepting paths.

A technically novel aspect of the proofs of the two main theorems (Theorems 4.7 and 4.12, each in effect a metatheorem) is that those proofs each provide, in a unified way for a broad class of functions, an analysis of value-growth in the context of iterated functions.

Cai and Hemachandra's [13] result FewP $\subseteq \oplus$P was proven (as was an even more general result about a class known as "Few") by the iterative constant-setting technique. Beigel, Gill, and Hertrampf [5], while generously noting that "this result can also be obtained by a close inspection of Cai and Hemachandra's proof," proved the far stronger result FewP $\subseteq \mathrm{RC}_{\{1,3,5,\ldots\}}$ simply and directly rather than by iterative constant-setting. Borchert, Hemaspaandra, and Rothe's [7] even more general result, noted above for its proof, resurrected the iterative constant-setting technique, using it to understand one particular level of ambiguity. This present paper is, in effect, an immersion into the far richer world of possibilities that the iterative constant-setting technique can offer, if one puts in the work to analyze and bound the growth rates of certain constants central to the method. In particular, as noted above we use the iterative constant-setting method to obtain a broad range of results (see Table 1) regarding how ambiguity-limited nondeterminism is not more powerful than appropriately nongappy restricted counting classes.

Each of our results has immediate consequences regarding the power of the primes as a restricted-counting acceptance type. Borchert, Hemaspaandra, and Rothe's result implies that if the set of primes has an $(n + \mathcal{O}(1))$-nongappy, P-printable subset, then FewP $\subseteq \mathrm{RC}_{\mathrm{PRIMES}}$. However, it is a long-open research issue whether there exists *any* infinite, P-printable subset of the primes, much less an $(n + \mathcal{O}(1))$-nongappy one. Our results lower the bar on what one must assume about how nongappy hypothetical infinite, P-printable subsets of the primes are in order to imply that some superconstant-ambiguity-limited nondeterministic version of NP is contained in $\mathrm{RC}_{\mathrm{PRIMES}}$. We prove that even infinite, P-printable sets of primes with merely exponential upper bounds on the size of their gaps would yield such a result. We also prove – by exploring the relationship between density and nongappiness – that the Lenstra–Pomerance–Wagstaff Conjecture [35, 38] (regarding the asymptotic density of the Mersenne primes) implies that $\mathrm{UP}_{\leq \mathcal{O}(\log\log n)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$. The Lenstra–Pomerance–Wagstaff Conjecture is characterized in Wikipedia [41] as being "widely accepted," the fact that it disagrees with a different conjecture (Gillies' Conjecture [22]) notwithstanding.

Additional results, discussions and comments, and the omitted proofs of Theorems 4.3, 4.12, 4.13, 4.14, and 4.19, Propositions 2.5, 4.9, and 4.17, and Corollary 4.15 can be found our full technical report version [26].

2 Definitions

$\mathbb{N} = \{0, 1, 2, \ldots\}$. $\mathbb{N}^+ = \{1, 2, \ldots\}$. Each positive natural number, other than 1, is prime or composite. A prime number is a number that has no positive divisors other than 1 and itself. PRIMES $= \{i \in \mathbb{N} \mid i \text{ is a prime}\} = \{2, 3, 5, 7, 11, \ldots\}$. A composite number is one that has at least one positive divisor other than 1 and itself; COMPOSITES $= \{i \in \mathbb{N} \mid i \text{ is a composite number}\} = \{4, 6, 8, 9, 10, 12, \ldots\}$. $\mathbb{R}$ is the set of all real numbers,

$\mathbb{R}^+ = \{x \in \mathbb{R} \mid x > 0\}$, and $\mathbb{R}^{\geq 1} = \{x \in \mathbb{R} \mid x \geq 1\}$. All logs in this paper (thus those involved in log, loglog, logloglog, loglogloglog, and $\log^{[i]}$, and also those called within the definitions of $\log^*$ and our new $\log^{\circledast}$) are base 2. Also, each call of the log function in this paper, $\log(\cdot)$, is implicitly a shorthand for $\log(\max(1, \cdot))$. We do this so that formulas such as $\log\log\log(\cdot)$ do not cause domain problems on small inputs. (Admittedly, this is also distorting log in the domain-valid open interval (0,1). However, that interval never comes into play in our paper except incidentally when iterated logs drop something into it, and also in the definitions of $\log^*$ and $\log^{\circledast}$ but in those two cases – see the discussion in Footnotes 2 and 8 of [26] – the max happens not to change what those evaluate to on (0,1).)

As mentioned earlier, for any NPTM N and any string x, $\#\mathrm{acc}_N(x)$ will denote the number of accepting computation paths of N on input x. #P [37] is the counting version of NP: $\#\mathrm{P} = \{f : \Sigma^* \to \mathbb{N} \mid (\exists \text{ NPTM } N)(\forall x \in \Sigma^*)[\#\mathrm{acc}_N(x) = f(x)]\}$. $\oplus$P ("Parity P") is the class of sets L such that there is a function $f \in \#\mathrm{P}$ such that, for each string x, it holds that $x \in L \iff f(x) \equiv 1 \pmod 2$ [34, 23].

We will use $\mathcal{O}$ in its standard sense, namely, if f and g are functions (from whose domain negative numbers are typically excluded), then we say $f(n) = \mathcal{O}(g(n))$ exactly if there exist positive integers c and n_0 such that $(\forall n \geq n_0)[f(n) \leq cg(n)]$. We sometimes will also, interchangeably, speak of or write a $\mathcal{O}$ expression as representing a set of functions (e.g., writing $f(n) \in \mathcal{O}(g(n))$) [10, 11], which in fact is what the "big O" notation truly represents.

The notions RC_S, UP, and $\mathrm{UP}_{\leq f(n)}$ are as defined in Section 1. For each $k \geq 1$, Watanabe [39] implicitly and Beigel [4] explicitly studied the constant-ambiguity classes $\mathrm{RC}_{\{1,2,3,\ldots,k\}}$ which, following the notation of Lange and Rossmanith [32], we will usually denote $\mathrm{UP}_{\leq k}$. We extend the definition of $\mathrm{UP}_{\leq f(n)}$ to classes of functions as follows. For classes $\mathcal{F}$ of functions mapping $\mathbb{N}$ to $\mathbb{N}^+$ or $\mathbb{N}$ to $\mathbb{R}^{\geq 1}$, we define $\mathrm{UP}_{\leq \mathcal{F}} = \bigcup_{f \in \mathcal{F}} \mathrm{UP}_{\leq f(n)}$. We mention that the class $\mathrm{UP}_{\leq \mathcal{O}(1)}$ is easily seen to be equal to $\bigcup_{k \in \mathbb{N}^+} \mathrm{UP}_{\leq k}$, which is a good thing since that latter definition of the notion is how $\mathrm{UP}_{\leq \mathcal{O}(1)}$ was defined in the literature more than a quarter of a century ago [29]. $\mathrm{UP}_{\leq \mathcal{O}(1)}$ can be (informally) described as the class of all sets acceptable by NPTMs with constant-bounded ambiguity. Other related classes will also be of interest to us. For example, $\mathrm{UP}_{\leq \mathcal{O}(\log n)}$ captures the class of all sets acceptable by NPTMs with logarithmically-bounded ambiguity. Allender and Rubinstein [3] introduced and studied FewP, the polynomial-ambiguity NP languages, which can be defined by $\mathrm{FewP} = \{L \mid (\exists \text{ polynomial } f)[L \in \mathrm{UP}_{\leq f(n)}]\}$.

The $\mathrm{UP}_{\leq f(n)}$ classes, which will be central to this paper's study, capture ambiguity-bounded versions of NP. They are also motivated by the fact that they completely characterize the existence of ambiguity-bounded (complexity-theoretic) one-way functions.[1]

▶ **Proposition 2.1.** *Let f be any function mapping from $\mathbb{N}$ to $\mathbb{N}^+$. $\mathrm{P} \neq \mathrm{UP}_{\leq f(n)}$ if and only if there exists an $f(n)$-to-one one-way function.*

[1] A (possibly nontotal) function g is said to be a one-way function exactly if (a) g is polynomial-time computable, (b) g is honest (i.e., there exists a polynomial q such that, for each y in the range of g, there exists a string x such that $g(x) = y$ and $|x| \leq q(|y|)$; simply put, each string y mapped to by g is mapped to by some string x that is not much longer than y), and (c) g is not polynomial-time invertible (i.e., there exists no (possibly nontotal) polynomial-time function h such that for each y in the range of g, it holds that $h(y)$ is defined and $g(h(y))$ is defined and $g(h(y)) = y$) [24]. For each $f : \mathbb{N} \to \mathbb{N}^+$ and each (possibly nontotal) function $g : \Sigma^* \to \Sigma^*$, we say that g is $f(n)$-to-one exactly if, for each $y \in \Sigma^*$, $\|\{x \mid g(x) = y\}\| \leq f(|y|)$. When g is a one-way function, the function f is sometimes referred to as an ambiguity limit on the function g, and the special case of $f(n) = 1$ is the case of unambiguous one-way functions. (This is a different notion of ambiguity than that used for NPTMs, though Proposition 2.1 shows that the notions are closely connected.)

That claim holds even if f is not nondecreasing, and holds even if f is not a computable function. To the best of our knowledge, Proposition 2.1 has not been stated before for the generic case of any function $f : \mathbb{N} \to \mathbb{N}^+$. However, many concrete special cases are well known, and the proposition follows from the same argument as is used for those (see for example [27, Proof of Theorem 2.5] for a tutorial presentation of that type of argument). In particular, the proposition's special cases are known already for UP (due to [24, 30]), $\mathrm{UP}_{\leq k}$ (for each $k \in \mathbb{N}^+$) and $\mathrm{UP}_{\leq \mathcal{O}(1)}$ (in [29, 6]), FewP (in [3]), and (since the following is another name for NP) $\mathrm{UP}_{\leq 2^{n^{\mathcal{O}(1)}}}$ (folklore, see [27, Theorem 2.5, Part 1]). The proposition holds not just for single functions f, but also for classes that are collections of functions, e.g., $\mathrm{UP}_{\leq \mathcal{O}(\log n)}$.

For any function f, we use $f^{[n]}$ to denote function iteration: $f^{[0]}(\alpha) = \alpha$ and inductively, for each $n \in \mathbb{N}$, $f^{[n+1]}(\alpha) = f(f^{[n]}(\alpha))$. For each real number $\alpha \geq 0$, $\log^*(\alpha)$ ("(base 2) log star of α") is the smallest natural number k such that $\log^{[k]}(\alpha) \leq 1$. Although the logarithm of 0 is not defined, note that $\log^*(0)$ is well-defined, namely it is 0 since $\log^{[0]}(0) = 0$.

A set L is said to be P-printable [25] exactly if there is a deterministic polynomial-time Turing machine such that, for each $n \in \mathbb{N}$, the machine when given as input the string 1^n prints (in some natural coding, such as printing each of the strings of L in lexicographical order, inserting the character # after each) exactly the set of all strings in L of length less than or equal to n.

Notions of whether a set has large empty expanses between one element and the next will be central to our work in this paper. Borchert, Hemaspaandra, and Rothe [7] defined and used such a notion, in a way that is tightly connected to our work. We present here the notion they called "nongappy," but here, we will call it "nongappy$_{\text{value}}$" to distinguish their value-centered definition from the length-centered definitions that will be our norm in this paper.

▶ **Definition 2.2** ([7]). *A set $S \subseteq \mathbb{N}^+$ is said to be nongappy$_{value}$ if $S \neq \emptyset$ and $(\exists k > 0)(\forall m \in S)(\exists m' \in S)[m' > m \wedge m'/m \leq k]$.*

This says that the gaps between one element of the set and the next greater one are, as to the *values* of the numbers, bounded by a multiplicative constant. Note that, if we view the natural numbers as naturally coded in binary, that is equivalent to saying that the gaps between one element of the set and the next greater one are, as to the *lengths* of the two strings, bounded by an additive constant. That is, a nonempty set $S \subseteq \mathbb{N}^+$ is said to be nongappy$_{\text{value}}$ by this definition if the gaps in the lengths of elements of S are bounded by an additive constant, and thus we have the following result that clearly holds.

▶ **Proposition 2.3.** *A set $S \subseteq \mathbb{N}^+$ is nongappy$_{value}$ if and only if $S \neq \emptyset$ and $(\exists k > 0)(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq |m| + k]$.*

In Section 4 we define other notions of nongappiness that allow larger gaps than the above does. We will always focus on lengths, and so we will consistently use the term "nongappy" in our definitions to speak of gaps quantified in terms of the *lengths* of the strings involved. We now introduce a new notation for the notion nongappy$_{\text{value}}$, and show that our definition does in fact refer to the same notion as that of Borchert, Hemaspaandra, and Rothe.

▶ **Definition 2.4.** *A set $S \subseteq \mathbb{N}^+$ is $(n + \mathcal{O}(1))$-nongappy if $S \neq \emptyset$ and $(\exists f \in \mathcal{O}(1))(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq |m| + f(|m|)]$.*

While at first glance this might seem to be different from Borchert, Hemaspaandra, and Rothe's definition, it is easy to see that both definitions are equivalent.

▶ **Proposition 2.5.** *A set S is $(n + \mathcal{O}(1))$-nongappy if and only if it is nongappy$_{value}$.*

3 Related Work

The most closely related work has already largely been covered in the nonappendix part of the paper, but we now briefly mention that work and its relationship to this paper. In particular, the most closely related papers are the work of Cai and Hemachandra [13], Hemaspaandra and Rothe [28], and Borchert, Hemaspaandra, and Rothe [7], which introduced and studied the iterative constant-setting technique as a tool for exploring containments of counting classes. The former two (and also the important related work of Borchert and Stephan [8]) differ from the present paper in that they are not about restricted counting classes, and unlike the present paper, Borchert, Hemaspaandra, and Rothe's paper, as to containment of ambiguity-limited classes, addresses only FewP. (It is known that FewP is contained in the class known as SPP and is indeed so-called SPP-low [31, 17, 18], however that does not make our containments in restricted counting classes uninteresting, as it seems unlikely that SPP is contained in *any* restricted counting class, since SPP's "no" case involves potentially exponential numbers of accepting paths, not zero such paths.) The interesting, recent paper of Cox and Pay [16] draws on the result of Borchert, Hemaspaandra, and Rothe [7] that appears as our Theorem 4.1 to establish that FewP $\subseteq \mathrm{RC}_{\{2^t-1 \,|\, t\in\mathbb{N}^+\}}$ (note that the right-hand side is the restricted counting class defined by the Mersenne numbers), a result that itself implies FewP $\subseteq \mathrm{RC}_{\{1,3,5,\ldots\}}$.

"RC" (restricted counting) classes [7] are central to this paper. The literature's earlier "CP" classes [12] might at first seem similar, but they don't restrict rejection to the case of having zero accepting paths. Leaf languages [9], a different framework, do have flexibility to express "RC" classes, and so are an alternate notation one could use, though in some sense they would be overkill as a framework here due to their extreme descriptive power. The class $\mathrm{RC}_{\{1,3,5,\ldots\}}$ first appeared in the literature under the name $\mathrm{ModZ_2P}$ [5]. Ambiguity-limited classes are also quite central to this paper, and among those we study (see Section 2) are ones defined, or given their notation that we use, in the following papers: [36, 4, 39, 3, 32].

P-printability is due to Hartmanis and Yesha [25]. Allender [2] established a sufficient condition, which we will discuss later, for the existence of infinite, P-printable subsets of the primes. As discussed in the text right after Corollary 4.2 and in Footnote 2, none of the results of Ford, Maynard, Tao, and others [20, 33, 19] about "infinitely often" lower bounds on gaps in the primes, nor any possible future bounds, can possibly be strong enough to be the sole obstacle to a FewP $\subseteq \mathrm{RC}_{\mathrm{PRIMES}}$ construction.

4 Gaps, Ambiguity, and Iterative Constant-Setting

What is the power of NPTMs whose number of accepting paths is 0 for each string not in the set and is a prime for each string in the set? In particular, does that class, $\mathrm{RC}_{\mathrm{PRIMES}}$, contain FewP or, for that matter, any interesting ambiguity-limited nondeterministic class? That is the question that motivated this work.

Why might one hope that $\mathrm{RC}_{\mathrm{PRIMES}}$ might contain some ambiguity-limited classes? Well, we clearly have that NP $\subseteq \mathrm{RC}_{\mathrm{COMPOSITES}}$, so having the composites as our acceptance targets allows us to capture all of NP. Why? For any NP machine N, we can make a new machine N' that mimics N, except it clones each accepting path into four accepting paths, and so when N has zero accepting paths N' has zero accepting paths, and when N has at least one accepting path N' has a composite number of accepting paths.

On the other hand, why might one suspect that interesting ambiguity-limited nondeterministic classes such as FewP might *not* be contained in $\mathrm{RC}_{\mathrm{PRIMES}}$? Well, it is not even clear that FewP is contained in the class of sets that are accepted by NPTMs that accept via having a prime number of accepting paths, and reject by having a nonprime number of accepting paths (rather than being restricted to rejecting only by having zero accepting paths, as is $\mathrm{RC}_{\mathrm{PRIMES}}$). That is, even a seemingly vastly more flexible counting class does not seem to in any obvious way contain FewP.

This led us to revisit the issue of identifying the sets $S \subseteq \mathbb{N}^+$ that satisfy $\mathrm{FewP} \subseteq \mathrm{RC}_S$, studied previously by, for example, Borchert, Hemaspaandra, and Rothe [7] and Cox and Pay [16]. In particular, Borchert, Hemaspaandra, and Rothe showed, by the iterative constant-setting technique, the following theorem. From it, we immediately have Cor. 4.2.

▶ **Theorem 4.1** ([7, Theorem 3.4]). *If $T \subseteq \mathbb{N}^+$ has an $(n + \mathcal{O}(1))$-nongappy, P-printable subset, then* $\mathrm{FewP} \subseteq \mathrm{RC}_T$.

▶ **Corollary 4.2.** *If* PRIMES *contains an $(n + \mathcal{O}(1))$-nongappy, P-printable subset, then* $\mathrm{FewP} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.

Does PRIMES contain an $(n+\mathcal{O}(1))$-nongappy, P-printable subset? The Bertrand–Chebyshev Theorem [15] states that for each natural number $k > 3$, there exists a prime p such that $k < p < 2k - 2$. Thus PRIMES clearly has an $(n + \mathcal{O}(1))$-nongappy subset.[2] Indeed, since – with p_i denoting the ith prime – $(\forall \epsilon > 0)(\exists N)(\forall n > N)[p_{n+1} - p_n < \epsilon p_n]$ [40], it holds that represented in binary there are primes at all but a finite number of bit-lengths. Unfortunately, to the best of our knowledge it remains an open research issue whether there exists *any* infinite, P-printable subset of the primes, much less one that in addition is $(n + \mathcal{O}(1))$-nongappy. In fact, the best sufficient condition we know of for the existence of an infinite, P-printable set of primes is a relatively strong hypothesis of Allender [2, Corollary 32 and the comment following it] about the probabilistic complexity class R [21] and the existence of secure extenders. However, that result does not promise that the infinite, P-printable set of primes is $(n + \mathcal{O}(1))$-nongappy – not even now, when it is known that primality is not merely in the class R but even is in the class P [1].

So the natural question to ask is: Can we at least lower the bar for what strength of advance – regarding the existence of P-printable sets of primes and the nongappiness of such sets – would suffice to allow $\mathrm{RC}_{\mathrm{PRIMES}}$ to contain some interesting ambiguity-limited class?

In particular, the notion of nongappiness used in Theorem 4.1 above means that our length gaps between adjacent elements of our P-printable set must be bounded by an additive constant. Can we weaken that to allow larger gaps, e.g., gaps of multiplicative constants, and still have containment for some interesting ambiguity-limited class?

We show that the answer is yes. More generally, we show that there is a tension and trade-off between gaps and ambiguity. As we increase the size of gaps we are willing to tolerate, we can prove containment results for restrictive counting classes, but of increasingly small levels of ambiguity. On the other hand, as we lower the size of the gaps we are willing to tolerate, we increase the amount of ambiguity we can handle.

[2] We mention in passing that it follows from the fact that PRIMES clearly *does* have an $(n + \mathcal{O}(1))$-nongappy subset that none of the powerful results by Ford, Maynard, Tao, and others [20, 33, 19] about "infinitely often" lower bounds for gaps in the primes, or in fact any results purely about lower bounds on gaps in the primes, can possibly prevent there from being a set of primes whose gaps are small enough that the set could, if sufficiently accessible, be used in a Cai–Hemachandra-type iterative constant-setting construction seeking to show that $\mathrm{FewP} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$. (In fact – keeping in mind that the difference between the value of a number and its coded length is exponential – the best such gaps known are almost exponentially too weak to preclude a Cai–Hemachandra-type iterative constant-setting construction.) Rather, the only obstacle will be the issue of whether there is such a set that in addition is computationally easily accessible/thin-able, i.e., whether there is such an $(n + \mathcal{O}(1))$-nongappy subset of the primes that is P-printable.

It is easy to see that the case of constant-ambiguity nondeterminism is so extreme that the iterative constant-setting method works for all infinite sets regardless of how nongappy they are. (It is even true that the containment $\mathrm{UP}_{\leq k} \subseteq \mathrm{RC}_T$ holds for some finite sets T, such as $\{1, 2, 3, \ldots, k\}$; but our point here is that it holds for *all* infinite sets $T \subseteq \mathbb{N}^+$.)

▶ **Theorem 4.3.** *For each infinite set $T \subseteq \mathbb{N}^+$ and for each natural $k \geq 1$, $\mathrm{UP}_{\leq k} \subseteq \mathrm{RC}_T$.*

Theorem 4.3 should be compared with the discussion by Hemaspaandra and Rothe [28, p. 210] of an NP-many-one-hardness result of Borchert and Stephan [8] and a $\mathrm{UP}_{\leq k}$-1-truth-table-hardness result. In particular, both those results are in the *un*restricted setting, and so neither implies Theorem 4.3. The proof of Theorem 4.3 can be found as Appendix A of our [26]. However, we recommend that the reader read it, if at all, only after reading the proof of Theorem 4.7, whose proof also uses (and within this paper, is the key presentation of) iterative constant-setting, and is a more interesting use of that approach.

▶ **Corollary 4.4.** *For each infinite set $T \subseteq \mathbb{N}^+$, $\mathrm{UP}_{\leq \mathcal{O}(1)} \subseteq \mathrm{RC}_T$.*

▶ **Corollary 4.5.** $\mathrm{UP}_{\leq \mathcal{O}(1)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.

So constant-ambiguity nondeterminism can be done by the restrictive counting class based on the primes. However, what we are truly interested in is whether we can achieve a containment for superconstant levels of ambiguity. We in fact can do so, and we now present such results for a range of cases between constant ambiguity ($\mathrm{UP}_{\leq \mathcal{O}(1)}$) and polynomial ambiguity (FewP). We first define a broader notion of nongappiness.

▶ **Definition 4.6.** *Let F be any function mapping $\mathbb{R}^+$ to $\mathbb{R}^+$. A set $S \subseteq \mathbb{N}^+$ is F-nongappy if $S \neq \emptyset$ and $(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq F(|m|)]$.*[3]

This definition sets F's domain and codomain to include real numbers, despite the fact that the underlying F-nongappy set S is of the type $S \subseteq \mathbb{N}^+$. The codomain is set to include real numbers because many notions of nongappiness we examine rely on non-integer values. Since we are often iterating functions, we thus set F's domain to be real numbers as well. Doing so does not cause problems as to computability because F is a function that is never actually computed by the Turing machines in our proofs; it is merely one that is mathematically reasoned about in the analysis of the nongappiness of sets underpinning restricted counting classes.

The following theorem generalizes the iterative constant-setting technique that Borchert, Hemaspaandra, and Rothe used to prove Theorem 4.1.

▶ **Theorem 4.7.** *Let F be a function mapping from $\mathbb{R}^+$ to $\mathbb{R}^+$ and let n_0 be a positive natural number such that F restricted to the domain $\{t \in \mathbb{R}^+ \mid t \geq n_0\}$ is nondecreasing and for all $t \geq n_0$ we have (a) $F(t) \geq t + 2$ and (b) $(\forall c \in \mathbb{N}^+)[cF(t) \geq F(ct)]$. Let j be a function, mapping from $\mathbb{N}$ to $\mathbb{N}^+$, that is at most polynomial in the value of its input and is computable in time polynomial in the value of its input. Suppose $T \subseteq \mathbb{N}^+$ has an F-nongappy, P-printable subset S. Let $\lambda = 4 + |s|$ where s is the smallest element of S with $|s| \geq n_0$. If for some $\beta \in \mathbb{N}^+$, $F^{[j(n)]}(\lambda) = \mathcal{O}(n^\beta)$, then $\mathrm{UP}_{\leq j(n)} \subseteq \mathrm{RC}_T$.*

[3] In two later definitions, 4.8 and 4.18, we apply Definition 4.6 to classes of functions. In each case, we will directly define that, but in fact will do so as the natural lifting (namely, saying a set is $\mathcal{F}$-nongappy exactly if there is an $F \in \mathcal{F}$ such that the set is F-nongappy). The reason we do not directly define lifting as applying to all classes $\mathcal{F}$ is in small part that we need it only in those two definitions, and in large part because doing so could cause confusion, since an earlier definition (Def. 2.4) that is connecting to earlier work is using as a syntactic notation an expression that itself would be caught up by such a lifting (though the definition given in Def. 2.4 is consistent with the lifting reading, give or take the fact that we've now broadened our focus to the reals rather than the naturals).

This theorem has a nice interpretation: a sufficient condition for an ambiguity-limited class $\mathrm{UP}_{\leq j(n)}$ to be contained in a particular restricted counting class is for there to be at least $j(n)$ elements that are reachable in polynomial time in an F-nongappy subset of the set that defines the counting class, assuming that the nongappiness of the counting class and the ambiguity of the $\mathrm{UP}_{\leq j(n)}$ class satisfy the above conditions.

Proof of Theorem 4.7. Let F, j, n_0, T, and S be as per the theorem statement. Suppose $(\exists \beta' \in \mathbb{N}^+)[F^{[j(n)]}(\lambda) = \mathcal{O}(n^{\beta'})]$, and fix a value $\beta \in \mathbb{N}^+$ such that $F^{[j(n)]}(\lambda) = \mathcal{O}(n^{\beta})$.

We start our proof by defining three sequences of constants that will be central in our iterative constant-setting argument, and giving bounds on their growth. Set c_1 to be the least element of S with $|c_1| \geq n_0$. For $n \in \{2, 3, \ldots\}$, given $c_1, c_2, \ldots, c_{n-1}$, we set

$$b_n = \sum_{1 \leq \ell \leq n-1} c_\ell \binom{n}{\ell}. \tag{1}$$

With b_n set, we define a_n to be the least element of S such that $a_n \geq b_n$. Finally, we set $c_n = a_n - b_n$. We now show that $\max_{1 \leq \ell \leq j(n)} |a_\ell|$ and $\max_{1 \leq \ell \leq j(n)} |c_\ell|$ are both at most polynomial in n. Take any $i \in \{2, 3, \ldots\}$. By the construction above and since S is F-nongappy, we have $|c_i| \leq |a_i| \leq F(|b_i|)$. Using our definition of b_i from Eq. 1 we get $b_i = \sum_{1 \leq k \leq i-1} c_k \binom{i}{k} \leq (i-1)(\max_{1 \leq k \leq i-1} c_k)\binom{i}{\lceil \frac{i}{2} \rceil} \leq (\max_{1 \leq k \leq i-1} c_k)(2^{2i})$. Thus we can bound the length of b_i by $|b_i| \leq 2i + \max_{1 \leq k \leq i-1} |c_k| \leq 2i + \max_{1 \leq k \leq i} |c_k|$. Since this is true for all $i \in \{2, 3, \ldots\}$, it follows that if $\max_{1 \leq \ell \leq j(n)} |c_\ell|$ is at most polynomial in n, then $\max_{1 \leq \ell \leq j(n)} |b_\ell|$ is at most polynomial in n, and since for all i, $a_i = b_i + c_i$, $\max_{1 \leq \ell \leq j(n)} |a_\ell|$ is at most polynomial in n. We now show that $\max_{1 \leq \ell \leq j(n)} |c_\ell|$ is in fact polynomial in n.

Let $n \in \{2, 3, \ldots\}$ be arbitrary. For each $i \in \{2, 3, \ldots, j(n)\}$, we have that $|b_i| \geq |c_1| \geq n_0$. Since F restricted to $\{t \in \mathbb{R}^+ \mid t \geq n_0\}$ is nondecreasing,

$$|c_i| \leq F(|b_i|) \leq F(2i + \max_{1 \leq k \leq i-1} |c_k|). \tag{2}$$

Since Eq. 2 holds for $2 \leq i \leq j(n)$ we can repeatedly apply it inside the max to get

$$|c_i| \leq F(2i + F(2(i-1) + F(\cdots 2 \cdot 4 + F(2 \cdot 3 + F(2 \cdot 2 + |c_1|)) \cdots))). \tag{3}$$

Recall that $\lambda = 4 + |c_1|$. From condition (a) of the theorem statement and since $|c_1| \geq n_0$, we have $F(\lambda) \geq 2 + \lambda = 2 + 4 + |c_1| \geq 6$, and thus $|c_i| \leq F(2i + F(2(i-1) + F(\cdots 2 \cdot 4 + F(2F(\lambda)) \cdots)))$. Since it follows from our theorem's assumptions that $(\forall t \geq \lambda)(\forall c \in \mathbb{N}^+)[cF(t) \geq F(ct)]$, we have $|c_i| \leq F(2i + F(2(i-1) + F(\cdots 2 \cdot 4 + 2F(F(\lambda)) \cdots)))$. Continuing to use the inequalities $(\forall k \geq 3)[2 \cdot k \leq F^{[k-2]}(\lambda)]$ and $(\forall t \geq \lambda)(\forall c \in \mathbb{N}^+)[cF(t) \geq F(ct)]$ we get $|c_i| \leq (i-1)(F^{[i-1]}(\lambda))$. Since $(\forall t \geq \lambda)[F(t) \geq t]$ and $i \leq j(n)$, we have that $|c_i| \leq (i-1)(F^{[i-1]}(\lambda)) \leq j(n)F^{[j(n)]}(\lambda)$. Since this bound holds for all $i \in \{2, 3, \ldots, j(n)\}$, it follows that $\max_{2 \leq \ell \leq n} |c_\ell| \leq j(n)F^{[j(n)]}(\lambda)$, and thus $\max_{1 \leq \ell \leq n} |c_\ell| \leq j(n)F^{[j(n)]}(\lambda) + |c_1|$. By supposition, $F^{[j(n)]}(\lambda) = \mathcal{O}(n^{\beta})$. Also, from our theorem's assumptions, $j(n)$ is polynomial in the value n, which means we can find some β'' such that $j(n) = \mathcal{O}(n^{\beta''})$. Hence we have $j(n)F^{[j(n)]}(\lambda) = \mathcal{O}(n^{\beta+\beta''})$. Since $|c_1|$ is a finite constant, this means $j(n)F^{[j(n)]}(\lambda) + |c_1|$ is polynomially bounded, and so $\max_{1 \leq \ell \leq j(n)} |c_\ell|$ is at most polynomial in n. By the argument in the preceding paragraph, $\max_{1 \leq \ell \leq j(n)} |a_\ell|$ is at most polynomial in n.

We now show that $\mathrm{UP}_{\leq j(n)} \subseteq \mathrm{RC}_T$. Let L be in $\mathrm{UP}_{\leq j(n)}$, witnessed by an NPTM $\hat{N}$. To show $L \in \mathrm{RC}_T$ we describe an NPTM N that, on each input x, has 0 accepting paths if $x \notin L$, and has $\#\mathrm{acc}_N(x) \in T$ if $x \in L$. On input x, our machine N computes $j(|x|)$ and then computes the constants $c_1, c_2, \ldots, c_{j(|x|)}$ as described above. Then N nondeterministically guesses an integer $i \in \{1, 2, \ldots, j(|x|)\}$, and nondeterministically guesses a cardinality-i set of paths of $\hat{N}(x)$. If all the paths guessed in a cardinality-i set are accepting paths, then N branches into c_i accepting paths; otherwise, that branch of N rejects. If $\hat{N}(x)$ has fewer than i paths, then the subtree of N that guessed i will have 0 accepting paths, since we cannot guess i distinct paths of $\hat{N}(x)$. We claim that N shows $L \in \mathrm{RC}_T$.

Consider any input x. If $x \notin L$, then clearly for all $i \in \{1, 2, \ldots, j(|x|)\}$ each cardinality-i set of paths of $\hat{N}$ guessed will have at least one rejecting path, and so N will have no accepting path. Suppose $x \in L$. Then $\hat{N}$ must have some number of accepting paths k. Since $\hat{N}$ witnesses $L \in \mathrm{UP}_{\leq j(n)}$, we must have $1 \leq k \leq j(|x|)$. Our machine N will have c_1 accepting paths for each accepting path of $\hat{N}$, c_2 additional accepting paths for each pair of accepting paths of $\hat{N}$, c_3 additional accepting paths for each triple of accepting paths of $\hat{N}$, and so on. Of course, for any cardinality-i set where $i > k$, at least one of the paths must be rejecting, and so N will have no accepting paths from guessing each $i > k$. Thus we have $\#\mathrm{acc}_N(x) = \sum_{1 \leq \ell \leq k} c_\ell \binom{k}{\ell}$. If $k = 1$, we have $\#\mathrm{acc}_N(x) = c_1$. If $2 \leq k \leq j(|x|)$, then $\#\mathrm{acc}_N(x) = c_k + \sum_{1 \leq \ell \leq k-1} c_\ell \binom{k}{\ell} = c_k + b_k = a_k$. In either case, $\#\mathrm{acc}_N(x) \in S$, and hence $\#\mathrm{acc}_N(x) \in T$. To complete our proof for $L \in \mathrm{RC}_T$ we need to check that N is an NPTM.

Note that, by assumption, $j(|x|)$ can be computed in time polynomial in $|x|$. Furthermore, the value $j(|x|)$ is at most polynomial in $|x|$, and so N's simulation of each cardinality-i set of paths of $\hat{N}$ can be done in time polynomial in $|x|$. Since S is P-printable and $\max_{1 \leq i \leq j(|x|)} |a_i|$ is at most polynomial in $|x|$, finding the constants a_i can be done in time polynomial in $|x|$. Also, since $\max_{1 \leq i \leq j(|x|)} |c_i|$ is at most polynomial in $|x|$, the addition and multiplication to compute each c_i can be done in time polynomial in $|x|$. All other operations done by N are also polynomial-time, and so N is an NPTM. ◀

It is worth noting that in general iterative constant-setting proofs it is sometimes useful to have a nonzero constant c_0 in order to add a constant number $c_0 \binom{i}{0} = c_0$ of accepting paths. However, when trying to show containment in a restricted counting class (as is the case here), we set $c_0 = 0$ to ensure that $\#\mathrm{acc}_N(x) = 0$ if $x \notin L$, and so we do not even have a c_0 but rather start iterative constant-setting and its sums with the c_1 case (as in Eq. 1).

Theorem 4.7 can be applied to get complexity-class containments. In particular, we now define a notion of nongappiness based on a multiplicative-constant increase in lengths, and we show – as Theorem 4.10 – that this notion of nongappiness allows us to accept all sets of logarithmic ambiguity.

▶ **Definition 4.8.** *A set $S \subseteq \mathbb{N}^+$ is $\mathcal{O}(n)$-nongappy if $S \neq \emptyset$ and $(\exists f \in \mathcal{O}(n))(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq f(|m|)]$.*

The following proposition notes that one can view this definition in a form similar to Borchert, Hemaspaandra, and Rothe's definition to see that $\mathcal{O}(n)$-nongappy sets are, as to the increase in the lengths of consecutive elements, bounded by a multiplicative constant. (In terms of values, this means that the gaps between the values of one element of the set and the next are bounded by a polynomial increase.)

▶ **Proposition 4.9.** *A set $S \subseteq \mathbb{N}^+$ is $\mathcal{O}(n)$-nongappy if and only if there exists $k \in \mathbb{N}^+$ such that S is kn-nongappy.*

▶ **Theorem 4.10.** *If $T \subseteq \mathbb{N}^+$ has an $\mathcal{O}(n)$-nongappy, P-printable subset, then $\mathrm{UP}_{\leq \mathcal{O}(\log n)} \subseteq \mathrm{RC}_T$.*

Proof. By the "only if" direction of Proposition 4.9, there exists a $k \in \mathbb{N}^+$ such that T has a kn-nongappy, P-printable subset. We can assume $k \geq 2$ since if a set has a $1n$-nongappy, P-printable subset then it also has a $2n$-nongappy, P-printable subset. Let $F : \mathbb{R}^+ \to \mathbb{R}^+$

be the function $F(t) = kt$. The function F satisfies the conditions from Theorem 4.7 since for all $t \geq 2$, $F(t) = kt \geq t + 2$, $(\forall c)[cF(n) = ckn = F(cn)]$, and F is nondecreasing on $\mathbb{R}^+$. Let $\lambda = 4 + |s|$ where s is the smallest element of the kn-nongappy, P-printable subset of T such that the conditions on F hold for all $t \geq |s|$, i.e., s is the smallest element of the kn-nongappy, P-printable subset of T such that $|s| \geq 2$. For any function $g : \mathbb{N} \to \mathbb{R}^{\geq 1}$ satisfying $g(n) = \mathcal{O}(\log n)$ it is not hard to see (since for each natural n it holds that $\log(n + 2) \geq 1$) that there must exist some $d \in \mathbb{N}^+$ such that $(\forall n \in \mathbb{N}^+)[g(n) \leq d \log(n + 2)]$, and hence $\mathrm{UP}_{\leq g(n)} \subseteq \mathrm{UP}_{\leq d \log(n+2)} = \mathrm{UP}_{\leq \lfloor d \log(n+2) \rfloor}$. Additionally, $j(n) = \lfloor d \log(n + 2) \rfloor$ satisfies the conditions from Theorem 4.7 since $j(n)$ can be computed in time polynomial in n and has value at most polynomial in n. Applying Theorem 4.7, to prove that $\mathrm{UP}_{\leq j(n)} \subseteq \mathrm{RC}_T$ it suffices to show that there is some $\beta \in \mathbb{N}^+$ such that $F^{[j(n)]}(\lambda) = \mathcal{O}(n^\beta)$ where λ is given by the statement of the theorem. So it suffices to show that for some $\beta \in \mathbb{N}^+$ and for all but finitely many n, $F^{[j(n)]}(\lambda) \leq n^\beta$. Note that $F^{[j(n)]}(\lambda) = k^{j(n)}\lambda$. So it is enough to show that for all but finitely many n, $k^{j(n)}\lambda \leq n^\beta$, or (taking logs) equivalently that for all but finitely many n, $\lfloor d \log(n + 2) \rfloor \log k + \log \lambda \leq \beta \log n$. Set β to be the least integer greater than $2d \log k + \log \lambda$. Then for all $n \geq 2$ we have $\beta \log n \geq 2d \log k \log n + \log \lambda \log n \geq d \log k \log(n^2) + \log \lambda \log n \geq d \log k \log(n + 2) + \log \lambda \geq \lfloor d \log(n + 2) \rfloor \log k + \log \lambda$, which is what we needed. Thus for any function $g : \mathbb{N} \to \mathbb{R}^{\geq 1}$ satisfying $g(n) = \mathcal{O}(\log n)$ we have that there exists a function j such that $\mathrm{UP}_{\leq g(n)} \subseteq \mathrm{UP}_{\leq j(n)} \subseteq \mathrm{RC}_T$. ◀

▶ **Corollary 4.11.** *If* PRIMES *has an $\mathcal{O}(n)$-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(\log n)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.

In order for the iterative constant-setting approach used in Theorem 4.7 to be applicable, it is clear that we need to consider UP classes that have at most polynomial ambiguity, because otherwise the constructed NPTMs could not guess large enough collections of paths within polynomial time. Since in the statement of Theorem 4.7 we use the function j to denote the ambiguity of a particular UP class, this requires j to be at most polynomial in the value of its input. Furthermore, since our iterative constant-setting requires having a bound on the number of accepting paths the UP machine could have had on a particular string, we also need to be able to compute the function j in time polynomial in the value of its input. Thus the limitations on the function j are natural and seem difficult to remove. Theorem 4.7 is flexible enough to, by a proof similar to that of Theorem 4.10, imply Borchert, Hemaspaandra, and Rothe's result stated in Theorem 4.1 where j reaches its polynomial bound. Another limitation of Theorem 4.7 is that it requires that for all t greater than or equal to a fixed constant n_0, $(\forall c \in \mathbb{N}^+)[cF(t) \geq F(ct)]$. It is possible to prove a similar result where for all t greater than or equal to a fixed constant n_0, $(\forall c \in \mathbb{N}^+)[cF(t) \leq F(ct)]$, which we now do as Theorem 4.12.

▶ **Theorem 4.12.** *Let F be a function mapping from $\mathbb{R}^+$ to $\mathbb{R}^+$ and let n_0 be a positive natural number such that F restricted to the domain $\{t \in \mathbb{R}^+ \mid t \geq n_0\}$ is nondecreasing and for all $t \geq n_0$ we have (a) $F(t) \geq t + 2$ and (b) $(\forall c \in \mathbb{N}^+)[cF(t) \leq F(ct)]$. Let j be a function mapping from $\mathbb{N}$ to $\mathbb{N}^+$ that is computable in time polynomial in the value of its input and whose output is at most polynomial in the value of its input. Suppose $T \subseteq \mathbb{N}^+$ has an F-nongappy, P-printable subset S. Let $\lambda = 4 + |s|$ where s is the smallest element of S with $|s| \geq n_0$. If for some β, $F^{[j(n)]}(j(n)\lambda) = \mathcal{O}(n^\beta)$, then $\mathrm{UP}_{\leq j(n)} \subseteq \mathrm{RC}_T$.*

How does this theorem compare with our other metatheorem, Theorem 4.7? Since in both metatheorems F is nondecreasing after a prefix, speaking informally and broadly, the functions F where (after a prefix) $(\forall c \in \mathbb{N}^+)[cF(t) \leq F(ct)]$ holds grow faster than the functions F where (after a prefix) $(\forall c \in \mathbb{N}^+)[cF(t) \geq F(ct)]$ holds. (The examples we give of applying the two theorems reflect this.) So, this second metatheorem is accommodating larger gaps in the sets of integers that define our restricted counting class, but is also assuming a slightly stronger condition for the containment of an ambiguity-limited class to follow. More specifically, since we have the extra factor of $j(n)$ inside of the iterated application of F, we may need even more than $j(|x|)$ elements to be reachable in polynomial time (exactly how many more will depend on the particular function F).

We now discuss some other notions of nongappiness and obtain complexity-class containments regarding them using Theorem 4.12.

▶ **Theorem 4.13.** *If there exists a real number $k > 1$ such that $T \subseteq \mathbb{N}^+$ has an n^k-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(1)+\frac{\log\log n}{2\log k}} \subseteq \mathrm{RC}_T$.

Theorem 4.13 has an interesting consequence when applied to the Mersenne primes. In particular, as we now show, it can be used to prove that the Lenstra–Pomerance–Wagstaff Conjecture implies that the $\mathcal{O}(\log\log n)$-ambiguity sets in NP each belong to $\mathrm{RC}_{\mathrm{PRIMES}}$.

A Mersenne prime is a prime of the form $2^k - 1$. We will use the Mersenne prime counting function $\mu(n)$ to denote the number of Mersenne primes with length less than or equal to n (when represented in binary). The Lenstra–Pomerance–Wagstaff Conjecture [35, 38] (see also [14]) asserts that there are infinitely many Mersenne primes, and that $\mu(n)$ grows asymptotically as $e^\gamma \log n$ where $\gamma \approx 0.577$ is the Euler–Mascheroni constant. (Note: We say that $f(n)$ grows asymptotically as $g(n)$ when $\lim_{n\to\infty} f(n)/g(n) = 1$.) Having infinitely many Mersenne primes immediately yields an infinite, P-printable subset of the primes. In particular, on input 1^n we can print all Mersenne primes of length less than or equal to n in polynomial time by just checking (using a deterministic polynomial-time primality test [1]) each number of the form $2^k - 1$ whose length is less than or equal to n, and if it is prime then printing it. If the Lenstra–Pomerance–Wagstaff Conjecture holds, what can we also say about the gaps in the Mersenne primes? We address that with the following result.

▶ **Theorem 4.14.** *If the Lenstra–Pomerance–Wagstaff Conjecture holds, then for each $\epsilon > 0$ the primes (indeed, even the Mersenne primes) have an $n^{1+\epsilon}$-nongappy, P-printable subset.*

▶ **Corollary 4.15.** *If the Lenstra–Pomerance–Wagstaff Conjecture holds, then* $\mathrm{UP}_{\leq \mathcal{O}(\log\log n)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$ *(indeed,* $\mathrm{UP}_{\leq \mathcal{O}(\log\log n)} \subseteq \mathrm{RC}_{\mathrm{MersennePRIMES}}$*).*

We will soon turn to discussing more notions of nongappiness and what containment theorems hold regarding them. However, to support one of those notions, we first define a function that will arise naturally in Theorem 4.19.

▶ **Definition 4.16.** *For any $\alpha \in \mathbb{R}$, $\alpha > 0$, $\log^{\circledast}(\alpha)$ is the largest natural number k such that $\log^{[k]}(\alpha) \geq k$. We define $\log^{\circledast}(0)$ to be 0.*

For $\alpha > 1$, taking $k = 0$ satisfies $\log^{[k]}(\alpha) \geq k$. Also, for all $\ell \geq \log^*(\alpha)$, $\log^{[\ell]}(\alpha) \leq \log^{[\log^*(\alpha)]}(\alpha) \leq 1 \leq \ell$, and so no $\ell \geq \log^*(\alpha)$ can be used as the k in the definition above. So there is at least one, but only finitely many k such that $\log^{[k]}(\alpha) \geq k$, which means that $\log^{\circledast}(\alpha)$ is well-defined. Using the def. of $\log^{\circledast}(\alpha)$ and the above, we get $\log^{\circledast}(\alpha) \leq \log^*(\alpha)$ when $\alpha > 1$. For $\alpha \leq 1$, 0 is the only natural number for which the condition from the def. holds, and so $\log^{\circledast}(\alpha) = 0$ if $\alpha \leq 1$. Thus for $\alpha \leq 1$, $\log^{\circledast}(\alpha) = \log^*(\alpha)$. As to the relationship of its values to those of $\log^*$, we have the following proposition.

▶ **Proposition 4.17.** *For all $\alpha \geq 0$, $\log^*(\alpha) - \log^*(\log^*(\alpha) + 1) - 1 \leq \log^{\circledast}(\alpha) \leq \log^*(\alpha)$.*

▶ **Definition 4.18.** *A nonempty set* $S \subseteq \mathbb{N}^+$ *is*

1. $\mathcal{O}(n \log n)$*-nongappy if* $(\exists f \in \mathcal{O}(n \log n))(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq f(|m|)]$, *and*
2. $n^{(\log n)^{\mathcal{O}(1)}}$*-nongappy if* $(\exists f \in \mathcal{O}(1))(\forall m \in S)(\exists m' \in S)[m' > m \wedge |m'| \leq |m|^{(\log |m|)^{f(|m|)}}]$.

Definitions of $n^{\log n}$-nongappy and 2^n-nongappy are provided via Definition 4.6, since $n^{\log n}$ and 2^n are each a single function, not a collection of functions. Those two notions, along with the two notions of Definition 4.18, will be the focus of Theorem 4.19. That theorem obtains the containments related to those four notions of nongappiness. As one would expect, as the allowed gaps become larger the corresponding UP classes become more restrictive in their ambiguity bounds. Theorem 4.19 also gives a corollary about primes.

▶ **Theorem 4.19.** *Let* T *be a subset of* $\mathbb{N}^+$.

1. *If* T *has an* $\mathcal{O}(n \log n)$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(\sqrt{\log n})} \subseteq \mathrm{RC}_T$.
2. *If* T *has an* $n^{\log n}$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(1) + \frac{1}{2} \log \log \log n} \subseteq \mathrm{RC}_T$.
3. *If* T *has an* $n^{(\log n)^{\mathcal{O}(1)}}$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(1) + \frac{1}{3} \log \log \log \log n} \subseteq \mathrm{RC}_T$.
4. *If* T *has a* 2^n*-nongappy, P-printable subset* S*, then* $\mathrm{UP}_{\leq \max(1, \lfloor \frac{\log^{\circledast} n}{\lambda} \rfloor)} \subseteq \mathrm{RC}_T$ *(and so certainly also* $\mathrm{UP}_{\leq \max(1, \lfloor \frac{\log^*(n) - \log^*(\log^*(n)+1)-1}{\lambda} \rfloor)} \subseteq \mathrm{RC}_T$*), where* $\lambda = 4 + \min_{s \in S, |s| \geq 2}(|s|)$.

▶ **Corollary 4.20.**

1. *If* PRIMES *has an* $\mathcal{O}(n \log n)$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(\sqrt{\log n})} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.
2. *If* PRIMES *has an* $n^{\log n}$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(1) + \frac{1}{2} \log \log \log n} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.
3. *If* PRIMES *has an* $n^{(\log n)^{\mathcal{O}(1)}}$*-nongappy, P-printable subset, then* $\mathrm{UP}_{\leq \mathcal{O}(1) + \frac{1}{3} \log \log \log \log n} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$.
4. *If* PRIMES *has a* 2^n*-nongappy, P-printable subset* S*, then* $\mathrm{UP}_{\leq \max(1, \lfloor \frac{\log^{\circledast} n}{\lambda} \rfloor)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$ *(and so certainly also* $\mathrm{UP}_{\leq \max(1, \lfloor \frac{\log^*(n) - \log^*(\log^*(n)+1)-1}{\lambda} \rfloor)} \subseteq \mathrm{RC}_{\mathrm{PRIMES}}$*), where* $\lambda = 4 + \min_{s \in S, |s| \geq 2}(|s|)$.

5 Conclusions and Open Problems

We proved two flexible metatheorems that can be used to obtain containments of ambiguity-limited classes in restricted counting classes, and applied those theorems to prove containments for some of the most natural ambiguity-limited classes. Beyond the containments we derived based on Theorems 4.7 and 4.12, those two metatheorems themselves seem to reflect a trade-off between the ambiguity allowed in an ambiguity-limited class and the smallness of gaps in a set of natural numbers defining a restricted counting class. One open problem is to make explicit, in a smooth and complete fashion, this trade-off between gaps and ambiguity. Another challenge is to capture the relationship between $\log^{\circledast}$ and $\log^*$ more tightly than Proposition 4.17 does (see Section 4 of [26]). Finally, though it would be a major advance since not even any infinite, P-printable subsets of the primes are currently known, in light of Corollaries 4.11 and 4.20, a natural goal would be to prove that the primes have infinite, P-printable subsets that satisfy some, or all, of our nongappiness properties.

Abstract

Directed Token Sliding asks, given a directed graph and two sets of pairwise nonadjacent vertices, whether one can reach from one set to the other by repeatedly applying a local operation that exchanges a vertex in the current set with one of its out-neighbors, while keeping the nonadjacency. It can be seen as a reconfiguration process where a token is placed on each vertex in the current set, and the local operation slides a token along an arc respecting its direction. Previously, such a problem was extensively studied on undirected graphs, where the edges have no directions and thus the local operation is symmetric. Directed Token Sliding is a generalization of its undirected variant since an undirected edge can be simulated by two arcs of opposite directions.

In this paper, we initiate the algorithmic study of Directed Token Sliding. We first observe that the problem is PSPACE-complete even if we forbid parallel arcs in opposite directions and that the problem on directed acyclic graphs is NP-complete and W[1]-hard parameterized by the size of the sets in consideration. We then show our main result: a linear-time algorithm for the problem on directed graphs whose underlying undirected graphs are trees, which are called polytrees. Such a result is also known for the undirected variant of the problem on trees [Demaine et al. TCS 2015], but the techniques used here are quite different because of the asymmetric nature of the directed problem. We present a characterization of yes-instances based on the existence of a certain set of directed paths, and then derive simple equivalent conditions from it by some observations, which yield an efficient algorithm. For the polytree case, we also present a quadratic-time algorithm that outputs, if the input is a yes-instance, one of the shortest reconfiguration sequences.

1 Introduction

In a reconfiguration problem, we are given an instance of a decision problem with two feasible solutions I^{s} and I^{t}. The task is to decide if we can transform I^{s} into I^{t} by repeatedly applying a modification rule while maintaining the feasibility of intermediate solutions. Reconfiguration problems are studied for several problems such as Independent Set [17, 28, 8, 12, 13, 18, 4, 10, 29, 3, 26], Dominating Set [34, 16, 30], Clique [27], Matching [9, 5, 23], and Graph Coloring [7, 32, 6]. (See also surveys [35, 31].)

Among the problems, Independent Set Reconfiguration is one of the most well-studied problems. There are three different modification rules studied in the literature: Token Addition and Removal (TAR) [19, 28], Token Jumping (TJ) [24, 25, 10], and Token Sliding (TS) [17, 8, 12, 13, 18, 4, 29, 3, 26]. TAR allows us to add or remove any vertex in the current independent set as long as the size of the resultant set is at least a given threshold. TJ allows us to exchange any vertex in the set with any vertex outside the set. TS is a restricted version of TJ that requires the exchanged vertices to be adjacent. We call Independent Set Reconfiguration under TS simply Token Sliding. Observe that all these rules are *symmetric*: If one can transform I^{s} into I^{t}, then one also can transform I^{t} into I^{s}. Our question is: What happens if we adopt an *asymmetric* rule?

In this paper, we study a directed variant of Token Sliding, which we call Directed Token Sliding. In this problem, the input graph is directed and we can slide tokens along the arcs only in their directions. Here, we say that a set I of vertices of a directed graph G is an independent set when it is an independent set in the underlying undirected graph of G.[1] If we allow two arcs with the opposite directions, this problem is a generalization of Token Sliding, and thus PSPACE-complete in general.

We show three results for Directed Token Sliding. First, we show that the problem is PSPACE-complete even on oriented graphs, where antiparallel arcs (two parallel arcs with opposite directions) are not allowed. Second, if we restrict input graphs to directed acyclic graphs (DAGs), we prove that the problem is NP-complete. Moreover, the problem is $W[1]$-hard parameterized by the number of tokens. As for our positive and main result, we show that the problem can be solved in linear time on polytrees, that is, digraphs whose underlying graphs are trees. For a polytree, we show that all reconfiguration sequences have the same length. We can also construct one of them in $\mathrm{O}(k|V|)$ time, where k is the size of the input independent sets and V is the set of vertices of the input graph. Note that our algorithm is optimal in the following sense: We can show that there exists an infinite family of instances on directed paths whose reconfiguration sequences have length $\Omega(k|V|)$ (which is easily obtained from lower bound examples for undirected paths given in [12]). For Token Sliding on undirected trees, Demaine et al. [12] showed a linear-time algorithm to check the reconfigurability. They also showed an $\mathrm{O}(|V|^2)$-time algorithm to construct a reconfiguration sequence of length $\mathrm{O}(|V|^2)$ for yes-instances. However, the output sequence is not guaranteed to be shortest. The best known algorithm to output a shortest reconfiguration sequence for undirected trees runs in $\mathrm{O}(|V|^5)$ time [33]. In contrast to the undirected counterpart, our algorithm to construct a (shortest) reconfiguration sequence on polytrees runs in $\mathrm{O}(k|V|)$ time, which is optimal. It should be mentioned that our quadratic-time algorithm does not imply a quadratic-time algorithm for finding a shortest reconfiguration sequence for undirected trees since we do not allow polytrees to have antiparallel arcs.

[1] One may define an independent set of a digraph in an asymmetric way: A subset I of the vertex set V of the directed graph G is an independent set if $u \in I$ implies $v \notin I$ for all $u, v \in V$ such that G has an arc (u, v). However, this definition is the same as ours. (If u and v are adjacent in the underlying undirected graph, at most one of u and v can belong to I.)

Due to the space limitation, several proofs (marked with $\star$) are omitted and can be found in the full version [21].

Related work

Token Sliding on undirected graphs was introduced by Hearn and Demaine [17]. They show that the problem is PSPACE-complete even on planar graphs with maximum degree 3. The problem is also PSPACE-complete on bipartite graphs [29] and split graphs [3]. In contrast to these hardness results, the problem is polynomial-time solvable on cographs [28], claw-free graphs [8], trees [12], cactus graphs [18], interval graphs [4], bipartite permutation graphs, and bipartite distance-hereditary graphs [13].

Interestingly, Independent Set Reconfiguration on bipartite graphs is NP-complete under TAR and TJ [29]. Such graph classes are not known for TS. In this paper, we show that Directed Token Sliding is NP-complete on directed acyclic graphs (DAGs).

Token Sliding is also studied from the viewpoint of fixed-parameter tractability (FPT). When the parameter is the number of tokens, the problem is W[1]-hard both on C_4-free graphs and bipartite graphs, while it becomes FPT on their intersection, C_4-free bipartite graphs [2]. In this paper, we show that Directed Token Sliding is W[1]-hard on DAGs.

Although Token Sliding, as far as we know, has not been studied for digraphs, there are some studies on reconfiguration considering directions of edges. An orientation of a simple undirected graph is an assignment of directions to the edges of the graph. There are several studies for reconfiguring orientations of a graph, such as strong orientations [15, 14, 20], acyclic orientations [14], nondeterministic constraint logic [17], and α-orientations [1]. Very recently, Ito et al. [22] studied reconfiguration of several subgraphs in directed graphs, such as directed trees, directed paths, and directed acyclic subgraphs. Although these reconfiguration problems are defined on directed graphs, the reconfiguration rules are symmetric, meaning that if one solution X can be obtained from another solution Y by applying some reconfiguration rule, Y can be obtained from X by the same rule as well.

2 Preliminaries

In this section, we introduce notations on graphs and define our problem. For a positive integer k, we define $[k] \coloneqq \{1, \dots, k\}$. We also define $[0] \coloneqq \emptyset$.

2.1 Graph notation

Let G be a directed graph (digraph). We denote by $V(G)$ and $A(G)$ the vertex and arc sets of G, respectively. For a digraph G, its *underlying (undirected) graph*, denoted by G^{und}, is an undirected graph obtained by ignoring the directions of arcs in G. For an undirected graph G', we denote by $V(G')$ and $E(G')$ the vertex and edge sets of G', respectively. For a digraph G, a vertex set $S \subseteq V(G)$ is said to be *independent* if it is an independent set in the underlying graph G^{und}, i.e., for all two different vertices $u, v \in S$, we have $\{u, v\} \notin E(G^{\mathrm{und}})$. A digraph G is an *oriented graph* if, for all vertices $u, v \in V(G)$, G contains at most one of the possible arcs (u, v) or (v, u). If G contains no directed cycles, G is *acyclic* and such digraphs are called *directed acyclic graphs (DAGs)*. If G^{und} is a tree, G is a *polytree*. Similarly, if G^{und} is a forest, G is a *polyforest*.

For an arc $e = (u, v) \in A(G)$ of a digraph G, the vertex u is called the *tail* of e, and v called the *head* of e. The both u and v are called the *endpoints* of e. For $e \in A(G)$ and $v \in V(G)$, e is *incident to* v if v is an endpoint of e. If $(u, v) \in A(G)$, u is an *in-neighbor* *of v in G* and v is an *out-neighbor of u in G*. In addition, u is a *neighbor* of v and v is a *neighbor* of u. For a vertex v, we denote by $N^+_G(v)$ and $N^-_G(v)$ the sets of out-neighbors and in-neighbors of v in G, respectively, that is, $N^+_G(v) \coloneqq \{u \in V(G) \mid (v,u) \in A(G)\}$ and $N^-_G(v) \coloneqq \{u \in V(G) \mid (u,v) \in A(G)\}$. We denote by $N_G(v)$ the set of neighbors of v, that is, $N_G(v) \coloneqq N^+_G(v) \cup N^-_G(v)$. In addition, we define $N_G[v] \coloneqq N_G(v) \cup \{v\}$. We also define $\Gamma^+_G(v) \coloneqq \big\{(v,u) \bigm| u \in N^+_G(v)\big\}$, $\Gamma^-_G(v) \coloneqq \big\{(u,v) \bigm| u \in N^-_G(v)\big\}$, and $\Gamma_G(v) \coloneqq \Gamma^+_G(v) \cup \Gamma^-_G(v)$. If no confusion arises, we omit the subscript G from $N_G(v)$, $N^+_G(v)$, $N^-_G(v)$, $N_G[v]$, $\Gamma^+_G(v)$, $\Gamma^-_G(v)$, and $\Gamma_G(v)$. A *directed path* P is a sequence of vertices and arcs $(v_1, e_1, \dots, e_{\ell-1}, v_\ell)$ such that, all the vertices are distinct and, for every $i \in [\ell-1]$, $e_i = (v_i, v_{i+1})$ holds. We call v_1 and v_ℓ the *source* and *sink* of P, and denote by $s(P)$ and $t(P)$, respectively. This P is called a *v_1-v_ℓ (directed) path* or a *(directed) path from v_1 to v_ℓ*. The *length* of P is the number of arcs and we denote it by $|P|$, that is, $|P| = \ell - 1$. For a directed path P with $|P| \geq 2$, we define $s'(P) \coloneqq v_2$ and $t'(P) \coloneqq v_{\ell-1}$. For vertex sets X and Y with the same size k on a digraph, we refer to a set $\mathcal{P} = \{P_1, \dots, P_k\}$ of directed paths as a *directed path matching from X to Y* if $\mathcal{P}$ have distinct sources and distinct sinks, that is, $\{s(P_i) \mid i \in [k]\} = X$ and $\{t(P_i) \mid i \in [k]\} = Y$. Note that two sets X and Y may intersect in this definition.

2.2 Definition of Directed Token Sliding

Let I^{s} and I^{t} be independent sets in a digraph G with $|I^{\mathsf{s}}| = |I^{\mathsf{t}}|$. A sequence $\langle I_0, \dots, I_\ell \rangle$ of independent sets of G is a *reconfiguration sequence from I^{s} to I^{t} in G* if $I_0 = I^{\mathsf{s}}, I_\ell = I^{\mathsf{t}}$, and for all $i \in [\ell]$ we have $I_{i-1} \setminus I_i = \{u\}$ and $I_i \setminus I_{i-1} = \{v\}$ with $(u,v) \in A$. The *length* of $\langle I_0, \dots, I_\ell \rangle$ is ℓ. We say that *I^{s} is reconfigurable into I^{t} in G* and *I^{t} is reconfigurable from I^{s} in G* if there is a reconfiguration sequence from I^{s} to I^{t}.

We study the following problem:

Problem Directed Token Sliding
Instance A triple $(G, I^{\mathsf{s}}, I^{\mathsf{t}})$, where G is a digraph and $I^{\mathsf{s}}, I^{\mathsf{t}} \subseteq V(G)$ are independent sets in G with $|I^{\mathsf{s}}| = |I^{\mathsf{t}}|$.
Question Is I^{s} reconfigurable into I^{t}?

In Directed Token Sliding, the sets I^{s} and I^{t} can be seen as the initial and target positions of "tokens" placed on the vertices in the sets, and then the problem asks whether we can move the tokens from I^{s} to I^{t} by repeatedly sliding tokens along arcs keeping that the tokens are not adjacent. The difference between our problem and Token Sliding is that, in the former, the input graph is directed and we can slide tokens along the arcs only in their directions. However, since we can simulate an undirected edge with the two arcs with the opposite directions, the problem is a generalization of Token Sliding. It immediately follows from the PSPACE-completeness of Token Sliding [17] that Directed Token Sliding is PSPACE-complete in general.

3 Hardness results

In this section, we provide hardness results for Directed Token Sliding. The first hardness result is the PSPACE-completeness of Directed Token Sliding for oriented graphs. This follows from a reduction from Token Sliding on undirected graphs, which is PSPACE-complete [17].

The idea of the proof of Theorem 1 as follows. From an undirected graph G, we construct a directed graph G' by replacing each edge of G with two directed arcs in opposite directions. Then, $(G, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance of Token Sliding if and only if $(G', I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance of Directed Token Sliding. To make G' being an oriented graph (that is, G' has at most one arc of (u, v) and (v, u) for $u, v \in V(G)$), we replace each vertex v of G with two copies of vertices v_1 and v_2 and each edge $\{u, v\}$ of G with a strongly connected tournament on $\{u_1, u_2, v_1, v_2\}$, instead of the above replacement. This yields an oriented graph G' and we can show that $(G, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance of Token Sliding if and only if $(G', J^{\mathsf{s}}, J^{\mathsf{t}})$ is a yes-instance of Directed Token Sliding, where $J^{\mathsf{s}} = \{v_1 \mid v \in I^{\mathsf{s}}\}$ and $J^{\mathsf{t}} = \{v_1 \mid v \in I^{\mathsf{t}}\}$.

▶ **Theorem 1** (⋆). *Directed Token Sliding is PSPACE-complete on oriented graphs.*

The second hardness result is the NP-completeness and W[1]-hardness of Directed Token Sliding for DAGs. These results are obtained by reducing Multicolored Independent Set, which is known to be NP-complete and W[1]-hard parameterized by the solution size k [11], to Directed Token Sliding.

▶ **Theorem 2** (⋆). *Directed Token Sliding on DAGs is NP-complete and W[1]-hard parameterized by the number of tokens.*

4 Linear-time algorithm for polytrees

This section is devoted to proving our main result Theorem 3 below, a linear-time algorithm for Directed Token Sliding on polytrees.

▶ **Theorem 3.** *Let $T = (V, A)$ be a polytree. Directed Token Sliding on T can be solved in $\mathrm{O}(|V|)$ time. Moreover, if the answer is affirmative, then all reconfiguration sequences have the same length, and one of them can be constructed in $\mathrm{O}(k|V|)$ time, where k is the size of the input independent set.*

To establish Theorem 3, we give a simple characterization for yes-instances of Directed Token Sliding on polytrees. This characterization is described by the concept of directed path matchings, which will be given in the next subsection, and is a vital role in proving Theorem 3. We would like to mention that our characterization is rather simple but its proof is highly non-trivial. Given this characterization, we devise a linear time algorithm for Directed Token Sliding on polytrees and a quadratic time algorithm for constructing an actual reconfiguration sequence if the answer is affirmative, which will be given in Section 4.4.

4.1 Directed path matching

Let I^{s} and I^{t} be independent sets in T with $|I^{\mathsf{s}}| = |I^{\mathsf{t}}|$ such that I^{s} is reconfigurable into I^{t}. In a reconfiguration sequence from I^{s} to I^{t}, the i-th token moves along some directed path P_i. Clearly $\mathcal{P} := \{P_1, \dots, P_k\}$ forms a directed path matching from I^{s} to I^{t}. Thus, the existence of a directed path matching is a trivial necessary condition for yes-instances. However, the converse is not true in general. Let us consider a digraph such that its underlying graph is the star with four leaves and its center has two in-neighbors and two out-neighbors. We set I^{s} (resp. I^{t}) to be the set of in-neighbors (resp. out-neighbors) of the center. Then this graph has a directed path matching from I^{s} to I^{t}, while it is a no-instance. Nevertheless, directed path matchings still give us some insight on Directed Token Sliding for polytrees, which is vital for our linear-time algorithm. To this end, in this subsection, we give a characterization of the existence of a directed path matching between given two sets of vertices in a polytree. This characterization is described in terms of an invariant associated with each arc e.

Let X and Y be (not necessarily disjoint) sets of vertices of a polytree $T = (V, A)$ with $|X| = |Y|$, and π a bijection from X to Y. Since T is a polytree, for each $x \in X$ an (undirected) x-$\pi(x)$ path P_x is uniquely determined in T^{und}. For each $e \in A$, we define $w(e; X, Y, \pi) \coloneqq |\{x \in X \mid \overrightarrow{P_x} \text{ has } e\}| - |\{x \in X \mid \overrightarrow{P_x} \text{ has the reverse of } e\}|$, where $\overrightarrow{P_x}$ is a directed path obtained from P_x by orienting arcs from x to $\pi(x)$. The following lemma states that $w(e; X, Y, \pi)$ does not depend on a particular π. Let T' be the polyforest obtained from T by removing an arc e. Let C_e^+ (resp. C_e^-) denote the vertices of the (weakly) connected component in T' containing the head of e (resp. the tail of e).

▶ **Lemma 4** (⋆). *Let X and Y be (not necessarily disjoint) sets of vertices of T with $|X| = |Y|$, and $e \in A$ an arc of T. For each bijection $\pi : X \to Y$, we have $w(e; X, Y, \pi) = |C_e^- \cap X| - |C_e^- \cap Y|$.*

Based on this fact, we define a function w on A with respect to two vertex sets X and Y:

$$w(e; X, Y) \coloneqq |C_e^- \cap X| - |C_e^- \cap Y| \qquad (e \in A).$$

Then, we show the necessary and sufficient conditions mentioned above.

▶ **Lemma 5** (⋆). *There exists a directed path matching from X to Y if and only if $w(e; X, Y) \geq 0$ for every arc $e \in A$.*

By Lemmas 4 and 5, we can observe the following corollaries.

▶ **Corollary 6.** *For a yes-instance, the number of tokens passing through an arc e is equal to $w(e; I^{\mathrm{s}}, I^{\mathrm{t}})$ in every reconfiguration sequence. In particular, all reconfiguration sequences have the same length $\sum_{e \in A} w(e; I^{\mathrm{s}}, I^{\mathrm{t}})$.*

▶ **Corollary 7.** *If there exists an arc $e \in A$ such that $w(e; I^{\mathrm{s}}, I^{\mathrm{t}}) < 0$, then the instance is not reconfigurable.*

In the following argument, we assume $w(e; I^{\mathrm{s}}, I^{\mathrm{t}}) \geq 0$ for all $e \in A$. By depth-first search on T, we can compute the function $w(e; I^{\mathrm{s}}, I^{\mathrm{t}})$ for all e in linear time.

4.2 Tokens that move at most once

In a reconfiguration sequence, there may be a token that moves at most once. In other words, a token may not move at all or may move from the initial position to one of its out-neighbors and stay there. Such a token causes an exception in our further discussion, and thus we want to remove such tokens in advance. In this subsection, we show that such tokens are determined regardless of reconfiguration sequences, and that we can remove such tokens from the input without changing the reconfigurability.

First, we consider tokens that never move. The following lemma states that such tokens are uniquely determined from the instance $(T, I^{\mathrm{s}}, I^{\mathrm{t}})$ (not depending on an actual reconfiguration sequence). From now on, we simply write $w(e)$ to denote $w(e; I^{\mathrm{s}}, I^{\mathrm{t}})$.

▶ **Lemma 8** (⋆). *Let $(T, I^{\mathrm{s}}, I^{\mathrm{t}})$ be a yes-instance. For every reconfiguration sequence, the set of vertices containing tokens that do not move in the sequence is equal to*

$$R \coloneqq \{v \in I^{\mathrm{s}} \cap I^{\mathrm{t}} \mid w(e) = 0 \text{ for all } e \in \Gamma(v)\}.$$

A token on a vertex $v \in R$ is said to be *rigid*. By Lemma 8, all rigid tokens do not move in any reconfiguration sequence.

For some $v \in R$, suppose that there exists $u \in N(v)$ such that T has an arc $e \in \Gamma(u)$ with $w(e) > 0$. If $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance, in any reconfiguration sequence, some token passes through e, implying that this token is placed on u at some point. However, since the token on v is rigid, these tokens must be adjacent. Thus, we obtain the following corollary.

▶ **Corollary 9.** *For $v \in R$, if there exists $u \in N(v)$ such that T has an arc $e \in \Gamma(u)$ with $w(e) > 0$, then the instance $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a no-instance.*

Next, we consider tokens that move exactly once. We can show that the set of arcs used by such tokens is uniquely determined from the instance $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ (not depending on an actual reconfiguration sequence) by a similar argument as in Lemma 8.

▶ **Lemma 10** ($\star$)**.** *Let $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ be a yes-instance. For every reconfiguration sequence, the set of arcs used by tokens that move exactly once in the sequence is equal to*

$$B \coloneqq \{e = (u, v) \in A \mid w(e) = 1 \text{ and } w(e') = 0 \text{ for every } e' \in (\Gamma(u) \cup \Gamma(v)) \setminus \{e\}\}.$$

Take any $(u, v) \in B$. By Lemma 10, for every reconfiguration sequence the token on u slides to an out-neighbor v of u and stays there, which also implies $u \in I^{\mathsf{s}}$ and $v \in I^{\mathsf{t}}$. Since the tokens must form an independent set, the other tokens can be placed on neither u nor v. Given this, we refer to an arc $e \in B$ as a *blocking arc* in $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$.

We can compute the rigid tokens and blocking arcs from $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ in linear time. Let R be the set of vertices containing rigid tokens and B the set of blocking arcs. Let T' be the polyforest obtained from T by removing each arc f such that f is incident to a vertex in R, or $f \notin B$ and f is incident to an endpoint of $e \in B$. Then, every component of T' is either an isolated vertex in R, a component containing the two vertices connected by an arc in B, or a component without any rigid tokens or blocking arcs. The following lemma reduces our problem to a slightly simplified one.

▶ **Lemma 11** ($\star$)**.** *Suppose that for every $v \in R$, there is no $u \in N(v)$ such that T has an arc $e \in \Gamma(u)$ with $w(e) > 0$. Then, $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance if and only if $(T', I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance.*

It is easy to see that if T' has more than one connected components, then we can solve the problem independently on each connected component. Moreover, the problem is trivial on a component of size at most two. Hence, we can assume that the input polytree has no vertices on which rigid tokens are placed or blocking arcs.

4.3 Necessary and sufficient conditions for yes-instances

In this subsection, we show the necessary and sufficient conditions for yes-instances. By Lemma 11, we may assume that the instance does not contain rigid tokens and blocking arcs. For a yes-instance, pick some reconfiguration sequence and let P_i be a directed path along which the i-th token moves in the reconfiguration sequence. $\mathcal{P} = \{P_1, \dots, P_k\}$ is obviously a directed path matching from I^{s} to I^{t}. Since the instance does not contain rigid tokens and blocking arcs, we have $|P_i| \geq 2$ for every $i \in [k]$. In addition, the successors of source vertices in $\mathcal{P}$ must be distinct. To see this, observe that if the source vertices of two paths P_i and P_j in $\mathcal{P}$ have a common successor $x \coloneqq s'(P_i) = s'(P_j)$, then the tokens on $s(P_i)$ and $s(P_j)$ are both "gazing" the vertex x, and thus we cannot slide either of the tokens on $s(P_i)$ and $s(P_j)$ at all. Therefore, $\mathcal{P}$ must satisfy that $s'(P_i) \neq s'(P_j)$ for all $i, j \in [k]$ with $i \neq j$. Symmetrically, the predecessors of sink vertices must be distinct, that is, $t'(P_i) \neq t'(P_j)$ for all $i, j \in [k]$ with $i \neq j$. The goal of this subsection is to show that these necessary conditions are also sufficient.

▶ **Lemma 12.** *Let $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ be an instance of* Directed Token Sliding *without rigid tokens and blocking arcs. Then $(T, I^{\mathsf{s}}, I^{\mathsf{t}})$ is a yes-instance if and only if there exists a set $\mathcal{P} = \{P_1, \ldots, P_k\}$ of directed paths satisfying all the following conditions:*

(P1) $|P_i| \geq 2$ *for all* $i \in [k]$,

(P2) $\mathcal{P}$ *is a directed path matching from* I^{s} *to* I^{t},

(P3) $s'(P_i) \neq s'(P_j)$ *for all* $i, j \in [k]$ *with* $i \neq j$, *and*

(P4) $t'(P_i) \neq t'(P_j)$ *for all* $i, j \in [k]$ *with* $i \neq j$.

We refer to the four conditions (P1)–(P4) as the *path-set conditions.*

We have already seen the only-if direction as above. In the following, we show the other direction. We call a vertex in a path other than the source or the sink an *internal vertex.* For vertices $u, v \in V$, we define $\mathrm{dist}(u, v)$ as the length of the unique directed u-v path in T if such a path exists. We refer to a pair of directed paths P and P' satisfying the following conditions as a *biased path pair*:

- P and P' have a common internal vertex x,
- $\mathrm{dist}(s(P), x) > \mathrm{dist}(s(P'), x)$ and $\mathrm{dist}(x, t(P)) > \mathrm{dist}(x, t(P'))$.

▶ **Lemma 13** ($\star$). *If there exists a set of paths satisfying the path-set conditions, then there also exists a set of paths that satisfies the path-set conditions and does not include any biased path pair.*

In the following, let $\mathcal{P}^* = \{P_1^*, \ldots, P_k^*\}$ be a set of paths that satisfies the path-set conditions and has no biased path pairs. We show that there exists a bijection $\pi : [k] \to [k]$ having the following property $(*)$:

$(*)$ I^{s} is reconfigurable into I^{t} in a path-by-path manner following π; that is, by first moving the $\pi(1)$-th token from $s(P^*_{\pi(1)})$ all the way to $t(P^*_{\pi(1)})$ along $P^*_{\pi(1)}$, then moving the $\pi(2)$-th token from $s(P^*_{\pi(2)})$ all the way to $t(P^*_{\pi(2)})$ along $P^*_{\pi(2)}$, and so on.

From now on, we consider how to construct π satisfying $(*)$. For a vertex v and a directed path P, we say that v *touches* P or P *touches* v if $N[v] \cap V(P) \neq \emptyset$, where $V(P)$ denotes the set of vertices in P. For $i \neq j$, let (A) and (B) be the following conditions:

(A) $s(P_i^*)$ touches P_j^*;

(B) $t(P_j^*)$ touches P_i^*.

A binary relation $\dashleftarrow$ is defined as: $i \dashleftarrow j$ if and only if at least one of (A) and (B) holds for different i and j. Let $G_{\dashleftarrow}$ be the directed graph such that the vertex set of $G_{\dashleftarrow}$ is $[k]$ and, for $i, j \in [k]$, $G_{\dashleftarrow}$ has the arc (i, j) if and only if $j \dashleftarrow i$ holds.

If $G_{\dashleftarrow}$ is a directed acyclic graph, then we can construct π satisfying $(*)$ as follows. Since $G_{\dashleftarrow}$ is a DAG, there is a vertex i such that its out-degree is 0. For any $j \neq i$, every vertex in P_i^* does not belong to $N[s(P_j^*)]$ since P_i^* does not touch $s(P_j^*)$, and every vertex in P_j^* does not belong to $N[t(P_i^*)]$ since P_j^* does not touch $t(P_i^*)$. The former implies that the token on $s(P_i^*)$ sliding to $t(P_i^*)$ along P_i^* does not make adjacent token pairs and hence forms a reconfiguration sequence from I^{s} to $I^{\mathsf{s}} \setminus \{s(P_i^*)\} \cup \{t(P_i^*)\}$. The latter implies that the graph $G_{\dashleftarrow}$ for the resulting independent set $I^{\mathsf{s}} \setminus \{s(P_i^*)\} \cup \{t(P_i^*)\}$ is obtained by deleting the vertex i, which is still a DAG. By repeating the above procedure, I^{s} is reconfigurable into I^{t} in a path-by-path manner. Thus a bijection $\pi : [k] \to [k]$ satisfying $\pi(1) < \pi(2) < \cdots < \pi(k)$ with respect to a topological order of $G_{\dashleftarrow}$ admits $(*)$, as required.

The following lemma says that $G_{\dashleftarrow}$ is actually a directed acyclic graph, which verifies the if-condition of Lemma 12.

▶ **Lemma 14.** *$G_{\dashleftarrow}$ is a directed acyclic graph.*

Proof. Suppose, to the contrary, that there is a directed cycle in $G_{\dashleftarrow}$. We can assume that $(1, 2, \ldots, \ell, 1)$ is a minimal one. For convenience, the addition $+$ and subtraction $-$ are taken over modulo ℓ, i.e., $\ell + 1$ is regarded as 1 and 0 is regarded as ℓ.

Suppose moreover that P^*_i and P^*_{i+1} have a common internal vertex for all $i \in [k]$. Let x and y be the source and the sink of the maximal common subpath of P^*_i and P^*_{i+1}, respectively. Since T is a polytree, these x and y are uniquely determined. For $i \in [\ell]$, at least one of (A) and (B) holds. If (A) $s(P^*_i)$ touches P^*_{i+1}, then we have $\mathrm{dist}(s(P^*_i), x) \leq 1$. If $\mathrm{dist}(s(P^*_i), x) \geq \mathrm{dist}(s(P^*_{i+1}), x)$, either $s'(P^*_i) = s'(P^*_{i+1})$ or $s(P^*_i)$ and $s(P^*_{i+1})$ are adjacent, which do not hold as (P3) or the fact that I^{s} is an independent set. Thus, we have $\mathrm{dist}(s(P^*_i), x) < \mathrm{dist}(s(P^*_{i+1}), x)$. If (B) $t(P^*_{i+1})$ touches P^*_i, then we have $\mathrm{dist}(y, t(P^*_{i+1})) \leq 1$. Then, by a symmetric argument, we have $\mathrm{dist}(y, t(P^*_i)) > \mathrm{dist}(y, t(P^*_{i+1}))$. Let z_i be an arbitrary common internal vertex of P^*_i and P^*_{i+1}. The above argument is summarised as

$$\mathrm{dist}(s(P^*_i), z_i) < \mathrm{dist}(s(P^*_{i+1}), z_i) \text{ or } \mathrm{dist}(z_i, t(P^*_i)) > \mathrm{dist}(z_i, t(P^*_{i+1})). \tag{1}$$

Equation (1) and the non-existence of biased pairs together imply that for every i, we have

$$\mathrm{dist}(s(P^*_i), z_i) \leq \mathrm{dist}(s(P^*_{i+1}), z_i) \text{ and } \mathrm{dist}(z_i, t(P^*_i)) \geq \mathrm{dist}(z_i, t(P^*_{i+1})). \tag{2}$$

For a walk W in T^{und}, let $\overrightarrow{W}$ be an oriented walk obtained from W by orienting each edge from (arbitrary) one of the end vertices to the other. Let $\mathrm{fwd}(\overrightarrow{W})$ and $\mathrm{rev}(\overrightarrow{W})$ be the numbers of times that $\overrightarrow{W}$ passes through arcs in the forward and reverse directions in T, respectively. Here, by the fact that $\mathrm{dist}(s(P^*_i), z_i) \leq \mathrm{dist}(s(P^*_{i+1}), z_i)$ (Equation (2)), there exists an oriented walk $\overrightarrow{W}$ from $s(P^*_i)$ to $s(P^*_{i+1})$ satisfying $\mathrm{fwd}(\overrightarrow{W}) \leq \mathrm{rev}(\overrightarrow{W})$. This can be obtained by traversing T^{und} from $s(P^*_i)$ to $s(P^*_{i+1})$ via z_i (which we denote by $s(P^*_i) \to z_i \to s(P^*_{i+1})$). In particular, if $\mathrm{dist}(s(P^*_i), z_i) < \mathrm{dist}(s(P^*_{i+1}), z_i)$, then $\mathrm{fwd}(\overrightarrow{W}) < \mathrm{rev}(\overrightarrow{W})$ holds. Suppose that $\mathrm{dist}(s(P^*_1), z_1) < \mathrm{dist}(s(P^*_2), z_1)$ holds. Then, the closed oriented walk

$$\overrightarrow{W_s} \coloneqq s(P^*_1) \to z_1 \to s(P^*_2) \to \cdots \to s(P^*_\ell) \to z_\ell \to s(P^*_1)$$

satisfies $\mathrm{fwd}(\overrightarrow{W_s}) < \mathrm{rev}(\overrightarrow{W_s})$. See Figure 1 for an illustration. This implies that there is an arc e in T such that e occurs in $\overrightarrow{W_s}$ at least once and the number of occurrences of e is strictly smaller than that of the reverse of e in $\overrightarrow{W_s}$. This contradicts the fact that T is a polytree. Thus suppose $\mathrm{dist}(s(P^*_1), z_1) \geq \mathrm{dist}(s(P^*_2), z_1)$ holds. Then $\mathrm{dist}(z_1, t(P^*_1)) > \mathrm{dist}(z_1, t(P^*_2))$ follows from Equation (1). By a similar argument as above, we can construct a closed oriented walk $\overrightarrow{W_t}$ from $t(P^*_1)$ to $t(P^*_1)$ satisfying $\mathrm{fwd}(\overrightarrow{W_t}) > \mathrm{rev}(\overrightarrow{W_t})$. This also contradicts the fact that T is a polytree. Thus, we derive a contradiction, assuming that $G_{\dashleftarrow}$ has a directed cycle and P^*_i and P^*_{i+1} have a common internal vertex for all $i \in [k]$.

The remaining task is to show that P^*_i and P^*_{i+1} have a common internal vertex for all i under the assumption that $G_{\dashleftarrow}$ has a directed cycle. Suppose to the contrary that P^*_i and P^*_{i+1} have no common internal vertex. We only consider the case where the condition (A) in the definition of $\dashleftarrow$ holds for $i \dashleftarrow i{+}1$, that is, P^*_{i+1} touches $s(P^*_i)$; the case for (B) is symmetric. As $|P^*_i| \geq 2$, P^*_i has an arc $(s'(P^*_i), x^*)$. See Figure 2 for an illustration. For $x \in N_T(s'(P^*_i))$, we denote by C_x the weakly connected component containing x in the polyforest obtained from T by deleting the arc $(s'(P^*_i), x)$. Then observe that $V(P^*_{i+1}) \cap C_{x^*} = \emptyset$. To see this, if $V(P^*_{i+1}) \cap C_{x^*} \neq \emptyset$, then P^*_{i+1} must have the arc $(s'(P^*_i), x^*)$ as P^*_{i+1} touches $s(P^*_i)$. This particularly implies that $s'(P^*_i)$ belongs to P^*_{i+1} and is different from $t(P^*_{i+1})$ due to the direction of arc $(s'(P^*_i), x^*)$. Since I^{s} is an independent set, we have $s'(P^*_i) \neq s(P^*_{i+1})$. Thus P^*_i and P^*_{i+1} have a common internal vertex $s'(P^*_i)$, contradicting the assumption that P^*_i and P^*_{i+1} have no common internal vertex. Hence we obtain $V(P^*_{i+1}) \cap C_{x^*} = \emptyset$.

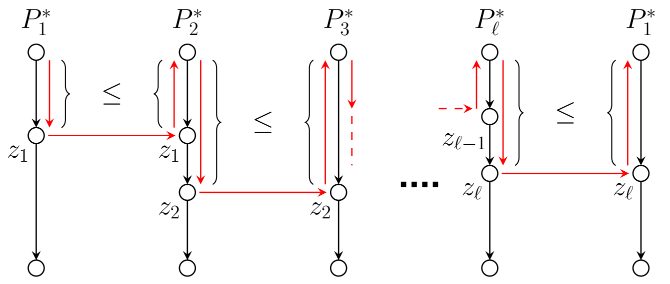

Figure 1 Closed oriented walk $s(P_1^*) \to z_1 \to s(P_2^*) \to \cdots \to s(P_\ell^*) \to z_\ell \to s(P_1^*)$.

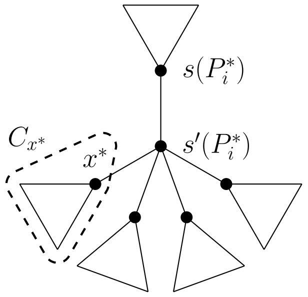

Figure 2 An illustration of a polytree considered in the proof of Lemma 14.

Suppose $i-1 = i+1$, i.e., $i+1 \dashleftarrow i$ (which implies $\ell = 2$). Then P_i^* touches $s(P_{i+1}^*)$ or P_{i+1}^* touches $t(P_i^*)$. In the former case, since $V(P_{i+1}^*) \cap C_{x^*} = \emptyset$ and I^{s} is an independent set, $s(P_{i+1}^*)$ must belong to $N_T(s'(P_i^*))$. Then we have $s'(P_{i+1}^*) = s'(P_i^*)$ by $i \dashleftarrow i+1$, which contradicts (P3). In the latter case, since $V(P_{i+1}^*) \cap C_{x^*} = \emptyset$, we have $x^* = t(P_i^*)$ and $s'(P_i^*) \in V(P_{i+1}^*)$. Moreover, neither $s'(P_i^*) = s(P_{i+1}^*)$ nor $s'(P_i^*) = t(P_{i+1}^*)$, since I^{s} and I^{t} are independent sets. Thus $s'(P_i^*)$ must be an internal vertex of P_{i+1}^*, contradicting the assumption.

Suppose $i-1 \neq i+1$ (which implies $\ell \geq 3$). Observe that $V(P_{i-1}^*) \cap C_{s(P_i^*)} = \emptyset$. To see this, suppose $V(P_{i-1}^*) \cap C_{s(P_i^*)} \neq \emptyset$. As $i-1 \dashleftarrow i$, either $s(P_{i-1}^*)$ touches P_i^* or $t(P_i^*)$ touches P_{i-1}^*. In both cases, $s(P_i^*)$ touches P_{i-1}^* and hence $i \dashleftarrow i-1$, contradicting the minimality of the cycle $(1, 2, \ldots, \ell, 1)$. Observe also that $s'(P_i^*) \notin V(P_{i-1}^*)$ as otherwise we obtain $i \dashleftarrow i-1$, which again contradicts the minimality of the cycle $(1, 2, \ldots, \ell, 1)$. Here we additionally distinguish the two cases: (i) $s'(P_i^*) \in V(P_{i+1}^*)$ and (ii) $s'(P_i^*) \notin V(P_{i+1}^*)$.

(i) $s'(P_i^*) \in V(P_{i+1}^*)$. Since P_i^* and P_{i+1}^* have no common internal vertices, we have $t(P_{i+1}^*) = s'(P_i^*)$. By the minimality of the cycle $(1, 2, \ldots, \ell, 1)$, P_{i-1}^* has none of vertices in $N_T[s'(P_i^*)]$. This implies, together with $i-1 \dashleftarrow i$ and $V(P_{i-1}^*) \cap C_{s(P_i^*)} = \emptyset$, that $V(P_{i-1}^*) \subseteq C_{x^*}$ and $x^* \notin V(P_{i-1}^*)$. By $i+1 \dashleftarrow i+2 \dashleftarrow \cdots \dashleftarrow i-1$, there is an index m with $i-1 \neq m \neq i+1$ such that $x^* \in V(P_m^*)$. This implies $m \dashleftarrow i+1$, contradicting the minimality of the cycle.

(ii) $s'(P_i^*) \notin V(P_{i+1}^*)$. In this case, P_{i+1}^* has a vertex in $N[s(P_i^*)] \setminus \{s'(P_i^*)\}$ and does not have the arc $(s(P_i^*), s'(P_i^*))$. Thus we have $V(P_{i+1}^*) \subseteq C_{s(P_i^*)}$. By $i+1 \dashleftarrow i+2 \dashleftarrow \cdots \dashleftarrow i-1$, there is an index m with $i-1 \neq m \neq i+1$ such that $s'(P_i^*) \in V(P_m^*)$. This implies $i \dashleftarrow m$, contradicting the minimality of the cycle.

This completes the proof of Lemma 14. ◀

4.4 Algorithms

In this subsection, we provide an algorithm for checking the reconfigurability in $\mathrm{O}(|V|)$ time, and that for constructing a reconfiguration sequence in $\mathrm{O}(k|V|)$ time, where k is the size of the input independent set. (if the answer is affirmative), proving Theorem 3.

For $U \subseteq V$, we define $N^+(U)$ (resp. $N^-(U)$) as $N^+(U) := \bigcup_{u \in U} N^+(u) \setminus U$ (resp. $N^-(U) := \bigcup_{u \in U} N^-(u) \setminus U$). For a mapping $f \colon I^{\mathsf{s}} \to N^+(I^{\mathsf{s}})$, let $f(I^{\mathsf{s}})$ denote the image of f, i.e., $f(I^{\mathsf{s}}) := \{f(x) \mid x \in I^{\mathsf{s}}\}$. Similarly, the image of $g \colon I^{\mathsf{t}} \to N^-(I^{\mathsf{t}})$ is denoted as $g(I^{\mathsf{t}})$.

4.4.1 Algorithm for checking the reconfigurability

Suppose that there is a set $\mathcal{P} = \{P_1, \dots, P_k\}$ of directed paths satisfying the path-set conditions. Then the set of paths obtained from $\mathcal{P}$ by exchanging each P_i with the subpath from $s'(P_i)$ to $t'(P_i)$ is a directed path matching from $\{s'(P_i) \mid i \in [k]\}$ to $\{t'(P_i) \mid i \in [k]\}$. In this case, the mappings $f \colon I^{\mathsf{s}} \to N^+(I^{\mathsf{s}})$ and $g \colon I^{\mathsf{t}} \to N^-(I^{\mathsf{t}})$ defined by $f(s(P_i)) := s'(P_i)$ and $g(t(P_i)) := t'(P_i)$, respectively, satisfy the following four conditions:

(C1) f and g are injective,
(C2) $(s, f(s)) \in A$ for all $s \in I^{\mathsf{s}}$,
(C3) $(g(t), t) \in A$ for all $t \in I^{\mathsf{t}}$, and
(C4) $w(e; f(I^{\mathsf{s}}), g(I^{\mathsf{t}})) \geq 0$ for each arc e.

In particular, (C1) follows from (P3) and (P4), and (C4) follows from Lemma 5.

Conversely, if there are mappings $f \colon I^{\mathsf{s}} \to N^+(I^{\mathsf{s}})$ and $g \colon I^{\mathsf{t}} \to N^-(I^{\mathsf{t}})$ satisfying the above four conditions (C1)–(C4), then we can construct a set of directed paths satisfying the path-set conditions (P1)–(P4) as follows. By Lemma 5 and (C4), there exists a directed path matching $\mathcal{P}' = \{P'_1, \dots, P'_k\}$ from $f(I^{\mathsf{s}})$ to $g(I^{\mathsf{t}})$. Define a set $\mathcal{P} = \{P_1, \dots, P_k\}$ of paths from $\mathcal{P}'$ by appending $f^{-1}(s(P'_i))$ and $g^{-1}(t(P'_i))$ before the source and after the sink for each P'_i, respectively. Then $|P_i| \geq 2$ for each $i \in [k]$, and $\mathcal{P}$ is a directed path matching from I^{s} and I^{t}. Moreover, since $\mathcal{P}'$ is a directed path matching from $f(I^{\mathsf{s}})$ to $g(I^{\mathsf{t}})$, we have $s'(P_i) \neq s'(P_j)$ and $t'(P_i) \neq t'(P_j)$ for $i \neq j$, implying that $\mathcal{P}$ satisfies the path-set conditions.

By the above argument, we obtain the following necessary and sufficient conditions for the reconfigurability:

▶ **Lemma 15.** *For an instance without rigid tokens and blocking arcs, there exists a set of paths satisfying the path-set conditions if and only if there exist mappings $f \colon I^{\mathsf{s}} \to N^+(I^{\mathsf{s}})$ and $g \colon I^{\mathsf{t}} \to N^-(I^{\mathsf{t}})$ satisfying* (C1)*–*(C4)*.*

By Lemmas 12 and 15, for checking the reconfigurability it suffices to compute f and g satisfying (C1)–(C4) or determine that such f and g do not exist; it can be done in $\mathrm{O}(|V|)$ time in a greedy manner as follows. In the following description, we regard T as a rooted tree with an arbitrary root. We initialize the values of f and g as $f(s) := \bot$ for all $s \in I^{\mathsf{s}}$ and $g(t) := \bot$ for all $t \in I^{\mathsf{t}}$ ($\bot$ means “undefined”). To let f and g satisfy the conditions in Lemma 15, we define each value of f and g one by one. We write $I^{\mathsf{s}}_{\mathrm{undef}} \subseteq I^{\mathsf{s}}$ (resp. $I^{\mathsf{s}}_{\mathrm{def}} \subseteq I^{\mathsf{s}}$) as the set of the vertices for which the values of f have been undefined (resp. defined). We also define $I^{\mathsf{t}}_{\mathrm{undef}}$ and $I^{\mathsf{t}}_{\mathrm{def}}$ in the same way. Throughout the following process to determine f and g, we keep an invariant that the conditions (C1)–(C3) hold for $s \in I^{\mathsf{s}}_{\mathrm{def}}$ and $t \in I^{\mathsf{t}}_{\mathrm{def}}$, moreover, for each arc e, $w(e; I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) \geq 0$.

In the following, we describe each step of the algorithm. Let $v^* \in I^{\mathsf{s}}_{\mathrm{undef}} \cup I^{\mathsf{t}}_{\mathrm{undef}}$ be a vertex with the largest depth among $I^{\mathsf{s}}_{\mathrm{undef}} \cup I^{\mathsf{t}}_{\mathrm{undef}}$ in the rooted tree. If $v^* \in I^{\mathsf{s}}_{\mathrm{undef}}$, we define

$$N_{\mathrm{cand}}(v^*) := \left\{u \in N^+(v^*) \setminus f(I^{\mathsf{s}}_{\mathrm{def}}) \;\middle|\; w((v^*, u); I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) \geq 1\right\}.$$

Otherwise, i.e., $v^* \in I^{\mathsf{t}}_{\mathrm{undef}} \setminus I^{\mathsf{s}}_{\mathrm{undef}}$, define

$$N_{\mathrm{cand}}(v^*) := \left\{u \in N^-(v^*) \setminus g(I^{\mathsf{t}}_{\mathrm{def}}) \;\middle|\; w((u, v^*); I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) \geq 1\right\}.$$

If $N_{\mathrm{cand}}(v^*)$ is empty, terminate the execution. Otherwise, choose $u^* \in N_{\mathrm{cand}}(v^*)$ with the largest depth among $N_{\mathrm{cand}}(v^*)$ and define $f(v^*) := u^*$ if $v^* \in I^{\mathsf{s}}_{\mathrm{undef}}$ and define $g(v^*) := u^*$ otherwise. When $f(v^*)$ or $g(v^*)$ is newly defined in this step, we accordingly update $I^{\mathsf{s}}_{\mathrm{def}}$, $I^{\mathsf{s}}_{\mathrm{undef}}$, $I^{\mathsf{t}}_{\mathrm{def}}$, and $I^{\mathsf{t}}_{\mathrm{undef}}$.

Note that each vertex in $I^{\mathsf{s}} \cup I^{\mathsf{t}}$ is selected as v^* at most twice. After the execution of the above algorithm, output f and g if $f(s) \neq \bot$ for all $s \in I^{\mathsf{s}}$ and $g(t) \neq \bot$ for all $t \in I^{\mathsf{t}}$; otherwise, we conclude that no such f and g exist. In each iteration, only one arc (v^*, u^*) or (u^*, v^*) decreases its w-value by 1: If $v^* \in I^{\mathsf{s}}_{\mathrm{undef}}$,

$$\begin{aligned} &w(e; I^{\mathsf{s}}_{\mathrm{undef}} \setminus \{v^*\} \cup f(I^{\mathsf{s}}_{\mathrm{def}}) \cup \{u^*\}, I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) \\ &= \begin{cases} w(e; I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) & \text{if } e \neq (v^*, u^*) \\ w(e; I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \cup g(I^{\mathsf{t}}_{\mathrm{def}})) - 1 & \text{if } e = (v^*, u^*); \end{cases} \end{aligned}$$

and otherwise $w(e; I^{\mathsf{s}}_{\mathrm{undef}} \cup f(I^{\mathsf{s}}_{\mathrm{def}}), I^{\mathsf{t}}_{\mathrm{undef}} \setminus \{v^*\} \cup g(I^{\mathsf{t}}_{\mathrm{def}}) \cup \{u^*\})$ can be computed in a symmetric fashion. Using this property, we can implement the algorithm that runs in $\mathrm{O}(|V|)$ time. More precisely, we maintain the values of w and the indicator functions of $I^{\mathsf{s}}_{\mathrm{def}}$ and $I^{\mathsf{t}}_{\mathrm{def}}$ in tables. By referring the tables, we can compute $N_{\mathrm{cand}}(v^*)$ in $\mathrm{O}(|N(v^*)|)$ time. Moreover, we can update the tables in $\mathrm{O}(1)$ time. Therefore each iteration runs in $\mathrm{O}(|N(v^*)|)$ time, and thus the algorithm runs in total in $\mathrm{O}(|V|)$ time since each edge is touched twice.

▶ **Lemma 16** ($\star$). *If there exist mappings f and g that satisfy the conditions in Lemma 15, then the algorithm described above correctly outputs one of such mappings. Otherwise the algorithm reports that no such mappings exist.*

4.4.2 Algorithm for constructing a reconfiguration sequence

By Corollary 6, if the instance is a yes-instance, all reconfiguration sequences have the same length. In this subsection, we present an algorithm to construct one of them in $\mathrm{O}(k|V|)$ time, where k is the size of the input independent set. We first assume that two mappings f and g satisfying conditions (C1)–(C4) have already been computed. If such f and g do not exist, the instance is a no-instance by Lemma 15. Here, our target is to fill in gaps between $f(I^{\mathsf{s}})$ and $g(I^{\mathsf{t}})$ avoiding biased path pairs. For preparation of further arguments, we define *weakly biased path pairs* by relaxing "common internal vertex" to "common vertex" in the definition of biased path pairs. If there is a directed path matching $\mathcal{P} = \{P_1, \dots, P_k\}$ from $f(I^{\mathsf{s}})$ to $g(I^{\mathsf{t}})$ without any weakly biased path pairs (not necessarily satisfying the path-set conditions), we can easily construct a directed path matching $\mathcal{P}' = \{P'_1, \dots, P'_k\}$ from I^{s} to I^{t} satisfying the path-set conditions: P'_i is obtained from P_i by appending $f^{-1}(s(P_i))$ before P_i and $g^{-1}(t(P_i))$ after P_i. Thus, in the following, it suffices to show that $\mathcal{P}$ can be constructed in $\mathrm{O}(k|V|)$ time.

Fix an arbitrary vertex $r \in V$. For each $v \in V$, we denote by $P_{r,v}$ the unique path between r and v in T^{und}. Let $\overrightarrow{P_{r,v}}$ be a directed path obtained by orienting each edge of $P_{r,v}$ from r to v. We define $d_r(v) = \mathrm{fwd}(\overrightarrow{P_{r,v}}) - \mathrm{rev}(\overrightarrow{P_{r,v}})$, where $\mathrm{fwd}(\overrightarrow{P_{r,v}})$ and $\mathrm{rev}(\overrightarrow{P_{r,v}})$ denote the numbers of arcs in T that $\overrightarrow{P_{r,v}}$ passes in the forward and reverse directions, respectively.

Using the values of $d_r(v)$ for $v \in V$, we iteratively construct a directed path matching $\mathcal{P} = \{P_1, \dots, P_k\}$ from $f(I^{\mathsf{s}})$ to $g(I^{\mathsf{t}})$ as follows. In the i-th step of the algorithm, we construct P_i. Let $X_i \subseteq f(I^{\mathsf{s}})$ and $Y_i \subseteq g(I^{\mathsf{t}})$ be the sets of vertices that are not chosen for the sources and sinks of $P_1, \dots, P_{i-1}$, respectively. Throughout the execution of the algorithm, we keep an invariant that for each arc e, $w(e; X_i, Y_i) \geq 0$, which means that there is a directed path matching from X_i to Y_i by Lemma 5.

Let $x \in X_i$ be a vertex with the smallest value of $d_r(x)$ among X_i. Let $Y'_i \subseteq Y_i$ be the set of vertices to which there is a directed path from x consisting of only arcs with $w(e; X_i, Y_i) > 0$. Since there exists some directed path matching from X_i to Y_i by our invariant that $w(e, X_i, Y_i) \geq 0$ for $e \in A$, the set Y'_i is not empty. Choose an arbitrary vertex $y \in Y_i'$ with the smallest value of $d_r(y)$. We set P_i to the unique directed path from x to y in T. Since we use only arcs e with $w(e; X_i, Y_i) > 0$ to construct P_i, we have $w(e; X_{i+1}, Y_{i+1}) \geq 0$, where $X_{i+1} = X_i \setminus \{x\}$ and $Y_{i+1} = Y_i \setminus \{y\}$, for all arcs and the invariant still holds. We repeat this until $X_i = \emptyset$ (and hence $Y_i = \emptyset$).

Here, we show that the obtained directed path matching $\{P_1, \ldots, P_k\}$ does not contain any weakly biased path pairs. Assume that P_i and P_j $(i < j)$ have a common vertex v. By the choice of x in the construction above, $d_r(s(P_i)) \leq d_r(s(P_j))$ holds. Thus, we have

$$\mathrm{dist}(s(P_i), v) = -d_r(s(P_i)) + d_r(v) \geq -d_r(s(P_j)) + d_r(v) = \mathrm{dist}(s(P_j), v).$$

As v is a common vertex of P_i and P_j, $t(P_j) \in Y_i'$ and thus $d_r(t(P_i)) \leq d_r(t(P_j))$ holds by the choice of y. Then, similarly we have

$$\mathrm{dist}(v, t(P_i)) = -d_r(v) + d_r(t(P_i)) \leq -d_r(v) + d_r(t(P_j)) = \mathrm{dist}(v, t(P_j)).$$

Therefore, P_i and P_j do not form a weakly biased path pair. We can compute each P_i in $\mathrm{O}(|V|)$ time, and thus the whole running time (including computing f and g) is $\mathrm{O}(k|V|)$.

Automating OBDD proofs is NP-hard

Dmitry Itsykson
Steklov Institute of Mathematics at St. Petersburg, Russia

Artur Riazanov
Steklov Institute of Mathematics at St. Petersburg, Russia

Abstract

We prove that the proof system OBDD($\wedge$, weakening) is not automatable unless P = NP. The proof is based upon the celebrated result of Atserias and Müller [5] about the hardness of automatability for resolution. The heart of the proof is lifting with multi-output indexing gadget from resolution block-width to dag-like multiparty number-in-hand communication protocol size with $o(n)$ parties, where n is the number of variables in the non-lifted formula. A similar lifting theorem for protocols with $n + 1$ participants was proved by Göös et. el. [12] to establish the hardness of automatability result for Cutting Planes.

1 Introduction

Boolean satisfiability is one of the central problems in Computer Science. The input to this problem is a CNF formula and the goal is to determine whether it is satisfiable or not. This is a standard example of an NP-complete problem, and it has been very thoroughly studied. While the consensus is that there is no polynomial algorithm for satisfiability, contemporary SAT-solvers have been quite successful in solving it for many instances appearing "in practice".

SAT-solvers are tightly connected to proof complexity. A propositional proof system is a formal way of certifying that a CNF formula is unsatisfiable. The execution log of an SAT-solver running on an unsatisfiable input φ can serve as a certificate of unsatisfiability of φ. Then SAT-solvers face the following trade-off: on the one hand, their underlying proof system must be sufficiently strong to have short proofs of all formulas of interest, on the other hand, it must be sufficiently weak so short proofs can be found fast. This tradeoff is witnessed by the success of CDCL-solvers, which are based on (subsystems of) Resolution which is a pretty weak proof system. Nevertheless, so far SAT-solvers based on stronger proof systems have not enjoyed the widespread success of resolution-based solvers.

A propositional proof system Π is called automatable (quasi-automatable) if there exists an algorithm $\mathcal{E}$ that given an unsatisfiable CNF φ produces a Π-proof of φ in time polynomial (quasi-polynomial) in size of φ plus the size of the shortest Π-proof of φ.

However, for many non-trivial proof systems, there are known pieces of evidence that they likely are not automatable or quasi-automatable. A long line of results on resolution automatability [15, 19, 2, 3] is concluded with the recent breakthrough result by Atserias and Müller [5] stating that resolution is not automatable unless P = NP and not quasi-automatable under a stronger assumption. This result sparked a series of follow-up results that establish the hardness of automating for many other proof systems; these results are either based on Atserias-Müller's result directly or follow their plan closely. If P $\neq$ NP, then the following proof systems are not automatable: Nullstellensatz and Polynomial Calculus [13]; Cutting Planes [12]; Res(2) [11]. Under stronger assumptions one can show non-automatability of Frege systems [17, 7, 6].

We continue this line of research and study the automatability of OBDD-based systems. OBDD (or ordered binary decision diagram) is a simple but rather expressive way to represent Boolean functions introduced by Bryant [8]. An OBDD is a very restricted case of a branching program, wherein for all paths from the source to a sink, variables appear in the same order. It is known that branching programs are at least as powerful as Boolean formulas, hence proving superpolynomial lower bounds on size of branching programs for explicit functions is an extremely hard problem. But exponential lower bounds are known for restricted versions of branching programs, including OBDDs. However, this restriction allows performing many important operations with OBDDs very efficiently: testing satisfiability, computing binary operations, applying restrictions, minimization, and so on. These properties have paved the way for OBDD-based propositional proof systems introduced by Atserias, Kolaites, and Vardi [4] to serve as a base for OBDD based SAT-solvers [1, 20].

An OBDD($\wedge$, weakening) refutation of a CNF φ is a sequence of OBDDs that query variables in the same order; the last OBDD in the sequence is identically false and each of those diagrams either represents a clause of φ or follows semantically from two OBDDs that appear earlier in the sequence (formally there are two rules: by the first ($\wedge$) we can derive conjunction of two OBDDs and by the second (weakening) we can derive any semantic implication of a single OBDD). The correctness of application of these rules can be efficiently verified since binary operations for two OBDDs with the same order of variab can be computed in polynomial time. This system simulates Resolution and CP* (Cutting Planes with unary coefficients); it has short refutations of unsatisfiable linear systems over $\mathbb{F}_2$ [4] and clique-coloring tautologies [9] (the latter are hard for Cutting Planes [22]).

Atserias-Müller's approach for establishing hardness of automatability requires proving a lower bound on the proof size of some specific CNF-formula. Unfortunately the tools for proving lower bounds on OBDD($\wedge$, weakening) are quite limited and related to monotone circuit complexity. All known lower bound proofs consist of two steps.

1. To prove the lower bound for a fixed order of variables in OBDDs. Such a lower bound was proved by Atserias et. al. [4]; an exponential lower bound on the size of OBDD($\wedge$, weakening) refutations of clique-coloring tautologies with a particular order of variables follows from monotone interpolation.
2. To transform a formula that is hard for one order into a formula that is hard for all orders. The first transformation of this kind was devised by Krajićek [16]: formulas are equipped with additional variables that parameterize a permutation of main variables such that by fixing these additional variables we can get the initial formula, where variables are permuted by any desired permutation. Segerlind [23, 24] invented a more concise transformation using 2-independent permutation family together with orification of variables; Segerlind used it to prove that OBDD($\wedge$, weakening) may require exponentially longer proofs than Res($O(\log n)$).

Our contribution. Our main result is the following theorem:

▶ **Theorem 1.** *There exist a constant α and a polynomially computable function $\mathcal{R}$ mapping CNF formulas to CNF formulas with the following properties. For any 3-CNF φ with n variables such that: if φ is satisfiable, then $\mathcal{R}(\varphi)$ has a resolution refutation of size at most n^α; if φ is unsatisfiable, then any* OBDD($\wedge$, *weakening) refutation of $\mathcal{R}(\varphi)$ has size $2^{\Omega(n)}$.*

Since $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ simulates resolution, any automation algorithm for $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ can be used to solve 3-SAT: if it finds proofs in fixed polynomial time, then the input formula is satisfiable, otherwise, it is unsatisfiable.

Our technique can be applied to other proof systems as well since the only thing that we use about OBDDs is that the value of an OBDD of size S can be computed using $O(\ell \log S)$ bits of communication in the ℓ-party number-in-hand communication model if the partition of variables agrees with the order. For example, this property holds for k-OBDDs for small k, hence our technique can be applied for proof system k-OBDD($\wedge$, weakening) [14].

Technique. The proof consists of two parts:

1. Prove the weaker version of Theorem 1, where the lower bound holds only for refutations that consist of OBDDs in some particular order π.
2. Devise a polynomial-time algorithm that transforms formulas with short resolution refutations to formulas with short resolution refutations; and transforms formulas that are hard for $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ with a specific order to formulas that are hard for $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ for all orders.

To implement the second part we use Segerlind's transformation. It almost suits our case, but the property for resolution works only with an additional condition: if a formula has a short resolution proof with at most constant number negative literals in every clause (we say that the *negative width* of the proof is $O(1)$), then the result of Segerlind's transformation has a short resolution proof.

The first part is much more involved. The construction is built on the following result proved by Atserias and Müller [5]. There exists an algorithm $\mathcal{E}$ that given a 3-CNF formula φ produces in polynomial time another CNF formula $\mathcal{E}(\varphi)$ such that

- if φ is satisfiable, $\mathcal{E}(\varphi)$ admits a polynomial-size resolution refutation;
- if φ is unsatisfiable, the shortest refutation of $\mathcal{E}(\varphi)$ has size $2^{|\varphi|^{\Omega(1)}}$.

We get our result by applying lifting to $\mathcal{E}(\varphi)$. Lifting is a technique to obtain lower bounds for strong computational models from lower bounds for weaker models. Recently, Garg, et. al. [10] proved two similar lifting theorems lifting from resolution width to refutation size in (1) any semantic proof system operating with proof lines of small 2-party communication complexity and (2) cutting planes (precisely it works for proof systems, where proof lines can be computed by 1-round real communication protocol).

The first lifting theorem (applied to $\mathcal{E}(\varphi)$) seems enticing for us since a function computable by an OBDD can be computed with small 2-party communication. Unfortunately, we can not apply this theorem directly since $\mathcal{E}(\varphi)$ can have large resolution width even for a satisfiable φ so after the application of lifting the resulting CNF might have only exponential-size $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutations. Göös et. al. [12] face the same problem for Cutting Planes and deal with it by lifting from block-width instead of the plain width. However the lifting theorem in [10] does not work for block-width, so Göös et. al. [12] prove a weaker version of it: they lift from resolution block-width to k-dimensional simplex-dags, where k is the number of variables in the lifted formula plus one. Cutting planes refutations can be converted to k-dimensional simplex-dags of the same size. However, for OBDD($\wedge$, weakening) refutations, the size is raised to the power of k, hence we need a lifting theorem for a smaller value of k.

We prove another lifting theorem: we lift from resolution block-width to k-dimensional box dag size, where k is the size of the largest block in the partition w.r.t. which the block-width is computed, plus one. In our proof, we use the structural properties of rectangles from [10] and extend them to show the structural properties of boxes. The same theorem seems to hold for simplex-dags (the proof in [12] can be adapted as well), but it is not clear whether there exist context where such change in the dimension matters.

We also show that OBDD($\wedge$, weakening) refutations with a specific order of variables of size S can be converted to k-dimensional box dags of size $S^{O(k)}$. In actuality, we prove it for every proof system that operates with proof lines that can be computed by k party communication protocols in the number-in-hand model with a small cost.

2 Preliminaries

Notation. We use the standard notation $[n] = \{1, \dots, n\}$. $\mathrm{Vars}(\varphi)$ denotes the set of propositional variables of a formula φ. We refer to a uniform distribution over a set X by $\mathcal{U}(X)$.

Resolution. A resolution refutation of an unsatisfiable CNF φ is a sequence of clauses ending with the empty clause such that each clause of the sequence is either a clause of φ or is derived from the previous clauses in the sequence with a resolution rule: $\frac{A \vee x \quad B \vee \neg x}{A \vee B}$.

The *width* of a clause is the number of literals in it, and the width of a formula is the maximum width of a clause in it. The *size* of a resolution refutation is the number of clauses in it. The width of a resolution refutation is the largest width of a clause in it.

Let X be a set of propositional variables and $U = U_1, \dots, U_k$ be a partition of X. Let us define the *block-width* of a clause C over variables X as the number of blocks among $U_1, \dots, U_k$ that contain variables of C: $|\{i \in [k] \mid \mathrm{Vars}(C) \cap U_i \neq \emptyset\}|$. The block-width of a resolution refutation is the maximum block-width of a clause in it. For an unsatisfiable CNF φ we denote $\mathrm{bw}(\varphi)$ as the smallest block-width of a resolution refutation of φ.

Ordered Binary Decision Diagrams. A branching program (BP) is a directed acyclic graph with a single source and two sinks: 0-sink and 1-sink. Each of the nodes of the BP except the sinks is labeled with a variable x_i for $i \in [n]$ and has two outgoing edges, one labeled with 1 and another with 0. Let us define the function computed by a BP. For a node u in a BP let $f_u : \{0,1\}^n \to \{0,1\}$ be a function computed by it. We then define $f_{\text{0-sink}} \equiv 0$, $f_{\text{1-sink}} \equiv 1$, $f_u(x) := f_v(x)$ if $x_i = 0$ and $f_u(x) := f_w(x)$ if $x_i = 1$ where u is labeled with the variable x_i, v is 0-successor of u and w is the 1-successor of u. Then we define the function computed by the BP itself as the function computed by its source.

A π-OBDD where $\pi \in S_n$ is a BP computing a function $f : \{0,1\}^n \to \{0,1\}$ such that for any path from the source to a sink each of the node labels appears at most once and the order of the labels appearing in the path respects π. That is, the labels appearing on the path always have form $x_{\pi(i_1)}, x_{\pi(i_2)}, \dots, x_{\pi(i_k)}$ where $1 \le i_1 < i_2 < \dots < i_k \le n$.

OBDDs have the following nice property: for every order of variables every Boolean function has a unique minimal OBDD. For a given order π, the minimal π-OBDD of a function f may be constructed in polynomial time from any π-OBDD for the same function [18]. There are also known polynomial-time algorithms that efficiently perform all the Boolean binary operations, negation and projection (elimination of the existential quantifier) to π-OBDDs [18] (we refer to [26] for an introduction to OBDDs).

OBDD refutations. A π-OBDD-refutation of a CNF formula φ is a sequence of π-OBDDs $D_1, \dots, D_s$ such that D_s computes the identically false function and each D_i either computes a clause of φ or is obtained from the previous diagrams in the sequence by one of the rules below.

conjunction rule ($\wedge$) D_i computes the conjunction of D_j and D_k for $j, k < i$;

weakening rule D_i computes a function implied by D_j where $j < i$;

projection rule ($\exists$) D_i computes a function $\exists x f$ where f is computed by D_j with $j < i$, and $x \in \mathrm{Vars}(\varphi)$.

The size of an π-OBDD-refutation is the sum of sizes of all diagrams in it. Using the properties of OBDD it is easy to see that the correctness of a π-OBDD-refutation can be verified in time polynomial in its size and the size of the refuted formula [4]. An OBDD refutation is a π-OBDD refutation for some order π.

Depending on the set of the allowed rules we have several different propositional proof systems: $\mathrm{OBDD}(\wedge)$ where only the conjunction rule is allowed, $\mathrm{OBDD}(\wedge, \exists)$ where the conjunction and the projection rules are allowed, and $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ where the conjunction and the weakening rules are allowed. Since the projection rule is a special case of the weakening rule, we do not include both of them simultaneously.

For an unsatisfiable CNF φ we denote by $\pi\text{-}\mathrm{OBDD}(\varphi)$ the size of the smallest π-$\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutation of φ and by $\mathrm{OBDD}(\varphi)$ the size of the smallest $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutation of φ.

▶ **Proposition 2** ([4]). $\mathrm{OBDD}(\wedge, \exists)$ *(and, thus,* $\mathrm{OBDD}(\wedge, \mathrm{weakening})$*) polynomially simulates resolution: if an unsatisfiable CNF has a resolution refutation of size S, then it has an* $\mathrm{OBDD}(\wedge, \exists)$ *refutation of size* $\mathrm{poly}(S)$*.*

Search$_\varphi$. Search_φ is the following search problem: given an assignment to the variables of the unsatisfiable CNF φ, find a clause that is falsified by this assignment. Formally it can be defined as a relation $\{(x, C) \mid x \in \{0,1\}^{\mathrm{Vars}(\varphi)};\ C \in \varphi;\ C(x) = 0\}$.

Dags solving relations.

▶ **Definition 3** ([25]). *Let $\mathcal{F}$ be a family of subsets of a finite set $\mathcal{X}$ and $S \subseteq \mathcal{X} \times \mathcal{O}$ be a relation. Let $\mathcal{D}$ be a single-source (which we refer to as root) acyclic graph. We call $\mathcal{D}$ an* $\mathcal{F}$-dag *solving S if for every node u there exists a set $R_u \in \mathcal{F}$ such that:*

(root condition) *for the root r of the dag $R_r = \mathcal{X}$;*

(leaf condition) *for each leaf (sink) ℓ of the dag there exists $o \in \mathcal{O}$ such that for all $x \in R_\ell$, $(x, o) \in S$;*

(local condition) *each inner node u has out-degree 2 and its two descendants v and w satisfy the property $R_u \subseteq R_v \cup R_w$.*

The size of an $\mathcal{F}$-dag *is the number of nodes in it. We denote the smallest size of* $\mathcal{F}$-dag *solving S by* $\mathcal{F}$-dag(S)*. We usually identify the nodes of an* $\mathcal{F}$-dag *with the sets R_u.*

Now we define several special cases of this general definition.

Decision dag. Assume that we have Boolean domain $\mathcal{X} = \{0,1\}^n$ that we view as a set of values of n propositional variables. A partial assignment is an element of $\{0,1,*\}^n$, where $*$ means that the corresponding variable is not assigned. Let $\mathrm{fix}(\rho) = \rho^{-1}(\{0,1\})$ be the set of assigned variables. If $\mathrm{fix}(\rho) = [n]$ then ρ is a full assignment.

Any partial assignment defines a subcube $\mathrm{Cube}(\rho) = \{\alpha \in \{0,1\}^n \mid \forall i \in \mathrm{fix}(\rho) : \rho(i) = \alpha(i)\}$ that is the set of all full assignments agreeing with ρ.

Let $S \subseteq \{0,1\}^n \times \mathcal{O}$ be a relation and $\mathcal{F}$ be a set of all subcubes $\{\mathrm{Cube}(\rho) \mid \rho \in \{0,1,*\}^n\}$, then we call an $\mathcal{F}$-dag for S a decision dag. We denote the smallest size of a decision dag solving S by $\mathsf{dec\text{-}dag}(S)$.

Observe that a decision tree is a decision dag: a node u of a decision tree can be labeled with a set $\mathrm{Cube}(\rho)$, where ρ is a partial assignment corresponding to the path from the root to u. Hence, since for any total relation there exists a decision tree solving it, any total relation has a decision dag as well.

Let $U = U_1, \dots, U_k$ be a partition of $[n]$. The block-width of a decision dag is defined as follows: for a node labeled with $\mathrm{Cube}(\rho)$ we compute $|\{i \in [k] \mid U_i \cap \mathsf{fix}(\rho) \neq \emptyset\}|$, the blockwidth of a decision dag is the maximum of this value among the nodes. For a relation S we denote the smallest block-width of a decision dag that solves it as $\mathrm{bw}(S)$.

Observe that a resolution refutation of an unsatisfiable CNF φ can be converted to a decision dag solving Search_φ of the same size: the topology of the dag is the topology of the resolution refutation, a node corresponding to a clause C is labeled with a set $C^{-1}(0) = \{x \in \{0,1\}^n \mid C(x) = 0\}$. It is easy to see that this set is a subcube. If C is derived from D and E via a resolution rule then C is implied by the conjunction of D and E thus $C^{-1}(0) \subseteq (D \wedge E)^{-1}(0) = D^{-1}(0) \cup E^{-1}(0)$. Clearly the root and the leaf properties of the constructed decision dag also hold: for a leaf ℓ labeled with $C^{-1}(0)$ for $C \in \varphi$ every point in $C^{-1}(0)$ falsifies φ by definition; the root corresponds to the empty clause so it is labeled with $\{0,1\}^n$. The reverse also holds, one can convert a decision dag solving Search_φ to a resolution refutation of φ of the same size.

▶ **Proposition 4** ([10]). *There exists a resolution refutation of φ of size S and block-width b if and only if there exists a decision dag solving* Search_φ *of size S and block-width b.*

Box dag. Let $S \subseteq \mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k \times \mathcal{O}$ be a relation. Let $\mathcal{F}$ be a set of boxes $\{A_1 \times A_2 \times \dots \times A_k \mid A_1 \subseteq \mathcal{X}_1, A_2 \subseteq \mathcal{X}_2, \dots, A_k \subseteq \mathcal{X}_k\}$. Then we call an $\mathcal{F}$-dag a box dag. Let $U = U_1, \dots, U_k$ be a partition of $[n]$. If $\mathcal{X}_i = \{0,1\}^{U_i}$ for all $i \in [k]$, then we denote the class of box dags as $\mathsf{box\text{-}dag}_U$ or $\mathsf{box\text{-}dag}_{U_1,\dots,U_k}$.

▶ Remark 5. We can convert a π-OBDD refutation of a formula φ of size S to an $\mathcal{F}$-dag for Search_φ, where $\mathcal{F}$ consists of zero-sets of π-OBDDs of size at most S. In Section 5 we show that if a partition of variables into k parts agrees with an order π, such a dag can be converted to a box dag of size $S^{O(k)}$.

Automatability. A propositional proof system Π is called *automatable* if there exists an algorithm $\mathcal{A}_\Pi$ that given an unsatisfiable CNF φ produces its refutation in Π in time polynomial in $|\varphi|$ and the size of the shortest refutation of φ in Π.

3 The outline of the proof of Theorem 1

Our starting point is the following theorem that is essentially proved in [13].

▶ **Theorem 6** (Lemma 2.2 from [13]). *For any constant $c \geq 2$ there exists a polynomial-time algorithm $\mathcal{E}$ such that given a 3-CNF formula φ of size n it produces a $O(\log n)$-CNF formula $\mathcal{E}(\varphi)$ such that*

- *there exists a partition $B_1, \dots, B_k$ of the variables of $\mathcal{E}(\varphi)$ such that $|B_1| = |B_2| = \dots = |B_k| = O(n)$ and $k = O(n^{c+1})$ and this partition can be computed in polynomial time;*
- *if $\varphi \in$ SAT then $\mathcal{E}(\varphi)$ has a resolution refutation π such that $|\pi| = n^{O(c)}$ and* $\mathrm{bw}(\pi) = O(1)$ *w.r.t. partition $B_1, \dots, B_k$;*
- *if $\varphi \notin$ SAT then any resolution refutation of $\mathcal{E}(\varphi)$ has block-width at least n^{c-1} w.r.t. $B_1, \dots, B_k$.*

Notice that the statement of Theorem 6 is slightly different from one explicitly stated in [13]. First, it is not stated that all blocks B_i have equal sizes and their sizes are $O(n)$, but this is clear from the definition in Section 3.1 of [13]. Second, the theorem is stated and proved only for $c = 2$ but essentially the same proof holds for larger c, the only change is that we should reduce from rPHP_{n^c} instead of rPHP_{n^2} (see Section 5 of [13] for details).

To prove Theorem 1 we follow the plan below:

Lifting with multi-output indexing function. In Section 4 we define a block-wise indexing function $\textsc{Ind}_{\ell\times m}$ and its composition with relations and formulas. In Section 4 we will see that if a CNF formula φ has short resolution refutation of constant block-width then $\varphi \circ \textsc{Ind}^n_{\ell\times m}$ has a short resolution refutation. In the remainder of Section 4 we show that if a CNF formula φ with variables partitioned into n blocks of size ℓ requires resolution refutations of block-width at least b, then $\mathrm{Search}_\varphi \circ \textsc{Ind}^n_{\ell\times m}$ and consequently $\mathrm{Search}_{\varphi\circ\textsc{Ind}^n_{\ell\times m}}$ requires large $(\ell+1)$-dimensional box dags.

Making box dags out of π-OBDD refutations. In Section 5 we show that if Search_φ requires k-dimensional box dags of size S, then it requires π-OBDD$(\wedge, \text{weakening})$ refutations of size $S^{\Omega(1/k)}$ for some fixed π.

Making all orders hard. In Section 6 we adapt Segerlind's transformation from [24] to show that there exists a CNF-to-CNF mapping that maps CNF formulas with polynomial resolution size to CNF formulas with polynomial resolution size and maps CNF formulas that are hard for π-OBDD$(\wedge, \text{weakening})$ with a fixed π to CNF formulas that are hard for OBDD$(\wedge, \text{weakening})$.

Putting the pieces together. In Section 7 we compose $\mathcal{E}_c$ with the two mappings above to obtain Theorem 1.

4 Lifting with multi-output indexing function

In this section, we prove the lifting theorem for box dags. First, let us formally define the gadget we are going to lift with.

▶ **Definition 7** (Block-wise indexing, [12]). *$\textsc{Ind}_{\ell\times m} : [m] \times \{0,1\}^{\ell\times m} \to \{0,1\}^\ell$ is defined as $\textsc{Ind}_{\ell\times m}(x, y) = (y_{1,x}, y_{2,x}, \dots, y_{\ell,x})$ i.e. given an index $x \in [m]$ and a matrix $y \in \{0,1\}^{\ell\times m}$, it returns the xth column of y. For a set $R \subseteq [m]^n \times (\{0,1\}^{\ell\times m})^n$ we define $\textsc{Ind}^n_{\ell\times m}(R) = \{(\textsc{Ind}_{\ell\times m}(x_1, y_1), \dots, \textsc{Ind}_{\ell\times m}(x_n, y_n)) \in \{0,1\}^{n\ell} \mid (x_1, x_2, \dots, x_n, y_1, y_2, \dots, y_n) \in R\}$.*

Let $\varphi = \bigwedge_{i=1}^t C_i$ be an unsatisfiable CNF with $n\ell$ variables that are partitioned into n blocks of size ℓ. Let us define a CNF $\psi = \varphi \circ \textsc{Ind}^n_{\ell\times m}$. First let us define $C \circ \textsc{Ind}^n_{\ell\times m}$ for a clause C. The resulting CNF formula will compute the function $C \circ \textsc{Ind}^n_{\ell\times m} = C(\textsc{Ind}_{\ell\times m}(x_1, y_1), \dots, \textsc{Ind}_{\ell\times m}(x_n, y_n))$. Then we define $\varphi\circ\textsc{Ind}^n_{\ell\times m} := \bigwedge_{i=1}^t \left(C_i \circ \textsc{Ind}^n_{\ell\times m}\right)$.

Now let us construct a CNF representation of $C \circ \textsc{Ind}^n_{\ell\times m}$. Let $z_{i,j}$ for $i \in [n]$, $t \in [\ell]$ be the tth variable of the ith block of φ. Let $i_1, \dots, i_b \in [n]$ be indices of the blocks that are touched by C and let C_j for $j \in [b]$ be the part of the variables of C from the i_jth block: $C = C_1 \vee \dots \vee C_b$. Let $P_j := \{k \in [\ell] \mid z_{i_j,k} \in C\}$ be the indices (inside a block) of positive literals in C_j and $N_j := \{k \in [\ell] \mid \neg z_{i_j,k} \in C\}$ be the indices of negative literals in C_j. Then the CNF representation of $C \circ \textsc{Ind}^n_{\ell\times m}(x_1, y_1, \dots, x_n, y_n)$ consists of clauses of form $\left(\left(\bigwedge_{j=1}^b (x_{i_j} = \alpha_j)\right) \to \left(\bigvee_{j=1}^b \left(\bigvee_{k\in P_j} y_{k,\alpha_j} \vee \bigvee_{k\in N_j} \neg y_{k,\alpha_j}\right)\right)\right)$ for each $\alpha_1, \dots, \alpha_b \in [m]$.

The size of this representation is $|\varphi| \cdot m^b$ where b is the largest block-width of a clause in φ, so this representation is short for formulas of constant block-width.

▶ **Theorem 8** (the last inequality in Theorem 4 from [12]). *Let φ be an unsatisfiable CNF with $n\ell$ variables that are partitioned into n blocks of size ℓ such that there exists a resolution refutation of φ of size s and block-width b. Then there exists a resolution refutation of $\varphi \circ \textsc{Ind}^n_{\ell\times m}$ of size $m^{O(b)} \cdot s$.*

4.1 Lifting theorem

For a relation $S \subseteq (\{0,1\}^\ell)^n \times \mathcal{O}$ its composition with block-wise indexing is defined as
$$S \circ \textsc{Ind}^n_{\ell\times m} := \left\{ (x_1,\dots,x_n,y_1,\dots,y_n,o) \;\middle|\; \begin{array}{l} x_i \in [m];\ y_i \in \{0,1\}^{\ell\times m};\ o \in \mathcal{O}; \\ (\textsc{Ind}_{\ell\times m}(x_1,y_1),\dots,\textsc{Ind}_{\ell\times m}(x_n,y_n),o) \in S \end{array} \right\}.$$

This is a direct analog of the composition of two functions: we first plug the output of indexing to each ℓ-bit block of the input of S and then “compute” S on the resulting input.

We assume that m is a power of 2 so the relation $S \circ \textsc{Ind}^n_{\ell\times m}$ can be viewed as defined on a binary domain $\{0,1\}^{n\log_2 m + \ell n m}$.

Let us define a partition of the input bits of relation $S \circ \textsc{Ind}^n_{\ell\times m}$. Consider an element of the input domain $(x_1,\dots,x_n,y_1,\dots,y_n) \in [m]^n \times \left(\{0,1\}^{\ell\times m}\right)^n$ where $x_1,\dots,x_n \in [m]$ and $y_1,\dots,y_n$ are matrices in $\{0,1\}^{\ell\times m}$. Let A consist of bits corresponding to of $x_1,\dots,x_n$, (in other words A corresponds to the first $n\log_2 m$ bits of the input), B_j for $j \in [\ell]$ consists of bits corresponding to jth rows of all the matrices $y_1,\dots,y_n$. We are going to imagine that we have $\ell+1$ parties: Alice who receives the bits A of the input, Bob$_1$, Bob$_2$, …, Bob$_\ell$, where Bob$_j$ receives the bits B_j of the input.

Then let $\mathcal{A} := \{0,1\}^A = [m]^n$ be the set of Alice's inputs and let $\mathcal{B}_j := \{0,1\}^{B_j} = \{0,1\}^m$ be the set of Bob$_j$'s inputs.

The following theorem is similar with Theorem 8 form [12], but for box dags instead of simplex dags and, crucially, for a smaller number of parties, $\ell+1$ instead of $n\ell+1$.

▶ **Theorem 9.** *Let Δ be a large enough integer constant. Let $S \subseteq (\{0,1\}^\ell)^n \times \mathcal{O}$ be a total relation where $\ell < \frac{n}{2}$ and $m = (n\ell)^\Delta$. Then $m^{\Omega(\mathrm{bw}(S))} \le \textsf{box-dag}_{A,B_1,\dots,B_\ell}(S \circ \textsc{Ind}^n_{\ell\times m})$, where the block partition of inputs of S is the natural partition into n blocks of size ℓ.*

Let us outline the proof of Theorem 9. The proof is constructive, i.e., we take a box dag $\mathbb{B}$ solving $S \circ \textsc{Ind}^n_{\ell\times m}$ and extract from it a decision dag solving S of block-width $O(\log|\mathbb{B}|/\log m)$. The idea is to split boxes in the box dag into “structured” boxes that naturally correspond to partial assignments from $\{0,1,*\}^n$ (notice that there is a one-to-one correspondence between partial assignments and subcubes). We then take the assignments that our structured boxes correspond to and construct a decision dag for S out of them (we will need some auxiliary partial assignments as well). A first attempt to formulate what this “structuredness” could mean is the following: a box B is ρ-like if $\textsc{Ind}^n_{\ell\times m}(B) = \mathrm{Cube}(\rho)$. It turns out that we actually can (with some caveats) partition any box in $\mathcal{A} \times \mathcal{B}_1 \times \cdots \times \mathcal{B}_\ell$ into boxes that are ρ-like for some assignments ρ. Unfortunately, we need some additional properties of these boxes to be able to connect them into a valid decision dag.

Our definition of structured boxes is different from the one given in [12], we formulate it in a different way reducing the structuredness of boxes to the structuredness of rectangles (2-dimensional boxes) that is used to prove the lifting theorem in [10]. In Subsection 4.2 we formulate the properties of structured rectangles that we need, in Subsection 4.3 we define and prove the analogous properties for structured boxes, and in Subsection 4.4 we construct the decision dag solving S.

4.2 Structured Rectangles

Lifting theorems from [10] rely heavily on the notion of *structuredness* of rectangles. To simplify things we will not define it explicitly, but instead, state its properties that we are going to use.

Let $\mathsf{Rect}_{m,n}$ be the set of subrectangles of $[m]^n \times \left(\{0,1\}^{1\times m}\right)^n$: $\{A \times B \mid A \subseteq [m]^n;\ B \subseteq \left(\{0,1\}^{1\times m}\right)^n\}$. We are going to define several properties of predicates on $\mathsf{Rect}_{m,n} \times \{0,1,*\}^n$ i.e. predicates on pairs of form (rectangle, partial assignment). Let $\mathcal{W}$ be a predicate on $\mathsf{Rect}_{m,n} \times \{0,1,*\}^n$.

▶ **Definition 10.** *We say that $\mathcal{W}$* observes row-structure *if $\mathcal{W}(X \times Y, \rho)$ implies that for all $x \in X$, $\textsc{Ind}^n_{1\times m}(\{x\} \times Y) \subseteq \mathrm{Cube}(\rho)$, and $\Pr_{x\leftarrow\mathcal{U}(X)}\left[\textsc{Ind}^n_{1\times m}(\{x\} \times Y) \neq \mathrm{Cube}(\rho)\right] \leq \frac{2}{n}$.*

▶ **Definition 11.** *We say that $\mathcal{W}$ is* partitionable *if for every $X \subseteq [m]^n$ there exist a partition $X := \bigsqcup_{j\in J} \tilde{X}_j$ and a family $\{F_j\}_{j\in J}$, $F_j \subseteq [n]$, and for every $R = X \times Y \in \mathsf{Rect}_{m,n}$, for every parameter $k \leq n \log n$ there exists a partition $R = \bigsqcup_{i\in I} R_i$, where $R_i = X_i \times Y_i \in \mathsf{Rect}_{m,n}$, a family of assignments $\{\rho_i\}_{i\in I}$, and sets $X_{err} \subseteq X, Y_{err} \subseteq Y$ such that $|X_{err}| \leq m^n/2^k$, $|Y_{err}| \leq 2^{mn-k}$ and the following properties hold:*

1. *for each i one of the following holds: either $\mathcal{W}(R_i, \rho_i)$ and $|\mathrm{fix}(\rho_i)| = O(k/\log n)$; or R_i is covered by $X_{err} \times \left(\{0,1\}^{1\times m}\right)^n \cup [m]^n \times Y_{err}$.*
2. *For every $i \in I$ there exists $j \in J$ such that $\tilde{X}_j = X_i$ and $\mathrm{fix}(\rho_i) = F_j$* [1]*.*

▶ **Definition 12.** *We say that $\mathcal{W}$* respects largeness *if for all $X \times Y$ such that $|X| \geq m^n \cdot 0.99$ and $|Y| \geq 2^{mn} \cdot 0.99$ $\mathcal{W}(X \times Y, *^n)$ holds.*

▶ **Theorem 13** (Lemma 4.4, Lemma 4.5 from [10])**.** *There exists a constant Δ such that for any $m \geq n^{\Delta}$ there exists a predicate $\mathcal{W}$ on $\mathsf{Rect}_{m,n} \times \{0,1,*\}^n$ such that it* observes row-structure[2]*;* is partitionable*;* respects largeness[3]*. We say that a rectangle R is ρ-*structured *iff $\mathcal{W}(R, \rho)$ holds.*

4.3 Structured Boxes

Now let us generalize the notion of structuredness from rectangles to boxes.

▶ **Definition 14.** *Let $R = X \times Y_1 \times \cdots \times Y_\ell$, where $X \subseteq \mathcal{A} = [m]^n$, $Y_j \subseteq \mathcal{B}_j = (\{0,1\}^{1\times m})^n$ be a box and $\rho \in \{0,1,*\}^{n\ell}$ be a partial assignment. We view ρ as an assignment to variables of input to $S \subseteq (\{0,1\}^\ell)^n \times \mathcal{O}$ that are partitioned into n blocks of size ℓ. Let $\rho_i \in \{0,1,*\}^n$ for $i \in [\ell]$ be the marginal assignment of ρ assigning the ith variable of each block in the partition of variables of S. We say that R is a ρ-*structured box *if for each $i \in [\ell]$ the rectangle $X \times Y_i$ is ρ_i-structured.*

We now show that our definition of the structuredness satisfies the analogues of conditions from Definitions 10, 11, and 12.

▶ **Lemma 15.** *Assume that $n > 2\ell$. Let $R = X \times Y_1 \times \cdots \times Y_\ell \subseteq \mathcal{A} \times \mathcal{B}_1 \times \cdots \times \mathcal{B}_\ell$ be a ρ-structured box where $\rho \in \{0,1,*\}^{n\ell}$. Then for all $x \in X$, $\textsc{Ind}^n_{\ell\times m}(\{x\} \times Y_1 \times \cdots \times Y_\ell) \subseteq \mathrm{Cube}(\rho)$ and there exists $x \in X$ such that $\textsc{Ind}^n_{\ell\times m}(\{x\} \times Y_1 \times \cdots \times Y_\ell) = \mathrm{Cube}(\rho)$.*

[1] This property is not explicitly stated in [10], although it is clear from the Rectangle Scheme that generates the partition: first X is partitioned and then each part $X_i \times Y$ is partitioned separately.

[2] Although Lemma 4.4 of [10] is not stated in strong enough form to satisfy Definition 10, the needed property is actually proved in Section 9 of [10].

[3] This property is implicit in [10], see the full version of the paper for the details.

Proof. If there exist $x \in X, y_1 \in Y_1, \dots, y_\ell \in Y_\ell$ such that $\alpha := \textsc{Ind}^n_{\ell\times m}(x, y_1, \dots, y_\ell)$ does not agree with ρ, then there exists $i \in [\ell]$ such that $\textsc{Ind}^n_{1\times m}(x, y_i)$ does not agree with ρ_i which violates Definition 10.

Now let us prove the second statement. By Definition 10 for each $i \in [\ell]$ we have $\Pr_{x\leftarrow\mathcal{U}(X)}\left[\textsc{Ind}^n_{1\times m}(\{x\}\times Y_i) \neq \mathrm{Cube}(\rho_i)\right] \leq \frac{2}{n}$. Then $\Pr_{x\leftarrow\mathcal{U}(X)}\left[\textsc{Ind}^n_{\ell\times m}(\{x\}\times Y_1 \times Y_2 \times \cdots \times Y_\ell) \neq \mathrm{Cube}(\rho)\right]$ is bounded by $\sum_{i=1}^{\ell} \Pr_{x\leftarrow\mathcal{U}(X)}\left[\textsc{Ind}^n_{1\times m}(\{x\}\times Y_i) \neq \mathrm{Cube}(\rho_i)\right] \leq \frac{2\ell}{n} < 1$. ◀

▶ **Lemma 16.** *If $R = X \times Y_1 \times \cdots \times Y_\ell \subseteq \mathcal{A} \times \mathcal{B}_1 \times \cdots \times \mathcal{B}_\ell$ is such that $|X| \geq m^n \cdot 0.99$ and $|Y_i| \geq 2^{mn} \cdot 0.99$ for each $i \in [\ell]$, then R is $*^{n\ell}$-structured.*

Proof. By Definition 12 we have that each of the $X \times Y_i$ is $*^n$-structured which by definition implies $*^{n\ell}$-structuredness of R. ◀

▶ **Lemma 17.** *Let $R = X \times Y_1 \times \cdots \times Y_\ell \subseteq \mathcal{A} \times \mathcal{B}_1 \times \cdots \times \mathcal{B}_\ell$ be an arbitrary box and $k \leq n \log n$ be a parameter. Then there exist sets $X^{err} \subseteq \mathcal{A}, Y_1^{err} \subseteq \mathcal{B}_1, \dots, Y_\ell^{err} \subseteq \mathcal{B}_\ell$, a partition $R = \bigsqcup_{i\in I} R_i$, and a family of partial assignments $\{\rho^i\}_{i\in I}$, where $R_i = X^i \times Y_1^i \times \cdots \times Y_\ell^i$ is a box and $\rho^i \subseteq \{0, 1, *\}^{n\ell}$ satisfying the following conditions.*

(1*) $|X^{err}| \leq \frac{m^n\cdot\ell}{2^k}$, $|Y_i^{err}| \leq 2^{nm-k}$.

(2*) *For each $i \in I$ at least one of the following statements holds:*
- *R_i is ρ^i-structured and ρ^i assigns $O(k/\log n)$ blocks from the standard partition of $[n\ell]$ into n blocks of size ℓ;*
- *R_i is covered by one of the error sets i.e. $X^i \subseteq X^{err}$ or there exists $j \in [\ell]$ such that $Y_j^i \subseteq Y_j^{err}$.*

(3*) *For each $x \in X \setminus X^{err}$ there exists a set $I_x \subseteq [n\ell]$ that is a union of $O(k/\log n)$ blocks (i.e. it either contains all the indices from a block or none) such that $x \in X^i$ implies $\mathrm{fix}(\rho^i) \subseteq I_x$.*

4.4 Proof of Theorem 9

Recall that the inequality we are to prove is $m^{\Omega(\mathrm{bw}(S))} \leq \mathsf{box\text{-}dag}_{A,B_1,\dots,B_\ell}(S \circ \textsc{Ind}^n_{\ell\times m})$. It is equivalent to $\mathrm{bw}(S) = O\left(\log \mathsf{box\text{-}dag}_{A,B_1,\dots,B_\ell}(S \circ \textsc{Ind}^n_{\ell\times m})/\log m\right)$.

Consider the smallest $\mathsf{box\text{-}dag}_{A,B_1,\dots,B_\ell}$ $\mathbb{B}$ solving $S \circ \textsc{Ind}^n_{\ell\times m}$. We construct a decision dag solving S of block-width $O(\log|\mathbb{B}|/\log m) = O(\log|\mathbb{B}|/\log n)$.

Similarly to [10] we first assume that partitions yielded by Lemma 17 are always errorless, i.e. $X^{err} = Y_1^{err} = \cdots = Y_\ell^{err} = \emptyset$. Then we will fix the proof so it works without this assumption, this part of the proof repeats the argument from Section 5.3 in [10] more or less verbatim, so we omit it in this version of the paper. We apply Lemma 17 to each of the boxes in $\mathbb{B}$ with some parameter k that we fix later to achieve the needed lower bound.

Let us construct a decision dag $\mathbb{D}$ that solves S. Each node of a decision dag labeled with function f naturally corresponds to a partial assignment ρ_f such that $\mathrm{Cube}(\rho_f) = f^{-1}(0)$. We will identify nodes of a decision dag with the assignments corresponding to them. That suggests the construction of $\mathbb{D}$: for each of the nodes of $\mathbb{B}$ we apply Lemma 17 to it and for each ρ-structured box in the resulting partition add the node ρ to $\mathbb{D}$. To turn this collection of nodes into a correct decision dag, we need to locate the root, the leaves, and connect (via auxiliary nodes) the nodes between each other such that the conditions on dags are met. More precisely, it is sufficient to show that:

1. The partition of the root of $\mathbb{B}$ consists of a single $*^{n\ell}$-structured box.
2. If an o-labeled leaf of $\mathbb{B}$ contains a ρ-structured box in its partition, then for every $x \in \mathrm{Cube}(\rho)$, $(x, o) \in S$.
3. Suppose a node u in $\mathbb{B}$ has direct descendants v_1 and v_2. Then let $\rho^u_1, \dots, \rho^u_{t_u}$ be the assignments yielded by the partition of the box u, $\rho^{v_q}_1, \dots, \rho^{v_q}_{t_{v_q}}$ be the assignments yielded by the partition of the box v_q for $q \in \{1, 2\}$. Then there exists a assignment-labeled dag with sources $\rho^u_1, \dots, \rho^u_{t_u}$, leaves $\rho^{v_q}_1, \dots, \rho^{v_q}_{t_{v_q}}$ for $q \in \{1, 2\}$ that satisfies the local condition of a decision dag having block-width $O(k/\log n)$.

Proof of 1. By Lemma 16 we have that the entire root of $\mathbb{B}$ is $*^{n\ell}$-structured, thus we may assume that its partition is a single box.

Proof of 2. Let u be an o-labeled leaf of $\mathbb{B}$. Suppose that $B = X \times Y_1 \times \cdots \times Y_\ell$ is a ρ-structured box in the partition of u. By Lemma 15 there exists x_0 such that $\mathrm{I}\textsc{nd}^n_{\ell\times m}(\{x_0\} \times Y_1 \times \cdots \times Y_\ell) = \mathrm{Cube}(\rho)$, i.e. for every $\alpha \in \mathrm{Cube}(\rho)$ there exist $y_1, \dots, y_\ell$ such that $(x_0, y_1, \dots, y_\ell) \in B$ and $\mathrm{I}\textsc{nd}^n_{\ell\times m}(x_0, y_1, \dots, y_\ell) = \alpha$. Then since $\mathbb{B}$ is a box-dag for $S \circ \mathrm{I}\textsc{nd}^n_{\ell\times m}$, $(\alpha, o) \in S$.

Proof of 3. It is sufficient to construct a separate dag with local property rooted in ρ^u_i with leaves from $\mathcal{L} := \{\rho^{v_q}_p\}_{q\in\{1,2\},\, p\in[t_{v_q}]}$ of block-width $O(k/\log n)$.

Recall that we abuse notation by identifying nodes of a box dag with their underlying boxes. Let $B = X \times Y_1 \times \cdots \times Y_\ell$ be a ρ^u_i-structured box from the partition of u. And let $x \in X$ be such that $\mathrm{I}\textsc{nd}^n_{\ell\times m}(\{x\} \times Y_1 \times \cdots \times Y_\ell) = \mathrm{Cube}(\rho^u_i)$. By the property of a box-dag, B is covered by the union of boxes v_1 and v_2. Thus $\{x\} \times Y_1 \times \cdots \times Y_\ell$ is also covered by $v_1 \cup v_2$. Let $I^{v_1}_x, I^{v_2}_x \subseteq [n\ell]$ be the variable sets from Lemma 17. Let our ρ^u_i-rooted decision dag consist of two parts. The first part is a decision tree querying one by one all variables from $I^{v_1}_x \cup I^{v_2}_x \setminus \mathrm{fix}(\rho^u_i)$. From each leaf of this decision tree we direct both edges to one of the nodes of $\mathcal{L}$. Observe that by the part (3) of Lemma 17, $I^{v_1}_x$ and $I^{v_2}_x$ are unions of $O(k/\log n)$ blocks and $\mathrm{fix}(\rho^u_i)$ touches $O(k/\log n)$ blocks. Thus block-width of the resulting dag is also $O(k/\log n)$.Consider any leaf of the decision tree $\theta \in \{0, 1, *\}^{n\ell}$. Since $\mathrm{I}\textsc{nd}^n_{\ell\times m}(\{x\} \times Y_1 \times \cdots \times Y_\ell) = \mathrm{Cube}(\rho^u_i)$ and θ extends ρ^u_i (i.e., $\mathrm{Cube}(\theta) \subseteq \mathrm{Cube}(\rho^u_i)$), there exist $y_1 \in Y_1, \dots, y_\ell \in Y_\ell$ such that $\mathrm{I}\textsc{nd}^n_{\ell\times m}(x, y_1, \dots, y_\ell) \in \mathrm{Cube}(\theta)$. Then consider an ω-structured box B_0 from a partition of v_1 or v_2 for $\omega \in \mathcal{L}$ that contains $(x, y_1, \dots, y_\ell)$. Observe that $\mathrm{fix}(\omega) \subseteq I^{v_1}_x \cup I^{v_2}_x \subseteq \mathrm{fix}(\theta)$. The first inclusion holds by the part (3) of Lemma 17, the second holds by the construction of the decision tree. Since by Lemma 15, $\mathrm{I}\textsc{nd}^n_{\ell\times m}(x, y_1, \dots, y_\ell) \in \mathrm{Cube}(\omega)$, $\mathrm{Cube}(\omega)$ and $\mathrm{Cube}(\theta)$ have a point in common, then $\mathrm{fix}(\omega) \subseteq \mathrm{fix}(\theta)$ implies $\mathrm{Cube}(\omega) \supseteq \mathrm{Cube}(\theta)$. Then we can direct both edges from ω to θ. That finishes the proof under the errorless assumption.

5 From Box-Dags to OBDD Refutations

▶ **Lemma 18** (a generalization of a similar lemma in [25]). *Let $U_1, \dots, U_k$ be a partition of $[n]$. Let $\mathcal{F}$ be the class of* functions *that are computable by k-party number-in-hand communication protocol*[4] *of cost c w.r.t. partition $U_1, \dots, U_k$ of $[n]$. Let $S \subseteq \{0,1\}^{U_1} \times \cdots \times \{0,1\}^{U_k} \times Y$ be a relation and let D be a $\mathcal{F}$-dag that solves it. Then there exists a* $\mathsf{box\text{-}dag}_{U_1,\dots,U_k}$ *D' of size $O(|D| \cdot 2^{3c})$ that solves S.*

[4] For a formal definition of number-in-hand protocol see e.g. [21].

Let X be a set of propositional variables of size n, $\mathcal{V} := (V_1, \dots, V_k)$ be a partition of X: $X = V_1 \sqcup \dots \sqcup V_k$, and $\pi : [n] \to X$ be a bijection (order on the variables X). We say that a partition $\mathcal{V}$ *agrees with* π if V_1 comes first in the order, then goes V_2 and so on until V_k.

▶ **Theorem 19.** *Let φ be an unsatisfiable CNF over variables X. Let $\pi : [n] \to X$ be an order of variables and $\mathcal{V}$ be a partition of X agreeing with π. Let $D_1, \dots, D_t$ be a π-OBDD($\wedge$, weakening) refutation of φ of size S. Then $\textsf{box-dag}_{\mathcal{V}}(\mathrm{Search}_{\varphi}) \le S^{O(k)}$.*

▶ **Lemma 20.** *Let D be a π-OBDD over variables X computing a function f and $\mathcal{V} = (V_1, \dots, V_k)$ be a partition of X that agrees with π. Then there exists a k-party number-in-hand communication protocol computing f with cost $k\lceil \log_2 |D| \rceil$.*

Proof of Theorem 19. By Lemma 20, a π-OBDD refutation of φ of size $S = \sum_{i=1}^{t} |D_i|$ can be viewed as an $\mathcal{F}$-dag solving $\mathrm{Search}_{\varphi}$ (for the diagrams derived via the weakening rule we direct both of the outgoing edges to the same node), where $\mathcal{F}$ is the class of functions that can be computed with cost at most $k\lceil \log_2 S \rceil$ by a k-party number-in-hand communication protocol with input partition $\mathcal{V}$. Then by Lemma 18, there exists a $\textsf{box-dag}_{\mathcal{V}}$ of size $S \cdot 2^{3k \log S} = S^{O(k)}$ solving $\mathrm{Search}_{\varphi}$. ◀

6 Making all orders hard

Let *negative width* of a resolution refutation be the maximal number of negative literals in a clause of the refutation.

▶ **Theorem 21** ([24]). *There exists a polynomial-time algorithm $\mathcal{T}_0$ that given a CNF φ over n variables returns a CNF-formula $\mathcal{T}_0(\varphi)$ such that*

- *for any variable ordering π, π-OBDD$(\varphi) \le$ OBDD$(\mathcal{T}_0(\varphi))$ (Lemma 14 from [24]);*
- *If φ has a resolution refutation of size s and* negative width *w, then $\mathcal{T}_0(\varphi)$ has resolution size at most $s \cdot n^{O(w)}$, (Corollary 9 and Lemma 12 from [24]).*

▶ **Lemma 22.** *If a CNF-formula φ has a resolution refutation of size s and the size of the smallest π-OBDD refutation of φ is t, then there exists polynomial-time algorithm that given φ outputs a formula φ' and a variable order π' such that φ' has a resolution refutation of size $O(s)$ and negative width $O(1)$, and the size of the smallest π'-OBDD refutation of φ' is at least t.*

▶ **Corollary 23.** *There exists a polynomial-time algorithm $\mathcal{T}$ that given a CNF φ over n variables returns a CNF-formula $\mathcal{T}(\varphi)$ such that for any variable ordering π, π-OBDD$(\varphi) \le$ OBDD$(\mathcal{T}(\varphi))$; and if φ has a resolution refutation of size s, then the resolution size of $\mathcal{T}(\varphi)$ is at most $s \cdot n^{O(1)}$.*

Proof. The new algorithm $\mathcal{T}$ first applies the transformation from Lemma 22 to a CNF formula and only then applies the algorithm $\mathcal{T}_0$ from Theorem 21 to it. ◀

7 Putting the pieces together

▶ **Theorem 1.** *There exist a constant α and a polynomially computable function $\mathcal{R}$ mapping CNF formulas to CNF formulas with the following properties. For any 3-CNF φ with n variables such that: if φ is satisfiable, then $\mathcal{R}(\varphi)$ has a resolution refutation of size at most n^{α}; if φ is unsatisfiable, then any* OBDD$(\wedge$, weakening$)$ *refutation of $\mathcal{R}(\varphi)$ has size $2^{\Omega(n)}$.*

Proof. Let $\mathcal{E}$ be the algorithm from Theorem 6 with the parameter $c = 3$, and $\mathcal{T}$ be the algorithm from Corollary 23. Let n be the number of variables of φ and let n_φ be the number of variables in $\mathcal{E}(\varphi)$. Let ℓ_φ be the size of the blocks in the block partition in Theorem 6, $\ell_\varphi = O(n)$. Then let $m_\varphi = (n_\varphi \ell_\varphi)^\Delta$ where Δ is from Theorem 9 and let $\mathcal{R}(\varphi) := \mathcal{T}(\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi})$.

Let us first consider the case of $\varphi \in \mathrm{SAT}$. Then by Theorem 6, $\mathcal{E}(\varphi)$ has a resolution refutation π such that $|\pi| = |\varphi|^{O(1)}$ and $\mathrm{bw}(\pi) = O(1)$. Then applying Theorem 8 we get that there exists a resolution refutation of $\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}$ of size $|\varphi|^{O(1)}$. Then by Corollary 23 $\mathcal{T}(\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi})$ has a resolution refutation of size $|\varphi|^{O(1)}$.

Let us proceed with the case $\varphi \notin \mathrm{SAT}$. Suppose $\mathcal{R}(\varphi)$ has a $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutation of size S. Then by Corollary 23 the formula $\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}$ has a π-$\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutation of size S for any variable order π. Then consider the order of variables π_0 where the variables of $\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}$ are ordered as follows:

- All the variables corresponding to the indices in an arbitrary order (denote this set by A);
- All the variables from the first rows of the matrices (denote this set by B_1);
- ...
- All the variables from the ℓ_φth rows of the matrices (denote this set by B_{ℓ_φ}).

The size of π_0-$\mathrm{OBDD}(\wedge, \mathrm{weakening})$ refutation of $\mathcal{E}(\varphi) \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}$ is at most S which by Theorem 19 implies that $\textsf{box-dag}_{A,B_1,\ldots,B_\ell}\left(\mathrm{Search}_{\mathcal{E}(\varphi)\circ\textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}}\right) \le S^{O(\ell_\varphi + 1)}$.

Then the fact that $\mathrm{Search}_{\mathcal{E}(\varphi)\circ\textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}}$ is at least as hard as $\mathrm{Search}_{\mathcal{E}(\varphi)} \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}$ and the inequality $\textsf{box-dag}_{A,B_1,\ldots,B_\ell}\left(\mathrm{Search}_{\mathcal{E}(\varphi)} \circ \textsc{Ind}^{n_\varphi}_{\ell_\varphi \times m_\varphi}\right) \ge m_\varphi^{\Omega(\mathrm{bw}(\mathcal{E}(\varphi)))}$ implied by Theorem 9 together imply that $S \ge m_\varphi^{\Omega(\mathrm{bw}(\mathcal{E}(\varphi))/(\ell_\varphi+1))}$. By Theorem 6 using Proposition 4 to switch from decision dag to resolution refutation we have $\mathrm{bw}(\mathcal{E}(\varphi)) = \Omega(n^{c-1}) = \Omega(n^2)$ which implies that $S \ge m_\varphi^{\Omega(n)}$ since $\ell_\varphi = O(n)$. This completes the proof of the theorem since $m_\varphi \ge 2$. ◀

▶ **Corollary 24.** *If* $\mathrm{OBDD}(\wedge, \mathrm{weakening})$ *is automatable then* $\mathrm{P} = \mathrm{NP}$.

Abstract

Schelling's famous model of segregation assumes agents of different types, who would like to be located in neighborhoods having at least a certain fraction of agents of the same type. We consider natural generalizations that allow for the possibility of agents being tolerant towards other agents, even if they are not of the same type. In particular, we consider an ordering of the types, and make the realistic assumption that the agents are in principle more tolerant towards agents of types that are closer to their own according to the ordering. Based on this, we study the strategic games induced when the agents aim to maximize their utility, for a variety of tolerance levels. We provide a collection of results about the existence of equilibria, and their quality in terms of social welfare.

1 Introduction

Residential segregation is a broad phenomenon affecting most metropolitan areas, and is known to be caused due to racial or socio-economic differences. The severity of its implications to society [5] is the main reason for the vast research attention it has received, with many different models being proposed over the years that aim to conceptualize it (e.g., see [23]). The most prominent of those models is that of Schelling [21, 22], which studies how motives at an individual level can lead to macroscopic behavior and, ultimately, to segregation. In particular, the individuals are modelled as agents of two different types (usually referred to using colors, such as red and blue), and the environment is abstracted by a topology (such as a grid graph), representing a city. The agents occupy nodes of the topology, and prefer neighborhoods in which the presence of their own type exceeds a specified tolerance threshold. If an agent is unhappy with her current location, then she either jumps to a randomly selected empty node of the topology, or swaps positions with another random unhappy agent. Schelling's crucial observation was that such dynamics might lead to largely segregated placements, even when the agents are relatively tolerant of mixed neighborhoods.

A recent series of papers (discussed in Section 1.2) have generalized Schelling's model to include more than two types, and have taken a game-theoretic approach, according to which the agents behave strategically rather than randomly, aiming to maximize their individual *utility*. There are many ways to define the utility of an agent i of type T. For instance, Elkind et al. [16] defined it as the ratio of the number of agents of type T in i's neighborhood over the *total* number of agents therein. Echzell et al. [15] proposed a similar definition, which however does not take into account all the agents of different type in the denominator, but only those of the *majority* type. The first definition essentially assumes that the agents view

all the agents of different type as *enemies*. On the other hand, the second definition assumes that the agents view only the majority type as hostile. An alternative way of thinking about these particular utility functions is as if the agents have binary *tolerance* towards other agents in the sense that agents are either friends or enemies; in the case of Elkind et al. all the neighbors of an agent are taken into account when computing her utility, whereas in the case of Echzell et al. some of her neighbors are ignored.

These functions are natural generalizations of the quantity that determines the happiness of agents in Schelling's original model for two types. However, they fail to capture realistic scenarios in which the agents do not have a single-dimensional view of the other agents, but rather have different *preferences* over the different types of agents. For example, suppose that the agents correspond to voters while the types correspond to political parties. In this case the preferences of voters over other voters are defined based on the distances of the political views expressed by the parties they are affiliated with. Another example is when the types correspond to research areas, in which case people working on a specific research agenda will be more willing to collaborate with other people working on related problems.

1.1 Our Contribution

To capture scenarios like the examples above, we propose a clean model that naturally extends the model of Elkind et al. [16] by incorporating *different levels of tolerance* among agent types, and study the induced strategic games in terms of the existence and quality of their equilibria; in Section 5, we discuss potential generalizations of our model.

To be more specific, our model consists of a set of agents who are partitioned into $\lambda \geq 2$ types of equal size, a graph topology, and an ordering of the different agent types which determines the relative tolerance among agents of different types. Naturally, we assume that there is higher tolerance between agents whose types are closer according to the ordering. The exact degree of tolerance between the different types is specified by a *tolerance vector*, which consists of weights representing the tolerance between the different types depending on their distance in the given ordering. For example, agents of the same type are in distance 0 and are fully tolerant towards each other, which is captured by a weight of 1. The utility of an agent can then be computed as a weighted average of the tolerance that she has towards her neighbors, and every agent aims to occupy a node of the topology to maximize her utility; agents are allowed to unilaterally *jump* to empty nodes to increase their utility.

We study the dynamics of such *tolerance Schelling games*. We first focus on questions related to equilibrium existence. For general games, we show that equilibria are not guaranteed to exist if agents are not fully tolerant towards agents in type-distance 1 (Theorem 2). We complement this impossibility by showing many positive results for important subclasses of games, in which the topology is a structured graph (such a 4-grid or a tree) and the tolerance vector satisfies certain properties (Theorems 3, 5, 6 and 7). We then turn our attention to the quality of equilibria measured by the social welfare objective, defined as the total utility of the agents, and prove (asymptotically tight) bounds on the price of anarchy [19] (Theorems 8 and 9) and price of stability [2] (Theorem 14), which depend on the number of types, the number of agents and/or the tolerance parameters.

1.2 Related Work

Residential segregation, and Schelling's original randomized model in particular, has been the basis of a continuous stream of multidisciplinary research in Sociology [13], Economics [20, 25], Physics [24], and Computer Science [4, 6, 8, 9, 17].

Most related to our work is a quite recent series of papers in the TCS and AI communities, which deviated from the premise of random behavior, and instead studied the strategic games induced when the agents act as utility-maximizers. Chauhan et al. [12] studied questions related to dynamics convergence in games with two types of agents who can either jump to empty nodes of a topology (as in our case) or *swap* locations with other agents to minimize a *cost* function; their model was generalized to multiple types of agents by Echzell et al. [15]. In this paper we extend the utility model of Elkind et al. [16], who initially refined the cost model of Chauhan et al. [12]. They introduced a simpler utility function (fraction of same-type agents in the one's neighborhood) which the agents aim to maximize, and studied the existence, complexity and quality of equilibria in jump games with multiple types of agents and general topologies. They also proposed many interesting variants, such as *enemy aversion* (agents might prefer being alone to being in a group full of agent of different type than their own) and *social Schelling games* (where the agents types are determined by a social network), which have been partially studied by Kanellopoulos et al. [18] and Chan et al. [11], respectively. Agarwal et al. [1] studied similar existence, complexity and qualitative questions for swap games. Bilò et al. [7] also focused on swap games, and in particular, on a constrained setting, where the agents can only view a small part of the topology near their current location and can only swap with agents in this part of the topology. Finally, Bullinger et al. [10] and Deligkas et al. [14] studied the (parameterized) complexity of computing assignments with good welfare guarantees, focusing on the social welfare, Nash welfare, and Pareto optimality, and many other welfare objectives.

2 Preliminaries

A λ-*type tolerance Schelling game* consists of:

- A set N of $n \geq 4$ *agents*, partitioned into $\lambda \geq 2$ disjoint sets $T_1, \dots, T_\lambda$ representing *types*, such that $\bigcup_{\ell \in [\lambda]} T_\ell = N$.
- A simple connected undirected graph $G = (V, E)$ called *topology*, such that $|V| > n$.
- A *tolerance vector* $\mathbf{t}_\lambda = [t_0, \dots, t_{\lambda-1}]$ consisting of λ parameters, such that t_d represents the tolerance that agents of type T_ℓ have towards agents of type T_k in Manhattan distance $|\ell - k| = d \in \{0, \dots, \lambda - 1\}$ according to a given ordering $\succ$ of the types (say, $T_1 \succ \dots \succ T_\lambda$). We assume that agents are more tolerant towards agents of types that are closer to their own according to $\succ$, and we thus have that $1 = t_0 \geq \dots \geq t_{\lambda-1} \geq 0$. We also assume that $t_{\lambda-1} < 1$; otherwise, all agents are completely tolerant towards all others and the game is trivial. Let $\tau = \sum_{d=0}^{\lambda-1} t_d$ be the sum of all tolerance parameters.

Clearly, the class of λ-type tolerance Schelling games includes as a special case the classic Schelling games studied in the related literature (e.g., see [16]), for which $t_0 = 1$ and $t_d = 0$ for every $d \in \{1, \dots, \lambda - 1\}$. Because of this particular tolerance vector, we will use the term λ-*type zero-tolerance games* to refer to the classic Schelling games.

In this paper we consider *balanced* games, in which the agents are partitioned in types of equal size, such that $|T_\ell| = n/\lambda \geq 2$ for every $\ell \in [\lambda]$; thus, n is a multiple of λ. Balanced games are the most fundamental ones that admit non-trivial and interesting results[1]. We use the abbreviation λ-*TS* to refer to such a balanced λ-type tolerance Schelling game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$. For convenience, we will also use the abbreviation λ-*ZTS* to refer to a balanced λ-type zero-tolerance game $\mathcal{I} = (N, G)$.

[1] Note that equilibria are not guaranteed to exist even for balanced games (see Theorem 2), while it is not hard to observe that the price of anarchy can be unbounded when the sizes of the types are arbitrary [16].

Let $\mathbf{v} = (v_i)_{i \in N}$ be an *assignment* specifying the node v_i of G that each agent $i \in N$ *occupies*, such that $v_i \neq v_j$ for $i \neq j$. The *neighborhood* of a node v consists of the nodes at distance 1 from v in G. For every node v, we denote by $n_\ell(v|\mathbf{v})$ the number of agents of type T_ℓ that occupy nodes in the neighborhood of v according to the assignment $\mathbf{v}$, and also let $n(v|\mathbf{v}) = \sum_{\ell \in [\lambda]} n_\ell(v|\mathbf{v})$. Given an assignment $\mathbf{v}$, the utility of agent i of type T_ℓ is computed as

$$u_i(\mathbf{v}) = \frac{1}{n(v_i|\mathbf{v})} \sum_{k \in [\lambda]} t_{|\ell-k|} \cdot n_k(v_i|\mathbf{v}),$$

if $n(v_i|\mathbf{v}) \neq 0$, and 0 otherwise (in which case we say that the agent is *isolated*). The agents are *strategic* and aim to maximize their utility by *jumping* to empty nodes of the topology if they can increase their utility by doing so. We say that an assignment $\mathbf{v}$ is an *equilibrium* if no agent i of any type T_ℓ has incentive to jump to any empty node v of the topology, that is, $u_i(\mathbf{v}) \geq u_i(v, \mathbf{v}_{-i})$, where $(v, \mathbf{v}_{-i})$ is the assignment resulting from this jump. Let $\text{EQ}(\mathcal{I})$ be the set of equilibrium assignments of a given λ-TS game $\mathcal{I}$.

The *social welfare* of an assignment $\mathbf{v}$ is defined as the total utility of the agents, that is,

$$\text{SW}(\mathbf{v}) = \sum_{i \in N} u_i(\mathbf{v}).$$

Let $\text{OPT}(\mathcal{I}) = \max_{\mathbf{v}} \text{SW}(\mathbf{v})$ be the maximum social welfare among all possible assignments in the λ-TS game $\mathcal{I}$. For a given subclass $\mathcal{C}$ of λ-TS games, the *price of anarchy* is defined as the worst-case ratio, over all possible games $\mathcal{I} \in \mathcal{C}$ such that $\text{EQ}(\mathcal{I}) \neq \varnothing$, between $\text{OPT}(\mathcal{I})$ and the *minimum* social welfare among all equilibria:

$$\text{PoA}(\mathcal{C}) = \sup_{\mathcal{I} \in \mathcal{C}: \text{EQ}(\mathcal{I}) \neq \varnothing} \frac{\text{OPT}(\mathcal{I})}{\min_{\mathbf{v} \in \text{EQ}(\mathcal{I})} \text{SW}(\mathbf{v})}.$$

Similarly, the *price of stability* takes into account the ratio between $\text{OPT}(\mathcal{I})$ and the *maximum* social welfare among all equilibria:

$$\text{PoS}(\mathcal{C}) = \sup_{\mathcal{I} \in \mathcal{C}: \text{EQ}(\mathcal{I}) \neq \varnothing} \frac{\text{OPT}(\mathcal{I})}{\max_{\mathbf{v} \in \text{EQ}(\mathcal{I})} \text{SW}(\mathbf{v})}.$$

3 Equilibrium Existence

In this section, we show several positive and negative results about the existence of equilibrium assignments, for interesting subclasses of tolerance Schelling games. We start with the relation of equilibrium assignments in λ-ZTS games and general λ-TS games.

▶ **Theorem 1.** *Consider a λ-ZTS game $\mathcal{I} = (N, G)$ and a λ-TS game $\mathcal{I}' = (N, G, \mathbf{t}_\lambda)$. For $\lambda = 2$, $EQ(\mathcal{I}') \subseteq EQ(\mathcal{I})$ and $EQ(\mathcal{I}) \setminus EQ(\mathcal{I}')$ consists of assignments with isolated agents. For $\lambda \geq 3$, $EQ(\mathcal{I})$ and $EQ(\mathcal{I}')$ are incomparable.*

Proof. We start with $\lambda = 2$; for convenience, we will refer to the two types as red and blue. Let $\mathbf{v}$ be an equilibrium of $\mathcal{I}'$. Clearly, for $\mathcal{I}$ and $\mathcal{I}'$ to be different, it must be the case that $t_1 > 0$. Consequently, there are no isolated agents in $\mathbf{v}$ as they would have incentive to deviate to nodes that are adjacent to any other agent and increase their utility from 0 to (at least) t_1. We will show that $\mathbf{v}$ is an equilibrium of $\mathcal{I}$ as well. Without loss of generality, consider a red agent i who occupies a node v_i that is adjacent to $n_r(v_i)$ red and $n_b(v_i)$ blue agents. Since agent i is not isolated, it holds that $n_r(v_i) + n_b(v_i) \geq 1$. If $n_b(v_i) = 0$, then agent i has maximum utility 1 in both $\mathcal{I}$ and $\mathcal{I}'$. Hence, we can assume that $n_b(v_i) \geq 1$. Since $\mathbf{v}$ is an equilibrium of $\mathcal{I}'$, agent i has no incentive to unilaterally jump to any empty node v of the topology. That is,

$$\frac{n_r(v_i) + t_1 \cdot n_b(v_i)}{n_r(v_i) + n_b(v_i)} \geq \frac{n_r(v) + t_1 \cdot n_b(v)}{n_r(v) + n_b(v)} \Leftrightarrow (1 - t_1) \left(\frac{n_r(v_i)}{n_b(v_i)} - \frac{n_r(v)}{n_b(v)} \right) \geq 0,$$

where $n_r(v)$ and $n_b(v)$ are the number of red and blue agents that are adjacent to v *after* agent i jumps to v; observe that $n_b(v) \geq 1$, as otherwise agent i would obtain maximum utility of 1 by jumping to v, contradicting that $\mathbf{v}$ is an equilibrium of $\mathcal{I}'$. Since $t_1 < 1$, we equivalently have that

$$\frac{n_r(v_i)}{n_b(v_i)} \geq \frac{n_r(v)}{n_b(v)} \Leftrightarrow \frac{n_r(v_i)}{n_r(v_i) + n_b(v_i)} \geq \frac{n_r(v)}{n_r(v) + n_b(v)}.$$

Therefore, agent i has no incentive to jump to the empty node v in $\mathcal{I}$, and $\mathbf{v}$ is an equilibrium of $\mathcal{I}$ as well. Using similar arguments, we can show that any equilibrium of $\mathcal{I}$ such that there is no isolated agent is also an equilibrium of $\mathcal{I}'$.

For $\lambda \geq 3$, to show that $\text{EQ}(\mathcal{I})$ is incomparable to $\text{EQ}(\mathcal{I}')$, consider the tolerance vector $\mathbf{t_3} = (1, 1/2, 0)$ and the following two partial assignments $\mathbf{v}$ and $\mathbf{v}'$:

- In $\mathbf{v}$, an agent i of type T_1 occupies a node v_i which is adjacent to two nodes, one occupied by an agent of type T_1 and one occupied by an agent of type T_3. There is also an empty node v which is adjacent to two nodes, one occupied by an agent of type T_1 and one occupied by an agent of type T_2. In $\mathcal{I}$, agent i has no incentive to jump from v_i to v as both nodes give her utility 1/2. On the other hand, in $\mathcal{I}'$, agent i has utility $(1+t_2)/2 = 1/2$ and has incentive to jump to v to increase her utility to $(1+t_1)/2 = 3/4$. Hence, $\mathbf{v}$ can be an equilibrium of $\mathcal{I}$, but not of $\mathcal{I}'$.
- In $\mathbf{v}'$, an agent i of type T_1 occupies a node v_i which is adjacent to three nodes, one occupied by an agent of type T_1, one occupied by an agent of type T_2 and one occupied by an agent of type T_3. There is also an empty node v which is adjacent to two nodes, one occupied by an agent of type T_1 and one occupied by an agent of type T_3. In $\mathcal{I}$, agent i has incentive to jump from v_i to v in order to increase her utility from 1/3 to 1/2. However, in $\mathcal{I}'$, agent i has no incentive to jump as she has utility $(1 + t_1)/3 = 1/2$ by occupying node v_i, which is exactly the utility she would also obtain by jumping to v. Consequently, $\mathbf{v}'$ can be an equilibrium of $\mathcal{I}'$, but not of $\mathcal{I}$.

This completes the proof. ◀

Since there exist simple 2-ZTS games that do not admit any equilibria [16], the first part of Theorem 1 implies that equilibria are not guaranteed to exist for general 2-TS games as well. In fact, by carefully inspecting the proof of Elkind et al. [16] that λ-ZTS games played on trees do not always admit equilibria for every $\lambda \geq 2$, we can show the following stronger impossibility result.

▶ **Theorem 2.** *For every $\lambda \geq 2$ and every tolerance vector $\mathbf{t}_\lambda$ such that $t_1 < 1$, there exists a λ-TS game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$ in which G is a tree and does not admit any equilibrium.*

Since Theorem 2 implies that it is impossible to hope for general positive existence results, in the remainder of this section we focus on games with structured topologies and tolerance vectors. In particular, we consider the class of α-binary λ-TS games with $\alpha \in \{1, \dots, \lambda\}$ in which the tolerance vector $\mathbf{t}_\lambda$ is such that

$$t_d = \begin{cases} 1, & \text{if } d < \alpha \\ 0, & \text{otherwise.} \end{cases}$$

Clearly, the class of 1-binary λ-TS games coincides with that of λ-ZTS.

We next show that when the topology is a grid[2] or a tree, there exist values of $\alpha \in \{1, \dots, \lambda\}$ for which α-binary λ-TS games played on such a topology always admit at least one equilibrium. Our first result for grids is the following.

▶ **Theorem 3.** *Every 2-ZTS game $\mathcal{I} = (N, G)$ in which G is a grid admits at least one equilibrium.*

The proof of Theorem 3 is constructive and such that in the computed equilibrium no agent is isolated. Consequently, in combination with Theorem 1, it further implies the following:

▶ **Corollary 4.** *Every 2-TS game $\mathcal{I} = (N, G, \mathbf{t_2})$ in which G is a grid admits at least one equilibrium.*

Unfortunately, showing a result similar to Theorem 3 for every $\lambda \geq 3$ is a very challenging task. Instead, we show the following result for 2-binary games.

▶ **Theorem 5.** *Every 2-binary λ-TS game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$ in which G is a grid admits at least one equilibrium.*

Proof. Consider a 2-binary λ-TS game with n agents played on an $m \times M$ grid (m rows and M columns) such that $m \leq M$. Let $x = n/\lambda \geq 2$ be the number of agents per type and $e = mM - n$ be the number of empty nodes.

We compute an equilibrium assignment $\mathbf{v}$ using Algorithm 1, which in turn relies on the TILE procedure described in Algorithm 2. In particular, Algorithm 2 considers the yet unassigned agents in increasing type according to the ordering $\succ$, and assigns them in an $r \times M$ subgrid having row s as the top row, so that the k leftmost nodes of the top row are left empty, while all other nodes host an agent (assuming the number of unassigned agents is large enough). TILE visits these rows in a column-major order, skipping the empty nodes. Informally, Algorithm 1 repeatedly calls Algorithm 2 to compute an assignment for consecutive sub-grids, along the largest dimension of the topology. The exact size of the sub-grid considered at each time is determined by the number of remaining rows of the topology.

Algorithm 1 terminates immediately (at any step) when all agents have been assigned. First, observe that if it terminates in Lines 3 or 7, each agent of type ℓ has neighbors of types in $\{\ell - 1, \ell, \ell + 1\}$, and, hence, $\mathbf{v}$ is an equilibrium. Note that the algorithm cannot terminate at Line 11 since $e < M$, so let us assume that the algorithm terminates in Line 14. Again, all agents placed in Line 3 have utility 1. Each agent i of type ℓ placed during Line 11 has utility at least 2/3; indeed, i has at least one neighbor of type ℓ, at least one neighbor of a type in $\{\ell - 1, \ell + 1\}$, and at most one neighbor of type at distance at least 2. If $\alpha = 1$ all agents placed in Line 14 have utility 1. Otherwise, agents placed in Line 14 at the last $x - 1$ rows have utility 1, while any agent on the row with the empty nodes has utility at least 1/2 when $e = M - 1$, and at least 2/3 otherwise.

[2] We focus on 4-grids where internal nodes have 4 neighbors.

Algorithm 1 Equilibrium construction for a 2-binary λ-TS game on an $m \times M$ grid.

```
   /* $x$: number of agents per type                                              */
   /* $e$: number of empty nodes                                                  */
   /* The algorithm terminates immediately when all agents have been assigned.    */
1  Initialize $k = 0$
2  while $x \leq m - k$ and $e \geq M$ do
3      Tile$(k+1, x, 0)$
4      leave the next row empty
5      update $k := k + x + 1$, $e := e - M$
6  if $x > m - k$ then
7      Tile$(k+1, m-k, 0)$
8  else /* In this case it holds that $e < M$ and $x \leq m - k$                 */
9      Define non-negative integers $\alpha \in \mathbb{N}_{>0}$ and $\beta \leq x - 1$ such that $m - k = \alpha x + \beta$
10     for $i = 1, \dots, \alpha - 1$ do
11         Tile$(k+1, x, 0)$
12         update $k := k + x$
13     if $\beta = 0$ then
14         Tile$(k+1, x, e)$
15     else if $\beta = 1$ then
16         if Line 3 was executed then
17             Shift all agents down by one row
18             Tile$(1, 1, e)$
19             Tile$(k+2, x, 0)$
20         else
21             Tile$(k+1, 1, e)$
22             Tile$(k+2, x, 0)$
23     else
24         Tile$(k+1, x, 0)$
25         Tile$(k+x+1, \beta, e)$
```

Algorithm 2 Tile(s, r, k).

```
/* $s, r$: starting row and number of rows defining an $r \times M$ grid         */
/* $k$: number of nodes to be left empty                                          */
for $i = 1$ to $k$ do
    mark node $(s, i)$ as empty
for $j = 1$ to $M$ do
    for $i = s$ to $s + r - 1$ do
        if node $(i, j)$ is unmarked then
            place the next agent (if one exists) according to the ordering $\succ$ at node
             $(i, j)$
```

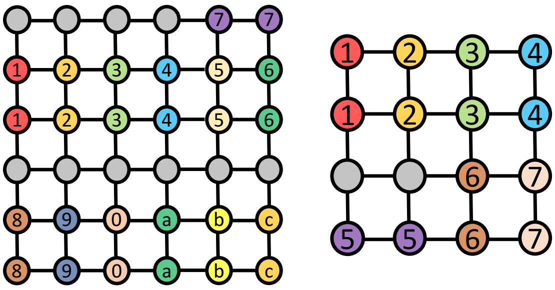

Figure 1 On the left, an example of how Algorithm 1 operates when it terminates in Line 19. On the right, an example when the algorithm terminates in Line 14. Agents of the same number and color are of the same type, while $\succ$ is $\{1, 2, \dots, 9, 0, a, b, c\}$.

If the algorithm terminates in Line 19 (see also the leftmost part of Figure 1), agents placed in Lines 3, 11, or 19 have utility at least 2/3, while agents placed in Line 18 have utility at least 1/2. If the algorithm terminates in Line 22, agents placed in Line 3 have utility 1, agents placed in Lines 11 and 22 have utility at least 2/3, while agents placed in Line 21 have utility at least 2/3 except (perhaps) the first and the last agent on the row that have utility at least 1/3. If the algorithm terminates in Line 25, again all agents placed in Line 3 have utility 1, while agents placed in Lines 11 and 24 have utility at least 2/3. Finally, the agents placed in Line 25 have utility at least 1/2 if $e = M - 1$ and at least 2/3 otherwise.

We now argue that no agent has an incentive to jump. Note that an empty node may have another empty node as a top or bottom neighbor if the algorithm terminates in Line 3, or in Line 7, or in Line 14 in case $\alpha = 1$. In all these cases, by the discussion above, all agents have utility 1 and the assignment is an equilibrium. Also, note that an empty node has always a bottom neighbor, while the only case the empty node has no top neighbor is if the algorithm terminates in Line 19. In that case, any agent with utility less than 1 can obtain utility at most 1/2 by jumping; again, $\mathbf{v}$ is an equilibrium.

So, in the following we assume that any empty node has a top and bottom neighboring agent. Observe that, in that case, an agent gets utility at most 2/3 by jumping to an empty node, since either the top or the bottom neighbor will have a large type distance and there is no left neighbor. As in almost all cases, agents in $\mathbf{v}$ have utility at least 2/3, it remains to argue about the nodes that have utility less than that. The agent in Line 14 with utility 1/2 (when $\alpha > 1$) obtains utility at most 1/2 by jumping, the agents in Line 21 with utility at least 1/3 obtain utility at most 1/3 by jumping, and, finally, the agent in Line 25 with utility 1/2 obtains utility at most 1/2 by jumping. We conclude that $\mathbf{v}$ is an equilibrium and the theorem follows. ◀

Note that Algorithm 1 may fail to return an equilibrium for lexicographically larger tolerance vectors. Indeed, consider a 4×4 grid and 7 types of two agents each. Algorithm 1 puts agents of types 1 to 4 in each of the first two rows, skips 2 nodes, puts agents of types 6 and 7 in the third row, and places agents of types 5, 5, 6 and 7 in the last row; see also the rightmost example in Figure 1. Under tolerance vector $\mathbf{t_7} = \{1, 1, 0, 0, 0, 0, 0\}$ the assignment is an equilibrium (by Theorem 5), while under tolerance vector $\mathbf{t}'_\mathbf{7} = \{1, 1, t_2 > \frac{1}{2}, 0, 0, 0, 0\}$, the agent of type 4 in the second row has utility 2/3, but can obtain utility $\frac{1+2t_2}{3} > 2/3$ by jumping to the rightmost empty node.

So, a different algorithm is needed for computing equilibria in α-binary games with $\alpha \geq 3$. While we have not been able to show this result for every α, we do show it for $\alpha \geq \sqrt{\lambda}$. In particular, the equilibrium constructed in the proof of the next theorem guarantees a utility of 1 to all agents, and thus it is also an equilibrium for games with lexicographically larger tolerance vectors, not necessarily binary ones.

Algorithm 3 Equilibrium construction for a $\lfloor\frac{\lambda}{2}\rfloor$-binary λ-TS game on a tree (or games with lexicographically larger tolerance vectors).

```
   /* $tree_1,\dots,tree_k$ denote the subtrees of the tree topology in non-increasing order
      by size, when the topology is rooted at a centroid node.                          */
1  Run Bottom-Up($tree_1, T_1, T_2, \dots, T_{\lceil\frac{\lambda}{2}\rceil}$). If at least one agent of type $T_1$ remains
     unassigned, repeat with the next subtree. Let $a \leq \lceil\frac{\lambda}{2}\rceil$ be the smallest type index
     among unassigned agents, and let $tree_{k_1}$ be the last subtree considered in this step.
2  Run Bottom-Up($tree_{k_1+1}, \mathcal{T}_\lambda, \mathcal{T}_{\lambda-1}, \dots, \mathcal{T}_{\lceil\frac{\lambda+1}{2}\rceil}$), where $\mathcal{T}_i$ are the unassigned
     agents of types $T_i$, $i = \lambda, \dots, \lceil\frac{\lambda+1}{2}\rceil$. If at least one agent of type $T_\lambda$ remains
     unassigned, repeat with the next subtree. Let $b \geq \lceil\frac{\lambda+1}{2}\rceil$ be the largest type index
     among unassigned agents, and let $tree_{k_2}$ be the last subtree considered in this step.
3  Run Bottom-Up($tree_{k_2+1}, \mathcal{T}_a, \mathcal{T}_{a+1}, \dots, \mathcal{T}_b$), where $\mathcal{T}_i$ are the unassigned agents of
     types $T_i$, $i = a, \dots, b$. Repeat with the next subtree and the unassigned agents of
     these types, until all agents have been assigned.
4  If the last subtree among the ones considered in the previous steps contains at least
     two isolated agents, then rearrange them within this subtree so that each of them
     has at least one neighbor. If the last subtree contains a single isolated agent, then
     move this agent to the root of the tree.
```

▶ **Theorem 6.** *For $\lambda \geq 3$, every $\sqrt{\lambda}$-binary λ-TS game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$ in which G is a grid admits at least one equilibrium.*

Next we turn our attention to games in which the topology is a tree. We show the following result for α-binary games when $\lambda \geq 3$.

▶ **Theorem 7.** *Every 2-binary 3-TS game $\mathcal{I} = (N, G, \mathbf{t_3})$ and every α-binary λ-TS game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$ where $\alpha \geq \lfloor\frac{\lambda}{2}\rfloor$ for $\lambda \geq 4$, in which G is a tree, admit at least one equilibrium.*

Proof. To construct an equilibrium, we exploit the following known property of trees: Every tree with $x \geq 3$ nodes contains a *centroid* node, whose removal splits the tree into at least two subtrees with at most $x/2$ nodes each. We root the tree from such a centroid node, and leave the root empty. This leads to a partition of the topology in $k \geq 2$ subtrees, which we order in non-increasing size and denote by $tree_1, \dots, tree_k$.

To assign the agents we use Algorithm 3, which in turn uses the Bottom-Up allocation procedure (described in Algorithm 4). The procedure Bottom-Up($tree, \mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_s$) assigns the unassigned agents of types $\mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_s$ to the nodes of the subtree *tree* from bottom to top (higher to lower depth), so that all the agents of $\mathcal{T}_1$ are covered by either agents of the same type or agents of type $\mathcal{T}_2$, and the assignment for the remaining agents is connected. Informally, Algorithm 3 roots the topology at a centroid node and considers subtrees in non-increasing size. As long as agents of type T_1 are remaining, Algorithm 3 applies the Bottom-Up procedure to the next subtree with agents in increasing type index. Then, as long as agents of type T_λ are remaining, Algorithm 3 applies the Bottom-Up procedure to the next subtree with agents in decreasing type index. The remaining (smaller) subtrees are filled with the remaining agents, again using the Bottom-Up procedure.

We first claim that at the end of Step 3 of Algorithm 3, every agent either gets utility 1 or gets utility 0 if she is isolated. Indeed, it holds that agents of type T_1 can only be adjacent to agents of type T_1 and T_2. Similarly, the agents of type T_λ can only be adjacent to agents of type T_λ and $T_{\lambda-1}$. In addition, by design, the maximum type distance among all the other agents assigned in Steps 1 and 2 is $\lceil\frac{\lambda}{2}\rceil - 2$. By this discussion, all agents have utility 1 when $\lambda = 3$ and the game is 2-binary. Below, we assume that $\lambda \geq 4$.

Algorithm 4 Bottom-Up($tree, \mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_s$).

```
/* For $i = 1, \dots, s$, $\mathcal{T}_i$ is the set of unassigned agents of a given type */
/* The algorithm terminates immediately when all agents have been assigned or all
   nodes of $tree$ have been occupied. */
1 Start at the lowest level of $tree$ and place agents of type $\mathcal{T}_1$ so that an agent of type
   $\mathcal{T}_1$ is placed at level $h$ only if all nodes at levels at least $h + 1$ have been filled.
   Furthermore, and assuming the previous condition holds, after filling a node at level
   $h$ we give priority to its sibling nodes. Continue until all agents of type $\mathcal{T}_1$ have been
   assigned.
2 Consider the agents of type $\mathcal{T}_2$. Begin by placing an agent of type $\mathcal{T}_2$ to any empty
   node having a child occupied by an agent of type $\mathcal{T}_1$ and repeat until the parent
   nodes of all agents of type $\mathcal{T}_1$ are occupied. This is feasible as long as there are at
   least as many agents of type $\mathcal{T}_2$ as there are agents of type $\mathcal{T}_1$. Continue by placing
   agents of type $\mathcal{T}_2$ arbitrarily in $tree$ by maintaining a connected assignment.
3 Arbitrarily assign the remaining agents in order of input so that the assignment
   remains connected after assigning each agent.
```

To see the claim is true for agents assigned in Step 3, observe that if Step 2 is applied on a subtree of at least $n/3$ nodes, then since we visit subtrees in non-increasing order of their size, Step 1 is also applied on a subtree of at least $n/3$ nodes. Hence, at most $n/3$ agents remain to be allocated. Otherwise, if no subtree on which Step 2 is applied has at least $n/3$ nodes, then, again due to the order we visit subtrees, any subtree to which we perform Step 3 has less than $n/3$ nodes. In any case, at most $n/3$ agents will be allocated at Step 3 at any given subtree. These agents belong to at most $\lceil \lambda/3 \rceil + 1$ different types and, due to Steps 2 and 3 in Algorithm 4, we are guaranteed that no agent allocated in Step 3 will have a neighbor of type-distance $\lceil \lambda/3 \rceil$. Since $\lceil \lambda/3 \rceil - 1 \leq \lfloor \lambda/2 \rfloor - 1$, such agents either get utility 1, or 0 if they are isolated, as required.

It remains to argue that after a possible execution of Step 4, no agent has a profitable deviation. We distinguish between the following two cases when Step 4 is performed:

- Case I: There are at least two isolated agents in the last subtree among those considered in the first three steps. First observe that, since the subtrees are considered in non-increasing order by size and the last subtree contains at least two agents, there is no subtree with a single isolated agent. Now, by the definition of the bottom-up-like allocation algorithm, all these agents must be of the last type T_b, since if agents of two or more types are assigned in the same subtree, the resulting assignment therein is by construction connected. Therefore, by rearranging the agents of type T_b in the last subtree so that all of them have at least one neighbor, each of them gets utility 1 and the assignment is an equilibrium.
- Case II: There is a single isolated agent i in the last subtree of the last type T_b considered, who is moved to the root of the tree. Since Step 4 is performed, all the subtrees that have been considered in the first three steps are full, with the exception of the last subtree which has been left empty after moving agent i. Thus, the empty nodes of the topology are only adjacent to other empty nodes or the root. As a result, an agent of some type $\ell \in [\lambda]$ would be able to get utility $t_{|\ell-b|}$ by jumping to an empty node that is adjacent to the root, and utility 0 by jumping to any other empty node. However, every agent $j \neq i$ already has utility at least $t_{|\ell-b|}$. In particular, agent j has utility 1 if she is not adjacent to the root, utility at least $\frac{1+t_{|\ell-b|}}{2} \geq t_{|\ell-b|}$ if she is adjacent to the root but not isolated before moving i to the root, and utility exactly $t_{|\ell-b|}$ if she is adjacent to the root and was isolated before moving i to the root.

This completes the proof. ◀

For $\lambda = 3$, Theorem 7 is tight in the sense that equilibria are not guaranteed to exist when $t_1 < 1$ (Theorem 2). For $\lambda \geq 4$, it is not hard to observe that the assignment computed is also an equilibrium in games with lexicographically larger vectors (not necessarily binary ones) than the one stated.

4 Quality of Equilibria

In this section, we consider the quality of equilibria measured in terms of social welfare, and bound the price of anarchy and price of stability. Recall that these notions compare the social welfare achieved in the *worst* and *best* equilibrium to the maximum possible social welfare achieved in any assignment. We start with a general upper bound on the price of anarchy, whose proof follows by bounding the social welfare at equilibrium by the total utility the agents would be able to obtain by jumping to an arbitrary empty node. Recall that $\tau = \sum_{d=0}^{\lambda-1} t_d$.

▶ **Theorem 8.** *The price of anarchy of λ-TS games with tolerance vector $\mathbf{t}_\lambda$ is at most $\frac{\lambda n}{\tau n - \lambda}$.*

Proof. Consider a λ-TS game $\mathcal{I} = (N, G, \mathbf{t}_\lambda)$ with $\text{EQ}(\mathcal{I}) \neq \varnothing$. Let $\mathbf{v}$ be an equilibrium, and denote by v an empty node. The utility that an agent of type T_ℓ, $\ell \in [\lambda]$ would obtain by unilaterally jumping to v is

- $\frac{1}{n(v)} \sum_{k\in[\lambda]} t_{|\ell-k|} \cdot n_k(v)$ if she is not adjacent to v;
- $\frac{1}{n(v)-1} \left(\sum_{k\in[\lambda]} t_{|\ell-k|} \cdot n_k(v) - 1\right)$ otherwise.

Also observe that for every type T_ℓ, $\ell \in [\lambda]$ there are exactly $\frac{n}{\lambda} - n_\ell(v)$ agents that are not adjacent to v, and $n_\ell(v)$ agents that are adjacent to v. Since $\mathbf{v}$ is an equilibrium, every agent of type T_ℓ is guaranteed to have at least as much utility as if she were to deviate to v, and therefore the social welfare is

$$\begin{aligned}
\text{SW}(\mathbf{v}) &\geq \frac{1}{n(v)} \sum_{\ell\in[\lambda]} \left(\frac{n}{\lambda} - n_\ell(v)\right) \sum_{k\in[\lambda]} t_{|\ell-k|} \cdot n_k(v) \\
&\quad + \frac{1}{n(v)-1} \sum_{\ell\in[\lambda]} n_\ell(v) \cdot \left(\sum_{k\in[\lambda]} t_{|\ell-k|} \cdot n_k(v) - 1\right) \\
&\geq \frac{1}{n(v)} \sum_{\ell\in[\lambda]} \left(\frac{n}{\lambda} \sum_{k\in[\lambda]} t_{|\ell-k|} \cdot n_k(v) - n_\ell(v)\right) \\
&= \frac{1}{n(v)} \sum_{\ell\in[\lambda]} n_\ell(v) \cdot \left(\frac{n}{\lambda} \sum_{k\in[\lambda]} t_{|\ell-k|} - 1\right) \\
&= \frac{1}{\lambda \cdot n(v)} \sum_{\ell\in[\lambda]} n_\ell(v) \left(n \sum_{k\in[\lambda]} t_{|k-\ell|} - \lambda\right).
\end{aligned}$$

The second inequality is due to increasing the denominator of the second fraction. The first equality follows by aggregating the factors of $n_\ell(v)$ for every $\ell \in [\lambda]$. Finally, the second equality follows by factorizing λ. Now observe that because the tolerance vector $\mathbf{t}_\lambda$ is non-increasing, we have that $\sum_{k\in[\lambda]} t_{|\ell-k|} \geq \sum_{d=0}^{\lambda-1} t_d = \tau$. Combining this together with the fact that $n(v) = \sum_{\ell\in[\lambda]} n_\ell(v)$, we obtain

$$\text{SW}(\mathbf{v}) \geq \frac{\tau n - \lambda}{\lambda}.$$

The bound on the price of anarchy follows by the fact that the optimal welfare is at most n (the maximum utility of any agent is 1). ◀

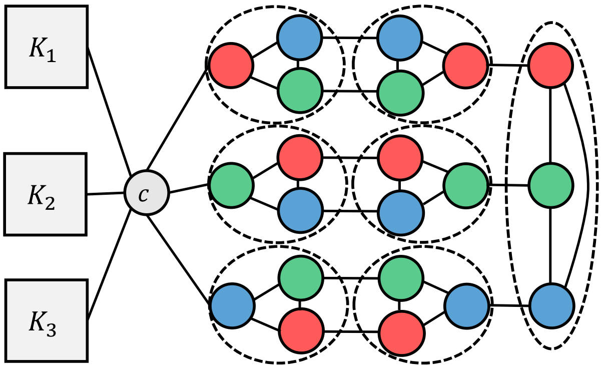

Figure 2 An instance used for the proof of Theorem 9 for the case of 3 types and 21 agents, so that each type has 7 agents. The big squares K_1, K_2, K_3 correspond to cliques of size 7 (the number of agents per type), while the ovals represent cliques of size 3 (the number of types). In an optimal assignment, each large clique contains agents of the same type and each agent gets utility 1. In a bad equilibrium, each small clique contains a single agent of each type and all gray nodes are left empty. For each type $\ell \in [3]$, all but one agents of type ℓ get utility $\tau_\ell/3$, while the last agent gets utility $(\tau_\ell - 1)/2$.

For each $\ell \in \{1, \dots, \lambda\}$, let $\tau_\ell = \sum_{k\in[\lambda]} t_{|\ell-k|}$ be the total tolerance of agents of type ℓ towards any subset containing one agent of every type. We can show the following general lower bound on the price of anarchy, as a function of these parameters; see Figure 2 for a sketch of the proof for $\lambda = 3$.

▶ **Theorem 9.** *The price of anarchy of λ-TS games with tolerance vector $\mathbf{t}_\lambda$ is at least*

$$\frac{\lambda n}{\frac{\sum_{\ell\in[\lambda]} \tau_\ell}{\lambda} n - \frac{\lambda^2 - \sum_{\ell\in[\lambda]} \tau_\ell}{\lambda - 1}} \geq \frac{\lambda n}{\frac{2(\lambda-1)\tau}{\lambda} n - \frac{\lambda^2}{\lambda-1} + 2\tau}.$$

From Theorems 8 and 9 we obtain an asymptotically tight bound for general λ-TS games.

▶ **Corollary 10.** *The price of anarchy in λ-TS games is $\Theta(\lambda/\tau)$.*

Theorem 9 allows us to provide concrete bounds for subclasses of λ-TS games. In particular, for λ-ZTS games, since $\tau_\ell = 1$ for every $\ell \in [\lambda]$, we have $\sum_{\ell\in[\lambda]} \tau_\ell = \lambda$, and thus the left-hand-side of the inequality in Theorem 9 allows us to improve upon the weaker lower of [16] and obtain the following tight bound, for any values of n and λ.

▶ **Corollary 11.** *The price of anarchy of λ-ZTS games is $\frac{\lambda n}{n-\lambda}$.*

We now define the following two natural classes of λ-TS games in which the tolerance parameters are specific functions of the distance between the types. In the first one, the difference of the tolerance level is proportional to the type distance, while in the other, the difference of the tolerance is decreasing in the type distance in an inversely proportional way.

- *Proportional* λ-TS games: $t_d = 1 - \frac{d}{\lambda-1}$ for each $d \in \{0, \dots, \lambda-1\}$, while $\tau = \sum_{\ell\in[\lambda]} \frac{\ell-1}{\lambda-1} = \frac{\lambda}{2}$.
- *Inversely proportional* λ-TS games: $t_d = \frac{1}{d+1}$ for every $d \in \{0, \dots, \lambda - 1\}$. We have $\tau = \sum_{\ell\in[\lambda]} \frac{1}{\ell} = H_\lambda$, where H_λ is the λ-th harmonic number.

By Theorems 8, 9 and the above definitions, we obtain the following corollaries.

▶ **Corollary 12.** *For every $\lambda \geq 2$, the price of anarchy of proportional λ-TS games is at most $\frac{2n}{n-2}$ and at least $\frac{\lambda n}{(\lambda-1)n-\frac{\lambda}{\lambda-1}}$.*

▶ **Corollary 13.** *For every $\lambda \geq 2$, the price of anarchy of inversely proportional λ-TS games is at most $\frac{\lambda n}{H_\lambda n-\lambda}$ and at least $\frac{\lambda n}{\frac{2(\lambda-1)}{\lambda} H_\lambda n-\frac{\lambda^2}{\lambda-1}+2H_\lambda}$.*

We conclude our technical contribution with a lower bound on the price of stability for the case of two types of agents. For 2-ZTS games, the following lower bound improves upon the bound of 34/33 of Elkind et al. [16], and is also tight when the number of agents tends to infinity because of the upper bound implied by Theorem 8; recall that $\tau = 1$ for λ-ZTS games.

▶ **Theorem 14.** *The price of stability of 2-TS games is at least $2/\tau - \epsilon$, for any $\epsilon > 0$.*

5 Open Problems

The most important question that our work leaves open is the characterization of games for which equilibria always exist. As this is a quite general and challenging direction, one could start with games that exhibit some structure in terms of the topology or the tolerance vector. For instance, do equilibria exist when the topology is a grid (4-grid or 8-grid) or a regular graph, for *every* tolerance vector?

The tolerance model we defined in this paper depends on a given ordering of the types and the tolerance parameters are symmetric. While this model captures certain interesting settings, there are multiple ways in which it can be generalized. For example, the tolerance parameters do not need to be symmetric and a different tolerance vector could be defined per type. Taking this further, the tolerance between types does not need to depend on an ordering of the types. Instead, one could define a weighted, directed *tolerance graph* that is defined over the different types such that the edge weights indicate the tolerance of a type towards another type; our ordered model can be thought of as the special case with an undirected tolerance line graph. In fact, one could further generalize this idea by considering scenarios in which there are no types of agents at all, but rather the agents are connected to each other via a complete weighted social network, with the different weights indicating tolerance levels. This is essentially a generalization of the class of social Schelling games proposed by Elkind et al. [16], and is inspired by fractional hedonic games [3].

On the Skolem Problem for Reversible Sequences

George Kenison ✉
Institute of Logic and Computation, TU Wien, Vienna, Austria

Abstract

Given an integer linear recurrence sequence $\langle X_n\rangle_{n=0}^{\infty}$, the Skolem Problem asks to determine whether there is an $n \in \mathbb{N}_0$ such that $X_n = 0$. Recent work by Lipton, Luca, Nieuwveld, Ouaknine, Purser, and Worrell proved that the Skolem Problem is decidable for a class of reversible sequences of order at most seven. Here we give an alternative proof of their result. Our novel approach employs a powerful result for Galois conjugates that lie on two concentric circles due to Dubickas and Smyth.

1 Introduction

The Skolem Problem

An integer-valued *linear recurrence sequence* $\langle X_n\rangle_{n=0}^{\infty}$ satisfies a relation of the form

$$X_{n+d} = a_{d-1}X_{n+d-1} + \cdots + a_1X_{n+1} + a_0X_n \tag{1}$$

for each $n \in \mathbb{N}_0$. Without loss of generality, we shall assume that each of the coefficients $a_0, a_1, \ldots, a_{d-1} \in \mathbb{Z}$ and additionally that $a_0 \neq 0$. We call d the *length* of the recurrence relation and the *order* of $\langle X_n\rangle_n$ is the length of the shortest relation satisfied by $\langle X_n\rangle_n$. The polynomial $f(x) = x^d - a_{d-1}x^{d-1} - \cdots - a_1x - a_0$ is the *characteristic polynomial* associated with relation (1). Given such a sequence, the *Skolem Problem* [8, 11] asks to determine whether there exists an $n \in \mathbb{N}$ such $X_n = 0$. The Skolem Problem is well-motivated with connections to research topics such as program verification [27]. Take, for example, the following linear loop P with inputs $\underline{w}, \underline{b} \in \mathbb{Z}^d$ and $A \in \mathbb{Z}^{d\times d}$ where

$$P\colon \underline{v} \leftarrow \underline{w};\ \ \textbf{while}\ \ \underline{b}^{\top}\underline{v} \neq 0\ \ \textbf{do}\ \ \underline{v} \leftarrow A\underline{v}. \tag{2}$$

Let $\langle X_n\rangle_n$ be the linear recurrence sequence with terms given by $X_n = \underline{b}^{\top}A^n\underline{w}$. It is clear that loop P terminates if and only if there exists an $n \in \mathbb{N}_0$ such that $X_n = 0$.

Motivation

A recent resurgence of interest in the Skolem Problem (and related problems) has lead to the publication of a number of papers that consider restricted variants. The resulting specialised decision procedures generally fall into two categories: those that consider an infinite subset of the natural numbers [14, 20] or those that restrict the class of linear recurrence sequences. Our motivation is the latter type of specialisation and, in particular, a recent paper by Lipton et al. [19] that establishes the following theorem.

▶ **Theorem 1.** *The Skolem Problem is decidable for the class of reversible integer linear recurrences of order at most seven.*

An integer linear recurrence sequence $\langle X_n \rangle_{n=0}^{\infty}$ is *reversible* if it satisfies a recurrence relation of the form (1) such that $a_0 = \pm 1$. As observed in Lipton et al. [19], given an integer linear recurrence sequence $\langle X_n \rangle_{n=0}^{\infty}$, the unique bi-infinite extension $\langle X_n \rangle_{n=-\infty}^{n=\infty}$ has integral terms if and only if $\langle X_n \rangle_{n=0}^{\infty}$ is reversible (this claim follows from a classical observation for Fatou rings [9]). We can also characterise the subclass of while loops (as in (2)) naturally associated with reversible sequences: the update matrix A with characteristic polynomial f is *unimodular*; that is, A has integer entries and $\det(A) = -f(0) = \pm 1$. If A is unimodular, then A^{-1} also has integer entries. Thus, again, $\langle X_n \rangle_{n=-\infty}^{n=\infty}$ with each $X_n = \underline{b}^{\top} A^n \underline{w}$ (as above) is integer-valued.

Unimodular matrices appear elsewhere in the dynamical systems literature. Some classes lead to prototypical invertible maps with hyperbolic and ergodic properties; specifically, classes of *linear toral automorphisms* $T_A \colon \mathbb{R}^d \to \mathbb{R}^d$ given by $T_A(\underline{x}) = A\underline{x}$ [13].

A famous example of a reversible sequence is the Fibonacci sequence, which is defined by the initial values $X_0 = 0$, $X_1 = 1$ and for each $n \in \mathbb{N}_0$, $X_{n+2} = X_{n+1} + X_n$. The Fibonacci sequence can be uniquely extended to a bi-infinite sequence of integer values $\langle \ldots, 5, -3, 2, -1, 1, 0, 1, 1, 2, 3, 5, \ldots \rangle$.

In the sequel, we call the restricted variant of the Skolem Problem for reversible sequences the *Reversible Skolem Problem*.

Background

Let us assess the current state of play with regards to the decidability of the Skolem Problem. A classical result due to Skolem [31] (which was later generalised by Mahler [22, 23], and Lech [18]) states that $\{n \in \mathbb{N} : X_n = 0\}$ is the union of a finite set together with a finite number of (infinite) arithmetic progressions. The phenomenon that causes these vanishing arithmetic progressions is termed *degeneracy*. A sequence is *degenerate* when one of the ratios of two distinct characteristic roots of the sequence is a root of unity. These arithmetic progressions can be determined algorithmically and so, from the viewpoint of verification, to decide the Skolem Problem it suffices to consider *non-degenerate* recurrence sequences – those sequences that have only finitely many zeros. Indeed, this is where the difficulty lies: there is no known general method to compute this finite set. We refer the interested reader to Corollary 1.20 and Chapter 2 in [8] for further details. In summary, all known proofs of the Skolem–Mahler–Lech Theorem (as it is now known) are non-constructive and so the decidability of the Skolem Problem remains open.

Limited progress has been made on the decidability of the Skolem Problem when one considers linear recurrence sequences of low order. Groundbreaking work by Mignotte, Shorey, and Tijdeman [24], and, independently, Vereshchagin [35] establish the following.

▶ **Theorem 2.** *The Skolem Problem is decidable for the class of non-degenerate linear recurrences with at most three simple characteristic roots that are maximal in modulus.*

As a consequence, the Skolem Problem is decidable for linear recurrences of order at most four. The aforementioned papers employ techniques from p-adic analysis and algebraic number theory and, in addition, Baker's theorem for linear forms in logarithms of algebraic numbers. Unfortunately the route taken via Baker's Theorem does not appear to extend easily to recurrences of higher order.

A class of recurrence sequences of order five that the state of the art cannot handle impedes further progress on the decidability of the Skolem Problem [25]. The minimal polynomial for each member of this class has four distinct roots $\alpha, \overline{\alpha}, \beta, \overline{\beta} \in \mathbb{C}$ (two pairs of complex-conjugate roots) such that $|\alpha| = |\beta|$, and a fifth real root γ of strictly smaller modulus. Hence the terms of such a sequence $\langle X_n \rangle_n$ are given by an exponential polynomial of the form $X_n = a(\alpha^n + \overline{\alpha}^n) + b(\beta + \overline{\beta}^n) + c\gamma^n$. Here $a, b, c \in \mathbb{R}$ are algebraic numbers and, as far as we are aware, there is no known general procedure to determine $\{n \in \mathbb{N} : X_n = 0\}$ when $|a| \neq |b|$.

Complexity

In [3], Blondel and Portier proved that the Skolem Problem is NP-hard. As a brief aside, let us consider the complexity of the reversible variant of the Skolem Problem. One of the questions considered by S. Akshay et al. [1] is the complexity of the Skolem Problem for the restricted class of linear recurrence sequences whose characteristic roots are all roots of unity (the so-called *Cyclotomic Skolem Problem*). Those authors showed, by a reduction from the Subset-Sum Problem, that the Cyclotomic Skolem Problem is NP-hard. Because the characteristic polynomial associated with each element in this restricted class is given by a product of cyclotomic polynomials, it follows that each instance of the Cyclotomic Skolem Problem is an instance of the Reversible Skolem Problem. Thus the Reversible Skolem Problem is also NP-hard.

Contributions

The main contribution in this note is an alternative proof of Theorem 1. By comparison to the extensive case analysis employed in [19], we use results in number theory for Galois conjugates that obey polynomial identities. In particular, we make repeated use of a result due to Dubickas and Smyth [7] for algebraic integers that lie alongside all their Galois conjugates on two (but not one) concentric circles centred at the origin.

For context, Dubickas and Smyth's result is part of a large corpus of research on algebraic numbers whose conjugates lie on a conic or a union of conics. Let α be an algebraic number with Galois conjugates $\alpha = \alpha_1, \ldots, \alpha_d$. We call the set $S(\alpha) := \{\alpha_1, \ldots, \alpha_d\}$ the *conjugate set* of α. When $S(\alpha)$ is a subset of the unit circle, a result of Kronecker's (a weaker version of Theorem 5) proves that α is a root of unity. Number theorists have long-studied classes of algebraic integers where one or more of the conjugates leaves the circle; for example, a real algebraic integer α is a *Salem number* if $\alpha > 1$, $\alpha^{-1} \in S(\alpha)$, and the remaining conjugates all lie on the unit circle, i.e., $S(\alpha) = \{\alpha^{\pm 1}, \mathrm{e}^{\pm \mathrm{i}\theta_2}, \ldots, \mathrm{e}^{\pm \mathrm{i}\theta_d}\}$.

With regards to the Reversible Skolem Problem at order eight, we exhibit a family of recurrence sequences that, as far as we know, are not amenable to standard techniques and so decidability is very much open. The authors of [19] also demonstrated a concrete family of examples in this regard. It is interesting to note that the techniques used and families obtained are very different. Each member of our family is an octic palindromic polynomial (the same is not true for the family of examples in [19]). The coefficients of a *palindromic* polynomial form a palindromic string of integers. For example, two palindromes that are also family members are $x^8+x^7-x^6+x^5+5x^4+x^3-x^2+x+1$ and $x^8+x^7-3x^6+x^5+9x^4+x^3-3x^2+x+1$. Using any modern computer algebra system, it is easy to verify that the roots of each polynomial satisfy the following. First, the roots lie on two (but not one) concentric circles centred at the origin. Second, no ratio of any two of its roots is a root of unity. The calculations involved in preparing these (and later) examples were performed in PARI/GP [34]. In Subsection 4.2, we study the Galois groups of irreducible palindromic octics in the aforementioned family as a further investigation into the symmetries between their roots.

In Subsections 5.1 and 5.2, we prove new decidability results on restricted variants of the Positivity and Skolem Problems using Dubickas and Smyth's theorem and make suggestions for further work in these directions. For brevity, we refer to the Positivity Problem for the class of simple reversible integer linear recurrences as the *Simple Reversible Positivity Problem*. Here a linear recurrence is *simple* if the associated characteristic polynomial has no repeated roots. We have the following results:

▶ **Corollary 3.** *The Simple Reversible Positivity Problem is decidable for integer-valued linear recurrences of order at most ten.*

▶ **Corollary 4.** *The Skolem Problem is decidable for rational-valued linear recurrences that satisfy a relation of the form $X_{n+5} = a_4X_{n+4} + a_3X_{n+3} + a_2X_{n+2} + a_1X_{n+1} \pm X_n$ with $a_1, a_2, a_3, a_4 \in \mathbb{Q}$.*

Structure

The remainder of this paper is structured as follows. In the next section we review necessary preliminary material. In Section 3, we give a new and novel proof of Theorem 1. In Section 4, we construct a family of octic palindromes that shows the current state of the art cannot settle decidability of the Reversible Skolem Problem at order eight and then discuss the Galois groups associated with the irreducible members of this family. In the final section, Section 5, we discuss directions and motivate this discussion with the proofs of Corollaries 3 and 4.

2 Preliminaries

2.1 Recurrence Sequences

A sequence $\langle X_n\rangle_{n=0}^{\infty}$ of integers satisfying a recurrence relation of the form (1) with fixed integer constants $a_0, a_1, \dots, a_{d-1}$ such that $a_0 \neq 0$ is a *linear recurrence sequence*. The sequence $\langle X_n\rangle_n$ is then wholly determined by the recurrence relation and the initial values $X_0, X_1, \dots, X_{d-1}$. The polynomial $f(x) = x^d - a_{d-1}x^{d-1} - \cdots - a_1x - a_0$ is the *characteristic polynomial* associated with relation (1). From our earlier definition, it is clear that $\langle X_n\rangle_n$ is reversible if and only if $f(0) = \pm 1$. There is a recurrence relation of minimal length associated to $\langle X_n\rangle_n$ and we call the characteristic polynomial of this minimal length relation the *minimal polynomial* of $\langle X_n\rangle_n$. The *order* of a linear recurrence sequence is the degree of its minimal polynomial.

Let f be the minimal polynomial of a linear recurrence sequence $\langle X_n\rangle_n$ and K the splitting field of f. The polynomial f factorises as a product of powers of distinct linear factors like so $f(x) = \prod_{\ell=1}^{m}(x - \lambda_\ell)^{n_\ell}$. The constants $\lambda_1, \lambda_2, \dots, \lambda_m \in K$ are the *characteristic roots* of $\langle X_n\rangle_n$ with multiplicities $n_1, n_2, \dots, n_m$. One can realise the terms of a linear recurrence sequence as an *exponential polynomial* $X_n = \sum_{\ell=1}^{m} p_\ell(n)\lambda_\ell^n$ where the λ_ℓ are the aforementioned characteristic roots of $\langle X_n\rangle_n$ and the polynomial coefficients $p_\ell \in K[x]$ are determined by the initial values. We say a characteristic root of $\langle X_n\rangle_n$ is *dominant* if in the set of characteristic roots of $\langle X_n\rangle_n$ it is maximal in modulus. Thus, by Theorem 2, the Skolem Problem is decidable for the class of non-degenerate linear recurrence sequences with at most three dominant characteristic roots [24, 35].

2.2 Number Theory

We shall assume some familiarity with Galois theory and the theory of number fields. The necessary background material can be found in a number of standard textbooks [5, 33].

Recall the following theorem due to Kronecker [16].

▶ **Theorem 5.** *Let $f \in \mathbb{Z}[x]$ be a monic polynomial such that $f(0) \neq 0$. Suppose that all the roots of f have absolute value at most 1, then f is a product of cyclotomic polynomials. Therefore all the roots of f are roots of unity.*

Thus, if $f \in \mathbb{Z}[x]$ is the characteristic polynomial of a reversible linear recurrence sequence such that the roots of f all lie in the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$. Then the roots of f are all roots of unity. It follows that the associated recurrence sequence is either order one (and is thus constant) or degenerate. In either case the Skolem Problem is decidable. Thus in the sequel we shall always assume, without loss of generality, that the dominant roots of f lie on a circle with radius strictly larger than 1.

In the sequel, our construction of an infinite family of octics uses the following corollary of Vieta's formulae.

▶ **Lemma 6.** *Suppose that $f \in \mathbb{Z}[x]$ is a monic irreducible polynomial such that $f(x) = \prod_{i=1}^{d}(x - \lambda_i)$. Let $f_n(x) := \prod_{i=1}^{d}(x - \lambda_i^n)$. Then $f_n \in \mathbb{Z}[x]$ for each $n \in \mathbb{N}$.*

Proof. The coefficients of the polynomial f_n are determined by symmetric polynomials in d variables. By the fundamental theorem of symmetric polynomials, each symmetric polynomial is given by a $\mathbb{Z}$-linear combination of elementary symmetric polynomials. The result follows as a straightforward application of Vieta's formulae and the evaluation of elementary symmetric polynomials over conjugate algebraic integers. ◀

The roots of an irreducible polynomial are necessarily Galois conjugates. We use the term *conjugate ratios* for the ratios between two distinct roots of an irreducible polynomial. A non-zero algebraic number α is *reciprocal* if α is conjugate to α^{-1}. Let τ be a Salem number whose minimal polynomial has degree $2d$ or a reciprocal quadratic. In the former case, $S(\tau) = \{\tau^{\pm 1}, \tau_2^{\pm 1}, \ldots, \tau_d^{\pm 1}\}$ and in the latter, $S(\tau) = \{\tau^{\pm 1}\}$. An algebraic number ψ is a *Salem half-norm* if $\psi = \tau^{\varepsilon_1}\tau_2^{\varepsilon_2} \cdots \tau_d^{\varepsilon_d}$ for some such τ and $\varepsilon_j = \pm 1$ for each $j \in \{1, \ldots, d\}$. The properties of Salem half-norms are discussed further in [7].

In the ring of algebraic integers of a given number field K, $\gamma \in K$ is a *unit* (sometimes an *algebraic unit*) if it has a multiplicative inverse δ so that $\gamma\delta = \delta\gamma = 1$. Let $\alpha \in K$ be an algebraic integer. Then the constant coefficient of the minimal polynomial $f \in \mathbb{Z}[x]$ of α is equal to ± 1 if and only if α is a unit. This observation follows easily from norm considerations and the fact that the constant coefficient of f (up to sign) is given by the product of α and its Galois conjugates. Since the characteristic polynomial $f \in \mathbb{Z}[x]$ of a reversible sequence $\langle X_n \rangle_n$ has constant coefficient ± 1, we deduce that each of the characteristic roots of $\langle X_n \rangle_n$ is a unit. In the sequel we make frequent use of the following simple observation.

▶ **Lemma 7.** *If α is an algebraic unit that lies on the circle $|z| = R$ with $R > 1$, then a conjugate of α lies in the interior of the unit disk.*

Key to the proofs in the sequel is a powerful result due to Dubickas and Smyth [7] concerning polynomial identities between the roots of irreducible polynomials. Theorem 8 gives necessary conditions for a unit in the algebraic integers and all its Galois conjugates to lie on two (but not one) concentric circles centred at the origin [7]. In fact, Dubickas and Smyth prove a far more general result [7, Theorem 2.1], but we need only the specialised version for units below.

▶ **Theorem 8.** *Suppose that α is a unit in the algebraic integers of degree d lying, with all its Galois conjugates, on two circles $|z| = r$ and $|z| = R$, but not just one. Without loss of generality assume that at most half of the conjugates lie on $|z| = r$. Then, one of the following holds:*

1. *$d = 3m$, $R = r^{-1/2}$ such that there are $d/3$ conjugates of α on $|z| = r$, and the remaining $2d/3$ lie on $|z| = r^{-1/2}$. Assume, without loss of generality, $|\alpha| = r$. Then, in addition, there exists an $n \in \mathbb{N}$ such that α^n is a real, but non-totally real, cubic unit.*
2. *$d = 2m$, $R = r^{-1}$ where $R > 1$ without loss of generality, and $d/2$ Galois conjugates of α lie on each circle. Further, there exists an $n \in \mathbb{N}$ such that $\alpha^n =: \psi$ is a Salem half-norm defined by a Salem number or a reciprocal quadratic.*

Let us explain the term *totally real* in the last theorem. An algebraic number α is *totally real* if α and all its Galois conjugates are real. A number field K is *totally real* if $K = \mathbb{Q}[\alpha]$ such that α is totally real.

From this point to the end of the subsection, the terminology and results we recall are used only in Section 4 (and so are not required for the proof of Theorem 1).

A field is *Kroneckerian* if it is either a totally real algebraic number field or a totally imaginary quadratic extension of a totally real field. In the sequel, we make use of the following observation about complex conjugation lying in the centre of the Galois group of a Kroneckerian field (see [30, Chapter 6]).

▶ **Corollary 9.** *A number field K is Kroneckerian if and only if for every $\alpha \in K$ one has $\overline{\alpha} \in K$ and for every embedding σ of K into $\mathbb{C}$ one has $\overline{\alpha^\sigma} = \overline{\alpha}^\sigma$.*

A unit is *unimodular* if it lies on the unit circle in $\mathbb{C}$. In [21], MacCluer and Parry prove that a normal imaginary field contains unimodular units other than roots of unity exactly when its real subfield is not normal over $\mathbb{Q}$. Daileda [6] generalises this result and provides the following classification of the number fields that have unimodular units that are not roots of unity. Recall that a number field K is a *CM-field* if K is a totally complex quadratic extension of a totally real field.

▶ **Theorem 10.** *Let K be a number field closed under complex conjugation. Then K contains unimodular units that are not roots of unity if and only if K is imaginary and not a CM-field.*

2.3 Group Theory

In the sequel we employ the notation S_n for the symmetric group on n elements, A_n for the alternating group on n elements, D_n for the Dihedral group of order $2n$, C_n for the cyclic group on n elements, and K_4 for the Klein 4-group.

The action of G on a set X is *transitive* if for every pair $x, y \in X$ there is a $g \in G$ such that $gx = y$; that is to say, there is a single group orbit. We note here (and again later) that S_4, A_4, D_4, C_4, and K_4 are the transitive subgroups of S_4.

3 Proof of Theorem 1

We briefly outline our route to proving Theorem 1. We claim that if $\langle X_n \rangle_n$ is a non-degenerate reversible integer recurrence sequence of order at most seven, then $\langle X_n \rangle_n$ has at most three dominant characteristic roots. The decidability of the Skolem Problem for such instances then follows from Theorem 2. The above claim follows as a corollary of the next theorem.

▶ **Theorem 11.** *No monic polynomial $f \in \mathbb{Z}[x]$ with constant coefficient ± 1 of degree at most seven satisfies the following two properties:*

(H1) *f has at least four distinct dominant roots; and*

(H2) *no quotient of two distinct roots of f is a root of unity.*

Thus all that remains is to prove Theorem 11. This result is an immediate consequence of the sequence of Propositions 12, 14, and 15 below. In each of the proofs of these propositions we play a similar game: we assume, for a contradiction, that there exists a polynomial $f \in \mathbb{Z}[x]$ (of degree five, six, or seven respectively) that satisfies hypotheses H1 and H2. We show that such a candidate is necessarily irreducible. We then employ Theorem 8 to derive a contradiction: such a candidate cannot satisfy both H1 and H2 and, at the same time, satisfy the restrictive root identities prescribed by Theorem 8.

For the avoidance of doubt, this route to Theorem 1 is similar to that carved out by [19]. The contribution of this paper is the novel application of Theorem 8. Indeed, our assumption, that each of the characteristic roots of a recurrence in our class of non-degenerate reversible sequences is a unit, leads to (rather startling) restrictive polynomial relations between Galois conjugates.

We begin our sequence of propositions.

▶ **Proposition 12.** *No monic polynomial $f \in \mathbb{Z}[x]$ of degree at most five with constant term ± 1 satisfies hypotheses H1 and H2.*

Proof. Assume, for a contradiction, that such an f of degree $d \le 5$ exists. By Theorem 5, the dominant roots lie on the circle $|z| = R$ for some $R > 1$ for otherwise the roots of f are necessarily all roots of unity, which is not permitted under hypothesis H2. Each of the dominant roots of f is a unit in the algebraic integers and so, by Lemma 7, has a Galois conjugate in the interior of the unit disk. In order that f satisfies hypothesis H1, we conclude that f has four simple dominant roots and a single non-dominant root. Since f has degree $d = 5$ and $f(0) = \pm 1$, all the dominant roots of f are (Galois) conjugate to the single non-dominant root, f is irreducible.

Let α be a root of f. Then α is an algebraic integer of degree 5, a unit, and lies with all its Galois conjugates on two circles. We apply Theorem 8 to the quintic f and find that 5 is either even, or a multiple of 3, a contradiction. ◀

▶ Remark 13. The application of Theorem 8 in the proof of Proposition 12 is excessive (even if the derived contradiction is rather satisfying). By comparison, the approach in Lipton et al. [19] is direct. We reproduce the final part of those authors' proof below as it gives a gentle introduction to some of the techniques we apply in Proposition 14 and Proposition 15.

Proof of Proposition 12 (cf. [19]). Let $\alpha, \overline{\alpha}, \beta, \overline{\beta}$ be the four dominant roots of f and ρ the non-dominant root of f. Since f is irreducible, the Galois group G of f acts transitively on the roots of f. Thus there exists a $\sigma \in G$ such that $\sigma(\alpha) = \rho$. The element σ must preserve the equality $\alpha\overline{\alpha} = \beta\overline{\beta}$ and so we have $\rho\sigma(\overline{\alpha}) = \sigma(\beta)\sigma(\overline{\beta})$. We derive a contradiction: $|\rho||\sigma(\overline{\alpha})| \neq |\sigma(\beta)||\sigma(\overline{\beta})|$ since the two roots $\sigma(\beta)$ and $\sigma(\overline{\beta})$ on the right-hand side are necessarily dominant. ◀

▶ **Proposition 14.** *No monic polynomial $f \in \mathbb{Z}[x]$ of degree six with constant term ± 1 satisfies hypotheses H1 and H2.*

Proof. Assume, for a contradiction, that such an f exists. As in the proof of Proposition 12, f has at least four simple dominant roots $\alpha, \overline{\alpha}, \beta, \overline{\beta}$ that lie on a circle $\{z \in \mathbb{C} : |z| = R\}$ for some $R > 1$ as complex-conjugate pairs. We note that the group G of automorphisms of the splitting field of f must preserve the equality $\alpha\overline{\alpha} = \beta\overline{\beta}$. Because α is a unit on $|z| = R$, by Lemma 7 there is both a root γ of f that lies in the unit disk and a permutation $\sigma \in G$ such that $\sigma(\alpha) = \gamma$. Now consider $\sigma(\alpha)\sigma(\overline{\alpha}) = \sigma(\beta)\sigma(\overline{\beta})$. It is straightforward to elicit a contradiction that breaks this equality if either $\sigma(\overline{\alpha})$ is non-dominant, or both $\sigma(\beta)$ and $\sigma(\overline{\beta})$ are dominant. Thus we can assume that f has two non-dominant roots and further that they are of equal modulus. Clearly these two roots $\gamma, \overline{\gamma}$ are a complex-conjugate pair by H2. Combining these observations of the roots of f, we quickly deduce that f is necessarily irreducible.

Because the roots of the irreducible polynomial $f \in \mathbb{Z}[x]$ lie on two concentric circles, we can apply Theorem 8. Thus there is a non-dominant root, γ say, and $m \in \mathbb{N}$ such that γ^m is a real cubic unit. It follows that $\gamma^m/\overline{\gamma}^m = 1$ and so one of the conjugate ratios of f is a root of unity, which contradicts hypothesis H2. ◀

▶ **Proposition 15.** *No monic polynomial $f \in \mathbb{Z}[x]$ of degree seven with constant term ± 1 satisfies hypotheses H1 and H2.*

Proof. Assume, for a contradiction, that such an f exists. As in the proof of Proposition 12, f has at least four simple dominant roots $\alpha, \overline{\alpha}, \beta, \overline{\beta}$ that lie on a circle $\{z \in \mathbb{C} : |z| = R\}$ for some $R > 1$ as complex-conjugate pairs. Mutatis mutandis, one can use the methods in the proof of Proposition 14 to make the following two deductions. First, f is irreducible. Second, f has precisely one real root δ and another complex-conjugate pair of roots $\gamma, \overline{\gamma}$. Additionally, we have that $\delta, \gamma, \overline{\gamma}$ are all non-dominant roots of f such that $|\gamma| \neq |\delta|$. We note that if one supposes, for a contradiction, that the septic polynomial f has $|\gamma| = |\delta|$ or $|\alpha| = |\delta|$, then, by Theorem 8, it follows that 7 is either even, or a multiple of 3.

Because f is irreducible, the Galois group of f acts transitively on the roots of f. Thus there is a permutation σ in the Galois group of f such that $\sigma(\alpha) = \delta$. We know that σ must preserve the equality $\alpha\overline{\alpha} = \beta\overline{\beta}$ and so we have $|\delta\sigma(\overline{\alpha})| = |\sigma(\beta)\sigma(\overline{\beta})|$. The left-hand side is equal to one of $|\delta||\gamma|$ or $|\delta|R$ depending on $\sigma(\overline{\alpha})$. There are three cases to consider for the right-hand side. The roots $\sigma(\beta)$ and $\sigma(\overline{\beta})$ are either both dominant, both non-dominant, or one of each. It is clear that the modulus in each of these (respective) cases R^2, $|\gamma|^2$, and $|\gamma|R$ breaks the aforementioned equality between the left- and right-hand sides, a contradiction. ◀

Hence we have proved Theorem 11, as required.

4 Palindromic Octics

A monic polynomial $f \in \mathbb{Z}[x]$ is *palindromic* if its coefficients string together to form a palindrome. That is to say, for $f(x) = x^d + a_{d-1}x^{d-1} + \cdots + a_1x + 1$ we have that $a_k = a_{d-k}$ for each $k \in \{0, 1, \ldots, d\}$. In other sources, the term *self-reciprocal* is sometimes used since if α is a root of f then α^{-1} is also a root of f. If $\alpha \in \mathbb{C}$ is a root of f, then so are $\bar{\alpha}, 1/\alpha$, and $1/\bar{\alpha}$. Further, when α is neither real nor lies on the unit circle then these four roots are distinct. The class of palindromic polynomials appear in areas across mathematics and computer science in fields such as: coding theory, algebraic curves over finite fields, knot theory, and linear feedback shift registers, to name but a few (see the survey [12]).

▶ Remark 16. Let us further motivate the study of the *Palindromic Skolem Problem* (the Skolem Problem restricted to the study of sequences with palindromic characteristic polynomials). From the viewpoint of dynamical systems, we observe that the equations of motion (1) governing a recurrence sequence with palindromic characteristic polynomial (hereafter a *palindromic recurrence sequence*) possess a *time-reversing symmetry*; that is to say, the recurrence relation is invariant under the time reversal map $n \mapsto -n$. More concretely, let $\langle X_n \rangle_{n=0}^{\infty}$ and $\langle Y_{-n} \rangle_{n=0}^{\infty}$ be recurrence sequences satisfying the palindromic relations

$$\begin{aligned} X_{n+d} &= a_{d-1}X_{n+d-1} + \cdots + a_{d-1}X_{n+1} + X_n \qquad \text{and} \\ Y_{-n-d} &= a_{d-1}Y_{-n-d+1} + \cdots + a_{d-1}Y_{-n-1} + Y_{-n}, \end{aligned}$$

respectively. Then $Y_{-n} = X_n$ for each $n \in \mathbb{N}_0$ if $Y_{-m} = X_m$ for each $m \in \{0, 1, \ldots, d-1\}$.

For further information on the topic of time-reversing symmetries, we refer the interested reader to the exposition in Lamb's article [17] and the recent survey by Baake [2] (and the references therein).

4.1 Hard instances of the Reversible Skolem Problem at order eight

In Proposition 17, we construct an infinite family of palindromic octics that satisfy both H1 and H2. This result blocks any obvious attempt to settle decidability of the Reversible Skolem Problem at order eight with current state-of-the-art techniques. Another family of octics that satisfy both H1 and H2 is discussed in Lipton et al. [19]. The additional restriction (palindromic coefficients) we require demonstrates a refinement in the discussion of hard instances of the Reversible Skolem Problem at order eight.

▶ **Proposition 17.** *There are infinitely many palindromic octics in $\mathbb{Z}[x]$ that satisfy both H1 and H2.*

Proof. Let $f \in \mathbb{Z}[x]$ be such a palindromic octic with four simple dominant roots (that is, two complex-conjugate pairs) that lie on a circle of radius $r > 1$. Write $f(x) = \prod_{i=1}^{8}(x - \lambda_i)$ and for each $n \in \mathbb{N}$, define $f_n(x) := \prod_{i=1}^{8}(x - \lambda_i^n)$. By the symmetries in the roots λ_i^n, it is straightforward to verify the following three observations. First, each octic f_n in the sequence $\langle f_n \rangle_{n=1}^{\infty}$ is palindromic. Second, each octic f_n satisfies both H1 and H2. Third, by Lemma 6, $f_n \in \mathbb{Z}[x]$ for each $n \in \mathbb{N}$.

We finish the proof by showing that there are infinitely many distinct polynomials in the sequence $\langle f_n \rangle_{n=1}^{\infty}$. Let $r\mathrm{e}^{\pm \mathrm{i}\theta}, r\mathrm{e}^{\pm \mathrm{i}\psi}$ be the four dominant roots of f. Let $f_n(x) = x^8 + a_{7,n}x^7 + \cdots + 1$. Then, by Vieta's formulae, $a_{7,n}$ is given by the sum of the nth powers of the roots of f; that is,

$$a_{7,n} = (r^n + r^{-n})(\mathrm{e}^{n\mathrm{i}\theta} + \mathrm{e}^{-n\mathrm{i}\theta} + \mathrm{e}^{n\mathrm{i}\psi} + \mathrm{e}^{-n\mathrm{i}\psi}).$$

Assume, for a contradiction, that the non-degenerate integer linear recurrence sequence $\langle a_{7,n} \rangle_n$ takes only finitely many values. By the Pigeonhole Principle, there is an $a \in \mathbb{Z}$ and an infinite subsequence $\langle n_k \rangle_k$ of natural numbers such that $a_{7,n_k} = a$ for each $k \in \mathbb{N}$. We make two observations. First, the integer linear recurrence sequence $\langle a_{7,n} - a \rangle_n$ has characteristic polynomial $f(x)(x-1)$ (see [8, Theorem 1.1]) and so is non-degenerate. Second, the sequence $\langle a_{7,n} - a \rangle_n$ vanishes infinitely often. We have a contradiction: a non-degenerate linear recurrence sequence has only finitely many zero terms. It follows that there are infinitely many distinct palindromic octics in the sequence $\langle f_n \rangle_n$, as desired. ◀

▶ Remark 18. A *symplectic matrix* M is a $2\ell \times 2\ell$ matrix that preserves the *symplectic form* J in 2ℓ dimensions; that is to say, $M^\top JM = J$ where

$$J = \begin{pmatrix} 0 & I_\ell \\ -I_\ell & 0 \end{pmatrix}.$$

It is well-known that the characteristic polynomial of a symplectic matrix is a palindromic polynomial. In fact, the following constructive result proves the converse. Rivin [28, Theorem A.1] attributes the result to Kirby [15][1].

▶ **Theorem 19.** *For each monic palindromic polynomial $f \in \mathbb{Z}[x]$ of degree 2ℓ, there is a symplectic matrix $M \in \mathbb{Z}^{2\ell \times 2\ell}$ such that $\det(xI_{2\ell} - M) = f(x)$.*

Note the group of $2\ell \times 2\ell$ symplectic matrices with entries in $\mathbb{Z}$ is closed under multiplication. This observation leads to an alternative proof of Proposition 17 as follows. Let $f \in \mathbb{Z}[x]$ be an octic palindrome satisfying H1 and H2. Now let $M \in \mathbb{Z}^{8\times 8}$ be a symplectic matrix with characteristic polynomial f. Consider the sequence $\langle f_n \rangle_n$ where $f_n(x) := \det(xI_{2\ell} - M^n) \in \mathbb{Z}[x]$. As before, we need to verify that each polynomial in this sequence satisfies the root assumptions H1 and H2. We then proceed in a similar fashion to the proof of Proposition 17, in order to generate an infinite sequence of octic palindromes with the desired properties.

4.2 Galois theory of octic palindromes

It is interesting to consider the root symmetries of the characteristic polynomials of reversible linear recurrence sequences. In this subsection we focus our attention on the Galois groups of octic palindromes; in particular, those underlying hard instances of the Reversible Skolem Problem. We present a new result (Theorem 20). The problem of root symmetries follows naturally from our approach to Theorem 1 where we explored polynomial identities between roots of certain irreducible polynomials. Such results are also motivated by hard open problems such as (polynomial) invariant generation and loop synthesis in the field of program verification.

The task of computing the Galois groups of irreducible polynomials in $\mathbb{Z}[x]$ is well-known. Families of polynomials associated with reversible sequences include the cyclotomic and Salem polynomials. The authors of [4] discuss ramifications to the Galois group of moving two of the Galois conjugates off of the unit circle. For the interested reader, two accounts of the Galois theory of palindromic polynomials are [36, 29]. 'Generically', the Galois group of a palindromic polynomial of degree $2d$ is $S_d \wr C_2$ (the *signed permutation group* or the *hyperoctahedral group*). In the case $d = 4$, the order of $S_4 \wr C_2$ is 384.

Here we shall consider the Galois groups associated with irreducible octic palindromes of the form constructed in Proposition 17. Recall that each polynomial in that family has roots of the form $r^{\pm 1}\mathrm{e}^{\pm \mathrm{i}\theta}, r^{\pm 1}\mathrm{e}^{\pm \mathrm{i}\psi}$. When a polynomial with this root distribution is irreducible, some of the powers of these roots are given by Salem half-norms (Theorem 8).

▶ **Theorem 20.** *Suppose that $f \in \mathbb{Z}[x]$ is an irreducible and simple palindromic octic with four dominant roots such that none of its conjugate ratios are roots of unity (so that H1 and H2 are satisfied). Then, the associated Galois group is isomorphic to either $S_4 \times C_2$ or $A_4 \times C_2$.*

Proof. Let $\alpha, \overline{\alpha}, \beta, \overline{\beta}$ be the four dominant roots of f. As before, we can assume without loss of generality that these roots lie on a circle $|z| = R$ with $R > 1$. The Galois group of the splitting field of f is necessarily a subgroup of the group of automorphisms G of the set $\{\alpha^{\pm 1}, \overline{\alpha}^{\pm 1}, \beta^{\pm 1}, \overline{\beta}^{\pm 1}\} \subset \mathbb{C}$. Further, the Galois group necessarily contains permutations

[1] The author was unable to access Kirby's article in order to verify this attribution.

that fix the relations $xx^{-1} = 1$ for x in the set and $\alpha\alpha^{-1} - \beta\beta^{-1} = 0$. We note that G also contains the *inversion map* $x \mapsto x^{-1}$. The action of G on the roots induces an action of (a subgroup of) S_4 on the set of C_2 orbits $\{x, x^{-1}\}$, which we lift to an action of (a subgroup of) S_4 on the roots.

It is easily verified that the transposition (12) induces one of the maps

$$(\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\overline{\alpha}, \alpha, \beta, \overline{\beta}), \quad \text{or} \quad (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\overline{\alpha}^{-1}, \alpha^{-1}, \beta^{-1}, \overline{\beta}^{-1}).$$

Both of these maps commute with inversion and we note the latter is obtained from the former by applying the inversion map. Thus, without loss of generality, we take (12) as the former map.

In fact, every transposition can be lifted and commutes with inversion. Hence $G = S_4 \times C_2$. The transformations are as follows:

$$\begin{aligned}
&(12)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\overline{\alpha}, \alpha, \beta, \overline{\beta})\\
&(13)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\beta^{-1}, \overline{\alpha}, \alpha^{-1}, \overline{\beta})\\
&(14)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\overline{\beta}^{-1}, \overline{\alpha}, \beta, \alpha^{-1})\\
&(23)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\alpha, \beta^{-1}, \overline{\alpha}^{-1}, \overline{\beta})\\
&(24)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\alpha, \overline{\beta}^{-1}, \beta, \overline{\alpha}^{-1})\\
&(34)\colon (\alpha, \overline{\alpha}, \beta, \overline{\beta}) \mapsto (\alpha, \overline{\alpha}, \overline{\beta}, \beta).
\end{aligned}$$

By way of explanation, these transformations are deduced as follows. First, when choosing a lift of a transposition from the set of C_2-orbits to the set of roots, one can invert an even number of the orbit pairs $\{x, x^{-1}\}$. Second, the choice of inverting none or all four orbit pairs differs only by the inversion map. Similarly, the two options when inverting two of the orbit pairs differ only by inversion. A transposition σ necessarily preserves $\alpha\overline{\alpha} - \beta\overline{\beta} = 0$. Some careful accounting shows that permutations such as $\sigma(\overline{\alpha}) = \beta$ (or $\sigma(\overline{\alpha}) = \overline{\beta}$) lead to $\alpha\beta - \overline{\alpha\beta} = 0$ (or $\alpha\overline{\beta} - \overline{\alpha}\beta = 0$) and so $\alpha\beta \in \mathbb{R}$ (or $\alpha\overline{\beta} \in \mathbb{R}$). Such conclusions contradict our assumptions on the conjugate ratios of f. Similar arguments lead to the conclusion that there is a unique (that is to say, unique up to inversion) automorphism of the roots that preserves the aforementioned relations. Hence the Galois group is a subgroup of $S_4 \times C_2$.

We make the following useful observations. Firstly, the Galois group is a transitive subgroup of $S_4 \times C_2$ because f is irreducible. Secondly, since the action of C_2 on the roots is *free* (given $g, h \in C_2$ and a root x with $gx = hx$ then necessarily $g = h$), the transitive subgroups of $S_4 \times C_2$ are precisely the direct product of C_2 and a transitive subgroup of S_4. Finally, we note that (12)(34), representing complex conjugation, is certainly an element of the Galois group.

The transitive subgroups of S_4 are isomorphic to S_4, A_4, D_4, C_4, and K_4. Because C_4 and K_4 are Abelian groups, (12)(34) either lies in the centre of each group or the subgroup does not contain (12)(34). In the former case we deduce that the splitting field is a Kroneckerian field (by Corollary 9) and so the splitting field is either CM or totally real. The field cannot be totally real by our assumption that f has non-real roots. The field is also not a CM-field for otherwise the conjugate ratios are necessarily roots of unity by Theorem 10.

We now focus on eliminating the possibility that the Galois group of f is $D_4 \times C_2$. There are three conjugate subgroups of S_4 that are isomorphic to D_4:

$$\begin{aligned}
D_{4,0} &= \{e, (12), (34), (12)(34), (13)(24), (14)(23), (1324), (1423)\} = \langle (1324), (12)\rangle,\\
D_{4,1} &= \{e, (13), (24), (13)(24), (12)(34), (14)(23), (1234), (1432)\} = \langle (1234), (13)\rangle, \text{ and}\\
D_{4,2} &= \{e, (14), (23), (14)(23), (12)(34), (13)(24), (1243), (1342)\} = \langle (1243), (14)\rangle.
\end{aligned}$$

Note (12)(34) lies in the centre of $D_{4,0}$ and so we can once again employ Theorem 10 to deduce that $D_{4,0} \times C_2$ cannot be the Galois group of the splitting field of f. Assume, for a contradiction, that $D_{4,1} \times C_2$ is the Galois group of the splitting field of f. It is easily verified that $\alpha/\beta + \overline{\alpha/\beta}$ is invariant under the action of $D_{4,1} \times C_2$. Hence $\alpha/\beta + \overline{\alpha/\beta} \in \mathbb{Q}$. Since $\alpha/\beta \notin \mathbb{Q}$, we deduce that

$$(x - \alpha/\beta)(x - \overline{\alpha/\beta}) = x^2 - (\alpha/\beta + \overline{\alpha/\beta})x + 1 \in \mathbb{Q}[x].$$

Thus α/β satisfies a quadratic monic polynomial; moreover, since α/β is an algebraic integer it follows that $\alpha/\beta + \overline{\alpha/\beta} \in \mathbb{Z}$. Since $|\alpha/\beta| = 1$, we find $\alpha/\beta + \overline{\alpha/\beta} \in \{\pm 2, \pm 1, 0\}$. Each of the roots of the five possible polynomials are roots of unity, which contradicts our assumption on the conjugate ratios. Mutatis mutandis, one eliminates the possibility that the Galois group is $D_{4,2} \times C_2$ by similar consideration of $\alpha/\overline{\beta} + \overline{\alpha}/\beta$.

Thus the Galois group of the splitting field of f is either $S_4 \times C_2$ or $A_4 \times C_2$, as required. ◀

▶ Remark 21. It is not possible to strengthen the above result: the Galois group of the palindrome $x^8 + x^7 - x^6 + x^5 + 5x^4 + x^3 - x^2 + x + 1$ is $S_4 \times C_2$, whilst the Galois group of the palindrome $x^8 + x^7 - 3x^6 + x^5 + 9x^4 + x^3 - 3x^2 + x + 1$ is $A_4 \times C_2$. Both polynomials satisfy the assumptions in Theorem 20. For the avoidance of doubt, the converse of the statement in Theorem 20 is not true: the Galois group of the palindrome $x^8 + x^6 + 6x^5 + 9x^4 + 6x^3 + x^2 + 1$, which possesses a single complex-conjugate pair of dominant roots, is $S_4 \times C_2$.

5 Directions for Future Research

Our main contribution to the state of the art is a new proof of Theorem 1: the Skolem Problem is decidable for the class of reversible integer linear recurrence sequences of order at most seven. The benefit of our approach (by comparison to the case analysis in [19]) is the potential for applications to related decision problems. In this section we suggest directions for future research; in particular, variations on the Positivity and Skolem Problems for linear recurrence sequences.

5.1 The Simple Reversible Positivity Problem

The *Positivity Problem* asks to decide whether the terms in an integer linear recurrence sequence are all non-negative. Ouaknine and Worrell [26] demonstrated that the Positivity Problem is decidable for *simple* linear recurrence sequences (those whose characteristic polynomials have no repeated roots) of order at most nine. The proofs therein very much depend on an approach via Baker's Theorem for linear forms in logarithms. Those authors identify the class of non-degenerate linear recurrence sequences of order ten that are not amenable to said approach: the characteristic polynomials in this class have one dominant real root, four complex-conjugate pairs of dominant roots, and one non-dominant root.

Consider the family of monic polynomials in $\mathbb{Z}[x]$ of degree ten, with constant coefficient ± 1, and the above distribution of roots. Suppose that $f \in \mathbb{Z}[x]$ is a polynomial in this class. We immediately find that f is irreducible since each dominant root of f is necessarily conjugate to the single non-dominant root. The roots of f lie on two concentric circles centred at the origin and so we can invoke Theorem 8 to derive a contradiction. Thus the obstruction to decidability falls away under our extra assumptions and so we extend the result in [26] in this restricted setting. In summary, the *Simple Reversible Positivity Problem* is decidable for recurrences of order at most ten and so we have proved Corollary 3.

▶ Remark 22. Let us give an alternative proof for Corollary 3; this alternative proof does not invoke Theorem 8.

Observe that any candidate polynomial in our discussion is irreducible. We can invoke standard results for irreducible polynomials with many dominant roots. For example, versions of the following lemma are found in [32, 10].

▶ **Lemma 23.** *Suppose that α is an algebraic number with Galois conjugates β and γ satisfying $\alpha^2 = \beta\gamma$. Then the conjugate ratio α/β is a root of unity.*

Now suppose that a polynomial $f \in \mathbb{Z}[x]$ of degree ten has the aforementioned distribution of roots and is the characteristic polynomial of a non-degenerate linear recurrence sequence. Since f is necessarily irreducible and has a dominant positive root, we can invoke Lemma 23. We deduce that f is the characteristic polynomial of a degenerate recurrence sequence, a contradiction. Thus the obstacle to deciding positivity of simple linear recurrence sequences at order ten falls away under our additional assumption of reversibility: there are no sequences in the aforementioned class. As an aside, Lemma 23 is used by Dubickas and Smyth [7] as a stepping-stone towards Theorem 8.

We propose that such approaches as outlined above could lead to further decidability results for variants of the Positivity Problem. The key observations on the characteristic polynomials were: irreducibility and a dominant positive root. Here we can make the latter assumption without loss of generality. Indeed, let us recall the following classical consequence of Pringsheim's Theorem in complex analysis that is pertinent to deciding positivity.

▶ **Lemma 24.** *Suppose that a non-zero real-valued linear recurrence sequence $\langle X_n \rangle_n$ has no positive dominant characteristic root. Then the cardinalities of the sets $\{n \in \mathbb{N} : X_n > 0\}$ and $\{n \in \mathbb{N} : X_n < 0\}$ are both infinite.*

5.2 The Skolem Problem and unit-norm roots

In this paper we invoke results such as Theorem 8 in order to reduce the reversible Skolem Problem at orders five, six, and seven, to decidable instances of the Skolem Problem (Theorem 2). It is interesting to speculate that techniques involving identities between roots (the Galois theory underlying Theorem 8) have further applications in establishing decidability results for linear recurrence sequences. Indeed, the general version of Theorem 8 (see [7, Theorem 2.1]) considers not only algebraic integers that are units, but also algebraic numbers that are *unit-norms*. An algebraic number α is a *unit-norm* if the minimal polynomial of α is of the form $a_d x^d - a_{d-1}x^{d-1} - \cdots - a_1 x - a_0 \in \mathbb{Z}[x]$ such that $|a_d| = |a_0|$. So the unit-norm algebraic integers are the units.

We can strengthen the statement in Proposition 12 by invoking [7, Theorem 2.1]: we deduce there is no polynomial $a_5x^5 - a_4x^4 - a_3x^3 - a_2x^2 - a_1x \pm a_5 \in \mathbb{Z}[x]$ that satisfies hypotheses H1 and H2. Thus not only do we settle decidability of the reversible Skolem Problem at order five, but also decidability of the Skolem Problem at order five for the class of rational-valued linear recurrence sequences that satisfy a relation of the form

$$X_{n+5} = a_4X_{n+4} + a_3X_{n+3} + a_2X_{n+2} + a_1X_{n+1} \pm X_n$$

with $a_1, a_2, a_3, a_4 \in \mathbb{Q}$. Thus we have established Corollary 4.

Abstract

A graph is temporally connected if there exists a strict temporal path, i.e., a path whose edges have *strictly increasing* labels, from every vertex u to every other vertex v. In this paper we study *temporal design* problems for undirected temporally connected graphs. The basic setting of these optimization problems is as follows: given a connected undirected graph G, what is the smallest number $|\lambda|$ of time-labels that we need to add to the edges of G such that the resulting temporal graph (G, λ) is temporally connected? As it turns out, this basic problem, called Minimum Labeling (ML), can be optimally solved in polynomial time. However, exploiting the temporal dimension, the problem becomes more interesting and meaningful in its following variations, which we investigate in this paper. First we consider the problem Min. Aged Labeling (MAL) of temporally connecting the graph when we are given an upper-bound on the allowed *age* (i.e., maximum label) of the obtained temporal graph (G, λ). Second we consider the problem Min. Steiner Labeling (MSL), where the aim is now to have a temporal path between any pair of "important" vertices which lie in a subset $R \subseteq V$, which we call the *terminals*. This relaxed problem resembles the problem Steiner Tree in static (i.e., non-temporal) graphs. However, due to the requirement of *strictly* increasing labels in a temporal path, Steiner Tree is *not* a special case of MSL. Finally we consider the age-restricted version of MSL, namely Min. Aged Steiner Labeling (MASL). Our main results are threefold: we prove that (i) MAL becomes NP-complete on undirected graphs, while (ii) MASL becomes W[1]-hard with respect to the number $|R|$ of terminals. On the other hand we prove that (iii) although the age-unrestricted problem MSL remains NP-hard, it is in FPT with respect to the number $|R|$ of terminals. That is, adding the age restriction, makes the above problems *strictly harder* (unless P=NP or W[1]=FPT).

1 Introduction

A temporal (or dynamic) graph is a graph whose underlying topology is subject to discrete changes over time. This paradigm reflects the structure and operation of a great variety of modern networks; social networks, wired or wireless networks whose links change dynamically, transportation networks, and several physical systems are only a few examples of networks that change over time [23, 33, 35]. Inspired by the foundational work of Kempe et al. [25], we adopt here a simple model for temporal graphs, in which the vertex set remains unchanged while each edge is equipped with a set of integer time-labels.

▶ **Definition 1** (temporal graph [25]). *A* temporal graph *is a pair* (G, λ)*, where* $G = (V, E)$ *is an underlying (static) graph and* $\lambda : E \to 2^{\mathbb{N}}$ *is a* time-labeling *function which assigns to every edge of* G *a set of discrete time-labels.*

Here, whenever $t \in \lambda(e)$, we say that the edge e is *active* or *available* at time t. Throughout the paper we may refer to "time-labels" simply as "labels" for brevity. Furthermore, the *age* (or *lifetime*) $\alpha(G, \lambda)$ of the temporal graph (G, λ) is the largest time-label used in it, i.e., $\alpha(G, \lambda) = \max\{t \in \lambda(e) : e \in E\}$. One of the most central notions in temporal graphs is that of a *temporal path* (or *time-respecting path*) which is motivated by the fact that, due to causality, entities and information in temporal graphs can "flow" only along sequences of edges whose time-labels are strictly increasing, or at least non-decreasing.

▶ **Definition 2** (temporal path). *Let* (G, λ) *be a temporal graph, where* $G = (V, E)$ *is the underlying static graph. A* temporal path *in* (G, λ) *is a sequence* $(e_1, t_1), (e_2, t_2), \ldots, (e_k, t_k)$*, where* $(e_1, e_2, \ldots, e_k)$ *is a path in* G*,* $t_i \in \lambda(e_i)$ *for every* $i = 1, 2, \ldots, k$*, and* $t_1 < t_2 < \ldots < t_k$*.*

A vertex v is *temporally reachable* (or *reachable*) from vertex u in (G, λ) if there exists a temporal path from u to v. If every vertex v is reachable by every other vertex u in (G, λ), then (G, λ) is called *temporally connected*. Note that, for every temporally connected temporal graph (G, λ), we have that its age is at least as large as the diameter d_G of the underlying graph G. Indeed, the largest label used in any temporal path between two anti-diametrical vertices cannot be smaller than d_G. Temporal paths have been introduced by Kempe et al. [25] for temporal graphs which have only one label per edge, i.e., $|\lambda(e)| = 1$ for every edge $e \in E$, and this notion has later been extended by Mertzios et al. [28] to temporal graphs with multiple labels per edge. Furthermore, depending on the particular application, both variations of temporal paths with non-decreasing [6, 25, 26] and with strictly increasing [15, 28] labels have been studied. In this paper we focus on temporal paths with *strictly increasing* labels. Due to the very natural use of temporal paths in various contexts, several path-related notions, such as temporal analogues of distance, diameter, reachability, exploration, and centrality have also been studied [1–3, 6, 8, 10, 11, 13, 15–18, 20, 26, 28, 32, 34, 36].

Furthermore, some non-path temporal graph problems have been recently introduced too, including for example temporal variations of maximal cliques [7, 37], vertex cover [4, 21], vertex coloring [31], matching [29], and transitive orientation [30]. Motivated by the need of restricting the spread of epidemic, Enright et al. [15] studied the problem of removing the smallest number of time-labels from a given temporal graph such that every vertex can only temporally reach a limited number of other vertices. Deligkas et al. [12] studied the problem of accelerating the spread of information for a set of sources to all vertices in a temporal graph, by only using delaying operations, i.e., by shifting specific time-labels to a later time slot. The problems studied in [12] are related but orthogonal to our temporal connectivity problems. Various other temporal graph modification problems have been also studied, see for example [6, 11, 13, 16, 34].

The time-labels of an edge e in a temporal graph indicate the discrete units of time (e.g., days, hours, or even seconds) in which e is active. However, in many real dynamic systems, e.g., in synchronous mobile distributed systems that operate in discrete rounds, or in unstable chemical or physical structures, maintaining an edge over time requires energy and thus comes at a cost. One natural way to define the *cost* of the whole temporal graph (G, λ) is the *total number* of time-labels used in it, i.e., the total cost of (G, λ) is $|\lambda| = \sum_{e \in E} |\lambda_e|$.

In this paper we study *temporal design* problems of undirected temporally connected graphs. The basic setting of these optimization problems is as follows: given an undirected graph G, what is the smallest number $|\lambda|$ of time-labels that we need to add to the edges of G such that (G, λ) is temporally connected? As it turns out, this basic problem can be optimally solved in polynomial time, thus answering to a conjecture made in [2]. However, exploiting the temporal dimension, the problem becomes more interesting and meaningful in its following variations, which we investigate in this paper. First we consider the problem variation where we are given along with the input also an upper bound of the allowed *age* (i.e., maximum label) of the obtained temporal graph (G, λ). This age restriction is sensible in more pragmatic cases, where delaying the latest arrival time of any temporal path incurs further costs, e.g., when we demand that all agents in a safety-critical distributed network are synchronized as quickly as possible, and with the smallest possible number of communications among them. Second we consider problem variations where the aim is to have a temporal path between any pair of "important" vertices which lie in a subset $R \subseteq V$, which we call the *terminals*. For a detailed definition of our problems we refer to Section 2.

Here it is worth noting that the latter relaxation of temporal connectivity resembles the problem Steiner Tree in static (i.e., non-temporal) graphs. Given a connected graph $G = (V, E)$ and a set $R \subseteq V$ of terminals, Steiner Tree asks for a smallest-sized subgraph of G which connects all terminals in R. Clearly, the smallest subgraph sought by Steiner Tree is a tree. As it turns out, this property does not carry over to the temporal case. Consider for example an arbitrary graph G and a terminal set $R = \{a, b, c, d\}$ such that G contains an induced cycle on four vertices a, b, c, d; that is, G contains the edges ab, bc, cd, da but not the edges ac or bd. Then, it is not hard to check that only way to add the smallest number of time-labels such that all vertices of R are temporally connected is to assign one label to each edge of the cycle on a, b, c, d, e.g., $\lambda(ab) = \lambda(cd) = 1$ and $\lambda(bc) = \lambda(cd) = 2$. The main underlying reason for this difference with the static problem Steiner Tree is that temporal connectivity is *not transitive* and *not symmetric:* if there exists temporal paths from u to v, and from v to w, it is not a priori guaranteed that a temporal path from v to u, or from u to w exists.

Temporal network design problems have already been considered in previous works. Mertzios et al. [28] proved that it is APX-hard to compute a minimum-cost labeling for temporally connecting an input *directed* graph G, where the age of the graph is upper-bounded by the diameter of G. This hardness reduction was strongly facilitated by the careful placement of the edge directions in the constructed instance, in which every vertex was reachable in the static graph by only constantly many vertices. Unfortunately this cannot happen in an undirected connected graph, where every vertex is reachable by all other vertices. Later, Akrida et al. [2] proved that it is also APX-hard to *remove* the largest number of time-labels from a given temporally connected (undirected) graph (G, λ), while still maintaining temporal connectivity. In this case, although there are no edge directions, the hardness reduction was strongly facilitated by the careful placement of the initial time-labels of λ in the input temporal graph, in which every pair of vertices could be connected by only a few different temporal paths, among which the solution had to choose. Unfortunately this cannot happen when the goal is to add time-labels to an undirected connected graph, where there are potentially multiple ways to temporally connect a pair of vertices (even if we upper-bound the largest time-label by the diameter).

Summarizing, the above technical difficulties seem to be the reason why the problem of *adding* the minimum number of time-labels with an age-restriction to an *undirected* graph to achieve temporal connectivity remained open until now for the last decade. In this paper we overcome these difficulties by developing a hardness reduction from a variation of the problem Max XOR SAT (see Theorem 12 in Section 3) where we manage to add the appropriate (undirected) edges among the variable-gadgets such that simultaneously (i) the distance between any two vertices from different variable gadgets remains small (constant) and (ii) there is no shortest path between two vertices of the *same* variable gadget that leaves this gadget.

Our contribution and road-map. In the first part of our paper, in Section 3, we present our results on Min. Aged Labeling (MAL). This problem is the same as ML, with the additional restriction that we are given along with the input an upper bound on the allowed *age* of the resulting temporal graph (G, λ). Using a technically involved reduction from a variation of Max XOR SAT, we prove that MAL is NP-complete on undirected graphs, even when the required maximum age is equal to the diameter d_G of the input static graph G.

In the second part of our paper, in Section 4, we present our results on the Steiner-tree versions of the problem, namely on Min. Steiner Labeling (MSL) and Min. Aged Steiner Labeling (MASL). The difference of MSL from ML is that, here, the goal is to have a temporal path between any pair of "important" vertices which lie in a given subset $R \subseteq V$ (the *terminals*). In Section 4.1 we prove that MSL is NP-complete by a reduction from Vertex Cover, the correctness of which requires showing structural properties of MSL. Here it is worth recalling that, as explained above, the classical problem Steiner Tree on static graphs is *not* a special case of MSL, due to the requirement of strictly increasing labels in a temporal path. Furthermore, we would like to emphasize here that, as temporal connectivity is neither transitive nor symmetric, a straightforward NP-hardness reduction from Steiner Tree to MSL does not seem to exist. For example, as explained above, in a graph that contains a C_4 with its four vertices as terminals, labeling a Steiner tree is sub-optimal for MSL.

In Section 4.2 we provide a fixed-parameter tractable (FPT) algorithm for MSL with respect to the number $|R|$ of terminal vertices, by providing a parameterized reduction to Steiner Tree. The proof of correctness of our reduction, which is technically quite involved, is of independent interest, as it proves crucial graph-theoretical properties of minimum temporal Steiner labelings. In particular, for our algorithm we prove (see Lemma 14) that, for any undirected graph G with a set R of terminals, there always exists at least one minimum temporal Steiner labeling (G, λ) which labels edges either from (i) a tree or from (ii) a tree with one extra edge that builds a C_4.

In Section 4.3 we prove that MASL is W[1]-hard with respect to the number $|R|$ of terminals. Our results actually imply the stronger statement that MASL is W[1]-hard even with respect to the number of time-labels of the solution (which is a larger parameter than the number $|R|$ of terminals).

Finally, we complete the picture by providing some auxiliary results in our preliminary Section 2. More specifically, in Section 2.1 we prove that ML can be solved in polynomial time, and in Section 2.2 we prove that the analogue minimization versions of ML and MAL on directed acyclic graphs are solvable in polynomial time.

Due to space constraints, proofs of results marked with $\star$ are (partially) deferred to a full version on arXiv [27].

2 Preliminaries and notation

Given a (static) undirected graph $G = (V, E)$, an edge between two vertices $u, v \in V$ is denoted by uv, and in this case the vertices u, v are said to be *adjacent* in G. If the graph is directed, we will use the ordered pair (u, v) (resp. (v, u)) to denote the oriented edge from u to v (resp. from v to u). The *age* of a temporal graph (G, λ) is denoted by $\alpha(G, \lambda) = \max\{t \in \lambda(e) : e \in E\}$. A temporal path $(e_1, t_1), (e_2, t_2), \ldots, (e_k, t_k)$ from vertex u to vertex v is called *foremost*, if it has the smallest arrival time t_k among all temporal paths from u to v. Note that there might be another temporal path from u to v that uses fewer edges than a foremost path. A temporal graph (G, λ) is *temporally connected* if, for every pair of vertices $u, v \in V$, there exists a temporal path (see Definition 2) P_1 from u to v and a temporal path P_2 from v to u. Furthermore, given a set of terminals $R \subseteq V$, the temporal graph (G, λ) is *R-temporally connected* if, for every pair of vertices $u, v \in R$, there exists a temporal path from u to v and a temporal path from v to u; note that P_1 and P_2 can also contain vertices from $V \setminus R$. Now we provide our formal definitions of our four decision problems.

MIN. LABELING (ML)

Input: A static graph $G = (V, E)$ and a $k \in \mathbb{N}$.
Question: Does there exist a temporally connected temporal graph (G, λ), where $|\lambda| \leq k$?

MIN. AGED LABELING (MAL)

Input: A static graph $G = (V, E)$ and two integers $a, k \in \mathbb{N}$.
Question: Does there exist a temporally connected temporal graph (G, λ), where $|\lambda| \leq k$ and $\alpha(\lambda) \leq a$?

MIN. STEINER LABELING (MSL)

Input: A static graph $G = (V, E)$, a subset $R \subseteq V$ and a $k \in \mathbb{N}$.
Question: Does there exist a temporally R-connected temporal graph (G, λ), where $|\lambda| \leq k$?

MIN. AGED STEINER LABELING (MASL)

Input: A static graph $G = (V, E)$, a subset $R \subseteq V$, and two integers $a, k \in \mathbb{N}$.
Question: Does there exist a temporally R-connected temporal graph (G, λ), where $|\lambda| \leq k$ and $\alpha(\lambda) \leq a$?

Note that, for both problems MAL and MASL, whenever the input age bound a is strictly smaller than the diameter d of G, the answer is always NO. Thus, we always assume in the remainder of the paper that $a \geq d$, where d is the diameter of the input graph G. For simplicity of the presentation, we denote next by $\kappa(G, d)$ the smallest number k for which (G, k, d) is a YES instance for MAL.

▶ **Observation 3 ($\star$).** *For every graph G with n vertices and diameter d, we have that $\kappa(G, d) \leq n(n - 1)$.*

The next lemma shows that the upper bound of Observation 3 is asymptotically tight as, for cycle graphs C_n with diameter d, we have that $\kappa(C_n, d) = \Theta(n^2)$.

▶ **Lemma 4 ($\star$).** *Let C_n be a cycle on n vertices, where $n \neq 4$, and let d be its diameter. Then*

$$\kappa(C_n, d) = \begin{cases} d^2, & \text{when } n = 2d \\ 2d^2 + d, & \text{when } n = 2d + 1. \end{cases}$$

2.1 A polynomial-time algorithm for ML

As a first warm-up, we study the problem ML, where no restriction is imposed on the maximum allowed age of the output temporal graph. It is already known by Akrida et al. [2] that any undirected graph can be made temporally connected by adding at most $2n-3$ time-labels, while for trees $2n-3$ labels are also necessary. Moreover, it was conjectured that every graph needs at least $2n-4$ time-labels [2]. Here we prove their conjecture true by proving that, if G contains (resp. does not contain) the cycle C_4 on four vertices as a subgraph, then (G,k) is a YES instance of ML if and only if $k \geq 2n-4$ (resp. $k \geq 2n-3$). The proof is done via a reduction to the gossip problem [9] (for a survey on gossiping see also [22]).

The related problem of achieving temporal connectivity by assigning to every edge of the graph at most one time-label, has been studied by Göbel et al. [19], where the relationship with the gossip problem has also been drawn. Contrary to ML, this problem is NP-hard [19]. That is, the possibility of assigning two or more labels to an edge makes the problem computationally much easier. Indeed, in a C_4-free graph with n vertices, an optimal solution to ML consists in assigning in total $2n-3$ time-labels to the $n-1$ edges of a spanning tree. In such a solution, one of these $n-1$ edges receives one time-label, while each of the remaining $n-2$ edges receives two time-labels. Similarly, when the graph contains a C_4, it suffices to span the graph with four trees tooted at the vertices of the C_4, where each of the edges of the C_4 receives one time-label and each edge of the four trees receives two labels. That is, a graph containing a C_4 can be temporally connected using $2n-4$ time-labels.

In the gossip problem we have n agents from a set A. At the beginning, every agent $x \in A$ holds its own secret. The goal is that each agent eventually learns the secret of every other agent. This is done by producing a sequence of unordered pairs (x,y), where $x,y \in A$ and each such pair represents one phone call between the agents involved, during which the two agents exchange all the secrets they currently know.

The above gossip problem is naturally connected to ML. The only difference between the two problems is that, in gossip, all calls are non-concurrent, while in ML we allow concurrent temporal edges, i.e., two or more edges can appear at the same time slot t. Therefore, in order to transfer the known results from gossip to ML, it suffices to prove that in ML we can equivalently consider solutions with non-concurrent edges.

▶ **Theorem 5** ($\star$). *Let $G=(V,E)$ be a connected graph. Then the smallest $k \in \mathbb{N}$ for which (G,k) is a YES instance of ML is:*

$$k = \begin{cases} 2n-4, & \text{if } G \text{ contains } C_4 \text{ as a subgraph,} \\ 2n-3, & \text{otherwise.} \end{cases}$$

2.2 A polynomial-time algorithm for directed acyclic graphs

As a second warm-up, we show that the minimization analogues of ML and MAL on directed acyclic graphs (DAGs) are solvable in polynomial time. More specifically, for the minimization analogue of ML we provide an algorithm which, given a DAG $G=(V,A)$ with diameter d_G, computes a temporal labeling function λ which assigns the smallest possible number of time-labels on the arcs of G with the following property: for every two vertices $u,v \in V$, there exists a directed temporal path from u to v in (G,λ) if and only if there exists a directed path from u to v in G. Moreover, the age $\alpha(G,\lambda)$ of the resulting temporal graph is *equal* to d_G. Therefore, this immediately implies a polynomial-time algorithm for the minimization analogue of MAL on DAGs. For notation uniformity, we call these minimization problems $\text{ML}_{directed}$ and $\text{MAL}_{directed}$, respectively.

▶ **Theorem 6** (⋆). *Let $G = (V, E)$ be a DAG with n vertices and m arcs. Then $ML_{directed}(G)$ and $MAL_{directed}(G)$ can be both computed in $O(n(n + m))$ time.*

3 MAL is NP-complete

In this section we prove that it is NP-hard to determine the number of labels in an optimal labeling of a static, undirected graph G, where the age, i.e., the maximum label used, is not larger than the diameter of the input graph.

To prove this we provide a reduction from the NP-hard problem Monotone Max XOR(3) (or MonMaxXOR(3) for short). This is a special case of the classical Boolean satisfiability problem, where the input formula ϕ consists of the conjunction of *monotone* XOR clauses of the form $(x_i \oplus x_j)$, i.e., variables x_i, x_j are non-negated. If each variable appears in exactly r clauses, then ϕ is called a *monotone* Max XOR(r) formula. A clause $(x_i \oplus x_j)$ is *XOR-satisfied* (or simply *satisfied*) if and only if $x_i \neq x_j$. In Monotone Max XOR(r) we are trying to find a truth assignment τ of ϕ which satisfies the maximum number of clauses. As it can be easily checked, MonMaxXOR(3) encodes the problem Max-Cut on cubic graphs, which is known to be NP-hard [5]. Therefore we conclude the following.

▶ **Theorem 7** ([5]). *MonMaxXOR(3) is NP-hard.*

Now we explain our reduction from MonMaxXOR(3) to the problem Minimum Aged Labeling (MAL), where the input static graph G is undirected and the desired age of the output temporal graph is the diameter d of G . Let ϕ be a monotone Max XOR(3) formula with n variables $x_1, x_2, \ldots, x_n$ and m clauses $C_1, C_2, \ldots, C_m$. Note that $m = \frac{3}{2}n$, since each variable appears in exactly 3 clauses. From ϕ we construct a static undirected graph G_ϕ with diameter $d = 10$, and prove that there exists a truth assignment τ which satisfies at least k clauses in ϕ, if and only if there exists a labeling λ_ϕ of G_ϕ, with $|\lambda_\phi| \leq \frac{13}{2}n^2 + \frac{99}{2}n - 8k$ labels and with age $\alpha(G, \lambda) \leq 10$.

High-level construction

For each variable x_i, $1 \leq i \leq n$, we construct a variable gadget X_i that consists of a "starting" vertex s_i and three "ending" vertices t_i^ℓ (for $\ell \in \{1, 2, 3\}$); these ending vertices correspond to the appearances of x_i in three clauses of ϕ. In an optimum labeling $\lambda(\phi)$, in each variable gadget there are exactly two labelings that temporally connect starting and ending vertices, which correspond to the True or False truth assignment of the variable in the input formula ϕ. For every clause $(x_i \oplus x_j)$ we identifying corresponding ending vertices of X_i and X_j (as well as some other auxiliary vertices and edges). Whenever $(x_i \oplus x_j)$ is satisfied by a truth assignment of ϕ, the labels of the common edges of X_i and X_j in an optimum labeling coincide (thus using few labels); otherwise we need additional labels for the common edges of X_i and X_j.

Detailed construction of G_ϕ

For each variable x_i from ϕ we create a variable gadget X_i, that consists of a *base* BX_i on 11 vertices, $BX_i = \{s_i, a_i, b_i, c_i, d_i, e_i, \overline{a_i}, \overline{b_i}, \overline{c_i}, \overline{d_i}, \overline{e_i}\}$, and three *forks* F^1X_i, F^2X_i, F^3X_i, each on 9 vertices, $F^\ell X_i = \{t_i^\ell, f_i^\ell, g_i^\ell, h_i^\ell, m_i^\ell, \overline{f_i}^\ell, \overline{g_i}^\ell, \overline{h_i}^\ell, \overline{m_i}^\ell\}$, where $\ell \in \{1, 2, 3\}$. Vertices in the base BX_i are connected in the following way: there are two paths of length 5: $s_i a_i b_i c_i d_i e_i$ and $s_i \overline{a_i} \overline{b_i} \overline{c_i} \overline{d_i} \overline{e_i}$, and 5 extra edges of form $y_i \overline{y_i}$, where $y \in \{a, b, c, d, e\}$. Vertices in each fork $F^\ell X_i$ (where $\ell \in \{1, 2, 3\}$) are connected in the following way: there are two paths of length

4: $t_i^\ell m_i^\ell h_i^\ell g_i^\ell f_i^\ell$ and $t_i^\ell \overline{m_i}^\ell \overline{h_i}^\ell \overline{g_i}^\ell \overline{f_i}^\ell$, and 4 extra edges of form $y_i\overline{y_i}^\ell$, where $y \in \{m, h, g, f\}$. The base BX_i of the variable gadget X_i is connected to each of the three forks $F^\ell X_i$ via two edges $e_i f_i^\ell$ and $\overline{e_i}\overline{f_i}^\ell$, where $\ell \in \{1, 2, 3\}$. For an illustration see Figure 1.

For an easier analysis we fix the following notation. The vertex $s_i \in BX_i$ is called a *start vertex* of X_i, vertices t_i^ℓ ($\ell \in \{1, 2, 3\}$) are called *ending vertices* of X_i, a path connecting s_i, t_i^ℓ that passes through vertices $a_i b_i c_i d_i e_i f_i^\ell g_i^\ell h_i^\ell m_i^\ell$ (resp. $\overline{a_i}\overline{b_i} \dots \overline{m_i}^\ell$) is called the *left* (resp. *right*) s_i, t_i^ℓ-path. The left (resp. right) s_i, t_i^ℓ-path is a disjoint union of the left (resp. right) path on vertices of the base BX_i of X_i, an edge of form $e_i f_i^\ell$ (resp. $\overline{e_i}\overline{f_i}^\ell$) called the left (resp. right) *bridge edge* and the left (resp. right) path on vertices of the ℓ-th fork $F^\ell X_i$ of X_i. The edges $y_i\overline{y_i}$, where $y \in \{a, b, c, d, e, f^\ell, g^\ell, h^\ell, m^\ell\}$, $\ell \in \{1, 2, 3\}$, are called *connecting edges*.

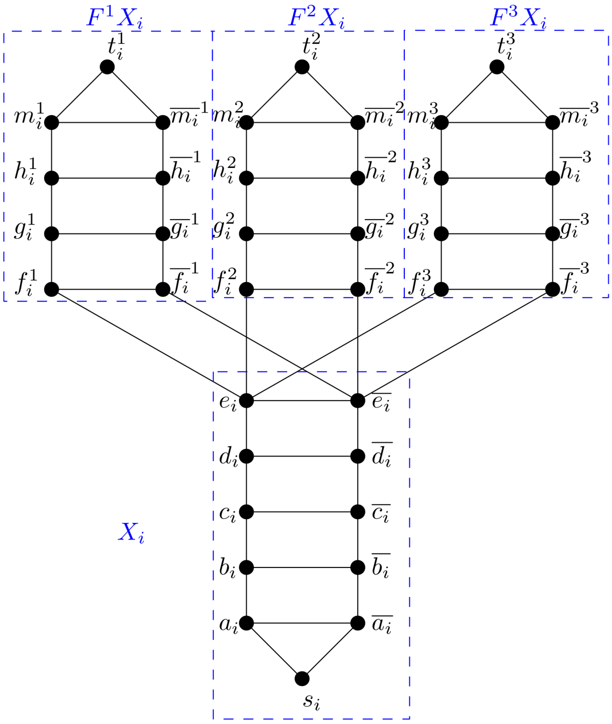

Figure 1 An example of a variable gadget X_i in G_ϕ, corresponding to the variable x_i from ϕ.

Connecting variable gadgets

There are two ways in which we connect two variable gadgets, depending whether they appear in the same clause in ϕ or not.

1. Two variables x_i, x_j do not appear in any clause together. In this case we add the following edges between the variable gadgets X_i and X_j:
   - from e_i (resp. $\overline{e_i}$) to $f_j^{\ell'}$ and $\overline{f_j}^{\ell'}$, where $\ell' \in \{1, 2, 3\}$,
   - from e_j (resp. $\overline{e_j}$) to f_i^ℓ and $\overline{f_i}^\ell$, where $\ell \in \{1, 2, 3\}$,
   - from d_i (resp. $\overline{d_i}$) to d_j and $\overline{d_j}$.

   We call these edges the *variable edges*. For an illustration see Figure 2.

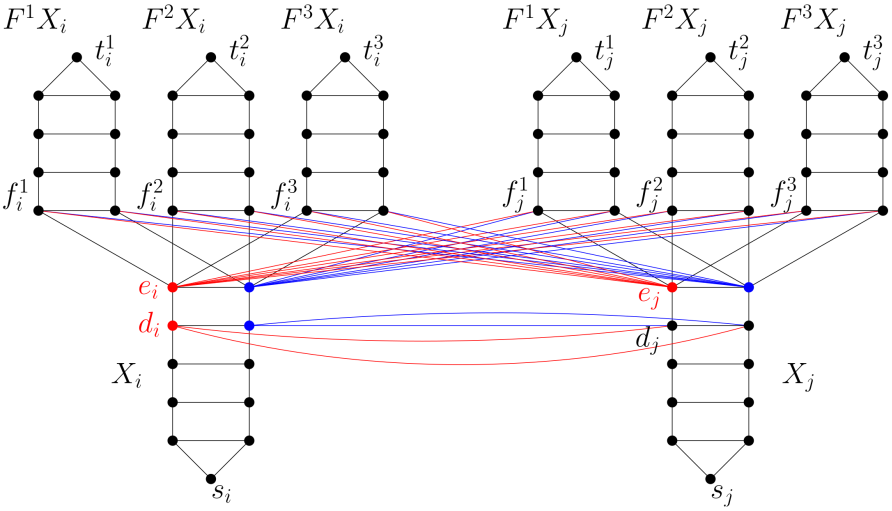

Figure 2 An example of two non-intersecting variable gadgets and variable edges among them.

2. Let $C = (x_i \oplus x_j)$ be a clause of ϕ, that contains the r-th appearance of the variable x_i and r'-th appearance of the variable x_j. In this case we identify the r-th fork F^rX_i of X_i with the r'-th fork $F^{r'}X_j$ of X_j in the following way:
   - $t_i^r = t_j^{r'}$,
   - $\{f_i^r, g_i^r, h_i^r, m_i^r\} = \{\overline{f_j}^{r'}, \overline{g_j}^{r'}, \overline{h_j}^{r'}, \overline{m_j}^{r'}\}$ respectively, and
   - $\{\overline{f_i}^{r}, \overline{g_i}^{r}, \overline{h_i}^{r}, \overline{m_i}^{r}\} = \{f_j^{r'}, g_j^{r'}, h_j^{r'}, m_j^{r'}\}$ respectively.

   Besides that we add the following edges between the variable gadgets X_i and X_j:
   - from e_i (resp. $\overline{e_i}$) to $f_j^{\ell'}$ and $\overline{f_j}^{\ell'}$, where $\ell' \in \{1,2,3\} \setminus \{r'\}$,
   - from e_j (resp. $\overline{e_j}$) to f_i^{ℓ} and $\overline{f_i}^{\ell}$, where $\ell \in \{1,2,3\} \setminus \{r\}$,
   - from d_i (resp. $\overline{d_i}$) to d_j and $\overline{d_j}$.

   For an illustration see Figure 3.

This finishes the construction of G_ϕ. Before continuing with the reduction, we prove the following structural property of G_ϕ.

▶ **Lemma 8** ($\star$). *The diameter d_ϕ of G_ϕ is* 10.

▶ **Theorem 9** ($\star$). *If $OPT_{\text{MonMaxXOR(3)}}(\phi) \geq k$ then $OPT_{MAL}(G_\phi, d_\phi) \leq \frac{13}{2}n^2 + \frac{99}{2}n - 8k$, where n is the number of variables in the formula ϕ.*

Before proving the statement in the other direction, we have to show some structural properties. Let us fix the following notation. If a labeling λ_ϕ labels all left (resp. right) paths of the variable gadget X_i (i.e., both bottom-up from s_i to t_i^1, t_i^2, t_i^3 and top-down from t_i^1, t_i^2, t_i^3 to s_i with labels $1, 2 \ldots, 10$ in this order), then we say that the variable gadget X_i is *left-aligned* (resp. *right-aligned*) in the labeling λ_ϕ. Note, if at least one edge on any of these left (resp. right) paths of X_i is not labeled with the appropriate label between 1 and 10, then the variable gadget is *not* left-aligned (resp. *not* right-aligned). Every temporal path from s_i to t_i^ℓ (resp. from t_i^ℓ to s_i) of length 10 in X_i is called an *upward path* (resp. a *downward path*) in X_i. Any part of an upward (resp. downward) path is called a *partial* upward (resp. downward) path. Note that, for any $\ell, \ell' \in \{1,2,3\}$, $\ell \neq \ell'$, a temporal path from t_i^ℓ to $t_i^{\ell'}$ of length 10 is the union of a partial downward path on the fork F_i^ℓ and a partial upward path on $F_i^{\ell'}$. Moreover, note that these two partial downward/upward paths

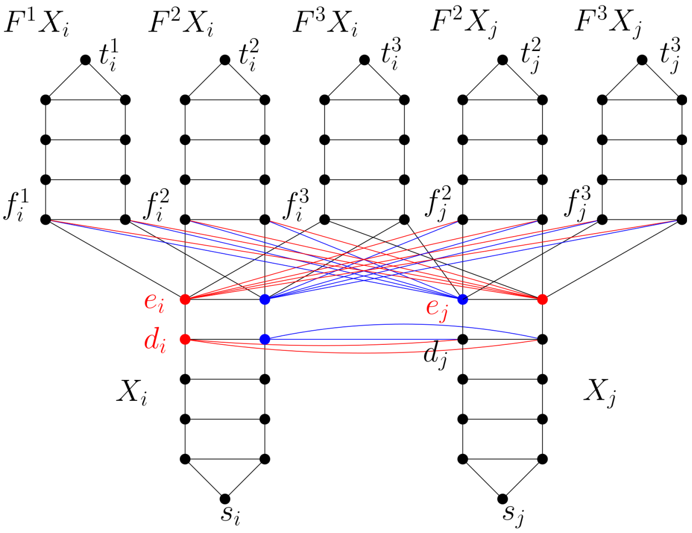

Figure 3 An example of two intersecting variable gadgets X_i, X_j corresponding to variables x_i, x_j, that appear together in some clause in ϕ, where it is the third appearance of x_i and the first appearance of x_j.

must be either both parts of a left temporal path or both parts of a right temporal path between s_i and $t_i^{\ell}, t_i^{\ell'}$. The following technical lemma will allow us to prove the correctness of our reduction.

▶ **Lemma 10** ($\star$). *Let λ_ϕ be a minimum labeling of G_ϕ. Then λ_ϕ can be modified in polynomial time to a minimum labeling of G_ϕ in which each variable gadget X_i is either left-aligned or right-aligned.*

▶ **Theorem 11** ($\star$). *If $OPT_{\text{MAL}}(G_\phi, d_\phi) \leq \frac{13}{2}n^2 + \frac{99}{2}n - 8k$ then $OPT_{\text{MonMaxXOR(3)}}(\phi) \geq k$, where n is the number of variables in the formula ϕ.*

Since MAL is clearly in NP, the next theorem follows directly by Theorems 7, 9, and 11.

▶ **Theorem 12.** *MAL is NP-complete on undirected graphs, even when the required maximum age is equal to the diameter of the input graph.*

4 The Steiner-Tree variations of the problem

In this section we investigate the computational complexity of the Steiner-Tree variations of the problem, namely MSL and MASL. First, we prove in Section 4.1 that the age-unrestricted problem MSL remains NP-hard, using a reduction from Vertex Cover. In Section 4.2 we prove that this problem is in FPT, when parameterized by the number $|R|$ of terminals. Finally, using a parameterized reduction from Multicolored Clique, we prove in Section 4.3 that the age-restricted version MASL is W[1]-hard with respect to $|R|$, even if the maximum allowed age is a constant.

4.1 MSL is NP-complete

▶ **Theorem 13** ($\star$). *MSL is NP-complete.*

Proof sketch. MSL is clearly contained in NP. To prove that the MSL is NP-hard we provide a polynomial-time reduction from the NP-complete Vertex Cover problem [24].

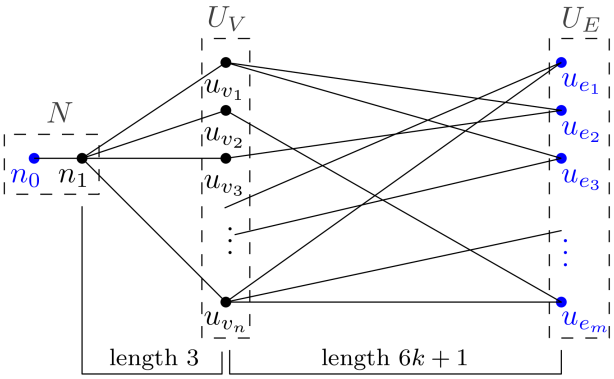

Figure 4 An example of construction of the input graph for MSL.

Vertex Cover
Input: A static graph $G = (V, E)$, a positive integer k.
Question: Does there exist a subset of vertices $S \subseteq V$ such that $|S| = k$ and $\forall e \in E, e \cap S \neq \emptyset$.

Let (G, k) be an input of the Vertex Cover problem and denote $|V(G)| = n, |E(G)| = m$. We assume w.l.o.g. that G does not admit a vertex cover of size $k-1$. We construct (G^*, R^*, k^*), the input of MSL using the following procedure. The vertex set $V(G^*)$ consists of the following vertices:

- two starting vertices $N = \{n_0, n_1\}$,
- a “vertex-vertex” corresponding to every vertex of G: $U_V = \{u_v | v \in V(G)\}$,
- an “edge-vertex” corresponding to every edge of G: $U_E = \{u_e | e \in E(G)\}$,
- $2n + 12m \cdot k$ “dummy” vertices.

The edge set $E(G^*)$ consists of the following edges:

- an edge between starting vertices, i.e., $n_0 n_1$,
- a path of length 3 between a starting vertex n_1 and every vertex-vertex $u_v \in U_V$ using 2 dummy vertices, and
- for every edge $e = vw \in E(G)$ we connect the corresponding edge-vertex u_e with the vertex-vertices u_v and u_w, each with a path of length $6k+1$ using $6k$ dummy vertices.

We set $R^* = \{n_0\} \cup U_E$ and $k^* = 6k + 2m(6k+1) + 1$. This finishes the construction. It is not hard to see that this construction can be performed in polynomial time. For an illustration see Figure 4. Note that any two paths in G^* can intersect only in vertices from $N \cup U_V \cup U_E$ and not in any of the dummy vertices. At the end G^* is a graph with $3n + m(12k+1) + 2$ vertices and $1 + 3n + 2m(6k+1)$ edges.

In the full proof we prove that (G, k) is a YES instance of the Vertex Cover if and only if (G^*, R^*, k^*) is a YES instance of the MSL. ◀

4.2 An FPT-algorithm for MSL with respect to the number of terminals

In this section we provide an FPT-algorithm for MSL, parameterized by the number $|R|$ of terminals. The algorithm is based on a crucial structural property of minimum solutions for MSL: there always exists a minimum labeling λ that labels the edges of a subtree of the input graph (where every leaf is a terminal vertex), and potentially one further edge that forms a C_4 with three edges of the subtree.

Intuitively speaking, we can use an FPT-algorithm for Steiner Tree parameterized by the number of terminals [14] to reveal a subgraph of the MSL instance that we can optimally label using Theorem 5. Since the number of terminals in the created Steiner Tree instance is larger than the number of terminals in the MSL instance by at most a constant, we obtain an FPT-algorithm for MSL parameterized by the number of terminals.

▶ **Lemma 14** ($\star$). *Let $G = (V, E)$ be a graph, $R \subseteq V$ a set of terminals, and k be an integer such that (G, R, k) is a YES instance of MSL and $(G, R, k-1)$ is a NO instance of MSL.*

- *If k is odd, then there is a labeling λ of size k for G such that the edges labeled by λ form a tree, and every leaf of this tree is a vertex in R.*
- *If k is even, then there is a labeling λ of size k for G such that the edges labeled by λ form a graph that is a tree with one additional edge that forms a C_4, and every leaf of the tree is a vertex in R.*

The main idea for the proof of Lemma 14 is as follows. Given a solution labeling λ, we fix one terminal r^* and then (i) we consider the minimum subtree in which r^* can reach all other terminal vertices and (ii) we consider the minimum subtree in which all other terminal vertices can reach r^*. Intuitively speaking, we want to label the smaller one of those subtrees using Theorem 5 and potentially adding an extra edge to form a C_4; we then argue that the obtained labeling does not use more labels than λ. To do that, and to detect whether it is possible to add an edge to create a C_4, we make a number of modifications to the trees until we reach a point where we can show that our solution is correct.

Having Lemma 14, we can now give our algorithm for MSL. As mentioned before, it uses an FPT-algorithm for Steiner Tree parameterized by the number of terminals [14] as a subroutine.

▶ **Theorem 15** ($\star$). *MSL is in FPT when parameterized by the number of terminals.*

4.3 Parameterized Hardness of MASL

Note that, since MASL generalizes both MSL and MAL, NP-hardness of MASL is already implied by both Theorems 12 and 13. In this section, we prove that MASL is W[1]-hard when parameterized by the number $|R|$ of the terminals, even if the restriction a on the age is a constant. To this end, we provide a parameterized reduction from Multicolored Clique. This, together with Theorem 15, implies that MASL is strictly harder than MSL (parameterized by the number $|R|$ of terminals), unless FPT=W[1].

▶ **Theorem 16** ($\star$). *MASL is W[1]-hard when parameterized by the number $|R|$ of the terminals, even if the restriction a on the age is a constant.*

Note here that, in the constructed instance of MASL in the proof of Theorem 16, the number of labels is also upper-bounded by a function of the number of colors in the instance of Multicolored Clique. Therefore the proof of Theorem 16 implies also the next result, which is even stronger (since in every solution of MASL the number of time-labels is lower-bounded by a function of the number $|R|$ of terminals).

▶ **Corollary 17.** *MASL is W[1]-hard when parameterized by the number k of time-labels, even if the restriction a on the age is a constant.*

5 Concluding remarks

Several open questions arise from our results. As we pointed out in Lemma 4, $\kappa(C_n, d) = \Theta(n^2)$, while $\kappa(G, d) = O(n^2)$ for every graph G by Observation 3. For which graph classes $\mathcal{G}$ do we have $\kappa(G, d) = o(n^2)$ (resp. $\kappa(G, d) = O(n)$) for every $G \in \mathcal{G}$?

As we proved in Theorem 12, MAL is NP-complete when the upper age bound is equal to the diameter d of the input graph G. In other words, it is NP-hard to compute $\kappa(G, d)$. On the other hand, $\kappa(G, 2r)$ can be easily computed in polynomial time, where r is the *radius* of G. Indeed, using the results of Section 2.1, it easily follows that, if G contains (resp. does not contain) a C_4 then $\kappa(G, 2r) = 2n - 4$ (resp. $\kappa(G, 2r) = 2n - 3$). For which values of an upper age bound a, where $d \leq a \leq 2r$, can $\kappa(G, a)$ computed efficiently? In particular, can $\kappa(G, d + 1)$ or $\kappa(G, 2r - 1)$ be computed in polynomial time for every undirected graph G?

With respect to parameterized algorithmics, is MAL FPT with respect to the number k of time-labels?

Beyond Value Iteration for Parity Games: Strategy Iteration with Universal Trees

Abstract

Parity games have witnessed several new quasi-polynomial algorithms since the breakthrough result of Calude et al. (STOC 2017). The combinatorial object underlying these approaches is a *universal tree*, as identified by Czerwiński et al. (SODA 2019). By proving a quasi-polynomial lower bound on the size of a universal tree, they have highlighted a barrier that must be overcome by all existing approaches to attain polynomial running time. This is due to the existence of worst case instances which force these algorithms to explore a large portion of the tree.

As an attempt to overcome this barrier, we propose a strategy iteration framework which can be applied on any universal tree. It is at least as fast as its value iteration counterparts, while allowing one to take bigger leaps in the universal tree. Our main technical contribution is an efficient method for computing the least fixed point of 1-player games. This is achieved via a careful adaptation of shortest path algorithms to the setting of ordered trees. By plugging in the universal tree of Jurdziński and Lazić (LICS 2017), or the Strahler universal tree of Daviaud et al. (ICALP 2020), we obtain instantiations of the general framework that take time $O(mn^2 \log n \log d)$ and $O(mn^2 \log^3 n \log d)$ respectively per iteration.

1 Introduction

A *parity game* is an infinite duration game between two players Even and Odd. It takes place on a sinkless directed graph $G = (V, E)$ equipped with a *priority* function $\pi : V \to \{1, 2, \ldots, d\}$. Let $n = |V|$ and $m = |E|$. The node set V is partitioned into $V_0 \sqcup V_1$ such that nodes in V_0 and V_1 are owned by Even and Odd respectively. The game starts when a token is placed on a node. In each turn, the owner of the current node moves the token along an outgoing arc to the next node, resulting in an infinite walk. If the highest priority occurring infinitely often in this walk is even, then Even wins. Otherwise, Odd wins.

By the positional determinacy of parity games [8], there exists a partition of V into two subsets from which Even and Odd can force a win respectively. The main algorithmic problem of parity games is to determine this partition, or equivalently, to decide the winner given a starting node. This is a notorious problem that lies in NP $\cap$ co-NP [9], and also in UP $\cap$ co-UP [14], with no known polynomial algorithm to date.

Due to its intriguing complexity status, as well as its fundamental role in automata theory and logic [9, 18], parity games have been intensely studied over the past three decades. Prior to 2017, algorithms for solving parity games, e.g. [27, 15, 26, 4, 24, 17, 25, 20, 2], are either exponential or subexponential. In a breakthrough result, Calude et al. [5] gave the first quasi-polynomial algorithm. Since then, many other quasi-polynomial algorithms [10, 16, 19, 22, 3] have been developed. Most of them have been unified by Czerwiński et al. [6] via the concept of a *universal tree*. A universal tree is an ordered tree into which every ordered tree of a certain size can be isomorphically embedded. They proved a quasi-polynomial lower bound on the size of a universal tree.

Value iteration. The starting point of this paper is the classic *progress measure* algorithm [15, 16] for solving parity games. It belongs to a broad class of algorithms called *value iteration* – a well-known method for solving more general games on graphs such as mean payoff games and stochastic games. In value iteration, every node v in G is assigned a value $\mu(v) \in \mathcal{V}$ from some totally ordered set $\mathcal{V}$, and the values are locally improved until we reach the *least fixed point* of a set of operators associated with the game. The set $\mathcal{V}$ is called the *value domain*, which is usually a bounded set of real numbers or integers. For the progress measure algorithm, its value domain is the set of leaves $L(T)$ in a universal tree T. As the values are monotonically improved, the running time is proportional to $|L(T)|$. The first progress measure algorithm of Jurdziński [15] uses a perfect n-ary tree, which runs in exponential time. Its subsequent improvement by Jurdziński and Lazić [16] uses a quasi-polynomial-sized tree, which runs in $n^{\log(d/\log n)+O(1)}$ time.

Despite having good theoretical efficiency, the progress measure algorithm is not robust against its worst-case behaviour. In fact, it is known to realize its worst-case running time on very simple instances. As an example, let (G, π) be an arbitrary instance with maximum priority d, with d being even. For a small odd constant k, if we add two nodes of priority k as shown in Figure 1, then the progress measure algorithm realizes its worst-case running time. This is because the values of those nodes are updated superpolynomially many times.

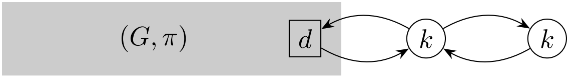

Figure 1 A worst-case construction for the progress measure algorithm. Nodes in V_0 and V_1 are drawn as squares and circles, respectively.

Strategy iteration. A different but related method for solving games on graphs is *strategy iteration*. For a parity game (G, π), a *(positional) strategy* τ for a player (say Odd) is a choice of an outgoing arc from every node in V_1. Removing the unchosen outgoing arcs from every node in V_1 results in a *strategy subgraph* $G_\tau \subseteq G$. A general framework for strategy iteration is given, e.g., in [12]. Following that exposition, to rank the strategies for Odd, one fixes a suitable value domain $\mathcal{V}$ and associates a valuation $\mu : V \to \mathcal{V}$ to each strategy. This induces a partial order over the set of strategies for Odd. Note that most valuations used in the literature can be thought of as fixed points of a set of operators associated with the

1-player game (G_τ, π) for Even. In every iteration, the algorithm maintains a strategy τ for Odd and its corresponding valuation $\mu : V \to \mathcal{V}$. Based on a *pivot rule*, it modifies τ to a better strategy τ', and updates μ to the valuation μ' of τ'. Note that $\mu' \geq \mu$. This process is repeated until we reach the optimal strategy for Odd.

Originally introduced by Hoffman and Karp for stochastic games [13], variants of strategy iteration for parity games have been developed [23, 26, 4, 24]. They usually perform well in practice, but tedious constructions of their worst case (sub)exponential complexity are known [11]. Motivated by the construction of small universal trees [16, 7], a natural question is whether there exists a strategy iteration algorithm with value domain $L(T)$ for a universal tree T. It is not hard to see that with value domain $L(T)$, unfortunately, the fixed point of a 1-player game (G_τ, π) may not be unique. Moreover, in a recent thesis [21], Ohlmann showed that a valuation that is fit for strategy iteration cannot be defined using $L(T)$.

Our contribution. We show that an adaptation of strategy iteration with value domain $L(T)$ is still possible. To circumvent the impossibility result of Ohlmann [21], we slightly alter the strategy iteration framework as follows. After pivoting to a strategy τ' in an iteration, we update the current node labeling μ to the least fixed point of $(G_{\tau'}, \pi)$ that is *pointwise at least* μ. In other words, we force μ to increase (whereas this happens automatically in the previous framework). Since the fixed point of a 1-player game may not be unique, this means that we may encounter a strategy more than once during the course of the algorithm. The motivation of our approach comes from tropical geometry, as discussed in the full version.

To carry out each iteration efficiently, we give a combinatorial method for computing the least fixed point of 1-player games with value domain $L(T)$. It relies on adapting the classic techniques of label-correcting and label-setting from the shortest path problem to the setting of ordered trees. When T is instantiated as a specific universal tree constructed in the literature, we obtain the following running times:

- The universal tree of Jurdziński and Lazić [16] takes $O(mn^2 \log n \log d)$.
- The Strahler universal tree of Daviaud et al. [7] takes $O(mn^2 \log^3 n \log d)$.
- The perfect n-ary tree of height $d/2$ takes $O(d(m + n \log n))$.

The total number of strategy iterations is trivially bounded by $n|L(T)|$, the same bound for the progress measure algorithm. Whereas we do not obtain a strict improvement over previous running time bounds, it is conceivable that our algorithm would terminate in fewer iterations than the progress measure algorithm on most examples. Moreover, our framework provides large flexibility in the choice of pivot rules. Identifying a pivot rule that may provide strictly improved (and possibly even polynomial) running time is left for future research.

Computing the least fixed point of 1-player games. Let (G_τ, π) be a 1-player game for Even, and μ^* be its least fixed point with value domain $L(T)$ for some universal tree T. Starting from $\mu(v) = \min L(T)$ for all $v \in V$, the progress measure algorithm successively lifts the label of a node based on the labels of its out-neighbours until μ^* is reached. However, this is not polynomial in general, even on 1-player games. So, instead of approaching μ^* from below, we approach it from above. This is reminiscent of shortest path algorithms, where node labels form upper bounds on the shortest path distances throughout the algorithm. In a label-correcting method like the Bellman–Ford algorithm, to compute shortest paths to a target node t, the label at t is initialized to 0, while the label at all other nodes is initialized to $+\infty$. By iteratively checking if an arc violates feasibility, the node labels are monotonically decreased. We refer to Ahuja et al. [1] for an overview on label-correcting and label-setting techniques for computing shortest paths.

In our setting, the role of the target node t is replaced by a (potentially empty) set of *even* cycles in G_τ. A cycle is said to be *even* if its maximum priority is even. However, this set is not known to us a priori. To overcome this issue, we define *base nodes* as candidate target nodes. A node $w \in V$ is a *base node* if it *dominates* an even cycle in G_τ, that is, it is a node with the highest priority in the cycle. Note that $\pi(w)$ is even.

To run a label-correcting method, we need to assign initial labels ν to the nodes in G_τ. The presumably obvious choice is to set $\nu(w) \leftarrow \min L(T)$ if w is a base node, and $\nu(w) \leftarrow \top$ otherwise, where $\top$ is bigger than every element in $L(T)$ ($\top$ is analogous to $+\infty$ for real numbers). However, this only works when T is a perfect n-ary tree. For a more complicated universal tree, the number of children at each internal vertex of T is not the same. Hence, it is possible to have $\nu(w) < \mu^*(w)$ for a base node w. We also cannot make $\nu(w)$ too large, as otherwise we may converge to a fixed point that is not pointwise minimal.

To correctly initialize $\nu(w)$ for a base node w, let us consider the cycles dominated by w in G_τ. Every such cycle C induces a subgame (C, π) on which Even wins because C is even. The least fixed point of (C, π) consists of leaves of an ordered tree T_C of height $j := \pi(w)/2$. Initializing $\nu(w)$ essentially boils down to finding such a cycle C with the "narrowest" T_C. To this end, let $\mathcal{T}_j$ be the set of *distinct* subtrees of height j of our universal tree T. We will exploit the fact that $\mathcal{T}_j$ is a poset with respect to the partial order of embeddability. In particular, let $\mathcal{C}_j$ be a set of chains covering $\mathcal{T}_j$, and fix a chain $\mathcal{C}_j^k$ in $\mathcal{C}_j$. We define the *width* of a cycle C as the "width" of the smallest tree in $\mathcal{C}_j^k$ into which T_C is embeddable. Then, we show that our problem reduces to finding a minimum width cycle dominated by w in G_τ.

To solve the latter problem, we construct an arc-weighted *auxiliary digraph* D on the set of base nodes. Every arc uv in D represents a path from base node u to base node v in G_τ, in such a way that minimum bottleneck cycles in D correspond to minimum width cycles in G_τ. It follows that the desired cycle C can be obtained by computing a minimum bottleneck cycle in D containing w. After getting C, we locate the corresponding subtree T' of T into which T_C is embeddable. Then, the label at w is initialized as $\nu(w) \leftarrow \min L(T')$.

With these initial labels, we show that a generic label-correcting procedure returns the desired least fixed point μ^* in $O(mn)$ time. The overall running time of this label-correcting method is dominated by the initialization phase, whose running time is proportional to the size of the chain cover $\mathcal{C}_j$. We prove that the quasi-polynomial universal trees constructed in the literature [16, 7] admit small chain covers. Using this result, we then give efficient implementations of our method for these trees.

In the full version of the paper, we also develop a label-setting method for computing μ^*, which is faster but only applicable when T is a perfect n-ary tree. Unlike the label-correcting approach, in a label-setting method such as Dijkstra's algorithm, the label of a node is fixed in each iteration. In the shortest path problem, Dijkstra's algorithm selects a node with the smallest label to be fixed in every iteration. When working with labels given by the leaves of a universal tree, this criterion does not work anymore. Let H be the subgraph of G_τ obtained by deleting all the base nodes. For $p \in \mathbb{N}$, let H_p be the subgraph of H induced by the nodes with priority at most p. We construct a suitable potential function by interlacing each node label with a tuple that encodes the topological orders in $H_2, H_4, \ldots$. In every iteration, a node with the smallest potential is selected, and its label is fixed.

Paper organization. In Section 2, we introduce notation and provide the necessary preliminaries on parity games and universal trees. Section 3 contains our strategy iteration framework based on universal trees. In Section 4, we give a label-correcting method for computing the least fixed point of 1-player games. The label-setting method, on the other hand, is given in the full version. Missing proofs can also be found in the full version.

2 Preliminaries on Parity Games and Universal Trees

For $d \in \mathbb{N}$, let $[d] = \{1, 2, \ldots, d\}$. For a graph G, we use $V(G)$ as its vertex set, and $E(G)$ as its edge set. A parity game instance is given by (G, π), where $G = (V, E)$ is a sinkless directed graph with $V = V_0 \sqcup V_1$, and $\pi : V \to [d]$ is a priority function. Without loss of generality, we may assume that d is even. In this paper, we are only concerned with positional strategies. A *strategy* for Odd is a function $\tau : V_1 \to V$ such that $v\tau(v) \in E$ for all $v \in V_1$. Its *strategy subgraph* is $G_\tau = (V, E_\tau)$, where $E_\tau := \{vw \in E : v \in V_0\} \cup \{v\tau(v) : v \in V_1\}$. A strategy for Even and its strategy subgraph are defined analogously. We always denote a strategy for Even as σ, and a strategy for Odd as τ. If we fix a strategy τ for Odd, the resulting instance (G_τ, π) is a *1-player game* for Even.

For the sake of brevity, we overload the priority function π as follows. Given a subgraph $H \subseteq G$, let $\pi(H)$ be the highest priority in H. The subgraph H is said to be *even* if $\pi(H)$ is even, and *odd* otherwise. For a fixed π, we denote by $\Pi(H)$ the set of nodes with the highest priority in H. If $v \in \Pi(H)$, we say that v *dominates* H. For $p \in [d]$, H_p refers to the subgraph of H induced by nodes with priority at most p. For a node v, let $\delta^-_H(v)$ and $\delta^+_H(v)$ be the incoming and outgoing arcs of v in H respectively. Similarly, let $N^-_H(v)$ and $N^+_H(v)$ be the in-neighbors and out-neighbors of v in H respectively. When H is clear from context, we will omit it from the subscripts.

The win of a player can be certified by *node labels* from a *universal tree*, as stated in Theorem 3. We give the necessary background for this now.

2.1 Ordered Trees and Universal Trees

An *ordered tree* T is a prefix-closed set of tuples, whose elements are drawn from a linearly ordered set M. The linear order of M lexicographically extends to T. Equivalently, T can be thought of as a rooted tree, whose root we denote by r. Under this interpretation, elements in M correspond to the branching directions at each vertex of T (see Figures 2 and 3 for examples). Every tuple then corresponds to a vertex $v \in V(T)$. This is because the tuple can be read by traversing the unique r-v path in T. Observe that v is an h-tuple if and only if v is at depth h in T. In particular, r is the empty tuple.

In this paper, we always use the terms "vertex" and "edge" when referring to an ordered tree T. The terms "node" and "arc" are reserved for the game graph G.

Given an ordered tree T of height h, let $L(T)$ be the set of leaves in T. For convenience, we assume that every leaf in T is at depth h throughout. The tuple representing a leaf $\xi \in L(T)$ is denoted as $\xi = (\xi_{2h-1}, \xi_{2h-3}, \ldots, \xi_1)$, where $\xi_i \in M$ for all i. We refer to ξ_{2h-1} as the *first* component of ξ, even though it has index $2h - 1$. For a fixed $p \in [2h]$, the *p-truncation* of ξ is $\xi|_p := \begin{cases} (\xi_{2h-1}, \xi_{2h-3}, \ldots, \xi_{p+1}), & \text{if } p \text{ is even} \\ (\xi_{2h-1}, \xi_{2h-3}, \ldots, \xi_p), & \text{if } p \text{ is odd.} \end{cases}$
In other words, the p-truncation of a tuple is obtained by deleting the components with index less than p. Note that a truncated tuple is an ancestor of the untruncated tuple in T.

▶ **Definition 1.** *Given ordered trees T and T', we say that T* embeds into *T' (denoted $T \sqsubseteq T'$) if there exists an* injective *and* order-preserving *homomorphism from T to T' such that leaves in T are mapped to leaves in T'. Formally, this is an injective function $f : V(T) \to V(T')$ which satisfies the following properties:*

1. *For all $u, v \in V(T)$, $uv \in E(T)$ implies $f(u)f(v) \in E(T')$;*
2. *For all $u, v \in V(T)$, $u \le v$ implies $f(u) \le f(v)$.*
3. *$f(u) \in L(T')$ for all $u \in L(T)$.*

We write $T \equiv T'$ if $T \sqsubseteq T'$ and $T' \sqsubseteq T$. Also, $T \sqsubset T'$ if $T \sqsubseteq T'$ and $T \not\equiv T'$.

In the definition above, since f is order-preserving, the children of every vertex in T are mapped to the children of its image injectively such that their order is preserved. As an example, the tree in Figure 3 embeds into the tree in Figure 2. It is easy to verify that $\sqsubseteq$ is a partial order on the set of all ordered trees.

▶ **Definition 2.** *An* (ℓ, h)-universal tree *is an ordered tree T' of height h such that $T \sqsubseteq T'$ for every ordered tree T of height h and with at most ℓ leaves, all at depth exactly h.*

The simplest example of an (ℓ, h)-universal tree is the perfect ℓ-ary tree of height h, which we call a *perfect universal tree*. The linearly ordered set M for this tree can be chosen as $\{0, 1, \ldots, \ell - 1\}$ (see Figure 2 for an example). It has ℓ^h leaves, which grows exponentially with h. Jurdziński and Lazić [16] constructed an (ℓ, h)-universal tree with at most $\ell^{\log h + O(1)}$ leaves, which we call a *succinct universal tree*. In this tree, every leaf ξ corresponds to an h-tuple of binary strings with at most $\lfloor \log(\ell) \rfloor$ bits in total[1]. We use $|\xi|$ and $|\xi_i|$ to denote the total number of bits in ξ and ξ_i respectively. The linearly ordered set M for this tree consists of finite binary strings, where $\varepsilon \in M$ is the empty string (see Figure 3 for an example). For any pair of binary strings $s, s' \in M$ and a bit b, the linear order on M is defined as $0s < \varepsilon < 1s'$ and $bs < bs' \iff s < s'$.

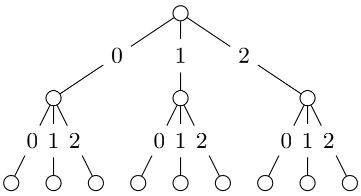

Figure 2 The perfect (3,2)-universal tree.

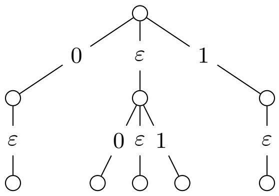

Figure 3 The succinct (3,2)-universal tree.

2.2 Node Labelings from Universal Trees

Let (G, π) be a parity game instance and T be an ordered tree of height $d/2$. We augment the set of leaves with an extra *top* element $\top$, denoted $\bar{L}(T) := L(T) \cup \{\top\}$, such that $\top > v$ for all $v \in V(T)$. We also set $\top|_p := \top$ for all $p \in [d]$. A function $\mu : V \to \bar{L}(T)$ which maps the nodes in G to $\bar{L}(T)$ is called a *node labeling*. For a subgraph H of G, we say that μ is *feasible in H* if there exists a strategy $\sigma : V_0 \to V$ for Even with $v\sigma(v) \in E(H)$ whenever $\delta^+_H(v) \neq \emptyset$, such that the following condition holds for every arc vw in $H \cap G_\sigma$:

- If $\pi(v)$ is even, then $\mu(v)|_{\pi(v)} \geq \mu(w)|_{\pi(v)}$.
- If $\pi(v)$ is odd, then $\mu(v)|_{\pi(v)} > \mu(w)|_{\pi(v)}$ or $\mu(v) = \mu(w) = \top$.

An arc vw which does not satisfy the condition above is called *violated* (with respect to μ). On the other hand, if $\mu(v)$ is the smallest element in $\bar{L}(T)$ such that vw is non-violated, then vw is said to be *tight*. Any arc which is neither tight nor violated is called *loose*. We say that a subgraph is tight if it consists of tight arcs.

In the literature, a node labeling which is feasible in G is also called a *progress measure*. The node labeling given by $\mu(v) = \top$ for all $v \in V$ is trivially feasible in G. However, we are primarily interested in progress measures with minimal top support, i.e. such that the set of nodes having label $\top$ is inclusion-wise minimal.

[1] A slightly looser bound of $\lceil \log \ell \rceil$ was derived in [16, Lemma 1]. It can be strengthened to $\lfloor \log \ell \rfloor$ with virtually no change in the proof.

▶ **Theorem 3** ([15, Corollaries 7–8]). *Given an $(n, d/2)$-universal tree T, let $\mu^* : V \to \bar{L}(T)$ be a node labeling which is feasible in G and has minimal top support. Then, Even wins from $v \in V$ if and only if $\mu^*(v) \neq \top$.*

The above theorem formalizes the following intuition: nodes with smaller labels are more advantageous for Even to play on. Note that if μ is a minimal node labeling which is feasible in G, i.e. μ' is infeasible in G for all $\mu' < \mu$, then there exists a strategy σ for Even such that $v\sigma(v)$ is tight for all $v \in V_0$. The next observation is well-known (see, e.g., [16, Lemma 2]) and follows directly from the definition of feasibility.

▶ **Lemma 4** (Cycle Lemma). *Let μ be a node labeling and C be a cycle such that $\mu(v) \neq \top$ for all $v \in V(C)$. If μ is feasible in C, then C is even. If C is also tight, then $\mu(v) = \mu(w)$ for all $v, w \in \Pi(C)$.*

We assume to have access to the following algorithmic primitive, whose running time we denote by $\gamma(T)$. Its implementation depends on the ordered tree T. For instance, $\gamma(T) = O(d)$ if T is a perfect $(n, d/2)$-universal tree. If T is a succinct $(n, d/2)$-universal tree, Jurdziński and Lazić [16, Theorem 7] showed that $\gamma(T) = O(\log n \log d)$.

Tighten(μ, vw)

Given a node labeling $\mu : V \to \bar{L}(T)$ and an arc $vw \in E$, return the unique element $\xi \in \bar{L}(T)$ such that vw is tight after setting $\mu(v)$ to ξ.

Given a node labeling $\mu : V \to \bar{L}(T)$ and an arc $vw \in E$, let $\mathrm{lift}(\mu, vw)$ be the smallest element $\xi \in \bar{L}(T)$ such that $\xi \geq \mu(v)$ and vw is not violated after setting $\mu(v)$ to ξ. Observe that if vw is violated, $\mathrm{lift}(\mu, vw)$ is given by Tighten(μ, vw). Otherwise, it is equal to $\mu(v)$. Hence, it can be computed in $\gamma(T)$ time.

Let $\mathcal{L}$ be the finite lattice of node labelings mapping V to $\bar{L}(T)$. For a sinkless subgraph $H \subseteq G$, consider the following operators. For every node $v \in V_0$, define $\mathrm{Lift}_v : \mathcal{L} \times V \to \bar{L}(T)$ as $\mathrm{Lift}_v(\mu, u) := \min_{vw \in E(H)} \mathrm{lift}(\mu, vw)$ if $u = v$, and $\mu(u)$ otherwise. For every arc $vw \in E(H)$ where $v \in V_1$, define $\mathrm{Lift}_{vw} : \mathcal{L} \times V \to \bar{L}(T)$ as $\mathrm{Lift}_{vw}(\mu, u) := \mathrm{lift}(\mu, vw)$ if $u = v$, and $\mu(u)$ otherwise. We denote $\mathcal{H}^{\uparrow} = \{\mathrm{Lift}_v : v \in V_0\} \cup \{\mathrm{Lift}_{vw} : v \in V_1\}$ as the operators in H. Since they are inflationary and monotone, for any $\mu \in \mathcal{L}$, the *least* simultaneous fixed point of $\mathcal{H}^{\uparrow}$ that is *pointwise at least* μ exists. It is denoted as $\mu^{\mathcal{H}^{\uparrow}}$. Note that a node labeling is a simultaneous fixed point of $\mathcal{H}^{\uparrow}$ if and only if it is feasible in H. The *progress measure algorithm* [15, 16] is an iterative application of the operators in $\mathcal{G}^{\uparrow}$ to μ to obtain $\mu^{\mathcal{G}^{\uparrow}}$.

3 Strategy Iteration with Tree Labels

In this section, we present a strategy iteration algorithm (Algorithm 1) whose pivots are guided by a universal tree. It takes as input an instance (G, π), a universal tree T, and an initial strategy τ_1 for Odd. Throughout, it maintains a node labeling $\mu : V \to \bar{L}(T)$, initialized as the least simultaneous fixed point of $\mathcal{G}^{\uparrow}_{\tau_1}$. At the start of every iteration, the algorithm maintains a strategy τ for Odd, and a node labeling $\mu : V \to \bar{L}(T)$ which is feasible in G_τ. Furthermore, there are no loose arcs in G_τ with respect to μ. So, every arc in G_τ is either tight (usable by Even in her counterstrategy σ) or violated (not used by Even). Note that our initial node labeling satisfies these conditions with respect to τ_1.

For $v \in V_1$, we call a violated arc $vw \in E$ with respect to μ *admissible* (as it admits Odd to perform an improvement). If there are no admissible arcs in G, then the algorithm terminates. In this case, μ is feasible in G. Otherwise, Odd pivots to a new strategy τ' by

Algorithm 1 Strategy iteration with tree labels: (G, π) instance, T universal tree, τ_1 initial strategy for Odd.

```
procedure StrategyIteration($(G, \pi), T, \tau_1$)
    $\mu(v) \leftarrow \min L(T)\ \forall v \in V$
    $\tau \leftarrow \tau_1$, $\mu \leftarrow \mu^{\mathcal{G}^{\uparrow}_{\tau}}$
    while $\exists$ an admissible arc in $G$ with respect to $\mu$ do
        Pivot to a strategy $\tau'$ by selecting admissible arc(s)        ▷ requires a pivot rule
        $\tau \leftarrow \tau'$, $\mu \leftarrow \mu^{\mathcal{G}^{\uparrow}_{\tau}}$
    return $\tau$, $\mu$
```

switching to admissible arc(s). The choice of which admissible arc(s) to pick is governed by a *pivot rule*. Then, μ is updated to $\mu^{\mathcal{G}^{\uparrow}_{\tau'}}$. Due to the minimality of $\mu^{\mathcal{G}^{\uparrow}_{\tau'}}$, there are no loose arcs in $G_{\tau'}$ with respect to $\mu^{\mathcal{G}^{\uparrow}_{\tau'}}$, so this invariant continues to hold in the next iteration.

The correctness of Algorithm 1 follows from the Knaster–Tarski Theorem. We remark that a strategy τ may occur more than once during the course of the algorithm, as mentioned in the description of strategy iteration in Section 1. This is because the fixed points of $\mathcal{G}^{\uparrow}_{\tau}$ are not necessarily unique. See Figure 4 for an example run with a succinct universal tree.

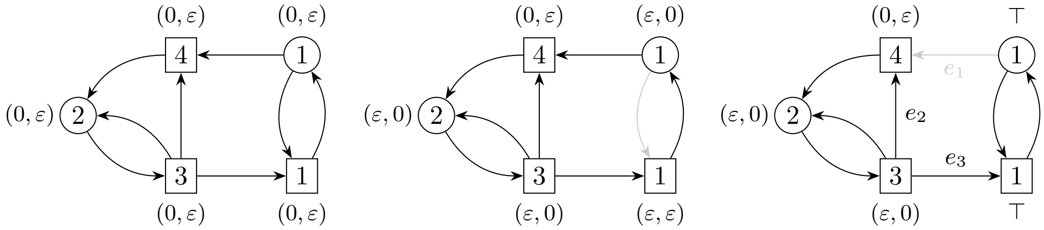

Figure 4 An example run of Algorithm 1 with the succinct (3,2)-universal tree. The left figure depicts a game instance (nodes in V_0 and V_1 are drawn as squares and circles respectively). The next two figures show Odd's strategy and the node labeling at the start of Iteration 1 and 2. Arcs not selected by Odd are greyed out. In the right figure, e_1 is loose, e_2 is tight, and e_3 is violated.

4 Computing the Least Fixed Point of 1-Player Games

Let (G_τ, π) be a 1-player game for Even, and let $\mu \in \mathcal{L}$ be a node labeling such that there are no loose arcs in G_τ. In this section, we develop an efficient method for computing $\mu^{\mathcal{G}^{\uparrow}_{\tau}}$. We know that applying the operators in $\mathcal{G}^{\uparrow}_{\tau}$ to μ is not polynomial in general. So, we will approach $\mu^{\mathcal{G}^{\uparrow}_{\tau}}$ from above instead.

Given a node labeling $\nu : V \to \bar{L}(T)$ and an arc $vw \in E$, let $\mathrm{drop}(\nu, vw)$ be the largest element $\xi \in \bar{L}(T)$ such that $\xi \leq \nu(v)$ and vw is not loose after setting $\nu(v)$ to ξ. Observe that if vw is loose, then $\mathrm{drop}(\nu, vw)$ is given by $\textsc{Tighten}(\nu, vw)$. Otherwise, it is equal to $\nu(v)$. Hence, it can be computed in $\gamma(T)$ time.

We are ready to define the deflationary counterpart of Lift_{vw}. For every arc $vw \in E_\tau$, define the operator $\mathrm{Drop}_{vw} : \mathcal{L} \times V \to \bar{L}(T)$ as $\mathrm{Drop}_{vw}(\nu, u) := \mathrm{drop}(\nu, vw)$ if $u = v$, and $\nu(v)$ otherwise. For a subgraph $H \subseteq G_\tau$, we denote $\mathcal{H}^{\downarrow} = \{\mathrm{Drop}_e : e \in E(H)\}$ as the operators in H. Since they are deflationary and monotone, for any $\nu \in \mathcal{L}$, the *greatest* simultaneous fixed point of $\mathcal{H}^{\downarrow}$ that is *pointwise at most* ν exists. It is denoted as $\nu^{\mathcal{H}^{\downarrow}}$. Note that a node labeling is a simultaneous fixed point of $\mathcal{H}^{\downarrow}$ if and only if there are no loose arcs in H with respect to it.

Our techniques are inspired by the methods of *label-correcting* and *label-setting* for the shortest path problem. In the shortest path problem, we have a designated target node t whose label is initialized to 0. For us, the role of t is replaced by a (potentially empty) set of even cycles in G_τ, which we do not know a priori. So, we define a set of candidates nodes called *base nodes*, whose labels need to be initialized properly.

▶ **Definition 5.** *Given a 1-player game (G_τ, π) for Even, we call $v \in V$ a* base node *if $v \in \Pi(C)$ for some even cycle C in G_τ. Denote $B(G_\tau)$ as the set of base nodes in G_τ.*

The base nodes can be found by recursively decomposing G_τ into strongly connected components. Initially, for each strongly connected component K of G_τ, we delete $\Pi(K)$. If $\pi(K)$ is even and $|V(K)| > 1$, then $\Pi(K)$ are base nodes and we collect them. Otherwise, we ignore them. Then, we are left with a smaller subgraph of G, so we repeat the process. Using Tarjan's strongly connected components algorithm, this procedure takes $O(dm)$ time.

In the next subsection, we develop a label-correcting method for computing $\mu^{\mathcal{G}_\tau^\uparrow}$, and apply it to the quasi-polynomial universal trees constructed in the literature [16, 7]. The label-setting method, which is faster but only applicable to perfect universal trees, is deferred to the full version.

4.1 Label-Correcting Method

The Bellman–Ford algorithm for the shortest path problem is a well-known implementation of the generic label-correcting method [1]. We start by giving its analogue for ordered trees. Algorithm 2 takes as input a 1-player game (G_τ, π) for Even and a node labeling $\nu : V \to \bar{L}(T)$ from some ordered tree T. Like its classical version for shortest paths, the algorithm runs for $n - 1$ iterations. In each iteration, it replaces the tail label of every arc $e \in E_\tau$ by $\mathrm{drop}(\nu, e)$. Clearly, the running time is $O(mn\gamma(T))$. Moreover, if ν' is the returned node labeling, then $\nu' \geq \nu^{\mathcal{G}_\tau^\downarrow}$.

Algorithm 2 Bellman–Ford: (G_τ, π) 1-player game for Even, $\nu : V \to \bar{L}(T)$ node labeling from an ordered tree T.

```
procedure BellmanFord($((G, \pi), \nu)$)
    for $i = 1$ to $n - 1$ do
        for all $vw \in E$ do                          ▷ In any order
            $\nu(v) \leftarrow \mathrm{drop}(\nu, vw)$
    return $\nu$
```

Recall that we have a node labeling $\mu \in \mathcal{L}$ such that G_τ does not have loose arcs, and our goal is to compute $\mu^{\mathcal{G}_\tau^\uparrow}$. We first state a sufficient condition on the input node labeling ν such that Algorithm 2 returns $\mu^{\mathcal{G}_\tau^\uparrow}$. In the shortest path problem, we set $\nu(t) = 0$ at the target node t, and $\nu(v) = \infty$ for all $v \in V \setminus \{t\}$. When working with node labels given by an ordered tree, one has to ensure that the algorithm does not terminate with a fixed point larger than $\mu^{\mathcal{G}_\tau^\uparrow}$, motivating the following definition.

▶ **Definition 6.** *Given a node labeling $\mu \in \mathcal{L}$, the* threshold label *of a base node v is*

$$\hat{\mu}(v) := \min_{\tilde{\mu} \in \mathcal{L}} \{\tilde{\mu}(v) : \tilde{\mu}(v) \geq \mu(v) \text{ and } \tilde{\mu} \text{ is feasible in a cycle dominated by } v\} \quad .$$

The next lemma follows directly from the pointwise minimality of $\mu^{\mathcal{G}_\tau^\uparrow}(v)$.

▶ **Lemma 7.** *Let $\mu \in \mathcal{L}$ be a node labeling such that G_τ does not have loose arcs. For every base node $v \in B(G_\tau)$, we have $\widehat{\mu}(v) \geq \mu^{\mathcal{G}_\tau^\uparrow}(v)$.*

The next theorem shows that if we initialize the base nodes with their corresponding threshold labels, then Algorithm 2 returns $\mu^{\mathcal{G}_\tau^\uparrow}$. Even more, it suffices to have an initial node labeling $\nu \in \mathcal{L}$ such that $\mu^{\mathcal{G}_\tau^\uparrow}(v) \leq \nu(v) \leq \widehat{\mu}(v)$ for all $v \in B(G_\tau)$. For the other nodes $v \notin B(G_\tau)$, we can simply set $\nu(v) \leftarrow \top$.

▶ **Theorem 8.** *Let $\mu \in \mathcal{L}$ be a node labeling such that G_τ does not have loose arcs. Given $\nu \in \mathcal{L}$ where $\nu \geq \mu^{\mathcal{G}_\tau^\uparrow}$ and $\nu(v) \leq \widehat{\mu}(v)$ for all $v \in B(G_\tau)$, Algorithm 2 returns $\mu^{\mathcal{G}_\tau^\uparrow}$.*

Our strategy for computing such a ν is to find the cycles in Definition 6. In particular, for every base node $v \in B(G_\tau)$, we aim to find a cycle C dominated by v such that $\widehat{\mu}(v)$ can be extended to a node labeling that is feasible in C. To accomplish this goal, we first introduce the notion of *width* in Section 4.1.1, which allows us to evaluate how "good" a cycle is. It is defined using chains in the poset of subtrees of T, where the partial order is given by $\sqsubseteq$. Then, in Section 4.1.2, we show how to obtain the desired cycles by computing minimum bottleneck cycles on a suitably defined auxiliary digraph.

4.1.1 Width from a Chain of Subtrees in T

Two ordered trees T' and T'' are said to be *distinct* if $T' \not\equiv T''$ (not isomorphic in the sense of Definition 1). Let h be the height of our universal tree T. For $0 \leq j \leq h$, denote $\mathcal{T}_j$ as the set of distinct (whole) subtrees rooted at the vertices of depth $h - j$ in T. For example, $\mathcal{T}_h = \{T\}$, while $\mathcal{T}_0$ contains the trivial tree with a single vertex. Since we assumed that all the leaves in T are at the same depth, every tree in $\mathcal{T}_j$ has height j. We denote $\mathcal{T} = \cup_{j=0}^{h} \mathcal{T}_j$ as the union of all these subtrees. The sets $\mathcal{T}$ and $\mathcal{T}_j$ form posets with respect to the partial order $\sqsubseteq$. The next definition is the usual chain cover of a poset, where we additionally require that the chains form an indexed tuple instead of a set.

▶ **Definition 9.** *For $0 \leq j \leq h$, let $\mathcal{C}_j = (\mathcal{C}_j^0, \mathcal{C}_j^1, \dots, \mathcal{C}_j^\ell)$ be a tuple of chains in the poset $(\mathcal{T}_j, \sqsubseteq)$. We call $\mathcal{C}_j$ a* cover of $\mathcal{T}_j$ *if $\cup_{k=0}^{\ell} \mathcal{C}_j^k = \mathcal{T}_j$. A* cover of $\mathcal{T}$ *is a tuple $\mathcal{C} = (\mathcal{C}_0, \mathcal{C}_1, \dots, \mathcal{C}_h)$ where $\mathcal{C}_j$ is a cover of $\mathcal{T}_j$ for all $0 \leq j \leq h$. We refer to $\mathcal{C}_j$ as the* jth-subcover *of $\mathcal{C}$. Given a cover $\mathcal{C}$ of $\mathcal{T}$, we denote the trees in the chain $\mathcal{C}_j^k$ as $T_{0,j}^k \sqsubset T_{1,j}^k \sqsubset \cdots \sqsubset T_{|\mathcal{C}_j^k|-1,j}^k$.*

An example of an ordered tree with its cover is given in Figure 5. We are ready to introduce the key concept of this subsection.

▶ **Definition 10.** *Let $\mathcal{C}$ be a cover of $\mathcal{T}$. Let H be a subgraph of G_τ and $j = \lceil \pi(H)/2 \rceil$. For a fixed chain $\mathcal{C}_j^k$ in $\mathcal{C}_j$, the* kth-width *of H, denoted $\alpha_{\mathcal{C}}^k(H)$, is the smallest integer $i \geq 0$ such that there exists a node labeling $\nu : V(H) \to L(T_{i,j}^k)$ which is feasible in H. If i does not exist, then $\alpha_{\mathcal{C}}^k(H) = \infty$.*

Note that $T_{i,j}^k$ is the $(i+1)$-th smallest tree in the chain $\mathcal{C}_j^k$. We are mainly interested in the case when H is a cycle, and write $\alpha^k(H)$ whenever the cover $\mathcal{C}$ is clear from context. Observe that the definition above requires $\nu(v) \neq \top$ for all $v \in V(H)$. Hence, an odd cycle has infinite kth-width by the Cycle Lemma. As $(\mathcal{C}_j^k, \sqsubseteq)$ is a chain, for all finite $i \geq \alpha^k(H)$, there exists a node labeling $\nu : V(H) \to L(T_{i,j}^k)$ which is feasible in H. The next lemma illustrates the connection between the kth-width of an even cycle and its path decomposition.

▶ **Lemma 11.** *Let $\mathcal{C}$ be a cover of $\mathcal{T}$. For an even cycle C, let $\Pi(C) = \{v_1, v_2, \dots, v_\ell\}$ and $j = \pi(C)/2$. Decompose C into arc-disjoint paths $P_1, P_2, \dots, P_\ell$ such that each P_i ends at v_i. Then, $\alpha^k(C) = \max_{i \in [\ell]} \alpha^k(P_i)$ for all $0 \leq k < |\mathcal{C}_j|$.*

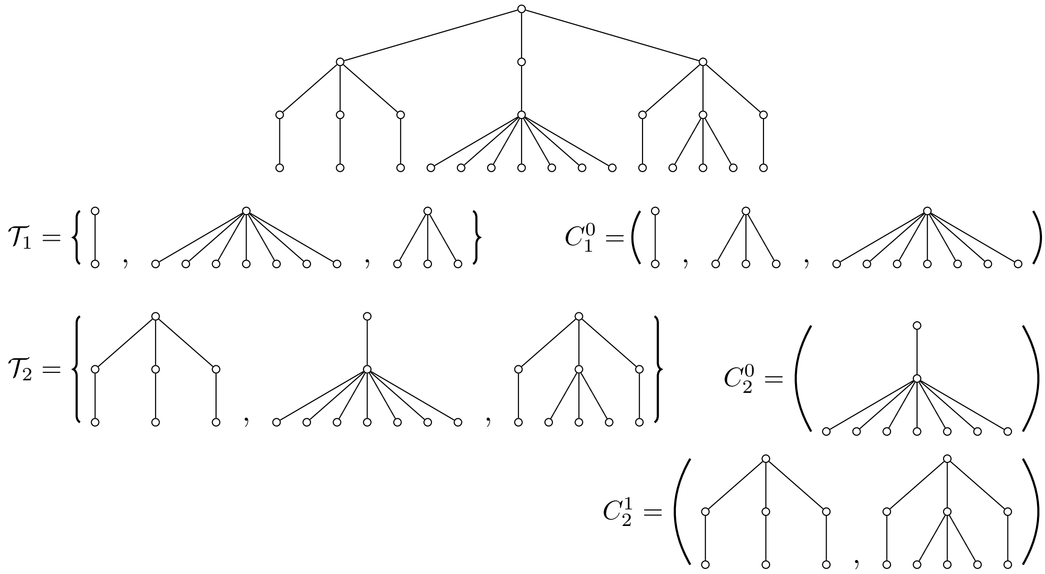

Figure 5 An ordered tree T of height 3, and a cover $\mathcal{C}_j$ of $\mathcal{T}_j$ for all $0 < j < 3$. Recall that $\mathcal{T}_j$ is the set of distinct subtrees of T rooted at depth $3 - j$, while $\mathcal{C}_j^k$ is the kth chain in $\mathcal{C}_j$.

For a base node $v \in B(G_\tau)$, let us consider the cycles in G_τ which are dominated by v. Among them, we are interested in finding one with the smallest kth-width. So, we extend the notion of kth-width to base nodes in the following way.

▶ **Definition 12.** *Let $\mathcal{C}$ be a cover of $\mathcal{T}$. Let $v \in B(G_\tau)$ be a base node and $j = \pi(v)/2$. For $0 \leq k < |\mathcal{C}_j|$, define the* kth-width *of v as $\alpha^k_{\mathcal{C}}(v) := \min\left\{\alpha^k_{\mathcal{C}}(C) : C \text{ is a cycle dominated by } v\right\}$.*

Again, we write $\alpha^k(v)$ whenever $\mathcal{C}$ is clear from context. Observe that $T^k_{\alpha^k(v),\pi(v)/2}$ is the smallest tree in the chain $\mathcal{C}^k_{\pi(v)/2}$ which can encode a node labeling that is feasible on some cycle dominated by v.

Given a leaf $\xi \in L(T)$ and integers $i, j, k \in \mathbb{Z}_{\geq 0}$, the following subroutine locates a subtree of T that is a member of the chain $\mathcal{C}^k_j$ and into which $T^k_{i,j}$ is embeddable.

Raise(ξ, i, j, k)

Given a leaf $\xi \in L(T)$ and integers $i, j, k \in \mathbb{Z}_{\geq 0}$, return the smallest leaf $\xi' \in L(T)$ such that (1) $\xi' \geq \xi$; and (2) ξ' is the smallest leaf in the subtree $T^k_{i',j}$ for some $i' \geq i$. If ξ' does not exist, then return $\top$.

Now, fix a base node $v \in B(G_\tau)$. For any $0 \leq k < |\mathcal{C}_{\pi(v)/2}|$, notice that the label returned by Raise$(\mu(v), \alpha^k(v), \frac{\pi(v)}{2}, k)$ is an upper bound on the threshold label $\widehat{\mu}(v)$. The smallest such label over all k is precisely the threshold label $\widehat{\mu}(v)$, as the next lemma shows.

▶ **Lemma 13.** *Fix $v \in B(G_\tau)$. Let ξ^k be the label returned by* Raise$(\mu(v), \alpha^k(v), \frac{\pi(v)}{2}, k)$ *for all $0 \leq k < |\mathcal{C}_{\pi(v)/2}|$. If there are no loose arcs in G_τ with respect to μ, then $\widehat{\mu}(v) = \min_k \xi^k$.*

The necessary number of chains in the subcover $\mathcal{C}_{\pi(v)/2}$ can be large if T is an arbitrary ordered tree. Fortunately, the universal trees constructed in the literature admit covers with small subcovers. In the full version, we prove that a succinct (n, h)-universal tree has a cover with only 1 chain per subcover, whereas a succinct Strahler (n, h)-universal tree (introduced by Daviaud et al. [7]) has a cover with at most $\log n$ chains per subcover.

Let $\rho(T, \mathcal{C})$ denote the running time of Raise. We provide efficient implementations of Raise for succinct universal trees and succinct Strahler universal trees in the full version. They have the same running time as Tighten, i.e., $\rho(T, \mathcal{C}) = O(\log n \log h)$.

4.1.2 Estimating the Width of Base Nodes

In light of the previous discussion, we can now focus on computing the kth-width of a base node $w \in B(G_\tau)$. Fix a $0 \leq k < |\mathcal{C}_{\pi(w)/2}|$. Since we ultimately need a label that lies between $\mu^{\mathcal{G}_\tau^\uparrow}(w)$ and $\widehat{\mu}(w)$ in order to initialize Algorithm 2, it suffices to compute a "good" under-estimation of $\alpha^k(w)$. In this subsection, we reduce this problem to computing a minimum bottleneck cycle in an auxiliary digraph D with nonnegative arc costs $c^k \geq 0$.

For a base node $w \in B(G_\tau)$, let K_w denote the strongly connected component containing w in $(G_\tau)_{\pi(w)}$, the subgraph of G_τ induced by nodes with priority at most $\pi(w)$. Let $K'_w \subseteq K_w$ be the subgraph obtained by deleting the incoming arcs $\delta^-(v)$ for all $v \in \Pi(K_w) \setminus \{w\}$. Then, we define J_w as the subgraph of K'_w induced by those nodes which can reach w in K'_w. These are the nodes which can reach w in K_w without encountering an intermediate node of priority $\pi(w)$.

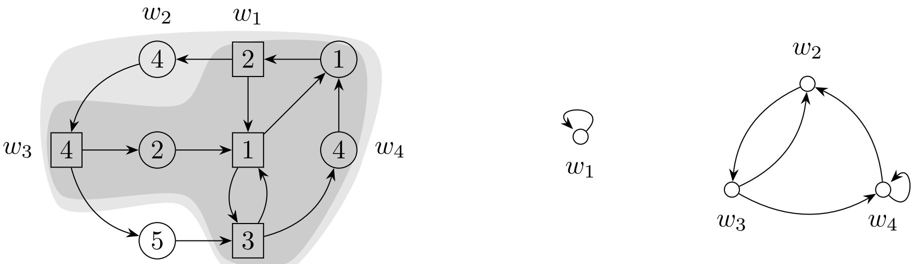

Figure 6 An example of a 1-player game (G_τ, π) for Even is given on the left, with its auxiliary digraph D on the right. Nodes in V_0 and V_1 are drawn as squares and circles respectively. Base nodes are labeled as w_1, w_2, w_3, w_4. The light gray region is K_{w_4}, while the dark gray region is J_{w_4}.

The auxiliary digraph D is constructed as follows. Its node set is $B(G_\tau)$. For every ordered pair (v, w) of base nodes where $\pi(v) = \pi(w)$, add the arc vw if v has an outgoing arc in J_w. Note that if $(v, w) \in D$, then v can reach w by only seeing smaller priorities on the intermediate nodes. As ordered pairs of the form (v, v) are also considered, D may contain self-loops. Observe that D is a disjoint union of strongly connected components, each of which consists of base nodes with the same priority (see Figure 6 for an example). For $w \in B(G_\tau)$, we denote D_w as the component in D which contains w.

To finish the description of D, it is left to assign the arc costs c^k. Note that the graph structure of D is independent of k. We give a range in which the cost of each arc should lie. Fix a base node $w \in B(G_\tau)$ and let $j = \pi(w)/2$. Recall that $\mathcal{J}_w^\downarrow = \{\text{Drop}_e : e \in E(J_w)\}$ is the set of Drop operators in the subgraph $J_w \subseteq G_\tau$. For each $0 \leq i < |\mathcal{C}_j^k|$, let $\lambda_{i,w}^k : V(J_w) \to \bar{L}(T_{i,j}^k)$ be the greatest simultaneous fixed point of $\mathcal{J}_w$ subject to $\lambda_{i,w}^k(w) = \min L(T_{i,j}^k)$. Then, for each arc $vw \in E(D)$, the lower and upper bounds of $c^k(vw)$ are given by

$$\begin{aligned} \underline{c}^k(vw) &:= \min\left\{i : \lambda_{i,w}^k(u) \neq \top \text{ for some } u \in N_{J_w}^+(v)\right\} \\ \bar{c}^k(vw) &:= \min\left\{\alpha^k(P) : P \text{ is a } u\text{-}w \text{ path in } J_w \text{ where } u \in N_{J_w}^+(v)\right\} \end{aligned} \tag{1}$$

respectively. The lower bound $\underline{c}^k(vw)$ is the smallest integer $i \geq 0$ such that the greatest simultaneous fixed point $\lambda_{i,w}^k$ assigns a non-top label to an out-neighbor of v in J_w. On the other hand, the upper bound $\bar{c}^k(vw)$ is the minimum kth-width of a path from an out-neighbor of v to w in J_w. Note that these quantities could be equal to $+\infty$.

▶ **Lemma 14.** *For every arc $vw \in E(D)$, we have $\underline{c}^k(vw) \le \overline{c}^k(vw)$.*

For a cycle C in D, its (bottleneck) c^k-*cost* is defined as $c^k(C) := \max_{e \in E(C)} c^k(e)$. Note that self-loops in D are considered cycles. The next theorem allows us to obtain the desired initial node labeling ν for Algorithm 2 by computing minimum bottleneck cycles in D.

▶ **Theorem 15.** *Let $\mathcal{C}$ be a cover of $\mathcal{T}$. Let $\mu \in \mathcal{L}$ be a node labeling such that G_τ does not have loose arcs. For a base node w, let c^k be arc costs in D_w such that $\underline{c}^k \le c^k \le \overline{c}^k$ for all $0 \le k < |\mathcal{C}_{\pi(w)/2}|$. For each k, let i^k be the minimum c^k-cost of a cycle containing w in D_w, and ξ^k be the label returned by* $\textsc{Raise}(\mu(w), i^k, \frac{\pi(w)}{2}, k)$. *Then, $\mu^{\mathcal{G}_\tau^\uparrow}(w) \le \min_k \xi^k \le \widehat{\mu}(w)$.*

4.1.3 The Label-Correcting Algorithm

The overall algorithm for computing $\mu^{\mathcal{G}_\tau^\uparrow}$ is given in Algorithm 3. The main idea is to initialize the labels on base nodes via the recipe given in Theorem 15, before running Algorithm 2. The labels on $V \setminus B(G_\tau)$ are initialized to $\top$. The auxiliary graph D serves as a condensed representation of the "best" paths between base nodes. The arc costs are chosen such that minimum bottleneck cycles in D give a good estimate on the width of base nodes.

Algorithm 3 Label-Correcting: (G_τ, π) 1-player game for Even, $\mathcal{C}$ cover of $\mathcal{T}$ for some universal tree T, $\mu : V \to \bar{L}(T)$ node labeling such that G_τ does not contain loose arcs.

```
procedure LabelCorrecting($(G_\tau, \pi), \mathcal{C}, \mu$)
    $\nu(v) \leftarrow \top$ for all $v \in V$
    Construct auxiliary digraph $D$
    for all components $H$ in $D$ do
        for $k = 0$ to $|\mathcal{C}_{\pi(H)/2}| - 1$ do
            Assign arc costs $c^k$ to $H$ where $\underline{c}^k \le c^k \le \overline{c}^k$
            for all $v \in V(H)$ do
                $i^k \leftarrow$ minimum $c^k$-cost of a cycle containing $v$ in $H$
                $\nu(v) \leftarrow \min(\nu(v), \textsc{Raise}(\mu(v), i^k, \frac{\pi(v)}{2}, k))$
    $\nu \leftarrow \textsc{BellmanFord}((G_\tau, \pi), \nu)$
    return $\nu$
```

In Algorithm 3, the arc costs c^k can be obtained using Algorithm 2. For each base node $w \in B(G_\tau)$, in order to compute $c^k(e)$ for all incoming arcs $e \in \delta_D^-(w)$, we run Algorithm 2 on the subgraph J_w for $|\mathcal{C}^k_{\pi(w)/2}|$ times. If the chain $\mathcal{C}^k_{\pi(w)/2}$ is too long, then this can be sped up using binary search. For specific families of trees such as succinct universal trees, one can compute c^k even faster. More details are given in the full version. Overall, this yields the following generic running time bound.

▶ **Theorem 16.** *In $O(mn^2\gamma(T) \cdot \max_{j,k} |\mathcal{C}_j| \min\{|\mathcal{C}_j^k|, n \log |\mathcal{C}_j^k|\} + n\rho(T, \mathcal{C}) \cdot \max_j |\mathcal{C}_j|)$ time, Algorithm 3 returns $\mu^{\mathcal{G}_\tau^\uparrow}$.*

As mentioned in Section 4.1.1, a succinct $(n, d/2)$-universal tree has a cover with 1 chain per subcover, while a succinct Strahler $(n, d/2)$-universal tree has a cover with at most $\log n$ chains per subcover. So, applying Algorithm 3 to these trees yields the following runtimes.

▶ **Corollary 17.** *For a succinct universal tree, $\mu^{\mathcal{G}_\tau^\uparrow}$ is returned in $O(mn^2 \log n \log d)$.*

▶ **Corollary 18.** *For a succinct Strahler universal tree, $\mu^{\mathcal{G}_\tau^\uparrow}$ is returned in $O(mn^2 \log^3 n \log d)$.*

Countdown μ-Calculus

Jędrzej Kołodziejski
University of Warsaw, Poland

Bartek Klin
University of Oxford, UK

Abstract

We introduce the countdown μ-calculus, an extension of the modal μ-calculus with ordinal approximations of fixpoint operators. In addition to properties definable in the classical calculus, it can express (un)boundedness properties such as the existence of arbitrarily long sequences of specific actions. The standard correspondence with parity games and automata extends to suitably defined countdown games and automata. However, unlike in the classical setting, the scalar fragment is provably weaker than the full vectorial calculus and corresponds to automata satisfying a simple syntactic condition. We establish some facts, in particular decidability of the model checking problem and strictness of the hierarchy induced by the maximal allowed nesting of our new operators.

1 Introduction

The modal μ-calculus [14] is a well-known logic for defining and verifying behavioural properties of state-and-transition systems. It extends propositional logic with basic next-step modalities and fixpoint operators to describe long-term behaviour. It is expressive enough to include other temporal logics such as CTL* as fragments, but it has good computational properties, and its simple syntax and semantics makes it a convenient formalism to study.

The μ-calculus has a straightforward inductively-defined semantics, but it is often useful to consider an alternative (but equivalent) semantics based on parity games. A formula φ together with a model $\mathcal{M}$ define a game between two players called ∀dam and ∃ve. Positions in the game are of the form (m, ψ) where m is a point in $\mathcal{M}$ and ψ is a subformula of φ, and moves are defined so that ∃ve has a winning strategy from (m, φ) if and only if φ holds in m. Among other advantages, the game-based semantics provides more efficient algorithms for model checking of μ-calculus formulas than an inductive computation of fixpoints [9].

The model component can be abstracted away from parity games. Indeed, a formula φ itself gives rise to an alternating parity automaton $\mathcal{A}_\varphi$ that recognizes models. The behaviour of an automaton on a model is defined in terms of a parity game, states of $\mathcal{A}_\varphi$ are subformulas of φ, and the transition relation is defined so that it accepts a model $\mathcal{M}$ rooted in a point m if and only if φ holds in m. The advantage of this is that $\mathcal{A}_\varphi$, while conceptually closer to a parity game, is a finite structure even if it is then applied to infinite models.

The modal μ-calculus is a rather expressive formalism: it can define all bisimulation-invariant properties definable in monadic second-order logic (MSO) [13], such as "there is an infinite path of τ-labeled edges". However, there are some properties of interest which are not definable even in MSO. Notable examples include (un)boundedness properties such as "for every number n, there is a path with at least n consecutive τ-labeled edges". An extension of

MSO called MSO+U, aimed at defining such properties, has been considered [6]. However, the satisfiability problem of MSO+U turned out to be undecidable even for word models [4]. Since the modal μ-calculus is a fragment of MSO, it is worthwhile to extend it with a mechanism for defining (un)boundedness properties, in the hope of retaining decidability.

In this paper we propose such an extension: the *countdown μ-calculus* μ^α-ML. In addition to μ-calculus operators, it features countdown operators μ^α and ν^α parametrized by ordinal numbers α. Instead of least and greatest fixpoints, they define ordinal approximations of those fixpoints. Intuitively, while the meaning of classical μ-calculus formulas $\mu x.\varphi(x)$ and $\nu x.\varphi(x)$ is defined by infinite unfolding of the formula φ until a fixpoint is reached, for $\mu^\alpha x.\varphi(x)$ and $\nu^\alpha x.\varphi(x)$ the unfolding stops after α steps (which makes a difference if α is smaller than the *closure ordinal* of φ). The classical fixpoint operators are kept but renamed to μ^∞ and ν^∞, to make clear the lack of any restrictions on the unfolding process.

An inductive definition of the semantics of countdown formulas is just as straightforward as in the classical case. With some more effort, we are able to formulate game-based semantics as well. We introduce *countdown games* and *countdown automata*, which are similar to parity games and alternating automata known from the classical setting, but are additionally equipped with counters that are decremented and reset by the two players according to specific rules. Intuitively, the counters say how many more times various ranks can be visited, in similar manner to the signatures introduced by Walukiewicz [17, Section 3]. A player responsible for decrementing a counter may lose the game if the value of that counter is zero, just as a player responsible for finding the next position in a game may lose if there is no position to go to. The key mechanism of countdown games is implicit in [11], where the authors investigate a nonstandard semantics for the scalar fragment of the μ-calculus equivalent to replacing every μ and ν by our countdown operators μ^α and ν^α, respectively. However, the authors do not abstract from formulas in their definition of games, nor consider the full vectorial calculus that corresponds to automata.

A correspondence between countdown formulas, automata and games is as tight as for the classical μ-calculus. However, complications arise: the distinction between *vectorial* and *scalar* formulas, which in the classical case disappears to a large extent due to the so-called Bekić principle, now becomes pronounced. We prove that vectorial countdown calculus is more expressive than its scalar fragment. We also prove that the countdown operator nesting hierarchy of formulas is proper.

We conjecture that the satisfiability problem is decidable for μ^α-ML. Unfortunately, the lack of positional determinacy in countdown games prevents us from using proof techniques known from parity automata (where one can transform an alternating automaton into a nondeterministic one that guesses the positional strategy). Nevertheless, the existence of an automata model equivalent to logic is encouraging. Apart from allowing us to solve some fragments of the logic, it implies that μ^α-ML does not share some of the troublesome properties of MSO + U that result in undecidability. In particular, it can be used to show that all languages definable in μ-ML have *bounded topological complexity* (i.e. at most Σ^1_2, see [15] for an introduction to topological methods in computer science). Since MSO + U defines a Σ^1_n-complete language for every $n < \omega$ [12, Theorem 2.1], [15, Theorem 7], it follows that some MSO + U-definable languages are not expressible in μ^α-ML (whether μ^α-ML-definability implies MSO + U-definability remains an open question). Since by [8, Theorem 1.3] every logic closed under boolean combinations, projections and defining the language U from Example 4 contains MSO + U, this means that our calculus is *not closed under projections*. This is an arguably good news, as in the light of [3, Theorem 1.4], giving up closure under projections is the only way to go if one wants to design a decidable extension of MSO closed under boolean operations. Decidability of the weak variant $\mathsf{WMSO}+\mathsf{U}$ of $\mathsf{MSO}+\mathsf{U}$ over infinite words [2] and infinite (ranked) trees [5] shows that such extensions are possible. In fact, both results are obtained by establishing a correspondence with equivalent automata models, namely deterministic max-automata [2, Theorem 1] and nested limsup automata [5, Theorem 2]. Since the existence of accepting runs for such automata can be expressed in μ^α-ML, we get that μ^α-ML contains $\mathsf{WMSO}+\mathsf{U}$ on infinite words and trees. The opposite inclusion is false (due to topological reasons), at least for the trees. The relation between μ^α-ML and the ωB-, ωS- and ωBS-automata of [7] remains unclear, as these models do not admit determinization. Also, the relation between our logic and regular cost functions (see e.g. [10]) is less immediate than it could seem at first glance and requires further research.

2 Preliminaries

Fixpoints. Let Ord be the class of all ordinals, and Ord_∞ the class Ord extended with an additional element ∞ greater than all ordinals.

Knaster-Tarski theorem says that every monotonic function $F : A \to A$ on a complete lattice A has the least and the greatest fixpoint, which we denote F^∞_μ and F^∞_ν. Moreover:

- F^∞_μ is the limit of the increasing sequence $F^\alpha_\mu = \bigvee_{\beta<\alpha} F(F^\beta_\mu)$
- F^∞_ν is the limit of the decreasing sequence $F^\alpha_\nu = \bigwedge_{\beta<\alpha} F(F^\beta_\nu)$

where $\alpha \in \mathsf{Ord}$ and $\bigvee, \bigwedge$ are the join and meet operations in A.

Parity games. A *parity game* is played between two players $\exists$ve and $\forall$dam (or simply $\exists$ and $\forall$). It consists of a set of *positions* $V = V_\exists \sqcup V_\forall$ divided between both players, an edge relation $E \subseteq V \times V$, and a labeling $\mathsf{rank} : V \to \mathcal{R}$ for some finite linear order $\mathcal{R} = \mathcal{R}_\exists \sqcup \mathcal{R}_\forall$ divided between the two players.

A *play* is a sequence of positions. After a play $\pi = v_1 \dots v_n \in V^*$, the owner of v_n chooses $(v_n, v_{n+1}) \in E$ and the game moves to v_{n+1}. A player who has no legal moves loses immediately. To determine the winner of an infinite play, we look at the highest $r \in \mathcal{R}$ such that positions with rank r appear infinitely often in the play, and the owner of r loses.

A *strategy* for a player $P \in \{\exists, \forall\}$ is a partial map $\sigma : V^*V_P \to E$ that tells the player how to move. A play $v_1v_2\dots$ is *consistent* with σ if for every n such that $v_n \in V_P$ we have $\sigma(v_1 \dots v_n) = v_{n+1}$. A strategy σ is *winning* from a position v if every play that begins in v and is consistent with σ is a win for P. A strategy is *positional* if $\sigma(\pi)$ depends only on the last position in π. Parity games are *positionally determined*: if a player has a winning strategy from v then (s)he has a winning positional strategy.

Modal μ-calculus. A model $\mathcal{M}$ for a fixed set Act of atomic *actions* consists of a set of *points* $M \ni \mathsf{m}, \mathsf{n}, \cdots$ together with a binary relation $\xrightarrow{\tau} \subseteq M \times M$ for every $\tau \in \mathsf{Act}$.

Formulas of the modal μ-calculus μ-ML are given by the grammar:

$$\varphi ::= x \mid \top \mid \bot \mid \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2 \mid \mu x.\varphi \mid \nu x.\varphi \mid \langle\tau\rangle\varphi \mid [\tau]\varphi \tag{1}$$

where x ranges over a fixed infinite set Var of variables and $\tau \in \mathsf{Act}$. Given a valuation $\mathsf{val} : \mathsf{Var} \to \mathcal{P}(M)$, the semantics $[\![\varphi]\!]^{\mathsf{val}} \subseteq M$ for all formulas φ is defined inductively, with $\mu x.\varphi$ and $\nu x.\varphi$ denoting the least and greatest fixpoints, respectively, of the monotonic function $H \mapsto [\![\varphi]\!]^{\mathsf{val}[x \mapsto H]}$ on the complete lattice $\mathcal{P}(M)$. More details can be found e.g. in [1, 16], but they can also be discerned from Section 3 below, where the semantics of countdown μ-calculus is presented in detail.

The above syntax does not include negation, but μ-calculus formulas are semantically closed under negation. For every formula $\widetilde{\varphi}$ there is a formula $\widetilde{\varphi}$ that acts as the negation of φ on every model, defined by induction in a straightforward way:

$$\widetilde{\varphi_1 \vee \varphi_2} = \widetilde{\varphi_1} \wedge \widetilde{\varphi_2}, \qquad \widetilde{\langle\tau\rangle\varphi} = [\tau]\widetilde{\varphi}, \qquad \widetilde{\mu x.\varphi} = \nu x.\widetilde{\varphi}, \qquad \text{etc.} \tag{2}$$

Vectorial μ-calculus. A syntactically richer version of the modal μ-calculus admits mutual fixpoint definitions of multiple properties, in formulas such as $\mu_1(x_1, x_2).(\varphi_1, \varphi_2)$, where variables x_1 and x_2 may occur both in φ_1 and φ_2. Given a valuation val as before, this formula is interpreted as the least fixpoint of the monotonic function $(H_1, H_2) \mapsto ([\![\varphi_1]\!]^{\mathsf{val}[x_i \mapsto H_i]}, [\![\varphi_1]\!]^{\mathsf{val}[x_i \mapsto H_i]})$ on the complete lattice $\mathcal{P}(M)^2$; the resulting pair of sets is then projected to the first component as dictated by the subscript in μ_1. Tuples of any size are allowed. This *vectorial* calculus is expressively equivalent to the scalar version described before, thanks to the so-called *Bekić principle* which says that the equality:

$$\mu \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} . \begin{pmatrix} f_1(x_1, x_2) \\ f_2(x_1, x_2) \end{pmatrix} = \begin{pmatrix} \mu x_1.f_1(x_1,\ \mu x_2.f_2(x_1, x_2)) \\ \mu x_2.f_2(\mu x_1.f_1(x_1, x_2),\ x_2) \end{pmatrix} \tag{3}$$

holds for every pair of monotone operations $f_i : A_1 \times A_2 \to A_i$ on complete lattices A_1, A_2, and similarly for the greatest fixpoint operator ν in place of μ.

3 Countdown μ-calculus

We now introduce the *countdown μ-calculus* μ^α-ML. We begin with the scalar version.

3.1 The scalar fragment

As before, fix an infinite set Var of variables and a set Act of actions. The syntax of *(scalar) countdown μ-calculus* is defined as follows:

$$\varphi ::= x \mid \top \mid \bot \mid \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2 \mid \mu^\alpha x.\varphi \mid \nu^\alpha x.\varphi \mid \langle\tau\rangle\varphi \mid [\tau]\varphi \tag{4}$$

for $x \in \mathsf{Var}$, $\tau \in \mathsf{Act}$ and $\alpha \in \mathsf{Ord}_\infty$; the presence of ordinal numbers α is the only syntactic difference with (1). A formula with no free variables is called a *sentence*. In case $|\mathsf{Act}| = 1$, we may skip the labels and write $\Diamond$ and $\Box$ instead of $\langle\tau\rangle$ and $[\tau]$. In statements that apply both to least and greatest fixpoints, we will sometimes use η^α to denote either μ^α or ν^α.

Given a model $\mathcal{M}$, for every valuation $\mathsf{val} : \mathsf{Var} \to \mathcal{P}(M)$, the *semantics* $[\![\varphi]\!]^{\mathsf{val}} \subseteq M$ is defined inductively as follows:

$$\begin{aligned}
[\![x]\!]^{\mathsf{val}} &= \mathsf{val}(x); \\
[\![\top]\!]^{\mathsf{val}} = M \quad &\text{and} \quad [\![\bot]\!]^{\mathsf{val}} = \emptyset \\
[\![\varphi_1 \vee \varphi_2]\!]^{\mathsf{val}} = [\![\varphi_1]\!]^{\mathsf{val}} \cup [\![\varphi_2]\!]^{\mathsf{val}} \quad &\text{and} \quad [\![\varphi_1 \wedge \varphi_2]\!]^{\mathsf{val}} = [\![\varphi_1]\!]^{\mathsf{val}} \cap [\![\varphi_2]\!]^{\mathsf{val}}; \\
[\![\langle\tau\rangle\varphi]\!]^{\mathsf{val}} = \{\mathsf{m} \in M \mid \exists_{\mathsf{n} \in [\![\varphi]\!]^{\mathsf{val}}}\ \mathsf{m} \xrightarrow{\tau} \mathsf{n}\} \quad &\text{and} \quad [\![[\tau]\varphi]\!]^{\mathsf{val}} = \{\mathsf{m} \in M \mid \forall_{\mathsf{n} \in [\![\varphi]\!]^{\mathsf{val}}}\ \mathsf{m} \xrightarrow{\tau} \mathsf{n}\}; \\
[\![\mu^\alpha x.\varphi]\!]^{\mathsf{val}} = F^\alpha_\mu \quad &\text{and} \quad [\![\nu^\alpha x.\varphi]\!]^{\mathsf{val}} = F^\alpha_\nu
\end{aligned}$$

where in the last clause $F(H) = [\![\varphi]\!]^{\mathsf{val}[x \mapsto H]}$. We will skip the index val if it is immaterial or clear from the context.

This obviously contains the classical μ-calculus, but is capable of capturing *boundedness* and *unboundedness* properties which are not expressible in the classical setting:

▶ **Example 1.** For $|\mathsf{Act}| = 1$, consider the formula $\nu^\alpha x.\Diamond x$. In a model $\mathcal{M}$, for $\alpha < \omega$ the set $[\![\nu^\alpha x.\Diamond x]\!]$ consists of the points from which there is a path of length at least α. Hence, $\nu^\omega x.\Diamond x$ holds in a point if there are arbitrarily long finite paths starting from there.

3.2 The vectorial calculus

The (full) *countdown μ-calculus* is defined as for its scalar fragment, except that fixpoint operators act on tuples (vectors) of formulas rather than on single formulas.

▶ **Definition 2.** *The syntax of* countdown μ-calculus *is given as follows:*

$$\varphi ::= x \mid \top \mid \bot \mid \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2 \mid \mu_i^\alpha \overline{x}.\overline{\varphi} \mid \nu_i^\alpha \overline{x}.\overline{\varphi} \mid \langle\tau\rangle\varphi \mid [\tau]\varphi$$

for $1 \leq i \leq n < \omega$, $\overline{x} = \langle x_1, ..., x_n\rangle \in \mathsf{Var}^n$, $\overline{\varphi} = \langle\varphi_1, ..., \varphi_n\rangle$ a tuple of formulas, $\tau \in \mathsf{Act}$ and $\alpha \in \mathsf{Ord}_\infty$.

▶ **Definition 3.** *The meaning $[\![\varphi]\!]^{\mathsf{val}} \subseteq M$ of a formula φ in a model $\mathcal{M}$ under valuation* val *is defined by induction the same way as for the scalar formulas except for the operators μ_i^α and ν_i^α, in which case:*

$$[\![\mu_i^\alpha \overline{x}.\overline{\varphi}]\!]^{\mathsf{val}} = \pi_i(F_\mu^\alpha) \quad \text{and} \quad [\![\nu_i^\alpha \overline{x}.\overline{\varphi}]\!]^{\mathsf{val}} = \pi_i(F_\nu^\alpha)$$

where the monotone map $F : (\mathcal{P}(M))^n \to (\mathcal{P}(M))^n$ is given as:

$$F(H_1, ..., H_n) = ([\![\varphi_1]\!]^{\mathsf{val}'}, ..., [\![\varphi_n]\!]^{\mathsf{val}'})$$

for $\mathsf{val}' = \mathsf{val}[x_1 \mapsto H_1, ..., x_n \mapsto H_n]$ and $\pi_i : (\mathcal{P}(M))^n \to \mathcal{P}(M)$ is the i-th projection.

Note that operators μ^∞ and ν^∞ are equivalent to μ and ν from the classical μ-calculus. Furthermore, for every ordinal α, the formula $\mu_i^{\alpha+1}\overline{x}.\overline{\psi}$ is equivalent to

$$\psi_i[x_1 \mapsto \mu_1^\alpha \overline{x}.\overline{\psi}, \dots, x_n \mapsto \mu_n^\alpha \overline{x}.\overline{\psi}]$$

and similarly for $\nu^{\alpha+1}$. As a result, without loss of generality we may assume that in countdown operators μ^α and ν^α only limit ordinals α are used.

The countdown μ-calculus is semantically closed under negation in the same way as the classical calculus, extending (2) with the straightforward $\widetilde{\mu_i^\alpha \overline{x}.\overline{\varphi}} = \nu_i^\alpha \overline{x}.\overline{\widetilde{\varphi}}$ and $\widetilde{\nu_i^\alpha \overline{x}.\overline{\varphi}} = \mu_i^\alpha \overline{x}.\overline{\widetilde{\varphi}}$.

In Section 6 we will compare the expressive power of the vectorial and scalar countdown μ-calculus in detail. For now, let us show that Bekić principle (3) fails for countdown operators:

▶ **Example 4.** An infinite word $W \in \Gamma^\omega$ over the alphabet $\Gamma = \{\mathsf{a}, \mathsf{b}\}$ can be seen as a model for $\mathsf{Act} = \Gamma$ with ω as the set of points and with transition relations defined by:

$$n \xrightarrow{\tau} m \iff m = n + 1 \text{ and } W_n = \tau.$$

For every regular language $K \subseteq \Gamma^*$ and $x \in \mathsf{Var}$, it is straightforward to define a fixpoint formula (in the classical μ-calculus, so without countdown operators) $\langle K\rangle x$ that holds in a point n, for a valuation val, if and only if there exists a word $w \in K$ and a path in W labelled with w that starts in n and ends in a point that belongs to $\mathsf{val}(x)$. Then, the formula:

$$\varphi = \nu_1^\omega(x_1, x_2).(\langle\Gamma^*\rangle x_2, \langle\mathsf{a}\rangle x_2)$$

is true in a word W iff it contains arbitrarily long blocks of consecutive a's. To see this, observe that at the i-th step of approximation: (i) the second component (x_2) contains a point n iff the next i transitions are all labelled with a, and (ii) the first component (x_1) contains a point n iff the second component contains at least one point after n.

However, the following scalar formula constructed by analogy to the Bekić principle:

$$\psi = \nu^\omega x_1.\langle\Gamma^*\rangle(\nu^\omega x_2.\langle\mathsf{a}\rangle x_2)$$

is equivalent to $\langle\Gamma^*\rangle(\nu^\omega x_2.\langle\mathsf{a}\rangle x_2)$, and the formula under $\langle\Gamma^*\rangle$ holds in a point iff all the future transitions from that point are labelled with a. Thus, ψ holds (in any point) iff the word W is of the form $\Gamma^*\mathsf{a}^\omega$, and so ψ is not equivalent to φ.

4 Countdown Games

The notion of a countdown game extends that of a parity game. As for parity games, it assumes a fixed finite linear order of ranks $\mathcal{R} = \mathcal{R}_\exists \sqcup \mathcal{R}_\forall$. In addition, we fix a subset $\mathcal{D} \subseteq \mathcal{R}$ of *nonstandard* ranks; at positions with these ranks countdowns will occur. Denote $\mathcal{D}_\exists = \mathcal{D} \cap \mathcal{R}_\exists$ and $\mathcal{D}_\forall = \mathcal{D} \cap \mathcal{R}_\forall$.

A *countdown game* consists of a set of *positions* $V = V_\exists \sqcup V_\forall$ divided between players ∃ve and ∀dam, an edge relation $E \subseteq V \times V$, a labelling $\mathsf{rank} : V \to \mathcal{R}$, and an initial counter valuation $\mathsf{ctr}_I : \mathcal{D} \to \mathsf{Ord}$. Each nonstandard rank has an associated counter.

Each game *configuration* consists of a position $v \in V$ together with a counter valuation $\mathsf{ctr} : \mathcal{D} \to \mathsf{Ord}$. We consider *positional* and *countdown* configurations, denoted respectively $\langle v, \mathsf{ctr}\rangle$ and $[v, \mathsf{ctr}]$, with the following moves allowed:

- From a positional configuration $\langle v, \mathsf{ctr}\rangle$, the owner of v chooses an edge $(v, w) \in E$ and the game proceeds from the countdown configuration $[w, \mathsf{ctr}]$;
- From a countdown configuration $[v, \mathsf{ctr}]$, the owner of $r = \mathsf{rank}(v)$ chooses a counter valuation ctr' such that:
  - $\mathsf{ctr}'(r') = \mathsf{ctr}_I(r')$ for $r' < r$,
  - $\mathsf{ctr}'(r) < \mathsf{ctr}(r)$ (if r is nonstandard),
  - $\mathsf{ctr}'(r') = \mathsf{ctr}(r')$ for $r' > r$,

  and the game proceeds from the positional configuration $\langle v, \mathsf{ctr}'\rangle$. In words: counters for ranks lower than r are reset, the counter for r (if any) is decremented, and counters for higher ranks are left unchanged. Note that if r is standard then there is no real choice here: ctr' is determined by ctr. And if r is nonstandard then the move amounts to choosing an ordinal $\alpha < \mathsf{ctr}(r)$.

Every play of the game alternates between positional and countdown configurations, and in each move only one component of the configuration is modified. Therefore, although a play is formally a sequence of configurations, it can be more succinctly represented as an alternating sequence of positions and counter valuations:

$$\pi = v_1 \mathsf{ctr}_2 v_2 \mathsf{ctr}_2 v_3 \mathsf{ctr}_3 \cdots \tag{5}$$

This has the same length as the sequence of configurations, and we will call it the length of the play. A *phase* of a game is a set of its finite plays that is convex with respect to the prefix ordering.

In any configuration, if the player responsible for making the next move is stuck, (s)he looses immediately. Otherwise, in an infinite play, the owner of the greatest rank appearing infinitely often looses, as in parity games. Strategies and winning strategies are defined as for classical parity games, as partial functions from finite plays to moves.

Given configuration γ, we denote the game *initialized in the configuration* γ by $\mathcal{G}, \gamma$. The default initial counter assignment is ctr_I and the default initial mode is the positional one, meaning that $\mathcal{G}, v$ stands for $\mathcal{G}, \langle v, \mathsf{ctr}_I\rangle$.

Note that the only way the counters may interfere with a play is when a counter has value 0 and so its owner cannot decrement it. It is therefore beneficial for a player to have greater ordinals at his/her counters.

Countdown games are not positionally determined, in the sense that the players may need to look at the counter values in order to choose a winning move (although they are *configurationally determined*, since a countdown game $\mathcal{G}$ can be seen as a parity game with configurations of $\mathcal{G}$ as its positions).

5 Countdown Automata

Countdown automata are a stepping stone between formulas and games. A countdown formula will define an automaton, which will then recognize a model in terms of a countdown game. Since formulas can have free variables, for technical reasons we will also consider automata with free variables. These variables resemble terminal states in that they can be targets of transitions, but no transitions originate in them, and whether they accept or not depends on an external valuation.

▶ **Definition 5.** *A* countdown automaton *consists of:*

- *a finite set of states $Q = Q_\exists \sqcup Q_\forall$ divided between two players;*
- *an initial state $q_I \in Q$;*
- *a transition function $\delta : Q \to \mathcal{P}(Q \sqcup \mathsf{Var}) \sqcup (\mathsf{Act} \times (Q \sqcup \mathsf{Var}))$ (we call the left part* ϵ-transitions *and the right one* modal transitions*);*
- *an assignment of ranks $\mathsf{rank} : Q \to \mathcal{R}$ and an assignment of initial counter values $\mathsf{ctr}_I : \mathcal{D} \to \mathsf{Ord}$, as in a countdown game.*

The language of an automaton is defined in terms of a countdown game, analogously to parity games and parity automata.

▶ **Definition 6.** *Fix an automaton $\mathcal{A} = (Q, q_I, \delta, \mathsf{rank}, \mathsf{ctr}_I)$. Given a model $\mathcal{M}$, a valuation $\mathsf{val} : \mathsf{Var} \to \mathcal{P}(M)$ and a point $\mathsf{m}_I \in M$, we define the semantic game $\mathcal{G}^{\mathsf{val}}(\mathcal{A})$ to be the countdown game $(V, E, \mathsf{rank}', \mathsf{ctr}_I)$ where positions are of the form $V = M \times (Q \sqcup \mathsf{Var})$ and the edge relation E is defined as follows. In a position (m, q) for $q \in Q$:*

- *if $\delta(q) \subseteq Q \sqcup \mathsf{Var}$, outgoing edges (called ϵ-edges, or ϵ-moves) are $\{((\mathsf{m}, q), (\mathsf{m}, z)) \mid z \in \delta(q)\}$,*
- *if $\delta(q) = (\tau, p)$, outgoing edges (modal edges, modal moves) are $\{((\mathsf{m}, q), (\mathsf{n}, p)) \mid \mathsf{m} \xrightarrow{\tau} \mathsf{n}\}$.*

There are no outgoing edges from positions (m, x) for $x \in \mathsf{Var}$.

For $q \in Q$, the owner of the position (m, q) is the owner of the state q, and $\mathsf{rank}'(\mathsf{m}, q) = \mathsf{rank}(q)$. For $x \in \mathsf{Var}$, the position (m, x) belongs to $\forall$dam if $\mathsf{m} \in \mathsf{val}(x)$ and to $\exists$ve otherwise. The rank $\mathsf{rank}'(\mathsf{m}, x)$ can be set arbitrarily, as it does not affect the outcome of the game. The initial counter assignment ctr_I is kept the same.

The language $[\![\mathcal{A}]\!]^{\mathsf{val}} \subseteq M$ of an automaton $\mathcal{A}$ is the set of all points $\mathsf{m} \in M$ for which the configuration $\langle(\mathsf{m}, q_I), \mathsf{ctr}_I\rangle$ in the game $\mathcal{G}^{\mathsf{val}}(\mathcal{A})$ is winning for $\exists$ve.

It is worth to mention that although in general countdown games are not positional, one can show a much weaker but still useful fact: in the particular case of semantic games, the winning player always has a strategy that does not look at the counters in the initial *pre-modal* phase of the game (that is, *before the first modal move*).

The countdown calculus and countdown automata have the same expressive power, i.e. there are language-preserving translations $\varphi \mapsto \mathcal{A}_\varphi$ and $\mathcal{A} \mapsto \varphi_\mathcal{A}$ between formulas and automata. As in the classical setting, the link between formulas and automata is very useful in establishing facts about the logic. For example, one can use game semantics to show that every formula of the standard μ-ML can be transformed into an equivalent guarded one. Thanks to the equivalence between *countdown* formulas and *countdown* automata, the same is true for μ^α-ML.

We will now explain the translations between logic and automata in turn.

5.1 From formulas to automata – Game Semantics

Every countdown formula $\varphi \in \mu^{\alpha}$-ML gives rise to a countdown automaton $\mathcal{A}_\varphi$ such that $[\![\varphi]\!]^{\mathsf{val}} = [\![\mathcal{A}_\varphi]\!]^{\mathsf{val}}$ for every model $\mathcal{M}$ and valuation val. Specifically, given a formula φ (with some free variables), we define an automaton $\mathcal{A}_\varphi = (Q, q_I, \delta, \mathsf{rank}, \mathsf{ctr}_I)$ (over the same free variables) as follows:

- $Q = \mathsf{SubFor}(\varphi) - \mathsf{FreeVar}(\varphi)$ is the set of all subformulas other than the free variables of φ (*without* identifying different occurrences of identical subformulas, i.e., here a subformula means a path in the syntactic tree of φ from the root of φ to the root node of the subformula). Ownership of a state in Q depends on the topmost connective, with $\exists$ve owning $\vee$ and $\langle\tau\rangle$ and $\forall$dam owning $\wedge$ and $[\tau]$; ownership of fixpoint subformulas, countdown subformulas and variables can be set arbitrarily as it will not matter;
- $q_I = \varphi$;
- the transition function is defined by cases:
  - $\delta(\theta_1 \vee \theta_2) = \delta(\theta_1 \wedge \theta_2) = \{\theta_1, \theta_2\}$,
  - $\delta(\langle\tau\rangle\theta) = \delta([\tau]\theta) = (\tau, \theta)$,
  - $\delta(\eta_i^{\alpha}\overline{x}.\overline{\theta}) = \{\theta_i\}$ (for $\eta = \mu$ or $\eta = \nu$),
  - $\delta(x) = \{\theta_i\}$, where $\eta_j^{\alpha}(x_1, ..., x_n).(\theta_1, ..., \theta_n)$ is the (unique) subformula of φ binding x with $x = x_i$.
- For the ranking function, assume that the lowest rank in $\mathcal{R}$ is standard and call it 0 (ownership of this rank does not matter). Then let rank assign 0 to all subformulas of φ except for immediate subformulas of fixpoint operators. To those, assign ranks in such a way that subformulas have strictly smaller ranks than their superformulas, and for every subformula $\eta_i^{\alpha}\overline{x}.\overline{\varphi}$:
  - all formulas in the tuple $\overline{\varphi}$ have the same rank r,
  - r belongs to $\exists$ve if $\eta = \mu$ and to $\forall$dam if $\eta = \nu$, and
  - if $\alpha = \infty$ then r is standard, otherwise it is nonstandard and $\mathsf{ctr}_I(r) = \alpha$.

We denote $\mathcal{G}^{\mathsf{val}}(\varphi) = \mathcal{G}^{\mathsf{val}}(\mathcal{A}_\varphi)$.

▶ **Theorem 7** (Adequacy). *For every model $\mathcal{M}$ and valuation* val, $[\![\varphi]\!]^{\mathsf{val}} = [\![\mathcal{A}_\varphi]\!]^{\mathsf{val}}$.

Proof (sketch). As with the classical *mu*-calculus, the proof proceeds by induction on the complexity of the formula. The only new cases of $\mu^{\alpha}\overline{x}.\overline{\varphi}$ and $\nu^{\alpha}\overline{x}.\overline{\varphi}$ are proven by transfinite induction on α. ◀

▶ **Example 8.** For $\mathsf{Act} = \{\tau\}$, consider the formula $\varphi = \nu^{\omega}x.\Diamond x$ from Example 1. The automaton $\mathcal{A}_\varphi$ has three states: $Q = \{\varphi, \Diamond x, x\}$, with φ the initial state, and the transition function comprises two deterministic ϵ-transitions and one modal transition:

$$\delta(\varphi) = \{\Diamond x\}, \qquad \delta(\Diamond x) = (\tau, x), \qquad \delta(x) = \{\Diamond x\}.$$

The state $\Diamond x$ is owned by $\exists$ve; ownership of the other two states does not matter. The automaton uses two ranks, $0 < 1$, where 0 is standard and 1 is nonstandard, assigned to states by: $\mathsf{rank}(\varphi) = \mathsf{rank}(x) = 0$ and $\mathsf{rank}(\Diamond x) = 1$. Rank 1 is owned by $\forall$dam; ownership of rank 0 does not matter. (Note how the state $\Diamond x$ is owned by $\exists$ve, but its rank is owned by $\forall$dam). The initial counter value is $\mathsf{ctr}_I(1) = \omega$.

Now consider any model $\mathcal{M}$. Since Act has only one element, $\mathcal{M}$ is simply a directed graph. The semantic game $\mathcal{G}(\varphi)$ on $\mathcal{M}$ (φ has no free variables, so neither has $\mathcal{A}_\varphi$ and we need not consider valuations val) has positions of the form (m, q) where $\mathsf{m} \in M$ and $q \in Q$, with ownership and rank inherited from q. Edges are of the form:

- $((\mathsf{m}, \varphi), (\mathsf{m}, \Diamond x))$ and $((\mathsf{m}, x), (\mathsf{m}, \varphi))$ – the ϵ-edges,
- $((\mathsf{m}, \Diamond x), (\mathsf{n}, x))$ such that $\mathsf{m} \to \mathsf{n}$ is an edge in $\mathcal{M}$ – the modal edges.

Configurations of the game arise from positions together with counter valuations; there is only one nonstandard rank, so a counter valuation is simply an ordinal.

For a point $\mathsf{m} \in \mathcal{M}$, the default initial configuration of the game is the positional configuration $\langle(\mathsf{m}, \varphi), \omega\rangle$. A play that begins in this configuration proceeds as follows:

1. The first move is deterministic, to the countdown configuration $[(\mathsf{m}, \diamond x), \omega]$.
2. $\forall$dam, as the owner of the rank of $\diamond x$, makes the next move: he chooses a number $k < \omega$, and the games moves to the positional configuration $\langle(\mathsf{m}, \diamond x), k\rangle$.
3. $\exists$ve owns the position, so she makes the next move: she chooses a point $\mathsf{n} \in M$ such that $\mathsf{m} \xrightarrow{\tau} \mathsf{n}$, and the game moves to the countdown configuration $[(\mathsf{n}, x), k]$.
4. The rank of x is standard, so in the next move the counter does not change and the game moves to $\langle(\mathsf{n}, x), k\rangle$. The next move is also deterministic, to the countdown configuration $[(\mathsf{n}, \diamond x), k]$. The game then goes back to step 2. above, with k in place of ω.

From this it is clear that $\exists$ve wins from $\langle(\mathsf{m}, \varphi), \omega\rangle$ if and only if $\mathcal{M}$ has arbitrarily long paths that begin in m, as stated in Example 1.

5.2 From automata to formulas

▶ **Theorem 9.** *For every countdown automaton $\mathcal{A}$ there exists a countdown formula $\varphi_{\mathcal{A}}$ s.t. $[\![\mathcal{A}]\!]^{\mathsf{val}} = [\![\varphi_{\mathcal{A}}]\!]^{\mathsf{val}}$ for every model $\mathcal{M}$ and valuation* val.

Proof (sketch). We sketch the construction of $\varphi_{\mathcal{A}}$. For an automaton $\mathcal{A} = (Q, q_I, \delta, \mathsf{rank}, \mathsf{ctr}_I)$, by induction on $r \in \mathcal{R}$ we build a formula $\psi_{r,q}$ for each $q \in Q$. Then we put $\varphi_{\mathcal{A}} = \psi_{r_{\mathsf{max}}, q_I}$. Thus for the base case of the lowest rank $r = 0$:

- if $\delta(s) = (\tau, p)$ then for $\psi_{0,s}$ we put $\langle\tau\rangle x_p$ if q belongs to $\exists$ve and $[\tau]x_p$ if q belongs to $\forall$dam,
- if $\delta(s) \subseteq Q$ then for $\psi_{0,s}$ we put $\bigvee_{p \in \delta(s)} x_p$ if q belongs to $\exists$ve and $\bigwedge_{p \in \delta(s)} x_p$ if q belongs to $\forall$dam.

For the inductive step, let $q_1, \ldots, q_d$ be all states in Q with rank r. For every q_i define the vectorial formula:

$$\theta_i = \eta^{\alpha}_{q_i}(x_{q_1}, \ldots, x_{q_d}).(\psi_{r,q_1}, \ldots, \psi_{r,q_d})$$

with $\alpha = \mathsf{ctr}_I(r)$ and $\eta = \mu$ if r belongs to $\exists$ve and $\eta = \nu$ if r belongs to $\forall$dam. Then put $\psi_{r+1,q} = \psi_{r,q}[x_{q_1} \mapsto \theta_1, \ldots, x_{q_d} \mapsto \theta_d]$. ◀

6 Vectorial vs. scalar calculus

In this section we investigate the relation between scalar and vectorial formulas. We have already seen with Example 4 that unlike with standard fixpoints, the Bekić principle is not valid in the countdown setting. Interestingly, scalar formulas correspond to automata with a simple syntactic restriction.

▶ **Proposition 10.** *Scalar countdown formulas and automata where every two states have different ranks have equal expressive power.*

Proof (sketch). Inspecting the translations between formulas and automata from Sections 5.1 and 5.2, it is evident that injectively ranked automata are translated to scalar formulas, and that, although in our translation the choice of the assignment of ranks is not deterministic, every scalar formula can be translated to an injectively ranked automaton. ◀

Since the Bekić principle fails, a natural question is whether there is another way of transforming vectorial formulas to scalar form (or, equivalently, arbitrary countdown automata to injectively ranked ones). We shall give a negative answer in Theorem 11. However, before we proceed, let us analyse the following example, which shows that scalar formulas are more expressive than they may seem, covering in particular the property from Example 4.

6.1 Languages of unbounded infixes

Fix a regular language of finite words $L \subseteq \Gamma^*$. Let $\mathcal{U}(L) \subseteq \Gamma^\omega$ be the language of all infinite words that contain arbitrarily long infixes from L. For instance, the language from Example 4 is $\mathcal{U}(\mathsf{a}^*)$. We shall now show that $\mathcal{U}(L)$ can be defined in the countdown μ-calculus, first by a vectorial formula, then by a scalar one.

Consider a finite deterministic automaton $\mathcal{A} = (Q, \delta, q_I, F)$ that recognizes L. Let $\delta^+ : \Gamma^+ \times Q \to Q$ be the unique inductive extension of the transition function $\delta : \Gamma \times Q \to Q$ to nonempty words. Define $K_{p,q} = \{w \in \Gamma^+ \mid \delta^+(w, p) = q\}$ the (regular) language of nonempty words leading from p to q in $\mathcal{A}$, and let $K_{p,F}$ denote the union $\bigcup_{q \in F} K_{p,q}$. By the pigeonhole principle we have $\mathcal{U}(L) = \bigcup_{q \in Q} \mathcal{U}_q(L)$, where $\mathcal{U}_q(L) \subseteq \Gamma^\omega$ consists of words such that for every $n < \omega$, w has an infix $w_n = v_I u_1 ... u_n v_F \in L$ s.t. (i) $v_I \in K_{q_I,q}$, (ii) $u_1, ..., u_n \in K_{q,q}$, and (iii) $v_F \in K_{q,F}$. Then $\mathcal{U}_q(L)$ can be defined by a vectorial formula:

$$\mathcal{U}_q(L) = [\![\nu_1^\omega(x_1, x_2).(\langle \Gamma^* K_{q_I,q} \rangle x_2, \langle K_{q,q} \rangle x_2 \wedge \langle K_{q,F} \rangle \top)]\!]$$

where $\langle K \rangle \psi$ is the formula as explained in Example 4. Indeed, the corresponding semantic game on a word w proceeds as follows:

1. $\forall$dam chooses a number $n < \omega$ as the value of his only counter,
2. $\exists$ve skips a prefix $v_0 v_I \in \Gamma^* K_{q_I,q}$ of w,
3. $\forall$dam decrements his counter;
4. $\exists$ve keeps moving through $u_1, u_2, ... \in K_{q,q}$ so that after each step, some state in F is reachable from q by some prefix of the remaining word. After each such choice of u_i $\forall$dam has to decrement his counter, and so $\exists$ve wins iff she can make at least $n - 1$ such steps.

The two different stages in which $\forall$dam's counter is decremented reflect the two-phase dynamics of the game: first $\forall$dam challenges $\exists$ve with a number, and then $\exists$ve shows that she can provide an infix long enough.

It is more tricky to define the language $\mathcal{U}_q(L)$ with a scalar formula, but it turns out to be possible. To this end, observe that without loss of generality we may restrict attention to words w such that:

1. the infixes $w_n \in L$ start arbitrarily far in w;
2. each w_n can be decomposed as $v_I u_1 ... u_n v_F \in L$ s.t. (i) $v_I \in K_{q_I,q}$, (ii) $u_1, ..., u_n \in K_{q,q}$, (iii) $v_F \in K_{q,F}$, and additionally *(iv) all u_i begin with the same letter* $\mathsf{a} \in \Gamma$;
3. there are at least two distinct letters $\mathsf{a}, \mathsf{b} \in \Gamma$ that appear infinitely often in w;
4. the first letter of w is b.

Indeed, for (1) note that otherwise w_n start in the same position k for all n large enough. But then even the stronger property "There exists a position k such that the run of $\mathcal{A}$ from k visits q and F infinitely often" holds, and this is easily definable by a fixpoint formula.

Item (2) follows from the pigeonhole principle and the observation that in $w_{n\times|\Gamma|} = v_I u_1 ... u_{n\times|\Gamma|} v_F$ at least n u_i's begin with the same letter.

For (3) observe that otherwise w has a suffix a^ω for some $\mathsf{a} \in \Gamma$, in which case membership in $\mathcal{U}_q(L)$ is definable by a fixpoint formula. This is because an ultimately periodic word is bisimilar to a finite model, and so every monotone map reaches its fixpoints in finitely many steps, meaning that the countdown operator ν^ω is equivalent to ν^∞.

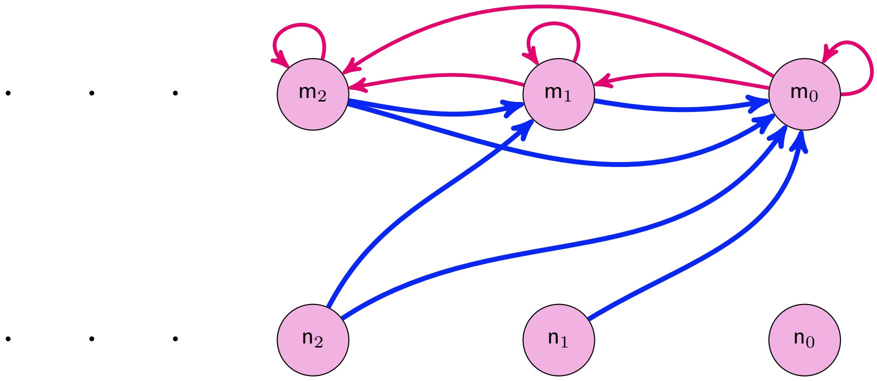

Figure 1 The model $\mathcal{M}$. Blue arrows represent edges labeled both with a and b, and pink arrows are edges labeled only with b.

Finally, for (4) note that the language $\mathcal{U}_q(L)$ is closed under adding and removing finite prefixes, and so if a formula φ defines $\mathcal{U}_q(L) \cap \mathsf{b}\Gamma^\omega$, then the formula $\langle\Gamma^*\rangle(\langle\mathsf{b}\rangle\top \wedge \varphi)$ defines $\mathcal{U}_q(L)$.

With this in mind, define:

$$\varphi = \nu^\omega x.(\langle\mathsf{b}\rangle\top \wedge \langle\Gamma^* K_{q_I,q}\rangle(\langle\mathsf{a}\rangle\top \wedge x)) \vee (\langle K_{q,q}\rangle(\langle\mathsf{a}\rangle\top \wedge x) \wedge \langle\mathsf{a}\rangle\top \wedge \langle K_{q,F}\rangle\top).$$

Note how $\langle\mathsf{b}\rangle\top \wedge x$ and $\langle\mathsf{a}\rangle\top \wedge x$ replace x_1 and x_2 from the vectorial formula. Consider the corresponding semantic game on a word w. Consider configurations of the game with the main disjunction as the formula component. Every infinite play of the game must visit such configurations infinitely often. In such a configuration, if the next letter in the model is either a or b then $\exists$ve must choose the right or left disjunct respectively. In particular, once the game reaches a configuration where $\langle\mathsf{a}\rangle\top$ holds, it must also hold every time the variable x in unraveled in the future. As a result, $\exists$ve wins from a configuration where $\langle\mathsf{a}\rangle\top$ holds against $\forall$dam's counter $n < \omega$ iff there is $u_1 ... u_{n+1} v_F$ starting in the current position such that $u_1, ..., u_{n+1} \in K_{q,q}$, each u_i starts with a, and $v_F \in K_{q,F}$. Moreover, $\exists$ve wins from a position where $\langle\mathsf{b}\rangle\top$ holds, against $\forall$dam's $n+1 < \omega$, iff there is $v_I \in \Gamma^* K_{q_I,q}$ starting in the current position such that the next position after v_I satisfies $\langle\mathsf{a}\rangle\top$ and $\exists$ve wins from there against n. Putting this together, we get that $\exists$ve wins from a position satisfying $\langle\mathsf{b}\rangle\top$ against n iff there is $v_I u_1 ... u_n v_F = w_n$ as in condition (2) above. Since the game starts with $\forall$dam choosing an arbitrary $n < \omega$, it follows that indeed φ defines $\mathcal{U}_q(L)$.

6.2 Greater expressive power of the vectorial calculus

We now show an example of a property that is definable in the vectorial countdown calculus but not in the scalar one.

Fixing $\mathsf{Act} = \{\mathsf{a}, \mathsf{b}\}$, consider a model $\mathcal{M} = (M, \xrightarrow{\mathsf{a}}, \xrightarrow{\mathsf{b}})$ with points $M = \{\mathsf{m}_i, \mathsf{n}_i \mid i < \omega\}$, and with exactly the edges: $\mathsf{m}_i \xrightarrow{\mathsf{a}} \mathsf{m}_j$, $\mathsf{n}_i \xrightarrow{\mathsf{a}} \mathsf{m}_j$ and $\mathsf{n}_i \xrightarrow{\mathsf{b}} \mathsf{m}_j$ for all $i > j$; and $\mathsf{m}_i \xrightarrow{\mathsf{b}} \mathsf{m}_j$ for all i and j. Note that the relation $\xrightarrow{\mathsf{a}}$ is a subset of $\xrightarrow{\mathsf{b}}$. The model is shown in Fig. 1.

Consider the vectorial sentence $\nu_1^\omega(x_1, x_2).(\langle\mathsf{b}\rangle x_2, \langle\mathsf{a}\rangle x_2)$. This describes the property *there are arbitrarily long paths with labels in* ba^*, and so it is true in all points m_i and false in all points n_i. The following result immediately implies that this property cannot be defined in the scalar countdown calculus:

▶ **Theorem 11.** *For every scalar sentence φ, there exists $i < \omega$ s.t.* $\mathsf{n}_i \in [\![\varphi]\!] \iff \mathsf{m}_i \in [\![\varphi]\!]$.

Proof (sketch). The heart of the proof is Proposition 10 which says that scalar formulas correspond to injectively ranked automata. In such an automaton, whenever the counter corresponding to rank r is modified, the automaton must be in *the same state*, which allows the players to copy their strategies between different positions of the semantic game. ◀

7 Strictness of the countdown nesting hierarchy

A natural question is whether greater *coutdown nesting*, i.e. the maximal nesting of μ^α and ν^α operators with $\alpha \neq \infty$, results in more expressive power. We give a positive answer: under mild assumptions, the hierarchy is strict. From now on, focus on the monomodal case (i.e. $|\mathsf{Act}| = 1$) and we assume that the only ordinal used by formulas is ω.[1]

▶ **Theorem 12.** *For every $k < \omega$, formulas with countdown nesting $k + 1$ have strictly more expressive power than those with nesting at most k.*

In order to prove strictness, it suffices to prove it on a restricted class of models. We will show that the hierarchy is strict already on the class of transitive, linear, well-founded models – i.e. (up to isomorphism) ordinals.

More specifically, an ordinal $\kappa \in \mathsf{Ord}$ can be seen as a model with $\alpha \to \beta$ iff $\alpha > \beta$. Since κ is an induced submodel of κ' whenever $\kappa \leq \kappa'$, we can consider a single ordinal model with κ big enough. For our purposes, the first uncountable ordinal ω_1 is be sufficient.

We call a subset $S \subseteq \omega_1$ *stable above* α if either $[\alpha, \omega_1) \subseteq S$ or $[\alpha, \omega_1) \cap S = \emptyset$. A *stabilization point* of a valuation $\mathsf{val} : \mathsf{Var} \to \mathcal{P}(\omega_1)$ is the least $\alpha \leq \omega_1$ such that interpretations of all the variables are stable above α.

Observe that the set $[\omega^k, \omega_1) \subseteq [0, \omega_1)$ can be defined by the following sentence with countdown nesting k:

$$[\omega^k, \omega_1) = [\![\nu^\omega x_1 ... \nu^\omega x_k . \Diamond(\textstyle\bigwedge_{i \leq k} x_i)]\!]. \tag{6}$$

Indeed, the semantic game can be decomposed into two alternating phases: (i) ∀dam chooses a tuple of finite ordinals $(\alpha_1, ..., \alpha_k) \in \omega^k$ and (ii) ∃ve responds with a successor in the model. Since at each step ∀dam has to pick a lexicographically smaller tuple (and he starts by picking any tuple) it is easy to see that he wins iff the initial point is at least ω^k. We will show that for all $k > 0$, countdown nesting k is *necessary* to define this language. The proof relies on the following lemma.

▶ **Lemma 13.** *For every $k < \omega$ and a formula φ with countdown nesting k, there exists an ordinal $\alpha_\varphi < \omega^{k+1}$ such that φ stabilizes α_φ above the valuation, i.e. for every valuation* val *stabilizing at β, $[\![\varphi]\!]^{\mathsf{val}}$ is stable above $\beta + \alpha_\varphi$.*

Proof (sketch). By induction on the complexity of the formula φ. The base case is immediate, as for every $x \in \mathsf{Var}$ it suffices to take $\alpha_x = 0$. For propositional connectives and modal operators we take $\alpha_{\psi_1 \vee \psi_2} = \alpha_{\psi_1 \wedge \psi_2} = \mathsf{max}(\alpha_{\psi_1}, \alpha_{\psi_2})$ and $\alpha_{\Diamond\psi} = \alpha_{\Box\psi} = \alpha_\psi + 1$. The most interesting case are countdown and fixpoint operators. There the lemma follows from the fact that for every formula φ there is a finite constant $t_\varphi < \omega$ such that for every valuation val stable above κ, in the part $[\kappa, \omega_1)$ of the model above κ, φ changes its truth value at most t_φ times. ◀

[1] This assumption could be replaced with a weaker requirement: there exists a maximal ordinal α that we are allowed to use, and α is additively indecomposable.

From this the theorem follows immediately, as the sentence φ has no free variables and thus it stabilizes at $\alpha_\varphi < \omega^{k+1}$ regardless of the valuation.

8 Decidability issues

We briefly discuss decidability issues in the countdown μ-calculus. Note that in a finite model every monotone map reaches its fixpoints in finitely many steps. Hence, if we replace every η^α in φ with η^∞ and denote the resulting formula by $\widehat{\varphi}$, then *in every finite model* $[\![\varphi]\!] = [\![\widehat{\varphi}]\!]$. It immediately follows that:

▶ **Proposition 14.** *The model checking problem for the μ^α-ML, i.e. the problem: "Given $\varphi \in \mu^\alpha$-ML and a point m in a (finite) model $\mathcal{M}$, does $\mathsf{m} \models \varphi$?" is decidable.*

Note that as a corollary we get that deciding the winner of a given (finite) countdown game $\mathcal{G}$ is also decidable, as set of positions where ∃ve wins can be easily defined in μ^α-ML.

A more interesting problem is *satisfiability*: "Given $\varphi \in \mu^\alpha$-ML, is there a model $\mathcal{M}$ and a point m s.t. $\mathsf{m} \models \varphi$?".

▶ **Proposition 15.** *A formula $\varphi \in \mu^\alpha$-ML has* positive countdown *if it does not use ν^α with $\alpha \neq \infty$. The satisfiability problem is decidable for such formulas.*

Proof. Observe that for φ with positive countdown, in every model we have $[\![\varphi]\!] \subseteq [\![\widehat{\varphi}]\!]$. Hence, if φ is satisfiable, then so is $\widehat{\varphi}$ – but since μ-ML has a finite model property, this means that $\widehat{\varphi}$ has a *finite* model, where $\widehat{\varphi}$ and φ are equivalent. Thus, φ is satisfiable iff $\widehat{\varphi}$ is, and the problem reduces to μ-ML satisfiability. ◀

Dualizing the above we get that the *validity* problem is decidable for formulas with *negative countdown*, i.e. with $\alpha = \infty$ for every μ^α.

Abstract

Valiant, in his seminal paper in 1979, showed an efficient simulation of algebraic formulas by determinants, showing that VF, the class of polynomial families computable by polynomial-sized algebraic formulas, is contained in VDet, the class of polynomial families computable by polynomial-sized determinants. Whether this containment is strict has been a long-standing open problem. We show that algebraic formulas can in fact be efficiently simulated by the determinant of tetradiagonal matrices, transforming the open problem into a problem about determinant of general matrices versus determinant of tetradiagonal matrices with just three non-zero diagonals. This is also optimal in a sense that we cannot hope to get the same result for matrices with only two non-zero diagonals or even tridiagonal matrices, thanks to Allender and Wang (Computational Complexity'16) which showed that the determinant of tridiagonal matrices cannot even compute simple polynomials like $x_1x_2 + x_3x_4 + \cdots + x_{15}x_{16}$.

Our proof involves a structural refinement of the simulation of algebraic formulas by width-3 algebraic branching programs by Ben-Or and Cleve (SIAM Journal of Computing'92). The tetradiagonal matrices we obtain in our proof are also structurally very similar to the tridiagonal matrices of Bringmann, Ikenmeyer and Zuiddam (JACM'18) which showed that, if we allow approximations in the sense of geometric complexity theory, algebraic formulas can be efficiently simulated by the determinant of tridiagonal matrices of a very special form, namely the continuant polynomial. The continuant polynomial family is closely related to the Fibonacci sequence, which was used to model the breeding of rabbits. The determinants of our tetradiagonal matrices, in comparison, is closely related to Narayana's cows sequences, which was originally used to model the breeding of cows. Our result shows that the need for approximation can be eliminated by using Narayana's cows polynomials instead of continuant polynomials, or equivalently, shifting one of the outer diagonals of a tridiagonal matrix one place away from the center.

Conversely, we observe that the determinant (or, permanent) of band matrices can be computed by polynomial-sized algebraic formulas when the bandwidth is bounded by a constant, showing that the determinant (or, permanent) of bandwidth k matrices for all constants $k \geq 2$ yield VF-complete polynomial families. In particular, this implies that the determinant of tetradiagonal matrices in general and Narayana's cows polynomials in particular yield complete polynomial families for the class VF.

1 Introduction

Valiant in his seminal work [20] laid the foundation for investigation of algebraic analog of the P versus NP problem, the flagship problem of theoretical computer science. He introduced algebraic formulas and determinants as models for computing polynomial families and identified them as notions of efficient computation, while the permanent family, $\mathrm{per}_n(x_{11},\ldots,x_{nn}) := \sum_{\sigma\in\mathbb{S}_n}\prod_{i=1}^{n} x_{i,\sigma(i)}$ was identified as a family that is highly likely to be hard to compute. He defined the complexity class VF as the set of polynomial families that can be computed by formulas of polynomially-bounded size, and VDet as the set of families that can be expressed as the determinant of a symbolic matrix of polynomially-bounded dimension. He also showed, among other things, that a polynomial computable by an algebraic formula of size s can be expressed as the determinant of a symbolic matrix of size $(s+2)\times(s+2)$, thus showing the containment $\mathsf{VF}\subseteq\mathsf{VDet}$. Conversely, the smallest known formulas for the determinant family, $\det_n(x_{11},\ldots,x_{nn}) := \sum_{\sigma\in\mathbb{S}_n}\mathrm{sgn}(\sigma)\prod_{i=1}^{n} x_{i,\sigma(i)}$, have size $n^{O(\log n)}$ [11, 6]. Thus the two notions of efficient computation are not known to be equivalent. It is a long standing open problem whether algebraic formulas of polynomial size exist for the determinant family.

▶ **Problem 1.** *Is the determinant family strictly more expressive than algebraic formulas? In other words, is* $\mathsf{VF}\subsetneq\mathsf{VDet}$*?*

An improved construction of a formula for the determinant family has resisted all attempts for long, which can be interpreted as an evidence to an affirmative answer to Problem 1. Though the relationship between the classes VF and VDet is poorly understood as of now, they themselves are very natural otherwise. Not only they contain many natural examples of polynomial families, there are many differing, but equivalent, ways to define them too.

For example, the class VDet is equivalently captured by the model of algebraic branching programs of polynomial size, denoted VBP. Recall, an algebraic branching program (ABP) is a directed acyclic graph G with two special nodes, say s (source node) and t (sink node), and edges labeled with variables or constants. For every s-to-t path p in G we associate a monomial m_p obtained by multiplying the edge labels on this path. The polynomial computed by the algebraic branching program G is defined to be the sum over all monomials given by s-to-t paths, i.e., $\sum_{p:\ s\text{-to-}t\text{ path }p} m_p$. Rephrasing the characterization, we know $\mathsf{VDet}=\mathsf{VBP}$. We can assume, wlog, branching programs to be layered, i.e., the vertices are topologically ordered in layers, from left to right, such that the edges only go between consecutive layers. Then the *width* of a branching program is defined to be the maximum number of vertices in any one layer.

In an influential work, Ben-Or and Cleve [5] showed that branching programs of constant width characterize formulas. In other words, they showed $\mathsf{VF}=\mathsf{VBP}_3$, where VBP_3 denotes the class of algebraic branching programs of width 3 and polynomial size. In light of this, Problem 1 can be rephrased as asking whether $\mathsf{VBP}_3\subsetneq\mathsf{VBP}$, that is, whether algebraic branching programs of width 3 are computationally strictly weaker than algebraic branching programs of arbitrary width. This seems even more likely when phrased this way!

In a recent work, Bringmann, Ikenmeyer and Zuiddam [8] took this one step further by showing that the topological closure of VF is equivalent to the topological closure of VBP_2, i.e. $\overline{\mathsf{VF}}=\overline{\mathsf{VBP}_2}$, where VBP_2 is the class corresponding to algebraic branching programs of width 2! Stated differently, they showed that algebraic branching programs of width 2 can efficiently *approximate* all polynomials that are efficiently computed (or, approximated) by algebraic formulas. In fact, the equivalent width 2 algebraic branching programs given by the reduction have very special structure, which make them equivalent to the determinant of tridiagonal symbolic matrices of a very special form. These tridiagonal matrices have non-trivial entries, variables and constants, on the main diagonal while the other two diagonals are fixed to all ±1s. Determinant of such tridiagonal symbolic matrices is well-studied in the literature and is known as the *continuant*, deriving its name from continued fractions since continuants are used to represent the convergents of continued fractions. They are also related to the Fibonacci sequence via the following recursive definition: $F_0 := 1$, $F_1 := x_1$, and $F_n := x_n F_{n-1} + F_{n-2}$ for all $n \geq 2$. Thus, for a positive resolution of Problem 1, it is sufficient to show that the determinant of certain family of tridiagonal matrices, namely the continuant family $\{F_n\}$, *cannot* efficiently approximate the determinant of general matrices.

The continuant is known to have rich algebraic structures [16, 10, 9, 17], which may be helpful in separating VF from VDet. Although quite promising, an additional challenge this formulation poses is that we now need to deal with approximations. In other words, we need to show a stronger separation $\overline{\mathsf{VF}} \subsetneq \mathsf{VDet}$. It would be very pleasing if we could have the result of Bringmann, Ikenmeyer and Zuiddam [8] without using approximations. That is, if the following would be true – the continuant family $\{F_n\}$ can *efficiently exactly* simulate formulas. However, such a result is an impossibility! Allender and Wang [4] showed that the simple polynomial, $x_1x_2 + x_3x_4 + \cdots + x_{15}x_{16}$, cannot even be expressed by the continuant family, irrespective of efficiency. Thus, one may wonder what is the *simplest* class of matrices whose determinants can *efficiently exactly* simulate algebraic formulas?

Motivated by this question, we study the determinant of matrices with few diagonals, also known as band matrices, and identify two polynomial families that are as simple as the continuant family $\{F_n\}$, but unlike it they simulate formulas exactly and efficiently.

The Narayana's cows polynomial. The m-th polynomial in this family, denoted $N_m(x_1, \ldots, x_m)$, is defined by the recurrence $N_0 := 1$, $N_1 := x_1$, $N_2 := x_1x_2$, and $N_m = x_m N_{m-1} + N_{m-3}$ for all $m \geq 3$. Just as the continuant polynomial is based on the Fibonacci sequence, the Narayana's cows polynomial is based on the Narayana's cows sequence [1, 21]. This sequence originated in the following problem studied by the 14-th century mathematician Narayana Pandita in his book Ganita Kaumudi [18]: *A cow produces a calf every year. Cows start producing calves from the beginning of the fourth year. Then, starting from* 1 *cow in the first year, how many cows are there after m years?* This sequence is given by the recurrence: $N_m = N_{m-1} + N_{m-3}$ with $N_0 = N_1 = N_2 = 1$, where N_{m-1} gives the population after m years. Thus, the sequence captures the growth in the population of cows in the same way as the Fibonacci sequence captures the growth in the population of rabbits. The Narayana's cows sequence has wide applications in combinatorics. (See, e.g., [1, 14] and references therein.)

The Padovan polynomial. The recurrences for Fibonacci and Narayana's cows sequences are similar. Exploring this similarity and considering the only remaining two-term recurrence: $P_n = P_{n-2} + P_{n-3}$, we obtain another lesser known cousin of Fibonacci, called as the Padovan sequence [2, 23, 19]. Analogously, we can define the Padovan polynomial via the recurrence $P_0 := 1$, $P_1 := 0$, $P_2 := x_1$, and $P_n = x_{n-1}P_{n-2} + P_{n-3}$ for all $n \geq 3$. This generalizes the univariate Padovan polynomial that is known in the literature [22].

Our results complement the results of Bringmann, Ikenmeyer and Zuiddam [8] by showing that the aforementioned polynomial families, namely Narayana's cows and Padovan, based on the lesser known cousins of Fibonacci, are complete for the class VF. In other words, both families can efficiently exactly simulate formulas.

Figure 1 Polynomial families defined by determinants of simple matrices and their recurrences.

1.1 Our findings

We discover the simplest class of matrices whose determinants characterize algebraic formulas. We find that tetradiagonal matrices of a very special form suffice for this purpose.

▶ **Theorem 2** (Informal, See Theorem 16 and Corollary 23). *The determinant family of tetradiagonal symbolic matrices is polynomially equivalent to algebraic formulas.*

In fact, the tetradiagonal matrices (Figures 1b and 1c) that is sufficient for efficiently simulating algebraic formulas are remarkably similar to the tridiagonal matrices (Figure 1a) used by Bringmann, Ikenmeyer and Zuiddam [8] to efficiently approximate algebraic formulas. It follows from the above theorem and Allender and Wang's separation [4], that tetradiagonal matrices are more expressive than tridiagonal matrices, but at the same time it can also be seen (Figure 1) to be nearly as simple as tridiagonal matrices – having just one extra diagonal whose entries are all 0s! We thus have the following equivalent reformulation of Problem 1.

> *Is the minimum size of a tetradiagonal matrix whose determinant equals* $\det_n$ *superpolynomially large, where* $\det_n$ *is the determinant of a general* $n \times n$ *symbolic matrix?*

This further motivated us to investigate matrices with few non-zero diagonals. Such matrices are called *band matrices* in the literature. We say that a matrix M is a band matrix of type (k_1, k_2) if all the non-zero entries of the matrix is concentrated between k_1 diagonals below the main diagonal and k_2 diagonals above the main diagonal. That is, $M_{ij} = 0$ if $j < i - k_1$ or $j > i + k_2$. A band matrix of type (k_1, k_2) will also be referred as (k_1, k_2)-diagonal matrix. The bandwidth of such matrices are defined to be $k := \max(k_1, k_2)$.

For example, diagonal matrices are $(0, 0)$-diagonal and has bandwidth 0, tridiagonal matrices are $(1, 1)$-diagonal with bandwidth 1, tetradiagonal matrices are either $(1, 2)$-diagonal or $(2, 1)$-diagonal with bandwidth 2, and pentadiagonal matrices are $(2, 2)$-diagonal with bandwidth 2. Figures 1b and 1c are examples of $(1, 2)$-diagonal matrices.

If follows from Theorem 2 that $(1, 2)$-diagonal matrices can simulate formulas, and hence any (k_1, k_2)-diagonal matrix can simulate formulas as long as $\min(k_1, k_2) \geq 1$ and $\max(k_1, k_2) \geq 2$. It is then interesting to investigate the converse, i.e., for which (k_1, k_2)-diagonal matrices their determinants have small formulas?

We observe that determinants of bandwidth k matrices can be computed by polynomial-sized algebraic formulas when the bandwidth k is bounded by a constant. In fact, our constructions give efficient *(syntactic) multilinear* ABPs and circuits for low bandwidth matrices. These are circuits for which *every* intermediate polynomial that is computed is also multilinear. A polynomial is said to be *multilinear* if every monomial of the polynomial is multilinear, and a monomial is called *multilinear* if every variable has degree at most 1 in it. In comparison, polynomial size circuits for the determinant of general matrices given by Berkowitz [6] and polynomial size ABPs given by Mahajan and Vinay [15] are non-multilinear.

▶ **Theorem 3** (Informal, See Corollary 23). *Determinants of symbolic band matrices are computable by polynomial-sized algebraic formulas when bandwidth is bounded by a constant.*

In fact, the above theorem holds for the permanent of a band matrix too. Combining Theorems 2 and 3, we get a nice characterization of algebraic formulas in terms of determinants (or, permanents) of band matrices of small bandwidth. In other words, determinants of band matrices with bounded bandwidth yield polynomial families which are complete for the complexity class VF.

▶ **Theorem 4** (Informal, See Theorem 16, Theorem 19, and Corollary 23). *For all constant $k \geq 2$, the determinant (or, permanent) family of symbolic matrices of bandwidth k is* VF*-complete.*

1.2 Proof methods

Ideas for Theorem 2 (Simulating formulas via determinant of tetradiagonal matrices). We prove Theorem 2 in Section 3, where we begin with tetradiagonal matrices of type $(1, 2)$. That is, the non-zero entries are limited to one diagonal below the main diagonal, the main diagonal, and two diagonals above the main diagonal. We first show that the symbolic determinant of such tetradiagonal matrices can be written as a product of 3×3 matrices whose entries are variables (or their negations), 0, and 1, where the number of matrices in the product is linear in the size of the original matrix. This is obtained by exploiting a simple recurrence revealed while computing the determinant of these $(1, 2)$ tetradiagonal matrices using Laplace expansion, see Lemma 12. Thus, to prove Theorem 2, it is sufficient to show that algebraic formulas can be efficiently simulated by the matrix product of the 3×3 matrices obtained above. In fact, Ben-Or and Cleve, in their simulation of algebraic formulas using width 3 algebraic branching programs, showed that algebraic formulas can be efficiently simulated by the matrix product of 3×3 matrices. Thus, it might be tempting to conclude that we are already done. However, it turns out that the 3×3 matrices whose products equals the determinant of tetradiagonal matrices desire more structure than the matrices used in the proof of Ben-Or and Cleve. This is where the core technical novelty of our work lies – we show that algebraic formulas can indeed be efficiently simulated by product of 3×3 matrices of the form whose products are equivalent to the determinant of $(1, 2)$-tetradiagonal matrices. In fact, we are able to efficiently simulate formulas with even more structure on the matrices, allowing us to conclude that formulas can be efficiently simulated by tetradigonal matrices where the variable entries are only on the main diagonal, the diagonal below the main diagonal is all 1s, whereas the two diagonals above the main diagonal are all 0s and all 1s respectively, see Section 3.1 for details.

Ideas for Theorem 3 (Formulas for determinant of symbolic band matrices). Theorem 3 is relatively simpler to derive from the literature. We prove it in Section 4 taking two different constructions for computing determinants of general matrices and carefully specializing those constructions in the case of bandwidth k matrices, ensuring that the undesirable blowups are limited to parameter k, allowing us to get polynomial-sized formulas when k is bounded by a constant. In our first construction, we modify the construction of Grenet for computing permanent of an $n \times n$ matrix using algebraic branching programs. For bandwidth k matrices, we are able to get syntactic multilinear ABPs of length linear in the size of matrix and exponential in the bandwidth, see Theorem 22 for details. Applying standard conversion from ABPs to formulas yield Theorem 3. This gives us a formula of depth $O(k \log(n))$ and size $n^{O(k)}$. In our second construction, we adapt the generalized Laplace expansion to low bandwidth matrices, see Theorem 26 for details. The construction yields a syntactic multilinear arithmetic circuit of size $O(\exp(k)n)$ and depth $O(\mathrm{poly}(k)\log(n))$, which can be converted to algebraic formulas using standard conversion from circuits to formulas, giving an alternative proof of Theorem 3.

The rest of this paper is organized as follows: Section 3 gives efficient simulations of algebraic formulas via determinant of tetradiagonal symbolic matrices. Subsections 3.1 and 3.2 show that Narayana's cows polynomials and Padovan polynomials are complete for VF. Section 4 shows that determinants of all matrices with constant bandwidth have polynomial size formulas. See the full version [13] for omitted proofs.

2 Preliminaries

We define computational models that are of interest in this paper.

▶ **Definition 5.** *An* algebraic circuit *C is a rooted directed acyclic graph where the source nodes are labeled by elements of $\mathbb{F}$ or variables $x_1, \ldots, x_n$, and the internal nodes have in-degree 2 and are labeled by $+$ or $\times$. It naturally computes a polynomial $p \in \mathbb{F}[x_1, \ldots, x_n]$ in a bottom-up fashion. An* algebraic formula *is a circuit whose underlying graph is a tree. The* size *of a circuit is the number of nodes in the graph and the* depth *of a circuit is the number of edges on the longest path from the root to some source node.*

We recall the definition of ABPs.

▶ **Definition 6.** *An ABP is a layered directed acyclic graph with source node s and sink node t such that each edge is labeled by a variable or a constant. The polynomial computed by the ABP is given by $\sum_p m_p$, where p is an s to t path and m_p is the product of edge labels on the path p. The* width *of an ABP is the maximum number of nodes in any layer and the* length *is the number of layers.*

It is easy to see that width-w, length-ℓ ABPs are equivalent to product of a sequence of ℓ matrices of order $w \times w$.

We now define a notion of reduction that allows us to relate the complexity of polynomials under the above model.

▶ **Definition 7.** *A polynomial $f(x) \in \mathbb{F}[x_1, \ldots, x_n]$ is a* projection *of a polynomial $g(y) \in \mathbb{F}[y_1, \ldots, y_m]$, denoted $f \leq g$, if and only if $f(x_1, \ldots, x_n) = g(a_1, \ldots, a_m)$, where $a_i \in \mathbb{F} \cup \{x_1, x_2, \ldots, x_n\}$.*

It is easy to see that if g is computed by a formula of size s and depth d and $f \leq g$, then f is also computed by a formula of size at most s and depth at most d.

As is usually the case in algorithms and complexity, formula size or depth for fixed polynomials is rarely of interest. Instead, we look at families of polynomials and the asymptotic growth of size and depth of formulas computing them.

▶ **Definition 8.** *A* polynomial family *over a field $\mathbb{F}$ is a sequence $f = (f_n)_{n\in\mathbb{N}}$ of polynomials such that both the number of variables and the degree of f_n are polynomially bounded functions in n.*

A sequence of formulas $F = (F_n)_{n\in\mathbb{N}}$ is said to compute a polynomial family $f = (f_n)$ if and only if F_n computes f_n for all n. The size *and* depth *of the sequence F is defined as functions such that $s(n)$ and $d(n)$ are the size and depth of F_n.*

We now extend the definition of reductions to families.

▶ **Definition 9.** *A polynomial family (f_n) is a p-*projection *of another family (g_m), denoted $(f_n) \leq_p (g_m)$ if and only if there exists a polynomially bounded function $t : \mathbb{N} \mapsto \mathbb{N}$ such that $f_n \leq g_{t(n)}$ for all n.*

Note that if (g_n) is computed by polynomial size formulas and $(f_n) \leq_p (g_n)$, then (f_n) is also computed by polynomial size formulas.

▶ **Definition 10.** *The algebraic class* VF *is defined as the set of all polynomial families that have polynomial size formulas.*

The class VDet *(equivalently* VBP*) is defined as the set of all polynomial families f such that $f \leq_p \det$, where $\det$ is the family of determinants over $n \times n$ symbolic matrices.*

Using the above notion of reduction, we can define completeness for classes.

▶ **Definition 11.** *A polynomial family $f = (f_n)$ is said to be* complete *for a class $\mathcal{C}$ w.r.t p-projections if and only if $f \in \mathcal{C}$ and for all $g \in \mathcal{C}$, we have $g \leq_p f$.*

Note that det is trivially complete for VDet. Ben-Or and Cleve [5] showed that the polynomial family $\mathrm{per}_{3,n}$, the $(1,1)$ entry of the product of n 3×3 symbolic matrices is complete for VF.

3 Determinant of $(1,2)$-diagonal matrix versus algebraic formulas

In this section, we show that the determinants of $(1,2)$-diagonal symbolic matrices are polynomially equivalent to algebraic formulas, thereby, proving Theorem 2. We begin with the easier direction, that is, by showing that the determinant of $(1,2)$-diagonal symbolic matrix has polynomial-sized algebraic formulas. In fact, we give a polynomial-sized algebraic branching programs for them of width-3, which can then be converted into a polynomial-sized formula using a divide and conquer algorithm.

▶ **Lemma 12.** *The determinant (or, permanent) of $(1,2)$-diagonal symbolic matrix of dimensions $n \times n$ can be computed by a width-3 syntactic multilinear ABP of length at most $3n - 2$.*

In particular, they can be computed by (syntactic) multilinear formulas of size poly(n)*.*

Proof. Let M denote the following $(1,2)$-diagonal symbolic matrix,

$$M = \begin{pmatrix} x_{11} & x_{12} & x_{13} & & \\ x_{21} & \ddots & \ddots & \ddots & \\ & \ddots & \ddots & \ddots & x_{n-2,n} \\ & & \ddots & \ddots & x_{n-1,n} \\ & & & x_{n,n-1} & x_{n,n} \end{pmatrix}. \tag{1}$$

For $0 \leq i \leq n-1$, define $K(n-i)$ to be the determinant of the principal submatrix of M obtained by deleting both the first i rows and columns. Furthermore, set $K(0) := 1$ and $K(-1) := 0$. Note that, by definition, $K(n) = \det(M)$ and $K(1) = x_{nn}$. Then we have the following recursive formula for $K(n)$:

$$K(n) \quad = x_{11}K(n-1) - x_{12}x_{21}K(n-2) + x_{13}x_{32}x_{21}K(n-3). \tag{2}$$

The correctness of the above formula easily follows from a backward induction on i. Rewriting the recurrence in a matrix form we obtain

$$\begin{bmatrix} K(n) \\ K(n-1) \\ K(n-2) \end{bmatrix} = \begin{bmatrix} x_{11} & -x_{12}x_{21} & x_{13}x_{32}x_{21} \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} K(n-1) \\ K(n-2) \\ K(n-3) \end{bmatrix} \tag{3}$$

$$= \begin{bmatrix} x_{21} & x_{11} & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & -x_{12} & x_{13} \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & x_{32} \end{bmatrix} \begin{bmatrix} K(n-1) \\ K(n-2) \\ K(n-3) \end{bmatrix} \tag{4}$$

Unrolling Eq. (4) and using $K(1) = x_{nn}$, $K(0) = 1$, and $K(-1) = 0$ we obtain the claimed width-3 ABP for $K(n)$. ◀

We now consider a special kind of $(1, 2)$-diagonal symbolic matrices where entries in both the lowermost and the uppermost diagonals are only 1. We show that the determinant (or, permanent) of such a matrix is equivalent to a special kind of width-3 ABP. These matrices would serve as the key building block in our main proofs. However, we first need a name for the special kind of $(1, 2)$-diagonal matrices that we are going to be dealing with.

▶ **Definition 13.** *Let* $(\alpha, \beta, \gamma, \delta) \in (\mathbb{F} \cup \{*\})^4$. *A* $(1, 2)$*-diagonal matrix is said to be of type* $(\alpha, \beta, \gamma, \delta)$ *if all entries on the lowermost diagonal, main diagonal, first upper diagonal and second upper diagonal equals* α*,* β*,* γ *and* δ *respectively. Furthermore, if* α*,* β*,* γ*, or* δ *equals* $*$ *then the entries on the respective diagonals are* ***not*** *restricted.*

For example, a general $(1, 2)$-diagonal symbolic matrix, shown in Equation 1, is of type $(*, *, *, *)$ and a $(1, 2)$-diagonal matrix of type $(\alpha, \beta, \gamma, \delta) \in \mathbb{F}^4$ is also a *Toeplitz* matrix. The special kind of $(1, 2)$-diagonal matrices that we consider are of type $(1, *, *, 1)$. We now characterize the determinant of such matrices by a restricted width-3 ABP where the interconnections between layers are given by a special 3×3 matrix.

▶ **Lemma 14.** *Let* M *denote the following* $(1, 2)$*-diagonal symbolic matrix of type* $(1, *, *, 1)$ *of dimension* $n \times n$*:*

$$M = \begin{pmatrix} x_{11} & x_{12} & 1 & & \\ 1 & \ddots & \ddots & \ddots & \\ & \ddots & \ddots & \ddots & 1 \\ & & \ddots & \ddots & x_{n-1,n} \\ & & & 1 & x_{n,n} \end{pmatrix}.$$

Then, $\det(M)$ *is given by the* $(1, 1)$ *entry of the following iterated matrix multiplication over* 3×3 *matrices,*

$$\begin{bmatrix} x_{11} & -x_{12} & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_{22} & -x_{23} & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \cdots\cdots \begin{bmatrix} x_{(n-1)(n-1)} & -x_{(n-1)n} & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_{nn} & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}.$$

Conversely, the $(1,1)$ *entry of the following iterated matrix multiplication:*

$$\begin{bmatrix}\alpha_1 & \beta_1 & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\begin{bmatrix}\alpha_2 & \beta_2 & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\cdots\cdots\begin{bmatrix}\alpha_{(n-1)} & \beta_{(n-1)} & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\begin{bmatrix}\alpha_n & \beta_n & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix},$$

is given by the determinant of the following $(1,2)$*-diagonal matrix of type* $(1,*,*,1)$*,*

$$M = \begin{pmatrix} \alpha_1 & -\beta_1 & 1 & & \\ 1 & \ddots & \ddots & \ddots & \\ & \ddots & \ddots & \ddots & 1 \\ & & \ddots & \ddots & -\beta_{n-1} \\ & & & 1 & \alpha_n \end{pmatrix}.$$

Proof. The equivalence follows from observing that in this special case the recurrence of (3) becomes

$$\begin{bmatrix}K(n)\\ K(n-1)\\ K(n-2)\end{bmatrix} = \begin{bmatrix}x_{11} & -x_{12} & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\begin{bmatrix}K(n-1)\\ K(n-2)\\ K(n-3)\end{bmatrix},$$

$$= \begin{bmatrix}x_{11} & -x_{12} & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\cdots\begin{bmatrix}x_{(n-1)(n-1)} & -x_{(n-1)n} & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}\begin{bmatrix}K(1)\\ K(0)\\ K(-1)\end{bmatrix},$$

where $K(i), -1 \leq i \leq n$, as defined in the proof of Lemma 12, is the determinant of the principal submatrix of M obtained by deleting both the first $n-i$ rows and columns with $K(0) = 1$ and $K(-1) = 0$. ◀

3.1 Narayana's cows polynomial is VF-complete

In this section, we simulate algebraic formulas with tetradiagonal matrices of type (1,$*$,0,1). The determinant of such matrices follow the same recurrence as that of Narayana's cows polynomial described in Section 1. This simulation along with Lemma 12 finishes the proof of completeness of Narayana's cows polynomial families for the class VF.

We know from Lemma 14 that the determinant (or, permanent) of $(1,2)$-diagonal matrices of type $(1,*,0,1)$ is equivalent to the $(1,1)$ entry of an iterated matrix multiplication where the base matrices are of the form: $\begin{bmatrix}* & 0 & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}$. For notational convenience, let us denote the base matrix $\begin{bmatrix}z & 0 & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}$ by $A(z)$. In the following we will only work with iterated matrix multiplication over the base matrix $A(*)$ and use the equivalence given by Lemma 14 to represent the matrix product as the determinant (or, permanent) of $(1,2)$-diagonal matrix of type $(1,*,0,1)$.

For a better understanding of the algorithm we will present the algorithm in a recursive way. In particular we will have intermediate computations where the matrices will be of the form $\begin{bmatrix}0 & f & 1\\ 1 & 0 & 0\\ 0 & 1 & 0\end{bmatrix}$. We will denote such matrices by $B(f)$. Note that $A(0) = B(0)$. We now state and prove our simulation of formulas as a product of base matrices $A(z)$.

▶ **Lemma 15.** *Let p be a polynomial computed by a formula of depth d. Then, both $A(p)$ and $A(-p)$ can be expressed as an iterated matrix multiplication of length at most $30 \cdot 4^d - 29$ over the base matrices $A(z)$, where z is either a field constant, a variable, or a negated variable.*

Proof. The proof is by induction on depth.

Base case: $d = 0$. Then it computes either a field constant, a variable or a negated variable which can be represented by a single base matrix $A(z)$, where z is the label of the node.

Induction step: $d = m$. There are two cases to be considered depending on whether the node at depth m is an addition or a multiplication node.

Case 1: (Addition). Suppose $p = f + g$, where f and g are computable by depth $m - 1$ formulas. By induction hypothesis, we can express both $A(f)$ and $A(g)$. Then, $A(p) = A(f) \cdot A(0) \cdot A(0) \cdot A(g)$. In other words,

$$\begin{bmatrix} f+g & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} = \begin{bmatrix} f & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} g & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}.$$

Similarly one can express $A(-p)$.

Case 2: (Multiplication). Suppose $p = f \cdot g$, where f and g are computable by depth $m - 1$ formulas. We will use the following equation to compute $f \cdot g$.

$$A(f \cdot g) = A(0) \cdot A(0) \cdot B(-g) \cdot B(f) \cdot A(0) \cdot B(g) \cdot B(-f). \tag{5}$$

We will now show how to compute $B(f)$ using matrices of type $A(\cdot)$ which will complete the recursive algorithm. Similar to Eq. (5), the following equation computes $B(f \cdot g)$ using matrices of type $A(\cdot)$.

$$B(f \cdot g) = A(0) \cdot A(-f) \cdot A(0) \cdot A(g) \cdot A(f) \cdot A(0) \cdot A(-g). \tag{6}$$

We can thus use appropriate substitutions in Eq. (6) to get $B(f)$, $B(g)$, $B(-f)$, and $B(-g)$ and complete the algorithm. However, note that to compute $B(f)$ we need to make two calls to f as $A(-f)$ and $A(f)$. This would result in a total length of $O(8^d)$. To bring down the length to $O(4^d)$, we now show how to compute $B(f)$ using a single call to $A(f)$. Consider the following equation:

$$B(f) = A(0) \cdot B(-1) \cdot A(0) \cdot A(1) \cdot A(f) \cdot A(0) \cdot A(-1) \cdot B(1) \cdot A(0) \cdot A(0). \tag{7}$$

We can use Eq. (6) to obtain $B(-1)$ and $B(1)$, thus completing the algorithm to compute $B(f)$ with a single call to $A(f)$. We can now use equations (5) and (7) to compute $A(f \cdot g)$. Similarly one can express $A(-p)$.

The upper bound on the length of the iterated matrix multiplication follows from the following recurrence: $T(d) \leq 4 \cdot T(d-1) + 87$ and $T(0) = 1$. ◀

As a corollary to Lemmas 12 and 15, we obtain the following characterization of formulas.

▶ **Theorem 16.** *Let M_n denote the following $(1, 2)$-diagonal symbolic matrix of type $(1, *, 0, 1)$ of dimension $n \times n$:*

$$M_n = \begin{pmatrix} x_1 & 0 & 1 & & \\ 1 & \ddots & \ddots & \ddots & \\ & \ddots & \ddots & \ddots & 1 \\ & & \ddots & \ddots & 0 \\ & & & 1 & x_n \end{pmatrix}.$$

Then the sequences of polynomials $\{\det(M_n)\}_{n \geq 1}$ and $\{\mathrm{per}(M_n)\}_{n \geq 1}$ are VF*-complete with respect to p-projections.*

Proof. Follows from Lemmas 12 and 15, and depth reduction of formulas [7]. ◀

We are now all set to deduce the completeness of the Narayana's Cows polynomial family for class VF.

▶ **Theorem 17.** *Narayana's cows polynomial family is* VF*-complete.*

Proof. We observe that the determinants of the sequence of $(1,2)$-diagonal symbolic matrices of type $(1,*,0,1)$ follow the recurrence $N_m = x_m N_{m-1} + N_{m-3}$ for all $m \geq 3$, which is precisely the recurrence defining the Narayana's cows polynomials as described in Section 1. ◀

3.2 Padovan polynomial is VF-complete

In this section, we simulate algebraic formulas with tetradiagonal matrices of type $(1,0,*,1)$ instead. This time, the determinant of such matrices follow the same recurrence as that of Padovan polynomial described in Section 1. This simulation along with Lemma 12 finishes the proof of completeness of Padovan polynomial families for the class VF.

Again from Lemma 14 we know that the determinant (or, permanent) of $(1,2)$-diagonal matrices of type $(1,0,*,1)$ is equivalent to the $(1,1)$ entry of an iterated matrix multiplication where the base matrices are of the form: $\begin{bmatrix} 0 & * & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}$. Recall we denote base matrices of the form $\begin{bmatrix} 0 & z & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}$ by $B(z)$. In the following we will only work with iterated matrix multiplication over the base matrix $B(*)$ and use the equivalence given by Lemma 14 to represent the matrix product as the determinant (or, permanent) of $(1,2)$-diagonal matrix of type $(1,0,*,1)$.

▶ **Lemma 18.** *Let p be a polynomial computed by a formula of depth d. Then, both $B(p)$ and $B(-p)$ can be expressed as an iterated matrix multiplication of length at most $30 \cdot 4^d - 29$ over the base matrices $B(z)$, where z is either a field constant, a variable, or a negated variable.*

The proof is analogous to the proof of Lemma 15. (See the full version [13].)

As a corollary to Lemmas 12 and 18, we obtain another characterization of formulas.

▶ **Theorem 19.** *Let M_n denote the following $(1,2)$-diagonal symbolic matrix of type $(1,0,*,1)$ of dimension $n \times n$:*

$$M_n = \begin{pmatrix} 0 & x_1 & 1 & & \\ 1 & \ddots & \ddots & \ddots & \\ & \ddots & \ddots & \ddots & 1 \\ & & \ddots & \ddots & x_{n-1} \\ & & & 1 & 0 \end{pmatrix}.$$

Then the sequences of polynomials $\{\det(M_n)\}_{n\geq 2}$ and $\{\mathrm{per}(M_n)\}_{n\geq 2}$ are VF*-complete with respect to p-projections.*

Proof. The containment in VF follows from Lemma 12. While the hardness follows by translating the iterated product in Lemma 18 to a $(1,2)$-diagonal symbolic matrix of type $(1,0,*,1)$ using Lemma 14. Note that to apply Lemma 14 one has to multiply the iterated product on the right by $B(0)$ (to move the polynomial to $(1,1)$ entry). However, this only increases the length by 1. Finally using the depth reduction of formulas [7] completes the proof. ◀

We are now all set to deduce the completeness of Padovan polynomial family for class VF.

▶ **Theorem 20.** *Padovan polynomial family is* VF*-complete.*

Proof. We observe that the determinants of the sequence of $(1,2)$-diagonal symbolic matrices of type $(1,0,*,1)$ in Theorem 19 follow the recurrence $P_n = x_{n-1}P_{n-2} + P_{n-3}$, for all $n \geq 3$, if we negate all variables in the matrix, which is precisely the recurrence for the Padovan polynomials as described in Section 1. ◀

4 Matrices of small bandwidth

Our main goal in this section is to prove that for all fixed k, the determinant of matrices of bandwidth k can be computed by polynomial sized formulas. Along with the results in Section 3, this gives a complete characterization of the algebraic complexity of the determinant of constant bandwidth matrices (Theorem 24). Following the spirit of parameterized algorithms, we consider the bandwidth k as a parameter, and show that we can construct efficient syntactic multilinear ABPs (Theorem 22) and circuits (Theorem 26) for computing the determinant where the undesirable blowup (exponential for size, polynomial for depth) is limited to the parameter k.

Our parameterized constructions are derived from Grenet's syntactic multilinear ABP construction for the $n \times n$ permanent [12] and the generalized Laplace expansion that constructs syntactic multilinear circuits for the $n \times n$ determinant and permanent. We state the bounds given by those constructions below:

▶ **Lemma 21.** *The determinant (or, permanent) of an $n \times n$ symbolic matrix can be computed by a syntactic multilinear circuit of size $O(n2^n)$ and depth $O(n)$. Moreover, it can be computed by a syntactic multilinear ABP of length at most $n+2$ and width at most $\binom{n}{n/2}$.*

Notice that the ABP in Lemma 21 has width that is exponential in n. Our construction for matrices of bandwidth k shows that this exponential blowup can be limited to k.

▶ **Theorem 22.** *The determinant (permanent) of a (k,k)-diagonal symbolic matrix of dimension $n \times n$ can be computed using a syntactic multilinear ABP of length $n+2$ and width $\binom{2k}{k}$.*

Proof. We begin with a high-level recall of Grenet's construction [12]. In his construction, the start node is in layer 0. All monomials computed at layer i correspond to some permutation that maps rows $[i]$ to some set of i columns. Further, a node in a particular layer keeps track of the subset of columns in the monomials computed at that node. This means that in layer $n/2$, it has to keep track of $\binom{n}{n/2}$ distinct sets resulting in exponential (in n) width. The edges between layers are specified such that these invariants are preserved.

We now build a layered ABP for small bandwidth matrices that is a modification of Grenet's construction.

For matrices of bandwidth k, we can make use of the fact that rows that are separated by at least $2k$ rows have no common non-zero columns. Therefore, instead of keeping track of a subset of all columns, we can keep track of a subset of only a few columns. More specifically, any monomial computed at layer i (assume $k \leq i \leq n-k$ for simplicity, the rest of the rows are handled similarly) must pick i columns from $[i+k]$ since all columns further to the right are zero for these rows. Moreover, the columns $[i-k]$ have to be picked by the first i rows since these columns are zero from row $i+1$. Therefore, rows up to i must pick exactly k columns from the $2k$ sized set of columns $[i-k+1, i+k]$. In layer i, we have exactly one node for each k sized subset of this $2k$ sized set. This ABP has $n + 2$ layers and each layer has at most $\binom{2k}{k}$ nodes. This is precisely where we improve over Grenet's construction when specialized to matrices of bandwidth k. We refer to the full version [13] for details. ◀

By using standard conversion from ABP to formula, we obtain the following corollary.

▶ **Corollary 23.** *For all fixed k, the determinant (or, permanent) of symbolic matrices of bandwidth k can be computed using polynomial sized formulas.*

Along with the results in Section 3, the above corollary gives a complete characterization of the algebraic complexity of determinant (or, permanent) of constant bandwidth matrices.

▶ **Theorem 24.** *For all constant $k \geq 2$, the determinant (or, permanent) family of symbolic matrices of bandwidth k is* VF*-complete.*

▶ Remark 25. For completeness, we add that for $k = 0$ (symbolic diagonal matrices), the determinant (or, permanent) family is complete for width-1 ABPs, and for $k = 1$, the determinant (or, permanent) family is complete for width-2 ABPs.

The ABP given by Theorem 22 has depth n. On the other hand, converting it to a formula makes the depth $O(k \log(n))$ but the size $n^{O(k)}$. If we are interested in arithmetic circuits, we can eliminate the dependence of k in the exponent of n while keeping the depth logarithmic in n. Compared to Lemma 21, our construction, which is an adaption of the generalized Laplace expansion to low bandwidth matrices, limits the exponential blowup in size *and* the polynomial blowup in depth to the parameter k.

▶ **Theorem 26.** *The determinant (or, permanent) of an $n \times n$ (k, k)-diagonal symbolic matrix can be computed using a syntactic multilinear circuit of size $O(exp(k)n)$ and depth $O(k \log(n))$.*

We refer to the full version [13] for details.

Finding 3-Swap-Optimal Independent Sets and Dominating Sets Is Hard

Abstract

For PLS-complete local search problems, there is presumably no polynomial-time algorithm which finds a locally optimal solution, even though determining whether a solution is locally optimal and replacing it by a better one if this is not the case can be done in polynomial time.

We study local search for Weighted Independent Set and Weighted Dominating Set with the 3-swap neighborhood. The 3-swap neighborhood of a vertex set S in G is the set of vertex sets which can be obtained from S by exchanging at most three vertices. We prove the following dichotomy: On the negative side, the problem of finding a 3-swap-optimal independent set or dominating set is PLS-complete. On the positive side, locally optimal independent sets or dominating sets can be found in polynomial time when allowing all 3-swaps except a) the swaps that remove two vertices from the current solution and add one vertex to the solution or b) the swaps that remove one vertex from the current solution and add two vertices to the solution.

1 Introduction

Local search is one of the most successful paradigms for developing algorithms for NP-hard optimization problems. In the most fundamental version of local search, the hill-climbing algorithm, one starts by computing some feasible solution to the problem at hand. This solution is then replaced by a better solution in its local neighborhood, as long as such a better solution exists. The final output is a locally optimal solution. Even though such a locally optimal solution might be arbitrarily bad in comparison to a globally optimal solution, local search approaches turned out to find good solutions in practice [1, 3, 6]. A crucial aspect in this approach is the definition of the local neighborhood of solutions. Intuitively, there is the following trade-off: for more restricted neighborhoods, computing a local optimum should be easier but the quality of the local optimum may be worse than for less restricted neighborhoods. Note that the choice of the neighborhood may affect the computational difficulty of each improvement step as well as the number of necessary improvement steps. Naturally, in applications of hill-climbing, the neighborhoods are chosen in such a way that each improvement step can be performed efficiently.

To study the difficulty of computing locally optimal solutions in such a setting, Johnson et al. [5] introduced the complexity class PLS. This class contains all local search problems for which one can compute some starting solution and search the local neighborhood of a feasible solution S in polynomial time. Thus, the local search problems in PLS are exactly those that have a hill-climbing algorithm where each step only takes polynomial time.

For many unweighted problems, membership in PLS directly implies a polynomial-time algorithm for computing locally optimal solutions, since the maximum objective value is bounded by a polynomial of the input size. The situation is different for weighted problems, where we may need a superpolynomial number of improvement steps to reach a local optimum. To give evidence that for some local search problems in PLS it may be hard to compute locally optimal solutions, Johnson et al. [5] introduced PLS-reductions and showed that there are PLS-complete problems. These problems are as hard as any problem in PLS and none of them is known to be solvable in polynomial time.

We study two famous graph problems, Weighted Independent Set and Weighted Dominating Set through the lens of PLS-completeness. The solutions in both problems are vertex sets and we consider the most fundamental neighborhoods for such solutions: k-swap-neighborhoods, where we may add or remove up to k vertices from a solution.

Previous Work. PLS-completeness has been shown for a number of problems [4, 5, 11, 13, 14]. The initial PLS-complete problem is called Flip, where the input is a Boolean circuit [5]. Another prominent PLS-complete problem is Max Cut with the flip neighborhood, where the neighbors of a partition (A, B) are the partitions that can be obtained by moving one vertex from A to B or vice versa [13]. Max Cut with the flip neighborhood is PLS-complete on graphs with maximum degree 5 [4] and polynomial-time solvable on 3-regular graphs [12].

Johnson et al. [5] already considered the Weighted Independent Set problem and argued that one can show PLS-completeness for a neighborhood that is inspired by the Kernighan-Lin algorithm for Max Cut [7]. Moreover, Johnson et al. [5] specifically called for the study of simpler neighborhoods for the Weighted Independent Set problem. Schäffer and Yannakakis [13] argued that Weighted Independent Set is PLS-complete for a 2-step neighborhood which consists of an addition of a vertex v to the independent set S and a removal of all its neighbors from S in the first step and a (maximal) series of improving vertex additions in the second step. Note that the first step is not necessarily improving. Further studies have shown PLS-completeness for Weighted Independent Dominating Set with a k-swap neighborhood with constant but unspecified k [8] and for Weighted Max-Π-Subgraph with hereditary properties Π and the above-described 2-step-neighborhood [14]. We are not aware of any results for the k-swap neighborhoods with small constant k considered in this work.

From a more applied point of view, local search has been shown to give very good results for Independent Set [1, 2, 3, 6, 9] and weighted Weighted Independent Set [10]. In particular, for Independent Set, Andrade et al. [1] presented fast algorithms for finding improving 5-swaps and showed that the subroutine of finding 5-swap optimal solutions gives very good results when used in an iterative local search framework. Later, it was shown that k-swap-optimal solutions for Independent Set can be efficiently computed for k up to 25 and that, on a set of large sparse real-world networks globally optimal solutions can be found via a simple hill-climbing algorithm for $k \geq 9$ [6].

Our Results. We provide a complexity analysis for Weighted Independent Set with the k-swap neighborhood, denoted Weighted Independent Set/k-swap. Our main result is the PLS-completeness of Weighted Independent Set/3-swap on graphs of constant[1] maximum degree. We first show in Section 3 that Weighted Independent Set/7-swap is PLS-complete on graphs of maximum degree at most 6. Then, in Section 4, we extend the constructed instance of Weighted Independent Set/7-swap to obtain PLS-completeness for Weighted Independent Set/3-swap. Next, we show that by a small modification of the construction, the PLS-completeness for 3-swaps can be transferred to Weighted Dominating Set. Finally, in Section 5, we show that if we allow all 3-swaps except either a) the swaps that remove two vertices and add one or b) the swaps that remove one vertex and add two, we can find locally optimal solutions for Weighted Independent Set and Weighted Dominating Set in polynomial time. We extend this result to a slightly more general neighborhood and a certain type of subset optimization problems. Proofs of statements marked with a ”(*)” are deferred to the full version.

2 Preliminaries

For integers i and j with $i \leq j$, we define $[i, j] := \{k \in \mathbb{N} \mid i \leq k \leq j\}$. For two sets A and B, we denote with $A \oplus B := (A \setminus B) \cup (B \setminus A)$ the *symmetric difference* of A and B.

An (undirected) graph $G = (V, E)$ consists of a set of vertices V and a set of edges $E \subseteq \{\{u, v\} \mid u \in V, v \in V, u \neq v\}$. For vertex sets $S \subseteq V$ and $T \subseteq V$ we denote with $E_G(S, T) := \{\{s, t\} \in E \mid s \in S, t \in T\}$ the edges between S and T. Moreover, we define $G[S] := (S, E_G(S, S))$ as the *subgraph of G induced by S*. For a vertex $v \in V$, we denote with $N_G(v) := \{w \in V \mid \{v, w\} \in E\}$ the *open neighborhood* of v in G and with $N_G[v] := \{v\} \cup N_G(v)$ the *closed neighborhood* of v in G. Analogously, for a vertex set $S \subseteq V$, we define $N_G[S] := \bigcup_{v \in S} N_G[v]$ and $N_G(S) := \bigcup_{v \in S} N_G(v) \setminus S$. If G is clear from the context, we may omit the subscript.

A vertex set $S \subseteq V$ is an *independent set* in G if there is no edge between any pair of vertices of S in G and a *clique* in G if there is an edge between each pair of vertices of S in G. A vertex set $S \subseteq V$ is a *dominating set* in G if for each vertex v of G, at least one vertex of $N[v]$ is contained in S.

The two main problems considered here are now defined as follows.

Weighted Independent Set
Input: A graph $G = (V, E)$ and a vertex-weight function $\omega : V \to \mathbb{N}$.
Output: An independent set in G of maximum total weight.

Weighted Dominating Set
Input: A graph $G = (V, E)$ and a vertex-weight function $\omega : V \to \mathbb{N}$.
Output: A dominating set in G of minimum total weight.

An *optimization problem* L consists of a set $\mathcal{D}_L$ of *instances*, for each instance $I \in \mathcal{D}_L$, a set of *feasible solutions* $\mathcal{S}_L(I)$ for I, an *objective function* val_L which assigns a non-negative rational number to each pair (I, s), and is specified to be either a *minimization* or a *maximization* problem. An optimization problem L is an NP-*optimization problem* if the encoding length of each solution $s \in \mathcal{S}_L(I)$ of I is polynomially bounded by $|I|$, one can determine in polynomial time for each pair (I, s) whether $s \in \mathcal{S}_L(I)$, and the objective function can be evaluated in polynomial time.

[1] Our proof gives a degree bound of 3140.

Let I be an instance and of an optimization problem L and let s and s' be feasible solutions for I. We say that *s is better than s'* if a) L is a maximization problem and $\text{val}_L(I, s) > \text{val}_L(I, s')$ or b) L is a minimization problem and $\text{val}_L(I, s) < \text{val}_L(I, s')$.

▶ **Definition 2.1.** *An* NP*-optimization problem L is a* subset-weight optimization problem *if it consists of*

- *a polynomial-time computable function U that maps each instance I of L to a universe $U(I)$ and each feasible solution of I is a subset of $U(I)$,*
- *a polynomial-time computable function f which checks for an instance I of L and a set $S \subseteq U(I)$ if S is a feasible solution for I,*
- *a polynomial-time computable function g which computes for an instance I of L some feasible solution for I, and*
- *a polynomial-time computable weight function ω which assigns a non-negative rational weight to each pair (I, u), where I is an instance of L and u is an element of $U(I)$*

and one wants to find a feasible solution S for I of either minimal or maximal weight, where the weight of S is defined as $\omega(I, S) := \sum_{u \in S} \omega(I, u)$.

If one wants to find a feasible solution of maximal weight, L is a *subset-weight maximization problem*; otherwise, L is a *subset-weight minimization problem.*

Weighted Independent Set is a subset-weight maximization problem: the feasible solutions are the independent sets of G, these are all subsets of the vertex set V (the universe), one can check in polynomial time if a vertex set S is an independent set, and the total weight of S is defined as the sum of the weights of the vertices of S. Similarly, Weighted Dominating Set is a subset-weight minimization problem.

Let L be a subset-weight optimization problem, let I be an instance of L, and let $S \subseteq U(I)$ be a feasible solution for I. A *k-swap*, for $k \in \mathbb{N}$, is a subset $W \subseteq U(I)$ of size at most k. We say that W is *valid for S in I* if $S \oplus W$ is also a feasible solution for I. We say that two feasible solutions S and S' for I are *k-neighbors in I* if $W := S \oplus S'$ has size at most k. Additionally, we say that S' is an *improving k-neighbor of S in I* and that W is an *improving k-swap* if the total weight of S' is better than the total weight of S. If there is no improving k-neighbor of S in I, S is *k-optimal in I*. Let S be a subset of $U(I)$ and let k, k_{in}, and k_{out} be natural numbers such that $k_{\text{in}} + k_{\text{out}} \leq k$. A k-swap W is a *$(k_{\text{in}}, k_{\text{out}})$-swap for S in G*, if $|W \setminus S| \leq k_{\text{in}}$ and if $|W \cap S| \leq k_{\text{out}}$. Similar to k-swaps, we also define the notions of *valid $(k_{\text{in}}, k_{\text{out}})$-swaps*, *improving $(k_{\text{in}}, k_{\text{out}})$-swaps*, *$(k_{\text{in}}, k_{\text{out}})$-neighbors*, *improving $(k_{\text{in}}, k_{\text{out}})$-neighbors*, and *$(k_{\text{in}}, k_{\text{out}})$-optimal.*

A *partition of a graph $G = (V, E)$* is a pair (A, B), where $A \cup B = V$ and $A \cap B = \emptyset$. The *cut* of a partition (A, B) is the edge set $E_G(A, B)$, that is, the set of edges having one endpoint in A and one endpoint in B. Let $\omega : E \to \mathbb{N}$ be an edge-weight function. A *flip of a vertex $v \in V$ in a partition* (A, B) is the partition (A', B'), where $A' := A \oplus \{v\}$ and $B' := B \oplus \{v\}$. Moreover, we say that *(A', B') is improving over* (A, B) if the total weight of cut $E_G(A', B')$ is larger than the total weight of the cut $E_G(A, B)$, that is, if $\omega(E_G(A', B')) > \omega(E_G(A, B))$. Furthermore, we say that a partition (A, B) is *flip-optimal* if there is no vertex $v \in V$ such that the flip (A', B') of v in (A, B) is improving over (A, B).

In the corresponding minimization problem one wants to find a cut of maximal weight.

Max Cut
Input: A graph $G = (V, E)$ and an edge-weight function $\omega : E \to \mathbb{N}$.
Output: A partition (A, B) of G such that $E_G(A, B)$ has maximum total weight.

A *local search problem* $(L, \mathcal{N})$ consists of

- an optimization problem L and
- a *neighborhood structure* $\mathcal{N}$ *for* L that maps for each instance I of L, each valid solution S of I to a set $\mathcal{N}(I, S) \subseteq \mathcal{S}_L(I)$ of valid solutions for I, the *neighbors of* S *with respect to* $\mathcal{N}$.

The goal of $(L, \mathcal{N})$ is to find for a given instance I of L a *locally optimal solution* S *with respect to* $\mathcal{N}$, that is, a feasible solution for I such that no solution in $\mathcal{N}(I, S)$ is better than S. We may write a local search problem $(L, \mathcal{N})$ as $L/\mathcal{N}$. An example for a local search problem is Weighted Independent Set/k-swap, where the neighbors of an independent set S are the valid k-swap neighbors of S.

A local search problem $(L, \mathcal{N})$ *is in the complexity class* PLS, if

- there is an algorithm which computes in polynomial time some feasible solution S for a given instance I of L and
- there is an algorithm which in polynomial time determines whether a given solution S is locally optimal with respect to $\mathcal{N}$ for an instance I of L and, if this is not the case, outputs a better neighbor for S.

Note that for each constant k, Weighted Independent Set/k-swap is contained in PLS.

Let $(L_1, \mathcal{N}_1)$ and $(L_2, \mathcal{N}_2)$ be local search problems. We say that $(L_1, \mathcal{N}_1)$ *is* PLS-*reducible to* $(L_2, \mathcal{N}_2)$ if for each instance I_1 of L_1, one can compute in polynomial time an instance I_2 of L_2 and a *solution mapper* f, that is, a polynomial-time computable function f that maps each solution S_2 of I_2 to a solution $f(S_2)$ of I_1 such that if S_2 is locally optimal for I_2 with respect to $\mathcal{N}_2$, then $f(S_2)$ is locally optimal for I_1 with respect to $\mathcal{N}_1$. A local search problem $(L, \mathcal{N})$ is PLS-*hard* if for each local search problem $(L', \mathcal{N}')$ of PLS, there is a PLS-reduction from $(L', \mathcal{N}')$ to $(L, \mathcal{N})$. Due to the transitivity of PLS-reductions, this can be done by proving a PLS-reduction from any PLS-hard local search problem $(L', \mathcal{N}')$. Moreover, $(L, \mathcal{N})$ is PLS-*complete* if $(L, \mathcal{N})$ is contained in PLS and PLS-hard. An example for a PLS-complete local search problem is Max Cut/flip, where the neighbors of a partition (A, B) are the improving partitions of (A, B) one can obtain by flipping some vertex of G [13]. This is the case even on graphs of degree at most 5 [4].

3 Hardness of Finding 7-optimal Independent Sets

To obtain the PLS-completeness of Weighted Independent Set/3-swap on graphs of constant maximum degree, we first show PLS-completeness for Weighted Independent Set/7-swap and use the obtained graph as starting point in a subsequent reduction to Weighted Independent Set/3-swap.

▶ **Theorem 3.1.** *Weighted Independent Set/7-swap is* PLS*-complete on graphs of maximum degree 6.*

As mentioned above, Weighted Independent Set/k-swap is contained in PLS for each constant value of k. Hence, we only have to show that Weighted Independent Set/7-swap is PLS-hard.

Construction. We present a PLS-reduction from Max Cut/flip to Weighted Independent Set/7-swap. Let $I = (G = (V, E), \omega)$ be an instance of Max Cut/flip where G has a maximum degree of five. For these instances Max Cut/flip is known to be PLS-complete [4]. We describe how to obtain in polynomial time an instance $I' = (G' = (V', E'), \omega')$ of Weighted Independent Set/7-swap and a polynomial-time computable solution-mapper f for I and I' such that if an independent set S is 7-optimal in I', then $f(S)$ is flip-optimal in I.

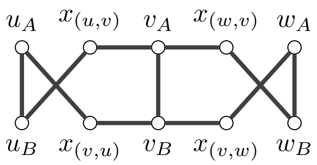

Figure 1 An example for the vertices and edges added to G' for a vertex $v \in V$ with two neighbors u and w in G in the reduction from Max Cut/flip to Weighted Independent Set/7-swap.

We start with an empty graph G' and add, for each vertex $v \in V$, two new adjacent vertices v_A and v_B to G'. Next, for each edge $\{u, v\} \in E$, we add two new vertices $x_{(u,v)}$ and $x_{(v,u)}$ to G' and make $x_{(u,v)}$ adjacent to u_B and v_A and $x_{(v,u)}$ adjacent to u_A and v_B. This completes the construction of G'. Figure 1 shows an example for the vertices and edges added to G' for a vertex $v \in V$ with two neighbors u and w in G. Note that G' has a maximum degree of six. In the following, let $V_A := \{v_A \mid v \in V\}$ and $V_B := \{v_B \mid v \in V\}$.

Next, we define the weight function $\omega' : V' \to \mathbb{N}$. Let $Z := \sum_{e \in E} \omega(e)$ denote the total weight of all edges. We set for each vertex $v \in V$, $\omega'(v_A) := \omega'(v_B) := 16 \cdot Z$ and for each edge $\{u, v\} \in E$, we set $\omega'(x_{(u,v)}) := \omega'(x_{(v,u)}) := 8 \cdot \omega(\{u, v\})$. In principle, the factors of 8 can be omitted but they will come in handy later when we present the PLS-reduction to Weighted Independent Set/3-swap.

This completes the construction of I'. It remains to define the solution-mapper f. For an independent set S, we define $f(S)$ to be the partition (A, B) of G where $A := \{v \in V \mid v_A \in S\}$ and $B := V \setminus A$. Recall that for vertex $v \in V$, the vertices v_A and v_B are adjacent in G'.

Correctness. To show the correctness of the reduction, we first analyze the structure of 7-optimal independent sets in G'. To this end, we define a notion of *nice* independent sets in G' and show that all 7-optimal independent sets in G' are nice. Recall that if some vertex v of V is contained in A for $f(S) = (A, B)$, then v_B is not contained in S.

▶ **Definition 3.2.** *Let S be an independent set in G' and let $A := \{v \in V \mid v_A \in S\}$ and let $B := \{v \in V \mid v_B \in S\}$. We call S* nice *if (A, B) is a partition of G and for each edge $\{u, v\} \in E$ with $(u, v) \in A \times B$, $x_{(u,v)} \in S$.*

▶ **Lemma 3.3 (*).** *If an independent set S in G is not nice, then S is not 7-optimal in G'.*

Hence, we only have to consider nice independent sets in G' when considering 7-optimal independent sets in G'. Now, to prove Theorem 3.1 it remains to show the following.

▶ **Lemma 3.4.** *Let S be a nice independent set in G'. If $f(S)$ is not flip-optimal in G, then S is not 7-optimal in G'.*

Proof. Let $(A, B) := f(S)$. By definition of f and the fact that S is nice, $A = \{v \in V \mid v_A \in S\}$ and $B = \{v \in V \mid v_B \in S\}$. Suppose that (A, B) is not flip-optimal in G. Then, there is some vertex $v \in V$ where the total weight of the edges that are incident with v and that are in the cut $E_G(A, B)$ is less than the total weight of the edges that are incident with v and that are not in the cut $E_G(A, B)$. That is, either a) $v \in A$ and $\omega(E_G(\{v\}, A)) > \omega(E_G(\{v\}, B))$ or b) $v \in B$ and $\omega(E_G(\{v\}, B)) > \omega(E_G(\{v\}, A))$.

Without loss of generality we may assume that $v \in A$ and $\omega(E_G(\{v\}, A)) > \omega(E_G(\{v\}, B))$. Let $X_A := N_G(v) \cap A$ denote the neighbors of v in A and let $X_B := N_G(v) \cap B$ denote the neighbors of v in B. Since S is nice, we know that $x_{(v,u)} \in S$ for each $u \in X_B$. Moreover,

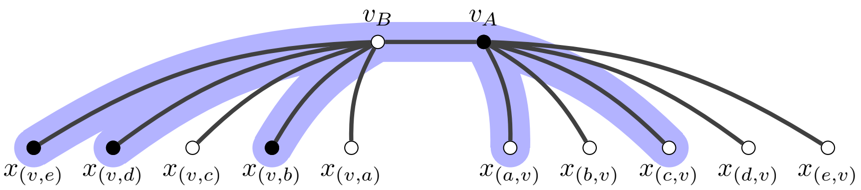

Figure 2 An example of an improving 7-swap W for a nice independent set S in G' that simulates the flip of a vertex $v \in V$ from A to B in G, where $N_G(v) = \{a, b, c, d, e\}$ and $N_G(v) \cap B = \{b, d, e\}$. The black vertices are the vertices of S and all vertices of W are highlighted by the blue shape.

for each $w \in X_A$, $x_{(v,w)} \notin S$ since $w_A \in S$ and $x_{(w,v)} \notin S$ since $v_A \in S$. We show that the swap $W := \{v_A, v_B\} \cup \{x_{(v,u)} \mid u \in X_B\} \cup \{x_{(w,v)} \mid w \in X_A\}$ is a valid improving 7-swap for S in G'. An example of the swap W is illustrated in Figure 2. First of all, note that W has size at most 7 since G has a maximum degree of 5 and thus $|X_A \cup X_B| \leq 5$. Moreover, by the fact that $\omega'(x_{(y,z)}) := \omega'(x_{(z,y)}) := 8 \cdot \omega(\{y, z\})$ for each edge $\{y, z\} \in E$,

$$\begin{aligned}\omega'(\{x_{(w,v)} \mid w \in X_A\}) &= 8 \cdot \omega(\{\{v, w\} \mid w \in X_A\}) \\ &> 8 \cdot \omega(\{\{v, u\} \mid u \in X_B\}) = \omega'(\{x_{(v,u)} \mid u \in X_B\}).\end{aligned}$$

Hence, W is improving, since $\omega'(v_A) = \omega'(v_B)$. It remains to show that W is valid. Since W removes all adjacent vertices of v_B from S, $S \oplus W$ does not contain any neighbor of v_B. Moreover, since $v_A \in W$ and for each $w \in X_A$, $w_A \in S \oplus W$ and thus $w_B \notin S \oplus W$, no vertex $x_{(w,v)}$ is adjacent to any vertex in $S \oplus W$. As a consequence, W is valid and thus S is not 7-optimal. ◀

4 Hardness of Finding 3-optimal Independent Sets

The main result of this section is the following.

▶ **Theorem 4.1.** *Weighted Independent Set/3-swap is* PLS*-complete on graphs of constant maximum degree.*

Construction. To show this, we extend the graph G' by additional gadgets to simulate 7-swaps by a sequence of 3-swaps. We describe how to obtain in polynomial time an instance $I'' = (G'' = (V'', E''), \omega'')$ of Weighted Independent Set/3-swap and a polynomial-time computable solution-mapper f for I and I'' such that if an independent set S is 3-optimal in I'', then $f(S)$ is flip-optimal in I. As described above, we extend the graph G' and the weight function ω' of the instance $I' = (G' = (V', E'), \omega')$ of Weighted Independent Set/7-swap described above. As above, let $V_A := \{v_A \mid v \in V\}$ and let $V_B := \{v_B \mid v \in V\}$. Moreover, we set for each $v \in V$, $X_v := \{x_{(v,w)}, x_{(w,v)} \mid w \in N(v)\}$, that is, X_v is the set of vertices in G' that were introduced for the incident edges of v in G. We write $N_G(v)$ and $N_G[v]$ when considering the neighborhood of a vertex v of V in G and $N(v)$ or $N[v]$ when considering the neighborhood of a vertex v of V'' in G''.

Initially, we add edges such that for each vertex $v \in V$, $u \in N_G(v)$, and $w \in N_G(V)$, the vertices $x_{(u,v)}$ and $x_{(v,w)}$ are adjacent in G''. Note that this includes edges between $x_{(u,v)}$ and $x_{(v,u)}$ in G'' for each edge $\{u, v\} \in E$. The idea is that in an independent set S in G'', for each vertex $v \in V$, there is no vertex $x_{(u,v)} \in S$ if S already contains a vertex $x_{(v,w)}$. Hence, for each vertex v of G, at most one of v_A and v_B has neighbors in $X_v \cap S$.

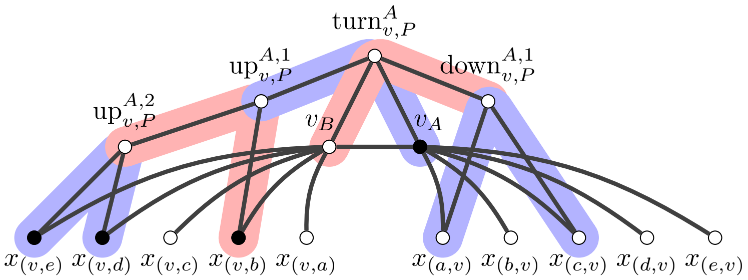

Figure 3 A sequence $(W_1, W_2, W_3, W_4, W_5)$ of improving 3-swaps (from left to right highlighted alternating by either a blue or a red shape) for a nice independent set S in G'' that simulates the flip of a vertex $v \in V$ from A to B in G, where $N_G(v) = \{a, b, c, d, e\}$ and $P = N_G(v) \cap B = \{b, d, e\}$ with $P(1) = b$, $P(2) = d$, and $P(3) = e$. The black vertices are the vertices of S. Note that not all edges of this subgraph are shown but only the important ones for the sequence of improving 3-swaps.

Next, we add gadgets to allow us to simulate 7-swaps in G' by a sequence of 3-swaps in G''. To this end, we first compute for each vertex $v \in V$ the collection $\mathcal{P}_v$ of subsets $P \subseteq N_G(v)$ fulfilling $\omega(E_G(\{v\}, P)) < \omega(E_G(\{v\}, N_G(v) \setminus P))$. Intuitively, if in a partition (A, B) of G, flipping a vertex v from A to B is improving, then the set $N_G(v) \cap B$ is contained in $\mathcal{P}_v$ and vice versa. Note that $\emptyset \in \mathcal{P}_v$ and $N_G(v) \notin \mathcal{P}_v$ for each $v \in V$. Next, we add, for each $P \in \mathcal{P}_v$ with $P \neq \emptyset$, a set of $|N_G(v)| - 1$ new vertices to G''. Let $Q := N_G(v) \setminus P$. Now, fix an ordering on both P and Q and let $P(i)$ denote the ith element of P and let $Q(j)$ denote the jth element of Q where $i \in [1, |P|]$ and $j \in [1, |Q|]$.

These vertices are of three types: up, turn, and down. To simulate a flip of v from A to B, we have to remove the neighbors of v_B from S, add v_B to S and add the vertices representing edges of $(A \cap N_G(v)) \times \{v\}$ to S. Intuitively, the up-vertices allow us – with a sequence of improving 3-swaps – to remove all neighbors of v_B from S except v_A and the up-vertex of highest level. Afterwards, the turn-vertex allows us – with two improving 3-swaps – to remove v_A from S and add v_B and the down-vertex of highest level to S. Finally, the down-vertices allow us – with a sequence of improving 3-swaps – to add the vertices representing edges of $(A \cap N_G(v)) \times \{v\}$ to S such that at the end, none of these auxiliary vertices remains in S. In total, this allows us to simulate improving 7-swaps in I' and thus improving flips in I by a sequence of improving 3-swaps in I''. An example for a sequence of improving 3-swaps in G'' to simulate a flip in G is illustrated in Figure 3. This figure shows only the edges that are important for the sequence of improving 3-swaps and not all edges of this subgraph.

First, we add for each $i \in [1, |P|-1]$, a new vertex $\mathrm{up}^{A,i}_{v,P}$ to G such that the neighborhood of $\mathrm{up}^{A,i}_{v,P}$ is exactly X_v minus the vertices $\{x_{(v,P(j))} \mid j < i\}$. Hence, $\mathrm{up}^{A,1}_{v,P}$ is adjacent to all vertices of X_v. Furthermore, we add an edge between $\mathrm{up}^{A,i}_{v,P}$ and each vertex of $\{w_A \mid w \in P\} \cup \{w_B \mid w \in Q\}$ and an edge between $\mathrm{up}^{A,i}_{v,P}$ and v_B. Moreover, we set

$$\omega''(\mathrm{up}^{A,i}_{v,P}) := 4 - i + 8 \cdot \sum_{j=i}^{|P|} \omega(\{v, P(j)\}) = 4 - i + \sum_{j=i}^{|P|} \omega''(x_{(v,P(j))}).$$

Intuitively, one can obtain an improving 3-neighbor for S in G as follows:

1. if $w_A \notin S$ for any neighbor $w \in N_G(v)$ in P and $u_B \notin S$ for any neighbor $u \in N_G(v)$ in P, then we remove $x_{(v,P(|P|-1))}$ and $x_{(v,P(|P|))}$ and add $\mathrm{up}^{A,|P|-1}_{v,P}$, and
2. if $\mathrm{up}^{A,j}_{v,P} \in S$, where $j \in [2, |P| - 1]$, then we remove $\mathrm{up}^{A,j}_{v,P}$ and $x_{(v,P(j))}$ and add $\mathrm{up}^{A,j-1}_{v,P}$.

Hence, during the simulation of an improving flip of a vertex v in a partition (A, B) from A to B in G, we can replace all vertices of X_v by the vertex $\text{up}_{v,P}^{A,1}$ with a sequence of improving 3-swaps, where $P = N_G(v) \cap B$.

Second, we add a vertex $\text{turn}_{v,P}^{A}$ to G'' which is adjacent to all vertices of X_v, $\{v_A, v_B\}$, and to the vertices of $\{w_A \mid w \in P\} \cup \{w_B \mid w \in Q\}$. Recall that $\omega''(v_A) = \omega''(v_B) = 16 \cdot Z$ where $Z = \sum_{e \in E} \omega(e)$. We set

$$\omega''(\text{turn}_{v,P}^{A}) := 4 + \omega''(v_A) + 8 \cdot \sum_{w \in P} \omega(\{v, w\}) = 4 + 16 \cdot Z + \sum_{w \in P} \omega''(x_{(v,w)}).$$

Intuitively, one can obtain an improving 3-neighbor for S in G if $\text{up}_{v,P}^{A,1}$ is contained in S, by removing both $\text{up}_{v,P}^{A,1}$ and v_A from S and adding $\text{turn}_{v,P}^{A}$ to S.

Third, we add, similar to $\text{up}_{v,P}^{A,i}$, for each $i \in [1, |Q| - 1]$ a new vertex $\text{down}_{v,P}^{A,i}$ to G such that the neighborhood of $\text{down}_{v,P}^{A,i}$ is exactly $X_v \setminus \{x_{(Q(j),v)} \mid j < i\}$. Hence, $\text{down}_{v,P}^{A,1}$ is adjacent to all vertices of X_v. Furthermore, we add an edge between $\text{down}_{v,P}^{A,i}$ and each vertex of $\{w_A \mid w \in P\} \cup \{w_B \mid w \in Q\}$ and we also an edge between $\text{down}_{v,P}^{A,i}$ and v_A. Moreover, we set

$$\omega''(\text{down}_{v,P}^{A,i}) := i - 4 + 8 \cdot \sum_{j=i}^{|Q|} \omega(\{v, Q(j)\}) = i - 4 + \sum_{j=i}^{|Q|} \omega''(x_{(v,Q(j))}).$$

Note that $\omega''(\text{down}_{v,P}^{A,i}) > 0$ since $Q \neq \emptyset$ and the images of ω are positive numbers. Intuitively, one can obtain an improving 3-neighbor for S in G as follows:

1. if $\text{turn}_{v,P}^{A} \in S$, then we remove $\text{turn}_{v,P}^{A}$ and add $\text{down}_{v,P}^{A,1}$ and v_B,
2. if $\text{down}_{v,P}^{A,j} \in S$ for some $j < |Q| - 1$, then we remove $\text{down}_{v,P}^{A,j}$ and add $\text{down}_{v,P}^{A,j+1}$ and $x_{(Q(j),v)}$, and
3. if $\text{down}_{v,P}^{A,|Q|-1} \in S$, then we remove $\text{down}_{v,P}^{A,|Q|-1}$ and add $x_{(Q(|Q|-1),v)}$ and $x_{(Q(|Q|),v)}$.

With the current graph, it is possible to simulate a flip of a vertex v from A to B. To also simulate a flip of vertex v from B to A, we add symmetric vertices to G'', that is, for each vertex $\text{up}_{v,P}^{A,j}$, we add a vertex $\text{up}_{v,P}^{B,j}$, for each vertex $\text{turn}_{v,P}^{A}$, we add a vertex $\text{turn}_{v,P}^{B}$, and for each vertex $\text{down}_{v,P}^{A,j}$, we add a vertex $\text{down}_{v,P}^{B,j}$.

The formal definition of these symmetric vertices is deferred to the full version.

Note that we did not add any vertices for $P = \emptyset \in \mathcal{P}_v$ to the graph G''. In the correctness proof, we show that a single improving 3-swap for S is sufficient to simulate the flip of a vertex v of G if no edge incident with v is currently in the cut.

For each vertex $v \in V$, let V_v denote the set of the additional vertices associated with v:

$$V_v := \bigcup_{P \in \mathcal{P}_v, P \neq \emptyset, C \in \{A,B\}} (\{\text{up}_{v,P}^{C,i} \mid i < |P|\} \cup \{\text{turn}_{v,P}^{C}\} \cup \{\text{down}_{v,P}^{C,i} \mid i < |N_G(v) \setminus P|\}).$$

To complete the construction, for each $v \in V$, we make the set $\bigcup_{w \in N_G[v]} V_w$ a clique in G''.

▶ **Lemma 4.2** (*). *The graph G'' has maximum degree at most 3140.*

It remains to define the solution-mapper f. Analogously to the solution-mapper of the presented PLS-reduction for WEIGHTED INDEPENDENT SET/7-swap, for an independent set S, we define $f(S)$ to be the partition (A, B) of G where $A := \{v \in V \mid v_A \in S\}$ and $B := V \setminus A$.

Correctness. To show the correctness of the PLS-reduction, we first analyze the structure of 3-optimal independent sets in G''. To this end, we show in the auxiliary Lemmas 4.3 – 4.5 that we can assume that each 3-optimal independent set in G'' contains for each $v \in V$ either the vertex v_A or the vertex v_B. Recall that for vertex $v \in V$, the vertices v_A and v_B are adjacent in G''. As a consequence, this then implies that for $f(S) = (A, B)$, B is exactly the set $\{v \in V \mid v_B \in S\}$. Finally, in Lemma 4.6, we then show that such an independent set S is not 3-optimal in I'' if $f(S)$ is not flip-optimal in G.

▶ **Lemma 4.3.** *Let S be an independent set in G''. If S contains a vertex $\mathrm{up}_{v,P}^{C,i}$ for $C \in \{A, B\}$, then S is not 3-optimal.*

Proof. First, we show the statement for $i = 1$. By construction, the closed neighborhood $N[\mathrm{turn}_{v,P}^{C}]$ is exactly $N[\mathrm{up}_{v,P}^{C,1}] \cup \{v_C\}$ and $\omega''(\mathrm{turn}_{v,P}^{C}) = 1 + \omega''(\mathrm{up}_{v,P}^{C,1}) + \omega''(v_C)$. Hence, S is not 3-optimal in G'' since $S' := (S \cup \{\mathrm{turn}_{v,P}^{C}\}) \setminus \{\mathrm{up}_{v,P}^{C,1}, v_C\}$ is an improving 3-neighbor of S in G''. This holds even if v_C is not in S.

Second, we show the statement for $i > 1$. Let $r := x_{(v,P(i-1))}$ if $C = A$ and $r := x_{(P(i-1),v)}$ if $C = B$. Note that by construction, the closed neighborhood $N[\mathrm{up}_{v,P}^{C,i-1}]$ is exactly $N[\mathrm{up}_{v,P}^{C,i}] \cup \{r\}$ and $\omega''(\mathrm{up}_{v,P}^{C,i-1}) = 1 + \omega''(\mathrm{up}_{v,P}^{C,i}) + \omega''(r)$. Hence, if an independent set S contains $\mathrm{up}_{v,P}^{C,i}$ with $i > 1$, then S is not 3-optimal in G'' since $(S \cup \{\mathrm{up}_{v,P}^{C,i-1}\}) \setminus \{\mathrm{up}_{v,P}^{C,i}, r\}$ is an improving 3-neighbor of S in G''. This holds even if r is not in S. ◀

▶ **Lemma 4.4 (*).** *Let S be an independent set in G''. If there is a vertex $v \in V$ such that S avoids v_A, v_B, and $T_v := \{\mathrm{turn}_{v,P}^{A}, \mathrm{turn}_{v,P}^{B} \mid P \in \mathcal{P}_v, P \neq \emptyset\}$, then S is not 3-optimal.*

Hence, we can assume that each 3-optimal independent set S in G'' contains for each vertex $v \in V$ either v_A, v_B, or exactly one vertex of $T_v := \{\mathrm{turn}_{v,P}^{A}, \mathrm{turn}_{v,P}^{B} \mid P \in \mathcal{P}_v, P \neq \emptyset\}$, and no vertex of $\{\mathrm{up}_{v,P}^{A,i}, \mathrm{up}_{v,P}^{B,i} \mid P \in \mathcal{P}_v, P \neq \emptyset, i < |P|\}$. In the following, we call an independent set S of G'' *nice* if $S \subseteq V' = V_A \cup V_B \cup \bigcup_{v \in V} X_v$ and if S is a nice independent set for the instance I' of Weighted Independent Set/7-swap. That is, if for $A := \{v \in V \mid v_A \in S\}$ and $B := \{v \in V \mid v_B \in S\}$, (A, B) is a partition of G and for each edge $\{u, v\} \in E$ with $(u, v) \in A \times B$, the vertex $x_{(u,v)}$ is contained in S. Next, we show similar to Lemma 3.4, that an independent set S in G'' is not 3-optimal if S is not nice.

▶ **Lemma 4.5.** *Let S be an independent set in G''. If S is not nice, then S is not 3-optimal.*

Proof. Let S be an independent set in G'' which is not nice. Due to Lemma 4.3, we know that S is not 3-optimal if some vertex $\mathrm{up}_{v,P}^{C,i}$ for $C \in A, B$ is contained in S. Hence, in the following, we assume that none of these vertices is contained in S. Moreover, due to Lemma 4.4, we also know that S is not 3-optimal if there is some vertex $v \in V$ such that S does not contain v_A, v_B, and no vertex of $\{\mathrm{turn}_{v,P}^{A}, \mathrm{turn}_{v,P}^{B} \mid P \in \mathcal{P}_v, P \neq \emptyset\}$. Hence, in the following we further assume that S contains one of these vertices for some $v \in V$.

In a first step, we show that if for some $v \in V$, S contains some vertex of $\{\mathrm{turn}_{v,P}^{A}, \mathrm{turn}_{v,P}^{B} \mid P \in \mathcal{P}_v, P \neq \emptyset\}$, then S is not 3-optimal. Assume without loss of generality that $\mathrm{turn}_{v,P}^{A} \in S$ and let $Q := N_G(v) \setminus P$. Recall that $\bigcup_{w \in N_G[v]} V_w$ is a clique in G'' which implies that for each $w \in N_G(v)$, S contains no vertex of $\{\mathrm{turn}_{w,P'}^{A}, \mathrm{turn}_{w,P'}^{B} \mid P' \in \mathcal{P}_w, P' \neq \emptyset\} \subseteq V_w$. Hence, due to Lemma 4.4, to for each $w \in N_G(v)$, S contains either w_A or w_B. Moreover, $\mathrm{turn}_{v,P}^{A}$ is adjacent to all vertices of X_v, all vertices of $\{w_A \mid w \in P\}$, and all vertices of $\{w_B \mid w \in Q\}$. As a consequence, for each $w \in P$, $w_B \in S$, and $w_A \notin S$, and for each $u \in Q$, $u_A \in S$ and $u_B \notin S$. Furthermore, S contains no other neighbor of v_A or v_B. Recall that $P \neq N_G(v)$ which implies $Q = \emptyset$. In the following, it suffices to distinguish between $|Q| = 1$ and $|Q| > 1$.

First, suppose that $|Q| = 1$ and let w denote the unique vertex of Q. We show that $S' := (S \cup \{v_B, x_{(w,v)}\}) \setminus \{\text{turn}^A_{v,P}\}$ is an improving 3-neighbor of S in G''. By construction, v_B and $x_{(w,v)}$ are non-adjacent in G'' and

$$\begin{aligned}\omega''(v_B) + \omega''(x_{(w,v)}) &= 16 \cdot Z + 8 \cdot \omega(\{v,w\}) = 16 \cdot Z + 8 \cdot \sum_{u \in Q} \omega(\{v,u\}) \\ &> 16 \cdot Z + 4 + 8 \cdot \sum_{u \in P} \omega(\{v,u\}) = \omega''(\text{turn}^A_{v,P})\end{aligned}$$

since the images of ω are positive numbers and $P \in \mathcal{P}_v$ which implies $\sum_{u \in Q} \omega(\{v,u\}) > \sum_{u \in P} \omega(\{v,u\})$. Hence, it remains to show that S is an independent set. Since by definition, $N[v_B] \subseteq N[\text{turn}^A_{v,P}]$, we only have to show that there is no other neighbor of $x_{(w,v)}$ in S besides $\text{turn}^A_{v,P}$. By construction, the neighborhood of $x_{(w,v)}$ in G'' is a subset of $\{v_A, w_B\} \cup V_v \cup V_w \cup X_v \cup X_w$. Now, $\text{turn}^A_{v,P}$ is adjacent to all vertices of this set except for some vertices of X_w. Hence, we only have to consider the neighbors of $x_{(w,v)}$ in X_w. By construction, these are the vertices $x_{(u,w)}$ where $u \in N_G(w)$. Since w_A is contained in S and each of these vertices $x_{(u,w)}$ is adjacent to w_A in G'', $x_{(w,v)}$ has no neighbor in S besides $\text{turn}^A_{v,P}$. As a consequence, S' is an improving 3-neighbor of S.

Second, suppose that $|Q| > 1$. Then, the vertex $\text{down}^{A,1}_{v,P}$ exists. We show that $S' := (S \cup \{v_B, \text{down}^{A,1}_{v,P}\}) \setminus \{\text{turn}^A_{v,P}\}$ is an improving 3-neighbor of S in G''. By construction, v_B and $\text{down}^{A,1}_{v,P}$ are non-adjacent in G'' and

$$\begin{aligned}\omega''(v_B) + \omega''(\text{down}^{A,1}_{v,P}) &= 16 \cdot Z - 3 + 8 \cdot \sum_{w \in Q} \omega(\{v,w\}) \\ &> 16 \cdot Z + 4 + 8 \cdot \sum_{u \in P} \omega(\{v,u\}) = \omega''(\text{turn}^A_{v,P})\end{aligned}$$

since the images of ω are positive numbers and $P \in \mathcal{P}_v$ which implies $\sum_{u \in Q} \omega(\{v,u\}) > \sum_{u \in P} \omega(\{v,u\})$. Hence, it remains to show that S is an independent set. By definition, $N[v_B] \subseteq N[\text{turn}^A_{v,P}]$ and $N[\text{down}^{A,1}_{v,P}] \subseteq N[\text{turn}^A_{v,P}]$, which implies that $\text{turn}^A_{v,P}$ is the unique neighbor of both v_B and $\text{turn}^A_{v,P}$ in S. As a consequence, S' is an independent set and thus an improving 3-neighbor of S. Hence, in the following, we can also assume that for each $v \in V$, S contains either v_A or v_B.

Next, we show that if for some $v \in V$, there is some vertex $r \in V_v$ contained in S, then S is not 3-optimal. Note that we already showed that this is the case if r is $\text{up}^{A,i}_{v,P}$, $\text{up}^{B,i}_{v,P}$, $\text{turn}^A_{v,P}$, or $\text{turn}^B_{v,P}$. Hence, it remains to show the claim for r being $\text{down}^{A,i}_{v,P}$ or $\text{down}^{B,i}_{v,P}$. Assume without loss of generality that there is a nonempty set $P \in \mathcal{P}_v$ and some $i < |Q|$ with $Q := N_G(v) \setminus P$ such that $\text{down}^{A,i}_{v,P}$ is contained in S. The proof of the fact that in this case S is not 3-optimal is deferred to the full version.

Summarizing, we can assume in the following that $S \subseteq V' = V_A \cup V_B \cup \bigcup_{v \in V} X_v$ and that (A, B) is a partition of G, where $A := \{v \in V \mid v_A \in S\}$ and $B := \{v \in V \mid v_B \in S\}$. Note that for each edge $\{v, w\} \in E$ with $(v, w) \notin A \times B$, the vertex $x_{(v,w)}$ is not contained in S since $v_B \in S$ or $w_A \in S$, and both these vertices are adjacent to $x_{(v,w)}$. Hence, it remains to show that if there is some edge $\{v, w\} \in E$ with $(v, w) \in A \times B$ such that $x_{(v,w)}$ is not contained in S, then S is not 3-optimal in G''. To this end, we show that $S \cup \{x_{(v,w)}\}$ is an independent set in G''. By construction, $x_{(v,w)}$ is adjacent to v_B, w_A, some vertices of $V_v \cup V_w$, and the vertices $\{x_{(u,v)} \mid u \in N_G(v)\} \cup \{x_{(w,u)} \mid u \in N_G(w)\}$. Recall that S contains no vertex of $V_v \cup V_w$. Moreover, since $(v, w) \in A \times B$, v_A and w_B are contained in S which implies that v_B and w_A are not contained in S. Furthermore, since all vertices of $\{x_{(u,v)} \mid u \in N_G(v)\}$ are adjacent to v_A, all vertices of $\{x_{(w,u)} \mid u \in N_G(w)\}$ are adjacent to w_B, and v_A and w_B are contained in S, $S \cup \{x_{(v,w)}\}$ is an independent set in G''.

We conclude that if S is not nice in G'', then S is not 3-optimal. ◀

Now the following implies the correctness of the PLS-reduction.

▶ **Lemma 4.6 (*).** *Let S be a nice independent set in G'' and let $A := \{v \in V \mid v_A \in S\}$ and $B := \{v \in V \mid v_B \in S\}$. If (A, B) is not flip-optimal in G, then S is not 3-optimal.*

Next, we obtain similar results for Weighted Dominating Set.

▶ **Theorem 4.7 (*).** *Let $k \geq 3$. There is a PLS-reduction from Weighted Independent Set/k-swap to Weighted Dominating Set/k-swap where the maximum degree of the output graph is at most two times the maximum degree of the input graph.*

Hence, we obtain the following due to Theorem 4.7, Theorem 3.1, and Theorem 4.1.

▶ **Corollary 4.8.** *Weighted Dominating Set/7-swap is PLS-complete on graphs of maximum degree at most 12 and Weighted Dominating Set/3-swap is PLS-complete on graphs of constant maximum degree.*

5 Finding Locally Optimal Solutions for Restricted 3-Swaps

We now show that we can find locally optimal solutions in polynomial time for Weighted Independent Set and Weighted Dominating Set if we restrict the allowed 3-swaps as follows: we either only allow swaps that add at most one vertex to the current solution or we allow only swaps that remove at most one vertex from the solution. These are exactly the $(1, 2)$-swaps and $(2, 1)$-swaps, respectively, since a 3-swap that removes three vertices from the current solution or that adds three vertices to the solution is either not improving, or the solution is not 1-optimal.

Recall that a $(k^{\text{in}}, k^{\text{out}})$-swap W for a set S is a k-swap with $k^{\text{in}} + k^{\text{out}} \leq k$ such that $|W \setminus S| \leq k^{\text{in}}$ and $|W \cap S| \leq k^{\text{out}}$.

First, we show that we can compute in $\mathcal{O}(n \cdot \log(n) + m)$ time a $(1, 2)$-optimal independent set S. More precisely, we show that S is even $(1, k)$-optimal for every $k \in \mathbb{N}$.

▶ **Theorem 5.1 (*).** *One can compute in $\mathcal{O}(n \cdot \log(n) + m)$ time an independent set which is $(1, k)$-optimal for every $k \in \mathbb{N}$.*

Second, we show that we can also compute in $\mathcal{O}(n \cdot \log(n) + m)$ time a $(2, 1)$-optimal dominating set S. More precisely, we show that S is even $(k, 1)$-optimal for every $k \in \mathbb{N}$.

▶ **Theorem 5.2 (*).** *One can compute in $\mathcal{O}(n \cdot \log(n) + m)$ time a dominating set which is $(k, 1)$-optimal for every $k \in \mathbb{N}$.*

▶ **Theorem 5.3.** *Let L be a subset-weight maximization problem, let I be an instance of L, and let $k \in \mathcal{O}(1)$. One can compute in polynomial time a $(k, 1)$-optimal solution S for I.*

Proof. Recall that since L is a subset-weight maximization problem, L consists of functions U, f, g, and ω, where for each instance I of L, $U(I)$ is the universe of I, $f(I, S)$ checks if S is a solution for I, $g(I)$ computes some feasible solution for I, and $\omega(I, u)$ assigns a weight to each $u \in U(I)$. Moreover, the functions U, f, g, and ω are polynomial-time computable.

Let I be an instance of L and let $k \geq 0$. Note that we can compute some feasible solution $S_0 := g(I)$ in polynomial time. Since $U(I)$ can be computed in polynomial time, $U(I)$ has polynomial size. Let $n := |U(I)|$. Since f and ω can be computed in polynomial time, we can check for a given solution S in $n^{\mathcal{O}(k)}$ time if there is an improving $(k+1)$-swap W such that W is a $(k,1)$-swap for S by considering all subsets of size at most $k+1$ of $U(I)$. Note that this is polynomial time since k is a constant. Hence, we can determine whether a solution S is $(k,1)$-optimal and, if this is not the case, replace S by a $(k,1)$-neighbor, both in polynomial time. Let S_x be a $(k,1)$-optimal feasible solution in I which can be obtained by a sequence $(S_0, S_1, \dots, S_x)$ of consecutive improving $(k,1)$-neighbors in I starting from $g(I) = S_0$. We show that $x \in \mathcal{O}(n^3)$, which implies that a $(k,1)$-optimal feasible solution for I can be computed in polynomial time. Let $\ell \in [1,x]$. To this end, we first show that S_ℓ is never smaller than $S_{\ell-1}$. Assume towards a contradiction that $|S_\ell| < |S_{\ell-1}|$. Then there is some $u \in S_{\ell-1}$ such that $S_\ell = S_{\ell-1} \setminus \{u\}$ since S_ℓ is a $(k,1)$-neighbor of $S_{\ell-1}$ in I. Since the weight of S_ℓ is defined as the sum of weights of the elements of S_ℓ and each element $u \in U(I)$ has a positive weight $\omega(I,u)$, the total weight of S_ℓ is not larger than the total weight of $S_{\ell-1}$, a contradiction. As a consequence, there are at most $y \leq |U(I)|$ distinct indices $\ell_1, \dots, \ell_y$ such that S_{ℓ_i} is larger than S_{ℓ_i-1}. To prove that $x \in \mathcal{O}(n^3)$, we now show that for each $\ell \in [1, x-n^2]$, there is some $z \in [\ell, \ell+n^2]$ where S_z is larger than $S_{\ell-1}$. In other words, after at most n^2 improving swaps that do not increase the size of the solution, the next improving swap increases the size of the solution.

Let $\ell \in [1, x - U(I)^2]$, let $\sigma = (u_1, \dots, u_n)$ be a fixed increasing order of the elements of $U(I)$ according to their weight, and let for each $j \in [\ell, \ell+n^2]$, $q_j := \sum_{u_i \in S_j} i$ denote the sum of the indices of S_j in σ. Note that if S_j and S_{j-1} have same size, $S_j = (S_{j-1} \cup \{u_2\}) \setminus \{u_1\}$ for two elements $u_1 \in U(I)$ and $u_2 \in U(I)$ where the weight of u_2 is larger than the weight of u_1. Hence, q_j is larger than q_{j-1} if S_j and S_{j-1} have same size. Since the value q_j can never exceed n^2, there is some $z \in [\ell, \ell+n^2]$ where the size of S_z is larger than the size of $S_{\ell-1}$. We conclude that $x \in \mathcal{O}(n^3)$ which implies that we can compute in polynomial time a feasible solution S of I such that S is $(k,1)$-optimal in I. ◀

▶ **Corollary 5.4 (*).** *Let L be a subset-weight minimization problem, let I be an instance of L and let $k \in \mathcal{O}(1)$. One can compute in polynomial time a $(1,k)$-optimal solution S for I.*

By the fact that for a maximization problem there is no improving swap that only removes elements from the solution and for a minimization problem there is no improving swap that only adds elements to the solution, Theorem 5.3 and Corollary 5.4 imply that one can find for each subset weight optimization problem L, a 2-optimal solution in polynomial time.

Since Weighted Independent Set is a subset-weight maximization problem and since Weighted Dominating Set is a subset-weight minimization problem, we conclude the following.

▶ **Corollary 5.5.** *Let k be a constant. One can compute in polynomial time a $(k,1)$-optimal independent set and one can compute in polynomial time a $(1,k)$-optimal dominating set.*

Consequently, if we allow only $(1,2)$-swaps or only $(2,1)$-swaps, we can find locally optimal solutions for Weighted Independent Set and Weighted Dominating Set in polynomial time. In contrast, if we allow $(1,2)$-swaps and $(2,1)$-swaps, then we allow all 3-swaps and both problems become PLS-complete even on graphs of constant maximum degree.

6 Conclusion

From a theoretical point of view, the most important open topic is to determine the precise degree bounds that separate the polynomial-time solvable and PLS-complete cases for Weighted Independent Set and Weighted Dominating Set for k-swaps with small constant k-values. From a practical point of view, our findings motivate, for both problems, the use of gap-variants of local search where we are searching for solutions that improve the objective value by at least some threshold d, the hope being that this decreases the number of necessary iterations while preserving solution quality.

Abstract

Finding exact circuit size is notoriously hard. Whereas modern computers and algorithmic techniques allow to find a circuit of size seven in the blink of an eye, it may take more than a week to search for a circuit of size thirteen. One of the reasons of this behavior is that the search space is enormous: the number of circuits of size s is $s^{\Theta(s)}$, the number of Boolean functions on n variables is 2^{2^n}.

In this paper, we explore the following natural heuristic idea for decreasing the size of a given circuit: go through all its subcircuits of moderate size and check whether any of them can be improved by reducing to SAT. This may be viewed as a local search approach: we search for a smaller circuit in a ball around a given circuit. Through this approach, we prove new upper bounds on the circuit size of various symmetric functions. We also demonstrate that some upper bounds that were proved by hand decades ago, can nowadays be found automatically in a few seconds.

1 Boolean Circuits

A Boolean *straight line program* of size r for input variables $(x_1, \ldots, x_n)$ is a sequence of r instructions where each instruction $g \leftarrow h \circ k$ applies a binary Boolean operation $\circ$ to two operands h, k each of which is either an input bit or the result of a previous instruction. If m instructions are designated as outputs, the straight line program computes a function $\{0,1\}^n \to \{0,1\}^m$ in a natural way. We denote the set of all such functions by $B_{n,m}$ and we let $B_n = B_{n,1}$. For a Boolean function $f\colon \{0,1\}^n \to \{0,1\}^m$, by size$(f)$ we denote the minimum size of a straight line program computing f. A Boolean *circuit* shows a graph of a program: for every instruction $g \leftarrow h \circ k$, there is a node g with two directed incoming edges from nodes h and k.

Figure 1 gives an example for the $\mathrm{SUM}_n\colon \{0,1\}^n \to \{0,1\}^l$ function that computes the binary representation of the sum of n bits:

$$\mathrm{SUM}_n(x_1, \ldots, x_n) = (w_0, w_1, \ldots, w_{l-1})\colon \sum_{i=1}^{n} x_i = \sum_{i=0}^{l-1} 2^i w_i, \quad \text{where } l = \lceil \log_2(n+1) \rceil .$$

This function transforms n bits of weight 0 into l bits of weights $(0, 1, \ldots, l-1)$.

```
def sum2(x1, x2):
    w0 = x1 ^ x2
    w1 = x1 * x2
    return w0, w1
```

```
def sum3(x1, x2, x3):
    a = x1 ^ x2
    b = x2 ^ x3
    c = a | b
    w0 = a ^ x3
    w1 = c ^ w0
    return w0, w1
```

Figure 1 Optimal size straight line programs and circuits for SUM$_2$ and SUM$_3$. These two circuits are known as *half adder* and *full adder*.

The straight line programs are given in `Python` so that it is particularly easy to verify their correctness. For example, the program for SUM$_3$ can be verified with just three lines of code:

```
from itertools import product

for x1, x2, x3 in product(range(2), repeat=3):
    w0, w1 = sum3(x1, x2, x3)
    assert x1 + x2 + x3 == w0 + 2 * w1
```

Determining size(f) requires proving lower bounds: to show that size$(f) > \alpha$, one needs to prove that *every* circuit of size at most α does not compute f. Known lower bounds are far from being satisfactory: the strongest known lower bound for a function family in NP is $(3+1/86)n - o(n)$ [7]. Here, by a *function family* we mean an infinite sequence of functions $\{f_n\}_{n=1}^{\infty}$ where $f_n \in B_n$. Even proving lower bounds for specific functions (rather than function families) is difficult. Brute force approaches become impractical quickly: $|B_n| = 2^{2^n}$, hence already for $n = 6$, one cannot just enumerate all functions from B_n; also, the number of circuits of size s is $s^{\Theta(s)}$, hence checking all circuits of size s takes reasonable time for small values of s only. Knuth [11] found the exact circuit size of all functions from B_4 and B_5.

Finding the exact value of size(f) for $f \in B_6$ is already a difficult computational task for modern computers and techniques. One approach is to translate a statement "there exists a circuit of size s computing f" to a Boolean formula and to pass it to a SAT solver. Then, if the formula is satisfiable, one decodes a circuit from its satisfying assignment; otherwise, one gets a (computer generated) proof of a lower bound size$(f) > s$. This circuit synthesis approach was proposed by Kojevnikov et al. [13] and, since then, has been used in various circuit synthesis programs (`abc` [1], `mockturtle` [24], `sat-chains` [10]).

State-of-the-art SAT solvers are surprisingly efficient and allow to handle various practically important problems (with millions of variables) and even help to resolve open problems in mathematics [2]. Still, already for small values of n and s the problem of finding a circuit of size s for a function from B_n is difficult for SAT solvers. We demonstrate the limits of this approach on *counting* functions: $\mathrm{MOD}_n^{m,r}(x_1, \ldots, x_n) = [x_1 + \cdots + x_n \equiv r \bmod m]$ (here, $[\cdot]$ is the Iverson bracket: $[S]$ is equal to 1 if S is true and is equal to 0 otherwise). Using SAT solvers, Knuth [12, solution to exercise 480] found size$(\mathrm{MOD}_n^{3,r})$ for all $3 \le n \le 5$ and all $0 \le r \le 2$. Generalizing the found values, he made the following conjecture:

$$\text{size}(\mathrm{MOD}_n^{3,r}) = 3n - 5 - [(n+r) \equiv 0 \bmod 3] \text{ for all } n \ge 3 \text{ and } r. \tag{1}$$

He was also able to prove (using SAT solvers) that size$(\mathrm{MOD}_6^{3,0}) = 12$ and wrote: "The case $n = 6$ and $r \neq 0$, which lies tantalizingly close to the limits of today's solvers, is still unknown."

Knuth also describes various symmetry breaking heuristics and shows which of them give a significant speedup. Haaswijk et al. [8] show another way of speeding up the SAT-based approach for circuit synthesis: first, generate all possible circuit topologies, then, for each topology check using SAT solvers whether one can assign Boolean operation to the gates so that the resulting circuit computes a given function.

To summarize, our current abilities for checking whether there exists a Boolean circuit of size s are roughly the following: for $s \leq 6$, this can be done in a few seconds; for $7 \leq s \leq 12$, this can (sometimes) be done in a few days; for $s \geq 13$, this is out of reach.

1.1 New Results

In this paper, we explore the limits of the following natural idea: given a circuit, try to improve its size by improving (using SAT solvers, for example) the size of its subcircuit of size seven. This is a kind of a local search approach: we have no possibility to go through the whole space of all circuits, but we can at least search in a neighborhood of a given circuit. This allows us to work with circuits consisting of many gates.

As the results of experiments, we show several circuits for which the approach described above leads to improved upper bounds.

- We support Knuth's conjecture (1) for $\mathrm{MOD}_n^{3,r}$ by proving the matching upper bound:

  $$\mathrm{size}(\mathrm{MOD}_n^{3,r}) \leq 3n - 5 - [(n+r) \equiv 0 \bmod 3] \text{ for all } n \geq 3 \text{ and } r.$$

  This improves slightly the previously known upper bound $\mathrm{size}(\mathrm{MOD}_n^{3,r}) \leq 3n - 4$ by Demenkov et al. [4]. To prove Knuth's conjecture, one also needs to prove a lower bound on $\mathrm{size}(\mathrm{MOD}_n^{3,r})$. The currently strongest known lower bound for $\mathrm{size}(\mathrm{MOD}_n^{3,r})$ is $2.5n - O(1)$ due to Stockmeyer [25].
- We present improvements for $\mathrm{size}(\mathrm{SUM}_n)$ for various small n and show that some of these circuits and their parts can be used as building blocks to design efficient circuits for other functions in semiautomatic fashion. In particular, we show that a part of an optimal circuit for SUM_5 can be used to build optimal circuits of size $2.5n$ for $\mathrm{MOD}_n^{4,r}$ [25] and best known circuits of size $4.5n+o(n)$ for SUM_n [4]. In turn, an efficient circuit for SUM_5 can be found in a few seconds if one starts from a standard circuit for SUM_5 composed out of two full adders and one half adder.
- We design new circuits for the threshold function defined as follows:

  $$\mathrm{THR}_n^k(x_1, \dots, x_n) = [x_1 + \dots + x_n \geq k] \,.$$

  The best known upper bounds for THR are the following:

  $$\mathrm{size}(\mathrm{THR}_n^k) \leq kn + o(n) \text{ for } 2 \leq k \leq 4 \text{ [5] (see also [26, 6.2, Theorem 2.3])},$$
  $$\mathrm{size}(\mathrm{THR}_n^k) \leq 4.5n + o(n) \text{ for } 5 \leq k \text{ [4]}.$$

  We get the following improvement: $\mathrm{size}(\mathrm{THR}_n^k) \leq (4.5 - 2^{2-\lceil \log_2 k \rceil})n + o(n)$ for $4 \leq k = O(1)$. In particular, $\mathrm{size}(\mathrm{THR}_n^4) \leq 3.5n + o(n)$ and $\mathrm{size}(\mathrm{THR}_n^k) \leq 4n + o(n)$ for $5 \leq k \leq 8$.

The improved upper bounds are obtained in a semiautomatic fashion: first, we automatically improve a given small circuit with a fixed number of inputs using SAT solvers; then, we generalize it to every input size. For some function families, the second step is already known (for example, given a small circuit for SUM_5, it is not difficult to use it as a building block to design an efficient circuit for SUM_n for every n; see Section 3.1), though in general this still needs to be done manually.

1.2 Related work

The approach we use in this paper follows the SAT-based local improvement method (SLIM): to improve an existing discrete structure one goes through all its substructures of size accessible to a SAT solver. SLIM has been applied successfully to the following structures: branchwidth [16], treewidth [6], treedepth [20], Bayesian network structure learning [21], decision tree learning [22].

2 Program: Feature Overview and Evaluation

The program is implemented in `Python`. We give a high-level overview of its main features below. All the code shown below can be found in the file `tutorial.py` at [3]. One may run it after installing a few `Python` modules. Alternatively, one may run the Jupyter notebook `tutorial.ipynb` in the cloud (without installing anything) by pressing the badge "Colab" at the repository page [3].

2.1 Manipulating Circuits

This is done through the `Circuit` class. One can load and save circuits as well as print and draw them. A nicely looking layout of a circuit is produced by the `pygraphviz` module [19]. The program also contains some built-in circuits that can be used as building blocks. The following sample code constructs a circuit for SUM$_5$ out of two full adders and one half adder. This construction is shown in Figure 2(a). Then, the circuit is verified via the `check_sum_circuit` method. Finally, the circuit is drawn. As a result, one gets a picture similar to the one in Figure 2(b).

```
circuit = Circuit(input_labels=['x1', 'x2', 'x3', 'x4', 'x5'])
x1, x2, x3, x4, x5 = circuit.input_labels
a0, a1 = add_sum3(circuit, [x1, x2, x3])
b0, b1 = add_sum3(circuit, [a0, x4, x5])
w1, w2 = add_sum2(circuit, [a1, b1])
circuit.outputs = [b0, w1, w2]
check_sum_circuit(circuit)
circuit.draw('sum5')
```

2.2 Finding Efficient Circuits

The class `CircuitFinder` allows to check whether there exists a circuit of the required size for a given Boolean function. For example, one may discover the full adder as follows. (The function `sum_n` returns the list of $\lceil \log_2(n+1) \rceil$ bits of the binary representation of the sum of n bits.)

```
def sum_n(x):
    return [(sum(x) >> i) & 1 for i in range(ceil(log2(len(x) + 1)))]

circuit_finder = CircuitFinder(dimension=3, number_of_gates=5,
                               function=sum_n)
circuit = circuit_finder.solve_cnf_formula()
circuit.draw('sum3')
```

(c)

Figure 2 (a) A schematic circuit for SUM$_5$ composed out of two full adders and one half adder. (b) The corresponding circuit of size 12. (c) An improved circuit of size 11.

This is done by encoding the task as a CNF formula and invoking a SAT solver (via the `pysat` module [9]). The reduction to SAT is described in [13]. Basically, one translates a statement "there exists a circuit of size s comuting a given function $f\colon \{0,1\}^n \to \{0,1\}^m$" to CNF-SAT. To do this, one introduces many auxiliary variables: for example, for every $x \in \{0,1\}^n$ and every $1 \le i \le r$, one uses a variable that is responsible for the value of the i-th gate on the input x.

As mentioned in the introduction, the limits of applicability of this approach (for finding a circuit of size s) are roughly the following: for $s \le 6$, it usually works in less than a minute; for $7 \le s \le 12$, it may already take up to several hours or days; for $s \ge 13$, it becomes almost impractical. The running time may vary a lot for inputs of the same length. In particular, it usually takes much longer to prove that the required circuit does not exist (by proving that the corresponding formula is unsatisfiable). Table 1 reports the running time of this approach on several datasets.

2.3 Improving Circuits

The method `improve_circuit` goes through all subcircuits of a given size of a given circuit and checks whether any of them can be replaced by a smaller subcircuit (computing the same function) via `find_circuit`. For example, applying this method to the circuit from Figure 2(b) gives the circuit from Figure 2(c) in a few seconds.

```
circuit = Circuit(input_labels=[f'x{i}' for i in range(1, 6)], gates={})
circuit.outputs = add_sum5_suboptimal(circuit, circuit.input_labels)
improved_circuit = improve_circuit(circuit, subcircuit_size=5,
                                   connected=True)
print(improved_circuit)
improved_circuit.draw('sum5')
```

Table 1 The running time of `CircuitFinder` on various Boolean functions.

function	circuit size	status	time (sec.)
SUM_5	12	SAT	141.4
SUM_5	11	SAT	337.8
$\mathrm{MOD}_4^{3,0}$	7	SAT	0.2
$\mathrm{MOD}_4^{3,0}$	6	UNSAT	1178.8
$\mathrm{MOD}_4^{3,1}$	7	SAT	0.2
$\mathrm{MOD}_4^{3,1}$	6	UNSAT	1756.5
$\mathrm{MOD}_4^{3,2}$	6	SAT	0.2
$\mathrm{MOD}_4^{3,2}$	5	UNSAT	12.6
$\mathrm{MOD}_5^{3,0}$	10	SAT	90.1
$\mathrm{MOD}_5^{3,1}$	9	SAT	50.1
$\mathrm{MOD}_5^{3,2}$	10	SAT	74.3

Table 2 shows the time taken by `improve_circuit` to improve some of the known circuits for SUM, MOD^3, and THR^4. For SUM, we start from known circuits of size about $5n$ (composed out of full adders and half adders). For MOD^3, we start from circuits of size $3n-4$ presented by Demenkov et al. [4]. For THR^4, we start from circuits of size about $5n$ (we start by computing SUM_n and then compare the resulting $\log n$-bit integer to 4).

Table 2 The running time of `improve_circuit` on various Boolean functions.

function	circuit size	time (sec.)
SUM_5	$12 \to 11$	6.7
SUM_7	$20 \to 19$	5.8
$\mathrm{MOD}_6^{3,0}$	$15 \to 14$	17.0
$\mathrm{MOD}_6^{3,1}$	$15 \to 14$	17.2
$\mathrm{MOD}_6^{3,2}$	$14 \to 13$	16.7
$\mathrm{MOD}_7^{3,0}$	$17 \to 16$	31.3
$\mathrm{MOD}_7^{3,1}$	$17 \to 16$	33.6
$\mathrm{MOD}_7^{3,2}$	$16 \to 15$	30.5
THR_5^4	$23 \to 10$	38.6
THR_6^4	$28 \to 14$	42.1
THR_7^4	$31 \to 17$	43.8
THR_8^4	$40 \to 22$	55.1

3 New Circuits

In this section, we present new circuits for symmetric functions found with the help of the program. A function $f(x_1, \ldots, x_n)$ is called *symmetric* if its value depends on $\sum_{i=1}^n x_i$ only. They are among the most basic Boolean functions:

- to specify an arbitrary Boolean function from B_n, one needs to write down its truth table of length 2^n; symmetric functions allow for more compact representation: it is enough to specify $n+1$ bits (for each of $n+1$ values of $\sum_{i=1}^n x_i$);

- circuit complexity of almost all functions of n variables is exponential ($\Theta(2^n/n)$), whereas any symmetric function can be computed by a linear size circuit ($O(n)$).

Despite simplicity of symmetric functions, we still do not know how optimal circuits look like for most of them. Below, we present new circuits for some of these functions.

3.1 Sum Function

The SUM function is a fundamental symmetric function: for any symmetric $f \in B_n$, $\text{size}(f) \leq \text{size}(\text{SUM}_n) + o(n)$. The reason for this is that any function from B_n can be computed by a circuit of size $O(2^n/n)$ by the results of Muller [18] and Lupanov [17]. This allows to compute any symmetric $f(x_1, \dots, x_n) \in B_n$ as follows: first, compute $\text{SUM}_n(x_1, \dots, x_n)$ using $\text{size}(\text{SUM}_n)$ gates; then, compute the resulting bit using at most $O(2^{\log n}/\log n) = o(n)$ gates. For the same reason, any lower bound $\text{size}(f) \geq \alpha$ for a symmetric function $f \in B_n$ implies a lower bound $\text{size}(\text{SUM}_n) \geq \alpha - o(n)$. Currently, we know the following bounds for SUM_n: $2.5n - O(1) \leq \text{size}(\text{SUM}_n) \leq 4.5n + o(n)$. The lower bound is due to Stockmeyer [25], the upper bound is due to Demenkov et al. [4].

A circuit for SUM_n can be constructed from circuits for SUM_k for some small k. For example, using full and half adders as building blocks, one can compute SUM_n (for any n) by a circuit of size $5n$ as follows. Start from n bits $(x_1, \dots, x_n)$ of weight 0. While there are three bits of the same weight k, replace them by two bits of weights k and $k+1$ using a full adder. This way, one gets at most two bits of each weight $0, 1, \dots, l-1$ ($l = \lceil \log_2(n+1) \rceil$) in at most $5(n-l)$ gates (as each full adder reduces the number of bits). To leave exactly one bit of each weight, it suffices to use at most l half or full adders ($o(n)$ gates). Let us denote the size of the resulting circuit by $s(n)$. The first row of Table 3 shows the values of $s(n)$ for some $n \leq 15$ (see (28) in [11]).

Table 3 The first row gives the size $s(n)$ of a circuit for SUM_n composed out of half and full adders, the second row shows known upper bounds for $\text{size}(\text{SUM}_n)$ (all of them were known before our work, see (28) in [11]).

n	2	3	4	5	6	7	8	9	10	15
$s(n)$	2	5	9	12	17	20	26	29	34	55
$\text{size}(\text{SUM}_n)$	2	5	9	11	≤ 16	≤ 19	≤ 25	≤ 27	≤ 32	≤ 53

In a similar fashion, one can get an upper bound (see Theorem 1 in [14])

$$\text{size}(\text{SUM}_n) \leq \frac{\text{size}(\text{SUM}_k)}{k - \lceil \log_2(k+1) \rceil} \cdot n + o(n)\,. \tag{2}$$

This motivates the search for efficient circuits for SUM_k for small values of k. The bottom row of Table 3 gives upper bounds that we were able to find using the program. The table shows that the first value where $s(n)$ is not optimal is $n = 5$. The best upper bound for SUM_n given by (2) is $4.75n + o(n)$ for $k = 7$. The upper bound for $k = 15$ is $53n/11 + o(n)$ which is worse than the previous upper bound. But if it turned out that $\text{size}(\text{SUM}_{15}) \leq 52$, it would give a better upper bound.

The found circuits for SUM_n for $n \leq 15$ do not allow to improve the strongest known upper bound $\text{size}(\text{SUM}_n) \leq 4.5n + o(n)$ due to Demenkov et al. [4]. Below, we present several interesting observations on the found circuits.

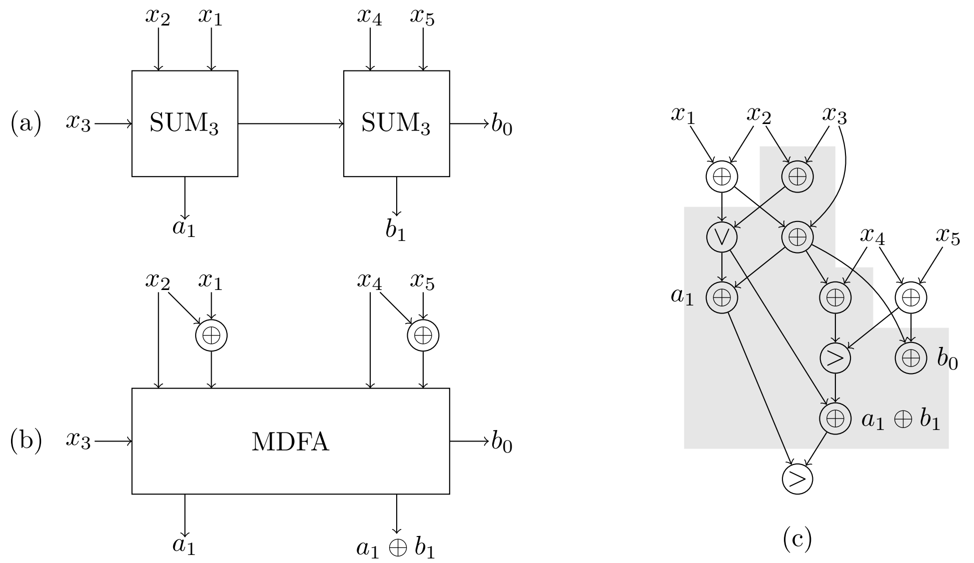

Figure 3 (a) Two consecutive SUM$_3$ blocks. (b) The MDFA block. (c) The highlighted part of the optimal circuit for SUM$_5$ computes MDFA.

3.1.1 Best Known Upper Bound for the SUM Function

The optimal circuit of size 11 for SUM$_5$ shown in Figure 2(c) can be used to get an upper bound $4.5n + o(n)$ for size(SUM$_n$) (though not through (2) directly). To do this, consider two consecutive SUM$_3$ circuits shown in Figure 3(a). They compute a function DFA$(x_1, x_2, x_3, x_4, x_5) = (b_0, b_1, a_1)$ (for double full adder) such that, for every $x_1, \ldots, x_5 \in \{0, 1\}$, $x_1 + \cdots + x_5 = b_0 + 2(b_1 + a_1)$. Figure 3(a) shows that size(DFA) ≤ 10. One can construct a similar block, called MDFA (for modified double full adder), such that

$$\text{MDFA}(x_1 \oplus x_2, x_2, x_3, x_4, x_4 \oplus x_5) = (b_0, a_1, a_1 \oplus b_1)\,,$$

see Figure 3(b).

The fact that MDFA uses the encoding $(p, p \oplus q)$ for pairs of bits (p, q), allows to use it recursively to compute SUM$_n$. As the original construction is presented in [4], below we give a sketch only.

1. Compute $x_2 \oplus x_3, x_4 \oplus x_5, \ldots, x_{n-1} \oplus x_n$ ($n/2$ gates).
2. Apply at most $n/2$ MDFA blocks (no more than $4n$ gates).
3. The last MDFA block outputs two bits: a and $a \oplus b$. Instead of them, one needs to compute $a \oplus b$ and $a \wedge b$. To achieve this, it suffices to apply $x > y = (x \wedge \overline{y})$ operation: $a \wedge b = a > (a \oplus b)$.

Figure 4 shows an example for $n = 17$.

The MDFA block was constructed by Demenkov et al. [4] in a semiautomatic manner. And it turns out that MDFA is just a subcircuit of the optimal circuit for SUM$_5$! See Figure 3(c).

3.1.2 Best Known Circuits for SUM with New Structure

For many upper bounds from the bottom row of Table 3, we found circuits with the following interesting structure: the first thing the circuit computes is $x_1 \oplus x_2 \oplus \cdots \oplus x_n$; moreover the variables $x_2, \ldots, x_n$ are used for this only. This is best illustrated by an example, see Figure 5.

Figure 4 A circuit computing SUM_{17} composed out of MDFA blocks.

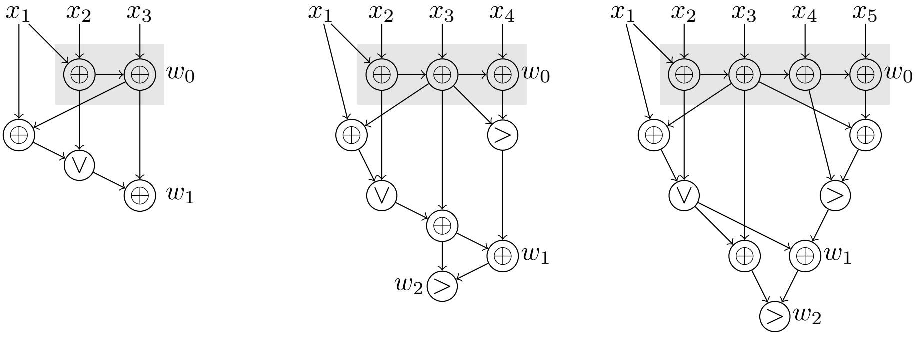

Figure 5 Optimal circuits computing SUM_n for $n = 3, 4, 5$ with a specific structure: every input, except for x_1, has out-degree one.

These circuits can be found using the following code. It demonstrates two new useful features: fixing gates and forbidding wires between some pairs of gates.

```
def sum_n(x):
    return [(sum(x) >> i) & 1 for i in range(ceil(log2(len(x) + 1)))]

for n, size in ((3, 5), (4, 9), (5, 11)):
    circuit_finder = CircuitFinder(dimension=n, number_of_gates=size,
                                   function=sum_n)
    circuit_finder.fix_gate(n, 0, 1, '0110')
    for k in range(n - 2):
        circuit_finder.fix_gate(n + k + 1, k + 2, n + k, '0110')
    for i in range(1, n):
        for j in range(n, n + size):
            if i + n - 1 != j:
                circuit_finder.forbid_wire(i, j)
    circuit = circuit_finder.solve_cnf_formula(verbose=0)
    circuit.draw(f'sum{n}')
```

3.1.3 Optimal Circuits for Counting Modulo 4

The optimal circuit for SUM_5 can be used to construct an optimal circuit of size $2.5n+O(1)$ for $\mathrm{MOD}_n^{4,r}$ due to Stockmeyer [25] (recall that $\mathrm{MOD}_n^{4,r}(x_1,\dots,x_n) = [x_1+\dots+x_n \equiv r \bmod 4]$). To do this, note that there is a subcircuit (of the circuit in Figure 2(c)) of size 9 that computes the two least significant bits (w_0, w_1) of $x_1+\dots+x_5$ (one removes the gates g_5, w_2). To compute $x_1 + \dots + x_n \bmod 4$, one first applies $\frac{n}{4}$ such blocks and then computes the parity of the resulting bits of weight 1 (every block takes four fresh inputs as well as one bit of weight 0 from the previous block). The total size is $9 \cdot \frac{n}{4} + \frac{n}{4} = 2.5n$. Thus, block that Stockmeyer constructed by hand in 1977 to compute MOD_n^4 nowadays can be found automatically in a few seconds.

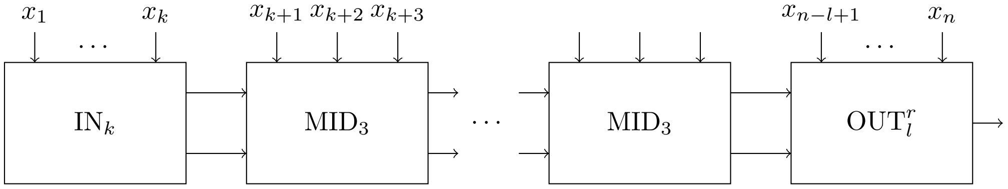
3.2 Modulo-3 Function

In [13], Kojevnikov et al. presented circuits of size $3n + O(1)$ for $\mathrm{MOD}_n^{3,r}$ (for any r). Later, Knuth [12, solution to exercise 480] analyzed their construction and proved an upper bound $3n-4$. Also, by finding the exact values for $\mathrm{size}(\mathrm{MOD}_n^{3,r})$ for all $3 \le n \le 5$ and all $0 \le r \le 2$, he made the conjecture (1). Using our program, we proved the conjectured upper bound for all n.

▶ **Theorem 1.** *For all $n \ge 3$ and all $r \in \{0,1,2\}$,*

$$\mathrm{size}(\mathrm{MOD}_n^{3,r}) \le 3n - 5 - [(n+r) \equiv 0 \bmod 3]\,.$$

Proof. As in [13], we construct the required circuit out of constant size blocks. Schematically, the circuit looks as follows.



Here, the n input bits are passed from above. What is passed from block to block (from left to right) is the pair of bits (r_0, r_1) encoding the current remainder r modulo 3 as follows: if $r = 0$, then $(r_0, r_1) = (0, 0)$; if $r = 1$, then $(r_0, r_1) = (0, 1)$; if $r = 2$, then $r_0 = 1$. The first block IN_k takes the first k input bits and computes the remainder of their sum modulo 3. It is followed by a number of MID_3 blocks each of which takes the current remainder and three new input bits and computes the new remainder. Finally, the block OUT_l^r takes the remainder and the last l input bits and outputs $\mathrm{MOD}_n^{3,r}$. The integers k, l take values in $\{2,3,4\}$ and $\{1,2,3\}$, respectively. Their exact values depend on r and $n \bmod 3$ as described below.

The theorem follows from the following upper bounds on the circuit size of the just introduced functions: $\mathrm{size}(\mathrm{IN}_2) \le 2$, $\mathrm{size}(\mathrm{IN}_3) \le 5$, $\mathrm{size}(\mathrm{IN}_4) \le 7$, $\mathrm{size}(\mathrm{MID}_3) \le 9$, $\mathrm{size}(\mathrm{OUT}_2^0) \le 5$, $\mathrm{size}(\mathrm{OUT}_1^1) \le 2$, $\mathrm{size}(\mathrm{OUT}_3^2) \le 8$. The corresponding circuits are presented in [15] by a straightforward `Python` code that verifies their correctness. (The presented code proves the mentioned upper bounds by providing explicit circuits. We have also verified that no smaller circuits exist meaning that the inequalities above are in fact equalities.) Table 4 shows how to combine the blocks to get a circuit computing $\mathrm{MOD}_n^{3,r}$ of the required size. ◀

Table 4 Choosing parameters k, m, l depending on $n \bmod 3$ and r. The circuit is composed out of blocks as follows: $\mathrm{IN}_k + m \times \mathrm{MID}_3 + \mathrm{OUT}_r^l$. For each pair $(n \bmod 3, r)$ we show three things: the triple (k, m, l); the sizes of two blocks: $\mathrm{size}(\mathrm{IN}_k)$ and $\mathrm{size}(\mathrm{OUT}_r^l)$; the size of the resulting circuit computed as $s = \mathrm{size}(\mathrm{IN}_k) + 9m + \mathrm{size}(\mathrm{OUT}_r^l)$. For example, the top left cell is read as follows: when $r = 0$ and $n = 3t$, we set $k = 4, m = t-2, l = 2$; the resulting circuit is then $\mathrm{IN}_4 + (t-2) \times \mathrm{MID}_3 + \mathrm{OUT}_0^2$; since $\mathrm{size}(\mathrm{IN}_4) = 7$ and $\mathrm{size}(\mathrm{OUT}_0^2) = 5$, the size of the circuit is $7 + 9(t-2) + 5 = 9t - 6 = 3n - 6$. There are three corner cases that are not well-defined as they require the number of MID blocks to be negative $(k = t-2)$: $(n = 3, r = 0)$, $(n = 3, r = 2)$, and $(n = 4, r = 2)$.

	$n = 3t$	$n = 3t+1$	$n = 3t+2$
$r = 0$	$(4, t-2, 2)$, $(7, 5)$, $3n-6$	$(2, t-1, 2)$, $(2, 5)$, $3n-5$	$(3, t-1, 2)$, $(5, 5)$, $3n-5$
$r = 1$	$(2, t-1, 1)$, $(2, 2)$, $3n-5$	$(3, t-1, 1)$, $(5, 2)$, $3n-5$	$(4, t-1, 1)$, $(7, 2)$, $3n-6$
$r = 2$	$(3, t-2, 3)$, $(5, 8)$, $3n-5$	$(4, t-2, 3)$, $(7, 8)$, $3n-6$	$(2, t-1, 3)$, $(2, 8)$, $3n-5$

3.3 Threshold Function

Recall that $\mathrm{THR}_n^2(x_1, \dots, x_n) = [x_1 + \dots + x_n \geq 2]$.

▶ **Theorem 2.** *For any $k \geq 4$,*

$$\mathrm{size}(\mathrm{THR}_n^k) \leq (4.5 - 2^{2-\lceil \log_2 k \rceil})(n + 2^{\lceil \log_2 k \rceil} - k) + o(n)\,.$$

Proof. For a sequence of $2m$ formal variables $y_1, z_1, \dots, y_m, z_m$, consider a function $g \in B_{2m}$ that takes $y_1, y_1 \oplus z_1, y_2, y_2 \oplus z_2, \dots, y_m, y_m \oplus z_m$ as input and outputs $\mathrm{THR}_{2m}^2(y_1, z_1, \dots, y_m, z_m)$. Note that $\mathrm{THR}_{2m}^2(y_1, z_1, \dots, y_m, z_m) = 1$ iff there is a pair containing two 1's or there are two pairs each containing at least one 1: $\mathrm{THR}_{2m}^2(y_1, z_1, \dots, y_m, z_m) = 1$ iff there exists $1 \leq i \leq m$ such that $y_i = z_i = 1$ or $\mathrm{THR}_m^2(y_1 \oplus z_1, \dots, y_m \oplus z_m) = 1$. The condition $y_i = z_i = 1$ can be computed through y_i and $y_i \oplus z_i$ using a single binary gate: $(y_i \wedge z_i) = (y_i \wedge \overline{(y_i \oplus z_i)})$. Thus,

$$g(y_1, y_1 \oplus z_1, \dots, y_m, y_m \oplus z_m) = \mathrm{THR}_m^2(y_1 \oplus z_1, \dots, y_m \oplus z_m) \vee \bigvee_{i=1}^{m} (y_i \wedge \overline{(y_i \oplus z_i)})\,.$$

Now, $\mathrm{size}(\mathrm{THR}_m^2) \leq 2m + o(m)$ as shown by Dunne [5]. Also, clearly,

$$\mathrm{size}\left(\bigvee_{i=1}^{m} (y_i \wedge \overline{(y_i \oplus z_i)})\right) \leq 2m - 1\,.$$

Thus,

$$\mathrm{size}(g) \leq 4m + o(m)\,. \tag{3}$$

To construct a circuit for THR_n^k, first, consider the case $k = 2^t$ where $t \geq 2$ is an integer. Apply $t - 1$ layers of MDFA's (as in Figure 4). It takes

$$\frac{n}{2} + n \sum_{i=1}^{t-1} 2^{2-i} = (4.5 - 2^{3-t})n$$

gates. As a result, we get bits $w_0, \dots, w_{t-2}, a_1, a_1 \oplus b_1, \dots, a_m, a_m \oplus b_m$, where $m = n/2^t$, such that

$$x_1 + \dots + x_n = w_0 + 2w_1 + \dots + 2^{t-2} w_{t-2} + 2^{t-1}(a_1 + b_1 + \dots + a_m + b_m)\,.$$

Note that $w_0 + 2w_1 + \cdots + 2^{t-2}w_{t-2} < 2^{t-1}$. Hence,

$$[x_1 + \cdots + x_n \geq 2^t] = [a_1 + b_1 + \cdots + a_m + b_m \geq 2]\,.$$

Thus, it remains to compute the function g given $2m$ bits $a_1, a_1 \oplus b_1, \ldots, a_m, a_m \oplus b_m$. By (3), it takes $4m + o(m) = 2^{2-t}n + o(n)$ gates. The total size of the constructed circuit is

$$(4.5 - 2^{3-t} + 2^{2-t})n + o(n) = (4.5 - 2^{2-t})n + o(n)\,.$$

Now, assume that $2^{t-1} < k < 2^t$ (hence $\lceil \log_2 k \rceil = t$). Clearly,

$$[x_1 + \cdots + x_n \geq k] = [(2^t - k) + x_1 + \cdots + x_n \geq 2^t]\,.$$

By the previous argument, there exists a circuit C computing $\mathrm{THR}^{2^t}_{n+(2^t-k)}$ of size

$$(4.5 - 2^{2-t})(n + (2^t - k)) + o(n) = (4.5 - 2^{2-\lceil \log_2 k \rceil})(n + 2^{\lceil \log_2 k \rceil} - k) + o(n)\,.$$

By replacing arbitrary $(2^t - k)$ inputs of C by 1's, one gets a circuit computing THR^k_n. ◀

▶ **Corollary 3.** *For* $4 \leq k = O(1)$, $\mathrm{size}(\mathrm{THR}^k_n) \leq (4.5 - 2^{2-\lceil \log_2 k \rceil})n + o(n)$. *In particular,* $\mathrm{size}(\mathrm{THR}^4_n) \leq 3.5n + o(n)$ *and* $\mathrm{size}(\mathrm{THR}^k_n) \leq 4n + o(n)$ *for* $5 \leq k \leq 8$.

We conclude by presenting an example of a reasonably small circuit that our program fails to improve though a better circuit is known. The reason is that these two circuits are quite different. Figures 6 and 7 show circuits of size 31 and 29 for THR^2_{12}. They are quite different and our program is not able to find out that the circuit of size 31 is suboptimal. The code below shows how one can construct the two circuits in the program.

```
c = Circuit(input_labels=[f'x{i}' for i in range(1, 13)], gates={})
c.outputs = add_naive_thr2_circuit(c, c.input_labels)
c.draw('thr2naive')

c = Circuit(input_labels=[f'x{i}' for i in range(1, 13)], gates={})
c.outputs = add_efficient_thr2_circuit(c, c.input_labels, 3, 4)
c.draw('thr2efficient')
```

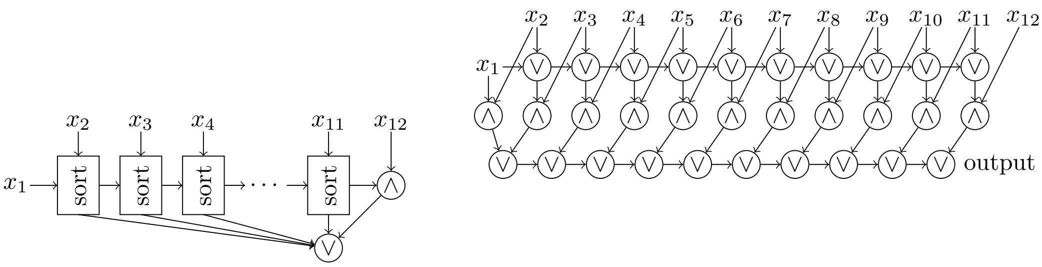


Figure 6 A circuit of size 31 for THR^2_{12}: (a) block structure and (b) gate structure. The $\mathrm{SORT}(u,v)$ block sorts two input bits as follows: $\mathrm{SORT}(u,v) = (\min\{u,v\}, \max\{u,v\}) = (u \wedge v, u \vee v)$. The circuit performs one and a half iterations of the bubble sort algorithm: one first finds the maximum bit among n input bits; then, it remains to compute the disjunction of the remaining $n-1$ bits to check whether there is at least one 1 among them. In general, this leads to a circuit of size $3n-5$.

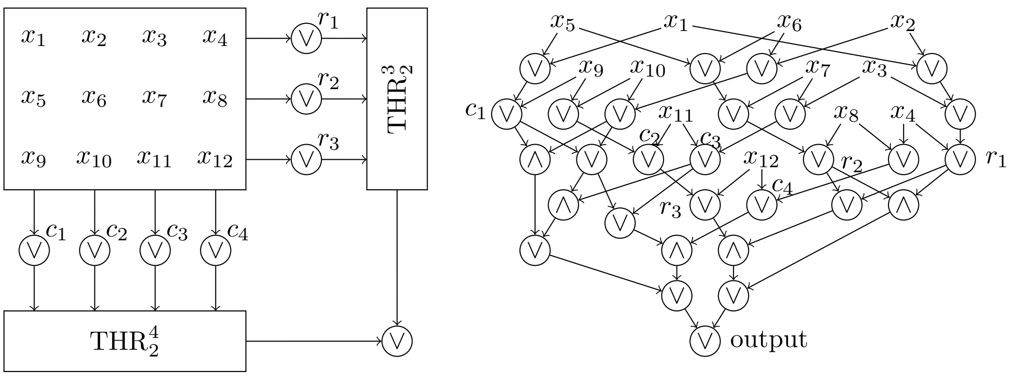

Figure 7 A circuit of size 29 for THR^2_{12}: (a) block structure and (b) gate structure. It implements a clever trick by Dunne [5]. Organize 12 input bits into a 3×4 table. Compute disjunctions r_1, r_2, r_3 of the rows and disjunctions c_1, c_2, c_3, c_4 of the columns. Then, there are at least two 1's among $x_1, \dots, x_{12}$ if and only if there are at least two 1's among either r_1, r_2, r_3 or c_1, c_2, c_3, c_4. This allows to proceed recursively. In general, it leads to a circuit of size $2n + o(n)$. (Sergeev [23] showed recently that the *monotone* circuit size of THR^2_n is $2n + \Theta(\sqrt{n})$.)

4 Further Directions

We focus mainly on proving asymptotic upper bounds for symmetric function families (that is, upper bounds that hold for every input size). A natural further step is to apply the program to specific circuits that are used in practice. It would also be interesting to extend the program so that it is able to discover the circuit from Figure 7. Finally, it would be interesting to generalize circuits for SUM_n presented in Section 3.1.2.

Complexity of the Cluster Vertex Deletion Problem on H-Free Graphs

Hoang-Oanh Le
Independent Researcher, Berlin, Germany

Van Bang Le
Institut für Informatik, Universität Rostock, Germany

Abstract

The well-known Cluster Vertex Deletion problem (CLUSTER-VD) asks for a given graph G and an integer k whether it is possible to delete at most k vertices of G such that the resulting graph is a cluster graph (a disjoint union of cliques). We give a complete characterization of graphs H for which CLUSTER-VD on H-free graphs is polynomially solvable and for which it is NP-complete.

1 Introduction and result

A very extensively studied version of graph modification problems asks to modify a given graph to a graph that satisfies a certain property $\mathcal{G}$ by deleting a minimum number of vertices. The case $\mathcal{G}$ being 'edgeless' is the well-known VERTEX COVER problem, one of the classical NP-hard problems. If $\mathcal{G}$ is a 'cluster graph', a graph in which every connected component is a clique, the corresponding problem is another well-known NP-hard problem, the CLUSTER VERTEX DELETION problem (CLUSTER-VD for short). In this paper, we revisit the computational complexity of CLUSTER-VD, formally given below.

CLUSTER-VD
Instance: A graph $G = (V, E)$ and an integer k.
Question: Does there exist a vertex set $S \subseteq V$ of size at most k such that $G - S$ is a cluster graph?

Being an hereditary property on induced subgraphs, CLUSTER-VD is NP-complete [16], even when restricted to planar graphs [20] and to bipartite graphs [21], and to bipartite graphs of maximum degree 3 [13]. Most recent works on CLUSTER-VD deal with exact, fpt and approximation algorithms [1, 2, 14, 19].

It is noticeable that there are only a few known cases where the problem can be solved efficiently: CLUSTER-VD is polynomially solvable on block graphs and split graphs [3], and on graphs of bounded treewidth [18]. On the other hand, the complexity status of CLUSTER-VD on many well-studied graph classes is still open, e.g., chordal graphs discussed in [3] and planar bipartite graphs mentioned in [4].

In this paper we initiate studying the computational complexity of CLUSTER-VD on graphs defined by forbidding certain induced subgraphs. We remark that related approaches for other problems are quite common in the literature, e.g., for VERTEX COVER (aka INDEPENDENT SET) [9, 12] and COLORING [10, 15], and that many popular graph classes are defined or characterized by forbidding induced subgraphs, e.g., chordal and bipartite graphs (by infinitely many forbidden subgraphs), and cographs and line graphs (by finitely many forbidden subgraphs).

All graphs considered are undirected and finite and have no multiple edges or self-loops. Let H be a given graph. A graph G is *H-free* if no induced subgraph in G is isomorphic to H. A path with n vertices and $n-1$ edges is denoted by P_n. The main result of the present paper is the following complexity dichotomy:

▶ **Theorem 1.** *Let H be a fixed graph.* CLUSTER-VD *is polynomially solvable on H-free graphs if H is an induced subgraph of the 4-vertex path P_4, and* NP*-complete otherwise.*

Theorem 1 is remindful of the main result in [15] which characterizes all graphs H for which coloring H-free graphs is easy and for which it is hard. In fact, the present paper was motivated by this H-free coloring theorem.

For a set $\mathcal{H}$ of graphs, $\mathcal{H}$-free graphs are those in which no induced subgraph is isomorphic to a graph in $\mathcal{H}$. We denote by $K_{1,n}$ the tree with $n \geq 3$ vertices and n leaves, by C_n the n-vertex cycle, and as usual, by $\overline{G}$ the complement of a graph G. The union $G + H$ of two vertex-disjoint graphs G and H is the graph with vertex set $V(G) \cup V(H)$ and edge set $E(G) \cup E(H)$; we write pG for the union of p copies of G. For a subset $S \subseteq V(G)$, we let $G[S]$ denote the subgraph of G induced by S; $G - S$ stands for $G[V(G) \setminus S]$. By 'G contains an H' we mean G contains H as an induced subgraph.

A graph G is a *cluster graph* if each of its connected components is a clique. Observe that G is a cluster graph if and only if G is P_3-free. If $S \subseteq V(G)$ is a subset of vertices of G such that $G - S$ is P_3-free, then S is called a *cluster vertex deletion set* of G. An *optimal* cluster vertex deletion set is one of minimum size.

We first address the polynomial part of Theorem 1 in the next section. Then we present two new NP-completeness results for CLUSTER-VD in Sections 3 and 4. These hardness results allow us to clear the NP-completeness part of Theorem 1 in Section 5. The last section concludes the paper.

2 Polynomial cases

The polynomial part in Theorem 1 consists of six cases; see also Fig. 1 for all graphs H for which CLUSTER-VD is polynomially solvable on H-free graphs.

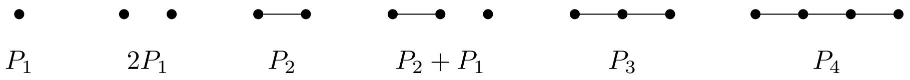

Figure 1 The graphs H for which CLUSTER-VD is polynomially solvable on H-free graphs.

Observe that H-freeness is hereditary, meaning if H' is an induced subgraph of H then H'-free graphs are H-free graphs. Thus, it suffices to prove the polynomial part only for the case where H is the 4-vertex path P_4.

We now are going to describe how to solve CLUSTER-VD in polynomial time when restricted to P_4-free graphs. P_4-free graphs are also called *cographs* [6]. More precisely, for vertex-disjoint graphs $G_i = (V_i, E_i)$, $i = 1, 2$, let $G_1 \circledcirc G_2$ be the union (or *co-join*) of G_1 and G_2,

$$G_1 \circledcirc G_2 = (V_1 \cup V_2, E_1 \cup E_2),$$

and let $G_1 \textcircled{1} G_2$ be the *join* of G_1 and G_2,

$$G_1 \textcircled{1} G_2 = (V_1 \cup V_2, E_1 \cup E_2 \cup \{uv \mid u \in V_1, v \in V_2\}).$$

With these notations, cographs are exactly those graphs that can be constructed from the one-vertex graph by applying the join and co-join operations. Thus, a cograph is the one-vertex graph or is the join of two smaller cographs or is the co-join of two smaller cographs.

Recall that $S \subseteq V(G)$ is a vertex cover if $G - S$ is edgeless and is a cluster vertex deletion set if $G - S$ is a cluster graph. Let $\tau(G)$ and $\varsigma(G)$ denote the vertex cover number and the cluster vertex deletion number of G, respectively,

$$\tau(G) = \min\{|S| : S \text{ is a vertex cover of } G\},$$
$$\varsigma(G) = \min\{|S| : S \text{ is a cluster vertex deletion set of } G\}.$$

We will see that $\tau(G)$ and $\varsigma(G)$ can be computed efficiently when restricted to cographs. The calculation is based on the following fact:

▶ **Lemma 2.** *For any (not necessarily P_4-free) graphs G_1 and G_2, the following relations hold:*

$$\tau(G_1 \textcircled{0} G_2) = \tau(G_1) + \tau(G_2); \tag{1}$$
$$\tau(G_1 \textcircled{1} G_2) = \min\{\tau(G_1) + |V(G_2)|, \tau(G_2) + |V(G_1)|\}; \tag{2}$$
$$\varsigma(G_1 \textcircled{0} G_2) = \varsigma(G_1) + \varsigma(G_2); \tag{3}$$
$$\varsigma(G_1 \textcircled{1} G_2) = \min\{\varsigma(G_1) + |V(G_2)|, \varsigma(G_2) + |V(G_1)|, \tau(\overline{G_1}) + \tau(\overline{G_2})\}. \tag{4}$$

Proof. (1) and (3) are trivial.

(2): Let S_i be a vertex cover of G_i of optimal size $\tau(G_i)$, $i = 1, 2$. Then $S_1 \cup V(G_2)$ and $S_2 \cup V(G_1)$ are vertex covers of $G_1 \textcircled{1} G_2$. Hence $\tau(G_1 \textcircled{1} G_2) \leq \min\{|S_1| + |V(G_2)|, |S_2| + |V(G_1)|\} = \min\{\tau(G_1) + |V(G_2)|, \tau(G_2) + |V(G_1)|\}$.

For the other direction, let S be a vertex cover of $G_1 \textcircled{1} G_2$ of optimal size, and write $S_i = S \cap V(G_i)$. Then S_i is a vertex cover of G_i, and moreover, $S_1 = V(G_1)$ or else $S_2 = V(G_2)$. Hence $\tau(G_1 \textcircled{1} G_2) \geq \min\{|S_1| + |V(G_2)|, |S_2| + |V(G_1)|\} \geq \min\{\tau(G_1) + |V(G_2)|, \tau(G_2) + |V(G_1)|\}$.

(4): Let S_i be a cluster vertex deletion set of G_i of optimal size $\varsigma(G_i)$, $i = 1, 2$. Then $S_1 \cup V(G_2)$ and $S_2 \cup V(G_1)$ are cluster vertex deletion sets of $G_1 \textcircled{1} G_2$. Hence $\varsigma(G_1 \textcircled{1} G_2) \leq \min\{|S_1| + |V(G_2)|, |S_2| + |V(G_1)|\} = \min\{\varsigma(G_1) + |V(G_2)|, \varsigma(G_2) + |V(G_1)|\}$. Let S_i be a vertex cover of $\overline{G_i}$ of optimal size $\tau(\overline{G_i})$, $i = 1, 2$. Then $S_1 \cup S_2$ is a cluster vertex deletion set of $G_1 \textcircled{1} G_2$, hence $\varsigma(G_1 \textcircled{1} G_2) \leq |S_1| + |S_2| = \tau(\overline{G_1}) + \tau(\overline{G_2})$.

For the other direction, let S be a cluster vertex deletion set of $G_1 \textcircled{1} G_2$ of optimal size, and write $S_i = S \cap V(G_i)$. Then S_i is a cluster vertex deletion set of G_i, and moreover,

- if $G_1 - S_1$ is not a clique then $S_2 = V(G_2)$, likewise
- if $G_2 - S_2$ is not a clique then $S_1 = V(G_1)$.

In these two cases, $|S| = \varsigma(G_1 \textcircled{1} G_2) \geq \min\{|S_1| + |V(G_2)|, |S_2| + |V(G_1)|\} \geq \min\{\varsigma(G_1) + |V(G_2)|, \varsigma(G_2) + |V(G_1)|\}$. In the third case where each of $G_1 - S_1$ and $G_2 - S_2$ is a clique, S_1 and S_2 are vertex covers of $\overline{G_1}$ and $\overline{G_2}$, respectively. Hence in this case, $|S| = \varsigma(G_1 \textcircled{1} G_2) = |S_1| + |S_2| \geq \tau(\overline{G_1}) + \tau(\overline{G_2})$. ◀

▶ Remark 3. For any integer $r \geq 2$, Lemma 2 holds accordingly for $G_1 \textcircled{0} G_2 \textcircled{0} \cdots \textcircled{0} G_r = G_1 \textcircled{0} (G_2 \textcircled{0} \cdots \textcircled{0} G_r)$ and $G_1 \textcircled{1} G_2 \textcircled{1} \cdots \textcircled{1} G_r = G_1 \textcircled{1} (G_2 \textcircled{1} \cdots \textcircled{1} G_r)$. We also note that Lemma 2 holds for the weighted version, too.

With each cograph $G = (V, E)$, one can associate a so-called *cotree* T of G as follows.

- The leaves of T are the vertices of G;
- Every internal node of T has a label ⓪ or ①, and has at least two children;
- No two internal nodes of T with the same label are adjacent;
- Two vertices u and v of G are (non-)adjacent if and only if the least common ancestor of u and v in T has label ① (respectively, ⓪).

In particular, the cotree of an n-vertex cograph has at most $2n - 1$ nodes.

Note that, for any internal node v of T, the subtree T_v of T rooted at v is the cotree of the subgraph of G induced by the leaves of T_v. The cograph corresponding to T_v where v has label ⓪ is the disjoint union of the cographs corresponding to the children of v. The cograph corresponding to T_v where v has label ① is the join of the cographs corresponding to the children of v.

In particular, the cotree of $\overline{G}$ can be obtained from the cotree of G by changing the label ⓪ to ① and ① to ⓪.

In [7], a linear time algorithm is given for recognizing if a given graph is a cograph, and if so, constructing its cotree. Note that the cotree can immediately be transformed to an equivalent binary tree; see Fig. 2 for an example of a cograph G and the cotree of G and its binary version. For simplification, we will use the binary cotree in our algorithm below.

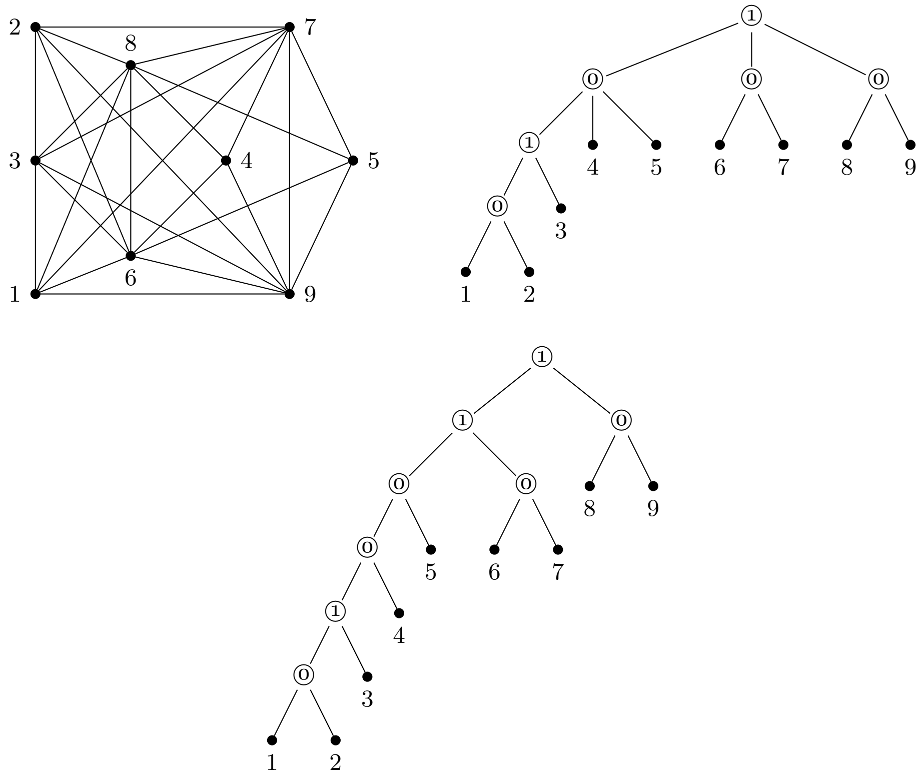

Figure 2 A cograph G, the cotree of G and its binary version.

Now, given a cograph G together with its binary cotree T, the bottom-up Algorithm 1 below computes the cluster vertex deletion number $\varsigma(G)$ of G, as suggested by Lemma 2. The algorithm uses the following notations. For a node v of T,

- if v is an internal node then $\ell(v)$ and $r(v)$ stands for the left child and the right child of v, respectively;

- $n(v)$ denotes the size of the subgraph of G induced by the leaves of T_v. Thus, if v is a leaf then $n(v) = 1$ and if v is the root of T then $n(v) = |V(G)|$;
- $\varsigma(v)$ denotes the cluster vertex deletion number of the subgraph of G induced by the leaves of T_v. Thus, if v is a leaf then $\varsigma(v) = 0$ and if v is the root of T then $\varsigma(v) = \varsigma(G)$;
- $\overline{\tau}(v)$ denotes the vertex cover number of the *complement* of the subgraph of G induced by the leaves of T_v. Thus, if v is a leaf then $\overline{\tau}(v) = 0$ and if v is the root of T then $\overline{\tau}(v) = \tau(\overline{G})$.

Algorithm 1 `computing cluster vertex deletion number.`

```
Input: A cograph $G = (V, E)$ together with its (binary) cotree $T$.
Output: $\varsigma(G)$, the cluster vertex deletion number of $G$

Traverse $T$ by post-order and let $v$ be the current node
if $v$ is a leaf then
    $n(v) \leftarrow 1$; $\overline{\tau}(v) \leftarrow 0$; $\varsigma(v) \leftarrow 0$
end
else
    $n(v) \leftarrow n(\ell(v)) + n(r(v))$
    if $v$ has label ⓪ then
        $\overline{\tau}(v) \leftarrow \min\{\overline{\tau}(\ell(v)) + n(r(v)), \overline{\tau}(r(v)) + n(\ell(v))\}$
        $\varsigma(v) \leftarrow \varsigma(\ell(v)) + \varsigma(r(v))$
    end
    if $v$ has label ① then
        $\overline{\tau}(v) \leftarrow \overline{\tau}(\ell(v)) + \overline{\tau}(r(v))$
        $\varsigma(v) \leftarrow \min\{\varsigma(\ell(v)) + n(r(v)), \varsigma(r(v)) + n(\ell(v)), \overline{\tau}(v)\}$
    end
end
```

▶ **Proposition 4.** *Given a P_4-free n-vertex graph G together with its cotree, Algorithm 1 correctly computes the cluster deletion number $\varsigma(G)$ of G in $O(n)$ time.*

Proof. The correctness of Algorithm 1 directly follows from Lemma 2. Since per node in the cotree a constant number of operations are performed, the algorithm runs in $O(n)$ time. ◀

We remark that Algorithm 1 can be slightly modified for computing a minimum cluster vertex deletion set. Also, since Lemma 2 holds accordingly for the weighted version, the minimum weight cluster vertex deletion number of cographs can be computed in linear time, too.

Another approach is based on the concept of clique-width of graphs in connection with the so-called $LinEMSOL_{\tau_{1,p}}$ problems (problems definable in monadic second-order logic and allowed in searching optimal sets of vertices with respect to some linear objective function). We refer to [8] for details. It is well known that cographs have clique-width at most 2 and a corresponding 2-expression can be constructed in linear time. Hence, every $LinEMSOL_{\tau_{1,p}}$ problem on cographs can be solved in linear time [8, Theorem 4].

Observe that the optimization version of CLUSTER-VD, MINIMUM CLUSTER-VD, is a $LinEMSOL(\tau_1, p)$ problem, since it can be expressed as follows:

minimize $|S|$ with respect to
$\forall u, v, w\big(\neg S(u) \wedge \neg S(v) \wedge \neg S(w) \wedge E(u,v) \wedge E(v,w) \wedge (u \neq w) \rightarrow E(u,w)\big)$,

where $S(x)$ means $x \in S$ and $E(x,y)$ means $xy \in E(G)$.

We remark that MINIMUM WEIGHT CLUSTER-VD is also a $LinEMSOL_{\tau_{1,p}}$ problem, hence it can be solved in linear time on cographs, too.

3 Cluster-VD on sparse graphs

Recall that CLUSTER-VD is NP-complete on bipartite graphs [21], even when restricted to bipartite graphs of maximum degree 3 [13]. In this section, we show that, for any given tree T containing two vertices of degree 3, CLUSTER-VD remains NP-complete when restricted to T-free bipartite graphs of maximum degree 3 and with arbitrarily large girth. The girth $g(G)$ of a graph G is the smallest length of a cycle in G; we set $g(G) = \infty$ if G is a forest. Thus, for any fixed $g \geq 3$, $g(G) > g$ if and only if G is $\{C_3, C_4, \ldots, C_g\}$-free.

▶ **Theorem 5.** *For any given integer $g \geq 3$ and any given tree T containing two degree-3 vertices,* CLUSTER-VD *is* NP*-complete on T-free bipartite graphs of maximum degree 3 and with girth $> g$.*

In particular, CLUSTER-VD *is* NP*-complete on bipartite graphs of maximum degree 3 and with girth $> g$.*

Proof. We give a polynomial reduction from CLUSTER-VD on bipartite graphs of maximum degree 3 to CLUSTER-VD on T-free bipartite graphs of maximum degree 3 and of girth $> g$. (Note that NP-membership of CLUSTER-VD restricted to these graphs is clear.)

First, given a bipartite graph G of maximum degree 3 with m edges, let G' be obtained from G by subdividing each edge $e = xy$ in G with three new vertices e_x, e_{xy} and e_y, thus obtaining the 5-vertex path $xe_xe_{xy}e_yy$ in G' in which all new vertices are of degree 2. Note that like G, G' is bipartite. We claim that G has a cluster vertex deletion set of size at most k if and only if G' has a cluster vertex deletion set of size at most $k + m$. For one direction, extend a cluster vertex deletion set $S \subseteq V(G)$ to a cluster vertex deletion set $S' \subseteq V(G')$ of size $|S| + m$ as follows: initially, set $S' = S$. Then, for each edge $e = xy$ in G,

- if both x and y are in S or outside S, put e_{xy} into S';
- if $x \in S$ and $y \notin S$, put e_y into S';
- if $x \notin S$ and $y \in S$, put e_x into S'.

To see that $G' - S'$ is P_3-free, notice that by construction, for each edge $e = xy$ in G, exactly one of e_x, e_{xy} and e_y is in S', and if $e_x, e_{xy} \notin S'$ then $x \in S$, and if $e_x, x \notin S'$ then $y \in S$. Since each P_3 in G' has the form xe_xe_{xy}, $e_xe_{xy}e_y$ or $e_xxe'_x$ for some edge $e = xy$ and $e' = xz$, it follows from these facts that $G' - S'$ is P_3-free.

For the other direction, suppose that G' has a cluster deletion set of size at most $k + m$, and consider such a set S' of minimum size. Then, we may assume that, for each edge $e = xy$ in G, S' contains exactly one of e_x, e_{xy} and e_y: note that $e_xe_{xy}e_y$ is a P_3, hence $|S' \cap \{e_x, e_{xy}, e_y\}| \geq 1$, and by minimality, $|S' \cap \{e_x, e_{xy}, e_y\}| \leq 2$. Now, if $|S' \cap \{e_x, e_{xy}, e_y\}| = 2$ for some edge $e = xy$ in G, then S' can be modified to a minimum cluster vertex deletion set containing exactly one of e_x, e_{xy} and e_y as follows:

- suppose that $e_x, e_{xy} \in S'$. Then $x, y \notin S'$ (if $x \in S'$ then $S' - e_x$ would be a cluster vertex deletion set of G', and if $y \in S'$ then $S' - e_{xy}$ would be a cluster vertex deletion set of G', contradicting the minimality of S'), and $S'' = S' - e_{xy} + y$ is a desired cluster vertex deletion set of minimum size;
- suppose that $e_y, e_{xy} \in S'$. Then similar to the above case, $x, y \notin S'$, and $S'' = S' - e_{xy} + x$ is a desired cluster vertex deletion set of minimum size;
- suppose that $e_x, e_y \in S'$. Then $x, y \notin S'$ (if $x \in S'$ or $y \in S'$ then $S'' = S' - e_x$, respectively $S' - e_y$, would be a cluster vertex deletion set of G', contradicting the minimality of S'), and $S'' = S' - e_x + x$ is a desired cluster vertex deletion set of minimum size.

Hence, $S = S' \cap V(G)$ has at most k vertices, and $G - S$ is P_3-free: if there would be an induced P_3 xyz in G with edges $e = xy$ and $e' = yz$, then, as $|S' \cap \{e_x, e_{xy}, e_y\}| = 1$ $= |S' \cap \{e'_y, e'_{yz}, e'_z\}|$, one of the 3-paths xe_xe_{xy}, $e_yye'_y$ and $e'_{yz}e'_zz$ would be outside S'.

Thus, G has a cluster vertex deletion set of size at most k if and only if G' has a cluster vertex deletion set of size at most $k + m$, as claimed.

Now, given $g > 0$ and a tree T with two degree-3 vertices, repeating the construction $t = \max\{\log_4(g/g(G)) + 1, |V(T)|\}$ times, the final bipartite graph has girth $4^t g(G) > g$ and maximum degree 3 and contains no induced subgraph isomorphic to T. ◀

4 Cluster-VD on dense graphs

In this section, we give a polynomial reduction from VERTEX COVER to CLUSTER-VD, showing that CLUSTER-VD remains NP-complete when restricted to $\{3P_1, 2P_2\}$-free graphs.

Recall that the VERTEX COVER problem asks, for a given graph G and an integer k, if one can delete a vertex set S of size at most k such that $G - S$ is edgeless. Let (G, k) be an instance for VERTEX COVER. We may assume that

- G is not perfect.[1] This is because VERTEX COVER is polynomially solvable on perfect graphs (see [11]); notice that G is perfect if and only if $\overline{G}$ is perfect and perfect graphs can be recognized in polynomial time [5]),
- G has girth $> g$ for any given integer $g \geq 3$ (see, e.g., [17]), and
- $k \leq |V(G)|/2$. This fact is probably known and can be easily seen as follows: given G with n vertices and an integer k, let G' be obtained from G by adding $p = \max\{0, 2k - n\}$ isolated vertices. Then $k = |V(G')|/2$ and $(G, k) \in$ VERTEX COVER if and only if $(G', k) \in$ VERTEX COVER. Notice that like G, G' satisfies the first two conditions, too.

From (G, k) we construct an equivalent instance (G', k') for CLUSTER-VD as follows: G' is obtained from two disjoint copies of $\overline{G}$, G_1 and G_2, by adding all possible edges between $V(G_1)$ and $V(G_2)$. Set $k' = 2k$.

We argue that $(G, k) \in$ VERTEX COVER if and only $(G', k') \in$ CLUSTER-VD. First, let $S \subset V(G)$ with $|S| \leq k$ be such that $G - S$ is edgeless. Let S_1 and S_2 be the copy of S in G_1 and G_2, respectively. Then $G_i - S_i$ is a clique in $G_i = \overline{G}$, hence $G' - S'$ is a clique in G' where $S' = S_1 \cup S_2$ with $|S'| = 2|S| \leq 2k = k'$. Conversely, let $S' \subseteq V(G')$ be a cluster vertex deletion set of G' with $|S'| \leq k' = 2k$. Observe that $S' \cap V(G_i)$ is a proper nonempty subset of both $V(G_1)$ and $V(G_2)$: if for some i, $S' \cap V(G_i) = \emptyset$ then G_i (hence G) would be perfect, and if $V(G_i) \subset S'$ then $2k \geq |S'| > |V(G_i)| = |V(G)|$, contradicting $k \leq |V(G)|/2$. It follows from the above that $G' - S'$ is a single clique, implying for each i, $G_i - S_i$ is a

[1] Actually, we will only use the fact that $\overline{G}$ contains at least one induced P_3.

clique in G_i where $S_i = S' \cap V(G_i)$. Since $|S'| \leq 2k$, $|S_1| \leq k$ or $|S_2| \leq k$. Let $|S_1| \leq k$, say, and let $S \subseteq V(G)$ be the set of the corresponding vertices in G. Then $G - S$ is edgeless with $|S| \leq k$.

We have seen that G has a vertex cover of size at most k if and only if G' has a cluster vertex deletion set of size at most k', as claimed.

Now, observe that, for any *connected* graph X, if G is X-free then G' is $\overline{X}$-free. Since G has girth $> g$, we obtain:

▶ **Theorem 6.** *For any fixed $g \geq 3$,* CLUSTER-VD *is* NP*-complete on $\{\overline{C_3}, \overline{C_4}, \ldots, \overline{C_g}\}$-free graphs.*

In particular, CLUSTER-VD *is* NP*-complete on $\{3P_1, 2P_2\}$-free graphs.*

5 NP-completeness cases

In this section we give the proof of the NP-completeness part of Theorem 1.

Let H be a fixed graph. By Proposition 4, CLUSTER-VD is polynomially solvable on H-free graphs whenever H is an induced subgraph of the 4-vertex path P_4. The following fact is easy to see:

▶ **Observation 7.** *A graph is an induced subgraph of the 4-path P_4 if and only if it is a $\{3P_1, 2P_2\}$-free forest.*

Thus, it remains to consider the cases where H contains a cycle or a $3P_1$ or a $2P_2$ as an induced subgraph.

Now, if H contains a cycle then graphs of girth $> g = |V(H)|$ are H-free, hence Theorem 5 implies that CLUSTER-VD is NP-complete on H-free graphs. If H contains a $3P_1$ or a $2P_2$ then $\{3P_1, 2P_2\}$-free graphs are H-free graphs, hence Theorem 6 implies that CLUSTER-VD is NP-complete on H-free graphs.

The proof of Theorem 1 is complete.

6 Conclusion

We have found a complete characterization of graphs H for which CLUSTER-VD on H-free graphs is polynomially solvable and for which it is NP-complete (Theorem 1).

We remark that a complexity dichotomy for VERTEX COVER on H-free graphs, like Theorem 1 for CLUSTER-VD, seems very hard to achieve. Indeed, it is a long-standing open problem whether there exists a constant t for which VERTEX COVER is NP-complete on P_t-free graphs. So far it is known that such a constant t, if any, must be at least 7 [12].

Let $\mathcal{H}$ be a set of (possibly infinitely many) graphs. A natural question generalizing the case of one forbidden induced subgraph is: what is the complexity of CLUSTER-VD on $\mathcal{H}$-free graphs? The case $\mathcal{H} = \{H\}$ is completely solved by Theorem 1. The case $\mathcal{H} = \{C_\ell \mid \ell \geq 4\}$ addressed in [3] is still open. The next step may be the case of two-element sets $\mathcal{H} = \{H_1, H_2\}$. This case is more complex and currently we are investigating the case $\mathcal{H} = \{H, \overline{H}\}$. Another interesting problem is to clear the complexity of CLUSTER-VD on line graphs, a well-studied graph class defined by excluding nine small induced subgraphs.

Abstract

The Contraction(vc) problem takes as input a graph G on n vertices and two integers k and d, and asks whether one can contract at most k edges to reduce the size of a minimum vertex cover of G by at least d. Recently, Lima et al. [MFCS 2020, JCSS 2021] proved, among other results, that unlike most of the so-called *blocker problems*, Contraction(vc) admits an XP algorithm running in time $f(d) \cdot n^{\mathcal{O}(d)}$. They left open the question of whether this problem is FPT under this parameterization. In this article, we continue this line of research and prove the following results:

- Contraction(vc) is W[1]-hard parameterized by $k + d$. Moreover, unless the ETH fails, the problem does not admit an algorithm running in time $f(k + d) \cdot n^{o(k+d)}$ for any function f. In particular, this answers the open question stated in Lima et al. [MFCS 2020] in the negative.
- It is NP-hard to decide whether an instance (G, k, d) of Contraction(vc) is a Yes-instance even when $k = d$, hence enhancing our understanding of the classical complexity of the problem.
- Contraction(vc) can be solved in time $2^{\mathcal{O}(d)} \cdot n^{k-d+\mathcal{O}(1)}$. This XP algorithm improves the one of Lima et al. [MFCS 2020], which uses Courcelle's theorem as a subroutine and hence, the $f(d)$-factor in the running time is non-explicit and probably very large. On the other hand, this shows that when $k = d$, the problem is FPT parameterized by d (or by k).

1 Introduction

Graph modification problems have been extensively studied in theoretical computer science, in particular for their vast expressive power and their applicability in a number of scenarios. Such problems can be generically defined as follows. For a fixed graph class $\mathcal{F}$ and a fixed set $\mathcal{M}$ of allowed graph modification operations, such as vertex deletion, edge deletion, edge addition, edge editing or edge contraction, the $\mathcal{F}$-$\mathcal{M}$-Modification problem takes as input a graph G and a positive integer k, and the goal is to decide whether at most k operations from $\mathcal{M}$ can be applied to G so that the resulting graph belongs to the class $\mathcal{F}$. For most natural graph classes $\mathcal{F}$ and modification operations $\mathcal{M}$, the $\mathcal{F}$-$\mathcal{M}$-Modification problem is NP-hard [15, 16]. To cope up with this hardness, these problems have been examined via the lens of parameterized complexity [1, 3]. With an appropriate choice of $\mathcal{F}$ and the allowed modification operations $\mathcal{M}$, $\mathcal{F}$-$\mathcal{M}$-Modification can encapsulate well-studied problems like Vertex Cover, Feedback Vertex Set (FVS), Odd Cycle Transversal (OCT), Chordal Completion, or Cluster Editing, to name just a few.

The most natural and well-studied modification operations are, probably in this order, vertex deletion, edge deletion, and edge addition. In recent years, the *edge contraction* operation has begun to attract significant scientific attention. (When contracting an edge uv in a graph G, we delete u and v from G, add a new vertex and make it adjacent to vertices that were adjacent to u or v.) In parameterized complexity, $\mathcal{F}$-Contraction problems, i.e., $\mathcal{F}$-$\mathcal{M}$-Modification problems where the only modification operation in $\mathcal{M}$ is edge contraction, are usually studied with the number of edges allowed to contract, k, as the parameter. A series of more than 15 recent papers studied the parameterized complexity of $\mathcal{F}$-Contraction for various graph classes $\mathcal{F}$ (see [14] and the references therein, as well as the full version of this article, for the precise list of these classes $\mathcal{F}$).

For all the $\mathcal{F}$-$\mathcal{M}$-Modification problems mentioned above, a typical definition of the problem contains a description of the target graph class $\mathcal{F}$. For example, Vertex Cover, FVS, and OCT are $\mathcal{F}$-$\mathcal{M}$-Modification problems where $\mathcal{F}$ is the collection of edgeless graphs, forests, and bipartite graphs, respectively, and $\mathcal{M}$ contains only vertex deletion. Recently, a different formulation of these graph modification problems, called *blocker problems*, has been considered. In this formulation, the target graph class is defined in a *parametric way* from the input graph. To make the statement of such problems precise, consider an invariant $\pi : \mathcal{G} \mapsto \mathbb{N}$, where $\mathcal{G}$ is the collection of all graphs. For a fixed invariant π, a typical input of a blocker problem consists of a graph G, a budget k, and a threshold value d, and the question is whether G can be converted into a graph G' using at most k allowed modifications such that $\pi(G') \leq \pi(G) - d$. This is the same as determining whether (G, k, d) is a Yes-instance of $\mathcal{F}^{\pi}_{G,d}$-$\mathcal{M}$-Modification where $\mathcal{F}^{\pi}_{G,d} = \{G' \in \mathcal{G} \mid \pi(G') \leq \pi(G) - d\}$.

Consider the following examples of this formulation. For the invariant $\pi(G) = |E(G)|$, threshold $d = |E(G)|$, and vertex deletion as the modification operation in $\mathcal{M}$, $\mathcal{F}^{\pi}_{G,d}$-$\mathcal{M}$-Modification is the same as Vertex Cover. Setting the threshold d to a fixed integer p leads to Partial Vertex Cover. In a typical definition of this problem, the input is a graph G and two integers k, p, and the objective is to decide whether there is a set of vertices of size at most k that has at least p edges incident on it. Consider another example when

$\pi(G) = \texttt{vc}(G)$, the size of a minimum vertex cover of G, the threshold value $d = \texttt{vc}(G) - 1$, and the allowed modification operation is edge contraction. To reduce the size of a minimum vertex cover from $\texttt{vc}(G)$ to 1 by k edge contractions, we need to find a connected vertex cover of size $k + 1$. Hence, in this case $\mathcal{F}^{\pi}_{G,d}$-$\mathcal{M}$-Modification is the same as Connected Vertex Cover. In all these cases, we can think of the set of vertices or edges involved in the modifications as "blocking" the invariant π, that is, preventing π from being smaller.

With "vertex deletion" or "edge deletion" as the allowed graph modification operation, blocker problems have been investigated for numerous graph invariants (see the full version of this article for an exhaustive list of these invariants, along with the appropriate references). Blocker problems for edge contraction have already been studied with respect to the chromatic number, clique number, independence number [6, 13], the domination number [8, 10], total domination number [9], and the semitotal domination number [7].

This article is strongly motivated by the results in [12]. They proved, in particular, that it is coNP-hard to test whether we can reduce the size of a minimum feedback vertex set or of a minimum odd cycle transversal of a graph by one, i.e., $d = 1$, by performing one edge contraction, i.e., $k = 1$. This is consistent with earlier results, as blocker problems are generally very hard, and become polynomial-time solvable only restricted to specific graph classes. However, the notable exception is when the invariant is the size of a minimum vertex cover of the input graph. We define the problem before mentioning existing results and our contribution (G/F denotes the graph obtained from G by contracting the edges in F).

Contraction($\texttt{vc}$)
Input: An undirected graph G and two non-negative integers k and d.
Question: Does there exist a set $F \subseteq E(G)$ such that $|F| \leq k$ and $\texttt{vc}(G/F) \leq \texttt{vc}(G) - d$?

Our results. A simple reduction, briefly mentioned in [12], shows that the above problem is NP-hard for *some* k in $\{d, d+1, \ldots, 2d\}$. In our first result, we enhance our understanding of the classical complexity of the problem and prove that the problem is NP-hard even when $k = d$. As any edge contraction can decrease $\texttt{vc}(G)$ by at most one, if $k < d$ then the input instance is a trivial No-instance. To state our first result, we introduce the notation of $\mathsf{rank}(G)$, which is the number of vertices of G minus its number of connected components (or equivalently, the number of edges of a set of spanning trees of each of the connected components of G). Note that it is sufficient to consider values of k that are at most $\mathsf{rank}(G)$, as otherwise it is possible to transform G to an edgeless graph with at most k contractions, and therefore in this case G is a yes-instance for Contraction($\texttt{vc}$) if and only if $\texttt{vc}(G) \geq d$.

▶ **Theorem 1.** *To decide whether an instance (G, k, d) of* Contraction($\texttt{vc}$) *is a* Yes-*instance is*
- coNP-hard *if $k = \mathsf{rank}(G)$,*
- coNP-hard *if $k < \mathsf{rank}(G)$ and $2d \leq k$, and*
- NP-hard *if $k < \mathsf{rank}(G)$ and $k = d + \frac{\ell-1}{\ell+3} \cdot d$ for any integer $\ell \geq 1$ such that k is an integer.*

As one needs to contract at least d edges to reduce the size of a minimum vertex cover by d, the above theorem, for $\ell = 1$, implies that the problem is para-NP-hard when parameterized by the "excess over the lower bound", i.e., by $k - d$. Since we can assume that $d \leq k$, d is a "stronger" parameter than k. One of the main results of [12] is an XP algorithm for Contraction($\texttt{vc}$) with running time $f(d) \cdot n^{\mathcal{O}(d)}$. Here, and in the rest of the article, we denote by n the number of vertices of the input graph. The authors explicitly asked whether the problem admits an FPT algorithm parameterized by d. As our next result, we answer this question in the negative by proving that such an algorithm is highly unlikely, even when parameterized by the larger parameter $d + k$ (or equivalently, just k, as discussed above).

▶ **Theorem 2.** Contraction(vc) *is* W[1]-hard *parameterized by $k + d$. Moreover, unless the* ETH *fails*[1]*, it does not admit an algorithm running in time $f(k + d) \cdot n^{o(k+d)}$ for any computable function $f : \mathbb{N} \mapsto \mathbb{N}$. The result holds even if we assume that the input (G, k, d) is such that $k < \mathsf{rank}(G)$ and $d \le k < 2d$, and G is a bipartite graph with a bipartition $\langle X, Y\rangle$ such that X is a minimum vertex cover of G.*

For the XP algorithm in [12], the authors did not explicitly mention an upper bound on the corresponding function f, but it is expected to be quite large since it uses Courcelle's theorem [2] as a subroutine. Our next result provides a concrete upper bound on the running time, and distinguishes in a precise way the contribution of k and d.

▶ **Theorem 3.** *There exists an algorithm that solves* Contraction(vc) *in time $2^{\mathcal{O}(d)} \cdot n^{k-d+\mathcal{O}(1)}$. Moreover, for an input (G, k, d), the algorithm runs in time $2^{\mathcal{O}(d)} \cdot n^{\mathcal{O}(1)}$ unless $k < \mathsf{rank}(G)$ and $d \le k < 2d$.*

Note that the above result implies, in particular, that the problem is FPT parameterized by d when $k - d$ is a constant.

Our methods. A central tool in both our negative and positive results is Lemma 6, which allows us to reformulate the problem as follows. As discussed later, by applying appropriate FPT reductions to the input graph G, it is possible to assume that we have at hand a minimum vertex cover X of G. We say that a set of edges F is a *solution* of (G, k, d) if $|F| \le k$ and $\mathsf{vc}(G/F) \le \mathsf{vc}(G) - d$. Lemma 6 implies that there exists such a solution (i.e., an edge set) if and only if there exist vertex subsets $X_s \subseteq X$ and $Y_s \subseteq V(G) \setminus X$ such that the pair $\langle X_s, Y_s\rangle$, which we call a *solution pair*, satisfies the technical conditions mentioned in its statement (and which we prefer to omit here). This reformulation allows us to convert the problem of finding a subset F of edges to the problem of modifying the given minimum vertex cover X to obtain another vertex cover $X_{\mathsf{el}} = (X \setminus X_s) \cup Y_s$ such that $|X_{\mathsf{el}}| \le |X| + (k - d)$ and $\mathsf{rank}(X_{\mathsf{el}}) \ge k$. Here, we define $\mathsf{rank}(X_{\mathsf{el}}) := \mathsf{rank}(G[X_{\mathsf{el}}])$. See the full version for an illustration.

In our hardness reductions, another simple, yet critical, tool is Lemma 7, which states that if there is a vertex which is adjacent to a pendant vertex (i.e., a vertex of degree one), then there is a solution pair that does not contain this vertex. We present overviews of the reductions in Section 3 and in the full version to demonstrate the usefulness of these two lemmas in the respective hardness results. The reduction that we use to prove the third item in the statement of Theorem 1 (which is the most interesting case) is from a variant of Multicolored Independent Set, while the one in the proof of Theorem 2 is from Edge Induced Forest, a problem that we define and that we prove to be W[1]-hard in Theorem 8, by a parameter preserving reduction from, again, Multicolored Independent Set. It is worth mentioning that the W[1]-hardness in Theorem 8 holds even if we assume that the input graph G is a bipartite graph with a bipartition $\langle X, Y\rangle$ such that X is a minimum vertex cover of G, and such that $k < \mathsf{rank}(G)$ and $d \le k < 2d$. This case is the crux of the difficulty of the problem. This becomes clear in the XP algorithm of Theorem 3 that we proceed to discuss.

[1] The Exponential Time Hypothesis (ETH) is a conjecture stating that N-variable 3-SAT cannot be solved in time $2^{o(N)}$. We refer the reader to [4, Chapter 14] for the formal definition and related literature.

Figure 1 Diagram of the algorithm for Contraction(vc) given by Theorem 3. Recall that we can assume that $d \leq k \leq \mathsf{rank}(G)$, hence the case distinction considered in the beginning is exhaustive. Note also that, in the case where $d \leq k < 2d$, it holds that $\mathcal{O}^\star(2^{\mathcal{O}(k)}) = \mathcal{O}^\star(2^{\mathcal{O}(d)})$.

The algorithm for Contraction(vc), which is our main technical contribution, is provided in Section 4 and summarized in the diagram of Figure 1. By a standard Knapsack-type dynamic programming, mentioned in [12], we can assume that the input graph G is connected. We distinguish three cases depending on the relation between k, d, and $\mathsf{rank}(G)$. The first two cases are easy, and can be solved in time $2^{\mathcal{O}(d)} \cdot n^{\mathcal{O}(1)}$, by essentially running an FPT algorithm to determine whether $\mathsf{vc}(G) < d$; see Lemma 12 and Lemma 13. We now present an overview of the algorithm for the third case, namely when its input (G, k, d) is with guarantees that $k < \mathsf{rank}(G)$ and $d \leq k < 2d$ (cf. Lemma 14). Inspired by Lemma 6, we introduce an annotated version of the problem called Annotated Contraction(vc). We first argue (cf. Lemma 15) that there is a $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ algorithm that either correctly concludes that (G, k, d) is a Yes-instance of Contraction(vc) or finds a minimum vertex cover X of G such that $\mathsf{rank}(X) < d$. Using X, we can construct $2^{\mathcal{O}(d)}$ many instances of Annotated Contraction(vc) such that (G, k, d) is a Yes-instance of Contraction(vc) if and only if at least one of these new instances is a Yes-instance of Annotated Contraction(vc) (cf. Lemma 16). Hence, it suffices to design an algorithm to solve Annotated Contraction(vc). We show that we can apply a simple reduction rule (cf. Lemma 17) that allows us to assume that the input graph G of Annotated Contraction(vc) is bipartite with bipartition $\langle X, Y\rangle$ such that X is a minimum vertex cover of G, as mentioned above.

A solution of an instance of Annotated Contraction(vc) is a solution pair $\langle X_s, Y_s\rangle$ as stated in Lemma 6. We find convenient to present an algorithm that finds a partition $\langle V_L, V_R\rangle$ of $V(G)$ instead of a solution pair $\langle X_s, Y_s\rangle$. To formalize this, we introduce the problem called Constrained MaxCut and we show it to be equivalent to Annotated Contraction(vc) (cf. Lemma 18). We partition the input instances of Constrained MaxCut into the following two types: (1) $k = d$, and (2) $k > d$. For the instances of the second type, we construct $2^{\mathcal{O}(d)} \cdot n^{k-d}$ many instances of the first type such that the input instance is a Yes-instance if and only if at least one of these newly created instances is a Yes-instance (cf. Lemma 19). We remark that this is the only step in the whole algorithm where an n^{k-d}-factor appears (note that this is unavoidable by Theorem 8).

Finally, to handle the instances of the first type (i.e., with $k = d$), we apply a simplification based on the existence of a matching saturating X (cf. Lemma 20), we introduce a directed variation of the problem called Constrained Directed MaxCut, and we prove it to be equivalent to its undirected version (cf. Lemma 21). We then present a dynamic programming algorithm, with running time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$, that critically uses the fact that $k = d$ (cf. Lemma 22), in particular to "merge" appropriately some directed cycles in order to obtain a directed *acyclic* graph, whose topological ordering gives a natural way to process the vertices of the input graph in a dynamic programming fashion. At the end of Section 4 we present an overview of this algorithm.

Organization. Due to space limitations, in this extended abstract most of the technical contents of the paper can only be found in the full version, in particular the proofs of the statements marked with "($\star$)". In Section 2 we present some notations and preliminary results about Contraction(vc). The proof of Theorem 1 can be found in the full version. In Section 3 we present the proof of Theorem 2. Section 4 is the most technical part of the paper, and contains the description of the algorithm to solve Contraction(vc) mentioned in Theorem 3. We conclude the article in Section 5 with some open problems.

2 Preliminaries

We use standard graph-theoretic notation, and we refer the reader to [5] for any undefined notation. Similarly, we use standard terminology of parameterized complexity, and we refer the reader to [4]. For completeness, we present in the full version the required basic preliminaries about graph theory and parameterized complexity, and we provide here some non-standard definitions and useful properties of the Contraction(vc) problem.

For a positive integer q, we denote the set $\{1, 2, \ldots, q\}$ by $[q]$. We use $\mathbb{N}$ to denote the collection of all non-negative integers. A *spanning forest* of a graph is a collection of spanning trees of its connected components. As already mentioned in Section 1, the *rank* of a graph G, denoted by $\mathsf{rank}(G)$, is the number of edges of a spanning forest of G. The *rank* of a set $X \subseteq V(G)$ of vertices, denoted by $\mathsf{rank}(X)$, is the rank of $G[X]$. The *rank* of a set $F \subseteq V(G)$ of edges, denoted by $\mathsf{rank}(F)$, is the rank of $V(F)$. Note that an edge contraction decreases the rank of a graph G by exactly one. We present a couple of observations regarding an instance (G, k, d) of the Contraction(vc) problem. Later, we present a lemma that helps us to characterize the problem as finding a vertex cover with special properties.

▶ **Observation 4** ($\star$)**.** *Consider an instance (G, k, d) of* Contraction(vc) *such that $k = \mathsf{rank}(G)$. Then, (G, k, d) is a* Yes*-instance if and only if $d \leq \mathsf{vc}(G)$.*

▶ **Observation 5** ($\star$)**.** *Consider an instance (G, k, d) of* Contraction(vc) *such that G is a connected graph, $k < \mathsf{rank}(G)$, and $2d \leq k$. Then, (G, k, d) is a* Yes*-instance if and only if $d < \mathsf{vc}(G)$.*

Suppose that (G, k, d) is a YES-instance of CONTRACTION(vc). We say that a set $F \subseteq E(G)$ is a *solution* of (G, k, d) if $|F| \leq k$ and $\mathsf{vc}(G/F) \leq \mathsf{vc}(G) - d$. Fix a minimum vertex cover X of G. As X is a vertex cover, for every edge in F, *at least one* of its endpoints is in X. We argue that one can construct an *enlarged vertex cover* X_{el} of G such that for every edge in F, *both* of its endpoints are in X_{el}. Also, X_{el} is not much larger than X. In order to construct X_{el} from X, one needs to remove and add some vertices to X. We denote the removed and added vertices by X_s and Y_s, respectively, and call $\langle X_s, Y_s \rangle$ a *solution pair*. See the corresponding figure in the full version for an illustration. The following lemma relates a solution (a set of edges) to a solution pair (a tuple of disjoint vertex sets).

▶ **Lemma 6** ($\star$). *Consider a connected graph G, a minimum vertex cover X of G, a proper subset F of edges of a spanning forest of G (i.e., $|F| < \mathsf{rank}(G)$), and a non-negative integer d. Then, $\mathsf{vc}(G/F) \leq \mathsf{vc}(G) - d$ if and only if there exists subsets $X_s \subseteq X$ and $Y_s \subseteq V(G) \setminus X$ such that (i) $X_{\mathsf{el}} := (X \setminus X_s) \cup Y_s$ is a vertex cover of G, (ii) $\mathsf{rank}((X \setminus X_s) \cup Y_s) \geq |F|$, and (iii) $|Y_s| - |X_s| \leq |F| - d$, i.e., $|X_{\mathsf{el}}| \leq |X| + |F| - d$.*

In the following lemma, we argue that there exists a solution pair $\langle X_s, Y_s \rangle$ such that X_s does not contain any vertex in X which is adjacent to a pendant vertex. For example, in the aforementioned figure in the full version, there exists a solution pair $\langle X_s, Y_s \rangle$ such that $x_1 \notin X_s$.

▶ **Lemma 7** ($\star$). *Consider a connected graph G, a minimum vertex cover X of G, and two integers ℓ and d. Suppose that there exists a vertex x° in X which is adjacent to a pendant vertex. Suppose that there are subsets $X_s \subseteq X$ and $Y_s \subseteq V(G) \setminus X$ such that (i) $(X \setminus X_s) \cup Y_s$ is a vertex cover of G, (ii) $\mathsf{rank}((X \setminus X_s) \cup Y_s) \geq \ell$, and (iii) $|Y_s| - |X_s| \leq \ell - d$. Then, there are subsets $X'_s \subseteq X$ and $Y'_s \subseteq V(G) \setminus X$ that satisfy these three conditions and $x^\circ \notin X'_s$.*

3 W[1]-hardness results

In this section we prove Theorem 2. To do so, we introduce the EDGE INDUCED FOREST problem, defined below, and present a parameter preserving reduction from MULTICOLORED INDEPENDENT SET to it. This reduction, along with known results about MULTICOLORED INDEPENDENT SET (cf. the preliminaries in the full version), imply the corresponding result for EDGE INDUCED FOREST. We then present a parameter preserving reduction from EDGE INDUCED FOREST to CONTRACTION(vc). This reduction, along with Theorem 8, yield Theorem 2.

EDGE INDUCED FOREST
Input: A graph G and an integer ℓ.
Question: Is there a set F of at least ℓ edges in G such that $G[V(F)]$ is a forest?

We note that a similar problem called INDUCED FOREST has already been studied. In this problem, the input is the same but the objective is to find a subset X of *vertices* of G of size at least ℓ such that $G[X]$ is a forest. The general result of Khot and Raman [11] implies that INDUCED FOREST is W[1]-hard when parameterized by the size of the solution ℓ. As expected, we can prove a similar result for EDGE INDUCED FOREST.

▶ **Theorem 8** ($\star$). EDGE INDUCED FOREST, *parameterized by the size of the solution ℓ, is* W[1]-hard. *Moreover, unless the* ETH *fails, it does not admit an algorithm running in time $f(\ell) \cdot n^{o(\ell)}$ for any computable function $f : \mathbb{N} \mapsto \mathbb{N}$.*

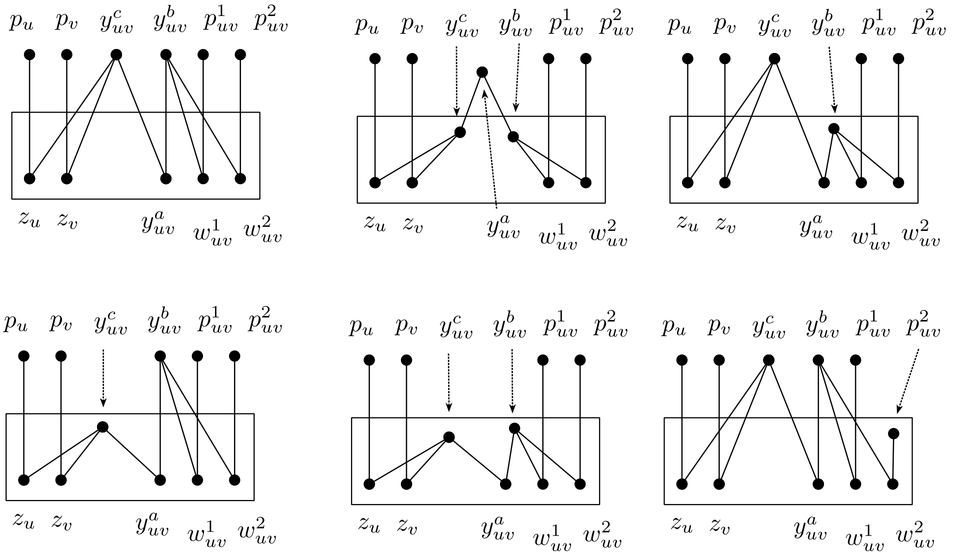

Figure 2 The top-left figure illustrates an encoding of edge uv in G while reducing from an instance of Edge Induced Forest to an instance of Contraction(vc). The remaining five figures correspond to the partition of Y_s mentioned in the proof of Lemma 11.

We now present a parameter preserving reduction from Edge Induced Forest to Contraction(vc), which takes an instance (G, ℓ) of Edge Induced Forest and returns an instance (G', k, d) of Contraction(vc). It constructs a graph G' from G as follows:

- Initialize $V(G') = E(G') = \emptyset$.
- For every vertex u in $V(G)$, add two vertices z_u, p_u to $V(G')$ and the edge $z_u p_u$ to $E(G')$.
- For every edge uv in $E(G)$, add the vertex set $\{y^a_{uv}, y^b_{uv}, y^c_{uv}, w^1_{uv}, w^2_{uv}, p^1_{uv}, p^2_{uv}\}$ to $V(G')$. Add edges $\{z_u y^c_{uv}, z_v y^c_{uv}\}$ to $E(G')$. These edges encode adjacency relations in G. Add also the edges $\{y^a_{uv} y^b_{uv}, y^a_{uv} y^c_{uv}, y^b_{uv} w^1_{uv}, y^b_{uv} w^2_{uv}, w^1_{uv} p^1_{uv}, w^2_{uv} p^2_{uv}\}$ to $E(G')$. These edges are part of a gadget which is private to edge uv.

This completes the construction of G'. The reduction sets $k = 4 \cdot \ell$, $d = 3 \cdot \ell$, and returns (G', k, d) as the constructed instance. Note that, indeed, $k < \mathsf{rank}(G')$ and $d \le k < 2d$ (more precisely, $k - d = \frac{d}{3}$). See Figure 2 for an illustration. Before proving the correctness of the reduction, we first note some properties of the graph G'. We define the following sets:

- $Z := \{z_u \in V(G') \mid u \in V(G)\}$,
- $Y^{abc} := Y^a \cup Y^b \cup Y^c$ where $Y^a := \{y^a_{uv} \in V(G') \mid uv \in E(G)\}$, $Y^b := \{y^b_{uv} \in V(G') \mid uv \in E(G)\}$, and $Y^c := \{y^c_{uv} \in V(G') \mid uv \in E(G)\}$,
- $W := \{w^1_{uv}, w^2_{uv} \in V(G') \mid uv \in E(G)\}$, and
- $P := \{p_u \in V(G') \mid u \in V(G)\} \cup \{p^1_{uv}, p^2_{uv} \mid uv \in E(G)\}$.

Note that $\langle Z, Y^{abc}, W, P\rangle$ is a partition of $V(G')$ where each vertex in P is a pendant vertex and each vertex in $Z \cup W$ is adjacent to a pendant vertex in P. Moreover, $\mathsf{rank}(G') > k$. Note that $X := Z \cup W \cup Y^a$ is an independent set in G'. In the next lemma, we argue that it is also a minimum vertex cover of G', which implies that, as claimed in the statement of Theorem 2, G' is a bipartite graph with a bipartition $\langle X, Y\rangle$ such that X is a minimum vertex cover of G'.

▶ **Lemma 9** ($\star$)**.** *The set $X = Z \cup W \cup Y^a$ is a minimum vertex cover of G'.*

The following lemma corresponds to the "easy" direction of the reduction.

▶ **Lemma 10** ($\star$). *If* (G, ℓ) *is a* Yes*-instance of* Edge Induced Forest*, then* (G', k, d) *is a* Yes*-instance of* Contraction(vc)*.*

We now present a brief overview of the proof of the correctness in the backward direction, corresponding to Lemma 11, whose full proof can be found in the full version. By Lemma 6, there is a solution F of (G', k, d) if and only if there exists a solution pair $\langle X_s, Y_s\rangle$ such that (i) $X_{\mathsf{el}} = (X \setminus X_s) \cup Y_s$ is a vertex cover of G', (ii) $\mathsf{rank}(X_{\mathsf{el}}) \geq |F| = k = 4 \cdot \ell$, and (iii) $|Y_s| - |X_s| \leq k - d = \ell$. Note that as X and $Y = V(G') \setminus X$ are independent sets in G', every edge in $E(X_{\mathsf{el}})$ is incident on exactly one vertex in Y_s. We can interpret the second condition as a *value function* and the third condition as a *cost function*. In other words, our objective is to find sets X_s, Y_s such that their cost, i.e., $|Y_s| - |X_s|$, is at most ℓ whereas their value, i.e., the rank of edges in $E(X_{\mathsf{el}})$ that are incident on Y_s, is at least $4 \cdot \ell$. Lemma 7 implies that the vertices of the form z_u, w^1_{uv}, and w^2_{uv} are in X_{el}. The first condition implies that only the five configurations shown in Figure 2 are possible (the top-left is *not* a configuration). Starting from top-middle and moving row-wise, the individual value and cost of these configurations are $(4, 1)$, $(3, 1)$, $(3, 1)$, $(6, 2)$, and $(1, 1)$, respectively. To meet both the value and budget constraints, every vertex in X_s, Y_s needs to be the of first type. This implies there are ℓ vertices in X_s that are of the form y^a_{uv}, and Y_s contains the corresponding vertices of the form y^b_{uv} and y^c_{uv}. We argue that the edges corresponding to vertices in Y^c_{uv} form a solution of (G, ℓ) and formalize these ideas in the next lemma.

▶ **Lemma 11** ($\star$). *If* (G', k, d) *is a* Yes*-instance of* Contraction(vc)*, then* (G, ℓ) *is a* Yes*-instance of* Edge Induced Forest*.*

We are ready to present the proof of Theorem 2.

Proof of Theorem 2. Consider the reduction presented in this subsection. Lemma 10 and Lemma 11 imply that the reduction is safe. By the description of the reduction, it outputs the constructed instance in polynomial time. The W[1]-hardness of Contraction(vc) follows from Theorem 8. As $k = 4 \cdot \ell$ and $d = 3 \cdot \ell$, if Contraction(vc) admits an algorithm with running time $f(k + d) \cdot n^{o(k+d)}$, then Edge Induced Forest also admits an algorithm with running time $f(\ell) \cdot n^{o(\ell)}$, which contradicts Theorem 8. ◀

4 Algorithm for Contraction(vc)

In this section we present the main ideas of the proof of Theorem 3, following the sketch provided in Section 1 and summarized in Figure 1. Due to space limitations, most of the technical content can be found in the full version Namely, we present an algorithm that takes as input an instance (G, k, d) of Contraction(vc) and returns either Yes or No, and whose high-level description is as follows (cf. Figure 1):

- If $k = \mathsf{rank}(G)$, then it uses the algorithm mentioned in Lemma 12.
- If $k < \mathsf{rank}(G)$ and $2d \leq k$, then it uses the algorithm mentioned in Lemma 13.
- If $k < \mathsf{rank}(G)$ and $d \leq k < 2d$, then it uses the algorithm mentioned in Lemma 14.

Note that, since we can safely assume that $d \leq k \leq \mathsf{rank}(G)$, the above three cases are exhaustive. The first two cases turn out to be quite easy to handle.

▶ **Lemma 12** ($\star$). *There exists an algorithm that, given as input an instance* (G, k, d) *of* Contraction(vc) *with a guarantee that* $k = \mathsf{rank}(G)$*, runs in time* $1.2738^d \cdot n^{\mathcal{O}(1)}$*, and correctly determines whether it is a* Yes*-instance.*

▶ **Lemma 13** (⋆). *There exists an algorithm that, given as input an instance (G, k, d) of* Contraction(vc) *with guarantees that $k < \mathsf{rank}(G)$ and $2d \leq k$, runs in time $1.2738^d \cdot n^{\mathcal{O}(1)}$, and correctly determines whether it is a* Yes-*instance.*

We may assume that G is a connected graph; we justify this assumption in the full version. In order to deal with the third case above, our objective is to prove the following lemma.

▶ **Lemma 14.** *There exists an algorithm that, given as input an instance (G, k, d) of* Contraction(vc) *with guarantees that $k < \mathsf{rank}(G)$ and $d \leq k < 2d$, runs in time $2^{\mathcal{O}(d)} \cdot n^{k-d+\mathcal{O}(1)}$, and correctly determines whether it is a* Yes-*instance.*

We start with the following result, which will allow us to assume henceforth that we are equipped with a minimum vertex cover of the input graph with small rank.

▶ **Lemma 15** (⋆). *There exists an algorithm that, given as input an instance (G, k, d) of* Contraction(vc) *with guarantees that $k < \mathsf{rank}(G)$ and $d \leq k < 2d$, runs in time $2.6181^k \cdot n^{\mathcal{O}(1)}$, and either correctly concludes that (G, k, d) is a* Yes-*instance, or computes a minimum vertex cover X of G such that $\mathsf{rank}(\mathrm{X}) < d$.*

Our next step is to provide an FPT-reduction from Contraction(vc) to the Annotated Contraction(vc) problem, defined as follows.

Annotated Contraction(vc)
Input: An instance (G, k, d) of Contraction(vc), a minimum vertex cover X of G, and a tuple $\langle X_L, X_R \rangle$ such that X_L, X_R are disjoint subsets of X.
Question: Do there exist sets $X_s \subseteq X$ and $Y_s \subseteq Y$ $(= V(G) \setminus X)$ such that (i) $(X \setminus X_s) \cup Y_s$ is a vertex cover of G, (ii) $\mathsf{rank}((X \setminus X_s) \cup Y_s) \geq k$, (iii) $|Y_s| - |X_s| \leq k - d$, and (iv) $X_L \cap X_s = \emptyset$ and $X_R \subseteq X_s$?

The first three conditions correspond to the three conditions mentioned in Lemma 6. We remark that there is a small technical caveat while using Lemma 6. Consider an instance (G, k, d) of Contraction(vc), and let F be a solution. Lemma 6 implies that there are subsets $X_s \subseteq X$ and $Y_s \subseteq V(G) \setminus X$ such that (i) $(X \setminus X_s) \cup Y_s$ is a vertex cover of G, (ii) $\mathsf{rank}((X \setminus X_s) \cup Y_s) \geq |F|$, and (iii) $|Y_s| - |X_s| \leq |F| - d$. However, the statement of Annotated Contraction(vc) specifies the integer k and not the actual size of a minimum solution F. For example, if there exists a solution F of size, say, $k/2$, then Lemma 6 ensures that $\mathsf{rank}((X \setminus X_s) \cup Y_s) \geq k/2$, however $\mathsf{rank}((X \setminus X_s) \cup Y_s)$ can be smaller than k. To overcome this, we assume that $(G, k-1, d)$ is a No-instance of Contraction(vc). This implies that if there is a subset F of $E(G)$ of size *at most* k such that $\mathsf{vc}(G/F) \leq \mathsf{vc}(G) - d$, then F is of size *exactly* k. We summarize below all the assumptions on the input instance.

▶ **Guarantee 4.1.** *Consider an instance (G, k, d) of* Contraction(vc) *that satisfies the following conditions.*

- *G is a connected graph, $k < \mathsf{rank}(G)$, and $d \leq k$.*
- *A minimum vertex cover X of G is provided as an additional part of the input.*
- $\mathsf{rank}(X) < d$.
- *$(G, k-1, d)$ is a* No-*instance of* Contraction(vc).

Unless stated otherwise, we denote the independent set $V(G) \setminus X$ by Y.

Consider an instance (G, k, d) of Contraction(vc) with Guarantee 4.1. Using Lemma 6, we construct $2^{\mathcal{O}(d)}$ many instances of Annotated Contraction(vc) such that (G, k, d) is a Yes-instance if and only if at least one of these newly created instances is a Yes-instance.

Informally, let F be the set of edges in a spanning forest of $G[X]$. As $\mathsf{rank}(X) < d$, we have $|F| < d$. We iterate over all "valid" partitions $\langle X_L, X_R \rangle$ of $V(F)$. We construct an instance of Annotated Contraction(vc) for each such a partition. We formalize this intuition and prove its correctness in the following lemma.

▶ **Lemma 16** ($\star$). *Suppose that there is an algorithm that solves* Annotated Contraction(vc) *in time $f(n, k, d)$. Then, there exists an algorithm that given as input an instance (G, k, d) of* Contraction(vc) *with Guarantee 4.1, runs in time $3^d \cdot n^{\mathcal{O}(1)} \cdot f(n, k, d)$, and correctly determines whether it is a* Yes*-instance.*

To solve an instance of Annotated Contraction(vc), we reduce it to an equivalent instance of the Constrained MaxCut problem. To present such a reduction, it is convenient to work with an instance $((G, k, d), X, \langle X_L, X_R \rangle)$ of Annotated Contraction(vc) where X is an independent set. This is guaranteed by the following reduction rule.

▶ **Reduction Rule 4.1.** *Let $((G, k, d), X, \langle X_L, X_R \rangle)$ be an instance of* Annotated Contraction(vc)*, $F_1 = E(X_L, X_R)$, and F_2 be the set of edges in a spanning forest of $G[X_L]$.*

- *Delete the edges in F_1.*
- *Contract the edges in F_2 and reduce both k and d by $|F_2|$.*

Return the instance $((G', k', d'), X', \langle X'_L, X_R \rangle)$ where $G' = (G - F_1)/F_2$, $k' = k - |F_2|$, $d' = d - |F_2|$, $X' = V(G[X]/F_2)$, and $X'_L = V(G[X_L]/F_2)$.

▶ **Lemma 17** ($\star$). *Reduction Rule 4.1 is safe. Therefore, it is safe to assume that we are given an instance $((G, k, d), X, \langle X_L, X_R \rangle)$ of* Annotated Contraction(vc) *such that X is an independent set and a minimum vertex cover of G.*

We find the following reformulation of Annotated Contraction(vc) convenient to present an algorithm to solve it.

Constrained MaxCut
Input: An instance (G, k, d) of Contraction(vc), a minimum vertex cover X of G, and a tuple $\langle X_L, X_R \rangle$ such that X_L, X_R are disjoint subsets of X.
Question: Does there exist a partition $\langle V_L, V_R \rangle$ of $V(G)$ such that (i) $E(V_L \cap Y, V_R \cap X) = \emptyset$, (ii) $\mathsf{rank}(E(V_L \cap X, V_R \cap Y)) \geq k$, (iii) $|V_R \cap Y| - |V_R \cap X| \leq k - d$, and (iv) $X_L \subseteq V_L$ and $X_R \subseteq V_R$?

Note that in Annotated Contraction(vc) we are seeking for a pair of subsets, whereas in Constrained MaxCut we are looking for a partition of $V(G)$. Such a formulation allows us to handle vertices that we have decided to keep out of a solution pair. Note that the input instances for both of these problems are the same. Hence, due to Lemma 17, it is safe to assume that X is a minimum vertex cover and an independent set in G. In the next lemma we show that both problems are in fact equivalent.

▶ **Lemma 18** ($\star$). *An instance $((G, k, d), X, \langle X_L, X_R \rangle)$ is a* Yes*-instance of* Annotated Contraction(vc) *if and only if it is a* Yes*-instance of* Constrained MaxCut.

Consider an instance $((G, k, d), X, \langle X_L, X_R \rangle)$ of Constrained MaxCut. We consider the following two cases: (1) $k = d$, and (2) $d < k < 2d$. (Recall that we are in the case where $k < 2d$.) The first case, as we will see, allows us to impose additional restrictions on the vertices that are in V_R. It also helps us to set up some conditions such that, if they are satisfied while running the algorithm, then it can terminate and safely conclude that the input is a Yes-instance. In the second case, even for $k = d + 1$, we do not have these privileges. We deal with each of the two cases separately. Namely, Lemma 19 states that if an input instance is of the second type, then we can construct a collection of $2^{\mathcal{O}(d)} \cdot n^{k-d}$ many instances of the first type such that the input instance is a Yes-instance if and only if at least one of these newly created instances is a Yes-instance. We remark that this is the only place, in the whole algorithm, where an n^{k-d}-factor appears in the running time. Recall that Theorem 2 implies that this factor is unavoidable. After this lemma we present an algorithm to solve the instances that are of the first type.

▶ **Lemma 19** ($\star$). *Suppose that there is an algorithm that, given an instance* $((G,k,d),X,\langle X_L,X_R\rangle)$ *of* Constrained MaxCut *with a guarantee that* $k = d$*, runs in time* $f(n,k,d)$ *and correctly determines whether it is a* Yes*-instance. Then, there is an algorithm that solves* Constrained MaxCut *in time* $f(n,k,d) \cdot 2^{\mathcal{O}(d)} \cdot n^{k-d+1}$.

We proceed to present an algorithm to solve an instance $((G,k,d),X,\langle X_L,X_R\rangle)$ of Constrained MaxCut with a guarantee that $k = d$. We first present a reduction rule to simplify these instances under the presence of a matching saturating X.

▶ **Reduction Rule 4.2.** *Consider an instance* $((G,k,d),X,\langle X_L,X_R\rangle)$ *of* Constrained MaxCut *such that* $k = d$ *and* X *is an independent set in* G*. Let* M *be a matching in* G *saturating* X*.*

- *If there exists* $x \in X \setminus X_L$ *such that* $N(x) \setminus V(M) \neq \emptyset$*, then add* x *to* X_L*.*
- *If there exists* $x \in X_L$ *such that* $N(x) \setminus V(M) \neq \emptyset$*, then delete all vertices in* $N(x) \setminus V(M)$*.*

Return instance $((G',k,d),X,\langle X'_L,X_R\rangle)$ *where* $G' = G - (N(x) \setminus V(M))$ *and* $X'_L = X_L \cup \{x\}$*.*

▶ **Lemma 20** ($\star$). *Reduction Rule 4.2 is safe.*

The full version contains an informal description of the algorithm for Constrained MaxCut with a guarantee that $k = d$. We now briefly describe the algorithm formally.

We consider directed graphs that can have parallel arcs. We define the *rank* of a digraph, and the rank of a subset of its vertices or arcs using its underlying undirected graph.

Constrained Digraph MaxCut
Input: A digraph D, a tuple $\langle X_L,X_R\rangle$ of disjoint subsets of X, and an integer k.
Question: Does there exist a partition (V_L,V_R) of $V(G)$ such that (i) $A(V_R,V_L) = \emptyset$, (ii) $\mathsf{rank}(A(V_L,V_R)) \geq k$, and (iii) $X_L \subseteq V_L$ and $X_R \subseteq V_R$?

We say that a partition $\langle V_L,V_R\rangle$ is a *solution* of $(D,\langle X_L,X_R\rangle,k)$ if it satisfies all the three conditions in the statement of the problem. We present a reduction that, given an instance $((G,k,d),X,\langle X_L,X_R\rangle)$ of Constrained MaxCut, returns an instance $(D,\langle X_L,X_R\rangle,k)$ of Constrained Directed MaxCut. The reduction takes as input an instance $((G,k,d),X,\langle X_L,X_R\rangle)$ of Constrained MaxCut on which Reduction Rule 4.2 is not applicable. It starts with a copy of the graph G and constructs a digraph D. The reduction finds (in polynomial time) a matching M in G that saturates all vertices in X. For every $xy \in E(G)$, where $x \in X$ and $y \in Y$, it deletes edge xy and adds arc (x,y) (i.e., it directs edges from X to Y). For every arc (x,y) in M, it adds arc (x_1,x) for every in-neighbour x_1 of y, and then deletes vertex y. This completes the construction of D. The reduction returns $(D,\langle X_L,X_R\rangle,k)$ as the instance of Constrained Digraph MaxCut.

▶ **Lemma 21** ($\star$). $((G,k,d),X,\langle X_L,X_R\rangle)$ *is a* Yes*-instance of* Constrained MaxCut *if and only if* $(D,\langle X_L,X_R\rangle,k)$ *is a* Yes*-instance of* Constrained Digraph MaxCut*.*

We present a dynamic programming algorithm for Constrained Directed MaxCut.

▶ **Lemma 22** ($\star$)**.** *There is an algorithm that, given an instance* $(G, \langle X_L, X_R\rangle, k)$ *of* Constrained Directed MaxCut*, runs in time* $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ *and correctly determines whether it is a* Yes*-instance.*

We finally have all the ingredients to prove Lemma 14, and consequently Theorem 3 as well. The proofs are provided in the full version.

5 Conclusion

In this article we considered the problem of reducing the size of a minimum vertex cover of a graph G by at least d using at most k edge contractions. Note that the problem is trivial when $k < d$. A few simple observations prove that when $d \leq 2k$, the problem is coNP-hard and FPT when parameterized by $k + d$. Almost all of our technical work is to handle the case when $d \leq k < 2d$. We proved that the problem is NP-hard when $k = d + \frac{\ell-1}{\ell+3} \cdot d$ for any integer $\ell \geq 1$ such that k is an integer (in particular, $\ell = 1$). This implies that the problem is hard for various values of $k - d$ in the set $\{0, 1, \ldots, d - 1\}$. We were able to prove that if $(k - d)$ is a constant then the problem is FPT when parameterized by $k + d$. However, if no such a condition is imposed, then the problem is W[1]-hard. More precisely, we presented an algorithm with running time $2^d \cdot n^{k-d+\mathcal{O}(1)}$ and proved that the problem is W[1]-hard when parameterized by $k + d$ in the case where $k - d = \frac{d}{3}$ (see the proof of Theorem 2).

We believe that it should be possible to prove that the problem is NP-hard for *every* value of $k - d$ in the set $\{0, 1, \ldots, d - 1\}$. Such a reduction has the potential to sharpen the distinction between FPT and W[1]-hard cases as $k - d$ varies in this range. It might also simplify the analysis of our XP algorithm or lead to a simpler algorithm. It would be interesting to analyze the parameterized complexity of the problem with respect to structural parameters like the vertex cover number or the treewidth of the input graph. Note that the problem is trivially FPT when parameterized by the vertex cover number. Finally, it is worth mentioning that we did not focus on optimizing the degree of the polynomial term $n^{\mathcal{O}(1)}$ in our XP algorithm, although it is reasonably small.

Abstract

When we bundle quantifiers and modalities together (as in $\exists x\Box$, $\Diamond\forall x$ etc.) in first-order modal logic (FOML), we get new logical operators whose combinations produce interesting *bundled* fragments of FOML. It is well-known that finding decidable fragments of FOML is hard, but existing work shows that certain bundled fragments are decidable [14], without any restriction on the arity of predicates, the number of variables, or the modal scope. In this paper, we explore generalized bundles such as $\forall x\forall y\Box, \forall x\exists y\Diamond$ etc., and map the terrain with regard to decidability, presenting both decidability and undecidability results. In particular, we propose the loosely bundled fragment, which is decidable over increasing domains and encompasses all known decidable bundled fragments.

1 Introduction

While propositional modal logic (ML) has had extensive applications in system verification and artificial intelligence, and first-order logic (FOL) in finite model theory and database theory, first-order modal logic (FOML) has been studied much less, as it seems to combine the worst of both computationally, leading to undecidability. FOML is a natural specification language for state transition systems where states are given by first-order descriptions of computational domains, with applicability in the realm of database updates, in the control of infinite-state systems, networks with unbounded parallelism and cryptographic protocols. This motivates the study of *decidable fragments* of FOML.

This is a challenge, since even the two-variable fragment of FOML with one unary predicate is undecidable over almost all useful model classes [15]. This situation is to be contrasted against the robust decidability of propositional modal logics ([16, 1, 7]), and the many decidable fragments of first-order logic ([4]).

Despite such discouragement, there have been a few successful attempts: for instance, the *monodic restriction*, mandating only one free variable in the scope of any modal subformula, yields decidability when combined with a decidable fragment of FOL ([8, 19]). This idea, arising originally from description logics (cf. [9]) has led to applications in temporal and epistemic logics ([6], [10], [2, 3]).

Rather than placing a restriction on variables, or on *quantification scope* as in the case of guarded fragments [1], Wang ([17]) suggested a fragment in which the existential quantifier and the box modality were always bundled together to appear as a single quantifier-modality pair ($\exists x\Box$). The resulting fragment of FOML enjoys many attractive properties: finite tree model property, PSpace decision procedure and a simple axiom system, without any restriction on predicates or the occurrences of variables. The new operator $\exists x\Box$ captures the logical structure of various *knowing-wh* expressions such as *knowing what, knowing how, knowing why*, and so on (cf. [18]), e.g., *knowing how to achieve* φ can be rendered as *there is* a plan x such that the agent *knows that* x can be executed and will guarantee φ.

In [14], we took the next step by considering not only the combination $\exists x\Box$ but also its companion $\forall x\Box$: the logic with both of these combinations continued to be decidable (over increasing domain models). Such modal-quantifier combinations were thus called *bundled fragments* of FOML. Over models where the domain remains the same in all states, the fragment with both $\exists x\Box$ and $\forall x\Box$ is undecidable, while the $\exists x\Box$-fragment is still decidable.

Clearly, we can define more bundles such as $\Box\forall x$, $\Box\exists x$, etc., and indeed further combinations such as $\forall x\forall y\Box$, and combinations thereof. These (generalized) bundled fragments offer us many interesting possibilities for system specification:

- $\neg\exists x\Box\ (x < c)$: No element is guaranteed to be bounded by constant c (after update).
- $\exists x\Box\ \Box\exists y\ (x > y)$: There is an element that dominates some element after every update.
- $\Box\exists x\ \Box\forall y\ (x \leq y)$: All updates admit a local minimum.
- $\exists x\Box\ (\exists y\Box\ (x > y) \land \exists y\Box\ (x < y))$: There is an element that dominates another no matter the update and is dominated by another no matter the update.

Computationally this raises the natural question of what is the most general *bundled fragment* that is decidable. This is the project taken up in this paper. We consider all possible combinations of the bundled formulas and classify their decidability status. The classification is described in Table 1. We provide a trichotomy: decidable fragments, undecidable fragments and fragments that do not have a finite model property (but where decidability is open).

Towards proving the trichotomy, we first define the notion of *loosely bundled fragment* which subsumes many decidable bundled fragments of FOML and prove its decidability via a tableau method. We also prove the decidability of another combination of bundled operators where we allow only formulas of the form $\forall x\Box + \Box\forall x + \Box\exists x$ (but is not included in the loosely bundled fragment). This requires us to introduce a new proof technique that helps us switch quantifiers in a specific context.

Due to space restrictions, we present only the main ideas and proof techniques of the decidable fragments over increasing domain models in the paper. The proof details, as well as undecidability and lack of finite model property for the other fragments can be found in the detailed technical report in the arXiv [13].

2 Syntax and Semantics

The syntax of first-order modal logic is given by extending the first-order logic with modal operators. Note that we exclude equality, constants and function symbols from the syntax.

▶ **Definition 1** (FOML syntax). *Given a countable set of predicates $\mathcal{P}$ and a countable set of variables* Var*, the syntax of* FOML *is given by:*

$$\alpha ::= P(x_1, \ldots, x_n) \mid \neg\alpha \mid \alpha \wedge \alpha \mid \exists x\alpha \mid \Box\alpha$$

where $P \in \mathcal{P}$ has arity n and $x, x_1, \ldots, x_n \in$ Var.

The boolean connectives $\vee, \rightarrow, \leftrightarrow$, and the modal operator $\Diamond$ which is the dual of $\Box$, and the quantifier $\forall$ are all defined in the standard way. The notion of free variables, denoted by $\mathsf{FV}(\alpha)$ is similar to what we have for first-order logic with $\mathsf{FV}(\Box\alpha) = \mathsf{FV}(\alpha)$. We write $\alpha(x)$ to mean that x occurs as a free variable of α. Also, $\alpha[y/x]$ denotes the formula obtained from α by replacing every free occurrence of x by y.

▶ **Definition 2** (FOML structure). *An increasing domain model for* FOML *is a tuple $\mathcal{M} = (\mathcal{W}, \mathcal{D}, \delta, \mathcal{R}, \rho)$ where $\mathcal{W}$ is a non-empty countable set called* worlds*;*[1] *$\mathcal{D}$ is a non-empty countable set called* domain*; $\mathcal{R} \subseteq (\mathcal{W} \times \mathcal{W})$ is the* accessibility relation*. The map $\delta : \mathcal{W} \mapsto 2^{\mathcal{D}}$ assigns to each $w \in \mathcal{W}$ a non-empty local domain set such that whenever $(w, v) \in \mathcal{R}$ we have $\delta(w) \subseteq \delta(v)$ and $\rho : (\mathcal{W} \times \mathcal{P}) \mapsto \bigcup_n 2^{\mathcal{D}^n}$ is the* valuation function*, which specifies the interpretation of predicates at every world over the local domain with appropriate arity. The model $\mathcal{M}$ is said to be a* constant domain model *if for all $w \in \mathcal{W}$ we have $\delta(w) = \mathcal{D}$.*

The monotonicity condition requiring $\delta(w) \subseteq \delta(v)$ for $(w, v) \in \mathcal{R}$ is required for evaluating the free variables present in the formula [11]. Because of this, the models are called *increasing domain models.*

For a given model $\mathcal{M}$ we denote $\mathcal{W}^{\mathcal{M}}, \mathcal{R}^{\mathcal{M}}$ etc to indicate the corresponding components. We simply use $\mathcal{W}, \mathcal{R}, \delta$ etc when $\mathcal{M}$ is clear from the context.

[1] Note that FOML can be translated into two-sorted FOL, and due to the Löwenheim–Skolem theorem for countable languages, every model has an equivalent countable model, cf. [5].

To evaluate formulas, we need an assignment function for variables. For a given model $\mathcal{M}$, an assignment function $\sigma : \mathsf{Var} \mapsto \mathcal{D}$ is *relevant* at $w \in \mathcal{W}$ if $\sigma(x) \in \delta(w)$ for all $x \in \mathsf{Var}$.

▶ **Definition 3** (FOML semantics). *Given an* FOML *model* $\mathcal{M} = (\mathcal{W}, \mathcal{D}, \delta, \mathcal{R}, \rho)$ *and* $w \in \mathcal{W}$, *and* σ *relevant at* w, *for all* FOML *formulas* α *define* $\mathcal{M}, w, \sigma \models \alpha$ *inductively as follows:*

$\mathcal{M}, w, \sigma \models P(x_1, \ldots, x_n)$	$\Leftrightarrow$	$(\sigma(x_1), \ldots, \sigma(x_n)) \in \rho(w, P)$
$\mathcal{M}, w, \sigma \models \neg\alpha$	$\Leftrightarrow$	$\mathcal{M}, w, \sigma \not\models \alpha$
$\mathcal{M}, w, \sigma \models \alpha \wedge \beta$	$\Leftrightarrow$	$\mathcal{M}, w, \sigma \models \alpha$ *and* $\mathcal{M}, w, \sigma \models \beta$
$\mathcal{M}, w, \sigma \models \exists x\alpha$	$\Leftrightarrow$	*there is some* $d \in \delta(w)$ *such that* $\mathcal{M}, w, \sigma_{[x \mapsto d]} \models \alpha$
$\mathcal{M}, w, \sigma \models \Box\alpha$	$\Leftrightarrow$	*for every* $u \in \mathcal{W}$ *if* $(w, u) \in \mathcal{R}$ *then* $\mathcal{M}, u, \sigma \models \alpha$

We sometimes write $\mathcal{M}, w \models \alpha(a)$ to mean $\mathcal{M}, w, [x \mapsto a] \models \alpha(x)$.

A formula α is *satisfiable* if there is some FOML structure $\mathcal{M}$ and $w \in \mathcal{W}$ and some assignment σ relevant at w such that $\mathcal{M}, w, \sigma \models \alpha$. In the sequel, we will only talk about the relevant σ for a given pointed model. Also, while evaluating α, it is enough to consider σ to be a partial function that gives an interpretation for the free variables of α. A formula α is *valid* if $\neg\alpha$ is not satisfiable.

2.1 Bundled fragments

The motivation for "bundling" is to restrict the occurrences of quantifiers using modalities. For instance, allowing only formulas of the form $\forall x \Box \alpha$ is one such bundling. We could also have $\Diamond \exists y \alpha$. Thus, there are many ways to "bundle" the quantifiers and modalities. We call these the "bundled operators/modalities". The following syntax defines all possible bundled operators of one quantifier and one modality:

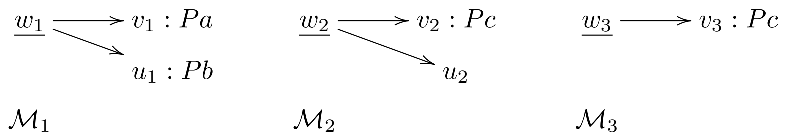
▶ **Definition 4** (Bundled-FOML syntax). *The bundled fragment of* FOML *is the set of all formulas constructed by the following syntax:*

$$\alpha ::= P(x_1, \ldots, x_n) \mid \neg\alpha \mid \alpha \wedge \alpha \mid \Box\alpha \mid \exists x \Box\alpha \mid \forall x \Box\alpha \mid \Box\exists x\alpha \mid \Box\forall x\alpha$$

where $P \in \mathcal{P}$ *has arity* n *and* $x, x_1, \ldots, x_n \in$ *Var.*

Note that the duals of the bundled operators give us the formulas of the form $\forall x \Diamond \alpha$, $\exists x \Diamond \alpha$, $\Diamond \forall x \alpha$, $\Diamond \exists x \alpha$. Also, note that $\Box\alpha$ can be defined using any one of the bundled operators where the quantifier is applied to a variable that does not occur in α. However, we retain $\Box\alpha$ in the syntax for technical convenience.

The following *constant domain* models may help to get familiar with bundles.



Let $\mathcal{D}^{\mathcal{M}_1} = \{a, b\}$, $\mathcal{D}^{\mathcal{M}_2} = \mathcal{D}^{\mathcal{M}_3} = \{c\}$. $\Box\exists x Px$ holds at w_1 and w_3 but not at w_2; $\exists x \Box Px$ holds only at w_3; $\neg\forall x \Box Px$ holds at w_1 and w_2; $\neg\Box\forall x \neg Px$ holds at all the w_i.

We denote $\forall\Box$-fragment to be the language that allows only atomic formulas, negation, conjunction, $\Box\alpha$ and $\forall x \Box\alpha$ (dually $\exists x \Diamond \alpha$) formulas, similarly for $\exists\Box$-fragment and so on. In general, these fragments are not equally expressive, e.g., as shown by [17], the $\exists\Box$-fragment cannot express $\Box\exists$, $\forall\Box$ and $\Box\forall$ bundles over models with increasing (or constant) domains.

In [14, 12] we proved that the $\forall\Box + \exists\Box$ and $\Box\forall + \Box\exists$ fragments are decidable over increasing domain models, while $\forall\Box$-fragment and $\Box\forall$-fragment are undecidable over constant domain models. Since simple bundles become undecidable over constant domain models, in this paper we focus on generalized bundles over increasing domain models.

Note that we can have more general bundled operators of the form $\forall x \forall y \Box \alpha$ etc. This naturally raises the question of what is the most general fragment of this form that is decidable. Towards this, we define a general fragment that subsumes all known decidable bundled fragments so far.

2.2 The Loosely Bundled Fragment

Note that a bundled formula of the form $\exists x \Box \alpha$ imposes a restriction that there is exactly one modal formula in the scope of $\exists x$. But this is a strong requirement. We weaken this condition to allow formulas of the form $\exists x \beta$ where β is a boolean combination of atomic formulas and modal formulas. Moreover, we can allow a quantifier alternation of the form $\exists x_1 \cdots \exists x_n \, \forall y_1 \cdots \forall y_m \, \beta$. As we will see, the fact that the existential quantifiers are outside the scope of universal quantifiers can help us to obtain decidability results over increasing domain models.

▶ **Definition 5** (LBF syntax). *The loosely bundled fragment of* FOML *is the set of all formulas constructed by the following syntax:*

$$\begin{aligned}\psi ::= & P(z_1,\dots z_n) \mid \neg P(z_1,\dots z_n) \mid \psi \wedge \psi \mid \psi \vee \psi \mid \Box\alpha \mid \Diamond\alpha \\ \alpha ::= & \psi \mid \alpha \wedge \alpha \mid \alpha \vee \alpha \mid \exists x_1 \dots \exists x_k \forall y_1 \dots \forall y_l \ \psi\end{aligned}$$

where $k, l, n \geq 0$ and $P \in \mathcal{P}$ has arity n and $x_1, \dots x_k$, $y_1, \dots y_l$, $z_1, \dots, z_n \in$ Var.

Let LBF be the set of all formulas that can be obtained from the grammar of α above. Note that the syntax does not allow a quantifier alternation of the form $\forall x \exists y \ \alpha$. Also, inside the scope of quantifier prefix $\exists^*\forall^*$, we can only have boolean combinations of atomic and modal formulas. The $\exists^*\forall^*$ fragment in FO, (Bernays-Schönfinkel-Ramsey class) has a similar quantifier prefix structure but is different in spirit since there is no modality.

The loosely bundled fragment subsumes some of the combinations of bundled fragments. Hence proving the decidability for LBF implies the decidability for these combinations as well.

▶ **Proposition 6.** *The fragments $\forall\Box + \exists\Box$ and $\Box\forall + \Box\exists$ are subfragments of LBF.*

Note that many combinations of bundled operators (for instance $\Box\forall + \exists\Box$) do not form a subfragment of LBF.

3 Tableau Procedure

Note that the formulas of LBF are in negation normal form (where $\neg$ appears only in front of atomic formulas). We first define some useful terms and notations.

▶ **Definition 7.** *For any* FOML *formula φ:*

- *φ is a literal if φ is of the form $P(x_1,\dots x_n)$ or of the form $\neg P(x_1,\dots x_n)$*
- *φ is a module if φ is a literal or φ is of the form $\Delta\alpha$ where $\Delta \in \{\Box, \Diamond\}$*
- *The component of φ is defined inductively as follows:*
  - *If φ is a module then $C(\varphi) = \{\varphi\}$*
  - *If φ is of the form $\varphi_1 \wedge \varphi_2$ or $\varphi_1 \vee \varphi_2$ then $C(\varphi) = C(\varphi_1) \cup C(\varphi_2)$*
  - *If φ is of the form $\forall x \ \varphi_1$ or $\exists x \ \varphi_1$ then $C(\varphi) = \{\varphi\} \cup C(\varphi_1)$*
- *A formula φ is called Existential-safe if every $\psi \in C(\varphi)$ is a module or of the form $\forall x \ \psi'$. A finite set of formulas Γ is Existential-safe if every $\varphi \in \Gamma$ is Existential-safe.*

Intuitively, $\mathsf{C}(\varphi)$ is the set of all subformulas of φ that are "to be evaluated" at the current world. An $\mathsf{Existential\text{-}safe}$ formula φ does not need any witness from the current local domain in order to make the formula true. The notions of components and existential-safeness will play a role in the tableau-based decision procedure to be introduced below.

Before going into the specific tableau rules, we first explain the general method. A *tableau* is a tree-like structure generated from a single formula α by repeatedly applying a few rules with some auxiliary information as the root of the tree. Intuitively, a tableau for α is a pseudo model which can be transformed into a real model of α under some simple consistency conditions. We can then decide the satisfiability of a formula by trying to find a proper tableau. As in [17], a tableau T in our setting is a tree structure such that each node is a triple (w, Γ, σ) where w is a symbol or a finite sequence of symbols intended as the *name* of a possible world in the real model, Γ is a finite set of FOML-formulas, and σ is an assignment function for variables. Since we intend to use the set of variables as the domain in the tableau-induced real model, σ is simply a *partial* identity function on Var, i.e., $\sigma(x) = x$ for all $x \in Dom(\sigma) \subseteq \mathsf{Var}$, where the domain of σ, $Dom(\sigma)$, is intended to be the local domain of the real model. The intended meaning of the node (w, Γ, σ) is that all the formulas in Γ are satisfied on w with the assignment σ, thus we also write $(w : \Gamma, \sigma)$ for the triple.

A tableau rule specifies how the node in the premise of the rule is transformed to or connected with one or more new nodes given by the conclusion of the rule. Applying the rules can generate a tree-like structure, a tableau, which is saturated if every leaf node contains only literals. For any formula α, we refer to a saturated tableau of α simply as a tableau of α. Further, a saturated tableau is *open* if in every node $(w : \Gamma, \sigma)$ of the tableau, Γ does not contain both β and $\neg\beta$ for any formula β.[2]

We call a formula *clean* if no variable occurs both bound and free in it and every use of a quantifier quantifies a distinct variable. A finite set of formulas Γ is *clean* if $\bigwedge \Gamma$, the conjunction of all formulas in Γ, is clean. Note that every FOML-formula can be rewritten into an equivalent clean formula. For instance, the formulas $\exists x \Box Px \vee \forall x \Diamond Qx$ and $Px \wedge \Box \exists x Qx$ are not clean, whereas $\exists x \Box Px \vee \forall y \Diamond Qy$ and $Px \wedge \Box \exists y Qy$ are their clean equivalents respectively. Clean formulas help in handling the witnesses for existential formulas in the tableau in a syntactic way.

Consider a finite set of formulas Γ that is clean. Suppose we want to expand Γ to $\Gamma \cup \{\alpha_1, \dots \alpha_k\}$, then even if each of α_i is clean, it is possible that a bound variable of α_i also occurs in some $\varphi \in \Gamma$ or another α_j. To avoid this, first, we rewrite the bound variables in each α_i one by one by using the fresh variables that do not occur in Γ and other previously rewritten α_j.

Such a rewriting can be fixed by always using the first fresh variable in a fixed enumeration of all the variables. When Γ and $\{\alpha_1, \dots \alpha_k\}$ are clear from the context, we denote α_i^* to be such a fixed rewriting of α_i into a clean formula. It is not hard to see that the resulting finite set $\Gamma \cup \{\alpha_1^*, \dots \alpha_k^*\}$ is clean.

3.1 Tableaux for LBF

The tableau rules for the LBF fragment are described in Fig. 1. The $(\wedge)$ and $(\vee)$ rules are standard, where we make a non-deterministic choice of one of the branches for $(\vee)$. The rule (END) says that if we are left with only modules and there are no $\Diamond$ formulas, then the branch does not need to be explored further. The $(\Diamond)$ rule creates one successor world for every $\Diamond$ formula at the current node and includes all the $\Box$ formulas that need to be

[2] Refer [17] for an illustration of a similar tableau construction.

$$\frac{w : \varphi_1 \vee \varphi_2, \Gamma, \sigma}{w : \varphi_1, \Gamma, \sigma \mid\mid w : \varphi_2, \Gamma, \sigma}\ (\vee) \qquad \frac{w : \varphi_1 \wedge \varphi_2, \Gamma, \sigma}{w : \varphi_1, \varphi_2, \Gamma, \sigma}\ (\wedge)$$

$$\frac{w : \exists x\varphi,\ \Gamma,\ \sigma}{w : \varphi,\ \Gamma,\ \sigma'}(\exists)$$

where $\sigma' = \sigma \cup \{(x, x)\}$

$$\frac{w : \forall y\varphi,\ \Gamma,\ \sigma}{w :\ \{\varphi^*[z/y] \mid z \in Dom(\sigma)\},\ \Gamma,\ \sigma}(\forall)$$

where Γ is Existential-safe and every $\varphi^*[z/y]$ is a clean rewriting of $\varphi[z/y]$ with respect to $\Gamma \cup \{\varphi[z/y] \mid z \in Dom(\sigma)\}$

Given $n \geq 1$: and $m, s \geq 0$

$$\frac{\begin{matrix} w : \Diamond\varphi_1, \dots, \Diamond\varphi_n \\ \Box\beta_1, \dots \Box\beta_m \end{matrix}\ l_1, \cdots, l_s,\ \ \sigma}{\langle wv_i : \varphi_i,\ \{\beta_j \mid j \in [1, m]\},\ \sigma\rangle\ \text{ for all } i \in [1, n]}\quad (\Diamond)$$

Given $m \geq 1, s \geq 0$:

$$\frac{w : \Box\beta_1, \dots \Box\beta_m,\ l_1, \dots, l_s, \sigma}{w : l_1, \cdots, l_s, \sigma}\quad (\texttt{END})$$

Figure 1 Tableau rules for LBF, here every l_i is a literal.

satisfied along with the $\Diamond$ formula and σ is inherited in the successor worlds to preserve the increasing domain property. The $(\exists)$ rule picks x itself as the witness to satisfy $\exists x\varphi$ and $(\forall)$ rule expands the set of formulas to include a clean version of $\varphi[z/y]$ for every variable z in the current local domain.

Note that only the $(\Diamond)$ rule can change (the name of) the possible world, thus creating a new successor. It simply extends the name w by new symbols v_i for each successor. Therefore there can be many nodes in the tableau sharing the same world name but such nodes form a path. Given w we use t_w to denote the *last node* sharing the first component w. Given a node $t = (w : \Gamma, \sigma)$ in a tableau, we use $Dom(t)$ to denote the domain of σ.

Also, there is an implicit ordering on how the rules are applied: $(\Diamond)$ rule can be applied at a node (w, Γ, σ) only if all formulas of Γ are modules and hence may be applied only after the $(\wedge, \vee, \forall, \exists)$ rules have been applied as many times as necessary at w. Similarly $(\forall)$ rule can be applied only when Γ is Existential-safe which means that the $(\exists)$ rule cannot be applied anymore at the current node.

▶ **Proposition 8.** *For every tableau T and every node $v = (w, \Gamma, \sigma)$ in T, if v is a leaf then either Γ contains only literals or there is some rule that can be applied at v.*

The proposition is true since the LBF ensures that if Γ is not Existential-safe and the $(\wedge, \vee, \Diamond, \texttt{END})$ rules cannot be applied, then it has to be the case that there is some $\exists x\varphi \in \Gamma$, for which we can apply the $(\exists)$ rule.

▶ **Theorem 9.** *For any clean LBF formula θ, let σ_r be an identity mapping over FV$(\theta) \cup \{z\}$ where z does not occur in θ. There is an open tableau T with root $(r : \{\theta\}, \sigma_r)$ iff θ is satisfiable in an increasing domain model.*

Proof. First, we claim that the rules preserve the cleanliness of the formulas. To see this, we verify that for every rule, if Γ in the antecedent of the rule is clean, then the Γ' obtained after the application of the rules is also clean. This is obvious for $(\wedge), (\vee), (\Diamond)$ and $(\texttt{END})$ rules. The $(\exists)$ rule preserves cleanliness because it frees variable x which is not bound by any other quantifier in the antecedent. The $(\forall)$ rule preserves cleanliness by rewriting.

($\Rightarrow$): Let T be an open tableau rooted at $(r : \{\theta\}, \sigma_r)$. Define a model $\mathcal{M} = (\mathcal{W}, \mathcal{D}, \delta, \mathcal{R}, \rho)$ as follows:

- $\mathcal{W} = \{w \mid (w : \Gamma, \sigma) \text{ is a node in } T\}$
- $\mathcal{D} = \mathsf{Var}$
- $\mathcal{R} = \{(w, v) \mid v \text{ is of the form } wv' \text{ for some } v'\}$
- For every $w \in \mathcal{W}$, define $\delta(w) = Dom(t_w)$ where t_w is the last node of w in T
- For every $w \in \mathcal{W}$ and $p \in \mathcal{P}$, define $\rho(w, P) = \{\overline{x} \mid P\overline{x} \in \Gamma \text{ where } t_w = (w, \Gamma, \sigma)\}$

Clearly, $\mathcal{M}$ is an increasing domain model, and since $z \in Dom(\sigma_r)$, there is no empty local domain. As T is an open tableau, ρ is well-defined.

Claim. For every node $(w : \Gamma, \sigma)$ in T and for every LBF formula φ, if $\varphi \in \Gamma$ then $\mathcal{M}, w, \sigma \models \varphi$.

The claim is proved using a standard argument by induction on the height of the nodes of T from the leaves to the root (details in [13]). Thus, from the claim it follows that $\mathcal{M}, r, \sigma_r \models \theta$ since the label of the root of T is $(r : \{\theta\}, \sigma_r)$.

($\Leftarrow$) From Proposition 8 it follows that we can always apply some rule until every leaf node $(w : \Gamma, \sigma)$ is such that Γ contains only literals. Thus every (partial) tableau can be extended to a saturated tableau. To prove that such a tableau is open, it suffices to show that all rules preserve satisfiability (details in [13]). ◀

Note that the depth of the tableau is linear in the size of the formula. However, as we have to rewrite formulas using new variables when applying ($\forall$) rule, the size of the domain is exponential in the size of the formula. Hence, the tableau procedure can be implemented in ExpSpace.

▶ **Corollary 10.** *LBF is decidable in ExpSpace.*

4 The (Un)decidability Border

Note that the fragment LBF cannot express formulas of the form $\forall x \exists y \Box\ \alpha$ and also $\forall x \Box \forall y \Box \forall z \alpha$. There are many combinations of the bundled fragments that can express thesse formulas (like $\exists\Box + \Box\forall$ and $\forall\Box + \exists\Box + \Box\exists$ fragments). In fact, we can prove that a bundled fragment is undecidable if we can assert both $\forall x \exists y \Box \alpha$ and $\forall x \Box \forall y \Box \forall z\ \alpha$ in the fragment.

To prove this, we can use tiling encoding where $\forall x \exists y \Box \alpha$ can be used to assert that every "grid point" x has a horizontal/vertical successor y. In this case, it is important that both quantifiers are applicable over the same local domain and $\Box \alpha$ in $\forall x \exists y \Box \alpha$ ensures that the witness y acts uniformly across all the descendants. The second formula $\forall x \Box \forall y \Box \forall z\ \alpha$ is used to verify the "diagonal property" of the grid. In the companion technical report of this paper [13] we prove these results formally.

Also, note that there are fragments like $\exists\Box + \Box\exists$ where $\forall x \exists y \Box \alpha$ is expressible but not $\forall x \Box \forall y \Box \forall z\ \alpha$. In these cases, we can prove that such fragments do not have a finite model property. This is also proved in the companion technical report [13] where we show that this fragment gives a formula that can induce a linear order on the local domain of some world in the model and assert that this linear order does not have a maximal element.

This leaves us with the fragments that cannot express $\forall x \exists y \Box \alpha$ formulas and LBF is one such fragment which we proved to be decidable. The fragments $\forall\Box + \exists\Box$ and $\Box\forall + \Box\exists$ also fall in this category and since they are subfragments of LBF, decidability follows. So we *only* need to consider the fragment $\forall\Box + \exists\Box + \Box\forall$ to complete the terrain (cf. Table. 1).

5 The $\forall\Box + \Box\forall + \Box\exists$ Fragment

In this fragment, we are allowed to express $\forall x\Box\alpha$, $\Box\forall x\alpha$ and $\Box\exists x\alpha$ and their duals. Note that this fragment is not closed under subformulas. For instance, $\varphi := \forall x\left(\exists y\Diamond\alpha \vee \forall z\Box\beta\right)$ is a subformula of $\varphi' := \Diamond\forall x\left(\exists y\Diamond\alpha \vee \forall z\Box\beta\right)$. But φ' is in the fragment and φ is not in the fragment. We say that φ is a subformula of $\forall\Box + \Box\forall + \Box\exists$ if there is some formula $\varphi' \in \forall\Box + \Box\forall + \Box\exists$ such that φ is a subformula of φ'.

Note that even though we cannot express formulas of the form $\forall x\exists y\Box\varphi$ in the fragment, $\forall x\exists y\Diamond\varphi$ is still allowed. For instance, the formula $\Diamond\forall x\left(\exists y\Diamond\alpha\right)$ is in the fragment. Thus, we can have $\forall x\exists y\Diamond\varphi$ but not $\forall x\exists y\Box\varphi$. Intuitively this means that the different witnesses y for each x can work on *different* successor worlds. The fragment cannot enforce the interaction between x and y at all successors. This property can be used to prove that we can reuse the witnesses by creating new successor subtrees as required.

To get the decidability for $\forall\Box + \Box\forall + \Box\exists$ fragment, the main idea is to prove that the formulas of the form $\forall x\exists y\Diamond\varphi$ can be satisfied by picking some boundedly many witnesses y that will work for *all* x. This is the same as proving that if $\forall x\exists y\Diamond\varphi$ is satisfiable then $\exists y_1,\dots\exists y_l\forall x\big(\bigvee\Diamond\varphi[y/y_i]\big)$ is satisfiable (where l is bounded). We illustrate the proof idea with an example.

▶ **Example 11.** Consider the formula $\alpha := \forall x\Big(\Box\neg Pxx \wedge \exists y\Diamond Pxy\Big)$ which is a subformula of the fragment. Let $\mathcal{T}, r \models \alpha$ where $\mathcal{T}$ is a tree model rooted at r. Now we will modify $\mathcal{T}$ to obtain $\mathcal{M}$ which is also a tree model rooted at r such that $\mathcal{M}, r \models \exists y_1\exists y_2\forall x\left(\Box\neg Pxx \wedge \left(\,\Diamond Pxy_1 \vee \Diamond Pxy_2\,\right)\right)$.

The model $\mathcal{M}$ is obtained by extending $\mathcal{T}$ in the following way. Let $\delta^{\mathcal{T}}(r) = \mathcal{D}_r$. To obtain $\mathcal{M}$, first we extend the local domain of r by adding a fresh element a. The idea is that for every $d \in \mathcal{D}_r$ (when assigned to x) we will ensure that the new element a can be picked as the y-witness. To achieve this, we do the following: For every $d \in \mathcal{D}_r$ let $d' \in \mathcal{D}_r$ and $(r, s^d) \in \mathcal{R}^{\mathcal{T}}$ such that $\mathcal{T}, s^d \models Pdd'$. Let $\mathcal{T}^d$ be the subtree of $\mathcal{T}$ rooted at s^d. We will create a new copy of $\mathcal{T}^d$ and call its root u^d. Now, in the new subtree rooted at u^d, we make the new element a "behave" like d' and we add an edge from r to u^d. So, in particular, $\mathcal{M}$ will have $(r, u^d) \in \mathcal{R}^{\mathcal{M}}$ such that $\mathcal{M}, u^d \models Pda$. Since we do this construction for every $d \in \mathcal{D}_r$ we obtain that for all $d \in \mathcal{D}_r$ we have $\mathcal{M}, r \models \Diamond Pda$.

Now note that while evaluating α at $(\mathcal{M}, r)$ the $\forall x$ quantification will now also apply to a (since a is added to the local domain at r in $\mathcal{M}$). But then, we cannot use a itself as the witness for a since we also need to ensure that $\mathcal{M}, r \models \forall x\Box\neg Pxx$. Hence we will add another element b that acts as a witness for a. Further, b also needs a witness. But now we can choose a to be the witness for b since that does not violate the formula $\forall x\Box\neg Pxx$.

So to complete the construction, we pick some arbitrary $d \in \mathcal{D}_r$ for which we have some $d' \in \mathcal{D}_r$ and $(r, s^d) \in \mathcal{R}^{\mathcal{T}}$ such that $\mathcal{T}, s^d \models Pdd'$. We create two copies of $\mathcal{T}^d$ (subtree rooted at s^d) and call their roots as v^d and w^d respectively. In the subtree rooted at v^d we ensure that a and b "behave" like d, d' respectively and in the subtree rooted at w^d we ensure that a and b "behave" like d', d respectively. In particular, we have $\mathcal{M}, v^d \models Pab$ and $\mathcal{M}, w^d \models Pba$. Finally we add edges from r to v^d and from r to w^d in $\mathcal{M}$.

Thus, we have: $\delta^{\mathcal{M}}(r) = \delta^{\mathcal{T}}(r) \cup \{a, b\}$ and $\mathcal{M}, r \models \exists y_1\exists y_2\forall x\left(\Box\neg Pxx \wedge \left(\,\Diamond Pxy_1 \vee \Diamond Pxy_2\,\right)\right)$. With the above construction, this assertion can be verified by assigning y_1 and y_2 to a and b respectively.

Note that in principle, it is possible for an $\exists$ quantified formula to occur in the scope of a $\forall$ quantifier as a boolean combination with other $\exists$ quantified formulas and modules. Moreover, these additional formulas can assert some "type" information that may force us to pick additional witnesses. For example, if the formula is

$$\forall x\Big[\Big(\Box(\neg Pxx \wedge Rx) \vee \Box(\neg Pxx \wedge \neg Rx)\Big) \wedge \exists y \Diamond\big(Rx \to (Pxy \wedge \neg Ry) \ \wedge\ \neg Rx \to (Pxy \wedge Ry)\big)\Big]$$

then we need two initial y-witnesses a_1, a_2 where one is used for witness whose "type" is $\Box(\neg Pyy \wedge Ry)$ and other for witness whose "type" is $\Box(\neg Pyy \wedge \neg Ry)$ and we also need the corresponding additional witnesses b_1, b_2. In general, the formula can force us to pick witnesses of a particular "1-type" which means we might need exponentially many witnesses.

Thus, we need to replace one $\exists$ inside the scope of $\forall$ by $2l$ many $\exists$ quantifiers outside the scope of $\forall$ where l is bounded exponentially in the size of the given formulas. We now prove this formally.

For any formula φ if $\alpha \in \mathsf{C}(\varphi)$ we denote this by $\varphi[\alpha]$. This means that α does not occur inside the scope of any modality in φ. Further, for every $\alpha \in \mathsf{C}(\varphi)$ and a formula β, we denote $\varphi[\beta/\alpha]$ obtained by rewriting φ where every occurrence of α in φ is replaced by β. In particular, we are interested in the case where α is of the form $\exists y \Diamond \psi$. Thus we always consider $\varphi[\exists y \Diamond \psi]$.

For every $l \geq 0$ if $\overline{y} = y_1, y'_1 \dots y_l, y'_l$ are fresh variables, we denote $\overline{y}\Diamond\psi$ to be the formula $\bigvee\limits_{i \leq l} \big(\Diamond\psi[y_i/y] \vee \Diamond\psi[y'_i/y]\big)$ which is a big disjunction where each disjunct replaces y in ψ with one of y_i or y'_i. Further, we denote $\varphi[\overline{y}\Diamond\psi/\exists y\Diamond\psi]$ as simply $\varphi[\overline{y}\Diamond\psi]$.

For instance, for the formula $\varphi := \Big(Px \ \vee\ \exists y \Diamond Qxy\Big)$ where $\psi := \exists y \Diamond Qxy$, for $l = 2$ and $\overline{y} = y_1, y'_1, y_2, y'_2$ being fresh variables, $\varphi[\overline{y}\Diamond\psi]$ is given by: $\Big(Px \ \vee \big(\Diamond Qxy_1 \vee \Diamond Qxy'_1 \vee \Diamond Qxy_2 \vee \Diamond Qxy'_2\big)\Big)$.

The size of a formula, denoted by $|\varphi|$, is the number of symbols occurring in φ and for a finite set of formulas Γ, let $|\Gamma| = \sum\limits_{\varphi \in \Gamma} |\varphi|$.

▶ **Lemma 12.** *Let Γ' be a clean finite set of formulas such that every $\alpha \in \Gamma$ is a subformula of $\forall\Box + \Box\forall + \Box\exists$ where $\Gamma' = \Gamma \cup \{\forall x \varphi[\exists y \Diamond\psi]\}$. If $\bigwedge \Gamma \wedge \forall x \varphi[\exists y \Diamond \psi]$ is satisfiable then there exists $l \leq 2^{|\Gamma'|}$ such that $\bigwedge \Gamma \ \wedge\ \exists y_1 \exists y'_1 \exists y_2 \exists y'_2 \dots \exists y_l \exists y'_l\ \forall x\ \varphi[\overline{y}\Diamond\psi]$ is satisfiable, where $\overline{y} = y_1, y'_1, \dots y_l, y'_l$ are fresh variables.*

Note that the $\exists y$ quantifier is pulled outside the scope of the $\forall x$ quantifier and replaced with a bounded number of witnesses $y_1, y'_1, y'_2, y'_2 \dots y_l, y'_l$. Consequently $\Diamond\ \psi$ is replaced with a disjunction each replacing y with one of y_i or y'_i for every $i \leq l$.

To prove the lemma first we formally define the tree editing operation described in the example. Given a tree model $\mathcal{T}$ rooted at r, let $d \notin \mathcal{D}^{\mathcal{T}}$. To add the new domain element d to a local domain of r, we also need to specify the "type" of the new element d at r and its descendants. Towards this, we pick some domain element c that is already present in $\delta(r)$ and assign the type of d to the type of c at every world.

▶ **Definition 13.** *Given a tree model $\mathcal{T} = (\mathcal{W}, \mathcal{D}, \mathcal{R}, \delta, \rho)$ rooted at r, let $d \notin \mathcal{D}$ and $c \in \delta(r)$. Define the operation of "adding d to $\delta(r)$ by mimicking c", denoted by $\mathcal{T}_{d \mapsto c} = (\mathcal{W}, \mathcal{D}', \mathcal{R}, \delta', \rho')$ where:*

- $\mathcal{D}' = \mathcal{D} \cup \{d\}$
- *for all $w \in \mathcal{W}$ we have $\delta'(w) = \delta(w) \cup \{d\}$*

- *For every $w \in \mathcal{W}$ and predicate P define* $\rho'(w,P) = \{\overline{e'} \mid$ *there is some* $\overline{e} \in \rho(w,P)$ *and* $\overline{e'}$ *is obtained from* $\overline{e}$ *by replacing zero or more occurrences of* c *in* $\overline{e}$ *by* $d\}$.

Suppose that we want to extend the domain with $\overline{d} = d_1 \cdots d_n$ *which are fresh. Let* $\omega : \overline{d} \mapsto \mathcal{D}'$ *where* $\mathcal{D}' \subseteq \delta^T(r)$ *and we want each* d_i *to mimic* $\omega(d_i)$*. Then we denote* $\mathcal{T}_\omega$ *to be the tree obtained by* $\Big((\mathcal{T}_{d_1 \mapsto \omega(d_1)})_{d_2 \mapsto \omega(d_2)\ldots}\Big)_{d_n \mapsto \omega(d_n)}$.

▶ **Proposition 14.** *Let* $\mathcal{T} = (\mathcal{W}, \mathcal{D}, \mathcal{R}, \delta, \rho)$ *be a tree model rooted at* r *with* $\mathcal{T}_{d \mapsto c}$ *being an extended tree where* $d \notin \mathcal{D}$ *and* $c \in \delta(r)$*. Then for all interpretations* σ *and for all* FOML *formulas* φ *and for all* $w \in \mathcal{W}$ *we have:*
$\mathcal{T}, w, \sigma_{[x \mapsto c]} \models \varphi$ *iff* $\mathcal{T}_{d \mapsto c}, w, \sigma_{[x \mapsto c]} \models \varphi$ *iff* $\mathcal{T}_{d \mapsto c}, w, \sigma_{[x \mapsto d]} \models \varphi$.

The proposition holds since there is no equality in the syntax and at every world in the extended model, the new element d "behaves" like c and the old elements "behave" like themselves (details in [13]). Now we are ready to prove Lemma 12.

Proof of Lemma 12. Let $\mathcal{T}$ be a tree model rooted at r such that $\mathcal{T}, r, \sigma \models \bigwedge \Gamma \wedge \forall x \varphi[\exists y \Diamond \psi]$. For every domain element $a \in \delta^T(r)$ define:

$$\Pi(r,a) = \bigcup_{\forall x' \alpha \in \Gamma'} \{\lambda \mid \lambda \in \mathsf{C}(\alpha) \text{ and } T, r, \sigma_{[x' \mapsto a]} \models \lambda\}$$

Note that $\Pi(r,a)$ formalizes the notion of "type" of a at the world r. This includes the information of all subformulas that are true at the current world, when a universal variable is instantiated with a. Also, since the size of $|\mathsf{C}(\alpha)|$ is at most the size of Γ', the set $\Pi(r) = \{\Pi(r,a) \mid a \in \delta^T(r)\}$ has size $|\Pi(r)| = l$ where $l \leq 2^{|\Gamma'|}$. Enumerate $\Pi(r) = \{\Lambda_1, \ldots \Lambda_l\}$ and for every $i \leq l$ pick $a_i \in \delta^T(r)$ such that $\Pi(r, a_i) = \Lambda_i$. Now let $\overline{d} = d_1, d_1', d_2, d_2', \ldots d_l, d_l'$ be fresh domain elements and let $\omega : \overline{d} \mapsto \{a_1, a_2, \ldots a_l\}$ where for all $i \leq l$ we have $\omega(d_i) = \omega(d_i') = a_i$. We define the required model $\mathcal{M} = (\mathcal{W}', \mathcal{D}', \mathcal{R}', \delta', \rho')$ as follows:

Let $\mathcal{M}_0 = \mathcal{T}_\omega$ be the new tree model rooted at r obtained by adding $d_1, d_1', \ldots, d_l, d_l'$ to $\delta^T(r)$ where each d_i and d_i' mimics a_i. Now $\mathcal{M}$ is obtained by extending $\mathcal{M}_0$ as follows:

For every $c \in \delta(r)$ such that $\mathcal{T}, r, [x \mapsto c] \models \exists y \Diamond \psi$ we pick $c' \in \delta^T(r)$ and $r \to s^c$ be such that $\mathcal{T}, s^c, [xy \mapsto cc'] \models \psi$. Let $\mathcal{T}^c$ be the sub-tree of $\mathcal{T}$ rooted at s^c and $\Pi(r,c') = \Lambda_j$. Create a new subtree $\mathcal{T}_0^c = \mathcal{T}_{\omega'}^c$ where for all $h \neq j$ we have $\omega'(d_h) = \omega'(d_h') = a_h$ and $\omega'(d_j) = \omega'(d_j') = c'$. Let u^c be the root of $\mathcal{T}_0^c$. Add an edge from r to u^c in $\mathcal{M}$.
Further, for every $i \leq l$ if $\mathcal{T}, r, \sigma_{[x \mapsto a_i]} \models \exists y \Diamond \psi$ then let $b \in \delta^T(r)$ and $r \to s^i \in \mathcal{R}^T$ be such that $\mathcal{T}, s^i, \sigma_{[xy \mapsto a_i b]} \models \psi$. Let $\Pi(r,b) = \Lambda_j$. Then create $\mathcal{T}_1^i = \mathcal{T}_{\omega_1}^i$ and $\mathcal{T}_2^i = \mathcal{T}_{\omega_2}^i$ where ω_1 and ω_2 are defined as follows:

- For all $h \neq j$, $\omega_1(d_h) = \omega_1(d_h') = \omega_2(d_h) = \omega_2(d_h') = a_h$
- $\omega_1(d_j) = a_j$ and $\omega_1(d_j') = b$
- $\omega_2(d_j) = b$ and $\omega_2(d_j') = a_j$

Let v^i and w^i be the root of $\mathcal{T}_1^i$ and $\mathcal{T}_2^i$ respectively. Add the edges from r to v^i and from r to w^i in $\mathcal{M}$. The two copies of subtrees are intended to provide witnesses for $\exists y \Diamond \psi$ for d_j and d_j' respectively. We need the two copies to ensure that ω_1 and ω_2 are well defined in the case when $i = j$ and $a_j \neq b$.

We now explain the idea behind the construction. Note that $\mathcal{T}_0^c$ rooted at u^c is created for every $c \in \delta^T(r)$ such that $\mathcal{T}, r, \sigma_{[x \mapsto c]} \models \exists y \Diamond \psi$. If c' is the picked witness for c with $(r, s^c) \in \mathcal{R}^T$ such that $\mathcal{T}, s^c, \sigma_{[xy \mapsto cc']} \models \psi$ and $\Pi(r,c') = \Lambda_j$ then by construction, $\mathcal{T}_0^c$ is rooted u^c where d_j mimics c' in the subtree rooted at u^c. All these together indicate that we can use d_j and the subtree rooted at u^c in $\mathcal{M}$ to verify that $\mathcal{M}, u^c, \sigma_{[xy \mapsto cd_j]} \models \psi$. Also note that for all $h \neq j$ the fresh elements d_h and d'_h mimic a_h in the subtree $\mathcal{T}_0^c$ (i.e, we have not added any extra "types").

Further, we want the type of d_i and d'_i at r in $\mathcal{M}$ to mimic the type of a_i at r in $\mathcal{T}$. All type information is taken care of in $\mathcal{M}_0$ where both d_i and d'_i mimic a_i except the formula $\exists y \Diamond \psi$. So if $\mathcal{T}, r, \sigma_{[x \mapsto a_i]} \models \exists y \Diamond \psi$ then we need a witness to verify $\mathcal{M}, r, \sigma_{[x \mapsto d_i]} \models \exists y \Diamond \psi$ and $\mathcal{M}, r, \sigma_{[x \mapsto d'_i]} \models \exists y \Diamond \psi$. If the witness for y for a_i is b and $\Pi(r, b) = \Lambda_j$ then we want d'_j to be the witness for d_i and d_j to be the witness for d'_i.

Consequently if s^i is the world such that $a \to s^i \in \mathcal{R}^T$ and $\mathcal{T}, s^i, [xy \mapsto a_i b] \models \psi$ then we create two new copies of subtree $\mathcal{T}^i$ rooted at s^i and call it $\mathcal{T}_1^i$ and $\mathcal{T}_2^i$. By construction, in particular, the new element d_i mimics a_i and d'_j mimics b in $\mathcal{T}_1^i$. Similarly d'_i mimics a_i and d_j mimics b in $\mathcal{T}_2^i$. Thus, we can pick d'_j to be the witness for d_i (and consider $\mathcal{T}_1^i$) and pick d_j to be the witness for d'_i (and consider $\mathcal{T}_2^i$).

Also, it is important to note that for every $r \to v \in \mathcal{R}^M$, if d_i mimics c and d'_i mimics c' at v then we will always have $\Pi(r, c) = \Pi(r, c') = \Lambda_i = \Pi(r, a_i)$. Now it can be verified that $\mathcal{M}, r, \sigma \models \bigwedge \Gamma \ \wedge \ \exists y_1 \exists y'_1 \ldots \exists y_l \exists y'_l \ \forall x \varphi[\overline{y} \Diamond \psi]$.

The details are provided in [13]. ◀

▶ **Corollary 15.** *Let Γ' be a clean finite set of formulas such that every $\alpha \in \Gamma$ is a subformula of $\forall\Box + \Box\forall + \Box\exists$ where $\Gamma' = \Gamma \cup \{\forall x \varphi[\exists y \Diamond \psi]\}$. If $\bigwedge \Gamma \wedge \forall x \varphi[\exists y \Diamond \psi]$ is satisfiable then $\bigwedge \Gamma \wedge \exists y_1 \exists y'_1 \exists y_2 \exists y'_2 \ldots \exists y_l \exists y'_l \ \forall x \ \varphi[\overline{y} \Diamond \psi]$ is satisfiable, where $l = 2^{|\Gamma'|}$ and $\overline{y} = y_1, y'_1, \ldots y_l, y'_l$ are fresh variables.*

To see why the corollary is true, by Lemma 12 we get some $l \leq 2^{|\Gamma'|}$, and we can pad sufficiently many dummy variables to get a strict equality. This gives us a useful tableau rule which we call $(\forall\exists\Diamond)$ rule for $\forall\Box + \Box\forall + \Box\exists$ fragment, described in Fig. 2. The full tableau rules for $\forall\Box + \Box\forall + \Box\exists$ is given by the tableau rules of LBF (Fig. 1) along with the $(\forall\exists\Diamond)$-rule.

$$\frac{w : \forall x \ \varphi[\exists y \Diamond \psi], \ \Gamma, \ \sigma}{w : \forall x \ \varphi[\overline{y} \Diamond \psi], \ \Gamma, \ \sigma'} (\forall\exists\Diamond)$$

where $l = 2^{|\Gamma| + |\varphi|}$ and $\overline{y} = y_1, y'_1, \ldots y_l, y'_l$
are fresh variables and $\sigma' = \sigma \cup \{(y_i, y_i) \ , (y'_i, y'_i) \mid i \leq l\}$

Figure 2 (The $\forall\exists\Diamond$) rule for $\forall\Box + \Box\forall + \Box\exists$ fragment.

▶ **Theorem 16.** *For any clean $\forall\Box + \Box\forall + \Box\exists$ formula θ, let σ_r be an identity mapping over $FV(\theta) \cup \{z\}$ where z does not occur in θ. There is an open tableau with $(r : \{\theta\}, \sigma_r)$ as the root iff θ is satisfiable in an increasing domain model.*

The proof follows along the lines of Theorem 9. The only interesting part of the proof is to show that the $(\forall\exists\Diamond)$ rule preserves satisfiability and this is by Lemma 12(details in [13]).

Note that at if we start with a formula of length n then the application of $(\forall\exists\Diamond)$ rule will blow up the formula to size 2^n. So we have a tableau procedure that can be implemented as an algorithm in ExpSpace.

▶ **Corollary 17.** *The fragment $\forall\Box + \Box\forall + \Box\exists$ is decidable in ExpSpace.*

6 Conclusion

In this paper, we have studied the decidability of bundled fragments of FOML, where we have no restrictions on the use of variables or arity of relations. Specifically, we proved the decidability of the loosely bundled fragment LBF and the $\forall\Box + \Box\forall + \Box\exists$ fragment. The decidability of these fragments hinges on the observation that $\forall x \exists y \Box \alpha$ is not expressible. A NEXPTIME lower bound follows for $\forall\Box + \exists\Box$ and $\Box\forall + \Box\exists$ (via encoding the corresponding version of the tiling problem [13]), which implies the same lower bound for LBF and $\forall\Box + \Box\forall + \Box\exists$. There is a significant gap between the upper and lower complexity bounds and we need sharper technical tools for investigating lower bounds for bundled fragments.

Note that the quantifier prefix in LBF is of the form $\exists^*\forall^*$ and hence any extension of this quantifier prefix or extending LBF with negation closure will result in a fragment that will be able to express $\forall x \exists y \Box\ \alpha$ (and hence will not have the finite model property, [13]). In this sense, LBF is the largest fragment in which $\forall x \exists y \Box \alpha$ is not (syntactically) expressible. For the fragment $\forall\Box + \Box\forall + \Box\exists$ we introduced a technique to pull out $\exists$ quantifiers outside the immediate scope of $\forall$ and obtain a finite model property. This technique may be useful in studying other fragments of first-order modal logic.

The results in the paper, along with those in [13], provide a trichotomy classification of combinations of bundled operators over increasing domain models (Table 1). The fragments in which we can express both $\forall x \exists y \Box \alpha$ and $\forall x \Box \forall y \Box \forall z \beta$ are undecidable, fragments in which we can express the former but not the latter lack finite model property (but decidability is open) and fragments where we cannot express the former are decidable. Similar trichotomy can also be proved for satisfiability over constant domain models [13].

We have considered only the "pure" fragments, without constants, function symbols, or equality. The addition of constants is by itself simple, but equality complicates things considerably. Since equality is extensively used in specifications, mapping fragments with equality is an important direction. The study of bundles over models with various frame conditions is also relevant for applications. Unfortunately, while it is clear that equivalence frames lead to undecidability [17], even with transitive frames the situation is unclear. Obtaining good decidable fragments over linear frames is an important challenge.

In the context of verification of infinite-state systems, we are often more interested in the MODEL CHECKING problem than in satisfiability. If the domain is finite, the problem is no different from model checking of first-order modal logic. However, we are usually interested in the specification being checked against a finitely specified (potentially infinite) model, e.g., when the domain elements form a *regular* infinite set. This is a direction to be pursued in the context of bundled fragments.

We have presented tableau-based decision procedures that are easily implementable, but inference systems for reasoning in these logics require further study.

Abstract

We show that the subset sum problem, the knapsack problem and the rational subset membership problem for permutation groups are NP-complete. Concerning the knapsack problem we obtain NP-completeness for every fixed $n \geq 3$, where n is the number of permutations in the knapsack equation. In other words: membership in products of three cyclic permutation groups is NP-complete. This sharpens a result of Luks [36], which states NP-completeness of the membership problem for products of three abelian permutation groups. We also consider the context-free membership problem in permutation groups and prove that it is PSPACE-complete but NP-complete for a restricted class of context-free grammars where acyclic derivation trees must have constant Horton-Strahler number. Our upper bounds hold for black box groups. The results for context-free membership problems in permutation groups yield new complexity bounds for various intersection non-emptiness problems for DFAs and a single context-free grammar.

1 Introduction

Membership problems in groups. The general problem that we study in this paper is the following: Fix a class $\mathcal{C}$ of formal languages. We assume that members of $\mathcal{C}$ have a finite description; typical choices are the class of regular or context-free languages, or a singleton class $\mathcal{C} = \{L\}$. We are given a language $L \in \mathcal{C}$ with $L \subseteq \Sigma^*$, a group G together with a morphism $h : \Sigma^* \to G$ from the free monoid Σ^* to the group G, and a word $w \in \Sigma^*$. The question that we want to answer is whether $w \in h^{-1}(h(L))$, i.e., whether the group element $h(w)$ belongs to $h(L)$. One can study this problem under several settings, and each of these settings has a different motivation. First of all, one can consider the case where G is a fixed finitely generated group that is finitely generated by Σ. One could call this problem the $\mathcal{C}$-membership problem for the group G. The best studied case is the *rational subset membership problem*, where $\mathcal{C}$ is the class of regular languages. It generalizes the subgroup membership problem for G, a classical decision problem in group theory. Other special cases of the rational subset membership problem that have been studied in the past are the submonoid membership problem, the knapsack problem and the subset sum problem, see e.g. [31, 37]. It is a simple observation that for the rational subset membership problem, the word w (which is tested for membership in $h^{-1}(h(L))$ can be assumed to be the empty word, see [28, Theorem 3.1].

In this paper, we study another setting of the above generic problem, where G is a finite group that is part of the input (and L still comes from a languages class $\mathcal{C}$). For the rest of the introduction we restrict to the case where G is a finite symmetric group S_m (the set of

all permutations on $\{1, \ldots, m\}$) that is represented in the input by the integer m in unary representation, i.e., by the word $\$^m$.[1] Our applications only make use of this case, but we remark that our upper complexity bounds can be proven in the more general black box setting [6] (in particular, one could replace symmetric groups by matrix groups over a finite field and still obtain the same complexity bounds). Note that $|S_m| = m!$, hence the order of the group is exponential in the input length.

Membership problems for permutation groups. One of the best studied membership problems for permutation groups is the *subgroup membership problem*: the input is a unary encoded number m and a list of permutations $a, a_1, \ldots, a_n \in S_m$, and it is asked whether a belongs to the subgroup of S_m generated by $a_1, \ldots, a_n$. The famous Schreier-Sims algorithm solves this problem in polynomial time [39], and the problem is known to be in NC [5].

Several generalizations of the subgroup membership problem have been studied. Luks defined the k-membership problem ($k \geq 1$) as follows: The input is a unary encoded number m, a permutation $a \in S_m$ and a list of k permutation groups $G_1, G_2, \ldots, G_k \leq S_m$ (every G_i is given by a list of generators). The question is whether a belongs to the product $G_1 \cdot G_2 \cdots G_k$. It is a famous open problem whether 2-membership can be solved in polynomial time. This problem is equivalent to several other important algorithmic problems in permutation groups: computing the intersection of permutation groups, computing set stabilizers or centralizers, checking equality of double cosets, see [36] for details. On the other hand, Luks has shown in [36] that k-membership is NP-complete for every $k \geq 3$. In fact, NP-hardness of 3-membership holds for the special case where $G_1 = G_3$ and G_1 and G_2 are both abelian.

Note that the k-membership problem is a special case of rational subset membership for symmetric groups. Let us define this problem again for the setting of symmetric groups (here, 1 denotes the identity permutation and we identify a word over the alphabet S_m with the permutation to which it evaluates):

▶ **Problem 1.1** (rational subset membership problem for symmetric groups).
Input: a unary encoded number m and a nondeterministic finite automaton (NFA) $\mathcal{A}$ over the alphabet S_m.
Question: Does $1 \in L(\mathcal{A})$ hold?

An obvious generalization of the rational subset membership problem for symmetric groups is the *context-free subset membership problem for symmetric groups*; it is obtained by replacing the NFA $\mathcal{A}$ in Problem 1.1 by a context-free grammar $\mathcal{G}$.

Two restrictions of the rational subset membership problem that have been intensively studied for infinite groups in recent years are the *knapsack problem* and *subset sum problem*, see e.g. [4, 8, 9, 21, 22, 29, 32, 34, 37]. For symmetric groups, these problems are defined as follows (note that the number $n + 1$ of permutations is part of the input):

▶ **Problem 1.2** (subset sum problem for symmetric groups).
Input: a unary encoded number m and permutations $a, a_1, \ldots, a_n \in S_m$.
Question: Are there $i_1, \ldots, i_n \in \{0, 1\}$ such that $a = a_1^{i_1} \cdots a_n^{i_n}$?

Note that the subset sum problem is the membership problem for *cubes*, which are subsets of the form $\{a_1^{i_1} \cdots a_n^{i_n} \mid i_1, \ldots, i_n \in \{0, 1\}\}$ [6].

[1] We could also consider the case where G is a subgroup of S_m that is given by a list of generators (i.e., G is a permutation group), but this makes no difference for our problems.

▶ **Problem 1.3** (knapsack problem for symmetric groups).
Input: a unary encoded number m and permutations $a, a_1, \dots, a_n \in S_m$.
Question: Are there $i_1, \dots, i_n \in \mathbb{N}$ such that $a = a_1^{i_1} \cdots a_n^{i_n}$?

We will also consider the following restrictions of these problems.

▶ **Problem 1.4** (abelian subset sum problem for symmetric groups).
Input: a unary encoded number m and pairwise commuting permutations $a, a_1, \dots, a_n \in S_m$.
Question: Are there $i_1, \dots, i_n \in \{0,1\}$ such that $a = a_1^{i_1} \cdots a_n^{i_n}$?

The following problem is the special case of Luks' k-membership problem for cyclic groups. Note that k is a fixed constant here.

▶ **Problem 1.5** (k-knapsack problem for symmetric groups).
Input: a unary encoded number m and $k+1$ permutations $a, a_1, \dots, a_k \in S_m$.
Question: Are there $i_1, \dots, i_k \in \mathbb{N}$ such that $a = a_1^{i_1} \cdots a_k^{i_k}$?

Main results. Our main result for rational subset membership in symmetric groups is:

▶ **Theorem 1.6.** *Problems 1.1–1.4 and Problem 1.5 for $k \geq 3$ are* NP*-complete.*

In contrast, we will show that the 2-knapsack problem can be solved in polynomial time (Theorem 5.7). The NP upper bound for the rational subset membership problem will be shown for black-box groups.

▶ Remark 1.7. The abelian variant of the knapsack problem, i.e., Problem 1.3 with the additional restriction that the permutations $s_1, \dots, s_n$ pairwise commute is of course the abelian subgroup membership problem and hence belongs to NC.

▶ Remark 1.8. Analogously to the k-knapsack problem one might consider the k-subset sum problem, where the number n in Problem 1.2 is fixed to k and not part of the input. This problem can be solved in time $2^k \cdot m^{\mathcal{O}(1)}$ (check all 2^k assignments for exponents $i_1, \dots, i_k$) and hence in polynomial time for every fixed k.

Finally, for the context-free subset membership problem for symmetric groups we show:

▶ **Theorem 1.9.** *The context-free membership problem for symmetric groups is* PSPACE*-complete.*

If we restrict the class of context-free grammars in Theorem 1.9 we can improve the complexity to NP: A derivation tree of a context-free grammar is called *acyclic* if no nonterminal appears twice on a path from the root to a leaf. Hence, the height of an acyclic derivation tree is bounded by the number of nonterminals of the grammar. The *Horton-Strahler number* $\mathrm{hs}(t)$ of a binary tree t (introduced by Horton and Strahler in the context of hydrology [25, 40]; see [19] for a good survey emphasizing the importance of Horton-Strahler numbers in computer science) is recursively defined as follows: If t consists of a single node then $\mathrm{hs}(t) = 0$. Otherwise, assume that t_1 and t_2 are the subtrees rooted in the two children of the node. If $\mathrm{hs}(t_1) = \mathrm{hs}(t_2)$ then $\mathrm{hs}(t) = 1 + \mathrm{hs}(t_1)$, and if $\mathrm{hs}(t_1) \neq \mathrm{hs}(t_2)$ then $\mathrm{hs}(t) = \max\{\mathrm{hs}(t_1), \mathrm{hs}(t_2)\}$. For $k \geq 1$ let $\mathrm{CFG}(k)$ be the set of all context-free grammars in Chomsky normal form (hence, derivation trees are binary trees if we ignore the leaves labelled with terminal symbols) such that every acyclic derivation tree has Horton-Strahler number at most k.

▶ **Theorem 1.10.** *For every $k \geq 1$, the context-free membership problem for symmetric groups restricted to context-free grammars from $\mathrm{CFG}(k)$ is* NP*-complete.*

Table 1 Complexity of various intersection non-emptiness problems.

	no CFG	one CFG(k)	one CFG
DFAs	PSPACE-c. [30]	EXPTIME-c. for k large enough	EXPTIME-c. [41]
group DFAs	NP-c. [11]	NP-c. for all $k \geq 1$	PSPACE-c.

Theorem 1.10 generalizes the statement for rational subsets in Theorem 1.6: Every regular grammar (when brought into Chomsky normal form) belongs to CFG(1). Linear context-free grammars belong to CFG(1) as well. Note that Theorem 1.10 is a promise problem in the sense that coNP is the best upper bound for testing whether a given context-free grammar belongs to CFG(k) that we are aware of; see [33, Theorem A.2]. The upper bounds in Theorems 1.6, 1.9, and 1.10 will actually be shown for black box groups.

Application to intersection non-emptiness problems. We can apply Theorems 1.9 and 1.10 to intersection non-emptiness problems. The *intersection non-emptiness problem for deterministic finite automata* (DFAs) is the following problem:

▶ **Problem 1.11** (intersection non-emptiness problem for DFAs)**.**
Input: DFAs $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$
Question: Is $\bigcap_{1 \leq i \leq n} L(\mathcal{A}_i)$ *non-empty?*

Kozen [30] has shown that this problem is PSPACE-complete. When restricted to group DFAs (see Section 2) the intersection non-emptiness problem was shown to be NP-complete by Blondin et al. [11]. Based on Cook's characterization of EXPTIME by polynomially space bounded AuxPDAs [13], Swernofsky and Wehar [41] showed that the intersection non-emptiness problem is EXPTIME-complete for a list of general DFAs and a single context-free grammar; see also [24, p. 275] and see [18] for a related EXPTIME-complete problem. Using Theorems 1.9 and 1.10 we can easily show the following new results:

▶ **Theorem 1.12.** *The following problem is* NP*-complete for every* $k \geq 1$*:*

Input: A list of group DFAs $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ *and a context-free grammar* $\mathcal{G} \in \mathrm{CFG}(k)$*.*
Question: Is $L(\mathcal{G}) \cap \bigcap_{1 \leq i \leq n} L(\mathcal{A}_i)$ *non-empty?*

▶ **Theorem 1.13.** *The following problem is* PSPACE*-complete:*

Input: A list of group DFAs $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ *and a context-free grammar* $\mathcal{G}$*.*
Question: Is $L(\mathcal{G}) \cap \bigcap_{1 \leq i \leq n} L(\mathcal{A}_i)$ *non-empty?*

Table 1 gives an overview on the complexity of intersection non-emptiness problems. For the intersection non-emptiness problem for arbitrary DFAs and one grammar from CFG(k) one has to notice that the EXPTIME-hardness proof from [41] works for a fixed context-free grammar. Moreover, every fixed context-free grammar belongs to CFG(k) for some $k \geq 1$.

Related work. Computationally problems for permutation groups have a long history (see e.g. the text book [38]), and have applications, e.g. for graph isomorphism testing [3, 35]. A problem that is similar to subset sum is the *minimum generator sequence problem* (MGS) [20]: The input consists of unary encoded numbers m, ℓ and a list of permutations $a, a_1, \ldots, a_n \in S_m$. The question is, whether a can be written as a product $b_1 b_2 \cdots b_k$ with $k \leq \ell$ and $b_1, \ldots, b_k \in \{a_1, \ldots, a_n\}$. The problem MGS was shown to be NP-complete in [20]. For the case, where the number ℓ is given in binary representation, the problem is PSPACE-complete [27]. This yields in fact the PSPACE-hardness in Theorem 1.9.

Intersection nonemptiness problems have been studied intensively in recent years, see e.g. [1, 14]. The papers [10, 26] prove PSPACE-hardness of the intersection nonemptiness problem for inverse automata (DFAs, where the transition monoid is an inverse monoid).

There are several algorithms for context-free (and other) grammars that exploit that an input grammar is *index-m*, meaning that *all* derivation trees have Horton-Strahler number $\leq m$, where m is part of the input in unary notation [17, 12, 16, 15, 7, 2] (see [19] for a survey). This assumption, called *finite-index*, is incomparable to our CFG(k)-assumption: In CFG(k), the k is fixed but one only considers acyclic derivation trees.

2 Preliminaries

Groups. Let G be a finite group and let G^* be the free monoid of all finite words over the alphabet G. There is a canonical morphism $\phi_G : G^* \to G$ that is the identity mapping on $G \subseteq G^*$. Throughout this paper we suppress applications of ϕ_G and identify words over the alphabet G with the corresponding group elements. For a subset $S \subseteq G$ we denote with $\langle S \rangle$ the subgroup generated by S. The following folklore lemma is a straightforward consequence of Lagrange's theorem (if A and B are subgroups of G with $A < B$, then $|B| \geq 2 \cdot |A|$).

▶ **Lemma 2.1.** *Let G be a finite group and $S \subseteq G$ a generating set for G. Then, there exists a subset $S' \subseteq S$ such that $\langle S' \rangle = G$ and $|S'| \leq \log_2 |G|$.*

Assume that $G = \langle S \rangle$. A *straight-line program* over the generating set S is a sequence of definitions $\mathcal{S} = (x_i := r_i)_{1 \leq i \leq n}$ where the x_i are variables and every right-hand side r_i is either from S or of the form $x_j x_k$ with $1 \leq j, k < i$. Every variable x_i evaluates to a group element $g_i \in G$ in the obvious way: if $r_i \in S$ then $g_i = r_i$ and if $r_i = x_j x_k$ then $g_i = g_j g_k$. Then, $\mathcal{S}$ is said to *produce* g_n. The size of $\mathcal{S}$ is n. The following result is known as the reachability theorem [6, Theorem 3.1].

▶ **Theorem 2.2** (reachability theorem). *Let G be a finite group, $S \subseteq G$ a generating set for G, and $g \in G$. Then there exists a straight-line program over S of size at most $(1 + \log_2 |G|)^2$ that produces the element g.*

For a set Q let S_Q be the *symmetric group* on Q, i.e., the set of all permutations on Q with composition of permutations as the group operation. If $Q = \{1, \ldots, m\}$ we also write S_m for S_Q. Let $a \in S_Q$ be a permutation and let $q \in Q$. We also write q^a for $a(q)$. We multiply permutations from left to right, i.e., for $a, b \in S_Q$, ab is the permutation with $q^{ab} = (q^a)^b$ for all $q \in Q$. A *permutation group* is a subgroup of some S_Q.

Quite often, the permutation groups we consider are actually direct products $\prod_{1 \leq i \leq d} S_{m_i}$ for small numbers m_i. Clearly, we have $\prod_{1 \leq i \leq d} S_{m_i} \leq S_m$ for $m = \sum_{1 \leq i \leq d} m_i$ and an embedding of $\prod_{1 \leq i \leq d} S_{m_i}$ into S_m can be computed in polynomial time.

Horton-Strahler number. Recall the definition of the Horton-Strahler number $\mathrm{hs}(t)$ of binary trees t from the introduction. We need the following simple fact; see [33, Lemma 2.3]. Here, the *height* of a tree is the maximal number of edges on a path from the root to a leaf.

▶ **Lemma 2.3.** *Let t be a binary tree of height d and let $s = \mathrm{hs}(t)$. Then, t has at most d^s many leaves and therefore at most $2 \cdot d^s$ many nodes.*

Formal languages. We assume that the reader is familiar with basic definitions from automata theory. Our definitions of deterministic finite automata (DFA), nondeterministic finite automata (NFA), and context-free grammars are the standard ones.

Consider a DFA $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$, where $q_0 \in Q$ is the initial state, $\delta : Q \times \Sigma \to Q$ is the transition mapping and $F \subseteq Q$ is the set of final states. The *transformation monoid* of $\mathcal{A}$ is the submonoid of Q^Q (the set of all mappings on Q and composition of functions as the monoid operation) generated by all mappings $q \mapsto \delta(q, a)$ for $a \in \Sigma$. A *group DFA* is a DFA whose transformation monoid is a group.

Context-free grammars will be always in Chomsky normal form. When we speak of a *derivation tree* of a context-free grammar, we always assume that the root of the tree is labelled with the start nonterminal and every leaf is labelled with a terminal symbol. When we talk about the Horton-Strahler number of such a tree, we remove all terminal-labelled leaves so that the resulting tree is a binary tree (due to the Chomsky normal form). In a *partial derivation tree*, we also allow leaves labelled with nonterminals (but we still assume that the root is labelled with the start nonterminal).

3 Black box groups

More details on black box groups can be found in [6, 38]. Roughly speaking, in the black box setting group elements are encoded by bit strings of a certain length b and there exist oracles for multiplying two group elements, computing the inverse of a group element, checking whether a given group element is the identity, and checking whether a given bit string of length b is a valid encoding of a group element (the latter operation is not allowed in [6]). As usual, each execution of an oracle operation counts one time unit, but the parameter b enters the input length additively.

Formally, a *black box* is a tuple $B = (b, c, \mathsf{valid}, \mathsf{inv}, \mathsf{prod}, \mathsf{id}, G, f)$ such that G is a finite group (the *group in the box*), $b, c \in \mathbb{N}$, and the following properties hold:

- $f : \{0,1\}^b \to G \uplus \{*\}$ satisfies $G \subseteq f(\{0,1\}^b)$. Here, $f^{-1}(g)$ is the set of *names* of $g \in G$.
- $\mathsf{valid} : \{0,1\}^b \to \{\mathsf{yes}, \mathsf{no}\}$ is such that $\forall x \in \{0,1\}^b : f(x) \in G \iff \mathsf{valid}(x) = \mathsf{yes}$.
- $\mathsf{inv} : \{0,1\}^b \to \{0,1\}^b$ is such that $\forall x \in f^{-1}(G) : f(\mathsf{inv}(x)) = f(x)^{-1}$.
- $\mathsf{prod} : \{0,1\}^b \times \{0,1\}^b \to \{0,1\}^b$ is such that $\forall x, y \in f^{-1}(G) : f(\mathsf{prod}(x, y)) = f(x)f(y)$.
- $\mathsf{id} : \{0,1\}^b \times \{0,1\}^c \to \{\mathsf{yes}, \mathsf{no}\}$ is such that for all $x \in f^{-1}(G)$: $f(x) = 1$ iff there exists $y \in \{0,1\}^c$ with $\mathsf{id}(x, y) = \mathsf{yes}$ (such a y is called a *witness* for $f(x) = 1$).

We call b the *code length* of the black box.

A *black box Turing machine* is a deterministic or nondeterministic oracle Turing machine T that is equipped with oracles for the four operations valid, inv, prod, and id. The input for T consists of two unary encoded numbers b and c and some additional problem specific input. In order to determine the behavior of T, it must be coupled with a black box $B = (b, c, \mathsf{valid}, \mathsf{inv}, \mathsf{prod}, \mathsf{id}, G, f)$ (where b and c must match the first part of the input of T). Then, given bit strings $x, y \in \{0,1\}^b$ on a special tape of T, it can compute instantaneously in a single computation step the bit string $\mathsf{prod}(x, y)$. Analogous instantaneous computations can be done for the operations valid, inv, and id. We denote with T_B the machine T coupled with the black box B. Note that the black box $B = (b, c, \mathsf{valid}, \mathsf{inv}, \mathsf{prod}, \mathsf{id}, G, f)$ is not part of the input of T, only the unary encoded numbers b and c are part of the input.

Assume that $\mathcal{P}$ is an algorithmic problem for finite groups. The input for $\mathcal{P}$ is a finite group G and some additional data X (e.g. a context-free grammar with terminal alphabet G in the next section). We do not specify exactly, how G is represented. The additional input X may contain elements of G. We will say that $\mathcal{P}$ belongs to NP for black box groups if there is a nondeterministic black box Turing machine T, whose input is of the form b, c, X with unary encoded numbers b and c, such that for every black box $B = (b, c, \mathsf{valid}, \mathsf{inv}, \mathsf{prod}, \mathsf{id}, G, f)$ the following holds: T_B accepts the input b, c, X (where X denotes the additional input for $\mathcal{P}$ and group elements in X are represented by bit strings from $f^{-1}(G)$) if and only if (G, X) belongs to $\mathcal{P}$. The running time of T_B is polynomial in $b + c + |X|$. Note that since G may have order 2^b, the order of G may be exponential in the input length. We will use the analogous definition for other complexity classes, in particular for PSPACE.

In the rest of the paper we handle black box groups in a slightly more casual way. We identify bits strings from $x \in f^{-1}(G)$ with the corresponding group elements. So, we will never talk about bit strings $x \in f^{-1}(G)$, but instead directly deal with elements of G. The reader should notice that we cannot directly verify whether a given element $g \in G$ is the identity. This is only possible in a nondeterministic way by guessing a witness $y \in \{0,1\}^c$. The same applies to the verification of an identity $g = h$, which is equivalent to $gh^{-1} = 1$. This allows to cover also quotient groups by the black box setting; see [6].

We need the following well-known fact from [6]:

▶ **Lemma 3.1.** *The subgroup membership problem for black box groups (given group elements $g, g_1, \dots, g_n$, does $g \in \langle g_1, \dots, g_n \rangle$ hold?) belongs to* NP.

This is a consequence of the reachability theorem: Let b be the code length of the black box. Hence there are at most 2^b group elements. By the reachability theorem (Theorem 2.2) it suffices to guess a straight-line program over $\{g_1, \dots, g_n\}$ of size at most $(1 + \log_2 2^b)^2 = (b+1)^2$, evaluate it using the oracle for prod (let g' be the result of the evaluation) and check whether $g'g^{-1} = 1$. The later can be done nondeterministically using the oracle for id.

4 Context-free membership in black box groups

In this section, we sketch the proofs for the following two results.

▶ **Theorem 4.1.** *The context-free membership problem for black box groups is in* PSPACE.

▶ **Theorem 4.2.** *For every $k \geq 1$, the context-free membership problem for black box groups restricted to context-free grammars from* $\mathrm{CFG}(k)$ *is in* NP.

Recall the definition of the class $\mathrm{CFG}(k)$ from the introduction. Let us first derive some corollaries. Theorem 4.2 directly implies Theorem 1.10. Applied to regular grammars (which are in $\mathrm{CFG}(1)$ after bringing them to Chomsky normal form), it yields:

▶ **Corollary 4.3.** *The rational subset membership problem for black box groups is in* NP. *In particular, the rational subset membership problem for symmetric groups is in* NP.

Also Theorem 1.9 can be easily obtained now: The upper bound follows directly from Theorem 4.1. The lower bound can be obtained from a result of Jerrum [27]. In the introduction we mentioned that Jerrum proved the PSPACE-completeness of the MGS problem for the case where the number ℓ is given in binary notation. Given permutations $a_1, \dots, a_n \in S_m$ and a binary encoded number ℓ one can easily construct a context-free grammar for $\{1, a_1, \dots, a_n\}^\ell \subseteq S_m$. Hence, the PSPACE-hard MGS problem with ℓ given in binary notation reduces to the context-free membership problem for symmetric groups. This reduction shows that Theorem 1.9 still holds if the input grammar is index-m (see the end of the introduction) with m being part of the input in unary notation.

The rest of the section is devoted to the upper bounds in Theorems 4.1 and 4.2. Detailed proofs of all lemmas can be found in the long version [33].

Outline. A straightforward algorithm for the context-free membership problem constructs an exponential-sized pushdown automaton and check the latter for emptiness. This would yield an EXPTIME upper bound. Hence, the difficulty is to achieve this in PSPACE. To this end, we exploit the fact that every subgroup of a black box group can be stored in polynomial space. Since context-free subsets of a finite group G are not necessarily subgroups, we need to find a way to encode information about derivations, as subgroups. We do this as follows. Recall that $\phi_G : G^* \to G$ is the canonical morphism from Section 2. For a context-free grammar $\mathcal{G}$ with terminal alphabet G and a nonterminal A we define

$$G_A = \{(\phi_G(u), \phi_G(v)) \mid u, v \in G^*,\ A \Rightarrow^*_{\mathcal{G}} uAv\}.$$

This is a subgroup of $G \times \hat{G}$, where $\hat{G}$ is the *dual group* of G: It has the same underlying set as G and if $g \cdot h$ is the product in G then the multiplication $\circ$ in $\hat{G}$ is defined by $g \circ h = h \cdot g$. A black box for G easily yields a black box for $G \times \hat{G}$. Thus, G_A and its subgroups have polynomial-size generating sets. When given generating sets for all G_A, one can check membership in $L(\mathcal{G})$ in PSPACE. Therefore, the idea is to compute G_A by saturating underapproximating subgroups H_A of G_A: Initially, H_A is the trivial subgroup of $G \times \hat{G}$ for each A. At each step, the groups H_A yield underapproximations of the sets $L(A)$ of all $w \in G^*$ derivable from a nonterminal A (as usual, we identify $L(A)$ with $\phi_G(L(A))$). The underapproximation of $L(A)$, in turn, is used to enlarge the subgroups H_A, yielding a better underapproximation of the G_A. Finally, we obtain the entire groups G_A.

The operations Δ and Γ. We fix a finite group G that is only accessed via a black box. We now define the operations Δ and Γ, which turn underapproximations of G_A into underapproximations of $L(A)$ (or vice versa, resp.). Let $\mathcal{G} = (N, G, P, S)$ be a context-free grammar in Chomsky normal form that is part of the input, whose terminal alphabet is the finite group G. When we speak of the input size in the following, we refer to $|\mathcal{G}| + b + c$, where b and c are the two unary encoded numbers from the black box for G and the size $|\mathcal{G}|$ is defined as the number of productions of the grammar.

Recall from the introduction that a derivation tree T is acyclic if a nonterminal does not occur twice on a path from the root to a leaf of T. The height of an acyclic derivation tree is at most $|N|$. We now define two operations Δ and Γ. The operation Δ maps a tuple $s = (H_A)_{A \in N}$ of subgroups $H_A \le G \times \hat{G}$ to a tuple $\Delta(s) = (L_A)_{A \in N}$ of subsets $L_A \subseteq G$ (not necessarily subgroups), whereas Γ maps a tuple $t = (L_A)_{A \in N}$ of subsets $L_A \subseteq G$ to a tuple $\Gamma(t) = (H_A)_{A \in N}$ of subgroups $H_A \le G \times \hat{G}$.

We start with Δ. Let $s = (H_A)_{A \in N}$ be a tuple of subgroups $H_A \le G \times \hat{G}$. The tuple $\Delta(s) = (L_A)_{A \in N}$ of subsets $L_A \subseteq G$ is obtained as follows: Let T be an acyclic derivation tree with root r labelled by $A \in N$. We assign inductively a set $L_v \subseteq G$ to every inner node v: Let B the label of v. If v has only one child it must be a leaf since our grammar is in Chomsky normal form. Let $g \in G$ be the label of this leaf. Then we set $L_v = \{h_1 g h_2 \mid (h_1, h_2) \in H_B\}$. If v has two children v_1, v_2 (where v_1 is the left child and v_2 the right child), then the sets $L_{v_1} \subseteq G$ and $L_{v_2} \subseteq G$ are already determined and we set

$$L_v = \{h_1 g_1 g_2 h_2 \mid (h_1, h_2) \in H_B, g_1 \in L_{v_1}, g_2 \in L_{v_2}\}.$$

We set $L(T) = L_r$ and finally define L_A as the union of all sets $L(T)$ where T is an acyclic derivation whose root is labelled with A.

The second operation Γ is defined as follows: Let $t = (L_A)_{A \in N}$ be a tuple of subsets $L_A \subseteq G$. Then we define the tuple $\Gamma(t) = (H_A)_{A \in N}$ with $H_A \le G \times \hat{G}$ as follows: Fix a nonterminal $A \in N$. Consider a sequence $p = (A_i \to A_{i,0} A_{i,1})_{1 \le i \le m}$ of productions

$(A_i \to A_{i,0}A_{i,1}) \in P$ and a sequence $d = (d_i)_{1 \le i \le m}$ of directions $d_i \in \{0,1\}$ such that $A_{i+1} = A_{i,d_i}$ for all $1 \le i \le m$, $A_1 = A = A_{m,d_m}$. Basically, p and d define a path from A back to A. For every $1 \le i \le m$ we define the sets

$$M_i = \begin{cases} L_{A_{i,0}} \times \{1\} \text{ if } d_i = 1 \\ \{1\} \times L_{A_{i,1}} \text{ if } d_i = 0 \end{cases}$$

We view M_i as a subset of $G \times \hat{G}$ and define $M(p,d) = M_1 \cdot \ldots \cdot M_m$, in which $\cdot$ refers to the product in $G \times \hat{G}$. If p and d are the empty sequences ($m = 0$) then $M(p,d) = \{(1,1)\}$. Finally we define H_A as the set of all $M(p,d)$, where $p = (A_i \to A_{i,0}A_{i,1})_{1 \le i \le m}$ and $d = (d_i)_{1 \le i \le m}$ are as above (including the empty sequences). This set H_A is a subgroup of $G \times \hat{G}$. To see this, it suffices to argue that H_A is a monoid. The latter follows from the fact that two pairs of sequences (p,d) and (p',d') of the above form can be composed to a single pair (pp',dd').

In the following, we will speak of NP algorithms with oracles. Here, we mean nondeterministic polynomial-time Turing machines with oracles. However, the oracle can only be queried positively: There is an instruction that succeeds if the oracle answers "yes", but cannot be executed if the oracle would answer "no". This implies that if there is an NP (resp. PSPACE algorithm) for the oracle queries, there exists an NP (resp. PSPACE) algorithm for the entire problem. Likewise, we will use the notion of oracle PSPACE algorithms.

▶ **Lemma 4.4.** *For tuples $t = (L_A)_{A \in N}$, there is an* NP *algorithm for membership to the entries of $\Gamma(t)$, with access to an oracle for the entries of t.*

The main idea for the proof is to represent the entries of $\Gamma(t)$ (which are subgroups of $G \times \hat{G}$) by NFAs over the alphabet $G \times \hat{G}$ (the NFA will not be given explicitly to us) and to guess generating sets for the subgroups in $\Gamma(t)$ using the so-called spanning tree approach. Finally, one checks membership in the entries of $\Gamma(t)$ using Lemma 3.1.

▶ **Lemma 4.5.** *Assume that the input grammar $\mathcal{G}$ is restricted to the class* CFG(k) *for some fixed k. For tuples $s = (H_A)_{A \in N}$ of subgroups $H_A \le G \times \hat{G}$, there exists an* NP *algorithm for membership to entries in $\Delta(s)$, with access to an oracle for membership to each entry of s.*

To prove this lemma, we guess an acyclic derivation tree of $\mathcal{G}$; by Lemma 2.3 its size is bounded by $2|N|^k$. Moreover, for every internal B-labelled node v (with $B \in N$) we guess a pair $(h_{v,1}, h_{v,2}) \in G \times \hat{G}$ and verify in NP that $(h_{v,1}, h_{v,2}) \in H_A$. Then we evaluate the derivation tree in the right way (following the definition of $\Delta(s)$) and check that we obtain the the input group element that we want to test for membership.

If the input grammar $\mathcal{G}$ is not restricted to a class CFG(k) for some k then we can still prove the following PSPACE-version of Lemma 4.5.

▶ **Lemma 4.6.** *For tuples $s = (H_A)_{A \in N}$ of subgroups $H_A \le G \times \hat{G}$, there is a* PSPACE *algorithm for membership to $\Delta(s)$, using an oracle for membership to the entries of s.*

For the proof we can no longer guess an acyclic derivation tree, since it may have exponential size. Instead, we guess the derivation tree in an incremental way and store on a stack of size at most $|N|$ (the maximal height of an acyclic derivation tree) the information that is needed in order to evaluate the derivation tree.

The following lemma is a straightforward consequence of Lemma 2.1:

▶ **Lemma 4.7.** *For tuples $s = (H_A)_{A \in N}$ subgroups $H_A \le G \times \hat{G}$, there exists an* NP *algorithm, with access to an oracle for membership to each entry of s, with the following properties:*

- *On every computation path the machine outputs a tuple $(S_A)_{A \in N}$ of subsets $S_A \subseteq H_A$.*
- *There is at least one computation path on which the machine outputs a tuple $(S_A)_{A \in N}$ such that every S_A generates H_A.*

▶ **Lemma 4.8.** $\Delta((G_A)_{A\in N}) = (L(A))_{A\in N}$.

Let $s_0 = (H_A)_{A\in N}$ with $H_A = \{(1,1)\}$ for all $A \in N$ be the tuple of trivial subgroups of $G \times \hat{G}$. For two tuples $s_1 = (H_{A,1})_{A\in N}$ and $s_2 = (H_{A,2})_{A\in N}$ of subgroups of $G \times \hat{G}$ we write $s_1 \leq s_2$ if $H_{A,1} \leq H_{A,2}$ for every $A \in N$. Since Γ and Δ are monotone w.r.t. component-wise inclusion, we have $(\Gamma\Delta)^i(s_0) \leq (\Gamma\Delta)^{i+1}(s_0)$ for all i. We can thus define $\lim_{i\to\infty}(\Gamma\Delta)^i(s_0)$.

▶ **Lemma 4.9.** *$(G_A)_{A\in N} = \lim\limits_{i\to\infty}(\Gamma\Delta)^i(s_0) = (\Gamma\Delta)^j(s_0)$ where $j = 2 \cdot |N| \cdot \lfloor \log_2 |G| \rfloor$.*

Let us briefly sketch the proof of this lemma. From the definition of Γ and Δ we easily obtain $(\Gamma\Delta)^i(s_0) \leq (G_A)_{A\in N}$ by induction on $i \geq 0$. To show $(G_A)_{A\in N} \leq \lim_{i\to\infty}(\Gamma\Delta)^i(s_0)$, we define $(H_A)_{A\in N} = \lim_{i\to\infty}(\Gamma\Delta)^i(s_0)$ and take a pair $(g,h) \in G_A$. Hence, there exists a derivation $A \Rightarrow_G^* uAv$ such that $g = \phi_G(u)$ and $h = \phi_G(v)$. One can prove $(g,h) \in H_A$ by an induction on the length of this derivation. This shows the identity $(G_A)_{A\in N} = \lim\limits_{i\to\infty}(\Gamma\Delta)^i(s_0)$.

For the second identity in Lemma 4.8 note that since all G_A are finite groups there is a smallest number $j \geq 0$ such that $(\Gamma\Delta)^j(s_0) = (\Gamma\Delta)^{j+1}(s_0)$. We then have $(\Gamma\Delta)^j(s_0) = \lim_{i\to\infty}(\Gamma\Delta)^i(s_0)$. It remains to show that $j \leq 2 \cdot |N| \cdot \log_2 |G|$. In each component of the $|N|$-tuples $(\Gamma\Delta)^i(s_0)$ $(0 \leq i \leq j)$ we have a chain of subgroups of $G \times \hat{G}$. By Lagrange's theorem, any chain $\{(1,1)\} = H_0 < H_1 < \cdots < H_{k-1} < H_k \leq G \times \hat{G}$ satisfies $k \leq 2 \cdot \log_2 |G|$. This shows that $j \leq 2 \cdot |N| \cdot \log_2 |G|$.

Proofs of Theorem 4.1 and 4.2. We start with Theorem 4.2. By Lemmas 4.5 and 4.8 it suffices to decide membership to G_A in NP. For this, we construct a nondeterministic polynomial time machine that computes on every computation path a subset $S_A \subseteq G_A$ for every $A \in N$ such that on at least one computation path it computes a generating set for groups G_A for all $A \in N$. Then, by Lemma 3.1, membership for each $\langle S_A \rangle$ is in NP.

We compute S_A by initializing $S_A = \{(1,1)\}$ for every $A \in N$ and then performing $2 \cdot |N| \cdot \log_2 |G|$ iterations of the following procedure: Suppose we have already produced the subsets $(S_A)_{A\in N}$. Membership in $\langle S_A \rangle$ can be decided in NP by Lemma 3.1. Hence, by Lemmas 4.4 and 4.5 one can decide membership in every entry of the tuple $\Gamma(\Delta((\langle S_A \rangle)_{A\in N}))$ in NP. Finally, by Lemma 4.7 we can produce nondeterministically in polynomial time a subset $S'_A \subseteq G \times \hat{G}$ for every $A \in N$ such that for every computation path we have $(\langle S'_A \rangle)_{A\in N} \leq \Gamma(\Delta((\langle S_A \rangle)_{A\in N}))$ and for at least one computation path the machine produces subsets S'_A with $(\langle S'_A \rangle)_{A\in N} = \Gamma(\Delta((\langle S_A \rangle)_{A\in N}))$. With the sets S'_A we go into the next iteration. By Lemma 4.9 there will be at least one computation path on which after $2 \cdot |N| \cdot \log_2 |G|$ iterations we get a generating set for the entire groups G_A. This concludes Theorem 4.2. The proof of Theorem 4.1 only differs by using Lemma 4.6 instead of Lemma 4.5. ◀

5 Subset sum and knapsack in symmetric groups

In this section, we want to contrast the general upper bounds from the previous sections with lower bounds for symmetric groups and restricted versions of the rational subset membership problem. We start with the subset sum problem. The following result refers to the abelian group $\mathbb{Z}_3^m$, for which we use the additive notation.

▶ **Theorem 5.1.** *The following problem is* NP*-hard:*
Input: unary encoded number m and a list of group elements $g, g_1, \ldots, g_n \in \mathbb{Z}_3^m$.
Question: Are there $i_1, \ldots, i_n \in \{0,1\}$ such that $g = \sum_{1\leq k\leq n} i_k \cdot g_k$?

The proof uses a straightforward reduction from the *exact 3-hitting set problem* (X3HS):

▶ **Problem 5.2** (X3HS).
Input: a finite set A and a set $\mathcal{B} \subseteq 2^A$ of subsets of A, all of size 3.
Question: Is there a subset $A' \subseteq A$ such that $|A' \cap C| = 1$ for all $C \in \mathcal{B}$?

X3HS is the same problem as positive 1-in-3-SAT, which is NP-complete [23, Problem LO4]. The reduction of X3HS to the problem from Theorem 5.1 can be found in [33, Theorem 5.1]. Since $\mathbb{Z}_3^m \leq S_{3m}$ we obtain the following corollary:

▶ **Corollary 5.3.** *The abelian subset sum problem for symmetric groups is* NP*-hard.*

Let us remark that the subset sum problem for $\mathbb{Z}_2^m$ (with m part of the input) is equivalent to the subgroup membership problem for $\mathbb{Z}_2^m$ (since every element of $\mathbb{Z}_2^m$ has order two) and therefore can be solved in polynomial time.

We now come to the knapsack problem in permutation groups. NP-hardness of the general version of knapsack can be easily deduced from a result of Luks: Recall from the introduction that Luks [36] proved NP-completeness of 3-membership for the special case of membership in a product GHG where G and H are abelian subgroups of S_m. Let $g_1, g_2, \ldots, g_k$ be the given generators of G and let $h_1, h_2, \ldots, h_l$ be the given generators of H. Then $s \in GHG$ is equivalent to the solvability of the following knapsack equation:

$$s = g_1^{x_1} g_2^{x_2} \cdots g_k^{x_k} h_1^{y_1} h_2^{y_2} \cdots h_l^{y_l} g_1^{z_1} g_2^{z_2} \cdots g_k^{z_k}.$$

We next want to prove that already 3-knapsack is NP-hard. In other words: the k-membership problem is NP-hard for every $k \geq 3$ even if the groups are cyclic.

Let $p > 0$ be an integer. For the rest of the section we write $[p]$ for the cycle $(1, 2, \ldots, p)$ mapping p to 1 and i to $i + 1$ for $1 \leq i \leq p - 1$. The proofs for the following two lemmas are available in the full version [33].

▶ **Lemma 5.4.** *Let $p, q \in \mathbb{N}$ such that q is odd and $p > q > 0$ holds. Then the products $[p][q]$ and $[q][p]$ are cycles of length p.*

▶ **Lemma 5.5.** *Let $p, q \in \mathbb{N}$ be primes such that $2 < q < p$ holds. Then*

$$[p]^{-x_2}[q]^{x_1}([p][q])^{x_2} = [q] = [q]^{x_1}[p]^{-x_2}([p][q])^{x_2} \tag{1}$$

if and only if ($x_1 \equiv 1 \bmod q$ and $x_2 \equiv 0 \bmod p$) or ($x_1 \equiv 0 \bmod q$ and $x_2 \equiv 1 \bmod p$).

We now come to our main result for the knapsack problem:

▶ **Theorem 5.6.** *The problem 3-knapsack for symmetric groups is* NP*-hard.*

Proof. To prove the theorem we give a log-space reduction from the NP-complete problem X3HS (Problem 5.2) to 3-knapsack. Let A be a finite set and $\mathcal{B} \subseteq 2^A$ such that every $C \in \mathcal{B}$ has size 3. W.l.o.g.let $A = \{1, \ldots, m\}$ and let $\mathcal{B} = \{C_1, C_2, \ldots, C_d\}$ where $C_i = \{\alpha(i,1), \alpha(i,2), \alpha(i,3)\}$ for a mapping $\alpha : \{1, \ldots, d\} \times \{1, 2, 3\} \to \{1, \ldots, m\}$.

Let $p_1, \ldots, p_m, r_1, \ldots, r_m, q_1, \ldots, q_d$ be the first $2m + d$ odd primes such that $p_j > r_j > 2$ and $p_j > q_i > 2$ for $1 \leq i \leq d$ and $1 \leq j \leq m$ hold. Moreover let $P = \max_{1 \leq j \leq m} p_j$. Intuitively, the primes p_j and r_j ($1 \leq j \leq m$) belong to $j \in A$ and the prime q_i ($1 \leq i \leq d$) belongs to the set C_i. We will work in the group

$$G = \prod_{j=1}^{m} \mathcal{V}_j \times \prod_{i=1}^{d} \mathcal{C}_i,$$

where $\mathcal{V}_j \leq S_{4p_j+r_j}$ and $\mathcal{C}_i \leq S_{q_i+3P}$. More precisely we have

$$\mathcal{V}_j = S_{p_j} \times S_{p_j} \times \mathbb{Z}_{p_j} \times \mathbb{Z}_{p_j} \times \mathbb{Z}_{r_j} \text{ and } \mathcal{C}_i = \mathbb{Z}_{q_i} \times S_P \times S_P \times S_P.$$

In the following, we denote the identity element of a symmetric group S_m with id in order to not confuse it with the generator of a cyclic group $\mathbb{Z}_m$.

We now define four group elements $g, g_1, g_2, g_3 \in G$. We write $g = (v_1, \ldots, v_m, c_1, \ldots c_d)$ and $g_k = (v_{k,1}, \ldots, v_{k,m}, c_{k,1}, \ldots, c_{k,d})$ with $v_j, v_{k,j} \in \mathcal{V}_j$ and $c_i, c_{k,i} \in \mathcal{C}_i$. These elements are defined as follows:

$$\begin{array}{rclllll}
v_j & = & ([r_j], & [r_j], & 0, & 0, & 0) \\
v_{1,j} & = & ([r_j], & [p_j]^{-1}, & 1, & 1, & 1) \\
v_{2,j} & = & ([p_j]^{-1}, & [r_j], & -1, & 0, & -1) \\
v_{3,j} & = & ([p_j][r_j], & [p_j][r_j], & 0, & -1, & 0)
\end{array}
\qquad
\begin{array}{rcllll}
c_i & = & (1, & \mathsf{id}, & \mathsf{id}, & \mathsf{id}) \\
c_{1,i} & = & (1, & [q_i]^{-1}, & [p_{\alpha(i,2)}]^{-1}, & [q_i][p_{\alpha(i,3)}]) \\
c_{2,i} & = & (1, & [q_i][p_{\alpha(i,1)}], & [q_i]^{-1}, & [p_{\alpha(i,3)}]^{-1}) \\
c_{3,i} & = & (1, & [p_{\alpha(i,1)}]^{-1}, & [q_i][p_{\alpha(i,2)}], & [q_i]^{-1})
\end{array}$$

We claim that there is a subset $A' \subseteq A$ such that $|A' \cap C_i| = 1$ for every $1 \leq i \leq d$ if and only if there are $z_1, z_2, z_3 \in \mathbb{Z}$ with $g = g_1^{z_1} g_2^{z_2} g_3^{z_3}$ in the group G. Due to the direct product decomposition of G and the above definition of g, g_1, g_2, g_3, the statement $g = g_1^{z_1} g_2^{z_2} g_3^{z_3}$ is equivalent to the conjunctions of the following statements (read the above definitions of the $v_j, v_{k,j}, c_i, c_{k,i}$ columnwise) for all $1 \leq j \leq m$ and $1 \leq i \leq d$:

(a) $[r_j] = [r_j]^{z_1}[p_j]^{-z_2}([p_j][r_j])^{z_3}$
(b) $[r_j] = [p_j]^{-z_1}[r_j]^{z_2}([p_j][r_j])^{z_3}$
(c) $z_1 \equiv z_2 \bmod p_j$
(d) $z_1 \equiv z_3 \bmod p_j$
(e) $z_1 \equiv z_2 \bmod r_j$
(f) $1 \equiv z_1 + z_2 + z_3 \bmod q_i$
(g) $\mathsf{id} = [q_i]^{-z_1}([q_i][p_{\alpha(i,1)}])^{z_2}[p_{\alpha(i,1)}]^{-z_3}$
(h) $\mathsf{id} = [p_{\alpha(i,2)}]^{-z_1}[q_i]^{-z_2}([q_i][p_{\alpha(i,2)}])^{z_3}$
(i) $\mathsf{id} = ([q_i][p_{\alpha(i,3)}])^{z_1}[p_{\alpha(i,3)}]^{-z_2}[q_i]^{-z_3}$

Recall that by Lemma 5.4, $[p_j][r_j]$ and $[q_i][p_j]$ are cycles of length p_j. Due to the congruences in (c), (d), and (e), the conjunction of (a)–(i) is equivalent to the conjunction of (j)–(p):

(j) $z_1 \equiv z_2 \equiv z_3 \bmod p_j$
(k) $z_1 \equiv z_2 \bmod r_j$
(l) $[p_j]^{-z_1}[r_j]^{z_2}([p_j][r_j])^{z_1} = [r_j] = [r_j]^{z_2}[p_j]^{-z_1}([p_j][r_j])^{z_1}$
(m) $1 \equiv z_1 + z_2 + z_3 \bmod q_i$
(n) $\mathsf{id} = [q_i]^{-z_1}([q_i][p_{\alpha(i,1)}])^{z_1}[p_{\alpha(i,1)}]^{-z_1}$
(o) $\mathsf{id} = [p_{\alpha(i,2)}]^{-z_1}[q_i]^{-z_2}([q_i][p_{\alpha(i,2)}])^{z_1}$
(p) $\mathsf{id} = ([q_i][p_{\alpha(i,3)}])^{z_1}[p_{\alpha(i,3)}]^{-z_1}[q_i]^{-z_3}$

By Lemma 5.5, the conjunction of (j)–(p) is equivalent to the conjunction of (q)–(u):

(q) ($z_1 \equiv z_2 \equiv z_3 \equiv 0 \bmod p_j$ and $z_1 \equiv z_2 \equiv 1 \bmod r_j$) or
($z_1 \equiv z_2 \equiv z_3 \equiv 1 \bmod p_j$ and $z_1 \equiv z_2 \equiv 0 \bmod r_j$)
(r) $1 \equiv z_1 + z_2 + z_3 \bmod q_i$
(s) $\mathsf{id} = [q_i]^{-z_1}([q_i][p_{\alpha(i,1)}])^{z_1}[p_{\alpha(i,1)}]^{-z_1}$
(t) $\mathsf{id} = [p_{\alpha(i,2)}]^{-z_1}[q_i]^{-z_2}([q_i][p_{\alpha(i,2)}])^{z_1}$
(u) $\mathsf{id} = ([q_i][p_{\alpha(i,3)}])^{z_1}[p_{\alpha(i,3)}]^{-z_1}[q_i]^{-z_3}$

Let us now assume that $A' \subseteq A$ is such that $|A' \cap C_i| = 1$ for every $1 \leq i \leq d$. Let $\sigma : \{1, \ldots, m\} \to \{0, 1\}$ such that $\sigma(j) = 1$ iff $j \in S'$. Thus, $\alpha(i,1) + \alpha(i,2) + \alpha(i,3) = 1$ for all $1 \leq i \leq d$. By the Chinese remainder theorem, we can set $z_1, z_2, z_3 \in \mathbb{Z}$ such that

- $z_1 \equiv z_2 \equiv z_3 \equiv \sigma(j) \bmod p_j$ and $z_1 \equiv z_2 \equiv 1 - \sigma(j) \bmod r_j$ for $1 \leq j \leq m$,
- $z_k \equiv \sigma(\alpha(i,k)) \bmod q_i$ for $1 \leq i \leq d$ and $1 \leq k \leq 3$.

Then (q) and (r) hold. For (s), one has to consider two cases: if $\sigma(\alpha(i,1)) = 0$, then $z_1 \equiv 0 \bmod q_i$ and $z_1 \equiv 0 \bmod p_{\alpha(i,1)}$. Hence, the right-hand side of (s) evaluates to

$$[q_i]^{-0}([q_i][p_{\alpha(i,1)}])^0[p_{\alpha(i,1)}]^{-0} = \mathsf{id}.$$

On the other hand, if $\sigma(\alpha(i,1)) = 1$, then $z_1 \equiv 1 \bmod q_i$ and $z_1 \equiv 1 \bmod p_{\alpha(i,1)}$ and the right-hand side of (s) evaluates again to

$$[q_i]^{-1}[q_i][p_{\alpha(i,1)}][p_{\alpha(i,1)}]^{-1} = \mathsf{id}.$$

In the same way, one can show that also (t) and (u) hold.

For the other direction, assume that $z_1, z_2, z_3 \in \mathbb{Z}$ are such that (q)–(u) hold. We define $A' \subseteq \{1, \dots, m\}$ such that for every $1 \le j \le m$:

- $j \notin S'$ if $z_1 \equiv z_2 \equiv z_3 \equiv 0 \bmod p_j$ and $z_1 \equiv z_2 \equiv 1 \bmod r_j$, and
- $j \in S'$ if $z_1 \equiv z_2 \equiv z_3 \equiv 1 \bmod p_j$ and $z_1 \equiv z_2 \equiv 0 \bmod r_j$.

Consider a set $C_i = \{\alpha(i,1), \alpha(i,2), \alpha(i,3)\}$. From the equations (s), (t), and (u) we get for every $1 \le i \le d$ and $1 \le k \le 3$:

- if $z_1 \equiv 0 \bmod p_{\alpha(i,k)}$ then $z_k \equiv 0 \bmod q_i$
- if $z_1 \equiv 1 \bmod p_{\alpha(i,k)}$ then $z_k \equiv 1 \bmod q_i$

Together with $1 \equiv z_1 + z_2 + z_3 \bmod q_i$ and $q_i \ge 3$, this implies that there must be exactly one $k \in \{1,2,3\}$ such that $z_1 \equiv 1 \bmod p_{\alpha(i,k)}$. Hence, for every $1 \le i \le d$ there is exactly one $k \in \{1,2,3\}$ such that $\alpha(i,k) \in A'$. ◀

Theorem 1.6 is an immediate consequence of Corollaries 4.3 and 5.3 and Theorem 5.6.

Theorem 5.6 leads to the question what the exact complexity of the 2-knapsack problem for symmetric groups is. Recall that the complexity of Luks' 2-membership problem is a famous open problem in the algorithmic theory of permutation groups. The restriction of the 2-membership problem to cyclic groups is easier. The proof of the following theorem uses a reduction to the membership problem for commutative subgroups of matrix groups [8] and then applies [4, Theorem 1.4]; see [33, Theorem 5.8].

▶ **Theorem 5.7.** *The* 2*-knapsack problem for symmetric groups belongs to* P.

6 Application to intersection problems

It remains to show Theorems 1.12 and 1.13. We obtain the upper bound in Theorem 1.12 from Theorem 1.10: Let $\mathcal{G}$ be a grammar from $\mathsf{CFG}(k)$ and let $\mathcal{A}_i = (Q_i, \Sigma, q_{i,0}, \delta_i, F_i)$ be be a group DFA for $1 \le i \le n$. W.l.o.g. assume that the Q_i are pairwise disjoint and let $Q = \bigcup_{1 \le i \le n} Q_i$. To every $a \in \Sigma$ we can associate a permutation $\pi_a \in S_Q$ by setting $\pi_a(q) = \delta_i(q,a)$ if $q \in Q_i$. Let $\mathcal{G}' \in \mathsf{CFG}(k)$ be the context-free grammar over the terminal alphabet S_Q obtained by replacing in $\mathcal{G}$ every occurence of $a \in \Sigma$ by π_a. Then, we have $L(\mathcal{G}) \cap \bigcap_{1 \le i \le n} L(\mathcal{A}_i) \neq \emptyset$ if and only if there exists a permutation $\pi \in L(\mathcal{G}')$ such that $\pi(q_{i,0}) \in F_i$ for every $1 \le i \le n$. We can nondeterministically guess such a permutation and check $\pi \in L(\mathcal{G}')$ in NP using Theorem 1.10. This proves the upper bound from Theorem 1.12.

The upper bound from Theorem 1.13 can be obtained in the same way from Theorem 1.9. For the lower bounds in Theorems 1.12 and 1.13, a simple reduction from the lower bounds in Theorems 1.10 and 1.9 can be employed; see [33, Section 6] for details.

Streaming Word Problems

Markus Lohrey

Lukas Lück
Universität Siegen, Germany

Abstract

We study deterministic and randomized streaming algorithms for word problems of finitely generated groups. For finitely generated linear groups, metabelian groups and free solvable groups we show the existence of randomized streaming algorithms with logarithmic space complexity for their word problems. We also show that the class of finitely generated groups with a logspace randomized streaming algorithm for the word problem is closed under several group theoretical constructions: finite extensions, direct products, free products and wreath products by free abelian groups. We contrast these results with several lower bound. An example of a finitely presented group, where the word problem has only a linear space randomized streaming algorithm, is Thompson's group F.

1 Introduction

The word problem for a finitely generated group G is the following computational problem: Fix a finite set of generators Σ for G (which means that every element of G can be written as a finite product of elements from Σ. The input for the word problem is a finite word $a_1 a_2 \cdots a_n$ over the alphabet Σ and the question is whether this word evaluates to the group identity of G. The word problem was introduced by Dehn in 1911 [10]. It is arguably the most important computational problem in group theory and has been studied by group theorists as well as computer scientists; see [29] for a good survey. In recent years, complexity theoretic investigations of word problems moved into the focus. For many important classes of groups it turned out that the word problem belongs to low-level complexity classes. The first result in this direction was proved by Lipton and Zalcstein [23] (if the field F has characteristic zero) and Simon [36] (if the field F has prime characteristic): if G is a finitely generated linear group over an arbitrary field F (i.e., a finitely generated group of invertible matrices over F), then the word problem for G can be solved in deterministic logarithmic space. Related results can be found in [20, 41].

The word problem of a group G with a finite generating set Σ can be identified with a formal language $\mathsf{WP}(G, \Sigma)$ consisting of all words over the alphabet Σ that evaluate to the group identity of G. Language theoretic aspects of the word problem have been studied intensively in the past. For instance, Anissimov and Seifert [2] showed that $\mathsf{WP}(G, \Sigma)$ is regular if and only if G is finite, and Muller and Schupp showed that $\mathsf{WP}(G, \Sigma)$ is context-free [31] if and only if G is virtually free,[1] see [18] for an overview.

[1] If C is a property or class of groups, then a group is virtually C if it is a finite extension of a C-group.

In this paper we initiate the study of streaming algorithms for word problems. These are algorithms that do not have random access on the whole input. Instead, the k-th input symbol is only available at time k [1]. Typically, streaming algorithms are randomized and have a bounded error probability. Usually, one is interested in the space used by a streaming symbol, but also update times have been investigated. Clearly, every regular language has a streaming algorithm with constant space. Randomized streaming algorithms for context-free languages have been studied in [4, 7, 12, 26].

Let us now explain the main results of this paper. For a finitely generated group G with generating set Σ, the *deterministic (resp., randomized) streaming space complexity* of $\mathsf{WP}(G, \Sigma)$ is the space complexity of the best deterministic (resp., randomized) streaming algorithm for $\mathsf{WP}(G, \Sigma)$. The concrete choice of the generating set has only a minor influence on the deterministic (resp., randomized) streaming space complexity of $\mathsf{WP}(G, \Sigma)$; see Lemma 2 for a precise statement. In statements where the influence of the generating set on the streaming space complexity is blurred by the Landau notation, we speak of the deterministic/randomized streaming space complexity of the word problem of G or simply the deterministic/randomized streaming space complexity of G.

The deterministic streaming space complexity of $\mathsf{WP}(G, \Sigma)$ is directly linked to the growth function $\gamma_{G,\Sigma}(n)$ of the group G. The latter is the number of different group elements of G that can be represented by words over the generating set Σ of length at most n (also here the generating set Σ only has a minor influence). The deterministic streaming space complexity of the word problem for G turns out to be $\log_2 \gamma_{G,\Sigma}(n/2)$ up to a small additive constant (Theorem 3). The growth of finitely generated groups is a well investigated topic in geometric group theory. A famous theorem of Gromov says that a finitely generated group has polynomial growth if and only if it is virtually nilpotent; see [9, 28] for a discussion. Theorem 3 reduces all questions about the deterministic streaming space complexity of word problems to questions about growth functions. Due to this, we mainly study randomized streaming algorithms for word problems in this paper.

In the randomized setting, the growth of G still yields a lower bound: The randomized streaming space complexity of the word problem of G is lower bounded by $\Omega(\log\log \gamma_{G,\Sigma}(n/2))$ (Theorem 4). A large class of groups, where this lower bound can be exactly matched by an upper bound are finitely generated linear groups. Recall that Lipton and Zalcstein [23] and Simon [36] showed that the word problem of a finitely generated linear group can be solved in logarithmic space. Their algorithm can be turned into a randomized streaming algorithm with logarithmic space complexity. In order to plug these streaming algorithms into closure results for randomized streaming space complexity (that are discussed below) we need an additional property that we call ϵ-injectivity. Roughly speaking, a randomized streaming algorithm for a finitely generated group G with generating set Σ is *ϵ-injective* if for all words $u, v \in \Sigma^*$ of length at most n we have that: (i) if u and v evaluate to the same element of G then with probability at least $1 - \epsilon$, u and v lead to the same memory state of the streaming algorithm, and (ii) if u and v evaluate to different elements of G then with probability at least $1 - \epsilon$, u and v lead to different memory states of the streaming algorithm; see Section 5. We then show that for every finitely generated linear group G there is a randomized ϵ-injective streaming algorithm with space complexity $\mathcal{O}(\log n)$ (Theorem 8). If G is moreover virtually nilpotent, then the space complexity can be further reduced to $\mathcal{O}(\log\log n)$. In fact, using a known gap theorem for the growth of linear groups [30, 42], it turns out that the randomized streaming space complexity of the word problem for a finitely generated linear group G is either $\Theta(\log\log n)$ (if G is virtually nilpotent) or $\Theta(\log n)$ (if G is not virtually nilpotent), see Theorem 11.

For non-linear groups the situation turns out to be more difficult. We show that the randomized streaming space complexity of word problems is preserved by certain group constructions including finite extensions (Theorem 10), direct products (Lemma 12), free products (Theorem 20) and wreath products by free abelian groups (Theorem 17). For the latter two constructions we also get an additional additive term $\Theta(\log n)$ in the space bounds. For a wreath product $A \wr G$ with A free abelian (resp., a free product $G * H$) it is also important that we start with an ϵ-injective randomized streaming algorithm for G (and H). Using these transfer results we obtain also non-linear groups with a logarithmic randomized streaming space complexity, e.g., metabelian groups (Corollary 13) and free solvable groups (Corollary 18).

In the last section of the paper, we prove lower bounds for the randomized streaming space complexity of word problems. For wreath products of the form $G \wr S$ such that G is non-abelian and S is infinite, we can show that the randomized streaming space complexity is $\Theta(n)$ by a reduction from the randomized communication complexity of disjointness (Theorem 21). A concrete finitely presented group with randomized streaming space complexity $\Theta(n)$ is Thompson's group F (Corollary 22). Thompson's groups F (introduced by Richard Thompson in 1965) belongs due to its unusual properties to the most intensively studied infinite groups; see e.g. [8]. From a computational perspective it is interesting to note that F is co-context-free (i.e., the set of all non-trivial words over any set of generators is a context-free language) [22]. This implies that the word problem for Thompson's group is in LogCFL. To the best of our knowledge no better upper complexity bound is known. Finally, we consider the famous Grigorchuk group G [14], which was the first example of a group with intermediate word growth as well as the first example of a group that is amenable but not elementary amenable. We show that the deterministic streaming space complexity of G is $\mathcal{O}(n^{0.768})$, whereas the randomized streaming space complexity of G is $\Omega(n^{0.5})$ (Theorem 23).

Related results. In this paper, we are only interested in streaming algorithms for a fixed infinite group. Implicitly, streaming algorithms for finite groups are studied in [13]. Obviously, every finite group has a deterministic streaming space complexity $\mathcal{O}(\log |G|)$.[2] In [13], it is shown that for the group $G = \mathsf{SL}(2, \mathbb{F}_p)$ this upper bound is matched by a lower bound, which even holds for the randomized streaming space complexity. More precisely, Gowers and Viola study the communication cost of the following problem: Alice receives a sequence of elements $a_1, \ldots, a_n \in G$, Bob receives a sequence of elements $b_1, \ldots, b_n \in G$ and they are promised that the interleaved product $a_1 b_1 \cdots a_n b_n$ is either 1 or some fixed element $g \in G \setminus \{1\}$ and their job is to determine which of these two cases holds. For $G = \mathsf{SL}(2, \mathbb{F}_p)$ it is shown that the randomized communication complexity of this problem is $\Theta(\log |G| \cdot n)$ (the upper bound is trivial). From this it follows easily that the randomized streaming space complexity of $\mathsf{SL}(2, \mathbb{F}_p)$ is $\Omega(\log |G|)$.

2 Streaming algorithms

For integers $a < b$ let $[a, b] = \{a, a+1, \ldots, b\}$. Fix a finite alphabet Σ. For a word $w \in \Sigma^*$ let $|w|$ be its length and let $\Sigma^{\leq n} = \{w \in \Sigma^* \colon |w| \leq n\}$ be the set of words of length at most n.

In the following we introduce probabilistic finite automata [33, 34] as a model for randomized streaming algorithms. A *probabilistic finite automaton* (PFA) $\mathcal{A} = (Q, \Sigma, \iota, \rho, F)$ consists of a finite set of states Q, an alphabet Σ, an *initial state distribution* $\iota \colon Q \to \{r \in$

[2] In our setting, $|G|$ would be a constant, but for the moment let us make the dependence on the finite group G explicit.

$\mathbb{R}\colon 0 \leq r \leq 1\}$, a *transition probability function* $\rho\colon Q \times \Sigma \times Q \to \{r \in \mathbb{R}\colon 0 \leq r \leq 1\}$ and a set of final states $F \subseteq Q$ such that $\sum_{q \in Q} \iota(q) = 1$ and $\sum_{q \in Q} \rho(p, a, q) = 1$ for all $p \in Q$, $a \in \Sigma$. If ι and ρ map into $\{0, 1\}$, then $\mathcal{A}$ is a *deterministic finite automaton* (DFA). If only ρ is required to map into $\{0, 1\}$, then $\mathcal{A}$ is called *semi-probabilitistic.* A *run* on a word $a_1 \cdots a_m \in \Sigma^*$ in $\mathcal{A}$ is a sequence $\pi = (q_0, a_1, q_1, a_2, \ldots, a_m, q_m)$ where $q_0, \ldots, q_m \in Q$. Given such a run π in $\mathcal{A}$ we define $\rho_\iota(\pi) = \iota(q_0) \cdot \prod_{i=1}^{n} \rho(q_{i-1}, a_i, q_i)$. For each $w \in \Sigma^*$ the function ρ_ι is a probability distribution on the set $\mathrm{Runs}(w)$ of all runs of $\mathcal{A}$ on w. A run $\pi = (q_0, a_1, \ldots, a_m, q_m)$ is *correct* with respect to a language $L \subseteq \Sigma^*$ if $q_m \in F \Leftrightarrow a_1 \cdots a_m \in L$ holds. The *error probability* of $\mathcal{A}$ on w for L is

$$\epsilon(\mathcal{A}, w, L) = \sum \{\rho_\iota(\pi) : \pi \in \mathrm{Runs}(w) \text{ is not correct w.r.t. } L\}.$$

If $\mathcal{A}$ is semi-probabilitistic then we can identify ρ with a mapping $\rho : Q \times \Sigma \to Q$, where $\rho(p, a)$ is the unique state q with $\rho(p, a, q) = 1$. This mapping ρ is extended to a mapping $\rho : Q \times \Sigma^* \to Q$ in the usual way: $\rho(p, \varepsilon) = p$ and $\rho(p, aw) = \rho(\rho(p, a), w)$. We then obtain

$$\epsilon(\mathcal{A}, w, L) = 1 - \sum \{\iota(q) : q \in Q, \delta(q, w) \in F \Leftrightarrow w \in L\}.$$

A (non-uniform) *randomized streaming algorithm* is a sequence $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ of PFA $\mathcal{A}_n$ over the same alphabet Σ. If every $\mathcal{A}_n$ is deterministic (resp., semi-probabilitistic), we speak of a *deterministic (resp., semi-randomized)* streaming algorithm.

Let $0 \leq \epsilon \leq 1$ be an error probability. A randomized streaming algorithm $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ is ϵ-*correct* for a language $L \subseteq \Sigma^*$ if for every $n \geq 0$ and every word $w \in \Sigma^{\leq n}$ we have $\epsilon(\mathcal{A}_n, w, L) \leq \epsilon$. We say that $\mathcal{R}$ is a *randomized streaming algorithm for* L if it is 1/3-correct for L. The choice of 1/3 for the error probability is not important. Using a standard application of the Chernoff bound one can reduce the error probability from 1/3 to every constant. If $\mathcal{R}$ is deterministic and 0-correct for L then we say that $\mathcal{R}$ is a *deterministic streaming algorithm for* L. The *space complexity* of the randomized streaming algorithm $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ is the function $s(\mathcal{R}, n) = \lceil \log_2 |Q_n| \rceil$, where Q_n is the state set of $\mathcal{A}_n$. The motivation for this definition is that states of Q_n can be encoded by bit strings of length at most $\lceil \log_2 |Q_n| \rceil$. The *deterministic/randomized streaming space complexity of the language* L is the smallest possible function $s(\mathcal{R}, n)$, where $\mathcal{R}$ is a deterministic/randomized streaming algorithm for L. By a result of Rabin [34, Theorem 3], the deterministic streaming space complexity of a language L is bounded by $2^{\mathcal{O}(S(n))}$, where $S(n)$ is the randomized streaming space complexity of L.

The deterministic streaming space complexity of a language L is directly linked to the *automaticity of* L. The automaticity of $L \subseteq \Sigma^*$ is the the function $A_L(n)$ that maps n to the number of states of a smallest DFA $\mathcal{A}_n$ such that for all words $w \in \Sigma^{\leq n}$ we have: $w \in L$ if and only if w is accepted by $\mathcal{A}_n$. Hence, the deterministic streaming space complexity of L is exactly $\lceil \log_2 A_L(n) \rceil$. The automaticity of languages was studied in [35]. Interesting in our context is the following result of Karp [19]: if L is a non-regular language then $A_L(n) \geq (n+3)/2$ for infinitely many n. Hence, for every non-regular language the deterministic streaming space complexity of L is at least $\log_2(n) - c$ for a constant c and infinitely many n. Another related measure is the online space complexity from [11], which is defined by the growth function of an infinite automaton for a language L.

Note that our concept of streaming algorithms is non-uniform in the sense that for every input length n we have a separate streaming algorithm $\mathcal{A}_n$. This makes lower bounds stronger. On the other hand, the streaming algorithms that we construct for concrete groups will be uniform in the sense that the streaming algorithms $\mathcal{A}_n$ follow a common pattern. The following result uses non-uniformity in a crucial way; its proof (see [25, Theorem 3.1]) is similar to Newman's theorem on public versus private coins in communication complexity, see e.g. [21].

▶ **Theorem 1.** *Let $\mathcal{R}$ be a randomized streaming algorithm such that $s(\mathcal{R}, n) \geq \Omega(\log n)$ and $\mathcal{R}$ is ϵ-correct for a language L. Then there exists a semi-randomized streaming algorithm $\mathcal{S}$ such that $s(\mathcal{S}, n) = \Theta(s(\mathcal{R}, n))$ and $\mathcal{S}$ is 2ϵ-correct for the language L.*

3 Groups and word problems

For a group G and a subset $\Sigma \subseteq G$, we denote with $\langle \Sigma \rangle$ the subgroup of G generated by Σ. It is the set of all products of elements from $\Sigma \cup \Sigma^{-1}$. We only consider *finitely generated (f.g.) groups* G, for which there is a finite set $\Sigma \subseteq G$ such that $G = \langle \Sigma \rangle$; such a set Σ is called a *finite generating set* for G. If $\Sigma = \Sigma^{-1}$ then we say that Σ is a *finite symmetric generating set* for G. In the following we assume that all finite generating sets are symmetric. Every word $w \in \Sigma^*$ evaluates to a group element $\pi_G(w)$ in the natural way; here $\pi_G : \Sigma^* \to G$ is the canonical morphism from the free monoid Σ^* to G. Instead of $\pi_G(u) = \pi_G(v)$ we also write $u \equiv_G v$.

Let $C(G, \Sigma)$ be the Cayley graph of G with respect to the finite symmetric generating set Σ. It is the edge-labelled graph whose vertex set is G and that has an a-labelled edge from $\pi_G(u)$ to $\pi_G(ua)$ for all $u \in \Sigma^*$ and $a \in \Sigma$. Let $\mathsf{WP}(G, \Sigma) = \{w \in \Sigma^* \mid \pi_G(w) = 1\}$ be the *word problem for* G with respect to the generating set Σ.

We are interested in streaming algorithms for words problems $\mathsf{WP}(G, \Sigma)$. The following lemma is easy to prove; see [25, Lemma 4.1].

▶ **Lemma 2.** *Let Σ_1 and Σ_2 be finite symmetric generating sets for the group G and let $s_i(n)$ be the deterministic/randomized streaming space complexity of* $\mathsf{WP}(G, \Sigma_i)$*. Then there exists a constant c that depends on G, Σ_1 and Σ_2 such that $s_1(n) \leq s_2(c \cdot n)$.*

By Lemma 2, the dependence of the streaming space complexity from the generating set is often blurred by the use of the $\mathcal{O}$-notation. In such situations we will speak of the deterministic/randomized streaming space complexity for the group G (instead of the deterministic/randomized streaming space complexity of the language $\mathsf{WP}(G, \Sigma)$).

4 Streaming algorithms for word problems and growth

Let G be a finitely generated group and let Σ be a finite symmetric generating set for G. For $n \in \mathbb{N}$ let $B_{G,\Sigma}(n) = \pi_G(\Sigma^{\leq n}) \subseteq G$ be the ball of radius n in the Cayley-graph of G with center 1. The growth function $\gamma_{G,\Sigma} : \mathbb{N} \to \mathbb{N}$ is the function with $\gamma_{G,\Sigma}(n) = |B_{G,\Sigma}(n)|$. The deterministic streaming space complexity of G is completely determined by the growth of G:

▶ **Theorem 3.** *Let G be a finitely generated infinite group and let Σ be a finite symmetric generating set for G. Define the function $S(n)$ by $S(n) = \gamma_{G,\Sigma}(\lfloor n/2 \rfloor) + (n \bmod 2)$. Then, the deterministic streaming space complexity of* $\mathsf{WP}(G, \Sigma)$ *is $\lceil \log_2 S(n) \rceil$.*

Proof. We start with the upper bound in case n is even. In the following we identify the ball $B_{G,\Sigma}(n/2)$ with its induced subgraph of the Cayley graph $C(G, \Sigma)$. We define a deterministic finite automaton $\mathcal{A}_n$ by taking the edge-labelled graph $B_{G,\Sigma}(n/2)$ with the initial and unique final state 1. It can be viewed as a partial DFA in the sense that for every $g \in B_{G,\Sigma}(n/2)$ and every $a \in \Sigma$, g has at most one outgoing edge labelled with a (that leads to $g \cdot a$ if $g \cdot a \in B_{G,\Sigma}(n/2)$). In order to add the missing transitions we choose an element $g_f \in B_{G,\Sigma}(n/2) \setminus B_{G,\Sigma}(n/2 - 1)$ (here, we set $B_{G,\Sigma}(-1) = \emptyset$). Such an element exists because G is infinite. If $g \in B_{G,\Sigma}(n/2)$ has not outgoing a-labelled edge in $B_{G,\Sigma}(n/2)$ then we add an a-labelled edge from g to g_f. We call those edges *spurious*. The resulting DFA is $\mathcal{A}_n$.

We claim that for every word $w \in \Sigma^{\leq n}$, w is accepted by $\mathcal{A}_n$ if and only if $w \in \mathsf{WP}(G, \Sigma)$. This is clear, if no spurious edge is traversed while reading w into $\mathcal{A}_n$. In this case, after reading w, we end up in state $\pi_G(w)$. Now assume that a spurious edge is traversed while reading w into $\mathcal{A}_n$ and let x be the shortest prefix of w such that a spurious edge is traversed while reading the last symbol of x. Let us write $w = xy$. We must have $|x| > n/2$ and $\pi_G(x) \notin B_{G,\Sigma}(n/2)$. Moreover, $|y| < n - n/2 = n/2$. Since $\pi_G(x) \notin B_{G,\Sigma}(n/2)$, we have $w = xy \notin \mathsf{WP}(G, \Sigma)$. Moreover, w is rejected by $\mathcal{A}_n$, because x leads in $\mathcal{A}_n$ from the initial state 1 to state g_f and there is no path of length at most $n/2 - 1$ from g_f back to the final state 1.

For the case that n is odd, we take the ball $B_{G,\Sigma}(\lfloor n/2 \rfloor)$. Instead of adding spurious edges we add a failure state f. If $g \in B_{G,\Sigma}(\lfloor n/2 \rfloor)$ has no outgoing a-labelled edge in $B_{G,\Sigma}(\lfloor n/2 \rfloor)$, then we add an a-labelled edge from g to f. Moreover, for every $a \in \Sigma$ we add an a-labelled loop at state f. As for the case n even, one can show that the resulting DFA accepts a word $w \in \Sigma^{\leq n}$ if and only if $w \in \mathsf{WP}(G, \Sigma)$.

For the lower bound, let $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$ be a smallest DFA such that for every word $w \in \Sigma^{\leq n}$, w is accepted by $\mathcal{A}$ if and only if $w \in \mathsf{WP}(G, \Sigma)$. We have to show that $|Q| \geq S(n)$. Let us consider two words $u, v \in \Sigma^*$ of length at most $\lfloor n/2 \rfloor$ such that $u \not\equiv_G v$ and $\delta(q_0, u) = \delta(q_0, v)$. We then have $uv^{-1} \notin \mathsf{WP}(G, \Sigma)$ and $vv^{-1} \in \mathsf{WP}(G, \Sigma)$. On the other hand, we have $\delta(q_0, uv^{-1}) = \delta(q_0, vv^{-1})$, which is a contradiction (note that $|uv^{-1}|, |vv^{-1}| \leq n$). Hence, if $\delta(q_0, u) = \delta(q_0, v)$ for two words $u, v \in \Sigma^*$ of length at most $\lfloor n/2 \rfloor$, then $u \equiv_G v$.

Let $Q' = \{\delta(q_0, w) \mid w \in \Sigma^*, |w| \leq \lfloor n/2 \rfloor\} \subseteq Q$. The previous paragraph shows that $|Q'| \geq \gamma_{G,\Sigma}(\lfloor n/2 \rfloor)$. If n is even then $\lfloor n/2 \rfloor = n/2$ and we are done. So, let us assume that n is odd.

If $|Q| > \gamma_{G,\Sigma}(\lfloor n/2 \rfloor)$ then we are again done. So, let us assume that $Q = Q'$ and $|Q| = \gamma_{G,\Sigma}(\lfloor n/2 \rfloor)$. Then, to every state $q \in Q$ we can assign a unique group element $g_q \in B_{G,\Sigma}(\lfloor n/2 \rfloor)$ such that for every word $w \in \Sigma^*$ with $|w| \leq \lfloor n/2 \rfloor$ we have $\delta(q_0, w) = q$ if and only if $\pi_G(w) = g_q$. The mapping $q \mapsto g_q$ is a bijection between Q and $B_{G,\Sigma}(\lfloor n/2 \rfloor)$.

Let us now take a state $q \in Q$ and a generator $a \in \Sigma$ such that $g_q \cdot a \notin B_{G,\Sigma}(\lfloor n/2 \rfloor)$. Such a state and generator must exist since G is infinite. Let $u, v \in \Sigma^*$ be words of length at most $\lfloor n/2 \rfloor$ such that $\delta(q_0, u) = q$ and $\delta(q_0, v) = \delta(q, a) = \delta(q_0, ua)$. We obtain $\delta(q_0, vv^{-1}) = \delta(q_0, uav^{-1})$. But $vv^{-1} \in \mathsf{WP}(G, \Sigma)$ and $uav^{-1} \notin \mathsf{WP}(G, \Sigma)$ since $\pi_G(uav^{-1}) = g_q \cdot a \cdot \pi_G(v^{-1})$ and $g_q \cdot a \notin B_{G,\Sigma}(\lfloor n/2 \rfloor)$, $\pi_G(v^{-1}) \in B_{G,\Sigma}(\lfloor n/2 \rfloor)$. This is a contradiction since vv^{-1} and uav^{-1} both have length at most n. ◀

The growth of f.g. groups is well-studied and Theorem 3 basically closes the chapter on deterministic streaming algorithms for word problems. Hence, in the rest of the paper we focus on randomized streaming algorithms. Here, we can still prove a lower bound (that will turn out to be sharp in some cases but not always) using the randomized one-way communication complexity of the equality problem; see [25, Theorem 5.2] for details.

▶ **Theorem 4.** *Let G be a finitely generated group and let Σ be a finite symmetric generating set for G. The randomized streaming space complexity of* $\mathsf{WP}(G, \Sigma)$ *is* $\Omega(\log\log \gamma_{G,\Sigma}(\lfloor n/2 \rfloor))$.

▶ Remark 5. Since every f.g. infinite group has growth at least n, Theorem 4 has the following consequence: If G is a f.g. infinite group, then the randomized streaming space complexity of G is $\Omega(\log\log n)$.

▶ Remark 6. Later in this paper, we will make use of the following two famous results on the growth of groups, see also [9, 28]:

- Gromov's theorem [16]: A f.g. group has polynomial growth iff it is virtually nilpotent.

- Wolf-Milnor theorem [30, 42]; see also [9, p. 202]: A f.g. solvable group G is either virtually nilpotent (and hence has polynomial growth) or there is a constant $c > 1$ such that G has growth c^n (i.e., G has exponential growth). It is well known that the same dichotomy also holds for f.g. linear groups. This is a consequence of Tits alternative [37]: A f.g. linear group G is either virtually solvable or contains a free group of rank at least two (in which case G has exponential growth).

The dichotomy theorem of Milnor and Wolf does not generalize to all f.g. groups. Grigorchuk [14] constructed a f.g.group whose growth is lower bounded by $\exp(n^{0.515})$ [6] and upper bounded by $\exp(n^{0.768})$ [5]. The streaming space complexity of this remarkable group will be studied in Theorem 23.

5 Injective randomized streaming algorithms

For a semi-probabilistic finite automaton $\mathcal{A} = (Q, \Sigma, \iota, \rho, F)$ and some boolean condition $\mathcal{E}(q)$ that depends on the state $q \in Q$, we define the probability

$$\mathsf{Prob}_{q \in Q}[\mathcal{E}(q)] = \sum_{q \in Q, \mathcal{E}(q)=1} \iota(q).$$

Let G be a f.g. group G with the finite generating set Σ. A randomized streaming algorithm $(\mathcal{A}_n)_{n \geq 0}$ with $\mathcal{A}_n = (Q_n, \Sigma, \iota_n, \rho_n, F_n)$ is called ϵ*-injective* for G (with respect to Σ) if the following properties hold for all $n \geq 0$ and all words $u, v \in \Sigma^{\leq n}$:

- $\mathcal{A}_n$ is semi-randomized.
- If $u \equiv_G v$ then $\mathsf{Prob}_{q \in Q_n}[\rho_n(q, u) = \rho_n(q, v)] \geq 1 - \epsilon$.
- If $u \not\equiv_G v$ then $\mathsf{Prob}_{q \in Q_n}[\rho_n(q, u) \neq \rho_n(q, v)] \geq 1 - \epsilon$.

Note that the set F_n of final states of $\mathcal{A}_n$ is not important and we will just write $\mathcal{A}_n = (Q_n, \Sigma, \iota_n, \rho_n)$ in the following if we talk about an ϵ-injective randomized streaming algorithm $(\mathcal{A}_n)_{n \geq 0}$. The easy proof of the following lemma can be found in [25, Lemma 6.1].

▶ **Lemma 7.** *If $\mathcal{R}$ is an ϵ-injective randomized streaming algorithm for G w.r.t. Σ, then* $\mathsf{WP}(G, \Sigma)$ *has an ϵ-correct semi-randomized streaming algorithm with space complexity $2 \cdot s(\mathcal{R}, n)$.*

Due to Lemma 7, our goal in the rest of the paper will the construction of space efficient ϵ-injective randomized streaming algorithms for groups. We will need ϵ-injectivity for wreath products and free products; see Sections 7.2 and 7.3.

6 Randomized streaming algorithms for linear groups

For every f.g. linear group, the word problem can be solved in logarithmic space. This was shown by Lipton and Zalcstein [23] (if the underlying field has characteristic zero) and Simon [36] (if the underlying field has prime characteristic). The idea is to carry out all computations modulo sufficiently many small prime numbers. This idea can be easily turned into a randomized streaming algorithm by randomly choosing a small prime number. With some care, one can turn their idea into an $\epsilon(n)$-injective randomized streaming algorithm with $\epsilon(n) = 1/n^c$ for a constant c and space complexity $\mathcal{O}(\log n)$; see [25, Theorem 7.1] for details.

▶ **Theorem 8.** *For every f.g. linear group G and every $c > 0$ there exists an $\epsilon(n)$-injective randomized streaming algorithm with $\epsilon(n) = 1/n^c$ and space complexity $\mathcal{O}(\log n)$.*

Every nilpotent group is linear. For nilpotent groups we can improve the algorithm from the proof of Theorem 8, at least if we sacrifice the inverse polynomial error probability. The proof of the following theorem (see [25, Theorem 7.2]) uses the fact that every f.g. nilpotent group is a finite extension of a nilpotent group that can be embedded in the group $\mathsf{UT}_d(\mathbb{Z})$ of d-dimensional unitriangular matrices over $\mathbb{Z}$. The entries in a product of n such matrices $A_1, \ldots, A_n$ can be bounded by $\mathcal{O}(n^{d-1})$, provided all entries in the A_i are of size $\mathcal{O}(1)$ (in absolute value). This allows to compute modulo a random prime number with $\mathcal{O}(\log\log n)$ bits.

▶ **Theorem 9.** *For every f.g. nilpotent group G and every constant $c > 0$ there exists an $\epsilon(n)$-injective randomized streaming algorithm with $\epsilon(n) = 1/\log^c n$ and space complexity $\mathcal{O}(\log\log n)$.*

Note that if G is infinite, the upper bound from Theorem 9 is sharp up to constant factors even if we allow a constant error probability; see Remark 5.

7 Closure properties for streaming space complexity

In this section, we will show that many group theoretical constructions preserve randomized streaming space complexity.

7.1 Easy cases: finite extensions and direct products

For many algorithmic problems in group theory, the complexity is preserved by finite extensions. This is also true for the streaming space complexity of the word problem; see also [25, Theorem 8.1]:

▶ **Theorem 10.** *Assume that H is a f.g. group and G is a subgroup of H of finite index (hence, also G must be finitely generated). Assume that $\mathcal{R}$ is an ϵ-injective randomized streaming algorithm for G. Then H has an ϵ-injective randomized streaming algorithm with space complexity $s(\mathcal{R}, c \cdot n) + \mathcal{O}(1)$ for some constant c.*

Recall that Gromov proved that a finitely generated group has polynomial growth if and only if it is virtually nilpotent.

▶ **Corollary 11.** *Let G be an infinite finitely generated linear group.*

- *If G is virtually nilpotent then the randomized streaming space complexity of G is $\Theta(\log\log n)$.*
- *If G is not virtually nilpotent then the randomized streaming space complexity of G is $\Theta(\log n)$.*

Proof. The upper bounds follow from Theorems 8 and 9. Since G is infinite, the randomized streaming space complexity of the word problem of G is $\Omega(\log\log n)$ (see Remark 5), which yields the lower bound for the virtually nilpotent case. If G is not virtually nilpotent, then G has growth c^n for some constant $c > 1$ (see Remark 6), which yields the lower bound $\Theta(\log n)$ by Theorem 4. ◀

It is conjectured that for every f.g. group G that is not virtually nilpotent the growth is lower bounded by $\exp(n^{0.5})$. This is known as the *gap conjecture* [15]. It would imply that for every f.g. group that is not virtually nilpotent the randomized streaming space complexity is lower bounded by $\Omega(\log n)$.

Also direct products preserve the streaming space complexity of the word problem (simply run the streaming algorithms for the two factor groups in parallel):

▶ **Lemma 12.** *Let G and H be f.g. groups for which there exist $\epsilon(n)$-injective randomized streaming algorithms $\mathcal{R}$ and $\mathcal{S}$, respectively. Then there exists a $2\epsilon(n)$-injective randomized streaming algorithm for $G \times H$ with space complexity $s(\mathcal{R}, n) + s(\mathcal{S}, n)$.*

Recall that a group G is metabelian if it has an abelian normal subgroup $A \leq G$ such that the quotient G/A is abelian as well. Every f.g. metabelian group can be embedded into a direct product of linear groups (over fields of different characteristics) [40]. Hence, with Lemma 12 and Theorem 8 we obtain:

▶ **Corollary 13.** *For every f.g. metabelian group and every $c > 0$ there exists an $\epsilon(n)$-injective randomized streaming algorithm with $\epsilon(n) = 1/n^c$ and space complexity $\mathcal{O}(\log n)$.*

7.2 Randomized streaming algorithms for wreath products

Let G and H be groups. Consider the direct sum $K = \bigoplus_{g \in G} H_g$, where H_g is a copy of H. We view K as the set $H^{(G)}$ of all mappings $f \colon G \to H$ such that $\mathsf{supp}(f) := \{g \in G \mid f(g) \neq 1\}$ is finite, together with pointwise multiplication in H as the group operation. The set $\mathsf{supp}(f) \subseteq G$ is called the *support* of f. The group G has a natural left action on $H^{(G)}$ given by $gf(a) = f(g^{-1}a)$, where $f \in H^{(G)}$ and $g, a \in G$. The corresponding semidirect product $H^{(G)} \rtimes G$ is the (restricted) *wreath product* $H \wr G$. In other words:

- Elements of $H \wr G$ are pairs (f, g), where $g \in G$ and $f \in H^{(G)}$.
- The multiplication in $H \wr G$ is defined as follows: Let $(f_1, g_1), (f_2, g_2) \in H \wr G$. Then $(f_1, g_1)(f_2, g_2) = (f, g_1 g_2)$, where $f(a) = f_1(a) f_2(g_1^{-1} a)$ for all $a \in G$.

Intuitively, the mapping $a \mapsto f_2(g_1^{-1}a)$ is the mapping f_2 shifted by g_1.

Clearly, G is a subgroup of $H \wr G$. We also regard H as a subgroup of $H \wr G$ by identifying H with the set of all $f \in H^{(G)}$ with $\mathsf{supp}(f) \subseteq \{1\}$. This copy of H together with G generates $H \wr G$. In particular, if $G = \langle \Sigma \rangle$ and $H = \langle \Gamma \rangle$ with $\Sigma \cap \Gamma = \emptyset$ then $H \wr G$ is generated by $\Sigma \cup \Gamma$. In [32] it was shown that the word problem of a wreath product $H \wr G$ is TC^0-reducible to the word problems for G and H.

In this section, we study streaming algorithms for wreath products. The case of a wreath product $H \wr G$ with G finite is easy:

▶ **Proposition 14.** *Let H be a f.g. group for which there exists an ϵ-injective randomized streaming algorithm $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ and let G be a finite group of size c. Then, there exists an $(c \cdot \epsilon)$-injective randomized streaming algorithm for $H \wr G$ with space complexity $\mathcal{O}(s(\mathcal{R}, n))$.*

Proof. We run c independent copies of $\mathcal{A}_n$ (for the direct product of c copies of H). In addition we have to store an element of G. ◀

The case of a wreath product $H \wr G$ with G infinite turns out to be more interesting. In Section 8 we will prove a lower bound for the case that H is non-abelian. In this section, we consider the case where H is abelian. Our construction will start with ϵ-injective randomized streaming algorithms for G and uses the following simple fact.

▶ **Lemma 15.** *Let $(\mathcal{A}_n)_{n \geq 0}$ be an ϵ-injective randomized streaming algorithm for the finitely generated group G with respect to the generating set Σ. Let $\mathcal{A}_n = (Q_n, \Sigma, \iota, \rho)$. Consider a set $S \subseteq \Sigma^{\leq n}$. For every state q of $\mathcal{A}_n$ consider the equivalence relation $\equiv_q$ on S with $u \equiv_q v$ if and only if $\rho_n(q, u) = \rho_n(q, v)$. Then*

$$\operatorname*{\mathsf{Prob}}_{q \in Q_n}[\equiv_q \textit{ coincides with } \equiv_G \textit{ on } S] \geq 1 - \epsilon \cdot \binom{|S|}{2}.$$

Proof. For all $u, v \in S$, the probability that either $u \equiv_G v$ and $u \not\equiv_q v$ or $u \not\equiv_G v$ and $u \equiv_q v$ is bounded by ϵ. The lemma follows from the union bound since there are $\binom{|S|}{2}$ many unordered pairs. ◀

We start with the case of a wreath product $\mathbb{Z} \wr G$. Note that the following theorem makes only sense if $\epsilon < 1/2n^2$. On the other hand, such an inverse polynomial error probability can be achieved for linear groups by Theorem 8.

▶ **Theorem 16.** *Let G be a f.g. infinite group and $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ an ϵ-injective randomized streaming algorithm for G. Let d be a fixed constant and $\zeta = 2\epsilon n^2 + \max\{\epsilon, 1/n^d\}$. Then there exists an ζ-injective randomized streaming algorithm $\mathcal{S} = (\mathcal{B}_n)_{n \geq 0}$ for $\mathbb{Z} \wr G$ with space complexity $2 \cdot s(\mathcal{R}, n) + \Theta(\log n)$.*

Proof sketch. A complete proof of the theorem can be found in [25, Theorem 8.9]. Fix a symmetric generating set Σ for G and let a be a generator of $\mathbb{Z}$. Let $\mathcal{A}_n = (Q_n, \Sigma, \iota_n, \rho_n)$. W.l.o.g. we can assume that $Q_n = [0, |Q_n| - 1]$. Fix an input length n. For an input word $w \in (\Sigma \cup \{a, a^{-1}\})^{\leq n}$ our randomized streaming algorithm for $\mathbb{Z} \wr G$ runs $\mathcal{A}_n$ on the projection $\pi_\Sigma(w)$ of the word w to the subalphabet Σ. Initially, the algorithm guesses a state $q \in Q_n$ according to the initial state distribution ι_n and (independently from q) a prime number $p \in [2, \alpha]$. The number α will be fixed latter. For the moment, let us only mention that p will have at most $s(\mathcal{R}, n) + \Theta(\log n)$ bits. Apart from the current state of $\mathcal{A}_n$ the algorithm also stores a number $z \in [0, p-1]$ which initially is set to zero.

Assume that at some time instant the algorithm reads the letter a^γ, where $\gamma \in \{-1, 1\}$. Let q be the current $\mathcal{A}_n$-state, which is a number in the range $[0, |Q_n| - 1]$. The above prime number p has to be chosen uniformly from the set of all primes of size $\Theta(|Q_n| \cdot n^{d+1})$. Then the algorithm updates $z \in [0, p-1]$ as follows:

$$z := (z + \gamma \cdot (n+1)^q) \bmod p.$$

With our input word w and a state q of $\mathcal{A}_n$ we associate a polynomial $P_{q,w}(x) \in \mathbb{Z}[x]$ as follows: Let R_w be the set of all prefixes of w that end with a letter a^γ and for $s \in R_w$ define $\sigma(s) = \gamma \in \{-1, 1\}$ if s ends with a^γ. Moreover, for every $s \in R_w$ consider the $\mathcal{A}_n$-state $q_s = \rho_n(q, \pi_\Sigma(s)) \in [0, |Q_n| - 1]$. We then define the polynomial

$$P_{q,w}(x) := \sum_{s \in R_w} \sigma(s) \cdot x^{q_s}.$$

Note that this polynomial has degree at most $|Q_n| - 1$ and all its coefficients have absolute value at most n. Moreover, the number $z = z(p, q, w)$ computed by the algorithm on input w for the random choice $p \in [2, \alpha], q \in [0, |Q_n| - 1]$ is

$$z(p, q, w) = P_{q,w}(n+1) \bmod p. \tag{1}$$

This concludes the description of the streaming algorithm. It remains to show for all words $u, v \in (\Sigma \cup \{a, a^{-1}\})^{\leq n}$ the following:

(a) If $u \equiv_{\mathbb{Z} \wr G} v$ then $\underset{p \in [2,\alpha], q \in Q_n}{\mathsf{Prob}}[\rho_n(q, \pi_\Sigma(u)) = \rho_n(q, \pi_\Sigma(v)) \wedge z(p, q, u) = z(p, q, v)] \geq 1 - \zeta$.

(b) If $u \not\equiv_{\mathbb{Z} \wr G} v$ then $\underset{p \in [2,\alpha], q \in Q_n}{\mathsf{Prob}}[\rho_n(q, \pi_\Sigma(u)) \neq \rho_n(q, \pi_\Sigma(v)) \vee z(p, q, u) \neq z(p, q, v)] \geq 1 - \zeta$.

Let $(f_u, g_u) \in \mathbb{Z} \wr G$ (resp., $(f_v, g_v) \in \mathbb{Z} \wr G$) be the group element represented by the word u (resp., v). First assume that $u \equiv_{\mathbb{Z} \wr G} v$, i.e., $f_u = f_v$ and $g_u = g_v$. From $g_u = g_v$ we get

$$\underset{q \in Q_n}{\mathsf{Prob}}[\rho_n(q, \pi_\Sigma(u)) = \rho_n(q, \pi_\Sigma(v))] \geq 1 - \epsilon. \tag{2}$$

Moreover, from $f_u = f_v$ and Lemma 15 one can deduce

$$\underset{p\in[2,\alpha],q\in Q_n}{\mathsf{Prob}}[z(p,q,u) = z(p,q,v)] \geq \underset{q\in Q_n}{\mathsf{Prob}}[P_{q,u}(x) = P_{q,v}(x)] \geq 1 - 2\epsilon n^2. \tag{3}$$

Finally, (2) and (3) easily yield the conclusion of point (a). Now assume that $u \not\equiv_{\mathbb{Z}\wr G} v$. If $g_u \neq g_v$, i.e., then we get

$$\underset{q\in Q_n}{\mathsf{Prob}}[\rho_n(q,\pi_\Sigma(u)) \neq \rho_n(q,\pi_\Sigma(v))] \geq 1 - \epsilon \geq 1 - \zeta.$$

On the other hand, if the mappings f_u and f_v differ, then from Lemma 15 we obtain

$$\underset{q\in Q_n}{\mathsf{Prob}}[P_{q,u}(n+1) \neq P_{q,v}(n+1)] \geq \underset{q\in Q_n}{\mathsf{Prob}}[P_{q,u}(x) \neq P_{q,v}(x)] \geq 1 - 2\epsilon n^2.$$

The first inequality follows from Cauchy's bound. This, together with (1) and some standard bounds on the number of different prime factors of $|P_{q,u}(n+1) - P_{q,v}(n+1)|$ yields $\mathsf{Prob}_{p\in[2,\alpha],q\in Q_n}[z(p,q,u) \neq z(p,q,v)] \geq 1 - \zeta$ and finally the conclusion of point (b). ◀

It is easy to extend Theorem 16 to a wreath product $\mathbb{Z}_p \wr G$ with p prime. For a wreath product $\mathbb{Z}_{p^k} \wr G$ with p a prime and $k \geq 2$ we can only prove the following weaker statement using a polynomial identity testing algorithm for local rings from [3]. Putting it all together we can show the following result; see [25, Section 8.3] for details.

▶ **Theorem 17.** *Let G be a f.g. group for which there exists an ϵ-injective randomized streaming algorithm $\mathcal{R}$. Let A be a finitely generated abelian group. Then for all constants $\epsilon \leq \epsilon' < 1$ and $d \geq 1$ there exists a ζ-injective randomized streaming algorithm $\mathcal{S}$ for $A \wr G$ with the following properties:*

- *$\zeta \leq \mathcal{O}(\epsilon' + \epsilon n^2)$ and $s(\mathcal{S}, n) \leq \mathcal{O}(s(\mathcal{R}, n)^2 + \log n)$*
- *$\zeta \leq \mathcal{O}(1/n^d + \epsilon n^2)$ and $s(\mathcal{S}, n) \leq \mathcal{O}(s(\mathcal{R}, n) + \log n)$ if A is a direct product of copies of $\mathbb{Z}$ and $\mathbb{Z}_p$ with p prime.*

▶ **Corollary 18.** *Every free solvable group has randomized streaming space complexity $\Theta(\log n)$.*

Proof. Magnus' embedding theorem [27] says that every free solvable group can be embedded into an iterated wreath product $\mathbb{Z}^m \wr (\mathbb{Z}^m \wr (\mathbb{Z}^m \wr \cdots))$. Since $\mathbb{Z}^m$ is linear, we can, using Theorem 8, obtain an $\epsilon(n)$-injective randomized streaming algorithm for $\mathbb{Z}^m$ with space complexity $\mathcal{O}(\log n)$ for every inverse polynomial $\epsilon(n)$. We then apply the second statement of Theorem 17 a constant number of times and obtain a randomized streaming algorithm with space complexity $\mathcal{O}(\log n)$. The lower bound follows from Theorem 4 and the Milnor-Wolf theorem (see Remark 6). ◀

In [38] it is shown that the word problem of a free solvable group can be solved with a randomized algorithm running in time $\mathcal{O}(n \cdot \log^k n)$ for some constant k. Our algorithm achieves the same running time (because for every new input symbol, only numbers of bit length $\mathcal{O}(\log n)$ have to be manipulated). In contrast to our algorithm, the algorithm from [38] is non-streaming and does not work in logarithmic space.

7.3 Randomized streaming algorithms for free products

In [39], Waack proved that the word problem of a free product $G * H$ of two f.g. groups G and H can be solved in logspace if the word problems of G and H can be solved in logspace. Here, we show that Waack's reduction can be also used for randomized streaming algorithms.

For a group G and two subgroups $A, B \leq G$, the commutator subgroup $[A, B] \leq G$ is the group generated by all commutators $[a, b] = a^{-1}b^{-1}ab$ with $a \in A$ and $b \in B$. Let us denote with $F(\Sigma)$ the free group generated by the set Σ. A free group F is freely generated by the set $A \subseteq F$ if F is isomorphic to $F(A)$. It is well known that the free group $F_2 = F(\{a, b\})$ of rank 2 contains a copy of the free group $F(\mathbb{N})$ of countable infinite rank. For instance, the mapping $\phi : \mathbb{N} \to F_2$ with $\phi(n) = a^{-n}ba^n$ defines an injective homomorphism $\phi : F(\mathbb{N}) \to F_2$. The following group theoretic lemma underlies Waack's reduction:

▶ **Lemma 19** (c.f. [39, Proposition 4.2]). *Let G and H be groups. Then $[G, H]$ is a normal subgroup of the free product $G * H$ such that $(G * H)/[G, H] \cong G \times H$. Moreover, $[G, H]$ is a free group that is freely generated by the set of commutators $\{[g, h] \mid g \in G \setminus \{1\}, h \in H \setminus \{1\}\}$.*

▶ **Theorem 20.** *Let G and H be a f.g. groups for which there exist ϵ-injective randomized streaming algorithms $\mathcal{R} = (\mathcal{A}_n)_{n\geq 0}$ and $\mathcal{S} = (\mathcal{B}_n)_{n\geq 0}$, respectively. Then, there exists a $(4n^2 + 1)\epsilon$-injective randomized streaming algorithm $(\mathcal{C}_n)_{n\geq 0}$ for $G * H$ with space complexity $s(\mathcal{R}, n) + s(\mathcal{S}, n) + \mathcal{O}(\log n)$.*

The proof of Theorem 20 is a bit technical and can be found in [25, Section 8.2]. In order to test whether a word w is trivial in $G * H$, Waack checks whether the image of w in the quotient $(G * H)/[G, H] \cong G \times H$ is trivial (for which algorithms for G and H can be used). If this holds, then w represents an element of the free group $[G, H]$, which by the above remark can be embedded into F_2. Waack then computes from w the corresponding image in F_2. Basically, we follow the same strategy but only obtain the image in F_2 with high probability using Lemma 15. For F_2 (a linear group) we can then apply Theorem 8.

8 Lower bounds

In this section, we will construct groups with a large randomized streaming space complexity. We will make use of the disjointness problem from communication complexity. The *disjointness problem* is defined as follows: Alice (resp., Bob) has a bit string $u \in \{0, 1\}^n$ (resp., $v \in \{0, 1\}^n$) and their goal is to determine whether there is a position $1 \leq i \leq n$ such that $u[i] = v[i] = 1$ ($u[i]$ and $v[i]$ are the bits at position i). It is well known that the randomized communication complexity for the disjointness problem is $\Theta(n)$, see e.g. [21, Section 4.6].

▶ **Theorem 21.** *Let H be a f.g. non-abelian group and G be a f.g. infinite group. The randomized streaming space complexity of $H \wr G$ is $\Theta(n)$.*

Proof. Let $\mathcal{R} = (\mathcal{A}_n)_{n\geq 0}$ be a randomized streaming algorithm for the word problem of $H \wr G$. We show that we obtain a randomized communication protocol for the disjointness problem with communication cost $3 \cdot s(\mathcal{R}, 12n - 8)$.

Fix $n \geq 1$ and two elements $g, h \in H$ with $[g, h] \neq 1$. We can assume that g and h are generators of H. We also fix a finite generating set for G. Let $s := t_1 t_2 \cdots t_{n-1}$ be a word over the generators of G such that $t_1 t_2 \cdots t_i$ and $t_1 t_2 \cdots t_j$ represent different elements whenever $i \neq j$. Such a word exists since the Cayley graph of G is an infinite locally finite graph and hence contains an infinite ray. For a word $w = a_0 a_1 \cdots a_{n-1} \in \{0, 1\}^n$ and an element $x \in \{g, h, g^{-1}, h^{-1}\}$ define the word $w[x] = x^{a_0} t_1 x^{a_1} t_2 \cdots x^{a_{n-2}} t_{n-1} x^{a_{n-1}} s^{-1}$. It represents the element $(f_{w,x}, 1) \in H \wr G$ with $\mathsf{supp}(f_{w,x}) = \{t_1 \ldots t_i \mid i \in [0, n-1], w[i] = 1\}$ and $f_{w,x}(t) = x$ for all $t \in \mathsf{supp}(f_{w,x})$. Therefore, for two words $u, v \in \{0, 1\}^n$ we have $u[g]v[h]u[g^{-1}]v[h^{-1}] = 1$ in $H \wr G$ if and only if there is a position $i \in [0, n-1]$ with $u[i] = v[i] = 1$. Note that the length of the word $u[g]v[h]u[g^{-1}]v[h^{-1}]$ is $4(3n - 2) = 12n - 8$.

Our randomized communication protocol for the disjointness problem works as follows, where $u \in \{0, 1\}^n$ is the input for Alice and $v \in \{0, 1\}^n$ is the input for Bob.

- Alice reads the word $u[g]$ into $\mathcal{A}_{12n-8}$ and sends the resulting state to Bob.
- Bob continues the run in the state he received from Alice, reads the word $v[h]$ into the automaton and sends the resulting state back to Alice.
- Alice continues the run with the word $u[g^{-1}]$ and sends the resulting state of Bob.
- Bob continues the run with $v[h^{-1}]$ and finally accepts if the resulting state is accepting.

Both Alice and Bob use their random coins in order to make the random decisions in the PFA $\mathcal{A}_{12n-8}$. Clearly, the protocol is correct and its communication cost is $3 \cdot s(\mathcal{R}, 12n-8)$. We hence must have $3 \cdot s(\mathcal{R}, 12n-8) \in \Omega(n)$ which implies $s(\mathcal{R}, m) \in \Omega(m)$. ◀

In 1965, Thompson introduced three finitely presented groups $F < T < V$ acting on the unit-interval, the unit-circle and the Cantor set, respectively. Of these three groups, F received most attention (the reader should not confuse F with a free group). This is mainly due to the still open conjecture that F is not amenable. The group F consists of all homeomorphisms of the unit interval that are piecewise affine, with slopes a power of 2 and dyadic breakpoints. It is a finitely presented group. Important for us is the fact that F contains a copy of $F \wr \mathbb{Z}$ [17, Lemma 20]. Since F is non-abelian, Theorem 21 implies:

▶ **Corollary 22.** *The randomized streaming space complexity of Thompson's group F is $\Theta(n)$.*

Grigorchuk's group was introduced by Grigorchuk in [14]. It is a f.g. group of automorphisms of the infinite binary tree; the generators are usually denoted a, b, c, d and satisfy the identities $a^2 = b^2 = c^2 = d^2 = 1$ and $bc = cb = d, bd = db = c, dc = cd = b$. Grigorchuk's group is a f.g. infinite torsion group and was the first example of a group with intermediate growth and the first example of a group that is amenable but not elementary amenable.

▶ **Theorem 23.** *Let G be the Grigorchuk group. Then the following hold:*

- *The deterministic streaming space complexity of G is $\mathcal{O}(n^{0.768})$.*
- *The randomized streaming space complexity of G is $\Omega(n^{0.5})$.*

Proof sketch. The first statement follows from Theorem 3 and the upper growth bound $\exp(n^{0.768})$ for the Grigorchuk group; see [5]. For the second statement we use a non-abelian subgroup $K \leq G$ such that K contains a copy of $K \times K$, see [9, p. 262]. This allows a similar reduction from the disjointness problem as in the proof of Theorem 21; see [25, Theorem 9.3] for details. ◀

9 Open problems

We conclude with some open problems.

- Can the space bound $\mathcal{O}(s(\mathcal{R}, n)^2 + \log n)$ in Theorem 17 be reduced to $\mathcal{O}(s(\mathcal{R}, n) + \log n)$?
- What is the space complexity of randomized streaming algorithms for hyperbolic groups? The best complexity bound for the word problem for a hyperbolic group is LogCFL, which is contained in $\mathsf{DSPACE}(\log^2 n)$ [24].
- Is there a group that is not residually finite and for which there exists a randomized streaming algorithm with space complexity $o(n)$? An example of group that is not residually finite is the Baumslag-Solitar group $\mathsf{BS}(2, 3)$. The word problem for every Baumslag-Solitar group $\mathsf{BS}(p, q)$ can be solved in logarithmic space [41].

Abstract

The Skolem Problem asks to decide whether a given integer linear recurrence sequence (LRS) has a zero term. Decidability of this problem has been open for many decades, with little progress since the 1980s. Recently, a new approach was initiated via the notion of a Skolem set – a set of positive integers relative to which the Skolem Problem is decidable. More precisely, $\mathcal{S}$ is a Skolem set for a class $\mathcal{L}$ of integer LRS if there is an effective procedure that, given an LRS in $\mathcal{L}$, decides whether the sequence has a zero in $\mathcal{S}$. A recent work exhibited a Skolem set for the class of all LRS that, while infinite, had density zero. In the present work we construct a Skolem set of positive lower density for the class of simple LRS.

1 Introduction

An (integer) linear recurrence sequence (LRS) $\langle u_n \rangle_{n=0}^{\infty}$ is a sequence of integers satisfying a recurrence of the form

$$u_{n+k} = a_1 u_{n+k-1} + \cdots + a_k u_n \qquad (n \in \mathbb{N}), \tag{1}$$

where the coefficients $a_1, \ldots, a_k$ are integers. The celebrated theorem of Skolem, Mahler, and Lech [23, 16, 14] describes the set of zero terms of such a recurrence:

▶ **Theorem 1.** *Given an integer linear recurrence sequence $\langle u_n \rangle_{n=0}^{\infty}$, the set $\{n \in \mathbb{N} : u_n = 0\}$ is a union of finitely many arithmetic progressions together with a finite set.*

The statement of Theorem 1 can be refined by considering the notion of *non-degeneracy* of an LRS. An LRS is non-degenerate if in its minimal recurrence the quotient of no two distinct roots of the characteristic polynomial is a root of unity. A given LRS can be effectively decomposed as the merge of finitely many non-degenerate sequences, some of which may be identically zero. The core of the Skolem-Mahler-Lech Theorem is the fact that a non-zero non-degenerate linear recurrence sequence has finitely many zero terms. Unfortunately, all known proofs of this last result are ineffective: it is not known how to compute the finite set

of zeros of a given non-degenerate linear recurrence sequence. It is readily seen that existence of a procedure to do so is equivalent to the existence of a procedure to decide whether an arbitrary given LRS has a zero term. The problem of deciding whether an LRS has a zero term is variously known as Skolem's Problem or the Skolem-Pisot Problem. We refer to [5, Chapter 6] and [24, Chapter X] for expository accounts of the Skolem-Mahler-Lech Theorem and discussion of the ineffectiveness of known proofs.

Decidability of Skolem's Problem is known only for certain special cases, based on the relative order of the absolute values of the characteristic roots. Say that a characteristic root λ is *dominant* if its absolute value is maximal among all the characteristic roots. Decidability is known in case there are at most 3 dominant characteristic roots, and also for recurrences of order at most 4 [18, 26]. However for LRS of order 5 it is not currently known how to decide Skolem's Problem. For a (highly restricted) subclass of LRS, the paper [1] obtains nearly matching complexity lower and upper bounds for the problem.

In computer science, Skolem's Problem lies at the heart of key decision problems in formal power series [21, 4], stochastic model checking [20], control theory [6, 10], and loop termination [19]. The problem is also closely related to membership problems on commutative matrix groups and semigroups, as considered in [7, 13]. We note that in several of the above-mentioned citations, the Skolem Problem is used as a reference to show hardness of other open decision problems.

A recent paper [15] initiated a new approach to the decidability of Skolem's Problem. Rather than place syntactic restrictions on sequences (e.g., on the order of the recurrence or dominance pattern of the characteristic roots), the idea is to restrict the domain in which to search for zeros. To this end, [15] introduced the following definition.

▶ **Definition 2.** *An infinite set $\mathcal{S} \subseteq \mathbb{N}$ is a* Skolem set *for a class $\mathcal{L}$ of LRS if there is an effective procedure that, given an LRS $\langle u_n \rangle_{n=0}^{\infty}$ in $\mathcal{L}$, determines whether there exists $n \in \mathcal{S}$ with $u_n = 0$.*

The main technical contribution of [15] was to exhibit a Skolem set for the class of all LRS. Such sets are called *Universal Skolem sets.* Specifically, define $f : \mathbb{N} \setminus \{0\} \to \mathbb{N}$ by $f(n) = \lfloor \sqrt{\log n} \rfloor$, and inductively define the sequence $\langle s_n \rangle_{n=0}^{\infty}$ by $s_0 = 1$ and $s_n = n! + s_{f(n)}$ for $n > 0$. Then $\{s_n : n \in \mathbb{N}\}$ is a Universal Skolem set. This construction yields a very sparse set, which has density zero. This leads to the question of whether one can construct Skolem sets of positive lower density. Decidability of the Skolem Problem is, by definition, equivalent to the assertion that $\mathbb{N}$ is a Universal Skolem set (in fact, decidability follows already from the existence of Universal Skolem set that contains an infinite arithmetic progression). Hence seeking Skolem sets of increasingly higher density is a natural direction in which to make progress on the Skolem Problem.

The main result of the present paper exhibits a set $\mathcal{S}$ of positive lower density, i.e., having

$$\liminf_{n\to\infty} \frac{|\mathcal{S} \cap \{1,\dots,n\}|}{n} > 0\,,$$

such that $\mathcal{S}$ is a Skolem set for the class of simple LRS. For short we call $\mathcal{S}$ a *Simple Universal Skolem set.* Recall that a simple LRS is one for which the characteristic roots of its minimal-order recurrence are simple. The Skolem Problem for simple LRS is open already for LRS of order 5.

The construction of $\mathcal{S}$ is fundamentally different from the example in [15]. Roughly speaking, our set consists of positive integers n that admit many representations of the form $n = Pq + a$, with P, q prime and q, a logarithmic in n. The formal definition of the set is given in Section 3. In Section 4 we show that one can decide, given a simple LRS

$\langle u_n\rangle_{n=0}^{\infty}$, whether there exists $n \in \mathcal{S}$ with $u_n = 0$. The crucial ingredients here are results of Schlickewei and Schmidt [22] that give explicit upper bounds on the number of solutions of certain exponential Diophantine equations. Such results have previously been used to give effective upper bounds on the *number* of zeros of a given non-degenerate LRS (see [8, Theorem 2.7]), thereby strengthening the statement of the Skolem-Mahler-Lech Theorem (which, recall, asserts mere finiteness of the number of zeros). However such bounds do not obviously yield a solution to the Skolem Problem itself, which would instead require effective bounds on the *magnitude* of the zeros of an LRS. The essential novelty of our approach is, via the notion of representation, to leverage bounds on the number of solutions of exponential Diophantine equations to obtain bounds on the magnitude of the zeros of a simple LRS that lie in $\mathcal{S}$. In Section 5, we show that the set $\mathcal{S}$ has positive lower density. Here, classical number-theoretic techniques for upper bounding the number of pairs of primes in certain linear relations (such as twin primes) play the main role.

As discussed in the Conclusion, an extended version of this paper will show that for the set $\mathcal{S}$ introduced in this paper, the Skolem Problem is decidable relative to $\mathcal{S}$ for the class of all LRS, not just the simple ones. In the Conclusion we also briefly discuss the prospects of refining our analysis of the density of $\mathcal{S}$.

2 Background

In this section we briefly recall some relevant notation and definitions concerning number fields. We also recall a result from [9, 25] on unit equations that is derived from the Subspace Theorem and that will play a crucial role in our construction of a Simple Universal Skolem set.

Throughout we use the Vinogradov notation $f \ll g$ for $f \in O(g)$.

Recall that a *number field* $\mathbb{K}$ is a subfield of $\mathbb{C}$ that is finite dimensional as a vector space over $\mathbb{Q}$. The subring of algebraic integers in $\mathbb{K}$ is denoted $\mathcal{O}_{\mathbb{K}}$. For such a field $\mathbb{K}$, we denote by $\mathrm{Gal}(\mathbb{K}/\mathbb{Q})$ the group of automorphisms of $\mathbb{K}$. Given $\alpha \in \mathbb{K}$, the norm of α is defined by

$$N_{\mathbb{K}/\mathbb{Q}}(\alpha) = \prod_{\sigma \in \mathrm{Gal}(\mathbb{K}/\mathbb{Q})} \sigma(\alpha)\,.$$

The *norm* $N_{\mathbb{K}/\mathbb{Q}}(\alpha)$ is rational for all $\alpha \in \mathbb{K}$; moreover $N_{\mathbb{K}/\mathbb{Q}}(\alpha)$ is an integer if $\alpha \in \mathcal{O}_{\mathbb{K}}$. Clearly we have $|N(\alpha)| < M^{d_{\mathbb{K}}}$, where $d_{\mathbb{K}}$ is the degree of $\mathbb{K}$ and

$$M := \max_{\sigma \in \mathrm{Gal}(\mathbb{K}/\mathbb{Q})} |\sigma(\alpha)|$$

is the *house* of α.

We say that $\alpha, \beta \in \mathbb{K}$ are *multiplicatively dependent* if there exist integers k, ℓ, not both zero, such that $\alpha^k = \beta^\ell$. Observe that if $\alpha \in \mathbb{K}$ is not a root of unity then given $\sigma \in \mathrm{Gal}(\mathbb{K}/\mathbb{Q})$, every multiplicative relations $\alpha^k = \sigma(\alpha)^\ell$ is such that $k = \pm\ell$. Indeed, repeatedly applying σ to this relation we deduce that $\alpha^{k^d} = (\sigma^d(\alpha))^{\ell^d}$ for all $d \geq 1$. In particular, choosing d to be the order of σ we get that $\alpha^{k^d} = \alpha^{\ell^d}$ and hence $k = \pm\ell$.

We recall that every ideal in $\mathcal{O}_{\mathbb{K}}$ can be written uniquely as the product of prime ideals. Given a rational prime $p \in \mathbb{Z}$, we say that a prime ideal $\mathfrak{p}$ lies above p if $\mathfrak{p}$ is a factor of $p\mathcal{O}_{\mathbb{K}}$. In this case we have that $p \mid N_{\mathbb{K}/\mathbb{Q}}(\alpha)$ for all $\alpha \in \mathfrak{p}$.

We will need a result of Schlickewei and Schmidt [22] that gives upper bounds on the number of integer solutions of certain exponential Diophantine equations. The result (which we have specialised to our setting) is as follows:

▶ **Theorem 3** ([22, Theorem 1]). *For $i = 1, \dots, \ell$, let α_i, β_i, C_i be non-zero and lie in a number field of degree d over $\mathbb{Q}$. Suppose that the system of equations*

$$\alpha_i^{z_1}\beta_i^{z_2} = \alpha_j^{z_1}\beta_j^{z_2} \quad i, j \in \{1, \dots, \ell\}$$

has no non-zero solution in integers z_1, z_2. Then the number of solutions of the equation

$$\sum_{i=1}^{\ell} C_i\alpha_i^{x_1}\beta_i^{x_2} = 0 \tag{2}$$

in integers x_1, x_2 for which no proper sub-sum of the left-hand side vanishes is at most $2^{35\ell^2}d^{6\ell^2}$.

3 The Definition of the Set $\mathcal{S}$

In this section we give the definition of our Simple Universal Skolem set $\mathcal{S}$.

For a positive real number $x > 0$, denote by $\log x$ the natural logarithm of x. For a positive integer $k \geq 1$, we inductively define the iterated logarithm function $\log_k x$ as follows: $\log_1 x := \log x$, and for $k \geq 2$ we set $\log_k x := \max\{1, \log_{k-1}(\log x)\}$. Thus, for x sufficiently large, $\log_k x$ is the k-fold iterate of log applied to x. We omit the subscript when $k = 1$.

Fix a positive integer parameter X. We define disjoint intervals

$$A(X) := \left[\log_2 X, \sqrt{\log X}\right] \quad \text{and} \quad B(X) := \left[\frac{\log X}{\sqrt{\log_3 X}}, \frac{2\log X}{\sqrt{\log_3 X}}\right].$$

We further define a *representation* of an integer $n \in [X, 2X]$ to be a triple (q, P, a) such that $q \in A(X)$, $a \in B(X)$, P and q are prime, and $n = Pq + a$. We say that two representations (q, P, a) and (q', P', a') of the same number *overlap* if either $a + q = a' + q'$ or $a - q = a' - q'$. It is clear that two overlapping representations $(q, P, a) \neq (q', P', a')$ must have both $a \neq a'$ and $q \neq q'$.

We denote by $r(n)$ the number of representations of n. Finally we put

$$\mathcal{S}(X) := \{n \in [X, 2X] \ : \ r(n) > \log_4 X \text{ and no two representations of } n \text{ overlap}\}$$

and we define

$$\mathcal{S} := \bigcup_{X \geq 1} \mathcal{S}(X).$$

This completes the definition of the set $\mathcal{S}$. The rest of the paper is devoted to showing that $\mathcal{S}$ is a Simple Universal Skolem set and that it has positive lower density.

4 Solving the Simple Skolem Problem Relative to $\mathcal{S}$

The following result is the first half of the argument that the set $\mathcal{S}$, defined in Section 3, is a Simple Universal Skolem set. We use the bounds on the solutions of exponential Diophantine equations stated in Section 2 to show that the Skolem Problem for simple LRS is decidable relative to $\mathcal{S}$.

▶ **Proposition 4.** *Given a non-degenerate simple linear recurrence sequence $\langle u_n \rangle_{n=0}^{\infty}$, there is an effectively computable upper bound on the set $\{n \in \mathcal{S} : u(n) = 0\}$.*

Proof. Fix a non-degenerate simple linear recurrence sequence $\langle u_n\rangle_{n=0}^\infty$ with distinct characteristic roots $\alpha_1,\ldots,\alpha_\ell$. Recall that non-degeneracy is the condition that α_i/α_j is not a root of unity for all $i\neq j$. It is well-known that u_n admits an exponential-sum representation

$$u_n=\sum_{i=1}^{\ell} C_i\alpha_i^n\,,$$

where the constants C_i lie in the number field $\mathbb{K}:=\mathbb{Q}(\alpha_1,\ldots,\alpha_\ell)$. Multiplying the sequence $\langle u_n\rangle_{n=0}^\infty$ by a suitable integer, we may assume without loss of generality that the C_i lie in the ring of integers $\mathcal{O}_\mathbb{K}$.

Suppose that $n\in\mathcal{S}$ is such that $u_n=0$. By the definition of $\mathcal{S}$ we have that $n\in\mathcal{S}(X)$ for some positive integer X. We show that there is an upper bound on X that is effectively computable from the description of the sequence $\langle u_n\rangle_{n=0}^\infty$. Since $n\leq 2X$ this gives the desired effective upper bound on n.

Fix $n\in\mathcal{S}(X)$ such that $u_n=0$ and consider a representation (q,P,a) of n. Then $n=qP+a\geq X$, and so

$$P\geq\frac{X-a}{q}\geq\frac{X-\log X}{\sqrt{\log X}}>\sqrt{X} \tag{3}$$

for X sufficiently large.

Let $\mathfrak{p}$ be a prime ideal of $\mathcal{O}_\mathbb{K}$ lying above P and let $\sigma\in\mathrm{Gal}(\mathbb{K}/\mathbb{Q})$ be a Frobenius automorphism corresponding to $\mathfrak{p}$, that is, such that $\sigma(\alpha)\equiv\alpha^P \bmod \mathfrak{p}$ for all $\alpha\in\mathcal{O}_\mathbb{K}$. From $u_n=0$ and $n=qP+a$ we have

$$\sum_{i=1}^{\ell} C_i\alpha_i^{qP+a}=0\,.$$

Since $\sigma(\alpha_i)\equiv\alpha_i^P \bmod \mathfrak{p}$ for all $i\in\{1,\ldots,\ell\}$, we can write

$$\sum_{i=1}^{\ell} C_i\sigma(\alpha_i)^q\alpha_i^a\equiv 0 \bmod \mathfrak{p}\,. \tag{4}$$

Taking norms, we see that P divides

$$N:=N_{\mathbb{K}/\mathbb{Q}}\left(\sum_{i=1}^{\ell} C_i\sigma(\alpha_i)^q\alpha_i^a\right)\,.$$

Moreover, we have the inequality

$$|N|\leq M^{(1+q+a)d_\mathbb{K}}\,, \tag{5}$$

where $M=\max\{|\alpha_i|,|\beta_i|,|C_i|:1\leq i\leq\ell\}$ and $d_\mathbb{K}$ is the degree of $\mathbb{K}$ over $\mathbb{Q}$.

From the fact that $q\in A(X)$ and $a\in B(X)$, we see that for X sufficiently large we have $a,q<\frac{\log X}{8d_\mathbb{K}\log M}$. In this case, Equation (5) yields $N\ll X^{1/4}$. Hence for X large enough, using Equation (3), we have $N<X^{1/2}<P$. But N is an integer that is divisible by P, so it must be zero. We conclude that, for sufficiently large X, the left-hand side of (4) is zero; that is,

$$\sum_{i=1}^{\ell} C_i\sigma(\alpha_i)^q\alpha_i^a=0\,. \tag{6}$$

Carrying over the terminology for representations, let us say that two different solutions q, a and q', a' of Equation (6) *overlap* if either $a+q = a'+q'$ or $a-q = a'-q'$. Our goal is to give an explicit upper bound on the size of any collection of pairwise non-overlapping solutions of (6). For this, it is enough to give an upper bound under the additional assumption that no vanishing proper sub-sum of the left-hand side of (6) vanishes. Multiplying the latter quantity by the number (at most 2^ℓ) of possible sub-sums gives the desired upper bound on the total number of non-overlapping solutions.

Consider an instance of Equation (6) for which no proper sub-sum vanishes. Let $\mathcal{G}$ be the additive group of vectors $(z_1, z_2) \in \mathbb{Z}^2$ such that

$$\sigma(\alpha_i)^{z_1}\alpha_i^{z_2} = \sigma(\alpha_j)^{z_1}\alpha_j^{z_2}$$

for all $1 \leq i < j \leq \ell$. Note that there exist effective upper bounds on the magnitude of the entries a basis of $\mathcal{G}$ [17].

For $(z_1, z_2) \in \mathcal{G}$ we have $\sigma(\alpha_i/\alpha_j)^{z_1} = (\alpha_i/\alpha_j)^{-z_2}$. As shown in Section 2, since α_i/α_j is not a root of unity we must have either $z_1 = z_2$ or $z_1 = -z_2$. We thus have the following three possibilities for the form of the group $\mathcal{G}$ – either $\mathcal{G} = \{\mathbf{0}\}$, $\mathcal{G} = \{(z,z) : z \in m\mathbb{Z}\}$, or $\mathcal{G} = \{(z,-z) : z \in m\mathbb{Z}\}$, where $m \in \mathbb{Z}$. We consider three cases according to these three eventualities.

Case (i): $\mathcal{G} = \{\mathbf{0}\}$. Applying Theorem 3, the total number of solutions (overlapping or not) of Equation (6) in this case is at most $2^{35\ell^2}(d_{\mathbb{K}})^{6\ell^2}$.

Case (ii): $\mathcal{G} = \{(z,z) : z \in m\mathbb{Z}\}$ for some $m \in \mathbb{Z}$. In this case we have that $\sigma(\alpha_i)^m\alpha_i^m$ takes the same value for all $i \in \{1, \ldots, \ell\}$. Dividing Equation (6) by the $\lfloor q/m \rfloor$-th power of this common value we get

$$\sum_{i=1}^{\ell} \widetilde{C}_i \alpha_i^{a-q} = 0\,,$$

where each constant $\widetilde{C}_i$ is uniquely determined by C_i and the residue of q modulo m.

In other words, for every solution (q, a) of Equation (6), we have that $q - a$ is a zero of one of a finite number (at most m^ℓ) of non-degenerate LRS, each of which takes values in $\mathbb{K}$ and has order at most k. Applying Theorem 3, the number of different values of $q - a$ over all solutions (q, a) is at most $(2k)^{35k^2}(d_{\mathbb{K}})^{6k^2}m^\ell$. But the latter quantity is then a bound on the cardinality of a set of pairwise non-overlapping solutions of Equation (6).

Case (iii): $\mathcal{G} = \{(z,-z) : z \in m\mathbb{Z}\}$ for some $m \in \mathbb{Z}$. The argumentation is almost exactly as in Case (ii). We have that $\sigma(\alpha_i)^m\alpha_i^{-m}$ takes the same value for all $i \in \{1, \ldots, \ell\}$. Dividing Equation (6) by the $\lfloor q/m \rfloor$-th power of this common value we get

$$\sum_{i=1}^{\ell} \widetilde{C}_i \alpha_i^{a+q} = 0$$

where each constant $\widetilde{C}_i$ is uniquely determined by C_i and the residue of q modulo m. The argument now follows exactly as in Case (ii). In particular, we get the same upper bound on the number of solutions under Case (iii) as under Case (ii).

We can now summarise and wrap up. If $n \in \mathcal{S}(X)$ is a zero of u_n then for every representation $n = qP + a$ it holds that (q, a) is a solution of Equation (6). Moreover, since $n \in \mathcal{S}(X)$, no two representations of n are overlapping. Since we have an effective upper bound on the cardinality of a set of pairwise non-overlapping solutions of (6), we get an effective upper bound (that does not depend on n) for the number of representations of n. Finally, since by the definition of $\mathcal{S}(X)$ the number of representations is at least $\log_4 X$, we obtain the desired upper bound on X. ◀

5 The Set $\mathcal{S}$ has Positive Lower Density

Our goal in this section is to show that the set $\mathcal{S}$ has positive lower density. The key tool is the following result, (see [11, Chapter 2.6, Theorem 2.3]), derived using Selburg's upper-bound sieve, that bounds from above the number of times that two linear forms simultaneously take prime values.

▶ **Theorem 5.** *Let a_1, a_2, b_1, b_2 be integers such that*

$$E := |a_1 a_2 (a_1 b_2 - a_2 b_1)|$$

is non-zero. Then

$$|\{t \leq X : a_1 t + b_1, a_2 t + b_2 \textit{ both prime}\}| \ll \frac{X}{(\log X)^2} \frac{E}{\varphi(E)}\,,$$

where the implied constant is independent of a_1, a_2, b_1, b_2, and φ denotes Euler's totient function.

To help illustrate this result, observe that in case $a_1 = a_2 = 1$, $b_1 = 0$, and $b_2 = 2$, Theorem 5 gives an upper bound on the number of twin primes less than X.

We will also need the following straightforward proposition. (Note that here and in the rest of this section, variables p and q always range over prime numbers.)

▶ **Proposition 6.** $\sum_{q \in A(X)} \frac{1}{q} \sim \log_3 X$

Proof. We use the fact (see [3, Theorem 13.6]) that there exists an absolute constant c such that

$$\sum_{p \leq t} \frac{1}{p} = \log\log t + c + O\left(\frac{1}{\log t}\right)$$

for all $t \geq 2$. Using this fact, we have

$$\begin{aligned}
\sum_{q \in A(X)} \frac{1}{q} &= \log\log\sqrt{\log X} - \log\log\log_2 X + o(1) \\
&= \log_3 X - \log_4 X + o(1) \\
&\sim \log_3 X
\end{aligned}$$

for large enough X. ◀

We further note the following useful fact concerning the Euler function (see [3, Exercise 2.10(xii)]):

$$\sum_{k=1}^{n} \frac{k}{\varphi(k)} \ll n\,. \tag{7}$$

The rest of this section is devoted to a proof of the following result:

▶ **Theorem 7.** *The set $\mathcal{S}$, defined in Section 3, has strictly positive lower density.*

Recall from Section 3 that $\mathcal{S} := \bigcup_{X \geq 1} \mathcal{S}(X)$, where $\mathcal{S}(X) \subseteq [X, 2X]$. Hence, to prove that $\mathcal{S}$ has positive lower density, it suffices to show that $|\mathcal{S}(X)| \gg X$ for X sufficiently large. We first argue that for sufficiently large X we have

$$|\{n \in [X, 2X] : r(n) > \log_4 X\}| \gg X\,. \tag{8}$$

After that, we deal with those n that have overlapping representations (cf. the definition of $\mathcal{S}(X)$ in Section 3).

To prove (8) we use the moment method. To set this up, let

$$S_i := \sum_{\substack{n\in[X,2X]\\ r(n)>\log_4 X}} r(n)^i \qquad \text{for } i \in \{0,1,2\}\,.$$

The inequality (8) is equivalent to the assertion that $S_0 \gg X$. Thinking of S_1 as the inner product of the vector

$$\langle r(n) : n \in [X,2X], r(n) > \log_4 X\rangle$$

and the constant all 1's vector, applying the Cauchy-Schwartz inequality we get that

$$S_2 S_0 \geq S_1^2.$$

To show that $S_0 \gg X$ we will use a lower bound on S_1 and an upper bound on S_2.

5.1 Lower bound on S_1

In this section we show that $S_1 \gg X\sqrt{\log_3 X}$.

Fix $q \in A(X)$. Then for $P \in \left[\frac{X}{q}, \frac{1.5X}{q}\right]$ we have that $qP \in [X, 1.5X]$. Furthermore, if $a \in B(X)$, then for sufficiently large X we have $a < \log X < 0.5X$, so that $qP + a \in [X, 2X]$. Thus, for large X and each fixed prime $q \in A(X)$, the number of representations (q, P, a) with $qP + a \in [X, 2X]$ is at least the product of the number of primes $P \in \left[\frac{X}{q}, \frac{1.5X}{q}\right]$ and the cardinality of the set $B(X)$. But, for large enough X, the number of primes $P \in \left[\frac{X}{q}, \frac{1.5X}{q}\right]$ is

$$\pi\left(\frac{1.5X}{q}\right) - \pi\left(\frac{X}{q}\right) > \frac{0.3X}{q\log X}\,.$$

Thus, for fixed q, the number of representations (q, P, a) with $qP + a \in [X, 2X]$ is at least

$$\frac{0.3X}{q\log X}\,\frac{\log X}{\sqrt{\log_3 X}} \gg \frac{X}{q\sqrt{\log_3 X}}\,, \tag{9}$$

where the implied constant is independent of q.

Summing the lower bound (9) over $q \in A(X)$, we have

$$\begin{aligned}\sum_{n\in[X,2X]} r(n) \quad &\gg \quad \frac{X}{\sqrt{\log_3 X}}\left(\sum_{q\in A(X)} \frac{1}{q}\right)\\ &\gg \quad X\sqrt{\log_3 X} \quad \text{(by Proposition 6).}\end{aligned}$$

Finally, in order to get a lower bound on S_1 we must remove from the left-hand side above, the summands $r(n)$ for which $r(n) \leq \log_4 X$. But the contribution of these to the total sum is $O(X\log_4 X) = o(X\sqrt{\log_3 X})$, and so we conclude that $S_1 \gg X\sqrt{\log_3 X}$.

For future reference, we observe that essentially the same argument shows that $S_1 \ll X\sqrt{\log_3 X}$. Indeed, for each fixed $q \in A(X)$, the number of primes P such that $qP \in [X, 2X]$ is $\ll \frac{X}{q\log X}$. Since the number of $a \in B(X)$ is at most $\frac{\log X}{\sqrt{\log_3 X}}$, the number of representations (q, P, a) such that $qP + a \in [X, 2X]$ is $\ll \frac{X}{q\sqrt{\log_3 X}}$. Now, summing over $q \in A(X)$ and using Proposition 6, we obtain the bound $S_1 \ll X\sqrt{\log_3 X}$.

5.2 Upper bound on S_2

Our goal is to show that $S_2 \ll X \log_3 X$. To this end we consider S_2 as the number of pairs of representations $(q, P, a), (q', P', a')$ such that $qP + a = q'P' + a'$, with the common sum lying in the interval $[X, 2X]$. We break the count down into three cases.

Case (i). Let us first consider the number of such pairs with $a = a'$. In this case we have $qP = q'P'$. But then, since q and q' are small and P and P' are large, we get that $q = q'$ and $P = P'$, and hence $(q, P, a) = (q', P', a')$. Thus the number of such pairs is equal to S_1. But, as noted at the conclusion of Section 5.1, we have $S_1 \ll X\sqrt{\log_3 X}$.

Case (ii). We next consider the number of pairs of representations with $a \neq a'$ and $q = q'$. In this case we have

$$P - P' = m, \qquad \text{where} \qquad m := \frac{a - a'}{q}.$$

By Theorem 5, for each fixed m the number of primes $P \le X/q$ such that $P + m$ is also prime is

$$\ll \frac{X}{q(\log X)^2} \frac{m}{\varphi(m)}.$$

Furthermore, for fixed q and m, the number of choices of a, a' with $m = \frac{a-a'}{q}$ is at most the number of choices of a, that is, at most $\frac{2\log X}{\sqrt{\log_3 X}}$. Thus, for fixed q and m, the total number of pairs of representations $(q, P, a), (q', P', a')$ with $qP + a = q'P' + a' \in [X, 2X]$ and $m = \frac{a-a'}{q}$ is

$$\begin{aligned} &\ll \frac{X}{q(\log X)^2} \frac{m}{\varphi(m)} \frac{2\log X}{\sqrt{\log_3 X}} \\ &= \frac{2X}{q(\log X)\sqrt{\log_3 X}} \frac{m}{\varphi(m)}. \end{aligned}$$

From the fact that $a, a' \in A(X)$ we have $m \le \frac{2\log X}{q\sqrt{\log_3 X}}$. Summing up over all values of m, we get that the total number of solutions for fixed q is

$$\begin{aligned} &\ll \frac{2X}{q(\log X)\sqrt{\log_3 X}} \left(\sum_{m \le \frac{2\log X}{q\sqrt{\log_3 X}}} \frac{m}{\varphi(m)} \right) \\ &\ll \frac{X}{q^2 \log_3 X}. \end{aligned}$$

In the above, we used the fact (see Equation (7)) that $\sum_{m \le t} m/\varphi(m) \ll t$.

Now we sum up over $q > \log_2 X$, getting that the number of such solutions is at most

$$\frac{X}{\log_3 X} \sum_{q > \log_2 X} \frac{1}{q^2} \ll \frac{X}{(\log_2 X)\log_3 X} = o(X).$$

Case (iii). Finally, let us count the rest of the solutions; namely the ones for which $a \neq a'$ and $q \neq q'$. Fixing a, a', q, q' we have

$$qP - q'P' = a' - a.$$

The general solution of the above equation in integers P and P' can be written in the form $P = p_0 + q't$ and $P' = p_0' + qt$, where t is an integer parameter and p_0, p_0' is a particular solution, chosen to be minimal among positive integer solutions (simultaneously, in both

coordinates). The condition that $Pq + a \leq 2X$ implies that $P \leq 2X/q$ and hence that $t \leq \frac{2X}{qq'}$.
Using the assumption $a \neq a'$, we can apply Theorem 5 to deduce that the number of $t \leq \frac{2X}{qq'}$ such that both $p_0 + q't$ and $p_0' + qt$ are prime is

$$\ll \frac{X}{qq'(\log X)^2} \frac{|a-a'|}{\varphi(|a-a'|)} .$$

We keep a and q fixed and sum up over $q' \neq q$ and $a' \neq a$, getting a bound of

$$\begin{aligned} &\ll \frac{X}{q(\log X)^2} \left(\sum_{q' \in A(X)} \frac{1}{q'} \right) \sum_{\substack{a' \in B(X) \\ a \neq a}} \frac{|a-a'|}{\varphi(|a-a'|)} \\ &\ll \frac{X}{q(\log X)^2} \cdot \log_3 X \cdot \frac{2\log X}{\sqrt{\log_3 X}} \quad \text{(by Proposition 6 and Equation 7)} \\ &= \frac{X\sqrt{\log_3 X}}{q \log X} . \end{aligned}$$

To conclude the argument, we sum up over all a's and all q's, getting an upper bound

$$\begin{aligned} &\ll \frac{X\sqrt{\log_3 X}}{\log X} \frac{2\log X}{\sqrt{\log_3 X}} \left(\sum_{q \in A(X)} \frac{1}{q} \right) \\ &\ll X \log_3 X \quad \text{(by Proposition 6).} \end{aligned}$$

Combining the bounds in the above three cases, we conclude that $S_2 \ll X \log_3 X$.

5.3 Putting Things Together

From the Cauchy-Schwarz inequality $S_0 S_2 \geq S_1^2$ and the above-established bounds $S_1 \gg X\sqrt{\log_3 X}$ and $S_2 \ll X \log_3 X$, we get that $S_0 \gg X$.

To transform the lower bound on S_0 to one on $\mathcal{S}(X)$, it remains to estimate the number of $n \in [X, 2X]$ that admit two overlapping representations. We claim that the total number of such n is $o(X)$. From this we conclude that $|\mathcal{S}(X)| \gg X$, which was our ultimate goal.

We conclude by justifying the preceding claim. For this it suffices to show that the number of pairs of overlapping representations in the interval $[X, 2X]$ is $o(X)$. To this end, consider two representations $(q, P, a) \neq (q', P', a')$ of the same number $n \in [X, 2X]$. Assume that $q + a = q' + a'$ (the argument in case $q - a = q' - a'$ requires only minor changes).

Now $n - (q + a) = q(P - 1) = q'(P' - 1)$, and so $qP - q'P' = (q' - q)$. Furthermore, as noted in Section 3, for two such overlapping representations, we have $q \neq q'$. Thus the general solution of the equation $qP - q'P' = (q' - q)$ in positive integers P and P' has the form $P = 1 + tq'$ and $P' = 1 + qt$ for a nonnegative integer parameter $t \ll X/qq'$. By Theorem 5, the number of t such that both $1 + tq$ and $1 + tq'$ are prime is

$$\begin{aligned} &\ll \frac{X}{qq'(\log X)^2} \frac{|q-q'|}{\varphi(|q-q'|)} \\ &\ll \frac{X \log_3 X}{qq'(\log X)^2} . \end{aligned}$$

In the above we have used the inequality $m/\varphi(m) \ll \log_2 m$ [12, Theorem 328], with $m = |q - q'| < \log X$ for large X.

The argument above shows that for $q \neq q'$, the number of pairs of primes P, P' for which there exist pairs of overlapping representations $(q, P, a), (q', P, a')$ of some $n \in [X, 2X]$ is at most $\frac{X \log_3 X}{qq'(\log X)^2}$. Summing up over the at most $\log X$ possible values of $a \in B(X)$, we see that for fixed $q \neq q'$ the total number of such pairs of overlapping representations is

$$\ll \frac{X \log_3 X}{qq' \log X}\,.$$

Here we used the fact that, thanks to the equation $q + a = q' + a'$, the choice of q, q', a uniquely determines a'.

Summing up over q, q', we get that the number of such possibilities is

$$\begin{aligned} &\ll \quad \frac{X \log_3 X}{\log X} \left(\sum_{q \in A(X)} \frac{1}{q} \right)^2 \\ &\ll \quad \frac{X (\log_3 X)^3}{\log X} \quad \text{(by Proposition 6)} \\ &= \quad o(X)\,. \end{aligned}$$

This concludes the proof of the claim.

6 Conclusion

We have defined a set $\mathcal{S} \subseteq \mathbb{N}$ of positive lower density relative to which the Skolem Problem for simple LRS is decidable. In an extended version of this paper we will show that we can solve the Skolem Problem relative to (a slight variant of) $\mathcal{S}$ for all LRS, not just the simple ones. For this we use methodology of Amoroso and Viada [2] to give effective upper bounds on the number of solutions of a class of bivariate polynomial-exponential Diophantine equations, generalising the analysis in Section 4. We are also continuing to study the lower density of $\mathcal{S}$. In particular, a future work will show that the set has lower density one, under certain heuristic assumptions on the distributions of primes, similar to the Cramér heuristic (as used to justify Cramér's conjecture on prime gaps).

Learning Deterministic Visibly Pushdown Automata Under Accessible Stack

Jakub Michaliszyn

University of Wrocław, Poland

Abstract

We study the problem of active learning deterministic visibly pushdown automata. We show that in the classical L^*-setting, efficient active learning algorithms are not possible. To overcome this difficulty, we propose the accessible stack setting, where the algorithm has the read and write access to the stack. In this setting, we show that active learning can be done in polynomial time in the size of the target automaton and the counterexamples provided by the teacher. As counterexamples of exponential size are inevitable, we consider an algorithm working with words in a compressed representation via (visibly) Straight-Line Programs. Employing compression allows us to obtain an algorithm where the teacher and the learner work in time polynomial in the size of the target automaton alone.

1 Introduction

Visibly pushdown automata (VPA), also known as input-driven pushdown automata, are a subclass of pushdown automata, in which the type of stack operation is determined by the input letter [33, 4]. This implies that the stack height, but not its content, is determined by the input word. This enables the construction of the *product* VPA from two given VPA. In consequence, the class of visibly pushdown languages recognized by VPA is closed under intersection, union and complement, which makes the universality problem decidable.

Even though VPA can be determinized, *deterministic* VPA (DVPA) enjoy better complexity properties: DVPA recognizing the union, the intersection or the complement of other DVPAs can be computed in polynomial time. In consequence, inclusion, equivalence and universality for DVPA can be decided in polynomial time. In contrast, the universality problem for VPA is **ExpTime**-complete, which implies that the exponential blow-up in the complementation (resp., determinization) of VPA is unavoidable. These properties render DVPA attractive for verification [16, 2, 28, 15], XML processing [31], approximating recurrent neural networks [12] and others [22].

For successful applications of DVPA, elimination of redundancy is essential. Furthermore, beyond minimization of a given DVPA [17], the automaton can be given implicitly, or before the minimization it can be too big to be constructed. The problem of minimization without explicit construction of the input DVPA can be addressed with active learning.

Active learning of automata has been originally proposed for deterministic finite-state automata (DFA) [6] with a *minimally adequate teacher*, which is an oracle for a hidden regular language L. *The teacher* answers *membership queries* whether a given word belongs to L, and *equivalence queries* whether a proposed automaton recognizes L, and if not it

47th International Symposium on Mathematical Foundations of Computer Science (MFCS 2022).

returns a counterexample. There is a polynomial-time algorithm, called the L* algorithm, which only asks membership and equivalence queries and returns the minimal DFA $\mathcal{A}_L$ recognizing L. Therefore, to construct the minimal DFA $\mathcal{A}_L$, we only need to be able to answer the above queries; the explicit construction of the input automaton can be avoided.

While the L* algorithm is versatile and has been generalized to various types of automata, extensions of the L* algorithm to pushdown languages are elusive [7]. The main problems are the lack of the counterpart of the Myhill-Nerode theorem for pushdown languages (despite some attempts [13]) and the complexity of equivalence checking for DPDA, which is decidable but currently the only upper bound is primitive recursive [41, 24]. However, there is a counterpart of Myhill-Nerode theorem for visibly pushdown languages [3] and equivalence checking for DVPA is decidable in polynomial time. Thus, we focus our research on DVPA.

Still, active learning visibly pushdown languages is elusive. First, the canonical DVPA defined based on the right congruence relation from [3] is not a minimal-size DVPA recognizing a given language; it can be even exponentially larger than a minimal equivalent DVPA [3]. Second, a minimal-size DVPA recognizing a given visibly pushdown language is not unique, which indicates difficulty in improving the definition of the canonical DVPA. Finally, the minimization problem for DVPA is **NP**-complete, which rules out possible generalizations of the L* algorithm, which would return any minimal-size DVPA (unless **P**=**NP**). For these reasons, we adapt the active learning framework to learn DVPA rather than their languages, i.e., we consider queries, which depend on the automaton structure.

1.1 Our framework

In our framework, we consider a hidden DVPA, which we call the *target automaton*, and the teacher answering queries about it. The learning algorithm is expected to return a DVPA equivalent to the target DVPA. We assume that we can observe the stack content. To model this, we introduce a third type of queries, called *stack content queries*, which return the stack content of the hidden automaton upon reading a given input.

This alone is insufficient to circumvent the hardness inherited from minimization of DVPA (see Proposition 1). Thus, we additionally assume that we can change the stack content during the computation. To model writing, we employ *control words* consisting of standard letters and special *control letters*. A control letter is of the form $\underline{u}$, where u is the stack content. Upon reading $\underline{u}$, the automaton swaps its stack content to u, while retaining the current state. Control words can be sent by the algorithm as parameters for appropriate queries. The ability to swap the stack content to the one provided in the word makes it possible to reveal behavior of the target automaton under certain stack contents.

We first discuss the framework, in which there may be an arbitrary number of control letters altering the stack content. Such an approach directly reduces active learning of DVPA to active learning of regular languages. This technique can be employed for minimization of the product of DVPA while avoiding the need of the construction of the whole product in the first place (Section 5.1). The drawback is that the returned automata may contain states unreachable with any path that obeys stack operations (i.e., the usual runs in DVPA).

To avoid unreachable states, we propose another framework, in which all words contain at most one control letter (Section 6). In this setting, active learning can be done in polynomial time in the size of the target automaton and the counterexamples provided by the teacher. Unfortunately, the length of counterexamples may be exponential, making the whole learning process intractable. We consider two solutions: bounding the length of considered counterexamples (Section 7) and employing grammar-based compression (Section 8). This leads us to a scenario where the teacher and the learning algorithm work in time polynomial in the size of the target automaton alone, learning a DVPA equivalent to the target one.

1.2 Related work

Learning context-free languages has been intensively studied. Typically, the context-free grammars (CFGs) have been considered as the representation of a language rather than pushdown automata. On the negative side, it has been shown that learning a CFG from membership and equivalence queries is intractable under reasonable cryptographic assumptions [7]. To overcome this difficulty, as well as to learn grammars more humanly understandable, learning structurally equivalent grammars has been considered [40, 12]. Two grammars are strongly equivalent [37] if their sets of derivation trees with erased names of non-terminals are the same. The problem with that approach is the complexity of checking strong equivalence, which is in **ExpTime**, but **PSpace**-hard [39]. Furthermore, some grammar-based learning algorithms [40] are based on the L^* algorithm for regular tree languages. Basically, for a CFG G, one can learn a tree language of derivations in G of all words from $L(G)$. However, the minimal deterministic bottom-up tree automaton recognizing all derivation trees in G can be exponentially larger than G. This extends to visibly pushdown languages and such a tree automaton can be exponentially larger than a DVPA recognizing the visibly pushdown language.

Besides [40], there is a large body of work on learning CFGs [26, 43, 5, 42, 19]. Among them, [5] shares some similarities to our approach. However, the framework from [5] can be considered as learning the transitions of a pushdown automaton with known states, while in our approach we learn the set of states and the transitions.

While CFGs fit well into the active learning setting, pushdown automata are better suited and more popular in verification [1]. The above-mentioned algorithms cannot be used to learn automata. Active learning of automata is an active research topic. Initially, active learning has been developed for DFA in the seminal paper by Angluin [6]. Recently, there has been a renewed interest in learning various types of automata [11, 32, 9, 8, 10, 36, 34]. Learning based on syntactic properties of the target automaton has been recently proposed in [35], where a syntactic property called the *loop index* has been employed to overcome the difficulty of learning automata on infinite words.

Learning DVPA is studied in [23]. The algorithm provided there learns the canonical DVPA defined by the congruence relation introduced in [3]. It uses only membership and equivalence queries and works in polynomial time in the size of the canonical automaton. However, the size of the canonical DVPA can be exponential in the size of a minimal DVPA [3]. Therefore, the time and space complexity of the algorithm presented in [23] is exponential.

Another approach to learning VPA from [27] considers VPA with significant stack limitations so that every VPA has a unique minimal equivalent DVPA, computable in polynomial time. For this restricted class, polynomial-time learning using only membership and equivalence queries is possible.

A comprehensive survey of related work has been presented in [23, Chapter 7].

2 Preliminaries

Given a finite alphabet Σ of letters, a *word* w is a finite sequence of letters. For a word w, we define $w[i]$ as the i-th letter of w and $|w|$ as its length. We denote the set of all words over Σ by Σ^*. We use ϵ to denote the empty word.

The *index* of an equivalence relation is the number of its equivalence classes. An equivalence relation $\equiv$ on words Σ^* is a *right congruence* relation if and only if for all words $w_1, w_2 \in \Sigma^*$ and all $a \in \Sigma$, if $w_1 \equiv w_2$, then $w_1 a \equiv w_2 a$.

Real-time Pushdown automata. A *(non-deterministic) real-time pushdown automaton* (rt-PDA) is a tuple consisting of: (1) Σ, an input alphabet, (2) Γ, a finite stack alphabet, (3) Q, a finite set of states, (4) $Q_0 \subseteq Q$, a set of initial states, (5) $\delta \subseteq Q \times \Sigma \times (\Gamma \cup \{\bot\}) \times Q \times \Gamma^*$, a finite transition relation, and (6) $F \subseteq Q$, a set of accepting states. We assume that $\bot$ is never popped from the stack, i.e., for every $(q, a, \bot, q', u) \in \delta$, the stack update u starts with $\bot$. The size of an rt-PDA $\mathcal{A}$, denoted by $|\mathcal{A}|$, is defined as the number of states plus the number of transitions, i.e., $|Q| + |\delta|$. An rt-PDA is *deterministic* if $|Q_0| = 1$ and δ is a function from $Q \times \Sigma \times (\Gamma \cup \{\bot\})$ to $Q \times \Gamma^*$. Deterministic rt-PDA are denoted as rt-DPDA.

Semantics of rt-PDA. Consider an rt-PDA $\mathcal{A} = (\Sigma, \Gamma, Q, Q_0, \delta, F)$. A *configuration* of $\mathcal{A}$ is a pair consisting of the current state $q \in Q$ of $\mathcal{A}$ and its current stack content $u \in (\bot \cdot \Gamma^*)$. An rt-PDA defines an infinite-state transition system over its configurations $Q \times (\bot \cdot \Gamma^*)$, where configurations $Q_0 \times \{\bot\}$ are initial. For $a \in \Sigma$, let $\rightarrow^a_{\mathcal{A}}$ be an auxiliary relation defined such that $(q, uB) \rightarrow^a_{\mathcal{A}} (q', uv)$ if $(q, a, B, q', v) \in \delta$, where q, q' are states, uB, uv are stack contents with B being a single (top) symbol. For a word $w = a_1 \dots a_n$, we define $\rightarrow^w_{\mathcal{A}}$ as the composition of relation $\rightarrow^{a_1}_{\mathcal{A}} \dots \rightarrow^{a_n}_{\mathcal{A}}$, i.e., $(q, u_0) \rightarrow^w_{\mathcal{A}} (q', u_n)$ if there exist intermediate configurations $(q_1, u_1), \dots, (q_{n-1}, u_{n-1})$ such that for each $1 \leq i \leq n$ we have $(q_{i-1}, u_{i-1}) \rightarrow^{a_i}_{\mathcal{A}} (q_i, u_i)$.

A word w is *accepted* by $\mathcal{A}$ if there are $q_0 \in Q_0$, $q \in F$ and $u \in \bot \cdot \Gamma^*$ such that $(q_0, \bot) \rightarrow^w_{\mathcal{A}} (q, u)$. The *language recognized by* $\mathcal{A}$, denoted $\mathcal{L}(\mathcal{A})$, is the set of words accepted by $\mathcal{A}$. For an rt-DPDA $\mathcal{A}$, we define the stack content upon reading w, denoted by $SC_{\mathcal{A}}(w)$, as the unique u such that $(q_0, \bot) \rightarrow^w_{\mathcal{A}} (q', u)$ for some q'.

Visibly pushdown automata. Consider a partition of the alphabet Σ into three sets $(\Sigma_c, \Sigma_l, \Sigma_r)$ called, respectively, the sets of *call*, *local* and *return* letters. We say that a rt-PDA $\mathcal{A} = (\Sigma, \Gamma, Q, Q_0, \delta, F)$ is a *visibly pushdown automaton* (VPA) (with respect to the partition $(\Sigma_c, \Sigma_l, \Sigma_r)$) if the following conditions hold:

- transitions over letters from Σ_c (*call transitions*) push a single symbol on the stack and do not depend on the stack content, i.e., if $(q, a, B, q', v) \in \delta$, then $v = BG$, where $G \in \Gamma$ and for all $B' \in \Gamma \cup \{\bot\}$ we have $(q, a, B', q', B'G) \in \delta$,
- transitions over letters from Σ_l (*local transitions*) neither change nor depend on the stack content, i.e., if $(q, a, B, q', v) \in \delta$, then $v = B$ and for all $B' \in \Gamma \cup \{\bot\}$ we have $(q, a, B', q', B') \in \delta$,
- transitions over letters from Σ_r (*return transitions*) pop a single symbol from a nonempty stack; if the stack is empty they leave $\bot$ on the stack.

Since VPA are a subclass of rt-PDA, the definitions of size, determinacy, and semantics carry over from rt-PDA to VPA. Since DVPA are a subclass of rt-DPDA, the stack content upon reading w, $SC_{\mathcal{A}}(w)$, is well defined.

3 The L* algorithm

We briefly describe a variant of the L* algorithm for active learning of a hidden regular language L [6], which is similar to the algorithms we propose later on. To learn the language L, the algorithm asks the following queries to an oracle called *the teacher*:

- *membership queries*: given $w \in \Sigma^*$, is $w \in L$?, and
- *equivalence queries*: given a DFA $\mathcal{A}$, is $\mathcal{L}(\mathcal{A}) = L$? If not, return a counterexample, which is a word distinguishing $\mathcal{A}$ and L (i.e., from the symmetric difference of $\mathcal{L}(\mathcal{A})$ and L).

The L* algorithm constructs the minimal DFA $\mathcal{A}_L$ recognizing L by refining approximations of the right congruence relation $\sim_L \subseteq \Sigma^* \times \Sigma^*$ defined such that $u \sim_L v$ if and only if $\forall w(uw \in L \iff vw \in L)$. Due to the Myhill–Nerode theorem, the right congruence relation $\sim_L$ defines $\mathcal{A}_L$.

The algorithm maintains two sets of words: the set of *selectors* S containing ϵ, and the set of *test words* C. The set C defines an approximation $\sim_L^C$ of the right congruence relation defined such that $u \sim_L^C v$ if and only if $\forall w \in C(uw \in L \iff vw \in L)$. The set S contains exactly one selector of each equivalence class of $\sim_L^C$. More precisely, the algorithm maintains two properties: *separability*: different words from S are not $\sim_L^C$-equivalent, and *closedness*: for every $s \in S$ and $a \in \Sigma$, there is some word $s' \in S$ such that $sa \sim_L^C s'$. Note that if the pair S, C satisfies the above properties, we can construct a DFA corresponding to S, C, i.e., a DFA whose states are S and the transition relation is defined based on $\sim_L^C$, i.e., the successor of $s \in S$ over a is $s' \in S'$ such that $sa \sim_L^C s'$.

The algorithm starts with $S = \{\epsilon\}$ and $C = \emptyset$ and it iterates the following steps in the loop until it terminates in Step 2.

Step 1. Starting with separable S, C, close S, C, i.e., construct $S' \supseteq S$ and $C' \supseteq C$ that are closed and remain separable.

Step 2. Construct the DFA A corresponding to the separable and closed pair S', C'. Check whether A recognizes L; if yes, return A (and terminate).

Step 3. Otherwise, take the counterexample w and find $s \in S$, $a \in \Sigma$ and a suffix w' of w such that $S \cup \{sa\}, C \cup \{w'\}$ is separable, i.e., sa is a new selector for $\sim_L^{C \cup \{w'\}}$.

The L* algorithm returns the minimal DFA recognizing $\mathcal{A}_L$ and it works in polynomial time in $|\mathcal{A}_L|$ and the total length of returned counterexamples.

3.1 Difficulty of adapting L* to visibly pushdown languages

We discuss the difficulty of learning visibly pushdown languages, which motivates our learning framework presented in the following sections.

The key property used by the L*-algorithm is that for every regular language there is the canonical DFA recognizing it, which is also the minimal-size DFA for that language. Visibly pushdown languages do not have this property [3]. First, minimal-size DVPA are not unique; for a given visibly pushdown language $\mathcal{L}$ there can be multiple non-isomorphic minimal-size DVPA recognizing $\mathcal{L}$ [3, Proposition 1]. Second, a notion of canonical automaton for visibly pushdown languages was proposed in [3], but the canonical automaton can be exponentially larger than a minimal-size DVPA.

Furthermore, assuming that $\mathbf{P} \neq \mathbf{NP}$, there is no polynomial-time L*-type learning algorithm for visibly pushdown languages. L*-type algorithms learn a minimal-size automaton and run in polynomial time, and hence such an algorithm for DVPA can be used to minimize DVPA in polynomial time by running the learning algorithm as a black-box and computing answers to all its queries in polynomial time. The automaton returned by the algorithm would be a minimal-size DVPA language-equivalent to the input one $\mathcal{T}$. However, the minimization problem for DVPA (its decision version) is **NP**-complete [20]. For these reasons, we settle for learning automata rather than languages.

One may suspect that there is an L*-type learning algorithm, which only queries the stack content along the run on the input word. We show, however, that the **NP**-hardness proof from [20] can be adjusted to DVPA with singleton stack alphabets (i.e., where $|\Gamma| = 1$):

▶ **Proposition 1.** *The following problem is* $\mathbf{NP}$*-complete: given a DVPA $\mathcal{T}$ with a singleton stack alphabet (a deterministic visibly counter automaton) and $N > 0$, decide whether there is a DVPA with a singleton stack alphabet language-equivalent to $\mathcal{T}$ that has at most N states.*

For DVPA over a singleton stack alphabet, the stack height, which is the only information the stack provides, can be deduced from the input word. Therefore, allowing for stack observation alone does not lead to a polynomial-time learning algorithm.

4 Theoretical underpinnings

We introduce *control words*, which are words able to alter automata stack content. Then, we state and prove a Myhill-Nerode type theorem for DVPA using control words.

Control words. For a stack alphabet Γ, let $\underline{\Gamma}$ be defined as the infinite set $\{\underline{\bot \cdot u} \mid u \in \Gamma^*\}$, consisting of *control letters*. The intuitive meaning of the letter $\underline{\bot \cdot u}$ is "set the stack to $\bot \cdot u$". Given an alphabet Σ, a *control word* is a word over $\Sigma \cup \underline{\Gamma}$. The size of a control word w, denoted by $\mathrm{size}(w)$, is the sum of the number of letters from Σ and the sum of lengths of control letters from $\underline{\Gamma}$. We will sometimes use the term *standard word* to emphasize that the considered word does not contain control letters, i.e., it belongs to Σ^*.

Restricted control words. Let Σ be a finite alphabet and Γ be a finite stack alphabet. We define the set of *initializing words* $\mathrm{Init}^{\Sigma,\Gamma} = \underline{\Gamma} \cdot (\Sigma \cup \underline{\Gamma})^*$, the set of control words, in which the first letter is a control letter. Furthermore, we define *single-reset words* $\mathrm{Reset_1}^{\Sigma,\Gamma} = \Sigma^* \cdot \underline{\Gamma} \cdot \Sigma^*$ to be the set of control words with exactly one control letter, and the set of *single-reset initializing words* $\mathrm{Init_1}^{\Sigma,\Gamma} = \underline{\Gamma} \cdot \Sigma^*$, in which the first letter is a control letter and the remaining letters are standard. We will omit the superscript Σ, Γ for readability.

Automata processing control words. Let $\mathcal{T}$ be a DVPA over the alphabet Σ and the stack alphabet Γ. We extend the relation $\xrightarrow{w}_{\mathcal{T}}$ defined over words to control words as follows: let $v \in \bot \cdot \Gamma^*$, for every configuration (q, u) we have $(q, u) \xrightarrow{[\underline{v}]}_{\mathcal{T}} (q', u')$ if and only if $q = q'$ and $u' = v$, i.e., a control letter $\underline{v}$ resets the stack content of the automaton to v, while it retains the state. We straightforwardly generalize acceptance to control words. A control word w is *accepted* by $\mathcal{T}$ if there are $q_0 \in Q_0$, $q \in F$ and $u \in \bot \cdot \Gamma^*$ such that $(q_0, \bot) \xrightarrow{w}_{\mathcal{T}} (q, u)$. The language of control words accepted by $\mathcal{T}$ is denoted by $\underline{L}(\mathcal{T})$.

We define a counterpart of the right congruence of a regular language.

▶ **Definition 2.** *Let $C \subseteq Init$ be a set of initializing words. We define the relation $\equiv_{\mathcal{T}}^{C}$ on control words as follows: we have $w_1 \equiv_{\mathcal{T}}^{C} w_2$ if and only if (1) for each $v \in C$ we have $w_1 v \in \underline{L}(\mathcal{T}) \iff w_2 v \in \underline{L}(\mathcal{T})$ and (2) for each $v \in C$ we have $SC_{\mathcal{T}}(w_1 v) = SC_{\mathcal{T}}(w_2 v)$.*

For every C, the relation $\equiv_{\mathcal{T}}^{C}$ is an equivalence relation. The definition of $\equiv_{\mathcal{T}}^{C}$ is monotonic w.r.t. C, i.e., for all sets $C_1 \subseteq C_2$, the relation $\equiv_{\mathcal{T}}^{C_2}$ is a refinement of $\equiv_{\mathcal{T}}^{C_1}$. In particular, the index of $\equiv_{\mathcal{T}}^{C_1}$ does not exceed the index of $\equiv_{\mathcal{T}}^{C_2}$.

We require $C \subseteq \mathrm{Init}$, because otherwise the relation $\equiv_{\mathcal{T}}^{C}$ may have infinitely many equivalence classes, which correspond to configurations rather than states of $\mathcal{T}$.

For C being a strict subset of control words, $\equiv_{\mathcal{T}}^{C}$ need not be a right congruence; $w_1 \equiv_{\mathcal{T}}^{C} w_2$ does not imply $w_1 a \equiv_{\mathcal{T}}^{C} w_2 a$. Intuitively, words w_1, w_2 may lead to the same state in the automaton, but different configurations and after a single transition over letter a we obtain two configurations with different states. Thus, the right-congruence notion is incompatible with DVPA. We solve these problems by introducing another notion of congruence and restricting considered sets of control words.

Control right congruence. A relation $\simeq$ is a *control right congruence* if and only if for all words $w_1, w_2 \in (\Sigma \cup \underline{\Gamma})^*$ and $\alpha \in \underline{\Gamma} \cdot \Sigma$ we have $w_1 \simeq w_2$ implies $w_1\alpha \simeq w_2\alpha$.

▶ **Example 3.** Consider the *equal-state* relation $\simeq_{\mathcal{T}}$: for all $w_1, w_2 \in \Sigma^*$, we have $w_1 \simeq_{\mathcal{T}} w_2$ if and only if configurations reached by the DVPA $\mathcal{T}$ over w_1 and w_2 respectively, have the same state, i.e., there are a state q and stack contents u_1, u_2 such that $(q_0, \bot) \rightarrow^{w_1}_{\mathcal{T}} (q, u_1)$ and $(q_0, \bot) \rightarrow^{w_2}_{\mathcal{T}} (q, u_2)$. The relation $\simeq_{\mathcal{T}}$ need not be a right congruence relation as w_1 and w_2 can reach the same state with different symbols on the tops of stacks, and hence the states reached over w_1a and w_2a may differ, i.e., $w_1a \not\simeq_{\mathcal{T}} w_2a$. However, the relation $\simeq_{\mathcal{T}}$ is a control right congruence as the first control letter of $\alpha = ca$ resets the stack to the same value in w_1c and w_2c, and hence these words lead to the same configuration and the next transition over a leads to the same configuration. In consequence, $w_1ca \simeq_{\mathcal{T}} w_2ca$.

We show that $\equiv^{\text{Init}}_{\mathcal{T}}$ is a control right congruence with the index bounded by the number of states of $\mathcal{T}$. Therefore, there is a finite C such that $\equiv^{C}_{\mathcal{T}}$ and $\equiv^{\text{Init}}_{\mathcal{T}}$ coincide. We also show that $\equiv^{\text{Init}}_{\mathcal{T}}$ allows us to construct the transition relation of a DVPA corresponding to $\equiv^{\text{Init}}_{\mathcal{T}}$.

▶ **Lemma 4.** *Let $\mathcal{T}$ be a DVPA. (1) The relation $\equiv^{Init}_{\mathcal{T}}$ is a control right congruence, (2) the index of $\equiv^{Init}_{\mathcal{T}}$ is bounded by $|\mathcal{T}|$, and (3) the relation $\equiv^{Init}_{\mathcal{T}}$ defines a unique DVPA $\mathcal{A}$, which is language-equivalent to $\mathcal{T}$.*

▶ **Example 5.** We discuss why the second condition of the definition of $\equiv^{C}_{\mathcal{T}}$ is needed. Consider $\Sigma = \Sigma_c \cup \Sigma_l \cup \Sigma_r$ and a DVPA $\mathcal{A} = (\Sigma, \Gamma, Q, q_0, \delta, F)$. We assume that the sets Q, Σ, Γ and $\{\#, \$\}$ are pairwise disjoint. Let $\Sigma'_c = \Sigma_c \cup Q$, $\Sigma'_r = \Sigma_r \cup \{\$\}$, $\Sigma'_l = \Sigma_l \cup \{\#\}$ and $\Sigma' = \Sigma'_c \cup \Sigma'_r \cup \Sigma'_l$.

We consider a language $\mathcal{L}$ over the alphabet Σ' that consists of the words of the form $w_q\#w\#w_\$$, where $w_q \in Q^*$ and $w_\$ \in \{\$\}^*$. The idea is as follows: we want to accept words that make the stack empty (hence we use \$ at the end, to remove remaining stack elements) such that $\mathcal{A}$ after reading w is in one of the states listed in w_q.

The language $\mathcal{L}$ can be recognized by the automaton $\mathcal{A}'$ that works in three stages. First, it pushes all the symbols from w_q on the stack. Then, it emulates $\mathcal{A}$ on w. Finally, it pops stack symbols and checks whether the state of $\mathcal{A}$ after reading w is on the stack.

We argue that the automaton $\mathcal{A}'$ has the following property: its behaviour on the w_q part has no impact on its behaviour on the w part, but is crucial for the acceptance. Thus, the symbols that are put on the stack in the w_q part are significant only in processing the $w_\$$ part. This shows *non-locality*: the behaviour of $\mathcal{A}'$ on $w_\$$ is defined by w_q, which are separated by an arbitrary long word w.

Such non-locality is what often makes the learning problems intractable. To avoid this, we allow the learning algorithm to read the stack content, and we use the definition of the relation $\equiv^{C}_{\mathcal{T}}$. There, we require that for each $a \in \Sigma$ and for each $c \in \{\underline{\bot\gamma} \mid \gamma \in \Gamma \cup \{\epsilon\}\}$ we have $SC_{\mathcal{T}}(w_1ca) = SC_{\mathcal{T}}(w_2ca)$. In this way, the parts of the automaton reading w_q and $w_\$$ can be learned independently, as the results of reading letters on the stack are immediate.

If control letters are applied after each transition, DVPA behaves essentially as a DFA (see Section 5) and hence we attempt to minimize the use of control letters. In particular, we argue that considering $C = \text{Init}_1$ instead of Init is sufficient, i.e., single-reset initializing words are sufficient. We formalize it below.

We say that a DVPA $\mathcal{A}$ is *constructed from* the equivalence relation $\equiv^{\text{Init}_1}_{\mathcal{T}}$ if its states are selectors of the equivalence classes of $\equiv^{\text{Init}_1}_{\mathcal{T}}$ and if $\mathcal{A}$ has a transition $\delta(s, a, \alpha, s', \gamma)$, then either $s\underline{\bot\alpha}a \equiv^{\text{Init}_1}_{\mathcal{T}} s'$, or $\alpha = \bot$ and a is a return letter, and $s\underline{\bot\alpha}a$ and s' are equivalent over words $\underline{\bot}w'$ only. The stack content after reading $s\underline{\bot\alpha}a$ is updated according to γ. Such an automaton is not necessarily unique as $\equiv^{\text{Init}_1}_{\mathcal{T}}$ is not a control right congruence in general. However, we show that any such DVPA is admissible:

Table 1 Queries for learning with control words.

Query	membership query	stack-content query	equivalence query
Input	a control word w	a control word w	a DVPA $\mathcal{A}$
Output	whether $\mathcal{T}$ accepts w	$SC_{\mathcal{T}}(w)$	YES if $\mathcal{A}$ and $\mathcal{T}$ are language-equivalent, otherwise a control word w distinguishing $\mathcal{A}$ and $\mathcal{T}$

▶ **Lemma 6.** *Any DVPA constructed from $\equiv_{\mathcal{T}}^{Init_1}$ restricted to standard words is language-equivalent with $\mathcal{T}$.*

All equivalence classes of $\equiv_{\mathcal{T}}^{\mathrm{Init}}$, which do not contain standard words are irrelevant for language-equivalence as they correspond to unreachable states. Thus, Lemma 6 implies that in order to learn a DVPA language-equivalent to $\mathcal{T}$, we can construct $\equiv_{\mathcal{T}}^{\mathrm{Init}_1}$ restricted to standard words. This observation is the backbone of the learning algorithm presented in Section 6.

5 Learning with resets

We present the first active learning algorithm for DVPA based on control words and discuss its applications. We consider a learning framework with three types of queries: (modified) membership and equivalence queries and a new type called *stack-content queries*, which return the content of the stack upon reading a given word. The queries involve control letters, as we showed that using only standard words is insufficient (Section 3.1). Here, control words can have any number of control letters. In such a case, learning DVPA boils down to the standard learning of DFA. Indeed, with arbitrarily many control letters every path in a DVPA can be realized. Furthermore, we can address each transition and learn how the stack changes with stack-content queries. The solution for learning with unlimited control letters is a simple adaptation of the original L* algorithm.

We consider an oracle, called the *teacher*, which has access to the target DVPA $\mathcal{T}$ and answers the following three types of queries detailed in Table 1. Note that the counterexample can contain control letters as well.

We reduce active learning of DVPA to active learning of regular languages. Consider $\Sigma^{\mathrm{lab}} = (\Sigma_c \times \Gamma) \cup \Sigma_l \cup (\Sigma_r \times (\Gamma \cup \{\bot\}))$, which characterizes labels of transitions of $\mathcal{T}$: (1) call transitions are characterized by a call letter $a \in \Sigma_c$ and a stack symbol $B \in \Gamma$ pushed to the stack, (2) local transitions are characterized by a local letter alone $a \in \Sigma_l$, and (3) return transitions are characterized by a call letter $a \in \Sigma_r$ and the top of the stack symbol $\gamma \in \Gamma \cup \{\bot\}$.

Let $\mathcal{L}^{\mathrm{lab}}(\mathcal{T})$ be the language of words w over Σ^{lab}, which correspond to paths in $\mathcal{T}$ terminating in an accepting state. Note that paths need not obey the stack; for instance pushing a symbol A can be followed by pulling a symbol B, and hence not all paths correspond to runs of $\mathcal{T}$. However, the language $\mathcal{L}^{\mathrm{lab}}(\mathcal{T})$ is regular and hence can be learned with the L*-algorithm for DFA. The detailed constructions have been relegated to the appendix.

▶ **Theorem 7.** *Assume that the teacher returns minimal-size counterexamples. Then, active learning of DVPA with a teacher answering queries detailed in Table 1 can be done in time polynomial in the size of the target automaton.*

Table 2 Queries for learning with single resets.

Query	membership query	stack-content query	equivalence query
Input	a single-reset word w	a single-reset word w	a DVPA $\mathcal{A}$
Output	whether $\mathcal{T}$ accepts w	$SC_{\mathcal{T}}(w)$	YES if $\mathcal{A}$ and $\mathcal{T}$ are language-equivalent, otherwise, a (standard) word w distinguishing $\mathcal{A}$ and $\mathcal{T}$

5.1 Applications

The active learning of DVPA can be used for reducing the number of states of DVPA given implicitly. For instance, consider a model M consisting of k components $\mathcal{A}_1, \ldots, \mathcal{A}_k$ being DVPA. Models that are products of smaller components occur frequently in verification tasks (e.g., to express union or intersection of languages) and there is a large body of work on efficient model checking on such models [38, 21]. Even though the size of M is the product of sizes of $\mathcal{A}_1, \ldots, \mathcal{A}_k$, the number of reachable states may be considerably smaller, so it can be explicitly represented.

We can use the above active learning algorithm for DVPA to construct a reduced model of $\mathcal{A}_1 \times \ldots \times \mathcal{A}_k$ without the need of constructing the whole product. Now having DVPA $\mathcal{A}_1, \ldots, \mathcal{A}_k$, we can compute the values of membership and stack-content queries. For the equivalence queries with a given $\mathcal{A}$, we can check whether for all i we have $\mathcal{L}(\mathcal{A}_i) \supseteq \mathcal{L}(\mathcal{A})$, which implies that the language of the product of automata contains the language of $\mathcal{A}$. The opposite inclusion can be approximated with queries over random words, guided by various heuristics as is often the case with equivalence queries [12, 18]. It is difficult to answer equivalence queries for the product of automata as it subsumes the emptiness problem for intersections of regular languages, which is **PSpace**-complete.

Note that the constructed automaton can have states that are not reachable by any run (see Example 8). This is an inherent problem of considered words with multiple control letters; it diminishes the influence of the stack on reachability. To solve this problem, we focus on the single-reset approach presented in the following Section 6.

▶ **Example 8** (Automaton with redundant states)**.** Consider a DVPA $\mathcal{T}$ and its state q, which is reachable only with call transitions pushing A on the stack. Suppose that q has an outgoing return transition over $A' \neq A$, which leads to a component $\mathcal{B}$ of $\mathcal{T}$ not reachable with any other transition. Then, the algorithm from Theorem 7 explores the component $\mathcal{B}$ of $\mathcal{T}$ as it is reachable over words with multiple control letters and hence the returned DVPA contains redundant states.

6 Learning with a single reset

Here we study a learning framework with three types of queries as in Section 5, but restricted to words with one control letter. Those queries are detailed in Table 2. For a finite $C \subseteq \mathrm{Init}_1$, these queries are sufficient to decide whether $w_1 \equiv^C_{\mathcal{T}} w_2$ holds over $w_1, w_2 \in \Sigma^*$; the first condition from the definition of $\equiv^C_{\mathcal{T}}$ (Definition 2) can be implemented with membership queries, and the second one with stack-content queries.

We present an active learning algorithm for DVPA, which works in polynomial time in size of the target automaton and the size of counterexamples provided by the teacher. The algorithm is a modification of the L* algorithm, so we discuss only the differences with the vanilla L* algorithm. The main difference is that while L* constructs the right congruence relation of the target language $\mathcal{L}$, our algorithm constructs $\equiv^{\mathrm{Init}_1}_{\mathcal{T}}$ over standard words.

Our algorithm, similarly to L*, maintains two sets of words: a set of *selectors* S and a set of *test words* C such that S are selectors of equivalence classes of $\equiv^{C}_{\mathcal{T}}$. Selectors in $S \subset \Sigma^*$ are standard words over Σ and test words in $C \subset \text{Init}_1$ are single-reset initializing words. We start with $S = \{\epsilon\}$ and $C = \{\underline{\bot}\epsilon\}$.

We adjust the terminology to the current setting as follows. *Separability* means that different words from S are not $\equiv^{C}_{\mathcal{T}}$-equivalent. *Closedness* means that for every $s \in S$, $a \in \Sigma$ and $B \in \Gamma \cup \{\epsilon\}$, there is some word $s' \in S$ such that $s \cdot \underline{\bot \cdot B} \cdot a \equiv^{C}_{\mathcal{T}} s'$. The algorithm maintains separability and some restricted form of closedness. The latter is due to the fact that some transitions may be unreachable in a DVPA. For example, if the only way to reach some state is to push B on the stack, then all the transitions assuming that the top of the stack is not B are unreachable and thus irrelevant. For that reason, two steps in the L* algorithm: computing closure of S, C and generating the corresponding automaton, are interleaved and encapsulated in a single procedure *generate automaton*.

Generating automata. Given S, C and access to the teacher for $\mathcal{T}$, we construct a (partial) DVPA whose set of states is $S \subset \Sigma^*$, possibly extended with some additional states as discussed below. The initial state is $\epsilon \in S$. The accepting states are those states $w \in S$ such that the membership query on w returns true, i.e., w is accepted by $\mathcal{T}$. It remains to compute the transition function δ.

Consider a state $s \in S$, a letter $a \in \Sigma$ and $\gamma \in \Gamma \cup \{\bot\}$. To find $\delta(s, a, \gamma)$, we feed s to the target automaton $\mathcal{T}$, implant γ on the top of its stack and take the transition over a. Next, we identify the state from S equivalent to the current state of $\mathcal{T}$ or create a new one, if there is no fitting one in S. The details are in the appendix.

Equivalence and processing a counterexample. Given a partial DVPA $\mathcal{A}$, we complete it to a DVPA $\mathcal{A}^c$ by setting all undefined transitions so that their destination is ϵ and putting some designated $B_0 \in \Gamma$ on the stack over call transitions. Next, we test for equivalence and if it happens to be language-equivalent to $\mathcal{T}$ we return $\mathcal{A}^c$. Otherwise, we get a counterexample that distinguishes $\mathcal{A}^c$ and $\mathcal{T}$. We show how to use it to ensure progress of the algorithm. There are two possible cases of counterexamples: either the stack content diverges at some point, or the values of some suffixes mismatch. In both cases, we can modify S and C to ensure the progress. The details are in the appendix.

Irredundancy. Observe that all states in the returned automaton are reachable by some run (in contrast to the automaton from Example 8). To see this, note that we start with the initial state ϵ. Next, new successors are added either in the automata construction or in processing of a counterexample. In the former case, the new state is a successor of some reachable state over a consistent transition. That is, it is a call or local transition, which can be always executed, or it is a return transition and the stack content over w_s reaching $s \in S$ in the constructed automaton is consistent with the expected stack content in the transition. In the latter case, the successor va is added because the values of suffixes mismatch. There va is not $\equiv^{C'}_{\mathcal{T}}$-equivalent to any state from S and hence upon reading va the automaton reaches the new state va. Therefore, the algorithm with single-reset words avoids computation of redundant states in contrast to the algorithm from Section 5.

Complexity. The algorithm always terminates and works in polynomial time in the size of the target automaton and the size of teachers' responses. The details are in the appendix.

▶ **Theorem 9.** *Active learning of DVPA with teacher answering queries detailed in Table 2 can be done in time polynomial in the sizes of the target automaton and teachers' responses.*

For L*, if we assume that the teacher always returns a minimal-length counterexample, the algorithm works in polynomial time in the size of the target automaton alone. For DVPA, the shortest counterexample for language-equivalence can be of exponential-size in $|\mathcal{T}|$. In the following sections we propose two approaches to solve this problem: the first one is based on relaxed equivalence and the second one on employing grammar-based compression.

7 Active learning with bounded counterexamples

To avoid processing exponentially-long counterexamples, we can impose a bound on the length of admissible counterexamples. In some scenarios we may be interested in trading accuracy for performance and focus on words of length bounded by some fixed value t. A similar approach led to the development of *bounded model checking* methods, which are highly efficient [14, 25]. Furthermore, in applications of active learning of automata, equivalence queries, which are often costly to implement, are only approximated by equivalence over bounded-length words [12, 18].

Two DVPA $\mathcal{A}_1, \mathcal{A}_2$ are t-equivalent, where $t \in \mathbb{N}$, if and only if their languages agree on all words of the length bounded by t. We adjust the framework in a natural way: we replace equivalence queries with *t-equivalence* queries, which say whether a given DVPA $\mathcal{A}$ is t-equivalent to $\mathcal{T}$. If it is not, then we require a counterexample of length bounded by t.

Under the modified framework, we can run the algorithm described in Section 6. Note that each counterexample there is bounded by t and the algorithm terminates when $\mathcal{A}$ is t-equivalent to $\mathcal{T}$. Furthermore, each counterexample can be used to increase the size of S, which is bounded by the number of states of $\mathcal{T}$. In consequence, we have:

▶ **Theorem 10.** *Active learning of DVPA with teacher answering membership and stack-content queries defined in Table 2 and t-equivalence queries can be done in time polynomial in the size of the target automaton and t.*

Finally, observe that the teacher can answer t-equivalence queries in polynomial time in $|\mathcal{A}| + |\mathcal{T}| + t$. It suffices to construct a DFA $\mathcal{A}_t$ accepting all words of the length at most t and compute the emptiness of the intersection of the languages $\mathcal{A}$, $\mathcal{A}_t$ and $\mathcal{T}^C$, where $\mathcal{T}^C$ is the complemented $\mathcal{T}$.

8 Active learning with compressed representation

Here we propose to solve the problem of exponential counterexamples using compression by means of visibly context-free grammars to represent counterexamples as well as selectors and test words. We show that in this setting the teacher can always provide a counterexample of polynomial size in the size of the target automaton and a candidate automaton sent in the equivalence query. If the teacher does so, the algorithm we propose works in polynomial time in size of the target automaton.

Context-free grammars (which are equivalent to pushdown automata) can generate finite languages with exponential-length words. This observation led to the development of grammar-based compression, where a word w is represented through a context-free grammar (called Straight-Line Programs or SLPs) generating exactly one word w. Equivalence of SLPs with other compression methods and algorithmic problems are discussed in [30].

Table 3 Queries for learning with vSLP.

Query	membership query	stack-content query	equivalence query
Input	a vSLP representing a single-reset word w	a vSLP representing a single-reset word w	a DVPA $\mathcal{A}$
Output	whether $\mathcal{T}$ accepts w	$SC_{\mathcal{T}}(w)$	YES if $\mathcal{A}$ and $\mathcal{T}$ are language-equivalent, otherwise, a vSLP representing a standard word w distinguishing $\mathcal{A}$ and $\mathcal{T}$

We use polynomial-size SLPs to represent counterexamples as well as selectors. Note that processing SLPs can be expensive in general. There is a visibly pushdown language $\mathcal{L}_h$ such that the membership problem for this language over words given by SLPs is **PSpace**-complete [29]. However, if we restrict SLPs to those that are represented by *visibly pushdown grammars* G (over the same alphabet partition as the visibly pushdown language $\mathcal{L}_h$) defined below, then the membership problem is equivalent to the emptiness problem for the intersection of $\mathcal{L}_h$ and $\mathcal{L}(G)$, and hence it can be decided in polynomial time.

Visibly pushdown grammars. A *visibly pushdown grammar* (VPG) is a syntactically restricted pushdown grammar (see [4] for details). Consider a partition of Σ into $(\Sigma_c, \Sigma_l, \Sigma_r)$. A VPG is a triple $G = (V, S, P)$, where $V = V_0 \cup V_1$ is a set of *non-terminal symbols* partitioned into V_0 and V_1, $I \in V$ is the *start symbol*, and P is the set of *productions* of the following form:

- $X \to \epsilon$, where $X \in V$
- $X \to aY$, where $X, Y \in V$, and if $X \in V_0$, then $a \in \Sigma_l$ and $Y \in V_0$
- $X \to aYbZ$, where $X \in V$, $Y \in V_0$, $a \in \Sigma_c$, $b \in \Sigma_r$, and if $X \in V_0$, then $Z \in V_0$.
- $X \to YZ$, where $X, Y \in V$, and if $X \in V_0$, then $Y, Z \in V_0$.

The last rule is not present in the original definition, but it can be safely added as VPL are closed under concatenation.

VPA and VPG are language-wise polynomially equivalent [4] (i.e., there is a polynomial-time procedure that, given a PDA, outputs a CFG of the same language and vice versa).

For a VPG G, we define derivation $\to_G$ as a relation on $(\Sigma \cup V)^* \times (\Sigma \cup V)^*$ as follows: $w \to_G w'$ if and only if $w = w_1 X w_2$, with $X \in V$, and $w' = w_1 u w_2$ for some $u \in (\Sigma \cup V)^*$ such that $X \to u$ is a production from G. We define $\to_G^*$ as the transitive closure of $\to_G$. The *language generated by* G, denoted by $\mathcal{L}(G) = \{w \in \Sigma^* \mid s \to_G^* w\}$ is the set of words that can be derived from I. VPA and VPG are language-wise polynomially equivalent [4] (i.e., there is a polynomial-time procedure that, given a PDA, outputs a CFG of the same language and vice versa). The size of a VPG $G = (V, I, P)$, denoted by $|G|$, is $|V| + |P|$.

A *visibly Straight Line Program* (vSLP) is a visibly pushdown grammar G, which generates a single word denoted by w_G.

Now, selectors in S and test words in C will be represented by vSLPs. We introduce the framework and assume that words are represented as vSLPs, as detailed in Table 3. Importantly, the teacher can always return a polynomial size vSLP representing a counterexample.

▶ **Lemma 11.** *Given two DVPA $\mathcal{A}_1, \mathcal{A}_2$ such that $\mathcal{L}(\mathcal{A}_1) \neq \mathcal{L}(\mathcal{A}_2)$, there exists a polynomial size vSLP G such that w_G belongs to the symmetric difference of $\mathcal{L}(\mathcal{A}_1)$ and $\mathcal{L}(\mathcal{A}_2)$. Furthermore, this vSLP can be computed in polynomial time in $|\mathcal{A}_1| + |\mathcal{A}_2|$.*

The words represented by vSLPs can be efficiently processed. The procedure generating a DVPA from S, C requires efficient computation of concatenation of vSLPs and compressed membership and stack-content queries. Observe that for a polynomial-size vSLP G, the length of $SC_{\mathcal{T}}(w_G)$ is polynomial in $|\mathcal{T}|$ even though $|w_G|$ can be exponential and hence the answers to these queries have polynomial size. Processing counterexamples is more difficult as it involves finding the prefixes of the counterexample w_G with certain properties. Note that these prefixes can be identified with binary search and hence only polynomially many candidates need to be considered. It suffices to compute, for a given vSLP G, the prefix of the first i letters of w_G, which is possible in polynomial time in $|G|$. In consequence, we have the following:

▶ **Theorem 12.**

(i) *The teacher can answer membership and equivalence queries with vSLP input in polynomial time in the input size and $|\mathcal{T}|$.*

(ii) *The teacher can answer equivalence queries with polynomial size vSLP encoding a counterexample in polynomial time (in the input size and $|\mathcal{T}|$).*

(iii) *For the teacher as in* **(i)** *and* **(ii)***, active learning of DVPA with teacher answering queries detailed in Table 3 can be done in time polynomial in the size of the target automaton alone.*

9 Future work

We have presented the first work on polynomial-time learning DVPA. The queries we use depend not only on the language of the automaton, but its structure as well. It allows us to bypass problems arising from the difficulty of minimizing DVPA.

There is an open field of possible future directions, which we discuss below.

Dropping the stack content queries. Control words are crucial in our solution, i.e, the ability to alter the stack. We also assume that the stack can be observed, using the stack content queries. While this is a reasonable assumption, we have not shown whether it is necessary. In particular, we may explore the scenario from Section 5.1, in which we attempt to minimize both the state space and the stack alphabet and hence we consider the stack alphabet as unknown. We leave this as an open question.

Queries with registers. Another interesting scenario, but closely related to the previous one, is where we cannot read and write the stack directly, but we can save its value to a register and then use it. This corresponds to the case when we have access to the device memory, but the stack is represented in a way that we cannot manipulate it (e.g. it is encrypted). Note that in Section 6, we either use the stack contents that have been produced by some runs with at most one symbol pushed on the top. Is active learning in polynomial time possible if the stack content can be only copied between runs?

Learning all rt-DPDA. In the algorithm presented in Section 6, we rely on the fact that call and local letters do not depend on the stack content. We can possibly improve the algorithm to omit that assumption at the cost of more complex algorithm. We leave this problem for further investigation.

Learning all DPDA. Another challenging area is learning DPDA. One of the key challenges is to deal with ϵ-transitions. The problem there is that for some DPDA there can be states that are reachable with only ϵ-transitions, i.e., states without selectors. A solution to this problem would require a new insight into the representation of states.

Cohomology in Constraint Satisfaction and Structure Isomorphism

Adam Ó Conghaile

The Alan Turing Institute, United Kingdom

Abstract

Constraint satisfaction (CSP) and structure isomorphism (SI) are among the most well-studied computational problems in Computer Science. While neither problem is thought to be in PTIME, much work is done on PTIME approximations to both problems. Two such historically important approximations are the k-consistency algorithm for CSP and the k-Weisfeiler-Leman algorithm for SI, both of which are based on propagating local partial solutions. The limitations of these algorithms are well-known – k-consistency can solve precisely those CSPs of bounded width and k-Weisfeiler-Leman can only distinguish structures which differ on properties definable in C^k. In this paper, we introduce a novel sheaf-theoretic approach to CSP and SI and their approximations. We show that both problems can be viewed as deciding the existence of global sections of presheaves, $\mathcal{H}_k(A, B)$ and $\mathcal{I}_k(A, B)$ and that the success of the k-consistency and k-Weisfeiler-Leman algorithms correspond to the existence of certain efficiently computable subpresheaves of these. Furthermore, building on work of Abramsky and others in quantum foundations, we show how to use Čech cohomology in $\mathcal{H}_k(A, B)$ and $\mathcal{I}_k(A, B)$ to detect obstructions to the existence of the desired global sections and derive new efficient cohomological algorithms extending k-consistency and k-Weisfeiler-Leman. We show that cohomological k-consistency can solve systems of equations over all finite rings and that cohomological Weisfeiler-Leman can distinguish positive and negative instances of the Cai-Fürer-Immerman property over several important classes of structures.

1 Introduction

Constraint satisfaction problems (CSP) and structure isomorphism (SI) are two of the most well-studied problems in complexity theory. Mathematically speaking, an instance of one of these problems takes a pair of structures (A, B) as input and asks whether there is a homomorphism $A \to B$ for CSP or an isomorphism $A \cong B$ for SI. These problems are not in general thought to be tractable. Indeed the general case of CSP is NP-Complete and restricting our structures to graphs the best known algorithm for SI is Babai's quasi-polynomial time algorithm [8]. As a result, it is common in complexity and finite model theory to study approximations of the relations → and ≅.

The k-consistency and k-Weisfeiler-Leman[1] algorithms efficiently determine two such approximations to $\rightarrow$ and $\cong$ which we call $\rightarrow_k$ and $\equiv_k$. These relations have many characterisations in logic and finite model theory, for example in [18] and [13]. One that is particularly useful is that of the existence of winning strategies for Duplicator in certain Spoiler-Duplicator games with k pebbles [28, 25]. For both of these games Duplicator's winning strategies can be represented as non-empty sets $S \subset \mathbf{Hom}_k(A, B)$ of k-local partial homomorphisms which satisfy some extension properties and connections between these games have been studied before. For example, a joint comonadic semantics is given by the pebbling comonad of Abramsky, Dawar and Wang [4].

The limitations of these approximations are well-known. In particular, it is known that k-consistency only solves CSPs of *bounded width* and k-Weisfeiler-Leman can only distinguish structures which differ on properties expressible in the infinitary counting logic C^k. Feder and Vardi [18] showed that CSP encoding linear equations over the finite fields do not have bounded width, while Cai, Fürer, and Immerman [13] demonstrated an efficiently decidable graph property which is not expressible in C^k for any k.

In the present paper, we introduce a novel approach to the CSP and SI problems based on presheaves of k-local partial homomorphisms and isomorphisms, showing that the problems can be reframed as deciding whether certain presheaves admit global sections. We show that the classic k-consistency and k-Weisfeiler-Leman algorithms can be derived by computing greatest fixpoints of presheaf operators which remove some efficiently computable obstacles to global sections. Furthermore, we show how invariants from sheaf cohomology can be used to find further obstacles to combining local homomorphisms and isomorphisms into global ones. We use these to construct new efficient extensions to the k-consistency and k-Weisfeiler-Leman algorithms computing relations $\rightarrow_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$ which refine $\rightarrow_k$ and $\equiv_k$.

The application of presheaves has been particularly successful in computer science in recent decades with applications in semantics [32, 19], information theory [33] and quantum contextuality [3, 5, 2]. This work draws in particular on the application of sheaf theory to quantum contextuality, pioneered by Abramsky and Brandenburger [3] and developed by Abramsky and others for example in [5] and [2].

Using this work, we prove that these new cohomological algorithms are strictly stronger than k-consistency and k-Weisfeiler-Leman. In particular, we show that cohomological k-consistency decides solvability of linear equations with k variables per equation over all finite rings and that there is a fixed k such that $\equiv_k^{\mathbb{Z}}$ distinguishes structures which differ on Cai, Fürer and Immerman's property.

It is also interesting to compare $\rightarrow_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$ with other well-studied refinements of $\rightarrow_k$ and $\equiv_k$. For $\rightarrow_k$, such refinements include the algorithms of Bulatov [12] and Zhuk [35] which decide all tractable CSPs and the algorithms of Brakensiek, Guruswami, Wrochna and Živný [11] and Ciardo and Živný [14] for Promise CSPs. For $\equiv_k$, comparable approximations to $\cong$ include linear Diophantine equation methods employed by Berkholz and Grohe [9] and the invertible-map equivalence of Dawar and Holm [17] which bounds the expressive power of rank logic. The latter was recently used by Lichter [30] to demonstrate a property which is decidable in PTIME but not expressible in rank logic. In our paper, we show that $\equiv_k^{\mathbb{Z}}$, for some fixed k, can distinguish structures which differ on this property. Comparing $\rightarrow_k^{\mathbb{Z}}$ to the Bulatov-Zhuk algorithm and algorithms for PCSPs remains a direction for future work.

[1] The algorithm we call "k-Weisfeiler-Leman" is more commonly called "$(k-1)$-Weisfeiler-Leman" in the literature, see for example [13]. We prefer "k-Weisfeiler-Leman" to emphasise its relationship to k-variable logic and sets of k-local isomorphisms.

The rest of the paper proceeds as follows. Section 2 establishes some background and notation. Section 3 introduces the presheaf formulation of CSP and SI and new formulations of k-consistency and k-Weisfeiler-Leman in this framework. Section 4 demonstrates how to apply aspects of sheaf cohomology to CSP and SI and defines new algorithms along these lines. Section 5 surveys the strength of these new cohomological algorithms. Section 6 concludes with some open questions and directions for future work. Major proofs and additional background are left to the full version.

2 Background and definitions

In this section, we record some definitions and background which are necessary for our work.

2.1 Relational structures & finite model theory

Throughout this paper we use the word *structure* to mean a relational structure over some finite relational signature σ. A structure A consists of an underlying set (which we also call A) and for each relational symbol R of arity r in σ a subset $R^A \subset A^r$ or tuples related by R. A *homomorphism* of structures A, B over a common signature is a function between the underlying sets $f\colon A \to B$ which preserves related tuples. An *isomorphism* of structures is a bijection between the underlying sets which both preserves and reflects related tuples. A partial function $s\colon A \rightharpoonup B$ (seen as a set $s \subset A \times B$) is a *partial homomorphisms* if it preserves the related tuples in $\mathbf{dom}(s)$. s is a *partial isomorphism* if it is a bijection onto its image and both preserves and reflects related tuples. A partial homomorphism or isomorphism is said to be *k-local* if $|\mathbf{dom}(s)| \leq k$. For two structures over the same signature we write $\mathbf{Hom}_k(A, B)$ and $\mathbf{Isom}_k(A, B)$ respectively for the sets of k-local homomorphisms and isomorphisms from A to B.

In the paper, we make reference to several important logics from finite model theory and descriptive complexity theory. The logics we make reference to in this paper are as follows.

- Fixed-point logic with counting (written FPC) is first-order logic extended with operators for inflationary fixed-points and counting, for example see [20].
- For any natural number k, C^k is infinitary first-order logic extended with counting quantifiers with at most k variables. This logic bounds the expressive power of FPC in the sense that, for each k' there exists k such that any FPC formula in k' variables is equivalent to one in C^k. We write C^ω for the union of these logics.
- Rank logic is first-order logic extended with operators for inflationary fixed-points and computing ranks of matrices over finite fields, see [34].
- Linear algebraic logic is first-order infinitary logic extended with quantifiers for computing *all* linear algebraic functions over finite fields, see [15]. This logic bounds rank logic in the sense described above.

At different points in the history of descriptive complexity theory, both FPC and rank logic were considered as candidates for "capturing `PTIME`" and thus refuting a well-known conjecture of Gurevich [23]. Each has since been proven not to capture `PTIME`, for FPC see Cai, Fürer and Immerman [13], for rank logic see Lichter [30]. Infinitary logics such as C^ω and linear algebraic logic are capable of expressing properties which are not decidable in `PTIME` but have been shown not to contain any logic which does not capture `PTIME`. For C^ω, see Cai, Fürer and Immerman [13] and for linear algebraic logic, see Dawar, Grädel, and Lichter [16].

2.2 Constraint satisfaction problems & Structure Isomorphism

Assuming a fixed relational signature σ, we write CSP for the set of all pairs of σ-structures (A, B) such that there is a homomorphism witnessing $A \to B$. We use $CSP(B)$ to denote the set of relational structures A such that $(A, B) \in CSP$. We also use CSP and $CSP(B)$ to denote the decision problem on these sets. For general B, $CSP(B)$ is well-known to be `NP-complete`. However for certain structures B the problem is in `PTIME`. Indeed, the Bulatov-Zhuk Dichotomy Theorem (formerly the Feder-Vardi Dichotomy Conjecture) states that, for any B, $CSP(B)$ is either `NP`-complete or it is `PTIME`. Working out efficient algorithms which decide $CSP(B)$ for larger and larger classes of B was an active area of research which culminated in Bulatov and Zhuk's exhaustive classes of algorithms [12, 35].

Similarly, we write SI for the set of all pairs of σ-structures (A, B) such that there is an isomorphism witnessing $A \cong B$. The decision problem for this set is also thought not to be in `PTIME` however there are no general hardness results known for this. The best known algorithm (in the case where σ is the signature of graphs) is Babai's [8] which is quasi-polynomial.

There are many efficient algorithms which approximate the decision problems of CSP and SI. Two such examples, which are of particular importance to this paper, are the k-consistency and k-Weisfeiler-Leman algorithms. Explicit modern presentations of these algorithms can be seen, for example, in [7] and [27]. We instead focus on equivalent formulations in terms of positional Duplicator winning strategies. These are given by Kolaitis and Vardi [28] for k-consistency and Hella [24] for k-Weisfeiler-Leman. In the case of k-consistency, a pair (A, B) is accepted by the algorithm if and only if there is a non-empty subset $S \subset \mathbf{Hom}_k(A, B)$ which is downward-closed and satisfies the so-called forth property. This means any $s \in S$ with $|\mathbf{dom}(s)| < k$ satisfies the property $\mathbf{Forth}(S, s)$ which is defined as

$$\forall a \in A,\ \exists b \in B \text{ s.t. } s \cup \{(a, b)\} \in S.$$

If such an S exists we write $A \to_k B$. The similar strategy-based characterisation of k-Weisfeiler-Leman is captured by non-empty downward-closed sets $S \subset \mathbf{Isom}_k(A, B)$ where each element satisfies the bijective forth property $\mathbf{BijForth}(S, s)$ defined by

$$\exists b_s \colon A \to B \text{ a bijection s.t. } \forall a \in A\ s \cup \{(a, b_s(a))\} \in S.$$

If such an S exists we write $A \equiv_k B$. For more details, see the full version of this paper.

2.3 Presheaves & cohomology

Here we give a brief account of the category-theoretic preliminaries for this paper. For a more comprehensive introduction to category theory we refer to Chapter 1 of Leinster's textbook [29] and for a complete account of presheaves we refer to Chapter 2 of MacLane and Moerdijk [31].

Given two categories $\mathbf{C}$ and $\mathbf{S}$, an $\mathbf{S}$-valued presheaf over $\mathbf{C}$ is a contravariant functor $\mathcal{F} \colon \mathbf{C}^{op} \to \mathbf{S}$. We will assume that $\mathbf{C}$ is some subset of the powerset of some set X with subset inclusion as the morphisms. We call X the underlying space of $\mathbf{C}$. For this reason, when $U' \subset U$ in $\mathbf{C}$ we write $(\cdot)_{|_{U'}}$ for the restriction map $\mathcal{F}(U' \subset U) \colon \mathcal{F}(U) \to \mathcal{F}(U')$. We assume $\mathbf{S}$ is either the category $\mathbf{Set}$ of sets or the category $\mathbf{AbGrp}$ of abelian groups. We call $\mathbf{AbGrp}$-valued presheaves, abelian presheaves. $\mathbf{Set}$-valued presheaves are just called presheaves or presheaves of sets where there is ambiguity.

For any $\mathbf{C}$ and $\mathbf{S}$ as above, the category of presheaves $\mathbf{PrSh}(\mathbf{C}, \mathbf{S})$ has as objects the presheaves $\mathcal{F}\colon \mathbf{C}^{op} \to \mathbf{S}$ and, as morphisms, natural transformations between these functors. If $\mathbf{S}$ has a terminal object 1 (as both $\mathbf{Set}$ and $\mathbf{AbGp}$ do) then the presheaf $\mathbb{I} \in \mathbf{PrSh}(\mathbf{C}, \mathbf{S})$ which sends all elements of $\mathbf{C}$ to 1 is a terminal object in $\mathbf{PrSh}(\mathbf{C}, \mathbf{S})$. For any $\mathcal{F} \in \mathbf{PrSh}(\mathbf{C}, \mathbf{S})$, a *global section* of $\mathcal{F}$ is a natural transformation $S\colon \mathbb{I} \implies \mathcal{F}$.

3 Presheaves of local homomorphisms and isomorphisms

Some important efficient algorithms for CSP and SI involve working with sets of k-local homomorphisms between the two structures in a given instance. These sets of partial homomorphisms of domain size $\leq k$ are useful for constructing efficient algorithms because computing the sets $\mathbf{Hom}_k(A, B)$ and $\mathbf{Isom}_k(A, B)$ can be done in polynomial time in $|A| \cdot |B|$. In this section, we see that these sets can naturally be given the structure of sheaves, that the CSP and SI problems can be seen as the search for global sections of these sheaves and that the k-consistency and k-Weisfeiler-Leman algorithms can both be seen as determining the existence of certain special subpresheaves. The framework of considering sheaves of local homomorphisms and isomorphisms is novel in this work and essential for the main cohomological algorithms later. The results in Section 3.3 are from a technical report of Samson Abramsky [1] and we thank him for his permission to include them here.

3.1 Defining presheaves of homomorphisms and isomorphisms

Let A and B be relational structures over the same signature. A *partial homomorphism* is a partial function $s\colon A \rightharpoonup B$ that preserves related tuples in $\mathbf{dom}(s)$. A *partial isomorphism* is a partial homomorphism $s\colon A \rightharpoonup B$ which is injective and reflects related tuples from $\mathbf{im}(s)$. A *k-local homomorphism (resp. isomorphism)* is a partial homomorphism (resp. isomorphism) s such that $|\mathbf{dom}(s)| \leq k$. We write $\mathbf{Hom}_k(A, B)$ (resp. $\mathbf{Isom}_k(A, B)$) for the sets of k-local homomorphisms (resp. isomorphisms). We write $\mathbf{Hom}(A, B)$ for the union $\bigcup_{1 \leq k \leq |A|} \mathbf{Hom}_k(A, B)$ and $\mathbf{Isom}(A, B)$ for the union $\bigcup_{1 \leq k \leq |A|} \mathbf{Isom}_k(A, B)$.

It is not hard to see that these sets can be given the structure of presheaves on the underlying space A. Indeed, we define the *presheaf of homomorphisms from A to B* $\mathcal{H}(A, B)\colon \mathbf{P}(\mathbf{A})^{op} \to \mathbf{Set}$ as $\mathcal{H}(A, B)(U) = \{s \in \mathbf{Hom}(A, B) \mid \mathbf{dom}(s) = U\}$ with restriction maps $\mathcal{H}(A, B)(U' \subset U)$ given by the restriction of partial homomorphisms $(\cdot)_{|_{U'}}$. Similarly, let $\mathcal{I}(A, B)$ be the subpresheaf of $\mathcal{H}(A, B)$ containing only partial isomorphisms. Now, consider the cover of A by subsets of size at most k, written $A^{\leq k} \subset P(A)$. We define the *presheaves of k-local homomorphisms and isomorphisms* $\mathcal{H}_k(A, B)$ and $\mathcal{I}_k(A, B)$ as the functors $\mathcal{H}(A, B)$ and $\mathcal{I}(A, B)$ restricted to the subcategory $(\mathbf{A}^{\leq \mathbf{k}})^{op} \subset \mathbf{P}(\mathbf{A})^{op}$.

We now see how these presheaves and their global sections encode the CSP and SI problems for the instance (A, B).

3.2 CSP and SI as search for global sections

Fix an instance (A, B) for the CSP or SI problem and let $\mathcal{H}$ and $\mathcal{I}$ stand for the presheaves of all partial homomorphisms and isomorphisms between A and B defined in the last section. For either of these presheaves $\mathcal{S}$ a global section $s\colon \mathbb{I} \implies \mathcal{S}$ is a collection $\{s_U \in \mathcal{S}(U)\}_{U \in P(A)}$ where naturality implies that for any subsets U and U' of A $(s_U)_{|_{U \cap U'}} = (s_{U'})_{|_{U \cap U'}}$. As the poset $P(A)$ has a maximal element, namely A, any such global section is determined by a choice of $s_A \in \mathcal{S}(A)$. This leads us to the following observation.

▶ **Observation 1.** *Given a pair (A, B) relational structures over the same signature then*

$$(A, B) \in CSP \iff \mathcal{H} \text{ has a global section}$$

and if $|A| = |B|$ then

$$(A, B) \in SI \iff \mathcal{I} \text{ has a global section.}$$

This observation reframes the CSP and SI problems in terms of presheaves but algorithmically this not a particularly useful restating as computing the full objects $\mathcal{H}$ and $\mathcal{I}$ requires solving the CSP and SI problems for all subsets of A and B. A much more interesting equivalent condition is that for large enough k, whether or not a particular instance (A, B) is in CSP or SI is determined by the global sections of the presheaves of k-local homomorphisms and isomorphisms.

▶ **Lemma 2.** *For a pair (A, B) relational structures over the same signature, σ, and k at least the arity of sigma then*

$$(A, B) \in CSP \iff \mathcal{H}_k \text{ has a global section}$$

and if $|A| = |B|$ then

$$(A, B) \in SI \iff \mathcal{I}_k \text{ has a global section.}$$

Proof. See full version. ◀

This is more interesting than the previous observation as $\mathcal{H}_k$ and $\mathcal{I}_k$ can be computed for any relational structures A and B in $\mathcal{O}(\text{poly}(|A| \cdot |B|))$. Indeed, we can just list all $\mathcal{O}(|A|^k \cdot |B|^k)$ possible k-local functions and check which ones preserve (and reflect) related tuples. This also gives us an interesting starting point for designing efficient algorithms for approximating CSP and SI. In particular, any efficient algorithms which finds obstacles to the existence of global sections in $\mathcal{H}_k$ and $\mathcal{I}_k$ will provide a tractable approximation to CSP and SI. We now see how this approach can be used to capture some classical approximations of these problems.

3.3 Algorithms and games in terms of presheaves

In this section, we consider the approximations $A \to_k B$ and $A \equiv_k B$ to CSP and SI which are computed respectively by the k-consistency and k-Weisfeiler-Leman algorithms and we show that these algorithms can be seen as searching for certain obstructions to global sections in $\mathcal{H}_k(A, B)$ and $\mathcal{I}_k(A, B)$. In particular, we define efficiently computable monotone operators on subpresheaves of $\mathcal{H}_k$ and $\mathcal{I}_k$ and show that they have non-empty greatest fixpoints if and only if (A, B) are accepted by k-consistency and k-Weisfeiler-Leman respectively. Proposition 3 is reproduced with permission from an unpublished technical report of Samson Abramsky and the formulation of the fixpoint operators is inspired by the same report.

3.3.1 Flasque presheaves and k-consistency

Recall that $A \to_k B$ if and only if there is a positional winning strategy for Duplicator in the existential k-pebble game [18] and that a presheaf $\mathcal{F}$ is flasque if all of the restriction maps $\mathcal{F}(U \subset U')$ are surjective. In a recent technical report, Abramsky [1] proves the following characterisation of these strategies in our presheaf setting.

▶ **Proposition 3.** *For A, B relational structures and any k there is a bijection between:*

- *positional strategies in the existential k-pebble game from A to B, and*
- *non-empty flasque subpresheaves $\mathcal{S} \subset \mathcal{H}_k(A, B)$.*

This gives an alternative description of the k-consistency algorithm as constructing the largest flasque subpresheaf $\overline{\mathcal{H}_k}$ of $\mathcal{H}_k$ and checking if it is empty. As pointed out by Abramsky [1], this is the process of coflasquification of the presheaf $\mathcal{H}_k$ and can be seen as dual to the Godement construction [21], an important early construction in homological algebra. $\overline{\mathcal{H}_k}$ can be computed efficiently as the greatest fixpoint of the presheaf operator $(\cdot)^{\uparrow\downarrow}$ which computes the largest subpresheaf of a presheaf $\mathcal{S} \subset \mathcal{H}_k$ such that every $s \in \mathcal{S}^{\uparrow\downarrow}(C)$ satisfies the forth property $\mathbf{Forth}(\mathcal{S}, s)$. For further details see the full version of this paper.

3.3.2 Greatest fixpoints and k-Weisfeiler-Leman

In a similar way to the k-consistency algorithm, k-Weisfeiler-Leman can be formulated as determining the existence of a positional strategy for Duplicator in the k-pebble bijection game between A and B. This inspires the definition of another efficiently computable presheaf operator $(\cdot)^{\#\downarrow}$ which computes the largest subpresheaf of a presheaf $\mathcal{S} \subset \mathcal{I}_k$ such that for every $s \in \mathcal{S}^{\#\downarrow}(C)$ satisfies the bijective forth property $\mathbf{BijForth}(\mathcal{S}, s)$. We call the greatest fixpoint of this operator $\overline{\overline{\mathcal{S}}}$ and we have that $A \equiv_k B$ if and only if $\overline{\overline{\mathcal{I}_k}}$ is non-empty. For more details, see the full version of this paper.

To conclude, in this section, we have seen how to reformulate the search for homomorphisms and isomorphisms between relational structures A and B as the search for global sections in the presheaves $\mathcal{H}_k(A, B)$ and $\mathcal{I}_k(A, B)$. We have also seen that well-known approximations of homomorphism and isomorphism, $\rightarrow_k$ and $\equiv_k$, can be computed as greatest fixpoints of presheaf operators which remove elements which cannot form part of any global section. In the next section, we look at sheaf-theoretic obstructions to forming a global section which come from cohomology and see how these can be used to define stronger approximations of homomorphism and isomorphism.

4 Cohomology of local homomorphisms and isomorphisms

As we showed in the previous section, an instance of CSP and SI with input (A, B) can be seen as determining the existence of a global section for the presheaf $\mathcal{H}_k(A, B)$ or $\mathcal{I}_k(A, B)$ respectively and that the classic k-consistency and k-Weisfeiler-Leman algorithms can be reformulated as computing greatest fixed points of presheaf operations which successively remove sections which are obstructed from being part of some global section. In this section, we extend these algorithms by considering further efficiently computable obstructions which arise naturally from presheaf cohomology. From this we derive new cohomological algorithms for CSP and SI.

4.1 Cohomology and local vs. global problems

The notion of computing cohomology valued in an **AbGp**-valued presheaf $\mathcal{F}$ on a topological space X has a long history in algebraic geometry and algebraic topology which dates back to Grothendieck's seminal paper on the topic [22]. The cohomology valued in $\mathcal{F}$ consists of a sequence of abelian groups $H^i(X, \mathcal{F})$ where $H^0(X, \mathcal{F})$ is the free $\mathbb{Z}$-module over global sections of $\mathcal{F}$. As seen in the previous section we may be interested in such global sections but their existence may be difficult to determine. This is where the functorial nature of cohomology is extremely useful. Indeed, any short exact sequence of presheaves

$$0 \rightarrow \mathcal{F}_L \rightarrow \mathcal{F} \rightarrow \mathcal{F}_R \rightarrow 0$$

lifts to a long exact sequence of cohomology groups

$$0 \to H^0(X, \mathcal{F}_L) \to H^0(X, \mathcal{F}) \to H^0(X, \mathcal{F}_R) \to H^1(X, \mathcal{F}_L) \to \dots .$$

This tells us that the global sections of $\mathcal{F}_R$ which are not images of global sections of $\mathcal{F}$ are mapped to non-trivial elements of the group $H^1(X, \mathcal{F}_L)$ by the maps in this sequence. This means that these higher cohomology groups can be seen as a source of obstacles to lifting "local" solutions in $\mathcal{F}_R$ to "global" solutions in $\mathcal{F}$.

An important recent example of such an application of cohomology to finite structures can be found in the work of Abramsky, Barbosa, Kishida, Lal and Mansfield [2] in quantum foundations. They show that cohomological obstructions of the type described above can be used to detect contextuality (locally consistent measurements which are globally inconsistent) in quantum systems which were earlier given a presheaf semantics by Abramsky and Brandenburger [3]. In the full version of this paper, we describe these obstructions in general and show how the presheaves we constructed in the last section admit the same cohomological obstructions. This similarity inspires the definitions and algorithms which follow in the next two sections.

4.2 $\mathbb{Z}$-local sections and $\mathbb{Z}$-extendability

Returning to presheaves of local homomorphisms and isomorphisms let $\mathcal{S}$ be a subpresheaf of $\mathcal{H}_k$. Then we define the presheaf of $\mathbb{Z}$-linear local sections of $\mathcal{S}$ to be the presheaf of formal $\mathbb{Z}$-linear sums of local sections of $\mathcal{S}$. This means that for any $C \in A^{\leq k}$

$$\mathbb{Z}\mathcal{S}(C) := \left\{ \sum_{s \in \mathcal{S}(C)} \alpha_s s \;\mid\; \alpha_s \in \mathbb{Z} \right\}.$$

This is an abelian presheaf on $A^{\leq k}$ and we call the global sections $\{r_U \in \mathbb{Z}\mathcal{S}(U)\}_{U \in A^{\leq k}}$ $\mathbb{Z}$-linear global sections of $\mathcal{S}$. We say that a local section $s \in \mathcal{S}(C)$ is $\mathbb{Z}$-extendable if there is a $\mathbb{Z}$-linear global section $\{r_U \in \mathbb{Z}\mathcal{S}(U)\}_{U \in A^{\leq k}}$ such that $r_C = s$. We write this condition as $\mathbb{Z}\mathbf{ext}(\mathcal{S}, s)$. As outlined by Abramsky, Barbosa and Mansfield [5], this condition corresponds to the absence of a cohomological obstruction to $\mathcal{S}$ containing a global section involving s.

Importantly for our purposes, deciding the condition $\mathbb{Z}\mathbf{ext}(\mathcal{S}, s)$ for any $\mathcal{S} \subset \mathcal{H}_k(A, B)$ is computable in polynomial time in the sizes of A and B. This is because the compatibility conditions for a collection $\{r_U \in \mathbb{Z}\mathcal{S}(U)\}_{U \in A^{\leq k}}$ being a global section of $\mathbb{Z}\mathcal{S}$ can be expressed as a system of polynomially many linear equations in polynomially many variables. Indeed, we write each r_U as $\sum_{s \in \mathcal{S}(U)} \alpha_s s$ where α_s is a variable for each $s \in \mathcal{S}(U)$. This gives a total number of variables bounded by $\mathcal{O}(|A|^k \cdot |B|^k)$, the size of $\mathbf{Hom}_k(A, B)$. For each of the $\mathcal{O}(|A|^{2k})$ pairs of contexts $U, U' \in A^{\leq k}$, the compatibility condition $(r_U)_{|U \cap U'} = (r_{U'})_{|U \cap U'}$ yields a linear equation in the α_s variables for each $s' \in \mathcal{S}(U \cap U')$, leading to a total number of equations bounded by $\mathcal{O}(|A|^{2k} \cdot |B|^k)$. By an algorithm of Kannan and Bachem [26] can be solved in polynomial time in the sizes of A and B. This allows us to define the following efficient algorithms for CSP and SI based on removing cohomological obstructions.

4.3 Cohomological algorithms for CSP and SI

We saw in Section 3 that the k-consistency and k-Weisfeiler-Leman algorithms can be recovered as greatest fixpoints of presheaf operators removing local sections which fail the forth and bijective-forth properties respectively. Now that we have from cohomological considerations a new necessary condition $\mathbb{Z}\mathbf{ext}(\mathcal{S}, s)$ for a local section to feature in a global section of $\mathcal{S}$, we can define natural extensions to the k-consistency and k-Weisfeiler-Leman algorithms as follows.

4.3.1 Cohomological k-consistency

To define the cohomological k-consistency algorithm, we first define an operator which removes those local sections which admit a cohomological obstruction. Let $(\cdot)^{\mathbb{Z}\downarrow}$ be the operator which computes for a given presheaf $\mathcal{S} \subset \mathcal{H}_k$ the subpresheaf $\mathcal{S}^{\mathbb{Z}\downarrow}$ where $\mathcal{S}^{\mathbb{Z}\downarrow}(C)$ contains exactly those local sections $s \in \mathcal{S}(C)$ which satisfy both the forth property $\mathbf{Forth}(\mathcal{S}, s)$ and the $\mathbb{Z}$-extendability property $\mathbb{Z}\mathbf{ext}(\mathcal{S}, s)$. As this process may remove the local sections in $\mathcal{S}$ which witness the extendability of other local sections we need to take a fixpoint of this operator to get a presheaf with the right extendability properties at every local section. So, we write $\overline{\mathcal{S}}^{\mathbb{Z}}$ for the greatest fixpoint of this operator starting from $\mathcal{S}$. As both $\mathbf{Forth}(\mathcal{S}, s)$ and $\mathbb{Z}\mathbf{ext}(\mathcal{S}, s)$ are both computable in polynomial time in the size of $\mathcal{S}$ and $\overline{\mathcal{S}}^{\mathbb{Z}}$ has a global section if and only if $\mathcal{S}$ has a global section, this allows us to define the following efficient algorithm for approximating CSP.

▶ **Definition 4.** *The* cohomological k-consistency algorithm *accepts an instance (A, B) if the greatest fixpoint $\overline{\mathcal{H}_k(A, B)}^{\mathbb{Z}}$ is non-empty and otherwise rejects.*
If (A, B) is accepted by this algorithm we write $A \to_k^{\mathbb{Z}} B$ and say that the instance (A, B) is cohomologically k-consistent.

We conclude this section by showing that the relation $\to_k^{\mathbb{Z}}$ is transitive.

▶ **Proposition 5.** *For all k, given A, B and C structures over a common finite signature*

$$A \to_k^{\mathbb{Z}} B \to_k^{\mathbb{Z}} C \implies A \to_k^{\mathbb{Z}} C.$$

Proof. See full version. ◀

4.3.2 Cohomological k-Weisfeiler-Leman

We now define cohomological k-equivalence to generalise k-WL-equivalence in the same way as we did for cohomological k-consistency, by removing local sections which are not $\mathbb{Z}$-extendable. As $\mathbb{Z}$-extendability in $S \subset \mathbf{Isom}_k(A, B)$ is not *a priori* symmetric in A and B we need to check that both s is $\mathbb{Z}$-extendable in S and s^{-1} is $\mathbb{Z}$-extendable in $S^{-1} = \{t^{-1} \mid t \in S\}$. We call this s being *$\mathbb{Z}$-bi-extendable* in S and write it as $\mathbb{Z}\mathbf{bext}(\mathcal{S}, s)$. We incorporate this into a new presheaf operator $(\cdot)^{\mathbb{Z}\#}$ as follows. Given a presheaf $\mathcal{S} \subset \mathcal{I}_k$ let $\mathcal{S}^{\mathbb{Z}\#}$ be the largest subpresheaf of $\mathcal{S}$ such that every $s \in \mathcal{S}^{\mathbb{Z}\#}(C)$ satisfies both the bijective forth property $\mathbf{BijForth}(\mathcal{S}, s)$ and the $\mathbb{Z}$-bi-extendability property $\mathbb{Z}\mathbf{bext}(\mathcal{S}, s)$. We write $\overline{\overline{\mathcal{S}}}^{\mathbb{Z}}$ for the greatest fixpoint of this operator starting from $\mathcal{S}$. As both $\mathbf{BijForth}(\mathcal{S}, s)$ and $\mathbb{Z}\mathbf{bext}(\mathcal{S}, s)$ are computable in polynomial time in the size of $\mathcal{S}$ and $\overline{\overline{\mathcal{S}}}^{\mathbb{Z}}$ has a global section if and only if $\mathcal{S}$ has a global section, this allows us to define the following efficient algorithm for approximating SI.

▶ **Definition 6.** *The* cohomological k-Weisfeiler-Leman *accepts an instance (A, B) if the greatest fixpoint $\overline{\overline{\mathcal{I}_k(A, B)}}^{\mathbb{Z}}$ is non-empty and otherwise rejects.*
If (A, B) is accepted by this algorithm we write $A \equiv_k^{\mathbb{Z}} B$ and say that the instance (A, B) is cohomologically k-equivalent.

Finally, we observe that the existence of a non-empty subpresheaf of $\mathcal{I}_k$ satisfying the $\mathbf{BijForth}$ and $\mathbb{Z}\mathbf{bext}$ properties also satisfies the conditions for witnessing cohomological k-consistency of the pairs (A, B) and (B, A). Formally we have

▶ **Observation 7.** *For any two structures A and B, $A \equiv_k^{\mathbb{Z}} B$ implies that $A \to_k^{\mathbb{Z}} B$ and $B \to_k^{\mathbb{Z}} A$.*

In Section 5, we will demonstrate the power of these new algorithms by showing that both cohomological k-consistency and cohomological k-Weisfeiler-Leman can solve instances of CSP and SI on which the non-cohomological versions fail. Before doing this, we briefly review some other algorithms for CSP and SI which involve solving systems of linear equations and establish a possible connection to be explored in future work.

4.4 Other algorithms for CSP and SI

While the connections to cohomology in approximating CSP and SI are novel in this paper, the algorithms introduced here are not the first to use solving systems of linear equations to approximate these problems.

On the CSP side, some examples of such algorithms include the BLP+AIP [11] and CLAP [14] algorithms studied in the Promise CSP community. One difference here is that for an instance (A, B) the variables in BLP and AIP are indexed by valid assignments to each variable and to each related tuple instead of being indexed by valid k-local homomorphisms as in the algorithm derived above. This means that directly comparing these algorithms as stated is not straightforward and is beyond the scope of this paper. However, it seems likely that these algorithms can also be expressed in terms of appropriate presheaves. For example, let $\mathbf{C}(\mathbf{A})$ be the category whose objects are the elements of A and the related tuples of A and with maps for each projection from a related tuple to an element, and let the **Set**-valued presheaf $\mathcal{H}_C(A, B)$ on $\mathbf{C}(\mathbf{A})$ map any $a \in A$ to the set of all elements in B and any $\mathbf{a} \in R^A$ to the set of all related tuples R^B. Then, in a similar way to above, we can see that global sections of $\mathcal{H}_C$ are homomorphisms from A to B. In future work, we will compare the fixpoints $\overline{\mathcal{H}_C}$ and $\overline{\mathcal{H}_C}^{\mathbb{Z}}$ with solutions to the BLP and AIP systems of equations and we will explore a possible presheaf representation for CLAP.

On the SI side, Berkholz and Grohe [9] have studied $\mathbb{Z}$-linear versions of the Sherali-Adams hierarchy of relaxations of the graph isomorphism problem. They establish that no level of this hierarchy decides the full isomorphism relation on graphs. Their algorithm for the k^{th} level of the hierarchy appears similar to checking the $\mathbb{Z}$-extendability in $\mathcal{H}_k^{A,B}$ of the empty solution $\epsilon \in \mathcal{H}_k^{A,B}(\emptyset)$. A full comparison of this algorithm and the algorithm described above is an interesting direction for future work.

5 The (unreasonable) effectiveness of cohomology in CSP and SI

In this section, we prove that the new algorithms arising from this cohomological approach to CSP and SI are substantially more powerful than the k-consistency and k-Weisfeiler-Leman algorithms. In particular, we show that cohomological k-consistency resolves CSP over all domains of arity less than or equal to k which admit a ring representation and that for a fixed small k cohomological k-Weisfeiler-Leman can distinguish structures which differ on a very general form of the CFI property, in particular, showing that cohomological k-Weisfeiler-Leman can distinguish a property which Lichter [30] claims not to be expressible in rank logic.

5.1 Cohomological k-consistency solves all affine CSPs

In this section, we demonstrate the power of the cohomological k-consistency algorithm by proving that it can decide the solvability of systems of equations over finite rings.

To express the main theorem of this section in terms of the finite relational structures on which our algorithm is defined, we first need to fix a notion of ring representation of a relational structure. Let A be a relational structure over signature σ with relations given by $\{R^A\}_{R\in\sigma}$. We say that A has a *ring representation* if we can give the set A a ring structure $(A,+,\cdot,0,1)$ such that for every relational symbol $R \in \sigma$ the set $R^A \subset A^m$ is an affine subset of the ring $(A,+,\cdot,0,1)$, meaning that there exists $b_1^R,\dots,b_m^R,a^R \in A$ such that

$$R^A = \{\mathbf{x} \in A^m \mid \sum_{i\in[m]} b_i^R \cdot x_i = a^R\}$$

With this necessary background we state the main theorem of this section.

▶ **Theorem 8.** *For any structure B with a ring representation, there is a k such that the cohomological k-consistency algorithm decides* $\mathbf{CSP}(B)$.
Alternatively stated, there exists a k such that for all σ-structures A

$$A \rightarrow_k^{\mathbb{Z}} B \iff A \rightarrow B$$

Proof. See full version. ◀

This theorem is notable because there are relational structures B with ring representations for which there are families of structures A_k such that $A_k \rightarrow_k B$ but $A_k \not\rightarrow B$, see for example the examples given by Feder and Vardi [18]. Furthermore, there exist pairs (A_k, B_k) where $A_k \equiv_k B_k$, $B_k \rightarrow B$ and $A_k \rightarrow_k B$ but $A_k \not\rightarrow B$, see for example the work of Atserias, Bulatov and Dawar [6]. As the sequence of relations $\equiv_k$ bounds the expressive power of FPC, this effectively proves that the solvability of systems of linear equations over $\mathbb{Z}$, which is central to the cohomological k-consistency algorithm, is not expressible in FPC. This result was not previously known to the author.

5.2 Cohomological k-Weisfeiler-Leman decides the CFI property

The Cai-Fürer-Immerman construction [13] on ordered finite graphs is a very powerful tool for proving expressiveness lower bounds in descriptive complexity theory. While it was originally used to separate the infinitary k variable logic with counting from `PTIME`, it has since been used in adapted forms to prove bounds on invertible maps equivalence [15], computation on Turing machines with atoms [10] and rank logic [30]. In this section, we show that $\equiv_k^{\mathbb{Z}}$ separates a very general form of this

The version we consider in this paper is parameterised by a prime power q and takes any totally ordered graph $(G,<)$ and any map $g\colon E(G) \rightarrow \mathbb{Z}_q$ to a relational structure $\mathbf{CFI}_q(G,g)$. The construction effectively encodes a system of linear equations over $\mathbb{Z}_q$ based on the edges of G and the "twists" introduced by the labels g. The result is the following well-known fact.

▶ **Fact 9.** *For any prime power, q, ordered graph G, and functions $g,h\colon E(G) \rightarrow \mathbb{Z}_q$,*

$$\mathbf{CFI}_q(G,g) \cong \mathbf{CFI}_q(G,h) \iff \sum g = \sum h$$

We say that the structure $\mathbf{CFI}_q(G,g)$ has the *CFI property* if $\sum g = 0$. For more details on this construction we refer to the recent paper of Lichter [30] whose presentation we follow in the full version of this paper.

We now recall the two major separation results based on this construction. The first is a landmark result of descriptive complexity from the early 1990's.

▶ **Theorem 10** (Cai, Fürer, Immerman [13]). *There is a class of ordered (3-regular) graphs $\mathcal{G} = \{G_n\}_{n\in\mathbb{N}}$ such that in the respective class of CFI structures*

$$\mathcal{K} = \{\mathbf{CFI}_2(G,g) \mid G \in \mathcal{G}, g\colon V(G) \to \mathbb{Z}_2\}$$

the CFI property is decidable in polynomial-time but cannot be expressed in FPC.

The second is a recent breakthrough due to Moritz Lichter.

▶ **Theorem 11** (Lichter [30]). *There is a class of ordered graphs $\mathcal{G} = \{G_n\}_{n\in\mathbb{N}}$ such that in the respective class of CFI structures*

$$\mathcal{K} = \{\mathbf{CFI}_{2^k}(G,g) \mid G \in \mathcal{G}\}$$

the CFI property is decidable in polynomial-time (indeed, expressible in choiceless polynomial time) but cannot be expressed in rank logic.

Despite this CFI property proving to be inexpressible in both FPC and rank logic, we show that (perhaps surprisingly) there is a fixed k such that cohomological k-Weisfeiler-Leman algorithm can separate structures which differ on this property in the following general way. The proof of this theorem relies the on showing that $\equiv_k^{\mathbb{Z}}$ behaves well with logical interpretations and the details are left to the full version of this paper.

▶ **Theorem 12.** *There is a fixed k such that for any q given $\mathbf{CFI}_q(G,g)$ and $\mathbf{CFI}_q(G,h)$ with $\sum g = 0$ we have*

$$\mathbf{CFI}_q(G,g) \equiv_k^{\mathbb{Z}} \mathbf{CFI}_q(G,h) \iff \mathbf{CFI}_q(G,g) \cong \mathbf{CFI}_q(G,h)$$

Proof. See full version. ◀

As a direct consequence of this result, there is some k such that the set of structures with the CFI property in Lichter's class $\mathcal{K}$ from Theorem 11 is closed under $\equiv_k^{\mathbb{Z}}$. This means that, by the conclusion of Theorem 11, the equivalence relation $\equiv_k^{\mathbb{Z}}$ can distinguish structures which disagree on a property that is not expressible in rank logic. Indeed, Dawar, Grädel and Lichter [16] show further that this property is also inexpressible in linear algebraic logic. By the definition of our algorithm for $\equiv_k^{\mathbb{Z}}$ this implies that solvability of systems of $\mathbb{Z}$-linear equations is not definable in linear algebraic logic.

6 Conclusions & future work

In this paper, we have presented novel approach to CSP and SI in terms of presheaves and have used this to derive efficient generalisations of the k-consistency and k-Weisfeiler-Leman algorithms, based on natural considerations of presheaf cohomology. We have shown that the relations, $\to_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$, computed by these new algorithms are strict refinements of their well-studied classical counterparts $\to_k$ and $\equiv_k$. In particular, we have shown in Theorem 8 that cohomological k-consistency suffices to solve linear equations over all finite rings and in Theorem 12 that cohomological k-Weisfeiler-Leman distinguishes positive and negative instances of the CFI property on the classes of structures studied by Cai, Fürer and Immerman [13] and more recently by Lichter [30]. These results have important consequences for descriptive complexity theory showing, in particular, that the solvability of systems of linear equations over $\mathbb{Z}$ is not expressible in FPC, rank logic or linear algebraic logic. Furthermore, the results of this paper demonstrate the unexpected effectiveness of a cohomological approach to constraint satisfaction and structure isomorphism, analogous to that pioneered by Abramsky and others for the study of quantum contextuality.

The results of this paper suggest several directions for future work to establish the extent and limits of this cohomological approach. We ask the following questions which connect it to important themes in algorithms, logic and finite model theory.

Cohomology and constraint satisfaction. Firstly, Bulatov and Zhuk's recent independent resolutions of the Feder-Vardi conjecture [12, 35], show that for all domains B either $\mathbf{CSP}(B)$ is `NP-Complete` or B admits a weak near-unanimity polymorphism and $\mathbf{CSP}(B)$ is tractable. As the cohomological k-consistency algorithm expands the power of the k-consistency algorithm which features as one case of Bulatov and Zhuk's general efficient algorithms, we ask if it is sufficient to decide all tractable **CSP**s.

▶ **Question 13.** *For all domains B which admit a weak near-unanimity polymorphism, does there exists a k such that for all A*

$$A \to B \iff A \to_k^{\mathbb{Z}} B?$$

Cohomology and structure isomorphism. Secondly, as cohomological k-Weisfeiler-Leman is an efficient algorithm for distinguishing some non-isomorphic relational structures we ask if it distinguishes all non-isomorphic structures. As the best known structure isomorphism algorithm is quasi-polynomial [8], we do not expect a positive answer to this question but expect that negative answers would aid our understanding of the hard cases of structure isomorphism in general.

▶ **Question 14.** *For every signature σ does there exists a k such that for all σ-structures A, B*

$$A \cong B \iff A \equiv_k^{\mathbb{Z}} B?$$

Cohomology and game comonads. Thirdly, as $\to_k$ and $\equiv_k$ have been shown by Abramsky, Dawar, and Wang [4] to be correspond to the coKleisli morphisms and isomorphisms of a comonad $\mathbb{P}_k$, we ask whether a similar account can be given to $\to_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$. As the coalgebras of the $\mathbb{P}_k$ comonad relate to the combinatorial notion of treewidth, an answer to this question could provide a new notion of "cohomological" treewidth.

▶ **Question 15.** *Does there exist a comonad $\mathbb{C}_k$ for which the notion of morphism and isomorphism in the coKleisli category are $\to_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$?*

The search for a logic for `PTIME`. Finally, as the algorithms for $\to_k^{\mathbb{Z}}$ and $\equiv_k^{\mathbb{Z}}$ are likely expressible in rank logic extended with a quantifier for solving systems of linear equations over $\mathbb{Z}$ and as $\equiv_k^{\mathbb{Z}}$ distinguishes all the best known family separating rank logic from `PTIME`, we ask if solving systems of equations over $\mathbb{Z}$ is enough to capture all `PTIME` queries.

▶ **Question 16.** *Is there a logic FPC+rk+$\mathbb{Z}$ incorporating solvability of $\mathbb{Z}$-linear equations into rank logic which captures `PTIME`?*

Deciding Emptiness for Constraint Automata on Strings with the Prefix and Suffix Order

Dominik Peteler ✉
Universität Leipzig, Germany

Karin Quaas ✉
Universität Leipzig, Germany

Abstract

We study constraint automata that accept data languages on finite string values. Each transition of the automaton is labelled with a constraint restricting the string value at the current and the next position of the data word in terms of the prefix and the suffix order. We prove that the emptiness problem for such constraint automata with Büchi acceptance condition is NL-complete. We remark that since the constraints are formed by two partial orders, prefix and suffix, we cannot exploit existing techniques for similar formalisms. Our decision procedure relies on a decidable characterization for those infinite paths in the graph underlying the automaton that can be completed with string values to yield a Büchi-accepting run. Our result is - to the best of our knowledge - the first work in this context that considers both prefix and suffix, and it is a first step into answering an open question posed by Demri and Deters.

1 Introduction

Motivated by applications in formal verification, automated reasoning and databases, logics and automata over *infinite* alphabets are in the focus of active and broad research activities in theoretical computer science. A typical example for logics over infinite alphabets is *constraint linear temporal logic*, CLTL for short [2, 10, 11, 9, 6, 5, 14]. CLTL extends classical LTL with a finite set of variables ranging over the domain of some infinite relational structure like $(\mathbb{N};=)$ or $(\mathbb{Q};<)$. Atomic formulas in CLTL are *constraints* in terms of the variables and the relation symbols from the structure; atomic formulas can be combined with Boolean operations and the usual temporal modalities. Models of CLTL formulas are *data words*, that is, infinite sequences of data values coming from the domain of the relational structure. For instance, the CLTL formula $\mathsf{G}(\mathsf{X}x < x)$ over the relational structure $(\mathbb{Z};<)$ states: "globally, the value of the variable x at the next position is smaller than the value of x at the current position". The data word $4, 3, 2, 1, 0, -1, -2, \ldots$ is a model of this formula. Note that the same formula has no model if instead of $(\mathbb{Z};<)$ we evaluate the formula over the relational structure $(\mathbb{N};<)$ – this to illustrate that deciding the satisfiability of a given formula in this logic heavily relies on the considered relational structure.

A natural counterpart to CLTL are *constraint automata* [7, 15, 28, 19]. Like CLTL, constraint automata are parameterized over a relational structure. Transitions are labelled with constraints in terms of the variables of the automaton and the relation symbols from the

structure; the satisfaction of the constraints along a transition determines the behaviour of the automaton. Constraint automata generalize Büchi automata and accept data languages, that is sets of data words. Following the classical automata-theoretic approach by Vardi and Wolper, one can reduce the satisfiability problem for CLTL to the non-emptiness problem for constraint automata (cf. [29, 14]). We remark that constraint automata are very much related to the well known class of register automata [17, 24, 13, 4, 8].

For CLTL, constraint automata, and other formalisms parameterized over relational structures, a lot of remarkable results concerning satisfiability, model-checking, and the emptiness problem have been achieved, see [14] for a recent survey. This includes results for specific relational structures – for instance, the satisfiability problem for CLTL over $(\mathbb{Z}; <)$ is PSPACE-complete [2, 10] – but there are also noteworthy unifying approaches that capture logics and automata over certain *classes* of, e.g., linear orders [28, 6, 5] or oligomorphic data domains [3].

In contrast to linear orders, relatively little is known about relational structures where the domain equals the set of strings A^* over some fixed (finite or countably infinite) alphabet A, and relations defined over A^*, like the *prefix order* or the *subsequence order*. While relational structures over linear orders are useful for analysing systems that manipulate counters or constrain real-timed variables, relational structures over strings are interesting for reasoning about systems that manipulate pushdown stacks, queues, or other data structures that involve strings. Reasoning on string variables has a long tradition in theoretical computer science, with roots in algebra and combinatorics on words, and recent developments in the area of string constraint solving (see [1] for a recent survey). Several works concern first-order (FO) logics over finite strings [20, 18, 16, 21]. Thereof, a recent undecidability result [16] for the Σ_1-fragment of FO logic over $(\Sigma^*; \leq_{\text{sub}}, (=w)_{w\in\Sigma^*})$, where Σ is a finite alphabet and $\leq_{\text{sub}}$ denotes the subsequence order over Σ^*, immediately implies the undecidability of the satisfiability problem for CLTL over that structure. Regarding the relational structure $(A^*; <_p, =, (=w)_{w\in A^*})$, where $<_p$ is the prefix order over A^*, we know: the satisfiability problem for constraint LTL is PSPACE-complete (by an interesting reduction to the same problem for $(\mathbb{N}; <, =, (=n)_{n\in\mathbb{N}})$) [9]. The emptiness problem for constraint automata is PSPACE-complete [19]. On the other hand, a unifying, model-theoretic approach for a large family of temporal logics, including ECTL*, which is applicable to linear orders, fails for the prefix order over finite strings [5].

Demri and Deters proposed to study the satisfiability problem for CLTL when evaluated over the structure $(A^*; <_p, <_s, =, (=w)_{w\in A^*})$ with both the prefix and the suffix order [9]. This enables us to express properties like "the beginning of the content of a string is equal to the end of some other string". Using the obvious symmetry between the prefix order and the suffix order, one can conclude that the above mentioned results for the prefix order hold for the relational structure where $<_p$ is *replaced* by $<_s$ [9]. However, the situation changes drastically when both $<_p$ and $<_s$ are in the relational structure. For instance, the FO theory on the prefix order alone is decidable [27], but becomes undecidable for the relational structure containing both prefix and suffix (this follows from the undecidability result for the FO theory for the substring (infix) order [20], and the fact that the substring order is FO-definable using prefix and suffix). For finite strings over a finite alphabet, it has been remarked in [9] that the Σ_1-fragment of FO logics is decidable, using an algorithm based on the word equation approach by Makanin [22, 26]. It is thus far from clear whether satisfiability for CLTL, or, equivalently, the emptiness problem for constraint automata, is decidable or not. The techniques used in other works for, e.g. the prefix order alone, or linear orders, turn out to be not applicable at all.

In this paper, we prove that the emptiness problem for constraint automata over prefix and suffix is decidable in NL if the automaton uses only a single variable. This is a standard restriction, comparable to one-counter automata [12] or single-clock timed automata [25]. Our decision procedure relies on a reduction to reachability queries on the finite graph underlying the automaton, and it applies to finite strings over both finite and countably infinite alphabets. We may also test whether the string equals the empty string (similar to a zero test in one-counter automata). We further obtain NL-completeness for the emptiness problem for single-register automata over this relational structure. Last but not least, our result implies PSPACE-completeness for the satisfiability of CLTL for the case that the formulas in CLTL only use a single variable.

We leave open the decidability status for the case where equality with arbitrary finite strings over A and/or constraints involving more than one variable are allowed, that is, by now we cannot fully answer the question raised by Demri and Deters. We remark that both extensions may be harmful: for instance, while emptiness is decidable for one-counter automata [12], it is undecidable for two-counter automata [23]; while the Σ_1-fragment of FO logic for finite strings over a finite alphabet with the subsequence order *without constants* is decidable [20], it is undecidable as soon as we allow constants in the relational structure [16].

2 Preliminaries

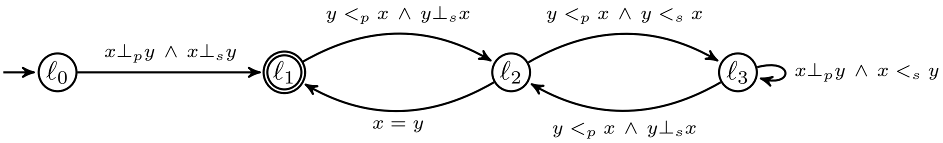
A *relational signature* $\sigma = \{R_1, R_2, \dots\}$ is a countable set of relation symbols. Each symbol R_i is associated with some non-negative arity k_i. A *relational structure over* σ, or σ*-structure* for short, is a tuple $\mathcal{D} = (D; R_1^{\mathcal{D}}, R_2^{\mathcal{D}}, \dots)$, where D is the domain of the structure, and $R_i^{\mathcal{D}} \subseteq D^{k_i}$ is the interpretation of the symbol R_i in D. We will often omit the symbol $\mathcal{D}$ in $R_i^{\mathcal{D}}$ and simply write R_i instead.

We use Σ to denote a finite alphabet, $\mathbb{N}$ as a countably infinite alphabet, and A as finite or countably infinite alphabet. We use A^* to denote the set of finite strings over A. The symbol ε denotes the empty string, and we use A^+ to denote the set $A^* \setminus \{\varepsilon\}$ of non-empty strings over A. Given $u, v \in A^*$, we say that u is a *strict prefix* (*strict suffix*, respectively) of v, written $u <_p v$ ($u <_s v$, respectively), if $v = u \cdot u'$ ($v = u' \cdot u$, respectively) for some $u' \in A^+$. We say that u and v are *incomparable with respect to the prefix order*, written $u \perp_p v$, if $u = w \cdot a \cdot u'$ and $v = w \cdot b \cdot v'$ for some $w \in A^*$, $a, b \in A$ such that $a \neq b$, and $u', v' \in A^*$. *Incomparability with respect to the suffix order*, written $u \perp_s v$, is defined analogously.

Let σ^{ps} be the signature consisting of the binary symbols $<_p$, $<_s$, and $=$. In this paper, we are interested in the σ^{ps}-structures $(\Sigma^*; <_p, <_s, =)$ and $(\mathbb{N}^*; <_p, <_s, =)$, where, in both structures, $<_p$ and $<_s$ are interpreted as the prefix and the suffix order over the set of strings over Σ and $\mathbb{N}$, respectively, and $=$ is interpreted as the identity. If the context is clear, we may write Σ^* and $\mathbb{N}^*$ to denote the respective structures, and A^* to denote any of these structures.

Constraint automata are generalizations of Büchi automata that are parameterized by σ-structures, where σ is a relational signature. The transitions are labelled with Boolean combinations of atomic formulas, called *constraints*, in terms of the relations of the σ-structure. A constraint automaton processes *data words*. A data word is a finite or infinite sequence $d_1, d_2, d_3 \dots$, where $d_i \in D$ is a data value from the domain of the σ-structure. A transition of a constraint automaton can be taken if the current and the next data value of the processed data word satisfy the constraint labelling the transition.

In the following, we assume that constraint automata are parameterized by the σ^{ps}-structures Σ^* or $\mathbb{N}^*$, and the transitions are labelled by Boolean combinations of atomic formulas of the form $z \bowtie z'$, where $z, z' \in \{x, y\}$ and $\bowtie \in \sigma^{ps}$. Intuitively, x stands for



ℓ_0
ℓ_1
ℓ_2
ℓ_3
$x\perp_p y \wedge x\perp_s y$
$y <_p x \wedge y\perp_s x$
$x = y$
$y <_p x \wedge y <_s x$
$y <_p x \wedge y\perp_s x$
$x\perp_p y \wedge x <_s y$

Figure 1 Example of a constraint automaton over A^*

the string at the current position, and y stands for the string at the next position of the processed data word. For the sake of readability we will restrict the labels of the transitions to be *maximally consistent*. Formally, we define Ψ to be the set of formulas $\psi(x, y)$ of the following form:

$$\begin{array}{cccc} x = y, & x <_p y \wedge x <_s y, & x <_p y \wedge x\perp_s y, & x\perp_p y \wedge x <_s y \\ y <_p x \wedge y <_s x, & y <_p x \wedge y\perp_s x, & y\perp_p x \wedge y <_s x, & x\perp_p y \wedge x\perp_s y. \end{array}$$

Each of these formulas is called *constraint*. Constraints that contain the formula $y <_p x$ or $y <_s x$ are called *reducing* as they reduce the length of the string at the next position with regard to the string at the current position. All other constraints except for $x = y$ are called *generous*, because they allow for infinitely many choices of the string value at the next position. The satisfaction relation $\models$ is defined in the obvious way. For instance, if ψ is of the form $x <_p y \wedge x <_s y$, then we have $\mathbb{N}^* \models \psi(0, 01210)$ and $\Sigma^* \not\models \psi(a, abab)$.

A *constraint automaton* over a σ^{ps}-structure A^* is a tuple $\mathcal{A} = (\mathcal{L}, \ell_{\text{in}}, \mathcal{L}_{\text{acc}}, E)$, where

- $\mathcal{L}$ is a finite set of locations (control states);
- $\ell_{\text{in}} \in \mathcal{L}$ is the initial location;
- $\mathcal{L}_{\text{acc}} \subseteq \mathcal{L}$ is the set of accepting locations; and
- $E \subseteq \mathcal{L} \times \Psi \times \mathcal{L}$ is the set of edges.

A *path* of $\mathcal{A}$ is a finite or infinite sequence $\ell_0, \ell_1, \ell_2, \ldots$ of locations satisfying, for all $i \geq 1$, $(\ell_{i-1}, \psi_i, \ell_i) \in E$ for some constraint $\psi_i \in \Psi$. We may sometimes also write $\ell_0 \xrightarrow{\psi_1} \ell_1 \xrightarrow{\psi_2} \ell_2, \ldots$ to indicate the precise edges that are used. A finite path $\ell_0 \xrightarrow{\psi_1} \ell_1 \xrightarrow{\psi_2} \ell_2 \ldots \xrightarrow{\psi_n} \ell_n$ is *stable* if ψ_i is of the form $x = y$ for all $1 \leq i \leq n$; it is *generous* if there exists some $1 \leq i \leq n$ such that ψ_i is generous. A path as above is a *cycle starting in* ℓ_0 if $\ell_0 = \ell_n$.

A *state* of $\mathcal{A}$ is a pair (ℓ, w), where $\ell \in \mathcal{L}$ and $w \in A^*$ is the current value of the string variable. We postulate a labelled transition relation $\rightarrow$ over the set $\mathcal{L} \times A^*$ of states of $\mathcal{A}$, as follows: $(\ell, w) \rightarrow (\ell, w')$ if there exists a transition $(\ell, \psi(x, y), \ell') \in E$ such that $A^* \models \psi(w, w')$. A *run* of $\mathcal{A}$ is a finite or infinite sequence of transitions of $\mathcal{A}$. A run $(\ell_0, w_0) \rightarrow (\ell_1, w_1) \rightarrow (\ell_2, w_2) \ldots$ is *initialized* if $\ell_0 = \ell_{\text{in}}$. A run is *Büchi-accepting* if it is initialized and it contains infinitely many locations in $\mathcal{L}_{\text{acc}}$. We define the language of $\mathcal{A}$ by $L(\mathcal{A}) = \{(w_0 w_1 w_2 \cdots \mid (\ell_0, w_0) \rightarrow (\ell_1, w_1) \rightarrow (\ell_2, w_2) \ldots$ is a Büchi-accepting run of $\mathcal{A}\}$.

For an example, consider the constraint automaton $\mathcal{A} = (\{\ell_0, \ell_1, \ell_2, \ell_3\}, \ell_0, E, \{\ell_1\})$ over $\mathbb{N}^*$, where E is as depicted in Figure 1. A finite initialized run of this automaton is $(\ell_0, 20) \rightarrow (\ell_1, 346345346343) \rightarrow (\ell_2, 34634534634) \rightarrow (\ell_3, 34634) \rightarrow (\ell_2, 346)$ (cf. Example 6).

The *emptiness problem* for constraint automata is to decide, given a constraint automaton $\mathcal{A}$, whether $L(\mathcal{A}) = \emptyset$. In section 4, we prove that this problem is NL-complete.

3 Rewriting Operation

For deciding the emptiness problem, we will prove the existence of string values that satisfy the constraints that occur in a given path. During the process of defining such string values, we will need to change already defined string values using a *rewriting operation*. In this section, we define this operation and prove some important properties.

Recall that A denotes a finite or countably infinite alphabet. Given $w \in A^*$ and two non-empty strings $u, u' \in A^+$, we define the *left-to-right rewriting operation of u to u' in w*, denoted by $w[u \leftarrow u']_\triangleright$, to be the string that is obtained from w by replacing, from left to right, every occurrence of u in w by u'. Formally, assume $w = a_1 a_2 \ldots a_n$ and define, recursively, $w[u \leftarrow u']_\triangleright := w$ if $a_i a_{i+1} \ldots a_{i+|u|-1} \neq u$ for all $1 \leq i \leq n$ (that is, u does not occur in w), $w[u \leftarrow u']_\triangleright := a_1 \ldots a_{i-1} \cdot u' \cdot ((a_{i+|u|} \ldots a_n)[u \leftarrow u']_\triangleright)$ if $1 \leq i \leq n$ is the minimal index such that $a_i a_{i+1} \ldots a_{i+|u|-1} = u$. Note that if u occurs in $a_1 \ldots a_{i-1} \cdot u'$, then u is not replaced in any further steps of the recursive definition. For instance, $1100210[10 \leftarrow 1]_\triangleright = 11021$. We define completely analogously the right-to-left version of this operation, that is, $w[u \leftarrow v]_\triangleleft := w$ if u does not occur in w, and $w[u \leftarrow v]_\triangleleft := ((a_1 \ldots a_{i-1})[u \leftarrow u']_\triangleright) \cdot u' \cdot a_{i+|u|} \ldots a_n$, if $i \geq 1$ is the maximal index such that $a_i \ldots a_{i+|u|-1} = u$. Note that $w[u \leftarrow v]_\triangleright$ may be different from $w[u \leftarrow v]_\triangleleft$; for instance, $w = 111$, $u = 11$ and $v = 0$ yields $w[u \leftarrow v]_\triangleright = 01$ and $w[u \leftarrow v]_\triangleleft = 10$. It is easy to see that this is the case if there exist two overlapping occurrences of u in w. Formally, we say that *u is overlapping in w* if there exist $1 \leq i < j < i + |u| \leq n$ such that $a_i a_{i+1} \ldots a_{i+|u|-1} = a_j a_{j+1} \ldots a_{j+|u|-1} = u$. The proof of the following lemma is simple.

▶ **Lemma 1.** *For all $w \in A^*$ and $u, u' \in A^+$, if u is not overlapping in w, then we have $w[u \leftarrow u']_\triangleright = w[u \leftarrow u']_\triangleleft$.*

In Subsection 4.1 we will guarantee that the rewriting operation is only applied to strings w and u such that u is not overlapping in w, so that the left and right versions of rewriting yield the same string. The reason why we still define both the left and right version of rewriting is that certain properties of the prefix order – stated in the next lemma – can be proved very conveniently using the left-to-right rewriting operation, and the same properties can be proved symmetrically for the suffix order using the right-to-left rewriting operation (Lemma 3).

▶ **Lemma 2.** *For all $u, u' \in A^+$ with $u <_p u'$, for all $w, w' \in A^*$, and for all $\bowtie \in \{=, <_p, \perp_p\}$ we have*

$$w \bowtie w' \iff w[u \leftarrow u']_\triangleright \bowtie w'[u \leftarrow u']_\triangleright.$$

Proof. Let $u, u' \in A^+$ be such that $u <_p u'$, that is, there exists some $u'' \in A^+$ such that $u' = u \cdot u''$. Let $w, w' \in A^*$ be of the form $w = a_1 a_2 \ldots a_m$ and $w' = a'_1 a'_2 \ldots a'_n$. Let N and N', respectively, be the number of (non-overlapping, from left to right) occurrences of u in w and w', respectively. The proof is by induction on the sum $i := N + N'$. For the induction base, assume $i = 0$. But then $w[u \leftarrow u']_\triangleright = w$ and $w'[u \leftarrow u']_\triangleright = w'$, so that the claim clearly holds. For the induction step, suppose that the claim holds for all $0 \leq j < i$. We prove the claim for i. We distinguish three cases:

1. $N = i$ and $N' = 0$. By $N = i > 0$, w contains u. Since $u <_p u'$, also $w[u \leftarrow u']_\triangleright$ contains u. By $N' = 0$, w' does not contain u and $w'[u \leftarrow u']_\triangleright = w'$, so that $w'[u \leftarrow u']_\triangleright$ does not contain u either. Using this, it is easy to see that none of the following cases can hold: $w = w'$, $w <_p w'$, $w[u \leftarrow u']_\triangleright = w'[u \leftarrow u']_\triangleright$ and $w[u \leftarrow u']_\triangleright <_p w'[u \leftarrow u']_\triangleright$. So let us prove $w \perp_p w' \iff w[u \leftarrow u']_\triangleright \perp_p w'$. For this suppose $w[u \leftarrow u']_\triangleright$ is of the form

$b_1 b_2 \dots b_q$. Let $1 \leq d \leq e \leq m$ be such that $a_d \dots a_e = u$ is the *first* occurrence of u in w. By $u <_p u'$, $b_d \dots b_e = u$ is also the first occurrence of u in $w[u \leftarrow u']_{\triangleright}$, and hence $a_1 \dots a_e = b_1 \dots b_e$. We hence obtain

$$\begin{aligned} & w \perp_p w' \\ \iff \quad & \exists k \leq e \text{ such that } a_1 \dots a_{k-1} = a'_1 \dots a'_{k-1} \text{ and } a_k \neq a'_k \\ \iff \quad & \exists k \leq e \text{ such that } b_1 \dots b_{k-1} = a'_1 \dots a'_{k-1} \text{ and } b_k \neq a'_k \\ \iff \quad & w[u \leftarrow u']_{\triangleright} \perp_p w' \end{aligned}$$

where $k \leq e$ holds by the fact that u is not contained in w'.

2. $N = 0$ and $N' = i$. By $N = 0$, w does not contain u and hence neither does $w[u \leftarrow u']_{\triangleright}$ as $w[u \leftarrow u']_{\triangleright} = w$. By $N' = i > 0$, w' contains u. Using this, it is easy to see that the following two cases cannot hold: $w = w'$ and $w[u \leftarrow u']_{\triangleright} = w'[u \leftarrow u']_{\triangleright}$. The proof for $w \perp_p w' \iff w \perp_p w'[u \leftarrow u']_{\triangleright}$ is symmetric to the proof in the previous case. So let us prove $w <_p w' \iff w <_p w'[u \leftarrow u']_{\triangleright}$. For this let $w'[u \leftarrow u']_{\triangleright}$ be of the form $b'_1 \dots b'_q$. Let $1 \leq d \leq e \leq n$ be such that $a'_d \dots a'_e = u$ is the *first* occurrence of u in w'. By $u <_p u'$, $b'_d \dots b'_e = u$ is also the first occurrence of u in $w'[u \leftarrow u']_{\triangleright}$, and hence $a'_1 \dots a'_e = b'_1 \dots b'_e$. We hence obtain

$$\begin{aligned} & w <_p w' \\ \iff \quad & a_1 \dots a_m = a'_1 \dots a'_m \\ \iff \quad & a_1 \dots a_m = b'_1 \dots b'_m \\ \iff \quad & w <_p w'[u \leftarrow u']_{\triangleright} \end{aligned}$$

where the second equivalence holds because $m < e$ (as otherwise u would be contained in w).

3. $N > 0$ and $N' > 0$. Let $1 \leq d \leq e \leq m$ be such that $a_d \dots a_e = u$ is the first occurrence of u in w, and similarly, let $1 \leq d' \leq e' \leq n$ be such that $a'_{d'} \dots a'_{e'} = u$ is the first occurrence of u in w'. In other words, we can write

$$w = a_1 \dots a_{d-1} \cdot u \cdot v \quad \text{and} \quad w' = a'_1 \dots a'_{d'-1} \cdot u \cdot v',$$

where $v = a_e \dots a_m$ and $v' = a'_{e'} \dots a'_n$. By definition and $u' = u \cdot u''$, we have

$$w[u \leftarrow u']_{\triangleright} = a_1 \dots a_{d-1} \cdot u \cdot u'' \cdot (v[u \leftarrow u']_{\triangleright})$$

and

$$w'[u \leftarrow u']_{\triangleright} = a'_1 \dots a'_{d'-1} \cdot u \cdot u'' \cdot (v'[u \leftarrow u']_{\triangleright}).$$

We distinguish four cases:

a. $a_1 \dots a_{d-1} \cdot u = a'_1 \dots a'_{d'-1} \cdot u$. This implies

$$w \bowtie w' \iff v \bowtie v' \quad \text{and} \quad w[u \leftarrow u']_{\triangleright} \bowtie w'[u \leftarrow u']_{\triangleright} \iff v[u \leftarrow u']_{\triangleright} \bowtie v'[u \leftarrow u']_{\triangleright}$$

for $\bowtie \in \{<_p, =, \perp_p\}$. The sum $M + M'$ of the occurrences of u in v and v' must be strictly smaller than i. By induction hypothesis,

$$v \bowtie v' \iff v[u \leftarrow u']_{\triangleright} \bowtie v'[u \leftarrow u']_{\triangleright}.$$

Hence the result.

b. $a_1 \dots a_{d-1} \cdot u <_p a'_1 \dots a'_{d'-1} \cdot u$. This contradicts the minimality of d', and hence this case cannot happen.

c. $a'_1 \dots a'_{d'-1} \cdot u <_p a_1 \dots a_{d-1} \cdot u$. This contradicts the minimality of d, and hence this case cannot happen.

d. $a_1 \dots a_{d-1} \cdot u \perp_p a'_1 \dots a'_{d'-1} \cdot u$. Hence there exists some $1 \leq j \leq \min(d-1, d'-1)$ such that $a_1 \dots a_{j-1} = a'_1 \dots a'_{j-1}$ and $a_j \neq a'_j$. This immediately implies $w \perp_p w'$ and also $w[u \leftarrow u']_\triangleright \perp_p w'[u \leftarrow u']_\triangleright$, hence the result. ◀

A proof for the following lemma can be done symmetrically to the proof of Lemma 2.

▶ **Lemma 3.** *For all $u, u' \in A^+$ and $w, w' \in A^*$, if $u <_s u'$, then $w \bowtie w'$ if, and only if, $w[u \leftarrow u']_\triangleleft \bowtie w'[u \leftarrow u']_\triangleleft$ for all $\bowtie \in \{=, <_s, \perp_s\}$.*

The following lemma will be crucial in Subsection 4.1.

▶ **Lemma 4.** *For all $v, w \in A^*$ and $u, u' \in A^+$, if u is not overlapping in v, u is not overlapping in w, $u <_p u'$, and $u <_s u'$, then $A^* \models \psi(v, w)$ if, and only if, $A^* \models \psi(v[u \leftarrow u']_\triangleright, w[u \leftarrow u']_\triangleright)$ for all $\psi \in \Psi$.*

Proof. The proof is an easy case distinction depending on the form of ψ. We give the proof for ψ being of the form $x <_p y \wedge x \perp_s y$.

$$\begin{aligned}
& \mathbb{N}^* \models \psi(v, w) \\
\iff & v <_p w \text{ and } v \perp_s w \quad \text{(by definition)} \\
\iff & v[u \leftarrow u']_\triangleright <_p w[u \leftarrow u']_\triangleright \text{ and } v \perp_s w \quad \text{(by Lemma 2)} \\
\iff & v[u \leftarrow u']_\triangleright <_p w[u \leftarrow u']_\triangleright \text{ and } v[u \leftarrow u']_\triangleleft \perp_s w[u \leftarrow u']_\triangleleft \quad \text{(by Lemma 3)} \\
\iff & v[u \leftarrow u']_\triangleright <_p w[u \leftarrow u']_\triangleright \text{ and } v[u \leftarrow u']_\triangleright \perp_s w[u \leftarrow u']_\triangleright \quad \text{(by Lemma 1)} \\
\iff & \mathbb{N}^* \models \psi(v[u \leftarrow u']_\triangleright, w[u \leftarrow u']_\triangleright) \quad \text{(by definition)}
\end{aligned}$$

The proofs for the other cases are completely analogous. ◀

4 Deciding Emptiness for Constraint Automata over $\mathbb{N}^*$

In this section, we solve the emptiness problem for constraint automata over $\mathbb{N}^*$. We start in the next subsection with presenting an algorithm that returns for every *finite* sequence of constraints $\psi_1, \dots, \psi_n$ a sequence of string values $w_0, w_1, \dots, w_n$ such that $\mathbb{N}^* \models \psi_i(w_{i-1}, w_i)$ for all $1 \leq i \leq n$. The sequence $\psi_1, \dots, \psi_n$ may correspond to the sequence of constraints occurring in a finite path $\pi = \ell_0 \xrightarrow{\psi_1} \dots \xrightarrow{\psi_n} \ell_n$ of a constraint automaton $\mathcal{A}$, and by constructing string values $w_0, w_1, \dots, w_n$ we actually prove that π can be completed to a finite run $(\ell_0, w_0) \xrightarrow{\psi_1} \dots \xrightarrow{\psi_n} (\ell_n, w_n)$ of $\mathcal{A}$. This already implies NL-membership of the reachability problem for constraint automata (Corollary 8).

We remark that for *infinite* sequences of constraints $\psi_1, \psi_2, \dots$ it is not the case that we can always find string values $w_0, w_1, \dots$ satisfying $\mathbb{N}^* \models \psi_i(w_{i-1}, w_i)$. Consider for instance the sequence $(x \perp_p y \wedge x \perp_s y)\,(y <_p x \wedge y \perp_s x)^\omega$ (cf. Figure 1). The constraint $y <_p x \wedge y \perp_s x$ is reducing and requires the strings in the ω-sequence to become shorter infinitely often, which is impossible. In Subsection 4.2 we give a characterization for when infinite paths can be extended to infinite runs, which, together with the results obtained before, yields a decision procedure for the emptiness problem.

For the rest of this section, let $\mathcal{A} = (\mathcal{L}, \ell_{\text{in}}, \mathcal{L}_{\text{acc}}, E)$ be a constraint automaton over $\mathbb{N}^*$.

4.1 Extending Finite Paths to Finite Runs

The main part of this subsection is dedicated to prove the following result.

▶ **Proposition 5.** *For every sequence $\psi_1, \ldots, \psi_n$ of constraints in Ψ and non-empty string $w_{\text{in}} \in \mathbb{N}^+$, we can define non-empty strings $w_0, w_1, \ldots, w_n \in \mathbb{N}^+$ such that $\mathbb{N}^* \models \psi_i(w_{i-1}, w_i)$ for all $1 \leq i \leq n$. Moreover, if ψ_1 is generous, then $w_0 = w_{\text{in}}$.*

Let $\psi_1, \ldots, \psi_n$ be a finite sequence of constraints in Ψ, and let w_{in} be an initial non-empty string value. The idea is to construct, one after the other, string values that satisfy the constraints. During the process, formerly defined string values may need to be rewritten using the left-to-right-rewriting operation defined in Section 3 (so that w_0 may not be equal to the input string w_{in}). We take advantage of the fact that we have an unbounded supply of "fresh" letters as we operate on the infinite alphabet $\mathbb{N}$: we can assign string values in such a way that constraints that are satisfied *before* a rewriting still hold true *after* a rewriting. Given a string $w \in \mathbb{N}^*$, we let $\max(w)$ be the maximal number occurring as a letter in w if $w \neq \varepsilon$ and $\max(w) = 0$ otherwise.

For $1 \leq i \leq n$, suppose we have already defined string values $w_0^{i-1}, w_1^{i-1}, \ldots, w_{i-1}^{i-1}$ such that $\mathbb{N}^* \models \psi_j(w_{j-1}^{i-1}, w_j^{i-1})$ for all $1 \leq j < i$, where $w_0^0 = w_{\text{in}}$. Define $M_i = \max\{w_0^{i-1}, \ldots, w_{i-1}^{i-1}\} + 1$, so that M_i is a "fresh" letter not occurring in any of the already defined string values. Depending on the form of ψ_i, we define $w_0^i, w_1^i, \ldots, w_i^i$ such that $\mathbb{N}^* \models \psi_j(w_{j-1}^i, w_j^i)$ for all $1 \leq j \leq i$. We consider the following cases:

1. ψ_i is of the form $x = y$. Define $w_i^i = w_{i-1}^{i-1}$, and $w_j^i = w_j^{i-1}$ for all $0 \leq j < i$.
2. ψ_i is of the form $x <_p y \wedge x <_s y$. Define $w_i^i = w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}$, and $w_j^i = w_j^{i-1}$ for all $0 \leq j < i$.
3. ψ_i is of the form $x <_p y \wedge x \bot_s y$. Define $w_i^i = w_{i-1}^{i-1} \cdot M_i$, and $w_j^i = w_j^{i-1}$ for all $0 \leq j < i$.
4. ψ_i is of the form $x \bot_p y \wedge x <_s y$. Define $w_i^i = M_i \cdot w_{i-1}^{i-1}$, and $w_j^i = w_j^{i-1}$ for all $0 \leq j < i$.
5. ψ_i is of the form $y <_p x \wedge y <_s x$. Define $w_i^i = w_{i-1}^{i-1}$, and for all $0 \leq j < i$ define $w_j^i = w_j^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]_\triangleright$.
6. ψ_i is of the form $y <_p x \wedge y \bot_s x$. Define $w_i^i = w_{i-1}^{i-1} \cdot M_i$, and for all $0 \leq j < i$ define $w_j^i = w_j^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]_\triangleright$.
7. ψ_i is of the form $y \bot_p x \wedge y <_s x$. Define $w_i^i = M_i \cdot w_{i-1}^{i-1}$, and for all $0 \leq j < i$ define $w_j^i = w_j^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]_\triangleright$.
8. ψ_i is of the form $x \bot_p y \wedge x \bot_s y$. Define $w_i^i = M_i$ and $w_j^i = w_j^{i-1}$ for all $0 \leq j < i$.

▶ **Example 6.** Let us illustrate the construction with the sequence ψ_1, ψ_2, ψ_3 and $w_{\text{in}} = 3$, where $\psi_1 = \psi_3 = (y <_p x \wedge y \bot_s x)$, and $\psi_2 = (y <_p x \wedge y <_s x)$. For $i = 1$, we are in case **6**. We have $M_1 = 4$ and obtain $w_1^1 = w_0^0 \cdot M_1 = 34$ and $w_0^1 = w_0^0[3 \leftarrow 343]_\triangleright = 343$. Clearly $\mathbb{N}^* \models \psi_1(w_0^1, w_1^1)$. For $i = 2$, we are in case **5** and define $w_2^2 = w_1^1 = 34$. We further rewrite $w_1^2 = w_1^1[34 \leftarrow 34534]_\triangleright = 34534$, and $w_0^2 = w_0^1[34 \leftarrow 34534]_\triangleright = 345343$. So even after rewriting, we have $\mathbb{N}^* \models \psi_i(w_{i-1}^2, w_i^2)$ for $i = 1, 2$. For $i = 3$, we are again in case **6**. We obtain $w_3^3 = 346$; w_2^3, w_1^3 and w_0^3, respectively, are rewritten to 34634, 34634534634 and 346345346343, respectively. All constraints are indeed satisfied.

Let us state an important property of the construction, which will be key for the correctness of the construction.

▶ **Invariant 7.** *For every $0 \leq i \leq n$ and every $0 \leq j \leq i$, w_i^i is not overlapping in w_j^i.*

Proof. The proof is by induction on i. The induction base, $i = 0$, is trivial. So assume that the claim holds for all $0 \leq k < i$. We prove it for i. We consider different cases, based on the form of ψ_i. Let $0 \leq j < i$ (the case $j = i$ is trivial).

1. Suppose we are in cases **1**, **2**, **3**, **4**, or **8**, that is, $w_j^i = w_j^{i-1}$ (no rewriting happens). In case **1**, $w_i^i = w_{i-1}^{i-1}$, we can apply the induction hypothesis to obtain the result. In the remaining four cases, the string w_i^i contains the letter M_i, which, by definition, does not occur in w_j^{i-1}. Hence w_i^i cannot occur at all in w_j^{i-1}.
2. Suppose we are in cases **5**, **6**, or **7**, that is, $w_j^i = w_j^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]$ (rewriting happens). By induction hypothesis, w_{i-1}^{i-1} is not overlapping in w_j^{i-1}. If N is the number of occurrences of w_{i-1}^{i-1} in w_j^{i-1}, we can hence write

   $$w_j^{i-1} = u_0 \cdot w_{i-1}^{i-1} \cdot u_1 \cdot w_{i-1}^{i-1} \cdot u_2 \ldots u_{N-1} \cdot w_{i-1}^{i-1} \cdot u_N$$

   for some $u_0, \ldots, u_N \in \mathbb{N}^*$. By definition,

   $$w_j^i = u_0 \cdot w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1} \cdot u_1 \cdot w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1} \cdot u_2 \ldots u_{N-1} \cdot w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1} \cdot u_N.$$

   In case **5**, $w_i^i = w_{i-1}^{i-1}$, so that w_i^i does not contain M_i by definition. The only way for w_i^i to be overlapping in w_j^i is in $u_0 \cdot w_{i-1}^{i-1}$, in $w_{i-1}^{i-1} \cdot u_k \cdot w_{i-1}^{i-1}$ for some $1 \le k < N$, or in $w_{i-1}^{i-1} \cdot u_N$. But this would contradict that w_{i-1}^{i-1} is not overlapping in w_j^{i-1}. In case **6**, $w_i^i = w_{i-1}^{i-1} \cdot M_i$. By definition, w_j^{i-1} does not contain M_i. Hence the only way for w_i^i to be contained at all in w_j^i is so that no overlap can occur. The reasoning for case **7**, where $w_i^i = M_i \cdot w_{i-1}^{i-1}$, is analogous. ◀

Let us finally prove the correctness of the construction, that is, for all $1 \le i \le n$, we have $\mathbb{N}^* \models \psi_j(w_{j-1}^i, w_j^i)$ for all $1 \le j \le i$. The proof is by induction on i. For the base case $i = 1$ observe that w_0^1 and w_1^1 are defined such that $\mathbb{N}^* \models \psi_1(w_0^1, w_1^1)$. So suppose that the claim holds for all $1 \le k < i$. We prove it for i. For $j = i$, it is again easy to see that $\mathbb{N}^* \models \psi_i(w_{i-1}^i, w_i^i)$. So let $1 \le j < i$. By induction hypothesis, we have $\mathbb{N}^* \models \psi_j(w_{j-1}^{i-1}, w_j^{i-1})$. Depending on the form of ψ_i, we either have

- $w_{j-1}^i = w_{j-1}^{i-1}$ and $w_j^i = w_j^{i-1}$, so that we have $\mathbb{N}^* \models \psi_j(w_{j-1}^i, w_j^i)$; or
- $w_{j-1}^i = w_{j-1}^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]_\triangleright$ and $w_j^i = w_j^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]_\triangleright$. By Invariant 7, w_{i-1}^{i-1} is not overlapping in w_{j-1}^{i-1}, w_{i-1}^{i-1} is not overlapping in w_j^{i-1}, and $w_{i-1}^{i-1} <_p w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}$, and $w_{i-1}^{i-1} <_s w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}$. By Lemma 4 we obtain $\mathbb{N}^* \models \psi_j(w_{j-1}^i, w_j^i)$.

Setting $w_i = w_i^n$ for all $0 \le i \le n$, we are done with the proof of the first claim of Proposition 5.

Let us prove the second claim and suppose that ψ_1 is generous. We prove below that for all $1 \le i \le n$, w_i^i contains some letter not occurring in w_0^i. Note that this implies $w_0^0 = w_0^1 = \cdots = w_0^n$. The proof is by induction on i. For the induction base, set $i = 1$. Since ψ_1 is generous, we are in one of the cases **2**, **3**, **4**, or **8**. Here, w_1^1 contains M_1, which, by definition, is not occurring in w_0^0, and $w_0^1 = w_0^0$. Hence w_1^1 contains a letter not occurring in w_0^1. For the induction step, suppose the claim holds for all $1 \le j < i$. We prove it for i. Note that depending on the form of ψ_i, w_i^i is defined as w_{i-1}^{i-1}, a fresh letter M_i, or a composition of these two. For w_0^i, we either have $w_0^i = w_0^{i-1}$, in which case the induction hypothesis and/or freshness of M_i immediately establishes the claim, or we have $w_0^i = w_0^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}]$. But by induction hypothesis, w_{i-1}^{i-1} contains some letter not occurring in w_0^{i-1}, so that w_{i-1}^{i-1} cannot occur in w_0^{i-1} and thus $w_0^{i-1}[w_{i-1}^{i-1} \leftarrow w_{i-1}^{i-1} \cdot M_i \cdot w_{i-1}^{i-1}] = w_0^{i-1}$. Hence w_i^i contains some letter not occurring in w_0^i. This finishes the proof of Proposition 5.

The *(control-state) reachability problem for constraint automata* is the problem to decide, given a constraint automaton $\mathcal{A} = (\mathcal{L}, \ell_{\text{in}}, \mathcal{L}_{\text{acc}}, E)$ over $\mathbb{N}^*$ and some target location $\ell \in \mathcal{L}$, whether there exists a run from (ℓ_{in}, w_0) to (ℓ, w), for some $w_0, w \in \mathbb{N}^*$.

▶ **Corollary 8.** *The reachability problem for constraint automata is NL-complete.*

Proof. For the upper bound, it suffices to decide whether there exists a path from ℓ_{in} to ℓ, which can be done in NL. If no such path exists, then there exists no run from (ℓ_{in}, w_0) to (ℓ, w) for some $w_0, w \in \mathbb{N}^*$. If such a path, say $\ell_0 \xrightarrow{\psi_1} \dots \xrightarrow{\psi_n} \ell_n$, exists, we use Proposition 5 with $\psi_1, \dots, \psi_n$ and some $w_{\text{in}} \in \mathbb{N}^+$ to obtain $w_0, w_1, \dots, w_n \in \mathbb{N}^+$ such that $\mathbb{N}^* \models \psi_i(w_{i-1}, w_i)$ for all $1 \leq i \leq n$. Then $(\ell_0, w_0) \xrightarrow{\psi_1} \dots \xrightarrow{\psi_n} (\ell_n, w_n)$ is a finite run of $\mathcal{A}$. A reduction from the reachability problem for finite directed graphs yields the lower bound. ◀

4.2 Characterization for Büchi-accepting Runs

As mentioned above, there are infinite sequences of constraints $\psi_1, \psi_2, \dots$ for which it may not be possible to find $w_0, w_1, w_2 \dots$ such that $\mathbb{N}^* \models \psi(w_{i-1}, w_i)$ for all $i \geq 1$. In the following proposition, we give a decidable characterization for when an infinite path of $\mathcal{A}$ can be completed with string values to obtain an infinite run of $\mathcal{A}$.

▶ **Proposition 9.** *The following three statements are equivalent:*

1. *There exists a Büchi-accepting run of $\mathcal{A}$.*

2. *There exists an infinite path π of $\mathcal{A}$ satisfying the following conditions:*

  a. *π starts in ℓ_{in},*

  b. *π contains infinitely many occurrences of ℓ_{acc}, for some $\ell_{\text{acc}} \in \mathcal{L}_{\text{acc}}$, and*

  c. *if π contains only finitely many generous constraints, then π contains only finitely many reducing constraints.*

3. *There exists a path from ℓ_{in} to ℓ_{acc}, for some $\ell_{\text{acc}} \in \mathcal{L}_{\text{acc}}$, and one of the following holds:*

  a. *there exists some stable cycle starting in ℓ_{acc}, or*

  b. *there exists some generous cycle starting in ℓ_{acc}.*

Proof. For the proof from **1.** to **2.**, let $(\ell_0, w_0) \xrightarrow{\psi_1} (\ell_1, w_1) \xrightarrow{\psi_2} \dots$ be a Büchi-accepting run of $\mathcal{A}$. Define π to be the infinite path $\ell_0 \xrightarrow{\psi_1} \ell_1 \xrightarrow{\psi_2} \dots$. Clearly, π satisfies conditions **2.a** and **2.b**; we prove that condition **2.c** also holds. Towards contradiction, suppose that π contains finitely many generous constraints but infinitely many reducing constraints. Then there exists some $i \geq 1$ such that ψ_j is reducing or of the form $x = y$, for all $j \geq i$. Note that this implies $|w_j| \geq |w_{j+1}|$ for all $j \geq i$. Moreover, since there are infinitely many reducing constraints, there exists an infinite sequence $i \leq i_1 < i_2 < i_3 \dots$ of indices such that ψ_{i_j} is reducing and hence $|w_{i_j}| > |w_{i_j+1}|$. Since $|w_j|$ is finite, this leads to a contradiction.

For the proof from **2.** to **1.**, let $\pi = \ell_0 \xrightarrow{\psi_1} \ell_1 \xrightarrow{\psi_2} \dots$ be an infinite path of $\mathcal{A}$ satisfying the three conditions stated in **2.** Using condition **2.c**, we prove that we can complete π with string values to yield an infinite run of $\mathcal{A}$; that this run is Büchi-accepting, follows by conditions **2.a** and **2.b**. We distinguish two cases.

- Suppose π contains only finitely many generous constraints. By condition **2.c**, π contains only finitely many reducing constraints. Then there exists some $i \geq 0$ such that ψ_j is of the form $x = y$ for all $j > i$. Use Proposition 5 with the sequence $\psi_1, \dots, \psi_i$ and $w_{\text{in}} = 0$ to obtain string values $w_0, w_1, \dots, w_i \in \mathbb{N}^+$ such that $\mathbb{N}^* \models \psi_j(w_{j-1}, w_j)$ for all $1 \leq j < i$. Then $(\ell_0, w_0) \xrightarrow{\psi_1} (\ell_1, w_1) \xrightarrow{\psi_2} \dots \xrightarrow{\psi_i} (\ell_i, w_i) \xrightarrow{\psi_{i+1}} (\ell_{i+1}, w_i) \xrightarrow{\psi_{i+2}} (\ell_{i+2}, w_i) \xrightarrow{\psi_{i+3}} \dots$ is an infinite run of $\mathcal{A}$.
- Suppose that π contains infinitely many generous constraints. Let $i_1, i_2, i_3 \dots$ be the sequence of all $j \geq 1$ such that ψ_{i_j} is generous. Use Proposition 5 with the sequence $\psi_1, \dots, \psi_{i_1 - 1}$ and $w_{\text{in}} = 0$ to obtain string values $w_0, w_1, \dots, w_{i_1 - 1} \in \mathbb{N}^+$ such that $\mathbb{N}^* \models \psi_k(w_{k-1}, w_k)$ for all $1 \leq k < w_{i_1 - 1}$. For every $j \geq 1$, use Proposition 5 with the

sequence $\psi_{i_j}, \dots, \psi_{i_{j+1}-1}$ and the initial string value $w_{\text{in}}^j := w_{i_j-1}$ to obtain string values $w_{i_j-1}, w_{i_j}, \dots, w_{i_{j+1}-1} \in \mathbb{N}^+$ such that $\mathbb{N}^* \models \psi_k(w_{k-1}, w_k)$ for all $i_j \leq k < i_{j+1} - 1$. By the second claim of Proposition 5, since ψ_{i_j} in π_j is generous, the initial string value w_{i_j-1} is never rewritten. Hence $\Pi_{i \geq 0} \rho_i$ is an infinite run of $\mathcal{A}$, where $\rho_0 := (\ell_0, w_0) \xrightarrow{\psi_1} (\ell_1, w_1) \xrightarrow{\psi_2} \dots \xrightarrow{\psi_{i_1-1}} (\ell_{i_1-1}, w_{i_1-1})$, and $\rho_j := (\ell_{i_j-1}, w_{i_j-1}) \xrightarrow{\psi_{i_j}} (\ell_{i_j}, w_{i_j}) \xrightarrow{\psi_{i_j+1}} \dots \xrightarrow{\psi_{i_{j+1}-1}} (\ell_{i_{j+1}-1}, w_{i_{j+1}-1})$ for all $j \geq 1$.

For the proof from **2.** to **3.**, let $\pi = \ell_0 \xrightarrow{\psi_1} \ell_1 \xrightarrow{\psi_2} \dots$ be an infinite path of $\mathcal{A}$ satisfying the three conditions stated in **2.** We distinguish two cases:

- Suppose π contains only finitely many generous constraints. By condition **2.c**, π contains only finitely many reducing constraints. Then there exists some $i \geq 0$ such that ψ_j is of the form $x = y$ for all $j > i$. By condition **2.b**, there are infinitely many indices $j > i$ such that $\ell_j = \ell_{\text{acc}}$. Pick two such indices $j < k$ satisfying $\ell_j = \ell_k = \ell_{\text{acc}}$. We have $\ell_0 = \ell_{\text{in}}$ by condition **2.a**, so that clearly, the path $\ell_0 \xrightarrow{\psi_1} \dots \xrightarrow{\psi_j} \ell_j$ is a path from ℓ_{in} to ℓ_{acc}, and the path $\ell_j \xrightarrow{\psi_{j+1}} \dots \xrightarrow{\psi_{k-1}} \ell_k$ is a stable cycle starting in ℓ_{acc}.
- Suppose π contains infinitely many generous constraints. By condition **2.b**, there are infinitely many indices $i \geq 0$ such that $\ell_i = \ell_{\text{acc}}$, so that we can clearly pick three indices j, k, n such that $0 \leq j < k \leq n$, $\ell_j = \ell_n = \ell_{\text{acc}}$, and ψ_k is generous. We have $\ell_0 = \ell_{\text{in}}$ by condition **2.a**, so that clearly, the path $\ell_0 \xrightarrow{\psi_1} \dots \xrightarrow{\psi_j} \ell_j$ is a path from ℓ_{in} to ℓ_{acc}, and the path $\ell_j \xrightarrow{\psi_{j+1}} \dots \xrightarrow{\psi_{k-1}} \ell_k$ is a generous cycle starting in ℓ_{acc}.

For the proof from **3.** to **2.**, suppose π_{in} is a path from ℓ_{in} to ℓ_{acc} for some accepting location $\ell_{\text{acc}} \in \mathcal{L}_{\text{acc}}$, and π_{cyc} is a cycle starting in ℓ_{acc}. Clearly $\pi_{\text{in}} \cdot (\pi_{\text{cyc}})^\omega$ is an infinite path of $\mathcal{A}$ satisfying conditions **2.a** and **2.b**. If π_{cyc} is stable, then this path contains only finitely many reducing constraints. If π_{cyc} is generous, then this path contains infinitely many generous constraints. Hence, condition **2.c** holds, too. ◀

▶ **Theorem 10.** *The emptiness problem for constraint automata over $\mathbb{N}^*$ is NL-complete.*

Proof. For the upper bound, by Proposition 9, it suffices to decide whether there exists some $\ell_{\text{acc}} \in \mathcal{L}_{\text{acc}}$ such that there exists a path from ℓ_{in} to ℓ_{acc}, and one of the following two conditions hold:

- there exists a stable cycle starting in ℓ_{acc}, or
- there exists some genereous transition $(\ell, \psi(x,y), \ell') \in E$ such that there exists a path from ℓ_{acc} to ℓ, and there exists a path from ℓ' to ℓ_{acc}.

All conditions can be checked in NL. A reduction from the emptiness problem for Büchi automata yields the lower bound. ◀

5 Further Results

5.1 Testing Equality with the Empty String

We extend the signature σ^{ps} by a new symbol $=\varepsilon$, which is interpreted as *equality with the empty string*. This enables us to test whether the string value equals the empty string – very similar to testing whether the value of a counter in a counter automaton is equal to zero, or whether the stack of a pushdown automaton is empty. Let us use $\sigma^{ps\varepsilon}$ to denote this signature. We can give a decidable characterization for Büchi-accepting runs of $\mathcal{A}$ and hence obtain:

▶ **Theorem 11.** *The emptiness problem for constraint automata over the extended signature $\sigma^{ps\varepsilon}$ with domain $\mathbb{N}^*$ is NL-complete.*

5.2 Emptiness for Constraint Automata over Σ^*

The decision procedure for solving the emptiness problem for constraint automata over $\mathbb{N}^*$ relies heavily on the existence of "fresh" letters, of which there are unboundedly many in $\mathbb{N}$. We can clearly not apply this algorithm if the constraint automaton is over the structure Σ^*, where Σ is a *finite* alphabet.

Let σ be a relational signature, and let $\mathcal{D}_1$ and $\mathcal{D}_2$ be two σ-structures. A mapping $h : \mathcal{D}_1 \to \mathcal{D}_2$ is a σ-embedding if h is injective, and for all symbols R of arity k, and all $a_1, \dots, a_k \in \mathcal{D}_1$, $R^{\mathcal{D}_1}(a_1, \dots, a_k)$ holds if, and only if, $R^{\mathcal{D}_2}(h(a_1), \dots, h(a_k))$.

Let $\Sigma = \{a, b\}$. Define the mapping $g : \mathbb{N} \to \Sigma$ by $n \mapsto ab^n a$ for all $n \in \mathbb{N}$, and let $h : \mathbb{N}^* \to \Sigma^*$ be its homomorphic extension, that is, $h(n_1 \dots n_k) = g(n_1) \dots g(n_k)$ for all $n_1, \dots, n_k \in \mathbb{N}$, and $h(\varepsilon) = \varepsilon$. One can easily see that h is a $\sigma^{ps\varepsilon}$-embedding. We can conclude that a constraint automaton over Σ^* is a positive instance of the emptiness problem iff the same constraint automaton over $\mathbb{N}^*$ is a positive instance; thus:

▶ **Theorem 12.** *The emptiness problem for constraint automata over the extended signature $\sigma^{ps\varepsilon}$ with domain Σ^* is NL-complete.*

5.3 Emptiness for Single-Register Automata over A^*

Register automata (also known as *finite-memory automata*) [17, 13, 24] are a very popular computational model for the analysis of data languages. Like constraint automata, register automata are parameterized by a σ-structure; in contrast to constraint automata, register automata are "fed" with some input data word, that is a finite or infinite sequence of data values in the domain of the σ-structure. The data language accepted by such an automaton is the set of input data words for which there is an accepting run. Different to the transitions in constraint automata, the transitions of register automata are labelled with constraints of the form $r \bowtie d$, where r corresponds to one of finitely many *registers* of the automaton, d corresponds to the current datum of the input data word, and $\bowtie$ is a binary relation in σ. Further, the current input data value can be stored into one of the registers of the automaton after a transition has been taken.

So far, register automata have mostly been studied for the structure $(\mathbb{N}; =)$ and linear dense orders like $(\mathbb{Q}; <, =)$ [17, 24, 13, 4, 8]. The emptiness problem for register automata is decidable and PSPACE-complete (NL-complete if only one register is used) [13]; the decision procedure relies on a finite abstraction of the infinite state space induced by the input register automaton. This abstraction cannot be applied to register automata over $\sigma^{ps\varepsilon}$-structures Σ^* and $\mathbb{N}^*$.

A register automaton with a single register that stores the current input datum *in every transition* into the register can actually be regarded as a constraint automaton as defined in Section 2: the current value of the register r corresponds to the value of the variable x, and the input datum d corresponds to the value of the variable y at the next position in a run. However, it might be the case that some of the transitions in the register automaton may compare the value of the register *without storing the input datum into the register.* There is no direct way to translate this into constraint automata as defined above. However, an easy extension of our model where we compare x with y, but then set the value of y to x, would make such a translation possible. It can be easily seen that this extension does not cause any problems when applying the developed decision procedure for solving the emptiness problem, so that we can conclude:

▶ **Theorem 13.** *The emptiness problem for single-register automata over the extended signature $\sigma^{ps\varepsilon}$ (with domains $\mathbb{N}^*$ or Σ^*) is NL-complete.*

5.4 Constraint LTL with a Single Variable over A^*

Our result for constraint automata can be used to partially answer the question raised by Demri and Deters [9] concerning the decidability status for CLTL over $\sigma^{ps\varepsilon}$. More detailed, we can prove PSPACE-completeness for the fragment of CLTL that only uses a single variable.

Let $\mathbb{P}$ be a countably infinite set of propositional variables. The set of formulas in CLTL$_1$ is defined by the following grammar

$$\varphi ::= p \mid \psi \mid \neg\varphi \mid \varphi \vee \varphi \mid \mathsf{X}\varphi \mid \varphi\mathsf{U}\varphi,$$

where $p \in \mathbb{P}$ and $\psi \in \Psi$. CLTL$_1$ formulas are evaluated over data words over $2^{\mathbb{P}}$ and A^*. Formally, let $u = (a_1, w_1)(a_2, w_2)\dots$ and $i \geq 1$. The satisfaction relation $\models$ is defined as follows:

$$\begin{aligned}
(u,i) \models p \quad &\Leftrightarrow \quad p \in a_i \\
(u,i) \models \psi \quad &\Leftrightarrow \quad A^* \models \psi(w_i, w_{i+1}) \\
(u,i) \models \neg\varphi \quad &\Leftrightarrow \quad \text{not}(u,i) \models \varphi \\
(u,i) \models \varphi_1 \vee \varphi_2 \quad &\Leftrightarrow \quad (u,i) \models \varphi_1 \text{ or } (u,i) \models \varphi_2 \\
(u,i) \models \mathsf{X}\varphi \quad &\Leftrightarrow \quad (u,i+1) \models \varphi \\
(u,i) \models \varphi_1\mathsf{U}\varphi_2 \quad &\Leftrightarrow \quad \exists j \geq i(u,j) \models \varphi_2, \forall i \leq k < j(u,k) \models \varphi_1
\end{aligned}$$

We define $L(\varphi) = \{u \in (2^{\mathbb{P}} \times A^*)^\omega \mid (u,1) \models \varphi\}$. Following the standard translation from LTL to Büchi automata by Vardi and Wolper [29], one can construct from every formula φ a constraint automaton $\mathcal{A}_\varphi$ such that $L(\mathcal{A}_\varphi)$ corresponds to $L(\varphi)$ (cf. [14]). In other words, deciding the satisfiability of φ can be reduced to deciding the non-emptiness of $L(\mathcal{A}_\varphi)$, so that we obtain the following result.

▶ **Theorem 14.** *The satisfiability problem for CLTL$_1$ over the extended signature $\sigma^{ps\varepsilon}$ (with domains $\mathbb{N}^*$ or Σ^*) is PSPACE-complete.*

Abstract

A function f uniformizes a relation R(X,Y) if R(X,f(X)) holds for every X in the domain of R. The uniformization problem for a logic L asks whether for every L-definable relation there is an L-definable function that uniformizes it. Gurevich and Shelah proved that no Monadic Second-Order (MSO) definable function uniformizes relation “Y is a one element subset of X” in the full binary tree. In other words, there is no MSO definable choice function in the full binary tree.

The cross-section of a relation R(X,Y) at D is the set of all E such that R(D,E) holds. Hence, a function that uniformizes R chooses one element from every non-empty cross-section. The relation “Y is a one element subset of X” has finite and countable cross-sections.

We prove that in the full binary tree the following theorems hold:

▶ **Theorem** (Finite cross-sections). *If every cross-section of an MSO definable relation is finite, then it has an MSO definable uniformizer.*

▶ **Theorem** (Uncountable cross-section). *There is an MSO definable relation R such that every MSO definable relation included in R and with the same domain as R has an uncountable cross-section.*

1 Introduction

Let $R \subseteq D_1 \times D_2$ be a binary relation. For $d_1 \in D_1$ the cross-section of R at d_1 is the set $R_{d_1} := \{d \in D_2 \mid (d_1, d) \in R\}$. The domain of R is the set $\{d_1 \in D_1 \mid \exists d_2 (d_1, d_2) \in R\}$.

A uniformizer of R is a subset R^* of R such that for all x: $\exists y R(x,y) \Leftrightarrow \exists! y R^*(x,y)$ (where $\exists!$ stands for “there exists unique”). Hence, a uniformizer for R is a partial function that chooses an element from each non-empty cross-section of R and has the same domain as R (see Fig. 1).

In other words, given an input x for which the original relation R has a non-empty cross-section, a uniformizer returns a single value from the cross-section at x. This is a special case of a choice function.

The axiom of choice implies that a uniformizer always exists; however, it is often important that a uniformizer has some “nice” properties. This is where the uniformization theorems come into action. They guarantee that, if R satisfies certain properties, then it has a uniformizer that has other desirable properties.

A set of relations $\mathfrak{R}$ has the uniformization property if every $R \in \mathfrak{R}$ has a uniformizer in $\mathfrak{R}$.

We consider the set of relations over the full binary tree definable in the Monadic Second-Order Logic (MSO). The seminal Rabin’s theorem states that the Monadic Second-Order Logic is decidable over the full binary tree [8].

The monadic second-order logic is an extension of first-order logic by set variables (which range over the subsets of the domain of a structure), and the quantifiers over the set variables (see Section 2.1).

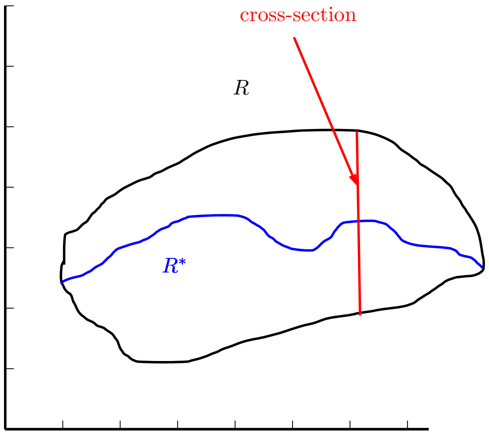

Figure 1 R^* uniformizes R.

An MSO formula $\alpha(X, Y)$ with free set (second-order) variables X and Y defines a binary relation on the subsets of the full binary tree. Rabin [8] proved the basis theorem that states: every non-empty relation definable by an MSO formula $\alpha(Y)$ contains an MSO definable set. The basis theorem is a simple (degenerate) instance of the uniformization property. Rabin asked whether the class of relations definable in the monadic second-order logic over the full binary tree has the uniformization property. Gurevich and Shelah [6] gave a negative solution to Rabin's question with the formula $\alpha(X, Y)$ saying "if X is non-empty, then Y is a one element subset of X" as a counter-example. A function that uniformizes "Y is a one element subset of X" is a choice function; it chooses one element from every non-empty set X. The Gurevich-Shelah Theorem states that there is no MSO definable choice function in the full binary tree.

Since MSO definable relations over the tree do not have the uniformization property, a natural task is to decide whether an MSO definable relation has a (MSO-definable) uniformizer; another natural task is to provide a characterization of those relations which have a uniformizer. The decidability whether a relation has a uniformizer is open. However, we provide a sufficient condition for a relation to have a uniformizer.

▶ **Theorem** (Finite cross-sections). *If the cross-sections of an MSO definable relation over the full binary tree are finite, then it has an MSO definable uniformizer.*

Note that the Gurevich-Shelah Theorem and the above Theorem imply that there are MSO definable relations that do not include MSO definable relations with the same domain and only finite cross-sections.

A natural question is whether an MSO definable relation always includes an MSO definable relation with the same domain and at most countable cross-sections. We provide a negative answer to this question.

▶ **Theorem** (Uncountable cross-section). *There is an MSO definable relation R such that any MSO definable relation which is included in R and has the same domain as R has an uncountable cross-section.*

Hence, it is even impossible to choose in a definable way a countable subset from every non-empty cross-section.

The paper is organized as follows. Section 2 recalls standard definitions about monadic second-order logics, trees, and presents elements of composition method which are used in our proofs. Section 4 provides a proof of Finite cross-section theorem. Section 5 discusses the consequences of undefinability of choice function; it also introduces some notions which are helpful for the proof of Uncountable cross-section theorem given in Section 6. Section 7 contains conclusions and further results.

2 Preliminaries

We use standard notations and terminology. We use n, k, m, l for natural numbers. We use capital letters A, B, C for sets, and lower case letters a, b, c for elements of sets. The powerset of a set D is denoted by $\mathbb{P}(D)$. We use the expressions "chain" and "linear order" interchangeably; we use ω for the order type of the natural numbers.

2.1 Monadic Second-Order Logic

We use standard notations and terminology about Monadic Second-Order logic (MSO) [8, 12, 10].

Let σ be a relational signature. A structure (for σ) is a tuple $\mathcal{M} = (D, \{R^{\mathcal{M}} \mid R \in \sigma\})$ where D is a domain, and each symbol $R \in \sigma$ is interpreted as a relation $R^{\mathcal{M}}$ on D.

MSO formulas use first-order variables, which are interpreted as elements of the structure, and monadic second-order variables, which are interpreted as sets of elements. Atomic MSO formulas are of the following form:

- $R(x_1, \dots, x_n)$ for an n-ary relational symbol R and first-order variables $x_1, \dots, x_n$
- $x = y$ for two first-order variables x and y
- $x \in X$ for a first-order variable x and a second-order variable X

MSO formulas are constructed from the atomic formulas, using boolean connectives, the first-order quantifiers, and the second-order quantifiers.

We write $\psi(X_1, \dots, X_n, x_1, \dots, x_m)$ to indicate that the free variables of the formula ψ are $X_1, \dots, X_n$ (second-order variables) and $x_1, \dots, x_m$ (first-order variables). We write $\mathcal{M}, A_1, \dots, A_n, a_1, \dots, a_m \models \psi$ or $\mathcal{M} \models \psi(A_1, \dots, A_n, a_1, \dots a_m)$ if ψ holds in $\mathcal{M}$ when subsets A_i are assigned to X_i for $i = 1, \dots, n$ and elements a_i are assigned to variables $x_1, \dots, x_m$ for $i = 1, \dots, m$. Whenever $\mathcal{M}$ is clear from the context we will further abbreviate this to $\psi(A_1, \dots, A_n, a_1, \dots a_m)$. Sometimes, we abuse notations and use X for a variable and for the set assigned to it.

▶ **Definition 2.1** (Definability). *Let $\psi(X_1, \dots, X_n)$ be an MSO formula and $\mathcal{M}$ a structure. The relation defined by ψ in $\mathcal{M}$ is the set*

$$\psi\mathcal{M} := \{(D_1, \dots, D_n) \in \mathbb{P}(D)^n \mid \mathcal{M} \models \psi(D_1 \dots, D_n)\}.$$

A relation is MSO-definable in $\mathcal{M}$ if it is equal to $\psi\mathcal{M}$ for an MSO formula ψ. A set $U \subseteq D$ is MSO-definable in $\mathcal{M}$ if there is a formula $\psi(X)$ such that $\psi\mathcal{M} = \{U\}$. A function is MSO-definable in $\mathcal{M}$ if its graph is.

Let $\psi(X_1, \dots, X_n, Y_1, \dots Y_l)$ be an MSO formula and $\mathcal{M}$ a structure. Let $\overline{C}$ be an l-tuple of subsets of the domain D of $\mathcal{M}$. The relation defined by ψ in $\mathcal{M}$ with parameters *$\overline{C}$ is the set*

$$\psi(\mathcal{M}, \overline{C}) := \{(D_1, \dots, D_n) \in \mathbb{P}(D)^n \mid \mathcal{M} \models \psi(D_1 \dots, D_n, \overline{C}\}.$$

The definability of a subset and of a function in $\mathcal{M}$ with parameters is defined in a similar way.

2.2 Trees

We view the set $\{l, r\}^*$ of finite words over the alphabet $\{l, r\}$ as the domain of the full binary tree, where the empty word ϵ is the root of the tree, and for each node $v \in \{l, r\}^*$, we call $v \cdot l$ the left child of v, and $v \cdot r$ the right child of v.

We define a tree order "$\leq$" as a partial order such that $\forall u, v \in \{l, r\}^* : u \leq v$ iff u is a prefix of v.

Nodes u and v are incomparable - denoted by $u \perp v$ - if neither $u \leq v$ nor $v \leq u$; a set U of nodes is an **antichain**, if its elements are incomparable with each other.

We say that an infinite sequence $\pi = v_0, v_1, \ldots$ is a **tree branch** if $v_0 = \epsilon$ and $\forall i \in \mathbb{N} : v_{i+1} = v_i \cdot l$ or $v_{i+1} = v_i \cdot r$.

A path is a finite or infinite sequence $v_0 \ldots v_i \ldots$ such that if v_i is not the last node, then $v_{i+1} = v_i \cdot l$ or $v_{i+1} = v_i \cdot r$.

We consider the full binary tree as a structure for a signature $\{\leq, left, right\}$ where unary relation symbols $left$ and $right$ are interpreted as $\{wl | w \in \{l, r\}^*\}$ and $\{wr | w \in \{l, r\}^*\}$, respectively; $\leq$ is interpreted as the prefix relation.

A k-tree is an expansion of the full binary tree by k unary predicates. Whenever k is clear from the context or unimportant we will use "labelled tree" for "k-tree."

Given a k-tree $\mathfrak{T} := (T, P_1, \ldots, P_k)$ and a node v in $\mathfrak{T}$, the k-tree $\mathfrak{T}_{\geq v} := (T_{\geq v}, P'_1, \ldots, P'_k)$ (called the subtree of $\mathfrak{T}$, rooted at v) is defined by $T_{\geq v}$ is the full binary tree, and $u \in P'_i$ iff $vu \in P_i$ for $i = 1, \ldots, k$.

Let F be an antichain in a k-tree $\mathfrak{T}$ and let $\mathfrak{T}_1$ be a k-tree. The **grafting** of $\mathfrak{T}_1$ at F in $\mathfrak{T}$ is denoted by $\mathfrak{T}\{\mathfrak{T}_1/F\}$ and is the k-tree obtained from $\mathfrak{T}$ when the subtrees rooted at F are replaced by $\mathfrak{T}_1$.

Formally, $\mathfrak{T}' := \mathfrak{T}\{\mathfrak{T}_1/F\}$ is defined as follows: let $u \in \{l, r\}^*$ be a node. (i) if $\neg\exists f \in F(f \leq u)$ then $P_i^{\mathfrak{T}'}(u)$ iff $P_i^{\mathfrak{T}}(u)$; else (ii) $u = fv$ for a unique $f \in F$, and $P_i^{\mathfrak{T}'}(u)$ iff $P_i^{\mathfrak{T}_1}(v)$.

2.3 Composition Method

The proofs presented in this paper make use of the technique known as the "composition method." To fix notations and to aid the reader not familiar with this technique, we briefly review those definitions and results that we need. A more detailed presentation can be found in [11] or [5, 7].[1]

Let σ be a finite relational signature. Write σ_k for the signature σ with k (fresh) unary predicate $P_1, \cdots, P_k$ symbols. Thus, a σ_k-structure $\mathfrak{A}$ has the form $(A, P_1^{\mathfrak{A}}, \cdots, P_k^{\mathfrak{A}})$, where A is a σ-structure. The quantifier rank of a formula φ, denoted $\mathrm{qr}(\varphi)$, is the maximum depth of the nesting of quantifiers in φ. For example, if ψ and φ are quantifier-free, then the quantifier rank of $(\exists x \forall Y \forall Z \psi) \wedge (\forall Y \exists u \varphi)$ is 3. For $r, k \in \mathbb{N}$ we denote by $\mathfrak{Form}_k^r$ the set of formulas of quantifier rank $\leq r$ and with free variables among $X_1, \ldots, X_k$ in signature σ.

For σ_k-structures $\mathfrak{A}, \mathfrak{B}$ write $\mathfrak{A} \equiv_k^r \mathfrak{B}$ if for every $\varphi \in \mathfrak{Form}_k^r$,

$$\mathfrak{A} \models \varphi(P_1^{\mathfrak{A}}, \cdots, P_k^{\mathfrak{A}}) \text{ if and only if } \mathfrak{B} \models \varphi(P_1^{\mathfrak{B}}, \cdots, P_k^{\mathfrak{B}}).$$

Clearly, $\equiv_k^r$ is an equivalence relation and the set $\mathfrak{Form}_k^r$ is infinite. Since the signature σ_k is finite and relational, the set $\mathfrak{Form}_k^r$ contains only finitely many semantically distinct formulas, so there are only finitely many $\equiv_k^r$-classes of σ_k-structures. The following lemma isolates maximally consistent formulas.

[1] In [9], [6], and several other papers, the technique is further developed and a much deeper application of it is made than will be made here.

▶ **Lemma 2.2** (Hintikka lemma). *Let σ be a finite relational signature. For $r, k \in \mathbb{N}$, there is* a finite *set $H_k^r \subseteq \mathfrak{Form}_k^r$ such that:*

1. *For every σ_k-structure $\mathfrak{A}$ there is a* unique *$\tau \in H_k^r$ with $\mathfrak{A} \models \tau(P_1^{\mathfrak{A}}, \cdots, P_k^{\mathfrak{A}})$.*
2. *If $\tau \in H_k^r$ and $\varphi \in \mathfrak{Form}_k^r$, then $\tau \models \varphi$ or $\tau \models \neg\varphi$.*[2]

Elements of H_k^r are called (r, k)-*Hintikka formulas.*

▶ **Definition 2.3** (type of a structure). *For a σ_k-structure $\mathfrak{A}$, write* $\text{type}_k^r(\mathfrak{A})$ *for the unique $\tau(X_1, \cdots, X_k) \in H_k^r$ such that $\mathfrak{A} \models \tau(P_1^{\mathfrak{A}}, \cdots, P_k^{\mathfrak{A}})$, and call it the* (r, k)-type *of $\mathfrak{A}$.*

Thus, $\text{type}_k^r(\mathfrak{A})$ determines for which formulas $\varphi \in \mathfrak{Form}_k^r$ it holds that $\mathfrak{A} \models \varphi(P_1^{\mathfrak{A}}, \cdots, P_k^{\mathfrak{A}})$. Since k is often clear, we may drop it, and write $\text{type}^r(\mathfrak{A})$ and call it the r-type of $\mathfrak{A}$.

We now state weak versions of the composition theorem for MSO over chains and trees, see [9] or [6, 5] for details. The first deals with a representation of ω-chains as a concatenation of finite chains; the second considers a branch in a tree.

▶ **Lemma 2.4** (Weak Composition Theorem for ω-chains). *Let $(L, <)$ be a linear order isomorphic to ω. Let $v_1 < v_2 < \cdots < v_n < \cdots$ be a sequence of elements in L, where v_1 is the minimal element of L. Let $\mathcal{L} := (L, <, P_1, \cdots, P_k)$ be an expansion of $(L, <)$ by unary predicates, and let $\mathcal{L}_i$ be the substructure of $\mathcal{L}$ over $\{v \mid v_i \leq v < v_{i+1}\}$. Then, type$^m(\mathcal{L})$ is determined by the sequence type$^m(\mathcal{L}_i)$ $(i = 1, \ldots)$.*

▶ **Lemma 2.5** (Weak Composition Theorem for a Tree Branch). *Let T be the full binary tree and let P_1, P_2, Q_1, Q_2 be subsets of the nodes of T. Let $T^1 := (T, P_1, Q_1)$ and $T^2 := (T, P_2, Q_2)$ be the expansion of T by the unary predicates. Let $\pi := v_1 v_2 \ldots$ be a branch in T. Let u_i be a child of v_{i-1} different from v_i. Let $\tau_1^i :=$ type$^n(T^1_{\geq u_i})$ and $\tau_2^i :=$ type$^n(T^2_{\geq u_i})$. Assume that $\forall i. \tau_1^i = \tau_2^i$ and $\pi \cap P_1 = \pi \cap P_2$ and $\pi \cap Q_1 = \pi \cap Q_2$. Then type$^n(T^1) =$ type$^n(T^2)$.*

A lemma similar to Lemma 2.5 holds when pairs $\langle P_i, Q_i \rangle$ are replaced by tuples $\langle P_i, Q_i, R_i, \cdots \rangle$.

3 Uniformization

▶ **Definition 3.1** (Uniformization). *Let $\varphi(\overline{X}, \overline{Y})$, $\psi(\overline{X}, \overline{Y})$ be formulas and $\mathcal{C}$ a class of structures. We say that ψ* uniformizes *(or is a* uniformizer *for) φ* over *$\mathcal{C}$ iff for all $\mathcal{M} \in \mathcal{C}$:*

1. *$\mathcal{M} \models \forall \overline{X} \exists^{\leq 1} \overline{Y} \psi(\overline{X}, \overline{Y})$,*
2. *$\mathcal{M} \models \forall \overline{X} \forall \overline{Y} (\psi(\overline{X}, \overline{Y}) \to \varphi(\overline{X}, \overline{Y}))$, and*
3. *$\mathcal{M} \models \forall \overline{X} \big(\exists \overline{Y} \varphi(\overline{X}, \overline{Y}) \to \exists \overline{Y} \psi(\overline{X}, \overline{Y})\big)$.*

Here, $\overline{X}, \overline{Y}$ are tuples of distinct variables and "$\exists^{\leq 1}\overline{Y} \ldots$" stands for "there exists at most one ...". Hence, the first item says that ψ is a graph of a partial function.

The class $\mathcal{C}$ is said to have the uniformization property *iff every formula φ has a uniformizer ψ over $\mathcal{C}$.*

If $\mathcal{C} = \{\mathcal{M}\}$ consists of a single structure, we speak of uniformization in *$\mathcal{M}$ rather than* over *$\mathcal{C}$.*

First, note that, strictly speaking, the question whether φ uniformizes ψ over $\mathcal{C}$ depends not only on formulas φ and ψ, but on the formulas together with a partition of their free-variables into domain variables $\overline{X}$ and image variables $\overline{Y}$. In the few cases where we use

[2] Furthermore, H_k^r is computable from r, k, and there is an algorithm that given τ and φ decides between $\tau \models \varphi$ and $\tau \models \neg\varphi$. We do not use these facts.

letters other than X and Y, we shall state explicitly which variables are to be taken as domain variables and which as image variables and say that φ uniformizes ψ for $(\overline{U};\overline{V})$ over $\mathcal{C}$ if $\overline{U}$ is the set of domain variables and $\overline{V}$ is the set of image variables.

If the cross-sections of a relation R are finite, we say that R is a *finitary* relation.

▶ **Lemma 3.2** (Reducing image variables). *Assume that every finitary relation in $\mathcal{M}$ definable by an* MSO *formula with one image variable has an* MSO *definable uniformizer. Then, every* MSO *definable finitary relation in $\mathcal{M}$ has an* MSO *definable uniformizer.*

4 Finite Cross-sections

▶ **Theorem 4.1** (Finite cross-sections). *If the cross-sections of an MSO definable relation over the full binary tree are finite, then it has an MSO definable uniformizer.*

▶ Remark 4.2 (On computability). It is decidable whether the cross sections of the relation definable by an MSO formula are finite. Our proof of Theorem 4.1 is constructive, and an algorithm which provides an MSO formula that defines a uniformizer can be easily extracted from the proof.

By Lemma 3.2, it is sufficient to prove Theorem 4.1 for the relations definable by formulas with one image variable. To simplify notations we consider formulas with one domain and one image variables. However, everywhere in the proof a domain variable can be replaced by a tuple of domain variables.

▶ **Notations 4.3.** *For a formula $\alpha(X,Y)$ and a subset P of the full binary tree we denote*

1. $\Im\alpha(P) := \{Q \mid \alpha(P,Q)\}$ *- the α-image of P (this is the cross-section of the relation defined by α at P).*
2. $\max_{\subseteq}\Im\alpha(P) := \{Q \in \Im\alpha(P) \mid \neg\exists Y' \in \Im\alpha(P)(Q \subsetneq Y')$ *- $\subseteq$-maximal elements of* $\Im\alpha(P)\}$*. This set is non-empty when $\Im\alpha(P)$ is finite and non-empty.*

It is clear that $\Im\alpha(P)$ and $\max_{\subseteq}\Im\alpha(P)$ are MSO-definable with parameter P.

▶ **Open Question.** *Does there exist an MSO definable linear order on the subsets of the full binary tree?*

If the answer to the question is positive, we can define a uniformizer for α which for every X returns a minimal element in $\Im\alpha(X)$. We have not succeeded to answer the question. However, we still can construct an MSO-definable uniformizer for α. If $\max_{\subseteq}\Im\alpha(P)$ has only one element, the uniformizer chooses it. In Subsection 4.1 we will show how to choose in a definable way between two elements. Relying on this construction, we show in Subsection 4.2 how to choose in a definable way from a finite $\max_{\subseteq}\Im\alpha(P)$, and therefore, from any finite cross-section.

4.1 Choose one Set from two Sets

Here, we are going to show how to choose in a definable way between two elements $Q_1, Q_2 \in \max_{\subseteq}\Im\alpha(P)$.

Let $U_1 := Q_1 \setminus Q_2$ and $U_2 := Q_2 \setminus Q_1$. U_1 and U_2 are non-empty and disjoint. We will use $v\uparrow$ for $\{u \mid v \le u\}$.

Generate a path π as described in **Procedure** Generate π on page 7. We start from the root and at every iteration extend the path by one node. The procedure maintains the invariant: if u is not the last node on the path, then $u\uparrow \cap U_1 \neq \emptyset \neq u\uparrow \cap U_2$ holds. The generated path might be finite (in this case the procedure returns from line 4, 7 or 10) or infinite.

Procedure Generate π.

```
$u \leftarrow root$; $\pi \leftarrow \{u\}$
while $true$ do
    if $u \in U_1 \cup U_2$ then
        return                                                              // (a)
    else if $ul\!\uparrow$ has a non-empty intersection exactly with one of $U_1, U_2$ then
        $\pi \leftarrow \pi \cup \{ul\}$
        return                                                              // (b)
    else if $ur\!\uparrow$ has a non-empty intersection exactly with one of $U_1, U_2$ then
        $\pi \leftarrow \pi \cup \{ur\}$
        return                                                              // (b)
    else if $ul\!\uparrow \cap U_1 \neq \emptyset \neq ul\!\uparrow \cap U_2$ then
        $u \leftarrow ul$
        $\pi \leftarrow \pi \cup \{u\}$
    else
        /* in this case $ur\!\uparrow \cap U_1 \neq \emptyset \neq ur\!\uparrow \cap U_2$                   */
        $u \leftarrow ur$
        $\pi \leftarrow \pi \cup \{u\}$
```

It is clear that π is MSO-definable with parameters U_1 and U_2, i.e., there is an MSO formula $\mu(X_1, X_2, Z)$ such that $\mu(U_1, U_2, \pi)$ holds iff π is generated by this procedure. Moreover, the formula is symmetrical in the parameters, i.e., $\mu(U_1, U_2, \pi) \leftrightarrow \mu(U_2, U_1, \pi)$.

Abbreviations. Below we will abbreviate $\text{type}^n(T, P, Q)$ as $\text{type}^n(P, Q)$ and $\text{type}^n(T, P, Q)_{\geq v}$ as $\text{type}^n(P, Q)_{\geq v}$.

Let us analyse what happens if $\pi := u_1 u_2 \dots$ is infinite. In this case for every i: $u_i \notin (U_1 \cup U_2)$ and $u_i\!\uparrow \cap U_1 \neq \emptyset \neq u_i\!\uparrow \cap U_2$.

Let v_i be a child of u_{i-1} different from u_i. Let n be the quantifier rank of α. Let $\tau_1^i := type^n(P, Q_1)_{\geq v_i}$ and $\tau_2^i := type^n(P, Q_2)_{\geq v_i}$.

▷ Claim 4.4. If π is infinite, then $\exists i(\tau_1^i \neq \tau_2^i)$.

Proof. Toward a contradiction we assume $\forall i(\tau_1^i = \tau_2^i)$, and derive that $\exists^{2^{\aleph_0}} Y \alpha(P, Y)$.

Indeed, let $D := \{i \in \mathbb{N} \mid U_1 \cap (v_i\!\uparrow) \neq \emptyset\}$. First, we observe that D is infinite. Indeed, assume that D is finite and i_0 is its maximal element. Note that $(u_i\!\uparrow \cap U_1) = \{u \in \pi \cap U_1 \mid u \geq u_i\} \cup \bigcup_{j>i}(v_j\!\uparrow \cap U_1)$. Since $\pi \cap U_1 = \emptyset$ and $v_j\!\uparrow \cap U_1 = \emptyset$ for $i > i_0$, we conclude that $u_i\!\uparrow \cap U_1 = \emptyset$ for $i > i_0$. A contradiction.

Now, for every $I \subseteq D$, define $Q_I := \bigcup_{i \in I}(v_i\!\uparrow \cap Q_1) \cup \bigcup_{i \notin I}(v_i\!\uparrow \cap Q_2)$. For every $i \in \mathbb{N}$:

$$\tau_1^i = type^n(P, Q_1)_{\geq v_i} = \tau_2^i = type^n(P, Q_2)_{\geq v_i} = type^n(P, Q_I)_{\geq v_i}.$$

Therefore, by Lemma 2.5

$$type^n(P, Q_1) = type^n(P, Q_I \cup (Q_1 \cap \pi)) \text{ for every } I.$$

Since $\alpha(P, Q_1)$ and the quantifier rank of α is n, we obtain that

$$\alpha(P, Q_I \cup (Q_1 \cap \pi)) \text{ for every } I.$$

For $I_1 \neq I_2 \subseteq D$ we have $Q_{I_1} \neq Q_{I_2}$; moreover, both Q_{I_1} and Q_{I_2} have the empty intersection with π. Therefore, $(Q_{I_1} \cup (Q_1 \cap \pi)) \neq (Q_{I_2} \cup (Q_1 \cap \pi))$, for $I_1 \neq I_2 \subseteq D$. Hence, $|\Im\alpha(P)| \geq |\{I \mid I \subseteq D\}| = 2^{\aleph_0}$. This contradicts our assumption that the cross-sections are finite.

Hence, if π is infinite, then there is $v_i \in \pi$ such that $\tau_1^i \neq \tau_2^i$. ◁

For every P and $Q_1 \neq Q_2 \in \max_{\subseteq} \Im\alpha(P)$ let π be the corresponding path. Define

$$G(P, Q_1, Q_2) = \begin{cases} \text{the last element on } \pi & \text{if } \pi \text{ is finite} \\ \text{the minimal } u_i \in \pi \text{ with } \tau_1^i \neq \tau_2^i & \text{otherwise} \end{cases}$$

From Claim 4.4 and definability of π, we derive that G is total and an MSO definable function.

The next Lemma summarizes properties of a formula which defines G.

▶ **Lemma 4.5.** *There is $\psi(X, Y_1, Y_2, z)$ such that*

1. $\psi(X, Y_1, Y_2, z) \leftrightarrow \psi(X, Y_2, Y_1, z)$
2. $(\psi(X, Y_1, Y_2, z) \wedge Y_1, Y_2 \in \max_{\subseteq} \Im\alpha(X) \wedge Y_1 \neq Y_2) \rightarrow \exists! z \psi(X, Y_1, Y_2, z)$
3. *if $\psi(X, Y_1, Y_2, z) \wedge Y_1, Y_2 \in \max_{\subseteq} \Im\alpha(X) \wedge Y_1 \neq Y_2$, then one of the following conditions holds:*
   a. $z \in Y_1 \Delta Y_2$ *(z in the symmetric difference of Y_1 and Y_2),*
   b. *let $U_1 := Y_1 \setminus Y_2$ and $U_2 := Y_2 \setminus Y_1$, then $U_1 \cap z\!\uparrow \neq \emptyset \wedge U_2 \cap z\!\uparrow = \emptyset$, or $U_1 \cap z\!\uparrow = \emptyset \wedge U_2 \cap z\!\uparrow \neq \emptyset$,*
   c. $\mathit{type}^n(X, Y_1)_{\geq z} \neq \mathit{type}^n(X, Y_2)_{\geq z}$.

Now, we are ready to explain how to choose in a definable way between two elements $Y_1, Y_2 \in \max_{\subseteq} \Im\alpha(X)$. We are going to choose according to the cases (a)-(c) of Lemma 4.5(3). If 3(a) holds, then if $z \in Y_1$ choose Y_1 else choose Y_2. If 3(a) fails, but 3(b) holds, then if $U_1 \cap z\!\uparrow \neq \emptyset$ choose Y_1 else choose Y_2. Let $\leq_n$ be any linear order on a finite set of n-types. If 3(a) and 3(b) fail, then 3(c) holds. In this case, if $\mathit{type}^n(X, Y_1)_{\geq z} <_n \mathit{type}^n(X, Y_2)_{\geq z}$ choose Y_1 else Y_2.

4.2 Choose a Set from Finitely Many Sets

Below we explain how to choose from $\max_{\subseteq} \Im\alpha(P)$ when its cardinality is finite and > 2.

Let $F(X, Y) := \{z \mid (\exists Y' \in \max_{\subseteq} \Im\alpha(X))\psi(X, Y, Y', z)\}$.

F is an MSO-definable function. $F(X, Y)$ maps $\max_{\subseteq} \Im\alpha(P)$ to finite non-empty sets.

Recall that the lexicographical order $<_{lex}$ is an MSO-definable linear order on the nodes of the full binary tree. Define a linear order $\prec_{lex}$ on the finite sets as: $Z' \prec_{lex} Z$ if there is $z \in Z \setminus Z'$ such that $\forall y <_{lex} z (y \in Z \leftrightarrow y \in Z')$. It is clear that $\prec_{lex}$ is MSO-definable.

Assume $Y_1 \neq Y_2 \in \max_{\subseteq} \Im\alpha(X)$ and $F(X, Y_1) = F(X, Y_2) = Z$. Let $z := G(X, Y_1, Y_2)$. Then, $z \in Z$ and one of the conditions 3(a)-3(c) of Lemma 4.5 holds.

Now let us explain how to choose Y from $\max_{\subseteq} \Im\alpha(X)$. It will be easy to see that all the sets and relations described below are MSO-definable. (We will give a verbal description of the relation, leaving it to the reader to check that this verbal description is expressible by an MSO formula.)

1. Let $Z_{\min} := \min_{\prec_{lex}} \{Z = F(X, Y) \mid Y \in \max_{\subseteq} \Im\alpha(X)\}$. We will choose Y from $\Gamma := \{Y \in \max_{\subseteq} \Im\alpha(X) \mid F(X, Y) = Z_{\min}\}$.
2. Define (linear) pre-orders $<_A$, $<_B$ and $<_C$ on Γ (these correspond to items 3(a), 3(b) and 3(c) of Lemma 4.5).

   $Y_1 <_A Y_2$ if $(Y_1 \cap Z_{\min}) \prec_{lex} (Y_2 \cap Z_{\min})$

Let $\Gamma_A :=$ the set of $<_A$ minimal elements of Γ. It is easy to see that if $Y_1, Y_2 \in \Gamma_A$, $Y_1 \neq Y_2$ and $\psi(X, Y_1, Y_2, z)$, then condition 3(a) of Lemma 4.5 fails. Indeed, if 3(a) holds, then $z \in Z_{\min}$ and $z \in Y_1 \Delta Y_2$. However, the minimality of Γ_A implies that $(Y_1 \cap Z_{\min}) = (Y_2 \cap Z_{\min})$ for every $Y_1, Y_2 \in \Gamma_A$. Contradiction.

Now define $<_B$ on Γ_A. Let $U_1 := Y_1 \setminus Y_2$ and $U_2 := Y_2 \setminus Y_1$,

$$Y_1 <_B Y_2 \text{ if } \exists z \in Z_{\min} \text{ such that } U_2 \cap z{\uparrow} \neq \emptyset \wedge U_1 \cap z{\uparrow} = \emptyset \wedge$$
$$\forall z' \in Z_{\min}\ z' <_{lex} z \to (U_1 \cap z'{\uparrow} = \emptyset) \leftrightarrow (U_2 \cap z'{\uparrow} = \emptyset)$$

Let $\Gamma_B :=$ the set of $<_B$ minimal elements of Γ_A. It is easy to see that if $Y_1, Y_2 \in \Gamma_B$, and $Y_1 \neq Y_2$ and $\psi(X, Y_1, Y_2, z)$, then condition 3(b) of Lemma 4.5 fails.

Recall that $\leq_n$ is a linear order on a finite set of n-types. Define $<_C$ on Γ_B.

$$Y_1 <_C Y_2 \text{ if } \exists z \in Z_{\min} \text{ such that}$$
$$\mathit{type}^n(X, Y_1)_{\geq z} <_n \mathit{type}^n(X, Y_2)_{\geq z} \wedge$$
$$\forall z' \in Z_{\min}\ z' <_{lex} z \to (\mathit{type}^n(X, Y_1)_{\geq z'} = \mathit{type}^n(X, Y_2)_{\geq z'})$$

Observe

▷ Claim 4.6. $<_C$ is a linear order on Γ_B.

Proof. It is clear that $<_C$ is irreflexive. We will prove that (1) $<_C$ is transitive and (2) If $Y_1 \neq Y_2$ then $Y_1 <_C Y_2$ or $Y_2 <_C Y_1$. These imply that $<_C$ is a linear order.

(1) $<_C$ is transitive. Indeed, let $Y_1, Y_2, Y_3 \in \Gamma_B$ and $Y_1 <_C Y_2 <_C Y_3$. Assume that $z_{1,2}$ is a witness that $Y_1 <_C Y_2$, i.e., $\mathit{type}^n(X, Y_1)_{\geq z_{1,2}} <_n \mathit{type}^n(X, Y_2)_{\geq z_{1,2}}$ and $\forall z' \in Z_{\min}\ z' <_{lex} z_{1,2} \to (\mathit{type}^n(X, Y_1)_{\geq z'} = \mathit{type}^n(X, Y_2)_{\geq z'}$. Assume that $z_{2,3}$ is a witness that $Y_2 <_C Y_3$.

If $z_{1,2} <_{lex} z_{2,3}$, then $z_{1,2}$ is a witness that $Y_1 <_C Y_3$; otherwise $z_{2,3}$ is a witness that $Y_1 <_C Y_3$. Hence, $<_C$ is transitive.

(2) Now, we prove that If $Y_1 \neq Y_2$ then $Y_1 <_C Y_2$ or $Y_2 <_C Y_1$.

Since, $Y_1, Y_2 \in \Gamma_B$, we know that

if $\psi(X, Y_1, Y_2, z)$, then 3(a) and 3(b) of Lemma 4.5 fail. Hence, 3(c) holds, i.e., $\mathit{type}^n(X, Y_1)_{\geq z} \neq \mathit{type}^n(X, Y_2)_{\geq z}$ Therefore,

$$\exists z \in Z_{\min} \text{ such that } \mathit{type}^n(X, Y_1)_{\geq z} \neq \mathit{type}^n(X, Y_2)_{\geq z} \wedge$$
$$\forall z' \in Z_{\min}\ z' <_{lex} z \to (\mathit{type}^n(X, Y_1)_{\geq z'} = \mathit{type}^n(X, Y_2)_{\geq z'}$$

Hence, $Y_1 <_C Y_2$ or $Y_2 <_C Y_1$. ◁

Now, we choose (a unique) $<_C$-minimal element of Γ_B.

Below is the summary of our choice of $Y \in \max_{\subseteq} \Im\alpha(X)$:

1. $Z_{\min} := \min_{\prec_{lex}}\{Z = F(X, Y) \mid Y \in \max_{\subseteq} \Im\alpha(X)\}$ and $\Gamma := \{Y \in \max_{\subseteq} \Im\alpha(X) \mid F(X, Y) = Z_{\min}\}$.
2. $\Gamma_A :=$ the set of $<_A$ minimal elements of Γ.
3. $\Gamma_B :=$ the set of $<_B$ minimal elements of Γ_A.
4. We choose a unique $<_C$ minimal elements of Γ_B.

It is clear that the above choice can be formalized in MSO.

5 Choice Function and Fooling Sets

A *choice function* is a mapping which assigns to each non-empty set of nodes one element from the set.

Gurevich and Shelah [6] proved:

▶ **Theorem 5.1** (Gurevich and Shelah [6]). *There is no MSO-definable choice function in the full-binary tree.*

A simplified combinatorial proof of Theorem 5.1 was given in [2, 3].

In the rest of this section we introduce some notions and prove lemmas which will be used in the next section to prove uncountable cross-section theorem.

Choice Function on antichains. A choice function on antichains is a mapping which assigns to each non-empty antichain in the full binary tree one element from the antichain.

▶ **Corollary 5.2.** *There is no MSO-definable choice function on antichains.*

Proof. If $\beta(X, y)$ defines a choice function on antichains then $\alpha(X, y) := \exists Z$ "Z is the set of $\leq$ minimal elements of X"$\wedge\beta(Z, y)$ defines a choice function - a contradiction. ◀

▶ **Definition 5.3** (Fooling set). *Assume $\alpha(X, y) \rightarrow y \in X$. A set P is fooling for $\alpha(X, y)$ (wrt choice) if $P \neq \emptyset$ and $\neg\exists!y\alpha(P, y)$. P is a fooling set for a set Φ of formulas if it is a fooling set for each formula in Φ. If, in addition, P is an antichain, we say that P is a fooling antichain.*

It is helpful to use the following convention: If $\alpha(X, y)$ does not imply $y \in X$, then every set is fooling for α. As a consequence: P is fooling for a set Φ of formulas iff P is fooling for $\{\varphi \in \Phi \mid \varphi \rightarrow y \in X\}$. Theorem 5.1 and Corollary 5.2 imply that every formula has a fooling set and a fooling antichain.

▶ **Lemma 5.4.** *The following statements hold in the full binary tree:*

1. *There is no MSO-definable choice function.*
2. *Every $\alpha(X, y)$ has a fooling set.*
3. *Every finite set of formulas has a fooling set.*
4. *There is no MSO-definable choice function on antichains.*
5. *Every formula has a fooling antichain.*
6. *Every finite set of formulas has a fooling antichain.*

Proof. First we prove that implications (1) ⇒ (2) ⇒ (3) ⇒(1) hold in every structure. These and Theorem 5.1 imply that (1)-(3) are true in the full binary tree.

(1)⇒(2). If $\alpha(X, y)$ does not define a choice function and $\alpha(X, y) \rightarrow y \in X$, then there is a fooling set for α.

(2)⇒(3). Let $\alpha_1(X, y), \dots, \alpha_n(X, y)$ be a finite sequence of formulas such that $\alpha_i(X, y) \rightarrow y \in X$.

Define

$$Fool_i(X) := X \neq \emptyset \wedge \neg\exists!y\alpha_i(X, y)$$

$Fool_i(X)$ holds iff X is a fooling set for α_i.

If $\bigwedge_{i=1}^{n} Fool_i(X)$ is satisfiable, then there is a fooling set for $\{\alpha_i \mid i = 1, \dots n\}$.

Toward a contradiction we assume that $\bigwedge_{i=1}^{n} Fool_i(X)$ is unsatisfiable, and construct a formula that has no fooling set.

For $I \subseteq \{1,\dots,n\}$ define $FOOL_I(X) := \bigwedge_{i\in I} Fool_i(X) \wedge \bigwedge_{j\notin I} \neg Fool_j(X)$.

Observe that $FOOL_I(X)$ for $I \subsetneq \{1,\dots,n\}$ defines a partition, i.e., if $I_1 \neq I_2$, then $FOOL_{I_1}(X) \wedge FOOL_{I_2}(X)$ is unsatisfiable, and $\bigvee_{I\subsetneq\{1,\dots,n\}} FOOL_I(X)$ holds for every X.

Let c be a function which assigns to every proper subset of $\{1,\dots,n\}$ an element in its complement. For $I \subsetneq \{1,\dots,n\}$ define

$$\beta_I(X,y) := FOOL_I(X) \wedge \alpha_j(X,y) \text{ for } j = c(I) \notin I$$

and

$$\gamma(X,y) := \bigvee_{I\subsetneq\{1,\dots,n\}} \beta_I$$

For every P there is a unique $I \subsetneq \{1,\dots,n\}$ such that $FOOL_I(P)$. Hence, by the definition of γ: $\gamma(P,y)$ iff $FOOL_I(P) \wedge \alpha_j(P,y)$ for $j = c(I)$. Now, $FOOL_I(P)$ implies $\neg Fool_j(P)$ for $j = c(I)$. Therefore, if $P \neq \emptyset$ then $\exists! y \alpha_j(P,y)$, and therefore, $\exists! y \beta_I(P,y)$, and $\exists! y \gamma(P,y)$. A contradiction to "γ has a fooling set."

Hence, there is a fooling set for $\{\alpha_i \mid i = 1,\dots n\}$.

(3)⇒(1) trivial.

(4) - this is Corollary 5.2.

Finally, the proof of the equivalences between (4),(5) and (6) is obtained by replacing "fooling set" by "fooling antichain" in the proof of the equivalences between (1),(2) and (3). ◀

Recall that there are finitely many (semantically distinct) formulas of qr $\leq n$ with free variables X and y. We say that P is **n-fooling** if it is fooling for the formulas of qr $\leq n$. Hence, by Lemma 5.4,

▶ **Corollary 5.5.** *For every n there is an n-fooling set.*

6 Uncountable Cross-section Theorem

In this section we prove Uncountable Cross-section Theorem which is stated in the Introduction. The idea is to force infinitely many choices from a fooling set. Since every choice leads to at least two possibilities, infinitely many choices lead to uncountable many possibilities. Below are details.

Consider a relation $R^{\infty}_{choice}(X,Y)$ defined as: "Y is a subset of X such that for every n: $r^n l{\uparrow} \cap Y$ is a one element set." It is clear that $R^{\infty}_{choice}(X,Y)$ is MSO definable.

Let P be a subset of $\{l,r\}^*$ and let $r^*lP := \{u \mid u = r^n lv \text{ for } v \in P \text{ and } n \geq 0\}$. Below "$\exists^{2^{\aleph_0}} Y$" stands for "there are at least $2^{\aleph_0}$ different Y."

▶ **Proposition 6.1.**

1. *Assume that $\alpha(X,Y)$ has* qr $\leq n$ *and P is an $n+1$-fooling set. If the cross-section of $\alpha(X,Y)$ at r^*lP is included in the cross-section of $R^{\infty}_{choice}(X,Y)$ at r^*lP, then $T, r^*lP \models \exists Y \alpha(X,Y) \rightarrow \exists^{2^{\aleph_0}} Y \alpha(X,Y)$.*
2. *The relation $R^{\infty}_{choice}(X,Y)$ contains no* MSO*-definable relation with the same domain and only cross-sections of cardinality less than $2^{\aleph_0}$.*

Proof. (2) immediately follows from (1).

(1) First, observe that if P is an $n+1$-fooling set, then no $\beta(X,Y)$ of qr $\leq n$ can choose a unique one element subset of P, i.e., $\neg\big(\exists! Y \beta(P,Y) \wedge \exists Y(\beta(X,Y) \wedge \exists y Y = \{y\})\big)$. Indeed, if β chooses a one element subset of P, then $\exists Y \beta(X,Y) \wedge y \in Y$ chooses a unique element from P. This contradicts that P is $n+1$-fooling.

Second, observe that (T, P) is isomorphic to $(T, r^*lP)_{\geq r^n l}$ for every n, and (T, r^*lP) is obtained from $(T, \emptyset)$ by grafting (T, P) at an antichain $\{r^i l \mid i \in \mathbb{N}\}$.

Let Q be such that $T, r^*lP, Q \models \alpha(X, Y)$. Since $\forall Y(\alpha(r^*lP, Y) \to R^{\infty}_{choice}(r^*lP, Y))$, there are $w_i \in P$ such that $(r^i l{\uparrow} \cap Q) = \{r^i l w_i\}$. Let $\tau_i(X, Y)$ be the n-type of the subtree rooted at $r^i l$ in (T, r^*lP, Q). Then $T, P, \{w_i\} \models \tau_i(X, Y)$. Since P is an $n+1$-fooling set, by the first observation above, there is $W'_i \neq \{w_i\}$ such that $T, P, W'_i \models \tau_i(X, Y)$.

Let $\pi_r := v_1 v_2 \ldots$ be the rightmost branch in the full binary tree T, i.e., $v_i = r^i$ for $i \in \mathbb{N}$. For $I \subseteq \mathbb{N}$ define $Q_I := \{r^i l w_i \mid i \in I\} \cup \bigcup_{i \notin I} r^i l W'_i$. Then the assumptions of Lemma 2.5 hold for $\pi := \pi_r$, $T^1 := (T, r^*lP, Q)$ and $T^2 := (T, r^*lP, Q_I)$. Therefore, by Lemma 2.5, $T, r^*lP, Q_I \models \alpha$ for every $I \subseteq \mathbb{N}$. Since $Q_I \neq Q_{I'}$ for $I \neq I'$, we obtain $T, r^*lP \models \exists^{2^{\aleph_0}} Y \alpha(X, Y)$. ◀

The next proposition describes a property that is more natural than R^{∞}_{choice}, and which also implies Uncountable Cross-section Theorem.

▶ **Proposition 6.2.** *The relation "Y is a branch such that $X \cap Y$ is infinite" contains no* MSO*-definable relation with the same domain and only cross-sections of cardinality* $< 2^{\aleph_0}$.

7 Conclusions and Further Results

Let us introduce some weaker variants of uniformization. Let $R^* \subseteq R$ be two relations with the same domain. If the cross-sections of a relation R^* are at most l for some $l \in \mathbb{N}$ (respectively, finite, countable), we say that R^* is an l-relation (respectively, a finitary relation, an $\aleph_0$-relation).

If R^* is an l-relation for some $l \in \mathbb{N}$ (respectively, a finitary or an $\aleph_0$-relation) we say that R^* is an l-uniformizer of R (respectively, finitary uniformizer, $\aleph_0$-uniformizer).

We say that ψ is an l-uniformizer of φ in a structure $\mathcal{M}$, if the relation definable by ψ in $\mathcal{M}$ is an l-uniformizer of the relation definable by φ in $\mathcal{M}$.

$\mathcal{M}$ has the l-uniformization property if for every MSO formula φ there is an MSO formula ψ that is an l-uniformizer of φ in $\mathcal{M}$. Finitary (and $\aleph_0$) uniformizers and the finitary (and $\aleph_0$) uniformization property are defined similarly.

For $l \in \mathbb{N}$, we say that the **uniformization rank** of R is l if R has an MSO-definable l-uniformizer and either $l = 1$ or R has no MSO-definable $(l-1)$-uniformizer. We say that the uniformization rank of R is finitary if R has an MSO-definable finitary uniformizer and has no MSO-definable l-uniformizer for $l \geq 1$. We say that the uniformization rank of R is $\aleph_0$ if R has an MSO-definable $\aleph_0$-uniformizer and has no finitary uniformizer. We say that the uniformization rank of R is $2^{\aleph_0}$ if R has no uniformizer with the cross-section of cardinality $< 2^{\aleph_0}$.

Our result can be restated as:

▶ **Corollary 7.1.** *The only ranks for* MSO*-definable relations in the full binary tree are one,* $\aleph_0$ *and* $2^{\aleph_0}$.

Indeed, the finite cross-section theorem implies that the rank is one or infinite. The relation $y \in X$ has rank $\aleph_0$. The relations $R^{\infty}_{choice}(X, Y)$ and "Y is a branch such that $X \cap Y$ is infinite" have rank $2^{\aleph_0}$. For the MSO-definable (with parameters) relation the continuum hypothesis holds [1]. Therefore, the infinite cross-sections of MSO-definable relations are either countable or have cardinality $2^{\aleph_0}$. Hence, Corollary 7.1 holds.

7.1 Ranks over Integers

In [4] the uniformization of MSO over the integers with the successor function was investigated. Consider, $\varphi_2(X,Y) := \forall t(Y(t) \leftrightarrow \neg Y(t+1))$. Note that φ_2 does not depend on X and there are exactly two sets Y_{even} := "the set of even integers" and Y_{odd} :="the set of odd integers" that satisfy φ_2. Note also that there is an order preserving automorphism of integers that maps Y_{even} onto Y_{odd}. Therefore, no MSO formula distinguishes between Y_{even} and Y_{odd}. Hence, the uniformization rank of φ_2 is two. Similarly, for every l one can define an MSO formula φ_l which has the uniformization rank l over the integers. It was proved in [4] that the uniformization rank of an MSO formula over integers is computable.

It is open whether the uniformization rank of an MSO formula over the full binary tree is computable.

7.2 Ranks over Ordinals

Lifsches and Shelah [7] considered the uniformization problem over the class of trees and the class of ordinals. Recall that a structure $\mathcal{M}$ is said to have the uniformization property if every MSO definable relation (in $\mathcal{M}$) has an MSO definable uniformizer. Lifsches and Shelah proved that an ordinal α has the uniformization property iff $\alpha < \omega^\omega$.

In the full paper we consider uniformization over ordinals. We have not provided an algorithm to decide the uniformization rank of a formula. However, we prove that if an MSO definable relation over an ordinal has only countable cross-sections, then it has a uniformizer. Moreover, the only ranks for the MSO-definable relations over a countable ordinal are one and $2^{\aleph_0}$.

7.3 Uniformization Degrees

We know that the formula $\psi_1 := y \in X$ has no MSO uniformizer in the full binary tree. Now, let us look at the formula ψ_2 stating that"Y is a branch such that $Y \cap X$ is infinite."

This formula has no MSO uniformizer. But are there any other interesting relations between these two formulas? Can we say, for instance, that ψ_2 is even "harder" to uniformize than ψ_1 (whatever this might mean)? Or, perhaps the other way round? Do we feel that the example of ψ_2 "contains a new idea" when it comes to our discussion of uniformization? To turn these admittedly vague questions into mathematical ones, we require a notion of comparing formulas and perhaps an equivalence relation on them. However, as our example shows, the semantical equivalence seems not to be the right notion. Note, however, the following. For any set X let $X{\uparrow} := \{z \mid \exists x \in X(z \geq x)\}$ be the upward closure of X. X is non-empty iff there is a branch Y such that $|Y \cap X{\uparrow}|$ is infinite. Moreover, if $Y \cap X \neq \emptyset$, then $Y \cap X{\uparrow}$ has a minimal point y which is in X. Hence, by using any uniformizer for ψ_2 we succeeded to define (in MSO) a uniformizer for ψ_1.

This suggests the following definition.

Let $\mathcal{M}$ be a structure in a signature Σ and $\psi(\overline{X},\overline{Y})$ and $\psi_2(\overline{U},\overline{V})$ be formulas in Σ. ψ_1 is easier to uniformize (in $\mathcal{M}$) than ψ_2 if there is an MSO formula $\varphi(\overline{X},\overline{Y})$ (reduction formula) in an expansion of Σ by a relational symbol c such that:

if $\mathcal{M}[c]$ is an expansion of $\mathcal{M}$, where c is interpreted as a uniformizer of ψ_2, then $\varphi(\overline{X},\overline{Y})$ is a uniformizer of ψ_1.

We write $\psi_1 \preceq_{un} \psi_2$ if ψ_1 is easier to uniformize than ψ_2. The relation $\preceq_{un}$ is a preorder relation and its equivalence classes can be called (uniformization) degrees.

We can show that "$y \in X$," $R^{\infty}_{choice}(X,Y)$, "Y is a branch such that $Y \cap X$ is infinite," "Y is a branch such that $Y \cap X$ is finite" and "Y is a finite non-empty subset of an antichain X" have the same degree. It is interesting to study the structure of degrees. In particular, we do not know whether there is a maximal degree.

Abstract

The study of the Knot-Free Vertex Deletion problem emerges from its application in the resolution of deadlocks called knots, detected in a classical distributed computation model, that is, the OR-model. A strongly connected subgraph Q of a digraph D with at least two vertices is said to be a knot if there is no arc (u,v) of D with $u \in V(Q)$ and $v \notin V(Q)$ (no-out neighbors of the vertices in Q). Given a directed graph D, the Knot-Free Vertex Deletion (KFVD) problem asks to compute a minimum-size subset $S \subset V(D)$ such that $D[V \setminus S]$ contains no knots. There is no exact algorithm known for the KFVD problem in the literature that is faster than the trivial $\mathcal{O}^\star(2^n)$ brute-force algorithm. In this paper, we obtain the first non-trivial upper bound for KFVD by designing an exact algorithm running in time $\mathcal{O}^\star(1.576^n)$, where n is the size of the vertex set in D.

1 Introduction

In concurrent computing, a deadlock [6] is a state in which each group member waits for another member, including itself, to take action such as sending a message or, more commonly, releasing a lock. Deadlocks are a common problem in multiprocessing systems, parallel computing, and distributed systems. Resolving these deadlocks is a fundamental problem in distributed settings with no efficient (known) algorithms. Note that while distributed systems are dynamic, a deadlock is a stable property. In other words, once a deadlock occurs in the system, it would remain there until it is resolved. Two of the main classic deadlock models are the AND-model and the OR-model [1,2,14,17]. Deadlocks are characterized by the existence of cycles in the AND-model and by the existence of knots in the OR-model. Hence the problem of preventing deadlocks in the AND-model is equivalent to the Directed Feedback Vertex Set (DFVS) problem and in the OR-model, it is equivalent to the Knot-Free Vertex Deletion (KFVD) problem [13].

A *wait-for* graph is useful to analyze deadlock situations. In a wait-for graph, $D = (V; E)$, the vertex set V represents processes, and the set E of directed arcs represents wait-conditions.

A knot in a directed graph D is a strongly connected subgraph Q of D with at least two vertices, such that no vertex in $V(Q)$ has an out-neighbor in $V(D) \setminus V(Q)$. The number of processes needed to be preempted to prevent a deadlock in the OR-model is essentially the same as solving the KFVD problem in wait-for graphs. Formally, the problem of finding a vertex subset $S \subseteq V$ of minimum cardinality such that $D[V \setminus S]$ does not contain any knots is known as the KFVD problem.

Recently, KFVD has been studied extensively from algorithmic perspectives. In particular, the problem has been studied on graph classes satisfying some structural properties and from the viewpoint of parameterized complexity [4]. In this paper, we study KFVD from yet another algorithmic paradigm, that is, exact exponential-time algorithms. There has been immense progress in this area in the last two decades, resulting in non-trivial exact exponential algorithms for numerous problems, including Chromatic Number, Hamiltonian Cycle and Satisfiability [3, 9, 12, 16] We refer to the monograph of Fomin and Kratsch for a detailed exposition of the field [11].

1.1 Our contribution

In this paper, using the powerful method of *Measure & Conquer*, pioneered by Fomin, Kratsch, and Woeginger [10], we design the first non-trivial exact algorithm for the KFVD problem. In particular, we obtain the following result.

▶ **Theorem 1.** *There exists an algorithm for* Knot-free vertex deletion *running in* $\mathcal{O}^*(1.576^n)$ *time.*

The starting point of our algorithm is the following simple observation: *a graph is knot-free if and only if every vertex has a path to a sink.* Moreover, finding a minimum size knot-free deletion set is equivalent to finding a subset Z of *sinks (vertices with no out-neighbors)* such that $N^+(Z)$ is exactly the deletion set [2], that is $N^+(Z) = S$. Our algorithm utilizes this observation, and rather than obtaining a minimum deletion set S; it constructs a sink set Z such that every vertex in $D - N^+(Z)$ has a path in $D - N^+(Z)$ to some vertex in Z. Note that Z does not complement S The measure associated with the instance $I = (D, V_1, V_2)$, is given by $\phi(I) = |V_1| + \frac{|V_2|}{2}$. We select a vertex $u \in V_1$ to branch, which means that either u is a sink, or it is not. If u is going to be a sink, then observe that all its out-neighbors, $N^+(u)$, must be in the deletion set and be safely deleted. Further, every vertex that can reach u in $D - N^+(u)$, say in-reachable vertices, must not go to the deletion set. However, we can remove them and work on a smaller graph. Thus removing in-reachable vertices is a prepossessing step that reduces the size of the graph. In the branch where we decide that u is not part of the sink set, we cannot delete this vertex, and thus, to capture our progress, we move the vertex u from V_1 to V_2, resulting in ϕ decreasing by 0.5. To show the desired running time, we first do "potential sensitive" branching and then do an extensive case analysis based on the degree of the vertex in V_1.

1.2 Previous Work

Observe that any directed feedback vertex set (a set of vertices that intersect every cycle in the digraph) is a knot-free deletion set as it removes any strongly connected component of size at least 2. Hence, the size of the smallest directed feedback vertex set gives an upper bound on the size of the smallest knot-free vertex deletion set. One way of eliminating knots in a graph could be to use known algorithms for the Directed Feedback Vertex Set (DFVS) problem. While DFVS has been extensively studied [7, 15], the KFVD problem is yet to receive the same scale of attention. Notice that the optimal solution for KFVD could be significantly smaller than the solution returned by invoking an existing algorithm for DFVS, which motivated a closer look at the KFVD problem itself.

Carneiro, Souza, and Protti [5] first studied the problem and showed that KFVD is NP-complete even when restricted to planar bipartite graphs with the maximum degree 4. They also presented a polynomial-time algorithm for graphs with the maximum degree 3. Recently, KFVD was studied in the parameterized framework. Carneiro et al. [4] showed that KFVD is W[1]-hard when parameterized by the size of the solution, but it can be solved in $2^{k \log \phi} n^{\mathcal{O}(1)}$ time, where ϕ is the size of the largest strongly connected subgraph. KFVD parameterized by the size of the solution k, is W[1]-hard even when the length of a longest directed path of the input graph, as well as its Kenny-width, are bounded by constants [2]. However, the problem is known to be in FPT parameterized by either clique-width or treewidth of the underlying undirected graph. Moreover, the KFVD problem is known to admit FPT algorithms when parameterized by *dfvs+maximum path length* or *dfvs+Kenny-width* where, *dfvs* denotes the size of the smallest directed feedback vertex set in the graph.

Organization of the paper: In Section 3, we start by providing our algorithm, and we verify the correctness of each of its steps in Section 4. The running time is analyzed in Section 5, while Section 6 provides a lower bound on the worst-case performance of our algorithm.

2 Preliminaries and Auxiliary Results

In this section, we first state some notations, definitions, and useful auxiliary results. We also formalize an appropriate potential function based on which we later design our algorithm. A few reduction rules are proved towards the end of this section which are used throughout the paper.

Standard Notation. For a digraph D, $V(D)$ and $E(D)$ denote the set of vertices and arcs, respectively. We denote an arc from u to v by the ordered pair (u, v). For a vertex v of D, the out-neighborhood of v is denoted by $N^+(v) = \{u \mid (v, u) \in E(D)\}$. Similarly, we denote its in-neighborhood by $N^-(v) = \{u \mid (u, v) \in E(D)\}$ and $N(v) = N^+(v) \cup N^-(v)$. A vertex v is called a *source vertex*, if $N^-(v) = \emptyset$. Similarly it is called a *sink vertex*, if $N^+(v) = \emptyset$. We define the *in-reachability set* of a vertex v as the set of vertices that can reach the vertex v via some directed path in $D - N^+(v)$ and we denote it by $R^-(v)$. Notice that $v \in R^-(v)$. We define, $R(v) = N^+(v) \cup R^-(v)$. For a set $S \subseteq V(D)$, $D - S$ denotes the digraph obtained by deleting the vertices S and the edges incident on the vertices of S and $D[S]$ denotes the subgraph of D induced on S. A *path* P of length ℓ is a sequence of distinct vertices $v_1, v_2, \ldots, v_\ell$ such that (v_i, v_{i+1}) is an arc, for each i, $i \in [\ell - 1]$. In our algorithm, branching vector (a, b) means a branching where in the first branch, the potential (measure) drops by a while in the second branch, the potential drops by b. It is a measure of the effectiveness of any branching step. Later we provide a detailed description of such a potential function and how it relates to the hardness of our instance. For graph-theoretic terms and definitions not stated explicitly here, we refer to [8].

2.1 Auxiliary Results

In this subsection, we first state some of the known reduction rules and some new reduction rules for the problem that we use in our branching algorithm.

▶ **Reduction Rule 2** ([2]). *Let $v \in D$ be such that $N^-(v) = \emptyset$, Then (D, k) is a yes-instance if and only if $(D - v, k)$ is a yes-instance.*

▶ **Reduction Rule 3** ([2]). *Let $v \in D$ be such that $N^+(v) = \emptyset$, Then (D, k) is a yes-instance if and only if $(D - R^-(v), k)$ is a yes-instance.*

▶ **Proposition 4** ([2]). *A digraph D is knot-free if and only if for every vertex v of D, v has a path to a sink.*

▶ **Corollary 5** ([2]). *For any optimal solution $S \subseteq V(D)$ with the set of sink vertices Z in $D - S$, we have $N^+(Z) = S$.*

Proposition 4 and Corollary 5 imply that given a digraph D, the problem of finding a set of sink vertices Z such that every vertex in $V(D) \setminus N^+(Z)$ has a directed path to a vertex in Z and $|N^+(Z)|$ is minimum; is equivalent to the Knot-free Vertex Deletion (KFVD) problem. Therefore, our algorithm aims to identify a set of (eventually, to be) sink vertices Z while minimizing $|N^+(Z)|$ instead of directly looking for the deletion set.

Strategy of our Algorithm. We design a branching algorithm for KFVD in general digraphs. At any iteration in our algorithm, we branch on a potential vertex $v \in V(D)$ based on the two possibilities that either v is a sink vertex or a non-sink vertex in an optimal solution. Observe that even if a vertex becomes a non-sink vertex corresponding to an optimal solution, there are two possibilities: it belongs to the deletion set or does not. So we can not simply forget about this vertex, which means its behavior in the final knot-free graph remains inconclusive. To track the possible vertices that become the sink or non-sink, we use a potential function (ϕ) for $V(D)$ defined as follows.

▶ **Definition 6** (Potential function). *Given a digraph $D = (V, E)$, we define a* potential function *on $V(D)$, $\phi : V(D) \to \{0.5, 1\}$ such that $\phi(v) = 1$, if v is a potential vertex to become a sink in an optimal solution and $\phi(v) = 0.5$, if v is a non-sink vertex. For any subset $V' \subseteq V(D)$, $\phi(V') = \sum_{x \in V'} \phi(x)$. We call a vertex v as an* undecided *vertex if $\phi(v) = 1$ and a* semi-decided *vertex if $\phi(v) = 0.5$.*

To solve the Knot-free Vertex Deletion problem on a digraph D, we initialize the potential values of all vertices to 1. As soon as we decide a vertex to be a non-sink vertex, we drop its potential by 0.5. Any vertex whose potential is 0.5 can not become a sink in the final knot-free graph resulting from removing an optimal vertex deletion set from D.

▶ **Definition 7** (Feasible solution). *A set $S \subseteq V(D)$ is called a feasible solution for (D, ϕ) if $D - S$ is knot-free and for any sink vertex s in $D - S$, $\phi(s) = 1$.* KFVD(D, ϕ) *is the size of an optimal solution for (D, ϕ).*

▶ **Reduction Rule 8.** *If all the vertices in D are semi-decided and D has no source or sink vertices, then $V(D)$ is contained inside any feasible solution for (D, ϕ).*

Proof. If S is a solution for (D, ϕ), then $D - S$ is knot-free. Since all vertices of D are semi-decided, $D - S$ has no sink vertices. Therefore, $D - S$ is an empty graph. In other words, $S = V(D)$. ◀

Let S_{opt} and Z_{opt} be the set of deleted vertices and the set of sink vertices with respect to some optimal solution KFVD(D, ϕ).

▷ Claim 9. If $x \in Z_{opt}$, then $N^+(x)$ is in S_{opt} and $S_{opt} \cap R^-(x) = \emptyset$.

Proof. By the definition of a sink vertex, if $x \in Z_{opt}$ then $N^+(x)$ is in S_{opt}. Let $Y = S_{opt} \cap R^-(x)$. We claim $S' = S_{opt} \setminus Y$ is also a solution which will contradict the fact that S_{opt} is an optimal solution. Suppose S' is not a solution, then there exists a vertex v in $G \setminus S'$, that do not reach to a sink s in $G \setminus S'$ but v reaches to some sink s in $G \setminus S_{opt}$. Since every vertex in Y reaches to some sink x in $G \setminus S'$, $v \notin Y$. If s is not a sink vertex in $G \setminus S'$, then some vertex $y \in Y$ is an out-neighbor of s. But then v can reach the sink x in $G \setminus S'$ via y. Hence, S' is a solution of strictly smaller size than S_{opt}, which is a contradiction. ◁

▷ Claim 10. If $x \in Z_{opt}$, then $|S_{opt}| = |N^+(x)| + \mathsf{KFVD}(D - R(x), \phi)$.

Proof. First, we prove that $S' = S_{opt} \setminus N^+(x)$ is a solution to $(D - R(x), \phi)$. If this is not true, then there exists a vertex v in $D - (R(x) \cup S')$ that do not reach any sink. Since $S_{opt} \subseteq R(x) \cup S'$, $v \notin S_{opt}$. But S_{opt} is a solution to (D, ϕ) and v can reach some sink $s \in Z_{opt}$ in $D - S_{opt}$. First we claim that $s \neq x$. Note that v is not in $R(x)$ and it can only reach x via some vertex in $N^+(x)$. So v can not reach x in $D - S_{opt}$ as $N^+(x) \subseteq S_{opt}$. Hence $s \neq x$. Then v has a path to s which is disjoint from $S_{opt} \supseteq N^+(x)$. Moreover this path is also disjoint from the set $R(x) \setminus N^+(x)$, since $v \notin (R(x)$. Hence this path is disjoint from $R(x)$ and S_{opt}. Therefore, v can reach s via the same path in $D - (R(x) \cup S')$. If s is a sink in $D - S_{opt}$, then s is also a sink in $(D - R(x)) \setminus S'$. Hence, v has a path to a sink in D, which is a contradiction. It implies that $S' = S_{opt} \setminus N^+(x)$ is a solution to $(D - R(x))$ and therefore, $|S_{opt}| - |N^+(x)| \geq \mathsf{KFVD}(D - R(x), \phi)$.

To prove the other direction, assume that S'' is an optimal solution to $(D - R(x), \phi)$. We claim that $S' = S'' \cup N^+(x)$ is a solution for (D, ϕ). Suppose not, then there exists a vertex v that does not reach a sink in $D - S'$. Note that $v \notin R(x)$ as all vertices in $R(x)$ can reach sink x in $D - S'$. Then $v \notin R(x) \cup S'$ and hence it is also in $D - (R(x) \cup S'')$ and it reaches a sink s. Since this path is disjoint from $S'' \cup R(x)$, v still can reach s via the same path in $D - S'$. Note that s is not a sink in $D - S'$ only if it has an out-neighbor in $R(x) \setminus N^+(x)$. But then s and v are in $R(x)$ which is not possible. Hence, v can still reach the same sink s and $S' = S'' \cup N^+(x)$ is a solution to D. Thus, $S_{\mathsf{opt}} \leq |N^+(x)| + \mathsf{KFVD}(D - R(x))$. ◁

3 An algorithm to compute minimum knot-free vertex deletion set

In this section, we design an exact algorithm to compute a minimum knot-free vertex deletion set. As mentioned earlier, we start by initializing the potential values of all vertices to 1. As soon as we decide a vertex is a non-sink vertex, we drop its potential by 0.5. In the following algorithm, at any step, if there are vertices with no out-neighbors (sinks) or no in-neighbors (sources), we remove such vertices with the help of Reduction Rules 2 and 3. If all the vertices are semi-decided, we apply Reduction Rule 8 to solve the instance in polynomial time. At any step, if there is an undecided vertex x with $\phi(R(x)) \geq 3.5$), we branch on the possibility of x being a sink or non-sink in the optimal solution. Here we use the large potential drop in the branch where x is chosen to be a sink to our advantage and obtain a $(3.5, 0.5)$ branching. If there are no such vertices, we look for an undecided vertex x such that all its neighbors are semi-decided, and we branch on x. If there are no such vertices, we branch on undecided vertices of degrees 2 and 3. Notice that in these branching steps, even if there is not a large potential drop when x is a sink, in the other branch when x is a non-sink vertex, we still find an undecided vertex s close to x, which is forced to be a sink. Hence the potential drop together in both the branches ensure *good* running time for our algorithm. If all undecided vertices have only one neighbor each, then we remove such vertices with the help of Reduction Rules 2 and 3.

Algorithm 1 KFVD (D, ϕ).

```
    Input: A directed graph $D$ and a potential function $\phi$
    Output: Size of a minimum knot-free vertex deletion set
 1  if $\exists$ $x$ such that $N^-(x) = \emptyset$ then
 2      return KFVD($D - \{x\}, \phi$);
 3  if $\exists$ $x$ such that $N^+(x) = \emptyset$ then
 4      return KFVD($D - R(x), \phi$);
 5  if $\forall v \in D$, $\phi(v) = 0.5$ then
 6      return $|V(D)|$;
 7  if $\exists$ $x \in D$ such that $\phi(x) = 1$ & $\phi(R(x)) \geq 3.5$ then
 8      $D_1 = D - R(x)$;
 9      $D_2 = D$;

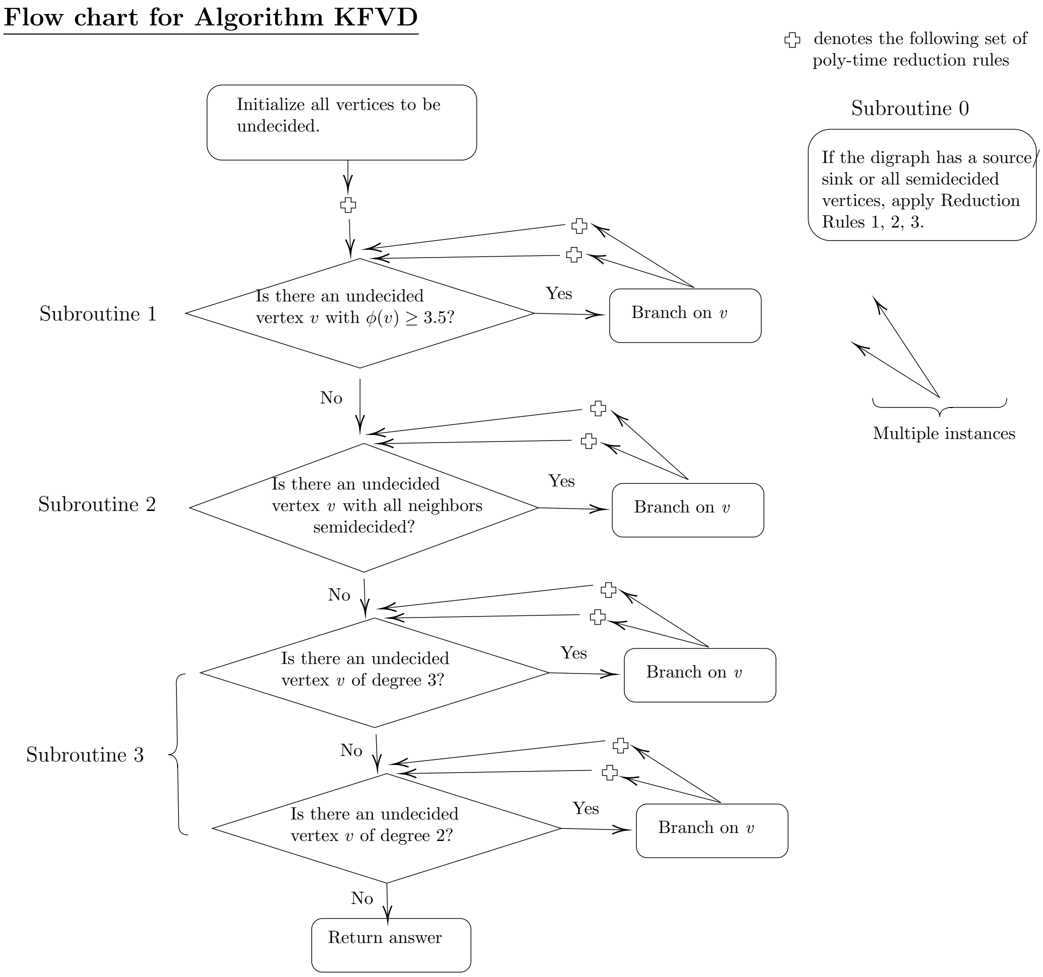
34      $\phi_1 = \phi$;
35      $D_2 = D - R(y)$;
36      $\phi_2 = \phi$;
37      $D_3 = D - R(z)$;
38      $\phi_3 = \phi$;
39      return
          min{KFVD($D_1, \phi_1$) + $|N^+(x)|$, KFVD($D_2, \phi_2$) + $|N^+(y)|$, KFVD($D_3, \phi_3$) + $|N^+(z)|$};
```

4 Correctness of the Algorithm

In this section, we prove that the Algorithm KFVD returns a knot-free vertex deletion set of minimum size. We denote the steps from the lines 1-6 of the algorithm as *Subroutine* 0. The correctness of the lines 1-4 follows from the Reduction Rules 2, and 3 and the correctness of the lines 5-6 follows from the Reduction Rule 8. We call the steps from the lines 7-13, 14-25 and 26-39 of Algorithm KFVD as *Subroutine* 1, *Subroutine* 2, and *Subroutine* 3, respectively.

In the subsequent subsections, we will prove the correctness of Subroutines 1, 2, and 3.

Below we provide a flowchart for Algorithm KFVD.



Flow chart for Algorithm KFVD

Return answer

4.1 Correctness of Subroutine 1

Subroutine 1 branches on an undecided vertex $x \in V(D)$, if $\phi(R(x)) \geq 3.5$. Notice that for any solution S in polynomial time we can determine the set of sink vertices, say Z_S, corresponding to set S.

▶ **Lemma 11.** *If $x \in V(D)$ such that $\phi(x) = 1$ and $\phi(R(x)) \geq 3.5$, then* $\mathsf{KFVD}(D, \phi) = \min\{\mathsf{KFVD}(D_1, \phi_1) + |N^+(x)|,\ \mathsf{KFVD}(D_2, \phi_2)\}$ *where $D_1 = D - R(x)$, $D_2 = D$ and $\phi_1 = \phi$, $\phi_2(v) = \phi(v)$, for all $v \in V(D) \setminus \{x\}$ and $\phi_2(x) = 0.5$.*

Proof. We use induction on the total potential $\phi(V(D))$ of the digraph D to prove the lemma. For the base case, assume that $\phi(V(D)) = 1$ and there exists exactly one undecided vertex x. Note that the given recurrence relation holds in this case. Next assume that $\mathsf{KFVD}(D_1, \phi_1)$ and $\mathsf{KFVD}(D_2, \phi_2)$ compute the optimal solution correctly, say S_1 and S_2, respectively. Let S be an optimal solution for $\mathsf{KFVD}(D, \phi)$. We consider the following two cases:

Case 1: $\boldsymbol{x \in Z_S}$.

Here we claim that $S_1 \cup N^+(x)$ is an optimal solution for $\mathsf{KFVD}(D,\phi)$ if and only if S_1 is an optimal solution for $\mathsf{KFVD}(D_1,\phi_1)$. The arguments are exactly the same as that in Claim 6. And by construction, $Z_S \in \phi^{-1}(1)$ if and only if $Z_S \in \phi_1^{-1}(1)$ where $S' = S \setminus N^+(x)$. We also claim that $\mathsf{KFVD}(D_2,\phi_2) \geq \mathsf{KFVD}(D_1,\phi_1) + |N^+(x)|$. For contradiction suppose KFVD $(D_2,\phi_2) < \mathsf{KFVD}(D_1,\phi_1) + |N^+(x)|$. Then any optimal solution S_2 for (D_2,ϕ_2) is also a feasible solution for $\mathsf{KFVD}(D,\phi)$. But S_2 has size strictly smaller than S, which is a contradiction. Hence, $\mathsf{KFVD}(D,\phi) = \min\{\mathsf{KFVD}$ $(D_1,\phi) + |N^+(x)|,$ $\mathsf{KFVD}(D,\phi_2)\}$.

Case 2: $\boldsymbol{x \notin Z_S}$.

In this case, $\mathsf{KFVD}(D_2,\phi_2) = \mathsf{KFVD}(D,\phi)$, by definition. Also $\mathsf{KFVD}(D_2,\phi_2) \leq \mathsf{KFVD}(D_1,\phi_1) + |N^+(x)|$, otherwise we have $S' = S_1 \cup N^+(x)$ as a solution with size strictly smaller than S for $\mathsf{KFVD}(D,\phi)$, where $x \in Z_{S'}$, and that is a contradiction. Hence, $\mathsf{KFVD}(D,\phi) = \min\{\mathsf{KFVD}(D_1,\phi) + |N^+(x)|,$ $\mathsf{KFVD}(D,\phi_2)\}$. ◀

In Subroutine 1, we get a $(3.5, 0.5)$ branching. If Subroutine 1 is no longer applicable on the instance, the digraph has no undecided vertices with $\phi(R(x)) \geq 3.5$. This fact is crucial to obtaining desirable branching vectors for Subroutine 2 and Subroutine 3.

▶ Remark 12. After Subroutine 1 completion, there are no undecided vertices with degree more than 4.

4.2 Correctness of Subroutine 2

Subroutine 2 branches on any undecided vertex x who has semi-decided neighbors only. Note that x has at least one out-neighbor and at least one in-neighbor; otherwise, reduction rules 2 or 3 would have been applied.

▷ Claim 13. Let D be a digraph such that $\phi(R(v)) < 3.5$, for every vertex $v \in V(D)$ and x be an undecided vertex in D such that for all $v \in N(x)$, $\phi(v) = 0.5$. If x is a non-sink vertex in an optimal solution S for (D,ϕ), then there exist vertices $y \in N^-(x)$ and $z \in N^+(x)$ such that there exists a unique $s \in N^-(y) \cap N^+(z)$ with $\phi(s) = 1$ and s is a sink vertex in $D - S$.

Proof. If x is not a sink vertex, then there exists a vertex $z \in N^+(x)$ such that it does not belong to S. Therefore, in digraph $D - S$ the vertex z must reach to a sink s i.e., there exists a path between z and the undecided vertex s. It implies that the vertices $x,\ z,\ s$ belong to $R(s)$. Therefore, $\phi(R(s)) \geq 3.5$ as $\phi(x) = \phi(s) = 1$, which is not possible. It implies that $s \in N^+(z)$ with $\phi(s) = 1$. Since vertex x must have one in-neighbor, say $y \in N^-(x)$. Next, s can not have an out-neighbor outside the set $\{x,y,z\}$, otherwise $\phi(R(x)) \geq 3.5$ which is not possible. Moreover, x or z cannot be an out-neighbor of s as x has no undecided out-neighbor and z does not belong to S_{opt}. Hence, $y \in N^+(s)$ which implies that $s \in R(x)$. Since $\phi(R(x)) < 3.5$, there does not exist any vertex $u \in N^-(y)$ except s such that $\phi(u) = 1$. Hence, s is a unique vertex such that $s \in N^-(y) \cap N^+(z)$ with $\phi(s) = 1$. ◁

Next, we prove the correctness of Subroutine 2.

▶ **Lemma 14.** *Let D be a digraph such that $\phi(R(v)) < 3.5$, for every vertex $v \in V(D)$ and $x \in V(D)$ be such that $\phi(x) = 1$ and for all $v \in N(x)$, $\phi(v) = 0.5$. If $y \in N^-(x)$ and $z \in N^+(x)$, then*

$$\mathsf{KFVD}(D,\phi) = \begin{cases} \min\Big\{\mathsf{KFVD}(D_1,\phi_1) + |N^+(x)|, \\ \qquad \mathsf{KFVD}(D_2,\phi_2) + |N^+(s)|\Big\} & \text{if } \exists\ s \in N^-(y) \cap N^+(z) \text{ with } \phi(s) = 1, \\ \\ \mathsf{KFVD}(D_1,\phi_1) + |N^+(x)| & \text{otherwise,} \end{cases}$$

where $D_1 = D - R(x)$*,* $D_2 = D - R(s)$ *and* $\phi_1 = \phi_2 = \phi$*.*

Proof. Let S, S_1 ans S_2 be the optimal solutions for $\mathsf{KFVD}(D, \phi)$, $\mathsf{KFVD}(D_1, \phi_1)$ and $\mathsf{KFVD}(D_2, \phi_2)$, respectively. We use induction on the total potential $\phi(V(D))$ of the digraph to prove the correctness of the above claim. Let $y \in N^-(x)$ and $z \in N^(x)$. Now, we consider the following two cases:

Case 1: $\boldsymbol{\exists s \in N^-(y) \cap N^+(z)}$ **such that** $\boldsymbol{\phi(s) = 1}$**.**

Assume that there exists $s \in N^-(y) \cap N^+(z)$ with $\phi(s) = 1$. From Claim 13, we know that either x or s will be a sink in an optimal solution. Let $x \in Z_S$, then from Claim 10, $|S| = \mathsf{KFVD}(D_1, \phi_1) + |N^+(x)|$. And $S_2 \cup N^+(s)$ is a feasible solution to $\mathsf{KFVD}(D, \phi)$ and hence $\mathsf{KFVD}(D_2, \phi_2) + |N^+(s)| \geq |S| = \mathsf{KFVD}(D_1, \phi_1) + |N^+(x)|$. Similarly, if $s \in Z(S)$ then from Claim 10, $|S| = \mathsf{KFVD}(D_2, \phi_2) + |N^+(s)|$. Note that $S_1 \cup N^+(x)$ is also a feasible solution to $\mathsf{KFVD}(D, \phi)$ and therefore, $\mathsf{KFVD}(D_1, \phi_1) + |N^+(x)| \geq |S| = \mathsf{KFVD}(D_2, \phi_2) + |N^+(s)|$. Hence, we have $\mathsf{KFVD}(D, \phi) = \min\{\mathsf{KFVD}(D_1, \phi_1) + |N^+(x)|, \mathsf{KFVD}(D_2, \phi_2) + |N^+(s)|\}$.

Case 2: $\boldsymbol{\nexists s \in N^-(y) \cap N^+(z)}$ **such that** $\boldsymbol{\phi(s) = 1}$**.**

Suppose there does not exist any vertex $s \in N^-(y) \cap N^+(z)$ such that $\phi(s) = 1$. Observe that in this case, the vertex x has to be a sink; otherwise, by Claim 13 there exists a vertex $s \in N^-(y) \cap N^+(z)$ with $\phi(s) = 1$, which is a contradiction. Therefore, the vertex x has to be a sink. Hence, $\mathsf{KFVD}(D, \phi) = \mathsf{KFVD}(D_1, \phi_1) + N^+(x)$ by Claim 10, where $D_1 = D - R(x)$. ◀

▶ Remark 15. If Subroutine 2 is no longer applicable, the instance has no undecided vertices with a degree more than 3.

4.3 Correctness of Subroutine 3

Subroutine 3 branches on undecided vertices with degrees 2 and 3. When Subroutine 0, 1, and 2 are no longer applicable, there are no vertices with all semi-decided neighbors. Also there is no undecided vertex x with degree 4 as $\phi(R(x)) \geq 3.5$. So any undecided vertex has degree at most 3. Moreover, any undecided vertex x of degree 3 has exactly one undecided vertex. We will prove the correctness of branching in Subroutine 3 in two parts. First, we analyze the branching vector for degree 3 undecided vertices and then for degree 2 undecided vertices.

Branching on a degree 3 vertex

Given an undecided vertex x of degree 3, there are two cases; either x has one in-neighbor and two out-neighbors or x has two in-neighbors and one out-neighbor.

Case 1: x has one in-neighbor y_1 and two out-neighbors z_1, z_2

Out of three neighbors, x has exactly one neighbor which is undecided. So we have the following 3 three subcases.

Subcase 1: $\boldsymbol{\phi(y_1) = 1}$ **and** $\boldsymbol{\phi(z_1) = \phi(z_2) = 0.5}$**.**

- If x is a sink, there is a potential drop of at least 3 since $\{y_1, z_1, z_2, x\} \in R(x)$.
- If x is not a sink, then x and some $z \in N^+(x)$ are not in the deletion set.Without loss of generality, let $z = z_1$. Now z_1 reaches a sink $s \in Z_{opt}$ in $D - S_{opt}$. If z_1 can reach a sink s ($\neq y_1$), then $\{y_1, x, z_1, s\} \subseteq R(s)$. This is true since s can not have x or z_1 as its out-neighbor and either y_1 is an out-neighbor of s or $y_1 \in R^-(x)$. It implies that

$\phi(R(s)) \geq 3.5$, which is a contradiction. Hence y_1 is the only sink that z_1 must reach. Note that $\phi(R(y_1)) \geq 2.5$.

This gives us a $(3, 2.5)$ branching vector.

Subcase 2: $\phi(y_1) = 0.5$, $\phi(z_1) = 1$ and $\phi(z_2) = 0.5$.

- If x is a sink, the potential drops by at least 3.
- If x is not a sink and z_1 is not in the deletion set, then z_1 reaches a sink say, s in Z_{opt} in $D - S_{opt}$. If z_1 can reach a sink s ($\neq z_1$), then $\{y_1, x, z_1, s\} \subseteq R(s)$ as s can not have x , z_1 or y_1 as its out-neighbors. Therefore, $\phi(R(s)) \geq 3.5$ which is a contradiction. Therefore z_1 has to be a sink when x is not a sink. Note that $\phi(R(z_1)) \geq 2.5$.

This gives us a $(3, 2.5)$ branching vector.

Subcase 3: $\phi(y_1) = \phi(z_1) = 0.5$ and $\phi(z_2) = 1$.

- if x is a sink, again the potential drops by at least 3 in (D_1, ϕ_1).
- If x is not a sink and z_1 is not in the deletion set, then z_1 reaches s in Z_{opt} in $D - S_{opt}$. Suppose z_1 can reach a sink, say s ($\neq z_2$). If z_1 has an out-neighbor outside $\{y_1, x, z_1\}$ then $\phi(R(s)) \geq 3.5$, which is a contradiction. Otherwise y_1 is its only out-neighbor. But then $\{s, y_1, x, z_1, x, z_2\} \subseteq R(x)$ and $\phi(R(s)) \geq 4$, which is not possible. Therefore, the only possibility for z_2 is to be the sink for z_1 when x is not a sink. Note that $\phi(R(z_2)) \geq 2.5$.

Hence we have a $(3, 2.5)$ branching vector.

Case 2: x has two in-neighbors y_1, y_2 and one out-neighbor z_1

Subcase 1: $\phi(y_1) = \phi(y_2) = 0.5$ and $\phi(z) = 1$.

- If x is a sink, there is a potential drop of at least 3.
- If x is not a sink, then z_1 is not in the deletion set. Note that z_1 reaches a sink, say $s \in Z_{opt}$ in $D - S_{opt}$. If z_1 can reach a sink s ($\neq z_1$), then $\{y_1, x, z_1, s\} \subseteq R(s)$. But then $\phi(R(s)) \geq 3.5$ which is a contradiction. The only possibility is for z_1 itself to be a sink when x is not a sink. Note that $\phi(R(z_1)) \geq 2.5$.

Hence we have a $(3, 2.5)$ branching vector.

Subcase 2: $\phi(y_1) = 1$ and $\phi(y_2) = \phi(z_1) = 0.5$.

- If x is a sink, the potential drops by 3.
- If x is not a sink, then z_1 is not in the deletion set. Therefore, z_1 reaches a sink s. If there is a path from z_1 to s not using y_1, y_2, then $\phi(R(s)) \geq 4$, which is not possible. Otherwise if there is a path from z_1 to s via y_1 or y_2, then $\phi(R(s)) \geq 4$, which is again not possible. Hence, the only possibility is that y_1 becomes a sink such that z_1 reaches y_1. Note that in this case, the potential drops by at least 2.5.

Hence we have a $(3, 2.5)$ branching vector in this case.

Branching on a degree 2 vertex

This subsection analyzes the potential drop while branching on a degree 2 undecided vertex x, which has an undecided neighbor. An undecided vertex x of degree 2 has exactly one in-neighbor and one out-neighbor. Let $y \in N^-(x)$ and $z \in N^+(x)$. We consider the following three cases.

Case 1: $\phi(y) = 1$ and $\phi(z) = 0.5$.

- If x is a sink, the potential drops by 2.5.
- If x is not a sink, then z is not in the deletion set and it reaches a sink s. If $s \neq y$, then $\{y, x, z, s\} \subseteq R(s)$ and $\phi(R(s)) \geq 3.5$, which is not possible. Hence, the only possibility is that y is a sink that z reaches. Note that here the potential drops by 2.5.

Hence, we get a $(2.5, 2.5)$ branching vector.

Case 2: $\phi(y) = 0.5$ and $\phi(z) = 1$.

- If x is a sink, the potential drops by 2.5.
- If x is not a sink, then z is not in the deletion set. Therefore, z reaches a sink, say s. If $s \neq y$ then $\{y, x, z, s\} \subseteq R(s)$ and $\phi(R(s)) \geq 3.5$, which is not possible. Hence, the only possibility is for z to be a sink itself. Note that in this case, the potential drops by 2.5

Hence we have a $(2.5, 2.5)$ branching vector.

Case 3: $\phi(y) = 1$ and $\phi(z) = 1$.

- If x is a sink, potential drops by 3.
- If x is not a sink, then z is not in the deletion set. Therefore, z reaches a sink, say s. If $s \neq y$ and $s \neq z$, then $\{y, x, z, s\} \subseteq R(s)$ and $\phi(R(s)) \geq 3.5$, which is not possible. Hence, the only possibility is for z to be a sink itself or to reach sink y. Note both in these cases, the potential drops by at least 3.

Hence we have a (3, 3, 3) branching vector.

Next, we give a formal proof of the correctness for Subroutine 3.

▶ **Lemma 16.** *Let D be a digraph such that $\phi(R(v)) < 3.5$, for every vertex $v \in V(D)$ and $x \in V(D)$ be such that $d(x) \in \{2, 3\}$, $\phi(x) = 1$ and there exists some vertex $s \in N(x)$ such that $\phi(s) = 1$. Then* $\mathsf{KFVD}(D, \phi) = \min\{\mathsf{KFVD}(D_1, \phi) + |N^+(x)|,\ \mathsf{KFVD}(D_2, \phi) + N^+(s)\}$ *where $D_1 = D - R(x)$, $D_2 = D - R(s)$ and $\phi_1 = \phi_2 = \phi$.*

Proof. Notice that there is no vertex v with $\phi(v) \geq 3.5$ and no vertex v that has all its neighbors with potential 0.5. We use induction on the potential function to prove the correctness of the claim. Let $\mathsf{KFVD}(D_1, \phi_1)$ and $\mathsf{KFVD}(D_2, \phi_2)$ correctly compute optimal solution (S_1, Z_1) and (S_2, Z_2), where $Z_i \subseteq \phi^{-1}(1)$. Let (S, Z) be an optimal solution for $\mathsf{KFVD}(D, \phi)$.

Case 1: $x \in Z$.

In this case, we know that $S_1 \cup N^+(x)$ is an optimal solution for $\mathsf{KFVD}(D, \phi)$ if and only if S_1 is an optimal solution for $\mathsf{KFVD}(D_1, \phi_1)$ and $|S_2 \cup N^+(s)| \geq |S_1 \cup N^+(x)|$, since it is also a solution to $\mathsf{KFVD}(D, \phi)$ that does not contain $x \in z$. Hence $\mathsf{KFVD}(D, \phi)$=$\min\{\mathsf{KFVD}(D_2, \phi_2) + |N^+(x)|,\ \mathsf{KFVD}(D_1, \phi_1) + |N^+(s)|\}$.

Case 2: $x \notin Z$.

By arguments made in the branching steps for degree 3 and 2 vertices, we can always find an s that must be a sink in Z. And hence $S_2 \cup N^+(s)$ is an optimal solution for for $\mathsf{KFVD}(D, \phi)$ if and only if S_1 is an optimal solution for $\mathsf{KFVD}(D_2, \phi_2)$. $|S_1 \cup N^+(x)| \geq |S_2 \cup N^+(s)|$ since it is also a solution to $\mathsf{KFVD}(D, \phi)$ that does contain $x \in z$. Hence $\mathsf{KFVD}(D, \phi)$=$\min\{\mathsf{KFVD}(D_2, \phi_2) + |N^+(x)|,\ \mathsf{KFVD}(D_1, \phi_1) + |N^+(s)|\}$. ◀

5 Running time analysis

Reduction Rules 1, 2 and 3 are applied on the instance (D, ϕ) in $n^{\mathcal{O}(1)}$ time. In Subroutine 1, while branching we get a potential drop of at least 3.5 in one branch, while in the other branch the potential drop is at least 0.5. Hence, we get the recurrence $f(\mu) \leq f(\mu - 3.5) + f(\mu - .5)$, which solves to $f(\mu) = \mathcal{O}(1.576^\mu)$. Similarly for Subroutine 2, we have a branching vector $(2, 3)$. Therefore, we have the recurrence $f(\mu) \leq f(\mu - 2) + f(\mu - 3)$, which solves to $f(\mu) = \mathcal{O}(1.324^\mu)$. For Subroutine 3, we have branching vectors $(3, 2.5), (2.5, 2.5)$, and $(3, 3, 3)$, out of which $(3, 3, 3)$ gives the worst running time. This solves to $f(\mu) = \mathcal{O}(1.442^\mu)$.

To solve the Knot-free Vertex Deletion, when we call KFVD(D, ϕ), potentials of all the vertices of D are initialized to 1 and $\phi(V(D)) = |V(D)| = n$. Moreover, in the recursive calls to the algorithm, the potential of the input graph never drops below 0. Hence we can upper bound the running time of Algorithm KFVD by the worst-case running subroutine (Subroutine 1). Thus we obtain the following theorem.

▶ **Theorem 17.** *Algorithm* KFVD *solves* Knot-free vertex deletion *in* $\mathcal{O}^*(1.576^n)$ *time.*

6 A lower bound on the worst case running time of our algorithm

In this section, we give a lower bound on the worst-case running time of our algorithm.

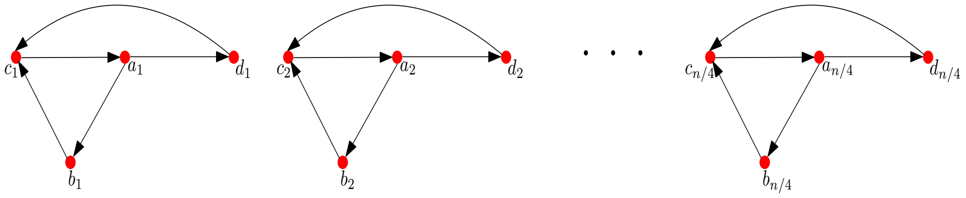

Figure 1 Illustration of a worst-case instance for our algorithm.

We run our algorithm KFVD on the graph D (shown in Figure 1), where $V(D) = \cup_{i=1}^{n/4}\{a_i, b_i, c_i, d_i\}$ and $E(D) = \cup_{i=1}^{n/4}\{(a_i, b_i), (b_i, c_i), (c_i, a_i), (a_i, d_i), (d_i, c_i)\}$. We claim that in the worst case, our algorithm takes $\mathcal{O}*(2^{n/2})$ time to solve KFVD on D. We will give this lower bound via adversarial arguments.

Let $V_i = \{a_i, b_i, c_i, d_i\}$ where $i \in [1, n/4]$. Since the potentials of all the vertices are initialized to 1, we have $\phi(R(a_i)) = 4$, $\phi(R(b_i)) = 3$, $\phi(R(c_i)) = 4$, $\phi(R(d_i)) = 3$. The adversary chooses the vertex a_i for KFVD to branch on. If a_i is a sink, all the four vertices are deleted. If a_i is a non-sink vertex, its potential drops by 0.5 while all other vertices' potentials remain unchanged. In the next iteration, $\phi(R(c_i)) = 3.5$, so we branch on c_i. Again, if c_i is a sink then all four vertices get deleted. If c_i is not a sink, then its potential drops by 0.5. In the next step, b_i and d_i are vertices where all their neighbors are semi-decided. The adversary chooses b_i to branch on. If b_i becomes a sink all the vertices are again removed. Else, when b_i is a non-sink d_i has to be a sink and all vertices are removed. There are four leaves of the branching tree while branching on the set of vertices $\{a_i, b_i, c_i, d_i\}$. This gives us a recurrence equation: $T(n) = 4T(n-4)$ which solves to $4^{n/4} = 1.414^n$.

▶ **Theorem 18.** *Algorithm* KFVD *runs in time* $\Omega(1.414^n)$.

7 Conclusion

We obtain a $\mathcal{O}(1.576^n)$ time and polynomial space algorithm for KFVD problem. Notice that our algorithm is not optimal and its improvement is a suggested direction for future work. Also exact algorithms for KFVD with dependency on number of edges instead of vertices can be an interesting research topic.

On Extended Boundary Sequences of Morphic and Sturmian Words

Abstract

Generalizing the notion of the boundary sequence introduced by Chen and Wen, the nth term of the ℓ-boundary sequence of an infinite word is the finite set of pairs (u, v) of prefixes and suffixes of length ℓ appearing in factors uyv of length $n + \ell$ ($n \geq \ell \geq 1$). Otherwise stated, for increasing values of n, one looks for all pairs of factors of length ℓ separated by $n - \ell$ symbols.

For the large class of addable numeration systems U, we show that if an infinite word is U-automatic, then the same holds for its ℓ-boundary sequence. In particular, they are both morphic (or generated by an HD0L system). We also provide examples of numeration systems and U-automatic words with a boundary sequence that is not U-automatic. In the second part of the paper, we study the ℓ-boundary sequence of a Sturmian word. We show that it is obtained through a sliding block code from the characteristic Sturmian word of the same slope. We also show that it is the image under a morphism of some other characteristic Sturmian word.

1 Introduction

Let $\mathbf{x}$ be an infinite word, i.e., a sequence of letters belonging to a finite alphabet. Imagine a window of size n moving along $\mathbf{x}$. Such a reading frame permits to detect all factors of length n occurring in $\mathbf{x}$. For instance, the factor complexity function of $\mathbf{x}$ mapping $n \in \mathbb{N}$ to the number of distinct factors of length n is extensively studied in combinatorics on words. Now let n, ℓ be such that $n \geq \ell$. Assume that within the sliding window, we only focus on its first and last ℓ symbols. Otherwise stated, for a factor uyv of length n, we only consider its borders u and v of length ℓ.

For any given window length n, we would like to determine what are the pairs of length-ℓ borders that may occur. This leads to the following definition, where, to simplify notation, we consider borders of factors of length $n + \ell$ rather than n.

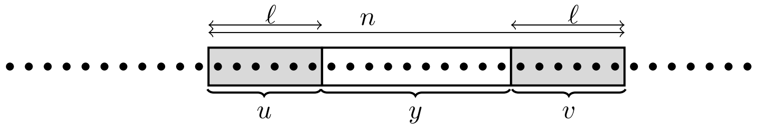

Figure 1 A sliding window where we focus on two regions of a fixed length.

▶ **Definition 1.1.** *Let $\ell \in \mathbb{N}_{>0}$ and $\mathbf{x} \in A^{\mathbb{N}}$. For $n \geq \ell$, we define the n*th boundary set *by*

$$\partial_{\mathbf{x},\ell}[n] := \{(u,v) \in A^\ell \times A^\ell \mid uyv \text{ is a factor of } \mathbf{x} \text{ for some } y \in A^{n-\ell}\}$$

*and call the sequence $\partial_{\mathbf{x},\ell} := (\partial_{\mathbf{x},\ell}[n])_{n\geq\ell}$ the ℓ-*boundary sequence *of $\mathbf{x}$. When $\ell = 1$, we write $\partial_{\mathbf{x},1} = \partial_{\mathbf{x}}$ and simply talk about the* boundary sequence.

The ℓ-boundary sequence takes values in $2^{A^\ell \times A^\ell}$, and hence itself can be seen as an infinite word over a finite alphabet. We give an introductory example.

▶ **Example 1.2.** Consider the Fibonacci word $\mathbf{f} = 0100101001\cdots$; the fixed point of the morphism $0 \mapsto 01, 1 \mapsto 0$. We have $\partial_{\mathbf{f}} = a\,b\,b\,a\,b\,b\,b\,b\,a\,b\,b\,a\,b\,b\,b\,b\,a\,b\,b\,b\,b\,a\,b\,b\,a\,b\,b\,b\,b\cdots$, where $a := \{(0,0),(0,1),(1,0)\}$ and $b := \{0,1\} \times \{0,1\}$. For instance, $\partial_{\mathbf{f}}[1] = a$ because the length-2 factors of $\mathbf{f}$ are $00, 01, 10$, while $\partial_{\mathbf{f}}[2] = b$ because its length-3 factors are of the form 0_0, 0_1, 1_0, 1_1 (they are in fact $010, 001, 100, 101$). The 2-boundary sequence starts with

$$\partial_{\mathbf{f},2} = a_0\ a_1\ a_2\ a_3\ a_4\ a_5\ a_1\ a_2\ a_3\ a_1\ a_2\ a_3\ a_4\ a_5\ a_1\ a_2\ a_3\ a_4\ a_5\ a_1\ a_2\ a_3\ a_1\ a_2\ a_3\cdots$$

where

$$\begin{aligned}
a_0 &:= \{(00,10),(01,00),(01,01),(10,01),(10,10)\},\\
a_1 &:= \{(00,00),(00,01),(01,01),(01,10),(10,00),(10,10)\},\\
a_2 &:= \{(00,01),(00,10),(01,00),(01,10),(10,00),(10,01)\},\\
a_3 &:= \{(00,00),(00,10),(01,00),(01,01),(10,01),(10,10)\},\\
a_4 &:= \{(00,01),(01,01),(01,10),(10,00),(10,01),(10,10)\},\\
a_5 &:= \{(00,10),(01,00),(01,01),(01,10),(10,01),(10,10)\}.
\end{aligned}$$

The first element $\partial_{\mathbf{f},2}[2] = a_0$ is peculiar; it corresponds exactly to the five length-4 factors occurring in $\mathbf{f}$. Our Proposition 4.8 shows that a_0 appears only once in $\partial_{\mathbf{f}}$. Then, e.g., $\partial_{\mathbf{f},2}[3] = a_1$ because the length-5 factors of $\mathbf{f}$ are of the form 00_00, 00_01, 01_01, 01_10, 10_00 and 10_10 (the factors are 00100, 00101, 01001, 10100, 10010, and 01010). For length-6 factors, note that two are of the form $10u01$ for some $u \in \{0,1\} \times \{0,1\}$. For $i \geq 1$, the letter a_i appears infinitely often in $\partial_{\mathbf{f},2}$: see Theorem 4.1.

1.1 Motivation and related work

In combinatorics on words, borders and boundary sets are related to important concepts. For instance, a word v is *bordered* if there exist u, x, y such that $v = ux = yu$ and $0 < |u| < |v|$. One reason to study bordered words is Duval's theorem: for a sufficiently long word v, the maximum length of unbordered factors of v is equal to the period of v [14]. In formal language theory, a language L is *locally ℓ-testable* (LT) if the membership of a word w in L only depends on the prefix, suffix and factors of length ℓ of w. In [35], the authors consider the so-called *separating problem* of languages by LT languages; they utilize *ℓ-profiles* of a word, which can again be related to boundary sets. Let us also mention that, in bioinformatics and computational biology, one of the aims is to reconstruct sequences from subsequences [26]. To determine DNA segments by bottom-up analysis, *paired-end* sequencing is used. In this case both ends of DNA fragments of known length are sequenced. See, for instance, [18]. This is quite similar to the theoretical concept we discuss here.

The notion of a (1-)boundary sequence was introduced by Chen and Wen in [8] and was further studied in [19], where it is shown that the boundary sequence of a *k-automatic* word (in the sense of Allouche and Shallit [1]: see Definition 2.2) is k-automatic. It is well-known that a k-automatic word $\mathbf{x}$ is *morphic*, i.e., there exist morphisms $f\colon A \to A^*$ and $g\colon A \to B$ and a letter $a \in A$ such that $\mathbf{x} = g(f^\omega(a))$, where $f^\omega(a) = \lim_{n\to\infty} f^n(a)$. However, k-automatic words (with k ranging over the integers) do not capture all morphic words: a well-known characterization of k-automatic words is given by Cobham [9] (the generating morphism f maps each letter to a length-k word). This paper is driven by the natural question whether, in general, the ℓ-boundary sequence of a morphic word is morphic. In case such generating morphisms can be constructed, we have at our disposal a simple algorithm providing the set of length-ℓ borders in factors of all lengths.

We briefly present several situations in which the notion of boundary sets is explicitly or implicitly used. In [12, Thm. 4], the authors study the boundary sequence to exhibit a squarefree word for which each subsequence arising from an arithmetic progression contains a square. Boundary sets play an important role in the study of so-called *k-abelian* and *k-binomial complexities* of infinite words (for definitions, see [37]). For instance, computing the 2-binomial complexity of generalized Thue–Morse words [25] requires inspecting pairs of prefixes and suffixes of factors, which is again related to the boundary sequence when these prefixes and suffixes have equal length. The k-binomial complexities of images of binary words under powers of the Thue–Morse morphism are studied in [39]; there some general properties of boundary sequences of binary words are required. Moreover, if $\partial_{\mathbf{x}}$ is automatic, then the abelian complexity of the image of $\mathbf{x}$ under a so-called Parikh-constant morphism is automatic [8]. Guo, Lü, and Wen combine this result with theirs in [19] to establish a large family of infinite words with automatic abelian complexity.

Let $k \geq 1$. We let $\equiv_k$ denote the k-abelian equivalence, i.e., $u \equiv_k v$ if the words u and v share the same set of factors of length at most k with the same multiplicities [22]. For u and v equal length factors of a Sturmian word $\mathbf{s}$, we have $u \equiv_k v$ if and only if they share a common prefix and a common suffix of length $\min\{|u|, k-1\}$ and $u \equiv_1 v$ [22, Prop. 2.8]. Under the assumption that the largest power of a letter appearing in $\mathbf{s}$ is less than $2k-2$, the requirement $u \equiv_1 v$ in the previous result may be omitted [33, Thm. 3.6] (compare to Proposition 4.8). Thus the quotient of the set of factors of length n occurring in a Sturmian word by the relation $\equiv_k$ is completely determined by $\partial_{\mathbf{s},k-1}[n-k+1]$ for large enough k (depending on $\mathbf{s}$). Other families of words with k-abelian equivalence determined by the boundary sets are given in [33, Prop. 4.2].

1.2 Our contributions

Up to our knowledge, we are the first to propose a systematic study of the ℓ-boundary sequences of infinite words. It is therefore natural to consider the notion on well-known classes of words. In this paper, we consider morphic words and Sturmian words.

Any morphic word is S-automatic for some abstract numeration system S [38]. With Theorem 3.1, we prove that for a large class of numeration systems U, if $\mathbf{x}$ is a U-automatic word, then the boundary sequence $\partial_{\mathbf{x}}$ is again U-automatic. Our approach generalizes the arguments provided by [19]. Considering exotic numeration systems allows a better understanding of underlying mechanisms, which do not arise in the ordinary integer base systems. In particular, we deal with addition within the numeration system; in integer base systems, the carry propagation is easy to handle (by a two-state finite automaton). Our arguments apply to so-called *addable* numeration systems (see Definition 2.1).

As an alternative, we observe that the Büchi–Bruyère theorem [5] can be extended to addable positional numeration systems U (Theorem 2.6). The U-automaticity of the ℓ-boundary sequence then follows from the fact that it is definable by a first-order formula of the structure $\langle \mathbb{N}, + \rangle$ extended with a unary function relating an integer with the least element of U properly appearing in its representation.

This alternative proof however hides the important details that might help identifying the technical limits of the result: not all morphic words allow an addable system to work with. However, the framework we consider captures all morphic words (see Theorem 2.4). Also, one practical difficulty when one wants to use automatic provers (such as Walnut [28]) is to be able to provide the relevant automaton for addition. To identify the contours of our result, we also discuss the case where $\mathbf{x}$ is U-automatic and $\partial_{\mathbf{x}}$ is not U-automatic. To construct such examples, we have to consider non-addable numeration systems in Section 3.2.

We then turn to the other class of words under study. Letting $\mathbf{s}$ be a Sturmian word with slope α, with Theorem 4.1 we show that the ℓ-boundary sequence of $\mathbf{s}$ is obtained through a sliding block code from the *characteristic Sturmian word of slope* α (see Section 4 for a definition) up to the first letter. This result holds even for non-morphic Sturmian words, so for an arbitrary irrational α. Where the techniques used in the first part of the paper have an automata-theoretic flavor, the second part relies on the geometric characterization of Sturmian words as codings of rotations. We provide another description of the ℓ-boundary sequence of a Sturmian word as the morphic image of some characteristic Sturmian word in Proposition 4.10. We remark that it is unclear to us whether some of the results in Section 4 can be proved automatically using the very recent tool developed in [21].

2 Preliminaries

Throughout this paper we let A denote a finite alphabet. Then A^n denotes the set of length-n words. For an infinite word $\mathbf{x}$, we let $\mathbf{x}[n]$ denote its nth letter, for all $n \geq 0$. For general references on numeration systems, see [16] and [4, Chap. 1–3]. We assume that the reader has some knowledge in automata theory. For a reference see [40] or [36, Chap. 1].

2.1 Numeration systems and automatic words

Let $U = (U_n)_{n \geq 0}$ be an increasing sequence of integers such that $U_0 = 1$. Any integer n can be decomposed (not necessarily uniquely) as $n = \sum_{i=0}^{t} c_i\, U_i$ with non-negative integer coefficients c_i. The finite word $c_t \cdots c_0 \in \mathbb{N}^*$ is a *U-representation* of n. If this representation is computed greedily [16, 36], then for all $j \leq t$ we have $\sum_{i=0}^{j} c_i\, U_i < U_{j+1}$ and $\operatorname{rep}_U(n) = c_t \cdots c_0$ is said to be the *greedy* (or *normal*) U-representation of n. By convention, the greedy representation of 0 is the empty word ε and the greedy representation of $n > 0$ starts with a non-zero digit. An extra condition on the boundedness of $\sup_{i \geq 0}(U_{i+1}/U_i)$ implies that the digit-set for greedy representations is finite. For any $c_t \cdots c_0 \in \mathbb{N}^*$, we let $\operatorname{val}_U(c_t \cdots c_0)$ denote the integer $\sum_{i=0}^{t} c_i\, U_i$. A sequence U satisfying all the above conditions is said to define a *positional numeration system*. For the following, we refer to the terminology in [32] (addable systems are called regular in [41]).

▶ **Definition 2.1.** *A positional numeration system U with digit-set A is* addable *if the following* graph of addition*, denoted by $\mathcal{L}_+$, is regular:*

$$\left\{ \begin{pmatrix} u \\ v \\ w \end{pmatrix} \in (0^* \operatorname{rep}_U(\mathbb{N}))^3 \cap (A \times A \times A)^* \mid \operatorname{val}_U(u) + \operatorname{val}_U(v) = \operatorname{val}_U(w) \right\} \setminus \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} (A \times A \times A)^*.$$

Notice that words in $\operatorname{rep}_U(\mathbb{N})$ do not start with 0; however, when dealing with tuples of such words, shorter U-representations are padded with leading zeroes to get words of equal length (so they can be processed by an automaton over tuples of letters).

For general references about automatic words and abstract numeration systems, see [1] and [38] or [4, Chap. 3]. An *abstract numeration system* is a triple $S = (L, A, <)$ with L an infinite regular language over the totally ordered alphabet A (with $<$). Genealogically (i.e., radix or length-lexicographic) ordering L gives a one-to-one correspondence rep_S between $\mathbb{N}$ and L; the S-representation of n is the $(n+1)$st word of L, and the inverse map is denoted by val_S. A *deterministic finite automaton with output* (DFAO) $\mathcal{A}$ is a DFA (with state set Q) equipped with a mapping $\tau \colon Q \to A$ (with A an alphabet). The output $\mathcal{A}(w)$ of $\mathcal{A}$ on a word w is $\tau(q)$, where q is the state reached by reading w from the initial state.

▶ **Definition 2.2.** *An infinite word $\mathbf{x}$ is S-*automatic *if there exists a DFAO $\mathcal{A}$ such that $\mathbf{x}[n] = \mathcal{A}(\operatorname{rep}_S(n))$. In particular, for $k \geq 2$ an integer, if $\mathcal{A}$ is fed with the genealogically ordered language $L = \{\varepsilon\} \cup \{1, \ldots, k-1\}\{0, \ldots, k-1\}^*$, then $\mathbf{x}$ is said to be k-*automatic*.*

We introduce abstract numeration systems due to the following theorem:

▶ **Theorem 2.3** ([38])**.** *A word $\mathbf{x}$ is morphic if and only if it is S-automatic for some abstract numeration system S.*

Fix $s \in A^*$. For a word $\mathbf{x}$, define the subsequence $\mathbf{x} \circ s$ by $(\mathbf{x} \circ s)[n] := \mathbf{x}[\operatorname{val}_S(p_{s,n}\, s)]$, where $p_{s,n}$ is the nth word in the genealogically ordered language $Ls^{-1} = \{u \in A^* \mid us \in L\}$. The *$S$-kernel* of the word $\mathbf{x}$ is defined as the set of words $\{\mathbf{x} \circ s \mid s \in A^*\}$. The following theorem is critical to our arguments. Details are given in [4, Prop. 3.4.12–16].

▶ **Theorem 2.4** ([38])**.** *A word $\mathbf{x}$ is S-automatic if and only if its S-kernel is finite.*

▶ **Example 2.5.** Consider the Fibonacci numeration system based on the sequence $(F_n)_{n \geq 0}$ with $F_0 = 1$, $F_1 = 2$, and $F_{n+1} = F_n + F_{n-1}$ for $n \geq 1$. The first few terms of the associated subsequences $\mu_s : \mathbb{N} \to \mathbb{N}$, such that $(\mathbf{x} \circ s)[n] = \mathbf{x}[\mu_s(n)]$, are given in Table 1. One simply computes the numerical value of all the Fibonacci representations with the suffix s.

Table 1 The first few terms of some subsequences μ_s for the Fibonacci numeration system.

s	$(\mu_s(n))_{n\geq 0}$	s	$(\mu_s(n))_{n\geq 0}$
ε	0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...	01	4, 6, 9, 12, 14, 17, 19, 22, 25, ...
0	2, 3, 5, 7, 8, 10, 11, 13, 15, ...	00	3, 5, 8, 11, 13, 16, 18, 21, 24, ...
1	1, 4, 6, 9, 12, 14, 17, 19, 22, 25, ...	10	2, 7, 10, 15, 20, 23, 28, 31, 36, 41, ...

Notice that some kernel elements $\mathbf{x} \circ s$ may be finite; more precisely, this occurs exactly when the language Ls^{-1} is finite. Our reasoning will not be affected by such particular cases, and we let the reader adapt it to such situations.

We now set our **general assumptions**. From now on we let U be a positional numeration system with digit-set A such that $\operatorname{rep}_U(\mathbb{N})$ is regular, and thus it is an abstract numeration system $(\operatorname{rep}_U(\mathbb{N}), A, <)$ for the natural ordering of the digits; this is because for all $m, n \in \mathbb{N}$ we have $m < n$ if and only if $\operatorname{rep}_U(m) <_{\text{gen}} \operatorname{rep}_U(n)$ for the genealogical order.

In Section 3.1, we further require U to be addable. All these assumptions are shared by many systems. For instance, classical integer base systems or the Fibonacci numeration system have all the assumed properties including being addable. For the latter system, the minimal automaton (reading most significant digits first) of $\mathcal{L}_+$ has 17 states (its transition table is given in [29]). The one reading least significant digits first has 22 states. The largest known family of positional systems with all these properties (addable with $\operatorname{rep}_U(\mathbb{N})$ being regular) is the one of those based on a linear recurrence sequence whose characteristic polynomial is the minimal polynomial of a Pisot number [5, 36].

2.2 Link with first-order logic

The result stated below is nothing else but the Büchi–Bruyère theorem [5, Thm. 16], originally given in the context of Pisot numeration systems. Its proof can be straightforwardly adapted to the case where U is addable, as the key ingredients are that $\operatorname{rep}_U(\mathbb{N})$ and the graph of addition $\mathcal{L}_+$ are regular languages. For a positional numeration system U, we define the map V_U by $V_U(n) = U_j$ whenever $n \in \mathbb{N}$ and $\operatorname{rep}_U(n) = c_t \cdots c_j 0^j$ and $c_j \neq 0$.

▶ **Theorem 2.6.** *Let U be an addable positional numeration system. A word $\mathbf{x}$ over B is U-automatic if and only if for each symbol $b \in B$, the set $\{n \geq 0 \mid \mathbf{x}[n] = b\}$ can be defined by a first-order formula $\varphi_b(n)$ of the structure $\langle \mathbb{N}, +, V_U \rangle$.*

As already mentioned in [19], the boundary sequence of a k-automatic word $\mathbf{x}$ may be defined by means of a first-order formula and therefore automaticity readily follows. This extends to addable systems: let $\mathbf{x} \in B^{\mathbb{N}}$ be U-automatic for an addable system U. The above theorem implies that, for all $b \in B$, we have a formula $\varphi_b(n)$ which is true if and only if $\mathbf{x}[n] = b$. We have $(u_1 \cdots u_\ell, v_1 \cdots v_\ell) \in \partial_{\mathbf{x},\ell}[m]$ if and only if

$$(\exists i) \bigwedge_{j=1}^{\ell} \varphi_{u_j}(i + j - 1) \wedge \bigwedge_{j=1}^{\ell} \varphi_{v_j}(i + m + j - 1).$$

For each subset R of $A^\ell \times A^\ell$ there is thus a formula $\psi_R(m)$ which is true if and only if $\partial_{\mathbf{x},\ell}[m] = R$. We may now apply Theorem 2.6 to conclude that $\partial_{\mathbf{x},\ell}$ is U-automatic. We remark that a similar proof of our Theorem 3.1 as sketched above is given in a forthcoming book of Shallit [41]. Also, this proof works for U not necessarily positional using [7, Lem. 37 and Thm. 55]. In particular, they show the following: Let $\mathbf{x}$ be an S-automatic sequence, where S is an addable abstract numeration system. Any first-order formula involving the predicates defined by the letters of $\mathbf{x}$ leads to an automaton accepting the S-representations of integers for which the formula holds.

3 On the boundary sequences of automatic words

In this section we provide the first of our main contributions, an alternative proof (not relying on Theorem 2.6) to the fact that a U-automatic word has a U-automatic boundary sequence whenever U is addable and satisfies the assumptions laid down in Section 2.1. We then show that this result does not necessarily hold for non-addable U.

3.1 Addable systems: automatic boundary sequences

For the sake of presentation, we only consider the case of the 1-boundary sequence. Our proof provides a precise description of a set containing the U-kernel of $\partial_{\mathbf{x}}$ in terms of three equivalence relations based on the kernel of $\mathbf{x}$, the graph of addition, and the numeration language; see (2). This set is finite, and so Theorem 2.3 gives the claim. In particular, one is the Myhill–Nerode congruence associated with the graph of addition since we have to consider the elements $\mathbf{x}[i]$ and $\mathbf{x}[i+m]$ for some $m > 0$. For $\ell > 1$, the only technical difference is that we have to consider longer factors $\mathbf{x}[i] \cdots \mathbf{x}[i+\ell-1]$ and $\mathbf{x}[i+m] \cdots \mathbf{x}[i+m+\ell-1]$.

▶ **Theorem 3.1.** *Let U be an addable numeration system with digit-set A and $\mathbf{x}$ be a U-automatic word. The boundary sequence $\partial_{\mathbf{x}}$ is U-automatic.*

Proof. Thanks to Theorem 2.4, the U-kernel of $\mathbf{x}$ is finite, say of cardinality m. Moreover, since $L = \mathrm{rep}_U(\mathbb{N})$ and $\mathcal{L}_+$ are regular, the following two sets of languages are finite by the Myhill–Nerode theorem [40, Sec. 3.9], say of cardinality k and ℓ, respectively:

$$\{Ls^{-1} \mid s \in A^*\} \quad \text{and} \quad \left\{\mathcal{L}_+ \begin{pmatrix} s \\ t \\ r \end{pmatrix}^{-1} \,\middle|\, \begin{pmatrix} s \\ t \\ r \end{pmatrix} \in (A \times A \times A)^*\right\}.$$

Let $\partial_{\mathbf{x}}$ be the boundary sequence of $\mathbf{x}$. An element of the U-kernel of $\partial_{\mathbf{x}}$ is given by $\partial_{\mathbf{x}} \circ s = \partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,0}s)]\ \partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,1}s)]\ \partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,2}s)] \cdots$ where $p_{s,n}$ is the nth word in the language Ls^{-1}, $n \geq 0$. Let us inspect the nth term of such an element of the kernel: it is precisely the set

$$\partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,n}s)] = \{(\mathbf{x}[i],\, \mathbf{x}[i + \mathrm{val}_U(p_{s,n}s)]) \mid i \geq 0\} \tag{1}$$

of pairs of letters. Let t, r be length-$|s|$ suffixes of words in L for which $\mathcal{L}_+(s,t,r)^{-1}$ is non-empty. There exist words w, x, y such that ws, xt, $yr \in 0^*L$ and $\mathrm{val}_U(ws) + \mathrm{val}_U(xt) = \mathrm{val}_U(yr)$. We let $\mathcal{P}(s)$ denote the set of such pairs $(t,r) \in (A \times A)^{|s|}$. Now partition (1) depending on the suffixes of length $|s|$ of $\mathrm{rep}_U(i)$ and $\mathrm{rep}_U(i + \mathrm{val}_U(p_{s,n}s))$: we may write

$$\partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,n}s)] = \bigcup_{(t,r)\in\mathcal{P}(s)} \left\{(\mathbf{x}[\mathrm{val}_U(xt)],\, \mathbf{x}[\mathrm{val}_U(yr)]) \,\middle|\, \begin{pmatrix} w \\ x \\ y \end{pmatrix} \in \mathcal{L}_+ \begin{pmatrix} s \\ t \\ r \end{pmatrix}^{-1} \wedge w \in 0^* p_{s,n}\right\}.$$

Roughly speaking, we look at all pairs of positions such that the first one is represented by a word ending with t, the second position is a shift of the first one by $\mathrm{val}_U(p_{s,n}s)$ and is represented by a word ending with r.

For convenience, we set $L(s,t,r,n) := \mathcal{L}_+ \begin{pmatrix} s \\ t \\ r \end{pmatrix}^{-1} \cap (0^*p_{s,n} \times A^* \times A^*)$ for all $n \geq 0$. Note that if $\mathcal{L}_+(s,t,r)^{-1} = \mathcal{L}_+(s',t',r')^{-1}$ and $Ls^{-1} = Ls'^{-1}$ then, for all n, $L(s,t,r,n) = L(s',t',r',n)$. Indeed, the second condition means that $p_{s,n} = p_{s',n}$ for all n.

Ordering $L(s,t,r,n)$. For each w, x of the same length, there is at most one y not starting with 0 such that (w,x,y) belongs to $\mathcal{L}_+(s,t,r)^{-1}$. Similarly if y does not start with 0, for each $w \in A^{|y|}$ (resp., $x \in A^{|y|}$) there is at most one x (resp., w) such that (w,x,y) belongs to $\mathcal{L}_+(s,t,r)^{-1}$.

Now let (w,x,y) and (w',x',y') in $L(s,t,r,n)$. We will always assume (this is not a restriction) that triplets do not start with $(0,0,0)$ – otherwise, different triplets may have the same numerical value. Note that $\mathrm{val}_U(x) < \mathrm{val}_U(x')$ if and only if $\mathrm{val}_U(y) < \mathrm{val}_U(y')$. Indeed, w, w' both belong to $0^*p_{s,n}$ thus $\mathrm{val}_U(ws) = \mathrm{val}_U(p_{s,n}s) = \mathrm{val}_U(w's)$. We have

$$\mathrm{val}_U(yr) - \mathrm{val}_U(xt) = \mathrm{val}_U(ws) = \mathrm{val}_U(w's) = \mathrm{val}_U(y'r) - \mathrm{val}_U(x't),$$

so, since U is positional, $\mathrm{val}_U(y0^{|r|}) - \mathrm{val}_U(y'0^{|r|}) = \mathrm{val}_U(x0^{|r|}) - \mathrm{val}_U(x'0^{|r|})$. Without loss of generality, we may assume that x and x' (resp., y and y') have the same length (indeed one can pad shorter representations with leading 0's). Then the above equation means that x is lexicographically less than x' if and only if the same holds for y and y'. We can thus order $L(s,t,r,n)$ by the numerical value of the second component of an element, and therefore the jth element of $L(s,t,r,n)$ is well-defined.

Defining two subsequences by the maps $\lambda_{s,t,r,n} : \mathbb{N} \to \mathbb{N}$ and $\mu_{s,t,r,n} : \mathbb{N} \to \mathbb{N}$. Let (w_j, x_j, y_j) be the jth element in $L(s,t,r,n)$ with $j \geq 0$. After removing the leading 0's, the word x_j belongs to $Lt^{-1} \cup \{\varepsilon\}$, which can also be ordered by genealogical order. We let $\lambda_{s,t,r,n}(j)$ denote the index (i.e., position counting from 0) of x_j within this language. Similarly, the word y_j belongs to $Lr^{-1} \cup \{\varepsilon\}$ and has an index $\mu_{s,t,r,n}(j)$ within this language.

Note that if $\mathcal{L}_+(s,t,r)^{-1} = \mathcal{L}_+(s',t',r')^{-1}$, $Ls^{-1} = Ls'^{-1}$, and $Lt^{-1} = Lt'^{-1}$ then, for all n, the maps $\lambda_{s,t,r,n}$ and $\lambda_{s',t',r',n}$ are the same. Indeed, the first two conditions imply that $L(s,t,r,n) = L(s',t',r',n)$. Similarly, if $\mathcal{L}_+(s,t,r)^{-1} = \mathcal{L}_+(s',t',r')^{-1}$, $Ls^{-1} = Ls'^{-1}$, and $Lr^{-1} = Lr'^{-1}$ then, for all n, the maps $\mu_{s,t,r,n}$ and $\mu_{s',t',r',n}$ are the same.

We now obtain

$$\begin{aligned}
\partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,n}s)] &= \bigcup_{(t,r)\in\mathcal{P}(s)} \left\{ (\mathbf{x}[\mathrm{val}_U(xt)],\, \mathbf{x}[\mathrm{val}_U(yr)]) \;\middle|\; \left(\begin{smallmatrix} w \\ x \\ y \end{smallmatrix}\right) \in \mathcal{L}_+ \left(\begin{smallmatrix} s \\ t \\ r \end{smallmatrix}\right)^{-1} \wedge w \in 0^* p_{s,n} \right\} \\
&= \bigcup_{(t,r)\in\mathcal{P}(s)} \left\{ (\mathbf{x}[\mathrm{val}_U(x_j t)],\, \mathbf{x}[\mathrm{val}_U(y_j r)]) \;\middle|\; \left(\begin{smallmatrix} w_j \\ x_j \\ y_j \end{smallmatrix}\right) \in L(s,t,r,n), j \geq 0 \right\} \\
&= \bigcup_{(t,r)\in\mathcal{P}(s)} \{ ((\mathbf{x}\circ t)[\lambda_{s,t,r,n}(j)], (\mathbf{x}\circ r)[\mu_{s,t,r,n}(j)]) \mid j \geq 0 \}\,.
\end{aligned}$$

Let us define an equivalence relation on triplets by $(s,t,r) \sim (s',t',r')$ if and only if all the following hold:

$$\begin{gathered}
\mathcal{L}_+ \left(\begin{smallmatrix} s \\ t \\ r \end{smallmatrix}\right)^{-1} = \mathcal{L}_+ \left(\begin{smallmatrix} s' \\ t' \\ r' \end{smallmatrix}\right)^{-1}, \quad Ls^{-1} = Ls'^{-1}, \quad Lt^{-1} = Lt'^{-1}, \quad Lr^{-1} = Lr'^{-1}, \\
\mathbf{x}\circ t = \mathbf{x}\circ t', \quad \text{and} \quad \mathbf{x}\circ r = \mathbf{x}\circ r'.
\end{gathered} \tag{2}$$

Since we have regular languages and the kernel of $\mathbf{x}$ is finite by assumption, this relation has a finite index (bounded by $\ell k^3 m^2$). Given s, the set $\{(s,t,r) \mid (t,r) \in \mathcal{P}(s)\}$ can be replaced by a set $\Lambda(s)$ of representatives of the equivalence classes for $\sim$. Since $\sim$ has a finite index, there are finitely many possible subsets of the form $\Lambda(s)$. So, we can write

$$\partial_{\mathbf{x}}[\mathrm{val}_U(p_{s,n}s)] = \bigcup_{(b,c,a)\in\Lambda(s)} \{ ((\mathbf{x}\circ c)[\lambda_{b,c,a,n}(j)], (\mathbf{x}\circ a)[\mu_{b,c,a,n}(j)]) \mid j \geq 0 \}\,.$$

Now if s and s' are such that $Ls^{-1} = Ls'^{-1}$ and $\Lambda(s) = \Lambda(s')$, then $\partial_{\mathbf{x}} \circ s = \partial_{\mathbf{x}} \circ s'$. This proves that the kernel of $\partial_{\mathbf{x}}$ is finite (of size bounded by $k \cdot 2^{\ell k^3 m^2}$). ◀

3.2 Non-addable systems: counterexamples

Our aim is to show that the boundary sequence of a U-automatic word is not always U-automatic. We give two such examples. The numeration system defined first is a variant of the base-2 system.

▶ **Example 3.2.** Take the numeration system $(U_n)_{n\geq 0}$ defined by $U_n = 2^{n+1} - 1$ for all $n \geq 0$. We have $0^* \operatorname{rep}_U(\mathbb{N}) = (0+1)^*(\varepsilon + 20^*)$. Consider the characteristic word $\mathbf{u}$ of U, i.e., $\mathbf{u}[n] = 1$ if and only if $n \in \{U_j \mid j \geq 0\}$. The boundary sequence $\partial_{\mathbf{u}}$ starts with

$$a\,b\,a\,b\,a\,b\,a\,b\,a\,a\,a\,b\,a\,b\,a\,b\,a\,a\,a\,a\,a\,a\,a\,b\,a\,a\,a\,b\,a\,b\,a\,b\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,b\,a\,a\,a\cdots$$

where $a := \{(0,0),(0,1),(1,0)\}$ and $b := \{0,1\} \times \{0,1\}$.

One can show that the language $\{\operatorname{rep}_U(n) \colon \partial_{\mathbf{u}}[n] = b\}$ is not regular, hence:

▶ **Proposition 3.3.** *Let $U = (2^{n+1} - 1)_{n\geq 0}$. The word $\mathbf{u}$ from Example 3.2 is U-automatic but its boundary sequence $\partial_{\mathbf{u}}$ is not U-automatic.*

As a consequence of the previous proposition and Theorem 3.1, U is non-addable.

▶ Remark 3.4. One may notice that both $\mathbf{u}$ and $\partial_{\mathbf{u}}$ are 2-automatic: this follows by Theorem 2.6 from the set $X := \{U_{m+r} - U_m \mid m \geq 0, r > 0\}$ (which equals $\{n \in \mathbb{N}\colon \partial_{\mathbf{u}}[n] = b\}$) being 2-definable by the formula $\varphi(n) := (\exists x)\,(\exists y)\,(x < y \wedge V_2(x) = x \wedge V_2(y) = y \wedge n = y - x)$, where $V_2(y)$ is the smallest power of 2 occurring with a non-zero coefficient in the binary expansion of y.

In view of the above remark, Example 3.2 could be considered as unsatisfactory. We now make use of a similar strategy but with a more complicated numeration system, for which we do not know any analogue of Remark 3.4. To this end, consider the non-addable numeration system from [17, Ex. 3] or [27, Ex. 2] defined by

$$V_0 = 1,\ V_1 = 4,\ V_2 = 15,\ V_3 = 54 \quad \text{and} \quad V_n = 3V_{n-1} + 2V_{n-2} + 3V_{n-4}, \quad \forall\, n \geq 4. \tag{3}$$

▶ **Example 3.5.** Consider the characteristic word $\mathbf{v}$ of V, i.e., $\mathbf{v}[n] = 1$ if and only if $n \in \{V_j \mid j \geq 0\}$. This word is trivially V-automatic. The boundary sequence $\partial_{\mathbf{v}}$ starts with

$$a\,a\,b\,a\,a\,a\,a\,a\,a\,a\,b\,a\,a\,b\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,b\,a\,a\,a\,a\,a\,a\,a\,a\,a\,a\,b\cdots$$

where again $a := \{(0,0),(0,1),(1,0)\}$ and $b := \{0,1\} \times \{0,1\}$.

Similar to the above, $\{\mathrm{rep}_V(n)\colon \partial_{\mathbf{v}}[n] = b\}$ is not regular, whence

▶ **Proposition 3.6.** *Let V be the numeration system given by (3). The word $\mathbf{v}$ from Example 3.5 is V-automatic but its boundary sequence $\partial_{\mathbf{v}}$ is not V-automatic.*

▶ Remark 3.7. We do not know whether $\mathbf{v}$ and $\partial_{\mathbf{v}}$ are both V'-automatic for some numeration system V'.

4 The extended boundary sequences of Sturmian words

We give two descriptions of the ℓ-boundary sequences of Sturmian words (Theorem 4.1 and Proposition 4.10) and discuss some of their word combinatorial properties. We first recap minimal background on Sturmian words seen as codings of rotations. For a general reference, see [24, §2]. Let α, $\rho \in \mathbb{T} := [0,1)$ with α irrational. Define the *rotation* of the 1-dimensional torus $R_\alpha\colon \mathbb{T} \to \mathbb{T}$ by $R_\alpha(x) = \{x + \alpha\}$, where $\{\,\cdot\,\}$ denotes the fractional part. Let $I_0 = [0, 1-\alpha)$ (or $I_0 = (0, 1-\alpha]$) and $I_1 = \mathbb{T} \setminus I_0$. (The endpoints of I_0 will not matter in the forthcoming arguments.) Define the coding $\nu\colon \mathbb{T} \to \{0,1\}$ by $\nu(x) = 0$ if $x \in I_0$, otherwise $\nu(x) = 1$. We define the word $\mathbf{s}_{\alpha,\rho}$ by $\mathbf{s}_{\alpha,\rho}[n] = \nu(R_\alpha^n(\rho))$, for all $n \geq 0$. We call α the *slope* and ρ the *intercept* of $\mathbf{s}_{\alpha,\rho}$. The *characteristic Sturmian word of slope* α is $\mathbf{s}_{\alpha,\alpha}$.

4.1 A description of the extended boundary sequence

In the following, a *sliding block code of length* r is a mapping $\mathfrak{B}\colon A^{\mathbb{N}} \to B^{\mathbb{N}}$ defined by $\mathfrak{B}(\mathbf{x})[n] = \mathcal{B}(\mathbf{x}[n] \cdots \mathbf{x}[n + r - 1])$ for all $n \geq 0$ and some $\mathcal{B}\colon A^r \to B$. Let $T\colon A^{\mathbb{N}} \to A^{\mathbb{N}}$ denote the shift map $Tx_0x_1x_2\cdots = x_1x_2\cdots$.

▶ **Theorem 4.1.** *For a Sturmian word $\mathbf{s}$ of slope α (and intercept ρ) and $\ell \geq 1$, the (shifted) ℓ-boundary sequence $T\partial_{\mathbf{s},\ell}$ is obtained by a sliding block code of length 2ℓ applied to the characteristic Sturmian word of slope α.*

To prove the theorem we develop the required machinery. For a word $u = u_0 \cdots u_{\ell-1}$, we let $I_u = \bigcap_{i=0}^{\ell-1} R_\alpha^{-i}(I_{u_i})$. It is well-known that u occurs at position i in $\mathbf{s}_{\alpha,\rho}$ if and only if $R_\alpha^i(\rho) \in I_u$. These intervals of factors of length ℓ can also be described as follows: order the set $\big\{\{-j\alpha\}\big\}_{j=0}^{\ell}$ as $0 = i_0 < i_1 < i_2 < \cdots < i_\ell$. For convenience, we set $i_{\ell+1} = 1$. If the $\ell+1$ factors of length ℓ of the Sturmian word $\mathbf{s}_{\alpha,\rho}$ are lexicographically ordered as $w_0 < w_1 < \cdots < w_\ell$, then $I_{w_j} = [i_j, i_{j+1})$ for each $j \in \{0, \dots, \ell\}$. From the following claim it is evident that the intercept ρ plays no further role in our considerations. (This also follows from the fact that two Sturmian words have the same set of factors if and only if they have the same slope.)

▷ Claim 4.2. Let $n \geq \ell$ and u, v be length-ℓ factors of $\mathbf{s}_{\alpha,\rho}$. Then $(u, v) \in \partial_{\mathbf{x},\ell}[n]$ if and only if $R_\alpha^n(I_u) \cap I_v \neq \emptyset$.

The endpoints of I_u are of the form i_j and i_{j+1} for some $j \in \{0, \dots, \ell\}$. Hence, for $n \geq \ell$, the set of pairs belonging to $\partial_{\mathbf{x},\ell}[n]$ is determined by the positions of the rotated endpoints $R_\alpha^n(i_j)$ within the intervals I_{w_k}. Notice that each rotated endpoint $R_\alpha^n(i_j)$ always lies in the interior of some I_{w_k} whenever $n > \ell$. When $n = \ell$, we have $R_\alpha^n(\{-\ell\alpha\}) = 0$, which is an endpoint of one of the intervals I_{w_k}. For the time being we assume $n > \ell$, and return to the case $n = \ell$ in Proposition 4.8. Now, for example, if $R_\alpha^n(i_j) \in I_{w_k}$ then we have (w_j, w_k), $(w_{j-1}, w_k) \in \partial_{\mathbf{x},\ell}[n]$ (if $j = 0$, w_{j-1} is replaced with w_ℓ). Determining the boundary sets can be quite an intricate exercise; see Example 4.4.

An alternative to considering the positions of the points $R_\alpha^n(i_j)$ within the intervals I_{w_k} is to consider the positions of the points $R_\alpha^n(\{-j\alpha\})$ within the intervals I_{w_k} – the only difference is the order of enumeration. For each $n > \ell$, there is a map $\sigma = \sigma_n \in T_\ell$, where T_ℓ is the set of mappings from $\{0, \dots, \ell\}$ to itself, such that

$$R_\alpha^n(\{-j\alpha\}) \in I_{w_{\sigma(j)}} \quad \forall\, j \in \{0, \dots, \ell\}. \tag{4}$$

The realizable such configurations in (4) are called *constellations*. These points, when ordered according to the i_j's, determine the boundary set $\partial_{\mathbf{s},\ell}[n]$ as described above. See Example 4.4 for an illustration of the construction.

▶ **Definition 4.3.** *Let $\sigma \in T_\ell$ be such that* (4) *holds for some $n \in \mathbb{N}$. We define $\partial_\sigma \in 2^{A^\ell \times A^\ell}$ as the boundary set corresponding to any constellation inducing σ.*

It is now evident that if $\sigma_n = \sigma_m =: \sigma$, then $\partial_{\mathbf{s},\ell}[n] = \partial_\sigma = \partial_{\mathbf{s},\ell}[m]$.

▶ **Example 4.4.** The Fibonacci word $\mathbf{f}$ is $\mathbf{s}_{\alpha,\alpha}$ for $\alpha = (3 - \sqrt{5})/2 \simeq 0.382$. In Figure 2, the outer circle shows the partition with the interval $I_{w_0}, \dots, I_{w_\ell}$ and the inner circle shows the positions of the points $R_\alpha^n(\{-j\alpha\})$ for $\ell = 4$ and $n = 17$. The corresponding words $w_0, \dots, w_\ell$ are written next to their interval. Here σ_n is defined by $(0, 1, 2, 3, 4) \mapsto (2, 0, 3, 1, 4)$. For any constellation inducing σ_n, we see the pairs belonging to $\partial_{\sigma_n} = \partial_{\mathbf{f},4}[17]$ from Figure 2: the inner intervals (obtained from the outer intervals by applying R_α^{17}) give the prefix matching the suffix of the overlapping outer intervals, in clockwise order:

$$\binom{0010}{0101}, \binom{0010}{1001}, \binom{0100}{1001}, \binom{0100}{1010}, \binom{0101}{1010}, \binom{0101}{0010}, \binom{1001}{0010}, \binom{1001}{0100}, \binom{1010}{0100}, \binom{1010}{0101}.$$

Coming back to the introductory Example 1.2, the five sets $a_1, \dots, a_5$ correspond to the situations depicted from left to right in Figure 3. For instance, in the fourth picture, we understand why 10 is a prefix belonging to three pairs in a_4: the red inner interval intersects the three outer intervals of the partition. The situation is similar in the fifth picture where 01 is the prefix of three pairs in a_5. It is however not the case with the first three sets/pictures.

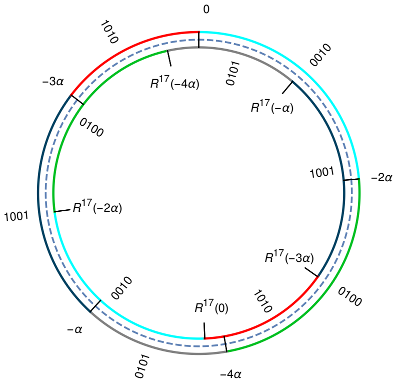

Figure 2 A constellation for $\alpha = (3 - \sqrt{5})/2$, $\ell = 4$ and $n = 17$.

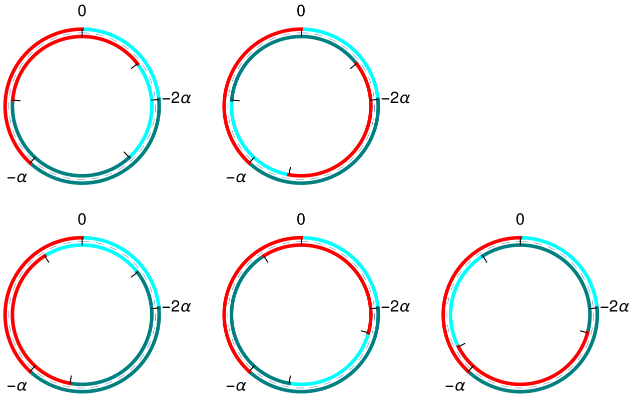

Figure 3 Some constellations for $\alpha = (3-\sqrt{5})/2$ and $\ell = 2$ inducing the five maps σ_n sending $(0, 1, 2)$, resp., to $(0, 2, 1)$, $(1, 0, 2)$, $(2, 1, 0)$, $(1, 2, 1)$, $(2, 1, 2)$.

▶ Remark 4.5. It is possible that $\partial_\sigma = \partial_{\sigma'}$ for distinct maps σ, $\sigma' \in T_\ell$. Indeed, for the Fibonacci word and $\ell = 1$, we have equality for the identity mapping id and $\sigma\colon (0, 1) \mapsto (1, 0)$; in this case $\partial_{\text{id}} = \partial_\sigma = \{0, 1\} \times \{0, 1\}$. So two constellations inducing different maps in T_ℓ lead to the same set of boundary pairs. (See however Lemma 4.15.)

▶ **Definition 4.6.** *Let* $\mathbf{r}$ *be the rotation word defined by* $\mathbf{r}[n] = \eta(R^n_\alpha(\alpha))$ *for all* $n \geq 0$*, where* $\eta\colon \mathbb{T} \to \{0, \ldots, \ell\}$ *is defined by* $\eta(x) = j$ *when* $x \in I_{w_j}$ *(recall* I_{w_i} *corresponds to the ith factor of length* ℓ*).*

We have that $\mathbf{r}[n] = j$ if and only if the characteristic Sturmian word $\mathbf{s}_{\alpha,\alpha}$ has the length-ℓ factor w_j occurring at position n.

Proof sketch of Theorem 4.1. It can be shown that the boundary sequence of $\mathbf{s}$ can be obtained from $\mathbf{r}$ constructed above using a sliding block code of length $\ell + 1$. Notice that by definition $\mathbf{r}$ is obtained by a sliding block code of length ℓ of the characteristic Sturmian word $\mathbf{s}_{\alpha,\alpha}$. The claim follows as composing sliding block codes of length r and r', respectively, yields a sliding block code of length $r + r' - 1$. ◀

▶ **Example 4.7.** We apply Theorem 4.1 to the Fibonacci word $\mathbf{f}$. Take $\alpha = (3-\sqrt{5})/2$, $\ell = 1$, $I_0 = [0, 1 - \alpha)$ and $I_1 = [1 - \alpha, 1)$. Then the rotation word $\mathbf{r}$ associated with the partition $\{I_0, I_1\}$, slope α, and intercept α is $\mathbf{s}_{\alpha,\alpha}$ by definition, which happens to be the Fibonacci word $\mathbf{f}$. We have $\mathbf{f} = 0\,1\,0\,0\,1\,0\,1\,0\,0\,1\,0\,0\,1\,0\,1\,0\,0\,1\,0\,1\,0\,0\,1\,0\,0\,1\,0\,1\,0\,0\,1 \cdots$. Recall from the construction that the length-2 factors of the rotation word determine the boundary sets. The three length-2 factors of $\mathbf{f}$ are 01, 10, and 00 occurring at positions $m = 0$, 1, and 2, respectively. We get the three maps $\sigma_{m+2} \in T_1$ defined by $(0, 1) \mapsto (1, 0)$, $(0, 1) \mapsto (0, 1)$, and $(0, 1) \mapsto (0, 0)$, respectively. We deduce that an occurrence of 01 or 10 corresponds to the boundary set $b := \{0, 1\} \times \{0, 1\}$, and 00 to $a := \{(0, 0), (0, 1), (1, 0)\}$. We may therefore define $\mathcal{B}\colon 01, 10 \mapsto b$, $00 \mapsto a$ and the associated sliding block code $\mathfrak{B}$ of length 2; applying $\mathfrak{B}$ to $\mathbf{f}$, we get

$$\begin{aligned}&\mathfrak{B}((01)(10)(00)(01)(10)(01)(10)(00)(01)(10)(00)(01)(10)(01)(10)(00)(01)(10)(01)\cdots)\\ &= \;b \quad b \quad a \quad b \quad b \quad b \quad b \quad a \quad b \quad b \quad a \quad b \quad b \quad b \quad b \quad a \quad b \quad b \quad b\cdots,\end{aligned}$$

which indeed gives back Example 1.2 after prepending the letter a.

We next discuss the first element $\partial_{\mathbf{s},\ell}[\ell]$ of the (extended) boundary sequence. Notice that the set is in one-to-one correspondence with the factors of length 2ℓ, and thus has cardinality $2\ell+1$. The points $\{-j\alpha\}$ and $R_\alpha^\ell(\{-j\alpha\})$, $j \in \{0,\ldots,\ell\}$, on the torus still determine the boundary set, but notice that there are only $2\ell+1$ distinct pairs. The following proposition describes rather precisely how the first element appears in the boundary sequence.

▶ **Proposition 4.8.** *For a Sturmian word* $\mathbf{s}$*, the boundary set* $\partial_{\mathbf{s},\ell}[\ell]$ *appears infinitely often in* $\partial_{\mathbf{s},\ell}$ *if and only if* $0^{2\ell}$ *or* $1^{2\ell}$ *appears in* $\mathbf{s}$*. Otherwise it appears exactly once.*

Notice that either 00 or 11 appears in a Sturmian word $\mathbf{s}$, so the above implies that the first letter of the (1-)boundary sequence $\partial_{\mathbf{s}}$ always appears infinitely often in the sequence. Returning to Example 1.2, since 0^4 does not appear in the Fibonacci word, the letter a_0 appears only once in $\partial_{\mathbf{f},2}$.

We conclude with the immediate corollary of Theorem 4.1 and Proposition 4.8; here we say that a word $\mathbf{w}$ is *uniformly recurrent* if each of its factors occurs infinitely often within bounded gaps (the distance between two consecutive occurrences depends on the factor). It is known that, e.g., Sturmian words are uniformly recurrent.

▶ **Corollary 4.9.** *For any Sturmian word* $\mathbf{s}$*, the shifted sequence* $T\partial_{\mathbf{s},\ell}[n]$ *is uniformly recurrent. The sequence* $\partial_{\mathbf{s},\ell}$ *is uniformly recurrent if and only if* $0^{2\ell}$ *or* $1^{2\ell}$ *appears in* $\mathbf{s}$*.*

4.2 Another description of the extended boundary sequence

We give another description of the ℓ-boundary sequences of Sturmian words when $\ell \geq 2$. For any irrational number $\alpha \in (0,1)$ there is a unique infinite continued fraction expansion (CFE)

$$\alpha = [0; a_1, a_2, a_3, \ldots] := \cfrac{1}{a_1 + \cfrac{1}{a_2 + \cfrac{1}{a_3 + \ldots}}},$$

where $a_n \geq 1$ are integers for all $n \geq 1$. Then the characteristic Sturmian word $\mathbf{s}_{\alpha,\alpha}$ of slope α equals $\lim_{k\to\infty} S_k$, where $S_{-1} = 1$, $S_0 = 0$, $S_1 = S_0^{a_1-1}S_{-1}$, and $S_{k+1} = S_k^{a_{k+1}}S_{k-1}$ for all $k \geq 1$ [1, Chap. 9]. The main result of this part is the following.

▶ **Proposition 4.10.** *Let* $\mathbf{s}$ *be a Sturmian word of slope* $\alpha = [0; a_1+1, a_2, \ldots]$*. For each* $\ell \geq 2$*, there exists* $k_\ell \in \mathbb{N}$ *such that for any* $k \geq k_\ell$ *there is a morphism* $h_{k,\ell}$ *such that* $T\partial_{\mathbf{s},\ell} = h_{k,\ell}(\mathbf{s}_{\beta_k,\beta_k})$*, where* $\beta_k = [0; a_{k+1}+1, a_{k+2}, \ldots]$*.*

▶ **Example 4.11.** Take the slope $\alpha = (3-\sqrt{5})/2$; its CFE is $[0; 2, 1, 1, 1, \ldots]$. Using the previous notation, $S_{-1} = 1$, $S_0 = 0$, and $S_{k+1} = S_kS_{k-1}$ for all $k \geq 0$. Then the sequence $(S_k)_{k\geq 0}$ converges to the Fibonacci word; the first few words in the sequence $(S_k)_{k\geq 0}$ are $0, 01, 010, 01001, 01001010$.

Now for any $\ell \geq 2$, the above proposition thus gives that $\partial_{\mathbf{f},\ell}$ is the morphic image of the characteristic Sturmian word of slope $\beta = \alpha$. In other words, the ℓ-boundary sequence is always a morphic image of $\mathbf{f}$.

We generalize the last observation made in the above example.

▶ **Corollary 4.12.** *Let* $\mathbf{s}$ *be a Sturmian word with quadratic slope. Then* $\partial_{\mathbf{s},\ell}$ *is morphic. In particular, the* ℓ*-boundary sequence of a Sturmian word fixed by a non-trivial morphism is morphic.*

Proof. A remarkable result of Yasutomi [43] (see also [3]), characterizing those Sturmian words that are fixed by some non-trivial morphism, implies that if a Sturmian word is fixed by a non-trivial morphism, then so is the characteristic Sturmian word of the same slope. Furthermore, the slope is characterized by the property that its CFE is of the form $[0;1,a_2,\overline{a_3,\ldots,a_r}]$ with $a_r \geq a_2$ or $[0;1+a_1,\overline{a_2,\ldots,a_r}]$ with $a_r \geq a_1 \geq 1$ [11, 30] (see also [24, Thm. 2.3.25]). Here $\overline{x_1,\ldots,x_t}$ indicates the periodic tail of the infinite CFE. Let $\mathbf{s}$ have slope α; since α is quadratic, it has an eventually periodic CFE. There thus exist arbitrarily large k for which the characteristic Sturmian word of slope $\beta_k := [0;a_k+1,a_{k+1},\ldots]$ is a fixed point of a non-trivial morphism (it is of the latter form). Proposition 4.10 then posits that $T\partial_{\mathbf{s},\ell}$ is the morphic image of such a word, and the claim follows (because prepending the letter $\partial_{\mathbf{s},\ell}[\ell]$ preserves morphicity [1, Thm. 7.6.3]). ◀

Notice that given the morphism fixing a Sturmian word $\mathbf{s}$, one can compute (the CFE of) its quadratic slope (and intercept) [42, 34, 23].

The above corollary has an alternative proof via the logical approach as well. For the definitions of notions that follow, we refer to the cited papers. From the work of Hieronymi and Terry [20], it is known that addition in the *Ostrowski-numeration system* based on an irrational quadratic number α is recognizable by a finite automaton. This motivated Baranwal, Schaeffer, and Shallit to introduce *Ostrowski-automatic sequences* in [2]. For example, they showed that the characteristic Sturmian word of slope α is Ostrowski α-automatic. Since the numeration system is addable, the above corollary follows by the same arguments as in Section 2.2.

4.3 Factor complexities of the extended boundary sequences

▶ **Definition 4.13.** *An infinite word over an alphabet A is of* minimal complexity *if its factor complexity is $n+|A|-1$ for all $n \geq 1$.*

Minimal complexity words can be seen as a generalization of Sturmian words to larger alphabets: if a word (containing all letters of A) has less than $n+|A|-1$ factors of length n for some n, then it is ultimately periodic. Otherwise it is aperiodic (a consequence of the Morse–Hedlund theorem). See [10, 31, 15, 6, 13] for characterizations and generalizations.

The following proposition is almost immediate after the key Lemma 4.15.

▶ **Proposition 4.14.** *Let $\ell \geq 2$. The ℓ-boundary sequence of a Sturmian word is a minimal complexity word (of complexity $n \mapsto n+2\ell$, $n \geq 1$).*

▶ **Lemma 4.15.** *Let σ and $\sigma' \in T_\ell$, $\ell \geq 2$, be distinct mappings both satisfying* (4) *(for different n). Then $\partial_\sigma \neq \partial_{\sigma'}$.*

We conclude with a formula for the factor complexity of the 1-boundary sequence of Sturmian words.

▶ **Proposition 4.16.** *Let r be the maximal integer such that $(01)^r$ appears in the Sturmian word $\mathbf{s}$. The boundary sequence $\partial_{\mathbf{s}}$ has factor complexity* $n \mapsto \begin{cases} n+1, & \text{if } n < 2r; \\ n+2, & \text{otherwise.} \end{cases}$

As an immediate corollary, we see that the ℓ-boundary sequence is aperiodic for all $\ell \geq 1$.

Higher-Order Causal Theories Are Models of BV-Logic

Abstract

The Caus[−] construction takes a compact closed category of basic processes and yields a *-autonomous category of higher-order processes obeying certain signalling/causality constraints, as dictated by the type system in the resulting category. This paper looks at instances where the base category C satisfies additional properties yielding an affine-linear structure on Caus[$\mathcal{C}$] and a substantially richer internal logic. While the original construction only gave multiplicative linear logic, here we additionally obtain additives and a non-commutative, self-dual sequential product yielding a model of Guglielmi's BV logic. Furthermore, we obtain a natural interpretation for the sequential product as "A can signal to B, but not vice-versa", which sits as expected between the non-signalling tensor and the fully-signalling (i.e. unconstrained) par. Fixing matrices of positive numbers for $\mathcal{C}$ recovers the BV category structure of probabilistic coherence spaces identified by Blute, Panangaden, and Slavnov, restricted to normalised maps. On the other hand, fixing the category of completely positive maps gives an entirely new model of BV consisting of higher order quantum channels, encompassing recent work in the study of quantum and indefinite causal structures.

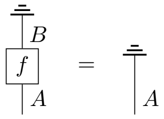
1 Introduction

The causality condition [8] is a simple equation one can impose on a family of processes that states essentially that "discarding the output of f is the same as discarding its input." Pictorially:[1]



(1)

[1] We will use *string diagram* notation for monoidal categories throughout, depicting morphisms as boxes, composition as "plugging" boxes from bottom-to-top and ⊗ as placing boxes side-by-side. See e.g. [25].

for some fixed family of “discarding” processes $\bar{\bar{\top}}_A$. While this seems to be a simple equation, and reasonable to impose on most sane collections of physical processes, it deserves the somewhat lofty name of *causality* because it really seems to capture the essence of influences moving in a single direction: forward in time. In particular, it guarantees that distant agents cannot send messages to one another without their existing a forward-directed path in the diagram of their processes. Without referring explicitly to spacetime, this serves as an abstract stand-in for what a relativity theorist would also call causality, namely the limitation that influences cannot propagate faster than the speed of light [17].

In concrete categories of interest, namely those of probabilistic and quantum maps, equation (1) simply imposes that processes should preserve normalised states. Iterating this, we might wish to consider second-order processes that preserve processes that preserve normalised states, and so on. This turns out to provide a rich landscape for modelling causal relationships between events, enabling for example chains [6, 13] (or directed acyclic graphs [19]) of events in a definite causal order, probabilistic mixtures of causal orderings, or even exotic indefinite causal structures [1, 9, 22].

There are several routes to constructing a framework for characterising and composing such higher-order processes, including describing acyclic graphs of interactions between discrete first-order channels [4, 7] or building an infinite hierarchy of types recursively out of constructors describing a kind of causal relationship [2].

The Caus[−] construction of Kissinger and Uijlen [19] fits the latter style through a category where morphisms map normalised states of the source type to normalised states of the target type. For example, Caus[CP*] describes higher-order generalisations of CPTP-maps, containing quantum combs [7], process matrices [22], and bipartite second-order maps [18] which include the quantum switch [9], which have collectively been critical in the formulation and study of indefinite causal structures. The typing of a morphism is a judgement about externally-observable properties of normalisation and information flow as opposed to any assumed internal structure or spacetime geometry. The type constructors model the operators of Multiplicative Linear Logic (MLL), i.e. it forms a $*$-autonomous category. MLL features two logical connectives, tensor and par, which serve as two extremes in the Caus[−] construction. Tensor yields a *non-signalling* composition of processes, where causal influences are not allowed to pass from one side to the other, whereas par gives a *fully-signalling* composition, i.e. one that imposes no signalling constraints.

In between this lies the *one-way signalling* processes, where causal influences can flow from one agent (say, Alice in the past) to another (say, Bob in the future). While special cases of such processes were treated in an *ad hoc* way in [19], here we will show that one-way signalling can in fact be treated as a fully-fledged connective in its own right, yielding a substantially richer logical structure.

BV-logic [11] adds a third logical connective that is non-commutative to capture sequentiality in a similar way to Retoré’s pomset logic [24]. It admits a categorical characterisation via BV-categories, and has previously been applied to the study of (probabilistic) coherence spaces [3] and a certain graph-based model of quantum causal structures called discrete quantum causal dynamics [4].

In this paper, we will adapt the Caus[−] construction by modifying some of the assumptions on the base category, requiring it to be *additive precausal.* The extra structure allows us to consider new ways of combining processes and types to describe operational constructions such as binary tests, probability distributions, and one-way signalling processes. These correspond to extending the logical structure of Caus[$\mathcal{C}$] with the additive connectives (sometimes called “with” and “plus”) of linear logic, as well as the sequential connective of BV. We show that the main classical and quantum examples of precausal categories are furthermore additive precausal, enabling Caus[$\mathcal{C}$] to model higher-order theories and classical and quantum causal structures, respectively. We also note the existence of non-standard models, such as higher-order affine (a.k.a. quasi-probabilistic) processes.

During the development of this paper, independent work by Hoffreumon and Oreshkov [14] investigated the same spaces of higher-order one-way signalling processes specifically in quantum theory and identified the same self-duality along with some additional results on decompositions into intersections and unions of spaces. Additionally, Cavalcanti et al. [5] obtained the same characterisation of non-signalling spaces as the affine closure of separable processes for multi-partite first-order channels in any generalised probabilistic theory with local tomography.

We refer the reader to the arXiv version of this paper [26] for full proofs of all the results presented here.

2 Higher-Order Causal Structure

We use "process theory" style terminology (see e.g. [10]) for monoidal categories throughout. Namely, we use the terms *type* or *system* interchangeably to refer to objects of a symmetric monoidal category, *process* to refer to a generic morphism $f : A \to B$, *state* to refer to a morphism $\rho : I \to A$ from the tensor unit, *effect* to refer to a morphism $\pi : A \to I$ to the tensor unit, and *scalar* to refer to a morphism $\lambda : I \to I$. In categories admitting higher-order structure, we think of first-order types as state spaces and first-order processes as maps that transform first-order states to first-order states. Higher-order processes are transformations where the input or output system is itself a map. The main example used in causality literature is a quantum 2-comb which is a process taking a channel over first-order types as an input and transforms it into a new channel, typically by composing with some pre- and post-processing which may share some memory channel. One can extend this to an infinite hierarchy of higher-order processes where an $(n+1)$-comb transforms an n-comb into a 1-comb (a channel) [7]. A higher-order process theory is one which describes processes in such an infinite hierarchy uniformly.

Higher-order theories are commonly achieved by providing a mechanism to encode transformations into states of some function type. In category theory, this corresponds to an internal hom in monoidal closed categories, i.e. a bifunctor $\multimap : \mathcal{C}^{op} \times \mathcal{C} \to \mathcal{C}$ such that $\mathcal{C}(C \otimes A, B) \simeq \mathcal{C}(C, A \multimap B)$ and this is natural in all arguments. Wilson and Chiribella [27] demonstrate that adding basic manipulations (morphisms that capture sequential and parallel composition of such encoded functions) is sufficient to permit the inductive generation of comb types. However, with higher-order theories, there are more ways of composing processes that need not be obtainable in this way.

To solve this, we may further ask that $\mathcal{C}$ be a *compact closed category*, i.e. we require every object A has a "cup" state $\eta_A : I \to A^* \otimes A$ and a "cap" effect satisfying the so-called "yanking equations": $(\mathrm{id}_A \otimes \eta_A) \fatsemi (\epsilon_A \otimes \mathrm{id}_A) = \mathrm{id}_A$ and $(\eta_A \otimes \mathrm{id}_{A^*}) \fatsemi (\mathrm{id}_{A^*} \otimes \epsilon_A) = \mathrm{id}_{A^*}$. These enable us to convert inputs to outputs at will, which in turn lets us "wire up" processes in arbitrary ways to each other. Namely, we can treat all higher order processes as states, and use "caps" to connect them to each other in arbitrary ways. See Figure 1 for an example and [19, Section 2.1] for more details.

The causality condition in equation (1) specialises to states as the requirement that $\rho \fatsemi \bar{\bar{\top}}_A = \mathrm{id}_I =: 1$ for any state ρ, i.e. it imposes that states be normalised with respect to the discarding effect. Discarding is unique in the sense that it is the only effect normalised for all states. However, for the higher-order analogue of state spaces, there might be more such effects, motivating the following definition.

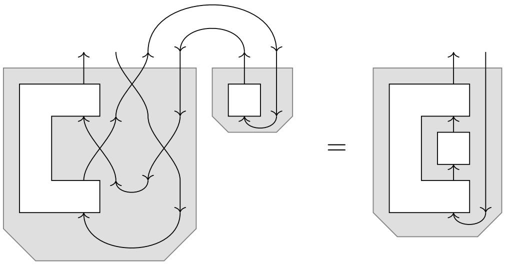

Figure 1 Example of embedding higher-order processes and composition via compact closure.

▶ **Definition 1.** *For $c \subseteq \mathcal{C}(I, A)$, the dual set is $c^* := \{\pi \in \mathcal{C}(A, I) \,|\, \forall \rho \in c.\rho \,⨾\, \pi = \mathrm{id}_I\}$.*

▶ Remark 2. In this paper, we will freely mix between treating c/c^* as a set of states in $\mathcal{C}(I, A)/\mathcal{C}(I, A^*)$ and a set of effects in $\mathcal{C}(A^*, I)/\mathcal{C}(A, I)$, depending on the context. They are equivalent through the transpose isomorphism induced by compact closure.

From this we can recover the space of first-order/*causal* states for a system A as $\left\{\overset{=}{\top}_A\right\}^*$. For example, in quantum theory we take $\overset{=}{\top}_A \in \mathcal{C}(A, I)$ to represent the partial trace over the system A, so this set describes the space of trace-1 density matrices. First-order/causal processes from A to B are those that map every state in $\left\{\overset{=}{\top}_A\right\}^*$ to a state in $\left\{\overset{=}{\top}_B\right\}^*$ (equivalent to mapping the effect $\overset{=}{\top}_B$ to $\overset{=}{\top}_A$ when our category has enough states/well-pointedness), which we can encode as $\left\{\left\{\overset{=}{\top}_A\right\}^* \otimes \overset{=}{\top}_B\right\}^* \subseteq \mathcal{C}(I, A^* \otimes B)$. These concepts are used to define a precausal category, which specifies one possible set of conditions to enable discussions of higher-order causal structures.

▶ **Definition 3.** *A compact closed category $\mathcal{C}$ is a precausal category if:*

PC1. *$\mathcal{C}$ has a discarding process $\overset{=}{\top}_A \in \mathcal{C}(A, I)$ for every system A, compatible with the monoidal structure as below;*

$$\overset{=}{\top}_{A\otimes B} = \overset{=}{\top}_A \otimes \overset{=}{\top}_B \tag{2}$$

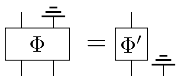
$$\overset{=}{\top}_I = \mathrm{id}_I \tag{3}$$

PC2. *The dimension $d_A := \underset{=}{\bot}_A \,⨾\, \overset{=}{\top}_A$ is invertible for all non-zero A;*

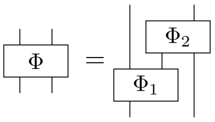
PC3. *$\mathcal{C}$ has enough causal states: $\forall f, g : A \to B. \left(\forall \rho \in \left\{\overset{=}{\top}_A\right\}^* .\rho \,⨾\, f = \rho \,⨾\, g\right) \Rightarrow f = g$;*

PC4. *Causal one-way signalling processes on first-order types factorise: for any causal $\Phi : A \otimes B \to C \otimes D$,*

$\left(\exists \Phi' : A \to C \text{ causal.} \right.$



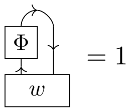
$\left. \right) \Rightarrow \left(\exists Z, \Phi_1 : A \to C \otimes Z \text{ causal}, \quad \Phi_2 : Z \otimes B \to D \text{ causal.} \right.$



$\left. \right) \tag{4}$

PC5. *For all $w : I \to A \otimes B^*$:*

$\left(\forall \Phi : A \to B \text{ causal.} \right.$



$\left. \right) \Rightarrow \left(\exists \rho : I \to A \text{ causal.} \right.$

$\left. \right) \tag{5}$

Note that in [19], PC4 and PC5 are rolled into a single axiom (C4), which is then proven equivalent to PC4 and PC5.

▶ **Example 4.** Mat$[\mathbb{R}^+]$ is a precausal category, whose objects are natural numbers and whose morphisms $M : m \to n$ are $n \times m$ matrices. Then, $\otimes$ is given by tensor product (a.k.a. Kronecker product) of matrices and consequently the tensor unit is the natural number 1. Hence states are column vectors, discarding maps $\bar{\bar{\top}}_m : m \to 1$ are given by row vectors of all 1's, and the causality condition for states $\rho \mathbin{⨾} \bar{\bar{\top}} = \mathrm{id}_1$ imposes the condition that the entries of ρ sum to 1. The conditions PC1, PC2, and PC3 are easily checked, whereas PC4 and PC5 follow from the product rule for conditional probability distributions (see [19]).

▶ **Example 5.** CP is a precausal category, whose objects are algebras $\mathcal{L}(H)$ of linear operators from a finite-dimensional Hilbert space to itself, and whose morphisms are completely positive maps (CP-maps). $\otimes$ is given by tensor product and consequently the tensor unit is the 1D algebra $\mathcal{L}(\mathbb{C}) \cong \mathbb{C}$. States are CP-maps $\mathbb{C} \to \mathcal{L}(H)$, which correspond to positive semidefinite operators $\rho \in \mathcal{L}(H)$. Discarding is given by the trace, hence causal states are the trace-1 positive semidefinite operators, a.k.a. quantum (mixed) states. Again the conditions PC1, PC2, and PC3 are easily checked, whereas PC4 and PC5 follow from the essential uniqueness of purification for CP-maps (see [19]).

Given a precausal category $\mathcal{C}$, we can refine to a category Caus$[\mathcal{C}]$ which equips each object with a nice set of states that should be considered "normalised" (or "causal") and restricts to the morphisms that preserve them. First, we'll define what it means for a set of states to be suitably nice.

▶ **Definition 6.** *A set $c \subseteq \mathcal{C}(I, A)$ is closed if $c = c^{**}$ and flat if either there exist invertible scalars λ, μ such that $\lambda \cdot \underline{\underline{\perp}}_A \in c$ and $\mu \cdot \bar{\bar{\top}}_A \in c^*$ or A is a zero system.*

▶ **Definition 7.** *Given a precausal category $\mathcal{C}$, the category* Caus$[\mathcal{C}]$ *has as objects pairs $\mathbf{A} = (A, c_{\mathbf{A}} \subseteq \mathcal{C}(I, A))$ where $c_{\mathbf{A}}$ is closed and flat. A morphism $f : \mathbf{A} \to \mathbf{B}$ is a morphism $f : A \to B$ in $\mathcal{C}$ such that $\forall \rho \in c_{\mathbf{A}}. \rho \mathbin{⨾} f \in c_{\mathbf{B}}$.*

Caus$[\mathcal{C}]$ inherits a monoidal structure and monoidal closure from $\mathcal{C}$, from which one can show that it is $*$-autonomous [19]. This is in fact a full subcategory of a particular double gluing construction (specifically the tight orthogonality subcategory of the double glueing construction using the $\{1\}$-focussed orthogonality [16]). Aside from the flatness restriction, this is therefore a relatively well-known means of constructing models of linear logic.

$$\begin{array}{lrl}
\text{First-order states} & \mathbf{A^1} := & \left(A, \left\{\bar{\bar{\top}}_A\right\}^*\right) \\
\text{Dual} & \mathbf{A}^* := & (A^*, c_{\mathbf{A}}^*) \\
\text{Tensor product} & \mathbf{A} \otimes \mathbf{B} := & (A \otimes B, \{\rho_A \otimes \rho_B | \rho_A \in c_{\mathbf{A}}, \rho_B \in c_{\mathbf{B}}\}^{**}) \\
\text{Par} & \mathbf{A} \parr \mathbf{B} := & (\mathbf{A}^* \otimes \mathbf{B}^*)^* \\
\text{Internal hom} & \mathbf{A} \multimap \mathbf{B} := & \mathbf{A}^* \parr \mathbf{B} \\
\text{Monoidal unit} & \mathbf{I} := & (I, \{1\})
\end{array}$$

The intuition between the two monoidal products is that $\mathbf{A} \otimes \mathbf{B}$ is the closure of the space of local processes and hence we can compose the $\mathbf{A}$ and $\mathbf{B}$ components however we choose, whereas $\mathbf{A} \parr \mathbf{B}$ is the space of bipartite processes that are normalised in local contexts so we generally cannot compose the components, just act locally on each side. Both share the same unit $\mathbf{I} = \mathbf{I}^*$ and there is a canonical inclusion $\mathbf{A} \otimes \mathbf{B} \hookrightarrow \mathbf{A} \parr \mathbf{B}$ making Caus$[\mathcal{C}]$ into an isomix category.

From these operators, we can build objects capturing the set of processes compatible with some common causal structures. For example, $(\mathbf{A^1} \multimap \mathbf{B^1}) \parr (\mathbf{C^1} \multimap \mathbf{D^1})$ includes all causal bipartite first-order processes, $(\mathbf{A^1} \multimap \mathbf{B^1}) \otimes (\mathbf{C^1} \multimap \mathbf{D^1})$ is the subset of those that are non-signalling [19, Theorem 6.2], and $(\mathbf{A^1} \multimap \mathbf{B^1}) \multimap (\mathbf{C^1} \multimap \mathbf{D^1})$ includes all 2-combs that map causal channels $\mathbf{A^1} \multimap \mathbf{B^1}$ to causal channels $\mathbf{C^1} \multimap \mathbf{D^1}$.

3 Additive Precausal Categories

When investigating higher order causal theories, it is useful to strengthen the definition of a precausal category in a handful of ways. For the remainder of this paper, we will adapt the definition of $\mathrm{Caus}[\mathcal{C}]$ to be built from an additive precausal category $\mathcal{C}$.

▶ **Definition 8.** *Let $\mathcal{C}$ be a compact closed category with products (and hence biproducts and additive enrichment [15]). $\mathcal{C}$ is an additive precausal category if:*

APC1. *$\mathcal{C}$ has a discarding process $\overset{=}{\top}_A \in \mathcal{C}(A, I)$ for every system A, compatible with the monoidal and biproduct structures as below;*

$$\overset{=}{\top}_{A\otimes B} = \overset{=}{\top}_A \otimes \overset{=}{\top}_B \tag{6}$$

$$\overset{=}{\top}_I = \mathrm{id}_I \tag{7}$$

$$\overset{=}{\top}_{A\oplus B} = \left[\overset{=}{\top}_A, \overset{=}{\top}_B\right] \tag{8}$$

APC2. *The dimension $d_A := \underset{=}{\bot}_A \fatsemi \overset{=}{\top}_A$ is invertible for all non-zero A;*

APC3. *Each object $A \in \mathrm{Ob}(\mathcal{C})$ has a finite causal basis: some $\{\rho_i\}_i \subseteq \left\{\overset{=}{\top}_A\right\}^*$ such that $\forall B.\forall f, g \in \mathcal{C}(A, B).(\forall i.\ \rho_i \fatsemi f = \rho_i \fatsemi g) \Rightarrow f = g$.*

APC4. *Addition of scalars is cancellative ($\forall x, y, z.\ x+z = y+z \Rightarrow x = y$), totally pre-ordered ($\forall x, y.\exists z.\ x + z = y \vee x = y + z$), and all non-zero scalars have a multiplicative inverse.*

APC5. *All effects have a complement with respect to discarding: for any $\pi \in \mathcal{C}(A, I)$, there exists some $\pi' \in \mathcal{C}(A, I)$ and scalar λ such that $\pi + \pi' = \lambda \cdot \overset{=}{\top}_A$.*

The first 3 axioms relate closely to the corresponding ones in Definition 3, whereas the last two are quite different in flavour, and are in some sense more elementary, as their proofs don't rely on any particularly deep facts about our main classical and quantum examples (see Examples 13 and 15 below).

The axioms APC1 and APC2 above are essentially identical to the corresponding axioms in Definition 3 of precausal categories, with the additional requirement that discarding be compatible with biproducts as well as tensor products.

APC3 is a strengthening of condition PC3. Rather than requiring us to check a pair of processes agree on *all* causal states to be equal, we only require agreement on some fixed finite set of states. In other other words, each system has a set of states that behaves like a basis spanning all of the others, for the purposes of distinguishing maps. In the quantum foundations literature, this is sometimes called a *fiducial set of states*.

APC4 says that the semiring of scalars $\mathcal{C}(I, I)$ behaves somewhat like the set of non-negative real numbers $\mathbb{R}^+$. While the scalars need not be a field (indeed our main example $\mathbb{R}^+$ is not), any field satisfies this axiom as well. We do however exclude categories of non-determinstic processes such as Rel, since the scalars are boolean values with addition given by the (non-cancellative) operation of disjunction.

Note that, with the help of bases (APC3), we can promote additive cancellativity of scalars to additive cancellativity for all processes.

▶ **Proposition 9.** *In an additive precausal category:*

$$\forall f, g, h \in \mathcal{C}(A, B).\ f + h = g + h \Rightarrow f = g \tag{APC5a}$$

This condition allows us to define the free *subtractive closure* $\mathrm{Sub}(\mathcal{C})$ which extends $\mathcal{C}$ with all negatives and prove that there exists a faithful embedding $[-] : \mathcal{C} \to \mathrm{Sub}(\mathcal{C})$. More details on the explicit construction of $\mathrm{Sub}(\mathcal{C})$, its properties, and the embedding functor are given in the full version of this paper [26].

The utility of freely introducing negatives is summarised in the following proposition.

▶ **Proposition 10.** *For a precausal category $\mathcal{C}$, the scalars $K := \mathrm{Sub}(\mathcal{C})(I, I)$ are a field, and hence $\mathrm{Sub}(\mathcal{C})$ is enriched over K-vector spaces.*

In particular, we can therefore treat processes in $\mathcal{C}(A, B)$ as being embedded in an ambient vector space $\mathrm{Sub}(\mathcal{C})(A, B)$. So, while we might not be able to make all linear algebraic constructions directly in $\mathcal{C}$, we can do so in $\mathrm{Sub}(\mathcal{C})$. An important example of this is the ability to extend any independent set of states to a basis of states in $\mathcal{C}$ as well as its corresponding dual basis of effects in $\mathrm{Sub}(\mathcal{C})$.

▶ **Lemma 11.** *Given any set of morphisms in $\mathcal{C}(A, B)$ that are linearly independent in $\mathrm{Sub}(\mathcal{C})$, they can be extended to a basis in $\mathcal{C}$ with a dual basis in $\mathrm{Sub}(\mathcal{C})$.*

While the dual basis in $\mathrm{Sub}(\mathcal{C})$ may not be physically meaningful (e.g. in the classical case it will contain vectors with negative probabilities), it will be a useful mathematical tool for working with the morphisms in $\mathcal{C}$.

APC5 allows us to interpret effects (up to some renormalisation) as testing some predicate. To see how this works, first assume for simplicity that $\lambda = \mathrm{id}_I$. For a type A, we can think of $\pi : A \to I$ as some predicate over A, and π' as its negation. For some causal state ρ, we can think of the composition $p_1 := \rho \mathbin{⨟} \pi$ as the probability that π is true for ρ and $p_2 := \rho \mathbin{⨟} \pi'$ as the probability that π is false. The fact that $\pi + \pi' = \overset{=}{\top}$ lets us conclude that those probabilities sum to 1:

$$p_1 + p_2 = \rho \mathbin{⨟} \pi + \rho \mathbin{⨟} \pi' = \rho \mathbin{⨟} (\pi + \pi') = \rho \mathbin{⨟} \overset{=}{\top} = \mathrm{id}_I$$

If $\lambda \neq \mathrm{id}_I$, the previous reasoning holds after re-normalising, i.e. replacing π and π' with $\lambda^{-1} \cdot \pi$ and $\lambda^{-1} \cdot \pi'$.

Thanks to compact closure, we can promote APC5 to a property about all processes. Namely, any process $f : A \to B$ has a complement f' where, up to re-normalisation, $f + f'$ gives the uniform noise process.

▶ **Proposition 12.** *For any $f : A \to B$ in an additive precausal category, there exists $f' : A \to B$ and a scalar λ such that:*

$$f + f' = \lambda \cdot \overset{=}{\top}_A \mathbin{⨟} \underset{=}{\bot}_B \tag{APC5a}$$

▶ **Example 13.** $\mathrm{Mat}[\mathbb{R}^+]$ defined as in Example 4 is also an additive precausal category, where $\oplus$ is given by the direct sum of matrices. The standard basis of unit vectors gives a basis for APC3, the semiring of scalars $\mathrm{Mat}[\mathbb{R}^+](I, I) \cong \mathbb{R}^+$ satisfies APC4, and for APC5, we just need to choose a suitably large λ such that $\pi' := \lambda \cdot \overset{=}{\top}_A - \pi$ contains all positive numbers.

▶ **Example 14.** In addition to $\mathbb{R}^+$, we can construct an additive precausal category $\mathrm{Mat}[K]$ for any field of characteristic 0. In particular, $\mathrm{Mat}[\mathbb{R}]$ is an additive precausal category that is identical to $\mathrm{Mat}[\mathbb{R}^+]$ but without any positivity constraint, describing affine or "quasi-probabilistic" maps where negative probabilities are permitted. In this case, the subtractive closure gives an equivalent category to $\mathrm{Mat}[\mathbb{R}]$ itself.

▶ **Example 15.** The quantum example is very nearly the category CP, as defined in Example 5, but CP doesn't have biproducts. If we freely add biproducts, we obtain a category CP^* whose objects are all finite-dimensional C*-algebras (or equivalently, algebras of the form $\mathcal{L}(H_1) \oplus \ldots \oplus \mathcal{L}(H_k)$) and completely positive maps. Discarding is again given by the trace operator, so APC1 and APC2 are straightforward to verify. For APC3, we can fix a (non-orthogonal) basis of states for each type. As in the classical case, the scalars are $\mathbb{R}^+$, so APC4 is immediate and since $\bar{\bar{\top}}_A$ is an interior point in the cone of positive effects, π' can defined as $\lambda \cdot \bar{\bar{\top}}_A - \pi$ for suitably large λ.

Given an additive precausal category, we can apply the Caus construction in the same way as before. However, it may now be easier to devise interesting closed sets or interpret the impact of the closure operator since it just corresponds to taking affine combinations of states. For this to make sense, we should say precisely what we mean to take affine combinations of states in $\mathcal{C}$.

▶ **Definition 16.** *For a set of states $c \subseteq \mathcal{C}(I, A)$, we define sets $\mathsf{aff}(c) \subseteq \mathrm{Sub}(\mathcal{C})(I, A)$ and $\mathsf{aff}^+(c) \subseteq \mathcal{C}(I, A)$ as follows, for $K := \mathrm{Sub}(\mathcal{C})(I, I)$:*

$$\mathsf{aff}(c) := \left\{ \rho \,\middle|\, \exists \{\rho_i\}_i \subseteq \mathcal{C}(I, A), \{\lambda_i\}_i \subseteq K.\ \sum_i \lambda_i = \mathrm{id}_I, \rho = \sum_i \lambda_i \cdot [\rho_i] \right\}$$

$$\mathsf{aff}^+(c) := \{\rho \,|\, \exists \rho' \in \mathsf{aff}(c).\ \rho' = [\rho]\}$$

If we identify the set $\mathcal{C}(I, A)$ with its image under $[-]$, we can think if $\mathsf{aff}^+(c)$ as the intersection of the affine closure of c with the set $\mathcal{C}(I, A) \subseteq \mathrm{Sub}(\mathcal{C})(I, A)$ of “positive” states embedded in the subtractive closure. In the classical and quantum case, $\mathsf{aff}^+(-)$ arises from taking all of the affine combinations of elements of c, then intersecting the resulting set with the positive cone of (unnormalised) probability distributions or quantum states, respectively.

▶ **Theorem 17.** *Given any flat set $c \subseteq \mathcal{C}(I, A)$ for a non-zero A, $c^{**} = \mathsf{aff}^+(c)$.*

This characterises the tensor space $c_{\mathbf{A} \otimes \mathbf{B}} = \{\rho_A \otimes \rho_B | \rho_A \in c_{\mathbf{A}}, \rho_B \in c_{\mathbf{B}}\}^{**}$ in $\mathrm{Caus}[\mathcal{C}]$ as the affine closure of the separable states, from which we can prove the following property.

▶ **Theorem 18.** *If $\mathbf{A} = (A, c_{\mathbf{A}})$ with $c_{\mathbf{A}} = \{\mu \cdot \text{⏚}_A\}$ for any non-zero A, then every $h \in c_{\mathbf{A} \otimes \mathbf{B}}$ is a product morphism of the form $\mu \cdot \text{⏚}_A \otimes g$ for some $g \in c_{\mathbf{B}}$.*

This captures what [27] refers to as the principle of “no interaction with trivial degrees of freedom”. In particular, it recovers the precausal category axiom PC5 by showing that every state of $(\mathbf{A}^\mathbf{1} \multimap \mathbf{B}^\mathbf{1})^* = (\mathbf{A}^{\mathbf{1}^*} \parr \mathbf{B}^\mathbf{1})^* = \mathbf{A}^\mathbf{1} \otimes \mathbf{B}^{\mathbf{1}^*}$ decomposes into a product of a state of $\mathbf{A}^\mathbf{1}$ (i.e. a causal state) and ⏚_{B^*}.

It should be noted that we have completely dropped condition PC4 on our underlying category of basic processes. In Section 5 we will recover a slightly weaker version of this condition by the equivalence of one-way signalling and the affine closure of semi-localisability (Theorem 30). Fortunately, we can still reuse the same proof to show that $\mathrm{Caus}[\mathcal{C}]$ is $*$-autonomous for additive precausal $\mathcal{C}$ since it doesn’t rely on PC4.

4 Additive Types

We may also lean on the relation to the double glueing construction to add type constructors corresponding to the additives of linear logic. In categorical models of linear logic, additive conjunction of types is captured by cartesian product and additive disjunction by coproduct, satisfying a De Morgan duality with one another [20]. In terms of resources, these represent a classical choice: an instance of $A \times B$ is a single resource unit that we can choose to be used either as an instance of A or an instance of B, whereas an instance of $A + B$ is a single resource unit which is fixed on creation as either a unit of A or a unit of B.

The concept of classical choice is often built into operational theories in the form of probability distributions, classical outcomes of tests, and conditional tests. This is typically deemed essential for any experimentalist who is bound to classical data to interact with and make inference from an experiment. On the other hand, the Caus construction concerns the underlying systems present in the physical theory without consideration of any classical agent. We can recover finite-outcome random variables by incorporating binary classical choice through new additive type constructors, i.e. finding constructions for products and coproducts in $\mathrm{Caus}[\mathcal{C}]$.

▶ **Definition 19.** *Given types* $\mathbf{A} = (A, c_{\mathbf{A}}), \mathbf{B} = (B, c_{\mathbf{B}})$ *in* $\mathrm{Caus}[\mathcal{C}]$*, we define* $\mathbf{A} \times \mathbf{B} := (A \oplus B, c_{\mathbf{A}\times\mathbf{B}})$ *and* $\mathbf{A} \oplus \mathbf{B} := (A \oplus B, c_{\mathbf{A}\oplus\mathbf{B}})$ *where:*

$$\begin{aligned} c_{\mathbf{A}\times\mathbf{B}} &= \left(\{p_A \mathbin{⨾} \pi_A | \pi_A \in c_{\mathbf{A}}^* \subseteq \mathcal{C}(A, I)\} \cup \{p_B \mathbin{⨾} \pi_B | \pi_B \in c_{\mathbf{B}}^* \subseteq \mathcal{C}(B, I)\}\right)^* \\ &= \{\langle \rho_A, \rho_B \rangle | \rho_A \in c_{\mathbf{A}}, \rho_B \in c_{\mathbf{B}}\} \end{aligned} \tag{9}$$

$$\begin{aligned} c_{\mathbf{A}\oplus\mathbf{B}} &= \left(\{\rho_A \mathbin{⨾} \iota_A | \rho_A \in c_{\mathbf{A}}\} \cup \{\rho_B \mathbin{⨾} \iota_B | \rho_B \in c_{\mathbf{B}}\}\right)^{**} \\ &= \{[\pi_A, \pi_B] \,|\pi_A \in c_{\mathbf{A}}^* \subseteq \mathcal{C}(A, I), \pi_B \in c_{\mathbf{B}}^* \subseteq \mathcal{C}(B, I)\}^* \end{aligned} \tag{10}$$

▶ **Lemma 20.** *The alternative definitions of* $c_{\mathbf{A}\times\mathbf{B}}$ *and* $c_{\mathbf{A}\oplus\mathbf{B}}$ *are equivalent; that is, Equations 9 and 10 hold.*

▶ **Corollary 21.** *The operators* $\times$ *and* $\oplus$ *are De Morgan duals under* $(-)^*$*.*

▶ **Proposition 22.** $\mathbf{A} \times \mathbf{B}$ *is a categorical product in* $\mathrm{Caus}[\mathcal{C}]$*.*

▶ **Proposition 23.** $\mathbf{A} \oplus \mathbf{B}$ *is a categorical coproduct in* $\mathrm{Caus}[\mathcal{C}]$*.*

The zero object 0 has a unique state $0_{I,0} \in \mathcal{C}(I, 0)$ by terminality and a unique effect $0_{0,I} \in \mathcal{C}(0, I)$ by initiality. There are only two candidates for causal sets: the empty set $\emptyset$ and the singleton $\{0_{I,0}\}$. These have roles in our causal category as the additive units.

▶ **Proposition 24.** *The initial object in* $\mathrm{Caus}[\mathcal{C}]$ *is* $\mathbf{0} := (0, \emptyset)$ *and the terminal object is* $\mathbf{1} := (0, \{0_{I,0}\})$*. Furthermore, they are duals of each other and are units for* $\oplus$ *and* $\times$ *respectively.*

▶ Remark 25. The product and coproduct constructions are only partially-defined as they may not always yield flat sets of states when incorporating the initial or terminal. Specifically, given any $\mathbf{A}$ on a non-zero system, we have

$$\begin{array}{lclclcl} c_{\mathbf{A}\times\mathbf{0}} & = & \emptyset & & c_{\mathbf{A}\times\mathbf{0}}^* & \simeq & \mathcal{C}(A, I) \\ c_{\mathbf{A}\oplus\mathbf{1}} & \simeq & \mathcal{C}(I, A) & & c_{\mathbf{A}\oplus\mathbf{1}}^* & = & \emptyset \end{array} \tag{11}$$

though it may be possible that a careful weakening of the flatness condition may permit this more generally without sacrificing some of the other results of this paper.

Thinking of first-order types as describing systems with no input (i.e. no choice in how to consume them), both the product and coproduct have interesting interactions with first-order types because of where the classical choice happens. For coproducts, the choice is already fixed in the creation of a state so we expect it to preserve the first-order property. However, products introduce freedom of choice in effects allowing us to view the projectors as inputs to the system dictating whether it should prepare the left or the right state.

▶ **Proposition 26.** *If* $\mathbf{A}$ *and* $\mathbf{B}$ *are both first-order types, then so is* $\mathbf{A} \oplus \mathbf{B}$*.*

▶ **Proposition 27.** *If* A *and* B *are non-zero, then* $\mathbf{A} \times \mathbf{B}$ *is never a first-order type.*

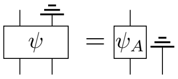
We have both $*$-autonomy and all finite products and coproducts, which is all the evidence required to show that Caus[$\mathcal{C}$] is a model of linear logic with additives. For both the multiplicative and additive structures, we found that the Caus construction took a degenerative categorical structure and generated non-degenerate structures from them. For example, the compact closure of $\mathcal{C}$ means that it is a $*$-autonomous category in which the two monoidal products are the same, but Caus[$\mathcal{C}$] is $*$-autonomous with distinct $\otimes$ and $\parr$. Similarly, the construction for the additives takes biproducts/the zero object and yields distinct products and coproducts/initial and terminal objects. The degenerate exception here is that $\mathbf{I}$ is still the unit for both $\otimes$ and $\parr$.

5 One-Way Signalling Types

When examining multi-partite systems, causal structures can be investigated from the perspective of information signalling (which parties can observe changes to another party's inputs) or decompositions (does the channel admit a decomposition into local channels compatible with some configuration of time- and space-like separations between the parties). In the bipartite case, we can compare these perspectives with the examples of one-way signalling and semi-localisable channels.

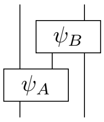
The one-way signalling causal structure refers to a bipartite system (say, between Alice and Bob) in which causal influence may only exist in one direction. There is a standard definition given in causality literature for one-way signalling for quantum channels.

▶ **Definition 28.** *A bipartite process is one-way signalling (Alice to Bob) if discarding Bob's output admits a decomposition into local processes.*



Semi-localisability is an alternative to one-way signalling for expressing compatibility with a time-like separation of parties, giving a constructive example of how the combined channel can be decomposed into local operations.

▶ **Definition 29.** *A bipartite channel between Alice and Bob is semi-localisable (with Alice before Bob) if it decomposes into local processes with a channel from Alice to Bob.*

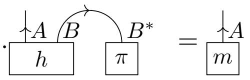


Both of these properties state that the channel is compatible with the setting where Bob is in Alice's future light cone. It is important to note that both are judgements of compatibility with a causal structure rather than inference of any necessary causal relationship between Alice and Bob - completely local processes trivially satisfy these properties but obviously have no causal influence between the parties.

These definitions are specific to first-order channels, but we can consider situations where Alice and Bob have higher-order systems $\mathbf{A}, \mathbf{B} \in \text{Ob}(\text{Caus}[\mathcal{C}])$ representing some more complex interaction with their environments. We will describe these properties as constructions on the causal sets.

The essence of one-way signalling is that Alice's local effect is independent of any input given to Bob by his context:

$$c_{\mathbf{A}} < c_{\mathbf{B}} := \left\{ h \in c_{\mathbf{A} \parr \mathbf{B}} \,\middle|\, \exists m \in c_{\mathbf{A}} . \forall \pi \in c_{\mathbf{B}^*} . \right.$$

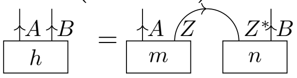


$$\left. \vphantom{\int} \right\} \qquad (12)$$

When this property holds, we refer to m as the *(left-)residual* of h (with *right-residual* for the corresponding component in the symmetrically-defined $c_{\mathbf{A}} > c_{\mathbf{B}}$). The residual represents the constant local effect Alice observes regardless of inputs provided to Bob. In the case where $\mathbf{A}$ and $\mathbf{B}$ both describe first-order channels, this exactly reduces to Definition 28, since the only causal contexts for a causal channel is to provide an arbitrary state at the input and discard the output.

For semi-localisability, it is not enough to consider a factorisation by any system, but specifically by a first-order system:

$$c_{\mathbf{A}} \lhd c_{\mathbf{B}} := \left\{ h \in c_{\mathbf{A} \parr \mathbf{B}} \,\middle|\, \exists \mathbf{Z} = \left(Z, \left\{ \bar{\top}_Z \right\}^* \right), m \in c_{\mathbf{A} \parr \mathbf{Z}}, n \in c_{\mathbf{Z}^* \parr \mathbf{B}} . \right.$$



$$\left. \vphantom{\int} \right\} \qquad (13)$$

This is because using a higher-order system (e.g. the dual of a first-order system) may allow information to flow in the opposite direction. Again, we recover the original definition of semi-localisability if we fix $\mathbf{A}$ and $\mathbf{B}$ to types of first-order channels (up to our encoding of channels via the Choi-Jamiołkowski isomorphism).

Intuitively, based on the interpretation of the sequence operator in a BV-category as representing an ordered combination of systems, both of these would be good candidates for sequence operator in Caus$[\mathcal{C}]$. It is also interesting to compare them to sequence operators from other BV-categories. The following construction is inspired by that of the BV-category of probabilistic coherence spaces [3]:

$$c_{\mathbf{A}} \obslash c_{\mathbf{B}} := \left\{ h \in c_{\mathbf{A} \parr \mathbf{B}} \,\middle|\, \begin{array}{l} \exists \mathcal{I}, \{f_i\}_{i \in \mathcal{I}} \subseteq \mathrm{Sub}(\mathcal{C})(I, A \otimes B), \{g_i\}_{i \in \mathcal{I}} \subseteq c_{\mathbf{B}}, f \in c_{\mathbf{A}} . \\ {[h]} \sim \sum_{i \in \mathcal{I}} f_i \otimes [g_i] \wedge [f] \sim \sum_{i \in \mathcal{I}} f_i \end{array} \right\} \qquad (14)$$

Note this definition refers to maps in the subtractive closure Sub$(\mathcal{C})$ to make use of the affine-linear structure.

A core result in the field of causal structures is the equivalence of one-way signalling and semi-localisability for first-order channels [8]. In the setting provided by the Caus construction, we find a higher-order generalisation of this, where all three of these definitions coincide up to affine closure, as well as a proof that they are self-dual properties.

▶ **Theorem 30.** $c_{\mathbf{A}} < c_{\mathbf{B}} = \left(c_{\mathbf{A}}^* < c_{\mathbf{B}}^*\right)^* = \left(c_{\mathbf{A}} \lhd c_{\mathbf{B}}\right)^{**} = c_{\mathbf{A}} \obslash c_{\mathbf{B}}$

$c_{\mathbf{A}} < c_{\mathbf{B}}$ is closed, since it the dual of another set, and flat, since $c_{\mathbf{A} \otimes \mathbf{B}} \subseteq c_{\mathbf{A}} < c_{\mathbf{B}}$ gives the uniform state and $c_{\mathbf{A} \parr \mathbf{B}}^* \subseteq (c_{\mathbf{A}} < c_{\mathbf{B}})^*$ gives discarding. We can therefore elevate it to a genuine object $\mathbf{A} < \mathbf{B} := (A \otimes B, c_{\mathbf{A}} < c_{\mathbf{B}})$ in Caus$[\mathcal{C}]$.

We can go further into the categorical structure induced by this type constructor and show that it adds another monoidal structure with a weak interchange with both $\otimes$ and $\parr$, turning Caus$[\mathcal{C}]$ into a model of BV-logic.

▶ **Definition 31.** *Given a symmetric, linearly distributive category $\mathcal{D}$, a weak interchange is an additional monoidal structure $(\mathcal{D}, \obslash, I_{\obslash})$ with natural transformations*

$$\begin{array}{llll} w_{\otimes} & : (R \obslash U) \otimes (T \obslash V) \to (R \otimes T) \obslash (U \otimes V) & w_{I_{\otimes}} & : I_{\otimes} \to I_{\otimes} \obslash I_{\otimes} \\ w_{\parr} & : (C \parr E) \obslash (D \parr F) \to (C \obslash D) \parr (E \obslash F) & w_{I_{\parr}} & : I_{\parr} \obslash I_{\parr} \to I_{\parr} \end{array}$$

which are compatible with the structure isomorphisms of $(\mathcal{D}, \otimes, I_\otimes)$ *and* $(\mathcal{D}, \parr, I_\parr)$ *and the distributive structure (we refer the reader to Blute, Panangaden, and Slavnov [3, Definition 4.1] for the full set of conditions).*

A BV*-category is a symmetric linearly distributive category with a weak interchange and an isomorphism* $m : I_\obslash \to I_\otimes$ *such that* m *is an isomix map and* m^{-1} *is a counit for* $w_{I_\otimes}$*:*

$$(\mathrm{id}_{I_\obslash} \otimes m) \fatsemi \rho^\otimes_{I_\obslash} = (m \otimes \mathrm{id}_{I_\obslash}) \fatsemi \lambda^\otimes_{I_\obslash} : I_\obslash \otimes I_\obslash \to I_\obslash$$

$$w_{I_\otimes} \fatsemi (m^{-1} \obslash \mathrm{id}_{I_\otimes}) \fatsemi \lambda^\obslash_{I_\otimes} = \mathrm{id}_{I_\otimes} = w_{I_\otimes} \fatsemi (\mathrm{id}_{I_\otimes} \obslash m^{-1}) \fatsemi \rho^\obslash_{I_\otimes} : I_\otimes \to I_\otimes$$

▶ **Theorem 32.** $\mathrm{Caus}[\mathcal{C}]$ *is a* BV*-category.*

The equivalence of one-way signalling and (the affine closure of) semi-localisability show that any directed information signalling will always exhibit an equivalent construction where the information transfer is mediated by first-order types. Moreover, first-order types (or scaled versions thereof) are *exactly* those that can carry information in one direction.

▶ **Theorem 33.** $\mathbf{A}^* \parr \mathbf{A} = \mathbf{A}^* < \mathbf{A} \Leftrightarrow |c^*_{\mathbf{A}}| = 1.$

This result presents a characterisation of first-order system types that can be interpreted in any BV-category, which may be a useful lemma in characterising which categories arise as $\mathrm{Caus}[\mathcal{C}]$ for some additive precausal $\mathcal{C}$.

6 Non-Signalling Systems

The one-way signalling structure is not the only interesting causal structure on a bipartite system. For example, the non-signalling causal structure is a symmetric property about the statistical independence of the different parties.

▶ **Definition 34.** *A bipartite process is non-signalling if it satisfies the one-way signalling condition in both directions.*

This is a necessary condition for compatibility with the setting where Alice and Bob are space-like separated. However, this is not a sufficient condition since there exist non-signalling processes, such as a quantum implementation of a PR box, that cannot be factorised into local processes with a shared history [23].

In [19], the tensor product of first-order channel types $(\mathbf{A^1} \multimap \mathbf{B^1}) \otimes (\mathbf{C^1} \multimap \mathbf{D^1})$ was shown to exactly contain those bipartite channels that are non-signalling [19]. This proof relied on some properties that do not generalise beyond first-order channels, such as the ability to apply PC5 to decompose causal contexts for channels into a causal input state and discarding the output. Between Gutoski [12] and Chiribella et al. [9], it was shown that the space of non-signalling channels in quantum theory can be characterised as the affine closure of product channels. By translating this proof into categorical terms, we can generalise the result to hold for arbitrary higher-order systems in $\mathrm{Caus}[\mathcal{C}]$ for any additive precausal $\mathcal{C}$.

▶ **Theorem 35.** $(c_{\mathbf{A}} < c_{\mathbf{B}}) \cap (c_{\mathbf{A}} > c_{\mathbf{B}}) = c_{\mathbf{A} \otimes \mathbf{B}}.$

7 Conclusion

By extending the assumptions on the base category with additive structure, the Caus construction yields a BV-category with additives within which the characterisation of first-order types resembles the causality condition expressed as an equation of types. We also obtain general characterisations of $(-)^{**}$ as affine closure and the tensor product as the space of non-signalling bipartite processes. A number of the proofs are similar to those used to show that probabilistic coherence spaces form a BV-category [3], and the characterisation of non-signalling processes as affine closure of local processes for first-order channels in quantum theory [12]. As BV-logic is known to prove a strict subset of the theorems of pomset logic [21], it remains for future work to investigate whether the Caus construction yields models of the latter or if it is limited to BV-logic.

We recover almost all of the precausal conditions from an additive precausal category. Instead of the equivalence of one-way signalling and semi-localisability for first-order channels (Condition PC4), we obtained equivalence with the affine closure of semi-localisability for arbitrary higher-order systems (Theorem 30). Since existing proofs of PC4 for precausal categories rely on the essential uniqueness of purification, it may be possible to strengthen this result in future work by incorporating notions of purity and purification into this framework.

There are still other interesting process theories that cannot be considered as either the base category or the result of the Caus construction in which it would be interesting to analyse constructions for one-way signalling and their logical role. For example, settings with infinite-dimensional systems are rarely compact closed, real quantum mechanics doesn't have enough causal states (since it is compact closed but doesn't admit local discrimination), and Rel fails Condition PC5. We needn't expect the results of this paper to generalise to other theories since (non-deterministic) coherence spaces form a BV-category using a similar construction to $\mathbf{A} \obslash \mathbf{B}$ for the non-commutative operator [3], but this is distinct from the naive adaptation of $\mathbf{A} < \mathbf{B}$ (instead of a constant residual, every local effect must be a subset of some constant clique) which is not self-dual in this category.

Space-Bounded Unitary Quantum Computation with Postselection

Seiichiro Tani

Abstract

Space-bounded computation has been a central topic in classical and quantum complexity theory. In the quantum case, every elementary gate must be unitary. This restriction makes it unclear whether the power of space-bounded computation changes by allowing intermediate measurement. In the bounded error case, Fefferman and Remscrim [STOC 2021, pp.1343–1356] and Girish, Raz and Zhan [ICALP 2021, pp.73:1–73:20] recently provided the break-through results that the power does not change. This paper shows that a similar result holds for space-bounded quantum computation with *postselection*. Namely, it is proved possible to eliminate intermediate postselections and measurements in the space-bounded quantum computation in the bounded-error setting. Our result strengthens the recent result by Le Gall, Nishimura and Yakaryilmaz [TQC 2021, pp.10:1–10:17] that logarithmic-space bounded-error quantum computation with *intermediate* postselections and measurements is equivalent in computational power to logarithmic-space unbounded-error probabilistic computation. As an application, it is shown that bounded-error space-bounded one-clean qubit computation (DQC1) with postselection is equivalent in computational power to unbounded-error space-bounded probabilistic computation, and the computational supremacy of the bounded-error space-bounded DQC1 is interpreted in complexity-theoretic terms.

1 Introduction

1.1 Background

Space-bounded computation is one of the most fundamental topics in complexity theory that have been studied in the classical and quantum settings, since it reflects common practical situations where available memory space is much less than input size. Watrous [25, 26] initiated the study of space-bounded quantum computation based on quantum Turing machines and proved that, in the unbounded-error setting, space-bounded quantum computation is equivalent in computational power to space-bounded probabilistic computation: $\mathsf{PrQSPACE}(s) = \mathsf{PrSPACE}(s)$ for any space-constructible s with $s(n) \in \Omega(\log n)$. This and the classical results [5, 13] imply that unbounded-error space-bounded quantum computation can be simulated by deterministic computation with the squared amount of the space used by the former model.

There are some subtleties (see [16] for the details) in considering space-bounded quantum computation. The most relevant one is whether we allow intermediate measurements, that is, the measurements made during computation, which are allowed in, e.g., [25, 26, 24]. In

the case of polynomial-time quantum computation, it is well-known that all intermediate measurements can be deferred to the end of computation by coherently copying the state of the qubits to be measured to ancilla qubits, and keeping their contents unchanged through the computation. This may require a polynomial number of ancilla qubits to store the copies, since there may exist a polynomial number of intermediate measurements in the original computation. This is acceptable in the polynomial-time quantum computation. However, this method is not applicable in general in the case of space-bounded quantum computation. For instance, if we consider a logarithmic-space quantum computation that runs in polynomial time, the above transformation may require a polynomial number of ancilla qubits, much more than the available space. Thus, it is a fundamental question in space-bounded quantum computation whether it is possible to space-efficiently eliminate intermediate measurements. Recently, Fefferman and Remscrim [7] and Girish, Raz and Zhan [12] independently provided the breakthrough results that it is possible in the bounded error setting.

Postselection is a fictitious function that projects a quantum state on a single qubit to the prespecified state (say, $|1\rangle$) with certainty, as far as the former state has a non-zero overlap with the latter. Since Aaronson [1] introduced postselection to the quantum complexity theory field, it has turned out to be very effective concept in the field although it is unrealistic. In particular, Aaronson succeeded in characterizing a classical complexity class in a quantum way by introducing postselection: $\mathsf{PP} = \mathsf{PostBQP}$ [1]. This characterization gives one-line proofs of the classical results [4, 8], for which only involved classical proofs had been known, and has been a foundation for establishing the quantum computational supremacy of subuniversal quantum computation models (e.g., [6, 2, 17]) under complexity-theoretic assumptions. Another example of characterizing classical complexity classes with postselection is that PSPACE is equal to $\mathsf{PostQMA}$ [19], the class of languages that can be recognized by quantum Merlin-Arthur proof systems with polynomial-time quantum verifier with the ability of postselection. Along this line of work, Le Gall et al. [11] recently considered logarithmic-space quantum computation with postselection in the bounded-error setting and proved that its associated complexity class $\mathsf{PostBQL}$ is equivalent to PL, the class of languages that can be recognized with unbounded error by logarithmic-space probabilistic computation. This beautiful result can be regarded as the equivalent of $\mathsf{PP} = \mathsf{PostBQP}$ in the logarithmic-space quantum computation. Their model allows intermediate postselections as well as intermediate measurements, which play a key role for space-efficiency since the qubits on which intermediate postselections or measurements are made can be reused as initialized ancilla qubits for subsequent computation. Thus, a straightforward question is whether it is possible to space-efficiently eliminate intermediate postselections and measurements. Our main result answers this question affirmatively.

1.2 Our Contribution

We consider the space-bounded quantum computation that allows postselections and measurements only at the end of computation, which we call space-bounded *unitary* quantum computation with postselection. Our result informally says that such quantum computation is equivalent in computational power to the space-bounded quantum computation that allows intermediate postselections and measurements. More concretely, for a space-constructible function s with $s(n) \in \Omega(\log n)$, let $\mathsf{PostBQSPACE}(s)$ be the class of languages that can be recognized with bounded-error by quantum computation with (intermediate) postselections and measurements that uses $O(s)$ qubits and runs in $2^{O(s)}$ time, and let $\mathsf{PostBQuSPACE}(s)$ be the unitary version of $\mathsf{PostBQSPACE}(s)$. By the definition, it holds $\mathsf{PostBQuSPACE}(s) \subseteq \mathsf{PostBQSPACE}(s)$. We show the converse is also true.

▶ **Theorem 1.** *For any space-constructible function s with $s(n) \in \Omega(\log n)$, it holds that*

$$\mathsf{PostBQuSPACE}(s) = \mathsf{PostBQSPACE}(s) = \mathsf{PrSPACE}(s).$$

This strengthens the result of $\mathsf{PostBQSPACE}(s) = \mathsf{PrSPACE}(s)$, which can be derived straightforwardly from the proof of $\mathsf{PostBQL} = \mathsf{PL}$ in [11, 21]. A special case of Theorem 1 with $s = \log n$ is the following corollary, where we define $\mathsf{PostBQL} \equiv \mathsf{PostBQSPACE}(\log)$ and $\mathsf{PostBQuL} \equiv \mathsf{PostBQuSPACE}(\log)$.

▶ **Corollary 2.** $\mathsf{PostBQuL} = \mathsf{PostBQL} = \mathsf{PL}$.

Theorem 1 holds even when the completeness and soundness errors are $2^{-2^{O(s)}}$ (see Theorem 10 for a more precise statement). This justifies defining the bounded-error class $\mathsf{PostBQuSPACE}$ (note that it is non-trivial to reduce errors in the space-bounded unitary computation).

As an application, we characterize the power of space-bounded computation with postselection on a quantum model that is inherently unitary. The deterministic quantum computation with one quantum bit (DQC1)[15], often mentioned as the one-clean-qubit model, is one of well-studied quantum computation models with limited computational resources (e.g., [3, 23, 17, 9, 18, 10]). This model was originally motivated by nuclear magnetic resonance (NMR) quantum information processing, where it is difficult to initialize qubits to a pure state. In the DQC1 model, the initial state is thus the completely mixed state except for a single qubit, i.e., $|0\rangle\langle 0| \otimes (\mathrm{I}/2)^{\otimes m}$, if the total number of qubits is $m + 1$. This model is inherently unitary, since if intermediate measurements or postselections were allowed, the completely mixed state could be projected to the all-zero state $|0^m\rangle$ and thus the DQC1 model would become the ordinary quantum computation model, which is supplied with the all-zero state as the initial state.

Although DQC1 is considered very weak, a polynomial-size DQC1 circuit followed by postselection is surprisingly powerful: The corresponding bounded-error class $\mathsf{PostBQ_{[1]}P}$ is equal to $\mathsf{PostBQP}$ $(= \mathsf{PP})$ [17, 10]. Although this class is unrealistic, it plays an essential role in giving a strong evidence of computational supremacy of the DQC1 computation over classical computation: If any polynomial-size DQC1 circuit is classically simulatable in polynomial time, then the polynomial hierarchy (PH) collapses [17, 10].

Let us consider the space-bounded version of $\mathsf{PostBQ_{[1]}P}$. For a space-constructible function s with $s(n) \in \Omega(\log n)$, let $\mathsf{PostBQ_{[1]}SPACE}(s)$ be the class of languages that can be recognized with bounded-error by DQC1 computation with postselection that uses $O(s)$ qubits and runs in $2^{O(s)}$ time, where all postselections and measurements are made at the the end of computation.

▶ **Theorem 3.** *For any space-constructible function s with $s(n) \in \Omega(\log n)$, it holds that*

$$\mathsf{PostBQ_{[1]}SPACE}(s) = \mathsf{PostBQuSPACE}(s) = \mathsf{PrSPACE}(s).$$

In particular, $\mathsf{PostBQ_{[1]}L} = \mathsf{PostBQuL} = \mathsf{PL}$.

This result relates quantum computational supremacy of space-bounded DQC1 computation with complexity theory as in the time-bounded case. Namely, if any s-space DQC1 computation can be classically simulated with space bound s, then it must hold that $\mathsf{PrSPACE}(s) \subseteq \mathsf{PostBSPACE}(s)$ by Theorem 3, where $\mathsf{PostBSPACE}(s)$ is the classical counterpart of $\mathsf{PostBQuSPACE}(s)$. This relation is the space-bounded equivalent of $\mathsf{PP} \subseteq \mathsf{PostBPP}$. Note that $\mathsf{PP} \subseteq \mathsf{PostBPP}$ leads to the collapse of PH [6], since $\mathsf{PostBPP}$ is in the third level of PH. However, it is open whether $\mathsf{PrSPACE}(s) \subseteq \mathsf{PostBSPACE}(s)$ implies implausible consequences.

1.3 Technical Outline

Since space-bounded quantum computation with postselection can trivially simulate the unitary counterpart by the definition, our main technical contribution is to show that the unitary counterpart can simulate unbounded-error probabilistic computation. Our starting point is the simulation of unbounded-error probabilistic computation by the space-bounded quantum computation with postselection [11]. The simulation [11] consists of two components: the first one, Q_x, simulates the unbounded-error probabilistic computation with acceptance probability p_a on input x to output the state (up to a normalizing factor) $|\Psi_\delta\rangle = (1/2 + p_a)|0\rangle + \delta(1/2 - p_a)|1\rangle$ for a given positive parameter δ; the second one decides whether $p_a > 1/2$ or $p_a < 1/2$ with bounded error by repeatedly running Q_x to prepare the states $|\Psi_\delta\rangle$ for various values of δ and measuring them in the basis $\{|+\rangle, |-\rangle\}$ (based on a modification of the idea [1]). We eliminate the intermediate postselection in Q_x space-efficiently by, every time postselection is made in Q_x, incrementing a counter coherently if the postselection qubit is in the non-postselecting state. It is not difficult to see that this works since Q_x includes only intermediate postselections (and does not include intermediate measurements). This gives a unitary version V_x of Q_x. However, the second component includes both intermediate postselections and measurements, and needs run Q_x sequentially (because running Q_x in parallel is not space-efficient). We then construct two subroutines U_+ and U_-, which accumulate the amplitudes of $|+\rangle$ and $|-\rangle$, respectively, in the states obtained by repeatedly running V_x for various values of δ, as the amplitude of the all-zero state. Finally, we run U_+ and U_- in orthogonal spaces, respectively, followed by postselecting the all-zero state on the qubits that U_+ and U_- act on. The resulting state is significantly supported by one of the spaces, which determines whether $p_a > 1/2$ or $p_a < 1/2$ with high probability.

1.4 Organization

Sec. 2 introduces definitions, basic claims and known theorems. Sec. 3 provides the formal statement of our main result and proves it by using a lemma, which is proved in Sec. 4. Sec. 5 provides an application of the result.

2 Prelimiaries

Let $\mathbb{N}, \mathbb{Z}, \mathbb{R}$ be the sets of natural numbers, integers, and real numbers, respectively. For $m \in \mathbb{N}$, let $[m]$ be the set of $\{1, \dots, m\}$. Assume that Σ is the set $\{0, 1\}$. A *promise problem* $L = (L_Y, L_N)$ is a pair of disjoint subsets of Σ^*. In the special case of promise problems such that $L_Y \cup L_N = \Sigma^*$, we say that L_Y is a *language*.

Classical Space-Bounded Computation

We say that a function $s : \mathbb{N} \to \mathbb{N}$ is *space-constructible* if there exists a deterministic Turing machine (DTM) that compute $s(|x|)$ in space $O(s(|x|))$ on input x. Suppose that s is a space constructible function. Then, we say that a function $f : \mathbb{N} \to \mathbb{R}$ is *s-space computable* if there exists a DTM that computes $f(|x|)$ in space $O(s(|x|))$ on input x. For $s \in \Omega(\log n)$, $\mathsf{PrSPACE}(s)$ is the class of promise problems L such that there exists a probabilistic Turing machine (PTM) M running with space $O(s)$ that satisfies the following: For every input $x \in L_Y$, the probability that M accepts x is greater than $1/2$, and for every input $x \in L_N$, the probability that M accepts x is at most $1/2$. We can replace the condition in the case of $x \in L_N$ with "the probability that M accepts x is *less* than $1/2$" without changing the class $\mathsf{PrSPACE}\,(s)$. In this paper, we adopt the latter definition. It is known that the class $\mathsf{PrSPACE}(s)$ does not change even if we impose the time bound $2^{O(s)}$ on the corresponding PTM with space bound s [13] (see also [22]). We define $\mathsf{PL} \equiv \mathsf{PrSPACE}\,(\log)$.

Quantum Circuits

We below introduce just notations and terminologies relevant to this paper. For the basics of quantum computing, see standard textbooks (e.g., [20, 14]). Let $|+\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$ and $|-\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$.

A *quantum gate* implements a unitary operator. We say that a quantum gate is *elementary* if it acts on a constant number of qubits. We may use a quantum gate and its unitary operator that the gate implements interchangeably. Examples of elementary gates are $\mathrm{H} \equiv |+\rangle\langle 0|+|-\rangle\langle 1|$, $\mathrm{X} \equiv |0\rangle\langle 1|+|1\rangle\langle 0|$, $\mathrm{T} \equiv |0\rangle\langle 0|+e^{i\pi/4}|1\rangle\langle 1|$, and $\mathrm{CNOT} \equiv |0\rangle\langle 0|\otimes \mathrm{I}+|1\rangle\langle 1|\otimes \mathrm{X}$. For unitary gate g, $\wedge_k(g)$ denotes the unitary gate acting on $k+1$ qubits such that it applies g to the last qubit if the contents of the first k qubits are all 1, and it applies the identity otherwise. We may simply say that $\wedge_k(g)$ is a *k-qubit-controlled* g. In the case of $k=1$, we may use $\wedge(g)$ to denote $\wedge_1(g)$. For instance, $\wedge_2(\mathrm{X})$ is the Toffoli gate and $\wedge(\mathrm{X})$ is the CNOT gate. We also define $\vee_k(g)$ as the unitary gate acting on $k+1$ qubits such that it applies g to the last qubit if the contents of the first k qubits are not all-zero, and it applies the identity otherwise. Gate set G is defined as $G_1 \cup G_2 \cup G_3$ for $G_1 \equiv \{\mathrm{H}, \mathrm{T}, \mathrm{CNOT}\}$, the set G_2 of a constant number of additional elementary gates used for block encoding in [11], and the set G_3 of $\wedge(g)$ for all $g \in G_1 \cup G_2$. This choice of gates is not essential for our results when completeness and soundness errors are allowed to be $2^{-O(s)}$ for space bound s, because of space-efficient version of Solovay-Kitaev theorem (see [16, Theorem 4.3]), which says that it is possible to ϵ-approximate every unitary gate with a sequence of gates in any fixed gate set that is finite and universal in $O(\mathrm{polylog}\,(1/\epsilon))$ deterministic time and $O(\log\,(1/\epsilon))$ deterministic space.

For simple descriptions, we will also use k-qubit-controlled gates $\wedge_k\,(g)$ for $g \in G_1 \cup G_2$ and $k \geq 2$ in the following section, since $\wedge_k\,(g)$ can be implemented with gate set G together with $O(1)$ reusable ancilla qubits with negligible gate overhead:

▷ Claim 4. For every gate g, $\wedge_k(g)$ can be implemented with $\wedge(g)$, and $O(k)$ CNOT and T gates together with $O(1)$ ancilla qubits initialized to $|0\rangle$. Similarly, $\vee_k(g)$ can be implemented with $\wedge(g)$, and $O(k)$ CNOT, T and X gates together with $O(1)$ ancilla qubits initialized to $|0\rangle$. Moreover, the states of the ancilla qubits return to $|0\rangle$ after applying $\wedge_k(g)$ $(\vee_k(g))$.

Since the overhead of $O(k)$ gates can be ignored in our setting of $O(s)$ space and $2^{O(s)}$ time computation, we can effectively use $\wedge_k(g)$ freely. The proofs of Claim 4 and the following Claim 5 are provided in the full version.

Next, we define a special gate that will be used many time in this paper. Let INC_{2^n} be the unitary gate acting on n qubits that transforms $\mathrm{INC}_{2^n} : |j\rangle \mapsto |(j+1) \mod 2^n\rangle$ for all $j \in \{0, \ldots, 2^n - 1\}$. Intuitively, INC_{2^n} increments a counter over $\mathbb{Z}_{2^n}$.

▷ Claim 5. $\wedge_k(\mathrm{INC}_{2^n})$ can be implemented with $O(k+n^2)$ CNOT and T gates with the help of $O(1)$ ancilla qubits initialized to $|0\rangle$. Similarly, $\vee_k(\mathrm{INC}_{2^n})$ can be implemented with $O(k+n^2)$ CNOT, T, and X gates with the help of $O(1)$ ancilla qubits initialized to $|0\rangle$. The states of the ancilla qubits return to $|0\rangle$ after applying $\wedge_k(\mathrm{INC}_{2^n})$ $(\vee_k(\mathrm{INC}_{2^n}))$.

Since the overhead of $O(k+n^2)$ gates with $n, k \in O(s)$ can be ignored in our setting of $O(s)$ space and $2^{O(s)}$ time computation, we can effectively use $\wedge_k(\mathrm{INC}_{2^n})$ freely.

A *quantum circuit* consists of quantum gates in a fixed universal set of a constant number of unitary gates, and (intermediate) measurements. A *quantum circuit with postselection* is a quantum circuit with the ability of postselection even at intermediate points in the circuit. Here, the *postselection* [1] is a fictitious function that projects a quantum state on a single qubit to the state $|1\rangle$ with certainty, as far as there exists a non-zero overlap between the state and $|1\rangle$. For instance, if we make postselection on the first qubit of quantum state $\alpha\,|0\rangle\,|\psi_0\rangle + \beta\,|1\rangle\,|\psi_1\rangle$ with $\beta \neq 0$, resulting state is $|1\rangle\,|\psi_1\rangle$. Since the qubit on which postselection has been made is in the state $|1\rangle$ by the definition, we can reuse them as initialized qubits for subsequent computation. This can greatly save the space (i.e., the number of ancilla qubits) as in the case of intermediate measurements. We say that $|1\rangle$ is the postselecting state, and the state orthogonal to the postselecting state, $|0\rangle$, is the non-postselecting state. To simplify descriptions, we may say "postselect $|\phi\rangle$" to mean that we first apply a single-qubit unitary U such that $|1\rangle = U|\phi\rangle$ and then postselect $|1\rangle$. We may also say "postselect $|\phi_1\rangle \otimes \cdots \otimes |\phi_m\rangle$," where $|\phi_i\rangle$ is a single-qubit pure state for every i, to mean postselecting $|\phi_i\rangle$ on the ith qubit for each $i = 1, \ldots,\ m$. For instance, we may say "postselecting the all-zero state" (i.e., postselecting $|0^m\rangle$). A *unitary quantum circuit* consists of only (unitary) quantum gates and does not include any measurement or postselection. To perform computational tasks, a unitary quantum circuit will be followed by measurements (and postselections).

We say that, for a promise problem L, a family of quantum circuits $\{Q_x : x \in L\}$ with postselections (a family of unitary quantum circuits $\{U_x : x \in L\}$) is *s-space uniform* if there exists a DTM that, on input $x \in L$, outputs a description of Q_x (U_x, respectively) with the use of space $O(s(|x|))$ (and hence in $2^{O(s(|x|))}$ time).

Let $s\colon \mathbb{N} \to \mathbb{N}$ be a space-constructible function with $s(n) = \Omega(\log n)$. Assume that functions $c, d\colon \mathbb{N} \to [0,1]$ are s-space computable, and $c(n) > d(n)$ for sufficiently large $n \in \mathbb{N}$.

▶ **Definition 6** (PostQSPACE). *Let* PostQSPACE $(s)\,[c,d]$ *be the class of promise problems* $L = (L_Y, L_N)$ *for which there exists an s-space uniform family of quantum circuits with postselection,* $\{Q_x : x \in L\}$*, that act on* $m = O(s\,(|x|))$ *qubits and consist of* $2^{O(s(|x|))}$ *elementary gates such that, when applying* Q_x *to* $|0\rangle^{\otimes m}$*, (1) the probability* p_{post} *of measuring* $|1\rangle$ *on every postselection qubit is strictly positive; (2) for* $x \in L_Y$*, conditioned on all the postselection qubits being* $|1\rangle$*, the probability that* Q_x *accepts is at least* $c\,(|x|)$*; (3) for* $x \in L_N$*, conditioned on all the postselection qubits being* $|1\rangle$*, the probability that* Q_x *accepts is at most* $d\,(|x|)$*.*

▶ **Definition 7** (PostQuSPACE). *Let* PostQuSPACE$(s)[c.d]$ *be the class of promise problems* $L = (L_Y, L_N)$ *for which there exists an s-space uniform family of unitary quantum circuits,* $\{U_x\colon x \in L\}$*, that act on* $m \in O(s(|x|))$ *qubits and consist of* $2^{O(s(|x|))}$ *elementary gates, followed by postselection on the first qubit and measurement on the output qubit (say, the second qubit) in the computational basis, such that, when applying* U_x *to* $|0\rangle^{\otimes m}$*, (1) the probability* p_{post} *of measuring* $|1\rangle$ *on the first qubits is strictly positive; (2) for* $x \in L_Y$*, conditioned on the first qubit being* $|1\rangle$*, the probability that* U_x *accepts is at least* $c(|x|)$*; (3) for* $x \in L_N$*, conditioned on the first qubit being* $|1\rangle$*, the probability that* U_x *accepts is at most* $d(|x|)$*.*

Definition 7 assumes that postselection is made only on a single qubit. This is general enough since, if there are k postselection qubits, then we can aggregate them into a single postselection qubit by using $\wedge_k(\mathrm{X})$ and $O(1)$ ancilla qubits. Obviously, this aggregation does not change p_{post} and the acceptance probability.

Define $\mathsf{PostBQSPACE}(s) \equiv \mathsf{PostQSPACE}(s)[2/3, 1/3]$ and $\mathsf{PostBQL} \equiv \mathsf{PostBQSPACE}(\log)$. Similarly, define $\mathsf{PostBQuSPACE}(s) \equiv \mathsf{PostQuSPACE}(s)[2/3, 1/3]$ and $\mathsf{PostBQuL} \equiv \mathsf{PostBQuSPACE}(\log)$. Le Gall, Nishimura and Yakaryilmaz [11] proved the following.

▶ **Theorem 8** ([11]). $\mathsf{PostBQL} = \mathsf{PL}$.

Moreover, it is straightforward to extend the result to the general space bound.

▶ **Theorem 9** ([11]). *For any space-constructible function* $s\colon \mathbb{N} \to \mathbb{N}$ *with* $s(n) \in \Omega(\log n)$*, it holds that* $\mathsf{PrSPACE}(s) = \mathsf{PostQSPACE}(s)[1 - 2^{-2^{O(s)}}, 2^{-2^{O(s)}}] = \mathsf{PostBQSPACE}(s)$.

In [11], $\mathsf{PostBQL}$ is defined based on the space-bounded quantum Turing machine (QTM), following the definition provided in [26]. It is not difficult to see that their proof works for the circuit-based definition. Consequently, the QTM-based definition and the circuit-based definition are equivalent in computational power.

3 Main Results

Theorem 10 provides a formal statement of our main result, which shows that the class of promise problems that can be solved with an s-space uniform family of *unitary* quantum circuits with postselection by using $O(s)$ space and $2^{O(s)}$ time in the *bounded-error* setting is equal to the class of promise problems by *unbounded-error* probabilistic computation with space bound s.

▶ **Theorem 10.** *For any space-constructible function* $s : \mathbb{N} \to \mathbb{N}$ *with* $s(n) = \Omega(\log n)$*,*

$$\mathsf{PrSPACE}(s) = \mathsf{PostQuSPACE}(s)\left[1 - 2^{-2^{O(s)}}, 2^{-2^{O(s)}}\right] = \mathsf{PostBQuSPACE}(s).$$

In particular, $\mathsf{PostBQuL} = \mathsf{PL}$.

Theorems 9 and 10 imply that intermediate postselections and measurements add no extra computational power, as stated formally in the following corollary.

▶ **Corollary 11** (Restatement of Theorem 1). *For any space-constructible function* $s : \mathbb{N} \to \mathbb{N}$ *with* $s(n) = \Omega(\log n)$*,*

$$\mathsf{PostBQuSPACE}(s) = \mathsf{PostBQSPACE}(s) = \mathsf{PrSPACE}(s).$$

In particular, $\mathsf{PostBQL} = \mathsf{PostBQuL}$.

Proof of Theorem 10. By the definition, we have $\mathsf{PostQuSPACE}(s)\left[1 - 2^{-2^{O(s)}}, 2^{-2^{O(s)}}\right] \subseteq \mathsf{PostBQuSPACE}(s)$. Then, the theorem follows from Lemmas 12 and 13, stated as follows. ◀

▶ **Lemma 12.** *For any space-constructible function* $s : \mathbb{N} \to \mathbb{N}$ *with* $s(n) = \Omega(\log n)$*,*

$$\mathsf{PostBQuSPACE}(s) \subseteq \mathsf{PrSPACE}(s).$$

Proof. By the definition, we have $\mathsf{PostBQuSPACE}(s) \subseteq \mathsf{PostBQSPACE}(s)$. Since $\mathsf{PostBQSPACE}(s) = \mathsf{PrSPACE}(s)$ by Theorem 9, the lemma follows. ◀

▶ **Lemma 13.** *For any space-constructible function* $s : \mathbb{N} \to \mathbb{N}$ *with* $s(n) = \Omega(\log n)$*,*

$$\mathsf{PrSPACE}(s) \subseteq \mathsf{PostQuSPACE}(s)\left[1 - 2^{-2^{O(s)}}, 2^{-2^{O(s)}}\right].$$

The proof is provided in the following section.

4 Proof of Lemma 13

To prove Lemma 13, we use the fact proved in [11].

▶ **Lemma 14** ([11])**.** *Suppose that, for any input x, a PTM with space bound $s = s\left(|x|\right)$ accepts with probability $p_a = p_a(x)$ and rejects with probability $1 - p_a$ after running in a prespecified time $T(|x|) \in 2^{O(s)}$. There exists an s-space uniform family of quantum circuits Q_x on $m + \lceil \log_2\left(T+1\right)\rceil$ qubits for $m \in O(s)$ that consist of $2^{O(s)}$ elementary gates in the gate set G and intermediate postselections such that, for every $k \in \{0, \dots, T\}$, it holds that*

$$Q_x|0^m\rangle|k\rangle = \frac{|\Psi_k\rangle|0^{m-1}\rangle|k\rangle}{\||\Psi_k\rangle|0^{m-1}\rangle|k\rangle\|},$$

where $|\Psi_k\rangle \equiv \left(1/2 + p_a\right)|0\rangle + 2^{T-k}\left(1/2 - p_a\right)|1\rangle$.

Let L be a promise problem in $\mathsf{PrSPACE}(s)$. Then, there exists a PTM M that recognizes L with unbounded error in space $O(s\left(|x|\right))$ on input x. By the result by Jung [13] (see also [22]), we assume without loss of generality that M runs in time $T(|x|) \in 2^{O(s(|x|))}$. Since the computation path is split into two paths in each step with equal probability, the accepting probability p_a is of the form $a/2^T$ for some integer $a \in \{0, \cdots, 2^T\} \setminus 2^{T-1}$ (assuming $p_a \neq 1/2$ without loss of generality). There exist an s-space uniform family of quantum circuits Q_x defined in Lemma 14. Note that Q_x makes intermediate postselections and thus Q_x is not unitary. Since we have assumed $p_a \neq 1/2$, we can decide whether p_a is larger or smaller than $1/2$ with unbounded error by measuring $|\Psi_T\rangle$ in the basis $\{|+\rangle, |-\rangle\}$. To distinguish the two cases with bounded error, we need to reduce error probability. For this, Le Gall et al. [11] uses essentially the same idea as is used in [1], repeating the following operations for every k: prepare $|\Psi_k\rangle$ and measure it in the basis $\{|+\rangle, |-\rangle\}$. Since the qubits on which measurements or postselections have been made can be reused by initializing them using block encoding with postselection, the space requirement is bounded by $O\left(s\right)$. Thus, intermediate postselections and measurements play a key role in space efficiency.

4.1 Base Unitary Circuit V_x

Our goal is to move every postselection and measurement down to the end of computation while increasing the space requirement by at most a constant factor.

This is not difficult for the Q_x part. The following modification can make Q_x unitary: We prepare an $N \in O(s)$ bit counter C initialized to the all-zero state $\left|0^N\right\rangle$ in a quantum register C. Here, we take a sufficiently large integer in $O(s)$ as N. Then, every time postselection is made in Q_x, we instead increment the counter C coherently if the postselection qubit is in the non-postselecting state, and perform the other operations (i.e., unitary gates) in the same way as in the original circuit Q_x. If we assume without loss of generality that non-postselecting state is $|0\rangle$, then the counter C is incremented by applying the X gate to the postselection qubit, applying $\wedge(\mathrm{INC}_{2^N})$ gate controlled by that qubit, and then applying the X gate to that qubit, namely, $(\mathrm{X} \otimes \mathrm{I})\left(\wedge\left(\mathrm{INC}_{2^N}\right)\right)(\mathrm{X} \otimes \mathrm{I})$. Let V_x denote the modified circuit.

By the above construction and the standard analysis (e.g., [25]), if we measure the counter C and postselect the all-zero state after applying V_x to $|0^m\rangle|k\rangle$, the output state is $|\Psi_k\rangle|0^{m-1}\rangle|k\rangle$ up to a normalizing factor. More concretely, every time postselection is made in Q_x, the modified circuit V_x moves the non-postselecting state into the space associated with the counter value being non-zero, that is, the space orthogonal to the space where the postselecting state lies. By setting N so that the maximum counter value $2^N - 1$ is larger than the number of postselections in Q_x, it holds that, once the counter C is incremented, the counter value never returns to zero. Thus, the quantum interference between the states associated with the counter-values being zero and non-zero never occurs. This implies that, if the content of counter register C is zero, the state must be projected to the postselecting state in *every* postselection points in Q_x, and thus the entire register except C is in the state that is equal to $Q_x|0^m\rangle|k\rangle$. Thus, for certain normalized states $|bad_k(j)\rangle$ and $\ell = m + O(1) \in O(s)$, we can write

$$V_x|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|k\rangle_{\mathsf{K}} = \left[\gamma_k|\Psi_k\rangle_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0^N\rangle_{\mathsf{C}} + \sqrt{1-\|\gamma_k|\Psi_k\rangle\|^2}\sum_{j\geq 1}|bad_k(j)\rangle_{\mathsf{R}}|j\rangle_{\mathsf{C}}\right]|k\rangle_{\mathsf{K}}, \tag{1}$$

where $0 < \gamma_k < 1$, and

$$|\Psi_k\rangle \equiv (1/2 + p_a)\,|0\rangle + 2^{T-k}\,(1/2 - p_a)\,|1\rangle = \alpha_k|+\rangle + \beta_k|-\rangle, \tag{2}$$

for $\alpha_k = \langle +|\Psi_k\rangle$ and $\beta_k = \langle -|\Psi_k\rangle$. Here, register K consists of $\lceil \log_2(T+1)\rceil$ qubits and stores the argument $k \in \{0,\dots,T\}$. The first register $\mathsf{R} \equiv (\mathsf{R}_1, \mathsf{R}_2)$ is the working register except registers C and K, where R_1 is the subregister of R corresponding to the first qubit and R_2 consists of the remaining qubits. Note that V_x uses the register C in addition to registers (R, K) of $O(s)$ qubits, and applies $\wedge(\mathrm{INC}_{2^N})$ instead of every intermediate postselection made in Q_x. Since Q_x consists of $2^{O(s)}$ unitary gates and intermediate postselections on $O(s)$ qubits, and since Claim 5 implies that $\wedge(\mathrm{INC}_{2^N})$ is implementable with $O(N^2)$ $(= O(s))$ CNOT and T gates with $O(1)$ ancilla qubits, which are reusable for other $\wedge(\mathrm{INC}_{2^N})$, it holds that V_x consists of $2^{O(s)}$ gates in G and acts on $O(s)$ qubits.

4.2 Subroutine Unitary Circuits U_+ and U_-

In the following subsections, we will describe the entire algorithm, which includes the error-reduction step. For this, we first provide two unitary subroutines U_+ and U_- in Figure 1. They use V_x and act on registers $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$, where D is an $O(s)$-qubit quantum register used as another $O(s)$-bit counter D. We assume without loss of generality that the two registers C and D consist of N qubits for sufficiently large $N \in O(s)$. The following lemmas tell us about the actions of U_+ and U_-.

▶ **Lemma 15.** *For every $k \in \{0,\dots,T\}$, let α_k and γ_k be the coefficients appearing in Eqs. (1) and (2). Then, U_+ given in Figure 1 acts on $O(s)$ qubits, consists of $2^{O(s)}$ gates in the gate set G, and satisfies*

$$U_+|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\gamma|\alpha_T|^2\cdots|\alpha_0|^2|0\rangle_{\mathsf{R,C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1}|\phi_T(j)\rangle_{\mathsf{R,C}}|j\rangle_{\mathsf{D}}\right]|0\rangle_{\mathsf{K}}$$

for certain unnormalized quantum states $|\phi_T(j)\rangle$ on registers (R, C) for each $j \geq 1$, where $\gamma = |\gamma_T|^2 \cdots |\gamma_0|^2$. Moreover, for every $r \in \mathbb{N} \cap 2^{O(s)}$, $(U_+)^r$ acts on $O(s)$ qubits, consists of $2^{O(s)}$ gates in the gate set G, and satisfies

$$(U_+)^r|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\left(\gamma|\alpha_T|^2\cdots|\alpha_0|^2\right)^r|0\rangle_{\mathsf{R,C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1}|\phi_T^{(r)}(j)\rangle_{\mathsf{R,C}}|j\rangle_{\mathsf{D}}\right]|0\rangle_{\mathsf{K}},$$

where $|\phi_T^{(r)}(j)\rangle$ is a certain unnormalized quantum state on registers (R, C) for each $j \geq 1$.

Subroutine U_+ associated with V_x

Repeat the following steps $T+1$ times.

1. Perform V_x on $(\mathsf{R},\mathsf{C},\mathsf{K})$.
2. If the content of C is non-zero or the first qubit in R is in state $|-\rangle$, then apply INC_{2^N} to register D to increment the counter D.
3. If the content of D is zero, then invert the Step1 on $(\mathsf{R},\mathsf{C},\mathsf{K})$, i.e, apply $V_x^\dagger$.
4. If the content of (R,C) is not all-zero, then apply INC_{2^N} to register D to increment the counter D.
5. Apply INC_{T+1} to register K to increment the content in register K.

Apply $\mathrm{INC}_{T+1}^\dagger$ $T+1$ times to initialize register K to the all-zero state.

Subroutine U_- associated with V_x

Same as U_+ except that Step 2 is replaced with the following operation.

2. If the content of C is non-zero or the first qubit in R is in state $|+\rangle$, then apply INC_{2^N} to register D to increment the counter D.

Figure 1 Subroutines U_+ and U_- associated with V_x.

Proof. We first give the analysis of the first repetition on registers $(\mathsf{R},\mathsf{C},\mathsf{D},\mathsf{K})$ initialized to the all-zero state. Step 1 applies V_x to $|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|k\rangle_{\mathsf{K}}$ with $k=0$. By Eq (1), the resulting state in (R,C) is

$$\gamma_k(\alpha_k|+\rangle+\beta_k|-\rangle)_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0\rangle_{\mathsf{C}}+\sqrt{1-\|\gamma_k|\Psi_k\rangle\|^2}\sum_{j\geq 1}|bad_k(j)\rangle_{\mathsf{R}}|j\rangle_{\mathsf{C}},$$

where we omit the register K for simplicity. Then, Step 2 appends register D and increments the counter D if the content of the register C is not zero or the register R_1 is in the state $|-\rangle$. Thus, the resulting state is

$$\begin{aligned}&\mapsto \gamma_k\alpha_k|+\rangle_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}\\&\quad+\left(\gamma_k\beta_k|-\rangle_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0\rangle_{\mathsf{C}}+\sqrt{1-\|\gamma_k|\Psi_k\rangle\|^2}\sum_{j\geq 1}|bad_k(j)\rangle_{\mathsf{R}}|j\rangle_{\mathsf{C}}\right)|1\rangle_{\mathsf{D}}\\&\qquad\qquad\qquad=\gamma_k\alpha_k|+\rangle_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}+|\phi\rangle_{\mathsf{R,C}}|1\rangle_{\mathsf{D}},\end{aligned}$$

where $|\phi\rangle_{\mathsf{R,C}}=\gamma_k\beta_k|-\rangle_{\mathsf{R1}}|0^{\ell-1}\rangle_{\mathsf{R2}}|0\rangle_{\mathsf{C}}+\sqrt{1-\|\gamma_k|\Psi_k\rangle\|^2}\sum_{j\geq 1}|bad_k(j)\rangle_{\mathsf{R}}|j\rangle_{\mathsf{C}}$. Step 3 then inverts the Step1 on $(\mathsf{R},\mathsf{C},\mathsf{K})$, i.e, applies $V_x^\dagger$, if the content of D is zero. Since $\langle+|_{\mathsf{R1}}\langle 0^{\ell-1}|_{\mathsf{R2}}\langle 0|_{\mathsf{C}}\langle k|_{\mathsf{K}}V_x|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|k\rangle_{\mathsf{K}}=\gamma_k\alpha_k$, the resulting state is

$$\mapsto \gamma_k\alpha_k\left((\gamma_k\alpha_k)^*|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}+\sqrt{1-|\gamma_k\alpha_k|^2}|0^\perp\rangle_{\mathsf{R,C}}\right)|0\rangle_{\mathsf{D}}+|\phi\rangle_{\mathsf{R,C}}|1\rangle_{\mathsf{D}},$$

where $|0^\perp\rangle$ is a certain state orthogonal to the all-zero state. Step 4 then increments the counter D if the content of (R,C) is not all-zero; we have

$$\mapsto |\gamma_k\alpha_k|^2|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}+\sum_{j=1}^{2}|\phi_k(j)\rangle_{\mathsf{R,C}}|j\rangle_{\mathsf{D}},$$

for certain states $|\phi_k(j)\rangle$ for $j = 1, 2$. Step 5 increments the content in register K to get the state on $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$:

$$\left[|\gamma_k \alpha_k|^2 \, |0\rangle_{\mathsf{R}} \, |0\rangle_{\mathsf{C}} \, |0\rangle_{\mathsf{D}} + \sum_{j=1}^{2} |\phi_k(j)\rangle_{\mathsf{R},\mathsf{C}} \, |j\rangle_{\mathsf{D}} \right] |k+1\rangle_{\mathsf{K}} \, .$$

Then, we repeat the same procedure. A simple induction on k shows that the final state after applying U_+ to $|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|0^N\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}}$ is

$$U_+|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|0^N\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\gamma|\alpha_T|^2 \cdots |\alpha_0|^2 |0\rangle_{\mathsf{R},\mathsf{C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1} |\phi_T(j)\rangle_{\mathsf{R},\mathsf{C}}|j\rangle_{\mathsf{D}} \right] |0\rangle_{\mathsf{K}},$$

where $\gamma = |\gamma_T|^2 \cdots |\gamma_0|^2$. Thus, if we repeat U_+ r times, the resulting state is

$$(U_+)^r|0^\ell\rangle_{\mathsf{R}}|0^N\rangle_{\mathsf{C}}|0^N\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\left(\gamma|\alpha_T|^2 \cdots |\alpha_0|^2\right)^r |0\rangle_{\mathsf{R},\mathsf{C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1} |\phi_T^{(r)}(j)\rangle_{\mathsf{R},\mathsf{C}}|j\rangle_{\mathsf{D}} \right] |0\rangle_{\mathsf{K}},$$

for some unnormalized states $|\phi_T^{(r)}(j)\rangle$.

Next, we consider the space and gate complexities of U_+ (see the full version for a rigorous analysis). Recall that V_x can be implemented with $2^{O(s)}$ gates in G by using $O(1)$ reusable ancilla qubits. One can show by using Claims 4 and 5 that every other step in U_+ can also be implemented with $2^{O(s)}$ gates in G by using $O(1)$ reusable ancilla qubits. Consequently, U_+ can be implemented with $2^{O(s)}$ gates in G and requires $O(1)$ ancilla qubits in addition to $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$, which is $O(s)$ qubits in total. Since the ancilla qubits are reusable, $(U_+)^r$ is also implementable with $r \cdot 2^{O(s)} = 2^{O(s)}$ gates in G and acts on $O(s)$ qubits. ◀

We can prove the following lemma for U_- in almost the same way.

▶ **Lemma 16.** *For every $k \in \{0, \ldots, T\}$, let β_k and γ_k be the coefficients appearing in Eqs. (1) and (2). Then, U_- given in Figure 1 acts on $O(s)$ qubits, consists of $2^{O(s)}$ gates in the gate set G, and satisfies*

$$U_-|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\gamma|\beta_T|^2 \cdots |\beta_0|^2 |0\rangle_{\mathsf{R},\mathsf{C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1} |\psi_T(j)\rangle_{\mathsf{R},\mathsf{C}}|j\rangle_{\mathsf{D}} \right] |0\rangle_{\mathsf{K}}$$

for certain unnormalized quantum states $|\psi_T(j)\rangle$ on registers (R, C) for each $j \geq 1$, where $\gamma = |\gamma_T|^2 \cdots |\gamma_0|^2$. Moreover, for every $r \in \mathbb{N} \cap 2^{O(s)}$, $(U_-)^r$ acts on $O(s)$ qubits, consists of $2^{O(s)}$ gates in the gate set G, and satisfies

$$(U_-)^r|0\rangle_{\mathsf{R}}|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{D}}|0\rangle_{\mathsf{K}} = \left[\left(\gamma|\beta_T|^2 \cdots |\beta_0|^2\right)^r |0\rangle_{\mathsf{R},\mathsf{C}}|0\rangle_{\mathsf{D}} + \sum_{j\geq 1} |\psi_T^{(r)}(j)\rangle_{\mathsf{R},\mathsf{C}}|j\rangle_{\mathsf{D}} \right] |0\rangle_{\mathsf{K}},$$

where $|\psi_T^{(r)}(j)\rangle$ is a certain unnormalized quantum state on registers (R, C) for each $j \geq 1$.

4.3 Final Unitary Circuit

Figure 2 shows a unitary quantum circuit with postselection acting on five registers $(\mathsf{W}, \mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$, where W is a single-qubit register. Now, we finalize the proof of Lemma 13 with this circuit.

Unitary Quantum Circuit with Postselection for $\mathsf{PrSPACE}(s)$ problems

Initialize registers $(\mathsf{W}, \mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$ to the all-zero state.

1. Apply the Hadamard gate H to register W.
2. If the content of W is 0, then apply $(U^{+})^{r}$ to registers $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$; otherwise, apply $(U^{-})^{r}$ to registers $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$.
3. Postselect the all-zero state on register D.
4. Measure register W in the basis $\{|0\rangle, |1\rangle\}$. If the outcome 0, then accept ($p_a > 1/2$); otherwise reject (i.e., $p_a < 1/2$).

Figure 2 Unitary Quantum Circuit with Postselection for $\mathsf{PrSPACE}(s)$ problems.

For simplicity, we first assume that $r = 1$. It is straightforward to extend the proof to the general r. It follows from Lemmas 15 and 16 that after Step 2, the state in the register $(\mathsf{W}, \mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K}))$ is

$$\frac{1}{\sqrt{2}}|0\rangle_{\mathsf{W}}\left[\gamma|\alpha_T|^2\cdots|\alpha_0|^2|0\rangle_{\mathsf{R,C}}|0\rangle_{\mathsf{D}}+\sum_{j\geq 1}|\phi_T(j)\rangle_{\mathsf{R,C}}|j\rangle_{\mathsf{D}}\right]|0\rangle_{\mathsf{K}}$$
$$+\frac{1}{\sqrt{2}}|1\rangle_{\mathsf{W}}\left[\gamma|\beta_T|^2\cdots|\beta_0|^2|0\rangle_{\mathsf{R,C}}|0\rangle_{\mathsf{D}}+\sum_{j\geq 1}|\psi_T(j)\rangle_{\mathsf{R,C}}|j\rangle_{\mathsf{D}}\right]|0\rangle_{\mathsf{K}}. \quad (3)$$

Step 3 postselects the all-zero state in register D. Thus, the resulting state in the register $(\mathsf{W}, \mathsf{R}, \mathsf{C})$ is

$$\gamma'\left(|\alpha_T|^2\cdots|\alpha_0|^2|0\rangle_{\mathsf{W}}+|\beta_T|^2\cdots|\beta_0|^2|1\rangle_{\mathsf{W}}\right)|0\rangle_{\mathsf{R,C}} \quad (4)$$

where γ' is the normalizing factor. Here, the probability of measuring postselecting state is

$$p_{post}=\frac{1}{2}\left(\left(\gamma|\alpha_T|^2\cdots|\alpha_0|^2\right)^2+\left(\gamma|\beta_T|^2\cdots|\beta_0|^2\right)^2\right).$$

Recall that $\alpha_k = \langle +|\Psi_k\rangle$ and $\beta_k = \langle -|\Psi_k\rangle$, where $|\Psi_k\rangle$ is defined as Eq. (2). If $p_a > 1/2$, then $\beta_k > 0$ for all k. If $p_a < 1/2$, then $\alpha_k > 0$ for all k. Since $\gamma \neq 0$, p_{post} is strictly positive in both cases.

If $p_a < 1/2$, then $|\alpha_k|^2 > |\beta_k|^2 \geq 0$ for all k, and $|\alpha_k|^2 > (1+\delta)|\beta_k|^2$ for some k and some constant δ, say, $16/9$. Since $\frac{|\beta_T|^2\cdots|\beta_0|^2}{|\alpha_T|^2\cdots|\alpha_0|^2} < \frac{1}{1+\delta} = \frac{9}{25}$, the probability that $|0\rangle_W$ is measured in Step 4, that is, the probability of obtaining the outcome 0 when measuring register W in Eq. (4) in the basis $\{|0\rangle, |1\rangle\}$, is

$$\frac{|\alpha_T|^4\cdots|\alpha_0|^4}{|\alpha_T|^4\cdots|\alpha_0|^4+|\beta_T|^4\cdots|\beta_0|^4}=\frac{1}{1+\left(|\beta_T|^4\cdots|\beta_0|^4\right)/\left(|\alpha_T|^4\cdots|\alpha_0|^4\right)}>\frac{1}{1+(9/25)^2}=\frac{625}{706}.$$

If $p_a > 1/2$, then $0 \leq |\alpha_k|^2 < |\beta_k|^2$ for all k, and $(1+\delta)|\alpha_k|^2 < |\beta_k|^2$ for some k and a constant $\delta = 16/9$. Thus, the probability that $|1\rangle_{\mathsf{W}}$ is measured in Step 4 is at least $\frac{625}{706}$ in the same analysis as in the case of $p_a < 1/2$.

For a general $r \in 2^{O(s)}$, the state in the register $(\mathsf{W}, \mathsf{R}, \mathsf{C})$ after Step 3 is

$$\gamma''\left(\left(|\alpha_T|^2\cdots|\alpha_0|^2\right)^r|0\rangle_{\mathsf{W}}+\left(|\beta_T|^2\cdots|\beta_0|^2\right)^r|1\rangle_{\mathsf{W}}\right)|0\rangle_{\mathsf{R,C}},$$

where γ'' is the normalizing factor. For $p_a < 1/2$, thus, the probability that $|0\rangle$ is measured in Step 4 is

$$\frac{\left(|\alpha_T|^4 \cdots |\alpha_0|^4\right)^r}{\left(|\alpha_T|^4 \cdots |\alpha_0|^4\right)^r + \left(|\beta_T|^4 \cdots |\beta_0|^4\right)^r} > \frac{1}{1+(9/25)^{2r}} > 1 - \frac{81^r}{625^r + 81^r} > 1 - \frac{1}{2^r}.$$

Similarly, for $p_a > 1/2$, the probability that $|1\rangle$ is measured in Step 4 is at least $1 - \frac{1}{2^r}$.

Finally, we consider the space and gate complexities. The quantum circuit in Figure 2 acts on a single-qubit register W in addition to $(\mathsf{R}, \mathsf{C}, \mathsf{D}, \mathsf{K})$. In this circuit, every gate $g \in G$ used in $(U_+)^r$ and $(U_-)^r$ is replaced with $\wedge(g)$, which can be implemented with $O(1)$ gates in G with $O(1)$ resuable ancilla qubits by Claim 4. Since Step 2 is dominant, and $(U_+)^r$ and $(U_-)^r$ use $O(s)$ qubits and $2^{O(s)}$ gates in G by Lemmas 15 and 16, the entire circuit uses $O(s)$ qubits and $2^{O(s)}$ gates in G.

5 Application to One-Clean Qubit Model

As introduced in Section 1, DQC1 is a model of quantum computing such that the input state is completely mixed except for one qubit, which is initialized to $|0\rangle$.

▶ **Definition 17** ($\mathsf{PostQ_{[1]}SPACE}$)**.** *Let s be any space-constructible function with $s(n) \in \Omega(\log n)$, and let c, d be s-space computable functions.* $\mathsf{PostQ_{[1]}SPACE}(s)[c,d]$ *is the class of promised problems $L = (L_Y, L_N)$ for which there exists an s-space uniform family of unitary quantum circuits $\{U_x : x \in L\}$ consisting of $2^{O(s)}$ elementary gates on $m+1$ qubits for $m \in O(s)$ such that, when applying U_x to the $m+1$ qubits in state $|0\rangle\langle 0| \otimes (\mathrm{I}/2)^{\otimes m}$, followed by postselections and measurements, (1) the probability p_{post} of measuring $|1\rangle$ on all postselection qubits is strictly positive; (2) for $x \in L_Y$, conditioned on all the postselection qubits being $|1\rangle$, the probability that U_x accepts is at least $c(|x|)$; (3) for $x \in L_N$, conditioned on all the postselection qubits being $|1\rangle$, the probability that U_x accepts is at most $d(|x|)$. In particular, define* $\mathsf{PostBQ_{[1]}SPACE}(s) \equiv \mathsf{PostQ_{[1]}SPACE}(s)[2/3, 1/3]$*, and* $\mathsf{PostBQ_{[1]}L} \equiv \mathsf{PostBQ_{[1]}SPACE}(\log)$*.*

In the above definition, we allow postselection to be made on multiple qubits, since it does not seem possible in general to aggregate multiple postselection qubits to a single qubit due to the lack of initialized qubits. Theorem 3 follows from Theorems 10 and 18.

▶ **Theorem 18.** *For any space-constructible function s with $s(n) \in \Omega(\log n)$ and any s-space computable functions c and d such that $c(n) > d(n)$ for sufficiently large $n \in \mathbb{N}$,*

$$\mathsf{PostQ_{[1]}SPACE}(s)[c,d] = \mathsf{PostQuSPACE}(s)[c,d].$$

In particular, $\mathsf{PostBQ_{[1]}SPACE}(s) = \mathsf{PostBQuSPACE}(s)$ *and* $\mathsf{PostBQ_{[1]}L} = \mathsf{PostBQuL}$*.*

The proof is provided in the full version.

Abstract

Given a set P of n points that are moving in the plane, we consider the problem of computing a spanning tree for these moving points that does not change its combinatorial structure during the point movement. The objective is to minimize the bottleneck weight of the spanning tree (i.e., the largest Euclidean length of all edges) during the whole movement. The problem was solved in $O(n^2)$ time previously [Akitaya, Biniaz, Bose, De Carufel, Maheshwari, Silveira, and Smid, WADS 2021]. In this paper, we present a new algorithm of $O(n^{4/3}\log^3 n)$ time.

1 Introduction

Given a set P of n points in the plane, let G_P be the complete graph whose vertex set is P such that the weight of each edge connecting two points p and q of P is the Euclidean distance between p and q. The *Euclidean minimum spanning tree (EMST)* of P is the spanning tree of G_P with minimum sum of edge weights. The *Euclidean minimum bottleneck spanning tree (EMBST)* of P is the spanning tree of G_P whose largest edge weight is minimized. It is well known that a Delaunay triangulation of P contains an EMST of P [24] and thus an EMST of P can be computed in $O(n \log n)$ time by constructing a Delaunay triangulation of P first. This is also the case for the bottleneck problem.

In this paper, motivated by visualizations of time-varying spatial data [2], we consider a moving version of the EMBST problem where every point of P is moving during a time interval. Without loss of generality, we assume that the time interval is $[0, 1]$. A *moving point* $p \in P$ is a continuous function $p : [0, 1] \to \mathbb{R}^2$. Let $p(t)$ denote the location of p at time $t \in [0, 1]$. We assume that p moves on a straight line segment with a constant velocity, i.e., $p(t)$ is linear in t and points of $\{p(t)|\ t \in [0, 1]\}$ form a straight line segment in the plane (see Fig. 1; different points may have different velocities). A *moving spanning tree* T of P connects all points of P and does not change its connection during the whole time interval (i.e., for any two points $p, q \in P$, the path connecting p and q in T always contains the same set of edges). We use $T(t)$ to denote the tree at the time t. The *instantaneous bottleneck* $b_T(t)$ at time t is the maximum length of all edges in $T(t)$. The *bottleneck* $b(T)$ of

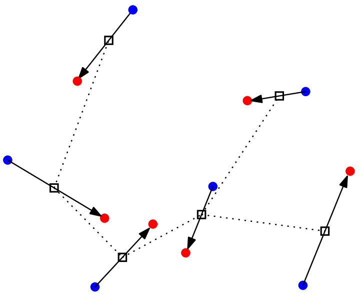

Figure 1 Each pair of red and blue points connected by an arrow represents a moving point. Blue points denote locations at $t = 0$ and red points are locations at $t = 1$. Black boxes are locations of these moving points at certain time and the dashed segments form a spanning tree.

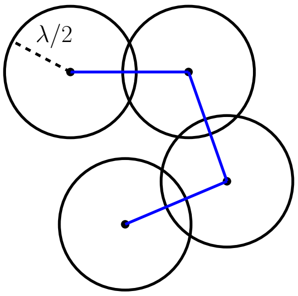

Figure 2 Illustrating a unit-disk graph. Two points are connected (by a blue segment) if their distance is less than or equal to λ. In other words, two points are connected if congruent disks centered at them with radius $\lambda/2$ intersect.

the moving spanning tree T is defined to be the maximum instantaneous bottleneck during the whole time interval, i.e., $b(T) = \max_{t\in[0,1]} b_T(t)$. The *Euclidean minimum bottleneck moving spanning tree* (or *moving-EMBST* for short) T^* refers to the moving spanning tree of P with minimum bottleneck.

In this paper, we study the problem of computing the moving-EMBST T^* for a set P of n moving points in the plane as defined above. Previously, this problem was solved in $O(n^2)$ time by Akitaya, Biniaz, Bose, De Carufel, Maheshwari, Silveira, and Smid [2]. To solve the problem, the authors of [2] first proved the following *key property*: The function of the distance between two moving points over time is convex (this is because each point moves linearly with constant velocity), implying that the maximum distance between two moving points is achieved at $t = 0$ or $t = 1$ (note that this does not mean T^* is attained at either $t = 0$ or $t = 1$; a counterexample is provided in [2]). Using the above property, the authors of [2] proposed the following simple algorithm to compute T^*. First, compute a complete graph G with P as the vertex set such that the weight of each edge connecting two points p and q of P is defined as the maximum length of their distances at $t = 0$ and at $t = 1$. Then the authors [2] showed that a minimum bottleneck spanning tree (MBST) of G is also a moving-EMBST of P and thus it suffices to compute an MBST in G. Since an MBST of a graph can be computed in linear time in the graph size [7], the entire algorithm for computing T^* runs in $O(n^2)$ time in total [2].

1.1 Our result

We present an algorithm of $O(n^{4/3}\log^3 n)$ time to compute T^*. We sketch the main idea below.

For any two points p and q in the plane, let $|pq|$ denote their Euclidean distance. Due to the above key property from [2], we observe that $b(T^*)$ must be equal to $|pq|_{\max}$ for two moving points p and q of P, where $|pq|_{\max} = \max\{|p(0)q(0)|, |p(1)q(1)|\}$, i.e., $b(T^*) \in \{|pq|_{\max} \mid p, q \in P\}$. As such, our main idea is to find $b(T^*)$ in $\{|pq|_{\max} \mid p, q \in P\}$ by binary search. To this end, we first solve a *decision problem*: Given any value $\lambda > 0$, decide whether $b(T^*) \leq \lambda$. We reduce the decision problem to the problem of finding a common spanning tree in two unit-disk graphs. Specifically, the *unit-disk graph* $G_\lambda(Q)$ for a set Q of points in the plane with respect to a parameter λ is an undirected graph whose vertex set is Q such that an edge connects two points $p, q \in Q$ if $|pq| \leq \lambda$ (alternatively, $G_\lambda(Q)$ can be viewed as the intersection graph of the set of congruous disks centered at the points of Q with radius $\lambda/2$, i.e., two vertices are connected if their disks intersect; see Fig. 2). Observe that $b(T^*) \leq \lambda$ if and only if the unit-disk graph $G_\lambda(P)$ for P at time $t = 0$ and the unit-disk graph $G_\lambda(P)$ for P at time $t = 1$ share a common spanning tree. To determine whether the two unit-disk graphs share a common spanning tree, we apply breadth-first-search (BFS) on the two graphs simultaneously. To avoid quadratic time, we do not compute these unit-disk graphs explicitly. Instead, we use a batched range searching technique of Katz and Sharir [19] to obtain a compact representation for searching one graph. For searching the other graph, we derive a semi-dynamic data structure for the following *deletion-only unit-disk range emptiness query* problem: Preprocess a set Q of n points in the plane with respect to λ so that the following two operations can be performed efficiently: (1) given a query point p, determine whether Q has a point q such that $|pq| \leq \lambda$, and if yes, return such a point q; (2) delete a point from Q. We refer to the first operation as *unit-disk range emptiness query* (or UDRE query for short). We build a data structure of $O(n)$ space in $O(n \log n)$ time such that each UDRE query can be answered in $O(\log n)$ time while each deletion can be performed in $O(\log n)$ amortized time. This result might be interesting in its own right. Combining this result with the batched range searching [19], we implement the BFS simultaneously on the two unit-disk graphs in $O(n^{4/3} \log^2 n)$ time, which solves the decision problem.

Next, equipped with the above decision algorithm, we find $b(T^*)$ from the set $\{|pq|_{\max} \mid p, q \in P\}$ by binary search. Computing the set explicitly would take $\Omega(n^2)$ time. We avoid doing so by resorting to the distance selection algorithm of Katz and Sharir [19], which can compute the k-th smallest distance among all interpoint distances of a set of n points in the plane in $O(n^{4/3} \log^2 n)$ time for any k with $1 \leq k \leq \binom{n}{2}$. Combining with our decision algorithm, $b(T^*)$ can be computed in $O(n^{4/3} \log^3 n)$ time. Applying the value $\lambda = b(T^*)$ to the decision algorithm can produce the optimal spanning tree T^* in additional $O(n^{4/3} \log^2 n)$ time.

1.2 Related work

Similar to the moving-EMBST problem, one can consider the Euclidean minimum moving spanning tree (moving-EMST) for a set of moving points (i.e., minimizing the total sum of the edge weights instead). The authors of [2] proved that the moving-EMST problem is NP-hard and they gave an $O(n^2)$ time 2-approximation algorithm and another $O(n \log n)$ time $(2+\epsilon)$-approximation algorithm for any $\epsilon > 0$. These spanning tree problems for moving points are relevant in the realm of moving networks that is motivated by the increase in mobile data consumption and the network architecture containing mobile nodes [2].

Geometric problems for moving objects have been studied extensively in the literature, e.g., [3, 4]. In particular, kinetic data structures were proposed to maintain the minimum spanning tree for moving points in the plane [3, 25]. Different from our problem, research in this domain focuses on bounds of the number of combinatorial changes in the minimum spanning tree during the point movement [4].

For solving the deletion-only UDRE query problem, by the standard lifting transformation, one can reduce the problem to maintaining the lower envelope of a dynamic set of planes in $\mathbb{R}^3$, which has been extensively studied [1, 9, 15, 18]. Applying Chan's recent work [11] for the problem can achieve the following result: With $O(n \log n)$ preprocessing time, each UDRE query can be answered in $O(\log^2 n)$ time and each point deletion can be handled in $O(\log^4 n)$ amortized time (the data structure is actually fully-dynamic and can also handle each point insertion in $O(\log^2 n)$ amortized time). The same problem in 2D (whose dual problem becomes maintaining the convex hull for a dynamic set of points) is easier and has also been studied extensively, e.g., [5, 8, 17, 23]. In addition, Wang [26] studied the unit-disk range counting query problem for a static set of points in the plane, by extending the techniques for half-plane range counting query problem [10, 20, 21].

Our algorithm for the decision problem uses some techniques for unit-disk graphs. Many problems on unit-disk graphs have been studied, i.e., shortest paths and reverse shortest paths [6, 12, 13, 27–30], clique [14], independent set [22], diameter [12, 13, 16], etc. Although a unit-disk graph of n vertices may have $\Omega(n^2)$ edges, many problems can be solved in subquadratic time by exploiting its underlying geometric structures, e.g., computing shortest paths [6, 27]. Our $O(n^{4/3}\log^2 n)$ time algorithm for finding a common spanning tree in two unit-disk graphs adds one more problem to this category.

Outline. In the following, we present our algorithm for the moving-EMBST problem in Section 2. The algorithm uses our data structure for the deletion-only unit-disk range emptiness query problem, which is given in Section 3. Section 4 concludes. Due to the space limit, some proofs are omitted but can be found in the full paper.

2 Algorithm for moving-EMBST

We follow the notation in Section 1, e.g., P, t, $b(T)$, $b_T(t)$, T^*, $|pq|$, $|pq|_{\max}$, $G_\lambda(P)$, etc. Given a set P of n points in the plane, our goal is to compute $b(T^*)$. As discussed in Section 1.1, we first consider the decision problem: Given any $\lambda > 0$, decide whether $b(T^*) \leq \lambda$. We refer to the original problem for computing $b(T^*)$ as the *optimization problem*. In what follows, we solve the decision problem in Section 2.1 and the algorithm for the optimization problem is described in Section 2.2.

2.1 The decision problem

Given any $\lambda > 0$, the decision problem is to decide whether $b(T^*) \leq \lambda$.

For any time $t \in [0, 1]$, we use $P(t)$ to denote the set of points of P at their locations at time t, i.e., $P(t) = \{p(t) \mid p \in P\}$. Consider the two unit-disk graphs $G_\lambda(P(0))$ and $G_\lambda(P(1))$. To simplify the notation, we use $G_\lambda(t)$ to refer to $G_\lambda(P(t))$ for any $t \in [0, 1]$. For every point $p \in P$, we consider $p(0)$ in $G_\lambda(0)$ and $p(1)$ in $G_\lambda(1)$ as the same vertex p, and thus define $G_\lambda = G_\lambda(0) \cap G_\lambda(1)$ as the *intersection graph* of $G_\lambda(0)$ and $G_\lambda(1)$, i.e., the vertex set of G_λ is P and G_λ has an edge connecting two vertices p and q if and only $G_\lambda(0)$ has an edge connecting $p(0)$ and $q(0)$ and $G_\lambda(1)$ has an edge connecting $p(1)$ and $q(1)$. A spanning tree of G_λ is called a *common spanning tree* of $G_\lambda(0)$ and $G_\lambda(1)$.

The following observation has been proved in [2].

▶ **Observation 1** ([2]). *$\max_{t\in[0,1]} |p(t)q(t)| = \max\{|p(0)q(0)|, |p(1)q(1)|\}$ holds for every pair of points $p, q \in P$.*

Using the above observation, the following lemma reduces the decision problem to the problem of finding a common spanning tree of $G_\lambda(0)$ and $G_\lambda(1)$. The proof can be found in the full paper.

▶ **Lemma 2.** *Given any $\lambda > 0$, $b(T^*) \leq \lambda$ if and only if $G_\lambda(0)$ and $G_\lambda(1)$ have a common spanning tree.*

In light of Lemma 2, to solve the decision problem, it suffices to determine whether $G_\lambda(0)$ and $G_\lambda(1)$ have a common spanning tree, or alternatively, whether the intersection graph G_λ has a spanning tree, which is true if and only if the graph is connected. To determine whether G_λ is connected, we perform a breadth-first search (BFS) in G_λ, or equivalently, we perform a BFS on $G_\lambda(0)$ and $G_\lambda(1)$ simultaneously; we do so without computing the two unit-disk graphs explicitly to avoid the quadratic time. Our algorithm relies on the following lemma for the deletion-only UDRE query problem, which will be proved in Section 3.

▶ **Theorem 3.** *Given a value λ and a set Q of n points in the plane, we can build a data structure of $O(n)$ space in $O(n \log n)$ time such that the following first operation can be performed in $O(\log n)$ worst case time while the second operation can be performed in $O(\log n)$ amortized time.*

1. Unit-disk range emptiness (UDRE) query*: Given a point p, determine whether there exists a point $q \in Q$ such that $|pq| \leq \lambda$, and if yes, return such a point q.*
2. Deletion*: delete a point from Q.*

In the following, we begin with an algorithm overview and then flesh out the details.

Algorithm overview. Starting from an arbitrary point $s \in P$, we run BFS in the graph G_λ. For each $i = 0, 1, 2, \ldots$, let P_i be the set of points whose shortest path lengths from s in G_λ are equal to i. In each i-th iteration, the algorithm computes P_i. Initially, $P_0 = \{s\}$. The algorithm stops once we have $P_i = \emptyset$, after which we check whether all points of P have been discovered. If yes, then the BFS tree is a spanning tree of G_λ; otherwise, G_λ is not connected. Consider the i-th iteration. Suppose P_{i-1} is already known. For each point $p \in P_{i-1}$, we wish to find the set $S(p)$ of all points $q \in P$ such that (1) q has not been discovered yet, i.e., $q \notin \bigcup_{j=0}^{i-1} P_j$; (2) $|p(0)q(0)| \leq \lambda$; (3) $|p(1)q(1)| \leq \lambda$. To implement this step efficiently, we use two techniques. First, we use a batched range searching technique of Katz and Sharir [19] to obtain a compact representation of all points of $P(0)$. The compact representation can provide us with a collection $\mathcal{N}(p)$ of canonical subsets of P whose union is exactly the subset of points q of P such that $|p(0)q(0)| \leq \lambda$. Second, for each subset Q of $\mathcal{N}(p)$, a data structure of Theorem 3 is constructed for $Q(1) = \{q(1) \mid q \in Q\}$, i.e., the set of points of Q at their locations at time $t = 1$. Then, we apply the UDRE query with $p(1)$ as the query point; if the query returns a point $q(1)$, then we know that q is in $S(p)$ and we delete q from Q (we also delete q from other canonical subsets of the compact representation that contain q; the deletion guarantees that points of P already discovered by the BFS have been removed from the canonical subsets of the compact representation) and applying the UDRE query with $p(1)$ again. We keep doing this until the UDRE query does not return any point, and then we process the next subset of $\mathcal{N}(p)$ in the same way. In this way, $S(p)$ will be computed, which is a subset of P_i. Processing every point $p \in P_{i-1}$ as above will produce P_i. The details of the algorithm are given below.

Preprocessing. Before running BFS, we conduct some preprocessing work.

First, using a batched range searching technique [19], we have the following lemma (which is essentially Theorem 3.3 in [19]) for computing a *compact representation* of all pairs (p, q) of points of P with $|p(0)q(0)| \leq \lambda$.

▶ **Lemma 4** (Theorem 3.3 [19]). *We can compute a collection $\{X_r \times Y_r\}_r$ of complete edge-disjoint bipartite graphs in $O(n^{4/3} \log n)$ time and space, where $X_r, Y_r \subseteq P$, with the following properties.*

1. *For any r, $|p(0)q(0)| \leq \lambda$ holds for any point $p \in X_r$ and any point $q \in Y_r$.*
2. *The number of these complete edge-disjoint bipartite graphs is $O(n^{4/3})$, and both $\sum_r |X_r|$ and $\sum_r |Y_r|$ are bounded by $O(n^{4/3} \log n)$.*
3. *For any two points $p, q \in P$ with $|p(0)q(0)| \leq \lambda$, there exists a unique r such that $p \in X_r$ and $q \in Y_r$.*

We refer to each X_r (resp., Y_r) as a *canonical subset* of P. After the collection $\{X_r \times Y_r\}_r$ is computed, we further do the following. For each point $p \in P$, if p is in X_r, then we add (the index of) Y_r to $\mathcal{N}(p)$. By Lemma 4(3), subsets of $\mathcal{N}(p)$ are pairwise disjoint and the union of them is exactly the subset of points $q \in P$ with $|p(0)q(0)| \leq \lambda$. Similarly, for each point $p \in P$, if p is in Y_r, then we add (the index of) Y_r to $\mathcal{M}(p)$. The purpose of having $\mathcal{M}(p)$ is that after a point p is identified in P_i, we will need to remove p from all subsets Y_r that contain p (so $\mathcal{M}(p)$ helps us to keep track of these subsets Y_r). We can compute $\mathcal{N}(p)$ and $\mathcal{M}(p)$ for all points $p \in P$ in $O(n^{4/3}\log n)$ time since both $\sum_r |X_r|$ and $\sum_r |Y_r|$ are $O(n^{4/3}\log n)$ by Lemma 4(2). For the same reason, both $\sum_{p\in P} |\mathcal{N}(p)|$ and $\sum_{p\in P} |\mathcal{M}(p)|$ are bounded by $O(n^{4/3}\log n)$.

In addition, for each canonical subset Y_r, we construct the data structure of Theorem 3 for $Y_r(1) = \{q(1) \mid q \in Y_r\}$, denoted by $\mathcal{D}(Y_r)$. Since $\sum_r |Y_r| = O(n^{4/3}\log n)$, constructing the data structures for all Y_r can be done in $O(n^{4/3}\log^2 n)$ time and $O(n^{4/3}\log n)$ space.

This finishes our preprocessing work, which takes $O(n^{4/3}\log^2 n)$ time in total.

Implementing the BFS algorithm. We next implement the BFS algorithm as overviewed above (we follow the same notation).

For each point $p \in P_{i-1}$, the key step is to compute the subset $S(p)$ of P. We implement this step as follows. For each $Y_r \in \mathcal{N}(p)$, we perform a UDRE query with $p(1)$ on the data structure $\mathcal{D}(Y_r)$. If the query returns a point $q(1)$, then we add q to $S(p)$ and delete $q(1)$ from the data structure $\mathcal{D}(Y'_r)$ for every $Y'_r \in \mathcal{M}(q)$. Next, we perform a UDRE query with $p(1)$ on $\mathcal{D}(Y_r)$ again and repeat the same process as above until the query does not return any point. According to the definitions of $\mathcal{N}(p)$ and $\mathcal{M}(p)$ and also due to the deletions on $\mathcal{D}(Y'_r)$ for all $Y'_r \in \mathcal{M}(q)$, the union of $S(p)$ thus computed for all $p \in P_{i-1}$ is exactly P_i. This finishes the i-th iteration of the BFS algorithm.

For the time analysis, since both $\sum_{p\in P} |\mathcal{N}(p)|$ and $\sum_{p\in P} \mathcal{M}(p)$ are $O(n^{4/3}\log n)$, the total number of UDRE queries and deletions on the data structures $\mathcal{D}(Y_r)$ in the entire algorithm is $O(n^{4/3}\log n)$, which together take $O(n^{4/3}\log^2 n)$ time. Therefore, the BFS algorithm runs in $O(n^{4/3}\log^2 n)$ time.

The following theorem summarizes our result for the decision problem.

▶ **Theorem 5.** *Given a value $\lambda > 0$, we can decide whether $b(T^*) \leq \lambda$ in $O(n^{4/3}\log^2 n)$ time, and if yes, a moving spanning tree T of P with $b(T) \leq \lambda$ can be found in $O(n^{4/3}\log^2 n)$ time.*

2.2 The optimization problem

As discussed in Section 1, by Observation 1, $b(T^*)$ is equal to $|p(0)q(0)|$ or $|p(1)q(1)|$ for two moving points $p, q \in P$. As such, we can compute $b(T^*)$ by searching the two sets $S(0)$ and $S(1)$ using our decision algorithm in Theorem 5, where $S(t)$ is defined as $\{|p(t)q(t)| \mid p, q \in P\}$ for any $t \in [0,1]$. To avoid explicitly computing $S(0)$ and $S(1)$, which would take $\Omega(n^2)$ time, we resort to the distance selection algorithm of Katz and Sharir [19], which can compute the k-th smallest distance among all interpoint distances of a set of n points in the plane in $O(n^{4/3}\log^2 n)$ time for any k with $1 \leq k \leq \binom{n}{2}$. Combining the distance selection algorithm and our decision algorithm, we can compute $b(T^*)$ in $O(n^{4/3}\log^3 n)$ time by doing binary search on the values of $S(0)$ and $S(1)$. The details are given in the proof of the following theorem, which can be found in the full paper.

▶ **Theorem 6.** *Given a set P of n moving points in the plane, we can compute a Euclidean minimum bottleneck moving spanning tree for them in $O(n^{4/3}\log^3 n)$ time.*

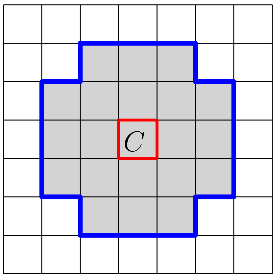

Figure 3 The cells in the gray region bounded by the blue curve are all neighbors of the red cell.

3 Deletion-only unit-disk range emptiness query data structure

In this section, we prove Theorem 3. We follow the notation in the theorem, e.g., Q, λ.

We use a *unit-disk* to refer to a disk with radius λ. For any point p in the plane, we use A_p to denote the unit-disk centered at p. With this notation, a unit-disk range emptiness (UDRE) query with query point p becomes the following: Determine whether $A_p \cap Q$ is empty, and if not, return a point from $A_p \cap Q$.

We use a grid Ψ_λ to capture the neighboring information of the points of Q, which partitions the plane into square cells of side length $\lambda/\sqrt{2}$ by horizontal and vertical lines, so that the distance of any two points in each cell is at most λ. For ease of discussion, we assume that each point of Q is in the interior of a cell of Ψ_λ. Define $Q(C)$ as the subset of points of Q lying in a cell C. A cell C' of Ψ_λ is a *neighbor* of another cell C if the minimum distance between a point of C and a point of C' is at most λ (see Fig. 3). For each cell C, we use $N(C)$ to denote the set of neighbors of C in Ψ_λ; for convenience, we let $N(C)$ include C itself. Note that the number of neighbors of each cell of Ψ_λ is $O(1)$ and each cell is a neighbor of $O(1)$ cells (since $C' \in N(C)$ if and only if $C \in N(C')$). Let $\mathcal{C}$ denote the set of cells of Ψ_λ that contain at least one point of Q as well as their neighbors. Note that $\mathcal{C}$ has $O(n)$ cells. By the definition of $\mathcal{C}$, the following observation is self-evident.

▶ **Observation 7.** *For any point p in the plane, if p is not in any cell of $\mathcal{C}$, then $A_p \cap Q = \emptyset$.*

The grid technique was widely used in algorithms for unit-disk graphs [12,27,29,30]. The following lemma has been proved in [26].

▶ **Lemma 8** ([26]).

1. *The set $\mathcal{C}$, along with the subsets $Q(C)$ and $N(C)$ for all cells $C \in \mathcal{C}$, can be computed in $O(n \log n)$ time and $O(n)$ space.*
2. *With $O(n \log n)$ time and $O(n)$ space preprocessing, given any point p in the plane, we can do the following in $O(\log n)$ time: Determine whether p is in a cell C of $\mathcal{C}$, and if yes, return C and the set $N(C)$.*

Note that we do not compute the entire grid Ψ_λ but only compute the information in Lemma 8. We next prove Theorem 3 using the information computed in Lemma 8.

Consider a UDRE query with a query point p. By Lemma 8(2), we can determine whether p is in a cell $C \in \mathcal{C}$. If not, by Observation 7, we are done with the query. Below we assume that p is in a cell $C \in \mathcal{C}$. In this case, $A_p \cap Q \neq \emptyset$ if and only if $A_p \cap Q(C') \neq \emptyset$ for a cell $C' \in N(C)$. As such, as $|N(C)| = O(1)$, it suffices to check for each cell $C' \in N(C)$, whether $A_p \cap Q(C') = \emptyset$. In this way, we reduce our original problem for Q to $Q(C')$. As such, below we construct a data structure $\mathcal{D}_C(C')$ for $Q(C')$ with respect to C. Note that we also need to handle deletions for $Q(C')$. Depending on whether $C' = C$, there are two cases.

If $C' = C$, then all points of $Q(C')$ are in the disk A_p and thus we can return an arbitrary point of $Q(C')$ as the answer to the UDRE query. To support the deletions on $Q(C')$, we build a balanced binary search tree $T(C')$ for all points of $Q(C')$ sorted by their indices (we can arbitrarily assign indices to points of Q) as our data structure $\mathcal{D}_C(C')$. In this way, deleting a point from $\mathcal{D}_C(C')$ can be done in $O(\log n)$ time. Therefore, in the case where $C' = C$, we can perform each UDRE query and each deletion in $O(\log n)$ time.

In what follows, we assume that $C' \neq C$, which is our main focus. In this case, C' and C are separated by an axis-parallel line. Without loss of generality, we assume that they are separated by a horizontal line ℓ such that C' is above ℓ and C is below ℓ. We further assume that ℓ contains the upper edge of C. The rest of this section is organized as follows. In Section 3.1, we first present some observations which our approach is based on. We describe our preprocessing algorithm for $Q(C')$ in Section 3.2 while handling the UDRE queries and deletions is discussed in Section 3.3. Section 3.4 finally summarizes everything. In the following, we let $m = |Q(C')|$.

3.1 Observations

Our basic idea is to maintain the portion $\mathcal{U}$ inside C of the lower envelope of the unit-disks centered at points of $Q(C')$. Then, $A_p \cap Q(C') \neq \emptyset$ if and only if p is above $\mathcal{U}$. Determining whether p is above $\mathcal{U}$ can be easily done by binary search because $\mathcal{U}$ is x-monotone. To handle deletions, we borrow an idea from Hershberger and Suri [17] for maintaining the convex hull of a semi-dynamic (deletion-only) set of points in the plane. To make our approach work, we first present some observations in this subsection.

Recall that A_q denotes a unit-disk centered at point q. We use ∂A_q to denote the boundary of A_q, which is a unit-circle. Let $\xi_q = \partial A_q \cap C$, i.e., the portion of the circle ∂A_q inside C. Note that it is possible that $\xi_q = \emptyset$, in which case either $A_q \cap C = \emptyset$ or $C \subseteq A_q$. If $A_q \cap C = \emptyset$, then $|pq| > \lambda$ holds for all points $p \in C$ and thus q can be ignored from constructing our data structure $\mathcal{D}_C(C')$. If $C \subseteq A_q$, then $|pq| \leq \lambda$ always holds for all points $p \in C$ and thus we can process all such points q in the same way as the above case $C' = C$. As such, in the following we assume that $\xi_q \neq \emptyset$ for every point $q \in Q(C')$. Because the radius of A_q is λ while the side-length of C is $\lambda/\sqrt{2}$, ξ_q consists of at most two arcs of ∂A_q. Further, ξ_q has exactly two arcs only if ∂A_q intersects the lower edge of C. For simplicity of discussion, we remove the lower edge from C and make C a bottom-unbounded rectangle (i.e., C's upper edge does not change, its two vertical edges extend downwards to the infinity, and its lower edge is removed); so now C has three edges. In this way, $\xi_q = \partial A_q \cap C$ is always a single arc.

Since q is above the horizontal line ℓ, which contains the upper edge of C, ξ_q must be x-monotone. This means the lower envelope $\mathcal{U}$ of $\Xi = \{\xi_q \mid q \in Q(C')\}$ is also x-monotone (see Fig. 4). We will show that $\mathcal{U}$ can be computed in linear time by a Graham's scan style algorithm once the arcs of Ξ are ordered in a certain way. To define this special order, we first introduce some notation below.

Recall that the boundary ∂C consists of three edges. Let l^* denote the lower endpoint of the left edge of C at $-\infty$; similarly, let r^* denote the lower endpoint of the right edge of C (see Fig. 4). For any two points a and b on ∂C, we say that a is *left of* b if a is counterclockwise from b around C (i.e., if we traverse from l^* to r^* along ∂C, a will be encountered earlier than b). For each arc ξ_q, if a and b are its two endpoints and a is left of b (see Fig. 4), then we call a the *left endpoint* of ξ_q and b the *right endpoint.* For ease of exposition, we make a general position assumption that no two arcs of Ξ share a common endpoint. The special order mentioned above for the Graham's scan style algorithm is the order of arcs of Ξ by their right endpoints on ∂C, called *right-endpoint left-to-right order.* To justify the correctness, we prove some properties for the lower envelope $\mathcal{U}$ below.

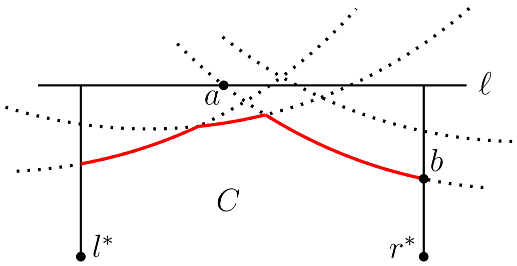

Figure 4 Illustrating the lower envelope (the red curve).

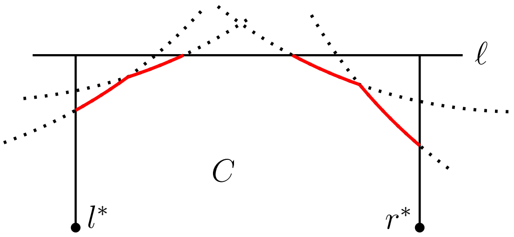

Figure 5 Illustrating a lower envelope (the red curve) that has two connected components.

Suppose we traverse on ∂C from l^* until we meet $\mathcal{U}$, and then we traverse on $\mathcal{U}$ until we come back on ∂C again. We keep traversing. We may meet $\mathcal{U}$ again if $\mathcal{U}$ has multiple connected components (see Fig. 5). We continue in this way until we arrive at r^*. The order of the arcs of Ξ that appear on $\mathcal{U}$ encountered during the above traversal is called the *traversal order* of $\mathcal{U}$. The following is a crucial lemma that our algorithm relies on. The proof can be found in the full paper.

▶ **Lemma 9.** *Every arc of Ξ has at most one portion on $\mathcal{U}$ and the traversal order of $\mathcal{U}$ is consistent with the right-endpoint left-to-right order of Ξ (i.e., if an arc ξ appears in the front of another arc ξ' in the traversal order of $\mathcal{U}$, then the right endpoint of ξ is to the left of that of ξ').*

3.2 Preprocessing

We perform the following preprocessing algorithm for $Q(C')$. Due to Lemma 9, we are able to extend to our problem a technique from Hershberger and Suri [17] for maintaining the convex hull for a semi-dynamic (deletion-only) set of points in the plane (in the dual plane, the problem is to maintain the lower/upper envelope for a semi-dynamic set of lines). Recall that $m = |Q(C')|$.

We first compute the arcs of Ξ and sort them by their right endpoints from left to right on ∂C. Let T be a complete binary tree whose leaves correspond to arcs in the above order. For each node v, let $\Xi(v)$ denote the subset of arcs in the leaves of the subtree of T rooted at v.

For any subset Ξ' of Ξ, let $\mathcal{U}(\Xi')$ denote the lower envelope of the arcs of Ξ'. We use a tree $T(\Xi')$ (which can be considered as a subtree of T) to represent $\mathcal{U}(\Xi')$. Initially, we have the tree $T(\Xi)$, and later $T(\Xi)$ is modified due to point deletions from $Q(C')$ (and correspondingly arc deletions from Ξ). The tree $T(\Xi')$ is defined as follows. For each arc $\xi \in \Xi'$, we copy the leaf of T storing ξ along with all ancestors of the leaf into $T(\Xi')$. If we define $\Xi'(v) = \Xi(v) \cap \Xi'$ for any node v of T, then v is copied into $T(\Xi')$ if and only if $\Xi'(v) \neq \emptyset$. Later we will add some additional node-fields to $T(\Xi')$ to represent the lower envelope $\mathcal{U}(\Xi')$. We call $T(\Xi')$ an *envelope tree.*

We wish to have each node v of $T(\Xi')$ represent the lower envelope $\mathcal{U}(\Xi'(v))$ of arcs of $\Xi'(v)$, i.e., arcs stored in the leaves of the subtree of $T(\Xi')$ rooted at v. We add a node-field $arcs(v)$ for that purpose. Storing the entire lower envelope $\mathcal{U}(\Xi'(v))$ at each $arcs(v)$ of $T(\Xi')$ leads to superlinear total space. To achieve $O(m)$ space, we use the following standard approach (which has been used elsewhere, e.g., [17, 23]): For each arc ξ stored in a leave $v \in T(\Xi')$, ξ is stored only at $arcs(u)$ for the highest ancestor u of v in $T(\Xi')$ such that ξ

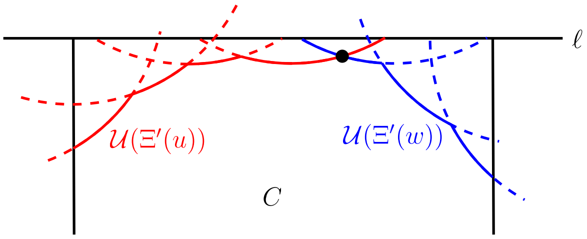

Figure 6 Illustrating Lemma 10: The red (resp., blue) arcs are those from $\Xi'(u)$ (resp., $\Xi'(w)$). There is only one intersection between $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w))$.

contributes an arc in the lower envelope $\mathcal{U}(\Xi'(u))$. Arcs of $arcs(v)$ in each node v of $T(\Xi')$ are stored in a doubly linked list. Note that if v is the root of $T(\Xi')$, then $arcs(v)$ stores the whole lower envelope $\mathcal{U}(\Xi')$ of Ξ'.

The following lemma, which can be easily obtained from Lemma 9, is crucial to the success of our approach. The proof can be found in the full paper.

▶ **Lemma 10.** *For each node $v \in T(\Xi')$, the lower envelopes $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w))$ have at most one intersection, where u and w are the left and right children of v, respectively (see Fig. 6).*

By Lemma 10, we add another node-field $X(v)$ for each node $v \in T(\Xi')$ to store the two arcs that define the intersection of $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w))$, where u and w are the left and right children of v in $T(\Xi')$, respectively. If $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w))$ do not intersect, then $X(v)$ stores the rightmost arc of $\mathcal{U}(\Xi'(u))$ and the leftmost arc of $\mathcal{U}(\Xi'(w))$. As will be seen later in Section 3.3, the two node-fields $X(v)$ and $arcs(v)$ in $T(\Xi')$ allow us to efficiently maintain the envelope tree $T(\Xi')$ subject to deletions of arcs. We next have the following lemma for constructing $T(\Xi)$ initially.

▶ **Lemma 11.** *Given the set Ξ of m arcs, we can build the envelope tree $T(\Xi)$ in $O(m \log m)$ time.*

Proof. First of all, we can construct the tree T in $O(m \log m)$ time by sorting the arcs of Ξ by their right endpoints on ∂C. The rest of the work is thus to compute the fields $arcs(v)$ and $X(v)$ for all nodes v of T. This can be done in a bottom-up manner as follows.

At the outset, we have $arcs(v) = \Xi(v) = \{\xi\}$ for each leaf node $v \in T$, where ξ is the arc stored at v. We also set $X(v)$ to null. Next, we compute $arcs(\cdot)$ and $X(\cdot)$ for other nodes by merging the lower envelopes of their children. Specifically, consider a node v whose left and right children are u and w, respectively. We assume that $arcs(u)$ and $arcs(w)$ store the lower envelopes $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$ in their traversal orders, respectively. The first thing is to compute the lower envelope $\mathcal{U}(\Xi(v))$. By Lemma 10, $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$ have at most one intersection. Since each lower envelope is x-monotone, $\mathcal{U}(\Xi(v))$, which is also the lower envelope of $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$, can be computed by a standard line sweep procedure. Specifically, a vertical sweeping line ℓ' sweeps the plane from left to right. During the sweeping, we maintain the two arcs of $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$ intersecting ℓ', respectively. An event happens if ℓ' hits a vertex of either $\mathcal{U}(\Xi(u))$ or $\mathcal{U}(\Xi(w))$. The sweeping procedure takes $O(|\Xi(v)|)$ time (note that $\Xi(v) = \Xi(u) \cup \Xi(w)$).

- If $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$ do not have any intersection, then $\mathcal{U}(\Xi(v))$ is just the concatenation of $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$, i.e., we concatenate $arcs(u)$ and $arcs(w)$ and store the result at $arcs(v)$; we also need to reset both $arcs(u)$ and $arcs(w)$ to null. In addition, $X(v)$ is set to including the rightmost arc of $\mathcal{U}(\Xi(u))$ and the leftmost arc of $\mathcal{U}(\Xi(w))$.

- If $\mathcal{U}(\Xi(u))$ and $\mathcal{U}(\Xi(w))$ have an intersection, say, a^*, then let $\xi_u \in \mathcal{U}(\Xi(u))$ and $\xi_v \in \mathcal{U}(\Xi(v))$ be the two arcs that intersect at a^*. We concatenate the part of $\mathcal{U}(\Xi(u))$ left to a^* and the part of $\mathcal{U}(\Xi(w))$ right to a^* (ξ_u and ξ_w are cut off at a^*); the result is $\mathcal{U}(\Xi(v))$ and we store it into $arcs(v)$. Further, arcs left to a^* (including ξ_u) in $\mathcal{U}(\Xi(u))$ and arcs right to a^* (including ξ_w) in $\mathcal{U}(\Xi(w))$ are removed from $arcs(u)$ and $arcs(w)$, respectively. In addition, $X(v)$ is set to $\{\xi_u, \xi_w\}$.

As such, computing the node-fields of v takes $O(|\Xi(v)|)$ time. Doing this for all nodes v in the same level of the tree takes $O(m)$ time as the union of $\Xi(v)$ of all nodes v in the same level is exactly Ξ. Therefore, the construction of the envelope tree $T(\Xi)$ can be done in $O(m \log m)$ time in total. ◀

The above finishes our preprocessing for the points $Q(C')$, which takes $O(m \log m)$ time and $O(m)$ space. Our preprocessing builds the envelope tree $T(\Xi)$, which is our data structure $\mathcal{D}_C(C')$. Once points from $Q(C')$ are deleted we use Ξ' to refer to the subset of Ξ defined by the remaining points and use $T(\Xi')$ to refer to the corresponding envelope tree.

3.3 Handling UDRE queries and point deletions

We now discuss how to handle the UDRE queries and point deletions.

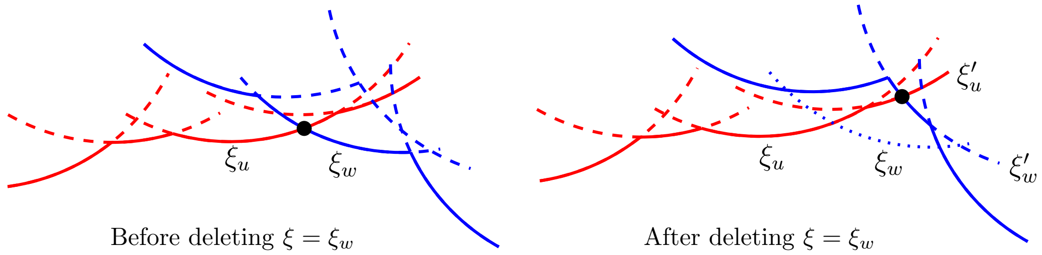
UDRE queries. Handling the UDRE queries is relatively easy. Consider a query point p in the cell C. We wish to determine whether $A_p \cap Q(C') = \emptyset$, and if not, return a point $q \in A_p \cap Q(C')$. Let Ξ' be the set of arcs defined by the points in the current set $Q(C')$. As discussed before, it suffices to determine whether p is above the lower envelope $\mathcal{U}(\Xi')$. To this end, since $\mathcal{U}(\Xi')$ is x-monotone, let a and b be the two adjacent vertices of $\mathcal{U}(\Xi')$ such that p's x-coordinate is between those of a and b. Let ξ_q be the arc that contains the portion of $\mathcal{U}(\Xi')$ between a and b, where q is the center of the arc (and thus $q \in Q(C')$). As such, p is above $\mathcal{U}(\Xi')$ if and only if p is above ξ_q (i.e., p is inside the unit-disk A_q). If yes, then $q \in A_p \cap Q(C')$ and thus we can return q as the answer to the query. Therefore, it suffices to compute the arc ξ_q. To this end, one may attempt to perform binary search on the vertices of $\mathcal{U}(\Xi')$ to find a and b first. However, although the whole $\mathcal{U}(\Xi')$ is stored in $arcs(v)$ at the root v, arcs of $arcs(v)$ are stored in a doubly linked list, which does not support binary search. To circumvent the issue, we can actually perform binary search using the node-fields $X(\cdot)$ of $T(\Xi')$ as follows.

Observe that each vertex of $\mathcal{U}(\Xi')$ appears as the intersection of the two arcs of $X(v)$ for some node $v \in T(\Xi')$. The subtree of $T(\Xi')$ rooted at any node v represents $\mathcal{U}(\Xi'(v))$ by the intersections of the arcs of $X(\cdot)$ stored at its nodes. To find ξ_q, starting from the root, for each node v of $T(\Xi')$, we compute the intersection a^* of the arcs of $X(v)$. If the x-coordinate of p is smaller or equal to that of a^*, we proceed on the left subtree of v recursively; otherwise, we proceed on the right subtree. At the end we will reach a leaf and the arc stored at the leaf is ξ_q. As such, ξ_q can be found in $O(\log m)$ time.

Therefore, each UDRE query can be answered in $O(\log m)$ time.

Deletions. Next, we discuss point deletions. To delete a point q from $Q(C')$, it boils down to deleting the arc ξ_q defined by q from the envelope tree $T(\Xi')$. The next lemma provides an algorithm for this.

▶ **Lemma 12.** *Deleting an arc from the envelope tree $T(\Xi')$ can be done in $O(\log m)$ amortized time.*



Before deleting $\xi = \xi_w$

After deleting $\xi = \xi_w$

Figure 7 Illustrating the deletion of $\xi = \xi_w$. The red (resp., blue) arcs are those from $\Xi'(u)$ (resp., $\Xi'(w)$).

Proof. Let ξ be the arc we wish to delete from $T(\Xi')$ and let z be the leaf node of the tree storing ξ. To delete ξ, we need to update $arcs(\cdot)$ and $X(\cdot)$ for all ancestors of z.

The algorithm is recursive. Starting from the root, for each node v, we process it by calling Delete(ξ, v) as follows. We assume that $arcs(v)$ now stores the whole lower envelope $\mathcal{U}(\Xi'(v))$, which is true initially when v is the root. Let u and w denote the left and right children of v, respectively. We assume that the leaf z is in the right subtree of v since the other case is symmetric. Let $X(v) = \{\xi_u, \xi_w\}$, with $\xi_u \in \mathcal{U}(\Xi'(u))$ and $\xi_w \in \mathcal{U}(\Xi'(w))$, i.e., the intersection of ξ_u and ξ_w, denoted by a^*, is the intersection between $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w))$. We first restore $\mathcal{U}(\Xi'(u))$, by concatenating the part of $arcs(v)$ left to a^* and $arcs(u)$. Restoring $\mathcal{U}(\Xi'(w))$ can be done in a similar way. Depending on whether $w = z$, there are two cases.

If w is the leaf z (which is the base case of our recursive algorithm), then $arcs(w) = \{\xi\}$ and we reset the right child of v and field $X(v)$ to null. We also reset $arcs(v) = arcs(u)$ and $arcs(u) = null$.

If w is not z, then to update $arcs(v)$ and $X(v)$, observe that if $\xi \notin X(v)$, then deleting ξ does not affect the intersection between $\mathcal{U}(\Xi'(u))$ and the new lower envelope $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$, i.e., $X(v)$ does not change. Hence, if $\xi \notin X(v)$, we proceed on w by calling Delete(ξ, w). After Delete(ξ, w) is returned, the new $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ is stored in $arcs(w)$ and we cut $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ using $X(v)$ to obtain $arcs(v)$ in the same way as the tree construction algorithm in Lemma 11, which takes $O(1)$ time as each $arcs(\cdot)$ is stored by a doubly linked list. In the following, we discuss the case where $\xi \in X(v) = \{\xi_u, \xi_w\}$.

Since ξ is in the right subtree of v, ξ must be ξ_w. In this case, $X(v)$ will be changed after the deletion of ξ and thus we need to compute the new arcs that define the intersection of $\mathcal{U}(\Xi'(u))$ and the new lower envelope $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ (see Fig. 7). We proceed on w by calling Delete(ξ, w). After Delete(ξ, w) is returned, the new $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ is stored in $arcs(w)$. Let $\{\xi'_u, \xi'_w\}$ be the new $X(v)$ to be computed, with ξ'_v and ξ'_w in $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$, respectively. Observe that ξ'_u cannot lie to the left of ξ_u in $arcs(u)$ while ξ'_w must lie on the part of the new $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ between the two old neighbors of ξ (=ξ_w) on $\mathcal{U}(\Xi'(w))$ (see Fig. 7). As such, we compute ξ'_u and ξ'_w using a line sweep procedure that is similar to the algorithm in Lemma 11, but to make the algorithm faster, due to the above observation it suffices to start the sweeping line from the left of the following two arcs: ξ_u and the left neighbor of ξ in the original lower envelope $\mathcal{U}(\Xi'(w))$. We stop the sweeping once the intersection of $\mathcal{U}(\Xi'(u))$ and $\mathcal{U}(\Xi'(w) \setminus \{\xi\})$ is found, after which, we reset $arcs(v)$ as well as $arcs(u)$ and $arcs(w)$ in constant time in a way similar to the algorithm in Lemma 11.

The pseudocode summarizing the algorithm can be found in the full paper.

For the time analysis, the time we spend on each node v is $O(1)$ except the line sweep procedure for computing ξ'_u and ξ'_w in the case where $\xi \in X(v)$. The procedure takes time $O(1 + k_u + k_w)$, where k_u is the number of arcs between ξ_u and ξ'_u in $\mathcal{U}(\Xi'(u))$ and k_w is the number of arcs between ξ_w and ξ'_w in $\mathcal{U}(\Xi'(w))$. Observe that the arcs between ξ_u and ξ'_u in $\mathcal{U}(\Xi'(u))$ are moved up from node u to node v after the deletion of ξ (i.e., they were originally stored at $arcs(u)$ but are stored at $arcs(v)$ after the deletion). Similarly, the arcs between ξ_w and ξ'_w in $\mathcal{U}(\Xi'(w))$ are moved up to w from some lower levels after the deletion (see Fig. 7). Because each arc can be moved up at most $O(\log m)$ times for all m point deletions of $Q(C')$, the total sum of $k_u + k_w$ for all deletions is bounded by $O(m \log m)$. As such, each deletion takes $O(\log m)$ amortized time. ◀

3.4 Putting everything together

The above shows that we can build a data structure $\mathcal{D}_C(C')$ for the points of $Q(C')$ with respect to C in $O(m \log m)$ time and $O(m)$ space, such that each UDRE query with a query point in C can be answered in $O(\log m)$ time and deleting a point from $Q(C')$ can be handled in $O(\log m)$ amortized time.

To solve our original problem on Q, i.e., proving Theorem 3, for each cell $C \in \mathcal{C}$, we build data structures $\mathcal{D}_C(C')$ for all cells $C' \in N(C)$. Because $|N(C)| = O(1)$ for every $C \in \mathcal{C}$ and each cell C' is in $N(C)$ for a constant number of cells $C \in \mathcal{C}$, the total space for all these data structures $\mathcal{D}_C(C')$ is $O(n)$ and the total preprocessing time is $O(n \log n)$.

For each UDRE query with a query point p, we first use Lemma 8(2) to determine whether p is in a cell of $\mathcal{C}$. If not, then by Observation 7, $A_p \cap Q = \emptyset$ and thus we are done with the query. Otherwise, Lemma 8(2) will return the cell C that contains p as well as $N(C)$. Then, for each $C' \in N(C)$, we solve the query using the data structure $\mathcal{D}_C(C')$. The total query time is $O(\log n)$ as $|N(C)| = O(1)$.

To delete a point q from Q, using Lemma 8(2) we first find the cell C' that contains q as well as $N(C')$. Notice that $N(C')$ exactly consists of those cells C with $C' \in N(C)$. We then delete q from the data structure $\mathcal{D}_C(C')$ for each $C \in N(C')$. As $|N(C')| = O(1)$, the total deletion time is $O(\log n)$ amortized time. This proves Theorem 3.

4 Conclusion

In this paper, we presented an $O(n^{4/3} \log^3 n)$ time algorithm for computing a Euclidean minimum bottleneck moving spanning tree for a set of n moving points in the plane, which significantly improves the previous $O(n^2)$ time solution [2]. To solve the problem, we first solved the decision problem in $O(n^{4/3} \log^2 n)$ time. This is done by reducing it to the problem of computing a common spanning tree in two unit-disk graphs. To avoid computing the unit-disk graphs explicitly, which would cost $\Omega(n^2)$ time, we used a batched range searching technique [19] to obtain a compact representation for searching one graph, and derived a semi-dynamic (deletion-only) unit-disk range emptiness query data structure for searching the other graph. We believe our data structure is interesting in its own right and will certainly find applications elsewhere. We finally remark that although in our problem each moving point is required to move linearly with constant velocity, our algorithm still works for other types of point movements as long as Observation 1 holds.

Abstract

The Traveling Tournament Problem (TTP) is a well-known benchmark problem in the field of tournament timetabling, which asks us to design a double round-robin schedule such that each pair of teams plays one game in each other's home venue, minimizing the total distance traveled by all n teams (n is even). TTP-k is the problem with one more constraint that each team can have at most k consecutive home games or away games. The case where $k = 3$, TTP-3, is one of the most investigated cases. In this paper, we improve the approximation ratio of TTP-3 from $(1.667 + \varepsilon)$ to $(1.598 + \varepsilon)$, for any $\varepsilon > 0$. Previous schedules were constructed based on a Hamiltonian cycle of the graph. We propose a novel construction based on triangle packing. Then, by combining our triangle packing schedule with the Hamiltonian cycle schedule, we obtain the improved approximation ratio. The idea of our construction can also be extended to $k \geq 4$. We demonstrate that the approximation ratio of TTP-4 can be improved from $(1.750+\varepsilon)$ to $(1.700+\varepsilon)$ by the same method. As an additional product, we also improve the approximation ratio of LDTTP-3 (TTP-3 where all teams are allocated on a straight line) from $4/3$ to $(6/5 + \varepsilon)$.

1 Introduction

In the field of the tournament schedule, the traveling tournament problem (TTP) is a widely known benchmark problem that was first systematically introduced in [10]. This problem aims to find a double round-robin tournament satisfying some constraints, minimizing the total distance traveled by all participant teams. In a double round-robin tournament of n teams, each team will play 2 games against each of the other $n - 1$ teams, one at its home venue and one at its opponent's home venue. Additionally, each team should play one game a day, all games need to be scheduled on $2(n - 1)$ consecutive days, and so there are exactly $n/2$ games on each day. According to the definition, we know that n is always even. For TTP, we have the following two basic constraints or assumptions on the double round-robin tournament.

Traveling Tournament Problem (TTP).

- *No-repeat*: Two teams cannot play against each other on two consecutive days.
- *Direct-traveling*: Before the first game, all teams are at home, and they will return home after the last game. Furthermore, a team travels directly from its game venue on ith day to its game venue on $(i+1)$th day.

TTP-k, a well-known variant of TTP, is to add the following constraint on the maximum number of consecutive home games and away games.

- *Bounded-by-k*: Each team can have at most k consecutive home games or away games.

The smaller the value of k, the more frequently a team has to return home. By contrast, if k is very large, say $k = n - 1$, then this constraint loses meaning, and TTP-k becomes TTP where a team can schedule their travel distance as short as that in the traveling salesman problem (TSP).

A weight function w on the complete undirected graph is called a *metric* if it satisfies the symmetry and triangle inequality properties: $w(a,b) = w(b,a)$ and $w(a,c) \leq w(a,b) + w(b,c)$ for all $a,b,c \in V$.

The input of TTP-k contains a complete graph where each vertex is a team, and the weight between two vertices u and v is the distance from the home of team u to the home of team v. In this paper, we only consider the case when the weight function w is a metric. Due to page limitations, the proofs of some lemmas and theorems marked with '*' may be omitted or incomplete. The full proofs can be found in the full version of this paper.

1.1 Related Work

TTP and TTP-k are difficult optimization problems. The NP-hardness of TTP and TTP-k with $k \geq 3$ has been established [2, 24, 5]. Although the hardness of TTP-2 is still not formally proved, it is believed that TTP-2 is also hard since it is also not easy to construct a feasible solution to it. In the literature there is a large number of contributions on approximation algorithms [25, 28, 31, 30, 6, 21, 29, 18, 27, 16, 17] and heuristic algorithms [11, 20, 1, 9, 13, 14].

For heuristic algorithms, most known works are concerned with the case of $k = 3$. Since the search spaces of TTP and TTP-k are usually very large, many instances of TTP-3 with more than 10 teams in the online benchmark [26, 3] have not been completely solved even by using high-performance machines.

In terms of approximation algorithms, most results are based on the assumption that the distance holds the symmetry and triangle inequality properties. This is natural and practical in the sports schedule. For $k = 2$, one significant contribution to TTP-2 was done by Thielen and Westphal [25]. They proposed a $(1 + 16/n)$-approximation algorithm for $n/2$ being even and a $(3/2 + O(1/n))$-approximation algorithm for $n/2$ being odd. Currently, approximation ratios for these two cases have been improved to $(1 + 3/n)$ and $(1 + 12/n)$, respectively [30, 31]. For $k = 3$, the first approximation algorithm, proposed by Miyashiro *et al.*, admits a $2 + O(1/n)$ approximation ratio using the Modified Circle Method [21]. Then, the approximation ratio was improved to $5/3 + O(1/n)$ by Yamaguchi *et al.* [29]. Their approximation algorithm also works for $3 < k \ll n$. For $k = 4$, the ratio is $1.750 + O(1/n)$ and for $4 < k \ll n$, the ratio is $(5k - 7)/(2k) + O(k/n)$ [29]. For $k = \Theta(n)$, Westphal and Noparlik proposed a 5.875 approximation algorithm for any choice of $k \geq 4$ and $n \geq 6$ [27], and Imahori *et al.* gave a 2.75 approximation algorithm for $k = n - 1$ where they also proved the approximation ratio can be further improved to 2.25 if the optimal TSP is given [18]. The current best approximation ratio for $k = 3$ is still $5/3 + O(1/n)$ [29].

We refer the readers to [3] for more variants of TTP (including the traveling tournament problem with predefined venues, the time-relaxed traveling tournament problem, etc.) with detailed benchmarks for each.

1.2 Our Results

In this paper, we consider TTP-k with the cases of $k = 3$ and $k = 4$. Our contributions can be summarized as follows.

We mainly focus on TTP-3. Firstly, we analyze the structural properties in more detail, which leads us to strengthen some of the current-known lower bounds and propose several new ones. Secondly, we design an approximation algorithm that improves the approximation ratio from $(5/3 + \varepsilon)$ to $(139/87 + \varepsilon)$. Our algorithm consists of two constructions. The first construction is based on the Hamiltonian cycle, which is a well-known method. The Hamiltonian cycle used is commonly generated by the Christofides-Serdyukov algorithm, while we propose a new Hamiltonian cycle that uses the minimum weight perfect matching. The second construction proposed by us is based on triangle packing which can be seen as a generalization of the matching packing schedule in TTP-2.

For a special case of TTP-3 where all teams are located on a line, Linear Distance TTP-3 (LDTTP-3), we prove that the approximation ratio of our triangle packing construction can achieve $(6/5 + \varepsilon)$, which improves the previous approximation ratio of $4/3$ [15].

Finally, we extend our method to TTP-4 and show that we can improve the approximation ratio from $(7/4 + \varepsilon)$ to $(17/10 + \varepsilon)$.

2 Preliminaries

We will always use n to denote the total number of teams in the problem. The set of n teams is denoted by $V = \{t_1, t_2, \dots, t_n\}$. Recall that n is even. For TTP-3, there are three cases of n we consider: $n \equiv 0 \pmod 6$, $n \equiv 2 \pmod 6$ and $n \equiv 4 \pmod 6$. Due to the different structural properties, these three cases have to be handled separately. We mainly describe the case of $n \equiv 0 \pmod 6$ due to page limitations. So from here on, we assume that n is a number divisible by 6.

We use $G = (V, E)$ to denote the complete graph on the n vertices representing the n teams. There is a positive weight function $w : E \to \mathbb{R}_{\geq 0}$ on the edges of G. We often write $w(u, v)$ to mean the weight of the edge uv, instead of $w(uv)$. Note that $w(u, v)$ would be the same as the distance between the home of team u and the home of team v. For any weight function $w : X \to \mathbb{R}_{\geq 0}$, we extend it to subsets of X. Define $w(Y) = \sum_{x \in Y} w(x)$ for $Y \subseteq X$.

The weight of a minimum weight spanning tree in G is denoted by $\mathrm{MST}(G)$. We use $\delta(u)$ to denote the set of edges incident on u in G. We also use $\deg(u)$ to denote the weighted degree of a vertex. That is the total weight of all edges incident on u in G, i.e., $\deg(u) = w(\delta(u))$. We also let Δ to be the sum of the weighted degrees, i.e., $\Delta = \sum_{u \in V} \deg(u) = 2w(E)$.

A cycle on k vertices is called a k-cycle. A triangle uvw is a 3-cycle on three different vertices $\{u, v, w\}$. Two subgraphs or sets of edges are *vertex-disjoint* if they do not share a common vertex. A *triangle packing* in G, denoted by T, is a set of edges such that each component is a triangle, and all vertices are covered. Equivalently, it can be seen as the edges of m vertex-disjoint triangles. Similarly, a P_3 *path* is a simple path on three different vertices $\{u, v, w\}$, which can be represented by u-v-w. A P_3 *path packing* in G is a set of edges such that every component is a P_3 path, and each vertex is covered. We can obtain a triangle packing from a P_3 packing by connecting the two non-adjacent vertices in each component.

Let $m = \frac{n}{3}$, and then m is an even number. For a fixed triangle packing T of G, let the components be $u_1, \dots, u_m$. $U = \{u_1, \dots, u_m\}$ is a partition of V. Each $u \in U$ is referred as a *super-team*. We define a complete graph $H = (U, F)$ on U. We will also have a cost function $c(u, v)$ defined on vertices in U. It is $c(u, v) = \sum_{u' \in u, v' \in v} w(u', v')$ for each edge $uv \in F$. For simplicity we also define $c(u, u) = 0$. Despite not using this property, it is worth noting that the cost function c is also a metric.

We also define $c(u)$ for $u \in U$ to be the same as $w(a, b) + w(b, c) + w(c, a)$ for $a, b, c \in u$. Note that $c(U) = \sum_{u \in U} c(u) = w(T)$. We can easily get

$$\frac{1}{2}\Delta = w(E) = c(F) + c(U) = c(F) + w(T). \tag{1}$$

The remaining parts of the paper are organized as follows. In Section 3, we focus on TTP-3. Specifically, in Section 3.1, we introduce some basic notations and propose several new lower bounds. In Section 3.2, we give a brief introduction to the well-known construction based on the Hamiltonian cycle. In Section 3.3, we propose a novel construction based on triangle packing. Although these two constructions cannot make any improvement separately, in Section 3.4, we show that together they can guarantee an improved approximation ratio for TTP-3. In Section 4, we analyze the approximation ratio of our algorithm for LDTTP-3. In Section 5, we extend our methods and prove that we can also improve the approximation ratio for TTP-4.

3 TTP-3

3.1 The Independent Lower Bounds

For TTP and TTP-k, a well-known method to obtain the lower bounds is to use an independent relaxation [4, 10]. The basic idea is to obtain a lower bound on the traveling distance of each team independently without considering the feasibility of other teams and then sum them together. Although there exist many independent lower bounds for TTP-3 [21, 29, 27], we can not use them directly to get our result. We are interested in a stronger bound. Before we make some observations on the independent lower bounds, we first need to explore some properties of TTP-k.

For TTP-k, each team needs to visit each other team's home once in the tournament. A *road trip* of a team v is a simple cycle starting and ending at v. A *k-itinerary* of v, is a connected subgraph of G that consists of road trips with each simple cycle of length at most $k+1$, and each vertex other than v in V has degree 2.

For TTP-3, the length of each road trip is at most 4. For simplicity, we omit k when k is implicit. In the remainder of this section, $k = 3$.

An itinerary is *optimal* for a team if it is the itinerary of minimum weight.

Considering an optimal itinerary I_v for team v, we will use $w(I_v)$ to denote the weight of the optimal itinerary for team v. Then, $\psi = \sum_{v \in V} w(I_v)$ is a simple independent lower bound for the minimum weight solution of TTP-3. Note that this lower bound was also used in the experiment [10]. However, it is NP-hard to compute $w(I_v)$. Hence, we want to find an alternative lower bound for each team's optimal itinerary.

When $n \equiv 0 \pmod 6$ and $n \equiv 4 \pmod 6$, we can prove that there always exists an optimal itinerary with no 2-cycles.

▶ **Lemma 1.** *For TTP-3 with the cases of* $n \equiv 0 \pmod 3$ *and* $n \equiv 1 \pmod 3$*, there exists an optimal itinerary with no 2-cycles for each team.*

Proof. Consider an optimal itinerary I_v of team v with the minimum number of 2-cycles. Assume I_v contains a 2-cycle. Since all cycles share the vertex v, by the triangle inequality, we can get a 3-cycle by shortcutting two 2-cycles, and the 3-cycle has a weight no greater than the sum weight of the two 2-cycles. This shows that I_v contains exactly one 2-cycle. Similarly, by the triangle inequality, a 4-cycle can be obtained by shortcutting one 2-cycle and one 3-cycle without increasing the total weight. This shows there cannot be any 3-cycle. Thus, there exists only one 2-cycle, and the rest of the cycles are all 4-cycles. Thus, we will get $n \equiv 2 \pmod 3$, a contradiction to $n \equiv 0 \pmod 3$ or $n \equiv 1 \pmod 3$. ◀

3.1.1 Bounds on optimal itinerary

For this subsection, we fix a single team v and start to consider the optimal itinerary I_v for this team. We will write I as I_v to simplify the notation within this subsection. We will give a more refined analysis than previous results [29].

Recall that we consider the case of $n \equiv 0 \pmod 6$ here. By Lemma 1, there exists an optimal itinerary I with no 2-cycles, and it consists of a set of 4-cycles and a set of 3-cycles. Hence we will partition I into two sets of edges I_3 and I_4, where I_3 consists of all 3-cycles and I_4 consists of all 4-cycles. Define $0 \leq \gamma \leq 1$, such that $w(I_4) = \gamma w(I)$, and so $w(I_3) = (1-\gamma)w(I)$. Hence γ measures the proportion of weights of the 4-cycles compared to the entire itinerary. The edges in G incident to v in I are called *home-edges*, which is the same as $\delta(v) \cap I$. Let a and b be the proportion of weights of the home-edges in I_4 and I_3, respectively. Namely, $aw(I_4) = w(I_4 \cap \delta(v))$ is the weight of all home-edges in I_4, and $bw(I_3) = w(I_3 \cap \delta(v))$ is the weight of all home-edges in I_3.

Now, we are ready to give some stronger bounds for the optimal itinerary.

▶ **Lemma 2.** *Let C be a minimum weight Hamiltonian cycle in G. Then $w(I) \geq w(C)$.*

Proof. According to the definition of the itinerary, we know that each vertex in I has an even degree. Then, we can get an Euler tour in I and obtain a Hamiltonian cycle in graph G by shortcutting I. Hence $w(I) \geq w(C)$. ◀

We also recall the following result.

▶ **Lemma 3** ([7, 23]). *For a graph G, let C be a minimum weight Hamiltonian cycle, and C' be a Hamiltonian cycle obtained by the Christofides-Serdyukov algorithm. Then $w(C') \leq MST(G) + \frac{1}{2}w(C)$.*

For ease of proofs in the rest of the section, we also define V_3 and V_4 that partition the vertices in $V \setminus \{v\}$, where V_3 consists of all vertices in I_3 except v, and V_4 consists of all vertices in I_4 except v. Our results are mostly simple counting arguments.

▶ **Lemma 4.** $(1 - \frac{1}{2}\gamma + a\gamma)w(I) \geq (\frac{1}{2} + a)\gamma w(I) + b(1-\gamma)w(I) \geq \deg(v)$.

Proof. By the definition of b, we have $b \leq 1$. So, we have $(1 - \frac{1}{2}\gamma + a\gamma)w(I) = (\frac{1}{2} + a)\gamma w(I) + (1-\gamma)w(I) \geq (\frac{1}{2} + a)\gamma w(I) + b(1-\gamma)w(I)$. The left inequality holds. Now we show the right inequality.

First, one can see $\deg(v) = \sum_{u \in V_3} w(u,v) + \sum_{u \in V_4} w(u,v)$.

Next, recall that $b(1-\gamma)w(I) = w(I_3 \cap \delta(v))$ is the total weight of all home-edges in 3-cycles. Thus, we have $\sum_{u \in V_3} w(u,v) = b(1-\gamma)w(I)$. Similarly $a\gamma w(I) = w(I_4 \cap \delta(v))$.

For any 4-cycle $vv_1v_2v_3$ in I_4, we note that the edges v_1v and v_3v are home-edges which can be counted by $w(I_4 \cap \delta(v))$, but the edge v_2v is not a home-edge. By the triangle inequality, we know that $w(v,v_2) \leq \frac{1}{2}(w(v,v_1) + w(v_1,v_2) + w(v_2,v_3) + w(v_3,v))$. Therefore, the weight of the uncounted edge is at most half that of the 4-cycle.

Thus, we have $(\frac{1}{2}+a)\gamma w(I) \geq \sum_{u\in V_4} w(u,v)$. Then, we have $(\frac{1}{2}+a)\gamma w(I)+b(1-\gamma)w(I) \geq \sum_{u\in V_3} w(u,v) + \sum_{u\in V_4} w(u,v) = \deg(v)$. ◀

▶ **Lemma 5.** $(1-\frac{1}{2}a)\gamma w(I) + (1-\frac{1}{2}b)(1-\gamma)w(I) \geq MST(G)$.

Proof. In the optimal itinerary of v, we note that the total weight of all home-edges is $a\gamma w(I) + b(1-\gamma)w(I)$. For each cycle, there are exactly two home-edges. We can delete the longer edge from each cycle from I, and we can get a spanning tree with the total weight less than $(1-\frac{1}{2}a)\gamma w(I) + (1-\frac{1}{2}b)(1-\gamma)w(I)$. Since the weight of a minimum spanning tree is $\mathrm{MST}(G)$, we have that $(1-\frac{1}{2}a)\gamma w(I) + (1-\frac{1}{2}b)(1-\gamma)w(I) \geq \mathrm{MST}(G)$. ◀

Note that our bounds in Lemmas 4 and 5 are stronger than that in [29]. Next, we will propose two new lower bounds on minimum weight matching and triangle packing.

▶ **Lemma 6.** *Let M be a minimum weight perfect matching in G. Then $\frac{1}{2}\gamma w(I) + (1-b)(1-\gamma)w(I) \geq w(M)$.*

Proof. We note that the number of vertices in V_3 is even but odd in V_4. Since any pair of 3-cycles only share one common vertex v, after we delete both of home-edges for each 3-cycle, we can get a perfect matching M_1 in graph $G[V_3]$ with a total weight of $(1-b)(1-\gamma)w(I)$.

Then, by a similar argument with the proof of Lemma 2, we know that $\gamma w(I) = w(I_4)$, is greater than the weight of the minimum weight Hamiltonian cycle in graph $G[V_4 \cup \{v\}]$. Since the number of vertices in this graph is even, any Hamiltonian cycle in this graph can be decomposed into two perfect matching. Thus, we can get a perfect matching M_2 in this graph with a total weight less than $\frac{1}{2}\gamma w(I)$. Therefore, $M_1 \cup M_2$ is a perfect matching, and $w(M) \leq w(M_1 \cup M_2) \leq \frac{1}{2}\gamma w(I) + (1-b)(1-\gamma)w(I)$. ◀

▶ **Lemma 7.** *For a graph G, let P^* be a minimum weight P_3 packing, and T^* be a minimum weight triangle packing. Then $(\frac{2}{3}+\frac{1}{3}\gamma-a\gamma)w(I) = (1-a)\gamma w(I) + \frac{2}{3}(1-\gamma)w(I) \geq w(P^*) \geq \frac{1}{2}w(T^*)$.*

Proof. First, we show $w(P^*) \geq \frac{1}{2}w(T^*)$. Let T' be the triangle packing obtained by completing the P_3 packing. For any P_3 path in P^*, saying uvw, we obtain $w(u,v)+w(v,w) \geq w(u,w)$ by the triangle inequality. This shows $2w(P^*) \geq w(T') \geq w(T^*)$, and we are done.

We note that the number of vertices is divisible by 3 in V_4 but not in V_3. Since any pair of 4-cycles only share one common vertex v, after we delete both of home-edges for each 4-cycle, we can get a P_3 path packing P' in graph $G[V_4]$ such that $w(P') = (1-a)\gamma w(I)$.

Then, by a similar argument with the proof of Lemma 2, we know that $(1-\gamma)w(I) = w(I_3) \geq w(C)$ where C is the minimum weight Hamiltonian cycle in graph $G[V_3 \cup \{v\}]$. Since the number of vertices in this graph equals n minus the number of vertices in V_4, which is divisible by 3, we can delete some edges in C to get a vertex disjoint P_3 path packing P'' such that $w(P'') \leq \frac{2}{3}w(C)$. $P' \cup P''$ is a P_3 packing in $G[V]$. Thus, we have that $(1-a)\gamma w(I) + \frac{2}{3}(1-\gamma)w(I) \geq w(P' \cup P'') \geq w(P^*)$. ◀

3.1.2 Independent lower bounds

Now, we are ready for the independent lower bounds, which are found by summing the individual optimal itineraries. Note that the notations I, I_3, I_4, V_3, V_4, γ, a and b in the previous subsection refer to I_v, $I_{v,3}$, $I_{v,4}$, $V_{v,3}$, $V_{v,4}$, γ_v, a_v and b_v. We omitted the subscripts for the simplification.

For each team v, I_v is the optimal itinerary of v. Recall that $\psi = \sum_{v\in V} w(I_v)$. $I_{v,3}$ and $I_{v,4}$ consist of all 3-cycles and all 4-cycles of I_v, respectively.

Define γ, a and b so that $\gamma\psi = \sum_{v\in V} w(I_{v,4}) = \sum_{v\in V} \gamma_v w(I_v)$, $a\gamma\psi = \sum_{v\in V} w(\delta(v) \cap I_{v,4}) = \sum_{v\in V} a_v\gamma_v w(I_v)$, and $b(1-\gamma)\psi = \sum_{v\in V} w(\delta(v) \cap I_{v,3}) = \sum_{v\in V} b_v(1-\gamma_v)w(I_v)$ hold. Then, we have $0 \leq \gamma, a, b \leq 1$.

The lemmas we proved previously can be summed together to obtain different independent lower bounds.

▶ **Lemma 8.** *Let C be a minimum weight Hamiltonian cycle in G. Then $\psi \geq nw(C)$.*

Proof. Recall that $\psi = \sum_{v\in V} \psi_v$. By Lemma 2, we have that $\psi = \sum_{v\in V} w(I_v) \geq nw(C)$. ◀

▶ **Lemma 9.** $(1 - \frac{1}{2}\gamma + a\gamma)\psi \geq (\frac{1}{2} + a)\gamma\psi + b(1-\gamma)\psi \geq \Delta$.

Proof. By the definitions of γ, a and b, we know that $(1 - \frac{1}{2}\gamma + a\gamma)\psi = \sum_{v\in V}(1 - \frac{1}{2}\gamma_v + a_v\gamma_v)w(I_v)$ and $(\frac{1}{2} + a)\gamma\psi + b(1-\gamma)\psi = \sum_{v\in V}((\frac{1}{2} + a_v)\gamma_v w(I_v) + b_v(1-\gamma_v)w(I_v))$.

Recall that $\Delta = \sum_{v\in V} \deg(v)$. By Lemma 4, it holds that $\sum_{v\in V}(1 - \frac{1}{2}\gamma_v + a_v\gamma_v)w(I_v) \geq \sum_{v\in V}((\frac{1}{2} + a_v)\gamma_v w(I_v) + b_v(1-\gamma_v)w(I_v)) \geq \sum_{v\in V} \deg(v) = \Delta$. Therefore, we have that $(1 - \frac{1}{2}\gamma + a\gamma)\psi \geq (\frac{1}{2} + a)\gamma\psi + b(1-\gamma)\psi \geq \Delta$. ◀

We note that $(1 - \frac{1}{2}\gamma + a\gamma) \leq \frac{3}{2}$. Thus, we have that $\Delta = O(1)\psi$.

▶ **Lemma 10.** $(1 - \frac{1}{2}a)\gamma\psi + (1 - \frac{1}{2}b)(1-\gamma)\psi \geq nMST(G)$.

Proof. Note that $(1 - \frac{1}{2}a)\gamma\psi + (1 - \frac{1}{2}b)(1-\gamma)\psi = \sum_{v\in V}((1 - \frac{1}{2}a_v)\gamma_v w(I_v) + (1 - \frac{1}{2}b_v)(1-\gamma_v)w(I_v))$.

By Lemma 5, we know that $(1 - \frac{1}{2}a)\gamma\psi + (1 - \frac{1}{2}b)(1-\gamma)\psi = \sum_{v\in V}((1 - \frac{1}{2}a_v)\gamma_v w(I_v) + (1 - \frac{1}{2}b_v)(1-\gamma_v)w(I_v)) \geq n\mathrm{MST}(G)$. ◀

By Lemmas 9 and 10, we have that

$$(1 + \tfrac{1}{4}\gamma)\psi \geq \tfrac{1}{2}\Delta + n\mathrm{MST}(G). \tag{2}$$

▶ **Lemma 11.** *Let M be a minimum weight perfect matching in G. Then $\frac{1}{2}\gamma\psi + (1-b)(1-\gamma)\psi \geq nw(M)$.*

Proof. Note that $\frac{1}{2}\gamma\psi + (1-b)(1-\gamma)\psi = \sum_{v\in V}(\frac{1}{2}\gamma_v w(I_v) + (1-b_v)(1-\gamma_v)w(I_v))$.

By Lemma 6, we know that $\frac{1}{2}\gamma\psi + (1-b)(1-\gamma)\psi = \sum_{v\in V}(\frac{1}{2}\gamma_v w(I_v) + (1-b_v)(1-\gamma_v)w(I_v)) \geq nw(M)$. ◀

By Lemmas 9 and 11, we have that

$$(1 + a\gamma)\psi \geq \Delta + nw(M) \tag{3}$$

for a minimum weight matching M.

▶ **Lemma 12.** *For a graph G, let P^* be a minimum weight P_3 packing, and T^* be a minimum weight triangle packing. Then $(\frac{2}{3} + \frac{1}{3}\gamma - a\gamma)\psi = (1-a)\gamma\psi + \frac{2}{3}(1-\gamma)\psi \geq nw(P^*) \geq \frac{1}{2}nw(T^*)$.*

Proof. Note that $(\frac{2}{3} + \frac{1}{3}\gamma - a\gamma)\psi = \sum_{v\in V}(\frac{2}{3} + \frac{1}{3}\gamma_v - a_v\gamma_v)w(I_v)$ and $(1-a)\gamma\psi + \frac{2}{3}(1-\gamma)\psi = \sum_{v\in V}((1-a_v)\gamma_v w(I_v) + \frac{2}{3}(1-\gamma_v)w(I_v))$.

By Lemma 7, it holds that $\sum_{v\in V}(\frac{2}{3} + \frac{1}{3}\gamma_v - a_v\gamma_v)w(I_v) \geq \sum_{v\in V}((1-a_v)\gamma_v w(I_v) + \frac{2}{3}(1-\gamma_v)w(I_v)) \geq nw(P^*) \geq \frac{1}{2}nw(T^*)$. Therefore, we have that $(\frac{2}{3} + \frac{1}{3}\gamma - a\gamma)\psi = (1-a)\gamma\psi + \frac{2}{3}(1-\gamma)\psi \geq nw(P^*) \geq \frac{1}{2}nw(T^*)$. ◀

Next, we will describe our algorithm. Our algorithm consists of two constructions, where the first is based on the Hamiltonian cycle and the second is based on the triangle packing. The approximation quality of each will be analyzed after showing the construction. Finally, we will make a trade-off between them and get the final approximation ratio.

3.2 The Hamiltonian Cycle Construction

In our algorithm, the idea of Hamiltonian cycle construction is to make use of the canonical schedule [19, 8] and a Hamiltonian cycle. For TTP-k, there are many approximation algorithms using this method [29, 27, 18], and hence we will directly use the well-analyzed schedule in [29]. However, we will give a tighter analysis. Next, we give a brief introduction to this construction.

Roughly speaking, this schedule is generated by a rotation scheme that can make sure that almost all road trips of each team t_i are 4-cycles and in each road trip, team t_i visits a set of consecutive teams along the Hamiltonian cycle.

▶ **Lemma 13** ([29]). *Let C be a Hamiltonian cycle in graph G. For TTP-3, there is a polynomial-time algorithm that can generate a solution with a total weight of at most $\frac{2}{3}nw(C) + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi$.*

Note that the Hamiltonian cycle used in [29] is generated by the Christofides-Serdyukov algorithm. In our algorithm, we also consider another Hamiltonian cycle that uses the minimum weight perfect matching. We will select the better one between these two cycles.

▶ **Lemma 14** (*). *Let M be a perfect matching in graph G. Then there is a polynomial-time algorithm that can generate a Hamiltonian cycle C such that $w(C) = w(M) + \frac{1}{n}w(E) + O(\frac{1}{n^2})w(E)$.*

Note that Lemma 14 holds for any perfect matching. We will consider the Hamiltonian cycle that uses a minimum weight perfect matching.

▶ **Theorem 15.** *For any $\varepsilon > 0$, there is a polynomial-time algorithm that can generate a feasible schedule for TTP-3 with an approximation ratio of $\min\{\frac{4}{3} + \frac{1}{3}a\gamma,\ 1 - \frac{1}{6}\gamma + a\gamma\} + \varepsilon$.*

Proof. Here we use C to denote a minimum weight Hamiltonian cycle in G. If we use the Hamiltonian cycle C' obtained by the Christofides-Serdyukov algorithm, we can construct a feasible schedule with a total weight of at most $\frac{2}{3}nw(C') + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi$ by Lemma 13. Then, we have that

$$\begin{aligned}\frac{2}{3}nw(C') + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi &\leq \frac{2}{3}n\left(\mathrm{MST}(G) + \frac{1}{2}w(C)\right) + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi\\ &= \frac{2}{3}n\mathrm{MST}(G) + \frac{1}{3}nw(C) + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi\\ &\leq (\frac{4}{3} + \frac{1}{3}a\gamma)\psi + O(\frac{1}{n})\psi,\end{aligned}$$

where the first inequality follows from Lemma 3 and the second follows from Lemmas 8 and 9, and (2).

Similarly, if we use a minimum weight perfect matching M to obtain the Hamiltonian cycle C_M in Lemma 14, we can construct a feasible schedule with a total weight of at most

$$\begin{aligned}\frac{2}{3}nw(C_M) + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi &\leq \frac{2}{3}n\left(w(M) + \frac{1}{n}w(E) + O(\frac{1}{n^2})w(E)\right) + \frac{2}{3}\mathit{\Delta} + O(\frac{1}{n})\psi\\ &\leq \frac{2}{3}nw(M) + \mathit{\Delta} + O(\frac{1}{n})\psi\\ &\leq (1 - \frac{1}{6}\gamma + a\gamma)\psi + O(\frac{1}{n})\psi,\end{aligned}$$

where the first inequality follows from Lemma 14, the second follows from $w(E) = \frac{1}{2}\mathit{\Delta} \leq O(1)\psi$, and the last follows from Lemma 9 and (3).

Since we select the better one between these two Hamiltonian cycles, then the approximation ratio is $\min\{\frac{4}{3}+\frac{1}{3}a\gamma,\ 1-\frac{1}{6}\gamma+a\gamma\}+O(\frac{1}{n})$. Hence, there exists a constant c such that the ratio is bounded by $\min\{\frac{4}{3}+\frac{1}{3}a\gamma,\ 1-\frac{1}{6}\gamma+a\gamma\}+\frac{c}{n}$. For an arbitrary $\varepsilon>0$, if $n\leq\frac{c}{\varepsilon}=O(1)$, we can find an optimal solution by brute force, otherwise we use the approximation algorithm. This establishes the approximation ratio of $\min\{\frac{4}{3}+\frac{1}{3}a\gamma,\ 1-\frac{1}{6}\gamma+a\gamma\}+\varepsilon$. ◀

Note that $\max_{0\leq a,\gamma\leq 1}\min\{\frac{4}{3}+\frac{1}{3}a\gamma,\ 1-\frac{1}{6}\gamma+a\gamma\}+\varepsilon$ is maximized when $a=\gamma=1$ with value $(\frac{5}{3}+\varepsilon)$. However, this would require $0=(\frac{2}{3}+\frac{1}{3}\gamma-a\gamma)\psi\geq nw(P^*)\geq\frac{1}{2}nw(T^*)$ by Lemma 12. If we use any constant ratio approximation algorithm for minimum weight P_3 path packing or minimum weight triangle packing, we may get a much better schedule based on them and therefore, we will show that we can do better than $(\frac{5}{3}+\varepsilon)$ by combining the Hamiltonian cycle construction with the triangle packing construction shown next.

3.3 The Triangle Packing and P_3 Path Packing Constructions

In this section, we will construct a feasible schedule based on a triangle packing or a P_3 path packing. The idea is similar to the packing schedule based on a minimum weight perfect matching for TTP-2 [25, 28, 30, 31, 17]. Given a triangle packing (resp., a P_3 path packing), we consider the three normal teams in a triangle (resp., a P_3 path) as a super-team. The packing construction is to first arrange a single round-robin for super-teams and then extend the single round-robin into a double round-robin for normal teams. Although the construction is similar for a given triangle packing and a given P_3 packing, the analysis and the approximation ratio may be different.

3.3.1 Construction

First, we will introduce the single round-robin of super-teams.

Given a triangle packing T (resp., P_3 path packing P) of G, recall that we take the three teams in each triangle (resp., P_3 path) as a super-team. There are n normal teams and then there are $m=\frac{n}{3}$ super-teams. The set of super-teams is $U=\{u_1,u_2,\dots,u_{m-1},u_m\}$. We relabel the n teams such that $u_i=\{t_{3i-2},t_{3i-1},t_{3i}\}$ for each i.

In the construction, the case of $n=6$ is easy, and hence we assume here that $n\geq 12$. Each super-team will attend $m-1$ super-games in $m-1$ time slots. Each super-game in the first $m-2$ time slots will be extended to normal games that span six days, and each super-game in the last time slot will be extended to normal games that span ten days. Therefore, we have $6\times(m-2)+10=6m-2=2n-2$ days of normal games in total. This is the number of days in a double round-robin. We will construct the schedule for super-teams from the first time slot to the last time slot $m-1$. In each of the $m-1$ time slots, we have $\frac{m}{2}$ super-games. The schedule in the last time slot is different from the schedules in the first $m-2$ time slots.

For the first time slot, the $\frac{m}{2}$ super-games are arranged as shown in Figure 1. The super-game including super-team u_m is called *left super-game* and we put a letter 'L' on the edge to indicate it. All other super-games are called *normal super-games*. Each super-game is represented by a directed edge, where a directed edge from u_i to u_j means a super-game between them at the home of u_j. The information of which will be used to extend super-games to normal games between normal teams.

In Figure 1, we can see that the last super-team u_m is denoted as a dark node and all other super-teams $u_1,\dots,u_{m-1}$ are denoted as white nodes which form a cycle. In the second time slot, we keep the position of u_m and change the positions of white super-teams in the cycle by moving one position in the clockwise direction, and we also change the direction of each edge. In the second time slot, there are still $\frac{m}{2}-1$ normal super-games and one left super-game.

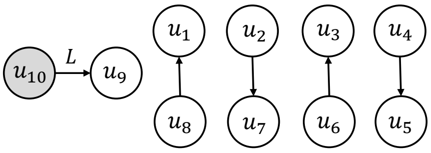

Figure 1 The super-game schedule in the first time slot for an instance with $m = 10$.

Table 1 Extending normal super-games where home games are marked in bold.

	$6q-5$	$6q-4$	$6q-3$	$6q-2$	$6q-1$	$6q$
a	x	z	y	$\boldsymbol{x}$	$\boldsymbol{z}$	$\boldsymbol{y}$
b	y	x	z	$\boldsymbol{y}$	$\boldsymbol{x}$	$\boldsymbol{z}$
c	z	y	x	$\boldsymbol{z}$	$\boldsymbol{y}$	$\boldsymbol{x}$
x	$\boldsymbol{a}$	$\boldsymbol{b}$	$\boldsymbol{c}$	a	b	c
y	$\boldsymbol{b}$	$\boldsymbol{c}$	$\boldsymbol{a}$	b	c	a
z	$\boldsymbol{c}$	$\boldsymbol{a}$	$\boldsymbol{b}$	c	a	b

Table 2 Extending left super-games where home games are marked in bold.

	$6q-5$	$6q-4$	$6q-3$	$6q-2$	$6q-1$	$6q$
a	x	z	$\boldsymbol{y}$	$\boldsymbol{x}$	$\boldsymbol{z}$	y
b	y	x	$\boldsymbol{z}$	$\boldsymbol{y}$	$\boldsymbol{x}$	z
c	z	y	$\boldsymbol{x}$	$\boldsymbol{z}$	$\boldsymbol{y}$	x
x	$\boldsymbol{a}$	$\boldsymbol{b}$	c	a	b	$\boldsymbol{c}$
y	$\boldsymbol{b}$	$\boldsymbol{c}$	a	b	c	$\boldsymbol{a}$
z	$\boldsymbol{c}$	$\boldsymbol{a}$	b	c	a	$\boldsymbol{b}$

The schedules for the other middle slots are derived analogously. Before we introduce the super-games in the last time slot, we first explain how to extend the super-games in the first $m-2$ time slots to normal games. In these time slots, we have two different kinds of super-games: normal super-games and left super-games. We first consider normal super-games.

Case 1. Normal super-games: Each normal super-game will be extended to eighteen normal games in six days. Assume that in a normal super-game, super-team u_i plays against the super-team u_j at the home of u_j in time slot q ($1 \leq i, j \leq m$ and $1 \leq q \leq m-1$). For ease of presentation, we let $u_i = \{t_{3i-2}, t_{3i-1}, t_{3i}\} = \{a, b, c\}$ and $u_j = \{t_{3j-2}, t_{3j-1}, t_{3j}\} = \{x, y, z\}$. The super-game will be extended to eighteen normal games in six corresponding days from $6q-5$ to $6q$, as shown in Table 1 where home games are marked in bold.

Case 2. Left super-games: Each left super-game will be extended to eighteen normal games in six days. Assume that in a left super-game, super-team $u_i = \{a, b, c\}$ plays against super-team $u_j = \{x, y, z\}$ at the home of u_j in time slot q ($2 \leq i \leq m-1$ and $1 \leq q \leq m-2$). The super-game will be extended to normal games in six corresponding days from $6q-5$ to $6q$, as shown in Table 2.

The first $m-2$ time slots will be extended to $6 \times (m-2) = 2n-12$ days according to the above rules. Each normal team will have ten remaining games, which correspond to the super-games in the last time slot. Figure 2 shows the schedule in the last time slot. All super-games in the last time slot are *last super-game* where we put a letter 'Z' to indicate it.

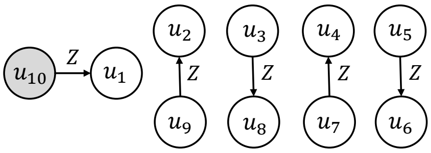

Figure 2 The super-game schedule in the last time slot for an instance with $m = 10$.

Table 3 Extending last super-games where home games are marked in bold.

	$6q-5$	$6q-4$	$6q-3$	$6q-2$	$6q-1$	$6q$	$6q+1$	$6q+2$	$6q+3$	$6q+4$
a	x	z	y	$\boldsymbol{x}$	$\boldsymbol{z}$	$\boldsymbol{y}$	c	b	$\boldsymbol{c}$	$\boldsymbol{b}$
b	y	x	c	$\boldsymbol{y}$	$\boldsymbol{x}$	$\boldsymbol{c}$	z	$\boldsymbol{a}$	$\boldsymbol{z}$	a
c	z	y	$\boldsymbol{b}$	$\boldsymbol{z}$	$\boldsymbol{y}$	b	$\boldsymbol{a}$	$\boldsymbol{x}$	a	x
x	$\boldsymbol{a}$	$\boldsymbol{b}$	z	a	b	$\boldsymbol{z}$	y	c	$\boldsymbol{y}$	$\boldsymbol{c}$
y	$\boldsymbol{b}$	$\boldsymbol{c}$	$\boldsymbol{a}$	b	c	a	$\boldsymbol{x}$	z	x	$\boldsymbol{z}$
z	$\boldsymbol{c}$	$\boldsymbol{a}$	$\boldsymbol{x}$	c	a	x	$\boldsymbol{b}$	$\boldsymbol{y}$	b	y

Case 3. Last super-games: Each normal super-game will be extended to thirty normal games in ten days. Assume that in the last time slot $q = m - 1$, super-team $u_i = \{a, b, c\}$ plays against super-team $u_j = \{x, y, z\}$ $(1 \leq i, j \leq m)$ at the home of u_j. The super-game will be extended to thirty normal games in ten corresponding days from $6q - 5$ to $6q + 4$, as shown in Table 3.

▶ **Theorem 16** **(*).** *For TTP-3 with n teams such that $n \equiv 0 \pmod 6$, the above construction can generate a feasible schedule.*

3.3.2 Analyzing the Approximation Quality

Note that all teams play three consecutive away games and three consecutive home games in a normal super-game. Indeed, all teams are at home before and after each normal super-game in the schedule, otherwise, it will break the bounded-by-3 property. Using this property, we can get the total cost of normal super-games by analyzing each normal super-game separately.

▶ **Lemma 17** **(*).** *If there is a normal super-game between super-teams u_i and u_j at the home of u_j, then the cost of all normal teams in u_i and u_j is at most $\frac{4}{3}c(u_i, u_j) + 2c(u_i) + 2c(u_j)$.*

To analyze the total weight of our schedule, we first analyze the total cost of normal super-games. Recall that there is exactly one super-game between each pair of super-teams in U and then, there are $\frac{m(m-1)}{2}$ super-games in total. We define $R(u_i, u_j) = 1$ if the super-game between super-teams u_i and u_j is a normal super-game, and $R(u_i, u_j) = 0$ otherwise. By Lemma 17 and (1), we know that the total cost of all normal super-games E_0 satisfies that

$$\begin{array}{rcl} E_0 & \leq & \sum_{1 \leq i < j \leq m} \left(\frac{4}{3}c(u_i, u_j) + 2c(u_i) + 2c(u_j)\right) R(u_i, u_j) \\ & \leq & \sum_{1 \leq i < j \leq m} \left(\frac{4}{3}c(u_i, u_j) + 2c(u_i) + 2c(u_j)\right) \\ & = & \frac{4}{3}c(F) + 2(m-1)w(T) \\ & \leq & \frac{2}{3}\Delta + \frac{2}{3}nw(T). \end{array} \tag{4}$$

The total cost of all left super-games and all last super-games are denoted by E_1 and E_2, respectively.

▶ **Lemma 18** **(*).** *By using $O(n^3)$ time to reorder all super-teams, we can make*

$$E_1 + E_2 = O(\tfrac{1}{n})\psi.$$

Based on Lemma 18 and (4), we can get

▶ **Theorem 19.** *For TTP-3 with the case of $n \equiv 0 \pmod 6$, suppose there exists a triangle packing T in graph G, then there is a polynomial-time algorithm to generate a feasible schedule with a total weight of at most $\frac{2}{3}\Delta + \frac{2}{3}nw(T) + O(\frac{1}{n})\psi$.*

▶ **Theorem 20.** *Suppose there exist ρ_t and ρ_p approximation algorithms for minimum weight triangle packing and P_3 path packing problems respectively, then for an arbitrary $\varepsilon > 0$, there is a polynomial-time algorithm for TTP-3 with the case of $n \equiv 0 \pmod 6$, whose approximation ratio is $\frac{8\rho+6}{9} + \frac{4\rho-3}{9}\gamma - \frac{4\rho-2}{3}a\gamma + \varepsilon$, where $\rho = \min\{\rho_p, \rho_t\}$.*

Proof. First, we consider that the schedule uses a triangle packing T of G. By Theorem 19, we know that the total weight is bounded by $\frac{2}{3}\Delta + \frac{2}{3}nw(T) + O(\frac{1}{n})\psi$. Suppose the triangle packing T is obtained by using a ρ_t-approximation algorithm, i.e., $w(T) \leq \rho_t w(T^*)$, then by Lemmas 9 and 12, we have that

$$\begin{aligned}\frac{2}{3}\Delta + \frac{2}{3}nw(T) + O(\frac{1}{n})\psi &\leq \frac{2}{3}\Delta + \frac{2}{3}\rho_t nw(T^*) + O(\frac{1}{n})\psi\\ &\leq \frac{2}{3}\Delta + \frac{4}{3}\rho_t nw(P^*) + O(\frac{1}{n})\psi\\ &\leq (\frac{8\rho_t+6}{9} + \frac{4\rho_t-3}{9}\gamma - \frac{4\rho_t-2}{3}a\gamma)\psi + O(\frac{1}{n})\psi.\end{aligned}$$

Then, we consider that the schedule uses a P_3 path packing P of G. Suppose the P_3 path packing P is obtained by using a ρ_p-approximation algorithm, i.e., $w(P) \leq \rho_p w(P^*)$, then we can get a triangle packing T' by completing the P_3 path packing P such that $w(T') \leq 2w(P) \leq 2\rho_p w(P^*)$ by the triangle inequality. Thus, by Lemmas 9 and 12, the total weight of our schedule is bounded by

$$\begin{aligned}\frac{2}{3}\Delta + \frac{2}{3}nw(T') + O(\frac{1}{n})\psi &\leq \frac{2}{3}\Delta + \frac{4}{3}\rho_p nw(P^*) + O(\frac{1}{n})\psi\\ &\leq (\frac{8\rho_p+6}{9} + \frac{4\rho_p-3}{9}\gamma - \frac{4\rho_p-2}{3}a\gamma)\psi + O(\frac{1}{n})\psi.\end{aligned}$$

By selecting the better schedule, we can get the approximation ratio of $\frac{8\rho+6}{9} + \frac{4\rho-3}{9}\gamma - \frac{4\rho-2}{3}a\gamma + \varepsilon$, where $\rho = \min\{\rho_p, \rho_t\}$. Note that the algorithm of our triangle packing construction runs in polynomial time since it takes $O(n^3)$ time to reorder all super-teams and $O(n^2)$ time to construct the schedule. ◀

3.4 Trade-off between Two Constructions

▶ **Theorem 21 (*).** *Suppose there exist ρ_t and ρ_p approximation algorithms for minimum weight triangle packing and P_3 path packing problems respectively, for TTP-3 with an arbitrary $\varepsilon > 0$, there is an approximation algorithm whose ratio is $\frac{11}{6} - \frac{5}{2(4\rho+1)} + \varepsilon$ when $\rho \leq \frac{9}{4}$, and $\frac{5}{3} - \frac{2}{3(4\rho-1)} + \varepsilon$ otherwise, where $\rho = \min\{\rho_t, \rho_p\}$. Given $\rho = \frac{8}{3}$, the approximation ratio is $\frac{139}{87} + \varepsilon < 1.598 + \varepsilon$ which improves the previous ratio of $\frac{5}{3} + \varepsilon < 1.667 + \varepsilon$.*

Proof. For the case of $n \equiv 0 \pmod 6$, our algorithm will select the better schedule from the two constructions. By Theorem 15, the ratio of the Hamiltonian cycle construction is $\min\{\frac{4}{3} + \frac{1}{3}a\gamma,\ 1 - \frac{1}{6}\gamma + a\gamma\} + \varepsilon$, and by Theorem 20, the ratio of the triangle packing construction is $\frac{8\rho+6}{9} + \frac{4\rho-3}{9}\gamma - \frac{4\rho-2}{3}a\gamma + \varepsilon$. Therefore, the ratio of our algorithm in the worst case is

$$\max_{0 \leq a, \gamma \leq 1} \min\left\{\frac{4}{3} + \frac{1}{3}a\gamma,\ 1 - \frac{1}{6}\gamma + a\gamma,\ \frac{8\rho+6}{9} + \frac{4\rho-3}{9}\gamma - \frac{4\rho-2}{3}a\gamma\right\} + \varepsilon.$$

We can transform it into the following linear programming where we let $\widetilde{\gamma} = a\gamma$.

$$\begin{aligned}
\max\quad & y \\
\text{s.t.}\quad & y \le \frac{4}{3} + \frac{1}{3}\widetilde{\gamma}, \\
& y \le 1 - \frac{1}{6}\gamma + \widetilde{\gamma}, \\
& y \le \frac{8\rho+6}{9} + \frac{4\rho-3}{9}\gamma - \frac{4\rho-2}{3}\widetilde{\gamma}, \\
& 0 \le \widetilde{\gamma} \le \gamma \le 1.
\end{aligned}$$

It shows that the ratio is $\frac{11}{6} - \frac{5}{2(4\rho+1)} + \varepsilon$ when $\rho \le \frac{9}{4}$, and $\frac{5}{3} - \frac{2}{3(4\rho-1)} + \varepsilon$ otherwise.

To our best knowledge, both of the current best-known ratios for minimum weight triangle packing and minimum weight P_3 path packing problems are $\frac{8}{3}$ [12]. Therefore, given $\rho = \rho_p = \rho_t = \frac{8}{3}$, the final approximation ratio of our algorithm is $\frac{139}{87} + \varepsilon < 1.598 + \varepsilon$.

Note that the cases $n \equiv 2 \pmod 6$ and $n \equiv 4 \pmod 6$ have not been analyzed yet. Since n is not divisible by 3 for these two cases, there is no perfect P_3 path packing or triangle packing in G. However, with some modifications, we can extend the second construction and its analysis to get the same approximation ratio. ◀

By Theorem 21, we know that the approximation ratio can achieve $(4/3 + \varepsilon)$ if $\rho = 1$.

▶ **Corollary 22.** *If a minimum weight triangle packing or P_3 path packing is given, there exists a $(4/3 + \varepsilon)$-approximation algorithm for TTP-3, for an arbitrary $\varepsilon > 0$.*

4 LDTTP-3

When all teams are located on a straight line, this problem is known as Linear Distance TTP-3 (LDTTP-3) [15]. For this problem, the minimum weight triangle packing and P_3 path packing can be found in polynomial time. Thus, for LDTTP-3, our algorithm has an approximation ratio of $(4/3 + \varepsilon)$, which also matches the current best-known ratio of 4/3 (however, note that their construction only works for the case of $n \equiv 4 \pmod 6$) [15]. Their ratio is based on a stronger lower bound of LDTTP-3. If we use this lower bound, the approximation ratio of our triangle packing construction can be proved to be $(6/5 + \varepsilon)$.

▶ **Theorem 23 (*).** *For LDTTP-3, there is an approximation algorithm whose ratio is $(6/5 + \varepsilon)$, for an arbitrary $\varepsilon > 0$.*

5 TTP-4

It is natural to use the same idea to solve TTP-4. For the problem of minimum weight P_4 path packing, to our best knowledge, the current best-known ratio is 3/2 [22]. If we use the construction based on the Hamiltonian cycle and the construction based on P_4 path packing, we can get a $(17/10 + \varepsilon)$-approximation algorithm for TTP-4 which improves the previous approximation ratio of $(7/4 + \varepsilon)$ [29].

▶ **Theorem 24 (*).** *For TTP-4 with any $\varepsilon > 0$, there is an algorithm whose approximation ratio is $(17/10 + \varepsilon)$ which improves the previous approximation ratio of $(7/4 + \varepsilon)$.*

For TTP-k with $k \ge 5$, we note that both of the best-known approximation ratios for minimum weight k-cycle packing and P_k path packing are $4(1 - 1/k) > 3$ [12]. The approximation ratios are too large and we can not improve TTP-k by using the same idea.
