All implementations are freely available and will be part of the next release of the open source C++ *Open Graph algorithms and Datastructures Framework* [14] (www.ogdf.net). All experiments were performed on an Intel Xeon Gold 6134 with 256 GB RAM under Debian 10.2 using gcc 8.3.0-6 (-O3). For BBMR, we use CPLEX 20.1 [19] as the LP solver. When conducting an experimental study, and i.p. due to the page restriction, one has to decide between in-depth analyses of a smaller set of certain aspects or a broader approach of reporting the overall algorithmic behaviors over a larger field of questions and parameterizations. As our goal herein is to broadly assess competing algorithmic ideas, the second option makes more sense. However, all detailed data of our experiments is available at [7] for other researchers (or a subsequent longer journal version) to investigate further.

■ **Table 2** Solved instances per algorithm and average time for successful cases.

Library	ADDJS	BS	KP	BBMR	EN
Random	98.62% (2.96 s)	100.00% (0.03 s)	66.67% (2.46 s)	70.16% (3.07 s)	100.00% (3.10 s)
Steinlib	99.88% (0.48 s)	100.00% (0.11 s)	91.55% (1.91 s)	83.79% (5.32 s)	100.00% (0.37 s)
Tsplib	81.75% (4.98 s)	98.71% (1.47 s)	33.01% (14.75 s)	60.74% (5.70 s)	76.05% (3.11 s)
All	98.46% (0.92 s)	99.91% (0.21 s)	86.02% (2.30 s)	80.91% (5.21 s)	98.20% (0.66 s)

■ **Figure 1** Instances solved by KP within the time limit for each instance library. There are no further solved instances for larger ρ_a .

■ **Figure 2** Comparing ADDJS, BS, and EN for $n = 500$ (\times) and $n = 1000$ ($+$). BBMR cannot solve any of these instances.

Parameterizing the Randomized Algorithms. To fairly evaluate the randomized algorithms BS and EN, we first need to investigate their parameterizations. We report on these additional experiments in [15, Appendix B]. In the following, we use the most competitive settings of 1000 iterations for BS and 200 iterations for EN with $\varepsilon = 0.8$.

4.1 Running Time

We start with investigating the running times of our algorithms. We set a time limit of 60 seconds for each calculation: ADDJS, BS, and EN can solve the majority of all instances within this limit (cf. Table 2), and an additional pilot study shows that higher limits of 90 or 120 seconds do not significantly increase the number of solved instances. Before comparing the algorithms, we discuss their runtime behavior individually. In the following, when speaking about averages we consider the standard arithmetic mean, unless specified otherwise.

ADDJS. The running time is linear in m for fixed n . Almost all Steinlib instances can be solved within 6 seconds and all Tsplib instances with $n \leq 1200$ within the time limit. The densest instances over all libraries with $\rho_r \geq 90\%$ and $n \approx 1000$ can barely be solved within the time limit. The running time shows a dependency on the graph weights: unweighted graphs can be solved 33.45% faster than weighted ones. Furthermore, higher stretches are faster to compute. There is one peculiar outlier: while all other combinations of weights and stretches allow all Random instances to be solved within the time limit, $\alpha = 2$ for weighted (and **W1**-weighted, see also Sect. 4.2) instances is drastically slower and only achieves a success rate of 89%. This is also the only case where **W1** yields higher running times than **W2** and the unweighted case. Over the solved unweighted instances, $\alpha = 2$ is 42.61% slower than $\alpha = 3$ (while, e.g., $\alpha = 3$ is only 6.19% slower than $\alpha = 4$).

BS. The clustering approach is very fast. Every instance from Random is solved in under 0.6 seconds. The running time behaves linearly in m , as expected. Analogous to ADDJS, unweighted instances are faster, but in contrast, a *lower* stretch is faster as well. For Random, the running times for **W1** are in-between those of **W2** and unit weights. Almost all instances of the Tsplib can be solved; only the two largest instances ($n = 5915, 7397$) exceed the time limit for $\alpha \geq 5$. The majority of the Steinlib instances can be solved within a second. Generally, BS seems to have difficulties with large, very sparse graphs; for these graphs with $\varrho_r \leq 0.01\%$, the running time is up to 17.5 seconds (cf. [15, Appendix, Figure 8]). These are Steinlib instances from the subsets LIN, ALUT, and ALUE (grid graphs with holes, $n \geq 20000$).

KP. Surprisingly, there is no clear relationship between the running time and n , m , or ϱ_r ; however the absolute density is limiting: For instances with $40 \lesssim \varrho_a \lesssim 60$, the running time drastically starts to increase in comparison to $\varrho_a \lesssim 40$ and no instances with $\varrho_a \gtrsim 60$ can be solved in time (cf. Fig. 1). This behavior is consistent over all three libraries except for a handful of outliers from Tsplib. Regarding Steinlib, the sets 2R, I320, C, PUC and the largest instances of LIN require higher running times due to the very large n . The complete graphs of Tsplib can be solved with up to 120 vertices, which corresponds to $\varrho_a = 59.5$.

BBMR. Its running time depends on α and the weights: Similar to ADDJS, unweighted graphs are slightly faster (by 10.28%), but a higher stretch results in a lower running time. It also shares the performance degradation for $\alpha = 2$ on unweighted graphs. Overall, both the timeout rates and the running times are very high. Regarding the instance sizes, the number of edges has a disproportionate impact on the running time, i.e., only Steinlib instances with $m \leq 5000$ edges can be solved, regardless of the number of vertices. This is not surprising since the antispanner creation and minimization depends on the original graph's edges. Graphs from Random and Tsplib can only be solved if they have less than 250 nodes. Even though BBMR has a probability of failing, we never observed any failure during the experiments.

EN. We observe a linear running time in m . We measured the time until the first success, so previous failures are included in the running times. EN can solve graphs with up to 1000 vertices for Random and Tsplib, with a smaller stretch being slightly faster, as the BFS depth depends on α . The maximum time for Steinlib is 14 seconds.

Comparison. Table 3 shows the percentage of instances an algorithm can solve strictly faster than another algorithm, as well as the average relative speed-up factor in these cases. An example is provided in Fig. 2 for unweighted instances and $\alpha = 5$. Clearly, BBMR is the slowest of the considered algorithms. Only KP was sometimes slower (in 8.2% of the cases, roughly 14-fold); but when KP was faster, it was so by a factor of over 116. BS shows a significant number of instances where it is fastest, as it benefits from traversing adjacency lists instead of calculating distances. Also, its speed-up factor in these cases is rather strong. EN and ADDJS both share a similar number of instances each can solve faster. This is no surprise since EN's BFS for each node is similar to the Dijkstra runs for ADDJS in the unweighted setting. Only for large or dense instances, ADDJS gets noticeably faster than EN (cf. Fig. 2). If these values were to be restricted to larger or denser graphs (e.g. $n \geq 100$ or $\varrho_r \geq 5\%$), the results would be even clearer due to the fact that all small/sparse instances can be solved within fractions of seconds by most algorithms.

■ **Table 3** Percentage of instances where A was strictly faster than B. “–” denotes that the algorithms cannot be directly compared due to their incompatible stretch restrictions (2 vs. odd), see Table 1. The speed-up factor is given in parentheses. Only instances both algorithms can solve are included.

A \ B	ADDJS	BS	KP	BBMRY	EN
ADDJS		14.83% (1.45)	51.23% (123.61)	93.24% (210.88)	19.38% (1.07)
BS	36.07% (24.71)		–	92.99% (188.60)	28.70% (30.23)
KP	1.19% (1.27)	–		86.65% (116.61)	–
BBMRY	0.00% (–)	0.00% (–)	8.20% (14.17)		0.00% (–)
EN	27.10% (2.68)	11.52% (0.45)	–	93.37% (170.12)	

4.2 Quality

We may now consider the standard measures for spanners: their lightness and sparseness.

Weight functions for the Random instances. A key observation from the running times above also holds true for the solutions’ quality: The unweighted instances and the weighting **W1** behave very similarly. In any measure, **W1** lies between **W2** and the unweighted case, but is always very close to the latter; with increasing graph size, the sparseness of **W1** converges to that of the latter. Thus, in the following discussions regarding Random, we focus on unweighted instances and **W2**; all statements about the former are also true for **W1**.

Lightness. As a concept different from size, the lightness is only relevant for weighted instances. **BBMRY** and **BS** do not provide any guarantees, and indeed, both yield arbitrarily high lightness values in practice across all instance libraries (cf. Fig. 3). **BBMRY**’s lightness is on average 33.5 times higher than **ADDJS**’s; and **BS**’s lightness is 11.8 times higher. **BS** and **BBMRY** never yield a lower lightness than **ADDJS** on any instance. In summary, there is no alternative to **ADDJS** for applications requiring a lightness guarantee.

Sparseness. First, consider $\alpha = 2$ and unweighted graphs. Surprisingly, **KP** yields a lower sparseness than **ADDJS** for $q_r \gtrsim 50\%$ (cf. Fig. 4). **BBMRY** yields only high sparseness in comparison to those algorithms. On **Tsplib** (i.e., complete graphs), **KP** always finds the trivial optimal solution of a star due to the way the algorithm works. In contrast, **KP** can only sparsify 22% of the Steinlib instances in comparison to 78% by **ADDJS** and 62% by **BBMRY**.

■ **Figure 3** Lightness for **ADDJS**, **BBMRY** and **BS**. **ADDJS** has a maximum lightness of 1.3.

■ **Figure 4** Sparseness comparison averaged on all instances from Random.

■ **Figure 5** Sparseness for unweighted graphs with different stretches: $\alpha = 3$ (Δ), $\alpha = 5$ (+), and $\alpha = 7$ (\times).

■ **Figure 6** Sparseness for weighted graphs. BBMRV and BS have significantly higher sparseness than ADDJS.

For unweighted instances with odd stretch, ADDJS, BS, and EN behave similarly, see Fig. 5. For dense graphs, the sparseness converges and higher stretches unsurprisingly result in lower sparseness. ADDJS generally yields the lowest sparseness, followed by BS and then EN. E.g., over all libraries for $\alpha = 5$, BS yields 37% higher sparseness than ADDJS, and EN 47% higher than BS. Although BBMRV’s sparseness seems stretch-independent, it is very high compared to all other algorithms. EN shows a higher variance of the sparseness; e.g. for $\alpha = 3$ its standard deviation is about 4 times that of ADDJS. With higher stretches, the variance decreases.

On weighted graphs, BBMRV and BS yield comparable sparseness; both are, however, significantly worse than ADDJS, see Fig. 6. All algorithms except for ADDJS cannot significantly sparsify the already sparse graphs ($\varrho_r \leq 10\%$) from Steinlib too much: ADDJS’s average sparseness is 71.7%, while the sparsenesses of all other algorithms are between 92% and 97%.

Effective stretch. For instances with $n \leq 1000$ ($n \leq 11000$ for Steinlib), we computed an APSP on the input graphs and the resulting spanners to calculate the effective stretches. More precisely, for each vertex pair (u, v) , we can compare the length of the shortest path in the input graph to that in the spanner, and obtain an effective stretch specific to (u, v) . We can aggregate over the effective stretches for all vertex pairs. Table 4 provides an overview of the effective mean, mean maximum, and maximum stretches over all instances. ADDJS gives the overall highest mean stretch and thus always utilizes the limit provided by α . Interestingly, BBMRV, BS, and EN never use the available stretch of 7 for unweighted graphs. For unweighted complete graphs, EN does not yield a mean stretch over 2 (cf. [15, Appendix, Figure 11]), regardless of α . KP behaves similar to ADDJS and even yields a higher mean stretch on those instances both ADDJS and KP could solve. BBMRV and BS yield lower mean stretches in comparison to ADDJS for weighted graphs. In summary, these results directly correlate to the previous observations. By having a low mean stretch and not utilizing the allowed stretch, it is clear that some potential for sparsification is not fully exploited, so the lightness and sparseness are also worse.

4.3 Further Properties for Weighted Spanners

Finally, we want to touch on the graph structure of spanners particularly on *weighted graphs*. We are interested in their mean degrees, and the number of edges in the shortest paths.

■ **Table 4** Effective mean (mean max, max) stretch for multiple configurations.

	α	ADDJS	BS	BBMR	KP/EN
unweighted	2	1.36 (1.98, 2.00)	–	1.10 (1.86, 2.00)	KP: 1.36 (1.87, 2.00)
	3	1.77 (2.94, 3.00)	1.53 (2.77, 3.00)	1.12 (2.06, 3.00)	EN: 1.43 (2.61, 3.00)
	4	2.16 (3.89, 4.00)	–	1.13 (2.13, 4.00)	–
	5	2.47 (4.77, 5.00)	1.77 (3.68, 5.00)	1.13 (2.11, 4.00)	EN: 1.59 (3.13, 5.00)
	7	2.86 (6.43, 7.00)	1.83 (4.16, 6.00)	1.13 (2.12, 5.00)	EN: 1.73 (3.52, 6.00)
weighted	2	1.03 (1.85, 2.00)	–	1.00 (1.19, 2.00)	–
	3	1.07 (2.70, 3.00)	1.01 (1.16, 2.61)	1.00 (1.65, 3.00)	–
	4	1.11 (3.49, 4.00)	–	1.01 (1.99, 4.00)	–
	5	1.16 (4.20, 5.00)	1.01 (1.37, 3.26)	1.01 (2.30, 5.00)	–
	7	1.25 (5.44, 7.00)	1.01 (1.60, 3.49)	1.01 (2.69, 7.00)	–

Degree. For $\alpha = 3$, BS yields a higher mean degree by 30% than BBMR, but is slightly lower for $\alpha \geq 5$; BS is the only algorithm where a higher stretch results in lower mean degrees. Overall, BBMR and BS yield very high mean degrees (similar to the lightness and sparseness) while ADDJS has mean degrees around 3–5. For the Steinlib instances, ADDJS’s spanners yields a mean degree of (on average) 57% of the mean degree of the input graph. In contrast to this, all other algorithms’ spanners have more than 96% of the original mean degree, see [15, Appendix, Figure 10]. All algorithms show a constant or moderately (linearly) increasing dependency between mean degrees of the original graph and the spanner, except for KP. There, the spanners’ mean degrees first increase together with the original mean degree, but for instances with $\rho_r \gtrsim 50\%$ the former decrease again. Analogous to the sparseness, the mean degrees become lower than ADDJS’s for large relative densities.

Hops. Lastly, we take a look at the number of edges (*hops*) of all shortest paths (again considering the instances described for the effective stretch). Overall, the mean hop difference is always positive, i.e., shortest paths in the spanner on average use more edges than in the original graph. Only 2.27% of all vertex pairs have shortest paths with fewer hops in the spanner than in the original graph; 58.90% retain their hop count, and 38.82% gain at least one hop. ADDJS has a higher average mean hop difference of 3.98 than BS (0.26) and BBMR (0.15). The tendency for all algorithms is to yield a higher hop difference with higher stretch.

5 Conclusions and Questions

We conducted the first experimental evaluation of polynomial spanner approximations. We can provide a rough guideline on which algorithm to use. If one has the special case of $\alpha = 2$ and no edge weights, KP may be used for graphs with $\rho_r \gtrsim 50$ as long as it can solve the instances in feasible time. In all other cases ADDJS (the oldest and most simplistic approach!) should be the algorithm of choice, as long as the graphs have reasonable sizes. It provides the sparsest and lightest spanners within a reasonable running time. Especially for weighted graphs, no other algorithm can calculate spanners of comparable quality. Only for very large unweighted graphs, BS is a good alternative to ADDJS due to its low running time. BBMR’s subpar performance makes its only sensible for directed graphs, as it is the only algorithm capable of handling such instances. Lastly, while EN can produce good spanners, it is never strictly better in running time nor quality than ADDJS or BS.

Overall, the practical strength of the algorithmic idea of ADDJS seems to be established. Based thereon, it now seems worthwhile to investigate the practical performance of proposed improvements. In particular, this includes the mentioned implementation-wise more intricate

but theoretically faster variants [42, 45] which lose the lightness guarantees. Furthermore, we may ask whether ADDJS can be improved for unweighted graphs by using a specific edge order. Formally, an arbitrary order suffices, but using a BFS or DFS order, or sequentially considering sets of independent edges, may further decrease the spanner size in practice. It may also be interesting to investigate the algorithmic reasons for the significant running time degradation of ADDJS (and BBMY) for $\alpha = 2$ on unweighted graphs, and to find theoretical results complementing the practical findings on the measures considered in Sect. 4.3.

Determinants from Homomorphisms

Radu Curticapean

Basic Algorithms Research Copenhagen, Denmark

Abstract

We give a new combinatorial explanation for well-known relations between determinants and traces of matrix powers. Such relations can be used to obtain polynomial-time and poly-logarithmic space algorithms for the determinant. Our new explanation avoids linear-algebraic arguments and instead exploits a classical connection between subgraph and homomorphism counts.

1 Introduction

The determinant of $n \times n$ matrices is, up to scaling, the unique function from $n \times n$ matrices to scalars that is linear and alternating in the rows and columns. It admits the well-known *Leibniz formula*

$$\det(A) = \sum_{\pi \in S_n} \operatorname{sgn}(\pi) \prod_{i=1}^n a_{i, \pi(i)}, \quad (1)$$

where S_n denotes the set of permutations of $\{1, \dots, n\}$ and $\operatorname{sgn} : S_n \rightarrow \{-1, 1\}$ denotes the permutation sign. Writing $\sigma(\pi)$ for the number of cycles in π , the permutation sign can be expressed as $\operatorname{sgn}(\pi) = (-1)^{n+\sigma(\pi)}$.

When presented with only the right-hand side of (1), unaware of the connection to the determinant, one would likely struggle to evaluate this sum of $n!$ terms efficiently. For comparison, it is $\#\text{P}$ -hard to compute the similarly defined *permanent* [8], which is obtained by omitting the sign factors from the expression.

Yet, determinants can be evaluated efficiently, e.g., via Gaussian elimination in $O(n^3)$ field operations, including divisions. Asymptotically optimal algorithms achieve $O(n^\omega)$ operations, where $\omega < 3$ is the exponent of matrix multiplication [2, Exercise 28.2-3]. Note that $\det(A)$ is defined over any ring containing the entries of A ; there are also algorithms computing determinants with a polynomial number of ring operations, i.e., excluding divisions [6, 1, 7].

Determinants from matrix powers

It is classically known in linear algebra that $\det(A)$ for $n \times n$ matrices A can be computed from the matrix traces $\operatorname{tr}(A^k)$ for $1 \leq k \leq n$. In the following, assume that A is defined over an algebraically closed field \mathbb{F} , such that A has eigenvalues $\lambda_1, \dots, \lambda_n \in \mathbb{F}$. The idea is to express $\det(A)$ and $\operatorname{tr}(A^k)$ for $1 \leq k \leq n$ as particular polynomials in the eigenvalues $\lambda_1, \dots, \lambda_n$ and then relate these polynomials.

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- The determinant can be expressed as $\det(A) = \lambda_1 \dots \lambda_n$; this is the n -th elementary symmetric polynomial in the eigenvalues. Generally, the k -th elementary symmetric polynomial $e_k(x_1, \dots, x_n)$ in n variables is the sum of monomials $\sum_S \prod_{i \in S} x_i$, where S ranges over all k -subsets $S \subseteq \{1, \dots, n\}$.
- The matrix trace satisfies $\operatorname{tr}(A) = \lambda_1 + \dots + \lambda_n$, and more generally, $\operatorname{tr}(A^k) = \lambda_1^k + \dots + \lambda_n^k$. This is the k -th power-sum polynomial in the eigenvalues. Generally, the k -th power sum polynomial is $p_k(x_1, \dots, x_n) = x_1^k + \dots + x_n^k$.

The Girard–Newton identities then allow us to relate the power-sum and elementary symmetric polynomials. They state that, for all $1 \leq k \leq n$,

$$k e_k(x_1, \dots, x_n) = \sum_{i=1}^k (-1)^{i-1} e_{k-i}(x_1, \dots, x_n) p_i(x_1, \dots, x_n).$$

For \mathbb{F} of characteristic 0, a recursive application of these identities allows us to compute $\det(A) = e_n(\lambda_1, \dots, \lambda_n)$ from the values $p_k(\lambda_1, \dots, \lambda_n) = \operatorname{tr}(A^k)$ for $1 \leq k \leq n$. Csanky’s algorithm [4, Chapter 31] implements this approach with an arithmetic circuit of bounded fan-in, $O(\log^2 n)$ depth, and polynomial size. In other words, it shows that determinants can be computed with $O(\log^2 n)$ operations on a polynomial number of parallel processors.

Our result

The main result of this paper is a novel and self-contained derivation of a known and algorithmically useful formula that expresses the determinant of $n \times n$ matrices A as a polynomial combination of traces of matrix powers:

$$\det(A) = (-1)^n \sum_{\lambda \vdash n} (-1)^{|\lambda|} \prod_{\ell=1}^n \frac{\operatorname{tr}(A^\ell)^{s_\ell(\lambda)}}{s_\ell(\lambda)! \cdot \ell^{s_\ell(\lambda)}}. \quad (2)$$

Some remarks on the notation are in order. The sum ranges over partitions λ of n , which are multi-sets of positive numbers summing to n . We write $\lambda \vdash n$ to indicate that λ is a partition of n and write $|\lambda|$ for its number of parts. For $\ell \in \mathbb{N}$, we write $s_\ell(\lambda) \in \mathbb{N}$ for the number of occurrences of ℓ in λ .

The previous subsection essentially gives a proof of (2) by appropriately expanding the recursive applications of the Girard–Newton identities. The new proof we present in this paper bypasses notions like eigenvalues, symmetric polynomials, and the Girard–Newton identities, and instead relies on ideas from the theory of graph homomorphism counts.

Our proof of (2) is contained in Section 2. We then sketch in Section 3 how this formula can be used to obtain polynomial-time and parallel algorithms for the determinant.

2 Proof of Equation (2)

In the following, let $[n] = \{1, \dots, n\}$ and let $A = (a_{i,j})_{i,j \in [n]}$ be a matrix. We will study the determinant of A using graph-theoretic language. The graphs G we consider are *directed* and may feature *self-loops*, and some graphs may feature *parallel edges* between the same pair of vertices. We write $V(G)$ and $E(G)$ for the vertices and edges of G .

2.1 Determinants are sums of cycle covers

The matrix A induces an edge-weighted complete directed graph with self-loops on the vertex set $V(A) = [n]$. Abusing notation, we also write A for this weighted graph. In this view, permutations correspond to *cycle covers*, which are edge-sets $C \subseteq E(A)$ inducing vertex-disjoint cycles that cover all vertices of A .

We require the more general notion of a k -*partial cycle cover* for $0 \leq k \leq n$, which is a collection of vertex-disjoint cycles with k edges in total. We write $\sigma(C)$ for the number of cycles in C , define the sign of C analogously to the permutation sign as $\text{sgn}(C) = (-1)^{|C|+\sigma(C)}$, and define the *format* of C as the partition $\lambda \vdash k$ induced by the multi-set of cycle lengths. Finally, let $\mathcal{C}(n, k)$ be the set of k -partial cycle covers of the complete directed graph on vertex set $[n]$.

Partial cycle covers are connected to k -*partial determinants*. Up to sign, these are the coefficients of characteristic polynomials, and they can be defined as

$$\det_k(A) = \sum_{S \subseteq [n] \text{ of size } k} \det(A[S]),$$

where $A[S]$ is the square sub-matrix of A defined by restricting to the rows and columns contained in S . From the Leibniz formula (1), it follows that

$$\det_k(A) = \sum_{C \in \mathcal{C}(n, k)} \text{sgn}(C) \prod_{uv \in C} a_{u,v}. \quad (3)$$

Given $\lambda \vdash k$, let $C_\lambda \in \mathcal{C}(n, k)$ be any fixed cycle cover of format λ . We can regroup terms in (3) to obtain

$$\det_k(A) = \sum_{\lambda \vdash k} \text{sgn}(C_\lambda) \underbrace{\sum_{\substack{C \in \mathcal{C}(n, k) \text{ of} \\ \text{format } \lambda}} \prod_{uv \in C} a_{u,v}}_{=: \text{sub}(C_\lambda \rightarrow A)}. \quad (4)$$

Note that the quantity $\text{sub}(C_\lambda \rightarrow A)$ defined above is a weighted sum over the cycle covers C isomorphic to C_λ , weighted by the product of the edge-weights in C .

2.2 Relating subgraphs, embeddings and homomorphisms

Let L be a graph, possibly containing parallel edges. The weighted *homomorphism* and *embedding* counts from L into A are defined as

$$\text{hom}(L \rightarrow A) = \sum_{f: V(L) \rightarrow [n]} \prod_{\substack{e \in E(L) \\ \text{with } e=uv}} a_{f(u), f(v)}, \quad (5)$$

$$\text{emb}(L \rightarrow A) = \sum_{\substack{f: V(L) \rightarrow [n] \\ \text{injective}}} \prod_{\substack{e \in E(L) \\ \text{with } e=uv}} a_{f(u), f(v)}. \quad (6)$$

For example, if C_ℓ denotes the directed ℓ -cycle for $\ell \in \mathbb{N}$, then $\text{hom}(C_\ell \rightarrow A) = \text{tr}(A^\ell)$. Moreover, for $\lambda \vdash k$, recall that $s_\ell(\lambda)$ counts the occurrences of part ℓ in λ . We have

$$\text{hom}(C_\lambda \rightarrow A) = \prod_{\ell=1}^k \text{tr}(A^\ell)^{s_\ell(\lambda)}, \quad (7)$$

since homomorphisms from a disjoint union of graphs can be chosen independently for the individual components; this implies that $\text{hom}(C_\lambda \rightarrow A)$ is the product of homomorphism counts for the individual cycles in C_λ .

Given a graph P without parallel edges, an *automorphism* of P is an isomorphism into itself. We write $\text{aut}(P)$ for the number of automorphisms of P . For example,

$$\text{aut}(C_\lambda) = \prod_{\ell=1}^k s_\ell(\lambda)! \cdot \ell^{s_\ell(\lambda)}, \quad (8)$$

38:4 Determinants from Homomorphisms

since any automorphism of C_λ (i) permutes the set of $s_\ell(\lambda)$ cycles for any fixed length ℓ , which gives rise to a factor of $s_\ell(\lambda)!$ in the above product, and (ii) independently applies an automorphism to each cycle, giving rise to a factor of ℓ for every cycle of length ℓ .

With these notions set up, we can successively express subgraph counts from cycle covers, as defined in (4), via homomorphism counts. First, we transition from subgraph to embedding counts: As every subgraph isomorphic to C_λ gives rise to $\text{aut}(C_\lambda)$ many embeddings with the same image, we obtain

$$\text{sub}(C_\lambda \rightarrow A) = \frac{\text{emb}(C_\lambda \rightarrow A)}{\text{aut}(C_\lambda)}. \quad (9)$$

Next, we transition from embedding to homomorphism counts. Roughly speaking, embedding counts from a graph H are equal to homomorphism counts from H plus “lower-order terms” involving only homomorphism counts from graphs F with strictly less vertices than H . This follows directly from [5, (5.18)] and we include a simple proof for completeness, also contained in [3].

► **Lemma 1.** *For any fixed graph H , there are coefficients $\beta_F \in \mathbb{Z}$ for all graphs F with $|V(F)| < |V(H)|$ such that*

$$\text{emb}(H \rightarrow A) = \text{hom}(H \rightarrow A) + \sum_{\substack{\text{graphs } F \text{ with} \\ |V(F)| < |V(H)|}} \beta_F \text{hom}(F \rightarrow A).$$

Proof. Given a partition ρ of the set¹ $V(H)$, the *quotient* H/ρ is the multigraph obtained by identifying the vertices within each block of ρ while keeping all possibly emerging self-loops and multi-edges. We have

$$\text{hom}(H \rightarrow A) = \sum_{\substack{\text{partition } \rho \\ \text{of } V(H)}} \text{emb}(H/\rho \rightarrow A), \quad (10)$$

since any homomorphism $f : V(H) \rightarrow [n]$ induces a partition $\rho = \{f^{-1}(i) \mid i \in [n]\}$ by which f may be viewed as an embedding from H/ρ to A .

Write \perp for the finest partition of the set $V(H)$, that is, the partition consisting of $|V(H)|$ singleton parts. By rearranging (10) and using $H/\perp = H$, we obtain

$$\text{emb}(H \rightarrow A) = \text{hom}(H \rightarrow A) - \sum_{\substack{\text{partition } \rho \neq \perp \\ \text{of } V(H)}} \text{emb}(H/\rho \rightarrow A). \quad (11)$$

Note that all graphs H/ρ with $\rho \neq \perp$ have strictly less vertices than H . We can therefore apply (11) again to express each term $\text{emb}(H/\rho \rightarrow A)$ on the right-hand side as $\text{hom}(H/\rho \rightarrow A)$ minus embedding counts from smaller graphs. This process can be iterated until reaching single-vertex graphs, from which homomorphism and embedding counts coincide trivially. Upon termination of this process, all occurrences of embedding counts have been replaced by homomorphism counts. ◀

Combining (4), (9), and Lemma 1, it follows that the k -partial determinant is a linear combination of homomorphism counts from k -partial cycle covers plus “lower-order terms”.

¹ Note that ρ here is a partition of a *set*, not a partition of a *number*.

► **Corollary 2.** For any fixed $k \in \mathbb{N}$, there are coefficients $\alpha_F \in \mathbb{Q}$ for all graphs F with $|V(F)| < k$ such that, for any $n \times n$ matrix A ,

$$\det_k(A) = \left(\sum_{\lambda \vdash k} \frac{\text{sgn}(C_\lambda)}{\text{aut}(C_\lambda)} \text{hom}(C_\lambda \rightarrow A) \right) + \sum_{\substack{F \text{ with} \\ |V(F)| < k}} \alpha_F \text{hom}(F \rightarrow A). \quad (12)$$

2.3 Lower-order terms vanish

As it turns out, the “lower-order terms” in (12) vanish. To show this, we use Kronecker products to lift this equality to a polynomial identity and then compare coefficients. For $t \in \mathbb{N}$, the *Kronecker product*² $A \otimes J_t$ of A with the $t \times t$ all-ones matrix J_t is an $nt \times nt$ matrix with row and column indices from $[n] \times [t]$, such that the entry at row (i, r) and column (j, r') equals $a_{i,j}$. In other words, each entry $a_{i,j}$ of A is replaced in $A \otimes J_t$ by a $t \times t$ matrix that contains only $a_{i,j}$.

It turns out that (12) “reacts polynomially” to this operation: When fixing $k = n$ and replacing A by $A \otimes J_t$ for varying t in (12), the homomorphism counts $\text{hom}(S \rightarrow A \otimes J_t)$ for graphs S on the right-hand side become polynomials in t . In fact, each such homomorphism count contains only a single monomial:

► **Claim 3.** For any graph S , we have $\text{hom}(S \rightarrow A \otimes J_t) = t^{|V(S)|} \text{hom}(S \rightarrow A)$.

Proof. Every function $f : V(S) \rightarrow [n]$ induces $t^{|V(S)|}$ functions $f' : V(S) \rightarrow [n] \times [t]$, all of the same edge-weight product, by choosing an index $r_v \in [t]$ for each vertex $v \in V(S)$. Conversely, every such function is induced by the function that forgets the second component of the images. ◁

Applying Claim 3 on (12) with $k = n$, and with $A \otimes J_t$ instead of A , we obtain

$$\det_n(A \otimes J_t) = t^n \left(\sum_{\lambda \vdash n} \frac{\text{sgn}(C_\lambda)}{\text{aut}(C_\lambda)} \text{hom}(C_\lambda \rightarrow A) \right) + \sum_{\substack{F \text{ with} \\ |V(F)| < n}} t^{|V(F)|} \alpha_F \text{hom}(F \rightarrow A). \quad (13)$$

We now observe that $\det_n(A \otimes J_t)$ is proportional to t^n . This will allow us to ignore the lower-order graphs F in (13).

► **Claim 4.** We have $\det_n(A \otimes J_t) = t^n \det(A)$.

Proof. By definition of the partial determinant, we have

$$\det_n(A \otimes J_t) = \sum_{\substack{S \subseteq [n] \times [t] \\ \text{with } |S|=n}} \det((A \otimes J_t)[S]).$$

If S contains two pairs that agree in the first component, then the $n \times n$ matrix $(A \otimes J_t)[S]$ contains two equal columns and its determinant vanishes. We can therefore restrict the summation to index sets of the form $S = \{(1, r_1), \dots, (n, r_n)\}$ for $r_1, \dots, r_n \in [t]$. There are t^n sets S of this form, each with $(A \otimes J_t)[S] = A$. The claim follows. ◁

² The Kronecker product $A \otimes B$ can be defined for general A and B , but we only require $B = J_t$.

38:6 Determinants from Homomorphisms

Now consider the polynomial identity (13) again. By Claim 4, the left-hand side equals $t^n \det(A)$. Then comparing the coefficients of t^n on both sides yields

$$\det(A) = \sum_{\lambda \vdash n} \frac{\text{sgn}(C_\lambda)}{\text{aut}(C_\lambda)} \text{hom}(C_\lambda \rightarrow A) \quad (14)$$

$$= \sum_{\lambda \vdash n} (-1)^{n+|\lambda|} \prod_{\ell=1}^n \frac{\text{tr}(A^\ell)^{s_\ell(\lambda)}}{s_\ell(\lambda)! \cdot \ell^{s_\ell(\lambda)}}. \quad (15)$$

For the last equation, we expanded $\text{hom}(C_\lambda \rightarrow A)$ via (7) and $\text{aut}(C_\lambda)$ via (8), and we used the definition of $\text{sgn}(C_\lambda)$. This proves (2).

► **Remark.** The above argument applies more generally. Consider any function $F : \mathbb{Q}^{k \times k} \rightarrow \mathbb{Q}$ that admits a set \mathcal{H} of k -vertex graphs and coefficients $\alpha_H \in \mathbb{Q}$ for $H \in \mathcal{H}$ such that

$$F(A) = \sum_{H \in \mathcal{H}} \alpha_H \text{emb}(H \rightarrow A).$$

By Lemma 1, every $\text{emb}(H \rightarrow A)$ is a sum of $\text{hom}(H \rightarrow A)$ and lower-order homomorphism counts; this yields an analogue of (12). If F vanishes on $k \times k$ matrices with two identical rows/columns, then an analogue of Claim 4 holds, and it follows as above that the lower-order homomorphism counts vanish.

3 Algorithmic applications

Equation (2) does not directly imply a polynomial-time algorithm for the determinant, as the sum over partitions $\lambda \vdash n$ involves a super-polynomial number of terms. Nevertheless, this sum can be computed in polynomial time via dynamic programming or polynomial multiplication, as shown below.

► **Lemma 5.** *Given $\text{tr}(A^\ell)$ for all $1 \leq \ell \leq n$, we can compute $\det(A)$ with $O(n^3)$ operations.*

Proof. Let X be a formal indeterminate. For $1 \leq \ell \leq n$, define the polynomial

$$p_\ell(X) = \sum_{i=0}^{\lfloor n/\ell \rfloor} (-1)^i \frac{\text{tr}(A^\ell)^i}{i! \cdot \ell^i} X^{\ell i}.$$

We observe first that the coefficient of X^n in the product $(-1)^n p_1 \dots p_n$ is the desired sum in (2), and then focus on computing that coefficient.

For the first part, note that the coefficient of X^n can be viewed as a weighted count of all ways to choose a power X^{i_ℓ} from each polynomial p_ℓ , subject to $\sum_\ell \ell \cdot i_\ell = n$. These choices yield a partition $(1^{i_1}, \dots, n^{i_n}) \vdash n$ that is weighted by $\prod_{\ell=1}^n (-1)^{i_\ell} \frac{\text{tr}(A^\ell)^{i_\ell}}{i_\ell! \cdot \ell^{i_\ell}}$. Thus, the coefficient of X^n in $(-1)^n p_1 \dots p_n$ can be viewed as a sum over partitions $\lambda \vdash n$ whose terms correspond to those in (2).

We compute the first $n+1$ coefficients of $(-1)^n p_1 \dots p_n$, including the coefficient of X^n , by iteratively multiplying p_t onto $p_1 \dots p_{t-1}$ and truncating the intermediate result to the first $n+1$ coefficients. Using standard polynomial multiplication, each of the n iterations takes $O(n^2)$ operations. Overall, this procedure requires $O(n^3)$ operations. ◀

By naively iterating matrix multiplication, we can compute $\text{tr}(A^\ell)$ for all $1 \leq \ell \leq n$ with $O(n^{\omega+1})$ overall operations, where ω is the exponent of matrix multiplication. This implies:

► **Theorem 6.** *The determinant $\det(A)$ can be computed with $O(n^{\omega+1})$ operations.*

The traces and subsequent application of (2) can also be computed with arithmetic circuits of constant fan-in and poly-logarithmic depth: Any product of two matrices can be computed trivially in $O(\log n)$ depth and $O(n^3)$ size. Repeated squaring allows us to compute all matrix powers A^ℓ and their traces $\text{tr}(A^\ell)$ for $1 \leq \ell \leq n$ in $O(\log^2 n)$ depth and $\tilde{O}(n^4)$ overall size.

After all traces are computed, the polynomial multiplications from the proof of Lemma 5 can be performed in $O(\log^2 n)$ depth and $\tilde{O}(n^3)$ size: A single polynomial multiplication can be computed in $O(\log n)$ depth and $\tilde{O}(n^2)$ size. The truncation of the product $(-1)^n p_1 \dots p_n$ to the first $n + 1$ coefficients can then be computed as an $O(\log n)$ -depth binary tree, with p_1, \dots, p_n at the leaves, and each internal node performing a polynomial multiplication followed by truncating to the first $n + 1$ coefficients. This implies:

► **Theorem 7.** *The determinant $\det(A)$ can be computed with an arithmetic circuit of constant fan-in, $O(\log^2 n)$ depth, and $\tilde{O}(n^4)$ size.*

Conditional Lower Bounds for Dynamic Geometric Measure Problems

Justin Dallant  

Université libre de Bruxelles, Belgium

John Iacono  

Université libre de Bruxelles, Belgium

Abstract

We give new polynomial lower bounds for a number of dynamic measure problems in computational geometry. These lower bounds hold in the Word-RAM model, conditioned on the hardness of either 3SUM, APSP, or the Online Matrix-Vector Multiplication problem [Henzinger et al., STOC 2015]. In particular we get lower bounds in the incremental and fully-dynamic settings for counting maximal or extremal points in \mathbb{R}^3 , different variants of Klee’s Measure Problem, problems related to finding the largest empty disk in a set of points, and querying the size of the i ’th convex layer in a planar set of points. We also answer a question of Chan et al. [SODA 2022] by giving a conditional lower bound for dynamic approximate square set cover. While many conditional lower bounds for dynamic data structures have been proven since the seminal work of Pătraşcu [STOC 2010], few of them relate to computational geometry problems. This is the first paper focusing on this topic. Most problems we consider can be solved in $O(n \log n)$ time in the static case and their dynamic versions have only been approached from the perspective of improving known upper bounds. One exception to this is Klee’s measure problem in \mathbb{R}^2 , for which Chan [CGTA 2010] gave an unconditional $\Omega(\sqrt{n})$ lower bound on the worst-case update time. By a similar approach, we show that such a lower bound also holds for an important special case of Klee’s measure problem in \mathbb{R}^3 known as the Hypervolume Indicator problem, even for amortized runtime in the incremental setting.

1 Introduction

In 1995, Gajentaan and Overmars [30] introduced the notion of 3SUM hardness, showing that a number of problems in computational geometry can not be solved in subquadratic time, assuming the so-called 3SUM problem can not be solved in subquadratic time.¹ The general approach of proving polynomial lower bounds based on a few conjectures about key problems has since grown into its own subfield of complexity theory known as *fine-grained*

¹ In 2014, Grønlund and Pettie [31] showed that the 3SUM problem can be solved in (slightly) subquadratic time. The modern formulation thus replaces “subquadratic” with “truly subquadratic”, i.e. $O(n^{2-\varepsilon})$ for some constant $\varepsilon > 0$.

complexity. The most popular of these conjectures concern the aforementioned 3SUM problem, All-Pairs-Shortest-Paths (APSP), Boolean Matrix Multiplication (BMM), Triangle finding in a graph, Boolean Satisfiability (SAT) and the Orthogonal Vectors problem (2OV) (see for example the introductory surveys by Bringmann [13] and V. V. Williams [55]). Another problem which crops up as a bottleneck in computational geometry is Hopcroft’s problem (see the recent paper by Chan and Zheng [24]).

Pătraşcu [50] launched the study of such polynomial lower bounds for dynamic problems, where instead of simply computing a function on a single input, we want to be able to update that input and get the corresponding output of the function without having to recompute it from scratch. In particular, he introduced the Multiphase problem and showed a polynomial lower bound on its complexity, conditioned on the hardness of the 3SUM problem. Using the Multiphase problem as a stepping stone, he showed conditional hardness results for a variety of dynamic problems. Improvements and other conditional lower bounds for dynamic problems (data structure problems) have since appeared in the literature [1–3, 5–7, 9, 11, 12, 25, 27, 34, 35, 38, 40, 41, 49, 53]. Of particular interest for the purpose of this work is a paper by Kopelowitz et al. [41] where the approach of Pătraşcu is improved by showing a tighter reduction from 3SUM to the so-called Set Disjointness problem (an intermediate problem between 3SUM and the Multiphase problem), as well as a paper by V. V. Williams and Xu [56], which obtains a similar reduction from the so-called Exact Triangle problem. Also particularly relevant here is the work of Henzinger et al. [34], who show that many of the known bounds on dynamic problems can be derived (and even strengthened) by basing proofs on a hardness conjecture about the Online Boolean Matrix-Vector Multiplication (OMv) problem which they introduce.

While computational geometry was one of first fields where conditional lower bounds for algorithms were applied, for example by showing that determining if a point set is in general position is 3SUM hard [30], the progress in conditional lower bounds for dynamic problems has not found widespread application to computational geometry; recent work has been largely confined to improved upper bounds. The only examples before the first version of this paper² relate to (approximate) nearest-neighbor search under different metrics (see the paper by Rubinfeld [51], the introductory article by Bringmann [14] as well as a preprint by Ko and Song [39]), a paper by Lau and Ritossa [44] with results for orthogonal range update on weighted point sets and an (unconditional) lower bound by Chan [17] for a dynamic version of Klee’s Measure Problem. After a previous version of the present paper appeared on arXiv, and independent of our work, Jin and Xu [37] studied generalized versions of the OMv and BMM problems and proved polynomial lower bounds for various dynamic problems based on their hardness, among which Dynamic 2D Orthogonal Range Color Counting, Counting Maximal Points, Dynamic Klee’s measure problem for unit hypercubes and Chan’s Halfspace Problem.

In this work, we exploit the results of Pătraşcu, Kopelowitz et al., V. V. Williams and Xu, and Henzinger et al. to give conditional polynomial lower bounds for a variety of dynamic problems in computational geometry, based on the hardness of 3SUM, APSP and Online Boolean Matrix-Vector Multiplication. Almost all the problems we study here share the common characteristic of being about computing a single global metric for a set of objects in space subject to updates. Moreover, in the static case (where there are no updates) most of these metrics can be computed in worst-case $O(n \log n)$ time using standard computational

² We exclude from this list examples where (conditional) bounds on the static case trivially imply polynomial bounds on the dynamic case.

geometry results. In particular, we show conditional hardness results for orthogonal range marking, maintaining the number of maximal or extremal points in a set of points in \mathbb{R}^3 , dynamic approximate square set cover, problems related to Klee’s Measure Problem, problems related to finding the largest empty disk in a set of points, testing whether a set of disks covers a given rectangle, and querying for the size of the i ’th convex layer of a set of points in the plane. We also give an unconditional lower bound for the incremental Hypervolume Indicator problem in \mathbb{R}^3 , where the goal is to maintain the volume of the union of a set of axis-aligned boxes which all have the origin as one of their vertices.

The most basic of these problems, and the one we present first, is Square Range Marking: given a set of n initially unmarked points in the plane, preprocess them to allow marking of the points in any given axis-aligned square and testing if there is any unmarked point. This encompasses the idea of augmenting a range query structure where augmentations can be applied to all data in a query range; a mark is the simplest such augmentation. While many variants of augmented orthogonal range queries have been studied (especially in the static case) [4, 21, 22, 32, 33, 36, 42, 45, 46, 52], this natural variant has been given little attention. This is perhaps no coincidence, as we show that the straightforward polynomial-time solution based on kd-trees is likely almost optimal, in contrast to standard 1-D range marking and other augmentation problems which are easily handled by suitable variants of BSTs [26, Ch. 14].

Lau and Ritossa [44] give similar lower bounds for data structures on weighted points, conditioned on the hardness of Online Boolean Matrix-Vector Multiplication, but explicitly leave open questions on points which have a color or a “category.” They show for example a lower bound for a data structure which allows to increment the weight of all points in an orthogonal range and to query the sum of weights for all points in a given range, as well as for variants of this problem.

1.1 Setting and computational model

We work in the standard Word RAM model, with words of $w = \Theta(\log n)$ bits unless otherwise stated, and for randomized algorithms we assume access to a perfect source of randomness. We will base our conditional lower bounds on the following well known hardness conjectures.

► **Conjecture 1** (3SUM conjecture). *The following problem (3SUM) requires $n^{2-o(1)}$ expected time to solve: given a set of n integers in $\{-n^3, \dots, n^3\}$, decide if three of them sum up to 0 .³*

► **Conjecture 2** (APSP conjecture). *The following problem (APSP) requires $n^{3-o(1)}$ expected time to solve: given an integer-weighted directed graph G on n vertices with no negative cycles, compute the distance between every pair of vertices in G .*

The 3SUM problem can easily be solved in $O(n^2)$ time, while APSP can be solved in cubic time by the Floyd–Warshall algorithm, for example. The best known methods improve these runtimes by subpolynomial factors [19, 54].

In addition to being the basis for these standard conjectures in fine-grained complexity, the 3SUM problem and the APSP problem are related in other ways (see [56]). In particular, they both fine-grained reduce to the Exact Triangle problem, meaning that if either the 3SUM conjecture or the APSP conjecture is true, then the following conjecture is true.

³ The assumption that the integers are in $\{-n^3, \dots, n^3\}$ is done without loss of generality. In the model we consider one can always reduce the problem to this setting while preserving the expected run-time, via known hashing methods [8].

► **Conjecture 3** (Exact Triangle conjecture). *The following problem (Exact Triangle) requires $n^{3-o(1)}$ expected time to solve: given an integer-weighted graph G and a target weight T , determine if there is a triangle in G whose edge weights sum to T .*

Thus, any bound conditioned on this conjecture also holds conditioned on the 3SUM conjecture or the APSP conjecture. We also consider a conjecture introduced by Henzinger et al. [34], which can be thought of as a weakening of the informal conjecture which says that “combinatorial” matrix multiplication on $n \times n$ matrices requires essentially cubic time (note that the term “combinatorial” is not well defined).

► **Conjecture 4** (OMv conjecture). *The following problem (OMv) requires $n^{3-o(1)}$ expected time to solve:*

We are given a $n \times n$ boolean matrix M . We can preprocess this matrix, after which we are given a sequence of n boolean column-vectors of size n denoted by v_1, \dots, v_n , one by one. After seeing each vector v_i , we must output the product Mv_i before seeing v_{i+1} .

The OMv problem can be solved in total time $O(n^3)$ by the naive algorithm. Here the best known method improves this runtime by a subpolynomial factor [43]. The conjecture was originally introduced in the Monte-Carlo setting (i.e. algorithms with a deterministic runtime but which are allowed to err with a small enough probability). We state it in the Las Vegas setting for the sake of uniformity of presentation. All the results of Henzinger et al. carry over to that setting with no difficulty.

While Henzinger et al. showed that most known lower bounds on dynamic problems derived from the 3SUM conjecture can be derived from the OMv conjecture (and often even strengthened), it is not known whether one conjecture implies the other. For most of our problems we derive polynomial lower bounds from both the OMv conjecture and the Exact Triangle conjecture. In such cases, we still get such lower bounds if at least one of the four considered conjectures is true. Moreover, the reductions used here could also give bounds in the case some of these conjecture fail by a small enough polynomial factor (for example if 3SUM requires $\Omega(n^{4/3})$ time).

Note also that recent work by Chan et al. [23] directly implies that the lower bounds we obtain from the APSP conjecture also hold in the so-called Real RAM model (conditioned on the analogous Real-APSP conjecture) and in restricted versions of the model. For the real versions of the 3SUM and Exact Triangle conjectures, combining our reductions with theirs would also imply polynomial lower bounds for many of the problems considered here, although weaker than the ones we obtain in the Word RAM model.

1.2 Main results

In the full version of this paper we obtain (conditional) polynomial lower bounds for a variety of dynamic geometric problems, and an unconditional bound for the incremental Hypervolume Indicator problem in \mathbb{R}^3 . Our bounds are stated as inequalities which imply trade-offs between achievable update and query times. The lower bounds we get on the maximum of both are summarized in Table 1, together with known upper bounds. Note that the bounds we get for squares or square ranges imply the same bounds for rectangles or general orthogonal ranges, although we sometimes get better trade-offs in these cases. Here we focus on some results for Square Range Marking, Counting Extremal Points in \mathbb{R}^3 and unweighted Square Set Cover, in the fully-dynamic setting. The other results can be found in the full version [28].

■ **Table 1** Non-trivial known upper bounds and new (at the time of the first version of this paper being made public) lower bounds on the maximum over update and query time derived from the Exact Triangle conjecture, the OMv conjecture or (in the case of the Hypervolume Indicator problem) unconditionally. The \tilde{O} notation hides polylog factors, while the O^* notation hides factors which are $o(n^\varepsilon)$ for an arbitrarily small constant $\varepsilon > 0$. All upper bounds are for data structures with at most $O^*(n)$ preprocessing. Note that the lower bounds for Square Range Marking also hold in the case of a static set of points (with some assumptions on preprocessing time) and that the lower bound for the Depth Problem derived from the OMv conjecture also holds for amortized runtime in the incremental setting. The lower bound obtained for counting maximal points has since been superseded by the more general result of Jin and Xu [37] who obtain lower bounds also in higher dimension.

Problem	Upper Bound	Lower Bound
Square Range Marking [§2.2,28]	$\tilde{O}(n^{1/2})^{\dagger,\ddagger}$ [15]	From Exact Triangle: $n^{1/4-o(1)^{\dagger}}$ From OMv: $n^{1/2-o(1)^{\dagger}}$
Counting Extremal Points in \mathbb{R}^3 [§3,28]	$O^*(n^{7/8})^{\dagger}$ [16]	From Exact Triangle: $n^{1/5-o(1)^{\dagger,\ddagger}}$ $n^{1/4-o(1)^{\ddagger,\S}}$ From OMv: $n^{1/2-o(1)^{\dagger,\ddagger}}$
Largest Empty Disk in Query Region [28]	$O^*(n^{11/12})^{\ddagger}$ [18]	
Largest Empty Disk in a Set of Disks [28]		
Rectangle Covering with Disks [28]		From OMv: $n^{1/2-o(1)^{\dagger,\ddagger}}$
Square Covering with Squares [28]	$\tilde{O}(n^{1/2})^{\ddagger}$ [57]	
Convex Layer Size in \mathbb{R}^2 [28]		
Counting Maximal Points in \mathbb{R}^3 [§3,28]	$\tilde{O}(n^{2/3})^{\ddagger}$ [18]	From Exact Triangle: $n^{1/4-o(1)^{\dagger}}$ $n^{1/3-o(1)^{\ddagger}}$
$O(n^\alpha)$ -approx. Weighted Square Set Cover [28]		From OMv: $n^{1/2-o(1)^{\dagger,\ddagger}}$
Klee's Measure Problem with Squares [28]	$\tilde{O}(n^{1/2})^{\ddagger}$ [57]	
Discrete KMP with Squares [28]	$O(n^{1/2})^{\dagger,\ddagger}$ [58]	
Depth Problem with Squares [28]	$\tilde{O}(n^{1/2})^{\ddagger}$ [57]	From Exact Triangle: $n^{1/3-o(1)^{\dagger,\ddagger}}$ From OMv: $n^{1/2-o(1)^{\dagger,\ddagger}}$
$O(1)$ -approximate Square Set Cover [§4,28]	$O^*(n^{1/2})^{\ddagger}$ [20]	From OMv: $n^{1/3-o(1)^{\dagger,\ddagger}}$
Hypervolume Indicator in \mathbb{R}^3 [28]	$\tilde{O}(n^{2/3})^{\ddagger}$ [18]	$\Omega(\sqrt{n})^{\#}$

[†] per-operation runtime in the incremental setting.

[‡] amortized runtime in the fully-dynamic setting.

[§] assuming $n^{1+o(1)}$ expected preprocessing time.

[#] unconditional lower bound in the incremental setting on amortized time, assuming at most polynomial time preprocessing, or on worst-case time without preprocessing assumptions.

Some of the lower bounds reveal interesting separations between geometric dynamic problems whose operations can be supported in subpolynomial or $O(n^\varepsilon)$ time and similar problems which require polynomial time with a fixed exponent (under the hardness conjectures we consider).

- Orthogonal range queries with dynamic updates on single points can be done with polylog time operations, while dynamic updates on orthogonal ranges of points require polynomial time.
- Dynamically maintaining maximal points in a point set can be done in polylog time in \mathbb{R}^2 , while maintaining only their number in \mathbb{R}^3 already requires polynomial time.
- The same separation between dimensions 2 and 3 applies for maintaining (the number of) extremal points.
- Related to the previous point, the ability to query for the size of any convex layer on a dynamic set of points in \mathbb{R}^2 requires polynomial time (compared to polylog time when we are only interested in the first convex layer, i.e. the convex hull).
- Maintaining a $O(1)$ -approximation for the size of dynamic unit square set cover can be done in $2^{O(\sqrt{\log n})}$ amortized time per update [20], while maintaining the size of a $O(n^\alpha)$ -approximation (for a constant $0 \leq \alpha < 1$) requires polynomial time for arbitrarily sized squares (with an exponent dependent on α).
- In the weighted case of the previous problem, we also get such a separation: $O(1)$ -approximate weighted unit square set cover can be done in $O(n^\varepsilon)$ time [20] while $O(n^\alpha)$ -approximate weighted dynamic square set cover requires polynomial time, with an exponent independent of α .

2 The general approach

In all the problems we consider, we have a data structure D which maintains a set S of $O(n)$ geometric objects, supporting some form of update and query (a query is any operation which never impacts the result of any subsequent operation). We say that a data structure (or that the set of objects it maintains) is *incremental* when it allows updates which consist of inserting a new object in S . We use the term *fully-dynamic* when both insertions and deletions are allowed. The set S can be initialized in a preprocessing phase.

2.1 General reduction schemes

All our reductions have the same basic structure based on a geometric view of Pătraşcu’s Multiphase problem [50], where we encode a family $\mathcal{F} = \{F_1, \dots, F_k\}$ of subsets of $\{1, \dots, m\}$ as a grid of objects where the presence (or absence) of an object at the grid coordinates (x, y) encodes $x \in F_y$. We can then select some of the columns $I \in \{1, \dots, k\}$ and a row $j \in \{1, \dots, m\}$, allowing us to test if $I \cap F_j \neq \emptyset$ efficiently. We abstract some of the commonalities of the reductions in the following “general” reduction schemes, so we can focus on the specifics of each problem and avoid repetitions later on. Rather than give the original definition of the Multiphase problem, let us define what it means for a data structure to solve it, as this will make the statements of reductions easier, more uniform, and makes the required constraints on the data structure we consider explicit.

► **Definition 5** (Solving the Multiphase problem). *Let $\mathcal{F} = \{F_1, \dots, F_k\}$ be a family of k subsets of $\{1, 2, \dots, m\}$. Let $s_{\mathcal{F}} = \sum_{F \in \mathcal{F}} |F|$. Consider a data structure D with an undo operation⁴ which maintains a set S of $O(n)$ objects with expected preprocessing time $O(t_p)$, expected amortized update time $O(t_u)$ and expected amortized query time $O(t_q)$. Suppose it allows us to do the following.*

- (Step 1) *First, we read \mathcal{F} and store a set of n objects in S using only the preprocessing operation of D .*
- (Step 2) *Then, we receive a subset $J \subset \{1, 2, \dots, m\}$ and perform u_J updates on S .*
- (Step 3) *Finally, we are given an index $1 \leq i \leq k$ and after $O(1)$ updates and queries on S we decide if $J \cap F_i \neq \emptyset$.*

Assume that the time of each of these three steps is dominated by the time of the operations on D and that in each step, the only information available from the previous steps is what is accessible through D . Let $t_{uq} = t_q$ if only queries are performed in Step 3, otherwise let $t_{uq} = t_u + t_q$.

We say that such a data structure solves the Multiphase problem.

As mentioned in the introduction, Pătraşcu gave lower bounds on the time required to solve the Multiphase problem conditioned on the 3SUM conjecture and reduced this problem to various dynamic problems. His reduction from 3SUM has since been tightened by Kopelowitz et al. [41] and reductions from the Exact Triangle and OMv conjectures have been found by Vassilevska Williams and Xu [56] and Henzinger et al. [34] respectively.

We summarize the implications from these works for different parameters in the following theorems. While this results in somewhat verbose statements, we chose this approach in order to streamline the reductions in this paper and to make the lower bounds we obtain explicit in terms n .

► **Theorem 6.** *Let D be a data structure which solves the Multiphase problem. If the Exact Triangle conjecture is true (or in particular if either the 3SUM or APSP conjecture is true), then for any $0 < \gamma < 1$:*

- (Scenario 1) *If $n = O(m \cdot k)$ and $u_J = O(m)$, we have*

$$t_p + t_u \cdot n + t_{uq} \cdot n^{\frac{1+\gamma}{3-2\gamma}} = \Omega\left(n^{\frac{2}{3-2\gamma}-o(1)}\right).$$

- (Scenario 2) *If $n = O(m \cdot k)$ and $u_J = O(|J|)$, we have*

$$t_p + t_u \cdot n^{\frac{2-\gamma}{3-2\gamma}} + t_{uq} \cdot n^{\frac{1+\gamma}{3-2\gamma}} = \Omega\left(n^{\frac{2}{3-2\gamma}-o(1)}\right).$$

- (Scenario 3) *If $n = O(s_{\mathcal{F}})$ and $u_J = O(m)$, we have*

$$t_p + t_u \cdot n^{\frac{3-2\gamma}{2-\gamma}} + t_{uq} \cdot n^{\frac{1+\gamma}{2-\gamma}} = \Omega\left(n^{\frac{2}{2-\gamma}-o(1)}\right).$$

- (Scenario 4) *If $n = O(s_{\mathcal{F}})$ and $u_J = O(|J|)$, we have*

$$t_p + t_u \cdot n + t_{uq} \cdot n^{\frac{1+\gamma}{2-\gamma}} = \Omega\left(n^{\frac{2}{2-\gamma}-o(1)}\right).$$

Note that for incremental (or fully-dynamic) data structures where we can insert objects, we can always assume $t_p = O(t_u \cdot n)$ by inserting the $O(n)$ initial objects individually.

⁴ A data structure is said to have an undo operation if for any update U there is complementary update U' so that if U and U' are executed sequentially the results of subsequent operations are identical to the case where U and U' were never executed. This requirement is easily satisfied in structures that maintain a set and have insertion and deletion update operations.

The results of Henzinger et al. [34] imply that whenever we have such lower bounds from the hardness of Exact Triangle, we can get stronger bounds if we assume hardness of the OMv problem instead.

► **Theorem 7.** *Let D be a data structure which solves the Multiphase problem. Assume $n = O(m^{c_1} \cdot k^{c_2})$ for some constants $c_1, c_2 > 0$, $u_J = O(m)$, and the expected preprocessing time t_p is at most polynomial in n . If the OMv conjecture is true, then for any $0 < \gamma < 1$,*

$$t_u \cdot n^\gamma + t_{uq} \cdot n^{\frac{1-c_1\gamma}{c_2}} = \Omega\left(n^{\frac{1+(c_2-c_1)\gamma}{c_2}-o(1)}\right).$$

In particular if $n = O(m \cdot k)$ (as is the case in the four scenarios of Theorem 6), for any $0 < \gamma < 1$ we have $t_u \cdot n^\gamma + t_{uq} \cdot n^{1-\gamma} = \Omega(n^{1-o(1)})$. For $\gamma = 1/2$, we thus have $t_u + t_q = \Omega(n^{1/2-o(1)})$.

These results follow from straightforward adaptations of Pătraşcu’s proofs [50] together with the more recent results from Williams and Xu [56] and Henzinger et al. [34], and are implicit in the two latter papers. To apply these theorems, we need data structures with an undo operation. When considering structures in the fully-dynamic setting where updates consist of inserting or deleting an object, then this requirement is automatically satisfied. For structures with guarantees on the runtime per operation (rather than amortized guarantees), we can use the following standard technique (see for example [47, Theorem 2.1]).

► **Lemma 8.** *Any data structure with guarantees on the runtime per operation (non-amortized) can be augmented to support an undo operation with the same guarantees.*

From now on, whenever we consider a structure with per-operation runtime guarantees, we assume (without loss of generality) that it has been augmented to support undo.

2.2 An example: Square Range Marking

We illustrate the use of these theorems on the following problem.

Square Range Marking. Preprocess a static set of n initially unmarked points, where an update consists of marking all points in a given axis-aligned square range and a query returns if there is any unmarked point in the set.

Here the dynamic part of the problem is rather limited as only the markings of the points can change after an update, the set of points itself is static. The updates are even monotone in the sense that once a point has been marked it is never unmarked (in particular, the number of unmarked points can never increase). Even for this seemingly simple problem, we can use Theorems 6 and 7 to get the following (conditional) polynomial lower bounds.

► **Theorem 9.** *Let D be a data structure for Square Range Marking with t_p expected preprocessing time and t_u expected time per update (i.e. non-amortized). If the Exact Triangle conjecture holds, then*

$$t_p + t_u \cdot \left(n^{\frac{3-2\gamma}{2-\gamma}} + n^{\frac{1+\gamma}{2-\gamma}}\right) + t_q \cdot n^{\frac{1+\gamma}{2-\gamma}} = \Omega\left(n^{\frac{2}{2-\gamma}-o(1)}\right).$$

If the OMv conjecture holds and t_p is at most polynomial then for any $0 < \gamma < 1$

$$t_u \cdot (n^{1-\gamma} + n^\gamma) + t_q \cdot n^{1-\gamma} = \Omega\left(n^{1-o(1)}\right).$$

In particular, by setting $\gamma = 1/2$, we have $t_u + t_q = \Omega(n^{1/2-o(1)})$.

Proof. It suffices to show that such a data structure fits the conditions of Scenario 3 in Theorem 6. Let $\mathcal{F} = \{F_1, \dots, F_k\}$ be a family of k subsets of $\{1, 2, \dots, m\}$.

We perform Step 1 by initializing D with the following points: for each $1 \leq i \leq k$ and $1 \leq j \leq m$ for which $j \in F_i$, we put a point $p_{i,j}$ at coordinates $((k+2)j+1, i+1)$. The total number of points is $n = s_{\mathcal{F}}$.

To perform Step 2 when given $J \subset \{1, 2, \dots, m\}$, we mark the points inside a square range of side-length $k+2$ whose lower-left corner has coordinates $((k+2)j, 1)$, for all $j \notin J$. This requires $O(m)$ updates on D . The unmarked points are exactly the $p_{i,j}$'s such that $j \in J$.

In Step 3, when given an index $1 \leq i' \leq k$, we mark the points inside the two squares of side-length $(k+2)m$ whose lower-left corners lie at coordinates $(0, i'+1/2)$ and $(0, i'-(k+2)m-1/2)$ respectively. Now there is an unmarked point if and only if there is some point $p_{i,j}$ such that $j \in J$ and $p_{i,j}$ was not marked by these two last updates. This is the case if and only if $i = i'$. By construction, such a point exists if and only if there is some $j \in J$ such that $j \in F_{i'}$ (i.e. $J \cap F_{i'} \neq \emptyset$). Thus, we can answer a Step 3 query after two more updates to D .

By applying Theorems 6 and 7 we get the result. \blacktriangleleft

If we assume truly subquadratic expected preprocessing time we get polynomial lower bounds on t_u or t_q from the Exact Triangle conjecture. The bounds from the OMv conjecture are almost tight, as an upper bound can easily be obtained by taking a two-dimensional kd-tree [10] and augmenting it by adding markers to the nodes indicating if the points in the corresponding subtrees are marked. We then get a data structure with $O(n \log n)$ worst-case preprocessing time and $O(\sqrt{n})$ worst-case time per update. As noted by Cardinal et al. [15], using standard dynamization techniques such a data structure can even be made to support insertion and deletion of points in $O(\log^2 n)$ worst-case time.

3 Counting the number of extremal points in \mathbb{R}^3

We show polynomial lower bounds for the following problem, which in the plane can be solved in polylog worst-case time per operation by known techniques [48].

Counting Extremal Points in \mathbb{R}^3 . Maintain a dynamic set of $O(n)$ points in \mathbb{R}^3 and allow for queries counting the number of extremal points in the set.

► **Theorem 10.** *Let D be a fully-dynamic data structure for Extremal Points in \mathbb{R}^3 with t_p expected preprocessing time, t_u expected amortized update time and t_q expected amortized query time. If the Exact Triangle conjecture holds, then*

$$t_p + t_u \cdot \left(n^{\frac{2-\gamma}{3-2\gamma}} + n^{\frac{1+\gamma}{3-2\gamma}} \right) + t_q \cdot n^{\frac{1+\gamma}{3-2\gamma}} = \Omega \left(n^{\frac{2}{3-2\gamma}-o(1)} \right).$$

If the OMv conjecture holds, then for any $0 < \gamma < 1$, $t_u \cdot (n^{1-\gamma} + n^\gamma) + t_q \cdot n^{1-\gamma} = \Omega(n^{1-o(1)})$. In particular, by setting $\gamma = 1/2$, we have $t_u + t_q = \Omega(n^{1/2-o(1)})$.

Because we can assume $t_p = O(t_u \cdot n)$ this also implies that under the Exact Triangle conjecture we have $t_u = \Omega(n^{1/5-o(1)})$.

Before proving this theorem, let us introduce some notation. We let $\mathcal{F} = \{F_1, \dots, F_k\}$ be a family of k subsets of $\{1, \dots, m\}$, where $m, k \geq 5$. Here we work in cylindrical coordinates (r, θ, z) (where this would denote the point $(r \cos \theta, r \sin \theta, z)$ in Cartesian coordinates).

Let $R = 4k^2m^2$. For all $0 \leq i \leq k$ and $1 \leq j \leq m$, let $q_{i,j}$ be the point with cylindrical coordinates $(R - (2i+1)^2, \frac{2\pi}{m}j, 2i+1)$. Similarly, for all $1 \leq j \leq m$ and $1 \leq i \leq k$ such that $j \in F_i$, let $p_{i,j}$ be the point with cylindrical coordinates $(R - (2i)^2, \frac{2\pi}{m}j, 2i)$. We let $S_{\mathcal{F}}$ denote the set consisting of all these points.

■ **Figure 1** Illustration (not to scale) of the set of points obtained for $m = k = 5$ and the family of sets $\mathcal{F} = \{\{1\}, \{2\}, \dots, \{5\}\}$. The points $q_{\bullet, \bullet}$ are represented in white, the points $p_{\bullet, \bullet}$ in black and all these points lie on the translucent gray surface. The points b_{\bullet} are represented with a cross in a white circle and are above the translucent gray surface. The asterisks represent the points of the form t_{\bullet} and lie on the axis of rotational symmetry of the translucent gray surface.

For all $1 \leq j \leq m$, we let b_j denote the point with cylindrical coordinates $(R-1, \frac{2\pi}{m}j, 2k+2)$. For all $1 \leq i \leq k+1$, we let t_i denote the point lying on the longitudinal axis (the z -axis) at height $\frac{R+(2i-1)^2}{2(2i-1)}$. Note that for all $1 \leq i_1 \leq i_2 \leq k+1$, the point t_{i_1} is higher on the z -axis than t_{i_2} and that all points t_{\bullet} have a larger z -coordinate than all other previously defined points. See Figure 1 for an illustration.

► **Lemma 11.** *Let S be a set of points such that $S_{\mathcal{F}} \subset S \subset S_{\mathcal{F}} \cup \{b_j \mid 1 \leq j \leq m\} \cup \{t_i \mid 1 \leq i \leq k\}$. Let $1 \leq j' \leq m$ and $1 \leq i' \leq k$. Then:*

- *The point $q_{0, j'}$ is extremal.*
- *The point $q_{i', j'}$ is extremal if and only if $b_{j'} \notin S$ and for all $1 \leq i \leq i'$, $t_i \notin S$. If $p_{i', j'} \in S$ (i.e. $j' \in F_{i'}$), then the same holds for $p_{i', j'}$.*
- *If $t_{i'} \in S$, then $t_{i'}$ is extremal if and only if for all $1 \leq i < i'$, $t_i \notin S$.*

Moreover, this remains true even if all points are arbitrarily perturbed by moving them a distance of at most $1/R^2$.

See the full version of the paper [28] for the proof of this lemma.

Proof of Theorem 10. It suffices to show that such a data structure fits the conditions of Scenario 2 in Theorem 6. Let $\mathcal{F} = \{F_1, \dots, F_k\}$ be a family of k subsets of $\{1, 2, \dots, m\}$. We use the notation of Lemma 11. We first describe the procedure without discussing issues of finite precision and later show how this can be carried out on a Word RAM machine with words of $O(\log n)$ bits.

We perform Step 1 by initializing D with all points of the form $q_{\bullet, \bullet}$, $p_{\bullet, \bullet}$ and b_{\bullet} . This costs t_u expected time, for a total number of points $n = \Theta(m \cdot k)$.

To perform Step 2 when given $J \subset \{1, 2, \dots, m\}$, we delete the points b_j for all $j \in J$. This requires $O(|J|)$ updates on D .

In Step 3, when given an index $1 \leq i' \leq k$ we start by inserting the point $t_{i'+1}$ to D and getting the count c of extremal points. By Lemma 11, the extremal points of S at this point are exactly those of the following 6 types:

1. the point $t_{i'+1}$,
2. the points b_j for all j such that $j \notin J$,
3. the points $q_{i,j}$ for all i, j such that $j \in J$ and $i < i'$,
4. the points $p_{i,j}$ for all i, j such that $j \in F_i$, $j \in J$ and $i < i'$.
5. the points $q_{i',j}$ for all j such that $j \in J$,
6. the points $p_{i',j}$ for all j such that $j \in F_{i'}$ and $j \in J$.

To answer the query, we want to know if the number of points of the last type is greater than 0. We know that the number of points of the fifth category is exactly $|J|$. Notice that if we now insert $t_{i'}$ to D and get the new count c' of extremal points, we are counting exactly the first four categories of points, where we have replaced $t_{i'+1}$ with $t_{i'}$. Thus, we can test if the number of points of the last category is 0 simply by testing if $c - c' = |J|$. We can thus perform Step 3 with $O(1)$ updates.

We can adapt this to work on a Word RAM machine with words of length $w \geq \log n$ by moving the points to vertices of the integer lattice (after appropriate scaling). This is detailed in the full version of the paper [28]. By applying Theorems 6 and 7 we get the result. \blacktriangleleft

In the fully-dynamic setting, Chan [18] gives a data structure for this problem with $O(n^{1+\varepsilon})$ preprocessing time and $O(n^{11/12+\varepsilon})$ amortized update and query time, for an arbitrary $\varepsilon > 0$. In the more restricted semi-online setting (which generalizes the incremental case), another paper by the same author [16] gives a data structure with $O(n^{1+\varepsilon})$ preprocessing time and $O(n^{7/8+\varepsilon})$ worst-case time per operation.

4 Dynamic geometric Set Cover with squares

In this section we answer a question by Chan et al. [20], by giving a conditional polynomial lower bound on the time required to approximately maintain (the size of) a dynamic square set cover in the plane under range updates.

Dynamic Square Set Cover. Maintain a set S of n points and axis-aligned squares in the plane to support queries asking for the size of the smallest subset of squares which covers all points.

Even the static version of this problem with unit squares is NP-complete [29], thus the focus on approximations. Chan et al. [20] recently gave a $O(1)$ -approximate solution in the fully dynamic case where both squares and points may be inserted or deleted. This (Monte Carlo randomized) solution achieves $O(n^{1/2+\varepsilon})$ amortized update and query time. The authors ask if there is a conditional polynomial lower bound for this problem. We show the following.

► **Theorem 12.** *Let $0 \leq \alpha < 1$ be an efficiently computable⁵ constant. If there is a fully-dynamic data structure for $O(n^\alpha)$ -approximate Dynamic Square Set Cover with t_u expected amortized update time and t_q expected query time, then the Multiphase problem can be solved with $n = O\left(k^{1/(1-\alpha)} \cdot m^{2/(1-\alpha)^2}\right)$, $t_{uq} = t_u + t_q$ and $u, J = O(m)$.*

⁵ We say that a number α is efficiently computable if there is an algorithm which, for any $k \geq 0$, can output the first k bits of α in $O(\text{poly}(k))$ time.

■ **Figure 2** Illustration (not to scale) of the instance obtained after Step 2 in the proof of Theorem 12, for a data structure with a constant approximation ratio of $\beta = 3/2$. The illustrated instance has $m = 4$, $k = 3$, $\mathcal{F} = \{\{1, 2, 3\}, \{2, 4\}, \{2\}\}$, $J = \{1, 4\}$ and $c = 10$.

Together with Theorem 7 this implies polynomial lower bounds under the OMv conjecture, for all $0 \leq \alpha < 1$. In particular, for $\alpha = 0$ (i.e. for a constant approximation factor) it implies $t_u + t_q = \Omega(n^{1/3 - o(1)})$.

Proof. We first prove the result in the case of arbitrary axis-aligned rectangles and then show how to adapt it to use only squares. Let $\mathcal{F} = \{F_1, \dots, F_k\}$ be a family of k subsets of $\{1, 2, \dots, m\}$. Suppose D achieves an approximation ratio of at most $\beta \cdot n^\alpha$ for some constant integer $\beta > 1$ (we can assume this without loss of generality). Let c be an integer value which we specify later.

We perform Step 1 by initializing D with the following points and rectangles:

- for each $1 \leq i \leq k$ and $1 \leq j \leq m$ for which $j \in F_i$, we put a point $p_{i,j}^a$ at coordinates $(c \cdot j + a, i)$ for each $0 \leq a < c$;
- for each $1 \leq j \leq m$ and each $0 \leq a < c$, we put a thin vertical rectangle which covers exactly the points of the form $p_{\bullet,j}^a$.

The total number of points and rectangles at this point is $n_1 = s_{\mathcal{F}} + m \cdot c \leq m \cdot (k + 1) \cdot c$. Set c to be the smallest integer such that $c > \beta(n_1 + m + 2)^\alpha \cdot (m + 2)$ (note that the value of n_1 depends on c , but c is nonetheless well defined and can be computed in $O(\text{polylog}(m \cdot k))$ time). We then have $n_1 = O(k^{1/(1-\alpha)} \cdot m^{2/(1-\alpha)^2})$.

To perform Step 2 when given $J \subset \{1, 2, \dots, m\}$, we insert a rectangle covering all points of the form $p_{\bullet,j}^a$ for each $j \notin J$. This requires $O(m)$ updates on D . See Figure 2 for an illustration of the first two steps.

In Step 3, when given an index $1 \leq i' \leq k$, we insert two rectangles: the first covers all points $p_{i,\bullet}^a$ with $i < i'$ and the second covers all points $p_{i,\bullet}^a$ with $i > i'$. The total number of points and rectangles at this point is $n \leq n_1 + m + 2$. Now, if $J \cap F_{i'} = \emptyset$ then all points can be covered with at most $m + 2$ rectangles: the (at most) m rectangles inserted in step 2 together with the two rectangles inserted in Step 3. On the other hand, if there is some $j \in J \cap F_{i'}$, then the points of the form $p_{i,j}^a$ can only be covered by choosing c thin rectangles created in Step 1. Thus, any approximation of the set cover with a ratio better than $\frac{c}{m+2}$ suffices to distinguish between the two cases. Moreover, we have $\frac{c}{m+2} > \beta \cdot (n_1 + m + 2)^{\alpha \frac{m+2}{m+2}} \geq \beta \cdot n^\alpha$. We can then answer a Step 3 query by asking the data structure for a $\beta \cdot n^\alpha$ approximation of the size of the minimum set cover.

To see how to adapt this reduction using only squares, notice that we can increase the height of any rectangle without affecting the results. Thus, we can stretch the whole configuration of points and rectangles horizontally until the thinnest vertical rectangles become squares, and adjust the heights of the other rectangles to make them squares as well. ◀

Contrast this lower bound with the case of *unit* axis-aligned squares, for which Chan et al. [20] give a data structure for $O(1)$ -approximation achieving $2^{O(\sqrt{\log n})}$ amortized update and query time.

A Simpler QPTAS for Scheduling Jobs with Precedence Constraints

Abstract

We study the classical scheduling problem of minimizing the makespan of a set of unit size jobs with precedence constraints on parallel identical machines. Research on the problem dates back to the landmark paper by Graham from 1966 who showed that the simple List Scheduling algorithm is a $(2 - \frac{1}{m})$ -approximation. Interestingly, it is open whether the problem is NP-hard if $m = 3$ which is one of the few remaining open problems in the seminal book by Garey and Johnson. Recently, quite some progress has been made for the setting that m is a constant. In a breakthrough paper, Levey and Rothvoss presented a $(1 + \epsilon)$ -approximation with a running time of $n^{(\log n)^{O((m^2/\epsilon^2) \log \log n)}}$ [STOC 2016, SICOMP 2019] and this running time was improved to quasi-polynomial by Garg [ICALP 2018] and to even $n^{O_{m,\epsilon}(\log^3 \log n)}$ by Li [SODA 2021]. These results use techniques like LP-hierarchies, conditioning on certain well-selected jobs, and abstractions like (partial) dyadic systems and virtually valid schedules.

In this paper, we present a QPTAS for the problem which is arguably simpler than the previous algorithms. We just guess the positions of certain jobs in the optimal solution, recurse on a set of guessed subintervals, and fill in the remaining jobs with greedy routines. We believe that also our analysis is more accessible, in particular since we do not use (LP-)hierarchies or abstractions of the problem like the ones above, but we guess properties of the optimal solution directly.

1 Introduction

A classical problem in scheduling theory is the problem to schedule jobs on parallel machines in order to minimize the makespan, while obeying precedence constraints between the jobs. It goes back to the 1966 when Graham proved in his seminal paper [5] that the simple List Scheduling algorithm yields a $(2 - \frac{1}{m})$ -approximation algorithm. Formally, the input consists of a set J of n jobs, a number of machines $m \in \mathbb{N}$, and each job $j \in J$ is characterized by a processing time $p_j \in \mathbb{N}$. We seek to schedule them non-preemptively on m machines in order to minimize the time when the last job finishes, i.e., to minimize the makespan. Additionally, there is a precedence order \prec which is a partial order between the jobs. Whenever $j \prec j'$ for two jobs $j, j' \in J$ then job j' can only be started when j has already finished. Given that the List Scheduling algorithm is essentially a simple greedy routine, one may imagine that one can achieve a better approximation ratio with more sophisticated algorithmic techniques. However, Svensson showed that even for unit size jobs (i.e., $p_j = 1$ for each $j \in J$) there can be no $(2 - \epsilon)$ -approximation algorithm for any $\epsilon > 0$ [9], assuming a variant of the Unique Games Conjecture. Hence, under this conjecture List Scheduling is the essentially best possible algorithm. Slight improvements are known for unit size jobs: there is an algorithm by Coffman and Graham [1] which computes an optimal solution when $m = 2$, and a which is a $(2 - \frac{2}{m})$ -approximation algorithm for general m , as shown by Lam and Sethi [6]. Also, there is an $(2 - \frac{7}{3m+1})$ -approximation algorithm known

due to Gangal and Ranade [2]. In fact, the setting of unit-size jobs is interesting since then the complexity of the problem stems purely from the precedence constraints and not from the processing times of the jobs (which might encode problems like PARTITION). We assume this case from now.

In practical settings m might be small, e.g., m might be the number of processors in a system, or the number of cores of a CPU. Thus, it is a natural question whether better approximation ratios are possible when m is a constant. Note that the mentioned lower bound of $2 - \epsilon$ [9] does not hold if $m = O(1)$. For $m = 2$ the mentioned algorithm by Coffman and Graham [1] computes an optimal solution; however, even if $m = 3$ it is not known whether the problem is NP-hard! In fact, it is one of the few remaining open problems in the book by Garey and Johnson [3].

In a break-through result, Levey and Rothvoss presented a $(1 + \epsilon)$ -approximation with a running time of $n^{(\log n)^{O((m^2/\epsilon^2) \log \log n)}}$ [7]. Subsequently, the running time was improved by Garg [4] to $n^{O_{m,\epsilon}(\log^{O(m^2/\epsilon^2)} n)}$ which is quasi-polynomial. Both algorithms are based on the natural-LP relaxation of the problem, (essentially) lifted by a certain number r of rounds of the Sherali-Adams hierarchy, and it can be solved in time $n^{O(r)}$. Given the optimal LP-solution x^* , they *condition* on certain variables in the support of x^* , which effectively fixes time slots for the corresponding jobs. Each conditioning operation changes not only the variable that one conditions on, but possibly also other variables in the support. After a well-chosen set of conditioning operations, they recurse into smaller subintervals and give each of them a copy of the current LP-solution (which might be different from x^* due to the conditioning operations). Intuitively, in each recursive call for some subinterval I they seek to schedule jobs that can only be scheduled during I according to the previous conditionings and the precedence constraints; they call these jobs *bottom jobs* and the other jobs *top* and *middle jobs*. The middle jobs can be discarded. For the top jobs, they first use a matching argument to show that most of the top jobs can be inserted if one can ignore the precedence constraints between top jobs. Knowing this, they insert most of the top jobs with a variation of Earliest-Deadline-First (EDF), such that all precedence constraints are satisfied; some of the top jobs are discarded in the process. The discarded jobs are later inserted in a greedy manner which is affordable since they are very few.

A different approach is used by Li [8] who improved the running time further to $n^{O_{m,\epsilon}(\log^3 \log n)}$. Instead of working with an LP, he guesses directly certain properties of the optimal solution. While in the above argumentation each conditioning step costs a factor $n^{O(1)}$ in the running time, he argues that – roughly speaking – most of the time the information he guesses is binary and hence costs only a factor of 2 in the running time. More precisely, he guesses properties of a technical abstraction based on *dyadic systems*, *partial dyadic systems*, and *virtually valid schedules*. On a high level, he shows that based on the optimal schedule one can define a corresponding dyadic system and a virtually valid schedule for it, at the cost of discarding a few jobs. His algorithm then searches for the dyadic system and a virtually valid schedule for it that discards as few jobs as possible. Then, he shows that based on them, he can construct an actually valid schedule, which discards only few additional jobs.

1.1 Our Contribution

In this paper we present a QPTAS for the makespan minimization problem with unit size jobs on a constant number of machines along with precedence constraints ($Pm|prec, p_j = 1|C_{\max}$ in the three-field notation) which is arguably simpler than the $(1 + \epsilon)$ -approximation algorithms

sketched above. We do not use an LP-formulation and in particular no LP-hierarchy or a similar approach based on conditioning on variables. Instead, we guess properties of the optimal solution directly, similarly as Li [8]. However, we do not use the reduction to dyadic systems or a similar abstraction but work with the optimal solution directly. We believe that this makes the algorithm and the analysis easier to understand. Our running time is $n^{O_{m,\epsilon}((\log n)^{m/\epsilon})}$ so it is asymptotically better than the running time by Garg [4] up to hidden constants.

Our algorithm is actually pretty simple. Let T be the optimal makespan (which we guess). For a parameter $k = (\log n)^{O(1)}$ we guess the placement of k jobs in OPT and a partition of $[0, T)$ into at most k intervals. For each interval I , there are some jobs that need to be scheduled during I according to our guesses and the precedence constraints. We recurse on each interval I and its corresponding jobs. Then, we add all remaining jobs with a simple variant of EDF where the release dates and deadlines are defined such that the precedence constraints between these jobs and the other jobs (that we recursed on) are satisfied. For the correct guesses, we show that the resulting schedule discards at most $O(\epsilon T)$ jobs, and we add those jobs at the end with a simple greedy routine.

In our analysis, we use a hierarchical decomposition of intervals, like the previous results [8, 7, 4]. In contrast to those, we define the decomposition such that each interval is subdivided into $O(\log n/\epsilon)$ subintervals (instead of 2 subintervals) since this makes the analysis easier. Based on the optimal solution, for each level we identify certain jobs that we want to guess in that level later. Also, we assign a level to each job. Via a shifting step, we show that we can discard the jobs from intuitively every (m/ϵ) -th level. Based on these levels, we argue that there are guesses for our algorithm that yield a small total number of discarded jobs. Intuitively, we guess the jobs from the first m/ϵ levels that we identified above and the intervals of the $(m/\epsilon + 1)$ -th level. We recurse on the latter intervals. When we insert the jobs of the first m/ϵ levels via EDF (those jobs that we did not guess already), the jobs from our recursion and their precedence constraints dictate for each inserted job j a time window $[r_j, d_j)$. It might happen that the position of j in the optimal solution is not contained in $[r_j, d_j)$, but we show that it is always contained in the larger time window of $[r_j - \lambda, d_j + \lambda)$ for a small value $\lambda > 0$. We show that we need to discard at most $O(mT \frac{\epsilon}{\log n})$ jobs to compensate for this error and due to the precedence constraints between the inserted jobs. We analyze EDF directly and do not need to go via a matching argumentation as done in [7]. It turns out that our algorithm recurses for at most $O(\frac{\epsilon}{m} \log n)$ levels and hence this yields $O(\frac{\epsilon \log n}{m} \cdot mT \frac{\epsilon}{\log n}) = O(\epsilon^2 T)$ discarded jobs in total.

While our analysis borrows ideas from the mentioned previous results [8, 7, 4] we believe that our algorithm and our analysis are simpler and more accessible.

2 Algorithm

We present a simple QPTAS for the problem $Pm|prec, p_j = 1|C_{\max}$. Let $\epsilon > 0$ and assume w.l.o.g. that $1/\epsilon \in \mathbb{N}$. We guess $T := \text{OPT}$ and assume w.l.o.g. that T is a power of 2 (if this is not the case, then we can add some dummy jobs that need to be processed after all other jobs; note that a $(1 + \epsilon)$ -approximate solution for this larger instance is a $(1 + 2\epsilon)$ -approximate solution for the original instance). Also, w.l.o.g. we assume that in OPT each job starts and ends at an integral time point, i.e., during a time interval of the form $[t, t + 1)$ for some $t \in \mathbb{N}$. We will refer to such a time interval as a *time slot*. Furthermore, we assume that w.l.o.g. that the precedence constraints are transitive, i.e., if $j \prec j'$ and $j' \prec j''$ then also $j \prec j''$.

Our algorithm works on a “guess and recurse” framework. Define a parameter $k := (m \log n / \varepsilon)^{m/\varepsilon+1}$. The reader can think of the parameter k as $O_{m,\varepsilon}((\log n)^{m/\varepsilon+1})$, where $O_{m,\varepsilon}()$ hides constants that are only dependent on m, ε . Our algorithm has three steps. First, we guess up to k jobs from OPT and their time slots in OPT, i.e., we try all combinations of up to k input jobs and all combinations for their time slots to schedule them. Then, we guess a partition of $[0, T)$ into at most k intervals, i.e., we try all combinations of partitioning $[0, T)$ into at most k intervals. By allowing empty intervals, we assume w.l.o.g. that we guess exactly k intervals and denote them by I_1, \dots, I_k . Let J_{guess} denote the guessed jobs. There might be precedence constraints between jobs in J_{guess} and jobs in $J \setminus J_{guess}$. In particular, these precedence constraints might dictate that some job $j \in J \setminus J_{guess}$ needs to be scheduled within some interval I_j . In this case, we say that j is a *bottom job*. Let $J_{bottom} \subseteq J \setminus J_{guess}$ denote the set of all bottom jobs. We call each job $j \in J \setminus (J_{guess} \cup J_{bottom}) =: J_{top}$ a *top job*.

Given our guess for the jobs J_{guess} and their time slots and our guessed partitioning of $[0, T)$, we make k recursive calls: one for each interval I_i with $i = 1, 2, \dots, k$. Let us denote by $J_{bottom}^{(i)}$ the subset of jobs in J_{bottom} that need to be scheduled within I_i according to our guesses above, and let $J_{guess}^{(i)}$ denote the jobs in J_{guess} for which we guessed a time slot within I_i . We make a recursive call on the interval I_i whose input are the jobs $J_{bottom}^{(i)} \cup J_{guess}^{(i)}$ and the guessed time slots for the jobs in $J_{guess}^{(i)}$. In this recursive call, we want to compute a schedule in which

- all jobs in $J_{guess}^{(i)}$ are scheduled in the time slots that we had guessed for them,
- a (hopefully very large) subset of the jobs in $J_{bottom}^{(i)}$ are scheduled; we denote by $J_{disc}^{(i)} \subseteq J_{bottom}^{(i)}$ the jobs in $J_{bottom}^{(i)}$ that were not scheduled, we call them the *discarded jobs*, and
- we obey the precedence constraints between the jobs in $J_{bottom}^{(i)} \cup J_{guess}^{(i)}$. We ignore all precedence constraints that involve the jobs in $J_{disc}^{(i)}$.

Suppose that we are given a solution from each recursive call. We define $J_{disc} := \bigcup_{i=1}^k J_{disc}^{(i)}$. We ignore these discarded jobs for now. We want to schedule the jobs in J_{top} . Recall that these are jobs in $J \setminus J_{bottom} \cup J_{guess}$. To this end, for each job $j \in J_{top}$ we define an artificial release date r_j and an artificial deadline d_j . Let $j \in J_{top}$. We define r_j to be the earliest start time of an interval I_i at which each job $j' \in J_{guess} \cup J_{bottom}$ with $j' \prec j$ has completed; we define $r_j := 0$ if there is no such job j' . Similarly, we define d_j to be the latest end time of an interval I_i at which no job $j'' \in J_{guess} \cup J_{bottom}$ with $j \prec j''$ has already started; again, if there is no such job j'' we define $d_j := T$. In order to find slots for the jobs in J_{top} we use the following variation of the Earliest Deadline First (EDF) algorithm. We sweep the time axis from left to right. For each time $t = 0, 1, 2, \dots$ we consider the not yet scheduled jobs $j \in J_{top}$ with $r_j \leq t$ whose predecessors in $J_{guess} \cup J_{bottom} \setminus J_{disc}$ we have already scheduled before time t . We sort these jobs non-decreasingly by their deadlines (breaking ties arbitrarily) and add them in this order to the machines that are idle during $[t, t+1)$. We do this until no more machine is idle during $[t, t+1)$. It might happen that a job $j \in J_{top}$ misses its deadline at the current time t , i.e., it holds that $t = d_j$ but j has not been scheduled by us at any slot $r_j \leq t' \leq t$ and during $[t', t'+1)$ all machines are busy. In this case we add j to the set J_{disc} . Among all our guesses for the jobs and the partition into intervals, we output the solution in which at the very end the smallest number of jobs is in the set J_{disc} (breaking ties arbitrarily).

Each recursive call for an interval works similarly as the main call of the recursion described above. The (straightforward) differences are the following: the input of each recursive call consists of the interval \bar{I} , a set of jobs \bar{J}_{guess} which were guessed in previous levels in the recursion, together with their guessed time slots, and a set of (not yet scheduled)

jobs \bar{J} . We guess the time slots for up to k guessed jobs $J_{guess} \subseteq \bar{J}$, and we require that these guesses do not violate the precedence constraints with the jobs in \bar{J}_{guess} . Also, we guess a partition of I into k intervals (rather than a partition of $[0, T)$). The input for each recursive call for a subinterval \bar{I}_i of \bar{I} consists of \bar{I}_i , $\bar{J}_{guess} \cup J_{guess}$, and the jobs in \bar{J} that need to be scheduled within \bar{I}_i according to our guesses for $\bar{J}_{guess} \cup J_{guess}$. We return the computed schedule for \bar{I} for a subset of the jobs $\bar{J}_{guess} \cup \bar{J}$ and the discarded jobs in $\bar{J}_{guess} \cup \bar{J}$.

If the algorithm is called on an interval of length 1 then we skip the step of partitioning the interval further into at most k subintervals (and in particular we do not recurse anymore). We will show later that there are guesses that lead to an $(1 + \epsilon)$ -approximate solution such that the recursion depth is $\frac{\epsilon}{m} \log n$. In order to enforce that the recursion depth is $\frac{\epsilon}{m} \log n$ (limiting the running time of the algorithm), we define that a recursive call at recursion depth $\frac{\epsilon}{m} \log n + 1$ simply outputs a solution in which all of the jobs in \bar{J} are discarded and the algorithm does not recurse further.

After running the recursive algorithm described above, we need to schedule the jobs in J_{disc} . Intuitively, for each such job $j \in J_{disc}$ we create an empty time slot that we add into our schedule and inside which we schedule j . This will increase our makespan by $|J_{disc}|$. Formally, we consider the jobs $j \in J_{disc}$ in an arbitrary order. For each job $j \in J_{disc}$ we determine a time t such that all its predecessors in our current schedule have finished by time t , but none of its successors in our current schedule have started yet. Such a time t always exists since we show later that we obtain a feasible schedule for all jobs in $J \setminus J_{disc}$ and we assumed that the precedence constraints are transitive. We insert an empty time slot $[t, t + 1]$ into our schedule, i.e., we move all jobs scheduled during $[t, \infty)$ by one unit to the right, and we schedule j during $[t, t + 1]$. This completes the description of our algorithm.

3 Analysis

In this section, we prove that the above algorithm is a QPTAS.

► **Lemma 1.** *The above algorithm runs in time $n^{(\log n)^{O_{m,\epsilon}(m/\epsilon)}}$.*

Proof. For the running time, we observe that there are at most $n^{O(k)}$ choices for the guessed k jobs, at most $T^{O(k)} = (n)^{O(k)} = n^{O(k)}$ choices for their time slots, and similarly $n^{O(k)}$ choices for the at most k intervals that we guess. Since we bound the recursion depth to be at most $\log n + 1$, this yields a running time of $n^{O(k \log n)} = n^{(\log n)^{O_{m,\epsilon}(m/\epsilon)}}$. ◀

Now we prove the approximation ratio of our algorithm. To this end, we define guesses for jobs and their time slots and intervals in each call of our recursion, such that for these guesses our algorithm outputs a schedule with makespan at most $1 + 6\epsilon$.

3.1 Laminar family of intervals

For this, we define a laminar family \mathcal{L} of intervals. Recall that we assumed that T , the guessed makespan, is a power of 2. We define that the entire interval $[0, T)$ forms the (only) interval of level 0. Let us define $\rho = \lceil \log(\log n / \epsilon) \rceil$. Consider an interval I of some level $\ell = 0, 1, 2, \dots$ (we will argue the number of levels later). If $|I| \geq 2^\rho$ then I is partitioned into $2^\rho = \Theta(\log n / \epsilon)$ equal-sized intervals of length $|I|/2^\rho$. These intervals constitute the level $\ell + 1$ of the family \mathcal{L} . For each interval $I \in \mathcal{L}$, we denote by $\ell(I)$ the level of I .

If $1 < |I| < \rho$ then I is partitioned into $|I|$ intervals of level $\ell + 1$ of length 1 each. If $|I| = 1$ then I is not partitioned further.

► **Lemma 2.** *The total number of levels in the laminar family \mathcal{L} is at most $\log n / \log(\log n / \varepsilon) + 1$.*

Proof. By construction, each interval at a particular level $\ell = 0, 1, 2, \dots$ is of equal length. Hence the length of an interval at level ℓ is at most $T / (\log n / \varepsilon)^\ell$. Further, once the length of intervals of a level becomes less than $2^p \leq 2 \log n / \varepsilon$, there could only be one additional level where every interval is of length 1. Hence the total number of levels could be at most $\log T / \log(\log n / \varepsilon) + 1 \leq \log n / \log(\log n / \varepsilon) + 1$ ◀

3.2 Gussed, top, and bottom jobs

Next, we assign the jobs to levels. More precisely, for each level ℓ we define a set of *gussed jobs* $J_{guess}^{(\ell)}$ and a set of *top jobs* $J_{top}^{(\ell)}$. The intuition is that later we want to guess the jobs in $\bigcup_{\ell'=0}^{\ell} J_{guess}^{(\ell')}$ and the jobs in $\bigcup_{\ell'=0}^{\ell} J_{top}^{(\ell')}$ will form top jobs. We say that a *chain of jobs* is a set of jobs $J' = \{j_1, j_2, \dots, j_c\}$ for some $s \in \mathbb{N}$ such that $j_i \prec j_{i+1}$ for each $i \in \{1, \dots, c-1\}$, and we say that c is the *length* of the chain.

We define these sets $J_{guess}^{(\ell)}$ and $J_{top}^{(\ell)}$ level by level in the order $\ell = 0, 1, 2, \dots$. Consider a level ℓ . Let I be an interval of level ℓ . We initialize $J_{guess}^{(\ell)} = J_{top}^{(\ell)} = \emptyset$. Our plan is that we add jobs to $J_{guess}^{(\ell)}$ step by step. Let J_I denote the jobs that can only be scheduled during I , assuming that we schedule the jobs in $J_{guess}^{(0)} \cup \dots \cup J_{guess}^{(\ell-1)}$ exactly as in OPT. We say that a job $j \in J_I$ is *flexible* if it can still be scheduled in more than one subinterval of level $\ell + 1$ of I , assuming that we schedule the jobs in $J_{guess}^{(0)} \cup \dots \cup J_{guess}^{(\ell)}$ exactly as in OPT. Suppose that there is a chain $J' \subseteq J_I \setminus J_{guess}^{(\ell)}$ of length at least $\varepsilon |I| / 2^{\lceil \log \log n \rceil}$ that contains only flexible jobs. Then for each interval I' of level $\ell + 1$ we add to $J_{guess}^{(\ell)}$ the first and the last job from J' that is scheduled during I' in OPT. If we guess these jobs in our algorithm, the effect is that each job in J' that we did *not* add to $J_{guess}^{(\ell)}$ can be scheduled only during one interval of level $\ell + 1$. Hence, one way to think of this procedure is that we push these jobs one level down. We do this operation until there is no more chain J' of length at least $\varepsilon |I| / 2^{\lceil \log \log n \rceil}$ that contains only flexible jobs. We define that $J_{top,I}^{(\ell)}$ contains all remaining flexible jobs in J_I . We do this procedure for each interval I of level ℓ , and define at the end $J_{top}^{(\ell)} := \bigcup_I J_{top,I}^{(\ell)}$.

► **Proposition 3.** *For every job $j \in J$, there exists a unique $\ell \in \{0, 1, 2, \dots, \rho\}$ such that $j \in J_{top}^{(\ell)}$.*

3.3 Few rejected jobs

With the preparation above, we will show that there are guesses of our algorithm for the gussed jobs and the intervals that lead to few discarded jobs overall, at most $O(\varepsilon T)$ many. Since the algorithm selects the guesses that lead to the minimum total number of discarded jobs, we will show that it computes a solution with at most $O(\varepsilon T)$ discarded jobs. We need some preparation for this. First, we establish that we can afford to discard all jobs in sets $J_{top}^{(a+r \cdot m/\varepsilon)}$ for $r \in \mathbb{N}_0$, for some offset a .

► **Lemma 4.** *There is an offset $a \in \{0, 1, \dots, \frac{m}{\varepsilon} - 1\}$ such that $\left| \bigcup_{r \in \mathbb{N}_0} J_{top}^{(a+r \cdot m/\varepsilon+1)} \right| \leq \varepsilon T$.*

Proof. For every $a \in \{0, 1, \dots, \frac{m}{\varepsilon} - 1\}$, we define $\mathcal{L}_a = \{\ell : \ell = (a + r \cdot m/\varepsilon + 1), r \in \mathbb{N}_0\}$ and the set $\bigcup_{\ell \in \mathcal{L}_a} J_{top}^{(\ell)}$. Now Proposition 3 implies that the resulting sets $\bigcup_{\ell \in \mathcal{L}_a} J_{top}^{(\ell)}$ are pairwise disjoint. Since T is the optimal makespan, the total number of jobs cannot exceed mT . Hence, there exists some $a \in \{0, 1, \dots, \frac{m}{\varepsilon} - 1\}$ such that $|\bigcup_{\ell \in \mathcal{L}_a} J_{top}^{(\ell)}| \leq \varepsilon T$. ◀

For the root problem of the recursion, we will show that the following guesses lead to few discarded jobs overall: the guessed subintervals are the subintervals of the laminar family at level $a + 1$ where a which is the offset as identified by the above lemma. The guessed jobs are all jobs in $\bigcup_{\ell=0}^a J_{guess}^{(\ell)}$ and we guess their time slots in OPT. We recurse on the guessed intervals of level $a + 1$ of the laminar family. Suppose that in some level $r \in \mathbb{N}$ of the recursion we are given as input an interval \bar{I} of some level $\ell_r = a + (r - 1) \cdot m/\epsilon$ of the laminar family, together with a set of jobs of the form $\bar{J} = \bar{J}_{bottom} \dot{\cup} \bar{J}_{guess}$ such that for each job $j \in \bar{J}_{guess}$ we are given a (guessed) time slot that equals the time slot in OPT during which j is executed, but we are not given a time slot for any job in \bar{J}_{bottom} . We will show that the following guesses lead to few discarded jobs overall: we guess the intervals of level $\ell_{r+1} = a + r \cdot m/\epsilon + 1$ of the laminar family; the guessed jobs are all jobs in $\bar{J}_{bottom} \cap \bigcup_{\ell=a+(r-1)\cdot m/\epsilon+1}^{a+r\cdot m/\epsilon} J_{guess}^{(\ell)}$ that are scheduled in \bar{I} in OPT and we guess their time slots in OPT.

With the next lemma, we prove inductively that there are few discarded jobs. We define $r_{\max} := \lceil \epsilon(\log n / \log \log n + 1) / m \rceil$ which is an upper bound on the number of recursion levels that we need in this way.

► **Lemma 5.** *Consider a recursive call of our algorithm in which the input is of the following form:*

- *an interval \bar{I} such that $\bar{I} = [0, T)$ (we define $r = 0$ in this case) or \bar{I} is an interval of some level $\ell_r = a + (r - 1) \cdot m/\epsilon$ of the laminar family, for some $r \in \mathbb{N}$,*
- *a set of jobs $\bar{J} = \bar{J}_{bottom} \dot{\cup} \bar{J}_{guess}$ such that*
 - *for each job $j \in \bar{J}_{guess}$ we are given a time slot that coincides with the time slot during which j is scheduled in OPT,*
 - *each job $j \in \bar{J}_{bottom}$ is scheduled during \bar{I} in OPT.*

Then our algorithm returns a schedule for \bar{J} in which at most

$$\sum_{\ell' \in \mathcal{L}_a} \sum_{\bar{I}' \in \mathcal{L}(\bar{I}') = \ell' \wedge \bar{I}' \subsetneq \bar{I}} \left| J_{top, \bar{I}'}^{(\ell')} \right| + \frac{5m\epsilon}{\log n} (r_{\max} - r) |\bar{I}| \quad (1)$$

jobs are discarded.

Our goal is now to prove Lemma 5. Consider a recursive call of our algorithm of the form specified in Lemma 5 for some $r \in \mathbb{N}$. If $r = r_{\max}$ then our algorithm simply enumerates over all possible schedules for \bar{J}_{bottom} and thus finds a schedule in which no job is discarded (since this is the case in OPT). Suppose by induction that the claim is true for all $r \geq r^* + 1$ for some r^* . We want to prove that it is true also for $r = r^*$ so we consider such a recursive call. Let \tilde{J}_{guess} denote the guessed jobs and let $\tilde{I}_1, \dots, \tilde{I}_k$ denote the guessed partition of \bar{I} into subintervals, according to our description right before Lemma 5. Let $\tilde{J}_{top} \subseteq \bar{J}$ and $\tilde{J}_{bottom} \subseteq \bar{J}$ denote the resulting set of top and bottom jobs, respectively (thus, the sets $\bar{J}, \bar{J}_{guess}, \bar{J}_{bottom}$ are part of the input, while the sets $\tilde{J}_{guess}, \tilde{J}_{top}, \tilde{J}_{bottom}$ and intervals $\tilde{I}_1, \dots, \tilde{I}_k$ stem from our guesses). Recall that for each job $j \in \tilde{J}_{top}$ we define a release time r_j and a deadline d_j in our algorithm. Let λ denote the length of each interval \tilde{I}_i (note that they all have the same length), i.e., the length of the intervals of level $\ell_{r+1} = a + r \cdot m/\epsilon + 1$ (where $r = 0$ in the root problem of the recursion). Note that $\lambda \leq |\bar{I}| / (\log n / \epsilon)^{m/\epsilon+1}$. We show in the next lemma that in OPT each job $j \in \tilde{J}_{top}$ is essentially scheduled during $[r_j, d_j]$ and thus r_j and d_j are almost consistent with OPT.

► **Lemma 6.** *For each job $j \in \tilde{J}_{top}$ it holds that in OPT the job j is scheduled during $[r_j - \lambda, d_j + \lambda)$.*

Proof. Let us recall that for each job $j \in \bar{J}_{top}$ the release time r_j is defined to be the earliest start time of an interval $\tilde{I}_i, i = 1, 2, 3, \dots, k$ such that every job $j' \in \bar{J}_{guess} \cup \bar{J}_{bottom}$ with $j' \prec j$ is completed before r_j . We want to prove in OPT the job j does not start before time $r_j - \lambda$. Let $\hat{I} = [t_1, t_2]$ denote the interval of level $\ell_{r+1} = a + r \cdot m/\epsilon + 1$ for which $t_2 = r_j$ (and observe that $t_2 = t_1 + \lambda$). By definition of r_j , there exists a job $j' \in \bar{J}_{guess} \cup \tilde{J}_{guess} \cup \tilde{J}_{bottom}$ with $j' \prec j$ that completes in \hat{I} in the schedule that we obtained from the recursive call in \hat{I} . Since we assumed that our guessed time slots for the jobs in $\bar{J}_{guess} \cup \tilde{J}_{guess}$ are identical to the corresponding time slots in OPT, we conclude that also in OPT the job j' is scheduled during \hat{I} . Thus, in OPT the job j cannot start before time $t_1 = r_j - \lambda$. An analogous argument shows that j cannot be scheduled in OPT after $d_j + \lambda$. ◀

We want to show now that our variant of EDF discards only few jobs from \tilde{J}_{top} . To this end, we partition \tilde{J}_{top} into the sets $\tilde{J}_{top,1} := \tilde{J}_{top} \cap \bigcup_{\ell=a+(r-1) \cdot m/\epsilon+1}^{a+r \cdot m/\epsilon} J_{top}^{(\ell)}$ and $\tilde{J}_{top,2} := \tilde{J}_{top} \cap J_{top}^{(a+r \cdot m/\epsilon+1)}$. We can afford to discard all jobs in $\tilde{J}_{top,2}$, see (1), but we need to bound the number of discarded jobs in $\tilde{J}_{top,1}$. For a job $j \in \tilde{J}_{top}$ it can happen that $r_j = d_j$. In this case we say that j is *degenerate*. Note that a degenerate job is always discarded.

► **Lemma 7.** *There are at most $2m\epsilon|\bar{I}|/\log n$ degenerate jobs in $\tilde{J}_{top,1}$.*

Proof. Consider any job $j \in \tilde{J}_{top,1}$. By definition, there exist two adjacent intervals $I' = [t'_1, t'_2), I'' = [t'_2, t'_3)$ such that $\ell(I') = \ell(I'') = a + r \cdot m/\epsilon$ such that j can be potentially scheduled during both the intervals as dictated by the guessed jobs \bar{J}_{guess} . Thus, if j is degenerate, then $r_j = d_j = t'_2$. Further, by Lemma 6, all jobs $j \in \tilde{J}_{top,1}, r_j = d_j = t'_2$ must be scheduled in OPT in the interval $[t'_2 - \lambda, t'_2 + \lambda]$. Hence the total number of such jobs is upper bounded by

$$\begin{aligned} & m \cdot 2\lambda |\{I' : I' \in \mathcal{L} \wedge \ell(I') = a + r \cdot m/\epsilon \wedge I' \subset \bar{I}\}| \\ & \leq 2m \cdot (\log n/\epsilon)^{m/\epsilon} \cdot \frac{|\bar{I}|}{(\log n/\epsilon)^{m/\epsilon+1}} \\ & = 2m\epsilon|\bar{I}|/\log n \end{aligned} \quad \blacktriangleleft$$

Our goal now is to bound the number of discarded non-degenerate jobs in $\tilde{J}_{top,1}$. We partition \bar{I} into *meta-intervals* $\hat{I}_1, \hat{I}_2, \dots, \hat{I}_{k'}$ with $k' \leq k$ with the properties that each interval $\hat{I}_i \in \{\hat{I}_1, \hat{I}_2, \dots\}$ is of the form $\hat{I}_i = [t_1, t_2)$ for some $t_1, t_2 \in \mathbb{N}$ such that

- each value t_1, t_2 is the start or the end point of some interval in $\tilde{I}_1, \dots, \tilde{I}_k$,
- at time t_2 there is no (non-degenerate) job $j \in \tilde{J}_{top}$ pending that was released before t_2 ,
- for each $t \in [t_1, t_2)$ such that t is the start or end point of some interval in $\tilde{I}_1, \dots, \tilde{I}_k$, some non-degenerate job $j \in \tilde{J}_{top}$ is pending at time t .

Now the intuition is that during each meta-interval $\hat{I}_i = [t_1, t_2)$ EDF tries to schedule only jobs that OPT schedules during $[t_1 - \lambda, t_2 + \lambda)$ (due to Lemma 6), so essentially we have enough space on our machines to schedule all these jobs. We might waste space due to the precedence constraints. However, this space is bounded via the following lemma.

► **Lemma 8.** *Let \tilde{I}_i be an interval such that at each time $t \in \tilde{I}_i$ some job $j \in \tilde{J}_{top}$ is pending. Then during \tilde{I}_i there are at most $|\tilde{I}_i| \frac{\epsilon}{\log n}$ time slots $[t, t+1)$ with $t \in \mathbb{N}$ such that some machine is idle during $[t, t+1)$.*

Proof. For the interval $\hat{I}_i = [t_1, t_2)$, let $J_{\hat{I}_i}$ denote the subset of jobs in $j \in \tilde{J}_{top,1}$ such that $r_j \leq t_1$. We now create a partition of $J_{\hat{I}_i}$ according to the precedence constraints. Let $J_0 \subseteq J_{\hat{I}_i}$ denote the jobs whose preceding jobs have been either scheduled or discarded

before t_1 . For every $p = 1, 2, \dots, \eta$ (where η is some positive integer), let J_p denote the set of jobs $j \in J_{\hat{I}_i}$ for which there exists a job $j' \in J_{p-1}$ such that $j' \prec j$ and there is no job $j'' \in J_{\hat{I}_i} \setminus J_{p-1}$ such that $j'' \prec j$.

Let $\tau_1, \tau_2, \tau_3, \dots, \tau_{\eta'}$ be defined such that the time slots $[\tau_1, \tau_1 + 1), [\tau_2, \tau_2 + 1), \dots, [\tau_{\eta'}, \tau_{\eta'} + 1)$ are exactly the time slots during \hat{I}_i such that some machine is idle for the entire respective time slot. We claim that any job $j' \in \tilde{J}_{top}$ that is pending at the end of a time slot $[\tau_q, \tau_q + 1)$ with $q = \{1, 2, 3, \dots\}$ must belong to J_p for some $p > q$. We prove this by induction. Since no jobs are released inside \hat{I}_i , no job in J_0 is pending at time $\tau_0 + 1$ since otherwise this would contradict the definition of our variant of EDF and the fact that a machine is idle during $[\tau_0, \tau_0 + 1)$. Now assume the hypothesis to be true for the time slots $[\tau_1, \tau_1 + 1), [\tau_2, \tau_2 + 1), \dots, [\tau_q, \tau_q + 1)$ for some q and consider the time slot $[\tau_{q+1}, \tau_{q+1} + 1)$. If a job $j' \in \tilde{J}_{top}$ is pending at time $\tau_q + 1$ then $j' \in J_{p'}$ for some $p' > q$ by the induction hypothesis. This means that all jobs in $\bigcup_{p=0}^q J_p$ have completed before time $\tau_q + 1$. Hence, the jobs in J_{q+1} can be scheduled at any time after time $\tau_q + 1$. Suppose that there is a pending job j at time $\tau_{q+1} + 1$. Since a machine is idle during $[\tau_{q+1}, \tau_{q+1} + 1)$ we have that $j \in J_{p'}$ for some $p' > q + 1$ since otherwise our variant of EDF would have scheduled j during $[\tau_{q+1}, \tau_{q+1} + 1)$. By our construction of the guessed, top and bottom jobs in Section 3.2 the length of the longest chain of the jobs in \tilde{J}_{top} is at most $\varepsilon |\tilde{I}_i| / 2^{\lceil \log \log n \rceil} \leq |\tilde{I}_i| \frac{\varepsilon}{\log n}$. Therefore, $\eta' \leq \eta \leq |\tilde{I}_i| \frac{\varepsilon}{\log n}$ which completes our proof. \blacktriangleleft

Also, we show that there are only few meta-intervals which – together with the argumentation above – yields the following lemma.

► **Lemma 9.** *The total number of discarded non-degenerate jobs in $\tilde{J}_{top,1}$ is at most $m|\bar{I}| \left(\frac{2\varepsilon}{\log^2 n} + \frac{\varepsilon}{\log n} \right)$.*

Proof. Consider a meta-interval \hat{I}_i . Let j be the last non-degenerate job in $\bar{J}_{top,1}$ that is discarded during \hat{I}_i . Let t_1 denote the beginning of the interval \hat{I}_i . We know that d_j is the end point of some interval $\tilde{I}_{i'}$. Since j is non-degenerate we know that $[r_j, d_j] \neq \emptyset$ and by definition of \hat{I}_i this implies that at each time $t \in [t_1, d_j]$ there is some job from \bar{J}_{top} pending. Using Lemma 8, the total number of (wasted) idle slots across all machines during $[t_1, d_j]$ is at most $m\varepsilon|[t_1, d_j]|/m \log n$.

We further invoke Lemma 6 to argue that all jobs in \tilde{J}_{top} that we schedule or discard during $[t_1, d_j]$ are scheduled in OPT during $[t_1 - \lambda, d_j + \lambda)$. The maximum number of jobs that OPT could have scheduled during $[t_1 - \lambda, d_j + \lambda)$ is hence $m(d_j - t_1 + 2\lambda)$. Since our wasted space during $[t_1, d_j]$ is at most $m\varepsilon|[t_1, d_j]|/m \log n$, we conclude that we discard at most

$$m(d_j - t_1 + 2\lambda) - m(d_j - t_1) + \frac{\varepsilon}{\log n}(d_j - t_1) = 2\lambda m + \frac{\varepsilon}{\log n}(d_j - t_1)$$

jobs during $[t_1, d_j]$. By definition, for each job $j \in \bar{J}_{top,1}$ we have that $j \in J_{top}^{(\ell)}$ for some level ℓ with $\ell \leq a + (r + 1) \cdot m/\varepsilon - 1$. Thus, for such a job j we have that r_j and d_j lie in different intervals of level $a + (r + 1) \cdot m/\varepsilon$ of \mathcal{L} . Thus, if during a meta-interval \hat{I}_i a job $j \in \bar{J}_{top,1}$ is discarded, then \hat{I}_i has non-empty intersection with at least two different intervals of level $a + (r + 1) \cdot m/\varepsilon$ of \mathcal{L} . Hence, there can be at most $(\log n/\varepsilon)^{m/\varepsilon-1}$ such meta-intervals. We conclude that in total we discard at most

$$(\log n/\varepsilon)^{m/\varepsilon-1} \cdot 2\lambda m + \frac{\varepsilon}{\log n} |\bar{I}| \leq m \frac{2|\bar{I}|(\log n/\varepsilon)^{m/\varepsilon-1}}{(\log n/\varepsilon)^{m/\varepsilon+1}} + \frac{\varepsilon}{\log n} |\bar{I}| \leq m|\bar{I}| \left(\frac{2\varepsilon}{\log^2 n} + \frac{\varepsilon}{\log n} \right)$$

jobs in $\bar{J}_{top,1}$. \blacktriangleleft

40:10 A Simpler QPTAS for Scheduling Jobs with Precedence Constraints

Now we are ready to bound the total number of discarded jobs using Lemmas 7, 9, and the induction hypothesis.

Proof of Lemma 5. We shall prove the lemma for the input interval \bar{I} at level $\ell_{r^*} = a + (r^* - 1) \cdot m/\varepsilon$. By induction hypothesis, suppose (1) is true for all $r \geq r^* + 1$. Hence, applying our recursive algorithm with the input intervals $\tilde{I}_i, i = 1, 2, \dots, k$ returns a schedule where number of discarded jobs is at most

$$\sum_{\ell' \in \mathcal{L}_a} \sum_{\bar{I}' \in \mathcal{L}: \ell(\bar{I}') = \ell' \wedge \bar{I}' \subsetneq \tilde{I}_i} \left| J_{top, \bar{I}'}^{(\ell')} \right| + \frac{5m\varepsilon}{\log n} (r_{\max} - (r^* + 1)) |\tilde{I}_i| \quad (2)$$

Summing (2) over all $i = 1, 2, \dots, k$ and observing that $\bar{I} = \bigcup_{i=1}^k \tilde{I}_i$ yields that the total number of discarded jobs is at most

$$\sum_{\ell' \in \mathcal{L}_a} \sum_{\bar{I}' \in \mathcal{L}: \ell(\bar{I}') = \ell' \wedge \bar{I}' \subsetneq \bar{I}} \left| J_{top, \bar{I}'}^{(\ell')} \right| + \frac{5m\varepsilon}{\log n} (r_{\max} - (r^* + 1)) |\bar{I}| \quad (3)$$

We would now like to prove the statement for $r = r^*$. Now at the recursive call at level $r = r^*$ with the input subinterval $|\bar{I}|$ consider the guesses as described in the preceding discussion. Using Lemmas 9 and 7, the total number of jobs rejected from $\tilde{J}_{top,1}$ under these guesses is at most

$$2\varepsilon m |\bar{I}| / \log n + m |\bar{I}| \left(\frac{2\varepsilon}{\log^2 n} + \frac{\varepsilon}{\log n} \right) \leq 5m\varepsilon |\bar{I}| / \log n \quad (4)$$

Further, we could have potentially rejected all the jobs in $\tilde{J}_{top,2}$. The total number of such jobs is

$$|\tilde{J}_{top,2}| = \sum_{\bar{I}' \in \mathcal{L}: \ell(\bar{I}') = \ell', \ell' = a + r^* \cdot m/\varepsilon} \left| J_{top, \bar{I}'}^{(\ell')} \right| \quad (5)$$

Adding the above two quantities (4) and (5) to the quantity (3) and observing that our recursive algorithm selects the guesses at a particular level that minimizes the number of discarded jobs, the lemma holds for a recursive call at level r^* . ◀

► **Lemma 10.** *Our algorithm computes a solution with a makespan of at most $(1 + 6\varepsilon)T$.*

Proof. The input at the top level recursive call in our algorithm is an interval $\bar{I} = [0, T)$ and the entire set of jobs J . Plugging in $r = 0$ in Lemma 5 and using Lemma 4, the first term in (1) is bounded by $\sum_{\ell' \in \mathcal{L}_a} |J_{top}^{\ell'}| \leq \varepsilon T$. Since $r_{\max} := \lceil \varepsilon(\log n / \log \log n + 1) / m \rceil$, the second term for $r = 0$ in (1) bounded by $5\varepsilon^2 T / (\log \log n + 1)$.

Hence, the number of discarded jobs in our algorithm is upper bounded by $6\varepsilon T$. All the other jobs are scheduled within the interval $[0, T)$. We potentially need to introduce one additional time-slot of the form $[t, t + 1)$ for each discarded job. We observe that for each discarded job j we can find a position to insert a time-slot for j since we assumed the precedence constraints to be transitive and we obtained a feasible schedule for all non-discarded jobs. Hence, the total length of the schedule is at most $(1 + 6\varepsilon)T$. ◀

Combining Lemma 10 and Lemma 1 gives us the following theorem.

► **Theorem 11.** *There exists an algorithm for the precedence constrained scheduling on identical parallel machines that is a $(1 + \varepsilon)$ -approximation and runs in time $n^{O_{m,\varepsilon}((\log n)^{m/\varepsilon})}$.*

Abstract

Since the celebrated PPAD-completeness result for Nash equilibria in bimatrix games, a long line of research has focused on polynomial-time algorithms that compute ε -approximate Nash equilibria. Finding the best possible approximation guarantee that we can have in polynomial time has been a fundamental and non-trivial pursuit on settling the complexity of approximate equilibria. Despite a significant amount of effort, the algorithm of Tsaknakis and Spirakis [36], with an approximation guarantee of $(0.3393 + \delta)$, remains the state of the art over the last 15 years. In this paper, we propose a new refinement of the Tsaknakis-Spirakis algorithm, resulting in a polynomial-time algorithm that computes a $(\frac{1}{3} + \delta)$ -Nash equilibrium, for any constant $\delta > 0$. The main idea of our approach is to go beyond the use of convex combinations of primal and dual strategies, as defined in the optimization framework of [36], and enrich the pool of strategies from which we build the strategy profiles that we output in certain bottleneck cases of the algorithm.

1 Introduction

The notion of *Nash equilibrium* has been undoubtedly a fundamental solution concept in strategic games, ever since the seminal result of Nash [33], on the existence of equilibria for all finite games. Nash’s theorem however is only *existential*; it only shows that such an equilibrium always exists, but it does not provide an efficient algorithm to find one. In fact, many years after the work of Nash, in a series of breakthrough results, it was proven that computing a Nash equilibrium is PPAD-complete [16], even for *bimatrix* games [10], which provides strong evidence that computing an equilibrium is an intractable problem.

These negative results have naturally led to the study of *approximate* Nash equilibria. In an ε -approximate Nash equilibrium (ε -NE), no player can increase her payoff more than ε , by unilaterally changing her strategy. In contrast to exact Nash equilibria, the relaxation

to ϵ -NE does admit subexponential algorithms. More precisely, the quasi polynomial-time approximation scheme (QPTAS) of [27] can find an ϵ -NE in time $n^{O(\log n/\epsilon^2)}$, for a game with n available pure strategies per player. One can then wonder whether the QPTAS could be improved to a PTAS or even a FPTAS. Unfortunately this does not seem to be the case, as the result of Chen, Deng, and Teng [10] already ruled out the existence of an FPTAS, unless $\text{PPAD}=\text{P}$. Some years later, in another breakthrough result, Rubinfeld [35] showed that, assuming the exponential-time hypothesis for PPAD, there exists a very small, yet unspecified, constant ϵ^* such that finding an ϵ -NE requires quasi polynomial time for every constant $\epsilon < \epsilon^*$. This would rule out a PTAS too.

Although it seems unlikely to have a polynomial time algorithm for any $\epsilon > 0$, it is still important to identify the best constant ϵ for which we can have an efficient algorithm. In fact, this has been one of the fundamental questions of algorithmic game theory, that is still unresolved. Soon after the initial PPAD-hardness results of [10, 16], there was a flourish of works along this direction. Kontogiannis, Panagopoulou, and Spirakis [23] derived a polynomial-time algorithm for $\epsilon = 3/4$; Daskalakis, Mehta, and Papadimitriou [17, 18] improved it to $\epsilon = 1/2$ and $\epsilon \approx 0.382$; Bosse, Byrka, and Markakis [7] achieved $\epsilon = 0.364$; and finally Tsaknakis and Spirakis [36] attained a bound of $\epsilon = 0.3393 + \delta$, for any constant $\delta > 0$. Ever since this last work however, the progress on this front has stalled, and the result of Tsaknakis and Spirakis (referred to as the TS algorithm from now on) remains the state of the art over the last 15 years. It is particularly puzzling that so far, it has remained an open problem to even improve the approximation to $1/3 + \delta$ (even though it has been conjectured that such an approximation should be feasible). To make things worse, in the very recent work of [12], it was shown that the TS algorithm and its analysis are tight.

In order to beat the 0.3393-guarantee of the TS algorithm, it is instructive to understand first its bottleneck cases. At a high level, we can think of the algorithm as consisting of two phases: the *Descent phase* and the *Strategy-construction phase*. In the Descent phase, it performs “gradient descent” on the maximum regret among the two players, i.e., the maximum additional gain that a player can have by a unilateral deviation to another strategy. This process terminates at an approximate “stationary” point, i.e., a strategy profile such that any local change does not decrease the value of the maximum regret. When we reach a δ -stationary point for some small constant δ , the Strategy-construction phase begins. This phase performs a case analysis, based on certain relevant parameters of the game, and tries to decide which strategy profile to output in each of the five cases that arise.

In doing so, the algorithm has at its disposal the δ -stationary profile, along with a “dual” strategy profile (produced by solving the dual of the linear program used in the Descent phase). A close inspection reveals that one of these two profiles suffices to guarantee a $(\frac{1}{3} + \delta)$ -NE in three out of the five cases. In the remaining two cases, the algorithm outputs a convex combination of the stationary and the dual strategies, and this is where the bottleneck occurs, causing the algorithm to output a $(0.3393 + \delta)$ -NE.

Our contribution

We improve upon the state of the art and provide a polynomial-time algorithm for computing a $(\frac{1}{3} + \delta)$ -NE in bimatrix games, for any constant $\delta > 0$. More specifically, we modify sufficiently the TS algorithm by designing an *improved* Strategy-construction phase to handle the problematic cases of TS. Our main insights in doing so are as follows:

- Apart from convex combinations between primal (stationary) and dual strategies, we also consider best response strategies to such convex combinations. Hence, we enrich the pool of strategies, out of which we choose the profile to output in each case. As a result,

in the cases where the δ -stationary point or the dual profile (or their combinations) do not have the desired guarantee, we have one of the players use a carefully chosen convex combination between our newly defined strategies and her dual strategy.

- We produce a more refined case analysis, that is based on the values of some new auxiliary parameters (e.g., the quantities v_r, t_r and $\hat{\mu}$, defined in Section 4). These parameters encode payoff differences or regrets of the players for using specific strategies, and they help us in two ways. First, they are used to obtain improved upper bounds on the maximum regret of the δ -stationary profile (Section 4.1). Secondly, their values greatly help us in decomposing our analysis into convenient subcases in order to establish the approximation guarantee.

Further related work

A different notion of approximation of NE is that of ε -well-supported NE (ε -WSNE). In an ε -WSNE every player is required to place positive probability only to actions that are within ε of being best responses. Hence, ε -WSNE are more constrained than ε -NE, where the players can place a positive probability on any strategy. After a series of papers on the topic [24, 21], the currently best approximation is for $\varepsilon = 0.6528$ due to [14].

Another line of research has focused on more structured classes of bimatrix games such as: constant-rank games, where the matrix defined by the sum of the two payoff matrices has constant rank [1, 22, 31]; win-lose games, where the payoff for every pure action is either 0 or 1 [11, 13, 28]; sparse games, where there are only “a few” outcomes that yield a non-zero payoff for each player [9], imitation games, where the payoff matrix for one of the players is the identity matrix [29, 30, 32]; random games, where the payoff entries are drawn from certain distributions [4, 34]; symmetric games, where the payoff matrix of one player is the transpose of the other [15, 25]. In most of these classes, it has been possible to obtain improved approximation guarantees and have a better understanding of how to construct approximate equilibria.

Concerning quasi-polynomial algorithms, in addition to the QPTAS of [27], three new QPTASs have been obtained, which contain the original result of [27] as a special case: [5] gave a refined, parameterized, approximation scheme; [3] gave a QPTAS that can be applied to multi-player games as well; [19] gave a more general approach for approximation schemes for the existential theory of the reals. More recently, more negative results for ε -NE were derived: [26] gave an unconditional lower bound, based on the sum of squares hierarchy; [6] proved PPAD-hardness in the smoothed analysis setting; [8, 20, 2] gave quasi-polynomial time lower bounds for constrained ε -NE, under the exponential time hypothesis.

2 Preliminaries

In what follows, let $[n] := \{1, 2, \dots, n\}$, and let Δ^n denote the $(n - 1)$ -dimensional simplex. We focus on $n \times n$ bimatrix games, where n denotes the number of available pure strategies per player. Such games are defined by a pair $(R, C) \in [0, 1]^{n \times n}$ of two matrices: R and C are the payoff matrices for the *row* player and the *column* player respectively. We follow the usual assumption in the relevant literature that the matrices are normalized, so that all entries are in $[0, 1]$. It is also assumed without loss of generality, that both players have the same number of pure strategies, since otherwise one can add dummy strategies to equalize the rows and columns. The semantics of the payoff matrices are that when the row player picks a row $i \in [n]$, and the column player picks a column $j \in [n]$, then they receive a payoff of R_{ij} and C_{ij} respectively.

41:4 A Polynomial-Time Algorithm for 1/3-NE in Bimatrix Games

A *mixed strategy* is a probability distribution over $[n]$. We use $\mathbf{x} \in \Delta^n$ to denote a mixed strategy for the row player and x_i to denote the probability the player assigns to the pure strategy i . For the column player, we use $\mathbf{y} \in \Delta^n$ and y_i , respectively. If \mathbf{x} and \mathbf{y} are mixed strategies for the row and the column player, then we call (\mathbf{x}, \mathbf{y}) a (*mixed*) *strategy profile*. It is often also convenient to represent pure strategies as vectors. Hence, we will use the vector e_i , which has 1 at index i and zero elsewhere, to denote the i -th pure strategy, in other words the distribution where a player assigns probability one to play the pure strategy i .

Given a strategy profile (\mathbf{x}, \mathbf{y}) , the expected payoff of the row player is $\mathcal{R}(\mathbf{x}, \mathbf{y}) := \mathbf{x}^T R \mathbf{y}$, and the expected payoff of the column player is $\mathcal{C}(\mathbf{x}, \mathbf{y}) := \mathbf{x}^T C \mathbf{y}$. Thus, for a pure strategy e_i , the term $\mathcal{R}(e_i, \mathbf{y}) := \sum_j R_{ij} y_j$, denotes the expected payoff of the row player, when she plays the pure strategy i against strategy \mathbf{y} of the column player. Similarly, $\mathcal{C}(\mathbf{x}, e_j)$ is the expected payoff of the column player when she plays the pure strategy j against \mathbf{x} . We say that a pure strategy is a *best-response strategy* for a player if it maximizes her expected payoff against a chosen strategy of her opponent. So, under a strategy profile (\mathbf{x}, \mathbf{y}) , the set of pure best responses for the row player is $B_r(\mathbf{y}) := \{i \in [n] : \mathcal{R}(e_i, \mathbf{y}) = \max_{i' \in [n]} \mathcal{R}(e_{i'}, \mathbf{y})\}$, and for the column player, it is $B_c(\mathbf{x}) := \{j \in [n] : \mathcal{C}(\mathbf{x}, e_j) = \max_{j' \in [n]} \mathcal{C}(\mathbf{x}, e_{j'})\}$.

The *regret* of the row player at a profile (\mathbf{x}, \mathbf{y}) , is $\text{reg}_r(\mathbf{x}, \mathbf{y}) = \max_i \mathcal{R}(e_i, \mathbf{y}) - \mathcal{R}(\mathbf{x}, \mathbf{y})$ and the regret of the column player is $\text{reg}_c(\mathbf{x}, \mathbf{y}) = \max_j \mathcal{C}(\mathbf{x}, e_j) - \mathcal{C}(\mathbf{x}, \mathbf{y})$. The strategy profile (\mathbf{x}, \mathbf{y}) is an ε -*Nash equilibrium*, or ε -NE, if the regret of both players is bounded by $\varepsilon \in [0, 1]$, formally $\max\{\text{reg}_r(\mathbf{x}, \mathbf{y}), \text{reg}_c(\mathbf{x}, \mathbf{y})\} \leq \varepsilon$. If $\varepsilon = 0$, then the strategy profile (\mathbf{x}, \mathbf{y}) is an exact Nash equilibrium.

3 The Tsaknakis-Spirakis algorithm

In this section we give a description of the algorithm by [36] and we highlight the bottleneck cases, where it fails to provide a $(\frac{1}{3} + \delta)$ -approximation. In order to have a self-contained exposition, we also present some of the lemmas that are used in the analysis of [36], which are needed for our work as well.

The core of the algorithm is to consider the function $g(\mathbf{x}, \mathbf{y}) = \max\{\text{reg}_r(\mathbf{x}, \mathbf{y}), \text{reg}_c(\mathbf{x}, \mathbf{y})\}$, i.e., the maximum regret among the two players. Clearly, if we arrive at a profile (\mathbf{x}, \mathbf{y}) such that $g(\mathbf{x}, \mathbf{y}) \leq \varepsilon$, then (\mathbf{x}, \mathbf{y}) is an ε -Nash equilibrium. At a high level, one can think of TS as consisting of two phases: the *Descent* phase, and the *Strategy-construction* phase.

Descent Phase. During this phase, TS performs “gradient descent” on the function $g(\mathbf{x}, \mathbf{y})$, until it reaches a “*stationary point*”, i.e., a strategy profile such that any local change does not decrease the value of g . More concretely, every iteration of the Descent phase performs a series of steps: given the current profile under consideration, it equalizes the regrets of the players, then it solves an appropriate linear program to identify a feasible direction, and finally depending on the solution of the LP, it either updates the strategy profile, or it decides that it has reached an approximate stationary point.

The first step runs the RegretEqualization procedure described below. This procedure is based on solving a single linear program to equalize the regrets of the two players, and most importantly, it guarantees that the maximum regret does not increase.

RegretEqualization($\mathbf{x}_0, \mathbf{y}_0$)

Input: A strategy profile $(\mathbf{x}_0, \mathbf{y}_0)$.

Output: A strategy profile (\mathbf{x}, \mathbf{y}) such that $\text{reg}_r(\mathbf{x}, \mathbf{y}) = \text{reg}_c(\mathbf{x}, \mathbf{y}) \leq g(\mathbf{x}_0, \mathbf{y}_0)$.

1. If $\text{reg}_r(\mathbf{x}_0, \mathbf{y}_0) \geq \text{reg}_c(\mathbf{x}_0, \mathbf{y}_0)$, keep \mathbf{y}_0 fixed and solve the following linear program:

Minimize $\text{reg}_r(\mathbf{x}, \mathbf{y}_0)$

Such that $\text{reg}_r(\mathbf{x}, \mathbf{y}_0) \geq \text{reg}_c(\mathbf{x}, \mathbf{y}_0)$ and $\mathbf{x} \in \Delta^n$.

Return $(\mathbf{x}, \mathbf{y}_0)$, where \mathbf{x} is the solution of the linear program.

2. If $\text{reg}_r(\mathbf{x}_0, \mathbf{y}_0) < \text{reg}_c(\mathbf{x}_0, \mathbf{y}_0)$, keep \mathbf{x}_0 fixed and solve the following linear program:

Minimize $\text{reg}_c(\mathbf{x}_0, \mathbf{y})$

Such that $\text{reg}_c(\mathbf{x}_0, \mathbf{y}) \geq \text{reg}_r(\mathbf{x}_0, \mathbf{y})$ and $\mathbf{y} \in \Delta^n$.

Return $(\mathbf{x}_0, \mathbf{y})$, where \mathbf{y} is the solution of the linear program.

Given the output (\mathbf{x}, \mathbf{y}) of RegretEqualization, the next step is to either find a feasible direction to follow so as to decrease the maximum regret, or to decide that (\mathbf{x}, \mathbf{y}) is an approximate stationary point. This is enforced by solving the following linear program.

Primal Linear Program: Primal(\mathbf{x}, \mathbf{y})

minimize γ

s.t. $\gamma \geq \mathcal{R}(e_i, \mathbf{y}') - \mathcal{R}(\mathbf{x}, \mathbf{y}') - \mathcal{R}(\mathbf{x}', \mathbf{y}) + \mathcal{R}(\mathbf{x}, \mathbf{y}), \quad \forall i \in B_r(\mathbf{y}),$

$\gamma \geq \mathcal{C}(\mathbf{x}', e_j) - \mathcal{C}(\mathbf{x}', \mathbf{y}) - \mathcal{C}(\mathbf{x}, \mathbf{y}') + \mathcal{C}(\mathbf{x}, \mathbf{y}), \quad \forall j \in B_c(\mathbf{x}),$

$\mathbf{x}' \in \Delta^n, \quad \mathbf{y}' \in \Delta^n.$

It is proved in [36] that the solution of Primal(\mathbf{x}, \mathbf{y}) guarantees one of the following:

1. it either identifies a strategy profile $(\mathbf{x}', \mathbf{y}')$ such that the maximum regret can be strictly decreased by a constant fraction, if we move from (\mathbf{x}, \mathbf{y}) towards $(\mathbf{x}', \mathbf{y}')$;
2. or it decides that (\mathbf{x}, \mathbf{y}) is a δ -stationary point¹, which is the termination criterion of the descent.

Putting everything together, the Descent phase of the TS algorithm is described below, starting from some arbitrary initial strategy profile, and its main properties are captured by the following lemma.

► **Lemma 1** ([36]). *For any constant $\delta > 0$, the Descent phase computes a δ -stationary point, in time polynomial in $1/\delta$ and in the size of the game.*

Descent Phase

Input: A strategy profile (\mathbf{x}, \mathbf{y}) , a small constant $\delta > 0$ ($\delta \ll 1/3$).

Output: A δ -stationary profile $(\mathbf{x}_s, \mathbf{y}_s)$ with equal regrets.

1. Equalize the regrets of the two players, i.e., set $(\mathbf{x}, \mathbf{y}) \leftarrow \text{RegretEqualization}(\mathbf{x}, \mathbf{y})$.

2. Solve Primal(\mathbf{x}, \mathbf{y}) and compute \mathbf{x}', \mathbf{y}' , and γ .

3. If $\gamma - g(\mathbf{x}, \mathbf{y}) \geq -\delta$, set $\mathbf{x}_s \leftarrow \mathbf{x}, \mathbf{y}_s \leftarrow \mathbf{y}$ and stop.

4. Else, set $\mathbf{x} \leftarrow (1 - \frac{\delta}{\delta+2}) \cdot \mathbf{x} + \frac{\delta}{\delta+2} \cdot \mathbf{x}'$, $\mathbf{y} \leftarrow (1 - \frac{\delta}{\delta+2}) \cdot \mathbf{y} + \frac{\delta}{\delta+2} \cdot \mathbf{y}'$ and go to Step 1.

¹ This means that the directional derivative of $g(\mathbf{x}, \mathbf{y})$ is at least $-\delta$. For the definition of directional derivative, see [36].

Strategy-construction Phase. In this phase, the algorithm utilizes the dual linear program of Primal(\mathbf{x}, \mathbf{y}), in order to identify some alternative candidate strategies for the players.

Dual Linear Program: Dual(\mathbf{x}, \mathbf{y})

$$\begin{aligned}
& \text{maximize} && P \cdot \mathcal{R}(\mathbf{x}, \mathbf{y}) + Q \cdot \mathcal{C}(\mathbf{x}, \mathbf{y}) + a + b \\
& \text{s.t.} && p_i \geq 0, \quad i \in B_r(\mathbf{y}), \\
& && q_j \geq 0, \quad j \in B_c(\mathbf{x}), \\
& && P = \sum_{i \in B_r(\mathbf{y})} p_i, \quad Q = \sum_{j \in B_c(\mathbf{x})} q_j, \\
& && P + Q = 1, \\
& && a \leq \sum_{i \in B_r(\mathbf{y})} -\mathcal{R}(e_k, \mathbf{y}) \cdot p_i + \sum_{j \in B_c(\mathbf{x})} [-\mathcal{C}(e_k, \mathbf{y}) + C_{kj}] \cdot q_j, \quad 1 \leq k \leq n \\
& && b \leq \sum_{j \in B_c(\mathbf{x})} -\mathcal{C}(\mathbf{x}, e_l) \cdot q_j + \sum_{i \in B_r(\mathbf{y})} [-\mathcal{R}(\mathbf{x}, e_l) + R_{il}] \cdot p_i, \quad 1 \leq l \leq n.
\end{aligned}$$

Given the δ -stationary profile $(\mathbf{x}_s, \mathbf{y}_s)$ from the Descent phase, the algorithm solves Dual($\mathbf{x}_s, \mathbf{y}_s$) and computes the following (from the optimal dual variables).

- The dual strategy \mathbf{w} for the row player, where $w_i = p_i / \sum_{j \in B_r(\mathbf{y}_s)} p_j$, for $i \in B_r(\mathbf{y}_s)$, and 0 elsewhere; note that by construction, \mathbf{w} is a best-response strategy against \mathbf{y}_s .
- The dual strategy \mathbf{z} for the column player, where $z_i = q_i / \sum_{j \in B_c(\mathbf{x}_s)} q_j$, for $i \in B_r(\mathbf{x}_s)$, and 0 elsewhere; by construction, \mathbf{z} is a best-response strategy against \mathbf{x}_s .
- The dual variables $P, Q \in [0, 1]$, that are useful for the approximation analysis.

In addition, we define the following two quantities λ and μ , that help in parameterizing the maximum regret bound. These quantities are equal to the payoff difference of a player between the dual and the primal strategies, when the other player uses her dual strategy:

$$\lambda = \mathcal{R}(\mathbf{w}, \mathbf{z}) - \mathcal{R}(\mathbf{x}_s, \mathbf{z}), \quad \mu = \mathcal{C}(\mathbf{w}, \mathbf{z}) - \mathcal{C}(\mathbf{w}, \mathbf{y}_s). \quad (1)$$

Fact. Obviously, $\lambda \leq 1$, and $\mu \leq 1$ and furthermore, $\mathcal{R}(\mathbf{w}, \mathbf{z}) \geq \lambda$, and $\mathcal{C}(\mathbf{w}, \mathbf{z}) \geq \mu$. The algorithm then constructs and outputs a strategy profile as follows.

Strategy-Construction Phase

Input: A δ -stationary strategy profile $(\mathbf{x}_s, \mathbf{y}_s)$ from the Descent phase, the dual strategies \mathbf{w}, \mathbf{z} , and the parameters λ, μ .

1. If $\min\{\lambda, \mu\} \leq \frac{1}{2}$, then return $(\mathbf{x}_s, \mathbf{y}_s)$.
2. If $\min\{\lambda, \mu\} \geq \frac{2}{3}$, then return (\mathbf{w}, \mathbf{z}) .
3. If $\min\{\lambda, \mu\} > \frac{1}{2}$ and $\max\{\lambda, \mu\} \leq \frac{2}{3}$, then return $(\mathbf{x}_s, \mathbf{y}_s)$.
4. Else if $\lambda \geq \mu$, then return the strategy profile with the minimum regret between $\left(\frac{1}{1+\lambda-\mu} \cdot \mathbf{w} + \frac{\lambda-\mu}{1+\lambda-\mu} \cdot \mathbf{x}_s, \mathbf{z}\right)$ and $(\mathbf{x}_s, \mathbf{y}_s)$.
5. Else if $\lambda < \mu$, then return the strategy profile with the minimum regret between $\left(\mathbf{w}, \frac{1}{1+\mu-\lambda} \cdot \mathbf{z} + \frac{\mu-\lambda}{1+\mu-\lambda} \cdot \mathbf{y}_s\right)$ and $(\mathbf{x}_s, \mathbf{y}_s)$.

► **Theorem 2** ([36]). *For any constant $\delta > 0$, the TS algorithm computes in polynomial time a $(0.3393 + \delta)$ -NE.*

► **Remark 3.** One could also check all the proposed profiles of this phase at every iteration of the Descent phase, as presented in [36], and stop if we have reached already the desired approximation. But this does not affect the worst-case running time, which occurs when the Descent phase terminates at a δ -stationary point.

We present below some important lemmas from [36] that are needed in our analysis too.

The first, and most important, lemma below shows how $\text{Primal}(\mathbf{x}_s, \mathbf{y}_s)$ and $\text{Dual}(\mathbf{x}_s, \mathbf{y}_s)$ can be used to bound the value of the maximum regret, $g(\mathbf{x}_s, \mathbf{y}_s)$.

► **Lemma 4** (implied by [36]). *Let $(\mathbf{x}_s, \mathbf{y}_s)$ be a δ -stationary point produced by the Descent Phase, for a constant $\delta > 0$. Let also \mathbf{w}, \mathbf{z} and P , be derived by an optimal solution to $\text{Dual}(\mathbf{x}_s, \mathbf{y}_s)$, as seen before. Then, for any strategy profile $(\mathbf{x}', \mathbf{y}')$, it holds that*

$$g(\mathbf{x}_s, \mathbf{y}_s) \leq P \cdot (\mathcal{R}(\mathbf{w}, \mathbf{y}') - \mathcal{R}(\mathbf{x}', \mathbf{y}_s) - \mathcal{R}(\mathbf{x}_s, \mathbf{y}') + \mathcal{R}(\mathbf{x}_s, \mathbf{y}_s)) + (1 - P) \cdot (\mathcal{C}(\mathbf{x}', \mathbf{z}) - \mathcal{C}(\mathbf{x}', \mathbf{y}_s) - \mathcal{C}(\mathbf{x}_s, \mathbf{y}') + \mathcal{C}(\mathbf{x}_s, \mathbf{y}_s)) + \delta.$$

Lemma 4 plays a crucial role as it allows us to bound $g(\mathbf{x}_s, \mathbf{y}_s)$ in terms of λ, μ and P , by making appropriate choices for \mathbf{x}' and \mathbf{y}' . This is used both in the following lemma and in Lemma 11 of Section 4.

► **Lemma 5** ([36]). *Let $(\mathbf{x}_s, \mathbf{y}_s)$ be a δ -stationary point produced by the Descent phase, for a constant $\delta > 0$, and let P be obtained by an optimal solution of $\text{Dual}(\mathbf{x}_s, \mathbf{y}_s)$. It holds that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \min\{P \cdot \lambda, (1 - P) \cdot \mu\} + \delta \leq \frac{\lambda \cdot \mu}{\lambda + \mu} + \delta \leq \frac{\lambda + \mu}{4} + \delta$.*

One may worry that the bound $\frac{\lambda \cdot \mu}{\lambda + \mu}$ is not well-defined when $\lambda + \mu = 0$. However, as we explain below, this is not a concern.

► **Corollary 6.** *We can assume that both $\lambda > 0$ and $\mu > 0$, otherwise $(\mathbf{x}_s, \mathbf{y}_s)$ is a δ -Nash equilibrium.*

The definitions of λ and μ , along with Lemma 5 can immediately be used to prove that Cases 1-3 from the Strategy-construction phase return a $(\frac{1}{3} + \delta)$ -Nash equilibrium. Hence, the bottleneck of the TS algorithm comes from Cases 4 and 5. In fact, it was also recently shown in [12] that the analysis of these cases in [36] is tight, and therefore one needs to come up with a different construction in order to obtain an improvement.

► **Lemma 7** ([36]). *Cases 1-3 from the Strategy-construction phase return a $(\frac{1}{3} + \delta)$ -Nash equilibrium.*

Proof. We will consider every case independently.

- If $\min\{\lambda, \mu\} \leq \frac{1}{2}$, by Lemma 5 we have that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \frac{\lambda \cdot \mu}{\lambda + \mu} + \delta \leq \frac{\min\{\lambda, \mu\}}{\min\{\lambda, \mu\} + 1} + \delta \leq \frac{1/2}{1/2 + 1} + \delta \leq \frac{1}{3} + \delta$. Here, the second inequality comes from the fact that $\frac{\lambda \cdot \mu}{\lambda + \mu}$ is an increasing function of $\max\{\lambda, \mu\}$, and also $\max\{\lambda, \mu\} \leq 1$.
- If $\min\{\lambda, \mu\} \geq \frac{2}{3}$, then $g(\mathbf{w}, \mathbf{z}) \leq \max\{1 - \mathcal{R}(\mathbf{w}, \mathbf{z}), 1 - \mathcal{C}(\mathbf{w}, \mathbf{z})\}$. But since $\mathcal{R}(\mathbf{w}, \mathbf{z}) \geq \lambda$ and $\mathcal{C}(\mathbf{w}, \mathbf{z}) \geq \mu$, we have that the regret is at most $1 - \min\{\lambda, \mu\} \leq \frac{1}{3}$.
- If $\min\{\lambda, \mu\} > \frac{1}{2}$ and $\max\{\lambda, \mu\} \leq \frac{2}{3}$, by Lemma 5 we have $g(\mathbf{x}_s, \mathbf{y}_s) \leq \frac{\lambda \cdot \mu}{\lambda + \mu} + \delta \leq \frac{\frac{2}{3} \cdot \frac{2}{3}}{\frac{2}{3} + \frac{2}{3}} + \delta \leq \frac{1}{3} + \delta$, since $\frac{\lambda \cdot \mu}{\lambda + \mu}$ is an increasing function of λ and μ . ◀

Thus, in the next section, we will focus on the remaining cases, when $\min\{\lambda, \mu\} \in (\frac{1}{2}, \frac{2}{3}]$ and $\max\{\lambda, \mu\} \in (\frac{2}{3}, 1]$.

4 Improved Strategy-construction Phase

In this section we replace Cases 4 and 5 from the original TS algorithm in order to bypass the bottleneck in the approximation. To do so, we utilize the δ -stationary point $(\mathbf{x}_s, \mathbf{y}_s)$, the dual strategies \mathbf{w}, \mathbf{z} , their convex combinations and best-response strategies to such

combinations. We then perform a more refined analysis and prove that in every case we can efficiently construct a tailored strategy profile that is a $(\frac{1}{3} + \delta)$ -Nash equilibrium. We note that all missing proofs from this section can be found in the full version of our work.

Our new Strategy-construction phase works as follows.

Improved Strategy-construction Phase

Input: A δ -stationary point $(\mathbf{x}_s, \mathbf{y}_s)$ from the Descent phase, the dual strategies \mathbf{w} , \mathbf{z} , and the parameters λ, μ .

1. If $\min\{\lambda, \mu\} \leq \frac{1}{2}$, then return $(\mathbf{x}_s, \mathbf{y}_s)$.
2. If $\min\{\lambda, \mu\} \geq \frac{2}{3}$, then return (\mathbf{w}, \mathbf{z}) .
3. If $\min\{\lambda, \mu\} > \frac{1}{2}$ and $\max\{\lambda, \mu\} \leq \frac{2}{3}$, then return $(\mathbf{x}_s, \mathbf{y}_s)$.
4. If $\frac{1}{2} < \lambda \leq \frac{2}{3} < \mu$:
 - Set $\hat{\mathbf{y}} = \frac{1}{2} \cdot \mathbf{y}_s + \frac{1}{2} \cdot \mathbf{z}$.
 - Find a best response $\hat{\mathbf{w}}$ against $\hat{\mathbf{y}}$.
 - Set $t_r = \mathcal{R}(\hat{\mathbf{w}}, \hat{\mathbf{y}}) - \mathcal{R}(\mathbf{w}, \hat{\mathbf{y}})$; $v_r = \mathcal{R}(\mathbf{w}, \mathbf{y}_s) - \mathcal{R}(\hat{\mathbf{w}}, \mathbf{y}_s)$; $\hat{\mu} = \mathcal{C}(\hat{\mathbf{w}}, \mathbf{z}) - \mathcal{C}(\hat{\mathbf{w}}, \mathbf{y}_s)$.
 - 4.1 If $v_r + t_r \geq \frac{\mu - \lambda}{2}$ and $\hat{\mu} \geq \mu - v_r - t_r$, then set $p = \frac{2 \cdot (v_r + t_r) - (\mu - \lambda)}{2 \cdot (v_r + t_r)}$ and return the strategy profile with the minimum regret among $(p \cdot \mathbf{w} + (1 - p) \cdot \hat{\mathbf{w}}, \mathbf{z})$ and $(\mathbf{x}_s, \mathbf{y}_s)$.
 - 4.2 Else, set $q = \frac{1 - \mu/2 - t_r}{1 + \mu/2 - \lambda - t_r}$ and return the strategy profile with the minimum regret among $(\mathbf{w}, (1 - q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$ and $(\mathbf{x}_s, \mathbf{y}_s)$.
5. If $\frac{1}{2} < \mu \leq \frac{2}{3} < \lambda$ (symmetric to Case 4):
 - Set $\hat{\mathbf{x}} = \frac{1}{2} \cdot \mathbf{x}_s + \frac{1}{2} \cdot \mathbf{w}$.
 - Find a best response $\hat{\mathbf{z}}$ against $\hat{\mathbf{x}}$.
 - Set $t_c = \mathcal{C}(\hat{\mathbf{x}}, \hat{\mathbf{z}}) - \mathcal{C}(\hat{\mathbf{x}}, \mathbf{z})$; $v_c = \mathcal{C}(\mathbf{x}_s, \mathbf{z}) - \mathcal{C}(\mathbf{x}_s, \hat{\mathbf{z}})$; $\hat{\lambda} = \mathcal{R}(\mathbf{w}, \hat{\mathbf{z}}) - \mathcal{R}(\mathbf{x}_s, \hat{\mathbf{z}})$.
 - 5.1 If $v_c + t_c \geq \frac{\lambda - \mu}{2}$ and $\hat{\lambda} \geq \lambda - v_c - t_c$, then set $p = \frac{2 \cdot (v_c + t_c) - (\lambda - \mu)}{2 \cdot (v_c + t_c)}$ and return the strategy profile with the minimum regret among $(\mathbf{w}, p \cdot \mathbf{z} + (1 - p) \cdot \hat{\mathbf{z}})$ and $(\mathbf{x}_s, \mathbf{y}_s)$.
 - 5.2 Else, set $q = \frac{1 - \lambda/2 - t_c}{1 + \lambda/2 - \mu - t_c}$ and return the strategy profile with the minimum regret among $((1 - q) \cdot \hat{\mathbf{x}} + q \cdot \mathbf{w}, \mathbf{z})$ and $(\mathbf{x}_s, \mathbf{y}_s)$.

Note that Cases 1-3 are identical to the Strategy-construction phase of the TS algorithm. Thus, by Lemma 7 they return a $(\frac{1}{3} + \delta)$ -Nash equilibrium. The new part concerns Cases 4 and 5. The analysis in both cases is based on certain auxiliary parameters (v_r, t_r and $\hat{\mu}$ for Case 4 and analogously for Case 5), that we define in the statement of the algorithm. These parameters encode payoff differences or regrets of the players for using specific strategies, and they help us decompose the problem into convenient subcases, so as to obtain better upper bounds on the maximum regret.

Our main result is as follows:

► **Theorem 8.** *For any constant $\delta > 0$, we can compute in polynomial-time a $(\frac{1}{3} + \delta)$ -Nash equilibrium.*

To prove the theorem, it suffices to analyze Case 4, where $\frac{1}{2} < \lambda \leq \frac{2}{3} < \mu$, since Case 5 is symmetric to Case 4 and is analyzed in exactly the same way.

Intuition and Roadmap. The overall analysis in the sequel looks rather technical, therefore, we will first provide some elaboration on the choices that the algorithm makes in Case 4. The first crucial component in the design of the new algorithm is that the upper bounds on the regret of the δ -stationary point $(\mathbf{x}_s, \mathbf{y}_s)$, obtained in Lemma 5, can be further refined based on the values of the parameters $\lambda, \mu, \hat{\mu}, v_r$. This is precisely implemented in Section 4.1 with Lemmas 11, 12, and 13. Once this is done, we then try to answer the following question: Whenever $(\mathbf{x}_s, \mathbf{y}_s)$ does not provide a $(\frac{1}{3} + \delta)$ -approximation, which profiles can form alternative candidates for a better performance? One idea is to exploit the dual strategies \mathbf{w} , and \mathbf{z} , as was also done in [36]. However, the profile (\mathbf{w}, \mathbf{z}) may not be a $(\frac{1}{3} + \delta)$ -equilibrium either (in most cases). A next attempt then is to consider appropriate convex combinations of the primal and the dual strategy for each player, i.e., a combination of \mathbf{x}_s and \mathbf{w} for the row player and \mathbf{y}_s and \mathbf{z} for the column player. Unfortunately, this again does not work in all cases. But one next step is to also take into consideration best-response strategies against such convex combinations. E.g., the strategy $\hat{\mathbf{w}}$ defined in Case 4 is a best response to the equiprobable combination of \mathbf{y}_s and \mathbf{z} . This completes our weaponry, and at the end, in all subcases of Case 4, we consider profiles where the row player uses a convex combination of \mathbf{w} and $\hat{\mathbf{w}}$, and the column player selects a combination between her primal and dual strategies, \mathbf{y}_s and \mathbf{z} . Analogous profiles with the roles of the players reversed are constructed for Case 5 too. Finally, we also know that whenever $(\mathbf{x}_s, \mathbf{y}_s)$ does not attain a $(\frac{1}{3} + \delta)$ -approximation, this restricts the relation between the parameters $\lambda, \mu, \hat{\mu}$ and v_r due to the lemmas of Section 4.1. This is exploitable for us in the sense that it allows us to construct the exact coefficients for the convex combinations that we use so as to have the desired approximation.

To proceed, we start with two helpful observations, which are used repeatedly for the analysis of Cases 4.1 and 4.2.

► **Lemma 9.** *It holds that $\mathcal{R}(\hat{\mathbf{w}}, \mathbf{z}) \geq \lambda + v_r + 2t_r$.*

Proof. By the definition of t_r , inside Case 4, we have that it holds that $\mathcal{R}(\hat{\mathbf{w}}, \hat{\mathbf{y}}) = \mathcal{R}(\mathbf{w}, \hat{\mathbf{y}}) + t_r$. Hence,

$$\frac{\mathcal{R}(\hat{\mathbf{w}}, \mathbf{y}_s)}{2} + \frac{\mathcal{R}(\hat{\mathbf{w}}, \mathbf{z})}{2} = \mathcal{R}(\hat{\mathbf{w}}, \hat{\mathbf{y}}) = \frac{\mathcal{R}(\mathbf{w}, \mathbf{y}_s)}{2} + \frac{\mathcal{R}(\mathbf{w}, \mathbf{z})}{2} + t_r \Rightarrow$$

$$\mathcal{R}(\hat{\mathbf{w}}, \mathbf{z}) = (\mathcal{R}(\mathbf{w}, \mathbf{y}_s) - \mathcal{R}(\hat{\mathbf{w}}, \mathbf{y}_s)) + \mathcal{R}(\mathbf{w}, \mathbf{z}) + 2t_r \geq \lambda + v_r + 2t_r,$$

since $\mathcal{R}(\mathbf{w}, \mathbf{y}_s) - \mathcal{R}(\hat{\mathbf{w}}, \mathbf{y}_s) = v_r$, and $\mathcal{R}(\mathbf{w}, \mathbf{z}) \geq \lambda$ (by the fact after Equation (1)). ◀

► **Corollary 10.** *It holds that $v_r \leq 1 - \lambda - 2t_r$, or equivalently $t_r \leq \frac{1 - \lambda - v_r}{2}$.*

Proof. By the previous lemma we have $\mathcal{R}(\hat{\mathbf{w}}, \mathbf{z}) \geq \lambda + v_r + 2t_r \Rightarrow v_r \leq 1 - \lambda - 2t_r$, since $\mathcal{R}(\hat{\mathbf{w}}, \mathbf{z}) \leq 1$. ◀

4.1 Bounding the regret of δ -stationary points

In this subsection, we establish three important lemmas that provide different ways of bounding the maximum regret of any δ -stationary point. The first of these lemmas is an improvement over [36], where we add a third upper bound for the δ -stationary point, in addition to the bounds stated in Lemma 5 from Section 3.

► **Lemma 11.** *Let $(\mathbf{x}_s, \mathbf{y}_s)$ be a δ -stationary point with $\delta \geq 0$, and let P be obtained by an optimal solution of $\text{Dual}(\mathbf{x}_s, \mathbf{y}_s)$, as the sum of the dual variables: $P = \sum_{i \in B_r(\mathbf{y}_s)} p_i$. It holds that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \min\{P \cdot \lambda, (1 - P) \cdot \mu, P \cdot v_r + (1 - P) \cdot \hat{\mu}\} + \delta$.*

41:10 A Polynomial-Time Algorithm for 1/3-NE in Bimatrix Games

Proof. By Lemma 5 it holds that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \min\{P \cdot \lambda, (1-P) \cdot \mu\} + \delta$. So, it suffices to prove that $g(\mathbf{x}_s, \mathbf{y}_s) \leq P \cdot v_r + (1-P) \cdot \hat{\mu} + \delta$. This follows from Lemma 4 when we set $(\mathbf{x}', \mathbf{y}') = (\hat{\mathbf{w}}, \mathbf{y}_s)$. Indeed, in this case we have $g(\mathbf{x}_s, \mathbf{y}_s) \leq P \cdot (\mathcal{R}(\mathbf{w}, \mathbf{y}_s) - \mathcal{R}(\hat{\mathbf{w}}, \mathbf{y}_s) - \mathcal{R}(\mathbf{x}_s, \mathbf{y}_s) + \mathcal{R}(\mathbf{x}_s, \mathbf{y}_s)) + (1-P) \cdot (\mathcal{C}(\hat{\mathbf{w}}, \mathbf{z}) - \mathcal{C}(\hat{\mathbf{w}}, \mathbf{y}_s) - \mathcal{C}(\mathbf{x}_s, \mathbf{y}_s) + \mathcal{C}(\mathbf{x}_s, \mathbf{y}_s)) = P \cdot v_r + (1-P) \cdot \hat{\mu} + \delta$, by the definitions of v_r and $\hat{\mu}$. \blacktriangleleft

The remaining two lemmas help in attaining a more fine-grained analysis on upper bounding the regret of the players, under the restrictions on the values of λ and μ in Case 4.

► **Lemma 12.** *Let $(\mathbf{x}_s, \mathbf{y}_s)$ be a δ -stationary point with $\delta \geq 0$, and let $\hat{\mu} \geq v_r$, and $\lambda > \frac{1}{2}$. Then, it holds that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \frac{\hat{\mu} \cdot \lambda}{\lambda + \hat{\mu} - v_r} + \delta$.*

Proof. By Lemma 11 we have $g(\mathbf{x}_s, \mathbf{y}_s) \leq \min\{P \cdot \lambda, P \cdot v_r + (1-P) \cdot \hat{\mu}\} + \delta$. Note that $P \cdot \lambda$ is an increasing linear function of P , and $P \cdot v_r + (1-P) \cdot \hat{\mu}$ is a decreasing linear function of P , because $\hat{\mu} \geq v_r$. Therefore, the maximum of the minimum of these two functions is achieved at the point where they are equal, which is for $P' = \frac{\hat{\mu}}{\lambda + \hat{\mu} - v_r}$, as long as $P' \in [0, 1]$ (recall that P is constrained to belong to this interval). To check that P' is a valid point, observe first that since $\lambda > \frac{1}{2}$ and $\hat{\mu} \geq v_r$, the denominator of P' is positive. Also, again using that $\lambda > \frac{1}{2}$, Corollary 10 implies that $v_r \leq 1 - \lambda \leq \frac{1}{2}$, hence $\lambda > v_r$, which means that $P' \in [0, 1]$. Thus, $g(\mathbf{x}_s, \mathbf{y}_s) \leq \lambda \cdot P' + \delta = \frac{\hat{\mu} \cdot \lambda}{\lambda + \hat{\mu} - v_r} + \delta$. \blacktriangleleft

► **Lemma 13.** *Let $(\mathbf{x}_s, \mathbf{y}_s)$ be a δ -stationary point with $\delta \geq 0$, and let $\hat{\mu} < v_r$, $\lambda > \frac{1}{2}$, and $\mu > \frac{2}{3}$. Then, it holds that $g(\mathbf{x}_s, \mathbf{y}_s) \leq \frac{v_r \cdot \mu}{\mu - \hat{\mu} + v_r} + \delta$.*

4.2 Case 4.1 of the Improved Strategy-construction Phase

We now analyze the approximation we obtain, when we fall into Case 4.1 of the algorithm. We establish that either the δ -stationary point has the desired approximation or otherwise, this is achieved by having the row player use an appropriate convex combination of \mathbf{w} and $\hat{\mathbf{w}}$ and the column player play the dual strategy \mathbf{z} .

► **Lemma 14.** *If $v_r + t_r \geq \frac{\mu - \lambda}{2}$, and $\hat{\mu} \geq \mu - v_r - t_r$, then for the strategy profile $(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z})$, with $p = \frac{2 \cdot (v_r + t_r) - (\mu - \lambda)}{2 \cdot (v_r + t_r)}$, the payoff of both the row and the column player is at least $\frac{\lambda + \mu}{2}$.*

Proof. Note first that under the assumptions of the lemma, and since $\mu > \lambda$, the parameter p is a valid probability. For the row player, we have that her payoff is

$$\begin{aligned} \mathcal{R}(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z}) &= p \cdot \mathcal{R}(\mathbf{w}, \mathbf{z}) + (1-p) \cdot \mathcal{R}(\hat{\mathbf{w}}, \mathbf{z}) \\ &\geq p \cdot \lambda + (1-p) \cdot \lambda + (1-p) \cdot (v_r + t_r) \quad (\text{from Lemma 9}) \\ &= \lambda + (1-p) \cdot (v_r + t_r) \\ &= \lambda + \frac{(\mu - \lambda)}{2} \quad \left(\text{since } 1-p = \frac{\mu - \lambda}{2 \cdot (v_r + t_r)} \right) \\ &= \frac{\lambda + \mu}{2}. \end{aligned}$$

For the column player we have that her payoff is

$$\begin{aligned}
\mathcal{C}(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z}) &= p \cdot \mathcal{C}(\mathbf{w}, \mathbf{z}) + (1-p) \cdot \mathcal{C}(\hat{\mathbf{w}}, \mathbf{z}) \\
&\geq p \cdot \mu + (1-p) \cdot \hat{\mu} \quad (\text{Since } \hat{\mu} = \mathcal{C}(\hat{\mathbf{w}}, \mathbf{z}) - \mathcal{C}(\hat{\mathbf{w}}, \mathbf{y}_s) \leq \mathcal{C}(\hat{\mathbf{w}}, \mathbf{z})) \\
&\geq p \cdot \mu + (1-p) \cdot \mu - (1-p) \cdot (v_r + t_r) \quad (\text{Since } \hat{\mu} \geq \mu - v_r - t_r) \\
&= \mu - \frac{(\mu - \lambda)}{2} \quad \left(\text{since } 1-p = \frac{\mu - \lambda}{2 \cdot (v_r + t_r)} \right) \\
&= \frac{\mu + \lambda}{2}. \quad \blacktriangleleft
\end{aligned}$$

► **Lemma 15.** *Let $p \in [0, 1]$, be such that $\mathcal{R}(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z}) \geq \frac{\lambda + \mu}{2}$, and $\mathcal{C}(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z}) \geq \frac{\lambda + \mu}{2}$. Then, either $(\mathbf{x}_s, \mathbf{y}_s)$ is a $(\frac{1}{3} + \delta)$ -Nash equilibrium, or $(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z})$ is a $\frac{1}{3}$ -Nash equilibrium.*

Proof. The regret of either player at the strategy profile $(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z})$ is at most $1 - \frac{\lambda + \mu}{2}$, since the payoff of any player is no less than $\frac{\lambda + \mu}{2}$ and the best-response payoff is at most 1. On the other hand, by Lemma 5 the regret of each player at the δ -stationary point $(\mathbf{x}_s, \mathbf{y}_s)$ is at most $\frac{\lambda + \mu}{4} + \delta$. Thus, if $\lambda + \mu \leq \frac{4}{3}$, then $g(\mathbf{x}_s, \mathbf{y}_s) \leq \frac{1}{3} + \delta$. Otherwise, the maximum regret at the profile $(p \cdot \mathbf{w} + (1-p) \cdot \hat{\mathbf{w}}, \mathbf{z})$ is at most $1 - \frac{\lambda + \mu}{2} \leq \frac{1}{3}$. ◀

4.3 Case 4.2 of the Strategy-construction phase

In this case it holds that either $v_r + t_r < \frac{\mu - \lambda}{2}$ or $\hat{\mu} < \mu - v_r - t_r$. It turns out that this is a technically more intriguing case, and the reason is that the parameters are less constrained, compared to Case 4.1. As a result, we need to consider different subcases in order to have tighter upper bounds. We recall that the algorithm in this case outputs either $(\mathbf{x}_s, \mathbf{y}_s)$, or a profile where the row player selects her dual strategy \mathbf{w} , which is a best response against \mathbf{y}_s , and the column player plays a convex combination between $\hat{\mathbf{y}}$ and \mathbf{z} , which by the definition of $\hat{\mathbf{y}}$, is a convex combination of her primal strategy \mathbf{y}_s and her dual strategy \mathbf{z} .

► **Lemma 16.** *The regret of the row player at $(\mathbf{w}, \hat{\mathbf{y}})$ is t_r , and the regret of the column player is at most $1 - \frac{\mu}{2}$.*

Proof. By definition, the regret of the row player is t_r , since $\hat{\mathbf{w}}$ is a best-response strategy against $\hat{\mathbf{y}}$. On the other hand, recall by the definition of μ , that $\mathcal{C}(\mathbf{w}, \mathbf{z}) \geq \mu$. So, we have that $\mathcal{C}(\mathbf{w}, \hat{\mathbf{y}}) = \frac{\mathcal{C}(\mathbf{w}, \mathbf{y}_s)}{2} + \frac{\mathcal{C}(\mathbf{w}, \mathbf{z})}{2} \geq \frac{\mathcal{C}(\mathbf{w}, \mathbf{z})}{2} \geq \frac{\mu}{2}$. Thus, since the maximum payoff is less than or equal to 1, we have that the regret of the column player is at most $1 - \frac{\mu}{2}$. ◀

We now quantify the regret of the players at the profile $(\mathbf{w}, (1-q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$, that is considered by the algorithm. In particular, we obtain an upper bound as a function of the parameters λ, μ , and t_r .

► **Lemma 17.** *Consider the strategy profile $(\mathbf{w}, (1-q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$ with $q = \frac{1 - \mu/2 - t_r}{1 + \mu/2 - \lambda - t_r}$. Then, the regret of each player is no greater than $q \cdot (1 - \lambda) + (1 - q) \cdot t_r = \frac{1 - \mu/2 - t_r - \lambda + \mu \cdot \lambda/2 + \mu \cdot t_r}{1 + \mu/2 - \lambda - t_r}$.*

We now come to the core of the proof and establish that either the δ -stationary point, or the strategy profile $(\mathbf{w}, (1-q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$ yields a good approximation. This is established by the following lemma.

► **Lemma 18.** *Under the assumptions of Case 4.2, either $(\mathbf{x}_s, \mathbf{y}_s)$ is a $(\frac{1}{3} + \delta)$ -Nash equilibrium, or $(\mathbf{w}, (1-q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$ with $q = \frac{1 - \mu/2 - t_r}{1 + \mu/2 - \lambda - t_r}$, is a $\frac{1}{3}$ -Nash equilibrium.*

41:12 A Polynomial-Time Algorithm for 1/3-NE in Bimatrix Games

Proof. Since we are in Case 4.2, where either $v_r + t_r < \frac{\mu - \lambda}{2}$, or $\hat{\mu} < \mu - v_r - t_r$, we will split the analysis into further subcases, so that we have a more concrete relation between the relevant parameters in each subcase. More precisely, we will consider the following three subcases.

4.2(i) $v_r + t_r < \frac{\mu - \lambda}{2}$.

4.2(ii) $\hat{\mu} < \mu - v_r - t_r$, and $\hat{\mu} \geq v_r$.

4.2(iii) $\hat{\mu} < \mu - v_r - t_r$, and $\hat{\mu} < v_r$.

So far, we have not been able to have a unifying argument for all these different subcases. Consequently, we need to proceed with a separate analysis for each of them. Due to space constraints, we defer the first two subcases to the full version of this work, and we present here only Subcase 4.2(iii). We note also that among them, it was Subcase 4.2(ii) that turned out to be the lengthier and technically most subtle in obtaining the approximation bound.

Subcase 4.2(iii). Let us begin by observing that if $v_r \leq \frac{1}{3}$, then the strategy profile $(\mathbf{x}_s, \mathbf{y}_s)$ is a $(\frac{1}{3} + \delta)$ -NE. Indeed, from Lemma 13, and since $\hat{\mu} < v_r$, we get that the approximation guarantee of the stationary strategy profile is $\frac{v_r \cdot \mu}{\mu - \hat{\mu} + v_r} + \delta \leq v_r + \delta \leq \frac{1}{3} + \delta$. Hence, in what follows, we will assume that $v_r > \frac{1}{3}$. So, from Corollary 10 we have that

$$t_r \leq \frac{1 - \lambda - v_r}{2} < \frac{\frac{2}{3} - \lambda}{2} = \frac{1}{3} - \frac{\lambda}{2}. \quad (2)$$

Assume now for the sake of contradiction, that $(\mathbf{w}, (1 - q) \cdot \hat{\mathbf{y}} + q \cdot \mathbf{z})$ is not a $\frac{1}{3}$ -NE, i.e., the maximum regret is higher than $1/3$. Combining this with the bound of Lemma 17 on the regret, and by simplifying the resulting expression, we get the following inequality:

$$\frac{\lambda\mu}{2} - \frac{2\mu}{3} - \frac{2\lambda}{3} + \left(\mu - \frac{2}{3}\right) \cdot t_r + \frac{2}{3} > 0. \quad (3)$$

We will focus on the LHS of (3) and we will upper bound it by a non-positive value. Suppose that the regret at the stationary point $(\mathbf{x}_s, \mathbf{y}_s)$ is greater than $(\frac{1}{3} + \delta)$. This means from Lemma 5 that $\frac{\lambda \cdot \mu}{\lambda + \mu} > \frac{1}{3}$, which implies that $\mu > \frac{\lambda}{3\lambda - 1}$. In addition, observe that since $\mu > 2/3$, the LHS of (3) is increasing with t_r . Hence, if we use Inequality (2), we get that the LHS of (3) is upper bounded by

$$\begin{aligned} \frac{\lambda\mu}{2} - \frac{2\mu}{3} - \frac{2\lambda}{3} + \left(\mu - \frac{2}{3}\right) \cdot \left(\frac{1}{3} - \frac{\lambda}{2}\right) + \frac{2}{3} &= -\frac{\mu}{3} - \frac{\lambda}{3} + \frac{4}{9} \\ &< -\frac{\lambda}{9\lambda - 3} - \frac{\lambda}{3} + \frac{4}{9} \quad \left(\text{since } \mu > \frac{\lambda}{3\lambda - 1}\right). \end{aligned}$$

It is easy to verify though that this quantity is non-positive for every $\lambda \in [\frac{1}{2}, \frac{2}{3}]$, which in turn contradicts Inequality (3). \blacktriangleleft

5 Discussion

Our algorithm is the first improvement for a foundational problem after 15 years, during which progress had stalled. We hope that our result will again ignite the spark for actively studying ε -NE in bimatrix games. There is still a large gap between the quasi polynomial-time lower bound for some very small constant ε^* from [35], and our newly-established upper bound of $1/3$. We conjecture that closing this gap requires radically new ideas.

Our result has some extra positive consequences for games with more than two players. In [7] it was shown that if we have an algorithm that finds an α -Nash equilibrium in a $(k - 1)$ -player game, then in polynomial time we can compute a $(\frac{1}{2-\alpha})$ -NE for any k -player game. Thus, our algorithm improves the state of the art for k -player normal-form games, for any $k > 2$. Namely, we get a $(0.6 + \delta)$ -NE for three-player games, a $(5/7 + \delta)$ -NE for four-player games, and so on.

Abstract

In a graph G with a source s , we design a distance oracle that can answer the following query: $\text{QUERY}(s, t, e)$ – find the length of shortest path from a fixed source s to any destination vertex t while avoiding any edge e . We design a deterministic algorithm that builds such an oracle in $\tilde{O}(m\sqrt{n})$ time¹. Our oracle uses $\tilde{O}(n\sqrt{n})$ space and can answer queries in $\tilde{O}(1)$ time. Our oracle is an improvement of the work of Bilò et al. (ESA 2021) in the preprocessing time, which constructs the first deterministic oracle for this problem in $\tilde{O}(m\sqrt{n} + n^2)$ time.

Using our distance oracle, we also solve the *single source replacement path problem* (SSRP problem). Chechik and Cohen (SODA 2019) designed a randomized combinatorial algorithm to solve the SSRP problem. The running time of their algorithm is $\tilde{O}(m\sqrt{n} + n^2)$. In this paper, we show that the SSRP problem can be solved in $\tilde{O}(m\sqrt{n} + |\mathcal{R}|)$ time, where \mathcal{R} is the output set of the SSRP problem in G . Our SSRP algorithm is optimal (upto polylogarithmic factor) as there is a conditional lower bound of $\Omega(m\sqrt{n})$ for any combinatorial algorithm that solves this problem.

1 Introduction

Real-life graph networks are prone to failures, e.g., nodes or links can fail. Thus, algorithms developed for these networks must be resilient to failures. For example, there may be some edges or links which are not working in the network and we want to avoid them. In this paper, we present an algorithm to create an oracle for the single source shortest path problem in a fault-prone graph. Such algorithms are also called fault-tolerant algorithms.

Consider an undirected and unweighted graph G with a source s . We want to build an oracle that can find the length of shortest path from s to any other vertex in the presence of faulty edges – such an oracle is also called a *fault-tolerant distance oracle*. Formally,

► **Definition 1.** *A fault-tolerant distance oracle answers the following query in a graph G :*

$\text{QUERY}(s, t, F)$: *Find the length of shortest path from s to t avoiding the set F of edges.*

¹ $\tilde{O}()$ hides polylog n factor

The time it takes to answer a query is called the *query time*. If the query is always from a fixed source s and $|F| \leq f$, then the distance oracle is called a f -edge fault tolerant single source distance oracle, or $\text{SDO}(f)$ in short. If all vertices can be sources, the oracle is called f -edge fault tolerant distance oracle, or $\text{DO}(f)$. We list some results related to distance oracles:

Demetrescu et al. [12] designed a $\text{DO}(1)$ with $\tilde{O}(n^2)$ space and $O(1)$ query time. Bernstein and Karger[3] showed that this oracle can be built in $\tilde{O}(mn)$ time. Pettie and Duan [15] extended the result of Demetrescu et al. to two faults. They designed a $\text{DO}(2)$ with $\tilde{O}(n^2)$ space and $\tilde{O}(1)$ query time. Gupta and Singh [20] designed a $\text{SDO}(1)$ with $\tilde{O}(n\sqrt{n})$ space and $\tilde{O}(1)$ query time. Recently Bilò et al. [5] built the $\text{SDO}(1)$ (described in [20]) in $\tilde{O}(m\sqrt{n} + n^2)$ time. They also showed that, the lower bound of size for such an oracle is $O(n\sqrt{n})$. Many different aspects of distance oracles have been studied in literature [4, 3, 6, 9, 10, 14, 29]. In the line of k simple shortest paths the some important works are [27, 28, 2]

In this paper, we will focus our attention on building $\text{SDO}(1)$. Due to Bilò et al. [5], the time to build $\text{SDO}(1)$ is $\tilde{O}(m\sqrt{n} + n^2)$. Chechik and Cohen [8] showed that, the first term in this running time is a conditional lower bound for SSRP problem. But it is not clear if the second term is necessary. In this paper, we build a $\text{SDO}(1)$ in $\tilde{O}(m\sqrt{n})$ time – this preprocessing algorithm has a better runtime than [5] for sparse graphs, which is state of the art for this problem till now. Using our $\text{SDO}(1)$ data structure, we are able to reduce the runtime of the algorithm solving SSRP problem too. Our distance oracle is quite different from the distance oracle of Gupta and Singh [20] – though we use the main technical idea of [20] crucially in our paper too. The construction of this new oracle is the main technical result of this paper.

► **Theorem 2.** *For undirected, unweighted graphs there is a deterministic algorithm that can build a $\text{SDO}(1)$ of size $\tilde{O}(n\sqrt{n})$ and query time $\tilde{O}(1)$ in $\tilde{O}(m\sqrt{n})$ time.*

1.1 Application: Single Source Replacement Path Problem

Let us first look at the *replacement path problem*. In this problem, we are given a source s and a destination t . We assume that there is a unique shortest path from s to t , denoted by st .

► **Definition 3** (Replacement Path Problem). *Let s be a source and vertex t be the destination in G . For each $e \in st$ path, output the length of the shortest path from s to t avoiding e .*

The replacement path problem was first investigated due to its relation with auction theory [21, 24] and has been studied extensively. For an undirected graph with non-negative edge weights, the replacement path problem can be solved in $\tilde{O}(m + n)$ time[22, 21, 23]. We look at the generalization of the replacement path problem – the single source replacement path problem.

► **Definition 4** (SSRP problem). *Let s be a source in a graph G which is undirected and unweighted. For each vertex $t \in G$ and each $e \in st$ path, output the length of the shortest path from s to t avoiding e .*

Chechik and Cohen [8] designed a randomized combinatorial algorithm that solves the SSRP problem in $\tilde{O}(m\sqrt{n} + n^2)$ time. They also showed a matching conditional lower bound via Boolean Matrix Multiplication.

► **Lemma 5** ([8]). *Let $BMM(n, m)$ be the time taken to multiply two $n \times n$ boolean matrices with a total of m ones. Under the assumption that any combinatorial algorithm for $BMM(n, m)$ requires $mn^{1-o(1)}$ time², any combinatorial algorithm for SSRP problem requires $\Omega(m\sqrt{n})$ time.*

It may seem that the algorithm of Chechik and Cohen [8] is nearly optimal. It is indeed the case if the output size is $O(n^2)$. However, for a low-diameter graph, this extra additive factor seems unnecessary. If the graph is dense ($m \geq n^{3/2}$), then the n^2 factor is subsumed by the first term $m\sqrt{n}$. Thus, when $m < n^{3/2}$ and the graph has a low diameter, can we improve the running time of the SSRP problem? For such a graph, the algorithm of Chechik and Cohen [8] is not optimal. Similar to [8], Gupta et al. [18] also designed an algorithm for the SSRP problem. Even this algorithm has the running time $\tilde{O}(m\sqrt{n} + n^2)$ – though it uses an entirely different approach compared to [8]. Thus, the main question is: *can we remove this extra additive factor of n^2 from the running time of the SSRP problem?* In this paper, we design such an algorithm:

► **Theorem 6.** *There is a deterministic algorithm for SSRP problem with a running time of $\tilde{O}(m\sqrt{n} + |\mathcal{R}|)$ where $|\mathcal{R}|$ is the output size of SSRP problem in G .*

In the above theorem, $|\mathcal{R}|$ is the output size, thus an implicit lower bound on the SSRP problem. Using Lemma 5, we conclude that our algorithm is nearly optimal up to a polylogarithmic factor.

To build an algorithm for the SSRP problem, we first build a SDO(1). Then, for each $t \in G$ and each $e \in st$ path, we call $\text{QUERY}(s, t, e)$ and output the answer. Thus, we claim the following lemma:

► **Lemma 7.** *If we can build a SDO(1) with query time q in time T , then there is an algorithm for SSRP problem with a running time $O(T + q|\mathcal{R}|)$, where $|\mathcal{R}|$ is the output size in G .*

The above lemma, along with Theorem 2 implies Theorem 6.

1.2 Related Work

Other related problems include the fault-tolerant subgraph problem. In this problem, we want to find a subgraph of G such that the shortest path from s is preserved in the subgraph after any edge deletion. Parter and Peleg [26] designed an algorithm to compute a single fault-tolerant subgraph with $O(n^{3/2})$ edges. They also showed that their result could be easily extended to multiple sources. This result was later extended to dual fault by Parter [16] with $O(n^{5/3})$ edges. Gupta and Khan [19] extended the above result to multiple sources. All the above results are optimal due to a result by Parter [25] which states that a multiple source f -fault tolerant subgraph requires $\Omega\left(n^{2-\frac{1}{f+1}}\right)$ edges. Bodwin et al. [7] showed the existence of a f -fault tolerant subgraph of size $O\left(fn^{2-\frac{1}{2f}}\right)$.

2 Preliminaries

Let $G(V, E)$ be an undirected unweighted graph with a source s . Given two vertices u and v in a graph H , unless otherwise stated, $(uv)_H$ denotes the shortest path from u to v in H . If $H = G$, we will remove the subscript and the brackets – we will apply this policy for all the

² In a RAM model with words of $O(\log n)$ bits.

notations below. $|uv|_H$ denotes the length of the shortest path in H . Some of our graphs will be weighted, even though G is unweighted. If H is weighted, then we will abuse notation and use $|uv|_H$ to denote the weight of the shortest path from u to v in H . The edges and vertices of H will be denoted by E_H and V_H , respectively. Additionally, m_H and n_H will denote the number of edges and vertices in H , respectively. $\text{SPT}_H(s)$ denotes the shortest path tree from s in H . We can view the $\text{SPT}_H(s)$ to be drawn from top to bottom with the top vertex being s . For any two vertices u, v on the st path in $\text{SPT}_H(s)$, we say that u is before / above v if $|su|_H < |sv|_H$. Similarly, we say that u is after/below v if $|su|_H > |sv|_H$. For an edge e in a weighted graph H , $wt_H(e)$ will denote the weight of e . Given two paths $(uw)_H$ and $(vw)_H$, the path $(uw)_H + (vw)_H$ denotes their concatenation. $P[u, v]$ denotes a contiguous subpath of P starting at u and ending at v . Sometimes, we may also write *the interval* $[u, v]$ of P to denote $P[u, v]$. We say u comes before v on a path R starting from s , if $|R[s, u]| < |R[s, v]|$. Similarly, we can define the term u comes after v on path R .

A replacement path R is the shortest path from s to t avoiding an edge e on st path. There can be many replacement paths of the same length avoiding e . To ensure uniqueness, we will use the following definition of replacement path³.

■ **Figure 1** Replacement path with detour uv and detour point u .

► **Definition 8 (Replacement Path).** A path R from s to t avoiding e is called a replacement path if (1) it diverges from and merges to the st path just once (2) its divergence point from the st path is as close to s as possible. (3) it is the **lexicographically smallest**⁴ shortest path in G satisfying (1) and (2).

We now define some terms related to replacement paths. $(st \diamond e)_H$ denotes the replacement path from s to t avoiding the edge e in H . We can generalize this notation to a replacement path that avoids a set of edges. Thus, $(st \diamond F)_H$ denotes the replacement path from s to t in H avoiding a set F of edges. In our algorithm, after we find the replacement path $(st \diamond e)_H$, we will store its length in $d_H(s, t, e)$. Sometimes, we also want to store the length of $(st \diamond F)_H$. In that case, we will store it in $d_H(s, t, F)$.

► **Definition 9 (Detour and Detour point of a replacement path).** Let $R = st \diamond e$. Then, the detour of R is $R \setminus st$. That is, let us assume that R leaves st above e at a vertex u , and merges back on st at vertex v after e , then detour of R is $R[u, v]$. Also, the vertex at which the detour starts is called the detour point of R . So, u is the detour point of R or in short $DP(R) = u$.

³ This was referred to as *preferred replacement path* in [19].

⁴ Let P and P' first diverge from each other to $x \in P$ and $x' \in P'$ respectively. If the index of x is lower than x' , then P is said to be lexicographically smaller than P' .

Lastly, in our algorithm, we will need to find least common ancestor of any two vertices u and v in $\text{SPT}_H(s)$. Let $\text{LCA}_H(u, v)$ denotes the least common ancestor of u and v in $\text{SPT}_H(s)$. To find the LCA, we will use the following result:

► **Lemma 10** (See [1] and its references). *Given a tree T on n vertices, we can build a data structure of size $O(n)$ in $O(n)$ time such that the least common ancestor query can be answered in $O(1)$ time.*

3 Overview of our algorithm to build SDO(1)

We will use divide and conquer approach to build SDO(1). This strategy has been previously used for directed graphs in [16, 11]. However, simply using this strategy will not get us close to our desired bound of $\tilde{O}(m\sqrt{n})$. For that, we need to combine this divide and conquer strategy with an idea of Gupta and Singh [20]. This combination is one of the technical contributions of the paper.

Like [16, 11], we use the following separator lemma to divide the graph G .

► **Theorem 11** (Separator Lemma [16, 11]). *Given a tree T with n nodes rooted at a source s , one can find in $O(n)$ time a vertex r that separates the tree T into edge disjoint sub-trees M, N such that $E_M \cup E_N = E_T, V_M \cap V_N = \{r\}$ and $\frac{n}{3} \leq |V_M|, |V_N| \leq \frac{2n}{3}$.*

Without loss of generality, we will assume that $s \in V_M$. Thus, r is the root of N . Also, note that s and r may or may not be the same. Let G_M and G_N be the graph induced by the vertices of M and N , respectively. There is one more important term that we will use in our paper:

► **Definition 12** (Primary Path \mathcal{P}). *Using the separator lemma, $\text{SPT}(s)$ can be divided into two sub-trees M and N with roots s and r . The path from s to r is called the primary path and is denoted by \mathcal{P} .*

We now describe our data structure that we will build recursively. We can view the data structure as a binary tree \mathcal{T} . The root contains data structure for the entire graph G . We will abuse notation and say the root is the graph G .

The left child of the root will contain the graph G_M and some weighted edges – we will describe the utility of these weighted edges in the next section. These weighted edges are not in G but are added by our algorithm. We will then build a data structure for G_M recursively. The right child of the root will contain the graph G_N , again with some weighted edges.

At the root of \mathcal{T} , we store the following data structures. For each $v \in G$, set $d(s, v) = |sv|$. Similarly, set $d(r, v) = |rv|$. For each $v \in G_N$, set $d(s, v, G_N) = |sv \diamond G_N|$. Similarly, for each $v \in G_M$, set $d(s, v, G_M) = |sv \diamond G_M|$. All these quantities can be computed using a single source shortest path algorithm in $\tilde{O}(m+n)$ time. Additionally, we will find the length of all replacement paths from s to r avoiding edges on the primary path \mathcal{P} . This can be done in $\tilde{O}(m+n)$ time using⁵ [21]. We will set $d(s, r, e) = |sr \diamond e|$ for each edge $e \in \mathcal{P}$.

We store the above data-structure in each node of \mathcal{T} . If a node of \mathcal{T} contains graph H , then we can construct the above data-structures in $\tilde{O}(m_H + n_H)$ time. We now describe our algorithm that finds replacement paths using \mathcal{T} .

Let us see how we find and store lengths of the replacement paths at the root of \mathcal{T} , that contains graph G . First, we find the replacement paths for edges on the primary path. Let $R = st \diamond e$ where $e \in \mathcal{P}$. We define R to be either *jumping* or *departing* depending on whether it merges back to the primary path or not.

⁵ This algorithm work for graphs with non-negative edge weights. And our graph may have weighted edges.

► **Definition 13** (Jumping and Departing paths [11, 17]). Let $R = st \diamond e$ where $e \in \mathcal{P}$. R is called a **jumping path** if it uses some vertex $u \in \mathcal{P}$ after e . If the path is not jumping then it is a **departing path**. If a replacement path is jumping, then it is called jumping replacement path. Similarly, we define departing replacement path. See Figure 2 for a visualization of these two kinds of paths.

(a) Departing Replacement Path.

(b) Jumping Replacement Path.

■ **Figure 2** Departing and Jumping Replacement Path.

Note that, jumping or departing path is defined only when the edge fault is on the primary path. Also, if a replacement path is departing, then the destination t cannot lie on \mathcal{P} . In Section 4, we will find all jumping replacement paths.

In Section 5, we design a new algorithm for finding and storing all departing replacement paths. To this end, we will use the main idea in the paper of Gupta and Singh [20]. In [20], the authors sampled a set of vertices with probability of $O(\frac{1}{\sqrt{n}})$. Then, for a vertex $t \in G$, they find a sampled vertex near t on the st path. They call this vertex t_s . Then, they show the following important lemma, which is the main idea of their paper:

► **Lemma 14** (Lemma 11 in [20]). *The number of replacement paths from s to t that avoid edges in st_s path and also avoid t_s is $O(\sqrt{n})$.*

An astute reader can see that the definition of replacement paths in the above definition looks very similar to departing replacement paths. We prove that this is indeed the case. Thus, we can transfer the result in Lemma 14 to departing replacement paths. This is the main novelty of the paper. The main technical result of Section 5 is as follows:

► **Lemma 15.** *For each $t \in G$, all departing replacement paths to t can be found in deterministic $\tilde{O}(m\sqrt{n})$ time. Moreover, the length of all such departing paths can be stored in a data structure of size $\tilde{O}(n\sqrt{n})$ and can be queried in $\tilde{O}(1)$ time.*

4 Algorithm to build SDO(1): Replacement paths that are not departing

In Section 5, we will find all and store all departing replacement paths. Thus, we just need to concentrate on the replacement paths that are either jumping or the faulty edge $e \notin \mathcal{P}$. We now divide remaining replacement paths depending on where the destination t and faulty edge e lies. There are following cases:

■ **Figure 3** $e \in G_M$ and $t \in G_N$.

4.1 $e \in G_M$ and $t \in G_N$

This case itself can be divided into two cases depending on whether e lies on the primary path or not.

1. $e \in \mathcal{P}$ (See Figure 3(a))

Let $R = st \diamond e$. If R is departing then we will see how to find it in Section 5. So, assume that R is jumping. This implies that R merges back to \mathcal{P} at a vertex, say w , after the edge e . Since $t \in G_N$, $st = sw + wr + rt$. Thus, after merging with \mathcal{P} at w , the replacement path passes through r . In that case, $|st \diamond e| = |sr \diamond e| + |rt|$. We can easily find the right hand side of the above equality as we have stored $d(s, r, e) = |sr \diamond e|$ and $d(r, t) = |rt|$.

2. $e \notin \mathcal{P}$ (See Figure 3(b))

In this case, we claim that $st \diamond e = st$. The st path has \mathcal{P} as its prefix. Since \mathcal{P} lies in G_M and survives after the deletion of e , st path remains intact.

4.2 $e \in G_M$ and $t \in G_M$

Since both e and t lie in G_M , one may think that we can recurse our algorithm in G_M to find $st \diamond e$. If $st \diamond e$ completely lies inside G_M , this is indeed the case. However, $st \diamond e$ may also use edges of G_N . To handle such cases, before recursing in G_M , we will add weighted edges to it. For each $v \in G_M$, we will add an edge from r to v with a weight $|rv \diamond G_M|$. We have already calculated this weight, it is stored in $d(r, v, G_M)$. Let the set of weighted edges added to G_M be called X . We now look at two cases, (1) $e \in \mathcal{P}$ and (2) $e \notin \mathcal{P}$.

4.2.1 $e \in \mathcal{P}$

Let $R = st \diamond e$ be a jumping replacement path. We will show that $st \diamond e = sr \diamond e + rt$. As we have calculated the length of both the paths in the right-hand side of the above equality, there is no need to even recurse in this case. To prove the above equality, we first prove the following simple lemma:

► **Lemma 16.** *Let $e \in \mathcal{P}$, $t \in G_M$. Assume that the jumping replacement path $R = st \diamond e$ uses some edges of G_N . Then $st \diamond e$ passes through r .*

Proof. Since R is jumping, it merges with \mathcal{P} . There are two ways in which R can merge with \mathcal{P} .

1. R merges with \mathcal{P} and then visits the edges of G_N .

Let us assume that u is the last vertex of G_N in the path R and R merges with \mathcal{P} at w . Since R first merges with \mathcal{P} and then visits the edges of G_N , u comes after w on R .

(a) $e \in \mathcal{P}, t \in G_M$ and the jumping replacement path uses G_N .

(b) $e \in G_M \setminus \mathcal{P}, t \in G_M$ and the replacement path uses G_N .

■ **Figure 4** $e \in G_M$ and $t \in G_M$.

Since w is below e on \mathcal{P} , we claim that the sub-path wu of su survives in $G \setminus e$ and is also the shortest path from w to u . But wu path passes through r . Thus, $st \diamond e$ passes through r by construction in Theorem 11.

2. R visits an edge of G_N and then merges with \mathcal{P} (See Figure 4(a))

In this case, we will show that R merges with \mathcal{P} at r . For contradiction, let w be the vertex at which R merges with \mathcal{P} such that $w \neq r$. Let u be the first vertex of G_N visited by R . Also, w lies after u on path R . Thus, the replacement path $R = R[s, u] + R[u, w] + R[w, t]$. Since w lies below e on \mathcal{P} , wu sub-path of su does not contain e and is also the shortest path from w to u . Thus, $R[u, w] = uw$. But uw path passes through r . This implies that R merges with \mathcal{P} at r contradicting our assumption that $w \neq r$. ◀

We are now ready to prove the main lemma in this subsection.

► **Lemma 17.** *Let $e \in \mathcal{P}$ and $t \in G_M$. Assume that the jumping replacement path $R = st \diamond e$ uses some edges of G_N . Then $|st \diamond e| = |sr \diamond e| + |rt|$.*

Proof. Using Lemma 16, R passes through r . So, we have $R = R[s, r] + R[r, t]$. The first summand on the right hand side of the above equality represent a path from s to r avoiding e . Thus, $|R[s, r]| = |sr \diamond e|$.

We will now show that $|R[r, t]| = |rt|$. Clearly $|R[r, t]| \geq |rt|$ as the first path avoid e and the second path may or may not. We will now show that the second path also avoids e which will imply that both paths are of same length. For contradiction, assume that rt passes through e . Let us assume that there is a vertex w before the edge e on path \mathcal{P} such that $rt = rw + wt$. Thus, rw passes through e but wt avoids e . But then, there is a path R' such that $R' = sw + wt$ which avoids e . We claim that $|R'| < |R|$ contradicting the fact that R is the replacement path from s to t avoiding e .

To this end,

$$\begin{aligned} |R| &= |sr \diamond e| + |R[r, t]| \\ &\geq |sr \diamond e| + |rt| \\ &= |sr \diamond e| + |rw| + |wt| \\ &\geq |sr \diamond e| + |wt| \end{aligned}$$

$$\begin{aligned} \text{Since } |sw| < |sr|, |sw| &< |sr \diamond e| \\ &> |sw| + |wt| \\ &= |R'|. \end{aligned}$$

This completes the proof of the lemma. ◀

4.2.2 $e \notin \mathcal{P}$

In this case, we will show a path in $G_M \cup X$ such that it avoids e and has the same length as $st \diamond e$. Please see Figure 4(b) for a visualization of this case.

► **Lemma 18.** *Let $e \in G_M \setminus \mathcal{P}$ and $t \in G_M$. Assume that the replacement path $R = st \diamond e$ uses some edges of G_N . Then there is a path in $G_M \cup X$ that avoids e and has length $|st \diamond e|$.*

Proof. Let us first prove that R can alternate between edges of G_N and G_M just once. To this end, let u be the last vertex of G_N visited by R . Thus, $R = R[s, u] + R[u, t]$. But the shortest path su remains intact in $G \setminus e$ as $e \notin \mathcal{P}$ and the shortest su path passes through r . This implies that $R = R[s, u] + R[u, t] = R[s, r] + R[r, u] + R[u, t]$. By construction, the first path $R[s, r] = sr$ and it completely lies in G_M . The second path $R[r, u] = ru$ and it completely lies in G_N . Let v be the vertex just after u in R . So, $v \in G_M$. So we have $R = sr + ru + (u, v) + R[v, t]$. By construction, $R[v, t]$ completely lies in G_M . Thus, R alternates from edges of G_N to G_M just once.

From the above discussion $R = R[s, r] + R[r, u] + (u, v) + R[v, t] = R[s, r] + R[r, v] + R[v, t]$. The first and the last paths of the above equality completely lies in G_M . By construction, $R[r, v]$ does not contain any edge of G_M . Thus, $R[r, v]$ is the shortest path from r to v avoiding edges of G_M , that is $|R[r, v]| = |rv \diamond G_M| = d(r, v, G_M)$.

Since we have added an edge from r to v with weight $d(r, v, G_M)$, we will now show that there is a path in $G_M \cup X$ that avoids e and has same weight as R . Consider the path $R' = R[s, r] + (r, v) + R[v, t]$. The reader can check all the three subpaths lie completely in $G_M \cup X$. Moreover, $(r, v) \in X$ is a weighted edge. Thus the weight of $|R'| = |R[s, r]| + wt_{(G_M \cup X)}(r, v) + |R[v, t]| = |R[s, r]| + d(r, v, G_M) + |R[v, t]| = |R[s, r]| + |R[r, v]| + |R[v, t]| = |R|$. This completes the proof. ◀

4.3 $e \in G_N$ and $t \in G_M$

In this case, st path completely lies in G_M and thus survives. Thus, $|st \diamond e| = |st| = d(s, t)$.

4.4 $e \in G_N$ and $t \in G_N$

In this case, we will recurse in G_N . However, G_N may not contain the source s if $s \neq r$. In that case, before recursing, we add a new source s_N in G_N . We also add some *weighted* edges to G_N . For each $v \in G_N$, we add an edge from s_N to v with a weight $d(s, v, G_N) = |sv \diamond G_N|$. Let this set of edges be called Y . Let us now show that we will find all the replacement paths if we recurse in $G_N \cup Y$.

► **Lemma 19.** *Let $e \in G_N$ and $t \in G_N$. There is a path from s_N to t in $G_N \cup Y$ that avoids e and has weight $|st \diamond e|$.*

Proof. Let $R = st \diamond e$. Let us first prove that once R visits an edge of G_N , it cannot visit an edge of G_M anymore. Let u be the last vertex of G_M visited by R and v be the vertex after u in R . Thus, $v \in G_N$. Thus, $R = R[s, u] + (u, v) + R[v, t]$. By construction, $R[v, t]$ completely lies in G_N . The shortest path su remains intact in $G \setminus e$ as $e \in G_N$ and the path su completely lies in G_M . Thus, $R[s, u] = su$. So, the path R first visits only edges of G_M (in $R[s, u]$), then goes to G_N (by taking the edge (u, v)) and then remains in G_N (in $R[v, t]$). Thus, R does not visit any edge of G_M once it visits an edge of G_N .

By the above discussion, $R = R[s, u] + (u, v) + R[v, t] = R[s, v] + R[v, t]$ such that $R[v, t]$ completely lies in G_N . Also, $R[s, v]$ completely lies in G_M except the last edge which has one endpoint in G_M and other endpoint $v \in G_N$. Thus, $R[s, v] = |sv \diamond G_N| = d(s, v, G_N)$ and we have $R = sv \diamond G_N + R[v, t]$.

Now consider a path R' that avoids e from s_N to t in $G_N \cup Y$. We construct this path as follows: we will first take the weighted edge $s_N \rightarrow v$ and then the path $R[v, t]$. The reader can check that these two subpaths completely lie in $G_N \cup Y$. The weight of this path is $|R'| = |s_N \diamond G_N| + |R[v, t]| = d(s, v, G_N) + |R[v, t]| = |R[s, v]| + |R[v, t]| = |R|$. ◀

4.5 One endpoint of e is in G_M and the other is in G_N and $t \in G$

This is an easy case as the st path survives in $G \setminus e$ as st does not contain e . Thus, $st \diamond e = st$

5 Departing Replacement paths

In the previous section, we have already found out a replacement path if it is jumping or if the edge failure is not on the primary path. In this section, we will try to find the best departing path after an edge failure. To this end, we define the following:

► **Definition 20** (Candidate departing paths). *Let $e \in \mathcal{P}$ and let D be the set of all paths avoiding e that do not use any vertex of \mathcal{P} after e . $P \in D$ is called the candidate departing path for e , if among paths in D , P has the minimum length. In case there are many departing paths avoiding same edge with same length, we will break ties using Definition 8.*

Note that, a candidate departing path may or may not be a replacement path. In case it is, we call it a departing replacement path. Also, P may be a candidate departing path for all edges in an interval, say $yz \in \mathcal{P}$, but may be a replacement path for a sub-interval of yz . With this definition in hand, we will now find all candidate departing paths.

5.1 Finding all candidate departing paths

In the previous section, we added some weighted edges in the graph when we recurse. Thus, there might be two types of edges in the graph – *weighted* and *unweighted*. The weighted edges represent paths in the graph G , and the unweighted edges are present in G . G contains only unweighted edges. However, the graph at an internal node of \mathcal{T} , say graph \widehat{G} , may have weighted as well as unweighted edges.

In the ensuing discussion, let \widehat{G} be the graph processed by our algorithm at some internal node of \mathcal{T} . In the graph \widehat{G} , we will assume that there is a source s . Let \overline{G} be the parent of \widehat{G} . In our algorithm, we partition \overline{G} into two disjoint graphs and then recurse on it. If \widehat{G} is the left child of \overline{G} , then it includes a set X of weighted edges added by us in Section 4.2. Similarly, if \widehat{G} is the right child of \overline{G} then it includes a set Y of weighted edges added by us in Section 4.4. Using the separator lemma, we will find the vertex r that partitions $\text{SPT}_{\widehat{G}}(s)$. Also, the primary path $\mathcal{P} = sr$.

We now give an overview of our method to find candidate departing paths in \widehat{G} . To this end, we will use the main idea in the paper of Gupta and Singh [20]. In [20], the authors proved Lemma 14. Though they did not mention it, the paths in the Lemma 14 look very much like the departing paths. Indeed, that lemma is more general than what the authors originally intended it to be. The authors show the above lemma for a specific vertex t_s , but a careful reading of the paper suggests that the above lemma is true for any vertex on the st path. We now generalise this lemma. However, there is one problem. The above result holds only for an unweighted graph, whereas \widehat{G} is weighted. Thus, we cannot prove the above lemma as it is. However, we will prove the following weaker lemma:

► **Lemma 21.** *Let \widehat{G} be the graph at an internal node in the binary tree \mathcal{T} . Let s be the source of \widehat{G} . For a destination $t \in \widehat{G}$, let p be any vertex on st path. The number of replacement paths from s to t that avoid edges on sp path and also avoid p is $O(\sqrt{n})$.*

Some discussion is in order. In an ideal case, the number of replacement paths that avoid edges on sp and also avoid p should have been $O(\sqrt{n_{\widehat{G}}})$. This result would have been similar to Lemma 14. Unfortunately, we cannot prove this result as \widehat{G} is weighted. However, if we just expand the weighted edge in the graph \widehat{G} , then we will get an unweighted graph. By expanding, we mean that for each weighted edge, add the path that represents that weighted edge. However, this process may increase the number of vertices in the graph to n . Now, we can adapt Lemma 14. For an unweighted graph with n vertices, this lemma guarantees that the number of replacement paths avoiding p will be at most \sqrt{n} . Indeed, this is our result in Lemma 21. Interested reader can find the proof of this in the full version of the paper [13] as it is an extension of the proof in [20].

Lemma 21 implies that there are only $O(\sqrt{n})$ replacement paths that have some special properties which are similar to the properties of departing paths. So, our plan of action is as follows:

1. Show that there are only $O(\sqrt{n})$ candidate departing paths to t in \widehat{G} . This will be done by showing the similarity between the replacement paths in Lemma 21 and candidate departing paths.
2. Show that we can find the lengths of all the candidate departing paths in \widehat{G} in $O(m_{\widehat{G}}\sqrt{n})$ time. Additionally, we show that we can store the lengths in a compact data structure of size $O(n_{\widehat{G}}\sqrt{n})$. Given any query $\text{QUERY}(s, t, e)$ to this data-structure such that $s, t \in \widehat{G}$ and e is on the primary path of \widehat{G} , we can find the length of corresponding candidate departing path in $\widetilde{O}(1)$ time.

This completes the overview of our algorithm for finding candidate departing paths.

5.2 Similarity between candidate departing paths and replacement paths in Lemma 21

Let us first prove some simple results that will help us prove this section's main idea.

► **Lemma 22.** *Let $t \in \widehat{G}$ and $p = \text{LCA}(t, r)$. All the candidate departing paths from s to t avoiding edges on sp path also avoid p . For any edge e on pr path, $st \diamond e = st$.*

Proof. Let $R = st \diamond e$ where $e \in sp$ and R is departing. The detour of R must start above e on \mathcal{P} . Since R is departing, it can not merge with the path \mathcal{P} again. So, it avoids p also.

The st path passes through p and does not use any vertex of \mathcal{P} below p . So, removing any edge on pr path does not disturb st path. So, for any edge $e \in pr$, $st \diamond e = st$. ◀

We now show that the candidate departing paths and the replacement paths in Lemma 21 have the same property.

► **Lemma 23.** *For any vertex $t \in \widehat{G}$, there are $O(\sqrt{n})$ candidate departing paths to t .*

Proof. The proof of the lemma can be derived using Lemma 22 and Lemma 21 together. For complete proof please see the full version [13]. ◀

Given the above lemma, we need to store $O(\sqrt{n})$ candidate departing paths to t in \widehat{G} . Before designing an algorithm to find candidate departing paths, we first see how we plan to store these paths in a compact data structure.

5.3 The data-structure at each node of \mathcal{T}

Let us first discuss a small technical detail that may be perceived as a problem but is not. Our graph \widehat{G} is weighted. It stands to reason that even the primary path \mathcal{P} in \widehat{G} maybe weighted. Since candidate departing paths are only for the faults on the primary path, it may not be clear what happens if the edge on the primary path is weighted. To this end, we show that on any st path in \widehat{G} , all edges except may be the first one, are unweighted.

► **Lemma 24.** *For $t \in \widehat{G}$, except may be the first edge of $(st)_{\widehat{G}}$, all other edges of $(st)_{\widehat{G}}$ are unweighted.*

Proof. We will prove using induction on the nodes of \mathcal{T} . In the root of \mathcal{T} , we have the graph G . Clearly, the graph G satisfies the property of the lemma. Let us assume using induction that the parent of the graph \widehat{G} satisfies the property of the lemma. Let \overline{G} be the parent of \widehat{G} . Let \bar{s} be the source in \overline{G} . Thus, in the graph \overline{G} , using the separator lemma, we find a \bar{r} that divides \overline{G} into two parts. The path from \bar{s} to \bar{r} , say $\overline{\mathcal{P}}$ is the primary path. By induction, only the first edge of the primary path may be weighted. There are two cases:

1. \widehat{G} is the left child of \overline{G} .

In this case, the source of \widehat{G} is also \bar{s} . For each $t \in \widehat{G}$, it can be observed that the path $(\bar{s}t)_{\overline{G}} = (\bar{s}t)_{\widehat{G}}$. Using induction hypothesis, since $(\bar{s}t)_{\overline{G}}$ satisfies the statement of lemma, so does $(\bar{s}t)_{\widehat{G}}$.

2. \widehat{G} is the right child of \overline{G} .

There are two cases. When $\bar{s} = \bar{r}$, then we fall back in point(1). So, let us look at the case when $\bar{s} \neq \bar{r}$.

For a $t \in \widehat{G}$, by construction, $(\bar{s}t)_{\overline{G}}$ passes through \bar{r} . Thus, $(\bar{s}t)_{\overline{G}} = (\bar{s}\bar{r})_{\overline{G}} + (\bar{r}t)_{\overline{G}}$. In \widehat{G} , we add a new source s . Also, we add a weighted edge from s to \bar{r} in \widehat{G} . The weight of this edge is $|\bar{s}\bar{r} \diamond \widehat{G}|_{\overline{G}}$. Also, $(\bar{r}t)_{\overline{G}} = (\bar{r}t)_{\widehat{G}}$. This implies that there is path in \widehat{G} from s to t , $(s, \bar{r}) + (\bar{r}t)_{\widehat{G}}$. By induction, we claim that on this path except (s, \bar{r}) , all the edges are unweighted. ◀

Using the above lemma, all except the first edge of the primary path are unweighted. The weighted edges represent edges for which we have already found candidate departing paths at the parent or an ancestor of \widehat{G} . Thus, we will only find candidate departing paths for unweighted edges in \mathcal{P} . In the ensuing discussion, whenever we mention a path avoiding an edge on the primary path, it will always refer to an unweighted edge.

We now prove some simple lemmas that will help us build data structures for candidate departing paths.

► **Lemma 25.** *Let R and R' be two different candidate departing paths from s to t avoiding edges e and e' respectively on the path \mathcal{P} . If e lies above e' on \mathcal{P} , then $|R| > |R'|$.*

Proof. The detour of the candidate departing R starts before e , and once it departs, it does not merge with \mathcal{P} again. As e lies above e' on \mathcal{P} , R also avoids e' . If $|R| \leq |R'|$, then by Definition 8, R must be the candidate departing path avoiding e' , leading to a contradiction. So, it must be the case that $|R| > |R'|$. ◀

► **Lemma 26.** *Let R be a candidate departing path. Let yz be the maximal subpath of \mathcal{P} such that R is the candidate departing path for edges in yz . Then $DP(R) = y$.*

Proof. For complete proof of the lemma please see the full version [13]. ◀

The above lemma states that if R avoids edges in yz , then the detour of R necessarily starts from y . We will now prove the contrapositive of the Lemma 25.

► **Lemma 27.** *Let R and R' be two different candidate departing paths from s to t . If $|R| > |R'|$, then $DP(R)$ lies above $DP(R')$ on \mathcal{P} .*

Proof. For complete proof of the lemma please see the full version [13]. ◀

We will now use the above lemmas and our deduction to build a compact data-structure for all candidate departing paths. To this end, we will store an array $DEP(t)$ for each $t \in \widehat{G}$. $DEP(t)$ will store candidate departing paths from s to t in increasing order of their lengths. By Lemma 23, there are $O(\sqrt{n})$ such paths. let us denote them by R_1, R_2, \dots, R_k where $k = O(\sqrt{n})$. For any two consecutive candidate departing paths R_i and R_{i+1} , using Lemma 27 and Lemma 26, we claim that R_{i+1} is the candidate departing path avoiding edges in $[DP(R_{i+1}), DP(R_i)]$ on the primary path \mathcal{P} . Since the size of $DEP(t) = O(\sqrt{n})$, the total size of DEP data-structure is bounded by $O(n_{\widehat{G}}\sqrt{n})$.

► **Lemma 28.** $\sum_{t \in \widehat{G}} \text{size of } DEP(t) = O(n_{\widehat{G}}\sqrt{n})$

5.4 Finding and storing all candidate departing paths efficiently

Let us first describe the setting that will be used throughout this section. At an internal node \widehat{G} of \mathcal{T} , we are planning to find all candidate departing paths from the source s . To this end, we will find a vertex r that will divide $SPT_{\widehat{G}}(s)$ roughly equally. Also, $\mathcal{P} = sr$.

To find all candidate departing path, we will build an auxiliary graph G which we will build incrementally. The source in this graph is (s) . All other vertices in G are tuples of the form $(v, |R|)$, where $v \in \widehat{G} \setminus \mathcal{P}$ and R is a candidate departing path to v . During initialization, we will add $(v, |sv|_{\widehat{G}})$ in G for each $v \in \widehat{G} \setminus \mathcal{P}$. Also, there will be an edge from (s) to $(v, |sv|_{\widehat{G}})$ with weight $|sv|_{\widehat{G}}$. We will show the following property at the end of our analysis.

► **Property 29.** *Let R be the candidate departing path to v avoiding edge on the subpath yz of \mathcal{P} . Then, there is a vertex $(v, |R|)$ in G . Moreover the shortest path from (s) to $(v, |R|)$ in the graph G is of length $|R|$, that is $|R| = |(s)(v, |R|)|_G$*

In Lemma 30, we will show that Property 29 is true for all the nodes added during initialization. Also, we will create $DEP(v)$ for each v during initialization. We will store candidate departing paths in $DEP(v)$ in increasing order of lengths. Given a departing path R , we will assume that we will store the following information about R in $DEP()$.

1. The endpoints of R .
2. The weight of path R .
3. The last edge of R and its weight.
4. $DP(R)$.

After initialization, we will run a variant of Dijkstra's algorithm in G . To this end, we will construct a min-heap H in which we will store all the departing paths that we have discovered at any point in the algorithm. We use the first two points of Definition 9 to select the minimum element from H , i.e., given two candidate departing paths R and R' , R is *smaller* than R' if $|R| < |R'|$ or $|R| = |R'|$ and $DEP(R)$ is closer to s than $DEP(R')$. If $DEP(R) = DEP(R')$, then we can break ties arbitrarily.

We now explain the adaptation of Dijkstra's algorithm. After initialization, for each $(v, |sv|)$, and for each neighbor w of v , we add the departing path $sv + (v, w)$ in H if $w \notin \mathcal{P}$. Then, we go over all the elements of the heap till it is empty. Let us assume that R is the minimum element of the heap and it ends at v and $(u, v) \in \widehat{G}$ is the last edge of R . This implies that R was added in H while processing a candidate departing path for u . Let this path be R_u . Thus, there is a node $(u, |R_u|)$ in G . We now need to decide whether R is a candidate departing path for v .

To this end, we look at the last candidate departing path added by us in $\text{DEP}(v)$, let it be Q . We then check if the $d_{\widehat{G}}(s, \text{DP}(R))$ is less than $d_{\widehat{G}}(s, \text{DP}(Q))$. If yes, then we have found a new candidate departing path to v that avoids all edges in $[\text{DP}(R), \text{DP}(Q)]$ of \mathcal{P} . Thus, we will add the vertex $(v, |R|)$ in the graph with an edge of weight $wt_{\widehat{G}}(u, v)$ from $(u, |R_u|)$. Also, for each neighbor w of v , we will add the departing path $R + (v, w)$ to the heap if $w \notin \mathcal{P}$. For the formal pseudocode, see the full version [13] of this paper.

5.5 Correctness and running time of the algorithm storing candidate departing paths

We claim that, the time taken to construct the $\text{DEP}()$ data-structure at a node of the binary tree with graph \widehat{G} is $O(m_{\widehat{G}}\sqrt{n})$. Moreover, the size of the data-structure is $O(n_{\widehat{G}}\sqrt{n})$. At first, we prove that our algorithm stores correct lengths of all candidate departing paths.

► **Lemma 30.** *Let R be a candidate departing path to v where $v \in \widehat{G} \setminus \mathcal{P}$. Let yz be the maximal subpath of \mathcal{P} such that R is the candidate departing path for edges in yz . Then $(v, |R|) \in G$ and satisfies Property 29.*

Proof. We will prove the above lemma using induction on the weighted distance of a vertex from (s) in G . During initialization, for each $v \in G \setminus \mathcal{P}$, we add a vertex $(v, |sv|_{\widehat{G}}) \in G$. Also, the weight of the edge from (s) to $(v, |sv|_{\widehat{G}})$ is $|sv|_{\widehat{G}}$. We claim that the statement of the lemma is true for the smallest candidate departing path to v . Indeed, using Lemma 22, $(sv)_{\widehat{G}}$ is the a replacement path for the edges in subpath pr on \mathcal{P} where $p = \text{LCA}_{\widehat{G}}(v, r)$. Also, $(sv)_{\widehat{G}}$ is the smallest replacement path because it is the shortest path from s to v in \widehat{G} . Thus, the base case is true for all $v \in \widehat{G} \setminus \mathcal{P}$.

Let us now assume that the statement of the lemma is true for all candidate departing paths to v with length $< |R|$. Let the second last vertex of R be u . Since R is a candidate departing path, even $R \setminus (u, v)$ is a candidate departing path. Since $R[s, u]$ has length less than R , by induction hypothesis, there is a vertex $(u, |R \setminus (u, v)|)$ in G . Also there is at least one replacement path in $\text{DEP}(v)$ of weight less than $|R|$ – as we have added $(sv)_{\widehat{G}}$ in $\text{DEP}(v)$. Let Q be a candidate departing path of largest weight less than the weight of R . Let us also assume that Q avoids edge on subpath $zz' \in \mathcal{P}$. Thus, using Lemma 26, $\text{DP}(Q) = z$. Since $|Q| < |R|$, using Lemma 27, $\text{DP}(R)$ lies above $\text{DP}(Q)$ on \mathcal{P} . Using the induction hypothesis, there is a vertex $(v, |Q|)$ in G .

We will now show that our algorithm will add $(v, |R|)$ in G . There are four cases:

1. Our algorithm does not add any vertex for v after $(v, |Q|)$
But our algorithm does process the vertex $(u, |R \setminus (u, v)|)$. Thus, it will check each neighbour of u . When it checks the neighbor v , it will add the departing path R in the heap H . Thus, we will add the vertex $(v, |R|)$ in G while processing R , leading to a contradiction.
2. Our algorithm adds a vertex $(v, |R'|)$ where $\text{DP}(R)$ lies above $\text{DP}(R')$ on \mathcal{P}
We claim that the weight of R' cannot be less than the weight of R as then R is not the candidate departing path for all the edges in $\text{DP}(R')z$ subpath, contradicting the statement of the lemma. So let us assume that $|R| = |R'|$. But then $\text{DP}(R)$ lies above $\text{DP}(R')$ on \mathcal{P} . Thus, the min-heap will give preference to the replacement path R first, and our algorithm will make the vertex $(v, |R|)$. Again a contradiction.
3. Our algorithm adds a vertex $(v, |R'|)$ where $\text{DP}(R)$ lies below $\text{DP}(R')$ on \mathcal{P}
Again, we claim that the weight of R' cannot be less than the weight of R as then it R is not the replacement path for all edges in yz subpath, contradicting the statement of the

lemma. So let us assume that $|R| = |R'|$. But $\text{DP}(R')$ is closer to s than $\text{DP}(R)$. Thus, R' should be the candidate departing path avoiding edges of yz . This contradicts our assumption that R is the candidate departing path for all edges in yz .

4. Our algorithm adds a vertex $(v, |R'|)$ where $\text{DP}(R) = \text{DP}(R')$
 $|R'|$ cannot be less than $|R|$ as otherwise our algorithm will give preference to path R .
 But, if $|R| = |R'|$, then there is a vertex $(v, |R'|) = (v, |R|)$ in G .

So, we add the node $(v, |R|)$ in the graph G . At that moment, we also add an edge from $(u, R \setminus (u, v))$ to $(v, |R|)$ in G with weight $wt_{\widehat{G}}(u, v)$. Using induction, $|(s)(u, R \setminus (u, v))|_G = |R \setminus (u, v)|$. Thus, $|(s)(v, |R|)|_G = |R \setminus (u, v)| + wt_{\widehat{G}}(u, v) = |R|$. This completes our proof. \blacktriangleleft

Let's determine the running time of our algorithm. Using Lemma 23, for each $v \in \widehat{G}$, we make $O(\sqrt{n})$ entries in $\text{DEP}(v)$. In other words, we make $O(\sqrt{n})$ nodes of type (v, \cdot) in G . Whenever we add a node $(v, |R|)$ in G , we see all the edges of v . This implies that the total time taken to process all the vertices of v in G is $O(\sqrt{n} \deg_{\widehat{G}}(v))$. Summing it over all the vertices gives us the bound of $O(m_{\widehat{G}}\sqrt{n})$. Using a similar calculation, the total size of our data-structure for \widehat{G} is $O(n_{\widehat{G}}\sqrt{n})$. Thus, we claim the following lemma:

► **Lemma 31.** *The time taken to construct the $\text{DEP}()$ data-structure at a node of the binary tree with graph \widehat{G} is $O(m_{\widehat{G}}\sqrt{n})$. Moreover, the size of the data-structure is $O(n_{\widehat{G}}\sqrt{n})$.*

5.6 Querying for a candidate departing path

In this section, we describe how to find a candidate departing path using our data-structure $\text{DEP}()$. Let $t \in \widehat{G} \setminus \mathcal{P}$ and $e \in \mathcal{P}$ be an edge on st path. Let $st \diamond e$ be a candidate departing path, then we can find it using the algorithm given in the full version of this paper [13].

In this algorithm, we perform a binary search in $\text{DEP}(t)$ to find two consecutive paths R and Q such that e lies in the interval $[\text{DEP}(R), \text{DEP}(Q)]$ of \mathcal{P} . Using Lemma 27 and Lemma 26, R is the candidate departing path avoiding e .

6 Construction time, size and query time of the SDO(1)

In this section, we show that the construction time of our algorithm is $\widetilde{O}(m\sqrt{n})$. We also bound the size of the data-structure of our algorithm by $\widetilde{O}(n\sqrt{n})$. We also design a query algorithm with a query time $\widetilde{O}(1)$. This proves the main result of the paper.

At the root of \mathcal{T} , except for the recursions, we claim that constructing all other data-structures take $O(m\sqrt{n})$ time. This is because, the construction time is dominated by the time to construct $\text{DEP}()$, which using Lemma 31, is $O(m\sqrt{n})$. At the second level of the tree \mathcal{T} , we have two nodes. In the left child, we have the graph $G_M \cup X$. This graph has $m_{G_M} + n_{G_M}$ edges and n_{G_M} vertices. Again applying Lemma 31, the time taken to construct all the data-structures in the left child of root is $(m_{G_M} + n_{G_M})\sqrt{n}$. In the right child of the root, we have the graph $G_N \cup Y$. This graph has $m_{G_N} + n_{G_N}$ edges and $n_{G_N} + 1$ vertices. The +1 is for the new root in G_N . Again applying Lemma 31, the time taken to construct all the data-structures in the right child of root is $(m_{G_N} + n_{G_N})\sqrt{n}$. Thus, the total time taken at the second level of \mathcal{T} is $(m_{G_M} + n_{G_M})\sqrt{n} + (m_{G_N} + n_{G_N})\sqrt{n}$. Since $m_{G_M} + m_{G_N} \leq m$ and $n_{G_M} + n_{G_N} = n + 1$, the total time taken is $\leq (m + n + 1)\sqrt{n}$. Note that $n_{G_M} + n_{G_N} = n + 1$ because r is shared both by G_M and G_N . Since, the number of nodes in \mathcal{T} is $O(n)$, we claim that the number of vertices shared by sibling graphs at any level of \mathcal{T} is $O(n)$. Similar to the second level, we claim that the time taken at level ℓ is $\widetilde{O}((m + n + \#\text{nodes shared at level } \ell)\sqrt{n}) = \widetilde{O}((m + n)\sqrt{n})$. We can assume that our graph

G is connected as we need not even process a component that is not reachable from our source s . Thus, the previous running time bound is equal to $\tilde{O}(m\sqrt{n})$. Since the height of the tree is $\tilde{O}(1)$, the total time taken to construct our data-structure is $\tilde{O}(m\sqrt{n})$. Using the same argument, we can bound the size of the data-structure of our algorithm by $\tilde{O}(n\sqrt{n})$.

6.1 The Query Algorithm

In this section, we will design our query algorithm that will take s, t, e as its parameter. Additionally, it also takes the root of the tree \mathcal{T} as a parameter which contains data structures of the main graph G . The algorithm then basically goes over all the possible cases described in Section 4 (Please see algorithm 3). Also, the algorithm compares that output with the best candidate departing path given by and return the minimum among them.

■ **Algorithm 1** QUERY(s, t, e, \mathcal{T}).

```

1 mindist  $\leftarrow$   $\infty$ ;
  /* Section 4.1 */
2 if  $e \in G_M, t \in G_N$  then
3   if  $e \in \mathcal{P}$  then
4     /* if  $st \diamond e$  happens to be departing */
4     mindist  $\leftarrow$  QUERY-DEP( $s, t, e$ ) using DEP() data-structure at  $\mathcal{T}$ ;
5     /* if  $st \diamond e$  happens to be jumping */
5     mindist  $\leftarrow$  min{mindist,  $|sr \diamond e| + |rt|$ }
6   else
7     mindist  $\leftarrow$   $|st|$ 
  /* Section 4.2 */
8 if  $e \in G_M, t \in G_M$  then
9   /* Section 4.2.1 */
9   if  $e \in \mathcal{P}$  then
10    /* if  $st \diamond e$  happens to be departing */
10    mindist  $\leftarrow$  QUERY-DEP( $s, t, e$ ) using DEP() data-structure at  $\mathcal{T}$ ;
11    /* if  $st \diamond e$  happens to be jumping */
11    mindist  $\leftarrow$  min(mindist,  $|sr \diamond e| + |rt|$ )
12   /* Section 4.2.2 */
12   if  $e \in G_M \setminus \mathcal{P}$  then
13     mindist  $\leftarrow$  QUERY( $s, t, e$ , left child of  $\mathcal{T}$ )
  /* Section 4.3 */
14 if  $e \in G_N, t \in G_M$  then
15   mindist  $\leftarrow$   $|st|$ ;
  /* Section 4.4 */
16 if  $e \in G_N, t \in G_N$ , then
17   mindist  $\leftarrow$  QUERY( $s, t, e$ , right child of  $\mathcal{T}$ );
  /* Section 4.5 */
18 if one endpoint of  $e$  is in  $G_M$  and other in  $G_N$  then
19   mindist  $\leftarrow$   $|st|$ ;
20 return mindist;
```

The reader can see that the time taken by the algorithm (excluding recursion) is $\tilde{O}(1)$. Since, at each step in this algorithm, we either go to the left child of a node in the tree \mathcal{T} or to the right child, the number of recursive steps in this algorithm is $\tilde{O}(1)$ or to be specific $O(\log n)$. Then for each child the call to $\text{QUERY-DEP}(s, t, e)$ takes $O(\log n)$ time. This implies that the running time of the query algorithm is $O(\log^2 n)$ or $\tilde{O}(1)$. Thus, we have proven the main theorem of the paper.

Fast Computation of Zigzag Persistence

Abstract

Zigzag persistence is a powerful extension of the standard persistence which allows deletions of simplices besides insertions. However, computing zigzag persistence usually takes considerably more time than the standard persistence. We propose an algorithm called FASTZIGZAG which narrows this efficiency gap. Our main result is that an input simplex-wise zigzag filtration can be converted to a *cell-wise non-zigzag* filtration of a Δ -complex with the same length, where the cells are copies of the input simplices. This conversion step in FASTZIGZAG incurs very little cost. Furthermore, the barcode of the original filtration can be easily read from the barcode of the new cell-wise filtration because the conversion embodies a series of *diamond switches* known in topological data analysis. This seemingly simple observation opens up the vast possibilities for improving the computation of zigzag persistence because any efficient algorithm/software for standard persistence can now be applied to computing zigzag persistence. Our experiment shows that this indeed achieves substantial performance gain over the existing state-of-the-art softwares.

1 Introduction

Standard persistent homology defined over a growing sequence of simplicial complexes is a fundamental tool in topological data analysis (TDA). Since the advent of persistence algorithm [18] and its algebraic understanding [30], various extensions of the basic concept have been explored [6, 8, 12, 13]. Among these extensions, zigzag persistence introduced by Carlsson and de Silva [6] is an important one. It empowered TDA to deal with filtrations where both insertion and deletion of simplices are allowed. In practice, allowing deletion of simplices does make the topological tool more powerful. For example, in dynamic networks [15, 21] a sequence of graphs may not grow monotonically but can also shrink due to disappearance of vertex connections. Furthermore, zigzag persistence seems to be naturally connected with the computations involving multiparameter persistence, see e.g. [16, 17].

Zigzag persistence possesses some key differences from standard persistence. For example, unlike standard (non-zigzag) modules which decompose into only finite and infinite intervals, zigzag modules decompose into four types of intervals (see Definition 2). Existing algorithms for computing zigzag persistence from a zigzag filtration [8, 22, 23, 24] are all based on maintaining explicitly or implicitly a consistent basis throughout the filtration. This makes these algorithms for zigzag persistence more involved and hence slower in practice than

algorithms for the non-zigzag version though they have the same time complexity [25]. We sidestep the bottleneck of maintaining an explicit basis and propose an algorithm called FASTZIGZAG, which converts the input zigzag filtration to a *non-zigzag* filtration with an efficient strategy for mapping barcodes of the two bijectively. Then, we can apply any efficient algorithm for standard persistence on the resulting non-zigzag filtration to compute the barcode of the original filtration. Considering the abundance of optimizations [2, 3, 4, 5, 10, 11] of standard persistence algorithms and a recent GPU acceleration [29], the conversion in FASTZIGZAG enables zigzag persistence computation to take advantage of any existing or future improvements on standard persistence computation. Our implementation, which uses the PHAT [4] software for computing standard persistence, shows substantial performance gain over existing state-of-the-art softwares [26, 28] for computing zigzag persistence (see Section 3.5). We make our software publicly available through: <https://github.com/taohou01/fzz>.

To elaborate on the strategy of FASTZIGZAG, we first observe a special type of zigzag filtrations called *non-repetitive* zigzag filtrations in which a simplex (or more generally, a *cell*) is never added again once deleted. Such a filtration admits an *up-down* filtration as its canonical form that can be obtained by a series of *diamond switches* [6, 7, 8]. The up-down filtration can be further converted into a *non-zigzag* filtration again using diamond switches as in the Mayer-Vietoris pyramid presented in [8]. Individual switches are atomic tools that help us to show equivalence of barcodes, but we do not need to actually execute them in computation. Instead, we go straight to the final form of the filtration quite easily and efficiently. Finally, we observe that any zigzag filtration can be treated as a non-repetitive *cell-wise* filtration of a Δ -complex [20] consisting of multisets of input simplices. This means that each repeatedly added simplex is treated as a different cell in the Δ -complex, so that we can apply our findings for non-repetitive filtrations to arbitrary filtrations. The conversions described above are detailed in Section 3.

1.1 Related works

Zigzag persistence is essentially an A_n -type quiver [14] in mathematics which is first introduced to the TDA community by Carlsson and de Silva [6]. In their paper [6], Carlsson and de Silva also study the Mayer-Vietoris diamond used in this paper and propose an algorithm for computing zigzag barcodes from zigzag modules (i.e., an input is a sequence of vector spaces connected by linear maps encoded as matrices). Carlsson et al. [8] then propose an $O(mn^2)$ algorithm for computing zigzag barcodes from zigzag filtrations using a structure called right filtration. In their paper [8], Carlsson et al. also extend the classical sublevelset filtrations for functions on topological spaces by proposing levelset zigzag filtrations and show the equivalence of levelset zigzag with the extended persistence proposed by Cohen-Steiner et al. [12]. Maria and Outdot [22, 23] propose an alternative algorithm for computing zigzag barcodes by attaching a reversed standard filtration to the end of the partial zigzag filtration being scanned. Their algorithm maintains the barcode over the Surjective and Transposition Diamond on the constructed zigzag filtration [22, 23]. Maria and Schreiber [24] propose a Morse reduction preprocessing for zigzag filtrations which speeds up the zigzag barcode computation. Carlsson et al. [9] discuss some matrix factorization techniques for computing zigzag barcodes from zigzag modules, which, combined with a divide-and-conquer strategy, lead to a parallel algorithm for computing zigzag persistence. Almost all algorithms reviewed so far have a cubic time complexity. Milosavljević et al. [25] establish an $O(m^\omega)$ theoretical complexity for computing zigzag persistence from filtrations, where $\omega < 2.37286$ is the matrix multiplication exponent [1]. Recently, Dey and Hou [15] propose near-linear algorithms for computing zigzag persistence from the special cases of graph filtrations, with the help of representatives defined for the intervals and some dynamic graph data structures.

■ **Figure 1** Examples of Δ -complexes with two triangles sharing 0, 1, 2, or 3 edges on their boundaries.

2 Preliminaries

Δ -complex. In this paper, we build filtrations on Δ -complexes which are extensions of simplicial complexes described in Hatcher [20]. These Δ -complexes are derived from a set of standard simplices by identifying the boundary of each simplex with other simplices while preserving the vertex orders. For distinction, building blocks of Δ -complexes (i.e., standard simplices) are called *cells*. Motivated by a construction from the input simplicial complex described in Algorithm 3.1, we use a *more restricted* version of Δ -complexes, where boundary cells of each p -cell are identified with *distinct* $(p - 1)$ -cells. Notice that this makes each p -cell combinatorially equivalent to a p -simplex. Hence, the difference of the Δ -complexes in this paper from the standard simplicial complexes is that common faces of two cells in the Δ -complexes can have more relaxed forms. For example, in Figure 1, two “triangles” (2-cells) in a Δ -complex having the same set of vertices can either share 0, 1, 2, or 3 edges in their boundaries; note that the two triangles in Figure 1d form a 2-cycle.

Formally, we define Δ -complexes recursively similar to the classical definition of *CW-complexes* [20] though it need not be as general; see Hatcher’s book [20] for a more general definition. Note that simplicial complexes are trivially Δ -complexes and therefore most definitions in this section target Δ -complexes.

► **Definition 1.** A Δ -complex is defined recursively with dimension:

1. A 0-dimensional Δ -complex K^0 is a set of points, each called a 0-cell.
2. A p -dimensional Δ -complex K^p , $p \geq 1$, is a quotient space of a $(p - 1)$ -dimensional Δ -complex K^{p-1} along with several standard p -simplices. The quotienting is realized by an attaching map $h : \partial(\sigma) \rightarrow K^{p-1}$ which identifies the boundary $\partial(\sigma)$ of each p -simplex σ with points in K^{p-1} so that h is a homeomorphism onto its image. We term the standard p -simplex σ with boundary identified to K^{p-1} as a *p -cell* in K^p . Furthermore, we have that the restriction of h to each proper face of σ is a homeomorphism onto a cell in K^{p-1} .

Notice that the original (more general) Δ -complexes [20] require specifying vertex orders when identifying the cells. However, the restricted Δ -complexes defined above do not require specifying such orders because we always identify the boundaries of cells by *homeomorphisms* and hence the vertex orders for identification are implicitly derived from a vertex order of a seeding cell.

Homology. Homology in this paper is defined on Δ -complexes, which is defined similarly as for simplicial complexes [20]. All homology groups are taken with \mathbb{Z}_2 -coefficients and therefore vector spaces mentioned in this paper are also over \mathbb{Z}_2 .

Zigzag filtration and barcode. A *zigzag filtration* (or simply *filtration*) is a sequence of Δ -complexes

$$\mathcal{F} : K_0 \leftrightarrow K_1 \leftrightarrow \cdots \leftrightarrow K_m,$$

in which each $K_i \leftrightarrow K_{i+1}$ is either a forward inclusion $K_i \hookrightarrow K_{i+1}$ or a backward inclusion $K_i \leftarrow K_{i+1}$. For computational purposes, we only consider *cell-wise* filtrations in this paper, i.e., each inclusion $K_i \leftrightarrow K_{i+1}$ is an addition or deletion of a *single* cell; such an inclusion is sometimes denoted as $K_i \xrightarrow{\sigma} K_{i+1}$ with σ indicating the cell being added or deleted.

We call \mathcal{F} as *non-repetitive* if whenever a cell σ is deleted from \mathcal{F} , the cell σ is never added again. We call \mathcal{F} an *up-down* filtration [8] if \mathcal{F} can be separated into two parts such that the first part contains only forward inclusions and the second part contains only backward ones, i.e., \mathcal{F} is of the form $\mathcal{F} : K_0 \hookrightarrow K_1 \hookrightarrow \cdots \hookrightarrow K_\ell \leftarrow K_{\ell+1} \leftarrow \cdots \leftarrow K_m$. Usually in this paper, filtrations start and end with empty complexes, e.g., $K_0 = K_m = \emptyset$ in \mathcal{F} .

Applying the p -th homology functor on \mathcal{F} induces a *zigzag module*:

$$H_p(\mathcal{F}) : H_p(K_0) \leftrightarrow H_p(K_1) \leftrightarrow \cdots \leftrightarrow H_p(K_m),$$

in which each $H_p(K_i) \leftrightarrow H_p(K_{i+1})$ is a linear map induced by inclusion. It is known [6, 19] that $H_p(\mathcal{F})$ has a decomposition of the form $H_p(\mathcal{F}) \simeq \bigoplus_{k \in \Lambda} \mathcal{I}^{[b_k, d_k]}$, in which each $\mathcal{I}^{[b_k, d_k]}$ is a special type of zigzag module called *interval module* over the interval $[b_k, d_k]$. The (multi-)set of intervals denoted as $\text{Pers}_p(\mathcal{F}) := \{[b_k, d_k] \mid k \in \Lambda\}$ is an invariant of \mathcal{F} and is called the *p -th barcode* of \mathcal{F} . Each interval in $\text{Pers}_p(\mathcal{F})$ is called a *p -th persistence interval* and is also said to be in dimension p . Frequently in this paper, we consider the barcode of \mathcal{F} in all dimensions $\text{Pers}_*(\mathcal{F}) := \bigsqcup_{p \geq 0} \text{Pers}_p(\mathcal{F})$.

► **Definition 2** (Open and closed birth/death). For a zigzag filtration $\mathcal{F} : \emptyset = K_0 \leftrightarrow K_1 \leftrightarrow \cdots \leftrightarrow K_m = \emptyset$, the start of any interval in $\text{Pers}_*(\mathcal{F})$ is called a **birth index** in \mathcal{F} and the end of any interval is called a **death index**. Moreover, a birth index b is said to be **closed** if $K_{b-1} \hookrightarrow K_b$ is a forward inclusion; otherwise, b is **open**. Symmetrically, a death index d is said to be **closed** if $K_d \leftarrow K_{d+1}$ is a backward inclusion; otherwise, d is **open**. The types of the birth/death ends classify intervals in $\text{Pers}_*(\mathcal{F})$ into four types: **closed-closed**, **closed-open**, **open-closed**, and **open-open**.

► **Remark 3.** If \mathcal{F} is a levelset zigzag filtration [8], then the open and closed ends defined above are the same as for levelset zigzag.

► **Remark 4.** An inclusion $K_i \leftrightarrow K_{i+1}$ in a cell-wise filtration either provides $i + 1$ as a birth index or provides i as a death index (but cannot provide both).

Mayer-Vietoris diamond. The algorithm in this paper draws upon the Mayer-Vietoris diamond proposed by Carlsson and de Silva [6] (see also [7, 8]), which relates barcodes of two filtrations differing by a local change:

► **Definition 5** (Mayer-Vietoris diamond [6]). Two cell-wise filtrations \mathcal{F} and \mathcal{F}' are related by a **Mayer-Vietoris diamond** if they are of the following forms (where $\sigma \neq \tau$):

$$\begin{array}{c} \mathcal{F} : \\ K_0 \longleftrightarrow \cdots \longleftrightarrow K_{j-1} \begin{array}{c} \nearrow \sigma \\ \searrow \tau \end{array} K_j \begin{array}{c} \nwarrow \tau \\ \nearrow \sigma \end{array} K_{j+1} \longleftrightarrow \cdots \longleftrightarrow K_m \\ \mathcal{F}' : \\ \phantom{K_{j-1}} \phantom{K_{j+1}} \\ \phantom{K_{j-1}} \phantom{K_{j+1}} \end{array} \quad (1)$$

In the above diagram, \mathcal{F} and \mathcal{F}' differ only in the complexes at index j and \mathcal{F}' is derived from \mathcal{F} by switching the addition of σ and deletion of τ . We also say that \mathcal{F}' is derived from \mathcal{F} by an **outward** switch and \mathcal{F} is derived from \mathcal{F}' by an **inward** switch.

► **Remark 6.** In Equation (1), we only provide a specific form of Mayer-Vietoris diamond which is sufficient for our purposes; see [6, 8] for a more general form. According to [6], the diamond in Equation (1) is a Mayer-Vietoris diamond because $K_j = K_{j-1} \cup K_{j+1}$ and $K'_j = K_{j-1} \cap K_{j+1}$.

We then have the following fact:

► **Theorem 7** (Diamond Principle [6]). *Given two cell-wise filtrations $\mathcal{F}, \mathcal{F}'$ related by a Mayer-Vietoris diamond as in Equation (1), there is a bijection from $\text{Pers}_*(\mathcal{F})$ to $\text{Pers}_*(\mathcal{F}')$ as follows:*

$\text{Pers}_*(\mathcal{F})$	$\text{Pers}_*(\mathcal{F}')$
$[b, j-1]; b \leq j-1$	$[b, j]$
$[b, j]; b \leq j-1$	$[b, j-1]$
$[j, d]; d \geq j+1$	$[j+1, d]$
$[j+1, d]; d \geq j+1$	$[j, d]$
$[j, j]$ of dimension p	$[j, j]$ of dimension $p-1$
$[b, d];$ all other cases	$[b, d]$

Note that the bijection preserves the dimension of the intervals except for $[j, j]$.

► **Remark 8.** In the above bijection, only an interval containing *some but not all* of $\{j-1, j, j+1\}$ maps to a different interval or different dimension.

3 FASTZIGZAG algorithm

In this section, we show that computing barcodes for an arbitrary zigzag filtration of simplicial complexes can be reduced to computing barcodes for a certain *non-zigzag* filtration of Δ -complexes. The resulting algorithm called FASTZIGZAG is more efficient considering that standard (non-zigzag) persistence admits faster algorithms [2, 3, 4, 5, 10, 11, 29] in practice. We confirm the efficiency with experiments in Section 3.5.

3.1 Overview

Given a *simplex-wise* zigzag filtration

$$\mathcal{F} : \emptyset = K_0 \xleftarrow{\sigma_0} K_1 \xleftarrow{\sigma_1} \dots \xleftarrow{\sigma_{m-1}} K_m = \emptyset$$

of simplicial complexes as input, the FASTZIGZAG algorithm has the following main procedure:

1. Convert \mathcal{F} into a *non-repetitive* zigzag filtration of Δ -complexes.
2. Convert the non-repetitive filtration to an *up-down* filtration.
3. Convert the up-down filtration to a *non-zigzag* filtration with the help of an *extended persistence* filtration.
4. Compute the standard persistence barcode, which is then converted to the barcode for the input filtration based on rules given in Proposition 15 and 19.

■ **Figure 2** The Δ -complex resulting from performing an inward switch around \hat{K}_4 for the example shown in Figure 5.

Step 1 is achieved by simply treating each repeatedly added simplex in \mathcal{F} as a new cell in the converted filtration (see also [25]). Throughout the section, we denote the converted non-repetitive, *cell-wise* filtration as

$$\hat{\mathcal{F}} : \emptyset = \hat{K}_0 \xleftarrow{\hat{\sigma}_0} \hat{K}_1 \xleftarrow{\hat{\sigma}_1} \dots \xleftarrow{\hat{\sigma}_{m-1}} \hat{K}_m = \emptyset.$$

Notice that each \hat{K}_i in $\hat{\mathcal{F}}$ is homeomorphic to K_i in \mathcal{F} , and hence $\text{Pers}_*(\mathcal{F}) = \text{Pers}_*(\hat{\mathcal{F}})$. However, we get an important difference between \mathcal{F} and $\hat{\mathcal{F}}$ by treating the simplicial complexes as Δ -complexes. For example, in Figure 5 presented later in this section, the first addition of edge c in \mathcal{F} corresponds to a cell c_0 in $\hat{\mathcal{F}}$ and its second addition in \mathcal{F} corresponds to a cell c_1 . Performing an inward switch around \hat{K}_4 (switching $\xleftarrow{c_0}$ and $\xleftarrow{c_1}$) turns \hat{K}_4 into a Δ -complex as shown in Figure 2. However, we cannot perform such a switch in \mathcal{F} which consists of simplicial complexes, because diamond switches require the switched simplices or cells to be different (see Definition 5).

In Section 3.2 and 3.3, we provide details for Step 2 and 3 as well as propositions for converting barcodes mentioned in Step 4. We summarize the filtration converting process in Section 3.4 by providing pseudocodes (Algorithm 3.1) and examples (Figure 5 and 6).

3.2 Conversion to up-down filtration

► **Proposition 9.** *For the filtration $\hat{\mathcal{F}}$, there is a cell-wise up-down filtration*

$$U : \emptyset = L_0 \hookrightarrow L_1 \hookrightarrow \dots \hookrightarrow L_n \hookleftarrow L_{n+1} \hookleftarrow \dots \hookleftarrow L_{2n} = \emptyset$$

derived from $\hat{\mathcal{F}}$ by a sequence of inward switches. Note that $m = 2n$

Proof. Let $\hat{K}_i \xleftarrow{\hat{\sigma}_i} \hat{K}_{i+1}$ be the first deletion in $\hat{\mathcal{F}}$ and $\hat{K}_j \xleftarrow{\hat{\sigma}_j} \hat{K}_{j+1}$ be the first addition after that. That is, $\hat{\mathcal{F}}$ is of the form

$$\hat{\mathcal{F}} : \hat{K}_0 \hookrightarrow \dots \hookrightarrow \hat{K}_i \xleftarrow{\hat{\sigma}_i} \hat{K}_{i+1} \xleftarrow{\hat{\sigma}_{i+1}} \dots \xleftarrow{\hat{\sigma}_{j-2}} \hat{K}_{j-1} \xleftarrow{\hat{\sigma}_{j-1}} \hat{K}_j \xleftarrow{\hat{\sigma}_j} \hat{K}_{j+1} \hookrightarrow \dots \hookrightarrow \hat{K}_m.$$

Since $\hat{\mathcal{F}}$ is non-repetitive, we have $\hat{\sigma}_{j-1} \neq \hat{\sigma}_j$. So we can switch $\xleftarrow{\hat{\sigma}_{j-1}}$ and $\xleftarrow{\hat{\sigma}_j}$ (which is an inward switch) to derive a filtration

$$\hat{K}_0 \hookrightarrow \dots \hookrightarrow \hat{K}_i \xleftarrow{\hat{\sigma}_i} \hat{K}_{i+1} \xleftarrow{\hat{\sigma}_{i+1}} \dots \xleftarrow{\hat{\sigma}_{j-2}} \hat{K}_{j-1} \xleftarrow{\hat{\sigma}_j} \hat{K}'_j \xleftarrow{\hat{\sigma}_{j-1}} \hat{K}_{j+1} \hookrightarrow \dots \hookrightarrow \hat{K}_m.$$

We then continue performing such inward switches (e.g., the next switch is on $\xleftarrow{\hat{\sigma}_{j-2}}$ and $\xleftarrow{\hat{\sigma}_j}$) to derive a filtration

$$\hat{\mathcal{F}}' : \hat{K}_0 \hookrightarrow \dots \hookrightarrow \hat{K}_i \xleftarrow{\hat{\sigma}_j} \hat{K}'_{i+1} \xleftarrow{\hat{\sigma}_i} \dots \xleftarrow{\hat{\sigma}_{j-3}} \hat{K}'_{j-1} \xleftarrow{\hat{\sigma}_{j-2}} \hat{K}'_j \xleftarrow{\hat{\sigma}_{j-1}} \hat{K}_{j+1} \hookrightarrow \dots \hookrightarrow \hat{K}_m.$$

Note that from $\hat{\mathcal{F}}$ to $\hat{\mathcal{F}}'$, the up-down “prefix” grows longer. We can repeat the above operations on the newly derived $\hat{\mathcal{F}}'$ until the entire filtration turns into an up-down one. ◀

Throughout the section, let

$$\mathcal{U} : \emptyset = L_0 \xleftarrow{\tau_0} \dots \xleftarrow{\tau_{n-1}} L_n \xleftarrow{\tau_n} \dots \xleftarrow{\tau_{2n-1}} L_{2n} = \emptyset$$

be the up-down filtration for $\hat{\mathcal{F}}$ as described in Proposition 9, where $m = 2n$. We also let $\hat{K} = L_n$.

In a cell-wise filtration, for a cell σ , let its addition (insertion) be denoted as $\downarrow\sigma$ and its deletion (removal) be denoted as $\uparrow\sigma$. From the proof of Proposition 9, we observe the following: during the transition from $\hat{\mathcal{F}}$ to \mathcal{U} , for any two additions $\downarrow\sigma$ and $\downarrow\sigma'$ in $\hat{\mathcal{F}}$ (and similarly for deletions), if $\downarrow\sigma$ is before $\downarrow\sigma'$ in $\hat{\mathcal{F}}$, then $\downarrow\sigma$ is also before $\downarrow\sigma'$ in \mathcal{U} . We then have the following fact:

► **Fact 10.** *Given the filtration $\hat{\mathcal{F}}$, to derive \mathcal{U} , one only needs to scan $\hat{\mathcal{F}}$ and list all the additions first and then the deletions, following the order in $\hat{\mathcal{F}}$.*

► **Remark 11.** Figure 3 gives an example of $\hat{\mathcal{F}}$ and its corresponding \mathcal{U} , where the additions and deletions in $\hat{\mathcal{F}}$ and \mathcal{U} follow the same order.

► **Definition 12** (Creator and destroyer). *For any interval $[b, d] \in \text{Pers}_*(\hat{\mathcal{F}})$, if $\hat{K}_{b-1} \xleftarrow{\hat{\sigma}_{b-1}} \hat{K}_b$ is forward (resp. backward), we call $\downarrow\hat{\sigma}_{b-1}$ (resp. $\uparrow\hat{\sigma}_{b-1}$) the **creator** of $[b, d]$. Similarly, if $\hat{K}_d \xleftarrow{\hat{\sigma}_d} \hat{K}_{d+1}$ is forward (resp. backward), we call $\downarrow\hat{\sigma}_d$ (resp. $\uparrow\hat{\sigma}_d$) the **destroyer** of $[b, d]$.*

By inspecting the interval mapping in the Diamond Principle, we have the following fact:

► **Proposition 13.** *For two cell-wise filtrations $\mathcal{L}, \mathcal{L}'$ related by a Mayer-Vietoris diamond, any two intervals of $\text{Pers}_*(\mathcal{L})$ and $\text{Pers}_*(\mathcal{L}')$ mapped by the Diamond Principle have the same set of creator and destroyer, though the creator and destroyer may swap. This observation combined with Proposition 9 implies that there is a bijection from $\text{Pers}_*(\mathcal{U})$ to $\text{Pers}_*(\hat{\mathcal{F}})$ s.t. every two corresponding intervals have the same set of creator and destroyer.*

► **Remark 14.** The only time when the creator and destroyer swap in a Mayer-Vietoris diamond is when the interval $[j, j]$ for the upper filtration in Equation (1) turns into the same interval (of one dimension lower) for the lower filtration.

Consider the example in Figure 3 for an illustration of Proposition 13. In the example, $[1, 2] \in \text{Pers}_1(\hat{\mathcal{F}})$ corresponds to $[1, 4] \in \text{Pers}_1(\mathcal{U})$, where their creator is $\downarrow a$ and their destroyer is $\uparrow d$. Moreover, $[4, 6] \in \text{Pers}_0(\hat{\mathcal{F}})$ corresponds to $[4, 5] \in \text{Pers}_1(\mathcal{U})$. The creator of $[4, 6] \in \text{Pers}_0(\hat{\mathcal{F}})$ is $\uparrow e$ and the destroyer is $\downarrow c$. Meanwhile, $[4, 5] \in \text{Pers}_1(\mathcal{U})$ has the same set of creator and destroyer but the roles swap.

For any $\downarrow\sigma$ or $\uparrow\sigma$ in $\hat{\mathcal{F}}$, let $\text{id}_{\hat{\mathcal{F}}}(\downarrow\sigma)$ or $\text{id}_{\hat{\mathcal{F}}}(\uparrow\sigma)$ denote the index (position) of the addition or deletion. For example, for an addition $\hat{K}_i \xleftarrow{\hat{\sigma}_i} \hat{K}_{i+1}$ in $\hat{\mathcal{F}}$, $\text{id}_{\hat{\mathcal{F}}}(\downarrow\hat{\sigma}_i) = i$. Proposition 13 indicates the following explicit mapping from $\text{Pers}_*(\mathcal{U})$ to $\text{Pers}_*(\hat{\mathcal{F}})$:

► **Proposition 15.** *There is a bijection from $\text{Pers}_*(\mathcal{U})$ to $\text{Pers}_*(\hat{\mathcal{F}})$ which maps each $[b, d] \in \text{Pers}_p(\mathcal{U})$ by the following rule:*

Type	Condition		Type	Interval in $\text{Pers}_*(\hat{\mathcal{F}})$	Dim
closed-open	-	\mapsto	closed-open	$[\text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1}) + 1, \text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_d)]$	p
open-closed	-	\mapsto	open-closed	$[\text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_{b-1}) + 1, \text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d)]$	p
closed-closed	$\text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1}) < \text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d)$	\mapsto	closed-closed	$[\text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1}) + 1, \text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d)]$	p
	$\text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1}) > \text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d)$	\mapsto	open-open	$[\text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d) + 1, \text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1})]$	$p-1$

■ **Figure 3** An example of filtration $\hat{\mathcal{F}}$ and its corresponding up-down filtration \mathcal{U} . For brevity, $\hat{\mathcal{F}}$ does not start and end with empty complexes (which can be treated as a truncated case).

► **Remark 16.** Notice that $\text{Pers}_*(\mathcal{U})$ contains no open-open intervals. However, a closed-closed interval $[b, d] \in \text{Pers}_p(\mathcal{U})$ turns into an open-open interval in $\text{Pers}_{p-1}(\hat{\mathcal{F}})$ when $\text{id}_{\hat{\mathcal{F}}}(\downarrow\tau_{b-1}) > \text{id}_{\hat{\mathcal{F}}}(\uparrow\tau_d)$. Such a change happens when a closed-closed interval turns into a single point interval $[j, j]$ during the sequence of outward switches, after which the closed-closed interval $[j, j]$ becomes an open-open interval $[j, j]$ with a dimension shift (see Theorem 7).

► **Remark 17.** Although it may take $O(m^2)$ diamond switches to go from $\hat{\mathcal{F}}$ to \mathcal{U} or from \mathcal{U} to $\hat{\mathcal{F}}$ as indicated in Proposition 9, we observe that these switches do not need to be actually executed in the algorithm. To convert the intervals in $\text{Pers}_*(\mathcal{U})$ to those in $\text{Pers}_*(\hat{\mathcal{F}})$, we only need to follow the mapping in Proposition 15, which takes constant time per interval.

We can take the example in Figure 3 for the mapping in Proposition 15. The interval $[4, 5] \in \text{Pers}_1(\mathcal{U})$ is a closed-closed one whose creator is $\downarrow c$ and destroyer is $\uparrow e$. We have that $\text{id}_{\hat{\mathcal{F}}}(\downarrow c) = 6 > \text{id}_{\hat{\mathcal{F}}}(\uparrow e) = 3$. So the corresponding interval in $\text{Pers}_0(\hat{\mathcal{F}})$ is

$$[\text{id}_{\hat{\mathcal{F}}}(\uparrow e) + 1, \text{id}_{\hat{\mathcal{F}}}(\downarrow c)] = [4, 6].$$

3.3 Conversion to non-zigzag filtration

We first convert the up-down filtration \mathcal{U} to an extended persistence [12] filtration \mathcal{E} , which is then easily converted to an (absolute) non-zigzag filtration using the “coning” technique [12].

Inspired by the Mayer-Vietoris pyramid in [8], we relate $\text{Pers}_*(\mathcal{U})$ to the barcode of the filtration \mathcal{E} defined as:

$$\mathcal{E} : \emptyset = L_0 \hookrightarrow \cdots \hookrightarrow L_n = (\hat{K}, L_{2n}) \hookrightarrow (\hat{K}, L_{2n-1}) \hookrightarrow \cdots \hookrightarrow (\hat{K}, L_n) = (\hat{K}, \hat{K})$$

where $L_n = \hat{K} = (\hat{K}, L_{2n} = \emptyset)$. When denoting the persistence intervals of \mathcal{E} , we let the increasing index for the first half of \mathcal{E} continue to the second half, i.e., (\hat{K}, L_{2n-1}) has index $n+1$ and (\hat{K}, L_n) has index $2n$. Then, it can be verified that an interval $[b, d] \in \text{Pers}_*(\mathcal{E})$ for $b < n < d$ starts with the complex L_b and ends with (\hat{K}, L_{3n-d}) .

► **Remark 18.** A filtration in extended persistence [12] is originally defined for a PL function f , where the first half is the lower-star filtration of f and the second half (the relative part) is derived from the upper-star filtration of f . The filtration \mathcal{E} defined above is a generalization of the one in [12].

► **Proposition 19.** *There is a bijection from $\text{Pers}_*(\mathcal{E})$ to $\text{Pers}_*(\mathcal{U})$ which maps each $[b, d] \in \text{Pers}_*(\mathcal{E})$ of dimension p by the following rule:*

Type	Condition		Type	Interv. in $\text{Pers}_*(\mathcal{U})$	Dim
Ord	$d < n$	\mapsto	closed-open	$[b, d]$	p
Rel	$b > n$	\mapsto	open-closed	$[3n - d, 3n - b]$	$p-1$
Ext	$b \leq n \leq d$	\mapsto	closed-closed	$[b, 3n - d - 1]$	p

► **Remark 20.** The types “Ord”, “Rel”, and “Ext” for intervals in $\text{Pers}_*(\mathcal{E})$ are as defined in [12], which stand for intervals from the *ordinary* sub-barcode, the *relative* sub-barcode, and the *extended* sub-barcode.

► **Remark 21.** The above proposition can also be stated by associating the creators and destroyers as in Proposition 13 and 15. The association of additions in the first half of \mathcal{U} and \mathcal{E} is straightforward and the deletion of a σ in \mathcal{U} is associated with the addition of σ (to the second complex in the pair) in \mathcal{E} . Then, corresponding intervals in $\text{Pers}_*(\mathcal{E})$ and $\text{Pers}_*(\mathcal{U})$ in the above proposition also have the same set of creators and destroyers. Combined with Proposition 13, we further have that intervals in $\text{Pers}_*(\mathcal{F})$ and $\text{Pers}_*(\mathcal{E})$ can be associated by a bijection where corresponding intervals have the same pairs of simplices though they may switch roles of being creators and destroyers.

Proof. We can build a Mayer-Vietoris pyramid relating the second half of \mathcal{E} and the second half of \mathcal{U} similar to the one in [8]. A pyramid for $n = 4$ is shown in Figure 4, where the second half of \mathcal{E} is along the left side of the triangle and the second half of \mathcal{U} is along the bottom. In Figure 4, we represent the second half of \mathcal{E} and \mathcal{U} in a slightly different way considering that $L_4 = \hat{K}$ and $L_8 = \emptyset$. Also, each vertical arrow indicates the addition of a simplex in the second complex of the pair and each horizontal arrow indicates the deletion of a simplex in the first complex.

To see the correctness of the mapping, we first note that each square in the pyramid is a (more general version of) Mayer-Vietoris diamond as defined in [8]. Then, the mapping stated in the proposition can be verified using the Diamond Principle (Theorem 7). However, there is a quicker way to verify the mapping by observing the following: corresponding intervals in $\text{Pers}_*(\mathcal{E})$ and $\text{Pers}_*(\mathcal{U})$ have the same set of creator and destroyer if we ignore whether it is the addition or deletion of a simplex. For example, an interval in $\text{Pers}_*(\mathcal{E})$ may be created by the addition of a simplex σ in the first half of \mathcal{E} and destroyed by the addition of another simplex σ' in the second half of \mathcal{E} . Then, its corresponding interval in $\text{Pers}_*(\mathcal{U})$ is also created by the addition of σ in the first half but destroyed by the *deletion* of σ' in the second half. Note that the dimension change for the case $b > n$ is caused by the swap of creator and destroyer. ◀

By Proposition 15 and 19, we only need to compute $\text{Pers}_*(\mathcal{E})$ in order to compute $\text{Pers}_*(\mathcal{F})$. The barcode of \mathcal{E} can be computed using the “coning” technique [12], which converts \mathcal{E} into an (absolute) non-zigzag filtration $\hat{\mathcal{E}}$. Specifically, let ω be a vertex different from all vertices in \hat{K} . For a p -cell σ of \hat{K} , we let $\omega \cdot \sigma$ denote the *cone* of σ , which is a $(p + 1)$ -cell having cells $\{\sigma\} \cup \{\omega \cdot \tau \mid \tau \in \partial\sigma\}$ in its boundary. The *cone* $\omega \cdot L_i$ of a complex L_i consists of three parts: the vertex ω , L_i , and cones of all cells of L_i . The filtration $\hat{\mathcal{E}}$ is then defined as [12]:

$$\hat{\mathcal{E}} : L_0 \cup \{\omega\} \hookrightarrow \dots \hookrightarrow L_n \cup \{\omega\} = \hat{K} \cup \omega \cdot L_{2n} \hookrightarrow \hat{K} \cup \omega \cdot L_{2n-1} \hookrightarrow \dots \hookrightarrow \hat{K} \cup \omega \cdot L_n$$

We have that $\text{Pers}_*(\mathcal{E})$ equals $\text{Pers}_*(\hat{\mathcal{E}})$ discarding the only infinite interval [12]. Note that if a cell σ is added (to the second complex) from (\hat{K}, L_i) to (\hat{K}, L_{i-1}) in \mathcal{E} , then the cone $\omega \cdot \sigma$ is added from $\hat{K} \cup \omega \cdot L_i$ to $\hat{K} \cup \omega \cdot L_{i-1}$ in $\hat{\mathcal{E}}$.

■ **Figure 4** A Mayer-Vietoris pyramid relating the second half of \mathcal{E} and \mathcal{U} for $n = 4$.

3.4 Summary of filtration conversion

We summarize the filtration conversion process described in this section in Algorithm 3.1, in which we assume that each simplex in \mathcal{F} is given by its set of vertices. The converted standard filtration $\hat{\mathcal{E}}$ is represented by its boundary matrix D , whose columns (and equivalently the chains they represent) are treated as sets of identifiers of the boundary cells. Algorithm 3.1 also maintains the following data structures:

- `cid` denotes the map from a simplex σ to the identifier of the *most recent* copy of cell corresponding to σ .
- `del_list` denotes the list of cell identifiers deleted in the input filtration.
- `cone_id` denotes the map from the identifier of a cell to that of its coned cell.

Subroutine `CELLBOUNDARY` in Line 8 converts boundary simplices of σ_i to a column of cell identifiers based on the map `cid`. Subroutine `CONEDCELLBOUNDARY` in Line 16 returns boundary column for the cone of the cell identified by `del_id`.

We provide an example of the up-down cell-wise filtration \mathcal{U} built from a given simplex-wise filtration \mathcal{F} in Figure 5. In the example, edge c and triangle t are repeatedly added twice in \mathcal{F} , and therefore each correspond to two copies of cells in \mathcal{U} . We provide another example of a complete conversion from a given zigzag filtration to a non-zigzag filtration in Figure 6.

With the `CONVERTFILT` subroutine, Algorithm 3.2 provides a concise summary of `FASTZIGZAG`. Given that for a filtration \mathcal{F} of length m , `CONVERTFILT` takes $O(m)$ time and `CONVERTBARCODE` takes $O(1)$ time per bar, we now have the following conclusion:

► **Theorem 22.** *Given a simplex-wise zigzag filtration \mathcal{F} with length m , `FASTZIGZAG` computes $\text{Pers}_*(\mathcal{F})$ in time $T(m) + O(m)$, where $T(m)$ is the time used for computing the barcode of a non-zigzag cell-wise filtration with length m .*

► **Remark 23.** Theoretically, $T(m) = O(m^\omega)$ [25], where $\omega < 2.37286$ is the matrix multiplication exponent [1]. So the theoretical complexity of `FASTZIGZAG` is $O(m^\omega)$.

■ **Algorithm 3.1** Pseudocode for converting input filtration.

```

1: procedure CONVERTFILT( $\mathcal{F}$ )
2:   initialize boundary matrix  $D$ , cell-id map  $\text{cid}$ , deleted cell list  $\text{del\_list}$  as empty
3:   append an empty column to  $D$  representing vertex  $\omega$  for coning
4:    $\text{id} \leftarrow 1$  ▷ variable keeping track of id for cells
5:   for each  $K_i \xleftarrow{\sigma_i} K_{i+1}$  in  $\mathcal{F}$  do
6:     if  $\sigma_i$  is being inserted then
7:        $\text{cid}[\sigma_i] = \text{id}$  ▷ get a new cell as a copy of simplex  $\sigma_i$ 
8:        $\text{col} \leftarrow \text{CELLBOUNDARY}(\sigma_i, \text{cid})$ 
9:       append  $\text{col}$  to  $D$ 
10:       $\text{id} \leftarrow \text{id} + 1$ 
11:     else
12:       append  $\text{cid}[\sigma_i]$  to  $\text{del\_list}$ 
13:   initialize map  $\text{cone\_id}$  as empty ▷  $\text{cone\_id}$  tracks id for coned cells
14:   for each  $\text{del\_id}$  in  $\text{del\_list}$  (accessed reversely) do
15:      $\text{cone\_id}[\text{del\_id}] \leftarrow \text{id}$  ▷ get a new coned cell
16:      $\text{col} \leftarrow \text{CONEDCELLBOUNDARY}(\text{del\_id}, D, \text{cone\_id})$ 
17:     append  $\text{col}$  to  $D$ 
18:      $\text{id} \leftarrow \text{id} + 1$ 
19:   return  $D$ 

```

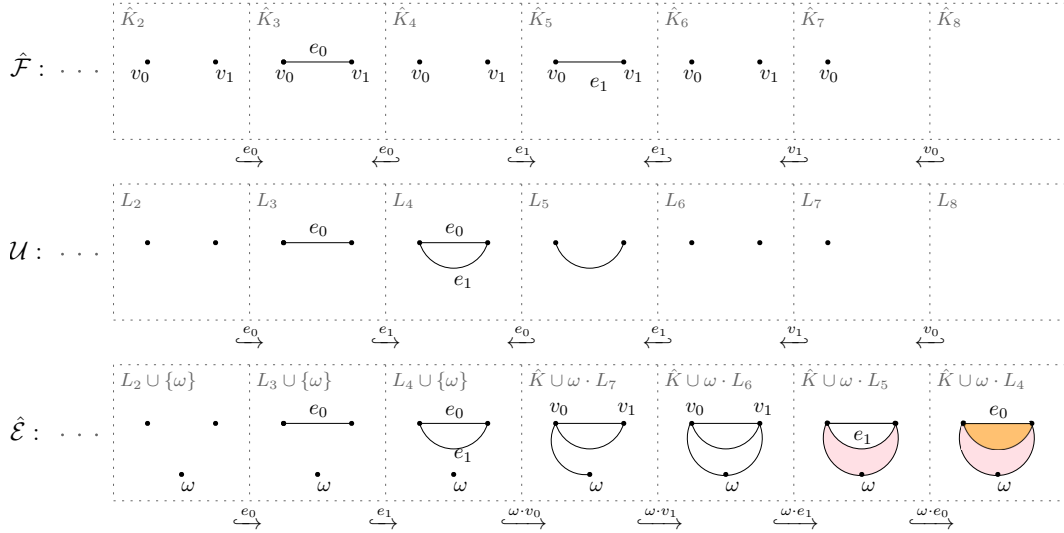

■ **Figure 5** An example of an up-down cell-wise filtration \mathcal{U} built from a given simplex-wise filtration \mathcal{F} . For brevity, \mathcal{F} does not start and end with empty complexes. The final conversion to $\hat{\mathcal{E}}$ is not shown for this example due to page-width constraint. A complete conversion for a smaller example is shown in Figure 6.

■ **Algorithm 3.2** Pseudocode for FASTZIGZAG.

```

1: procedure FASTZIGZAG( $\mathcal{F}$ )
2:    $D \leftarrow \text{CONVERTFILT}(\mathcal{F})$ 
3:    $B \leftarrow \text{COMPUTEBARCODE}(D)$ 
4:    $B' \leftarrow \text{CONVERTBARCODE}(B)$ 
5:   return  $B'$ 

```

■ **Figure 6** An example of converting a zigzag filtration $\hat{\mathcal{F}}$ to a non-zigzag filtration.

3.5 Experiments

We implement the FASTZIGZAG algorithm described in this section and compare the performance with DIONYSUS2 [26] (implementing the algorithm in [8]) and GUDHI¹ [28] (implementing the algorithm in [22, 24]). When implementing FASTZIGZAG, we utilize the PHAT [4] software for computing non-zigzag persistence. Our implementation is publicly available through: <https://github.com/taohou01/fzz>.

To test the performance, we generate eleven simplex-wise filtrations of similar lengths (5~6 millions; see Table 1). The reason for using filtrations of similar lengths is to test the impact of *repetitiveness* on the performance for different algorithms, where repetitiveness is the average times a simplex is repeatedly added in a filtration (e.g., repetitiveness being 1 means that the filtration is non-repetitive). We utilize three different approaches for generating the filtrations:

- The two non-repetitive filtrations (No. 1 and 2) are generated by first taking a simplicial complex with vertices in \mathbb{R}^3 , and then taking the height function h along a certain axis. After this, we build an up-down filtration for the complex where the first half is the lower-star filtration of h and the second half is the (reversed) upper-star filtration of h . We then randomly perform outward switches on the up-down filtration to derive a non-repetitive filtration. Note that the simplicial complex is derived from a triangular mesh supplemented by a Vietoris-Rips complex on the vertices; one triangular mesh (Dragon) is downloaded from the Stanford Computer Graphics Laboratory.
- Filtration No. 3 – 8 are generated from a sequence of edge additions and deletions, for which we then take the *clique complex* (up to a certain dimension) for each edge set in the sequence. The edge sequence is derived by randomly adding and deleting edges for a set of points.
- The remaining filtrations (No. 9 – 11) are the *oscillating Rips zigzag* [27] generated from point clouds of size 2000 – 4000 sampled from some triangular meshes (Space Shuttle from an online repository²; Bunny and Dragon from the Stanford Computer Graphics Laboratory).

¹ The code is shared by personal communication.

² Ryan Holmes: <http://www.holmes3d.net/graphics/offfiles/>

Table 1 lists running time of the three algorithms on all filtrations, where the length, maximum dimension (D), repetitiveness (Rep), and maximum complex size (MaxK) are also provided for each filtration. From Table 1, we observe that FASTZIGZAG (T_{FZZ}) consistently achieves the best running time across all inputs, with significant speedups (see column “SU” in Table 1). The speedup is calculated as the min-time of DIONYSUS2 and GUDHI divided by the time of FASTZIGZAG. Notice that since GUDHI only takes a sequence of edge additions and deletions as input (and builds clique complexes on-the-fly), we do not run GUDHI on the first two inputs in Table 1, which are only given as simplex-wise filtrations. We also observe that the speedup of FASTZIGZAG tends to be less prominent as the repetitiveness increases. This is because higher repetitiveness leads to smaller max/average complex size in the input zigzag filtration, so that algorithms directly working on the input filtration could have less processing time [8, 22, 24]. On the other hand, the complex size in the converted non-zigzag filtration that FASTZIGZAG works on is always increasing.

■ **Table 1** Running time of DIONYSUS2, GUDHI, and FASTZIGZAG on different filtrations of similar lengths with various repetitiveness. All tests were run on a desktop with Intel(R) Core(TM) i5-9500 CPU @ 3.00GHz, 16GB memory, and Linux OS.

No.	Length	D	Rep	MaxK	T_{DIO2}	T_{GUDHI}	T_{FZZ}	SU
1	5,260,700	5	1.0	883,350	2h02m46.0s	—	8.9s	873
2	5,254,620	4	1.0	1,570,326	19m36.6s	—	11.0s	107
3	5,539,494	5	1.3	1,671,047	3h05m00.0s	45m47.0s	3m20.8s	13.7
4	5,660,248	4	2.0	1,385,979	2h59m57.0s	29m46.7s	4m59.5s	6.0
5	5,327,422	4	3.5	760,098	43m54.8s	10m35.2s	3m32.1s	3.0
6	5,309,918	3	5.1	523,685	5h46m03.0s	1h32m37.0s	19m30.2s	4.7
7	5,357,346	3	7.3	368,830	3h37m54.0s	57m28.4s	30m25.2s	1.9
8	6,058,860	4	9.1	331,211	53m21.2s	7m19.0s	3m44.4s	2.0
9	5,135,720	3	21.9	11,859	23.8s	15.6s	8.6s	1.9
10	5,110,976	3	27.7	11,435	36.2s	39.9s	8.5s	4.3
11	5,811,310	4	44.2	7,782	38.5s	36.9s	23.9s	1.5

Table 2 lists the memory consumption of the three algorithms. We observe that FASTZIGZAG tends to consume more memory than the other two on the non-repetitive filtrations (No. 1 and 2) and the random clique filtrations (No. 3 – 8). However, FASTZIGZAG is consistently achieving the best memory footprint on the oscillating Rips filtrations (No. 9 – 11) despite the high repetitiveness.

4 Conclusions

In this paper, we propose a zigzag persistence algorithm called FASTZIGZAG by first treating repeatedly added simplices in an input zigzag filtration as distinct copies and then converting the input filtration to a non-zigzag filtration. The barcode of the converted non-zigzag filtration can then be easily mapped back to barcode of the input zigzag filtration. The efficiency of our algorithm is confirmed by experiments. This research also brings forth the following open questions:

■ **Table 2** Memory consumption (in gigabytes) of the three algorithms on all filtrations.

- Parallel versions [9, 29] of the algorithms for computing standard and zigzag exist. While the computation of standard persistence in our FASTZIGZAG algorithm can directly utilize the existing parallelization techniques, we ask if the conversions done in FASTZIGZAG can be efficiently parallelized. Such an extension can provide further speedups by harnessing multi-cores.
- While persistence intervals are important topological descriptors, their *representatives* also reveal critical information (e.g., a recently proposed algorithm [16] for updating zigzag barcodes over local changes uses representatives explicitly). Can the FASTZIGZAG algorithm be adapted so that representatives for the input zigzag filtration are recovered from representatives for the converted non-zigzag filtration?

Turbocharging Heuristics for Weak Coloring Numbers

Abstract

Bounded expansion and nowhere-dense classes of graphs capture the theoretical tractability for several important algorithmic problems. These classes of graphs can be characterized by the so-called weak coloring numbers of graphs, which generalize the well-known graph invariant degeneracy (also called k -core number). Being NP-hard, weak-coloring numbers were previously computed on real-world graphs mainly via incremental heuristics. We study whether it is feasible to augment such heuristics with exponential-time subprocedures that kick in when a desired upper bound on the weak coloring number is breached. We provide hardness and tractability results on the corresponding computational subproblems. We implemented several of the resulting algorithms and show them to be competitive with previous approaches on a previously studied set of benchmark instances containing 86 graphs with up to 183831 edges. We obtain improved weak coloring numbers for over half of the instances.

1 Introduction

A *degeneracy ordering* of a graph G can be obtained by iteratively removing an arbitrary vertex of minimum degree from G and putting it in front of the current ordering [30]. The *degeneracy* of a graph is the largest degree of a vertex encountered at removal. Degeneracy orderings are immensely useful when solving various tasks on graphs both in theory and practice [8, 18, 27, 37, 22, 6]. A key observation is that many graphs in practice have small degeneracy (e.g., in the order of hundreds for millions of edges) [18]. Thus, when looking for, e.g., maximum-size cliques, it is sufficient to look within the small number of neighbors in front of each vertex in the degeneracy ordering.

However, degeneracy is not robust under local changes: e.g., contracting edges in a graph may arbitrarily increase its degeneracy. This property makes problems intractable on graphs that have small degeneracy if these problems are less local than finding maximum-size cliques. For example, detecting mild clique relaxations is hard on graphs of bounded degeneracy [27, 23]. Hence, we are searching for robust sparsity measures within the framework of structural sparsity [33].

We can obtain a robust variant of the class of graphs with bounded degeneracy by using the family of measures called weak r -coloring numbers [26]. For an integer r , the weak r -coloring number (wcol_r) of a graph G is the least integer k such that there is a vertex ordering with the property that, for each vertex v , there are at most k vertices u that are reachable from v by a path P of length at most r such that P does not use vertices that come before u in the ordering. The integer r , also called radius, interpolates between the degeneracy plus one ($r = 1$) and the so-called treedepth of G ($r = |V(G)|$ [20]), a measure of tree-likeness [3, 4, 25] and target of a recent implementation challenge [28].

It is important to compute the wcol_r of real-world graphs for two reasons. First, the wcol_r plays an important role in algorithmic and combinatorial techniques in structural sparsity (e.g., [2, 7, 15, 16, 17, 24, 29, 34, 36, 40]). For instance, a central concept therein is nowhere denseness and a subgraph-closed class of graphs is nowhere dense if and only if for each fixed integer r and $\epsilon > 0$ each graph G in the class has wcol_r at most $O(|V(G)|^\epsilon)$ [42]. Thus, obtaining the wcol_r s of real-world graphs will help us gauge how well this theory fits practice. Second, there is a prospect that wcol_r s will help us solve other computational problems on real-world graphs more efficiently: On nowhere-dense graph classes each problem expressible in first-order logic can be solved in near-linear time [21]. There is indeed indication that relevant classes of real-world networks, including certain scale-free networks, are nowhere dense [10]. Thus, wcol_r s may help us transfer the above theoretical near-linear-time algorithms into something practically useful. For example, this work is underway for counting subgraphs [35, 39], which is the underlying computational problem of computing graph motifs or graphlets in biological and social networks [31, 38].

Computing the wcol_r of a graph is an algorithmically challenging task: for each $r \geq 2$ it is NP-complete [20, 5]. So far, there is but one work that studies computing upper bounds for wcol_r s in real-world graphs: Nadara et al. [32] used greedy heuristics that build the associated vertex ordering by iteratively choosing a yet unordered vertex that seems favorable and putting it at the front (or the back) of the current subordering (an ordering of a subset of all vertices). Afterwards, they apply local-search techniques that make local shifts in the ordering that decrease the associated weak r -coloring number. This yields upper bounds; to date the true weak r -coloring numbers of the studied graphs are unknown, even for the smallest part of Nadara et al.'s dataset that contains graphs with 62 to 930 edges.

In this work, we study a paradigm that has previously been successfully applied to improve the quality of the results computed by greedy heuristics: turbocharging [41, 14, 1, 19]. The basic idea is that we pre-specify an upper bound $k \in \mathbb{N}$ on the wcol_r of the ordering that we want to compute. We carry out the greedy heuristic that computes the ordering iteratively. If at some point it can be detected that the ordering will yield wcol_r larger than k – the *point of regret* – we start a turbocharging algorithm. This algorithm tries to modify the current ordering, by reordering or replacing certain vertices, so as to make it possible to achieve wcol_r at most k again. Then we continue with the greedy heuristic.

Our contribution is to develop the turbocharging algorithms applied at the point of regret, obtaining running-time guarantees and lower bounds, and to implement, engineer, and evaluate these algorithms on Nadara et al.'s dataset. The two main approaches that we

study are as follows. We fix a *reconstruction parameter* $c \in \mathbb{N}$. At the point of regret, in order to obtain a subordering of wcol_r at most k we either (a) replace the last c vertices of the current subordering with new, yet unordered vertices or (b) take c vertices out of the ordering and merge them into the subordering at possibly different positions. The formal definitions are given in Section 2. We show that both approaches are NP-hard in general (see Section 3) and hence we also consider the influence of small parameters on the achievable running-time guarantees. That is, we aim to show *fixed-parameter tractability* by giving algorithms with $f(p) \cdot n^{O(1)}$ running time for a small parameter p and input size n . On the negative side, approach (a) is W[1]-hard with respect to even both c and k (Theorem 2). That is, an algorithm with running time $f(c, k) \cdot \text{poly}(n)$ is unlikely, where n is the number of vertices. This stands in contrast to Gaspers et al. [19] who obtained such an algorithm when the goal is to compute the treewidth of the input graph instead of its wcol_r . On the positive side, approach (a) is trivially tractable in polynomial time for constant c . For approach (b), we obtain a fixed-parameter algorithm with respect to $c + k$ (Theorem 4). We implemented a set of algorithms including the two previously mentioned ones and report on implementation considerations and results in Section 4. The results indicate that on average the weak r -coloring numbers achieved by Nadara et al. [32] can be improved by 5% by using our turbocharging algorithms. Using turbocharging we obtain smaller weak coloring numbers than all previous approaches on 181 of the in total 334 instances used by Nadara et al. [32].

Due to space constraints, we defer some details of proofs, implementations, and evaluations to a full version [13].

2 Preliminaries and turbocharging problems

General preliminaries. We only consider undirected, unweighted graphs G without loops. By $V(G)$ and $E(G)$ we denote the vertex set and edge set of G , respectively. For $S \subseteq V(G)$, $G[S]$ is the *induced subgraph* on vertices in S . A *path* $P = (v_1, \dots, v_n)$ in G is a non-empty sequence of vertices, such that consecutive vertices are connected by an edge. The *length* of a path is $|V(P)| - 1$. In particular, a path of length 0 consists of a single vertex. We use $\text{dist}_G(u, v)$ to denote the length of the shortest path between vertices u and v in G .

A *vertex ordering* L of a graph G is a linear ordering of $V(G)$. We write $u \prec_L v$ if vertex u precedes vertex v in L . In this case we say that u is *left of* v w.r.t. L . Equivalently, we write $u \preceq v$ if $u \prec v$ or $u = v$. We also denote vertex orderings L as sequences of its elements, that means $L = (v_1, \dots, v_n)$ represents the vertex ordering where $v_i \prec_L v_j$ iff $i < j$. We denote by $\Pi(G)$ the set of all vertex orderings of G . A *subordering* is a linear ordering of a subset $S \subseteq V(G)$. The notation L_S shall always denote a subordering where S is the set of vertices ordered in the subordering. We call the vertices in $V(G) \setminus S$ *free* with respect to L_S . Usually we will denote the set of free vertices with respect to a subordering by T . For a subordering L_S and $S' \subseteq S$ we denote by $L_S[S']$ the subordering that *agrees with* L_S on S' , that is, for all $u, v \in S'$ we have that $u \prec_{L_S[S']} v$ iff $u \prec_{L_S} v$, and all vertices in $V(G) \setminus S'$ are free w.r.t. $L_S[S']$. For a subordering L_S and $S' \supseteq S$, a subordering $L_{S'}$ is a *right extension* of L_S if $L_{S'}[S] = L_S$ and $u \prec_{L_{S'}} v$ for all $u \in S$ and $v \in S' \setminus S$. If $S' = V$, then $L_{S'}$ is called *full right extension*.

Weak coloring numbers. For a vertex ordering L of G and $r \in \mathbb{N}$, a vertex u is *weakly r -reachable* from a vertex v w.r.t. L if there exists a path P of length ℓ with $0 \leq \ell \leq r$ between u and v such that $u \preceq_L w$ for all $w \in V(P)$. Let $\text{Wreach}_r(G, L, v)$ be the set of vertices that are weakly r -reachable from v in G w.r.t. L . The *weak r -coloring number* $\text{wcol}_r(G, L)$ of a vertex ordering L is $\text{wcol}_r(G, L) = \max_{v \in V(G)} |\text{Wreach}_r(G, L, v)|$, and the weak r -coloring number $\text{wcol}_r(G)$ of G is $\text{wcol}_r(G) = \min_{L \in \Pi} \text{wcol}_r(G, L)$.

Turbocharging. Our goal is to find a vertex ordering L of a given graph G with small $\text{wcol}_r(G, L)$ by applying turbocharging. We start with two well-known iterative greedy heuristics (descriptions will follow) of Nadara et al. [32] that build vertex orderings with small weak r -coloring number from left to right. That is, these heuristics start with the empty subordering $L_S = \emptyset$ and in each step compute a right extension of L_S that contains one more vertex. This process is continued until the constructed subordering contains all vertices. A key observation about this process that we can use for turbocharging is that the size of the weakly reachable set of each vertex cannot decrease:

► **Observation 1.** *Let L_S be a subordering, $u, v \in V(G)$, and L be a full right extension of L_S . If $u = v$, or $u \in S$ and there exists a path P of length ℓ with $0 \leq \ell \leq r$ between u and v such that $u \preceq_{L_S} w$ for all $w \in V(P) \cap S$, then $u \in \text{Wreach}_r(G, L, v)$.*

For u and v as in Observation 1 we extend the definition of weak r -reachability to suborderings L_S by defining $u \in \text{Wreach}_r(G, L_S, v)$ and $\text{wcol}_r(G, L_S) = \max_{v \in V(G)} |\text{Wreach}_r(G, L_S, v)|$. We immediately obtain that $\text{wcol}_r(G, L_S)$ is a lower bound; that is, if L is a full right extension of L_S (such as obtained by one of the heuristics), then $\text{wcol}_r(G, L) \geq \text{wcol}_r(G, L_S)$.

The two heuristics of Nadara et al. that we apply are:

- The Degree-Heuristic: This heuristic orders vertices by descending degree, ties are broken arbitrarily.
- The Wreach-Heuristic: For a subordering L_S , this heuristic picks the free vertex v with the largest $\text{Wreach}_r(G, L_S, v)$. Ties are broken by descending degree.

Nadara et al. proposed several other heuristics, but those heuristics do not build vertex orderings from left to right, but in different orders. Additionally, the above heuristics are among the best-performing ones with regard to computed weak coloring numbers and runtime.

In what follows, let us assume that we want to compute a vertex ordering L of a graph G with $\text{wcol}_r(G, L) \leq k$ where $k \in \mathbb{N}$. We might apply one of the heuristics until we obtain a subordering L_S such that $\text{wcol}_r(G, L_S) > k$. We call such a subordering *non-extendable* (and otherwise the subordering is *extendable*); we also say that this point in the execution of the heuristic is the *point of regret*. We then consider two exact *turbocharging problems* that try to locally augment L_S , such that it is extendable again. If the *turbocharging algorithms* for these problems that we later propose are successful in making L_S extendable, then we continue applying the heuristic until we have to repeat this process (trying to find a vertex order L with $\text{wcol}_r(G, L) \leq k$).

Motivated by a turbocharging algorithm for computing tree-decompositions by Gaspers et al. [19] we consider replacing a bounded-length suffix of the current subordering. That is, we specify a *reconstruction parameter* $c \in \mathbb{N}$ in advance and, at the point of regret, we remove the last c vertices from L_S and then try to add c (possibly) different vertices. This leads to the following turbocharging problem.

INCREMENTAL CONSERVATIVE WEAK r -COLORING (IC-WCOL(r))

Instance: A graph G , a subordering L_S , and positive integers k and c .

Question: Is there an extendable right extension $L_{S'}$ of L_S such that $|S' \setminus S| = c$?

Our second turbocharging approach is based on a vertex v with $|\text{Wreach}_r(G, L_S, v)| > k$. Therein, instead of the suffix of the current order, we choose a set S_2 of vertices related to the weakly r -reachable set of v (details follow in Section 4). We remove the vertices in S_2 from L_S , leaving us with the subordering L_{S_1} , and then we try to reinsert the vertices in S_2 while decreasing the weak coloring number.

WCOL-MERGE(r)

Instance: A graph G , an integer k , two disjoint sets S_1 and S_2 such that $S_1, S_2 \subseteq V(G)$, and a subordering L_{S_1} .

Question: Is there an extendable subordering $L_{S_1 \cup S_2}$ such that $L_{S_1 \cup S_2}[S_1] = L_{S_1}$?

Herein, we put the *reconstruction parameter* c equal to $|S_2|$ and denote by T the set of free vertices $V(G) \setminus (S_1 \cup S_2)$.

3 Algorithms and running-time bounds

We continue by providing algorithmic upper and lower bounds for INCREMENTAL CONSERVATIVE WEAK r -COLORING (IC-WCOL(r)) and WCOL-MERGE(r), starting with IC-WCOL(r).

3.1 IC-WCOL(r)

The first theoretical result that we want to present is the NP-hardness of INCREMENTAL CONSERVATIVE WEAK r -COLORING for each $r \geq 1$ by giving a reduction from INDEPENDENT SET. INDEPENDENT SET takes as input a graph G and a positive integer p and asks if there is a set of vertices I of size at least p such that $\{u, v\} \not\subseteq I$ for all $\{u, v\} \in E(G)$.

► **Theorem 2.** *For each fixed $r \geq 1$, INCREMENTAL CONSERVATIVE WEAK r -COLORING is NP-hard and $W[1]$ -hard when parameterized by $k + c$.*

The proof can be found in the full version of this paper [13] and gives a polynomial reduction from of INDEPENDENT SET which is NP-complete to an instance of IC-WCOL(r). The idea is that the parameter p – the desired independent set size of a given INDEPENDENT SET instance – is transformed to the parameters $c = p$ and $k = 2$ of IC-WCOL(r), giving us a parameterized reduction from INDEPENDENT SET to IC-WCOL(r). INDEPENDENT SET is $W[1]$ -hard when parameterized by p , and thus we obtain the stated $W[1]$ -hardness.

On the other hand, it is not hard to see that INCREMENTAL CONSERVATIVE WEAK r -COLORING is in XP: We can simply try placing any of the vertices from $V(G) \setminus S$ into the next free position right of L_S . As there are c free positions the overall algorithm runs in $\mathcal{O}(|V(G) \setminus S|^c \cdot |V(G)|^{\mathcal{O}(1)}) \subseteq \mathcal{O}(|V(G)|^c \cdot |V(G)|^{\mathcal{O}(1)})$ time.

► **Proposition 3.** *INCREMENTAL CONSERVATIVE WEAK r -COLORING parameterized by the reconstruction parameter c is in XP.*

Our algorithm for INCREMENTAL CONSERVATIVE WEAK r -COLORING is based on Proposition 3, we will go into more detail in Section 4.

3.2 WCOL-Merge(r)

It is easy to see that WCOL-MERGE(r) is NP-hard for $r \geq 2$: Given a graph G , we can decide $\text{wcol}_r(G) \leq k$ by creating an instance (H, S_1, S_2, L_{S_1}) of WCOL-MERGE(r), setting $S_1 = L_{S_1} = \emptyset$, $H = G$, and $S_2 = V(G)$. As deciding $\text{wcol}_r(G) \leq k$ is NP-hard for $r \geq 2$ [20, 5], so is WCOL-MERGE(r). On the positive side, we can show fixed-parameter tractability of WCOL-MERGE(r) parameterized by k and $|S_2|$.

► **Theorem 4.** *WCOL-MERGE(r) is solvable in time $\mathcal{O}(|S_2|! \cdot k^{|S_2|} \cdot |V(G)|^{\mathcal{O}(1)})$. In particular, WCOL-MERGE(r) is fixed-parameter tractable when parameterized by $k + |S_2|$.*

Intuitively, the algorithm behind Theorem 4 tries to place each vertex v in S_2 one by one by trying all relevant positions. The key insight is that only few positions are relevant (called breakpoints below). Namely those positions that correspond to vertices that are weakly r -reachable from v when placed at the end of the ordering. As only few vertices can be reachable from v when placed in the correct position, we only need to try the first k corresponding positions.

To describe the algorithm we need definitions for two operations that we use throughout.

► **Definition 5.** Let G be a graph, $L_S = (s_1, \dots, s_n)$ a subordering, and $v \in V(G) \setminus S$. We denote by $\text{placeafter}(L_S, s_i, v)$ the subordering of vertices $S \cup \{v\}$ that is obtained by placing v directly after s_i . To be precise, $\text{placeafter}(L_S, s_i, v) := (s_1, \dots, s_i, v, s_{i+1}, \dots, s_n)$. Equivalently, $\text{placebefore}(L_S, s_i, v) := (s_1, \dots, s_{i-1}, v, s_i, \dots, s_n)$.

This leads to the definitions of breakpoints, which are crucial for the proof of Theorem 4.

► **Definition 6.** Let G be a graph, $L_S = (s_1, \dots, s_n)$ a subordering, and $v \in V(G) \setminus S$. A vertex $s \in S$ is called *breakpoint* of v if $\text{Wreach}_r(G, \text{placebefore}(L_S, s, v), v) \neq \text{Wreach}_r(G, \text{placeafter}(L_S, s, v), v)$. Let $\text{bp}(G, L_S, v) \subseteq S$ be the set of breakpoints of v .

We also notice another useful property of breakpoints, which is proved in the full version of this paper [13].

► **Lemma 7.** Let $v \in V(G) \setminus S$. We have $s \notin \text{bp}(G, L_S, v)$ if and only if for all $u \in V(G)$

$$\text{Wreach}_r(G, \text{placebefore}(L_S, s, v), u) = \text{Wreach}_r(G, \text{placeafter}(L_S, s, v), u).$$

If we add a vertex v to a subordering L_S to obtain a new subordering $L_{S \cup \{v\}}$, then the weakly reachable vertices $\text{Wreach}_r(G, L_{S \cup \{v\}}, v)$ consist of v and a subset of $\text{bp}(G, L_S, v)$. We formalize this as follows.

► **Lemma 8.** Let G be a graph, $L_S = (s_1, \dots, s_n)$ be a subordering, and $v \in V(G) \setminus S$. Furthermore, let $L_{S \cup \{v\}}$ be a subordering such that $L_{S \cup \{v\}}[S] = L$. Then

$$\text{Wreach}_r(G, L_{S \cup \{v\}}, v) \setminus \{v\} = \{s \in \text{bp}(G, L_S, v) \mid s \preceq_{L_{S \cup \{v\}}} v\}.$$

Proof. Let X be the set $\{s \in \text{bp}(G, L_S, v) \mid s \preceq_{L_{S \cup \{v\}}} v\}$, we prove both inclusions of the equation $\text{Wreach}_r(G, L_{S \cup \{v\}}, v) \setminus \{v\} = X$.

Assume that $s \in (\text{Wreach}_r(G, L_{S \cup \{v\}}, v) \setminus \{v\})$. As s is weakly r -reachable from v , there is a path $P = (v, u_1, \dots, u_\ell, s)$ of length of at most r that does not go left of s w.r.t. to $L_{S \cup \{v\}}$. Consider the same path P in $\text{placeafter}(L_S, s, v)$. Clearly, s is also weakly r -reachable in this subordering because of the same path. Contrary to that, s cannot be weakly r -reachable from v in $\text{placebefore}(L_S, s, v)$ because v is left of s in that subordering. Hence, $s \in \text{bp}(G, L_S, v)$ and $\text{Wreach}_r(G, L_{S \cup \{v\}}, v) \setminus \{v\} \subseteq X$.

Assume that $s \in X$. Then s must be weakly r -reachable from v w.r.t. $\text{placeafter}(L_S, s, v)$ through a path P of length at most r . But s is also weakly r -reachable from v w.r.t. $L_{S \cup \{v\}}$ through the same path P . Hence, $X \subseteq \text{Wreach}_r(G, L_{S \cup \{v\}}, v) \setminus \{v\}$ also holds. ◀

Using the above tools, we can now formally describe Algorithm 1, which obtains the stated runtime of Theorem 4 and is given as a recursive function `RECURSIVE-MERGE`. As alluded to before, the intuition is that for each vertex $v \in S_2$ we only have to consider placing it before its breakpoints w.r.t. L_{S_1} . As the breakpoints of a vertex will be in its weakly r -reachable set, only the leftmost k breakpoints are relevant. A detailed proof of the correctness and the runtime can be found in the full version of this paper [13].

■ **Algorithm 1** Recursive FPT-algorithm for $\text{WCOL-MERGE}(r)$.

```

1 Recursive-merge( $S_1, S_2, T, L_{S_1}$ ):
2   if  $|S_2| = 0 \wedge \forall v \in V(G) : |\text{Wreach}_r(G, L_{S_1}, v)| \leq k$  then return  $L_{S_1}$ ;

12     $L_{S_1 \cup \{v\}} \leftarrow \text{placeafter}(L_{S_1}, s, v)$ ;
13    if  $|\text{Wreach}_r(G[S_1 \cup T \cup \{v\}], L_{S_1 \cup \{v\}}, v)| \leq k$  then
14      answer  $\leftarrow \text{Recursive-merge}(S_1 \cup \{v\}, S_2 \setminus \{v\}, T, L_{S_1 \cup \{v\}})$ ;
15      if answer  $\neq$  false then return answer;
16    end
17  end
18  return false

```

4 Implementation and experiments

This section contains implementation details for the heuristics and both turbocharging algorithms. Furthermore, we give the experimental setup and experimental results.

4.1 Algorithm implementations and heuristic improvements

Interesting details are omitted from the algorithmic results of Section 3. We want to give some implementation details for $\text{IC-WCOL}(r)$ and $\text{WCOL-MERGE}(r)$, and how the algorithms for these problems are combined with the heuristics. Additionally, we give a third turbocharging approach called $\text{IC-WCOL-RL}(r)$ in this section.

In our implementations of heuristics and turbocharging algorithms we store and update the current subordering L_S in a simple array. We also store and update the sets $\text{Wreach}_r(G, L_S, v)$ and $\text{Wreach}_r^{-1}(G, L_S, v) = \{w \in V(G) : v \in \text{Wreach}_r(G, L_S, w)\}$ (see below for their usage). Updating weakly r -reachable sets during placements and removals of vertices v is done by computing the set $\text{Wreach}_r^{-1}(G, L_S, v)$ via a breadth-first search that respects the order L_S , and updating the corresponding weakly r -reachable sets.

Additionally, we slightly adapt the Degree-Heuristic: We aim for vertex orderings L with $\text{wcol}_r(G, L) \leq k$. Consider a subordering L_S that was created by the heuristic and needs to be extended. To obtain weak coloring number k it would intuitively make sense to place a free vertex v with $\text{wcol}_r(G, L_S) = k$ immediately to the right of that subordering s.t. its weakly r -reachable set cannot increase anymore. This is indeed always correct – if there is a full right extension L of L_S with $\text{wcol}_r(G, L) \leq k$, then there is another one that starts by placing v immediately to the right of L_S (for a formal statement and a proof we refer to the full version of this paper [13]). In our implementation of the Degree-Heuristic we apply this observation and place such a vertex v immediately. The Wreach-Heuristic does this implicitly.

We continue by explaining individual details for IC-WCOL(r) and WCOL-MERGE(r), and how they are applied to a non-extendable subordering L_S with free vertices T .

IC-WCOL(r). We have implemented the XP-algorithm for INCREMENTAL CONSERVATIVE WEAK r -COLORING as outlined in Proposition 3. Given a subordering L_S , we have to extend L_S to the right by c vertices, that means that we have c positions to fill. We implement a search tree algorithm that fills these positions from left to right recursively. That is, in a search tree node we try all possibilities of placing a free vertex into the leftmost free position i and recurse into search tree nodes that try placing the remaining free vertices into position $i + 1$, and so on, until all c positions are filled.

If after a placement of a vertex we obtain a non-extendable subordering, we can cut off this branch of the search tree, as weakly r -reachable sets of vertices can only increase in this branch. We also store edges of $G[T]$ separately as an array of hash sets. This enables, in a search tree node, to update the sets $\text{Wreach}_r^{-1}(G, L_S, v)$ on placement/removal by a simple depth- r breadth-first-search in $G[T]$. This decreases the number of enumerated edges compared to the trivial approach.

Free vertices T are placed into a position i in a specific order inside a search tree node: let L_S be the non-extendable subordering that triggered turbocharging and let v be the rightmost vertex of L_S . We try placing $u_1 \in T$ before $u_2 \in T$ into the free slot i if $\text{dist}_G(u_1, v) < \text{dist}_G(u_2, v)$. Preliminary experiments suggested that this order is preferable to a random one. We compute $\text{dist}_G(u, v)$ for all u, v with Johnson's Algorithm [9] for sparse graphs once in the beginning.

WCOL-Merge(r). We apply WCOL-MERGE(r) to a non-extendable subordering L_S in the following way. Let $U = \{v \in V(G) : |\text{Wreach}_r(G, L_S, v)| > k\}$ be the set of *overfull* vertices. Let c be a positive integer and let X be a random subset of $\bigcup_{v \in U} \text{Wreach}_r(G, L_S, v)$ of size $\min(c, |\bigcup_{v \in U} \text{Wreach}_r(G, L_S, v)|)$. If the size of X is less than c , we randomly add additional vertices from $V(G)$ to X , until the size of X is c . We try to fix L_S by defining an instance of WCOL-MERGE(r). Namely, we set $S_1 = S \setminus X$, $S_2 = X$, and $L_{S_1} = L_S[S_1]$. We then solve this instance using Algorithm 1. By Theorem 4 we obtain a turbocharging algorithm that has fixed-parameter tractable running time when parameterized by the desired coloring number k and reconstruction parameter c .

In our implementation we apply WCOL-MERGE(r) multiple times with different randomly selected sets X as defined above, until we obtain an extendable subordering. Preliminary experiments showed that choosing the whole set $\bigcup_{v \in U} \text{Wreach}_r(G, L_S, v)$ as X leads to timeouts often whereas random subsets still allowed us to fix L_S . If we do not find an extendable subordering after the 10th application of WCOL-MERGE(r), we report that turbocharging was not successful.

We now discuss the implementation of Algorithm 1. Consider the vertex v in Algorithm 1. We only have to iterate over the k leftmost breakpoints of v due to Lemma 8, which can be easily done by storing and maintaining $\text{Wreach}_r^{-1}(G[S_1 \cup T \cup \{v\}], L_{S_1 \cup T}, v)$. Let s be a breakpoint of v and let $L_{S_1 \cup \{v\}} = \text{placeafter}(L_{S_1}, s, v)$. The leftmost $s' \in \text{Wreach}_r^{-1}(G[S_1 \cup T \cup \{v\}], L_{S_1 \cup \{v\}}, v)$ that is not v is the next possible breakpoint of v . Additionally, we do not need to recurse if the size of some set $\text{Wreach}_r(G[S_1 \cup T], L_{S_1}, v)$ exceeds k for some $v \in S_1 \cup T$, as these sets can only increase in subsequent recursion calls.

We also know that subsets of some weakly r -reachable sets of vertices T are already fixed. Namely, for all vertices v in the r -neighborhood of u in $G[T \cup \{u\}]$ with $u \in S_2$, vertex u will always be in the weakly r -reachable set of v if u is placed somewhere into the subordering L_{S_1} . We take this into account when calculating lower bounds for the sizes of weakly r -reachable sets of vertices in T (and break the search if they exceed size k).

IC-WCOL-RL(r). We also implemented a turbocharging algorithm that is not discussed above. It is based on the *Sreach-Heuristic*, which builds a vertex ordering of low weak coloring number from right to left (instead of from left to right as above) [32]. It starts with an empty subordering L_S and, during each step, the heuristic adds to the left front of L_S a free vertex v that minimizes the number of so-called potentially strongly r -reachable vertices after being placed. Herein, a vertex u is *potentially strongly r -reachable* w.r.t. L_S from a vertex $v \in S$ if $u \in \text{Wreach}_r(G[S], L_S, v)$ or there is a path P of length at most r from v to u in G such that $V(P) \cap T = \{u\}$. It can be shown (refer to a formal statement and a proof in the full version of this paper [13]) that the set of potentially strongly r -reachable vertices of v only grows when extending L_S to the left and that, when $S = V(G)$, this set equals $\text{Wreach}_r(G, L_S, v)$. Thus, we define a *point of regret* for this heuristic as a point in the execution where there is a vertex v such that the size of its potentially strongly r -reachable set exceeds the desired weak coloring number k . Accordingly, we say that L_S is *non-extendable*, and otherwise it is *extendable*. We then solve the turbocharging problem in which we aim to replace the c leftmost vertices of L_S with arbitrary free vertices in order to make L_S extendable again. We do this using a search-tree algorithm analogous to IC-WCOL(r). We also use the above turbocharging approach with a heuristic that chooses the next vertex among the free vertices based on the smallest degree. We call this heuristic Degree-Heuristic¹.

We tried further heuristic optimizations, mainly for the left-to-right approaches, based on lower bounds (for early search termination), guided branching (towards faster decomposition into trivial instances), and ordered adjacency lists (to speed up computation of weakly reachable sets) but they did not improve the resulting coloring numbers.

4.2 Experiments setup

Computation environment. All experiments were performed on a cluster of 20 nodes. Each node is equipped with two Intel Xeon E5-2640 v4, 2.40GHz 10-core processors and 160 GB RAM. The optimization for each instance and an algorithm was pinned to a specific core of a cluster node (simultaneous multithreading was disabled). All implementations of heuristics and turbocharging algorithms were done in C++17, and made use of the Boost library², version 1.77.0. The code was compiled on Linux with g++ version 7.5.0 and with the flags `-std=c++17 -O2`. The optimization process (see *application of turbocharging* below) that calls the heuristics combined with the turbocharging algorithms (implemented in C++) was implemented in Python3 and executed with Python 3.7.13. A memory limit of 16 GB was set (a process only starts if the required memory is free). The source code is available online [12].

Instances. Each instance in our data set is a tuple consisting of a graph G and a radius $r \in \mathbb{N}$. The radii r are between 2 and 5, as also used by Nadara et al. [32]. The graphs G form a subset of the graphs used by Nadara et al. This enables us to use weak coloring numbers of orderings computed by Nadara et al. as a baseline. Furthermore, we can compare for a heuristic, the improvement achieved by the local search of Nadara et al. to the improvement achieved by our turbocharging algorithms.

The graphs consist of real-world data, the PACE 2016 Feedback Vertex Set problems, random planar graphs, and random graphs with bounded expansion. Nadara et al. classified the graphs into four classes based on the number of edges – small (up to 1k edges), medium (up to 10k edges), big (up to 48k edges), and huge. For a detailed explanation and references

¹ The name is the same as in the left-to-right setting; there will be no confusion between the two because the direction will be clear from the context.

² <https://www.boost.org/>

■ **Algorithm 2** Algorithm for iteratively decreasing the weak coloring number by turbocharging.

Input: A graph G , an integer r , a heuristic \mathcal{H} , and a turbocharged heuristic $TC\text{-}\mathcal{H}$
Output: An ordering L of vertices V

- 1 $L \leftarrow$ ordering of vertices V computed by the heuristic \mathcal{H} ;
- 2 $k \leftarrow \text{wcol}_r(G, L)$;
- 3 Start a timer; after t seconds abort the program, and **return** the current value of L
- 4 **while true do**
- 5 $c \leftarrow 1$;
- 6 **while true do**
- 7 Try to compute an ordering of vertices V with weak r -coloring number $k - 1$
 using $TC\text{-}\mathcal{H}$ with reconstruction parameter c ;
- 8 If successful, assign this ordering to L , set $k \leftarrow \text{wcol}_r(G, L)$, and **break**;
- 9 Otherwise, set $c \leftarrow c + 1$;
- 10 **end**
- 11 **end**

for all input graphs we refer to Nadara et al. [32]; the instances are available online³. We considered all instances except those where one of the three heuristics of Nadara et al. that we also consider did not yield a result (the Degree-Heuristic, Wreach-Heuristic, and Sreach-Heuristic). That is, they timed out after 300 seconds or ran into a memory limit (16 GB). In total, our dataset contains 334 instances.

Application of turbocharging. Our application of turbocharging with a heuristic \mathcal{H} works as follows. Given a graph G and a radius r , we start with a run of \mathcal{H} without turbocharging to produce a vertex ordering for G with a baseline weak r -coloring number k . We then start a timer that runs for t seconds, aborting the rest of the algorithm when it terminates. We then iteratively decrease k and apply \mathcal{H} together with the turbocharging approach to try and find a vertex ordering for G with weak r -coloring number at most k . In each such try, we start with the reconstruction parameter $c = 1$. If no ordering with the desired weak r -coloring number was produced by the turbocharged heuristic, we increase c by one and try again. If an ordering with weak r -coloring number $k' \leq k$ was produced, we set $k = k' - 1$ and repeat the process. The precise algorithm is given in Algorithm 2.

For our experiments we applied all compatible combinations of heuristics and the turbocharged versions to each instance. Furthermore, we computed orderings for radii ranging from 2 to 5, motivated by Nadara et al. who used the same values. We run all experiments twice, once with timeout $t = 300s$ and once with $t = 3600s$. Results with $t = 300s$ are directly compared with the results of Nadara et al. who used 300 seconds as timeout. Results with $t = 3600s$ give us the ability to investigate the potential of turbocharging over longer periods of time.

■ **Figure 1** Line plot of the cumulative absolute improvements over time achieved by the turbocharging approaches broken down by the underlying heuristics. The x -axis (time) is scaled logarithmically.

4.3 Results

We now show to which extent our turbocharging approaches improve the results of heuristics, compare the achieved weak coloring numbers to the ones of Nadara et al., and provide observations about the performance of turbocharging.

Impact of turbocharging. Turbocharging has the advantage that investing gradually more time will yield gradually better results – setting the reconstruction parameter to $c = |V(G)|$, we (in theory) even can provably obtain the optimum. Figure 1 shows the cumulative sum of absolute improvements over time when comparing each turbocharged heuristic with the underlying plain heuristic. That is, for a specific time t , the cumulative sum of absolute improvements for a turbocharging algorithm \mathcal{A} and a heuristic \mathcal{H} is $\sum_{I \in \text{instances}} (k_{I, \mathcal{H}} - k_{I, \mathcal{A}, \mathcal{H}, t})$, where $k_{I, \mathcal{H}}$ is the coloring number achieved by the heuristic and $k_{I, \mathcal{A}, \mathcal{H}, t}$ is the coloring number achieved by the turbocharged heuristic after time t . Note that the y -axes do not have the same ranges as the underlying heuristics have different performance levels. All plots exhibit logarithmic or similar to logarithmic growth, which means that the gained absolute improvement is approximately logarithmic in the invested time in the most cases. WCOL-MERGE(r) clearly yields faster and larger improvements than IC-WCOL(r), and it also supersedes IC-WCOL-RL(r) for the Degree-Heuristic. One reason may be that WCOL-MERGE(r) is fixed-parameter tractable and the associated parameters are small.

Further evaluations of the executions of turbocharging algorithms are analysed in detail in the full version of this paper [13]. Some observations therein are that the number of applications of turbocharging per run of a heuristic ranges in the order of at most hundreds for IC-WCOL(r) and WCOL-MERGE(r) and on average in the single digits; for IC-WCOL-RL(r) these numbers are one to two orders of magnitude larger. Successful applications of a turbocharged heuristic (those where the weak coloring number could be improved) mostly only use very little time and search tree nodes, and have small reconstruction parameters – mostly $c = 1$. That is, it is mostly the case that a heuristic wants to place a vertex that is “suboptimal”, while placing nearly any other vertex will achieve lower weak coloring number. The fraction of time spent on turbocharging is also low, which means that most of the time when we can improve the weak coloring number achieved by a heuristic, this can be done easily and in little time.

■ **Table 1** IC-WCOL(r): White columns give relative improvements, light gray columns give quality ratios, dark gray columns give average/maximum absolute improvements. For improvements, we compare to the underlying heuristic without turbocharging and without local search. Time limit: 300s.

By dataset group and radius. Next, we fix a time threshold of 300s (same as Nadara et al.) that we might reasonably invest in practice for computing weak coloring numbers. We present the improvements in weak coloring numbers gained by turbocharging over the plain heuristics broken down according to the instance group (small, medium, big, huge) and the radius r . We again provide absolute improvements when comparing with the underlying heuristic, and we also consider the average *relative improvement* of the weak r -coloring number when comparing the turbocharged heuristic to the plain heuristic; that is, the relative improvement is $1 - k_{I,\mathcal{A},\mathcal{H},t}/k_{I,\mathcal{H}}$ for $t = 300s$. For each turbocharging algorithm we show results for both turbocharged heuristics. For IC-WCOL(r) and WCOL-MERGE(r) these are the Wreach- and Degree-Heuristic, and for IC-WCOL-RL(r) these are the Sreach- and Degree-Heuristic. The results are given in three tables corresponding to the three turbocharging approaches.

We furthermore compare the achieved coloring numbers of each approach to the best coloring numbers computed by Nadara et al.: For each instance I , let $\text{bestNadara}(I)$ be the smallest weak r -coloring number of an ordering of vertices of instance I achieved by an approach of Nadara et al. Note that they implemented seven different heuristics and for each computed ordering they applied a local search to iteratively reduce the weak r -coloring number. To evaluate one of our approaches, we take the weak r -coloring number $k_{I,\mathcal{A},\mathcal{H},t}$ for instance I obtained by our approach for $t = 300s$ and compute the average $1 - k_{I,\mathcal{A},\mathcal{H},t}/\text{bestNadara}(I)$ (in percent) taken over all instances I in the corresponding data set. We call this value *quality ratio*. Note that positive values mean that the approach achieves lower weak coloring numbers on average when compared to the best weak coloring numbers achieved by Nadara et al.

■ **Table 2** WCOL-MERGE(r): White columns give relative improvements, light gray columns give quality ratios, dark gray columns give average/maximum absolute improvements. For improvements, we compare to the underlying heuristic without turbocharging and without local search. Time limit: 300 s.

tests	r	Wreach	WCOL-MERGE(r)		Degree	WCOL-MERGE(r)

	3	-20.5%	1.8/5		-21.9%	27.4/49	
	4	-6.7%	0.5/2		-27.6%	11.2/20	
	5	-8.7%	1.0/2		-15.5%	6.0/14	

In Table 1 we present the performance of the IC-WCOL(r) approach. It is evident that the relative and absolute improvements achieved for the Degree-Heuristic is significantly higher than for the Wreach-Heuristic, although this is partly due to the fact that the Degree-Heuristic achieves worse results than the Wreach-Heuristic before turbocharging. Relative and absolute improvements decrease for larger instances.

Table 2 contains the results for WCOL-MERGE(r). Here, turbocharging achieves positive quality ratios for some instance classes and radii. The relative and absolute improvements are much larger than for IC-WCOL(r), especially for the huge instances and the Degree-Heuristic. It is also interesting that while the Degree-Heuristic generally computes orderings of higher weak coloring number than the Wreach-Heuristic, the turbocharged version of the Degree-Heuristic computes orderings of similar or even lower weak coloring numbers than the turbocharged version of the Wreach-Heuristic for the small and medium instances. We do not see an obvious reason for that, but it could again indicate the power of the fixed-parameter algorithm.

Table 3 contains the results for IC-WCOL-RL(r). Although the relative and absolute improvements of turbocharging the Degree-Heuristic are slightly higher, the quality ratios for the turbocharged version of the Sreach-Heuristic are significantly better. This could imply that IC-WCOL-RL(r) struggles to turbocharge slightly worse heuristics such as the Degree-Heuristic. Furthermore, we see that for the Sreach-Heuristic the quality ratios are better for larger radii. The reason for this could be that the Sreach-Heuristic performs well for larger radii even before turbocharging. We also notice that for the medium graph class the quality ratios get worse. The reason is that the implementation of IC-WCOL-RL(r) is slightly more computationally expensive than for the other approaches.

■ **Table 3** IC-WCOL-RL(r): White columns give relative improvements, light gray columns give quality ratios, dark gray columns give average/maximum absolute improvements. For improvements, we compare to the underlying heuristic without turbocharging and without local search. Time limit: 300s.

Achieved coloring numbers in comparison to Nadara et al. Figure 2 illustrates the distribution of results for all turbocharging algorithms in a scatter plot. Data points below y -value zero mean that the turbocharging algorithm improves a bound on the weak r -coloring number of an instance. Among our approaches, we see that while WCOL-MERGE(r) performs well for small radii, IC-WCOL-RL(r) performs well for larger radii. Together with the analysis from above we can conclude that Nadara et al.’s approaches yield lower weak coloring numbers on average but there is fraction of roughly one half instances where our approaches supersede Nadara et al.’s, in particular if the computed weak coloring numbers are small. Overall, we improved bounds for 172 of the 334 considered instances after $t = 300s$. The resulting new bounds are lower by 5% on average over all instances. Follow-up investigations also showed that the relative improvement of turbocharging negatively correlates with the average degree of the graph, suggesting that our turbocharging algorithms work better for particularly sparse graphs.

As mentioned, our approach has the advantage that investing more time yields gradually better results. Figure 3 shows the number of instances for which a turbocharging approach improve weak coloring numbers compared to Nadara et al. after a specific time. That is, for a time t , the y -value of a line corresponds to the number of instances I such that $k_{I,A,H,t} < \text{bestNadara}(I)$. The values for the line $best$ are determined by taking the number of instances I where any of the turbocharging approaches is better than $\text{bestNadara}(I)$. Interestingly, IC-WCOL-RL(r) starts off with more improved instances, however, after 3600 seconds, WCOL-MERGE(r) achieved more instances with smaller coloring numbers than Nadara et al. After 3600 seconds, IC-WCOL(r) was able to improve 24 instances compared to Nadara et al., WCOL-MERGE(r) 144 instances, and IC-WCOL-RL(r) 115 instances. Overall, we could improve upper bounds for 181 of the 334 instances with $t = 3600s$. These are nine more than for $t = 300s$.

■ **Figure 2** Scatter plot of the results for turbocharging algorithms broken down by radius. Each data point corresponds to an instance and a turbocharging algorithm. The x -value is the best weak coloring number achieved by Nadara et al. for this instance, the y -value is the difference of coloring numbers between the best weak coloring number achieved by Nadara et al. and the weak coloring number $k_{I,\mathcal{A}}$ achieved by the turbocharging algorithm \mathcal{A} (minimum over both turbocharged heuristics). The x -axis is scaled logarithmically and the y -axis is scaled pseudo-logarithmically. Time limit: 300 s.

■ **Figure 3** Line plot of the number of instances where a turbocharging approach achieves better coloring numbers than Nadara et al. over time. The time is scaled logarithmically.

5 Conclusion

On the theoretical side, we determined obstructions (running-time lower bounds) and promising avenues (a fixed-parameter algorithm) for applying the turbocharging framework to computing vertex orderings of small weak coloring numbers. On the experimental side, on a diverse set of instances each of the turbocharging approaches we use yields large improvements over the plain heuristics. This is most pronounced for the fixed-parameter turbocharging WCOL-MERGE(r). Then we compared turbocharging to the best results gained by the seven heuristics that Nadara et al. [32] employed together with local search

procedures. Turbocharging so far yields on average larger weak coloring numbers than the best of the previous approaches. However, for 173 of the in total 334 instances, turbocharging outperforms all of the previous approaches combined. It works particularly well for small computed coloring numbers and sparse input instances.

Abstract

Motivated by a real-world vehicle routing application, we consider the maximum-weight independent set problem: Given a node-weighted graph, find a set of independent (mutually nonadjacent) nodes whose node-weight sum is maximum. Some of the graphs arising in the vehicle routing application are large, having hundreds of thousands of nodes and hundreds of millions of edges.

To solve instances of this size, we develop a new local search algorithm, which is a metaheuristic based on the greedy randomized adaptive search (GRASP) framework. This algorithm, named METAMIS, uses a wider range of simple local search operations than previously described in the literature. We introduce data structures that make these operations efficient. A new variant of path-relinking is introduced to escape local optima and so is a new alternating augmenting-path local search move that improves algorithm performance.

We compare an implementation of our algorithm with a state-of-the-art publicly available code on public benchmark sets, including some large instances. Our algorithm is, in general, competitive and outperforms this openly available code on large vehicle routing instances of the maximum weight independent set problem. We hope that our results will lead to even better maximum-weight independent set algorithms.

1 Introduction

Given an undirected graph $G = (V, E)$, where V is the set of nodes and E the set of edges, an *independent set* $S \subseteq V$ is a set of mutually non-adjacent nodes of graph G . If each node $v \in V$ is assigned a weight w_v , a maximum-weight independent set (*MWIS*) of nodes $S^* \subseteq V$ is an independent set whose sum of weights, $W(S^*) = \sum_{v \in S^*} w_v$ is maximum. We denote $n = |V|$ and $m = |E|$.

¹ The work was done while the author was at Amazon.com

A simple way to state MWIS is as an *Integer Linear Program (ILP)*. Let x_v be a binary decision variable such that $x_v = 1$ if node $v \in S \subseteq V$ and $x_v = 0$ otherwise, where S is an independent set of nodes. A simple integer programming (IP) formulation for selecting a maximum-weight independent set of nodes is

$$\begin{aligned} & \max \sum_{v \in V} w_v x_v \\ & \text{subject to} \\ & \quad x_u + x_v \leq 1, \forall (u, v) \in E \\ & \quad x_v \in \{0, 1\}, \forall v \in V. \end{aligned}$$

A well-known way to strengthen the formulation is to add *clique inequalities*. Let C be a subset of all cliques in the input graph. We add the constraints

$$\sum_{v \in Q} x_v \leq 1 \quad \forall Q \in C.$$

While these constraints are redundant for the ILP problem, they strengthen the linear programming relaxation of the problem.

MWIS is a classical optimization problem that has been extensively studied and has many applications [2]. Solving the MWIS problem is hard. It is one of Karp's original NP-complete problems [10, 12]. The problem is also hard to approximate [11]. Over the years, heuristics have been the workhorse for solving large instances of the maximum independent set problem approximately [18]. In particular, the most successful heuristics have been the ones based on metaheuristic algorithms, such as GRASP [8], tabu search [9], and iterated local search [1, 17].

In this paper we introduce *METAMIS*, a new metaheuristic algorithm for the MWIS problem. METAMIS is based on the *greedy randomized adaptive search procedure* – GRASP [20], with *truncated path-relinking* [19]. GRASP is a procedure consisting of iterations made up from successive constructions of a greedy randomized solution and subsequent iterative improvements of it through a local search, and path-relinking is a technique for escaping local optima by generating intermediate solutions along a path that connects two known high-quality solutions. Our motivation is a long-haul vehicle routing (VR) application that yields large MWIS problems, some with close to 900 thousand nodes. Compared to benchmark instances used in previously published work, the VR-MWIS instances are often larger and have a very different structure. We conduct experiments with METAMIS on MWIS instances arising in different applications, including on our VR-MWIS instances and on other publicly available ones. Due to page limit, we omit some of the details of our implementation. See the full version of the paper [4] for details.

We start with known local search moves and perturbation techniques and introduce new local search moves with data structures to make these moves efficient. We also introduce improved perturbation technique variants. Although our algorithm is a general-purpose heuristic, our motivation comes from the VR problem. A variant of our algorithm takes advantage of the application-specific features. In this application, we have a good initial solution which can be used to for warm-start. In addition, graphs from this application come with a large set of known cliques. This allows us to get a good relaxed LP solution, which we use to guide local search.

Due to the page limit, we omit some of the algorithm and implementation details and focus only on the benchmark from our motivating vehicle routing application. We also omit some intuition and discussions. The full paper [4] covers this material.

2 High Level Description

The MWIS algorithm is an iterative local search algorithm based on the *Greedy Randomized Adaptive Search Procedure (GRASP)* metaheuristic, which is a general metaheuristic for combinatorial optimization [6, 7, 20]. The algorithm also uses *path-relinking* to escape local optima [15, 20].

Algorithm 1 Algorithm Overview.

```

1: procedure MWIS( $G = (V, E, w)$ , maxTime,  $S_0$ )
2:    $S \leftarrow \text{localSearch}(G, S_0)$ 
3:    $\mathcal{ES} \leftarrow \{\}$  ▷ Empty set of elite solutions
4:    $\mathcal{ES}.\text{add}(S)$ 
5:   while  $t \leq \text{maxTime}$  do
6:      $S_G \leftarrow \text{findRandomizedGreedySolution}(G)$ 
7:     if LsBeforeRelinking then ▷ Optional local search
8:        $S_G \leftarrow \text{localSearch}(G, S_G)$ 
9:     end if
10:     $S_e \leftarrow \mathcal{ES}.\text{randomEliteSolution}()$ 
11:     $S' \leftarrow \text{pathRelinking}(G, S_G, S_e)$ 
12:     $S' \leftarrow \text{localSearch}(G, S')$ 
13:     $\mathcal{ES}.\text{tryToAddAndEvict}(S')$  ▷ Add solution to elite set, if full evict similar
    solution of lesser value (or don't insert if no worse elite solution exists)
14:  end while
15:  return  $\mathcal{ES}.\text{bestSolution}()$ 
16: end procedure

```

Algorithm 1 gives a high-level view of the algorithm. In addition to the graph, the input to the algorithm includes a stopping criterion, e.g., a time limit, and an initial solution. When no such solution is available, one can find a solution using the randomized greedy algorithm described later in this section. The algorithm applies local search to improve the initial solution and enters the main loop. At termination of the local search procedure, we are at a local optimum.

The algorithm maintains a set of *elite* solutions \mathcal{ES} , which are the best solutions we have seen so far. We add a solution to \mathcal{ES} immediately after a local search, so the elite solutions are always locally optimal. At each iteration of the loop, we first attempt to escape the local optimum corresponding to the elite solution. In this process, we can decrease the objective function. To escape a local optimum, we first find a randomized greedy solution S_G . Optionally, we apply local search to improve S_G . Then we apply path-relinking to S_G and a random elite solution from \mathcal{ES} to find a new solution S' . Then we apply local search to improve S' , and update S^* if we find a better solution.

For the VR-MWIS instances, the algorithm variant without the optional local search (on line 8) works better, so we omit the search for these instances. We also set the size of the elite set \mathcal{ES} to 1, so we only retain the best solution. This setting works best for the VR-MWIS instances. For other problem families, different parameter choices were found to work better [13, 14].

2.1 Greedy Algorithm

The GRASP framework needs a randomized greedy procedure that produces diverse initial solutions.

2.2 Local Search

■ Algorithm 2 Local Search Procedure

```

1: procedure LOCALSEARCH( $G = (V, E, w), S, \text{numIterations}$ )
2:    $i \leftarrow 1$ 
3:    $S^* \leftarrow S$ 
4:   while  $i \leq \text{numIterations}$  do
5:      $S_i \leftarrow \{\}$  ▷ Empty solution
6:     while  $w(S_i) < w(S)$  do ▷ Repeat until no improvement is found
7:        $S_i \leftarrow S$ 
8:        $S \leftarrow \text{starOneMoves}(G, S)$ 
9:        $S \leftarrow \text{AAPMoves}(G, S)$ 
10:       $S \leftarrow \text{oneStarMoves}(G, S)$ 
11:      if  $w(S_i) < w(S)$  then break ▷ Solution improved
12:      end if
13:       $S \leftarrow \text{twoStarMoves}(G, S)$ 
14:    end while
15:    if  $w(S) > w(S^*)$  then
16:       $S^* \leftarrow S$ 
17:       $i \leftarrow 1$ 
18:    else
19:       $S \leftarrow \text{perturb}(S)$ 
20:    end if
21:  end while
22:  return  $S^*$ 
23: end procedure

```

The local search procedure, outlined in Algorithm 2, repeatedly performs local moves with positive gain. We aim to find positive gain (*improving*) moves until we reach a local optimum, and then we perform a random perturbation of the solution. If we find an improving move, we apply it immediately. We use a subset of (x, y) moves and *alternating augmenting path moves* (AAP-moves). While the (x, y) moves have been studied previously, the AAP moves are new. We describe the moves at a high level in this section, and give a detailed description in Section 3.

An (x, y) move removes x nodes from the solution and adds y nodes to it while maintaining solution independence. We use $*$ instead of x or y to denote an arbitrary positive integer. Note that the number of applicable moves increases significantly as x and y increase. Previous algorithms used (x, y) moves for small values of x and y . In particular, the algorithm of [17] uses $(*, 1)$ and $(1, *)$ moves. Our algorithm uses $(*, 1)$, $(1, *)$, and $(2, *)$ moves. The number of $(2, *)$ moves is large. We use data structures and operation ordering that make improving moves more likely, which makes our algorithm more efficient. If an (x, y) move renders S non-maximal, we add nodes without a neighbor in S to the independent set in random order until S becomes maximal. Note that through this update sequence, S remains an independent set.

A $(*, 1)$ move inserts a single node u into the current solution S and removes its neighbors from S . Procedure $\text{starOneMoves}(G, S)$ applies the $(*, 1)$ moves until there is no such improving move.

A $(1, *)$ move removes a node v from S and adds to S an independent subset I of the nodes whose only neighbor in S before the removal is v . Usually one has multiple choices of independent sets to add. A good heuristic is to add a maximum weight set of the neighbors that maintains independence. This is done when the number of neighbors is small (at most seven in our experiments). We use a naive recursive algorithm: Pick a node u in the neighborhood and recursively solve two subproblems. The first subproblem results by adding u to S and deleting its neighbors from the graph. We get the second subproblem by deleting u without adding it to S . The better of the two corresponding solutions is returned. Procedure $\text{oneStarMoves}(G, S)$ applies the $(1, *)$ moves until there is no such improving move.

A $(2, *)$ move removes two nodes, u and v , from S and adds to S an independent subset I of the nodes whose only neighbors in S before the removal is u , or v , or both u and v . Generally, this set is significantly larger than the corresponding set for the $(1, *)$ moves, and the recursive operation used for the $(1, *)$ moves is too expensive. One could use greedy addition, but in our experiments a random addition, that adds to S a random node from I that has no neighbors in S , was better. Procedure $\text{twoStarMoves}(G, S)$ applies the $(2, *)$ moves until it finds an improving move or there is no improving $(2, *)$ move. Note that unlike the corresponding procedures for other moves, twoStarMoves exits as soon as it finds an improving move.

Our idea for AAP moves comes from matching algorithms [5], although we use a somewhat different definition. Given an independent set S , we define an AAP P as follows. Let $I = S \cap P$ and $O = P - S$ be nodes of P that are in and out of S , respectively.

1. if $v \in I$, then the neighbors of v on P are in O ,
2. if $v \in O$, then the neighbors of v on P are in I ,
3. if we *flip* the path, i.e., set $S = S - I + O$, S remains an independent set.

An AAP move finds an alternating augmenting path, flips it, and looks at the change in $w(S)$. If the change is positive, we accept the AAP move; otherwise we reject the move. For efficiency, we apply a limited number of AAP moves. Procedure $\text{AAPMoves}(G, S)$ applies the AAP moves until there is no such improving move or we reach the limit on the number of AAP moves.

During an execution of the algorithm, most local search moves do not improve solution quality and thus do not change the solution. Note that complexity of evaluating $(2, *)$ moves is significantly higher than those for the other moves. Our local search repeatedly applies starOneMoves , AAPMoves , and oneStarMoves procedures while these procedures find improving moves. If we find an improving move, an immediate application of these procedures may find additional improvements due to neighborhood changes, so we iterate. Only when these procedures fail to find improving moves we call twoStarMoves . If twoStarMoves fails to improve the solution, we perform a random perturbation.

The perturbation adds a small set of random nodes to S and removes their neighbors. After perturbing, we resume local search. The local search algorithm terminates if there has been no improvement to the best solution after a predefined number of iterations.

2.3 Using the Relaxed LP Solution

In our VR application, we use clique information and get a relaxed LP solution to the relaxed problem. The solution assigns a value $x_v \in [0, 1]$ to each node v . We use these values to bias random node selection in the perturbation step of the local search. When performing

a random perturbation in Algorithm 2, we add a node v to the solution with probability proportional to $x_v + \epsilon$. Here ϵ is a positive value (set to $\epsilon = 0.005$) that ensures that each node can be picked, even if $x_v = 0$. This guides the local search by biasing route selection toward nodes with higher fractional relaxed solution value. Using prefix sums we can pick a random node in time $\mathcal{O}(\log |V|)$: We draw a random floating-point number $z \in [0, \sum_{v \in V} x_v)$ and use binary search on the prefix sum array to pick a node such that the sum up to but excluding the node is less than z , and the sum up to and including the node is greater or equal to z .

2.4 Adaptive Path-relinking

Path-relinking is a technique for escaping local optima by generating intermediate solutions along a path that connects two known high-quality solutions. We discuss this technique in the context of MWIS and reversible local search moves. Define an undirected graph associated with the search space MWIS, where the nodes correspond to feasible solutions and the edges correspond to local search moves that transform the solution corresponding to the tail of the edge to the solution corresponding to the head. A path in this graph corresponds to a sequence of the moves that transform the solution at one end of the path into a solution at the other end. Note that the moves need not improve the objective function value. The underlying assumption of path-relinking is that if the end-points of a path correspond to high quality solutions, then the path will contain previously undiscovered high-quality solutions.

For our local search, given two solutions S and T , we can transform S into T as follows. Initialize $S' = S$. At every step, we do either a $(*, 1)$ move or a $(1, *)$ move. In the former case, pick a node $v \in T - S'$, add v to S' , and remove neighbors of v from S' . In the latter case, pick a node $v \in S'$, $v \notin T$ and remove v from S' . Let $N(v)$ denote the set of neighbors of v . Then we iterate over nodes u in $N(v) \cap T$. If $N(u) \cap S' = \emptyset$, we add u to S' .

For large graphs, finding good solutions is expensive. Instead of combining two good solutions, we apply path-relinking to combine the randomized greedy solution S_G with the current best solution S^* , which is locally optimal. While S^* is a good solution, S_G may not be good, and the solutions on the path far from S^* are usually not good either. We modify path-relinking so that it examines only a prefix of the path close to S^* . The prefix is small enough so that the solution quality remains good, yet big enough so that the subsequent local search will not end up with a locally optimal solution equivalent to S^* . This an adaptive variant of the *truncated greedy path-relinking* described in [19].

The first modification is to choose the node x to add to S or to remove from S greedily. We pick a node that maximizes the weight of the solution we get after the move. A second modification is to do a truncated path-relinking: we stop the process after a certain number of steps, which we adjust adaptively. We start with a small limit on the number of steps and increase the limit if the algorithm gets stuck in a local optimum of weight $w(S^*)$.

3 Data Structures and Optimizations

For large graphs, the choice of data structures is important for the efficiency of the algorithm. When making trade-offs between performance on sparse and dense graphs we favor the former because our motivating application yields relatively sparse graphs.

Several of our data structures use sets of objects. We use a representation of sets based on hashing. This representation allows constant time addition, deletion, and membership query, and linear time iteration over all set elements. We also assume that if we add an element to the set that already contains the element, the set does not change. Similarly, if we delete an element not in the set, the set does not change.

3.1 Input Graph

The input graph is static: it does not change throughout the execution. We assign to the nodes of the graph integer IDs from $[0, \dots, n - 1]$ and place them in an array, with node i in position i . Each node has an array of edges incident to it. This places the edges incident to a node in contiguous memory locations, assuring that a common operation of scanning an edge list has a good memory locality. We sort edges by IDs of the head node. This allows us to do neighborhood queries (e.g., “Is v in $N(u)$?”) in time logarithmic in the degree of u using binary search.

Note that using sets to represent neighborhoods would give constant neighborhood queries and linear time edge list scan. However, the constant factors, both in terms of running time and memory consumption, associated with hashing are large. In addition, we lose the locality in edge list scans. For graphs arising from our motivating application, the array-based implementation is significantly faster than the one based on sets.

3.2 Interstate Graph

The *interstate graph* makes the local search operations more efficient. To describe this graph, we need a few definitions.

For a node $u \in S$, $(u, v) \in E$, we say that v is a *1-tight neighbor* of u if $N(v) \cap S = \{u\}$ [1]. Note that if we remove u from S , we can add to S any 1-tight neighbor of u .

Two nodes $u, v \in S$ are *mates* if for at least one node $w \notin S$, w has exactly two neighbors in S : $N(w) \cap S = \{u, v\}$. We call the node w a *2-tight neighbor* of u and v . We say that w is a 2-tight neighbor of u if u has a mate v such that w is a 2-tight neighbor of u and v . If we delete u and v from S , we can replace them by an independent set of the union of three sets: the set of the 1-tight neighbors of u , the set of 1-tight neighbors of v , and the set of the shared 2-tight neighbors of u and v .

Our main data structure is the *interstate graph* $G_{IS} = (V, E_{IS}, w)$. For G_{IS} , the nodes and node weights are the same as in the input graph G . The edge set E_{IS} is changed dynamically depending on the nodes in the current independent set S . E_{IS} has three types of edges:

1. $e = (u, v) \in E$, where $u \in S$ and v is a *1-tight neighbor* of u ;
2. $e = (u, w) \in E$, where $u \in S$ and w is a *2-tight neighbor* of u ;
3. $e = (u, v)$, where $u, v \in S$ are *mates*.

We represent the three edge types separately.

1. For every $u \in S$, we represent its 1-tight neighbors as sets. For $v \notin S$ that is a 1-tight neighbor of u we add the *1-tight edge* (v, u) .
2. For every pair of mates u and v , we maintain a set of 2-tight neighbors of u and v . For every 2-tight neighbor $w \notin S$, we add the pair of *2-tight edges* (w, u) and (w, v) .
3. For every node v in S , we maintain a set M_v of its mates. Every mate $w \in M_v$ corresponds to a *mate edge* (v, w) .

3.3 Efficient Implementation of (x, y) Moves

In this section we show how to efficiently implement (x, y) moves using the interstate graph and two additional optimizations, one for the $(1, *)$ moves and another for $(*, y)$ moves. We discuss maintenance of the interstate graph in Section 3.2.

To implement $(*, 1)$ operations efficiently, we use an idea from [17]. For every $u \notin S$, we maintain a value

$$\Delta(u) = w(u) - \sum_{v \in S \cap N(u)} w(v)$$

to speed up the $(*, 1)$ moves. Such a move is an improving move when $\Delta(u) > 0$. We keep a set S^+ of the nodes u with $\Delta(u) > 0$. Note that for an efficient implementation of $(*, 1)$ moves, we need to update the vector $\Delta(\cdot)$ and the set S^+ . We do this as follows. Every time we add a node u to S , we remove u from S^+ . Then for each $v \in N(u)$, $v \notin S$, we set $\Delta(v) = \Delta(v) - w(u)$. Every time we remove u from S , we scan the edge list of u and compute $\Delta(u)$. If $\Delta(u) > 0$, we add u to S^+ . Also during the scan, for every neighbor v of u such that $v \notin S$, we increase $\Delta(v)$ by $w(u)$, and if $\Delta(v)$ becomes positive, we add v to S^+ . We have an improving $(*, 1)$ move if and only if S^+ is non-empty. In this case, we can pick a node u from S^+ and apply the $(*, 1)$ move to it.

Since for every $u \in S$ we maintain a set of its 1-tight neighbors as a hash set, we can efficiently run the recursive or the greedy algorithm described in Section 2 on this set. Similarly, since for every $u \in S$ we maintain the set of its mates, we can iterate over all mates of u . Furthermore, for a pair of mates u and v , we have the set of the common 2-tight neighbors, and we can apply the randomized algorithm to this set.

Next we describe an optimization that prunes $(1, *)$ and $(2, *)$ moves that are unlikely to improve the solution. For the $(1, *)$ move that removes u , we evaluate the move only if the 1-tight neighborhood of u changed since the last time we evaluated the move but failed to improve the solution. We say that the neighborhood changed if we add u to S and u has a non-trivial 1-tight neighborhood. Since our implementation of the $(1, *)$ move is deterministic and depends only on the 1-tight neighborhood, we know that the move will fail. We maintain the set S_1 of nodes $u \in S$ whose 1-tight neighborhood changed but is not empty. We pick nodes for $(1, *)$ moves from S_1 . While initializing G_{IN} , we initialize S_1 to include all nodes with non-trivial 1-tight neighborhoods. When we update G_{IN} , we also update S_1 (see Section 3.5).

For the $(2, *)$ move, we maintain a set S_2 of mate pairs $\{u, v\}$ which are eligible for the move. We delete a pair from S_2 and evaluate the move that removes this pair from S . We add a pair $\{u, v\}$ to S_2 when they become 2-tight mates, or when $\{u, v\}$ are 2-tight mates and their 2-tight neighborhood changes, or when they are 2-tight mates and the 1-tight neighborhood of either u or v changes. Our implementation of the $(2, *)$ move depends only on the 2-tight neighborhood of the mates. However, the implementation is randomized. Although it is possible that one evaluation of the move succeeds and another fails when the 2-tight neighborhood stays the same, we assume this is unlikely and prune the move. We maintain the set S_2 of mates whose 2-tight neighborhood changed. We pick mates for $(2, *)$ moves from S_2 . While initializing G_{IN} , we initialize S_2 to all pairs of mates. When we update G_{IN} , we update S_2 as well.

3.4 AAP Moves

For efficiency, we only look for alternating augmenting paths (AAPs) in the interstate graph. The only edges on any AAP are either edges from members of S to their 1-tight and 2-tight neighbors (as edges between 2-tight mates would not yield an alternating path). To limit the number of AAP move evaluations, we start a search for an AAP from a 1-tight neighbor of $v \in S_1$ (S_1 was introduced in Section 3.3). This way we guarantee that the move will not decrease the cardinality of S , making the move more likely to succeed. The alternating path initially contains v and its single neighbor $u \in S$. We grow the path as follows. Let $u \in S$ be

the last node on the current AAP, and let U be the set of nodes on the AAP that are in S and \bar{U} be the set of nodes on the AAP that are not in S . We pick a mate w and a 2-tight neighbor x of u such that

- x is not a neighbor of any node of \bar{U} in the input graph (so that the extended path will be an AAP),
- neither x nor w are already in AAP,
- the gain of flipping the extended path is maximized.

If we succeed in finding such a $\{w, x\}$ pair, we add w and x to the path. Then we redefine u to be x and continue growing the path. To introduce additional randomness, we increase the gain for every $\{w, x\}$ pair by a random real number $\epsilon \in [-\delta, \delta]$ and maximize the perturbed gains. We use $\delta = 50$ in our experiments. We terminate the search if the length of the path exceeds a threshold or the gain of flipping the path falls below a (negative) threshold. We then perform the highest positive gain move that flips a prefix of the final path. If no positive gain move is encountered, we do nothing (the move fails).

3.5 Maintaining the Interstate Graph

The vast majority of the local search moves we evaluate do not improve the solution and G_{IN} does not change. We need to update the graph only when a move succeeds, which happens rarely. Our data structures speed up move evaluations and support move pruning. The added overhead is in data structure initialization and updates. The update complexity is non-trivial, but for sparse graphs the complexity is much smaller than the time we save due to the improved move efficiency and pruning.

Let $\rho(u) = |N(u) \cap S|$ denote the number of the neighbors of u in S . Note that for nodes $u \in S$, $\rho(u) = 0$. We maintain $\rho(u)$ for all nodes $u \in V$.

Given an initial solution S , we build G_{IN} , S_1 , and S_2 as follows. We process all nodes $u \notin S$. For each u , we scan its edge list in G and initialize $\rho(u)$. If $\rho(u) = 1$, we let $N(u) \cap S = \{v\}$, add the 1-tight edge (u, v) to the edge list of u in G_{IN} , and add u to the set of 1-tight neighbors of v . If $\rho(u) = 2$, we let $N(u) \cap S = \{v, w\}$, add v to the set of mates of w and add w to the set of mates of v . We also add the pair of 2-tight edges (u, v) and (u, w) to G_{IN} . Finally, we add u to the set of 2-tight neighbors of the mates $\{v, w\}$. We initialize S_1 to the set of all nodes $u \in S$ with non-empty set of 1-tight neighbors. We initialize S_2 to the set of all mate pairs $\{u, v\}$. The initialization takes linear time.

Our algorithm updates S by removing a set of nodes S^- and adding a set of nodes S^+ . We break the update into a sequence of single-node updates: first we remove nodes of S^- one by one, then we add nodes of S^+ one by one. We update G_{IN} after each individual update of S .

After removing a node u from S , we empty its set of 1-tight neighbors and remove u from S_1 . For each mate v of u , we set the corresponding set of 2-tight neighbors to empty and remove u from the set of mates of v . We also remove the pair $\{u, v\}$ from S_2 . Afterwards, we empty the set of mates of u . We then visit its neighbors $v \in V \setminus S$. For each neighbor v , we decrement $\rho(v)$. We need to update G_{IN} if $\rho(v)$ becomes zero, one, or two.

Cases for zero and two are simpler. If the value is zero, we set the 1-tight neighbor of v to null. If the value is two, let $N(v) \cap S = \{a, b\}$. We can find a and b by scanning the edge list of v in G . We add a to the set of mates of b and vice versa. We also add v to the set of 2-tight neighbors of $\{a, b\}$. Finally, we add the 2-tight pair of edges (v, a) and (v, b) to G_{IN} .

If the value is one, we have to update both the old 2-tight neighborhood and the new 1-tight neighborhood. For the latter, we set the 1-tight neighbor of v to the unique neighbor $w \in S$, and add v to the 1-tight neighbor set of w . For the former update, note that v was a 2-tight neighbor for mates $\{w, x\}$ for some $w \in S$ before the removal of v . We remove v from the set of 2-tight neighbors of w and delete the 2-tight edge pair (v, w) and (v, x) from G_{IN} .

Now consider the addition of a node u to S that maintains the independence of S . We scan the edge list of u and for all neighbors v (guaranteed not to be in S) and increment $\rho(v)$. We need to update G_{IN} if $\rho(v)$ becomes one, two, or three.

Cases for one and three are simpler. If the value is one, we add the 1-tight edge (v, u) to G_{IN} , add v to the set of 1-tight neighbors of u , and add u to S_1 . If the value is three, v has a pair of 2-tight edges (v, a) and (v, b) , where a and b are mates. We delete (v, a) and (v, b) from G_{IN} . Then we remove v from the set of 2-tight neighbors of a and b . If the set becomes empty, a and b are no longer mates, so we remove a from the set of mates of b , remove b from the list of mates of a , and remove $\{a, b\}$ from S_2 .

If the value is two, we have to update both the old 1-tight neighborhood and the new 2-tight neighborhood. For the former, let (v, w) be the 1-tight edge. We remove the edge and remove v from the set of 1-tight neighbors of w . If the set becomes empty, we remove w from S_1 . In the latter case, $N(v) \cap S = \{v, w\}$ for some $w \in S$. We add u to the set of mates of w and vice versa. We also add v to the set of 2-tight neighbors of v and w . Finally, we add $\{a, b\}$ to S_2 .

Note that since when we add or remove u to or from S , we may need to scan edge lists of multiple neighbors of u , updating G_{IN} when G is dense may be expensive.

4 Experimental results

4.1 Algorithms and Computational Environment

We implemented our algorithm, which we call *METAMIS*, in Java because it is used in a production system at Amazon and Java is a requirement. For the same reason, we use doubles for node weights. Furthermore, due to licensing restrictions, we use only standard Java libraries. We compiled our code using Java 8.

Although one can tune our algorithm for specific problem families, we use fixed parameter settings in all experiments.

We compare our implementation to the *ILSVND* algorithm of [17]. The publicly available code of [17] is implemented in C++ and represents weights using integers. We made one modification to ILSVND: added the ability to warm start from an initial solution. Given a solution in the input, we initialize the current solution of ILSVND to the input solution. We compiled ILSVND using full optimization (-O3).

For a given instance, algorithm time-quality plots give a lot of information about relative performance of the algorithms. For example, one algorithm may dominate another, or one can converge to a better solution but take longer to converge, etc. The algorithms we compare are stochastic and algorithm performance depends on the pseudo-random seed we use. Furthermore, the algorithms we compare do not know if and when they reach an optimal solution. Usually there is a chance that a solution may improve. However, the algorithms *converge* in a sense that it may reach a point of diminishing returns when a substantial improvement becomes unlikely. To compare the two algorithms, we put a time limit T on their executions. For different problem families, the limit may be different. We run each instance with five different pseudo-random seeds and report the best solution value the algorithm finds. In many cases the algorithms converge. However, for harder problems this may take too long, and the algorithms do not converge within the time limit.

For representative instances, we give the time-quality plots, but we have too many instances to give all the plots. Therefore, we report solution quality at times $T/10$ and $T/2$. In addition, we report the time t^* defined as follows. For a given problem instance, consider the set of final solution values over all algorithms and seed values. Let s be the smallest one

of these values. For a given algorithm, consider the run producing the best final solution value. For this algorithm, we define t^* to be the earliest time this run reaches the value of s or higher. Intuitively, we are comparing best runs of the algorithms being evaluated.

For graph algorithms, C++ is usually faster than Java by a factor from three to six. We expect this to hold for our algorithm as well, especially since we make heavy use of standard Java hash set library, which incurs significant overhead compared to C++. Although we do not adjust the runtimes we report, one has to keep this in mind that if re-implemented in C++, our algorithm would be faster.

We run our experiments on an AWS r3.4xlarge instance with 122GiB RAM and 16 virtual CPUs on Intel Xeon Ivy Bridge processors.

4.2 Computational Results

Our full study [4] uses three benchmark families, but due to the page limit we focus on the benchmark from our motivating application, vehicle routing [3]. In this application, the MWIS problem comes up in several contexts, and we have several instances for each of these contexts.

Tables and plots appear in the appendix. Table 1 lists the *VR instances* with their sizes. The number of nodes in these instances ranges from 979 to 883,238; the number of edges ranges from 3,140 to 389,304,424. The instances are moderately sparse, but the density tends to grow with the problem size. The average degree is below 4 on some small instances and over 400 on some large ones.

Table 1 has additional information: values for the initial solutions we use and upper bounds on optimal solution values. We obtain the upper bounds by solving the corresponding LP relaxation problems to optimality. The initial solution are good: their values are close to the upper bound. Note that an optimal solution may not achieve the upper bound.

For VR instances, we have additional information: relaxed LP solutions and initial solutions. We use this information in practice as it yields better results. In our experiments, we give results both for runs with and runs without initial solutions. We also run our algorithm with initial solutions but without the relaxed solutions to see how much a good initial solution matters, and to have an apples to apples comparison with ILSVND, which does not use this information.

In this section we discuss *VR Instances* [3], which motivated our work. Plot for 2-hour runs of all algorithms on one of the largest instances, CR-S-L-4, given in Figure 1, provides insight into relative algorithm performance. All codes converge, and METAMIS dominates corresponding ILSVND runs. Without warm start, ILSVND solution is worse than the initial solution while METAMIS finds a better solution. With warm start, both algorithms find better solutions. Although plots for METAMIS with and without LP data look very close. However, Table 3 shows that the best solution value with LP was 1% better than without LP: 5,775,704 vs. 5,715,256.

Next we discuss performance of VR instances in detail. Here we set the time limit $T = 3600$ seconds. Table 2 gives results for MWIS with no additional data. For each instance in the table, column $w_{10\%}$ shows the best solution value found at time point $T/10$, column $w_{50\%}$ shows the best solution value found at time point $T/2$, and column w shows the best solution value found when the process is finished at time T . METAMIS finds better solutions than ILSVND except for three instances. For two instances, MT-D-01 and MT-W-01, solution quality is the same. On MW-W-01, the ILSVND solution is better, but only by 0.8%. All three exceptions happen on smaller instances and both algorithms converge quickly. There is no improvement after time $T/10$.

An interesting observation is that on MT-D-01 and MT-W-01, solution values match the corresponding upper bounds given in Table 1, so the solutions are optimal. Since the upper bound need not be tight, it is possible that we solve other instances to optimality, but do not have a proof.

On larger instances, METAMIS has better final values as well as better values at times $T/10$ and $T/2$. On the problem with the highest number of nodes, CR-S-L-3, the difference in the final values is 2.1%. Note that on large instances, neither algorithms converged in time T .

Table 3 shows results for the VR instances for METAMIS+LP, METAMIS, and ILSVND. Note that on three instances, MT-D-FN, MW-D-FN, and MW-W-FN, ILSVND fails to improve the initial solution and t^* is undefined. METAMIS improves the solution on these instances, probably due to a more sophisticated set of local search operations. While both algorithms allow a warm start from a given solution, the METAMIS+LP version of our algorithm uses clique information to compute the relaxed LP solution, and uses it to guide local search. We evaluate both versions of METAMIS to see how much the LP relaxation helps. As in the case of no initial solution, the algorithms converge on most of the small instances and do not converge on larger instances.

Recall that with no initial solution, we found optimal solutions for MT-D-01 and MT-W-01. With the initial solution, METAMIS+LP finds an optimal solution for two more instances, MT-W-FN and MR-W-FN. METAMIS finds an optimal solution for the latter instance, but not for the former. ILSVND does not find any new optimal solutions.

Next we discuss the effect of a good initial solution, comparing results for METAMIS and ILSVND from Tables 2 and 3. Comparing initial solution values from Table 1 with solutions obtained by solving the problems from scratch, we see that in many cases, the initial solution is better than the solution computed from scratch. In fact, for ILSVND, most solutions are worse than the corresponding initial solution. This confirms that our initial solutions are good.

With the warm start, both variants of our algorithm, METAMIS and METAMIS+LP, dominate ILSVND, producing same or (in most cases) better quality solutions. ILSVND is also slower on all instances except one.

To evaluate the benefit of using LP relaxation, we compare METAMIS+LP with METAMIS. On most instances, METAMIS+LP dominates METAMIS. The latter never finds a better solution. For about 1/3 of the instances, solution quality is the same, and for the remaining 2/3, METAMIS+LP performs better. The same holds for intermediate times $T/10$ and $T/2$ except for one instance at $T/2$ where METAMIS solution value is slightly better.

5 Concluding remarks

We developed METAMIS for a real-world VR application for which even a small improvement in solution quality yields substantial cost reduction. Our study is the first to include the benchmark of VR instances [3]. We show that METAMIS works well on the VR instances. We also observed that the VR instances have a structure that is different from that of computer, road, and social network (CRS) instances [16]. The main result of Lamm [16] are local transformations which reduce a MWIS problem to an equivalent problem that is much smaller. On the VR instances, the transformations failed to reduce the problem size significantly.

Our full paper shows that METAMIS works well of the CRS instances. The algorithm of Lamm [16] solves these instances to optimality. Instances of Lamm [16] are hard to reproduce due to weight randomization. In the full paper, we define weights so that they are easy to reproduce. It would be interesting to run the algorithm of Lamm [16] and compare the results.

METAMIS uses a more sophisticated set of local search moves and introduces data structures and lazy evaluation techniques that facilitate efficient implementation of these moves. We also introduce a new variation of path-relinking tailored to large problems. In addition, we show how to use a good relaxed solution to guide local search. These techniques add to the metaheuristic design toolset. We hope that our ideas will lead to even more efficient MWIS algorithms. The ideas may also prove useful in metaheuristic algorithms for other problems.

Abstract

For several decades, much effort has been put into identifying classes of CNF formulas whose satisfiability can be decided in polynomial time. Classic results are the linear-time tractability of Horn formulas (Aspvall, Plass, and Tarjan, 1979) and Krom (i.e., 2CNF) formulas (Dowling and Gallier, 1984). Backdoors, introduced by Williams, Gomes and Selman (2003), gradually extend such a tractable class to all formulas of bounded distance to the class. Backdoor size provides a natural but rather crude distance measure between a formula and a tractable class. Backdoor depth, introduced by Mählmann, Siebertz, and Vigny (2021), is a more refined distance measure, which admits the utilization of different backdoor variables in parallel. Bounded backdoor size implies bounded backdoor depth, but there are formulas of constant backdoor depth and arbitrarily large backdoor size.

We propose FPT approximation algorithms to compute backdoor depth into the classes Horn and Krom. This leads to a linear-time algorithm for deciding the satisfiability of formulas of bounded backdoor depth into these classes. We base our FPT approximation algorithm on a sophisticated notion of obstructions, extending Mählmann et al.’s obstruction trees in various ways, including the addition of separator obstructions. We develop the algorithm through a new game-theoretic framework that simplifies the reasoning about backdoors.

Finally, we show that bounded backdoor depth captures tractable classes of CNF formulas not captured by any known method.

1 Introduction

Deciding the satisfiability of a propositional formula in conjunctive normal form (CNFSAT) is one of the most important NP-complete problems [4, 16]. Despite its theoretical intractability, heuristic algorithms work surprisingly fast on real-world CNFSAT instances [7]. A common explanation for this discrepancy between theoretical hardness and practical feasibility is the presence of a certain “hidden structure” in realistic CNFSAT instances [14]. There are various approaches to capturing the vague notion of a “hidden structure” with a mathematical concept. One widely studied approach is to consider the hidden structure in terms of decomposability. For instance, CNFSAT can be solved in quadratic time for classes of CNF formulas of bounded branchwidth [2] or bounded treewidth [24].

A complementary approach proposed by Williams et al. [26] considers the hidden structure of a CNFSAT instance in terms of a small number of key variables, called *backdoor variables*, that when instantiated move the instance into a polynomial-time solvable class. More precisely, a *backdoor*¹ of size k of a CNF formula F into a polynomial-time solvable class \mathcal{C} is a set B of k variables such that for all partial assignments τ to B , the instantiated formula $F[\tau]$ belongs to \mathcal{C} . In fact, CNFSAT can be solved in linear time for any class of CNF formulas that admit backdoors of *bounded size* into the class of *Horn*, *dual Horn* or *Krom* (i.e., 2CNF) formulas².

The size of a smallest backdoor of a CNF formula F into a class \mathcal{C} is a fundamental but rather simple distance measure between F and \mathcal{C} . Mählmann, Siebertz, and Vigny [17] proposed to consider instead the smallest *depth* over all backdoors of a formula F into a class \mathcal{C} as distance measure. It is recursively defined as follows:

$$\text{depth}_{\mathcal{C}}(F) := \begin{cases} 0 & \text{if } F \in \mathcal{C} \\ 1 + \min_{x \in \text{var}(F)} \max_{\epsilon \in \{0,1\}} \text{depth}_{\mathcal{C}}(F[x = \epsilon]) & \text{if } F \notin \mathcal{C} \text{ and } F \text{ is connected} \\ \max_{F' \in \text{Conn}(F)} \text{depth}_{\mathcal{C}}(F') & \text{otherwise} \end{cases} \quad (1)$$

$\text{Conn}(F)$ denotes the set of connected components of F ; precise definitions are given in Section 2. We can certify $\text{depth}_{\mathcal{C}}(F) \leq k$ with a *component \mathcal{C} -backdoor tree* of depth $\leq k$ which is a decision tree that reflects the choices made in the above recursive definition.

Backdoor depth is based on the observation that if an instance F decomposes into multiple connected components of $F[x = 0]$ and $F[x = 1]$, then each component can be treated independently. This way, one is allowed to use in total an unbounded number of backdoor variables. However, as long as the depth of the component \mathcal{C} -backdoor tree is bounded, one can still utilize the backdoor variables to solve the instance efficiently. In the context of graphs, similar ideas are used in the study of tree-depth [19, 20] and elimination distance [3, 6]. Bounded backdoor size implies bounded backdoor depth, but there are classes of formulas of unbounded backdoor size but bounded backdoor depth.

The challenging algorithmic problem \mathcal{C} -BACKDOOR DEPTH is to find for a fixed base class \mathcal{C} and a given formula F , a component \mathcal{C} -backdoor tree of F of depth $\leq k$. Mählmann et al. [17] gave an FPT-approximation algorithm for this problem, with k as the parameter) where \mathcal{C} is the trivial class NULL for formulas without variables. A component NULL-backdoor tree must instantiate all variables of F .

New Results. In this paper, we give the first positive algorithmic results for backdoor depth into nontrivial classes. A minimization problem admits a *standard fixed-parameter tractable approximation (FPT-approximation)* [18] if for an instance of size n and parameter k there is an *FPT-algorithm*, i.e., an algorithm running in time $f(k)n^{\mathcal{O}(1)}$, that either outputs a solution of size at most $g(k)$ or outputs that the instance has no solution of size at most k , for some computable functions f and g ; $g(k)$ is also referred to as the performance ratio of the algorithm.

► **Main Result 1** (Theorem 15). *\mathcal{C} -BACKDOOR DEPTH admits an FPT-approximation algorithm if \mathcal{C} is any of the Schaefer classes Horn, dual Horn, or Krom.*

¹ We focus only on strong backdoors, as weak backdoors only apply to satisfiable formulas.

² According to Schaefer's Theorem [25], these three classes are the largest nontrivial classes of CNF formulas defined in terms of a property of clauses, for which CNFSAT can be solved in polynomial time.

Since our FPT algorithms have linear running time for fixed backdoor depth k , we obtain the following corollary:

► **Main Result 2** (Corollary 16). *CNFSAT can be solved in linear time for formulas of bounded backdoor depth into the Schaefer classes Horn, dual Horn, and Krom.*

Backdoor depth is a powerful parameter that is able to capture and exploit structure in CNFSAT instances that is not captured by any other known method. We list some well-known parameters which render CNFSAT fixed-parameter tractable (the list is not complete but covers some of the most essential parameters). For all these parameters, there exist CNF formulas with constant backdoor depth (into *Horn*, *dual Horn*, and *Krom*) but where the other parameter is arbitrarily large: (i) backdoor size into Horn, dual Horn, and Krom [21]; (ii) number of leaves of backdoor trees into Horn, dual Horn, and Krom [23, 22]; (iii) backdoor depth into the class of variable-free formulas [17]; (iv) backdoor treewidth to Horn, dual Horn, and Krom [9, 8]; (v) backdoor size into heterogeneous base classes based on Horn, dual Horn, and Krom [11]; (vi) backdoor size into scattered base classes based on Horn, dual Horn, and Krom [10]; (vii) deletion backdoor size into the class of quadratic Horn formulas [12]; (viii) backdoor size into bounded incidence treewidth [13]. We give definitions and separation proofs in the full version.

Approach and Techniques. A common approach to construct backdoors is to compute in parallel both an upper bound and a lower bound. The upper bounds are obtained by constructing the backdoor itself, and lower bounds are usually obtained in the form of so-called *obstructions*. These are parts of an instance that are proven to be “far away” from the base class. Our results and techniques build upon the pioneering work by Mählmann et al. [17], who introduce *obstruction trees* for backdoor depth. A main drawback of their approach is that it is limited to the trivial base class NULL, where the obstructions are rather simple because they can contain only boundedly many variables. Our central technical contribution is overcoming this limitation by introducing *separator obstructions*.

Separator obstructions allow us to algorithmically work with obstruction trees containing an unbounded number of variables, an apparent requirement for dealing with nontrivial base classes different from NULL. In the context of backdoor depth, it is crucial that an existing obstruction is disjoint from all potential future obstructions, so they can later be joined safely into a new obstruction of increased depth. Mählmann et al. [17] ensure this by placing the whole current obstruction tree into the backdoor – an approach that only works for the most trivial base class because only there the obstructions have a bounded number of variables. As one considers more and more general base classes, one needs to construct more and more complex obstructions to prove lower bounds. For example, as instances of the base class no longer have bounded diameter (of the incidence graph of the formula) or bounded clause length, neither have the obstructions one needs to consider. Such obstructions become increasingly hard to separate. Our separator obstructions can separate obstruction trees containing an unbounded number of variables from all potential future obstruction trees. We obtain backdoors of bounded depth by combining the strengths of separator obstructions and obstruction trees. We further introduce a *game-theoretic framework* to reason about backdoors of bounded depth. With this notion, we can compute winning strategies instead of explicitly constructing backdoors, greatly simplifying the presentation of our algorithms.

We provide the proofs of statements marked with \star in the full version.

2 Preliminaries

Satisfiability. A *literal* is a propositional variable x or a negated variable $\neg x$. A *clause* is a finite set of literals that does not contain a complementary pair x and $\neg x$ of literals. A propositional formula in conjunctive normal form, or *CNF formula* for short, is a set of clauses. We denote by \mathcal{CNF} the class of all CNF formulas. Let $F \in \mathcal{CNF}$ and $c \in F$. We denote by $\text{var}(c)$ the set of all variables occurring in c , i.e., $\text{var}(c) = \{x \mid x \in c \vee \neg x \in c\}$ and we set $\text{var}(F) = \bigcup_{c \in F} \text{var}(c)$. For a set of literals L , we denote by $\bar{L} = \{\neg l \mid l \in L\}$, the set of complementary literals of the literals in L . The *size* of a CNF formula F is $\|F\| = \sum_{c \in F} |c|$.

Let $\tau : X \rightarrow \{0, 1\}$ be an assignment of some set X of propositional variables. If $X = \{x\}$ and $\tau(x) = \epsilon$, we will sometimes also denote the assignment τ by $x = \epsilon$ for brevity. We denote by $\text{true}(\tau)$ ($\text{false}(\tau)$) the set of all literals satisfied (falsified) by τ , i.e., $\text{true}(\tau) = \{x \in X \mid \tau(x) = 1\} \cup \{\neg x \in \bar{X} \mid \tau(x) = 0\}$ ($\text{false}(\tau) = \overline{\text{true}(\tau)}$). We denote by $F[\tau]$ the formula obtained from F after removing all clauses that are satisfied by τ and from the remaining clauses removing all literals that are falsified by τ , i.e., $F[\tau] = \{c \setminus \text{false}(\tau) \mid c \in F \text{ and } c \cap \text{true}(\tau) = \emptyset\}$. We say that an assignment satisfies F if $F[\tau] = \emptyset$. We say that F is *satisfiable* if there is some assignment $\tau : \text{var}(F) \rightarrow \{0, 1\}$ that satisfies F , otherwise F is *unsatisfiable*. CNFSAT denotes the propositional satisfiability problem, which takes as instance a CNF formula, and asks whether the formula is satisfiable.

The *incidence graph* of a CNF formula F is the bipartite graph G_F whose vertices are the variables and clauses of F , and where a variable x and a clause c are adjacent if and only if $x \in \text{var}(c)$. We identify a subgraph G' of the incidence graph G_F with the formula F' consisting of all the clauses of F that are in G' , each restricted to the adjacent variables in G' . With slight abuse of notation, we define $\text{var}(F')$ to be the variables occurring in G' . Via incidence graphs, graph theoretic concepts directly translate to CNF formulas. For instance, we say that F is *connected* if G_F is connected, and F' is a *connected component* of F if F' is a maximal connected subset of F . $\text{Conn}(F)$ denotes the set of connected components of F . We will also consider the *primal graph* of a CNF formula F , which has as vertex set $\text{var}(F)$, and has pairs of variables $x, y \in \text{var}(F)$ adjacent if and only if $x, y \in \text{var}(c)$ for some $c \in F$.

Base classes. Let $\alpha \subseteq \{+, -\}$ with $\alpha \neq \emptyset$, let $F \in \mathcal{CNF}$ and $c \in F$. We say that a literal l is an α -*literal* if it is a positive literal and $+$ $\in \alpha$ or it is a negative literal and $- \in \alpha$. We say that a variable v α -*occurs* in a clause c , if v or $\neg v$ is an α -literal that is contained in c . We denote by $\text{var}_\alpha(c)$ the set of variables that α -occur in c . For $\alpha \subseteq \{+, -\}$ with $\alpha \neq \emptyset$ and $s \in \mathbb{N}$, let $\mathcal{C}_{\alpha, s}$ be the class of all CNF formulas F such that every clause of F contains at most s α -literals. For $\mathcal{C} \subseteq \mathcal{CNF}$, we say that a clause c is \mathcal{C} -*good* if $\{c\} \in \mathcal{C}$. Otherwise, c is \mathcal{C} -*bad*. Let τ be any (partial) assignment of the variables of F . We will frequently make use of the fact that $\mathcal{C}_{\alpha, s}$ is *closed under assignments*, i.e., if $F \in \mathcal{C}_{\alpha, s}$, then also $F[\tau] \in \mathcal{C}_{\alpha, s}$. Therefore, whenever a clause $c \in F$ is $\mathcal{C}_{\alpha, s}$ -good it will remain $\mathcal{C}_{\alpha, s}$ -good in $F[\tau]$ and conversely whenever a clause is $\mathcal{C}_{\alpha, s}$ -bad in $F[\tau]$ it is also $\mathcal{C}_{\alpha, s}$ -bad in F .

The classes $\mathcal{C}_{\alpha, s}$ capture (according to Schaefer's Dichotomy Theorem [25]) the largest syntactic classes of CNF formulas for which the satisfiability problem can be solved in polynomial time: The class $\mathcal{C}_{\{+\}, 1} = \text{HORN}$ of *Horn formulas*, the class of $\mathcal{C}_{\{-\}, 1} = \text{DHORN}$ of *dual Horn formulas*, and the class $\mathcal{C}_{\{+, -\}, 2} = \text{KROM}$ of *Krom* (or *2CNF*) *formulas*. Note also that the class NULL of formulas containing no variables considered by Mählmann et al. [17] is equal to $\mathcal{C}_{\{+, -\}, 0}$. We follow Williams et al. [26] and focus on classes that are closed under assignments and therefore we do not consider the classes of 0/1-valid and affine formulas.

Note that every class $\mathcal{C}_{\alpha,s}$ (and therefore also the classes of Krom, Horn, and dual Horn formulas) is trivially *linear-time recognizable*, i.e., membership in the class can be tested in linear-time. We say that a class \mathcal{C} of formulas is *tractable* or *linear-time tractable*, if CNFSAT restricted to formulas in \mathcal{C} can be solved in polynomial-time or linear-time, respectively. The classes HORN, DHORN, KROM are linear-time tractable [1, 5].

3 Backdoor Depth

A *binary decision tree* is a rooted binary tree T . Every inner node t of T is assigned a propositional variable, denoted by $\text{var}(t)$, and has exactly one left and one right child, which corresponds to setting the variable to 0 or 1, respectively. Moreover, every variable occurs at most once on any root-to-leaf path of T . We denote by $\text{var}(T)$ the set of all variables assigned to any node of T . Finally, we associate with each node t of T , the truth assignment τ_t that is defined on all the variables $\text{var}(P) \setminus \{\text{var}(t)\}$ occurring on the unique path P from the root of T to t such that $\tau_t(v) = 0$ ($\tau_t(v) = 1$) if $v \in \text{var}(P) \setminus \{\text{var}(t)\}$ and P contains the left child (right child) of the node t' on P with $\text{var}(t') = v$. Let \mathcal{C} be a base class, F be a CNF formula, and T be a decision tree with $\text{var}(T) \subseteq \text{var}(F)$. Then T is a *\mathcal{C} -backdoor tree* of F if $F[\tau_t] \in \mathcal{C}$ for every leaf t of T [23].

Component backdoor trees generalize backdoor trees as considered by Samer and Szeider [23] by allowing an additional node type, *component nodes*, where the current instance is split into connected components. More precisely, let \mathcal{C} be a base class and F a CNF formula. A *component \mathcal{C} -backdoor tree* for F is a pair (T, φ) , where T is a rooted tree and φ is a mapping that assigns each node t a CNF formula $\varphi(t)$ such that the following conditions are satisfied:

1. For the root r of T , we have $\varphi(r) = F$.
2. For each leaf ℓ of T , we have $\varphi(\ell) \in \mathcal{C}$.
3. For each non-leaf t of T , there are two possibilities:
 - a. t has exactly two children t_0 and t_1 , where for some variable $x \in \text{var}(\varphi(t))$ we have $\varphi(t_i) = \varphi(t)[x = i]$; in this case we call t a *variable node*.
 - b. $\text{Conn}(\varphi(t)) = \{F_1, \dots, F_k\}$ for $k \geq 2$ and t has exactly k children t_1, \dots, t_k with $\varphi(t_i) = F_i$; in this case we call t a *component node*.

Thus, a backdoor tree is just a component backdoor tree without component nodes. The *depth* of a \mathcal{C} -backdoor is the largest number of variable nodes on any root-to-leaf path. The *\mathcal{C} -backdoor depth* $\text{depth}_{\mathcal{C}}(F)$ of a formula F into a base class \mathcal{C} is the smallest depth over all component \mathcal{C} -backdoor trees of F . Alternatively, we can define \mathcal{C} -backdoor depth recursively as in equation (1) from the introduction. For a component backdoor tree (T, φ) let $\text{var}(T, \varphi)$ be the set of all variables x such that some variable node t of T branches on x . We observe that one can use component \mathcal{C} -backdoor trees to decide the satisfiability of a formula.

► **Lemma 1** (\star). *Let $\mathcal{C} \subseteq \text{CNF}$ be tractable, let $F \in \text{CNF}$, and let (T, φ) be a component \mathcal{C} -backdoor tree of F of depth d . Then, we can decide the satisfiability of F in time $(2^d \|F\|)^{\mathcal{O}(1)}$. Moreover, if \mathcal{C} is linear-time tractable, then the same can be done in time $\mathcal{O}(2^d \|F\|)$.*

Let $\mathcal{C} \subseteq \text{CNF}$ and $F \in \text{CNF}$. A (strong) *\mathcal{C} -backdoor* of F is a set $B \subseteq \text{var}(F)$ such that $F[\tau] \in \mathcal{C}$ for each $\tau : B \rightarrow \{0, 1\}$. Assume \mathcal{C} is closed under partial assignments (which is the case for many natural base classes and the classes $\mathcal{C}_{\alpha,s}$) and (T, φ) a component \mathcal{C} -backdoor tree of F . Then $\text{var}(T, \varphi)$ is a \mathcal{C} -backdoor of F .

4 Technical Overview

We present all our algorithms in this work within a game-theoretic framework. This framework builds upon the following equivalent formulation of backdoor depth using splitter games. Similar games can be used to describe treedepth and other graph classes [15].

► **Definition 2.** Let $\mathcal{C} \subseteq \text{CNF}$ and $F \in \text{CNF}$. We denote by $\text{GAME}(F, \mathcal{C})$ the so-called \mathcal{C} -backdoor depth game on F . The game is played between two players, the connector and the splitter. The positions of the game are CNF formulas. At first, the connector chooses a connected component of F to be the starting position of the game. The game is over once a position in the base class \mathcal{C} is reached. We call these positions the winning positions (of the splitter). In each round the game progresses from a current position J to a next position as follows:

- the splitter chooses a variable $v \in \text{var}(J)$.
- The connector chooses an assignment $\tau: \{v\} \rightarrow \{0, 1\}$ and a connected component J' of $J[\tau]$. The next position is J' .

In the (unusual) case that a position J contains no variables anymore but J is still not in \mathcal{C} , the splitter loses. For a position J , we denote by τ_J the assignment of all variables assigned up to position J .

The following observation follows easily from the definition of the game and the fact that the (strategy) tree obtained by playing all possible plays of the connector against a given d -round winning strategy for the splitter forms a component backdoor tree of depth d , and vice versa. In particular, the splitter choosing a variable v at position J corresponds to a variable node and the subsequent choice of the connector for an assignment τ of v and a component of $J[\tau]$ corresponds to a component node (and a subsequent variable or leaf node) in a component backdoor tree.

► **Observation 3.** The splitter has a strategy for the game $\text{GAME}(F, \mathcal{C})$ to reach within at most d rounds a winning position if and only if F has \mathcal{C} -backdoor depth at most d .

Using backdoor depth games, we no longer have to explicitly construct a backdoor. Instead, we present so called *splitter-algorithms* that play the backdoor depth game from the perspective of the splitter. The algorithms will have some auxiliary internal state that they modify with each move. Formally, a splitter-algorithm for the \mathcal{C} -backdoor depth game to a base class \mathcal{C} is a procedure that

- gets as input a (non-winning) position J of the game, together with an internal state
- and returns a valid move for the splitter at position J , together with an updated internal state.

We will usually use the internal state to hold an obstruction that the splitter will periodically increase in size. Assume we have a game $\text{GAME}(F, \mathcal{C})$ and some additional input S . For a given strategy of the connector, the splitter-algorithm plays the game as one would expect: In the beginning, the internal state is initialized with S (if no additional input is given, the state is initialized empty). Whenever the splitter should make its next move, the splitter-algorithm is queried using the current position and internal state, and afterwards the internal state is updated accordingly.

► **Definition 4.** We say a *splitter-algorithm* implements a strategy to reach for a game $\text{GAME}(F, \mathcal{C})$ and input S within at most d rounds a position and internal state with some property if and only if initializing the internal state with S and then playing $\text{GAME}(F, \mathcal{C})$ according to the splitter-algorithm leads – no matter what strategy the connector is using – after at most d rounds to a position and internal state with said property.

The following observation converts splitter-algorithms into algorithms for bounded depth backdoors. It builds component backdoor trees by trying all moves of the connector.

► **Lemma 5** (\star). *Let $\mathcal{C} \subseteq \text{CNF}$ and $f_{\mathcal{C}}: \mathbb{N} \rightarrow \mathbb{N}$. Assume there exists a splitter-algorithm that implements a strategy to reach in each play in the game $\text{GAME}(F, \mathcal{C})$ and non-negative integer d within at most $f_{\mathcal{C}}(d)$ rounds either:*

- i) *a winning position, or*
- ii) *(an internal state representing) a proof that the \mathcal{C} -backdoor depth of F is at least d .*

Further assume this splitter-algorithm always takes at most $\mathcal{O}(\|F\|)$ time to compute its next move. Then there is an algorithm that, given F and d , in time at most $3^{f_{\mathcal{C}}(d)} \mathcal{O}(\|F\|)$ either:

- i) *returns a component \mathcal{C} -backdoor tree of depth at most $f_{\mathcal{C}}(d)$, or*
- ii) *concludes that the \mathcal{C} -backdoor depth of F is at least d .*

For the sake of readability, we may present splitter-algorithms as continuously running algorithms that periodically output moves (via some output channel) and always immediately as a reply get the next move of the connector (via some input channel). Such an algorithm can easily be converted into a procedure that gets as input a position and internal state and outputs a move and a modified internal state: The internal state encodes the whole state of the computation, (e.g., the current state of a Turing machine together with the contents of the tape and the position of the head). Whenever the procedure is called, it “unfreezes” this state, performs the computation until it reaches its next move and then “freezes” and returns its state together with the move.

Our main result is an approximation algorithm (Theorem 15) that either concludes that there is no backdoor of depth d , or computes a component backdoor tree of depth at most $2^{2^{\mathcal{O}(d)}}$. By Lemma 5, this is equivalent to a splitter-algorithm that plays for $2^{2^{\mathcal{O}(d)}}$ rounds to either reach a winning position or a proof that the backdoor depth is larger than d .

Following the approach of Mählmann et al. [17], our proofs of high backdoor depth come in the form of so-called *obstruction trees*. These are trees in the incidence graph of a CNF formula. Their node set therefore consists of both variables and clauses. Obstruction trees of depth d describe parts of an instance for which the splitter needs more than d rounds to win the backdoor depth game. For depth zero, we simply take a single (bad) clause that is not allowed by the base class. Roughly speaking, an obstruction tree of depth $d > 0$ is built from two “separated” obstruction trees T_1, T_2 of depth $d - 1$ that are connected by a path. Since the two obstruction trees are separated but in the same component, we know that for any choice of the splitter (i.e., choice of a variable v), there is a response of the connector (i.e., an assignment of v and a component) in which either T_1 or T_2 is whole. Then the splitter needs by induction still more than $d - 1$ additional rounds to win the game.

► **Definition 6.** *Let $F \in \text{CNF}$ and $\mathcal{C} = \mathcal{C}_{\alpha, s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. We inductively define \mathcal{C} -obstruction trees T for F of increasing depth.*

- *Let c be a \mathcal{C} -bad clause of F . The set $T = \{c\}$ is a \mathcal{C} -obstruction tree in F of depth 0.*
- *Let T_1 be a \mathcal{C} -obstruction tree of depth i in F . Let β be a partial assignment of the variables in F . Let T_2 be an obstruction tree of depth i in $F[\beta]$ such that no variable $v \in \text{var}(F[\beta])$ occurs both in a clause of T_1 and T_2 . Let further P be (a CNF formula representing) a path that connects T_1 and T_2 in F . Then $T = T_1 \cup T_2 \cup \text{var}(P) \cup P$ is a \mathcal{C} -obstruction tree in F of depth $i + 1$.*

► **Lemma 7** (\star). *Let $F \in \text{CNF}$ and $\mathcal{C} = \mathcal{C}_{\alpha, s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. If there is a \mathcal{C} -obstruction tree of depth d in F , then the \mathcal{C} -backdoor depth of F is larger than d .*

Our splitter-algorithm will construct obstruction trees of increasing depth by a recursive procedure (Lemma 14) that we outline now. We say a splitter-algorithm satisfies *property i* if it reaches in each game $\text{GAME}(F, \mathcal{C})$ within $g_{\mathcal{C}}(i, d)$ rounds (for some function $g_{\mathcal{C}}(i, d)$) either

- 1) a winning position, or
- 2) a position J and a \mathcal{C} -obstruction tree T of depth i in F such that no variable in $\text{var}(J)$ occurs in a clause of T , or
- 3) a proof that the \mathcal{C} -backdoor depth of F is at least d .

If we have a splitter algorithm satisfying property $d+1$ then our main result, the approximation algorithm for backdoor depth, directly follows from Lemma 7 and Lemma 5. Assume we have a strategy satisfying property $i-1$, let us describe how to use it to satisfy property i . If at any point we reach a winning position, or a proof that the \mathcal{C} -backdoor depth of F is at least d , we are done. Let us assume this does not happen, so we can focus on the much more interesting second case.

We use property $i-1$ to construct a first tree T_1 of depth $i-1$, and reach a position J_1 . We use it again, starting at position J_1 to construct a second tree T_2 of depth $i-1$ that is completely contained in position J_1 . Since in the beginning the connector selected a connected component, T_1 and T_2 are in the same component of F and we can find a path P connecting them. Let β be the assignment that assigns all the variables the splitter chose until reaching position J_1 . Then T_2 is an obstruction tree not only in J_1 but also in $F[\beta]$. In order to join both trees together into an obstruction of depth i , we have to show, according to Definition 6 that no variable $v \in \text{var}(F[\beta])$ occurs both in a clause of T_1 and T_2 . Since no variable in $\text{var}(J_1)$ occurs in a clause of T_1 (property $i-1$), and T_2 was built only from J_1 , this is the case. The trees T_1 and T_2 are “separated” and can be safely joined into a new obstruction tree T of depth i (see also Figure 3 on page 15 and the proof of Lemma 14 for details).

The last thing we need to ensure is that we reach a position J such that no variable in $\text{var}(J)$ occurs in a clause of T . This then guarantees that T is “separated” from all future obstruction trees that we may want to join it with to satisfy property $i+1$, $i+2$ and so forth. This is the major difficulty and main technical contribution of this paper.

It is important to note here, that the exact notion of “separation” between obstruction trees plays a crucial role for our approach and is one of the main differences to Mählmann et al. [17]. Mählmann et al. solve the separation problem in a “brute-force” manner: If we translate their approach to the language of splitter-algorithms, then the splitter simply selects all variables that occur in a clause of T . For their base class – the class NULL of formulas without variables – there are at most $2^{\mathcal{O}(d)}$ variables that occur in an obstruction tree of depth d . Thus, in only $2^{\mathcal{O}(d)}$ rounds, the splitter can select all of them, fulfilling the separation property. This completes the proof for the base class NULL.

However, already for backdoor depth to KROM, this approach cannot work since instances in the base class have obstruction trees with arbitrarily many clauses. Moreover, the situation becomes even more difficult for backdoors to HORN, since additionally clauses are allowed to contain arbitrary many literals. Mählmann et al. acknowledge this as a central problem and ask for an alternative approach to the separation problem that works for more general base classes.

5 Separator Obstructions

The main technical contribution of this work is a separation technique that works for the base classes $\mathcal{C} = \mathcal{C}_{\alpha, s}$. The separation technique is based on a novel form of obstruction, which we call *separator obstruction*. Obstruction trees are made up of paths, therefore, it is

sufficient to separate each new path P that is added to an obstruction. Note that P can be arbitrarily long and every clause on P can have arbitrary many variables and therefore the splitter cannot simply select all variables in (clauses of) P . Instead, given such a path P that we want to separate, we will use separator obstructions to develop a splitter-algorithm (Lemma 12) that reaches in each game $\text{GAME}(F, \mathcal{C})$ within a bounded number of rounds either

- 1) a winning position, or
- 2) a position J such that no variable in $\text{var}(J)$ occurs in a clause of P , or
- 3) a proof that the \mathcal{C} -backdoor depth of F is at least d .

Informally, a separator obstruction is a sequence $\langle P_1, \dots, P_\ell \rangle$ of paths that form a tree T_ℓ together with an assignment τ of certain *important* variables occurring in T_ℓ . The variables of τ correspond to the variables chosen by the splitter-algorithm and the assignment τ corresponds to the assignment chosen by the connector. Each path P_i adds at least one \mathcal{C} -bad clause b_i to the separator obstruction, which is an important prerequisite to increase the backdoor depth by growing the obstruction. Moreover, by choosing the important variables and the paths carefully, we ensure that for every *outside* variable, i.e., any variable that is not an important variable assigned by τ , there is an assignment and a component (which can be chosen by the connector) that leaves a large enough part of the separator obstruction intact. Thus, if a separator obstruction is sufficiently large, the connector can play such that even after d rounds a non-empty part of the separator obstruction is still intact. This means a large separator obstruction is a proof that the backdoor depth is larger than d .

To illustrate the growth of a separator obstruction (and motivate its definition) suppose that our splitter-algorithm is at position J of the game $\text{GAME}(F, \mathcal{C})$ and has already built a separator obstruction $X = \langle \langle P_1, \dots, P_i \rangle, \tau \rangle$ (with corresponding tree T_i) containing \mathcal{C} -bad clauses b_1, \dots, b_i ; note that τ is compatible with τ_J (i.e., τ and τ_J agree on the common assigned variables). If J is already a winning position, then property i is satisfied. Therefore, J has to contain a \mathcal{C} -bad clause. If no \mathcal{C} -bad clause has a path to T_i in J , then J satisfies 2) of property i and we are also done. Otherwise, let b_{i+1} be a \mathcal{C} -bad clause in J that is closest to T_i and let P_{i+1} be a shortest path from b_{i+1} to T_i in J . Then, we extend our separator obstruction X by attaching the path P_{i+1} to T_i (and obtain the tree T_{i+1}). Our next order of business is to choose a bounded number of important variables occurring on P_{i+1} that we will add to X . Those variables need to be chosen such that no outside variable can destroy too much of the separator obstruction. Apart from destroying the paths of the separator obstruction, we also need to avoid that assigning any outside variable makes too many of the \mathcal{C} -bad clauses b_1, \dots, b_{i+1} \mathcal{C} -good. Therefore, a natural choice would be to add all variables of b_{i+1} to X , i.e., to make those variables important. Unfortunately, this is not possible since b_{i+1} can contain arbitrarily many literals. Instead, we will only add the variables of b_{i+1} to X that α -occur in b_{i+1} . By the following lemma, the number of those variables is bounded.

► **Lemma 8** (\star). *Let $F \in \mathcal{CNF}$ and $\mathcal{C} = \mathcal{C}_{\alpha, s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. If F has \mathcal{C} -backdoor depth at most some integer d , then every clause of F contains at most $d + s$ α -literals.*

While this still allows for outside variables to occur in many of the \mathcal{C} -bad clauses b_1, \dots, b_{i+1} , it already ensures that no outside variable can α -occur in any of these clauses. This helps us, since when $|\alpha| = 1$ (i.e., the only case where α -occurs means something different than just occurs), it provides us with an assignment of any such outside variable that the connector can play without making the \mathcal{C} -bad clauses in which it occurs \mathcal{C} -good. For instance, if $\alpha = \{+\}$, then any outside variable v can only occur negatively in a \mathcal{C} -bad clause and moreover setting v to 0 ensures that the \mathcal{C} -bad clauses remain \mathcal{C} -bad.

■ **Figure 1** A separator obstruction containing three paths P_1 , P_2 , and P_3 . The figure shows vertices and edges of the incidence graph. Only the colorful edges are part of separator obstruction's tree. Gray variables and clauses are mentioned under the names b_i , e , and c in Definition 9.

Next, we need to ensure that any outside variable cannot destroy too many paths. By choosing a *shortest* path P_{i+1} , we have already ensured that no variable occurs on more than two clauses of P_{i+1} (such a variable would be a shortcut, meaning P_{i+1} was not a shortest path). Moreover, because P_{i+1} is a shortest path from b_{i+1} to T_i , every variable that occurs on T_i and on P_{i+1} must occur in the clause c in P_{i+1} that is closest to T_i but not in T_i itself. Similarly, to how we dealt with the \mathcal{C} -bad clauses, we will now add all variables that α -occur in c to X . This ensures that no outside variable can α -occur in both T_i and P_{i+1} , which (by induction over i) implies that every outside variable α -occurs in at most two clauses (either from T_i or from P_{i+1}) and therefore provides us with an assignment for the outside variables that removes at most two clauses from X . However, since removing any single clause can be arbitrarily bad if the clause has a high degree in the separator obstruction, we further need to ensure that all clauses of the separator obstruction in which outside variables α -occur have small degree. We achieve this by adding the variables α -occurring in any clause as soon as its degree (in the separator obstruction) becomes larger than two, which happens whenever the endpoint of P_{i+1} in T_i is a clause. Finally, if the endpoint of P_{i+1} in T_i is a variable, we also add this variable to the separator obstruction to ensure that no variable has degree larger than three in T_{i+1} . This leads us to the following definition of separator obstructions (see also Figure 1 for an illustration).

► **Definition 9.** Let $F \in \mathcal{CNF}$ and $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. A \mathcal{C} -separator obstruction for F is a tuple $X = \langle (P_1, \dots, P_\ell), \tau \rangle$ (where P_1, \dots, P_ℓ are paths in F and τ is an assignment of variables of F) satisfying the following recursive definition.

- P_1 is a shortest path between two \mathcal{C} -bad clauses b_0 and b_1 in F . Let $B_1 = \{b_0, b_1\}$, let V_1 be the set of all variables that α -occur in any clause in B_1 , let $\tau_1 : V_1 \rightarrow \{0, 1\}$ be any assignment of the variables in V_1 , and let $T_1 = P_1$.
- For every i with $1 < i \leq \ell$, let b_i be a \mathcal{C} -bad clause in $F[\tau_{i-1}]$ of minimal distance to T_{i-1} in $F[\tau_{i-1}]$. Then, P_i is a shortest path (of possibly length zero) in $F[\tau_{i-1}]$ from T_{i-1} to b_i and $T_i = T_{i-1} \cup P_i$. Moreover, let e be the variable or clause that is both in T_{i-1} and P_i . We define B_i and V_i by initially setting $B_i = B_{i-1} \cup \{b_i\}$ and $V_i = V_{i-1} \cup \text{var}_\alpha(b_i)$ and distinguishing two cases:
 - If e is a variable, then let c be the clause on P_i incident with e (note that it is possible that $c = b_i$). Then, we add c to B_i and we add $\{e\} \cup \text{var}_\alpha(c)$ to V_i .

- If e is a clause, then either $e = b_i$ or $e \neq b_i$ and there is a clause c that is closest to e on P_i (it may be that $c = b_i$). In the former case we leave B_i and V_i unchanged and in the latter case, we add e and c to B_i and we add $\text{var}_\alpha(e) \cup \text{var}_\alpha(c)$ to V_i .
- $\tau_i : V_i \rightarrow \{0, 1\}$ is any assignment of the variables in V_i that is compatible with τ_{i-1} .

We set $\tau = \tau_\ell$. The size of X is the number of paths in $T = T_\ell$, i.e., $\ell + 1$.

The assignment τ is a central part of the definition, guiding the connector in Lemma 11 and thereby establishing a lower bound on the backdoor depth. We start by observing some simple but important properties of separator obstructions.

► **Lemma 10** (\star). *Let $F \in \text{CNF}$, $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$, and let $X = \langle \langle P_1, \dots, P_\ell \rangle, \tau \rangle$ be a \mathcal{C} -separator obstruction in F , then for every $i \in [\ell]$:*

- (C1) T_i is a tree.
- (C2) Every variable $v \notin V_i$ occurs in at most two clauses of P_j for every j with $1 \leq j \leq i$ and moreover those clauses are consecutive in P_j .
- (C3) Every variable $v \notin V_i$ α -occurs in at most two clauses of T_i and moreover those clauses are consecutively contained in one path of T_i .
- (C4) Every variable $v \in V_i \setminus V_{i-1}$ α -occurs in most four clauses of T_i .
- (C5) If a variable $v \notin V_i$ α -occurs in a clause c of T_i , then c has degree at most two in T_i .
- (C6) Every variable of F has degree at most three in T .
- (C7) If every clause of F contains at most x α -literals, then $|V_i \setminus V_{i-1}| \leq 2s + x + 1$.

We now show the main result of this subsection, namely, that also separator obstructions can be used to obtain a lower bound on the backdoor depth of CNF formulas.

► **Lemma 11.** *Let $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$ and $F \in \text{CNF}$. If F has a \mathcal{C} -separator obstruction of size at least $\ell = (8^d(14^2 + 2d))^{2^d}$, then F has \mathcal{C} -backdoor depth at least d .*

Proof. Let $X = \langle \langle P_1, \dots, P_\ell \rangle, \tau \rangle$ be a \mathcal{C} -separator obstruction for F of size at least ℓ with V_i, B_i, T_i, T as in Definition 9. Let J be a position in the game $\text{GAME}(F, \mathcal{C})$. We say that a subtree T' of $T = T_\ell$ is *contained* in J if every variable and clause of T' occurs in J . Let T' be a subtree of T that is contained in J . Let P_j be a path of X . We say that P_j is *active* in T' if either $V(P_j) = \{b_j\}$ and T' contains b_j or T' contains a vertex in $V(P_j) \setminus V(T_{j-1})$. Moreover, we say that P_j is *intact* in T' at position J if $V(P_j) \subseteq V(T')$ and b_j is a \mathcal{C} -bad clause in J . Otherwise, we say that P_j is *broken* in T' at position J .

We show by induction on the number of rounds that there is a strategy \mathbf{S} for the connector such that the following holds for every position J reached after i rounds in the game $\text{GAME}(F, \mathcal{C})$ against \mathbf{S} : At position J , there is a subtree T' of T contained in J that contains at least $\ell_i = (\ell^{1/2})^i / 8^i$ intact paths and at most $z_i = 2i$ broken paths of X . This then shows the statement of the lemma because $\ell_d = \ell^{1/2^d} / 8^d = 14^2 + 2d \geq 1$ and therefore any position J reached after d rounds in the game $\text{GAME}(F, \mathcal{C})$ contains at least one clause that is \mathcal{C} -bad in J .

The claim clearly holds for $i = 0$ since $\ell_0 = \ell$ and $z_0 = 0$ and the connector can choose the component of F containing T . Assume now that $i > 0$ and let J be the position reached after $i - 1$ rounds. By the induction hypothesis, at position J there is a subtree T' of T contained in J containing at least $\ell_{i-1} = \ell^{(1/2)^{i-1}} / 8^{i-1}$ intact paths and at most $z_{i-1} = 2(i - 1)$ broken paths of X . Suppose that the splitter chooses variable v as its next move. Moreover, let o be the smallest integer such that $v \in V_o$; if $v \notin V_\ell$ we set $o = \ell + 1$. Note that $v \notin V_j$ for every

$i < o$. Let I be the set of all paths P_j of X that are intact in T' at position J and let $I_{<o}$ ($I_{>o}$) be the subset of I containing only the paths P_j with $j < o$ ($j > o$). Finally, let $T'_{<o}$ be the subtree of T' restricted to the paths P_j of X with $j < o$. Note that at position J , $T'_{<o}$ is connected and the paths in $I_{<o}$ are intact also in $T'_{<o}$. Then, the connector chooses the assignment $\beta : \{v\} \rightarrow \{0, 1\}$ such that:

$$\beta(v) = \begin{cases} \tau(v) & |I_{<o}| < \sqrt{\ell_{i-1}}, \\ 1 & |I_{<o}| \geq \sqrt{\ell_{i-1}} \text{ and } + \in \alpha, \\ 0 & \text{otherwise.} \end{cases}$$

As we will show below, β is defined in such a manner that the position $J' = J[\beta]$ reached after the next round of the game $\text{GAME}(F, \mathcal{C})$ contains a subtree T'' of T' containing at least $\ell_i = \sqrt{\ell_{i-1}}/8$ paths that are intact in J' and at most $z_i = z_{i-1} + 2$ broken paths, which completes the proof since the connector can now choose the component of J' containing T'' to fulfill the induction invariant. We distinguish the following cases; refer also to Figure 2 for an illustration of the two cases.

Case 1: $|I_{<o}| \geq \sqrt{\ell_{i-1}}$. We will show that T'' can be obtained as a subtree of $T'_{<o}$.

Note first that all clauses b_j with $j < o$ that are \mathcal{C} -bad in J are also \mathcal{C} -bad in J' . This is because $v \notin V_j$ (because $j < o$ and $v \notin V_{o-1}$) and therefore v cannot α -occur in b_j , which implies that b_j remains \mathcal{C} -bad and not satisfied after setting v to $\beta(v)$.

The tree $T'_{<o}$ in J may decompose into multiple components in J' . We will argue that one of these components contains many intact paths and only at most two more broken paths than $T'_{<o}$. Since the \mathcal{C} -bad clauses of an intact path remain \mathcal{C} -bad in J' , the only way in which an intact path can become broken is if parts of the path get removed, i.e., either v or clauses satisfied by setting v to $\beta(v)$.

If $\beta(v) = 1$ then $+ \in \alpha$. If $\beta(v) = 0$ then $+ \notin \alpha$, and since $\alpha \neq \emptyset$, then $- \in \alpha$. Thus, in $J' = J[\beta]$, the only elements that are removed are the variable v as well as clauses in which v α -occurs. By Lemma 10 (C3), v α -occurs in at most two clauses of $T'_{<o}$ and because of (C5) those clauses have degree at most two in $T'_{<o}$. Therefore, setting v to $\beta(v)$ removes at most two clauses from $T'_{<o}$, each of which having degree at most two. Moreover, according to Lemma 10 (C6), v itself has degree at most three in $T'_{<o}$. This implies that setting v to $\beta(v)$ splits $T'_{<o}$ into at most $2 \cdot 2 + 3 = 7$ components.

Moreover, because of Lemma 10 (C3), the at most two clauses of $T'_{<o}$ in which v α -occurs are located on the same path P_j . Therefore, at most two paths that are complete in $T'_{<o}$, i.e., the path P_j and the at most one path containing v , can become broken. Therefore, there is a component of J' that contains a subtree of $T'_{<o}$ that contains at least $|I_{<o}|/7 - 2 \geq \sqrt{\ell_{i-1}}/7 - 2$ intact paths and at most $z_{i-1} + 2 \leq 2i = z_i$ broken paths of X . Note that $\sqrt{\ell_{i-1}} \geq \ell_d \geq 14^2 + 2d \geq 14^2$ and therefore $\sqrt{\ell_{i-1}}/7 - 2 \geq \sqrt{\ell_{i-1}}/8 = \ell_i$.

Case 2: $|I_{<o}| < \sqrt{\ell_{i-1}}$. This means $\beta(v) = \tau(v)$. In this case, we will build the subtree T'' by picking only one path from $T'_{<o}$ and the remaining paths from P_{o+1}, \dots, P_ℓ . Let A be the set of all paths of X that are active in T' and let $A_{>o}$ ($A_{<o}$) be the subset of A containing only the paths P_j with $j > o$ ($j < o$). We say that a path P_a of X is *attached* to a path P_b of X if $a > b$, $V(P_a) \cap V(P_b) \neq \emptyset$ and there is no $b' < b$ with $V(P_a) \cap V(P_{b'}) \neq \emptyset$. We say that a path P_a in $A_{>o}$ is *weakly attached* to a path P_b in $A_{<o}$ if either:

- P_a is attached to P_b or
- P_a is attached to a path P_c in $A_{>o}$ that is in turn weakly attached to P_b .

■ **Figure 2** Left: Case 1. The set $I_{<o}$ is large. Assigning v to $\beta(v)$ decomposes the tree $T'_{<o}$ into at most seven components. The largest component T'' is still large. Right: Case 2. The set $I_{<o}$ is small. There is a path P to which many paths are weakly attached, forming a tree T_P . Assigning v to $\beta(v)$ splits T_P in at most three parts. The largest component T'' of T_P is still large.

Note that because T' is a tree, every path in $A_{>o}$ is weakly attached to exactly one path in $A_{<o}$. Moreover, for the same reason any path in $A_{<o}$ together with all paths in $A_{>o}$ that are weakly attached to it forms a subtree of T' .

Therefore, there is a path P in $A_{<o}$ such that at least $|I_{>o}|/|A_{<o}|$ paths in $I_{>o}$ are weakly attached to P . Moreover, the union T_P of P and all paths in $A_{>o}$ that are weakly attached to P is a subtree of T' . Note that T_P has at least $|I_{>o}|/|A_{<o}|$ paths that are intact in T_P and at most z_{i-1} paths that are broken in T_P at position J . Since $\sqrt{\ell_{i-1}} \geq \ell_d = 14^2 + 2d \geq 2d$ and $z_{i-1} \leq z_d = 2d$, it holds that $|I_{<o}| + z_{i-1} \leq 2\sqrt{\ell_{i-1}}$ (because also $|I_{<o}| \leq \sqrt{\ell_{i-1}}$). Therefore,

$$\begin{aligned}
 |I_{>o}|/|A_{<o}| &\geq (\ell_{i-1} - |I_{<o}|)/(|I_{<o}| + z_{i-1}) \\
 &\geq (\ell_{i-1} - |I_{<o}|)/(2|I_{<o}|) \\
 &\geq (\ell_{i-1})/(2\sqrt{\ell_{i-1}}) - 1/2 \\
 &\geq \sqrt{\ell_{i-1}}/2 - 1/2 \\
 &= 8\ell_i/2 - 1 \geq 3\ell_i.
 \end{aligned}$$

Because $\beta(v) = \tau(v)$, all paths P_j with $j > o$ that are active in T_P are still contained in J' and moreover if P_j is intact in J , then it is still intact in J' . Moreover, because of Lemma 10 (C2), v occurs in at most two clauses of P and because $\beta(v) = \tau(v)$ all paths P_{o+1}, \dots, P_ℓ that are attached to P are still attached to P after setting v to $\beta(v)$. It follows that setting v to $\beta(v)$ removes at most two clauses and at most one variable (i.e., the variable v) from P and also from T_P . Therefore, $J' = J[\beta]$ contains a component that contains a subtree T'' of T_P with at least $3\ell_i/3 = \ell_i$ paths that are intact in T'' and at most $z_{i-1} + 1 \leq z_i$ paths that are broken in T'' . ◀

6 Winning Strategies and Algorithms

We are ready to present our algorithmic results. Earlier, we discussed that separator obstructions are used to separate existing obstruction trees from future obstruction trees. As all obstruction trees are built only from shortest paths, it is sufficient to derive a splitter-algorithm that takes a shortest path P and separates it from all future obstructions. By reaching a position J such that no variable in $\text{var}(J)$ occurs in a clause of P , we are guaranteed that all future obstructions are separated from P , as future obstructions will only contain clauses and variables from J .

► **Lemma 12** (\star). Let $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. There exists a splitter-algorithm that implements a strategy to reach for each game $\text{GAME}(F, \mathcal{C})$, non-negative integer d , and shortest path P between two \mathcal{C} -bad clauses in F within at most $(3s + d + 1)(8^d(14^2 + 2d))^{2^d}$ rounds either:

- 1) a winning position, or
- 2) a position J such that no variable in $\text{var}(J)$ occurs in a clause of P , or
- 3) a proof that the \mathcal{C} -backdoor depth of F is at least d .

This algorithm takes at most $\mathcal{O}(\|F\|)$ time per move.

Since selecting more variables can only help the splitter in archiving their goal, we immediately also get the following statement from Lemma 12.

► **Corollary 13**. Consider $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$, a game $\text{GAME}(F, \mathcal{C})$ and a position J' in this game, a non-negative integer d and shortest path P between two \mathcal{C} -bad clauses in F . There exists a splitter-algorithm that implements a strategy that continues the game from position J' and reaches within at most $(3s + d + 1)(8^d(14^2 + 2d))^{2^d}$ rounds either:

- 1) a winning position, or
- 2) a position J such that no variable in $\text{var}(J)$ occurs in a clause of P , or
- 3) a proof that the \mathcal{C} -backdoor depth of F is at least d .

This algorithm takes at most $\mathcal{O}(\|F\|)$ time per move.

As described at the end of Section 4, we can now construct in the following lemma obstruction trees of growing size, using the previous corollary to separate them from potential future obstruction trees.

► **Lemma 14**. Let $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. There is a splitter-algorithm that implements a strategy to reach for a game $\text{GAME}(F, \mathcal{C})$ and non-negative integers i, d with $1 \leq i \leq d$ within at most $(2^i - 1)(3s + d + 1)(8^d(14^2 + 2d))^{2^d}$ rounds either:

- 1) a winning position, or
- 2) a position J and a \mathcal{C} -obstruction tree T of depth i in F such that no variable in $\text{var}(J)$ occurs in a clause of T , or
- 3) a proof that the \mathcal{C} -backdoor depth of F is at least d .

This algorithm takes at most $\mathcal{O}(\|F\|)$ time per move.

Proof. We will prove this lemma by induction over i . Our splitter-algorithm will try construct an obstruction tree of depth i by first using the induction hypothesis to build two obstruction trees T_1 and T_2 of depth $i - 1$ and then joining them together. After the construction of the first tree T_1 , we reach a position J_1 and by our induction hypothesis no variable in $\text{var}(J_1)$ occurs in a clause of T_1 . This encapsulates the core idea behind our approach, as it means that T_1 is separated from all potential future obstruction trees T_2 that we build from position J_1 . Therefore, we can compute the next tree T_2 in J_1 and join T_1 and T_2 together in accordance with Definition 6 by a path P . At last, we use Corollary 13 to also separate this path from all future obstructions. If at any point of this process we reach a winning position or a proof that the \mathcal{C} -backdoor depth of F is at least d , we can stop. Let us now describe this approach in detail.

For convenience, let $x = (3s + d + 1)(8^d(14^2 + 2d))^{2^d}$. We start our induction with $i = 1$. If there is no \mathcal{C} -bad clause in F , then it is a winning position and we can stop. Assume there is exactly one \mathcal{C} -bad clause c in F . By Lemma 8, if c contains more than $d + s$ α -literals, we have a proof that the \mathcal{C} -backdoor depth of F is at least d and we archive case 3) of the lemma. On the other hand, if c contains at most $d + s$ α -literals, the splitter can obtain a

■ **Figure 3** Overview of the construction in Lemma 14. First, T_1 is chosen in F , yielding J_1 . Then, T_2 is chosen in J_1 , yielding J_2 . In the end the connecting path P is chosen yielding J . A gray doublesided arrow between a position \hat{J} and structure \hat{T} symbolizes that no variable $v \in \text{var}(\hat{J})$ occurs in a clause of \hat{T} .

winning position in $\text{GAME}(F, \mathcal{C})$ after at most $d + s \leq (2^i - 1)x$ rounds by choosing a new variable α -occurring in c at every round. Assume there is more than one \mathcal{C} -bad clause in F . Thus, we pick \mathcal{C} -bad clauses c_1 and c_2 and compute a shortest path P between c_1 and c_2 in F . By Definition 6, $T = \{c_1\} \cup \{c_2\} \cup \text{var}(P) \cup P$ is a \mathcal{C} -obstruction tree of depth 1 in F . We then continue the game using Corollary 13 (for the path P) to reach a position J' satisfying (1), (2), or (3) after at most $x \leq (2^i - 1)x$ rounds, with each round taking at most $\mathcal{O}(\|F\|)$ time.

We now assume the statement of this lemma to hold for $i - 1$ and we show it also holds for i . To this end, we start playing the game $\text{GAME}(F, \mathcal{C})$ according to the existing splitter-algorithm for $i - 1$. If we reach (within at most $(2^{i-1} - 1)x$ rounds) a winning position or a proof that the \mathcal{C} -backdoor depth of F is at least d then we are done. Assuming this is not the case, we reach a position J_1 and a \mathcal{C} -obstruction tree T_1 of depth $i - 1$ in F such that no variable $v \in \text{var}(J_1)$ occurs in a clause of T_1 .

We continue playing the game at position J_1 according to the existing splitter-algorithm for $\text{GAME}(J_1, \mathcal{C})$ and $i - 1$. The \mathcal{C} -backdoor depth of F is larger or equal to the \mathcal{C} -backdoor depth of J_1 . Thus again (after at most $(2^{i-1} - 1)x$ rounds) we either are done (because we reach a winning position or can conclude that the \mathcal{C} -backdoor depth of J_1 is at least d) or we reach a position J_2 and a \mathcal{C} -obstruction tree T_2 of depth $i - 1$ in J_1 such that no variable $v \in \text{var}(J_2)$ occurs in a clause of T_2 .

We pick two clauses $c_1 \in T_1$ and $c_2 \in T_2$ that are \mathcal{C} -bad in F and compute a shortest path P between c_1 and c_2 in F . We now argue that $T = T_1 \cup T_2 \cup \text{var}(P) \cup P$ is a \mathcal{C} -obstruction tree of depth i in F . Let $\beta = \tau_{J_1}$ be the assignment that assigns all the variables the splitter chose until reaching position J_1 to the value given by the connector. Note that J_1 is a connected component of $F[\beta]$.

Since all variables and clauses belonging to T_2 induce a connected subgraph of J_1 , T_2 is a \mathcal{C} -obstruction tree of depth $i - 1$ not only in J_1 , but also in $F[\beta]$. Let $v \in \text{var}(F[\beta])$. We show that v does not occur both in some clause of T_1 and of T_2 . To this end, assume v is contained in a clause of T_2 . Since all clauses of T_2 are in J_1 and J_1 is a connected component of $F[\beta]$, we further have $v \in \text{var}(J_1)$. On the other hand (as discussed earlier), no variable $v \in \text{var}(J_1)$ is contained in a clause of T_1 . By Definition 6, $T = T_1 \cup T_2 \cup \text{var}(P) \cup P$ is a \mathcal{C} -obstruction tree of depth i in F .

We use Corollary 13 to continue playing the game at position J_2 . Again, if we reach a winning position or a proof that the \mathcal{C} -backdoor depth of F is at least d we are done. So we focus on the third case that we reach (within at most x rounds) a position J such that

no variable $v \in \text{var}(J)$ is contained in a clause of P . We know already that no variable $v \in \text{var}(J_1)$ is contained in a clause of T_1 and no variable $v \in \text{var}(J_2)$ is contained in a clause of T_2 . Since $\text{var}(J) \subseteq \text{var}(J_2) \subseteq \text{var}(J_1)$, and $T = T_1 \cup T_2 \cup \text{var}(P) \cup P$, we can conclude that no variable $v \in \text{var}(J)$ is contained in a clause of T .

In total, we played for $(2^{i-1} - 1)x + (2^{i-1} - 1)x + x = (2^i - 1)x$ rounds. The splitter-algorithm in Corollary 13 takes at most $\mathcal{O}(\|F\|)$ time per move. The same holds for the splitter-algorithm for $i - 1$ that we use as a subroutine. Thus, the whole algorithm takes at most $\mathcal{O}(\|F\|)$ time per move. \blacktriangleleft

The main results now follow easily by combining Lemmas 1, 5, 7, and 14.

- **Theorem 15** (\star). *Let $\mathcal{C} = \mathcal{C}_{\alpha,s}$ with $\alpha \subseteq \{+, -\}$, $\alpha \neq \emptyset$, and $s \in \mathbb{N}$. We can, for a given $F \in \text{CNF}$ and a non-negative integer d , in time at most $2^{2^{2^{\mathcal{O}(d)}}} \|F\|$ either*
- 1) *compute a component \mathcal{C} -backdoor tree of F of depth at most $2^{2^{\mathcal{O}(d)}}$, or*
 - 2) *conclude that the \mathcal{C} -backdoor depth of F is larger than d .*

► **Corollary 16.** *Let $\mathcal{C} \in \{\text{HORN}, \text{DHORN}, \text{KROM}\}$. The CNFSAT problem can be solved in linear time for any class of formulas of bounded \mathcal{C} -backdoor depth.*

7 Conclusion

We show that CNFSAT can be solved in linear-time for formulas of bounded \mathcal{C} -backdoor depth whenever \mathcal{C} is any of the well-known Schaefer classes. We achieve this by showing that \mathcal{C} -backdoor depth can be FPT-approximated for any class $\mathcal{C} = \mathcal{C}_{\alpha,s}$. This allows us to extend the results of Mählmann et al. [17] for the class of variable-free formulas to all Schaefer classes. Our results provide an important milestone towards generalizing and unifying the various tractability results based on variants of \mathcal{C} -backdoor size (see also future work below) to the only recently introduced and significantly more powerful \mathcal{C} -backdoor depth.

Let us finish with some natural and potentially significant extensions of backdoor depth that can benefit from our approach based on separator obstructions. Two of the probably most promising ones that have already been successfully employed as extensions of backdoor size are the so-called *scattered* and *heterogeneous* backdoor sets [11, 10].

Interestingly, while those two notions lead to orthogonal tractable classes in the context of backdoor size, they lead to the same tractable class for backdoor depth. Therefore, lifting these two extensions to backdoor depth, would result in a unified and significantly more general approach. While we are hopeful that our techniques can be adapted to this setting, one of the main remaining obstacles is that obstructions of depth 0 no longer are single (bad) clauses. For instance, consider the heterogeneous class $\mathcal{C} = \text{HORN} \cup \text{KROM}$. Here, a CNF formula may not be in \mathcal{C} due to a pair of clauses, one in $\text{HORN} \setminus \text{KROM}$ and another one in $\text{KROM} \setminus \text{HORN}$. Finally, an even more general but also more challenging tractable class to consider for backdoor depth is the class of Q-HORN formulas, which generalizes the heterogeneous class obtained as the union of all considered Schaefer classes.

Abstract

We study two variants of the fundamental problem of finding a cluster in incomplete data. In the problems under consideration, we are given a multiset of incomplete d -dimensional vectors over the binary domain and integers k and r , and the goal is to complete the missing vector entries so that the multiset of complete vectors either contains (i) a cluster of k vectors of radius at most r , or (ii) a cluster of k vectors of diameter at most r . We give tight characterizations of the parameterized complexity of the problems under consideration with respect to the parameters k , r , and a third parameter that captures the missing vector entries.

1 Introduction

We consider two formulations of the fundamental problem of finding a sufficiently large cluster in incomplete data [2, 3, 18, 24]. In the setting under consideration, the input is a multiset M of d -dimensional Boolean vectors – regarded as the rows of a matrix, some of whose entries might be missing – and two parameters $k, r \in \mathbb{N}$. In the first problem under consideration, referred to as DIAM-CLUSTER-COMPLETION, the goal is to decide whether there is a completion of M that admits a multiset of k vectors (which we call a k -cluster) of diameter at most r ; that is, a k -cluster such that the Hamming distance between any two cluster-vectors is at most r . In the second problem, referred to as RAD-CLUSTER-COMPLETION, the goal is to decide whether there is a completion of M that admits a k -cluster of radius at most r ; that is, a k -cluster such that there is a *center* vector $\vec{s} \in \{0, 1\}^d$ with Hamming distance at most r to each cluster-vector.

The cluster-diameter and cluster-radius are among the most widely used measures for intra-cluster similarity [5, 8, 12, 15, 16, 17, 18]. Our interest in studying these problems stems from the recent relevant research within the theory community [9, 14, 19, 20, 21], as well as the ubiquitous presence of incomplete data in relevant areas, such as recommender systems, machine learning, computer vision, and data science [1, 10, 11, 28].

We study the parameterized complexity of the above problems with respect to the two parameters k , r , and a third parameter that captures the occurrence of missing vector entries. Naturally, parameterizing by the number of missing entries alone is not desirable since one would expect that number to be rather large. In their recent related works on clustering problems, Koana, Froese, and Niedermeier [20, 21] restricted the occurrence of missing entries by using the maximum number of missing entries per row as the parameter. Another parameter for restricting the occurrence of missing entries is the minimum number of vectors plus coordinates needed to “cover” all missing entries, which was proposed and used by Eiben et al. [9] and Ganian et al. [14], who studied various data completion and clustering problems. In this paper, we propose and use a parameter that unifies and subsumes both previous parameterizations: the “*deletion distance to near-completion*”, denoted $\lambda(M)$, which is the minimum integer p such that at most p vectors can be removed from M so that every remaining vector contains at most p missing entries. Clearly, the parameter $\lambda(M)$ is computable in polynomial time and is not larger than any of (and hence subsumes) the two parameters considered by Koana et al. [20, 21], Eiben et al. [9], and Ganian et al. [14].

Results and Techniques. We perform an in-depth analysis of the two considered data completion problems w.r.t. the aforementioned parameterizations. We obtain results that provide a nearly complete complexity landscape of these problems. An overview of our results is provided in Table 1. As a byproduct, our results establish that both problems under consideration are fixed-parameter tractable parameterized by $k + r$ when the data is complete, which answers an open question in the literature [2, 3].

■ **Table 1** Overview of the results obtained in this paper.

We summarize the new results obtained in this paper below.

1. We show that DIAM-CLUSTER-COMPLETION is fixed-parameter tractable (FPT) parameterized by $r + \lambda(M)$ (Theorem 9). The significance of the above result is in removing the dependency on the cluster size k in the running time of the algorithm, thus showing that finding a large cluster in incomplete data can be feasible when both the cluster diameter and the parameter $\lambda(M)$ are small. This result is the pinnacle of our technical contributions and relies on two ingredients: a fixed-parameter algorithm for the same problem parameterized by $k + r + \lambda(M)$ (Theorem 1), which is then used as a subroutine in the main algorithm, and a new technique that we dub *iterative sunflower harvesting*. Crucial to this new technique is a general structural lemma, allowing us to represent a family of sets in a succinct manner in terms of sunflower cores, which we believe to be interesting in its own right. We note that the use of sunflowers to obtain a succinct set representation (leading to a kernel) is not uncommon in such settings [20, 21, 22, 25]. What makes the sunflower harvesting technique novel is that it allows us to (1) show

that each solution can be covered by a small number of sunflowers, and to (2) iteratively “harvest” these sunflowers to obtain a solution in boundedly-many (in the parameter) branching steps.

2. We give an XP-algorithm for DIAM-CLUSTER-COMPLETION parameterized by k alone (Theorem 10). Together with Theorem 11 (showing the $W[1]$ -hardness of DIAM-CLUSTER w.r.t. k) and Theorem 12 (showing the $W[1]$ -hardness for DIAM-CLUSTER-COMPLETION w.r.t. k even for $r = 0$), this gives a complete complexity landscape for DIAM-CLUSTER-COMPLETION parameterized by any combination of the parameters k , r , and $\lambda(M)$.
3. We show that RAD-CLUSTER-COMPLETION is FPT parameterized by $k + r + \lambda(M)$ (Theorem 15); this result answers open questions in the literature [2, 3], which asked about the fixed-parameter tractability of the easier complete version of the problem (i.e., when $\lambda(M) = 0$).
4. We provide an XP-algorithm for RAD-CLUSTER-COMPLETION parameterized by $r + \lambda(M)$ in which the degree of the polynomial in the runtime has only a logarithmic dependence on r (Theorem 16). We remark that the problem is in XP parameterized by k alone (Observation 13).
5. We provide an accompanying $W[1]$ -hardness result for RAD-CLUSTER-COMPLETION that rules out its fixed-parameter tractability when parameterized by $k + r$ (Theorem 12). Since the problem is NP-hard for fixed r (as also follows from Theorem 12), this leaves only two questions open for the considered parameterizations: whether RAD-CLUSTER-COMPLETION is FPT when parameterized by either $k + \lambda(M)$ or by $r + \lambda(M)$.
6. We give an FPT-approximation scheme for the optimization version (w.r.t. the cluster size) of RAD-CLUSTER-COMPLETION.

Related Work

The RAD-CLUSTER problem (i.e., RAD-CLUSTER-COMPLETION for complete data) and variants of it were studied as early as the 1980’s, albeit under different names. Dyer and Frieze presented a heuristic algorithm for approximating a variant of RAD-CLUSTER, referred to as the p -CENTER problem, where the goal is to compute $p \in \mathbb{N}$ clusters, each of radius at most r , that contain all vectors of M ; hence, RAD-CLUSTER corresponds to the case of p -CENTER where $p = 1$ and $k = |M|$ (i.e., when the cluster contains all vectors in M). Cabello et al. [4] studied the parameterized complexity of the geometric p -CENTER PROBLEM in \mathbb{R}^d .

Frances and Litman [13] studied the complexity of RAD-CLUSTER with $k = |M|$, in the context of computing the radius of a binary code; they referred to it as the COVERING RADIUS problem and showed it to be NP-hard. Gąsieniec et al. [15, 16] studied (the optimization versions of) RAD-CLUSTER and DIAM-CLUSTER with $k = |M|$ and obtained polynomial-time algorithms as well as lower bounds for a number of cases. They also obtained 2-approximation algorithms for these problems by extending an earlier algorithm by Gonzalez [17].

The RAD-CLUSTER problem restricted to the subcase of $k = |M|$ was also extensively studied under the nomenclature CLOSEST STRING. Li et al. [24] showed that the problem admits a polynomial time approximation scheme if the goal is to minimize r . Gramm et al. [18] studied CLOSEST STRING from the parameterized complexity perspective and showed it to be fixed-parameter tractable parameterized by r . Following this naming convention, Boucher and Ma [2], and Bulteau and Schmid [3] studied the parameterized complexity of RAD-CLUSTER under the nomenclature CLOSEST STRING WITH OUTLIERS. They considered several parameters, including some of the parameters under consideration in this paper. Notably, the restriction of our fixed-parameter algorithm for RAD-CLUSTER parameterized

by $k + r + \lambda$ to the subcase where $\lambda = 0$ answers an open question in [2, see, e.g., Table 1]. Moreover, our XP algorithm for RAD-CLUSTER-COMPLETION provided in Theorem 16 that has a run-time in which the degree of the polynomial has only a logarithmic dependence on r , immediately implies an algorithm of the same running time for CLOSEST STRING WITH OUTLIERS, as a special case.

For incomplete data, Hermelin and Rozenberg [19] studied the parameterized complexity of RAD-CLUSTER-COMPLETION for $k = |M|$ under the nomenclature CLOSEST STRING WITH WILDCARDS problem, with respect to several parameterizations. Very recently, Koana et al. [20] revisited the earlier work of Hermelin and Rozenberg [19] and obtained, among other results, a fixed-parameter algorithm for the problem parameterized by r plus the maximum number of missing entries per row. Even more recently, the same group [21] also studied a problem related to DIAM-CLUSTER-COMPLETION for $k = |M|$. They obtain a classical-complexity classification w.r.t. constant lower and upper bounds on the diameter and the maximum number of missing entries per row.

2 Preliminaries

We assume basic familiarity with parameterized complexity, including the classes $W[1]$, FPT, XP, as well as Turing kernelization and FPT-approximation schemes [7, 6, 27].

Vector Terminology. Let \vec{a} and \vec{b} be two vectors in $\{0, 1, \square\}^d$, where \square is used to represent coordinates whose value is unknown (i.e., missing entries). We denote by $\Delta(\vec{a}, \vec{b})$ the set of coordinates in which \vec{a} and \vec{b} are guaranteed to differ, i.e., $\Delta(\vec{a}, \vec{b}) = \{i \mid (\vec{a}[i] = 1 \wedge \vec{b}[i] = 0) \vee (\vec{a}[i] = 0 \wedge \vec{b}[i] = 1)\}$, and we denote by $\delta(\vec{a}, \vec{b})$ the *Hamming distance* between \vec{a} and \vec{b} measured only between known entries, i.e., $|\Delta(\vec{a}, \vec{b})|$. Moreover, for a subset $D' \subseteq [d]$ of coordinates, where $[d] = \{1, \dots, d\}$, we denote by $\vec{a}[D']$ the vector \vec{a} restricted to the coordinates in D' .

There is a one-to-one correspondence between vectors in $\{0, 1\}^d$ and subsets of coordinates, i.e., for every vector, we can associate the unique subset of coordinates containing all its one-coordinates and vice-versa. It will be useful to represent a vector by the set of coordinates where the vector has the value 1. We introduce the following notation for vectors to switch between their set-representation and vector-representation. We denote by $\Delta(\vec{a})$ the set $\Delta(\vec{0}, \vec{a})$. We extend this notation to sets of vectors as follows: for a set N of vectors in $\{0, 1, \square\}^d$, we denote by $\Delta(N)$ the set $\{\Delta(\vec{v}) \mid \vec{v} \in N\}$. We say that a vector $\vec{a} \in \{0, 1, \square\}^d$ is a *t-vector* if $|\Delta(\vec{a})| = t$ and we say that \vec{a} *contains* a subset S of coordinates if $S \subseteq \Delta(\vec{a})$.

We say that a multiset¹ $M^* \subseteq \{0, 1\}^d$ is a *completion* of a multiset $M \subseteq \{0, 1, \square\}^d$ if there is a bijection $\alpha : M \rightarrow M^*$ such that for all $\vec{a} \in M$ and all $i \in [d]$ it holds that either $\vec{a}[i] = \square$ or $\alpha(\vec{a})[i] = \vec{a}[i]$. For a multiset M of vectors over $\{0, 1, \square\}^d$, we let the *deletion distance to near-completion*, $\lambda(M)$, denote the minimum integer such that there exists a subset $D_M \subseteq M$ with the following properties: (a) $|D_M| \leq \lambda(M)$, and (b) every vector in $M \setminus D_M$ contains at most $\lambda(M)$ missing entries. We call D_M the *deletion (multi-)set*, and observe that $\lambda(M)$ along with a corresponding deletion set can be trivially computed from M in linear time.

A *sunflower* in a set family \mathcal{F} is a subset $\mathcal{F}' \subseteq \mathcal{F}$ such that all pairs of elements in \mathcal{F}' have the same intersection. We will say that a multiset P is a *DIAM-Cluster* (or $|P|$ -*DIAM-Cluster*) if $\delta(\vec{p}, \vec{q}) \leq r$ for every pair $\vec{p}, \vec{q} \in P$. Similarly, P is a *RAD-Cluster* (or $|P|$ -*RAD-Cluster*) if there exists a vector $\vec{c} \in \{0, 1\}^d$ such that $\delta(\vec{c}, \vec{p}) \leq r$ for every $\vec{p} \in P$.

¹ We remark that, in the interest of brevity and when clear from context, we will sometimes use standard set notation such as $A \subseteq B$ in conjunction with multisets.

In all problems under consideration, the input size is considered to be $|M|$, i.e., the size of the matrix including multiplicities.

3 Finding a DIAM-Cluster in Incomplete Data

In this section, we present our results for DIAM-CLUSTER-COMPLETION. Our main algorithmic results are that DIAM-CLUSTER-COMPLETION is FPT parameterized by $r + \lambda(M)$ and is in XP parameterized by k alone. Together with Theorem 11 (showing the W[1]-hardness of DIAM-CLUSTER parameterized by k) and Theorem 12 (showing the W[1]-hardness of DIAM-CLUSTER-COMPLETION parameterized by k even for $r = 0$), this gives a complete complexity landscape for DIAM-CLUSTER-COMPLETION parameterized by any combination of the parameters k , r , and $\lambda(M)$.

3.1 DIAM-CLUSTER-COMPLETION Parameterized by $k + r + \lambda(M)$

We start by showing that DIAM-CLUSTER-COMPLETION parameterized by $k + r + \lambda(M)$ is FPT. We will later show a stronger result, namely that the same result already holds if we only parameterize by $r + \lambda(M)$. Showing the weaker result here is important for the following reasons: (1) we use the algorithm presented here as a subroutine in our result for the parameterization $r + \lambda(M)$, (2) the techniques developed here can also be employed for RAD-CLUSTER-COMPLETION, and (3) we obtain a Turing kernel of size polynomial in k .

The main approach behind the Turing kernel is to guess two vectors of maximum distance in the desired cluster. This will allow us to pre-process the instance such that if the resulting instance contains too many vectors, then it has a solution. Note that this approach only works for the case that a solution contains at least two vectors from $M \setminus D_M$ (recall that D_M denotes the deletion set); otherwise, we can guess the at most one vector from $M \setminus D_M$ that is in the solution and remove all the other vectors from $M \setminus D_M$. Therefore, in all cases, we end up with a reduced instance with boundedly many vectors and we will then show that we can remove all but boundedly many coordinates while preserving solutions.

► **Theorem 1.** *DIAM-CLUSTER-COMPLETION parameterized by $k + r + \lambda(M)$ has a Turing-kernel containing at most $n = k3^{2\lambda(M)+r} + \lambda(M) + 2$ vectors, each having at most $\max\{r(n-1) + \lambda(M), \binom{\lambda(M)}{2}(r+1)\}$ coordinates.*

3.2 DIAM-CLUSTER-COMPLETION Parameterized by $r + \lambda(M)$

With Theorem 1 in hand, we can move on to establishing the fixed-parameter tractability of DIAM-CLUSTER-COMPLETION parameterized by $r + \lambda(M)$. At the heart of our approach lies a new technique for analyzing the structure of vectors through sunflowers in their set representations, which we dub *iterative sunflower harvesting*. We first preprocess the instance to establish some basic properties. We then show a general result about sunflowers that allows us to derive a succinct representation of the solution cluster – in particular, this guarantees that the hypothetical solution can be described by a bounded number of sunflower cores. Finally, we proceed to “harvesting” these sunflowers cores using a branching procedure, thus computing the solution cluster.

3.2.1 Preprocessing the Instance

Let (M, k, r) be an instance of DIAM-CLUSTER-COMPLETION, let M^* be a completion of M that contains a maximum size DIAM-Cluster, and fix P^* to be such a maximum size DIAM-Cluster in M^* . We also fix D_M to be a $\lambda(M)$ -deletion set. The goal of the algorithm is to find M^* and P^* .

If $k < \lambda(M) + 2$, then we can use the algorithm in Theorem 1 to obtain a Turing kernel whose size is a function of $r + \lambda(M)$, which, in turn, would imply that DIAM-CLUSTER-COMPLETION is FPT parameterized by $r + \lambda(M)$, thus giving the desired result. We assume henceforth that P^* contains the completion of at least two vectors in $M \setminus D_M$. We can guess the subset P_R of D_M that will be completed to vectors in P^* , and restrict our attention to finding a DIAM-Cluster in $M \setminus D_M$ of size $|P^* \setminus D_M|$. We will do so by enumerating all such DIAM-Cluster's in $M \setminus D_M$ and at the end check whether one of them, together with P_R , can be extended into a DIAM-Cluster.

Therefore, we will focus on what follows on finding a cluster in $M \setminus D_M$. We first guess two vectors \vec{v} and \vec{u} in $M \setminus D_M$, together with their completions \vec{v}^* and \vec{u}^* , respectively, such that \vec{v}^* and \vec{u}^* are both in P^* and are the farthest vectors apart in $P^* \setminus D_M$; fix $r_{\max} = \delta(\vec{v}^*, \vec{u}^*)$. We remove all other vectors that can be completed into \vec{v}^* or \vec{u}^* , and reduce k accordingly; hence, we do not keep duplicates of the two vectors that we already know to be in P^* . We then normalize all vectors in M so that \vec{v}^* becomes the all-zero vector, i.e., we replace \vec{v}^* by the all-zero vector, and for every other vector $\vec{w} \neq \vec{v}$, we replace it with the vector \vec{w}' such that $\vec{w}'[i] = 0$ if $\vec{v}^*[i] = \vec{w}[i]$, $\vec{w}'[i] = \square$ if $\vec{w}[i] = \square$, and $\vec{w}'[i] = 1$, otherwise. Finally, for each vector $\vec{w} \in M \setminus D_M$, we compute the set $\Lambda(\vec{w})$ of all completions of \vec{w} at distance at most r_{\max} from both \vec{v}^* and \vec{u}^* . Note that $\Lambda(\vec{w})$ can be computed in $\mathcal{O}(2^{\lambda(M)} \cdot d)$ time for each vector in $M \setminus D_M$, where d is the dimension of the vectors in M . We then remove all vectors \vec{w} with $\Lambda(\vec{w}) = \emptyset$ from $M \setminus D_M$.

We will extend the notation $\Lambda(\vec{w})$ to $\Lambda_C(\vec{w})$, for a multiset C of vectors in $\{0, 1\}^d$, such that $\Lambda_C(\vec{w})$ is the set of all completions of a vector \vec{w} at distance at most r_{\max} to all vectors in C . We are now ready to show that after normalizing the vectors in P^* , the multiset $P^* \setminus D_M$ satisfies certain structural properties that we refer to as an r -saturated subset (of M^*); these structural properties allow for a succinct representation of P^* .

3.2.2 Sunflower Fields or Representing Sets by Cores of Sunflowers

In this subsection, we provide the central component for our algorithm based on the iterative sunflower harvesting technique. Crucial to this component is a general structural lemma that allows us to represent a family of sets in a succinct manner in terms of sunflower cores, which we believe to be interesting in its own right. We first state the result in its most general form (for sets), and then show how to adapt it to our setting.

► **Definition 2.** *Let U be a universe, \mathcal{B} a family of subsets of U and $\mathcal{A} \subseteq \mathcal{B}$. We say that \mathcal{A} is an r -saturated subfamily of \mathcal{B} (for $r \in \mathbb{N}$) if the following holds for every $t \in \mathbb{N}$ and every sunflower $S \subseteq \mathcal{A}$ containing at least $r + 1$ sets of cardinality t with core C : \mathcal{A} contains every set $B \in \mathcal{B}$ of cardinality t such that $C \subseteq B$.*

Intuitively, this property states that \mathcal{A} contains all sets in \mathcal{B} which are super-sets of cores of every sufficiently-large sunflower in \mathcal{A} (with sets of the same cardinality).

The connection of this set property to clusters is as follows. We will show that every maximal cluster is an r -saturated subset of M^* . Since P^* contains the all-zero vector \vec{v}^* , any vector in P^* contains at most r ones. Fix $t \in [r]$, and consider the set of all vectors in P^* containing exactly t ones. The above notion will allow to draw the following assumption: if the aforementioned set of vectors is large, then it must contain a large sunflower and all the vectors in M whose completions share the core of this sunflower *must be* in P . This property will subsequently allow us to represent every hypothetical solution using a bounded number of sunflowers, as we show next.

The crucial insight now is that every r -saturated subfamily containing only sets of bounded size admits a succinct representation, where we can completely describe the set via a bounded number of sunflower cores. This is made precise in the following lemma.

► **Lemma 3.** *Let \mathcal{A} and \mathcal{B} be two families of sets of cardinality at most r' over universe U such that $\mathcal{A} \subseteq \mathcal{B}$. If \mathcal{A} is an r -saturated subset of \mathcal{B} , then there is a set \mathcal{S} of at most $(rr')^{r'}$ subsets of U such that \mathcal{A} is equal to the set of all sets B in \mathcal{B} satisfying that $S \subseteq B$ for some $S \in \mathcal{S}$. Moreover, for each set $S \in \mathcal{S}$, S is either the core of a sunflower in \mathcal{A} with at least $r + 1$ petals, or $|S| = r'$.*

We will now show how Lemma 3 can be employed in our setting. Let $M, M' \subseteq \{0, 1\}^d$ with $M' \subseteq M$. Then M' is an r -saturated subset of M if $\Delta(M')$ is an r -saturated subset of $\Delta(M)$. Herein, one can think of M as being (a part of) the input matrix and M' as being an inclusion-wise maximal cluster; we will later show that this property guarantees that M' is an r -saturated subset of M . Using this definition, the following corollary now follows immediately from Lemma 3.

► **Corollary 4.** *Let $r', r \in \mathbb{N}$ and $M, M' \subseteq \{0, 1\}^d$ be sets of r' -vectors such that M' is an r -saturated subset of M . There is a set \mathcal{S} of at most $(rr')^{r'}$ subsets of $[d]$ such that M' is equal to the set of all vectors \vec{m} in M satisfying $S \subseteq \Delta(\vec{m})$ for some $S \in \mathcal{S}$. Moreover, for each set $S \in \mathcal{S}$, S is either a core of a sunflower in $\Delta(M')$ with at least $r + 1$ petals, or $|S| = r'$.*

We now can show that after normalizing the vectors in P^* , the multiset $P^* \setminus D_M$ is an r -saturated subset of M^* .

► **Lemma 5.** *Let (M, k, r) be an instance of DIAM-CLUSTER-COMPLETION, let M^* be a completion of M and let P^* be a DIAM-Cluster in M^* of maximum size such that $\vec{0} \in P^*$. Then for every $N \subseteq M^*$, $P^* \setminus N$ is an r -saturated subset of $M^* \setminus N$.*

Since $P^* \setminus N$ is an r -saturated subset of $M^* \setminus N$, by Corollary 4, applied separately for each $r' \in [r]$, there exists a set $\mathcal{S} = \{(S_1, r_1), \dots, (S_\ell, r_\ell)\}$, with $\ell \leq \sum_{r' \in [r]} (rr')^{r'} \leq r^{2r+1}$, such that $P^* \setminus N$ contains precisely all the vectors \vec{w} in M^* , such that for some (S_i, r_i) , $i \in [\ell]$, $S_i \subseteq \Delta(\vec{w})$ and $|\Delta(\vec{w})| = r_i$.

We call the pair (S_i, r_i) an r_i -center (of $P^* \setminus N$ in $M^* \setminus N$). We say that a vector $\vec{w} \in \{0, 1, \square\}^d$ is *compatible* with r_i -center (S_i, r_i) if there is a completion $\vec{w}^* \in \{0, 1\}^d$ of \vec{w} , called *witness of compatibility*, such that $S_i \subseteq \Delta(\vec{w}^*)$ and $|\Delta(\vec{w}^*)| = r_i$. We say that $\vec{w} \in \{0, 1, \square\}^d$ is *compatible* with \mathcal{S} if it is compatible with some $(S_i, r_i) \in \mathcal{S}$.

The *size* of an r_i -center is the number of vectors that are compatible with it in M . Moreover, for a set $\mathcal{S} = \{(S_1, r_1), \dots, (S_\ell, r_\ell)\}$ and a multiset C of vectors from $\{0, 1\}^d$, we say that \mathcal{S} *defines* C , if every vector $\vec{c} \in C$ is compatible with \mathcal{S} and for every $(S_i, r_i) \in \mathcal{S}$ there is a vector in C compatible with (S_i, r_i) . We say that \mathcal{S} *properly defines* C , if $|\mathcal{S}| \leq r^{2r+1}$, \mathcal{S} defines C , and for every $(S_i, r_i) \in \mathcal{S}$ either:

- $|S_i| = r_i$ and the unique vector that is compatible with (S_i, r_i) is in C ; or
- $|S_i| < r_i$ and C contains a set N of $r + 1$ r_i -vectors such that $\Delta(N)$ forms a sunflower with core S_i .

Note that if every vector in C has at most r_{\max} 1's, then since C is an r -saturated subset of C , it follows from Corollary 4 that there always exists a set \mathcal{S} that properly defines C .

► **Observation 6.** *Let C be a multiset of vectors from $\{0, 1\}^d$, with $\max_{\vec{c} \in C} |\Delta(\vec{c})| \leq r$. Then there exists a set \mathcal{S} of at most r^{2r+1} r_i -centers that properly defines C .*

Suppose that we have a correct guess for \mathcal{S} , then we can already solve the problem as follows. For each $(S_i, r_i) \in \mathcal{S}$ such that $|S_i| = r_i$, there is only one possible r_i -vector that contains S_i . If our guess is correct, then P^* contains at least one vector that can be completed to this particular r_i -vector, and by maximality of P^* , P^* has to contain all such vectors. If $(S_i, r_i) \in \mathcal{S}$ such that $|S_i| < r_i$, then P^* contains a sunflower containing r_i -vectors of size at least $r + 1$ whose core is S_i . Clearly, P^* contains all the vectors that can be completed to an r_i -vector containing S_i , since Lemma 5 holds for any completion M^* of M that contains P^* as a subset. The following lemma shows that all such vectors can be completed arbitrarily since all that matters is that their completion is compatible with \mathcal{S} .

► **Lemma 7.** *Let (M, k, r) be an instance of DIAM-CLUSTER-COMPLETION, M^* a completion of M , P^* a DIAM-Cluster in M^* of maximum size with $\vec{0} \in P^*$, and $N \subseteq M^*$. If \mathcal{S} properly defines $P^* \setminus N$, then for every pair of vectors $\vec{w}_1, \vec{w}_2 \in \{0, 1\}^d$ compatible with \mathcal{S} it holds that $\delta(\vec{w}_1, \vec{w}_2) \leq r$.*

It is easy to see that there are at most d^{r+1} choices for a pair (S_i, r_i) (i.e., a r_i -center), and hence we have at most $(d^{r+1})^{r^{2r+1}} = d^{\mathcal{O}(r^{2r+2})}$ possible choices for the set \mathcal{S} that properly defines P^* . This bound already implies an XP-algorithm. To obtain a fixed-parameter algorithm, it suffices to find the correct guess for \mathcal{S} in FPT-time, which is our next goal.

3.2.3 Iterative Sunflower Harvesting

We are now ready to describe the iterative sunflower harvesting procedure, which allows us to obtain the desired FPT-algorithm. Namely, we show that instead of enumerating all $d^{r^{2r+2}}$ possible sets \mathcal{S} of r_i -centers to find the one that properly defines $P^* \setminus D_M$, it suffices to enumerate only $f(r, \lambda(M))$ -many “important” r_i -centers for each choice of \vec{v}^* and \vec{u}^* (recall that \vec{v}^* and \vec{u}^* are the two fixed vectors in $P^* \setminus D_M$ that were guessed), where f is some function that depends only on r and $\lambda(M)$. Moreover, we can enumerate these possibilities in FPT-time.

We compute \mathcal{S} by iteratively adding r_i -centers one by one. The main idea is to show that, for any partial solution \mathcal{S}' , there is a bounded number of choices for the next r_i -center to add. As a first step in this direction, the following lemma shows that for \mathcal{S}' , there is always a “large” r_i -center (S_i, r_i) that can be added to \mathcal{S}' , i.e., of size at least a $(2^r r^{2r+1})$ -fraction of the remaining vectors. Before we state the lemma, we introduce the following notations. If \vec{w} is compatible with \mathcal{S} , we will denote by $\zeta^{\mathcal{S}}(\vec{w})$ the set of witnesses of compatibility for \vec{w} and \mathcal{S} . Recall that, for a vector $\vec{w} \in \{0, 1, \square\}^d$ and multiset C of vectors from $\{0, 1\}^d$, $\Lambda_C(\vec{w})$ denotes the set of all completions of vector \vec{w} at distance at most r_{\max} to all vectors in C , i.e., $\max_{\vec{c} \in C} \{\delta(\vec{c}, \vec{c}_w)\} \leq r_{\max}$.

► **Lemma 8.** *Let P^* be a maximum DIAM-Cluster in (M, k, r) , \mathcal{S} the set of r_i -centers that properly define $P^* \setminus D_M$, and $\mathcal{S}' \subseteq \mathcal{S}$. Moreover, let C' be the multiset of vectors \vec{w} in $M \setminus D_M$ with $\zeta^{\mathcal{S}'}(\vec{w}) \neq \emptyset$ and C the multiset containing a vector $\vec{w}_c \in \zeta^{\mathcal{S}'}(\vec{w})$ for every $\vec{w} \in C'$. Finally, let M' be the multiset consisting of all the vectors $\vec{w} \in M \setminus (C \cup D_M)$ with $\Lambda_C(\vec{w}) \neq \emptyset$. Then there exists $(S_i, r_i) \in \mathcal{S} \setminus \mathcal{S}'$ such that at least $(|M'|/2^{r_{\max}} - |D_M|)/r^{2r+1}$ vectors in M' are compatible with (S_i, r_i) .*

Note that each normalised vector \vec{w} can be compatible with at most $2^{r+\lambda(M)}$ r_i -centers (S_i, r_i) , since $S_i \subseteq \Delta(\vec{w}^*)$ for some completion \vec{w}^* of \vec{w} . Now it follows from a counting argument that the number of large r_i -centers is at most $2^{r+\lambda(M)}(2^r r^{2r+1}) = 2^{2r+\lambda(M)} r^{2r+1}$ and those can be enumerated in time $\mathcal{O}(2^{r+\lambda(M)} |M|)$. By Observation 6, $|\mathcal{S}|$ and hence the depth of the branching algorithm, is at most r^{2r+1} , which implies the following theorem.

► **Theorem 9.** *DIAM-CLUSTER-COMPLETION is fixed-parameter tractable parameterized by $r + \lambda(M)$.*

3.3 DIAM-CLUSTER-COMPLETION Parameterized by k

Here, we use an Integer Linear Programming subroutine to show that DIAM-CLUSTER-COMPLETION parameterized by k is in XP.

Moreover, we also observe in Theorem 11 that, unless $W[1]=FPT$, this cannot be improved to an FPT-algorithm even for complete data.

► **Theorem 10.** DIAM-CLUSTER-COMPLETION is in XP parameterized by k .

Proof. Let (M, k, r) be an instance of DIAM-CLUSTER-COMPLETION. The algorithm works by enumerating all potential clusters C of size exactly k , and then uses a reduction to an ILP instance with $f(k)$ variables to check whether C can be completed into a cluster. Since there are at most $|M|^k$ many potential clusters of size exactly k , it only remains to show how to decide whether a given set C of exactly k vectors in M can be completed into a DIAM-Cluster. Let M_C be the submatrix of M containing only the vectors in C . Then M_C has at most 3^k distinct columns, and moreover, each of those columns can be completed in at most 2^k possible ways. Let T be the set of all columns occurring in M_C and for a column $\vec{t} \in T$, let $F(\vec{t})$ be the set of all possible completions of \vec{t} , and let $\#(\vec{t})$ denote the number of columns in M_C equal to \vec{t} . For a vector $\vec{f} \in \{0, 1\}^k$ (representing the completion of a column), let $T(\vec{f})$ denote the subset of T containing all columns \vec{t} with $\vec{f} \in F(\vec{t})$. Moreover, for every i and j with $1 \leq i < j \leq k$ (representing the i -th and the j -th vectors in C), we denote by $FD(i, j)$ the set of all vectors (completions of columns) $\vec{f} \in \{0, 1\}^k$ such that $\vec{f}[i] \neq \vec{f}[j]$.

We are now ready to construct an ILP instance \mathcal{I} with at most $3^k 2^k$ variables that is feasible if and only if C can be completed into a DIAM-Cluster. \mathcal{I} has one variable $x_{\vec{t}, \vec{f}}$ for every $\vec{t} \in T$ and every $\vec{f} \in F(\vec{t})$ whose value (in a feasible assignment) represents how many columns of type \vec{t} in M_C will be completed to \vec{f} . Moreover, \mathcal{I} has the following constraints:

- One constraint for every $\vec{t} \in T$ stipulating that every column of type \vec{t} in M_C is completed in some manner:

$$\sum_{\vec{f} \in F(\vec{t})} x_{\vec{t}, \vec{f}} = \#(\vec{t}).$$

- For every i and j with $1 \leq i < j \leq k$ (representing the i -th and the j -th vectors in C), one constraint stipulating that the Hamming distance between the i -th and the j -th vectors in C does not exceed r :

$$\sum_{\vec{f} \in FD(i, j)} x_{\vec{t}, \vec{f}} \leq r.$$

This completes the construction of \mathcal{I} and it is straightforward to verify that \mathcal{I} has a feasible assignment if and only if C can be completed to a DIAM-Cluster. Since \mathcal{I} has at most $3^k 2^k$ variables, and since it is well known that ILP can be solved in FPT-time w.r.t. the number of variables [23], \mathcal{I} can be solved in FPT-time w.r.t. k . ◀

► **Theorem 11.** DIAM-CLUSTER-COMPLETION is $W[1]$ -hard parameterized by k even if $\lambda(M) = 0$.

We note that our second result also establishes the $W[1]$ -hardness of RAD-CLUSTER-COMPLETION (since both problems coincide when $r = 0$).

► **Theorem 12.** DIAM-CLUSTER-COMPLETION and RAD-CLUSTER-COMPLETION are both $W[1]$ -hard parameterized by k even if $r = 0$.

4 Finding a RAD-Cluster in Incomplete Data

In this section, we present our results for RAD-CLUSTER-COMPLETION. We will show that RAD-CLUSTER-COMPLETION is FPT parameterized by $k + r + \lambda(M)$, and is in XP parameterized by $r + \lambda$ alone. Notably, the degree of the polynomial in the run-time of our XP algorithm grows only logarithmically in r and the algorithm can be employed to solve the CLOSEST STRING WITH OUTLIERS problem [2, 3].

Before proceeding to the main contributions of this section, we observe that, by combining the trivial branching procedure, in which we branch over all sets of k vectors from M (where in each branch we proceed under the assumption that all vectors outside of the set can be deleted), with a previous result of Hermelin and Rozenberg [19, Theorem 2], which solves the special case of RAD-CLUSTER-COMPLETION for $k = |M|$, we obtain:

► **Observation 13.** RAD-CLUSTER-COMPLETION parameterized by k is in XP.

Together with the previously-established Theorem 12 (showing the W[1]-hardness for RAD-CLUSTER-COMPLETION w.r.t. k even for $r = 0$), this gives us an almost complete picture of the parameterized complexity of RAD-CLUSTER-COMPLETION for any combination of the parameters $k, r, \lambda(M)$. The only two questions that remain open are whether the XP result for $r + \lambda(M)$ can be improved to an FPT-result (as this has been the case for DIAM-CLUSTER-COMPLETION), and whether it is possible to obtain an FPT-algorithm either for parameter k or $k + \lambda(M)$. As a first step in this direction, we present an FPT-approximation scheme for parameter $r + \lambda(M)$ in Section 4.3. The following observation will be useful:

► **Observation 14.** Given a (complete) vector $\vec{s} \in \{0, 1\}^d$, in time $\mathcal{O}(|M|d)$ we can decide if \vec{s} is the center of a RAD-CLUSTER of k vectors in M .

Observation 14 is straightforward since we can find all vectors $\vec{w} \in M$ that can be completed to a vector \vec{w}^* at distance at most r from \vec{s} by letting $\vec{w}^*[i] = \vec{s}[i]$ wherever $\vec{w}^*[i] = \square$, and then decide whether \vec{w}^* is such a vector by computing $\delta(\vec{w}^*, \vec{s})$.

4.1 RAD-CLUSTER-COMPLETION Parameterized by $k + r + \lambda(M)$

We start by showing that, as in the case of DIAM-CLUSTER-COMPLETION, RAD-CLUSTER-COMPLETION parameterized by $k + r + \lambda(M)$ has a Turing kernel. The approach is similar to that in Subsection 3.1.

► **Theorem 15.** RAD-CLUSTER-COMPLETION parameterized by $k + r + \lambda(M)$ has a Turing-kernel containing at most $n = k3^{\lambda(M)+2r} + \lambda(M) + 2$ vectors, each having at most $\max\{2r(n-1) + \lambda(M), \binom{\lambda(M)}{2}(2r+1)\}$ coordinates.

4.2 RAD-CLUSTER-COMPLETION Parameterized by $r + \lambda(M)$

While, it is relatively easy to see that RAD-CLUSTER-COMPLETION parameterized by $r + \lambda(M)$ can be solved in time $f(\lambda(M), r)n^{\mathcal{O}(r)}$, here we provide a more efficient algorithm by reducing the degree of the polynomial in the run-time from $\mathcal{O}(r)$ to $\log r$. Moreover, our algorithm can be applied to the CLOSEST STRING WITH OUTLIERS problem [3].

► **Theorem 16.** RAD-CLUSTER-COMPLETION can be solved in time $\mathcal{O}(|M|2^{\lambda(M)}(|M|(2^{2r} + d))^{\log r + 1})$ and is therefore in XP parameterized $r + \lambda(M)$.

Proof Sketch. The main ideas behind the algorithm are captured by the following definition and discussions. Let $F \subseteq [d]$ and let t be an integer, where $0 \leq t \leq r$. We say that a vector $\vec{v} \in \{0, 1\}^d$ is an (F, t) -seed for a center $\vec{c} \in \{0, 1\}^d$ of a solution for (M, k, r) if it satisfies:

- (C1) \vec{c} agrees with \vec{v} on all coordinates in F ; and
 (C2) \vec{c} differs from \vec{v} on at most t coordinates outside of F .

We can show the following statement. If \vec{v} is an (F, t) -seed for \vec{c} , then either \vec{v} is the center of a solution for (M, k, r) , or there is a vector $\vec{m} \in M$ with $r < \delta(\vec{v}, \vec{m}) \leq 2r$ and a subset $C \subset D \setminus F$, where $D = \Delta(\vec{v}, \vec{m})$, such that the vector \vec{v}' obtained from \vec{v} by complementing all coordinates in C is an $(F \cup D, t/2)$ -seed for \vec{c} . Note that testing the former possibility, that is, whether a vector $\vec{v} \in \{0, 1\}^d$ is a center of a solution for (M, k, r) , can be done in time $\mathcal{O}(|M|d)$ by Observation 14.

Since there are at most $M2^{2r}$ possibilities for \vec{m} and C , we can use the above statement to obtain a $(F \cup D, t/2)$ -seed from a given (F, t) -seed. This can be employed within a recursive procedure that, given a (\emptyset, r) -seed for some center \vec{c} of a solution either obtains a center of a solution or obtains a $(F', 0)$ -seed (which itself is the center of a solution), in at most $\log r$ recursive steps. It only remains to find a (\emptyset, r) -seed for some center \vec{c} of a solution, which can be achieved by guessing the completion \vec{v} of any vector in $M \setminus D_M$ that will be in a solution. Note that if $M \setminus D_M$ does not contain a vector in the solution, then $k \leq \lambda(M)$ and the result follows from Theorem 15. \blacktriangleleft

We note that the algorithm provided by the above theorem generalizes a previous algorithm of Marx [26, Lemma 3.2] for CLOSEST SUBSTRING to strings that may contain unknown characters. In particular, it lifts the concept of “generators” to strings with unknown characters by showing that there are $\log r$ vectors that can be computed efficiently and that define at most $r \log r$ “important” coordinates for the center of some solution.

4.3 FPT Approximation Scheme Parameterized by $r + \lambda(M)$

In this subsection we give an algorithm that, for a given instance (M, k, r) of RAD-CLUSTER-COMPLETION and $\varepsilon \in \mathbb{R}$, where $0 < \varepsilon < 1$, computes in FPT-time parameterized by $r + \lambda(M) + \frac{1}{\varepsilon}$ a center of a RAD-cluster of size at least $(1 - \varepsilon)k$, or it correctly concludes that no RAD-Cluster of size k exists.

► **Theorem 17.** *Given an instance (M, k, r) of RAD-CLUSTER-COMPLETION and $\varepsilon \in \mathbb{R}$, where $0 < \varepsilon < 1$, there exists an FPT algorithm \mathcal{A} , parameterized by $r + \lambda(M) + \frac{1}{\varepsilon}$, such that \mathcal{A} either computes a RAD-Cluster of size at least $(1 - \varepsilon)k$, or correctly concludes that M does not contain a RAD-Cluster of size k .*

Proof Sketch. The algorithm starts by performing a similar branching and pre-processing to the FPT algorithm for DIAM-CLUSTER-COMPLETION parameterized by $r + \lambda(M)$. Fix M^* to be a completion of M that contains a maximum size RAD-Cluster, let P^* be such a maximum size RAD-Cluster in M^* , and let \vec{s}^* be a center of P^* . The goal of the algorithm is to find \vec{s}^* , as given \vec{s}^* , by Observation 14, we can decide the instance in time $\mathcal{O}(|M|d)$.

If $k < \frac{2\lambda(M)}{\varepsilon} + 2$, then we use the algorithm in Theorem 15 to obtain a Turing kernel. Otherwise, we can guess two vectors \vec{u} and \vec{v} in $M \setminus D_M$, together with their respective completions \vec{u}^* and \vec{v}^* , such that \vec{u}^* and \vec{v}^* are the farthest vectors apart in $P^* \setminus D_M$; fix $r_{\max} = \delta(\vec{v}^*, \vec{u}^*)$. We normalize all the vectors in M so that \vec{v}^* becomes the all-zero vector. Finally, for each vector $\vec{w} \in M$, we can in time $r_{\max} \cdot d$, where d is the dimension of the vectors in M , check if there is a completion \vec{w}^* of \vec{w} such that the distance from \vec{w}^* to both \vec{v}^* and \vec{u}^* is at most r_{\max} ; we remove all vectors \vec{w} that do not have such a completion. Note here that some vectors in $P^* \cap D_M$ could have been removed from M at this step. However, we did not remove any vector from $P^* \setminus D_M$. Hence, after the preprocessing, M contains a RAD-Cluster with center \vec{s}^* and at least $k' = (1 - \frac{\varepsilon}{2})k$ vectors. Our goal is to

find a center for a RAD-Cluster with at least $(1 - \frac{\varepsilon}{2})k' = (1 - \frac{\varepsilon}{2})^2 k \geq (1 - \varepsilon)k$ vectors. For ease of exposition, we let $\varepsilon' = \frac{\varepsilon}{2}$ and we let $k' \geq (1 - \varepsilon')k$ be the number of vectors of P^* still in M . Now we can show the following statement: After the above pre-processing, in time $\mathcal{O}(2^{r_{\max}} \cdot |M|)$, we can find a center for a RAD-Cluster of size $\frac{|M|}{2^{r_{\max}}}$.

Therefore, we can assume henceforth that $k' \geq \frac{|M|}{2^{r_{\max}}}$. Now the algorithm sets $\vec{s}_0^* = \vec{v}^* = \vec{0}$ and the goal is to iteratively compute $\vec{s}_1^*, \vec{s}_2^*, \vec{s}_3^*, \dots, \vec{s}_{r'}^*$, $r' \leq r$, such that:

1. for all $i \in [r']$, we have $\Delta(\vec{s}_i^*) = \Delta(\vec{s}_{i-1}^*) \cup \{c_i\}$ for some coordinate $c_i \in \Delta(\vec{s}^*) \setminus \Delta(\vec{s}_{i-1}^*)$;
2. for all $j \in [r' - 1]$, the number of vectors \vec{w} with $\delta(\vec{w}, \vec{s}_j^*) \leq r$ is less than $(1 - \varepsilon')k'$; and
3. the number of vectors \vec{w} with $\delta(\vec{w}, \vec{s}_{r'}^*) \leq r$ is at least $(1 - \varepsilon')k'$.

Let \vec{s}_i^* be such that $\Delta(\vec{s}_i^*) \subseteq \Delta(\vec{s}^*)$ for some $i \in [r' - 1]$. The number of vectors at distance at most r from \vec{s}_i^* , $i < r'$, is less than $(1 - \varepsilon')k'$. This means that at least $\varepsilon'k' \geq \frac{\varepsilon'|M|}{2^{r_{\max}}}$ vectors whose completions are in P^* are at distance at least $r + 1$ from \vec{s}_i^* . For every such vector \vec{w} , it is easy to see that, since $\Delta(\vec{s}_i^*) \subseteq \Delta(\vec{s}^*)$, it must be the case that $(\Delta(\vec{s}^*) \cap \Delta(\vec{w})) \setminus \Delta(\vec{s}_i^*)$ is nonempty. Note that $|\Delta(\vec{s}^*)| \leq r$, and hence there exists $c_{i+1} \in \Delta(\vec{s}^*)$ such that, for at least $\frac{\varepsilon'|M|}{2^{r_{\max} \cdot r}}$ vectors \vec{w} in M at distance at least $r + 1$ from \vec{s}_i^* , it holds that $c_{i+1} \in \Delta(\vec{w})$. Moreover, for every vector $\vec{w} \in M$, we have $|\Delta(\vec{w})| \leq r_{\max}$. It follows—by a straightforward counting argument—that there are at most $\frac{2^{r_{\max} \cdot r}}{\varepsilon} \cdot r_{\max}$ coordinates $c \in [d]$ such that, for at least $\frac{\varepsilon'|M|}{2^{r_{\max} \cdot r}}$ vectors \vec{w} , it holds that $c \in \Delta(\vec{w})$. Therefore, to obtain \vec{s}_{i+1}^* such that $\Delta(\vec{s}_{i+1}^*) \subseteq \Delta(\vec{s}^*)$, we only need to branch on one of at most $\frac{2^{r_{\max} \cdot r}}{\varepsilon} \cdot r_{\max}$ coordinates. The statement of the theorem follows since we can exhaustively branch on the coordinates that are set to 1 in at least $\frac{\varepsilon'|M|}{2^{r_{\max} \cdot r}}$ many vectors in M , until either the number of vectors at distance at most r from \vec{s}_i^* is at least $(1 - \varepsilon')k'$ or $i \geq r$. ◀

5 Concluding Remarks

We studied the parameterized complexity of two fundamental problems pertaining to incomplete data that have applications in data analytics. In most cases, we were able to provide a complete landscape of the parameterized complexity of the problems w.r.t. the parameters under consideration. It is worth noting that all algorithmic upper bounds obtained in this paper can also be directly generalized to vectors (i.e., matrices) over a domain whose size is bounded by the parameter value by using the encoding described by Eiben et al. [9].

Two important open questions ensue from our work, namely determining the parameterized complexity of RAD-CLUSTER-COMPLETION w.r.t. each of the two parameterizations $k + \lambda$ and $r + \lambda$. In particular, the restrictions of these two problems to complete data (i.e., $\lambda = 0$) remain open, resulting in two important questions about the parameterized complexity of RAD-CLUSTER parameterized by the cluster size k or the cluster radius r .

Lyndon Arrays Simplified

Jonas Ellert  

Department of Computer Science, Technische Universität Dortmund, Germany

Abstract

A Lyndon word is a string that is lexicographically smaller than all of its proper suffixes (e.g., **airbus** is a Lyndon word; **amtrak** is not a Lyndon word because its suffix **ak** is lexicographically smaller than **amtrak**). The Lyndon array (sometimes called Lyndon table) identifies the longest Lyndon prefix of each suffix of a string. It is well known that the Lyndon array of a length- n string can be computed in $\mathcal{O}(n)$ time. However, most of the existing algorithms require the suffix array, which has theoretical and practical disadvantages. The only known algorithms that compute the Lyndon array in $\mathcal{O}(n)$ time without the suffix array (or similar data structures) do so in a particularly space efficient way (Bille et al., ICALP 2020), or in an online manner (Badkobeh et al., CPM 2022). Due to the additional goals of space efficiency and online computation, these algorithms are complicated in technical detail. Using the main ideas of the aforementioned algorithms, we provide a simpler and easier to understand algorithm that computes the Lyndon array in $\mathcal{O}(n)$ time.

1 Related Work

A Lyndon word is a string that is lexicographically smaller than all of its proper suffixes (e.g., **airbus** is a Lyndon word; **amtrak** is not a Lyndon word because its suffix **ak** is lexicographically smaller than **amtrak**). The Lyndon array (sometimes called Lyndon table) identifies the longest Lyndon prefix of each suffix of a string (a precise definition follows later). It has both theoretical and practical applications related to repetitiveness in strings. Most notably, it is a crucial component for showing that a length- n string contains less than n maximal repetitions (the “Runs” theorem by Bannai et al. [3]), and it is useful for computing all of these maximal repetitions in optimal time [8]. Other applications of the Lyndon array include text compression and indexing [16].

There is a close relation [12] between the Lyndon array and the suffix array (one of the most fundamental data structures in string algorithmics [15]). This inspired research focused on computing the Lyndon array from the suffix array [9], computing both arrays simultaneously [2, 13], and also using properties of the Lyndon array to compute the suffix array [2, 4]. One of the conceptually simplest methods for computing the Lyndon array combines the (inverse) suffix array with a folklore algorithm for the computation of nearest smaller values [9, Algorithm ISA-NSV] (we will discuss this algorithm in Section 4).

However, using the suffix array is both a theoretical and practical drawback. From a theoretical point of view, computing the suffix array of a length- n string over a general ordered alphabet takes $\Omega(n \lg n)$ time. This is due to the well-known information-theoretic lower bound on the number of comparisons for sorting. We can only compute the suffix array in optimal $\mathcal{O}(n)$ time, if the alphabet can be sorted in $\mathcal{O}(n)$ time (e.g., a polynomial integer alphabet $\Sigma = \{1, \dots, n^{\mathcal{O}(1)}\}$ on a word RAM of width $w \geq \log_2 n$). This is not a concern

in practice, where this requirement is virtually always met. Nevertheless, even the fastest algorithms for the suffix array are relatively slow in practice, and the computation appears to be somewhat excessive for the seemingly simpler task of computing the Lyndon array.

There are two known algorithms that compute the Lyndon array by mere symbol comparisons, without using the suffix array, and in optimal $\mathcal{O}(n)$ time. The first one [5] computes the Lyndon array using only $\mathcal{O}(1)$ words of additional working space, or the succinct $2n$ -bit version of the Lyndon array using only $o(n)$ bits of additional working space. The second one [1] is an online algorithm that computes the Lyndon array from right to left. The technical details of these algorithms are rather intricate, and many of the used techniques are only needed due to the goals of space efficiency and online computation.

Contributions. We present a simple $\mathcal{O}(n)$ time and space algorithm that computes the Lyndon array of a length- n string in the comparison model (i.e., the only elementary operations allowed on symbols of the string are comparisons of the form less-greater-equal). It requires no precomputed data structures (like the suffix array), and works by exploiting the powerful combinatorial properties of Lyndon words. Many of the used techniques are simpler versions of what was done in [5, 1]. The final trick used to achieve linear time is similar to Manacher’s classic algorithm for longest palindromic substrings [14].

The proof of correctness is still rather technical, but the resulting algorithm is incredibly easy to implement. The provided C++ implementation consists of not even 50 lines of code, and uses neither external nor standard libraries.

2 Preliminaries

We use the interval notations $[i, j] = [i, j + 1) = (i - 1, j] = (i - 1, j + 1)$ to denote the integer set $\{i, i + 1, \dots, j\}$ (or \emptyset if $i > j$). A *string* $x = x[1..n]$ over an *ordered alphabet* Σ is a sequence $x = x[1]x[2] \cdots x[n]$ of *symbols* drawn from some totally ordered set Σ . We write $|x| = n$ to denote the length of the string. The set Σ^* contains all strings over Σ , including the *empty string* ϵ of length 0. The concatenation of two strings $x[1..n]$ and $y[1..m]$ is the sequence $x[1] \dots x[n]y[1] \dots y[m]$, and simply written as xy (or $x \cdot y$). The total order of symbols from Σ induces the *lexicographical order* of strings from Σ^* . We say that x is *lexicographically smaller* than y and write $x \prec y$, if and only if either $y = xw$ for some non-empty string w , or $x = urv$ and $y = usw$ for (possibly empty) strings u, v, w and symbols $r < s$. We write $x \preceq y$ to denote $x = y \vee x \prec y$.

For $i, j \in [1, n]$ with $i \leq j$, the *substring* $x[i..j] = x[i..j + 1) = x(i - 1..j] = x(i - 1..j + 1)$ of $x[1..n]$ is the sequence $x[i]x[i + 1] \cdots x[j]$. If $i > j$, then $x[i..j]$ equals the *empty string* denoted by ϵ . If $x[i..j] \neq \epsilon$ then $x[i..j]$ is a *proper* substring. A substring of the form $x[1..j]$ is called *prefix* of x , while $x[i..n]$ is called *suffix* of x . We use the simplified notation $x_i = x[i..n]$ for the suffix starting at position i . The *longest common extension (LCE)* of two suffixes x_i and x_j is defined as the length of the longest common prefix of the suffixes, formally $\text{LCE}(i, j) = \max\{|u| \mid u, v, w \in \Sigma^* \wedge x_i = uv \wedge x_j = uw\}$.

Sentinel Symbols. Throughout this work, we often compare two suffixes x_i, x_j of the same string $x[1..n]$. The special case where one suffix is a prefix of another, e.g., $i < j$ and $x_i = x_jx_{i+|x_j|}$, often complicates the notation of definitions and algorithms. This can be avoided by assuming that the text starts and ends with special *sentinel symbols* $x[1] = \#$ and $x[n] = \$$. The sentinels are smaller than all other symbols, i.e., $\forall k \in (1, n) : x[k] > \$ > \#$. In definitions and lemmas we emphasize the presence of sentinels by writing $x = x[1..n] = \#x(1..n)\$$. (Note

that n is the length of the string *including* the sentinels.) The usage of sentinels is of purely cosmetic nature. Particularly, they do not affect the lexicographical order of suffixes, i.e., it holds $x[i..n]\$ \prec x[j..n]\$$ if and only if $x[i..n] \prec x[j..n]$. In practice, we can add sentinels to any string by either physically prepending and appending them, or by using an appropriate wrapper function¹ when accessing the string.

Lyndon Words and Arrays

There are multiple equivalent definitions of Lyndon words. We use Duval's characterization based on the lexicographical order of suffixes:

► **Definition 1** ([7, Proposition 1.2]). *A string $x[1..n]$ is a Lyndon word, if and only if it is lexicographically smaller than all of its proper non-empty suffixes, i.e., $\forall i \in [2, n] : x \prec x_i$.*

The Lyndon array of a string and its close relatives, the nearest smaller suffix arrays, capture the combinatorial structure of Lyndon substrings. We denote the Lyndon array by λ , which was also done in [5, 9]. Other notations are *Lynd* in [6, 1], l in [3], and \mathcal{L} in [10, 11].

► **Definition 2.** *The Lyndon array $\lambda[1..n]$, the previous smaller suffix array $\text{prev}[1..n]$, and the next smaller suffix array $\text{next}[1..n]$ of a string $x = \#x(1..n)\$$ are defined as:*

- (i) $\forall i \in [1, n] : \lambda[i] = \max\{m \mid m \in [1, n - i + 1] \wedge x[i..i + m] \text{ is a Lyndon word}\}$,
i.e., $x[i..i + \lambda[i]]$ is the longest Lyndon prefix of suffix x_i
- (ii) $\forall i \in (1, n) : \text{prev}[i] = \max\{j \mid j \in [1, i) \wedge x_j \prec x_i\}$, $\text{prev}[1] = 0$, $\text{prev}[n] = 1$,
i.e., $x_{\text{prev}[i]}$ is the nearest suffix starting left of i that is lex. smaller than x_i
- (iii) $\forall i \in (1, n) : \text{next}[i] = \min\{j \mid j \in (i, n] \wedge x_j \prec x_i\}$, $\text{next}[1] = n + 1$, $\text{next}[n] = n + 1$,
i.e., $x_{\text{next}[i]}$ is the nearest suffix starting right of i that is lex. smaller than x_i

Figure 1a shows an example of these arrays. In drawings, we use a directed edge from position i to position j of a string to indicate that either $\text{prev}[i] = j$ (whenever the edge is directed from right to left) or $\text{next}[i] = j$ (whenever the edge is directed from left to right). We refer to these edges as PSS and NSS edges. It is no coincidence that in the example it holds $\text{next}[i] = i + \lambda[i]$ for all i . In fact, this is a fundamental combinatorial property of the Lyndon array, which was first (indirectly in a different form) shown by Hohlweg and Reutenauer [12]. Subsequently, Franek et al. [9, Lemma 15] and Franek and Liut [11, Lemma 1]² proved the property in the form stated below.

► **Lemma 3** ([12, 9, 11]). *Let $x = \#x(1..n)\$$ be a string with Lyndon array λ and next smaller suffix array next , then it holds $\forall i \in [1, n] : \text{next}[i] = i + \lambda[i]$.*

Another property shown by Bille et al. [5] relates prev and Lyndon words:

► **Lemma 4** ([5, Lemma 4]). *Let $x = \#x(1..n)\$$ be a string with previous smaller suffix array prev . For every $i \in [2, n]$, the string $x[\text{prev}[i]..i]$ is a Lyndon word.*

² Lemma 1 (b) in [11] should state “ $x[i..j]$ is proto-Lyndon” rather than “ $x[i..n]$ is proto-Lyndon”

3 Key Properties of Nearest Smaller Suffixes

(a) Example of arrays λ , next and prev.

(b) Drawing for Lemma 5.

(c) Drawing for Lemma 6.

(d) Drawing for Lemma 7(ii).

(e) Drawing for Lemma 7(iii).

Figure 1 Examples and technical drawings for Sections 2 and 3. PSS edges are solid and red. NSS edges are dashed and blue. Dotted black edges are either NSS or PSS edges.

In this section, we show combinatorial properties of prev and next that are essential for all algorithms presented in this paper. Some of the properties have been shown (in a similar form) in [5, 1]. Proving Lemmas 5–7 is helpful for truly understanding the mechanisms at play. The reader is encouraged to do so on their own, with the help of the provided supplementary drawings. The full proofs are given in Section 7.

Naming of variables. Throughout the remainder of the paper, we use the variables ℓ and r to denote positions of the string. The intended meaning of these variables is *left* and *right*, i.e., whenever we use ℓ and r it holds $\ell < r$.

PSS and NSS edges are intersection-free. The first property that we show is that, when drawn underneath the text as in the previous example, none of the PSS and NSS edges intersect. This is formally expressed by the following lemma (see also Figure 1b).

► **Lemma 5.** *Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix array prev and next . Let $\ell_1, \ell_2, r_1, r_2 \in [1, n]$ be indices with either $\text{next}[\ell_1] = r_1$ or $\text{prev}[r_1] = \ell_1$, and also either $\text{next}[\ell_2] = r_2$ or $\text{prev}[r_2] = \ell_2$. Then it does not hold $\ell_1 < \ell_2 < r_1 < r_2$.*

Chains of previous smaller suffixes. For arbitrary index $r \in [1, n]$ and integer $e \geq 0$, we recursively define $\text{prev}^0[r] = r$ and $\text{prev}^{e+1}[r] = \text{prev}^e[\text{prev}[r]]$. We write $\ell = \text{prev}^*[r]$ to denote that there is some integer $e \geq 0$ with $\ell = \text{prev}^e[r]$. Note that generally $1 = \text{prev}^*[r]$ (due to the sentinel $x[1] = \#$) and $r = \text{prev}^*[r]$. In drawings, $\ell = \text{prev}^e[r]$ means that there is a chain of PSS edges from r to ℓ . The following lemma states useful properties of PSS chains, which we will later use to compute the arrays `prev` and `next`. The lemma is visualized in Figure 1c.

► **Lemma 6.** *Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix arrays `prev` and `next`, and let $\ell, r \in [1, n]$ be arbitrary indices.*

- (i) *It holds $\text{prev}[r] = \text{prev}^*[r - 1]$.*
- (ii) *It holds $\text{next}[\ell] = r$ if and only if $\ell = \text{prev}^*[r - 1]$ and $\ell > \text{prev}[r]$.*

Finally, for some indices that are related via `next` and `prev`, we can deduce LCEs. The following lemma is visualized in Figures 1d and 1e.

► **Lemma 7.** *Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix arrays `prev` and `next`. Let $k \in (1, n)$ be an arbitrary index, and let $\ell = \text{prev}[k]$ and $r = \text{next}[k]$.*

- (i) *If $\text{LCE}(\ell, k) = \text{LCE}(k, r)$, then $\text{LCE}(\ell, r) \geq \text{LCE}(k, r)$ and either $\text{prev}[r] = \ell$ or $\text{next}[\ell] = r$.*
- (ii) *If $\text{LCE}(\ell, k) < \text{LCE}(k, r)$, then $\text{LCE}(\ell, r) = \text{LCE}(\ell, k)$ and $\text{prev}[r] = \ell$.*
- (iii) *If $\text{LCE}(\ell, k) > \text{LCE}(k, r)$, then $\text{LCE}(\ell, r) = \text{LCE}(k, r)$ and $\text{next}[\ell] = r$.*

4 Algorithms to Compute the Lyndon Array

Due to Lemma 3, instead of designing algorithms that compute the Lyndon array λ , we can design algorithms that compute the next smaller suffix array `next`. This has been done, e.g., by Bille et al. [5] and Crochemore et al. [1], and is also the general approach used in this paper. All of the presented algorithms are based on a simple folklore algorithm for nearest smaller values, where instead of comparing values we lexicographically compare suffixes (Algorithm 1(a)). We obtain three different versions of this algorithm depending on how the lexicographical comparisons are implemented: Algorithm 1(b) uses the inverse suffix array and is only shown because it is a standard solution for computing the Lyndon array. Algorithm 1(c) implements lexicographical comparisons with naively computed LCEs. Algorithm 1(d) refines the LCE computation such that it is more time efficient. In the remainder of this section, we explain each version of the algorithm in detail.

Algorithms 1(c) and 1(d) require super-linear time, but they can be seen as incremental stepping stones towards the final solution. In Section 5, we modify Algorithm 1(d) such that it runs in $\mathcal{O}(n)$ time.

Algorithm 1: The general approach. Due to the sentinels, we can directly assign `prev[1]`, `next[1]`, and `next[n]` (lines 1–2). We compute the arrays `next` and `prev` in $n - 1$ iterations of a simple for-loop (line 4). The goal of iteration r is to compute `prev[r]`, while also identifying all indices ℓ with `next[ℓ] = r`. A simple strategy for this is dictated by Lemma 6, which states that all the relevant indices lie on the chain of PSS edges that starts at position $r - 1$. We thus inspect the positions $\ell = \text{prev}^*[r - 1]$ one at a time, starting with $\ell = r - 1$ (line 5). As long as $x_\ell \succ x_r$, we assign `next[ℓ] ← r`, and then continue with the next index $\ell \leftarrow \text{prev}[\ell]$ on the chain of PSS edges (lines 6–8). As soon as $x_\ell \prec x_r$, we break out of the inner loop and finish the current iteration of the outer loop by assigning `prev[r] ← ℓ` (line 9). (The sentinel $x[1] = \#$ ensures that $1 = \text{prev}^*[r]$ and $x_1 \prec x_r$; thus we are guaranteed to reach some ℓ with $x_\ell \prec x_r$ eventually.) The correctness of the algorithm follows directly from Lemma 6. An example of an outer loop iteration is provided in Figure 2 (the arrays `lexrank`, `plice`, and `nlice` will be relevant later and can be ignored for now).

■ **Algorithm 1** Various algorithms for computing nearest smaller suffixes.

Require: string $x = x[1..n] = \#x(i..n)\$$

Ensure: previous and next smaller suffix arrays `prev` and `next`

- 1: `prev[1..n]` \leftarrow new array with `prev[1] = 0`
- 2: `next[1..n]` \leftarrow new array with `next[1] = next[n] = n + 1`

  return LCE-EXTEND(ℓ, r, 0)

```

to achieve $\mathcal{O}(n)$ time, substitute:
 line 7: $m \leftarrow \text{SMART-LCE}(\ell, r, 0)$
 line 11: $m \leftarrow \text{SMART-LCE}(\text{prev}[\ell], r, m)$
 (see Algorithm 2)

■ **Figure 2** For any of the Algorithms 1(a)–(d), we perform six suffix comparisons in outer loop iteration $r = 22$. We evaluate $x_\ell \succ x_r$ for each of the values $\ell = 21, 20, 17, 12, 5, 2$ (precisely in this order). For the first five values $\ell = 21, 20, 17, 12, 5$, we enter the body of the inner loop and thus assign $\text{next}[\ell] \leftarrow 22$. We break out of the inner loop by discovering that $x_2 \prec x_{22}$, after which we assign $\text{prev}[22] \leftarrow 2$. By design of the algorithm, and following Lemma 6, the values assumed by ℓ form a consecutive chain of PSS edges starting at position $r - 1 = 21$ (dashed edges).

Whenever we perform the lexicographical comparison of suffixes in line 6, we correctly assign either $\text{next}[\ell] \leftarrow r$ or $\text{prev}[r] \leftarrow \ell$ immediately afterwards. Since each entry of prev and next gets assigned exactly once, we perform exactly $2n - 3$ suffix comparisons; we enter the body of the inner loop exactly $n - 2$ times (once per entry of next , but not for $\text{next}[1] = \text{next}[n] = n + 1$), and break out of the inner loop exactly $n - 1$ times (once per outer loop iteration, or equivalently once per entry of prev , but not for $\text{prev}[1] = 0$). It follows that the algorithm takes $\mathcal{O}(n)$ time, plus the time needed to perform the suffix comparisons. Next, we discuss three possible implementations of these comparisons.

Algorithm 1(b): Using the inverse suffix array. The inverse suffix array $\text{lexrank}[1..n]$ of $x[1..n]$ is the unique permutation of $[1, n]$ that satisfies $\forall \ell, r \in [1, n] : x_\ell \prec x_r \iff \text{lexrank}[\ell] < \text{lexrank}[r]$ (an example is provided in Figure 2). Algorithm 1(b) precomputes the inverse suffix array, and then uses it to perform the lexicographical suffix comparisons. This idea was first proposed by Franek et al. [9, Algorithm NSVISA]. As discussed in Section 1, the precomputation takes $\mathcal{O}(n \lg n)$ time for general ordered alphabets, or $\mathcal{O}(n)$ time for linearly-sortable alphabets. The remainder of the algorithm takes $\mathcal{O}(n)$ time because we perform $\mathcal{O}(n)$ suffix comparisons, each of which takes constant time when using lexrank .

Algorithm 1(c): Using LCEs with simple scanning. If $\ell \neq r$ and $x[n] = \$$, then it holds $x_\ell \prec x_r \iff x[\ell + \text{LCE}(\ell, r)] < x[r + \text{LCE}(\ell, r)]$ (both of the conditions are satisfied for the comparisons performed by our algorithms). The LCE can be computed by simple scanning, as shown in Algorithm 1(e). Due to the sentinel $x[n] = \$$, no suffix is prefix of another suffix, and we always find a mismatching symbol eventually. Algorithm 1(c) implements the lexicographical suffix comparisons with LCEs (lines 7, 8, and 10). Additionally, it stores the computed LCEs in two arrays nlice and plice (lines 3–4, 9, and 15), where after termination it holds $\text{plice}[i] = \text{LCE}(\text{prev}[i], i)$ and $\text{nlice}[i] = \text{LCE}(i, \text{next}[i])$ for all $i \in (1, n)$. These arrays are of independent interest. For example, nlice is useful when computing maximal repetitions [8].

Computing some $\text{LCE}(\ell, r)$ by scanning takes $\text{LCE}(\ell, r) + 1$ symbol comparisons: $\text{LCE}(\ell, r)$ comparisons with outcome “equal”, and one comparison with outcome “not equal”. For the example iteration in Figure 2, we compute $\text{LCE}(21, 22) = 0$, $\text{LCE}(20, 22) = 1$, $\text{LCE}(17, 22) = 2$,

$\text{LCE}(12, 22) = 2$, $\text{LCE}(5, 22) = 6$ and $\text{LCE}(17, 22) = 2$, and thus we perform 19 symbol comparisons. In the worst case, a single LCE scan takes $\mathcal{O}(n)$ time, and thus Algorithm 1(c) takes $\mathcal{O}(n^2)$ time (the bound is tight, e.g., for the string $x = \#a^{n-2}\$$). If the string x is drawn uniformly at random from the set of length- n strings over Σ , where $|\Sigma| > 1$, then the expected running time of Algorithm 1(c) is $\mathcal{O}(n)$ (see [1, Theorem 7]).

Algorithm 1(d): Using LCEs with improved scanning. In a single outer loop iteration r of Algorithm 1(c), we may compute $\text{LCE}(\ell, r)$ for multiple different values of ℓ . So far, we always scanned each new LCE entirely from scratch (line 10). For many of the LCEs, we can avoid (a part of) the scan by utilizing Lemma 7. This is done in Algorithm 1(d), which is identical to Algorithm 1(c), except for the highlighted computation of the LCE in lines 10–13. At the point in time at which we reach line 10, let $k' = \ell$, $\ell' = \text{prev}[\ell]$, and $r' = r$. Note that $\ell' = \text{prev}[k']$ and $r' = \text{next}[k']$, and thus we can use ℓ' , k' , and r' to invoke Lemma 7. We already computed $\text{LCE}(\ell', k') = \text{plce}[k']$ (due to the iteration order of the algorithm) and $\text{LCE}(k', r') = \text{nlce}[k'] = m$ (this is the most recently computed LCE). Now we compute $\text{LCE}(\ell', r')$ according to the cases of Lemma 7:

- If $\text{LCE}(\ell', k') = \text{LCE}(k', r')$ then Lemma 7(i) implies $\text{LCE}(\ell', r') \geq \text{LCE}(k', r')$. We compute $\text{LCE}(\ell', r')$ by scanning, but we skip $m = \text{LCE}(k', r')$ symbol comparisons (lines 10–11).
- If $\text{LCE}(\ell', k') < \text{LCE}(k', r')$ then Lemma 7(ii) implies $\text{LCE}(\ell', r') = \text{LCE}(\ell', k')$. Since $\text{plce}[k'] = \text{LCE}(\ell', k')$, we can simply assign $m \leftarrow \text{plce}[k']$ (lines 12–13). Note that Lemma 7(ii) also implies $\text{prev}[r'] = \ell'$, which means that we will immediately break out of the inner loop and finish the current iteration of the outer loop.
- If $\text{LCE}(\ell', k') > \text{LCE}(k', r')$ then Lemma 7(iii) implies $\text{LCE}(\ell', r') = \text{LCE}(k', r')$. It already holds $m = \text{LCE}(k', r')$, and thus there is no need to do anything.

For the example iteration in Figure 2, we entirely skip the computation of $\text{LCE}(12, 22)$ due to Lemma 7(iii), as well as the computation of $\text{LCE}(2, 22)$ due to Lemma 7(ii). Additionally, we skip two symbol comparisons when computing $\text{LCE}(5, 22)$, and one symbol comparison when computing $\text{LCE}(17, 22)$. The number of symbol comparisons for iteration 22 is 10 (significantly less than the 19 comparisons needed by Algorithm 1(c)). However, Algorithm 1(d) still takes $\mathcal{O}(n^2)$ time in the worst case. In the next section, we slightly modify the algorithm such that it achieves linear time.

A note on the space complexity. Algorithms 1(c) and 1(d) require $4n \lceil \log_2 n \rceil$ bits to store the arrays `next`, `prev`, `nlce` and `plce`. For a small practical improvement, it is possible to remove the array `prev`. This is because the only access to `prev`[ℓ] occurs at the same time at which we assign `next`[ℓ] (see lines 9 and 14). Thus, we only need to maintain access to the values `prev`[ℓ] for positions with uninitialized `next`[ℓ], which means that we can use a single array for storing both PSS and NSS information. The total working space (without the input string) then becomes $3n \lceil \log_2 n \rceil + \mathcal{O}(\lg n)$ bits.

5 Achieving Linear Time

In order to achieve linear time, we use the function SMART-LCE (Algorithm 2) to more efficiently compute LCEs. A call to `SMART-LCE`(ℓ, r, m) means that we want to compute $\text{LCE}(\ell, r)$, and we have already established $\text{LCE}(\ell, r) \geq m$. We modify Algorithm 1(d) by replacing line 7 with $m \leftarrow \text{SMART-LCE}(\ell, r, 0)$, and line 11 with $m \leftarrow \text{SMART-LCE}(\text{prev}[\ell], r, m)$ (and leave everything else unchanged). In the remainder of the section, we show that SMART-LCE works correctly, and that the total time spent for all invocations of SMART-LCE is $\mathcal{O}(n)$. Then, it directly follows that the modified version of Algorithm 1(d) takes $\mathcal{O}(n)$ time. Note that Algorithm 2 is tailored to (and thus only works as a part of) Algorithm 1(d).

■ **Algorithm 2** Efficient LCE computation (only works in conjunction with Algorithm 1(d)).

Require: string $x = x[1..n] = \#x(i..n)\$$ with $x[\ell..r + m] = x[r..r + m]$.

Ensure: longest common extension $\text{LCE}(\ell, r)$

```

1: global variable  $c \leftarrow 0$ 
2: global variable  $d \leftarrow 0$ 
3: function SMART-LCE( $\ell, r, m$ )
4:   if  $r + m < c$  then
5:     if  $\text{next}[\ell - d] = r - d$  then  $m \leftarrow \text{nlce}[\ell - d]$ 
6:       else  $m \leftarrow \text{plce}[r - d]$ 
7:     if  $r + m < c$  then return  $m$ 
8:      $m \leftarrow c - r$ 
9:   while  $x[\ell + m] = x[r + m]$  do
10:     $m \leftarrow m + 1$ 
11:    $c, d \leftarrow r + m, r - \ell$ 
12:   return  $m$ 

```

In the following description, whenever we use the variables ℓ , r , and m , we mean the arguments of the function SMART-LCE (rather than the identically named variables from Algorithm 1(d)). Now we explain how the new LCE function works. Generally speaking, it computes LCEs with two different methods: naive scanning (as done before), and deduction from previously computed LCEs. Sometimes, a combination of both is necessary. Both methods rely on a global variable c (persistent between the function calls) that stores at all times the rightmost position of the string that we have already inspected (line 2).

Scanning LCEs. We start by explaining the simpler method of naive scanning. If at the beginning of the function call it holds $r + m \geq c$ (line 4), then we simply scan the remainder of the LCE (lines 9–10; identical to what we did in LCE-EXTEND). Let m' be the initial value of m before the scan, and let $m'' = \text{LCE}(\ell, r)$ be the final value of m after performing the scan. After the scan, the rightmost inspected position is $r + m''$, and we update c accordingly (line 11; the variable d is not relevant for now). Since we only perform the scan if $r + m' \geq c$, the assignment $c \leftarrow r + m''$ increases c by at least $m'' - m'$. Note that $m'' - m'$ is also exactly the number of times we execute line 10. Since c never exceeds n , we execute line 10 no more than n times during all the calls to SMART-LCE that initially satisfy $r + m \geq c$. It follows that, for all of these calls together, we spend at most $\mathcal{O}(n)$ time.

Deducing LCEs. If at the beginning of the function call it holds $r + m < c$, then we try to deduce $\text{LCE}(\ell, r)$ from previously computed LCEs (lines 4–8). Let r_c be the rightmost position for which we already computed some $\text{LCE}(\ell_c, r_c)$ with $r_c + \text{LCE}(\ell_c, r_c) = c$ (such a position must exist because otherwise we would not have inspected $x[c]$ yet). The global variable d contains at all times the distance $r_c - \ell_c$ (line 2; we update d together with c , see line 11). Let $\ell_* = \ell - d$ and $r_* = r - d$. The example in Figure 3 helps with understanding the notation. Later, we will show that (as suggested by the examples)

- (i) it holds $r_c \leq \ell < r < c$, and thus $\ell_c \leq \ell_* < r_* < \ell_c + \text{LCE}(\ell_c, r_c)$, and
- (ii) either $\text{prev}[r_*] = \ell_*$ (and thus $\text{plce}[r_*] = \text{LCE}(\ell_*, r_*)$)
or $\text{next}[\ell_*] = r_*$ (and thus $\text{nlce}[\ell_*] = \text{LCE}(\ell_*, r_*)$).

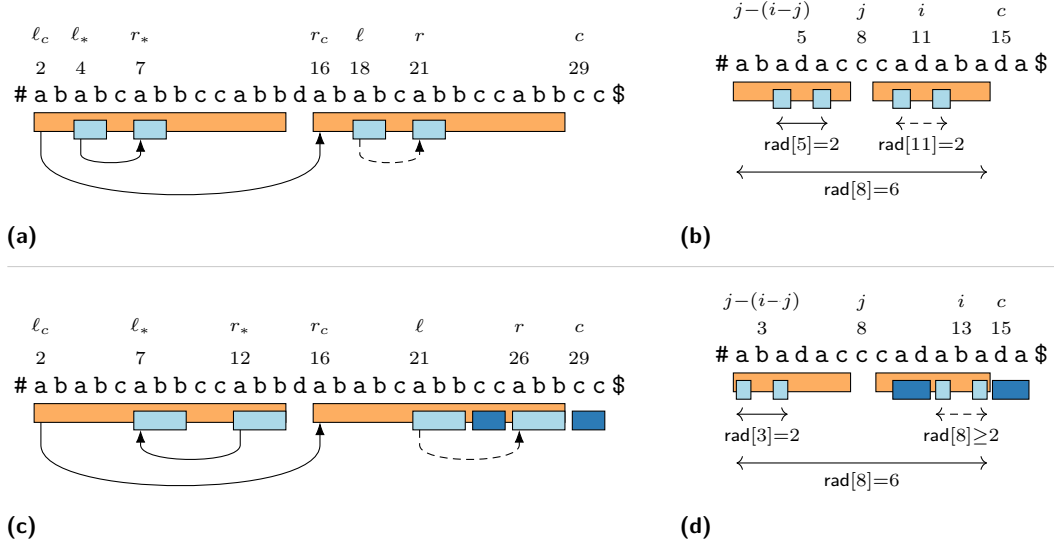

Figure 3 Deducing LCEs with Algorithm 2 in (a) and (c), and deducing longest palindromes with Manacher’s algorithm in (b) and (d). Boxes of equal color indicate equal substrings. In (b) and (d), boxes of equal color sometimes indicate substrings that are the reverse of each other.

When deducing LCEs, we first use (ii) to obtain $\text{LCE}(\ell_*, r_*)$ (lines 5–6). Note that, by the definition of ℓ_* and r_* , the relative positions of ℓ_* and r_* within $x[\ell_c.. \ell_c + \text{LCE}(\ell_c, r_c)]$ are the same as the relative positions of ℓ and r within $x[r_c.. r_c + \text{LCE}(\ell_c, r_c)]$ (and the positions are indeed within these intervals due to (i)). If $r + \text{LCE}(\ell_*, r_*) < c$ then

$$x[r..r + \text{LCE}(\ell_*, r_*)] = x[r_*..r_* + \text{LCE}(\ell_*, r_*)] \text{ and}$$

$$x[\ell..\ell + \text{LCE}(\ell_*, r_*)] = x[\ell_*..\ell_* + \text{LCE}(\ell_*, r_*)],$$

where both equalities follow from $x[\ell_c.. \ell_c + \text{LCE}(\ell_c, r_c)] = x[r_c.. r_c + \text{LCE}(\ell_c, r_c)]$. This implies $\text{LCE}(\ell, r) = \text{LCE}(\ell_*, r_*)$, and we return $\text{LCE}(\ell_*, r_*)$ in constant time (line 7). Since it holds $r + \text{LCE}(\ell, r) < c$, there is no need to update c and d . In Figure 3a, we have $21 + \text{LCE}(4, 7) = 23 < 29 = c$, and thus $\text{LCE}(18, 21) = \text{LCE}(4, 7) = 2$.

If, however, $r + \text{LCE}(\ell_*, r_*) \geq c$ then we cannot immediately deduce the exact value of $\text{LCE}(\ell, r)$ (as is the case in Figure 3c). We can still obtain some useful information because of

$$x[r..r + c - r] = x[r_*..r_* + c - r] = x[\ell_*..\ell_* + c - r] = x[\ell..\ell + c - r],$$

where the first and the third equality follow from $x[\ell_c.. \ell_c + \text{LCE}(\ell_c, r_c)] = x[r_c.. r_c + \text{LCE}(\ell_c, r_c)]$, and the second equality follows from $r + \text{LCE}(\ell_*, r_*) \geq c$, which is equal to $\text{LCE}(\ell_*, r_*) \geq c - r$. The equation implies $\text{LCE}(\ell, r) \geq c - r$, and we update m accordingly (line 8). In Figure 3c, we have $26 + \text{LCE}(7, 12) = 29 = c$, and thus $\text{LCE}(21, 26) \geq 29 - 26 = 3$.

We compute the remaining part of $\text{LCE}(\ell, r)$ by scanning (lines 9–10), and then update c and d (line 11). Since we assign $m \leftarrow (c - r)$ immediately before starting the scan, we can use the same argument as in the previous paragraph about scanning LCEs: For every symbol comparison of the scan (except for the last one), we will increase c by one. Therefore, the total number of symbol comparisons for all calls of SMART-LCE is $\mathcal{O}(n)$. In Figure 3c, the scan extends the LCE by two more positions, and we obtain $\text{LCE}(21, 26) = 5$. We then have to update $c \leftarrow 26 + 5 = 31$ and $d \leftarrow 26 - 21 = 5$.

The correctness of the algorithm follows from its description and the properties (i) and (ii), which we will show in the next paragraphs.

Showing Property (i). The property states that, if we call $\text{SMART-LCE}(\ell, r, m)$ with $r + m < c$, then $r_c \leq \ell < r < c$. Since trivially $\ell < r \leq r + m < c$, we only have to show $r_c \leq \ell$. The property is readily proven for the call $\text{SMART-LCE}(\ell, r, 0)$ in line 7 of Algorithm 1(d). It holds $\ell = r - 1$, and this is the first LCE that we compute between r and any smaller index. Since we already computed $\text{LCE}(\ell_c, r_c)$, it holds $r > r_c$ and $\ell = r - 1 \geq r_c$.

Now we consider the call $\text{SMART-LCE}(\ell, r, m)$ in line 11. As seen in the description of Algorithm 1(d), for this call it holds $m = \text{LCE}(\ell, k) = \text{LCE}(k, r)$, where $k \in (\ell, r)$ with $\text{prev}[k] = \ell$ and $\text{next}[k] = r$. For every $h \in (\ell, r)$, the definition of prev and next implies that $x_h \succeq x_k \succ x_r$. This also means that $m = \text{LCE}(k, r) \geq \text{LCE}(h, r)$. If $r = r_c$ then, because we already computed $\text{LCE}(\ell_c, r)$, and due to the iteration order of the algorithm, it holds $\ell < \ell_c$. Then, however, $\ell_c \in (\ell, r)$ and thus $m = \text{LCE}(k, r) \geq \text{LCE}(\ell_c, r) = c - r$, which contradicts $r + m < c$. We have shown that $r > r_c$, which also implies $r_* > \ell_c$. If $\ell < r_*$ then $r_* \in (\ell, r)$ and thus $m \geq \text{LCE}(r_*, r) = c - r$, which contradicts $r + m < c$. It follows that $\ell \geq r_* > \ell_c$. Finally, if $\ell \in (\ell_c, r_c)$ then $\ell_c < \ell < r_c < r$, which contradicts Lemma 5. The only remaining possibility is $\ell \geq r_c$, which is what we wanted to show.

Showing Property (ii). The property states that either $\text{prev}[r_*] = \ell_*$, or $\text{next}[\ell_*] = r_*$. By the definition of ℓ_* and r_* , and due to (i) and $x[\ell_c.. \ell_c + \text{LCE}(\ell_c, r_c)] = x[r_c..r_c + \text{LCE}(\ell_c, r_c)]$, it holds $x[\ell..r] = x[\ell_*..r_*]$. Since we want to compute $\text{LCE}(\ell, r)$, it holds either $\text{next}[\ell] = r$ or $\text{prev}[r] = \ell$. Therefore, either Lemma 3 or Lemma 4 implies that $x[\ell..r] = x[\ell_*..r_*]$ is a Lyndon word. Due to Lemma 3, we know that $\text{next}[\ell_*] \geq r_*$. If $\text{next}[\ell_*] = r_*$ or $\text{prev}[r_*] = \ell_*$, then there is nothing left to show. Thus, assume that $\text{next}[\ell_*] > r_*$ and $\text{prev}[r_*] > \ell_*$ (it cannot be that $\text{prev}[r_*] < \ell_*$ because then $\text{prev}[r_*] < \ell_* < r_* < \text{next}[\ell_*]$ contradicts Lemma 5). Let $p_r = r - (r_* - \text{prev}[r_*])$. Due to Lemma 4, the substring $x[\text{prev}[r_*]..r_*] = x[p_r..r]$ is a Lyndon word, and Lemma 3 implies $\text{next}[p_r] \geq r$. Since $p_r \in (\ell, r)$ it holds $\text{next}[p_r] \leq r$ (otherwise we contradict Lemma 5), and the only possible option is $\text{next}[p_r] = r$.

We have shown that $\text{next}[p_r] = r$ and thus $x_{p_r} \succ x_r$. By the definition of prev , it also holds $x_{\text{prev}[r_*]} \prec x_{r_*}$. Since we chose r_c to be the rightmost index with $r_c + \text{LCE}(\ell_c, r_c) = c$, it holds $r + \text{LCE}(p_r, r) < c$ (otherwise we would have updated r_c already). Therefore, we have

$$\begin{aligned} x[\text{prev}[r_*].. \text{prev}[r_*] + \text{LCE}(p_r, r)] &= x[p_r..p_r + \text{LCE}(p_r, r)], \text{ and} \\ x[r_*..r_* + \text{LCE}(p_r, r)] &= x[r..r + \text{LCE}(p_r, r)]. \end{aligned}$$

This, however, means that $x_{\text{prev}[r_*]} \prec x_{r_*} \iff x_{p_r} \prec x_r$, which contradicts our previous observation that $x_{p_r} \succ x_r$ and $x_{\text{prev}[r_*]} \prec x_{r_*}$. It follows that the assumption $\text{next}[\ell_*] > r_*$ and $\text{prev}[r_*] > \ell_*$ was wrong, and it holds $\text{next}[\ell_*] = r_*$ or $\text{prev}[r_*] = \ell_*$.

6 Similarity to Manacher's Algorithm

In this section, we want to briefly highlight the similarity between the technique of Section 5 and Manacher's algorithm for computing maximal palindromes [14]. For simplicity, we only consider odd palindromes. An *odd palindrome of radius* $|w| + 1$ is a string of the form $ws\bar{w}$, where s is a symbol, w is some possibly empty string, and \bar{w} is the *reverse string* of w defined by $|\bar{w}| = |w|$ and $\forall i \in [1, |w|] : \bar{w}[i] = w[|w| - i + 1]$. For a string $x[1..n]$, the presented version of Manacher's algorithm computes an array $\text{rad}[1..n]$, where $\forall i \in [1, n] :$

$$\text{rad}[i] = \max\{m \mid m \in [1, \min(i, n - i + 1)] \text{ and } x(i - m..i + m) \text{ is an odd palindrome}\}.$$

If we compute the entries of rad in left-to-right order, then we can sometimes fully or partially

■ **Algorithm 3** Manacher’s algorithm for odd palindromes.

<p>Require: string $x = \#x(1..n)\\$.</p> <p>Ensure: array rad containing the radii of the longest odd palindromes</p> <p>1: $\text{rad}[1..n] \leftarrow$ new array initialized with $\text{rad}[1] = \text{rad}[n] = 1$</p> <p>2: global variable $c \leftarrow 0$</p> <p>3: global variable $j \leftarrow 0$</p> <p>4: for $i = 2$ to $n - 1$ do</p> <p>5: $\text{rad}[i] \leftarrow \text{SMART-PALINDROME}(i, 1)$</p>	<p>1: function $\text{SMART-PALINDROME}(i, m)$</p> <p>2: if $i + m < c$ then</p> <p>3: $m \leftarrow \text{rad}[j - (i - j)]$</p> <p>4: if $i + m < c$ then return m</p> <p>5: $m \leftarrow c - i$</p> <p>6: while $x[i - m] = x[i + m]$ do</p> <p>7: $m \leftarrow m + 1$</p> <p>8: $c, j \leftarrow i + m, i$</p> <p>9: return m</p>
--	---

deduce an entry, see Figures 3b and 3d. This is highly similar to our observations for LCEs in Figures 3a and 3c. A possible implementation of Manacher’s algorithm is provided in Algorithm 3. It computes rad from left to right, while keeping track of the rightmost inspected position of the string. Whenever possible, the function SMART-PALINDROME partially or fully deduces $\text{rad}[i]$. Note that the functions SMART-LCE and SMART-PALINDROME are structurally identical and use the same algorithmic ideas. Due to space constraints, we omit further details on how and why Algorithm 3 functions as intended, and why it takes $\mathcal{O}(n)$ time. (However, we invite the reader to produce a proof of correctness on their own. This is much easier for Algorithm 3 than for Algorithm 1(d) and Algorithm 2. Particularly, it requires no complicated technicalities like properties (i) and (ii) in Section 5.)

7 Proofs for Section 3

► **Lemma 5.** *Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix array prev and next . Let $\ell_1, \ell_2, r_1, r_2 \in [1, n]$ be indices with either $\text{next}[\ell_1] = r_1$ or $\text{prev}[r_1] = \ell_1$, and also either $\text{next}[\ell_2] = r_2$ or $\text{prev}[r_2] = \ell_2$. Then it does not hold $\ell_1 < \ell_2 < r_1 < r_2$.*

Proof. Assume $\ell_1 < \ell_2 < r_1 < r_2$. Since $\ell_2 \in (\ell_1, r_1)$ and either $\text{next}[\ell_1] = r_1$ or $\text{prev}[r_1] = \ell_1$, Definition 2 implies $x_{\ell_2} \succ x_{r_1}$. However, it also holds $r_1 \in (\ell_2, r_2)$ and either $\text{next}[\ell_2] = r_2$ or $\text{prev}[r_2] = \ell_2$. Thus, Definition 2 also implies $x_{\ell_2} \prec x_{r_1}$, which is a contradiction. ◀

► **Lemma 6.** *Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix arrays prev and next , and let $\ell, r \in [1, n]$ be arbitrary indices.*

(i) *It holds $\text{prev}[r] = \text{prev}^*[r - 1]$.*

(ii) *It holds $\text{next}[\ell] = r$ if and only if $\ell = \text{prev}^*[r - 1]$ and $\ell > \text{prev}[r]$.*

Proof. For (i), assume that $\text{prev}[r] \neq \text{prev}^*[r - 1]$. Then there must be some $r' = \text{prev}^*[r - 1]$ with $\text{prev}[r] \in (\text{prev}[r'], r')$. However, $\text{prev}[r'] < \text{prev}[r] < r' < r$ contradicts Lemma 5.

For (ii), we show both directions separately. Assume that $\text{next}[\ell] = r$ then $\forall k \in [\ell, r) : x_k \succ x_r$, which means $\text{prev}[r] \notin [\ell, r)$ and thus $\text{prev}[r] < \ell$. Assume that $\ell \neq \text{prev}^*[r - 1]$, then there must be some $r' = \text{prev}^*[r - 1]$ with $\ell \in (\text{prev}[r'], r')$. However, then $\text{prev}[r'] < \ell < r' < r$ and Lemma 5 contradict the assumption that $\text{next}[\ell] = r$. Thus $\ell = \text{prev}^*[r - 1]$.

For the counter direction, assume that $\text{prev}[r] < \ell$ and $\ell = \text{prev}^*[r - 1]$. By the definition of prev , and due to $\ell \in (\text{prev}[r], r)$, it holds $x_\ell \succ x_r$. It is easy to see that $\ell = \text{prev}^*[r - 1]$ implies $\forall k \in (\ell, r) : x_k \succ x_\ell$ (when following a chain of PSS edges, by definition of prev , the visited suffixes are lexicographically decreasing, and all suffixes skipped by a PSS edge are lexicographically larger). From $x_\ell \succ x_r$ and $\forall k \in (\ell, r) : x_k \succ x_\ell$ follows $\text{next}[\ell] = r$. ◀

► **Lemma 7.** Let $x = \#x(1..n)\$$ be a string with previous and next smaller suffix arrays prev and next . Let $k \in (1, n)$ be an arbitrary index, and let $\ell = \text{prev}[k]$ and $r = \text{next}[k]$.

- (i) If $LCE(\ell, k) = LCE(k, r)$, then $LCE(\ell, r) \geq LCE(k, r)$ and either $\text{prev}[r] = \ell$ or $\text{next}[\ell] = r$.
- (ii) If $LCE(\ell, k) < LCE(k, r)$, then $LCE(\ell, r) = LCE(\ell, k)$ and $\text{prev}[r] = \ell$.
- (iii) If $LCE(\ell, k) > LCE(k, r)$, then $LCE(\ell, r) = LCE(k, r)$ and $\text{next}[\ell] = r$.

Proof. We start with (i). Definition 2 implies $\forall i \in (\ell, k) \cup (k, r) : x_k \prec x_i$. Since $\ell = \text{prev}[k]$ we have $x_\ell \prec x_k$ and thus $\forall i \in (\ell, r) : x_\ell \prec x_i$. Analogously, due to $r = \text{next}[k]$ we have $\forall i \in (\ell, r) : x_r \prec x_i$. Thus, if $x_\ell \prec x_r$ then $\text{prev}[r] = \ell$, and if $x_\ell \succ x_r$ then $\text{next}[\ell] = r$.

For showing (ii), let $u = x[\ell.. \ell + LCE(\ell, k)]$, $s = x[\ell + LCE(\ell, k)]$, and $t = x[k + LCE(\ell, k)]$. By the definition of LCEs, it holds $s \neq t$. Due to $\ell = \text{prev}[k]$ we have $us \cdot x_{\ell+|us|} = x_\ell \prec x_k = ut \cdot x_{k+|ut|}$, and therefore $s < t$. Because of $LCE(\ell, k) < LCE(k, r)$, suffix x_r has prefix ut . Thus, it holds $x_\ell = us \cdot x_{\ell+|us|} \prec ut \cdot x_{r+|ut|} = x_r$. Due to (i), this means $\text{next}[\ell] = r$. The proof of (iii) works analogously to the one for (ii). ◀

Abstract

We study how to utilize (possibly erroneous) predictions in a model for computing under uncertainty in which an algorithm can query unknown data. Our aim is to minimize the number of queries needed to solve the minimum spanning tree problem, a fundamental combinatorial optimization problem that has been central also to the research area of explorable uncertainty. For all integral $\gamma \geq 2$, we present algorithms that are γ -robust and $(1 + \frac{1}{\gamma})$ -consistent, meaning that they use at most γOPT queries if the predictions are arbitrarily wrong and at most $(1 + \frac{1}{\gamma})\text{OPT}$ queries if the predictions are correct, where OPT is the optimal number of queries for the given instance. Moreover, we show that this trade-off is best possible. Furthermore, we argue that a suitably defined *hop distance* is a useful measure for the amount of prediction error and design algorithms with performance guarantees that degrade smoothly with the hop distance. We also show that the predictions are PAC-learnable in our model. Our results demonstrate that untrusted predictions can circumvent the known lower bound of 2, without any degradation of the worst-case ratio. To obtain our results, we provide new structural insights for the minimum spanning tree problem that might be useful in the context of query-based algorithms regardless of predictions. In particular, we generalize the concept of witness sets – the key to lower-bounding the optimum – by proposing novel global witness set structures and completely new ways of adaptively using those.

1 Introduction

We introduce learning-augmented algorithms to the area of optimization under explorable uncertainty and focus on the fundamental *minimum spanning tree (MST) problem under explorable uncertainty*. We are given a (multi)graph $G = (V, E)$ with unknown edge weights $w_e \in \mathbb{R}_+$, for $e \in E$. For each edge e , an uncertainty interval I_e is known that contains w_e . A *query* on edge e reveals the true value w_e . The task is to determine an MST, i.e., a tree

that connects all vertices of G , of minimum total weight w.r.t. the true values w_e . A query set is called *feasible* if it reveals sufficient information to identify an MST (not necessarily its exact weight). As queries are costly, the goal is to find a feasible query set of minimum size.

We study *adaptive strategies* that make queries sequentially and utilize the results of previous steps to decide upon the next query. As there exist input instances that are impossible to solve without querying all edges, we evaluate our algorithms in an *instance-dependent* manner: For each input, we compare the number of queries made by an algorithm with the best possible number of queries *for that input*, using competitive analysis. For a given problem instance, let OPT denote an arbitrary optimal query set (we later give a formal definition of OPT). An algorithm is ρ -*competitive* if it executes, for any problem instance, at most $\rho \cdot |\text{OPT}|$ queries. While MST under explorable uncertainty is not a classical online problem where the input is revealed passively over time, the query results are uncertain and, to a large degree, dictate whether decisions to query certain edges were good or not. For analyzing an algorithm, it is natural to assume that the query results are determined by an adversary. This gives the problem a clear online flavor and prohibits the existence of 1-competitive algorithms even if we have unlimited running time and space [24]. We note that competitive algorithms in general do not have any running time requirements, but all our algorithm run in polynomial time.

The MST problem is among the most widely studied problems in the research area of *explorable uncertainty* [35] and has been a cornerstone in the development of algorithmic approaches and lower bound techniques [21, 22, 24, 27, 43, 44]. The best known deterministic algorithm for MST with uncertainty is 2-competitive, and no deterministic algorithm can be better [24]. A randomized algorithm with competitive ratio 1.707 is known [43]. Further work considers the non-adaptive problem, which has a very different flavor [44].

In this paper, we assume that an algorithm has, for each edge e , access to a prediction $\bar{w}_e \in I_e$ for the unknown value w_e . For example, machine learning (ML) methods could be used to predict the value of an edge. Given the tremendous progress in artificial intelligence and ML in recent decades, we can expect that those predictions are of good accuracy, but there is no guarantee and the predictions might be completely wrong. This lack of provable performance guarantees for ML often causes concerns regarding how confident one can be that an ML algorithm will perform sufficiently well in all circumstances. We address the very natural question whether the availability of such (ML) predictions can be exploited by query algorithms for computing with explorable uncertainty. Ideally, an algorithm should perform very well if predictions are accurate, but even if they are arbitrarily wrong, the algorithm should not perform worse than an algorithm without access to predictions. To emphasize that the predictions can be wrong, we refer to them as *untrusted predictions*.

We note that the availability of both uncertainty intervals and untrusted predictions is natural in many scenarios. For example, the quality of links (measured using metrics such as throughput and reliability) in a wireless network often fluctuates over time within a certain interval, and ML methods can be used to predict the precise link quality based on time-series data of previous link quality measurements [1]. The actual quality of a link can be obtained via a new measurement. If we wish to build a minimum spanning tree using links that currently have the highest link quality and want to minimize the additional measurements needed, we arrive at an MST problem with uncertainty and untrusted predictions.

We study for the first time the combination of explorable uncertainty and untrusted predictions. Our work is inspired by the vibrant recent research trend of considering untrusted (ML) predictions in the context of *online* algorithms, a different uncertainty model where the input is revealed to an algorithm incrementally. Initial work on online caching problems [40] has initiated a vast growing line of research on caching [5, 49, 53], rent-or-buy problems [31, 48, 54], scheduling [4, 9, 38, 45, 48], graph problems [19, 37, 39] and many more.

We adopt the following notions introduced in [40, 48]: An algorithm is α -consistent if it is α -competitive when the predictions are correct, and it is β -robust if it is β -competitive no matter how wrong the predictions are. Furthermore, we are interested in a smooth transition between the case with correct predictions and the case with arbitrarily incorrect predictions. We aim for performance guarantees that degrade gracefully with increasing prediction error.

Given predicted values for the uncertainty intervals, it is tempting to simply run an optimal algorithm under the assumption that the predictions are correct. This is obviously optimal with respect to consistency, but might give arbitrarily bad solutions in the case when the predictions are faulty. Instead of blindly trusting the predictions, we need more sophisticated strategies to be robust against prediction errors. This requires new lower bounds on an optimal solution, new structural insights, and new algorithmic techniques.

Main results

In this work, we show that, in the setting of explorable uncertainty, it is in fact possible to exploit ML predictions of the uncertain values and improve the performance of a query strategy when the predictions are good, while at the same time guaranteeing a strong bound on the worst-case performance even when the predictions are arbitrarily bad.

We give algorithms for the MST problem with uncertainty that are parameterized by a hyperparameter γ that reflects the user's confidence in the accuracy of the predictor. For any integral $\gamma \geq 2$, we present a $(1 + \frac{1}{\gamma})$ -consistent and γ -robust algorithm, and show that this is the best possible trade-off between consistency and robustness. In particular, for $\gamma = 2$, we obtain a 2-robust, 1.5-consistent algorithm. It is worth noting that this algorithm achieves the improved competitive ratio of 1.5 for accurate predictions while maintaining the worst-case ratio of 2. This is in contrast to many learning-augmented online algorithms where the exploitation of predictions usually incurs an increase in the worst-case ratio (e.g., [6, 48]).

Our main result is a second and different algorithm with a more fine-grained performance analysis that obtains a guarantee that improves with the accuracy of the predictions. Very natural, simple error measures such as the number of inaccurate predictions or the ℓ_1 -norm of the difference between predictions and true values turn out to prohibit any reasonable error-dependency. Therefore, we propose an error measure, called *hop distance* k_h , that takes structural insights about uncertainty intervals into account and may also be useful for other problems in computing with uncertainty and untrusted predictions. We give a precise definition of this error measure later. We also show in the full version [20] that the predictions are efficiently PAC-learnable with respect to k_h . Our main result is a learning-augmented algorithm with a competitive ratio with a linear error-dependency $\min\{(1 + \frac{1}{\gamma}) + \frac{5 \cdot k_h}{|\text{OPT}|}, \gamma + 1\}$, for any integral $\gamma \geq 2$. All our algorithms have polynomial running-times. We describe our techniques and highlight their novelty in the following section.

The integrality requirement for γ comes from using γ to determine set sizes and can be removed by randomization at the cost of a slightly worse consistency guarantee; for a proof we refer to the full version.

Further related work

There is a long history of research on the tradeoff between exploration and exploitation when coping with uncertainty in the input data. Often, stochastic models are assumed, e.g., in work on multi-armed bandits [16, 28, 52], Weitzman's Pandora's box [55], and query-variants of combinatorial optimization problems; see, e.g., [32, 41, 51] and many more. In our work, we assume no knowledge of stochastic information and aim for robust algorithms that perform well even in a worst case.

The line of research on explorable uncertainty has been initiated by Kahan [35] in the context of selection problems. Subsequent work addressed finding the k -th smallest value in a set of uncertainty intervals [26, 33], caching problems [47], computing a function value [36], sorting [34], and classical combinatorial optimization problems. Some of the major aforementioned results on the MST problem under explorable uncertainty have been extended to general matroids [23, 43, 44]. Further problems that have been studied are the shortest path problem [25], the knapsack problem [29] and scheduling problems [2, 3, 7, 10, 18]. Although optimization under explorable uncertainty has been studied mainly in an adversarial model, recently first results have been obtained for stochastic variants for sorting [17] and selection type problems (hypergraph orientation) [11].

There is a significant body of work on computing in models where information about a hidden object can be accessed only via queries. The hidden object can, for example, be a function, a matrix, or a graph. In the graph context, property testing [30] has been studied extensively and there are many more works, see [8, 12, 13, 42, 46, 50]. The bounds on the number of queries made by an algorithm are typically absolute (as a function of the input) and the resulting correctness guarantees are probabilistic. This is very different from our work, where we aim for a comparison to the minimum number of queries needed for the given graph.

2 Overview of techniques and definition of error measure

We assume that each uncertainty interval is either *open*, $I_e = (L_e, U_e)$, or *trivial*, $I_e = \{w_e\}$, and we refer to edge e as *non-trivial* or *trivial*, respectively; a standard assumption to avoid a simple lower bound of $|E|$ on the competitive ratio [24, 33].

Before we give an overview of the used techniques, we formally define feasible and optimal query sets. We say that a query set $Q \subseteq E$ is *feasible* if there exists a set of edges $T \subseteq E$ such that T is an MST for the true values w_e of all $e \in Q$ and *every possible* combination of edge weights in I_e for the unqueried edges $e \in E \setminus Q$. That is, querying a feasible query set Q must give us sufficient information to identify a spanning tree T that is an MST for the true values no matter what the true values of the unqueried edges $E \setminus Q$ actually are. We call a feasible query set Q *optimal* if it has minimum cardinality $|Q|$ among all feasible query sets. Thus, the optimal solution depends only on the true values and not on the predicted values.

As Erlebach and Hoffmann [21] give a polynomial-time algorithm that computes an optimal query set under the assumption that all query results are known upfront, we can use their algorithm to compute the optimal query set under the assumption that all predicted values match the actual edge weights and query the computed set in an arbitrary order. If the predicted values are indeed correct, this yields a 1-consistent algorithm. However, such an algorithm may have an arbitrarily bad performance if the predictions are incorrect. Similarly, the known deterministic 2-competitive algorithm for the MST problem with uncertainty (without predictions) [24] is 2-robust and 2-consistent. The known lower bound of 2 rules out any robustness factor less than 2. It builds on the following simple example with two intersecting intervals I_a, I_b that are candidates for the largest edge weight in a cycle. No matter which interval a deterministic algorithm queries first, say I_a , the realized value could be $w_a \in I_a \cap I_b$, which requires a second query. If the adversary chooses $w_b \notin I_a \cap I_b$, querying just I_b would have been sufficient to identify the interval with larger true value. See also [24, Example 3.8] and [43, Section 3] for an illustration of the lower bound example.

Algorithm overview

We aim for $(1 + \frac{1}{\gamma})$ -consistent and γ -robust algorithms for each integral $\gamma \geq 2$. The algorithm proceeds in two phases: The first phase runs as long as there are prediction mandatory edges, i.e., edges that must be contained in every feasible query set under the assumption that the predictions are correct; we later give a formal characterization of such edges. In this phase, we exploit the existence of those edges and their properties to execute queries with strong local guarantees, i.e., each feasible query set contains a large portion of our queries. For the second phase, we observe and exploit that the absence of prediction mandatory queries implies that the predicted optimal solution is a minimum vertex cover in a bipartite auxiliary graph. The challenge here is that the auxiliary graph can change with each wrong prediction. To obtain an error-dependent guarantee (our error measure k_h is discussed below) we need to adaptively query a dynamically changing minimum vertex cover.

Novel techniques

During the first phase, we generalize the classical witness set analysis. In computing with explorable uncertainty, the concept of *witness sets* is crucial for comparing the query set of an algorithm with an optimal solution (a way of lower-bounding). A witness set [15] is a set of elements for which we can guarantee that any feasible solution must query at least *one* of these elements. Known algorithms for the MST problem without predictions [24, 43] essentially follow the algorithms of Kruskal or Prim and only identify witness sets of size 2 in the cycle or cut that is currently under consideration. Querying disjoint witness sets of size 2 (witness pairs) ensures 2-robustness but does not lead to an improved consistency.

In our first phase, we extend this concept by considering *strengthened* witness sets of three elements such that any feasible query set must contain at least two of them. Since we cannot always find strengthened witness sets based on structural properties alone (otherwise, there would be a 1.5-competitive algorithm for the problem without predictions), we identify such sets under the assumption that the predictions are correct. Even after identifying such elements, the algorithm needs to query them in a careful order: if the predictions are wrong, we lose the guarantee on the elements, and querying all of them might violate the robustness. In order to identify strengthened witness sets, we provide new, more global criteria to identify additional witness sets (of size two) beyond the current cycle or cut. These new ways to identify witness sets are a major contribution that may be of independent interest regardless of predictions. During the first phase, we repeatedly query $\gamma - 2$ prediction mandatory edges together with a strengthened witness set, which ensures $(1 + \frac{1}{\gamma})$ -consistency. We query the elements in a carefully selected order while adjusting for errors to ensure γ -robustness.

For the second phase, we observe that the predicted optimal solution of the remaining instance is a minimum vertex cover VC in a bipartite auxiliary graph representing the structure of *potential* witness pairs (edges of the input graph correspond to vertices of the auxiliary graph). For instances with this property, we aim for 1-consistency and 2-robustness; the best-possible trade-off for such instances. If the predictions are correct, each edge of the auxiliary graph is a witness pair. However, if a prediction error is observed when a vertex of VC is queried, the auxiliary graph changes. This means that some edges of the original auxiliary graph are not actually witness pairs. Indeed, the size of a minimum vertex cover can increase and decrease and does not constitute a lower bound on $|\text{OPT}|$; we refer to the full version for an example.

If we only aim for consistency and robustness, we can circumvent this problem by selecting a distinct matching partner $h(e) \notin VC$ for each $e \in VC$ applying *König-Egerváry's* Theorem (duality of maximum matchings and minimum vertex covers in bipartite graphs, see e.g. [14]).

By querying the elements of VC in a carefully chosen order until a prediction error is observed for the first time, we can guarantee that $\{e, h(e)\}$ is a witness set for each $e \in VC$ that is already queried. In the case of an error, this allows us to extend the previously queried elements to disjoint witness pairs to guarantee 2-robustness. Then, we can switch to an arbitrary (prediction-oblivious) 2-competitive algorithm for the remaining queries.

If we additionally aim for an error-sensitive guarantee, however, handling the dynamic changes to the auxiliary graph, its minimum vertex cover VC and matching h requires substantial additional work, and we see overcoming this challenge as our main contribution. In particular, querying the partner $h(e)$ of each already queried $e \in VC$ in case of an error might be too expensive for the error-dependent guarantee. However, if we do not query these partners, the changed instance still depends on them, and if we charge against such a partner multiple times, we can lose the robustness. Our solution is based on an elaborate charging/counting scheme and involves:

- keeping track of matching partners of already queried elements of VC ;
- updating the matching and VC using an augmenting path method to bound the number of elements that are charged against multiple times in relation to the prediction error;
- and querying the partners of previously queried edges (and their new matching partners) as soon as they become endpoints of a newly matched edge, in order to prevent dependencies between the (only partially queried) witness sets of previously queried edges.

The error-sensitive algorithm achieves a competitive ratio of $1 + \frac{1}{\gamma} + \frac{5k_h}{|\text{OPT}|}$, at the price of a slightly increased robustness of $\gamma + 1$ instead of γ .

Hop distance as error metric

When we aim for a fine-grained performance analysis giving guarantees that depend on the quality of predictions, we need a metric to measure the prediction error. A very natural, simple error measure is the number of inaccurate predictions $k_{\#} = |\{e \in E \mid w_e \neq \bar{w}_e\}|$. However, we can show that even for $k_{\#} = 1$ the competitive ratio cannot be better than the known bound of 2 (see Lemma 19 in the full version). The reason for the weakness of this measure is that it completely ignores the interleaving structure of intervals. Similarly, an ℓ_1 error metric such as $\sum_{e \in E} |w_e - \bar{w}_e|$ would not be meaningful because only the *order* of the values and the interval endpoints matters for our problems.

We propose a refined error measure, which we call *hop distance*. It is very intuitive even though it requires some technical care to make it precise. If we consider only a single predicted value \bar{w}_e for some $e \in E$, then, in a sense, this value predicts the relation of the true value w_e to the intervals of edges $e' \in E \setminus \{e\}$. In particular, w.r.t. a fixed $e' \in E \setminus \{e\}$, the value \bar{w}_e predicts whether w_e is left of $I_{e'}$ ($\bar{w}_e \leq L_{e'}$), right of $I_{e'}$ ($\bar{w}_e \geq U_{e'}$), or contained in $I_{e'}$ ($L_{e'} < \bar{w}_e < U_{e'}$). Interpreting the prediction \bar{w}_e in this way, the prediction is “wrong” (w.r.t. a fixed $e' \in E \setminus \{e\}$) if the predicted relation of the true value w_e to interval $I_{e'}$ is not actually true, e.g., w_e is predicted to be left of $I_{e'}$ ($\bar{w}_e \leq L_{e'}$) but the actual w_e is either contained in or right of $I_{e'}$ ($w_e > L_{e'}$). Formally, we define the function $k_{e'}(e)$ that indicates whether the predicted relation of w_e to $I_{e'}$ is true ($k_{e'}(e) = 0$) or not ($k_{e'}(e) = 1$). With the prediction error $k^+(e)$ for a single $e \in E$, we want to capture the number of relations between w_e and intervals $I_{e'}$ with $e' \in E \setminus \{e\}$ that are not accurately predicted. Thus, we define $k^+(e) = \sum_{e' \in E \setminus \{e\}} k_{e'}(e)$. For a set of edges $E' \subseteq E$, we define $k^+(E') = \sum_{e \in E'} k^+(e)$. Consequently, with the error for the complete instance we want to capture the total number of wrongly predicted relations and, therefore, define it by $k_h = k^+(E)$. We call this error measure k_h the *hop distance*; see Figure 1 for an illustration.

Figure 1 Example of a single cycle (left) with uncertain edge weights from intersecting intervals $I_{e_1}, I_{e_2}, I_{e_3}, I_{e_4}$ (middle). Circles illustrate true values and crosses illustrate the predicted values.

Symmetrically, we can define $k^-(e) = \sum_{e' \in E \setminus \{e\}} k_e(e')$ and $k^-(E') = \sum_{e \in E'} k^-(e)$ for subset $E' \subseteq E$. Then $k^+(E) = k_h = k^-(E)$ follows by reordering the summations.

3 Structural results

In this section, we introduce some known concepts and prove new structural results on MST under explorable uncertainty, which we use later to design learning-augmented algorithms.

Witness sets and mandatory queries

Witness sets are the key to the analysis of query algorithms. They allow for a comparison of an algorithm’s query set to an optimal solution. A subset $W \subseteq E$ is a *witness set* if $W \cap Q \neq \emptyset$ for all feasible query sets Q . An important special case are witness sets of cardinality one, i.e., edges that are part of every feasible query set. We call such edges *mandatory*. Similarly, we call edges that are mandatory under the assumption that the predictions are correct *prediction mandatory*.

For an example, consider Figure 2. In the example, we see the uncertainty intervals, predicted values and true values of four edges that form a simple cycle. We can observe that both e_1 and e_2 are mandatory for this example. To see this, assume that e_1 is not mandatory. Then, there must be a feasible query set Q with $e_1 \notin Q$ for the instance, which implies that $Q = \{e_2, e_3, e_4\}$ must be feasible. But even after querying Q to reveal the true values of e_2, e_3 and e_4 , it still depends on the still unknown true value of e_1 whether there exists an MST T with $e_1 \in T$ (only if $w_{e_1} \leq w_{e_2}$) and/or $e_1 \notin T$ (only if $w_{e_2} \leq w_{e_1}$). Even after querying Q there is no spanning tree T that is an MST for each possible edge weight in I_{e_1} of the unqueried edge e_1 and, thus, Q is not feasible. This implies that e_1 is mandatory, and we can argue analogously that e_2 is mandatory as well.

To argue whether an edge is prediction mandatory, on the other hand, we assume that all queries reveal the predicted values as true values. Under this assumption, a query to e_1 in the example would reveal a value that is larger than all upper limits U_{e_i} with $i \in \{2, 3, 4\}$, which implies that e_1 cannot be part of any MST and that $T = \{e_2, e_3, e_4\}$ is an MST no matter what the true values of e_2, e_3 and e_4 actually are. Therefore, under the assumption that all predicted values match the true values, $Q = \{e_1\}$ is a feasible query set and, thus, e_2 is not prediction mandatory despite being mandatory. However, we can use a similar argumentation as above to argue that e_1 is also prediction mandatory.

We continue by giving properties that allow us to identify (prediction) mandatory edges. To that end, let the *lower limit tree* $T_L \subseteq E$ be an MST for values w^L with $w_e^L = L_e + \epsilon$ for an infinitesimally small $\epsilon > 0$. Analogously, let the *upper limit tree* T_U be an MST for values w^U with $w_e^U = U_e - \epsilon$. This concept has been introduced in [43] to identify mandatory

■ **Figure 2** Example of a single cycle (left) with uncertain edge weights from intersecting intervals $I_{e_1}, I_{e_2}, I_{e_3}, I_{e_4}$ (right). Circles illustrate true values and crosses illustrate the predicted values. For the example, $\{e_1, e_2\}$ is the set of all mandatory edges and $\{e_1\}$ is the set of all prediction mandatory edges.

queries; it is shown that every non-trivial $e \in T_L \setminus T_U$ is mandatory. Thus, we may repeatedly query edges in $T_L \setminus T_U$ until $T_L = T_U$ without worsening the competitive ratio. We can extend this preprocessing to achieve uniqueness for T_L and T_U and, thus, may assume unique $T_L = T_U$.

► **Lemma 1.** *By querying only mandatory elements we can obtain an instance with $T_L = T_U$ such that T_L and T_U are the unique lower limit tree and upper limit tree, respectively.*

Given an instance with unique $T_L = T_U$, we observe that each $e \in T_L$ that is not part of the MST for the true values is mandatory. Similarly, each $e \notin T_L$ that is part of the MST for the true values is mandatory as well. A stronger version of this observation is as follows.

► **Lemma 2.** *Let G be an instance with unique $T_L = T_U$ and let G' be an instance with unique $T'_L = T'_U$ obtained from G by querying set Q , then $e \in T_L \Delta T'_L = (T_L \setminus T'_L) \cup (T'_L \setminus T_L)$ implies $e \in Q$.*

Next we establish a relation between the set $E_M \subseteq E$ of mandatory queries, the set $E_P \subseteq E$ of prediction mandatory queries, and the hop distance k_h .

► **Lemma 3.** *Consider a given problem instance $G = (V, E)$ with predicted values \bar{w} . Each $e \in E_M \Delta E_P$ satisfies $k^-(e) \geq 1$. Consequently, $k_h \geq |E_M \Delta E_P|$.*

For a formal proof, we refer to the full version. Intuitively, if $e \in E_P \setminus E_M$, then it is possible to solve the instance without querying e . Thus, the relation of the true values $w_{e'}$ with $e' \in E \setminus \{e\}$ to interval I_e must be such that querying $E \setminus \{e\}$ allows us to verify that e is either part or not part of the MST. If the predicted relations of the true values $w_{e'}$ with $e' \in E \setminus \{e\}$ to interval I_e were the same, then querying $E \setminus \{e\}$ would also allow us to verify that e is either part or not part of the MST. Thus, the predicted relation of at least one $w_{e'}$ to interval I_e must be wrong. We can argue analogously for $e \in E_M \setminus E_P$.

Identifying witness sets

We introduce new structural properties to identify witness sets. Existing algorithms for MST under uncertainty [24, 43] essentially follow the algorithms of Kruskal or Prim, and only identify witness sets in the cycle or cut that is currently under consideration. Let f_1, \dots, f_l denote the edges in $E \setminus T_L$ ordered by non-decreasing lower limit. Then, C_i with $i \in \{1, \dots, l\}$ denotes the unique cycle in $T_L \cup \{f_i\}$.

For each $e \in T_L$, let X_e denote the set of edges in the cut of the two connected components of $T_L \setminus \{e\}$. Existing algorithms for MST under explorable uncertainty repeatedly consider (the changing) C_1 or X_e , where e is the edge in T_L with maximum upper limit, and identify

the maximum or minimum edge in the cycle or cut by querying witness sets of size two, until the problem is solved. For our algorithms, we need to identify witness sets in cycles $C_i \neq C_1$ and cuts $X_{e'} \neq X_e$.

► **Lemma 4.** *Consider cycle C_i with $i \in \{1, \dots, l\}$. Let $l_i \in C_i \setminus \{f_i\}$ such that $I_{l_i} \cap I_{f_i} \neq \emptyset$ and l_i has the largest upper limit in $C_i \setminus \{f_i\}$, then $\{f_i, l_i\}$ is a witness set. If $w_{f_i} \in I_{l_i}$, then l_i is mandatory.*

Characterization of prediction mandatory free instances

We say an instance is *prediction mandatory free* if it contains no prediction mandatory elements. A key part of our algorithms is to transform instances into prediction mandatory free instances while maintaining a competitive ratio that allows us to achieve the optimal consistency and robustness trade-off overall. We give the following characterization of prediction mandatory free instances, (cf. Figure 3). Then, we show that prediction mandatory free instances remain so as long as we ensure $T_L = T_U$.

■ **Figure 3** Intervals in a prediction mandatory free cycle with predictions indicated as red crosses.

► **Lemma 5.** *An instance G is prediction mandatory free if and only if $\bar{w}_{f_i} \geq U_e$ and $\bar{w}_e \leq L_{f_i}$ holds for each $e \in C_i \setminus \{f_i\}$ and each cycle C_i with $i \in \{1, \dots, l\}$. Once an instance is prediction mandatory free, it remains so even if we query further elements, as long as we maintain unique $T_L = T_U$.*

Making instances prediction mandatory free

In the full version, we give a powerful preprocessing algorithm that transforms arbitrary instances into prediction mandatory free instances.

► **Theorem 6.** *There is an algorithm that makes a given instance prediction mandatory free and satisfies $|\text{ALG}| \leq \min\{(1 + \frac{1}{\gamma}) \cdot (|\text{ALG} \cup D| \cap \text{OPT}| + k^+(\text{ALG}) + k^-(\text{ALG})), \gamma \cdot (|\text{ALG} \cup D| \cap \text{OPT}| + \gamma - 2)\}$ for the set of edges ALG queried by the algorithm and a set $D \subseteq E \setminus \text{ALG}$ of unqueried edges that do not occur in the remaining instance after executing the algorithm.*

The set D are edges that, even without being queried by the algorithm, are proven to be maximal in a cycle or minimal in a cut. Thus, they can be deleted or contracted w.l.o.g. and do not exist in the instance remaining *after* executing the preprocessing algorithm. This is an important property as it means that the remaining instance is independent of D and ALG (as all elements of ALG are already queried). Since the theorem compares $|\text{ALG}|$ with $|\text{ALG} \cup D| \cap \text{OPT}|$ instead of just $|\text{OPT}|$, this allows us to combine the given guarantee with the guarantees of dedicated algorithms for prediction mandatory free instances. However, we have to be careful with the additive term $\gamma - 2$, but we will see that we can charge this term against the improved robustness of our algorithms for prediction mandatory free instances.

4 An algorithm with optimal consistency and robustness trade-off

We give a bound on the best achievable tradeoff between consistency and robustness.

► **Theorem 7.** *Let $\beta \geq 2$ be a fixed integer. For the MST problem under explorable uncertainty with predictions, there is no deterministic β -robust algorithm that is α -consistent for $\alpha < 1 + \frac{1}{\beta}$. And vice versa, no deterministic α -consistent algorithm, with $\alpha > 1$, is β -robust for $\beta < \max\{\frac{1}{\alpha-1}, 2\}$.*

The main result of this section is an optimal algorithm w.r.t. this tradeoff bound.

► **Theorem 8.** *For every integer $\gamma \geq 2$, there exists a $(1 + \frac{1}{\gamma})$ -consistent and γ -robust algorithm for the MST problem under explorable uncertainty with predictions.*

To show this result, we design an algorithm for prediction mandatory free instances with unique $T_L = T_U$. We run it after the preprocessing algorithm which obtains such special instance with the query guarantee in Theorem 6. Our new algorithm achieves the optimal trade-off.

► **Theorem 9.** *There exists a 1-consistent and 2-robust algorithm for prediction mandatory free instances with unique $T_L = T_U$ of the MST problem under explorable uncertainty with predictions.*

In a prediction mandatory free instance $G = (V, E)$, each $f_i \in E \setminus T_L$ is predicted to be maximal on cycle C_i , and each $l \in T_L$ is predicted to be minimal in X_l (cf. Lemma 5). If these predictions are correct, then T_L is an MST and the optimal query set is a minimum vertex cover in a bipartite graph $\bar{G} = (\bar{V}, \bar{E})$ with $\bar{V} = E$ (excluding trivial edges) and $\bar{E} = \{\{f_i, e\} \mid i \in \{1, \dots, l\}, e \in C_i \setminus \{f_i\} \text{ and } I_e \cap I_{f_i} \neq \emptyset\}$ [21, 43]. We refer to \bar{G} as the *vertex cover instance*. Note that if a query reveals that an f_i is not maximal on C_i or an $l \in T_L$ is not minimal in X_l , then the vertex cover instance changes. Let VC be a minimum vertex cover of \bar{G} . Non-adaptively querying VC ensures 1-consistency but might lead to an arbitrarily bad robustness. Indeed, the size of a minimum vertex cover can increase and decrease drastically as we show in the full version. Thus, the algorithm has to be more adaptive.

The idea of the algorithm (cf. Algorithm 1) is to sequentially query each $e \in VC$ and charge for querying e by a distinct non-queried element $h(e)$ such that $\{e, h(e)\}$ is a witness set. Querying exactly one element per distinct witness set implies optimality. To identify $h(e)$ for each element $e \in VC$, we use the fact that *König-Egerváry's* Theorem (e.g., [14]) on the duality between minimum vertex covers and maximum matchings in bipartite graphs implies that there is a matching h that maps each $e \in VC$ to a distinct $e' \notin VC$. While the sets $\{e, h(e)\}$ with $e \in VC$ in general are not witness sets, querying VC in a specific order until the vertex cover instance changes guarantees that $\{e, h(e)\}$ is a witness set for each already queried e . The algorithm queries in this order until it detects a wrong prediction or solves the problem. If it finds a wrong prediction, it queries the partner $h(e)$ of each already queried edge e , and continues to solve the problem with a 2-competitive algorithm (e.g., [24, 43]). The following lemma specifies the order in which the algorithm queries VC .

► **Lemma 10.** *Let l'_1, \dots, l'_k be the edges in $VC \cap T_L$ ordered by non-increasing upper limit and let d be such that the true value of each l'_i with $i < d$ is minimal in cut $X_{l'_i}$, then $\{l'_i, h(l'_i)\}$ is a witness set for each $i \leq d$. Let f'_1, \dots, f'_g be the edges in $VC \setminus T_L$ ordered by non-decreasing lower limit and let b be such that the true value of each f'_i with $i < b$ is maximal in cycle $C_{f'_i}$, then $\{f'_i, h(f'_i)\}$ is a witness set for each $i \leq b$.*

■ **Algorithm 1** 1-consistent and 2-robust algorithm for prediction mandatory free instances.

Input: Prediction mandatory free graph $G = (V, E)$ with unique $T_L = T_U$.

- 1 Compute maximum matching h and minimum vertex cover VC for \tilde{G} ;
- 2 Set $W = \emptyset$, and let f'_1, \dots, f'_g and l'_1, \dots, l'_k be as described in Lemma 10;
- 3 **for** e chosen sequentially from the ordered list $f'_1, \dots, f'_g, l'_1, \dots, l'_k$ **do**
- 4 Query e and add $h(e)$ to W ;
- 5 **if** $k^+(e) \neq 0$ **then** query set W and solve the instance with a 2-competitive algorithm;

Proof. Here, we show the first statement and refer to the full version for the proof of the second statement. Consider an arbitrary l'_i and $h(l'_i)$ with $i \leq d$. By definition of h , the edge $h(l'_i)$ is not part of the lower limit tree. Consider $C_{h(l'_i)}$, i.e., the cycle in $T_L \cup \{h(l'_i)\}$, then we claim that $C_{h(l'_i)}$ only contains $h(l'_i)$ and edges in $\{l'_1, \dots, l'_k\}$ (and possibly irrelevant edges that do not intersect $I_{h(l'_i)}$). To see this, recall that $l'_i \in VC$, by definition of h , implies $h(l'_i) \notin VC$. For VC to be a vertex cover, each $e \in C_{h(l'_i)} \setminus \{h(l'_i)\}$ must either be in VC or not intersect $h(l'_i)$. Consider the relaxed instance where the true values for each l'_j with $j < d$ and $j \neq i$ are already known. By assumption each such l'_j is minimal in its cut $X_{l'_j}$. Thus, we can w.l.o.g. contract each such edge. It follows that in the relaxed instance l'_i has the highest upper limit in $C_{h(l'_i)} \setminus \{h(l'_i)\}$. According to Lemma 4, $\{l'_i, h(l'_i)\}$ is a witness set. ◀

Proof of Theorem 9. We first show 1-consistency. Assume that all predictions are correct, then VC is an optimal query set and $k^+(e) = 0$ holds for all $e \in E$. It follows that Line 5 never executes queries and the algorithm queries exactly VC . This implies 1-consistency.

Further, if the algorithm never queries in Line 5, then the consistency analysis implies 1-robustness. Suppose Line 5 executes queries. Let Q_1 denote the set of edges that are queried before the queries of Line 5 and let $Q_2 = \{h(e) \mid e \in Q_1\}$. Then Q_2 corresponds to the set W as queried in Line 5. By Lemma 10, each $\{e, h(e)\}$ with $e \in Q_1$ is a witness set. Further, the sets $\{e, h(e)\}$ are pairwise disjoint. Thus, $|Q_1 \cup Q_2| \leq 2 \cdot |\text{OPT} \cap (Q_1 \cup Q_2)|$. Apart from $Q_1 \cup Q_2$, the algorithm queries a set Q_3 in Line 5 to solve the remaining instance with a 2-competitive algorithm. So, $|Q_3| \leq 2 \cdot |\text{OPT} \setminus (Q_1 \cup Q_2)|$ and, adding up the inequalities, $|\text{ALG}| \leq 2 \cdot |\text{OPT}|$. ◀

A careful combination of Theorems 6 and 9 implies Theorem 8. Full proof in the full version.

5 An error-sensitive algorithm

In this section, we extend the algorithm of Section 4 to obtain error sensitivity. First, we note that $k_{\#} = 0$ implies $k_h = 0$, so Theorem 7 implies that no algorithm can simultaneously have competitive ratio better than $1 + \frac{1}{\beta}$ if $k_h = 0$ and β for arbitrary k_h . In addition, we can give the following lower bound on the competitive ratio as a function of k_h .

► **Theorem 11.** *Any deterministic algorithm for MST under explorable uncertainty with predictions has a competitive ratio $\rho \geq \min\{1 + \frac{k_h}{|\text{OPT}|}, 2\}$, even for edge disjoint prediction mandatory free cycles.*

Again, we design an algorithm for prediction mandatory free instances with unique $T_L = T_U$ and use it in combination with the preprocessing algorithm (Theorem 6) to prove the following.

► **Theorem 12.** *For every integer $\gamma \geq 2$, there exists a $\min\{1 + \frac{1}{\gamma} + \frac{5 \cdot k_h}{|\text{OPT}|}, \gamma + 1\}$ -competitive algorithm for the MST problem under explorable uncertainty with predictions.*

We actually show a robustness of $\max\{3, \gamma + \frac{1}{|\text{OPT}|}\}$ which might be smaller than $\gamma + 1$. Our algorithm for prediction mandatory free instances asymptotically matches the error-dependent guarantee of Theorem 11 at the cost of a slightly worse robustness.

► **Theorem 13.** *There exists a $\min\{1 + \frac{5 \cdot k_h}{|\text{OPT}|}, 3\}$ -competitive algorithm for prediction mandatory free instances with unique $T_L = T_U$ of the MST problem under explorable uncertainty with predictions.*

We follow the same strategy as before. However, Algorithm 1 just executes a 2-competitive algorithm once it detects an error. This is sufficient to achieve the optimal trade-off as we, if an error occurs, only have to guarantee 2-competitiveness. To obtain an error-sensitive guarantee however, we have to ensure both, $|\text{ALG}| \leq 3 \cdot |\text{OPT}|$ and $|\text{ALG}| \leq \text{OPT} + 5 \cdot k_h$ even if errors occur. Further, we might not be able to afford queries to the complete set W (Algorithm 1, Line 5) in the case of an error as this might violate $|\text{ALG}| \leq \text{OPT} + 5 \cdot k_h$.

We adjust the algorithm to query elements of f'_1, \dots, f'_g and l'_1, \dots, l'_k as described in Lemma 10 not only until an error occurs but until the vertex cover instance changes. That is, until some f_i that at the beginning of the iteration is not part of T_L becomes part of the lower limit tree, or some l_i that at the beginning of the iteration is part of T_L is not part of the lower limit tree anymore. Once the instance changes, we recompute both, the bipartite graph \bar{G} as well as the matching h and minimum vertex cover VC for \bar{G} . Instead of querying the complete set W , we only query the elements of W that occur in the recomputed matching, as well as the new matching partners of those elements. And instead of switching to a 2-competitive algorithm, we restart the algorithm with the recomputed matching and vertex cover. Algorithm 2 formalizes this approach. In the algorithm, h denotes a matching that matches each $e \in VC$ to a distinct $h(e) \notin VC$; we use the notation $\{e, e'\} \in h$ to indicate that h matches e and e' . For a subset $U \subseteq VC$ let $h(U) = \{h(e) \mid e \in U\}$. For technical reasons, the algorithm does not recompute an arbitrary matching h but follows the approach of Lines 10 and 11. Intuitively, an arbitrary maximum matching h might contain too many elements of W , which would lead to too many additional queries.

Let ALG denote the queries of Algorithm 2 on a prediction mandatory free instance with unique $T_L = T_U$. We show Theorem 13 by proving $\text{ALG} \leq \text{OPT} + 5 \cdot k_h$ and $\text{ALG} \leq 3 \cdot \text{OPT}$.

Before proving the two inequalities, we state some key observations about the algorithm. We argue that an element e' can never be part of a partial matching \bar{h} in an execution of Line 10 *after* it is added to set W . Recall that the vertex cover instances only contain non-trivial elements. Thus, if an element e is queried in Line 5 and the current partner $e' = h(e)$ is added to set W , then the vertex cover instance at the next execution of Line 10 does not contain the edge $\{e, e'\}$ and, therefore, e' is not part of the partial matching \bar{h} of that line. As long as e' is not added to the matching by Line 11, it, by definition, can never be part of a partial matching \bar{h} in an execution of Line 10. As soon as the element e' is added to the matching in some execution of Line 11, it is queried in the following execution of Line 12. Therefore, e' can also not be part of a partial matching \bar{h} in an execution of Line 10 after it is added to the matching again. This leads to the following observation.

► **Observation 14.** *An element e' can never be part of a partial matching \bar{h} in an execution of Line 10 after it is added to set W . Once e' is added to the matching again in an execution of Line 11, it is queried directly afterwards in Line 12, and cannot occur in Line 5 anymore.*

■ **Algorithm 2** Error-sensitive algorithm for prediction mandatory free instances.

Input: Prediction mandatory free graph $G = (V, E)$ with unique $T_L = T_U$.

- 1 Compute maximum matching h and minimum vertex cover VC for \bar{G} and set $W = \emptyset$;
- 2 Let f'_1, \dots, f'_g and l'_1, \dots, l'_k be as described in Lemma 10 for VC and h ;
- 3 $L \leftarrow T_L, N \leftarrow E \setminus T_L$; /* recompute the actual T_L after each query */
- 4 **for** e chosen sequentially from the ordered list $f'_1, \dots, f'_g, l'_1, \dots, l'_k$ **do**
- 5 If e is non-trivial, i.e., has not been queried yet, query e and add $h(e)$ to W ;
- 6 Apply Lemma 1 to ensure unique $T_L = T_U$. For each query e' , if
 $\exists a$ s.t. $\{e', a\} \in h$, query a ;
- 7 Let $\bar{G}' = (\bar{V}', \bar{E}')$ be the vertex cover instance for the current instance;
- 8 **if** some $e' \in L$ is not in T_L or some $e' \in N$ is in T_L **then**
- 9 **repeat**
- 10 Let $\bar{G} = \bar{G}'$ and $\bar{h} = \{\{e', e''\} \in h \mid \{e', e''\} \in \bar{E}'\}$;
- 11 Compute h and VC by completing \bar{h} with an augmenting path algorithm;
- 12 Query $R = (VC \cup h(VC)) \cap (W \cup \{e' \mid \exists e \in W \text{ with } \{e, e'\} \in h\})$;
- 13 Ensure unique $T_L = T_U$. For each query e' , if $\exists a$ s.t. $\{e', a\} \in h$, query a ;
- 14 Let $\bar{G}' = (\bar{V}', \bar{E}')$ be the vertex cover instance for the current instance;
- 15 **until** $R = \emptyset$;
- 16 Restart at Line 2. In particular, do *not* reset W ;

We first analyze the queries that are *not* executed in Line 12. Let $Q_1 \subseteq \text{ALG}$ denote the queries of Line 5. For each $e \in Q_1$ let $h^*(e)$ be the matching partner of e at the time it was queried, and let $h^*(Q_1) = \bigcup_{e \in Q_1} \{h^*(e)\}$. Finally, let Q_2 denote the queries of Lines 6 and 13 to elements of $h^*(Q_1)$, and let Q_3 denote the remaining queries of those lines.

► **Lemma 15.** $|Q_1 \cup Q_3 \cup h^*(Q_1)| \leq 2 \cdot |\text{OPT} \cap (Q_1 \cup Q_3 \cup h^*(Q_1))|$ and $|Q_1 \cup Q_2 \cup Q_3| \leq |\text{OPT} \cap (Q_1 \cup Q_3 \cup h^*(Q_1))| + k^-(Q_2 \cup Q_3)$.

Proof. First, consider Q_1 and $h^*(Q_1)$. By Lemma 5, the instance is prediction mandatory free at the beginning of each restart of the algorithm. By Lemma 10, each $\{e, h^*(e)\}$ with $e \in Q_1$ is a witness set. We claim that all such $\{e, h^*(e)\}$ are pairwise disjoint, which implies $|Q_1 \cup h^*(Q_1)| \leq 2 \cdot |\text{OPT} \cap (Q_1 \cup h^*(Q_1))|$. Otherwise, an element of $\{e, h^*(e)\}$ must occur a second time in Line 5 after e is queried and $h^*(e)$ is added to W . Thus, either e or $h^*(e)$ must become part of a recomputed matching in line 10. By Observation 14 and since e becomes trivial, this cannot happen.

Consider an $e \in Q_2 \subseteq h^*(Q_1)$ and let $e' \in Q_1$ with $h^*(e') = e$. Since $e' \in Q_1$, it was queried in Line 5. Observe that e must have been queried after e' , as otherwise either e' would not have been queried in Line 5 (but together with e in Line 6 or 13), or e would not have been the matching partner of e' when it was queried by Observation 14; both contradict $e' \in Q_1$ and $h^*(e') = e$. This and Observation 14 imply that, at the time e is queried, its current matching partner is either the trivial e' or it has no partner. So, e must have been queried because it was mandatory and not as the matching partner of a mandatory element. Thus, each query of Q_2 is mandatory but, by Lemma 5, not prediction mandatory at the beginning of the iteration in which it is queried. Therefore, Lemma 3 implies that all mandatory elements e of Q_2 have $k^-(e) \geq 1$. It follows $|Q_1 \cup Q_2| \leq |\text{OPT} \cap (Q_1 \cup h^*(Q_1))| + k^-(Q_2)$.

By the argument above, no element of Q_3 was queried as the matching partner to an element of $Q_2 \cup Q_1$. Thus, by Lemma 1 and the definition of the algorithm, at least half the elements of Q_3 are mandatory, and we have $|Q_3| \leq 2 \cdot |\text{OPT} \cap Q_3|$ (and $\frac{1}{2}|Q_3| \leq |\text{OPT} \cap Q_3|$), which implies $|Q_1 \cup Q_3 \cup h^*(Q_1)| \leq 2 \cdot |\text{OPT} \cap (Q_1 \cup Q_3 \cup h^*(Q_1))|$.

By the same argument as for Q_2 , all mandatory elements e of Q_3 have $k^-(e) \geq 1$. Thus, $k^-(Q_3) \geq \frac{1}{2} \cdot |Q_3|$. Combining $k^-(Q_3) \geq \frac{1}{2} \cdot |Q_3|$ and $\frac{1}{2}|Q_3| \leq |\text{OPT} \cap Q_3|$ implies $|Q_3| \leq |\text{OPT} \cap Q_3| + k^-(Q_3)$. So, $|Q_1 \cup Q_2 \cup Q_3| \leq |\text{OPT} \cap (Q_1 \cup Q_2 \cup Q_3)| + k^-(Q_2 \cup Q_3)$. ◀

The first part of Lemma 15 captures all queries outside of Line 12 and all queries of Line 12 to elements of $W = h^*(Q_1)$. Let Q'_4 be the remaining queries of Line 12. By definition of the algorithm, $|Q'_4| \leq |W|$. Since $|W| \leq |\text{OPT}|$, we can conclude the next lemma.

► **Lemma 16.** $|\text{ALG}| \leq 3 \cdot |\text{OPT}|$.

Next, we show $|\text{ALG}| \leq |\text{OPT}| + 5 \cdot k_h$. Lemma 15 implies $|Q_1 \cup Q_2 \cup Q_3| \leq |\text{OPT} \cap (Q_1 \cup Q_2 \cup Q_3)| + k^-(Q_2 \cup Q_3)$. Hence, it remains to upper bound $|Q_4|$ with $Q_4 = \text{ALG} \setminus (Q_1 \cup Q_2 \cup Q_3)$ by $4 \cdot k_h$. By definition, Q_4 only contains edges that are queried in Line 12. Thus, at least half the queries of Q_4 are elements of W that are part of the matching h . By Observation 14, no element of W is part of the partial matching \bar{h} in Line 10. Hence, in each execution of Line 12, at least half the queries are not part of \bar{h} in Line 10 but added to h in Line 11. Our goal is to bound the number of such elements.

We start with some definitions. Define G_j as the problem instance at the j 'th execution of Line 11, and let G_0 denote the initial problem instance. For each G_j , let $\bar{G}_j = (\bar{V}_j, \bar{E}_j)$, T_L^j and T_U^j denote the corresponding vertex cover instance and lower and upper limit trees. Observe that each G_j has unique $T_L^j = T_U^j$, and, by Lemma 5, is prediction mandatory free. Let Y_j denote the set of queries made by the algorithm to transform instance G_{j-1} into instance G_j . We partition Q_4 into subsets S_j , where S_j contains the edges of Q_4 that are queried in the j 'th execution of Line 12. We claim $|S_j| \leq 4 \cdot k^+(Y_j)$ for each j , which implies $|Q_4| \leq \sum_j |S_j| \leq 4 \cdot \sum_j k^+(Y_j) \leq 4 \cdot k_h$. To show the claim, we rely on the following lemma.

► **Lemma 17.** *Let l, f be non-trivial edges in G_j such that $\{l, f\} \in \bar{E}_{j-1} \Delta \bar{E}_j$, then $k^-(l), k^-(f) \geq 1$. Furthermore, $k^+(Y_j) \geq |U|$ for the set U of all endpoints of such edges $\{l, f\}$.*

► **Lemma 18.** $|\text{ALG}| \leq |\text{OPT}| + 5 \cdot k_h$.

Proof. We show $|S_j| \leq 4 \cdot k^+(Y_j)$ for each j , which, in combination with Lemma 15, implies the lemma. Consider an arbitrary S_j and the corresponding set Y_j . Further, let h_{j-1} denote the maximum matching computed and used by the algorithm for vertex cover instance \bar{G}_{j-1} , and let $\bar{h}_{j-1} = \{\{e, e'\} \in h_{j-1} \mid \{e, e'\} \in \bar{E}_j\}$. Finally, let h_j denote the matching that the algorithm uses for vertex cover instance \bar{G}_j . That is, h_j is computed by completing \bar{h}_{j-1} with a standard augmenting path algorithm. As already argued, at least half the elements of S_j are not matched by \bar{h}_{j-1} but are matched by h_j (cf. Observation 14).

We bound the number of such elements by exploiting that h_j is constructed from \bar{h}_{j-1} via a standard augmenting path algorithm. By definition, each iteration of the augmenting path algorithm increases the size of the current matching (starting with \bar{h}_{j-1}) by one and, in doing so, matches two new elements. In total, at most $2 \cdot (|h_j| - |\bar{h}_{j-1}|)$ previously unmatched elements become part of the matching. Thus, $|S_j| \leq 4 \cdot (|h_j| - |\bar{h}_{j-1}|)$.

We show $(|h_j| - |\bar{h}_{j-1}|) \leq k^+(Y_j)$. According to *Kőnig-Egerváry's Theorem* (e.g., [14]), the size of h_j is equal to the size $|VC_j|$ of the minimum vertex cover for \bar{G}_j . We show $|VC_j| \leq |\bar{h}_{j-1}| + k^+(Y_j)$, which implies $(|h_j| - |\bar{h}_{j-1}|) = |VC_j| - |\bar{h}_{j-1}| \leq k^+(Y_j)$, and, thus, the claim. Let $\overline{VC}_{j-1} = \{e \in VC_{j-1} \mid \exists e' \text{ s.t. } \{e, e'\} \in \bar{h}_{j-1}\}$, then $|\overline{VC}_{j-1}| = |\bar{h}_{j-1}|$.

We prove that we can construct a vertex cover for \bar{G}_j by adding at most $k^+(Y_j)$ elements to \overline{VC}_{j-1} , which implies $|VC_j| \leq |\bar{h}_{j-1}| + k^+(Y_j)$. Consider vertex cover instance \bar{G}_j and set \overline{VC}_{j-1} . By definition, \overline{VC}_{j-1} covers all edges that are part of partial matching \bar{h}_{j-1} .

Consider the elements of \bar{V}_j that are an endpoint of an edge in $\{e, f\} \in \bar{E}_j \Delta \bar{E}_{j-1}$ with e, f non-trivial in G_j . By Lemma 17, $k^-(e) \geq 1$ for each such e and $k^+(Y_j) \geq |U|$ for the set U of all such elements. Thus, we can afford to add U to the vertex cover.

Next, consider an edge $\{e, f\} \in \bar{E}_j$ that is not covered by $\bar{V}C_{j-1} \cup U$. Since $\{e, f\}$ is not covered by U , it must hold that $\{e, f\} \in \bar{E}_j \cap \bar{E}_{j-1}$. Thus, $\{e, f\}$ was covered by VC_{j-1} but is not covered by $\bar{V}C_{j-1}$. This implies $\{e, f\} \cap VC_{j-1} \neq \emptyset$ but $\{e, f\} \cap \bar{V}C_{j-1} = \emptyset$. Assume w.l.o.g. that $e \in VC_{j-1}$. Then, there must be an e' such that $\{e, e'\} \in h_{j-1}$ but $\{e, e'\} \notin \bar{h}_{j-1}$. It follows that $\{e, e'\} \notin \bar{E}_j$. As $\{e, f\}$ is not covered by U , the endpoint e' must be trivial in G_j but non-trivial in G_{j-1} . Thus, e' must have been queried (i) as a mandatory element (or a matching partner) in Line 6 or 13, (ii) as part of VC_{j-1} in Line 5 or (iii) in Line 12. Case (ii) implies $e' \in VC_{j-1}$, contradicting $e \in VC_{j-1}$. Cases (i) or (iii) imply a query to the matching partner e of e' , which contradicts $\{e, f\} \in \bar{E}_j$ (as e would be trivial). Thus, $\{e, f\}$ is covered by $\bar{V}C_{j-1} \cup U$, which implies that $\bar{V}C_{j-1} \cup U$ is a vertex cover for \bar{G}_j . Lemma 17 implies $|U| \leq k^+(Y_j)$. So, $|VC_j| \leq |\bar{h}_{j-1}| + k^+(Y_j)$ which concludes the proof. ◀

Lemmas 16 and 18 imply Theorem 13. Combining Theorems 6 and 13, we show Theorem 12.

6 Further research directions

Plenty other (optimization) problems seem natural in the context of explorable uncertainty with untrusted predictions. For our problem, it would be nice to close the gap in the robustness. We expect that our results extend to all matroids as it does in the classical setting. While we ask for the minimum number of queries to solve a problem *exactly*, it is natural to ask for approximate solutions. The bad news is that for the MST problem there is no improvement over the robustness guarantee of 2 possible even when allowing an arbitrarily large approximation of the exact solution [43, Section 10]. However, it remains open whether an improved consistency or an error-dependent competitive ratio are possible.

Abstract

We generalize the monotone local search approach of Fomin, Gaspers, Lokshtanov and Saurabh [J.ACM 2019], by establishing a connection between parameterized approximation and exponential-time approximation algorithms for *monotone subset minimization* problems. In a *monotone subset minimization* problem the input implicitly describes a non-empty set family over a universe of size n which is closed under taking supersets. The task is to find a minimum cardinality set in this family. Broadly speaking, we use *approximate monotone local search* to show that a parameterized α -approximation algorithm that runs in $c^k \cdot n^{\mathcal{O}(1)}$ time, where k is the solution size, can be used to derive an α -approximation randomized algorithm that runs in $d^n \cdot n^{\mathcal{O}(1)}$ time, where d is the unique value in $(1, 1 + \frac{c-1}{\alpha})$ such that $\mathcal{D}(\frac{1}{\alpha} \parallel \frac{d-1}{c-1}) = \frac{\ln c}{\alpha}$ and $\mathcal{D}(a \parallel b)$ is the Kullback-Leibler divergence. This running time matches that of Fomin et al. for $\alpha = 1$, and is strictly better when $\alpha > 1$, for any $c > 1$. Furthermore, we also show that this result can be derandomized at the expense of a sub-exponential multiplicative factor in the running time.

We use an approximate variant of the exhaustive search as a benchmark for our algorithm. We show that the classic $2^n \cdot n^{\mathcal{O}(1)}$ exhaustive search can be adapted to an α -approximate exhaustive search that runs in time $(1 + \exp(-\alpha \cdot \mathcal{H}(\frac{1}{\alpha})))^n \cdot n^{\mathcal{O}(1)}$, where \mathcal{H} is the entropy function. Furthermore, we provide a lower bound stating that the running time of this α -approximate exhaustive search is the best achievable running time in an oracle model. When compared to approximate exhaustive search, and to other techniques, the running times obtained by approximate monotone local search are strictly better for any $\alpha \geq 1$, $c > 1$.

We demonstrate the potential of approximate monotone local search by deriving new and faster exponential approximation algorithms for VERTEX COVER, 3-HITTING SET, DIRECTED FEEDBACK VERTEX SET, DIRECTED SUBSET FEEDBACK VERTEX SET, DIRECTED ODD CYCLE TRANSVERSAL and UNDIRECTED MULTICUT. For instance, we get a 1.1-approximation algorithm for VERTEX COVER with running time $1.114^n \cdot n^{\mathcal{O}(1)}$, improving upon the previously best known 1.1-approximation running in time $1.127^n \cdot n^{\mathcal{O}(1)}$ by Bourgeois et al. [DAM 2011].

1 Introduction

A lot of interesting problems are computationally hard as they do not admit polynomial-time algorithms. Still, many of them can be solved significantly faster than exhaustive search. The area of exact exponential algorithms studies the design of such techniques. Typically, for *subset problems*, where the goal is to find a subset of a given n -sized universe U that satisfies some property Π , a solution can be found by enumerating all 2^n subsets of U . Therefore, the goal is to design algorithms that beat this exhaustive search and run in time $\mathcal{O}^*(c^n)$ ¹ for as small $1 < c < 2$ as possible.

Exact Monotone Local Search. In a seminal work Fomin, Gaspers, Lokshtanov and Saurabh [13] showed that one can derive faster exact exponential algorithms for subset problems using a parameterized extension algorithm for the problem at hand. A parameterized extension algorithm for a subset problem additionally takes as input a parameter k and a set $X \subseteq U$, runs in time $\mathcal{O}^*(f(k))$, and outputs a set $S \subseteq U$ of size at most k such that $S \cup X$ is a solution, if such a set exists. Fomin et al. [13, Theorem 1.1] showed that if a subset problem admits a parameterized extension algorithm that runs in time $\mathcal{O}^*(c^k)$ for some absolute constant $c > 1$, then it admits a randomized exact exponential algorithm that runs in time $\mathcal{O}^*((\text{emls}(c))^n)$, where $\text{emls}(c) = 2 - \frac{1}{c}$. Their algorithm, called Exact Monotone Local Search (**Exact-MLS**), is simple and is based on monotone local search: it samples a set X of t elements at random, and then extends the set X to an optimum solution using the parameterized extension algorithm. The non-trivial part of the proof of [13, Theorem 1.1] is to analyze the value of t that optimizes the running time. This simple algorithm outperforms the exhaustive search for all subset problems that have parameterized extension algorithms running in $\mathcal{O}^*(c^k)$ time. Moreover, given the existence of a large number of problems that admit the desired parameterized extension algorithm, it yields the state-of-the-art exact exponential algorithms for several problems [13, Table 1].

Exponential Approximation. Another important algorithmic paradigm which deals with NP-hardness is the design of *approximation* algorithms, which are typically polynomial-time algorithms that compute a solution which is not necessarily optimum but has a worst-case guarantee on its *quality*. Though several NP-hard problems admit such algorithms with constant approximation ratios [30], there are many that do not, under reasonable complexity assumptions, for example DIRECTED FEEDBACK VERTEX SET [28]. Also, there are many for which the approximation guarantees cannot be improved beyond a fixed constant. For example, VERTEX COVER admits a 2-approximation but no $(2 - \epsilon)$ -approximation under the Unique Games Conjecture [17].

For problems where some hardness of approximation has been established, a natural question is to determine the smallest c such that the barriers of this hardness can be broken by taking $\mathcal{O}^*(c^n)$ time. Such algorithms are called *exponential approximation* algorithms and this topic has received attention in, e.g., [1, 2, 3, 7, 25].

Consider *subset minimization* problems where the goal is to find a subset of the n -sized universe U of *minimum cardinality*, also called an *optimum* solution, that satisfies some additional property Π . For any approximation ratio $\alpha \geq 1$, we say that a subset $S \subseteq U$ satisfying the property Π is an α -*approximate solution* if $|S| \leq \alpha \cdot |\text{OPT}|$, where $\text{OPT} \subseteq U$ is an optimum solution. An *exponential α -approximation algorithm* for a subset minimization problem returns an α -approximate solution and runs in $\mathcal{O}^*(c^n)$ time for some $1 < c < 2$.

¹ The \mathcal{O}^* notation hides polynomial factors in the input.

Parameterized Approximation. A *parameterized α -approximation* algorithm for a subset minimization problem additionally takes as input the parameter k , runs in time $\mathcal{O}^*(f(k))$, and outputs a solution of size at most $\alpha \cdot k$, if there exists a solution of size at most k . Analogous to parameterized algorithms, one can define the notion of extension algorithms here (see Section 2). The design of parameterized α -approximation algorithms has been an active area of research in the last few years, yielding a plethora of results for problems that exhibit some hardness either in the parameterized setting or in the approximation setting [4, 5, 8, 10, 11, 12, 14, 15, 16, 18, 21, 22, 23, 24, 26, 27, 29].

Approximate Monotone Local Search (Approximate-MLS). In this paper, we show that one can extend the idea of **Exact-MLS** [13] to *derive faster exponential approximation algorithms from parameterized approximation algorithms*. Let $\mathbf{amls}(\alpha, c)$ be the unique value in $(1, 1 + \frac{c-1}{\alpha})$ such that $\mathcal{D}\left(\frac{1}{\alpha} \parallel \frac{\mathbf{amls}(\alpha, c) - 1}{c - 1}\right) = \frac{\ln c}{\alpha}$ where $\mathcal{D}(a \parallel b)$ is the Kullback-Leibler divergence defined as $\mathcal{D}(a \parallel b) = a \ln\left(\frac{a}{b}\right) + (1 - a) \ln\left(\frac{1 - a}{1 - b}\right)$ (see, e.g., [6]). Our main result can be informally stated as follows.

If a monotone subset minimization problem admits a parameterized extension α -approximation algorithm that runs in $\mathcal{O}^*(c^k)$, then one can derive a randomized α -approximation algorithm that runs in time $\mathcal{O}^*((\mathbf{amls}(\alpha, c))^n)$ (see Theorem 2.1).

Since $\mathbf{amls}(1, c) = \mathbf{emls}(c) = 2 - \frac{1}{c}$ for every $c > 1$, our running time matches that of **Exact-MLS** when $\alpha = 1$.

Recall the **Exact-MLS** algorithm described earlier. The non-trivial part of the proof of [13, Theorem 1.1] is the analysis of the probability that the sampled set is *contained* in an optimum solution. To obtain our result, we use the same algorithm and show that if we allow the sampled set to also contain *some* items from outside the optimum solution, then one can speed-up the resulting exponential α -approximation algorithm. Since our analysis need to take into account the calculations for error in the sampled set, this makes analyzing the choice of t more difficult.

In order to better appreciate the running time of our algorithm, that does not seem to have a closed-form formula, we give a mathematical comparison of $\mathbf{amls}(\alpha, c)$ with various benchmark exponential approximation algorithms, showing that our algorithm outperforms all of them.

Benchmark 1: Brute-Force for Exponential Approximation. Since exhaustive search is a trivial benchmark against which the running times of (exact) exponential algorithms are measured, an important question to address is: *how much time does exhaustive search take to find an α -approximate solution?*

Consider a subset minimization problem that is also monotone, that is, for every $S \subseteq T \subseteq U$, if S is a solution, then T is also a solution. We show that for monotone subset minimization problems, the classic brute-force approach can be generalized to an *α -approximation brute-force algorithm* running in time $\mathcal{O}^*(\mathbf{brute}(\alpha)^n)$, where $\mathbf{brute}(\alpha) = 1 + \frac{(\alpha-1)^{\alpha-1}}{\alpha^\alpha} = 1 + \exp\left(-\alpha \cdot \mathcal{H}\left(\frac{1}{\alpha}\right)\right)$ and $\mathcal{H}(\alpha) = -\alpha \ln \alpha - (1 - \alpha) \ln(1 - \alpha)$ denotes the entropy function². The running time essentially follows by showing that a uniformly sampled set of $\alpha \cdot |\text{OPT}|$ items is an α -approximate solution with probability at least $\mathbf{brute}(\alpha)^{-n}$ (up to polynomial factors,

² We adopt the convention that $0^0 = 1$.

see Theorem 5.1). We complement this result by showing that this running time is *best possible*, given only membership oracle access to the problem (Theorem 5.1). For example, for $\alpha = 2$, this brute-force algorithm runs in time $\mathcal{O}^*(1.25^n)$. For $\alpha = 1.1$, it runs in time $\mathcal{O}^*(1.716^n)$ (see also Table 1).

Benchmark 2: Naive conversion from parameterized approximation to exponential approximation. Yet another upper bound on the running time of exponential approximation algorithms can be given as follows. Suppose there is a parameterized α -approximation for a monotone subset minimization problem that runs in $\mathcal{O}^*(c^k)$ time. Run the parameterized algorithm for every value of the parameter k between 0 to $\frac{n}{\alpha}$, and return the solution of minimum cardinality among the solutions returned by the parameterized algorithm. If no solution was found by the parameterized algorithm, then return the whole universe. It can be easily verified that this indeed yields an α -approximation algorithm with running time $\mathcal{O}^*(\text{naive}(\alpha, c)^n)$, where $\text{naive}(\alpha, c) = c^{\frac{1}{\alpha}}$. Observe that for large values of c and appropriate α , $\text{naive}(\alpha, c)$ could be much larger than even 2. But for smaller values of c , it could sometimes beat the brute-force approximation (see Section 2.4).

Benchmark 3: Exact-MLS in the approximate setting. From the description of the Exact-MLS algorithm, it is not difficult to deduce that given a parameterized extension α -approximation for a monotone subset minimization problem that runs in time $\mathcal{O}^*(c^k)$, one can derive an exponential α -approximation for the problem that runs in time $\mathcal{O}^*(\text{eMLS}(c)^n)$. This trivial generalization of Exact-MLS to the approximate setting already performs better than the naive conversion in cases when c is small. For example, VERTEX COVER has a parameterized (extension) 1.1-approximation algorithm that runs in time $\mathcal{O}^*(1.1652^k)$ [3]. Exact-MLS gives a 1.1-approximation running in time $\mathcal{O}^*(1.1417^n)$ whereas the naive conversion gives a running time of $\mathcal{O}^*(1.1462^n)$.

Comparisons. As stated earlier, we show that (see Lemma 1.1) Approximate-MLS is *strictly* faster than the brute-force algorithm (Benchmark 1) or the naive-conversion approach (Benchmark 2) described earlier, for every $\alpha \geq 1$ and $c > 1$. In fact, Lemma 1.1 shows that $\text{aMLS}(\alpha, c)$ converges to $\text{brute}(\alpha)$ as $c \rightarrow \infty$, which would be the expected behavior, because as the parameterized algorithm becomes “less useful”, the running time of our algorithm gets closer to the running time possible without the use of any problem-specific algorithm. Since $\text{aMLS}(1, c) = \text{eMLS}(c) = 2 - \frac{1}{c}$, Lemma 1.1 also shows that the running time is strictly better than that of Exact-MLS (Benchmark 3) when $\alpha > 1$.

► **Lemma 1.1** (\star^3). *For every $c > 1$ the following holds:*

1. $\text{aMLS}(\alpha, c) < \min\{\text{brute}(\alpha), \text{naive}(\alpha, c)\}$ for every $\alpha \geq 1$. In fact, $\text{aMLS}(\alpha, c) \xrightarrow{c \rightarrow \infty} \text{brute}(\alpha)$.
2. $\text{aMLS}(\alpha, c) < \text{eMLS}(c)$ for every $\alpha > 1$. In fact, $\text{aMLS}(\alpha, c)$ is a strictly decreasing function of α .

Applications and Derandomization. We show in Section 2.4 that Approximate-MLS can be used to derive new and faster exponential approximation algorithms for VERTEX COVER, 3-HITTING SET, DIRECTED FEEDBACK VERTEX SET, DIRECTED SUBSET FEEDBACK VERTEX SET, DIRECTED ODD CYCLE TRANSVERSAL and UNDIRECTED MULTICUT. We also show in Section 4 that, as in [13], our algorithm can be derandomized at the expense of a multiplicative sub-exponential factor in the running time.

³ The proofs of statements marked with \star appear in the full version of the paper [9].

2 Definitions and Our Results

2.1 Formal Definitions

We now give some formal definitions that will be required to formally state and describe our main results. An *implicit set system* is a function Φ that takes as input a string $I \in \{0, 1\}^*$, called an *instance*, and returns a set system (U_I, \mathcal{F}_I) where U_I is a universe and \mathcal{F}_I is a collection of subsets of U_I . We use n to denote the size of the universe, that is, $n := |U_I|$. We say that an implicit set system Φ is *polynomial-time computable* if there are two polynomial-time algorithms, the first one, given $I \in \{0, 1\}^*$, computes the set U_I , and the second one, given $S \subseteq U_I$, correctly decides if $S \in \mathcal{F}_I$. A family $\mathcal{F} \subseteq 2^U$ is called *monotone* if $U \in \mathcal{F}$ and for every $S \subseteq T \subseteq U$, if $S \in \mathcal{F}$, then $T \in \mathcal{F}$. We say that an implicit set system Φ is *monotone* if \mathcal{F}_I is monotone for every input I . Throughout the remainder of this work, we only deal with implicit set systems that are polynomial-time computable and monotone. So for the sake of convenience, we refer to a polynomial-time computable and monotone implicit set system simply as an implicit set system.

For an implicit set system Φ , the problem $\Phi_{\text{MIN-SUBSET}}$ takes as input a string $I \in \{0, 1\}^*$ and asks to find $S \in \mathcal{F}_I$ such that $|S|$ is minimum. We refer to the sets in \mathcal{F}_I as solutions of I and we call the sets in \mathcal{F}_I of minimum cardinality as minimum solutions or optimal solutions of I . For $\alpha \geq 1$, we say that an algorithm is a (randomized) α -approximation algorithm for $\Phi_{\text{MIN-SUBSET}}$ if on input I , it returns a set $S \in \mathcal{F}_I$ such that $|S| \leq \alpha \cdot |\text{OPT}|$ (with a constant probability), where OPT is an optimum solution of $\Phi_{\text{MIN-SUBSET}}$.

One can observe that many fundamental graph problems, such as VERTEX COVER, FEEDBACK VERTEX SET, DIRECTED FEEDBACK VERTEX SET, etc., can be cast as a $\Phi_{\text{MIN-SUBSET}}$ problem. Consider for example the VERTEX COVER problem. Given a graph $G = (V, E)$ we say a subset $S \subseteq V$ is a *vertex cover* if for every $(u, v) \in E$ it holds that $u \in S$ or $v \in S$. The input for the VERTEX COVER problem is a graph G and the objective is to find a vertex cover S of G such that $|S|$ is minimum. We can cast VERTEX COVER as a $\Phi_{\text{MIN-SUBSET}}$ problem for the implicit set system Φ_{VC} defined as follows. The instance of the problem is interpreted as a graph $G = (V, E)$. We define the universe U_G as the set of vertices V and the set of solutions $\mathcal{F}_G = \{S \subseteq V \mid S \text{ is a vertex cover of } G\}$ is the set of all vertex covers of G . Finally, we define $\Phi_{\text{VC}}(G) = (U_G, \mathcal{F}_G)$. It can be easily verified that Φ_{VC} is an implicit set system (i.e., it is polynomial-time computable and monotone).

We say an algorithm is a *parameterized (randomized) α -approximate Φ -extension* if, given an instance $I \in \{0, 1\}^*$, $X \subseteq U_I$ and a parameter $k \in \mathbb{N}$, it returns a set $Y \subseteq U_I$ which satisfies the following property (with a constant probability): if there exists a set $S \subseteq U_I$ such that $S \cup X \in \mathcal{F}_I$ and $|S| \leq k$, then it holds that $Y \cup X \in \mathcal{F}_I$ and $|Y| \leq \alpha \cdot k$. We use the shorthand *(randomized) (α, Φ) -extension algorithm* to refer to a *parameterized (randomized) α -approximate Φ -extension algorithm*. Observe that a parameterized α -approximation algorithm for VERTEX COVER can be turned into an $(\alpha, \Phi_{\text{VC}})$ -extension algorithm with the same running time, by taking the instance (G, X, k) of the $(\alpha, \Phi_{\text{VC}})$ -extension algorithm, and running the parameterized α -approximation algorithm on the instance $(G - X, k)$. Observe that this way of converting parameterized α -approximation algorithms to (α, Φ) -extension algorithms holds for various implicit set systems Φ , for example, when Φ corresponds to a vertex deletion problem to a hereditary graph class.

2.2 Our results

Given an (α, Φ) -extension algorithm with running time $\mathcal{O}^*(c^k)$ we design an α -approximation algorithm for $\Phi_{\text{MIN}}\text{-SUBSET}$ with running time $\mathcal{O}^*(\text{amls}(\alpha, c)^n)$ where amls is defined as the unique value $\gamma \in (1, 1 + \frac{c-1}{\alpha})$ such that $\mathcal{D}\left(\frac{1}{\alpha} \parallel \frac{\gamma-1}{c-1}\right) = \frac{\ln c}{\alpha}$. Note that $\text{amls}(\alpha, c)$ is indeed well-defined because for every $\alpha \geq 1$, the function $f(\delta) := \mathcal{D}\left(\frac{1}{\alpha} \parallel \delta\right)$ is monotonically decreasing in the interval $\delta \in (0, \frac{1}{\alpha})$ as well as $f(\delta) \xrightarrow{\delta \rightarrow 0} \infty$ and $f(\delta) \xrightarrow{\delta \rightarrow \frac{1}{\alpha}} 0$.

► **Theorem 2.1** (Approximate Monotone Local Search). *Let Φ be an implicit set system and $\alpha \geq 1$. If there is a randomized (α, Φ) -extension algorithm that runs in time $\mathcal{O}^*(c^k)$, then there is a randomized α -approximation algorithm for $\Phi_{\text{MIN}}\text{-SUBSET}$ that runs in time $\mathcal{O}^*(\text{amls}(\alpha, c)^n)$.*

The formula for $\text{amls}(\alpha, c)$ (which describes the running time of Theorem 2.1) is not a closed-form formula, and we do not expect a closed-form formula for general α, c to exist. However, it represents a *tight* analysis of our algorithm. Despite being represented as an implicit formula, its basic properties can be deduced (see Lemma 1.1). Also, amls can be easily evaluated for every $\alpha, c > 1$. Indeed, for every $\alpha \geq 1$, the function $f(\gamma) = \mathcal{D}\left(\frac{1}{\alpha} \parallel \frac{\gamma-1}{c-1}\right)$ is monotonically decreasing in the interval $(1, 1 + \frac{c-1}{\alpha})$. This means that $\text{amls}(\alpha, c)$ can be evaluated to an arbitrary precision, for every $\alpha \geq 1$ and $c > 1$, using binary search. In particular, the running time implied by Theorem 2.1 can be evaluated.

Theorem 2.1 can be used to obtain faster (than the state-of-art) exponential approximation algorithms for some $\Phi_{\text{MIN}}\text{-SUBSET}$ problems. For example, the brute-force 1.1-approximation algorithm runs in time $\mathcal{O}^*(\text{brute}(1.1)^n) = \mathcal{O}^*(1.716^n)$. The best parameterized 1.1-approximation for VERTEX COVER runs in time $\mathcal{O}^*(1.1652^k)$ [18], where k is the parameter. Using the naive conversion, we obtain a 1.1-approximation that runs in time $\mathcal{O}^*(\text{naive}(1.1, 1.1652)^n) = \mathcal{O}^*(1.149^n)$. The previously known fastest 1.1-approximation algorithm for VERTEX COVER runs in time $\mathcal{O}^*(1.127^n)$ [3]. Using Theorem 2.1 in conjunction with the $\mathcal{O}^*(1.1652^k)$ algorithm of [18], we get a 1.1-approximation algorithm for VERTEX COVER with running time $\mathcal{O}^*(1.114^n)$, improving over all of the above. We provide additional applications in Section 2.4.

In Section 4, we show that the algorithm of Theorem 2.1 can be derandomized, at the cost of a sub-exponential factor in the running time, by generalizing the construction of set inclusion families from [13].

► **Theorem 2.2** (Derandomization Approximate Monotone Local Search). *Let Φ be an implicit set system and $\alpha \geq 1$. If there is an (α, Φ) -extension algorithm that runs in time $\mathcal{O}^*(c^k)$, then there is an α -approximation algorithm for $\Phi_{\text{MIN}}\text{-SUBSET}$ that runs in time $\mathcal{O}^*\left((\text{amls}(\alpha, c))^{n+o(n)}\right)$.*

2.3 Approximate Monotone Local Search

We now present the algorithm underlying Theorem 2.1 and give a sketch for its analysis. Recall Φ is the implicit set family and $\alpha \geq 1$ is the approximation ratio. Let \mathcal{A}_{ext} denote the (α, Φ) -extension algorithm that runs in time $\mathcal{O}^*(c^k)$ where k is the parameter. Given an instance $I \in \{0, 1\}^*$, let $\Phi(I) = (U_I, \mathcal{F}_I)$. The algorithm for Theorem 2.1 is described in Algorithm 2, and it is denoted by **Approximate-MLS**. It uses the subroutine **Sample** (Algorithm 1) which samples a random set from U_I , which is subsequently extended, using \mathcal{A}_{ext} , to yield the solution. Algorithm 2 coincides with the algorithm of [13, Theorem 1.1] when $\alpha = 1$.

Algorithm 1 $\text{Sample}(I, k, t)$.

Input: $I \in \{0, 1\}^*$, $k \in \mathbb{N}$, $t \in \mathbb{N}$

- 1: Sample a set X of size t from U_I uniformly at random.
 - 2: $Y \leftarrow \mathcal{A}_{\text{ext}}(I, X, k - \lceil \frac{t}{\alpha} \rceil)$.
 - 3: $Z \leftarrow X \cup Y$.
 - 4: If $Z \in \mathcal{F}_I$ and $|Z| \leq \alpha \cdot k$, then **return** Z , otherwise **return** U_I .
-

Let OPT be an optimum solution of the instance I of $\Phi_{\text{MIN}}\text{-SUBSET}$. Consider the execution of Sample on the instance (I, k, t) where $k = |\text{OPT}|$. In Step 1 of Sample if $|X \cap \text{OPT}| \geq \frac{t}{\alpha}$ then $|\text{OPT} \setminus X| \leq k - \frac{t}{\alpha}$. Therefore, in Step 2 \mathcal{A}_{ext} must return a set Y such that $X \cup Y \in \mathcal{F}_I$ and $|Y| \leq \alpha \cdot (k - \frac{t}{\alpha}) = \alpha k - t$. Thus, the set $Z = X \cup Y$ computed in Step 3 is an α -approximate solution of I . Let $\text{hyper}(n, k, t, x)$ be the probability that a uniformly random set X of t items out of $[n] := \{1, \dots, n\}$ satisfies $|X \cap [k]| \geq x$. The distribution of $|X \cap [k]|$ is commonly referred as *hyper-geometric*. Since $\Pr(|X \cap \text{OPT}| \geq \frac{t}{\alpha}) = \text{hyper}(n, k, t, \frac{t}{\alpha})$, Sample returns an α -approximate solution of I with probability $\text{hyper}(n, k, t, \frac{t}{\alpha})$. Observe that the running time of the Sample subroutine is proportional (up to polynomial factors) to the running time of the call to \mathcal{A}_{ext} in Step 2. Thus, the Sample subroutine runs in time $\mathcal{O}^*(c^{k - \frac{t}{\alpha}})$.

Algorithm 2 $\text{Approximate-MLS}(I)$.

Input: $I \in \{0, 1\}^*$

- 1: Define $n = |U_I|$ and $\mathcal{S} \leftarrow \emptyset$.
 - 2: **for** k from 0 to $\frac{n}{\alpha}$ **do**
 - 3: $t \leftarrow \operatorname{argmin}_{t \in [0, \alpha k] \cap \mathbb{N}} \left(\frac{c^{k - \frac{t}{\alpha}}}{\text{hyper}(n, k, t, \frac{t}{\alpha})} \right)$.
 - 4: Run $\mathcal{S} = \mathcal{S} \cup \{\text{Sample}(I, k, t)\}$ for $(\text{hyper}(n, k, t, \frac{t}{\alpha}))^{-1}$ times.
 - 5: **Return** a minimum sized set in \mathcal{S} .
-

Now, let us consider the execution of Approximate-MLS on input I . The analysis of Approximate-MLS focuses on the iteration of Step 2 when $k = |\text{OPT}|$. In this iteration, each call to $\text{Sample}(I, k, t)$ returns an α -approximate solution with probability $\text{hyper}(n, k, t, \frac{t}{\alpha})$ (as argued above). Since in Step 4, Sample is invoked $(\text{hyper}(n, k, t, \frac{t}{\alpha}))^{-1}$ times, at the end of the execution of Step 4, the set \mathcal{S} contains an α -approximate solution of I with a constant probability.

The running time of a *fixed iteration* in Step 2 of Approximate-MLS is $(\text{hyper}(n, k, t, \frac{t}{\alpha}))^{-1}$ times the running time of Sample , that is, $\frac{c^{k - \frac{t}{\alpha}}}{\text{hyper}(n, k, t, \frac{t}{\alpha})}$. Let us denote $\text{iteration}_{n, k, c}(t) = \frac{c^{k - \frac{t}{\alpha}}}{\text{hyper}(n, k, t, \frac{t}{\alpha})}$. Observe that the value of t selected in Step 3 minimizes $\text{iteration}_{n, k, c}(t)$. From the algorithmic perspective the selection of the optimal value of t is straightforward as $\text{iteration}_{n, k, c}(t)$ can be computed in polynomial time for each value of t (given n and k). However, the asymptotic analysis of $\text{iteration}_{n, k, c}(t)$, and hence the overall running time, requires an in-depth understanding of the random process and serves as the main technical contribution of this paper.

As described earlier, when $\alpha = 1$, Algorithm 2 coincides with the algorithm of [13, Theorem 1.1]. The analysis of [13, Theorem 1.1] lower bounds the probability that the set X sampled on Step 1 of Sample satisfies $X \subseteq \text{OPT}$. The analysis of our algorithm lower bounds the probability that $\frac{|X \cap \text{OPT}|}{|X|} \geq \frac{1}{\alpha}$. In particular, the sampling step may select items which

are not in OPT , though the number of such items is restricted. This allows for an improved running time in comparison to that of [13] (see Lemma 1.1), but renders the analysis of the running time to be more involved.

For the analytical estimation of t , which is selected in Step 3 of **Approximate-MLS**, the question that one needs to understand is *how many items should the algorithm sample before it decides to use \mathcal{A}_{ext} to extend the sampled set*. Assume that the algorithm already sampled a set X of t items such that $|X \cap \text{OPT}| \approx \frac{t}{\alpha}$. Let $\varepsilon > 0$ be some small number. Observe that $U_I \setminus X$ contains $\approx k - \frac{t}{\alpha}$ items from OPT , and thus $\frac{|(U_I \setminus X) \cap \text{OPT}|}{|U_I \setminus X|} \approx \frac{k - \frac{t}{\alpha}}{n - t}$. The algorithm now has two options: it can either further sample a set A of additional $\varepsilon \cdot n$ items or, use \mathcal{A}_{ext} with the parameter $k - \frac{t}{\alpha}$ to extend X to a final solution. In the first case, the time taken to sample a set A of $\varepsilon \cdot n$ items such that $|A \cap \text{OPT}| \geq \frac{|A|}{\alpha} = \frac{\varepsilon \cdot n}{\alpha}$ holds with constant probability, is $(\Pr(|A \cap \text{OPT}| \geq \frac{\varepsilon \cdot n}{\alpha}))^{-1}$. In the second case, the algorithm spends an additional factor of $c^{\frac{\varepsilon \cdot n}{\alpha}}$ time to extend the set X , instead of $X \cup A$, to the final solution. Thus, if $\Pr(|A \cap \text{OPT}| \geq \frac{\varepsilon \cdot n}{\alpha}) > c^{-\frac{\varepsilon \cdot n}{\alpha}}$, it is better to continue sampling, and otherwise, it is better to run \mathcal{A}_{ext} on the instance $(I, X, k - \frac{t}{\alpha})$. Therefore, to understand the analytics of the chosen t , one needs to upper bound $\Pr(|A \cap \text{OPT}| \geq \frac{\varepsilon \cdot n}{\alpha})$.

We view the sampling of A as an iterative process in which the items are sampled one after the other. When sampling the ℓ -th item, the ratio between the remaining items in OPT and the available items is $\approx \frac{k - \frac{t}{\alpha} - \Delta}{n - t - \ell}$, where Δ is the number of items from OPT sampled in previous iterations and $0 \leq \Delta \leq \ell \leq \varepsilon \cdot n$. As $\varepsilon \cdot n$ is small, we estimate $\frac{k - \frac{t}{\alpha} - \Delta}{n - t - \ell} \approx \frac{k - \frac{t}{\alpha}}{n - t}$. Therefore, the probability that the ℓ -th sampled item is in OPT is roughly $\frac{k - \frac{t}{\alpha}}{n - t}$. Thus, $|A \cap \text{OPT}|$ can be estimated as the sum of $\varepsilon \cdot n$ Bernoulli random variables $x_1, \dots, x_{\varepsilon \cdot n}$ with probability $\frac{k - \frac{t}{\alpha}}{n - t}$. Thus,

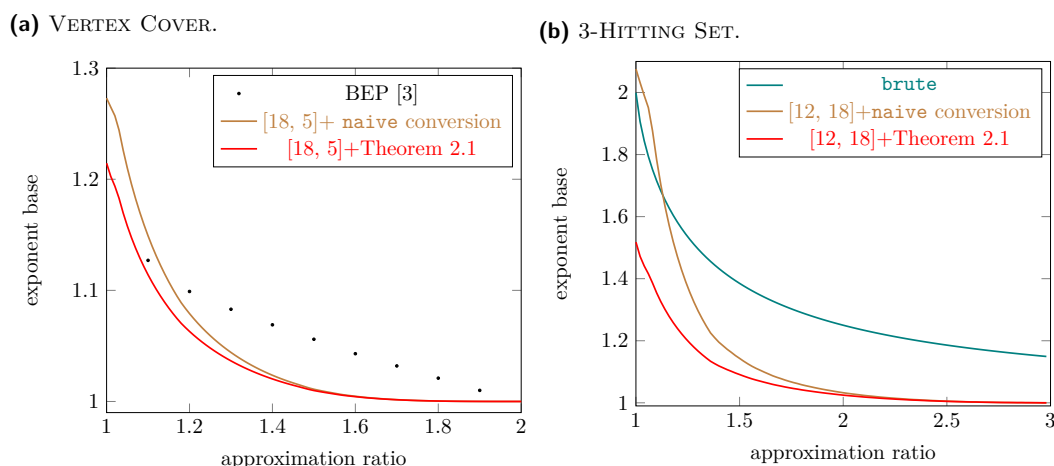

$$\Pr\left(|A \cap \text{OPT}| \geq \frac{\varepsilon \cdot n}{\alpha}\right) \approx \Pr\left(\sum_{i=1}^{\varepsilon \cdot n} x_i \geq \frac{\varepsilon \cdot n}{\alpha}\right) \approx \exp\left(-\varepsilon \cdot n \cdot \mathcal{D}\left(\frac{1}{\alpha} \left\| \frac{k - \frac{t}{\alpha}}{n - t} \right.\right)\right),$$

where the last estimation follows from a large deviation property of binomial distributions [6, Theorem 11.1.4] and assumes $|\text{OPT}| \leq \frac{n}{\alpha}$.

Therefore, the (optimal) selection of t which minimizes $\text{iteration}_{n,k,c}(t)$ is the largest t which satisfies $\exp\left(-\varepsilon \cdot n \cdot \mathcal{D}\left(\frac{1}{\alpha} \left\| \frac{k - \frac{t}{\alpha}}{n - t} \right.\right)\right) > c^{-\frac{\varepsilon \cdot n}{\alpha}}$, or equivalently, $\mathcal{D}\left(\frac{1}{\alpha} \left\| \frac{k - \frac{t}{\alpha}}{n - t} \right.\right) \approx \frac{\ln c}{\alpha}$. We use this value of t to bound the running time of an iteration of Step 2, that is, to upper bound $\min_{t \in [0, \alpha k] \cap \mathbb{N}} \text{iteration}_{n,k,c}(t)$. This analytical estimation of t forms the crux in analyzing the overall running time of Algorithm 2.

2.4 Applications of Approximate-MLS

In this section we use Theorem 2.1 to get faster randomized exponential approximation algorithms for VERTEX COVER, 3-HITTING SET, DIRECTED FEEDBACK VERTEX SET (DFVS), DIRECTED SUBSET FEEDBACK VERTEX SET (SUBSET DFVS), DIRECTED ODD CYCLE TRANSVERSAL (DOCT) and UNDIRECTED MULTICUT. One can observe that all these problems can be described as some Φ_{MIN} -SUBSET problem. Since all these problems can be interpreted as vertex deletion problems to some hereditary graph class, any parameterized α -approximation algorithm for these problems can be used as an (α, Φ) -extension algorithm, for the respective Φ .

■ **Figure 1** Results for VERTEX COVER and 3-HITTING SET. A dot at (α, d) means that the respective algorithm outputs an α -approximation in time $\mathcal{O}^*(d^n)$.

VERTEX COVER (VC). In [3] Bourgeois, Escoffier and Paschos designed several exponential approximation algorithms for VC for approximation ratios in the range $(1, 2)$. For any $\alpha \in (1, 2)$ the best known running time of a parameterized randomized α -approximation algorithm for VC is attained in [18] if $\alpha \gtrsim 1.03$, and in [5] if $\alpha \lesssim 1.03$. We use these algorithms in conjunction with Theorem 2.1 to obtain faster randomized exponential α -approximation algorithms for VC for values of α in the range $(1, 2)$. We compare our running times to the running times obtained by the naive conversion (Benchmark 2) and to the running times in [3].⁴ We present the running time for selected approximation ratios in Table 1 and give a graphical comparison in Figure 1a.

■ **Table 1** Results for VERTEX COVER and 3-HITTING SET. A value d at the column of an approximation ratio α means that the respective algorithm outputs an α -approximation in time $\mathcal{O}^*(d^n)$.

⁴ The result of [3] provides an α -approximation algorithm for every $\alpha \in (1, 2)$. As the evaluation of these running times is not trivial, we only provide the running times which were explicitly given in [3] for selected approximation ratios.

3-HITTING SET (3-HS). The problem admits a simple polynomial-time 3-approximation algorithm which cannot be improved assuming UGC [17]. For any $\alpha \in (1, 3)$ the best known running time of a parameterized α -approximation algorithm for 3-HS is attained by either [12] if $\alpha \lesssim 1.08$, or [18] if $\alpha \gtrsim 1.08$. Using these algorithms as parameterized extension algorithms, we calculate the running times of α -approximation algorithms for 3-HS attained using the naive conversion (Benchmark 2) and Theorem 2.1, for values of $\alpha \in (1, 3)$. We provide the running times for selected approximation ratios in Table 1 and a graphical comparison in Figure 1b.

DFVS, SUBSET DFVS, DOCT, UNDIRECTED MULTICUT. For all these problems [22] gave parameterized 2-approximation algorithms that run in time $\mathcal{O}^*(c^k)$, for some constant $c > 1$. One can easily observe from the description of the DFVS algorithm in [22] that it runs in time $\mathcal{O}^*(1024^k)$. Using Theorem 2.1 we get that DFVS admits an exponential 2-approximation algorithm that runs in time $\mathcal{O}^*(1.2498^n)$. This running time is significantly better than the running time derived using the naive conversion (Benchmark 2) of the algorithm of [22], which does not give anything meaningful for this problem. It is also significantly better than using **Exact-MLS** with the algorithm of [22], which gives $\mathcal{O}^*((\mathbf{e}\mathbf{m}\mathbf{l}\mathbf{s}(1024))^n) = \mathcal{O}^*(1.9991^n)$. It is also qualitatively better than the brute-force 2-approximation algorithm (Benchmark 1), which runs in time $\mathcal{O}^*(1.25^n)$.

Using Lemma 1.1, we can show that we get faster 2-approximation algorithms for all mentioned problems compared to the brute-force 2-approximation algorithm, or the naive conversion of the parameterized algorithms in [22] or the application of **Exact-MLS** with the algorithms of [22]. Note that even though the algorithms derived from Theorem 2.1 are only *qualitatively* better than brute-force approximation, we emphasize that **Approximate-MLS** is always strictly better than brute-force approximation (and the other benchmarks described earlier). Also, it reflects Part 1 of Lemma 1.1, that as c increases (that is, as the parameterized extension algorithm becomes slower), our algorithm converges to the brute-force approximation.

3 Analysis of Approximate Monotone Local Search

This section is dedicated to the proof of Theorem 2.1. As explained earlier, the algorithm promised in Theorem 2.1 is **Approximate-MLS** (Algorithm 2). In Lemma 3.1 we prove the correctness of Algorithm 2 and in Lemma 3.2 we provide a formula for its running time. Finally, in Lemma 3.4 we upper bound the running time of the formula obtained in Lemma 3.2 with $\mathcal{O}^*(\mathbf{a}\mathbf{m}\mathbf{l}\mathbf{s}(\alpha, c)^n)$, thereby proving Theorem 2.1.

► **Lemma 3.1** (Correctness \star). *Approximate-MLS (Algorithm 2) is a randomized α -approximation algorithm for $\Phi_{\text{MIN-SUBSET}}$.*

► **Lemma 3.2** (Running time). *Approximate-MLS (Algorithm 2) runs in time $f_{\alpha,c}(n) \cdot n^{\mathcal{O}(1)}$ where*

$$f_{\alpha,c}(n) := \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \frac{c^{k - \frac{t}{\alpha}}}{\mathbf{hyper}(n, k, t, \frac{t}{\alpha})}. \quad (1)$$

Proof. For each choice of k , Algorithm 2 chooses in Step 3 a number t that minimizes $\frac{c^{k - \frac{t}{\alpha}}}{\mathbf{hyper}(n, k, t, \frac{t}{\alpha})}$. Clearly, this step can be performed in time $n^{\mathcal{O}(1)}$. Afterwards, the algorithm calls Algorithm 1 $\mathbf{hyper}(n, k, t, \frac{t}{\alpha})^{-1}$ times which takes $\frac{c^{k - \frac{t}{\alpha}}}{\mathbf{hyper}(n, k, t, \frac{t}{\alpha})} \cdot n^{\mathcal{O}(1)}$ time in total. So overall, the running time is upper bounded by $f_{\alpha,c}(n) \cdot n^{\mathcal{O}(1)}$. ◀

We now proceed with the main part of the analysis which is to bound $f_{\alpha,c}(n)$ by $\text{amls}(\alpha, c)^n$ up to some polynomial factors. We remark at this point (without giving a proof) that our analysis is in fact tight, that is, it can be shown that $f_{\alpha,c}(n)$ is equal to $\text{amls}(\alpha, c)^n$ up to some polynomial factors in n .

Recall that $\mathcal{H}(p) = -p \ln p - (1-p) \ln(1-p)$ denotes the entropy function. We will use the following bound on binomial coefficients (see, e.g., [6, Example 11.1.3]):

$$\frac{1}{n+1} \cdot \exp\left(n \cdot \mathcal{H}\left(\frac{k}{n}\right)\right) \leq \binom{n}{k} \leq \exp\left(n \cdot \mathcal{H}\left(\frac{k}{n}\right)\right) \quad (2)$$

for all $n, k \in \mathbb{N}$ such that $0 \leq k \leq n$.

Moreover, we also need the following technical lemma. Intuitively speaking, it says that small perturbations to the values of a and b do not change the value of $a \cdot \mathcal{H}\left(\frac{b}{a}\right)$ by a large amount.

► **Lemma 3.3** (*). *For $0 \leq b \leq a \leq n$ and $\varepsilon, \delta \in [-1, 1]$ such that $a + \varepsilon \geq 0$ and $0 \leq b + \delta \leq a + \varepsilon$, we have $\left|a \cdot \mathcal{H}\left(\frac{b}{a}\right) - (a + \varepsilon) \cdot \mathcal{H}\left(\frac{b+\delta}{a+\varepsilon}\right)\right| = \mathcal{O}(\log(n))$.*

Finally, recall that $\mathcal{D}(a||b) = a \ln \frac{a}{b} + (1-a) \ln \frac{1-a}{1-b}$ denotes the Kullback-Leibler divergence (see, e.g., [6]).

► **Lemma 3.4.** *It holds that*

$$f_{\alpha,c}(n) = \mathcal{O}^*(\text{amls}(\alpha, c)^n).$$

Proof. Recall that $\text{hyper}(n, k, t, \frac{t}{\alpha})$ denotes the probability that a uniformly random set X of t elements out of $[n]$ satisfies that $|X \cap [k]| \geq \frac{t}{\alpha}$. Thus, we have that

$$\text{hyper}\left(n, k, t, \frac{t}{\alpha}\right) = \sum_{y \geq \lceil \frac{t}{\alpha} \rceil} \frac{\binom{k}{y} \binom{n-k}{t-y}}{\binom{n}{t}} \geq \frac{\binom{k}{\lceil \frac{t}{\alpha} \rceil} \binom{n-k}{t-\lceil \frac{t}{\alpha} \rceil}}{\binom{n}{t}} = \frac{\binom{t}{\lceil \frac{t}{\alpha} \rceil} \binom{n-t}{k-\lceil \frac{t}{\alpha} \rceil}}{\binom{n}{k}}, \quad (3)$$

where the last equality holds since the distribution of $|X \cap [k]|$, where $X \subseteq [n]$ is a uniformly random set of cardinality t , is identical to the distribution of $|Y \cap [t]|$ where $Y \subseteq [n]$ is a uniformly random set of cardinality k .

Using (3) we have

$$\begin{aligned} f_{\alpha,c}(n) &= \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \frac{c^{k-\frac{t}{\alpha}}}{\text{hyper}(n, k, t, \frac{t}{\alpha})} \leq \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \frac{c^{k-\frac{t}{\alpha}} \cdot \binom{n}{k}}{\binom{t}{\lceil \frac{t}{\alpha} \rceil} \binom{n-t}{k-\lceil \frac{t}{\alpha} \rceil}} \\ &\leq n^{\mathcal{O}(1)} \cdot \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k] \cap \mathbb{N}} \left(\left(k - \frac{t}{\alpha}\right) \ln(c) - t \cdot \mathcal{H}\left(\frac{\lceil \frac{t}{\alpha} \rceil}{t}\right) - (n-t) \cdot \mathcal{H}\left(\frac{k - \lceil \frac{t}{\alpha} \rceil}{n-t}\right) \right)\right) \quad (4) \\ &\leq n^{\mathcal{O}(1)} \cdot \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k] \cap \mathbb{N}} \left(\left(k - \frac{t}{\alpha}\right) \ln(c) - t \cdot \mathcal{H}\left(\frac{1}{\alpha}\right) - (n-t) \cdot \mathcal{H}\left(\frac{k - \frac{t}{\alpha}}{n-t}\right) \right)\right) \end{aligned}$$

where the second inequality follows from (2) and the third inequality follows from Lemma 3.3.

Define

$$g_{n,k}(t) := \left(k - \frac{t}{\alpha}\right) \ln(c) - t \cdot \mathcal{H}\left(\frac{1}{\alpha}\right) - (n-t) \cdot \mathcal{H}\left(\frac{k - \frac{t}{\alpha}}{n-t}\right).$$

50:12 Approximate Monotone Local Search

By Lemma 3.3 it holds that $|g_{n,k}(t) - g_{n,k}(t - \varepsilon)| = \mathcal{O}(\log n)$ for any $t \in [0, \alpha k]$ and $0 \leq \varepsilon \leq \min\{1, t\}$. Using this observation and (4) we get

$$\begin{aligned} f_{\alpha,c}(n) &\leq n^{\mathcal{O}(1)} \cdot \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k] \cap \mathbb{N}} g_{n,k}(t)\right) \\ &\leq n^{\mathcal{O}(1)} \cdot \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k]} g_{n,k}(t)\right). \end{aligned} \quad (5)$$

Observe that in the last term the range of t is not restricted to integral values.

Let $\delta^* = \frac{\text{amls}(\alpha, c) - 1}{c - 1}$. By the definition of amls it holds that $\delta^* \in (0, \frac{1}{\alpha})$ and $\mathcal{D}\left(\frac{1}{\alpha} \parallel \delta^*\right) = \frac{\ln(c)}{\alpha}$. Define $t^*(n, k) := \frac{k - n\delta^*}{\frac{1}{\alpha} - \delta^*}$, thus $\frac{k - \frac{t^*(n, k)}{\alpha}}{n - t^*(n, k)} = \delta^*$ and $\mathcal{D}\left(\frac{1}{\alpha} \parallel \frac{k - \frac{t^*(n, k)}{\alpha}}{n - t^*(n, k)}\right) = \frac{\ln c}{\alpha}$ for every $n \in \mathbb{N}$ and $k \in \mathbb{N}$. It can be verified that $g_{n,k}(t)$ is convex and has a global minimum at $t^*(n, k)$, though this observation is not directly used by our proof.

For any $n \in \mathbb{N}$ and $k \in [0, \frac{n}{\alpha}] \cap \mathbb{N}$ it holds that $t^*(n, k) = \frac{\alpha k (\frac{1}{\alpha} - \delta^*) + \alpha k \delta^* - n \delta^*}{\frac{1}{\alpha} - \delta^*} \leq \alpha k$ since $\alpha k \leq n$. Furthermore, $t^*(n, k) \geq 0$ if and only if $k \geq n\delta^*$. Following this observation we partition the summation in (5) into two parts. Define

$$A(n) = \sum_{k=0}^{\lfloor n\delta^* \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k]} g_{n,k}(t)\right) \text{ and } B(n) = \sum_{k=\lfloor n\delta^* \rfloor + 1}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \exp\left(\min_{t \in [0, \alpha k]} g_{n,k}(t)\right).$$

Thus, $f_{\alpha,c}(n) \leq n^{\mathcal{O}(1)} \cdot (A(n) + B(n))$. We bound each of the sums $A(n)$ and $B(n)$ separately.

In order to bound $B(n)$ we use the following algebraic identity.

▷ **Claim 3.5** (\star). It holds that

$$g_{n,k}(t) = \left(k - \frac{t}{\alpha}\right) \ln(c) + t \cdot \mathcal{D}\left(\frac{1}{\alpha} \parallel \frac{k - \frac{t}{\alpha}}{n - t}\right) + k \cdot \ln\left(\frac{k - \frac{t}{\alpha}}{n - t}\right) + (n - k) \cdot \ln\left(1 - \frac{k - \frac{t}{\alpha}}{n - t}\right).$$

For any $n \in \mathbb{N}$ and $k \in [n\delta^*, \frac{n}{\alpha}] \cap \mathbb{N}$ it holds that $0 \leq t^*(n, k) \leq \alpha k$. Thus,

$$\begin{aligned} \min_{t \in [0, \alpha k]} g_{n,k}(t) &\leq g_{n,k}(t^*(n, k)) \\ &= \left(k - \frac{t^*(n, k)}{\alpha}\right) \ln(c) + t^*(n, k) \cdot \mathcal{D}\left(\frac{1}{\alpha} \parallel \delta^*\right) + k \cdot \ln(\delta^*) + (n - k) \cdot \ln(1 - \delta^*) \\ &= k \cdot \ln(c) + k \cdot \ln(\delta^*) + (n - k) \cdot \ln(1 - \delta^*) \\ &= k \cdot \ln\left(\frac{c \cdot \delta^*}{1 - \delta^*}\right) + n \cdot \ln(1 - \delta^*), \end{aligned}$$

where the first equality uses Claim 3.5 and the second equality follows from $\mathcal{D}\left(\frac{1}{\alpha} \parallel \delta^*\right) = \frac{\ln(c)}{\alpha}$. Therefore,

$$\begin{aligned} B(n) &= \sum_{k=\lfloor n\delta^* \rfloor + 1}^{\lfloor \frac{n}{\alpha} \rfloor} \binom{n}{k} \cdot \exp\left(\min_{t \in [0, \alpha k]} g_{n,k}(t)\right) \leq \sum_{k=0}^n \binom{n}{k} \left(\frac{c \cdot \delta^*}{1 - \delta^*}\right)^k (1 - \delta^*)^n \\ &= (1 - \delta^*)^n \left(\frac{c \cdot \delta^*}{1 - \delta^*} + 1\right)^n = ((c - 1)\delta^* + 1)^n \end{aligned} \quad (6)$$

using the Binomial Theorem.

We now proceed to bound $A(n)$. For every $n \in \mathbb{N}$ and $0 \leq k \leq \delta^* n$ it holds that

$$\min_{t \in [0, \alpha k]} g_{n,k}(t) \leq g_{n,k}(0) = k \cdot \ln(c) - n \cdot \mathcal{H}\left(\frac{k}{n}\right) \leq k \cdot \ln c - \ln \binom{n}{k},$$

where the last inequality follows from (2). Therefore,

$$A(n) = \sum_{k=0}^{\lfloor n\delta^* \rfloor} \binom{n}{k} \cdot \exp\left(\min_{t \in [0, \alpha k]} g_{n,k}(t)\right) \leq \sum_{k=0}^{\lfloor n\delta^* \rfloor} c^k \leq n \cdot (c^{\delta^*})^n. \quad (7)$$

Finally, by using (6) and (7), we get

$$\begin{aligned} f_{\alpha,c}(n) &\leq n^{\mathcal{O}(1)} \cdot (A(n) + B(n)) \leq n^{\mathcal{O}(1)} \cdot \left((c^{\delta^*})^n + ((c-1)\delta^* + 1)^n\right) \\ &\leq n^{\mathcal{O}(1)} \cdot ((c-1)\delta^* + 1)^n, \end{aligned}$$

where the third inequality uses $c^{\delta^*} \leq (c-1)\delta^* + 1$ which holds because $f(x) := c^x - (c-1)x - 1$ is convex and has two roots at 0 and 1. By the definition of δ^* it holds that $(c-1)\delta^* + 1 = \text{aml}_s(\alpha, c)$ and thus, $f_{\alpha,c}(n) \leq n^{\mathcal{O}(1)} \cdot \text{aml}_s(\alpha, c)^n$. \blacktriangleleft

Finally, Theorem 2.1 is implied by Lemmas 3.1, 3.2 and 3.4.

4 Derandomization

In this section, we show how to derandomize Algorithm 2. In particular, we prove Theorem 2.2. As usual, let (U_I, \mathcal{F}_I) be a set system and let $k, t, n \in \mathbb{N}$ be the variables from Algorithm 2 and let $\alpha \geq 1$. In order to derandomize the algorithm, it is sufficient to find a collection \mathcal{C} of subsets of U_I of size t such that, for every possible solution set $S \subseteq U_I$ of size k , there is some set $X \in \mathcal{C}$ such that $|X \cap S| \geq \frac{t}{\alpha}$. We refer to such a family \mathcal{C} as an $(n, k, t, \frac{t}{\alpha})$ -set-intersection-family which is formally defined below.

► **Definition 4.1.** *Let U be a universe of size n and let $p, q, r \geq 1$ such that $n \geq p \geq r$ and $n - p + r \geq q \geq r$. A family $\mathcal{C} \subseteq \binom{U}{q}$ is a (n, p, q, r) -set-intersection-family if for every $T \in \binom{U}{p}$ there is some $X \in \mathcal{C}$ such that $|T \cap X| \geq r$.*

Given a $(n, k, t, \frac{t}{\alpha})$ -set-intersection-family \mathcal{C} we can derandomize Algorithm 2 by iterating over all choices $X \in \mathcal{C}$ instead of repeatedly sampling a set X uniformly at random. Observe that the derandomized algorithm (for a fixed k, t) runs in time $\mathcal{O}^*(|\mathcal{C}| \cdot c^{k - \frac{t}{\alpha}})$. Now, we define

$$\kappa(n, p, q, r) := \frac{\binom{n}{q}}{\binom{p}{r} \cdot \binom{n-p}{q-r}}.$$

The following theorem computes the desired set-intersection-family of small size.

► **Theorem 4.2** (\star). *There is an algorithm that, given a set U of size n and $p, q, r \geq 1$ such that $n \geq p \geq r$ and $n - p + r \geq q \geq r$, computes an (n, p, q, r) -set-intersection-family of size $\kappa(n, p, q, r) \cdot 2^{\mathcal{O}(n)}$ in time $\kappa(n, p, q, r) \cdot 2^{\mathcal{O}(n)}$.*

For the proof of Theorem 4.2 we extend the arguments from [13] which provide such a result for the special case when $q = r$ (which corresponds to the case $\alpha = 1$).

50:14 Approximate Monotone Local Search

Proof of Theorem 2.2. We proceed analogously to the proof of Theorem 2.1 with the following changes. In Algorithm 2, Step 3 we define

$$t := \operatorname{argmin}_{t \in [0, \alpha k] \cap \mathbb{N}} \kappa \left(n, k, t, \left\lceil \frac{t}{\alpha} \right\rceil \right) c^{k - \frac{t}{\alpha}}$$

and then compute an $(n, k, t, \frac{t}{\alpha})$ -set-intersection-family \mathcal{C} of size $\kappa(n, p, q, r) \cdot 2^{o(n)}$ using Theorem 4.2. Afterwards, we repeatedly execute Algorithm 1 for every $X \in \mathcal{C}$ (instead of sampling X uniformly at random). Repeating the analysis of Lemma 3.2 the running time is bounded by $\mathcal{O}^*(f_{\alpha, c}(n))$ where,

$$f_{\alpha, c}(n) = \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \kappa \left(n, k, t, \left\lceil \frac{t}{\alpha} \right\rceil \right) c^{k - \frac{t}{\alpha}} \cdot 2^{o(n)}.$$

As we already proved in Lemma 3.4 it holds that

$$\begin{aligned} \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \kappa \left(n, k, t, \left\lceil \frac{t}{\alpha} \right\rceil \right) c^{k - \frac{t}{\alpha}} &= \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \frac{c^{k - \lceil \frac{t}{\alpha} \rceil} \cdot \binom{n}{t}}{\binom{k}{\lceil \frac{t}{\alpha} \rceil} \binom{n-k}{t - \lceil \frac{t}{\alpha} \rceil}} \\ &= \sum_{k=0}^{\lfloor \frac{n}{\alpha} \rfloor} \min_{t \in [0, \alpha k] \cap \mathbb{N}} \frac{c^{k - \lceil \frac{t}{\alpha} \rceil} \cdot \binom{n}{k}}{\binom{t}{\lceil \frac{t}{\alpha} \rceil} \binom{n-t}{k - \lceil \frac{t}{\alpha} \rceil}} \leq \mathbf{amls}(\alpha, c)^n \cdot n^{\mathcal{O}(1)} \end{aligned}$$

which results in the running time stated in the theorem. \blacktriangleleft

5 The Brute-Force Approximation Algorithm

In this section we describe an α -approximate variant of exhaustive search that runs in time $\mathcal{O}^*((\mathbf{brute}(\alpha))^n)$, where $\mathbf{brute}(\alpha) = 1 + \exp(-\alpha \cdot \mathcal{H}(\frac{1}{\alpha}))$. We complement this result by showing that $\mathcal{O}^*((\mathbf{brute}(\alpha))^n)$ is the best possible running time of an α -approximation algorithm for a subset minimization problem in the *oracle model* defined below.

A (randomized) *oracle α -approximation minimum subset* algorithm takes as input a universe U and receives a membership oracle to a *monotone* family $\mathcal{F} \subseteq 2^U$. The algorithm returns a set $S \in \mathcal{F}$ such that $|S| \leq \alpha \cdot \min \{|T| \mid T \in \mathcal{F}\}$ (with constant probability).

► **Theorem 5.1.** *For any $\alpha \geq 1$, there is a deterministic oracle α -approximation minimum subset algorithm which runs in time $\mathcal{O}^*((\mathbf{brute}(\alpha))^n)$. Moreover, there is no randomized oracle α -approximation minimum subset algorithm which uses $\mathcal{O}^*(c^n)$ oracle queries for any $c < \mathbf{brute}(\alpha)$.*

The proof of Theorem 5.1 utilizes the technical bound proved in Lemma 5.2. The proof of Lemma 5.2 uses arguments that similar to the ones used in the proof of Lemma 3.4.

► **Lemma 5.2 (*)**. *For any $n \in \mathbb{N}$ and $\alpha \geq 1$ it holds that*

$$n^{-\mathcal{O}(1)} \cdot (\mathbf{brute}(\alpha))^n \leq \max_{k \in [0, \frac{n}{\alpha}] \cap \mathbb{N}} \frac{\binom{n}{k}}{\binom{\lfloor \alpha k \rfloor}{k}} \leq n^{\mathcal{O}(1)} \cdot (\mathbf{brute}(\alpha))^n$$

To obtain the claimed algorithm of Theorem 5.1 the basic idea is to sample $\mathcal{O}^*((\mathbf{brute}(\alpha))^n)$ random sets (of some size k) and show that the desired approximate solution is found with constant probability. This algorithm can be derandomized by using

Theorem 4.2 for the special case when $p = r$. However, this introduces another sublinear term in the exponent of the running time. Instead, in this special case, we can rely on existing results on covering families [19].

Let $k < t < n$ be natural numbers and recall $[n] := \{1, 2, \dots, n\}$. An (n, t, k) -covering is a family $\mathcal{C} \subseteq \{X \mid X \subseteq [n], |X| = t\}$ such that, for every $S \subseteq [n]$ of size $|S| = k$, there is some $X \in \mathcal{C}$ such that $S \subseteq X$. To construct the algorithm for Theorem 5.1, we exploit known constructions of (n, t, k) -coverings of almost optimal size.

► **Theorem 5.3** (Kuzjurin [19]). *There is an algorithm that, given $k < t < n$, computes an (n, t, k) -covering \mathcal{C} of size $(1 + o(1)) \cdot \binom{n}{k} / \binom{t}{k}$ in time $|\mathcal{C}| \cdot n^{\mathcal{O}(1)}$.*

Proof of Theorem 5.1. We first show the algorithmic part. By renaming elements, we may assume $U = [n]$. For every $k \leq n/\alpha$ we compute a $(n, \lfloor \alpha k \rfloor, k)$ -covering \mathcal{C}_k using Theorem 5.3 and check for every set $X \in \mathcal{C}_k$ whether it is contained in \mathcal{F} using the oracle. We return the smallest set that is contained in \mathcal{F} . If no such set is found, we return the entire universe.

It is easy to see that this algorithm is an α -approximation algorithm. Indeed, let $\text{OPT} \subseteq U$ be a solution set of minimum cardinality and let $k := |\text{OPT}|$. If $k \geq n/\alpha$, then the algorithm is clearly correct since even returning the entire universe gives the desired approximation ratio. So suppose that $k \leq n/\alpha$. By definition of an $(n, \lfloor \alpha k \rfloor, k)$ -covering there is some $X \in \mathcal{C}_k$ such that $\text{OPT} \subseteq X$ and $|X| = \lfloor \alpha k \rfloor \leq \alpha k$. Since \mathcal{F} is monotone we get that $X \in \mathcal{F}$ and the algorithm returns a solution set of size at most $|X| \leq \alpha k$.

By Theorem 5.3, the algorithm runs in time $\max_{k \in [0, \frac{n}{\alpha}] \cap \mathbb{N}} \binom{n}{k} / \binom{\lfloor \alpha k \rfloor}{k} \cdot n^{\mathcal{O}(1)}$. From Lemma 5.2 we get that the running time is bounded by $(\text{brute}(\alpha))^n \cdot n^{\mathcal{O}(1)}$.

Next, we prove the lower bound. For $n \in \mathbb{N}$ define $\kappa(n) = \arg\max_{k \in [0, \frac{n}{\alpha}] \cap \mathbb{N}} \binom{n}{k} / \binom{\lfloor \alpha k \rfloor}{k}$. For every $n \in \mathbb{N}$ we define $\mathcal{F}_{\text{adv}}(n) = \{S \subseteq [n] \mid |S| > \alpha \kappa(n)\}$. Also, for every $n \in \mathbb{N}$ and $X \subseteq [n]$ we define $\mathcal{F}(n, X) = \{S \subseteq [n] \mid X \subseteq S\} \cup \mathcal{F}_{\text{adv}}(n)$. It can be easily observed that $\mathcal{F}(n, X)$ and $\mathcal{F}_{\text{adv}}(n)$ are monotone set families. Our bound is based on the difficulty that algorithms have to distinguish between $\mathcal{F}_{\text{adv}}(n)$ and $\mathcal{F}(n, X)$.

Let \mathcal{A} be a randomized oracle α -approximation minimum subset algorithm. Without loss of generality we assume \mathcal{A} only returns a set S if it queried the oracle with that set (and got back a positive answer). Let $q(n)$ be the maximal number of oracle queries the algorithm uses given a universe of size n . As the algorithm is randomized, we use R to denote the random sequence of bits used by the algorithm.

Fix $n \in \mathbb{N}$. For any $j \in [q(n)]$ the j -th query to the oracle is a function of the previous answers the algorithm received from the oracle and the sequence of random bits the algorithm uses. Thus, there is a function $S_j(R)$ which returns the j -th query the algorithm sends to the oracle, given that the algorithm gets an oracle to $\mathcal{F}_{\text{adv}}(n)$. If the algorithm does not issue the j -th query given R we arbitrarily define $S_j(R) = \emptyset$.

Let $X \subseteq [n]$ be a random set of size $\kappa(n)$ which is sampled uniformly (and independently of R). Consider the execution of \mathcal{A} with the universe $[n]$ and an oracle for $\mathcal{F}(n, X)$. Define

$$\mathcal{C}(R) = \bigcup_{j=1}^{q(n)} \begin{cases} \{T \subseteq [n] \mid |T| = \kappa(n), T \subseteq S_j(R)\} & \text{if } |S_j(R)| \leq \alpha \cdot \kappa(n) \\ \emptyset & \text{otherwise} \end{cases}. \quad (8)$$

If $X \notin \mathcal{C}(R)$ then the answers the algorithm receives to its queries are identical to the answers it would have received if it was given an oracle $\mathcal{F}_{\text{adv}}(n)$. It therefore asks the same queries, and must return a set $S \in \mathcal{F}_{\text{adv}}(n)$. As \mathcal{A} is a randomized α -approximation algorithm, there is $\gamma \in (0, 1]$ such that \mathcal{A} returns a set $S \in \mathcal{F}(n, X)$ which satisfies $|S| \leq \alpha \cdot |X| = \alpha \cdot \kappa(n)$ with probability at least γ . As all the sets in $\mathcal{F}_{\text{adv}}(n)$ have cardinality greater than $\alpha \cdot \kappa(n)$ it follows that $\Pr(X \notin \mathcal{C}(R)) \leq 1 - \gamma$, or equivalently, $\Pr(X \in \mathcal{C}(R)) \geq \gamma$.

50:16 Approximate Monotone Local Search

By the definition of $\mathcal{C}(R)$ (8), each query $S_j(R)$ adds at most $\binom{\lfloor \alpha \cdot \kappa(n) \rfloor}{\kappa(n)}$ sets to $\mathcal{C}(R)$. Thus $|\mathcal{C}(R)| \leq q(n) \cdot \binom{\lfloor \alpha \cdot \kappa(n) \rfloor}{\kappa(n)}$. Since X is independent of R we have,

$$\gamma \leq \Pr(X \in \mathcal{C}(R)) \leq \frac{q(n) \cdot \binom{\lfloor \alpha \cdot \kappa(n) \rfloor}{\kappa(n)}}{\binom{n}{\kappa(n)}},$$

and hence

$$q(n) \geq \gamma \cdot \frac{\binom{n}{\kappa(n)}}{\binom{\lfloor \alpha \cdot \kappa(n) \rfloor}{\kappa(n)}} = \gamma \cdot \max_{k \in [0, \frac{n}{\alpha}] \cap \mathbb{N}} \frac{\binom{n}{k}}{\binom{\lfloor \alpha k \rfloor}{k}} \geq n^{-\mathcal{O}(1)} \cdot (\mathbf{brute}(\alpha))^n,$$

where the equality follows from the definition of $\kappa(n)$ and the last inequality follows from Lemma 5.2. In particular, \mathcal{A} does not use $\mathcal{O}^*(c^n)$ oracle queries for any $c < \mathbf{brute}(\alpha)$. ◀

6 Concluding Remarks

We introduced and analyzed approximate monotone local search **Approximate-MLS** which can be used to obtain faster exponential approximation algorithms from parameterized (extension) approximation algorithms for monotone subset minimization problems. In particular, we obtain faster exponential approximation algorithms for **VERTEX COVER**, **3-HITTING SET**, **DFVS**, **SUBSET DFVS**, **DOCT** and **UNDIRECTED MULTICUT** (for some approximation ratios).

Following the submission of this work we became aware of a similar application of monotone local search in the PhD thesis of Lee [20]. However, Lee mainly provides experimental evaluations of the running time of approximate monotone local search for specific problems such as **VERTEX COVER** and **FEEDBACK VERTEX SET**, and does not provide a rigorous analysis of the general running time which is the main focus of this work.

The significance of **Exact-MLS** stems from the abundance of existing parameterized (extension) algorithms which can be used to obtain the state-of-art exponential algorithms for multiple problems. **Approximate-MLS** has a similar potential in the context of exponential approximation algorithms. Thus, our result further emphasizes the importance of the already-growing field of parameterized approximation, by exhibiting its strong connections with exponential-time approximations.

Some interesting follow-up questions of our work are the following.

► **Problem 6.1.** *Can an α -approximate algorithm running in time $\mathcal{O}^*((\mathbf{brute}(\alpha) - \varepsilon)^n)$ be derived from a parameterized extension β -approximation algorithm for any $\beta > \alpha$?*

For example, for **DIRECTED FEEDBACK VERTEX SET** only a parameterized 2-approximation algorithm running in time $\mathcal{O}^*(c^k)$ [22] is currently available. The question is whether this algorithm can also be used to obtain an exponential 1.1-approximation algorithm that runs in time $\mathcal{O}^*((\mathbf{brute}(1.1) - \varepsilon)^n)$, for some $\varepsilon > 0$?

We also described and showed that the exhaustive search analog in the α -approximate setting achieves the best possible running time of $\mathcal{O}^*((\mathbf{brute}(\alpha))^n)$ when one only has access to a membership oracle for the problem. Observe that for $\alpha = 1$, **SETH** asserts that $(\mathbf{brute}(1))^n = 2^n$ is tight.

► **Problem 6.2.** *Does there exist a monotone subset minimization problem for which there is no α -approximation algorithm that runs in time $\mathcal{O}^*((\mathbf{brute}(\alpha) - \varepsilon)^n)$, assuming **SETH**?*

Recall that the `Approximate-MLS` algorithm only uses random sampling and the given parameterized α -approximation extension algorithm. Another interesting lower bound question is the following.

► **Problem 6.3.** *Can one show that the running time of `Approximate-MLS` is tight (up to polynomial factors) when one is only given access to a membership oracle and a parameterized α -approximation extension algorithm as a black-box?*

Intersection Searching Amid Tetrahedra in 4-Space and Efficient Continuous Collision Detection

Esther Ezra

Abstract

We develop data structures for intersection detection queries in four dimensions that involve segments, triangles and tetrahedra. Specifically, we study two main problems: (i) Preprocess a set of n tetrahedra in \mathbb{R}^4 into a data structure for answering segment-intersection queries amid the given tetrahedra (referred to as *segment-tetrahedron intersection queries*), and (ii) Preprocess a set of n triangles in \mathbb{R}^4 into a data structure that supports triangle-intersection queries amid the input triangles (referred to as *triangle-triangle intersection queries*). As far as we can tell, these problems have not been previously studied.

For problem (i), we first present a “standard” solution which, for any prespecified value $n \leq s \leq n^6$ of a so-called storage parameter s , yields a data structure with $O^*(s)$ storage and expected preprocessing, which answers an intersection query in $O^*(n/s^{1/6})$ time (here and in what follows, the $O^*(\cdot)$ notation hides subpolynomial factors). For problem (ii), using similar arguments, we present a solution that has the same asymptotic performance bounds.

We then improve the solution for problem (i), and present a more intricate data structure that uses $O^*(n^2)$ storage and expected preprocessing, and answers a segment-tetrahedron intersection query in $O^*(n^{1/2})$ time. Using the parametric search technique of Agarwal and Matoušek [3], we can obtain data structures with similar performance bounds for the *ray-shooting* problem amid tetrahedra in \mathbb{R}^4 . Unfortunately, so far we do not know how to obtain a similar improvement for problem (ii).

Our algorithms are based on a primal-dual technique for range searching with semi-algebraic sets, based on recent advances in this area [2, 11]. As this is a result of independent interest, we spell out the details of this technique.

As an application, we present a solution to the problem of “continuous collision detection” amid moving tetrahedra in 3-space. That is, the workspace consists of n tetrahedra, each moving at its own fixed velocity, and the goal is to detect a collision between some pair of moving tetrahedra. Using our solutions to problems (i) and (ii), we obtain an algorithm that detects a collision in $O^*(n^{12/7})$ expected time. We also present further applications, including an output-sensitive algorithm for constructing the arrangement of n tetrahedra in \mathbb{R}^4 and an output-sensitive algorithm for constructing the intersection or union of two or several nonconvex polyhedra in \mathbb{R}^4 .

1 Introduction

In this paper we consider various intersection problems involving segments, triangles and tetrahedra in \mathbb{R}^4 . In four dimensions, the interesting setups involve (i) intersections between (one-dimensional) segments and (three-dimensional) tetrahedra, and (ii) between (two-dimensional) triangles and (two-dimensional) triangles. We study both problems, and derive efficient solutions to each of them.

As an interesting application, we consider the *continuous collision detection* problem, where the input consists of n tetrahedra in \mathbb{R}^3 , each of which is moving at some constant velocity of its own, and the goal is to detect whether any pair of them collide. Adding the time as a fourth coordinate, this becomes a batched version of intersection detection in \mathbb{R}^4 , involving both setups (i) and (ii). Other applications include output-sensitive construction of the arrangement of n tetrahedra in \mathbb{R}^4 , and an output-sensitive algorithm for computing the intersection or the union of two or several not necessarily convex polyhedra in \mathbb{R}^4 . In the three-dimensional versions of these problems, which were recently studied in [7], the only setup that needed to be considered was segment intersection amid triangles. In four dimensions, though, we also face the triangle-triangle intersection problem, since we also need to find intersections between pairs of 2-faces of the input objects.

Setup (i): Segment-tetrahedron intersection queries. Consider first the case of segments vs. tetrahedra. In the setup considered here, the input objects are n (not necessarily pairwise openly disjoint) tetrahedra in \mathbb{R}^4 and the query objects are segments, and the goal is to detect, count, or report intersections between the query segment and the input tetrahedra.

As far as we can tell, this problem has not been explicitly studied so far. We first present, in Section 2, a “traditional” (albeit novel) solution, in which the problem is reduced to a range searching problem in a suitable parametric space, which, in the case of (lines supporting) segments in \mathbb{R}^4 , is six-dimensional. We carefully adapt and combine recent techniques, developed by Agarwal et al. [2] and Matoušek and Patáková [11], which provide algorithmic constructions of intricate space decompositions based on partitioning polynomials. Using this machinery, we solve the problem so that, with a so-called storage parameter s , a segment intersection query can be answered in¹ $O^*(n/s^{1/6})$ time, for any $n \leq s \leq n^6$, and the storage and preprocessing cost are both $O^*(s)$.

A special case of this setup is an extension to four dimensions of the classical *ray shooting* problem, which has mostly been studied in two and three dimensions. In a general setting, we are given a collection S of n simply-shaped objects, and the goal is to preprocess S into a data structure that supports efficient ray shooting queries, where each query specifies a ray ρ and asks for the first object of S hit by ρ , if such an object exists. In this work we only consider the (already challenging) case of input tetrahedra. Using the parametric search technique of Agarwal and Matoušek [3], ray shooting queries can be reduced to segment-intersection detection queries, up to a polylogarithmic factor in the query cost. By the above discussion, we obtain the following result:

► **Theorem 1.** *Given a collection \mathcal{T} of n tetrahedra in \mathbb{R}^4 , and any storage parameter $n \leq s \leq n^6$, we can preprocess \mathcal{T} into a data structure of size $O^*(s)$, in randomized $O^*(s)$ expected time, so that we can answer any segment-intersection or ray-shooting query in \mathcal{T} in $O^*(n/s^{1/6})$ time. The query time bound applies to segment-intersection detection and counting queries (and to ray shooting queries). The cost is $O^*(n/s^{1/6}) + O(k)$ for reporting queries.*

¹ As in the abstract, the $O^*(\cdot)$ notation hides subpolynomial factors, typically of the form n^ε , for any $\varepsilon > 0$, and their coefficients which depend on ε .

We later improve upon this standard algorithm in Section 4, where we show:

► **Theorem 2.** *A collection S of n arbitrary tetrahedra in \mathbb{R}^4 can be preprocessed into a data structure of size $O^*(n^2)$, in expected time $O^*(n^2)$, which supports segment-intersection detection and counting queries and ray-shooting queries in time $O^*(n^{1/2})$ per query.*

This indeed improves the bounds stated in Theorem 1, which, with $s = O^*(n^2)$ storage, has query time $O^*(n^{2/3})$. Furthermore, with the storage bound specified in Theorem 2, the query bound is similar to that obtained for ray-shooting amid hyperplanes (rather than tetrahedra) in \mathbb{R}^4 [3].

We then go on, in the full version of the paper² to extend the result to obtain a tradeoff between storage (and expected preprocessing time) and query time. We show that, with storage parameter s , which can vary between n and n^6 , we can answer a segment intersection or a ray shooting query in time

$$Q(n, s) = \begin{cases} O^*\left(\frac{n^{7/6}}{s^{1/3}}\right) & \text{for } s = O(n^2) \\ O^*\left(\frac{n^{3/4}}{s^{1/8}}\right) & \text{for } s = \Omega(n^2). \end{cases} \quad (1)$$

See Figure 1 for an illustration. This yields algorithms that answer m segment intersection or ray-shooting queries on n tetrahedra in $\max\{O^*(m^{3/4}n^{7/8} + n), O^*(m^{8/9}n^{2/3} + m)\}$ time and storage. The first (resp., second) bound dominates when $m \leq n^{3/2}$ (resp., $m \geq n^{3/2}$).

■ **Figure 1** The tradeoff between storage and query time. The breakpoint in the graph represents the case studied in Section 4. Both axes are drawn on a logarithmic scale.

Setup (ii): Triangle-triangle intersection detection. We next consider the other setup of intersection queries, where both input and query objects are triangles in \mathbb{R}^4 . We show that this setup can also be reduced, similar to setup (i), to a multi-level range searching problem in \mathbb{R}^6 involving semi-algebraic ranges. This allows us to obtain the same performance bounds here too. Namely we have:

► **Theorem 3.** *Given a collection Δ of n triangles in \mathbb{R}^4 , and any storage parameter $n \leq s \leq n^6$, we can preprocess Δ into a data structure of size $O^*(s)$, in randomized $O^*(s)$ expected time, so that we can answer any triangle-intersection query in Δ in $O^*(n/s^{1/6})$ time.*

² Soon to be available on arXiv.

Since both input and query objects are triangles, it is also interesting to consider the bichromatic batched version of the problem. Namely we have:

► **Theorem 4.** *Given two collections R and B of triangles in \mathbb{R}^4 , of respective sizes m and n , We can detect an intersection between some triangle of R and some triangle of B , or count all such intersections, in time $O^*(m^{6/7}n^{6/7} + m + n)$. We can also report all these intersections in time $O^*(m^{6/7}n^{6/7} + m + n + k)$, where k is the output size.*

As a consequence, integrating this bound with the one obtained in Theorem 1 (in which, similar to the preceding argument, we need to set $s = n^{12/7}$ to match the performance with that stated above, as is easily verified), we obtain an overall $O^*(n^{12/7})$ expected time solution for the continuous collision detection problem, that is:³

► **Theorem 5.** *Given n tetrahedra in \mathbb{R}^3 , each of which is moving at some constant velocity of its own, one can detect a collision between any pair of moving tetrahedra in $O^*(n^{12/7})$ expected time.*

Collision detection has been widely studied – see Lin, Manocha and Kim [10] for a recent comprehensive survey, and the references therein. We are not aware of any work that addresses the exact algorithmic approach for the specific setup considered here, although there are some works, such as Canny [6] or Schömer and Thiel [12], that address similar contexts.

We then consider the applications of our techniques to the problems of output-sensitive construction of an arrangement of tetrahedra in \mathbb{R}^4 , and of constructing the intersection or union of two or several (nonconvex) polyhedra in \mathbb{R}^4 . Using the bounds for setups (i) and (ii), we obtain, in Section 5:

► **Theorem 6.** *(i) Let \mathcal{T} be a collection of n tetrahedra in general position in \mathbb{R}^4 . We can construct the arrangement $\mathcal{A}(\mathcal{T})$ of \mathcal{T} in $O^*(n^{12/7} + n^{1/2}k_2 + k_4)$ expected time, where k_2 is the number of intersecting pairs of tetrahedra in \mathcal{T} , and k_4 is the number of vertices of $\mathcal{A}(\mathcal{T})$. (ii) Given two arbitrary polyhedra R and B in \mathbb{R}^4 , each of complexity $O(n)$, that lie in general position with respect to one another, the intersection $R \cap B$ can be computed in expected time $O^*(n^{12/7} + n^{1/2}k_2 + k_4)$, where k_2 is the number of 2-faces of $\mathcal{A}(R \cup B)$, and k_4 is the number of vertices of $\mathcal{A}(R \cup B)$.*

As another application of our technique we present, in the full version, an efficient algorithm for detecting or reporting intersections between n 2-flats and n lines in \mathbb{R}^4 . We show that, given n lines and n 2-flats in \mathbb{R}^4 , one can detect whether some line intersects some 2-flat in $O^*(n^{13/8})$ expected time. One can also report all k intersections in $O^*(n^{13/8} + k)$ expected time. This result is a degenerate special case of the triangle-triangle intersection setup, and admits a faster solution. (Note that in general position 2-flats and lines are not expected to meet in \mathbb{R}^4 , which makes this special case interesting.)

Setup (iii): Tetrahedron-segment intersection queries. We can also handle a symmetric setup, in which the input consists of n segments in \mathbb{R}^4 and the query is with a tetrahedron T , where the goal is to detect, count or report intersections between T and the input segments. Using a similar machinery, we obtain the same asymptotic performance bounds, as in the standard solution, for this setup too.

³ Here we use an obvious divide-and-conquer approach in order to reduce the general (non-bichromatic) problem to the bichromatic version.

► **Theorem 7.** *Given a collection S of n segments in \mathbb{R}^4 , and any storage parameter $n \leq s \leq n^6$, we can preprocess S into a data structure of size $O^*(s)$, in randomized $O^*(s)$ expected time, so that we can answer any tetrahedron-intersection query in S in $O^*(n/s^{1/6})$ time. The query time bound applies to tetrahedron-intersection detection and counting queries. The cost is $O^*(n/s^{1/6}) + O(k)$ for reporting queries.*

2 Segment-Intersection amid Tetrahedra: An Initial Algorithm

In this section we present an initial solution to the problem of segment-intersection detection amid tetrahedra in four dimensions, which is based on a careful combination of the recent range searching machinery of [2, 11]. We do so because (a) as far as we can tell, such a solution has not yet been spelled out in the literature, (b) the adaptation of the available techniques to this problem is not simple, requires nontrivial and careful enhancements, and is of independent interest, and (c) this gives a yardstick for appreciating the improvement obtained by our improved algorithm, presented in Section 4.

The parametric search technique of Agarwal and Matoušek [3] reduces ray shooting queries to segment-intersection detection queries, so it suffices to consider the latter problem. The reporting and counting variants are simple extensions of the same technique, as will be discussed as we go.

To obtain a tradeoff between the storage of the structure and the query time, our algorithm uses a primal-dual approach. However, both the primal and dual setups suffer from the fact that, in four dimensions, segments and tetrahedra require too many parameters to specify. Specifically, a segment requires eight parameters (e.g., by specifying its two endpoints), while a tetrahedron requires 16 parameters (e.g., by specifying the coordinates of its four vertices).

To address this issue, we use a multi-level data structure, where each level caters to one aspect of the condition that a segment crosses a tetrahedron. This is done so that, at each of these levels, the number of parameters that a segment or a tetrahedron requires is at most six. Specifically, the condition that a segment e , that lies on a line ℓ , intersects a tetrahedron Δ , supported by a hyperplane h_Δ , is the conjunction of the following conditions:

- (i) The two endpoints of e lie on different sides of h_Δ .
- (ii) With a suitable choice of a direction of ℓ and an orientation of Δ , ℓ has a positive orientation with respect to each of the 2-planes that support the four 2-faces of Δ .

Conditions (i) and (ii) are the conjunction of a total of six sub-conditions: the first two conditions tests the position of some endpoint of e with respect to the hyperplanes h_Δ , and the other four conditions tests the orientation of ℓ with respect to the 2-planes supporting specific 2-faces of the tetrahedra. Thus, the dual structure has six levels, two for testing the sub-conditions of condition (i) and four for testing the sub-conditions of condition (ii).

More precisely, each but the last level collects all the tetrahedra Δ that satisfy the corresponding sub-condition for the query segment (that a specific endpoint of e lies in a specific side of h_Δ for the first two levels, and that the oriented 2-plane supporting a specific 2-face of Δ is positively oriented with respect to the directed line ℓ for the last four levels), as the disjoint union of precomputed canonical sets of tetrahedra. The last level just tests whether the last sub-condition is satisfied for any tetrahedron in the current canonical set.

We use the fact that lines in \mathbb{R}^4 require six real parameters to specify. The space of lines in \mathbb{R}^4 is actually projective, but for simplicity of presentation we regard it as a real space, and ignore the special cases in which the real representation fails. Handling these cases follows the same approach, and is in fact simpler. Alternatively, a generic (say random) rotation of the coordinate frame allows us to ignore them altogether.

One simple way to represent a line ℓ in \mathbb{R}^4 is by the points $u_\ell^0 = (x_0, y_0, z_0, 0)$ and $u_\ell^1 = (x_1, y_1, z_1, 1)$ at which ℓ crosses the hyperplanes $w = 0$ and $w = 1$, respectively (ignoring lines that are orthogonal to the w -axis), so the line ℓ can be represented as the point $p_\ell = (x_0, y_0, z_0, x_1, y_1, z_1)$ in \mathbb{R}^6 , as desired.

Similarly, 2-planes in \mathbb{R}^4 also require six parameters to specify. This is simply because the duality in \mathbb{R}^4 maps lines to 2-planes and vice versa, but a concrete way to represent 2-planes by six parameters is to specify three points on a 2-plane π that are intersections of π with three fixed 2-planes, such as, say, $x = y = 0$, $x = 0$ and $y = 1$, and $x = y = 1$ (again ignoring special directions of π). Each of the intersection points has two degrees of freedom (as two of its coordinates are fixed), for a total of six. Denote these points as $v_\pi^{(00)}$, $v_\pi^{(01)}$, and $v_\pi^{(11)}$, and put $q_\pi = (v_\pi^{(00)}, v_\pi^{(01)}, v_\pi^{(11)})$, listing only the w - and z -coordinates of each point, so q_π is a point in \mathbb{R}^6 .

These observations are meaningful only for the last four levels of the structure. The first two levels are simpler, as they deal with points (the endpoints of e) and hyperplanes (those supporting the tetrahedra of \mathcal{T}) in \mathbb{R}^4 . Thus each of the first two levels is a halfspace range searching structure for points and halfspaces in \mathbb{R}^4 . (Actually, this is the case when we pass to the dual 4-space; in the primal we have a point-enclosure problem, where the query is a point and the input consists of halfspaces bounded by the relevant hyperplanes.) Using standard techniques (see, e.g., [1]), this can be done, for N halfspaces in the current canonical subset and using $O^*(N)$ storage, so that a query costs $O^*(N^{3/4})$ time.⁴ This cost will be subsumed by the query time bounds for the last four levels. The cost of a query includes the cost of reporting its output, as a list of canonical sets.

We next consider the (more involved) situation in the last four levels of the structure. Here the query segment is replaced by its supporting line ℓ , and each tetrahedron Δ is replaced by the 2-plane supporting a specific 2-face of Δ . In the primal setup, the line ℓ is represented as a point p_ℓ in (projective) 6-space, in the manner just described, and a tetrahedron Δ , represented by a suitable 2-plane π , is represented as a semi-algebraic region K_π , consisting of all points that represent (directed) lines that are positively oriented with respect to π . The problem that we face is a point-enclosure query, in which we want to determine whether p_ℓ lies in any of the regions K_π (alternatively, count or report all these regions). In the dual setup, the 2-planes π are represented as points in \mathbb{R}^6 , and the (directed) query line ℓ is represented as a semi-algebraic region Q_ℓ that consists of all (oriented) 2-planes that are positively oriented with respect to ℓ . The problem here is a semi-algebraic range searching query, where we want to determine whether Q_ℓ contains any input point (alternatively, count or report all these points).

The orientation test of ℓ with respect to π amounts to computing the sign of the 5×5 determinant

$$\begin{vmatrix} u_\ell^0 & 1 \\ u_\ell^1 & 1 \\ v_\pi^{(00)} & 1 \\ v_\pi^{(01)} & 1 \\ v_\pi^{(11)} & 1 \end{vmatrix}, \quad (2)$$

with a suitable orientation of the pair of points u_ℓ^0, u_ℓ^1 on ℓ (dictating the direction of ℓ), and of the triple of points $v_\pi^{(00)}, v_\pi^{(01)}, v_\pi^{(11)}$ on π (dictating the orientation of π).

⁴ A tradeoff between storage and query time is also available, but we do not need it here.

To compute these signs, at each of the four latter levels of the structure, we use a primal-dual approach, where the top part of the structure is in the primal, and at each of its leaf nodes we pass to the dual.

The dual setup. The dual setup is simpler, so we begin with its description. In the dual setup, each tetrahedron Δ of the current canonical subset of \mathcal{T} is mapped to the point $q_\pi = (v_\pi^{(00)}, v_\pi^{(01)}, v_\pi^{(11)})$ in \mathbb{R}^6 , where π is the 2-plane supporting the 2-face of Δ that corresponds to the present level. The query line ℓ is mapped to a semi-algebraic region Q_ℓ of constant complexity in \mathbb{R}^6 , consisting of all points q_π that represent (oriented) 2-planes that have positive orientation with respect to ℓ , that is, the corresponding determinant in (2) is positive. (The resulting polynomial is cubic in q_π .)

As already mentioned, the task at hand, at each but the last level, is to collect the points q_π that lie in Q_ℓ , as the disjoint union of a small number of precomputed canonical sets of tetrahedra, and the task at the last level is to determine whether Q_ℓ contains any point q_π , for π corresponding to the last 2-faces of the tetrahedra in the present canonical subset of \mathcal{T} . In other words, we have, at each of these levels, a problem involving range searching with semi-algebraic ranges in \mathbb{R}^6 . Using the algorithm of Matoušek and Patáková [11], which is a simplified version of the algorithm of Agarwal et al. [4], this can be done, for N tetrahedra with $O^*(N)$ storage, so that a query takes $O^*(N^{5/6})$ time (including the cost of reporting, without enumerating, the output canonical sets). See [1, Theorem 6.1] for more details.

The primal setup. With this procedure at hand, we go back to the primal structure, at each of the last four levels. As noted, the problem that we face there is a point enclosure problem, where the input consists of some N constant-complexity semi-algebraic regions in \mathbb{R}^6 of the form K_π , and the query is the point p_ℓ that represents ℓ , as defined earlier, and the task is to collect all the regions K_π that contain p_ℓ , as the disjoint union of a small number of precomputed canonical sets, or, at the last level, to determine whether p_ℓ is contained in any such region.

This problem has recently been studied in Agarwal et al. [2], using a multi-level polynomial partitioning technique, for the case where we allow maximum storage for the structure (that is, $O^*(N^6)$ in our case) and want the query time to be logarithmic. We next show that the structure can be modified so that its preprocessing stops “prematurely” when its overall storage attains some prescribed value, and each of the subproblems at the new leaves can be handled via the dual algorithm presented above.

The crucial technical tool in [2], on which their technique is based, is the following result. We give here a restricted specialized version that suffices for our purposes. (When applying this tool in d dimensions, the parameter 6 has to be replaced by d .)

► **Theorem 8** (A specialized version of Agarwal et al. [2, Corollary 4.8]). *Given a set Ψ of N constant-degree algebraic surfaces in \mathbb{R}^6 , and a parameter $0 < \delta < 1/6$, there are finite collections $\Omega_0, \dots, \Omega_6$ of semi-algebraic sets in \mathbb{R}^6 with the following properties.*

- *For each index i , each cell $\omega \in \Omega_i$ is a connected semi-algebraic set of constant complexity. The size $|\Omega_i|$ of Ω_i (the number of its sets) is a constant that depends on δ .*
- *For each index i and each $\omega \in \Omega_i$, at most $\frac{N}{4|\Omega_i|^{1/6-\delta}}$ surfaces from Ψ cross ω (intersect ω without fully containing it).*
- *The cells partition \mathbb{R}^6 , in the sense that $\mathbb{R}^6 = \bigsqcup_{i=0}^6 \bigsqcup_{\omega \in \Omega_i} \omega$, where \bigsqcup denotes disjoint union.*

The sets in $\Omega_0, \dots, \Omega_6$ can be computed in $O(n + m)$ expected time, where the constant of proportionality depends on δ , by a randomized algorithm. For each i and for every set $\omega \in \Omega_i$, the algorithm returns a semi-algebraic representation of ω , a reference point inside ω , and the subset of surfaces of Ψ that cross ω .

In our case, the surfaces of Ψ are the boundaries of the regions K_π . A straightforward enhancement of the algorithm of [2] also yields, for each i and each $\omega \in \Omega_i$, the set of regions K_π that fully contain ω , within the same asymptotic time bound.

We compute the partition of Theorem 8 and find, for each $\psi = \partial K_\pi \in \Psi$, the sets $\omega \in \Omega_i$, over all $i = 0, \dots, 6$, that ψ crosses, and those that are fully contained in K_π . For each i and $\omega \in \Omega_i$, let $\mathcal{K}_{i,\omega}$ (resp., $\mathcal{K}_{i,\omega}^0$) denote the set of tetrahedra $\Delta \in \mathcal{T}$ for which ∂K_π crosses ω (resp., K_π fully contains ω).

The overall size of the sets $\mathcal{K}_{i,\omega}^0$, over all i and $\omega \in \Omega_i$, is $O(N)$, with a constant that depends on δ (that is, on the sizes $|\Omega_i|$, which depend on δ).

For each i and ω we also have a recursive subproblem that involves the subset $\mathcal{K}_{i,\omega}$ of the tetrahedra Δ for which ∂K_π crosses ω . Putting $r_i := |\Omega_i|$, for $i = 0, \dots, 6$, we have, for each i and ω , $|\mathcal{K}_{i,\omega}| \leq \frac{N}{4r_i^{1/6-\delta}}$. We run the recursion, but not all the way through, as in [2].

Instead, we use the following storage allocation rule. We fix the storage that we are willing to allocate to the structure, and distribute it among the nodes of the recursion, as follows. To simplify the analysis, we distinguish between the storage itself, and the so-called *storage parameter* s , which is what we actually manage, but we have the property that the actual storage will always be $O^*(s)$.

Let s be the storage parameter that we allocate at the root of the structure. For each i and each set $\omega \in \Omega_i$, we allocate the storage parameter $s/(4|\Omega_i|)$ for ω . Hence, when we reach some set ω at a deeper level of recursion, say level j , the storage parameter allocated to ω is $\frac{s}{4^j |\Omega_{i_1}^{(1)}| \cdot |\Omega_{i_2}^{(2)}| \cdots |\Omega_{i_j}^{(j)}|}$, where $\Omega_{i_1}^{(1)}, \Omega_{i_2}^{(2)}, \dots, \Omega_{i_j}^{(j)}$, for indices $0 \leq i_1, i_2, \dots, i_j \leq 6$, are the partition families at the ancestors of ω in the recursion.

We stop the recursion when we reach nodes for which the allocated storage parameter is (roughly) equal to the number of tetrahedra at the node; a more precise statement of the termination rule is given shortly.

Put, for each set ω , $r_\omega := |\Omega_{i_1}^{(1)}| \cdot |\Omega_{i_2}^{(2)}| \cdots |\Omega_{i_j}^{(j)}|$, using the above notation for ω . The storage parameter allocated to ω is thus $s/(4^j r_\omega)$. Also, by Theorem 8, the number of tetrahedra Δ that participate in the subproblem at ω is at most

$$\frac{n}{4^j |\Omega_{i_1}^{(1)}|^{1/6-\delta} \cdot |\Omega_{i_2}^{(2)}|^{1/6-\delta} \cdots |\Omega_{i_j}^{(j)}|^{1/6-\delta}} = \frac{n}{4^j r_\omega^{1/6-\delta}},$$

and the stopping condition that we use is that $\frac{s}{4^j r_\omega} = \frac{n}{4^j r_\omega^{1/6-\delta}}$, or $r_\omega = (s/n)^{(6/5)/(1+6\delta/5)}$.

The size of a subproblem at a leaf is (using the $O^*(\cdot)$ notation to hide exponents that are proportional to δ and constants of proportionality that depend on δ)

$$n_\omega = \frac{n}{4^j r_\omega^{1/6-\delta}} = \frac{1}{4^j} O^* \left(\frac{n^{6/5}}{s^{1/5}} \right) = O^* \left(\frac{n^{6/5}}{s^{1/5}} \right).$$

In more detail, since all the parameters r_j in Theorem 8 are at least some sufficiently large constant that we can control, we can make the factor 4^j to be $O(s^\delta)$, for any $\delta > 0$ of our choice. To be more precise, the choice of δ determines how large the parameters r_j have to be taken to ensure that $4^j = O(s^\delta)$, and the choice of these parameters adds a constant factor to the query cost (incurred by the cost of locating, in brute force, the cells ω , at the various recursive levels, that contain p_ℓ), which depends on these parameters, and thus on δ .

At each leaf ω we pass to the dual structure reviewed above. It uses $O^*(n_\omega)$ storage and answers a query in time $O^*(n_\omega^{5/6}) = O^*(n/s^{1/6})$. To answer a query with a line ℓ in the combined structure, we search with its point p_ℓ in the primal substructure, in $O(\log n)$ time (with a constant of proportionality that depends on δ ; see below), to locate the leaf cell ω that contains p_ℓ (using the properties that (a) each recursive step involves a partitioning of constant size, and (b) the cells in the partition are pairwise disjoint). We then search with Q_ℓ in the dual structure at ω , which takes, as just noted, $O^*(n/s^{1/6})$ time. The overall cost of the query is therefore $O^*(n/s^{1/6})$.

As to the actual storage used by the structure, the allocation mechanism ensures that each level of the recursion uses storage that is at most $7/4$ times larger than the storage used in the previous level, because each node has seven child collections $\Omega_0, \dots, \Omega_6$, each of which is allocated an amount of storage $s/4$. Hence the overall storage used is $O((7/4)^j s)$, where j is the recursion depth. Arguing as in the query time analysis, we can make the factor $(7/4)^j$ to be $O(s^\delta)$, for any $\delta > 0$. That is, the overall storage used is $O(s^{1+\delta})$, or, in our notation, $O^*(s)$.

The above description of the structure applies to any single level among the four latter levels of the structure. The first two levels are considerably simpler and more efficient. The primal-dual approach is straightforward for halfspace range searching, and the parametric dimension is only four for the first two levels. The standard machinery (reviewed, e.g., in [1]) implies that, with s storage and N input tetrahedra, the cost of a query at each of these levels is $O^*(N/s^{1/4})$.

Putting everything together, and using standard arguments in the analysis of multi-level structures (see [1, Theorem 6.1] for details), the overall size of the six-level structure is $O^*(s)$, for any prescribed storage parameter s between n and n^6 , and a query takes $O^*(n/s^{1/6})$ time. That is, this finally concludes the proof of Theorem 1 for the case of intersection detection queries. Counting and reporting queries are handled similarly, with a similar analysis, exploiting the fact that the decomposition in Theorem 8 is into disjoint subsets, as is a similar decomposition used in the machinery of [11]. For reporting query, their cost involves an additional term $O(k)$, where k is the output size. \square

Remark. Our mechanism is in fact a special instantiation of the following general result, which is of independent interest, and which yields a trade-off bound for semi-algebraic range searching in any dimension d . That is, consider a general problem of this kind, that involves n points in \mathbb{R}^d , and aims to answer semi-algebraic range queries, where the ranges have constant complexity, and each range has d degrees of freedom (so the problem has a symmetric dual version). One can solve such a problem in time $O^*(n/s^{1/d})$ per query, using $O^*(s)$ space and preprocessing, where s is any parameter between n and n^d . These queries include detecting whether a query range contains any point from the input, counting the number of such points, or reporting them (with an additional term $O(k)$ in the query cost, where k is the output size). Using duality, we obtain the same performance bounds for point-enclosure queries, where the input consists on n constant-complexity semi-algebraic regions in \mathbb{R}^d , and the query is with a point p , where the goal is to detect, count or report containments of p in the input regions. The same asymptotic bound is obtained for simplex range searching [1], but our analysis shows that this bound corresponds to a much more general family of query ranges. The two extreme cases $s = n$ and $s = n^d$ have been treated in [11] and [2], respectively, but the tradeoff between these extreme cases has not been treated explicitly (for $d > 4$), as far as we can tell. As evidenced in the preceding analysis, this tradeoff is not as routine as one might think, because of the complicated nature of the partitioning used in Theorem 8 (as well as in [11, Theorem 1.1]). We summarize this result in the following corollary:

51:10 Intersection Searching Amid Tetrahedra in 4-Space

► **Theorem 9.** *Let P be a set of n points in \mathbb{R}^d , for any dimension d , and let Γ be a family of semi-algebraic ranges of constant complexity in \mathbb{R}^d , each of which has d degrees of freedom. Let $n \leq s \leq n^d$ be a prespecified storage parameter. Then one can preprocess P into a data structure of storage and preprocessing $O^*(s)$, such that a range-query, with a range $\gamma \in \Gamma$, can be answered in $O^*(n/s^{1/d})$ time. Such queries include detecting whether γ contains any point of P , counting the number of such points, and reporting them (with an additional $O(k)$ term in the latter case, where k is the number of these points). The same performance bounds apply to the dual point-enclosure case, where the input consists of n regions from Γ and the query is with a point $p \in \mathbb{R}^d$.*

Remarks.

- (i) Theorem 9 can be extended to the case where the number of degrees of freedom of the ranges is different from d , but the resulting performance bound has a more complicated expression, which is not spelled out in this work.
- (ii) We note that our technique can be extended to segment intersection detection queries amid a collection of n $(d-1)$ -simplices in any dimension d . In that case the structure has $d+2$ levels. The first two levels ensure that the endpoints of the query segment e lie on different sides of the hyperplane containing the input simplex Δ , and are implemented by halfspace range searching structures in \mathbb{R}^d . The last d levels ensure that the line containing e has positive orientation with respect to each of the $(d-2)$ -flats containing the facets of Δ , with suitable orientations of the line and the flats. Since lines and $(d-2)$ -flats in \mathbb{R}^d have $2d-2$ degrees of freedom, these levels are implemented using semi-algebraic range searching structures, where both primal and dual parts are in \mathbb{R}^{2d-2} . Hence the cost of the query at each of the last d levels dominates the overall cost, which is thus $O^*(n/s^{1/(2d-2)})$. The parameter s can vary between n and n^{2d-2} .
- (iii) A very similar mechanism, with the same performance bounds, handles the reverse situation, mentioned in the introduction, in which the input is a set of n segments in \mathbb{R}^4 , and the query is with a tetrahedron T , and the goal is to detect, count, or report intersections between T and the input segments. This property is stated in Theorem 7; we defer the relatively easy details to the full version.

3 Triangle-Triangle Intersection Queries in \mathbb{R}^4

Let Δ be a set of n triangles in \mathbb{R}^4 . We consider various triangle-triangle intersection problems, the simplest of which is just to detect whether the query triangle intersects any input triangle. Alternatively, we may want to count or to report all such intersections. For concreteness we consider only the detection problem in what follows, but, as in the previous section, the algorithm can be extended to also handle the other kinds of problems.

Similar to the preceding section, we use a multi-level data structure, where each level caters to one aspect of the condition that a triangle crosses another triangle. Specifically, let Δ_1 and Δ_2 be two triangles, and let π_1, π_2 be the respective 2-planes that contain them. Assuming general position, π_1 and π_2 always intersect at a single point ξ , and Δ_1 intersects Δ_2 if and only if ξ belongs to both triangles. As is easily verified, this latter condition is equivalent, with suitable orientations of π_1, π_2 , and of the lines supporting the edges of both triangles, to the conjunction of the following conditions:

- (i) π_1 is positively oriented with respect to each of the lines that support the edges of Δ_2 .
- (ii) π_2 is positively oriented with respect to each of the lines that support the edges of Δ_1 .

Conditions (i) and (ii) are the conjunction of a total of six sub-conditions, each of which tests the orientation of, say, the 2-plane π_1 with respect to the line supporting some specific edge of Δ_2 , or vice versa.

We can therefore apply a suitable variant of the same machinery of the preceding section, and obtain a proof of Theorem 3.

The batched bichromatic version. For the batched version of the triangle-triangle intersection problem, with m red triangles and n blue triangles (see Theorem 4), we choose the storage parameter s to be such that the cost of m queries with the red triangles is asymptotically roughly the same as the cost of preprocessing the blue triangles. That is, we set $s = mn/s^{1/6}$, or $s = m^{6/7}n^{6/7}$. For this choice to make sense, we need to ensure that $n \leq s \leq n^6$, or that $n^{1/6} \leq m \leq n^6$. When $m > n^6$ we only use the data structure of [2] and obtain the running time $O^*(m + n^6) = O^*(m)$, and when $m < n^{1/6}$ we only use the data structure of [11] and obtain the running time $O^*(mn^{5/6} + n) = O^*(n)$. Altogether we obtain the bound in Theorem 4.

4 Segment-Intersection amid Tetrahedra: An Improved Solution

In this section we present an improved algorithm for setup (i) of the paper, for a data structure of roughly quadratic size. Let \mathcal{T} be a collection of n tetrahedra in \mathbb{R}^4 . Our improved solution constructs a data structure that uses $O^*(n^2)$ storage (and expected preprocessing time), and answers a query in $O^*(n^{1/2})$ time. This is indeed a significant improvement over the standard algorithm in Section 2, in which, with storage $O^*(n^2)$, the query cost is $O^*(n^{2/3})$. With a suitable tradeoff, presented in the full version, the improvement can be extended for any storage parameter between n and n^6 , although it is most substantial when the storage is nearly quadratic; see Figure 1.

Assume, without loss of generality, that the query segment is bounded. The algorithm constructs a partitioning polynomial F in \mathbb{R}^4 of degree $O(D)$, for some large but constant parameter D , so that each cell of the partition is crossed by at most n/D^2 2-faces of the tetrahedra in \mathcal{T} and by a total of at most n/D tetrahedra. The existence of such a polynomial follows from Guth [8], and an expected linear-time algorithm for its construction (for constant D) is given in [2]. We classify each tetrahedron $\Delta \in \mathcal{T}$ as being *narrow* (resp., *wide*) with respect to a partition cell τ if a 2-face of Δ crosses τ (resp., Δ crosses τ but none of its 2-faces crosses τ). Let \mathcal{N}_τ (resp., \mathcal{W}_τ) denote the set of narrow (resp., wide) tetrahedra at τ .

There are two cases to consider in our analysis, depending on whether the query segment ρ is contained or not contained in the zero set $Z(F)$ of F . Each of these cases requires its own data structure. The latter case is an extension of the analysis in [7] (given there for the three-dimensional version of the problem), and the case where $\rho \subset Z(F)$ requires a different approach than that taken in [7] for handling queries on the zero set. Due to lack of space we only sketch the general framework; the details are given in the full version.

A sketch of the analysis. A query segment ρ that is not contained in $Z(F)$ crosses at most $O(D)$ cells of the partition. For each partition cell τ (an open connected component of $\mathbb{R}^4 \setminus Z(F)$) we construct an auxiliary data structure on the wide tetrahedra at τ , and preprocess the narrow tetrahedra at τ recursively. As we show below, the structure for the wide tetrahedra uses $S_0(n) = O^*(n^2)$ storage, and a query amid them takes $Q_0(n) = O^*(n^{1/2})$ time. We then output the wide tetrahedron returned by querying the auxiliary structure at τ , if such a tetrahedron exists. Otherwise, we return the tetrahedron produced by the

recursive call, if one exists. If no tetrahedron, wide or narrow, has been found, we proceed to the next cell τ' crossed by ρ , repeat the whole procedure at τ' , and keep doing this till we either find a tetrahedron hit by ρ or run out of cells, and then conclude that ρ does not hit any tetrahedron of \mathcal{T} .

The correctness of this procedure is clear (modulo that of the procedure for handling wide tetrahedra). Denote by $S(n)$ (resp., $Q(n)$) the maximum storage (resp., query time) required by the overall structure for n tetrahedra. Also denote by $S_1(n)$ (resp., $Q_1(n)$) the maximum storage (resp., query time) required for processing the input tetrahedra for intersection queries with segments contained in $Z(F)$, for any set of n tetrahedra in \mathbb{R}^4 . We then have, for a suitable absolute constant $c > 0$ (where the constant hidden in the $O_D(\cdot)$ notation depends on D),

$$\begin{aligned} S(n) &= O_D(S_0(n/D)) + S_1(n) + cD^4S(n/D^2) \\ Q(n) &= \max \{ O_D(Q_0(n/D)) + cDQ(n/D^2), Q_1(n) \}. \end{aligned}$$

We show, in the full version, that $S_1(n) = O_D^*(n^2)$ and $Q_1(n) = O_D^*(n^{1/2})$. Substituting these bounds, as well as the bounds for $S_0(n)$ and $Q_0(n)$, the solutions of these recurrences is $S(n) = O^*(n^2)$ and $Q(n) = O^*(n^{1/2})$. This establishes Theorem 2.

Handling the wide tetrahedra. Handling the wide tetrahedra is done via a secondary recursion, as follows. We choose some large constant parameter $r_0 \gg D$, and partition $\partial\tau$ into $O_D(1)$ $x_1x_2x_3$ -monotone strata (assuming a generic choice of the coordinate frame). This is fairly standard to do, see, e.g. [5]. We construct, for each stratum σ , a $(1/r_0)$ -cutting for the set of (constant-degree algebraic) 2-surfaces of intersection of σ with the wide tetrahedra in \mathcal{W}_τ . The cutting is constructed by projecting σ and the 2-surfaces that it contains onto the $x_1x_2x_3$ -subspace, constructing a $(1/r_0)$ -cutting, within that subspace, on the projected surfaces, and then lifting the resulting cutting back to σ . Using standard results on vertical decomposition in three dimensions (see, e.g., [13]) and the theory of cuttings [9], we obtain $O^*(r_0^3)$ cells of the cutting (referred to as (pseudo-)prisms, in accordance with the way in which the vertical-decomposition-based cutting is constructed), each of which is crossed by (intersects but not contained in) at most n/r_0 wide tetrahedra.

For each pair ψ_1, ψ_2 of prisms, we define S_{ψ_1, ψ_2} to be the set of all segments e so that e has an endpoint in ψ_1 and an endpoint in ψ_2 , and the relative interior of e is fully contained in τ . Clearly, S_{ψ_1, ψ_2} is a semi-algebraic set of constant complexity in a 6-dimensional parametric space,⁵ and we decompose it into its $O(1)$ connected components.

For each segment $e \in S_{\psi_1, \psi_2}$, let $\mathcal{T}(e)$ denote the set of all wide tetrahedra Δ of \mathcal{W}_τ that e crosses. We have the following crucial technical lemma, akin to Lemma 2.2 in [7]:

► **Lemma 10.** *Each connected component C of S_{ψ_1, ψ_2} can be associated with a fixed set \mathcal{T}_C of wide tetrahedra Δ of \mathcal{W}_τ , none of which crosses $\psi_1 \cup \psi_2$, so that, for each segment $e \in C$, $\mathcal{T}_C \subseteq \mathcal{T}(e)$, and each tetrahedron Δ in $\mathcal{T}(e) \setminus \mathcal{T}_C$ crosses either ψ_1 or ψ_2 .*

We illustrate the proof in Figure 10, and delegate the rest of the details to the full version of this paper.

⁵ Each segment is specified by its two endpoints; since they lie on $\partial\tau$, each has three degrees of freedom.

■ **Figure 2** The set \mathcal{T}_C (consisting of the tetrahedra depicted as black segments), and an illustration of the proof of Lemma 10: The tetrahedra that cross some fixed segment e_0 between ψ_1 and ψ_2 are the same tetrahedra that cross any other such segment e , except for those that cross ψ_1 or ψ_2 (like those depicted as magenta segments).

The analysis for wide tetrahedra. For each prism ψ , the *conflict list* K_ψ of ψ is the set of all wide tetrahedra that cross ψ . By construction, $|K_\psi| \leq n/r_0$. The same bound for crossing tetrahedra holds when ψ is lower-dimensional. If a lower-dimensional prism is contained in some tetrahedron there is no need to process ψ further, since any segment that meets ψ hits all these tetrahedra.

For each pair of prisms ψ_1, ψ_2 , we compute S_{ψ_1, ψ_2} and decompose it into its connected components. For each component C we compute the set \mathcal{T}_C of the wide tetrahedra, as in Lemma 10 (see the full version for details). This requires $O_D(r_0^6 n) = O_D(n)$ storage and computation time.

Let s be the storage parameter associated with the problem; we require that $n \leq s \leq n^3$. For each canonical set \mathcal{T}_C , we replace its tetrahedra by their supporting hyperplanes, and preprocess the resulting collection of hyperplanes for efficient segment intersection queries amid hyperplanes in \mathbb{R}^4 . Using the technique of Agarwal and Matoušek [3], this problem can be solved using $O^*(s)$ storage (and preprocessing), and a query takes $O(n \text{ polylog}(n)/s^{1/4}) = O^*(n/s^{1/4})$ time (see also [1]). Lemma 10 guarantees the correctness of this procedure (namely, that replacing each tetrahedron in \mathcal{T}_C by its supporting hyperplane does not cause any “false positive” answer).

We now process recursively each conflict list K_ψ , over all prisms ψ of the partition. Each recursive subproblem uses the same parameter r_0 , but the allocated storage parameter is now s/r_0^3 . We keep recursing until we reach conflict lists of size close to $n^{3/2}/s^{1/2}$. More precisely, after j levels of recursion, we get a total of at most $(c_0 r_0^3)^j = c_0^j r_0^{3j}$ subproblems, each involving at most n/r_0^j wide tetrahedra, for some constant c_0 that depend on D (but is considerably smaller than r_0).

We stop the recursion at the first level j^* at which $\frac{n}{r_0^{j^*}} \leq n^{3/2}/s^{1/2}$. As a result, we have $r_0^{j^*} = O(s^{1/2}/n^{1/2})$, and we get $c_0^{j^*} r_0^{3j^*} = O^*(s^{3/2}/n^{3/2})$ subproblems. Each of these subproblems involves at most $\frac{n}{r_0^{j^*}} = O^*\left(\frac{n^{3/2}}{s^{1/2}}\right)$ tetrahedra. Hence the overall size of the inputs, as well as of the canonical sets, at all the subproblems throughout the recursion, is $O^*\left(\frac{s^{3/2}}{n^{3/2}} \cdot \frac{n^{3/2}}{s^{1/2}}\right) = O^*(s)$. In particular, this is the asymptotic cost at the bottom level of the recursion.

51:14 Intersection Searching Amid Tetrahedra in 4-Space

As just described, at the bottom of the recursion, each subproblem contains at most $O^*(n^{3/2}/s^{1/2})$ wide tetrahedra, and we detect intersections with them by brute force. We thus obtain the following recurrence for the overall storage $S_0(N_W, s_W)$ for the structure constructed on N_W wide tetrahedra, where s_W denotes the storage parameter allocated to the structure (at the root $N_W = n, s_W = s$).

$$S_0(N_W, s_W) = \begin{cases} O_D^*(r_0^6 s_W) + c_0 r_0^3 S_0\left(\frac{N_W}{r_0}, \frac{s_W}{r_0^3}\right) & \text{for } N_W \geq \Theta^*(n^{3/2}/s^{1/2}), \\ O(N_W) & \text{for } N_W < \Theta^*(n^{3/2}/s^{1/2}). \end{cases}$$

Unfolding the recurrence up to the terminal level j^* , where $N_W = O^*(n^{3/2}/s^{1/2})$, the sum of the nonrecursive overhead terms, over all nodes at a fixed level j , is

$$c_0^j r_0^{3j} \cdot O^*\left(\frac{s_W}{r_0^{3j}}\right) = O^*(s_W).$$

Hence, starting the recurrence at $(N_W, s_W) = (n, s)$, the overall contribution of the overhead terms is $O^*(s)$. We showed above that this is also the asymptotic cost at the bottom of the recurrence. Therefore, the overall storage used by the data structure is $O^*(s)$. Using similar considerations, one can show that the overall expected preprocessing time is $O^*(s)$ as well, since the time obeys a similar asymptotic recurrence.

Answering a query. Given a query segment ρ , which is not contained in $Z(F)$, we find its $O(D)$ intersections with $Z(F)$, which decompose it into $O(D)$ segments, each fully contained in some partition cell. Moreover, except for the first and last segment, the endpoints of each of the other segments lie on the boundary of its cell. We process the segments in their order⁶ along ρ . Let e be the currently processed segment. If e is not the first or last segment, we find the prisms ψ_1, ψ_2 that contain its endpoints, and find the component C of S_{ψ_1, ψ_2} that contains e . If e is the first or last segment, we extend it backwards or forwards, respectively, till it meets the boundary of its cell, and call the resulting segment e' . We now compute for e' the corresponding set S_{ψ_1, ψ_2} and its component C that contains e' . Since D and r_0 are constants, all this takes constant time.

The query, on the wide tetrahedra at the present cell τ , performs a segment intersection detection query with e (or with e' when e is the first or last segment) in the set of hyperplanes containing the tetrahedra of \mathcal{T}_C , and, if no intersection is detected, continues recursively with \mathcal{T}_{ψ_1} and \mathcal{T}_{ψ_2} (at the bottom of recursion we apply a brute-force search). If no tetrahedron is found, in all the r_0 -recursive steps, we conclude that (the present subsegment of) ρ does not hit any wide tetrahedron within τ . Once again, the correctness of this procedure follows from Lemma 10.

The query time $Q_0(N_W, s_W)$ satisfies the recurrence

$$Q_0(N_W, s_W) = \begin{cases} O_D(1) + O^*\left(\frac{N_W}{s_W^{1/4}}\right) + 2Q\left(\frac{N_W}{r_0}, \frac{s_W}{r_0^3}\right) & \text{for } N_W \geq \Theta^*(n^{3/2}/s^{1/2}), \\ O(N_W) & \text{for } N_W < \Theta^*(n^{3/2}/s^{1/2}). \end{cases}$$

Unfolding the recurrence, the overall bound for the nonrecursive overhead terms, starting from $(N_W, s_W) = (n, s)$, is at most

$$O^*\left(\sum_{j \geq 0} \left(\frac{2}{r_0^{1/4}}\right)^j \cdot \frac{n}{s^{1/4}}\right) = O^*\left(\frac{n}{s^{1/4}}\right).$$

⁶ The order is immaterial for segment intersection detection queries, but is important for ray shooting.

Adding the cost at the 2^{j^*} subproblems at the bottom level j^* of the recursion, where the cost of each subproblem is at most $O^*(n^{3/2}/s^{1/2})$, we obtain the query time

$$Q_0(n, s) = O^* \left(\frac{n}{s^{1/4}} + \frac{n^{3/2}}{s^{1/2}} \right). \quad (3)$$

Therefore, for $s = n^2$ the query time is $O^*(n^{1/2})$. The bounds $S_0(n) := S_0(n, n^2) = O^*(n^2)$ and $Q_0(n) := Q_0(n, n^2) = O^*(n^{1/2})$ are the bounds promised earlier for the wide tetrahedra at a cell.

5 Output-Sensitive Construction of Arrangements of Tetrahedra and of Intersections of Polyhedra in \mathbb{R}^4

The results of Section 3 can be applied to construct the arrangement $\mathcal{A}(\mathcal{T})$ of a set \mathcal{T} of n tetrahedra in \mathbb{R}^4 in an output-sensitive manner. A complete discrete representation of $\mathcal{A}(\mathcal{T})$ requires, at the least, the collection of all faces, of all dimensions, of the arrangement, and their adjacency structure. Concretely, for each j -dimensional face φ , for $j = 0, 1, 2, 3$, we want the set of all $(j + 1)$ -dimensional faces that have φ on their boundary. Conversely, for each j -dimensional face φ , for $j = 1, 2, 3, 4$, we want the set of all $(j - 1)$ -dimensional faces that comprise $\partial\varphi$.

We begin by considering the task of computing all the nonempty intersections of pairs, triples, and quadruples of tetrahedra of \mathcal{T} . This will yield the set of vertices, and provide an infrastructure for computing the j -faces, for $j = 1, 2, 3$. Denote the number of these intersections as k_2 , k_3 , and k_4 , respectively. Note that we always have $k_4 \geq k_3 \geq k_2$.

To simplify the description we assume that the tetrahedra are in general position, although a suitable adaptation of the following machinery can handle degenerate cases too.

Reporting pairwise intersections. Two tetrahedra in general position in \mathbb{R}^4 intersect in a two-dimensional convex polygon of constant complexity, and it suffices to report one vertex of each nonempty polygon, in order to detect all intersecting pairs of tetrahedra. As is easily checked, such a vertex is either an intersection of an edge of one tetrahedron with the other tetrahedron, or an intersection of two 2-faces (triangles), one from each tetrahedron.

Reporting vertices of the first kind (edge-tetrahedron intersections) can be done using the machinery in Theorem 1, whose details are provided in Section 2, which takes $O^*(n^{12/7} + k_2)$ time.⁷ Reporting vertices of the second kind (triangle-triangle intersections) is done using the machinery in Section 3, which also takes $O^*(n^{12/7} + k_2)$ time.

Reporting triple and quadruple intersections. We iterate over the input tetrahedra. For each fixed tetrahedron T_0 , the previous step provides us with all the other tetrahedra that intersect T_0 . Denote their number as k_{T_0} , and observe that $\sum_{T_0} k_{T_0} = 2k_2$. We form the nonempty intersections $T_0 \cap T$, and triangulate each of them. We obtain a collection of $O(k_{T_0})$ triangles, all contained in $(T_0$ and therefore also in) the hyperplane h_{T_0} supporting T_0 .

We have thus reduced our problem to that of reporting all pairwise and triple intersections in a set of $m = O(k_{T_0})$ triangles in \mathbb{R}^3 . This can be solved using the algorithm in [7], by a procedure that runs in $O^*(m^{3/2} + \ell_{T_0})$ time, where ℓ_{T_0} is the number of triple intersections of the triangles. Note that $\sum_{T_0} \ell_{T_0} = O(k_4)$.

⁷ Although this part can be performed faster, as described in Section 4, we use the standard solution, since we do not have a similar improvement for the construction of vertices of the second kind.

Adding up this cost over all tetrahedra T_0 , the overall running time is

$$O^* \left(\sum_T k_T^{3/2} + k_4 \right) = O^* \left(n^{1/2} \sum_T k_T + k_4 \right) = O^*(n^{1/2}k_2 + k_4).$$

Constructing the arrangement. For each tetrahedron T_0 , it is fairly routine to obtain, from the information collected so far, the full three-dimensional arrangement within T_0 , using standard techniques in three dimensions; we omit here these standard details. This gives us all the j -faces of the four-dimensional arrangement \mathcal{A} , for $j = 0, 1, 2, 3$, and their adjacency information. The local adjacency information in \mathbb{R}^4 is also available from this data. By local adjacency we mean the adjacency between a j -face and the j' -faces on its boundary, for $j' < j$, over all such pairs of faces. For completion we need to identify disconnected pieces of the boundary of each four-dimensional cell, and record their adjacency to that cell. This can be done by x_4 -vertical ray shooting from the x_4 -highest point of each connected three-dimensional complex of faces. This calls for performing $O(n)$ x_4 -vertical ray shooting queries in a set of n tetrahedra in \mathbb{R}^4 , which can be done using the machinery presented in Theorem 1, or by an even simpler mechanism (since all the rays are vertical).

We have thus established the bound stated in Theorem 6.

Output-sensitive construction of the intersection of polyhedra in \mathbb{R}^4 . As another application, consider the problem where we have two not necessarily convex polyhedra R and B in \mathbb{R}^4 , whose boundaries consist of, or can be triangulated into $O(n)$ faces of all dimensions, which are segments, triangles, and tetrahedra. The goal is to construct their intersection $R \cap B$ in an output-sensitive manner; a similar application has been shown in [7] for the three-dimensional problem. We note that computing the union $B \cup R$ can be done using a very similar approach, within the same asymptotic time bound.

In order to compute $R \cap B$, we first apply the above algorithm to construct, in an output-sensitive manner, the arrangement $\mathcal{A}(R \cup B)$ of the two polyhedra R and B (specifically, we build the arrangement of the tetrahedra comprising the boundaries of B and R). We then label each cell (of any dimension) of $\mathcal{A}(R \cup B)$ with the appropriate Boolean operation, that is, whether it either lies in $R \setminus B$, $B \setminus R$, $B \cap R$, or in the complement of $B \cup R$. Collecting all the cells of the desired kind (e.g., those in $B \cap R$), and computing the adjacency relation between them, we obtain a suitable representation of the intersection. This establishes the bound stated in Theorem 6(ii).

We comment that extending the analysis to the intersection of more than two (albeit, still a constant number of) input polyhedra can also be done, following the same machinery as in the construction of an arrangement of tetrahedra, as presented above. It is easy to verify that in this case we obtain the same asymptotic bound stated in Theorem 6(ii).

Abstract

Despite a surge of interest in submodular maximization in the data stream model, there remain significant gaps in our knowledge about what can be achieved in this setting, especially when dealing with multiple constraints. In this work, we nearly close several basic gaps in submodular maximization subject to k matroid constraints in the data stream model. We present a new hardness result showing that super polynomial memory in k is needed to obtain an $o(k/\log k)$ -approximation. This implies near optimality of prior algorithms. For the same setting, we show that one can nevertheless obtain a constant-factor approximation by maintaining a set of elements whose size is independent of the stream size. Finally, for bipartite matching constraints, a well-known special case of matroid intersection, we present a new technique to obtain hardness bounds that are significantly stronger than those obtained with prior approaches. Prior results left it open whether a 2-approximation may exist in this setting, and only a complexity-theoretic hardness of 1.91 was known. We prove an unconditional hardness of 2.69.

1 Introduction

A set function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}$ over a ground set \mathcal{N} is *submodular* if

$$f(u \mid A) \geq f(u \mid B) \quad \text{for all } A \subseteq B \subseteq \mathcal{N} \text{ and } u \in \mathcal{N} \setminus B,$$

where, for a subset $S \subseteq \mathcal{N}$ and an element $u \in \mathcal{N}$, we denote by $f(u \mid S) := f(S \cup \{u\}) - f(S)$ the marginal contribution of u with respect to S . We say that f is *monotone* if $f(A) \leq f(B)$ for any $A \subseteq B \subseteq \mathcal{N}$.

The definition of submodular functions captures the natural property of diminishing returns, and the study of these functions has a rich history in optimization with numerous applications (see, e.g., the book [28]). Already in 1978, Nemhauser, Wolsey, and Fisher showed that a natural greedy algorithm achieves a tight approximation guarantee of $\frac{e}{e-1}$ for selecting the most valuable subset $S \subseteq \mathcal{N}$ of cardinality at most ρ (see [26] for the algorithm’s analysis and [8, 25] for matching hardness results). Since then, significant work has been devoted to extending their result to more general constraints.

A natural generalization of a cardinality constraint is the class of matroid constraints. While matroid constraints are much more expressive than cardinality constraints, both constraints often enjoy the same (or similar) algorithmic guarantees. Indeed, for the problem of maximizing a monotone submodular function subject to a single matroid constraint, Călinescu, Chekuri, Pál, and Vondrák [3] developed the continuous greedy method, and showed that it extends the $\frac{e}{e-1}$ -approximation guarantee to this more general setting. Moreover, for the maximization of a monotone submodular function subject to $k \geq 2$ matroid constraints, there is a $(k+1)$ -approximation guarantee by Fisher, Nemhauser and, Wolsey [11], which was improved to $k + \varepsilon$ by Lee, Sviridenko, and Vondrák [22] when the number k of matroid constraints is considered to be a constant.

While these algorithms are efficient in the traditional sense, i.e., they run in polynomial time in the offline “RAM” model, recent applications in data science and machine learning [21] with very large-scale problem instances have motivated the need for very space-efficient algorithms. In particular, it is interesting to study algorithms whose memory footprint is *independent of the ground set size*.¹ The task of designing such algorithms for (monotone) submodular function maximization has become a very active research area, especially in the context of the popular data stream computational model. Recent progress has resulted in a tight understanding of data stream algorithms² for maximizing monotone submodular functions with a single cardinality constraint: one can obtain a 2-approximation for this problem using a simple “threshold”-based algorithm that requires only $\tilde{O}(\rho)$ memory [2, 19], where ρ is the maximum number of elements allowed in the solution, and this is essentially optimal unless one is willing to have a space complexity that is linear in the size of the ground set [9]. However, our understanding of data stream algorithms for more general constraint families is currently much more limited. Closing this gap for natural settings of multiple matroid constraints is the motivation for our work.

Formally, we term the problem that we study **Submodular Maximization subject to k Matroid Constraints (SMkM)**. In this problem, we are given $k \geq 2$ matroids $M_1 = (\mathcal{N}, \mathcal{I}_1), M_2 = (\mathcal{N}, \mathcal{I}_2), \dots, M_k = (\mathcal{N}, \mathcal{I}_k)$ sharing a common ground set \mathcal{N} , and a non-negative submodular function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$.³ Our goal is to find a *common independent set* $S \subseteq \mathcal{N}$ (i.e., S is independent in all the matroids) that maximizes $f(S)$. In the data stream

¹ Technically, a logarithmic dependence on the ground set size is unavoidable because, at the very least, the algorithm has to store the indices of the elements in its solution. However, we wish to have a space complexity whose dependence on the ground set size is limited to this unavoidable logarithmic dependence.

² Data stream algorithms are sometimes called “streaming algorithms”; however, in this paper we reserve the term “streaming algorithms” to data streaming algorithms whose space complexity is poly-logarithmic in the natural parameters of the problem.

³ We recall that a matroid $M = (\mathcal{N}, \mathcal{I})$ is a tuple consisting of a finite ground set \mathcal{N} and a nonempty family $\mathcal{I} \subseteq 2^{\mathcal{N}}$ of subsets thereof fulfilling (i) if $I \in \mathcal{I}$ and $J \subseteq I$, then $J \in \mathcal{I}$, and (ii) if $I, J \in \mathcal{I}$ with $|I| < |J|$, then there is an element $e \in J \setminus I$ such that $I \cup \{e\} \in \mathcal{I}$. Moreover, a function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$, where \mathcal{N} is a finite set, is *submodular* if $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$. This is well-known to be equivalent to the *diminishing returns* property, which states that for $A \subseteq B \subseteq \mathcal{N}$ and $e \in \mathcal{N} \setminus B$, we have $f(A \cup \{e\}) - f(A) \geq f(B \cup \{e\}) - f(B)$.

version of this problem, the elements of the ground set \mathcal{N} appear one by one on a stream, and the algorithm should make a single pass over this stream and construct its output set S . (Some papers allow also algorithms that can do a few sequential passes over the stream; however, we consider the more practical and fundamental single-pass setting.)

The above high-level description of **SMkM** hides some important technical details regarding the way in which the objective function f and the matroid constraints are accessed. In the literature about matroids, it is customary to assume that the access of an algorithm to a matroid is done via an *independence oracle* that, given a set $S \subseteq \mathcal{N}$, indicates whether S is independent in the matroid. This notion can be extended to the intersection of k matroids in two natural ways: (i) having a single *common independence oracle*, which indicates whether S is independent in this intersection (i.e., in all the matroids), or (ii) having k independence oracles, one per matroid. Let us first consider the model with weaker access to the matroids, i.e., the one with a common independence oracle. This model already allows the implementation of a simple algorithm that greedily adds to its solution every element that does not violate feasibility. This natural greedy algorithm is a k -approximation for the special case of **SMkM** in which f is simply the cardinality function (i.e., $f(S) = |S|$) [17, 20] using a space complexity of $\tilde{O}(\rho)$, where ρ is the *common rank* of the k matroids, i.e., the cardinality of a maximum cardinality common independent set in the k matroids of the **SMkM** instance.⁴ We can show that this simple algorithm is almost best possible when access to the matroid is restricted to calls to a common independence oracle, unless one is willing to have a space complexity that is linear in $n := |\mathcal{N}|$.

► **Theorem 1.** *A data stream algorithm for **SMkM**, whose only access to the matroids is via the common independence oracle, and with expected approximation ratio $k - \varepsilon$ (for some $\varepsilon \in [0, k - 1)$), must use $\Omega(\varepsilon^n / k^5 \log k)$ memory. This holds even when the task is to find a maximum size common independent set in k partition matroids, and the common rank of these matroids is k .*

The proof of Theorem 1 is based on carefully defining k matroids such that stream prefixes lead to restricted matroids with many indistinguishable elements. This allows for hiding a large optimal solution. See the full version for details.

Given this inapproximability result, we turn our focus to the model in which we have access to a separate independence oracle for every matroid. A $4k$ -approximation algorithm with space complexity $\tilde{O}(\rho)$ was given for **SMkM** in this model by Chakrabarti and Kale [5] when the objective function f is guaranteed to be monotone, and $O(k)$ -approximation algorithms with similar space complexities were later obtained for the general case by Chekuri et al. [6] and Feldman et al. [10]. Our first main result shows that improving over the approximation guarantees of these algorithms by more than a logarithmic factor requires super polynomial space in k . Specifically, we prove the following theorem.

► **Theorem 2.** *Any data stream algorithm for **SMkM** that finds an α -approximate solution with probability at least $2/3$ uses memory at least $\Omega(e^{k/(8\alpha)} / k^2)$ assuming $\alpha \leq k / (32 \ln k)$. This holds even when the task is to find a maximum size common independent set in k partition matroids, and the common rank of these matroids is $O(\alpha) = O(k / \log k)$.*

The technique to prove Theorem 2 is discussed in Section 3. Interestingly, this technique also implies that any (even preemptive) online algorithm for **SMkM** must also have an approximation ratio of $\Omega(k / \log k)$. We remark that this lower bound is asymptotically the same as

⁴ For general **SMkM**, the state-of-the-art algorithm with a space complexity of $\tilde{O}(\rho)$ obtains a slightly worse approximation ratio of $O(k \log k)$ with a common independence oracle [12]. Moreover, this algorithm is applicable even to the more general class of k -extendible constraints.

the well-known approximation hardness for k -dimensional matching [13], which is a special case of the intersection of k matroids. However, note that this hardness does not carry over to our setting as our model has no restriction on computational power but only on memory.

In light of Theorem 2, it is arguably surprising that one can get essentially a 2-approximation for SMkM with space complexity independent of n .⁵

► **Theorem 3.** *For every $\varepsilon \in (0, 1/7)$, there exists a $(2 + O(\varepsilon))$ -approximation data stream algorithm for SMkM with space complexity $\text{poly}(k^{\rho^2 k}, \varepsilon^{-\rho})$.*

For monotone objective functions, Theorem 3 is based on merging ideas that appeared in recent papers by Huang et al. [14] and Huang and Ward [16] (see the full version for details). However, to obtain the same guarantee for non-monotone functions requires an interesting novel guessing scheme. Moreover, this theorem cannot be improved by much. The exponential dependence on k is necessary by Theorem 2, and the approximation ratio cannot be improved, even for a cardinality constraint, without using a linear in n memory because of the inapproximability result of [9]. It is open (even for a single partition matroid constraint) whether the exponential dependence on ρ in Theorem 3 is necessary.

Up to this point, our inapproximability results concentrated on the asymptotic approximation ratio obtainable as a function of k , which is more relevant for large values of k . Small values of k have also been considered extensively in the literature. For example, as aforementioned, the approximation ratio that can be obtained by a data streaming algorithm for a cardinality constraint, which is a special case of SMkM with $k = 1$, was the subject of a long line of research [1, 2, 9, 14, 19, 24] and is now essentially settled. Maximizing a monotone submodular function subject to a bipartite matching constraint is another important special case of SMkM, this time for $k = 2$.

Since ρ is usually polynomially related to n in bipartite matching constraints, the class of algorithms considered interesting for the last problem is more restricted than for general SMkM. Specifically, people are interested in algorithms that use $\tilde{O}(\rho)$ memory. That is, the algorithm does not use more memory (up to logarithmic factors) than what is required to simply store a solution. Such algorithms are known as semi-streaming algorithms. Recently, Levin and Wajc [23] described a semi-streaming algorithm for maximizing a monotone submodular function subject to a bipartite matching constraint which improves over the state-of-the-art for general SMkM with a monotone objective function. They also proved, conditioned on some complexity-theoretic assumption, a lower bound of 1.914 on the approximation ratio that can be obtained by a semi-streaming algorithm for the problem. Our final result improves over this upper bound and is independent of any complexity-theoretic assumption, but does assume that the graph can contain parallel edges (which are distinct elements from the point of view of the submodular objective function); the hardness of [23] applies even when this is not the case.

► **Theorem 4.** *No semi-streaming algorithm can obtain, with probability at least $2/3$, an approximation ratio of 2.692 for maximizing a non-negative monotone submodular function subject to a bipartite matching constraint.*

The last result is obtained by combining known hardness results for semi-streaming algorithms for the maximum cardinality matching problem [18] and submodular function maximization subject to a cardinality constraint [9] in a non-trivial way so that the obtained

⁵ For simplicity, the space complexity stated in Theorem 3 assumes that every element of the ground set can be stored in $O(1)$ space. Without this assumption, we get the unavoidable logarithmic dependence of the space complexity on n . Similarly, we also make the standard assumption that the value of $f(S)$ can be stored in constant space for every set $S \subseteq \mathcal{N}$.

hardness is stronger than what is known for any one of the two problems individually. Moreover, the reduction is general, and another consequence of it is the following: any semi-streaming algorithm for maximizing a monotone submodular function subject to a bipartite matching constraint that has an approximation guarantee better than 3 would yield an improved semi-streaming algorithm for the maximum cardinality bipartite matching problem, which is a longstanding notorious open problem. We refer to reader to the full version for further detail.

2 Preliminaries

In this section we give some additional technical details that are necessary for proving the results stated in Section 1. In Section 2.1 we discuss in more detail the oracles used to access the objective function and constraint matroids; and in Section 2.2 we present a known hard problem from which we often reduce to prove our inapproximability results.

2.1 More details about the access oracles

As mentioned above, the matroid constraints are accessed via either a common independence oracle or k distinct independence oracles, one per matroid. We also need to specify the method used to access the objective function f . In the submodular optimization literature, submodular objective functions such as f are usually accessed via a *value oracle* that, given a set $S \subseteq \mathcal{N}$, returns $f(S)$. In the context of data stream and online algorithms, it is important that the independence and value oracles do not leak information in a way that contradicts our expectations from such algorithms. Accordingly, our algorithms query the oracles only on sets of elements that are explicitly stored in their memory.

The above information leakage issue often makes proving inapproximability results more complicated because such results have to formalize in some way the types of queries that are allowed (i.e., queries that are not considered “leaky”). All our inapproximability results apply to the model used by our algorithmic results; namely, when the algorithm is allowed to query the oracles only on sets of elements that are explicitly stored in its memory – see [15] for a formal statement of this natural model. However, we strive to weaken this assumption, and prove most of our inapproximability results even for algorithms that enjoy a less limited access to the oracles. For example, the proof of Theorem 2 manages to avoid this issue completely using the following technique. The algorithm is given upfront a “super ground set” and fully known objective function and matroids over this super ground set. The real ground set is then chosen as some subset of this super ground set, and only the elements of this real ground set appear in the input stream of the algorithm. Since the challenge that the algorithm has to overcome in this case is to remember which elements belong to the real ground set, the oracles cannot leak important information to the algorithm, and therefore, we allow the algorithm unrestricted access to them.

The situation for Theorem 1 is a bit more involved because of the following observation. If the algorithm is allowed unrestricted access to the common independence oracle, then it can construct k matroids M_1, M_2, \dots, M_k that are consistent with this oracle, which makes the distinction between a single common independence oracle and k independence oracles mute. Therefore, some restriction on the access to the common independence oracle must be used. The (arguably) simplest and most natural restriction of this kind is to allow the algorithm to query the common independence oracle only on subsets that do not include any elements that did not appear in the stream so far; and it turns out that this simple restriction suffices for the proof of Theorem 1 to go through.

It remains to consider our last inapproximability result, namely Theorem 4. Here the elements of the ground set are edges, and the algorithm is given each edge in the form of its two endpoints. Therefore, there is no need for independence oracles. (Formally, this situation is equivalent to the case mentioned above in which there is a “super ground set” that is given upfront to the algorithm, and only part of this super ground set appears in the stream.) Unfortunately, preventing information leakage via the value oracle is more involved. For simplicity, the proof that we give in the full version assumes the same model that we use in our algorithmic results. However, our proof can be extended also to algorithms with a more powerful way to access the objective function f , such as the p -players model described in [9].

2.2 The $\text{CHAIN}_p(n)$ problem

Many of our inapproximability results use reductions to a (hard) problem named $\text{CHAIN}_p(n)$, introduced by Cormode, Dark, and Konrad [7], which is closely related to the Pointer Jumping problem (see [4]). In this problem, there are p players P_1, \dots, P_p . For every $1 \leq i < p$, player P_i is given a bit string $x^i \in \{0, 1\}^n$ of length n , and, for every $2 \leq i \leq p$, player P_i (also) has as input an index $t^i \in \{1, 2, \dots, n\}$. (Note that the convention in this terminology is that the superscript of a string/index indicates the player receiving it.) Furthermore, it is promised that either $x_{t^{i+1}}^i = 0$ for all $1 \leq i < p$ or $x_{t^{i+1}}^i = 1$ for all these i values. We refer to these cases as the 0-case and 1-case, respectively. The objective of the players in $\text{CHAIN}_p(n)$ is to decide whether the input instance belongs to the 0-case or the 1-case. The first player, based on the input bit string x^1 , sends a message M^1 to the second player. Any player $2 \leq i < p$, based on the message it receives from the previous player (i.e., M^{i-1}), the input bit string x^i and index t^i , sends message M^i to the next player. The last player, based on M^{p-1} and t^p , decides if we are in the 0-case or 1-case. Each player has unbounded computational power and can use any (potentially randomized) algorithm. We refer to the collections of the algorithms used by all the players as a protocol. The success probability of a protocol is the probability that its decision is correct, and the communication complexity of a protocol is the size of the maximum message sent (i.e., maximum size of M^1, \dots, M^{p-1}). In [9], the following lower bound was shown for the $\text{CHAIN}_p(n)$ problem, which is very similar to the lower bounds previously proved by [7].

► **Theorem 5** (Theorem 3.3 in [9]). *For any positive integers n and $p \geq 2$, any (potentially randomized) protocol for $\text{CHAIN}_p(n)$ with success probability of at least $2/3$ must have a communication complexity of at least $n/36p^2$. Furthermore, this holds even when instances are drawn from a known distribution $D(p, n)$.*

The distribution $D(p, n)$ referred to by Theorem 5 is simply the uniform distribution over all 0-case and 1-case instances (see the definition of D^p in Appendix C of [9]).

3 Inapproximability for Multiple Independence Oracles

In this section, we prove Theorem 2, which gives a strong inapproximability result for data stream algorithms as a function of the number k of matroids, even in the case when the objective function f is a linear function (unlike in the previous section, here we allow access to the independence oracles of the individual matroids).

► **Theorem 2.** *Any data stream algorithm for SMkM that finds an α -approximate solution with probability at least $2/3$ uses memory at least $\Omega(e^{k/(8\alpha)}/k^2)$ assuming $\alpha \leq k/(32 \ln k)$. This holds even when the task is to find a maximum size common independent set in k partition matroids, and the common rank of these matroids is $O(\alpha) = O(k/\log k)$.*

Note that the above result implies that (i) any data stream algorithm with an approximation guarantee $o(k/\log k)$ requires super polynomial memory in k , and (ii) any data stream algorithm with constant approximation guarantee requires exponential memory in k .

The techniques we use also readily imply hardness for the (preemptive) online version of this problem. In this version, the elements of the ground set \mathcal{N} arrive online, and upon receiving each element the algorithm has to decide either to add this element to the solution it maintains, or to reject the element. If the algorithm accepts an element to its solution, it may remove this element from the solution at a later point; however, a decision to reject an element (or remove it from the solution at a later time) is irrevocable. The algorithm is also required to keep its solution feasible at all times. We have the following hardness in this model.

► **Theorem 6.** *For $k \geq 2$, the competitive ratio of any online algorithm for $SMkM$ against an oblivious adversary is at least $\frac{k}{81 \ln k}$. This holds even when the task is to find a maximum size common independent set in k partition matroids, and the common rank of these matroids is $O(k/\log k)$.*

The key building block for both (streaming and online) hardness results is a “hard” distribution of instances described in Section 3.1. This distribution is then used to prove Theorems 2 and 6 in Sections 3.2 and 3.3, respectively, in a similar way to the proof of Theorem 1.

3.1 Description of hard distribution

Let p be a non-negative integer parameter of the construction. Our instances are subsets of the set $\mathcal{N} = [p]^k$, where we allow multiple elements with the same coordinates (i.e., “multi-subsets”). A set $S \subseteq \mathcal{N}$ is independent in the matroid M_i (for any integer $i \in [k]$) if and only if no two elements of S share the same value in coordinate number i (in other words, $u_i \neq v_i$ for every two distinct elements $u, v \in S$). One can observe that this definition makes M_i a partition matroid. We recall that $S \subseteq \mathcal{N}$ is a *common independent set* if it is independent in all matroids; otherwise, we will refer to it as *dependent*. Note that the common rank of the k matroids M_1, \dots, M_k is p .

In Algorithm 1 we describe a procedure for sampling $p-1$ many subsets $S_1, S_2, \dots, S_{p-1} \subseteq [p]^k$ and $p-1$ “hidden” optimal elements $o^{(1)} \in S_1, o^{(2)} \in S_2, \dots, o^{(p-1)} \in S_{p-1}$. In every iteration $r = 1, \dots, p-1$, the algorithm first forms S_r by sampling m elements independently and uniformly from those elements that form a common independent set with $\{o_1, \dots, o_{r-1}\}$. That is, S_r contains m uniformly random samples with replacements from

$$\{u \in \mathcal{N} \mid \forall 1 \leq i < r, 1 \leq j \leq k \ o_j^{(i)} \neq u_j\} .$$

Then, *after* the selection of S_r , the algorithm samples $o^{(r)}$ uniformly at random among the m elements in S_r .

We remark that the algorithm with small probability may sample the same element more than once when forming the set S_r . When this happens, we consider these samples to be unique elements on the stream (that are dependent). This allows us to simplify the notation in the following as each set S_r is now guaranteed to contain exactly m elements. Formally, this corresponds to extending the ground set \mathcal{N} by making m copies u^1, \dots, u^m of each element $u \in \mathcal{N}$, and whenever an element u is sampled i times, we include the copies u^1, \dots, u^i .

Algorithm 1 HARD INSTANCE GENERATION (p, m) .

- 1: **for** $r = 1$ **to** $p - 1$ **do**
 - 2: Obtain S_r by sampling m elements uniformly and with replacement from

$$\{u \in \mathcal{N} \mid \forall_{1 \leq i < r, 1 \leq j \leq k} o_j^{(i)} \neq u_j\} .$$
 - 3: Select $o^{(r)}$ from S_r uniformly at random.
 - 4: Output S_1, \dots, S_{p-1} and $o^{(1)}, \dots, o^{(p-1)}$.
-

We refer to Algorithm 1 as “HARD INSTANCE GENERATION” as it is the basic building block of our hardness results in both the online and streaming models. More specifically, our hardness result for the online model is based on the (random) stream obtained by first feeding the elements in S_1 (in any order), then S_2 (in any order), and so on until S_{p-1} is fed. The intuition is that when the algorithm has only seen the elements in S_1, \dots, S_i , it has no information about the selection of $o^{(i)}$ and so any online algorithm is unlikely to have saved the element $o^{(i)}$. In addition, while $\{o^{(1)}, \dots, o^{(p-1)}\}$ is a common independent set by construction, we prove (see Lemma 8 below) that any other two elements are likely to be dependent. This creates the “gap” between the values of the solution $\{o^{(1)}, o^{(2)}, \dots, o^{(p-1)}\}$ and a solution with any other elements, which in turn yields the desired hardness result. For our hardness in the data stream model, we forward a subset of the above-mentioned stream, and the difficulty for a low-space streaming algorithm is to “remember” whether the special elements $o^{(1)}, o^{(2)}, \dots, o^{(p-1)}$ appeared in the stream. This is formalized in the next sections.

We complete this section by proving that, with good probability, any large solution must contain the hidden elements $o^{(1)}, \dots, o^{(p-1)}$.

► **Definition 7.** *We say that the output of Algorithm 1 is successful if any two elements $e, f \in S_1 \cup S_2 \cup \dots \cup S_{p-1} \setminus \{o_1, \dots, o_{p-1}\}$ are dependent, i.e., there is a coordinate $i \in [k]$ such that $e_i = f_i$.*

► **Lemma 8.** *The output of Algorithm 1 is successful with probability at least $1 - \binom{pm}{2} e^{-k/p}$.*

Proof. Consider two elements $u \in S_{r_1} \setminus \{o_{r_1}\}$ and $v \in S_{r_2}$ with $r_1 \leq r_2$. As $u \neq o_{r_1}$, each coordinate of u equals that of v with probability at least $1/(p - r_1 + 1) \geq 1/p$. Now, as there are k coordinates, and each coordinate of u is sampled independently at random,

$$\Pr[\{u, v\} \text{ is a common independent set}] \leq (1 - 1/p)^k \leq e^{-k/p} .$$

The lemma now follows by taking the union bound over all possible pairs u, v ; the number of such pairs is upper bounded by $\binom{(p-1)m}{2}$. ◀

3.2 Hardness for online algorithms

Let $p = \lceil k/(27 \ln k) \rceil + 1$ and $m = k^3$. We will prove that the competitive ratio of any online algorithm is at least $k/(81 \ln k)$. We assume throughout that k is such that $k/(81 \ln k) > 1$. This is without loss of generality since the statement is trivial if $k/(81 \ln k) \leq 1$. We shall consider the following distribution of instances. Run Algorithm 1 with the parameters p and m to obtain sets S_1, \dots, S_{p-1} (and hidden elements $o^{(1)}, \dots, o^{(p-1)}$), and construct an input stream in which the elements of S_1 appear first (in any order) followed by those in S_2 and so on until the elements in S_{p-1} appear. We will show that any deterministic online algorithm ALG cannot be $((p-1)/3)$ -competitive on this distribution of instances. Theorem 6 then follows via Yao’s principle.

To analyze the competitive ratio of ALG, let O be the event that the output of ALG contains some element of $\{o^{(1)}, o^{(2)}, \dots, o^{(p-1)}\}$, and let S be the event that the instance is successful. Then, if we use $|ALG|$ to denote the size of the independent set outputted by ALG,

$$\mathbb{E}[|ALG|] \leq (1 - \Pr[\neg O, S]) \cdot k + 1 ,$$

where the inequality holds because any solution has size at most k , and if the algorithm fails to identify any element in $\{o^{(1)}, \dots, o^{(p-1)}\}$, then it can produce solution of size at most 1 for a successful instance.

Note that since $k/(81 \ln k) > 1$ we have that $p \leq 3 \cdot k/(27 \ln k) = k/(9 \ln k)$. Now, by Lemma 8 and the selection of p and m , we have

$$\Pr[S] \geq 1 - \binom{pm}{2} e^{-k/p} \geq 1 - k^8 \cdot e^{-9 \ln k} = 1 - 1/k .$$

To bound $\Pr[\neg O]$, note that the set S_r contains no information about $o^{(r)}$ because $o^{(r)}$ is selected uniformly at random from S_r . Moreover, when all m elements of S_r have been inspected in the stream, ALG keeps at most p independent elements. Any one of these elements is $o^{(r)}$ with probability at most p/m . In other words, the algorithm selects $o^{(r)}$ with probability at most p/m . Hence, by the union bound, the algorithm has selected any of the $p-1$ elements $\{o^{(1)}, \dots, o^{(p-1)}\}$ with probability at most $p/m \cdot (p-1) \leq 1/k$. We thus have $\Pr[\neg O] \geq 1 - 1/k$, and together with the above proved inequality $\Pr[S] \geq 1 - 1/k$, we get via the union bound

$$\mathbb{E}[|ALG|] \leq (1 - \Pr[\neg O, S]) \cdot k + 1 \leq (2/k) \cdot k + 1 = 3 .$$

Since the stream contains a solution $\{o^{(1)}, \dots, o^{(p-1)}\}$ of size $p-1$, this implies that ALG is not better than $((p-1)/3)$ -competitive, which in turn implies Theorem 6.

3.3 Hardness for streaming algorithms

Let ALG be a data stream algorithm for finding a set of maximum cardinality subject to k partition matroid constraints. Further suppose that ALG has the following properties:

- ALG uses memory M ;
- ALG outputs an α -approximate solution with probability at least $2/3$, where $\alpha \leq \frac{k}{32 \ln k}$ (note that α is also lower bounded by 1 since it is an approximation ratio).

Select $p = \lceil 3 \cdot \alpha \rceil$, and let m be the smallest power of two such that $m \geq e^{k/(8\alpha)}$. Note that this selection satisfies

$$p \in [3 \cdot \alpha, 4 \cdot \alpha] , \quad m \in [e^{k/(8\alpha)}, 2e^{k/(8\alpha)}] , \quad \text{and} \quad 8 \cdot p \leq k \leq m .$$

We will use ALG to devise a protocol for the $\text{CHAIN}_p(m)$ problem that succeeds with probability at least $2/3$ and has communication complexity at most $M + p \log_2 m$. Combining this reduction with Theorem 5 then yields Theorem 2, i.e., that any such algorithm ALG must have a memory footprint M that is at least $\Omega(e^{k/(8\alpha)}/k^2)$.

3.3.1 Description of protocol

We use ALG to obtain Protocol 2 for $\text{CHAIN}_p(m)$. The protocol consists of two phases: a precomputation phase that is independent of the $\text{CHAIN}_p(m)$ instance, followed by a description of the messages of the players.

■ **Figure 1** A tree representation of the sets computed during precomputation for $m = p = 3$.

3.3.1.1 Precomputation phase

In the precomputation phase, the players use shared random coins⁶ to generate instances from the same distribution produced by Algorithm 1 for all possible values of $t^2, \dots, t^p \in [m]$ in an instance of $\text{CHAIN}_p(m)$. Specifically, first a set T is sampled from the same distribution as the set S_1 produced by Algorithm 1. The elements of T are then randomly permuted. For $j \in [m]$, we let $T(j)$ denote the j -th element in the obtained ordered set. The reason that the elements in T are randomly permuted is to make sure that for any fixed $t^2 \in [m]$, the element $T(t^2)$ is uniformly random, and thus, has the same distribution as $o^{(1)}$ in Algorithm 1. Following the choice of $S_1 = T$ and $o^{(1)} \in S_1$, Algorithm 1 proceeds to sample S_2 to be m random elements that are independent with respect to $o^{(1)}$. In the precomputation phase we do so for each possible element in T , i.e., we sample sets T_1, T_2, \dots, T_m , one for each possible choice of $t^2 \in [m]$. Then, for each such T_{t^2} we sample m sets $T_{t^2,1}, T_{t^2,2}, \dots, T_{t^2,m}$ for all possible choices of $t^3 \in [m]$ and so on. The sets constructed in the precomputation phase can thus naturally be represented by a tree, where each path from the root T to a leaf corresponds to a particular choice of $t^2, t^3, \dots, t^p \in [m]$. For $m = 3$ and $p = 3$, this tree is depicted in Figure 1. The thick path corresponds to the case of $t_2 = 2$ and $t_3 = 3$.

As described above, we randomly permute the sets so as to make sure that, for fixed $t^2, t^3, \dots, t^r \in [m]$, the distribution of $o^{(1)}$ is the same as that of $T(t^2)$ and, in general, the distribution of $o^{(i)}$ is the same as that of $T_{t^2, \dots, t^i}(t^{i+1})$. This gives us the following observation.

► **Observation 9.** Fix $t^2, t^3, \dots, t^r \in [m]$. Over the randomness of the precomputation phase, the elements $o^{(1)} = T(t^2), o^{(2)} = T_{t^2}(t^3), \dots, o^{(r-1)} = T_{t^2, \dots, t^{r-1}}(t^r)$ and the sets $S_1 = T, S_2 = T_{t^2}, \dots, S_{r-1} = T_{t^2, \dots, t^{r-1}}$ have the same distribution as the output of Algorithm 1.

The reason the players do this precomputation is that, after they have commonly agreed on the tree-structure of sets (which can be generated using the public coins), it requires little communication to decide on a “hard” instance generated from the same distribution as Algorithm 1. Indeed, Player r only needs to know t^2, \dots, t^r ($r \log_2 m$ bits of information) in-order to know the set T_{t^2, \dots, t^r} .

⁶ We note that the hardness result of $\text{CHAIN}_p(m)$ (Theorem 5) holds when the players have access to public coins, i.e., shared randomness. This is proved, e.g., in Theorem 3.3 of [9]. In general, Newman’s theorem [27] says that we can turn any public coin protocol into a private coin protocol with little (logarithmic) increase in communication.

■ **Protocol 2** Reduction from $\text{CHAIN}_p(m)$ to SMkM .

Precomputation

- 1: Let T be a uniformly random subset of $\mathcal{N} = [p]^k$ of size m .
- 2: Order the elements of T randomly, and let $T(j)$ denote the j -th element.
- 3: **for** $r = 2, \dots, p - 1$ and $t^2, \dots, t^r \in [m]$ **do**
- 4: Identify $o^{(1)} = T(t^2), o^{(2)} = T_{t^2}(t^3), \dots, o^{(r-1)} = T_{t^2, \dots, t^{r-1}}(t^r)$.
- 5: Let T_{t^2, \dots, t^r} be a uniformly random subset of $\{u \in \mathcal{N} \mid \forall 1 \leq i < r, 1 \leq j \leq k \ o_j^{(i)} \neq u_j\}$ of size m .
- 6: Order the elements of T_{t^2, \dots, t^r} randomly, and let $T_{t^2, \dots, t^r}(j)$ denote the j -th element.

Player P_r 's Algorithm for $r = 1, \dots, p - 1$

- 1: Initialize ALG with the received memory state (or initial state if first player).
- 2: Simulate ALG on the elements $T_r = \{T_{t^2, \dots, t^r}(j) \mid j \in [n] \text{ with } x_j^t = 1\}$ given in any order.
- 3: Send to P_{r+1} the values t^2, t^3, \dots, t^r and the memory state of ALG .

Player P_p 's Algorithm

- 1: If ALG with the received memory state returns an independent set of size at least 2, output “1-case”; otherwise, output “0-case”.
-

3.3.1.2 The messages of the players

After generating the (common) sets in the precomputation phase using the public coins, the players now proceed as follows. The first player receives as input x^1 and simulates ALG on the subset $\{T(j) \mid x_j^1 = 1\}$ of T corresponding to the 1-bits. These elements are given to ALG as a stream in any order. Player 1 then sends to Player 2 the message containing the state of ALG after processing this stream of elements.

The second player receives input x^2, t^2 and initializes ALG with the state received from the first player. Then, the elements $\{T_{t^2}(j) \mid x_j^2 = 1\}$ of T_{t^2} that correspond to 1-bits of x^2 are streamed to ALG in any order. Player 2 sends to Player 3 a message containing the state of ALG after processing these elements and the index t^2 . Player r , for $r = 3, \dots, p - 1$, proceeds similarly to Player 2: given input x^r, t^r , ALG is first initialized with the state received from the previous player, and then the elements $\{T_{t^2, \dots, t^r}(j) \mid x_j^r = 1\}$ are streamed to ALG in any order. Notice that Player r knows t^2, \dots, t^{r-1} from the message of the previous player, t^r, x^r from the input, and T_{t^2, \dots, t^r} from the precomputation phase, and so the set $\{T_{t^2, \dots, t^r}(j) \mid x_j^r = 1\}$ can be computed. Finally, Player r sends to Player $r + 1$ a message consisting of the indices t^2, \dots, t^r and the memory state of ALG .

The final player initializes ALG with the received state and asks ALG to return an independent set. If the independent set consists of at least two elements, Player p outputs “1-case”, and otherwise, the output is “0-case”.

3.3.2 Analysis

The messages sent by the players contain the memory state of ALG and at most $p - 2$ indices $t^2, \dots, t^{p-1} \in [m]$. The memory state of ALG is at most M bits by assumption, and each index requires $\log_2 m$ bits. The communication complexity of the protocol is, therefore, upper bounded by $M + p \log_2 m$.

To analyze the success probability of the protocol, we have the following lemma.

► **Lemma 10.** *The instance that the players stream to ALG satisfies the following:*

- *In the 1-case, the stream contains $p - 1$ independent elements.*
- *In the 0-case, with probability at least $2/3$, any two elements in the stream are dependent.*

Proof. In the 1-case, we have $x_{t^2}^1 = x_{t^3}^2 = \dots = x_{t^p}^{p-1} = 1$ and so the elements $T(t^2)$, $T_{t^2}(t^3)$, \dots , $T_{t^2, \dots, t^{p-1}}(t^p)$ are part of the stream. By definition, they form an independent set consisting of $p - 1$ elements.

In the 0-case, we have that $x_{t^2}^1 = x_{t^3}^2 = \dots = x_{t^p}^{p-1} = 0$ and so any two elements e, f in the stream belong to the set $S_1 \cup S_2 \dots, S_{p-1} \setminus \{o^{(1)}, o^{(2)}, \dots, o^{(p-1)}\}$, where $S_1 = T$, $o^{(1)} = T(t^2)$ and $S_j = T_{t^2, \dots, t^j}, o^{(j)} = T_{t^2, \dots, t^j}(t^{j+1})$ for $j = 2, \dots, p - 1$. By Observation 9, we can apply Lemma 8 to obtain that, with probability at least $1 - \binom{pm}{2} e^{-k/p}$, any two elements in the stream are dependent. The statement now follows since the selection of our parameters p, m and k implies

$$\binom{pm}{2} e^{-k/p} \leq m^4 e^{-k/p} \leq 16e^{k/(8\alpha)} \cdot e^{-k/(4\alpha)} = 16e^{-k/(8\alpha)} \leq 1/3 ,$$

where for the first inequality we used $p \leq m$, and for the second inequality we used that $p \leq 4 \cdot \alpha$ and $m \leq 2e^{k/(8\alpha)}$. The last inequality holds for $k \geq 3$ (the case of $k = 2$ can be ignored because it implies $k/(32 \ln k) < 1$, which makes Theorem 2 trivial). \blacktriangleleft

We now argue how the above lemma implies that Protocol 2 has a success probability of $2/3$ in both the 0-case and 1-case. For 0-case instances, we have with probability $2/3$ that any two elements are dependent. Hence, with that probability, there is no way for ALG to return an independent set with more than one element. Thus, the output of Player p is correct with probability at least $2/3$ in the 0-case. In the 1-case, the stream always contains a solution of value $p - 1$. By the assumption that ALG returns an α -approximate solution with probability at least $2/3$, ALG returns an independent set of size at least $(p - 1)/\alpha$ with probability at least $2/3$. This implies that Player p is correct in this case with probability $2/3$ since

$$(p - 1)/\alpha \geq (3 \cdot \alpha - 1)/\alpha \geq 2 .$$

Using ALG we have, thus, devised a protocol for $\text{CHAIN}_p(m)$ that is correct with probability $2/3$ and has a communication complexity that is upper bounded by $M + p \log_2 m$. By Theorem 5, we thus must have $(M + p \log_2 m) \geq m/(36p^2)$. Now using that $p \leq k/8$ and $e^{k/(8\alpha)} \leq m$, we get

$$M \geq \frac{m}{36p^2} - p \log_2 m \geq \frac{64}{36} \frac{m}{k^2} - k^2 \geq \frac{64}{36} \frac{e^{k/(8\alpha)}}{k^2} - k^2 ,$$

which is $\Omega(e^{k/(8\alpha)}/k^2)$ since by assumption on α we have $e^{k/(8\alpha)} \geq k^4$. We have thus proved that the memory usage M of ALG must be at least $\Omega(e^{k/(8\alpha)}/k^2)$ as required by Theorem 2.

Abstract

Data reduction rules are an established method in the algorithmic toolbox for tackling computationally challenging problems. A data reduction rule is a polynomial-time algorithm that, given a problem instance as input, outputs an equivalent, typically smaller instance of the same problem. The application of data reduction rules during the preprocessing of problem instances allows in many cases to considerably shrink their size, or even solve them directly. Commonly, these data reduction rules are applied exhaustively and in some fixed order to obtain irreducible instances. It was often observed that by changing the order of the rules, different irreducible instances can be obtained. We propose to “undo” data reduction rules on irreducible instances, by which they become larger, and then subsequently apply data reduction rules again to shrink them. We show that this somewhat counter-intuitive approach can lead to significantly smaller irreducible instances. The process of undoing data reduction rules is not limited to “rolling back” data reduction rules applied to the instance during preprocessing. Instead, we formulate so-called backward rules, which essentially undo a data reduction rule, but without using any information about which data reduction rules were applied to it previously. In particular, based on the example of VERTEX COVER we propose two methods applying backward rules to shrink the instances further. In our experiments we show that this way smaller irreducible instances consisting of real-world graphs from the SNAP and DIMACS datasets can be computed.

■ **Figure 1** An example of how the order of reduction rules can affect the final instance. A VERTEX COVER instance with $k = 4$ is depicted left. By applying the Triangle Rule to b (red triangle), we obtain a graph with two edges (right). However, applying the rule to a and then c (therefore removing the two blue triangles) yields the smaller graph consisting only of the vertex b .

1 Introduction

Kernelization by means of applying data reduction rules is a powerful (and often essential) tool for tackling computationally difficult (e. g. NP-hard) problems in theory and in practice [11, 2]. A data reduction rule is a polynomial-time algorithm that, given a problem instance as input, outputs an “equivalent” and often smaller instance of the same problem. One may think of data reduction as identifying and removing “easy” parts of the problem, leaving behind a smaller instance containing only the more difficult parts. This instance can be significantly smaller than the original instance [1, 3, 16, 13, 18] which makes other methods like branch&bound algorithms a viable option for solving it. In this work, we apply existing data reduction rules “backwards”, that is, instead of smaller instances we produce (slightly) larger instances. The hope herein is, that this alteration of the instance allows subsequently applied data reduction rules to further shrink the instance, thus, producing even smaller instances than with “standard” application of data reduction rules.

We consider the NP-hard VERTEX COVER – the primary “lab animal” in parameterized complexity theory [9] – to illustrate our approach and to exemplify its strengths.

VERTEX COVER [12]

Input: An undirected graph $G = (V, E)$ and $k \in \mathbb{N}$.

Question: Is there a set $S \subseteq V$, $|S| \leq k$, covering all edges, i. e., $\forall e \in E: e \cap S \neq \emptyset$?

VERTEX COVER is a classic problem of computational complexity theory and one of Karp’s 21 NP-complete problems [15]. We remark that for presentation purposes we use the decision version of VERTEX COVER. All our results transfer to the optimization version (which our implementation is build for).

To explain our approach, assume that all we have is the following data reduction rule:

► **Reduction Rule 1** (Triangle Rule [9]). *Let $(G = (V, E), k)$ be an instance of VERTEX COVER and $v \in V$ a vertex with exactly two neighbors u and w . If the edge $\{u, w\}$ exists, then delete v , u , and w from the graph (and their incident edges), and decrease k by two.*

As illustrated in Figure 1, there are two options to apply Rule 1 for the instance $(G, 4)$. Picking the “bad” option, that is, applying it to b yields the instance $(G', 2)$. Note that (the correctness of) Rule 1 implies that $(G, 4)$ and $(G', 2)$ are “equivalent”, that is, either both of them are yes-instances or none of them are. Hence, if we have the instance $(G', 2)$ on the right side (either through the “bad” application of Rule 1 or directly as input), then we can

apply Rule 1 “backwards” and obtain the equivalent but larger instance $(G, 4)$ on the left side. Then, by applying Rule 1 to a and c , we can arrive at the edge-less graph $(\{b\}, \emptyset)$, thus “solving” the triangle-free instance $(G', 2)$ by only using the Triangle Rule.

More formally, the setting can be described as follows: A data reduction rule for a problem L is a polynomial-time algorithm which *reduces* an instance x to an equivalent instance x' , that is, $x \in L$ if and only if $x' \in L$. A set of data reduction rules thus implicitly partitions the space of all instances into classes of equivalent instances (two instances are in the same equivalence class if one of them can be obtained from the other by applying a subset of the data reduction rules). The more data reduction rules we have, the fewer and larger equivalence classes we have. Now, the overall goal of data reduction is to find the *smallest* instance in the same equivalence class. We demonstrate two approaches tailored towards (but not limited to) graph problems to tackle this task.

Let us remark that while there are some analogies to the branch&bound paradigm (searching for a solution in a huge search space), there are also notable differences: A branching rule creates several instances of which at least one is guaranteed to be equivalent to the original one. The problem is that, a priori, it is not known which of these instances is the equivalent one. Hence, one has to “solve” all instances before learning the solution. In contrast, our setting allows stopping at *any* time as the currently handled instance is *guaranteed* to be equivalent to the starting instance. This allows for considerable flexibility with respect to possible combinations with other approaches like heuristics, approximation or exact algorithms.

Related Work. Fellows et al. [9] are closest to our work. They propose a method for automated discovery of data reduction rules looking at rules that replace a small subgraph by another one. They noticed that if a so called *profile* (which is a vector of integers) of the replaced subgraph and of the one taking its place only differ by a constant in each entry, then this replacement is a data reduction rule. To then find data reduction rules, one can enumerate all graphs up to a certain size and compute their profile vectors. The downside of this approach is that in order to apply the automatically found rules one has solve a (computationally challenging) subgraph isomorphism problem or manually design new algorithms for each new rule.

VERTEX COVER is extensively studied from the the viewpoint of data reduction and kernelization; see Fellows et al. [9] for an overview. Akiba and Iwata [3] and Hesse et al. [14] provide exact solvers that include an extensive list of data reduction rules. The solver of Hesse et al. [14] won the exact track for VERTEX COVER at the 4th PACE implementation challenge [7]. We provide a list of data reduction rules for VERTEX COVER in the full version [10].

Alexe et al. [4] experimentally investigated by how much the so-called Struction data reduction rule for INDEPENDENT SET can shrink small random graphs. The Struction data reduction rule can always be applied to any graph and decreases the stability number¹ of a graph by one, but may increase the number of vertices quadratically each time it is applied. Gellner et al. [13] proposed a modification of the Struction rule for the MAXIMUM WEIGHTED INDEPENDENT SET problem. They first restricted themselves to only applying data reduction rules if they do not increase the number vertices in the graph, which they call the reduction phase. They then compared this method to an approach which allows

¹ An independent set is a set of pairwise nonadjacent vertices. The stability number or the independence number of a graph G is the size of a maximum independent set of G .

their modified Struction rule to also increase the number of vertices in the graph by a small fraction, which they call the blow-up phase. The experiments showed, that repetitions of the reduction and blow-up phase can significantly shrink the number of vertices compared to just the reduction phase.

Ehrig et al. [8] defined the notion of confluence from rewriting systems theory for kernelization algorithms. Intuitively, confluence in kernelization means that the result of applying a set of data reduction rules exhaustively to the input always results in the same instance, up to isomorphism, regardless of the order in which the rules were applied. It turns out that for our approach to work we require non-confluent data reduction rules.

Our Results. In Section 3, we provide two concrete methods to apply existing data reductions rules “backwards” and “forwards” in order to shrink the input as much as possible. We implemented these methods and applied them on a wide range of data reduction rules for VERTEX COVER. Our experimental evaluations are provided in Section 4 where we use our implementation on instances where the known data reductions rules are not applicable. Our implementation can also be used to preprocess a given graph G and it returns the smallest found kernel K after a user specified amount of time. Moreover, the implementation can translate a provided solution S_K for the kernel into a solution S_G for the initial instance such that $|S_G| \leq |S_K| + d$ where $d := \tau(G) - \tau(K)$ is the difference between the sizes of minimum vertex covers of G and K . Thus, if a minimum vertex cover for K is provided it will be translated into a minimum vertex cover for G .

2 Preliminaries

We use standard notation from graph theory and data reduction. In this work, we only consider simple undirected graphs G with vertex set $V(G)$ and edge set $E(G) \subseteq \{\{v, w\} \mid v, w \in V(G), v \neq w\}$. We denote by n and m the number of vertices and edges, respectively. For a vertex $v \in V(G)$ the open (closed) neighborhood is denoted with $N_G[v]$ ($N_G(v)$). For a vertex subset $S \subseteq V(G)$ we set $N_G[S] := \bigcup_{v \in S} N_G[v]$. When in context it is clear which graph is being referred to, the subscript G will be omitted in the subscripts.

Data Reduction Rules. We use notions from kernelization in parameterized algorithmics [11]. However, we simplify the notation to unparameterized problems. A data reduction rule for a problem $L \subseteq \Sigma^*$ is a polynomial-time algorithm, which *reduces* an instance x to an equivalent instance x' . We call an instance x *irreducible* with respect to a data reduction rule, if the data reduction rule does not change the instance x any further (that is, $x' = x$). The property that the data reduction rule returns an equivalent instance is called *safeness*. We call an instance obtained from applying data reduction rules *kernel*.

Often, data reduction rules can be considered nondeterministic, because a data reduction rule could change the input instance in a variety of ways (e. g., see the example in Section 1). To highlight this effect and to avoid confusion, we introduce the term *forward rule*. A forward rule is a subset $R_{\mathcal{A}} \subseteq \Sigma^* \times \Sigma^*$ associated with a nondeterministic polynomial-time algorithm \mathcal{A} , where $(x, y) \in R_{\mathcal{A}}$ if and only if y is one of the possible outputs of \mathcal{A} on input x . Intuitively, a forward rule captures all possible instances that can be derived from the input instance by applying a data reduction rule a single time. To define what it means to “undo” a reduction rule, we introduce the term *backward rule*. A backward rule is simply the converse relation $R_{\mathcal{A}}^{-1} := \{(y, x) \mid (x, y) \in R_{\mathcal{A}}\}$ of some forward rule $R_{\mathcal{A}}$.

Confluence. A set of data reduction rules is said to be terminating, if for all instances \mathcal{I} , the data reduction rules in the set cannot be applied to the instance \mathcal{I} infinitely many times. A set of terminating data reduction rules is said to be confluent if any exhaustive way of applying the rules yields a unique irreducible instance, up to isomorphism [8]. It is not hard to see that given a set of confluent data reduction rules, undoing any of them is of no use, because subsequently applying the data reduction rules will always result in the same instance.

► **Lemma 2.1.** *Let \mathcal{R} be a confluent set of forward rules, \mathcal{I} a problem instance, and $\mathcal{I}^{\mathcal{R}}$ the unique instance obtained by applying the rules in \mathcal{R} to \mathcal{I} .*

Further let $\overline{\mathcal{R}} = \{R^{-1} \mid R \in \mathcal{R}\}$ be the set of backward rules corresponding to \mathcal{R} . Let \mathcal{I}^- be an instance that was derived by applying some rules from $\mathcal{R} \cup \overline{\mathcal{R}}$. Then applying the rules in \mathcal{R} exhaustively in any order to \mathcal{I}^- will yield an instance isomorphic to $\mathcal{I}^{\mathcal{R}}$.

Proof. We prove the lemma by induction over the number of times backward rules were applied to obtain \mathcal{I}^- .

Base case: if no backward rules were applied to obtain \mathcal{I}^- , then by exhaustively applying \mathcal{R} we will obtain an instance isomorphic to $\mathcal{I}^{\mathcal{R}}$.

Inductive step: Assume only n backward rules were applied to obtain \mathcal{I}^- . Consider the sequence $\mathcal{I} = \mathcal{I}_1, \mathcal{I}_2, \dots, \mathcal{I}_{\ell-1}, \mathcal{I}_{\ell} = \mathcal{I}^-$ of instances which were on the way from \mathcal{I} to \mathcal{I}^- during the application of the rules in $\mathcal{R} \cup \overline{\mathcal{R}}$. Further let \mathcal{I}_i be the instance in the sequence after applying the n 'th backward rule R^{-1} . After applying R to \mathcal{I}_i the instance \mathcal{I}_{i-1} can be obtained, which was obtained by using only $n - 1$ backward rules. Because after R^{-1} only rules in \mathcal{R} were applied, which are confluent, we may instead assume that the first rule which was applied after R^{-1} was R . Consequently, by the induction hypothesis an instance isomorphic to $\mathcal{I}^{\mathcal{R}}$ will be obtained by exhaustively applying the rules in \mathcal{R} . ◀

3 Two Methods for Achieving Smaller Kernels

We apply data reduction rules “back and forth” to obtain an equivalent instance as small as possible. This gives rise to a huge search space for which exhaustive search is prohibitively expensive. Thus, some more sophisticated search procedures are needed. In this section, we propose two approaches which we call the Find and the Inflate-Deflate method. We implemented and tested both approaches; the experimental results are presented in Section 4.

The Find method (Section 3.1) shrinks the naive search tree with heuristic pruning rules in order to identify sequences of forward and backward rules, which when applied to the input instance, produce a smaller equivalent instance. We employ this method primarily to find such sequences which are *short*, so that those sequences may actually be used to formulate *new* data reduction rules. It naturally has a *local* flavor in the sense that changes of one iteration are bound to a (small) part of the input graph.

The Inflate-Deflate method (Section 3.2) is much less structured. It randomly applies backward rules until the instance size increased by a fixed percentage. Afterwards, all forward rules are applied exhaustively. If the resulting instance is smaller, then the process is repeated; otherwise, all changes are reverted.

3.1 Find Method

For finding sequences of forward and backward rules which when applied to the input instance produce a smaller instance, we propose a structured search approach based on recursion. Let \mathcal{I} be the input instance and let $\mathcal{F}_{\mathcal{I}}$ be the set of all instances reachable via one forward

or backward rule, i. e., $\mathcal{F}_{\mathcal{I}} = \{\mathcal{I}' \mid (\mathcal{I}, \mathcal{I}') \in R \text{ for any forward or backward rule } R\}$. If the input instance is irreducible with respect to the set of forward rules, then only backward rules will be applicable. We branch into $|\mathcal{F}_{\mathcal{I}}|$ cases where, for each $\mathcal{I}' \in \mathcal{F}_{\mathcal{I}}$, we try to recursively find forward and backward rules applicable to \mathcal{I}' and branch on each of them. This is repeated until some maximum recursion depth is reached or the sequence of forward and backward rule applications results in a smaller instance. In the latter case, the sequence of applied rules can be thought of as a new data reduction rule.

Note that the search space is immense: For example, consider the backward rule corresponding to Rule 1, which inserts three vertices u , v , and w , makes them pairwise adjacent, and inserts an arbitrary set of edges between u and v and the original vertices. Thus, for each original vertex, there are four options (make it adjacent to u , to v , to u and v , or neither). This results in 4^n options for applying just this one single backward rule. Hence, it is clear that we have to introduce suitable methods to cut off large parts of the resulting search tree. To this end, we heavily rely on the observation that many reduction rules have a “local flavor”.

Region of Interest. To avoid a very large search space we only consider applying forward and backward rules “locally”. For this, we define a “region of interest”, which for graph problems is a set $X \subseteq V$. Any forward or backward rule must only be applied within the region of interest. We initially start with a very modest region of interest, namely $X = \{v\}$ for all $v \in V$. Thus, we work with n regions of interest per graph, each one considered separately.

Forward and backward rules are allowed to leave the region of interest only if at least one vertex that is “relevant” for the rule is within the region of interest. Moreover, the region of interest is allowed to “grow” as rules are applied. This is because applications of rules might cause further rules to become applicable. For example, rules might become applicable to the neighbors of vertices modified by the previously applied rules.

Specifically, let M be the set of “modified” vertices, which are new vertices or vertices which gained or lost an edge as a result of applying a forward or backward rule, and let D be the set of vertices it deleted. In the case of VERTEX COVER, we suggest to expand the region of interest to $(X \cup N[M]) \setminus D$ after each rule application. The majority of forward rules for VERTEX COVER are “neighborhood based”. Of course, the region of interest could be expanded even further, e. g., by extending it by $N^2[M]$ instead, but this will of course increase the search space. With a larger region of interest we might find more reduction rules, but at the cost of higher running time. Additionally, the found reductions may be more complex, and modify a large subgraph and are therefore difficult to analyze or implement.

We will call the above method, which recursively applies forward and backward rules one by one restricted to only the region of interest, the Find method. Note that we “accept” a sequence of forward and backward rules if it decreases the number of vertices or the parameter k , without increasing either. We have done so to find only “nice” data reduction rules where there is no trade-off between decreasing the parameter k or the number of vertices. However, different conditions to “accept” a sequence of forward and backward rules are also possible. For example, by only requiring that the number of vertices or edges is decreased.

Graph modification. Our implementation of the Find method outputs sequences of rules which are able to shrink the graph. However, just knowing which rules and in what order they were applied may not be very helpful in understanding the changes made by the rules. Specifically, it does not show how the rules were applied.

■ **Figure 2** A graph modification example corresponding to the application of the Degree-2 Folding Rule that applies to vertices with exactly two non-adjacent neighbors (the rule merges the degree-two vertex and its neighbors). The set $B = \{b_1, b_2, b_3\}$ is the boundary of the graph modification. Notice that only vertices in B (the boundary) are adjacent to both vertices in $V(H)$ and $V(G) \setminus V(H)$.

For this reason, we introduce the notion of a *graph modification* based on the ideas by Fellows et al. [9]. A graph modification encodes how a single or multiple data reduction rules have changed a graph. We say the *boundary* of a subgraph H of a graph G is the set B of all vertices in $V(H)$ whose neighborhood in G contains vertices in $V(G) \setminus V(H)$.

► **Definition 3.1.** A graph modification is a 4-tuple of graphs (G, H, H', G') with the following properties

- $B = V(H') \cap V(G)$,
- H is a subgraph of G with boundary B , and
- G' is derived from G by deleting all vertices in $V(H) \setminus B$ and all edges among B from G and then adding the vertices in $V(H') \setminus B$ and adding all edges from H' .

See Figure 2 for an example of a graph modification. The Find method can be extended such that in addition to printing rule sequences it also outputs the graph modifications corresponding to each application of a rule from the found sequences. This can be achieved by keeping track of newly created or deleted vertices and edges by the applied rules.

Isomorphism. It may happen that two or more rule sequences change an instance in the same way, that is, they produce isomorphic graphs from the same input instance. In order to avoid double counting, we implemented an isomorphism test to avoid these issues; see the full version [10] for details.

The Find and Reduce Method. The Find and Reduce Method is just a small variation of Find. Instead of only searching for sequences of forward and backward rules which shrink the instance, upon finding such a sequence it is also immediately applied to the instance. The search for more sequences continues with the smaller instance. This method serves the dual purpose of both finding sequences of rules which shrink the instance (and therefore also finding reduction rules), but also that of producing a smaller irreducible instance. Another potential advantage of this method is that it finds only the rules which were used to produce the smaller instance, and may therefore be more practical than the ones found by Find. Recall, that Find only searches for reduction rules applicable directly to the input instance. Perhaps by applying a single such sequence, different sequences are needed to shrink the remaining instance further.

3.2 Inflate-Deflate

Both the Find and the Find and Reduce method only change a small part of the instance. It may, however, be necessary to change large parts of an instance before it can be shrunk to a size smaller than it was originally. For this reason, we propose the Inflate-Deflate inspired by the Cyclic Blow-Up Algorithm by Gellner et al. [13].

Essentially, Inflate-Deflate iteratively runs two phases: First, in the inflation phase, randomly applies a set of backward rules to the instance until it becomes some fixed percentage α larger than it was initially. Then, in the deflation phase, exhaustively apply a set of forward rules and repeat with the inflation phase again. Our implementation has the termination condition $|V| = 0$ which may never be met. Thus a timeout or limit on the number of iterations has to be specified. The inflation factor α can be freely set to any value greater zero. We investigate the effect of different inflation factors in Section 4 for values of α between 10% and 50%.

In our deflate procedure, we apply the set of forward rules exhaustively in a particular way: An applicable forward rule is randomly chosen, and then it is randomly applied to the instance, but only once. Afterwards another applicable rule is chosen randomly, and this is repeated until the instance becomes irreducible with respect to all forward rules. This randomized exhaustive application of the forward rules ensures that the rules are not applied in a predefined way, and different “interactions” of the rules are tested. For example, consider the case where in the inflate phase the Backward Degree-2 Folding Rule was applied, then likely one would not want to immediately exhaustively apply the (Forward) Degree-2 Folding Rule (see Figure 2) which could in effect directly cancel the changes made by that backward rule. Furthermore, in this way, each of the forward rules has a chance to be applied. This avoids any potential problems due to an inconvenient fixed rule order.

Because large sections of an instance are modified at once, no short sequences of forward and backward rules can be extracted from this method. As a result, it is unlikely that new reduction rules could be learned this way. However, the method produces smaller irreducible instances as we will see in Section 4.

Local Inflate-Deflate. Within Inflate-Deflate it may happen that if we inflate the instance and then deflate it again, often the resulting instance is larger. In such cases the number of “negative” changes to the instance outweigh the number of “positive” changes. To increase the success probability one may try to lower the inflation factor, however then it can also happen that positive changes are less likely.

An alternate way to try to increase the success probability, is to apply backward rules within a randomly chosen subgraph rather than the whole graph. For example, this subgraph could be the set of all vertices with some maximum distance to a randomly chosen vertex. Backward rules are then applied until the subgraph becomes larger by a factor of α , instead of the whole graph.

4 Experimental Evaluation

In this section, we describe the experiments which we performed based on an implementation of the methods described in Section 3.

■ **Table 1** A glossary of the forward and backward rules which were used in our implementation. Note that we apply the Structon Rule only if it does not increase k . In the columns named alias we provide shortened names for the rules. We refer to the full version of the paper [10] for detailed descriptions of these rules.

Forward rules		Backward rules	
Alias	Full name	Alias	Full name
Deg0	Degree-0	Undeg2	Backward Degree-2 Folding
Deg1	Degree-1	Undeg3	Backward Degree-3 Independent Set
Deg2	Degree-2 Folding	Uncn	Backward 2-Clique Neighborhood (special case)
Deg3	Degree-3 Independent Set	Undom	Backward Domination
Dom	Domination	Ununconf	Backward Unconfined
Unconf	Unconfined- κ ($\kappa = 4$)	OE_Ins	Optional Edge Insertion
Desk	Desk		
CN	2-Clique Neighborhood		
OE_Del	Optional Edge Deletion		
Struct	Structon ($k' \leq k$)		
Magnet	Magnet		
LP	LP		

4.1 Setup

Computing Environment. All our experiments were run on a machine running Ubuntu 18.04 LTS with the Linux 4.15 kernel. The machine is equipped with an Intel® Xeon® W-2125 CPU, with 4 cores and 8 threads² clocked at 4.0 GHz and 256GB of RAM.

Datasets. For our experiments we used three different datasets: DIMACS, SNAP and PACE; the lists of graphs are given in the full version [10]. The DIMACS and SNAP datasets are commonly used for graph-based problems, including VERTEX COVER [3, 16, 13]. We have used the instances from the 10th DIMACS Challenge [5], specifically from the Clustering, Kronecker, Co-author and Citation, Street Networks, and Walshaw subdatasets. In total these are 82 DIMACS instances. From the SNAP Dataset Collection [17] we have used the graphs from from the Social, Ground-Truth Communities, Communication, Collaboration, Web, Product Co-purchasing, Peer-to-peer, Road, Autonomous systems, Signed and Location subdatasets. In total we obtained 52 SNAP instances. Additionally, we used a dataset which was used specifically for benchmarking VERTEX COVER solvers in the 2019 PACE Challenge [7]. We used the set of 100 private instances [6], which were used for scoring submitted solvers.

Preprocessing and Filtering. We apply some preprocessing to our datasets. We obtain simple, undirected graphs by ignoring any potential edge direction or weight information from the instances and by deleting self-loops. To these graphs we apply the forward rules, see Table 1 and the full version [10] for an overview: Deg1, Deg2, Deg3, Unconf, Cn, LP, Struct, Magnet and Oe_delete exhaustively in the given order. We note that the kernels obtained this way always had fewer vertices than the kernels obtained with the data reduction suite used by Akiba and Iwata [3] and also Hesse et al. [14].

² All our implementations are single-threaded.

We filter out graphs that became empty as a result of applying these rules. These were 41 DIMACS, 33 SNAP and 12 PACE instances. Furthermore, we discard graphs which after applying these rules still had more than 50,000 vertices. These were 12 DIMACS and 3 SNAP instances. Because the PACE instances may also contain instances from the other two datasets, we have tested the graphs for isomorphism. We have found one PACE instance to be isomorphic to a SNAP instance (p2p-Gnutella09), which was already excluded, because it was shrunk to an empty graph.

In total, we are left with 31 DIMACS, 16 SNAP and 88 PACE graphs with at most 50,000 vertices – all of these graphs are irreducible with respect to the forward rules. When referring to the datasets DIMACS, SNAP and PACE we will be referring to these kernelized and filtered instances.

Implementation. The major parts of our implementation are written in C++11 and compiled using version 7.5 of g++ using the -O2 optimization flag. Smaller parts, such as scripts for visualization or automation were written in Python 3.6 or Bash. We provide the source code for our implementation at <https://git.tu-berlin.de/afigiel/undo-vc-drr>. This implementation contains our Find and Inflate-Deflate method, together with the two small variations Find and Reduce, and local Inflate-Deflate. Find uses the local isomorphism test which we describe in Section 3.1, and output a description of the graph modification in addition to the found sequences.

We also provide a VERTEX COVER solver implementation with all our forward rules implemented, and some new data reduction rules which are explained later in this section. The solver is based on the branch-and-reduce paradigm and is very similar to the VERTEX COVER solver by Akiba and Iwata [3]. Moreover, we provide a lifting algorithm that can transform solutions for the kernelized instances into solution for the original instances. We also provide a Python script that is used to visualize the graph modifications of the sequences of forward and backward rules that are output by our methods. However, our focus in this section is on the Find and Inflate-Deflate method.

Methodology. We have implemented our Find and Inflate-Deflate methods together with their two variations: Find and Reduce and local Inflate-Deflate. Almost all forward and backward rules described in the full version [10] are used by these methods, see Table 1 for an overview.

All rules increase or decrease k , but do not need to know k in advance. This allows us to run Find and Inflate-Deflate on all graphs, without having to specify a value for k . Instead, we set $k = 0$ for all instances. In the final instance (G', k') computed from $(G, k = 0)$ we will have $\tau(G') - k' = \tau(G)$, where $\tau(G)$ denotes the vertex cover number of G . For graphs G' which become empty, $-k'$ is the vertex cover number of the original graph G .

We set a maximum recursion limit for Find such that only sequences of at most two or three rules are found. We will refer to FAR2 and FAR3 as the Find and Reduce method which only searches for sequences of at most two or three forward and backward rules, respectively.

We used inflation ratios α equal to 10, 20 and 50 percent, and we will refer to the different Inflate-Deflate configurations as ID10, ID20, and ID50, respectively. We also tested our local Inflate-Deflate method with $\alpha = 20\%$, which we have found to work best in preliminary experiments, which we will refer to as LID20.

All these configurations were tested on the three datasets with a maximum running time of one hour.

■ **Figure 3** A matrix depicting which pairs of forward rules we have found to be non-confluent. A cell corresponding to a row rule R_a and a column rule R_b is colored white if the set $\mathcal{R} = \{R_a, R_b, \text{Deg0}\}$ is not confluent. The Degree-0 rule is always included to not take into account differences in number of isolated vertices left after applying the rules. Gray cells correspond to sets which may be confluent, meaning that no counter-example was found for them.

4.2 Results

Confluence. Confluence can be proved using for example conflict pair analysis [8], which is not straightforward and does not work for all types of data reduction rules. However, disproving confluence is potentially much easier, as it suffices to find one example where applying the rules in different order yields different instances.

For each pair of forward rules in Table 1, we tested on the set of all graphs with at most 9 vertices³ whether we can obtain irreducible, but non-isomorphic graphs by randomly applying the two rules to the same graph. More precisely, we test whether a set $\mathcal{R} = \{R_a, R_b, \text{Deg0}\}$ is confluent for two forward rules R_a and R_b . We include the Degree-0 Rule in these sets, because a difference in the number of isolated vertices is only a minor detail which we do not wish to take into account. We note that, the inclusion of the Degree-0 Rule in these sets was never the reason that a set was not confluent.

Our results are summarized in Figure 3. The figure clearly shows that most pairs of forward rules are not confluent. This means that the relative order of these rules may affect the final instance.

Instance Shrinking. Next, we demonstrate how much the Find and Reduce and Inflate-Deflate methods were able to shrink the irreducible DIMACS, SNAP, and PACE graphs, which were obtained by exhaustively applying a set of forward rules. The results are summarized in Figure 4 and Table 2.

Notably, ten DIMACS and four SNAP instances were reduced to an empty graph by the Inflate-Deflate methods. Five further DIMACS graphs shrank to around 80% of their size, and half of the DIMACS graphs did not really shrink at all. We conclude that the Inflate-Deflate approach seems to either work really well or nearly not at all for a given instance.

³ We obtained these graphs from Brendan McKay's website <https://users.cecs.anu.edu.au/~bdm/data/graphs.html>

■ **Figure 4** Cactus plots depicting how many irreducible instances were shrunk to a given fraction of their size (measured in vertices). The order of the instances is chosen for each configuration such that the size fractions of the instances are increasing. Note that the y-axis for DIMACS and SNAP start at zero (i. e. instances reduced to the empty graph); the y-axis for PACE does *not*.

■ **Table 2** Summary of the average relative size (in terms of number of vertices) achieved by each of the configurations on the three datasets. The best value per dataset is given in bold.

	FAR2	FAR3	ID10	ID20	ID50	LID20
DIMACS	82.6%	67.0%	62.9%	63.6%	66.1%	63.4%
SNAP	80.6%	66.8%	56.4%	59.3%	64.1%	56.4%
PACE	99.2%	97.4%	97.8%	98.1%	98.1%	98.0%

On average the ID10 configuration produced the smallest irreducible instances, see Table 2. From the FAR2 configuration it can be seen that already applying only two forward/backward rules in a sequence can considerably reduce the size of some graphs. In this case, the first rule is always a backward rule, and the second always a forward rule. However, using up to three rules in a sequence gave significantly better results.

For Inflate-Deflate, we see that small inflation ratios α around 10% perform best on average. Increasing the inflation ratio leads to slightly worse results, especially for the SNAP instances.

Next, in Figure 5, we see that the ID10 method was able to shrink graphs to empty graphs mostly for graphs with the lowest average degree (8–14), with the exception of one instance with an average degree of around 45. However, a large number of graphs with an average degree of 8–14 were not shrunk considerably. The other configurations, namely ID20, ID50, and FAR3 exhibit the same behavior. Similar behavior is also observed by replacing the average degree with the maximum degree. For the most part, only graphs with a relatively small maximum degree were able to be shrunk considerably. We conclude that our approach is most viable on sparse irreducible graphs.

In Figure 6, we show how the graph size changes over time with Find and Reduce and Inflate-Deflate on two example graphs. It can be clearly observed how ID10 repeatedly increases the number of vertices, which is the inflation phase, and then subsequently reduces it, which is the deflation phase. A slow downward trend of the number of vertices can be observed.

■ **Figure 5** Scatter plot relating the relative size (measured in vertices) of the shrunk instances to the average and maximum degree of these graphs for the ID10 configuration. Note that a logarithmic scale is used for the x-axis.

■ **Figure 6** The shrinkage of two instances by ID10 and FAR3 configurations on already kernelized instances. The x axis is time, and y is number of vertices. In the right figure red segments mean that the graph was shrunk by using a sequence of at least two forward and backward rules, whereas the blue segments indicate the use of forward rules only.

For the FAR3 configuration it can be seen that there are phases in which only forward rules have to be used to shrink the graph, and phases where longer sequences of forward and backward rules are needed. Sometimes a sudden large decrease in the number of vertices using only forward rules can be observed, which one may think of as a cascading effect. The graph only had to be changed by a small amount, triggering a cascade of forward rules.

5 Conclusion

Our work showed the large potential in the general idea of undoing data reduction rules to further shrink instances that are irreducible with respect to these rules. While the results for some instances are very promising, our experiments also revealed that other instances resist our attempts of shrinking them through preprocessing. From a theory point of view this is no surprise, as we deal with NP-hard problems after all. However, there is a lot of work

that still can be done in this direction. Similar to the branch&bound approach, many clever heuristic tricks will be needed to find solutions in the vast search space. Such heuristics might, for example, employ machine learning to guide the search. As mentioned before, our approach is not limited to VERTEX COVER. Looking at other problems is future work though. A framework for applying our approach on graph problems could be another next step. Also, our approach should be easily parallelizable.

Besides all these practical questions, there are also clear theoretical challenges: For example, for a given set of data reduction rules is there *always* (for each possible instance) a sequence of backwards and forward rules to obtain an equivalent instance of constant size? Note that this would not contradict the NP-hardness of the problems: Such sequences are probably hard to find and could even be of exponential length.

Improved Search of Relevant Points for Nearest-Neighbor Classification

Alejandro Flores-Velazco   

Department of Computer Science, University of Maryland, College Park, MD, USA

Abstract

Given a training set $P \subset \mathbb{R}^d$, the *nearest-neighbor classifier* assigns any query point $q \in \mathbb{R}^d$ to the class of its closest point in P . To answer these classification queries, some training points are more relevant than others. We say a training point is *relevant* if its omission from the training set could induce the misclassification of some query point in \mathbb{R}^d . These relevant points are commonly known as *border points*, as they define the boundaries of the Voronoi diagram of P that separate points of different classes. Being able to compute this set of points efficiently is crucial to reduce the size of the training set without affecting the accuracy of the nearest-neighbor classifier.

Improving over a decades-long result by Clarkson (FOCS'94), Eppstein (SOSA'22) recently proposed an *output-sensitive* algorithm to find the set of border points of P in $\mathcal{O}(n^2 + nk^2)$ time, where k is the size of such set. In this paper, we improve this algorithm to have time complexity equal to $\mathcal{O}(nk^2)$ by proving that the first phase of their algorithm, which requires $\mathcal{O}(n^2)$ time, are unnecessary.

1 Introduction

In the context of non-parametric classification, we are given a training set $P \subset \mathbb{R}^d$ consisting of n *labeled* points in d -dimensional Euclidean space, where the label of every point in P indicates the *class* (or *color*) that the point belongs to. The goal of a classifier is to use the training set P to *predict* the class for any *unlabeled* query point $q \in \mathbb{R}^d$, that is, to *classify* q .

The *nearest-neighbor classifier* (also known as *nearest-neighbor rule*) [13] stands out as a simple yet powerful method, that works by assigning any query point q to the class of its closest point in P . Despite its simplicity, the nearest-neighbor classifier is well-known to exhibit good classification accuracy both experimentally and theoretically [10, 11, 30]. In fact, it is still frequently used in many applications [5, 18, 22, 25–27, 29] over more recent and sophisticated techniques like support-vector machines [9] and deep neural networks [28].

One of the principal disadvantages of this technique is its high dependency on the size and dimensionality of the data, especially in light of *big data* applications. With training sets with billions of points becoming increasingly common, reducing the nearest-neighbor classifier's dependency on n and d is one approach to enhance its efficiency. There has been significant progress towards this goal, mainly focusing on two directions. The first involves the design of efficient data structures to answer approximate nearest-neighbor queries [2–4, 17, 19, 20, 23]. The second direction focuses on reducing the size of the training set used by the nearest-neighbor classifier, thus effectively reducing n . However, most practical techniques for training set reduction provide limited guarantees on the effect of this reduction to the accuracy of the nearest-neighbor classifier [1, 14–16].

■ **Figure 1** On the left, a training set P with points of three classes: *red*, *blue* and *yellow*. There the black lines highlight the *boundaries* of P between points of different classes. On the right, a subset of these points corresponding to the set of border points of P . Note that by definition, the boundaries between points of different classes remain the same for P and for its set of border points.

Only a handful of works [6, 8, 12] have proposed training set reduction algorithms that guarantee the same classification of every query point, before and after the reduction took place. These are called *boundary preserving* algorithms, and it is the focus of this paper.

The set of *border points* (or *relevant points*¹) of the training set P are those that define the boundaries between points of different classes, and whose omission from the training set would imply the misclassification of some query points in \mathbb{R}^d . Formally, two points $p, \hat{p} \in P$ are border points of P if they belong to different classes, and there exist some point $q \in \mathbb{R}^d$ such that q is equidistant to both p and \hat{p} , and no other point of P is closer to q than these two points (*i.e.*, the empty ball property of Voronoi Diagrams). See Figure 1 for an example of a training set P in \mathbb{R}^2 and its set of border points. Throughout, we let k denote the total number of border points in the training set. By definition, if instead of building the nearest-neighbor classifier with the entire training set P we use the set of border points of P , its dependency is reduced from n to k , while still obtaining the same classification for any query point in \mathbb{R}^d . This becomes particularly relevant for applications where $k \ll n$.

In this paper, we improve a recently proposed algorithm by [12] that computes the set of border points of any training set $P \subset \mathbb{R}^d$, where dimension d is assumed to be constant. While the original algorithm computes such set in $\mathcal{O}(n^2 + nk^2)$ time, where k is the number of border points of P , our new algorithm computes the same set in $\mathcal{O}(nk^2)$ time.

1.1 Previous Work

Other related problems in the realm of training set reduction are NP-hard [24, 31, 33] to solve exactly (*e.g.*, those of finding minimum cardinality *consistent* subsets and *selective* subsets). However, the problem of preserving the class boundaries of the nearest-neighbor classifier, or simply, finding the set of border points of P , is tractable.

For training sets $P \subset \mathbb{R}^2$ in 2-dimensional Euclidean space, Bremner *et al.* [6] proposed an output-sensitive algorithm for finding the set of border points of P in $\mathcal{O}(n \log k)$ worst-case time. However, how to generalize this algorithm for higher dimensions remained unclear.

¹ While [12] uses the term *relevant points*, the term *border points* has been the standard in the literature of this and other related problems [14, 15, 21, 32]. For this reason, we stick to the term *border points*.

Until very recently, the best result for the higher dimensional case was that of Clarkson [8]. He proposed an algorithm to find the set of border points of $P \subset \mathbb{R}^d$, with bounded d , that runs in $\mathcal{O}(\min(n^3, kn^2 \log n))$ worst-case time. For almost three decades, this remained the best result for training sets in \mathbb{R}^d . Recently, Eppstein [12] proposed a significantly faster algorithm for the d -dimensional Euclidean case, which runs in $\mathcal{O}(n^2 + nk^2)$ worst-case time.

Eppstein’s algorithm is strikingly simple, yet full of interesting ideas (see Algorithm 1). The algorithm works as follows: it begins by selecting an initial set of border points of P , one point from every class region. From here, the algorithm uses a series of subroutines which we will group together and denote as the “*inversion method*”, to find the remaining border points of P . Thus, the algorithm can be naturally split into two phases: the initialization of R with some border points, and the search process for the remaining border points of P .

■ **Algorithm 1** Recent Eppstein’s algorithm [12] to find the set of border points of P .

Input: Initial training set P
Output: The set of border points of P

- 1 Let M be the MST of P
- 2 Initialize R with the end points of every bichromatic edge of M
- 3 **foreach** $p \in R$ **do**
- 4 Let c be p ’s class and P_c be the points of P that belong to class c
- 5 Let S_p be the inverted points of $P \setminus P_c$ around p
- 6 Find all extreme points of S_p and their corresponding original points E_p
- 7 $R \leftarrow R \cup E_p$
- 8 **return** R

The initialization phase (lines 1–2 of Algorithm 1) involves finding a subset of border points such that at least one point for every class region is selected. Eppstein observes that this can be achieved by computing the Minimum Spanning Tree (MST) of P , identifying the edges of the MST that connect points of different classes (denoted as *bichromatic* edges), and selecting the endpoints of all such edges. This phase takes $\mathcal{O}(n^2)$ time, but we will prove that it is not necessary.

The search phase (lines 3–6 of Algorithm 1) is in charge of finding every remaining border point of P . This phase iterates over all selected points, and for each such point p , it performs what we call the inversion method. This method identifies a subset of border points of P , which are added to R . Once the algorithm has done the inversion method on every point of R , it terminates with the guarantee of having selected every border point of P .

Given any point $p \in P$, the inversion method on p is described in lines 4–6 of Algorithm 1. Let c be p ’s class, and P_c be the points of P that belong to class c , the inversion method on p consists of: (i) inverting all points of $P \setminus P_c$ around a ball centered at p (call the set of these inverted points as S_p and include p itself in the set), (ii) computing the set of extreme points of S_p , and finally (iii) returning the set E_p of those points of P that correspond to the extreme points of S_p before inversion. For a detailed description and proof of correctness of this method, we refer the reader to Eppstein’s paper [12]. However, for the purposes of this paper we only need a property presented in Lemma 3 of [12]: the points in E_p reported by the inversion method are the Delaunay neighbors of p with respect to the set $(P \setminus P_c) \cup \{p\}$.

Every call of the inversion method takes $\mathcal{O}(nk)$ time by leveraging well-known output-sensitive algorithms for computing extreme points. Given that this method is called exclusively on every border point of the training set, this yields a total of $\mathcal{O}(nk^2)$ time to complete the search phase of the algorithm. Overall, this implies that Eppstein’s algorithm computes the entire set of border points of P in $\mathcal{O}(n^2 + nk^2)$ worst-case time.

2 Our Approach

We propose a simple modification to Eppstein’s algorithm, which avoids the step of computing the MST of the training set P , along with the subsequent selection of bichromatic edges to produce the initial subset of border points.

Instead, we simply start the search process with any arbitrary point of P . The rest of the algorithm remains virtually unchanged (see Algorithm 2 for a formal description). We show that this new approach is not only correct, meaning that it only finds border points of P , but also complete, as all border points of P are eventually found by our algorithm. Additionally, by avoiding the main bottleneck of the original algorithm, our new algorithm computes the same result in $\mathcal{O}(nk^2)$ time, eliminating the $\mathcal{O}(n^2)$ term.

■ **Algorithm 2** New algorithm to find the set of border points of P .

Input: Initial training set P
Output: The set of border points of P

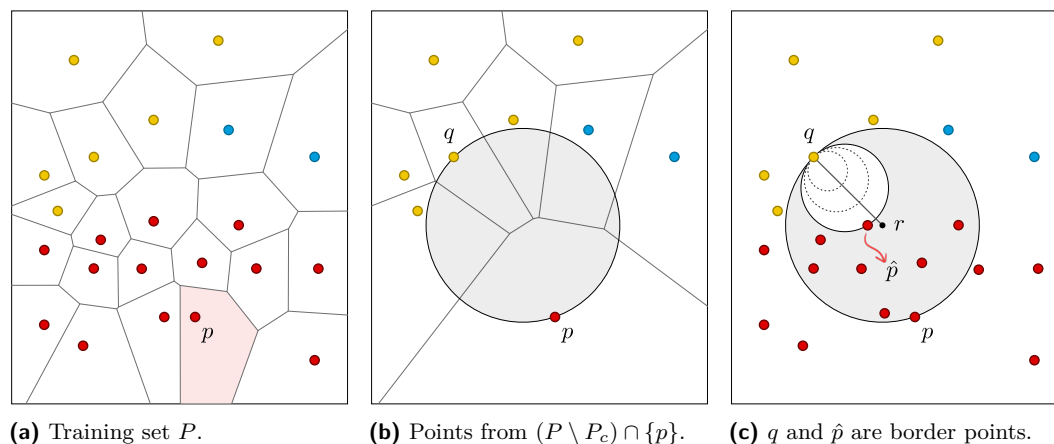

- 1 Let s be any “seed” point from P
- 2 $R \leftarrow \phi$
- 3 **foreach** $p \in R \cup \{s\}$ **do**
- 4 Let c be p ’s class and P_c be the points of P that belong to class c
- 5 Let S_p be the inverted points of $P \setminus P_c$ around p
- 6 Find all extreme points of S_p and their corresponding original points E_p
- 7 $R \leftarrow R \cup E_p$
- 8 **return** R

Before proceeding, it is useful to explore why Eppstein’s algorithm computes the MST of the training set P . First, note that the original algorithm only applies the inversion method on border points of P . In fact, Eppstein’s correctness proof relies on it: Lemma 6 in [12] proves that all points in E_p are border points by assuming that point p is also a border point. From the description of our algorithm, note that we initially apply the inversion method on a “seed” point s , which might not be a border point. Therefore, we need to generalize Lemma 6 in [12] for the case where p is not a border point of P . Additionally, using the points from all bichromatic pairs of the MST of P guarantees that Eppstein’s algorithm starts the search phase with at least one point from every boundary of P . Eppstein’s completeness proof shows that this search can then “move along” any given boundary and eventually select all its defining points. We show that the search process is far more powerful, and can even “jump” between nearby boundaries, thus rendering the MST computation unnecessary.

The following description outlines the necessary steps to prove both the correctness and completeness of our new algorithm, which are unfolded in the rest of this section.

- By applying the inversion method to any point of P , not necessarily a border point, all reported points are border points of P . This is established in Lemma 1, generalizing the statement of Lemma 6 of [12] for non-border points.
- For any class boundary of P , once the algorithm selects a point from this boundary, it will eventually select every other point defining the same boundary. This is originally proved in Lemma 10 [12], however, we provide simpler proofs in Lemmas 2 and 3.
- Given two disconnected boundaries separated by a class region, we prove that if our algorithm selects a defining point from one of the boundaries, it will eventually select all defining points from both boundaries. This is proved in Lemma 4.

All together, these lemmas are used to prove the main result: the correctness, completeness, and worst-case time complexity of Algorithm 2, as stated in Theorems 5 and 6.

■ **Figure 2** Example showing the inversion method from any point $p \in P$. On the left, training set P . The middle figure shows every non red point of P , except for p itself, along with a point q selected from the inversion method on p . On the right, we see evidence that q is a border point of P .

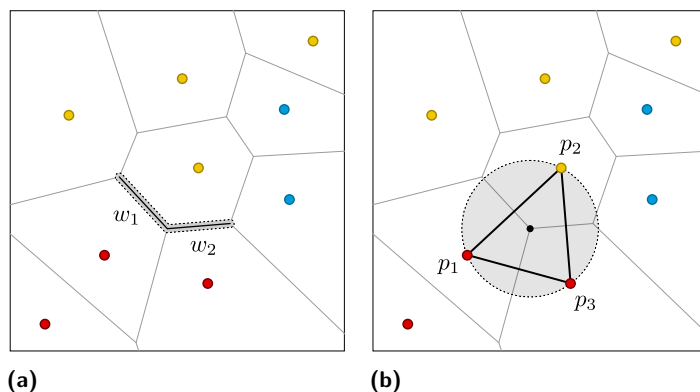

► **Lemma 1.** *Let $p \in P$ be any point of the training set. Then every point selected using the inversion method on p must be a border point of P .*

Proof. Let E_p be the points of P corresponding (before inversion) to the extreme points of S_p . According to Lemma 3 [12], every point in E_p is a neighbor of point p with respect to the Voronoi Diagram of set $(P \setminus P_c) \cup \{p\}$. This implies that for every point $q \in E_p$ other than p , there exists a ball such that both p and q are on its surface and no points of $P \setminus P_c$ lie inside (see Figures 2a and 2b). We can now leverage similar techniques to the ones described in [6], to find a “witness” point to the hypothesis that q must be a border point of P .

Recall that the empty ball we just described, as illustrated in Figure 2b, is empty from points of $P \setminus P_c$. However, there might be points of P_c inside. And moreover, we know that at least one point of P_c , point p , lies on its surface. Now, let r be the center of this ball, we grow an empty ball, this time with respect to the entire training set P , such that its center lies on the line \overline{qr} and point q is on its surface (see Figure 2c). This ball will grow until it hits another point \hat{p} of P , which we are guaranteed it will be of the same class as point p , and thus, of different class as point q . Finally, we have just found an empty ball with respect to P , which has points q and \hat{p} on its surface, and were the class of both points differ. Therefore, this implies that q is a border point of P . ◀

Before continuing, we need to formally define a few concepts. First, we define a *wall* of P as any $(d - 1)$ -dimensional face of the Voronoi Diagram of P . By known properties of these structures, every wall w is *defined* by two distinct points $p, q \in P$ such that any point on w has p and q as its two equidistant nearest-neighbors in the training set. We say two walls are *adjacent* if their intersection is not empty. That is, if there exists a point in \mathbb{R}^d with all the defining points of these two walls as its equidistant nearest-neighbors in P .

Additionally, we define a *class boundary* (or just *boundary*) of P as the union of adjacent walls, where each of these walls is defined by two points of different classes. Similarly, we define a *class region* of P as the union of adjacent Voronoi cells whose defining points belong to the same class. Based on these definitions, note that class boundaries are the ones that separate different class regions of P . Figure 4 illustrates a training set in \mathbb{R}^2 with points of three classes, whose Voronoi Diagram describes five class regions and two class boundaries.

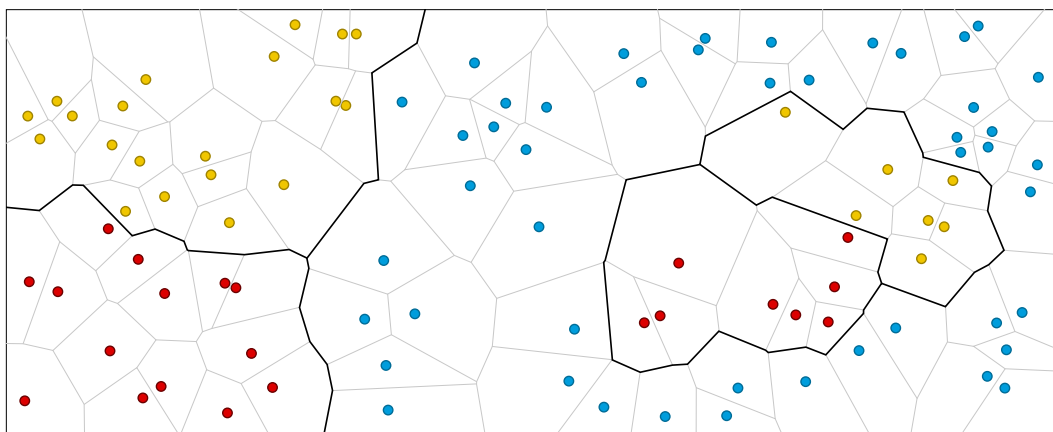

■ **Figure 3** By definition, any two adjacent walls w_1 and w_2 of the Voronoi Diagram of P hold the empty ball property with the points that define them. When these walls are part of the class boundaries of P , the points that define them belong to at least two classes.

► **Lemma 2.** Let w_1 and w_2 be two adjacent walls in a class boundary of P . If the algorithm selects one of the points defining one of these walls, it eventually selects the remaining points defining both walls.

Proof. Let \mathcal{W} be the set of points defining both walls w_1 and w_2 (see Figure 3). By definition, these two walls of the Voronoi Diagram of P are adjacent if there exists an empty ball with all the points of \mathcal{W} on its surface. Knowing these two walls are part of the class boundaries of P , the set \mathcal{W} must contain at least three points, and at least two classes.

Let p_1 be the first point of \mathcal{W} to be selected by the algorithm. When doing the inversion method on point p_1 , the algorithm will select all points of \mathcal{W} of different class than p_1 , of which we know there is at least one. Let p_2 be one such point. Finally, when doing the inversion method on point p_2 , the algorithm will select the remaining points of \mathcal{W} of the same class as p_1 . Therefore, all points of \mathcal{W} will eventually be selected by the algorithm. ◀

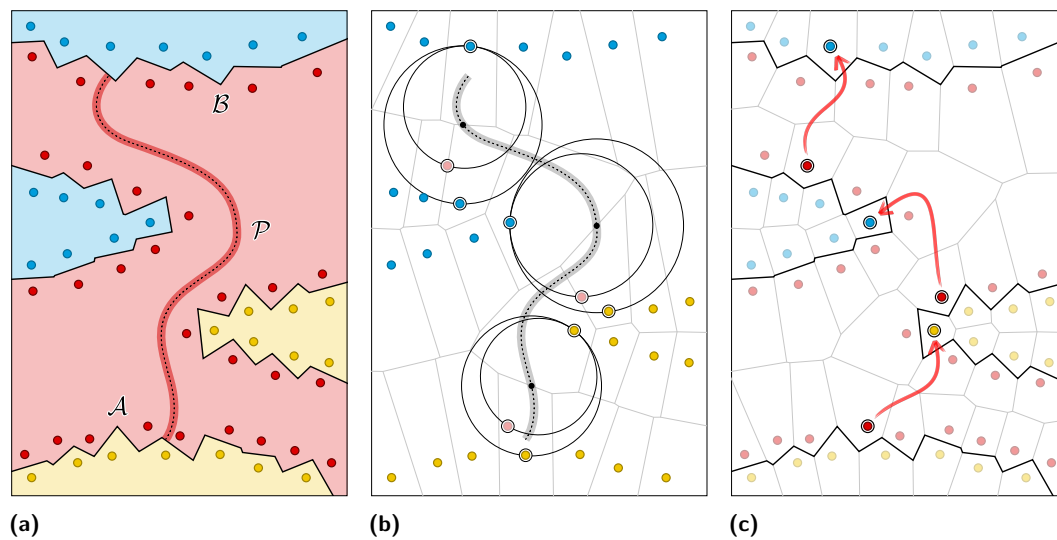

■ **Figure 4** A training set with five class regions (one blue, two red, and two yellow regions), along with two disconnected class boundaries that separate all these regions. On the left, a boundary separating the blue region and the leftmost yellow and red regions. On the right, a boundary that separates the same blue region and the remaining red and yellow regions.

► **Lemma 3.** *Let \mathcal{A} be a class boundary of P , and assume that the algorithm selects one of the defining points of \mathcal{A} . Then, the algorithm will eventually select all defining points of \mathcal{A} .*

This comes as a direct consequence of Lemma 2 and the definition of a class boundary of the training set P . It remains to show what happens with boundaries that are disconnected.

► **Lemma 4.** *Let \mathcal{A} and \mathcal{B} be two disconnected boundaries of P , such that there exists a path in space from \mathcal{A} to \mathcal{B} that is completely contained within one color region. Without loss of generality, say that every point that defines \mathcal{A} has been selected by the algorithm. Then, every point that defines \mathcal{B} must also be selected by the algorithm.*

Proof. Given these two disconnected boundaries \mathcal{A} and \mathcal{B} , we assume there exists some path \mathcal{P} in \mathbb{R}^d going from a wall of \mathcal{A} to a wall of \mathcal{B} , such that this path passes exclusively through a single class region (see Figure 5a). Without loss of generality, say this is a *red* class region. Formally, for every point r along \mathcal{P} we know r 's nearest-neighbor in P is red. Additionally, we assume that every border point defining \mathcal{A} is selected by the algorithm. Hence, the proof consists of showing that there exists a sequence of border points $\langle p_1, \hat{p}_1, p_2, \hat{p}_2, \dots, p_m, \hat{p}_m \rangle$ such that (i) p_1 and \hat{p}_m are defining points of \mathcal{A} and \mathcal{B} , respectively, (ii) \hat{p}_i is retrieved by the inversion method on p_i , for every $i \in [1, m]$, and finally (iii) points p_i and \hat{p}_{i-1} are both defining the same boundary, for every $i \in [2, m]$. See Figure 5 for a visual description.

■ **Figure 5** On the right, two disconnected boundaries \mathcal{A} and \mathcal{B} enclosing a red class region. Thus, there is a path \mathcal{P} completely contained inside such region and connecting both boundaries. Other boundaries can also be enclosing the same region and be near path \mathcal{P} . On the left, we prove that there exists a sequence of points that can be retrieved by calls to the inversion method, such that if points of \mathcal{A} are selected by the algorithm, eventually points of \mathcal{B} will also be selected.

By definition, for every point r along path \mathcal{P} we know r 's nearest-neighbor is a red point. Now, let's delete every red point from consideration, including the ones defining boundaries \mathcal{A} and \mathcal{B} (see Figure 5b). This immediately implies that r 's nearest-neighbor just became a non-red border point of P . The fact that r 's new nearest-neighbor is a border point is easy to prove, using similar arguments as the ones laid down in Lemma 1. Additionally, these border points could be defining other boundaries apart from \mathcal{A} and \mathcal{B} , as seen in Figure 5b.

Let's start moving along the path \mathcal{P} , starting from the end-point of the path that lies on a wall of boundary \mathcal{A} . Then, find all r_i points along the path, where each r_i has two equidistant nearest-neighbors among the remaining non-red points, and both points define

two distinct boundaries of P . We say there are m of these points along the path, and denote r_i 's two equidistant nearest-neighbors as $q_{i,1}$ and $q_{i,2}$ for $i \in [1, m]$. Clearly, $q_{i,1}$ and $q_{i-1,2}$ are border points defining the same boundary, for all $i \in [2, m]$. See Figure 5b, where the three black points along the path are the r_i points, and the *yellow* and *blue* points on the surface of the balls centered at each r_i are the corresponding $q_{i,1}$ and $q_{i,2}$ points.

For now, let's fix the analysis on one such r_i point, and consider the ball centered at r_i with both $q_{i,1}$ and $q_{i,2}$ on its surface. There must exist some other point $q_{i,3}$ lying inside of r_i 's ball, such that $q_{i,3}$ is one of the deleted red points defining the same boundary as $q_{i,1}$. It is now easy to see that there exist an empty ball, with respect to the set $P \setminus P_{red} \cup \{q_{i,3}\}$, with both $q_{i,3}$ and $q_{i,2}$ on its boundary. This implies that $q_{i,2}$ is retrieved by the inversion method on $q_{i,3}$. Therefore, let's add $p_i \leftarrow q_{i,3}$ and $\hat{p}_i \leftarrow q_{i,2}$ to the sequence of points that we are looking for. Repeat this for every r_i with $i \in [1, m]$ to identify all points in the sequence.

Finally, we have the sequence of border points $\langle p_1, \hat{p}_1, p_2, \hat{p}_2, \dots, p_m, \hat{p}_m \rangle$ such that for any $i \in [1, m]$ assuming that the algorithm selects the points defining the same boundary as p_i , it will also select \hat{p}_i , and leveraging Lemma 3 it will eventually select all other points defining the same boundary as \hat{p}_i . Given that p_1 and \hat{p}_m are defining border points of boundaries \mathcal{A} and \mathcal{B} , respectively, and by the assumption that all points defining \mathcal{A} are selected by the algorithm, we know that eventually, all points defining \mathcal{B} will be selected too. ◀

► **Theorem 5.** *The algorithm selects every border point of P in $\mathcal{O}(nk^2)$ time.*

Proof. Proving the worst-case time complexity of our algorithm follows directly from the time complexity of the search phase of Eppstein's algorithm [12]. However, the correctness and completeness of our algorithm follows from Lemmas 1 to 4.

First, we know by Lemmas 1-3 that Algorithm 2 will select the defining border points of at least one class boundary of P . Denote this boundary as \mathcal{A} and consider any other boundary \mathcal{B} of P . Evidently, we can draw a path \mathcal{P} from \mathcal{A} to \mathcal{B} , which would generally pass through several class regions. Then, let's split \mathcal{P} into several subpaths $\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_m$ such that each subpath is completely contained within a single class region. From this, we can directly apply Lemma 4 on each of the intermediate boundaries that "cut" \mathcal{P} into these subpaths. Finally, this implies that our algorithm will eventually select every defining point of boundary \mathcal{B} , and similarly, it will do the same with all other boundaries of P . ◀

► **Theorem 6.** *Leveraging Chan's algorithm [7] for finding extreme points, the algorithm selects every border point of P in randomized expected time $\mathcal{O}(nk \log k)$ for $d = 3$, and in*

$$\mathcal{O}\left(nk(\log k)^{\mathcal{O}(1)} + k(nk)^{1 - \frac{1}{\lfloor d/2 \rfloor + 1}} (\log n)^{\mathcal{O}(1)}\right)$$

time for all constant dimensions $d > 3$.

Just as with Eppstein's original algorithm, we can use Chan's randomized algorithm [7] for finding extreme points of point sets in \mathbb{R}^d , in order to reduce the expected time complexity of our improved algorithm. The remaining of the proof is the same as for Theorem 5.

Abstract

In 1959, Erdős and Gallai proved that every graph G with average vertex degree $\text{ad}(G) \geq 2$ contains a cycle of length at least $\text{ad}(G)$. We provide an algorithm that for $k \geq 0$ in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ decides whether a 2-connected n -vertex graph G contains a cycle of length at least $\text{ad}(G) + k$. This resolves an open problem explicitly mentioned in several papers. The main ingredients of our algorithm are new graph-theoretical results interesting on their own.

1 Introduction

The circumference of a graph is the length of its longest (simple) cycle. In 1959, Erdős and Gallai [4] gave the following, now classical, lower bound for the circumference of an undirected graph.

► **Theorem 1** (Erdős and Gallai [4]). *Every graph with n vertices and more than $\frac{1}{2}(n-1)\ell$ edges ($\ell \geq 2$) contains a cycle of length at least $\ell + 1$.*

We provide an algorithmic extension of the Erdős–Gallai theorem: A fixed-parameter tractable (FPT) algorithm with parameter k , that decides whether the circumference of a graph is at least $\ell + k$. To state our result formally, we need a few definitions. For an undirected graph G with n vertices and m edges, we define $\ell_{EG}(G) = \frac{2m}{n-1}$. Then by the Erdős–Gallai theorem, G always has a cycle of length at least $\ell_{EG}(G)$ if $\ell_{EG}(G) > 2$. The parameter $\ell_{EG}(G)$ is closely related to the *average degree* of G , $\text{ad}(G) = \frac{2m}{n}$. It is easy to see that for every graph G with at least two vertices, $\ell_{EG}(G) - 1 \leq \text{ad}(G) < \ell_{EG}(G)$.

55:2 Longest Cycle Above Erdős–Gallai Bound

The *maximum average degree* $\text{mad}(G)$ is the maximum value of $\text{ad}(H)$ taken over all induced subgraphs H of G . Note that $\text{ad}(G) \leq \text{mad}(G)$ and $\text{mad}(G) - \text{ad}(G)$ may be arbitrarily large. By Goldberg [13] (see also [12]), $\text{mad}(G)$ can be computed in polynomial time. By Theorem 1, we have that if $\text{ad}(G) \geq 2$, then G has a cycle of length at least $\text{ad}(G)$ and, furthermore, if $\text{mad}(G) \geq 2$, then there is a cycle of length at least $\text{mad}(G)$. Based on this guarantee, we define the following problem.

LONGEST CYCLE ABOVE MAD

Input: A graph G on n vertices and an integer $k \geq 0$.
Task: Decide whether G contains a cycle of length at least $\text{mad}(G) + k$.

Our main result is that this problem is FPT parameterized by k . More precisely, we show the following.

► **Theorem 2.** *LONGEST CYCLE ABOVE MAD can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ on 2-connected graphs.*

While Theorem 2 concerns the decision variant of the problem, its proof may be easily adapted to produce a desired cycle if it exists. We underline this because the standard construction of a long cycle that for every $e \in E(G)$ invokes the decision algorithm on $G - e$, does not work in our case, as edge deletions decrease the average degree of a graph.

Theorem 2 has several corollaries. The following question was explicitly stated in the literature [6, 9]. For a 2-connected graph G and a nonnegative integer k , how difficult is it to decide whether G has a cycle of length at least $\text{ad}(G) + k$? According to [9], it was not known whether the problem parameterized by k is FPT, W[1]-hard, or Para-NP. Even the simplest variant of the question, whether a path of length $\text{ad}(G) + 1$ can be computed in polynomial time, was open. Theorem 2 resolves this question because $\text{mad}(G) \geq \text{ad}(G)$ for every graph G .

► **Corollary 3.** *For a 2-connected graph G and a nonnegative integer k , deciding whether G has a cycle of length at least $\text{ad}(G) + k$ can be done in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.*

Similarly, we have the following corollary.

► **Corollary 4.** *For a 2-connected graph G and a nonnegative integer k , deciding whether G has a cycle of length at least $\ell_{EG}(G) + k$ can be done in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.*

An undirected graph G is *d-degenerate* if every subgraph of G has a vertex of degree at most d , and the *degeneracy* of G is defined to be the minimum value of d for which G is d -degenerate. Since a graph of degeneracy d has a subgraph H with at least $d \cdot |V(H)|/2$ edges, we have that $d \leq \text{ad}(H) \leq \text{mad}(G)$. Therefore, Theorem 2 implies the following corollary, which is the main result of [6].

► **Corollary 5 ([6]).** *For a 2-connected graph G of degeneracy d , deciding whether G has a cycle of length at least $d + k$ can be done in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.*

Theorem 1 provides the same lower bound on the number of vertices in a longest path. We consider the LONGEST PATH ABOVE MAD problem that, given a graph G and integer k , asks whether G has a path with at least $\text{mad}(G) + k$ vertices. Observe that a graph G has a path with ℓ vertices if and only if the graph G' , obtained by adding to G a universal vertex that is adjacent to every vertex of the original graph, has a cycle with $\ell + 1$ vertices. Because $\text{mad}(G') \geq \text{mad}(G)$, Theorem 2 yields the following.

► **Corollary 6.** *LONGEST PATH ABOVE MAD can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ on connected graphs.*

We complement Theorem 2 by observing that the 2-connectivity condition is crucial for tractability due to the fact that the considered properties are not closed under taking biconnected components. In particular, it may happen that every long cycle of a graph is in a biconnected component of small average degree. This yields the following theorem.

► **Theorem 7** (★).¹ *It is NP-complete to decide whether an n -vertex connected graph G has a cycle of length at least $\ell_{EG}(G) + 1$.*

The single-exponential dependence in k of algorithm in Theorem 2 is asymptotically optimal: it is unlikely that LONGEST CYCLE ABOVE MAD can be solved in $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ time. This immediately follows from the well-known result (see e.g. [2, Chapter 14]) that existence of an algorithm for HAMILTONIAN CYCLE with running time $2^{o(n)}$ would refute the *Exponential Time Hypothesis* (ETH) of Impagliazzo, Paturi, and Zane [14]. Thus LONGEST CYCLE ABOVE MAD cannot be solved in $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ time, unless ETH fails.

Comparison with the previous work. Two of the recent articles on the circumference of a graph above guarantee are most relevant to our work. The first is the paper of Fomin, Golovach, Lokshtanov, Panolan, Saurabh, and Zehavi [6] who gave an algorithm that in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ for a 2-connected graph G of degeneracy d , decides whether G has a cycle of length at least $d + k$. In the heart of their algorithm is the following “rerouting” argument: If a cycle hits a sufficiently “dense” subgraph H of G , then this cycle can be rerouted inside H to cover all vertices of H . The main obstacle on the way of generalizing the result of Fomin et al. [6] “beyond” the average degree was the lack of rerouting arguments in graphs of large average degree.

The rerouting arguments in the proof of Theorem 2 use the structural properties of dense graphs developed in the recent work of Fomin, Golovach, Sagunov, and Simonov [9] (see [8] for the full version) on parameterized complexity of finding a cycle above Dirac’s bound. We remind that by the classical theorem of Dirac [3], every 2-connected graph has a cycle of length at least $\min\{2\delta(G), |V(G)|\}$, where $\delta(G)$ is the minimum degree of G . Fomin et al. gave an algorithm that in time $2^{\mathcal{O}(k+|B|)} \cdot n^{\mathcal{O}(1)}$ decides whether a 2-connected graph G contains a cycle of length at least $\min\{2\delta(G-B), |V(G)| - |B|\} + k$, where B is a given subset of vertices which may have “small” degrees. The result of Fomin et al. [8, 9] is “orthogonal” to ours in the following sense: It does not imply Theorem 2 and Theorem 2 does not imply the theorem from [8]. However, the tools developed in [8], in particular the new type of graph decompositions called *Dirac decompositions*, appear to be useful in our case too.

From a more general perspective, our work belongs to a popular subfield of Parameterized Complexity concerning parameterization above/below specified guarantees. In addition to [9, 6], the parameterized complexity of paths and cycles above some guarantees was studied in [1, 15], and [7].

2 Overview of the proof of the main result

Here we outline the critical technical ideas leading to our main result, Theorem 2. We first explain our techniques for the LONGEST CYCLE ABOVE AD problem. Let us remind that in this problem, the task is to decide whether a graph G has a cycle of length at least $\text{ad}(G) + k$. (The difference with *mad* is that we do not take the maximum over all subgraphs.)

¹ The results with omitted proofs are marked with the “★” sign. Missing proofs can be found in the full version of this paper [10].

The nucleus of our proof is a novel structural analysis of dense subgraphs in graphs with large average degrees. Informally, we prove that if there is a cycle of length at least $\text{ad}(G) + k$ in G , then G contains a dense subgraph H and a long (of length at least $\text{ad}(G) + k$) cycle C that “revolves” around H (see Figure 1). By that, we mean the following. First, the number of times cycle C enters and leaves H is bounded by $\mathcal{O}(k)$. Second, C contains at least $\text{ad}(G) - ck$ vertices of H for some constant c . Moreover, we need a way stronger “routing” property of H . Basically for any possible “points of entry and departure” of cycle C in H , we show that these pairs of vertices could be connected in H by internally vertex-disjoint paths of total length at least $\text{ad}(G) - ck$. Furthermore, such paths could be found in polynomial time. Then everything boils down to the following problem. For a given subgraph H of G , we are looking for at most k internally vertex-disjoint paths outside H of total length $\Omega(k)$, each path starts and ends in H . This task can be done in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ by making use of color-coding. Finally, if we find such paths, then we could complete them to a cycle of length at least $\text{ad}(G) + k$ by augmenting them by the paths inside H .

■ **Figure 1** A cycle “revolving” around H . The segments of the cycle outside H are shown in green and the segments inside H are blue.

Identifying dense subgraph H . Notice that we can assume that $\text{ad}(G) \geq \alpha k$ for a sufficiently big positive constant α . Otherwise, we can solve the problem in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time using the known algorithm for LONGEST CYCLE [11]. We start with preprocessing rules “illuminating” some “useless” parts of the graph. If G contains several connected components, it suffices to keep only the densest of them, as its average degree is at least the average degree of G . Similarly, if G is connected but has a cut-vertex, keeping the densest block also suffices. Further, if there is a vertex v of degree less than $\frac{1}{2}\text{ad}(G)$, then v can be safely removed. By applying these reduction rules exhaustively, we find an induced 2-connected subgraph H of G whose minimum degree $\delta(H) \geq \frac{1}{2}\text{ad}(H) \geq \frac{1}{2}\text{ad}(G)$. Similarly to removing sparse blocks, if G contains a vertex separator X of size two such that there is a “sparse” component A of $G - X$, then A can be removed. By applying the last reduction rule we either find a cycle of length at least $\text{ad}(G) + k$ or can conclude that the resulting subgraph H is 3-connected.

If (G, k) is a yes-instance, that is, graph G contains a cycle of length at least $\text{ad}(G) + k$, there are two possibilities. Either in G a cycle of length at least $2\delta(H) + k$ “lives” entirely in H , or it passes through some other vertices of G . If a long cycle is entirely in H , we can employ the recent result of Fomin et al. [8] that finds in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ in a 2-connected graph G a cycle of length at least $2\delta(G) + k \geq \text{ad}(G) + k$. However, if no long cycle lives entirely in H , the result of Fomin et al. is not applicable.

The next step of constructing H crucially benefits from the graph-theoretical result of Fomin et al. [8]. Specifically, we use the theorem about the Dirac decomposition from [8]. The definition of the Dirac decomposition is technical and we give it in Section 4. For 2-connected graphs, the Dirac decomposition imposes a very intricate structure. However, since, thanks to the reduction rules, H is 3-connected, we bypass most of the technical details from [8]. Informally, the Dirac decomposition leads to the following win-win situation. By the Dirac's theorem [3], graph H contains a cycle S of length at least $2\delta(H) \geq \text{ad}(G)$. Moreover, we could find such a cycle in polynomial time. By the result of Fomin et al. [8], if the length of S is less than $2\delta(H) + k$, then either S can be enlarged in polynomial time, or (a) H is small, that is, $|V(H)| < \text{ad}(H) + k$, yielding that H is extremely dense; or (b) H has a vertex cover of size $\frac{1}{2}\text{ad}(H) - \mathcal{O}(k)$. If S got enlarged, we iterate until we achieve cases (a) or (b). If we are in case (a), the construction of H is completed. In case (b), we need to prune the obtained graph a bit more. More specifically, we can delete $\mathcal{O}(k)$ vertices in the vertex cover and select a subset of the independent set to achieve the property that (i) each of remaining vertices in the vertex cover is adjacent to at least $\text{ad}(H) - \mathcal{O}(k)$ vertices in the selected independent subset, and (ii) every vertex of the selected subset of the independent set sees nearly all vertices of the vertex cover. This means that the obtained induced subgraph is also “dense”, albeit in a different sense. Depending on the case, we use different arguments to establish the routing properties of H .

Routing in H . The case (a), when $|V(H)| < \text{ad}(H) + k$, is easier. In this case, the degrees of almost all vertices are close to $|V(H)|$. Let $S = \{x_1y_1, \dots, x_\ell y_\ell\}$ an arbitrary set of $\mathcal{O}(k)$ pairs of distinct vertices of H forming a linear forest (that is, the union of x_iy_i is a union of disjoint paths). The intuition behind S is that x_i corresponds to the vertex from where the long cycle leaves H and y_i when it enters H again. We show first how to construct a cycle in $H + S$ (that is, the graph obtained from H by turning the pairs of S into edges) containing every pair x_iy_i from S as an edge. This is done by performing constant-length jumps: any two vertices can be connected either by an edge, or through a common neighbor, or through a sequence of two neighbors. Then we extend the obtained cycle to a Hamiltonian cycle in $H + S$ – every vertex of H that is not yet on a cycle can be inserted due to the high degrees of the vertices. The extension of S into a Hamiltonian cycle is shown in Figure 2 (a).

■ **Figure 2** Constructing cycles. The set of pairs S that may be both edges and nonedges of H is shown by red lines and the extension of S into a long cycle is blue. The paths “revolving” around H are green. The vertex cover in c) is denoted by A .

Therefore, if there is a collection of at most k internally vertex disjoint paths going outside from H and returning back, the high density of H allows collecting all of them in a cycle containing all the vertices of H . Together with all the additional vertices these paths visit outside of H we construct a long cycle in G (see Figure 2 (b)). The only condition is that

these paths have to form a linear forest. Thus, if we find a collection of such paths with enough internal vertices, we immediately obtain a long cycle “revolving” around H . The crucial part of the proof is to show that if there is *any* cycle of length at least $\text{ad}(H) + k$ in G , then it can be assumed to have this form.

Let us remark that a similar “rerouting” property was used by Fomin et al. [6] in their above-degeneracy study. Actually, for case (a), we need only a minor adjustment of the arguments from [6]. However, in the “bipartite dense” case (b) the structure of the dense subgraph H is more elaborate and this case requires a new approach. Contrarily to case (a), the long cycle that we construct in $H + S$ is not Hamiltonian but visits all the vertices of the vertex cover (see Figure 2 (c)). In this case, the behavior of paths depends on which part of H they hit. Because of that, while establishing the routing properties, we have to take into account the difference between paths connecting vertices from the vertex cover, independent set, and both. Pushing the “rerouting” intuition through, in this case, turns out to be quite challenging.

Final steps. After finalizing the “rerouting” arguments above, it only remains to design an algorithm that checks whether there exists a collection of paths in G that start and end in H and have at least a certain number of internal vertices in total. We do it by a color-coding-style approach. For case (a), such a subroutine has already been developed in the above-degeneracy case [6]. On the other hand, for the “bipartite dense” case (b) we need to impose an additional restriction on the desired paths, as the length of the final cycle also depends on how the paths’ end-vertices are distributed between the two parts and we have to incorporate these kinds of constraints in our path-finding subroutine.

Finally, to solve LONGEST CYCLE ABOVE MAD, we use the fact that given a graph G , we can find an induced subgraph F with $\text{ad}(F) = \text{mad}(G)$ in polynomial time by the result of Goldberg [13] (see also [12]). Then we find a dense subgraph H of F with the described properties and use H to find a cycle of length at least $\text{mad}(G) + k$.

3 Preliminaries

In this section, we introduce basic notations, and a series of previously-known results that will be helpful to us.

We consider only finite undirected graphs. For a graph G , $V(G)$ and $E(G)$ denote its vertex and edge sets, respectively. Throughout the paper we use $n = |V(G)|$ and $m = |E(G)|$ whenever the considered graph G is clear from the context. For a graph G and a subset $X \subseteq V(G)$ of vertices, we write $G[X]$ to denote the subgraph of G induced by X . We write $G - X$ to denote the graph $G[V(G) \setminus X]$; for a single-element set $X = \{x\}$, we write $G - x$. Similarly, if Y is a set of pairs of distinct vertices, $G - Y = (V(G), E(G) \setminus Y)$. For a set Y of pairs of distinct vertices of G , $G + Y$ denotes the graph $(V(G), E(G) \cup Y)$, that is, the graph obtained by adding the edges in $Y \setminus E(G)$; slightly abusing notation we may denote the pairs of such a set Y in the same way as edges. For a vertex v , we denote by $N_G(v)$ the (*open*) *neighborhood* of v , i.e., the set of vertices that are adjacent to v in G . A set of vertices X is a *vertex cover* of G if for every edge xy of G , $x \in X$ or $y \in X$.

A *path* P in G is a subgraph of G with $V(P) = \{v_0, \dots, v_\ell\}$ and $E(P) = \{v_{i-1}v_i \mid 1 \leq i \leq \ell\}$. We write $v_0v_1 \dots v_\ell$ to denote P ; the vertices v_0 and v_ℓ are *end-vertices* of P , the vertices v_2, \dots, v_ℓ are *internal*, and ℓ is the *length* of P . For a path P with end-vertices s and t , we say that P is an (s, t) -path. Two paths P_1 and P_2 are *internally disjoint* if no internal vertex of one of the paths is a vertex of the other; note that end-vertices may be the same.

For two internally disjoint paths P_1 and P_2 having one common end-vertex, we write P_1P_2 to denote the *concatenation* of P_1 and P_2 . A graph F is a *linear forest* if every connected component of F is a path. Let S be a set of pairs of distinct vertices of G ; they may be either edges or nonedges. We say that S is *potentially cyclable* if $(V(G), S)$ is a linear forest. A *cycle* is a graph C with $V(C) = \{v_1, \dots, v_\ell\}$ for $\ell \geq 3$ and $E(C) = \{v_{i-1}v_i \mid 1 \leq i \leq \ell\}$, where $v_0 = v_\ell$. We may write that $C = v_1 \cdots v_\ell$. A cycle C (a path P , respectively) is *Hamiltonian* if $V(C) = V(G)$ ($V(P) = V(G)$, respectively). A graph G is *Hamiltonian* if it has a Hamiltonian cycle.

A set of vertices S is a *separator* of a connected graph G , if $G - S$ is disconnected. For a positive integer k , G is *k-connected* if $|V(G)| > k$ and for every set S of at most $k - 1$ vertices, $G - S$ is connected. If $S = \{v\}$ is a separator of size one, then v is called a *cut-vertex*. Note, in particular, that a connected graph with at least three vertices is 2-connected if it has no cut-vertex. A *block* of a connected graph with at least two vertices is an inclusion-wise maximal induced subgraph without cut-vertices, that is, either a 2-connected graph or K_2 .

The *degree* of a vertex v in a graph G is $d_G(v) = |N_G(v)|$. The *minimum degree* of G is $\delta(G) = \min\{d_G(v) \mid v \in V(G)\}$. For a nonempty set of vertices X , the *average degree* of X is $\text{ad}_G(X) = \frac{1}{|X|} \sum_{v \in X} d_G(v)$, and the *average degree* of G is $\text{ad}(G) = \text{ad}_G(V(G)) = \frac{2m}{n}$. The *maximum average degree* is $\text{mad}(G) = \max\{\text{ad}(H) \mid H \text{ is induced subgraph of } G\}$.

The following observation about the circumference lower bound $\ell_{EG}(G)$ and the average degree of G is useful for us.

► **Observation 8.** *For every graph G with at least two vertices $\ell_{EG}(G) - 1 \leq \text{ad}(G) < \ell_{EG}(G)$.*

Goldberg [13] proved that, given a graph G , an induced subgraph H of maximum *density*, that is, a subgraph with the maximum value $\frac{|E(H)|}{|V(H)|}$, can be found in polynomial time. This result was improved by Gallo, Grigoriadis, and Tarjan [12]. Note that if H is an induced subgraph of maximum density, then $\text{mad}(G) = \text{ad}(H)$.

► **Proposition 9** ([12]). *An induced subgraph of maximum density of a given graph G can be found in $\mathcal{O}(nm \log(n^2/m))$ time.*

We use the lower bound on the length of a longest (s, t) -path in a 2-connected graph via the average degree obtained by Fan [5].

► **Proposition 10** ([5, Theorem 1]). *Let s and t be two distinct vertices in a 2-connected graph G . Then G has an (s, t) -path of length at least $\text{ad}_G(V(G) \setminus \{s, t\})$.*

Notice that the proof of Proposition 10 in [5] is constructive and a required path can be found in polynomial time.

It is well-known that LONGEST CYCLE, which asks whether a graph has a cycle of length at least k , can be solved in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. The currently best deterministic algorithm is due to Fomin et al. [11].

► **Proposition 11** ([11]). *LONGEST CYCLE can be solved in $4.884^k \cdot n^{\mathcal{O}(1)}$ time.*

The task of LONGEST (s, t) -PATH is, given a graph G with two *terminal* vertices s and t , and a positive integer k , decide whether G has an (s, t) -path with at least k vertices. Fomin et al. [11] proved that this problem is FPT when parameterized by k .

► **Proposition 12** ([11]). *LONGEST (s, t) -PATH can be solved in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time.*

4 Finding a dense subgraph

Here we show that given an instance of LONGEST CYCLE ABOVE MAD, we can in polynomial time either solve the problem or find a dense induced subgraph of the input graph. This part crucially depends on structural and algorithmic results obtained by Fomin et al. in [8]. We derive the following structural corollary for 3-connected graphs from [8, Lemma 20].

► **Corollary 13** (★). *Let G be a 3-connected graph and k be an integer such that $0 < k \leq \frac{1}{24}\delta(G)$. Then there is an algorithm that, given a cycle C of length less than $2\delta(G) + k$, in polynomial time either*

- *returns a longer cycle in G , or*
- *returns a vertex cover of G of size at most $\delta(G) + 2k$, or*
- *reports that C is Hamiltonian.*

Now, by applying exhaustively the classical reduction rules from the proof of Theorem 1 and a new reduction rule that removes sparse 2-connected components, we reach the situation where we can apply Corollary 13. The result of this process is encapsulated in the next lemma.

► **Lemma 14** (★). *There is a polynomial-time algorithm that, given an instance (G, k) of LONGEST CYCLE ABOVE MAD, where $0 < k \leq \frac{1}{80}\text{mad}(G) - 1$, either*

- (i) *finds a cycle of length at least $\text{mad}(G) + k$ in G , or*
- (ii) *finds an induced subgraph H of G with $\text{ad}(H) \geq \text{mad}(G) - 1$ such that $\delta(H) \geq \frac{1}{2}\text{ad}(H)$ and $|V(H)| < \text{ad}(H) + k + 1$, or*
- (iii) *finds an induced subgraph H of G such that there is a partition $\{A, B\}$ of $V(H)$ with the following properties:*
 - *B is an independent set,*
 - *$\frac{1}{2}\text{mad}(G) - 4k \leq |A|$,*
 - *for every $v \in A$, $|N_H(v) \cap B| \geq 2|A|$,*
 - *for every $v \in B$, $d_H(v) \geq |A| - 2k - 2$.*

5 Covering vertices of dense graphs

In this section, we prove that, given a sufficiently dense graph G and a bounded-size set of pairs of distinct vertices S forming a linear forest, we can find a long cycle in $G + S$ containing all edges from S . First, we consider the case where there is a small number of vertices in the graph compared to the average degree. Then, we deal with the case where one part in a bipartition of a dense bipartite graph has bounded size. The proofs of the next two lemmas follow the strategy of using the high density of the graph to connect an arbitrary small subset of vertices in a cycle via constant-length jumps, and then extend this cycle to a long cycle using similar arguments. Recall that for a set S of pairs of distinct vertices of a graph G , we say that S is potentially cyclable if $(V(G), S)$ is a linear forest.

► **Lemma 15** (★). *Let G be a graph and k be an integer such that (i) $0 < k \leq \frac{1}{60}\text{ad}(G)$, (ii) $\delta(G) \geq \frac{1}{2}\text{ad}(G)$, and (iii) $\text{ad}(G) + k > n$. Let also S be a potentially cyclable set of at most k pairs of distinct vertices. Then $G + S$ has a Hamiltonian cycle containing every edge of S .*

Now we consider dense bipartite graphs. Similarly to Lemma 15, we show that for a given set of pairs of vertices forming a linear forest there is a cycle containing all these pairs in the extended graph, and also each vertex of the “high-degree” part of the graph. For an example, see Figure 3.

Figure 3 Structure of G and $G' = G + S$. The set of pairs S is shown by red lines and the edges of C that are not in S are green. Note that G' is not required to be bipartite.

► **Lemma 16** (\star). Let G be a bipartite graph, $\{A, B\}$ is a bipartition of $V(G)$ with $p = |A|$, and let k be an integer such that (i) $0 < k \leq \frac{1}{10}p$, (ii) for every $v \in A$, $d_G(v) \geq 2p$, and (iii) for every $v \in B$, $d_G(v) \geq p - k$. Let S be a potentially cyclable set of at most $\frac{9}{4}k$ pairs of distinct vertices. Then $G' = G + S$ has a cycle C containing every edge of S and every vertex of A . Furthermore, C is a longest cycle in G' containing the edges of S and the length of C is $2p - s + t$, where s is the number of edges of S with both end-vertices in A and t is the number of edges in S with both end-vertices in B .

6 Rerouting long cycles to dense subgraphs

In this section, we show that a dense induced subgraph can be used to find a long cycle in a 2-connected graph. Specifically, we show that one can always assume that a long cycle is an extension of a longest cycle in a dense subgraph. To state this more precisely, we need some additional terminology that we introduce next.

Let $T \subseteq V(G)$ for a graph G . A path P is called a T -segment if P has length at least two, the end-vertices of P lie in T , and $v \notin T$ for any internal vertex v of P . A set of internally disjoint paths $\mathcal{P} = \{P_1, \dots, P_r\}$ is a system of T -segments if (i) P_i is a T -segment for every $i \in \{1, \dots, r\}$, and (ii) the union of the paths in \mathcal{P} is a linear forest. Let $A, B \subseteq V(G)$ be disjoint sets of vertices in G . For a pair $\{x, y\}$ of distinct vertices in G , we say that $\{x, y\}$ is an A -pair (B -pair, respectively) if $x, y \in A$ ($x, y \in B$, respectively), and we say that $\{x, y\}$ is an (A, B) -pair if either $x \in A, y \in B$ or, symmetrically, $y \in A, x \in B$. If $\{A, B\}$ is a partition of $T \subseteq V(G)$, then for a T -segment P with end-vertices x and y , P is an A -segment if $\{x, y\}$ is an A -pair, P is a B -segment if $\{x, y\}$ is a B -pair, and P is an (A, B) -segment if $\{x, y\}$ is an $\{A, B\}$ -pair.

First, we consider the case when there is a dense subgraph H with the property that for every potentially cyclable set S of at most k pairs of distinct vertices, $H + S$ has a Hamiltonian cycle containing every edge of S . We show the following lemma whose proof is almost identical to the proof of Lemma 3 in [6].

► **Lemma 17** (\star). Let G be a 2-connected graph and let k be a positive integer. Suppose that H is an induced subgraph of G such that $|V(H)| \geq 2k$ and for every potentially cyclable set S of at most k pairs of distinct vertices of H , $H + S$ has a Hamiltonian cycle containing every edge of S . Then G has a cycle of length at least $|V(H)| + k$ if and only if one of the following holds:

- (i) There are two distinct vertices $s, t \in V(H)$ such there is an (s, t) -path P in G of length at least $k + 1$ whose internal vertices lie in $V(G) \setminus V(H)$.
- (ii) There is a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ such that $r \leq k$ and the total number of vertices on the paths in \mathcal{P} outside T is at least k and at most $2k - 2$.

55:10 Longest Cycle Above Erdős–Gallai Bound

Now we show a related result for dense induced subgraphs of another type. See Figure 4 for an illustration.

■ **Figure 4** Structure of segments in Case (ii) of Lemma 18. The A -segments are shown by green lines, the B -segments are red, and the (A, B) -segments are blue.

► **Lemma 18.** *Let G be a 2-connected graph and let k be a positive integer. Suppose that H is an induced subgraph of G whose set of vertices has a partition $\{A, B\}$ with $|A| \geq \frac{3}{2}k$ and B being an independent set. Suppose also that for every potentially cyclable set S in H of at most k pairs of distinct vertices in H , with s A -pairs and t B -pairs, $H + S$ has a cycle of length at least $2|A| - s + t$. Then G has a cycle of length at least $2|A| + k$ if and only if one of the following holds:*

- (i) *There are two distinct vertices $x, y \in V(H)$ such that H has an (x, y) -path P of length at least $k + 2$ whose internal vertices lie in $V(G) \setminus V(H)$.*
- (ii) *There is a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ with s A -segments and t B -segments such that*
 - (a) $r \leq k$,
 - (b) *every A -segment has at least two internal vertices,*
 - (c) *the total number of internal vertices on the paths in \mathcal{P} is at least $k + s - t$ and at most $3k - 2$.*

Proof. Let $T = V(H)$. First, we show that if either (i) or (ii) is fulfilled, then G has a cycle of length at least $|V(H)| + k$.

Suppose that there are distinct $x, y \in T$ and an (x, y) -path P in G with all internal vertices outside T such that the length of P is at least $k + 2$. Let $S = \{xy\}$. We have that $H + S$ has a cycle C containing xy of length at least $2|A| - 1$. We replace the edge xy in C by the path P . Then the length of the obtained cycle C' is at least $2|A| + k$ as required.

Assume that there is a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ with s A -segments and t B -segments such that (a)–(b) are fulfilled. Let x_i and y_i be the end-vertices of P_i for $i \in \{1, \dots, r\}$ and define $S = \{x_1y_1, \dots, x_ry_r\}$. Observe that S is a potentially cyclable set for H and $|S| \leq k$. Then $H + S$ has a cycle C of length at least $2|A|$ that contains every edge of S . We construct the cycle C' from C by replacing x_iy_i by the path P_i for every $i \in \{1, \dots, r\}$. Because the total number of internal vertices in the paths of \mathcal{P} is at least $k + s - t$, the length of C' is at least $|V(H)| + k$.

For the opposite direction, assume that G has a cycle C of length at least $2|A| + k$. We consider the following three cases.

Case 1. $V(C) \cap T = \emptyset$. Since G is a 2-connected graph, there are pairwise distinct vertices $x, y \in T$ and $x', y' \in V(C)$, and vertex disjoint (x, x') and (y, y') -paths P_1 and P_2 such that the internal vertices of the paths are outside $T \cup V(C)$. The cycle C has length at least $2|A| + k \geq 3k$. Therefore, C contains an (x', y') -path P with at least $k + 1$ vertices. The concatenation of P_1 , P and P_2 is an (x, y) -path in G of length at least $k + 2$ whose internal vertices are outside T . Hence, (i) is fulfilled.

Case 2. $|V(C) \cap T| = 1$. Let $V(C) \cap T = \{x\}$ for some vertex x . Since G is 2-connected, there is an (y, y') -path P in $G - x$ such that $y' \in V(C)$, $y \in T$, and the internal vertices are outside $T \cup V(C)$. Because the length of C is at least $3k$, C contains an (x', y') -path P' with at least $k + 2$ vertices. The concatenation of P' and P is an (s, t) -path in G of length at least $k + 2$ whose internal vertices are outside T . Hence, (i) holds.

Case 3. $|V(C) \cap T| \geq 2$. Observe that because B is an independent set, H has no cycle of length greater than $2|A|$. Therefore, as $k > 0$ and $|V(C)| \geq 2|A| + k$, $V(C) \setminus T \neq \emptyset$. Let P_1, \dots, P_ℓ be the “outside” segments of C with respect to H , that is, P_1, \dots, P_ℓ are paths on C such that (*) for every $i \in \{1, \dots, \ell\}$, P_i is an (x_i, y_i) -path with at least one internal vertex for some distinct $x_i, y_i \in T$ and the internal vertices of P_i are outside T , and (**) $\bigcup_{i=1}^{\ell} V(P_i) \setminus T = V(C) \setminus T$. If P_i has length at least $k + 2$ for some $i \in \{1, \dots, \ell\}$, then (i) holds. Assume that this is not the case, that is, the length of each P_i is at most $k + 1$. Let $I_A, I_B, I_{AB} \subseteq \{1, \dots, \ell\}$ be the subsets of indices such that P_i is an A -segment for $i \in I_A$, a B -segment for $i \in I_B$, and an (A, B) -segment for $i \in I_{AB}$; note that some of these sets may be empty.

First, we consider I_B . Suppose that the paths P_i for $i \in I_B$ have at least $k - |I_B|$ internal vertices. Consider an inclusion minimal subset of indices $J \subseteq I_B$ such that the paths P_i for $i \in J$ have at least $k - |J|$ internal vertices and let $S = \{x_i y_i \mid i \in J\}$. Observe that the pairs of S compose either a linear forest or a cycle. Suppose that the pairs in S form a cycle. Then every edge of C is outside H , and we have that C is the concatenation of the paths $P_i \in J$. Note that $|J| \geq 2$ in this case. Let $j \in J$. By the choice of J , the total number of internal vertices on the paths P_i for $i \in J \setminus \{j\}$ is at most $k - |J| - 1$. Because the length of P_j is at most $k + 1$, we have that $|V(C)| \leq (k - |J| - 1) + |J| + k = 2k - 1 < 2|A| + k$; a contradiction. Therefore, S forms a linear forest. We obtain that $\mathcal{P} = \{P_i \mid i \in J\}$ is a system of T segments and $|\mathcal{P}| \leq k$. To see that the total number of internal vertices on the paths in \mathcal{P} is at most $2k$, let $j \in J$. Because the total number of internal vertices on the paths P_i for $i \in J \setminus \{j\}$ is at most $k - |J| - 1$ and the length of P_j is at most $k + 1$, the number of internal vertices on the paths in \mathcal{P} is at most $(k - |J| - 1) + k \leq 3k - 2$. We conclude that (ii) is fulfilled.

Assume from now on that the paths P_i for $i \in I_B$ have at most $k - |I_B| - 1$ internal vertices. Then we analyse I_{AB} in a similar way. Let $t = |I_B|$. Suppose that the paths P_i for $i \in I_{AB} \cup I_B$ have at least $k - t$ internal vertices. Consider an inclusion minimal subset of indices $J \subseteq I_{AB}$ such that the paths P_i for $i \in J \cup I_B$ have at least $k - t$ internal vertices and let $S = \{x_i y_i \mid i \in J \cup I_B\}$. Notice that $|S| \leq k$. Again, we have that the pairs of S compose either a linear forest or a cycle. Then we exclude the possibility that S forms a cycle. If we have a cycle, then C is the concatenation of the paths $P_i \in J \cup I_B$. Pick an arbitrary $j \in J$. We have that the total number of internal vertices on the paths P_i for $i \in (J \setminus \{j\}) \cup I_B$ is at most $k - t - 1$. Because the length of P_j is at most $k + 1$, $|V(C)| \leq (k - t - 1) + (|J| + t) + k = 2k + |J| - 1 < 2|A| + k$ and we get a contradiction. Hence, S forms a linear forest and $\mathcal{P} = \{P_i \mid i \in J \cup I_B\}$ is a system of T segments and

$|\mathcal{P}| \leq k$. To upper bound the total number of internal vertices on the paths in \mathcal{P} , let $j \in J$. Because the total number of internal vertices on the paths P_i for $i \in (J \setminus \{j\}) \cup I_B$ is at most $k - t - 1$ and the length of P_j is at most $k + 1$, the number of internal vertices on the paths in \mathcal{P} is at most $2k - t - 1 \leq 3k - 2$. We obtain that (ii) holds.

It remains to consider the case where the paths P_i for $i \in I_{AB} \cup I_B$ have at most $k - t - 1$ internal vertices. For this we analyse I_A . Let $I'_A \subseteq I_A$ be the set of indices $i \in I_A$ such that P_i has at least two internal vertices. Let r be the number of internal vertices on the paths P_i with $i \in I'_A \cup I_B \cup I_{AB}$. Observe that because B is an independent set, $|V(C)| \leq r + t + 2|A| - |I'_A|$. Hence, $r + t - |I'_A| \geq k$. We select an inclusion minimal set of indices $J \subseteq I'_A$ such that the paths P_i for $i \in J \cup I_B \cup I_{AB}$ have at least $k - t + |J|$ internal vertices and let $S = \{x_i y_i \mid i \in J \cup I_B \cup I_{AB}\}$. Let also $s = |J|$. Observe that because P_i has at least two internal vertices for every $i \in I'_A$, $|S| \leq k$. In the same way as above, the pairs of S compose either a linear forest or a cycle, and we show that it should be a linear forest. If the pairs of S form a cycle, then C is the concatenation of the paths $P_i \in J$. Let $j \in J$. By the minimality of J , the total number of internal vertices on the paths P_i for $i \in (J \setminus \{j\}) \cup I_B \cup I_{AB}$ is at most $k + (s - 1) - t - 1$. Because the length of P_j is at most $k + 1$, $|V(C)| \leq (k + (s - 1) - t - 1) + (s + t + |I_{AB}|) + k = 2k + |I_{AB}| + 2s - 2$. Observe that $t + s + |I_{AB}| \leq k$, because if $t + s + |I_{AB}| \geq k + 1$, the total number of the internal vertices on the paths P_i for $i \in (J \setminus \{j\}) \cup I_B \cup I_{AB}$ would be at least $k + s$. Therefore, $|V(C)| \leq 2k + |I_{AB}| + 2s - 2 \leq 4k - 2 < 2|A| + k$; a contradiction. We obtain that S forms a linear forest and $\mathcal{P} = \{P_i \mid i \in J \cup I_B \cup I_{AB}\}$ is a system of T segments, and $|\mathcal{P}| \leq k$. To get the upper bound for the total number of internal vertices on the paths in \mathcal{P} , let $j \in J$. Because the total number of internal vertices on the paths P_i for $i \in (J \setminus \{j\}) \cup I_B$ is at most $k + (s - 1) - t - 1$ and the length of P_j is at most $k + 1$, the number of internal vertices on the paths in \mathcal{P} is at most $2k + s - t - 2 \leq 3k - 2$. We conclude that (ii) is fulfilled. This concludes the analysis of Case 3 and the proof of the lemma. \blacktriangleleft

Fomin et al. [6] proved the following algorithmic result about systems of T -segments.

► **Proposition 19** ([6, Lemma 4]). *Let G be a graph, $T \subseteq V(G)$, and let p and r be positive integers. Then it can be decided in $2^{\mathcal{O}(p)} \cdot n^{\mathcal{O}(1)}$ time whether there is a system of T -segments \mathcal{P} with r paths having p internal vertices in total.*

However, we need an algorithm for constructing a system of T -segments with additional properties described in Lemma 18. For this, we modify the algorithm from Proposition 19.

► **Lemma 20** (\star). *Let G be a graph, $T \subseteq V(G)$, and let $\{A, B\}$ be a partition of T . Let also p and r be positive integers, and suppose that s and t are nonnegative integers with $s + t \leq r$. Then it can be decided in $2^{\mathcal{O}(p)} \cdot n^{\mathcal{O}(1)}$ time whether there is a system of T -segments \mathcal{P} with r paths having p internal vertices in total such that (i) \mathcal{P} contains s A -segments, (ii) t B -segments, and (iii) every A -segment has at least two internal vertices.*

7 Proof of the main result

Now we have all ingredients to prove our main result. We restate it here for the reader's convenience.

► **Theorem 2.** *LONGEST CYCLE ABOVE MAD can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ on 2-connected graphs.*

Proof. Let (G, k) be an instance of LONGEST CYCLE ABOVE MAD, where G is a 2-connected graph. We use the algorithm from Proposition 9 and compute $\text{mad}(G)$ in polynomial time. If $k = 0$, the problem is trivial, because a cycle of length at least $\text{mad}(G)$ exists by Theorem 1. Hence, we can assume that $k \geq 1$. If $k > \frac{1}{88}\text{mad}(G) - 1$, we use Proposition 11 and solve the problem in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. From now, we assume that $0 < k \leq \frac{1}{88}\text{mad}(G) - 1$. In particular, $k \leq \frac{1}{80}\text{mad}(G) - 1$. We apply Lemma 14, and in polynomial time either

- (i) find a cycle of length at least $\text{mad}(G) + k$ in G , or
- (ii) find an induced subgraph H of G with $\text{ad}(H) \geq \text{mad}(G) - 1$ such that $\delta(H) \geq \frac{1}{2}\text{ad}(H)$ and $|V(H)| < \text{ad}(H) + k + 1$, or
- (iii) find an induced subgraph H of G such that there is a partition $\{A, B\}$ of $V(H)$ with the following properties:
 - B is an independent set,
 - $\frac{1}{2}\text{mad}(G) - 4k \leq |A|$,
 - for every $v \in A$, $|N_H(v) \cap B| \geq 2|A|$,
 - for every $v \in B$, $d_H(v) \geq |A| - 2k - 2$.

If the algorithm finds a cycle of length at least $\text{mad}(G) + k$, then we return it and stop. In Cases (ii) and (iii), we get a dense induced subgraph H that can be used to find a solution.

Case (ii). The algorithm from Lemma 14 returns an induced subgraph H of G with $\text{ad}(H) \geq \text{mad}(G) - 1$ such that $\delta(H) \geq \frac{1}{2}\text{ad}(H)$ and $|V(H)| < \text{ad}(H) + k + 1$. Let $k' = \lceil \text{mad}(G) \rceil + k - |V(H)|$. We have that G has a cycle of length at least $\text{mad}(G) + k$ if and only if G has a cycle of length at least $|V(H)| + k'$. Note that $k' \leq k + 1 \leq \frac{1}{88}\text{mad}(G) \leq \frac{1}{60}\text{ad}(H)$. By Lemma 15, for every potentially cyclable set S of at most $k + 1$ pairs of distinct vertices of H , $H + S$ has a Hamiltonian cycle containing every edge of S .

Suppose that $k' \leq 0$. Observe that H has a Hamiltonian cycle as we can use Lemma 15 for $S = \{e\}$, where e is an arbitrary edge $e \in E(H)$. Then we conclude that H has a cycle of length at least $\text{mad}(G) + k$ and stop. Assume that $k' > 0$. Note that $|V(H)| \geq \text{ad}(H) \geq 2k'$. Then by Lemma 17, G has a cycle of length at least $|V(H)| + k'$ if and only if one of the following holds:

- (a) There are two distinct vertices $s, t \in V(H)$ such that H has an (s, t) -path P of length at least $k' + 1$ whose internal vertices lie in $V(G) \setminus V(H)$.
- (b) There is a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ such that $r \leq k'$ and the total number of vertices on the paths in \mathcal{P} outside T is at least k' and at most $2k' - 2$.

First, we check if (a) can be satisfied. For this, we consider all pairs of distinct vertices s and t of H . For every pair, we construct $G' = G[(V(G) \setminus V(H)) \cup \{s, t\}]$ and use Proposition 12 to find an (s, t) -path of length at least $k' + 1$ in G' in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. If we find such a path for some pair, we report the existence of a cycle of length at least $\text{mad}(G) + k$ and stop. Otherwise, we verify (b) using Proposition 19. We use the algorithm from Proposition 19 for $r \in \{1, \dots, k'\}$ and for $p \in \{k', \dots, 2k' - 2\}$. If we find a required system of T -segments, then we return that G has a cycle of length at least $\text{mad}(G) + k$ and stop. If we fail to find such a system for every r and p , we conclude that G has no cycle of length at least $\text{mad}(G) + k$. Note that this can be done in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. This concludes Case (ii).

Case (iii). The algorithm from Lemma 14 returns an induced subgraph H of G such that there is a partition $\{A, B\}$ of $V(H)$ with the properties:

- B is an independent set,
- $\frac{1}{2}\text{mad}(G) - 4k \leq |A|$,
- for every $v \in A$, $|N_H(v) \cap B| \geq 2|A|$,
- for every $v \in B$, $d_H(v) \geq |A| - 2k - 2$.

Let $k' = \lceil \text{mad}(G) \rceil + k - 2|A|$. Observe that G has a cycle of length at least $\text{mad}(G) + k$ if and only if G has a cycle of length at least $2|A| + k'$. We have that $2|A| \geq \lceil \text{mad}(G) \rceil - 8k$ and, therefore, $k' \leq 9k$.

Note that $|A| \geq \frac{1}{2}\text{mad}(G) - 4k \geq 40k$, since $k \leq \frac{1}{88}\text{mad}(G) - 1$. Also, we have that for every $v \in B$, $d_H(v) \geq |A| - 4k$. Therefore, by Lemma 16, for every potentially cyclable set S of at most $9k$ pairs of distinct vertices, $G' = G + S$ has a cycle C containing every edge of S and the length of C is $2|A| - s + t$, where s is the number of edges of S with both end-vertices in A and t is the number of edges in S with both end-vertices in B .

Suppose that $k' \leq 0$. Then we observe that H has a cycle of length $2|A|$ because we can set $S = \{xy\}$, where $xy \in E(H)$ with $x \in A$ and $y \in B$. Then H has a cycle of length at least $2|A| + k'$ and we conclude that G has a cycle of length at least $\text{mad}(G) + k$. Assume that $k' > 0$. Since $|A| \geq 40k \geq \frac{3}{2}k'$, we can apply Lemma 18. We obtain that G has a cycle of length at least $2|A| + k'$ if and only if one of the following holds:

- (a) There are two distinct vertices $x, y \in V(H)$ such that H has an (x, y) -path P of length at least $k' + 2$ whose internal vertices are in $V(G) \setminus V(H)$.
- (b) There is a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ with s A -segments and t B -segments such that
 - $r \leq k' \leq 9k$,
 - every A -segment has at least two internal vertices,
 - the total number of internal vertices on the paths in \mathcal{P} is at least $k' + s - t$ and at most $3k' - 2 \leq 27k - 2$.

To verify (a), we use the same approach as in Case (ii), that is, we consider all pairs of distinct vertices x and y of H . For every pair, we construct $G' = G[(V(G) \setminus V(H)) \cup \{x, y\}]$ and use Proposition 12 to find an (x, y) -path of length at least $k' + 2$ in G in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. If we find such a path for some pair, we report the existence of a cycle of length at least $\text{mad}(G) + k$ and stop. Otherwise, we verify (b) using Lemma 20. We use the algorithm from this lemma for $r \in \{1, \dots, k'\}$, $s \in \{0, \dots, k'\}$ and $t \in \{0, \dots, k'\}$ such that $s + t \leq r$, and for $p \in \{k' + s - t, 3k' - 2\}$. If we find a system of T -segments $\mathcal{P} = \{P_1, \dots, P_r\}$ for $T = V(H)$ with s A -segments and t B -segments with the required properties, then we conclude that G has a cycle of length at least $2|A| + k'$ and stop. If such a system does not exist for every choice of r , s , t , and p , we have that G has no cycle of length at least $\text{mad}(G) + k$. By Lemma 20, this can be done in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time, because $k' \leq 9k$. This concludes Case (iii).

Because the algorithm from Lemma 14 is polynomial and the other subroutines used in our algorithm for LONGEST CYCLE ABOVE MAD run in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$, the overall running time is $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ and this concludes the proof.

Let us remark that since the algorithms for paths in Propositions 19 and 12 and Lemma 20 are, in fact, constructive, and the same holds for the algorithms for cycles in Lemmas 17 and 18 and Proposition 11, our algorithm is not only able to solve the decision problem, but also can find a cycle of length at least $\text{mad}(G) + k$ if it exists. ◀

Improved Polynomial-Time Approximations for Clustering with Minimum Sum of Radii or Diameters

Abstract

We give an improved approximation algorithm for two related clustering problems. In the Minimum Sum of Radii clustering problem (MSR), we are to select k balls in a metric space to cover all points while minimizing the sum of the radii of these balls. In the Minimum Sum of Diameters clustering problem (MSD), we are to simply partition the points of a metric space into k parts while minimizing the sum of the diameters of these parts. We present a 3.389-approximation for MSR and a 6.546-approximation for MSD, improving over their respective 3.504 and 7.008 approximations developed by Charikar and Panigrahy (2001). In particular, our guarantee for MSD is better than twice our guarantee for MSR.

Our approach refines a so-called bipoint rounding procedure of Charikar and Panigrahy's algorithm by considering centering balls at some points that were not necessarily centers in the bipoint solution. This added versatility enables the analysis of our improved approximation guarantees. We also provide an alternative approach to finding the bipoint solution using a straightforward LP rounding procedure rather than a primal-dual algorithm.

1 Introduction

Clustering, as one of the fundamental problems in information technology, has been studied in computing science and several other fields to a great extent. Different methods of clustering have been used significantly in data mining, bioinformatics, pattern recognition, computer vision, etc. The goal of clustering is to partition a set of data points into partitions, called clusters. Many of clustering problems involve finding k cluster centers and a mapping σ from data points to the centers to minimize some objective function. One of the most studied such objective functions is k -CENTER which minimizes the maximum diameter (or radius) [9, 18]. Another examples is the k -MEDIAN problem which aims to minimize sum of distances from data points to their centers, as extensively studied in [5, 6, 19, 20, 21].

In this paper, we focus on a different objective function for clustering that is more center-focused in that the cost of a cluster is the radius of the ball used to cover that cluster. Specifically, we study the following problem.

► **Definition 1.** In the MINIMUM SUM OF RADII problem (MSR), we are given a set X of n points in a metric space with distances d and a positive integer k . We are to select centers $C \subseteq X$, $|C| \leq k$ and assign each $i \in C$ a radius r_i so that each $j \in X$ lies within distance r_i of at least one $i \in C$ (i.e. $d(j, i) \leq r_i$). The goal is to minimize the total radii, i.e. $\sum_{i \in C} r_i$.

We also consider the related problem to minimize sum of diameters of the clusters chosen. Note this variant is simply about partitioning the point set, there are no centers involved.

► **Definition 2.** In the MINIMUMS SUM OF DIAMETERS problem (MSD), the input is the same as in MSR and our goal is to partition the points into k clusters X_1, X_2, \dots, X_k to minimize $\sum_{i=1}^k \max_{j, j' \in X_i} d(j, j')$, the sum of the diameters of the clusters.

It is easy to see that an α -approximation algorithm for MSR yields a 2α -approximation algorithm for MSD. That is, if OPT_R denotes the optimum MSR solution cost and OPT_D an optimum MSD solution cost, we have $OPT_R \leq OPT_D$ because in the optimum MSD solution we could pick any point from each cluster to act as its center (with radius equal to the diameter of the cluster). So if we have an MSR solution with cost at most $\alpha \cdot OPT_R$, then if we define clusters X_i by sending each point to some center whose ball covers that point, the diameter of cluster i would be $\leq 2 \cdot r_i$ so the sum of diameters would then be at most $2\alpha \cdot OPT_R \leq 2\alpha \cdot OPT_D$.

1.1 Our Contributions

Prior to this work, Charikar and Panigrahy presented a 3.504-approximation for MSR [7]. Since an α -approximation for MSR yields a 2α -approximation for MSD, this also yields a 7.008-approximation for MSD. These were the best polynomial-time approximations for these problems in general metrics.

In this paper, we first present an improved polynomial-time approximation algorithm for MSR. Specifically, we prove the following.

► **Theorem 3.** *There is a polynomial-time 3.389-approximation for MSR.*

We obtain this primarily by refining a so-called bipoint rounding step from [7]. That is, our improvement for MSR mainly focuses in the last phase of the algorithm in [7] which combines two subsets of balls that, together, open an *average* of k centers and whose average cost is low. Their algorithm focuses on selecting k of the centers from these two subsets. We expand the set of possible centers to choose and consider some that may not be centers in the averaging of the two subsets.

While not our main result, we also present an alternative way to obtain these two subsets of balls in that we consider a straightforward rounding of a linear programming (LP) relaxation, the Lagrangian relaxation of the problem obtained by relaxing the constraint that at most k centers are chosen, rather than a primal-dual technique as in [7]. Our rounding algorithm is incredibly simple and we employ fairly generic arguments to convert it to a bipoint solution for a single Lagrangian multiplier λ . This may be of independent interest as it should be easy to adapt to other settings where one wants to get a bipoint solution where both points are obtained from a common Lagrangian value λ , as long as the LMP approximation is from direct LP rounding. We emphasize this is only an alternative approach: we could work directly with their primal-dual approach.

Our second result is an improved MSD approximation that does not just use our MSR approximation as a black box.

► **Theorem 4.** *There is a polynomial-time 6.546-approximation for MSD.*

In particular, notice the guarantee is better than twice our approximation guarantee for MSR. This is obtained through a variation of our new ideas behind our MSR approximation.

We emphasize this is the first improvement to the approximation guarantee from polynomial-time algorithms for these problems in over 20 years.

1.2 Related Work

Gibson et al. show MSR is **NP**-hard even in metrics with constant doubling dimension or shortest-path metrics of edge-weighted planar graphs [10]. In polynomial time, the best approximation algorithm is the stated 3.504 approximation by Charikar and Panigrahy [7]. Interestingly, [10] show that MSR can be solved exactly in $n^{O(\log n \cdot \log \Gamma)}$ where Γ is the *aspect ratio* of the metric (maximum distance divided by minimum nonzero distance). By standard techniques, this yields a quasi-PTAS for MSR: i.e. a $(1 + \epsilon)$ -approximation with running time $n^{O(\log 1/\epsilon + \log^2 n)}$. A major open problem is to design a PTAS for MSR, or perhaps to demonstrate there is no PTAS for MSR under some strong lower bound (eg. the exponential-time hypothesis). For now, it is of interest to get improved constant-factor approximations for MSR. By way of analogy, the *unsplittable flow* problem was known to admit a quasi-PTAS [1, 2] yet improved constant-factor approximations were subsequently produced [15, 13, 14], that is until a PTAS was finally found by Grandoni et al. [12].

On the other hand MSD is hard to approximate: Doddi et al. show that unless $\mathbf{P} = \mathbf{NP}$, there is no $(2 - \epsilon)$ -approximation for MSD for any $\epsilon > 0$ even if the metric is the shortest path metric of an unweighted graph [8]. Prior to our work, the best approximation for MSD is simply twice the best polynomial-time approximation for MSR, i.e. $2 \cdot 3.504 = 7.008$ using the approximation for MSR from [7].

MSR and MSD have been studied in special cases as well. In constant-dimensional Euclidean metrics, MSR can be solved exactly in polynomial time [11]. This is particularly interesting in light of the fact that MSR is hard in doubling metrics. For MSD in constant-dimensional Euclidean metrics, if k is also regarded as a constant then MSD can be solved exactly [4]. In general metrics with $k = 2$, MSD can be solved exactly by observing that if we are given the diameters of the two clusters, we can use 2SAT to determine if we can place the points in these clusters while respecting the diameters [16]. However, MSD is **NP**-hard for even $k = 3$ as it captures the problem of determining if an unweighted graph can be partitioned into 3 cliques. Finally, if one does not allow balls with radius 0 in the solution, MSR can be solved in polynomial time in shortest path metrics of unweighted graphs [3, 17].

1.3 Organization

Our MSR approximation is given in Section 2. Our algorithm follows the same general structure as the algorithm in [7] so we defer the details behind one significant step (obtaining the “bipoint” solution) and focus on our new ideas. Our MSD approximation is then given in Section 3. Finally, our new approach to obtaining a clean bipoint solution is summarized in Section 4. For the sake of space, many proofs in Section 4 are deferred to the full version. Brief concluding remarks are given in Section 5.

2 Minimum Sum of Radii

2.1 Preliminaries

Throughout, $n = |X|$. We assume $d(i, i') > 0$ for distinct $i, i' \in X$ (i.e. there are no collocated points), clearly this is without loss of generality since we could restrict X to contain only one point from each group of collocated points. A **ball** in X is a set of the form $B(i, r) = \{j \in X : d(i, j) \leq r\}$ for some point $i \in X$ and radius $r \geq 0$. We sometimes also call a pair (i, r) a ball with the understanding it is referring to the set $B(i, r)$. One can view a solution to MSR as being a collection of balls.

In some places in our algorithm, we need to guess balls from the optimal solution or use LP variables corresponding to balls that may appear in the optimal solution: in these steps we only need to consider balls $B(i, r)$ where $r = d(i, j)$ for some $j \in X$ because it is clear that an optimal MSR solution will set each radius as to be the furthest point that is covered by that ball. So there are only $O(|X|^2)$ different balls to consider. We view a solution as a collection \mathcal{B} of pairs $(i, r), i \in X, r \geq 0$ describing the centers and radii of balls. For such a subset, we let $\text{cost}(\mathcal{B}) = \sum_{(i,r) \in \mathcal{B}} r$ be the total radii of these balls.

Fix some small constant $\epsilon > 0$ such that $1/\epsilon$ is an integer. Smaller ϵ lead to better guarantees with increased (but still polynomial) running times. Since the bound in the statement of Theorem 3 is just a rounded up version of the actual approximation guarantee, we will ultimately pick ϵ to be small enough to hide it in the approximation guarantee, which is why it does not appear in the statement. We assume $k > 1/\epsilon$, otherwise we can simply use brute force to find the optimum solution in $n^{O(1/\epsilon)}$ time.

Our algorithm for MSR is summarized in Algorithm 1 at the end of this section, though it makes reference to a fundamental subroutine to find our “bipoint” solution that we describe in Section 4. By bipoint, we simply mean two subsets of balls $\mathcal{B}_1, \mathcal{B}_2$ with $|\mathcal{B}_1| \geq k \geq |\mathcal{B}_2|$ so, in a sense to be described later, some averaging of these sets looks like a feasible fractional solution using exactly k balls.

2.2 Step 1: Guessing the Largest Balls

Let \mathcal{B}^* denote some fixed optimum solution with $\text{OPT} := \text{cost}(\mathcal{B}^*)$. Among all optimal solutions, we assume \mathcal{B}^* has the fewest balls. Thus, for distinct $(i, r), (i', r') \in \mathcal{B}^*$ we have that $i' \notin B(i, r)$ since, otherwise, $\mathcal{B}^* - \{(i, r), (i', r')\} \cup \{(i, r + r')\}$ is another optimal solution with even fewer balls.

Similar to [7], we guess the $1/\epsilon$ largest balls in \mathcal{B}^* by trying each subset \mathcal{B}' of $1/\epsilon$ balls and proceeding with the algorithm we describe in the rest of this paper. Let R_m be the minimum radius of a ball in \mathcal{B}' and note $R_m \leq \epsilon \cdot \text{OPT}$. We also let $k' := k - 1/\epsilon$, which is an upper bound on the number of balls in $\mathcal{B}^* - \mathcal{B}'$.

We now restrict ourselves to the instance with points $X' := X - \cup_{(i,r) \in \mathcal{B}'} B(i, r)$ to be covered. Since no center of a ball in \mathcal{B}^* is contained within another ball from \mathcal{B}^* , the remaining balls in $\mathcal{B}^* - \mathcal{B}'$ are also centered in X' . We will let $\text{OPT}' = \text{OPT} - \cup_{(i,r) \in \mathcal{B}'} r$ denote the optimal solution value to this restricted instance. The solution $\mathcal{B}^* - \mathcal{B}'$ for this instance satisfies $r \leq R_m \leq \epsilon \cdot \text{OPT}$ for any $(i, r) \in \mathcal{B}^* - \mathcal{B}'$. We also assume $|X'| > k'$, otherwise we just open zero-radius ball at each point in X' .

Before proceeding to the main part of the algorithm, we perform a “precheck” for this guess as follows: run a standard 2-approximation for the k' -MEDIAN instance on the metric restricted to X' (eg. [18]). If the solution returned has radius $> 2 \cdot R_m$, then we reject this guess \mathcal{B}' . This is valid because we know for a correct guess that the remaining points can each be covered using at most k' balls each with with radius at most R_m . From now on, we let \mathcal{A} denote the k' centers returned by this approximation: so each $j \in X'$ lies in at least one ball of the form $B(i, 2 \cdot R_m)$ for some $i \in \mathcal{A}$.

Summary. After guessing \mathcal{B}' we have restricted ourselves to an MSR instance with points X' , a bound k' on the number of balls to choose (where $k' < |X'|$), and a bound R_m . For a correct guess of \mathcal{B}' , there is an optimal solution that uses balls with radius at most R_m . Furthermore, \mathcal{A} is a set of k' centers such that every $j \in X'$ has $d(j, \mathcal{A}) \leq 2 \cdot R_m$ balls.

When analyzing the rest of the algorithm, will assume that \mathcal{B}' is guessed correctly, i.e. $\mathcal{B}' \subseteq \mathcal{B}^*$ and all $(i, r) \in \mathcal{B}^* - \mathcal{B}'$ have $r \leq R_m$. Our final solution will be the minimum-cost solution found over all guesses \mathcal{B}' that were not rejected, so it will be at most the cost of the solution found when \mathcal{B}' was guessed correctly.

2.3 Step 2: Getting a Bipoint Solution

The output from this step is similar to [7], except we obtain it with a different algorithm. We note that their approach would suffice for our purposes, our reasons for considering this different approach are described after the statement of Theorem 6 below. Some details are deferred to Section 4 and some to the full version of this paper, here we explain what is required to understand our ideas that lead to the improved approximation guarantee.

For a value $\lambda \geq 0$, $\mathbf{LP}(\lambda)$ is the linear program that results by considering the Lagrangian relaxation of MSR. That is, the LP has variables for each possible ball we may add except instead of restricting the number of balls to be at most k' , we simply pay λ for each ball.

Note. Terms of the LP that consider pairs (i, r) corresponding to balls with $i \in X'$ and r of the form $d(i, j)$ for some $j \in X'$ but only for those where $r \leq R_m$. Thus, the LP has $O(|X|^2)$ variables.

$$\begin{aligned} \min \quad & \sum_{(i,r)} (r + \lambda) \cdot x_{i,r} \\ \text{s.t.} \quad & \sum_{(i,r): j \in B(i,r)} x_{i,r} \geq 1 \quad \forall j \in X' \\ & x \geq 0 \end{aligned} \tag{LP(\lambda)}$$

The following is standard and follows by considering the natural integer solution corresponding to the balls in $\mathcal{B}^* - \mathcal{B}'$.

► **Lemma 5.** *For any $\lambda \geq 0$, let $OPT_{\mathbf{LP}(\lambda)}$ denote the optimum value of $\mathbf{LP}(\lambda)$. Then $OPT_{LP(\lambda)} - \lambda \cdot k' \leq OPT'$.*

We summarize the main properties of a bipoint solution that is required by our algorithm. The proof of the following is the subject of Section 4.

► **Theorem 6.** *There is a polynomial-time algorithm that will compute a single value $\lambda \geq 0$ and two sets of balls $\mathcal{B}_1, \mathcal{B}_2$ having respective sizes k_1, k_2 where $k_1 \geq k' \geq k_2$. Furthermore, for every $(i, r) \in \mathcal{B}_1$, there is some $(i', r') \in \mathcal{B}_2$ such that $B(i, r) \cap B(i', r') \neq \emptyset$. Finally, for both $\ell = 1$ and $\ell = 2$ we have the following properties:*

- for each $(i, r) \in \mathcal{B}_\ell$, we have $r \leq 3 \cdot R_m$,
- tripling the radii of each $(i, r) \in \mathcal{B}_\ell$ will cover X' , i.e. for each $j \in X'$ there is some $(i, r) \in \mathcal{B}_\ell$ such that $j \in B(i, 3 \cdot r)$, and
- $cost(\mathcal{B}_\ell) + \lambda \cdot k_\ell \leq OPT_{\mathbf{LP}(\lambda)}$

Again, we note that essentially the same result is found in [7], except it is slightly more technical to state since the two sets \mathcal{B}_1 and \mathcal{B}_2 are obtained through a LMP algorithm applied to different (but very close) values λ_1 and λ_2 which leads to an additional ϵ -loss in the approximation guarantee. Qualitatively speaking, the theorem statement itself is not new and the reader who is not interested in seeing a new technique can skip reading its proof.

As an easy warmup, notice that if $k_1 = k'$ then by Lemma 5 we have

$$cost(\mathcal{B}_1) \leq OPT_{\mathbf{LP}(\lambda)} - \lambda \cdot k' \leq OPT'.$$

In this case, tripling the radii of all balls in \mathcal{B}_1 covers all of X' with cost at most $3 \cdot OPT'$. Together with \mathcal{B}' , this is a feasible MSR solution with cost at most $3 \cdot OPT$. A similar approximation follows if $k_2 = k$. However, we do not distinguish these case in our full analysis below.

2.4 Step 3: Combining Bipoint Solutions

Let $\lambda, \mathcal{B}_1, \mathcal{B}_2$ be the *bipoint solution* from Theorem 6. For brevity, let $C_1 = \text{cost}(\mathcal{B}_1)$ and $C_2 = \text{cost}(\mathcal{B}_2)$. Since $k_1 \geq k' \geq k_2$, there are values $a, b \geq 0$ with $a+b = 1$ and $a \cdot k_1 + b \cdot k_2 = k'$. We fix these values throughout this section.

The following shows the *average* cost C_1 and C_2 is bounded by OPT' , the first inequality is by the last property listed in Theorem 6 and the second by Lemma 5.

$$a \cdot C_1 + b \cdot C_2 \leq a \cdot (OPT_{\text{LP}(\lambda)} - \lambda \cdot k_1) + b \cdot (OPT_{\text{LP}(\lambda)} - \lambda \cdot k_2) = OPT_{\text{LP}(\lambda)} - \lambda \cdot k \leq OPT' \quad (1)$$

The rest of our algorithm and analysis considers how to convert the two solutions $\mathcal{B}_1, \mathcal{B}_2$ to produce a feasible solution whose value is within a constant-factor of this averaging of C_1, C_2 . First, note tripling the radii in all balls in \mathcal{B}_2 will produce a feasible solution as $k_2 \leq k'$, but it may be too expensive. So we will consider two different solutions and take the better of the two. The first solution is what we just described: formally it is $\{(i, 3r) : (i, r) \in \mathcal{B}_2\}$, which is a feasible solution with cost $3 \cdot C_2$.

Constructing the second solution is our main deviation from the work in [7]. Intuitively, we want to cover all points by using balls $(i, 3 \cdot r)$ for $(i, r) \in \mathcal{B}_1$. The cheaper of this and the first solution can easily be shown to have cost at most $3 \cdot OPT'$. The problem is that this could open more than k' centers (if $k_1 > k'$). As in [7], we consolidate some of these balls into a single group based on their common intersection with some $(i', r') \in \mathcal{B}_2$. We will select some groups and merge their balls into a single ball so the number of balls is at most k' . Our improved approximation is enabled by considering different ways to cover balls in a group using a single ball, [7] only considered one possible way to cover a group with a single ball.

We now form groups. For each $(i, r) \in \mathcal{B}_2$, we create a group $G_{i,r} \subseteq \mathcal{B}_1$ as follows: for each $(i', r') \in \mathcal{B}_1$, consider any single $(i, r) \in \mathcal{B}_2$ such that $B(i, r) \cap B(i', r') \neq \emptyset$ and add (i', r') to $G_{i,r}$. If multiple $(i, r) \in \mathcal{B}_2$ satisfy this criteria, pick one arbitrarily. Let $\mathcal{G} = \{G_{i,r} : (i, r) \in \mathcal{B}_2 \text{ s.t. } G_{i,r} \neq \emptyset\}$ be the collection of all nonempty groups formed this way, note \mathcal{G} is a partitioning of \mathcal{B}_1 .

Covering a group with a single ball

From here, the approach in [7] would describe how to merge the balls in a group $G_{i,r} \in \mathcal{G}$ simply by centering a new ball at i , and making its radius sufficiently large to cover all points covered by the tripled balls $B(i', 3r')$ for $(i', r') \in G_{i,r}$. We consider choosing a different center when we consolidate the \mathcal{B}_1 balls in a group. In fact, it suffices to simply pick the minimum-radius ball that covers the union of the tripled balls in a group. This ball can be centered at any point in X' .

To analyze this, we describe a few candidate balls and argue that the cheapest of these has cost at most $\frac{11}{8} \cdot r + 3 \cdot \text{cost}(G_{i,r})$ for each $G_{i,r} \in \mathcal{G}$. The exact choice of ball we use for the analysis depends on the composition of the group, namely the total and maximum radii of balls in $G_{i,r}$ versus the radius r itself. In [7], the ball they select has cost at most $r + 4 \cdot \text{cost}(G_{i,r})$. While our analysis has a higher dependence on r , when considered as an alternative solution to the one that just triples all balls in \mathcal{B}_2 we end up with a better overall solution.

For now, fix a single group $G_{i,r} \in \mathcal{G}$. Let R_1 denote r , R_2 be the maximum radius of a ball in $G_{i,r}$ and R_3 be the maximum radius among all other balls in $G_{i,r}$ apart from the one defining R_2 . If $G_{i,r}$ has only one ball, then let $R_3 = 0$. That is, $0 \leq R_3 \leq R_2$ but it could be that $R_3 = R_2$, i.e. there could be more than one ball from $G_{i,r}$ with maximum radius. We also let i_1 denote i , i_2 be the center of any particular ball with maximum radius in $G_{i,r}$, and i_3 be any single point in $B(i_1, R_1) \cap B(i_2, R_2)$. There is at least one since each ball in $G_{i,r}$ intersects $B(i, r)$ by construction of the groups.

■ **Figure 1** A depiction of a group G_{i_1, R_1} . The solid ball is $B(i_1, R_1)$ and the dashed balls are those in G_{i_1, R_1} . Point j is covered by tripling the ball centered at i' . The dashed path depicts the way we bound $d(j, i_2)$ in the second part of the case **Centering at i_2** .

Next we describe the radius of a ball that would be required if we centered it at one of i_1, i_2 or i_3 . Consider any $j \in Y_{i, r}$ with, say, $j \in B(i', 3r')$ for some $(i', r') \in G_{i, r}$. Let i'' be any point in $B(i_1, r) \cap B(i', r')$. We bound the distance of j from each of i_1, i_2 and i_3 to see what radius would suffice for each of these three possible centers. Figure 1 depicts this group and one case of the analysis below.

- **Centering at i_1 .** Simply put,

$$\begin{aligned} d(j, i_1) &\leq d(j, i') + d(i', i'') + d(i'', i_1) \\ &\leq 3 \cdot R_2 + R_2 + R_1 \\ &= R_1 + 4 \cdot R_2. \end{aligned}$$

So radius $C^{(1)} := R_1 + 4 \cdot R_2$ suffices if we choose i_1 as the center.

- **Centering at i_2 .** If $(i', r') = (i_2, R_2)$ then $d(j, i_2) \leq 3 \cdot R_2$. Otherwise, $r' \leq R_3$ and

$$\begin{aligned} d(j, i_2) &\leq d(j, i') + d(i', i'') + d(i'', i_1) + d(i_1, i_3) + d(i_3, i_2) \\ &\leq 3 \cdot R_3 + R_3 + R_1 + R_1 + R_2 \\ &= 2 \cdot R_1 + R_2 + 4 \cdot R_3. \end{aligned}$$

So radius $C^{(2)} := \max\{3 \cdot R_2, 2 \cdot R_1 + R_2 + 4 \cdot R_3\}$ suffices if we choose i_2 as the center.

- **Centering at i_3 .** If $(i', r') = (i_2, R_2)$ then $d(j, i_3) \leq d(j, i_2) + d(i_2, i_3) \leq 3 \cdot R_2 + R_2 = 4 \cdot R_2$. Otherwise, $r' \leq R_3$ and we see

$$\begin{aligned} d(j, i_3) &\leq d(j, i') + d(i', i'') + d(i'', i_1) + d(i_1, i_3) \\ &\leq 3 \cdot R_3 + R_3 + R_1 + R_1 \\ &= 2 \cdot R_1 + 4 \cdot R_3. \end{aligned}$$

So radius $C^{(3)} := \max\{4 \cdot R_2, 2 \cdot R_1 + 4 \cdot R_3\}$ suffices if we choose i_3 as the center.

With these bounds, we now describe how to choose a single ball covering the points covered by tripled balls in $G_{i,r}$ in a way that gives a good bound on the minimum-radius ball covering these points. The following cases employ particular constants to decide which center should be used, these have been optimized for our approach. The final bounds are stated to be of the form $3 \cdot C_{i,r}$ plus some multiple of r . Let $C_{i,r} = \sum_{(i',r') \in G_{i,r}} r$ be the total radii of all balls in $G_{i,r}$. So $\sum_{G_{i,r} \in \mathcal{G}} C_{i,r} = \text{cost}(\mathcal{B}_1) = C_1$.

■ **Case:** $R_3 > R_2/3$.

Then the ball $B'_{i,r}$ is selected to be $B(i_1, C^{(1)})$. Note $4/3 \cdot R_2 < R_2 + R_3 \leq C_{i,r}$ so $C^{(1)} \leq r + 3 \cdot C_{i,r}$.

■ **Case:** $R_3 \leq R_2/3$ and $R_2 \geq \frac{6}{5} \cdot R_1$.

The ball $B'_{i,r}$ is selected to be $B(i_2, C^{(2)})$. Note $C^{(2)} \leq \frac{6}{5} \cdot R_1 + 3 \cdot R_2 \leq \frac{6}{5} \cdot r + 3 \cdot C_{i,r}$.

■ **Case:** $R_3 \leq R_2/3$ and $\frac{6}{5} \cdot R_1 > R_2 \geq \frac{3}{8} \cdot R_1$.

The ball $B'_{i,r}$ is selected to be $B(i_3, C^{(3)})$. Note $C^{(3)} \leq \frac{11}{8} \cdot R_1 + 3 \cdot R_2 \leq \frac{11}{8} \cdot r + 3 \cdot C_{i,r}$.

■ **Case:** $R_3 \leq R_2/3$ and $\frac{3}{8} \cdot R_1 > R_2$.

The ball $B'_{i,r}$ is selected to be $B(i_1, C^{(1)})$. Note $C^{(1)} \leq \frac{11}{8} \cdot R_1 + 3 \cdot R_2 \leq \frac{11}{8} \cdot r + 3 \cdot C_{i,r}$.

In any case, we see that by selecting $B'_{i,r}$ optimally, the radius is at most $\frac{11}{8} \cdot r + 3 \cdot C_{i,r}$. Also, since $R_1, R_2, R_3 \leq 3 \cdot R_m$ by Theorem 6, then the radius of $B'_{i,r}$ is also seen to be at most, say, $21 \cdot R_m$.

Choosing which groups to merge

For each group $G_{i,r} \in \mathcal{G}$, we consider two options. Either we select all balls in $G_{i,r}$ with triple their original radii (thus, with total cost $3 \cdot C_{i,r}$), or we select the single ball $B'_{i,r}$ described in the previous section. We want to do this to minimize the resulting cost while ensuring the number of centers open is at most k' . To help with this, we consider the following linear program. For each $G_{i,r} \in \mathcal{G}$ we have a variable $z_{i,r}$ where $z_{i,r} = 0$ corresponds to selecting the $|G_{i,r}|$ balls with triple their original radius and $z_{i,r} = 1$ corresponds to selecting the single ball $B'_{i,r}$. As noted in the previous section, the radius of $B'_{i,r}$ is at most $\frac{11}{8} \cdot r + 3 \cdot C_{i,r}$ and also at most $21 \cdot R_m$.

$$\begin{aligned} \text{minimize : } & \sum_{G_{i,r} \in \mathcal{G}} (1 - z_{i,r}) \cdot 3 \cdot C_{i,r} + z_{i,r} \cdot \text{cost}(\{B'_{i,r}\}) \\ \text{subject to : } & \sum_{G_{i,r} \in \mathcal{G}} ((1 - z_{i,r}) \cdot |G_{i,r}| + z_{i,r}) \leq k' \\ & z_{i,r} \in [0, 1] \quad \forall G_{i,r} \in \mathcal{G} \end{aligned} \quad (\text{LP-Choose})$$

To consolidate the groups, compute an optimal extreme point to **LP-Choose**. Since all but one constraint are $[0, 1]$ box constraints, there is at most one variable $z_{i,r}$ that does not take an integer value. Since $|G_{i,r}| \geq 1$, then setting $z_{i,r}$ to 1 yields a feasible solution whose cost increases by at most the radius of $B'_{i,r}$, which was observed to be at most $21 \cdot R_m \leq 21 \cdot \epsilon \cdot \text{OPT}$.

Recall that a, b are such that $a, b \geq 0, a + b = 1$ and $a \cdot k_1 + b \cdot k_2 = k'$. Setting $z_{i,r} = a$ for each $G_{i,r} = 1$ is feasible since $1 - z_{i,r} = b, \sum_{G_{i,r} \in \mathcal{G}} |G_{i,r}| = k_2$, and there are at most k'_1 terms in this sum. The value of this solution is

$$\sum_{G_{i,r} \in \mathcal{G}} (3 \cdot b + 3 \cdot a) \cdot C_{i,r} + \frac{11}{8} \cdot b \cdot r = 3 \cdot C_2 + \frac{11}{8} \cdot b \cdot C_1$$

so the optimum solution to **LP-Choose** has value at most this as well. Summarizing,

► **Lemma 7.** *In polynomial time, we can compute a set of at most k' balls with total radius at most $\frac{11}{8} \cdot b \cdot C'_1 + 3 \cdot C_2 + 21 \cdot \epsilon \cdot OPT$ which cover all points in X' .*

Finally, we can complete our analysis. Recall our simple solution of tripling the balls in \mathcal{B}'_1 has cost at most $3 \cdot C'_1$ and the more involved solution just described has cost at most $3 \cdot C_1 + \frac{11}{8} \cdot a \cdot C_2 + 21 \cdot \epsilon \cdot OPT$. Now,

$$\min \left\{ 3 \cdot C_2, 3 \cdot C_1 + \frac{11}{8} \cdot b \cdot C_2 \right\} \leq (1-d) \cdot 3 \cdot C_2 + d \cdot \left(b \cdot \frac{11}{8} \cdot C_2 + 3 \cdot C_1 \right)$$

holds for any $0 \leq d \leq 1$. To maximize the latter, we set $d = \frac{3(1-b)}{\frac{11}{8} \cdot b^2 - \frac{11}{8} \cdot b + 3}$ and see the minimum of these two terms is at most

$$\left(\frac{9}{\frac{11}{8} \cdot b^2 - \frac{11}{8} \cdot b + 3} \right) \cdot (aC_1 + bC_2) \leq \left(\frac{9}{\frac{11}{8} \cdot b^2 - \frac{11}{8} \cdot b + 3} \right) \cdot OPT'$$

where we have used bound 1 for the last step.

The worst case occurs at $b = \frac{1}{2}$, at which the bound becomes $85/288 \cdot OPT'$. Thus, the cost of the solution is at most $\frac{288}{85} \cdot OPT' + 21 \cdot \epsilon \cdot OPT$. Adding the balls \mathcal{B}' we guessed to also cover the points in $X - X'$, we get a solution covering all of X with total radii at most

$$\text{cost}(\mathcal{B}') + \frac{288}{85} \cdot OPT' + 21 \cdot \epsilon = OPT - OPT' + \frac{288}{85} \cdot OPT' + 21 \cdot \epsilon \cdot OPT \leq 3.389 \cdot OPT$$

for sufficiently small ϵ .

Algorithm Summary

The entire algorithm for MSR that we have just presented is summarized in Algorithm 1.

■ Algorithm 1 MSR Approximation.

$\mathcal{S} \leftarrow \emptyset$ {The set of all solutions seen over all guesses}

for each subset \mathcal{B}'_j of $1/\epsilon$ balls **do**

 let X', R_m be as described in Section 2.2

$(\mathcal{A}, R) \leftarrow k$ -MEDIAN 2-approximation on X'

if $R > 2 \cdot R_m$ **then**

reject this guess \mathcal{B}' and continue with the next

 let $\mathcal{B}_1, \mathcal{B}_2, \lambda$ be the bipoint solution described in Theorem 6

 let \mathcal{G} be the groups (a partitioning of \mathcal{B}_1) described in Section 2.4

 for each $G_{i,r} \in \mathcal{G}$, let $B'_{i,r}$ be the cheapest ball covering $\cup_{(i',r') \in G_{i,r}} B(i', 3 \cdot r')$

 let z' be an optimal extreme point to **LP-Choose**

$\mathcal{B}^{(1)} \leftarrow \{B'_{i,r} : z'_{i,r} > 0\} \cup \cup_{z'_{i,r}=0} \{(i', 3 \cdot r') : (i', r') \in G_{i,r}\}$

$\mathcal{B}^{(2)} \leftarrow \{(i, 3 \cdot r) : (i, r) \in \mathcal{B}_2\}$

 let \mathcal{B} be $\{(i, 3 \cdot r) : (i, r) \in \mathcal{B}'\}$ plus the cheaper of the two sets $\mathcal{B}^{(1)}$ and $\mathcal{B}^{(2)}$

$\mathcal{S} \leftarrow \mathcal{S} \cup \{\mathcal{B}\}$

return the cheapest solution from \mathcal{S}

3 Minimum Sum of Diameters

Here, we observe that a slight modification to the MSR approximation in fact yields a 6.546-approximation for MSD. Note that for any $Y \subseteq X$ with diameter, say, $\text{diam}(Y)$, for any $i \in Y$ we have $Y \subseteq B(i, \text{diam}(Y))$ and $\text{diam}(B(i, \text{diam}(Y))) \leq 2 \cdot \text{diam}(Y)$. So while it is difficult to guess any single cluster from the optimum MSD solution, we can guess the $1/\epsilon$ largest diameters (the values) and guess balls \mathcal{B}' with these radii that cover these largest-diameter clusters. Let OPT'_D denote the total diameter of the remaining clusters from the optimum solution, $k' = k - \frac{1}{\epsilon}$, X' be the remaining points to cluster, and $R_m = \min\{r : (i, r) \in \mathcal{B}'\} \leq \epsilon \cdot \text{OPT}'_D$.

For any $\lambda \geq 0$, note $\text{OPT}'_{\text{LP}(\lambda)} + \lambda \cdot k' \leq \text{OPT}'_D$ as picking any single center from each cluster in optimum solution on X' yields an MSR solution with cost at most OPT'_D . We then use Theorem 6 to get a bipoint solution $\mathcal{B}_1, \mathcal{B}_2, \lambda$.

If we triple the balls in \mathcal{B}_2 and output those clusters, we get a solution with total diameter $\leq 6 \cdot \text{cost}(\mathcal{B}_2)$. For the other case, we again form groups \mathcal{G} . Instead of picking a ball $B'_{i,r}$ for each group $G_{i,r} \in \mathcal{G}$, we simply let $B'_{i,r}$ be the set of points covered by the tripled balls in $G_{i,r}$. We claim $\text{diam}(B'_{i,r}) \leq 2 \cdot r + 6 \cdot C_{i,r}$.

To see this, consider any two points j', j'' covered by $\cup_{(i', r') \in G_{i,r}} B(i', 3 \cdot r')$, say (i', r') and (i'', r'') are the balls in $G_{i,r}$ which, when tripled, cover j' and j'' , respectively. If $(i', r') = (i'', r'')$ (i.e. it is the same tripled ball from $G_{i,r}$ that covers both j', j'') then $d(j', j'') \leq 6 \cdot r' \leq 6 \cdot C_{i,r}$. Otherwise, we have $r' + r'' \leq C_{i,r}$ and

$$d(j', j'') \leq d(j', i') + d(i', i'') + d(i'', i'') + d(i'', j'') \leq 4 \cdot r' + r + r + 4 \cdot r'' \leq 2 \cdot r + 4 \cdot C_{i,r}.$$

In either case, we can upper bound $d(j', j'') \leq 2 \cdot r + 6 \cdot C_{i,r}$, so $\text{diam}(B'_{i,r})$ is bounded by the same. We use an LP similar to **LP-Choose** except with the modified objective function to reflect the diameter costs of the corresponding choices.

$$\begin{aligned} \text{minimize : } & \sum_{G_{i,r} \in \mathcal{G}} (1 - z_{i,r}) \cdot 6 \cdot C_{i,r} + z_{i,r} \cdot \text{diam}(B'_{i,r}) \\ \text{subject to : } & \sum_{G_{i,r} \in \mathcal{G}} ((1 - z_{i,r}) \cdot |G_{i,r}| + z_{i,r}) \leq k' \\ & z_{i,r} \in [0, 1] \quad \forall G_{i,r} \in \mathcal{G} \end{aligned} \quad (\text{LP-Choose MSD})$$

For $a, b \geq 0$, we let $a + b = 1$ and $a \cdot k_1 + b \cdot k_2 = k'$, similar to MSR. Setting $z_{i,r} = a$ shows the optimum LP solution value is at most

$$\sum_{G_{i,r} \in \mathcal{G}} (6 \cdot b + 6 \cdot a) \cdot C_{i,r} + 2 \cdot b \cdot r = 6 \cdot C_2 + 2 \cdot b \cdot C_1.$$

In an optimal extreme point, at most one variable in **LP-Choose MSD** that is fractional so we set it to 1 we pick to corresponding group to be covered by a single ball. The final cost is $\min\{6 \cdot C_2, 6 \cdot C_1 + 2 \cdot b \cdot C_2 + O(\epsilon) \cdot \text{OPT}'_D\} \leq (1 - d) \cdot 6 \cdot C_2 + d \cdot (b \cdot 2 \cdot C_2 + 6 \cdot C_1)$ for any $d \in [0, 1]$. Let At $d = \frac{6(1-b)}{2 \cdot b^2 - 2 \cdot b + 6}$ the worst case for the final bound is at $b = 1/2$ at which we see the cost is at most $\frac{72}{11} \cdot \text{OPT}'_D + O(\epsilon) \cdot \text{OPT}'_D$. Adding this to the $1/\epsilon$ balls we guessed (whose diameters are at most twice their radius) and choosing ϵ sufficiently small shows we get a solution with an approximation guarantee of 6.546 for MSD, which is better than two times the MSR guarantee.

4 Getting the Bipoint Solution: Proof of Theorem 6

We again emphasize that one can slightly adapt the algorithm and analysis in [7] to prove a slightly weaker version of Theorem 6 that would still suffice for our approximation guarantees. The main difference is that the averaging of the bipoint solution costs as given in bound (1) from Section 2.4 would be bounded by $(1 + \epsilon') \cdot OPT$ for some $\epsilon' > 0$ (the running time depends linearly on $\log 1/\epsilon$).

We give an alternative approach that uses simple LP rounding. This may be of independent interest since our method of getting a single λ rather than two “close” values λ_1, λ_2 is simple in principle and may apply to other Lagrangian multiplier preserving (LMP) approximations that use direct LP rounding. That is, we give a recipe to find a single λ and two corresponding solutions $\mathcal{B}_1, \mathcal{B}_2$ that uses very generic properties of the rounding algorithm.

The proof of Theorem 6 proceeds through the usual approach of using a binary search using an LMP algorithm. We begin by describing our LMP algorithm followed by a simple consolidation step which is used in some parts of the binary search. Our direct LP rounding procedure is presented here as is an outline of the binary search routine. For the sake of space, full details of how our binary search works with the rounding procedure are deferred to full version.

4.1 A Simple LMP Algorithm via Direct LP Rounding

Algorithm 2 describes our rounding procedure. Note it only depends on x' and not on λ itself.

■ **Algorithm 2** ROUND(x').

```

 $\mathcal{B} \leftarrow \emptyset$ 
for  $(i, r)$  with  $x'_{i,r} > 0$  in non-increasing order of  $r$  do
  if  $B(i, r) \cap B(i', r') = \emptyset$  for each  $(i', r') \in \mathcal{B}$  then
     $\mathcal{B} \leftarrow \mathcal{B} \cup \{(i, r)\}$ 
return  $\mathcal{B}$ 

```

To analyze the performance of this algorithm, we also consider the dual of $\mathbf{LP}(\lambda)$.

$$\begin{array}{ll}
 \max & \sum_{j \in X'} y_j \\
 \text{s.t.} & \sum_{j \in B(i,r) \cap X'} y_j \leq r + \lambda \quad \forall (i, r), r \leq R_m \\
 & y \geq 0
 \end{array} \quad (\mathbf{DUAL}(\lambda))$$

► **Theorem 8.** *Let $\lambda \geq 0$. Let x' be an optimal solution for $\mathbf{LP}(\lambda)$ and y' be an optimal dual solution for $\mathbf{LP}(\lambda)$. Let \mathcal{B} denote the set returned by ROUND(x'). The balls in \mathcal{B} are pairwise-disjoint and for each $(i, r) \in \mathcal{B}$ we have $r \leq R_m$ and $r + \lambda = \sum_{j \in B(i,r)} y'_j$.*

Proof. Disjointedness follows by construction. Each ball \mathcal{B} has radius at most R_m since each ball is from the support of x' and $\mathbf{LP}(\lambda)$ only has variable for balls with radius $\leq R_m$. Again, since each $(i, r) \in \mathcal{B}$ lies in the support of x' then complementary slackness shows $r + \lambda = \sum_{j \in B(i,r)} y'_j$. ◀

Note the last condition shows $\text{cost}(\mathcal{B}) + \lambda \cdot |\mathcal{B}| \leq \sum_{j \in X'} y'_j = OPT_{\mathbf{LP}(\lambda)}$. Thus, we call this a “Lagrangian multiplier preserving” algorithm because if \mathcal{B}'' is obtained by tripling the radii of the balls returned by ROUND(x'), then $\text{cost}(\mathcal{B}'') + 3 \cdot \lambda \cdot |\mathcal{B}''| \leq 3 \cdot OPT_{\mathbf{LP}(\lambda)}$.

4.2 Sketch of the Binary Search

While it is fairly easy to see that using $\lambda = 0$ will have an optimal LP solution be rounded to $|X'| > k'$ balls, we need to ensure that for large enough λ that our rounding procedure produces $\leq k'$ balls in order to begin our binary search. Thus, we consider another step $\text{CONSOLIDATE}(\mathcal{B}, \lambda, \mathcal{A}, R_m)$ that tries to consolidate some of the balls output by $\text{ROUND}(x')$ using the balls from the k -MEDIAN approximation \mathcal{A} . Roughly speaking, if the single radius $3 \cdot R_m$ -ball centered at some $i' \in \mathcal{A}'$ is cheaper than the balls of \mathcal{B} it covers, we replace them with this single ball.

■ **Algorithm 3** $\text{CONSOLIDATE}(\mathcal{B}, \lambda, \mathcal{A}, R_m)$.

```

 $\mathcal{B}^c \leftarrow \emptyset$ 
for each  $i' \in \mathcal{A}$  do
  Let  $N_{i'} = \{(i, r) \in \mathcal{B} : i \in B(i', 2 \cdot R_m)\}$ 
  if  $3 \cdot R_m + \lambda \leq \sum_{(i,r) \in N_{i'}} (r + \lambda)$  then
     $\mathcal{B}^c \leftarrow \mathcal{B}^c \cup \{(i', 3 \cdot R_m)\}$ 
     $\mathcal{B} \leftarrow \mathcal{B} - N_{i'}$ 
 $\mathcal{B}^c \leftarrow \mathcal{B}^c \cup \mathcal{B}$ 
return  $\mathcal{B}^c$ 

```

We the following show in the full version.

► **Lemma 9.** *Let $\mathcal{B} = \text{ROUND}(x')$ for some optimal solution x' for $\text{LP}(\lambda)$ and $\mathcal{B}^c = \text{CONSOLIDATE}(\mathcal{B}, \lambda, \mathcal{A}, R_m)$.*

1. *If $\lambda \geq 4 \cdot R_m$, then $|\mathcal{B}^c| \leq k'$,*
2. *$r \leq 3 \cdot R_m$ for each $(i, r) \in \mathcal{B}^c$*
3. *for each $(i, r) \in \mathcal{B}^c$ there is some $X_{i,r} \subseteq B(i, r)$ such that $r + \lambda \leq \sum_{j \in X_{i,r}} y'_j$ where y' is an optimal solution to $\text{DUAL}(\lambda)$,*
4. *for different $(i, r), (i', r') \in \mathcal{B}^c$ we have $X_{i,r} \cap X_{i',r'} = \emptyset$, and*
5. *for each $j \in \mathcal{X}'$ we have $j \in B(i, 3 \cdot r)$ for some $(i, r) \in \mathcal{B}^c$.*

In particular, the total $(r + \lambda)$ -cost of \mathcal{B}^c is still at most $\text{OPT}_{\text{LP}(\lambda)}$ since properties 3 and 4 show each ball can be paid for some variables in the optimal dual solution and no variable in the dual is charged more than once this way.

In this way, we can start the binary search with $\lambda_1 = 0$ (for which ROUND will return exactly k' balls) and $\lambda_2 = 4 \cdot R_m$ (for which consolidating the rounded solution will produce $\leq k'$ balls). During the binary search, if at any step the optimal LP solution x_1 to $\text{LP}(\lambda_1)$ is also an optimal LP solution to $\text{LP}(\lambda_2)$ (here $[\lambda_1, \lambda_2]$ is the current interval enclosed by the binary search) or if $|\mathcal{B}| \geq k' \geq |\mathcal{B}^c|$ where \mathcal{B} is obtained by rounding an optimal solution to $\text{LP}(\lambda)$ and \mathcal{B}^c is obtained by consolidating it, it is easy to find the bipoint solution satisfying Theorem 6.

So we focus on *break points* λ which, intuitively, are values λ where the set of optimal extreme points to $\text{LP}(\lambda)$ changes. In the full version, we prove there is sufficiently-large distance between distinct breakpoints. So after a polynomial number of iterations, if the search did not terminate for one of the reasons mentioned above, then the window $[\lambda_1, \lambda_2]$ encloses exactly one break point.

We also show how to compute the largest λ such that x_1 remains optimal for $\text{LP}(\lambda)$ by solving yet another a linear program that exploits complementary slackness. After computing the only breakpoint in our final binary search window, it is easy to construct the bipoint solution satisfying the requirements of Theorem 6. We note that whenever we return a bipoint solution from this binary search, we consider a post-processing routine to ensure each ball in \mathcal{B}_1 will intersect at least one ball in \mathcal{B}_2 to fulfill the requirements of Theorem 6.

5 Concluding Remarks

It may be possible to improve our analysis further by considering an even more involved approach to analyzing how to optimally cover a group using a single ball, though such an approach seems likely to produce approximations that are still a constant-factor worse than 3. What is more interesting is an observation about our new approach to finding the bipoint solution. If we ever encounter a λ such that $|\mathcal{B}| \geq k' \geq |\mathcal{B}^c|$ where \mathcal{B} is the output of ROUND and \mathcal{B}^c is the output of CONSOLIDATE (using \mathcal{B}), then Check 1 will terminate the search with bipoint solution $\mathcal{B}, \mathcal{B}^c$. If we refine the CONSOLIDATE step to perform the consolidations for \mathcal{B} one at a time and stop when the number of clusters first becomes $\leq k'$, one can show that tripling the radii of these $\leq k'$ balls is a solution with cost at most $(3 + O(\epsilon)) \cdot OPT'$. But this is just for one case in our binary search. In general, is there a refinement of our binary search routine (or some other approach) that would always produce a $(3 + \epsilon)$ -approximation?

Simple Worst-Case Optimal Adaptive Prefix-Free Coding

Travis Gagie  

Faculty of Computer Science, Dalhousie University, Halifax, Canada

Abstract

We give a new and simple worst-case optimal algorithm for adaptive prefix-free coding that matches Gagie and Nekrich’s (2009) bounds except for lower-order terms, and uses no data structures more complicated than a lookup table.

2012 ACM Subject Classification Theory of computation → Design and analysis of algorithms

1 Introduction

Suppose Alice has a deck of n cards, each marked with a character from a known alphabet of size σ , and she wants to send the sequence of the cards’ characters to Bob over a noiseless binary channel. Moreover, suppose neither of them know in advance the frequencies of the distinct characters in the deck – perhaps it has just been shuffled – and Alice wants to encode each card’s character before looking at the next card, such that Bob can recognize the last bit of that character’s encoding when he receives it, and decode the character.

In 1973 Faller [1] proposed that Alice encode each card’s character with a Huffman code [7] for the distribution of characters she has already seen, modified to assign codewords also to characters she has not yet seen. Thus, Alice encodes the i th character using a code that depends only on the first $i - 1$ characters. Assuming Bob has already decoded the first $i - 1$ characters when he receives the encoding of the i th, he can build the same code. Because the codewords in a Huffman code are prefix-free – no codeword is a prefix of another – he can then use that code to decode the i th character when he receives the last bit of its encoding. Since the codes adapt to the frequencies of the characters as more and more are seen, Faller’s algorithm is said to perform adaptive Huffman coding or, more generally, *adaptive prefix-free coding*.

Building n Huffman codes from scratch takes $\Omega(n\sigma)$ time, but Faller showed how Alice and Bob can store a Huffman code such that after incrementing the frequency of a character, they can update the code in time proportional to the length of the codeword previously assigned to that character. It follows that Faller’s algorithm runs in time proportional to the total length of the encoding of the sequence. Gallager [6] and Knuth [11] further developed Faller’s algorithm in 1978 and 1985, respectively, and it is usually known as the FGK algorithm for their initials. It is commonly taught in courses on data compression and used in the classic UNIX utility `compact`, for example.

The same year Knuth published his work on the FGK algorithm, Vitter [15, 16, 17] gave a more sophisticated algorithm for adaptive Huffman coding. He showed it uses less than 1 more bit per character than Alice would use if she knew the characters’ frequencies in advance, built a single Huffman code for them, sent it to Bob, and then used it to encode and send the sequence of characters in the deck. In other words, Vitter’s algorithm uses at most about $n(H + 1 + \delta)$ bits and $O(n(H + 1))$ time overall, where

$$H = \sum_{j=1}^{\sigma} \frac{n_j}{n} \lg \frac{n}{n_j} \leq \lg \sigma$$

is the entropy of the distribution $\frac{n_1}{n}, \dots, \frac{n_{\sigma}}{n}$ of characters in the deck and $\delta \in [0, 1)$ is the redundancy of a Huffman code for that distribution. (When the distribution is dyadic – each frequency n_i is n divided by a power of 2 – then $\delta = 0$, and when nearly all the cards have the same character then δ is nearly 1.) Vitter’s algorithm is also commonly taught in courses on data compression.

Vitter attributed to Chazelle an observation that the FGK algorithm uses at most about twice as many bits as using a single Huffman code for the characters’ frequencies (the coefficient 2 can be reduced to about 1.44 using a result by Katona and Nemetz [10]), so the FGK algorithm also runs in $O(n(H + 1))$ time. In 1999 Milidiú, Laber and Pessoa [12] showed that with the FGK algorithm, Alice sends fewer than 2 more bits per character than she would with a single Huffman code for the characters’ frequencies, or at most about $n(H + 2 + \delta)$ bits overall.

In 2003 Gagie [3, 4] showed that if we modify the FGK algorithm to perform adaptive Shannon coding instead of adaptive Huffman coding, then Alice sends at most about $H + 1$ bits per character. A Shannon code [13] is a prefix-free code that assigns any character with probability p a codeword of length at most $\lceil \lg \frac{1}{p} \rceil$ so, if Alice pretends she has seen each character once before she starts encoding the sequence $S[1..n]$ of the cards’ characters, then she sends at most

$$\begin{aligned} & \sum_{i=1}^n \left\lceil \lg \frac{i + \sigma - 1}{\text{occ}(S[i], S[1..i - 1]) + 1} \right\rceil \\ & \leq \sum_{i=1}^n \lg(i + \sigma - 1) - \sum_{i=1}^n \lg(\text{occ}(S[i], S[1..i - 1]) + 1) + n \\ & < \lg n! + \sigma \lg(n + \sigma) - \sum_{j=1}^{\sigma} \lg n_j! + n \\ & = \lg \binom{n}{n_1, \dots, n_{\sigma}} + \sigma \lg(n + \sigma) + n \end{aligned}$$

bits, where $\text{occ}(S[i], S[1..i - 1])$ is the frequency of $S[i]$ in the prefix $S[1..i - 1]$ and $\binom{n}{n_1, \dots, n_{\sigma}}$ is the number of distinct ways of arranging the cards in the deck. By Stirling’s Approximation, $\lg \binom{n}{n_1, \dots, n_{\sigma}} \leq nH + O(\sigma \log n)$, so with Gagie’s algorithm Alice sends $n(H + 1) + o(n)$ bits as long as $\sigma \lg(n + \sigma) \in o(n)$.

In 2006 Karpinski and Nekrich [8, 9] gave a more sophisticated algorithm for adaptive Shannon coding, with which Alice sends $n(H + 1) + O(\sigma \log^2 n)$ bits and encodes S in $O(n)$ time, and Bob decodes it in $O(n(\log H + 1))$ time. Their algorithm uses canonical codes [14] and assumes Alice and Bob are working on word RAMs with $\Omega(\log n)$ -bit words, as we do henceforth. Notice speeding up encoding on a word RAM is generally easier than speeding up decoding: for example, given a single prefix-free code whose longest codeword fits in a constant number of machine words, Alice can build an $O(\sigma)$ -space lookup table that tells her the codeword for any character in constant time.

In 2009 Gagie and Nekrich [5] improved Karpinski and Nekrich’s algorithm so that Bob decodes S also in $O(n)$ time, at the cost of increasing the bound on the total encoding length to $n(H + 1) + O(\sigma \log^{5/2} n)$. They also proved Alice must send $n(\lg \sigma + 1 - o(1)) \geq$

■ **Table 1** The per-character bounds for the algorithms discussed, assuming $\sigma \in o\left(\frac{n^{1/2}}{\log n}\right)$, ignoring lower-order terms and omitting asymptotic notation.

authors	encoding length	encoding time	decoding time
FGK [1, 6, 11]	$H + 2 + \delta$	$H + 1$	$H + 1$
Vitter [15, 16, 17]	$H + 1 + \delta$	$H + 1$	$H + 1$
Gagie [3, 4]	$H + 1$	$H + 1$	$H + 1$
KN [8, 9]	$H + 1$	1	$\lg H + 1$
GN [5]	$H + 1$	1	1
new	$H + 1$	1	1

$n(H + 1 - o(1))$ bits in the worst case, even when even when $\sigma \in \omega(1)$. To see why, suppose $\sigma = 2^{\lceil \lg f(n) \rceil} + 1$ for some function $f(n) \in \omega(1)$, so $\sigma \in \omega(1)$ and any prefix-free code for the alphabet assigns some character a codeword of length $\lceil \lg f(n) \rceil + 1 = \lg \sigma + 1 - o(1)$. For each i , the adversary chooses $S[i]$ to be a character with codeword length at least $\lg \sigma + 1 - o(1)$ in the code Alice will use to encode $S[i]$.

Gagie and Nekrich's algorithm is simultaneously worst-case optimal in terms encoding and decoding time and of encoding length, as long as $\sigma \in o\left(\frac{n}{\log^{5/2} n}\right)$, but it relies on constant-time predecessor queries on sets of $O(\log^{1/6} n)$ elements. These are theoretically possible on a word RAM with $\Omega(\log n)$ -bit words [2] but very complicated and totally impractical. In this paper we give a new algorithm for adaptive prefix-free coding that is simple – it uses no data structures more complicated than a lookup table – but still uses $O(n)$ time for both encoding and decoding and $n(H + 1) + O\left(\frac{n}{\log n} + \sigma^2 \log^2 n\right)$ bits, which is within lower-order terms of optimal when $\sigma \in o\left(\frac{n^{1/2}}{\log n}\right)$. Table 1 shows the per-character bounds of all the algorithms we have discussed here, assuming $\sigma \in o\left(\frac{n^{1/2}}{\log n}\right)$, ignoring lower-order terms and omitting asymptotic notation. We leave as future work finding a simple algorithm that is worst-case optimal even when σ is closer to n .

2 Algorithm

Before we describe our new algorithm, we briefly review how length-restricting a prefix-free code can speed up decoding. Our starting point is Gagie's [3, 4] observation that if we smooth the probability distribution $\frac{n_1}{n}, \dots, \frac{n_\sigma}{n}$ by averaging it with the uniform distribution and apply Shannon's construction [13] to the result, then we obtain a prefix-free code with average codeword length

$$\sum_{j=1}^{\sigma} \frac{n_j}{n} \left\lceil \lg \frac{1}{\frac{1}{2} \left(\frac{n_j}{n} + \frac{1}{\sigma} \right)} \right\rceil < \sum_{j=1}^{\sigma} \frac{n_j}{n} \left(\lg \frac{n}{n_j} + 2 \right) = H + 2$$

when encoding S , and maximum codeword length at most $\lceil \lg \sigma \rceil + 1$.

In $O(\sigma)$ time we can build an $O(\sigma)$ -space lookup table that, for any binary string of length $\lceil \lg \sigma \rceil + 1$, tells us which character's codeword is a prefix of that string and the length of that codeword. If we encode S by replacing each character by its codeword – which we can do in $O(n)$ time using an $O(\sigma)$ -space lookup table that tells us the codeword for any character – then later we can decode S in $O(n)$ time by repeatedly taking prefixes of the encoding consisting $\lceil \lg \sigma \rceil + 1$ bits, looking up which character's codeword is a prefix of the encoding and the length of that codeword, and deleting the codeword from the beginning of the encoding. Unfortunately, we may use about $H + 2$ bits per character.

If we take a weighted average of $\frac{n_1}{n}, \dots, \frac{n_\sigma}{n}$ and the uniform distribution, however, then we can reduce the number of bits we use per character, at the cost of increasing the maximum codeword length and the space needed by the table. For example, if we assign weight $\frac{\lg n - 1}{\lg n}$ to $\frac{n_1}{n}, \dots, \frac{n_\sigma}{n}$ and weight $\frac{1}{\lg n}$ to the uniform distribution before averaging them and applying Shannon's construction, then the average codeword length when encoding S is

$$\sum_{j=1}^{\sigma} \frac{n_j}{n} \left[\lg \frac{1}{\frac{\lg n - 1}{\lg n} \cdot \frac{n_j}{n} + \frac{1}{\lg n} \cdot \frac{1}{\sigma}} \right] < \sum_{j=1}^{\sigma} \frac{n_j}{n} \left(\lg \frac{n}{n_j} + \lg \frac{\lg n}{\lg n - 1} + 1 \right) < H + 1 + \frac{\lg e}{\lg n - 1}$$

and the maximum codeword length is at most $\lceil \lg(\sigma \lg n) \rceil = \lceil \lg \sigma + \lg \lg n \rceil$, so the lookup table takes $O(2^{\lceil \lg \sigma + \lg \lg n \rceil}) = O(\sigma \lg n)$ space. Building this table takes $O(\sigma \lg n)$ time.

We are now ready to describe our new algorithm. First, Alice encodes $S[1..\lceil \sigma \lg n \rceil]$ using a Shannon code C_0 for the uniform distribution, that assigns every character a codeword of length $\lceil \lg \sigma \rceil$. This takes her $O(\sigma \lg n)$ time. Then, for $k \geq 1$, after encoding $S[1..k\lceil \sigma \lg n \rceil]$, Alice builds a Shannon code C_k for a weighted average of the distribution of characters she has encoded so far and the uniform distribution:

$$\frac{\lg n - 1}{\ln n} \cdot \frac{\text{occ}(a_1, S[1..k\lceil \sigma \lg n \rceil])}{k\lceil \sigma \lg n \rceil} + \frac{1}{\lg n} \cdot \frac{1}{\sigma}, \dots, \frac{\lg n - 1}{\ln n} \cdot \frac{\text{occ}(a_\sigma, S[1..k\lceil \sigma \lg n \rceil])}{k\lceil \sigma \lg n \rceil} + \frac{1}{\lg n} \cdot \frac{1}{\sigma},$$

where $\text{occ}(a_j, S[1..k\lceil \sigma \lg n \rceil])$ is the frequency in $S[1..k\lceil \sigma \lg n \rceil]$ of the j th character a_j in the alphabet. She builds an $O(\sigma)$ -space lookup table for C_k that lets her encode $S[k\lceil \sigma \lg n \rceil + 1..(k+1)\lceil \sigma \lg n \rceil]$ in $O(\sigma \lg n)$ time.

Because the codewords in C_0 have length $\lceil \lg \sigma \rceil$, Bob can build an $O(\sigma)$ -space lookup table that lets him decode $S[1..\lceil \sigma \lg n \rceil]$ in $O(\sigma \lg n)$ time. Then, for $k \geq 1$, after encoding $S[1..k\lceil \sigma \lg n \rceil]$, Bob builds the same Shannon code C_k that Alice used to encode $S[k\lceil \sigma \lg n \rceil + 1..(k+1)\lceil \sigma \lg n \rceil]$. Because the longest codeword in C_k has length at most $\lceil \lg \sigma + \lg \lg n \rceil$, Bob can build an $O(\sigma \lg n)$ -space lookup table that lets him decode $S[k\lceil \sigma \lg n \rceil + 1..(k+1)\lceil \sigma \lg n \rceil]$ in $O(\sigma \lg n)$ time.

3 Analysis

For each $k \geq 0$, building C_k and the lookup tables for encoding and decoding with it takes Alice and Bob $O(\sigma \lg n)$ time, and that cost is amortized over the $\lceil \sigma \lg n \rceil$ characters in $S[k\lceil \sigma \lg n \rceil + 1..(k+1)\lceil \sigma \lg n \rceil]$. Since encoding and decoding $S[k\lceil \sigma \lg n \rceil + 1..(k+1)\lceil \sigma \lg n \rceil]$ also takes $O(\sigma \lg n)$ time, Alice and Bob each spend $O(n)$ time in total, or constant time per character in S .

Probably the most complicated aspect of our algorithm is the analysis showing the total length of the encoding is at most $n(H + 1) + O\left(\frac{n}{\lg n} + \sigma^2 \log^2 n\right)$. Consider that each character in S is encoded with $O(\sigma \lg n)$ bits so, in particular, the first $\lceil \sigma \lg n \rceil$ occurrences of each distinct character are encoded with a total of $O(\sigma^2 \log^2 n)$ bits. Let I_j be the set of positions i such that character $S[i]$ of S is an occurrence of the j th character a_j in the alphabet but not one of a_j 's first $\lceil \sigma \lg n \rceil$ occurrences. For $i \in I_j$, Alice encodes $S[i]$ using at most

$$\left\lceil \lg \left(\frac{1}{\frac{\lg n - 1}{\lg n} \cdot \frac{i - 1}{\text{occ}(a_j, S[1..i]) - \lceil \sigma \lg n \rceil}} \right) \right\rceil < \lg \frac{i - 1}{\text{occ}(a_j, S[1..i]) - \lceil \sigma \lg n \rceil} + 1 + \frac{\lg e}{\lg n - 1}$$

bits. Therefore, the total number of bits in the encoding is

$$\sum_j \sum \left\{ \lg \frac{i - 1}{\text{occ}(a_j, S[1..i]) - \lceil \sigma \lg n \rceil} : i \in I_j \right\} + n + O\left(\frac{n}{\lg n} + \sigma^2 \log^2 n\right).$$

Notice $\sum_j \sum \{\lg(i-1) : i \in I_j\} \leq \lg n!$ and for each j ,

$$\sum \{\lg(\text{occ}(a_j, S[1..i]) - \lceil \sigma \lg n \rceil) : i \in I_j\} = \lg(n_j - \lceil \sigma \lg n \rceil)! = \lg n_j! - O(\sigma \log^2 n).$$

Therefore, the total number of bits in the encoding is at most

$$\begin{aligned} & \lg n! - \sum_{j=1}^{\sigma} \lg n_j! + n + O\left(\frac{n}{\log n} + \sigma^2 \log^2 n\right) \\ &= \lg \binom{n}{n_1, \dots, n_{\sigma}} + n + O\left(\frac{n}{\log n} + \sigma^2 \log^2 n\right) \\ &\leq n(H+1) + O\left(\frac{n}{\log n} + \sigma^2 \log^2 n\right). \end{aligned}$$

Abstract

We confirm a conjecture of Gartland and Lokshtanov [arXiv:2007.08761]: if for a hereditary graph class \mathcal{G} there exists a constant k such that no member of \mathcal{G} contains a k -creature as an induced subgraph or a k -skinny-ladder as an induced minor, then there exists a polynomial p such that every $G \in \mathcal{G}$ contains at most $p(|V(G)|)$ minimal separators. By a result of Fomin, Todinca, and Villanger [SIAM J. Comput. 2015] the latter entails the existence of polynomial-time algorithms for MAXIMUM WEIGHT INDEPENDENT SET, FEEDBACK VERTEX SET and many other problems, when restricted to an input graph from \mathcal{G} . Furthermore, as shown by Gartland and Lokshtanov, our result implies a full dichotomy of hereditary graph classes defined by a finite set of forbidden induced subgraphs into tame (admitting a polynomial bound of the number of minimal separators) and feral (containing infinitely many graphs with exponential number of minimal separators).

1 Introduction

For a graph G , a set $S \subseteq V(G)$ is a *minimal separator* if there are at least two connected components A, B of $G - S$ with $N(A) = N(B) = S$ (so that S is an inclusion-wise minimal set that separates a vertex of A from a vertex of B). Around the year 2000, Bouchitté and Todinca presented a theory of minimal separators and related objects called *potential maximal cliques* and showed their usefulness for providing efficient algorithms [2]. In particular, the MAXIMUM WEIGHT INDEPENDENT SET problem (given a vertex-weighted graph, find a subset of pairwise nonadjacent vertices of maximum total weight) can be solved in time bounded polynomially in the size and the number of minimal separators in the graph. This result has been generalized by Fomin, Todinca, and Villanger to a large range of problems that can be defined as finding an induced subgraph of constant treewidth with some CMSO₂-expressible property [3]; this includes, for example, LONGEST INDUCED PATH or MAX INDUCED FOREST, which is by complementation equivalent to FEEDBACK VERTEX SET.

When do these metaalgorithmic results give efficient algorithms? In other words, which restrictions on graphs guarantee a small number of minimal separators? On one hand, it is easy to see that an n -vertex chordal graph has $\mathcal{O}(n)$ minimal separators. On the other hand, consider the following two negative examples. For $k \geq 3$, the $(k, 1)$ -prism consists of two k -vertex cliques with vertex sets $X = \{x_1, \dots, x_k\}$ and $Y = \{y_1, \dots, y_k\}$ and a perfect matching $\{x_i y_i \mid i \in [k]\}$. It is easy to see that the $(k, 1)$ -prism has $2^k - 2$ minimal separators: any choice of one endpoint of each edge $x_i y_i$ gives a minimal separator, except for the choices X and Y . The $(k, 3)$ -theta consists of k independent edges $\{x_i y_i \mid i \in [k]\}$, a vertex x adjacent to all vertices x_i and a vertex y adjacent to all vertices y_i (the intuition behind the notation is that the graph consists of k paths of length 3, joining x and y). Again, any choice of one endpoint of each edge $x_i y_i$ gives a minimal separator. Thus, both the $(k, 1)$ -prism and the $(k, 3)$ -theta have an exponential (in the number of vertices) number of minimal separators.

In 2019, Milanič and Pivač initiated a systematic study of the question which graph classes admit a small bound on the number of minimal separators in its members [5, 6]. A graph class \mathcal{G} is *tame* if there exists a polynomial $p_{\mathcal{G}}$ such that for every $G \in \mathcal{G}$ the number of minimal separators of G is bounded by $p_{\mathcal{G}}(|V(G)|)$. Clearly, if \mathcal{G} is tame, then MAXIMUM WEIGHT INDEPENDENT SET and all problems captured by the formalism of [3] are solvable in polynomial time when the input graph comes from \mathcal{G} . On the opposite side of the spectrum, \mathcal{G} is *feral* if there exists $c > 1$ such that for infinitely many graphs $G \in \mathcal{G}$ it holds that G has at least $c^{|V(G)|}$ minimal separators. Following the previous examples, the class of chordal graphs is tame while the class of all $(k, 1)$ -prisms and/or all $(k, 3)$ -thetas (over all k) is feral. Milanič and Pivač provided a full tame/feral dichotomy for hereditary graph classes (i.e., closed under vertex deletion) defined by minimal forbidden induced subgraphs on at most 4 vertices [5, 6].

A subsequent work of Abrishami, Chudnovsky, Dibek, Thomassé, Trotignon, and Vusković [1] indicated that the main line of distinction between tame and feral graph classes should lie around the notion of a k -creature. A k -creature in a graph G is a tuple (A, B, X, Y) of pairwise disjoint nonempty vertex sets such that (i) A and B are connected, (ii) A is anti-adjacent to $Y \cup B$ and B is anti-adjacent to $A \cup X$, (iii) every $x \in X$ has a neighbor in A and every $y \in Y$ has a neighbor in B ; (iv) $|X| = |Y| = k$ and X and Y can be enumerated as $X = \{x_1, \dots, x_k\}$, $Y = \{y_1, \dots, y_k\}$ such that $x_i y_j \in E(G)$ if and only if $i = j$. We say that G is k -creature-free if G does not contain a k -creature as an induced subgraph. Similarly as in the examples of the $(k, 1)$ -prism and the $(k, 3)$ -theta, any choice of one endpoint of every edge $x_i y_i$ gives a minimal separator in the subgraph induced by the creature (which, in turn, can be easily lifted to a minimal separator in G). Hence, if G contains a k -creature as an induced subgraph, it contains at least 2^k minimal separators. In fact, the notion of a k -creature is a common generalization of the examples of the $(k, 1)$ -prism and the $(k, 3)$ -theta. Indeed, the $(k, 3)$ -theta contains a k -creature with $A = \{x\}$ and $B = \{y\}$ while the $(k, 1)$ -prism contains a $(k - 2)$ -creature with $A = \{x_{k-1}\}$, $B = \{y_k\}$, $X = \{x_1, \dots, x_{k-2}\}$, and $Y = \{y_1, \dots, y_{k-2}\}$. In particular, Abrishami et al. conjectured that if for a hereditary graph class \mathcal{G} there exists k such that no $G \in \mathcal{G}$ contains a k -creature as an induced subgraph, then \mathcal{G} is tame. (Observe that a presence of arbitrarily large creatures in a hereditary graph class does not immediately imply that the graph class is feral, as the sets A and B can be of superpolynomial size in k .)

A counterexample to the conjecture of [1] has been provided by Gartland and Lokshtanov in the form of a k -twisted ladder [4]. They observed that, despite the fact that the conjecture of [1] is false, every example they can construct “looks like a twisted ladder”, which indicates that the tame/feral boundary for hereditary graph classes should not be far from the said

conjecture. To support this intuition, they introduced the notion of a *k-skinny ladder* (a graph consisting of two induced antiadjacent paths $P = (p_1, \dots, p_k)$, $Q = (q_1, \dots, q_k)$, and independent set $R = (r_1, \dots, r_k)$, and edges $\{p_i r_i, q_i r_i \mid i \in [k]\}$), noted that a *k-skinny-ladder* is an induced minor of every counterexample they constructed, and proved the following.

► **Theorem 1.** *For every k there exists a constant c_k such that if a graph G is k -creature-free and does not contain a k -skinny-ladder as an induced minor, then the number of minimal separators in G is bounded by $c_k |V(G)|^{c_k \log |V(G)|}$, that is, quasi-polynomially in the size of G .*

Gartland and Lokshtanov conjectured that this dependency should be in fact polynomial. Our main result of this paper is a proof of this conjecture.

► **Theorem 2.** *For every $k \in \mathbb{N}$ there exists a polynomial q of degree $\mathcal{O}(k^3 \cdot (8k^2)^{k+2})$ such that every graph G that is k -creature-free and does not contain k -skinny-ladder as an induced minor contains at most $q(|V(G)|)$ minimal separators.*

That is, every hereditary graph class \mathcal{G} for which there exists k such that no member of \mathcal{G} contains a k -creature nor k -skinny-ladder as an induced minor, is tame.

As proven in [4], Theorem 2 implies a dichotomy result into tame and feral graph classes for all hereditary graph classes defined by a finite list of forbidden induced subgraphs. (For the exact definitions of graphs in the statement, we refer to [4].)

► **Theorem 3.** *Let \mathcal{G} be a graph class defined by a finite number of forbidden induced subgraphs. If there exists a natural number k such that \mathcal{G} does not contain all k -theta, k -prism, k -pyramid, k -ladder-theta, k -ladder-prism, k -claw, and k -paw graphs, then \mathcal{G} is tame. Otherwise \mathcal{G} is feral.*

Our proof builds upon the proof of Theorem 1 of [4] and provides a new way of analysing one of the core invariants. For a graph G and a set S , define

$$\zeta_G(S) = \max\{|I| : I \subseteq S \text{ is an independent set and for every } v \notin S \text{ we have } |N(v) \cap I| \leq 1\}.$$

That is, we want a set $I \subseteq S$ of maximum possible size that is not only independent, but no vertex outside S is adjacent to more than one vertex of I . In the proof of Theorem 1 of [4], an important step is to prove that a minimal separator S with huge $\zeta_G(S)$ gives rise to a large skinny ladder as an induced minor. Our main technical contribution is an improved way of analysing minimal separators S with small $\zeta_G(S)$.

► **Theorem 4.** *For every $k, L \in \mathbb{N}$ there exists a polynomial p of degree $\mathcal{O}(k^3 \cdot L)$, such that the following holds. For every k -creature-free graph G , the number of minimal separators S satisfying $\zeta_G(S) \leq L$ is at most $p(|V(G)|)$.*

After brief preliminaries in Section 2, we prove Theorem 4 in Section 3. We show how Theorem 4 implies Theorem 2 (with the help of some tools from [4]) in Section 4.

2 Preliminaries

Let G be a graph, v be a vertex of G , and S be a subset of vertices. By $N_G(v)$ we denote the set of neighbors of v . Similarly, by $N_G(S)$ we denote the set $\bigcup_{x \in S} N_G(x) \setminus S$. If the graph G is clear from the context, we simply write $N(v)$ and $N(S)$.

For sets A, B, C , whenever we write $A \setminus B \setminus C$, the set difference operation associates from the left, meaning that $A \setminus B \setminus C$ is equivalent to $(A \setminus B) \setminus C$ (and, alternatively, to $A \setminus (B \cup C)$).

By $G - S$ we denote the graph obtained from G by deleting all vertices from S along with incident edges, and by $G[S]$ we denote the graph induced by the set S , i.e., $G - (V(G) \setminus S)$. By $\text{CC}(G)$ we denote the set of connected components of G , given as vertex sets.

A *matching* in G is a set of pairwise disjoint edges. We say that a matching $\{x_i y_i \mid i \in [k]\}$ is a *semi-induced matching between* $\{x_1, \dots, x_k\}$ and $\{y_1, \dots, y_k\}$ if for all $i, j \in [k]$, $x_i y_j \in E(G)$ if and only if $i = j$.

For vertices u, v , a set $S \subseteq V(G) \setminus \{u, v\}$ is a *u - v -separator* if u and v are in different connected components of $G - S$. We say that S is a *minimal u - v -separator* if it is a u - v -separator and no proper subset of S is a u - v -separator. A set S is a *minimal separator* if it is a minimal u - v -separator for some u, v . Equivalently, S is a minimal separator if there are at least two components $A, B \in \text{CC}(G - S)$ such that $N(A) = N(B) = S$. Any component $A \in \text{CC}(G - S)$ with $N(A) = S$ is called *full to S* ; a minimal separator has at least two full components.

We define

$$S_G^v = \{N(v) \cap S : v \notin S \text{ and } S \text{ is a minimal separator of } G\}.$$

The following result of Gartland and Lokshtanov will be a crucial tool used in our argument.

► **Lemma 5** (Gartland and Lokshtanov [4]). *If G is a k -creature-free graph, then for every $v \in V(G)$ it holds that $|S_G^v| \leq |V(G)|^{k+1}$.*

Let us also recall the crucial definition. For a set $S \subseteq V(G)$ we define

$$\zeta_G(S) = \max\{|I| : I \subseteq S \text{ is an independent set and for every } v \notin S \text{ we have } |N(v) \cap I| \leq 1\}.$$

3 Proof of Theorem 4

We prove the theorem by induction on L with the exact bound of $n^{L(4+(k^2+2)(k+2))}$ minimal separators.

Note that if $S \neq \emptyset$, then $\zeta_G(S) \geq 1$, since for any $u \in S$, the set $I = \{u\}$ satisfies the required properties. Thus, in the base case, when $L = 0$, the only candidate for S is the empty set, therefore the claim holds vacuously. Also, the claim is immediate for $n = 1$, so we assume $n > 1$.

Let S be a minimal separator of G , and let A and B be two connected components of $G - S$ that are full to S . If there is a vertex $v \in V(G) \setminus S$ such that $N(v) \supseteq S$, then $S \in S_G^v$. There are at most n^{k+2} such separators S by Lemma 5; we may therefore assume that no such vertex exists. Let \tilde{B} be a minimal connected subset of B that still dominates S , i.e. such that $N(\tilde{B}) \supseteq S$. Let $u \in \tilde{B}$ be such that $\tilde{B} \setminus \{u\}$ is still connected. Such a vertex u can be found, for instance, as a leaf of a spanning tree of \tilde{B} . We define the following sets that will be important throughout the proof, see Figure 1.

- We let $v \in S \cap N(u) \setminus N(\tilde{B} \setminus \{u\})$. In words, v is a private neighbor (with respect to \tilde{B}) of u in S . Such a vertex v exists by the minimality of \tilde{B} .
- $S_u = N(u) \cap S$.
- $S_v = (N(v) \cap S) \setminus S_u$.
- $S_A = (S \setminus S_u \setminus S_v) \cap N(N(v) \setminus S \setminus B)$. That is, S_A contains the vertices of $S \setminus S_u \setminus S_v$ that have a common neighbor with v in $N(v) \setminus S \setminus B$.
- $S_B = (S \setminus S_u \setminus S_v \setminus S_A) \cap N(N(v) \cap B)$. Similarly, S_B contains the vertices of $S \setminus S_u \setminus S_v \setminus S_A$ that have a common neighbor with v in $N(v) \cap B$.

■ **Figure 1** Subsets of S defined in the proof of Theorem 4. The full lines indicate adjacencies. The dotted line inside S_u indicates a partition of S_u between the private neighbors of u (below) and other neighbors of u (above). The dashed line indicates there is no edge between the sets.

■ **Figure 2** The creatures of Theorem 4.

Our goal is now to identify a small set that dominates $S^* = S_u \cup S_v \cup S_A \cup S_B$. We will repeatedly use Lemma 5 on the vertices of this set in order to bound the number of choices for S^* . We then show that we can find a minimal separator S_0 in $S \setminus S^*$ such that A is a full component in $G - (S^* \cup S_0)$ and there is a component containing $\tilde{B} \setminus \{u\}$. We will be able to show that $\zeta_{G-S^*}(S_0) < \zeta_G(S)$ which allows us to conclude using the induction hypothesis on $G - S^*$.

▷ **Claim 6.** Let $Z_A \subseteq N(v) \setminus S \setminus B$ be a minimal set such that $N(Z_A) \supseteq S_A$. Then G contains a $|Z_A|$ -creature.

Proof. By the minimality of Z_A , each vertex of Z_A has a private neighbor in S_A . Hence, there is a semi-induced matching between Z_A and a size- $|Z_A|$ subset of S_A , say $S_{A,Z}$. We obtain the $|Z_A|$ -creature by considering the sets $(\{v\}, \tilde{B} \setminus \{u\}, Z_A, S_{A,Z})$, see Figure 2a. Indeed, note that by our choice of u , we have that $G[\tilde{B} \setminus \{u\}]$ is connected; v has no neighbors in $\tilde{B} \setminus \{u\}$, as it is a private neighbor of u ; v has no neighbors in $S_{A,Z}$ since $S_{A,Z} \subseteq S_A \subseteq S \setminus S_u \setminus S_v$; clearly there are no edges between $\tilde{B} \setminus \{u\}$ and Z_A since S is a separator; v dominates Z_A and $\tilde{B} \setminus \{u\}$ dominates $S_{A,Z}$. ◁

■ **Figure 3** Illustration of how Q is obtained in the proof of Theorem 4.

▷ **Claim 7.** Let $\mathcal{D} \subseteq \text{CC}(G[A \setminus N(v)])$ be a minimal set of such components that dominates $S \setminus S_u \setminus S_v \setminus S_A$. Then G contains a $|\mathcal{D}|$ -creature.

Proof. By the minimality of \mathcal{D} , for each $D \in \mathcal{D}$ there exists a vertex $y_D \in S \setminus S_u \setminus S_v \setminus S_A$ that is dominated only by vertices of D . Let x_D be a vertex of D that is adjacent to y_D and that is closest to $N(v) \cap A$ in $G[A]$. Note that the edges $\{x_D y_D : D \in \mathcal{D}\}$ form a semi-induced matching between $\{x_D : D \in \mathcal{D}\}$ and $\{y_D : D \in \mathcal{D}\}$ in G . Let P_D be the set of internal vertices on a shortest path between x_D and $N(v) \cap A$ via $G[A]$. Note that $P_D \subset D$ and that P_D is anti-adjacent to $\bigcup_{D \in \mathcal{D}} \{y_D\}$. Indeed, the vertices of P_D are not adjacent to y_D , as this would contradict the minimality of the distance between x_D and $N(v)$; and for any $D' \neq D$, the vertices of P_D are not adjacent to $y_{D'}$ as this vertex is only dominated by vertices of D' , by our choice of $y_{D'}$. Then we obtain a $|\mathcal{D}|$ -creature by considering the sets $(\{v\} \cup (N(v) \cap A) \cup (\bigcup_{D \in \mathcal{D}} P_D), \tilde{B} \setminus \{u\}, \bigcup_{D \in \mathcal{D}} \{x_D\}, \bigcup_{D \in \mathcal{D}} \{y_D\})$, see Figure 2b. Indeed, note that $G[\{v\} \cup (N(v) \cap A) \cup (\bigcup_{D \in \mathcal{D}} P_D)]$ and $G[\tilde{B} \setminus \{u\}]$ are connected; there are no edges between $\{v\} \cup (N(v) \cap A)$ and $\bigcup_{D \in \mathcal{D}} \{y_D\}$ since $(\bigcup_{D \in \mathcal{D}} \{y_D\}) \cap (S_A \cup S_v \cup S_u) = \emptyset$, neither edges between $\bigcup_{D \in \mathcal{D}} P_D$ and $\bigcup_{D \in \mathcal{D}} \{y_D\}$ as mentioned above. Note also that $\{v\} \cup (N(v) \cap A) \cup (\bigcup_{D \in \mathcal{D}} P_D) \cup (\bigcup_{D \in \mathcal{D}} \{x_D\})$ is anti-adjacent to $\tilde{B} \setminus \{u\}$ as argued in the proof of Claim 6. Finally, note that $(N(v) \cap A) \cup (\bigcup_{D \in \mathcal{D}} P_D)$ dominates $\bigcup_{D \in \mathcal{D}} \{x_D\}$, since every x_D either has a neighbor in P_D , or in $N(v) \cap A$ if $P_D = \emptyset$. Finally, it is easy to see that $\tilde{B} \setminus \{u\}$ dominates $\bigcup_{D \in \mathcal{D}} \{y_D\}$. ◁

▷ **Claim 8.** Let \mathcal{D} be as in Claim 7. For each $D \in \mathcal{D}$, let $Z_D \subseteq N(D) \cap B$ be a minimal set that dominates $N(D) \cap S_B$. Then G contains a $|\mathcal{D}|$ -creature.

Proof. By the minimality of Z_D , there is a semi-induced matching between Z_D and a size- $|Z_D|$ subset $S_{B,Z}$ of $N(D) \cap S_B$. We obtain a creature by considering the sets $(\{v\}, D, Z_D, S_{B,Z})$, see Figure 2c. Indeed, note that D is connected by definition; v is not adjacent to $S_{B,Z}$ since $S_{B,Z} \cap (S_u \cup S_v) = \emptyset$ and v is not adjacent to D since D is a connected component of $A \setminus N(v)$; D is not adjacent to Z_D since S is a separator; v dominates Z_D by definition of Z_D and $S_{B,Z} \subseteq N(D)$. ◁

Let $Z = \{u\} \cup Z_A \cup \bigcup_{D \in \mathcal{D}} Z_D$, where Z_A , \mathcal{D} , and Z_D for $D \in \mathcal{D}$ are as defined in Claims 6, 7 and 8, respectively. For all $z \in Z$, let $Q_z = N(z) \cap S$. Let $Q = \bigcup_{z \in Z} Q_z$. Note that Q contains S_u since $u \in Z$, that Q contains S_A since $Z_A \subseteq Z$, and that Q contains S_B . The

latter is due to the fact that the vertices in \mathcal{D} dominate S_B by choice, and each Z_D where $D \in \mathcal{D}$ dominates $N(D) \cap S_B$. We illustrate this situation in Figure 3. It remains to get a grip on S_v .

To do so, let $S' = (S \setminus \{v\}) \cup (N(v) \cap B)$, and note that S' separates $A \cup \{v\}$ from $\tilde{B} \setminus \{u\}$. Let S'' be a minimal subset of S' that still separates $A \cup \{v\}$ from $\tilde{B} \setminus \{u\}$. Note that there are components $A'' \supseteq A \cup \{v\}$ and $B'' \supseteq \tilde{B} \setminus \{u\}$ that are full to S'' and S'' is a minimal separator. Now let $R = N(v) \cap S'' \in S_G^v$, so there are at most n^{k+2} choices for R , by Lemma 5. We observe that $R \supseteq S_v$, which is due to the fact that $\tilde{B} \setminus \{u\}$ dominates S_v , and that S'' separates $\{v\}$ from $\tilde{B} \setminus \{u\}$.

▷ **Claim 9.** There are at most $n^{k^2(k+2)}$ choices for Q , and at most n^{k+2} choices for R .

Proof. We already observed the second statement of the claim above. For the first statement, by Claims 6, 7 and 8, we know that $|Z| < k^2$, so there are at most n^{k^2} choices for Z . For each $z \in Z$, $Q_z \in S_G^z$, so by Lemma 5, there are at most $n^{k^2(k+1)}$ choices for each Q_z , and therefore at most $n^{k^2(k+2)}$ choices for Q . ◁

Now, let $G_0 = G - (Q \cup R)$ and $S_0 = S \setminus Q \setminus R$. Note that $S_0 \subseteq S \setminus S_u \setminus S_v \setminus S_A \setminus S_B$. Moreover, A is a connected component of $G_0 - S_0$, and there is a connected component B_0 of $G_0 - S_0$ that contains $\tilde{B} \setminus \{u\}$. We conclude that S_0 is a minimal separator of G_0 , with A and B_0 being connected components of $G_0 - S_0$ that are full to S_0 . We now show that we can use the induction hypothesis to bound the number of choices for S_0 .

▷ **Claim 10.** $\zeta_{G_0}(S_0) < \zeta_G(S)$.

Proof. Let $I_0 \subseteq S_0$ be an independent set such that for all $y \in V(G_0) \setminus S_0$, $|N_{G_0}(y) \cap I_0| \leq 1$. Let $I = I_0 \cup \{v\}$; I is still an independent set since $S_0 \subseteq S \setminus N_G(v)$. We argue that for all $y \in V(G) \setminus S$, $|N_G(y) \cap I| \leq 1$. Suppose that $y \in N_G(v)$. Since $S_0 \cap (S_A \cup S_B) = \emptyset$, we have that $N_G(y) \cap S_0 = \emptyset$ and therefore $|N_G(y) \cap I| = 1$. We may now assume that $y \notin N_G(v)$. Suppose that $|N_G(y) \cap I| > 1$. Since $y \notin N_G(v)$, we conclude that $y \notin V(G_0) \setminus S_0$, otherwise y would have at least two neighbors in I_0 , a contradiction with the choice of I_0 in S_0 in the graph G_0 . This means that $y \in R \setminus S$, and therefore $y \in N_G(v) \cap B$, which is a contradiction with our assumption that $y \notin N_G(v)$. ◁

The number of choices for u, v, Q , and R is at most $n^{2+(k^2+1)(k+2)}$, see Claim 9. For S_0 , there are at most $n^{(L-1)(4+(k^2+2)(k+2))}$ choices by Claim 10 and the induction hypothesis. Given Q, R , and S_0 , there are at most n choices for $A \in \text{CC}(G - Q - R - S_0)$ and we obtain S as $N(A)$. Taking into account also at most n^{k+2} separators S for which there exists $v \in V(G) \setminus S$ with $S \subseteq N(v)$, the number of separators of G is bounded by

$$\begin{aligned} & n^{2+(k^2+1)(k+2)} \cdot n^{(L-1)(4+(k^2+2)(k+2))} \cdot n + n^{k+2} \\ & \leq n^{4+(k^2+1)(k+2)} \cdot n^{(L-1)(4+(k^2+2)(k+2))} \leq n^{L(4+(k^2+2)(k+2))}. \end{aligned}$$

This completes the proof.

4 Wrapping up the proof of Theorem 2

To conclude the proof of Theorem 2, we observe that the following statement essentially follows from the combinations of Lemma 9 and the proof of Lemma 15 of [4].

► **Lemma 11** ([4]). *If G is a k -creature-free graph that contains a minimal separator S with $\zeta_G(S) > (8k^2)^{k+2}$, then G contains a k -skinny-ladder as an induced minor.*

Proof (sketch). Let G and S be as in the lemma statement. Let $I_0 \subseteq S$ be an independent set of size $\zeta_G(S)$ such that no vertex $v \in V(G) \setminus S$ is adjacent to more than one vertex of I_0 .

Let L_0 and R_0 be two full sides of S . Lemma 9 of [4] asserts that there exists an induced path L in L_0 , an induced path R in R_0 , and a set $I \subseteq I_0$ of size at least $|I_0|/k^2 > (8k^2)^{k+1}$ such that L dominates I and R dominates I .

This is exactly the situation at the end of the first paragraph of the proof of Lemma 15 of [4]. A careful inspection of that proof shows that the remainder of the proof (as well as the invoked Lemmata 8, 13 and 14) do not use other assumptions of Lemma 15. Hence, we obtain the conclusion: a k -skinny ladder as an induced minor of G . ◀

By combining Theorem 4 and Lemma 11, we obtain Theorem 2.

5 Conclusion

In Theorem 2 we showed that if a graph class \mathcal{G} excludes k -creatures as induced subgraphs and k -skinny ladders as induced minors, then \mathcal{G} is tame. However, note that while k -creatures have exponential (in k) number of minimal separators, this is not the case for k -skinny ladders: the class of k -skinny ladders (over all k) is tame. Thus the implication reverse to the one in Theorem 2 does not hold.

Observe that the full tame/feral dichotomy for arbitrary hereditary graph classes is simply false due to some very obscure examples. Let H_k be the $(k, 2^k + 1)$ -theta graph: k paths of length $2^k + 1$ with common endpoints. Note that H_k has $2^{k^2} + 2^{\mathcal{O}(k)}$ minimal separators (2^{k^2} of them choose one internal vertex on each path) and $k2^k + 2$ vertices, so the number of minimal separators of H_k is around $|V(H_k)|^{\log |V(H_k)|}$. Hence, the hereditary class of all induced subgraphs of all graphs H_k for $k \in \mathbb{N}$ is neither tame nor feral.

However, it is still interesting to try to obtain a tighter classification between tame and feral graph classes for some more “well-behaved” hereditary graph classes. As discussed in Conjecture 4 of [4], a good restriction that excludes artificial examples as in the previous paragraph is to focus on induced-minor-closed graph classes.

Faster Path Queries in Colored Trees via Sparse Matrix Multiplication and Min-Plus Product

Younan Gao ✉

Meng He ✉

Faculty of Computer Science, Dalhousie University, Halifax, Canada

Abstract

Let T be an ordinal tree on n nodes in which each node is assigned a color. We consider the batched colored path counting problem and the batched path mode/least frequent element query problem, in which given n query paths, each identified by a pair of nodes in T , one is asked to answer queries of the following forms: How many distinct colors are there on each query path (i.e. the colored path counting problem); what is the color on each query path that occurs at least/most as frequently as any other colors (i.e. the path mode/least frequent element query problem). By reducing the batched colored path counting problem to sparse matrix multiplication, we design a solution that answers n colored path counting queries in $\tilde{O}(n^{\frac{2\omega}{\omega+1}}) = O(n^{1.40704})$ time in total, while we reduce batched path mode/least frequent element query to the min-plus-query-witness problem so that we can answer a batch of n queries in $\tilde{O}(n^{\frac{24+2\omega}{17+\omega}}) = O(n^{1.483814})$ time¹. Previously, both problems could only be solved in $\tilde{O}(n^{1.5})$ time.

Based on similar techniques, we design a dynamic colored path counting structure supporting both queries and updates in $\tilde{O}(n^{\frac{\omega+1}{\omega+3}}) = O(n^{0.627759})$ time, while our dynamic path mode/least frequent element query structures support each operation in $\tilde{O}(n^{\frac{16+\omega(1,2,1)}{26+\omega(1,2,1)}}) = O(n^{0.658139})$ time, where $\omega(1,2,1)$ denotes the minimum value such that the product of an $n \times n^2$ matrix and an $n^2 \times n$ matrix can be computed in $O(n^{\omega(1,2,1)+\epsilon})$ time for any constant $\epsilon > 0$. We also solve batched range mode/least frequent element query problems over arrays in $\tilde{O}(n^{\frac{18+2\omega}{13+\omega}}) = O(n^{1.479603})$ time. Both problems can be viewed as special cases of these batched path queries, and previously, the fastest algorithm for batched range mode queries and batched range least frequent element queries use $O(n^{1.4805})$ and $\tilde{O}(n^{1.5})$ time, respectively.

1 Introduction

Trees are used to represent information in many areas of computer science. In tree-structured data, additional properties such as categorical information are often encoded as colors of tree nodes. To facilitate the retrieval of color information, researchers have defined the following queries over an ordinal tree T on n nodes with each node assigned a color from

¹ The \tilde{O} notation hides the $\text{polylog}(n)$ factors, e.g., $O(n \lg^2 n) = \tilde{O}(n)$, and ω denotes the best possible exponent of square matrix multiplication.

$\{0, 1, \dots, C - 1\}$, where $C \leq n$: Given a path in T , a *path colored counting query* returns the number of distinct colors assigned to the nodes in this path, while a *path mode query* or a *path least frequent element query* returns the most frequent or the least frequent color among the multiset of colors assigned to nodes in this path, respectively². The color that is assigned to the most number of nodes in a path is called the *mode* of the path. These queries can be used to compute fundamental statistic information over tree-structured data.

Researchers have studied these query problems and designed data structure solutions [32, 11, 21]. Different time-space tradeoffs have been achieved, and among the best linear-space solutions under word RAM, the structure of He and Kazi [21] can answer a colored path counting query in $O(\sqrt{n} \lg \lg C)$ time, while the solutions of Durocher et al. [11] can answer a path mode query or a path least frequent element query in $O(\sqrt{n/w} \lg \lg n)$ time, where w denotes the number of bits stored in a word. The support for these queries is thus much slower than the support for many other path queries in trees such as path minimum [9, 2, 30, 10, 5, 8], path medium [32, 35, 24, 25], path counting [9, 32, 35, 24, 25] and path majority [11, 13], for which linear-space solutions with sublogarithmic or even constant query times exist.

However, researchers have given evidence to show that these solutions to colored path counting, path mode and path least frequent element are efficient, by proving conditional lower bounds. It has been shown that the multiplication of two $\sqrt{n} \times \sqrt{n}$ Boolean matrices can be performed by answering n colored path counting queries, n path mode queries or n path least frequent element queries. This reduction was explicitly given for colored path counting [21], while for the other two path queries, it follows from the same conditional lower bound on range mode queries [6] and range least frequent element queries [7] in arrays, for which we preprocess an array A , such that, given a range $[i, j]$, we can find the most frequent or least frequent element in $A[i, j]$ efficiently. Note that when the given tree has a single path only, path mode and path least frequent element queries become range mode and range least frequent element queries, respectively. This reduction means, with current knowledge, the total running time of answering n of these path or range queries, including preprocessing, cannot be faster than $n^{\omega/2}$, save for polylogarithmic speedups, where $\omega < 2.37286$ denotes the exponent of matrix multiplication [1]. Furthermore, since the best known combinatorial approach of multiplying two $n \times n$ Boolean matrices require $\Theta(n^3/\text{polylog}(n))$ time [38], the total time of answering n of these queries cannot be faster than $n^{1.5}$, save for polylogarithmic speedups, using pure combinatorial methods with current knowledge. Since the structures of He and Kazi [21] and Durocher et al. [11] can be built in $\tilde{O}(n^{1.5})$ time, they can be used to answer n colored path counting or path mode/least frequent element queries in $\tilde{O}(n^{1.5})$ time, matching this conditional lower bound on pure combinatorial methods within polylogarithmic factors.

The problem of answering n queries given offline is the batched version of these query problems. To achieve $O(n^{1.5-\epsilon})$ -time solutions for some positive constant ϵ , Williams and Xu [37] reduced batched range mode to the min-plus product of a pair of matrices of special structures, which makes it possible to answer a batch of n range mode queries over an array of length n in $O(n^{1.4854})$ time. Gu et al. [17] further improved the running time to $O(n^{1.4805})$. Similar ideas have also yielded dynamic range mode structures with $O(n^{0.655994})$ query and update times [17]. This is surprising as Jin and Xu [27] showed that dynamic range mode

² These problems can also be defined over free trees. However, we follow the definitions given in previous work [11, 21] and assume that T is an ordinal tree, as this allows us to directly apply previous solutions to the problems defined over ordinal trees.

structure cannot simultaneously support update and query in $O(n^{2/3-\epsilon})$ time for any positive constant ϵ using purely combinatorial method with current knowledge. Even before that, Kaplan et al. [31] used sparse matrix multiplication to answer n 2D orthogonal colored range counting queries over n colored points on the plane in $\tilde{O}(n^{\frac{2\omega}{\omega+1}})$ total time. This query counts the number of distinct colors assigned to points in an axis-aligned query rectangle and is related to path colored counting in the sense that they both generalize 1D colored range counting [14, 34] and have the same conditional lower bound.

Despite all these exciting works which beat the conditional lower bounds for combinatorial methods, no previous work was done to solve batched colored path counting or batched path mode in $O(n^{1.5-\epsilon})$ -time. No similar results were achieved for batched range least frequent queries in arrays or batched path least frequent element, either. Therefore, we use matrix multiplication and min-plus product to solve these problems and their dynamic versions.

1.1 Previous Work

The study on colored range counting started in the 1D case, for which Gupta et al. [19] showed a reduction to 2D orthogonal range counting over uncolored points, hence achieving a linear space solution with $O(\lg n / \lg \lg n)$ query time. This problem has been studied extensively in 2D [18, 31, 16, 33, 15], for which Kaplan et al. [29] proved the conditional lower bound based on Boolean matrix multiplication which we discussed previously. They further designed a data structure occupying $O((\frac{n}{t})^2 \lg^6 n + n \lg^4 n)$ words that supports 2D colored range counting in $O(t \lg^7 n)$ time for any $0 < t \leq n$, which was later improved by Gao and He [15] who shaved off several $\log n$ -factors in time/space bounds. Kaplan et al. also showed how to solve batched 2D orthogonal colored range counting in $\tilde{O}(n^{\frac{2\omega}{\omega+1}}) = O(n^{1.40704})$ time by reducing it to sparse matrix multiplication. Recently, Jin and Xu [27] presented a dynamic 2D orthogonal colored range counting structure with $\tilde{O}(n^{2/3})$ query and update times. Colored range counting has also been studied in high dimensions [18, 31, 16]. Finally, He and Kazi [21] considered colored path counting in trees and proved a conditional lower bound which is also based on Boolean matrix multiplication. They designed an $O(n + \frac{n^2}{t^2})$ -word structure that answers queries in $O(t \lg \lg C)$ time for any $t \in [1, n]$, and it can be constructed in $O(\frac{n^2}{t} \lg \lg C)$ time. Hence it implies an $O(n^{3/2} \lg \lg C)$ -time solution to batched colored path counting.

Since Krizanc et al. [32] proposed range and path mode query problems, a long series of papers have been published on these and related problems [32, 6, 7, 12, 37, 36, 17, 27]. The best linear-space solutions include the structure of Chan et al. [6] that answers range mode queries in arrays in $O(\sqrt{n/w})$ time, the structure of Durocher et al. [11] that answers range least frequent element queries in arrays in $O(\sqrt{n/w})$ time, and the structures of Durocher et al. [11] that answer path mode / least frequent elements in trees in $O(\sqrt{n/w} \lg \lg n)$ time. Chan et al. [6] also studied dynamic range mode in arrays, and their solution was later improved by El-Zein et al. [12], whose linear-space structure supports both queries and updates in $O(n^{2/3})$ time. El-Zein et al. also designed a linear-space structure supporting range least frequent element in $O(n^{2/3} \lg n \lg \lg n)$ time and updates in $O(n^{2/3})$ time; different from the original definition of range least frequent, the query is allowed to return a color that does not appear in the query range but appears elsewhere in the array. A Monte Carlo structure is designed in the dynamic case for the original range least frequent element query. It is worth mentioning that all the results summarized in this paragraph use purely combinatorial approaches. They match the conditional lower bounds [6, 7, 27] within polylogarithmic factors.

Recently, more efficient solutions to the batched range mode problem in arrays [36, 37, 17] have been found. Williams and Xu [37] reduced this problem to the min-plus product of a pair of matrices. The second matrix has the property that the entries at each row are non-decreasing, which allows designing a truly subcubic time algorithm for min-plus product of two $n \times n$ matrices. With it, they can solve batched range mode in $O(n^{1.4854})$ time. Later, the query time was improved by Gu et al. [17] to $O(n^{1.4805})$. Sandlund and Xu [36] broke the $O(n^{2/3})$ per-operation time barrier for dynamic range mode in arrays; they reduced the problem to the min-plus-query-witness problem, and achieved a dynamic data structure that supports both queries and updates in $O(n^{0.655994})$ time. Later, Gu et al. [17] further improved the time for each operation to $O(n^{0.6524})$.

1.2 Our Contributions

Our Results. We have achieved the following results:

- an $\tilde{O}(n^{\frac{2\omega}{\omega+1}}) = O(n^{1.40704})$ -time algorithm for batched colored path counting in trees, improving the previous best approach which solves this problem in $\tilde{O}(n^{1.5})$ time [21];
- an $\tilde{O}(n^{\frac{24+2\omega}{17+\omega}}) = O(n^{1.483814})$ -time algorithm for batched path mode/least frequent element queries in trees, improving the previous best result with $\tilde{O}(n^{1.5})$ running time [11];
- an $\tilde{O}(n^{\frac{18+2\omega}{13+\omega}}) = O(n^{1.479603})$ time algorithm for batched range mode/least frequent element queries in arrays, while the previous best results solve batched range mode in $O(n^{1.4805})$ time [17] and batched range least frequent element in $\tilde{O}(n^{1.5})$ time [11];
- a dynamic colored path counting structure for trees supporting queries and updates in $\tilde{O}(n^{\frac{\omega+1}{\omega+3}}) = O(n^{0.627759})$ time, while the best dynamic structure for 2D orthogonal colored range counting, as a related problem, supports each operation in $\tilde{O}(n^{2/3})$ time [27];
- a dynamic data structure for path mode/least frequent element queries in trees supporting queries and updates in $\tilde{O}(n^{\frac{16+\omega(1,2,1)}{26+\omega(1,2,1)}}) = O(n^{0.658139})$ worst-case time. Here, $\omega(1, 2, 1)$ denotes the minimum value such that the product of an $n \times n^2$ matrix and an $n^2 \times n$ matrix can be computed in $O(n^{\omega(1,2,1)+\epsilon})$ time for any constant $\epsilon > 0$. These bounds are close to the $O(n^{0.6524})$ query and update times for dynamic range mode [17] which can be viewed as a special case of dynamic path mode, while the previous best result for dynamic range least frequent element supports queries and updates in $\tilde{O}(n^{2/3})$ time [12].

Overview of Our Approach. To achieve these results, we develop new algorithmic ideas to address the challenges we encounter due to the tree topology. The first challenge is how to apply a divide-and-conquer approach to batched path queries. The solution of Williams and Xu [37] to batched range mode recursively divides the input array into halves, and at each level of recursion, they build data structures to answer queries whose ranges straddle the midpoint. This ensures that the set of possible queries considered share subranges instead of being disjoint, facilitating preprocessing. The solution of Kaplan et al. [31] to batched 2D orthogonal colored range counting is based on a similar idea in 2D. To adapt to tree topology, we apply the centroid decomposition of trees recursively instead. Then, in each component obtained as a result of the decomposition, we preprocess for queries whose paths cross the centroid. This decomposition scheme helps us solve all three batched path queries.

When preprocessing for query paths that contain the centroid in a component, we mark a subset of nodes and attempt to use either sparse matrix multiplication or min-plus product as in previous work. However, more twists to previous approaches are needed. In the solution of Kaplan et al. [31] to batched 2D orthogonal colored counting, the matrices that they need to multiply during preprocessing are already sparse. This is however not the case in

our solution to batched path colored counting. To resolve this, we use the properties of our node marking scheme to carefully reduce the problem of multiplying these matrices to the multiplication of two different but related matrices that are sparse. There is a similar challenge for batched path mode. Previous solutions to batched range mode in [36, 17] reduces the preprocessing for each set of query ranges to the min-plus-query-witness problem over two matrices of which the second matrix is monotone, i.e., entries in the same row are non-decreasing. This allows applying strategies such as dividing each entry by a carefully chosen integer and rounding down the result to decrease the number of different entries in the matrix. In our case, due to the tree topology, the second matrix is not monotone, so this way of applying integer division fails to decrease the number of different entries. To resolve this issue, we design a two-tier scheme to mark nodes for preprocessing, and use the properties of this marking scheme to reduce the weights of entries of the second matrix using different formulas depending on at which tier the corresponding tree nodes are marked. This allows us to decrease the number of different entries to speed up preprocessing.

In range mode queries over arrays, the input elements are split into two categories, i.e., frequent elements and infrequent elements, based on the frequency of each distinct element, and the elements in the different categories are processed in different ways. As mentioned above, the min-plus-query-witness problem was considered in [36, 17] to solve dynamic range mode, and it is used to handle frequent elements. Naturally, a data structure that solves dynamic range mode on arrays can answer static range mode queries as well. By combining an existing solution to the min-plus-query-witness problem shown in [17, Lemma 33] and a static data structure that handles infrequent elements shown in [37, Proof of Theorem 6.1], we design a static data structure for range mode queries on arrays. This simple combination leads to a new static data structure with faster preprocessing time and query time.

In this paper, we describe our solutions to batched colored path counting and batched path mode queries to show the details of these ideas. Due to space constraints, our solutions to other problems such as batched range mode queries in arrays, batched range least frequent element queries in arrays, dynamic path colored counting, dynamic path mode queries, and dynamic path least frequent queries are deferred to the full version of this paper.

2 Preliminaries

This section introduces the notation and the previous results used in this paper.

Notation. Given an ordinal tree T , let $|T|$ denote the number of nodes in T , and let \perp denote its root. For any two nodes $x, y \in T$, we use $P_{x,y}$ to represent the path whose endpoints are x and y . Thus, $P_{x,\perp}$ is a root-to-node path. If y is an ancestor of x , then $P'_{x,y}$ is defined to be the path whose endpoints are x and the child of y that is an ancestor of x , i.e., $P'_{x,y} = P_{x,y} \setminus \{y\}$. Furthermore, $c(x)$ denotes the color assigned to x , and $C(P_{x,y})$ (or $C(P'_{x,y})$) denotes the set of colors that appear in $P_{x,y}$ (or $P'_{x,y}$). Finally, T_x refers to the subtree of T rooted at node x , and $\text{parent}(x)$ is the parent of x .

Navigation in colored ordinal trees. Regarding each tree node color as integer label, the input tree, studied in this paper, is both an ordinal tree and a labeled tree. To support the basic navigational operations on it, we apply the succinct representation of ordinal trees by [22] and the result of He et al. [23] on labeled tree representations. The following lemma summarizes the operations used in our solution and the complexity. Following their notation, we call a node (resp. ancestor) assigned color α an α -node (resp. α -ancestor).

► **Lemma 1** ([22, 23]). *Let T be an ordinal tree on n nodes with each node assigned a color from $\{0, 1, \dots, C - 1\}$, where $C \leq n$. A data structure occupying $n \lg C + 2n + o(n \lg C)$ bits can be built over T in $O(n)$ time to support:*

- $\text{depth}_\alpha(x)$ in $O(\lg \lg C)$ time, which returns the number of α -ancestors of node x ,³
- $\text{depth}(x)$ in $O(1)$ time, which returns the number of ancestors of x ;
- $\text{LCA}(x, y)$ in $O(1)$ time, which returns the lowest common ancestor of nodes x and y .

Given a query path $P_{x,y}$ and a color α in a tree T represented by Lemma 1, He and Kazi [21] showed how to use depth_α and LCA to compute the number of appearances of α in $P_{x,y}$ in $O(\lg \lg C)$ time. This implies the support of *colored path emptiness*, which asks whether a color α appears in $P_{x,y}$. We can further use it to compute $\{|C(P_{x,\perp})| : x \in T\}$, i.e., the numbers of distinct colors on all root-to-node paths. To do this, perform a preorder traversal of T , and each time we visit a node x , we compute $|C(P_{x,\perp})|$ as follows: If x is the root, then $|C(P_{x,\perp})|$ is 1. Otherwise, locate $x' = \text{parent}(x)$, and answer a colored path emptiness query to find out whether $c(x)$ appears in $P_{x',\perp}$. If it does, set $|C(P_{x,\perp})| = |C(P_{x',\perp})|$; otherwise, $|C(P_{x,\perp})| = |C(P_{x',\perp})| + 1$. This process uses $O(n \lg \lg C)$ time.

Node sampling. In our solutions, we use the following lemma based on the pigeonhole principle to select a subset of tree nodes and precompute information for them.

► **Lemma 2** ([26]). *Let T be a tree on n nodes whose height is h . Given an integer $t \in [1, n]$, an integer $\ell \in [0, t - 1]$ can be found in $O(n)$ time such that the total number of nodes whose depths are $\ell + i \times t$ for some $i \in [0, \lfloor \frac{h-\ell}{t} \rfloor]$ is at most n/t .*

Sparse rectangular matrix multiplication. We use the following result of Kaplan et al. [31]:

► **Lemma 3** ([31, Theorem 2.5]). *Let A be an $m \times n$ matrix having at most t non-zero entries, where $t \geq m^{\frac{\omega+1}{2}}$. Then, given the list of non-zero entries of A as the input without storing A verbatim, the product of A and the transpose of A can be computed in $O(tm^{\frac{\omega-1}{2}})$ time.*

3 Batched Colored Path Counting

We first design a data structure to answer a restricted version of colored path counting which requires the query path to contain the root (Section 3.1). Then we generalize it to handle arbitrary paths, which yields a new result for batched colored path counting (Section 3.2).

3.1 Color Counting over Paths Containing the Root

Data structures. To design a data structure for a restricted version of colored path counting which requires the query path to contain the root, we first represent the tree T using Lemma 1. As discussed in Section 2, this structure supports colored path emptiness. Then, for an integer parameter $0 < X \leq n$ to be chosen later, we select at most n/X nodes of T using Lemma 2 and mark them. This means we mark nodes at every X levels of T , starting from some level $\ell \in [0, X - 1]$ determined by Lemma 2. In addition, we mark the root node as

³ Note that the structure of He et al. [23] can support $\text{depth}_\alpha(x, i)$ in $O(\lg \frac{\lg C}{\lg w})$ time, faster than what is stated in Lemma 1. However, this requires a string representation with support for rank and select [4] which uses perfect hashing, and it is not known how to construct this structure in $O(n)$ deterministic time. Therefore, we swap it with the string representation of Belazzougui et al. [3] which can be constructed in linear deterministic time and achieve the bounds in Lemma 1.

well. This means the number, m , of nodes that we mark satisfies $m \leq n/X + 1$. We refer to the i -th marked node visited in a preorder traversal as the i -th marked node for short, where i starts from 0, and this node is denoted by x_i . Thus, x_0 is the root. For each marked node x , we precompute $r(x)$ which is the rank of x among marked nodes defined this way, as well as the value $|C(P_{x,\perp})|$. Furthermore, each node in the tree stores a flag indicating whether it is marked, as well as a pointer to the lowest marked proper ancestor.

Next, we construct an $m \times m$ matrix M . For every pair of integers i and j in $[0, m - 1]$, $M[i, j]$ stores $|C(P_{x_i,\perp}) \cap C(P_{x_j,\perp})|$, i.e., the number of distinct colors that appear in both the path between the i -marked node and the root and the path between j -th marked node and the root. It is worth mentioning that our query algorithm to be described later only uses entries of M that correspond to two marked nodes whose lowest common ancestor is the root. The other entries are never used, but we precompute them regardless.

Overall, our data structures use $O(n + (\frac{n}{X})^2)$ words.

Query algorithm. To describe the query algorithm, let $P_{x,y}$ denote a query path containing the root. Since $\perp \in P_{x,y}$, we always have $\text{LCA}(x, y) = \perp$. W.l.o.g., we assume that neither x nor y is the root node. Let x' and y' denote the lowest marked ancestors of x and y , respectively, and we divide the query path $P_{x,y}$ into three disjoint subpaths: $P'_{x,x'}$, $P_{x',y'}$ and $P'_{y,y'}$. Following the inclusion-exclusion principle, we have that $|C(P_{x',y'})| = |C(P_{x',\perp})| + |C(P_{\perp,y'})| - M[r(x'), r(y')]$. Since the three terms at the right-hand side of this formula have all been precomputed, $|C(P_{x',y'})|$ can be computed in constant time. Next, we count the number of distinct colors that appear in $P'_{x,x'}$ but not in $P_{x',y'}$. This can be done by iterating through each node z in $P'_{x,x'}$ in the direction towards x and check whether $c(z)$ appears in $P_{\text{parent}(z),y'}$ by performing a path emptiness query. The number of distinct colors that are in $P'_{y,y'}$ but not in $P_{x,y'}$ can be counted in a similar way. Adding these two counts to $|C(P_{x',y'})|$ yields the answer. Since x (resp. y) and x' (resp. y') are at most $X - 1$ levels apart, the query time is $O(X \lg \lg C)$. This query algorithm is adapted from an algorithm of He and Kazi [21] for arbitrary query paths, though we use a different matrix.

Preprocessing. Lemmas 1 and 2, together with the discussions on how to compute $\{|C(P_{x,\perp})| : x \in T\}$ in Section 2, can be applied to construct all our data structure components except the matrix M in $O(n \lg \lg C)$ time. To compute M , one way is to define an $m \times C$ matrix A , in which entry $A[i, \alpha] = 1$ if color $\alpha \in C(P_{x_i,\perp})$, and it is 0 otherwise. Then we compute M as AA^T , where A^T denotes the transpose of A . However, since C can be as large as n , the multiplication of A and A^T can be costly.

Instead, to compute M , we use the computation of two related but different $m \times m$ matrices as stepping stones, and one of these two, which we call \hat{M} , can be computed via sparse rectangular matrix multiplication [31]. Before defining \hat{M} , we introduce more notation. Let a be a marked node and b its lowest marked proper ancestor. We define $\hat{C}(a) = C(P'_{a,b}) \setminus C(P_{b,\perp})$, i.e., the set of colors that appear on the path from a to b (including a but excluding b) but not on the path between and including b and the root. Since there are at most X nodes in $P'_{a,b}$, we have $|\hat{C}(a)| \leq X$.

With these definitions, we can define \hat{M} as an $m \times m$ matrix, in which, for each pair of integers $i, j \in [0, m - 1]$, $\hat{M}[i, j]$ stores $|\hat{C}(x_i) \cap \hat{C}(x_j)|$. To compute $\hat{M}[i, j]$, we define an $m \times C$ matrix \hat{A} , and for each integer $i \in [0, m - 1]$ and each color $\alpha \in [0, C - 1]$, $\hat{A}[i, \alpha]$ is set to be 1 if $\alpha \in \hat{C}(x_i)$ and 0 otherwise. Then $\hat{M} = \hat{A}\hat{A}^T$. Since each row of \hat{A} indicates whether each color appears in the set $\hat{C}(a)$ for some marked node a , each row has at most X non-zero entries. Since \hat{A} has m rows and $m \leq n/X + 1$, overall \hat{A} has at most $n + X \leq 2n$

non-zero entries only. A list of non-zero entries of \hat{A} can be computed in $O(n)$ time; the details are omitted due to page limit. With these non-zero entries as input, we can apply Lemma 3 to compute \hat{M} in $O(n^{(\omega+1)/2}/X^{(\omega-1)/2})$ time for any $X \in [n^{(\omega-1)/(\omega+1)}, n]$.

The other $m \times m$ matrix that is used to help us compute M is called M' . For each pair of integers $i, j \in [0, m-1]$, entry $M'[i, j]$ stores $|\hat{C}(x_i) \cap C(P_{x_j, \perp})|$. To compute M' , we perform a preorder traversal of T . Each time we visit a marked node x_j , we compute the j -th column of M' as follows: If $x_j = \perp$, then $j = 0$ and, for each $i \in [0, m-1]$, we set entry $M'[i, 0]$ to be 0, since $c(\perp) \notin \hat{C}(x_i)$. If x_j is not the root, we locate the lowest marked proper ancestor, y , of x_j . Since y is visited before x_j , $M'[i, r(y)]$ has already been computed, and we set $M'[i, j] = M'[i, r(y)] + \hat{M}[i, j]$. To see the correctness, observe that $M'[i, j] = |\hat{C}(x_i) \cap C(P_{x_j, \perp})| = |\hat{C}(x_i) \cap (C(P_{y, \perp}) \cup \hat{C}(x_j))|$; since $C(P_{y, \perp}) \cap \hat{C}(x_j) = \emptyset$, this is equal to $|\hat{C}(x_i) \cap C(P_{y, \perp})| + |\hat{C}(x_i) \cap \hat{C}(x_j)| = M'[i, r(y)] + \hat{M}[i, j]$. This way we can compute M' in $O(n + (\frac{n}{X})^2)$ time provided that \hat{M} is available.

After computing \hat{M} and M' , we can compute M by performing another preorder traversal of T . Each time we visit a marked node x_i , we compute the i -th row of M as follows: If $x_i = \perp$, then $M[i, j] = 1$ for any $j \in [0, m-1]$. Otherwise, we locate the lowest marked proper ancestor, y , of x_i . Since y is visited before x_i , $M[r(y), j]$ has already been computed, and we set $M[i, j] = M[r(y), j] + M'[i, j]$. To see the correctness, observe that $M[i, j] = |C(P_{x_i, \perp}) \cap C(P_{x_j, \perp})| = |(C(P_{y, \perp}) \cup \hat{C}(x_i)) \cap C(P_{x_j, \perp})|$; since $C(P_{y, \perp}) \cap \hat{C}(x_i) = \emptyset$, this is equal to $|C(P_{y, \perp}) \cap C(P_{x_j, \perp})| + |\hat{C}(x_i) \cap C(P_{x_j, \perp})| = M[r(y), j] + M'[i, j]$. In this way, we can compute M in $O(n + (\frac{n}{X})^2)$ time after computing \hat{M} and M' . The total preprocessing time is hence $O(n \lg C + (\frac{n}{X})^2 + \frac{n^{(\omega+1)/2}}{X^{(\omega-1)/2}})$ for any integer $X \in [n^{\frac{\omega-1}{\omega+1}}, n]$.

3.2 Color Counting on an Arbitrary Path

We now generalize the structure in the previous section to support queries over arbitrary paths. Our strategy is to decompose T recursively using *centroid decomposition* [28]; a *centroid* of an n -node tree is a node whose removal splits the tree into connected components each containing at most $n/2$ nodes, and this node can be found in $O(n)$ time.

At level 0 of the recursion, the given tree T is a connected component by itself and we call it the level-0 component. We find a centroid, u , of T , and define a new rooted tree T^u by designating u as the root of T , reorienting edges when necessary. Then we build the query structure in Section 3.1 over T^u . Afterwards, we remove u from T , and build our data structure recursively over each connected component that has more than X nodes. In general, at the i -th level of the recursion, we have a set of connected components called *level- i components* obtained by removing from T the centroids computed in previous levels of the recursion. For each component, we compute its centroid and designate the centroid as the root of this component to build the query structure of Section 3.1. One minor detail is that, before building the query structure over a component of size n' , we need to ensure that colors are encoded as nonnegative integers less than n' . Thus, when $n' \leq C$, we sort the colors that appear in this component using integer sorting in $O(n' \lg \lg n') = O(n' \lg \lg C)$ time [20] and re-encode these colors using their ranks. Then we remove the centroid of each level- i component to split it into a set of level- $(i+1)$ components and recurse. When a component has at most X nodes, we no longer apply this recursive procedure to it, and we call it a *base component*. Thus, we have $O(\lg(n/X))$ recursion levels.

In addition, for each node $x \in T$, we store a list of $O(\lg(n/X))$ pointers, and the i -th pointer maps x to its copy in a level- i component; this pointer is a null if x is removed as a centroid node found in a previous level. Furthermore, we build a weighted tree T' by assigning weights to the nodes of T as follows: If a node x is chosen as the centroid node of

a level- i component, its weight is i . If x is never chosen as a centroid, then its weight is ∞ . Then we construct the linear-space data structure of Chan et al. [8, Theorem 1.1] to support *path minimum queries* over T' in constant time; a path minimum query returns the node with minimum weight in a given query path.

Since we have $O(\lg(n/X))$ recursion levels, both the space costs and construction time of this new structure is a factor of $O(\lg(n/X))$ more than those of the structure in Section 3.1; the detailed analyses are deferred to the full version of this paper. To answer a query with $P_{x,y}$ as the query path, query T' to find the smallest weight, s , assigned to nodes in $P_{x,y}$. If $s = \infty$, then x and y are in the same base component, and thus $P_{x,y}$ has at most X vertices. We can traverse $P_{x,y}$ in T to count the number of distinct colors; each time we visit a new node, we perform a path emptiness query to determine whether we have already encountered this color. This way we can answer the query in $O(X \lg \lg C)$ time. Otherwise, observe that no nodes in $P_{x,y}$ are chosen as centroids for recursion level $s - 1$ or smaller. Therefore, x and y must reside in a same level- s component S , and $P_{x,y}$ contains the centroid of S . Since this centroid is designated as the root of S before building the query structure of Section 3.1 over S , we can use this query structure to answer the query in $O(X \lg \lg C)$ time. Thus we have:

► **Lemma 4.** *Let T be a colored ordinal tree on n nodes with each node assigned a color from $\{0, 1, \dots, C-1\}$, where $C \leq n$, and let X be an arbitrary integer in $[n^{\frac{\omega-1}{\omega+1}}, n]$. A data structure of $O((\lg \frac{n}{X})(n + \frac{n^2}{X^2}))$ words can be constructed in $O((\lg \frac{n}{X})(n \lg \lg C + (\frac{n}{X})^2 + \frac{n^{(\omega+1)/2}}{X^{(\omega-1)/2}}))$ time to support colored path counting query in $O(X \lg \lg C)$ time.*

We finally solve the batched colored path counting problem by first building the query structure of Lemma 4 and then using it to answer n queries. Setting $X = n^{\frac{\omega-1}{\omega+1}}$ yields:

► **Theorem 5.** *A batch of n colored path counting queries over a colored tree T on n nodes can be answered in $\tilde{O}(n^{\frac{2\omega}{\omega+1}}) = O(n^{1.40704})$ time in total.*

4 Batched Path Mode Queries

To solve batched path mode queries over tree T , let t_1 and t_2 be two constant parameters such that $0 \leq t_2 \leq t_1 \leq 1$. We categorize node colors into two different types: a color α is an *infrequent color* if it is assigned to at most n^{1-t_1} nodes in T ; otherwise, we call it a *frequent color*. Thereby, a mode of a query path could be either a frequent or an infrequent color. We use the following lemma to find the most frequent element in the multiset of infrequent colors assigned to the nodes in a query path $P_{x,y}$; due to space constraints, we defer the proof to the full version of this paper.

► **Lemma 6.** *An $O(n^{2-t_1} \lg^4 n)$ -word structure can be constructed in $O(n^{2-t_1} \lg^5 n)$ time, such that, given a query path $P_{x,y}$, the most frequent element and its frequency in the multiset of infrequent colors assigned to the nodes in $P_{x,y}$ can be computed in $O(n^{1-t_1} \lg^5 n)$ time.*

To find the most frequent element in the multiset of frequent colors that appear in $P_{x,y}$, we mark $O(n^{1-t_2})$ nodes using a two-level marking scheme (Section 4.1). Section 4.2 then handles the case in which the endpoints of a query path containing the root are both marked. Finally, We assemble all components in Section 4.3 and solve batched range mode.

4.1 Marking $O(n^{1-t_2})$ Nodes

Let X be an integer parameter in $[n^{t_2}, n]$ to be determined later. We choose at most n/X nodes of T using Lemma 2, mark these nodes and the root, and call them *tier-1 marked nodes*. Since the tier-1 marked nodes form a subset of levels of T , removing them splits T

into a forest of subtrees. Then we use the same lemma to mark nodes at every $\lceil n^{t_2} \rceil$ levels of each subtree starting from some level of the subtree, and these nodes are called *tier-2 marked nodes*. Since the total number of nodes over all subtrees is less than n , there are $O(n^{1-t_2})$ tier-2 marked nodes. We regard both tier-1 and tier-2 marked nodes as *marked nodes*, and there are $O(n/X + n^{1-t_2}) = O(n^{1-t_2})$ marked nodes in total. It follows that a path that connects any non-root node to its lowest marked proper ancestor contains no more than $\lceil n^{t_2} \rceil + 1$ nodes. As before, we refer to the i -th marked node, x_i , visited in a preorder traversal as the i -th *marked node* for short, starting from 0, and $r(x')$ is the rank of the marked node x' .

4.2 Paths with Marked Endpoints Containing the Root: Frequent Colors

Now, for a path $P_{x',y'}$ such that x' and y' are both marked nodes and $\perp \in P_{x',y'}$, we show how to find the most frequent element and its frequency in the multiset of frequent colors assigned to nodes in $P_{x',y'} \setminus \{\perp\} = P'_{x',\perp} \cup P'_{y',\perp}$. Note that for each color other than $c(\perp)$, its frequencies in $P'_{x',\perp} \cup P'_{y',\perp}$ and in $P_{x',y'}$ are exactly the same, while later we consider $c(\perp)$ separately. A frequent color appears more than n^{1-t_1} times in T , so there are only $O(n^{t_1})$ distinct frequent colors. We number the frequent colors incrementally starting from 0 in an arbitrary order, and we refer to the frequent color numbered by k as color f_k . Let μ denote the total number of marked nodes, and let κ denote the total number of distinct frequent colors. Then $\mu = O(n^{1-t_2})$ and $\kappa = O(n^{t_1})$. Next, we construct a $\mu \times \kappa$ matrix M . Corresponding to marked node x_i and frequent color f_k , $M_{i,k}$ stores the negation of the frequency of f_k in path $P'_{x_i,\perp}$. It follows that the min-plus product⁴ of M and its transpose, denoted by $M \star M^T$, is a $\mu \times \mu$ matrix, in which entry $(M \star M^T)_{i,j}$ stores the negation of the maximum frequency of a frequent color in $P'_{x_i,\perp} \cup P'_{x_j,\perp}$, provided $\perp \in P_{x_i,x_j}$. As before, some entries of this matrix correspond to a pair of nodes whose lowest common ancestor is not the root and are thus never used, but we compute these entries regardless. To compute $M \star M^T$ efficiently, it suffices to solve the following problem using M and M^T as input matrices.

► **Problem 1** (Min-Plus-Query-Witness problem [36]). *Build a data structure upon a pair of input matrices A and B , such that, given two integers i and j and a set S of integers in a query, the index k^* with $A_{i,k^*} + B_{k^*,j} = \min_{k \notin S} \{A_{i,k} + B_{k,j}\}$ can be found efficiently.*

Gu et al. [17] solved this problem with three preprocessing steps, which we generalize for our solution. Henceforth, we use k^* to denote the index such that $M_{i,k^*} + M^T_{k^*,j} = \min_{k \notin S} \{M_{i,k} + M^T_{k,j}\}$. All the proofs omitted from this section will be made available in the full version of this paper.

Preprocessing Step 1. Gu et al. provided an efficient solution to Problem 1 when the second input matrix is monotone, i.e., entries in the same row are non-decreasing. In our case, the second matrix, M^T , does not have such a property due to the tree topology. Therefore, our first step is to generalize their definition of *total range* over a monotone matrix to our notion of *total difference*, defined over an arbitrary $a \times b$ matrix A as $\sum_{j=1}^{b-1} (\sum_{k=0}^{a-1} \llbracket A_{k,j} \neq A_{k,j-1} \rrbracket)$, in which the Iverson bracket $\llbracket A_{k,j} \neq A_{k,j-1} \rrbracket$ evaluates to 1 if $A_{k,j} \neq A_{k,j-1}$ is true and 0 otherwise. We then bound the total difference of M^T :

⁴ Given an $m \times n$ matrix A and an $n \times p$ matrix B , the min-plus product of A and B , denoted by $A \star B$, is the $m \times p$ matrix in which entry $(A \star B)_{i,j} = \min_k \{A_{i,k} + B_{k,j}\}$.

► **Lemma 7.** *The total difference of the matrix M^T is $O(n)$.*

The total difference of M^T is however not small enough to lead to an efficient solution to Problem 1 directly. The strategy of Gu et al. is to divide each entry of the second input matrix by a carefully chosen integer and round down the result, to decrease the total difference of the matrix. However, the same method will fail to decrease the total difference of M^T , as M^T is not monotone, so we design a new approach to construct a matrix \tilde{B} from M^T that has a smaller total difference. To introduce this approach, we define $\hat{\text{parent}}_1(v)$ to be node v 's lowest proper ancestor that is tier-1 marked and $\hat{\text{parent}}(v)$ to be v 's lowest proper ancestor that is either tier-1 or tier-2 marked. For a tier-1 marked node \hat{v}_1 , let $R_k(\hat{v}_1)$ denote the frequency of the frequent color f_k in $P'_{\hat{v}_1, \perp}$, and for a tier-2 marked node \hat{v}_2 , let $R'_k(\hat{v}_2)$ denote the frequency of f_k in $P'_{\hat{v}_2, \hat{\text{parent}}(\hat{v}_2)}$ and $\Psi(\hat{v}_2)$ denote the set of tier-2 marked nodes in $P'_{\hat{v}_2, \hat{\text{parent}}_1(\hat{v}_2)}$. We define parameter W to be $\lfloor n^\theta \rfloor$, where θ is a constant with $0 \leq \theta \leq 1$. With the notations above, we introduce matrix \tilde{B} which has the same size as M^T . For each pair (k, j) , if the j -th column of M^T corresponds to a tier-1 marked node \hat{v}_1 , then $\tilde{B}_{k,j}$ stores $-\lfloor \frac{R_k(\hat{v}_1)}{W} \rfloor$. Otherwise, this column must correspond to a tier-2 marked node \hat{v}_2 ; let \hat{v}_1 denote $\hat{\text{parent}}_1(\hat{v}_2)$ and we set $\tilde{B}_{k,j} = -\lfloor \frac{R_k(\hat{v}_1)}{W} \rfloor - \sum_{u \in \Psi(\hat{v}_2)} \lfloor \frac{R'_k(u)}{W} \rfloor$. Then we can bound the total difference of \tilde{B} :

► **Lemma 8.** *The total difference of \tilde{B} is $O(\frac{n}{X} \cdot n^{t_1} + \frac{n}{W})$. Setting X to be $\lfloor Wn^{t_1} \rfloor$, the total difference of \tilde{B} is $O(n/W)$.*

We define a matrix \tilde{A} , in which entry $\tilde{A}_{i,k} = \lfloor \frac{M_{i,k}}{W} \rfloor$, and a matrix \tilde{C}' of the same size as matrix $M \star M^T$, in which $\tilde{C}'_{i,j}$ stores the $(|S|+1)$ -st smallest element in $\{\tilde{A}_{i,k} + \tilde{B}_{k,j} : k \in [\kappa]\}$. Let $[n]$ denote $\{0, 1, \dots, n-1\}$. For each $i \in [\mu]$ and each $j \in [\mu]$, we define set $L_{i,j}$ to be $\{(\tilde{A}_{i,k} + \tilde{B}_{k,j}, k) : k \in [\kappa]\}$. The small total difference of \tilde{B} allows us to borrow ideas from [17] to design a fast algorithm to compute \tilde{C}' and to build a structure that maintains $L_{i,j}$:

► **Lemma 9.** *Matrix \tilde{C}' can be computed in $\tilde{O}(n^{2-2t_2} + n^{(2-t_2)}/W)$ time using matrices \tilde{A} and \tilde{B} . Furthermore, in the same amount of time, a data structure of $\tilde{O}(n^{2-2t_2} + n^{(2-t_2)}/W)$ words can be constructed upon \tilde{A} and \tilde{B} , such that, given a pair (i, j) and an integer $t \geq 1$, the t smallest pairs in $L_{i,j}$, keyed by the first item of each pair, can be listed in $\tilde{O}(t)$ time.*

Preprocessing Step 2. In this step, we take matrices M , M^T and \tilde{C}' as input and partially solve Problem 1 under certain conditions. Let $\rho \geq 0$ be a parameter to be chosen later; let c be any constant that is no less than 1. For each $r \in [(c+2)\mu^\rho \ln n]$, we construct matrices A^r and B^r as follows: Sample j^r uniformly at random from $[\mu]$. Set $A^r_{i,k}$ to be $M_{i,k} + M^T_{k,j^r} - W \cdot \tilde{C}'_{i,j^r}$ if $|M_{i,k} + M^T_{k,j^r} - W \cdot \tilde{C}'_{i,j^r}| \leq 2(W-1) \cdot (3 + W \cdot n^{(t_1-t_2)})$ and $A^r_{i,k} = \infty$ for all $r' < r$; otherwise, set $A^r_{i,k} = \infty$. In addition, set entry $B^r_{k,j}$ to be $M^T_{k,j} - M^T_{k,j^r}$ if $M^T_{k,j^r} \neq \infty$; otherwise, set $B^r_{k,j} = 0$. Following [17], for a pair (i, k) , if $A^r_{i,k} \neq \infty$ for some r , we call (i, k) *covered*; otherwise it is *uncovered*. We call a triple (i, k, j) *weakly relevant* if $|M_{i,k} + M^T_{k,j} - W \cdot \tilde{C}'_{i,j}| \leq 2(W-1) \cdot (3 + W \cdot n^{(t_1-t_2)})$, and we call a triple (i, k, j) *almost relevant* if $0 \leq \tilde{A}_{i,k} + \tilde{B}_{k,j} - \tilde{C}'_{i,j} \leq \frac{(W-1) \cdot (3 + W \cdot n^{(t_1-t_2)})}{W}$. Let $\omega(1, t_1/(1-t_2), 1)$ denote the smallest number such that the product of an $n \times \lceil n^{t_1/(1-t_2)} \rceil$ matrix and an $\lceil n^{t_1/(1-t_2)} \rceil \times n$ matrix can be computed in $O(n^{\omega(1, t_1/(1-t_2), 1) + \epsilon})$ time for any constant $\epsilon > 0$. We have:

► **Lemma 10.** *Given matrices A^r and B^r , a data structure of $\tilde{O}(2(W-1)(3 + Wn^{(t_1-t_2)}) \cdot n^{(1-t_2) \cdot (\rho + 2 + \frac{t_1}{1-t_2} - \sigma)} + n^{(1-t_2) \cdot (\rho + 1 + \frac{2t_1}{1-t_2} - \sigma)})$ words can be built in $\tilde{O}(2(W-1)(3 + Wn^{(t_1-t_2)}) \cdot n^{(1-t_2) \cdot (\rho + \omega(1, t_1/(1-t_2), 1) + \frac{t_1}{1-t_2} - \sigma)})$ time to partially solve the min-plus-query-witness query*

problem upon matrices M and M^T . More precisely, given a query (S, i, j) , if (i, k^*) has been covered, then k^* can be found in $\tilde{O}(|S| + n^{(1-t_2) \cdot (\rho + \sigma)})$ time, where ρ and σ are two constant parameters with $\rho \geq 0$, $0 \leq \sigma \leq \frac{t_1}{1-t_2}$. The randomized part in this preprocessing step can be derandomized. Furthermore, after preprocessing, the number of triples that are almost relevant and uncovered is $O(n^{(1-t_2) \cdot (2 + \frac{t_1}{1-t_2} - \rho)})$.

Preprocessing Step 3. Finally, for each pair (i, j) , we define $V_{i,j} = \{(M_{i,k} + M_{k,j}^T, k) : (i, k, j) \text{ is an uncovered and almost relevant triple}\}$ and apply the same method in [17]:

► **Lemma 11.** *In $\tilde{O}(n^{2-2t_2} + n^{(2-t_2)}/W + n^{(1-t_2) \cdot (2 + \frac{t_1}{1-t_2} - \rho)})$ time, one can find all almost relevant and uncovered triples and build a data structure of $\tilde{O}(n^{2-2t_2} + n^{(1-t_2) \cdot (2 + \frac{t_1}{1-t_2} - \rho)})$ words upon them, such that, given a pair (i, j) and an integer $t \geq 1$, the t smallest elements in $V_{i,j}$, keyed by the first item in each pair, can be listed in $\tilde{O}(t)$ time.*

The Querying Procedure. The query algorithm is similar to the one shown in [17]. Let (S, i, j) be the query parameters. If (i, k^*) is covered, then we use Lemma 10 to find k^* in $\tilde{O}(|S| + n^{(1-t_2) \cdot (\rho + \sigma)})$ time. Otherwise, we claim that $\tilde{A}_{i,k^*} + \tilde{B}_{k^*,j} - \tilde{C}'_{i,j} \leq \frac{(W-1)(Wn^{t_1-t_2}+3)}{W}$ (the proof will be made available in the full version of this paper); therefore, either (i, k^*, j) is almost relevant, or $\tilde{A}_{i,k^*} + \tilde{B}_{k^*,j} - \tilde{C}'_{i,j} < 0$. If (i, k^*, j) is almost relevant, then $(M_{i,k^*} + M_{k^*,j}^T, k^*)$ is among the $(|S| + 1)$ smallest elements in $V_{i,j}$; thereby, we can find k^* in $\tilde{O}(|S|)$ time using Lemma 11. If $\tilde{A}_{i,k^*} + \tilde{B}_{k^*,j} - \tilde{C}'_{i,j} < 0$, then $(\tilde{A}_{i,k^*} + \tilde{B}_{k^*,j}, k^*)$ is among the $(|S| + 1)$ smallest elements in $L_{i,j}$; we can find k^* for this case in $\tilde{O}(|S|)$ time using Lemma 9. As a result, we have solved the min-plus-query-witness problem over M and M^T and achieved Lemma 12. Recall that parameter W was set to be $\lfloor n^\theta \rfloor$.

► **Lemma 12.** *A data structure of $\tilde{O}(n^{2-2t_2} + n^{(1-t_2)(1-\theta)+1} + n^{(1-t_2)(2 + \frac{t_1}{1-t_2} - \rho)} + n^{(1-t_2)(\rho+1 + \frac{2t_1}{1-t_2} - \sigma)} + n^{2\theta(1-t_2) + (t_1-t_2) + (1-t_2)(\rho+2 + \frac{t_1}{1-t_2} - \sigma)})$ words can be built upon M and M^T in $\tilde{O}(n^{1+(1-t_2)(1-\theta)} + n^{2\theta(1-t_2) + (t_1-t_2) + (1-t_2)(\rho + \omega(1, \frac{t_1}{1-t_2}, 1) + \frac{t_1}{1-t_2} - \sigma)} + n^{(1-t_2)(2 + \frac{t_1}{1-t_2} - \rho)})$ time, such that a query defined in Problem 1 can be answered in $\tilde{O}(|S| + n^{(1-t_2)(\sigma + \rho)})$ time, where $\rho \geq 0$, $0 \leq \sigma \leq \frac{t_1}{1-t_2}$, and $0 \leq \theta \leq 1$.*

As a result, we can apply Lemma 12 to find the most frequent element and its frequency in the multiset of frequent colors assigned to nodes in $P'_{x',\perp} \cup P'_{y',\perp}$ provided that x' and y' are marked and $\perp \in P_{x',y'}$. In the static case, the excluded set S is always set to be empty.

4.3 Mode Queries on an Arbitrary Path

We first represent tree T using Lemma 1. As discussed in Section 2, this structure supports finding the number of appearances of a color on a path in $O(\lg \lg C)$ time. Then we mark $O(n^{1-t_2})$ nodes of T as discussed in Section 4.1. We compute the number of appearances of each color on T to determine whether it is frequent or infrequent. Then we construct the data structures of Lemmas 6 and 12 for queries over infrequent and frequent colors, respectively.

Let $P_{x,y}$ be a query path containing the root. W.l.o.g., we assume that neither x nor y is the root node. If $P_{x,y}$ contains less than two marked nodes, then, by our node-marking strategy, $|P_{x,y}| = O(n^{t_2})$. In this case, a mode on $P_{x,y}$ can be found in $O(n^{t_2})$ time. Otherwise, let x' and y' denote the lowest marked ancestors of x and y , respectively, and we divide $P_{x,y}$ into four disjoint parts: $P'_{x,x'}$, $P'_{x',\perp} \cup P'_{y',\perp}$, \perp and $P'_{y,y'}$. Since there are $O(n^{t_2})$ nodes in $P'_{x,x'} \cup P'_{y,y'} \cup \perp$, it requires $O(n^{t_2} \lg \lg C)$ time to scan the nodes in $P'_{x,x'} \cup P'_{y,y'} \cup \perp$, and for each color encountered, count its occurrences in $P_{x,y}$. Let c_1 be the color with maximum

number of occurrences found this way. Then we apply Lemma 6 to find the infrequent color, c_2 , with maximum frequency in $P_{x',y'}$ in $\tilde{O}(n^{1-t_1})$ time, and we query over the data structure of Lemma 12, setting the excluded set $S = \emptyset$, to find the frequent color, c_3 , with maximum frequency in $P'_{x',\perp} \cup P'_{y',\perp}$ in $\tilde{O}(n^{(1-t_2)(\sigma+\rho)})$ time. We also obtain the frequency of c_2 in $P_{x',y'}$ and the frequency of c_3 in $P'_{x',\perp} \cup P'_{y',\perp}$ when finding c_2 and c_3 . Note that, if the mode is not c_1 , then the mode does not appear in $P'_{x,x'} \cup P'_{y,y'} \cup \perp$, so it must be either c_2 or c_3 . Hence it suffices to compare the frequency of c_1 in $P_{x,y}$, the frequency of c_2 in $P_{x',y'}$, and the frequency of c_3 in $P'_{x',\perp} \cup P'_{y',\perp}$ to find the answer to the query.

Finally, we apply the technique in Section 3.2 to compute the mode in an arbitrary path:

► **Lemma 13.** *Let T be a colored ordinal tree on n nodes with each node assigned a color from $\{0, 1, \dots, C-1\}$, where $C \leq n$. A data structure of $\tilde{O}(n^{2-t_1} + n^{2-2t_2} + n^{(1-t_2)(1-\theta)+1} + n^{(1-t_2)(\rho+1+\frac{2t_1}{1-t_2}-\sigma)} + n^{2\theta(1-t_2)+(t_1-t_2)+(1-t_2)(\rho+2+\frac{t_1}{1-t_2}-\sigma)} + n^{(1-t_2)(2+\frac{t_1}{1-t_2}-\rho)})$ words can be constructed in $\tilde{O}(n^{2-t_1} + n^{2\theta(1-t_2)+(t_1-t_2)+(1-t_2)(\rho+\omega(1,\frac{t_1}{1-t_2},1)+\frac{t_1}{1-t_2}-\sigma)} + n^{(1-t_2)(2+\frac{t_1}{1-t_2}-\rho)} + n^{1+(1-t_2)(1-\theta)})$ time, such that a path mode query can be answered in $\tilde{O}(n^{t_2} + n^{1-t_1} + n^{(1-t_2)(\sigma+\rho)})$ time, where $\rho \geq 0$, $0 \leq \sigma \leq \frac{t_1}{1-t_2}$, and $0 \leq \theta \leq 1$.*

Applying Lemma 13 to batched path mode and setting $t_1 = \frac{10}{17+\omega(1,1,1)}$, where $\omega(1,1,1) \in [2, 2.37286)$, $t_2 = 1 - t_1$, $\theta = \frac{2t_1-1}{t_1}$, $\rho = \frac{4t_1-2}{t_1}$, and $\sigma = \frac{3-5t_1}{t_1}$ yields:

► **Theorem 14.** *A batch of n path mode queries over a colored tree T on n nodes can be answered in $\tilde{O}(n^{\frac{24+2\omega}{17+\omega}}) = O(n^{1.483814})$ time.*

Abstract

The notions of edge-cuts and k -edge-connected components are fundamental in graph theory with numerous practical applications. Very recently, the first linear-time algorithms for computing all the 3-edge cuts and the 4-edge-connected components of a graph have been introduced. In this paper we present carefully engineered implementations of these algorithms and evaluate their efficiency in practice, by performing a thorough empirical study using both real-world graphs taken from a variety of application areas, as well as artificial graphs. To the best of our knowledge, this is the first experimental study for these problems, which highlights the merits and weaknesses of each technique. Furthermore, we present an improved algorithm for computing the 4-edge-connected components of an undirected graph in linear time. The new algorithm uses only elementary data structures, and is implementable in the pointer machine model of computation.

1 Introduction

Determining or testing the edge connectivity of a graph $G = (V, E)$, as well as computing notions of connected components or subgraphs, is a classical subject in graph theory, motivated by several application areas (see, e.g., [20]), that has been extensively studied since the 1970’s. An (*edge*) *cut* of G is a set of edges $S \subseteq E$ such that $G \setminus S$ is not connected. We say that S is a k -*cut* if its cardinality is $|S| = k$. A cut S is *minimal* if no proper subset of S is a cut of

G . The *edge connectivity* of G , denoted by $\lambda(G)$, is the minimum cardinality of an edge cut of G . A graph is *k -edge-connected* if $\lambda(G) \geq k$. A cut S separates two vertices u and v , if u and v lie in different connected components of $G \setminus S$. Vertices u and v are *k -edge-connected*, denoted by $u \stackrel{G}{\equiv}_k v$, if there is no $(k-1)$ -cut that separates them. By Menger's theorem [17], u and v are *k -edge-connected* if and only if there are *k -edge-disjoint paths* between u and v . A *k -edge-connected component* of G is a maximal set $C \subseteq V$ such that there is no $(k-1)$ -edge cut in G that disconnects any two vertices $u, v \in C$ (i.e., u and v are in the same connected component of $G \setminus S$ for any $(k-1)$ -edge cut S). We can define, analogously, the *vertex cuts* and the *k -vertex-connected components* of G . It is known how to compute the $(k-1)$ -edge cuts, $(k-1)$ -vertex cuts, *k -edge-connected components* and *k -vertex-connected components* of a graph in linear time for $k \in \{2, 3\}$ [6, 12, 19, 23, 26]. The case $k = 4$ has also received significant attention [2, 3, 13, 14], but until very recently, none of the previous algorithms achieved linear running time. In particular, Kanevsky and Ramachandran [13] showed how to test whether a graph is 4-vertex-connected in $O(n^2)$ time. Furthermore, Kanevsky et al. [14] gave an $O(m + n\alpha(m, n))$ -time algorithm to compute the 4-vertex-connected components of a 3-vertex-connected graph, where α is a functional inverse of Ackermann's function [25]. Using the reduction of Galil and Italiano [6] from edge connectivity to vertex connectivity, the same bounds can be obtained for 4-edge connectivity. Specifically, one can test whether a graph is 4-edge-connected in $O(n^2)$ time, and one can compute the 4-edge-connected components of a 3-edge-connected graph in $O(m + n\alpha(m, n))$ time. Dinitz and Westbrook [3] presented an $O(m + n \log n)$ -time algorithm to compute the 4-edge-connected components of a general graph G (i.e., when G is not necessarily 3-edge-connected). Nagamochi and Watanabe [21] gave an $O(m + k^2n^2)$ -time algorithm to compute the *k -edge-connected components* of a graph G , for any integer k .

Very recently, linear-time algorithms for computing the 4-edge-connected components of an undirected graph were presented in [8, 18]. Specifically, Nadara, Radecki, Smulewicz, and Sokołowski [18] gave two linear-time algorithms, a simple randomized and a more complicated deterministic algorithm. Georgiadis, Italiano, and Kosinas [8] also presented a linear-time deterministic algorithm that requires less machinery but a more detailed analysis. The main part in these algorithms is the computation of the 3-edge cuts of a 3-edge-connected graph G . The algorithms operate on a depth-first search (DFS) tree T of G [23], with start vertex r , and compute three types of 3-edge cuts $C = \{e_1, e_2, e_3\}$, depending on the number of tree edges in C . We refer to a cut C that consists of t tree edges of T as a *type- t cut of G* . The challenging cases are when C is a type-2 or type-3 cut. To handle type-2 cuts in linear time, both NRSS [18] and GIK [8] require the use of the static tree disjoint-set-union (DSU) data structure of Gabow and Tarjan [5], which is quite sophisticated and not amenable to simple implementations. Moreover, the deterministic algorithm of NRSS also employs a linear-time algorithm for computing offline nearest common ancestors [11]. NRSS [18] provided an elegant way to handle type-3 cuts. Specifically, they showed that computing all type-3 cuts can be reduced, in linear time, to computing type-1 and type-2 cuts, by contracting the edges of $G \setminus E(T)$. The algorithm of GIK [8], on the other hand, operates directly on the original graph, but requires a more involved case analysis and, as for type-2 cuts, uses the Gabow-Tarjan DSU data structure.

Our contribution. We present an improved version of the algorithm of GIK [8] for identifying type-2 cuts, so that it only uses simple data structures. The resulting algorithm relies only on basic properties of depth-first search (DFS) [23], and on parameters carefully defined on the structure of a DFS spanning tree (see Section 3.3). As a consequence, it is simple to describe and to implement, and it does not require the power of the RAM model of computation, thus implying the following *new results*:

► **Theorem 1.** *The 3-edge cuts of an undirected graph can be computed in linear time on a pointer machine.*

► **Corollary 2.** *The 4-edge-connected components of an undirected graph can be computed in linear time on a pointer machine.*

Next, we consider the practical performance of these algorithms. We provide carefully engineered implementations of the randomized algorithm of NRSS [18], the deterministic algorithm of GIK [8], as well as our new linear-time pointer-machine algorithm. Then, we conduct a thorough empirical study to highlight the merits and weaknesses of each technique. In particular, our experimental evaluation addresses the following questions:

- How well does the randomized algorithm perform with respect to its deterministic counterparts?
- How efficient is the graph contraction technique in practice?
- How does our new linear-time pointer-machine algorithm compare against the linear-time RAM algorithms?
- How fast can we compute the 4-edge-connected components of a graph compared to computing the k -edge-connected components for $k < 4$?

2 Linear-time algorithms for computing the 4-edge-connected components

Let $G = (V, E)$ be the input graph, which may have multiple edges. To compute the 4-edge-connected components of G , we can perform the following steps:

1. Compute the connected components of G .
2. For each connected component, we compute the 2-edge-connected components which are subgraphs of G .
3. For each 2-edge-connected component, we compute its 3-edge-connected components C_1, \dots, C_ℓ .
4. For each 3-edge-connected component C_i , we compute a 3-edge-connected auxiliary graph H_i , such that for any two vertices x and y , we have $x \stackrel{G}{\equiv}_4 y$ if and only if x and y are both in the same auxiliary graph H_i and $x \stackrel{H_i}{\equiv}_4 y$.
5. Finally, we compute the 4-edge-connected components of each H_i .

For Steps 1–3, we can compute the 1-edge and 2-edge cuts, and the 2-edge and 3-edge-connected components a graph in linear time by [6, 12, 19, 23, 26]. It can be easily demonstrated that the (subgraphs induced by the) k -edge-connected components of G , for $k = 1, 2$, have the same k' -edge-connected components as G , for all $k' > k$. However, the analogous property does not hold for $k = 3$. Thus we use the construction provided by Dinitz [2], which extends the 3-edge-connected components of G , by adding some extra edges to them, so that the resulting auxiliary graphs have the same k' -edge-connected components as G , for all $k' > 3$. To perform Step 4, we use the fact that we can construct a compact representation of the 2-cuts of any 2-edge-connected component H of G , which allows us to compute its 3-edge-connected components C_1, \dots, C_ℓ in linear time [10, 26]. We let $G[C_i]$ denote the subgraph of G that is induced by the vertices in C_i . By shrinking each 3-edge-connected component C_i of H into a single node, we obtain a quotient graph Q of H which has the structure of a tree of cycles [2], i.e., Q is connected and every edge of Q belongs to a unique cycle. Let (C_i, C_j) and (C_i, C_k) be two edges of Q which belong to the same cycle. Then (C_i, C_j) and (C_i, C_k) correspond to two edges (x, y) and (x', y') of G , with

$x, x' \in C_i$. If $x \neq x'$, we add a virtual edge (x, x') to $G[C_i]$, which acts as a substitute for the cycle of Q that contains (C_i, C_j) and (C_i, C_k) . Now let H_i be the graph $G[C_i]$ plus all those virtual edges. Then H_i is 3-edge-connected and its 4-edge-connected components are precisely those of G that are contained in C_i [2]. Thus we can compute the 4-edge-connected components of G by computing the 4-edge-connected components of the graphs H_i .

Hence, we have reduced the problem of computing the 4-edge-connected components of a (general) graph, to the computation of the 4-edge-connected components of a collection of auxiliary 3-edge-connected graphs.

So, from now on, we let G be a 3-edge-connected graph. We can compute its 4-edge-connected components by successively splitting G into smaller graphs according to its 3-cuts. When no more splits are possible, the connected components of the final split graph correspond to the 4-edge-connected components of G . (We refer to [8] for the details.) It remains to describe how to compute the 3-edge cuts of a 3-edge-connected graph G .

3 Computing the 3-cuts of a 3-edge-connected graph

In this section we give an overview of the algorithms of NRSS [18] and GIK [8] for computing the 3-edge cuts of a 3-edge-connected graph G . Then, we also present our new linear-time pointer-machine algorithm. Throughout this section, we assume that $G = (V, E)$ is a 3-edge-connected graph with n vertices and $m \geq 3n/2$ edges, and may have multiple edges. It is well-known that the number of the 3-edge-cuts of G is $O(n)$ [20], which also follows from the definition of the cactus graph [1, 15]). See also [8, 18] for an independent proof of this fact.

For a graph H , we let $V(H)$ and $E(H)$ denote the set of vertices and edges of H , respectively. If H is a subgraph of G then $G \setminus E(H)$ denotes the graph that results from G after deleting the edges of H .

3.1 Depth-first search and related notions

Here we introduce some concepts and parameters that are used in the algorithms, defined with respect to a depth-first search spanning tree. Let T be the spanning tree of G provided by a depth-first search (DFS) of G [23], with start vertex r . A vertex u is an ancestor of a vertex v (v is a descendant of u) in T if the tree path from r to v contains u . Thus, we consider a vertex to be both an ancestor and a descendant of itself. The edges in T are called *tree-edges*; the edges in $E(G) \setminus E(T)$ are called *back-edges*, as their endpoints have ancestor-descendant relation in T . We let $p(v)$ denote the parent of a vertex v in T . If u is a descendant of v in T , we denote the set of vertices of the simple tree path from u to v as $T[u, v]$. The expressions $T[u, v)$ and $T(u, v]$ have the obvious meaning (i.e., the vertex on the side of the parenthesis is excluded). We identify vertices with their preorder number assigned during the DFS. Thus, if v is an ancestor of u in T , then $v \leq u$. Let $T(v)$ denote the set of descendants of v , and let $ND(v) = |T(v)|$ denote the number of descendants of v . Then, vertex u is a descendant of v (i.e., $u \in T(v)$) if and only if $v \leq u < v + ND(v)$ [24].

Whenever (x, y) denotes a back-edge, we shall assume that x is a descendant of y . We say that a back-edge (x, y) leaps over a vertex v if x is a descendant of v and y is a proper ancestor of v . We let $B(v)$, for a vertex $v \neq r$, denote the set of all back-edges that leap over v , and we let $bcount(v) = |B(v)|$ denote the number of elements of $B(v)$. Thus, if we remove the tree-edge $(v, p(v))$, $T(v)$ remains connected to the rest of the graph through the back-edges in $B(v)$, which implies the following property:

► **Property 3** ([8]). *A connected graph G is 2-edge-connected if and only if $bcount(v) > 0$, for every $v \neq r$. Furthermore, G is 3-edge-connected only if $bcount(v) > 1$, for every $v \neq r$.*

This suggests that the sets $B(v)$ can be used to determine various connectivity relations in graphs. In fact, we can consider many useful notions extracted from those sets by considering the distribution of the ends of the back-edges that are contained in them. First, consider the lower ends of the back-edges in $B(v)$. We define the *low* point of vertex v , denoted by $low(v)$, as the minimum vertex y such that there exists a back-edge $(x, y) \in B(v)$. Formally, $low(v) := \min\{y \mid \exists(x, y) \in B(v)\}$. We also let $lowD(v)$ be x . That is, $lowD(v)$ is a descendant of v from which stems a back-edge that provides $low(v)$. (Notice that $lowD(v)$ is not uniquely determined.) We denote the back-edge $(lowD(v), low(v))$ as $MinUp(v)$. Similarly, we define the *high* point of v , denoted by $high(v)$, as the maximum vertex y such that there exists a back-edge $(x, y) \in B(v)$. Formally, $high(v) := \max\{y \mid \exists(x, y) \in B(v)\}$. We also let $highD(v)$ be x . That is, $highD(v)$ is a descendant of v from which stems a back-edge that provides $high(v)$. (Again, $highD(v)$ is not uniquely determined.) We denote the back-edge $(highD(v), high(v))$ as $MaxUp(v)$. Finally we let $l_1(v)$ be the minimum y such that there exists a back-edge of the form (v, y) (or v , if no such back-edge exists). Formally, $l_1(v) := \min(\{y \mid \exists(v, y) \in B(v)\} \cup \{v\})$. Furthermore, we define $l_2(v) := \min(\{y \mid \exists(v, y) \in B(v) \setminus \{(v, l_1(v))\}\} \cup \{v\})$.

Now we consider the higher ends of the back-edges in $B(v)$. First, we let $MinDn(v)$ (resp. $MaxDn(v)$) denote a back-edge in $B(v)$ with minimum (resp. maximum) higher end. We then define the *maximum* point $M(v)$ of v as the maximum vertex z such that $T(z)$ contains the higher ends of all back-edges in $B(v)$. In other words, $M(v)$ is the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$. See Figure 1. (Clearly, $M(v)$ is a descendant of v .) Let m be a vertex and v_1, \dots, v_k be all the vertices with $M(v_1) = \dots = M(v_k) = m$, sorted in decreasing order. Observe that v_{i+1} is an ancestor of v_i , for every $i \in \{1, \dots, k-1\}$, since m is a common descendant of all v_1, \dots, v_k . Then we have $M^{-1}(m) = \{v_1, \dots, v_k\}$, and we define $nextM(v_i) := v_{i+1}$, for every $i \in \{1, \dots, k-1\}$, and $prevM(v_i) := v_{i-1}$, for every $i \in \{2, \dots, k\}$. Thus, for every vertex v , $nextM(v)$ is the successor of v in the decreasingly sorted list $M^{-1}(M(v))$, and $prevM(v)$ is the predecessor of v in the decreasingly sorted list $M^{-1}(M(v))$.

Now let v be a vertex and let u_1, \dots, u_k be the children of v sorted in non-decreasing order w.r.t. their *low* point. We let $c_i(v)$ be u_i , if $i \in \{1, \dots, k\}$, and \emptyset if $i > k$. (Note that $c_i(v)$ is not uniquely determined, since some children of v may have the same *low* point.) Then we call $c_1(v)$ the *low1* child of v , and $c_2(v)$ the *low2* child of v . We let $\tilde{M}(v)$ denote the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x a proper descendant of $M(v)$. We leave $\tilde{M}(v)$ undefined if no such proper descendant x of $M(v)$ exists. We also define $M_{low1}(v)$ as the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x being a descendant of the *low1* child of $M(v)$, and also define $M_{low2}(v)$ as the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x a descendant of the *low2* child of $M(v)$. We leave $M_{low1}(v)$ (resp., $M_{low2}(v)$) undefined if no such proper descendant x of the *low1* (resp., *low2*) child of $M(v)$ exists.

We note that it is easy to compute all $l_1(v)$, $l_2(v)$, $low(v)$, $lowD(v)$, and $bcount(v)$ during the DFS. In particular, the notion of low points plays central role in classic algorithms for computing the biconnected components [23], the triconnected components [12] and the 3-edge-connected components [6, 12, 19, 26] of a graph. (Hopcroft and Tarjan [12] also use a concept of high points, which, however, is different from ours.) Furthermore, all $M(v)$, $\tilde{M}(v)$, $M_{low1}(v)$ and $M_{low2}(v)$, for all vertices v for which they are defined, can be computed in

■ **Figure 1** An illustration of the concepts defined on a depth-first search (DFS) spanning tree of an undirected graph. Vertices are numbered in DFS order and back-edges are shown directed from descendant to ancestor in the DFS tree. Vertices v_1 and v_2 have $M(v_1) = M(v_2) = m$, hence $\{v_1, v_2\} \subseteq M^{-1}(m)$, $nextM(v_1) = v_2$, and $prevM(v_2) = v_1$. Moreover, $(11, 3) \notin B(v_2)$, so $low_M(v_1) = 3$.

linear-time in pointer machines [8]. For the computation of all $high(v)$ (and $highD(v)$), [8] and [18] gave a linear-time algorithm that uses the static tree DSU data structure of Gabow and Tarjan [5], and thus their computation depends on the power of RAM machines.

3.2 Randomized algorithm of NRSS

We give an overview of the randomized linear-time algorithm of Nadara, Radecki, Smulewicz, and Sokołowski [18]. Let $H : E \mapsto 2^E$ be a function defined as follows. If e is a back-edge, $H(e) = \{e\}$. Otherwise, $H(e) = B(u)$, for the unique vertex $u \neq r$ such that $e = (u, p(u))$. Now NRSS provide an elegant characterization of 3-cuts: a triple of edges $\{e_1, e_2, e_3\}$ is a 3-cut if and only if $H(e_1) \oplus H(e_2) \oplus H(e_3) = \emptyset$ (where \oplus denotes the symmetric set difference). Then we get a useful equivalent characterization of 3-cuts by representing the sets $H(e)$ as bit-vectors. To be precise, we consider the composition of $\chi : 2^E \mapsto \{0, 1\}^E$ (the characteristic function on E) with $H : E \mapsto 2^E$; then we have that $\{e_1, e_2, e_3\}$ is a 3-cut if and only if $\chi_{H(e_1)} \oplus \chi_{H(e_2)} \oplus \chi_{H(e_3)} = 0$ (where \oplus here denotes the logical XOR function). Thus, if for an edge e we have a candidate e' that may provide a 3-cut of the form $\{e, e', e''\}$, for a third edge e'' , then e'' is uniquely determined by the expression $\chi_{H(e)} \oplus \chi_{H(e')}$.

Since we cannot compute all $\chi_{H(e)}$, for all edges e , in linear time, the idea of NRSS is to compress the bits of those vectors into a fixed number of RAM words. (We assume that a RAM cell can store $O(\log m)$ bits.) In particular, we select $b = \lceil 3 \lg m \rceil$ random bits to represent the characteristic function of $H(e)$, for every back-edge e , and we call this value $CH(e)$. (We may select a bigger multiple of $\lg m$ for higher precision; however, $\lceil 3 \lg m \rceil$ is enough for all practical purposes.) Then $CH(e)$, for a tree-edge e , corresponds to $\bigoplus_{e' \in H(e)} CH(e')$.

Now, for type-1 and type-2 cuts, we can find good candidate edges that may yield 3-cuts. Specifically, let $\{(u, p(u)), e, e'\}$ be a type-1 cut (i.e., e and e' are back-edges). Then one of e, e' is the back-edge that provides the low point of u . Thus, without loss of generality, we may assume that $e = \text{MinUp}(u)$. Then we can retrieve e' with high probability by determining $CH^{-1}(CH((u, p(u))) \oplus CH(e))$. Now let $\{(u, p(u)), (v, p(v)), e\}$ be a type-2 cut (where e is a back-edge). In this case u and v are related as ancestor and descendant, and thus we may

assume, without loss of generality, that u is a descendant of v . Then we have that either e leaps over u but not over v , or that e leaps over v but not over u . In the first case, e is the back-edge that provides the *high* point of u (that is, $e = \text{MaxUp}(u)$). Thus we can retrieve $(v, p(v))$ with high probability by determining $CH^{-1}(CH((u, p(u))) \oplus CH(\text{MaxUp}(u)))$. In the second case, e is either $\text{MinDn}(v)$ or $\text{MaxDn}(v)$. Thus we can retrieve $(u, p(u))$ with high probability from $CH((v, p(v)) \oplus \text{MinDn}(v))$ or $CH((v, p(v)) \oplus \text{MaxDn}(v))$. NRSS provide linear-time algorithms for computing all $\text{MaxUp}(v)$, $\text{MinDn}(v)$ and $\text{MaxDn}(v)$, for all vertices $v \neq r$, using the static-tree DSU data structure of Gabow and Tarjan [5]. (The inverses CH^{-1} can be computed efficiently by using e.g. hash tables.)

Finally, for type-3 cuts, NRSS provided a simple linear-time reduction to computing type-1 and type-2 cuts. First, compute the connected components C_1, \dots, C_k of $G \setminus E(T)$. Then, form a reduced graph G' by contracting each component C_i into a single vertex c_i . In this construction, we maintain parallel edges between two vertices but remove self-loops. Then, recursively compute the type-1 and type-2 cuts of G' . Assuming that G is 3-edge connected, it is easy to observe that G' satisfies the following properties: (i) G' is also 3-edge connected, and (ii) $|E(G')| \leq \frac{2}{3}|E(G)|$. The latter inequality follows from the fact that the minimum vertex degree in G is 3, and that $|E(G')| \leq |V(G)|$ due to the contractions. Then, the total running time spend during the recursive calls is bounded by $O(m)$.

3.3 Deterministic algorithm of GIK

Here we provide an overview of the deterministic linear-time algorithm of Georgiadis, Italiano, and Kosinas [8]. The idea is to distinguish various types of 3-cuts on a DFS tree of the graph, and then provide an algorithm specifically adapted for each particular case. The classification of GIK is heavily guided by some DFS parameters that can be extracted from the sets $B(v)$ of the back-edges that leap over a vertex v , for $v \neq r$, without computing the sets $B(v)$ explicitly.

First, let $\{(u, p(u)), e, e'\}$ be a type-1 cut. Then we obviously have $B(u) = \{e, e'\}$. Thus, in order to identify all those cuts, we need to have computed, for every vertex $u \neq r$, two back-edges that leap over u . We take as one of them a back-edge e that provides the *low* point of u . To get one more back-edge, we extend the definition of *low* points: we let $\text{low2}(u)$ be the lowest lower end of all back-edges in $B(u) \setminus \{e\}$, and let $\text{low2D}(u)$ be a descendant of u such that $(\text{low2D}(u), \text{low2}(u)) \in B(u) \setminus \{e\}$. Let $\text{low1}(u) := \text{low}(u)$ and $\text{low1D}(u) := \text{lowD}(u)$. (Refer to Figure 1.) Then, for every $u \neq r$, we have that $\{(\text{low1D}(u), \text{low1}(u)), (\text{low2D}(u), \text{low2}(u))\} \subseteq B(u)$, and these two back-edges form a 3-cut with $(u, p(u))$ if and only if $\text{bcount}(u) = 2$. We note that all back-edges $(\text{low2D}(v), \text{low2}(v))$ can be computed easily during the DFS, and thus all type-1 cuts can be computed in linear time in a pointer machine without using sophisticated data structures.

Now let $\{(u, p(u)), (v, p(v)), e\}$ be a type-2 cut (where e is a back-edge). Then we have that u and v are related as ancestor and descendant, and we may assume in what follows, without loss of generality, that u is a descendant of v . Then we have that either $B(u) = B(v) \sqcup \{e\}$ or $B(v) = B(u) \sqcup \{e\}$. In either case, we can exploit the similarity of the sets $B(u)$ and $B(v)$ to find good candidate pairs $\{u, v\}$ that may provide type-2 cuts of the form $\{(u, p(u)), (v, p(v)), e\}$, for a back-edge e . Take the case $B(u) = B(v) \sqcup \{e\}$ as an example. Then e must be the back-edge that provides the *high* point of u , and so $e = (\text{highD}(u), \text{high}(u))$. Depending on the location of $\text{highD}(u)$, we can relate $M(v)$ with a maximum point of u . Specifically, if $\text{highD}(u)$ is a descendant of $M(v)$, then $M(v) = M(u)$, and v is the greatest ancestor of u with this property (i.e., $v = \text{nextM}(u)$). If $\text{highD}(u)$ is an ancestor of $M(v)$, then $M(v) = \tilde{M}(u)$ and v is the greatest ancestor of u with this property. Finally, if $\text{highD}(u)$

is not related as ancestor or descendant with $M(v)$, then $M(v) = M_{low1}(u)$, and v is again the greatest ancestor of u with this property. These considerations are the basis of an efficient algorithm for determining, for a vertex u , a proper ancestor v of u , and a back-edge e , that may yield a type-2 cut of the form $\{(u, p(u)), (v, p(v)), e\}$. (In fact, once such a v has been found, we only have to check whether $bcount(u) = bcount(v) + 1$ to establish the existence of this cut.) The case $B(v) = B(u) \sqcup \{e\}$ can be handled in a similar manner. We refer to [8] for more details.

Finally, with a much more involved subdivision of type-3 cuts into more cases, and with extensive use of DFS parameters extracted from the sets of leaping back-edges, GIK provide linear-time algorithms to identify all those cuts. These algorithms use the *high* points in a way that seems difficult to avoid them. We need not mention any details of those cases because we can avoid them overall using the idea of NRSS for identifying all type-3 cuts on the contracted graph.

In the next section we will show how to handle the cases of type-2 cuts without the use of *high* points, thus providing the first linear-time pointer-machine algorithm for determining all 3-cuts of 3-edge-connected graphs.

3.4 A new linear-time pointer-machine algorithm

Our goal is to provide a method to compute all 3-cuts in linear time without using the *high* points (since the only known algorithm for computing all *high* points in linear time depends on the power of RAM machines [8, 18]). We achieve this through the following three improvements over the GIK algorithm. First, we introduce two new parameters, $low_M D(v)$ and $low_M(v)$, that yield the back-edge $(highD(u), high(u))$ that is needed in the case $B(u) = B(v) \sqcup \{e\}$, $M(u) = M(v)$ (see the previous subsection). Second, we replace all conditions provided by GIK for determining type-2 cuts with equivalent ones that avoid the invocation and the computation of the *high* points. And finally, we use the idea of NRSS to deal with type-3 cuts by reducing them to type-1 and type-2 cuts.

Let v be a vertex such that $nextM(v) \neq \emptyset$. Then we have $B(nextM(v)) \subset B(v)$. Thus we can define $low_M(v)$ as the lowest lower end of all back-edges in $B(v) \setminus B(nextM(v))$, and we let $low_M D(v)$ be a vertex such that $(low_M D(v), low_M(v))$ is a back-edge in $B(v) \setminus B(nextM(v))$. (Refer to Figure 1.) Formally, we have

- $low_M(v) := \min\{y \mid \exists(x, y) \in B(v) \setminus B(nextM(v))\}$.
- $low_M D(v) :=$ a vertex x such that $(x, low_M(v)) \in B(v)$.

All edges $(low_M D(v), low_M(v))$, for all vertices v for which they are defined, can be determined with a linear-time algorithm that uses only elementary data structures and depends on a specific ordering of the adjacency lists of the graph. Now, if we have a pair of vertices $\{u, v\}$ such that $B(u) = B(v) \sqcup \{e\}$, for a back-edge e , and $v = nextM(u)$, then it is certainly true that $e = (low_M D(u), low_M(u)) = (highD(u), high(u))$. This shows how to handle one of the three subcases of the lower type-2 cuts, described in the previous Section. For the other two subcases, as well as for the upper case of type-2 cuts, we can simply provide alternative criteria that characterize them, using most of the DFS notions in Section 3.1 in a way similar to [8] (but without using the *high* points). The algorithms that we get in this way are very similar to those given by GIK.

Due to the space constraints, we refer to [9] for a detailed description of those criteria and their proofs, as well as for an exposition and proof of correctness of the full algorithm for determining type-2 cuts. Throughout the remainder of the paper, we refer to this algorithm as *Linear*.

4 Empirical Analysis

We implemented our algorithms in C++, using g++ 7.5.0 with full optimization (flag -O4) to compile the code. The reported running times were measured on a GNU/Linux machine, with Ubuntu (18.04.6 LTS): a Dell Precision Tower 7820 server 64-bit NUMA machine with an Intel(R) Xeon(R) Gold 5220R processor and 192GB of RAM memory. The processor has 24.75MB of cache memory and 18 cores. In our experiments we did not use any parallelization, and each algorithm ran on a single core. We report CPU times measured with the `high_resolution_clock` function of the standard library `chrono`, averaged over ten different runs.

Implementation details

We tested four implementations, two for the randomized algorithm of Nadara, Radecki, Smulewicz, and Sokołowski [18] (NRSS and NRSS-sort), one for the deterministic algorithm of Georgiadis, Italiano, and Kosinas [8] (GIK), and one for our linear-time pointer machine algorithm (Linear). We did not include an implementation of the deterministic algorithm of [18], because it is more complicated than the routine in GIK for computing type-2 cuts, and it uses data structures for off-line nearest common ancestors (in addition to the static tree DSU data structure of Gabow and Tarjan). In NRSS we made use of a hash table in order to store the CH values of the tree-edges and to be able to retrieve them efficiently. An alternative suggestion for this problem is to use radix sort [18]. However, the latter is only significant for the theoretical analysis, since in practice we observed that this part of the algorithm does not play a significant role in the total running time (as this it is dominated by the computation of other parameters). Furthermore, we made the following improvements in this algorithm. First, we handle the case of type-1 cuts using the same idea as in GIK and in our linear-time pointer-machine algorithm. Specifically, we detect those cuts by using the values $bcount$, $low1D$, $low1$, $low2D$ and $low2$. (This method is also suggested in the the deterministic algorithm of [18].) This confers an obvious advantage, since (1) these parameters can be computed easily and fast during the DFS, and (2) we thus avoid having to store $O(m)$ CH values and pointers to the corresponding back-edges. Second, we implemented a simpler and faster linear-time algorithm for computing all $MinDn$ and $MaxDn$ values, that uses only elementary data-structures. We observed that this algorithm is several times faster than the one suggested by [18], but it only slightly affects the total running-time, since that is dominated by the computation of $high$ and $highD$ points (i.e., the $MaxUp$ edges). Finally, we used two different algorithms for $MaxUp$, since the total running time is heavily dependent on the way this computation is performed. The first algorithm (as in GIK) simply traverses the adjacency lists. This is enough for GIK, but for NRSS we then have to sort the adjacency lists, in order to keep pointers to the $MaxUp$ edges, and this incurs a significant overhead. The second implementation of NRSS uses bucket-sort on the back-edges (as suggested by [18]), and it is called NRSS-sort. In both GIK and NRSS(-sort) we implemented the DSU data-structure by using path-compression and union-by-size. Although this is not theoretically optimal, in practice it works efficiently and we get a linear-time behaviour.

Experimental results for real-world graphs

For the experimental evaluation, we considered several real-world (undirected) graphs, taken from various application areas, as well as random graphs. For each graph G , we also compute a corresponding sparse 4-edge-connectivity certificate of G . A k -edge-connectivity certificate

of G is a spanning subgraph H of G such that, for any two vertices u and v and any positive integer $k' \leq k$, u and v are k' -edge-connected in H if and only if they are k' -edge-connected in G . Such a subgraph H has at most $k(n-1)$ edges and can be computed in linear time [20]. The reason why we use both the original graphs and their sparse certificates is twofold. First, we would like to observe if sparsity affects the relative performance of the algorithms. Second, we would like to see how more efficient is the computation of the 4-edge-connected components on the sparse certificates rather than on the original graphs.

Table 1 shows some statistics about the real-world graphs used in our experimental evaluation. The running times of the algorithms for the original graphs and for their sparse certificates are shown in Table 2 and Table 3 respectively.¹ Figure 2 and 3 illustrate the detailed running times for each part of the 4-edge-connected components algorithms on the real-world graphs and their sparse certificates. For each algorithm, it depicts the running time for computing the $(k-1)$ -edge-cuts and the corresponding k -connected components for $k \in \{1, 2, 3, 4\}$.

■ **Table 1** Characteristics of real-world graphs taken from the SNAP [16]; n is the number of vertices, m is the number of edges, and $\#k\text{CCs}$ is the number of k -edge-connected components; m' is the number of edges in a 4-edge-connectivity certificate of G . The network types are: social (SN), product (PN), collaboration, (CN), road (RN), and internet topology (IT).

The algorithms GIK, Linear, NRSS and NRSS-sort compute the 4-edge-connected components, report the number of k -edge-connected components, for $k \leq 4$, and the corresponding times to compute them, as well as the number of minimal k -edge cuts, for $k \leq 3$. (We note that the number of minimal k -edge cuts can be as large as $O(n^2)$ and $O(n^3)$ for $k = 2, 3$, respectively.) For computing the k -edge-connected components for $k < 4$, all algorithms use the same routines. For $k = 1$ we simply perform a BFS; for $k = 2$ we implement the classic algorithm of Tarjan that uses the *low* points [23]. For $k = 3$ we use the algorithm of GK, which is the simplest and fastest known for computing 2-edge cuts and 3-edge-connected components [7, 10]. For every 3-edge-connected component that we compute, we construct the auxiliary 3-edge-connected graph that corresponds to it (which essentially maintains its k -edge cuts, for all $k \geq 3$) [2], by adding some virtual edges, and then we run the corresponding 3-edge cut algorithm on this graph. Finally, after we have computed all 3-edge cuts of each such graph (the number of those cuts is $O(n)$ in total), we compute its 4-edge-connected components by using the algorithm of [18] to compute the cactus tree.

¹ We note that we did not run the algorithms on the original com-Friendster graph, because its number of edges is too big for our implementations, due to our choice of variable types.

■ **Table 2** Running times in seconds of the algorithms for the real-world graphs of Table 1. For each algorithm we report the total running time and the time required to compute the 3-edge cuts and the corresponding 4-edge-connected components. Best running times for each graph are marked in bold.

From the running times reported in Tables 2 and 3, and plotted in Figures 2 and 3, we observe that running time of all algorithms is dominated by the computation of the 3-edge-cuts and the 4-edge-connected components. Indeed, computing the k -edge-connected components takes about twice as much as computing the $(k - 1)$ -edge-connected components. On average, the computation of the 3-edge-cuts and the 4-edge-connected components constitutes more than 60% of the running time of the NRSS algorithms and more than 40% of the running time of the GIK and Linear. Furthermore, as expected, all algorithms are executed faster on the sparse certificates, sometimes significantly, depending on the density of the original graph. (For instance, for twitch-gamers, all algorithms run about 7 times faster on the sparse certificate, while for com-LiveJournal, they run about 20 times faster on the sparse certificate.) Thus, for computing the 4-edge-connected components and the 3-cuts of a dense graph, it is more efficient to produce the sparse certificate (even with a straightforward algorithm that performs 4 passes over the edges of the graph) and apply any of those algorithms on it, than apply the algorithm directly on the original graph.

We observe that the running time of the Linear algorithm is very close to that of GIK. Indeed, GIK runs faster than Linear by about 7.5% on the original graphs and by about 3% on the sparse certificates. This means that the contraction operation does not incur a significant overhead in the total running time. One could expect the GIK algorithm to be worse than Linear, because it implements various sub-algorithms to handle the various subcases of type-3 cuts. However, all those sub-algorithms (except one, that needs an array of size $O(m)$) take time $O(n)$, because they rely on parameters already computed. Furthermore, although the Linear algorithm avoids the computation of *high* points, it uses as a replacement the $low_M D$ and low_M points, whose computation rely on a specific sorting of the adjacency lists.

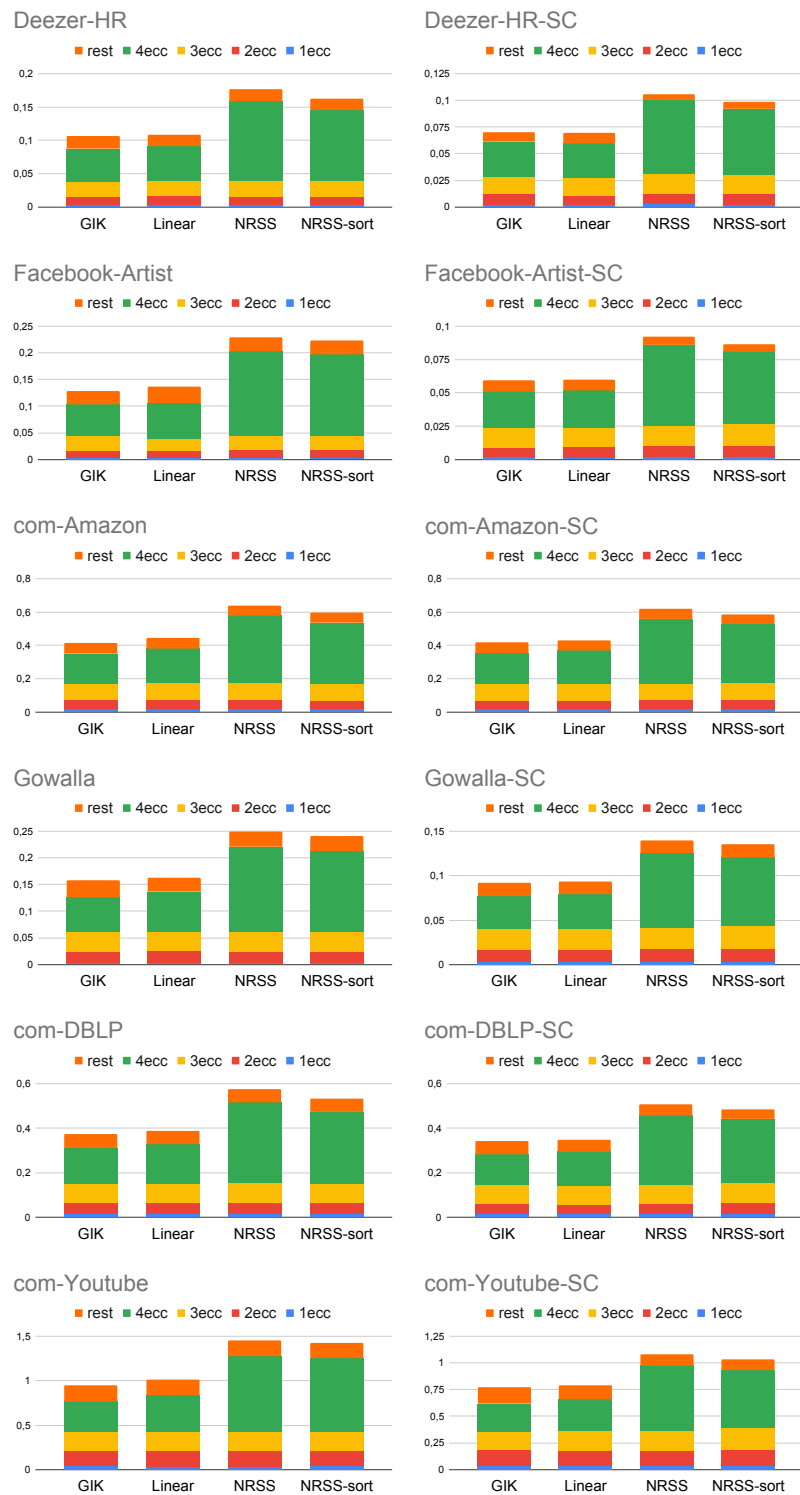

We also observe that the NRSS algorithms are consistently slower than GIK and Linear, by a significant factor, in both the original graphs and their sparse certificates. Specifically, GIK is about 40% faster than NRSS-sort on the original graphs, and about 35% faster on the sparse certificates. This is somewhat expected, because all these algorithms use the same parameters (or similar methods to compute those that they need), but the NRSS algorithms need also to maintain pointers to the edges that correspond to those parameters, and they also compute the CH values that use at least three RAM words for every edge.

■ **Table 3** Running times in seconds of the algorithms for the sparse certificates of the real-world graphs of Table 1. For each algorithm we report the total running time and the time required to compute the 3-edge cuts and the corresponding 4-edge-connected components. Experimental results for random graphs

Finally, we explore further the relative performance of the four algorithms for computing 3-edge cuts (in 3-edge-connected graphs). Thus we created random graphs with a fixed number of vertices and an increasing number of edges, and we applied four algorithms on those graphs and on their sparse certificates. We augmented the graphs, whenever needed, in order to become 3-edge-connected, by adding a relatively small number of new edges. Specifically, we computed their connected components, and we connected them on a path. Then we applied the algorithm of Eswaran and Tarjan [4] to introduce the smallest number of edges that are needed to make them 2-edge-connected. And finally we applied the algorithm of Naor et al. [22] to optimally increase the connectivity by one. The corresponding plots are shown in Figure 4. In these experiments we notice that the GIK algorithm can be as much as 50% faster than Linear, and more than twice as fast as NRSS(-sort). This fact is not easily observable in the full algorithms for computing the 4-edge-connected components, because there are other unrelated operations taking place, and also the sizes of the 3-edge-connected components are most probably not large enough to make this difference manifest. We also notice that the NRSS-sort algorithm has, in fact, somewhat worse performance than NRSS on dense graphs.

■ **Figure 2** Detailed running times for each part of the 4-edge-connected components algorithms on the first six real-world graphs of Table 1 and their sparse certificates. For each algorithm, we plot the running time for computing the $(k-1)$ -edge-cuts and the corresponding k -connected components for $k \in \{1, 2, 3, 4\}$.

■ **Figure 3** Detailed running times for each part of the 4-edge-connected components algorithms on the last six real-world graphs of Table 1 and their sparse certificates. For each algorithm, we plot the running time for computing the $(k - 1)$ -edge-cuts and the corresponding k -connected components for $k \in \{1, 2, 3, 4\}$.

Abstract

Given a graph and two vertex sets satisfying a certain feasibility condition, a reconfiguration problem asks whether we can reach one vertex set from the other by repeating prescribed modification steps while maintaining feasibility. In this setting, Mouawad et al. [IPEC 2014] presented an algorithmic meta-theorem for reconfiguration problems that says if the feasibility can be expressed in monadic second-order logic (MSO), then the problem is fixed-parameter tractable parameterized by treewidth + ℓ , where ℓ is the number of steps allowed to reach the target set. On the other hand, it is shown by Wrochna [J. Comput. Syst. Sci. 2018] that if ℓ is not part of the parameter, then the problem is PSPACE-complete even on graphs of bounded bandwidth.

In this paper, we present the first algorithmic meta-theorems for the case where ℓ is not part of the parameter, using some structural graph parameters incomparable with bandwidth. We show that if the feasibility is defined in MSO, then the reconfiguration problem under the so-called token jumping rule is fixed-parameter tractable parameterized by neighborhood diversity. We also show that the problem is fixed-parameter tractable parameterized by treedepth + k , where k is the size of sets being transformed. We finally complement the positive result for treedepth by showing that the problem is PSPACE-complete on forests of depth 3.

1 Introduction

A reconfiguration problem asks, given two feasible solutions S and S' of a combinatorial problem, whether there is a step-by-step transformation from S to S' without losing the feasibility [18]. The field studying such problems, called *combinatorial reconfiguration*, is growing rapidly. The source combinatorial problems in reconfiguration problems have spread in many subareas of theoretical computer science (see surveys [32, 38]). In this work, we focus on reconfiguration problems on graphs, especially the ones considering some vertex subsets as feasible solutions. Such problems involve classic properties like independent sets [19], vertex

covers [28], dominating sets [35], and some connected variants [26]. Restrictions to some important graph classes such as bipartite graphs [24], split graphs [3], and sparse graphs [25] are also studied.

Since many problems are studied under many settings in combinatorial reconfiguration, one may ask for a unified method, or an *algorithmic meta-theorem*, for handling reconfiguration problems like Courcelle’s theorem for classic (non-reconfiguration) problems [1, 6, 9, 10, 12]. Since reconfiguration problems are hard in general (often PSPACE-complete [18]), we need to consider some special cases or introduce some additional parameters to consider fixed-parameter tractability. One successful approach in this direction was taken by Mouawad et al. [30], who showed that if the feasible solutions in a graph can be expressed in monadic second-order logic, then the reconfiguration problem (under reasonable transformation rules) is fixed-parameter tractable parameterized simultaneously by the treewidth of the underlying graph and the length of a transformation sequence. Their method is quite general and can be applied to several other settings.¹ On the other hand, Wrochna [40] showed that if the length of a transformation sequence is not part of the parameter, then some problems that fit in this framework are PSPACE-complete even on graphs of bounded bandwidth.

The two results mentioned above (the tractability parameterized by treewidth + transformation length [30] and the intractability parameterized solely by bandwidth [40]) might be interpreted as that if we have the length of a transformation sequence in the parameter, then we can do pretty much everything we expect, and otherwise we can expect very little. Thus, one might conclude that this line of research is complete and the length of a transformation sequence is necessary and sufficient in some sense for having efficient algorithms. Indeed, to the best of our knowledge, the study of meta-algorithms for reconfiguration problems was not extended after these results.

In this paper, we revisit the investigation of meta-algorithms for reconfiguration problems and shed light on the settings where the length of a transformation sequence is *not* part of the parameter. In particular, we present fixed-parameter algorithms for the reconfiguration problem of vertex sets defined by a monadic second-order formula parameterized by vertex cover number or neighborhood diversity. We also show that when combined with the solution set size, treedepth can be used to obtain a fixed-parameter algorithm. We then complement this result by showing that when the solution size is not part of the parameter, the problem is PSPACE-complete on graphs of constant treedepth.

Due to the space limitation, the proofs of some results (marked with ★) are omitted or shortened. The full proofs will be included in the full version.

1.1 Our results

Now we give a little more precise description of our results. Formal definitions not given here can be found in Section 2 or in the full version.

For a graph G , we denote its clique-width by $\text{cw}(G)$, treewidth by $\text{tw}(G)$, treedepth by $\text{td}(G)$, vertex cover number by $\text{vc}(G)$, neighborhood diversity by $\text{nd}(G)$, cluster deletion number by $\text{cd}(G)$. (We define some of these parameters in the last part of Section 2.) See Figure 1 for the hierarchy among the graph parameters studied in this paper and some related ones. For a graph parameter f , we often say informally that a problem is fixed-parameter tractable “parameterized by f ” to mean “parameterized by $f(G)$, where G is the input graph.”

¹ We elaborate on this a little more in Section 1.2.

■ **Figure 1** The graph parameters studied in this paper. A connection between two parameters indicates the existence of a function in the one above that lower-bounds the one below.

Given a monadic second-order (MSO_1) formula ϕ with one free set variable, a graph G , and two vertex subsets S, S' of the same size, MSO_1 -RECONFIGURATION (MSO_1 -R) asks whether there exists a sequence of vertex subsets from S to S' such that each set in the sequence satisfies the property expressed by ϕ and each set in the sequence is obtained from the previous one by exchanging one vertex with another. Note that this rule allows to exchange any pair of vertices. Such a rule is well studied and called the *token jumping* rule [19]. There is another well-studied rule called the *token sliding* rule [17], which requires that the exchanged vertices are adjacent in G . We focus on the simpler rule token jumping in this paper and comment on the token sliding counter parts in the full version. MSO_2 -RECONFIGURATION (MSO_2 -R) with more general MSO_2 formulas is defined analogously.

To show a concrete example of MSO_1 -R, let $\phi(S) := \forall u \forall v: (u \in S \wedge v \in S) \Rightarrow \neg E(u, v)$. This ϕ is an MSO_1 formula (see Section 2) expressing that S is an independent set. Thus, MSO_1 -R with this ϕ is exactly INDEPENDENT SET RECONFIGURATION under the token jumping rule.

Now the main results in this paper can be summarized as follows.

1. MSO_1 -R is FPT parameterized by $\text{nd} + |\phi|$.
 - MSO_2 -R is FPT parameterized by $\text{vc} + |\phi|$, but not by $\text{nd} + |\phi|$ unless $\text{E} = \text{NE}$.
 - The positive results here strongly depend on the token jumping rule.
2. MSO_2 -R is FPT parameterized by $\text{td} + k + |\phi|$, where k is the size of input sets S and S' .
 - This result holds also under the token sliding rule.
 - As a by-product, we show that MSO_1 -R is FPT parameterized by $\text{cd} + k + |\phi|$. (Omitted in the short version.)
3. For some fixed ϕ , MSO_1 -R is PSPACE-complete even on forests of depth 3.
 - A similar hardness result can be shown under the token sliding rule.

In all positive results, we can find a shortest sequence for transformation (if any exists).

1.2 Related work

Wrochna [40] showed that MSO_1 -R is PSPACE-complete on graphs of constant bandwidth when ϕ expresses independent sets. This implies the PSPACE-completeness of MSO_1 -R on graphs of constant pathwidth, treewidth, and clique-width (see Figure 1). To cope with this intractability, Mouawad et al. [30] considered a variant with the additional restriction that the length of a transformation sequence cannot exceed some upper bound ℓ . They showed that this variant of MSO_2 -R is fixed-parameter tractable parameterized by $\ell + \text{tw} + |\phi|$. They reduce the reconfiguration problem to the model-checking problem of a single MSO_2 formula by expressing the existence of fewer than ℓ intermediate sets that satisfy ϕ and also expressing

that the change from a set to the next one obeys the transformation rule. Their framework is quite general and can be used in several other settings such as vertex sets defined by an MSO_1 formula with the parameter $\ell + \text{cw} + |\phi|$, or size- k vertex sets defined by a first-order formula with the parameter $\ell + k + |\phi|$ on a nowhere dense graph class (as observed also in [25]). Also, since the step-by-step modification can be defined by a formula, the results apply not only for the token jumping rule but also for several other rules including the token sliding rule.²

Another important line of studies on parameterized complexity of reconfiguration problems take the input set size k as the main parameter instead of a graph structural parameter. This line was initiated by Mouawad et al. [29], who showed several results parameterized solely by k and also by $k + \ell$. Recently, Bodlaender et al. [4, 5] further extended this line by showing that depending on whether and how the parameter depends on ℓ , the problem becomes complete to XL, XNL, or XNLP.

2 Preliminaries

We assume that the reader is familiar with the parameterized complexity theory. See a standard textbook (e.g., [13, 15, 16, 31]) for basic definitions.

Let $G = (V, E)$ be a graph. For $X \subseteq V$, we denote by $G[X]$ and $G - X$ the graphs induced by X and $V \setminus X$, respectively. We sometimes denote the vertex set of G by $V(G)$ and the edge set by $E(G)$. For a digraph D , we denote by $A(D)$ its arc set.

For a non-negative integer d , let $[d]$ denote the set $\{i \in \mathbb{Z} \mid 1 \leq i \leq d\}$. For two non-negative integers a, b with $a \leq b$, let $[a, b]$ denote the set $\{i \in \mathbb{Z} \mid a \leq i \leq b\}$.

Colored graphs. In this paper, we consider graphs in which each vertex has a (possibly empty) set of colors. We call them *colored graphs*. Formally, a colored graph G is a tuple (V, E, \mathcal{C}) such that the vertex set is V , the edge set $E \subseteq \binom{V}{2}$ is a set of unordered pairs of vertices, and $\mathcal{C} = \langle C_1, \dots, C_c \rangle$ is a tuple of subsets of V , where each C_i is called a *color*. For $v \in V$, let $\mathcal{C}(v)$ denote the set of colors that v belongs to. When $\mathcal{C}(v) = \emptyset$ for all $v \in V$, then the graph is *uncolored*. As we describe later, monadic second-order formulas treat the edge set as a symmetric binary relation on V and each color as a unary relation on V . As the number of colors a formula ϕ can access is bounded by $|\phi|$, which is always considered as a parameter or a constant in this paper, we can assume that the number of colors c is a parameter as well. We omit the information of colors and say $G = (V, E)$ when colors do not matter.

Two colored graphs $G = (V, E, \langle C_1, \dots, C_c \rangle)$ and $G' = (V', E', \langle C'_1, \dots, C'_c \rangle)$ are *isomorphic* if there is a color-preserving isomorphism $f: V \rightarrow V'$; that is,

- for all $u, v \in V$, $\{u, v\} \in E$ if and only if $\{f(u), f(v)\} \in E'$, and
- for all $v \in V$ and $1 \leq i \leq c$, $v \in C_i$ if and only if $f(v) \in C'_i$.

We also say that $\langle G, S \rangle$ and $\langle G', S' \rangle$ are isomorphic for sets $S \subseteq V$ and $S' \subseteq V'$ if the colored graphs $(V, E, \langle C_1, \dots, C_c, S \rangle)$ and $(V', E', \langle C'_1, \dots, C'_c, S' \rangle)$ are isomorphic.

Monadic second-order logic. In the monadic second-order logic on colored graphs, denoted MSO_1 , we can use vertex variables and vertex-set variables. The atomic formulas are the equality $x = y$ of vertex variables, the adjacency relation $E(x, y)$ which means $\{x, y\} \in E$, the color predicate $C_i(x)$ for each color C_i which means $x \in C_i$, and the inclusion predicate

² Actually, the rule used in [30] was another one called “token addition and removal.”

$X(x)$ for a variable x and a set variable X which means $x \in X$. The MSO_1 formulas are recursively defined from atomic formulas using the usual Boolean connectives (\neg , \wedge , \vee , \Rightarrow , \Leftrightarrow), and quantification of variables ($\forall x$, $\exists x$, $\forall X$, $\exists X$). For the sake of readability, we often use syntactic sugar in MSO_1 formulas (e.g., we write “ $\exists x \in X: \psi$ ” to mean “ $\exists x: X(x) \wedge \psi$ ”). As syntax sugars, we also use dotted quantifiers $\dot{\exists}$ and $\dot{\forall}$ to quantify distinct objects. For example, $\dot{\exists}a, b, c: \psi$ means $\exists a, b, c: (a \neq b) \wedge (b \neq c) \wedge (c \neq a) \wedge \psi$ and $\dot{\forall}a, b, c: \psi$ means $\forall a, b, c: ((a \neq b) \wedge (b \neq c) \wedge (c \neq a)) \Rightarrow \psi$.

MSO_2 is an extension of MSO_1 that additionally allows edge variables, edge-set variables, and an atomic formula $I(e, x)$ that represents the edge-vertex incidence relation. It is known that MSO_2 is strictly more powerful than MSO_1 in general [11].

An MSO_1 (or MSO_2) formula ϕ with free variables X_1, \dots, X_p is denoted by $\phi(X_1, \dots, X_p)$. For a graph G and vertex subsets S_1, \dots, S_p of G , we write $G \models \phi(S_1, \dots, S_p)$ if ϕ is true for G when the free variables X_1, \dots, X_p are interpreted as S_1, \dots, S_p . We call an MSO_1 (MSO_2) formula without free variables an MSO_1 (MSO_2 , resp.) *sentence*.

► **Proposition 2.1** (Folklore, see e.g., [23]). *Let G and G' be colored graphs and S and S' be some vertex subsets of them such that $\langle G, S \rangle$ and $\langle G', S' \rangle$ are isomorphic. Then, for every MSO_1 (or MSO_2) formula ϕ with one free set variable, $G \models \phi(S)$ if and only if $G' \models \phi(S')$.*

Problem definitions. For a colored graph G and an MSO_1 (or MSO_2) formula $\phi(X)$ a sequence S_0, \dots, S_ℓ of vertex subsets of G is a $\text{TJ}(\phi)$ -sequence from S_0 to S_ℓ (of length ℓ) if

- $|S_{i-1} \setminus S_i| = |S_i \setminus S_{i-1}| = 1$ for every $i \in [\ell]$, and
- $G \models \phi(S_i)$ for $0 \leq i \leq \ell$.

We denote by $\text{dist}_{\phi, G}(S, S')$ the minimum length of a $\text{TJ}(\phi)$ -sequence from S to S' , which is set to ∞ if there is no such sequence. We call a $\text{TJ}(\phi)$ -sequence of length 1 a $\text{TJ}(\phi)$ -move. Now the main problem studied in this paper can be formalized as follows.

MSO₁-RECONFIGURATION (MSO₁-R)

Input: An MSO_1 formula ϕ , a colored graph $G = (V, E, \mathcal{C})$, and sets $S, S' \subseteq V$ such that $|S| = |S'|$, $G \models \phi(S)$, and $G \models \phi(S')$.

Question: Is there a $\text{TJ}(\phi)$ -sequence from S to S' ?

We also study MSO_2 -R that allows MSO_2 formulas having one free vertex-set variable as ϕ . Observe that MSO_1 -R is PSPACE-hard as it generalizes various PSPACE-complete reconfiguration problems such as INDEPENDENT SET RECONFIGURATION. On the other hand, it still belongs to PSPACE since we can non-deterministically find the next vertex set R in the $\text{TJ}(\phi)$ -sequence and test whether $G \models \phi(R)$ holds in PSPACE [34, 39].

When describing a $\text{TJ}(\phi)$ -move from S_{i-1} to S_i , it is sometimes convenient to say that a *token* on the vertex $u \in S_{i-1} \setminus S_i$ is moved to the vertex $v \in S_i \setminus S_{i-1}$. The intuition behind this is that a vertex set in a $\text{TJ}(\phi)$ -sequence is considered as the positions of tokens and that in one $\text{TJ}(\phi)$ -move, token on some vertex jumps to another vertex. For simplicity, we sometimes write $S_{i-1} - u + v$ instead of $(S_{i-1} \setminus \{u\}) \cup \{v\}$.

Graph parameters. For a graph $G = (V, E)$, a set $S \subseteq V$ is a *vertex cover* if each $e \in E$ has at least one endpoint in S . The *vertex cover number* of G , denoted $\text{vc}(G)$, is the size of a minimum vertex cover of G . A vertex cover of size k of an n -vertex graph, if any exists, can be found in time $\mathcal{O}(c^k \cdot n)$ for some small constant c [8]. This implies that we can assume that a vertex cover of minimum size is given with the input when $\text{vc}(G)$ is part of the parameter.

Two vertices u and v are *twins* if $N(u) = N(v)$ or $N[u] = N[v]$. The *neighborhood diversity* of a graph G , denoted $\text{nd}(G)$, is the number of subsets V_i in the unique partition V_1, \dots, V_p of V into maximal sets of twin vertices. It is known that the neighborhood diversity and the corresponding partition can be computed in linear time [27,37]. From the definitions, we can see that $\text{nd}(G) \leq 2^{\text{vc}(G)} + \text{vc}(G)$ for every graph G [21].

The *treedepth* of a graph $G = (V, E)$, denoted $\text{td}(G)$, is the minimum depth d of a rooted forest F on the vertex set V such that each edge of G connects an ancestor and a descendant in F , where the depth of a forest is defined as the maximum distance between a root and a leaf. We call such a forest a *treedepth decomposition*. It is known a treedepth decomposition of depth d , if exists, can be found in time $2^{\mathcal{O}(d^2)} \cdot n$ [33]. Thus we may assume that a treedepth decomposition of depth $\text{td}(G)$ is given with the input when $\text{td}(G)$ is part of the parameter.

3 MSO₁-R parameterized by neighborhood diversity

The main result of this section is the following theorem.

► **Theorem 3.1.** *MSO₁-R parameterized by $\text{nd} + |\phi|$ is fixed-parameter tractable. Furthermore, for a yes instance of MSO₁-R, finding a shortest TJ(ϕ)-sequence is fixed-parameter tractable with the same parameter.*

We first prove Theorem 3.1 and then discuss the possibility of an extension to MSO₂-R. To prove Theorem 3.1, we first partition the feasible sets into a small number of equivalence classes. We show that the reachability between feasible sets can be checked by using an appropriately defined adjacency between the equivalence classes. Then, we take a deeper look at the connections between the equivalence classes and show that a shortest reconfiguration sequence can be found by finding some flow-like structure among the equivalence classes.

In the following, we fix the input of MSO₁-R as follows:

- $\phi(X)$: an MSO₁ formula with one free set variable X ;
 - $G = (V, E, \mathcal{C})$: a colored graph;
 - $S, S' \subseteq V$: the initial and target sets such that $G \models \phi(S)$, $G \models \phi(S')$, and $|S| = |S'| = k$.
- We say that a set $X \subseteq V$ is *feasible* if $G \models \phi(X)$.

We assume that the sets S and S' are colors in G ; that is, \mathcal{C} is of the form like $\langle C_1, \dots, C_c, S, S' \rangle$. If S and S' are originally not colors in G , we may add them and increase the number of colors only by 2.

Two vertices $u, v \in V$ in G are of the same *type* if u and v are twins and $\mathcal{C}(u) = \mathcal{C}(v)$. Let $\langle V_1, \dots, V_t \rangle$ be the partition of V into the sets of vertices of the same type. We call each V_i a *type*. Note that the type partition can be computed in polynomial time and that t depends only on the neighborhood diversity of G and the number of colors in \mathcal{C} .

For an MSO₁ formula ψ , let $\mathbf{q}(\psi) = 2^{\mathbf{q}_s} \cdot \mathbf{q}_v$, where \mathbf{q}_s and \mathbf{q}_v are the numbers of set and vertex quantifiers in ψ , respectively. Lampis [21] proved the following fact, which is one of the main ingredients in our algorithm.³

³ Note that Proposition 3.2 implies that, when neighborhood diversity is part of the parameter, the MSO₁ model-checking problem admits a small induced subgraph of the input graph as a kernel [21]. However, this does not directly show the fixed-parameter tractability of MSO₁-R (let alone the stronger claim of Theorem 3.1). In fact, as we will see later, an analogous result (Proposition 4.3) that implies a “natural” kernel for the MSO₁ model-checking problem parameterized by treedepth is known, while MSO₁-R is PSPACE-complete on graphs of constant treedepth (Theorem 5.1).

► **Proposition 3.2** ([21]). *Let ψ be an MSO_1 sentence. Assume that a graph H has more than $\mathfrak{q}(\psi)$ vertices of the same type, and H' is the graph obtained from H by removing a vertex in that type. Then, $H \models \psi$ if and only if $H' \models \psi$.*

We need the concept of “shapes” of vertex subsets that was used with Proposition 3.2 in the context of extended MSO_1 model-checking problems [20]. Here we introduce it in the following simplified form, which is sufficient for our purpose. The *signature* of $X \subseteq V$ is the mapping $\sigma_X: [t] \rightarrow \mathbb{Z}_{\geq 0}$ such that $\sigma_X(i) = |V_i \cap X|$. A *shape* is a mapping from $[t]$ to $\mathbb{Z}_{\geq 0} \cup \{\perp\}$ that maps each $i \in [t]$ to an element of $[0, \mathfrak{q}(\phi) - 1] \cup \{\perp\} \cup [|\mathbb{V}_i| - \mathfrak{q}(\phi) + 1, |\mathbb{V}_i|]$. Note that the number of shapes is $(2\mathfrak{q}(\phi) + 1)^t$. A set $X \subseteq V$ has shape $\bar{\sigma}$ if for every $i \in [t]$,

$$\bar{\sigma}(i) = \begin{cases} \perp & \mathfrak{q}(\phi) \leq \sigma_X(i) \leq |\mathbb{V}_i| - \mathfrak{q}(\phi), \\ \sigma_X(i) & \text{otherwise.} \end{cases}$$

We say that a shape $\bar{\sigma}$ is *k-feasible* if there is a feasible set $X \subseteq V$ of size k that has $\bar{\sigma}$ as its shape.

Let $\bar{\sigma}_S$ and $\bar{\sigma}_{S'}$ be the shapes of the input sets S and S' , respectively. Since S is a color of G , each type V_i either is a subset of S or has no intersection with S , that is,

$$\bar{\sigma}_S(i) = \begin{cases} |\mathbb{V}_i| & V_i \subseteq S, \\ 0 & \text{otherwise.} \end{cases}$$

This implies that a set $R \subseteq V$ has shape $\bar{\sigma}_S$ if and only if $R = S$. This applies to S' as well.

► **Observation 3.3.** *$R \subseteq V$ has shape $\bar{\sigma}_S$ ($\bar{\sigma}_{S'}$) if and only if $R = S$ ($R = S'$, resp.).*

Proposition 3.2 and the definition of shapes together give the following fact, which is known in more general forms in the previous studies (see e.g., [20]). This less general one is sufficient in our setting. We present a full proof in the full version to be self contained.

► **Lemma 3.4** (★). *If $R, R' \subseteq V$ have the same shape, then $G \models \phi(R)$ if and only if $G \models \phi(R')$.*

Lemma 3.4 implies in particular that if a shape $\bar{\sigma}$ is *k-feasible*, then every size- k set of shape $\bar{\sigma}$ is feasible.

► **Lemma 3.5** (★). *If feasible sets $R, R' \subseteq V$ have the same shape and size, then there is a $\text{TJ}(\phi)$ -sequence of length $|R \setminus R'|$ from R to R' such that all sets in the sequence have the same shape.*

We now introduce the *adjacency* between shapes. Intuitively, this concept captures how a single token jump connects different shapes. Let S_1 and S_2 be sets having different shapes $\bar{\sigma}_1$ and $\bar{\sigma}_2$, respectively, such that $S_1 \setminus S_2 = \{u\}$, $u \in V_i$, $S_2 \setminus S_1 = \{v\}$, $v \in V_j$, and $i \neq j$. For $h \in [t] \setminus \{i, j\}$, $\bar{\sigma}_1(h) = \bar{\sigma}_2(h)$ holds. Since $\bar{\sigma}_1 \neq \bar{\sigma}_2$, at least one of $\bar{\sigma}_1(i) \neq \bar{\sigma}_2(i)$ and $\bar{\sigma}_1(j) \neq \bar{\sigma}_2(j)$ holds. If $\bar{\sigma}_1(i) \neq \bar{\sigma}_2(i)$, then $|V_i \cap S_2| = |V_i \cap S_1| - 1$ implies that one of the following holds:

- A1: $\bar{\sigma}_1(i) \neq \perp$, $\bar{\sigma}_2(i) \neq \perp$, and $\bar{\sigma}_2(i) = \bar{\sigma}_1(i) - 1$;
- A2: $\bar{\sigma}_1(i) = \perp$ and $\bar{\sigma}_2(i) = \mathfrak{q}(\phi) - 1$; $(\sigma_{S_1}(i) = \mathfrak{q}(\phi))$
- A3: $\bar{\sigma}_1(i) = |\mathbb{V}_i| - \mathfrak{q}(\phi) + 1$ and $\bar{\sigma}_2(i) = \perp$. $(\sigma_{S_2}(i) = |\mathbb{V}_i| - \mathfrak{q}(\phi))$

Similarly, if $\bar{\sigma}_1(j) \neq \bar{\sigma}_2(j)$, then $|V_j \cap S_2| = |V_j \cap S_1| + 1$ implies that one of the following holds:

- B1: $\bar{\sigma}_1(j) \neq \perp$, $\bar{\sigma}_2(j) \neq \perp$, and $\bar{\sigma}_2(j) = \bar{\sigma}_1(j) + 1$;
- B2: $\bar{\sigma}_1(j) = \mathfrak{q}(\phi) - 1$ and $\bar{\sigma}_2(j) = \perp$; $(\sigma_{S_2}(j) = \mathfrak{q}(\phi))$
- B3: $\bar{\sigma}_1(j) = \perp$ and $\bar{\sigma}_2(j) = |\mathbb{V}_j| - \mathfrak{q}(\phi) + 1$. $(\sigma_{S_1}(j) = |\mathbb{V}_j| - \mathfrak{q}(\phi))$

Given the observation above, we say that two k -feasible shapes $\bar{\sigma}_1$ and $\bar{\sigma}_2$ are *adjacent* if and only if the following three conditions are satisfied.

- (1) One of the following holds:
 - $\bar{\sigma}_1$ and $\bar{\sigma}_2$ disagree at exactly two indices i and j such that i satisfies one of A1, A2, A3 and j satisfies one of B1, B2, B3;
 - $\bar{\sigma}_1$ and $\bar{\sigma}_2$ disagree at exactly one index i satisfying one of A1, A2, A3, or j satisfying one of B1, B2, B3.
- (2) There exists a size- k set S_1 of shape $\bar{\sigma}_1$ such that
 - if i is defined in (1) and $\bar{\sigma}_1(i) = \mathbb{I}$, then $\sigma_{S_1}(i) = \mathbf{q}(\phi)$;
 - if j is defined in (1) and $\bar{\sigma}_1(j) = \mathbb{I}$, then $\sigma_{S_1}(j) = |V_j| - \mathbf{q}(\phi)$.
- (3) There exists a size- k set S_2 of shape $\bar{\sigma}_2$ such that
 - if i is defined in (1) and $\bar{\sigma}_2(i) = \mathbb{I}$, then $\sigma_{S_2}(i) = |V_i| - \mathbf{q}(\phi)$;
 - if j is defined in (1) and $\bar{\sigma}_2(j) = \mathbb{I}$, then $\sigma_{S_2}(j) = \mathbf{q}(\phi)$.

The *size- k shape graph* \mathcal{S}_k has the set of k -feasible shapes as its vertex set and the adjacency between the vertices (shapes) is as defined above.

► **Lemma 3.6 (★).** *Let $\bar{\sigma}_1$ and $\bar{\sigma}_2$ be two different shapes that are k -feasible. Then, $\bar{\sigma}_1$ and $\bar{\sigma}_2$ are adjacent in \mathcal{S}_k if and only if there exist size- k feasible sets S_1 and S_2 of shapes $\bar{\sigma}_1$ and $\bar{\sigma}_2$, respectively, with $|S_1 \setminus S_2| = |S_2 \setminus S_1| = 1$.*

Since $|S| = |S'| = k$, the reachability between them can be reduced to the reachability between their shapes in \mathcal{S}_k .

► **Lemma 3.7 (★).** *Let $\bar{\sigma}$ and $\bar{\sigma}'$ be the shapes of S and S' , respectively. There is a $\text{TJ}(\phi)$ -sequence from S to S' if and only if $\bar{\sigma}$ and $\bar{\sigma}'$ belong to the same connected component of \mathcal{S}_k .*

Lemma 3.7 implies that $\text{MSO}_1\text{-R}$ can be solved by checking that the shapes of the initial and target sets belong to the same connected component of \mathcal{S}_k . We now show that \mathcal{S}_k can be constructed efficiently.

► **Lemma 3.8 (★).** *Constructing \mathcal{S}_k is fixed-parameter tractable parameterized by $t + \mathbf{q}(\phi)$.*

The lemma above already implies that $\text{MSO}_1\text{-R}$ is fixed-parameter tractable parameterized by $\text{nd} + |\phi|$. To find a shortest $\text{TJ}(\phi)$ -sequence, we take a closer look at \mathcal{S}_k .

A sequence $\bar{\sigma}_0, \dots, \bar{\sigma}_q$ of shapes with $\bar{\sigma}_i \neq \bar{\sigma}_{i+1}$ for $0 \leq i < q$ is the *shape sequence* of a $\text{TJ}(\phi)$ -sequence if the $\text{TJ}(\phi)$ -sequence can be split into $q + 1$ subsequences such that all sets in the i th subsequence have shape $\bar{\sigma}_i$ for $0 \leq i \leq q$.

► **Lemma 3.9 (★).** *If there is a $\text{TJ}(\phi)$ -sequence from S to S' , then there is a shortest one such that the corresponding shape sequence forms a simple path in \mathcal{S}_k .*

Lemma 3.9 implies that for finding a shortest $\text{TJ}(\phi)$ -sequence from S to S' , it suffices to first guess a path in \mathcal{S}_k and then find a shortest $\text{TJ}(\phi)$ -sequence having the path as its shape sequence. Note that $|V(\mathcal{S}_k)| \leq (2\mathbf{q}(\phi) + 1)^t$ and thus the number of candidates for such shape sequences is upper bounded by a function depending only on $\mathbf{q}(\phi)$ and t . (Recall that t is the number of types in G .) Therefore, the following lemma completes the proof of Theorem 3.1.

► **Lemma 3.10 (★).** *Given a sequence $\bar{\sigma}_0, \dots, \bar{\sigma}_q$ of shapes such that $\bar{\sigma}_0 = \bar{\sigma}_S$ and $\bar{\sigma}_q = \bar{\sigma}_{S'}$, finding a shortest $\text{TJ}(\phi)$ -sequence with the shape sequence $\bar{\sigma}_0, \dots, \bar{\sigma}_q$ is fixed-parameter tractable parameterized by $t + \mathbf{q}(\phi)$.*

Proof. We reduce the problem to MINIMUM-COST CIRCULATION defined as follows. Let $D = (X, A)$ be a directed graph. We define $\delta^{\text{in}}(v) = \{a \in A \mid a = (u, v) \in A\}$ and $\delta^{\text{out}}(v) = \{a \in A \mid a = (v, u) \in A\}$. A function $f: A \rightarrow \mathbb{R}$ is a *circulation* if $f(\delta^{\text{in}}(v)) = f(\delta^{\text{out}}(v))$ for each $v \in X$, where $f(A') = \sum_{a \in A'} f(a)$ for $A' \subseteq A$. A circulation f is an *integer circulation* if $f(a)$ is an integer for each $a \in A$. Given a *cost function* $w: A \rightarrow \mathbb{Q}$, the *cost* of a circulation f is defined as $\text{cost}(f) = \sum_{a \in A} w(a)f(a)$. Now, given a directed graph $D = (X, A)$, a *demand function* $d: A \rightarrow \mathbb{Q}$, a *capacity function* $c: A \rightarrow \mathbb{Q}$, and a cost function $w: A \rightarrow \mathbb{Q}$, MINIMUM-COST CIRCULATION asks to find a circulation f minimizing $\text{cost}(f)$ under the condition that $d(a) \leq f(a) \leq c(a)$ for each $a \in A$. It is known that MINIMUM-COST CIRCULATION can be solved in strongly polynomial time, and if the demand d and the capacity c take integer values only, then a minimum-cost integer circulation is found [36].

Now we construct an instance of MINIMUM-COST CIRCULATION from the graph $G = (V, E, \mathcal{C})$, its type partition (V_1, \dots, V_t) , and the shape sequence $\bar{\sigma}_0, \dots, \bar{\sigma}_q$. We first construct $D = (X, A)$. The digraph D contains two special vertices s and s' , and q sets L_0, L_1, \dots, L_{q-1} of vertices such that $L_j = \{v_1^j, \dots, v_t^j\}$ for $0 \leq j \leq q-1$. Each L_j is a bidirectional clique (i.e., there is an arc for each ordered pair of vertices in L_j). For $1 \leq j \leq q-1$, D contains the matching $\{(v_i^{j-1}, v_i^j) \mid 1 \leq i \leq t\}$ from L_{j-1} to L_j . There are arcs from s to all vertices in L_0 and from all vertices in L_{q-1} to s' . Additionally, D contains the arc (s', s) . Each arc a in each clique L_j has demand $d(a) = 0$, capacity $c(a) = \infty$, and cost $w(a) = 1$. All other arcs have cost 0. We set $d((s', s)) = c((s', s)) = k$. For $i \in [t]$, we set $d((s, v_i^0)) = c((s, v_i^0)) = |V_i \cap S|$ ($= \bar{\sigma}_0(i)$) and $d((v_i^{q-1}, s')) = c((v_i^{q-1}, s')) = |V_i \cap S'|$ ($= \bar{\sigma}_q(i)$). For $i \in [t]$ and $j \in [q-1]$, we set

$$d((v_i^{j-1}, v_i^j)) = \begin{cases} \mathfrak{q}(\phi) & \bar{\sigma}_j(i) = \mathbb{I}, \\ \bar{\sigma}_j(i) & \text{otherwise,} \end{cases} \quad c((v_i^{j-1}, v_i^j)) = \begin{cases} |V_i| - \mathfrak{q}(\phi) & \bar{\sigma}_j(i) = \mathbb{I}, \\ \bar{\sigma}_j(i) & \text{otherwise.} \end{cases}$$

In the full version, we show that there exists a $\text{TJ}(\phi)$ -sequence of length at most p with the shape sequence $\bar{\sigma}_0, \dots, \bar{\sigma}_q$ from S to S' if and only if the instance $\langle D, d, c, w \rangle$ of MINIMUM-COST CIRCULATION admits an integer circulation f of cost at most p . This completes the proof since MINIMUM-COST CIRCULATION is solvable in strongly polynomial time and the size of D depends only on t and the number of shapes. \blacktriangleleft

Using Lemma 6 in [21] and Theorem 3.1, we can show the following.

► **Corollary 3.11 (★).** *MSO₂-R parameterized by $\text{vc} + |\phi|$ is fixed-parameter tractable. Furthermore, for a yes instance of MSO₂-R, finding a shortest TJ-sequence is fixed-parameter tractable with the same parameter.*

On the other hand, using a hardness result in [22], we can show that an extension of Theorem 3.1 to MSO₂ is not possible under some reasonable assumption. Recall that $\text{E} = \text{DTIME}(2^{O(n)})$ and $\text{NE} = \text{NTIME}(2^{O(n)})$.

► **Theorem 3.12 (★).** *Unless $\text{E} = \text{NE}$, MSO₂-R on n -vertex uncolored graphs of neighborhood diversity 2 and twin cover number 3 cannot be solved in time $\mathcal{O}(n^{f(|\phi|)})$ for any function f .*

4 Fixed-parameter algorithm parameterized by the solution size and treedepth

In this section, we show that MSO₂-R is fixed-parameter tractable when parameterized simultaneously by treedepth, the length of the MSO₂ formula, and the size of input sets S and S' .

► **Theorem 4.1.** *MSO₂-R parameterized by $\text{td} + k + |\phi|$ is fixed-parameter tractable, where k is the size of input sets. Furthermore, for a yes instance of MSO₂-R, finding a shortest TJ-sequence is fixed-parameter tractable with the same parameter.*

As we show in Section 5, having the size of input sets is necessary since otherwise it is PSPACE-complete.

It is known (see e.g., [11]) that given a colored graph G and an MSO₂ sentence ϕ , one can compute in polynomial time a colored graph G' and an MSO₁ sentence ϕ' such that

- $G \models \phi$ if and only if $G' \models \phi'$;
- G' is obtained from G by subdividing each edge, and consider the new vertices introduced by the subdivisions as a color;
- the length of ϕ' is bounded by a function of $|\phi|$.

Observe that $\text{td}(G') \leq \text{td}(G) + 1$.⁴ Therefore, to prove Theorem 4.1, it suffices to show that MSO₁-R is fixed-parameter tractable parameterized by the claimed parameter.

Now we generalize the type of a vertex used in Section 3 to the type of a vertex set. For a colored graph $G = (V, E, \mathcal{C})$ and vertex sets $X, X' \subseteq V$, we say that X and X' have the same *type* if there is an isomorphism η from G to itself such that $\eta(X) = X'$, $\eta(X') = X$, and $\eta(v) = v$ for every $v \notin X \cup X'$. Note that from the definition of isomorphisms between colored graphs, $\mathcal{C}(v) = \mathcal{C}(\eta(v))$ holds for every $v \in V$. Note also that singletons $\{x\}, \{x'\} \subseteq V$ have the same type if and only if the vertices x and x' have the same type.

The next lemma says that if there are many disjoint vertex sets of the same type, then we can avoid most of them when finding TJ(ϕ)-sequences.

► **Lemma 4.2 (★).** *Let $\langle \phi, G, S, S' \rangle$ be a yes-instance of MSO₁-R with $|S| = |S'| = k$. Let C_1, \dots, C_t be a family of disjoint vertex sets with the same type not intersecting $S \cup S'$. If $t > k$, then for every $I \subseteq [t]$ with $|I| = k$, there is a shortest TJ(ϕ)-sequence S_0, \dots, S_ℓ from $S_0 = S$ to $S_\ell = S'$ such that $C_i \cap \bigcup_{0 \leq j \leq \ell} S_j \neq \emptyset$ only if $i \in I$.*

Next we further argue that if there are a much larger number of disjoint vertex sets of the same type, then we can safely remove some of them. Note that this claim is stronger than Lemma 4.2 in some sense. Since the formula $\phi(X)$ may depend on the whole structure of G (i.e., not only on $G[X]$), “not using it in a sequence” and “removing it from the graph” are different.

We need the following proposition, which is a generalization of Proposition 3.2.

► **Proposition 4.3** ([23]). *Let G be a colored graph and ϕ be an MSO₁ formula with one free set variable. Assume that G contains $t > 2^{p \cdot q(\phi)}$ disjoint size- p vertex sets with the same type. Let G' be the graph obtained from G by removing one of the t sets. Then, for every subset $X \subseteq V$ disjoint from the t sets, $G' \models \phi(X)$ if and only if $G \models \phi(X)$.*

Using Proposition 4.3, we can show the following.

► **Lemma 4.4 (★).** *Let $\langle \phi, G, S, S' \rangle$ be an instance of MSO₁-R with $|S| = |S'| = k$. Let C_1, \dots, C_t be a family of disjoint size- p vertex sets with the same type not intersecting $S \cup S'$. If $t > k + 2^{p \cdot q(\phi)}$, then for every $C \in \{C_1, \dots, C_t\}$, $\text{dist}_{\phi, G}(S, S') = \text{dist}_{\phi, G-C}(S, S')$.*

⁴ Starting with a treedepth decomposition F of G with depth at most d , we construct a treedepth decomposition F' of G' with depth at most $d + 1$ by adding the vertex corresponding to each edge $\{u, v\} \in E(G)$ as a leaf attached to one of u and v that is a descendant of the other.

The next lemma completes the proof of Theorem 4.1 as it means that we have a kernel of $\text{MSO}_1\text{-R}$ parameterized by $\text{td}(G) + k + |\phi|$ that preserves the minimum length of a $\text{TJ}(\phi)$ -sequence.

► **Lemma 4.5.** *Let $\langle \phi, G, S, S' \rangle$ be an instance of $\text{MSO}_1\text{-R}$ with $|S| = |S'| = k$. In polynomial time, one can compute a subgraph H of G such that $\text{dist}_{\phi, G}(S, S') = \text{dist}_{\phi, H}(S, S')$ and the size of H depends only on the parameter $\text{td}(G) + k + |\phi|$.*

Proof. Let F be a treedepth decomposition of depth $\text{td}(G)$. If F is not connected, then we add a new vertex r and add edges from the new vertex to the roots of trees in F and set r to the new root. We call the resultant tree T . If F is connected, then we just set $T = F$ and call its root r . Let d be the depth of T . Note that $d \leq \text{td}(G) + 1$.

A node in T has *height* h if the maximum distance to a descendant is h , where the height of a leaf is 0. Let $c(0) = 0$, $n(0) = 1$, and for $h \geq 0$, let

$$\begin{aligned} c(h+1) &= (k + 2^{n(h) \cdot q(\phi)}) \cdot 2^{|\phi| \cdot n(h)} \cdot 2^{(n(h)+d-h)^2} + 2k, \\ n(h+1) &= n(h) \cdot c(h+1) + 1. \end{aligned}$$

In the next paragraph, we show that after exhaustively applying Lemma 4.4 in a bottom-up manner along T , each node of height h has at most $c(h)$ children and each subtree rooted at a node of height h contains at most $n(h)$ nodes. This implies that H has at most $n(d)$ vertices, where $n(d)$ depends only on $\text{td}(G)$, k , and $|\phi|$. If $h = 0$, then the claim is trivial. Assume that the claim holds for some $h \geq 0$. It suffices to prove the upper bound $c(h+1)$ for the number of children as the upper bound $n(h+1)$ follows immediately. Suppose to the contrary that a node v of height $h+1$ has more than $c(h+1)$ children. Since $|S \cup S'| \leq 2k$, more than $c(h+1) - 2k$ subtrees rooted at the children of v have no intersection with $S \cup S'$. Let S_1, \dots, S_p be such subtrees. By the induction hypothesis, $|V(S_i)| \leq n(h)$ holds for $i \in [p]$. Let R be the vertices on the v - r path in T (including v and r). Observe that, in H , the vertices in $V(S_i)$ may have neighbors only in $V(S_i) \cup R$. Thus the number of different types of $V(S_1), \dots, V(S_p)$ is at most $2^{|\phi| \cdot n(h)} \cdot 2^{(n(h)+d-h)^2}$, where $2^{|\phi| \cdot n(h)}$ is the number of possible ways for coloring $n(h)$ vertices with subsets of at most $|\phi|$ colors and $2^{(n(h)+d-h)^2}$ is an upper bound on the number of different ways that $n(h)$ vertices form a graph and have additional neighbors in $d-h$ vertices. Since $p > c(h+1) - 2k = (k + 2^{n(h) \cdot q(\phi)}) \cdot 2^{|\phi| \cdot n(h)} \cdot 2^{(n(h)+d-h)^2}$, there is a subset $I \subseteq [p]$ such that $|I| > k + 2^{n(h) \cdot q(\phi)}$ and all vertex sets $V(S_i)$ with $i \in [I]$ have the same type. This is a contradiction as Lemma 4.4 can be applied here.

Finally, let us see how fast we can apply Lemma 4.4 exhaustively in a bottom-up manner. The description above immediately gives a fixed-parameter algorithm parameterized by $\text{td}(G) + k + |\phi|$, which is actually sufficient for our purpose. A polynomial-time algorithm can be achieved in pretty much the same way as presented in [14] for a reconfiguration problem of paths parameterized by td . The idea is to use a polynomial-time algorithm for labeled-tree isomorphism to classify subtrees into different types. Only the differences here are that the graph is colored and the parameters involved are larger. As the colors of the vertices can be handled by a labeling algorithm and the involved parameters do not matter when they are too large (i.e., if it is $|V|$ or more), we still obtain a polynomial-time algorithm. ◀

5 PSPACE-completeness on forests of depth 3

In this section, we complement Theorem 4.1 by showing that if the size of input sets is not part of the parameter, then the problem becomes PSPACE-complete.

For a set U , a subset family $\mathcal{C} \subseteq 2^U$ is an *exact cover* if the elements of \mathcal{C} are pairwise disjoint and $\bigcup_{C \in \mathcal{C}} C = U$. For two exact covers $\mathcal{C}_1, \mathcal{C}_2$ of U , we say that \mathcal{C}_1 can be obtained from \mathcal{C}_2 by a *merge* (and \mathcal{C}_2 can be obtained from \mathcal{C}_1 by a *split*) if $\mathcal{C}_1 \setminus \mathcal{C}_2 = \{D_1\}$ and $\mathcal{C}_2 \setminus \mathcal{C}_1 = \{D_2, D_3\}$ for some D_1, D_2, D_3 . Note that $D_1 = D_2 \cup D_3$ and $D_2 \cap D_3 = \emptyset$ as \mathcal{C}_1 and \mathcal{C}_2 are exact covers.

Given a set U , a family $\mathcal{D} \subseteq 2^U$, and two exact covers $\mathcal{C}, \mathcal{C}' \subseteq \mathcal{D}$ of U , EXACT COVER RECONFIGURATION asks whether there exists a sequence $\mathcal{C}_0, \dots, \mathcal{C}_\ell$ of exact covers of U from $\mathcal{C} = \mathcal{C}_0$ to $\mathcal{C}' = \mathcal{C}_\ell$ such that $\mathcal{C}_i \subseteq \mathcal{D}$ for all i and \mathcal{C}_i is obtained from \mathcal{C}_{i-1} by a split or a merge for each $i \in [\ell]$. It is known that EXACT COVER RECONFIGURATION is PSPACE-complete [7].

In this section, we prove the following hardness result by reducing EXACT COVER RECONFIGURATION to MSO₁-R. (Recall that MSO₁-R belongs to PSPACE.)

► **Theorem 5.1 (★).** *For some fixed ϕ , MSO₁-R is PSPACE-complete on uncolored forests of depth 3.*

Let $\langle U, \mathcal{D}, \mathcal{C}, \mathcal{C}' \rangle$ be an instance of EXACT COVER RECONFIGURATION. We construct an equivalent instance of MSO₁-R. Without loss of generality, we assume that U is a set of positive integers greater than or equal to 3.

For each set $D \in \mathcal{D}$, we construct a tree T_D as follows (see Figure 2). The tree T_D contains a central vertex called the *root*. For each $d \in D$, the root has a child with d grandchildren. We call the subtree rooted at a child of the root a *star* and each leaf in a star a *star leaf*. Additionally, the root has two more children that have degree 1. They are called the *antennae*.

■ **Figure 2** The tree T_D with $D = \{d_1, d_2, \dots, d_{|D|}\}$.

The entire forest F consists of trees T_D for all $D \in \mathcal{D}$ and eight isolated vertices. By I , we denote the set of the isolated vertices. Clearly, F has treedepth 3. The initial set S consists of all vertices in I and all star leaves of T_D for all $D \in \mathcal{C}$. Similarly, the target set S' consists of all vertices in I and all star leaves of T_D for all $D \in \mathcal{C}'$. Note that $|S| = |S'| = |U| + 8$.

For a set $R \subseteq V(F)$ and a set $D \in \mathcal{D}$, the tree T_D is *full (empty) under R* if R contains all (no, resp.) star leaves of T_D , and T_D is *clean* if it is full or empty. We also say that, for a set $R \subseteq V(F)$ and a set $D \in \mathcal{D}$, a star in T_D is *full (empty)* if R contains all (no, resp.) star leaves of the star, and the star is *clean* if it is full or empty.

A tree T_D is *marked* by a vertex set if both antennae are included in the vertex set. A star in T_D is *marked* by a vertex set if the center (i.e., the unique non-leaf vertex) of the star is included. We use the eight additional vertices to mark trees and stars.

We construct the MSO₁ formula $\phi(X)$ expressing that X satisfies 1 or 2 below.

1. All trees T_D are clean and exactly eight vertices in X are not star leaves.
2. Exactly three trees $T_{D_1}, T_{D_2}, T_{D_3}$ are marked, all other trees are clean, and the following conditions are satisfied.

- Exactly one of the three trees, say T_{D_3} , is clean.
- In each of T_{D_1} and T_{D_2} , exactly one star is marked and all other stars are clean.
- The marked star in T_{D_1} is clean if and only if so is the marked star in T_{D_2} .

Constructing such $\phi(X)$ is tedious but not difficult. The expression is given in the full version. Now it suffices to show that the constructed instance $\langle \phi, F, S, S' \rangle$ is a yes-instance of $\text{MSO}_1\text{-R}$ if and only if $\langle U, \mathcal{D}, \mathcal{C}, \mathcal{C}' \rangle$ is a yes-instance of $\text{EXACT COVER RECONFIGURATION}$. The rest of the proof is omitted in the short version.

6 Conclusion

We revisited the reconfiguration problems of vertex sets defined by MSO formulas, while putting the length constraint of reconfiguration sequence aside. We showed that the problem is fixed-parameter tractable parameterized solely by neighborhood diversity and by the combination of treedepth and the vertex-set size. The parameterization solely by treedepth would not work as we showed that the problem is PSPACE -complete on forests of depth 3.

Given the positive result for neighborhood diversity and the known hardness for clique-width (implied by the one for bandwidth [40]), a natural target would be an extension to modular-width, which is a parameter sitting between neighborhood diversity and clique-width (see Figure 1). It is known that a special case, the independent set reconfiguration, is fixed-parameter tractable parameterized by modular-width [2], but the algorithm in [2] is already quite nontrivial.

Another direction would be strengthening the hardness for treedepth. In Section 5, we showed the hardness for a quite complicated and rather unnatural formula ϕ , which simulates the merge and split operations. Although this rules out the possibility of meta-theorems parameterized by treedepth, it would be still interesting to investigate the complexity of specific more natural problems. For example, what is the complexity of the independent set reconfiguration and the dominating set reconfiguration parameterized solely by treedepth?

Abstract

It follows from the work of Tait and the Four-Color-Theorem that a planar cubic graph is 3-edge-colorable if and only if it contains no bridge. We consider the question of which planar graphs are subgraphs of planar cubic bridgeless graphs, and hence 3-edge-colorable. We provide an efficient recognition algorithm that given an n -vertex planar graph, augments this graph in $\mathcal{O}(n^2)$ steps to a planar cubic bridgeless supergraph, or decides that no such augmentation is possible. The main tools involve the GENERALIZED (ANTI)FACTOR-problem for the fixed embedding case, and SPQR-trees for the variable embedding case.

1 Introduction

Whether or not the 3-EDGE COLORABILITY-problem is solvable in polynomial time for planar graphs is one of the most fundamental open problems in algorithmic graph theory:

► **Question 1.** *Can we decide in polynomial time, whether the edges of a given planar graph can be colored in three colors such that any two adjacent edges receive distinct colors?*

In other words, can we decide for a planar graph G in polynomial time whether $\chi'(G) \leq 3$, where $\chi'(G)$ denotes the chromatic index of G ? Clearly, it is enough to consider planar graphs G of maximum degree $\Delta(G) = 3$. If G is planar and 3-regular, then by the Four-Color-Theorem [1, 2] and the work of Tait [26] we know that G is 3-edge-colorable if and only if G is bridgeless. An edge is a bridge if its removal increases the number of connected components (note that this definition also applies to disconnected graphs). As we can check the existence of bridges in linear time [28], we hence can decide in polynomial time whether a given 3-regular planar graph is 3-edge-colorable.

In particular, subgraphs of bridgeless 3-regular planar graphs are 3-edge-colorable. However, this does not answer Question 1 yet (as sometimes wrongly claimed, e.g., in [7]), because it is for example not clear which planar graphs of maximum degree 3 are subgraphs of bridgeless 3-regular planar graphs, and whether these can be recognized efficiently.

In this paper we consider the corresponding decision problem: Given a graph G , is there a bridgeless 3-regular planar graph H , such that $G \subseteq H$? In other words, can G be augmented, by adding edges and (possibly) vertices, to a supergraph H of G that is planar, 3-regular, and contains no bridge? For brevity we call such a supergraph H a *3-augmentation* of G and denote the above decision problem as 3-AUGMENTATION. Our main result is that 3-AUGMENTATION is in P.

■ **Figure 1** Example instances for the 3-AUGMENTATION problem.

► **Theorem 2.** *For a given n -vertex graph G we can construct in $\mathcal{O}(n^2)$ time a 3-regular bridgeless planar supergraph H of G , or conclude that no such exists.*

Theorem 2 is the main result of the present paper and we emphasize that this does not answer Question 1 yet. In fact, admitting a 3-augmentation is a sufficient condition for 3-edge colorability; but it is in general not necessary. For example, $K_{2,3}$ admits a proper 3-edge coloring but no 3-augmentation. Question 1 remains open and we discuss it and its connection to 3-augmentations in more detail in Section 3.

In order to decide the existence of a 3-augmentation (i.e., proving Theorem 2), we may of course assume that the graph G itself is planar and of maximum degree at most 3. Observe that in this case it is always possible to find a 3-regular planar supergraph of G , for example by adding the small gadget $K_4^{(1)}$ consisting of K_4 with one subdivided edge to each vertex that has not degree 3 yet, see Figure 1c. The difficult part is to prevent bridges in the resulting graph, even if the input graph G is already bridgeless. In fact, our task boils down to finding a suitable planar embedding of G such that for each vertex v of G and each missing edge at v , we can assign an incident face at v that should contain the new edge. We avoid the creation of bridges by assigning each face either no or at least two such new edges. Having assigned k new edges to a face f , we insert the small gadget $K_4^{(k)}$ consisting of K_4 with one edge subdivided k times into f . See Figure 1a for an example. Let us note that this might only work for some planar embeddings of G . See Figure 1b for a negative example.

We show Theorem 2 in three steps. First, we show that G admits a 3-augmentation if and only if each inclusion-maximal 2-connected component, called a *block*, of G admits a 3-augmentation. As all blocks can be found in linear time [27], we may restrict to the 2-connected case henceforth. Second, we consider a 2-connected G with a fixed planar embedding \mathcal{E} and use the GENERALIZED ANTIFACTOR-problem to test whether G admits a 3-augmentation $H \supseteq G$ with a planar embedding whose restriction to G equals \mathcal{E} . Finally, for a 2-connected G with variable embedding, we use an SPQR-tree of G to efficiently go through the possible planar embeddings of G with a dynamic program and to identify one such embedding that allows for a 3-augmentation, or conclude that no such exists.

Outline. After discussing related work below, we give necessary definitions in Section 1.1, including the GENERALIZED ANTIFACTOR-problem and SPQR-trees. In Section 2 we develop our algorithm for the 3-AUGMENTATION-problem, where we reduce to the 2-connected case in Section 2.1, and handle the fixed embedding in Section 2.2, and variable embedding in Section 2.3. Finally, in Section 3 we complete the loop back to the 3-EDGE COLORABILITY-problem for planar graphs. Lemmas marked with * are proven in the full version [13].

Related work. Hartmann, Rollin and Rutter [16] studied a similar augmentation problem for planar graphs, where we are only allowed to add edges (but no vertices) to the graph. In particular, for given $c, k \in \{1, \dots, 5\}$ they define the c -CONNECTED PLANAR k -REGULAR AUGMENTATION-problem where one seeks to add edges to a given planar graph G , so that the resulting supergraph H of G is planar, c -connected, and k -regular. Observe that the 2-CONNECTED PLANAR 3-REGULAR AUGMENTATION-problem is more restrictive than the 3-AUGMENTATION-problem: The former forbids to add new vertices, therefore refuses all input graphs with an odd number of vertices, and requires the result to be connected, therefore refusing all input graphs that are 3-regular and disconnected. In fact, reducing from PLANAR 3SAT, they show that 2-CONNECTED PLANAR 3-REGULAR AUGMENTATION is NP-complete [16, Theorem 3], while we show that 3-AUGMENTATION lies in P.

Let us mention a few more examples from the rich and diverse area of augmentation problems. Eswaran and Tarjan [12] pioneered the systematic investigation of augmentation problems. They presented algorithms to find in $\mathcal{O}(|V| + |E|)$ a smallest number of edges whose addition to a given (not necessarily planar) graph $G = (V, E)$ results in a 2-connected respectively 2-edge-connected graph (a connected graph with no bridge), while the weighted versions of either problem is NP-complete. If we additionally require the result to be planar, already both unweighted problems are NP-complete [18, 22]. Other problems of augmenting to a planar graph consider augmenting to a grid graph [3], or triangulating while minimizing the maximum degree [9, 19], avoiding separating triangles [4], creating a Hamiltonian cycle [11], or resulting in a chordal graph [20], just to name a few.

1.1 Preliminaries

All graphs considered here are finite, undirected, and contain no loops but possibly multiedges. We write $\|G\|$ for the *size* of G (its number of edges) and denote the degree of a vertex v by $\deg(v)$, the minimum degree in G by $\delta(G)$, and the maximum degree in G by $\Delta(G)$. A graph G is d -regular, for some non-negative integer d , if we have $\delta(G) = \Delta(G) = d$. A 3-regular graph is also called *cubic*, while a graph G is *subcubic* if $\Delta(G) \leq 3$.

A *bridge* in a graph G is an edge e whose removal increases the number of connected components, i.e., $G - e$ has strictly more components than G . Equivalently, e is a bridge if e is not contained in any cycle of G . A *bridgeless* graph is one that contains no bridge. Note that a bridgeless graph may be disconnected. On the other hand, for a positive integer k , a graph $G = (V, E)$ is k -connected if $|V| \geq k + 1$ and for any set U of $k - 1$ vertices in G the graph $G - U$ is connected. In particular, a graph G of maximum degree $\Delta(G) \leq 3$ is 2-connected if and only if G is connected and bridgeless. A 2-connected graph is sometimes also called *biconnected*, while a 3-connected graph is sometimes also called *triconnected*.

A *planar embedding* \mathcal{E} of a (planar) graph G is (in a sense that we need not make precise here) an equivalence class of crossing-free drawings of G in the plane. In particular, a planar embedding determines the set F of all *faces*, the distinguished *outer face* $f_0 \in F$, the clockwise ordering of incident edges around each vertex and the *boundary* of each face as a set of *facial walks*, each being a clockwise ordering of vertices and edges (with repetitions allowed). The edges and vertices incident to the outer face are called *outer edges* and *outer vertices*, while all others are *inner edges* and *inner vertices*. For every embedding \mathcal{E} of G we define the *flipped embedding* \mathcal{E}' to be the embedding obtained from \mathcal{E} by reversing the clockwise order of incident edges at each vertex. This operation changes neither the set of faces nor the outer face. Whitney's Theorem [30] states that a 3-connected planar graph G has a unique embedding (up to the choice of the outer face and flipping).

Generalized (Anti)factors. If G is a subgraph of H , denoted $G \subseteq H$, and v is a vertex of G , then we denote the degree of v in G by $\deg_G(v)$. If $V(G) = V(H)$, then G is called a *spanning* subgraph of H . If each vertex v of H is assigned a set $B(v) \subseteq \{0, \dots, \deg_H(v)\}$, then a spanning subgraph G of H is called a *B-factor* of H if and only if $\deg_G(v) \in B(v)$ for every vertex v . Lovász [21] introduced *B-factors* and the GENERALIZED FACTOR-problem that, given graph H and for each vertex v in H a set $B(v)$, asks whether H admits some *B-factor*. A set $B(v)$ is said to have a *gap of length* $\ell \geq 1$ if there is an integer $i \in B(v)$ such that $i + 1, \dots, i + \ell \notin B(v)$, and $i + \ell + 1 \in B(v)$. While the GENERALIZED FACTOR-problem is NP-complete in general [21], it can be solved in polynomial time if all gaps of each $B(v)$ have length one [8].

Now let $\bar{B}(v) \subseteq \{0, \dots, \deg_H(v)\}$ be another set assigned to each vertex v . A spanning subgraph G of H is called a *\bar{B} -antifactor*, if and only if $\deg_G(v) \notin \bar{B}(v)$. One can think of $\bar{B}(v)$ as forbidden degrees for v in G . The GENERALIZED ANTIFACTOR-problem asks whether H admits a *\bar{B} -antifactor*. Note that the set $\{0, \dots, \deg_H(v)\} \setminus \bar{B}(v)$ is finite, so the GENERALIZED ANTIFACTOR-problem is indeed a special case of the GENERALIZED FACTOR-problem. Therefore, an instance of the GENERALIZED ANTIFACTOR-problem with no two consecutive integers in any $\bar{B}(v)$ corresponds to an instance of the GENERALIZED FACTOR-problem with gaps of length at most one¹ and can be solved in polynomial time [8].

In Section 2.2 we use a theorem by Sebö [24], giving an efficient algorithm to compute generalized antifactors without two consecutive forbidden degrees.

► **Theorem 3** (Sebö [24]). *Let $H = (V, E)$ be a graph and for each vertex $v \in V$ let $\bar{B}(v) \subseteq \{0, \dots, \deg_H(v)\}$ be a set containing no two consecutive integers. Then we can compute a \bar{B} -antifactor in time $\mathcal{O}(|V| \cdot |E|)$, or conclude that no such exists.*

SPQR-Tree. The *SPQR-tree* is a tree-like data structure that compactly encodes all planar embeddings of a biconnected planar graph. It was introduced by Di Battista and Tamassia [10] and can be computed in linear time [15]. Its precise definition includes quite a number of technical terms, of which we define the crucial ones below. This makes our exposition self-contained, while also ensuring the established terminology for experienced readers. We give an illustrating example in Figure 2.

The SPQR-tree of a biconnected planar graph G is a rooted tree T , where each vertex μ of T is associated to a multigraph $\text{skel}(\mu)$ that is called the *skeleton* of μ . This multigraph $\text{skel}(\mu)$ must be of one of four types determining whether μ is an S-, a P-, a Q- or an R-vertex:

- S-vertex: $\text{skel}(\mu)$ is a simple cycle.
- P-vertex: $\text{skel}(\mu)$ consists of two vertices and at least three parallel edges.
- Q-vertex: $\text{skel}(\mu)$ consists of two vertices with two parallel edges.
- R-vertex: $\text{skel}(\mu)$ is triconnected.

Some of the edges of the skeletons can be marked as *virtual* edges. An edge $e = \mu\nu$ of the SPQR-tree T corresponds to two virtual edges, exactly one in $\text{skel}(\mu)$ and one in $\text{skel}(\nu)$. Conversely, each virtual edge corresponds to exactly one tree edge of T in this way. We refer again to Figure 2 for an example.

Under above conditions, the defining property of the SPQR-tree T is that G can be obtained by *gluing* along the virtual edges: For each tree edge $e = \mu\nu$, the skeletons $\text{skel}(\mu)$ and $\text{skel}(\nu)$ are identified at the corresponding endpoints of the two virtual edges associated to e and then the virtual edges are removed.

¹ Let us point out a subtlety here illustrating that this correspondence is not one-to-one. Requiring that $\bar{B}(v)$ does not contain two consecutive integers is stronger than requiring gaps of length 1 in $B(v) := \{0, \dots, \deg_H(v)\} \setminus \bar{B}(v)$. For example, consider a vertex v with $\deg_H(v) = 5$ and $\bar{B}(v) = \{1, 3, 4, 5\}$. Then $B(v) = \{0, 2\}$ has a gap of length 1, even though $\bar{B}(v)$ contained consecutive integers.

■ **Figure 2** A graph with an edge e_ρ (left) and its SPQR-tree rooted at the Q-vertex ρ corresponding to e_ρ (right). Each tree node μ shows the skeleton $\text{skel}(\mu)$ in which the virtual edge to its parent is shown thicker. The (blue) tree edges indicate the associated pairs of virtual edges.

We additionally require that no two S-vertices and no two P-vertices are adjacent in T , as otherwise the skeletons of two such vertices can be merged into the skeleton of a new vertex of the same type. Further, exactly one of the two parallel edges in a Q-vertex is a virtual edge while S-, P- and R-vertices contain only virtual edges. Under these conditions the SPQR-tree of G is unique. There is exactly one Q-vertex per edge in G and these form the leaves of the SPQR-tree. The inner S-, P- and R-vertices correspond more or less² to the separation pairs (that is, pairs of vertices forming a cut set) of G [10].

Assume that an arbitrary vertex ρ of T is fixed as the root. For some vertex μ in T let π be its parent. Further, let u, v be the endpoints of the virtual edge in $\text{skel}(\mu)$ associated with the tree edge $\mu\pi$ in T . Then the graph obtained by gluing $\text{skel}(\mu)$ with all skeletons in its subtree and without the virtual edge uv is called the *pertinent graph* of μ and denoted by $\text{pert}(\mu)$. Note that $\text{pert}(\mu)$ is always connected.

SPQR-Tree and Planar Embeddings. If the SPQR-tree T is rooted at a Q-vertex ρ corresponding to an edge e_ρ of G , then T represents all planar embeddings of G in which e_ρ is an outer edge [10]. When G is constructed by gluing corresponding virtual edges, one has the following choices on the planar embedding:

- Whenever the corresponding virtual edges of an S-, P- or R-vertex μ and its parent are glued together, this leaves two choices for the planar embedding: Having decided for an embedding \mathcal{E}_μ of $\text{pert}(\mu)$ already, we can insert \mathcal{E}_μ or the flipped embedding \mathcal{E}'_μ .
- The parallel virtual edges of a P-vertex μ associated to virtual edges of children can be permuted arbitrarily. Every permutation leads to a different planar embedding of $\text{skel}(\mu)$.
- Gluing at the virtual edge of a Q-vertex μ replaces the virtual edge uv by the “real” edge uv in G . This has no effect on the embedding.

Let \mathcal{E} be a planar embedding of G having e_ρ as an outer edge. Further, let μ be an inner vertex of the SPQR-tree and u_μ, v_μ be the endpoints of the virtual edge in $\text{skel}(\mu)$ corresponding to the parent edge of μ in T . Lastly, let \mathcal{E}_μ be the restriction of \mathcal{E} to $\text{pert}(\mu)$ and let f_μ^o be the outer face of \mathcal{E}_μ . As e_ρ is an outer edge of \mathcal{E} , it follows that u_μ and v_μ are outer vertices in \mathcal{E}_μ . The $u_\mu v_\mu$ -path in $\text{pert}(\mu)$ having f_μ^o to its left (right) is the *left (right) outer path* of \mathcal{E}_μ . Lastly, we define the *left (right) outer face* of \mathcal{E}_μ inside \mathcal{E} to be the face of \mathcal{E} left (right) of the left (right) outer path of \mathcal{E}_μ .

² In fact they correspond to so-called *split pairs*. However, we omit their formal discussion, as it is not needed here.

2 The 3-Augmentation-Problem

2.1 Reduction to the 2-Connected Case

► **Proposition 4.** *For a disconnected graph G with connected components G_1, \dots, G_k , $k \geq 2$, we have that*

- (i) *G has a 3-augmentation if and only if each G_i has a 3-augmentation, $i = 1, \dots, k$, and*
- (ii) *G has a 2-connected 3-augmentation if and only if each G_i has a 3-augmentation and no G_i is 3-regular, $i = 1, \dots, k$.*

Proof.

- (i) Any 3-augmentation of G is also a 3-augmentation of each G_i , showing already necessity. For sufficiency, observe that the 3-augmentations of different G_i are vertex-disjoint and hence their union is a 3-augmentation of G .
- (ii) Like above, a 2-connected 3-augmentation H of G is also a 3-augmentation of each G_i , $i = 1, \dots, k$. Moreover, as H is connected, each G_i has a vertex with at least one incident edge in $E(H) - E(G)$, showing that G_i is not 3-regular.

On the other hand, for $i = 1, \dots, k$ let H_i be a 3-augmentation of G_i . Without loss of generality each H_i is connected (hence 2-connected since 3-augmentations are bridgeless). As G_i is not 3-regular, we can pick an edge e_i from $E(H_i) - E(G_i)$, $i = 1, \dots, k$. Next, choose a planar embedding \mathcal{E} of the disjoint union $H_1 \cup \dots \cup H_k$ where each of e_1, \dots, e_k is an outer edge. Finally, add a copy of $K_4^{(2k)}$ into the outer face of \mathcal{E} , delete e_1, \dots, e_k , and connect the $2k$ degree-2 vertices of $H_1 \cup \dots \cup H_k$ with the $2k$ degree-2 vertices of $K_4^{(2k)}$ by a non-crossing matching. The result is a 2-connected 3-augmentation of G (by definition a 3-augmentation is bridgeless, so connectivity implies 2-connectivity). ◀

► **Proposition 5.** *A graph G admits a 3-augmentation if and only if $\Delta(G) \leq 3$ and each block of G admits a 3-augmentation.*

Proof. If G is bridgeless, then each connected component is a single block and thus admits a 3-augmentation by assumption. The disjoint union of these is a 3-augmentation of G .

Otherwise, consider G with a bridge $e = uv$. Let G_1 be the connected component of $G - e$ containing u , and let the remaining graph be $G_2 = G - G_1$. It is enough to show that if G_1 and G_2 have 3-augmentations H_1 respectively H_2 , then G has a 3-augmentation, too. To this end, consider an edge $e_1 \in E(H_1) - E(G_1)$ incident to u and an edge $e_2 \in E(H_2) - E(G_2)$ incident to v . These edges exist as $\deg_{G_1}(u), \deg_{G_2}(v) \leq \Delta(G) - 1 \leq 2$ but $\deg_{H_1}(u) = \deg_{H_2}(v) = 3$. Choose a planar embedding of $H_1 \cup H_2$ with e_1 and e_2 being outer edges. Denoting by a, b the endpoints of e_1, e_2 different from u, v , we see that $(H_1 - e_1) \cup (H_2 - e_2) \cup \{uv, ab\}$ is a 3-augmentation of G , as desired. ◀

2.2 The Fixed Embedding Setting

As usual for embedding-dependent problems for planar graphs, it makes sense to distinguish between the planar graph G being given with a fixed embedding that shall not be altered, and the setting with variable embedding where we solely have G as the input and shall find a suitable embedding for G or decide that no such exists. The 3-augmentation problem is formulated in the variable embedding setting. However, let us treat the variant with a fixed embedding first, as this will be a crucial subroutine for the variable embedding setting later.

► **Proposition 6.** *Let G be an n -vertex 2-connected planar multigraph of maximum degree $\Delta(G) \leq 3$ with a fixed planar embedding \mathcal{E} . Then we can compute in time $\mathcal{O}(n^2)$ a 3-augmentation H of G with a planar embedding \mathcal{E}_H whose restriction to G equals \mathcal{E} , or conclude that no such exists.*

Proof. Let V' denote the subset of the vertices of G with $\deg_G(v) \leq 2$ and let F denote the set of faces of \mathcal{E} . Note that since G is 2-connected, all $v \in V'$ have $\deg_G(v) = 2$. We consider the bipartite vertex-face incidence graph $I = (V' \cup F, E(I))$ with vertex-set $V' \cup F$ and edge-set $E(I) := \{vf \mid v \in V', f \in F, v \text{ is incident to } f\}$. Note that I has $O(n)$ vertices and at most $2n$ edges, since $\Delta(G) \leq 3$. We define an instance of the GENERALIZED ANTIFACTOR-problem by assigning each vertex x of I (corresponding to a vertex in G or a face in F) a set $\overline{B}(x) \subseteq \{0, \dots, \deg_I(x)\}$:

$$\overline{B}(x) := \begin{cases} \{0, 2\} & \text{for } x \in V' \\ \{1\} & \text{for } x \in F \end{cases}$$

Note that no $\overline{B}(x)$ contains two consecutive integers.

▷ **Claim 7.** Graph G admits a 3-augmentation H extending the embedding \mathcal{E} if and only if I admits a \overline{B} -antifactor.

Proof. First assume H is a 3-augmentation of G with a planar embedding \mathcal{E}_H that extends \mathcal{E} . Hence every edge $e \in E(H) - E(G)$ lies in a unique face of \mathcal{E} . We construct a \overline{B} -antifactor of I as follows. For each degree-2 vertex v of G , let f_v be the face of \mathcal{E} that contains the unique edge in $E(H) - E(G)$ incident to v . We claim that $J = (V' \cup F, \{vf_v \mid v \in V'\})$ is a \overline{B} -antifactor of I . In fact, $\deg_J(v) = 1$ for each degree-2 vertex $v \in V'$. Now if we would have $\deg_J(f) = 1$ for some face $f \in F$, then exactly one vertex $v \in V'$ has exactly one incident edge e lying in face f . In particular, the other endpoint of e is not a vertex of G . But then e is a bridge and H is not a 3-augmentation. Hence $\deg_J(f) \neq 1$ for each $f \in F$ and I indeed admits a \overline{B} -antifactor.

Conversely assume now that I has some \overline{B} -antifactor J . Then we construct the desired 3-augmentation H of G as follows. Inside each face f of \mathcal{E} with $\deg_J(f) > 0$ place a copy K_f of $K_4^{(\deg_J(f))}$. Connect the $\deg_J(f)$ degree-2 vertices $v \in V'$ with $vf \in E(J)$ by a non-crossing matching with the $\deg_J(f)$ degree-2 vertices of K_f . Call the resulting graph H and its resulting planar embedding \mathcal{E}_H . Then H is 2-connected (in particular bridgeless) as G is 2-connected and $\deg_J(f) \neq 1$ for each $f \in F$. Moreover, H is 3-regular. In fact, for each vertex $v \in V'$ we have $\deg_H(v) = \deg_G(v) + 1 = 3$, as J is a \overline{B} -antifactor. Finally, restricting \mathcal{E}_H to G gives back embedding \mathcal{E} . ◀

Now Claim 7 immediately finishes the proof because no $\overline{B}(x)$ contains two consecutive integers. Hence, by Sebö's algorithm [24] (cf. Theorem 3) we can compute a \overline{B} -antifactor of I in $\mathcal{O}(n^2)$ time, or conclude that no such exists. ◀

2.3 The Variable Embedding Setting

Even an unlabeled 2-connected subcubic planar graph G can have exponentially many different planar embeddings (e.g., the $(2 \times n)$ -grid graph). Thus, iterating over all embeddings of G and applying the algorithm from Proposition 6 to each of them is not a polynomial-time algorithm and hence no feasible approach for us. In this section we describe how to use the SPQR-tree of G to efficiently find a planar embedding \mathcal{E} of G such that there is a 3-augmentation H of G extending \mathcal{E} , or conclude that no such embedding exists. The algorithm from Proposition 6 will be an important subroutine.

► **Proposition 8.** *Let G be an n -vertex 2-connected planar graph of maximum degree $\Delta(G) \leq 3$. Then we can compute in $\mathcal{O}(n^2)$ time a 3-augmentation H of G or conclude that no such exists.*

Overview. The proof of Proposition 8 uses a bottom-up dynamic programming approach on the SPQR-tree T of G rooted at a Q-vertex ρ corresponding to some edge e_ρ in G . Consider a vertex $\mu \neq \rho$ in T . Let uv be the virtual edge in $\text{skel}(\mu)$ that is associated to the parent edge of μ . Recall that each embedding \mathcal{E} of G with e_ρ on the outer face, when restricted to the pertinent graph $\text{pert}(\mu)$, gives an embedding \mathcal{E}_μ of $\text{pert}(\mu)$ whose inner faces are also inner faces of \mathcal{E} , and with u and v being outer vertices of \mathcal{E}_μ . The outer face of \mathcal{E}_μ is composed of two (not necessarily edge-disjoint) u - v -paths; the left and right outer path of \mathcal{E}_μ , which are contained in the left and right outer face of \mathcal{E}_μ inside \mathcal{E} , respectively. We seek to partition the (possibly exponentially many) planar embeddings of $\text{pert}(\mu)$ with u, v on its outer face into a constant number of equivalence classes based on how many edges in a 3-augmentation of G could possibly “connect” $\text{pert}(\mu)$ with the rest of the graph G inside the left or right outer face of \mathcal{E}_μ inside \mathcal{E} . This corresponds³ to the number of degree-2 vertices on the left and right side in so-called *inner augmentations* of \mathcal{E}_μ . Loosely speaking, it will be enough for us to distinguish three cases for the left side (0, 1, or at least 2 connections), the symmetric three cases for the right side, and to record which of the nine resulting combinations are possible. Note that this grouping of embeddings of \mathcal{E}_μ into constantly many classes is the key insight that allows an efficient dynamic program.

Whether a particular equivalence class is realizable by some planar embedding \mathcal{E}_μ of $\text{pert}(\mu)$ will depend on the vertex type of μ (S-, P- or R-vertex) and the realizable equivalence classes of its children μ_1, \dots, μ_k . In the end, we shall conclude that the whole graph G has a 3-augmentation if and only if for the unique child μ of the root ρ of T the equivalence class of embeddings of $\text{pert}(\mu)$ for which neither the left nor the right side has any connections is non-empty.

Most of our arguments are independent of SPQR-trees and we instead consider so-called uv -graphs, which are slightly more general than pertinent graphs. We shall introduce inner augmentations of uv -graphs, which then give rise to label sets for uv -graphs, both in a fixed and variable embedding setting. These label sets encode the aforementioned number of connections between the uv -graph as a subgraph of G and the rest of G in a potential 3-augmentation. After showing that we can compute even variable label sets by resorting to the fixed embedding case and Proposition 6, we then present the final dynamic program along the rooted SPQR-tree T of G .

uv -Graphs and Labels. A uv -graph is a connected multigraph G_{uv} with $\Delta(G_{uv}) \leq 3$, two distinguished vertices u, v of degree at most 2, together with a planar embedding \mathcal{E}_{uv} such that u and v are outer vertices. A connected multigraph $H_{uv} \supseteq G_{uv}$ with planar embedding \mathcal{E}_H is an *inner augmentation* of G_{uv} if

- \mathcal{E}_H extends \mathcal{E}_{uv} and has u, v on its outer face,
- each of u, v has the same degree in H_{uv} as in G_{uv} ,
- every vertex of H_{uv} except for u, v has degree 1 or 3,
- every degree-1 vertex of H_{uv} lies in the outer face of \mathcal{E}_H and
- every bridge of H_{uv} that is not a bridge of G_{uv} is incident to a degree-1 vertex.

Because u, v are outer vertices in \mathcal{E}_H , one could add another edge e_{uv} (oriented from u to v) into the outer face of \mathcal{E}_H preserving planarity (this edge is not part of the inner augmentation). Then e_{uv} splits the outer face into two faces f_A, f_B left and right of e_{uv} , respectively. Each degree-1 vertex of H_{uv} now lies either inside f_A or f_B .

³ up to the fact that left and right outer path may share degree-2 vertices, each of which sends however its third edge into only one of the left and right outer face

We are interested in the number of degree-1 vertices in each of these faces of \mathcal{E}_H and write $d(H_{uv}, \mathcal{E}_H) = (a, b)$ if an inner augmentation H_{uv} of G_{uv} has exactly a degree-1 vertices inside f_A and exactly b degree-1 vertices inside f_B .

► **Lemma 9.** *Let H_{uv} be an inner augmentation of G_{uv} with $d(H_{uv}, \mathcal{E}_H) = (a, b)$. If $a \geq 2$, then G_{uv} has an inner augmentation H_{uv}^0 with $d(H_{uv}^0, \mathcal{E}_H^0) = (0, b)$ and an inner augmentation H_{uv}^1 with $d(H_{uv}^1, \mathcal{E}_H^1) = (1, b)$. A symmetric statement holds when $b \geq 2$.*

Proof. Add edge uv to the inner augmentation H_{uv} such that it has a degree-1 vertices in f_A . We add a copy of $K_4^{(a)}$ into f_A and identify the a degree-2 vertices of $K_4^{(a)}$ with the a degree-1 vertices in f_A in a non-crossing way. Ignoring edge uv , the obtained graph is the desired inner augmentation H_{uv}^0 with $d(H_{uv}^0, \mathcal{E}_H^0) = (0, b)$. We obtain H_{uv}^1 by additionally subdividing an edge of $K_4^{(a)}$ that is incident to f_A once and by attaching a degree-1 vertex to it into f_A . ◀

Motivated by Lemma 9, we focus on inner augmentations H_{uv} with $d(H_{uv}, \mathcal{E}_H) = (a, b)$ where $a, b \in \{0, 1\}$, and assign to H_{uv} in this case the *label* \mathbf{ab} with $\mathbf{a}, \mathbf{b} \in \{0, 1\}$.

The *embedded label set* $L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$ contains all labels \mathbf{ab} such that there is an inner augmentation H_{uv} of G_{uv} with label \mathbf{ab} . Allowing other planar embeddings of G_{uv} , we further define the *variable label set* as $L_{\text{var}}(G_{uv}) = \bigcup_{\mathcal{E}} L_{\text{emb}}(G_{uv}, \mathcal{E})$, where \mathcal{E} runs over all planar embeddings of G_{uv} where u and v are outer vertices. As this in particular includes for each embedding \mathcal{E} of G_{uv} also the flipped embedding \mathcal{E}' of G_{uv} , it follows that $\mathbf{ab} \in L_{\text{var}}(G_{uv})$ if and only if $\mathbf{ba} \in L_{\text{var}}(G_{uv})$. Whenever this property holds for a (variable or embedded) label set, we call the label set *symmetric*. Hence, all variable label sets are symmetric, but embedded label sets may or may not be symmetric.

For brevity, let us use \star as a wildcard character, in the sense that if $\{\mathbf{x0}, \mathbf{x1}\}$ is in an embedded or variable label set for some $\mathbf{x} \in \{0, 1\}$, then we shorten the notation and replace them by a label $\mathbf{x}\star$. Symmetrically, we use the notation $\star\mathbf{x}$ and in particular define $\{\star\star\} := \{00, 01, 10, 11\}$. Using this notation, the eight possible symmetric label sets are:

$$\emptyset, \{00\}, \{01, 10\}, \{11\}, \{0\star, \star 0\}, \{00, 11\}, \{1\star, \star 1\}, \{\star\star\} \quad (1)$$

The following lemma reveals the significance of inner augmentations and label sets.

► **Lemma 10.** *Let G be a 2-connected graph with $\Delta(G) \leq 3$ and \mathcal{E} be an embedding of G with some outer edge $e = xy$. Further, let G_{uv} be the uv -graph obtained from G by deleting e and adding two new vertices u, v with edges ux and vy into the outer face of \mathcal{E} . Then G has a 3-augmentation if and only if $00 \in L_{\text{var}}(G_{uv})$.*

Proof. First let $H \supseteq G$ be a 3-augmentation of G and let \mathcal{E}_H be an embedding of H with $e = xy$ being an outer edge. Then deleting e and adding two new vertices u, v with edges ux and vy into the outer face of \mathcal{E}_H results in an inner augmentation H_{uv} of G_{uv} with respect to the embedding of G_{uv} inherited from \mathcal{E}_H . As adding an edge e_{uv} from u to v into H_{uv} gives a graph with no degree-1 vertices, we have $00 \in L_{\text{var}}(G_{uv})$.

Conversely, assume that $00 \in L_{\text{var}}(G_{uv})$. Then there is an embedding \mathcal{E}_{uv} of G_{uv} that allows for some inner augmentation H_{uv} with embedding \mathcal{E}_H for which $H_{uv} + e_{uv}$ has no degree-1 vertices, where $e_{uv} = uv$ denotes a new edge between u and v . Thus, in H_{uv} the vertices u and v have degree 1 (as in G_{uv}), every vertex of H_{uv} except u, v has degree 3, and the only bridges of H_{uv} are the edges ux and vy . Then we obtain a 3-augmentation H of G by removing ux, vy from H_{uv} and adding the edge xy into the outer face of \mathcal{E}_H . In case, H_{uv} already contains the edge xy , this is replaced by a copy of $K_4^{(2)}$ with two non-crossing edges between x, y and the two degree-2 vertices of $K_4^{(2)}$. ◀

62:10 Efficient Recognition of Subgraphs of Planar Cubic Bridgeless Graphs

■ **Figure 3** a–g The seven gadgets for the seven non-empty variable label sets $L_{\text{var}}(G_{uv})$ of a uv -graph G_{uv} . h Modification to locally replace a degree-2 vertex by four degree-3-vertices.

Gadgets. In our algorithm below, we aim to replace certain uv -graphs X (with variable embedding) by uv -graphs Y with fixed embedding \mathcal{E}_Y , such that the variable label set $L_{\text{var}}(X)$ equals the embedded label set $L_{\text{emb}}(Y, \mathcal{E}_Y)$. This will allow us to use Proposition 6 from the fixed embedding setting as a subroutine.

The following lemma describes seven uv -graphs, each with a fixed embedding, corresponding to the seven different non-empty variable label sets as given in (1). For this purpose, each such *gadget* is itself a uv -graph Y with a fixed embedding \mathcal{E}_Y .

► **Lemma* 11.** *For every uv -graph G_{uv} with $L_{\text{var}}(G_{uv}) \neq \emptyset$ there exists a gadget Y with an embedding \mathcal{E}_Y such that u, v are outer vertices and $L_{\text{emb}}(Y, \mathcal{E}_Y) = L_{\text{var}}(G_{uv})$.*

Lemma 11 is proven in the full version [13], but the claimed gadgets are shown in Figure 3.

Computing a Label Set. In our algorithm below we want to compute the variable label sets of $\text{pert}(\mu)$ for vertices μ of the rooted SPQR-tree T of G . As we will see, we can reduce this to a constant number of computations of embedded label sets of certain uv -graphs that are specifically crafted to encode all the possible embeddings of $\text{pert}(\mu)$. The following lemma describes how to do this.

► **Lemma* 12.** *Let G_{uv} be an n -vertex uv -graph and \mathcal{E}_{uv} a planar embedding where u and v are outer vertices. Then we can check each of the following in time $\mathcal{O}(n^2)$:*

- Whether $00 \in L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$.
- Whether $01 \in L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$ or $10 \in L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$.
- Whether $11 \in L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$.

In particular, if $L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$ is symmetric, then this is sufficient to determine the exact embedded label set $L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$.

The idea for Lemma 12 is similar to Lemma 10: For each check, we do some small local modifications to G_{uv} in order to obtain an embedded planar graph G_{uv}^+ that has a 3-augmentation extending its embedding if and only if $L_{\text{emb}}(G_{uv}, \mathcal{E}_{uv})$ contains the specific label. Then the result follows from Proposition 6. A full proof is given in the full version [13].

Algorithm for Variable Embedding. In order to decide whether a given biconnected planar graph G admits some planar embedding which admits a 3-augmentation, we use the SPQR-tree T of G . Rooting T at some Q-vertex ρ , the pertinent graph $\text{pert}(\mu)$ of a vertex μ in T is a subgraph of G . Moreover, if $u_\mu v_\mu$ is the virtual edge in $\text{skel}(\mu)$ associated to the parent edge of μ , then $\text{pert}(\mu)$ is a uv -graph (with u_μ, v_μ taking the roles of u, v in the uv -graph). Now the variable label set $L_{\text{var}}(\text{pert}(\mu))$ is a constant-size representation of all possible labels that any possible embedding of an inner augmentation of $\text{pert}(\mu)$ can have (having u_μ and v_μ on its outer face). The remainder of this section describes how the variable label sets of all vertices in the SPQR-tree can be computed by a bottom-up dynamic program.

► **Lemma* 13.** *Let μ be an inner R-, S-, or P-vertex of the SPQR-tree and μ_1, \dots, μ_k be its children. Further assume that the variable label sets $L_{\text{var}}(\text{pert}(\mu_i))$, for $i = 1, \dots, k$, are non-empty and known. Then the variable label set $L_{\text{var}}(\text{pert}(\mu))$ can be computed in time $\mathcal{O}(\|\text{skel}(\mu)\|^2)$.*

The idea to prove Lemma 13 is to consider $\text{skel}(\mu)$ with its essentially unique embedding and to replace for each μ_i the associated virtual edge by the embedded gadget Y from Lemma 11 (cf. Figure 3) with $L_{\text{emb}}(Y, \mathcal{E}_Y) = L_{\text{var}}(\text{pert}(\mu_i))$. Then the virtual edge uv associated to the parent of μ gets removed to obtain an embedded uv -graph on $\mathcal{O}(\|\text{skel}(\mu)\|)$ vertices, whose embedded label set can then be computed with Lemma 12. A full proof is given in the full version [13].

Lemma 13 computes the variable label set of an inner vertex of the SPQR-tree, requiring that the variable label sets of its children are non-empty. If this condition is not satisfied, i.e., at least one vertex μ has $L_{\text{var}}(\text{pert}(\mu)) = \emptyset$, then the following lemma applies:

► **Lemma 14.** *If $L_{\text{var}}(\text{pert}(\mu)) = \emptyset$ for some vertex μ of the SPQR-tree T of G , then G has no 3-augmentation.*

Proof. Assuming that G has a 3-augmentation H , we shall show that $L_{\text{var}}(\text{pert}(\mu)) \neq \emptyset$ for every vertex μ of T . If μ is the root, let u, v be the two unique vertices in $\text{skel}(\mu)$ (because $\mu = \rho$ is a Q-vertex). If μ is not the root, let u, v be the endpoints of the virtual edge associated to the parent edge of μ .

By the definition of labels, $L_{\text{var}}(\text{pert}(\mu)) \neq \emptyset$ if there is some inner augmentation of $\text{pert}(\mu)$ for at least one of its planar embeddings with u, v on its outer face. But the 3-augmentation H of G induces an inner augmentation of $\text{pert}(\mu)$ as follows: Let \mathcal{E}_H be a planar embedding of H with outer edge e_ρ and \mathcal{E}_G its restriction to G . Recall that then u, v are outer vertices of $\text{pert}(\mu)$ in \mathcal{E}_G . Consider the embedded subgraph of H consisting of $\text{pert}(\mu)$ and all vertices and edges of H inside inner faces of $\text{pert}(\mu)$ in \mathcal{E}_G . For each vertex $w \neq u, v$ on the outer face of $\text{pert}(\mu)$ in \mathcal{E}_G incident to an edge of H in the outer face of $\text{pert}(\mu)$, we add a new pendant edge at w into the outer face of $\text{pert}(\mu)$ in \mathcal{E}_G . The resulting graph is an inner augmentation of $\text{pert}(\mu)$ and hence $L_{\text{var}}(\text{pert}(\mu)) \neq \emptyset$. ◀

Now that we considered S-, P- and R-vertices, we are finally set up to prove Proposition 8. There we claim that we can decide in polynomial time whether a biconnected planar graph G with $\Delta(G) \leq 3$ has a 3-augmentation.

Proof of Proposition 8. As mentioned above, we use bottom-up dynamic programming on the SPQR-tree T of G rooted at an arbitrary Q-vertex ρ corresponding to an edge e_ρ in G .

The base cases are the leaves of T , all of which are Q-vertices. The variable label set of a leaf μ is $L_{\text{var}}(\text{pert}(\mu)) = \{00\}$: $\text{pert}(\mu)$ is just a single edge and the only inner augmentation of $\text{pert}(\mu)$ is $\text{pert}(\mu)$ itself, and as such has label 00.

Now let μ be an inner vertex of T and thus be either an S-, a P- or an R-vertex. All its children μ_1, \dots, μ_k have already been processed and their variable label sets $L_{\text{var}}(\text{pert}(\mu_i))$ are known. Then the variable label set $L_{\text{var}}(\text{pert}(\mu))$ can be computed in time $\mathcal{O}(\|\text{skel}(\mu)\|^2)$ (which is actually $\mathcal{O}(1)$ in case of a P-vertex) by Lemma 13. To apply this lemma, we need to guarantee that the variable label sets $L_{\text{var}}(\text{pert}(\mu_i))$ of the children are non-empty. If this is not the case, then by Lemma 14 graph G has no 3-augmentation and we can stop immediately.

It remains to consider the root ρ of the SPQR-tree. Recall that $\text{pert}(\rho) = G$. Following the setup of Lemma 10, let x, y be the two unique vertices of $\text{skel}(\rho)$ and xy be the unique non-virtual edge, i.e., the edge $e_\rho = xy$ of G . Let G_{uv} be the uv -graph obtained from $G = \text{pert}(\rho)$ by deleting $e_\rho = xy$ and adding two new pendant edges ux, vy . Note that x and y have the same degree in G_{uv} as in G . By Lemma 10, G has a 3-augmentation if and only if $00 \in L_{\text{var}}(G_{uv})$.

To check whether $00 \in L_{\text{var}}(G_{uv})$, let μ be the unique child of ρ . Thus we have $\text{pert}(\mu) = G - e_\rho$. We have already computed $L_{\text{var}}(\text{pert}(\mu))$ and can assume by Lemma 14 that it is non-empty. Consider the gadget Y with embedding \mathcal{E}_Y from Lemma 11 such that $L_{\text{emb}}(Y, \mathcal{E}_Y) = L_{\text{var}}(\text{pert}(\mu))$. Let u' and v' denote the two degree-1 vertices in Y . If both x and y have degree 3 in G (hence also in G_{uv}), then $L_{\text{var}}(G_{uv}) = L_{\text{var}}(\text{pert}(\mu)) = L_{\text{emb}}(Y, \mathcal{E}_Y)$ and we already know whether or not 00 is contained in these label sets.

If x has degree 2 in G (hence also degree 2 in G_{uv} , while degree 1 in $\text{pert}(\mu)$), then x receives a new edge in inner augmentations of G_{uv} but not in inner augmentations of $\text{pert}(\mu)$. For Y to model $L_{\text{var}}(G_{uv})$ instead of $L_{\text{var}}(\text{pert}(\mu))$, we subdivide in Y the edge at u' by a new vertex x' . Similarly, if y has degree 2 in G , we subdivide in Y the edge at v' . For the resulting graph Y' with embedding $\mathcal{E}_{Y'}$ it follows that $L_{\text{var}}(G_{uv}) = L_{\text{emb}}(Y', \mathcal{E}_{Y'})$ and we can check whether 00 is contained in these label sets by calling Lemma 12 on Y' with embedding $\mathcal{E}_{Y'}$. This takes constant time, as Y' has constant size.

The overall runtime is the time needed to construct the SPQR-tree plus the time spent processing each of its vertices. Gutwenger and Mutzel [15] show how to construct the SPQR-tree in time $\mathcal{O}(n)$. The time for the dynamic program traversing the SPQR-tree T is

$$\mathcal{O}\left(\sum_{\mu \in V(T)} \|\text{skel}(\mu)\|^2\right) \subseteq \mathcal{O}\left(\left(\sum_{\mu \in V(T)} \|\text{skel}(\mu)\|\right)^2\right) \subseteq \mathcal{O}(n^2),$$

where the first step uses that for a set of positive integers the sum of their squares is at most the square of their sum, and the second step uses that the SPQR-tree has linear size. \blacktriangleleft

3 Discussion and Open Problems

In this paper we showed how to test in polynomial time whether a planar graph G is a subgraph of some bridgeless cubic planar graph H . (We call such H a 3-augmentation of G .) Our motivation was to test whether G admits a proper 3-edge-coloring, because admitting a 3-augmentation is sufficient to conclude that $\chi'(G) \leq 3$. (This follows from the Four-Color-Theorem [1, 2] and the work of Tait [26].) However, there are 3-edge-colorable planar graphs with no 3-augmentation; $K_{2,3}$ is an easy example. For another class of examples, consider for instance any 3-connected 3-regular plane graph G (that is, the dual of a plane triangulation) and subdivide (with a new degree-2 vertex each) any set of at least two edges, where no two of these are incident to the same face of G (so their dual edges form a matching in the triangulation). The resulting graph G' has only one embedding (up to the choice of the outer face) and clearly no 3-augmentation. On the other hand, Conjecture 15 below predicts that G' is 3-edge colorable.

The computational complexity of the 3-EDGE COLORABILITY-problem for planar graphs remains open, while it is known to be NP-complete already for 3-regular, but not necessarily planar, graphs [17]. Similarly to our methods in Section 2.1, one can easily show that a planar subcubic graph is 3-edge-colorable if and only if all of its blocks (inclusion-maximal biconnected subgraphs) are 3-edge-colorable, i.e., 3-EDGE COLORABILITY reduces to the 2-connected case. A simple counting argument shows that a 2-connected subcubic graph G with exactly one degree-2 vertex is not 3-edge-colorable (independent of whether G is planar or not). The following conjecture, attributed to Grötzsch by Seymour [25], states that in the case of planar graphs, this is the only obstruction.

► **Conjecture 15** (Grötzsch, cf. [25]). *If G is a 2-connected planar graph of maximum degree $\Delta(G) \leq 3$, then G is 3-edge-colorable, unless it has exactly one vertex of degree 2.*

If Conjecture 15 is true, 3-EDGE COLORABILITY would be in P, as its condition is easy to check in linear time.

Finally, let us also briefly discuss planar graphs of maximum degree larger than 3. Vizing conjectured in 1965 that all planar graphs of maximum degree $\Delta \geq 6$ are Δ -edge-colorable, proving it only for $\Delta \geq 8$ [29]. As of today, it is known that all planar graphs of maximum degree $\Delta \geq 7$ are Δ -edge-colorable [14, 23, 31], and optimal edge colorings can be computed efficiently in these cases. The case $\Delta = 6$ is still open, while for $\Delta = 3, 4, 5$ there are planar graphs of maximum degree Δ that are not Δ -edge-colorable [29], and at least for $\Delta = 4, 5$ the Δ -EDGE COLORABILITY-problem is suspected to be NP-complete for planar graphs [6].

Generalizing Conjecture 15, Seymour's Exact Conjecture [25] states that every planar graph G is $\lceil \eta'(G) \rceil$ -edge-colorable, where $\eta'(G)$ denotes the fractional chromatic index of G . It is worth noting that Seymour's Exact Conjecture implies Vizing's Conjecture, as well as the Four-Color-Theorem; see e.g., the recent survey [5].

Abstract

Embeddings of graphs into distributions of trees that preserve distances in expectation are a cornerstone of many optimization algorithms. Unfortunately, online or dynamic algorithms which use these embeddings seem inherently randomized and ill-suited against adaptive adversaries.

In this paper we provide a new tree embedding which addresses these issues by *deterministically* embedding a graph into a single tree containing $O(\log n)$ copies of each vertex while preserving the connectivity structure of every subgraph and $O(\log^2 n)$ -approximating the cost of every subgraph. Using this embedding we obtain the first deterministic bicriteria approximation algorithm for the online covering Steiner problem as well as the first poly-log approximations for demand-robust Steiner forest, group Steiner tree and group Steiner forest.

1 Introduction

Probabilistic embedding of general metrics into distributions over trees are one of the most versatile tools in combinatorial and network optimization. The beauty and utility of these tree embeddings comes from the fact that their application is often simple, yet extremely powerful. Indeed, when modeling a network with length, costs, or capacities as a weighted graph, these embeddings often allow one to pretend that the graph is a tree. A common template for countless network design algorithms is to (1) embed the input weighted graph G into a randomly sampled tree T that approximately preserves the weight structure of G ; (2) solve the input problem on T and; (3) project the solution on T back into G .

A long and celebrated line of work [32, 3, 6, 17] culminated in the embedding of Fakcharoenphol, Rao and Talwar [17] – henceforth the “FRT embedding” – which showed that any weighted graph on n nodes can be embedded into a distribution over weighted trees in a way that $O(\log n)$ -approximately preserves distances in expectation. Together with the above template this reduces many graph problems to much easier problems on trees at the cost of an $O(\log n)$ approximation factor. This has led to a myriad of approximation, online, and dynamic algorithms with poly-logarithmic approximations and competitive ratios for NP-hard problems such as for k -server [5], metrical task systems [8], group Steiner tree and group Steiner forest [2, 36, 21], buy-at-bulk network design [4] and (oblivious) routing [37]. For many of these problems tree embeddings are the only known way of obtaining such algorithms on general graphs.

However, probabilistic tree embeddings have one drawback: Algorithms based on them naturally require randomization and their approximation guarantees only hold in expectation. For approximation algorithms – i.e., in the offline setting – there are derandomization tools, such as the FRT derandomizations given in [12, 17, 7], to overcome these issues. These derandomization results are so general that essentially any offline algorithm based on tree embeddings can be transformed into a deterministic algorithm with matching approximation guarantees (with only a moderate increase in running time). Unfortunately, these strategies are not applicable to online or dynamic settings where an adversary progressively reveals the input. Indeed, most online and dynamic algorithms that use FRT are randomized (e.g. [23, 28, 2, 19, 8, 36, 14, 15]).

This overwhelming evidence in the literature is driven by a well-known and fundamental barrier to the use of probabilistic tree embeddings in deterministic online and dynamic algorithms. More specifically and even worse, this is a barrier which prevents these algorithms from working against all but the weakest type of adversary. In particular, designing an online or dynamic algorithm which is robust to an oblivious adversary (which fixes all requests in advance, independently of the algorithm’s randomness) is often much easier than designing an algorithm which is robust to an adaptive adversary (which chooses the next request based on the algorithm’s current solution). As the actions of a deterministic algorithm can be fully predicted this distinction only holds for randomized algorithms – any deterministic algorithm has to always work against an adaptive adversary. For these reasons, many online and dynamic algorithms have exponentially worse competitive ratios in the deterministic or adaptive adversary setting than in the oblivious adversary setting. This is independent of computational complexity considerations.

The above barrier results from a repeatedly recognized and seemingly unavoidable phenomenon which prevents online algorithms built on FRT from working against adaptive adversaries. Specifically, there are graphs where every tree embedding must have many node pairs with polynomially-stretched distances [6]. There is nothing that prevents an adversary then from learning through the online algorithm’s responses which tree was sampled and then tailoring the remainder of the online instance to pairs of nodes that have highly stretched distances. The exact same phenomenon occurs in the dynamic setting; see, for example, [23] and [28] for dynamic algorithms with expected cost guarantees that only hold against oblivious adversaries because they are based on FRT. In summary, online and dynamic algorithms that use probabilistic tree embeddings seem inherently randomized and seem to necessarily only work against adversaries oblivious to this randomness.

Similar, albeit not identical,¹ issues also arise in other settings, most notably demand-robust optimization. The demand-robust model is a well-studied model of optimization under uncertainty [13, 30, 18, 25, 26, 22] in which an algorithm first buys a partial solution given a large collection of potential problem instances. An “adaptive adversary” then chooses which of the potential instances must be solved and the algorithm must extend its partial solution to solve the selected instance at inflated costs. The adversary is adaptive in the sense that it chooses the final instance with full knowledge of the algorithm’s partial solution. To thwart an algorithm which reduces a demand-robust problem to its tree version via a sampled FRT tree, the adversary can present a collection of potential instances which for every tree T in the FRT distribution contains an instance for which T is an arbitrarily bad approximation and then always choose the worst-case problem instance. The fact that there do not exist any demand-robust algorithms which use FRT despite this setting having received considerable attention seems at least partially due to the issues pointed out here.

Overall it seems fair to say that prior to this work tree embeddings seemed fundamentally incapable of enabling adaptive-adversary-robust and deterministic algorithms in several well-studied settings.

1.1 Our Contributions

We provide a new type of metric embedding – the copy tree embedding – which is deterministic and therefore also adaptive-adversary-robust. Specifically, we show that any weighted graph G can be deterministically embedded into a single weighted tree with a small number of copies for each vertex. Any subgraph of G will project onto this tree in a connectivity and approximate-cost preserving way.

To precisely define our embeddings we define a copy mapping ϕ which maps a vertex v to its copies.

► **Definition 1** (Copy Mapping). *Given vertex sets V and V' we say $\phi : V \rightarrow 2^{V'}$ is a copy mapping if every node has at least one copy (i.e. $|\phi(v)| \geq 1$ for all $v \in V$), copies are disjoint (i.e. $\phi(v) \cap \phi(u) = \emptyset$ for $u \neq v$) and every node in V' is a copy of some node (i.e. for every $v' \in V'$ there is some $v \in V$ where $v' \in \phi(v$). For $v' \in V'$, we use the shorthand $\phi^{-1}(v')$ to stand for the unique $v \in V$ such that $v' \in \phi(v$).*

A copy tree embedding for a weighted graph G now simply consists of a tree T on copies of vertices of G with one distinguished root and two mappings $\pi_{G \rightarrow T}$ and $\pi_{T \rightarrow G}$ which map subsets of edges from G to T and from T to G in a way that preserves connectivity and approximately preserves costs. We say that two vertex subsets U, W are connected in a graph if there is a $u \in U$ and $w \in W$ such that u and w are connected. We also say that a mapping $\pi : 2^E \rightarrow 2^{E'}$ is *monotone* if for every $A \subseteq B$ we have that $\pi(A) \subseteq \pi(B)$. A rooted tree $T = (V, E, w)$ is *well-separated* if for all edges e if e' is a child edge of e in T then $w(e') \leq \frac{1}{2}w(e)$. In the below for $F \subseteq E$ we let $w(F) := \sum_{e \in F} w(e)$.

► **Definition 2** (α -Approximate Copy Tree Embedding with Copy Number χ). *Let $G = (V, E, w)$ be a weighted graph with some distinguished vertex $r \in V$ called the root. An α -approximate copy tree embedding with copy number χ consists of a weighted rooted tree $T = (V', E', w')$, a copy mapping $\phi : V \rightarrow 2^{V'}$ and edge mapping functions $\pi_{G \rightarrow T} : 2^E \rightarrow 2^{E'}$ and $\pi_{T \rightarrow G} : 2^{E'} \rightarrow 2^E$ where $\pi_{T \rightarrow G}$ is monotone and:*

¹ We remark that, unlike the online and dynamic setting, the barrier to obtaining demand-robust algorithms which work against the “adaptive adversary” implicit in the setting is merely computational and thus seems potentially less inherent.

■ **Figure 1** Illustration of our first construction where we merge $O(\log n)$ partial tree embeddings.

■ **Figure 2** Illustration of our second construction where we merge the $O(n \log n)$ trees in the FRT support.

1. **Connectivity Preservation:** For all $F \subseteq E$ and $u, v \in V$ if u, v are connected by F , then $\phi(u), \phi(v) \subseteq V'$ are connected by $\pi_{G \rightarrow T}(F)$. Symmetrically, for all $F' \subseteq E'$ and $u', v' \in V'$ if u' and v' are connected by F' then $\phi^{-1}(u')$ and $\phi^{-1}(v')$ are connected by $\pi_{T \rightarrow G}(F')$.
2. **α -Cost Preservation:** For any $F \subseteq E$ we have $w(F) \leq \alpha \cdot w'(\pi_{G \rightarrow T}(F))$ and for any $F' \subseteq E'$ we have $w'(F') \leq w(\pi_{T \rightarrow G}(F'))$.
3. **Copy Number:** $|\phi(v)| \leq \chi$ for all $v \in V$ and $\phi(r) = \{r'\}$ where r' is the root of T .

A copy tree embedding is efficient if T , ϕ , and $\pi_{T \rightarrow G}$ are deterministically poly-time computable and well-separated if T is well-separated.

We emphasize that, whereas standard tree embeddings guarantee costs are preserved in expectation, our copy tree embeddings preserve costs deterministically. Also notice that for efficient copy tree embeddings we do not require that $\pi_{G \rightarrow T}$ is efficiently computable; this is because $\pi_{G \rightarrow T}$ will be used in our analyses but not in any of our algorithms. The idea of embeddings which map vertices to several copies has previously been explored by [9] and was recently explored in a concurrent work of [20]. The key difference between these works and our own is that the number of copies that each vertex is mapped to is unboundedly large (in the case of [9]) or only small in expectation (in the case of [20]). On the other hand, the analogue of α -cost preservation in [9] (“path preservation”) is stronger than our α -cost preservation.

We first give two copy tree embedding constructions which trade off between the number of copies and cost preservation. Both constructions are based on the idea of merging appropriately chosen tree embeddings as pictured in Figure 1 and Figure 2 where we color nodes according to the node whose copy they are.

Construction 1: Merging Partial Tree Embeddings (full version). The cornerstone of our first construction is the idea of merging embeddings which give good *deterministic* distance preservation. If our goal is to embed the entire input metric into a tree this is impossible. However, it is possible to embed a random constant fraction of nodes in an input metric into a tree in a way that deterministically preserves distances of the embedded nodes; an embedding which we call a “partial tree embedding” (see also [24, 29]). We then use the method of conditional expectation to derandomize a node-weighted version of this random process and apply this derandomization $O(\log n)$ times, down-weighting nodes as

they are embedded. The result of this process is $O(\log n)$ partial tree embeddings where a multiplicative-weights-type argument shows that each node appears in a constant fraction of these embeddings. Merging these $O(\log n)$ embeddings gives our copy tree while an Euler-tour-type proof shows that subgraphs of the input graph can be mapped to our copy tree in a cost and connectivity-preserving fashion. The following theorem summarizes our first construction.

► **Theorem 3.** *There is a poly-time deterministic algorithm which given any weighted graph $G = (V, E, w)$ and root $r \in V$ computes an efficient and well-separated $O(\log^2 n)$ -approximate copy tree embedding with copy number $O(\log n)$.*

Construction 2: Merging FRT Support (full version). Our second construction follows from a known fact that the size of the support of the FRT distribution can be made $O(n \log n)$ and this support can be computed deterministically in poly-time [12]. Merging each tree in this support at the root and some simple probabilistic method arguments give a copy tree embedding that is $O(\log n)$ -cost preserving but with an $O(n \log n)$ copy number. Equivalently, it can be inferred from [9]. The next theorem summarizes this construction.

► **Theorem 4.** *There is a poly-time deterministic algorithm which given any weighted graph $G = (V, E, w)$ and root $r \in V$ computes an efficient and well-separated $O(\log n)$ -approximate copy tree embedding with copy number $O(n \log n)$.*

While our second construction achieves a slightly better cost bound than our first construction, it has the significant downside of a linear copy number. Notably, this linear copy number makes our second construction unsuitable for some applications, including, for example, our second application as described below. Moreover, our first construction also has several desirable properties which our second does not which we expect might be useful for future applications. These include: (1) $\pi_{G \rightarrow T}$ is monotone (in addition to $\pi_{T \rightarrow G}$ being monotone as stipulated by Definition 2); (2) if u and v are connected by $F \subseteq E$ then $\Omega(\log n)$ vertices of $\phi(u)$ are connected to $\Omega(\log n)$ vertices of $\phi(v)$ in $\pi_{G \rightarrow T}(F)$ (as opposed to just one vertex of $\phi(u)$ and one vertex of $\phi(v)$ as in Definition 2) and; (3) if u is connected to r by $F \subseteq E$ then every vertex in $\phi(u)$ is connected to $\phi(r)$ in $\pi_{G \rightarrow T}(F)$ (as opposed to just one vertex of $\phi(u)$ as in Definition 2).

We next apply our constructions to obtain new results for several online and demand-robust connectivity problems whose history we briefly summarize now. Group Steiner tree and group Steiner forest are two well-studied generalizations of set cover and Steiner tree. In the group Steiner tree problem, we are given a weighted graph $G = (V, E, w)$ and groups $g_1, \dots, g_k \subseteq V$ and must return a subgraph of G of minimum weight which contains at least one vertex from each group. The group Steiner forest problem generalizes group Steiner tree. Here, we are given $A_i, B_i \subseteq V$ pairs and for each i we must connect some vertex from A_i to some vertex in B_i . [2] and [36] each gave a poly-log approximation for online group Steiner tree and forest respectively but both of these approximation guarantees are randomized and only hold against oblivious adversaries because they rely on FRT. Indeed, [2] posed the existence of a deterministic poly-log approximation for online group Steiner tree as an open question which has since been restated several times [11, 10].

Another well-studied generalization of group Steiner tree is the covering Steiner problem which is defined as group Steiner tree but where we are additionally given a value $r_i \in (0, |g_i|]$ for each group g_i and must connected at least an r_i vertices of g_i in our subgraph. This problem was introduced by [35] and further studied in several follow-up works [16, 27].

Similarly, while demand-robust minimum spanning tree and special cases of demand-robust Steiner tree have received considerable attention [13, 34, 33], there are no known poly-log approximations for demand-robust Steiner tree, group Steiner tree or group Steiner forest.

The reason our embeddings are well-suited to group Steiner problems and its generalizations is that mapping it onto a copy tree embedding simply results in another instance of the group Steiner tree problem, this time on a tree. Indeed, our embeddings almost immediately reduce the open question of [2] – solving online group Steiner tree and forest deterministically on a general graph – to its tree case (see the full version for details). Equivalently, this reduction can be inferred from the embeddings [9], though [2] seems to have overlooked this connection.

Application 1: Deterministic Online Covering Steiner (Section 3). In our first application we make progress on the open question of [2] by showing that the online covering Steiner problem admits a *bicriteria* deterministic poly-log approximation. Specifically, note that the covering Steiner problem generalizes group Steiner tree but unlike group Steiner tree it admits a natural bicriteria relaxation: instead of connecting, for example, $\frac{1}{2}$ of the nodes in each group we could require that our algorithm only connects, say, $\frac{(1-\epsilon)}{2}$ of all nodes in each group for some $\epsilon > 0$. Thus, our result can be seen as showing that there is indeed a deterministic poly-log competitive algorithm for online group Steiner tree – as posed in the above open question of [2] – *provided the algorithm can be bicriteria* in the relevant sense. We use our embeddings for this application. Those of [9] or [20] are not suitable for our first application since this application requires a bound on the number of copies of each vertex. More formally, we obtain a deterministic poly-log bicriteria approximation for this problem which connects at least $\frac{1-\epsilon}{2}$ of the nodes in each group (notated “ $(1-\epsilon)$ -connection competitive” below) by using our copy tree embeddings and a “water-filling” algorithm to solve the tree case.

► **Theorem 5.** *There is a deterministic poly-time algorithm for online covering Steiner (on general graphs) which is $O(\frac{\log^3 n}{\epsilon} \cdot \max_i \frac{|g_i|}{r_i})$ -cost-competitive and $(1-\epsilon)$ -connection-competitive.*

As we later observe, providing a deterministic poly-log-competitive algorithm for the online covering Steiner problem with any constant bicriteria relaxation is strictly harder than providing a deterministic poly-log-competitive algorithm for online (non-group) Steiner tree. Thus, this result also generalizes the fact that a deterministic poly-log approximation is known for online (non-group) Steiner tree [31]. Additionally, as a corollary we obtain the first non-trivial deterministic approximation algorithm for online group Steiner tree – albeit one with a linear dependence on the maximum group size.²

► **Corollary 6.** *There is an $O(N \log^3 n)$ -competitive deterministic algorithm for online group Steiner tree where $N := \max_i |g_i|$ is the maximum group size.*

We next adapt and apply our embeddings in the demand-robust setting.

Application 2: Demand-Robust Steiner Problems (full version). We begin by generalizing copy tree embeddings to demand-robust copy tree embeddings. Roughly, these are copy tree embeddings which simultaneously work well for every possible demand-robust scenario.

² We explicitly note here that this bicriteria guarantee does not yield a solution to the open problem of [2] of finding a poly-log deterministic approximation to the online group Steiner tree problem.

We then adapt our analysis from our previous constructions to show that these copy tree embeddings exist. Lastly, we apply demand-robust copy tree embeddings to give poly-log approximations for the demand-robust versions of several Steiner problems – Steiner forest, group Steiner tree and group Steiner forest – for which, prior to this work, nearly nothing was known. In particular, the only non-trivial algorithms known for demand-robust Steiner problems prior to this work are an algorithm for demand-robust Steiner tree [13] and an algorithm for demand-robust Steiner forest *on trees* with exponential scenarios [18] (which is, in general, incomparable to the usual demand-robust setting). To show these results, we apply our demand-robust copy tree embeddings to reduce these problems to their tree case. Thus, we also give our results on trees which are themselves non-trivial.

► **Theorem 7.** *There is a randomized poly-time $O(\log^2 n)$ -approximation algorithm for the demand-robust group Steiner tree problem on weighted trees.*

► **Theorem 8.** *There is a randomized poly-time $O(D \cdot \log^3 n)$ -approximation algorithm for the demand-robust group Steiner forest problem on weighted trees of depth D .*

► **Theorem 9.** *There is a randomized poly-time $O(\log^4 n)$ -approximation algorithm for the demand-robust group Steiner tree problem on weighted graphs.*

► **Theorem 10.** *There is a randomized poly-time $O(\log^6 n)$ -approximation algorithm for the demand-robust group Steiner forest problem on weighted graphs with polynomially-bounded aspect ratio.*

Demand-robust group Steiner forest generalizes demand-robust Steiner forest and prior to this work no poly-log approximations were known for demand-robust Steiner forest; thus the above result gives the first poly-log approximation for demand-robust Steiner forest. We solve the tree case of the above problems by observing a connection between demand-robust and online algorithms. In particular, we exploit the fact that for certain online rounding schemes a demand-robust problem can be seen as an online problem with two time steps provided certain natural properties are met. Notably, these properties will be met for these problems *on trees*. Thus, we emphasize that going through the copy tree embedding is crucial for our application – a more direct approach of using online rounding schemes on the general problem does not seem to yield useful results.

Further Applications. Lastly, we note that copy tree embeddings were integral to another recent work of [29], who gave the first poly-log approximations for the hop-constrained version of many classic network design problems, including hop-constrained Steiner forest [1], group Steiner tree and buy-at-bulk network design [4].

2 Graph Notation And Assumptions

Throughout this paper we will work with weighted graphs of the form $G = (V, E, w)$ where V and E are the vertex and edge sets of G and $w : E \rightarrow \mathbb{R}_{\geq 1}$ gives the weight of edges. We typically assume that $n := |V|$ is the number of nodes and write $[n] = \{1, 2, \dots, n\}$. We will also use $V(G)$, $E(G)$ and w_G to stand for the vertex set, edge set and weight function of G . Similarly, we will use w_e to stand for $w(e)$ where convenient. For a subset of edges $F \subseteq E$, we use the notation $w(F) := \sum_{e \in F} w_G(e)$. We use $d_G : V \times V \rightarrow \mathbb{R}_{\geq 0}$ to give the shortest path metric according to w . We will talk about the diameter of a metric (V, d) which is $\max_{u, v \in V} d(u, v)$; we notate the diameter with D . We use $B(v, x) := \{u \in V : d(v, u) \leq x\}$ to stand for the closed ball of v of radius x in metric (V, d) and $B_G(v, x)$ if (V, d) is the shortest path metric of G and we need to disambiguate which graph we are taking balls with respect to. We will sometimes identify a graph with the metric which it induces.

Notice that we have assumed that edge weights are non-zero and at least 1. This will be without loss generality as for our purposes any 0 weight edges may be contracted and scaling of edge weights ensures that the minimum edge weight is at least 1.

3 Online Covering Steiner

In this section we give a deterministic bicriteria algorithm for the online covering Steiner problem which is the same as online group Steiner tree but where we must connect at least r_i vertices from each group g_i to the root. The algorithm is bicriteria in the sense that it relaxes both the r_i -connectivity guarantee and the cost.

As mentioned in the introduction, this problem generalizes group Steiner tree. Moreover, it is also easy to see that any deterministic bicriteria algorithm for online covering Steiner also gives a poly-log-competitive deterministic (unicriteria) algorithm for online (non-group) Steiner tree. In particular, given an instance of Steiner tree on weighted graph $G = (V, E, w)$ with root r where we must connect terminals $A \subseteq V$ to r , it suffices to solve the covering Steiner problem where each vertex in A is in a singleton group with any constant bicriteria relaxation. This is because connecting any $c > 0$ fraction of each group to r will connect at least one vertex to r by the integrality of the number of connected vertices. Thus, our result generalizes the fact that deterministic poly-log approximations are known for online (non-group) Steiner tree [31]. However, we do note that our (deterministic) poly-log-approximate bicriteria online covering Steiner problem algorithm does not imply there is a (deterministic) poly-log-approximate online (non-partial) group Steiner tree algorithm (due to the nature of the bicriteria guarantee).

Offline Covering Steiner Problem. In the covering Steiner problem we are given a weighted graph $G = (V, E, w)$ as well as pairwise disjoint groups $g_1, g_2, \dots, g_k \subseteq V$, desired connected vertices $1 \leq r_i \leq |g_i|$ for each group g_i and root $r \in V$. Our goal is to find a tree T rooted at r which is a subgraph of G and satisfies $|T \cap g_i| \geq r_i$ for every i . We wish to minimize our cost, $w(T) := \sum_{e \in E(T)} w(e)$.³

Online Covering Steiner Problem. The online covering Steiner problem is the same as offline covering Steiner problem but where our solution need not be a tree and groups are revealed in time steps $t = 1, 2, \dots$. That is, in time step t an adversary reveals a new group g_t and the algorithm must maintain a solution T_t where: (1) $T_{t-1} \subseteq T_t$; (2) T_t is feasible for the (offline) covering Steiner tree problem on groups g_1, \dots, g_t and; (3) T_t is cost-competitive with the optimal offline solution for this problem where the cost-competitive ratio of our algorithm is $\max_t w(T_t)/\text{OPT}_t$ where OPT_t is the cost of the optimal offline covering Steiner problem solution on the first t groups. We will give a bicriteria approximation for online covering Steiner; thus we say that an online solution is ρ -connection-competitive if for each t we have $|T_t \cap g_i| \geq r_i \cdot \rho$ for every $i \leq t$.

3.1 Online Covering Steiner on a Tree

We begin by giving a bicriteria deterministic online algorithm for covering Steiner on trees based on a “water-filling” approach. Informally, in iteration t each unconnected vertex in each group will grow the solution towards the root at an equal rate until at least $r_i \cdot (1 - \epsilon)$ vertices in g_t are connected to r .

³ As with group Steiner tree the assumption that the tree is rooted and that the groups are pairwise disjoint is without loss of generality.

3.1.1 Problem

More formally we will solve a problem which is a slight generalization of covering Steiner on trees. We solve this problem on a tree rather than just covering Steiner on a tree because, unlike group Steiner tree, the “groupified” version of covering Steiner is not necessarily another instance of covering Steiner. Roughly, instead of groups we now have groups of groups, hence we call this problem 2-level covering Steiner.

Offline 2-Level Covering Steiner Problem. In the 2-level covering Steiner problem we are given a weighted graph $G = (V, E, w)$, root $r \in V$ and groups of groups $\mathcal{G}_1, \dots, \mathcal{G}_k$ where \mathcal{G}_i consists of groups $\{g_1^{(i)}, \dots, g_{k_i}^{(i)}\}$ where each $g_j^{(i)} \subseteq V$. We are also given connectivity requirements r_1, \dots, r_k . Our goal is to compute a minimum-weight tree T containing r where for each $i \leq k$ we have $|\{g_j^{(i)} : g_j^{(i)} \cap T \neq \emptyset\}| \geq r_i$. We let $n_i := |\{v : \exists j \text{ s.t. } v \in g_j^{(i)}\}|$. Notice that covering Steiner is just 2-level covering Steiner where each $g_i^{(j)}$ is a singleton set.

Online 2-Level Covering Steiner Problem. Online 2-level covering Steiner is the same as the offline problem but where \mathcal{G}_t is revealed in time step t by an adversary. In particular, for each time step t we must maintain a solution T_t where: (1) $T_{t-1} \subseteq T_t$ for all t ; (2) T_t is feasible for the (offline) 2-level covering Steiner problem on $\mathcal{G}_1, \dots, \mathcal{G}_t$ with connectivity requirements r_1, \dots, r_t and; (3) T_t is cost-competitive with the optimal offline solution for this problem where the cost-competitive ratio of our algorithm is $\max_t w(T_t)/\text{OPT}_t$ where OPT_t is the cost of the optimal offline 2-level covering Steiner problem solution on the first t groups of groups.

We will give a bicriteria approximation for online 2-level covering Steiner problem on trees; thus we say that an online solution is ρ -connection-competitive if for each t we have $|\{g_j^{(i)} : g_j^{(i)} \cap T \neq \emptyset\}| \geq \rho \cdot r_i$ for every $i \leq t$.

3.1.2 Algorithm

We now formally describe our algorithm for the 2-level covering Steiner problem on weighted tree $T = (V, E, w)$ given an $\epsilon > 0$. We will maintain a fractional variable $0 \leq x_e \leq w_e$ for each edge indicating the extent to which we buy e where our x_e s will be monotonically increasing as our algorithm runs. Say that an edge e is saturated if $x_e = w_e$.

Let us describe how we update our solution in the t th time step. Let T_t be the connected component of all saturated edges containing r . Then, we repeat the following until $|\{g_j^{(t)} : g_j^{(t)} \cap T_t \neq \emptyset\}| \geq r_t \cdot (1 - \epsilon)$. Let $\mathcal{G}'_t := \{g_j^{(t)} \in \mathcal{G}_t : g_j^{(t)} \cap T_t = \emptyset\}$ be all groups in \mathcal{G}_t not yet connected and let $g'_t := \bigcup_{S \in \mathcal{G}'_t} S$ be all vertices in a group which have not yet been connected to r . We say that e is on the frontier for $v \in g'_t$ if it is the first edge on the path from v to r which is not saturated. Similarly, let r_e be the number of vertices in g'_t for which e is on the frontier for v . Then, for each edge e we increase x_e by $r_e \cdot \delta$ where $\delta = \min_e (w_e - x_e)/r_e$. Our solution in the t th time step is T_t once $|\{g_j^{(t)} : g_j^{(t)} \cap T_t \neq \emptyset\}| \geq (1 - \epsilon) \cdot r_t$.

We illustrate one iteration of this algorithm in Figure 3.

3.1.3 Analysis

We proceed to analyze the above algorithm and give its properties.

► **Theorem 11.** *There is a deterministic poly-time algorithm for online 2-level covering Steiner on trees which is $\frac{1}{\epsilon} \cdot (\max_i \frac{n_i}{r_i})$ -cost-competitive and $(1 - \epsilon)$ -connection-competitive.*

■ **Figure 3** Solution our algorithm gives after one group of groups, \mathcal{G}_1 , is revealed where $r_1 = 2$. Nodes in groups in \mathcal{G}_1 outlined in green and nodes colored according to the group of \mathcal{G}_1 which contains them. Saturated edges given in blue and edges with $0 < x_e < w_e$ annotated with “ x_e/w_e ”. All other edges labeled by w_e .

Proof. We begin by verifying that our algorithm returns a monotonically increasing and $(1 - \epsilon)$ -connection-competitive solution. First, notice that our solution is monotonically increasing since our x_e s are monotonically increasing and our solution only includes saturated edges. To see that our solution is $(1 - \epsilon)$ -connection-competitive notice that at least one new edge becomes saturated from each update to the x_e s (namely $\arg \min_e (w_e - x_e)/r_e$) and since if all edges are saturated then $T_t = T$ which clearly satisfies $|\{g_j^{(t)} : g_j^{(t)} \cap T_t \neq \emptyset\}| \geq (1 - \epsilon) \cdot r_t$, this process will eventually halt with a $(1 - \epsilon)$ -connection-competitive solution in the t th iteration. For the same reason our algorithm is deterministic poly-time.

It remains to argue that our solution is $\frac{1}{\epsilon} \cdot (\max_i \frac{n_i}{r_i})$ -cost-competitive. We will argue that we can uniquely charge each unit of increase of our x_e s to an appropriate cost portion of the optimal solution. Fix an iteration t . Next, let $\delta^{(i,j)}$ for $i \leq t$ be the value of δ in the i th iteration the j th time we increase the value of our x_e s. Similarly, let $\delta_x^{(i,j)}$ be the increase in $\sum_e x_e$ when we do so and let $\delta_y^{(i,j)}$ be the increase in $\sum_{e \in T_t^*} x_e$ where T_t^* is the optimal offline solution to the 2-level covering Steiner problem we must solve in the t th iteration. Lastly, let $y := \sum_{i \leq t} \sum_j \delta_y^{(i,j)}$ be the value of $\sum_{e \in T_t^*} x_e$ at the end of the t th iteration; clearly we have $y \leq \text{OPT}_t$. We claim that it suffices to show that for each $i \leq t$ and each j that $\delta_x^{(i,j)} \leq \frac{1}{\epsilon} \delta_y^{(i,j)} \frac{n_i}{r_i}$ since it would follow that at the end of iteration t we have that

$$w(T_t) \leq \sum_e x_e = \sum_{i \leq t} \sum_j \delta_x^{(i,j)} \leq \frac{1}{\epsilon} \sum_{i \leq t} \sum_j \frac{n_i}{r_i} \delta_y^{(i,j)} \leq \frac{1}{\epsilon} \left(\max_i \frac{n_i}{r_i} \right) y \leq \frac{1}{\epsilon} \left(\max_i \frac{n_i}{r_i} \right) \text{OPT}_t.$$

We proceed to show that $\delta_x^{(i,j)} \leq \frac{1}{\epsilon} \delta_y^{(i,j)} \frac{n_i}{r_i}$ for each $i \leq t$ and j . We fix an i and j and for cleanliness of notation we will drop the dependence on i and j in our δ s henceforth.

First, notice that we have that

$$\delta_x \leq n_i \cdot \delta \tag{1}$$

since each vertex $v \in g_i$ is uniquely responsible for up to a δ increase on x_e where e is the edge on v 's frontier.

On the other hand, notice that if a group in \mathcal{G}_i is connected to r by T_t^* but is not yet connected by T_t then such a group uniquely contributes at least δ to δ_y . Since T_t^* connects at least r_i groups in \mathcal{G}_i to r but at the moment of our increase T_t connects at most $(1 - \epsilon) \cdot r_i$, there are at least $\epsilon \cdot r_i$ such groups in \mathcal{G}_i which are connected to r by T_t^* but not by T_t . Thus, we have that

$$\delta_y \geq \epsilon \cdot r_i \cdot \delta \tag{2}$$

Combining Equations 1 and 2 shows $\delta_x \leq \frac{1}{\epsilon} \delta_y \frac{n_i}{r_i}$ as required. ◀

3.2 Online Covering Steiner on General Graphs

Next, we apply our first construction to give an algorithm for covering Steiner on general graphs. Crucially, the following result relies on a single copy tree embedding with polylogarithmic copy number, making our second construction unsuitable for this problem.

► **Theorem 5.** *There is a deterministic poly-time algorithm for online covering Steiner (on general graphs) which is $O\left(\frac{\log^3 n}{\epsilon} \cdot \max_i \frac{|g_i|}{r_i}\right)$ -cost-competitive and $(1 - \epsilon)$ -connection-competitive.*

Proof. We will use our copy tree embedding to produce a single tree on which we must deterministically solve online 2-level covering Steiner. We will then apply the algorithm from Theorem 11 to solve online 2-level covering Steiner on this tree.

More formally, consider an instance of online covering Steiner on weighted graph $G = (V, E, w)$ with root r . Then, we first compute a copy tree embedding $(T, \phi, \pi_{G \rightarrow T}, \pi_{T \rightarrow G})$ deterministically with respect to G and r as in Theorem 3 with cost approximation $O(\log^2 n)$ and copy number $O(\log n)$. Next, given our instance I_t of covering Steiner on G with groups g_1, \dots, g_t and connection requirements r_1, \dots, r_t we let I'_t be the instance of 2-level covering Steiner on T with groups of groups $\mathcal{G}_1, \dots, \mathcal{G}_t$ where $\mathcal{G}_i = \{\phi(v) : v \in g_i\}$, connection requirements r_1, \dots, r_t and root $\phi(r)$. Then if the adversary has required that we solve instance I_t in time step t , then we require that the algorithm in Theorem 11 solves I'_t in time step t and we let H'_t be the solution returned by our algorithm for I'_t . Lastly, we return as our solution for I_t in time step t the set $H_t := \pi_{T \rightarrow G}(H'_t)$.

Let us verify that the resulting algorithm is indeed feasible (i.e. monotone and $(1 - \epsilon)$ -connection-competitive) and of the appropriate cost.

First, we have that $H_t \subseteq H_{t+1}$ for every t since $H'_t \subseteq H'_{t+1}$ because our algorithm for trees returns a feasible solution for its online problem and $\pi_{T \rightarrow G}$ is monotone by definition of a copy tree embedding. Moreover, we claim that H_t connects at least $(1 - \epsilon) \cdot r_i$ vertices from g_i to r for $i \leq t$ and every t . To see this, notice that there are at least $(1 - \epsilon) \cdot r_i$ groups from \mathcal{G}_i containing a vertex connected to r by H'_t . Since each such group consists of the copies of a distinct vertex, by the connectivity preservation properties of a copy tree it follows that H_t connects at least $(1 - \epsilon) \cdot r_i$ vertices from g_i to r .

Next, we verify the cost of our solution. Let OPT'_t be the cost of the optimal solution to I'_t . Notice that since our copy number is $O(\log n)$, it follows that $n_i \leq O(\log n \cdot |g_i|)$. Thus, by the guarantees of Theorem 11 we have

$$w_T(H'_t) \leq \frac{1}{\epsilon} \cdot \left(\max_i \frac{n_i}{r_i} \right) \text{OPT}'_t \leq O\left(\frac{\log n}{\epsilon}\right) \cdot \left(\max_i \frac{|g_i|}{r_i} \right) \text{OPT}'_t. \quad (3)$$

Next, we bound OPT'_t . Let H_t^* be the optimal solution to I_t . We claim that $\pi_{G \rightarrow T}(H_t^*)$ is feasible for I'_t . This follows because H_t^* connects at least r_i vertices from g_i to r for $i \leq t$ and so by the connectivity preservation property of copy tree embeddings we know that there are at least r_i groups in \mathcal{G}_i with a vertex connected to r by $\pi_{G \rightarrow T}(H_t^*)$. Thus, combining this with the $O(\log^2 n)$ cost preservation of our copy tree embedding we have

$$\text{OPT}'_t \leq w_T(\pi_{G \rightarrow T}(H_t^*)) \leq O(\log^2 n) \cdot w_G(H_t^*). \quad (4)$$

Lastly, by the cost preservation property of our copy tree embedding we have that $w_G(H_t) \leq w_T(H'_t)$ which when combined with Equations 3 and 4 gives

$$w_G(H_t) \leq O\left(\frac{\log^3 n}{\epsilon} \cdot \max_i \frac{|g_i|}{r_i}\right) \cdot w_G(H_t^*).$$

thereby showing that our solution is within the required cost bound. ◀

Since group Steiner tree is exactly covering Steiner where $r_i = 1$ in which case $\max_i \frac{|g_i|}{r_i} \leq N$ where again N is the maximum size of a group. Moreover, since any solution can only connect an integral number of vertices from each group, it follows that a $\frac{1}{2}$ -connection-competitive solution for covering Steiner where $r_i = 1$ (i.e. for group Steiner tree) connects at least one vertex from each group. Thus, as a corollary of the above result we have the following deterministic algorithm for online group Steiner tree.⁴

► **Corollary 6.** *There is an $O(N \log^3 n)$ -competitive deterministic algorithm for online group Steiner tree where $N := \max_i |g_i|$ is the maximum group size.*

⁴ We note that one can use an aforementioned property of our first construction – that if u is connected to r by $F \subseteq E$ then every vertex in $\phi(u)$ is connected to $\phi(r)$ in $\pi_{G \rightarrow T}(F)$ – to reduce the $O(\log^3 n)$ s in this section to $O(\log^2 n)$ s. In particular, if one were to use this property then when we map the solution to our covering Steiner problem on G to our copy tree embedding, the resulting solution will connect at least r_i groups in \mathcal{G}_i at least $\Theta(\log n)$ times. It follows that when we run our water filling algorithm each time it increases $\sum_e x_e$ by 1 we know that it cover at least $\Omega(\log n)$ units of the optimal solution by weight rather than 1 unit of the optimal solution as in the current analysis.

Abstract

We revisit the complexity of the well-studied notion of Additively Separable Hedonic Games (ASHGs). Such games model a basic clustering or coalition formation scenario in which selfish agents are represented by the vertices of an edge-weighted digraph $G = (V, E)$, and the weight of an arc uv denotes the utility u gains by being in the same coalition as v . We focus on (arguably) the most basic stability question about such a game: given a graph, does a Nash stable solution exist and can we find it efficiently?

We study the (parameterized) complexity of ASHG stability when the underlying graph has treewidth t and maximum degree Δ . The current best FPT algorithm for this case was claimed by Peters [AAAI 2016], with time complexity roughly $2^{O(\Delta^5 t)}$. We present an algorithm with parameter dependence $(\Delta t)^{O(\Delta t)}$, significantly improving upon the parameter dependence on Δ given by Peters, albeit with a slightly worse dependence on t . Our main result is that this slight performance deterioration with respect to t is actually completely justified: we observe that the previously claimed algorithm is incorrect, and that in fact no algorithm can achieve dependence $t^{o(t)}$ for bounded-degree graphs, unless the ETH fails. This, together with corresponding bounds we provide on the dependence on Δ and the joint parameter establishes that our algorithm is essentially optimal for both parameters, under the ETH.

We then revisit the parameterization by treewidth alone and resolve a question also posed by Peters by showing that Nash Stability remains strongly NP-hard on stars under additive preferences. Nevertheless, we also discover an island of mild tractability: we show that Connected Nash Stability is solvable in pseudo-polynomial time for constant t , though with an XP dependence on t which, as we establish, cannot be avoided.

1 Introduction

Coalition formation is a topic of central importance in computational social choice and in the mathematical social sciences in general. The goal of its study is to understand how groups of selfish agents are likely to partition themselves into teams or clusters, depending on their preferences. The most well-studied case of coalition formation are *hedonic games*, which have the distinguishing characteristic that each agent's utility only depends on the coalition on which she is placed (and not on the coalitions of other players). Hedonic games

■ **Table 1** Summary of results. t, p, Δ, W denote the treewidth, pathwidth, maximum degree, and maximum absolute weight. Results denoted by (G) apply to general (possibly disconnected) NASH STABILITY, and by (C) to CONNECTED NASH STABILITY.

Parameter	Algorithms	Lower Bounds
t, p	$(nW)^{O(t^2)}$ (C) (Theorem 11)	Strongly NP-hard for Stars (G) (Theorem 9) No $f(p) \cdot n^{o(p/\log p)}$ (C) (Theorem 12)
$t, p + \Delta$	$(\Delta t)^{O(\Delta t)} (n + \log W)^{O(1)}$ (G) (Theorem 4)	No $(p\Delta)^{o(p\Delta)} (nW)^{O(1)}$ (G) (Theorem 5) No $\Delta^{o(\Delta)} (nW)^{O(1)}$ if $p = O(1)$ (G) (Corollary 6) No $p^{o(p)} n^{O(1)}$ if $\Delta, W = O(1)$ (Theorem 7) (G,C)

have recently been an object of intense study also from the computer science perspective [1, 2, 6, 7, 9, 10, 12, 19, 27, 33, 40], due in part to their numerous applications in, among others, social network analysis [34], scheduling group activities [15], and allocating tasks to wireless agents [39]. For more information we refer the reader to [13] and the relevant chapters of standard computational social choice textbooks [4].

Hedonic games are extremely general and capture many interesting scenarios in algorithmic game theory and computational social choice. Unfortunately, this generality implies that most interesting questions about such games are computationally hard; indeed, even encoding the preferences of agents generally takes exponential space. This has motivated the study of natural succinctly representable versions of hedonic games. In this paper, we focus on one of the most widely-studied such models called Additively-Separable Hedonic Games (ASHG). In this setting the interactions between agents are given by an edge-weighted directed graph $G = (V, E)$, where the weight of an arc $uv \in E$ denotes the utility that u gains by being placed in the same coalition as v . Thus, vertices which are not connected by an arc are considered to be indifferent to each other. Given a partition into coalitions, the utility of a player v is defined as the sum of the weights of out-going arcs from v to its own coalition.

A rich literature exists studying various questions about ASHGs, including a large spectrum of stability concepts and social welfare maximization [3, 5, 17, 20, 23, 34, 35, 41]. In this paper we focus on perhaps the most basic notion of stability one may consider. We say that a configuration π is *Nash Stable* if no agent v can unilaterally strictly increase her utility by selecting a different coalition of π or by forming a singleton coalition. The algorithmic question that we are interested in studying is the following: given an ASHG, does a Nash Stable partition exist? Even though other notions of stability exist (notably when deviating players are allowed to collaborate [11, 16, 37, 42]), fully understanding the complexity of NASH STABILITY is of particular importance, because of the fundamental nature of this notion.

NASH STABILITY of ASHGs has been thoroughly studied and is, unfortunately, NP-complete. We therefore adopt a parameterized point of view and investigate whether some desirable structure of the input can render the problem tractable. We consider two of the most well-studied graph parameters: the treewidth t and the maximum degree Δ of the underlying graph. The study of ASHGs in this light was previously taken up by Peters [36] and the goal of our paper is to improve and clarify the state of the art given by this previous work.

Summary of Results. Our results can be divided into two parts (see Table 1 for a summary). In the first part of the paper we parameterize the problem by $t + \Delta$, that is, we study its complexity for graphs that have simultaneously low treewidth and low maximum degree.

The study of hedonic games on such graphs was initiated by Peters [36], who already considered a wide variety of algorithmic questions on ASHG for these parameters and provided FPT algorithms using Courcelle’s theorem. Due to the importance of NASH STABILITY, more refined algorithmic arguments were given in the same work, and it was claimed that CONNECTED NASH STABILITY (the variant of the problem where coalitions must be connected in the underlying graph) and NASH STABILITY can be decided with parameter dependence roughly $2^{\Delta^2 t}$ and $2^{\Delta^5 t}$, respectively (though as we explain below, these claims were not completely justified). We thus revisit the problem with the goal of determining the optimal parameter dependence for NASH STABILITY in terms of t and Δ . Our positive contribution is an algorithm deciding NASH STABILITY in time $(\Delta t)^{O(\Delta t)} (n + \log W)^{O(1)}$, where W is the maximum absolute weight, significantly improving the parameter dependence for Δ (Theorem 4). This is achieved by reformulating the problem as a coloring problem with $t\Delta$ colors in a way that encodes the property that two vertices belong in the same coalition and then using dynamic programming to solve this problem. Our main technical contribution is then to establish that our algorithm is essentially optimal. To that end we first show that if there exists an algorithm solving NASH STABILITY in time $(p\Delta)^{o(p\Delta)} (nW)^{O(1)}$, where p is the pathwidth of the underlying graph, then the ETH is false (Theorem 5). Hence, it is not possible to obtain a better parameter dependence, even if we accept a pseudo-polynomial running time and a more restricted parameter.

If we were considering a parameterization with a single parameter, at this point we would be essentially done, since we have an algorithm and a lower bound that match. However, the fact that Δ and t are two a priori independent variables significantly complicates the analysis because, informally, the space of running time functions that depend on two variables is not totally ordered. To see what we mean by that, recall that [36] claimed an algorithm with complexity roughly $2^{\Delta^5 t}$, while our algorithm’s complexity has the form $(\Delta t)^{\Delta t}$. The two algorithms are not directly comparable in performance: for some values of Δ, t one is better and for some the other (though the range of parameters where $2^{\Delta^5 t} < (\Delta t)^{\Delta t}$ is quite limited). As a result, even though Theorem 5 shows that no algorithm can beat the algorithm of Theorem 4 in all cases, it does not rule out the possibility that some algorithm beats it in *some* cases, for example when Δ is much smaller than t , or vice-versa. We therefore need to work harder to argue that our algorithm is indeed optimal in essentially all cases. In particular, we show that even if pathwidth is constant the problem cannot be solved in $\Delta^{o(\Delta)} (nW)^{O(1)}$ (Corollary 6); and even if Δ and W are constant, the problem cannot be solved in $p^{o(p)} n^{O(1)}$ (Theorem 7) unless the ETH is false. Hence, we succeed in covering essentially all corner cases, showing that our algorithm’s slightly super-exponential dependence on *the product* of Δ and t is truly optimal, and we cannot avoid the slightly super-exponential on either parameter, even if we were to accept a much worse dependence on the other.

An astute reader will have noticed a contradiction between our lower bounds and the algorithms of [36]. It is also worth noting that Theorem 7 applies to both the connected and disconnected cases of the problem, using an argument due to [36]. Hence, Theorem 7 implies that, either the ETH is false, or *neither* of the aforementioned algorithms of [36] can have the claimed performance, as executing them on the instances produced by our reduction (which have $\Delta = O(1)$) would give parameter dependence $2^{O(t)}$, which is ruled out by Theorem 7. Indeed, in Section 3 we explain in more detail that the argumentation of [36] lacks an ingredient (the partition of vertices in each neighborhood into coalitions) which turns out to be necessary to obtain a correct algorithm and also key in showing the lower bound. Hence, the slightly super-exponential dependence on t cannot be avoided (under the ETH), and the dependence on t promised in [36] is impossible to achieve: the best one can hope for is the slightly super-exponential dependence on both t and Δ given in Theorem 4.

In the second part of the paper, we consider NASH STABILITY on graphs of low treewidth, without making any further assumptions (in particular, we consider graphs of arbitrarily large degree). This parameterization was considered by Peters [36] who showed that the problem is strongly NP-hard on stars and thus motivated the use of the double parameter $t + \Delta$. This would initially appear to settle the problem. However, we revisit this question and make two key observations: first, the reduction of [36] does not show hardness for additive games, but for a more general version of the problem where preferences of players are not necessarily additive but are described by a collection of boolean formulas (HC-nets [18, 25]). It was therefore explicitly posed as an open question whether *additive* games are also hard [36]. Second, in the reduction of [36] coalitions are disconnected. As noted in [26, 36], there are situations where Nash Stable coalitions make more sense if they are connected in the underlying graph. We therefore ask whether CONNECTED NASH STABILITY, where we impose a connectivity condition on coalitions, is an easier problem.

Our first contribution is to resolve the open question of [36] by showing that imposing either one of these two modifications does *not* render the problem tractable: NASH STABILITY of additive hedonic games is still strongly NP-hard on stars (Theorem 9); and CONNECTED NASH STABILITY of hedonic games encoded by HC-nets is still NP-hard on stars (Theorem 10). However, our reductions stubbornly refuse to work for the natural combination of these conditions, namely, CONNECTED NASH STABILITY for additive hedonic games on stars. Surprisingly, we discover that this is with good reason: CONNECTED NASH STABILITY turns out to be solvable in pseudopolynomial time on graphs of bounded treewidth (Theorem 11). More precisely, our algorithm, which uses standard dynamic programming techniques but crucially relies on the connectedness of coalitions, runs in “pseudo-XP” time, that is, in polynomial time when $t = O(1)$ and weights are polynomially bounded. Completing our investigation we show that this is essentially the best possible: obtaining a pseudo-polynomial time algorithm with FPT dependence on treewidth (or pathwidth) would contradict standard assumptions (Theorem 12). Hence, in this part we establish that there is an overlooked case of ASHG that does become somewhat tractable when we only parameterize by treewidth, but this tractability is limited.

Related work. Deciding if an ASHG admits a partition that is Nash Stable or has other desirable properties is NP-hard [3, 5, 34, 38, 41]. Hardness remains even in cases where a Nash Stable solution is guaranteed, such as symmetric preferences, where the problem is PLS-complete [21], and non-negative preferences, where it is NP-hard to find a non-trivial stable partition [35]. The problem generally remains hard when we impose the requirement that coalitions must be connected [8, 26].

A related MIN STABLE CUT problem is studied in [29], where we partition the vertices into two coalitions in a Nash Stable way. Interestingly, the complexity of that problem turns out to be $2^{O(\Delta t)}$, since each vertex has 2 choices; this nicely contrasts with NASH STABILITY, where vertices have more choices, and which is slightly super-exponential parameterized by treewidth. Similar slightly super-exponential complexities have been observed with other problems involving treewidth and partitioning vertices into sets [24, 32].

2 Preliminaries

We use standard graph-theoretic notation and assume that the reader is familiar with standard notions in parameterized complexity, including treewidth t and pathwidth p [14]. We mostly deal with directed graphs and denote an arc from vertex u to vertex v as uv .

When we talk about the degree or the neighborhood of a vertex v , we refer to its degree and its neighborhood in the underlying graph, that is, the graph obtained by forgetting the directions of all arcs. Throughout the paper $\Delta(G)$ (or simply Δ , when G is clear from the context) denotes the maximum degree of the underlying graph of G . The Exponential Time Hypothesis (ETH) is the assumption that there exists $c > 1$ such that 3-SAT on formulas with n variables does not admit a c^n algorithm [28]. We will mostly use a somewhat simpler to state (and weaker) form of this assumption stating that 3-SAT cannot be solved in time $2^{o(n)}$.

In this paper we will be mostly interested in *Additively Separable Hedonic Games* (ASHG). In an ASHG we are given a directed graph $G = (V, E)$ and a weight function $w : V \times V \rightarrow \mathbb{Z}$ that encodes agents' preferences. The function w has the property that for all $u, v \in V$ such that $uv \notin E$ we have $w(u, v) = 0$, that is, non-zero weights are only given to arcs. A solution to an ASHG is a partition π of V , where we refer to the sets of V as classes or, more simply, as coalitions. For each $v \in V$ and $S \subseteq V$ the utility that v derives from being placed in the coalition S is defined as $p_v(S) = \sum_{u \in S \setminus \{v\}} w(v, u)$. A partition π is Nash Stable if we have the following: for each $v \in V$, if v belongs in the class S of π , we have $p_v(S) \geq 0$ and for each $S' \in \pi$ we have $p_v(S) \geq p_v(S')$. In other words, no vertex can strictly increase its utility by joining another coalition of π or forming a singleton coalition. We also consider the notion of *Connected Nash Stable* partitions, which are Nash Stable partitions π with the added property that all classes of π are connected in the underlying undirected graph of G .

3 Parameterization by Treewidth and Degree

In this section we revisit NASH STABILITY parameterized by $t + \Delta$, which was previously studied in [36]. Our main positive result is an algorithm given in Section 3.1 solving the problem with dependence $(t\Delta)^{O(t\Delta)}$.

Our main technical contribution is then to show in Section 3.2 that this algorithm is essentially optimal, under the ETH. As explained, we need several different reductions to settle this problem in a satisfactory way. The main reduction is given in Theorem 5 and uses the fact that a partition restricted to the neighborhood of a vertex with degree Δ encodes roughly $\Delta \log \Delta$ bits of information, because there are around Δ^Δ partitions of Δ elements into equivalence classes. This key idea allows the first reduction to compress the treewidth more and more as Δ increases. Hence, we can produce instances where both t and Δ are super-constant, but appropriately chosen to match our bound. In this way, Theorem 5 rules out running times of the form, say $(t\Delta)^{t+\Delta}$, as when t, Δ are both super-constant, $t + \Delta = o(t\Delta)$. By modifying the parameters of Theorem 5 we then obtain Corollary 6 from the same construction, which states that no algorithm can have dependence $\Delta^{o(\Delta)}$, even on graphs of bounded pathwidth. On the other hand, this type of construction cannot show hardness for instances of bounded degree, as when $\Delta = O(1)$, then $\Delta^\Delta = O(1)$, so we cannot really compress the treewidth of the produced instance. Hence, we use a different reduction in Theorem 7, showing that the problem cannot be solved with dependence $p^{o(p)}$ on instances of bounded degree. This reduction uses a super-constant number of coalitions that “run through” the graph, and hence produces instances with super-constant t . The three complementary reductions together cover the whole range of possibilities and indicate that there is not much room for improvement in our algorithm.

It is worth discussing here that, assuming the ETH, Theorem 7 contradicts the claimed algorithms of [36], which for $\Delta = O(1)$ would solve (CONNECTED) NASH STABILITY with dependence $2^{O(t)}$, while Theorem 7 claims that the problem cannot be solved in time $2^{o(t \log t)}$.

Let us then briefly explain why the proof sketch for these algorithms in [36] is incomplete: the idea of the algorithms is to solve CONNECTED NASH STABILITY, and use the arcs of the instance to verify connectivity. Hence, the DP algorithm will remember, in a ball of distance 2 around each vertex, which arcs have both of their endpoints in the same coalition. The claim is that this information allows us to infer the coalitions. Though this is true if one is given this information for the whole graph, it is not true locally around a vertex where we only have information about other vertices which are close by. In particular, it could be the case that u has neighbors v_1, v_2 , which happen to be in the same coalition, but such that the path proving that this coalition is connected goes through vertices far from u . Because this cannot be verified locally, any DP algorithm would need to store some connectivity information about the vertices in a bag which, as implied by Theorem 7 inevitably leads to a dependence of the form t^t .

3.1 Improved FPT Algorithm

In order to obtain our algorithm for NASH STABILITY we will need two ingredients. The first ingredient will be a reformulation of the problem as a vertex coloring problem. We use the following definition where, informally, a vertex is stable if its outgoing weight to vertices of the same color cannot be increased by changing its color.

► **Definition 1.** *A Stable k -Coloring of an edge-weighted digraph G is a function $c : V \rightarrow [k]$ satisfying the following property: for each $v \in V$ we have $\sum_{u \in c^{-1}(c(v))} w(v, u) \geq \max_{j \in [k+1]} \sum_{u \in c^{-1}(j)} w(v, u)$.*

Note that in the definition above we take the maximum over $j \in [k+1]$ of the total weight of v towards color class j . Since c is a function that uses k colors, we have $c^{-1}(k+1) = \emptyset$ and hence this ensures that the total weight of v towards its own color must always be non-negative in a stable coloring. Also note that to calculate the total weight from v to a certain color class j , it suffices to consider the vertices of color j that belong in the out-neighborhood of v .

Our strategy will be to show that, for appropriately chosen k , deciding whether a graph admits a stable k -Coloring is equivalent to deciding whether a Nash Stable partition exists. Then, the second ingredient of our approach is to use standard dynamic programming techniques to solve Stable k -Coloring on graphs of bounded treewidth and maximum degree.

The key lemma for the first part is the following:

► **Lemma 2.** *Let $G = (V, E)$ be an edge-weighted digraph whose underlying graph has maximum degree Δ and admits a tree decomposition with maximum bag size t . Then, G has a Nash Stable partition if and only if it admits a Stable k -Coloring for $k = t \cdot \Delta$.*

Proof. First, suppose that we have a Stable k -Coloring $c : V \rightarrow [k]$ of the graph for some value k . We obtain a Nash Stable partition of $V(G)$ by turning each color class into a coalition. By the definition of Stable k -Coloring, each vertex has at least as high utility in its own color class (and hence its own coalition) as in any other, so this partition is stable.

For the converse direction, suppose that there exists a Nash Stable partition π of G . We will first attempt to color the coalitions of π in a way that any two coalitions which are at distance at most two receive distinct colors, while using at most $t \cdot \Delta$ colors. In the remainder, when we refer to the distance between two sets of vertices S_1, S_2 , we mean $\min_{u \in S_1, v \in S_2} d(u, v)$, where distances are calculated in the underlying graph.

Consider the graph G^2 obtained from the underlying graph of G by connecting any two vertices which are at distance at most 2 in the underlying graph of G . We can construct a tree decomposition of G^2 where all bags contain at most $t \cdot \Delta$ vertices by taking the assumed tree decomposition of G and adding to each bag the neighbors of all vertices contained in

that bag. Furthermore, we can assume without loss of generality that any equivalence class C of the Nash Stable partition π is connected in G^2 . If not, that would mean that there exists a class C that contains a connected component $C' \subseteq C$ such that C' is at distance at least 3 from $C \setminus C'$ in the underlying graph of G . In that case we could partition C into two classes $C', C \setminus C'$, without affecting the stability of the partition.

Formally now the claim we wish to make is the following:

▷ **Claim 3.** There is a coloring c of the equivalence classes of π with $k = t \cdot \Delta$ colors such that any two classes C_1, C_2 of π which are at distance at most two in the underlying graph of G receive distinct colors.

Proof. We prove the claim by induction on the number of equivalence classes of π . If there is only one class the claim is trivial.

Consider a rooted tree decomposition of G^2 . For an equivalence class C of π we say that the bag B is the top bag for C if B contains a vertex of C and no bag that is closer to the root contains a vertex of C . Select an equivalence class C of π whose top bag is as far from the root as possible. We claim that there are at most $t \cdot \Delta - 1$ classes C' which are at distance at most 2 from C in G .

In order to prove that there are at most $t \cdot \Delta - 1$ other classes at distance at most two from C , consider such a class C' , which is therefore at distance one from C in G^2 . Let B be the top bag of C . If C' does not contain any vertex that appears in B then we get a contradiction as follows: first, C' has a neighbor of a vertex of C , so these two vertices must appear together in a bag; since all vertices of C appear in the sub-tree rooted at B , some vertices of C' must appear strictly below B in the decomposition; since B is a separator of G^2 and C' is connected, if no vertex of C' is in B then all vertices of C' appear below B in the decomposition; but then, this contradicts the choice of C as the class whose top bag is as far from the root as possible. As a result, for each C' that is a neighbor of C in G^2 , there exists a distinct vertex of C' in B . Since $|B| \leq t \cdot \Delta$ and B contains a vertex of C , we get that the coalitions C' which are neighbors of C in G^2 are at most $t \cdot \Delta - 1$.

We now remove all vertices of C from the graph and claim that π restricted to the new graph is still a Nash Stable partition. By induction, there is a coloring of the remaining coalitions of π that satisfies the claim. We keep this coloring and assign to C a color that is not used by any of the at most $k - 1$ coalitions which are at distance two from C . Hence, we obtain the claimed coloring of the classes of π . ◀

From Claim 3 we obtain a coloring of the equivalence classes of π with $k = t \cdot \Delta$ colors, such that any two equivalence classes which are at distance at most 2 in the underlying graph of G receive distinct colors. We now obtain a coloring of V by assigning to each vertex the color of its class. In the out-neighborhood of each vertex v the partition induced by the coloring is the same as that induced by π , since all the vertices in the out-neighborhood of v are at distance at most 2 from each other in G . Hence, the k -Coloring must be stable, because otherwise a vertex would have incentive to deviate in π by joining another coalition or by becoming a singleton. ◀

► **Theorem 4.** *There exists an algorithm which, given an ASHG defined on a digraph $G = (V, E)$ whose underlying graph has maximum degree Δ and a tree decomposition of the underlying graph of G of width t , decides if a Nash Stable partition exists in time $(\Delta t)^{O(\Delta t)} (n + \log W)^{O(1)}$, where $n = |V|$ and W is the largest absolute weight.*

Proof. Using Lemma 2 we will formulate an algorithm that decides if the given instance admits a Stable k -Coloring for $k = (t + 1)\Delta$, since this is equivalent to deciding if a Nash Stable partition exists. We first obtain a tree decomposition of G^2 by placing into each bag of the given decomposition all the neighbors of all the vertices of the bag.

We now execute a standard dynamic programming algorithm for k -coloring on this new decomposition, so we sketch the details. The DP table has size $k^{(t+1)\Delta} = (\Delta t)^{O(\Delta t)}$ since we need to store as a signature of a partial solution the colors of all vertices contained in a bag. The only difference with the standard DP algorithm for coloring is that our algorithm, whenever a new vertex v is introduced in a bag B , considers all possible colors for v , and then for each $u \in B$, if all neighbors of u are contained in B , verifies for each signature whether u is stable. Signatures where a vertex is not stable are discarded. The key property is now that for any vertex u , there exists a bag B such that B contains u and all its neighbors (since in G^2 the neighborhood of u is a clique), hence only signatures for which all vertices are stable may survive until the root of the decomposition. ◀

3.2 Tight ETH-based Lower Bounds

► **Theorem 5.** *If the ETH is true, there is no algorithm which decides if an ASHG on a graph with n vertices, maximum degree Δ , and pathwidth p admits a Nash Stable partition in time $(p\Delta)^{o(p\Delta)}(nW)^{O(1)}$, where W is the maximum absolute weight.*

Proof. We will give a parametric reduction which, starting from a 3-SAT instance ϕ with n variables and m clauses, and for any desired parameter $d < n/\log n$, constructs an ASHG instance G with the following properties:

1. G can be constructed in time polynomial in n
2. G has maximum degree $O(d)$
3. G has pathwidth $O(\frac{n}{d \log d})$
4. the maximum absolute value W is $2^{O(d)}$
5. ϕ is satisfiable if and only if there exists a Nash Stable partition.

Before we go on, let us argue why a reduction that satisfies these properties does indeed establish the theorem: given a 3-SAT instance on n variables, we set $d = \lfloor \sqrt{n} \rfloor$. We construct G in polynomial time, therefore the size of G is polynomially bounded by n . Deciding if G has a Nash Stable partition is equivalent to solving ϕ by the last property. By the third property, the pathwidth of the constructed graph is $O(\frac{\sqrt{n}}{\log n})$, so $p\Delta = O(\frac{n}{\log n})$. Furthermore, $W = 2^{O(\sqrt{n})}$. If deciding if a Nash Stable partition exists can be done in time $(p\Delta)^{o(p\Delta)}(|G| \cdot W)^{O(1)}$, the total running time for deciding ϕ is $(p\Delta)^{o(p\Delta)}(|G| \cdot W)^{O(1)} = 2^{o(n)}$ contradicting the ETH.

We now describe our construction. We are given a 3-SAT instance ϕ with variables x_0, \dots, x_{n-1} , and a parameter d , which we assume to be a power of 2 (otherwise we increase its value by at most a factor of 2). We also assume without loss of generality that all clauses of ϕ have size exactly 3 (otherwise we repeat literals). We construct the following graph:

1. **Selection vertices:** for each $i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil\}$, $i_2 \in \{0, \dots, d-1\}$, $j \in \{0, \dots, m\}$, we construct a vertex $u_{(i_1, i_2, j)}$.
2. **Consistency vertices:** for each $i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil\}$, $j \in \{1, \dots, m-1\}$, we construct a vertex $c_{(i_1, j)}$. For $i_2 \in \{0, \dots, d-1\}$ we give weights: $w(c_{(i_1, j)}, u_{(i_1, i_2, j)}) = 4^{i_2}$; $w(c_{(i_1, j)}, u_{(i_1, i_2, j+1)}) = -4^{i_2}$; $w(u_{(i_1, i_2, j)}, c_{(i_1, j)}) = w(u_{(i_1, i_2, j+1)}, c_{(i_1, j)}) = -4^d$.
3. **Clause gadget:** for each $j \in \{1, \dots, m\}$ we construct two vertices s_j, s'_j and set $w(s_j, s'_j) = 2$. We also construct three vertices $\ell_{(j,1)}, \ell_{(j,2)}, \ell_{(j,3)}$ and set $w(\ell_{(j,1)}, s_j) = w(\ell_{(j,2)}, s_j) = w(\ell_{(j,3)}, s_j) = 2$ and $w(s_j, \ell_{(j,1)}) = w(s_j, \ell_{(j,2)}) = w(s_j, \ell_{(j,3)}) = -1$.
4. **Palette gadget:** we construct a vertex p and a helper p' . We set $w(p, p') = w(p', p) = 1$. Furthermore, for $i_1 = \lceil \frac{n}{d \log d} \rceil$ and for all $i_2 \in \{0, \dots, d-1\}$, we set $w(p, u_{(i_1, i_2, 0)}) = 1$ and $w(u_{(i_1, i_2, 0)}, p) = -1$. We call selection vertex $u_{(i_1, i_2, 0)}$ a *palette vertex*.

So far, we have described the main part of our construction, without yet specifying how we encode which literals appear in each clause. Before we move on to describe this part, let us give some intuition about the construction up to this point. The intended meaning of the palette gadget is that vertices $u_{(i_1, i_2, 0)}$ for $i_1 = \lceil \frac{n}{d \log d} \rceil$ and $i_2 \in \{0, \dots, d-1\}$ should be placed in distinct coalitions (p can be thought of as a stalker). These vertices form a “palette”, in the sense that every other selection vertex encodes an assignment to some of the variables of ϕ by deciding which of the palette vertices it will join. Hence, we intend to extract an assignment of ϕ from a stable partition by considering each vertex $u_{(i_1, i_2, 0)}$, for $i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil - 1\}$, $i_2 \in \{0, \dots, d-1\}$. For each such vertex we test in which of the d palette partitions the vertex was placed, and this gives us enough information to encode $\log d$ variables of ϕ . Since we have $\lceil \frac{n}{d \log d} \rceil \cdot d \geq \frac{n}{\log d}$ non-palette selection vertices, and each such selection vertex encodes $\log d$ variables, we will be able to encode an assignment to n variables. The role of the consistency vertices is to make sure that the partition of the selection vertices (and hence, the encoded assignment) stays consistent throughout our construction.

In order to complete the construction, let us make the above intuition more formal. For $i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil - 1\}$, $i_2 \in \{0, \dots, d-1\}$ and for any $j \in \{1, \dots, m\}$, we will say that $u_{(i_1, i_2, j)}$ encodes the assignment to variables x_k , with $k \in \{i_1 \cdot d \log d + i_2 \log d, \dots, i_1 \cdot d \log d + i_2 \log d + \log d - 1\}$. Equivalently, given an integer k , we can compute which selection vertices encode the assignment to x_k by setting $i_1 = \lfloor \frac{k}{d \log d} \rfloor$ and $i_2 = \lfloor \frac{k - i_1 d \log d}{\log d} \rfloor$. In that case, x_k is represented by $u_{(i_1, i_2, j)}$ (for any j).

Let us now explain precisely how an assignment to the variables of ϕ is encoded by the placement of selection vertices in coalitions. Let k be such that x_k is encoded by $u_{(i_1, i_2, j)}$ and let $i_3 = k - i_1 d \log d - i_2 \log d$. We have $i_3 \in \{0, \dots, \log d - 1\}$. If x_k is set to True in the assignment, then $u_{(i_1, i_2, j)}$ must be placed in the same coalition as a palette vertex $u_{\lceil \frac{n}{d \log d} \rceil, i'_2, 0}$ where i'_2 has the following property: if we write i'_2 in binary, then the bit in position i_3 must be set to 1. Similarly, if x_k is set to False, then we must place $u_{(i_1, i_2, j)}$ in the same coalition as a palette vertex $u_{\lceil \frac{n}{d \log d} \rceil, i'_2, 0}$ where writing i'_2 in binary gives a 0 in position i_3 . Observe that, given an assignment and a vertex $u_{(i_1, i_2, j)}$ which represents $\log d$ variables, this process fully specifies the palette vertex with which we must place $u_{(i_1, i_2, j)}$ to represent the assignment. In the converse direction, we can extract from the placement of $u_{(i_1, i_2, j)}$ an assignment to the vertices it represents if we know that all palette vertices are placed in distinct components, simply by finding the palette vertex $u_{(\lceil \frac{n}{d \log d} \rceil, i'_2, 0)}$ in the coalition of $u_{(i_1, i_2, j)}$, writing down i'_2 in binary, and using its $\log d$ bits in order to give an assignment to the $\log d$ variables represented by $u_{(i_1, i_2, j)}$.

We are now ready to complete the construction by considering each clause. Each vertex $\ell_{(j, \alpha)}$, $\alpha \in \{1, 2, 3\}$, corresponds to a literal of the j -th clause of ϕ . If this literal involves the variable x_k , we calculate integers i_1, i_2, i_3 from k as explained in the previous paragraph. Say, x_k is the i_3 -th variable represented by $u_{(i_1, i_2, j)}$. We set $w(\ell_{(j, \alpha)}, u_{(i_1, i_2, j)}) = 1$. Furthermore, for each $i'_2 \in \{0, \dots, d-1\}$ we look at the i_3 -th bit of the binary representation of i'_2 . If setting x_k to the value of that bit would make the literal represented by $\ell_{(j, \alpha)}$ True, we set $w(\ell_{(j, \alpha)}, u_{(\lceil \frac{n}{d \log d} \rceil, i'_2, j)}) = 1$; otherwise we set $w(\ell_{(j, \alpha)}, u_{(\lceil \frac{n}{d \log d} \rceil, i'_2, j)}) = 0$. We perform the above process for all $j \in \{1, \dots, m\}$, $\alpha \in \{1, 2, 3\}$.

Our construction is now complete, so we need to show that we satisfy all the claimed properties. It is not hard to see that the graph can be built in polynomial time, and the maximum absolute weight used is $2^{O(d)}$ (on arcs incident on some consistency vertices). The vertices with maximum degree are the consistency vertices and the vertices representing literals, both of which have degree $O(d)$.

To establish the bound on the pathwidth we first delete p, p' from the graph, as this can decrease pathwidth by at most 2. Now observe that, for each j , the set $C_j = \{c_{(i_1, j)} \mid i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil\}\}$ is a separator of the graph. We claim that if we fix a j , then the set $C_j \cup C_{j+1}$ separates the set $C'_j = \{u_{(i_1, i_2, j)} \mid i_1 \in \{0, \dots, \lceil \frac{n}{d \log d} \rceil\}, i_2 \in \{0, \dots, d-1\}\} \cup \{s_j, s'_j, \ell_{(j,1)}, \ell_{(j,2)}, \ell_{(j,3)}\}$ from the rest of the graph. We claim that we can calculate a path decomposition of the graph induced by $C_j \cup C'_j \cup C_{j+1}$ with width $O(\frac{n}{d \log d})$ such that the first bag contains C_j and the last bag contains C_{j+1} . If we achieve this we can construct a path decomposition of the whole graph by gluing these decompositions together in the obvious way (in order of increasing j). However, a path decomposition of this induced subgraph can be constructed by placing $C_j \cup C_{j+1} \cup \{s_j, s'_j, \ell_{(j,1)}, \ell_{(j,2)}, \ell_{(j,3)}\}$ and a distinct vertex of the remainder of C'_j in each bag. This decomposition has width $2|C_j| + O(1) = O(\frac{n}{d \log d})$.

Finally, let us establish the main property of the construction, namely that ϕ is satisfiable if and only if the ASHG instance admits a Nash Stable partition. If there exists a satisfying assignment to ϕ we construct a partition as follows: (i) p, p' are in their own coalition (ii) each consistency vertex is a singleton (iii) for $i_2 \in \{0, \dots, d-1\}$, the vertices of $\{u_{\lceil \frac{n}{d \log d} \rceil, i_2, j} \mid j \in \{1, \dots, m\}\}$ are placed in a distinct coalition (iv) we place the remaining selection vertices in one of the previous d coalitions in a way that represents the assignment as previously explained (v) for each $j \in \{1, \dots, m\}$ the j -th clause contains a True literal; we place the corresponding vertex $\ell_{(j, \alpha)}$ together with its out-neighbor in the selection vertices, and the remaining literal vertices together with s, s' in a new coalition. We claim that this partition is Nash Stable. We have the following argument: (i) p' is with p , while p cannot increase her utility by leaving p' , since all its other out-neighbors are in distinct coalitions (ii) for each i_1, i_2, j , the vertices $u_{(i_1, i_2, j)}, u_{(i_1, i_2, j+1)}$ are in the same coalition. Hence, the utility of each consistency vertex is 0 in any coalition, and such vertices are stable as singletons (iii) each selection vertex $u_{(i_1, i_2, j)}$ has utility 0, and such vertices only have out-going arcs of negative weight (iv) in each clause gadget we have a coalition with s_j, s'_j together with two literal vertices, say $\ell_{(j,1)}, \ell_{(j,2)}$; no vertex has incentive to leave this coalition (v) finally, for literal vertices $\ell_{(j, \alpha)}$ which we placed together with a selection vertex, we observe that if the assignment sets the corresponding literal to True, the selection vertex that is an out-neighbor of $\ell_{(j, \alpha)}$ must have been placed in a coalition that contains a palette vertex towards which $\ell_{(j, \alpha)}$ has positive utility, hence the utility of $\ell_{(j, \alpha)}$ is 2 and this vertex is stable.

For the converse direction, suppose that we have a Nash Stable partition π . We first prove that all vertices $u_{\lceil \frac{n}{d \log d} \rceil, i_2, 0}$, for $i_2 \in \{0, \dots, d-1\}$, must be in distinct coalitions. Indeed, if two of them are in the same coalition, p will have incentive to join the coalition that has the maximum number of such vertices. However, once p joins such a coalition, these vertices will have negative utility, contradicting stability. Second, we prove that for each i_1, i_2, j , the vertices $u_{(i_1, i_2, j)}, u_{(i_1, i_2, j+1)}$ must be in the same coalition. If not, consider two such vertices which are in distinct coalitions and maximize i_2 . We claim that in this case $c_{(i_1, j)}$ will always join $u_{(i_1, i_2, j)}$. Indeed, from the selection of i_2 , we have that for $i'_2 > i_2$, the contribution of arcs with absolute weight $4^{i'_2}$ to the utility of $c_{(i_1, j)}$ cancels out; while for $i'_2 < i_2$ the sum of all absolute utilities of arcs with weights $4^{i'_2}$ is too low to affect the placement of $c_{(i_1, j)}$ (in particular, $4^{i_2} - \sum_{j < i_2} 4^j > \sum_{j < i_2} 4^j$). But, if $c_{(i_1, j)}$ joins such a coalition, a selection vertex has negative utility, contradicting stability.

From the two properties above we can now extract an assignment to ϕ . For each selection vertex $u_{(i_1, i_2, j)}$, if this vertex is in the same coalition as $u_{(\lceil \frac{n}{d \log d} \rceil, i'_2, 0)}$, we give an assignment to the variables represented by $u_{(i_1, i_2, j)}$ as described, that is, we write i'_2 in binary and use one bit for each variable. Note that the choice of j here is irrelevant, as we have shown that thanks to the consistency vertices, for each i_1, i_2 , all vertices $u_{(i_1, i_2, j)}$ are in the same coalition.

If $u_{(i_1, i_2, j)}$ is not in the same coalition as any $u_{(\lceil \frac{n}{d \log d} \rceil, i'_2, 0)}$, we set its corresponding variables in an arbitrary way. To see that this assignment satisfies clause j , consider s_j , which, without loss of generality is placed with s'_j . If three of the vertices $\ell_{(j,1)}, \ell_{(j,2)}, \ell_{(j,3)}$ are in the same coalition as s_j , then s_j has negative utility, contradiction. Hence, one of these vertices, say $\ell_{(j,1)}$, is in another coalition. But then, since the neighbors of this vertex among vertices $u_{(\lceil \frac{n}{d \log d} \rceil, i_2, j)}$ are all in distinct coalitions, $\ell_{(j,1)}$ is in the same coalition with one such vertex and its out-neighbor selection vertex. But this means that we have extracted an assignment from the corresponding vertex and that this assignment sets the corresponding literal to True, satisfying the clause. ◀

▶ **Corollary 6.** *If the ETH is true, there is no algorithm which decides if an ASHG on a graph with n vertices, maximum degree Δ , and constant pathwidth admits a Nash Stable partition in time $\Delta^{o(\Delta)}(nW)^{O(1)}$, where W is the maximum absolute weight.*

Proof. We use the same reduction as in Theorem 5, from a 3-SAT formula on n variables, but set $d = \lfloor \frac{n}{2 \log n} \rfloor$. According to the properties of the construction, the pathwidth of the resulting graph is $O(\frac{n}{d \log d}) = O(1)$, the maximum degree is $O(n/\log n)$, the maximum weight is $2^{O(n/\log n)}$ and the size of the constructed graph is polynomial in n . If there exists an algorithm for finding a Nash Stable partition in the stated time, this gives a $2^{o(n)}$ algorithm for 3-SAT. ◀

▶ **Theorem 7.** *If the ETH is true, there is no algorithm which decides if an ASHG on a graph with n vertices, constant maximum degree Δ , and pathwidth p admits a Nash Stable partition in time $p^{o(p)}n^{O(1)}$, even if all weights have absolute value $O(1)$.*

▶ **Corollary 8.** *Theorem 7 also applies to CONNECTED NASH STABILITY.*

4 Parameterization by Treewidth Only

In this section we consider NASH STABILITY on graphs of bounded treewidth. Peters [36] showed that this problem is strongly NP-hard on stars, but for a more general version where preferences are described by boolean formulas (HC-nets). In Section 4.1 we strengthen this hardness result by showing that NASH STABILITY remains strongly NP-hard on stars for additive preferences. We also show that CONNECTED NASH STABILITY is strongly NP-hard on stars, albeit also using HC-nets.

The only case that remains is CONNECTED NASH STABILITY with additive preferences. Somewhat surprisingly, we show that this case evades our hardness results because it *is* in fact more tractable. We establish this via an algorithm running in pseudo-polynomial time when the treewidth is constant in Section 4.2. As a result, this is the only case of the problem which is not strongly NP-hard on bounded treewidth graphs (unless P=NP).

We then observe that our algorithm only establishes that the problem is in XP parameterized by treewidth (for weights written in unary). We show in Section 4.3 that this is inevitable, as the problem is W[1]-hard parameterized by treewidth even when weights are constant. Hence, our “pseudo-XP” algorithm is qualitatively optimal.

4.1 Refined paraNP-hardness

▶ **Theorem 9.** *NASH STABILITY of ASHG is strongly NP-hard for stars.*

Proof. We present a reduction from 3-PARTITION. In this problem we are given a set of $3n$ positive integers A , a target value T , and are asked to partition A into n triples, such that each triple has sum exactly T . This problem has long been known to be strongly

NP-hard [22]. Furthermore, we can assume that the sum of all elements of A is nT (otherwise the answer is clearly No); and that all elements have values strictly between $T/4$ and $T/2$, so sets of sizes other than three cannot have sum T (this can be achieved by adding T to all elements and setting $4T$ as the new target).

We construct an ASHG as follows: for each element of A we construct a vertex; we construct a set B of n additional vertices; we add a “stalker” vertex s and a helper s' . The preferences are defined as follows: for all $x \in A \cup B$ we set $w(x, s) = -1$; for each $x \in B$ we set $w(s, x) = 2T$; for each $x \in A$ we set $w(s, x) = -w(x)$, where $w(x)$ is the value of the corresponding element in the original instance. Finally, we set $w(s, s') = T$ and $w(s', s) = 1$. The graph is a star as all arcs are incident on s .

If there exists a valid 3-partition of A , we construct a stable partition of the new instance by placing s with s' and, for each triple placing its elements in a coalition with a distinct vertex of B . Vertices of $A \cup B$ have utility 0 in this configuration and no incentive to deviate; while s would have utility T in any existing coalition, so it has no incentive to leave s' ; s' is satisfied as she is together with s .

For the converse direction, if we have a stable configuration π , s' must be with s (otherwise s' has incentive to deviate). Furthermore, s cannot be with any vertex of $A \cup B$, as placing s with any such vertex would give that vertex incentive to leave. Hence, s, s' are one coalition of the stable partition, and s has utility T in this coalition. This implies that every coalition formed by vertices of $A \cup B$ must have utility at most T for s .

We now want to prove that every coalition of vertices of $A \cup B$ contains exactly one vertex of B . If we show this, then the weight of elements of A placed in each such coalition must be at least T , hence it must be exactly T (as the sum of all elements of A is nT). Therefore, we obtain a solution to the original instance.

To prove that every coalition that contains vertices of $A \cup B$ must contain exactly one vertex of B , suppose first that there exists a coalition that only contains vertices of A . Call the union of all such coalitions $A' \subseteq A$. Let C_1, \dots, C_k be the coalitions that contain some vertex of B , for some $k \leq |B| = n$. We now reach a contradiction as follows: first, since s does not have incentive to join C_i , for $i \in [k]$, we have $\sum_{v \in C_i} w(s, v) \leq T$, therefore $\sum_{i=1}^k \sum_{v \in C_i} w(s, v) \leq kT \leq nT$. On the other hand, $\sum_{i=1}^k \sum_{v \in C_i} w(s, v) \geq \sum_{v \in B} w(s, v) + \sum_{v \in A \setminus A'} w(s, v) > 2nT - nT = nT$, because if A' is non-empty $\sum_{v \in A \setminus A'} w(s, v) > -nT$. Hence we have a contradiction and from now on we suppose that every coalition that contains a vertex of $A \cup B$ has non-empty intersection with B .

Finally, consider a coalition that contains $k \geq 1$ vertices of B . These vertices give s utility $2kT$, meaning that the sum of weights of vertices of A placed in this coalition must be at least $(2k - 1)T$. Let t_i be the number of coalitions which contain exactly $i \geq 1$ vertices of B . We obtain the inequality $\sum_i t_i(2i - 1)T \leq nT$, because the weight of all elements of A is nT . On the other hand $\sum_i it_i = n$, as we have that $|B| = n$. We therefore have $\sum_i t_i(2i - 1) \leq n \Leftrightarrow \sum_i t_i \geq n = \sum_i it_i \Leftrightarrow \sum_{i>1} (1 - i)t_i \geq 0$, which can only hold if $t_i = 0$ for $i > 1$. \blacktriangleleft

► **Theorem 10.** *Deciding if a graphical hedonic game represented by an HC-net admits a connected Nash Stable partition is NP-hard even if the input graph is a star and all weights are in $\{1, -1\}$.*

4.2 Pseudo-XP algorithm for Connected Partitions

► **Theorem 11.** *There exists an algorithm which, given an ASHG instance on n vertices with maximum absolute weight W , along with a tree decomposition of the underlying graph of width t , decides if a connected Nash Stable partition exists in time $(nW)^{O(t^2)}$.*

Proof. Due to space constraints, we only sketch the proof. The algorithm uses standard DP techniques. In addition to connectivity information about which vertices of the bag are in the same connected component of the same coalition (which takes $t^{O(t)}$ to store in the DP table), we store for each vertex the utility it would have if it joined the coalition of each other vertex in the bag, and also the best coalition it has seen in the part of the graph that has already been processed. This gives $(nW)^t$ combinations per vertex in the bag, hence a DP table of the claimed size, and allows us to verify that all vertices are stable. The key property is that, since coalitions are connected, a coalition that has already been seen and does not contain any members in the bag is complete, in the sense that no further vertex can later be added to the coalition (as it would become disconnected). ◀

4.3 ETH-based lower bound for Connected Partitions

► **Theorem 12.** *If the ETH is true, deciding if an ASHG of pathwidth p admits a connected Nash Stable configuration cannot be done in time $f(p) \cdot n^{o(p/\log p)}$ for any computable function f , even if all weights are in $\{-1, 1\}$.*

By a slight modification of the previous proof we also obtain weak NP-hardness for the case where the input graph has vertex cover 2.

► **Corollary 13.** *It is weakly NP-hard to decide if an ASHG on a graph with vertex cover 2 admits a connected Nash Stable partition.*

5 Conclusions and Open Problems

Our results give strong evidence that the precise complexity of NASH STABILITY parameterized by $t + \Delta$ is in the order of $(t\Delta)^{O(t\Delta)}$. It would be interesting to verify if the same is true for CONNECTED NASH STABILITY, as this problem turned out to be slightly easier when parameterized only by treewidth, and is only covered by Corollary 8 for the case of bounded-degree graphs. Of course, it would also be worthwhile to investigate the fine-grained complexity of other notions of stability. In particular, versions which are complete for higher levels of the polynomial hierarchy [37] may well turn out to have double-exponential (or worse) complexity parameterized by treewidth [30, 31]. Finally, it would be worth to investigate precise complexity of other stability notions of hedonic games (e.g., individual stability and core stability), or other variants of hedonic games (e.g., fractional hedonic games and social distance games).

Abstract

A dynamic graph algorithm is a data structure that answers queries about a property of the current graph while supporting graph modifications such as edge insertions and deletions. Prior work has shown strong conditional lower bounds for general dynamic graphs, yet graph families that arise in practice often exhibit structural properties that the existing lower bound constructions do not possess. We study three specific graph families that are ubiquitous, namely constant-degree graphs, power-law graphs, and expander graphs, and give the first conditional lower bounds for them. Our results show that even when restricting our attention to one of these graph classes, any algorithm for fundamental graph problems such as distance computation or approximation or maximum matching, cannot simultaneously achieve a sub-polynomial update time and query time. For example, we show that the same lower bounds as for general graphs hold for *maximum matching* and *(s, t)-distance* in constant-degree graphs, power-law graphs or expanders. Namely, in an m -edge graph, there exists no dynamic algorithms with both $O(m^{1/2-\epsilon})$ update time and $O(m^{1-\epsilon})$ query time, for any small $\epsilon > 0$. Note that for *(s, t)-distance* the trivial dynamic algorithm achieves an almost matching upper bound of constant update time and $O(m)$ query time. We prove similar bounds for the other graph families and for other fundamental problems such as densest subgraph detection and perfect matching.

1 Introduction

A dynamic graph algorithm is a data structure that stores a graph and supports update operations, usually consisting of edge insertions and deletions, as well as query operations that ask about a specific property of the graph. The introduction of strong conditional lower bounds based on widely-believed complexity assumptions [1, 12] has had a fundamental influence on the field, pushing the design of new algorithms towards more specialized algorithms such as partially-dynamic or even offline-dynamic algorithms or towards approximate solutions. However, graphs arising in real-world applications often differ significantly from the very specifically crafted graphs for which the lower bound results are shown. Frequently, real-world

graphs have some special structure, such as having a power-law degree distribution, a constant degree, or being planar. Expanders, on the other side, have recently been used to design dynamic algorithms for *general* graphs. This naturally leads to the question of determining the complexity of dynamic graph algorithms for these graph classes, and this is exactly the question investigated in this paper.

While the complexity of dynamic graph algorithms for planar graphs has already been studied quite extensively [20, 14, 18, 16, 3, 2, 1, 15, 5], the question is still widely open for other families of graphs, including power-law graphs, constant-degree graphs, and expanders. Certain problems become easier for these graph classes: As an N -node¹ constant-degree graph has $O(N)$ edges, computing all-pairs shortest paths (APSP) takes only time $\tilde{O}(N^2)$, while the popular APSP conjecture postulates that for general graphs, there exists a small constant $c > 0$ such that any algorithm in the word RAM model with $O(\log N)$ -bit words requires $N^{3-o(1)}$ expected time to compute APSP. Moreover, some problems become trivial in these graph classes, e.g., computing shortest paths with logarithmic additive error on expander graphs is trivial, due to their low diameter.

In this paper we will concentrate on graph problems that have real-world applications such as shortest-paths (which has applications in online navigation), matching (which has applications in reconfigurable datacenters), and densest subgraphs (which has applications in network analysis), yet we believe that our general approach can be applied to further graph problems. For these three problems, the known conditional lower bounds construct graphs that are far from being in the classes we consider: They have maximum degree $\Omega(N)$ and small cuts, and their degree distribution is unknown as it depends on the instance that is postulated to be hard.

Constant-degree graphs. Various dynamic graph problems that admit strong lower bounds in general graphs have very efficient algorithms on constant-degree graphs. Let Δ be the maximum degree in the graph. For *local* problems, where the solution at a node v can be computed by simply analyzing information stored at the neighbors of v such as maintaining a maximal matching, a maximal independent set, or a $(\Delta + 1)$ -vertex coloring, there exist simple dynamic algorithms with $O(\Delta)$ update time and constant query time. Additionally, for various problems that count or detect certain fixed subgraphs with c nodes (such as triangle counting for $c = 3$) there exists dynamic algorithms with $O(\Delta^{c-1})$ update time and constant query time, even though they have polynomial conditional lower bounds in general graphs (see Table 1). These efficient algorithms for local problems rule out the possibility of any non-trivial lower bound in the constant-degree setting.

Furthermore, even for the non-local problem of maintaining a maximum matching Gupta and Peng [11] designed a $(1 + \delta)$ -approximation algorithm for any small $\delta > 0$ that runs in $O\left(\min\left\{\frac{m}{|M(t)|}, |M(t)|\right\}\delta^{-2}\right)$ amortized time per update, where $M(t)$ denotes the maximum cardinality matching after the t -th update operation. As in a graph with maximum degree Δ it holds that $|M(t)| \geq m/(2\Delta)$, their algorithm achieves an amortized update time of $O(\Delta\delta^{-2})$, which is $O(\delta^{-2})$ in constant-degree graphs. This raises the question of how efficiently other non-local dynamic graph problems such exact maximum matching, shortest paths, and densest subgraph can be solved in dynamic constant-degree graphs and whether it is possible to show (conditional) lower bounds for them.

¹ To avoid confusion with the parameters n and M used in the online-matrix-vector multiplication conjecture, we use N to denote the number of vertices and m the number of edges in the dynamic graphs.

■ **Table 1** Counting problems which admit polynomial conditional lower bounds on general graphs (amortized) and on Erdős-Rényi graphs (average case), but have algorithms with constant update and query times in constant-degree graphs. For the lower bounds above, there is no dynamic algorithm with pre-processing time $p(m, N)$, update time $u(m, N)$, and query time $q(m, N)$ unless the OMv conjecture is false. When $p(m, N)$ is unspecified, $\text{poly}(N)$ pre-processing time is allowed.

Problems	Lower bounds					Upper bounds	
	General graphs [12]		Erdős-Rényi avg-case [13]			constant Δ (trivial)	
	$u(m, N)$	$q(m, N)$	$p(m, N)$	$u(m, N)$	$q(m, N)$	$u(m, N)$	$q(m, N)$
Triangle counting	$m^{1/2-\epsilon}$	$m^{1-\epsilon}$	$N^{3-\epsilon}$	$m^{1/2-\epsilon}$	$m^{1-\epsilon}$	Δ	1
C_4 subgraph counting						Δ^3	1
5-length (s, t) -path count			$N^{2-\epsilon}$	$N^{\omega-2-\epsilon}$	1	Δ^4	1

Expanders. Expander decompositions are increasingly becoming a central tool for designing dynamic graph algorithms with improved running time bounds for various graph problems such as connectivity, minimum spanning tree, shortest paths, conductance, edge-connectivity, maximum flows, and minimum cuts [17, 9, 7, 6]. One of the central subproblems that these algorithms have to handle is to solve a graph problem on a dynamically changing expander. To understand the limitations of this approach it is crucial to understand which problems can be solved efficiently on expanders, and which cannot. We present novel lower bounds for dynamic problems on expanders, more specifically on constant-degree expanders.

Note that these results also have an interesting connection to the average-case hardness of dynamic graph algorithms. Recently, lower bounds on the average-case hardness were shown for various subgraph counting problems in dynamic Erdős-Rényi graphs (see Table 1 for some of them) [13]. As random graphs are usually expanders, giving lower bounds for a problem on dynamic expanders gives an indication that this problem might also be hard in the average case and can motivate further work in this direction.

Power-law graphs. Graphs are called *power-law graphs* if the fraction of nodes with degree d is proportional to $1/d^c$ for some constant $c > 0$. Static and dynamic power-law graphs arise surprisingly often in real-world networks, such as the Internet, the world-wide web, and citation graphs, as well as in physics, linguistics, and economics. Even though the existence of large dynamic power-law graphs was already pointed out in 2004 [10], no efficient dynamic algorithms have been developed specifically for this class of graphs. This leads to the question of whether sub-polynomial time dynamic algorithms are even possible for power-law graphs or not. In fact, dynamic power-law graphs were not only never studied, they were not even defined – removing even a single edge from a power-law graph changes the degree distribution and thus violates the power-law distribution. Hence, we first present several definitions of *dynamic* power-law graphs, where some slackness in the degree-distribution is allowed. Then we prove lower bounds that hold for all of these dynamic power-law graph definitions.

1.1 Our Results

Throughout the paper we use the standard assumption that queries output one value, such as the size, length or weight of the solution. Note that this makes it only more challenging to prove lower bounds. All our results are conditioned on the popular OMv conjecture [12], defined in Section 2, but to simplify the terminology we usually drop the word “conditional”. Our results are also summarized in Table 2.

1. *Main results.* We study the hardness of dynamic algorithms for (i) constant-degree graphs, (ii) expanders, and (iii) power-law graphs, for the following graph problems: Determining (a) the size of a maximum matching, (b) the length of the (s, t) shortest-path (i.e. (s, t) -distance), and (c) the density of the densest subgraph. Specifically, we show the following tradeoff between the update time u and the query time q in an m -edge graph for maximum matching and (s, t) -distance: There is no dynamic algorithm which achieves both $u = O(m^{1/2-\epsilon})$ and $q = O(m^{1-\epsilon})$ for any small $\epsilon > 0$. Note that these bounds match the bounds given for general graphs in [12] and that the lower bound for (s, t) -distance is almost tight as the simple algorithm that only records the edge change at update time and computes the solution from scratch at query time achieves $u = O(1)$ and $q = O(m)$. For densest subgraph we show that there is no dynamic algorithm which achieves both $u = O(N^{1/4-\epsilon})$ and $q = O(N^{1/2-\epsilon})$ for any small $\epsilon > 0$, which is weaker than the lower bound on general graphs (of $u = O(N^{1/2-\epsilon})$ and $q = O(N^{1-\epsilon})$).

The only relevant prior work are conditional lower bounds for planar graphs [1], which have constant degree: In unweighted graphs they show for all-pairs-shortest paths a weaker tradeoff between update time u and query time q than we do, namely they prove $\max(u^2 \cdot q, u \cdot q^2) = \Omega(m^{1-o(1)})$. In *weighted* graphs they show for (s, t) -distance a tradeoff of $\max(u, q) = \Omega(m^{1/2-o(1)})$. Note that our result is stronger as it shows that in *unweighted* graphs no algorithm with $u = \Omega(m^{49/100})$ and $q = \Omega(m^{99/100})$ is possible.

2. *Degree-lower bound trade-off.* While the constant-degree lower bounds are equal to the lower bounds for general graphs in terms of m , they are naturally quadratically lower in terms of the number of nodes N . To understand the behaviour of the bounds also with respect to N , we extend our constant-degree lower bounds for maximum matching, perfect matching, and (s, t) -distance to graphs with maximum degree $O(N^t)$, for any $0 \leq t \leq 1$. We show the following result: There is no dynamic algorithm which achieves both $u = O(N^{(1+t)/2-\epsilon})$ and $q = O(N^{1+t-\epsilon})$ in a graph with maximum degree $O(N^t)$ for any $\epsilon > 0$. These results hold even in bipartite graphs. Note that for $t = 1$ these results match exactly the bounds for general graphs in [12], and for $t = 0$, they match the aforementioned results for constant-degree graphs.
3. *Approximation results.* In constant-degree graphs we extend the lower bound to the problem of approximating the (s, t) -distance within a factor of $3 - \delta$, for any small constant δ . This naturally extends the $(3 - \delta)$ -approximation lower bounds on general graphs to the constant-degree case. In planar graphs, the (s, t) -distance lower bound holds only for exact answers.

Note that a similar extension to approximation algorithms is not possible for maximum cardinality matching and for densest subgraph: (a) For maximum matching, for any small $\delta > 0$ the above-mentioned $(1 + \delta)$ -approximation algorithm [11] achieves an amortized update time of $O(\delta^{-2})$, which is constant for a constant δ , thereby precluding any non-trivial lower bounds for approximate maximum matching in the constant-degree setting. Stated differently, *our work shows an interesting dichotomy for dynamic matching in constant-degree graphs*: For the exact setting there is no dynamic algorithm which achieves both $u = O(m^{1/2-\epsilon})$ and $q = O(m^{1-\epsilon})$ for any small $\epsilon > 0$, while a $(1 + \delta)$ -approximation can be achieved in constant time, for any small $\delta > 0$. (b) *The same dichotomy arises for densest subgraph*: For any small $\delta > 0$ there exists a $(1 - \delta)$ -approximation algorithm with polylogarithmic time per operation [19], while we show a polynomial lower bound for the exact value.

4. *Partially dynamic algorithms.* We extend the constant-degree reductions for maximum matching and (s, t) -distance also to the insertions-only and the deletions-only setting, achieving the same lower bound as in the fully dynamic setting.

■ **Table 2** Our results for graphs on N nodes with m edges. For every u and q stated above, there is no algorithm for the corresponding problem with amortized $O(u(m, N))$ update time and $O(q(m, N))$ query time simultaneously unless the OMv conjecture is false. The first three rows hold also for perfect matching. All the lower bounds in the table except for densest subgraph match the general OMv lower bounds.

Problem	Class	$u(m, N)$	$q(m, N)$
Maximum Matching	$\Delta \leq 3$	$m^{1/2-\epsilon}$	$m^{1-\epsilon}$
	constant degree & expansion		
	power-law graphs		
	$\Delta \leq 3$, partially dynamic		
	$\Delta \leq N^t$	$N^{(1+t)/2-\epsilon}$	$N^{1+t-\epsilon}$
(s, t) -distance	$\Delta \leq 3$	$m^{1/2-\epsilon}$	$m^{1-\epsilon}$
	$(3 - \delta)$ -approx, $\Delta \leq 3$		
	constant degree & expansion		
	power-law graphs		
	$\Delta \leq 3$, partially dynamic		
	$\Delta \leq N^t$	$N^{(1+t)/2-\epsilon}$	$N^{1+t-\epsilon}$
Densest Subgraph	$\Delta \leq 5$	$N^{1/4-\epsilon}$	$N^{1/2-\epsilon}$
	constant degree & expansion		
	power-law graphs		

5. *Perfect matching.* A special case of maximum cardinality matching is determining whether a perfect matching exists in a bipartite graph. For constant-degree graphs and expander graphs we show the following lower bound: There is no dynamic algorithm which achieves both $u = O(m^{1/2-\epsilon})$ and $q = O(m^{1-\epsilon})$ for any small $\epsilon > 0$. This can also be extended to the varying-degree setting.

To summarize, our paper opens up the research field of dynamic graph algorithms for more specific, practical graph classes, in contrast with previous work that concentrated on general or planar graphs. We believe that our techniques can be extended to further classes of dynamic graphs or even in other domains of theoretical computer science, such as distributed graph algorithms or streaming algorithms. One further interesting implication of our work is presenting the limitations of dynamic graph algorithms on expanders, thus complementing recent algorithmic results that use expander decompositions in dynamic graphs.

1.2 Our Techniques

We prove lower bounds by reductions from the online matrix vector (OMv) conjecture [12]. In these reductions, the input of an online problem, which is an $n \times n$ matrix M and a sequence of n pairs (u, v) of n -vectors, is translated into a dynamic graph. The reduction is built so that there exists a pair (u, v) satisfying $uMv = 1$ if and only if the dynamic graph has some desired property at some point of time. While we follow the general framework of OMv lower bounds, the details are delicate, as the dynamic graphs we construct should fall into specific graph classes at all times, while still maintaining the graph property under consideration. We give a high-level overview of our reductions below.

One way to turn known OMv-to-dynamic graphs reductions into reductions that produce bounded-degree graphs is by replacing high-degree nodes by bounded-degree trees. This technique has a rather clear and straightforward effect on the distances in the graph, so it is applicable when considering distance-related problems. This, however, is far from being

the case when considering other problems, such as maximum matchings. Here, replacing a high-degree node with a gadget could adversely affect the desired matching size, since the gadget might create several augmenting paths that would not have existed when it was a single high-degree node. To overcome this, we limit the possible maximum matching sizes, by designing a reduction graph with bounded-degree gadgets composed of paths, where the maximum matching is always either a perfect matching, or a near-perfect matching, i.e., the matching size is either $N/2$ or $N/2 - 1$. This reduction thus involves a large matching and a small gap between the $uMv = 0$ and $uMv = 1$ cases, and hence cannot be extended to achieve a lower bound for the approximation of the maximum matching size. While this might seem as a limitation of our construction, recall that this is actually not the case: As described above, for any small $\delta > 0$ there is a constant time $(1 + \delta)$ -approximation dynamic algorithm for the problem, and, thus, such a lower bound cannot exist.

An even more delicate reduction we present is for proving a lower bound on the densest-subgraph problem. A straightforward reduction would change $O(n)$ graph-edges for every bit of the input, which will allow us to make sure that the density of the densest subgraph changes by a significant amount when $uMv = 0$ versus when $uMv = 1$. However, this would involve $O(n^2)$ updates for each (u, v) input pair, and the reduction would fail to yield any non-trivial lower bound. Thus, we are forced to change very few edges for each input bit, which renders an almost negligible effect on the density, making it difficult to control the exact density of the densest subgraph. Our reduction balances these two factors, using a construction where each gadget is a sufficiently dense regular graph, while having each bit of the input translate into the existence or nonexistence of merely two edges inside specific gadgets. As in the case of matchings, our lower bounds cannot be extended to approximations, as for any $\delta > 0$ there exists a fast algorithm with polylogarithmic update time for computing $(1 - \delta)$ -approximations to the densest subgraph.

We then extend these reductions from bounded-degree graphs to constant-degree *constant-expansion* graphs. First, the standard lower bound reductions contain sparse cuts if the inputs M, u or v are sparse, making a standard reduction graph far from being an expander. Thus, we have to augment the graph with many more edges to make sure that it has no sparse cuts regardless of M, u and v . We do this augmentation “inside a layer” to prevent the additional edges from creating undesired short paths between s and t , or spurious augmenting paths in the case of matchings. Sparse cuts also exist in parts of the graph that do not depend on M, u or v , and to handle these, we add edges of a constant-degree expander between a well-chosen set of nodes, thus guaranteeing the expansion without changing the required graph property. Finally, in the case of distance-related problems, we note that expander graphs can have at most logarithmic diameter, but the substitution of nodes by trees described above increases the diameter to be at least logarithmic, leaving only a very small slack for our construction.

When studying densest subgraphs on expanders, adding edges in order to avoid sparse cuts might change the location and structure of the densest subgraph in an undesired way. In order to guarantee the expansion in this case, we add a copy of all the graph nodes, build a constant-degree expander on the copies of the nodes, and then connect each node to its copy by a matching.

In dynamic power-law graphs where the node degrees may depend on the inputs u, M, v and change over time, we have to guarantee that the degree changes incurred by the processing of different inputs do not cause a violation of the power-law distribution of degrees. As before, all the changes must also be done without changing the graph property under consideration, and without performing too many update operations. We address this problem by inserting or deleting edges in an online fashion in other parts of the reduction graph, to compensate for the changes incurred by processing the input vector pairs.

Organisation. Section 2 has notation and definitions. Section 3 presents the dynamic maximum matching lower bounds. The lower bounds for other problems, namely densest subgraph detection and (s, t) -distance, are briefly discussed in Section 4, and so is the partially dynamic setting. The full lower bounds, the results for partially dynamic graphs, and the missing proofs all appear in the full version of the paper.

2 Preliminaries

Throughout the paper, we consider vectors and matrices that are boolean, and so a vector-matrix-vector multiplication outputs a single bit. Henzinger *et al.* [12] define the *Online Matrix Vector* (OMv) and the *Online Vector Matrix Vector* (OuMv) multiplication problems.

► **Definition 1** (Online Matrix Vector Multiplication). *Let M be a boolean $n \times n$ matrix. Preprocessing the matrix is allowed. Then, n vectors v^1, v^2, \dots, v^n arrive one at a time, and the task is to output the product Mv^i before the next vector is revealed.*

► **Definition 2** (Online Vector Matrix Vector Multiplication). *Let M be a boolean $n \times n$ matrix. Preprocessing the matrix is allowed. Then, n vector pairs $(u^1, v^1), (u^2, v^2), \dots, (u^n, v^n)$ arrive one at a time, and the task is to output the bit $u^i M v^i$ before the next vector pair is revealed.*

In their paper, they show that the OuMv problem can be reduced to the OMv problem, and conjecture that there is no truly subcubic time algorithm for OMv.

► **Conjecture 3** (OMv). *There is no algorithm for the OMv (and hence the OuMv) problem running in time $O(n^{3-\epsilon})$ for any constant $\epsilon > 0$.*

We work with the OuMv problem for all the reductions in our paper. We denote the length of our input vectors u^i, v^i by n , and thus the matrix M is of dimension $n \times n$. We use upper indices to indicate the vector's location in the stream, but usually focus on one pair (u, v) omitting these indices. We use lower indices for a location in the vector or matrix, e.g., u_i and M_{ij} . We use N to denote the number of nodes in our reduction graph.

► **Definition 4** (Expansion). *The expansion parameter of a graph $G = (V, E)$ is defined as*

$$h = \min \left\{ \frac{|E(S, \bar{S})|}{|S|} \mid \emptyset \neq S \subseteq V, |S| \leq |V|/2 \right\}$$

where $E(S, \bar{S})$ is the number of edges from S to $V \setminus S$. We call a graph with expansion h a *h -expander*. Works on dynamic algorithms use a different definition of expansion parameter h' , called *volume expansion*. However, when considering constant-degree graphs with constant expansion (as we do in this paper), both parameters are within a Δ factor of each other, so we only consider the expansion parameter h in our proofs.

We study *power-law* graphs as introduced in [4], and only consider the setting where $\beta > 2$. In the following definition, if the number of nodes N in the graph is fixed, then we get that α is roughly $\ln N$.

► **Definition 5** (Power Law). *A graph is said to follow an (α, β) -power law distribution if the number N_d of nodes with degree d is inversely proportional to d^β for some constant $\beta > 0$. That is,*

$$N_d = \left\lfloor \frac{e^\alpha}{d^\beta} \right\rfloor \approx \left\lfloor \frac{1}{\zeta(\beta)} \cdot \frac{N}{d^\beta} \right\rfloor,$$

where $\zeta(\beta) = \sum_{i=1}^{\infty} 1/i^\beta$ is the Riemann Zeta function.

Since dynamic graphs allow edge insertions and deletions, it is impossible to maintain an exact degree distribution at all times. Hence, we introduce the notion of approximate power-law distributions to afford some slack for dynamic changes. One natural relaxation is to allow β to vary within an interval.

► **Definition 6** (*β -Varying Power Law*). *A graph is said to follow an $(\alpha, \beta_1, \beta_2)$ -varying power law distribution if the number N_d of nodes with degree d satisfies*

$$\min \left\{ \left\lfloor \frac{1}{\zeta(\beta_1)} \cdot \frac{N}{d^{\beta_1}} \right\rfloor, \left\lfloor \frac{1}{\zeta(\beta_2)} \cdot \frac{N}{d^{\beta_2}} \right\rfloor \right\} \leq N_d \leq \max \left\{ \left\lceil \frac{1}{\zeta(\beta_1)} \cdot \frac{N}{d^{\beta_1}} \right\rceil, \left\lceil \frac{1}{\zeta(\beta_2)} \cdot \frac{N}{d^{\beta_2}} \right\rceil \right\},$$

This relaxation of an exact power law, while being natural, is a global relaxation rather than a local one. Thus we also define two locally approximate definitions below that allow similar slack for all degrees.

► **Definition 7** (*Additively Approximate Power Law*). *A graph is said to follow an (α, β, c) -additively approximate power law distribution if the number N_d of nodes of degree d for a realisable degree d satisfies*

$$\left\lfloor \frac{1}{\zeta(\beta)} \cdot \frac{N}{d^\beta} \right\rfloor - c \leq N_d \leq \left\lceil \frac{1}{\zeta(\beta)} \cdot \frac{N}{d^\beta} \right\rceil + c$$

where we say that d is a realisable degree if there is a node of degree d in an (α, β) -power law graph.

► **Definition 8** (*Multiplicatively Approximate Power Law*). *A graph is said to follow an $(\alpha, \beta, \epsilon)$ -multiplicatively approximate power law distribution if the number N_d of nodes of degree d satisfies*

$$\frac{1}{(1 + \epsilon)} \cdot \left\lfloor \frac{1}{\zeta(\beta)} \cdot \frac{N}{d^\beta} \right\rfloor \leq N_d \leq (1 + \epsilon) \cdot \left\lceil \frac{1}{\zeta(\beta)} \cdot \frac{N}{d^\beta} \right\rceil$$

Our lower bounds contain at most four nodes that are one degree away from an exact power-law distribution, and thus hold in all the models discussed above with any reasonable parameter regime.

3 Lower Bounds for Dynamic Maximum Matching

The previous matching lower bounds on general graphs [12, 8] use reduction graphs that contain nodes with degree $\Omega(N)$. In this section, we construct a constant-degree reduction graph with constant expansion.

Reduction gadgets

Our gadget construction starts by replacing each node of a dense reduction by a path; we refer to each path as a “subgadget”.

Connecting every node of this new subgadget with nodes outside the subgadget might create unwanted matchings of larger sizes, so instead we carefully choose a subset of the path nodes to connect outside the subgadget. Figure 1 shows odd and even paths (“odd” and “even” describe the number of nodes) with a “canonical” matching for each of them marked in red. Next, we detail the connections outside the subgadgets.

■ **Figure 1** Odd and even sized paths used in the maximum matching lower bounds. The canonical matchings are marked in red.

Consider an odd path on $2n + 1$ vertices, and a bipartition of the vertices into (X', X) with $|X'| \leq |X|$. Indexing the vertices as $X[0]$ and $X'[i], X[i]$ for $1 \leq i \leq n$, our canonical matching matches $X[i]$ with $X'[i]$, and leaves $X[0]$ unmatched. We connect only the vertices $\{X[i] \mid 1 \leq i \leq n\}$ outside the subgadget, while vertices in X' and $X[0]$ only have edges inside the subgadget. For an even path on $2n + 2$ vertices indexed as above, our canonical matching is perfect, and matches $X[i]$ to $X'[i]$. Only vertex $X'[0]$ and all the vertices in X are connected outside the subgadget, and all vertices $X'[i], 1 \leq i \leq n$, only have edges within the subgadget.

While this suffices for sparsification, we need additional constructions in order to guarantee constant expansion. In particular, it turns out that adding edges inside a subgadget does not suffice for constant expansion, and we are forced to add edges between subgadgets. Our construction adds edges on the same side of the bipartition across subgadgets, and we show that if the newly added edges take part in any augmenting path, then there also exists an augmenting path in the subgraph devoid of any newly inserted edge.

The reduction graph consists of a left subgraph (L) and a right subgraph (R), connected together by edges corresponding to the matrix M . Note that for constant expansion, we need the number of edges of M to be a constant fraction of the sizes of L and R . While it would be possible to construct a reduction graph with $|L|$ and $|R|$ that depend on the input matrix M , we instead choose to augment the input matrix and vectors as it simplifies notation. We thus augment the input beforehand to ensure that there are $\Omega(n^2)$ edges crossing from L to R . To this end, we work with the vectors $\hat{u} = (u \ 0)$ and $\hat{v} = (v \ 0)$ of dimension $2n$, and the matrix $\hat{M} = \begin{pmatrix} M & \\ & 1 \end{pmatrix}$ of dimension $2n \times 2n$. It is easy to see that $uMv = 1 \iff \hat{u}\hat{M}\hat{v} = 1$.

► **Definition 9 (Reinforced gadget).** A reinforced gadget with x subgadgets of size y consists of x subgraphs, each of which is a path on y nodes. The nodes are bipartitioned into sets (X', X) with the larger side of the partition labelled as X in each subgadget. Thus $|X'| \leq |X|$. It is then augmented with the following edge-set: Consider a degree- d expander graph on $x \cdot \lceil \frac{y}{2} \rceil$ nodes, choose an arbitrary bijection between the expander nodes and X , and add the expander edges to these nodes accordingly. The resulting graph is the reinforced gadget.

Note that reinforced gadgets are not bipartite. Thus, while the constant-degree lower bounds hold for bipartite matching, the expander result is for maximum matching on general graphs. In what follows, we drop the hats from \hat{u}, \hat{M} and \hat{v} for simplicity, but continue our analysis with their dimensions as $2n, 2n \times 2n, 2n$ respectively.

Reduction Graph

We use the following reduction graph, composed of two odd-sized reinforced gadgets and two even-sized reinforced gadgets.

■ **Figure 2** The expander reduction graph for maximum matching. The red lines denote the canonical matching, the blue lines denote the paths in each subgadget, the grey lines denote the expander edges, and the green lines denote the input-dependent edges.

- A reinforced gadget with one subgadget of size $4n + 1$, on a set $L_1 \cup L_2$. The nodes are labelled $L_1[i]$ for $1 \leq i \leq 2n$, and $L_2[i]$ for $0 \leq i \leq 2n$. The path is from $L_2[0]$ to $L_2[2n]$, and the expander is on L_2 .
- A reinforced gadget with $2n$ subgadgets of size $4n + 2$, on a set $L_3 \cup L_4$. The subgadgets are labelled $LG[i]$ for $1 \leq i \leq 2n$, and the nodes of subgadget $LG[i]$ are labelled $L_3[i, j]$ or $L_4[i, j]$ for $0 \leq j \leq 2n$ depending on whether the node is in L_3 or L_4 . The path in each subgadget goes from $L_3[i, 0]$ to $L_4[i, 2n]$, and the expander is on L_4 .
- A copy of the above structure, with node sets marked R_i instead of L_i , respectively.
- For the matrix M , add the edge $(L_4[i, j], R_4[j, i])$ if $M_{ij} = 1$.
- Given an input vector u , for each $i \in [2n]$, add the edge $(L_2[i], L_3[i, 0])$ if $u_i = 1$, and $(L_2[i], L_4[i, 0])$ otherwise.
- Given an input vector v , for each $j \in [2n]$, add the edge $(R_2[j], R_3[j, 0])$ if $v_j = 1$, and add the edge $(R_2[j], R_4[j, 0])$ otherwise.

The total number of nodes in the reduction graph is $N = 16n^2 + 16n + 2 = \Theta(n^2)$.

Matchings in the Graph

We start by defining a base matching B on the graph, which is made up of the canonical matchings on each of the gadgets. On the left side, B matches $L_3[i, j]$ to $L_4[i, j]$, and $L_1[i]$ to $L_2[i]$ for all i, j . The matching on the right side is similar. Note that this matching always exists regardless of the input, and only $L_2[0]$ and $R_2[0]$ are unmatched in the entire graph. Thus $|B| = \frac{N}{2} - 1$. We claim that this graph has a perfect matching if and only if $uMv = 1$. Let C denote the maximum cardinality matching.

▶ **Lemma 10.** *If $uMv = 1$, then $|C| = \frac{N}{2}$, and otherwise $|C| = \frac{N}{2} - 1$.*

Proof. Since B is always a matching of size $\frac{N}{2} - 1$ regardless of the input, the claim is equivalent to showing that $uMv = 1$ if and only if there is an augmenting path with respect to the matching B .

(\implies) Suppose that $uMv = 1$, with $u_i = M_{ij} = v_j = 1$. Consider the path P composed of the following subpaths, of which all except P_4 start with an unmatched edge and end with a matched edge, while P_4 both starts and ends with an unmatched edge.

- $P_1 = L_2[0], L_1[1], L_2[1], \dots, L_2[i]$
- $P_2 = L_2[i], L_3[i, 0], L_4[i, 0], \dots, L_4[i, j]$
- $P_3 = L_4[i, j], R_4[j, i], R_3[j, i], \dots, R_3[j, 0]$
- $P_4 = R_3[j, 0], R_2[j], R_1[j], \dots, R_2[0]$

Thus, P is an augmenting path to the base matching B , which gives us that the maximum matching C has to have size $> \frac{N}{2} - 1$, implying that the maximum matching C is a perfect matching.

(\impliedby) Suppose now that there exists an augmenting path P to the base matching B that starts at $s = L_2[0]$ and ends at $t = R_2[0]$.

- Since $(\cup_i L_i, \cup_j R_j)$ is an (s, t) -cut, there is at least one crossing edge, say $(L_4[i, j], R_4[j, i])$, in P . Thus $M_{ij} = 1$.
- Since P leaves the subgadget $LG[i]$ using $(L_4[i, j], R_4[j, i])$, it should have entered the subgadget at some previous instance. Since $(L_4[i, j], R_4[j, i])$ is an unmatched edge and all the matching edges in $LG[i]$ are within the subgadget, P should have entered the subgadget using an unmatched edge. As all the matching edges in $LG[i]$ are between L_3 and L_4 , P cannot both enter and exit the subgadget through L_4 . Thus P enters $LG[i]$ through L_3 . However, the only possible unmatched edge from L_3 leaving the subgadget is the edge $(L_3[i, 0], L_2[i])$. Thus P uses the edge $(L_3[i, 0], L_2[i])$ to enter the subgadget $LG[i]$, and so $u_i = 1$.
- The path P now enters the subgadget $RG[j]$ through the unmatched edge $(L_4[i, j], R_4[j, i])$. As before, all the matched edges in $RG[j]$ are between R_4 and R_3 , and so P has to exit the subgadget using an unmatched edge from R_3 . However, the only possible unmatched edge from R_3 leaving the subgadget is the edge $(R_3[j, 0], R_2[j])$. Thus the edge $(R_3[j, 0], R_2[j])$ is used by P , giving us that $v_j = 1$.

This gives us that $uMv = 1$ as required. \blacktriangleleft

Complexity of the Reduction

On the arrival of a new vector pair, we first add all the edges corresponding to the new input (if they do not already exist), and then remove the previous vector pair's edges, as opposed to the usual convention of first deleting the previous edges and inserting the new ones. This ensures that the graph remains an expander at all steps. The proof of constant expansion is involved, and we defer it to the full version. Since number of edges in a constant-degree graph is $O(N)$, we get the following theorem for expanders.

► **Theorem 11.** *For any constant $\epsilon > 0$, there is no dynamic algorithm maintaining a maximum matching or determining the existence of a perfect matching, on all N -node graphs with constant degree and constant expansion, with amortized $O(N^{1/2-\epsilon})$ update time and $O(N^{1-\epsilon})$ query time, unless the OMv conjecture is false.*

Proof. Consider the reduction graph above. It consists of $N = 16n^2 + 16n + 2 = \Theta(n^2)$ nodes. Every time we get a new (u, v) input vector pair, we update $L_2 \times L_3$ and $R_2 \times R_3$ as detailed above. This takes $O(n)$ updates in total. After that, we query once for the size of the maximum matching in this new graph, and return 1 if and only if $|C| = \frac{N}{2}$.

65:12 Fine-Grained Complexity Lower Bounds for Families of Dynamic Graphs

Thus for each pair of input vectors, we perform $O(n)$ updates and $O(1)$ query. In total, checking n vector pairs takes us $O(n^2)$ updates and $O(n)$ query. If there were an algorithm for maximum matching on constant-degree graphs with update time $O(N^{1/2-\epsilon})$ (i.e., $O(n^{1-2\epsilon})$) and query time $O(N^{1-\epsilon})$ (i.e., $O(n^{2-2\epsilon})$), then we can decide if $uMv = 1$ for all n pairs in $O(n^{3-2\epsilon})$ time, contradicting the OMv conjecture. ◀

4 Other Lower Bounds

Dynamic Maximum Matching. All our lower bounds for the dynamic maximum matching problem are summarized in Theorem 12. Note that $m = O(N)$ for the first three graph classes below.

► **Theorem 12.** *For any constant $\epsilon > 0$, there is no dynamic algorithm for maintaining the size of the maximum matching on the following graph classes, with the amortized update time $u(N) = O(N^{1/2-\epsilon})$ and amortized query time $q(N) = O(N^{1-\epsilon})$,*

1. $\Delta \leq 3$,
 2. constant degree, constant expansion,
 3. power-law graph,
 4. $\Delta \leq O(N^t)$ with $u(N) = O(N^{(1+t)/2-\epsilon})$, and $q(N) = O(N^{1+t-\epsilon})$,
- unless the OMv conjecture is false.

Dynamic Densest Subgraph. Our lower bounds for the dynamic densest subgraph problem are summarized in Theorem 13.

► **Theorem 13.** *For any constant $\epsilon > 0$, there is no dynamic algorithm for maintaining the density of the densest subgraph on the following graph classes, with the amortized update time $u(N) = O(N^{1/4-\epsilon})$ and amortized query time $q(N) = O(N^{1/2-\epsilon})$,*

1. $\Delta \leq 7$,
 2. constant degree, constant expansion,
 3. power-law graph,
- unless the OMv conjecture is false.

Dynamic (s, t) -distance. Our lower bounds for the dynamic (s, t) -shortest paths problem are summarized in Theorem 14, and extend naturally to the SSSP and the APSP problems. Note that $m = O(N)$ for the first four classes below.

► **Theorem 14.** *For any constant $\epsilon > 0$, there is no dynamic algorithm for maintaining (s, t) -distance, SSSP, or APSP on the following graph classes, even for bipartite graphs, with the amortized update time $u(N) = O(N^{1/2-\epsilon})$ and amortized query time $q(N) = O(N^{1-\epsilon})$ (except for the last class), unless the OMv conjecture is false.*

1. $\Delta \leq 3$,
2. $(3 - \delta)$ -approximation, $\Delta \leq 3$,
3. constant degree, constant expansion,
4. power law graph,
5. $\Delta \leq O(N^t)$ with $u(N) = O(N^{(1+t)/2-\epsilon})$, and $q(N) = O(N^{1+t-\epsilon})$,

Partially Dynamic Algorithms. We summarize our lower bounds for partially dynamic algorithms in Theorem 15.

► **Theorem 15.** *For any constant $\epsilon > 0$, there is no algorithm in either the insertions-only or deletions-only setting maintaining (s, t) -distance or maximum matching, on all N -node graphs with maximum degree $\Delta \leq 3$, with amortized $O(N^{1/2-\epsilon})$ update time and $O(N^{1-\epsilon})$ query time, unless the OMv conjecture is false.*

$O(1)$ Steiner Point Removal in Series-Parallel Graphs

Jason Li ✉

Berkeley, CA, USA

Abstract

We study how to vertex-sparsify a graph while preserving both the graph’s metric and structure. Specifically, we study the Steiner point removal (SPR) problem where we are given a weighted graph $G = (V, E, w)$ and terminal set $V' \subseteq V$ and must compute a weighted minor $G' = (V', E', w')$ of G which approximates G ’s metric on V' . A major open question in the area of metric embeddings is the existence of $O(1)$ multiplicative distortion SPR solutions for every (non-trivial) minor-closed family of graphs. To this end prior work has studied SPR on trees, cactus and outerplanar graphs and showed that in these graphs such a minor exists with $O(1)$ distortion.

We give $O(1)$ distortion SPR solutions for series-parallel graphs, extending the frontier of this line of work. The main engine of our approach is a new metric decomposition for series-parallel graphs which we call a hammock decomposition. Roughly, a hammock decomposition is a forest-like structure that preserves certain critical parts of the metric induced by a series-parallel graph.

1 Introduction

Graph sparsification and metric embeddings aim to produce compact representations of graphs that approximately preserve desirable properties of the input graph. For instance, a great deal of work has focused on how, given some input graph G , we can produce a simpler graph G' whose metric is a good proxy for G ’s metric; see, for example, work on tree embeddings [4, 16], distance oracles [36, 35] and graph spanners [2, 1] among many other lines of work. Simple representations of graph metrics enable faster and more space efficient algorithms, especially when the input graph is very large. For this reason these techniques are the foundation of many modern algorithms for massive graphs.

Compact representations of graphs are particularly interesting when we assume that G is a member of a minor-closed graph family such as tree, cactus, series-parallel or planar graphs.¹ As many algorithmic problems are significantly easier on such families – see e.g. [26, 3, 37] – it is desirable that G' is not only a simple approximation of G 's metric but that it also belongs to the same family as G .

Steiner point removal (SPR) formalizes the problem of producing a simple G' in the same graph family as G that preserves G 's metric. In SPR we are given a weighted graph $G = (V, E, w)$ and a terminal set $V' \subseteq V$ where $V \setminus V'$ are called “Steiner points.” We must return a weighted graph $G' = (V', E', w')$ where:

1. G' is a minor of G ;
2. $d_G(u, v) \leq d_{G'}(u, v) \leq \alpha \cdot d_G(u, v)$ for every $u, v \in V'$;

and our aim is to minimize the multiplicative distortion α . We refer to a G' with distortion α as an α -SPR solution. In the above d_G and $d_{G'}$ give the distances in G and G' respectively.

If we only required that G' satisfies the second condition then we could always achieve $\alpha = 1$ by letting G' be the complete graph on V' where $w'(\{u, v\}) = d_G(u, v)$ for every $u, v \in V'$. However, such a G' forfeits any nice structure that G may have exhibited. Thus, the first condition ensures that if G belongs to a minor-closed family then so does G' . The second condition ensures that G' 's metric is a good proxy for G 's metric. G' is simpler than G since it is a graph only on V' while G' is a proxy for G 's metric by approximately preserving distances on V' .

As [22] observed, even for the simple case of trees we must have $\alpha > 1$. For example, consider the star graph with unit weight edges where V' consists of the leaves of the star. Any tree $G' = (V', E', w')$ has at least two vertices u and v whose connecting path consists of at least two edges. On the other hand, the length of any edge in G' is at least 2 and so $d_{G'}(u, v) \geq 4$. Since $d_G(u, v) = 2$ it follows that $\alpha \geq 2$. While this simple example rules out the possibility of 1-SPR solutions on trees, it leaves open the possibility of small distortion solutions for minor-closed families.

In this vein several works have posed the existence of $O(1)$ -SPR solutions for minor-closed families as an open question: see, for example, [5, 19, 8, 30, 11] among other works. A line of work (summarized in Figure 1) has been steadily making progress on this question for the past two decades. [22] showed that trees (i.e. connected K_3 -minor-free graphs) admit 8-SPR solutions.[20] recently gave a simpler proof of this result. [8] proved this was tight by showing that $\alpha \geq 8$ for trees which remains the best known lower bound for K_h -minor-free graphs. In an exciting recent work, [19] reduced $O(1)$ -SPR in K_h -minor-free graphs to computing “ $O(1)$ scattering partitions” and showed how to compute these partitions for several graph classes, including cactus graphs (i.e. all connected F -minor-free graphs where F is K_4 missing one edge). Lastly, a work of [5] generalizes these results by showing that outerplanar graphs (i.e. graphs which are both K_4 and $K_{2,3}$ -minor-free) have $\alpha = O(1)$ solutions.

¹ A graph G' is a minor of a graph G if G' can be attained (up to isomorphism) from G by edge contractions as well as vertex and edge deletions. A graph is F -minor-free if it does not have F as a minor. A family of graphs \mathcal{G} is said to be minor-closed if for any $G \in \mathcal{G}$ if G' is a minor of G then $G' \in \mathcal{G}$. A seminal work of Robertson and Seymour [34] demonstrated that every minor-closed family of graphs is fully characterized by a finite collection of “forbidden” minors. In particular, if \mathcal{G} is a minor-closed family then there exists a finite collection of graphs \mathcal{M} where $G \in \mathcal{G}$ iff G does not have any graph in \mathcal{M} as a minor. Here and throughout this work we will use “minor-closed” to refer to all non-trivial minor-closed families of graphs; in particular, we exclude the family of all graphs which is minor-closed but trivially so.

■ **Figure 1** A summary of the SPR distortion for (connected) K_h -minor-free graphs achieved in prior work and our own. Graph classes illustrated according to containment. We also give the forbidden minors for each graph family.

1.1 Our Contributions

In this work, we advance the state-of-the-art for Steiner point removal in minor-closed graph families. We show that series-parallel graphs (i.e. graphs which are K_4 -minor-free) have $O(1)$ -SPR solutions. The following theorem summarizes the main result of our paper.

► **Theorem 1.** *Every series-parallel graph $G = (V, E, w)$ with terminal set $V' \subseteq V$ has a weighted minor $G' = (V', E', w')$ such that for any $u, v \in V'$ we have*

$$d_G(u, v) \leq d_{G'}(u, v) \leq O(1) \cdot d_G(u, v).$$

Moreover, G' is poly-time computable by a deterministic algorithm.

Series-parallel graphs are a strict superset of all of the aforementioned graph classes for which $O(1)$ -SPR solutions were previously known; again, see Figure 1. Series-parallel graphs are one of the most well-studied graph classes in metric embeddings and serve as a frequent test bed for making progress on long-standing open questions. For example, series-parallel graphs are one of the few graph classes for which the well-known GNRS conjecture in metric embeddings has been successfully proven [25]. For further examples see, among many other works, those of [23, 7] and [13].

Relation to Prior Results

From a metric-embeddings perspective, series-parallel graphs are significantly more complex than outerplanar graphs (the largest minor-free graph class for which $O(1)$ -distortion Steiner point removal was known prior to our work). For example, [24] showed that outerplanar graphs can be embedded into “dominating tree metrics” with constant distortion but that such an embedding for series-parallel graphs incurs $\Omega(\log n)$ distortion. Likewise, outerplanar graphs embed isometrically into l_1 which is known to not be possible for series-parallel graphs; see [33] and [9] for details. Thus, the metrics induced by series-parallel graphs often behave very differently and in less well-structured ways than those induced by outerplanar graphs.

Furthermore, the techniques on which we rely are quite different than those of [5] for the outerplanar case. At least two aspects of these techniques may be of independent interest. We defer a more thorough overview of our techniques to Section 4 but briefly highlight these two points now.

A New Approach for Steiner Point Removal

First, much of our approach generalizes to any K_h -minor-free graph so our approach seems like a promising avenue for future work on $O(1)$ -SPR in minor-closed families. Specifically, we prove our result by beginning with the “chops” used by [29] to build low diameter decompositions for K_h -minor-free graphs. For input $\Delta > 0$ and root vertex r , these chops consist of deleting any edge which for some $i \in \mathbb{Z}$ has endpoints at distance $i\Delta$ and $i\Delta + 1$ from r ; removing such edges partitions the input graph into width Δ “annuli.” We begin with these chops but then slightly perturb them to respect the shortest path structure of the graph, resulting in what we call $O(1)$ -scattering chops. We argue that the result of repeating such scattering chops is a scattering partition which by the results of [19] can be used to construct an $O(1)$ -SPR solution.

The key to this strategy is arguing that series-parallel graphs admit a certain structure – which we call a hammock decomposition – that enables one to perform these perturbations in a principled way. If one could demonstrate a similar structure for K_h -minor-free graphs or otherwise demonstrate the existence of $O(1)$ -scattering chops for such graphs, then the techniques laid out in our work would immediately give $O(1)$ -SPR solutions for all K_h -minor-free graphs.

New Geometric Structure for Series-Parallel Graphs

Second, our hammock decompositions are a new metric decomposition for series-parallel graphs which may be interesting in their own right. We give significantly more detail in the full version of our work but briefly summarize our decomposition for now. We show that for any fixed BFS tree T_{BFS} there is a forest-like subgraph which contains all shortest paths between cross edges of T_{BFS} .² Specifically, the “nodes” of this forest are not vertices but highly structured subgraphs of the input series-parallel graph which we call hammock graphs. A hammock graph consists of two subtrees of the BFS tree and the cross edges between them.

Our hammock decompositions stand in contrast to the fact that the usual way in which one embeds a graph into a tree – by way of dominating tree metrics – are known to incur distortion $\Omega(\log n)$ in series-parallel graphs [25]. Furthermore, our decomposition can be seen as a metric-strengthening of the classic nested ear decompositions for series-parallel graphs of [28] and [15]. In general, a nested ear decomposition need not reflect the input metric. However, not only can one almost immediately recover a nested ear decomposition from a hammock decomposition, but the output nested ear decomposition interacts with the graph’s metric in a highly structured way (see the full version of our work).

Open Questions Resolved

Lastly, we note that, in addition to making progress on the existence of $O(1)$ -SPR solutions for every minor-closed family, our work also settles several open questions. The existence of $O(1)$ -SPR solutions for series-parallel graphs was stated as an open question by both [5] and [8]; our result answers this question in the affirmative. Furthermore, [20] posed the existence of $O(1)$ scattering partitions for outerplanar and series-parallel graphs as an open question; we prove our main result by showing that series-parallel graphs admit $O(1)$ scattering partitions, settling both of these questions.

² Here and throughout this work a cross edge is an edge that is in the input graph but not in T_{BFS} .

2 Related Work

We briefly review additional related work.

Since the introduction of SPR by [22], a variety of works have studied the bounds achievable for well-behaved families of graphs for several very similar problems. [30] studied a problem like SPR but where distances in G must be exactly preserved by G' and the number of Steiner vertices – that is, vertices not in V' – must be made as small as possible; this work showed that while $O(k^4)$ Steiner vertices suffice (where $k = |V'|$) for general graphs, better bounds are possible for well-behaved families of graphs. More generally, [11] studied how to trade off between the number of terminals and distortion of G' , notably showing $(1 + \epsilon)$ distortion is possible in planar graphs with $\tilde{O}(k^2/\epsilon^2)$ Steiner vertices. [14] showed that in minor-closed graphs distances can be preserved up to $O(1)$ multiplicative distortion in expectation by a distribution over minors as opposed to preserving distances deterministically with a single minor as in SPR.

A variety of recent works have also studied how to find minors which preserve properties of G other than G 's metric. [14] studied a flow/cut version of SPR where the goal is for G' to be a minor of G just on the specified terminals while preserving the congestion of multicommodity flows between terminals: this work showed that a convex combination of planar graphs can preserve congestion on V' up to a constant while for general graphs a convex combination of trees preserves congestion up to an $O(\log k)$. Similarly, [31] studied how to find minimum-size planar graphs which preserve terminal cuts. [21] studied how to find a minor of a directed graph with as few Steiner vertices and which preserves the reachability relationships between all k terminals, showing that $O(k^3)$ vertices suffices for general graphs but $O(\log k \cdot k^2)$ vertices suffices for planar graphs.

There has been considerable effort in the past few years on developing good SPR solutions for general graphs. [27] gave $O(\log^5 k)$ -SPR solutions for general graphs. This was improved by [10] who gave $O(\log^2 k)$ -SPR solutions which was, in turn, improved by [18] and [17] who gave $O(\log k)$ -SPR solutions for general graphs. We also note that [19] also achieved similar results by way of scattering partitions, albeit with a worse poly-log factor as well as the first $O(1)$ -SPR solutions for bounded pathwidth graphs.

3 Preliminaries

Before giving an overview of our approach we summarize the characterization of series-parallel graphs we use throughout this work as well as the scattering partition framework of [19] on which we build.

3.1 Characterizations of Series-Parallel Graphs

There are some minor inconsistencies in the literature regarding what is considered a series-parallel graph and so we clarify which notion of series-parallel we use throughout this paper. Some works – e.g. [15] – take series parallel graphs to be those which can be computed by iterating parallel and series compositions of graphs. Call these series-parallel A graphs.³

³ The following is a definition of series-parallel A graphs due to [15]. A graph is two-terminal if it has a distinct source s and sink t . Let G and H be two two-terminal graphs with sources s and s' and sinks t and t' . Then the series composition of G and H is the graph resulting from identifying t and s' as the same vertex. The parallel composition of G and H is the graph resulting from identifying s and s' as the same vertex and t and t' as the same vertex. A two-terminal series-parallel graph is a two-terminal graph which is either a single edge or the graph resulting from the series or parallel composition of two two-terminal series-parallel graphs. A graph is series-parallel A if it has some pair of vertices with respect to which it is two-terminal series-parallel.

(a) A clawed cycle. (b) A scattering partition.

■ **Figure 2** In (a) we illustrate a clawed cycle where the cycle C is given in solid black and each path is given in dotted black. In (b) we illustrate a scattering partition with $\tau = 3$ and how one path P of length at most Δ is incident to at most three parts where we color the subpaths of P according to the incident part.

Strictly speaking, series-parallel A graphs are not even minor-closed as they are not closed under edge or vertex deletion. Other works – e.g. [19] – take series-parallel graphs to be graphs whose biconnected⁴ components are each series-parallel A graphs; call these series-parallel B graphs. Series-parallel B graphs clearly contain series-parallel A graphs and, moreover, are minor-closed. For the rest of this work we will use the more expansive series-parallel B notion; henceforth we use “series-parallel” to mean series-parallel B.

It is well-known that a graph is K_4 -minor-free iff it is series-parallel [6]. Similarly a graph has treewidth at most 2 iff it is series-parallel [6]. In this work we will use an alternate definition in terms of “clawed cycles” which we illustrate in Figure 2a.⁵

► **Definition 2** (Clawed Cycle). *A clawed cycle is a graph consisting of a root r , a cycle C and three paths P_1 , P_2 and P_3 from r to vertices $v_1, v_2, v_3 \in C$ where $v_1 \neq v_2 \neq v_3$*

The fact that series-parallel graphs are exactly those that do not have any clawed cycles as a subgraph was proven by [12]; we give a proof for completeness.

► **Lemma 3** ([12]). *A graph G is series-parallel iff it does not contain a clawed cycle as a subgraph.*

Proof. K_4 is itself a clawed cycle and so a graph with no clawed cycle subgraphs is K_4 -minor-free and therefore series-parallel. If a graph contains a clawed cycle then we can construct a K_4 minor by arbitrarily contracting the graph into v_1, v_2, v_3 and r , as defined in Definition 2. ◀

3.2 Scattering Partitions

Our result will be based on a new graph partition introduced by [19], the scattering partition. Roughly speaking, a scattering partition of a graph is a low-diameter partition which respects the shortest path structure of the graph; see Figure 2b.⁶

⁴ A connected component C is biconnected if C remains connected even after the deletion of any one vertex in C .

⁵ We note that clawed cycles are also called “embedded Wheatstone bridge.”

⁶ We drop one of the parameters of the definition of [19] as it will not be necessary for our purposes.

► **Definition 4** (Scattering Partition). *Given a weighted graph $G = (V, E, w)$, a partition $\mathcal{P} = \{V_i\}_i$ of V is a (τ, Δ) scattering partition if:*

1. **Connected:** *Each $V_i \in \mathcal{P}$ is connected;*
2. **Low Weak Diameter:** *For each $V_i \in \mathcal{P}$ and $u, v \in V_i$ we have $d_G(u, v) \leq \Delta$;*
3. **Scattering:** *Every shortest path P in G of length at most Δ satisfies $|\{V_i : V_i \cap P \neq \emptyset\}| \leq \tau$.*

[19] extended these partitions to the notion of a scatterable graph.

► **Definition 5** (Scatterable Graph). *A weighted graph $G = (V, E, w)$ is τ -scatterable if it has a (τ, Δ) -scattering partition for every $\Delta \geq 0$.*

We will say that G is deterministic poly-time τ -scatterable if for every $\Delta \geq 0$ a (τ, Δ) -scattering partition is computable in deterministic poly-time.

As a concrete example of a τ -scatterable graph and as observed by [19] notice that all trees are $O(1)$ -scatterable. In particular, suppose we are given a tree and a $\Delta > 0$. If we fix a root vertex r and then delete any edge which for some $i \in \mathbb{Z}$ has endpoints at distance $\frac{i\Delta}{2}$ and $\frac{i\Delta}{2} + 1$ from r this breaks the input tree into connected components. Each component has diameter at most Δ by construction. Furthermore, it is easy to see that any path of length at most Δ is incident to a constant number of these components and so these components indeed form a scattering partition with $\tau = O(1)$. This construction is essentially a single chop of the aforementioned KPR strategy. However, while a KPR chop can be used to construct scattering partitions on trees, as we will see shortly, KPR chops on series-parallel graphs do not, in general, result in scattering partitions.

Lastly, the main result of [19] is that solving SPR reduces to showing that every induced subgraph is scatterable. In the following $G[A]$ is the subgraph of G induced by the vertex set A .

► **Theorem 6** ([19]). *A weighted graph $G = (V, E, w)$ with terminal set $V' \subseteq V$ has an $O(\tau^3)$ -SPR solution if $G[A]$ is τ -scatterable for every $A \subseteq V$. Furthermore, if $G[A]$ is deterministic poly-time scatterable for every $A \subseteq V$ then the $O(\tau^3)$ -SPR solution is computable in deterministic poly-time.*

4 Intuition and Overview of Techniques

We now give intuition and a high-level overview of our techniques. As discussed in the previous section, solving SPR with $O(1)$ distortion for any fixed graph reduces to showing that the subgraph induced by every subset of vertices is $O(1)$ -scatterable. Moreover, since every subgraph of a K_h -minor-free graph is itself a K_h -minor-free graph, it follows that in order to solve SPR on any fixed K_h -minor-free graph, it suffices to argue that every K_h -minor-free graph is $O(1)$ -scatterable.

Thus, the fact that we dedicate the rest of this document to showing is as follows.

► **Theorem 7.** *Every series-parallel graph G is deterministic, poly-time $O(1)$ -scatterable.*

Combining this with Theorem 6 immediately implies Theorem 1.

4.1 General Approach

Given a series-parallel graph G and some $\Delta \geq 1$, our goal is to compute an $(O(1), \Delta)$ -scattering partition for G . Such a partition has two non-trivial properties to satisfy: (1) each constituent part must have weak diameter at most Δ and (2) each shortest path of length at most Δ must be in at most $O(1)$ parts (a property we will call “scattering”).

■ **Figure 3** Two levels of Δ -chops on the grid graph for $\Delta = 3$. We give the edges of the BFS trees we use in pink; roots of these trees are given as squares. Background colors give the annuli of nodes.

■ **Figure 4** An example (of an outerplanar graph) where a Δ -chop does not produce a scattering partition but how perturbing said chop does. Here, we imagine that the root is at the top of the graph and each edge incident to the root has length $\Delta - 3$. We highlight the path P that either ends up in many or one connected component depending on whether we perturb our Δ -chop in yellow.

A well-known technique of [29] – henceforth “KPR” – has proven useful in finding so-called low diameter decompositions for K_h -minor-free graphs and so one might reasonably expect these techniques to prove useful for finding scattering partitions. Specifically, KPR shows that computing low diameter decompositions in a K_h -minor-free graph can be accomplished by $O(h)$ levels of recursive “ Δ -chops”. Fix a root r and a BFS tree T_{BFS} rooted at r . Then, a Δ -chop consists of the deletion of every edge with one vertex at depth $i \cdot \Delta$ and another vertex at depth $i \cdot \Delta + 1$ for every $i \in \mathbb{Z}_{\geq 1}$; that is, it consists of cutting edges between each pair of adjacent Δ -width annuli. KPR proved that if one performs a Δ -chop and then recurses on each of the resulting connected component then after $O(h)$ levels of recursive depth in a K_h -minor free graph the resulting components all have diameter at most $O(\Delta)$. We illustrate KPR on the grid graph in Figure 4.

Thus, we could simply apply Δ -chops $O(h)$ times to satisfy our diameter constraints (up to constants) and hope that the resulting partition is also scattering. Unfortunately, it is quite easy to see that (even after just one Δ -chop!) a path of length at most Δ can end up in arbitrarily many parts of the resulting partition. For example, the highlighted shortest path in Figures 4a and 4b repeatedly moves back and forth between two annuli and ends up in arbitrarily many parts after a single Δ -chop. Nonetheless, this example is suggestive of the basic approach of our work. In particular, if we merely perturbed our first Δ -chop to cut “around” said path as in Figures 4c and 4d then we could ensure that this path ends up in a small number of partitions.

More generally, the approach we take in this work is to start with the KPR chops but then slightly perturb these chops so that they do not cut *any* shortest path of length at most Δ more than $O(1)$ times. That is, all but $O(1)$ edges of any such path will have both vertices in the same (perturbed) annulus. We then repeat this recursively on each of the resulting connected components to a constant recursion depth. Since each subpath of a shortest path of length at most Δ is itself a shortest path with length at most Δ , we know that each such shortest path is broken into a constantly-many-more shortest paths at each level of recursion. Moreover, since we recurse a constant number of times, each path ends up in a constant number of components.

Implementing this strategy requires meeting two challenges. First, it is not clear that the components resulting from KPR still have low diameter if we allow ourselves to perturb our chops. Second, it is not clear how to perturb a chop so that it works *simultaneously* for every shortest path. Solving the first challenge will be somewhat straightforward while solving the second will be significantly more involved. In particular, what makes the second challenge difficult is that we cannot, in general, perturb a chop on the basis of one violated shortest path as in the previous example; doing so might cause other paths to be cut too many times which will then require additional, possibly conflicting, perturbations and so on. Rather, we must somehow perturb our chops in a way that takes every shortest path into account all at once.

4.2 Scattering Chops

The easier issue to solve will be how to ensure that our components have low diameter even if we perturb our chops. Here, by closely tracking various constants through a known analysis of KPR we show that the components resulting from KPR with (boundedly) perturbed cuts are still low diameter.

We summarize this fact and the above discussion with the idea of a scattering chop. A (τ, Δ) -scattering chop consists of cutting all edges at *about* every Δ levels in the BFS tree in such a way that no shortest path of length at most Δ is cut more than τ times. Our analysis shows that if all K_h -minor-free graphs admit $(O(1), \Delta)$ -scattering chops for every Δ then they are also $O(1)$ -scatterable and therefore also admit $O(1)$ -SPR solutions; this holds even for $h > 4$.

4.3 Hammock Decompositions and How to Use Them

The more challenging issue we must overcome is how to perturb our chops so that every shortest path of length at most Δ is only cut $O(1)$ times. Moreover, we must do so in a way that does not perturb our boundaries by too much so as to meet the requirements of a scattering chop. We solve this issue with our new metric decomposition for series-parallel graphs, the hammock decomposition.

Consider a shortest path P of length at most Δ . Such a path can be partitioned into a (possibly empty) prefix consisting of only edges in T_{BFS} , a middle portion whose first and last edges are cross edges of T_{BFS} and a (possibly empty) suffix which also only has edges in T_{BFS} . Thus, if we want to compute a scattering chop, it suffices to guarantee that any shortest path of length at most Δ which is either fully contained in T_{BFS} or which is between two cross edges of T_{BFS} is only cut $O(1)$ times by our chop; call the former a BFS path and the latter a cross edge path.

Next, notice that all BFS paths are only cut $O(1)$ times by our initial KPR chops. Specifically, each BFS path can be partitioned into a subpath which goes “up” in the BFS tree and a subpath which goes “down” in the BFS tree. As our initial KPR chops are Δ apart and each such subpath is of length at most Δ , each such subpath is cut at most $O(1)$ times. Thus provided our perturbations do not interfere *too much* with the initial structure of our KPR chops we should expect that our BFS paths will only be cut $O(1)$ times.

Thus, our goal will be to perturb our KPR chops to not cut any cross edge path more than $O(1)$ times while mostly preserving the initial structure of our KPR chops. Our hammock decompositions will allow us to do exactly this. They will have two key components.

The first part is a “forest of hammocks.” Suppose for a moment that our input graph had a forest subgraph F that contained all cross edge paths of our graph which were also shortest paths. Then, it is not too hard to see how to use F to perturb our chops to be scattering for

all cross edge paths. Specifically, for each tree T in our forest F we fix an arbitrary root and then process edges in a BFS order. Edges which we process will be marked or unmarked where initially all edges are unmarked. To process an edge $e = \{u, v\}$ we do the following. If e is marked or u and v both belong to the same annulus then we do nothing. Otherwise, e is unmarked and u is in some annulus A but v is in some other annulus A' (before any perturbation). We then propagate A an additional $\Theta(\Delta)$ deeper into T ; that is if we imagine that v is the child of u in F then we move all descendants of u in F within $\Theta(\Delta)$ of u into A . We then mark all edges in T whose endpoints are descendants of u and within $\Theta(\Delta)$ of u . A simple amortized analysis shows that after performing these perturbations every cross edge path is cut $O(1)$ times: if we think of following a cross edge path from one endpoint to the other, then each time this path is cut there must be at least $\Omega(\Delta)$ many edges we get to traverse until the next time it is cut again.

Unfortunately, it is relatively easy to see that such an F may not exist in a series-parallel graph. The forest of hammocks component of our decompositions is a subgraph which will be “close enough” to such an F , thereby allowing us to perturb our chops similarly to the above strategy. As mentioned in the introduction, a hammock graph consists of two subtrees of a BFS tree and the cross edges between them. A forest of hammocks is a graph partitioned into hammocks where every cycle is fully contained in one of the constituent hammocks. While the above perturbation will guarantee that our cross edge paths are not cut too often, it is not clear that such a perturbation does not change the structure of our initial chops in a way that causes our BFS paths to be cut too many times.

The second part of our hammock decompositions is what we use to guarantee that our BFS paths are not cut too many times by preserving the structure of our initial KPR chops. Specifically, the forest structure of our hammocks will reflect the structure of T_{BFS} . In particular, we can naturally associate each hammock H_i with a single vertex, namely the LCA of any u and v where u is in one tree of H_i and v is in the other. Then, our forest of hammocks will satisfy the property that if hammock H_i is a “parent” of hammock H_j in our forest of hammocks then the LCA corresponding to H_i is an ancestor of the LCA corresponding to H_j in T_{BFS} ; even stronger, the LCA of H_j will be contained in H_i . Roughly, the fact that our forest of hammocks mimics the structure of T_{BFS} in this way will allow us to argue that the above perturbation does not alter the initial structure of our KPR chops too much, thereby ensuring that BFS paths are not cut too many times.

The computation of our hammock decompositions constitutes the bulk of our technical work but is somewhat involved. The basic idea is as follows. We will partition all cross edges into equivalence classes where each cross edge in an equivalence class shares an LCA in T_{BFS} (though there may be multiple, distinct equivalence classes with the same LCA). Each such equivalence class will eventually correspond to one hammock in our forest of hammocks. To compute our forest of hammocks we first connect up all cross edges in the same equivalence class. Next we connect our equivalence classes to one another by cross edge paths which run between them. We then extend our hammocks along paths towards their LCAs to ensure the above-mentioned LCA properties. Finally, we add so far unassigned subtrees of T_{BFS} to our hammocks. We will argue that when this process fails it shows the existence of a K_4 -minor and, in particular, a clawed cycle.

5 Notation and Conventions

Before proceeding to our formal results we specify the notation we use throughout this work as well as some of the assumptions we make on our input series-parallel graph without loss of generality (WLOG).

Graphs. For a weighted graph $G = (V, E, w)$, we let $V(G) = V$ and $E(G) = E$ give the vertex set and edge sets of G respectively. We will sometimes abuse notation and use G to stand for V or E when it is clear from context if we mean G 's vertex or edge set. Our weight function on edges is $w : E \rightarrow \mathbb{Z}_{\geq 1}$. Given graphs G and H , we will use the notation $H \subseteq G$ to indicate that H is a subgraph of G . The weak diameter of a subgraph H is $\max_{u,v \in V(H)} d_G(u, v)$.

Assumption of Unique Shortest Paths and Unit Weights. We will assume throughout this work that in our input series-parallel graph for any vertices u and v the shortest path between u and v is unique and that $w(e) = 1$ for every e . It is easy to see that our algorithms extend to non-unique shortest paths and the non-unit weight edge cases by standard techniques. In particular, one can randomly perturb the initial weights of the input graph so as to guarantee the uniqueness of shortest paths. Similarly, one can expand each edge of weight $w(e)$ into a path of $w(e)$ edges while preserving series-parallelness and the metric on the nodes from the original graph which suffices for our purposes.

Induced Graphs and Edges. Given an edge set E and disjoint vertex sets V_1 and V_2 , we let $E(V_1, V_2) := \{e = \{v_1, v_2\} \in E : v_1 \in V_1, v_2 \in V_2\}$ be all edges between V_1 and V_2 . Given graph $G = (V, E)$ and a vertex set $U \subseteq V$, we let $G[U] = (U, E_U)$ be the ‘‘induced subgraph’’ of G where $\{u', v'\} \in E_U$ iff $\{u', v'\} \in E$. Given a collection of subgraphs $\mathcal{H} = \{H_i\}_i$ of a graph we call $G[\mathcal{H}] := (\bigcup_i V(H_i), \bigcup_i E(H_i))$ the induced subgraph of \mathcal{H} . Similarly, we will let $E(\mathcal{H}) := \bigcup_i E(H_i)$ give the edges of \mathcal{H} . We emphasize that it is not necessarily the case that $G[\mathcal{H}] = G[V(\mathcal{H})]$.

Paths. Given a path $P = (v_0, v_1, \dots, v_k, v_{k+1})$ we will use $\text{internal}(P) := \{v_1, \dots, v_k\}$ to refer to the internal vertices of P . We will say that a path P is between two vertex sets U and W if its first and last vertices are in U and W respectively and $\text{internal}(P) \cap U = \emptyset$ and $\text{internal}(P) \cap W = \emptyset$. We will sometimes abuse notation and use P and $E(P)$ interchangeably. We will also sometimes say such a path is ‘‘from’’ U to W interchangeably with a path is ‘‘between’’ U and W . We will use $P \oplus P'$ to refer to the concatenation of two paths which share an endpoint throughout this paper. For a tree T , we will let $T(u, v)$ stand for the unique path between u and v in T for $u, v \in V(T)$. We will sometimes assume that a path from a vertex set to another vertex set is directed in the natural way.

BFS Tree Notation. For much of this work we will fix a series-parallel graph $G = (V, E)$ along with a fixed but arbitrary root $r \in V$ and a fixed but arbitrary BFS tree T_{BFS} with respect to r . When we do so we will let $E_c := E \setminus E(T_{\text{BFS}})$ be all cross edges of T_{BFS} . For $u, v \in V$, if $u \in T_{\text{BFS}}(r, v) \setminus \{v\}$ then we say that u is an ancestor of v . In this case, we also say that v is a descendant of u . If u is an ancestor of v or v is an ancestor of u then we say that u and v are related; otherwise, we say that u and v are unrelated. For two vertices $u, v \in V$ we will use the notation $u \prec v$ to indicate that v is an ancestor of u and we will use the notation $u \preceq v$ to indicate that v is an ancestor of or equal to u . It is easy to verify that \preceq induces a partial order. We let $T_{\text{BFS}}(v) := T_{\text{BFS}}[\{v\} \cup \{u \in V : u \text{ is a descendant of } v\}]$ be the subtree of T_{BFS} rooted at v . Given a connected subgraph $T \subseteq T_{\text{BFS}}$, we will let $\text{high}(T)$ be the vertex in $V(T)$ which is an ancestor of all vertices in $V(T)$. Given a path $P \subseteq T_{\text{BFS}}$ we will say that P is monotone if $\text{high}(P)$ is an ancestor of all vertices in P and there is some vertex $\text{low}(P)$ which is a descendant of all vertices in P . We let $h(v)$ give the height of a vertex in T_{BFS} (where we imagine that the nodes furthest from r are at height 0). We let $\text{LCA}(e)$ be the least common ancestor of u and v in T_{BFS} for each $e = \{u, v\} \in E$.

Miscellaneous. We will use \sqcup for disjoint set union throughout this paper. That is $A \sqcup B$ is equal to $A \cup B$ but indicates that $A \cap B = \emptyset$.

6 Perturbing KPR and Scattering Chops

In this section we show that KPR still gives low diameter components even if its boundaries are perturbed and therefore somewhat “fuzzy.” We then observe that this fact shows that “ $O(1)$ -scattering chops” imply the existence of $O(1)$ -scattering partitions for K_h -minor-free graphs and therefore $O(1)$ -SPR solutions.

6.1 Perturbing KPR

We will repeatedly take the connected components of annuli with “fuzzy” boundaries. We formalize this with the idea of a c -fuzzy Δ -chop; see Figure 5a for an illustration.

► **Definition 8** (*c-Fuzzy Δ -Chop*). *Let $G = (V, E, w)$ be a weighted graph with root r and fix $0 \leq c < 1$ and $\Delta \geq 1$. Then a c -fuzzy Δ -chop is a partition of V into “fuzzy annuli” $\mathcal{A} = \{A_1, A_2, \dots\}$ where for every i and $v \in A_i$ we have*

$$(i-1)\Delta - \frac{c\Delta}{2} \leq d(r, v) < i \cdot \Delta + \frac{c\Delta}{2}.$$

As each fuzzy annulus in a fuzzy chop may contain many connected components we must be careful when specifying how recursive application of these chops break a graph into connected components; hence the following definitions. Given fuzzy annulus A_i , we let \mathcal{C}_i be the connected components of A_i .

► **Definition 9** (*Components Resulting from a c -Fuzzy Δ -Chop*). *Let $G = (V, E, w)$ be a weighted graph and let \mathcal{C} be a partition of V into connected components. Then we say that \mathcal{C} results from one level of c -fuzzy Δ -chops if there is a c -fuzzy Δ -chop \mathcal{A} with respect to some root $r \in V$ satisfying $\mathcal{C} = \bigcup_{i: A_i \in \mathcal{A}} \mathcal{C}_i$. Similarly, for $h \geq 2$ we say that \mathcal{C} results from h -levels of c -fuzzy Δ -chops if there is some \mathcal{C}' which results from one level of c -fuzzy Δ -chops and \mathcal{C} is the union of the result of $h-1$ levels of c -fuzzy Δ -chops on each $C' \in \mathcal{C}'$.*

We will now claim that taking $h-1$ levels of fuzzy chops in a K_h -minor-free graph will result in a connected, low weak diameter partition. In particular, we show the following lemma, the main result of this section.

► **Lemma 10.** *Let Δ and h satisfy $2 \leq h$, $\Delta \geq 1$ and fix constant $0 \leq c < 1$. Suppose \mathcal{C} is the result of $h-1$ levels of c -fuzzy Δ -chops in a K_h -minor-free weighted graph G . Then, the weak diameter of every $C \in \mathcal{C}$ is at most $O(h \cdot \Delta)$.*

For the rest of this section we identify the nodes of a minor of graph G with “supernodes.” In particular, we will think of each of the vertices of the minor as corresponding to a disjoint, connected subset of vertices in G (a supernode) where the minor can be formed from G (up to isomorphism) by contracting the constituent nodes of each such supernodes.

Our proof will closely track a known analysis of KPR [32]. The sketch of this strategy is as follows. We will argue that if we fail to produce parts with low diameter then we have found K_h as a minor. Our proof will be by induction on the number of levels of fuzzy chops. Suppose \mathcal{C} is produced by $h-1$ levels of fuzzy chops; in particular, suppose \mathcal{C} is produced by taking some fuzzy chop to get \mathcal{C}' and then taking $h-2$ levels of fuzzy chops on each $C' \in \mathcal{C}'$. Also assume that there is some $C \in \mathcal{C}$ which has *large* diameter. Then, C must result from taking $h-2$ levels of fuzzy chops on some $C' \in \mathcal{C}'$ where C' lies in some fuzzy

annulus A_i of G . By our inductive hypothesis it follows that C contains K_{h-1} as a minor. Our goal is to add one more supernode to this minor to get a K_h minor. We will do so by finding disjoint paths of length $O(\Delta)$ in the annulus above A_i from each of the K_{h-1} supernodes all of which converge on a single connected component. By adding these paths to their respective supernodes in the K_{h-1} minor and adding the connected component on which these paths converge to our collection of supernodes, we will end up with a K_h minor.

The main challenge in this strategy is to show how to find paths as above which are disjoint. We will do so by choosing these paths from a “representative” from each supernode where initially the representatives are $\Omega(h\Delta)$ far-apart and grow at most $O(\Delta)$ closer at each level of chops; since we do at most $O(h)$ levels of chops, the paths we choose will never intersect.

To formalize this strategy we must state a few definitions which will aid in arguing that these representatives are far apart.

► **Definition 11** (Δ -Dense). *Given sets $S, U \subseteq V$ we say S is Δ -dense in U if $d(u, S) \leq \Delta$ for every $u \in U$.*

► **Definition 12** (R -Represented). *A K_h minor is R -represented by set $S \subseteq V$ if each supernode $V_i \subseteq V$ of the minor in G contains a representative $v_i \in S \cap V_i$ and these representatives are pairwise at least R apart in G .*

Since V is clearly $(1+c)\Delta$ -dense in V , we can set S to V and j to $h-1$ in the following lemma to get Lemma 10.

► **Lemma 13.** *Fix $0 \leq c < 1$ and $h > j \geq 0$. Let S be any set which is $(1+c)\Delta$ -dense in V and suppose \mathcal{C} is the result of j levels of c -fuzzy Δ -chops and some $C \in \mathcal{C}$ has weak diameter more than $22h\Delta$. Then there exists a K_{j+1} minor which is $8(h-j)\Delta$ -represented by S .*

Proof. Our proof is by induction on j . The base case of $j = 0$ is trivial as K_1 is a minor of any graph with a supernode $+\infty$ -represented by any single vertex in V .

Now consider the inductive step on graph $G = (V, E)$. Fix some set S which is $(1+c)\Delta$ -dense in V and let \mathcal{C} be the result of j levels of c -fuzzy chops using root r with some $C' \in \mathcal{C}$ of diameter more than $22h\Delta$. Suppose C' is in fuzzy annulus A_k and suppose that C' is the result of applying $j-1$ levels of c -fuzzy chops to some C which resulted from 1 level of c -fuzzy chops in G ; note that C is a connected component of A_k and that C' is contained in C .

As an inductive hypothesis we suppose that any $j-1$ levels of c -fuzzy Δ -chops on any graph H which results in a cluster of weak diameter more than $22h\Delta$ demonstrates the existence of a K_j minor in H which is $8(h-j+1)\Delta$ -represented by any set S' which is $(1+c)\Delta$ -dense in $V(H)$. Here weak diameter is with respect to the distances induced by the original input graph.

Thus, by our inductive hypothesis we therefore know that C contains a K_j minor which is $8(h-j+1)\Delta$ -represented by any $S' \subseteq V(C)$ which is $(1+c)\Delta$ -dense in $V(C)$. In particular, we may let S' be the “upper boundary” of C ; that is, we let S' be all vertices v in C such that the shortest path from v to r does not contain any vertices in C . Clearly the shortest path from any vertex in C to r intersects a node in S' ; moreover, when restricted to C this shortest path has length at most $\Delta + c\Delta$ (since C is contained in A_k) which is to say that S' is $(1+c)\Delta$ -dense in C . Thus, by our induction hypothesis there is a K_j minor in C which is $8(h-j+1)\Delta$ -represented by S' . Let V_1, \dots, V_j be the nodes in the supernodes of the K_j minor.

66:14 $O(1)$ Steiner Point Removal in Series-Parallel Graphs

We now describe how to extend the K_j minor to a K_{j+1} minor which is $8(h-j)\Delta$ -represented by S . We may assume that $k \geq 9h+1$; otherwise the distance from every node in A_k to r would be at most $(9h+1)\Delta + \frac{c\Delta}{2} \leq (9h + \frac{3}{2})\Delta$ and so the weak diameter of C' would be at most $(18h+3)\Delta \leq 21h\Delta$, contradicting our assumption on C' 's diameter. It follows that for every $v \in A_k$ we have

$$d(v, r) \geq (k-1)\Delta - \frac{c\Delta}{2} \geq 9h\Delta - \frac{c\Delta}{2} \geq 8h\Delta. \quad (1)$$

We first describe how we grow each supernode V_i from the K_j minor to a new supernode V'_i . Let v_i be the representative in S' for V_i . Consider the path which consists of following the shortest path from v_i to r for distance 2Δ and then continuing on to the nearest node in S ; let v'_i be this nearest node; this path from v_i to v'_i has length at most $(3+c)\Delta$ since S is $(1+c)\Delta$ -dense in $V(G)$. Let V'_i be the union of V_i with the vertices in this path. Since each of these paths is of length at most $(3+c)\Delta \leq 4\Delta$, it follows that each of these paths for each i must be disjoint since each v_i is at least $8(h-j+1)\Delta > 8\Delta$ apart. Further, every v'_i must also, therefore, be at least $8(h-j)\Delta$ apart. Therefore, we let these v'_i form the representatives in S for each of the V'_i .

We now describe how we construct the additional supernode, V_0 , which we add to our minor to get a K_{j+1} minor. V_0 will “grow” from the root to S and each of the V'_i . In particular, let $u_i \in V'_i$ be the node in V'_i which is closest to r and let P_i be the shortest path from r to u_i , excluding u_i . Similarly, let v'_0 be the node in S closest to r and let P_0 be the shortest path from r to v'_0 , including v'_0 . Then, we let V_0 be $P_0 \cup P_1 \cup \dots \cup P_j$ and we let v'_0 be the representative for V_0 in S . We claim that for every $i \geq 1$ we have

$$d(P_0, V'_i) \geq 8(h-j)\Delta. \quad (2)$$

In particular, notice that since S is $(1+c)\Delta$ -dense in $V(G)$ we know that $d(r, v'_0) \leq (1+c)\Delta \leq 2\Delta$ and since $d(v, r) \geq 8h\Delta$ for every $v \in A_k$ by Equation (1) and $d(v'_i, A_k) \leq (3+c)\Delta \leq 4\Delta$, it follows that $d(P_0, V'_i) \geq (8h-6)\Delta \geq 8(h-j)\Delta$. Consequently, $d(v'_0, v'_i) \geq 8(h-j)\Delta$ for every $i \geq 1$. Thus, our representatives of each supernode are appropriately far apart.

It remains to show that our supernodes indeed form a K_{j+1} minor; clearly by construction they are all pair-wise adjacent and so it remains only to show that they are all disjoint from one another. We already argued above that for $i, j \geq 1$ any V'_i and V'_j are disjoint so we need only argue that V'_0 is disjoint from each V'_i for $i \geq 1$. P_0 must be disjoint from each V'_i for $i \geq 1$ by Equation (2) and so we need only verify that P_i is disjoint from V'_j for $i, j \geq 1$;

By construction if $i = j$ we know that P_i is disjoint from V'_j so we assume $i \neq j$ and that P_i intersects V'_j for the sake of contradiction. Notice that each P_i has length at most $k\Delta + \frac{c\Delta}{2} - 2\Delta = k\Delta + c\Delta - 2\Delta - \frac{c\Delta}{2} < (k-1)\Delta - \frac{c\Delta}{2}$ by how we construct V'_i . Thus, P_i must be disjoint from A_k . It follows that if P_i intersects V'_j then it must intersect $V'_j \setminus V_j$. However, since $d(v_i, v_j) \geq 8(h-j+1)\Delta \geq 16\Delta$ and the length of paths $V'_i \setminus V_i$ and $V'_j \setminus V_j$ are at most 4Δ we know that $d(V'_i \setminus V_i, V'_j \setminus V_j) \geq 8(h-j)\Delta \geq 8\Delta$. Thus, after intersecting $V'_j \setminus V_j$ and then continuing on to a vertex adjacent to $V'_i \setminus V_i$, we know P_i must travel at least 8Δ ; since the vertices of P_i are monotonically further and further from r , and the vertex in $V'_j \setminus V_j$ that P_i intersects must be distance at least $(k-1)\Delta - \frac{c\Delta}{2} - 4\Delta \geq (k-5)\Delta$ from r , then the last vertex of P_i must be distance at least $(k+3)\Delta$ from r , meaning P_i must intersect annulus A_k , a contradiction. \blacktriangleleft

(a) A c -fuzzy Δ -chop.

(b) Visualizing some paths.

■ **Figure 5** A c -fuzzy Δ -chop that is 1-scattering. We draw each fuzzy annulus in a distinct color. In (b) we visualize some shortest paths of length at most Δ and highlight cut edges in red.

6.2 Scattering Chops

Using Lemma 10 we can reduce computing a good scattering partition and therefore computing a good SPR solution to finding what we call a scattering chop. The following definitions are somewhat analogous to Definition 4 and Definition 5. However, notice that the second definition is for a family of graphs (as opposed to a single graph as in Definition 5). We illustrate a τ -scattering chop in Figure 5.

► **Definition 14** (τ -Scattering Chop). *Given a weighted graph $G = (V, E, w)$, let \mathcal{A} be a c -fuzzy Δ -chop with respect to some root $r \in V$. \mathcal{A} is a τ -scattering chop if each shortest path of length at most Δ has at most τ edges cut by \mathcal{A} where we say that an edge is cut by \mathcal{A} if it has endpoints in different fuzzy annuli of \mathcal{A} .*

► **Definition 15** (τ -Scatter-Choppable Graphs). *A family of graphs \mathcal{G} is τ -scatter-choppable if there exists a constant $0 \leq c < 1$ such that for any $G \in \mathcal{G}$ and $\Delta \geq 1$ there is some τ -scattering and c -fuzzy Δ -chop \mathcal{A} with respect to some root.*

We will say that \mathcal{G} is deterministic poly-time τ -scatter-choppable if the above chop \mathcal{A} for each $G \in \mathcal{G}$ can be computed in deterministic poly-time.

Lastly, we conclude that to give an $O(1)$ -scattering partition – and therefore to give an $O(1)$ -SPR solution – for a K_h -minor-free graph family it suffices to show that such a family is $O(1)$ -scatter choppable.

► **Lemma 16.** *Fix a constant $h \geq 2$ and let \mathcal{G}_h be all K_h -minor-free graphs. Then, if \mathcal{G}_h is τ -scatter-choppable then every $G \in \mathcal{G}_h$ is $O(\tau^{h-1})$ -scatterable.*

Proof. The claim is almost immediate from Lemma 10 and the fact that all subpaths of a shortest path are themselves shortest paths.

In particular, first fix a sufficiently small constant c' to be chosen later. Then, consider a $G \in \mathcal{G}_h$ and fix a Δ . By assumption we know that G is τ -scatter-choppable and since each subgraph of G is in \mathcal{G}_h so too is each subgraph of G . Thus, we may let \mathcal{C} be the connected components resulting from $h - 1$ levels of c' -fuzzy and $(c'\Delta)$ -chops which are τ -scattering.

We claim that for sufficiently small c' we have that \mathcal{C} is a $(\frac{\tau^{h-1}}{c'}, \Delta)$ -scattering partition. By Lemma 10 the diameter of each part in \mathcal{C} is at most $O(c' \cdot h \cdot \Delta) \leq \Delta$ for sufficiently small c' . Next, consider a shortest path P of length at most Δ . We can partition the edges of P into at most $\frac{1}{c'}$ shortest paths P_1, P_2, \dots , each of length at most $c' \cdot \Delta$. Thus, it suffices to show that each P_i satisfies $|\{C \in \mathcal{C} : P_i \cap C \neq \emptyset\}| \leq \tau^{h-1}$.

We argue by induction on the number of levels of chops that after $h' < h$ chops we have $|\{C \in \mathcal{C} : P_i \cap C \neq \emptyset\}| \leq \tau^{h'}$. Suppose we perform just one chop; i.e. $h' = 1$. Then, since our chops are τ -scattering we know that P will be cut at most τ times and so be incident to at

most τ components of \mathcal{C} as required. Next, suppose we perform $h' > 1$ levels of chops. Then our top-level chop will partition the vertices of P_i into at most τ components. By induction and the fact that each subpath of P_i is itself a shortest path of length at most $c'\Delta$, we know that the vertices of P_i in each such component are broken into at most $\tau^{h'-1}$ components and so P_i will be incident to at most $\tau^{h'}$ components as required. As we perform $h - 1$ levels of chops, it follows that \mathcal{C} is indeed a $\left(\frac{\tau^{h-1}}{c'}, \Delta\right)$ -scattering partition. \blacktriangleleft

Abstract

Let P be a set of n colored points. We develop efficient data structures that store P and can answer chromatic k -nearest neighbor (k -NN) queries. Such a query consists of a query point q and a number k , and asks for the color that appears most frequently among the k points in P closest to q . Answering such queries efficiently is the key to obtain fast k -NN classifiers. Our main aim is to obtain query times that are independent of k while using near-linear space.

We show that this is possible using a combination of two data structures. The first data structure allow us to compute a region containing exactly the k -nearest neighbors of a query point q , and the second data structure can then report the most frequent color in such a region. This leads to linear space data structures with query times of $O(n^{1/2} \log n)$ for points in \mathbb{R}^1 , and with query times varying between $O(n^{2/3} \log^{2/3} n)$ and $O(n^{5/6} \text{polylog } n)$, depending on the distance measure used, for points in \mathbb{R}^2 . These results can be extended to work in higher dimensions as well. Since the query times are still fairly large we also consider approximations. If we are allowed to report a color that appears at least $(1 - \varepsilon)f^*$ times, where f^* is the frequency of the most frequent color, we obtain a query time of $O(\log n + \log \log \frac{1}{1-\varepsilon} n)$ in \mathbb{R}^1 and expected query times ranging between $\tilde{O}(n^{1/2}\varepsilon^{-3/2})$ and $\tilde{O}(n^{1/2}\varepsilon^{-5/2})$ in \mathbb{R}^2 using near-linear space (ignoring polylogarithmic factors).

1 Introduction

One of the most popular approaches for classification problems is to use a k -Nearest Neighbor (k -NN) classifier [3, 10, 12, 14]. In a k -NN classifier the predicted class of a query item q is taken to be the most frequently appearing class among the k items most similar to q . One can model this as a geometric problem in which the input items are represented by a set P of n colored points in \mathbb{R}^d : the color of the points represents their class, and the distance between points measures their similarity. The goal is then to store P so that one can efficiently find the color (class) c^* most frequently occurring among the k points in P closest to a query point q . See Figure 1(left). We refer to such queries as *chromatic k -NN queries*. To answer such queries, k -NN classifiers often store P in, e.g., a kd-tree and answer queries by explicitly reporting the k points closest to q , scanning through this set to compute the most frequently occurring color [3]. Unfortunately, for many distance measures (including

■ **Figure 1** (left) A set of input points from three different classes (colors). The class of a query point q is determined by the labels of its k nearest neighbors (with $k = 7$ as shown here q is classified as red). (middle) The color partition for $k = 1$. (right) The color partition for $k = 3$.

the Euclidean distance) such an approach has no guarantees on the query time other than the trivial $O(n)$ time bound. Even assuming that the dependency on n during the query time is small (e.g. when the points are nicely distributed [11]), the approach requires $\Theta(k)$ time to explicitly process all k points closest to q , whereas the desired output is only a single value: the most frequently appearing color. Hence, our main goal is to design a data structure to store P that has sublinear query time in terms of both n and k , while still using only small space. We focus our attention on the L_2 (Euclidean) distance, and the L_∞ distance metrics. Most of our ideas extend to more general distance measures and higher dimensions as well. However, already in the restricted settings presented here, designing data structures that provide guarantees on the space and query time turns out to be a challenging task.

If the value k is fixed in advance, one possible solution is to build the k^{th} -order Voronoi diagram $Vor_k(P)$ of P , and preprocess it for point location queries. The k^{th} -order Voronoi diagram is a partition of \mathbb{R}^d into maximal cells for which all points in a cell (a *Voronoi region*) $V_{k,P}(S)$ have the same set S of k closest points from P . Hence, in each Voronoi region there is a fixed color that occurs most frequently among S . See Figure 1(right) for an illustration. By storing $Vor_k(P)$ in a data structure for efficient (i.e. $O(\log n)$ time) point location queries we can also answer chromatic k -NN queries efficiently. However, unfortunately $Vor_k(P)$ may have size $\Theta(k(n-k))$ [15] (for points in \mathbb{R}^2 and the L_2 distance). For other L_m distances the diagram is similarly large [17, 6]. Hence, we are interested in solutions that use less, preferably near-linear, space.

The only result on the theory of chromatic k -NN queries that we are aware of is that of Mount et al. [20]. They study the problem in the case that we measure distance using the Euclidean metric and that the number of colors c , as well as the parameter k , are small constants. Mount et al. state that it is unclear how to obtain a query time independent of k , and instead analyze the query times in terms of the *chromatic density* ρ of a query q . The chromatic density is a term depending on the distance from the query point q to the k^{th} nearest neighbor of q , and the distance from q to the first point at which the answer of the query would change (e.g. the $(k+t)^{\text{th}}$ nearest neighbor of q for some $t > 0$). The intuition is that if many points near q have the same color, queries should be easier to answer than when there are multiple colors with roughly the same number of points. The chromatic density term models this. Their main result is a linear space data structure for points in \mathbb{R}^d that supports $O(\log^2 n + (1/\rho)^d \log(1/\rho))$ time queries. We aim for bounds only in terms of combinatorial properties (i.e. n , c , and k) and allow the number of colors, as well as the parameter k , to be comparable to n . Our results are particularly relevant when k and c are large compared to n .

■ **Table 1** Our results for exact chromatic k -nearest neighbors problems. Bounds marked with * are expected bounds. The general L_m metric bounds hold for $m = O(1)$.

Dimension	Metric	Preprocessing time	Space	Query time
$d = 1$	L_m	$O(n^{3/2} \log n)$	$O(n)$	$O(n^{1/2} \log n)$
$d = 2$	L_m	$\tilde{O}(n^{2/(4+\delta)})$	$O(n)$	$\tilde{O}(n^{1-1/(12+3\delta)})$
$d \geq 3$	L_m	$\tilde{O}(n^{2-1/d} + n^{1+d/(2d-2+\delta)})$	$O(n)$	$\tilde{O}(n^{1-1/((d+1)(2d-2+\delta))})$
$d \geq 2$	L_∞	$O(n^{1+d/(d+1)})$	$O(n)$	$O(n^{1-1/(d+1)+\delta})$
		$\tilde{O}(n^{1+d/(d+1)})$	$O(n \log^{d-1} n)$	$O((n \log^{d-1} n)^{1-1/(d+1)})$
	L_2	$\tilde{O}(n^{2-1/d} + n^{1+d/(d+1)})^*$	$O(n)$	$\tilde{O}(n^{1-(d-1)/d(d+1)})$

■ **Table 2** Our results for the approximate chromatic k -nearest neighbors problems.

Dimension	Metric	Preprocessing time	Space	Query time
$d = 1$	L_m	$O(n \log_{\frac{1}{1-\varepsilon}} n)$	$O(n\varepsilon^{-1})$	$O(\log n + \log \log_{\frac{1}{1-\varepsilon}} n)$
$d = 2$	L_∞	$\tilde{O}(n\varepsilon^{-6})^*$	$\tilde{O}(n\varepsilon^{-6})$	$\tilde{O}(n^{1/2}\varepsilon^{-5/2})^*$
	L_2	$\tilde{O}(n^{1+\delta} + n\varepsilon^{-7})^*$	$\tilde{O}(n\varepsilon^{-4})$	$\tilde{O}(n^{1/2}\varepsilon^{-3/2})^*$

Our approach. Our main idea is to answer a query in two steps. (1) We identify a region $\mathcal{D}_m^k(q)$ that contains exactly the set $k\text{-NN}_m(q)$ of the k sites closest to q according to distance metric L_m . (2) We then find the *mode color* c^* ; that is, the most frequently occurring color among the points in the region $\mathcal{D}_m^k(q)$. This way, we never have to explicitly enumerate the set $k\text{-NN}_m(q)$. We will design separate data structures for these two steps. Our data structure for step (1) will find the smallest metric disk $\mathcal{D}_m^k(q)$ containing $k\text{-NN}_m(q)$ centered at q . We refer to such a query as a *range finding* query. If the distance used is clear from the context we may write $k\text{-NN}(q)$ and $\mathcal{D}^k(q)$ instead.

Range mode queries. The data structure in step (2) answers so-called *range mode* queries. For these data structures we exploit and extend the result of Chan et al. [8]. They show an array A with n entries can be stored in a linear space data structure that allows reporting the mode of a query range (interval) $A[i..j]$ in $O(n^{1/2})$ time. Furthermore, points in \mathbb{R}^d can be stored in $O(n \text{polylog } n + r^{2d})$ space so that range mode queries with axis-aligned orthogonal ranges can be answered in $O((n/r) \text{polylog } n)$ time. Here, $r \in [1, n]$ is a user-choosable parameter. In particular, setting $r = \lceil n^{1/2d} \rceil$ yields an $O(n \text{polylog } n)$ space solution with $O(n^{1-1/2d} \text{polylog } n)$ query time. Range mode queries with halfspaces can be answered in $O((n/r)^{1-1/d^2} + \text{polylog } n)$ time using $O(nr^{d-1})$ space [8]. Range mode queries in arrays have also been considered in an approximate setting [7]. The goal is then to report an element that appears sufficiently often in the range.

Results and organization. Refer to Table 1 for an overview of our exact solutions. We first consider the problem for n points in \mathbb{R}^1 . In this setting, we develop an optimal linear space data structure that can find $\mathcal{D}_m^k(q)$ in $O(\log n)$ time, for any $m \geq 1$ (Section 2). We then use Chan et al. [8]’s data structure to report the mode color in $\mathcal{D}_m^k(q)$. Since we present all of our data structures in the pointer machine model augmented with real-valued arithmetic, this

yields an $O(n^{1/2} \log n)$ time query algorithm. There is a conditional $\Omega(n^{1/2-\delta})$ lowerbound for chromatic k -NN queries using linear space and $O(n^{3/2})$ preprocessing time (refer to Section 5) so this result is likely near-optimal. In Section 3 we present our data structure for finding $\mathcal{D}_m^k(q)$ in \mathbb{R}^2 . For the L_∞ metric we show that we can essentially find $\mathcal{D}_m^k(q)$ using a binary search on the radius of the disk, and thus there is a simple $O(n \log n)$ size data structure that allows us to find the range $\mathcal{D}^k(q)$ in $O(\log^2 n)$ time (or $O(n^\delta)$ time, for an arbitrarily small $\delta > 0$, in case of a linear space structure). For the L_2 metric, we can no longer easily access a discrete set of candidate radii. It is tempting to therefore replace the binary search by a parametric search [18, 19]. However, the basic such approach squares the $\tilde{O}(n^{1/2})$ time required to solve the decision problem and is thus not applicable. The full strategy requires a way to generate independent comparisons; typically by designing a parallel decision algorithm [18]. Neither task is straightforward to achieve. Instead, we show that we can directly adapt the query algorithm for answering semi-algebraic range queries [2] (essentially the decision algorithm in the approach sketched above) to find $\mathcal{D}_2^k(q)$ in $O(n^{1/2} \text{polylog } n)$ time. Unfortunately, the final query time for chromatic k -NN queries is dominated by the $O(n^{5/6} \text{polylog } n)$ time range mode queries, for which we use a slight variation of the data structure of Chan et al. [8]. We briefly discuss these results in Section 4. We do show that the data structure can be constructed in $O(n^{5/3})$ expected time, rather than the straightforward $O(n^2)$ time implementation that directly follows from the description of Chan et al.. For the L_∞ metric we can answer range mode queries in $O(n^{3/4} \text{polylog } n)$ time using Chan et al.'s data structure for orthogonal ranges. However, we show that we can exploit that the ranges are squares and use a cutting-based approach (similar to the one used for the L_2 distance) to answer queries in $O(n^{2/3} \log^{2/3} n)$ time instead. If we wish to reduce the space from $O(n \log n)$ to linear the query time becomes $O(n^{2/3+\delta})$.

Since the query times are still rather large, we then turn our attention to approximations; refer to Table 2 for an overview. If f^* is the frequency of the mode color among k -NN(q) then our data structures may return a color that appears at least $(1 - \varepsilon)f^*$ times. In case of the L_2 distance our data structure presented in Section 6 now achieves roughly $\tilde{O}(n^{1/2} \varepsilon^{-3/2})$ query time, where the \tilde{O} notation hides polylogarithmic factors of n and ε . The main idea is that approximate levels in the arrangement of distance functions have relatively low complexity, and thus we can store them to efficiently answer approximate range mode queries.

2 The one-dimensional problem

In this section we consider the case where P is a set of n points in \mathbb{R}^1 . In this case all L_m -distance metrics with $m \geq 1$ are the same, i.e. $L_m(a, b) = |a - b|$. We develop a linear space data structure supporting queries in $O(n^{1/2} \log n)$ time. Building the data structure will take $O(n^{3/2})$ time. We follow the general two-step approach sketched in Section 1. We first show that there is an optimal, linear-space data structure with which we can find $\mathcal{D}^k(q)$ in $O(\log n)$ time, even if k is part of the query. As we then briefly describe how we can directly use the data structure by Chan et al. [8] to find the mode color of the points in $\mathcal{D}^k(q)$ in $O(n^{1/2} \log n)$ time.

Range finding queries. Given a set P of n points in \mathbb{R}^1 , we wish to store P so that given a query, consisting of a point $q \in \mathbb{R}^1$ and a natural number k , we can efficiently find the k^{th} furthest point from q , and thus $\mathcal{D}_m^k(q)$. We show that by storing P in sorted order in an appropriate binary search tree, we can answer such queries in $O(\log n)$ time. To this end, we first consider answering so called rank queries on a ordered set, represented by a pair of binary search trees. This turns out to be the crucial ingredient in the data structure.

Let $R \cup B$ be an ordered set of elements, and let T_R be a binary search tree whose internal nodes store the elements from R , and in which each node is annotated with the number of elements in that subtree. Similarly, let T_B be a binary search tree storing B . We can efficiently compute the element among $R \cup B$ with rank k (i.e. the k^{th} smallest element):

► **Lemma 2.1.** *Let T_B and T_R be two binary search trees with size annotations, and let k be a natural number. We can compute the element of rank k among $B \cup R$ in $O(\text{height}(T_B) + \text{height}(T_R))$ time.*

To support efficiently querying $\mathcal{D}^k(q)$ we now store P in a balanced binary search tree T_P with subtree-size annotations, so that we can: (i) search for the element of rank k , and (ii) given a query value $q \in \mathbb{R}^1$ we can split the tree at q in $O(\log n)$ time. We can implement T_P using e.g. a red black tree [22] (although with some care even a simple static balanced binary search tree will suffice). We will use the split operations only to answer queries; so we use path copying in this operation, so that we can still access the original tree once a query finishes [21]. The data structure uses $O(n)$ space, and can be built in $O(n \log n)$ time.

Given a query (q, k) the main idea is now to split T_P into two trees $T_{P^<}$ and $T_{P^{\geq}}$, where $P^< \subseteq P$ is the set of points left of q and $P^{\geq} = P \setminus P^<$ is the remaining set of points right of q (or coinciding with q). Observe that in these two trees, the points are actually ordered by distance to q (albeit for $T_{P^<}$ the points are stored in decreasing order while the points in $T_{P^{\geq}}$ are stored in increasing order). So, we can essentially use the procedure from Lemma 2.1 on the trees $T_{P^<}$ and $T_{P^{\geq}}$ to find the point in $P^{\leq} \cup P^>$ with rank k (according to the “by distance to q ”-order). The only difference with the algorithm as described in Lemma 2.1 is that for $T_{P^<}$ the roles of the left and right subtree are reversed. Splitting T into $T_{P^<}$ and $T_{P^{\geq}}$ takes $O(\log n)$ time. Since both subtrees have height at most $O(\log n)$, Lemma 2.1 also takes $O(\log n)$ time. So, we obtain the following result:

► **Theorem 2.2.** *Let P be a set of n points in \mathbb{R}^1 . In $O(n \log n)$ time we can build a linear space data structure so that given a query q, k we can find the smallest disk $\mathcal{D}_m^k(q)$, with respect to any L_m metric, containing k - $\text{NN}_m(q)$ in $O(\log n)$ time.*

Range mode queries. What remains is to store P such that given a query interval Q we can efficiently report the mode color among $P \cap Q$. Chan et al. [8] show that an array A of size n can be preprocessed in $O(n^{3/2})$ time into a linear space structure that can report the range mode of a query range $A[i : j]$ in $O(n^{1/2})$ time. By implementing arrays with balanced binary search trees, we can also implement this structure in the pointer machine model. This increases the query and preprocessing times by an $O(\log n)$ factor. We then store (the colors of) the points in increasing order in this structure. Together with Theorem 2.2 we obtain:

► **Theorem 2.3.** *Let P be a set of n points in \mathbb{R}^1 . In $O(n^{3/2} \log n)$ time, we can build a data structure of size $O(n)$, that answers chromatic k - NN queries on P in $O(n^{1/2} \log n)$ time.*

3 Range finding queries two dimensions

In this section we give a data structure that, given a query point $q \in \mathbb{R}^2$, reports the smallest range $\mathcal{D}_m^k(q)$ centered at q containing k - $\text{NN}_m(q)$. In Section 3.1 we consider the case where the L_∞ metric is used. In Section 3.2 we then consider the L_2 metric.

■ **Figure 2** The considered radii r_i , and r^* , for $k = 5$.

3.1 The L_∞ metric case

For a given value $r \geq 0$, define $S(q, r) = [q_x - r, q_x + r] \times [q_y - r, q_y + r]$ as the axis-aligned square with sidelength $2r$ centered at q . We call r the *radius* of such a square. Now observe that $\mathcal{D}^k(q) = S(q, r^*)$ is also an axis-aligned square, in particular with radius r^* equal to the distance $L_\infty(q, p)$ between q and the k^{th} nearest neighbor p of q . Thus we either have $r^* = |q_x - p_x|$ or $r^* = |q_y - p_y|$. This leads us to the following data structure. We store the x -coordinates x_1, \dots, x_n of the points in P in increasing order in a balanced binary search tree. Similarly, we store the y -coordinates of the points in P in sorted order y_1, \dots, y_n . We set $x_0 = y_0 = -\infty$ and $x_{n+1} = y_{n+1} = \infty$, and call these values coordinates as well. In addition, we store P in a data structure for $O(\log n)$ time orthogonal range counting queries, for which we use a range tree [5, 23]. The entire data structure can be constructed in $O(n \log n)$ time, and uses $O(n \log n)$ space.

Now let x_0, \dots, x_ℓ be the x -coordinates that are at most q_x . The sequence $r_i = |q_x - x_i|$, for $i = 0, \dots, \ell$, defines a sequence of decreasing radii. See Figure 2 for an illustration. We can find the smallest radius r_i for which $S(q, r_i)$ contains at least k points by performing binary search over the radii, performing orthogonal range counting at each step to guide the search. By performing a similar procedure for the x -coordinates greater than q_x , as well as for the y -coordinates, we obtain a set of four squares, that each contain at least k points. The smallest of these squares contains exactly k points and is thus $\mathcal{D}^k(q)$. As each procedure performs $O(\log n)$ orthogonal range counting queries, we obtain the following theorem.

► **Theorem 3.1.** *Let P be a set of n points in \mathbb{R}^2 . In $O(n \log n)$ time, we can build a data structure of size $O(n \log n)$, that can report $\mathcal{D}_1^k(q)$ and $\mathcal{D}_\infty^k(q)$ in $O(\log^2 n)$ time.*

Following an idea of Chan et al. [8] we can reduce the space used by replacing the binary range tree used for the orthogonal range queries by one with fanout n^δ for some constant $\delta > 0$. This increases the query time to $O(n^\delta + k')$ time, where k' is the output size.

► **Theorem 3.2.** *Let P be a set of n points in \mathbb{R}^2 . Let $\delta > 0$ be an arbitrarily small constant. In $O(n \log n)$ time, we can build a data structure of $O(n)$ size, that can report $\mathcal{D}_1^k(q)$ and $\mathcal{D}_\infty^k(q)$ in $O(n^\delta)$ time.*

3.2 The L_2 metric case

3.2.1 Randomized query times

In this section, we sketch a simple randomized data structure that finds $\mathcal{D}_2^k(q)$ in expected $O(n^{1/2} \log^{B+1} n)$ time¹. The data structure consists of the large fan-out partition tree of Agarwal et al. [2], used for semialgebraic range searching. Together with this tree, we take a random sample P' of P by including each point with probability $1/n^{1/2}$. Note that this random sample will contain $n^{1/2}$ points in expectation.

The main idea is to combine binary search on the ordered distances $R = \{L_2(q, p') \mid p' \in P'\}$ with circular range counting. Let r^* be the distance between q and its k^{th} nearest neighbor among P . We then search for two consecutive distances $r_i, r_{i+1} \in R$, such that $r_i \leq r^* \leq r_{i+1}$. Because the number of points $p \in P$ with $r_i \leq L_2(q, p) \leq r_{i+1}$ is $n^{1/2}$ in expectation, we can then afford to report these points with semialgebraic range reporting, and combining binary search with range counting again to find r^* . This leads to an expected query time of $O(n^{1/2} \log^{B+1} n)$.

3.2.2 Worst-case query times

In this section we show how to achieve the same complexity bounds of Section 3.2.1, but with a worst-case query time bound, rather than a randomized bound.

The data structure. For now, we assume that the set P lies in D_0 -general position for some constant D_0 (see [2] for a definition). The details on this assumption are not important, and we show in the full version of the paper how to handle arbitrary point sets. The data structure consists of two copies of the large fan-out (fan-out n^δ , for some constant $\delta > 0$) partition tree of Agarwal et al. [2], built on P . The first copy, which we call \mathcal{T} , will be augmented slightly to support generating candidate ranges (disks) that will eventually lead to $\mathcal{D}^k(q)$. The second copy will be used as a black box, answering circular range counting queries to guide the search for $\mathcal{D}^k(q)$ by counting the number of points inside the candidate ranges.

The tree \mathcal{T} is constructed by recursively partitioning the space into open, connected regions, called *cells*. Once a cell contains a small (constant) number of points of P , the recursion stops and \mathcal{T} gets a leaf node containing these points. There may be points of P that do not lie on these cells, but rather on the zero set of the partitioning polynomial used to partition the space. For range searching with arbitrary point sets, Agarwal et al. [2] store these points in an auxiliary data structure. However, with our assumption that P lies in D_0 -general position, we do not need this auxiliary data structure, and will simply store the points inside a leaf node, whose parent is the node corresponding to the partitioning polynomial. We further adjust \mathcal{T} such that each internal node corresponding to a cell ω stores an arbitrary point in ω . During the construction of \mathcal{T} , a point inside each cell is already computed. Hence the construction time is unaltered.

Answering a query. To query the structure with a query point q , we keep track of a set of nodes N_i for each level i of \mathcal{T} that is explored by our algorithm. With slight abuse of terminology, we refer to the sets P' of points stored in the leaves of \mathcal{T} as cells. Let Ω_i denote

¹ We would like to thank an anonymous reviewer for the solution sketched in this section, which led to our current solution for finding $\mathcal{D}_2^k(q)$ in Section 3.2.

■ **Figure 3** (left) A partitioning of P into four cells. The red crosses are the points $p(\omega)$. (right) The disk $\mathcal{D}^k(q)$ (dashed boundary) and the disks $D(q, r^-)$ (dotted boundary, dark gray) and $D(q, r^+)$ (dotted boundary, light gray).

the cells corresponding to the internal nodes in N_i , and P_i denote the cells corresponding to the leaf nodes in N_i . We maintain that $p^k(q)$, the k^{th} nearest neighbor of q , is contained in a cell in $\Omega_i \cup P_i$. Initially, N_1 contains the root node. If \mathcal{T} is a single leaf, then the cell corresponding to the root node will be stored in P_1 . Otherwise, it will be stored in Ω_1 .

The query algorithm works as follows. Say the algorithm is at level i in \mathcal{T} . For a cell $\omega \in \Omega_i$ stored in an internal node, let $p(\omega)$ be the point inside ω that was stored with it. Let

$$R_i = \{L_2(q, p(\omega)) \mid \omega \in \Omega_i\} \cup \bigcup_{P'_i \in P_i} \{L_2(q, p) \mid p \in P'_i\}$$

be the set of distances to these points $p(\omega)$, as well as to all points stored in the leaves in P_i and in the nodes in N_i . Let r^* be the distance between q and its k^{th} nearest neighbor among P . This is the radius of $\mathcal{D}^k(q)$. To find this radius, we compute the largest distance $r^- \in R_i$, and the smallest distance $r^+ \in R_i$, such that $r^- < r^* \leq r^+$. See Figure 3. If r^- (respectively r^+) does not exist, set it to 0 (respectively ∞). We show how to compute r^+ . Computing r^- works similarly.

To compute r^+ , we use a combination of median finding and binary search. For some radius $r \in R_i$, we decide if $r^+ > r$ or $r^+ \leq r$ using a circular counting query. If $D(q, r)$ contains less than k points, we have $r^+ > r$. Otherwise, we have $r^+ \leq r$. By performing this procedure for the median radius in R_i , we can discard half of R_i with each query.

Once we have that r^+ is the distance between q and a point in P (it is constructed through a leaf node of \mathcal{T}), we have found r^* . We then terminate the algorithm, returning the disk with the found radius. Otherwise we continue the search in the next level of \mathcal{T} . To continue the search through the tree, we construct the set N_{i+1} by replacing every node $\nu \in N_i$ with its children whose cells are crossed by one of $D(q, r^-)$ and $D(q, r^+)$. A cell ω is *crossed* by a disk D if $\omega \cap D \neq \emptyset$ and $\omega \not\subseteq D$. The sets Ω_{i+1} and P_{i+1} are then constructed from these child nodes. Once these sets are constructed, we advance the algorithm to level $i+1$ and repeat the procedure.

► **Lemma 3.3.** *The query algorithm correctly returns $\mathcal{D}^k(q)$.*

Proof. We claim that this algorithm correctly returns $\mathcal{D}^k(q)$. First, note that if the algorithm returns a disk, that disk contains k points, and its radius is equal to the distance between q and a point of P . Therefore, it is indeed $\mathcal{D}^k(q)$. We now show that our algorithm will always return a disk, and therefore that our algorithm is correct. To show this, it suffices to show that for every level i of \mathcal{T} traversed by our algorithm, the set $\Omega_i \cup P_i$ contains the cell containing $p^k(q)$.

We give a proof by induction. It holds trivially that $\Omega_1 \cup P_1$ contains a cell containing $p^k(q)$. We prove that if $\Omega_i \cup P_i$ contains a cell ω' containing $p^k(q)$, then either the algorithm terminates and returns $\mathcal{D}^k(q)$, or there is a cell $\omega \in \Omega_{i+1} \cup P_{i+1}$ containing $p^k(q)$.

If $\omega' \in P_i$, then R_i will contain r^* . It will then find $r^+ = r^*$ and terminate, returning $D(q, r^+) = \mathcal{D}^k(q)$. Now assume that $\omega' \in \Omega_i$. Let $\nu \in N_i$ be the internal node corresponding to ω' . Now let ω be the cell stored in a child of ν , such that $p^k(q)$ lies in ω . We show that $\omega \in \Omega_{i+1} \cup P_{i+1}$.

Our algorithm performs repeated median finding on the radii in R_i , resulting in the largest radius $r^- \in R_i$ and smallest radius $r^+ \in R_i$, such that $D(q, r^-)$ and $D(q, r^+)$, contains less than, respectively at least, k points of P . Let r_ω be the distance between q and $p(\omega)$, the point in ω that was stored in \mathcal{T} . If $r_\omega < r^*$, then we have that $r_\omega \leq r^-$, implying that $D(q, r^-)$ intersects ω . Also, because ω is open, and because $p^k(q) \in \omega$, there must be a point $p' \in \omega$ such that $r^- < r^* = L_2(q, p^k(q)) < L_2(q, p')$. This shows that ω is not contained in $D(q, r^-)$, and thus that $D(q, r^-)$ crosses ω . With similar reasoning, it can be seen that if $r_\omega \geq r^*$, then $D(q, r^+)$ crosses ω . Thus, ω will be crossed by at least one of $D(q, r^-)$ and $D(q, r^+)$, and thus $\omega \in \Omega_{i+1} \cup P_{i+1}$. Hence, our algorithm is correct. ◀

► **Theorem 3.4.** *Let P be a set of n points in \mathbb{R}^2 . Let $\delta > 0$ be an arbitrarily small constant. In $O(n^{1+\delta})$ expected time, we can build a data structure of $O(n)$ size, that can report $\mathcal{D}_2^k(q)$ in $O(n^{1/2} \text{polylog } n)$ time.*

4 Range mode queries in two dimensions

In this section we discuss answering range mode queries in \mathbb{R}^2 , and see how we can use them together with the data structures from Section 3 to answer chromatic k -NN queries. Our results build on the data structure of Chan et al. [8] for finding the mode color among three-dimensional points in halfspaces. We show that using a standard lifting transformation that maps the points $P \subseteq \mathbb{R}^2$ into planes in \mathbb{R}^3 , we can apply their result to answer range mode queries with disks in the L_2 metric. Our main contribution is that we show that a similar approach can answer range mode queries with squares (disks in the L_∞ metric). Somewhat surprisingly, this leads to better query times compared to directly using the existing range mode data structures for orthogonal ranges [8]. Finally, we show that we can, in fact, construct the data structures in (expected) $O(n^{5/3})$ time rather than $O(n^2)$ (worst-case) time. We briefly sketch these ideas here. Refer to the full version for details.

The data structure for the L_2 metric. We lift the set of points $P \subseteq \mathbb{R}^2$ to a set of planes H in \mathbb{R}^3 . The points in a query disk Q map to the subset of planes passing below a point h^* . Hence, we have to report the mode color c of these planes. The main idea in the data structure of Chan et al. [8] is to build a $(1/r)$ -cutting on the planes in H ; a subdivision of \mathbb{R}^3 into $O(r^3)$ interiorly disjoint cells, whose interiors are each crossed by at most n/r planes (for $r = n^{1/3}$). Let Δ be the cell containing the query point h^* . The key insight is that the mode color c of the planes passing below the query point h^* is either the mode color c_Δ of all planes passing below Δ , or the color of one of the planes that intersect Δ . The data structure stores the color c_Δ for each cell Δ , so at query time we only have to consider the at most n/r colors of the planes that intersect Δ . Our insight is that for k -NN queries we can use the tools from Section 3 to find these colors in $\tilde{O}(n^{1/2})$ time, leading to a total query time of $\tilde{O}(n^{5/6})$ (rather than $\tilde{O}(n^{8/9})$ time in the case of arbitrary query points in \mathbb{R}^3).

The data structure for the L_∞ metric. For a point $p \in P \subseteq \mathbb{R}^2$, the graph of the distance function $L_\infty(p, q) = \max\{|p_x - q_x|, |p_y - q_y|\}$ forms an upside-down pyramid ∇_p in \mathbb{R}^3 . For a point $q \in \mathbb{R}^2$ we have that $L_\infty(p, q) \leq r$ if and only if (q_x, q_y, r) lies above ∇_p . Thus, we can again transform the problem to that of finding the mode color among those graphs in \mathbb{R}^3 that lie below a given query point. Using a similar cutting-based solution as sketched above – again exploiting that we can quickly find the (colors of the) graphs intersecting a cell Δ in \mathbb{R}^2 rather than \mathbb{R}^3 – yields a linear space data structure answering queries in an $O(n^{2/3+\delta})$ time. Using $O(n \log n)$ space we can decrease the query time to $O(n^{5/3} \log^{2/3} n)$.

Construction. Our final contribution in terms of the range mode data structures is that we show how to efficiently construct the above data structures. In case of both the L_2 and the L_∞ metrics, there is a somewhat straightforward algorithm to construct the above data structures in $O(n^2)$ time. The bottleneck being the time required to compute the mode color c_Δ for all cells Δ of the cutting. We argue that this can actually be done in roughly $\tilde{O}(nr^2 + r^3 n^\alpha)$ time, for some $\alpha \in (0, 1)$. For our choice of parameter r , this leads to algorithms with subquadratic running time. We summarize our results for the chromatic k -NN problem in the following theorems.

► **Theorem 4.1.** *Let P be a set of n points in \mathbb{R}^2 . There is a linear space data structure that answers chromatic k -NN queries on P with respect to the L_2 metric. Building the data structure takes expected $O(n^{5/3})$ time, and queries take $O(n^{5/6} \text{polylog } n)$ time.*

► **Theorem 4.2.** *Let P be a set of n points in \mathbb{R}^2 . There is a linear space data structure that answers chromatic k -NN queries on P with respect to the L_∞ metric. Building the data structure takes $O(n^{5/3})$ time, and queries take $O(n^{2/3+\delta})$ time. We can decrease the query time to $O(n^{2/3} \log^{2/3} n)$ time using $O(n \log n)$ space and $O(n^{5/3} \log^{2/3} n)$ preprocessing time.*

5 Lower bounds

We now discuss to what extent our results for the exact version of the problem may be improved further. Chan et al. [8] show that there is a conditional $\Omega(n^{1/2-\delta})$ time lower bound on range mode queries, provided we insist on using only linear space and $O(n^{3/2})$ preprocessing time. We extend this bound to chromatic k -NN queries in \mathbb{R}^1 . More generally, Lemma 5.1 shows that we can reduce chromatic k -NN queries in \mathbb{R}^d to range mode queries using range counting. Due to space restrictions, further details on the lower bound can be found in the full version of the paper.

► **Lemma 5.1.** *Let P be a set of n points in \mathbb{R}^d . A range mode query with a query ball \mathcal{D}_m (with respect to the L_m metric) can be answered using a single range counting query with query range \mathcal{D}_m and a single chromatic k -NN query.*

Proof. We use the range counting query to find the number of points in the range \mathcal{D}_m . Let this be k , and let q be the center point of the ball \mathcal{D}_m . Hence, $\mathcal{D}_m^k(q) = \mathcal{D}_m$, and thus the answer to the chromatic k -NN query with center q and value k is the mode color of \mathcal{D}_m . ◀

Relations to range counting queries. Next, we relate the cost of range finding queries, i.e. the problem solved in our first step, to range counting queries. Given a data structure for range finding queries we can answer range counting queries using only logarithmic overhead:

► **Lemma 5.2.** *Let P be a set of n points in \mathbb{R}^d . A range counting query on P with a disk \mathcal{D}_m under metric m can be performed using $O(\log n)$ range finding queries.*

Proof. Let q be the center of the query disk. We binary search over the integers $0, \dots, n$, using a range finding query to find a disk $\mathcal{D}_m^k(q)$ for each considered integer k . If the reported disk is smaller than \mathcal{D}_m , the number of points inside \mathcal{D}_m is at least k . Otherwise, the number of points is smaller than k . It follows that with $O(\log n)$ range finding queries, we can count the number of points in \mathcal{D}_m . ◀

It thus follows that range finding is roughly as difficult as range counting. In particular, a $Q(n)$ time lower bound for range counting queries using $S(n)$ space implies an $\tilde{\Omega}(Q(n))$ time lower bound for range finding queries with $S(n)$ space. For example, in the semigroup model there is an $\tilde{\Omega}(n/S(n)^{1/d})$ time lower bound for halfspace range counting [4]. Since every halfspace is a disk \mathcal{D}_2 (of radius ∞), this lower bound also holds for range counting with disks in the L_2 metric, and thus also for range finding.

The range mode queries from step 2 are also related to a form of range counting. A “type-2” range counting query with query range Q asks for all the distinct colors appearing in Q together with their frequencies, i.e. for each reported color c we must also report the number of points in $P \cap Q$ that have color c [9]. Clearly, answering “type-2” queries is more difficult than range counting (just assign all points the same color), so the above lower bounds also hold for “type-2” queries. Such “type-2” queries however also allow us to solve the range mode problem. When the number of colors is small (e.g. two), and we already know the number of points k in the query range $\mathcal{D}^k(q)$ it seems that answering range mode queries is not much easier than answering (“type-2”) range counting queries. We therefore conjecture that answering range mode queries is roughly as difficult as answering range counting queries.

► **Conjecture 5.3.** *If answering a range counting query with a query range \mathcal{D} using $S(n)$ space requires $Q(n)$ time then answering a range mode query with query range \mathcal{D} using $S(n)$ space requires $\tilde{\Omega}(Q(n))$ time.*

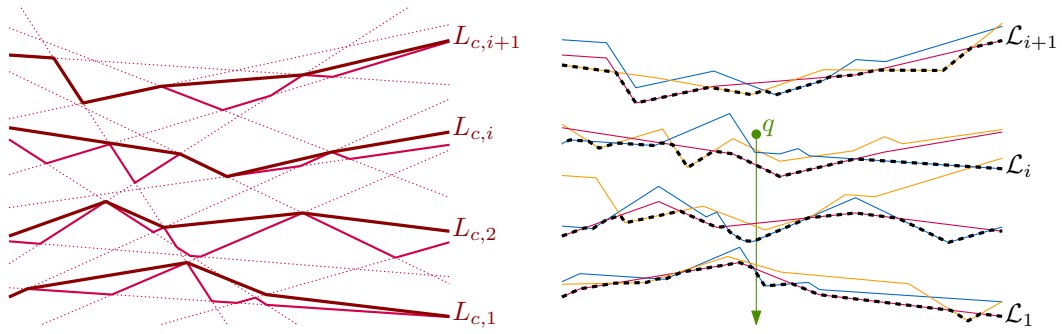

Note that this conjecture together with Lemma 5.1 would imply that answering a k -NN query is at least as hard as answering a range counting query. Furthermore, since we can answer a range counting query using $O(\log n)$ range finding queries (Lemma 5.2) that would then mean our two-step approach has negligible overhead with respect to an optimal solution to chromatic k -NN queries.

6 The approximate problems

In this section we sketch our approach for answering ε -approximate chromatic k -NN queries. Refer to the full version for details. Our goal is to report a color c that occurs at least $(1 - \varepsilon)f^*$ times, where f^* is the frequency of the mode color c^* of k -NN(q). We again use the two-step approach of finding the range $\mathcal{D}^k(q)$ (step (1)) and computing the mode of the range (step (2)). We use exact range finding data structures from Sections 2 and 3, and focus our attention on approximating step (2) for two reasons: first, the running times in our exact solutions are dominated by step (2), and second, it is unclear how to use approximate solutions to k -NN queries (that is, approximate ranges) and still obtain guarantees on the approximation factor of our ε -approximate chromatic k -NN queries.

For points in \mathbb{R}^1 we can directly use the result of Bose et al. [7] to answer $(1 - \varepsilon)$ -approximate range mode queries. In $O(n \log_{\frac{1}{1-\varepsilon}} n)$ time, we can thus build an $O(n/\varepsilon)$ size data structure that can answer k -NN queries in $O(\log n + \log \log_{\frac{1}{1-\varepsilon}} n)$ time.

For points in \mathbb{R}^2 , and the L_2 -metric, we answer approximate range mode queries as follows; we use similar ideas for the L_∞ metric. We use the standard lifting transformation to transform the set of points P a set of planes H . A query disk Q now corresponds to a

■ **Figure 4** (left) An illustration of the idea in \mathbb{R}^2 , the planes (here lines) of a single color, their $k_i = \left(\frac{1}{1-\alpha}\right)^i$ -levels (bright red), and the $g(\varepsilon)$ -approximate k_i -levels $L_{c,0}, L_{c,1}, \dots$ (in dark red). (right) For each i , the \mathcal{L}_i forms the lower envelope of the $L_{c,i}$ surfaces over all colors c . We search for the largest i for which q lies above \mathcal{L}_i (dashed).

vertical halfline with a top endpoint h^* , and the mode color c^* of $P \cap Q$ is the most frequently occurring color among the planes passing below h^* . Our aim is to report a color c such that at least $(1 - \varepsilon)f^*$ planes of that color pass below h^* .

The main idea to answer approximate range mode queries efficiently is to compute, for each color c , a series of $g(\varepsilon)$ -approximate k_i -levels (for some function g) considering only the planes of color c . For each choice of i , we then consider the lower envelope \mathcal{L}_i of all those k_i -levels among the various colors. See Figure 4 for an illustration. Now observe that if h^* lies in between \mathcal{L}_i and \mathcal{L}_{i+1} , the frequency f^* of a mode color c^* may only be a $g(\varepsilon)$ fraction larger than k_{i+1} , while the frequency of the color defining \mathcal{L}_i directly below h^* is at least k_i . So if $g(\varepsilon)$ and k_i/k_{i+1} are sufficiently small this is a $(1 - \varepsilon)$ -approximation. One additional complication is that even though our $g(\varepsilon)$ -approximate k_i -levels have fairly small complexity, their lower envelopes do not. So, we need to design a data structure that can test if h^* lies above or below \mathcal{L}_i without explicitly storing \mathcal{L}_i . We show that with near-linear space we can answer such queries in $O_\varepsilon(n^{1/2})$ time. This then leads to an $\tilde{O}_\varepsilon(n^{1/2})$ time query algorithm for answering k -NN queries.

We use the same approach to answer approximate queries under the L_∞ metric. Here, the approximate levels are constructed using the result of Kaplan et al. [13]. This leads to roughly the same complexities.

7 Concluding Remarks

We presented the first data structures for the chromatic k -NN problem with query times that depend only on the number of stored points. While we focused mostly on the two-dimensional case, our exact result extend to higher dimensions and other metrics as well (see full version). Our two-step approach essentially reduces the problem to efficiently answering range mode queries. The main open question is how to answer such queries efficiently. Since it is unlikely that we can answer such queries in $\Omega(n^{1/2})$ time (using only near-linear space), it is also particularly interesting to consider further improvements to the ε -approximate query data structures. For the Euclidean distance, finding the query range may now be the dominant factor (depending on the choice of ε). One option is to report a range that contains only approximately the k nearest neighbors of a query point. However, this further complicates the analysis. For the L_∞ distance it may also be possible to reduce the space usage by using a different method for computing the approximate levels (e.g. using the results by Agarwal et al. [1] or the recent results of Liu [16]).

Abstract

We consider the maximum weight b -matching problem in the random-order semi-streaming model. Assuming all weights are small integers drawn from $[1, W]$, we present a $2 - \frac{1}{2W} + \varepsilon$ approximation algorithm, using a memory of $O(\max(|M_G|, n) \cdot \text{poly}(\log(m), W, 1/\varepsilon))$, where $|M_G|$ denotes the cardinality of the optimal matching. Our result generalizes that of Bernstein [3], which achieves a $3/2 + \varepsilon$ approximation for the maximum cardinality simple matching. When W is small, our result also improves upon that of Gamlath *et al.* [11], which obtains a $2 - \delta$ approximation (for some small constant $\delta \sim 10^{-17}$) for the maximum weight simple matching. In particular, for the weighted b -matching problem, ours is the first result beating the approximation ratio of 2. Our technique hinges on a generalized weighted version of edge-degree constrained subgraphs, originally developed by Bernstein and Stein [5]. Such a subgraph has bounded vertex degree (hence uses only a small number of edges), and can be easily computed. The fact that it contains a $2 - \frac{1}{2W} + \varepsilon$ approximation of the maximum weight matching is proved using the classical König-Egerváry's duality theorem.

1 Introduction

The maximum weight (b -)matching problem is a classical problem in combinatorial optimization. In this paper we will study a sparsifier for that problem and use it in order to design a streaming algorithm for randomly-ordered streams of edges.

Our main tool is a generalized weighted version of the *edge-degree constrained subgraph* (EDCS), a graph sparsifier originally designed for the maximum matching problem by Bernstein and Stein [5]. Let us first recall the definition an EDCS H of a graph G [5].

► **Definition 1** (from [5]). *Let $G = (V, E)$ be a graph, and H a subgraph of G . Given any integer parameters $\beta \geq 2$ and $\beta^- \leq \beta - 1$, we say that H is a (β, β^-) -EDCS of G if H satisfies the following properties:*

- (i) For any edge $(u, v) \in H$, $\deg_H(u) + \deg_H(v) \leq \beta$
- (ii) For any edge $(u, v) \in G \setminus H$, $\deg_H(u) + \deg_H(v) \geq \beta^-$.

An EDCS has a size that can be easily controlled by the parameter β and it somehow “balances” the vertex degrees in the graph. A very nice property of this sparsifier is that, for well-chosen values of β and β^- , it always contains a $3/2 + \varepsilon$ approximation of the maximum cardinality matching [2, 6]:

► **Theorem 2** (from the recent work of Assadi and Bernstein [2]). *Let $0 < \varepsilon < 1/2$. Set $\lambda = \frac{\varepsilon}{32}$. Let $\beta \geq \beta^- + 1$ be integers such that $\beta \geq 8\lambda^{-2} \log(1/\lambda)$ and $\beta^- \geq (1 - \lambda) \cdot \beta$. Then any (β, β^-) -EDCS H of a graph G contains a matching M_H such that $(\frac{3}{2} + \varepsilon) \cdot |M_H| \geq |M_G|$ where M_G denotes the maximum cardinality matching.*

In our paper, we generalize the EDCS in two ways:

- we handle (small) integer-weighted edges;
- we handle the more general case of b -matchings.

To describe our generalization, first let us introduce some notation. A weighted multi-graph $G = (V, E)$ is defined by its set of vertices V and its multi-set of weighted edges E drawn from $V \times V \times \{1, 2, \dots, W\}$ (i.e., $e = (u, v, k)$ represents an edge between u and v of weight $w(e) = k$). We emphasize that E is a multi-set: not only can there be multiple edges between two vertices, but also some of these edges can have the same weight. We assume that the multi-graph does not contain any self-loop. For a given vertex $v \in V$ and a given subgraph H of G , $\delta_H(v)$ denotes the multi-set of incident edges to v in H , $\deg_H(v)$ the degree of v in the multi-graph H and $\mathbf{wdeg}_H(v)$ its *weighted degree* $\sum_{(u,v,w) \in \delta_H(v)} w$ in H . Given a weighted multi-graph $G = (V, E)$ and a set of capacities $b_v \in \mathbb{Z}_+$ associated to each vertex $v \in V$, a multi-set of weighted edges M is called a b -matching if for all $v \in V$ the number of edges incident to v in M is smaller than or equal to b_v . For a given subgraph H of G , we denote by M_H an arbitrary maximum weight b -matching included in H . The concept of b -matching encompasses that of matching and allows us to tackle a larger variety of real situations where the vertices have different capacities, e.g. [20]. In this paper we will assume that the number of edges between any two vertices u and v is at most $\min(b_u, b_v)$.¹

► **Definition 3.** *Let $G = (V, E)$ be a weighted multi-graph, where E is a multiset of edges drawn from $V \times V \times \{1, 2, \dots, W\}$, $\{b_v\}_{v \in V}$ be a set of constraints, and H be a subgraph of G . Given any integer parameters $\beta \geq 3$ and $\beta^- \leq \beta - 2$, we say that H is a (β, β^-) - w - b -EDCS of G if H satisfies the following properties:*

- (i) For any edge $(u, v, w_{uv}) \in H$, $\frac{\mathbf{wdeg}_H(u)}{b_u} + \frac{\mathbf{wdeg}_H(v)}{b_v} \leq \beta \cdot w_{uv}$
- (ii) For any edge $(u, v, w_{uv}) \in G \setminus H$, $\frac{\mathbf{wdeg}_H(u)}{b_u} + \frac{\mathbf{wdeg}_H(v)}{b_v} \geq \beta^- \cdot w_{uv}$.

An EDCS is a special case of a *weighted b -EDCS* when all the b_v s and all the weights are equal to 1. We can show that such w - b -EDCSes as described in Definition 3 always exist. Moreover, we can also prove that it uses only a reasonable number of edges (up to $2\beta \cdot |M_G|$) and it contains a relatively large weighted b -matching:

► **Theorem 4.** *Let $0 < \varepsilon < 1/2$ and let W be an integer parameter. Set $\lambda = \frac{\varepsilon}{100W}$. Let $\beta \geq \beta^- + 2$ be integers such that $\frac{\beta + 6W}{\log(\beta + 6W)} \geq 2W^2 \lambda^{-2}$ and $\beta^- - 6W \geq (1 - \lambda) \cdot (\beta + 6W)$. Then any (β, β^-) - w - b -EDCS H of a weighted multi-graph G with integer edge weights bounded by W contains a b -matching M_H such that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_H) \geq w(M_G)$.*

¹ This is actually a reasonable assumption as the maximum number of edges that are relevant between two given vertices u and v to construct a b -matching is at most $\min(b_u, b_v)$. This assumption is more debatable in the streaming setting, and this is why we explain how to handle this case in the full version of this paper.

In the full version of this paper, we give a whole class of tight examples reaching the bound of Theorem 4. Compared with the previous results of [2, 6] (Theorem 2) when $W = 1$, we can observe that the approximation ratio is the same, even though the constraints on β and β^- are a bit stricter here. Nonetheless, we can deal with b -matchings as well, even when $W > 1$. As a side note, we note that to satisfy the conditions stated in Theorem 4, it suffices that β is of order $\text{poly}(W, 1/\varepsilon)$ for some polynomial.

The *semi-streaming* model of computation [10] has been motivated by the recent rise of massive graphs, where we cannot afford to store the entire input in memory. Given that the graph is made of $|V| = n$ vertices and $|E| = m$ edges, in the semi-streaming model the graph is presented to the algorithm as a stream of edges e_1, \dots, e_m . The algorithm is allowed to make a single pass over that stream and can use a memory roughly proportional to the output size (up to a poly-logarithmic factor).

We note that in the most general model where an adversary decides the order of the elements, even for the maximum cardinality simple matching, it is still unclear whether it is possible to beat the approximation ratio of 2.

Our focus here is on the *random-order* streaming model, where the permutation of the edges in the stream is assumed to be chosen uniformly at random. This is a quite reasonable assumption as real-world data have little reason of being ordered in an adversarial way. In fact, as mentioned in [17], the random-order streaming model might better explain why certain algorithms perform better in practice than their theoretical bounds under an adversary model. It is noteworthy that under the random-order streaming model, there are already quite a few evidences to show that it is possible to beat the approximation factor of 2 [1, 3, 11, 17], at least for the simple matching.

Using an adaptation of EDCS, Bernstein [3] obtained a $3/2 + \varepsilon$ approximation in the random-order semi-streaming framework (with probability $1 - 2n^{-3}$ and using $O(n \cdot \log(n) \cdot \text{poly}(1/\varepsilon))$ memory). Similarly, we can adapt our w - b -EDCSes to design a semi-streaming algorithm for randomly-ordered streams of weighted edges:

► **Theorem 5.** *Let $0 < \varepsilon < \frac{1}{2}$ and let W be an integer parameter. There exists an algorithm that can extract with high probability (at least $1 - 2m^{-3}$) from a randomly-ordered stream of weighted edges having integer weights in $\{1, \dots, W\}$ a weighted b -matching with an approximation ratio of $2 - \frac{1}{2W} + \varepsilon$, using $O(\max(|M_G|, n) \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ memory.*

Theorem 5 is the first result for the maximum (integer-weighted) b -matching problem in the random-order semi-streaming framework. For the special case of simple matching, when $W = 1$, we essentially re-capture the result of Bernstein [3] (albeit using slightly more memory). When $W > 1$, we note that prior to our work, Gamlath *et al.* [11] have obtained an approximation ratio of $2 - \delta$ for some small $\delta \sim 10^{-17}$. Our result gives a better approximation when W is reasonably small (but using a memory depending polynomially in W) and we believe that our approach is significantly simpler.

► **Remark 6.** Another generalization of EDCS has been developed by Bernstein *et al.* [4] to maintain a $3/2 + \varepsilon$ approximation of the optimal weighted matching in a dynamic graph. However it is still unknown if their construction can actually lead to an algorithm in the random-order one-pass semi-streaming model [4], or applied to b -matchings.

Technical Overview

To generalize the EDCS to the weighted case, a natural first idea is to build multiple EDCSes, one for each edge-weight from 1 to W , and then take their union. We show in the full version of this paper that such an idea does not lead to a subgraph containing a matching that is better than a 2 approximation.

Our approach is a proper generalization of EDCS, as defined in Definition 3. In Theorem 4, we show that such a w - b -EDCS contains a matching of good approximation ratio. The proof of this theorem is technically the most innovative part of the present work. In order to handle integer-weighted matchings (see Section 2) we make use of Kőnig-Egerváry's duality theorem [7] and a specially-constructed auxiliary graph. The fact that the weights of the edges are integers is critical to get an approximation ratio better than 2 (especially for Claim 13). Then, to handle b -matchings (see Section 3), we build a reduction to simple matchings and show that by doing so we do not lose too much in the approximation ratio.

Regarding Theorem 5, when we design a semi-streaming algorithm to extract a b -matching there is an additional challenge: we do not know in advance the actual size of M_G , which cannot be bounded by n (for instance $|M_G|$ could be of size $n^{1.2}$ or even larger), but we still want to use as little memory as possible, *i.e.*, $O(\max(|M_G|, n) \cdot \text{poly}(\log(m), W, 1/\varepsilon))$. We tackle this issue by using a guessing strategy in the early phase of the stream (see Section 4).

Related Work

In the adversarial semi-streaming setting, for the unweighted case, the simple greedy algorithm building a maximal matching provides a 2 approximation, which is the best known approximation ratio. Knowing whether it is possible to achieve a better approximation ratio is a major open question in the field of streaming algorithms. For weighted matchings an approximation ratio of $2 + \varepsilon$ can be achieved [12, 18, 19]. For weighted b -matchings the approximation ratio $2 + \varepsilon$ can also be attained [14]. On the hardness side, we know that an approximation ratio better than $1 + \ln 2 \approx 1.69$ cannot be achieved [15].

In contrast, for the *random-order* stream, a first result was obtained by Konrad, Magniez, and Mathieu [17] with an approximation ratio strictly below 2 for unweighted simple matchings. The approximation ratio was then improved in a sequence of papers [11, 16, 9, 3]. Currently the best result is due to Assadi and Behnezhad [1], who obtained the ratio of $3/2 - \delta$ for some small constant $\delta \sim 10^{-14}$. Regarding weighted simple matchings, Gamlath *et al.* [11] obtained an approximation ratio of $2 - \delta$ for some small constant $\delta \sim 10^{-17}$. Regarding b -matchings, to our knowledge the only result is an approximation ratio of $2 - \delta$ *in expectation* for random-order online matroid intersection by Guruganesh and Singla [13] (hence it applies for unweighted bipartite b -matchings).

2 EDCS for Weighted Matchings

In this section we consider the problem of finding a maximum weight matching in an edge-weighted graph $G = (V, E)$ where the edges have integer weights in $[1, W]$. For ease of presentation, we will use simplified notations for *simple* graphs in this section. Here $w(u, v)$ denotes edge weight between vertices u and v . For a subgraph H of G and a vertex $u \in V$, we denote by $N_H(v)$ the set of vertices adjacent to v in H , by $\deg_H(v)$ the degree of v in H , *i.e.*, $\deg_H(v) = |N_H(v)|$, and by $\mathbf{wdeg}_H(v)$ the weighted degree of v in H , *i.e.*, $\mathbf{wdeg}_H(v) = \sum_{u \in N_H(v)} w(u, v)$. For a subgraph H of G , we will denote by M_H an arbitrary maximum weight matching in H . Then we define the notion of edge-degree constrained subgraphs for weighted graphs (w -EDCS), which in fact is just Definition 3 specialized to the setting in this section.

► **Definition 7.** Let $G = (V, E)$ be a graph with weighted edges, and H be a subgraph of G . Given any integer parameters $\beta \geq 3$ and $\beta^- \leq \beta - 2$, we say that H is a (β, β^-) - w -EDCS of G if H satisfies the following properties:

- (i) For any edge $(u, v) \in H$, $\mathbf{wdeg}_H(u) + \mathbf{wdeg}_H(v) \leq \beta \cdot w(u, v)$
- (ii) For any edge $(u, v) \in G \setminus H$, $\mathbf{wdeg}_H(u) + \mathbf{wdeg}_H(v) \geq \beta^- \cdot w(u, v)$.

Here is a first simple proposition on (β, β^-) - w -EDCS (coming from Property (i)).

► **Proposition 8.** *Let H be a (β, β^-) - w -EDCS of a given graph G . Then, for all $v \in V$, we have $\deg_H(v) \leq \beta$.*

Proof. Let $v \in V$. If $N_H(v) = \emptyset$, the stated property is trivial. Otherwise, pick a vertex u such that $w(u, v) = \min_{u' \in N_H(v)} w(u', v)$. Then, by Property (i), $\beta \cdot w(u, v) \geq \text{wdeg}_H(v)$. Therefore, $\deg_H(v) \leq \frac{\text{wdeg}_H(v)}{w(u, v)} \leq \beta$, as any edge incident to v in H has a weight larger than or equal to $w(u, v)$. ◀

We show the existence of w -EDCSes by construction, using a local search algorithm. The following proof closely follows the argument of [2].

► **Proposition 9.** *Any graph $G = (V, E)$ with weighted edges contains a (β, β^-) - w -EDCS for any parameters $\beta \geq \beta^- + 2$. Such a (β, β^-) - w -EDCS can be found in $O(\beta^2 W^2 \cdot n)$ local search steps.*

Proof. Start with an empty subgraph H . Then try the following local improvements of H , until it is no longer possible. If there is an edge in H violating Property (i) of Definition 7, then fix that edge by removing it from H . Otherwise, if there is an edge in $G \setminus H$ violating Property (ii), then fix that edge by inserting it in H .

Observe that we give the priority to the correction of violations of Property (i), so that at each step of the algorithm all the vertices have degrees bounded by $\beta + 1$ (as after inserting an edge, Proposition 8 may be violated). To prove that this algorithm terminates in finite time and to show the existence of a w -EDCS, we introduce a potential function:

$$\Phi(H) = (2\beta - 2) \sum_{(u,v) \in H} w(u, v)^2 - \sum_{u \in V} (\text{wdeg}_H(u))^2.$$

As the vertices have degrees bounded by $\beta + 1$ and the edges have weights bounded by W , the value of that potential function is bounded by $2\beta^2 W^2 \cdot n$. Then we can show that after each local improvement step, the value of $\Phi(H)$ increases at least by 2 (see the full version of this paper for details). Therefore, the algorithm terminates in $O(\beta^2 W^2 \cdot n)$ steps. ◀

We also introduce the notion of w -vertex-cover of the edge-weighted graph.

► **Definition 10.** *We say that the non-negative integer variables $(\alpha_v)_{v \in V}$ represent a w -vertex-cover of a subgraph H of G if for all $(u, v) \in H$, we have $w(u, v) \leq \alpha_u + \alpha_v$. The sum $\sum_{v \in V} \alpha_v$ is called the weight of the w -vertex-cover.*

To use this data structure for the maximum weight problem, we will use the theorem of König-Egerváry [7], which is a classic duality theorem.

► **Theorem 11 (König-Egerváry).** *In any edge-weighted bipartite subgraph H of G , the maximum weight of a matching equals the smallest weight of a w -vertex-cover.*

This theorem allows us to prove the following lemma, which is technically the most important part of the present work.

► **Lemma 12.** *Let $0 < \varepsilon < 1/2$ and W be an integer parameter. For $\beta \geq \beta^- + 2$ integers such that $\frac{\beta}{\beta^-} \leq 1 + \frac{\varepsilon}{5W}$ and $\beta^- \geq \frac{4W}{\varepsilon}$, we have that any (β, β^-) - w -EDCS H of a bipartite graph G (with integer edge weights bounded by W) contains a matching M_H such that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_H) \geq w(M_G)$.*

Proof. Using Kőnig-Egerváry's theorem in the bipartite graph H , we know that there exist integers $(\alpha_v)_{v \in V}$ such that:

- $\sum_{v \in V} \alpha_v = w(M_H)$
- for all $(u, v) \in H$, $w(u, v) \leq \alpha_u + \alpha_v$

Now consider the optimal matching M_G in G . The first idea is to use the duality theorem to relate $w(M_G)$ to $w(M_H)$, with a leftover term that will be analyzed in the second part of the proof. We introduce the notion of *good* and *bad* edges:

- the edges $(u, v) \in M_G$ such that $\beta^- \cdot w(u, v) \leq \beta \cdot (\alpha_u + \alpha_v)$, which are called *good edges*; the set of good edges is denoted as M_{good} ;
- the edges $(u, v) \in M_G$ such that $\beta^- \cdot w(u, v) > \beta \cdot (\alpha_u + \alpha_v)$, which are called *bad edges*; the set of bad edges is denoted as M_{bad} .

A key observation is that the edges in $M_G \cap H$ are necessarily good edges by the definition of the w -vertex-cover $(\alpha_v)_{v \in V}$ and the fact that $\beta^- < \beta$. Therefore, the bad edges (u, v) are in $G \setminus H$ and as a consequence they satisfy Property (ii) of Definition 7, *i.e.*, $\beta^- \cdot w(u, v) \leq \mathbf{wdeg}_H(u) + \mathbf{wdeg}_H(v)$.

Hence we can write the following:

$$\begin{aligned}
\beta^- \cdot w(M_G) &= \sum_{(u,v) \in M_{good}} \beta^- \cdot w(u, v) + \sum_{(u,v) \in M_{bad}} \beta^- \cdot w(u, v) \\
&\leq \sum_{(u,v) \in M_{good}} \beta \cdot (\alpha_u + \alpha_v) + \sum_{(u,v) \in M_{bad}} (\mathbf{wdeg}_H(u) + \mathbf{wdeg}_H(v)) \\
&= \sum_{(u,v) \in M_G} \beta \cdot (\alpha_u + \alpha_v) + \sum_{(u,v) \in M_{bad}} (\mathbf{wdeg}_H(u) + \mathbf{wdeg}_H(v) - \beta \cdot (\alpha_u + \alpha_v)) \\
&\leq \beta \cdot w(M_H) + \sum_{(u,v) \in M_{bad}} ((\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u)_+ + (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v)_+),
\end{aligned}$$

where $(x)_+$ denotes the non-negative part $\max(x, 0)$. In the last inequality we also used the fact that $\sum_{(u,v) \in M_G} (\alpha_u + \alpha_v) \leq \sum_{v \in V} \alpha_v = w(M_H)$, as each vertex of V is counted at most once in that sum. Now, denoting by V_{bad} the set of vertices which are the endpoints of a bad edge and such that $\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u > 0$, we get

$$\beta^- \cdot w(M_G) \leq \beta \cdot w(M_H) + \sum_{v \in V_{bad}} (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v). \quad (1)$$

Naturally, we want to upper-bound the value of $\sum_{v \in V_{bad}} (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v)$ and we will do so *via* a specially-constructed graph. Before we describe this graph, we can first easily observe that for any $v \in V_{bad}$, for any $u \in N_H(v)$, we have $w(u, v) \geq \frac{\mathbf{wdeg}_H(v)}{\beta} > \alpha_v$ (by Property (i) of Definition 7 and the definition of V_{bad}); moreover, as $(\alpha_v)_{v \in V}$ is a w -vertex-cover of H , we obtain that $\alpha_u > 0$. These observations will be useful in the following.

The new graph is $H_{bad} = (V_{bad} \cup \tilde{V}, \tilde{E})$. The vertices in H_{bad} are the vertices of V_{bad} as well as copies of the vertices of V such that $\alpha_v > 0$, *i.e.*, $\tilde{V} = \{\tilde{v} : v \in V, \alpha_v > 0\}$. We build the set of edges \tilde{E} as follows. For each $v \in V_{bad}$, for each $u \in N_H(v)$, we create in \tilde{E} an edge (v, \tilde{u}) such that $w(v, \tilde{u}) = w(v, u) - \alpha_v$ (note that if u is also in V_{bad} , then \tilde{E} will also contain another edge (u, \tilde{v}) such that $w(u, \tilde{v}) = w(u, v) - \alpha_u$). Note that $w(v, \tilde{u}) \in \mathbb{Z}_{>0}$, since $w(u, v) > \alpha_v$ as observed above. Therefore the graph H_{bad} still has non-negative integer-valued edge weights. We next remove some edges from \tilde{E} : while there exists a vertex $v \in V_{bad}$ such that $\mathbf{wdeg}_{H_{bad}}(v) > \mathbf{wdeg}_H(v) - \beta \cdot \alpha_v + W$, we pick an arbitrary edge $(v, \tilde{u}) \in \tilde{E}$ incident to v and remove it from H_{bad} . This process guarantees the following property:

$$\forall v \in V_{bad}, \mathbf{wdeg}_H(v) - \beta \cdot \alpha_v \leq \mathbf{wdeg}_{H_{bad}}(v) \leq \mathbf{wdeg}_H(v) - \beta \cdot \alpha_v + W. \quad (2)$$

This finishes the description of the graph H_{bad} . By (2), for any $(v, \tilde{u}) \in \tilde{E}$ we have:

$$\begin{aligned} \beta \cdot w(v, \tilde{u}) + W &= \beta \cdot (w(v, u) - \alpha_v) + W \geq \mathbf{wdeg}_H(v) - \beta \cdot \alpha_v + W + \mathbf{wdeg}_H(u) \\ &\geq \mathbf{wdeg}_{H_{bad}}(v) + \mathbf{wdeg}_{H_{bad}}(\tilde{u}). \end{aligned}$$

Summing this inequality over all the edges in \tilde{E} we obtain:

$$\begin{aligned} \beta \cdot w(\tilde{E}) + W \cdot |\tilde{E}| &\geq \sum_{(v, \tilde{u}) \in \tilde{E}} (\mathbf{wdeg}_{H_{bad}}(v) + \mathbf{wdeg}_{H_{bad}}(\tilde{u})) \\ &= \sum_{v \in V_{bad}} \deg_{H_{bad}}(v) \cdot \mathbf{wdeg}_{H_{bad}}(v) + \sum_{\tilde{u} \in \tilde{V}} \deg_{H_{bad}}(\tilde{u}) \cdot \mathbf{wdeg}_{H_{bad}}(\tilde{u}) \\ &\geq \sum_{v \in V_{bad}} \frac{\mathbf{wdeg}_{H_{bad}}(v)}{W} \cdot \mathbf{wdeg}_{H_{bad}}(v) + \sum_{\tilde{u} \in \tilde{V}} \frac{\mathbf{wdeg}_{H_{bad}}(\tilde{u})}{\alpha_u} \cdot \mathbf{wdeg}_{H_{bad}}(\tilde{u}) \\ &= \sum_{v \in V_{bad}} \frac{(\mathbf{wdeg}_{H_{bad}}(v))^2}{W} + \sum_{\tilde{u} \in \tilde{V}} \frac{(\mathbf{wdeg}_{H_{bad}}(\tilde{u}))^2}{\alpha_u} \\ &\geq \sum_{v \in V_{bad}} \frac{1}{W} \cdot \left(\frac{w(\tilde{E})}{|V_{bad}|} \right)^2 + \sum_{\tilde{u} \in \tilde{V}} \frac{1}{\alpha_u} \cdot \left(\frac{w(\tilde{E}) \cdot \alpha_u}{\sum_{\tilde{u}' \in \tilde{V}} \alpha_{u'}} \right)^2 \\ &= \frac{w(\tilde{E})^2}{W \cdot |V_{bad}|} + \frac{w(\tilde{E})^2}{\sum_{\tilde{u}' \in \tilde{V}} \alpha_{u'}}. \end{aligned}$$

The second inequality comes from the fact that the degree of a vertex can be lower-bounded by the weighted degree of that vertex divided by the weight of the largest edge incident to it (for $v \in V_{bad}$ this weight is W , and for $\tilde{u} \in \tilde{V}$ it is α_u , as $w(v, \tilde{u}) = w(v, u) - \alpha_v \leq \alpha_u$ for v adjacent to \tilde{u} in H_{bad}). The third inequality comes from the minimization of the function over the constraints $\sum_{v \in V_{bad}} \mathbf{wdeg}_{H_{bad}}(v) = \sum_{\tilde{u} \in \tilde{V}} \mathbf{wdeg}_{H_{bad}}(\tilde{u}) = w(\tilde{E})$. Now observing that $|\tilde{E}| \leq w(\tilde{E})$, we derive the following:

$$\beta + W \geq \frac{w(\tilde{E})}{W \cdot |V_{bad}|} + \frac{w(\tilde{E})}{\sum_{\tilde{u} \in \tilde{V}} \alpha_u}. \quad (3)$$

The following claim will help us lower bound the average weighted degree of the vertices of V_{bad} in H_{bad} , namely, $w(\tilde{E})/|V_{bad}|$. For this part it is crucial that the weights are integers.

▷ **Claim 13.** For all $(u, v) \in M_{bad}$, $(\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u)_+ + (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v)_+ \geq \frac{\beta^-}{1+\varepsilon/4}$

Proof. We proceed by contradiction. Suppose that there exists $(u, v) \in M_{bad}$ such that $(\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u)_+ + (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v)_+ < \frac{\beta^-}{1+\varepsilon/4}$. Then, as $\beta^- \cdot w(u, v) \leq \beta \cdot (\alpha_u + \alpha_v) + (\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u)_+ + (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v)_+$, it means that

$$\beta \cdot (\alpha_u + \alpha_v) < \beta^- \cdot w(u, v) < \beta \cdot (\alpha_u + \alpha_v) + \frac{\beta^-}{1+\varepsilon/4},$$

and therefore by dividing by β^- we obtain

$$\frac{\beta}{\beta^-} \cdot (\alpha_u + \alpha_v) < w(u, v) < \frac{\beta}{\beta^-} \cdot (\alpha_u + \alpha_v) + \frac{1}{1+\varepsilon/4}.$$

As $(\alpha_u + \alpha_v) \in \{0, 1, \dots, W\}$ (recall that (u, v) is a bad edge) and because $\frac{\beta}{\beta^-} \leq 1 + \frac{\varepsilon}{5W} < 1 + \frac{\varepsilon}{4W \cdot (1 + \varepsilon/4)}$, there cannot be any integer in the open interval

$$\left] \frac{\beta}{\beta^-} \cdot (\alpha_u + \alpha_v), \frac{\beta}{\beta^-} \cdot (\alpha_u + \alpha_v) + \frac{1}{1 + \varepsilon/4} \right[,$$

implying that $w(u, v)$, which is an integer, cannot exist. The proof follows. \triangleleft

Recall that u of $(u, v) \in M_{bad}$ is part of V_{bad} only if $\mathbf{wdeg}_H(u) - \beta \cdot \alpha_u > 0$. Claim 13 then implies that given $(u, v) \in M_{bad}$, if both u and v are in V_{bad} , then $\mathbf{wdeg}_{H_{bad}}(u) + \mathbf{wdeg}_{H_{bad}}(v) \geq \frac{\beta^-}{1 + \varepsilon/4}$; if only u is in V_{bad} , then $\mathbf{wdeg}_{H_{bad}}(u) \geq \frac{\beta^-}{1 + \varepsilon/4}$. We can thus infer that $\frac{w(\tilde{E})}{|V_{bad}|} \geq \frac{\beta^-}{2 \cdot (1 + \varepsilon/4)}$ and we can rewrite (3) as $\beta + W \geq \frac{\beta^-}{2W \cdot (1 + \varepsilon/4)} + \sum_{\tilde{u} \in \tilde{V}} \frac{w(\tilde{E})}{\alpha_u}$, and therefore

$$\left(\beta + W - \frac{\beta^-}{2W \cdot (1 + \varepsilon/4)} \right) \cdot \sum_{\tilde{u} \in \tilde{V}} \alpha_u \geq w(\tilde{E}). \quad (4)$$

We now can rebound the expression of (1) as follows:

$$\begin{aligned} \beta^- \cdot w(M_G) &\leq \beta \cdot w(M_H) + \sum_{v \in V_{bad}} (\mathbf{wdeg}_H(v) - \beta \cdot \alpha_v) \\ &\leq \beta \cdot w(M_H) + \sum_{v \in V_{bad}} \mathbf{wdeg}_{H_{bad}}(v) && \text{by (2)} \\ &\leq \beta \cdot w(M_H) + w(\tilde{E}) \\ &\leq \left(2\beta + W - \frac{\beta^-}{2W \cdot (1 + \varepsilon/4)} \right) \cdot w(M_H). && \text{by (4) and } \sum_{\tilde{u} \in \tilde{V}} \alpha_u \leq w(M_H) \end{aligned}$$

Re-arranging,

$$\left(2 \frac{\beta}{\beta^-} + \frac{W}{\beta^-} - \frac{1}{2W \cdot (1 + \varepsilon/4)} \right) \cdot w(M_H) \geq w(M_G).$$

As $\frac{\beta}{\beta^-} \leq 1 + \varepsilon/4$ and $\beta^- \geq \frac{4W}{\varepsilon}$ we obtain the desired result. \triangleleft

Then we can generalize this result to non-bipartite graphs.

► **Theorem 14.** *Let $0 < \varepsilon < 1/2$ and W be an integer parameter. Set $\lambda = \frac{\varepsilon}{100W}$. For $\beta \geq \beta^- + 2$ integers such that $\frac{\beta}{\log(\beta)} \geq 2W^2 \lambda^{-2}$ and $\beta^- \geq (1 - \lambda) \cdot \beta$, we have that any (β, β^-) - w -EDCS H of a graph G (with integer edge weights bounded by W) contains a matching M_H such that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_H) \geq w(M_G)$.*

Proof. The proof of this theorem relies on Lemma 12 and on the same construction as the one in [2], using the probabilistic method and Lovasz Local Lemma [8]. We provide the details of the proof in the full version of this paper. \triangleleft

3 EDCS for Weighted b -Matchings

From now on we consider the problem of finding a maximum weight b -matching in an edge-weighted multi-graph $G = (V, E)$. Hence we will use the notations described in the introduction. Here we recall the generalization of edge-degree constrained subgraphs (EDCS) to an edge-weighted multi-graph $G = (V, E)$ in the context of the b -matching problem.

► **Definition 15.** Let $G = (V, E)$ be a weighted multi-graph, where E is a multiset of edges drawn from $V \times V \times \{1, 2, \dots, W\}$, $\{b_v\}_{v \in V}$ be a set of constraints, and H be a subgraph of G . Given any integer parameters $\beta \geq 3$ and $\beta^- \leq \beta - 2$, we say that H is a (β, β^-) - w - b -EDCS of G if H satisfies the following properties:

- (i) For any edge $(u, v, w_{uv}) \in H$, $\frac{\text{wdeg}_H(u)}{b_u} + \frac{\text{wdeg}_H(v)}{b_v} \leq \beta \cdot w_{uv}$
- (ii) For any edge $(u, v, w_{uv}) \in G \setminus H$, $\frac{\text{wdeg}_H(u)}{b_u} + \frac{\text{wdeg}_H(v)}{b_v} \geq \beta^- \cdot w_{uv}$.

As for a w -EDCS (Proposition 8), we can bound the degree of a vertex in a w - b -EDCS H (with almost the same proof as that of Proposition 8).

► **Proposition 16.** Let H be a (β, β^-) - w - b -EDCS of a given graph G . Then, for all $v \in V$, we have $\deg_H(v) \leq \beta \cdot b_v$.

► **Proposition 17.** Let H be a (β, β^-) - w - b -EDCS of a given graph G . Then H contains at most $2\beta \cdot |M_G|$ edges.

Proof. A vertex $v \in V$ is called *saturated* by M_G if $|\delta_G(v) \cap M_G| = b_v$. We denote by V_{sat} the set of vertices saturated by M_G . As M_G is a maximal matching in G , it means that for all $(u, v, w_{uv}) \in G \setminus M_G$, either u or v is in V_{sat} . We denote by $M_{sat} \subseteq M_G$ the subset of edges in M_G that are incident to a vertex of V_{sat} . By this definition, we get:

$$\begin{aligned} |H| &= |H \cap (M_G \setminus M_{sat})| + |H \setminus (M_G \setminus M_{sat})| \leq |M_G| - |M_{sat}| + \sum_{v \in V_{sat}} \deg_H(v) \\ &\leq |M_G| - |M_{sat}| + \sum_{v \in V_{sat}} \beta \cdot b_v \leq |M_G| - |M_{sat}| + 2 \cdot |M_{sat}| \cdot \beta \leq 2\beta \cdot |M_G|, \end{aligned}$$

as for all $v \in V$, $\deg_H(v) \leq \beta \cdot b_v$ and $\sum_{v \in V_{sat}} b_v \leq 2 \cdot |M_{sat}|$. ◀

We can also show that such w - b -EDCSes always exist.

► **Proposition 18.** Any multi-graph $G = (V, E)$, along with a set of constraints $\{b_v\}_{v \in V}$, contains a (β, β^-) - w - b -EDCS for any parameters $\beta \geq \beta^- + 2$. Such a (β, β^-) - w - b -EDCS can also be found in $O(\beta^2 W^2 \cdot |M_G|)$ local search steps.

Proof. As in the proof of Proposition 9, we follow closely the argument of [2]. We use the same local-search algorithm as the one in Proposition 9, except that the properties violated are those of Definition 15. Here we also give the priority to the correction of violations of Property (i), so that the at each step of the algorithm all the vertices $v \in V$ have degrees bounded by $\beta \cdot b_v + 1$. To prove that this algorithm terminates and show the existence of a w - b -EDCS, we introduce the following potential function:

$$\Phi(H) = (2\beta - 2) \sum_{(u, v, w_{uv}) \in H} w_{uv}^2 - \sum_{u \in V} \frac{(\text{wdeg}_H(u))^2}{b_u}.$$

Observe that because of Proposition 17, the value of $\Phi(H)$ is bounded by $2\beta W^2 \cdot 2\beta \cdot |M_G|$. We can also show that after each local improvement, the value of $\Phi(H)$ increases by at least $3/2$ (see full version for details). Hence the algorithm terminates in $O(\beta^2 W^2 \cdot |M_G|)$ steps. ◀

The main interest of these w - b -EDCSes is that they contain an (almost) $2 - \frac{1}{2W}$ approximation, as in the case of w -EDCSes in simple graphs (Theorem 14).

► **Theorem 4.** *Let $0 < \varepsilon < 1/2$ and let W be an integer parameter. Set $\lambda = \frac{\varepsilon}{100W}$. Let $\beta \geq \beta^- + 2$ be integers such that $\frac{\beta+6W}{\log(\beta+6W)} \geq 2W^2\lambda^{-2}$ and $\beta^- - 6W \geq (1 - \lambda) \cdot (\beta + 6W)$. Then any (β, β^-) - w - b -EDCS H of a weighted multi-graph G with integer edge weights bounded by W contains a b -matching M_H such that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_H) \geq w(M_G)$.*

Proof. Consider a maximum weight b -matching M_G . We will build from H and M_G two simple graphs $G' = (V', E')$ and $H' = (V', E'_H)$. The set of vertices V' contains, for each vertex $v \in V$, b_v vertices v_1, \dots, v_{b_v} , so that V' contains $\sum_{v \in V} b_v$ vertices in total. To construct E' , for each $v \in V$, we will distribute the edges of $\delta(v) \cap (H \cup M_G)$ among the b_v vertices v_1, \dots, v_{b_v} in such a way so that the following three properties hold:

- (i) each v_i has a most one edge of M_G incident to it;
- (ii) G' is a simple graph;
- (iii) each v_i has a weighted degree in the interval $\left[\frac{\mathbf{wdeg}_H(v)}{b_v} - 2W, \frac{\mathbf{wdeg}_H(v)}{b_v} + 3W \right]$.

The existence of such a distribution is achieved by a greedy procedure (see the full version of this paper for a proof of this fact). For Property (ii), it is crucial that the graph G has at most $\min(b_u, b_v)$ edges between any vertices u and v . This property is important in the proof of Theorem 14 (where negative association is used). Then, for H' , we just consider the restriction of G' to the edges corresponding to H (ignoring those from $M_G \setminus H$ in the preceding construction).

Observe that M_G corresponds a simple matching in G' , and that any simple matching in H' corresponds to a b -matching in H . Next we show that H' is a $(\beta + 6W, \beta^- - 6W)$ -EDCS for simple graph G' . Consider an edge $(u_i, v_j) \in H'$. It corresponds to an edge (u, v, w_{uv}) of H so $\mathbf{wdeg}_{H'}(u_i) + \mathbf{wdeg}_{H'}(v_j) \leq \frac{\mathbf{wdeg}_H(u)}{b_u} + \frac{\mathbf{wdeg}_H(v)}{b_v} + 6W \leq (\beta + 6W) \cdot w_{uv}$, so Property (i) of Definition 7 holds. Consider next an edge $(u_i, v_j) \in G' \setminus H'$. It corresponds to an edge (u, v, w_{uv}) of $M_G \setminus H$, so $\mathbf{wdeg}_{H'}(u_i) + \mathbf{wdeg}_{H'}(v_j) \geq \frac{\mathbf{wdeg}_H(u)}{b_u} + \frac{\mathbf{deg}_H(v)}{b_v} - 6W \geq (\beta^- - 6W) \cdot w_{uv}$ (as there can be a difference of at most W between the weighted degree of u in G' and in H'). Thus Property (ii) of Definition 7 holds as well. To conclude, H' is a $(\beta + 6W, \beta^- - 6W)$ - w -EDCS of G' , so by Theorem 14 we have that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_{H'}) \geq w(M_{G'}) = w(M_G)$. As $w(M_H) \geq w(M_{H'})$ (because any matching in H' corresponds to a b -matching of the same weight in H), completing the proof. ◀

4 Application to b -Matchings in Random-Order Streams

In this section we consider the random-order semi-streaming model and we show how our results in the preceding section can be adapted to get a $2 - \frac{1}{2W} + \varepsilon$ approximation.

As our algorithm builds on that of Bernstein [3] for the unweighted simple matching, let us briefly summarize his approach. In the first phase of the streaming, he constructs a subgraph that satisfies only a weaker definition of EDCS in Definition 1 (only Property (i) holds). In the second phase of the streaming, he collects the “underfull” edges, which are those edges that violate Property (ii). He shows that in the end, the union of the subgraph built in the first phrase and the underfull edges collected in the second phase, with high probability, contains a $3/2 + \varepsilon$ approximation and that the total memory used is in the order of $O(n \cdot \log n)$. As we will show below, this approach can be adapted to our context of edge-weighted b -matching. Our main technical challenge lies in the fact that unlike the simple matching, the size of M_G can vary a lot. We need a “guessing” strategy to ensure that the required memory is proportional to $|M_G|$.

► **Definition 19.** *We say that a graph H has bounded weighted edge-degree β if for every edge $(u, v, w_{uv}) \in H$, $\frac{\mathbf{wdeg}_H(u)}{b_u} + \frac{\mathbf{wdeg}_H(v)}{b_v} \leq \beta \cdot w_{uv}$.*

► **Definition 20.** Let G be a edge-weighted multi-graph, and let H be a subgraph of G with bounded weighted edge-degree β . For any parameter β^- , we say that an edge $(u, v, w_{uv}) \in G \setminus H$ is (H, β, β^-) -underfull if $\frac{wdeg_H(u)}{b_u} + \frac{wdeg_H(v)}{b_v} < \beta^- \cdot w_{uv}$.

► **Lemma 21.** Let $0 < \varepsilon < 1/2$ be any parameter and W be an integer parameter. Set $\lambda = \frac{\varepsilon}{100W}$. Suppose that β^- and $\beta \geq \beta^- + 2$ are integers so that $\frac{\beta+8W}{\log(\beta+8W)} \geq 2W^2\lambda^{-2}$ and $\beta^- - 6W \geq (1 - \lambda) \cdot (\beta + 8W)$. Given an edge-weighted multi-graph G with integer weights in $1, \dots, W$, and a subgraph H with bounded weighted edge-degree β , if X contains all edges in $G \setminus H$ that are (H, β, β^-) -underfull, then $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_{H \cup X}) \geq w(M_G)$.

Proof. First, observe that $H \cup X$ is not necessarily a w - b -EDCS of G . Thereby we use another argument from [3]. Let M_G be a maximum weight b -matching in G , let $M_G^H = M_G \cap H$ and $M_G^{G \setminus H} = M_G \cap (G \setminus H)$. Let $X^M = X \cap M_G^{G \setminus H}$. We can observe that $w(M_G) = w(M_{H \cup M_G^{G \setminus H}})$. Then we can show that $H \cup X^M$ is a $(\beta + 2W, \beta^-)$ - w - b -EDCS of $H \cup M_G^{G \setminus H}$ (see the full version of this paper). As a result, Theorem 4 can be applied in this case and we get that $(2 - \frac{1}{2W} + \varepsilon) \cdot w(M_{H \cup X^M}) \geq w(M_{H \cup M_G^{G \setminus H}}) = w(M_G)$, thus concluding the proof. ◀

► **Remark 22.** One can easily notice that there exist integers β and β^- that are $O(\text{poly}(W, 1/\varepsilon))$ satisfying the conditions of Lemma 21. From now on, we will use the parameters λ, β , and β^- satisfying the conditions of Lemma 21 and they are of values $O(\text{poly}(W, 1/\varepsilon))$.

■ **Algorithm 1** Main algorithm computing a weighted b -matching for a random-order stream.

```

1:  $H \leftarrow \emptyset$ 
2:  $\forall 0 \leq i \leq \log_2 m, \alpha_i \leftarrow \left\lfloor \frac{\varepsilon \cdot m}{\log_2(m) \cdot (2^{i+2} \beta^2 W^2 + 1)} \right\rfloor$ 
3: for  $i = 0 \dots \log_2 m$  do
4:   PROCESSSTOPPED  $\leftarrow$  FALSE
5:   for  $2^{i+2} \beta^2 W^2 + 1$  iterations do
6:     FOUNDUNDERFULL  $\leftarrow$  FALSE
7:     for  $\alpha_i$  iterations do
8:       let  $(u, v, w_{uv})$  be the next edge in the stream
9:       if  $\frac{wdeg_H(u)}{b_u} + \frac{wdeg_H(v)}{b_v} < \beta^- \cdot w_{uv}$  then
10:        add edge  $(u, v, w_{uv})$  to  $H$ 
11:        FOUNDUNDERFULL  $\leftarrow$  TRUE
12:        while there exists  $(u', v', w_{u'v'}) \in H : \frac{wdeg_H(u')}{b_{u'}} + \frac{wdeg_H(v')}{b_{v'}} > \beta \cdot w_{u'v'}$  do
13:          remove  $(u', v', w_{u'v'})$  from  $H$ 
14:        if FOUNDUNDERFULL = FALSE then
15:          PROCESSSTOPPED  $\leftarrow$  TRUE
16:          break from the loop
17:   if PROCESSSTOPPED = TRUE then
18:     break from the loop
19:  $X \leftarrow \emptyset$ 
20: for each  $(u, v, w_{uv})$  remaining edge in the stream do
21:   if  $\frac{wdeg_H(u)}{b_u} + \frac{wdeg_H(v)}{b_v} < \beta^- \cdot w_{uv}$  then
22:     add edge  $(u, v, w_{uv})$  to  $X$ 
23: return the maximum weight  $b$ -matching in  $H \cup X$ 

```

The algorithm, formally described in Algorithm 1, consists of two phases. The first phase, corresponding to Lines 3-18, constructs a subgraph H of bounded weighted edge-degree β using only a ε fraction of the stream E^{early} . In the second phase, the algorithm collects the

68:12 Maximum Weight b -Matchings in Random-Order Streams

underfull edges in the remaining part of the stream E^{late} . As in [3] we use the idea that if no underfull edge was found in an interval of size α (see Lines 6-13), with high probability the number of underfull edges remaining in the stream is bounded by some value $\gamma = 4 \log(m) \frac{m}{\alpha}$. The issue is therefore to choose the right size of interval α , because we do not know the order of magnitude of $|M_G|$ in the b -matching problem: if we do as in [3] by choosing only one fixed size of intervals α , then if α is too small, the value of γ will be too big compared to $|M_G|$, whereas if the value of α is too large we will not be able to terminate the first phase of the algorithm within the early fraction of size εm . Therefore, the idea in the first phase of the algorithm is to “guess” the value of $\log_2 |M_G|$ by trying successively larger and larger values of i (see Line 3). In fact, by setting $i_0 = \lceil \log_2 |M_G| \rceil$, we know that the number of operations that can be performed on a w - b -EDCS is bounded by $2^{i_0+2} \beta^2 W^2$ (see the proof of Proposition 18). As a result we know that the first phase should always stop at a time where i is smaller than or equal to i_0 , and therefore at a time when $\alpha_i \geq \alpha_{i_0}$. Then we can prove that with high probability the number of remaining underfull edges in the stream is at most $\gamma_i = 4 \log(m) \frac{m}{\alpha_i}$.

Algorithm 1 works when M_G is neither too small nor too big. Here we will first argue that the other border cases can be handled anyway. We first have this easy lemma (its proof is very similar to that of Proposition 17, see the full version of this paper).

► **Lemma 23.** *We have the inequality $|G| \leq 2n \cdot |M_G|$.*

Then we use it to handle the case of small b -matchings.

▷ **Claim 24.** We can assume that $w(M_G) \geq \frac{3W^2}{2\varepsilon^2} \log(m)$.

Proof. In fact, if $w(M_G) < \frac{3W^2}{2\varepsilon^2} \log(m)$, then $|M_G| < \frac{3W^2}{2\varepsilon^2} \log(m)$ and by Lemma 23 the graph has only $m = O(n \cdot \frac{3W^2}{2\varepsilon^2} \cdot \log(m))$ edges, so the whole graph can be stored only using $O(n \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ memory, implying that we can compute an exact solution. ◁

▷ **Claim 25.** Assuming Claim 24, with probability at least $1 - m^{-3}$ the late part of the stream E^{late} contains at least a $(1 - 2\varepsilon)$ fraction of the optimal b -matching.

Proof. Consider a maximum weight b -matching $M_G = \{f_1, \dots, f_{|M_G|}\}$. We define the random variables $X_i = \mathbb{1}_{f_i \in E^{early}} \cdot w(f_i)$. Hence we have $\mathbb{E}[\sum X_i] = \varepsilon \cdot w(M_G)$. Moreover, the random variables X_i are negatively associated, so we can use Hoeffding’s inequality to get $\mathbb{P}\left[\sum_{i=1}^{|M_G|} X_i \geq 2\varepsilon \cdot w(M_G)\right] \leq \exp\left(-\frac{2 \cdot \varepsilon^2 \cdot w(M_G)^2}{|M_G| \cdot W^2}\right) \leq \exp\left(-\frac{2 \cdot \varepsilon^2 \cdot w(M_G)}{W^2}\right) \leq m^{-3}$, as we now assume that $w(M_G) \geq \frac{3W^2}{2\varepsilon^2} \log(m)$ (see Claim 24). ◁

Recall that we defined $i_0 = \lceil \log_2 |M_G| \rceil$.

▷ **Claim 26.** We can assume that $\frac{\varepsilon \cdot m}{\log_2(m) \cdot (2^{i_0+2} \beta^2 W^2 + 1)} \geq 1$.

Proof. If this is not the case, then we can just store all the edges of G as the number of edges m is bounded by $\frac{\log_2(m) \cdot (2^{i_0+2} \beta^2 W^2 + 1)}{\varepsilon} = O(|M_G| \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ (as β is $O(\text{poly}(W, 1/\varepsilon))$, see Remark 22). As a result, if at some point of the first phase we have not stopped and we have $\alpha_i = 0$, then we store all the remaining edges of E^{late} and we will be able to get a $(1 - 2\varepsilon)$ approximation with high probability (because of Claim 25) using $O(|M_G| \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ memory. ◁

Then we can move on to our main algorithm. The following lemma is very similar to the one used in [3] (see the proof in the full version of this paper). It can then be combined with previous lemmas and claims to prove that a $2 - \frac{1}{2W} + \varepsilon$ approximation can be achieved with high probability.

► **Lemma 27.** *The first phase of Algorithm 1 uses $O(\beta \cdot |M_G|)$ memory and constructs a subgraph H of G , satisfying the following properties:*

1. *The first phase terminates within the first εm edges of the stream.*
2. *When the first phase terminates after processing some edge, we have:*
 - a. *H has bounded weighted edge degree β , and contains at most $O(\beta \cdot |M_G|)$ edges.*
 - b. *With probability at least $1 - m^{-3}$, the total number of (H, β, β^-) -underfull edges in the remaining part of the stream is at most $\gamma = O(|M_G| \cdot (\log(m))^2 \cdot \beta^2 W^2 \cdot 1/\varepsilon)$.*

► **Theorem 28.** *Let $\varepsilon > 0$. Using Algorithm 1, with probability $1 - 2m^{-3}$, one can extract from a randomly-ordered stream of edges a weighted b -matching with an approximation ratio of $2 - \frac{1}{2W} + \varepsilon$, using $O(\max(|M_G|, n) \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ memory.*

Proof. Applying Lemma 21 to the graph $H \cup G^{\text{late}}$ we can get, choosing the right values β and β^- (which are $O(\text{poly}(W, 1/\varepsilon))$), $H \cup X$ contains a $(1 - 2\varepsilon)^{-1} \cdot (2 - \frac{1}{2W} + \varepsilon)$ approximation of the optimal b -matching (with probability at least $1 - m^{-3}$, see Claim 25), and with a memory consumption of $O(|M_G| \cdot \text{poly}(\log(m), W, 1/\varepsilon))$ (with probability at least $1 - m^{-3}$, see Lemma 27), with probability at least $1 - 2m^{-3}$ (union bound). Hence the proof. ◀

Abstract

Given a rooted, binary phylogenetic network and a rooted, binary phylogenetic tree, can the tree be embedded into the network? This problem, called TREE CONTAINMENT, arises when validating networks constructed by phylogenetic inference methods. We present the first algorithm for (rooted) TREE CONTAINMENT using the treewidth t of the input network N as parameter, showing that the problem can be solved in $2^{O(t^2)} \cdot |N|$ time and space.

1 Introduction

1.1 Background: phylogenetic trees and networks

Phylogenetic trees and networks are graphs used to represent evolutionary relationships. In particular, a *rooted phylogenetic network* is a directed acyclic graph with distinctly labelled leaves, a unique root and no indegree-1 outdegree-1 vertices. The labels of the leaves can, for example, represent a collection of studied biological species, and the network then describes how they evolved from a common ancestor (the root). Here, we will only consider rooted binary phylogenetic networks, which we will call *networks* for short. Vertices with indegree 2 in such a network are called *reticulations* and represent events where lineages combine, for example the emergence of new hybrid species. A network without reticulations is a *phylogenetic tree*.

■ **Figure 1** **Left:** a phylogenetic tree T . **Middle:** a phylogenetic network N displaying T (solid lines indicate an embedding of T ; black nodes indicate reticulations). **Right:** the display graph $D(N, T)$ of N and T (see Section 1.5) with the network part drawn on top and the tree part drawn on the bottom. Note that vertices of the display graph are not labelled. In the figure, the leaves (square vertices) are ordered in the same way as in N .

1.2 The Tree Containment problem

The evolutionary history of a small unit of hereditary information (for example a gene, a fraction of a gene or (in linguistics) a word) can often be described by a phylogenetic tree. This is because at each reticulation, each unit is inherited from only one parent. Hence, if we trace back the evolutionary history of such a hereditary unit in the network, we see that its phylogenetic tree can be embedded in the network. This raises the fundamental question: given a phylogenetic network and a phylogenetic tree, can the tree be embedded into the network? This is called the TREE CONTAINMENT problem (see Figure 1). To formalize this problem, we say that a network N *displays* a tree T if some subgraph of N is a subdivision of T .

TREE CONTAINMENT (TC)

Input: phylogenetic network N_{IN} and tree T_{IN} , both on the same set of leaf labels

Question: Does N_{IN} display T_{IN} ?

1.2.1 Motivation

Apart from being a natural and perhaps one of the most fundamental questions regarding phylogenetic networks, the TREE CONTAINMENT problem has direct applications in phylogenetics. The main application is the validation of phylogenetic network inference methods. After constructing a network, one may want to verify whether it is consistent with the phylogenetic trees. For example, if a heuristic method is used to generate a network for a genomic data set, and tree inference methods are used to generate trees for each gene, then the quality of the produced network can be assessed by computing the fraction of the gene trees that can be embedded into it. In addition, one may want to find the actual embeddings for visualisation purposes and/or to assess the importance of each network arc.

However, our main motivation for studying TREE CONTAINMENT is that it is a first step towards the wider application of treewidth based approaches in phylogenetics (see Sections 1.4 and 1.5). The techniques we develop are not exclusively designed for TREE CONTAINMENT but intended to be useful also for other problems such as NETWORK CONTAINMENT [31] and HYBRIDIZATION NUMBER [8, 41, 42, 43]. The former is the natural generalization of TREE CONTAINMENT in which we have two networks as input and want to decide whether one can be embedded into the other. It can, in particular, be used to decide whether two networks

are isomorphic. In the latter problem, HYBRIDIZATION NUMBER, the input consists of a set of phylogenetic trees, and the aim is to construct a network with at most k reticulations that embeds each of the input trees. Although this will certainly be non-trivial, we expect that at least part of the approach we introduce here can be applied to those and other problems in phylogenetics.

1.3 Previous work

TREE CONTAINMENT was shown to be NP-hard [32], even for tree-sibling, time-consistent, regular networks [29]. On the positive side, polynomial-time algorithms were found for other restricted classes, including tree-child networks [17, 18, 22, 24, 29, 44]. The first non-trivial FPT algorithm for TREE CONTAINMENT on general networks had running time $O(2^{k/2}n^2)$, where the parameter k is the number of reticulations in the network [32]. Another algorithm was proposed by [23] with the same parameter, but it is only shown to be FPT for a restricted class of networks. Since the problem can be split into independent subproblems at non-leaf cut-edges [29], the parameterization can be improved to the largest number of reticulations in any biconnected component (block), also called the *level* of the network. Further improving the parameterization, the maximum number t^* of “unstable component-roots” per biconnected component was considered and an algorithm (working also in the non-binary case) was found with running time $O(3^{t^*} |N||T|)$ [44]. Herein, a parameterization “improves” over another if the first is provably smaller than (a function of) the second in any input network.

Several generalizations and variants of the TREE CONTAINMENT problem have been studied. The more general NETWORK CONTAINMENT problem asks to embed a *network* in another and has been shown to be solvable in polynomial time on a restricted network class [31]. When allowing multifurcations and non-binary reticulations, two variants of TREE CONTAINMENT have been considered: In the FIRM version, each non-binary node (“polytomy”) of the tree has to be embedded in a polytomy of the network whereas, in the SOFT version, polytomies may be “resolved” into binary subtrees in any way [2]. Finally, the unrooted version of TREE CONTAINMENT was also shown to be NP-hard but fixed-parameter tractable when the parameter is the reticulation number (the number of edges that need to be deleted from the network to obtain a tree) [28]. While this version of the problem is also known to be fixed-parameter tractable with respect to the treewidth of the network [30], the work does not explicitly describe an algorithm and the implied running time depends on Courcelle’s theorem [10] which makes practical implementation virtually impossible.

Since the notion of “display” closely resembles that of “topological minor” (with the added constraint that the embedding must respect leaf-labels), TREE CONTAINMENT can be understood as a special case of a variant of the well-known TOPOLOGICAL MINOR CONTAINMENT (TMC) problem for directed graphs. TMC is known to be NP-complete in general by reduction from HAMILTONIAN CYCLE and previous algorithmic results focus on the undirected variant, parameterized by the *size* h of the sought topological minor H (corresponding to the input tree for TREE CONTAINMENT). In particular, undirected TMC can be solved in $f(h)n^{O(1)}$ time [21, 15]. In the directed case, even the definition of “topological minor” has been contested [19] and we are aware of little to no algorithmic results. In TREE CONTAINMENT, part of the embedding of the host tree in the guest network is fixed by the leaf-labeling. If the node-mapping is fixed for *all* nodes of the host, then directed TMC generalizes the DISJOINT PATHS problem [16], which is NP-complete for 2 paths or in case the host network is acyclic. Indeed, one can show TREE CONTAINMENT to be NP-hard in a similar fashion [32].

1.4 Treewidth

From the overview presented in Section 1.3, we see that the parameters that are most heavily used are the reticulation number and the level. This is true not only for TREE CONTAINMENT but more generally in the phylogenetic networks literature. Although these parameters are natural, their downside is that they are not necessarily much smaller than the input size. This is why we study a different parameter here.

The *treewidth* of a graph measures its tree-likeness (see definition below), similarly to the reticulation number and level. In that sense, it is also a natural parameter to consider in phylogenetics, where networks are often expected to be reasonably tree-like. A major advantage of treewidth is that it is expected to be much smaller than the reticulation number and level. In particular, there exist classes of networks for which the treewidth is at most a constant factor times the square-root of the level (see [33] for an example). Moreover, a broad range of advanced techniques have been developed for designing FPT algorithms for graph problems when the parameter is the treewidth [4, 12, 6, 13]. For these reasons, the treewidth has recently been studied for phylogenetics problems [30, 34, 33, 38] and related width parameters have been proposed [3]. However, using treewidth as parameter for phylogenetic problems poses major challenges and, therefore, there are still few algorithms in phylogenetics that use treewidth as parameter (see Section 1.5).

It will be convenient to define a *tree decomposition* of a graph $G = (V, E)$ as a rooted tree, where each vertex of the tree is called a *bag* and is assigned a partition (P, S, F) of V , where S is a separator between P and F . We will refer to S as the *present* of the bag. The set P is equal to the union of the presents of all descendant bags (minus the elements of S) and we refer to it as the *past* of the bag. The set $F = V \setminus (S \cup P)$ is referred to as the *future* of the bag. For each edge of the graph, there is at least one bag for which both endpoints of the edge are in the present of the bag. Finally, for each $v \in V$, the bags that have v in the present form a non-empty connected subtree of the tree decomposition. The *width* of a tree decomposition is one less than the maximum size of any bag's present and the *treewidth* $tw(G)$ of a graph G is the minimum width of any tree decomposition of G . The treewidth of a phylogenetic network or other directed graph is the treewidth of the underlying undirected graph.

Our dynamic programming works with *nice* tree decompositions, in which the root is assigned $(V, \emptyset, \emptyset)$ and each bag assigned (P, S, F) has exactly one of four types: *Leaf* bags have $P = S = \emptyset$ (hence $F = V$) and have no child, *Introduce* bags have a single child assigned $(P, S \setminus \{z\}, F \cup \{z\})$ for some $z \in S$, *Forget* bags have a single child assigned $(P \setminus \{z\}, S \cup \{z\}, F)$ for some $z \in P$, and *Join* bags have two children assigned $(L, S, F \cup R)$ and $(R, S, F \cup L)$ respectively, where (L, R) is a partition of P . When the treewidth is bounded by a constant, [5] showed that a minimum-width tree decomposition can be found in linear time and [36] showed that a nice tree decomposition of the same width can be obtained in linear time. Regarding approximation, it is known that, for all graphs G , tree decompositions of width $O(tw(G))$ can be computed in time single-exponential in $tw(G)$ [11, 7, 37] and tree decompositions of width $O(tw(G)\sqrt{\log tw(G)})$ can be computed in polynomial time [14].

1.5 Challenges

One of the main challenges of using treewidth as parameter in phylogenetics is that the central goal in this field is to infer phylogenetic networks and, thus, the network is not known *a priori* so a tree decomposition cannot be constructed easily. A possible strategy to overcome this problem is to work with the *display graph* (see Figure 1). Consider a problem

taking as input a set of trees, such as HYBRIDIZATION NUMBER. Then, the *display graph* of the trees is obtained by taking all trees and identifying leaves with the same label. Now we have a graph in the input and hence we can compute a tree decomposition. Moreover, in some cases, there is a strong relation between the treewidth of the display graph and the treewidth of an optimal network [20, 33, 30].

A few instances of exploiting (tree decompositions of) the display graph of input networks for algorithm design have been published. Famously, Bryant and Lagergren [9] designed MSOL formulations solving the TREE CONSISTENCY problem on display graphs, which have been improved¹ by a concrete dynamic programming on a given tree decomposition of the display graph [1]. Kelk et al. [34] also developed MSOL formulations on display graphs for multiple incongruence measures on trees, based on so-called “agreement forests”. For the TREE CONTAINMENT problem, MSOL formulations acting on the display graph have been used to prove fixed-parameter tractability with respect to the treewidth [30]. Analogously to the work of Baste et al. [1] for TREE CONSISTENCY, we develop in this manuscript a concrete dynamic programming algorithm for TREE CONTAINMENT acting on display graphs.

TREE CONTAINMENT is conceptually similar to HYBRIDIZATION NUMBER in the sense that the main challenge is to decide which tree vertices correspond to which vertices of the other trees (for HYBRIDIZATION NUMBER) or network vertices (for TREE CONTAINMENT). However, HYBRIDIZATION NUMBER is even more challenging since the network may contain vertices that do not correspond to any input vertex [41]. Therefore, TREE CONTAINMENT is a natural first problem to develop techniques for, aiming at extending them to HYBRIDIZATION NUMBER and other problems in phylogenetics in the long run.

That being said, solving TREE CONTAINMENT parameterized by treewidth poses major challenges itself. Even though the general idea of dynamic programming on a tree decomposition is clear, its concrete use for TREE CONTAINMENT is severely complicated by the fact that the tree decomposition does not know the correspondence between tree vertices and network vertices. For example, when considering a certain bag of the tree decomposition, a tree vertex that is in the present of that bag may have to be embedded into a network vertex that is in the past or in the future. It may also be necessary to map vertices from the future of the tree to the past of the network and vice versa. Therefore, it will not be possible to “forget the past” and “not worry about the future”. In particular, this makes it much more challenging to bound the number of possible assignments for a given bag. We will do this by bounding the number of “time-travelling” vertices by a function of the treewidth. We will describe these challenges in more detail in Section 2.2.

1.6 Our contribution

In this paper, we present an FPT-algorithm for TREE CONTAINMENT parameterized by the treewidth of the input network. Our algorithm is one of the first (constructive) FPT-algorithms for a problem in phylogenetics parameterized by treewidth. We believe that this is an important development as the treewidth can be much smaller than other parameters such as reticulation number and level which are easier to work with. We see this algorithm as an important step towards the wide application of treewidth-based methods in phylogenetics.

¹ Commonly, MSOL formulations are used to classify problems as FPT but are considered impractical since the resulting running times are dominated by a tower of exponentials of size bounded in the treewidth.

2 Preliminaries

2.1 Reformulating the problem

A key concept throughout this paper will be *display graphs* [9], which are the graphs formed from the union of a phylogenetic tree and a phylogenetic network by identifying leaves with the same labels. Throughout this paper we will let N_{IN} and T_{IN} denote the respective input network and tree in our instance of TREE CONTAINMENT. The main object of study will be the “display graph” of N_{IN} and T_{IN} . For the purposes of our dynamic programming algorithm, we will often consider graphs that are not exactly this display graph, but may be thought of as roughly corresponding to subgraphs of it (though they are not exactly subgraphs; see [40, Appendix A.1]). In order to incorporate such graphs as well, we will define display graphs in a slightly more general way than that usually found in the literature. In particular, we allow for the two “sides” of a display graph to be disconnected, and for some leaves to belong to one side but not the other.

► **Definition 1** (display graph). *A display graph is a directed acyclic graph $D = (V, A)$, with specified subsets $V_T, V_N \subseteq V$ such that $V_T \cup V_N = V$, satisfying the following properties:*

- *The graph $T := D[V_T]$ is an out-forest;*
- *Every vertex has in- and out-degree at most 2 and total degree at most 3;*
- *Any vertex in $V_N \cap V_T$ has out-degree 0 and in-degree at most 1 in both T and $N := D[V_N]$. Herein, we call T the tree side and N the network side of D and we will use the term $D(N, T)$ to denote a display graph with network side N and tree side T .*

Given a phylogenetic network N_{IN} and phylogenetic tree T_{IN} with the same leaf-label set, we define $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ to be the display graph formed by taking the disjoint union of N_{IN} and T_{IN} and identifying pairs of leaves that have the same label. We note that, while the leaves of N_{IN} and T_{IN} were originally labelled, this labelling does not appear in $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$. Labels were used to construct $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$, but in the rest of the paper we will not need to consider them. Indeed, such labels are relevant to the TREE CONTAINMENT problem only insofar as they establish a relation between the leaves of T_{IN} and N_{IN} , and this relation is now captured by the structure of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$.

We now reformulate the TREE CONTAINMENT problem in terms of an *embedding function* on a display graph. Unlike the standard definition of an embedding function (see, e.g., [29]), which is defined for a phylogenetic network N and tree T , our definition of an embedding function applies directly to the display graph $D(N, T)$. Because of our more general definition of display graphs, our definition of an embedding function will also be more general than that found in the literature. The key idea of an embedding function remains the same, however: it shows how a subdivision of T may be viewed as a subgraph of N .

► **Definition 2** (embedding function). *Let D be a display graph with network side N and tree side T , and let $\mathcal{P}(N)$ denote the set of all directed paths in N . An embedding function on D is a function $\phi : V(T) \cup A(T) \rightarrow V(N) \cup \mathcal{P}(N)$ such that:*

- (a) *for each $u \in V(T)$, $\phi(u) \in V(N)$ and, for each arc $uv \in A(T)$, $\phi(uv)$ is a directed $\phi(u)$ - $\phi(v)$ -path in N ;*
- (b) *for any distinct $u, v \in V(T)$, $\phi(u) \neq \phi(v)$;*
- (c) *for any $u \in V(T) \cap V(N)$, $\phi(u) = u$;*
- (d) *the paths $\{\phi(uv) \mid uv \in A(T)\}$ are arc-disjoint;*
- (e) *for any distinct $p, q \in A(T)$, $\phi(p)$ and $\phi(q)$ share a vertex z only if p and q share a vertex w with $z = \phi(w)$;*

Note that the standard definition of an embedding of a phylogenetic tree T into a phylogenetic network N (see e.g. [29]) coincides with the definition of an embedding function on $D(N, T)$. Property (e) ensures that, while the embeddings of arcs uv, vw_1, vw_2 can all meet at $\phi(v)$, the embeddings of different tree arcs cannot otherwise meet. (In particular, the path $\phi(uv)$ cannot end at a reticulation that is also an internal vertex of $\phi(u'v')$, something that is otherwise allowed by properties (a)–(d).)

► **Lemma 3.** *A phylogenetic network N displays a phylogenetic tree T if and only if there is an embedding function on $D(N, T)$.*

In light of Lemma 3, we may henceforth view TREE CONTAINMENT as the following problem:

TREE CONTAINMENT (TC)

Input: phylogenetic network N_{IN} and phylogenetic tree T_{IN} with the same leaf-label set
Task: Find an embedding function on $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$.

2.2 Overview of our approach

We study TREE CONTAINMENT parameterized by the treewidth of the input network N_{IN} . A key tool will be the following theorem.

► **Theorem 4** ([30]). *Let N and T be an unrooted binary phylogenetic network and tree, respectively, with the same leaf-label set. If N displays T then $tw(D(N, T)) \leq 2tw(N) + 1$.*

By Theorem 4, we suppose that the display graph $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ has treewidth at most $2k + 1$, where k is the treewidth of the underlying undirected graph N of N_{IN} as, otherwise, N does not display the unrooted version T of T_{IN} , implying that N_{IN} does not display T_{IN} .

As is often the case for treewidth parameterizations, we will proceed via a dynamic programming on a tree decomposition, in this case a tree decomposition of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$. Recall that we view a bag (P, S, F) in the tree decomposition as partitioning the vertices of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ into past, present and future. A typical dynamic programming approach is to store, for each bag, some set of information about the present, while forgetting most information about the past, and not yet caring about what happens in the future. The resulting information is stored in a “signature”, and the algorithm works by calculating which signatures are possible on each bag, in a bottom-up manner. This approach is complicated by the fact that the sought-for embedding of T_{IN} into N_{IN} may not map the past/present/future of T_{IN} into the past/present/future (respectively) of N_{IN} . Vertices from the past of T_{IN} may be embedded in the future of N_{IN} , or vice versa. Thus, we have to store more information than we might at first think. In particular, it is not enough to store information about which present vertices of T_{IN} are embedded in which present vertices of N_{IN} (indeed, depending on the bag, it may be that none of them are). As such, our notion of a “signature” has to track how vertices from the past of T_{IN} are embedded in the present and future of N_{IN} , and which vertices from the past of N_{IN} contain vertices from the present or future of T_{IN} . Vertices of the past which are mapped to vertices of the past, on the other hand, can mostly be forgotten about.

2.3 An informal guide to (compact) signatures

Roughly speaking, a *signature* σ for a bag (P, S, F) in the tree decomposition of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ consists of the following items (see Figure 3 for an example):

■ **Figure 2 Left:** An example of a display graph $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ for which N_{IN} displays T_{IN} as witnessed by the embedding function ϕ that is indicated by bold edges. Highlighting with dashed border represents the sets P and F , for some bag (P, S, F) in a tree decomposition of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$. **Right:** A representation of the (compact) signature for (P, S, F) derived from this solution. Vertices labelled PAST or FUTURE are highlighted in gray without border.

1. a display graph $D(N, T)$, some of whose vertices correspond (isomorphically) to $S \subseteq V(D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}}))$, and the rest of which are labeled PAST or FUTURE (which we may think of as vertices corresponding to some vertex of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ in P or F , respectively). We use a function ι on $V(D(N, T))$ to capture both this correspondence and labelling, where ι maps each vertex to an element of S or a label from $\{\text{PAST}, \text{FUTURE}\}$.
2. an embedding ϕ of T in N such that, for no arc uv , all of $V(\phi(uv)) \cup \{u, v\}$ have the same label $y \in \{\text{PAST}, \text{FUTURE}\}$ under ι .

Signatures may be seen as “partial embedding functions” on parts of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ in a straightforward way. In particular, we call σ *valid* for (P, S, F) if, roughly speaking, ϕ corresponds (via ι) to something that can be extended to an embedding function on the subgraph of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ induced by the vertices $P \cup S$ introduced below (P, S, F) . In our dynamic programming algorithm, we build valid signatures for a bag x from valid signatures of the child bag(s) of x (in particular, validity for x is implied by validity for the child bag(s)).

Since iterating over all signatures for a bag (P, S, F) (in order to check their validity) exceeds FPT time, we will instead consider “compact” signatures, whose number and size are bounded in the width $|S|$ of the bag (P, S, F) . If $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ admits an embedding function ϕ^* , then a compact signature corresponding to this embedding function exists. In the following, we informally describe the compaction process for this hypothetical solution ϕ^* , thus giving a rough idea of the definition of a “compact” signature. At all times, the (tentative) signature will contain a display graph $D(N, T)$ (initially $D(N, T) = D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$), and an embedding function of T into N (initially ϕ^*). For a more complete description of our approach, see Appendix A in [40], for the proofs and remaining details, see Appendix B, and for an illustration, see Figure 2.

Step 1 After initialization with ϕ^* , we assign a label FUTURE to all vertices of F , and a label PAST to all vertices in P (Observe that no vertex labeled PAST will be adjacent to a vertex labeled FUTURE, since S separates P from F in $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$). Then, we “forget” which vertices of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ the vertices labelled PAST or FUTURE correspond to. Our preliminary signature now contains (1) a display graph $D(N, T)$ whose vertices are either labelled FUTURE or PAST or correspond (isomorphically) to vertices in $S \subseteq V(D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}}))$ (we refer the reader to [40, Appendix A.1] for a more formal description), as well as (2) an embedding function for $D(N, T)$ into N .

■ **Figure 3** Example of a signature of a bag (P, S, F) . The S -part of $D(N_{\text{IN}}, T_{\text{IN}})$ is solid while the non- S part is faded. The embedding ϕ (right, indicated with gray edge-highlight) maps T into N . The dotted arcs labelled ι show the isomorphism between part of $D(N, T)$ and $S \subseteq V(D(N_{\text{IN}}, T_{\text{IN}}))$. Note that the part of $D(N, T)$ that is not mapped to S is not necessarily isomorphic to anything in $D(N_{\text{IN}}, T_{\text{IN}})$.

Step 2 We now simplify the structure of the preliminary signature. The main idea is that, if a is an arc of T with both endpoints labelled PAST and all vertices in the path $\phi(a)$ are also labelled PAST, then we can safely forget a and all the arcs in $\phi(a)$. Intuitively, the information that a will be embedded in $\phi(a)$ does not have any effect on the possible solutions one could construct on the part of $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ that is “above” the bag (P, S, F) . Similarly, we can forget any arc a of T whose endpoints, as well as every vertex in $\phi(a)$, are assigned the label FUTURE. Intuitively, this is because this information should have no bearing on whether a solution exists with this signature for $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ restricted to $P \cup S$. In a similar way, we forget any vertex $u \in V(T)$ and its embedding $\phi(u)$ if they are assigned the same label, provided that all their incident arcs can also be forgotten. We will call the vertices and arcs fulfilling these conditions “redundant” and we remove them from our tentative signature. We can also safely delete the vertices and arcs of N that are labelled $y \in \{\text{PAST}, \text{FUTURE}\}$ but are not part of the image of ϕ . As a result, we now have that for any remaining vertex $u \in T$, either one of $\{u, \phi(u)\}$ is labelled PAST and the other labelled FUTURE, or some vertex element of S must appear either one of $\{u, \phi(u)\}$, a neighbor of u , or a vertex in the path $\phi(a)$ for an incident arc a of u . Thus, we have “forgotten” all the aspects of the embedding except those that involve vertices from the present in some way, or those where the embedding “time-travels” between the past and future (see [40, Appendix A.3] for a more formal description of this process).

Step 3 Finally, we may end up with long paths of vertices with in-degree and out-degree 1 that are labelled PAST or FUTURE in N (for example, if u and v are labelled PAST, then $\phi(uv)$ may be a long path in N with all vertices labelled FUTURE). Such long paths do not contain any useful information to us, we therefore compress these by suppressing vertices with in-degree and out-degree 1 (This gives the *compact signature*, see [40, Appendix A.8]).

2.4 Bounding the number of signatures

We now outline the main arguments for why the number of possible (compact) signatures for a given bag (P, S, F) can be bounded in $|S|$. Such a bound on the number of signatures ensures that the running time of the algorithm is FPT, because the number of calculations required for each bag is bounded by a function of the treewidth.

The main challenge is to bound the size of the display graph $D(N, T)$ in a given signature for (P, S, F) . Once such a bound is achieved, this immediately implies upper bounds (albeit quite large) for the number of possible display graphs and the number of possible embeddings, and hence on the number of possible signatures. We will focus here on bounding the size of the tree part T . Once a bound is found for $|T|$ it is relatively straightforward to use that to give a bound on $|N|$ (because the arcs of N that are not used by the embedding of T into N are automatically deleted, unless they are themselves incident to a vertex in S , and because isolated vertices are deleted and long paths suppressed).

It can be seen that a vertex $u \in V(T)$ is redundant (and so would be deleted from the signature) unless one of the following properties holds:

- (1) $u \in S$,
- (2) $\phi(u) \in S$,
- (3) u is incident to an element of S
- (4) for some arc a incident to u , the path $\phi(a)$ contains a vertex from S or
- (5) u and $\phi(u)$ have different labels from $\{\text{PAST}, \text{FUTURE}\}$.

Essentially if none of (1)–(4) holds, then all the vertices mentioned in those properties have the same label as either u or $\phi(u)$, using the fact that S separates the vertices labelled PAST from the vertices labelled FUTURE. If u and $\phi(u)$ have the same label, then all these vertices have the same label, which is enough to show that u is redundant. It remains to bound the number of vertices satisfying one of these properties. For the first four properties, it is straightforward to find a bound in terms of $|S|$. The vertices satisfying the final property are “time-travelling” (in the sense that either u is labelled PAST and $\phi(u)$ FUTURE, or u is labelled FUTURE and $\phi(u)$ PAST). Because of the bounds on the other types of vertices, it is sufficient to provide a bound on the number of *lowest* time-travelling vertices in T .

To see the intuition why this bound should hold: consider some full solution on the original input, i.e. an embedding function on $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$, and suppose $u \in V(T_{\text{IN}})$ is a lowest tree vertex for which $u \in P, \phi(u) \in F$ (thus in the corresponding signature, u has label PAST and $\phi(u)$ has label FUTURE). Let $x \in V(N_{\text{IN}}) \cap V(T_{\text{IN}})$ be some leaf descendant of u . Then there is path in T_{IN} from u to x , and a path in N_{IN} from $\phi(u)$ to $\phi(x) = x$. Thus $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ has an (undirected) path from u to $\phi(u)$. As this is a path between a vertex in P and a vertex in F , some vertex on this path must be in S (since S separates P from F). Such a path must exist for every lowest time-travelling vertex u , and these paths are distinct. The existence of these paths can then be used to bound the number of lowest time-travelling vertices.

3 Algorithm and running time

The final algorithm first computes (or constant-factor approximates) the treewidth of the display graph $D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})$ and concludes non-containment if this computation already implies $tw(D_{\text{IN}}(N_{\text{IN}}, T_{\text{IN}})) > 2tw(N_{\text{IN}}) + 1$. Otherwise, we proceed with a bottom-up dynamic programming on a nice low-width tree-decomposition, which computes for each bag $x = (P, S, F)$ a set CV_x of “compact-valid signatures” for x (see Section 2.3 for a rough definition). We use “compact-restrictions” to convert a compact signature of one bag into a compact

signature for a different bag. Basically, such a restriction works by mapping certain vertices to a label PAST or FUTURE, removing redundant parts of the display graph and collapsing long paths (see Section 2.3; also see [40, Appendix A.3] for the formal definition).

Leaf bag. If x is a leaf bag, then $P = S = \emptyset$ and all compact signatures $\sigma = (D(N, T), \phi, \iota)$ for x with $\iota^{-1}(\text{PAST}) = \emptyset$ are valid for x (and, thus, included in CV_x).

Introduce- z bag. If x is an introduce bag with child $y = (P, S \setminus \{z\}, F \cup \{z\})$ in \mathcal{T} , then all compact signatures σ for x whose compact- $\{z \rightarrow \text{FUTURE}\}$ -restriction is valid for y (that is, contained in CV_y) are valid for x .

Forget- z bag. If x is a forget bag with child $y = (P \setminus \{z\}, S \cup \{z\}, F)$ in \mathcal{T} , then all compact- $\{z \rightarrow \text{PAST}\}$ -restrictions of compact-valid signatures σ for y are valid for x .

Join bag. For join bags, we use “reconciliations” which are, basically, 3-way analogues of signatures, using labels {LEFT, RIGHT, FUTURE} instead of {PAST, FUTURE} (see [40, Appendix A.7]). In particular, if x is a join bag with children $y_L = (L, S, R \cup F)$ and $y_R = (R, S, L \cup F)$, then we compute all compact reconciliations μ for x and check whether

- the compact- $\{\text{LEFT} \rightarrow \text{PAST}, \text{RIGHT} \rightarrow \text{FUTURE}\}$ -restriction of μ is valid for y_L and
- the compact- $\{\text{RIGHT} \rightarrow \text{PAST}, \text{LEFT} \rightarrow \text{FUTURE}\}$ -restriction of μ is valid for y_R .

Then, the compact- $\{\{\text{LEFT}, \text{RIGHT}\} \rightarrow \text{PAST}\}$ -restriction of each μ verifying these conditions is valid for x .

Correctness

The correctness of the computation of the sets CV_x follows from [40, Lemmas 15–17 and 19]. After having computed CV_x for the root bag r of the decomposition, we conclude that N_{IN} displays T_{IN} if and only if there is a compact-valid signature $(D(N, T), \phi, \iota)$ for the root bag with $\iota^{-1}(\text{FUTURE}) = \emptyset$. The correctness of this follows from [40, Lemma 10].

Running Time

To show that the running time is bounded in a function in the treewidth of N , the main challenge is to bound the number of compact signatures for a bag (P, S, F) by a function of $|S|$ (which, by Theorem 4, we may assume is at most $2tw(N) + 1$). In order to do this, we first bound the size of the display graph $D(N, T)$ in a signature by a function of $|S|$, straightforwardly implying bounds on the number of possible display graphs, embedding functions and isolabellings. Full details are given in [40]; to give a flavor of the proofs, we present the argument bounding the number of arcs in T .

► **Lemma 5.** *Any compact signature $(D(N, T), \phi, \iota)$ for a bag (P, S, F) has $|A(T)| \leq 6|S|$.*

Proof. Let A_S contain all arcs uv of $D(N, T)$ with $\iota(u) \in S$ or $\iota(v) \in S$. As there is only one vertex u with $\iota(u) = s$ for each $s \in S$ and every vertex in $D(N, T)$ has total degree at most 3, we have that $|A_S| \leq 3|S|$. As $\phi(uv)$ and $\phi(u'v')$ are arc-disjoint for any distinct tree arcs uv and $u'v'$, there are at most $|A_S \cap A(N)|$ arcs uv of T for which $\phi(uv)$ contains an arc in A_S . Further, at most $|A_S \cap A(T)|$ arcs in T are incident with a vertex in $\iota^{-1}(S)$. Thus, there are at most $|A_S|$ arcs uv in T for which $\{u, v\} \cup V(\phi(uv))$ contains a vertex of $\iota^{-1}(S)$.

Every remaining arc uv in T has $\iota(\{u, v\} \cup V(\phi(uv))) \subseteq \{\text{PAST}, \text{FUTURE}\}$. Further, we may assume the signature to be “well-behaved” (see [40, Sections A.4 and B.4]), which implies among other things that vertices mapped to PAST and FUTURE cannot be adjacent in $D(N, T)$, and that no arcs or vertices are redundant. Then we have $\iota(u) = \iota(v)$ and $\iota(u') = \iota(v')$ for every arc $u'v'$ in the path $\phi(uv)$. Then, for all but at most $|A_S| \leq 3|S|$ arcs uv of T , we have $\iota(u) = \iota(v) \in \{\text{PAST}, \text{FUTURE}\}$ as well as one of $\iota(V(\phi(uv))) = \{\text{PAST}\}$

and $\iota(V(\phi(uv))) = \{\text{FUTURE}\}$. If $\iota(u) = \iota(v) = \text{PAST}$ and $\iota(V(\phi(uv))) = \{\text{PAST}\}$, then uv is redundant w.r.t. $\{\text{PAST}\}$, a contradiction, and, similarly in case $\iota(u) = \iota(v) = \text{FUTURE}$ and $\iota(\phi(uv)) = \{\text{FUTURE}\}$. So, for all but at most $3|S|$ tree arcs uv , either $\iota(u) = \iota(v) = \text{PAST}$ and $\iota(\phi(uv)) = \{\text{FUTURE}\}$ or $\iota(u) = \iota(v) = \text{FUTURE}$ and $\iota(\phi(uv)) = \{\text{PAST}\}$. In particular, we have that $\iota(\phi(v)) \neq \iota(v)$, and for such vertices we may assume v has out-degree 2 (see Definition in [40, Appendix A.2]). Hence, any lowest arc uv in T is one of the at most $|A_S|$ many arcs uv for which $\{u, v\} \cup V(\phi(uv))$ contain a vertex of $\iota^{-1}(S)$. Thus, in total, T has at most $2|A_S| \leq 6|S|$ arcs. \blacktriangleleft

► **Theorem 6.** *TREE CONTAINMENT can be solved in $2^{O(tw(N_{IN})^2)} \cdot |A(N_{IN})|$ time.*

4 Future work

Before implementing our dynamic programming algorithm, one should first try to reduce the constant in the bound on the number of possible signatures as much as possible. Such reductions may be possible for instance by imposing further structural constraints on the signatures that need to be considered. If this constant can be reduced, possibly including heuristic improvements, it would be interesting to implement the algorithm and test it on practical data.

From a theoretical point of view, there are many opportunities for future work. First, there are multiple variants and generalizations of TREE CONTAINMENT that deserve attention: non-binary inputs, unrooted inputs and inputs consisting of two networks. Indeed, in order to decide if a network is contained in a second network, our approach would have to be extensively modified, since our size-bound on the signatures heavily relies on T_{IN} being a tree.

Second, a major open problem is whether the HYBRIDIZATION NUMBER problem is FPT with respect to the treewidth of the output network. Again there are different variants: rooted and unrooted, binary and non-binary, a fixed or unbounded number of input trees. For some applications, the definition of an embedding has to be relaxed (allowing, for example, multiple tree arcs embedded into the same network arc) [26, 25]. Other interesting candidate problems for treewidth-based algorithms include phylogenetic network drawing [35], orienting phylogenetic networks [27] and phylogenetic tree inference with duplications [39].

Finally, we believe that the approach taken in this paper (applying dynamic programming techniques on a tree decomposition of single graph representing all the input data, with careful attention given to the interaction between past and future) could potentially have applications outside of phylogenetics, in any context where the input to a problem consists of two or more distinct partially-labelled graphs that need to be reconciled.

Abstract

Recently, Chalermsook et al. [SODA'21] introduces a notion of *vertex sparsifiers for c -edge connectivity*, which has found applications in parameterized algorithms for network design and also led to exciting dynamic algorithms for c -edge st-connectivity [Jin and Sun FOCS'22].

We study a natural extension called *vertex sparsifiers for c -hyperedge connectivity* and construct a sparsifier whose size matches the state-of-the-art for normal graphs. More specifically, we show that, given a hypergraph $G = (V, E)$ with n vertices and m hyperedges with k terminal vertices and a parameter c , there exists a hypergraph H containing only $O(kc^3)$ hyperedges that preserves all minimum cuts (up to value c) between all subset of terminals. This matches the best bound of $O(kc^3)$ edges for normal graphs by [Liu'20]. Moreover, H can be constructed in almost-linear $O(p^{1+o(1)} + n(rc \log n)^{O(rc)} \log m)$ time where $r = \max_{e \in E} |e|$ is the rank of G and $p = \sum_{e \in E} |e|$ is the total size of G , or in $\text{poly}(m, n)$ time if we slightly relax the size to $O(kc^3 \log^{1.5}(kc))$ hyperedges.

1 Introduction

Graph sparsification has played a central role in graph algorithm research in the last two decades. Prominent examples include spanners [1], cut sparsifiers [3], and spectral sparsifiers [22]. Recently, there has been significant effort in generalizing the graph sparsification results to hypergraphs. For cut sparsifiers, Kogan and Krauthgamer [13] generalized the Benczúr and Karger's cut sparsifiers [3] by showing that, given any hypergraph $G = (V, E)$ with n vertices, there is a $(1+\epsilon)$ -approximate cut sparsifier H containing $\tilde{O}(nr/\epsilon^2)$ hyperedges where $r = \max_{e \in E} |e|$ denotes the *rank* of the hypergraph. After some follow-up work [5, 2], Chen, Khanna, and Nagda [6] finally improved the sparsifier size to $\tilde{O}(n/\epsilon^2)$ hyperedges, matching the optimal bound for normal graphs. Another beautiful line of work generalizes Spielman and Teng's spectral sparsifiers [22] to hypergraphs [2, 21, 10] and very recently results in spectral sparsifiers with $\tilde{O}(n/\text{poly}(\epsilon))$ hyperedges [11]. We also mention that the classical sparse connectivity certificates by Nagamochi and Ibaraki [19] were also generalized to hypergraphs by Chekuri and Xu [5].

This paper studies a graph sparsification problem recently introduced by Chalermsook et al. [4] called *vertex sparsifiers for c -edge connectivity*. It is closely related to the vertex sparsifiers for edge cuts [15, 12] and vertex cuts [14]. In this problem, we are given an

unweighted undirected graph $G = (V, E)$ and a set of terminals $\mathcal{T} \subseteq V$. For any disjoint subsets $A, B \subseteq \mathcal{T}$, let $\text{mincut}_G(A, B)$ denote the size of a minimum (edge-)cut that disconnects A and B . Now, a graph $H = (V_H, E_H)$ with $\mathcal{T} \subseteq V_H$ is a (\mathcal{T}, c) -sparsifier of G if for any disjoint subsets $A, B \subseteq \mathcal{T}$, $\min\{c, \text{mincut}_G(A, B)\} = \min\{c, \text{mincut}_H(A, B)\}$. Basically, H preserves all minimum cut structures between the terminals \mathcal{T} up to the value c . This notion of graph sparsifiers has found interesting applications in offline dynamic algorithms and network design problems [4]. Moreover, the very recent breakthrough on dynamic c -edge st-connectivity by Jin and Sun [9] is also crucially based on dynamic algorithms for maintaining (\mathcal{T}, c) -sparsifiers.

In the original paper by [4], they showed that, for any graph $G = (V, E)$ and terminal set \mathcal{T} of size k , there exists a (\mathcal{T}, c) -sparsifier containing $O(kc^4)$ edges (which can be constructed in $O(m(c \log n)^{O(c)})$ time) and also showed fast algorithms for constructing (\mathcal{T}, c) -sparsifiers of size $k \cdot O(c)^{2c}$ in $mc^{O(c)} \log^{O(1)} n$ time. Then, Liu [16] improved the size bound to $O(kc^3)$ together with polynomial-time algorithms (no exponential dependency on c) for constructing (\mathcal{T}, c) -sparsifiers with $O(kc^3 \log^{1.5} n)$ edges.

A natural question is then whether these results can be extended to hypergraphs. The notion of (\mathcal{T}, c) -sparsifiers itself can be naturally extended to hypergraphs by allowing G and H to be hypergraphs and letting $\text{mincut}_G(A, B)$ denote the value of the minimum hyperedge-cut instead. However, it is conceivable that there might not exist a (\mathcal{T}, c) -sparsifier with $\text{poly}(k, c)$. This bound might require bad dependency on the rank r , for example.

In this paper, we show that the state-of-the-art for normal graphs indeed extend to hypergraphs and we can even slightly improve the bounds:

► **Theorem 1.** *Let $G = (V, E)$ be a hypergraph with n vertices, m hyperedges, rank r and total size p . Let $\mathcal{T} \subseteq V$ be the set of k terminals. There are algorithms for computing the following:*

1. *a (\mathcal{T}, c) -sparsifier H of G with $O(kc^3)$ hyperedges in $O(p^{1+o(1)} + n(rc \log n)^{O(rc)} \log m)$ time, which is almost-linear in the input size when both r and $c = O(1)$, and*
2. *a (\mathcal{T}, c) -sparsifier H of G with $O(kc^3 \log^{1.5}(kc))$ hyperedges in $\text{poly}(m, n)$ time.*

The first result matches the best known bound of $O(kc^3)$ edges for normal graphs [16]. When $r = O(1)$, the first time bound slightly improves the $O(m(c \log n)^{O(c)})$ bound of [4] for normal graphs. The second result removes the exponential dependency on r and c after relaxing the size by a $\log^{1.5}(kc)$ factor. The number of hyperedges in our sparsifier is completely independent from n , while the polynomial time algorithm by Liu [16] gives the size of $O(kc^3 \log^{1.5} n)$. So this implies the first polynomial time construction of sparsifiers of size near-linear in k and independent of n , even for normal graphs.

Open Problems. Can we construct vertex sparsifiers for c -hyperedge connectivity of $k \cdot \text{poly}(c)$ size in near-linear time even when the rank is unbounded? This is a prerequisite to near-linear time algorithms for computing vertex sparsifiers for c -vertex connectivity of $k \cdot \text{poly}(c)$ size. Such a result might lead to dynamic c -vertex st-connectivity algorithm similar to the previous development where a near-linear time construction of vertex sparsifiers for c -edge connectivity leads to a dynamic algorithm for c -edge st-connectivity [9]. As dynamic c -vertex st-connectivity is one of the major open problems in dynamic graph algorithms (known solutions only works for very small $c \leq 3$ [7, 8, 20]), we view this work as a stepping stone towards this goal.

1.1 Technical Challenges

There are two main obstacles that prevent us extending the results of [16, 4] directly from normal graphs to hypergraphs. First, if we follow the divide and conquer framework of Chalermsook et al. [4] in a straightforward way, then we would end up with a much larger (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|(rc)^3)$ hyperedges. This is because, in [4], all vertices incident to the boundary edges are declared as new terminal vertices in the recursion. However in our case, each hyperedge may contain r vertices and this yields the dependency of r . To handle this issue, we instead introduce only two *anchor vertices* for each boundary hyperedge. Our divide and conquer framework requires slightly more careful analysis, but this naturally gives a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges.

The second obstacle is the near-linear time algorithm, Part (1) of Theorem 1. Chalermsook et al. [4] introduced *auxiliary graphs* and apply the ϕ -SPARSIFY procedure on it to identify all *essential* hyperedges, which roughly are hyperedges that will be kept in the sparsifier. However, there is a subtle small gap in [4]: their ϕ -SPARSIFY procedure could erroneously identify non-essential hyperedges as essential hyperedges. This is explained in more detail in the full version of the paper. This bug results in a much larger (\mathcal{T}, c) -sparsifier. In this paper we fix the bug by (1) introducing a notion of *useful* partitions of the terminal set and (2) providing an efficient algorithm that discards all non-useful partitions from the auxiliary graph. Then, we show that, after our modification, this approach indeed gives a small (\mathcal{T}, c) -sparsifier as desired.

1.2 Organization

In Section 2 we review some basic definitions of hypergraphs. In Section 3 we define contraction based (\mathcal{T}, c) -sparsifiers and introduce the divide and conquer framework. In Section 4 we show the existence of a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges. In Section 5 we give a near-linear-time algorithm that computes a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges, proving Part (1) of Theorem 1. For Part (2) of Theorem 1 we refer readers to the full version of the paper.

2 Preliminary

Let $G = (V, E)$ be a hypergraph. V is the set of vertices and E is a multiset of hyperedges with each hyperedge e being a subset of V . The *rank* $r := \max_{e \in E} |e|$ of a hypergraph is the size of the largest hyperedge, and the *total size* $p := \sum_{e \in E} |e|$ is the sum of all edge sizes.

For any two disjoint sets of vertices $A, B \subseteq V$, let $E_G(A, B)$ denote the set of hyperedges with at least one endpoint in A and at least one endpoint in B . For any set of vertices $X \subseteq V$, we denote the *boundary* of X of the graph G by $\partial_G X := E_G(X, V \setminus X)$. If the context is clear then we will omit the graph G and write ∂X instead.

Restrictions and Induced Sub-Hypergraphs. Let $\mathcal{T} \subseteq V \cup E$ be a mixed multiset of vertices and hyperedges, for any set of vertices $X \subseteq V$, we define the *restriction* of the multiset \mathcal{T} on X to be $\mathcal{T}|_X = (\mathcal{T} \cap X) \cup \{e \cap X \mid e \in (\mathcal{T} \cap E) \text{ and } e \cap X \neq \emptyset\}$. The *induced sub-hypergraph* $G[X]$ is then defined over the vertex set X with the restriction of all hyperedges $E|_X$, that is, $G[X] := (X, E|_X)$.

Incident Edges and Vertices. For any set of vertices $X \subseteq V$, define $E(X)$ to be the set of all hyperedges that incident to at least one vertex in X . For any set of hyperedges $Y \subseteq E$, define $V(Y) = \bigcup_{y \in Y} y$ to be the set of vertices incident to hyperedges in Y . Similarly, for any mixed set of vertices and hyperedges $\mathcal{T} \subseteq V \cup E$ we define $V(\mathcal{T}) = (\mathcal{T} \cap V) \cup V(\mathcal{T} \cap E)$ to be the set of all vertices that are in the set or incident to any hyperedge in the set.

3 Structural Properties on Hypergraphs

In this section, we explore more structural properties on hypergraphs. In particular, we introduce *anchored separated hyperedges*, and describe useful properties in a divide and conquer framework that leads to a construction of (\mathcal{T}, c) -sparsifiers.

3.1 Cuts in Hypergraphs

Let u and v be two elements in V . We say that u and v are *connected* in a hypergraph G , if there is a path connecting u and v . Let $A, B \subseteq V$ be two disjoint sets of vertices. A and B are *disconnected* if for any $a \in A$ and $b \in B$, a and b are not connected.

► **Definition 2** (Cuts and Minimum Cuts). *A cut is a bipartition $(X, V \setminus X)$ of vertices. The value of the cut is $|\partial X| = |E_G(X, V \setminus X)|$. For any disjoint subsets $A, B \subseteq V$, if $A \subseteq X$ and $B \subseteq (V \setminus X)$ then we say that $(X, V \setminus X)$ is an (A, B) -cut. A minimum (A, B) -cut or (A, B) -mincut is any (A, B) -cut with minimum value. Its value is denoted as $\text{mincut}_G(A, B)$. Given a parameter c , a c -thresholded (A, B) -mincut cut value is defined as*

$$\text{mincut}_G^c(A, B) := \min(\text{mincut}_G(A, B), c).$$

3.2 (\mathcal{T}, c) -Equivalency and (\mathcal{T}, c) -Sparsifiers

Our vertex sparsifier algorithms are based on identifying a set of hyperedges and contract them. Given a hypergraph $G = (V, E)$ and a hyperedge $e \in E$, the *contracted hypergraph* G/e is defined by identifying all incident vertices $V(e)$ as one vertex, and then remove e itself from the graph. For any set of terminals $T \subseteq V$, the effect of contracting an hyperedge e is denoted as T/e . Similarly, for any set $\hat{E} \subseteq E$, we denote G/\hat{E} the hypergraph obtained from G by contracting all hyperedges in \hat{E} (notice that all hyperedges in \hat{E} are removed after the contraction.)

► **Definition 3** ((\mathcal{T}, c) -Sparsifiers). *Let $G = (V_G, E_G)$ and $H = (V_H, E_H)$ be two hypergraphs. Let $\mathcal{T} \subseteq V_G$ be the set of terminals. We say H is a contraction based (\mathcal{T}, c) -sparsifier of G , if there exists a surjective (onto) projection $\pi : V_G \rightarrow V_H$, such that for any $e \in E_H$ there is an edge $f \in E_G$ such that $\pi(f) = \bigcup_{v \in f} \{\pi(v)\} = e$, and for any two subsets $T_1, T_2 \subseteq \mathcal{T}$,*

$$\text{mincut}_G^c(T_1, T_2) = \text{mincut}_H^c(\pi(T_1), \pi(T_2)).$$

Furthermore, if the terminals are not affected by the projection, i.e., $\pi(\mathcal{T}) = \mathcal{T}$, then we say that G and H are (\mathcal{T}, c) -equivalent.

Remark. A more general (\mathcal{T}, c) -sparsifier would allow an arbitrary mapping π on both vertices and edges. However, we note that all (\mathcal{T}, c) -sparsifiers constructed in this paper are always contraction based. Therefore, for the ease of the presentation we will omit the term “contraction based” when we mention (\mathcal{T}, c) -sparsifiers.

For the ease of the reading, we define the following set operations that allow us to add/remove hyperedges of G into a sparsifier H .

► **Definition 4.** Let $G = (V, E)$ be a hypergraph. For any multiset X of hyperedges over the vertices V , and any contraction based (\mathcal{T}, c) -sparsifier H with the projection π , define

- (Adding contracted hyperedges) $H \cup X := H \cup \pi(X)$, and
- (Removing contracted hyperedges) $H - X := H - \pi(X)$.

3.3 (\mathcal{T}, c) -Sparsifiers from a Divide and Conquer Framework

Another important concept to our contraction based (\mathcal{T}, c) -sparsifier construction is that we apply a divide and conquer framework to G . Let $G = (V, E)$ be a hypergraph and let (V_1, V_2) be a bipartition of vertices. We note that our divide and conquer framework is slightly different than just recurse on the induced sub-hypergraphs $G[V_1]$ and $G[V_2]$. In particular, for each *separated hyperedge* e we add two new *anchor vertices* to e , ended up slightly increasing the size of the vertex set in the next-level recursion.

Separated Hyperedges and Anchor Vertices. Let $e \in E(V_1, V_2)$ be a hyperedge across the bipartition. The *separated hyperedges* of e with respect to this bipartition (V_1, V_2) is the set composed of hyperedges of e restricted on both V_1 and V_2 . The *anchored separated hyperedges* are separated hyperedges with additional *anchor vertices*: let $e_1 = e|_{V_1}$ and $e_2 = e|_{V_2}$ be the separated hyperedges of e , then we introduce four new anchored vertices $v_{e,1}, v_{e,2}, v_{e,3}$, and $v_{e,4}$ and define $\hat{e}_1 := e_1 \cup \{v_{e,1}, v_{e,2}\}$ and $\hat{e}_2 := e_2 \cup \{v_{e,3}, v_{e,4}\}$. Let $S = E(V_1, V_2)$ be the set of crossing hyperedges, in this paper the set of anchored separated hyperedges respect to bipartition (V_1, V_2) are denoted by $Sep(S, V_1, V_2) := \{\hat{e}_1, \hat{e}_2 \mid e \in S\}$.

Let $A_1 = \{v_{e,1}, v_{e,2} \mid e \in E(V_1, V_2)\}$ and let $A_2 = \{v_{e,3}, v_{e,4} \mid e \in E(V_1, V_2)\}$ be the set of newly introduced anchor vertices. These anchor vertices will be added to the terminal set in order to correctly preserve the mincut values. That is, the terminal sets defined for the subproblems are $\mathcal{T}_1 := \mathcal{T}|_{V_1} \cup A_1$ and $\mathcal{T}_2 := \mathcal{T}|_{V_2} \cup A_2$. Now, we define the anchored induced sub-hypergraphs, which are useful when applying the divide and conquer framework.

► **Definition 5 (Anchored Induced Sub-Hypergraphs).** Let $G = (V, E)$ be a hypergraph and $V_1 \subseteq V$ be a subset of vertices. Define $V_2 = V \setminus V_1$, $G^{\text{sep}} = G \cup Sep(E(V_1, V_2), V_1, V_2) - E(V_1, V_2)$, and the set of anchored vertices to be $A_1 \cup A_2$. Then, the anchored induced sub-hypergraph for V_1 is defined as $\hat{G}[V_1] := G^{\text{sep}}|_{V_1 \cup A_1}$.

The Divide and Conquer Framework. The most generic divide and conquer method works as the follows. First, a bipartition (V_1, V_2) are determined. Then, the algorithm performs recursion on the anchored induced sub-hypergraphs $\hat{G}[V_1]$ and $\hat{G}[V_2]$ with terminal sets \mathcal{T}_1 and \mathcal{T}_2 respectively. After obtaining the (\mathcal{T}_1, c) -sparsifier and (\mathcal{T}_2, c) -sparsifier from the subproblems, the algorithm combines them by replacing the anchored separated hyperedges with the original hyperedges.

■ **Algorithm 1** A Divide and Conquer Framework.

Input: Hypergraph G , terminal set \mathcal{T} , bipartition (V_1, V_2) of vertices, parameter c .

Output: A (\mathcal{T}, c) -sparsifier H for G .

1 **(Divide)** Construct subproblems $(\hat{G}[V_1], \mathcal{T}_1)$ and $(\hat{G}[V_2], \mathcal{T}_2)$.

2 **(Conquer)** For $i \in \{1, 2\}$, obtain H_i , a (\mathcal{T}_i, c) -sparsifier of $\hat{G}[V_i]$.

3 **(Combine)** Return $H := H_1 \cup H_2 \cup E(V_1, V_2) - Sep(E(V_1, V_2), V_1, V_2)$.

We summarize the divide and conquer framework in Algorithm 1. The following lemma states the correctness of the framework.

► **Lemma 6.** H returned from Algorithm 1 is a (\mathcal{T}, c) -sparsifier.

Proof. Let $\pi_1 : V_1 \cup A_1 \rightarrow V_{H_1}$ and $\pi_2 : V_2 \cup A_2 \rightarrow V_{H_2}$ be the projection maps on H_1 and H_2 respectively. Since $V_1 \cup A_1$ and $V_2 \cup A_2$ are disjoint, it is natural to define $\pi : V \rightarrow V_H$ by simply combining both maps where $\pi(v) = \pi_1(v)$ if $v \in V_1$, and $\pi(v) = \pi_2(v)$ if $v \in V_2$.

Now, it suffices to show that for any two disjoint subsets $A, B \subseteq \mathcal{T}$, we have $\text{mincut}_G^c(A, B) = \text{mincut}_H^c(\pi(A), \pi(B))$.

Part 1. We first show that $\text{mincut}_G^c(A, B) \geq \text{mincut}_H^c(\pi(A), \pi(B))$. Let $(X, V \setminus X)$ be a minimum (A, B) -cut on G with size $|\partial X| \leq c$. Intuitively, we will construct the cuts in the subproblems $\hat{G}[V_1]$ and $\hat{G}[V_2]$ using $(X, V \setminus X)$. Then we will argue that the preserved mincuts in $\hat{G}[V_1]$ and $\hat{G}[V_2]$ can be merged back, proving that there is a $(\pi(A), \pi(B))$ -mincut in H with size no larger than $|\partial X|$.

Let $S = E_G(V_1, V_2)$ be the set of hyperedges across the bipartition in the divide and conquer framework, and let $\hat{V} = V \cup A_1 \cup A_2$ be the vertex set in G^{sep} . We define the set of vertices X^{sep} that contains X and all newly created anchor vertices that belongs to the X side: for any $e \in S$, we add $\{v_{e,1}, v_{e,2}, v_{e,3}, v_{e,4}\}$ to X^{sep} if $e \subseteq X$ (the hyperedge is fully in the X side). We add $\{v_{e,1}, v_{e,3}\}$ to X^{sep} if $e \in S$. We add nothing if $e \subseteq V \setminus X$.

Now, we have $\partial X^{\text{sep}} = (\partial X) \cup \text{Sep}((\partial X) \cap S, V_1, V_2) - (\partial X) \cap S$. Moreover, $(X^{\text{sep}}, \hat{V} \setminus X^{\text{sep}})$ is an $(A^{\text{ext}}, B^{\text{ext}})$ -cut in G^{sep} of size $|\partial X| + |(\partial X) \cap S|$, where

$$\begin{cases} A^{\text{ext}} := A \cup \{v_{e,1}, v_{e,3} \mid e \in ((\partial X) \cap S)\}, \text{ and} \\ B^{\text{ext}} := B \cup \{v_{e,2}, v_{e,4} \mid e \in ((\partial X) \cap S)\}. \end{cases}$$

Intuitively, by carefully extend the pair (A, B) to a larger pair $(A^{\text{ext}}, B^{\text{ext}})$ we ensure that *all* separated hyperedges $\text{Sep}((\partial X) \cap S, V_1, V_2)$ appear in every $(A^{\text{ext}}, B^{\text{ext}})$ -mincut on G^{sep} . See Figure 1.

■ **Figure 1** An illustration to the proof of Lemma 6. The gray circles represent hyperedges that cross the bipartition (V_1, V_2) in the divide and conquer framework. When these hyperedges are separated, new anchor vertices are introduced and added to the terminal sets. The newly created terminal vertices are forced to join different sides of the cut, if and only if the separated hyperedge crosses the (A, B) -mincut $(X, V \setminus X)$.

Suppose H_1 is a (\mathcal{T}_1, c) -sparsifier of $\hat{G}[V_1]$ and H_2 is a (\mathcal{T}_2, c) -sparsifier of $\hat{G}[V_2]$ obtained from the conquer step (Algorithm 1). Let $(Y_1, \pi(V_1 \cup A_1) \setminus Y_1)$ and $(Y_2, \pi(V_2 \cup A_2) \setminus Y_2)$ be a $(\pi(A^{\text{ext}}|_{V_1 \cup A_1}), \pi(B^{\text{ext}}|_{V_1 \cup A_1}))$ -mincut on H_1 and a $(\pi(A^{\text{ext}}|_{V_2 \cup A_2}), \pi(B^{\text{ext}}|_{V_2 \cup A_2}))$ -mincut on H_2 respectively. Notice that every hyperedge in $\text{Sep}((\partial X) \cap S, V_1, V_2)$ are in $\partial(Y_1 \cup Y_2)$. Let $Y_0 := Y_1 \cup Y_2$ and after removing all anchor vertices we get $Y = Y_0 \cap V$. Now $(Y, \pi(V) \setminus Y)$ is a $(\pi(A), \pi(B))$ -cut. Since for each hyperedge $e \in (\partial_G X) \cap S$, e is separated into two hyperedges and both of them are in $\partial_{H_1 \cup H_2} Y_0$, we have

$$|\partial_H Y| \leq |\partial_{H_1 \cup H_2} Y_0| - |(\partial_G X) \cap S|. \quad (1)$$

Notice that the inequality in Equation (1) comes from the fact that $\partial_{H_1 \cup H_2} Y_0$ may or may not contain more separated hyperedges from $Sep(S \setminus \partial X, V_1, V_2)$.

Finally we obtain

$$\begin{aligned} \text{mincut}_H^c(\pi(A), \pi(B)) &\leq |\partial_H Y| && (Y \text{ is some } (\pi(A), \pi(B))\text{-cut on } H) \\ &\leq |\partial_{H_1 \cup H_2} Y_0| - |(\partial X) \cap S| && (\text{by Equation (1)}) \\ &= |\partial_{H_1} Y_1| + |\partial_{H_2} Y_2| - |(\partial X) \cap S| \\ &&& (Y_0 \text{ is the disjoint union } Y_1 \cup Y_2) \\ &\leq |\partial_{G^{\text{sep}}} X^{\text{sep}}| - |(\partial X) \cap S| && (X^{\text{sep}} \text{ is some } (A^{\text{ext}}, B^{\text{ext}})\text{-cut}) \\ &= |\partial X| && (\text{exactly } |(\partial X) \cap S| \text{ hyperedges were separated}) \\ &= \text{mincut}_G^c(A, B) && (X \text{ is an } (A, B)\text{-mincut}) \end{aligned}$$

as desired.

Part 2. The proof of $\text{mincut}_H^c(\pi(A), \pi(B)) \geq \text{mincut}_G^c(A, B)$ is very similar to Part 1, so we defer the proof (for completeness) in the full version. ◀

3.4 $(5c, c)$ -Edge-Unbreakable Terminals

Let $G = (V, E)$ be a hypergraph and let $\mathcal{T} \subseteq V$ be the set of terminals. By adopting the notations from [17], we say that a terminal set \mathcal{T} is $(5c, c)$ -edge-unbreakable on G if for any bipartition (V_1, V_2) of V with no more than c crossing edges $|E_G(V_1, V_2)| \leq c$, either $|\mathcal{T}|_{V_1} < 5c$ or $|\mathcal{T}|_{V_2} < 5c$. That is, if there is a cut of size at most c , then at least one of the sides has less than $5c$ induced terminals.

Liu [16] obtained an (\mathcal{T}, c) -sparsifier of size $O(|\mathcal{T}|c^2)$ with a $(5c, c)$ -edge-unbreakable terminal set \mathcal{T} where each terminal vertex $v \in \mathcal{T}$ has degree 1. It turns out that Liu's techniques naturally extend to hypergraphs. We prove the following in the full version of the paper.

► **Lemma 7.** *Let $G = (V, E)$ be a hypergraph and let $\mathcal{T} \subseteq V$ be a set of degree-1 terminals. If \mathcal{T} is $(5c, c)$ -edge-unbreakable on G , then there exists a subset $E' \subseteq E$ with $O(|\mathcal{T}|c^2)$ hyperedges, such that $G/(E - E')$ is a (\mathcal{T}, c) -sparsifier of G .*

4 Existence of (\mathcal{T}, c) -Sparsifiers with $O(kc^3)$ Hyperedges

With all the tools equipped in the previous section, we are able to prove the existence of a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges.

► **Theorem 8.** *Let $G = (V, E)$ be a hypergraph and $\mathcal{T} \subseteq V$ be the set of terminals. Then there is a subset $E' \subseteq E$ such that $|E'| = O(|\mathcal{T}|c^3)$ and the contracted hypergraph $G/(E - E')$ is (\mathcal{T}, c) -equivalent to G .*

To prove Theorem 8, it suffices to prove the following Lemma 9 where every terminal vertex has degree 1:

► **Lemma 9.** *Let $G = (V, E)$ be a hypergraph and $\mathcal{T} \subseteq V$ be the set of degree 1 terminals. Then there is a subset $E' \subseteq E$ such that $|E'| = O(|\mathcal{T}|c^2)$ and the contracted hypergraph $G/(E - E')$ is (\mathcal{T}, c) -equivalent to G .*

70:8 Vertex Sparsifiers for Hyperedge Connectivity

Proof of Theorem 8. Without loss of generality, we may assume that each vertex in \mathcal{T} has degree at most c , by duplicating each terminal vertex and add c parallel edges between the duplicated vertex and the original vertex. Let \mathcal{T} be the terminal set of an input instance. Now, assuming each terminal has degree at most c , we can further duplicate each of these terminals c times so we have a set \mathcal{T}' of at most $|\mathcal{T}|c$ degree-1 terminal vertices. By Lemma 9, there exists a subset $E' \subseteq E$ such that $|E'| = O(|\mathcal{T}'|c^2) = O(|\mathcal{T}|c^3)$ and the contracted hypergraph $G/(E - E')$ is (\mathcal{T}, c) -equivalent to G . ◀

To prove Lemma 9, we first present an algorithm SPARSIFYSLOW (See Algorithm 2). The algorithm recursively apply divide and conquer framework until the terminal set is $(5c, c)$ -edge-unbreakable as the base case. After applying Lemma 7 on each base case, the algorithm combines the sparsifiers from the subproblems using Lemma 6.

■ **Algorithm 2** SPARSIFYSLOW SPARSIFYSLOW(G, \mathcal{T}, c).

Input: An undirected unweighted multi-hypergraph G , a set of degree-1 vertex terminals $\mathcal{T} \subseteq V$, and a constant c .

Output: A (\mathcal{T}, c) -sparsifier H for G .

- 1 **if** \mathcal{T} is $(5c, c)$ -edge-unbreakable **then**
- 2 Construct H , a (\mathcal{T}, c) -sparsifier of G using Lemma 7.
- 3 **return** H .
- 4 **else**
- 5 Let (V_1, V_2) be a bipartition of $V(G)$ that refutes the $(5c, c)$ -edge-unbreakable property. That is, $|E_G(V_1, V_2)| \leq c$ but $|\mathcal{T} \cap V_1| \geq 5c$ and $|\mathcal{T} \cap V_2| \geq 5c$.
- 6 Obtain $\begin{cases} H_1 \leftarrow \text{SPARSIFYSLOW}(\hat{G}[V_1], \mathcal{T}_1, c), \text{ and} \\ H_2 \leftarrow \text{SPARSIFYSLOW}(\hat{G}[V_2], \mathcal{T}_2, c). \end{cases}$
- 7 **return** $H \leftarrow H_1 \cup H_2 \cup E(V_1, V_2) - \text{Sep}(S, V_1, V_2)$.
- 8 **end**

Lemma 10 and Lemma 11 give the correctness proof and the size to the returned (\mathcal{T}, c) -sparsifier from Algorithm 2.

► **Lemma 10.** *Algorithm 2 returns a (\mathcal{T}, c) -sparsifier of G .*

Proof. First we notice that all vertices in \mathcal{T}_1 and \mathcal{T}_2 have degree 1 in $\hat{G}[V_1]$ and $\hat{G}[V_2]$ respectively: the anchor vertices have degree 1 and so the recursive calls in Algorithm 2 are valid. The correctness is then recursively guaranteed by Lemma 6 (divide-and-conquer step) and Lemma 7 (base case). ◀

► **Lemma 11.** *Let G be a hypergraph, $\mathcal{T} \subseteq V$ is the set of degree-1 terminal vertices, and let c be a constant. Let $H = \text{SPARSIFYSLOW}(G, \mathcal{T}, c)$ be the output of Algorithm 2. Then H has at most $O(|\mathcal{T}|c^2)$ hyperedges.*

The proof to Lemma 11 is via a potential function similarly defined in Liu [16].

Proof. The execution to Algorithm 2 defines a recursion tree. If $|\mathcal{T}| < 5c$, then the recursion terminates immediately because \mathcal{T} is trivially $(5c, c)$ -edge-unbreakable by definition and a (\mathcal{T}, c) -sparsifier of $O(|\mathcal{T}|c^2)$ hyperedges is returned by Lemma 7. Assume that $|\mathcal{T}| \geq 5c$, then each recursive call on the subproblem (G', \mathcal{T}') guarantees that $|\mathcal{T}'| \geq 5c$.

Now, it suffices to use the following potential function to prove that the total number of terminal vertices in all recursion tree leaves can be bounded by $O(|\mathcal{T}|)$. Define a potential function for each subproblem (G', \mathcal{T}') to be $\Phi(G', \mathcal{T}') := |\mathcal{T}'| - 5c$. Then, according to Algorithm 2, whenever (G', \mathcal{T}') splits into two subproblems $(\hat{G}'[V_1], \mathcal{T}'_1)$ and $(\hat{G}'[V_2], \mathcal{T}'_2)$ we have

$$\begin{aligned} \Phi(\hat{G}'[V_1], \mathcal{T}'_1) + \Phi(\hat{G}'[V_2], \mathcal{T}'_2) &\leq |\mathcal{T}' \cap V_1| + |\mathcal{T}' \cap V_2| + 4|E_{G'}(V_1, V_2)| - 10c \\ &\leq \Phi(G', \mathcal{T}') - c. \end{aligned}$$

Since every subproblem has a non-negative potential, and the sum of potential decreases by c at each divide-and-conquer step, the total number of leaf cases do not exceed $\Phi(G, \mathcal{T})/c \leq |\mathcal{T}|/c$. Hence, the total size from the base case is at most $\sum_{(G', \mathcal{T}'): \text{base case}} |\mathcal{T}'| \leq \Phi(G, \mathcal{T}) + (5c)(\# \text{ of leaf cases}) = O(|\mathcal{T}|)$.

By Lemma 7, the total number of hyperedges returned from Algorithm 2 is at most $O(|\mathcal{T}|c^2)$. The total number of hyperedges added back at Algorithm 2 is at most the number of divide-and-conquer steps times the cut size, which is at most $|\mathcal{T}|$. Therefore, the output (\mathcal{T}, c) -sparsifier H has at most $O(|\mathcal{T}|c^2)$ hyperedges as desired. \blacktriangleleft

Proof of Lemma 9. Lemma 9 follows immediately after the correctness proof (Lemma 10) and upper bounding the number of hyperedges (Lemma 11). \blacktriangleleft

5 An Almost-linear-time Algorithm Constructing a Sparsifier

This section is devoted to proving part (1) in Theorem 1. That is, we give a almost-linear-time (assuming a constant rank) algorithm that constructs a contraction based (\mathcal{T}, c) -sparsifier of $O(|\mathcal{T}|c^3)$ hyperedges which matches with Theorem 8 up to a constant factor. We summarize the result in Theorem 12.

► Theorem 12. *Let $G = (V, E)$ be a hypergraph with n vertices, m hyperedges, and rank $r = \max_{e \in E} |e|$. Let $\mathcal{T} \subseteq V$ be a terminal set $\mathcal{T} \subseteq V$. Then there exists a randomized algorithm which constructs a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges in $O(p + n(rc \log n)^{O(rc)} \log m)$ time.*

Overview of the algorithm. Although Algorithm 2 can construct a (\mathcal{T}, c) -sparsifier with $O(|\mathcal{T}|c^3)$ hyperedges, it is slow because we do not have an efficient algorithm searching for a bipartition that violates the $(5c, c)$ -edge-unbreakable property.

To construct our contraction-based (\mathcal{T}, c) -sparsifier, all we need to do is identifying *essential* hyperedges and contract non-essential ones. Essential hyperedges are indispensable to maintaining mincut between terminals. It seems to be challenging to identify essential hyperedges on an arbitrary graph without a $(5c, c)$ -edge-unbreakable guarantee. Fortunately, we notice there is an efficient way to identify essential hyperedges in an expander.

Naturally, we can utilize EXPANDERDECOMPOSE (where the version for hypergraphs is explicitly stated in [18]) which splits a hypergraph into expanders. Expander decomposition not only guarantees expander sub-hypergraphs, but also fits in the divide-and-conquer framework indicated by Lemma 6 with a favorable almost-linear time. Then, we can focus on identifying essential hyperedges in an expander.

To identify essential hyperedges in an expander, we first enumerate all *connected cuts*¹ with value at most c – the sub-hypergraph induced by the smaller side of a connected cut

¹ In Chalermsook et al. [4], the concept of connected cuts is not explicitly defined. We give a formal definition in the full version and hope it clarifies some ambiguity in their paper.

70:10 Vertex Sparsifiers for Hyperedge Connectivity

is connected; see Algorithm 3 and Algorithm 4. Then, we build a *pruned auxiliary graph* based on the cuts we have enumerated. The pruned auxiliary graph leads to an efficient way identifying essential hyperedges. Finally, we contract all detected non-essential hyperedges. We call the above procedure that sparsifies an expander ϕ -SPARSIFY. See Algorithm 5.

■ Algorithm 3 ENUMERATECUTS (G, ϕ, r, c).

Input: A ϕ -expander hypergraph $G = (V, E)$ with rank r , and a threshold parameter c .

Output: All connected cuts with value at most c .

```

1  $\mathcal{C} \leftarrow \emptyset$ . // Stores all found connected cuts.
2 for each  $v_{seed} \in V$  do
3   | /* Invokes a helper function to find all connected cuts involving  $v_{seed}$ . */
3   |  $\mathcal{C} \leftarrow \mathcal{C} \cup \text{ENUMERATECUTSHELP}(0, G, G, \phi, r, c, v_{seed})$ . // See Algorithm 4.
4 end
5 return  $\mathcal{C}$ .
```

■ Algorithm 4 ENUMERATECUTSHELP ($depth, H, G, \phi, r, c, v_{seed}$).

Input: The current recursion depth $depth$. A hypergraph $H = (V, E)$ with rank r . The original hypergraph G . Parameters c and ϕ . A seed vertex $v_{seed} \in V$.

Output: All connected cut with value at most c so that v_{seed} is in the smaller side.

```

1 if  $depth \leq rc$  then
2   | Run DFS from  $v_{seed}$  on  $H$  and stop as soon as visiting  $c\phi^{-1} + 1$  hyperedges.
3   | Let  $\hat{E}$  be the set of visited hyperedges and  $X$  be the set of visited vertices.
4   | if DFS gets stuck before visiting  $c\phi^{-1} + 1$  hyperedges then
5     |   if  $|\partial_G X| \leq c$  then
6       |     return  $\{(X, V \setminus X)\}$ . /* Some connected cut with value at most  $c$ . */

9     |   end
10  | else
11  |    $\mathcal{S} \leftarrow \emptyset$ .
12  |   for each  $e \in \hat{E}$  and for each  $v \in e, v \neq v_{seed}$  do
13  |     | Let  $e' \leftarrow e \setminus v$ . /* modify the boundary hyperedge into a smaller one. */
14  |     | // A recursive call with  $v$  being removed from  $e$ .
14  |     |  $\mathcal{S} \leftarrow \mathcal{S} \cup \text{ENUMERATECUTSHELP}(depth + 1, H - e + e', G, \phi, r, c, v_{seed})$ 
15  |     | end
16  |     return  $\mathcal{S}$ .
17  | end
18 else
19 | return  $\emptyset$ .
20 end
```

■ **Algorithm 5** ϕ -SPARSIFY ($G, \mathcal{T}, \phi, r, c$).

Input: ϕ -expander hypergraph $G = (V, E)$ with rank r , terminal set \mathcal{T} , threshold parameter c .

Output: A (\mathcal{T}, c) -sparsifier of G .

- 1 Run ENUMERATECUTS and construct the pruned auxiliary graph $G^{\text{aux}} = (V^{\text{aux}}, E^{\text{aux}})$, where $V^{\text{aux}} = P_0 \cup C_0 \cup E_0$.
- 2 Let $E' \leftarrow E \setminus E_0$.
- 3 **for** each $e \in E_0$ (in any order) **do**
- 4 Compute the set of partitions $P'_e := P_0 \cap N(N(e))$ who has at least one mincut that contains the edge e .
- 5 **if** $\forall p \in P'_e, N(p) \not\subseteq N(e)$ **then**
- 6 Remove $N(e)$ and all incident edges from G^{aux} .
- 7 $E' \leftarrow E' \cup \{e\}$. // e is non-essential.
- 8 **end**
- 9 **end**
- 10 **return** G/E' .

■ **Algorithm 6** SPARSIFYFAST (G, r, \mathcal{T}, c, C').

Input: hypergraph $G = (E, V)$ with rank r , terminal set \mathcal{T} , threshold parameter c , constant C' .

Output: a (\mathcal{T}, c) -sparsifier H .

- 1 $H \leftarrow G$.
- 2 $iter \leftarrow 0$. /* Number of iterations of the following while-loop. */
- 3 **do**
- 4 $G \leftarrow H$
- 5 $\phi^{-1} \leftarrow 4C'rc^4 \log^3 n$.
- 6 $\{V_i\}_{i=1}^t \leftarrow \text{EXPANDERDECOMPOSE}(G, \phi)$.
- 7 $G' \leftarrow G$ /* Anchored sub-hypergraphs will be separated from G' one by one. */
- 8 **for** each $i = 1, 2, \dots, t$ **do**
- 9 Apply the divide step in Algorithm 1 to G' with terminal \mathcal{T} and bipartition $(V_i, \bigcup_{\ell=i+1}^t V_\ell)$, and get $G_i \leftarrow \hat{G}'[V_i]$ and $G' \leftarrow \hat{G}'[\bigcup_{\ell=i+1}^t V_\ell]$.
- 10 (For each boundary hyperedge e with anchor vertices $v_{e,3}$ and $v_{e,4}$ created on the $\bigcup_{\ell=i+1}^t V_\ell$ side, we assign both $v_{e,3}$ and $v_{e,4}$ to an arbitrary V_j such that $j > i$ and $e \cap V_j \neq \emptyset$.)
- 11 $\{H_i\}_{i=1}^t \leftarrow \{\phi\text{-SPARSIFY}(G_i, V_i \cap \mathcal{T}, \phi, r, c)\}_{i=1}^t$. /* The conquer step. */
- 12 $H \leftarrow H_t$ /* Each sparsifier H_i will be merged with H one by one. */
- 13 **for** each $i = t-1, \dots, 1$ **do**
- 14 Apply the combine step in Algorithm 1 to merge H_i with H . That is, all anchor vertices introduced at the divide step are removed and all separated hyperedges are replaced by the boundary hyperedges before separating V_i from $\bigcup_{\ell=i}^t V_\ell$.
- 15 $iter = iter + 1$.
- 16 **while** $iter < \log m$.
- 17 **return** H .

With EXPANDERDECOMPOSE and ϕ -SPARSIFY procedures introduced above, we are able to construct the (\mathcal{T}, c) -sparsifier on general hypergraphs of size $O(|\mathcal{T}|c^3)$ efficiently. Our algorithm (Algorithm 6) is based on Chalermsook et al. [4] and consists of iterations of EXPANDERDECOMPOSE and ϕ -SPARSIFY. Each iteration implements the divide-and-conquer framework shown by Algorithm 1: we first apply EXPANDERDECOMPOSE and decompose the hypergraph into ϕ -expanders. Then we apply ϕ -SPARSIFY to sparsify the ϕ -expanders. Finally, we glue all sparsifiers of the ϕ -expanders by recovering the inter-cluster hyperedges between the ϕ -expanders. Similar to [4], we prove that $O(\log m)$ iterations suffice to obtain a (\mathcal{T}, c) -sparsifier of $O(|\mathcal{T}|c^3)$ hyperedges.

Due to the page limit, we refer the readers to the full version of this paper to see the details of the algorithms in this section.

Abstract

We study ROUND-UFP and ROUND-SAP, two generalizations of the classical BIN PACKING problem that correspond to the unsplittable flow problem on a path (UFP) and the storage allocation problem (SAP), respectively. We are given a path with capacities on its edges and a set of jobs where for each job we are given a demand and a subpath. In ROUND-UFP, the goal is to find a packing of all jobs into a minimum number of copies (rounds) of the given path such that for each copy, the total demand of jobs on any edge does not exceed the capacity of the respective edge. In ROUND-SAP, the jobs are considered to be rectangles and the goal is to find a non-overlapping packing of these rectangles into a minimum number of rounds such that all rectangles lie completely below the capacity profile of the edges.

We show that in contrast to BIN PACKING, both problems do not admit an asymptotic polynomial-time approximation scheme (APTAS), even when all edge capacities are equal. However, for this setting, we obtain asymptotic $(2 + \varepsilon)$ -approximations for both problems. For the general case, we obtain an $O(\log \log n)$ -approximation algorithm and an $O(\log \log \frac{1}{\delta})$ -approximation under $(1 + \delta)$ -resource augmentation for both problems. For the intermediate setting of the *no bottleneck assumption* (i.e., the maximum job demand is at most the minimum edge capacity), we obtain an absolute 12- and an asymptotic $(16 + \varepsilon)$ -approximation algorithm for ROUND-UFP and ROUND-SAP, respectively.

1 Introduction

The unsplittable flow on a path problem (UFP) and the storage allocation problem (SAP) are two well-studied problems in combinatorial optimization. In this paper, we study ROUND-UFP and ROUND-SAP, which are two related natural problems that also generalize the classical BIN PACKING problem.

In both ROUND-UFP and ROUND-SAP, we are given as input a path $G = (V, E)$ and a set of n jobs J . We assume that $\{v_0, v_1, \dots, v_m\}$ are the vertices in V from left to right and then for each $i \in \{1, \dots, m\}$ there is an edge $e_i := \{v_{i-1}, v_i\}$. Each job $j \in J$ has integral demand $d_j \in \mathbb{N}$, a source $v_{s_j} \in V$, and a sink $v_{t_j} \in V$. We say that each job j spans the path P_j which we define to be the path between v_{s_j} and v_{t_j} . For every edge $e \in E$, we are given

an integral capacity c_e . A useful geometric interpretation of the input path and the edge capacities is the following (see Figure 1): consider the interval $[0, m)$ on the x -axis and a function $c: [0, m) \rightarrow \mathbb{N}$. Each edge e_k corresponds to the interval $[k - 1, k)$ and each vertex v_i corresponds to the point i . For edge e_k , we define $c(x) = c_{e_k}$ for each $x \in [k - 1, k)$.

In the ROUND-UFP problem, the objective is to partition the jobs J into a minimum number of sets J_1, \dots, J_k (that we will denote by *rounds*) such that the jobs in each set J_i form a *valid packing*, i.e., they obey the edge capacities, meaning that $\sum_{j \in J_i: e \in P_j} d_j \leq c_e$ for each $e \in E$. In the ROUND-SAP problem, we require to compute additionally for each set J_i a non-overlapping set of rectangles underneath the capacity profile, corresponding to the jobs in J_i (see Figure 1). Formally, we require for each job $j \in J_i$ to determine a height h_j with $h_j + d_j \leq c_e$ for each edge $e \in P_j$, yielding a rectangle $R_j = (s_j, h_j) \times (t_j, h_j + d_j)$, such that for any two jobs $j, j' \in J_i$ we have that $R_j \cap R_{j'} = \emptyset$. Again, the objective is to minimize the number of rounds.

Note that unlike ROUND-SAP, in ROUND-UFP we do not need to pack the jobs as contiguous rectangles. Hence, intuitively in ROUND-UFP we can slice the rectangles vertically and place different slices at different heights. See Figure 1.

ROUND-UFP and ROUND-SAP arise naturally in the setting of resource allocation with connections to many fundamental optimization problems. One possible interpretation of the input path is that each vertex is a computer and that these computers are connected via some wired connection, e.g., optical fiber, ethernet, etc. Each direct connection between two computers is modeled by an edge in the input and it has a certain bandwidth, modeled by the capacity of the edge. Also, certain pairs of computers seek to send data from one to the other, and these pairs are represented by the input jobs. The size of each job corresponds to the amount of data that needs to be transported. Now it can happen that the bandwidths do not support all the jobs. In this case, a remedy is to partition the jobs into groups such that each group is supported by the bandwidths. It is desirable to have as few groups as possible, in order to send the data as quickly as possible. Now each of the mentioned groups corresponds to a round in ROUND-UFP, and therefore we seek to minimize the number of rounds. In ROUND-SAP, we require additionally that each job gets a contiguous portion of the communication bandwidths on each edge and also that this portion is the same on each edge. This is a requirement that arises in practice in wavelength division multiplexing and optical fiber minimization, see [4, 51].

An alternative interpretation of the path is that it represents a time axis. For example, the first edge e_1 would correspond to the time interval $[0, 1)$, the second edge e_2 to the interval $[1, 2)$, etc. The capacities of the edges represent the available amount of some resource of a machine, e.g., memory or transmission frequencies, etc., which might change over time. Each input job then represents a job that needs to be executed during some time interval, i.e., the time interval that corresponds to the edges of the path of the job. Similar to the above, it might be the case that not all jobs can be executed on the same machine because not enough resources are available on a machine. Then, we want to distribute the jobs on several machines, such that all jobs assigned to the same machine can run on that machine, i.e., enough resources are available. Here we assume that each machine has its own resources, e.g., its own CPUs or memory. The jobs on the same machine then form a round according to our definition of ROUND-UFP. Naturally, we seek to minimize the number of rounds, which corresponds to minimizing the number of machines. Similarly as above, in ROUND-SAP, we additionally require that each job gets a contiguous portion of the resource, e.g., a contiguous portion of the frequency spectrum or the memory [11]. Another application is ad-placement, where each job is an advertisement that requires a contiguous portion of the banner [45].

ROUND-UFP and ROUND-SAP are APX-hard as they contain the classical BIN PACKING problem as a special case when G has only one single edge. However, while for BIN PACKING there exists an asymptotic polynomial time approximation scheme (APTAS),¹ it is open whether such an algorithm exists for ROUND-UFP or ROUND-SAP. The best known approximation algorithm for ROUND-UFP is a $O(\min\{\log n, \log m, \log \log c_{\max}\})$ -approximation [35]. For the special case of ROUND-UFP of uniform edge capacities, Pal [49] gave a 3-approximation. Elbassioni et al. [21] gave a 24-approximation algorithm for the problem under the no-bottleneck assumption (NBA) which states that the maximum job demand is upper-bounded by the minimum edge capacity. A result in (the full version of) [45] states that any solution to an instance of UFP can be partitioned into at most 80 sets of jobs such that each of them is a solution to the corresponding SAP instance. This immediately yields approximation algorithms for ROUND-SAP: a 240-approximation for the case of uniform capacities, a 1920-approximation under the NBA, and a $O(\min\{\log n, \log m, \log \log c_{\max}\})$ -approximation for the general case. These are the best known results for ROUND-SAP.

1.1 Our Contributions

First, we show that both ROUND-SAP and ROUND-UFP, unlike the classical BIN PACKING problem, do not admit an APTAS, even in the uniform capacity case. We achieve this via a gap preserving reduction from the 3D matching problem. We create a numeric version of the problem and define a set of hard instances for both ROUND-SAP and ROUND-UFP. Together with a result of Chlebik and Chlebikova [15], we derive an explicit lower bound on the asymptotic approximation ratio for both problems. Our hardness result holds even for the case in which in the optimal packing no round contains more than $O(1)$ jobs, i.e., a case in which we can even enumerate all possible packings in polynomial time.

For the case of uniform edge capacities, we give asymptotic $(2 + \varepsilon)$ -approximation algorithms for both ROUND-UFP and ROUND-SAP, and absolute $(2.5 + \varepsilon)$ and 3-approximation algorithms for the two problems, respectively. This improves upon the previous absolute 3- and 240-approximation algorithms mentioned above. Note that for both problems our factor of 2 is a natural threshold: in many algorithms for UFP and SAP [10, 3, 33, 34, 45, 46], the

¹ For basic definitions related to approximation algorithms, we refer to Section 2.

input jobs are partitioned into jobs that are relatively small and relatively large (compared to the edge capacities). Then, both sets are handled separately with very different sets of techniques. This inherently loses a factor of 2. Our algorithms are based on a connection of our problems to the dynamic storage allocation (DSA) problem and we show how to use some known deep results for DSA [11] in our setting. In DSA the goal is to place some given jobs as non-overlapping rectangles, minimizing the height of the resulting packing. This problem might seem totally unrelated at first glance, in particular, unrelated to ROUND-UFP. The mentioned result produces an alignment of rectangles that correspond to our input jobs, based on which we assign jobs to the different rounds in ROUND-SAP and ROUND-UFP. In one of the two cases that we distinguish, we additionally use a dynamic program that finds an optimal solution for the relatively large jobs in the input. In comparison, the previously best-known algorithm for ROUND-UFP is just a greedy routine that sorts the input jobs and then assigns them greedily into the rounds. The previously best result for ROUND-SAP takes this packing (for ROUND-UFP) and applies a reduction from [45] as a black-box, using a (quite large) factor of 80, yielding a 240-approximation algorithm. In particular, our algorithm for ROUND-SAP yields a much smaller approximation ratio and uses techniques that are much better tailored to ROUND-SAP.

For the general cases of ROUND-UFP and ROUND-SAP, we give an $O(\log \log \min\{m, n\})$ -approximation algorithm. Depending on the concrete values of n , m , and c_{\max} , this constitutes an up to exponential improvement compared to the best known result for ROUND-UFP [35] and for ROUND-SAP (by the reasoning via [45] above). As done previously in the literature, we represent these large jobs by rectangles that are drawn as high as possible underneath the capacity profile and we seek a solution such that in each round, the rectangles corresponding to the jobs in the round are pairwise non-overlapping. In contrast to prior work, we formulate this problem as a configuration-LP and we show that we can solve it in polynomial time via a suitable separation oracle. The integral parts of its solution immediately yield an assignment of some input jobs into at most OPT many rounds. With an additional step, we show that the remaining problem (corresponding to the fractional part of the solution of the configuration-LP) can be reduced to several instances of ROUND-UFP/ ROUND-SAP with the property that each point is overlapped by at most $O(\log m)$ rectangles. This is crucial to be able to apply another novel step: we employ a recent result by Chalermsook and Walczak [12] that yields a bound on the coloring number of rectangle intersection graphs, and we put the rectangles from each color class into a separate round. Since each point is overlapped by at most $O(\log m)$ rectangles, this yields an approximation ratio of $O(\log \log m)$ only, and since w.l.o.g. $m \leq 2n$, also of $O(\log \log n)$. In comparison, the previously best-known algorithm for the general case of ROUND-UFP also uses the viewpoint of the rectangles above, but it pays up to a factor of $O(\log m)$ in order to reduce the general case to the special case in which each rectangle is stabbed by one or two lines from a suitably defined set of lines. For the latter case, it employs a polynomial-time 3-approximation algorithm. In particular, this algorithm neither employs a configuration-LP nor the mentioned result in [12].

Then we study the setting of resource augmentation, i.e., where we can increase the edge capacities by a factor of $1 + \delta$, while still comparing our solution with the optimal solution with original capacities. In this case, we show that we can reduce the given problem to the setting in which the edge capacities are in the range $[1, 1/\delta)$. Applying the algorithm from [35] then yields a $O(\log \log \frac{1}{\delta})$ -approximation for this case for ROUND-UFP, and with a similar argumentation as before also for ROUND-SAP.

Furthermore, for the case of the NBA we improve the absolute approximation ratio from 24 to 12 for ROUND-UFP, and from 1920 to 17 for ROUND-SAP, and we even obtain an asymptotic $(16 + \varepsilon)$ -approximation for ROUND-SAP. For ROUND-SAP we give a black-box

■ **Table 1** Overview of our results. We distinguish the settings according to uniform edge capacities, the no-bottleneck-assumption (NBA), general edge capacities, and general edge capacities with $(1 + \delta)$ -resource augmentation (r.a.). Also, we distinguish between absolute approximation ratios and asymptotic approximation ratios. All listed previous results are absolute approximation ratios.

Problem	Edge capacities	Previous approximation	Improved approximation

reduction to the case of uniform edge capacities. We first round the job sizes and the edge capacities to powers of 2. Then we partition the input jobs into classes according to their *bottleneck capacities* (the bottleneck capacity of a job is the minimum capacity of an edge through which the job passes). For each class of bottleneck capacities, we define a corresponding instance of ROUND-SAP with uniform edge capacities. The number of different job classes can be super-constant. However, we show that we can combine the solutions for this super-constant number of classes to a global solution for the given instance so that overall we obtain a constant asymptotic approximation ratio of $16 + \varepsilon$ for ROUND-SAP. We remark that our black-box reduction loses a fixed factor of 8, so any improvements for the case of uniform edge capacities would yield an improved approximation ratio for the case of the NBA as well. In comparison, the previously best-known result for ROUND-SAP under the NBA uses the known 24-approximation algorithm for ROUND-UFP and then invokes the mentioned result in [45] as a black-box, yielding a quite large approximation ratio of 1920.

For the setting of round-UFP under the NBA, the previously best-known 24-approximation algorithm in [21] loses a large factor of 16 for packing the small jobs. This algorithm is a simple greedy routine that sorts jobs by their left endpoints and places them appropriately into rounds. In contrast, we first scale up the job demands to integral powers of $1/2$ (assuming the minimum edge capacity to be 1) and then consider jobs based on their bottleneck capacities. We then devise a novel way of classifying the jobs based on the *density* of the jobs on various edges: for one class of jobs we show that a simple greedy algorithm loses only a factor of 4; for the other, our classification scheme ensures that the *congestion* on *every* edge is small which enables us to apply a result in [48], again losing a factor of 4. Also for the large jobs, we improve the best-known 8-approximation to a 4-approximation, thus getting an 12-approximation overall for ROUND-UFP under the NBA.

If in ROUND-UFP we are given a tree instead of a path, we obtain the ROUND-TREE problem. The best known result for it under the NBA is a 64-approximation [21] and a 6-approximation is known for uniform edge capacities [23]. We improve the best known approximation ratio under the NBA to 55 and also provide a 5.5-approximation algorithm for the case of uniform edge capacities.

See Table 1 for an overview of our results.

1.2 Other Related Work

Without the NBA, Epstein et al. [22] showed that no deterministic online algorithm can achieve a competitive ratio better than $\Omega(\log \log n)$ or $\Omega(\log \log \log(c_{\max}/c_{\min}))$ for ROUND-UFP. They also gave a $O(\log c_{\max})$ -competitive algorithm, where c_{\max} is the largest edge capacity. Without the NBA, recently Jahanjou et al. [35] gave a $O(\min(\log m, \log \log c_{\max}))$ -competitive algorithm. For the special case of ROUND-UFP for uniform edge capacities in the online setting, Adamy and Erlebach [2] gave a 195-competitive algorithm, which was subsequently improved to 10 [47, 5].

ROUND-UFP and ROUND-SAP are related to many fundamental optimization problems. For example, ROUND-SAP can be interpreted as an intermediate problem between two-dimensional bin packing (2BP) and the rectangle coloring problem (RC). In 2BP, the goal is to find an axis-parallel nonoverlapping packing of a given set of rectangles (which we can translate in both dimensions) into minimum number of unit square bins. If all edges have the same capacity then ROUND-SAP can be seen as a variant of 2BP in which the horizontal coordinate of each item is fixed and we can choose only the vertical coordinate. For 2BP, the present best asymptotic approximation guarantee is 1.406 [8]. On the other hand, in RC, all rectangles are fixed and the goal is to color the rectangles using a minimum number of colors such that no two rectangles of the same color intersect. For RC, recently Chalermsook and Walczak [12] have given a polynomial-time algorithm that uses only $O(\omega \log \omega)$ colors, where ω is the clique number of the corresponding intersection graph (and hence a lower bound on the number of needed colors). Another related problem is Dynamic Storage Allocation (DSA), where the objective is to pack the given jobs (with fixed horizontal location) such that the maximum vertical height, $\max_j(h_j + d_j)$ (called the *makespan*) is minimized. The current best known approximation ratio for DSA is $(2 + \epsilon)$ [11].

In a sense ROUND-UFP and ROUND-SAP are ‘BIN PACKING-type’ problems, and their corresponding ‘KNAPSACK-type’ problems are UFP and SAP, respectively, where each job has an associated profit and the goal is to select a subset of jobs which can be packed into one single round satisfying the corresponding valid packing constraints. There is a series of work [33, 7, 9, 3, 34, 32] in UFP, culminating in a PTAS [31]. It is maybe surprising that ROUND-UFP does not admit an APTAS, even though UFP admits a PTAS. For SAP, the currently best polynomial time approximation ratio is $2 + \epsilon$ [45], which has been recently improved to $1.969 + \epsilon$ [46] for the case of uniform capacities, and also a quasi-polynomial time $(1.997 + \epsilon)$ -approximation is known for quasi-polynomially bounded input data.

There are many other related problems, such as two-dimensional knapsack [26, 37, 28, 36], strip packing [27, 25, 20, 39], maximum independent set of rectangles [1, 12, 44, 29], guillotine separability of rectangles [41, 40, 42], weighted bipartite edge coloring [43], maximum edge disjoint paths [18], etc. We refer the readers to [38, 17] for an overview of these problems.

2 Preliminaries

Let OPT_{UFP} and OPT_{SAP} denote the optimal number of rounds required to pack all jobs of a given instance of ROUND-UFP and ROUND-SAP, respectively. By simple preprocessing, we can assume that each vertex in V corresponds to endpoint(s) of some job(s) in J , and hence $m \leq 2n - 1$. Job j is said to *pass through* edge e if $e \in P_j$. The *load* on edge e is defined as $l_e := \sum_{e \in P_j} d_j$, the total sum of demands of all jobs passing through e . Let $L := \max_e l_e$ denote the maximum *load*.

We now define some notions related to approximation algorithms. Consider a minimization problem Π . An algorithm \mathcal{A} has approximation guarantee of α ($\alpha > 1$), if $\mathcal{A}(I) \leq \alpha OPT(I)$ for all input instances I of Π . This is also known as *absolute approximation guarantee*. As

common in bin packing literature, we also study asymptotic approximation which intuitively is the approximation ratio when OPT tends to infinity. An algorithm \mathcal{A} has asymptotic approximation guarantee of α , if $\mathcal{A}(I) \leq \alpha OPT(I) + o(OPT(I))$ for all input instances I of Π . A problem admits polynomial time approximation scheme or PTAS (resp. asymptotic polynomial time approximation scheme or APTAS) if for every constant $\varepsilon > 0$, there exists a $(1 + \varepsilon)$ -approximation (resp. $(1 + \varepsilon)$ -asymptotic approximation) algorithm with running time $O(n^{f(1/\varepsilon)})$, for any function f that depends only on ε .

3 Lower Bounds

A simple reduction from the PARTITION problem shows that it is NP-hard to obtain a better approximation ratio than $3/2$ for the classical BIN PACKING problem. However, in the resulting instances, the optimal solutions use only two or three bins. On the other hand, BIN PACKING admits an APTAS [19] and thus, for any $\varepsilon > 0$, a $(1 + \varepsilon)$ -approximation algorithm for instances in which OPT is sufficiently large. Since ROUND-SAP and ROUND-UFP are generalizations of BIN PACKING (even if G has only a single edge), the lower bound of $3/2$ continues to hold. However, maybe surprisingly, we show that unlike BIN PACKING, ROUND-SAP and ROUND-UFP do not admit APTASes, even in the case of uniform edge capacities. More precisely, we provide a lower bound of $(1 + 1/1398)$ on the asymptotic approximation ratio for ROUND-SAP and ROUND-UFP via a reduction from the 2-BOUNDED OCCURRENCE MAXIMUM 3-DIMENSIONAL MATCHING (2-B-3-DM) problem.

In 2-B-3-DM, we are given as input three pairwise disjoint sets $X := \{x_1, x_2, \dots, x_q\}$, $Y := \{y_1, y_2, \dots, y_q\}$, and $Z := \{z_1, z_2, \dots, z_q\}$ and a set of triplets $\mathcal{T} \subseteq X \times Y \times Z$ such that each element of $X \cup Y \cup Z$ occurs in exactly two triplets in \mathcal{T} . Note that $|X| = |Y| = |Z| = q$ and $|\mathcal{T}| = 2q$. A *matching* is a subset $M \subseteq \mathcal{T}$ such that no two triplets in M agree in any coordinate. The goal is to find a matching of maximum cardinality (denoted by OPT_{3DM}). Chlebik and Chlebikova [15] gave the following hardness result.

► **Theorem 1** ([15]). *For 2-B-3-DM there exists a family of instances such that for each instance K of the family, either $OPT_{3DM}(K) < \alpha(q) := \lfloor 0.9690082645q \rfloor$ or $OPT_{3DM}(K) \geq \beta(q) := \lceil 0.979338843q \rceil$, and it is NP-hard to distinguish these two cases.*

Hardness of 2-B-3-DM has been useful in inapproximability results for various (multidimensional) packing, covering, and scheduling problems, e.g. vector packing [52], geometric bin packing [6], geometric bin covering [16], generalized assignment problem [13], etc. Similar to these results, we also use gadgets based on a reduction from 2-B-3-DM to the 4-Partition problem. However, the previous techniques are not directly transferable to our problem due to the inherent differences between these problems. Therefore, we first use the technique from [52] to associate certain integers with the elements of $X \cup Y \cup Z$ and \mathcal{T} and then adapt the numeric data in a different way to obtain the hard instances.

Let $\rho = 32q$ and let \mathcal{V} be the set of $5q$ integers defined as follows: $x'_i = i\rho + 1$, for $1 \leq i \leq |X|$, $y'_j = j\rho^2 + 2$, for $1 \leq j \leq |Y|$, $z'_k = k\rho^3 + 4$, for $1 \leq k \leq |Z|$, $\tau'_l = \rho^4 - k\rho^3 - j\rho^2 - i\rho + 8$, for each triplet $\tau_l = (x_i, y_j, z_k) \in \mathcal{T}$. Define $\gamma = \rho^4 + 15$. The following result is due to Woeginger [52]².

² There was a minor bug in [52], which was fixed by Ray [50]. See Lemma 2 in [50] for the proof of the lemma.

► **Lemma 2** ([52]). *Four integers in \mathcal{V} sum up to the value γ if and only if (i) one of them corresponds to some element $x_i \in X$, one to some element $y_j \in Y$, one to an element $z_k \in Z$, and one to some triplet $\tau_l \in \mathcal{T}$, and if (ii) $\tau_l = (x_i, y_j, z_k)$ holds for these four elements.*

Now, we create a hard instance, tailor-made for our problems. We define that our path $G = (V, E)$ has 40000γ vertices that we identify with the numbers $0, 1, \dots, 40000\gamma$. For each $x_i \in X$ (respectively $y_j \in Y, z_k \in Z$), we specify two jobs $a_{X,i}$ and $a'_{X,i}$ (respectively $a_{Y,j}, a'_{Y,j}$ and $a_{Z,k}, a'_{Z,k}$), which will be called *peers* of each other. Each job j is specified by a triplet (s_j, t_j, d_j) . We define

- $a_{X,i} = (0, 20000\gamma - 4x'_i, 999\gamma + 4x'_i)$ and $a'_{X,i} = (20000\gamma - 4x'_i, 40000\gamma, 1001\gamma - 4x'_i)$,
- $a_{Y,j} = (0, 20000\gamma - 4y'_j, 999\gamma + 4y'_j)$ and $a'_{Y,j} = (20000\gamma - 4y'_j, 40000\gamma, 1001\gamma - 4y'_j)$, and
- $a_{Z,k} = (0, 20000\gamma - 4z'_k, 999\gamma + 4z'_k)$ and $a'_{Z,k} = (20000\gamma - 4z'_k, 40000\gamma, 1001\gamma - 4z'_k)$.

For each $\tau_l \in \mathcal{T}$, we define two jobs b_l and b'_l (also *peers*) by:

- $b_l = (0, 19001\gamma - 4\tau'_l, 999\gamma + 4\tau'_l)$ and $b'_l = (19001\gamma - 4\tau'_l, 40000\gamma, 1001\gamma - 4\tau'_l)$.

Finally let D be a set of $5q - 4\beta(q)$ *dummy* jobs each specified by $(0, 40000\gamma, 2997\gamma)$. We define that each edge $e \in E$ has a capacity of $c_e := c^* := 4000\gamma$. This completes the reduction.

For any job $j = (s_j, t_j, d_j)$ we define its *width* $w_j := t_j - s_j$.

Let $A_X := \{a_{X,i} \mid 1 \leq i \leq q\}$ and $A'_X := \{a'_{X,i} \mid 1 \leq i \leq q\}$. The sets A_Y, A'_Y, A_Z, A'_Z are defined analogously. Let $A := A_X \cup A_Y \cup A_Z$ and $A' := A'_X \cup A'_Y \cup A'_Z$. Finally let $B := \{b_l \mid 1 \leq l \leq 2q\}$ and $B' := \{b'_l \mid 1 \leq l \leq 2q\}$.

To provide some intuition, we first give an upper bound on the number of jobs that can be packed in a round. All following lemmas, statements, and constructions hold for both ROUND-SAP and ROUND-UFP.

► **Lemma 3.** *In any feasible solution any round can contain at most 8 jobs.*

We say that a round is *nice* if it contains exactly 8 jobs. It turns out that such a round corresponds exactly to one element $\tau_l = (x_i, y_j, z_k) \in \mathcal{T}$. We say that the jobs $a_{X,i}, a'_{X,i}, a_{Y,j}, a'_{Y,j}, a_{Z,k}, a'_{Z,k}, b_l$, and b'_l correspond to $\tau_l = (x_i, y_j, z_k)$.

► **Lemma 4.** *We have that a round is nice if and only if there is an element $\tau_l = (x_i, y_j, z_k) \in \mathcal{T}$ such that the round contains exactly the jobs that correspond to $\tau_l = (x_i, y_j, z_k)$.*

Given an optimal solution OPT_{3DM} to 2-B-3-DM with $|OPT_{3DM}| \geq \beta(q)$, we construct a solution as follows:

1. Let \mathcal{M} be any subset of OPT_{3DM} with $|\mathcal{M}| = \beta(q)$. Create $\beta(q)$ nice rounds corresponding to the elements in \mathcal{M} , i.e., for each element $\tau_l = (x_i, y_j, z_k) \in \mathcal{M}$, create a round containing the jobs that correspond to $\tau_l = (x_i, y_j, z_k)$.
2. For each $\tau_l \in \mathcal{T} \setminus \mathcal{M}$, create a round containing b_l and b'_l along with a dummy job.
3. For each $x_i \in X$ (respectively $y_j \in Y, z_k \in Z$) not covered by \mathcal{M} , pack $a_{X,i}$ and $a'_{X,i}$ (respectively $a_{Y,j}, a'_{Y,j}$ and $a_{Z,k}, a'_{Z,k}$) together with one dummy job in one round.

► **Lemma 5.** *If $|OPT_{3DM}| \geq \beta(q)$ then the constructed solution is feasible and it uses at most $5q - 3\beta(q)$ rounds.*

Proof. One can easily check that all constructed rounds are feasible. In step (1) we construct exactly $\beta(q)$ rounds. In step (2), we construct $|\mathcal{T}| - \beta(q) = 2q - \beta(q)$ rounds, since $|\mathcal{T}| = 2q$. In step (3), we construct $3|\mathcal{T} \setminus \mathcal{M}| = 3q - 3|OPT_{3DM}|$ rounds. Hence, overall we construct at most $5q - 3|OPT_{3DM}| \leq 5q - 3\beta(q)$ rounds. ◀

Conversely, assume that $|OPT_{3DM}| < \alpha(q)$ and that we are given any feasible solution to our constructed instance. We want to show that it uses at least $5q - 3\beta(q) + \frac{1}{7}(\beta(q) - \alpha(q))$ rounds. For this, a key property of our construction is given in the following lemma.

► **Lemma 6.** *If a round contains a dummy job, then it can have at most three jobs: at most one dummy job, at most one job from $A \cup B$, and at most one job from $A' \cup B'$.*

Let n_g denote the number of nice rounds in our solution, n_d the number of rounds with a dummy job, and n_b the number of remaining rounds. Note that each of the latter rounds can contain at most 7 jobs each. Since all jobs in $A \cup A' \cup B \cup B'$ need to be assigned to a round, we have that $8n_g + 7n_b + 2n_d \geq 6q + 2|\mathcal{T}| = 10q$. Since the nice rounds correspond to a matching of the given instance of 2-B-3-DM, we have that $n_g \leq \alpha(q)$. Using this, we lower-bound the number of used rounds in the following lemma.

► **Lemma 7.** *If $|OPT_{3DM}| < \alpha(q)$ then the number of rounds in our solution is $n_d + n_g + n_b \geq (5q - 3\beta(q)) + \frac{1}{7}(\beta(q) - \alpha(q))$.*

Proof. Since $8n_g + 7n_b + 2n_d \geq 6q + 2|\mathcal{T}| = 10q$ and $n_d = 5q - 4\beta(q)$, we obtain that $8n_g + 7n_b \geq 8\beta(q)$. Thus $n_g + n_b \geq \frac{8}{7}\beta(q) - \frac{1}{7}n_g$. Since $n_g \leq \alpha(q)$ the number of rounds is at least $n_d + n_g + n_b \geq 5q - 4\beta(q) + \frac{8}{7}\beta(q) - \frac{1}{7}\alpha(q) = (5q - 3\beta(q)) + \frac{1}{7}(\beta(q) - \alpha(q))$. ◀

Now Lemmas 5 and 7 yield our main theorem.

► **Theorem 8.** *There exists a constant $\delta_0 > 1/1398$, such that it is NP-hard to approximate ROUND-UFP and ROUND-SAP in the case of uniform edge capacities with an asymptotic approximation ratio less than $1 + \delta_0$.*

4 Algorithms for Uniform Capacity Case

In this section, we provide asymptotic $(2 + \varepsilon)$ -approximation for ROUND-SAP and ROUND-UFP for the case of uniform edge capacities.

We distinguish two cases, depending on the value of $d_{\max} := \max_{j \in J} d_j$ compared to L .

4.1 Case 1: $d_{\max} \leq \varepsilon^7 L$

First, we invoke an algorithm from [11] for the dynamic storage allocation (DSA) problem. Recall that in DSA the input consists of a set of jobs like in ROUND-SAP and ROUND-UFP, but without upper bounds of the edge capacities. Instead, we seek to define a height h_j for each job j such that the resulting rectangles for the jobs are non-overlapping and the *makespan* $\max_j(h_j + d_j)$ is minimized. The maximum load L is defined as in our setting.

We invoke the following theorem on our input jobs J with $\delta := \varepsilon$.

► **Theorem 9** ([11]). *Assume that we are given a set of jobs J' such that $d_j \leq \delta^7 L$ for each job $j \in J'$. Then there exists an algorithm that produces a DSA packing of J' with makespan at most $(1 + \kappa\delta)L$, where $\kappa > 0$ is some global constant independent of δ .*

Let ξ denote the makespan of the resulting solution to DSA and let c^* denote the (uniform) edge capacity. For each $h \in \mathbb{R}$, we define the horizontal line $\ell_h := \mathbb{R} \times \{h\}$. A job j is said to be *sliced* by ℓ_h if for the computed packing of the jobs it holds that $h_j < h < h_j + d_j$. Now we will transform this into ROUND-SAP or ROUND-UFP packing.

We define a set of rounds Γ_1 . The set Γ_1 contains a round for each integer i with $0 \leq i \leq \lfloor \xi/c^* \rfloor$ and this round contains all jobs lying between ℓ_{ic^*} and $\ell_{(i+1)c^*}$. In this case, we define *congestion* $r = \lceil L/c^* \rceil$ (clearly, $r \leq OPT_{UFP} \leq OPT_{SAP}$). Thus, $|\Gamma_1| \leq \lfloor (1 + \kappa\varepsilon)L/c^* \rfloor + 1 \leq (1 + \kappa\varepsilon)r + 1$. There are two subcases.

Subcase A: Assume that $r > 1/(2\kappa\varepsilon)$. In this case $|\Gamma_1| \leq (1 + 3\kappa\varepsilon)r$. We define a set of rounds Γ_2 as follows. For each integer i with $1 \leq i \leq \lfloor \xi/c^* \rfloor$, Γ_2 has a round containing all jobs that are sliced by ℓ_{ic^*} . Thus $|\Gamma_2| \leq \lfloor (1 + \kappa\varepsilon)L/c^* \rfloor \leq (1 + \kappa\varepsilon)r$. Hence, the total number of rounds is bounded by $(2 + 4\kappa\varepsilon)r \leq (2 + O(\varepsilon))OPT_{UFP} \leq (2 + O(\varepsilon))OPT_{SAP}$.

71:10 Approximation Algorithms for Round-UFP and Round-SAP

Subcase B: Assume that $r \leq 1/(2\kappa\varepsilon)$. Now $\xi \leq (1+\kappa\varepsilon)L$, and therefore $\xi - L \leq \kappa\varepsilon L \leq c^/2$. Hence, we have $|\Gamma_1| \leq r + 1$ and the $(r + 1)^{\text{th}}$ round is filled up to a capacity of at most $c^*/2$ on each edge. Now the total load of the set of jobs that are sliced by $(\ell_{ic^*})_{1 \leq i \leq r}$ is at most $r \cdot \varepsilon^7 L$. We now invoke the following result on DSA to this set of jobs.*

► **Theorem 10** ([30]). *Let J' be a set of jobs with load L . Then a DSA packing of J' of makespan at most $3L$ can be computed in polynomial time.*

Thus the makespan of the computed solution is at most $3r \cdot \varepsilon^7 L \leq 3 \cdot \frac{1}{2\kappa\varepsilon} \cdot \varepsilon^7 \cdot \frac{c^*}{2\kappa\varepsilon} \leq c^*/2$, if ε is small enough. Hence these jobs can be added to the $(r + 1)^{\text{th}}$ round of Γ_1 . Therefore, we get a packing of J using at most $r + 1 \leq OPT_{UFP} + 1 \leq OPT_{SAP} + 1$ rounds.

4.2 Case 2: $d_{\max} > \varepsilon^7 L$

For this case, we have $c^* \geq d_{\max} > \varepsilon^7 L$ and therefore $r = \lceil L/c^* \rceil \leq 1/\varepsilon^7$. We partition the input jobs into *large* and *small* jobs by defining $J_{\text{large}} := \{j \in J \mid d_j > \varepsilon^{56} L\}$ and $J_{\text{small}} := \{j \in J \mid d_j \leq \varepsilon^{56} L\}$.

We start with the small jobs J_{small} . First, we apply Theorem 9 to them with $\delta := \varepsilon^8$ and obtain a DSA packing \mathcal{P} for them. We transform it into a solution to ROUND-SAP with at most $r + 1$ rounds as follows: we introduce a set Γ_1 consisting of $r + 1$ rounds exactly as in the previous case (when $r \leq 1/(2\kappa\varepsilon)$). The $(r + 1)^{\text{th}}$ round would be filled up to a capacity of at most $\kappa\varepsilon^8 L \leq \kappa\varepsilon c^*$. Again applying Theorem 10 to the remaining jobs, we get a DSA packing of makespan at most $3r \cdot \varepsilon^{56} L \leq 3 \cdot (1/\varepsilon^7) \cdot \varepsilon^{56} \cdot (c^*/\varepsilon^7) \leq c^*/2$, and therefore these jobs can be packed inside the $(r + 1)^{\text{th}}$ round. Hence, there exists a packing of J_{small} using at most $r + 1 \leq OPT_{UFP} + 1 \leq OPT_{SAP} + 1$ rounds.

Now we consider the large jobs J_{large} . Our strategy is to compute an optimal solution for them via dynamic programming (DP). Intuitively, our DP orders the jobs in J_{large} non-decreasingly by their respective source vertices and assigns them to the rounds in this order. Since the jobs are large, each edge is used by at most $1/\varepsilon^{56}$ large jobs, and using interval coloring one can show easily that at most $1/\varepsilon^{56} = O_\varepsilon(1)$ rounds suffice (e.g., we can color the jobs with $1/\varepsilon^{56}$ colors such that no two jobs with intersecting paths have the same color). This already gives a packing into at most $(2 + \varepsilon)OPT_{UFP} + O_\varepsilon(1)$ rounds. However, our DP will return an improved packing with at most $(2 + \varepsilon)OPT_{UFP} + 1$ rounds. In our DP we have a cell for each combination of an edge e and the assignment of all jobs passing through e to the rounds. Given this, the corresponding subproblem is to assign additionally all jobs to the rounds whose paths lie completely on the right of e .

For ROUND-SAP we additionally want to bound the number of possible heights h_j . To this end, we restrict ourselves to packings that are normalized which intuitively means that all jobs are pushed up as much as possible. Formally, we say that a packing for a set of jobs J' inside a round is *normalized* if for every $j \in J'$, either $h_j + d_j = c^*$ or $h_j + d_j = h_{j'}$ for some $j' \in J'$ such that $P_j \cap P_{j'} \neq \emptyset$.

► **Lemma 11.** *Consider a valid packing of a set of jobs $J' \subseteq J_{\text{large}}$ inside one round. Then there is also a packing for J' that is normalized.*

Now the important insight is that in a normalized packing of large jobs, the height h_j of a job j is the difference of (the top height level) c^* and the sum of at most $1/\varepsilon^{56}$ jobs in J_{large} . Thus, the number of possible heights is bounded by $n^{O(1/\varepsilon^{56})}$ and we can compute all these possible heights before starting our DP.

► **Lemma 12.** *Given J_{large} we can compute a set \mathcal{H} of $n^{O(1/\varepsilon^{56})}$ values such that in any normalized packing of a set $J' \subseteq J_{\text{large}}$ inside one round, the height h_j of each job $j \in J'$ is contained in \mathcal{H} .*

Now we can compute the optimal packing via a dynamic program as described above, which yields the following lemma.

► **Lemma 13.** *Consider an instance of ROUND-UFP or ROUND-SAP with a set of jobs J' satisfying the following conditions:*

(i) *The number of jobs using any edge is bounded by ω .*

(ii) *In the case of ROUND-SAP there is a given set \mathcal{H}' of allowed heights for the jobs.*

Then we can compute an optimal solution to the given instance in time $(n|\mathcal{H}'|)^{O(\omega)}$.

We invoke Lemma 13 with $J' := J_{\text{large}}$, $\omega = 1/\varepsilon^{56}$, and in the case of ROUND-SAP we define \mathcal{H}' to be the set \mathcal{H} due to Lemma 12. This yields at most OPT_{UFP} rounds in total for the large jobs J_{large} . Hence, we obtain a packing of J using at most $2 \cdot OPT_{UFP} + 1$ rounds.

Case 1 and 2 together imply a packing into at most $(2 + \varepsilon)OPT_{UFP} + 1$ rounds. This yields our main theorem for the case of uniform edge capacities.

► **Theorem 14.** *For any $\varepsilon > 0$, there exist asymptotic $(2 + \varepsilon)$ -approximation algorithms for ROUND-SAP and ROUND-UFP, assuming uniform edge capacities.*

We now derive some bounds on the absolute approximation ratios. If $OPT_{SAP} = 1$, our algorithm would return a packing using at most $(2 + \varepsilon) \cdot 1 + 1$ rounds, and hence at most 3 rounds. If $OPT_{SAP} \geq 2$, then our algorithm uses at most $(2 + \varepsilon) \cdot OPT_{SAP} + OPT_{SAP}/2 = (2.5 + \varepsilon)OPT_{SAP}$ rounds. Hence, we obtain the following result.

► **Theorem 15.** *There exists a polynomial time 3-approximation algorithm for ROUND-SAP, assuming uniform edge capacities.*

For ROUND-UFP, it is easy to check whether $OPT_{UFP} = 1$ by checking whether $L \leq c^*$. Otherwise, $OPT_{UFP} \geq 2$ and similar as above, the number of rounds used would be at most $(2.5 + \varepsilon) \cdot OPT_{UFP}$. This gives an improvement over the result of Pal [49].

► **Theorem 16.** *For any $\varepsilon > 0$, there exists a polynomial time $(2.5 + \varepsilon)$ -approximation algorithm for ROUND-UFP, assuming uniform edge capacities.*

5 General Case

In this section, we present our algorithms for the general cases of ROUND-UFP and ROUND-SAP. We begin with our $O(\log \log \min\{n, m\})$ -approximation algorithms where we consider ROUND-UFP first and describe later how to extend our algorithm to ROUND-SAP. We split the input jobs into large and small jobs. For each job j , we denote by \mathbf{b}_j the minimum capacity of the edges in P_j , i.e., $\min\{c_e : e \in P_j\}$. We call \mathbf{b}_j the *bottleneck capacity* of the job j . We define $J_{\text{large}} := \{j \in J \mid d_j > \mathbf{b}_j/4\}$ and $J_{\text{small}} := \{j \in J \mid d_j \leq \mathbf{b}_j/4\}$. For the small jobs, we invoke a result by Elbassioni et al. [21] that yields a 16-approximation.

► **Theorem 17 ([21]).** *We are given an instance of ROUND-UFP with a set of jobs J' such that $d_j \leq \frac{1}{4}\mathbf{b}_j$ for each job $j \in J'$. Then there is a polynomial time algorithm that computes a 16-approximate solution to J' .*

■ **Figure 2** (a) The capacity profile along with the sets of lines \mathcal{H} and \mathcal{V} and some top-drawn jobs; (b) The jobs after processing;

Now consider the large jobs J_{large} . For each job $j \in J_{\text{large}}$, we define a rectangle $R_j = (s_j, \mathbf{b}_j - d_j) \times (t_j, \mathbf{b}_j)$. Note that R_j corresponds to the rectangle for j in ROUND-SAP if we assign j the maximum possible height h_j (which is $h_j := \mathbf{b}_j - d_j$). We say that a set of jobs $J' \subseteq J_{\text{large}}$ is *top-drawn* (underneath the capacity profile), if their rectangles are pairwise non-overlapping, i.e., if $R_j \cap R_{j'} = \emptyset$ for any $j, j' \in J'$. If a set of jobs J' is top-drawn, then it clearly forms a feasible round in ROUND-UFP. However, not every feasible round of ROUND-UFP is top-drawn. Nevertheless, we look for a solution to ROUND-UFP in which the jobs in each round are top-drawn. The following lemma implies that this costs only a factor of 8 in our approximation ratio.

► **Lemma 18** ([10]). *Let $J' \subseteq J_{\text{large}}$ be a set of jobs packed in a feasible round for a given instance of ROUND-UFP. Then J' can be partitioned into at most 8 sets such that each of them is top-drawn.*

Let $\mathcal{R}_{\text{large}} := \{R_j | j \in J_{\text{large}}\}$ denote the rectangles corresponding to the large jobs and let ω_{large} be their clique number, i.e., the size of the largest set $\mathcal{R}' \subseteq \mathcal{R}_{\text{large}}$ such that all rectangles in \mathcal{R}' pairwise overlap. As a consequence of Helly's theorem³ for such a set of axis-parallel rectangles \mathcal{R}' there must be a point in which all rectangles in \mathcal{R}' overlap. Note that we need at least ω_{large} rounds since we seek a solution with only top-drawn jobs in each round.

We first reduce the original instance to the case where there are only $O(m^2)$ many distinct job demands. For each $i \in \{1, \dots, m\}$, let p_i denote the point (i, c_{e_i}) . We draw a horizontal and a vertical line segment passing through p_i and lying completely under the capacity profile (see Figure 2(a)). This divides the region underneath the capacity profile into at most m^2 regions. Let \mathcal{H} denote the set of horizontal lines and \mathcal{V} denote the set of vertical lines drawn. Thus, the top edge of any rectangle corresponding to a large job must touch a line in \mathcal{H} . Now consider any rectangle R_j corresponding to a job j . Let $h \in \mathcal{H}$ be the horizontal line segment lying just below the bottom edge of R_j . We increase the value of d_j so that the the bottom edge of R_j now touches the line segment h (see Figure 2(b)). Since the rectangles were top-drawn, the clique number of this new set of large rectangles (denoted by $\mathcal{R}'_{\text{large}}$) does not change. Also any feasible packing of $\mathcal{R}'_{\text{large}}$ is a feasible packing of $\mathcal{R}_{\text{large}}$.

Note that $\mathcal{R}'_{\text{large}}$ contains at most m^4 distinct types of jobs: the endpoints s_j and t_j can be chosen in $\binom{m+1}{2} \leq m^2$ ways and the top and bottom edges of R_j must coincide with two lines from \mathcal{H} , which can be again chosen in $\binom{m}{2} \leq m^2$ ways. Let U denote the number of types of job of the given instance and let $\mathcal{R}'_{\text{large}} = J_1 \cup J_2 \cup \dots \cup J_U$ be the decomposition of $\mathcal{R}'_{\text{large}}$ into the U distinct job types.

³ Project the family of rectangles onto both x and y dimensions. These projections are intervals that are pairwise intersecting. Helly's theorem states that a pairwise intersecting set of intervals share a common point. Then the product of each of these 1 dimensional common intersections is shared by each of the rectangles.

We now formulate the configuration LP for this instance. Let \mathcal{C} denote the set of all possible configurations of a round containing jobs from $\mathcal{R}'_{\text{large}}$, drawn as top-drawn sets. For each $C \in \mathcal{C}$, we introduce a variable x_C , which stands for the number of rounds having configuration $C \in \mathcal{C}$. We write $J_k \triangleleft C$ if configuration C contains a job from J_k (note that C can contain at most one job from J_k). Then the relaxed configuration LP and its dual (which contains a variable y_k for each set J_k) are as follows.

$$\begin{array}{ll} \text{minimize} & \sum_{C \in \mathcal{C}} x_C \\ \text{subject to} & \sum_{C: J_k \triangleleft C} x_C \geq |J_k|, \quad k = 1, \dots, U \\ & x_C \geq 0, \quad C \in \mathcal{C} \end{array} \quad \begin{array}{ll} \text{maximize} & \sum_{k=1}^U |J_k| y_k \\ \text{subject to} & \sum_{k: J_k \triangleleft C} y_k \leq 1, \quad C \in \mathcal{C} \\ & y_k \geq 0, \quad k = 1, \dots, U \end{array}$$

The dual LP can be solved via the ellipsoid method with a suitable separation oracle. We interpret y_k as the weight of each job in J_k . Given $(y_k)_{k \in \{1, \dots, U\}}$, the separation problem asks whether there exists a configuration where jobs are drawn as top-drawn sets and the total weight of all the jobs in the configuration exceeds 1. For this, we invoke the following result of Bonsma et al. [10].

► **Theorem 19** ([10]). *Given an instance of UFP with a set of jobs J' , the maximum-weight top-drawn subset of J' can be computed in $O(nm^3)$ time.*

Let $(x_C^*)_{C \in \mathcal{C}}$ be an optimal basic solution of the primal LP. By the rank lemma, there are at most U configurations C for which x_C^* is non-zero. For each non-zero x_C^* , we introduce $\lfloor x_C^* \rfloor$ rounds with configuration C , thus creating at most $8 \cdot OPT_{UFP}$ rounds (due to Lemma 18). Now let $\mathcal{R}''_{\text{large}} \subseteq \mathcal{R}'_{\text{large}}$ be the large jobs that are yet to be packed and let ω''_{large} be their clique number (and note that $\omega''_{\text{large}} \leq 8 \cdot OPT_{UFP}$). In particular, a feasible solution to the configuration LP for the rectangles in $\mathcal{R}''_{\text{large}}$ is to select one more round for each configuration C with $x_C^* > 0$. Therefore, we conclude that $\omega''_{\text{large}} \leq U \leq m^4$ since there are at most U configurations C with $x_C^* > 0$ and for each point, each configuration contains at most one rectangle covering this point.

Our strategy is to invoke the following theorem on $\mathcal{R}''_{\text{large}}$.

► **Theorem 20** ([12]). *Given a set of rectangles with clique number ω , in polynomial time, we can compute a coloring of the rectangles using $O(\omega \log \omega)$ colors such that no two rectangles of the same color intersect.*

Thus, if $\omega''_{\text{large}} = O(\log m)$ then we obtain an $O(\log \log m)$ -approximation as desired. However, it might be that ω''_{large} is larger. In that case, we partition $\mathcal{R}''_{\text{large}}$ into $\omega''_{\text{large}}/\log m$ sets, such that each of them has a clique size of $O(\log m)$.

► **Lemma 21.** *There is a randomized polynomial time algorithm that w.h.p. computes a partition $\mathcal{R}''_{\text{large}} = \mathcal{R}_1 \dot{\cup} \dots \dot{\cup} \mathcal{R}_{\omega''_{\text{large}}/\log m}$ such that for each set \mathcal{R}_i , the corresponding clique size is at most $O(\log m)$.*

Proof. We split the rectangles $\mathcal{R}''_{\text{large}}$ uniformly at random into $\omega''_{\text{large}}/\log m$ sets $\mathcal{R}_1, \dots, \mathcal{R}_{\omega''_{\text{large}}/\log m}$. Thus the expected clique size in each set \mathcal{R}_i at any point p under the profile is at most $\log m$. Using the Chernoff bound, the probability that the clique size at p is more than $8 \log m$ is at most $2^{-8 \log m} = 1/m^8$. As before, we draw the set of horizontal and vertical lines \mathcal{H} and \mathcal{V} , respectively, under the capacity profile, dividing the region underneath the profile into at most m^2 regions. Clearly, the clique number must

be the same at all points inside any such region. Thus the probability that there exists a point p under the capacity profile where the clique size is more than $8 \log m$ is at most $m^2/m^8 \leq 1/m^6$. Hence using union bound, probability that clique size is more than $8 \log m$ at some point in some set \mathcal{R}_i is at most $1/m^2$ (since $\omega''_{\text{large}} \leq m^4$). \blacktriangleleft

We apply Theorem 20 to each set \mathcal{R}_i separately and thus obtain a coloring with $O(\log m \log \log m)$ colors. Thus, for all sets \mathcal{R}_i together we use at most $\frac{\omega''_{\text{large}}}{\log m} O(\log m \log \log m) = O(\omega''_{\text{large}} \log \log m)$ colors. We pack the jobs from each color class to a separate round for our solution to ROUND-UFP. This yields an $O(\log \log m)$ -approximation, together with Theorem 17. Since $m \leq 2n - 1$ after our preprocessing, our algorithms are also $O(\log \log n)$ -approximation algorithms.

► **Theorem 22.** *There exists a randomized $O(\log \log \min\{n, m\})$ -approximation algorithm for ROUND-UFP for general edge capacities.*

In order to obtain an algorithm for ROUND-SAP, we invoke the following lemma due to [45] to each round of the computed solution to ROUND-UFP.

► **Lemma 23** ([45]). *Let J' be the set of jobs packed in a feasible round for a given instance of ROUND-UFP. Then in polynomial time we can partition J' into $O(1)$ sets and compute a height h_j for each job $j \in J'$ such that each set yields a feasible round of ROUND-SAP.*

This yields a solution to ROUND-SAP with only $O(OPT_{UFP} \log \log m) \leq O(OPT_{SAP} \log \log m)$ many rounds.

► **Theorem 24.** *There exists a randomized $O(\log \log \min\{n, m\})$ -approximation algorithm for ROUND-SAP for general edge capacities.*

5.1 An $O(\log \log \frac{1}{\delta})$ -approximation algorithm with $(1 + \delta)$ -resource augmentation

We show that if we are allowed a resource augmentation of a factor of $1 + \delta$ for some $\delta > 0$, we can get an $O(\log \log \frac{1}{\delta})$ -approximation for both ROUND-SAP and ROUND-UFP.

Consider ROUND-UFP first. Recall that \mathfrak{b}_j denotes the bottleneck capacity of job j , i.e. $\min\{c_e : e \in P_j\}$. For each $i \in \mathbb{N}$ we define the set $J^{(i)} := \{j \in J \mid \mathfrak{b}_j \in [1/\delta^i, 1/\delta^{i+1}]\}$ and consider one resulting set $J^{(i)}$. By definition no job in $J^{(i)}$ uses an edge whose capacity is less than $1/\delta^i$. Also, we can assume that the capacity of each edge is at most $2/\delta^{i+1}$ since for each edge e with a capacity of more than $1/\delta^{i+1}$, each jobs using it must also use the closest edge on the left or on the right of e with a capacity of at most $1/\delta^{i+1}$. Thus, in a feasible round, e is used by jobs from $J^{(i)}$ with a total demand of at most $2/\delta^{i+1}$. Thus, via scaling we can assume that the edge capacities are in the range $[1, 2/\delta)$ if our input consists of $J^{(i)}$ only.

► **Lemma 25.** *Let $J^{(i)} := \{j \in J \mid \mathfrak{b}_j \in [1/\delta^i, 1/\delta^{i+1}]\}$. For packing jobs in $J^{(i)}$, it can be assumed that the capacity of each edge lies in the range $[1/\delta^i, 2/\delta^{i+1})$.*

Hence using the following theorem, we get a $O(\log \log \frac{1}{\delta})$ -approximate solutions for each $J^{(i)}$, which in particular uses at most $O(OPT_{UFP} \log \log \frac{1}{\delta})$ rounds.

► **Theorem 26** ([35]). *There is a polynomial time $O(\log \log \frac{c_{\max}}{c_{\min}})$ -approximation algorithm for ROUND-UFP.*

Next, we argue that we can combine the rounds computed for the sets $J^{(i)}$. More precisely, we show that if we take one round from each set $J^{(0)}, J^{(2)}, J^{(4)}, \dots$ and form their union, then they form a feasible round for the given instance under $(1 + \delta)$ -resource augmentation: as argued above, each set $J^{(i)}$ uses at most a capacity of $2/\delta^{i+1}$ on each edge e in any feasible round. Also, if an edge e is used by a job from a set $J^{(i')}$ for an even $i' \in \mathbb{N}$ in a feasible round, then e has a capacity of at least $1/\delta^{i'}$. Therefore, if we have $(1 + 2\delta)$ -resource augmentation available, then by a geometric sum argument the gained capacity on e is enough for one round of each of the sets $J^{(i'-2)}, J^{(i'-4)}, J^{(i'-6)}, \dots$.

With a similar argumentation we can show that we obtain a feasible solution if we take one round from each set $J^{(1)}, J^{(3)}, J^{(5)}, \dots$.

► **Lemma 27.** *Take one computed round for each set $J^{(2k)}$ with $k \in \mathbb{N}$ or one computed round from each set $J^{(2k+1)}$ with $k \in \mathbb{N}$, and let J' be their union. Then J' is a feasible round for the given instance of ROUND-UFP under $(1 + \delta)$ -resource augmentation.*

Thus, due to Lemma 27 we obtain a solution with at most $O(OPT_{UFP} \log \log \frac{1}{\delta})$ rounds for the overall instance. As earlier, we take the given ROUND-UFP solution and apply Lemma 23 to it, which yields a solution to ROUND-SAP with at most $O(OPT_{SAP} \log \log \frac{1}{\delta})$ rounds.

► **Theorem 28.** *There exists an $O(\log \log \frac{1}{\delta})$ -approximation algorithm for ROUND-SAP and ROUND-UFP for general edge capacities and $(1 + \delta)$ -resource augmentation.*

6 Algorithms for the no-bottleneck-assumption

In this section, we present a $(16 + \varepsilon)$ -approximation algorithm for ROUND-SAP and a 12-approximation for ROUND-UFP, both under the no-bottleneck-assumption (NBA).

6.1 Algorithm for Round-SAP

For our algorithm for ROUND-SAP under NBA, we first scale down all job demands and edge capacities so that $c_{\min} := \min_{e \in E} c_e = 1$ (note that this implies that $d_j \leq 1$ for each job $j \in J$). Then, we scale down all edge capacities to the nearest power of 2 and let $(c'_e)_{e \in E}$ denote the new edge capacities. Define a set of horizontal lines $\mathcal{L} := \{\ell_{2^k} | k \in \mathbb{N}\}$. Let OPT'_{SAP} denote the optimal solution for the rounded down capacities $(c'_e)_{e \in E}$ under the additional constraint that there must be no job whose rectangle intersects a line in \mathcal{L} .

It can be shown that given a valid ROUND-SAP packing \mathcal{P} of a set of jobs J' for the edge capacities $(c_e)_{e \in E}$, there exists a valid packing of J' into 4 rounds $\mathcal{R}^1, \mathcal{R}^2, \mathcal{R}^3, \mathcal{R}^4$, under profile $(c'_e)_{e \in E}$ such that no job is sliced by a line in \mathcal{L} . This implies that $OPT'_{SAP} \leq 4 \cdot OPT_{SAP}$.

We shall now obtain a valid packing of J for the edge capacities $(c'_e)_{e \in E}$. Let $c'_{\max} := \max_{e \in E} c'_e$ and for each $i \in \{0, 1, \dots, \log c'_{\max}\}$ let $J^{(i)} \subseteq J$ denote the set of jobs with bottleneck capacity 2^i according to $(c'_e)_{e \in E}$. For each set $J^{(i)}$ we create a new (artificial) instance with uniform edge capacities: in the instance for $J^{(0)}$ all edges have capacity 1, and for each $i \in \{1, 2, \dots, \log c'_{\max}\}$ in the instance for $J^{(i)}$ all edges have capacity 2^{i-1} . For each $i \in \{0, 1, 2, \dots, \log c'_{\max}\}$, denote by $OPT^{(i)}$ the number of rounds needed in the optimal solution to the instance for $J^{(i)}$. Since in the solution OPT'_{SAP} , no rectangle is intersected by a line in \mathcal{L} , for each set $J^{(i)}$ we can easily rearrange the jobs in $J^{(i)}$ in OPT'_{SAP} such that we obtain a solution for $J^{(i)}$ with at most $2 \cdot OPT'_{SAP}$ rounds.

For each set $J^{(i)}$ we invoke our asymptotic $(2 + \varepsilon)$ -approximation algorithm for ROUND-SAP for uniform edge capacities (see Section 4) and obtain a solution $\Gamma^{(i)}$ which hence uses $\Gamma^{(i)} \leq (2 + \varepsilon) \cdot OPT^{(i)} + 1 \leq (4 + O(\varepsilon)) \cdot OPT'_{SAP} + 1 \leq (16 + O(\varepsilon)) \cdot OPT_{SAP} + 1$ rounds. Finally, we combine the solutions $\Gamma^{(i)}$ for all $i \in \{0, 1, 2, \dots, \log c'_{\max}\}$ to one global solution of J , which uses at most $\max^{(i)} \{\Gamma^{(i)}\}$ many rounds. Hence we have the following theorem.

► **Theorem 29.** *For any $\varepsilon > 0$, there exists a polynomial-time asymptotic $(16 + \varepsilon)$ -approximation and an absolute 17-approximation algorithm for ROUND-SAP under the NBA.*

6.2 Algorithm for Round-UFP

In this section, we present a 12-approximation for ROUND-UFP under NBA. In ROUND-UFP, it is not clear how to bootstrap the algorithm for the uniform case as we did for ROUND-SAP, since in the optimal solution it might not be possible to draw the jobs as non-overlapping rectangles. Instead, our algorithm refines combinatorial properties from [21] to obtain an improved approximation ratio.

For any edge e , we define the *congestion* $r_e := \lceil l_e/c_e \rceil$, and $r = \max_e r_e$ denotes the maximum congestion of any edge of the path. A result in [48] states that for the special case when all jobs have identical demands and all edge capacities are integral multiples of the demand, a ROUND-UFP packing using r rounds can be found efficiently.

Via scaling, we assume that $c_{\min} = 1$ and the demand of each job is at most 1. Let $J_{\text{large}} := \{j \in J \mid d_j > 1/2\}$ and $J_{\text{small}} := J \setminus J_{\text{large}}$. For jobs in J_{large} , applying the result due to [48] after scaling up all the demands to 1 and scaling down the capacity of each edge to the nearest integer directly yields a packing using at most $4r$ rounds.

Now for each job $j \in J_{\text{small}}$, we round up its demand to the next larger power of $1/2$. For each $i \in \mathbb{N}$, let $J^{(i)}$ denote the set of jobs whose demands after rounding equal $\frac{1}{2^i}$. For each edge e and each $i \in \mathbb{N}$, we define $n_{e,i} := |\{j \in J^{(i)} \mid e \in P_j\}|$. We partition each set $J^{(i)}$ into the sets $J'^{(i)} = \{j \in J^{(i)} \mid \exists e \in P_j : n_{e,i} < 2r\}$ and $J''^{(i)} = J \setminus J'^{(i)}$. Let $n'_{e,i} := |\{j \in J'^{(i)} \mid e \in P_j\}|$ and $n''_{e,i} := |\{j \in J''^{(i)} \mid e \in P_j\}|$. Clearly, $n'_{e,i} < 4r$ for each edge e and each i .

Since there are at most $4r$ jobs from each $J'^{(i)}$ over any edge, the jobs in $\bigcup_i J'^{(i)}$ can be easily packed into $4r$ rounds using interval coloring. For the jobs in $\bigcup_i J''^{(i)}$, we partition the available capacity inside each round among the sets $J''^{(i)}$; formally for each edge e , we reserve a capacity of $\frac{1}{2^i} \cdot \lfloor \frac{n_{e,i}}{2r} \rfloor$ for $J''^{(i)}$ (note $\sum_i \frac{1}{2^i} \lfloor \frac{n_{e,i}}{2r} \rfloor \leq c_e$). The resulting congestion of any edge having non-zero capacity is $\frac{\frac{1}{2^i} n''_{e,i}}{\frac{1}{2^i} \lfloor \frac{n_{e,i}}{2r} \rfloor} \leq \frac{\frac{n_{e,i}}{2r}}{\lfloor \frac{n_{e,i}}{2r} \rfloor} \cdot 2r \leq 4r$. Thus using the algorithm due to [48], jobs in $J''^{(i)}$ can be packed into at most $4r$ rounds with these capacities. Hence we obtain a valid packing of J_{small} using at most $4r + 4r = 8r$ rounds.

We thus have the following theorem.

► **Theorem 30.** *There exists a polynomial-time 12-approximation algorithm for ROUND-UFP under the NBA.*

7 Algorithms for Round-Tree

Extending the results for ROUND-UFP, using results on path coloring [24] and multicommodity demand flow [14], we obtain the following results for ROUND-TREE (we refer the reader to the full version of this paper for details).

► **Theorem 31.** *For ROUND-TREE, there exists a polynomial-time asymptotic (resp. absolute) 5.1- (resp. 5.5-) approximation algorithm for uniform edge capacities and an asymptotic (resp. absolute) 49- (resp. 55-) approximation algorithm for the general case under the NBA.*

Abstract

Network flow is one of the most studied combinatorial optimization problems having innumerable applications. Any flow on a directed acyclic graph G having n vertices and m edges can be decomposed into a set of $O(m)$ paths. The applications of such a flow decomposition range from network routing to the assembly of biological sequences. However, in some applications, each solution (decomposition) corresponds to some particular data that generated the original flow. Given the possibility of multiple optimal solutions, no optimization criterion ensures the identification of the correct decomposition. Hence, recently flow decomposition was studied [RECOMB22] in the Safe and Complete framework, particularly for RNA Assembly. The proposed solution reported *all* the *safe* paths, i.e., the paths which are subpath of every possible solution of flow decomposition.

They presented a characterization of the safe paths, resulting in an $O(mn + out_R)$ time algorithm to compute all safe paths, where out_R is the size of the raw output reporting each safe path explicitly. They also showed that out_R can be $\Omega(mn^2)$ in the worst case but $O(m)$ in the best case. Hence, they further presented an algorithm to report a concise representation of the output out_C in $O(mn + out_C)$ time, where out_C can be $\Omega(mn)$ in the worst case but $O(m)$ in the best case.

In this work, we study how different safe paths interact, resulting in optimal output-sensitive algorithms requiring $O(m + out_R)$ and $O(m + out_C)$ time for computing the existing representations of the safe paths. Our algorithm uses a novel data structure called *Path Tries*, which may be of independent interest. Further, we propose a new characterization of the safe paths resulting in the *optimal* representation of safe paths out_O , which can be $\Omega(mn)$ in the worst case but requires optimal $O(1)$ space for every safe path reported. We also present a near-optimal algorithm to compute all the safe paths in $O(m + out_O \log n)$ time. The new representation also establishes tighter worst case bounds $\Theta(mn^2)$ and $\Theta(mn)$ bounds for out_R and out_C (along with out_O), respectively.

Overall we further develop the theory of safe and complete solutions for the flow decomposition problem, giving an optimal algorithm for the explicit representation, and a near-optimal algorithm for the optimal representation of the safe paths.

1 Introduction

Network flow is one of the most studied problems in theoretical computer science with innumerable applications. For a flow network with a unique source s and a unique sink t , every valid flow can be decomposed into a set of weighted s - t paths and cycles [7]. For a directed acyclic graph (DAG) such a decomposition contains only paths. Such path (and cycle) view of a flow indicates how information optimally passes from s to t , being a key step in network routing problems (e.g. [10, 6, 9, 15]), transportation problems (e.g. [16, 17]), or in the more recent and prominent application of reconstructing biological sequences (*RNA transcripts*, see e.g. [18, 23, 8, 5, 22, 27], or *viral quasi-species genomes*, see e.g. [2, 1]).

Finding the minimum flow decomposition (i.e., having the minimum number of paths and cycles) is NP-hard, even if the flow network is a DAG [25]. This hardness result led to research on approximation algorithms [9, 21, 19, 15, 3], and FPT algorithms [12]. Practical approaches usually employ the standard *greedy width* heuristic [25], repeatedly removing an s - t path carrying the most amount of flow. Recently, another pseudo-polynomial-time heuristic was proposed [20] for biological data, which tries to iteratively simplify the graph such that the flow decomposition problem can be solved locally at some vertices.

In the routing and transportation applications, an optimal flow decomposition indicates how to send some information from s to t , and thus any optimal decomposition is satisfactory. However, this is not the case in the prominent application of reconstructing biological sequences, since each flow path represents a reconstructed sequence: a different optimal set of flow paths encodes different biological sequences, which may differ from the real ones. For a concrete example, consider the following application. In complex organisms, a gene may produce more RNA molecules (*RNA transcripts*, i.e., strings over an alphabet of four characters), each having a different abundance. Currently, given a sample, one can read the RNA transcripts and find their abundances using *high-throughput sequencing* [26]. This technology produces short overlapping substrings of the RNA transcripts. The main approach for recovering the RNA transcripts from such data is to build an edge-weighted DAG from these fragments and to transform the weights into flow values by various optimization criteria, and then to decompose the resulting flow into an “optimal” set of weighted paths (i.e., the RNA transcripts and their abundances in the sample) [14]. Clearly, if there are multiple optimal flow decomposition solutions, then the reconstructed RNA transcripts may not match the original ones, and thus be incorrect. Thus, the best possible solution is to find *whatever* can be *safely* reported as being *correct*.

1.1 Problem Definition and Related Work

Recently, Ma et al. [13] were the first to address the issue of multiple solutions to the flow decomposition problem, under a probabilistic framework. Later, they [28] solve a problem (*AND-Quant*), which, in particular, leads to a quadratic-time algorithm for the following problem: given a flow in a DAG, and edges e_1, e_2, \dots, e_k , decide if in *every* flow decomposition there is always a decomposed flow path passing through all of e_1, e_2, \dots, e_k . Thus, by taking the edges e_1, e_2, \dots, e_k to be the edges of a path p , the AND-Quant problem can decide if a path p (i.e., a given biological sequence) appears in all flow decompositions. This indicates that p is likely part of some original RNA transcript.

Another popular approach to address the issue of multiple solutions is the *safety* framework, which was introduced by Tomescu and Medvedev [24] for the genome assembly problem from bioinformatics. For a problem admitting multiple solutions, a partial solution is said to be *safe* if it appears in all solutions to a problem. For the flow decomposition problem, a

path p is safe if for *any* flow decomposition into paths $\mathcal{P} = \{p_1, \dots, p_k\}$, it holds that p is a subpath of some p_i . Considering the weight, a path p is further called *w-safe* if, in *any* flow decomposition, p is a subpath of some path(s) in \mathcal{P}_f whose total weight is at least w .

Khan et al. [11] built upon the AND-Quant problem by addressing flow decomposition under the *safety* framework. They presented a local characterization of safe flow paths as compared to the global characterization of AND-Quant. It was directly adaptable to give an optimal verification algorithm, and a simple enumeration algorithm enumerating all safe paths in $O(mn + out)$ time by applying the characterization on a candidate flow decomposition using the standard *two pointer algorithm*¹. They presented the maximal safe paths out in two formats, the raw output out_R reported each safe path explicitly, and a concise representation out_C which combined the safe paths occurring contiguously in the candidate flow decomposition. Using a worst case example they also proved that the size of out_R can be $\Omega(mn^2)$ in the worst case and $O(m)$ in the best case, whereas that of out_C can be $\Omega(mn)$ in the worst case and $O(m)$ in the best case. However, in their solution the concise representation of the solution depends on the underlying candidate solution used, which hence does not optimize the concise representation. Moreover, they did not address whether the concise representation is the most succinct approach to represent the safe paths.

1.2 Our results

Our main contributions can be described as follows:

1. **Merge-Diverge Property of safe paths.** We develop the theory of safe paths for flow decomposition further by studying the conditions for interaction of safe paths. We prove that two safe paths cannot *merge* at a vertex (or a set of vertices) and later *diverge*.
2. **Optimal output-sensitive enumeration algorithms for the current representations.** We use the *merge-diverge* property to present optimal output-sensitive algorithms for enumerating all safe paths explicitly in $O(m + out_R)$ time and their optimal concise representation in $O(m + out_C)$ time. Our algorithms uses a novel application of the Trie on paths, referred as *Path Tries* which may be of independent interest.
3. **Optimal representation of safe paths.** We present a novel characterization of safe paths out_O allowing us to represent a safe path optimally, requiring $O(1)$ space for every reported path.
 - **Remark 1.** In the worst case both concise representation out_C [11] and our optimal representation out_O may require $\Omega(mn)$ space, however space required per reported path can be much larger for out_C than the optimal $O(1)$ of out_O .
4. **Near optimal algorithm for the optimal output format.** We present an algorithm to report all safe paths using the optimal representation in $O(m + out_O \log n)$ time.
5. **Tighter worst case bounds on out_R and out_C .** Our characterization allows us to prove matching upper bounds for the worst case lower bounds [11] on out_R and out_C .

2 Preliminary

Consider a directed acyclic flow graph $G = (V, E)$ with $|V| = n$ vertices and $|E| = m$ edges, where each edge e has a flow (or weight) $f(e)$ passing through it. For simplicity we assume the graph is connected giving $m \geq n - 1$. For each vertex u , $f_{in}(u)$ and $f_{out}(u)$ denotes the

¹ Along a sample solution, the keeping the left end at the start, the right end is moved along the solution as long as the path is safe (evaluated using verification algorithm). This is reported as a maximal safe. Then right end is extended by an edge making the path unsafe, followed by moving the left pointer right until it is safe again. The process is repeated to report the next maximal safe path, and so on.

total flow on its incoming edges and total flow on its outgoing edges, respectively. A vertex v in the graph is called a *source* if $f_{in}(v) = 0$ and a *sink* if $f_{out}(v) = 0$. The set of sources and sinks of the graph G is denoted by $Source(G)$ and $Sink(G)$ respectively. Every other vertex v satisfies the *conservation of flow* $f_{in}(v) = f_{out}(v)$, making the graph a *flow graph*.

For the vertex u , $f_{max}(\cdot, u)$ (or $f_{max}(u, \cdot)$) denotes the maximum value of flow on the incoming edges (or outgoing edges) of u . The corresponding edge is represented by $e_{max}(\cdot, u)$ (or $e_{max}(u, \cdot)$) and its other endpoint (except u) is represented by $v_{max}(\cdot, u)$ (or $v_{max}(u, \cdot)$). Note that in case multiple incoming edges (or outgoing edges) have the maximum flow value, we prefer the edge whose other endpoint (except u) appears first in the topological order, making $e_{max}(\cdot, u)$ (or $e_{max}(u, \cdot)$) and $v_{max}(\cdot, u)$ (or $v_{max}(u, \cdot)$) distinct. Hence, it is referred as *preferred* maximum incoming (or outgoing) edge/vertex. Further, we represent $e_{max}^*(\cdot, u)$ (or $e_{max}^*(u, \cdot)$) as the *unique* maximum incoming (or outgoing) edge if $f_{max}(\cdot, u)$ (or $f_{max}(u, \cdot)$) corresponds to exactly one edge making it equal to $e_{max}(\cdot, u)$ (or $e_{max}(u, \cdot)$) in such a case, and null otherwise. We similarly define its other endpoint (except u) $v_{max}^*(\cdot, u)$ (or $v_{max}^*(u, \cdot)$) which is called *unique* maximum incoming (or outgoing) vertex.

For a path p in the graph, $|p|$ represents the number of its edges. A vertex u is called as being on the *left* of a vertex v on the path, if v is reachable from u on the path. Similarly, in such a case the vertex v is called as being on the *right* of a vertex u on the path. For any path p (or edge) we define its *left extension* to be a path created from p by repeatedly prepending the path with the unique maximum incoming edge of the first vertex of the (updated) path. Similarly, we define the *right extension* of a path to be a path created by repeatedly adding the unique maximum outgoing edge of the last vertex of the (updated) path.

The *flow decomposition* of G is a set of weighted *paths* \mathcal{P}_f such that the flow on each edge in the G equals the sum of the weights of the paths containing it. A path p is called *w-safe* if, in every possible flow decomposition, p is a subpath of some paths in \mathcal{P}_f whose total weight is at least w . A w -safe path with $w > 0$, is called a *safe flow path*, or simply *safe path*. A safe path is *left maximal* (or *right maximal*) if extending it to the left (or right) with any edge makes it unsafe. A safe path is *maximal* if it is both left and right maximal. The safety of a path can be characterized by its *excess flow* (see Figure 1) and properties of safe paths, described as follows.

■ **Figure 1** The excess flow of a path is the incoming or outgoing flow (*blue*) that passes through the path despite the flow (*red*) leaking at its internal vertices (reproduced from [11]).

► **Definition 2** (Excess flow [11]). *The excess flow f_p of a path $p = \{u_1, u_2, \dots, u_k\}$ is*

$$f_p = f(u_1, u_2) - \sum_{\substack{u_i \in \{u_2, \dots, u_{k-1}\} \\ v \neq u_{i+1}}} f(u_i, v) = f(u_{k-1}, u_k) - \sum_{\substack{u_i \in \{u_2, \dots, u_{k-1}\} \\ v \neq u_{i-1}}} f(v, u_i)$$

where the former and later equations are called *diverging* and *converging criterion*, respectively.

► **Theorem 3** (Safe flow paths [11]). *Safety of flow decomposition satisfy the following.*

- (a) A path p is w -safe iff its excess flow $f_p \geq w > 0$.
- (b) The converging and diverging criteria for a path $p = \{u_1, \dots, u_k\}$ are equivalent to

$$f_p = \sum_{i=1}^{k-1} f(u_i, u_{i+1}) - \sum_{i=2}^{k-1} f_{out}(u_i) = \sum_{i=1}^{k-1} f(u_i, u_{i+1}) - \sum_{i=2}^{k-1} f_{in}(u_i).$$

- (c) Adding an edge (u, v) to the start or the end of a path in the flow graph, reduces its excess flow by $f_{in}(v) - f(u, v)$, or $f_{out}(u) - f(u, v)$, respectively.

Additionally, we use the following data structure for answering the level ancestor queries.

- **Theorem 4** (Level Ancestors [4]). A given tree with n vertices can be preprocessed in $O(n)$ time to report the level ancestor $LA(v, d)$ for a vertex v at a depth d in $O(1)$ time.

3 Interaction of Safe Paths

The previous work [11] focused on properties of safe paths useful for applying the characterization directly in verification and enumeration algorithms. We now explore further properties of safe walks particularly related to the interaction of safe paths and its consequences.

- **Lemma 5** (Merge Diverge). Two safe paths cannot merge (through distinct edges) at an intermediate vertex (or vertices) and then diverge (through distinct edges).

Proof. Let two safe paths p and p' merge at a vertex v_1 , entering v_1 respectively by distinct edges e_1 and e'_1 , and then diverge at a vertex v_2 , leaving v_2 respectively by distinct edges e_2 and e'_2 (see Figure 2).

■ **Figure 2** The diverging and converging criterion applied to path p and p' respectively.

Using Theorem 3(c) we know that removing an edge from the end of a path increases the excess flow and hence remains safe. Thus, the subpaths $\{e_1 \cdots, e_2\}$ and $\{e'_1, \cdots, e'_2\}$ of safe paths p and p' respectively, are also safe. By diverging criterion of the safe path p we have $f(e_1) > f(e'_2)$. On the other hand, by converging criterion of the safe path p' we have $f(e'_2) > f(e_1)$, which is a contradiction. ◀

This *merge-diverge* property has an interesting consequence on the structure of a safe path having an edge that is not a unique maximum outgoing edge of a vertex.

- **Lemma 6.** Any safe path having an edge $e(u, v) \neq e_{max}^*(u, \cdot)$, can be extended to the left using only unique maximum incoming edges.

Proof. Consider a path p containing $e_1(u, v) \neq e_{max}^*(u, \cdot)$, which extends to the left of u using edges containing an edge which is not a unique maximum incoming edge $e_2(x, y) \neq e_{max}^*(\cdot, y)$. Now, using Theorem 3(c) we know subpath created by removing edges from the end is safe, as removing such edges only increases the excess flow. Hence, the subpath $p : \{e_2 \cdots e_1\}$ is safe. Further, Theorem 3(c) also implies that a path p' replacing (x, y) with an alternate $e'_2 = e_{max}(\cdot, y)$, and (u, v) with an alternate $e'_1 = e_{max}(u, \cdot)$ is also safe, as we replace an edge with another having at least the same weight. Note that e'_1 and e'_2 always exists since e_1 and e_2 are not unique maximum edges. Thus, both $p : \{e_2 \cdots e_1\}$ and $p' : \{e'_2 \cdots e'_1\}$ are safe which merge at y and then diverge at u using distinct edges, which is a contradiction. ◀

■ **Figure 3** Problem with the simplistic approach. While processing the vertex e , we get two safe paths $p_1 : \langle a, b, d, e \rangle$ and $p_2 : \langle a, c, d, e \rangle$. As we continue processing to reach h , both p_1 and p_2 are extended through f to get $p_{11} : \langle a, b, d, e, f, h, i \rangle$ and $p_{21} : \langle a, c, d, e, f, h, i \rangle$. However, when extending through g both get trimmed to give the same $p_{12}, p_{22} : \langle d, e, g, h, i \rangle$. Further, the paths p_{11} and p_{22} are again extended through j and k (recall the two pointer algorithm) to get four paths, $p_{111}, p_{211} : \langle d, e, f, h, i, j, l \rangle$ and $p_{112}, p_{212} : \langle d, e, f, h, i, k, l \rangle$. Moreover, paths p_{12}, p_{22} can also be extended through j and k to get $p_{121}, p_{221} : \langle h, i, j, l \rangle$ and $p_{122}, p_{222} : \langle h, i, k, l \rangle$. We thus obtain duplicate paths representing the same safe paths from different sources, and some non-maximal paths (p_{122}, p_{222}) which are subpath of the other reported paths.

4 Optimal computation of Raw Safe paths

The essential bottle-neck of the previous approach [11] was the use of a candidate flow decomposition, on whose subpaths the safety criteria was evaluated. The computation of a candidate flow decomposition itself requires $O(mn)$ time making it suboptimal. In order to avoid it we are required to process the graph in a structured manner. Given the graph is a DAG, the topological ordering of the graph serves this purpose.

A simple approach is to follow the topological order and maintain all maximal safe paths ending at the currently processed vertex explicitly. And use the two pointer algorithm to extend it as we continue processing the vertices in the topological order. However, to avoid duplicate and non-maximal results we need to identify the common suffixes of the safe paths, which can be processed accordingly (see Figure 3). Fortunately, for strings the data structure Trie (considered on reversed strings) serves exactly for the same purpose which motivates us to use Tries for storing all the left maximal safe paths ending at a vertex as follows.

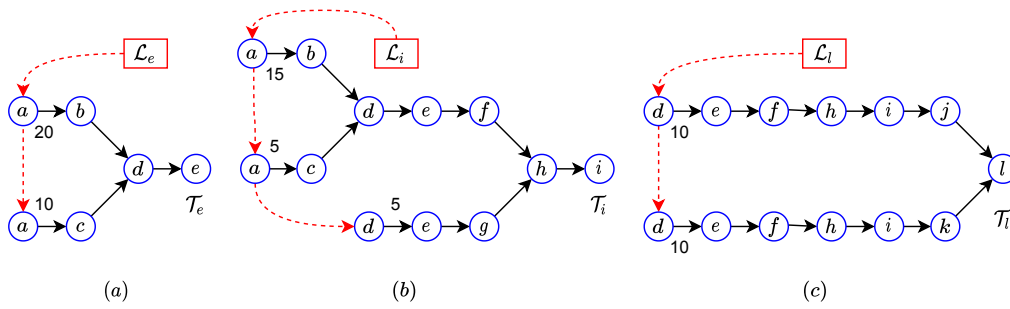

4.1 Data structures \mathcal{T}_u and \mathcal{L}_u

We build a Trie structure \mathcal{T}_u treating the reverse paths ending at a vertex u as strings, such that the common suffixes of the paths are combined. Note that a vertex v can appear multiple times in the Path Trie, if multiple paths containing v do not share v in their common suffix.

All left maximal safe paths ending at a vertex u are hence maintained in \mathcal{T}_u . Additionally, we maintain a linked list \mathcal{L}_u of the leaves of \mathcal{T}_u along with the path's corresponding excess flow, i.e. $\mathcal{L}_u = \{(v_1, f_1), (v_2, f_2), \dots\}$. Consider Figure 4, we show the path tries at the vertices e, i and l for the graph shown in Figure 3. Note that the leaves represent the left maximal safe paths without repetition or storing subpaths as in the simplistic approach.

4.2 Algorithm

The main idea behind our approach is to uniquely extend each safe path ending at a vertex to its preferred maximum out-neighbour in constant time associated with each edge. For the rest of the out-neighbours, we can build their safe paths from scratch at the expense of the path length. This requires us to process the vertices in the topological order of the graph, such that all the safe paths ending at a vertex are computed before it is processed. We maintain the left maximal safe paths ending at a vertex u in the Path Trie \mathcal{T}_u and the list of safe paths \mathcal{L}_u . Our algorithm uses optimal $O(m + out_R)$ time, where out_R is the size of the raw output, i.e., each safe path stored explicitly, which is optimal.

■ **Figure 4** Path Trie structure storing the left maximal paths ending at vertices (a) \mathcal{T}_e with \mathcal{L}_e , (b) \mathcal{T}_i and \mathcal{L}_i , and (c) \mathcal{T}_l and \mathcal{L}_l .

Algorithm 1 describes our approach, where vertices are processed in topological order such that while processing a vertex u , all the left maximal safe paths ending at u (along with their excess flow) are stored in \mathcal{T}_u and \mathcal{L}_u . While processing u all its safe paths are evaluated for a possible extension to its preferred maximum outgoing neighbour $v^* = v_{max}(u, \cdot)$, which always exists except when u is a sink. Note that v^* is not the unique maximum outgoing neighbour ($v_{max}^*(u, \cdot)$) rather preferred ($v_{max}(u, \cdot)$), so that \mathcal{T}_u can be used to extend to some vertex in case there is no unique maximum. Additionally, when u is a source, we have an empty \mathcal{T}_u , so we have no safe paths to extend. Hence, for the other cases we check all paths in \mathcal{L}_u for possible extension to v^* using Theorem 3(c). For this we add the complete \mathcal{T}_u as a child of \mathcal{T}_{v^*} . Thereafter, we need to trim the prefixes of paths in \mathcal{T}_{v^*} which are not safe and compute the list of safe paths \mathcal{L}_{v^*} . Further, we need to add the safe paths using every other outgoing edge (u, v) ($v \neq v^*$) in the corresponding \mathcal{T}_v .

We now process each path in \mathcal{L}_u . The paths which are not safe on extending to (u, v^*) are clearly right-maximal (and hence maximal), and hence are reported in the solution SOL. We extend all the paths in \mathcal{L}_u with (u, v^*) , and add their maximal suffixes which are safe to \mathcal{T}_{v^*} . Note that the entire path may be safe or at least the edge (u, v^*) is safe. So we start trimming \mathcal{T}_{v^*} until the path is safe. This is done by maintaining in f_x the excess flow of the path from x to v^* , where f_x is updated using Theorem 3(c). When (u, v^*) is added f_x may become negative in which case the path is trimmed from the left until f_x is positive. Now, since in a Trie an edge can be shared by multiple paths having a common suffix, we trim the edge only if it is a leaf, and similarly add to \mathcal{L}_{v^*} only if it starts from a leaf. Hence, multiple paths from \mathcal{L}_v will not add the same safe path to \mathcal{L}_{v^*} as it will start from a leaf only when the last such path is processed. This also avoids adding a non-maximal path which is a subpath of another safe path.

Finally, we need to add the safe paths to non-preferred maximum outgoing neighbours, which by Lemma 6 is always on a single path containing the unique maximum incoming edges. We thus compute the single safe left extension for all such neighbours explicitly using Theorem 3(c). We do this again by maintaining the excess flow of the path from x to v in f_x . As we start the path is a single edge with f_x necessarily positive, where we continue adding the preferred maximum incoming edge to the left until f_x is negative. Note that we do not insist on a unique maximum incoming edge as required by Lemma 6 as the flow f_x will itself become negative if the preferred maximum incoming edge is not unique.

```

4.3 Correctness

We prove the correctness of the algorithm by induction over the topological order of the graph. The underlying invariant is as follows:

After COMPUTE-SAFE(u) is executed, all left maximal safe paths having starting vertex and the internal vertices with topological order up to u , are stored in corresponding \mathcal{T}_v and \mathcal{L}_v . Also, all maximal safe paths ending at vertices with topological order up to u , are reported in SOL.

The base case is trivially true when no vertices are processed, as no safe paths exist. Now, when we start processing u , using the invariant we know all the *left maximal* safe paths not having u as internal vertex, and all the *maximal* safe paths ending at the vertex with topological order less than u are already in SOL. So we need to process only the *left maximal* paths having u , which necessarily have the last internal vertex as u , and all the *maximal* safe paths ending at u must be added to SOL. The prefix (not necessarily proper) of both these kinds of paths up to u , are clearly safe (using Theorem 3(c)) and hence are present in \mathcal{T}_u and \mathcal{L}_u by the invariant.

Now, all the *left maximal* safe paths are checked for a possible extension to v^* by construction, and for the remaining out-neighbours we explicitly add the single safe path possible (Lemma 6). Further, all the paths in \mathcal{L}_u are checked for being maximal and added to SOL in such a case. Note that processing the vertices in the topological order ensures that all safe paths ending at u have internal vertices already processed so that the complete path is present in \mathcal{T}_u and \mathcal{L}_u before it is processed.

4.4 Analysis

The total time required by the algorithm can be associated with the edges of the graph m or the total length of safe paths reported, i.e. size of the raw representation of the output out_R . Computing the topological order of the graph requires $O(m)$ time. Now, for each vertex u ,

processing the paths in \mathcal{L}_u either extends it to v^* in $O(1)$ time or reporting a safe path p and extending its subpath to v^* in $O(|p|)$ time. In the former case, the length of the safe path is increased by one (adding u), and the latter case is associated with the length of the reported path (as each safe path is reported exactly once). For residual out-neighbours, the time required is proportional to the size of added safe path. Hence we have the following:

► **Theorem 7.** *Given a flow graph (DAG) having n vertices and m edges, the set of all safe paths can be optimally reported in its raw representation in $O(m + out_R)$ time.*

5 Optimal computation of the optimal Concise Representation

Previous work [11] presented a simple algorithm for computing the concise representation of the solution. Hence instead of reporting each safe path individually which may have overlaps among each other, they combined several overlapping safe paths to report a single path p along with indices representing the subpaths of p which are maximally safe.

However, their concise representation was dependent on the underlying candidate path decomposition, which may be suboptimal. We shall now present an optimal algorithm for computing the optimal concise representation of the solution. Our algorithm again uses Path Tries \mathcal{T}_u with a modified version \mathcal{L}_u^+ of the list of safe paths to store the concise representation.

5.1 Data structures \mathcal{T}_u and \mathcal{L}_u^+

We again build a Trie structure on the reverse paths, whose common suffixes are combined. Similar to the previous algorithm, it stores all the left maximal safe paths ending at u .

Now, the concise representation of safe paths are reported in the form $\{(p_1, I_1), (p_2, I_2), \dots\}$, where each path p_i has maximal safe subpaths denoted by intervals $I_i = \{(l_1, r_1, f_1), (l_2, r_2, f_2), \dots\}$. Each (l_j, r_j) and f_j denote the corresponding end vertices of the maximal safe path on p_i and its excess flow, respectively. While processing u , the partial results are maintained in the list $\mathcal{L}_u^+ = \{(p_1, I_1), (p_2, I_2), \dots\}$ where p_i are the partially built concise representation of the safe paths, where the reported paths contain u . Further, for each I_i the last interval (l_j, r_j, f_j) has $r_j = u$ representing the left maximal safe path ending at u , whereas the remaining intervals are maximal. Note that while processing u , p_i does not include the last path from l_j to u .

5.2 Algorithm

The main idea behind our approach is to always attempt to extend a path p_i of the concise representation with the interval corresponding to a safe path that overlaps the most with p_i . Clearly, while extending the left maximal safe paths on u to its out-neighbours, the maximum such overlap with p_i would correspond to the safe path ending at the preferred maximum outgoing neighbour v^* , which is hence added to p_i . However, in case multiple paths p_i, p_j in the concise representation add exactly the same safe path p_{v^*} corresponding to v^* , it is not optimal to add p_{v^*} to both p_i and p_j . In such a case p_{v^*} can be added to anyone such path (say p_i), and p_j will add the maximum overlapping path p_v corresponding to some other out-neighbour v of u , if it exists. If no such neighbour exists, we will report p_j in the solution having the last interval ending at u . And in case the safe path $p_{v'}$ of some out-neighbour v' of u is not accommodated in the existing paths of the concise representation, we add a new path $p_{v'}$ to the concise representation. The optimality of our concise representation is guaranteed by our choice of maximum overlap, ensuring a new path in the concise representation is always of the minimum length.

Consider Algorithm 2, similar to the previous algorithm we process each vertex in the topological order, and when a vertex u is processed its \mathcal{T}_u and \mathcal{L}_u^+ have already been computed by its incoming neighbours. Similar to the previous approach for each out-neighbour v of u , that is not the preferred maximum out-neighbour of u exactly a single safe path exists containing the unique maximum incoming edges (Lemma 6). We compute it similar to the previous algorithm for each v from scratch, and update its corresponding \mathcal{T}_v , inserting the path p_v temporarily to \mathcal{L}_v^+ as a new path. This path can potentially be added to some existing path in \mathcal{L}_u^+ , for which we mark the starting vertex of p_v in \mathcal{T}_u .

Now, for the unique maximum outgoing neighbour v^* of u , we add \mathcal{T}_u as a child of v^* in \mathcal{T}_{v^*} and attempt to extend each path p_k in \mathcal{L}_u^+ to v^* using Theorem 3(c). Similar to the previous algorithm, this is accompanied by trimming the leaves of last interval of p_k from \mathcal{T}_u if they are not safe in \mathcal{T}_{v^*} . Again, if the start of the safe path x for v^* is no longer a leaf, then the same safe subpath is shared by some other safe path in \mathcal{L}_u^+ . In such a case we do not extend p_k to v^* , rather either (a) extend it to the out-neighbour v of u having the maximum overlap (lowest vertex marked in \mathcal{T}_u along the last interval of p_k) which is not a unique maximum out-neighbour of u , or (b) terminate p_k at u including it as its last interval. Thus, while processing \mathcal{T}_u for each path in \mathcal{L}_u^+ we deal with five distinct cases (see Algorithm 2).

- (a) **v^* is null because $u \in \text{Source}(G)$:** The list \mathcal{L}_u^+ is empty and each out-neighbour v of u is addressed as non-preferred maximum out-neighbour adding the corresponding edge to their \mathcal{T}_v and \mathcal{L}_v^+ computing from scratch.
- (b) **v^* is null because $u \in \text{Sink}(G)$:** For all paths in \mathcal{L}_u^+ , the left limit x reaches u (as f_x is always negative and no out-neighbour exists to mark a vertex in \mathcal{T}_u), which is hence updated to include the last interval of I_k and added to SOL.
- (c) **Path p_k is extended to include v^* :** The safe path is unique to p_k and hence the left limit of safe path x is always a leaf, terminating as soon as $f_x > 0$ and added to $\mathcal{L}_{v^*}^+$ accordingly. Note that no vertex before reaching $f_x > 0$ could have been marked, as left limit of v^* would be the lowest among all out-neighbours of u .
- (d) **Path p_k is extended to include some $v \neq v^*$:** This is possible only if the safe path for v^* is not unique to p_k , i.e., x is no longer a leaf. Then maximum overlap is the lowest vertex along x to u path, to which p_k is added accordingly.
- (e) **Path p_k is not extended and reported in Sol:** This is possible again when safe path for v^* is not unique, so x is no longer a leaf and x reaches u similar to case (b).

5.3 Correctness and Analysis

The optimality of out_C is ensured by appending a path in out_C with the safe path having the maximum overlap with the existing path. This is ensured by processing the marked vertices bottom-up, which represent the start vertex of the safe paths corresponding to the out-neighbour v of u , which is not a unique maximum out-neighbour of u . This guarantees that in case the path cannot be uniquely extended to v^* , the vertex v with the maximum overlap is selected resulting in an optimal concise representation.

The total time taken while processing u is dominated by the processing of \mathcal{L}_u^+ and building the safe paths for those out-neighbours of u which are not unique maximum out-neighbours of u , from scratch. Consider the cases (a), (b), (c) and (e), the time taken in processing \mathcal{L}_u^+ can be easily associated with the length of the path p_k in \mathcal{L}_u^+ since it will be reported exactly once (cases (b) and (e)), and removed from the last interval exactly once (case (c)). Case (a) is also easy to associate as it increases the corresponding paths in \mathcal{L}_v^+ , and hence can be associated with its length.

The only hard case is (d) as it computes the safe path for v from scratch, but extends it on an existing $p_k \in \mathcal{L}_u^+$ which takes more time than the increase in p_k . However, note that this is possible only when the left limit x is no longer a leaf, which implies that the extra processed path is a common suffix of multiple paths in \mathcal{L}_u^+ . And hence the suffix was accounted for only once for multiple paths, and now when p_k is detached from the common suffix the cost of the processed path can be associated with that of the detached path (previously unaccounted being a part of the common suffix). Thus, all the steps can be accounted for with the length of out_C and we get the following.

► **Theorem 8.** *Given a flow graph (DAG) having n vertices and m edges, the optimal concise representation out_C of the safe paths can be optimally reported in $O(m + out_C)$ time.*

■ **Algorithm 2** Optimally Computing concise Representation of Safe Paths.

6 Optimal Representation of Safe paths

The raw representation of the safe paths out_R can take $\Theta(mn^2)$ space and hence time in the worst case. The previous work [11] presented a concise representation of the safe paths reporting a combination of the overlapping safe paths along with its indices, requiring total $\Theta(mn)$ space. However, it may not be optimal as the total size of this concise representation may be much larger than the number of safe paths. We thus present an optimal representation of the safe path whose size requires $\Theta(1)$ space for every safe path reported.

6.1 Representative edge with left and right extensions

Lemma 6 presents an interesting property about safe paths being extendible in a preferred way to the left for edges which are not unique maximum outgoing edges of some vertex. We extend the notion further by considering a representative edge for each safe path such that the maximal path can always be generated by extending it to the left along unique maximum incoming edges and to the right along unique maximum outgoing edges as follows.

► **Theorem 9** (Representative edge). *Given a flow graph (DAG), every safe path p can be described using a representative edge e_p , such that p can be constructed by extending e_p to the left along the unique maximum incoming edges and to the right along the unique maximum outgoing edges.*

Proof. Given a maximal safe path p , let $e(x, y) \in p$ be the leftmost edge such that $e(x, y) \neq e_{max}^*(\cdot, y)$. If no such edge exists, we define the last edge as the representative edge of p , where rest of p is along its unique maximum incoming edges (left extension of e) proving the existence of the representative edge.

Now, by definition the prefix of p on the left of e is along the unique maximum incoming edges (left extension of e), so we only need to prove that the suffix of p after e is along the unique maximum outgoing edges (or the right extension of e). We shall prove it by contradiction, hence assume there exist an edge $e'(a, b) \in p$ to the right of e such that $e'(a, b) \neq e_{max}^*(a, \cdot)$. Clearly, the path $e_{max}^*(\cdot, y) \cup p[y, a] \cup e_{max}^*(a, \cdot)$ is also safe using Theorem 3(c). However, this violates the merge-diverge property (Lemma 5) contradicting our assumption and proving the existence of e as the representative edge of p . ◀

► **Remark 10.** Every safe path contains a representative edge which is either the last edge which is also unique maximum incoming edge, or an edge which is not a unique maximum incoming edge. For the sake of uniformity, in case multiple edges satisfy this property (not being unique maximum incoming edge) for a safe path p , we consider e_p to be the rightmost such edge.

Note that the safe paths when represented using such a representation requires $O(1)$ space per safe path to store the representative edge and its two endpoints, where a single representative edge may store multiple pairs of endpoints representing individual safe paths. We assume that the unique maximum incoming and outgoing edges of each vertex are known which can be pre-computed in $O(m)$ time and stored using $O(n)$ space.

6.2 Approach

As described previously in Remark 10, the representative edge e can be either (a) an edge which is not a unique maximum incoming edge, or (b) a unique maximum incoming edge. The former case is non-trivial as the edge can represent multiple safe paths, whereas the latter is trivial as the edge can represent at most one (can be zero) maximal safe path ending at e . So here we describe only the non-trivial case as trivial can be computed similarly.

Consider Figure 5 (a), where the edge (d, e) is a edge which is not a unique maximum incoming edge of e . The path $\langle a, b, c, d \rangle$ is its left extension (along unique maximum incoming edges), and the path $\langle e, f, g, h \rangle$ is its right extension (along unique maximum outgoing edges). Now, once we compute the left and right extensions we can easily compute all the safe paths represented by (d, e) using two pointer approach in time proportional to length of the path. We get the maximal safe paths $\langle b, c, d, e, f \rangle$ and $\langle d, e, f, g, h \rangle$.

However, assuming we have pre-computed the left and right extensions we can compute all the safe paths using binary search along the path in time $O(\log n)$ times the number of safe paths. This can be done by pre-computing the loss for extension along each edge

■ **Figure 5** Graphs describing (a) the left and right extensions of a representative edge, and (b) the cumulative losses on extension along each edge.

(Theorem 3(c)) and storing the cumulative value on the edge. Now, we find the safe paths as follows. Given the flow on (d, e) is 30 we search for the leftmost minimum value greater than -30 which we find as (b, c) with value -15 giving a left maximal safe path. We make it right maximal (and hence maximal) by searching for the rightmost minimum value greater than $-30 + 15 = -15$ which we find as (e, f) , giving our maximal safe path from b to f using two binary searches. Now, to find the next maximal we extend it to right including (f, g) and again find the left maximal on $-30 + 20$ as (d, e) , and thereafter right maximal on $-30 + 0$ as (g, h) , giving the second maximal safe path from d to h using another two binary searches.

6.3 Data structures

As described in our approach above we require pre-computed left and right extensions for each edge along with the cumulative losses on each edge for efficient search of the maximal safe paths. This can be efficiently computed by building all possible left and right extensions separately which will form two forests corresponding to all unique maximum incoming and outgoing edges. Further for $O(1)$ time access to elements on these forests for binary search we require the classical Level ancestor data structure.

1. Unique maximum incoming and outgoing forests \mathcal{F}_i and \mathcal{F}_o .

For each vertex in the graph, we add the unique maximum incoming edge (if exists) to \mathcal{F}_i . Clearly, each vertex has at most one incoming neighbour (parent) making \mathcal{F}_i a forest. Similarly, for each vertex, we add the *reverse* of the unique maximum outgoing edge (if exists) and \mathcal{F}_o . Again, each vertex has at most one incoming neighbour as a parent (as we added reverse edges), making \mathcal{F}_o .

Now, for each vertex v in the forest \mathcal{F}_i we store the cumulative loss $c_i[v]$ (using Theorem 3(c)) along the path v to the root of its tree $root[\mathcal{F}_i(v)]$. The cumulative loss for any subpath from v to u (where u is ancestor of v in \mathcal{F}_i), can be simply computed as $c_i[u] - c_i[v]$. Similarly, we store the cumulative loss for each vertex v on \mathcal{F}_o in $c_o[v]$. The corresponding forests \mathcal{F}_i and \mathcal{F}_o for Figure 3 are shown in Figure 6. Clearly, these structures can be computed in $O(m)$ time.

2. Level ancestors LA_i and LA_o

We use Theorem 4 to compute the data structure on \mathcal{F}_i and \mathcal{F}_o using $O(n)$ time, for reporting the level ancestors $LA_i(v, d)$ and $LA_o(v, d)$ of a vertex v at depth d in $O(1)$ time.

6.4 Algorithm

We now describe how our approach (described on paths) can be used to compute the optimal representation of all the maximal safe paths in $O(m + out_O \log n)$ time.

■ **Figure 6** For the graph in Figure 3 we show (a) the unique maximum incoming forest \mathcal{F}_i and (b) the unique maximum outgoing forest \mathcal{F}_o . Note that l (in \mathcal{F}_i) and i (in \mathcal{F}_o) do not have a parent in the absence of corresponding unique maximum edges.

We first address computing all non-trivial safe paths. Consider each edge which is not unique maximum incoming edge, say $e(u, v) \neq e_{max}^*(\cdot, u)$. We use the two pointer algorithm as described in [11] however in each step we perform a binary search to compute each safe path in $O(\log n)$ time. The binary search computes the excess flow on a path using the values of $c_o[v]$, $c_i[v]$, and probes an element by considering ancestors of u in \mathcal{F}_i and ancestors of v in \mathcal{F}_o which can be directly accessed in $O(1)$ time using LA_i and LA_o structures. The optimal output reports a list of pairs of end vertices for maximal safe paths represented by $e(u, v)$. However, we avoid this algorithm if the maximal safe path containing e is the single edge e , which is typically not reported. This can be evaluated in $O(1)$ time using Theorem 3(c) in both left and right directions.

For computing the trivial paths, we need to compute all maximal safe paths containing only unique maximum incoming edges. We simply look at the leaves of \mathcal{F}_i and search for the left maximal path ending on it, and thereafter continue the search using a modified two pointer algorithm (using binary search) on its ancestors. However, we need to ensure two aspects. Firstly, we do not perform a binary search in case there exist no maximal safe path, which is only possible if (a) $f(u, v) > |c_i[u]|$, implying the entire path to root is safe, and (b) $f(e_{max}(v, \cdot)) > |c_i[v]|$ implying the path till v is not maximal. In case only (a) is true we report a single safe path from the root to v , and if both are true we skip the leaf. Secondly, the two pointer algorithm on internal vertices may repeat the safe paths reported by other leaves as the internal vertices may be shared. Hence we mark the internal vertices which have been processed so as to avoid repetition of processing and results.

6.5 Implementation details

For the sake of completeness we now describe the two pointer algorithm using binary search on \mathcal{F}_i and \mathcal{F}_o in detail.

The algorithm computes all pairs of end points for safe paths represented by $e(u, v)$ as follows. It first computes the start of left maximal safe path ending at v by performing a binary search on the ancestors of u in \mathcal{F}_i . It computes the highest ancestor l of u such that excess flow of l to v is positive, i.e. $c_i[l] < c_i[u] + f(e)$. This search involves accessing the ancestor at mid-depth directly in $O(1)$ time using $LA_i(u, d[u]/2)$ and so on for the whole binary search. Thereafter, the algorithm computes the end r of right maximal path starting from l in ancestors of v in \mathcal{F}_o such that excess flow of the path $\langle l, \dots, u, v, \dots, r \rangle$ is positive, i.e. highest ancestor of v such that $c_o[r] < f(e) + c_i[u] + c_o[v] - c_i[l]$. We record

$[r, l]$ with the corresponding flow $f(e) + c_i[u] - c_i[l] + c_o[v] - c_o[r]$ as a safe path for e . Then we find the next start of the left maximal path ending at ancestor of r in \mathcal{F}_o , i.e., using $f(e) + c_o[v] - c_o[r]$ instead of $f(e)$ in the process described above. This continues until the left maximal reaches v or the right maximal reaches the root of \mathcal{F}_o containing v .

6.6 Correctness and Analysis

The correctness of our algorithm follows from that of the two pointer algorithm described in [11]. By construction, we show that the algorithm requires $O(1)$ time to check whether a safe path exists corresponding to a representative edge, and thereafter $O(\log n)$ time to report each safe path represented by the edge. Since any explicit representation of the safe paths would require $O(1)$ space for every safe path, out_O is the number of safe paths. We thus get the following result.

► **Theorem 11.** *Given a flow graph (DAG) having n vertices and m edges, the optimal representation out_O of the safe paths can be reported in $O(m + out_O \log n)$ time.*

7 Space bounds for different representations of safe paths

Previous work [11] presented a worst case example demonstrating that out_R and out_C can respectively be $\Omega(mn^2)$ and $\Omega(mn)$ in the worst case and $O(m)$ in the best case. The worst case example graph they presented also gives a bound of $\Omega(mn)$ in the worst case and $O(m)$ in the best case for out_O . In the light of the new characterization, we shall now understand these bounds in more detail.

Using Theorem 9, we know that every safe path can be represented as an edge with a subpath of its left and right extensions. Now, in the worst case each of the m edges can have left and right extensions of length $O(n)$ each, making a complete path of $O(n)$ size. Using the two pointer algorithm we know, that the number of maximal safe paths on a path p are $|p|$. Hence, for each edge we can have $O(n)$ safe paths, each of possibly $O(n)$ edges in the worst case.

This establishes an upper bound of $O(mn^2)$ on the size of out_R matching the $\Omega(mn^2)$ bound of [11], proving the tight bound of $\Theta(mn^2)$ on out_R in the worst case. Further, since each edge with its extensions creates a valid path for out_C , having $O(n)$ length and $O(n)$ indices on every path, we also get $O(mn)$ bound for out_C and out_O , resulting in tight worst case bound of $\Theta(mn)$ for both out_C and out_O .

8 Conclusion

We study the optimization of the solutions for the safety of flow paths in a given flow graph (DAG), which has applications in various domains, including the more prominent assembly of biological sequences. The previous work characterized such paths giving an optimal verification algorithm but suboptimal enumeration algorithms, which required computing a candidate flow decomposition taking $\Omega(mn)$ time even when the reported solution is small.

We present output-sensitive optimal algorithms for reporting the safe paths when represented in the raw format reporting each path explicitly, and optimal concise representation previously described. This is achieved by exploiting a crucial property related to the interaction of safe paths and a novel data structure Path Tries, which may be of independent interest. Further, we characterized an optimal representation of the safe paths, requiring $O(1)$ space for every safe path reported. We also presented a near optimal algorithm to

compute the optimal representation of the safe paths. The new characterization additionally allows us to understand the space bounds of various representations of all safe paths, where we match the existing lower bounds with worst case upper bounds.

In the future, it would be interesting to see an optimal output-sensitive algorithm for computing even the optimal representation of the safe paths (dropping the $O(\log n)$ factor). It would also be interesting to see if similar properties or algorithms can be used to solve related problems as path covers, or path decomposition for general graphs.

Scheduling Kernels via Configuration LP

Abstract

Makespan minimization (on parallel identical or unrelated machines) is arguably the most natural and studied scheduling problem. A common approach in practical algorithm design is to reduce the size of a given instance by a fast preprocessing step while being able to recover key information even after this reduction. This notion is formally studied as kernelization (or simply, kernel) – a polynomial time procedure which yields an equivalent instance whose size is bounded in terms of some given parameter. It follows from known results that makespan minimization parameterized by the longest job processing time p_{\max} has a kernelization yielding a reduced instance whose size is exponential in p_{\max} . Can this be reduced to polynomial in p_{\max} ?

We answer this affirmatively not only for makespan minimization, but also for the (more complicated) objective of minimizing the weighted sum of completion times, also in the setting of unrelated machines when the number of machine kinds is a parameter.

Our algorithm first solves the Configuration LP and based on its solution constructs a solution of an intermediate problem, called huge N -fold integer programming. This solution is further reduced in size by a series of steps, until its encoding length is polynomial in the parameters. Then, we show that huge N -fold IP is in NP, which implies that there is a polynomial reduction back to our scheduling problem, yielding a kernel.

Our technique is highly novel in the context of kernelization, and our structural theorem about the Configuration LP is of independent interest. Moreover, we show a polynomial kernel for huge N -fold IP conditional on whether the so-called separation subproblem can be solved in polynomial time. Considering that integer programming does not admit polynomial kernels except for quite restricted cases, our “conditional kernel” provides new insight.

1 Introduction

Kernelization, data reduction, or preprocessing: all of these refer to the goal of simplifying and reducing (the size of) the input in order to speed up computation of challenging tasks. Many heuristic techniques are applied in practice, however, we seek a theoretical understanding in the form of a procedure with guaranteed bounds on the sizes of the reduced data. We use the notion of kernelization from parameterized complexity (cf. [39, 9]), where along with an input instance I we get a positive integer k expressing the *parameter value*, which may be the size of the sought solution or some structural limitation of the input. A kernel is an algorithm running in time $\text{poly}(|I| + k)$ which returns a reduced instance I' of the same problem of size bounded in terms of k ; we sometimes also refer to I' as the kernel.

It is well known [6] that a problem admits a kernel if and only if it has an algorithm running in time $f(k) \text{poly}(|I|)$ for some computable function f (i.e., if it is fixed-parameter tractable, or FPT, parameterized by k). The “catch” is that this kernel may be very large (exponential or worse) in terms of k , while for many problems, kernels of size polynomial in k are known. This raises a fundamental question for any FPT problem: does it have a polynomial kernel? Answering this question typically provides deep insights into a problem and the structure of its solutions.

Parameterized complexity has historically focused primarily on graph problems, but it has been increasingly branching out into other areas. Kernelization, as arguably the most important subfield of parameterized complexity (cf. a recent monograph [15]), follows suit. Scheduling is a fundamental area in combinatorial optimization, with results from parameterized complexity going back to 1995 [3]. Probably the most central problem in scheduling is makespan minimization on identical machines, denoted as $P||C_{\max}$, which we shall define soon. It took until the seminal paper of Goemans and Rothvoß [20] to get an FPT algorithm for $P||C_{\max}$ parameterized by the number of job types (hence also by the largest job). Yet, the existence of a polynomial kernel for $P||C_{\max}$ remained open, despite being raised by Mnich and Wiese in 2013 [38] and reiterated by van Bevern¹. Here, we give an affirmative answer for this problem:

► **Corollary 1.** *There is a polynomial kernel for $P||C_{\max}$ when parameterized by the longest processing time p_{\max} .*

Let us now introduce and define the scheduling problems $P||C_{\max}$ and $P||\sum w_j C_j$. There are n jobs and m identical machines, and the goal is to find a schedule minimizing an objective. For each job $j \in [n]$, a *processing time* $p_j \in \mathbb{N}$ is given and a *weight* w_j are given; in the case of $P||C_{\max}$ the weights play no role and can be assumed to be all zero. A *schedule* is a mapping which to each job $j \in [n]$ assigns some machine $i \in [m]$ and a closed interval of length p_j , such that the intervals assigned to each machine do not overlap except for their endpoints. For each job $j \in [n]$, denote by C_j its *completion time*, which is the time when it finishes, i.e., the right end point of the interval assigned to j in the schedule. In the *makespan minimization* (C_{\max}) problem, the goal is to find a schedule minimizing the time when the last job finishes $C_{\max} = \max_{j \in [n]} C_j$, called the *makespan*. In the *minimization of sum of weighted completion times* ($\sum w_j C_j$), the goal is to minimize $\sum w_j C_j$. (In the rest of the paper we formally deal with *decision* versions of these problems, where the task is to decide whether there exists a schedule with objective value at most k . This is a necessary approach when speaking of kernels and complexity classes like NP and FPT.)

¹ The question was asked at the workshop “Scheduling & FPT” at the Lorentz Center, Leiden, in February 2019, as a part of the opening talk for the open problem session.

In fact, our techniques imply results stronger in three ways, where we handle:

1. the much more complicated $\sum w_j C_j$ objective function involving possibly large job weights,
2. the unrelated machines setting (denoted $R||C_{\max}$ and $R||\sum w_j C_j$), and
3. allowing the number of jobs and machines to be very large, known as the *high-multiplicity* setting.

For this, we need further notation to allow for different kinds of machines. For each machine $i \in [m]$ and job $j \in [n]$, a *processing time* $p_j^i \in \mathbb{N}$ is given. For a given scheduling instance, say that two jobs $j, j' \in [n]$ are of the same *type* if $p_j^i = p_{j'}^i$, for all $i \in [m]$ and $w_j = w_{j'}$, and say that two machines $i, i' \in [m]$ are of the same *kind* if $p_j^i = p_j^{i'}$ for all jobs $j \in [n]$. We denote by $\tau \in \mathbb{N}$ and $\kappa \in \mathbb{N}$ the number of job types and machine kinds, respectively, call this type of encoding the *high-multiplicity* encoding, and denote the corresponding problems $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$.

Our approach is indirect: taking an instance I of scheduling, we produce a small equivalent instance I' of a the so-called *huge N -fold integer programming* problem with a quadratic objective function (see more details below). This is known as *compression*, i.e., a polynomial time algorithm producing from I a small equivalent instance of a different problem:

► **Theorem 2.** *The problems $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$ parameterized by the number of job types τ , the longest processing time p_{\max} , and the number of machine kinds κ admit a polynomial compression to quadratic huge N -fold IP parameterized by the number of block types $\bar{\tau}$, the block dimension t , and the largest coefficient $\|E\|_{\infty}$.*

If we can then find a polynomial reduction from quadratic huge N -fold IP to our scheduling problems, we are finished. For this, it suffices to show NP membership, as we do in Lemma 13.

Configuration LP. Besides giving polynomial kernels for some of the most fundamental scheduling problems, we wish to highlight the technique behind this result, because it is quite unlike most techniques used in kernelization and is of independent interest. Our algorithm essentially works by solving the natural Configuration LP of $P||C_{\max}$ (and other problems), which can be done in polynomial time when p_{\max} is polynomially bounded, and then using powerful structural insights to reduce the scheduling instance based on the Configuration LP solution. The Configuration LP is a fundamental tool in combinatorial optimization which goes back to the work of Gilmore and Gomory in 1961 [18]. It is known to provide high-quality results in practice, in fact, the “modified integer round-up property (MIRUP)” conjecture states that the natural Bin Packing Configuration LP always attains a value x such that the integer optimum is at most $\lfloor x \rfloor + 1$ [40]. The famous approximation algorithm of Karmarkar and Karp [28] for Bin Packing is based on rounding the Configuration LP, and many other results in approximation use the Configuration LP for their respective problems as the starting point.

In spite of this centrality and vast importance of the Configuration LP, there are only few structural results providing deeper insight. Perhaps the most notable is the work of Goemans and Rothvoß [20] and later Jansen and Klein [26] who show that there is a certain set of “fundamental configurations” such that in any integer optimum, all but few machines (bins, etc.) will use these fundamental configurations. Our result is based around a theorem which shows a similar yet orthogonal result and can be informally stated as follows:

► **Theorem 3** (informal; see the full version). *There is an optimum of the Configuration IP where all but few configuration are those discovered by the Configuration LP, and the remaining configurations are not far from those discovered by the Configuration LP.*

We note that our result, unlike the ones mentioned above [20, 26], also applies to arbitrary separable convex functions. This has a fundamental reason: the idea behind both previous results is to shift weight from the inside of a polytope to its vertices without affecting the objective value, which only works for linear objectives.

Huge N -fold IP. Finally, we highlight that the engine behind our kernels, a conditional kernel for the so-called quadratic huge N -fold IP, is of independent interest. Integer programming is a central problem in combinatorial optimization. Its parameterized complexity has been recently intensely studied [11, 31, 33, 10, 7]. However, it turns out that integer programs cannot be kernelized in all but the most restricted cases [34, 35, 26]. We give a positive result about a class of block-structured succinctly encoded IPs with a quadratic objective function, so-called quadratic huge N -fold IPs, which was used to obtain many interesting FPT results [29, 31, 4, 17, 32, 5]. However, our result is conditional on having a polynomial algorithm for the so-called *separation subproblem* of the Configuration LP of the quadratic huge N -fold IP, so there is a price to pay for the generality of this fragment of IP. The separation subproblem is to optimize a certain objective function (which varies) over the set of configurations. In the cases considered here, we show that this corresponds to (somewhat involved) variations of the knapsack problem with polynomially bounded numbers; in other problems expressible as n -fold IP, the separation subproblem corresponds to a known hard problem. Informally, our result reads as follows:

► **Theorem 4** (informal; see the full version). *If the separation subproblem can be solved in polynomial time, then quadratic huge N -fold IP has a polynomial kernel parameterized by the block dimensions, the number of block types, and the largest coefficient.*

Because huge N -fold IP is essentially equivalent to the Configuration IP, the kernel of Theorem 3 can be viewed as a validation of the industry common wisdom that column generation works really well. Another view is that methods from mathematical programming, so far underrepresented in kernelization, deserve more attention.

One aspect of the algorithm above is reducing the quadratic objective function. The standard approach, also used in kernelization of weighted problems [13, 8, 2, 19, 42, 41, 21] is to use a theorem of Frank and Tardos [16] which “kernelizes” a linear objective function if the dimension is a parameter. However, we deal with

1. a quadratic convex (non-linear) function,
2. over a space of large dimension.

We are able to overcome these obstacles by a series of steps which first “linearize” the objective, then “aggregate” variables of the same type, hence shrinking the dimension, then reduce the objective using the algorithm of Frank and Tardos, and then we carefully reverse this process (see the full version for more details). This result has applications beyond this work: for example, the currently fastest strongly FPT algorithm for $R||\sum w_j C_j$ (i.e., an algorithm whose number of arithmetic operations does not depend on the weights w_j) has dependence of $m^2 \text{poly log}(m)$ on the number of machines m ; applying our new result instead of [11, Corollary 69] reduces this dependence to $m \text{poly log}(m)$.

Other Applications. Theorem 4 can be used to obtain kernels for other problems which can be modeled as huge N -fold IP. First, we may also optimize the ℓ_p norms of times when each machine finishes, a problem known as $R|HM|\ell_p$. Our results (Corollary 11) show that also in this setting the separation problem can be solved quickly. Second, the $P||C_{\max}$ problem is identical to Bin Packing (in their decision form), so our kernel also gives a kernel for

Bin Packing parameterized by the largest item size. Moreover, also the Bin Packing with Cardinality Constraints problem has a huge N -fold IP model [30, Lemma 54] for which Corollary 11 indicates that the separation subproblem can be solved quickly. Third, Knop et al. [30] give a huge N -fold IP model for the SURFING problem, in which many “surfers” make demands on few different “services” provided by few “servers”, where each surfer may have different costs of getting a service from a server; one may think of internet streaming with different content types, providers, and pricing schemes for different customer types. The separation problem there is polynomially solvable for an interesting reason: its constraint matrix is totally unimodular because it is the incidence matrix of the complete bipartite graph. Thus, Theorem 4 gives polynomial kernels for all of the problems above with the given parameters.

Related Work – Scheduling. Let us finally review related results in the intersection of parameterized complexity and scheduling; for a more comprehensive survey of parameterized results in scheduling see, e.g., [37]. First, to the best of our knowledge, the first to study scheduling problems from the perspective of multivariate complexity were Bodlaender and Fellows [3]. Fellows and McCartin [14] study scheduling on single machine of unit length jobs with (many) different release times and due dates. Single machine scheduling where two agents compete to schedule their private jobs is investigated by Hermelin et al. [22]. There are few other result [43, 27, 24, 23] focused on identifying tractable scenarios for various scheduling paradigms (such as flow-shop scheduling or e.g. structural limitations of the job–machine assignment).

Paper Organization. We begin with preliminaries (Section 2) which, besides introducing necessary notation and definitions, also states several results which we use later in the proofs of our results. Section 3 discusses how our scheduling problems are modeled as huge N -fold IP (3.1) and how to solve the ConfLP quickly for those models (3.2 and 3.3). Finally, in the full version, we show our “conditional kernel” for quadratic huge N -fold IP, which first reduces all parts of the instance except for the objective function, and finally deals with the objective. In the full version, we conclude with a short section giving an interpretation of our algorithm for $P||C_{\max}$ and $R||C_{\max}$. A word of caution: it is at first tempting to think that most of the machinery of our algorithm is not necessary for our simplest considered problem $P||C_{\max}$; however, as we discuss in the full version in detail, while some minor simplifications are possible, the only truly avoidable step is the objective reduction which is needed for the $\sum w_j C_j$ objective.

2 Preliminaries

We consider zero to be a natural number, i.e., $0 \in \mathbb{N}$. We write vectors in boldface (e.g., \mathbf{x}, \mathbf{y}) and their entries in normal font (e.g., the i -th entry of a vector \mathbf{x} is x_i). For positive integers $m \leq n$ we set $[m, n] := \{m, \dots, n\}$ and $[n] := [1, n]$, and we extend this notation for vectors: for $\mathbf{l}, \mathbf{u} \in \mathbb{Z}^n$ with $\mathbf{l} \leq \mathbf{u}$, $[\mathbf{l}, \mathbf{u}] := \{\mathbf{x} \in \mathbb{Z}^n \mid \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}\}$ (where we compare component-wise). For two vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, $\mathbf{z} = \max\{\mathbf{x}, \mathbf{y}\}$ is defined coordinate-wise, i.e., $z_i = \max\{x_i, y_i\}$ for all $i \in [n]$, and similarly for $\min\{\mathbf{x}, \mathbf{y}\}$.

If A is a matrix, $A_{i,j}$ denotes the j -th coordinate of the i -th row, $A_{i,\bullet}$ denotes the i -th row and $A_{\bullet,j}$ denotes the j -th column. We use $\log := \log_2$, i.e., all our logarithms are base 2. For an integer $a \in \mathbb{Z}$, we denote by $\langle a \rangle := 1 + \lceil \log(|a| + 1) \rceil$ the binary encoding length of a ; we extend this notation to vectors, matrices, and tuples of these objects. For example,

$\langle A, \mathbf{b} \rangle = \langle A \rangle + \langle \mathbf{b} \rangle$, and $\langle A \rangle = \sum_{i,j} \langle A_{i,j} \rangle$.² For a function $f: \mathbb{Z}^n \rightarrow \mathbb{Z}$ and two vectors $\mathbf{l}, \mathbf{u} \in \mathbb{Z}^n$, we define $f_{\max}^{[\mathbf{l}, \mathbf{u}]} := \max_{\mathbf{x} \in [\mathbf{l}, \mathbf{u}]} |f(\mathbf{x})|$; if $[\mathbf{l}, \mathbf{u}]$ is clear from the context we omit it and write just f_{\max} .

► **Proposition 5** ([15, Theorem 1.6]). *Let $(Q, \kappa), (R, \lambda)$ be parameterized problems such that Q is NP-hard and R is in NP. If (Q, κ) admits a polynomial compression into (R, λ) , then it admits a polynomial kernel.*

The above observation is useful when dealing with NP-hard problems. The proof simply follows by pipelining the assumed polynomial compression with a polynomial time (Karp) reduction from R to Q .

2.1 Scheduling Notation

Overloading the convention slightly, for each $i \in [\kappa]$ and $j \in [\tau]$, denote by p_j^i the processing time of a job of type j on a machine of kind i , by w_j the weight of a job of type j , by n_j the number of jobs of type j , by m_i the number of machines of kind i , and denote $\mathbf{n} = (n_1, \dots, n_\tau)$, $\mathbf{m} = (m_1, \dots, m_\kappa)$, $\mathbf{p} = (p_1^1, \dots, p_\tau^1, p_1^2, \dots, p_\tau^\kappa)$, $\mathbf{w} := (w_1, \dots, w_\tau)$, $p_{\max} := \|\mathbf{p}\|_\infty$, and $w_{\max} := \|\mathbf{w}\|_\infty$. We denote the high multiplicity versions of the previously defined problems $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$.

For an instance I of $R|C_{\max}$ or $R|\sum w_j C_j$, we define its size as $\langle I \rangle := \sum_{i=1}^\kappa \sum_{j=1}^\tau \langle p_j^i, w_j \rangle$, whereas for an instance I of $P|HM|C_{\max}$ or $P|HM|\sum w_j C_j$ we define its size as $\langle I \rangle = \langle \mathbf{n}, \mathbf{m}, \mathbf{p}, \mathbf{w} \rangle$. Note that the difference in encoding actually leads to different problems: for example, an instance of $R|HM|C_{\max}$ with 2^k jobs with maximum processing time p_{\max} can be encoded with $\mathcal{O}(k\tau\kappa \log p_{\max})$ bits while an equivalent instance of $R|C_{\max}$ needs $\Omega(2^k \log p_{\max})$ bits, which is exponentially more if $\tau, \kappa \in k^{\mathcal{O}(1)}$. The membership of high-multiplicity scheduling problems in NP was open for some time, because it is not obvious whether a compactly encoded instance also has an optimal solution with a compact encoding. This question was considered by Eisenbrand and Shmonin, and we shall use their result. For a set $X \subseteq \mathbb{Z}^d$ define the *integer cone* of X , denoted $\text{cone}_{\mathbb{N}}(X)$, to be the set $\text{cone}_{\mathbb{N}}(X) := \{ \sum_{\mathbf{x} \in X} \lambda_{\mathbf{x}} \mathbf{x} \mid \lambda \in \mathbb{N}^X \}$, where \mathbb{N}^X is the set of functions mapping $X \rightarrow \mathbb{N}$ viewed as vectors.

► **Proposition 6** (Eisenbrand and Shmonin [12, Theorem 2]). *Let $X \subseteq \mathbb{Z}^d$ be a finite set of integer vectors and let $\mathbf{b} \in \text{cone}_{\mathbb{N}}(X)$. Then there exists a subset $\tilde{X} \subseteq X$ such that $\mathbf{b} \in \text{cone}_{\mathbb{N}}(\tilde{X})$ and the following holds for the cardinality of \tilde{X} :*

1. *if all vectors of X are nonnegative, then $|\tilde{X}| \leq \langle \mathbf{b} \rangle$,*
2. *if $M = \max_{\mathbf{x} \in X} \|\mathbf{x}\|_\infty$, then $|\tilde{X}| \leq 2d(\log 4dM)$.*

One can use Proposition 6 to show that the decision version of $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$ have short certificates and thus belong to NP. We will later derive the same result as a corollary of the fact that both of these scheduling problems can be encoded as a certain form of integer programming, which we will show to have short certificates as well.

2.2 Conformal Order and Graver Basis

Let $\mathbf{g}, \mathbf{h} \in \mathbb{Z}^n$ be two vectors. We say that \mathbf{g} is *conformal* to \mathbf{h} (we denote it $\mathbf{g} \sqsubseteq \mathbf{h}$) if both $g_i \cdot h_i \geq 0$ and $|g_i| \leq |h_i|$ for all $i \in [n]$. In other words, $\mathbf{g} \sqsubseteq \mathbf{h}$ if they are in the same

² We note that our encoding of integers already contains the delimiter symbol.

orthant (the first condition holds) and \mathbf{g} is component-wise smaller than \mathbf{h} . For a matrix A we define its *Graver basis* (A) to be the set of all \sqsubseteq -minimal vectors in $\text{Ker}(A) \setminus \{\mathbf{0}\}$. We define $g_\infty(A) = \max\{\|\mathbf{g}\|_\infty \mid \mathbf{g} \in (A)\}$ and $g_1(A) = \max\{\|\mathbf{g}\|_1 \mid \mathbf{g} \in (A)\}$.

We say that two functions $f, g: \mathbb{Z}^d \rightarrow \mathbb{Z}$ are *equivalent* on a polyhedron $P \subseteq \mathbb{Z}^d$ if $f(\mathbf{x}) \leq f(\mathbf{y})$ if and only if $g(\mathbf{x}) \leq g(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y} \in P$. Note that if f and g are equivalent on P , then the sets of minimizers of $f(\mathbf{x})$ and $g(\mathbf{x})$ over P coincide.

► **Proposition 7** (Frank and Tardos [16]). *Given a rational vector $\mathbf{w} \in \mathbb{Q}^d$ and an integer M , there is a polynomial algorithm which finds a $\tilde{\mathbf{w}} \in \mathbb{Z}^d$ such that the linear functions $\mathbf{w}\mathbf{x}$ and $\tilde{\mathbf{w}}\mathbf{x}$ are equivalent on $[-M, M]^d$, and $\|\tilde{\mathbf{w}}\|_\infty \leq 2^{\mathcal{O}(d^3)} M^{\mathcal{O}(d^2)}$.*

The *dual graph* $G_D(A) = (V, E)$ of a matrix $A \in \mathbb{Z}^{m \times n}$ has $V = [m]$ and $\{i, j\} \in E$ if rows i and j contain a non-zero at a common coordinate $k \in [n]$. The dual treewidth $\text{tw}_D(A)$ of A is $\text{tw}(G_D(A))$. We do not define treewidth here, but we point out that $\text{tw}(T) = 1$ for every tree T .

► **Proposition 8** (Eisenbrand et al. [11, Theorem 98]). *An IP with a constraint matrix A can be solved in time $(\|A\|_\infty g_1(A))^{\mathcal{O}(\text{tw}_D(A))} \text{poly}(n, L)$, where n is the dimension of the IP and L is the length of the input.*

► **Proposition 9** (Eisenbrand et al. [11, Lemma 25]). *For an integer matrix $A \in \mathbb{Z}^{m \times n}$, we have $g_1(A) \leq (2\|A\|_\infty m + 1)^m$.*

2.3 N-fold Integer Programming

The INTEGER PROGRAMMING problem is to solve:

$$\min f(\mathbf{x}) : A\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \mathbf{x} \in \mathbb{Z}^n, \tag{IP}$$

where $f: \mathbb{R}^n \rightarrow \mathbb{R}$, $A \in \mathbb{Z}^{m \times n}$, $\mathbf{b} \in \mathbb{Z}^m$, and $\mathbf{l}, \mathbf{u} \in (\mathbb{Z} \cup \{\pm\infty\})^n$.

A *generalized N-fold IP matrix* is defined as

$$E^{(N)} = \begin{pmatrix} E_1^1 & E_1^2 & \cdots & E_1^N \\ E_2^1 & 0 & \cdots & 0 \\ 0 & E_2^2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & E_2^N \end{pmatrix}. \tag{1}$$

Here, $r, s, t, N \in \mathbb{N}$, $E^{(N)}$ is an $(r + Ns) \times Nt$ -matrix, and $E_1^i \in \mathbb{Z}^{r \times t}$ and $E_2^i \in \mathbb{Z}^{s \times t}$ for all $i \in [N]$, are integer matrices. Problem (IP) with $A = E^{(N)}$ is known as *generalized N-fold integer programming* (generalized N-fold IP). “Regular” N-fold IP is the problem where $E_1^i = E_1^j$ and $E_2^i = E_2^j$ for all $i, j \in [N]$. Recent work indicates that the majority of techniques applicable to “regular” N-fold IP also applies to generalized N-fold IP [11].

The structure of $E^{(N)}$ allows us to divide any Nt -dimensional object, such as the variables of \mathbf{x} , bounds \mathbf{l}, \mathbf{u} , or the objective f , into N bricks of size t , e.g. $\mathbf{x} = (\mathbf{x}^1, \dots, \mathbf{x}^N)$. We use subscripts to index within a brick and superscripts to denote the index of the brick, i.e., x_j^i is the j -th variable of the i -th brick with $j \in [t]$ and $i \in [N]$. We call a brick *integral* if all of its coordinates are integral, and *fractional* otherwise.

Huge N -fold IP. The *huge N -fold IP* problem is an extension of generalized N -fold IP to the high-multiplicity scenario, where blocks come in types and are encoded succinctly by type multiplicities. This means there could be an *exponential* number of bricks in an instance with a polynomial encoding size. The input to the huge N -fold IP problem with $\bar{\tau}$ types of blocks is defined by matrices $E_1^i \in \mathbb{Z}^{r \times t}$ and $E_2^i \in \mathbb{Z}^{s \times t}$, $i \in [\bar{\tau}]$, vectors $\mathbf{l}^1, \dots, \mathbf{l}^{\bar{\tau}}, \mathbf{u}^1, \dots, \mathbf{u}^{\bar{\tau}} \in \mathbb{Z}^t$, $\mathbf{b}^0 \in \mathbb{Z}^r$, $\mathbf{b}^1, \dots, \mathbf{b}^{\bar{\tau}} \in \mathbb{Z}^s$, functions $f^1, \dots, f^{\bar{\tau}}: \mathbb{R}^t \rightarrow \mathbb{R}$ satisfying $\forall i \in [\bar{\tau}], \forall \mathbf{x} \in \mathbb{Z}^t$ we have $f^i(\mathbf{x}) \in \mathbb{Z}$ and given by evaluation oracles, and integers $\mu^1, \dots, \mu^{\bar{\tau}} \in \mathbb{N}$ such that $\sum_{i=1}^{\bar{\tau}} \mu^i = N$. We say that a brick is of type i if its lower and upper bounds are \mathbf{l}^i and \mathbf{u}^i , its right hand side is \mathbf{b}^i , its objective is f^i , and the matrices appearing at the corresponding coordinates are E_1^i and E_2^i . Denote by T_i the indices of bricks of type i , and note $|T_i| = \mu_i$ and $|\bigcup_{i \in [\bar{\tau}]} T_i| = N$. The task is to solve (IP) with a matrix $E^{(N)}$ which has μ^i blocks of type i for each i . Knop et al. [30] have shown a fast algorithm solving huge n -fold IP. The main idea of their approach is to prove a powerful proximity theorem showing how one can drastically reduce the size of the input instance given that one can solve a corresponding configuration LP (which we shall formally define later). We will build on this approach here. When f^i are restricted to be separable quadratic (and convex) for all $i \in [\bar{\tau}]$, we call the problem *quadratic huge N -fold IP*.

2.4 Configuration LP of Huge N -fold IP

Let a huge N -fold IP instance with $\bar{\tau}$ types be fixed. Recall that μ^i denotes the number of blocks of type i , and let $\boldsymbol{\mu} = (\mu^1, \dots, \mu^{\bar{\tau}})$. We define for each $i \in [\bar{\tau}]$ the set of configurations of type i as

$$\mathcal{C}^i = \{ \mathbf{c} \in \mathbb{Z}^t \mid E_2^i \mathbf{c} = \mathbf{b}^i, \mathbf{l}^i \leq \mathbf{c} \leq \mathbf{u}^i \} .$$

Here we are interested in four instances of convex programming (CP) and convex integer programming (IP) related to huge N -fold IP. First, we have the *Huge IP*

$$\min f(\mathbf{x}) : E^{(N)} \mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \mathbf{x} \in \mathbb{Z}^{Nt} . \quad (\text{HugeIP})$$

Then, there is the *Configuration LP* of (HugeIP),

$$\begin{aligned} \min \mathbf{v}\mathbf{y} &= \sum_{i=1}^{\bar{\tau}} \sum_{\mathbf{c} \in \mathcal{C}^i} f^i(\mathbf{c}) \cdot y(i, \mathbf{c}) & (2) \\ \sum_{i=1}^{\bar{\tau}} E_1^i \sum_{\mathbf{c} \in \mathcal{C}^i} \mathbf{c} y(i, \mathbf{c}) &= \mathbf{b}^0 \\ \sum_{\mathbf{c} \in \mathcal{C}^i} y(i, \mathbf{c}) &= \mu^i & \forall i \in [\bar{\tau}] \\ \mathbf{y} &\geq \mathbf{0} . & (3) \end{aligned}$$

Let B be its constraint matrix and $\mathbf{d} = (\mathbf{b}^0, \boldsymbol{\mu})$ be the right hand side and shorten (2)-(3) to

$$\min \mathbf{v}\mathbf{y} : B\mathbf{y} = \mathbf{d}, \mathbf{y} \geq \mathbf{0} . \quad (\text{ConfLP})$$

Finally, by observing that $B\mathbf{y} = \mathbf{d}$ implies $y(i, \mathbf{c}) \leq \|\boldsymbol{\mu}\|_\infty$ for all $i \in [\bar{\tau}], \mathbf{c} \in \mathcal{C}^i$, defining $C = \sum_{i \in [\bar{\tau}]} |\mathcal{C}^i|$, leads to the *Configuration ILP*,

$$\min \mathbf{v}\mathbf{y} : B\mathbf{y} = \mathbf{d}, \mathbf{0} \leq \mathbf{y} \leq (\|\boldsymbol{\mu}\|_\infty, \dots, \|\boldsymbol{\mu}\|_\infty), \mathbf{y} \in \mathbb{N}^C . \quad (\text{ConfILP})$$

The classical way to solve (ConfLP) is by solving its dual using the ellipsoid method and then restricting (ConfLP) to the columns corresponding to the rows encountered while solving the dual, a technique known as column generation. The Dual LP of (ConfLP) in variables $\alpha \in \mathbb{R}^r$, $\beta \in \mathbb{R}^{\bar{\tau}}$ is:

$$\begin{aligned} \max \quad & \mathbf{b}^0 \alpha + \sum_{i=1}^{\bar{\tau}} \mu^i \beta^i \\ \text{s.t.} \quad & (\alpha E_1^i) \mathbf{c} - f^i(\mathbf{c}) \leq -\beta^i \quad \forall i \in [\bar{\tau}], \forall \mathbf{c} \in \mathcal{C}^i \end{aligned} \quad (4)$$

To verify feasibility of (α, β) for $i \in [\bar{\tau}]$, we need to maximize the left-hand side of (4) over all $\mathbf{c} \in \mathcal{C}^i$ and check if it is at most $-\beta^i$. This corresponds to solving the following *separation problem*: find integer variables \mathbf{c} which for a given vector (α, β) solve

$$\min f^i(\mathbf{c}) - (\alpha E_1^i) \mathbf{c} : E_2^i \mathbf{c} = \mathbf{b}^i, \mathbf{l}^i \leq \mathbf{c} \leq \mathbf{u}^i, \mathbf{c} \in \mathbb{Z}^t. \quad (\text{sep-IP})$$

Denote by $\text{sep}(\mathbf{l}^i, \mathbf{u}^i, f_{\max}^i, E_1^i, E_2^i)$ the time needed to solve (sep-IP).

► **Lemma 10** (Knop et al. [30, Lemma 12]). *An optimal solution \mathbf{y}^* of (ConfLP) with $|\text{supp}(\mathbf{y}^*)| \leq r + \bar{\tau}$ can be found in $(rt\bar{\tau} \langle f_{\max}, \mathbf{l}, \mathbf{u}, \mathbf{b}, \boldsymbol{\mu} \rangle)^{\mathcal{O}(1)} \cdot \max_{i \in [\bar{\tau}]} \text{sep}(\mathbf{l}^i, \mathbf{u}^i, f_{\max}^i, E_1^i, E_2^i)$ time.*

Since (sep-IP) is an IP, it can be solved using Proposition 8 in time $g_1(E_2^i)^{\text{tw}_D(E_2^i)} \cdot \text{poly}(\langle \mathbf{l}^i, \mathbf{u}^i, \mathbf{b}^i, \|E_1^i\|_{\infty} f_{\max} \rangle, t, \bar{\tau})$. Hence, together with Lemma 10, we get the following corollary:

► **Corollary 11.** *An optimal solution \mathbf{y}^* of (ConfLP) with $|\text{supp}(\mathbf{y}^*)| \leq r + \bar{\tau}$ can be found in time $(rt\bar{\tau} \langle f_{\max}, \mathbf{l}, \mathbf{u}, \mathbf{b}, \boldsymbol{\mu} \rangle)^{\mathcal{O}(1)} \cdot \max_{i \in [\bar{\tau}]} g_1(E_2^i)^{\text{tw}_D(E_2^i)}$.*

We later show how that for our formulations of $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$, indeed $g_1(E_2^i)$ is polynomial in τ, p_{\max} , and $\text{tw}_D(E_2^i) = 1$, hence the (ConfLP) optimum can be found in polynomial time.

3 Compressing High Multiplicity Scheduling to Quadratic N -fold IP

In this section we are going to prove Theorem 2. To that end, we use the following assumption, mainly to simplify notation.

► **Remark 12.** From here on, we assume $\tau \geq \|\mathbf{p}\|_{\infty}$, i.e., there is a job type for each possible job length $\{1, 2, \dots, \|\mathbf{p}\|_{\infty}\}$. This is without loss of generality in our regime since both quantities are parameters.

► **Theorem 2 (repeated).** *The problems $R|HM|C_{\max}$ and $R|HM|\sum w_j C_j$ parameterized by the number of job types τ , the longest processing time p_{\max} , and the number of machine kinds κ admit a polynomial compression to quadratic huge N -fold IP parameterized by the number of block types $\bar{\tau}$, the block dimension t , and the largest coefficient $\|E\|_{\infty}$.*

Recall that in order to use Theorem 2 to provide *kernels* for selected scheduling problems (which are NP-hard) we want to utilize Proposition 5. Thus, we have to show that the “target problem” quadratic huge N -fold IP is in NP.

► **Lemma 13.** *The decision version of quadratic huge N -fold IP belongs to NP.*

Proof. We will use Proposition 6 to show that there exists an optimum whose number of distinct configurations is polynomial in the input length. Such a solution can then be encoded by giving those configurations together with their multiplicities, and constitutes a polynomial certificate. Recall that (ConflLP) corresponding to the given instance of huge N -fold is

$$\min \mathbf{v}\mathbf{y} : B\mathbf{y} = \mathbf{d}, \mathbf{0} \leq \mathbf{y} \leq (\|\boldsymbol{\mu}\|_\infty, \dots, \|\boldsymbol{\mu}\|_\infty), \mathbf{y} \in \mathbb{N}^C .$$

Let X be the set of columns of the matrix B extended with an additional coordinate which is the coefficient of the objective function \mathbf{v} corresponding to the given column, that is, $\mathbf{v}\mathbf{b}$ for a column \mathbf{b} (i.e., the objective value of configuration \mathbf{b}). Hence $X \subseteq \mathbb{Z}^{r+\bar{\tau}+1}$ and $\|\mathbf{x}\|_\infty \leq \|\mathbf{l}, \mathbf{u}, f_{\max}\|_\infty =: M$ for any $\mathbf{x} \in X$. Applying Proposition 6, part 2, to X , yields that there exists an optimal solution \mathbf{y} of (ConflLP) with $\text{supp}(\mathbf{y}) = \tilde{X}$ satisfying $|\tilde{X}| \leq 2(r + \bar{\tau} + 1) \log(4(r + \bar{\tau} + 1)M)$, hence polynomial in the input length of the original instance. ◀

► **Remark 14.** Clearly Lemma 13 holds for any huge N -fold IP whose objective is restricted by some, not necessarily quadratic, polynomial. Moreover, using the newer technique of Aliev et al. [1] it is likely possible to remove any restrictions on the objective.

Using Theorem 2. Before we move to the proof of Theorem 2 we first derive two simple yet interesting corollaries.

► **Corollary 15.** *The problems $R||C_{\max}$ and $R||\sum w_j C_j$ admit polynomial kernelizations when parameterized by τ, κ, p_{\max} .*

Proof. Let $\text{obj} \in \{C_{\max}, \sum w_j C_j\}$. We describe a polynomial compression from $R||\text{obj}$ to quadratic huge N -fold IP which, by Lemma 13, yields the sought kernel, since $R||\text{obj}$ is NP-hard and huge N -fold with a quadratic objective is in NP.

We first perform the high-multiplicity encoding of the given instance I of $R||\text{obj}$, thus obtaining an instance I_{HM} of $R|HM|\text{obj}$ with the input encoded as $(\mathbf{n}, \mathbf{m}, \mathbf{p}, \mathbf{w})$. Now, we can apply Theorem 2 and obtain an instance $\tilde{I}_{\text{huge } N\text{-fold}}$ equivalent to I_{HM} with size bounded by a polynomial in κ, τ, p_{\max} . ◀

Proof of Corollary 1. This is now trivial, since it suffices to observe that $P||C_{\max}$ is a special case of $R||C_{\max}$, where there is only a single machine kind (i.e., $\kappa = 1$) and $\tau \leq p_{\max}$ job types. Our claim then follows by Corollary 15 (combined with the fact that $P||C_{\max}$ is NP-hard and $R||C_{\max}$ is in NP). ◀

3.1 Huge n -fold IP Models

Denote by \mathbf{n}_{\max} the τ -dimensional vector whose all entries are $\|\mathbf{n}\|_\infty$. It was shown [29, 30] that $R|HM|C_{\max}$ is modeled as a feasibility instance of huge n -fold IP as follows. Recall that we deal with the decision versions and that k is the upper bound on the value of the objective(s). We set $\mathbf{b}^0 = \mathbf{n}$, the number of block types is $\bar{\tau} = \kappa$, $E_1^i := (I \ \mathbf{0}) \in \mathbb{Z}^{\tau \times (\tau+1)}$, $E_2^i := (\mathbf{p}^i \ 1)$, $\mathbf{l}^i = \mathbf{0}$, $\mathbf{u}^i = (\mathbf{n}, \infty)$, $\mathbf{b}^i = k$, for $i \in [\kappa]$, and the multiplicities of blocks are $\boldsymbol{\mu} = \mathbf{m}$. The meaning is that the first type of constraints expressed by the E_1^i matrices ensures that every job is scheduled somewhere, and the second type of constraints expressed by the E_2^i matrices ensures that every machine finishes in time C_{\max} .

In the model of $R|HM|\sum w_j C_j$, for each machine kind $i \in [\kappa]$, we define \preceq^i to be the ordering of jobs by the w_j/p_j^i ratio non-increasingly, and let $\mathbf{a} = (a_1, a_2, \dots, a_\tau)$ be a reordering of \mathbf{p}^i according to \preceq^i . We let

$$G^i := \begin{pmatrix} a_1 & 0 & 0 & \dots & 0 \\ a_1 & a_2 & 0 & \dots & 0 \\ a_1 & a_2 & a_3 & \dots & 0 \\ \vdots & & & \ddots & \\ a_1 & a_2 & a_3 & \dots & a_\tau \end{pmatrix}, \quad H := -I,$$

with I the $\tau \times \tau$ identity, and define $F^i := (G^i \ H)$ in two steps. Denote by I^{\preceq^i} a matrix obtained from the $\tau \times \tau$ identity matrix by permuting its columns according to \preceq^i . The model is then $\mathbf{b}^0 = \mathbf{n}$, the number of block types is again $\bar{\tau} = \kappa$, for each $i \in [\kappa]$ we have $E_1^i = (I^{\preceq^i} \ \mathbf{0}) \in \mathbb{Z}^{\tau \times 2\tau}$, $E_2^i = \bar{F}^i$, $\mathbf{l}^i = \mathbf{0}$, $\mathbf{u}^i = (\mathbf{n}_{\max}, p_{\max} \tau \mathbf{n}_{\max})$, $\mathbf{b}^i = \mathbf{0}$, f^i is a separable convex quadratic function (whose coefficients are related to the w_j/p_j^i ratios), and again $\boldsymbol{\mu} = \mathbf{m}$. Intuitively, in each brick, the first τ variables represent numbers of jobs of each type on a given machine, and the second τ variables represent the amount of processing time spend by jobs of the first j types with respect to the ordering \preceq^i .

3.2 Solving The Separation Problem Quickly: C_{\max}

The crucial aspect of complexity of (sep-IP) is its constraint matrix E_2^i . For $R|HM|C_{\max}$, this is just the vector $(\mathbf{p}^i, 1)$. Clearly $\text{tw}_D((\mathbf{p}^i, 1)) = 1$ since $G_D((\mathbf{p}^i, 1))$ is a single vertex. By Proposition 9, $g_1((\mathbf{p}^i, 1)) \leq 2\|\mathbf{p}\|_\infty + 1$. Moreover, f_{\max} depends polynomially on $\|\mathbf{n}, \mathbf{m}, \mathbf{p}\|_\infty$. Hence, Corollary 11 states that (ConfLP) of the $R|HM|C_{\max}$ model can be solved in time $(rt\bar{\tau}(f_{\max}, \mathbf{l}, \mathbf{u}, \mathbf{b}, \boldsymbol{\mu}))^{\mathcal{O}(1)} \cdot \max_i g_1(E_2^i)^{\text{tw}_D(E_2^i)} = \text{poly}(p_{\max}, \tau, \log \|\mathbf{n}, \mathbf{m}, \mathbf{p}\|_\infty)$, which is polynomial in the input.

3.3 Solving The Separation Problem Quickly: $\sum w_j C_j$

The situation is substantially more involved in the case of $R|HM|\sum w_j C_j$: in order to apply Corollary 11, we need to again bound $g_1(E_2^i)$ and $\text{tw}_D(E_2^i)$, but the matrix E_2^i is more involved now. Let

$$\bar{G}^i := \begin{pmatrix} a_1 & 0 & \dots & 0 \\ 0 & a_2 & \dots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \dots & a_\tau \end{pmatrix}, \quad \bar{H} := \begin{pmatrix} -1 & 0 & 0 & \dots & 0 \\ 1 & -1 & 0 & \dots & 0 \\ 0 & 1 & -1 & \dots & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 1 & -1 \end{pmatrix},$$

and define $\bar{F}^i = (\bar{G}^i \ \bar{H})$. Now observe that F^i and \bar{F}^i are row-equivalent³. This means that we can replace F^i with \bar{F}^i without changing the meaning of the constraints and without changing the feasible set. But while $\text{tw}_D(F_i) = \tau$ (because it is the clique K_τ), we have

► **Lemma 16** (\star). *For each $i \in [\kappa]$, $\text{tw}_D(\bar{F}^i) = 1$.*

Note that application of Proposition 9 yields $g_1(E_2^i) \leq \mathcal{O}(\tau^\tau)$. This general upper bound, as we shall see, is not sufficient for our purposes, since we need $g_1(E_2^i) \leq \text{poly}(\tau)$. However, we can improve it significantly:

³ Two matrices A, A' are row-equivalent if one can be transformed into the other using elementary row operations.

► **Lemma 17** (Hill-cutting). *We have $g_\infty(F^i), g_\infty(\bar{F}^i) \leq \mathcal{O}(\tau^4)$ and $g_1(F^i), g_1(\bar{F}^i) \leq \mathcal{O}(\tau^5)$ for every $i \in [\kappa]$.*

Proof. Let $F = F^i$ for some $i \in [\kappa]$. Let $(\mathbf{x}, \mathbf{z}) \in \mathbb{Z}^{2\tau}$ be some vector satisfying $F \cdot (\mathbf{x}, \mathbf{z}) = \mathbf{0}$. Our goal now is to show that whenever there exists $k \in [\tau]$ with $|z_k - z_{k-1}| > 2\tau^3 + 1$ (where we define $z_0 := 0$ for convenience), then we can construct a non-zero integral vector $(\mathbf{g}, \mathbf{h}) \in \text{Ker}_{\mathbb{Z}}(F)$ satisfying $(\mathbf{g}, \mathbf{h}) \sqsubseteq (\mathbf{x}, \mathbf{z})$, which shows that $(\mathbf{x}, \mathbf{z}) \notin (A)$. If no such index k exists, it means that $\|\mathbf{x}\|_\infty \leq \mathcal{O}(\tau^3)$ because $z_k - z_{k-1} = a_k x_k$ holds in F (and \bar{F}^i). Moreover, if $|z_k - z_{k-1}| \leq 2\tau^3 + 1$ for all $k \in [\tau]$, then $|z_k| \leq \mathcal{O}(\tau^4)$ for every $k \in [\tau]$, hence $\|(\mathbf{x}, \mathbf{z})\|_\infty \leq \mathcal{O}(\tau^4)$. Note that, since the dimension of (\mathbf{x}, \mathbf{z}) is 2τ , this also implies $\|(\mathbf{x}, \mathbf{z})\|_1 \leq \mathcal{O}(\tau^5)$. Thus we now focus on the case when $\exists k \in [\tau] : |z_k - z_{k-1}| > 2\tau^3 + 1$.

Let us now assume that $(z_k - z_{k-1})$ is positive and $z_k \geq \tau^3$. There are three other possible scenarios: when $(z_k - z_{k-1})$ is positive but $z_k < \tau^3$, or when $(z_k - z_{k-1})$ is negative and $z_k < -\tau^3$ or $z_k \geq -\tau^3$. We will later show that all these situations are symmetric to the one we consider and our arguments carry over easily, hence our assumption is without loss of generality.

▷ **Claim 18** (★). If $(z_k - z_{k-1})$ is positive and $z_k \geq \tau^3$, then there exists nonzero $(\mathbf{g}, \mathbf{h}) \in \text{Ker}_{\mathbb{Z}}(F)$ with $(\mathbf{g}, \mathbf{h}) \sqsubseteq (\mathbf{x}, \mathbf{z})$.

Let us consider the remaining symmetric cases. If $z_k - z_{k-1}$ is negative and $z_k < -\tau^3$, then $(-\mathbf{x}, -\mathbf{z})$ satisfies the original assumption, leading to some $(\mathbf{g}', \mathbf{h}') \sqsubseteq (-\mathbf{x}, -\mathbf{z})$, hence $(-\mathbf{g}', -\mathbf{h}') \sqsubseteq (\mathbf{x}, \mathbf{z})$ and we are done. If $z_k - z_{k-1}$ is negative but $z_k > -\tau^3$, then we would pick the largest index ℓ smaller than k with $x_\ell > \tau$ and continue as before (the symmetry is that now ℓ is to the left of k rather than to its right; that is, the case distinction from the previous paragraph is according to the value of z_1). Lastly, if $z_k - z_{k-1}$ is positive but $z_k < \tau^3$, negating (\mathbf{x}, \mathbf{z}) gives a reduction to the previous case. ◀

Together with the observation from the previous section and using our newly obtained bounds together with Corollary 11, we obtain:

► **Corollary 19.** *Let $I = (\mathbf{n}, \mathbf{m}, \mathbf{p}, \mathbf{w})$ be an instance of $R|HM|C_{\max}$ or $R|HM|\sum w_j C_j$. A (ConfLP) optimum \mathbf{y}^* with $|\text{supp}(\mathbf{y}^*)| \leq r + \bar{\tau}$ can be found in time $\text{poly}(p_{\max}, \tau, \kappa, \langle \mathbf{n}, \mathbf{m}, \mathbf{p}, \mathbf{w} \rangle)$.*

4 Conclusions and Research Directions

On the side of theory, one may wonder why not apply the approach developed here to other scheduling problems, in particular those modeled as quadratic huge N -fold IP in [30], such as $R|r_j, d_j|\sum w_j C_j$. The answer is simple: we are not aware of a way to solve the separation problem in polynomial time; in fact, we believe this to be a hard problem roughly corresponding to UNARY VECTOR PACKING in variable dimension. However, the typical use of Configuration LP is not to obtain an exact optimum (which is often hard), but to obtain an approximation which is good enough. Perhaps a similar approach within our context may lead to so-called *lossy kernels* [36]? However, it is not even clear that an approximate analogue of Theorem 3 holds, because getting an LP solution whose value is close to optimal does not immediately imply getting a solution which is (geometrically) close to some optimum; cf. the discussions on ϵ -accuracy in [11, Definition 31] and [25, Introduction]. Another interesting problem highlighted here is to find a combinatorial algorithm computing the Carathéodory decomposition of the average configuration \mathbf{n}/m into machine configurations. The only approach we are aware of so far uses the equivalence of separation and optimization (thus, the ellipsoid method), which is impractical.

Abstract Morphing Using the Hausdorff Distance and Voronoi Diagrams

Abstract

This paper introduces two new abstract morphs for two 2-dimensional shapes. The intermediate shapes gradually reduce the Hausdorff distance to the goal shape and increase the Hausdorff distance to the initial shape. The morphs are conceptually simple and apply to shapes with multiple components and/or holes. We prove some basic properties relating to continuity, containment, and area. Then we give an experimental analysis that includes the two new morphs and a recently introduced abstract morph that is also based on the Hausdorff distance [23]. We show results on the area and perimeter development throughout the morph, and also the number of components and holes. A visual comparison shows that one of the new morphs appears most attractive.

1 Introduction

Morphing, also referred to as shape interpolation, is the changing of a given shape into a target shape over time. Applications include animation and medical imaging. Animation is often motivated by the film industry, where morphing can be used to create cartoons or visual effects. In medical imaging, the objective is a 3D reconstruction from cross-sections, such as those from MRI or CT scans. Reconstruction between two 2D slices is essentially 2D interpolation between shapes, which is a form of morphing. We regard morphing itself as the change of one shape into another shape by a parameter, or, more precisely, a function from the interval $[0, 1]$ to shapes in a space, such that the image at 0 is the one input shape and the image at 1 is the other input shape. It is often convenient to see the morphing parameter as time. In the rest of this paper, we will refer to the shape of the morph at any particular time value as an *intermediate shape*. See Figure 1 for an example of two halfway shapes between polygons resembling a butterfly and a spider.

The quality of a morph depends on the application. For medical imaging, the implied 3D reconstruction must be anatomically plausible. For morphing between two drawings of a cartoon character, the shapes in between must keep the dimensions of the limbs, for example. Furthermore, semantically meaningful features (nose, chin) should morph from their position in the one shape to their position in the other shape.

■ **Figure 1** The intermediate shapes of two different morphing methods at time value $1/2$ when morphing between the input shapes on the left. The middle shows the dilation morph (introduced in [23]), the right shows the Voronoi morph (introduced in this paper).

In this paper we concentrate on abstract morphing of shapes. A morphing task is abstract if there is no (semantic) reason to transform certain parts of a starting shape into certain parts of a goal shape. In a recent paper, van Kreveld et al. [23] presented a new type of abstract morphing based on the Hausdorff distance. It takes any two compact planar shapes A and B as input, and produces a morphed shape that interpolates smoothly between them. For a time value $\alpha \in [0, 1]$, this morph is equal to A at $\alpha = 0$ and to B at $\alpha = 1$. For any value of α it has Hausdorff distance α to A and Hausdorff distance $1 - \alpha$ to B , if the initial Hausdorff distance is 1 (the input can be scaled to make this true without changing intermediate shapes). Morphs with this property are called *Hausdorff morphs* [23]. The Hausdorff morph introduced by van Kreveld et al. is based on Minkowski sums with a disk, and hence we refer to this specific one as the *dilation morph*.

While the dilation morph has nice theoretical properties, in practice it will often grow intermediate shapes from A until $\alpha = 1/2$, at which point the greatly dilated shape will shrink back towards B . For α close to $1/2$, the morphed shape typically resembles neither of the input shapes unless they already looked alike. We can see this in Figure 1.

In this paper we present a new Hausdorff morph called *Voronoi morph* that gives a more visually convincing morph, while maintaining many of the properties of the previous work. Our morph uses Voronoi diagrams to partition each input shape into regions with the same closest point on the other shape, and then scales and moves each such region to that closest point based on the value of α . We show that the Voronoi morph is also a Hausdorff morph. It interpolates smoothly between A and B , but does not have the same problem of significantly increasing the area during the morph. We also present a variant called *mixed morph* that reduces the problem of unnecessarily increasing the perimeter of the interpolated shape. It uses dilation and erosion to overcome some shortcomings of the Voronoi morph.

Related work. The Hausdorff distance is a widely used distance metric that can be used for any two subsets of a space. It is a bottleneck measure: only a maximum distance determines the Hausdorff distance. Efficient algorithms to compute the Hausdorff distance between two simple polygons or their higher-dimensional equivalents exist [3, 4, 7]. The Hausdorff distance is used in computer vision [19] and computer graphics [6, 17] for template matching, and the computation of error between a model and its simplification.

Several algorithmic approaches to morphing have been described. Many of these are motivated by shape interpolation between slices (e.g., [2, 9, 10, 12], an overview can be found in [11]). Other papers discuss morphing explicitly and not as an interpolation problem. Many of these results use compatible triangulations [20, 24], in particular those that avoid self-intersections. It is beyond the scope of this paper to give a complete overview of morphing methods. For (not so recent) surveys of shape matching, interpolation, and correspondence, see [5, 22]. Our paper builds upon the morphing approach given in [23], which introduced Hausdorff morphs as a new technique for abstract morphing, and the dilation morph as a specific example of a Hausdorff morph.

Another shape similarity measure than the Hausdorff distance, the *Fréchet* distance, can also be used to define a morph. In particular, *locally correct Fréchet matchings* [14] immediately imply a smooth transition of one shape outline into another, because they match all pairs of points on the two curves. Similar approaches were given in [25, 26]. During the transition, however, the outline may be self-intersecting. This problem was addressed in [15, 16]. A more important shortcoming of morphing using the Fréchet distance is that it is unclear how to morph between shapes with different numbers of components and holes.

Much of the commercial software for morphing applies to images, with or without additional human control. Other software is meant as toolkits for designers to design their own morphs, most notably Adobe After Effects.

Our results. We introduce two new abstract morphs based on the Hausdorff distance. They are – just like the dilation morph – conceptually simple and easy to implement if one has code for Minkowski sum and difference with a disk, Voronoi diagrams, and polygon intersection and union. We examine basic properties of the two new morphs and compare how they relate to the dilation morph. In particular, we show that the Voronoi morph is a Hausdorff morph and that it is 1-Lipschitz continuous. We also show that for any morphing parameter (time), the Voronoi-morph intermediate shape is a subset of the mixed-morph intermediate shape, which in turn is a subset of the dilation-morph intermediate shape.

We then proceed with an extensive experimental analysis where we compare four basic quantities: area, perimeter, number of components, and number of holes. We show how these quantities develop throughout the three morphs. We also present visual results. As data we use simple drawings of animals, country outlines, and text (letters and whole words).

2 Preliminaries

Given two sets A and B , we can define the directed Hausdorff distance from A to B as

$$d_{\vec{H}}(A, B) := \sup_{a \in A} \inf_{b \in B} d(a, b),$$

where d denotes the Euclidean distance. The *undirected Hausdorff distance* between A and B is then defined as the maximum of both directed distances:

$$d_H(A, B) := \max(d_{\vec{H}}(A, B), d_{\vec{H}}(B, A)).$$

When A and B are closed sets, we can alternatively define the Hausdorff distance using Minkowski sums. Recall that the Minkowski sum $A \oplus B$ is defined as $\{a + b \mid a \in A, b \in B\}$; the directed Hausdorff distance between A and B is then the smallest value r for which $A \subseteq B \oplus D_r$, where D_r is a disk of radius r .

Van Kreveld et al. [23] then define a function that interpolates between two shapes in a Hausdorff sense: For any time parameter $\alpha \in [0, 1]$, they define the dilation morph

$$S_\alpha(A, B) := (A \oplus D_\alpha) \cap (B \oplus D_{1-\alpha}),$$

and prove that this shape has Hausdorff distance α to A and $1 - \alpha$ to B , and that it is the maximal shape with this property. Additionally, they show that this morph is 1-Lipschitz continuous: for two time parameters α and β , $d_H(S_\alpha(A, B), S_\beta(A, B)) \leq |\beta - \alpha|$. Note that we will omit the arguments A, B when they are clear from context.

Structurally, it turns out that the intermediate shapes may have quadratic complexity, even when the input is two simple polygons with n vertices each. For instance, if the input consists of a horizontal comb and an overlapping vertical comb, each with $n/4$ prongs, S_α will consist of $\Omega(n^2)$ components for any $\alpha \in (0, 1)$. In fact, this is not limited to the dilation morph: *any* intermediate shape with Hausdorff distance α to A and $1 - \alpha$ to B will have $\Omega(n^2)$ components [23], so every Hausdorff morph has this feature.

Note that both S_α and the morphing methods described below change when we translate one of the input shapes. That is, if we write $t + B$ to be the translation of B over a vector t , it is not true that $S_\alpha(A, t + B) = \alpha * t + S_\alpha(A, B)$, as one might expect. This is because the positions of the input shapes are important both for the Hausdorff distance and for the shape of S_α . However, we can simply calculate $S_\alpha(A, B)$ with A and B aligned in some way, and then generate $S_\alpha(A, t + B)$ by explicitly translating $S_\alpha(A, B)$ by $\alpha * t$. Sensible alignment methods include aligning the centroids, maximising the overlap of the shapes, and minimising the Hausdorff distance.

3 Voronoi morph

As demonstrated in Figure 1, one of the problems with the dilation morph is that the intermediate shapes tend to lose any resemblance to the input during the morphing process. The main reason for this is that the dilated shapes we are intersecting contain many points that do not influence the Hausdorff distance in any way, because they are not on the shortest path from a point on one shape to the closest point on the other. In other words, much of S_α can be removed without changing the Hausdorff distance to and from the input. That said, there is no obvious “correct” way to determine which parts should be removed to obtain the greatest resemblance to the input.

We propose a morph in which we only take the points of S_α that are on the shortest path between points in one input shape and the closest point on the other. Specifically, we only take the points where the ratio of distances to the one shape and the closest point on the other is $\alpha : 1 - \alpha$. More formally, we define our new morph T_α as follows:

$$T_\alpha(A, B) := \{a + \alpha(c(a, B) - a) \mid a \in A\} \cup \{b + (1 - \alpha)(c(b, A) - b) \mid b \in B\},$$

where $c(a, B)$ denotes the point on B closest to a . In other words, we move each point in A closer to the closest point in B by a fraction α of that distance, and each point in B closer to the closest point in A by a fraction $1 - \alpha$, and take the union of those two shapes. If a point is equidistant to multiple points in the other shape, we include all options. We can prove that this morph has the desired Hausdorff distances to the input.

► **Theorem 1.** *Let A and B be two compact sets in the plane with $d_H(A, B) = 1$. Then for any $0 \leq \alpha \leq 1$, we have $d_H(A, T_\alpha) = \alpha$ and $d_H(B, T_\alpha) = 1 - \alpha$.*

Proof. We first show that $d_H(A, T_\alpha) \leq \alpha$, and then show strict equality. The case for $d_H(B, T_\alpha)$ is analogous and therefore omitted.

By construction, any point $a \in A$ has a point at distance $\leq \alpha$ in T_α , showing that $d_H(A, T_\alpha) \leq \alpha$. Similarly, by construction, for each point $b \in B$ there is a point $t_b \in T_\alpha$ such that $t_b = (1 - \alpha)(c(b, A) - b)$. As $d(b, c(b, A)) \leq 1$, it must be the case that t_b has distance

■ **Figure 2** On the left, A is partitioned by the Voronoi diagram $V(B)$ of B . On the right, each partitioned part of A , shown in green, is scaled towards the closest point on B by a factor α .

at most α to $c(b, A)$. It follows that all points in T_α have distance at most α to a point in A , thereby showing that $d_{\bar{H}}(T_\alpha, A) \leq \alpha$. As we have both $d_{\bar{H}}(A, T_\alpha) \leq \alpha$ and $d_{\bar{H}}(T_\alpha, A) \leq \alpha$, it follows that $d_H(A, T_\alpha) \leq \alpha$.

To show strict equality, assume the Hausdorff distance is realised by some point $\hat{a} \in A$ with closest point $\hat{b} \in B$, i.e., $d(\hat{a}, \hat{b}) = 1$. By construction, there is a point $\hat{t} \in T_\alpha$ at distance α from \hat{a} and at distance $1 - \alpha$ from \hat{b} . As \hat{t} is the closest point to \hat{a} in T_α , we have $d_H(A, T_\alpha) = \alpha$, and as \hat{b} is the closest point to \hat{t} in B , we have $d_H(B, T_\alpha) = 1 - \alpha$. If the Hausdorff distance is realised by a point on B , we use a symmetric argument. ◀

We can additionally show that the Voronoi morph, like the dilation morph, is 1-Lipschitz continuous in a Hausdorff sense:

▶ **Lemma 2.** *Let $\alpha, \beta \in [0, 1]$. Then $d_H(T_\alpha, T_\beta) \leq |\beta - \alpha|$.*

Proof. Let t_α be any point on T_α . Assume without loss of generality that there is some $a \in A$ such that $t_\alpha = a + \alpha(c(a, B) - a)$ (the case for t_α being included due to a point in B is analogous). Now consider the point $t_\beta = a + \beta(c(a, B) - a)$: t_α and t_β are on the same straight line segment between a and $c(a, B)$, and have distance $|\beta - \alpha| \cdot |c(a, B) - a|$ to each other. As $d_H(A, B) = 1$, we know that $|c(a, B) - a| \leq 1$, and therefore that $|t_\beta - t_\alpha| \leq |\beta - \alpha|$. This holds for any $t_\alpha \in T_\alpha$, and the argument is symmetric for T_β . ◀

Note that this type of continuity implies that components of T_α can only form or disappear by merging with or splitting from another component.

In addition to the Hausdorff distance-related properties, it is also interesting to study the general geometric and topological properties of T_α . We first show that the number of components $\#C(T_\alpha)$ of T_α does not change during the morph, except possibly at $\alpha = 0$ and $\alpha = 1$. We prove this for the case of polygonal input; the proof can likely be generalised, but the formalisation is somewhat tedious and not particularly interesting.

Let $V(A)$ be the Voronoi diagram of the vertices, open edges and the interior components of A . We now define $\text{Par}(A, B)$ to be the input shape A partitioned into regions by $V(B)$. Note that $\text{Par}(A, B)$ is a set of regions of A that each have the closest point of B on the same vertex, edge or face of B . For some region $P \in \text{Par}(A, B)$, let P_α be the region obtained by scaling P towards the site of the Voronoi cell of B it is in by a factor α . If this site is a vertex, we simply scale P uniformly towards it; if it is an edge, we scale it perpendicular to the supporting line of that edge; and if it is a face, it does not scale or move at all; see Figure 2 for an illustration. Now let $\text{Par}_\alpha(A, B) := \{P_\alpha \mid P \in \text{Par}(A, B)\}$. Note that T_α is the union of all elements of $\text{Par}_\alpha(A, B)$ and $\text{Par}_{1-\alpha}(B, A)$.

► **Lemma 3.** *Let $0 < \alpha < \beta < 1$. Then $\#C(T_\alpha) = \#C(T_\beta)$.*

Proof. Assume that $\#C(T_\alpha) \neq \#C(T_\beta)$. We can assume without loss of generality that $\#C(T_\alpha) > \#C(T_\beta)$, as in the other case we can take $T_\alpha(B, A)$ instead of $T_\alpha(A, B)$ and get the same morph, but parametrised in reverse. We can also assume that for fixed α, β is the smallest value such that $\#C(T_\alpha) > \#C(T_\beta)$. In this case, there are two regions P and Q of $\text{Par}(A, B)$ or $\text{Par}(B, A)$ that are disjoint and in different components of T_α , but intersect and are in the same component of T_β . This is because, as a consequence of Lemma 2, components cannot appear or disappear. In the following we assume $P, Q \in \text{Par}(A, B)$; the arguments for when one or both are in $\text{Par}(B, A)$ are identical.

As $P_\beta \cap Q_\beta \neq \emptyset$, there must be some point p in both P_β and Q_β . As both P_β and Q_β are formed by regions moving towards the closest point on the other shape, this point is then on the intersection of two shortest paths between A and B . Let a_1, b_1, a_2 and b_2 be the endpoints of these paths intersecting in p . One of the two segments $\overline{pb_1}, \overline{pb_2}$ will be the shortest; assume without loss of generality that it is $\overline{pb_1}$. In this case the path a_2pb_1 is shorter than a_2pb_2 , and by the triangle inequality b_1 must be closer to a_2 than b_2 .

This contradicts the assumption that b_2 was the closest point to a_2 . We conclude that such shortest paths can never intersect, and therefore $P_\alpha \cap Q_\alpha = \emptyset$ for any $\alpha \in (0, 1)$. As such, components can never merge or split for $\alpha \in (0, 1)$, and as they also cannot appear or disappear by Lemma 2, the statement in the lemma follows. ◀

Note that the number of components can change at $\alpha = 0$ or $\alpha = 1$, as in these limit cases elements of $\text{Par}_\alpha(A, B)$ and $\text{Par}_\alpha(B, A)$ turn into points or line segments. Using the strategy from this proof, it also follows that $\text{Par}_\alpha(A, B)$ and $\text{Par}_{1-\alpha}(B, A)$ are interior-disjoint. An interesting corollary of this observation is that the area $|T_\alpha|$ of T_α is bounded from below by $(1 - \alpha)^2 |A| + \alpha^2 |B|$, which is attained when both shapes are disjoint and all parts are moving to a finite number of points (vertices) on the other shape.

3.1 A variant morph

One problem with the Voronoi morph is that it can introduce many slits into the boundary, thereby greatly increasing the perimeter of the shape. This is because parts of the input that have different closest points on the other shape will tend to move away from each other. We present a variant of the Voronoi morph that tries to reduce these problems. As it uses both the Voronoi morph and the dilation morph, we call this variant the *mixed morph*. The mixed morph $M_{\alpha, \varphi}$ is defined as follows:

$$M_{\alpha, \varphi}(A, B) := ((T_\alpha(A, B) \oplus D_\varphi) \ominus D_\varphi) \cap S_\alpha,$$

where \ominus is the Minkowski difference, defined as $A \ominus B := (A^c \oplus B)^c$, where A^c is the complement of A . Taking a Minkowski sum with a disk is also known as *dilation*, and the Minkowski difference with a disk is known as *erosion*. Performing first a dilation and then an erosion with disks of the same radius is known as *closing*, and can be used to close small gaps and holes in a shape without modifying the rest too much. The closing operator is widely used and studied in the field of image analysis [21].

The resulting morph may no longer be a Hausdorff morph: we may have increased the Hausdorff distance by closing certain gaps or holes. We therefore intersect the closed version of T_α with the dilation morph S_α , so that gaps that are necessary to obtain the appropriate Hausdorff distance are maintained. This results in the mixed morph $M_{\alpha, \varphi}$.

The mixed morph has a new parameter, φ , being the radius of the disk used in the closing. Note that $M_{\alpha,0} = T_\alpha$. We can show that $M_{\alpha,\varphi}$ contains all shapes obtained with the same α but smaller value of φ :

► **Lemma 4.** *Let $\varphi, \psi \in \mathbb{R}^+$ and $\varphi \leq \psi$. Then $M_{\alpha,\varphi} \subseteq M_{\alpha,\psi}$.*

Proof. Let us assume that $M_{\alpha,\varphi} \supset M_{\alpha,\psi}$ instead. Then there is some point p such that $p \in M_{\alpha,\varphi}$, but $p \notin M_{\alpha,\psi}$. There are two reasons why p might not be in $M_{\alpha,\psi}$: either $p \notin T_\alpha \oplus D_\psi$, or $p \in T_\alpha \oplus D_\psi$ but $p \notin (T_\alpha \oplus D_\psi) \ominus D_\psi$.

It can clearly not be the case that $p \in M_{\alpha,\varphi}$ but $p \notin T_\alpha \oplus D_\psi$: $M_{\alpha,\varphi}$ is a subset of $T_\alpha \oplus D_\varphi$, and as $\varphi \leq \psi$, we have that $T_\alpha \oplus D_\varphi \subseteq T_\alpha \oplus D_\psi$.

It must then be the case that $p \in T_\alpha \oplus D_\psi$ but $p \notin (T_\alpha \oplus D_\psi) \ominus D_\psi$. In this case, the distance between p and the boundary ∂T_α^\oplus of $T_\alpha \oplus D_\psi$ must be less than ψ . Let $q \in \partial T_\alpha^\oplus$ be the point on the boundary closest to p . As $p \in T_\alpha \oplus D_\varphi$ and $T_\alpha \oplus D_\varphi \subseteq T_\alpha \oplus D_\psi$, the segment \overline{pq} must intersect the boundary of $T_\alpha \oplus D_\varphi$ in some point q' . We must have that $d(p, q') \geq \varphi$, or p would not be in $M_{\alpha,\varphi}$, and we must have $d(q, q') \geq \psi - \varphi$, as $T_\alpha \oplus D_\psi = (T_\alpha \oplus D_\varphi) \oplus D_{\psi-\varphi}$. But then, by the triangle inequality, $d(p, q) \leq d(p, q') + d(q, q') \geq \psi$, which is a contradiction. Hence, $p \in M_{\alpha,\psi}$. As this holds for all $p \in M_{\alpha,\varphi}$, the statement in the lemma follows. ◀

Note that this means we now have the following hierarchical containment of morphs: $T_\alpha \subseteq M_{\alpha,\varphi} \subseteq M_{\alpha,\psi} \subseteq S_\alpha$, for $\varphi \leq \psi$. As T_α is a Hausdorff morph, and S_α is the maximal Hausdorff morph, this shows that $M_{\alpha,\varphi}$ is a Hausdorff morph as well. However, $M_{\alpha,\varphi}$ is not 1-Lipschitz continuous: components may suddenly merge when their distance falls below 2φ .

3.2 Algorithm

To give an algorithm for computing T_α , we assume A and B are (sets of) polygons, possibly with holes. As T_α is based on moving all points on the one shape to the closest point on the other shape, we can compute the Voronoi diagram of each input shape, and then use these to partition the other shapes. This gives us a partitioning of A into pieces that overlap B , or have the same closest point or edge on B , and vice versa. Pieces of A completely inside B are unchanged, pieces with a vertex as closest element are scaled uniformly towards that vertex by a factor α , and pieces with an edge as closest element are scaled perpendicular to the supporting line of that edge by a factor α . For pieces of B we do the same, except that we scale them with a factor $1 - \alpha$. Figure 2 shows an example of how a shape A is partitioned by the Voronoi diagram $V(B)$ of B , and each piece is scaled towards the closest point on B .

Given this algorithm, we can also straightforwardly compute $M_{\alpha,\varphi}$ by computing T_α and S_α , dilating and eroding T_α by a distance φ , and then intersecting the result with S_α .

Our computations rely solely on Voronoi diagrams, Minkowski sums and differences with disks, intersections and unions of polygons, all of which can be found in standard books or surveys [1, 8, 18] and an intermediate shape can be calculated in $O(n^2 \log n)$ time.

4 Experiments

We compare the dilation, Voronoi and mixed morphs experimentally on three data sets. The first data set is a collection of outlines of animals taken from [13]. The second is a selection of the outlines of European countries obtained from the Thematic Mapping World Borders data set;¹ we use the outlines of Austria, Belgium, Croatia, Czechia, France, Germany, Greece, Ireland, Italy, the Netherlands, Poland, Spain and Sweden. For these two sets we compute

¹ http://www.thematicmapping.org/downloads/world_borders.php

the morphs for all pairs of animals and all pairs of countries in the sets. None of the three morphs is translation-invariant or scale-invariant, so it matters where we place the shapes with respect to each other and what sizes they initially have. We choose to scale the shapes to have the same area and translate them to have a common centroid.

The third data set is a small collection of words and letters manually traced as polygons. We use three pairs of words (wish/luck, kick/stuff, try/it), and the letters f, i and u in a serif and a sans serif font. Observe that our morphs could in theory be used to define an infinite family of fonts by interpolating between the glyphs of each element. For these experiments we do not scale the shapes but use the font size, and we align them manually.

For each experiment, we measure the area, perimeter, number of components and number of holes of the morph for α values starting at zero and increasing in steps of $1/8$. The parameter φ of the mixed morph was universally set to 0.02 based on preliminary experimentation.

It is not necessarily insightful to compare areas and especially perimeters between experiments. To make the results more comparable, we make the assumption that an ideal morph linearly interpolates the area and perimeter between those of the input shapes. For each experiment, we can then give the ratio between the measured area and perimeter and these “ideal” values. For the number of components and holes this is less meaningful, as these are discrete values, so we simply record the numbers directly.

Each morphing method was implemented in C++, using Boost² to calculate intersections and unions of polygons, Voronoi diagrams, and Minkowski sums. Although efficiency is not the focus of this paper, running all our experiments only took a few minutes in total.

5 Results

A summary of our measurements of area and perimeter can be seen in Tables 1 and 2. A summary of the number of components and holes for only the animals data set can be seen in Table 3; we exclude the other data sets because the inputs have different numbers of components. Topological measurements for the animals data set can be viewed in Table 4; the measurements for the other experiments can be viewed in the full version. We note that the Voronoi and mixed morphs sometimes have spurious holes caused by numerical precision issues (e.g., the Voronoi morph should not have an intermediate shape with five holes in our experiment with the letter i). Animations of the different morphs for each experiment can be viewed online.³

In Figure 3 we can see that the average area of the dilation morph quickly grows as α increases, until reaching its peak at $\alpha = 1/2$, to about three times the desired size. For the perimeter we see the opposite trend, with the dilation morph typically having a lower perimeter than desired. This is a consequence of the dilation erasing details in the boundary of the input shapes. We can see in Figure 4 that this happens more quickly in the experiments with country shapes. This is expected, as most of the country shapes have more sharp coastline features and islands that quickly disappear, whereas the animal shapes are generally smoother and only have one component.

Our Voronoi morph on average has an area that is much closer to the desired value, and with much lower variance than the dilation morph. However, we see that on average the perimeter is much higher than the desired value. This is because points on opposite sides of a Voronoi edge move in different directions, causing new boundaries to appear in the interior

■ **Figure 4** The average perimeter over all experiments as a function of α , for both the animals and countries data sets.

of a shape as soon as $\alpha > 0$. We can see this happen in the middle column of Figure 5, and this is reflected in Figure 4, where we see the perimeter sharply increase and then stay mostly the same, before sharply dropping back down.

Our mixed morph achieves its purpose of reducing the perimeter of the Voronoi morph: the measured perimeters are close to the desired values, while the measured areas stay comparable to those of the Voronoi morph. In Figure 4, we see that the perimeter typically still increases during the morphing process, but does not jump up sharply as soon as $\alpha > 0$. This is because the small value of φ lets us close only the narrow gaps that appear around the edges of the Voronoi diagram, but not the gaps that develop as pieces of the shapes move apart significantly. We can see this when comparing the middle and right columns of Figure 5: fewer gaps are closed at $\alpha = 1/2$ than at the other time values.

In addition to area and perimeter, we also tracked the number of components and holes for each morph type. We observe that for the dilation morph, there is an intermediate shape with only one component in all but one of our experiments, showing that this morph tends to turn everything into a blob during the morphing process. On the other hand, the Voronoi morph tends to have an intermediate shape with a number of components much larger than either of the input shapes. The mixed morph exhibits neither of these behaviours. This is illustrated in Figure 5.

Inspecting the morphs visually (see both the full version online for more figures, as well as <https://hausdorff-morphing.github.io> for all experiments), our mixed morph looks quite reasonable, especially when the area of symmetric difference between the input shapes is small. In many cases, the intermediate shape at $\alpha = 1/2$ is a recognisable mix of the two input shapes. This is not the case for the dilation morph, where the Hausdorff distance needs to be very small compared to the size of the input shapes for it to look good. For instance, when one shape has some small islands far away, the dilation morph will grow to have a very large area, whereas with the Voronoi and mixed morphs, the islands just slowly move towards the closest point on the other shape; see the full version online. However, both the Voronoi and mixed morph can still look bad when the area of symmetric difference is large. It may therefore be best to align the input shapes such that the area of symmetric difference is minimised, rather than simply aligning the centroids.

■ **Figure 5** Intermediate shapes for $\alpha \in \{0, 1/4, 1/2, 3/4, 1\}$ when morphing between the outlines of Germany and Italy. The columns show the dilation morph, Voronoi morph and mixed morph from left to right.

■ **Figure 6** Intermediate shapes for $\alpha \in \{0, 1/4, 1/2, 3/4, 1\}$ when morphing between the outlines of the words try and it. The columns show the dilation morph, Voronoi morph and mixed morph from left to right. Note that some artefacts in the Voronoi and mixed morphs, such as in the curved part of the letter r, are caused by having polygonal input instead of smooth curves.

The morphs generally look less convincing on our experiments with text, as the shapes can be very different. For single letters the morphs can look convincing, but when morphing between words, especially of different numbers of letters, the intermediate shape at $\alpha = 1/2$ does not necessarily resemble both input shapes (see Figure 6). However, the intermediate shapes at $\alpha = 1/4$ and $\alpha = 3/4$ still do clearly resemble input shapes A and B , respectively, for the Voronoi and mixed morphs, but less so for the dilation morph. A better approach to morphing text may be to morph on a per-letter basis, rather than treating the whole text as a single shape. Some strategy would then have to be devised that determines which letter will morph to which, and how to deal with different Hausdorff distances between the letter pairs.

Both the Voronoi morph and the mixed morph often have small parts separating, moving, and then merging somewhere else (for example, the beak in the bird-to-ostrich morphs on <https://hausdorff-morphing.github.io>). Such artifacts may be circumvented by choosing a slightly warped Voronoi diagram, but this upsets the simplicity of the current methods. We can sometimes notice in the animations that the mixed morph is indeed not Lipschitz continuous, but since φ is rather small, this does not show clearly.

6 Conclusion

We introduced a new abstract morphing method based on Voronoi diagrams. This new method satisfies the same bounds on the Hausdorff distance as the previously introduced dilation morph, and is also 1-Lipschitz continuous. We have shown experimentally that the intermediate shapes of the Voronoi morph have areas that more closely match those of the input shapes than the dilation morph, but tends to have a perimeter that is larger than desired. To remedy this, we introduced a variant morph, the mixed morph, that we experimentally show to reduce this problem of increasing the perimeter. This mixed morph still satisfies the bounds on the Hausdorff distance, but is no longer 1-Lipschitz continuous. Our experimental analysis is the first we are aware of that analyses the development of area, perimeter, number of components and number of holes throughout the morphs.

An interesting open question is whether we can prevent the increase in perimeter caused by the Voronoi morph without losing 1-Lipschitz continuity. This would require somehow anticipating the moment when two pieces of boundary will meet, and smoothly bridging the gap between them over time, instead of just instantly filling it. To optimise the mixed morph, we can study the effects of choosing different φ , or even changing φ throughout the morph. Another direction is to develop other morphs that guarantee a smooth change of some distance measure other than the Hausdorff distance; we noted that it is unclear how to employ the Fréchet distance for morphing in the presence of multiple components.

A more practically oriented direction for further research would be to develop a less naive method of filling gaps than the mixed morph. It does not necessarily make sense to use the same radius for the closing operator everywhere, which sometimes closes gaps that will be opened again. However, any adaptation of this type will disrupt the conceptual simplicity of the Voronoi and mixed morphs.

Average Sensitivity of the Knapsack Problem

Soh Kumabe 

The University of Tokyo, Japan

Yuichi Yoshida  

National Institute of Informatics, Tokyo, Japan

Abstract

In resource allocation, we often require that the output allocation of an algorithm is stable against input perturbation because frequent reallocation is costly and untrustworthy. Varma and Yoshida (SODA'21) formalized this requirement for algorithms as the notion of average sensitivity. Here, the average sensitivity of an algorithm on an input instance is, roughly speaking, the average size of the symmetric difference of the output for the instance and that for the instance with one item deleted, where the average is taken over the deleted item.

In this work, we consider the average sensitivity of the knapsack problem, a representative example of a resource allocation problem. We first show a $(1 - \epsilon)$ -approximation algorithm for the knapsack problem with average sensitivity $O(\epsilon^{-1} \log \epsilon^{-1})$. Then, we complement this result by showing that any $(1 - \epsilon)$ -approximation algorithm has average sensitivity $\Omega(\epsilon^{-1})$. As an application of our algorithm, we consider the incremental knapsack problem in the random-order setting, where the goal is to maintain a good solution while items arrive one by one in a random order. Specifically, we show that for any $\epsilon > 0$, there exists a $(1 - \epsilon)$ -approximation algorithm with amortized recourse $O(\epsilon^{-1} \log \epsilon^{-1})$ and amortized update time $O(\log n + f_\epsilon)$, where n is the total number of items and $f_\epsilon > 0$ is a value depending on ϵ .

1 Introduction

1.1 Background and Motivation

The *knapsack problem* is one of the most fundamental models in *resource allocation*, which handles the selection of good candidates under a budget constraint. For example, it can model the hiring process of employees in a company and the selection process of government projects. The knapsack problem is formally defined as follows. The input is a pair (V, W) , where V is a set of n items, $W \in \mathbb{R}_{>0}$ is a weight limit, and each item $i \in V$ has a positive weight $w(i) \leq W$ and value $v(i)$. The goal of the problem is to find a set of items $S \subseteq V$ that maximizes the total value $\sum_{i \in S} v(i)$, subject to the weight constraint $\sum_{i \in S} w(i) \leq W$.

Sometimes, the information used to allocate resources is uncertain or outdated. For example, suppose that a satellite isolated from the Earth is taking actions. The satellite has a list of potential actions V , and each action has a fixed value $v(i)$ and fuel consumption $w(i)$. Some of the actions may be infeasible at the moment due to the satellite's conditions, such as the atmosphere or surrounding space debris. The satellite's objective is to find a combination of feasible actions with the highest possible total value without running out of W amount of fuel.

75:2 Average Sensitivity of the Knapsack Problem

The control room on the Earth wants to know the satellite’s action for future planning. Since direct communication to the satellite is not always possible, the control room would simulate the satellite’s decision process. However, the list V that the control room has as potential actions for the satellite may be different from the list that the satellite uses. Even in such a situation, the control room would like to predict the actual actions taken by the satellite with some accuracy. Such a purpose can be achieved by designing algorithms with small *average sensitivity* [24, 30].

The following definitions are necessary to formally define the average sensitivity. Let V be a finite set. Then, the *Hamming distance*¹ between two sets $S, S' \subseteq V$ is $|S \Delta S'|$, where $S \Delta S' = (S \setminus S') \cup (S' \setminus S)$ is the *symmetric difference*. For two probability distributions \mathcal{S} and \mathcal{S}' over sets in V , the *earth mover’s distance* $\text{EM}(\mathcal{S}, \mathcal{S}')$ between them is given by

$$\min_{\mathcal{D}} \mathbb{E}_{(S, S') \sim \mathcal{D}} |S \Delta S'|, \quad (1)$$

where the minimum is taken over distributions of a pair of sets such that its marginal distributions on the first and the second coordinates are equal to \mathcal{S} and \mathcal{S}' , respectively. Let \mathcal{A} be a (randomized) algorithm for the knapsack problem, and let (V, W) be an instance of the knapsack problem. We abuse the notation \mathcal{A} (resp., \mathcal{A}^i) to represent the output (distribution) of the algorithm \mathcal{A} on the instance (V, W) (resp., $(V \setminus \{i\}, W)$). Then, the *average sensitivity* of the algorithm (on the instance (V, W)) is

$$\frac{1}{n} \sum_{i \in V} \text{EM}(\mathcal{A}, \mathcal{A}^i). \quad (2)$$

An algorithm is informally called *stable-on-average* if its average sensitivity is small.

1.2 Our Contributions

Our main contribution is a fully polynomial-time randomized approximation scheme (FPRAS) for the knapsack problem with a small average sensitivity:

► **Theorem 1.** *For any $\epsilon > 0$, there is a $(1 - \epsilon)$ -approximation algorithm for the knapsack problem with time complexity polynomial in $\epsilon^{-1}n$ and average sensitivity $O(\epsilon^{-1} \log \epsilon^{-1})$, where n is the number of items.*

It is noteworthy that Kumabe and Yoshida [20] have presented a $(1 - \epsilon)$ -approximation algorithm with $O(\epsilon^{-1} \log^3(nW))$ average sensitivity for the knapsack problem with integer weights. In contrast, our algorithm can be applied to an instance with non-integer weight and has a smaller average sensitivity bound independent of the weight limit W .

The following proposition states that the algorithm that outputs an optimal solution has an unbounded average sensitivity. Thus to bound the average sensitivity, we should allow for approximation as in Theorem 1.

► **Proposition 2.** *The average sensitivity of the algorithm that outputs an optimal solution can be as large as $\Omega(n)$.*

Let $\text{opt}(V)$ be the optimal value of the original instance. The basic idea behind the algorithm of Theorem 1 is classifying items into two categories according to whether their values are more than a threshold $\approx \epsilon \cdot \text{opt}(V)$. It is not difficult to design stable-on-average

¹ The Hamming distance is usually defined for strings, but our definition matches the formal definition by considering a set $S \subseteq V$ as a binary string of length $|V|$.

$(1 - \epsilon)$ -approximation algorithms when all the items belong to one of the two categories. Indeed, if all the items are small, i.e., with values at most $\epsilon \cdot \text{opt}(V)$, then we can prove that a variant of the greedy algorithm has an approximation ratio $(1 - O(\epsilon))$ and an $O(\epsilon^{-1})$ average sensitivity. If all items are large, i.e., with values at least $\epsilon \cdot \text{opt}(V)$, then any algorithm has a small average sensitivity because any feasible solution contains at most ϵ^{-1} items. To combine these two algorithms, we add a subset of the large items selected by the *exponential mechanism* [23] to the output. However, if we apply the exponential mechanism to all possible sets of large items, the average sensitivity becomes too high because the number of such sets is exponentially large. Therefore, we need to reduce the number of candidate sets appropriately without sacrificing the approximation guarantee. A more detailed overview is provided in Section 4.1.

Next, we show that our upper bound on the average sensitivity is tight up to a logarithmic factor in ϵ^{-1} .

► **Theorem 3.** *Let $\epsilon > 0$. Then any $(1 - \epsilon)$ -approximation algorithm for the knapsack problem has average sensitivity $\Omega(\epsilon^{-1})$.*

The *simple knapsack problem* is a special case of the general knapsack problem in which the value of each item is proportional to its weight. For this problem, we obtain a deterministic algorithm with a better average sensitivity:

► **Theorem 4.** *For any $\epsilon > 0$, there is a deterministic $(1 - \epsilon)$ -approximation algorithm for the simple knapsack problem with time complexity polynomial in $\epsilon^{-1}n$ and average sensitivity $O(\epsilon^{-1})$, where n is the number of items.*

Finally, we discuss the connection to dynamic algorithms. In the *incremental dynamic knapsack problem*, items arrive one by one, and the goal is to maintain an approximate solution for the current set of items. The amortized recourse of a dynamic algorithm is the average Hamming distance between the outputs before and after an item arrives. More formally, the *amortized recourse* of a deterministic algorithm over a stream v_1, \dots, v_n of items is defined as $\frac{1}{n} \sum_{i=1}^n |X_{i-1} \Delta X_i|$, where X_i is the solution of the algorithm right after v_i is added. The amortized recourse of a randomized algorithm is the expectation of amortized recourse over the randomness of the algorithm. When the arrival order is random, we can construct an algorithm for the incremental dynamic knapsack problem using our stable-on-average algorithm:

► **Theorem 5.** *For any $\epsilon > 0$, there exists $f_\epsilon > 0$ such that there is a $(1 - \epsilon)$ -approximation algorithm with amortized recourse $O(\epsilon^{-1} \log \epsilon^{-1})$ and update time $O(f_\epsilon + \log n)$ for the incremental knapsack problem in the random-order setting.*

The fact that the output of our stable-on-average algorithm does not depend on the arrival order of the items but depends only on the current set of items implies that this result can also be applied to the *decremental knapsack problem*, in which we are to maintain a good solution while the items are removed one by one from the initial set of items.

1.3 Related Work

1.3.1 Knapsack Problem

The *knapsack problem* is one of the 21 problems that was first proved to be NP-hard by Karp [16], but admits a pseudo-polynomial time algorithm via dynamic programming [19]. Ibarra and Kim [13] proposed the first fully polynomial-time approximation scheme (FPTAS)

for the knapsack problem. The main idea is to round the values of items into multiples of a small value, and run a dynamic programming algorithm on the resulting instance. Since then, several faster algorithms have been developed [5, 15, 17, 18, 21, 27].

The knapsack problem has been studied in the context of online settings. In the most basic *online knapsack problem*, items arrive one by one, and when an item arrives, it is irrevocably added to the knapsack or discarded. The difference from our dynamic model is that, in the online knapsack problem, once an item is accepted or rejected, the decision cannot be reverted. However, this is not the case in our model. While Marchetti-Spaccamela and Vercellis [22] showed that no algorithm has a bounded competitive ratio for this problem in general, Buchbinder and Naor [4] proposed an $O(\log(U/L))$ -competitive algorithm for the case where all weights are much smaller than the weight limit, where U and L are the upper and lower bounds on the *efficiency* $w(i)/v(i)$. Zhou, Chakrabarty, and Lukose showed that this bound is tight [32]. Several variations of the online knapsack problem have been investigated, such as the *removable online knapsack problem* [14], which allows removing items added from the knapsack, the *knapsack secretary problem* [2], which concerns items arriving in random order, and the *online knapsack problem with a resource buffer* [12], in which we have a buffer that can contain higher weights of items than the weight limit, and at the end, we can select a subset of the stored items as the output.

The problem most closely related to ours is the *dynamic setting*. In this problem, the goal is to maintain a good solution while items are added or deleted dynamically. In this model, there is no restriction on adding items that were previously deleted from the knapsack (and vice versa). While designing fast algorithms that maintain an exact solution is a major issue of focus in the context of data structures [1], the problem of maintaining approximate solutions has also been investigated in a variety of problems including the shortest path problem [28, 29], maximum matching problem [11, 25], and set cover problem [9]. Recently, dynamic approximation algorithms with bounded recourse have been studied for several problems including the bin-packing problem [8], set cover problem [9], and submodular cover problem [10]. As for the knapsack problem, a recent work of Böhm et al. [3] presented an algorithm that maintains a $(1 - \epsilon)$ -approximate solution with polylogarithmic update time in the fully dynamic setting, where both additions and deletions of items are allowed. Because this model considers both additions and deletions, the solution must be drastically changed even after a single update operation. Therefore, they proposed an algorithm that maintains a data structure from which a good solution can be recovered (with a time proportional to the size of the output), rather than explicitly maintaining the solution as a set of items.

1.3.2 Average Sensitivity

Murai and Yoshida [24] introduced the notion of average sensitivity for centralities, i.e., importance of nodes and edges, on networks to compare various notions of centralities. The notion of average sensitivity for graph problems was recently introduced by Varma and Yoshida [30], in which they studied various graph problems, including the minimum spanning tree problem, minimum cut problem, maximum matching problem, and minimum vertex cover problem. Zhou and Yoshida [31] presented a $(1 - \epsilon)$ -approximation algorithm for the maximum matching problem with sensitivity solely depending on ϵ , where the (*worst-case*) *sensitivity* is defined as (2) with the average replaced by the maximum over i . Kumabe and Yoshida [20] presented a stable-on-average algorithm for the maximum weight chain problem on directed acyclic graphs. The approximation ratio of their algorithm is $(1 - \epsilon)$ and average sensitivity is polylogarithmic in the number of vertices in the graph, which roughly corresponds to the number of states of the dynamic programming. They designed

stable-on-average algorithms for a wide range of dynamic programming problems, including the knapsack problem with integer weights, by reducing them to the maximum weight chain problem. Peng and Yoshida [26] analyzed the average sensitivity of spectral clustering and showed that it is proportional to λ_2/λ_3^2 , where λ_i is the i -th smallest eigenvalue of the (normalized) Laplacian of the input graph. Intuitively, this bound indicates that spectral clustering is stable on average when the input graph can be well partitioned into two communities but not into three. This implies that spectral clustering is stable on average at relevant instances. The relation between *Differential privacy*, proposed by Dwork *et al.* [7], is given in the full version.

1.4 Organization

The rest of this paper is organized as follows. In Section 2, we review the basics of the knapsack problem, especially focusing on the fractional knapsack problem. In Section 3, we present a stable-on-average $(1 - O(\epsilon))$ -approximation algorithm when all items have value at most ϵ , where the analysis is given in the full version. In Section 4, we present an (inefficient) stable-on-average algorithm for the general setting, while some proofs are given in the full version. In the full version, we discuss on improving the time complexity to obtain an FPRAS, prove the $O(\epsilon^{-1})$ lower bound on the average sensitivity of $(1 - \epsilon)$ -approximation algorithms, present a deterministic $(1 - \epsilon)$ -approximation algorithm with $O(\epsilon^{-1})$ sensitivity for the simple knapsack problem, and discuss the application to the dynamic knapsack problem in the random-order setting.

2 Basic Facts about the Knapsack Problem

For an instance (V, W) of the knapsack problem, let $\text{opt}(V, W)$ be the optimal value for the instance. As W is often set to 1, we define $\text{opt}(V) := \text{opt}(V, 1)$ for convenience. In this work, we assume that each item has a unique (comparable) identifier that remains unchanged with the deletion of other items. This naturally defines the ordering of items. In our algorithms, we implicitly use this ordering for the tiebreak. For example, when we sort items, we use a sorting algorithm that is stable with respect to this ordering. For a set $S \subseteq V$, let $v(S)$ and $w(S)$ denote $\sum_{i \in S} v(i)$ and $\sum_{i \in S} w(i)$, respectively.

We consider the following fractional relaxation of the knapsack problem, which we call the *fractional knapsack problem*:

$$\begin{aligned} & \text{maximize} && \sum_{i \in V} v(i)x(i), \\ & \text{subject to} && \sum_{i \in V} w(i)x(i) \leq W, \\ & && 0 \leq x(i) \leq 1 \quad (i \in V). \end{aligned}$$

Then, we denote the optimal value of this problem by $\text{fopt}(V, W)$. We also define $\text{fopt}(V) := \text{fopt}(V, 1)$, and the *efficiency* of an item i is $v(i)/w(i)$. The following is well known:

► **Lemma 6** ([6]). *Suppose that items in V are sorted in non-increasing order of efficiency, i.e., $v(1)/w(1) \geq \dots \geq v(n)/w(n)$. Let k be the largest index with $w(1) + \dots + w(k) \leq 1$. Then, $\text{fopt}(V, 1)$ is achieved by the solution*

$$x(i) = \begin{cases} 1 & (i = 1, \dots, k), \\ \frac{1 - \sum_{j=1}^k w(j)}{w(i+1)} & (i = k + 1), \\ 0 & (i \geq k + 2). \end{cases}$$

75:6 Average Sensitivity of the Knapsack Problem

■ **Algorithm 1** A $(1 - O(\epsilon))$ -approximation algorithm with small average sensitivity.

```
1 Procedure MODIFIEDGREEDY( $\epsilon, V$ )
2   Reorder the items of  $V$  so that  $v(1)/w(1) \geq \dots \geq v(n)/w(n)$ ;
3   Let  $W$  be sampled from  $[1 - \epsilon, 1]$  uniformly at random;
4   Let  $t$  be the maximum index with  $\sum_{i=1}^t w(i) \leq W$ ;
5   return  $\{1, \dots, t\}$ .
```

Using Lemma 6, $\text{fopt}(V, W)$ can be computed in polynomial time. The following is a direct consequence of Lemma 6:

► **Lemma 7.** For $W \leq 1$, we have $\text{fopt}(V, W) \geq W \cdot \text{fopt}(V)$.

We give the proofs in the following two lemmas in full version.

► **Lemma 8.** $\text{opt}(V) \leq \text{fopt}(V) \leq 2\text{opt}(V)$ holds.

► **Lemma 9.** For an item set U and weight limit W , we have

$$\sum_{i \in U} (\text{fopt}(U, W) - \text{fopt}(U \setminus \{i\}, W)) \leq \text{fopt}(U, W).$$

3 Items with Small Values

In this section, we provide a stable-on-average algorithm for instances with each item having a small value. Specifically, we show the following:

► **Theorem 10.** For any $\epsilon, \delta > 0$, there exists an algorithm for the knapsack problem with average sensitivity $O(\epsilon^{-1})$ that, given an instance (V, W) with each item having value at most δ , outputs a solution with value at least $(1 - \epsilon)\text{fopt}(V, W) - \delta$.

This algorithm will be used in our algorithm for the general case as a subroutine in Section 4. Note that it suffices to design an algorithm for the case in which the weight limit is 1 because we can first divide the weight of each item by W and feed the resulting instance to the algorithm. Hence in the rest of this paper, we assume that the weight limit is 1 (and use the symbol W for a different purpose). A pseudocode of our algorithm is given in Algorithm 1. The proof of Theorem 10 is given in the full version.

4 General Case

In this section, we consider the general case of the knapsack problem, and prove the following:

► **Theorem 11.** For any $\epsilon > 0$, there exists a $(1 - \epsilon)$ -approximation algorithm for the knapsack problem with average sensitivity $O(\epsilon^{-1} \log \epsilon^{-1})$.

Note that this algorithm takes exponential time. We will discuss on improving time complexity in the full version.

4.1 Technical Overview and Algorithm Description

First, we explain the intuition behind our algorithm (Algorithm 2). As in Section 3, we assume that the weight limit is 1 without loss of generality. We fix a parameter $0 < \epsilon < 0.05$. We say that an item is *large* if its value is at least $\epsilon \cdot \text{fopt}(V)$ and *small* otherwise. If all items are small, MODIFIEDGREEDY (Algorithm 1) with the parameter ϵ has an approximation ratio $1 - O(\epsilon)$ and average sensitivity $O(\epsilon^{-1})$, and we are done. On the contrary, if all items are large, the procedure of outputting the optimal solution has average sensitivity $O(\epsilon^{-1})$ because any feasible solution has cardinality at most ϵ^{-1} . We combine these two observations to obtain an algorithm for the general case as follows. Note that here we don't concern about the running time; we accelerate it in the full version.

Let $L \subseteq V$ be the set of large items. First, we take a subset $R \subseteq L$ with $w(R) \leq 1$ that maximizes $v(R) + \text{opt}(V \setminus L, 1 - w(R))$. (Note that in this section, we do not take efficiency into consideration and therefore we assume that $\text{opt}(V \setminus L, 1 - w(R))$ can be computed.) Then, we output $R \cup \text{MODIFIEDGREEDY}(\epsilon, V \setminus L, 1 - w(R))$, where $\text{MODIFIEDGREEDY}(\epsilon, U, W)$ runs $\text{MODIFIEDGREEDY}(\epsilon, U)$ after replacing $w(i)$ with $w(i)/W$ for each $i \in U$.

However, this algorithm has the following two issues.

1. If the value of $\text{fopt}(V)$ changes upon deleting an item, the set L may drastically change. For example, consider the case when there are many items with values slightly less than $\epsilon \cdot \text{fopt}(V)$. Then, the set of small items added to the output may drastically change.
2. Even when the value $\text{fopt}(V)$ does not change, if the choice of R changes upon deleting an item, the value of $1 - w(R)$ also changes. Thus, the set of small items added to the output may drastically change.

To resolve the first issue, we sample a value threshold $c = O(\epsilon \cdot \text{fopt}(V))$ that classifies items as large or small from an appropriate distribution, instead of fixing it to $\epsilon \cdot \text{fopt}(V)$.

Now, we consider the second issue. Suppose we have sampled the same value threshold c both before and after deleting an item $i \in V$. There are two cases in which R changes after deleting the item i .

1. If the item i is large and $i \in R$, then the algorithm should change the choice of R because the item i would no longer exist.
2. If the item i is small, then the algorithm may change the choice of R because the value $\text{fopt}(V \setminus L, 1 - w(R))$ (for the original R) may decrease.

The first case is easy to resolve; R contains $O(\epsilon^{-1})$ many items and therefore, by taking average over i , this case contributes to the average sensitivity by $O(\epsilon^{-1})$.

To address the second case (deleting small items), we ensure that the distribution of R does not change significantly with small decreases in $\text{fopt}(V \setminus L, 1 - w(R))$. To this end, instead of considering the R with the maximum value of $v(R) + \text{fopt}(V \setminus L, 1 - w(R))$ among $R \subseteq L$, we apply the exponential mechanism [23]. Specifically, we sample R with probability proportional to the exponential of this value with appropriate scaling and rounding (see Line 13 in Algorithm 2). To ensure that the mechanism outputs a $(1 - \epsilon)$ -approximate solution, we reduce the number of candidates that can possibly be R to a constant. This is implemented by taking only one candidate A_t from the family of sets R with $w(R) \in [tc, (t + 1)c]$ for each integer t (see Line 7 in Algorithm 2). For technical reasons, we apply an exponential mechanism for the value $tc + \text{fopt}(V \setminus L, 1 - w(A_t))$, rather than the exact value $v(A_t) + \text{opt}(V \setminus L, 1 - w(A_t))$ (see Line 9).

In Sections 4.2 and 4.3, we analyze the approximation ratio and average sensitivity of Algorithm 2, respectively.

■ **Algorithm 2** A $(1 - O(\epsilon))$ -approximation algorithm with small average sensitivity.

```

15     $R = A_{t^\circ}$ ;
16  return  $R \cup \text{MODIFIEDGREEDY}(V \setminus L, 1 - w(A_t))$ ;
```

4.2 Approximation Ratio

First, we analyze the approximation ratio of Algorithm 2. Let S^* be a set of items that attains $\text{opt}(V)$. Let $t^* \geq 0$ be an integer such that $v(S^* \cap L) \in [t^*c, (t^* + 1)c)$.

The following lemma bounds the loss in the approximation ratio caused by considering only A_0, \dots, A_l instead of all subsets of L as candidate sets that can possibly be R .

► **Lemma 12.** $x_{t^*} \geq (1 - 4\epsilon) \text{opt}(V)$ holds.

Proof. We have

$$\begin{aligned} x_{t^*} &= t^*c + \text{fopt}(V \setminus L, 1 - w(A_{t^*})) \geq t^*c + \text{fopt}(V \setminus L, 1 - w(S^* \cap L)) \\ &\geq t^*c + v(S^* \setminus L) \geq v(S^* \cap L) - c + v(S^* \setminus L) = \text{opt}(V) - c \geq (1 - 4\epsilon) \text{opt}(V), \end{aligned}$$

where the first equality is from the definition of x_{t^*} , the first inequality is from $w(A_{t^*}) \leq w(S^* \cap L)$, which is ensured by Line 7 in the algorithm, the second inequality is from $\text{fopt}(V \setminus L, 1 - w(S^* \cap L)) \geq \text{opt}(V \setminus L, 1 - w(S^* \cap L)) = v(S^* \setminus L)$, the third inequality is from the definition of t^* , the second equality is from the optimality of S^* , and the last inequality is from $c \leq 2\epsilon \cdot \text{fopt}(V) \leq 4\epsilon \cdot \text{opt}(V)$. ◀

Next we analyze the loss in the approximation ratio caused by the exponential method applied at Line 13. We prove the following.

► **Lemma 13.** $\mathbb{E}[x_{t^\circ}] \geq (1 - 3\epsilon)x_{t^*}$ holds.

Proof. We have

$$\begin{aligned}
\Pr[x_{t^\circ} \leq (1 - \epsilon)x_{t^*}] &= \frac{\sum_{t \in \{0, \dots, l\} : x_t \leq (1 - \epsilon)x_{t^*}} \exp\left(\frac{x_t}{d}\right)}{\sum_{t \in \{0, \dots, l\}} \exp\left(\frac{x_t}{d}\right)} \leq \frac{(l + 1) \exp\left(\frac{(1 - \epsilon)x_{t^*}}{d}\right)}{\exp\left(\frac{x_{t^*}}{d}\right)} \\
&= (l + 1) \exp\left(-\frac{\epsilon x_{t^*}}{d}\right) \\
&\leq (l + 1) \exp\left(-\frac{\epsilon(1 - 4\epsilon)\text{opt}(V)}{d}\right) \leq (l + 1) \exp\left(-\frac{5}{2} \log \epsilon^{-1} (1 - 4\epsilon)\right) \\
&= (l + 1) \epsilon^{\frac{5}{2}(1 - 4\epsilon)} \leq 2\epsilon^{-1} \cdot \epsilon^2 = 2\epsilon. \tag{3}
\end{aligned}$$

Here, the first equality is from Line 13 of the algorithm, the first inequality is from the fact that there are at most $l + 1$ indices t with $x_t \leq (1 - \epsilon)x_{t^*}$, the second inequality is from Lemma 12, the third inequality is from

$$d = \frac{c}{10 \log \epsilon^{-1}} \leq \frac{\epsilon}{5 \log \epsilon^{-1}} \cdot \text{fopt}(V) \leq \frac{5}{2} \cdot \frac{\epsilon}{\log \epsilon^{-1}} \cdot \text{opt}(V),$$

and the last inequality is from $l + 1 \leq \epsilon^{-1} + 1 \leq 2\epsilon^{-1}$ and $\frac{5}{2}(1 - 4\epsilon) \geq 2$, which is from $\epsilon \leq 0.05$. Therefore, we have

$$\mathbb{E}[x_{t^\circ}] \geq (1 - \epsilon)x_{t^*} \Pr[x_{t^\circ} > (1 - \epsilon)x_{t^*}] \geq (1 - \epsilon)(1 - 2\epsilon)x_{t^*} \geq (1 - 3\epsilon)x_{t^*}.$$

Here, the second inequality is from (3). \blacktriangleleft

Combining the lemmas above yields the following.

► Lemma 14. $\mathbb{E}[v(A_{t^\circ}) + \text{fopt}(V \setminus L, 1 - w(A_{t^\circ}))] \geq (1 - 7\epsilon)\text{opt}(V)$ holds.

Proof. We have

$$\begin{aligned}
&\mathbb{E}[v(A_{t^\circ}) + \text{fopt}(V \setminus L, 1 - w(A_{t^\circ}))] \\
&\geq \mathbb{E}[x_{t^\circ}] \geq (1 - 3\epsilon)x_{t^*} \geq (1 - 3\epsilon)(1 - 4\epsilon)\text{opt}(V) \geq (1 - 7\epsilon)\text{opt}(V),
\end{aligned}$$

where the first inequality is from Line 9 of the algorithm, the second inequality is from Lemma 13, and the third inequality is from Lemma 12. \blacktriangleleft

Now we bound the approximation ratio of Algorithm 2. Let $\mathcal{A}_{\text{SMALL}}(V', W')$ be the output of Algorithm 1 on V' , where all weights in the input are divided by W' .

► Lemma 15. *The approximation ratio of Algorithm 2 is at least $1 - 12\epsilon$.*

Proof. Let \mathcal{A} be the output distribution of Algorithm 2 applied on the instance $(V, 1)$. We have

$$\begin{aligned}
\mathbb{E}[\mathcal{A}] &= \mathbb{E}[v(A_{t^\circ}) + v(\mathcal{A}_{\text{SMALL}}(V \setminus L, 1 - w(A_{t^\circ})))] \\
&\geq \mathbb{E}[v(A_{t^\circ}) + (1 - \epsilon)\text{fopt}(V \setminus L, 1 - w(A_{t^\circ})) - c] \\
&\geq \mathbb{E}[(1 - \epsilon)(v(A_{t^\circ}) + \text{fopt}(V \setminus L, 1 - w(A_{t^\circ}))) - c] \\
&\geq \mathbb{E}[(1 - \epsilon)(1 - 7\epsilon)\text{opt}(V) - c] \geq (1 - 12\epsilon)\text{opt}(V),
\end{aligned}$$

where the first inequality is from the analysis of Algorithm 1 given in the full version, the third inequality is from Lemma 14, and the last inequality is from $c \leq 2\text{fopt}(V) \leq 4\text{opt}(V)$. \blacktriangleleft

4.3 Average Sensitivity

In this section, we discuss bounding the average sensitivity of Algorithm 2. For the parameters used in the algorithm applied on the instance $(V \setminus \{i\}, 1)$, we use symbols c^i, d^i , and R^i to denote c, d , and R , respectively (and use c, d , and R for the instance $(V, 1)$). Similarly, we use the symbols A_t^i and x_t^i for $t = 0, \dots, l$ to denote A_t and x_t , respectively, for the instance $(V \setminus \{i\}, 1)$. We first prove that the distributions of R and R^i are sufficiently close on average, where the average is taken over $i \in V$ (Lemma 22). Subsequently, we combine the analysis for large and small items (Lemma 24).

The distributions of R and R^i may differ for the following two reasons: the difference between the distributions of c and c^i , and the absence of the item i in the instance $V \setminus \{i\}$. We first focus on the second reason. Specifically, we fix the value \hat{c} and assume $c = c^i = \hat{c}$. In this case, we prove that the distribution of R is sufficiently close to that of R^i on average, where the average is taken over $i \in V$. To this end, we analyze the following quantity:

$$\sum_{i \in V} \sum_{A \subseteq V} \max(0, \Pr[R = A \mid c = \hat{c}] - \Pr[R^i = A \mid c^i = \hat{c}]). \quad (4)$$

Because $\Pr[R = A \mid c = \hat{c}]$ is positive only if $A = A_t$ for some $t \in \{0, \dots, l\}$, we have

$$(4) = \sum_{i \in V} \sum_{t \in \{0, \dots, l\}} \max(0, \Pr[R = A_t \mid c = \hat{c}] - \Pr[R^i = A_t \mid c^i = \hat{c}]). \quad (5)$$

We analyze the sum in (5) by dividing it into two cases: $i \in L$ and $i \in V \setminus L$. We first show that $x_t \geq x_t^i$ holds for all i and t .

► **Lemma 16.** *For any $t \in \{0, \dots, l\}$ and $i \in V$, we have $x_t \geq x_t^i$.*

Proof. If $x_t = -\infty$, then we have $x_t^i = -\infty$ due to Line 6 of Algorithm 2. Hereafter, we assume $x_t \neq -\infty$. We prove the lemma by considering the following three cases:

▷ **Claim 17.** If $i \in L \setminus A_t$, we have $x_t = x_t^i$.

▷ **Claim 18.** If $i \in A_t$, we have $x_t \geq x_t^i$.

▷ **Claim 19.** If $i \in V \setminus L$, we have $x_t \geq x_t^i$.

We give the proofs of these claims in the full version. Then we complete the case analysis and the lemma is proved. ◀

The next lemma handles the case $i \in L$. We give the proof in the full version.

► **Lemma 20.** *For any $\hat{c} \in \mathbb{R}$, we have*

$$\sum_{i \in L} \sum_{t \in \{0, \dots, l\}} \max(0, \Pr[R = A_t \mid c = \hat{c}] - \Pr[R^i = A_t \mid c^i = \hat{c}]) \leq \epsilon^{-1}.$$

Now we consider the case $i \in V \setminus L$.

► **Lemma 21.** *For any $\hat{c} \in \mathbb{R}$, we have*

$$\sum_{i \in V \setminus L} \sum_{t \in \{0, \dots, l\}} \max(0, \Pr[R = A_t \mid c = \hat{c}] - \Pr[R^i = A_t \mid c^i = \hat{c}]) \leq 10\epsilon^{-1} \log \epsilon^{-1}.$$

Proof. Let $\hat{d} = \frac{\hat{c}}{10 \log(\epsilon^{-1})}$. Then, we have

$$\begin{aligned}
& \Pr[R = A_t \mid c = \hat{c}] - \Pr[R^i = A_t \mid c^i = \hat{c}] \\
&= \frac{\exp(x_t/\hat{d})}{\sum_{t \in \{0, \dots, l\}} \exp(x_t/\hat{d})} - \frac{\exp(x_t^i/\hat{d})}{\sum_{t \in \{0, \dots, l\}} \exp(x_t^i/\hat{d})} \leq \frac{\exp(x_t/\hat{d}) - \exp(x_t^i/\hat{d})}{\sum_{t \in \{0, \dots, l\}} \exp(x_t/\hat{d})} \\
&= \left(1 - \exp\left(-\frac{x_t - x_t^i}{\hat{d}}\right)\right) \frac{\exp(x_t/\hat{d})}{\sum_{t \in \{0, \dots, l\}} \exp(x_t/\hat{d})} \leq \frac{x_t - x_t^i}{\hat{d}} \Pr[R = A_t \mid c = \hat{c}]. \quad (6)
\end{aligned}$$

Here, the first equality is from Line 13 of Algorithm 2, the first inequality is from Lemma 16, and the last inequality is from $1 - \exp(-x) \leq x$. Now, we have

$$\begin{aligned}
& \sum_{i \in V \setminus L} \sum_{t \in \{0, \dots, l\}} \max(0, \Pr[R = A_t \mid c = \hat{c}] - \Pr[R^i = A_t \mid c^i = \hat{c}]) \\
&\leq \sum_{i \in V \setminus L} \sum_{t \in \{0, \dots, l\}} \frac{x_t - x_t^i}{\hat{d}} \cdot \Pr[R = A_t \mid c = \hat{c}] \\
&\leq \sum_{t \in \{0, \dots, l\}} \frac{\text{fopt}(V \setminus L, 1 - w(A_t))}{\hat{d}} \cdot \Pr[R = A_t \mid c = \hat{c}] \\
&\leq \frac{\text{fopt}(V)}{\hat{d}} \sum_{t \in \{0, \dots, l\}} \Pr[R = A_t \mid c = \hat{c}] \leq 10\epsilon^{-1} \log \epsilon^{-1}.
\end{aligned}$$

Here, the first inequality is obtained from (6) and Claim 19. The second inequality is obtained from:

$$\begin{aligned}
\sum_{i \in V \setminus L} (x_t - x_t^i) &= \sum_{i \in V \setminus L} (\text{fopt}(V \setminus L, 1 - w(A_t)) - \text{fopt}((V \setminus L) \setminus \{i\}, 1 - w(A_t))) \\
&\leq \text{fopt}(V \setminus L, 1 - w(A_t)),
\end{aligned}$$

which is obtained from Lemma 9. The last inequality is from Line 12 of Algorithm 2. ◀

Combining Lemmas 20 and 21, we obtain the following.

► **Lemma 22.** *We have*

$$\sum_{i \in V} \sum_{A \subseteq V} \max(0, \Pr[R = A \mid c = \hat{c}] - \Pr[R^i = A \mid c^i = \hat{c}]) \leq 11\epsilon^{-1} \log \epsilon^{-1}.$$

Proof. The claim immediately follows from Lemmas 20 and 21 and the fact that V is a disjoint union of $V \setminus L$ and L . ◀

Now, we evaluate the average sensitivity. Let \mathcal{A}^i be the output distribution of Algorithm 2 applied on the instance $V \setminus \{i\}$.

To bound the earth mover's distance, we consider transporting the probability mass in such a way the mass of \mathcal{A} corresponding to a particular choice of c is transported to that of \mathcal{A}^i for the same c^i (as far as we can). For the same choice of c and c^i , we consider transporting the probability mass in such a way that the mass corresponding to a particular choice of R is transported to that for the same R^i (as far as we can). For the same choice of c, R and c^i, R^i , we consider transporting the probability mass in a manner similar to the analysis of Algorithm 1. The remaining mass is transported arbitrarily.

First, we bound the contribution of the difference between the distributions of c and c^i to the earth mover's distance. Let f and f^i be the probability density functions of c and c^i , respectively. Precisely, $f(c) = \frac{1}{\epsilon \cdot \text{fopt}(V)}$ if $\epsilon \cdot \text{fopt}(V) \leq c \leq 2\epsilon \cdot \text{fopt}(V)$ and 0 otherwise. Similarly, $f^i(c^i) = \frac{1}{\epsilon \cdot \text{fopt}(V \setminus \{i\})}$ if $\epsilon \cdot \text{fopt}(V \setminus \{i\}) \leq c^i \leq 2\epsilon \cdot \text{fopt}(V \setminus \{i\})$ and 0 otherwise.

75:12 Average Sensitivity of the Knapsack Problem

► **Lemma 23.** *We have*

$$\sum_{i \in V} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} \max(0, f(\hat{c}) - f^i(\hat{c})) \, d\hat{c} \leq 2.$$

Proof. We have

$$\begin{aligned} \sum_{i \in V} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} \max(0, f(\hat{c}) - f^i(\hat{c})) \, d\hat{c} &= \sum_{i \in V} \int_{\max\{\epsilon \cdot \text{fopt}(V), 2\epsilon \cdot \text{fopt}(V \setminus \{i\})\}}^{2\epsilon \cdot \text{fopt}(V)} \frac{1}{\epsilon \cdot \text{fopt}(V)} \, d\hat{c} \\ &\leq \frac{1}{\epsilon \cdot \text{fopt}(V)} \sum_{i \in V} (2\epsilon \cdot (\text{fopt}(V) - \text{fopt}(V \setminus \{i\}))) \leq \frac{1}{\epsilon \cdot \text{fopt}(V)} \cdot 2\epsilon \cdot \text{fopt}(V) = 2, \end{aligned}$$

where the first inequality is from the fact that $f(\hat{c}) \leq f^i(\hat{c})$ holds if $\epsilon \cdot \text{fopt}(V) \leq \hat{c} \leq 2\epsilon \cdot \text{fopt}(V \setminus \{i\})$, and the last inequality is from Lemma 9. ◀

Finally, we bound the average sensitivity.

► **Lemma 24.** *The average sensitivity of Algorithm 2 is at most $12\epsilon^{-1} \log \epsilon^{-1}$.*

Proof. We have

$$\begin{aligned} &\frac{1}{n} \sum_{i \in V} \text{EM}(\mathcal{A}, \mathcal{A}^i) \\ &\leq \frac{1}{n} \sum_{i \in V} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} \max(0, f(\hat{c}) - f^i(\hat{c})) \, d\hat{c} \cdot n \\ &\quad + \frac{1}{n} \sum_{i \in V} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} \sum_{A \subseteq V} \left(\max(0, \Pr[R = A \mid c = \hat{c}] - \Pr[R^i = A \mid c^i = \hat{c}]) \cdot n \right. \\ &\quad \left. + \Pr[R = A \mid c = \hat{c}] \cdot \text{EM}(\mathcal{A}_{\text{SMALL}}(V \setminus L, 1 - w(A)), \mathcal{A}_{\text{SMALL}}((V \setminus L) \setminus \{i\}, 1 - w(A))) \right) f(\hat{c}) \, d\hat{c} \\ &\leq 2 + \frac{1}{n} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} \left(11\epsilon^{-1} \log \epsilon^{-1} n + \sum_{i \in V} \sum_{A \subseteq V} \Pr[R = A \mid c = \hat{c}] (\epsilon^{-1} + 1) \right) f(\hat{c}) \, d\hat{c} \\ &= 2 + \frac{1}{n} \int_{\epsilon \cdot \text{fopt}(V)}^{2\epsilon \cdot \text{fopt}(V)} (11\epsilon^{-1} \log \epsilon^{-1} n + (\epsilon^{-1} + 1) \cdot n) f(\hat{c}) \, d\hat{c} \\ &= 2 + 11\epsilon^{-1} \log \epsilon^{-1} + \epsilon^{-1} + 1 \leq 12\epsilon^{-1} \log \epsilon^{-1}, \end{aligned}$$

where the first inequality is due to the transport of the probability mass, and the second inequality is from Lemmas 23, 22, and the analysis of Algorithm 1 given in the full version. ◀

Proof of Theorem 11. Applying Lemma 15 and Lemma 24 and replacing ϵ with $\min(0.05, \epsilon/12)$ proves this theorem. ◀

Cardinality Estimation Using Gumbel Distribution

Aleksander Łukasiewicz  

Faculty of Mathematics and Computer Science, University of Wrocław, Poland

Przemysław Uznański  

Faculty of Mathematics and Computer Science, University of Wrocław, Poland

Abstract

Cardinality estimation is the task of approximating the number of distinct elements in a large dataset with possibly repeating elements. **LogLog** and **HyperLogLog** (c.f. Durand and Flajolet [ESA 2003], Flajolet et al. [Discrete Math Theor. 2007]) are small space sketching schemes for cardinality estimation, which have both strong theoretical guarantees of performance and are highly effective in practice. This makes them a highly popular solution with many implementations in big-data systems (e.g. Algebird, Apache DataSketches, BigQuery, Presto and Redis). However, despite having simple and elegant formulation, both the analysis of **LogLog** and **HyperLogLog** are extremely involved – spanning over tens of pages of analytic combinatorics and complex function analysis.

We propose a modification to both **LogLog** and **HyperLogLog** that replaces discrete geometric distribution with the continuous Gumbel distribution. This leads to a very short, simple and elementary analysis of estimation guarantees, and smoother behavior of the estimator.

1 Introduction

In the cardinality estimation problem we are presented with a dataset consisting of many items, and some of these items might appear more than once. Our goal is to process this dataset efficiently, in order to estimate the number n of *distinct* elements it contains. Here, efficiently means in small auxiliary space, and with fast processing time per each item. A natural scenario to consider is a *stream* processing of a dataset, with stream of events being either element *insertions* to the multiset or *queries* of the multiset cardinality.

A folklore information theoretic analysis reveals that this problem over universe of u elements requires at least u bits of memory to answer queries exactly. However, in many practical settings it is sufficient to provide an approximation of the actual cardinality. One of the possible real-world scenarios is a problem of estimating the number of unique addresses in packets that a router observes, in order to detect malicious behaviors and attacks. Here, the challenge arises from the limited computational capabilities of the router and sheer volume of the data that can be observed over e.g. a day.

The theoretical study of the *cardinality estimation* was initiated by the seminal work of Flajolet and Martin [20]. From that point, two separate lines of research follow. First, there has been a considerable effort put into developing approximation schemes with so called (ε, δ) -guarantees, meaning that they guarantee outputting $(1 + \varepsilon)$ -multiplicative approximation of

the cardinality, with probability at least $1 - \delta$. Here, we mention [6, 7, 8, 11, 22, 23, 29] on the upper-bound side and [6, 10, 27, 28, 36] on lower-bound side. The high-level takeaway message is that one can construct approximate schemes that provide $(1 + \varepsilon)$ -multiplicative approximation to the number of distinct elements, using an order of ε^{-2} space, and that this dependency on ε is tight. More specifically, the work of Błasiok [11] settles the bit-complexity of the problem, by providing $\mathcal{O}(\frac{\log \delta^{-1}}{\varepsilon^2} + \log n)$ bits of space upper-bound, and this complexity is optimal by a matching lower bound [28]. To achieve such small space usage, a number of issues have to be resolved, and a very sophisticated machinery of expanders and pseudo-randomness is deployed.

The other line of work is more practical in nature, and focuses on providing variance bounds for efficient algorithms. The bounds are usually of the form $\sim 1/\sqrt{k}$ where k is some measure of space-complexity of algorithms (usually, corresponds to the number of parallel estimation processes). This approach includes work of [9, 12, 14, 16, 18, 19, 21, 24, 30, 31, 34, 35]. Recently, Pettie and Wang started the study of the intrinsic tradeoff between the space complexity of the cardinality estimation sketch and its estimation error by introducing the notion of *memory-variance product* (MVP) [31]. They proposed a *Fishmonger* sketch that has an MVP equal to $H_0/I_0 \approx 1.98$ (where H_0, I_0 are some precisely defined constants) and they also proved that this is the best MVP that one can get in a class of *linearizable* sketches (in fact all the popular *mergeable* sketches are linearizable). In the very recent follow-up work Pettie, Wang and Yin studied the MVPs of non-mergeable sketches [32].

We now focus on two specific algorithms, namely **LogLog** [16] and its refined version called **HyperLogLog** [19]. The guarantees that these algorithms provide for variance are approximately $1.3/\sqrt{k}$ and $1.04/\sqrt{k}$ respectively, when using k integer registers. Both are based on a simple principle of observing the maximal number of trailing zeroes in the binary representation of hashes of elements in the stream, although they vary in the way they extract the final estimate from this observed value (we will discuss those details in the following section). In addition to being easy to state and provided with theoretical guarantees, they are highly practical in nature. We note the following works on algorithmic engineering of practical variants [17, 26, 37], with actual implementations e.g. in Algebird [1], BigQuery [2], Apache DataSketch [3], Presto [4] and Redis [5].

Despite its simplicity and popularity, **LogLog** and **HyperLogLog** are exceptionally tough to analyze. We note that both papers analyzing **LogLog** and later **HyperLogLog** use a heavy machinery of tools from analytic combinatorics and complex function analysis e.g. Mellin transform, poissonization and analytical depoissonization. In fact, unpacking the main tool used in the paper requires understanding of another tens of pages from [33]. Additionally, both papers are presented in a highly compressed form. Thus, the analysis is not easily digestible by a typical computer scientist, and has to be accepted “as it is” in a black-box manner, without actually unpacking it.

This creates an unsatisfactory situation where one of the most popular and most elegant algorithms for the cardinality estimation problem has to be treated as a black-box from the perspective of its performance guarantees. It is an obstacle both in terms of popularization of the **LogLog** and **HyperLogLog** algorithms, and in terms of scientific progress. We note that those algorithms are generally omitted during majority of theoretical courses on streaming and big data algorithms.

Our contribution: Gumbel distribution

Our contribution comes in two factors. First, we observe that the key part of **LogLog** and **HyperLogLog** algorithms is counting the trailing zeroes in the binary representation of a hash of element. This random variable is distributed according to a geometric distribution. Both

■ **Figure 1** Distribution of $\max\{X_1, \dots, X_k\}$ for $k \in \{1, 2, 4, 8, 16, 32, 64\}$ where X_i iid random variables distributed according to discrete Geometric distribution (on the left) and Gumbel distribution (on the right). Discrete distribution given by $f_k(x) = (1 - 2^{-x-1})^k - (1 - 2^{-x})^k$ is drawn with continuous intermediate values for smooth drawing.

LogLog and HyperLogLog estimate the cardinality using the maximum value of the count of trailing zeroes observed over all elements of the dataset. However, the distribution of the maximum of many discrete random variables drawn from an identical geometric distribution is not distributed according to a geometric distribution. This is unwieldy to handle in the analysis in [19].

We propose the following: as the first step we replace the discrete geometric distribution with its continuous counterpart, i.e. the exponential distribution with the CDF $1 - e^{-x}$. Next, we take a maximum of N independent repetitions of our algorithm which can be simulated by, e.g., replacing each update x with N updates of the form (x, i) for $i \in [N]$. This yields the CDF of the form $(1 - e^{-x})^N$. Intuitively, we expect this manipulation to have a smoothing effect on the irregularities of LogLog and HyperLogLog (which performance deteriorate greatly for very small values of n). Third and the final step is to take a limit of $N \rightarrow \infty$, while maintaining a proper normalization of the distribution (i.e., we take a shift by $\ln N$), resulting in a CDF of the form $F(X) = \lim_{N \rightarrow \infty} (1 - e^{-x - \ln N})^N$.

A little manipulation gives us $F(X) = \lim_{N \rightarrow \infty} (1 - \frac{e^{-x}}{N})^N = e^{-e^{-x}}$ which is precisely the CDF of the Gumbel distribution, with the following crucial property

If X_1, \dots, X_k are independent random variables drawn from a Gumbel distribution, then $Z = \max(X_1, \dots, X_k) - \ln(k)$ is also distributed according to the same Gumbel distribution.

This allows us to simplify extraction of the value of k from $\max(X_1, \dots, X_k)$, since we are always dealing with the same type of error (distributed according to the Gumbel distribution) on top of the value $\ln(k)$.

Our contribution: Simpler analysis

Our second contribution comes in the form of a simple analysis of the performance guarantees of the estimation. We note that since our observable can be interpreted as an observable from LogLog or HyperLogLog repeated N -times (for some very large value of N), we expect to get a similar type of the guarantees. One should be able to go with the tour-de-force analysis analogous to [16, 19]. However, we find it valuable to provide analysis that is tractable using just elementary and short proofs. We show that by taking advantage of the Gumbel

distribution being the limiting distribution, one can isolate a very simple combinatorial problem capturing the essence of the stochastic averaging. The analysis of this problem requires application of only some basic probabilistic inequalities and multinomial identities.¹

2 Related work

The key concept used in virtually all cardinality estimation results, can be summarized as follows: given a universe U of elements, we start by picking a hash-function. Then, given a subset $M \subseteq U$ which cardinality we want to estimate, we proceed by applying h to every element of M and operate only on $M' = \{h(x) : x \in M\} \subset [0, 1]$. The next step is computing an *observable* – i.e. a quantity that only depends on the underlying set and is independent of replications. In the final step we somehow extract the estimate of the cardinality from the observable.

For example [7] uses $h : M \rightarrow [0, 1]$ and the value $y = \min M' = \min_{x \in M} h(x)$ as an observable. We expect $y \sim \frac{1}{n+1}$, thus $\frac{1}{y} - 1$ is used as an estimate of the cardinality n . However, since we need to overcome the variance, one might need to average over many independent instances of the process, in order to achieve a good estimation. In this particular example, to get an $(1 + \varepsilon)$ approximation, we need to average over $\mathcal{O}(\varepsilon^{-2})$ independent copies of the algorithm. Therefore, the total memory usage becomes $\mathcal{O}(\varepsilon^{-2} \log n)$ bits.

Stochastic averaging

Naively averaging over k independent copies of the algorithm has an important drawback - the time for processing each query grows from $O(1)$ to $O(k)$. *Stochastic averaging* is a technique designed to address that issue. In our setting it works as follows: instead of processing each element in each of the k processes independently (which is a bottleneck), we randomly partition our input into k disjoint sub-inputs: $M = M_1 \cup \dots \cup M_k$, and we run each copy of an algorithm only on its corresponding sub-input. This is simulated by picking a second hash function $h' : M \rightarrow \{1, \dots, k\}$, and when we are processing an element x , it is assigned to M_i where $i = h'(x)$ is decided solely on the hash of x . Intuitively, we expect each M_i to contain roughly n/k elements. Note that the actual number of elements in all M_i follows a *multinomial distribution*, and this presents an additional challenge in the analysis.

LogLog sketching

Consider the following: we hash the elements to bitstrings, that is $h : M \rightarrow \{0, 1\}^\infty$, and consider the bit-patterns observed. For each element find the value $\text{bit}(x)$ such that $h(x)$ has a prefix $0^{\text{bit}(x)}1$. The particular value $\text{bit}(x) = c$ should be observed once every $\sim 2^c$ different hashes, and can be used to estimate the cardinality. The observable used in the **LogLog** is the value $\max_x \text{bit}(x)$ among all elements. Since we expect its value to be roughly of order $\log n$, we maintain the value of $\max \text{bit}(x)$ on $\mathcal{O}(\log \log n)$ bits.

Denote the observables produced in the concurrent copies of the algorithm as t_1, \dots, t_k . We expect the values of t_i to be such that $2^{t_i} \sim n/k$. One can easily show, that for any t_i , we have $\mathbb{E}[2^{t_i}] = \infty$, thus taking the arithmetic average over 2^{t_i} is not a feasible strategy.

¹ It is important to note that this is not the **first** cardinality estimation algorithm with a simple analysis, e.g. [7, 20] algorithms have relatively straightforward analysis. However, none of those techniques apply to the simplification of **LogLog** or **HyperLogLog** specifically, which are default practical choices for the cardinality estimation.

However, it turns out that the geometric average works in this setting, and we expect the $k \left(\prod_i 2^{t_i} \right)^{1/k}$ to be an estimate for n (one also needs a normalizing constant that depends solely on k). The analysis in [16] shows that the variance of the estimation is roughly $1.3/\sqrt{k}$.

HyperLogLog sketching

HyperLogLog ([19]) is an improvement over LogLog with the observation that the *harmonic average* achieves a better averaging performance over *geometric average*. Thus HyperLogLog is constructed by setting the estimator to $k^2 \left(\sum_i 2^{-t_i} \right)^{-1}$ with some normalizing constant (depending on k). The resulting algorithm has a variance which is roughly $1.04/\sqrt{k}$.

In fact it can be shown that the harmonic average is optimal in that setting: among observables that constitute of taking maximum of a hash function, harmonic average is a *maximum likelihood estimator* (see e.g. [13]). However, this claim is strict only without stochastic averaging.

Due to the space limitations, in this article we provide only the analysis of the LogLog version (with geometric average estimation) of our algorithm. The HyperLogLog version (using harmonic average estimation) is available in the full version of the paper. ²

3 Preliminaries

Computational model

We assume oracle access to a perfect source of randomness, that is a hash function $h : [u] \rightarrow \{0, 1\}^\infty$. If the sketch demands it, we allow it to access multiple independent such sources, which can be simulated with a help of bit and arithmetic operations. The oracle access is a standard assumption in this line of work (c.f. discussion in [31]) – the purpose of this assumption is to separate the analysis of the space complexity of the algorithm from the space complexity of the source of the randomness.

Besides that, we assume standard RAM model, with words of size u and standard arithmetic operations on those words taking constant time.

Gumbel distribution

We use the following distribution, which originates from the *extreme value theory*.

► **Definition 1** (Gumbel distribution [25]). *Let $\text{Gumbel}(\mu)$ denote the distribution given by a following CDF:*

$$F(x) = e^{-e^{-(x-\mu)}}.$$

Its probability density function is given by

$$f(x) = e^{-e^{-(x-\mu)}} e^{-(x-\mu)}.$$

Observe that, directly from the definition, if $X \sim \text{Gumbel}(\mu)$, then $X+c \sim \text{Gumbel}(\mu+c)$.

We also note that when $x \rightarrow \infty$, then $f(x) \approx e^{-(x-\mu)}$, thus the Gumbel distribution has an exponential tail on the positive side. The distribution has a doubly-exponential tail when $x \rightarrow -\infty$.

² The full version of the paper is available under the following link: <https://arxiv.org/abs/2008.07590>.

76:6 Cardinality Estimation Using Gumbel Distribution

We have the following basic property when $X \sim \text{Gumbel}(\mu)$ (c.f. [25]):

$$\mathbb{E}[e^{\alpha X}] = e^{\alpha\mu} \int_{-\infty}^{\infty} e^{-e^{-x}} e^{(\alpha-1)x} dx = e^{\alpha\mu} \Gamma(1 - \alpha), \quad (1)$$

from which it follows that $\mathbb{E}[e^{-X}] = e^{-\mu}$ and $\text{Var}[e^{-X}] = e^{-2\mu}$.

► **Property 2** (Sampling from Gumbel distribution.). *If $t \in [0, 1]$ is drawn uniformly at random, then $X = -\ln(-\ln t) + \mu$ has the distribution $\text{Gumbel}(\mu)$.*

The following property is the key property used in our algorithm analysis. It essentially states that Gumbel distribution is invariant under taking the maximum of independent samples (up to normalization).³

► **Property 3.** *If $x_1, x_2, \dots, x_n \sim \text{Gumbel}(0)$ are independent random variables, then for $Z = \max(x_1, \dots, x_n)$ we have $Z \sim \text{Gumbel}(\ln n)$.*

Proof.

$$\Pr(Z < x) = \prod_i \Pr(x_i < x) = (e^{-x})^n = e^{-x + \ln n}. \quad \blacktriangleleft$$

Multinomial distribution

We now discuss the multinomial distribution and its role in the analysis of the stochastic averaging.

► **Definition 4.** *We say that X_1, \dots, X_k are distributed according to $\text{Multinomial}(n; p_1, \dots, p_k)$ distribution for some $\sum_i p_i = 1$, if, for any $n_1 + \dots + n_k = n$ there is*

$$\Pr[X_1 = n_1 \wedge \dots \wedge X_k = n_k] = \binom{n}{n_1, \dots, n_k} p_1^{n_1} \dots p_k^{n_k}.$$

Consider a process of distributing n identical balls to k urns, where for each ball we place it in the urn i with probability p_i , fully independently between the balls. Then, the vector of the total number of balls in each urn X_1, \dots, X_k follows $\text{Multinomial}(n; p_1, \dots, p_k)$ distribution.

For our purposes we are interested in the following setting: let f be some real-valued function. Lets say that we have a stochastic process of estimating cardinality in a stream, that is if n distinct elements appear, the process outputs a value that is concentrated around its expected value $f(n)$. Now, we apply stochastic averaging, by splitting the stream into sub-streams, and feed each sub-stream to estimation process separately, say n_i going into sub-stream i . We can look at the following random variables:

$$S_n = \mathbb{E}\left[\sum_i f(n_i)\right] \quad \text{and} \quad P_n = \mathbb{E}\left[\prod_i f(n_i)\right].$$

³ In fact, the Fisher–Tippett–Gnedenko theorem (c.f. [15]) states, that for any distribution \mathcal{D} , if for some a_n, b_n the limit $\lim_{n \rightarrow \infty} \left(\frac{\max(X_1, \dots, X_n) - b_n}{a_n} \right)$ converges to some non-degenerate distribution, where $X_1, \dots, X_n \sim \mathcal{D}$ (and are independent), then it converges to one of three possible distribution families: a Fréchet distribution, a Weibull distribution or a Gumbel distribution. Thus, those three distributions can be viewed as a counterpart to normal distribution, w.r.t. to taking maximum (instead of repeated additions).

We expect $S_n \approx kf(n/k)$ and $P_n \approx f(n/k)^k$. Deriving actual concentration bounds for specifically chosen functions f gives us insight on how well harmonic average or geometric average performs when concentrating cardinality estimation processes under stochastic averaging.

The analysis of the stochastic averaging for a *generic* function f (under some regularity constraints) has been done in [13]. We actually derive a stronger set of bounds for very specific functions: $f(x) = \ln(x+1)$ and $f(x) = \frac{1}{x+1}$.

4 Geometric average estimation

We start by showing a simple concentration result for geometric average of independent random variables distributed according to the Gumbel distribution.

► **Lemma 5.** *Let G_1, \dots, G_k be independent random variables distributed according to $\text{Gumbel}(0)$, and let $G = \sum_i G_i$. If $k > 1$, then $\mathbb{E}[\exp(G/k)] = \Gamma(1 - 1/k)^k = \exp(\gamma)(1 + \frac{\pi^2}{12} \frac{1}{k} + \mathcal{O}(k^{-2}))$. If $k > 2$, then $\text{Var}[\exp(G/k)] = \Gamma(1 - 2/k)^k - \Gamma(1 - 1/k)^{2k} = \exp(2\gamma) \cdot (\frac{\pi^2}{6k} + \mathcal{O}(k^{-2}))$*

Proof.

$$\begin{aligned} \mathbb{E}[\exp(G/k)] &= \prod_i \mathbb{E}[\exp(G_i/k)] = \Gamma(1 - 1/k)^k \\ \text{Var}[\exp(G/k)] &= \prod_i \mathbb{E}[\exp(G_i/k)^2] - \prod_i \mathbb{E}[\exp(G_i/k)]^2 \\ &= \Gamma(1 - 2/k)^k - \Gamma(1 - 1/k)^{2k}. \end{aligned}$$

From the Taylor expansion of the log-gamma function we get that $\Gamma(1 - z) = \exp(\gamma z + \frac{\pi^2}{12} z^2 + \mathcal{O}(z^3))$, which yields the desired approximations. ◀

The following algorithm shows that if we are fine with slower updates, then the Gumbel distribution fits nicely into the standard cardinality estimation framework. The main idea is just to hash each element into a real-value distributed according to Gumbel distribution, and take the maximum across the values.

■ **Algorithm 1** Cardinality estimation using Gumbel distribution.

```

1 Procedure INIT()
2   pick  $r_1, \dots, r_k : U \rightarrow [0, 1]$  as independent hash functions
3    $X_1 \leftarrow -\infty, \dots, X_k \leftarrow -\infty$ 
4 Procedure UPDATE( $x$ )
5   for  $1 \leq i \leq k$  do
6      $v \leftarrow -\ln(-\ln r_i(x))$  //  $\text{Gumbel}(0)$  RV
7      $X_i \leftarrow \max(v, X_i)$ 
8 Procedure GEOMETRICESTIMATE()
9    $\alpha_k \leftarrow \Gamma(1 - 1/k)^{-k}$  // normalizing factor, for large  $k$ :  $\alpha_k \approx \exp(-\gamma)$ 
10  return  $Z = \exp(\frac{1}{k} \sum_i X_i) \cdot \alpha_k$ 

```

► **Theorem 6.** *Applied to a stream of n distinct elements, Algorithm 1 outputs Z such that $\mathbb{E}[Z] = n$ and if $k > 2$ then $\text{Var}[Z] = \frac{n^2}{k} \left(\frac{\pi^2}{6} + O(k^{-1}) \right)$. It uses k real-value registers and spends $\mathcal{O}(k)$ operations per single processed element of the input.*

Proof. We analyze the Algorithm 1 after processing a stream of n distinct elements. For each X_i , its value is a maximum of n random variables drawn from Gumbel(0) distribution, so by Property 3 we have that $X_i \sim \text{Gumbel}(\ln n)$. Hence, $X_i = G_i + \ln n$ where all G_i are identically distributed according to the Gumbel(0). Moreover, repeated occurrences of the elements do not change the state of the algorithm. Denoting $G = \sum_i G_i$, we get

$$\mathbb{E}[Z] = \Gamma(1 - 1/k)^{-k} \mathbb{E}[\exp(\ln n + G/k)] = n\Gamma(1 - 1/k)^{-k}\Gamma(1 - 1/k)^k = n$$

and

$$\text{Var}[Z] = n^2\Gamma(1 - 1/k)^{-2k} \text{Var}[\exp(G/k)] = n^2 \left(\frac{\Gamma(1 - 2/k)^k}{\Gamma(1 - 1/k)^{2k}} - 1 \right). \quad \blacktriangleleft$$

4.1 Stochastic averaging

We refine the Algorithm 1 by adding stochastic averaging. Application of the technique is straightforward, but for technical reasons we need to take care of the initialization of the registers – since the expected value of X_i is the logarithm of the number of the elements assigned to the i -th register, we don't want any of the registers to be empty at the and. Therefore, at the beginning we feed each of them with an artificial random element.

■ **Algorithm 2** Cardinality estimation using Gumbel distribution and stochastic averaging.

```

1 Procedure INIT()
2   pick  $h : U \rightarrow \{1, \dots, k\}$  and  $r : U \rightarrow [0, 1]$  as independent hash functions
3   for  $1 \leq i \leq m$  do
4      $X_i \leftarrow -\ln(-\ln u_i)$  where  $u_i$  is picked uniformly from  $[0, 1]$ . // Gumbel(0) RV
5 Procedure UPDATE( $x$ )
6    $t \leftarrow h(x)$ 
7    $v \leftarrow -\ln(-\ln r(x))$  // Gumbel(0) RV
8    $X_t \leftarrow \max(v, X_t)$ 
9 Procedure GEOMETRICESTIMATE()
10   $\alpha_k \leftarrow \Gamma(1 - 1/k)^{-k}$  // normalizing factor, for large  $k$ :  $\alpha_k \approx \exp(-\gamma)$ 
11  return  $Z = k \cdot \exp(\frac{1}{k} \sum_i X_i) \cdot \alpha_k$ 

```

► **Theorem 7.** *Applied to a stream of n distinct elements, Algorithm 2 outputs Z such that if $k > 1$ then $n \frac{k}{k+1} \leq \mathbb{E}[Z] \leq n + k$ and if $k > 2$ then $\text{Var}[Z] \leq 3.645 \frac{n^2}{k} + \mathcal{O}(n^2/k^2 + k^2)$. It uses k real-value registers and spends constant number of operations per single processed element of the input.*

Proof. We analyze Algorithm 2 after processing stream S of n distinct elements. Let n_1, \dots, n_k be the respective numbers of unique items hashed by h into registers $\{1, \dots, k\}$ respectively. It follows that $n_1, \dots, n_k \sim \text{Multinomial}(n; \frac{1}{k}, \dots, \frac{1}{k})$. For each X_i , its value is a maximum of $n_i + 1$ random variables drawn from the Gumbel(0) distribution (taking into account n_i updates to its value and the initialization). Thus, conditioned on the specific

values of n_1, \dots, n_k , we have that X_i follows the Gumbel distribution – more specifically $X_i | n_1, \dots, n_k \sim \text{Gumbel}(\ln(n_i + 1))$. Let us denote $G_i = X_i - \ln(n_i + 1)$, $G = \sum_i G_i$ and $Y = \sum_i \ln(n_i + 1)$. We observe that G_i 's are independent random variables distributed according to $\text{Gumbel}(0)$ (and independent from Y).

We now have

$$Z = k\Gamma(1 - 1/k)^{-k} \exp(Y/k) \exp(G/k).$$

Since $\mathbb{E}[\exp(G/k)] = \Gamma(1 - 1/k)^k$ and G and Y are independent, using Lemma 8 we get

$$\mathbb{E}[Z] = k \mathbb{E}[\exp(Y/k)] \geq n \cdot \frac{k}{k+1}$$

and

$$\mathbb{E}[Z] = k \mathbb{E}[\exp(Y/k)] \leq n + k.$$

Now, using $\text{Var}[AB] = \text{Var}[A] \mathbb{E}[B^2] + \mathbb{E}[A]^2 \text{Var}[B]$ identity for independent random variables and Lemma 8 we can bound

$$\begin{aligned} \text{Var}[Z] &= k^2 \Gamma(1 - 1/k)^{-2k} (\text{Var}[\exp(Y/k)] \mathbb{E}[\exp(G/k)^2] + \mathbb{E}[\exp(Y/k)]^2 \text{Var}[\exp(G/k)]) \\ &\leq (k^2 + 2n^2/k + O(n^2/k^2)) \frac{\Gamma(1 - 2/k)^k}{\Gamma(1 - 1/k)^{2k}} + (n + k)^2 \left(\frac{\Gamma(1 - 2/k)^k}{\Gamma(1 - 1/k)^{2k}} - 1 \right) \\ &= (k^2 + 2n^2/k + O(n^2/k^2))(1 + O(k^{-1})) + (n + k)^2 \left(\frac{\pi^2}{6k} + O(k^{-2}) \right), \end{aligned}$$

and the claim follows. ◀

► **Lemma 8.** *Let $n_1, \dots, n_k \sim \text{Multinomial}(n; 1/k, \dots, 1/k)$ and let $T = \sqrt[k]{\prod_i (n_i + 1)} = \exp(\frac{1}{k} \sum_i \ln(n_i + 1))$. Then there is $n/(k+1) \leq \mathbb{E}[T] \leq n/k + 1$ and $\text{Var}[T] \leq 1 + 2n^2/k^3 + \mathcal{O}(n^2/k^4)$.*

Proof. Denote $Y = \sum_i \ln(n_i + 1)$. By Lemma 9 bound we have

$$\begin{aligned} \mathbb{E}[\exp(Y/k)] &\geq \int_0^\infty \exp(\ln(n/k) - t/k) e^{-t} dt \\ &= n/k \int_0^\infty \exp(-\frac{k+1}{k}t) dt \\ &= n/(k+1). \end{aligned}$$

By concavity of a logarithm we have $Y = \sum_i \ln(n_i + 1) \leq k \ln(n/k + 1)$, so $\exp(Y/k) \leq n/k + 1$. Finally, by Lemma 9 bound we get

$$\begin{aligned} \text{Var}[\exp(Y/k)] &\leq \mathbb{E}[(\exp(Y/k) - n/k)^2] \\ &\leq ((n/k + 1) - n/k)^2 + \frac{n^2}{k^2} \int_0^\infty (1 - e^{-t/k})^2 e^{-t} dt \\ &= 1 + \frac{n^2}{k^2} \left(1 - 2\frac{k}{k+1} + \frac{k}{k+2} \right). \end{aligned} \quad \blacktriangleleft$$

► **Lemma 9.** *Let $n_1, \dots, n_k \sim \text{Multinomial}(n; 1/k, \dots, 1/k)$ and let $Y = \sum_i \ln(n_i + 1)$. Then $Y \geq k \ln(n/k) - t$ with probability at least $1 - e^{-t}$.*

76:10 Cardinality Estimation Using Gumbel Distribution

Proof. Consider $\mathbb{E}[e^{-Y}]$. We have

$$\begin{aligned}
 \mathbb{E}_{\text{Multinomial}}^{n_1, \dots, n_k \sim} [e^{-Y}] &= \mathbb{E}_{\text{Multinomial}}^{n_1, \dots, n_k \sim} \left[\prod_i \frac{1}{n_i + 1} \right] \\
 &= \sum_{i_1 + \dots + i_k = n} \Pr[n_1 = i_1 \wedge \dots \wedge n_k = i_k] \prod_i \frac{1}{i_i + 1} \\
 &= \sum_{i_1 + \dots + i_k = n} k^{-n} \binom{n}{i_1, \dots, i_k} \prod_i \frac{1}{i_i + 1} \\
 &= k^{-n} \sum_{i_1 + \dots + i_k = n} \frac{n!}{(i_1 + 1)! \dots (i_k + 1)!} \\
 &= k^{-n} \sum_{i_1 + \dots + i_k = n} \binom{n+k}{i_1 + 1, \dots, i_k + 1} \frac{n!}{(n+k)!} \\
 &\leq k^{-n} k^{n+k} \frac{n!}{(n+k)!} \\
 &\leq \left(\frac{k}{n}\right)^k.
 \end{aligned}$$

Thus, for any $t > 0$, by Markov's inequality

$$\begin{aligned}
 \Pr[Y \leq k \ln(n/k) - t] &= \Pr[e^{-Y} \geq e^{t - k \ln(n/k)}] \\
 &\leq \Pr[e^{-Y} \geq e^t \cdot \mathbb{E}[e^{-Y}]] \\
 &\leq e^{-t}.
 \end{aligned}$$

4.2 Discretization

Presented sketches use k real-value registers, which is in disadvantage when compared with LogLog and HyperLogLog, where only k integers are used, each taking $\mathcal{O}(\log \log n)$ bits. We now discuss how to reduce the memory footprint of the algorithms. This section exemplifies the usefulness of Gumbel distributions. In particular, this is a family of the limit distributions where *additive error* of registers corresponds to *multiplicative error* of estimation.

Simple rounding

First, we note that rounding the registers to nearest multiplicity of ε for some $\varepsilon > 0$ introduces at most $\exp(\varepsilon) = 1 + \varepsilon + \mathcal{O}(\varepsilon^2)$ multiplicative distortion in the estimation procedure `GeometricEstimate()` from both Algorithm 1 and 2. For example, for 1, we have, assuming X'_i are rounded registers: $|X'_i - X_i| \leq \varepsilon$, and so for $Z' = \alpha_k \exp(\frac{1}{k} \sum_i X'_i)$ there is $\frac{Z'}{Z} = \exp(\frac{1}{k} \sum_i (X'_i - X_i))$, so $\exp(-\varepsilon) \leq \frac{Z'}{Z} \leq \exp(\varepsilon)$. Since each register stores w.h.p. values of magnitude $2 \log n$, it can be implemented on integer registers using $\mathcal{O}(\log \frac{\log n}{\varepsilon}) = \mathcal{O}(\log \log n + \log \varepsilon^{-1})$ bits.

Randomized rounding

We now show how to eliminate the $\log \varepsilon^{-1}$ term. We define the following *shift-rounding*, for shift value $c \in [0, 1)$:

$$f_c(x) \stackrel{\text{def}}{=} \lfloor x + c \rfloor - c.$$

We note two key properties:

1. shift-rounding commutes with maximum, that is, for any x_1, \dots, x_k , we have $\max(f_c(x_1), \dots, f_c(x_k)) = f_c(\max(x_1, \dots, x_k))$,
2. If $c \sim U[0, 1]$, then $f_c(x) \sim U[x - 1, x]$, where $U[a, b]$ denotes uniform distribution on range $[a, b]$.

We thus show how to adapt the Algorithm 2 using shift-rounding.

The analysis of Algorithm 3 comes from following invariant: if Algorithms 3 and 2 are run side-by-side on the same input stream, at any given moment there is $X'_i = f_{c_i}(X_i)$. Thus, we have the following $X'_i \sim \text{Gumbel}(\ln(n_i + 1)) - U[0, 1] = \ln(n_i + 1) + \text{Gumbel}(0) - U[0, 1]$.

■ **Algorithm 3** Algorithm 2 with shift-rounding.

```

1 Procedure INIT()
2   pick  $h : U \rightarrow \{1, \dots, k\}$  and  $r : U \rightarrow [0, 1]$  as independent hash functions
3   for  $1 \leq i \leq m$  do
4      $c_i$  is picked uniformly from  $[0, 1]$ 
5      $X'_i \leftarrow \lfloor -\ln(-\ln u_i) + c_i \rfloor - c_i$ 
6     where  $u_i$  is picked uniformly from  $[0, 1]$ . // Gumbel(0) RV + randomized
7     rounding
7 Procedure UPDATE( $x$ )
8    $t \leftarrow h(x)$ 
9    $v \leftarrow \lfloor -\ln(-\ln h(x)) + u_i \rfloor - u_i$ 
10   $X'_i \leftarrow \max(v, X'_i)$ 
11 Procedure GEOMETRICESTIMATE()
12   $\alpha'_k \leftarrow \Gamma(1 - 1/k)^{-k} (1 - \exp(-1/k))^{-k} k^{-k}$  // normalizing factor, for large
13   $k: \alpha'_k \approx \exp(1/2 - \gamma)$ 
14  return  $Z = k \cdot \exp(\frac{1}{k} \sum_i X'_i) \cdot \alpha'_k$ 

```

Additionally, X'_i are independent as X_i were independent. We observe that for $X' \sim \text{Gumbel}(0) - U[0, 1]$, there is $\mathbb{E}[\exp(X'/k)] = \Gamma(1 - 1/k)(1 - \exp(-1/k))k$, so we have equivalents of Lemma 5 in the following sense: $\mathbb{E}[\exp(\frac{1}{k} \sum_i G'_i)] = \Gamma(1 - 1/k)^k (1 - \exp(-1/k))^k k^k \approx \exp(\gamma - 1/2)(1 + (\frac{\pi^2}{12} + \frac{1}{6})\frac{1}{k} + \mathcal{O}(k^{-2}))$, and $\text{Var}[\exp(\frac{1}{k} \sum_i G'_i)] \approx \exp(2\gamma - 1)((\frac{\pi^2}{6} + \frac{1}{3})\frac{1}{k} + \mathcal{O}(k^{-2}))$.

Thus an equivalent of Theorem 7 applies to Algorithm 3 with slightly worse constants.

► **Theorem 10.** *Applied to a stream of n distinct elements, Algorithm 3 outputs Z such that if $k > 1$ then $n \frac{k}{k+1} \leq \mathbb{E}[Z] \leq n + k$ and if $k > 2$ then $\text{Var}[Z] \leq 3.98 \frac{n^2}{k} + \mathcal{O}(n^2/k^2 + k^2)$. It uses k integer registers of size $\mathcal{O}(\log \log n)$ bits each and spends constant number of operations per single processed element of the input.*

We note that each X'_i takes values only from set $\mathbb{Z} - c_i$ of magnitude at most $2 \log n$, it can be stored using $\mathcal{O}(\log \log n)$ bits. Values of c_i do not need to be stored explicitly, as those can be extracted by picking a hash function $c : \{1, \dots, k\} \rightarrow [0, 1]$ and setting $c_i = c(i)$.

Abstract

We consider variants of the restricted assignment problem where a set of jobs has to be assigned to a set of machines, for each job a size and a set of eligible machines is given, and the jobs may only be assigned to eligible machines with the goal of makespan minimization. For the variant with interval restrictions, where the machines can be arranged on a path such that each job is eligible on a subpath, we present the first better than 2-approximation and an improved inapproximability result. In particular, we give a $(2 - \frac{1}{24})$ -approximation and show that no better than $9/8$ -approximation is possible, unless $P=NP$. Furthermore, we consider restricted assignment with R resource restrictions and rank D unrelated scheduling. In the former problem, a machine may process a job if it can meet its resource requirements regarding R (renewable) resources. In the latter, the size of a job is dependent on the machine it is assigned to and the corresponding processing time matrix has rank at most D . The problem with interval restrictions includes the 1 resource variant, is encompassed by the 2 resource variant, and regarding approximation the R resource variant is essentially a special case of the rank $R + 1$ problem. We show that no better than $3/2$, $8/7$, and $3/2$ -approximation is possible (unless $P=NP$) for the 3 resource, 2 resource, and rank 3 variant, respectively. Both the approximation result for the interval case and the inapproximability result for the rank 3 variant are solutions to open challenges stated in previous works. Lastly, we also consider the reverse objective, that is, maximizing the minimal load any machine receives, and achieve similar results.

1 Introduction

Makespan minimization on unrelated parallel machines, or unrelated scheduling for short, is considered a fundamental problem in approximation and scheduling theory. In this problem, a set \mathcal{J} of jobs has to be assigned to a set \mathcal{M} of machines via a schedule $\sigma : \mathcal{J} \rightarrow \mathcal{M}$. Each job j has a processing time p_{ij} depending on the machine i it is assigned to and the goal is to minimize the makespan $C_{\max}(\sigma) = \max_{i \in \mathcal{M}} \sum_{j \in \sigma^{-1}(i)} p_{ij}$. In 1990, Lenstra, Shmoys, and Tardos [10] presented a 2-approximation for this problem and further showed that no better than 1.5-approximation can be achieved (unless $P=NP$) already for the restricted assignment problem, where each job j has a size p_j and $p_{ij} \in \{p_j, \infty\}$ for each machine i .

For each job j we denote its set of eligible machines by $\mathcal{M}(j) = \{i \in \mathcal{M} \mid p_{ij} = p_j\}$. Closing or narrowing the gap between 2-approximation and 1.5-inapproximability is a famous open problem in approximation [18] and scheduling theory [15]. The present paper deals with certain subproblems of both unrelated scheduling and restricted assignment.

Interval Restrictions. In the variant of restricted assignment with interval restrictions, denoted as RAI in the following, there is a total order of the machines and each job j is eligible on a discrete interval of machines, i.e., $\mathcal{M} = \{M_1, M_2, \dots, M_m\}$ and $\mathcal{M}(j) = \{M_\ell, M_{\ell+1}, \dots, M_r\}$ for some $\ell, r \in [m]$. There are several variants and special cases of this problem that are known to admit a polynomial time approximation scheme (PTAS), see [6, 8, 9, 11, 14, 16], the most prominent of which is probably the hierarchical case [11] in which each job is eligible on an interval of the form $\{M_1, M_2, \dots, M_r\}$, i.e., the first machine is eligible for each job. For RAI, on the other hand, there is an $(1 + \delta)$ -inapproximability result for some small but constant $\delta > 0$ [12]. Furthermore, Schwarz [16] designed a $(2 - 2/(\max_{j \in \mathcal{J}} p_j))$ -approximation (assuming integral processing times); and Wang and Sitters [17] studied an LP formulation that provides an optimal solution for the special case with two distinct processing times and some additional assumption.

Resource Restrictions. In the restricted assignment problem with R resource restrictions, or $\text{RAR}(R)$, a set \mathcal{R} of R (renewable) resources is given, each machine i has a resource capacity $c_r(i)$ and each job j has a resource demand $d_r(j)$ for each $r \in \mathcal{R}$. The eligible machines are determined by the corresponding resource constraints, i.e., $\mathcal{M}(j) = \{i \in \mathcal{M} \mid \forall r \in \mathcal{R} : d_r(j) \leq c_r(i)\}$ for each job j . It is easy to see, that $\text{RAR}(1)$ corresponds to the mentioned hierarchical case which admits a PTAS [11]. On the other hand, there can be no approximation algorithm with ratios smaller than $48/47 \approx 1.02$ or 1.5 for $\text{RAR}(2)$ and $\text{RAR}(4)$, respectively, unless $\text{P}=\text{NP}$, see [12]. The same paper also points out that the case with one resource is a special case of the interval case which in turn is a special case of the two resource case, i.e., $\text{RAR}(1) \subset \text{RAI} \subset \text{RAR}(2)$. While the hierarchical case, i.e. $\text{RAR}(1)$, has been studied extensively before, $\text{RAR}(R)$ was first introduced in a work by Bhaskara et al. [1], who mentioned it as a special case of the next problem that we consider.

Low Rank Scheduling. In the rank D version of unrelated scheduling, or $\text{LRS}(D)$, the processing time matrix (p_{ij}) has a rank of at most D . Alternatively (see [3]), we can assume that each job j has a D dimensional size vector $s(j)$ and each machine i a D dimensional speed vector $v(i)$ such that $p_{ij} = \sum_{k=1}^D s_k(j)v_k(i)$. Now, $\text{LRS}(1)$ is exactly makespan minimization on uniformly related parallel machines, which is well known to admit a PTAS [7]. Bhaskara et al. [1], who introduced $\text{LRS}(D)$, presented a QPTAS for $\text{LRS}(2)$ along with some initial inapproximability results for $D > 2$. Subsequently, Chen et al. [4] showed that there can be no better than 1.5-approximation for $\text{LRS}(4)$ unless $\text{P}=\text{NP}$, and for $\text{LRS}(3)$ the same authors together with Marx [3] ruled out a PTAS. On an intuitive level, resource restrictions can be seen as a restricted assignment version of low rank scheduling. However, there is a more direct relationship between the two problems: for each $\text{RAR}(R)$ instance there exist $\text{LRS}(R + 1)$ instances that are arbitrarily good approximations of the former (see [12]). Hence, any approximation algorithm for $\text{LRS}(R + 1)$ can also be used for $\text{RAR}(R)$, and any inapproximability result for $\text{RAR}(R)$ carries over to $\text{LRS}(R + 1)$. In fact many (but not all) inapproximability results for low rank scheduling essentially have this form.

Results. We present improved approximation and inapproximability results for this family of problems. In particular:

- An approximation algorithm for RAI with ratio $2 - \frac{1}{24} \approx 1.96$ presented in Section 2;
- a reduction that rules out a better than 1.5 approximation unless $P=NP$, i.e., a 1.5-inapproximability result, for RAR(3) presented in Section 3.1;
- a $8/7$ -inapproximability result for RAR(2) not included in this version of the paper;
- a $9/8$ -inapproximability result for RAI presented in Section 3.2;
- and a 1.5-inapproximability result for LRS(3) not included in this version of the paper.

All the missing proofs and results can be found in the long version of the paper. The positive result for RAI can be considered the first of the two main contributions of this paper. Finding a better than 2-approximation for RAI was posed as an open challenge in previous works [8, 16, 17]. When considering the respective results in [17] and [16], in particular, it seems highly probable that the actual goal of the research was to address exactly that challenge. The presented approximation algorithm follows the approach of solving and rounding a relaxed linear programming formulation of the problem, which has been used in the classical work by Lenstra et al. [10] and many of the results thereafter. In particular, we extend the so called assignment LP due to Lenstra et al. [10] and design a customized rounding approach. Both the linear programming extension and the rounding approach utilize extensions and refinements of ideas from [16] and [17]. Our result joins the relatively short list of special cases of the restricted assignment problem that do not allow a PTAS and for which an approximation algorithm with rate smaller than 2 is known. Other notable entries are the restricted assignment problem with only two processing times [2] and the so-called graph balancing case [5], where each job is eligible on at most two machines.

The inapproximability results directly build upon the results presented in the paper [12], which in turn utilizes many of the previously published ideas, e.g., from [1, 3–5, 10]. We use the satisfiability problem presented in [12] as the starting point for all of our reductions. For the RAI result in particular, we refine and restructure the respective results from [12] aiming for a significantly better ratio. The respective reduction involves a sorting process and curiously the main improvement in the reduction involves changing a sorting process resembling insertion sort into one resembling bubble sort. Due to this change, the construction becomes locally less complex enabling the use of smaller processing times and hence a stronger inapproximability result. Furthermore, the simplified construction in the result enables us to use the basic structure of the reduction as a starting point for the second main result of the paper, namely, the 1.5-inapproximability result for RAR(3). For this reduction several additional considerations and gadgets are needed, arguably making it the most elaborate of the presented results. The search for an inapproximability result with a reasonably big ratio for RAR(3) was stated as an open challenge in the long version of [3]. Adding the new result yields a very clear picture regarding the approximability of low rank makespan minimization: There is a PTAS for LRS(1), a QPTAS for LRS(2), and a 1.5-inapproximability result for LRS(D) with $D \geq 3$. The last two reductions regarding RAR(2) and RAR(3) yield much improved inapproximability results for the respective problems using comparatively simple and elegant reductions. The result regarding RAR(3), in particular, closes a gap in the results of [12] and also yields an (arguably) easier, alternative proof for the result of [4]. Finally, we note that all of the inapproximability results regarding restricted assignment with resource restrictions can be directly applied to the so called fair allocation or santa claus versions of the problems. In these problem variants, we maximize the minimum load received by the machines rather than minimization of the maximum load, i.e., the objective function is given by $C_{\min}(\sigma) = \min_{i \in \mathcal{M}} \sum_{j \in \sigma^{-1}(i)} p_{ij}$ in this case.

Further Related Work. For a more detailed discussion of related work, we refer to [12] and the long version of this paper.

2 Approximation Algorithm for Makespan Minimization with Interval Restrictions

We establish the first approximation for RAI with an approximation factor better than 2:

► **Theorem 1.** *There is a $(2 - \gamma)$ -approximation for RAI with $\gamma = \frac{1}{24}$.*

The particular value of the parameter γ is justified in the end. To achieve this result, we first formulate a customized linear program based on the assignment LP due to Lenstra et al. [10] and develop a rounding approach that places different types of jobs in phases. Note that the placement of big jobs with size close to OPT (where OPT is the makespan of an optimal schedule) is often critical when aiming for an approximation ratio of smaller than 2 for a makespan minimization problem. For instance, the classical 2-approximation [10] for restricted assignment produces a schedule of length at most $\text{OPT} + \max_{j \in \mathcal{J}} p_j$ where OPT is the makespan of an optimal schedule and hence the approximation ratio is better if $\max_{j \in \mathcal{J}} p_j$ is strictly smaller than OPT. This is also the case with our approach – the main effort goes into the careful placement of such big jobs. In particular, we place the largest jobs in a first rounding step and the remaining big jobs in a second. All of these jobs have the property that each machine should receive at most one of them and they are placed accordingly. Moreover, the placement is designed to deviate not too much from the fractional placement due to the LP solution. In a last step, the remaining jobs are placed. Each rounding step is based on a simple heuristic approach that considers the machines from left to right and places the least flexible eligible jobs first, i.e., the jobs that have not been placed yet, are eligible on the current machine, and have a minimal last eligible machine in the ordering of the machines. Both the LP and the rounding approach reuse ideas from [16, 17]. Hence, the main novelty lies in the much more elaborate approach for placing the mentioned big jobs in two phases.

In the following, we first establish some preliminary considerations; then formulate the LP and argue that it is indeed a relaxation of the problem at hand; and then discuss and analyze the different phases of the rounding procedure step by step.

Preliminaries. For any integer k , we set $[k] = \{0, \dots, k - 1\}$. We apply the standard technique (see [10]) of using a binary search framework to guess a candidate makespan T . The goal is then to either correctly decide that no schedule with makespan T exists, or to produce a schedule with makespan at most $(2 - \gamma)T$. Given this guess T , we divide the jobs j into small ($p_j \leq 0.5T$), large ($0.5T < p_j \leq (0.5 + \xi)T$) and huge ($(0.5 + \xi)T < p_j$) jobs depending on some parameter $\xi = \frac{1}{24}$ which is justified later on. We denote the sets of small, large, and huge jobs as \mathcal{S} , \mathcal{L} , and \mathcal{H} , respectively. Furthermore, we fix the (total) order of the machines such that each job is eligible on consecutive machines. This is possible since we are considering RAI. For the sake of simplicity, we assume $\mathcal{M} = [m]$ with the ordering corresponding to the natural one and set $\mathcal{M}(\ell, r) = \{\ell, \dots, r\}$ for each $\ell, r \in \mathcal{M}$. When considering the machines, we use a left to right intuition with predecessor machines on the left and successor machines on the right. Note, that for each job j there exists a left-most and right-most eligible machine and we denote these by $\ell(j)$ and $r(j)$, respectively, i.e., $\mathcal{M}(j) = \mathcal{M}(\ell(j), r(j))$. For a set of jobs $J \subseteq \mathcal{J}$, we call a job $j \in J$ *least flexible* in J if $r(j)$ is minimal in $\{r(j') \mid j' \in J\}$, and a job j is called *less flexible* than a job j' if $r(j) \leq r(j')$. Lastly, we set $J(\ell, r) = \{j \in \mathcal{J} \mid \mathcal{M}(j) \subseteq \mathcal{M}(\ell, r)\}$ for each set of jobs $J \subseteq \mathcal{J}$ and pair of machines $\ell, r \in \mathcal{M}$, and $p(J) = \sum_{j \in \mathcal{J}} p_j$.

Linear Program. The classical assignment LP (see [10]) is given by assignment variables $x_{ij} \in [0, 1]$ for each $i \in \mathcal{M}$ and $j \in \mathcal{J}$ and the following constraints:

$$\sum_{i \in \mathcal{M}} x_{ij} = 1 \quad \forall j \in \mathcal{J} \quad (1)$$

$$\sum_{j \in \mathcal{J}} p_j x_{ij} \leq T \quad \forall i \in \mathcal{M} \quad (2)$$

$$x_{ij} = 0 \quad \forall j \in \mathcal{J}, i \in \mathcal{M} \setminus \mathcal{M}(j) \quad (3)$$

Equation (1) guarantees that each job is (fractionally) placed exactly once; Equation (2) ensures that each machine receives at most a load of T ; and due to Equation (3) jobs are only placed on eligible machines. We add additional constraints that have to be satisfied by any integral solution. In particular, we add the following constraints using parameters $UB(\ell, r)$ for each $\ell, r \in \mathcal{M}$ with $\ell \leq r$, which will be properly introduced shortly:

$$\sum_{j \in \mathcal{L} \cup \mathcal{H}} x_{ij} \leq 1 \quad \forall i \in \mathcal{M} \quad (4)$$

$$\sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{H}} x_{ij} \leq UB(\ell, r) \quad \forall \ell, r \in \mathcal{M}, \ell \leq r \quad (5)$$

Equation (4) captures the simple fact that no machine may receive more than one job of size larger than $0.5T$ and was used in [5] as well. The bound $UB(\ell, r)$, on the other hand, is defined in relation to the total load of small jobs that has to be scheduled in the respective interval $\mathcal{M}(\ell, r)$. In particular, we consider the overall load of small jobs that have to be placed in the interval together with the load due to huge jobs with their sizes rounded down to their minimum size. The respective load has to be bounded by T times the number of machines in the interval, i.e., $\sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{H}} (0.5 + \xi) T x_{ij} + p(\mathcal{S}(\ell, r)) \leq T |\mathcal{M}(\ell, r)|$. Since the number of huge jobs placed in an interval is integral for an integral solution, we can therefore set $UB(\ell, r) = \lfloor (T |\mathcal{M}(\ell, r)| - p(\mathcal{S}(\ell, r))) / ((0.5 + \xi) T) \rfloor$. We note that a constraint similar to Equation (5) is also used in [16, 17]. Summing up, we try to solve the linear program given by Equations (1)–(5) which is indeed a relaxation for RAI. If this is not successful, we reject T and otherwise round the solution x using the procedure described in the following and yielding a rounded solution \bar{x} .

Placement of Huge Jobs. Starting with the first machine in the ordering, we place the huge jobs as follows:

- Let i^* be the current machine and H the set of huge jobs that have not been placed yet and are eligible on i^* .
- If $\lfloor \sum_{i \in \mathcal{M}(0, i^*)} \sum_{j \in \mathcal{H}} x_{ij} \rfloor > \lfloor \sum_{i \in \mathcal{M}(0, i^* - 1)} \sum_{j \in \mathcal{H}} x_{ij} \rfloor$ and $H \neq \emptyset$, place a least flexible job $j \in H$ on i^* , i.e., we set $\bar{x}_{i^* j} = 1$.
- Consider the next machine in the ordering or stop if there is none.

This procedure indeed works and we preserve a connection to the original LP solution:

► **Lemma 2.** *All of the huge jobs are placed (on eligible machines) by the above procedure and, for each $\ell, r \in \mathcal{M}$ with $\ell \leq r$, we have $\sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{H}} \bar{x}_{ij} \leq \lceil \sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{H}} x_{ij} \rceil$.*

We note that this first rounding step is very similar to the first rounding step in [17].

Mapping out the Regions. In the next step, we divide the machines into regions, where each region did receive fractional large load of (roughly) one. To that end, we define a set of border machines \mathcal{B} as the machines considered from left to right where the sum of

fractionally placed large jobs hits a new integer, i.e., $\mathcal{B} = \{i' \in \mathcal{M} \mid [\sum_{i \in \mathcal{M}(0,i')} \sum_{j \in \mathcal{L}} x_{ij}] > [\sum_{i \in \mathcal{M}(0,i'-1)} \sum_{j \in \mathcal{L}} x_{ij}]\}$. Moreover, let $\mathcal{B} = \{i_1, \dots, i_q\}$ with $i_1 < \dots < i_q$ and i_0 the left-most machine with $\sum_{j \in \mathcal{L}} x_{i_0 j} > 0$. For each $s \in [q] = \{0, \dots, q-1\}$, we may initially define the s -th region as $R^s = \mathcal{M}(i_s, i_{s+1})$. At this point consecutive regions overlap by one machine. We want to change this, while guaranteeing that each region retains at least one *candidate machine* that may receive a large job in the following. In particular, a machine $i \in \mathcal{M}$ is a candidate if it did receive some fractional large or huge job in the LP solution, i.e., $\sum_{j \in \mathcal{H} \cup \mathcal{L}} x_{ij} > 0$, but no huge job afterwards, i.e., $\sum_{j \in \mathcal{H}} \bar{x}_{ij} = 0$. We denote the set of candidate machines as \mathcal{C} . For each $s \in [q-1]$, we apply the following procedure in incremental order:

- Check whether region R^s needs the last machine to have at least one candidate, i.e., $\mathcal{M}(i_s, i_{s+1} - 1) \cap \mathcal{C} = \emptyset$.
 - If this is the case, we set $R^{s+1} = \mathcal{M}(i_{s+1} + 1, i_{s+2})$ and otherwise set $R^s = \mathcal{M}(i_s, i_{s+1} - 1)$.
- After applying this procedure, we have:

► **Lemma 3.** *The regions are non-overlapping and each contain at least one candidate.*

Before proceeding with the placement of the large jobs, we note the following technical observation:

► **Lemma 4.** *Let $\ell, r \in \mathcal{M}$ with $\ell \leq r$, $\ell \in R^s$, $r \in R^t$, $k = |\{s, \dots, t\}|$, and $\text{fracLarge} = \sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{L}} x_{ij}$. Then we have $k - 2 < \text{fracLarge} < k + 2$. Furthermore, $\text{fracLarge} < k + 1$ if either $\ell > i_s$ or $r < i_{t+1}$ and $\text{fracLarge} < k$ if both of these conditions hold.*

Placement of Large Jobs. Using the regions, we place the large jobs via the following procedure starting with the first region:

- Let R^* be the current region and L the set of large jobs that have not been placed yet and are eligible on at least one candidate machine from R^* .
- Do the following *twice*: Pick a least flexible large job $j \in L$, place it on the leftmost eligible candidate machine $i \in R^*$, i.e. $\bar{x}_{ij} = 1$, and update L .
- Consider the next region in the ordering or stop if there is none.

Observe that the placement of both the large and huge jobs guarantees that only machines that did receive fractional large or huge load in the LP solution may receive any large or huge job and each such machine receives at most one such job. We argue that this procedure works and also retains some connection to the original LP solution x .

► **Lemma 5.** *All large jobs are placed (on eligible machines) by the described procedure and, for each $\ell, r \in \mathcal{M}$ with $\ell \leq r$, we have $\sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{L}} \bar{x}_{ij} < 2(\sum_{i \in \mathcal{M}(\ell, r)} \sum_{j \in \mathcal{L}} x_{ij} + 2)$.*

Proof. Regarding the second statement note that we place at most 2 jobs in each region and hence Lemma 4 directly yields the proof. As usual, we proof the first statement by contradiction. To that end, assume that there exists a large job j^* that is not placed by the procedure. First note, that there is at least one eligible candidate machine for j^* . To see this, consider the set M of eligible machines $i \in \mathcal{M}(j)$ that either received fractional load of j^* or some huge load, i.e., $x_{ij} > 0$ for $j \in \{j^*\} \cup \mathcal{H}$. Then Equation (4) implies $\sum_{i \in M} \sum_{j \in \mathcal{H}} x_{ij} \leq |M| - 1$. Hence, at most $|M| - 1$ many huge jobs are placed on machines from M due to Lemma 2 and therefore at least one of these machines is a candidate. There are two possibilities why j^* was not placed on such a machine: either a less flexible job got placed on the machine, or two other less flexible jobs were already placed in the same region. Let $r^* = r(j^*)$ and $\ell^* \leq \ell$ be minimal with the property that each large job that was placed

in $\mathcal{M}(\ell^*, r^*)$ is less flexible than j^* and each free candidate machine in the interval is free because two other machines in the same respective region already received a large job less flexible than j^* . Furthermore, let J^* be the set of large jobs placed in $\mathcal{M}(\ell^*, r^*)$ together with j^* . We argue that $\ell(j) \geq \ell^*$ for each $j \in J^*$. Otherwise, there exists a job $j \in J^*$ eligible on machine $\ell^* - 1$. Then there are three possibilities regarding this machine. It was not a candidate before the procedure; it was a candidate and received a job less flexible than j (and therefore also less flexible than j^*); or it was a candidate and did not receive a large job because two other machines in the same region received a job less flexible than j . Each yields a contradiction to the definition of ℓ^* . Let $\text{fracLarge} = \sum_{i \in \mathcal{M}(\ell^*, r^*)} \sum_{j \in \mathcal{L}} x_{ij}$ be the sum of fractional large jobs in $\mathcal{M}(\ell^*, r^*)$ according to x . Note that we did show $J^* \subseteq \mathcal{J}(\ell^*, r^*)$ and hence $\text{fracLarge} \geq |J^*|$.

Let $M^* \subseteq \mathcal{M}(\ell^*, r^*)$ be the set of machines that did receive a fraction of a job from $J^* \cup \mathcal{H}$. Then Equation (4) implies $\sum_{i \in M^*} \sum_{j \in \mathcal{H}} x_{ij} \leq |M^*| - |J^*|$, and furthermore Lemma 2 yields that at most $|M^*| - |J^*|$ huge jobs are placed on machines from $|M^*|$. Hence, there are at least $|J^*|$ candidate machines in $\mathcal{M}(\ell^*, r^*)$. Since not all of the jobs from J^* have been placed by the procedure, there is therefore at least one free machine in $i^* \in \mathcal{M}(\ell^*, r^*)$. The definition of ℓ^* yields, that two jobs less flexible than j^* have been placed in the same region as i^* and these jobs have to be included in J^* (and the machines they are placed on in $\mathcal{M}(\ell^*, r^*)$).

We now take a closer look at the regions (partially) included in $\mathcal{M}(\ell^*, r^*)$. Let $\ell^* \in R^s$, $r^* \in R^t$, and $k = |\{s, \dots, t\}|$. We consider three cases: If we have $\ell^* = i_s$ and $r^* = i_{t+1}$, i.e., the borders of the interval correspond to the (original) outer borders of their regions, then each of the regions R^s, \dots, R^t did receive at least one job from J^* and one received at least two yielding $k \leq |J^*| - 2 \leq \text{fracLarge} - 2$. Moreover, if $\ell^* > i_s$ or $r^* < i_{t+1}$, then one of the regions R^s, \dots, R^t may not have received a job from J^* changing the inequality to $k \leq \text{fracLarge} - 1$. Lastly, if both $\ell^* > i_s$ and $r^* < i_{t+1}$, then the two outer regions may have received no job from J^* yielding $k \leq \text{fracLarge}$. However, Lemma 4 considers the same three cases, yielding $\text{fracLarge} < k + 2$, $\text{fracLarge} < k + 1$, and $\text{fracLarge} < k$, respectively. ζ

Placement of Small Jobs. Lastly we place the small jobs. Starting with the first machine, we do the following:

- Let i^* be the current machine and J the set of jobs that have not been placed yet and are eligible on i^* .
- Successively place least flexible jobs j on i^* , i.e., set $\bar{x}_{i^*j} = 1$, until either $J = \emptyset$ or placing the next job would raise the load of i^* above $(2 - \gamma)T$.
- Consider the next machine in the ordering or stop if there is none.

We argue that this procedure works under certain conditions:

► **Lemma 6.** *All small jobs are placed (on eligible machines) by the described procedure if $\gamma \leq \xi$, $\gamma + \xi \leq \frac{1}{12}$, and $8\xi + 7\gamma \leq 0.75$ hold. In the resulting schedule, each machine has a load of at most $(2 - \gamma)T$.*

Proof (Idea). The main idea of the proof is to assume that some job cannot be placed and to use this to construct some interval in which each machine received some minimum amount of load and in which each placed job had to be placed in the respective interval. Then Lemma 2, Lemma 5, and the constraints of the LP are used to show a contradiction. Depending on the number of large jobs in the interval, either Equation (2) or Equation (5) are critical. \blacktriangleleft

Lastly, we choose values for ξ and γ which satisfy all the requirements of the above lemma and maximize γ . The biggest γ is achieved by setting $\gamma = \xi = \frac{1}{24}$. This concludes the proof of Theorem 1.

3 Complexity Results

Remember that we use the notation $[n] = \{0, \dots, n-1\}$ for each integer n . The complexity result in this work directly build upon the ones in [12]. In that work, a satisfiability problem denoted as 3-SAT* was introduced and shown to be NP-hard, and all reductions in the present work start from this problem. An instance of the problem 3-SAT* is a conjunction of clauses with exactly 3 literals each. Each of the clauses is either a 1-in-3-clause or a 2-in-3-clause, that is, they are satisfied if exactly one or two of their literals, respectively, evaluate to *true* in a given truth assignment. We denote a k -in-3-clause with literals x , y , and z as $(x, y, z)_k$ and the truth values true and false are denoted as \top and \perp in the following. There are as many 1-in-3-clauses in a 3-SAT* instance as there are 2-in-3-clauses, and, furthermore, each literal occurs exactly twice. Hence, a minimal example for a 3-SAT* instance is given by $(x_0, x_1, \neg x_2)_1 \wedge (\neg x_0, x_1, x_2)_1 \wedge (x_0, \neg x_1, \neg x_2)_2 \wedge (\neg x_0, \neg x_1, x_2)_2$: We have two 1-in-3-clauses and two 2-in-3-clauses, and two occurrences of x_i and $\neg x_i$ for each $i \in [3]$. The formula is satisfied if we map every variable to \perp .

In each reduction, we start with an instance I of 3-SAT* with m many 1-in-3-clauses C_0, \dots, C_{m-1} , m many 2-in-3-clauses C_m, \dots, C_{2m-1} and n variables x_0, \dots, x_{n-1} . Since there are $2m$ clauses with 3 literals each and 4 occurrences for each variable, we have $6m = 4n$. In the following, the precise positions of the occurrences of the variables are important and we have to make them explicit. To this end, let for each $j \in [n]$ and $t \in [4]$ the pair (j, t) correspond to the first or second positive occurrence of variable x_j if $t = 0$ or $t = 1$, respectively, and to the first or second negative occurrence of variable x_j if $t = 2$ or $t = 3$. Furthermore, let $\kappa : [n] \times [4] \rightarrow [2m] \times [3]$ be the bijection that maps (j, t) to the corresponding clause index and position in that clause. For instance, in the above example we have $\kappa(0, 2) = (1, 0)$ and $\kappa(2, 1) = (3, 2)$.

Next, we construct an instance I' of the problem considered in the respective case. For the restricted assignment type problems, all job sizes are integral and upper bounded by some constant T such that the overall size of the jobs equals $|\mathcal{M}|T$. Hence, if a machine receives jobs with overall size more or less than T , the objective function value is worse than T for both the makespan and fair allocation case. The goal is to show, that there is a schedule with makespan T for I' , if and only if I is a yes-instance. This rules out approximation algorithms with rate smaller than $(T+1)/T$ for the makespan problem, and with rate smaller than $T/(T-1)$ for the fair allocation variant since the overall load is $|\mathcal{M}|T$. For the low rank problem, we first design a restricted assignment reduction using the above approach and then show that there exist low rank scheduling instances that approximate the restricted assignment instance with arbitrary precision.

Simple Reduction. We start with a simple reduction for the general restricted assignment problem (with arbitrary restrictions) introducing several ideas and gadgets relevant for all of the following reductions. Note that the reduction is very similar to the one by Ebenlendr et al. [5] and to a reduction in [12].

We have three types of basic jobs and machines, namely, truth assignment machines and jobs that are used to assign truth values to variables, clause machines and jobs that model clauses being satisfied, and variable jobs that connect the first two types:

■ **Table 1** Resource demands and capacities of the jobs and machines, respectively, for the case with 3 resources.

Job/Mach.	Res. 1	Res. 2	Res. 3
$\text{TMach}(j, 0)$	$4j + 1$	$4n - 4j$	1
$\text{TMach}(j, 1)$	$4j + 3$	$4n - 4j$	0
$\text{TJob}(j)$	$4j$	$4n - 4j$	0
$\text{CMach}(i, s), \kappa^{-1}(i, s) = (j, t)$	$4j + t$	$4n - (4j + t)$	$2 + i$
$\text{CJob}(i, s)$	0	0	$2 + i$
$\text{VJob}(j, t)$	$4j + t$	$4n - (4j + t)$	$1 - \lfloor \frac{t}{2} \rfloor$

- There are truth assignment machines $\text{TMach}(j, q)$ with $j \in [n]$ and $q \in [2]$ and one truth assignment job $\text{TJob}(j)$ with size 2 and eligible on $\{\text{TMach}(j, 0), \text{TMach}(j, 1)\}$.
- There are clause machines $\text{CMach}(i, s)$ for each $i \in [2m]$ and $s \in [3]$ and three clause jobs $\text{CJob}(i, s)$ each eligible on $\{\text{CMach}(i, s') \mid s' \in [3]\}$. The job $\text{CJob}(i, 0)$ has size 1, $\text{CJob}(i, 2)$ has size 2, and $\text{CJob}(i, 1)$ has size 2 if clause C_i is a 1-in-3-clause and size 1 otherwise.
- Lastly, there are variable jobs $\text{VJob}(j, t)$ for each $j \in [n]$ and $t \in [4]$ each of size 1 and eligible on $\{\text{TMach}(j, \lfloor \frac{t}{2} \rfloor), \text{CMach}(\kappa(j, t))\}$.

First note:

▷ **Claim 7.** The overall job size $\sum_{j \in \mathcal{J}} p(j)$ is equal to $2|\mathcal{M}|$.

Consider the case that we have a satisfying truth assignment for instance I . If variable x_j is assigned to \top , we place $\text{TJob}(j)$ on $\text{TMach}(j, 0)$, $\text{VJob}(j, 0)$ and $\text{VJob}(j, 1)$ on $\text{CMach}(\kappa(j, 0))$ and $\text{CMach}(\kappa(j, 1))$, respectively, together with local size 1 clause jobs. Furthermore, $\text{VJob}(j, 2)$ and $\text{VJob}(j, 3)$ are placed on $\text{TMach}(j, 1)$ and $\text{CMach}(\kappa(j, 2))$ and $\text{CMach}(\kappa(j, 3))$ each receive a local size 2 clause job. If variable x_j is assigned to \perp , we place $\text{TJob}(j)$ on $\text{TMach}(j, 1)$, and the placement strategy of the positive and negative variable jobs is reversed. Note that the placement of the clause jobs has to work out since the truth assignment is satisfying. This approach yields a schedule with makespan 2. However, it is also easy to see that a schedule with makespan 2 yields a satisfying truth assignment by basing the assignment of x_j on the placement of $\text{TJob}(j)$, and hence we have:

► **Lemma 8.** *There is a satisfying truth assignment for I , if and only if there is a schedule with makespan 2 for I' .*

This reduction can be considered the basis of all the other ones considered in this work.

3.1 Three Resources

In the RAR(3) case, we can use essentially the same construction as above. However, the sets of eligible machines are defined using the resources and are slightly different. The resource demands and capacities are specified in Table 1. The choice of resources implies:

▷ **Claim 9.** We have $\mathcal{M}(\text{TJob}(j)) = \{\text{TMach}(j, 0), \text{TMach}(j, 1)\}$ for each $j \in [n]$ and $\mathcal{M}(\text{VJob}(j, t)) = \{\text{TMach}(j, \lfloor \frac{t}{2} \rfloor), \text{CMach}(\kappa(j, t))\}$ for each $j \in [n]$ and $t \in [4]$.

Hence, the truth assignment and variable jobs have the same sets of eligible machines as before. For the clause jobs this is not true, however, a similar claim holds. We call a schedule that assigns a load of exactly T to each machine a T -schedule. Using the fact, that in a 2-schedule each clause machine has to receive at least one clause job, it is easy to show the following:

77:10 Interval, Resource Restricted, and Low Rank Scheduling

▷ **Claim 10.** In any 2-schedule each machine from $\{\text{CMach}(i, s) \mid s \in [3]\}$ receives exactly one job from $\{\text{CJob}(i, s) \mid s \in [3]\}$.

Hence, Lemma 8 works the same as before and we have:

► **Theorem 11.** *There is no better than 1.5-approximation for RAR(3) and no better than 2-approximation for the fair allocation version of this problem, unless $P=NP$.*

3.2 Interval Restrictions

In order to motivate the new ideas for the RAI reduction and to make them easier to understand, it is helpful to revisit the reduction from [12] first. One of the main ingredients in that result is a simple trick that we will also use extensively.

Pyramid Trick. Consider the following setting: We have 2ℓ consecutive machines and ℓ pairs of jobs. The i -th pair of jobs is eligible on the i -th machine and up to and including the $(2\ell + 1 - i)$ -th machine. Furthermore, we assume that each machine has to receive at least one of the jobs. Then the first and last machine each have to receive one job from the first pair because there are no other eligible jobs that can be processed on these machines. Now, the same argument can be repeated for the second and second to last machine and so on. Hence, machine i and $(2\ell + 1 - i)$ each have to receive exactly one job from pair i .

Sorting. Next, consider that in the ordering of the machines the truth assignment machines are placed on the left and the clause machines on the right. We could use similar truth assignment and clause jobs as in the reduction in the beginning of this chapter. However, variable jobs each are eligible on one truth assignment and one clause machine. Hence they have to be eligible on all machines in between in a naive adaptation of the reduction to the interval case. If we want to use the pyramid trick to deal with this problem, then intuitively decisions regarding variables in later clauses have to be made before the decisions for variables in earlier clauses and this, of course, cannot be guaranteed regardless of the fixed order of the clauses or variables. The main work in [12] was to remedy this situation by – roughly speaking – sorting the information regarding the variables made in the truth assignment gadget to enable the use of the pyramid trick. To do so several gadgets have been introduced that were intertwined with the truth assignment gadget and carefully build up the ordered information using the pyramid trick and interlocking job sizes. The problem with this approach is that the job sizes can get big rather fast if too many different job types are eligible on the same machines resulting in a high value for T . Now, the main idea in the present work is to decouple the decision and the sorting process and make the sorting process as simple as possible to enable smaller job sizes and therefore a stronger result. Curiously, the sorting process in [12] could be interpreted as some variant of insertion sort, while the one used in the present reduction resembles bubble sort.

Machines and Order. Let $k \in \mathcal{O}(n^2)$ be a parameter to be specified later in this paragraph. In addition to the truth assignment and clause machines, we introduce the following ones:

- For each $j \in [n]$ and $t \in [4]$ there are two gateway machines: one forward $\text{FGMach}(j, t)$ and one backward gateway machine $\text{BGMach}(j, t)$.
- For each $\ell \in [k]$, $j \in [n]$, and $t \in [4]$ there are two sorting machines: one forward $\text{FSMach}(\ell, j, t)$ and one backward sorting machine $\text{BSMach}(\ell, j, t)$.

Let \mathcal{T} , \mathcal{G} , and \mathcal{C} be the sets of truth assignment, gateway, and clause machines, respectively. Moreover, for each $\ell \in [k]$ let $\mathcal{S}_\ell = \{\text{BSMach}(\ell, j, t), \text{FSMach}(\ell, j, t) \mid j \in [n], t \in [4]\}$ be the ℓ -th set of sorting machines. We define the overall order of the machines by setting an internal order for each set of machines as well as an order of the machine sets. However, before we can do so, we need some additional concepts and notation. In particular, let φ_0 be the sequence of (j, t) -pairs with $j \in [n]$, $t \in [4]$ with increasing lexicographical order and $\psi_0 = \kappa(\varphi_0)$, i.e., $\varphi_0 = ((0, 0), \dots, (0, 3), \dots, (n-1, 0), \dots, (n-1, 3))$ and $\psi_0 = (\kappa(0, 0), \dots, \kappa(0, 3), \dots, \kappa(n-1, 0), \dots, \kappa(n-1, 3))$. Hence, ψ_0 is a permutation of the pairs (i, s) with $i \in [2m]$ and $s \in [3]$. We consider sorting ψ_0 with the goal of reaching the increasing lexicographical order. Let k be the number of transpositions performed by bubble sort if we do this. Furthermore, let $\psi_{\ell+1}$ for $\ell \in [k]$ be the sequence we get after the first $(\ell+1)$ -transpositions and $\varphi_{\ell+1} = \kappa^{-1}(\psi_{\ell+1})$. The use of bubble sort guarantees that $k \in \mathcal{O}(n^2)$ and that two consecutive sequences $\varphi_\ell, \varphi_{\ell+1}$ differ only by two consecutive entries that are transposed. For any finite sequence χ , we denote the reversed sequence as $\bar{\chi}$. Now, the ordering is specified as follows:

- The sets are ordered as follows: $\mathcal{T}, \mathcal{G}, \mathcal{S}_0, \dots, \mathcal{S}_{k-1}, \mathcal{C}$.
- The truth assignment machines are ordered in *increasing* lexicographical order of the indices (j, q) .
- The clause machines are ordered in *decreasing* lexicographical order of the indices (i, s) .
- The backward gateway machines are placed before the forward gateway machines and for each $\ell \in [k]$ the backward sorting machines are placed before the forward sorting machines from \mathcal{S}_ℓ as well.
- The forward and backward gateway machines are ordered in increasing and decreasing lexicographical order of the indices (j, t) , i.e., φ_0 and $\bar{\varphi}_0$, respectively.
- For each $\ell \in [k]$, the backward sorting machines are sorted according to the placement of the (j, t) indices in $\bar{\varphi}_\ell$.
- For each $\ell \in [k]$, the forward sorting machines are sorted according to the placement of the (j, t) indices in $\varphi_{\ell+1}$.

The peculiar ordering of the machines is designed to enable the use of the pyramid trick.

Jobs, Sizes, and Eligibilities. We give a full list of all jobs together with their sizes and define the sets of eligible machines by stating the respective first and last eligible machine for each job. We will need one more definition: Let $\xi : [k] \rightarrow [n] \times [4]$ be the function that maps ℓ to the distinct pair (j, t) that has a higher index in $\varphi_{\ell+1}$ than in φ_ℓ .

- Truth assignment jobs: For each $j \in [n]$ there is a job $\text{TJob}(j)$ with size 2, first machine $\text{TMach}(j, 0)$ and last machine $\text{TMach}(j, 1)$.
- Variable jobs: For each $j \in [n]$, $t \in [4]$, and $\circ \in \{\top, \perp\}$ there is a job $\text{VJob}(j, t, \circ)$ with size 2 if $\circ = \perp$ and 3 otherwise, first machine $\text{TMach}(j, \lfloor t/2 \rfloor)$ and last machine $\text{BGMach}(j, t)$.
- Gateway jobs: For each $j \in [n]$, $t \in [4]$, and $\circ \in \{\top, \perp\}$ there is a job $\text{GJob}(j, t, \circ)$ with size 5 if $\circ = \perp$ and 4 otherwise, first machine $\text{BGMach}(j, t)$ and last machine $\text{FGMach}(j, t)$.
- Bridge jobs: For each $\ell \in [k+1]$, $j \in [n]$, $t \in [4]$, and $\circ \in \{\top, \perp\}$ there is a bridge job $\text{BJob}(\ell, j, t, \circ)$ with size 1 if $\circ = \perp$ and 2 otherwise, first machine either $\text{FGMach}(j, t)$ if $\ell = 0$ or $\text{FSMach}(\ell-1, j, t)$ otherwise, and last machine either $\text{BSMach}(\ell, j, t)$ if $\ell < k$ or $\text{CMach}(\kappa(j, t))$ otherwise.
- Sorting jobs: For each $\ell \in [k]$, $j \in [n]$, $t \in [4]$, and $\circ \in \{\top, \perp\}$ there is a job $\text{SJob}(\ell, j, t, \circ)$. If $\xi(\ell) = (j, t)$, it has size 4 if $\circ = \perp$ and 3 otherwise, and, if $\xi(\ell) \neq (j, t)$, it has size 7 if $\circ = \perp$ and 6 otherwise. The first machine of $\text{SJob}(\ell, j, t, \circ)$ is $\text{BSMach}(\ell, j, t)$ and the last machine is $\text{FSMach}(\ell, j, t)$.

■ **Figure 1** A visualization of the job and machine structure for the reduction regarding RAI. The lower part corresponds to sets of machines with arrows corresponding to the direction of their ordering; and the upper part to different job sets with lines corresponding to intervals of eligible machines for pairs of jobs. Truth assignment and clause jobs as well as private loads are not depicted.

- Clause jobs: For each $i \in [2m]$ and $s \in [3]$ there is a job $\text{CJob}(i, s)$ with size 7 if $s = 1$, $8 - k$ if $s = 2$ and C_i is a k -in-3-clause, and 6 if $s = 3$, first machine $\text{CMach}(i, 2)$ and last machine $\text{CMach}(i, 0)$.
- Private loads: Each truth assignment machine has a private load (a job eligible only one one machine) of 2, each backward or forward gateway machine a load of 1 or 2, respectively, and for each $\ell \in [k]$ the sorting machines $\text{BSMach}(\ell, \xi(\ell))$ and $\text{FSMach}(\ell, \xi(\ell))$ have a private load of 3.

Using this reduction, we can show:

- **Theorem 12.** *There is no better than $\frac{9}{8}$ -approximation for RAI and no better than $\frac{8}{7}$ -approximation for the fair allocation version of this problem, unless $P=NP$.*

While the formal proof of this result exceeds the scope of this short version of the paper, we briefly discuss the main idea: We have a truth assignment gadget that determines the truth values of the variables and is followed by the gateway gadget, whose sole purpose is to decouple the used job sizes in the truth assignment gadget and the sorting gadget. Next there is the sorting gadget that slowly reorders the information about the decisions in the truth assignment gadget, and lastly there is the clause gadget in which the truth assignment is evaluated. The connection between the truth assignment and gateway gadget is provided by the variable jobs and all other connections are realized via bridge jobs. A sketch of the overall structure of the reduction is provided in Figure 1.

4 Conclusion

We conclude this work with a brief discussion of possible future research directions. There are some obvious questions that can be pursued directly building upon the presented results, i.e., a better approximation ration for RAI or even stronger inapproximability results for RAI or RAR(2). Of course, an improved approximation ratio for any problem of the family would be interesting to develop. We would like to highlight LRS(2), in particular, as the in some sense easiest problem in the family without a known polynomial time approximation with ratio better than 2. Lastly, only very little is known regarding fixed-parameter tractable algorithms for this family of problems. For instance, it is open whether RAR(1) is fixed-parameter tractable with respect to the objective value.

Localized Geometric Moves to Compute Hyperbolic Structures on Triangulated 3-Manifolds

Clément Maria

Abstract

A fundamental way to study 3-manifolds is through the geometric lens, one of the most prominent geometries being the hyperbolic one. We focus on the computation of a complete hyperbolic structure on a connected orientable hyperbolic 3-manifold with torus boundaries. This family of 3-manifolds includes the knot complements.

This computation of a hyperbolic structure requires the resolution of gluing equations on a triangulation of the space, but not all triangulations admit a solution to the equations.

In this paper, we propose a new method to find a triangulation that admits a solution to the gluing equations, using convex optimization and localized combinatorial modifications. It is based on Casson and Rivin’s reformulation of the equations. We provide a novel approach to modify a triangulation and update its geometry, along with experimental results to support the new method.

1 Introduction

A main problem of knot theory is to tell whether two knots are equivalent or distinct. Equivalence between knots is defined by the existence of an isotopy of the ambient space that would turn one knot into the other, i.e., a continuous deformation of the space that preserves the entanglement.

Isotopies are too difficult to compute in practice, and practitioners use *invariants* to tackle the knot equivalence problem. A *topological invariant* is a quantity assigned to a presentation of a knot, that is invariant by isotopy.

An important family of knots are the *hyperbolic knots*, which are the knots whose complements admit a *complete hyperbolic metric*. They are the subjects of active mathematical research, which motivates the introduction of efficient algorithmic tools to study their geometric properties, and most notably their *hyperbolic volume*. The hyperbolic volume of a hyperbolic knot is a topological invariant which is powerful at distinguishing between non-equivalent knots, is non-trivial to compute, and is at the heart of several deep conjectures in topology [11].

If it exists, the complete hyperbolic metric on a 3-manifold is unique[10], and may be combinatorially represented by a *complete hyperbolic structure* (CHS). In order to compute geometric properties (such as volume) of a hyperbolic knot, one triangulates the knot complement, and try to assign hyperbolic shapes to its tetrahedra. If these *shapes* verify a set of non-linear constraints called the *gluing equations*, they form a CHS and encode the

■ **Table 1** On all ~ 9.7 millions prime knots with crossing numbers ranging from 12 to 17, alternating and non-alternating, we indicate (*% Failure on first try*) the percentage of knot complements (after triangulation and simplification) on which **SnapPy** fails to compute a CHS on first try. We also indicate (*Highest expected nb of retriang.*) the highest, over all knots, expected number of random re-triangulations necessary for **SnapPy** to succeed finding a CHS.

	Alternating						Non-Alternating					
#crossings	12	13	14	15	16	17	12	13	14	15	16	17
% Failure on first try	0.9	1.6	2.4	3.3	4.4	5.7	0.8	0.7	1.2	1.7	2.4	3.3
Expected nb of retriang.	2.9	3.9	6.2	7.1	9.5	15.9	2.0	3.1	6.1	11.8	9.7	13.5

■ **Figure 1** Distribution of the number of randomizations required to find a CHS for the complement of the knot “17nh_2654001” of the census, for 10000 tries. The mean is 10.3 randomizations, and the standard deviation is 8.7. The minimum number of re-triangulations is 1, and the maximum 92.

complete hyperbolic metric of the space. A major issue with this approach is that a solution to the constraints may not exist on all triangulations of a manifold, even if, as topological object, the manifold can carry a complete hyperbolic metric. Worst, it is not known whether every hyperbolic 3-manifold admits a triangulation on which a solution as CHS exists.

In practice, given an input knot, software can construct a triangulation of the knot complement, and simplify it to have a CHS. But if this fails, the only implemented practical solution, proposed by **SnapPy**[3], is to randomly modify and simplify the triangulation before trying again until a CHS is found.

Table 1 provides data on the search for a CHS with **SnapPy**, on the ~ 9.7 millions prime knots with crossing numbers up to 17. As observed, **SnapPy** has a high rate of success in finding a CHS after a standard triangulation and simplification of the knot complement. However, this standard construction of a triangulation fails to admit a CHS on more than 350 thousand knots in the census, and the percentage of problematic triangulations needing re-triangulations tends to increase with the number of crossings. Additionally, we observe that some knot complements may require in expectation a high number of random re-triangulations (up to 15.9), and the number of re-triangulations may itself suffer a high variance, as illustrated in Figure 1.

■ **Figure 2** Left: ideal triangulation of the complement of the 8-knot with two tetrahedra. The ideal vertex is truncated, and the red surface gives the torus link of the ideal vertex after gluing of the tetrahedra following the edge identifications. Middle: ideal tetrahedron in the upper half-space model, the dihedral angles are denoted α , β and γ , the complex shape parameter z is associated to the edge between 0 and ∞ . Right: example of shearing singularity, each triangle corresponds to a ideal tetrahedron seen from above (gray arrow).

Checking for the existence of a CHS requires the resolution of the non-linear gluing equations (with, e.g., Newton optimization method). Reducing the number of re-triangulations is consequently critical for performance of computation in knot theory, most notably for knots on which the state-of-the-art methods implemented in `SnapPy` require large numbers of re-triangulations, and even more so when proceeding to very large scale experiments such as the computation of the knot censuses [1] that are of great use to practitioners, where “difficult” knots are many.

Contribution. This paper introduces a new heuristic based algorithm to improve on the random approach for re-triangulating. The method is inspired by Casson and Rivin’s reformulation of the gluing equations [15, 4]: the gluing equations are split into a linear part and a non-linear part, and the resolution reduces to a convex optimization problem on a polytope domain. If the triangulation does not admit a complete structure, the optimization problem will converge on the boundary of the polytope and we exploit this information to introduce new *localized moves* to modify combinatorially the triangulation while reusing the partially computed geometry. We introduce necessary background on triangulations and geometry in Section 2, and the computation of hyperbolic structures with optimization in Section 3. We analyze precisely the behavior of the optimization phase on triangulations not admitting a CHS in Section 4, and introduce a re-triangulation algorithm in Section 5 guided by the partially computed geometry of the optimization phase. We illustrate experimentally the interest of the approach in Section 6 and propose a hybrid method with `SnapPy` in Section 6.2, that outperforms the state-of-the-art.

Note that, in this article we focus on complements of hyperbolic knots. However, the techniques introduced extend to more general hyperbolic 3-manifolds with torus boundaries [4].

2 Background

In this article, we focus on knot complements, i.e., non-compact 3-manifolds obtained by removing a closed regular neighborhood of a knot K in the sphere S^3 .

■ **Figure 3** Illustration of the Pachner moves 2-3 and 3-2.

2.1 Generalized and ideal triangulations

A *generalized triangulation* T is a collection of n abstract tetrahedra whose triangular facets are identified (e.g. Figure 2 (left)), or *glued*, in pairs. Note that the facets of the same tetrahedron may be glued together, and generalized triangulations are more general than simplicial complexes. The link of a vertex in T is the frontier of a closed regular neighborhood, and is itself a closed triangulated surface embedded in the triangulation. If the link of a vertex v is a 2-sphere, we call v an *internal* vertex, otherwise (e.g., if the link is a torus), we call v an *ideal* vertex.

A 1-vertex ideal triangulation is a triangulation with exactly 1 ideal vertex, and no internal vertices. They represent non-compact 3-manifolds, that can be recovered from the 1-vertex ideal triangulation by considering their realization where the vertex has been removed. Every knot complement can be represented by a 1-vertex ideal triangulation, where the link of the ideal vertex gives the frontier of a closed regular neighborhood of the knot. Intuitively, this is a triangulation of the sphere S^3 where the knot has been shrunk into a single point, distorting its neighborhood. Such 1-vertex ideal triangulations of a knot complement can be computed in polynomial time [6, 5] from a planar drawing of a knot.

Any two ideal triangulations of the same 3-manifold can be connected by a sequence of *Pachner moves* [13]. For 1-vertex ideal triangulations, they consist of the moves 2-3 and 3-2, inverse of each other, pictured in Figure 3.

2.2 Combinatorial description of hyperbolic geometry

Certain topological 3-manifolds can be equipped uniformly with a complete hyperbolic metric, which is unique up to isometry. They are called *hyperbolic manifolds*. They include the vast and important family of complements of *hyperbolic knots*.

We use the upper half-space model to represent the hyperbolic space \mathbb{H}^3 . This representation corresponds to $\{(z, r) | z \in \mathbb{C}, r \in \mathbb{R}_+^*\}$ with $\partial\mathbb{H}^3 = \mathbb{C} \cup \{\infty\}$ (from now on denoted $\partial\mathbb{H}^3$) consisting of the bottom plane $\mathbb{C} \times \{0\}$, together with the point at infinity, where geodesics are arcs of circles orthogonal to $\partial\mathbb{H}^3$. This model is *conformal*, i.e., Euclidean angles in the upper half space give the values of the angles in the hyperbolic space.

An *ideal hyperbolic tetrahedron* is the hyperbolic convex hull of four distinct points of $\partial\mathbb{H}^3$. These points are the (ideal) vertices of the tetrahedron.

A vertex on $\partial\mathbb{H}^3$ is a vertex at infinity, thus it is not part of the tetrahedron. An example of ideal tetrahedron is shown in Figure 2 (middle). Up to isometry, the geometric shape of an ideal tetrahedron can be represented by a single complex number:

► **Definition 1** (Shape parameter). *Given an ideal hyperbolic tetrahedron, there exists an isometry sending three of its vertices to 0, 1, and ∞ , and ensuring that the fourth vertex has positive imaginary part in the complex plane in $\partial\mathbb{H}^3 = \mathbb{C} \cup \{\infty\}$. The coordinate z of this fourth vertex is the shape parameter of the tetrahedron.*

The shape parameter defines and illustrates the shape of an ideal tetrahedron. It depends on which vertices are sent to 0, 1, and ∞ . Other permutations of the vertices give other equivalent shape parameters $z' = \frac{z-1}{z}$ and $z'' = \frac{1}{1-z}$ but the underlying tetrahedron is the same. The construction is well defined as isometries of \mathbb{H}^3 are determined by their action on three vertices of $\partial\mathbb{H}^3$.

Another way of characterizing the shape of an ideal hyperbolic tetrahedron is to consider its dihedral angles, i.e., the angle formed by two faces meeting on a common edge; see Figure 2 (middle). In an ideal tetrahedron, opposite angles are equal, and the sum of the six dihedral angles is 2π . We denote in the following the dihedral angles of a tetrahedron by a triplet (α, β, γ) with $(\alpha + \beta + \gamma) = \pi$.

3 Angle structures and hyperbolic volume

In this section, we introduce notions connected to the computation of complete hyperbolic structures on triangulations, via optimization methods. The approach given in this section is another formulation of Thurston's gluing equations, which are non-linear in the complex shape parameters mentioned above, we refer the reader to [4, 15] for more details.

3.1 Linear equations and angle structures

Let T be a 1-vertex ideal triangulation of a knot complement M with n tetrahedra. Since opposite edges have the same dihedral angles, all possible shapes of the tetrahedra can be represented by a vertex in \mathbb{R}^{3n} . We define an *angle structure*:

► **Definition 2** (Angle structures). *Given an ideal triangulation T , an angle structure is a value assignment to the dihedral angles of the tetrahedra of T such that:*

1. *all the angles are strictly positive;*
2. *the three dihedral angles (α, β, γ) of a tetrahedron sum to π ;*
3. *the dihedral angles around each edge of T sum to 2π .*

The set of angle structures on T is denoted $\mathcal{A}(T)$.

Conditions 1 and 2 ensure the angles are in $(0, \pi)$ and that the tetrahedra have the same orientation. Condition 3 is necessary for points on the interior of edges to have a neighborhood isometric to a hyperbolic ball.

Constraints 1, 2, 3 are linear, hence the set $\mathcal{A}(T)$ of angle structures of a triangulation is the relative interior of a polytope in \mathbb{R}^{3n} . It is of dimension $n + |\partial M|$ where $|\partial M|$ is the number of cusps of M ; in the case of knot complements, there is a single cusp. This polytope satisfies:

► **Theorem 3** (Casson; see [8]). *Let T be an ideal triangulation of M , an orientable 3-manifold with toric cusps. If $\mathcal{A}(T) \neq \emptyset$, then M admits a complete hyperbolic metric.*

Furthermore, [4] describes precisely a generating family for the tangent space of $\mathcal{A}(T)$ that can be computed in polynomial time.

3.2 Maximizing the hyperbolic volume

The hyperbolic volume of an ideal hyperbolic tetrahedron with dihedral angles $(\alpha, \beta, \gamma) \in (0, \pi)^3$ is given by the function vol :

$$\text{vol}(\alpha, \beta, \gamma) = L(\alpha) + L(\beta) + L(\gamma)$$

where L is the Lobachevsky function $L(x) = -\int_0^x \log |2 \sin t| dt$. The volume functional can be extended to the whole polytope $\mathcal{A}(T)$ by summing the volumes of the hyperbolic tetrahedra. The following result is due independently to Casson and Rivin.

► **Theorem 4** (Casson, Rivin[14]). *Let T be an ideal triangulation with n tetrahedra of M , an orientable 3-manifold with boundary consisting of tori. Then a point $p \in \mathcal{A}(T) \subset \mathbb{R}^{3n}$ corresponds to a complete hyperbolic metric on the interior of M if and only if p is a critical point of the function vol .*

Additionally, the volume functional is concave on $\mathcal{A}(T)$ and the maximum can be computed via convex optimization methods.

We can finally define CHS that represent combinatorially complete hyperbolic metrics:

► **Definition 5** (Complete Hyperbolic Structure). *A Complete Hyperbolic Structure (CHS) is a triangulation T equipped with an angle structure corresponding to the maximum of vol over $\mathcal{A}(T)$.*

► **Remark 6.** Angle structures are not CHS as they do not prevent shearing singularities, see Figure 2 (right), and consequently may represent *non-complete* hyperbolic metrics.

4 Behavior of the optimization

Exploiting the formalism of the previous section, one can design an algorithm [4] to find and compute a CHS by first finding a point in the polytope $\mathcal{A}(T)$, then computing a basis of the tangent space of $\mathcal{A}(T)$, and then maximizing the (concave) hyperbolic volume functional on this subspace. If $\mathcal{A}(T) \neq \emptyset$ and the procedure finds the point maximizing the volume in the inside of the polytope, then the triangulation admits a complete hyperbolic structure represented by this point. Finally, if $\mathcal{A}(T) \neq \emptyset$ but the maximum of the volume functional is on the boundary, then one needs to re-triangulate the manifold in order to search for a triangulation admitting a CHS.

In this section, we study the outcome of the hyperbolic volume maximization on the space of angle structures. The result is given by the following lemma, which also appeared independently in [12]:

► **Lemma 7.** *Let T be an ideal triangulation of M , a non-compact orientable 3-manifold with toric cusps. Let p be the point maximizing vol over $\overline{\mathcal{A}(T)}$ (the topological closure of $\mathcal{A}(T)$), then at p , if a tetrahedron has an angle equal to 0, then all other angles of the tetrahedron are in $\{0, \pi\}$.*

In other words, either the maximization succeeds on the interior of $\mathcal{A}(T)$, or there is at least one tetrahedron with angles $(0, 0, \pi)$ in p . Such tetrahedron is called *flat*. It is not possible to have a tetrahedron with angles $(0, a, b)$, $(a, b) \in (0, \pi)$ in p .

This lemma is proven by looking at the derivative of the volume around the boundary of $\mathcal{A}(T)$, see [9].

We introduce in the next section an algorithm that performs localized combinatorial modifications on a triangulation equipped with an angle structure, in order to get rid of flat tetrahedra.

5 Localized combinatorial modifications of triangulations

According to Lemma 7, the volume maximization either leads to a solution to the gluing equations, or to flat tetrahedra. In this section, we discuss a method to get rid of flat tetrahedra by combinatorial modifications of the triangulation, while attempting to maintain the value of the volume functional. This would lead to a triangulation admitting an angle structure with larger volume than the previous one, allowing to resume the maximization. In order to maintain the value of the volume functional, we introduce *geometric Pachner moves*.

5.1 Geometric Pachner moves

We perform Pachner moves on the triangulation that preserves the partial geometric data computed. More precisely, we define:

► **Definition 8** (Geometric Pachner move). *A geometric Pachner move in a triangulation T with angle structure is a Pachner move in T such that the resulting triangulation admits an angle structure with identical dihedral angles for the tetrahedra not involved in the move.*

To check if a geometric Pachner move can be done, it must be valid combinatorially, and it should be possible to assign dihedral angles to the new tetrahedra without altering the rest of the angle structure. The combinatorial conditions are simple [13]: for the 2-3 moves (resp. 3-2 move) in Figure 3, the tetrahedra sharing the common triangle BDC (resp. common edge AE) must be distinct. The conditions on the angle structures are given by the following lemma:

► **Lemma 9.** *Given a triangulation with angle structure T , if the combinatorial conditions given above are satisfied:*

- *a 3-2 move is always geometric;*
- *a 2-3 move is geometric if and only if the sum of the two dihedral angles around each edge of the common face is smaller than π .*

The idea to prove the lemma is to study the system of equations given by the assumption that the angle structure is not altered outside the move. Furthermore there are formulas to compute the new angles. The proofs of Lemma 9 and of this later claim are technical and can be found in [9].

► **Remark 10 (Non-conservation of the volume).** In Lemma 9, several angle structures are possible after the 2-3 move. Conversely, several angle structures lead to the same result for the 3-2 move. This is because angle structures are blind to shearing singularities, see Figure 2 (right). If such a singularity exists, a 3-2 move can still be performed while maintaining the whole angle structure, but it will decrease the hyperbolic volume of the structure. It is due to the fact that the singularity, which maximized the volume, is fixed in the process.

5.2 Getting rid of flat tetrahedra

Let T be a triangulation with an angle structure admitting a flat tetrahedron t , and (e, e') the associated edges with dihedral angle π . By Lemma 9, it is not possible to get rid of a tetrahedron with a geometric 2-3 move. Indeed, if an edge of t has a dihedral angle equal to π , the second tetrahedron concerned by the 2-3 move must have a dihedral angle equal to 0, and consequently a 2-3 move will produce a flat tetrahedron (see [9]).

In order to get rid of t , our strategy is to turn either e or e' into an edge of degree three, at the center of three tetrahedra on which a 3-2 move can be performed (central edge of Figure 3, right). Note that edges of degree 2 prevent the existence of an angle structure

■ **Figure 4** A sequence of moves getting rid of a flat tetrahedron. The bold vertical edge is contained in 4 tetrahedra, three of which are represented behind the edge. The fourth tetrahedron is implicit, situated at the front, and flat. First, create the red edge of the first drawing with a 2-3 move. Then delete the red edge of the second drawing with a 3-2 move.

as they force the two tetrahedra sharing the edge to be flat. As a consequence, we assume these configurations are removed, which can be done by `SnapPy`'s simplification for instance, see Section 6. Consequently, all edges have degree at least 3, and our strategy focuses on *reducing* the incidence degree of angle π edges.

To reduce the degree of an edge e , the strategy is to perform 2-3 moves on the tetrahedra containing e , such that each move reduces the degree of the edge by one. Either for topological (tetrahedron glued to itself) or geometrical reasons, these moves will not always be possible, and the order in which they are done matters. This is described in Figure 4.

► **Remark 11.** Doing a 2-3 move does not always reduce the degree of the edge, e.g., when a tetrahedron is represented several times around an edge. However, doing a move that does not decrease the degree of the edge may delete the multiple occurrences of a tetrahedron around the edge and allow to continue with the simplification.

► **Remark 12.** When a 2-3 move is performed around e , the value of the dihedral angle of the new tetrahedron around e is equal to the sum of the previous two dihedral angles around e . Since the sum of the dihedral angles of a tetrahedron is equal to π , this means successfully reducing the degree of e may unlock previously forbidden moves.

Recursive moves. If no geometric Pachner move is possible on an edge e , we attempt to reduce the degree of a nearby edge e_f , i.e., an edge for which there exists a tetrahedron containing e and e_f ; see Figure 5 where e_f is represented by the red dot, as it is seen from above. More precisely, let f be a triangle containing e such that the associated 2-3 move is forbidden for geometric reasons, then by Lemma 9 there is an edge e_f of f for which the associated dihedral angle is at least π .

In consequence, reducing the degree of e_f to three without modifying the tetrahedra containing f and then performing a 3-2 move at e_f will reduce the degree of e by one; see Figure 5.

Note that in case a geometric Pachner move is not possible on any pair of tetrahedra containing e_f either, we can call the procedure recursively in a neighborhood of e_f , using the argument above to pass from e to e_f .

► **Remark 13.** The choice of e_f in f is unique: it is not possible to have two dihedral angles larger than π ; selecting a move to reduce the degree of e boils down to selecting a triangle containing e .

■ **Figure 5** Sequences of moves to reduce the degree of an edge when no 2-3 move is available, seen from above (triangles represent sections of tetrahedra, edge section of triangles and dots section of edges, see Figure 2 (Right)). In all drawings, the gray rectangle represents the flat tetrahedron, e (light blue dot) is the edge of the flat tetrahedron of which we want to reduce the degree. Assuming no 2-3 move is available, we pick another edge e_f (red dot), if a 3-2 move can be performed on e_f , we are in case (B) and the 3-2 move reduces the degree of e (case (C)). Otherwise, we are in case (A) we need to create the red dashed tetrahedron by decreasing the degree of e_f , this can be done by calling recursively our procedure on e_f .

Procedure summary. The procedure to get rid of a flat tetrahedron is a tree-like *backtracking search*, each branch corresponding to a choice of 2-3 or 3-2 move to perform. The moves used are geometric to preserve the volume maximization advancement. A flat tetrahedron can only be deleted with a 3-2 move: the first step is to *reduce the degree* of one of its edges to three. To reduce the degree of an edge, the solution is to perform 2-3 moves on two tetrahedra containing this edge. If a 2-3 move is not possible for geometric reasons, we are in the situation of Figure 5, and the procedure to *reduce the degree* can be called *recursively* on a neighboring edge. Performing a 3-2 move on this latter edge resulting in a decrease of the degree of the initial one. The procedure ends when the initial edge has degree three and the flat tetrahedron can be removed or when no move can be applied.

5.3 Implementation details

The implementation faces several practical challenges.

Breaking infinite loops. As such, the algorithm may loop infinitely on some instance, as 2-3 and 3-2 moves may reverse themselves. To counteract this phenomenon and avoid redundant modifications, a solution is to store at each modification the *isomorphism signature* of the triangulation [2], characterizing uniquely the isomorphism type of the triangulation. This allows us to recognize already processed triangulations and break branches of the backtracking algorithms. Note however that this is costly compared to the Pachner moves, and it makes the procedure no longer local.

Selecting the edge e . When attempting to remove a flat tetrahedron, one needs to choose between the two π -angled edges e and e' to reduce. In our implementation, we consider both edges, and select the one that has the larger smallest angle in its link. This performs better than a random choice in our experiments.

Pruning the backtrack search. Some triangulations may have edges of large degree (more than 10), which produces wide search trees. Additionally, the recursive calls to the degree reduction procedure may induce trees of large depth. Experimentally, the better strategy consists of exploring exhaustively the first levels of the tree. We set the width of exploration to 8 and explore the first 2 levels of the search tree.

Sequencing of Pachner moves. Different sequencings of Pachner moves lead to different triangulations. In practice, we favor 2-3 moves over recursive ones, which performs best. Additionally, among the 2-3 moves performed to get rid of a flat tetrahedron containing edge e of angle π , we prioritize moves that eliminate tetrahedra for which e has a small dihedral angle. Among the recursive ones, we used the same method as the one choosing between e and e' , indeed choosing a recursive move boils down to choosing an edge to minimize its degree.

6 Experiments

In this section, we study the experimental performance of our approach¹ to find a triangulation with a CHS, and compare its behavior with the software `SnapPy` [3]. `SnapPy` is the state-of-the-art software to study the geometric properties of knots and 3-manifolds, and is widely used in the low-dimensional topology community. Following this analysis, we propose and study a hybrid method with practical interest.

SnapPy. `SnapPy`'s method is based on a random re-triangulation followed by a simplification. The first step is constituted of $4n$ random 2-3 moves, where n is the number of tetrahedra in the input triangulation. The simplification performs non-deterministic modifications to decrease the number of tetrahedra in the triangulation. Notably it removes some configurations that prevent angle structures from existing. The verification of the existence of a CHS is based on a Newton's method to solve the gluing equations [17].

Data set. We apply our algorithms to the census of prime hyperbolic knots with up to 19 crossings. This census has been constituted by the efforts of many researchers in the field, and recently completed with the exhaustive enumeration of all knots with crossing number smaller than 20^2 [1].

For each knot, given by a knot diagram, we compute a triangulation of the knot complement using `Regina` [2], and simplify it with `SnapPy`. We then keep the triangulations admitting an angle structure but not a CHS, and hence requiring re-triangulation. All the others, without angle structure or admitting a CHS, were discarded. They constitute the *Failure on first try* data of Table 1.

The knots are grouped by crossing numbers (from 14 to 19), and on whether they are alternating or not. In Section 6.1, our experiments are run on the first 2500 knots of each of the 12 groups having an angle structure but no CHS, and in Section 6.2 we use the first 10.000 knots of the same data sets.

6.1 Success rate and combinatorial performance

In terms of Pachner moves. Figure 6 (left) represents the rate of knots on which our algorithm succeeds to find a triangulation with a CHS, for all the 12 groups of knots. It represents the success rate as a function of the number of Pachner moves, the higher success rate groups are the alternating knots.

While there is a significant difference between the efficiency on alternating and non-alternating knots, all the curves have the same behavior: the first few Pachner moves are very effective. An important point is that, compared to the number of moves done by `SnapPy`,

¹ Our implementation uses the SLSQP [7] optimization method from SciPy [16].

² The census is available at <https://regina-normal.github.io/data.html>

■ **Figure 6** Left: on the sample of triangulations, success rate in finding a CHS against the number of Pachner moves for different crossing numbers and alternabilities. The limit rate of success for alternating knots is 0.98, the limit rate for non-alternating knots is 0.87. Right: Number of re-triangulations required by our method over the number of re-triangulations required by SnapPy on the 12 groups of knots, gathered in bins (the color indicates the log of the number of points inside). Since our method is deterministic, the points have discrete ordinates. The diagonal $x = y$ appears in red.

at least four times the number of tetrahedra and then roughly the same number for the simplification times the number of re-triangulation, our method uses a much lower number of Pachner moves on average (see Figure 6, left). This is of *combinatorial interest*, as doing a small number of moves can mitigate the impact of the procedure on the properties of the triangulation, such as keeping a small treewidth for instance.

After the first few steps, the growth of the success rate slows down drastically. An interpretation of this phenomenon is that the tetrahedra created by the 2-3 moves tend to be more flat than the original ones. This leads to an increase in the number of required re-triangulations and issues with floating point arithmetic.

In terms of re-triangulation. In order to compare the behaviors of our method and of the state of the art: we want to know if the two methods struggle on the same triangulations. Both methods using sequences of re-triangulations, we use the length of these sequences as metrics.

We compare in Figure 6 (right) the average number of randomized re-triangulations required by SnapPy to find a triangulation with a CHS, and the (deterministic) number of re-triangulations of our method. The majority of the CHS are found within few re-triangulations on average: both methods manage to find 78% of them within two steps.

However, it appears that for the manifolds requiring a large number of re-triangulations with either method, the other one will perform well on it: the performance of the methods are substantially orthogonal for the difficult cases. This phenomenon highlights the fact that the methods are *complementary*.

Limitations. It is to be noted that our method suffers from several phenomena: there are manifolds on which our method fails, the reasons to this being convergence problems because of the floating point arithmetic, the creation of flatter tetrahedra or the volume modification mentioned in Remark 10. Furthermore some triangulations have several very high degree edges and looking for the correct sequence of geometric Pachner moves can be costly. In terms of time performance, the constraint convex optimization is an important bottleneck, as well as the computation and book-keeping of a large number of isomorphism signatures.

However, in light of the previous results, we design a hybrid algorithm, mixing `SnapPy`'s pipeline together with the heuristics based on localized geometric Pachner moves introduced in this article, in order to outperform both methods in terms of experimental timings.

6.2 Hybrid algorithm and time performance

As is, `SnapPy` does not produce angle structures as defined in Section 3, as it constructs *negative tetrahedra*, i.e., tetrahedra whose shape has a negative imaginary part. Our hybrid method consists of calling `SnapPy` to randomize and simplify the triangulation, and, in case the triangulation admits only few negative tetrahedra (less than four in our experiments), call the resolution of flat tetrahedra with geometric Pachner moves on these negative tetrahedra, as introduced in Section 5. Loop until a CHS is found.

Our implementation is done in C directly in `SnapPy`'s kernel and consists of a simplified version of Section 5's method. For each negative tetrahedron, we try to reduce the degree of one of its edges down to 3 in turn using only geometric 2-3 moves, we try all the edges, and we do not use recursive moves or heuristics to perform the geometric moves.

The results of this method are summarized in Figure 7, where the time to compute the CHS are compared for the new hybrid method and the usual `SnapPy` pipeline, on the first 10.000 triangulations of the datasets of Section 6. The hybrid method using localized geometric Pachner moves shows, at worst, similar time performance compared to `SnapPy`, and performs significantly better overall. On average, the hybrid method is 20% faster, however, it is to be noted that, on most cases, few re-triangulations are required in which case the hybrid method and `SnapPy` show naturally similar time performance. More interestingly, on cases requiring many more re-triangulations in the `SnapPy` pipeline, the hybrid methods performs much better than `SnapPy`, with running times up to 18 times faster.

As indicator of the global behavior of both algorithms, we indicate the linear regression of the data points (purple dashed line, slope = 0.4) in Figure 7, to illustrate that the dense region is not concentrated on the $x = y$ diagonal.

■ **Figure 7** Left: time comparison of the hybrid method and `SnapPy` in seconds for the 10.000 first triangulations of each crossing number of the data set of the previous section, gathered in bins (the color indicates the log of the number of points inside). Line $x = y$ is plain and red, a linear regression through the data set is dashed and black. For readability, four outliers favoring the hybrid method are omitted. Right: distribution, in logarithmic scale, of the time required by `SnapPy` over the time required by the hybrid method.

Abstract

The *treedepth* of a graph G is the least possible depth of an *elimination forest* of G : a rooted forest on the same vertex set where every pair of vertices adjacent in G is bound by the ancestor/descendant relation. We propose an algorithm that given a graph G and an integer d , either finds an elimination forest of G of depth at most d or concludes that no such forest exists; thus the algorithm decides whether the treedepth of G is at most d . The running time is $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ and the space usage is polynomial in n . Further, by allowing randomization, the time and space complexities can be improved to $2^{\mathcal{O}(d^2)} \cdot n$ and $d^{\mathcal{O}(1)} \cdot n$, respectively. This improves upon the algorithm of Reidl et al. [ICALP 2014], which also has time complexity $2^{\mathcal{O}(d^2)} \cdot n$, but uses exponential space.

1 Introduction

An *elimination forest* of a graph G is a rooted forest F whose vertex set is the same as that of G , where for every edge uv of G , either u is an ancestor of v in F or vice versa. The *treedepth* of G is the least possible depth of an elimination forest of G . Compared to the better-known parameter *treewidth*, treedepth measures the depth of a tree-like decomposition of a graph, instead of width. The two parameters are related: if by $\text{td}(G)$ and $\text{tw}(G)$ we denote the treedepth and the treewidth of an n -vertex graph G , then it always holds that $\text{tw}(G) \leq \text{td}(G) \leq \text{tw}(G) \cdot \log_2 n$ (Section 6.4 of [16]). However, the two notions are qualitatively different: for instance, a path on t vertices has treewidth 1 and treedepth $\Theta(\log t)$.

Treedepth appears prominently in structural graph theory, especially in the theory of sparse graphs of Nešetřil and Ossona de Mendez. There, it serves as a basic building block for fundamental decompositions of sparse graphs – *low treedepth colorings* – which can

be used for multiple algorithmic purposes, including designing algorithms for SUBGRAPH ISOMORPHISM and model-checking First-Order logic. See [16, Chapters 6 and 7] for an introduction and [8, 9, 15, 17, 18, 19, 21, 20] for examples of applications.

In this work we are interested in using treedepth as a parameter for the design of fixed-parameter (FPT) algorithms. Clearly, every dynamic programming algorithm working on a tree decomposition of a graph can be adjusted to work also on an elimination forest, just because an elimination forest of depth d can be easily transformed into a tree decomposition of width $d - 1$. However, it has been observed in [7, 22, 10, 14, 20] that for multiple basic problems, one can design FPT algorithms working on elimination forests of bounded depth that have polynomial space complexity without sacrificing on the time complexity. These include the following: (In all results below, n is the vertex count and d is the depth of the given elimination forest.)

- A $3^d \cdot n^{\mathcal{O}(1)}$ -time $\mathcal{O}(d + \log n)$ -space algorithm for 3-COLORING [22].
- A $2^d \cdot n^{\mathcal{O}(1)}$ -time $n^{\mathcal{O}(1)}$ -space algorithm for counting perfect matchings [7].
- A $3^d \cdot n^{\mathcal{O}(1)}$ -time $n^{\mathcal{O}(1)}$ -space algorithm for DOMINATING SET [7, 22].
- A $d^{|V(H)|} \cdot n^{\mathcal{O}(1)}$ -time $n^{\mathcal{O}(1)}$ -space algorithm for SUBGRAPH ISOMORPHISM [20].
(Here, H is the sought pattern graph.)
- A $3^d \cdot n^{\mathcal{O}(1)}$ -time $n^{\mathcal{O}(1)}$ -space algorithm for CONNECTED VERTEX COVER [10].
- A $5^d \cdot n^{\mathcal{O}(1)}$ -time $n^{\mathcal{O}(1)}$ -space algorithm for HAMILTONIAN CYCLE [14].

We note that the approach used in [10, 14] to obtain the last two results applies also to several other problems with connectivity constraints. However, as these algorithms are based on the Cut&Count technique [4], they are randomized and no derandomization preserving the polynomial space complexity is known. An in-depth complexity-theoretical analysis of the time-space tradeoffs for algorithms working on different graph decompositions can be found in [22].

In the algorithms mentioned above one assumes that the input graph is supplied with an elimination depth of depth at most d . Therefore, it is imperative to design algorithms that given the graph alone, computes, possibly approximately, such an elimination forest. Compared to the setting of treewidth and tree decompositions, where multiple approaches have been proposed over the years (see e.g. [2, 11] for an overview), so far there is only a handful of algorithms to compute the treedepth exactly or approximately.

- It is well-known (see e.g. [16, Section 6.2]) that just running depth-first search and outputting the forest of recursive calls gives an elimination forest of depth at most $2^{\text{td}(G)}$. So this gives a very simple linear-time approximation algorithm, but with the approximation factor exponential in the optimum.
- Czerwiński et al. [5] gave a polynomial-time algorithm that outputs an elimination forest of depth at most $\mathcal{O}(\text{td}(G)\text{tw}(G) \log^{3/2} \text{tw}(G))$, which is thus an $\mathcal{O}(\text{tw}(G) \log^{3/2} \text{tw}(G))$ -approximation algorithm.
- Reidl et al. [23] gave an exact FPT algorithm that in time $2^{\mathcal{O}(d \cdot \text{tw}(G))} \cdot n$ either constructs an elimination forest of depth at most d , or concludes that the treedepth is larger than d .
- There is a naive algorithm computing treedepth directly from its definition that works in $\mathcal{O}(n^{\text{td}(G)})$ time and uses polynomial space.
- Using a tradeoff that runs either of the last two approaches, depending on whether d is greater than $\sqrt{\epsilon \cdot \log n}$ or not, for any fixed $\epsilon > 0$, one can obtain an algorithm running in time $2^{\mathcal{O}(\frac{d^3}{\epsilon})} + \mathcal{O}(n^{1+\epsilon})$ and using polynomial space.

Recall here that $\text{tw}(G) \leq \text{td}(G)$, hence when parameterized by treedepth only, the mentioned results can be seen as an $\mathcal{O}(\text{td}(G) \log^{3/2} \text{td}(G))$ -approximation in polynomial time, as well as an exact FPT algorithm with running time $2^{\mathcal{O}(d^2)} \cdot n$. In particular, obtaining a constant-factor

approximation for treedepth running in time $2^{\mathcal{O}(\text{td}(G))} \cdot n^{\mathcal{O}(1)}$ is a well-known open problem, see e.g. [5]. We note that implementation of practical FPT algorithms for computing treedepth was the topic of the 2020 Parameterized Algorithms and Computational Experiments (PACE) Challenge [12].

Our contribution. The exact algorithm of Reidl et al. [23] uses not only exponential time (in the treedepth), but also exponential space. This would make it a space bottleneck when applied in combination with any of the polynomial-space algorithms developed in [7, 22, 10, 14, 20]. The mentioned tradeoff trick brings back the polynomial space, but significantly deteriorates the running time both in terms of the factor exponential in d and the one polynomial in n . In this work we bridge these issues by proving the following result.

► **Theorem 1.** *There is an algorithm that given an n -vertex graph G and an integer d , either constructs an elimination forest of G of depth at most d , or concludes that the treedepth of G is larger than d . The algorithm runs in $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ time and uses $n^{\mathcal{O}(1)}$ space.*

The space and time complexities can be improved to $d^{\mathcal{O}(1)} \cdot n$ and expected $2^{\mathcal{O}(d^2)} \cdot n$, respectively, at the cost of allowing randomization: the algorithm may return a false negative with probability at most $\frac{1}{c \cdot n^c}$, where c is any constant fixed a priori; there are no false positives.

Thus, the randomized variant of the algorithm of Theorem 1 has the same time complexity as the algorithm of Reidl et al. [23], but uses polynomial space. However, the algorithm of Reidl et al. [23] is deterministic, contrary to ours. Note that apart from possible false negatives, the bound on the running time is only in expectation and not worst-case (in other words, our algorithm is both Monte Carlo and Las Vegas). However, one can turn this into a worst-case bound at the cost of increasing the probability of false negatives to $1/2$ by forcefully terminating the execution if the algorithm runs for twice as long as expected.

Simultaneously achieving time complexity linear in n and polynomial space complexity is a property that is desired from an algorithm for computing the treedepth of a graph. While many of the polynomial-space FPT algorithms working on elimination forests do not have time complexity linear in n due to the usage of various algebraic techniques, the simplest ones that exploit only recursion – like the ones for 3-COLORING or INDEPENDENT SET considered in [22] – can be easily implemented to run in time $2^{\mathcal{O}(d)} \cdot n$ and space $d^{\mathcal{O}(1)} \cdot n$. Thus, the randomized variant of the algorithm of Theorem 1 would neither be a bottleneck from the point of view of space complexity nor from the point of view of the dependency of the running time on n . Admittedly, the parametric factor in the runtime of our algorithm is $2^{\mathcal{O}(d^2)}$, as compared to $2^{\mathcal{O}(d)}$ in most of the aforementioned polynomial-space FPT algorithms working on elimination forests; this brings us back to the open problem about constant-factor approximation for treedepth running in time $2^{\mathcal{O}(\text{td}(G))} \cdot n^{\mathcal{O}(1)}$ raised in [5].

Let us briefly discuss the techniques behind the proof of Theorem 1. The algorithm of Reidl et al. [23] starts by approximating the treewidth of the graph (which is upper bounded by the treedepth) and tries to construct an elimination forest of depth at most d by bottom-up dynamic programming on the obtained tree decomposition. By applying the iterative compression technique, we may instead assume that we are supplied with an elimination forest of depth at most $d + 1$, and the task is to construct one of depth at most d .

Applying now the approach of Reidl et al. [23] directly (that is, after a suitable adjustment from the setting of tree decompositions to the setting of elimination forests) would not give an algorithm with polynomial space complexity. The reason is that their dynamic programming procedure is quite involved and in particular keeps track of certain disjointness conditions; this is a feature that is notoriously difficult to achieve using only polynomial space. Therefore,

we resort to the technique of *inclusion-exclusion branching*, used in previous polynomial-space algorithms working on elimination forests; see [7, 22] for basic applications of this approach. In a nutshell, the idea is to count more general objects where the disjointness constraints are relaxed, and to use inclusion-exclusion at each step of the computation to make sure that objects not satisfying the constraints eventually cancel out. We note that while the application of inclusion-exclusion branching was rather simple in [7, 22], in our case it poses a considerable technical challenge. In particular, along the way we do not count single values, but rather polynomials with one formal variable that keeps track of how much the disjointness constraints are violated. In the exposition layer, our application of inclusion-exclusion branching mostly follows the algorithm for DOMINATING SET of Pilipeczuk and Wrochna [22].

In this way, we can count the number of elimination forests¹ of depth at most d in time $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ and using polynomial space. So in particular, we can decide whether there exists at least one such elimination forest. Such a decision algorithm can be quite easily turned into a construction algorithm using self-reducibility of the problem. This establishes the first part of Theorem 1.

As for the second part – the randomized linear-time FPT algorithm using polynomial space – there are several obstacles that need to be overcome. First, there is a multiplicative factor n in the running time coming from the iterative compression scheme. We mitigate this issue by replacing iterative compression with the recursive contraction scheme used by Bodlaender in his linear-time FPT algorithm to compute the treewidth of a graph [1]. Second, when using self-reducibility, we may apply the decision procedure n times, each taking at least linear time. This is replaced by an approach based on color coding, whose correctness relies on the fact that in a connected graph of treedepth at most d there are at most $d^{\mathcal{O}(d)}$ different feasible candidates for the root of an optimum-depth elimination tree [3]. Finally, in the counting procedure we may operate on numbers of bitsize as large as polynomial in n . This is resolved by hashing them modulo a random prime of magnitude $\Theta(\log n)$, so that we may assume that arithmetic operations take unit time.

We remark that it is relatively rare that a polynomial-space algorithm based on algebraic techniques can be also implemented so that it runs in time linear in the input size. Therefore, we find it interesting and somewhat surprising that this can be achieved for the problem of computing the treedepth of a graph, which combinatorially is rather involved.

Organization. After brief preliminaries in Section 2, in Section 3 we prove the first part of Theorem 1: we give a deterministic algorithm that runs in time $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ time and uses polynomial space. Then, in Section 4 we improve the time and space complexities to $2^{\mathcal{O}(d^2)}n$ and $d^{\mathcal{O}(1)}n$ respectively, at the cost of introducing randomization. The proofs of the results marked \star are deferred to the full version of the work due to the space constraints.

2 Preliminaries

Standard notation. All graphs in this paper are finite, undirected, and simple (i.e. with no loops on vertices or multiple edges with the same endpoints). For a graph G and a vertex subset $A \subseteq V(G)$, by $N_G[A]$ we denote the *closed neighborhood* of A : the set consisting of all vertices that are in A or have a neighbor in A .

¹ Formally, we count only elimination forests satisfying some basic connectivity property, which we call *sensibility*.

For a function $f: A \rightarrow B$ and a subset of the domain $X \subseteq A$, by $f(X)$ we denote the image of f on X . The image of f is denoted $\text{im}(f) = f(A)$. For an element e outside of the domain and a value α , by $f[e \rightarrow \alpha]$ we denote the extension of f obtained by additionally mapping e to α .

We denote the set $\{1, 2, \dots, k\}$ as $[k]$. We assume the standard word RAM model of computation with words of length $\log n$, where n is the vertex count of the input graph.

(Elimination) forests and treedepth. Consider a rooted forest F . By Anc_F we denote the ancestor/descendant relation in F : for $u, v \in V(F)$, $\text{Anc}_F(u, v)$ holds if and only if u is an ancestor of v or v is an ancestor of u in F . We assume that a vertex is an ancestor of itself, so in particular $\text{Anc}_F(u, u)$ is always true. We also use the following notation. For $u \in V(F)$, by $\text{tail}_F[u]$ we denote the set of all ancestors of u (including u) and by $\text{tree}_F[u]$ we denote the set of all descendants of u , including u . Further, let $\text{tail}_F(u) = \text{tail}_F[u] - \{u\}$, $\text{tree}_F(u) = \text{tree}_F[u] - \{u\}$, and $\text{comp}_F[u] = \text{tail}_F[u] \cup \text{tree}_F[u]$. Note that $v \in \text{comp}_F[u]$ if and only if $\text{Anc}_F(u, v)$ holds. By $\text{chld}_F(u)$ we denote the set of children of u in F , and by $\text{depth}_F(u)$ we denote the depth of u in F , that is, $\text{depth}_F(u) = |\text{tail}_F[u]|$ (in particular, roots have depth one). The *depth* of a rooted forest F is the maximum depth_F among its vertices. For a set of vertices $A \subseteq V(F)$, by $\text{cl}_F(A) = \bigcup_{u \in A} \text{tail}_F[u]$ we denote the ancestor closure of A . A *prefix* of a rooted forest F is a rooted forest induced by some ancestor-closed set $A \subseteq V(F)$; that is, it is the forest on A with the parent-child relation inherited from F .

In this paper we are mostly interested in the notion of an elimination forest and of the treedepth of a graph.

► **Definition 2.** An elimination forest of a graph G is a rooted forest F on the same set of vertices as G such that for every edge $uv \in E(G)$, we have that $\text{Anc}_F(u, v)$ holds. The treedepth of a graph G is the least possible depth of an elimination forest of G .

Note that an elimination forest of a connected graph must be connected as well, so in this case we may speak about an *elimination tree* (however, elimination forest of a disconnected graph could be a tree as well). Sometimes, instead of identifying $V(G)$ and $V(F)$, we treat them as disjoint sets and additionally provide a bijective mapping $\phi: V(G) \rightarrow V(F)$ such that $uv \in E(G)$ entails $\text{Anc}_F(\phi(u), \phi(v))$. In such case we consider the pair (F, ϕ) to be an elimination forest of G . This will be always clear from the context. More generally, for $B \subseteq V(G)$ and a rooted forest F , we shall say that a mapping $\phi: B \rightarrow V(F)$ respects edges if $uv \in E(G)$ entails $\text{Anc}_F(\phi(u), \phi(v))$ for all $u, v \in B$. In this notation, (F, ϕ) is an elimination forest of G if and only if ϕ is a bijection from $V(G)$ to $V(F)$ that respects edges on $V(G)$.

3 Deterministic FPT algorithm

In this section we prove the first part of Theorem 1: we give a deterministic polynomial-space algorithm with running time $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ that for a given n -vertex graph G , either outputs an elimination forest of G of depth at most d or concludes that no such forest exists. The most complex part of the algorithm will be procedure `CountElimTrees`, which, roughly speaking, counts the number of different elimination trees of a connected graph G of depth at most d . We describe `CountElimTrees` first, and then we utilize it to achieve the main result.

3.1 Description of `CountElimTrees`

As mentioned above, procedure `CountElimTrees` counts the number of different elimination trees of G of depth at most d . However, we will not count all of them, but only such that are in some sense minimal; a precise formulation will follow later. We remark that this part is

inspired by the $3^d \cdot n^{\mathcal{O}(1)}$ -time polynomial space algorithm of Pilipczuk and Wrochna [22] for counting dominating sets in a graph of bounded treedepth. This algorithm exploits the same underlying trick – sometimes dubbed “inclusion-exclusion branching” – but the application here is technically more involved than in [22].

Before describing `CountElimTrees`, let us carefully define objects that we are going to count. We start by recalling the following standard fact about the existence of elimination forests with basic connectivity properties.

► **Lemma 3 (★)**. *Let H be a graph and let R be an elimination forest of H . Then there exists an elimination forest R' of H such that*

- *for every vertex u of H , we have $\text{depth}_{R'}(u) \leq \text{depth}_R(u)$; and*
- *whenever vertices $u, v \in V(H)$ belong to the same connected component of R' , they also belong to the same connected component of H .*

We remark that computing R' can be easily done in linear time by using depth-first search from the root of each elimination tree in R . This procedure will be used many times throughout the algorithm when justifying the usual assumption that our current graph is connected. (Disconnected graphs will often naturally appear when recursing after performing some deletions in the original graph.)

The following lemma can be proved using a very similar, though a bit more involved reasoning. We will work with a fixed connected graph G and its elimination tree T .

► **Lemma 4 (★)**. *Let G be a connected graph of treedepth at most d and T be an elimination tree of G (possibly of depth larger than d). Then there exists an elimination tree R of G of depth at most d that satisfies the following property: for every $u \in V(G)$ and $v_1, v_2 \in \text{chld}_T(u)$, $v_1 \neq v_2$, we have*

$$\text{cl}_R(\text{comp}_T[v_1]) \cap \text{cl}_R(\text{comp}_T[v_2]) = \text{cl}_R(\text{tail}_T[u]). \quad (1)$$

An elimination tree R of a graph G satisfying the conclusion of Lemma 4 (that is, the depth of R is at most d and for all $u \in V(G)$ and distinct $v_1, v_2 \in \text{chld}_T(u)$ we have (1)) will be called *sensible* with respect to T . In our search for elimination trees of low depth, we will restrict attention only to trees that are sensible with respect to some fixed elimination tree T . Then Lemma 4 justifies that we may do this without losing all solutions.

With all ingredients introduced, we may finally precisely state the goal of this section.

► **Lemma 5**. *There exists an algorithm `CountElimTrees`(G, T, d) that, given a connected graph G on n vertices, an elimination tree T of depth k , and an integer d , runs in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$, uses $n^{\mathcal{O}(1)}$ space, and outputs the number of different elimination trees of G of depth at most d that are sensible with respect to T .*

Note here that the input to `CountElimTrees` consists not only of G and d , but also of an auxiliary elimination tree T of G . The depth k of T may be, and typically will be, larger than d . Also, we assume that an elimination tree is represented solely by its vertex set and the ancestor relation. In particular, permuting children of a vertex yields the *same* elimination tree, which should be counted as the same object by procedure `CountElimTrees`.

The remainder of this section is devoted to the proof of Lemma 5. We first need to introduce some definition.

Let us arbitrarily enumerate the vertices of G as v_1, v_2, \dots, v_n in a top-down manner in T . That is, whenever v_i is an ancestor of v_j , we have $i \leq j$. Consider another rooted tree R and a mapping $\phi: V(T) \rightarrow V(R)$. For a vertex u of T , we call a vertex $v_i \in \text{tree}_T(u)$ a *proper surplus image* (for u and (R, ϕ)) if at least one of the following conditions holds:

- (i) $\phi(v_i) \in \text{cl}_R(\phi(\text{tail}_T[u]))$, or
- (ii) there exists j such that $j < i$, $v_j \in \text{tree}_T(u)$, and $\phi(v_j) = \phi(v_i)$.

We define *non-proper surplus images* analogously, but using sets $\text{tail}_T(u)$ and $\text{tree}_T[u]$ instead of $\text{tail}_T[u]$ and $\text{tree}_T(u)$, respectively.

We will work in the ring of polynomials $\mathbb{Z}[x]$, where x is a formal variable. By an abuse of notation, we equip this ring with an operation of division by x defined through equations:

$$\frac{x^i}{x} = \begin{cases} x^{i-1} & \text{if } i \geq 1, \\ 0 & \text{if } i = 0 \end{cases}$$

$$\frac{\alpha A + \beta B}{x} = \alpha \cdot \frac{A}{x} + \beta \cdot \frac{B}{x} \quad \text{for all } A, B \in \mathbb{Z}[x] \text{ and } \alpha, \beta \in \mathbb{Z}.$$

Formally speaking, division by x is just the unique function from $\mathbb{Z}[x]$ to $\mathbb{Z}[x]$ satisfying the two properties above.

Even though our final goal is to count the number of elimination trees, along the way we are going to count more general objects, called *generalized elimination trees*. A generalized elimination tree of a graph H is a rooted tree R along with a mapping $\phi: V(H) \rightarrow V(R)$ such that ϕ respects edges. Note that in particular, it may be the case that $\text{im}(\phi) \subsetneq V(R)$ or that $\phi(u) = \phi(v)$ for some $u, v \in V(H)$. Clearly, a generalized elimination tree is an elimination tree in the usual sense if and only if ϕ is a bijection between $V(H)$ and $V(R)$. We shall call two generalized elimination trees (R, ϕ) and (R', ϕ') *isomorphic* if there is an isomorphism of rooted trees ψ mapping R to R' such that $\phi' = \psi \circ \phi$.

A generalized elimination tree (R, ϕ) of an induced subgraph H of G is *sensible* for T if for every $u \in V(H)$ and distinct $v_1, v_2 \in \text{chld}_T(u) \cap V(H)$, we have $\text{cl}_R(\phi(\text{comp}_T[v_1])) \cap \text{cl}_R(\phi(\text{comp}_T[v_2])) = \text{cl}_R(\phi(\text{tail}_T[u]))$. Thus, this notion projects to sensibility of (standard) elimination trees when $H = G$ and (R, ϕ) is an elimination tree of G . Generalized elimination trees of induced subgraphs of G that are sensible for T shall be called *monsters*.

For a rooted tree K , a mapping ϕ with co-domain $V(K)$ is called a *cover* of K if $\text{cl}_K(\text{im}(\phi)) = V(K)$, or equivalently, every leaf of K is in the image of ϕ . For a vertex $u \in V(G)$, rooted tree K of depth at most d , a subset of vertices $A \subseteq V(K)$ that contains all leaves of K , and a mapping $\phi: \text{tail}_T(u) \rightarrow A$ that is a cover of K , we define

$$f(u, K, \phi, A) = \sum_{i=0}^n a_i x^i \in \mathbb{Z}[x],$$

where a_i is the number of non-isomorphic monsters $(R, \bar{\phi})$ such that:

- (i) $(R, \bar{\phi})$ is a generalized elimination tree of $G[\text{comp}_T[u]]$ of depth at most d ;
- (ii) K is a prefix of R ;
- (iii) $\bar{\phi}$ is an extension of ϕ satisfying

$$V(R) - V(K) \subseteq \text{im}(\bar{\phi}) \subseteq (V(R) - V(K)) \cup A; \quad \text{and}$$

- (iv) in $\text{tree}_T[u]$ there are exactly i non-proper surplus images for u and $(R, \bar{\phi})$.

Note that since ϕ is assumed to be a cover of K , and by the second and third condition, the last condition can be rephrased as follows:

$$i = |\text{tree}_T[u]| - |V(R) - V(K)|.$$

We define polynomial $g(u, K, \phi, L)$ analogously, but using $\text{tail}_T[u]$, $\text{tree}_T(u)$, and proper surplus images, instead of $\text{tail}_T(u)$, $\text{tree}_T[u]$ and non-proper surplus images. That in $\text{tree}_T(u)$ there are i proper surplus images is then equivalent to $i = |\text{tree}_T(u)| - |V(R) - V(K)|$.

Informally, f and g count partial solutions on subgraphs induced on subtrees of T , where in g we exclude the root u of the subtree. Values of g are computed by combining results of f from separate subtrees rooted at the children u into the result for the forest representing their union. Values of f are computed from the values of g by including a new vertex u that connects that forest into one tree.

Our goal now is to compute the polynomials $f(\cdot, \cdot, \cdot, \cdot)$ and $g(\cdot, \cdot, \cdot, \cdot)$ recursively over the elimination tree T . It can be easily seen that if $\text{chld}_T(u) = \emptyset$ then

$$g(u, K, \phi, A) = \begin{cases} 1 & \text{if } \phi \text{ respects edges,} \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Indeed, $(R, \bar{\phi}) = (K, \phi)$ is the only possible pair that can satisfy the last three conditions, and it is a sensible generalized elimination tree of $G[\text{comp}_T[u]]$ if and only if ϕ respects edges.

First, we show how to compute polynomials $g(u, \cdot, \cdot, \cdot)$ based on the knowledge of polynomials $f(v, \cdot, \cdot, \cdot)$ for children v of u .

► **Lemma 6 (★).** *If $\text{chld}_T(u) \neq \emptyset$, then for all relevant u, K, ϕ, A we have*

$$g(u, K, \phi, A) = \prod_{v \in \text{chld}_T(u)} f(v, K, \phi, A)$$

The detailed proof of this Lemma can be found in the full version, however a short justification is that monsters counted in the definition of $g(u, K, \Phi, A)$ can be expressed in a product structure of monsters counted in the definitions of $f(v_i, K, \Phi, A)$, where $\text{chld}_T(u) = \{v_1, \dots, v_c\}$.

Let us elaborate on the intuition on what happened in Lemma 4. Intuitively, we aggregated information about the children of u to the information about u itself. Since in the definitions of monsters we do not insist on the mappings being injective, this aggregation could have been performed by a simple product of polynomials (though, the assumption of sensibility was crucial for arguing the correctness). In a natural dynamic programming, such as the one in [23], one would need to ensure injectivity when aggregating information from the children of u , which would result in a dynamic programming procedure that would need to keep track of all subsets of K (and thus use exponential space). Thus, relaxing injectivity here allows us to use simple multiplication of polynomials, but obviously we will eventually need to enforce injectivity. The idea is that we enforce surjectivity instead, and make sure that the size of the co-domain matches the size of the domain. In turn, surjectivity is enforced using inclusion-exclusion in the computation of polynomials $f(u, \cdot, \cdot, \cdot)$ based on polynomials $g(u, \cdot, \cdot, \cdot)$, which is the subject of the next lemma. Ensuring that the size of the co-domain matches the size of the domain is done through maintaining the number of surplus images. The intuition behind their somewhat intricate definition is the following. We want to maintain the difference between (i) the number of vertices we have already processed and forgotten about, and (ii) the number of forgotten vertices in a monster that we introduced in order to accommodate the vertices (i). Vertices contributing to this difference are exactly the vertices that have been mapped to forgotten vertices of a monster that have already been “taken” or that have not been forgotten yet; this corresponds to the definition of surplus images. We know that if multiple vertices were mapped to the same vertex of a partial monster, then this partial monster will not become a valid treedepth decomposition. We do not have a way of discovering this immediately (as we cannot keep track of any disjointness conditions), but extensions of such partial monsters will not be counted in the final result. The reason for that is that either the sizes of the co-domains will not match the sizes of the domains, or they will cancel out in the exclusion-inclusion computation due to not being surjective.

► **Lemma 7 (★).** *For all relevant u, K, ϕ, A , we have:*

$$f(u, K, \phi, A) = \sum_{v \in A} x \cdot g(u, K, \phi[u \rightarrow v], A) + \sum_{w \in K} \sum_{p=1}^{d-\text{depth}(w)} \frac{1}{x^{p-1}} \sum_{B \subseteq \{w_1, \dots, w_{p-1}\}} (-1)^{p-1-|B|} g(u, K[w, w_1, \dots, w_p], \phi[u \rightarrow w_p], A \cup B \cup \{w_p\}),$$

where $K[w, w_1, \dots, w_p]$ denotes the rooted tree obtained from K by adding a path $[w, w_1, \dots, w_p]$ so that w is the parent of w_1 and each w_i is the parent of w_{i+1} , for $i \in \{1, \dots, p-1\}$.

We need to take an additional care of how to deduce the overall number of elimination trees based on the polynomial $f(\cdot, \cdot, \cdot, \cdot)$ and $g(\cdot, \cdot, \cdot, \cdot)$. Define polynomial

$$h = \sum_{p=1}^d \frac{1}{x^{p-1}} \sum_{B \subseteq \{w_1, \dots, w_{p-1}\}} (-1)^{p-1-|B|} g(r, [w_1, \dots, w_p], [r \rightarrow w_p], B \cup \{w_p\}) \in \mathbb{Z}[x],$$

where r is the root of T , $[w_1, \dots, w_p]$ is a path on p vertices rooted at w_1 , and $[r \rightarrow w_p]$ denotes the function with domain $\{r\}$ that maps r to w_p .

► **Lemma 8.** *The number of elimination trees of G that are sensible with respect to T and have depth at most d is the term in h standing by x^0 .*

Proof. By Lemma 7, the formula can be seen as the formula for $f(r, K, \phi, A)$ for empty K , ϕ , and A . Therefore, h can be written as $h = \sum_{i=0}^n a_i x^i$, where a_i is the number of non-isomorphic sensible generalized elimination trees $(R, \bar{\phi})$ such that R has depth at most d , $\bar{\phi}: V(G) \rightarrow V(R)$ is surjective, and in G there are i non-proper surplus images for r and $(R, \bar{\phi})$. However, since K is empty, the number of surplus images is exactly the number of vertices $v_j \in V(G)$ that are mapped by $\bar{\phi}$ to the same vertex of R as some other vertex of G with a smaller index. Then the assertion that $\bar{\phi}$ is injective is equivalent to the assertion that the number of such surplus images is 0. It follows that the number of non-isomorphic sensible elimination trees of G of depth at most d is equal to the term in h that stands by x^0 . ◀

Having established Lemmas 6, 7 and 8, we can conclude the description of procedure `CountElimTrees`. By 8, the goal is to compute polynomial h and return the coefficient standing by x^0 . We initiate the computation using the formula for h , and then we use two mutually-recursive procedures to compute polynomials $f(\cdot, \cdot, \cdot, \cdot)$ and $g(\cdot, \cdot, \cdot, \cdot)$ using formulas provided by Lemmas 6 and 7. The base case of recursion is for a leaf of T , where we use formula (2).

The correctness of the procedure is established by Lemmas 6, 7 and 8. So it remains to bound its time complexity and memory usage. It is clear that polynomials that we compute will always have degrees at most n . Trees K relevant in the computation will never have more than dk vertices, for at every recursive call the tree K can grow by at most d new vertices.

As the next step, we bound the numbers that can be present in the computations.

► **Lemma 9 (★).** *Every coefficient of $f(u, K, \phi, A)$ is an integer from the range $[0, (dk \cdot 2^d)^{|\text{tree}_T(u)|}]$ and every coefficient of $g(u, K, \phi, A)$ is an integer from the range $[0, (dk \cdot 2^d)^{|\text{tree}_T(u)|}]$. Hence, all integers present in the computations are at most $(dk2^d)^n$.*

79:10 Computing Treedepth in Polynomial Space and Linear FPT Time

It follows that all integers present in the computation have bitsize bounded polynomially in n .

As for the memory usage, the run of the algorithm is a recursion of depth bounded by $2k$. The memory used is a stack of at most $2k$ frames for recursive calls of procedures computing polynomials $f(\cdot, \cdot, \cdot, \cdot)$ and $g(\cdot, \cdot, \cdot, \cdot)$ for relevant arguments. Each of these frames requires space polynomial in n , hence the total space complexity is polynomial in n .

As for the time complexity, each call to a procedure computing a polynomial of the form $f(u, \cdot, \cdot, \cdot)$ makes at most $dk \cdot 2^d$ recursive calls to procedures computing polynomials of the form $g(u, \cdot, \cdot, \cdot)$. In turn, each of these calls makes one call to a procedure computing a polynomial of the form $f(v, \cdot, \cdot, \cdot)$ for each child v of u . It follows that the total number of calls to procedures computing polynomials of the form $f(u, \cdot, \cdot, \cdot)$ and $g(u, \cdot, \cdot, \cdot)$ is bounded by $2 \cdot (dk \cdot 2^d)^k = 2^{\mathcal{O}(dk)}$. The internal work needed in each recursive call is bounded by $2^{\mathcal{O}(d)} \cdot n^{\mathcal{O}(1)}$. As T has n vertices, the total time complexity is $2^{\mathcal{O}(dk)} \cdot 2^{\mathcal{O}(d)} \cdot n^{\mathcal{O}(1)} \cdot n = 2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$, as claimed. This concludes the proof of Lemma 5.

We note that having designed $\text{CountElimTrees}(G, T, d)$, it is easy to design a similar function $\text{CountElimForest}(G, T, d)$ that does not need an assumption of G being connected and where T is some elimination forest instead of an elimination tree (by using the procedure described after Lemma 3).

3.2 Utilizing CountElimTrees

With the description of CountElimTrees completed, we can describe how we can utilize it in order to construct a bounded-depth elimination tree of a graph. That is, we prove the first part of Theorem 1.

First, we lift CountElimTrees to a constructive procedure that still requires to be provided an auxiliary elimination tree of the graph.

► **Lemma 10.** *There is an algorithm $\text{ConstructElimForest}(G, T, d)$ that, given an n -vertex graph G , an elimination forest T of G of depth at most k , and an integer d , runs in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$, uses $n^{\mathcal{O}(1)}$ space, and either correctly concludes that $\text{td}(G) > d$ or returns an elimination forest of G of depth at most d .*

Proof. By treating every connected component separately, we may assume that G is connected (see the remark after Lemma 3). Thus T is an elimination tree of G .

The first step of $\text{ConstructElimForest}(G, T, d)$ is calling $\text{CountElimTrees}(G, T, d)$. If this call returns 0, we terminate $\text{ConstructElimForest}$ and report that $\text{td}(G) > d$; this is correct by Lemma 4. Otherwise we are sure that $\text{td}(G) \leq d$, and we need to construct any elimination tree of depth at most d . In order to do so, we check, for every vertex $v \in V(G)$, whether v is a feasible candidate for the root of desired elimination tree. Note that a vertex v can be the root of an elimination tree of G of depth at most d if and only if $\text{td}(G - v) < d$, or equivalently, if and only if the procedure $\text{CountElimForest}(G - v, T - v, d - 1)$ returns a positive value. (Here, by $T - v$ we mean the forest T with v removed and all former children of v made into children of the parent of v , or to roots in case v was a root.) As $\text{td}(G) \leq d$, we know that for at least one vertex v , this check will return a positive outcome. Then we recursively call $\text{ConstructElimForest}(G - v, T - v, d - 1)$, thus obtaining an elimination forest F' of $G - v$ of depth at most $d - 1$, and we turn it into an elimination tree F of G by adding v as the new root and making it the parent of all the roots of F' . As F has depth at most d , it can be returned as the result of the procedure.

That the procedure is correct is clear. As for the time and space complexity, it is easy to see that there will be at most dn calls to the procedure `CountElimTrees` in total, because at each level of the recursion there will be at most one invocation of `CountElimTrees` per vertex of the original graph. As each of these calls uses $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ time and $n^{\mathcal{O}(1)}$ space, the same complexity bounds also follow for `ConstructElimForest`. ◀

It remains to show how to lift the assumption of being provided an auxiliary elimination forest of bounded depth. For this we use the iterative compression technique.

Proof of the first part of Theorem 1. Arbitrarily enumerate the vertices of G as v_1, \dots, v_n . For $i \in \{1, \dots, n\}$, let $G_i = G[\{v_1, \dots, v_i\}]$ be the graph induced by the first i vertices. For each $i = 1, 2, \dots, n$ we will compute F_i , an elimination forest of G_i of depth at most d . For $i = 1$ this is trivial. Assume now that we have already computed F_i and want to compute F_{i+1} . We first construct T_{i+1} , an elimination tree of G_{i+1} , by taking F_i , adding v_{i+1} , and making v_{i+1} the parent of all the roots of F_i . Note that T_{i+1} has depth at most $d + 1$. We now call `ConstructElimForest`(G_{i+1}, T_{i+1}, d). If this procedure concludes that $\text{td}(G_{i+1}) > d$, then this implies that $\text{td}(G) > d$ as well, and we can terminate the algorithm and provide a negative answer. Otherwise, the procedure returns an elimination forest F_{i+1} of G_{i+1} of depth at most d , with which we can proceed. Eventually, the algorithm constructs an elimination forest $F = F_n$ of $G = G_n$ of depth at most d .

The algorithm is clearly correct. Since every call to `ConstructElimForest` is supplied with an elimination forest of depth at most $d + 1$, and there are at most n calls, the total time complexity is $2^{\mathcal{O}(d^2)} \cdot n^{\mathcal{O}(1)}$ and the space complexity is $n^{\mathcal{O}(1)}$, as desired. ◀

4 Randomized linear FPT algorithm

In this section we sketch the second part of Theorem 1, where we reduce the time and space complexities to linear in n at the cost of relying on randomization. There are three main reasons why the algorithm presented in the previous section does not run in time linear in n .

- First, in procedure `ConstructElimForest`, we applied `CountElimTrees` $\mathcal{O}(dn)$ times. Even if `CountElimTrees` runs in time linear in n , this gives at least a quadratic time complexity for `ConstructElimForest`.
- Second, in the iterative compression scheme we add vertices one by one and apply procedure `ConstructElimForest` n times. Again, even if `ConstructElimForest` runs in linear time, this gives at least a quadratic time complexity.
- Third, in procedure `CountElimTrees` we handle polynomials of degree at most n and with coefficients of bitsize bounded only polynomially in n . Algebraic operations on those need time polynomial in n .

In short, the second and third obstacles are mitigated as follows:

- Iterative compression is replaced by a contraction scheme of Bodlaender [1] that allows us to replace iteration with recursion, where every recursive step reduces the total number of vertices by a constant fraction, rather than peels off just one vertex.
- We observe that in `CountElimTrees`, we may care only about monomials with degrees bounded by dk , so the degrees are not a problem. As for coefficients, we hash them modulo a sufficiently large prime. This is another source of randomization.

As the techniques discussed above are rather standard, their details can be found in the full version only. Here we provide an overview of how we optimize the procedure `ConstructElimForest`, as this part contains original ideas.

Faster root recovery

We assume we have already improved the running time of `CountElimTrees` to linear. Now we are going to improve the running time of `ConstructElimForest` to linear. Recall that `ConstructElimForest` in its current version works over a connected graph G , iterates over all vertices $v \in V(G)$ and checks whether $\text{td}(G - v) \leq d - 1$ by calling `CountElimTrees` with appropriate parameters. Such vertices v could be placed as roots of an elimination tree of G of depth at most d . Finding any feasible root is the crucial part that needs to be optimized in order to achieve a linear running time for `ConstructElimForest`. The key fact we are going to use is that the number of possible roots of optimum-depth elimination forests of a connected graph is bounded in terms of the treedepth [3, 6].

► **Lemma 11 (★).** *Suppose G is a graph whose treedepth is equal to d . Then there are at most $d^{\mathcal{O}(d)}$ vertices $v \in V(G)$ such that $\text{td}(G - v) < d$.*

Observe that supposing G is connected, vertices v satisfying $\text{td}(G - v) < \text{td}(G)$ are exactly those that can be placed as roots of an optimum-depth elimination tree.

We are going to modify the procedure `CountElimTrees`(G, T, d) by introducing weights. Let G be a connected graph. Enumerate vertices of G as $V(G) = \{v_1, \dots, v_n\}$ and let t_i be the number of elimination trees of G that are sensible with respect to T and in which v_i is the root. Then the result of `CountElimTrees`(G, T, d) can be expressed as $t_1 + t_2 + \dots + t_n$. However, with a slight modification, we are able to compute $t_1\mu_1 + t_2\mu_2 + \dots + t_n\mu_n$ for any sequence $\mu_1, \mu_2, \dots, \mu_n \in \mathbb{Z}$. That can be achieved by multiplying by μ_i the contribution of transitions when we map v_i to the root of a monster.

Assume wishfully that there is exactly one vertex $v_i \in V(G)$ that could serve as the root of an elimination tree of G of depth d ; equivalently, v_i is the only vertex such that $\text{td}(G - v_i) < d$. In other words, t_j is nonzero if and only if $i = j$. Note that in such case we have $i = \frac{\sum_{j=1}^n j \cdot t_j}{\sum_{j=1}^n t_j}$. The denominator of this expression is simply the number of all elimination trees of G of depth at most d that are sensible with respect to T , while the numerator is the result of the modified version of `CountElimTrees` where we set $\mu_j = j$ for all $j \in [n]$. Hence, we can find i (that is: pinpoint the unique root) by dividing the outcomes of two calls to weighted `CountElimTrees`, instead of calling `CountElimTrees` n times, as we did previously.

Next, we lift the assumption about the uniqueness of the candidate for the root of an elimination tree. There are two key ingredients here. The first one is Lemma 11, which bounds the number of possible candidate roots for elimination trees of optimum depth. The second one is the color coding technique. The idea is to randomly color vertices into $d^{\mathcal{O}(d)}$ colors. Because there are at most $d^{\mathcal{O}(d)}$ possible roots, with high probability there will exist a color such that there is exactly one possible root in it. By modifying the idea from the previous paragraph, we can generalize it to identifying root within a color class provided there is exactly one possible root of this color.

Similarly as in the slower version, after identifying any possible root, we can delete it and recurse to connected components of the remaining part of the graph.

Abstract

We introduce the problem of finding a set B of k points in $[0, 1]^n$ such that the expected cost of the cheapest point in B that dominates a random point from $[0, 1]^n$ is minimized. We study the case where the coordinates of the random points are independently distributed and the cost function is linear. This problem arises naturally in various application areas where customers' requests are satisfied based on predefined products, each corresponding to a subset of features. We show that the problem is NP-hard already for $k = 2$ when each coordinate is drawn from $\{0, 1\}$, and obtain an FPTAS for general fixed k under mild assumptions on the distributions.

1 Introduction

Let $f: [0, 1]^n \rightarrow \mathbb{R}$ be a continuous cost function and $B \subseteq [0, 1]^n$ be a finite set. We consider the function

$$f_B: [0, 1]^n \rightarrow \mathbb{R} \cup \{\infty\}, \quad f_B(x) := \min\{f(b) : x \leq b, b \in B\},$$

where we write $x \leq b$ if x is less or equal than b in every coordinate and say that b covers x . In other words, $f_B(x)$ is the smallest cost needed to cover x with a point from B . We say that B is a *Pareto cover*¹ of a probability measure μ on $[0, 1]^n$ if a random point can be covered by at least one point from B almost surely, i.e., $\mu(\{x \in [0, 1]^n : x \leq b \text{ for some } b \in B\}) = 1$. Note that B is always a Pareto cover if it contains the all-ones vector $\mathbf{1}$ (but for some probability measures, B is not required to contain $\mathbf{1}$).

Given f , μ , and an integer $k \geq 1$, we study the problem of finding a Pareto cover B of μ with $|B| = k$ such that $E_\mu[f_B]$ is minimized. That is, we are searching for a Pareto cover B of predefined size such that the expected cost of covering a random point with a point from B is smallest possible.

As an illustration, imagine a city with tourist attractions $[n] := \{1, \dots, n\}$ and suppose that the city wants to design k books B of vouchers for subsets of these attractions. Each tourist x will pick the cheapest book $b \in B$ that covers all attractions that x wants to visit. We can think of x as a binary vector in $\{0, 1\}^n$. Assuming that we have some probability

¹ In the context of multi-objective optimization, $x \leq b$ is commonly referred to as b *Pareto-dominates* x .

■ **Figure 1** For the Lebesgue measure (uniform distribution) on $[0, 1]^2$ with cost $f(x_1, x_2) = x_1 + x_2$, the optimal Pareto covers of size $k = 3$ are $\{(12/23, 12/23), (18/23, 18/23), (1, 1)\}$, $\{(10/23, 18/23), (22/23, 12/23), (1, 1)\}$, and $\{(18/23, 10/23), (12/23, 22/23), (1, 1)\}$.

distribution over the tourists x , we want to determine k books that, in expectation, cover the tourists requests in the cheapest way. Note that, in this example, μ is a discrete measure on $\{0, 1\}^n$. Defining an appropriate cost function, an optimal Pareto cover of size k is attained by a set of vectors in $\{0, 1\}^n$, each corresponding to a book.

Similar applications can be given for other areas where customer’s requests are satisfied based on predefined products, each corresponding to a subset of features. Note that our model also allows for non-binary requests $x \in [0, 1]^n \setminus \{0, 1\}^n$, which may correspond to features that are available in different quality ranges.

For another application, imagine a gang of robbers that wants to steal paintings in an art gallery. To this end, every gang member studies one painting $i \in [n]$ and estimates the probability p_i of being able to steal it. Their boss decides in advance which subset $S \subseteq [n]$ of paintings to steal. If all corresponding gang members are successful (assuming that they act independently), then the gang will receive a value $v(S)$. Otherwise, they all get caught and the gang receives $v(\emptyset) = 0$. The problem of finding a subset of paintings that maximizes the expected return can be modeled within the above framework as follows. Let μ be the probability measure on $\{0, 1\}^n$ that corresponds to setting each coordinate independently to 1 with probability $1 - p_i$, and set $f(x) := v([n]) - v(\{i \in [n] : x_i = 0\})$ for all $x \in \{0, 1\}^n$. Denoting by $B^* = \{b^*, \mathbf{1}\}$ an optimal Pareto cover of size $k = 2$, it is easy to see that $S = \{i \in [n] : b_i^* = 0\}$ maximizes the expected return.

Determining optimal Pareto covers of a given size is a difficult problem. Finding an analytical solution seems to be non-trivial even for very basic probability measures and cost functions, see Figure 1. In this work, we study the problem from the point of view of complexity theory. We particularly focus on product measures and linear cost functions, for which the problem is already hard as our first results show.

Here, for $A = \{a_0, \dots, a_{M+1}\}$ with $0 = a_0 < a_1 < \dots < a_M < a_{M+1} = 1$ and a vector $p = ((p_\ell^i)_{\ell=0}^{M+1})_{i=1}^n \in [0, 1]^{(M+2) \times n}$ with $\sum_{\ell=0}^{M+1} p_\ell^i = 1$ for all $i \in [n]$, let $\mu_{A,p}$ denote the discrete product measure on $[0, 1]^n$ where x_i assumes a_ℓ with probability p_ℓ^i , that is,

$$\mu_{A,p}(\{(a_{\ell_i})_{i=1}^n\}) = \prod_{i=1}^n p_{\ell_i}^i \text{ for all } (a_{\ell_i})_{i=1}^n \in A^n. \tag{1}$$

In addition, for $A = \{0, 1\}$ and $p \in [0, 1]^n$, we define the binary product measure $\mu_p := \mu_{\{0,1\},p}$ where $q_0^i = 1 - p_i$ and $q_1^i = p_i$ for $i \in [n]$, that is, x_i is set to $a_1 = 1$ with probability p_i , and to $a_0 = 0$ with probability $1 - p_i$. Finally, for a linear cost function f given by $f(x) = c^\top x$ for some $c \in \mathbb{R}^n$ and a finite set B , we overload our notation $c_B := f_B$.

The Pareto cover problem turns out to be computationally difficult even in a setting where we restrict ourselves to binary product measures and linear cost functions.

► **Theorem 1.** *Let $k \in \mathbb{Z}$, $k \geq 2$. Given $p \in ([0, 1] \cap \mathbb{Q})^n$, $c \in \mathbb{Q}^n$, $\gamma \in \mathbb{Q}$, the problem of deciding whether there is some Pareto cover B of μ_p such that $|B| = k$ and $E_{\mu_p}[c_B] \leq \gamma$ is weakly NP-complete for k constant. Moreover, there are values of $k \in \Theta(n)$ for which it is strongly NP-hard.*

If the size of the Pareto cover is part of the input, we do not know whether the corresponding problem is in NP. In fact, computing the objective value of a single Pareto cover is already difficult:

► **Proposition 2.** *Given a Pareto cover B for the uniform distribution μ on $\{0, 1\}^n$, the problem of computing $E_\mu[\mathbf{1}_B]$ is #P-hard.*

Even when k is constant, it is not immediate how to determine, in polynomial time, the objective value $E_{\mu_p}[c_B]$ a certain Pareto cover $B = \{b^1, \dots, b^k\}$ attains for given probabilities $p \in ([0, 1] \cap \mathbb{Q})^n$ and a positive cost vector $c \in \mathbb{Q}^n$. In this respect, observe that it is infeasible to simply sum over all vectors $x \in \{0, 1\}^n$ since there is an exponential number of them. However, for constant k , we can afford to iterate over all subsets of $[k]$ instead. Moreover, it is not hard to see that for every $J \subseteq [k]$, c_B is constant on the set X_J consisting of all vectors $x \in [0, 1]^n$ that are covered precisely by those vectors b^j for which $j \in J$.

We show how to employ dynamic programming in order to compute the values $\mu(X_J)_{J \subseteq [k]}$ for arbitrary discrete product measures μ on $[0, 1]^n$. Using this observation as a starting point, we manage to derive a fully polynomial-time approximation scheme (FPTAS) for the case where k is constant.

► **Theorem 3.** *Let $k \in \mathbb{N}$ be fixed. Given a discrete product measure μ on $[0, 1]^n$ and $c \in \mathbb{Q}_{\geq 0}^n$, the problem of computing an optimal Pareto cover of size k with respect to μ and c admits an FPTAS.*

We further show how to extend our approach to general product measures that satisfy some mild assumptions. Essentially, we will consider products of *nice* measures $(\mu_i)_{i=1}^n$ on $[0, 1]$ that allow us to efficiently query an approximation of $\mu_i((a, b])$ for each a, b, i as well as a positive lower bound on the expectation of the identity on $[0, 1]$ with respect to each μ_i . A more formal definition will be given later.

Our paper is structured as follows. In Section 2 we briefly discuss related work. The proofs of Theorem 1 and Proposition 2 are given in Section 3, where we also derive results for general discrete product measures that will be used in our FPTAS. The latter and hence the proof of Theorem 3 is presented in Section 4. The full version of this paper shows how to extend our FPTAS result to very general (product) measures. We close with some open questions in Section 5.

2 Related Work

To the best of our knowledge our setting for the general case $k > 2$ has not been studied in the literature. For the case $k = 2$ similar problems have been studied in the area of *stochastic optimization* in the context of *chance constrained optimization*. Here one aims to find an optimal solution to a problem with stochastic constraints. A solution to the problem then needs to fulfill the constraints with probability $1 - \delta$ for some $\delta > 0$.

Linear chance constrained problems are of the form

$$\min\{\langle c, x \rangle : x \in X, \mathbb{P}_{\xi \sim \mu}[Ax \geq \xi] \geq 1 - \delta\} \quad (2)$$

for a domain X , a distribution μ , matrix A and parameter δ . Note that our problem for $k = 2$ with linear cost functions f can be formulated as such a problem under the assumption that every Pareto cover has to contain $\mathbf{1}$. It remains to find the second vector in the optimal Pareto cover, for which one can guess the probability that it covers an element drawn from μ . This fits exactly into the framework of (2) where A is the identity matrix and $X = [0, 1]^n$. For an overview on the topic, we refer to the work of Nemirovski and Shapiro [4] and Luedtke, Ahmed, and Nemhauser [3]. In principle, it is possible to extend this idea to the case $k \geq 3$, for instance by using techniques from [3]. However, it is unclear whether theoretically efficient (approximation) algorithms can be obtained by such an approach.

The Pareto cover problem has an interesting interpretation in the context of tropical geometry. It can be equivalently phrased as a problem of partitioning $[0, 1]^n$ into k regions R_i . For each region, one selects the *tropical barycenter*, which is the coordinate-wise maximum of all its elements. This resembles a tropicalized version of classical Euclidean clustering algorithms and barycenters.

For randomized algorithms, tools from *statistical learning theory* (sample complexity, coresets, ...) can be used to study the Pareto cover problem. A natural approach would be to replace μ by a probability distribution $\tilde{\mu}$ that is a combination of polynomially many Dirac-distributions such that $\tilde{\mu}$ is “close” to μ , and reduce the problem to finding an optimal Pareto cover for $\tilde{\mu}$. In this work, however, we focus on deterministic algorithms and defer a discussion of such techniques to the full version of our paper.

3 Hardness results

In this section, we show that finding optimal Pareto covers (of given sizes) is a computationally hard problem, even for simple binary product measures and linear cost functions. In particular, we prove Theorem 1 and Proposition 2.

In the first part, we focus on the case where μ is a binary product measure given by some input vector $p \in [0, 1]^n$ such that $\mu = \mu_p$, see (1). We consider the following problem.

► **Definition 4.** The decision variant of the *binary Pareto cover problem* is defined as follows: Given $p \in ([0, 1] \cap \mathbb{Q})^n$, $c \in \mathbb{Q}_{\geq 0}^n$, $\gamma \in \mathbb{Q}$, and $k \in \mathbb{Z}_{\geq 1}$, decide whether there is some Pareto cover B of μ_p such that $|B| = k$ and $\mathbb{E}_{\mu_p}[c_B] \leq \gamma$.

We assume that p , c , and γ are given by their binary encodings. We leave open how k is encoded since in our applications it will be always polynomially bounded in n (see Proposition 2) or mostly be even a constant.

In Section 3.1, we show that the binary Pareto cover problem is weakly NP-hard if k is a fixed constant. In addition, we show that for $k = \frac{n+5}{3}$, the problem is strongly NP-hard. For the case that k is part of the input, we prove Proposition 2 showing that the problem of computing $\mathbb{E}_{\mu_p}[c_B]$ for a given Pareto cover B is #P-hard in Section 3.2. In view of this, it is unclear whether the binary Pareto cover problem is in NP if k is part of the input. However, for constant k , we establish in Section 3.3 that the problem is in NP, even for general discrete product measures. This result completes the proof of Theorem 1 and plays an important role in the design of our approximation algorithm.

3.1 NP-hardness

In this section, we consider the binary Pareto cover problem. Note that it can be solved efficiently in the case $k = 1$ since then $B = \{b\}$ is an optimal solution, where $b \in \{0, 1\}^n$ with $b_i = 1$ if and only if $p_i > 0$. In the remainder, we show that the binary Pareto cover

problem is weakly NP-hard for $k = 2$. Similar, but slightly different proofs for the cases $k = 3$ and $k \geq 4$ can be found in the full version of this paper. Moreover, our reduction for $k \geq 4$ proves strong NP-hardness for $k = \frac{n+5}{3}$.

In order to show that the binary Pareto cover problem is NP-hard for $k = 2$, let us recall the PARTITION problem [2], which is well-known to be (weakly) NP-hard: Given $a_1, \dots, a_n \in \mathbb{Z}_{\geq 1}$ with $\sum_{i=1}^n a_i$ even, decide whether there is a subset $I \subseteq [n]$ such that $\sum_{i \in I} a_i = \frac{1}{2} \sum_{i=1}^n a_i$. We provide a reduction from PARTITION to the binary Pareto cover problem with $k = 2$.

Before defining it precisely, let us describe the idea first. Given a PARTITION instance a_1, \dots, a_n , set $\alpha := \frac{2}{a_1 + \dots + a_n}$ and consider an instance of the binary Pareto cover problem with $p_i = 1 - e^{-\alpha a_i}$ and $c_i = a_i$ for all $i \in [n]$. Since all c_i and p_i are positive, every optimal Pareto cover of μ_p is of the form $B = \{b, \mathbf{1}\}$ where $b \in \{0, 1\}^n$. Setting $I := \{i \in [n] : b_i = 0\}$, we see that the cost $E_{\mu_p}[c_B]$ of B satisfies

$$\begin{aligned} \sum_{i=1}^n a_i - E_{\mu_p}[c_B] &= \mathbf{1}^\top c - E_{\mu_p}[c_B] \\ &= \mathbf{1}^\top c - c^\top b \cdot \mu_p(\{x \in \{0, 1\}^n : x \leq b\}) - c^\top \mathbf{1} \cdot \mu_p(\{x \in \{0, 1\}^n : x \not\leq b\}) \\ &= c^\top (\mathbf{1} - b) \cdot \mu_p(\{x \in \{0, 1\}^n : x \leq b\}) \\ &= \prod_{i \in I} (1 - p_i) \cdot \sum_{i \in I} a_i \\ &= e^{-\alpha \sum_{i \in I} a_i} \cdot \sum_{i \in I} a_i \\ &= h\left(\sum_{i \in I} a_i\right), \end{aligned}$$

where $h: \mathbb{R} \rightarrow \mathbb{R}$, $h(x) = x \cdot e^{-\alpha x}$. Since h has its unique maximum at $x = \alpha^{-1}$, we see that $B = \{b, \mathbf{1}\}$ is a Pareto cover with $E_{\mu_p}[c_B] \leq \sum_{i=1}^n a_i - h(\alpha^{-1})$ if and only if $I = \{i \in [n] : b_i = 0\}$ satisfies $\sum_{i \in I} a_i = \alpha^{-1} = \frac{1}{2} \sum_{i=1}^n a_i$. In other words, if a_1, \dots, a_n is a “yes” instance for PARTITION, then there is a Pareto B cover of size $k = 2$ of μ_p with cost $E_{\mu_p}[c_B] \leq \sum_{i=1}^n a_i - h(\frac{1}{2} \sum_{i=1}^n a_i)$. If a_1, \dots, a_n is a “no” instance, then every Pareto cover of size $k = 2$ will have cost $E_{\mu_p}[c_B] > \sum_{i=1}^n a_i - h(\frac{1}{2} \sum_{i=1}^n a_i)$.

Unfortunately, the probabilities that we have used in the above argument cannot be polynomially represented. However, we show that we can efficiently round them such that the above strategy still works. More specifically, our probabilities and the threshold cost γ will be defined as follows.

► **Lemma 5.** *Given $a_1, \dots, a_n \in \mathbb{Z}_{\geq 1}$, we can compute $p_1, \dots, p_n \in [0, 1]$ and $\gamma \in \mathbb{Q}$ in polynomial time such that*

$$\frac{1 - \beta}{e^{\alpha a_i}} \leq 1 - p_i \leq \frac{1 + \beta}{e^{\alpha a_i}} \quad \text{for all } i \in [n], \text{ and } \frac{(1 - \beta)^{n+2}}{\alpha \cdot e} \leq \sum_{i=1}^n a_i - \gamma \leq \frac{(1 - \beta)^n}{\alpha \cdot e},$$

where $\alpha := \frac{2}{\sum_{i=1}^n a_i}$ and $\beta := \frac{\alpha^2}{48(n+1)}$.

Let p_1, \dots, p_n and γ be given as in the above statement. Note that we have $0 < p_i \leq 1$ for all $i \in [n]$ since $p_i \leq 1 - \frac{1 - \beta}{e^{\alpha a_i}} \leq 1$ and

$$p_i \geq 1 - \frac{1 + \beta}{e^{\alpha a_i}} > 1 - \frac{1 + \beta}{1 + \alpha \cdot a_i} \geq 1 - \frac{1 + \beta}{1 + \alpha} > 0.$$

Finally, set $c_i := a_i$ for all $i \in [n]$. It remains to prove the following lemma.

► **Lemma 6.** *There is a subset $I \subseteq [n]$ with $\sum_{i \in I} a_i = \frac{1}{2} \sum_{i=1}^n a_i$ if and only if there is a Pareto cover B of μ_p with $|B| = 2$ and $E_{\mu_p}[c_B] \leq \gamma$.*

The proves of the above lemmas can be found in the full version.

Note that we have shown that the binary Pareto cover problem is weakly NP-hard for constant k . We remark that, unless $P = NP$, the problem cannot be strongly NP-hard, as we derive an FPTAS in Section 4.

3.2 #P-hardness

In the previous section we have seen that the binary Pareto cover problem is NP-hard, already for constant k . The next natural question is whether the problem is in NP. At first sight, a Pareto cover $B \subseteq \{0, 1\}^n$ itself seems to be a canonical certificate for a “yes” instance. However, with this choice, we should be able to compute the cost $E_{\mu_p}[c_B]$ efficiently. Unfortunately, if k is not part of the input, i.e., B is not of constant size, computing $E_{\mu_p}[c_B]$ is hard. More precisely, let us prove Proposition 2, which states that, given a Pareto cover B for the uniform distribution μ on $\{0, 1\}^n$, the problem of computing $E_{\mu}[\mathbf{1}_B]$ is #P-hard.

Proof of Proposition 2. We use the fact that the problem of computing the number of vertex covers in a given undirected graph is #P-hard [5]. Given a graph $G = (V, E)$, identify V with $[n]$ and for every edge $e \in E$, let b_e denote the characteristic vector of $V \setminus e$, the set of nodes that are not part of e . Let μ denote the uniform distribution on $\{0, 1\}^n$, i.e., $\mu = \mu_p$ with $p = \frac{1}{2} \cdot \mathbf{1}$. Consider the Pareto cover $B := \{b_e : e \in E\} \cup \{\mathbf{1}\}$. Setting $c = \mathbf{1}$, the cost of B is equal to

$$\begin{aligned} E_{\mu}[c_B] &= (n-2) \cdot \mu(\{x \in \{0, 1\}^n : x \leq b_e \text{ for some } e \in E\}) \\ &\quad + n \cdot \mu(\{x \in \{0, 1\}^n : x \not\leq b_e \text{ for all } e \in E\}) \\ &= (n-2) + 2 \cdot \mu(\{x \in \{0, 1\}^n : x \not\leq b_e \text{ for all } e \in E\}) \\ &= (n-2) + \frac{|\{x \in \{0, 1\}^n : x \not\leq b_e \text{ for all } e \in E\}|}{2^{n-1}} \\ &= (n-2) + \frac{|\{U \subseteq [n] : U \cap e \neq \emptyset \text{ for all } e \in E\}|}{2^{n-1}}, \end{aligned}$$

and hence we see that $2^{n-1} \cdot (E_{\mu}[c_B] - (n-2))$ is the number of vertex covers in G . ◀

3.3 Membership in NP for constant k

For the binary Pareto cover problem, we have seen that computing the cost of a given Pareto cover B is hard if B can be of any size. In this section, we show that the cost can be computed efficiently if B is of constant size. In fact, we prove that this is the case for the discrete version of our problem (see (1)).

We introduce the following notation: For probability measures $(\mu_i)_{i=1}^n$ defined on (the Borel σ -algebra on) $[0, 1]$, we define their product $\mu := \prod_{i=1}^n \mu_i$ to be given by $\mu(I_1 \times \dots \times I_n) = \prod_{i=1}^n \mu_i(I_i)$, where $(I_i)_{i=1}^n$ are intervals contained in $[0, 1]$. In particular, for $A = \{a_0, \dots, a_{M+1}\}$ and $p = ((p_j^i)_{j=0}^{M+1})_{i=1}^n$ as in (1), $\mu = \mu_{A,p}$ is the product of the measures $\mu_i = \mu_{i,A,p}$ given by $\mu_i(\{a_j\}) = p_j^i$, $i \in [n]$, $j = 0, \dots, M+1$. We study the following problem.

► **Definition 7.** The decision variant of the *discrete Pareto cover problem* is the following: Given $A = \{a_0, \dots, a_{M+1}\}$ with $0 = a_0 < a_1 < \dots < a_M < a_{M+1} = 1$, $p = ((p_j^i)_{j=0}^{M+1})_{i=1}^n$ with $p_j^i \in [0, 1]$ and $\sum_{j=0}^{M+1} p_j^i = 1$ for all i , $c \in \mathbb{Q}_{\geq 0}^n$, $\gamma \in \mathbb{Q}$, and $k \in \mathbb{Z}_{\geq 1}$, decide whether there is some Pareto cover B of $\mu_{A,p}$ such that $|B| = k$ and $E_{\mu_p}[c_B] \leq \gamma$.

Again, we assume that A , p , c , and γ are given by their binary encodings. In our applications, k will be always constant.

Note that it is easy to check whether a finite set $B \subseteq [0, 1]^n$ is feasible for the above problem, i.e., that it is a Pareto cover of $\mu_{A,p}$. In fact, let $x^* \in [0, 1]^n$ be given by $x_i^* := \max\{a_j : p_j^i > 0\}$ for $i \in [n]$. Then B is a Pareto cover of $\mu_{A,p}$ if and only if $|B| = k$ and B contains at least one point that covers x^* .

Moreover, note that if B is feasible for the above problem, then we may assume that $B \subseteq A^n$ holds since otherwise we may lower entries of points in B without changing the set of points they cover and without increasing their cost.

► **Proposition 8.** *Let $k \in \mathbb{Z}_{\geq 1}$ be fixed. Given A, p, c as in the discrete Pareto cover problem and a Pareto cover $B \subseteq A^n$ for $\mu = \mu_{A,p}$ with $|B| = k$, we can compute $E_\mu[c_B]$ in polynomial time.*

Note that this shows that the discrete Pareto cover problem (and hence also the binary Pareto cover problem) is in NP if k is constant.

In order to prove Proposition 8, we make use of the following notation. For $i \in [n]$ vectors $b^1, \dots, b^k, x \in [0, 1]^n$, we define $J^i(x)$ to consist of all indices $j \in [k]$ such that b^j covers x , if we restrict both vectors to the first i coordinates. More precisely, we set

$$J^i(x) := \left\{ j \in [k] : x_1 \leq b_1^j, \dots, x_i \leq b_i^j \right\} \text{ for } i \in [n], \text{ and let } J(x) := J^n(x).$$

Whenever we refer to $J(x), J^1(x), \dots, J^n(x)$, the vectors b^1, \dots, b^k will be clear from the context. Observe that for $i \in [n]$ and $J \subseteq [k]$, the set $\{x \in [0, 1]^n : J^i(x) = J\}$ is a Borel set.

Note that $\{b^1, \dots, b^k\}$ is a Pareto cover for μ if and only if $\mu(\{x \in [0, 1]^n : J(x) = \emptyset\}) = 0$. Let us rephrase the cost of a Pareto cover using this new notation:

► **Lemma 9.** *Let μ be a probability measure on (the Borel σ -algebra on) $[0, 1]^n$ and let $B = \{b^1, \dots, b^k\}$ be a Pareto cover of μ . Then for every $c \in \mathbb{R}^n$ we have*

$$E_\mu[c_B] = \sum_{\emptyset \neq J \subseteq [k]} \mu(\{x \in [0, 1]^n : J(x) = J\}) \cdot \min_{j \in J} c^\top b^j.$$

Proof. For $J \subseteq [k]$, note that $c_B(x) = \min_{j \in J} c^\top b^j$ holds for all $x \in [0, 1]^n$ with $J(x) = J$. The claim follows since the sets $(\{x \in [0, 1]^n : J(x) = J\})_{J \subseteq [k]}$ are disjoint. ◀

Thus, in order to prove Proposition 8, it suffices to show that we can compute the values $\mu_{A,p}(\{x \in [0, 1]^n : J(x) = J\})$ for all $J \subseteq [k]$ in polynomial time. To this end, we show how to iteratively compute the values $\mu_{A,p}(\{x \in [0, 1]^n : J^i(x) = J\})$ for all $J \subseteq [k]$ and $i \in [n]$. Lemma 10 takes care of the base case $i = 1$, whereas Lemma 11 explains how to proceed from i to $i + 1$.

► **Lemma 10.** *Let μ_1, \dots, μ_n be probability measures on $[0, 1]$ and let $b^1, \dots, b^k \in [0, 1]^n$. For $\mu = \prod_{i=1}^n \mu_i$ and $J \subseteq [k]$ we have*

$$\mu(\{x \in [0, 1]^n : J^1(x) = J\}) = \mu_1((\alpha, \beta] \cap [0, 1]),$$

where $\alpha = \max_{j \in [k] \setminus J} b_1^j$ and $\beta = \min_{j \in J} b_1^j$.

Here, we use the convention $\max \emptyset := -\infty$ and $\min \emptyset := +\infty$.

Proof of Lemma 10. We have $J^1(x) = J$ if and only if $x_1 \leq b_1^j$ for all $j \in J$ and $x_1 > b_1^j$ for all $j \in [k] \setminus J$. That is, $\{x \in [0, 1]^n : J^1(x) = J\} = \{x \in [0, 1]^n : x_1 \in (\alpha, \beta]\}$. ◀

► **Lemma 11.** Let μ_1, \dots, μ_n be probability measures on $[0, 1]$ and let $b^1, \dots, b^k \in [0, 1]^n$. For $\mu = \prod_{i=1}^n \mu_i$, $J \subseteq [k]$, and $i \in \{2, \dots, n\}$ we have

$$\mu(\{x \in [0, 1]^n : J^i(x) = J\}) = \sum_{J \subseteq L \subseteq [k]} \mu(\{x \in [0, 1]^n : J^{i-1}(x) = L\}) \cdot \mu_i((\alpha_L, \beta_L] \cap [0, 1]),$$

where $\alpha_L = \max_{j \in L \setminus J} b_i^j$ and $\beta_L = \min_{j \in J} b_i^j$.

Proof. The claim follows from the fact that $\{x \in [0, 1]^n : J^i(x) = J\}$ is equal to

$$\bigcup_{J \subseteq L \subseteq [k]} \left[\{x \in [0, 1]^n : J^{i-1}(x) = L\} \cap \{x \in [0, 1]^n : x_i \leq b_i^j \text{ for all } j \in J, x_i > b_i^j \text{ for all } j \in L \setminus J\} \right]$$

and the observation that the above sets are disjoint. ◀

Note that for measures $\mu = \mu_{A,p} = \prod_{i=1}^n \mu_i$ and $\alpha, \beta \in \mathbb{Q} \cup \{\pm\infty\}$, we can compute $\mu_i((\alpha, \beta] \cap [0, 1])$ in polynomial time. Moreover, for constant k , the sum in Lemma 11 only has a constant number of summands. This yields Proposition 8.

4 Approximation algorithm

The goal of this section is to develop an FPTAS (see [1]) for the discrete Pareto cover problem, see Theorem 3. More precisely, we provide an algorithm that receives an instance I of the discrete Pareto cover problem and a parameter $\gamma \in (0, 1) \cap \mathbb{Q}$, and computes a $(1 + \gamma)$ -approximate solution to I in time polynomial in γ^{-1} and the encoding length of I . All proofs and an extension of our FPTAS to more general product measures can be found in the full version.

Let A, p, c, k define an instance of the discrete Pareto cover problem, where k is a constant. For every $i \in [n]$ let $l_i := \max\{l : p_l^i > 0\}$ and define $a^* := (a_{l_1}, \dots, a_{l_n})$. Recall that every Pareto cover B of $\mu = \mu_{A,p}$ must contain a point that covers a^* . Conversely, every finite set $B \subseteq [0, 1]^n$ containing a^* is a Pareto cover of μ . Since the costs are non-negative, we can restrict ourselves to Pareto covers that contain a^* .

Next, we discuss how to determine a cover of approximately minimum cost. Recall that in Section 3.3, Lemma 9, given a Pareto cover $B = \{b^1, \dots, b^k\}$, we have seen that we can express our objective as

$$E_\mu[c_B] = \sum_{\emptyset \neq J \subseteq [k]} \mu(\{x \in [0, 1]^n : J(x) = J\}) \cdot \min_{j \in J} c(b^j).$$

Even more, we know that we can iteratively compute the values $\mu(\{x \in [0, 1]^n : J^i(x) = J\})$ for $i \in [n]$ and $J \subseteq [k]$ in polynomial time, see Lemma 11. In doing so, the only information we need to proceed from i to $i + 1$ are the probabilities $\mu(\{x \in [0, 1]^n : J^i(x) = J\})$ for $J \subseteq [k]$ and the values $(b_{i+1}^j)_{j=1}^k$, but *no* further information on the values b_l^j for $l \in [i]$ and $j \in [k]$. What is more, by definition, the values $\mu(\{x \in [0, 1]^n : J^i(x) = J\})$ for $J \subseteq [k]$ and $\sum_{l=1}^i c_l \cdot b_l^j$ for $j \in [k]$ do not depend on the coordinates b_l^j , $l = i + 1, \dots, k$, $j \in [k]$. All in all, these are the best preconditions for a dynamic programming approach and motivate the following definition:

► **Definition 12.** For a Pareto cover $B = (b^j)_{j=1}^k$ with $b^k = a^*$ and $i \in [n]$ let

$$\text{Cand}^i(B) := (i, (P_J)_{J \subseteq [k]}, (C_j)_{j=1}^k),$$

where $P_J = \mu(\{x \in [0, 1]^n : J^i(x) = J\})$ for $J \subseteq [k]$ and $C_j = \sum_{l=1}^i c_l \cdot b_l^j$ for $j \in [k]$.

► **Definition 13.** A *candidate* is a triple $\mathcal{C} = (i, (P_J)_{J \subseteq [k]}, (C_j)_{j=1}^k)$.

The *cost* of the candidate \mathcal{C} is given by $\text{Cost}(\mathcal{C}) := \sum_{\emptyset \neq J \subseteq [k]} P_J \cdot \min_{j \in J} C_j$.

We call \mathcal{C} *valid* if there exists a Pareto cover $B = (b^j)_{j=1}^k$ with $b^k = a^*$ such that $\mathcal{C} = \text{Cand}^i(B)$, and say that B *witnesses* the validity of the candidate.

Note that the definition of the cost of a candidate is in accordance with Lemma 9.

A naive approach to tackle the discrete Pareto cover problem would now be to iteratively enumerate all valid candidates for $i = 1, \dots, n$, select a candidate for $i = n$ that yields the minimum objective value, and then back-trace to compute a corresponding cover. The problem with this idea is of course that we do not have a polynomial bound on the number of candidates we generate. To overcome this issue, we round the candidates appropriately to ensure a polynomial number of possible configurations, whilst staying close enough to the original values to obtain a good approximation of the objective for $i = n$. Observe that for constant k , the number of entries of each candidate is constant, which means that it suffices to polynomially bound the number of values each of them may attain.

To this end, consider Algorithm 1. The gray lines are not part of the algorithm itself, but only needed for its analysis. Before diving into the analysis of Algorithm 1, we would like to provide some intuition about what is happening. We start by enumerating all possible values $(b_1^j)_{j=1}^k$ may attain in a solution B with $b^k = a^*$ and use this information to compute $\text{Cand}^1(B)$ according to Definition 12. (Recall that this is independent of the values b_l^j for $l \geq 2, j = 1, \dots, k$.) Then, we round all non-zero entries of $\text{Cand}^1(B)$ (except for the first one, which is 1) down to the next power of $1 + \delta$, $\delta = \frac{\epsilon}{4n}$. Each rounded candidate \mathcal{C} is added to our table \mathcal{T} , and for back-tracing purposes, we store a cover B that leads to \mathcal{C} as $\text{Witness}(\mathcal{C})$. For the analysis, we further maintain an imaginary map AllWits mapping each rounded candidate $\mathcal{C} \in \mathcal{T}$ to the set of all possible witness covers that result in \mathcal{C} after (iterative) rounding.

After dealing with the base case $i = 1$, we enumerate possible values of $(b_i^j)_{j=1}^k$ for $i = 2, \dots, n$, loop over all rounded candidates for $i - 1$ and compute new rounded candidates for i according to Lemma 11. Moreover, we deduce witnesses for our new candidates for i from those stored for the candidates for $i - 1$ and the values $(b_i^j)_{j=1}^k$. This might of course lead to an exponential growth of the size of the imaginary map AllWits . However, the fact that the Witness-map only memorizes one witness per candidate keeps the total running time under control, provided we can come up with a polynomial bound on the number of candidates we generate. Lemma 14 takes care of this, and is the main ingredient of the proof of Theorem 15, which guarantees a polynomial running time.

► **Lemma 14.** *At each point during the algorithm, we have $|\mathcal{T}| \leq \alpha^{2^k} \cdot \beta^k \cdot n$, where*

$$\alpha = n + 2 - n \cdot \min \{ \log_{1+\delta}(p_l^i) : i \in [n], l \in \{0, \dots, M + 1\}, p_l^i > 0 \},$$

$$\beta = n + 2 + \log_{1+\delta}(c_1 + \dots + c_n) - \log_{1+\delta}(a_1) - \min \{ \log_{1+\delta}(c_i) : i \in [n] \}.$$

In particular, for constant k , $|\mathcal{T}|$ is polynomially bounded in the encoding length of the given instance of the discrete Pareto cover problem and ϵ^{-1} .

► **Theorem 15.** *Given an instance I of the discrete Pareto cover problem and a parameter $\epsilon \in (0, 1) \cap \mathbb{Q}$ as input, Algorithm 1 runs in time polynomial in $\text{size}(I)$ and ϵ^{-1} .*

Denote the set of all candidate in \mathcal{T} starting with i by \mathcal{T}_i . In order to finally obtain an FPTAS for the discrete Pareto cover problem, our goal for the remainder of this section is to prove the following result:

► **Theorem 16.** *Running Algorithm 1 and choosing the witness of a candidate of minimum cost in \mathcal{T}_n yields a $(1 + \epsilon)$ -approximation.*

■ **Algorithm 1** Dynamic program to compute rounded candidates.

Input: $(a_l)_{l=0}^{M+1}$, $((p_l^i)_{l=0}^{M+1})_{i=1}^n$, $(c_i)_{i=1}^n$, k , $\epsilon \in \mathbb{Q} \cap (0, 1)$
Output: a table \mathcal{T} of rounded candidates

- 23 $(b^{i-1, j})_{j=1}^k \leftarrow \text{Witness}((i - 1, (P_J^{i-1})_{J \subseteq [k]}, (C_j^{i-1})_{j=1}^k))$
- 24 Define $(b^{i, j})_{j=1}^k$ by $b_l^{i, j} := \begin{cases} b_l^{i-1, j} & , l \neq i \\ \beta_j & , l = i \end{cases}$
- 25 $\text{Witness}((i, (P_J^i)_{J \subseteq [k]}, (C_j^i)_{j=1}^k)) \leftarrow (b^{i, j})_{j=1}^k$
- 26 **foreach** $(\tilde{b}^{i-1, j})_{j=1}^k \in \text{AllWits}((i - 1, (P_J^{i-1})_{J \subseteq [k]}, (C_j^{i-1})_{j=1}^k))$ **do**
- 27 Define $(\tilde{b}^{i, j})_{j=1}^k$ by $\tilde{b}_l^{i, j} := \begin{cases} \tilde{b}_l^{i-1, j} & , l \neq i \\ \beta_j & , l = i \end{cases}$
- 28 $\text{AllWits}((i, (P_J^i)_{J \subseteq [k]}, (C_j^i)_{j=1}^k)) \leftarrow$
 $\text{AllWits}((i, (P_J^i)_{J \subseteq [k]}, (C_j^i)_{j=1}^k)) \cup \{(\tilde{b}^{i, j})_{j=1}^k\}$

28 **return** \mathcal{T}

The proof of Theorem 16 consists of two main steps. Lemma 17 shows that any rounded candidate \tilde{C} we store in \mathcal{T} invokes similar costs to those of any of its witness covers. Proposition 18 ensures that every cover $B = (b^j)_{j=1}^k$ with $b^k = a^*$ occurs as a possible witness for some candidate. In particular, this holds for an optimum cover B^* (with $b^{*,k} = a^*$) and by Lemma 17, we can therefore infer that the costs of the solution we return can only be by a factor of $1 + \epsilon$ larger than the optimum.

► **Lemma 17.** *Let $\tilde{C} \in \mathcal{T}_n$ and let $B \in \text{AllWits}(\tilde{C})$. Then $\text{Cost}(\tilde{C}) \leq E_\mu[c_B] \leq (1 + \epsilon) \cdot \text{Cost}(\tilde{C})$.*

► **Proposition 18.** *Let an instance of the discrete Pareto cover problem be given. For each $i \in [n]$ and each cover $B = (b^j)_{j=1}^k$ such that $b^k = a^*$ and $b_l^j = 0$ for $j = 1 \dots, k - 1$ and $l = i + 1, \dots, n$, there exists $\mathcal{C} \in \mathcal{T}_i$ such that $B \in \text{AllWits}(\mathcal{C})$.*

Combining Theorem 16, Lemma 14 and Theorem 15 and observing that we can compute the cost of a candidate in polynomial time for constant k , we obtain Theorem 3, which we restate once again:

► **Theorem 3.** *Let $k \in \mathbb{N}$ be fixed. Given a discrete product measure μ on $[0, 1]^n$ and $c \in \mathbb{Q}_{\geq 0}^n$, the problem of computing an optimal Pareto cover of size k with respect to μ and c admits an FPTAS.*

5 Conclusion

In this paper, we have introduced the Pareto cover problem and studied the case of product measures and linear cost functions. For fixed k , we have come to a pretty good understanding of its complexity: On the one hand, we could show weak NP-hardness of the problem. On the other hand, we have established the existence of an FPTAS.

However, there are several questions that remain open and constitute an interesting subject for future research. To begin with, we have seen that even in a very restricted setting such as the uniform probability distribution on $[0, 1]^n$, it seems non-trivial to find an optimum cover (see Figure 1). Consequently, in order to obtain a better feeling for the problem at hand, it can be worthwhile to examine the structure of optimum solutions for such special cases.

When dealing with the binary problem variant, another question that comes up is for which subsets of $\{0, 1\}^n$, there exists an instance they are optimum for. Any insights towards this question may lead to new, perhaps more efficient strategies to tackle the Pareto cover problem.

In addition to these rather concrete questions, there are also several more fundamental issues one may want to address. For instance, even though we have seen that computing the objective value attained by an arbitrary solution is #P-hard in general (i.e., for non-fixed k), this does not resolve containment in NP since there might be another choice of a certificate that does the trick. More generally, it would be interesting to fully understand the dependence of the problem complexity on the parameter k . To this end, note that the complexity does not simply “increase” with larger values of k , given that in the discrete setting, the problem is weakly NP-hard for constant $k \geq 2$, and strongly NP-hard, e.g., for $k = \frac{n+5}{3}$, but once k is at least as large as the number of all possible discrete vectors b , it is obvious what an optimum solution should look like (and we can output it in polynomial time, assuming an appropriate output encoding is chosen). Hence, it seems interesting to further investigate the hardness transition of the problem: When exactly does the problem become strongly NP-hard? When does it become easier again?

Finally, as all of our results apply to the case of product measures, it appears natural to ask what can be done for general probability measures. To this end, as alluded to in Section 2, it could be fruitful to explore connections to existing results from statistical learning theory.

A Unified Framework for Hopsets

Abstract

Given an undirected graph $G = (V, E)$, an (α, β) -hopset is a graph $H = (V, E')$, so that adding its edges to G guarantees every pair has an α -approximate shortest path that has at most β edges (hops), that is, $d_G(u, v) \leq d_{G \cup H}^{(\beta)}(u, v) \leq \alpha \cdot d_G(u, v)$. Given the usefulness of hopsets for fundamental algorithmic tasks, several different algorithms and techniques were developed for their construction, for various regimes of the stretch parameter α .

In this work we devise a single algorithm that can attain all state-of-the-art hopsets for general graphs, by choosing the appropriate input parameters. In fact, in some cases it also improves upon the previous best results. We also show a lower bound on our algorithm.

In [3], given a parameter k , a $(O(k^\epsilon), O(k^{1-\epsilon}))$ -hopset of size $\tilde{O}(n^{1+1/k})$ was shown for any n -vertex graph and parameter $0 < \epsilon < 1$, and they asked whether this result is best possible. We resolve this open problem, showing that any (α, β) -hopset of size $O(n^{1+1/k})$ must have $\alpha \cdot \beta \geq \Omega(k)$.

1 Introduction

Hopsets are graph theoretic structures that have gained much attention recently [5, 20, 14, 13, 8, 1, 10, 15, 7, 3]. They play a role in central algorithmic applications such as approximating shortest paths [16, 5, 2, 11], distributed computing tasks [9, 18, 4, 6], dynamic graph algorithms [14, 17], and many more.

Given a graph $G = (V, E)$, possibly with non-negative weights on the edges $w : E \rightarrow \mathbb{R}$, an (α, β) -hopset is a graph $H = (V, E')$ such that every pair in V has an α -approximate shortest path in $G \cup H$ with at most β hops. That is, for all $u, v \in V$,

$$d_G(u, v) \leq d_{G \cup H}^{(\beta)}(u, v) \leq \alpha \cdot d_G(u, v),$$

where $d_G(u, v)$ is the distance between u, v in G , and $d_{G \cup H}^{(\beta)}(u, v)$ stands for the length of the shortest path in $G \cup H$ between u, v that has at most β edges. The weight of an edge $(x, y) \in E'$ of H is defined to be the length of the shortest path in G that connects x and y .

Hopsets were first introduced by [5], although they were implicitly used before in [16]. In her seminal work, given a parameter k that determines the hopset size, [5] devised a construction of $(1 + \epsilon, \beta)$ -hopsets of size $O(n^{1+1/k} \cdot \log n)$ with $\beta = O\left(\frac{\log n}{\epsilon}\right)^{\log k}$. This result was recently improved by [8, 15, 10], who obtained $\beta = O\left(\frac{\log k}{\epsilon}\right)^{\log k}$ and size $O(n^{1+1/k})$.

On the opposite end of the stretch spectrum, for a stretch factor linear in k , it is folklore that the distance oracle of [21] (henceforth the TZ algorithm) is in fact a $(2k - 1, 2)$ -hopset of size $O(k \cdot n^{1+1/k})$.

A lower bound of [1] asserts that any $(1 + \epsilon, \beta)$ -hopset of size $O(n^{1+1/k})$ must have $\beta = \Omega\left(\frac{1}{\epsilon \log k}\right)^{\log k}$. This lower bound is meaningful only when the stretch is smaller than $1 + 1/\log k$, so it motivates the natural question: allowing the stretch to be larger than $1 + 1/\log k$, what is the trade off between stretch and hopbound?

This question was partially studied by [7, 3], who showed $(3 + \epsilon, \beta)$ -hopsets of size $O(n^{1+1/k} \cdot \log \Lambda)$ with improved $\beta = k^{\log(3+O(1/\epsilon))}$, where Λ is the aspect ratio of the graph¹ (In fact, [7] did not have the $\log \Lambda$ factor in the size, albeit their β had a somewhat worse exponent). More generally, for any $0 < \epsilon < 1$, [3] devised a $(O(k^\epsilon), O_\epsilon(k^{1-\epsilon}))$ -hopset of size $O(k^\epsilon \cdot n^{1+1/k} \cdot \log \Lambda)$. We note that by choosing $\epsilon = O(\frac{1}{\log k})$ they get a $(O(c), k^{1+O(1/\log c)})$ -hopset for any constant $c > 1$. The previous state-of-the-art results for hopsets are summarized in Table 1.

There are two main concerns with the current state of affairs regarding hopsets. First, there is no lower bound for any constant (or larger) stretch. Indeed, the tightness of the $(O(k^\epsilon), O_\epsilon(k^{1-\epsilon}))$ -hopset was asked as an open question in [3]. The second concern is that previous hopset constructions use a variety of different techniques for each possible range of the stretch α : from the sparse covers used by [5], to two types of the TZ sampling algorithm [21, 22], the superclustering technique of [12], and in some cases a certain combination of these with other ingredients. For instance, the algorithms of [3] for hopsets with stretch $3 + \epsilon$ and $O(k^\epsilon)$ are rather complicated, and contain a three-stage construction, involving a truncated application of the [22] algorithm, a superclustering phase, and a multiplicative spanner built on some cluster graph.

In this paper we devise a single framework that unifies all previous results for hopsets, matching and even improving upon the state-of-the-art in all the possible stretch regimes. In addition, we answer affirmatively the question of [3] mentioned above.

■ **Table 1** Previous results on (α, β) -hopsets for n -vertex weighted graphs, with parameter $k \geq 1$ (the dependence on k in the size is omitted for brevity).

Stretch	Hopbound	Hopset Size	Paper
$1 + \epsilon$	$O\left(\frac{\log k}{\epsilon}\right)^{\log k}$	$O(n^{1+\frac{1}{k}})$	[15, 10]
$3 + \epsilon$	$k^{\log(3+O(1/\epsilon))}$	$O(n^{1+\frac{1}{k}} \cdot \log \Lambda)$	[3]
$O(c)$	$k^{1+O(1/\log c)}$	$O(n^{1+\frac{1}{k}} \cdot \log \Lambda)$	[3]
$O(k^\epsilon)$	$O_\epsilon(k^{1-\epsilon})$	$O(n^{1+\frac{1}{k}} \cdot \log \Lambda)$	[3]
$2k - 1$	2	$O(n^{1+\frac{1}{k}})$	[21]

1.1 Our Results

We develop a generalization of the TZ-algorithms [21, 22], that achieves (and in some cases improves on) the state-of-the-art for hopsets. This unifies all previous results in a single framework, and greatly simplifies the constructions for hopsets with intermediate stretch (above $1 + \epsilon$ and below $2k - 1$). We also remove all the $\log \Lambda$ factors from the size. This result is summarized in Theorem 1 below.

¹ The aspect ratio is the ratio between the largest distance to the smallest distance in the graph.

In addition, we affirmatively resolve the open problem of [3] mentioned above, by proving that an (α, β) -hopset of size $O(n^{1+1/k})$ must have $\alpha \cdot \beta \geq \Omega(k)$. This lower bound asymptotically matches the upper bound of $(k^\epsilon, O_\epsilon(k^{1-\epsilon}))$ -hopset by [3] for every $0 < \epsilon < 1$.

In the full version of this paper, we also show that whenever our algorithm produces a hopset of size $O(n^{1+1/k})$ with stretch α , it must have a superlinear hopbound of $\beta = \Omega(\frac{1}{\alpha^2} k^{1+1/(2 \log \alpha)})$. This matches the upper bound shown in [3] and here, for all constant α . As our algorithm generalizes all previous constructions, we believe it is an indication that the question whether there exists an $(O(1), O(k))$ -hopset of size $O(n^{1+1/k})$, may have a negative answer.

► **Theorem 1.** *Let $G = (V, E)$ be a weighted undirected graph with n vertices, and fix an integer $k \geq 1$. Then there is an algorithm that can compute each of the following:*

1. *A hopset H of size $O(\log k \cdot n^{1+1/k})$, which is a $(1 + \epsilon, O(\frac{\log k}{\epsilon} \log k))$ -hopset for all $0 < \epsilon < 1$ simultaneously.*
2. *A hopset H of size $O(\log k \cdot n^{1+1/k})$, which is a $(3 + \epsilon, O(k^{\log_2(3 + \frac{16}{\epsilon})}))$ -hopset for all $0 < \epsilon < 1$ simultaneously.*
3. *For any integer $c \geq 1$, an $(8c + 3, O(k^{1 + \frac{2}{\ln c}}))$ -hopset of size $O(c \cdot \log_c k \cdot n^{1+1/k})$.*
4. *For any $0 < \epsilon < 1$, an $(O(e^{2/\epsilon} \cdot k^\epsilon), O(k^{1-\epsilon}))$ -hopset of size $O(n^{1+1/k}/\epsilon^2)$.*
5. *A $(2k - 1, 2)$ -hopset of size $O(k \cdot n^{1+1/k})$.*

1.1.1 Spanners

A closely related concept to hopsets is that of spanners: An (α, β) -spanner of G is a subgraph $H = (V, E'')$ such that for all $u, v \in V$, $d_G(u, v) \leq d_H(u, v) \leq \alpha \cdot d_G(u, v) + \beta$. In the full version of this paper, we describe a unified framework for building spanners, which is a variation of our unified framework for hopsets described here. This unified framework achieves the state-of-the-art results for spanners in essentially all possible values of α .

1.2 Our Techniques

1.2.1 Lower bound

The lower bound on the triple tradeoff between stretch, hopbound and size of (α, β) -hopsets, showing that $\alpha \cdot \beta = \Omega(k)$ whenever the size is $O(n^{1+1/k})$, uses the existence of $n^{1/g}$ -regular graphs with girth g . The basic idea is simple: locally (within distance less than $g/2$) the graph looks like a tree, so when considering short enough paths, of length less than g/α , there are no alternative paths with stretch at most α . This means that any hopset edge (u, v) can only be useful to pairs whose shortest path is “nearby” to u, v . Making this intuition precise, and defining what exactly is “nearby”, requires some careful counting arguments.

We remark that for (α, β) -spanners of size $O(n^{1+1/k})$, there is a better lower bound of $\alpha + \beta \geq \Omega(k)$, which also follows from the family of high girth graphs. (This is because such spanners are in particular $(\alpha + \beta, 0)$ -spanners.) However, this lower bound cannot hold for hopsets, as indicated by the existence of $(O(k^\epsilon), O(k^{1-\epsilon}))$ -hopsets for $\epsilon = 1/2$, say. Indeed, the analysis we use is inherently different, and more intricate, than the one used in the lower bound for spanners.

1.2.2 General algorithm

Before discussing our general algorithm for hopsets, let us review the previous TZ algorithm. Let $G = (V, E)$ be a (possibly weighted) graph with n vertices, and fix an integer parameter k . The algorithms of [21, 22] randomly sample a sequence of sets $V = A_0 \supseteq A_1 \supseteq \dots \supseteq A_F$,

for some F , where each A_{i+1} , $0 \leq i < F$, is sampled by including each vertex from A_i independently with some predefined probability. Then they define for each $v \in V$ its i -th *pivot* $p_i(v)$ as the closest vertex in A_i to v , and the i -th *bunch* as $B_i(v) = \{u \in A_i : d(u, v) < d(v, p_{i+1}(v))\}$. The hopset consists of all edges between each v and some of its bunches.

In [21], the sampling probabilities of each A_{i+1} from A_i were uniform $n^{-1/k}$, i.e., the exponent of $n^{-1/k}$ was linear, so we call this a *linear-TZ*. In this version, each vertex $v \in V$ can connect to vertices in $B_i(v)$ for all $0 \leq i \leq F$. The analysis can give a hopset with $\beta = 2$ and stretch $2k - 1$.

In [22], the sampling probabilities of each A_{i+1} from A_i were roughly $n^{-2^i/k}$, i.e., the exponent of $n^{-2^i/k}$ was exponential in i , so we naturally call this an *exponential-TZ*. As the probabilities are much lower here, the bunches will be larger, so vertices in $A_i \setminus A_{i+1}$ can only connect to their i -th bunch (in order to keep the size under control). This version can provide a near-exact stretch for the hopset.

1.2.3 Our algorithm

In this work, we devise the following generalization of both of these algorithms. Our algorithm expects as a parameter a function $f : \mathbb{N} \rightarrow \mathbb{N}$ that determines, for each level i , the highest bunch-level that vertices in $A_i \setminus A_{i+1}$ will connect to (in the linear-TZ we have $f(i) = F$, while in the exponential-TZ, $f(i) = i$ for all i). This function f implies what should the sampling probability be for each level i , in order to keep the total size of the hopset roughly $O(n^{1+1/k})$. We denote these probabilities by $n^{-\lambda_i/k}$, for parameters $\lambda_0, \lambda_1, \dots, \lambda_{F-1}$. The number of sets F is in turn determined by these λ_i (roughly speaking, it is when we expect A_F to be empty).

As this is a generalization of the algorithms of [21, 22], clearly it may achieve their results. One of our main technical contributions is showing that an *interleaving* of the linear-TZ and exponential-TZ probabilities, yields a hopset with a low hopbound, for any intermediate stretch between $3 + \epsilon$ and k . This means that we divide the integers in $[F]$ to F/t intervals, so that the λ_i 's are the same within each interval, and decays exponentially between intervals. The parameter t controls the stretch.

Our analysis combines ideas from previous works [22, 7, 3], with some novel insights that simplify some of the previously used arguments. In particular, [3] truncated the connections from every vertex in A_i to within a certain range. We show that in our approach, such truncation can be avoided at essentially no cost: this enables our analysis to be scale-free, thereby removing the $\log \Lambda$ factors from the size. In addition, our $(3 + \epsilon, \beta)$ -hopsets combine the best attributes of the hopsets of [7] and [3]: they have no dependence on $\log \Lambda$ and work for all ϵ simultaneously like [7], and have the superior β like [3]. The simplicity of our algorithm has other benefits: for instance, [3] devised two different algorithms, using different tools, for $(O(k^\epsilon), O(k^{1-\epsilon}))$ -hopsets; one for $\epsilon \in (0, 1/2]$ and the other for $\epsilon \in [1/2, 1)$. Our unified algorithm has no need for such separation.

1.3 Organization

In Section 2 we show our lower bound for hopsets. In Section 3 we describe our general algorithm for hopsets, and provide an analysis of its stretch and hopbound in Section 4.

2 Lower Bound for Hopsets

In this section we build a graph G , such that every hopset for G with stretch α and size $O(n^{1+\frac{1}{k}})$ must have a hopbound of at least $\approx \frac{k}{\alpha}$. G has high girth (the size of the smallest simple cycle) and high degree for each vertex, and we prove our lower bound by using counting arguments.

For the construction, we use the following result, which is a well known corollary from a paper by Lubotzky, Phillips and Sarnak [19]:

► **Theorem 2** ([19]). *Given an integer $\gamma \geq 1$, there are infinitely many integers $n \in \mathbb{N}$ such that there exists a $(p+1)$ -regular graph $G = (V, E)$ with $|V| = n$ and girth $\geq \frac{4}{3}\gamma(1 - o(1))$, where $p = D \cdot n^{\frac{1}{\gamma}}$, for some universal constant D .*

Fix $\alpha, \gamma \geq 1$ and a large enough n as above, and let $G = (V, E)$ be the matching $(p+1)$ -regular graph from the theorem. The girth of G is $\geq \frac{4}{3}\gamma(1 - o(1)) > \gamma$. We look at paths in G of distance $\delta := \lfloor \frac{\gamma-1}{\alpha+1} \rfloor$. For a path P , denote by $|P|$ its length. For $u, v \in V$, denote by $P_{u,v}$ a shortest path between them.

► **Lemma 3.** *Suppose $d(u, v) = \delta$. Then for every path P' between u, v such that $|P'| \leq \alpha\delta$, $P_{u,v} \subseteq P'$.*

Proof. If $P_{u,v} \not\subseteq P'$, then $P_{u,v} \cup P'$ contains a simple cycle of length $\leq |P_{u,v}| + |P'| \leq \delta + \alpha\delta = (\alpha+1)\delta \leq \gamma - 1$, in contradiction to the girth of G being $\geq \gamma$. ◀

Lemma 3 implies if $d(u, v) = \delta$, then $P_{u,v}$ is unique. Let $Q_\delta = \{P_{u,v} \mid d(u, v) = \delta\}$.

► **Lemma 4.** $|Q_\delta| \geq \frac{1}{2}np^\delta$.

Proof. Given a vertex $u \in V$, denote its BFS tree, up to the δ 'th level, by T . Since G 's girth is $> (\alpha+1)\delta$, there are no edges between the vertices of T , apart from the edges of T itself. That means that each vertex of T has at least p children at the next level, so we have at least p^δ leaves in T . Each of these leaves is a vertex of distance δ from u , and is connected to u with a δ -path. When summing this quantity over all the vertices $u \in V$, we count every path twice, so we get at least $\frac{1}{2} \sum_{u \in V} p^\delta = \frac{1}{2}np^\delta$ paths of length δ . ◀

We are now ready to prove the main theorem:

► **Theorem 5.** *For every positive integer k , a real number $\alpha > 0$, a constant $C > 0$ and for infinitely many integers n , there exists a graph G with n vertices such that every hopset H for G with size $\leq Cn^{1+\frac{1}{k}}$ and stretch $\leq \alpha$, H has a hopbound $\beta \geq \lfloor \frac{k-2}{\alpha+1} \rfloor$.*

Proof. For α, n and a fixed $\gamma \geq 1$ that will be chosen later, let $G = (V, E)$ be the $(p+1)$ -regular graph from Theorem 2 ($|V| = n$, girth $\geq \gamma$ and $p = D \cdot n^{\frac{1}{\gamma}}$). Define δ, Q_δ the same way as above.

Let H be an (α, β) -hopset for G with size $\leq Cn^{1+\frac{1}{k}}$, where $\beta < \delta$. For $e = (x, y) \in H$, we denote the weight of e , which is defined to be the distance $d(x, y)$, by $w(e)$ ($d(x, y)$ is the distance in the graph G . We omit the subscript from $d_G(u, v)$ for brevity). To formalize our next arguments, we think of a bipartite graph (A, B, \hat{E}) , where $A = Q_\delta$, $B = \{e \in H \mid w(e) \leq \alpha\delta\}$ and $\hat{E} = \{(P, (x, y)) \in A \times B \mid P \cap P_{x,y} \neq \emptyset\}$. We prove the following two properties of this graph ($deg_{\hat{E}}$ denotes the degree of a vertex in this graph):

1. $\forall P \in A \quad deg_{\hat{E}}(P) \geq 1$,
2. $\forall e \in B \quad deg_{\hat{E}}(e) \leq \alpha\delta^2 p^{\delta-1}$.

For (1), we need to show that if $d(u, v) = \delta$, then $\exists(x, y) \in H : P_{u,v} \cap P_{x,y} \neq \emptyset$ and $w(x, y) \leq \alpha\delta$. Let $P \subseteq G \cup H$ be the shortest path from u to v , that has at most β edges, and let \hat{P} be the same path as P , with every H -edge (x, y) replaced by $P_{x,y}$. In \hat{P} , we call the original edges from P *blue* edges, and the other edges *red* edges. By the hopset property: $|\hat{P}| = w(P) = d_{G \cup H}^{(\beta)}(u, v) \leq \alpha \cdot d(u, v) = \alpha\delta$.

From lemma 3, we know that $P_{u,v} \subseteq \hat{P}$, but since \hat{P} contains at most $\beta < \delta = |P_{u,v}|$ *blue* edges, that means that there is a *red* edge in \hat{P} which is in $P_{u,v}$. By the definition of *red* edges, there is some $(x, y) \in H$ such that $P_{x,y}$ contains this *red* edge, therefore $P_{u,v} \cap P_{x,y} \neq \emptyset$. This edge (x, y) is part of P , so we also have $w(x, y) \leq w(P) \leq \alpha\delta$.

For (2), given $(x, y) \in H$ such that $w(x, y) \leq \alpha\delta$, we need to bound the number of pairs $u, v \in V$ such that $d(u, v) = \delta$ and $P_{u,v} \cap P_{x,y} \neq \emptyset$. Let $(a, b) \in P_{x,y}$. Every path of length δ that passes through (a, b) is a concatenation of a path of length i that ends in a , the edge (a, b) and a path of length $\delta - 1 - i$ from b , for some $i \in [0, \delta - 1]$. Fixing i , we can look at the BFS trees T_a, T_b of a, b respectively, up to the i 'th and $(\delta - 1 - i)$ 'th level respectively. Since the degree of any vertex in G is $p + 1$, T_a contains at most p^i leaves, and T_b contains at most $p^{\delta-1-i}$ leaves. Therefore, the number of concatenations of paths as above is bounded by:

$$\sum_{i=0}^{\delta-1} p^i \cdot p^{\delta-1-i} = \sum_{i=0}^{\delta-1} p^{\delta-1} = \delta p^{\delta-1} .$$

Since $P_{x,y}$ contains at most $\alpha\delta$ edges, we get that the number of paths $P_{u,v}$ such that $P_{u,v} \cap P_{x,y} \neq \emptyset$ and $|P_{u,v}| = \delta$, is bounded by $\alpha\delta \cdot \delta p^{\delta-1} = \alpha\delta^2 p^{\delta-1}$. This concludes the proof of (2).

Finally, using the two properties of the bipartite graph, we bound its number of edges from both sides:

$$|\hat{E}| = \sum_{P \in A} \deg_{\hat{E}}(P) \stackrel{(1)}{\geq} |A| = |Q_\delta| \stackrel{\text{lemma 4}}{\geq} \frac{1}{2} np^\delta ,$$

$$|\hat{E}| = \sum_{e \in B} \deg_{\hat{E}}(e) \stackrel{(2)}{\leq} |B| \alpha \delta^2 p^{\delta-1} \leq |H| \alpha \delta^2 p^{\delta-1} .$$

Using these inequalities, we get

$$|H| \geq \frac{1}{2\alpha\delta^2} np = \frac{D}{2\alpha\delta^2} n \cdot n^{\frac{1}{\gamma}} = \frac{D}{2\alpha\delta^2} n^{1+\frac{1}{\gamma}} .$$

Recall that $|H| \leq Cn^{1+\frac{1}{k}}$, so when choosing large enough n , it must be that $k \leq \gamma$. Summarizing our proof so far, we showed that for fixed $\gamma \geq 1$, $\alpha > 0$ and a constant C , there is a graph G such that every (α, β) -hopset H for G , with size $\leq Cn^{1+\frac{1}{k}}$, either satisfies $\beta \geq \delta$, or satisfies $k \leq \gamma$.

Choose $\gamma = k - 1$. Now the matching graph G has the property that every (α, β) -hopset H for G , with size $\leq Cn^{1+\frac{1}{k}}$, must have $\beta \geq \delta$. By δ 's definition:

$$\beta \geq \delta = \lfloor \frac{\gamma - 1}{\alpha + 1} \rfloor = \lfloor \frac{k - 2}{\alpha + 1} \rfloor . \quad \blacktriangleleft$$

3 A Unified Construction of Hopsets

Let $G = (V, E)$ be a weighted undirected graph, and let k be some positive integer.

Our construction of a hopset is a simple generalization of the construction of [21]. We start by constructing a sequence of sets $V = A_0 \supseteq A_1 \supseteq A_2 \supseteq \dots$. The set A_{j+1} is defined by selecting each vertex from A_j independently with some probability that will be defined later.

Given this sequence, define some useful notations:

1. For a vertex $u \in V$, denote by $i(u)$ the *level* of u , which is the only i such that $u \in A_i \setminus A_{i+1}$.
2. The j 'th *pivot* of u , $p_j(u)$, is the vertex of A_j which is the closest to u .
3. The j 'th *bunch* of u is the set $B_j(u) = \{v \in A_j \mid d(u, v) < d(u, p_{j+1}(u))\}$.
(Whenever $A_{j+1} = \emptyset$ or A_{j+1} is undefined, then also $p_{j+1}(u)$ is undefined, and we say that $d(u, p_{j+1}(u)) = \infty$, so $B_j(u) = A_j$).

The hopset construction that relies on [21] adds an hopset edge from each $u \in V$ to the vertices in all of its bunches. Instead, in our case, we add a new parameter to the construction: A non-decreasing function $f : \mathbb{N} \rightarrow \mathbb{N}$ such that $\forall_{i \geq 0} i \leq f(i)$. Now instead of connecting $u \in V$ to *all* of its bunches, we connect it only to bunches $B_j(u)$ with index j between $i(u)$ and $f(i(u))$.

This choice gives us the freedom to change the sampling probability, i.e. the probability that some $v \in A_j$ is chosen to A_{j+1} ; As we will see later, this probability controls the size of the bunches $B_j(u)$, and since u now has less bunches to connect to, they can be larger. In turn, the sampling probability implies how many non-empty sets there will be in the sequence $V = A_0 \supseteq A_1 \supseteq \dots$.

For specifying this dependency between the sampling probability and the parameter f , we use here and throughout this paper, the following notation:

$$f^{-1}(j) = \min\{i \mid j \leq f(i)\}.$$

Given the parameters k, f , we define a sequence $\{\lambda_j\}$ by² $\lambda_j = 1 + \sum_{l < f^{-1}(j)} \lambda_l$.

The sampling probability of a vertex $v \in A_j$ into A_{j+1} is now defined as $n^{-\frac{\lambda_j}{k}}$ (recall that $n = |V|$). We also define $F = \min\{F' \mid \sum_{l < F'} \lambda_l \geq k + 1\}$, and one can simply check that w.h.p. $A_F = \emptyset$.

► **Definition 6.** Given an integer $k \geq 1$ and a non-decreasing function $f : \mathbb{N} \rightarrow \mathbb{N}$ such that $\forall_i f(i) \geq i$, the General Hopset $H(k, f)$, is the hopset:

$$H(k, f) = \bigcup_{u \in V} \bigcup_{j=0}^{F-1} \{(u, p_j(u))\} \cup \bigcup_{u \in V} \bigcup_{j=i(u)}^{f(i(u))} \{(u, v) \mid v \in B_j(u)\}.$$

The following lemma bounds the expected size of our hopset. Its proof appears in the full version of this paper.

► **Lemma 7.** $\mathbb{E}[|H(k, f)|] = O(Fn^{1+\frac{1}{k}})$.

² Note that in the definition of the sequence $\{\lambda_j\}$, no explicit base case was provided (i.e. a definition of λ_0). But, notice that the definition of $\{\lambda_j\}$ actually does contain a definition for λ_0 :

$$\lambda_0 = 1 + \sum_{l < f^{-1}(0)} \lambda_l = 1 + \sum_{l < 0} \lambda_l = 1,$$

where $f^{-1}(0) = 0$ is true by the definition of f^{-1} and the fact that $f(0) \geq 0$.

3.1 Examples

3.1.1 Linear TZ

When choosing $f(j) = k$ for all $j \leq k$, we get $\lambda_j = 1$ for all j (since $f^{-1}(j) = 0$ for all $j \leq k$), and $k + 1 = \sum_{j < F} \lambda_j = F$. The resulting hopset $H(k, f)$ relies on the same construction as in [21], and as observed in [3], it is a $(2k - 1, 2)$ -hopset.

3.1.2 Exponential TZ

Choose $f(j) = j$ for every j . Since $f^{-1}(j) = j$ for every j , we get $\lambda_j = 1 + \sum_{l < j} \lambda_l \Rightarrow \lambda_j = 2^j$ (proof by induction). Also, $k + 1 \approx \sum_{j < F} \lambda_j = 2^F - 1 \Rightarrow F = \lceil \log_2(k + 2) \rceil$. The resulting construction is the same as the emulator from section 4 in [22]. By the analysis of [15, 10], this emulator from [22] is actually a $(1 + \epsilon, O(\frac{\log k}{\epsilon})^{\log k})$ -hopset of size $O(\log k \cdot n^{1 + \frac{1}{k}})$, for every $0 < \epsilon < 1$ simultaneously.

4 Stretch and Hopbound Analysis Method

In this section we show that our general hopset can provide the state-of-the-art results for (α, β) -hopsets, for various regimes of α .

Given a weighted undirected graph G , and given k, f , we add another parameter, which is a sequence of non-negative real numbers: $\{r_i\}_{i=0}^F$. We stress that these parameters only play a part in the analysis.

The following definition of the *score* of a vertex is needed for the lemma that will be proved afterwards.

► **Definition 8.** *Given the function f and the sequence $\{r_i\}$, the **Score** of a vertex $u \in V$ is:*

$$\text{score}(u) = \max\{i > 0 \mid d(u, p_i(u)) > r_i \text{ and } \forall j \in [f^{-1}(i-1), i-1] d(u, p_j(u)) \leq r_j\},$$

where if $p_i(u)$ is not defined (e.g. when $i = F$ and $A_F = \emptyset$), we consider $d(u, p_i(u))$ to be ∞ .

► **Remark 9.** The set in the definition of $\text{score}(u)$ is not empty, so the score of each vertex is well defined and positive. To see this, note that if i is the minimal index such that $d(u, p_i(u)) > r_i$, then $i > 0$ (because $p_0(u) = u$, so $d(u, p_0(u)) = 0 \leq r_0$), $i \leq F$ (because $d(u, p_F(u)) = \infty > r_F$) and also for every $j \in [f^{-1}(i-1), i-1]$, by the minimality of i , $d(u, p_j(u)) \leq r_j$.

Denote $H = H(k, f)$.

► **Lemma 10 (Jumping Lemma).** *Suppose that $\text{score}(u) = i$, then for every $u' \in V$ such that $d(u, u') \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}$,*

$$d_{G \cup H}^{(3)}(u, u') \leq 3d(u, u') + 2(r_{i-1} + r_{f^{-1}(i-1)}).$$

Moreover, if also $d(u, u') \geq \frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)})$ for some $t > 0$, then:

$$d_{G \cup H}^{(3)}(u, u') \leq (t + 3)d(u, u').$$

Proof. Let $u \in V$ be some vertex with $\text{score}(u) = i$ and let $u' \in V$ be some other vertex. We have:

$$d(u', p_{i-1}(u')) \leq d(u', p_{i-1}(u)) \leq d(u', u) + d(u, p_{i-1}(u)) \leq d(u', u) + r_{i-1}. \quad (1)$$

Since $\text{score}(u) = i$, $\forall j \in [f^{-1}(i-1), i-1]$, we have $d(u, p_j(u)) \leq r_j$. In particular, $d(u, p_{f^{-1}(i-1)}(u)) \leq r_{f^{-1}(i-1)}$, and now we can see that:

$$\begin{aligned} d(p_{f^{-1}(i-1)}(u), p_{i-1}(u')) &\leq d(p_{f^{-1}(i-1)}(u), u) + d(u, u') + d(u', p_{i-1}(u')) \\ &\stackrel{(1)}{\leq} r_{f^{-1}(i-1)} + d(u, u') + (d(u, u') + r_{i-1}) \\ &= 2d(u, u') + r_{f^{-1}(i-1)} + r_{i-1}. \end{aligned}$$

For convenience, we denote $u_0 = p_{f^{-1}(i-1)}(u)$, and we also bound the distance $d(u_0, p_i(u_0))$.

$$r_i < d(u, p_i(u)) \leq d(u, p_i(u_0)) \leq d(u, u_0) + d(u_0, p_i(u_0)) \leq r_{f^{-1}(i-1)} + d(u_0, p_i(u_0))$$

$$\Rightarrow d(u_0, p_i(u_0)) > r_i - r_{f^{-1}(i-1)}.$$

■ **Figure 1** The potential path between u and u' . Notice that $d(u, p_{i-1}(u)) \leq r_{i-1}$ and $d(u, p_{f^{-1}(i-1)}(u)) \leq r_{f^{-1}(i-1)}$, since $\text{score}(u) = i$.

Since u_0 is a $f^{-1}(i-1)$ 'th pivot: $i(u_0) \geq f^{-1}(i-1)$, so using the fact that f is non-decreasing: $i-1 \leq f(f^{-1}(i-1)) \leq f(i(u_0))$. Also, since $d(u_0, p_i(u_0)) > r_i - r_{f^{-1}(i-1)} > 0$, it cannot be that $i(u_0) \geq i$ (otherwise $u_0 = p_i(u_0)$, so $d(u_0, p_i(u_0)) = 0$). Then we got that $i-1 \in [i(u_0), f(i(u_0))]$.

Therefore, u_0 is connected to every vertex of $B_{i-1}(u_0)$. Since $p_{i-1}(u') \in A_{i-1}$, a sufficient condition for $p_{i-1}(u')$ to be in $B_{i-1}(u_0)$, which would imply that $(u_0, p_{i-1}(u')) \in H$, is $2d(u, u') + r_{f^{-1}(i-1)} + r_{i-1} \leq r_i - r_{f^{-1}(i-1)}$, i.e.

$$d(u, u') \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}.$$

In case that this criteria is satisfied, and we get a 3-hops path from u to u' with weight:

$$\begin{aligned} d_{G \cup H}^{(3)}(u, u') &\leq r_{f^{-1}(i-1)} + (2d(u, u') + r_{f^{-1}(i-1)} + r_{i-1}) + (d(u, u') + r_{i-1}) \\ &= 3d(u, u') + 2(r_{i-1} + r_{f^{-1}(i-1)}). \end{aligned}$$

If also $r_{i-1} + r_{f^{-1}(i-1)} \leq \frac{t}{2}d(u, u')$ (or equivalently $d(u, u') \geq \frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)})$), then this path is of weight $\leq 3d(u, u') + td(u, u') = (t+3)d(u, u')$. ◀

81:10 A Unified Framework for Hopsets

Given lemma 10, it's best to choose $\{r_i\}$ such that $\frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)}) \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}$, i.e.

$$r_i \geq \left(1 + \frac{4}{t}\right)r_{i-1} + \left(2 + \frac{4}{t}\right)r_{f^{-1}(i-1)} \quad (2)$$

From now on, we assume that $\{r_i\}$ we chose satisfies this inequality. In particular, $\{r_i\}$ is non-decreasing.

Fix $u, v \in V$, and let $u = u_0, u_1, u_2, \dots, u_d = v$ be the shortest path between them.

► **Lemma 11.** *Suppose that $\text{score}(u_j) = i$ and let $l = \max\{l' \geq j \mid d(u_j, u_{l'}) \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}\}$. Then if $l < d$, we have:*

1. $d_{G \cup H}^{(4)}(u_j, u_{l+1}) \leq (t+3)d(u_j, u_{l+1})$
2. $d(u_j, u_{l+1}) \geq \frac{4}{t}r_{f^{-1}(i-1)}$

Proof. Denote by W the weight of the edge (u_l, u_{l+1}) . We look at two different cases.

The first case is that $d(u_j, u_l) \geq \frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)})$. In this case, by lemma 10:

$$\begin{aligned} d_{G \cup H}^{(4)}(u_j, u_{l+1}) &\leq d_{G \cup H}^{(3)}(u_j, u_l) + W \leq (t+3)d(u_j, u_l) + W \\ &< (t+3)(d(u_j, u_l) + W) = (t+3)d(u_j, u_{l+1}) . \end{aligned}$$

The second case is that $d(u_j, u_l) < \frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)})$. By lemma 10, inequality (2) and l 's definition:

$$\begin{aligned} d_{G \cup H}^{(4)}(u_j, u_{l+1}) &\leq d_{G \cup H}^{(3)}(u_j, u_l) + W \stackrel{10}{\leq} 3d(u_j, u_l) + 2(r_{i-1} + r_{f^{-1}(i-1)}) + W \\ &\stackrel{(2)}{\leq} 3d(u_j, u_l) + t\left(\frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}\right) + W \\ &\leq 3d(u_j, u_l) + t(d(u_j, u_l) + W) + W \\ &< (t+3)(d(u_j, u_l) + W) = (t+3)d(u_j, u_{l+1}) . \end{aligned}$$

In both cases, we saw that $d(u_j, u_{l+1}) \geq \frac{2}{t}(r_{i-1} + r_{f^{-1}(i-1)})$, so $d(u_j, u_{l+1}) \geq \frac{4}{t}r_{f^{-1}(i-1)}$. ◀

The following theorem presents the size, the stretch and the hopbound for our hopset, $H(k, f)$. It uses lemma 11 repeatedly between every pair of vertices $u, v \in V$. Note that we choose the minimal sequence $\{r_i\}$, for minimizing the hopbound.

► **Theorem 12.** *Fix an integer $k > 0$, a non-decreasing $f : \mathbb{N} \rightarrow \mathbb{N}$ such that $\forall_i f(i) \geq i$, parameters $\{\lambda_j\}$ such that $\forall_j \lambda_j \leq 1 + \sum_{l < f^{-1}(j)} \lambda_l$ and F such that $\sum_{j < F} \lambda_j \geq k + 1$. We can build a $(2t + 3, O(r_F))$ -hopset for an undirected weighted graph G , simultaneously for every $t > 0$, with size $O(Fn^{1+1/k})$, where $\{r_i\}$ satisfies $r_0 = 1$ and $\forall_{i>0} r_i = (1 + \frac{4}{t})r_{i-1} + (2 + \frac{4}{t})r_{f^{-1}(i-1)}$.*

Proof. Given G, k, f , build $H(k, f)$ on G . By lemma 7, this hopset has the wanted size. Fix $u, v \in V$, and let $u = u_0, u_1, u_2, \dots, u_d = v$ be the shortest path between them. We use lemma 11 to find a path between u and v .

Starting with $j = 0$, find $l = \max\{l' \geq j \mid d(u_j, u_{l'}) \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}\}$, where $\text{score}(u_j) = i$. If $l = d$, stop the process and denote $v' = u_j$. Otherwise, set $j \leftarrow l + 1$, and continue in the same way.

This process creates a subsequence of u_0, \dots, u_d : $u = v_0, v_1, v_2, \dots, v_b = v'$, such that for every $j < b$ we have $d_{G \cup H}^{(4)}(v_j, v_{j+1}) \leq (t+3)d(v_j, v_{j+1})$ (by lemma 11). For $v' = v_b$ we have $d(v', v) \leq \frac{r_i - r_{i-1}}{2} - r_{f^{-1}(i-1)}$, where $\text{score}(v') = i$. For this last segment, we get from lemma 10 that

$$d_{G \cup H}^{(3)}(v', v) \leq 3d(v', v) + 2(r_{i-1} + r_{f^{-1}(i-1)}) \leq 3d(v', v) + 4r_F .$$

When summing over the entire path, we get:

$$\begin{aligned} d_{G \cup H}^{(4b+3)}(u, v) &\leq \sum_{j=0}^{b-1} (t+3)d(v_j, v_{j+1}) + 3d(v', v) + 4r_F \\ &= (t+3)d(u, v') + 3d(v', v) + 4r_F \leq (t+3)d(u, v) + 4r_F . \end{aligned}$$

To bound b , we notice that by lemma 11, for every $j < b$: $d(v_j, v_{j+1}) \geq \frac{4}{t} r_{F^{-1}(i-1)} \geq \frac{4}{t} r_0$.

So, the number of these “jumps” couldn’t be greater than $\frac{d(u,v)}{\frac{4}{t}r_0} = \frac{t \cdot d(u,v)}{4r_0}$, and we finally got:

$$d_{G \cup H}^{\left(\frac{t \cdot d(u,v)}{r_0} + 3\right)}(u, v) \leq (t+3)d(u, v) + 4r_F .$$

This is true for every sequence $\{r_i\}$ that satisfies inequality (2) (even if it doesn’t satisfy $r_0 = 1$).

Given such sequence $\{r_i\}$, we can define a new sequence as follows:

$$r'_i = \frac{t \cdot d(u, v) \cdot r_i}{4r_F} .$$

This sequence clearly still satisfies (2), so if we use it instead of $\{r_i\}$, we get that for our specific u, v :

$$\begin{aligned} d_{G \cup H}^{\left(\frac{t \cdot d(u,v)}{r'_0} + 3\right)}(u, v) &\leq (t+3)d(u, v) + 4r'_F \Rightarrow \\ \Rightarrow d_{G \cup H}^{(4r_F + 3)}(u, v) &\leq (t+3)d(u, v) + t \cdot d(u, v) = (2t+3)d(u, v) , \end{aligned}$$

i.e. the stretch of this new path is $2t + 3$, and its hopbound is $4r_F + 3$.

Although we chose $\{r'_i\}$ for a specific pair of vertices, this choice of $\{r'_i\}$ **doesn’t change our construction at all**, but only the analysis. So, we proved that for each $u, v \in V$, there is a path between them in $G \cup H$, with stretch $2t + 3$ and hopbound $4r_F + 3$, for our initial choice of $\{r_i\}$. ◀

4.1 Applications

Table 2 demonstrates the different results that can be achieved by substituting different parameters in our construction. The technical computations can be found in the full version of this paper. All of these applications achieve equivalent or even improved results as of [3].

■ **Table 2** The results achieved by substituting different parameters in our construction.

Parameter Choices	Resulting Stretch	Resulting Hopbound	Resulting Hopset Size
$f(i) = i,$ $t = \frac{\epsilon}{2}$	$3 + \epsilon$	$O(k^{\log_2(3 + \frac{16}{\epsilon})})$	$O(\log k \cdot n^{1 + \frac{1}{k}})$
$f(i) = \lfloor \frac{i}{c} \rfloor \cdot c + c - 1,$ $t = 4c$	$8c + 3$	$O(k^{1 + \frac{2}{\ln c}})$	$O(\log_c k \cdot n^{1 + \frac{1}{k}})$
$f(i) = \lfloor \frac{i}{c} \rfloor \cdot c + c - 1,$ $t = 4c, c = \lceil k^\epsilon \rceil$	$O(e^{\frac{2}{\epsilon}} k^\epsilon)$	$O(k^{1-\epsilon})$	$O(n^{1 + \frac{1}{k}} / \epsilon)$

Note that in all 3 resulting hopsets, the hopset size is improved by a $\log \Lambda$ factor in comparison to [3]. Also, for a stretch of $3 + \epsilon$, we get a single hopset with the mentioned properties *simultaneously* for all $\epsilon > 0$. Finally, in comparison to [3], our $(O_\epsilon(k^\epsilon), O(k^{1-\epsilon}))$ -hopset construction enjoys a simpler algorithm and doesn’t require a separation to cases ($\epsilon < \frac{1}{2}$ and $\frac{1}{2} \leq \epsilon$, as in [3]).

Data Structures for Node Connectivity Queries

Zeev Nutov

Abstract

Let $\kappa(s, t)$ denote the maximum number of internally disjoint st -paths in an undirected graph G . We consider designing a data structure that includes a list of cuts, and answers the following query: given $s, t \in V$, determine whether $\kappa(s, t) \leq k$, and if so, return a pointer to an st -cut of size $\leq k$ (or to a minimum st -cut) in the list. A trivial data structure that includes a list of $n(n-1)/2$ cuts and requires $\Theta(kn^2)$ space can answer each query in $O(1)$ time. We obtain the following results.

- In the case when G is k -connected, we show that $2n$ cuts suffice, and that these cuts can be partitioned into $2k+1$ laminar families. Thus using space $O(kn)$ we can answer each min-cut query in $O(1)$ time, slightly improving and substantially simplifying the proof of a recent result of Pettie and Yin [18]. We then extend this data structure to subset k -connectivity.
- In the general case we show that $(2k+1)n$ cuts suffice to return an st -cut of size $\leq k$, and a list of size $k(k+2)n$ contains a minimum st -cut for every $s, t \in V$. Combining our subset k -connectivity data structure with the data structure of Hsu and Lu [7] for checking k -connectivity, we give an $O(k^2n)$ space data structure that returns an st -cut of size $\leq k$ in $O(\log k)$ time, while $O(k^3n)$ space enables to return a minimum st -cut.

1 Introduction

Let $\kappa(s, t) = \kappa_G(s, t)$ denote the maximum number of internally disjoint st -paths in a graph $G = (V, E)$. W.l.o.g. we will assume that G is connected. An **st -cut** is a subset $Q \subseteq V \cup E$ such that $G \setminus Q$ has no st -path. By Menger's Theorem, $\kappa(s, t)$ equals to the minimum size of an st -cut, and there always exists a minimum st -cut that contains no edge except of st . We consider designing a compact data structure that given $s, t \in V$ and $k < n = |V|$ answers the following k -bounded connectivity/cut queries.

$\text{PCON}_k(s, t)$ (partial connectivity query):	Determine whether $\kappa(s, t) \leq k$.
$\text{PCUT}_k(s, t)$ (partial cut query):	If $\kappa(s, t) \leq k$ then return an st -cut of size $\leq k$.
$\text{CON}_k(s, t)$ (connectivity query):	Return $\min\{\kappa(s, t), k+1\}$.
$\text{CUT}_k(s, t)$ (min-cut query):	If $\kappa(s, t) \leq k$ then return a minimum st -cut.

The query $\text{PCUT}_k(s, t)$ requires $\Theta(k)$ time just to write an st -cut. However, by slightly relaxing the definition, we allow the data structure to include a list of cuts, and to return just a pointer to an st -cut of size $\leq k$ in the list. How short can this list be? By choosing a minimum st -cut for each pair $\{s, t\}$, one gets a list of $n(n-1)/2$ cuts. This gives a trivial data structure, that answers both queries in $O(1)$ time, but requires $\Theta(kn^2)$ space – just store the pairwise connectivities in an $n \times n$ matrix, with pointers to the relevant $O(n^2)$ cuts. For edge connectivity, the Gomory-Hu Cut-Tree [5] shows that there exists such a list of $n-1$ cuts that form a laminar family. However, no similar result is known for the node connectivity case considered here.

A graph is **k -connected** if $\kappa(s, t) \geq k$ for all $s, t \in V$. Recently, Pettie and Yin [18], and earlier in the 90's Cohen, Di Battista, Kanevsky, and Tamassia [3], considered the above problem in k -connected graphs. Pettie and Yin [18] suggested for $n \geq 4k$ an $O(kn)$ space data structure, that answers $\text{CON}_k(s, t)$ in $O(1)$ time and $\text{CUT}_k(s, t)$ in $O(k)$ time; they showed that it can be constructed in $\tilde{O}(m + \text{poly}(k)n)$ time. The arguments in [18] are complex, and here by a simpler proof we obtain the following improvement on the $\text{CUT}_k(s, t)$ query.

► **Theorem 1.** *For any k -connected graph, there exists an $O(kn)$ space data structure, that includes a list of $2n$ cuts, that answers $\text{CON}_k(s, t)$ and $\text{CUT}_k(s, t)$ queries in $O(1)$ time.*

All our data structures can be constructed in polynomial time; we will not discuss designing efficient construction algorithms here. We note that the Pettie-Yin [18] data structure also includes a list of $O(n)$ cuts, and maybe it can be modified to return a pointer to a minimum st -cut in $O(1)$ time. In any case, our data structure and arguments are simpler, and we sketch the main ideas below.

- We observe that there exists a forest F , such that for any $st \in E$ with $\kappa(s, t) = k$, either one of s, t has degree k (and a minimum st -cut is the set of k edges incident to s or to t), or $st \in F$; this follows from Mader's Critical Cycle Theorem [12]. Thus for pairs $st \in E$ there are at most n relevant cuts, and it is not hard to see that matching between a pair s, t and its cut can be done in $O(1)$ time.
- For $A \subseteq B$ let ∂A denote the set of neighbors of A in G . Let \mathcal{C} be a family of sets obtained by picking for every node v an inclusion minimal set C_v with $v \in C_v$, $|\partial C_v| = k$, and $|C_v| \leq (n - k)/2$, if such a set exists (we show that C_v is unique, if exists). For any $st \notin E$ with $\kappa(s, t) = k$, a minimum st -cut $Q \subset V$ has a connected component of $G \setminus Q$ of size $\leq (n - k)/2$ that contains s or t ; thus $C_s \in \mathcal{C}$ or $C_t \in \mathcal{C}$. To store \mathcal{C} in $O(kn)$ space, we will show that \mathcal{C} can be partitioned into $O(k)$ laminar families (each laminar family can be represented by a tree). To check whether $\kappa(s, t) = k$ we just need to check that $t \notin C_s \cup \partial C_s$ or $s \notin C_t \cup \partial C_t$; this can be done in $O(1)$ time, using a data structure that answers in $O(1)$ time ancestor/descendant queries in trees.

For a set $S \subseteq V$ of terminals we say that a graph is **k - S -connected** if $\kappa(s, t) \geq k$ for all $s, t \in S$. We will extend Theorem 1 to k - S -connected graphs as follows.

► **Theorem 2.** *For any k - S -connected graph with $|S| \geq 3k$, there exists an $O(k|S|)$ space data structure, that includes a list of $3|S|$ cuts, and answers $\text{CON}_k(s, t)$ and $\text{CUT}_k(s, t)$ queries for node pairs in S in $O(1)$ time.*

For arbitrary graphs, a trivial data structure that answers $\text{CON}_k(s, t)$ and $\text{CUT}_k(s, t)$ queries in $O(1)$ time uses $\Theta(kn^2)$ space. Hsu and Lu [7] showed that there exists an auxiliary directed graph $H = (V, F)$ and an ordered partition S_1, S_2, \dots of V , such that:

- Every part S_i has at most $2k - 1$ neighbors in H , and all of them are in $S_{i+1} \cup S_{i+2} \cup \dots$.
- $\kappa(s, t) \geq k + 1$ iff s, t belong to the same part, or $st \in F$, or $ts \in F$.

They also gave a polynomial time algorithm for constructing such H . Augmenting H by a perfect hashing data structure enables to answer " $st \in F$?" queries in $O(1)$ time. Since $|F| = O(kn)$, this gives an $O(kn)$ space¹ data structure that determines whether $\kappa(s, t) \geq k + 1$ in $O(1)$ time. Furthermore, a collection of such data structures for each $k' = 1, \dots, k + 1$ enables to find $\min\{\kappa(s, t), k + 1\}$ in $O(\log k)$ time, using binary search. However, this data

¹ As in previous works, we ignore the unavoidable $O(\log n)$ factor invoked by storing the indexes of nodes, and assume that any basic arithmetic or comparison operation with indexes can be done in $O(1)$ time.

structure alone cannot answer cut queries for pairs that belong to the same part S_i of the partition. Using our data structure for k - S -connectivity from Theorem 2, and a new bound on the number of relevant cuts, we get the following, see also Table 1.

► **Theorem 3.** *There exists an $O(k^2n)$ space data structure that includes a list of $(2k + 1)n$ cuts, that answers $\text{CON}_k(s, t)$ and $\text{PCUT}_k(s, t)$ queries in $O(\log k)$ time; a list of $k(k + 2)n$ cuts and $O(k^3n)$ space allows to answer also $\text{CUT}_k(s, t)$ in $O(\log k)$ time. Furthermore, space $O(k^2n + n^2)$ allows to answer $\text{CON}_k(s, t)$ and $\text{PCUT}_k(s, t)$ in $O(1)$ time, and space $O(k^3n + n^2)$ allows to answer $\text{CON}_k(s, t)$ and $\text{CUT}_k(s, t)$ in $O(1)$ time.*

Theorems 1, 2, and 3 are proved in section 2, 3, and 4, respectively.

■ **Table 1** Summary of the results in Theorem 3. Note that when k is bounded by a constant, the last row data structure has linear space and answers all queries in $O(1)$ time, which is optimal.

In parallel to our work, Pettie, Saranurak, and Yin [17] gave a randomized $O(kn \log n)$ space data structure that answer $\text{CON}_k(s, t)$ queries in time $O(\log n)$. This data structure extends the data structure of Iszak and Nutov [8], that in turn is based on an idea of Chuzhoy and Khanna [2]. We briefly describe these results. Given a set $S \subseteq V$ of **terminals**, the edges and the nodes in $V \setminus S$ are called **elements**. The **element connectivity** between $s, t \in S$ is the maximum number of pairwise element disjoint st -paths. The Gomory-Hu tree extends to element connectivity (c.f. [19, 1]), and implies an $O(|S|)$ space data structure that answers element connectivity queries between terminals in $O(1)$ time. The data structure of [8] decomposes a node connectivity instance into $O(k^2 \log n)$ element connectivity instances with $\Theta(n/k)$ terminals each; we will give a generalization of this decomposition in Section 5. For any element connectivity instance G_S with terminal set S and $s, t \in S$, $\kappa(s, t)$ is at most the element st -connectivity in G_S , and for at least one instance an equality holds (an instance with $s, t \in S$ and $Q \cap S = \emptyset$ for some minimum st -cut Q). So, to find $\kappa(s, t)$, one has to find the minimum element st -connectivity, among all instances in which s, t are terminals. There are $O(k^2 \log n)$ element connectivity instances, with $\Theta(n/k)$ terminals each, hence the overall number of terminals is $O(k^2 \log n) \cdot (n/k) = O(kn \log n)$. Iszak and Nutov [8] considered designing a labeling scheme², where efficient query time is not required, and used the connectivity classes data structure in each instance; this enables answering $\text{CON}_k(s, t)$ queries in $O(k \log n)$ time. Pettie, Saranurak, and Yin [17] used element connectivity Gomory-Hu trees instead, and also designed a novel data structure that given s, t finds an instance with the minimum element st -connectivity in $O(\log n)$ time. They also

² For additional work on labeling schemes for node-connectivity, see for example, [10, 11, 7].

showed that for large values of k , any data structure for answering node connectivity queries needs at least $\Omega(kn/\log n)$ space, matching up to an $O(\log n)$ factor the $O(kn)$ space of a sparse certificate graph [14].

Let us compare between the [17] $O(kn \log n)$ space data structure that answers $\text{CON}_k(s, t)$ queries in $O(\log n)$ time, to our results. First thing to observe is that the [17] data structure can be augmented by a list of $O(kn \log n)$ cuts to support $\text{CUT}_k(s, t)$ queries. Our cut list has size $O(k^2n)$, which is better when $k < \log n$. Moreover, our query time is $O(\log k)$. For example for $k = \log n$ both data structures have space $O(n \log^2 n)$, but our query time is $O(\log \log n)$ while that of [17] is $O(\log n)$. Note that for $k \leq 4$ are known linear space data structures that can answer cut queries in $O(1)$ time; see [6] and [9] for the cases $k = 3$ and $k = 4$, respectively. Our work, that was done independently from [17] and uses totally different techniques, extend this to any constant k , bridging the gap between the result of [17] and the results known for $k \leq 4$.

2 k -connected graphs (Theorem 1)

In this section let $G = (V, E)$ be a k -connected graph. We first explain how to answer the queries for pairs s, t with $st \in E$. Let K denote the set of nodes of degree k in G . If $s \in K$ then the set of edges incident to s is a minimum st -cut for all t . There are $|K| \leq n$ such minimum cuts. This situation can be recognized in $O(1)$ time, hence we may omit such pairs from our analysis and assume that each of s, t has degree $\geq k + 1$.

We say that $st \in E$ is a **critical edge** if $\kappa(s, t) = k$. Let F be the set of critical edges $st \in E$ such that $s, t \in V \setminus K$. Mader's Critical Cycle Theorem [12] states that any cycle of critical edges contains a node of degree k , hence F is a forest. Thus just specifying the edges in F and a list of $|F| \leq n - |K| - 1$ minimum st -cuts for every $st \in F$, gives an $O(kn)$ space data structure that answers the relevant queries in $O(1)$ time.

Henceforth assume that $s, t \in V \setminus K$ and $st \notin E$. We will show that then there exists a list of $n - |K|$ cuts, such that whenever $\kappa(s, t) = k$, there exists a minimum st -cut in the list. However, this is not enough to answer the relevant queries in $O(1)$ time, since we still need to choose the right minimum cut from the list.

For a node subset $A \subseteq V$ let ∂A denote the set of neighbors of A in G . Let $A^* = V \setminus (A \cup \partial A)$ denote the "node complement" of A . We say that A is: a **tight set** if $|\partial A| = k$ and $A^* \neq \emptyset$, an **st -set** if $s \in A$ and $t \in A^*$, and a **small set** if $|A| \leq \frac{n-k}{2}$. Note that A is tight if and only if ∂A is a minimum cut, and A is a union of some, but not all, connected components of $G \setminus \partial A$. The following statement is a folklore, c.f. [15, 16].

► **Lemma 4.** *Let A, B be tight sets. If the sets $A \cap B^*, B \cap A^*$ are both nonempty then they are both tight. If A, B are small and $A \cap B \neq \emptyset$ then $A \cap B$ is tight.*

Let $R = \{s \in V \setminus K : \text{there exist a small tight set containing } s\}$. For $s \in R$ let C_s be the (unique, by Lemma 4) inclusion minimal small tight set that contains s . Let $\mathcal{C} = \{C_s : s \in R\}$. The following lemma shows that the family $\{\partial C : C \in \mathcal{C}\}$ is a "short" list of $n - |K|$ minimum cuts, that for every $s, t \in V \setminus K$ with $st \notin E$ includes a minimum st -cut.

► **Lemma 5.** *Let $s, t \in V \setminus K$ with $st \notin E$. Then $\kappa(s, t) = k$ if and only if at least one of the following holds: (i) $s \in R$ and C_s is an st -set, or (ii) $t \in R$ and C_t is a ts -set. Consequently, $\kappa(s, t) = k$ if and only if the family $\{\partial C : C \in \mathcal{C}\}$ contains a minimum st -cut.*

Proof. If (i) holds then ∂C_s is a minimum st -cut, while if (ii) holds then ∂C_t is a minimum st -cut. Thus $\kappa(s, t) = k$ if (i) or (ii) holds.

Assume now that $\kappa(s, t) = k$ and we will show that (i) or (ii) holds. Let $Q \subset V \setminus \{s, t\}$ be a minimum st -cut. Then one component A of $G \setminus Q$ contains s and the other B contains t . Since $|A| + |B| \leq n - |Q| = n - k$, one of A, B , say A is small. Thus $s \in R$. Since $C_s \subseteq A$ and since $t \in A^*$, we have $t \in C_s^*$. Consequently, ∂C_s is a minimum st -cut, as required. ◀

Two sets A, B are **laminar** if they are disjoint or one of them contains the other; equivalently, A, B are not laminar if they intersect but none of them contains the other. A set family is laminar if its members are pairwise laminar. A laminar family \mathcal{L} on V can be represented by a rooted tree $T = (\mathcal{L} \cup \{V\}, J)$ and a mapping $\psi : V \rightarrow \mathcal{L} \cup \{V\}$. Here B is a child of A in T if B is a maximal set in $\mathcal{L} \setminus \{A\}$ contained A , and for every $v \in V$, $\psi(v)$ is a minimal set in \mathcal{L} that contains v .

► **Lemma 6.** \mathcal{C} can be partitioned into at most $2k + 1$ laminar families.

Proof. Consider two sets $A = C_a$ and $B = C_b$ that are not laminar. Then $a \notin A \cap B$ since otherwise by Lemma 4 $A \cap B$ is a (small) tight set that contains a , contradicting the minimality of $A = C_a$. By a similar argument, $b \notin A \cap B$. We also cannot have both $a \in A \cap B^*$ and $b \in B \cap A^*$, as then by Lemma 4 $A \cap B^*$ is a tight set that contains a , contradicting the minimality of $A = C_a$. Consequently, $a \in \partial B$ or $b \in \partial A$.

Construct an auxiliary directed graph H on node set R and edges set $\{ab : a \in \partial C_b\}$. The indegree of every node in H is at most k . This implies that every subgraph of the underlying graph of H has a node of degree $2k$. A graph is d -degenerate if every subgraph of it has a node of degree d . It is known that any d -degenerate graph can be colored with $d + 1$ colors, in linear time, see [4, 13]. Hence H is $(2k + 1)$ -colorable. Consequently, we can compute in polynomial time a partition of R into at most $2k + 1$ independent sets. For each independent set R_i , the family $\{C_s : s \in R_i\}$ is laminar. ◀

Our data structure for pairs $s, t \in V \setminus K$ with $st \notin E$ consists of:

- A family \mathcal{T} of at most $2k + 1$ trees, where each tree $T \in \mathcal{T}$ with a mapping $\psi_T : V \rightarrow V(T)$ represents one of the at most $2k + 1$ laminar families of tight sets as in Lemma 6; the total number of edges in all trees in \mathcal{T} is at most $n - |K|$.
- For each tree $T \in \mathcal{T}$, a linear space data structure that answers ancestor/descendant queries in $O(1)$ time. This can be done by assigning to each node of T the in-time and the out-time in a DFS search on T .
- A list $\{\partial C_s : s \in R\}$ of $|R| = n - |K|$ minimum cuts; this can be also encoded by an auxiliary directed graph $H = (V, F)$ with edge set $F = \{ts : t \in \partial C_s\}$. Using perfect hashing data structure we can check whether $ts \in F$ in $O(1)$ time.

For every $s \in S$ let T_s be the (unique) tree in \mathcal{T} where C_s is represented. The next statement, that is a direct consequence of Lemma 5, specifies how we answer the queries.

► **Lemma 7.** Let $s, t \in V \setminus K$ with $st \notin E$.

- (i) If in T_s , $\psi_{T_s}(t)$ is not a descendant of $\psi_{T_s}(s)$ and $t \notin \partial C_s$, then ∂C_s is a minimum st -cut.
- (ii) If in T_t , $\psi_{T_t}(s)$ is not a descendant of $\psi_{T_t}(t)$ and $s \notin \partial C_t$, then ∂C_t is a minimum st -cut. Furthermore, if none of (i),(ii) holds then $\kappa(s, t) \geq k + 1$.

It is easy to see that with appropriate pointers, and using perfect hashing data structure to check adjacency in the auxiliary directed graph H , we get an $O(kn)$ space data structure that checks the two conditions in Lemma 7 in $O(1)$ time. If one of the conditions holds, the data structure return a pointer to one of ∂C_s or ∂C_t . Else, it reports that $\kappa(s, t) \geq k + 1$.

This concludes the proof of Theorem 1.

3 Subset connectivity (Theorem 2)

In this section let $G = (V, E)$ be a k - S -connected graph with $|S| \geq 3k$. For the simpler case $S = V$ we related cuts to node subsets. Unfortunately, for the more general subset k -connectivity case, we need slightly more complex objects than sets, as follows.

► **Definition 8.** An ordered pair $\mathbb{A} = (A, A^+)$ of subsets of a groundset V is called a **bisetet** if $A \subseteq A^+$; A is the **inner set** and A^+ is the **outer set** of \mathbb{A} , and $\partial\mathbb{A} = A^+ \setminus A$ is the **boundary** of \mathbb{A} . $A^* = V \setminus A^+$ is the **co-set** of \mathbb{A} and $\mathbb{A}^* = (A^*, V \setminus A)$ is the **co-bisetet** of \mathbb{A} . We say that \mathbb{A} is an **st-bisetet** if $s \in A$ and $t \in A^*$.

In the case $S = V$, the relevant bisetets were $(A, A^+) = (A, A \cup \partial A)$, where A was a tight set. Here we will say that \mathbb{A} is a **tight bisetet** if $A \cap S \neq \emptyset$, $A^* \cap S \neq \emptyset$, and $|\partial\mathbb{A}| + |\delta(\mathbb{A})| = k$, where $\delta(\mathbb{A})$ is the set of edges in G that go from A to A^* . Note that \mathbb{A} is tight if and only if $\partial\mathbb{A} \cup \delta(\mathbb{A})$ is a minimum st -cut for some $s \in A \cap S$ and $t \in A^* \cap S$. We will consider the family $\mathcal{F} = \{(A \cap S, A^+ \cap S) : \mathbb{A} \text{ is tight}\}$ obtained by projecting the tight bisetets on S . Note that for $\mathbb{A} \in \mathcal{F}$ there might be many tight bisetets in G whose projection on S is \mathbb{A} , and that there always exists at least one such bisetet.

► **Definition 9.** The **intersection** and the **union** of two bisetets \mathbb{A}, \mathbb{B} are the bisetets defined by $\mathbb{A} \cap \mathbb{B} = (A \cap B, A^+ \cap B^+)$ and $\mathbb{A} \cup \mathbb{B} = (A \cup B, A^+ \cup B^+)$. The bisetet $\mathbb{A} \setminus \mathbb{B}$ is defined by $\mathbb{A} \setminus \mathbb{B} = (A \setminus B^+, A^+ \setminus B)$. We say that \mathbb{A}, \mathbb{B} : **intersect** if $A \cap B \neq \emptyset$, **cross** if $A \cap B \neq \emptyset$ and $A^* \cap B^* \neq \emptyset$, and **co-cross** if $A \cap B^* \neq \emptyset$ and $B \cap A^* \neq \emptyset$.

We say that $\mathbb{A} \in \mathcal{F}$ is a **small bisetet** if $|A| \leq \frac{|S|-k}{2}$, and \mathbb{A} is a **large bisetet** otherwise. Clearly, $|\partial\mathbb{A}| \leq k$ for all $\mathbb{A} \in \mathcal{F}$. The family \mathcal{F} has the following properties, c.f. [15, 16].

► **Lemma 10.** The family $\mathcal{F} = \{(A \cap S, A^+ \cap S) : \mathbb{A} \text{ is tight}\}$ has the following properties:

1. \mathcal{F} is **symmetric**: $\mathbb{A}^* \in \mathcal{F}$ whenever $\mathbb{A} \in \mathcal{F}$.
2. \mathcal{F} is **crossing**: $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B} \in \mathcal{F}$ whenever $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ cross.
3. \mathcal{F} is **co-crossing**: $\mathbb{A} \setminus \mathbb{B}, \mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$ whenever $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ co-cross.
4. If $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ are small intersecting bisetets then $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B} \in \mathcal{F}$.

► **Definition 11.** We say that a bisetet \mathbb{B} **contains a bisetet** \mathbb{A} and write $\mathbb{A} \subseteq \mathbb{B}$ if $A \subseteq B$ and $A^+ \subseteq B^+$. \mathbb{A}, \mathbb{B} are **laminar** if one of them contains the other or if $A \cap B = \emptyset$. A bisetet family is laminar if its members are pairwise laminar.

For every $s \in S$ let \mathcal{C}_s be the family of all inclusion minimal bisetets $\mathbb{C} \in \mathcal{F}$ with $s \in C$ and $|C| \leq |C^*|$. Let $\mathcal{C} = \cup_{s \in S} \mathcal{C}_s$. Note that $|\mathcal{C}_s| \leq |S| - 1$ and that \mathcal{C}_s can be computed using $|S| - 1$ min-cut computations. The following observation follows from the symmetry of \mathcal{F} .

► **Lemma 12.** Let $\mathbb{A} \in \mathcal{F}$ be an st -bisetet. If $|A| \leq |A^*|$ then there is an st -bisetet in \mathcal{C}_s , and if $|A^*| \leq |A|$ then there is a ts -bisetet in \mathcal{C}_t . Consequently, for any $s, t \in S$, \mathcal{C} contains an st -bisetet or a ts -bisetet.

The next lemma shows that $|\mathcal{C}_s| \leq 3$ if $|S| \geq 3k$.

► **Lemma 13.** For any $s \in S$, \mathcal{C}_s contains at most one small bisetet and at most $\frac{2(|S|-1)}{|S|-k}$ large bisetets. In particular, if $|S| \geq 3k$ then in \mathcal{C}_s there are at most two large bisetets and $|\mathcal{C}| \leq 3|S|$.

Proof. In \mathcal{C}_s there is at most one small bisetet, by property 4 in Lemma 10. No two large bisetets $\mathbb{A}, \mathbb{B} \in \mathcal{C}_s$ cross, as otherwise $s \in \mathbb{A} \cap \mathbb{B}$ and (by property 2 in Lemma 10) $\mathbb{A} \cap \mathbb{B} \in \mathcal{F}$, contradicting the minimality of \mathbb{A}, \mathbb{B} . Thus the sets in $\{C^* : \mathbb{C} \in \mathcal{C}_s\}$ are pairwise disjoint. Furthermore, $|C^*| \geq |C| \geq \frac{|S|-k}{2}$ for every large bisetet $\mathbb{C} \in \mathcal{C}_s$. This implies that the number of large bisetets in \mathcal{C}_s is at most $\frac{|S|-1}{(|S|-k)/2} \leq \frac{2(3k-1)}{2k} < 3$ if $|S| \geq 3k$. ◀

By a proof identical to that of Lemma 6 we have the following.

► **Lemma 14.** *The family of small bisets in \mathcal{C} can be partitioned in polynomial time into at most $2k + 1$ laminar families.*

Proof. Consider two small bisets $\mathbb{A} \in \mathcal{C}_a$ and $\mathbb{B} \in \mathcal{C}_b$ that are not laminar. Then $a \notin A \cap B$ since otherwise $\mathbb{A} \cap \mathbb{B} \in \mathcal{F}$, contradicting the minimality of \mathbb{A} . Similarly, $b \notin A \cap B$. We also cannot have both $a \in A \cap B^*$ and $b \in B \cap A^*$, as then \mathbb{A}, \mathbb{B} co-cross and thus $\mathbb{A} \setminus \mathbb{B}, \mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$, contradicting the minimality of \mathbb{A}, \mathbb{B} . Consequently, $a \in \partial B$ or $b \in \partial A$. The rest of the proof coincides with that of Lemma 6. ◀

Later, we will prove the following.

► **Lemma 15.** *If $|S| \geq 3k$ then the family of large bisets in \mathcal{C} can be partitioned in polynomial time into at most $3(2k + 1)$ laminar families.*

Lemmas 14 and 15 imply that \mathcal{C} can be partitioned into at most $4(2k + 1)$ laminar families. For our purposes, we just need the family of the inner sets of each family to be laminar. Together with Lemma 13 this implies Theorem 2 in the same way as Lemma 6 implies Theorem 1, except the following minor differences.

- Here we have $4(2k + 1)$ laminar families instead of $2k + 1$ laminar families, and for each $s \in S$ we have by Lemma 13 $|\mathcal{C}_s| \leq 3$ instead of $|\mathcal{C}_s| = 1$.
- For each biset $\mathbb{C} \in \mathcal{C}$, our list of cuts will include a mixed cut $\partial \mathbb{A} \cup \delta(\mathbb{A})$ of some tight biset of G whose projection on S is \mathbb{C} .

These differences affect space and query time only by a small constant factor. Thus all we need is to prove Lemma 15, which we will do in the rest of this section.

► **Lemma 16.** *Let $\mathbb{A} \in \mathcal{C}_a$ and $\mathbb{B} \in \mathcal{C}_b$ be two non-laminar large bisets in \mathcal{C} . If $|S| \geq 3k$ then $a \in \partial \mathbb{B}$ or $b \in \partial \mathbb{A}$, or (see Fig. 1(a)): $a, b \in A \cap B$, $A^* \cap B^* = \emptyset$, and both $A \cap B^*, B \cap A^*$ are non-empty.*

Proof. Assume that $a \notin \partial \mathbb{B}$ and $b \notin \partial \mathbb{A}$. We will show that then the case in Fig. 1(a) holds.

Suppose that $a \in A \cap B$; the analysis of the case $b \in A \cap B$ is similar. Then $A^* \cap B^* = \emptyset$; otherwise, \mathbb{A}, \mathbb{B} cross and (by property 2 in Lemma 10) we get $\mathbb{A} \cap \mathbb{B} \in \mathcal{F}$, contradicting the minimality of \mathbb{A} . Furthermore, if $B \cap A^* = \emptyset$ we get $\frac{|S| - k}{2} < |A| \leq |A^*| = |\partial \mathbb{B} \cap A^*| \leq k$, contradicting that $|S| \geq 3k$. By a similar argument, $A \cap B^* \neq \emptyset$. If $a \in A \cap B$ and $b \in B \cap A^*$ (Fig. 1(b)), then \mathbb{A}, \mathbb{B} co-cross (by property 3 in Lemma 10) and thus $\mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$; this contradicts the minimality of \mathbb{B} .

If none of a, b is in $A \cap B$, then (see Fig. 1(c)) $a \in A \cap B^*$ and $b \in B \cap A^*$. Consequently, \mathbb{A}, \mathbb{B} -co-cross, and thus (by property 3 in Lemma 10) $\mathbb{A} \setminus \mathbb{B}, \mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$, contradicting the minimality of \mathbb{A}, \mathbb{B} .

Thus the only possible case is the one in Fig. 1(a), completing the proof of the lemma. ◀

From Lemma 16, by a proof identical to that of Lemma 6 we get the following.

► **Corollary 17.** *The family of large bisets in \mathcal{C} can be partitioned in polynomial time into at most $2k + 1$ parts such that any two bisets $\mathbb{A} \in \mathcal{C}_a$ and $\mathbb{B} \in \mathcal{C}_b$ that belong to the same part \mathcal{P} are either laminar, or have the following property: $a, b \in A \cap B$ and $A^* \cap B^* = \emptyset$.*

Thus the following lemma finishes the proof of Lemma 15, and also of Theorem 2.

► **Lemma 18.** *Let \mathcal{P} be one of the $2k + 1$ parts as in Corollary 17; in particular, if $\mathbb{A}, \mathbb{B} \in \mathcal{P}$ are not laminar then $A \cap B \neq \emptyset$ and $A^* \cap B^* = \emptyset$. Then \mathcal{P} can be partitioned in polynomial time into at most 3 laminar families.*

■ **Figure 1** Illustration to the proof of Lemma 16; dark gray sets are non-empty.

Proof. Let \mathcal{M} be the family of maximal members in \mathcal{P} . We will show later that the set family $\mathcal{H} = \{A^* : A \in \mathcal{M}\}$ has a hitting set U of size $|U| \leq 3$. Now note that:

- For every $v \in S$ the family $\mathcal{P}_v = \{A \in \mathcal{P} : v \in A^*\}$ is laminar, since $v \in A^* \cap B^*$ for any $A, B \in \mathcal{P}_v$, while $A^* \cap B^* = \emptyset$ for any non-laminar $A, B \in \mathcal{P}$.
- Since U is a hitting set of \mathcal{H} , for any $A \in \mathcal{P}$ there is $v \in U \cap A^*$, and then $A \in \mathcal{P}_v$.

Summarizing, each one of the families \mathcal{P}_v is laminar and $\cup_{v \in U} \mathcal{P}_v = \mathcal{P}$. By removing bisets that appear more than once, we get a partition of \mathcal{P} into $|U| \leq 3$ laminar families.

It remains to show that \mathcal{H} has a hitting set of size ≤ 3 . A **fractional hitting set** of \mathcal{H} is a function $h : S \rightarrow [0, 1]$ such that $h(A) = \sum_{v \in A} h(v) \geq 1$ for all $A \in \mathcal{H}$. For $v \in S$ let \mathcal{H}_v be the family of sets in \mathcal{H} that contain v , and let $\mathcal{M}_v = \{A \in \mathcal{M} : A^* \in \mathcal{H}_v\}$. Note that:

- $h(v) = \frac{2}{|S|^{-k+1}}$ for all $v \in S$ is a fractional hitting set of \mathcal{H} and $h(S) = \frac{2|S|}{|S|^{-k+1}} < 3$.
- No two bisets in \mathcal{M}_v intersect and $|\mathcal{H}_v| \leq |\mathcal{M}_v|$. This implies $|\mathcal{H}_v| \leq |\mathcal{M}_v| \leq \frac{2|S|}{|S|^{-k+1}} < 3$, so $|\mathcal{H}_v| \leq 2$ for all $v \in S$.

Since $|\mathcal{H}_v| \leq 2$ for all $v \in S$, computing a minimum hitting set of \mathcal{H} reduces to the minimum Edge-Cover problem, and \mathcal{H} has a hitting set U of size $|U| \leq \frac{4}{3} \cdot h(S)$ ($\frac{4}{3}$ is the integrality gap of the Edge-Cover problem). Since $\frac{4}{3} \cdot h(S) < \frac{4}{3} \cdot 3$, \mathcal{H} has a hitting set U of size $|U| \leq 3$. ◀

4 Arbitrary graphs (Theorem 3)

For the proof of Theorem 3, we will later prove the following.

► **Theorem 19.** *There exists a list of at most $(2k+1)n$ cuts that contains an st -cut of size $\leq k$ for any $s, t \in V$ with $\kappa(s, t) \leq k$.*

A union of list as in Theorem 19 for every $k' = 1, \dots, k$ is a list that includes a minimum st -cut for any $s, t \in V$ with $\kappa(s, t) \leq k$. The size of this list is $\sum_{k'=1}^k (2k'+1)n = k(k+2)n$. Thus we have the following.

► **Corollary 20.** *There exists a list of at most $k(k+2)n$ cuts that contains a minimum st -cut for any $s, t \in V$ with $\kappa(s, t) \leq k$.*

We can combine these bounds with the trivial data structure. The combined data structure will include a list of cuts, a $V \times V$ matrix, and for each matrix entry (s, t) the number $\min\{\kappa(s, t), k+1\}$ and a pointer to an st -cut in the list. We can answer in $O(1)$ time $\text{PCUT}_k(s, t)$ queries using list of size $O(kn)$ and $\text{CUT}_k(s, t)$ queries using list of size $O(k^2n)$. This proves the second part of Theorem 3.

For the first part of Theorem 3 we combine our bounds with the Hsu-Lu [7] data structure. Recall that this data structure has two ingredients:

- An ordered partition $\mathcal{P} = (S_1, S_2, \dots)$ of V .
- A directed graph $H = (V, F)$ such that every S_i has at most $2k-1$ neighbors in H , and all of them are in $S_{i+1} \cup S_{i+2} \cup \dots$; this implies that $|F| \leq (2k-1)n$.

■ **Figure 2** Illustration to the proof of Lemma 21.

Then $\kappa(s, t) \geq k + 1$ iff s, t belong to the same part, or $st \in F$, or $ts \in F$. Overall, this data structure can be implemented using $O(kn)$ space and answers $\text{PCON}_k(s, t)$ queries in $O(1)$ time.

We augment this data structure by adding to each part $S \in \mathcal{P}$ a data structure for subset k - S -connectivity, with a unified cut list as in Theorem 19; we add Theorem 2 data structure if $|S| \geq 3k$, and the trivial data structure (an $S \times S$ matrix) if $|S| < 3k$.

The dominating space of the combined data structure is $O(k^2n)$, due to storing the Theorem 19 cut list; other parts need substantially lower space. Ignoring the space of the cut list, subset k -connectivity data structures for $S \in \mathcal{P}$ with $|S| \geq 3k$ need total space $\sum_{S \in \mathcal{P}} O(|S|) = O(n)$. For $|S| < 3k$ the trivial data structure has space $O(|S|^2) = O(k|S|)$. It is not hard to see that the worse case is when there are $\Theta(n/k)$ parts in \mathcal{P} of size $\Theta(k)$ each. Thus the total space invoked by parts with $|S| < 3k$ is also $O(n)$. Finally, the space required to store F is $O(|F|) = O(kn)$.

Now we observe that a collection of such data structures for each $k' = 1, \dots, k + 1$ enables to find $\min\{\kappa(s, t), k + 1\}$ in $O(\log k)$ time, using binary search. Once $k' = \kappa(s, t)$ is determined, we can also answer any $\text{CUT}_k(s, t)$ query in $O(1)$ time. The dominating space of this data structure is $O(k^3n)$, due to storing the Corollary 20 cut list.

This concludes the proof of Theorem 2, except that we need to prove Theorem 19, which we will do in the rest of this section.

For a biset \mathbb{A} let $\psi(\mathbb{A}) = |\partial\mathbb{A}| + |\delta(\mathbb{A})|$. Here we will say that \mathbb{A} is an **st -tight biset** if \mathbb{A} is an st -biset and $\psi(\mathbb{A}) = \kappa(s, t)$. Note that then $\partial\mathbb{A} \cup \delta(\mathbb{A})$ is a minimum st -cut, and that for any minimum st -cut Q there exists an st -tight biset \mathbb{A} with $\partial\mathbb{A} \cup \delta(\mathbb{A}) = Q$. It is known that the function ψ satisfies the submodular inequality $\psi(\mathbb{A}) + \psi(\mathbb{B}) \geq \psi(\mathbb{A} \cap \mathbb{B}) + \psi(\mathbb{A} \cup \mathbb{B})$, and (by symmetry) also the co-submodular inequality $\psi(\mathbb{A}) + \psi(\mathbb{B}) \geq \psi(\mathbb{A} \setminus \mathbb{B}) + \psi(\mathbb{B} \setminus \mathbb{A})$.

It is known that if \mathbb{A}, \mathbb{B} are both st -tight then so are $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B}$. Let \mathbb{C}_{st} denote the (unique) inclusion minimal st -tight biset. For $s \in S$ let $T_s = \{t \in V : \kappa(s, t) \leq k, |\mathbb{C}_{st}| \leq |\mathbb{C}_{ts}|\}$. Let \mathcal{C}_s be the family of all inclusion minimal bisets in the family $\{\mathbb{C}_{st} : t \in T_s\}$. Let $\mathcal{C} = \cup_{s \in S} \mathcal{C}_s$. One can verify that for any $s, t \in V$ with $\kappa(s, t) \leq k$, \mathcal{C} contains an st -biset or a ts -biset \mathbb{C} with $\psi(\mathbb{C}) \leq k$. We will show that $|\mathcal{C}_s| \leq 2k + 1$ for all $s \in V$. For that, we need the following lemma.

► **Lemma 21.** *Let $\mathbb{A} = \mathbb{C}_{sa}$ and $\mathbb{B} = \mathbb{C}_{sb}$ be distinct bisets in \mathcal{C}_s . Then $a \in \partial\mathbb{B}$ or $b \in \partial\mathbb{A}$.*

Proof. Suppose to the contrary that $a \notin \partial\mathbb{B}$ and $b \notin \partial\mathbb{A}$. If one of a, b is in $A^* \cap B^*$, say $a \in A^* \cap B^*$ (see Fig. 2(a)), then $\mathbb{A} \cup \mathbb{B}$ is an sa -biset and $\mathbb{A} \cap \mathbb{B}$ is an sb -biset. Thus

$$\kappa(s, a) + \kappa(s, b) = \psi(\mathbb{A}) + \psi(\mathbb{B}) \geq \psi(\mathbb{A} \cap \mathbb{B}) + \psi(\mathbb{A} \cup \mathbb{B}) \geq \kappa(s, b) + \kappa(s, a) .$$

Hence equality holds everywhere, so $\mathbb{A} \cap \mathbb{B}$ is sb -tight. This contradicts the minimality of \mathbb{B} .

Else, $a \in A^* \cap B$ and $b \in B^* \cap A$ (see Fig. 2(b)). Then $A \setminus B$ is a bs -biset and $B \setminus A$ is an as -biset. Thus

$$\kappa(s, a) + \kappa(s, b) = \psi(A) + \psi(B) \geq \psi(A \setminus B) + \psi(B \setminus A) \geq \kappa(b, s) + \kappa(a, s).$$

Hence equality holds everywhere, so $A \setminus B$ is as -tight and $B \setminus A$ is bs -tight. This implies $|C_{sa}| > |C_{bs}|$ and $|C_{sb}| > |C_{as}|$, and we get the contradiction $|C_{sa}| + |C_{sb}| > |C_{bs}| + |C_{as}|$. ◀

► **Lemma 22.** $|\mathcal{C}_s| \leq 2k + 1$ for all $s \in V$.

Proof. The proof is similar to the one of Lemma 6. Construct an auxiliary directed graph H on node set T_s and edge set $\{ab : a \in \partial C_{sb}\}$. Note that if H has no edge between a and b then $C_{sa} = C_{sb}$. The indegree of every node in H is at most k . Thus by the same argument as in Lemma 6 we get that the underlying graph of H is $(2k + 1)$ -colorable, and thus T_s can be partitioned into at most $2k + 1$ independent sets. For each independent set T' , the family $\{C_{st} : t \in T'\}$ consists of a single biset. ◀

This concludes the proof of Theorem 19, and thus also of Theorem 3.

5 Decomposition of node connectivity into element connectivity

Recall that given a set $S \subseteq V$ of terminals, The element connectivity between $s, t \in S$ is the maximum number of pairwise element disjoint st -paths, where elements are the edges and the nodes in $V \setminus S$. Let $\kappa_G^S(s, t)$ denote the st -element-connectivity in G . By Menger's Theorem, $\kappa_G^S(s, t)$ equals the minimum size $|C|$ of a set C of elements with $C \cap S = \emptyset$ such $G \setminus C$ has not st -path. It is easy to see that $\kappa_G^S(s, t) \geq \kappa_G(s, t)$, and that an equality holds iff there exists a minimum st -cut C with $C \cap S = \emptyset$. We thus will consider the following problem: given a family \mathcal{C} of subsets of V , find a “small” family \mathcal{S} of subsets of V such that for every $s, t \in V$ and $C \in \mathcal{C}$ with $s, t \notin C$, there is $S \in \mathcal{S}$ with $s, t \in S$ and $C \cap S = \emptyset$; following [2], we will call such a family \mathcal{C} -resilient. The objective can be also to minimize $\sum_{S \in \mathcal{S}} |S|$. Chuzhoy and Khanna [2] showed that if $\{C \subseteq V : |C| \leq k\}$ is the family of all subsets of size $\leq k$, then there exists a \mathcal{C} -resilient family \mathcal{S} of size $|\mathcal{S}| = O(k^3 \ln n)$. They also gave a randomized polynomial time algorithm for finding such \mathcal{S} . The number of subsets of size $\leq k$ is $\binom{n}{k} \approx n^k$, while the relevant family in our case – as in Corollary 20, has a much smaller size $|\mathcal{C}| \leq k(k + 2)n$. We will consider the case of an arbitrary family $\mathcal{C} \subseteq \{C \subseteq V : |C| \leq k\}$, and prove the following.

► **Lemma 23.** *Let \mathcal{C} be a family of sets of size at most k each on a groundset V of size n . Then there exists a \mathcal{C} -resilient family \mathcal{S} of $O(k^2 \ln(n|\mathcal{C}|))$ subsets of V of size $r = \frac{n-k}{k+1}$ each. Furthermore, assigning to each set in $\mathcal{A} = \{S \subseteq V : |S| = r\}$ probability $\Delta = 1/\binom{n-k-2}{r-2}$ and applying randomized rounding $4 \ln(n|\mathcal{C}|)$ times gives such \mathcal{S} w.h.p.*

Proof. If $n \leq 3k + 1$, then the subsets of V of size 2 is a family as required of size $\frac{3k(3k+1)}{2}$, so assume that $n \geq 3k + 2$.

Let $\mathcal{A} = \{S \subseteq V : |S| = r\}$ and $\mathcal{B} = \{(\{s, t\}, C) : s, t \in V, C \in \mathcal{C}\}$. Define a bipartite graph with sides \mathcal{A}, \mathcal{B} by connecting $S \in \mathcal{A}$ to $(\{s, t\}, C) \in \mathcal{B}$ if $s, t \in S$ and $C \cap S = \emptyset$; in this case we will say that S covers $(\{s, t\}, C)$. This defines an instance of the SET COVER problem, where \mathcal{A} are the sets and \mathcal{B} are the elements. The lemma says that there exists a cover $\mathcal{S} \subseteq \mathcal{A}$ of \mathcal{B} that has size $|\mathcal{S}| = O(k^2 \log(n|\mathcal{C}|))$.

A fractional cover of \mathcal{B} is a function $h : \mathcal{A} \rightarrow [0, 1]$ such that

$$\sum \{h(S) : S \in \mathcal{A} \text{ covers } (\{s, t\}, C)\} \geq 1 \quad \forall (\{s, t\}, C) \in \mathcal{B}.$$

The **value** of a fractional cover h is $\sum_{S \in \mathcal{A}} h(S)$. It is known that if there is a fractional cover of value τ , then there is a cover of size $\tau(1 + \ln |\mathcal{B}|)$. We have $|\mathcal{B}| = \frac{n(n-1)}{2} |\mathcal{C}|$, hence $\ln |\mathcal{B}| \leq 2 \ln(n|\mathcal{C}|) - \ln 2$ and $\lceil 2 \ln |\mathcal{B}| \rceil \leq 4 \ln(n|\mathcal{C}|)$.

Our next goal is to show that there is a fractional cover of value $O(k^2)$. We have $|\mathcal{A}| = \binom{n}{r}$. The number of sets in \mathcal{A} that cover a given member $(\{s, t\}, C) \in \mathcal{B}$ is $\Delta = \binom{n-k-2}{r-2}$, which is the number of choices of a set $S \setminus \{s, t\}$ of size $r-2$ from the set $V \setminus (C \cup \{s, t\})$ of size $n-k-2$. Defining $h(S) = 1/\Delta$ for all $S \in \mathcal{A}$ gives a fractional cover of value $|\mathcal{A}|/\Delta$. Denote $m = n - k$. Then:

$$\frac{|\mathcal{A}|}{\Delta} = \frac{\binom{n}{r}}{\binom{m-2}{r-2}} = \frac{m(m-1)}{r(r-1)} \cdot \frac{n!}{(n-r)!} \cdot \frac{(m-r)!}{m!} \leq \frac{m^2}{(r-1)^2} \prod_{i=1}^r \frac{n-i+1}{m-i+1}.$$

Note that for $1 \leq i \leq r$ we have $\frac{n-i+1}{m-i+1} = 1 + \frac{n-m}{m-i+1} \leq 1 + \frac{k}{n-k-r}$. Let us choose r such that $\frac{k}{n-k-r} = \frac{1}{r}$, so $r = \frac{n-k}{k+1}$; assume that r is an integer, as adjustment to floors and ceilings only affects by a small amount the constant hidden in the $O(\cdot)$ term. Since $(1 + 1/r)^r \leq e$ we obtain

$$\prod_{i=1}^r \frac{n-i+1}{m-i+1} \leq \left(1 + \frac{1}{r}\right)^r \leq e.$$

Since we assume that $n \geq 3k + 2$, we have $\frac{n-k}{k+1} \geq 2$ and thus $\frac{m}{r-1} \leq 2(k+1)$. Consequently, we get that $\frac{|\mathcal{A}|}{\Delta} \cdot (1 + \ln |\mathcal{B}|) = O(k^2 \ln(n|\mathcal{C}|))$. This implies that a standard greedy algorithm for SET COVER, produces the required family of size $O(k^2 \ln n|\mathcal{C}|)$. There is a difficulty to implement this algorithm in time polynomial in n (unless $r = \frac{n-k}{k+1}$ is a constant), since $|\mathcal{A}| = \binom{n}{r}$ may not be polynomial in n . Thus we use a randomized algorithm for SET COVER, by rounding each entry to 1 with probability determined by our fractional cover. It is known that repeating this rounding $2 \lceil \ln |\mathcal{B}| \rceil \leq 4 \ln(n|\mathcal{C}|)$ times gives a cover w.h.p., and clearly its expected size is $2 \lceil \ln |\mathcal{B}| \rceil$ times the value of the fractional hitting set. In our case, $h(S) = 1/\Delta = 1/\binom{n-k-2}{r-2}$ for all $S \in \mathcal{A}$. Thus we just need to assign to each set in \mathcal{A} probability $1/\Delta$, and apply randomized rounding $4 \ln(n|\mathcal{C}|)$ times. \blacktriangleleft

Applying Lemma 23 on the family \mathcal{C} as in as in Corollary 20, that has size $|\mathcal{C}| \leq k(k+2)n$, we get that there exists a \mathcal{C} -resilient family \mathcal{S} of $O(k^2 \ln(n|\mathcal{C}|)) = O(k^2 \ln n)$ subsets of V of size $r = \frac{n-k}{k+1}$ each. On the other hand, if $|\mathcal{C}|$ is the family of all subsets of V of size k , then $|\mathcal{C}| = \binom{n}{k} < (ne/k)^k$ and we get the bound $O(k^2 \ln(n|\mathcal{C}|)) = O(k^3 \ln n)$ of Chuzhoy and Khanna [2].

Improved Bounds for Online Balanced Graph Re-Partitioning

Abstract

We study the online balanced graph re-partitioning problem (OBGR) which was introduced by Avin, Bienkowski, Loukas, Pacut, and Schmid [2] and has recently received significant attention [16, 12, 13, 10, 4] owing to potential applications in large-scale, data-intensive distributed computing. In OBGR, we have a set of ℓ clusters, each with k vertices (representing processes or virtual machines), and an online sequence of communication requests, each represented by a pair of vertices. Any request (u, v) incurs unit communication cost if u and v are located in different clusters (and zero otherwise). Any vertex can be migrated from one cluster to another at a migration cost of $\alpha \geq 1$. We consider the objective of minimizing the total communication and migration cost in the competitive analysis framework. The only known algorithms (which run in exponential time) include an $O(k^2\ell^2)$ competitive [2] and an $O(k\ell 2^{O(k)})$ competitive algorithm [4]. A lower bound of $\Omega(k\ell)$ is known [16]. In an effort to bridge the gap, recent results have considered *beyond worst case* analyses including resource augmentation (with augmented cluster capacity [2, 13, 12]) and restricted request sequences (the *learning* model [13, 12, 16]).

In this paper, we give *deterministic, polynomial-time* algorithms for OBGR, which *mildly* exploit resource augmentation (i.e. augmented cluster capacity of $(1 + \varepsilon)k$ for arbitrary $\varepsilon > 0$). We improve beyond $O(k^2\ell^2)$ -competitiveness (for general ℓ, k) by first giving a simple algorithm with competitive ratio $O(k\ell^2 \log k)$. Our main result is an algorithm with a significantly improved competitive ratio of $O(k\ell \log k)$. At a high level, we achieve this by employing i) an ILP framework to guide the allocation of large components, ii) a simple “any fit” style assignment of small components and iii) a charging argument which allows us to bound the cost of migrations. Like previous work on OBGR, our algorithm and analysis are phase-based, where each phase solves an independent instance of the learning model. Finally, we give an $\Omega(\alpha k \ell \log k)$ lower bound on the total cost incurred by any algorithm for OBGR under the learning model, which quantifies the limitation of a phase-based approach.

1 Introduction

Modern data intensive applications which are distributed across data centers or clusters generate a large amount of network traffic [21, 18, 3]. To enable efficient communication among processes or virtual machines that may be dispersed in these clusters, many distributed systems are increasingly re-configurable and demand-aware [5]. Since inter-cluster communication can incur significant cost due to physical distance and limited bandwidth, clusters may strategically migrate processes to reduce the cost of communication, subject to cluster capacity constraints. The online balanced graph re-partitioning (OBGR) problem, introduced by Avin, Bienkowski, Loukas, Pacut, and Schmid [2], is an algorithmic investigation of trade-offs between migration and inter-cluster communication in an environment where the sequence of communication requests is unknown or hard to predict.

In OGBR, we are given ℓ clusters (representing servers or data centers), each holding at most k vertices (representing processes or virtual machines), and an online sequence of edges (representing communication requests). The algorithm maintains a partition of the vertices among the ℓ clusters so that each set of the partition contains at most k vertices. The *communication cost* of serving a request (u, v) is 0 if u and v are in the same cluster and 1, otherwise. Prior to serving any request, an algorithm has the option of migrating any vertex from one cluster to another for a *migration cost* of $\alpha \in \mathbb{Z}^+$. Given an online sequence σ of requests, the cost incurred by an (online) algorithm \mathcal{A} , denoted by $c(\mathcal{A}, \sigma)$ is the sum of the communication costs and migration costs over σ . Let $OPT(\sigma)$ denote the cost incurred by an optimal offline algorithm, which knows σ in advance. We measure the performance of the algorithm in terms of the (*strict*) competitive ratio which is the minimum value of $\rho > 0$ such that for any input sequence σ and a fixed constant $\tau > 0$ (independent of the length of σ) we have $c(\mathcal{A}, \sigma) \leq \rho \cdot OPT(\sigma) + \tau$. We usually refer to $OPT(\sigma)$ as OPT when σ is clear from context.

The static version of balanced graph partitioning and its variants are well studied [14, 20, 15, 1]. In this problem, given a weighted graph on a set V of n vertices and an integer ℓ , the goal is to partition V into vertex sets V_1, \dots, V_ℓ such that the total weight of edges of the form (u, v) where $u \in V_i, v \in V_j, j \neq i$ is minimized. The problem is NP-hard and even hard to approximate within a finite factor. Note that for $k = 2$, this corresponds to maximum matching and for $\ell = 2$, this reduces to the minimum bisection problem which is already NP-hard [11]. Several approximation and bi-criteria approximation algorithms are known [9, 8, 6, 7] (for a discussion of results, see [2]). Since balanced graph partitioning is NP-hard in the static setting, exponential time competitive algorithms have been considered in the online setting [2, 16, 13]. Note that a balanced partition of the graph induced by the entire request sequence may not necessarily correspond to the optimal offline algorithm's strategy since this strategy overlooks the initial assignment of vertices in clusters (and thus, the migration cost required to mimic a balanced partition), the length of the sequence and its evolution over time. On the other hand, there is an approximation-preserving polynomial time reduction from the static version of OBGR to the offline version of OBGR that repeats the edges of the hard static instance sufficiently many times to derive a hard offline instance. Since the offline problem is unlikely to admit any known polynomial time optimal algorithms, beyond worst-case analysis has been employed to study competitiveness and running times of OBGR. We briefly discuss two such settings in which OBGR has been studied.

Resource Augmentation

In the resource augmented setting, an $(1 + \varepsilon)$ -*augmented* online algorithm is granted $(1 + \varepsilon)k$ capacity on each cluster for some constant $\varepsilon > 0$, and its performance is compared with the optimal offline algorithm with capacity exactly k per cluster. This is similar in vein to the offline bi-criteria versions of the offline balanced graph partitioning problem [6, 7] where the algorithm is required to partition V into ℓ clusters that minimizes the weighted sum of cut edges, such that the number of excess vertices assigned to any cluster is at most δk for some $\delta > 0$. The cost of an algorithm's obtained partition is compared to the cost of an optimal partition of V in which clusters are assigned exactly k vertices. We note that resource augmentation has been studied extensively in online algorithms (e.g., see [17, 24, 25]), and goes back as far as the earliest work on caching [22].

Constrained Input

A special case of OBGR that has been recently considered is the so-called *learning model*, introduced by Henzinger, Neumann, Räcke, and Schmid [12] and studied later in [4, 16]. In this model, the online sequence satisfies the condition that there exists a feasible assignment of vertices to clusters without any inter-cluster requests in the sequence. Thus, upon executing such an assignment of vertices, any algorithm incurs zero cost. In other words, an online algorithm in this model is required to *learn* an optimal partitioning of V into k clusters with no inter-cluster edges. In contrast to the *general model* (i.e. with an arbitrary request sequence), the learning model focuses only on migration costs.

1.1 Related work

OBGR without resource augmentation

In [2], an $O(k^2\ell^2)$ upper bound and an $\Omega(k)$ lower bound are established on the competitive ratio of any deterministic algorithm for OBGR without resource augmentation. The lower bound has been improved to $\Omega(k\ell)$ in recent work by Pacut, Parham, and Schmid [16]. The special cases of $k = 2$ (online re-matching problem) and $k = 3$ have also been studied [2, 16]. In very recent work, Bienkowski, Böhm, Koutecký, Rothvoß, Sgall, and Veselý [4] give an $O(k\ell 2^{O(k)})$ -competitive algorithm for OBGR, which is optimal for constant k .

OBGR with resource augmentation

The $\Omega(k)$ lower bound of [2] holds even when the algorithm is allowed an arbitrary amount of resource augmentation as long as $\ell \geq 2$ and all vertices do not fit into a single cluster. The main result of [2] is an $O(k \log k)$ -competitive deterministic algorithm for OBGR with $(2 + \varepsilon)k$ augmented cluster capacity for $\varepsilon \in (0, 1)$. Very recently, Forner, Räcke, and Schmid [10] give a *polynomial time* deterministic $O(k \log k)$ -competitive algorithm in the same setting.

The learning model

In [16], the authors present a tight $\Theta(k\ell)$ bound for the best deterministic competitive ratio in the learning model without resource augmentation. Moreover, they show that a lower bound of $\Omega(\ell)$ holds even in the $(1 + \varepsilon)$ -augmented setting for $\varepsilon < 1/3$. Henzinger, Neumann and Schmid [13] introduced the learning model of OBGR and give a $O((\ell \log \ell \log n)/\varepsilon)$ -competitive algorithm and a lower bound of $\Omega(1/\varepsilon + \log n)$ assuming $(1 + \varepsilon)k$ augmented capacity for $\varepsilon \in (0, 1/2)$. In more recent work, [12] establishes tight bounds of $\Theta(\log \ell + \log k)$ and $\Theta(\ell \log k)$ on the best competitive ratio of randomized and deterministic algorithms, respectively, for the learning model with resource augmentation.

Summarizing, for deterministic competitive ratios, the best known upper bound for OBGR is $O(k^2\ell^2)$ without resource augmentation and $O(k \log k)$ with $(2 + \varepsilon)$ -augmentation, while the best known lower bound is $\Omega(k\ell)$ without resource augmentation and $\Omega(k + \ell \log k)$ with $(1 + \varepsilon)$ -augmentation for $\varepsilon < 1/3$.

1.2 Our results

In this paper, we give online deterministic $(1 + \varepsilon)$ -augmented algorithms for OBGR in the general model, for an arbitrary constant $\varepsilon > 0$. We first observe that a ρ -competitive algorithm for OBGR in the learning model can be used to get a $\rho k \ell$ -competitive algorithm in the general model. The proof is deferred to Appendix A.

► **Observation 1.** *Any ρ -competitive algorithm for OBGR in the learning model can be transformed to a $O(\rho k\ell)$ -competitive algorithm for OBGR in the general model.*

Using the $(1 + \varepsilon)$ -augmented deterministic $O(\ell \log k)$ -competitive algorithm of [12] for the learning model, Observation 1 immediately yields $(1 + \varepsilon)$ -augmented deterministic $O(k\ell^2 \log k)$ -competitive and randomized $O(k\ell(\log k + \log \ell))$ -competitive algorithms for the general model. The algorithm of [12] for the learning model is quite sophisticated and relies on an intricate analysis. In Section 3, we give an alternative simpler algorithm for the general model referred to as \mathcal{A}_S , which admits a direct analysis and attains the same competitive ratio.

► **Theorem 2.** *There exists a deterministic, polynomial time, $(1 + \varepsilon)$ -augmented $O(k\ell^2 \log k)$ -competitive algorithm for OBGR in the general model, for arbitrary constant $\varepsilon > 0$.*

Our main result, given in Section 4, is a polynomial time *deterministic* $(1 + \varepsilon)$ -augmented $O(k\ell \log k)$ -competitive algorithm \mathcal{A}_G , for constant $\varepsilon > 0$; the competitive ratio nearly matches the lower bound of $\Omega(k\ell)$ without resource augmentation [16]. Under resource augmentation, our algorithm is optimal for constant k while for constant ℓ it is within a $O(\log k)$ factor of the optimal (following from the lower bound of $\Omega(k + \ell \log k)$ in the resource augmented setting). For many applications in which k is usually large (such as distributed communication between nodes placed in cloud servers), our algorithms have near-linear instead of an exponential [4] or quadratic [2] dependence on k in previous work.

► **Theorem 3.** *There exists a deterministic, polynomial time $(1 + \varepsilon)$ -augmented $O(k\ell \log k)$ -competitive algorithm for OBGR in the general mode, for arbitrary constant $\varepsilon > 0$.*

The algorithm of Theorem 3 is a “phase-based” algorithm in which each phase solves OBGR in the learning model. The key component of our proof is an upper bound of $O(\alpha k\ell \log k)$ on the total cost of the algorithm in the learning model, starting from an arbitrary initial assignment of vertices. It is natural to ask whether this bound can be improved since any improvement would also yield an improved competitive ratio for OBGR in the general model. The following lower bound, which can be derived from a lower bound instance of [12], rules this out, thus presenting a limitation of a phase-based analysis approach.

► **Theorem 4.** *For any online deterministic (resp., randomized) algorithm with $(1 + \varepsilon)$ -augmentation for the learning model where $\varepsilon > 0$ is an arbitrary constant, there exists a sequence of requests for which the cost (resp., expected cost) is $\Omega(\alpha k\ell \log k)$.*

1.3 Overview of techniques

We highlight the main techniques we use to get a significantly improved competitive ratio for OBGR in the general model. Our algorithms partition the online sequence of requests into contiguous phases, and keep track of the graph induced by the communication requests within a phase. In particular, the algorithms ensure that during any phase all vertices in a connected component of the graph associated with the phase are assigned to the same cluster. On any request (u, v) where u is in component P_1 and v in P_2 , P_1 and P_2 are merged into P_m and subsequently co-located. Components are classified as small or large based on a threshold size Dk where $D = \Theta(\varepsilon^2)$.

For the algorithm \mathcal{A}_S , if P_m is large, we solve an ILP to guide the assignment of large components. Small components may also need to be reassigned. If P_m is small, P_1 is migrated to P_2 's cluster as long as there is enough space. If that is not possible, small components are

reassigned. We ensure that the maximum assigned volume on any cluster is $(1 + \frac{\varepsilon}{4})k$ after the ILP is solved or small components are reassigned. By definition, large component merges happen only $O(1)$ times while at least $\frac{\varepsilon k}{4}$ total volume of small components is successfully migrated between any two small component reassignments. Using a charging argument, we show that every vertex can be charged at most $O(\ell \log k)$ before an optimal offline algorithm incurs a cost of 1 during that phase, yielding Theorem 2.

The approach for algorithm \mathcal{A}_G is as follows. Each small component assigned to a cluster is allocated a volume which is within a $(1 + \frac{\varepsilon}{4})$ factor of the component size. Once a large component is created during a phase, successive assignments of large components created by any merge are handled by ILP used in \mathcal{A}_S . We note that our ILP is similar to that of [12] and we follow their approach to invoke a result on sensitivity analysis of ILPs [19], which limits the change in assignments when a large component is created. This is not sufficient to establish Theorem 3, however, since small components can be completely displaced leading to high migration cost after every merge. Interestingly, we show that a simple “any fit” strategy for small components coupled with a charging argument is sufficient to bound the total migration cost by $O(k\ell \log k)$.

Finally, to establish the lower bound of Theorem 4, we show that for any competitive algorithm \mathcal{A} there exists a request sequence composed of $\Omega(\log k)$ batches of requests and an initial assignment which is $\Omega(k\ell)$ far apart from \mathcal{A} 's assignment such that \mathcal{A} incurs cost at least $\Omega(\alpha k\ell)$ on every batch.

2 Preliminaries

In this section, we present some definitions and high-level structure of our algorithms, which will be useful throughout the paper. Let $[n]$ denote the set of integers $\{1, 2, \dots, n\}$. Let V denote the set of $n = k\ell$ vertices. Let \mathcal{C} denote the set of ℓ clusters. Each cluster $C \in \mathcal{C}$ is initially assigned exactly k vertices. A request is an unordered pair of vertices (u, v) . A connected component P_i induced by a sequence of requests is the maximal set of vertices such that for any $u \in P_i$ there exists $v \in P_i$ s.t. (u, v) was a request in the sequence. The volume of any component P_i is its size $|P_i|$. Our algorithms maintain a set of connected components $\mathcal{P} = \{P_1, P_2, \dots, P_{|\mathcal{P}|}\}$ where $P_i \subseteq V$ for all i and $\bigcup_{i=1}^{|\mathcal{P}|} P_i = V$. Initially, $\mathcal{P} = \{\{u\} | u \in V\}$ i.e. the set of singleton vertices. We refer to a request (u_t, v_t) with $u_t \in P_1$ and $v_t \in P_2$ as an *inter-cluster request* (between P_1 and P_2) if P_1 and P_2 are assigned to different clusters at the start of time t .

Large and small components

Both our algorithms organize components into classes based on their volumes. A component P is in class i if $|P| \in [(1 + \frac{\varepsilon}{4})^{i-1}, (1 + \frac{\varepsilon}{4})^i)$. A component is small if it belongs to a class i where $i \leq c_s = \lfloor \frac{4}{\varepsilon} \ln(\frac{\varepsilon^2 k}{32}) - 2 \rfloor$ where c_s denotes the number of small component classes. Hence, a component is small if it has volume at most Dk where $D < \frac{\varepsilon^2}{32} < \frac{\varepsilon}{4}$ and large otherwise. Note that the number of large component classes, denoted by c_l satisfies $c_l \leq \frac{4+\varepsilon}{\varepsilon} \ln(\frac{1}{D}) + 2 = O(1)$. A *large component* P is understood to be in (large) component class i if it is in class $i + c_s$. We assume $\varepsilon \geq \frac{4}{k}$. For any cluster C , we use $V(C)$, $V_S(C)$, and $V_L(C)$ to denote the total volume of all, small, and large components, assigned to C , respectively.

Phase-based algorithms

Both our algorithms are phase-based: they divide the sequence of requests into phases, and treat each phase as an independent sequence of requests.

► **Definition 5 (Phase).** *A phase p of a sequence σ of requests is a maximal contiguous subsequence of σ such that there exists a feasible assignment of the set of large components induced by p to clusters in \mathcal{C} satisfying the constraint that the total volume of large components assigned to any cluster is at most $(1 + \frac{\varepsilon}{4})k$.*

A request sequence can be naturally partitioned into consecutive phases. Our algorithms begin a phase by setting \mathcal{P} to the set of singletons and an assignment of vertices to clusters such that every cluster $C \in \mathcal{C}$ is assigned exactly k vertices. For all phases p and all $P_i \in \mathcal{P}$ where \mathcal{P} is the set of components induced by p , vertices in P_i are assigned to the same cluster. Note that OPT increases by 1 per phase. For the sake of exposition, we give our algorithms for the case when $\alpha = 1$. In Appendix B, we show that a simple refinement of our algorithms handles the case when $\alpha > 1$, without asymptotically affecting the competitive ratios.

Merge cases

After any request, (u, v) between components P_1 and P_2 (where w.l.o.g., $|P_1| \leq |P_2|$) which are merged to form P_m , our algorithms consider two *merge cases*: *small*, when P_1, P_2 and P_m are small, and *large* when P_m is large. A merge is viewed as a *deletion* of components P_1, P_2 and an *insertion* of P_m .

3 An $O(k\ell^2 \log k)$ -competitive algorithm

In this section, we present \mathcal{A}_S , an $O(k\ell^2 \log k)$ -competitive algorithm. The algorithmic and analytic techniques developed play a key role in the improved algorithm \mathcal{A}_G of Section 4.

We describe how \mathcal{A}_S executes during any phase. Recall that for any inter-cluster request, our algorithm considers two merge cases. For both the cases, \mathcal{A}_S calls subroutine **Balance-Small** to migrate and re-assign small components. For the large merge case, \mathcal{A}_S calls subroutine **Reassign-Large** to solve an integer linear program (ILP) and guide the placement of large components. The ILP has a constant number of variables and constraints and hence can be solved in constant time. To present the ILP, we first introduce the notion of a signature, which encodes the number of large components of each class assigned to a cluster.

► **Definition 6 (Signature).** *A signature $\tau = (\tau_1, \tau_2, \dots, \tau_{c_l})$ for a cluster $C \in \mathcal{C}$ is a non-negative vector of dimension c_l where τ_i is the number of large components of class i that can be assigned to C such that $Dk \sum_{i=1}^{c_l} (1 + \frac{\varepsilon}{4})^{i-1} \tau_i \leq k$.*

► **Lemma 7 (Upper bound on number of signatures).** *The number of possible signatures for any cluster C is $O((\frac{1}{\varepsilon^2})^{c_l})$.*

Proof. Let τ be a possible signature. Note that $\tau_i \leq \frac{k}{Dk} = O(\frac{1}{\varepsilon^2})$ for all $i \in [c_l]$. Therefore, the total number of different signatures is $O((\frac{1}{\varepsilon^2})^{c_l})$. ◀

3.1 The ILP

We describe the ILP which is agnostic to the assignment of small components. Let $T = \{T_1, T_2, \dots\}$ denote the set of all possible signatures where w.l.o.g., T_1 is the all-zeroes vector. Let T_{ij} denote the j^{th} entry of signature T_i . From Lemma 7, $|T| = O(1)$. For each

signature, T_i let variable $x_i \in [0, \ell]$ denote the number of clusters assigned a signature T_i . Furthermore, let $\kappa_j \in [0, \lceil \frac{\ell}{D} \rceil]$ denote the total number of class j large components. The ILP is as follows.

$$\sum_{i=1}^{|T|} T_{ij} x_i = \kappa_j \text{ for all } j \quad \sum_{i=1}^{|T|} x_i = \ell \quad x_i \in [0, \ell] \text{ for all } i \quad (1)$$

In matrix form, the ILP has $n_r = O(\ln(1/\varepsilon^2)) = O(1)$ rows and $n_c = O(|T|) = O(1)$ columns. Thus, the ILP can be solved in polynomial time. The following lemma shows that the total volume of large components assigned to any cluster never exceeds cluster capacities by more than an $\frac{\varepsilon}{4}$ factor.

► **Lemma 8** (Total volume of large components). *Let τ denote the assigned signature to cluster C according to which large components are assigned to C . Then, $V_L(C) < (1 + \frac{\varepsilon}{4})k$.*

Proof. We note that $V_L(C) < (1 + \frac{\varepsilon}{4})Dk \sum_{i=1}^{c_i} (1 + \frac{\varepsilon}{4})^{i-1} \tau_i \leq (1 + \frac{\varepsilon}{4})k$. ◀

Next, we give subroutines **Balance-Small** and **Reassign-Large**.

■ **Algorithm Balance-Small.**

-
- 1: **for** each cluster $C \in \mathcal{C}$ s.t. $V(C) > (1 + \frac{\varepsilon}{4})k$:
 - 2: **while** $V(C) > (1 + \frac{\varepsilon}{4})k$:
 - 3: Migrate a small component P from C to C_1 where $C_1 \leftarrow \arg \min_{C_2 \in \mathcal{C}} V(C_2)$.
-

■ **Algorithm Reassign-Large.**

-
- 1: Solve ILP (1) to obtain solution x .
 - 2: **if** ILP is infeasible: return NULL.
 - 3: Unmark all clusters $C \in \mathcal{C}$ and all large components in \mathcal{P} .
 - 4: **for** $i \in [|T|]$:
 - 5: **for** $r \in [x_i]$:
 - 6: Assign signature T_i to an unmarked cluster C , and mark C .
 - 7: **for** $j \in [c_j]$:
 - 8: Assign an unmarked large component P of class j to C and mark P .
 - 9: Migrate P , if necessary.
-

If large components are assigned according to the subroutine **Reassign-Large**, then $V_L(C) \leq (1 + \frac{\varepsilon}{4})k$ for all $C \in \mathcal{C}$ which follows from Lemma 8. On the other hand, if $V_L(c) \leq (1 + \frac{\varepsilon}{4})k$ for all $C \in \mathcal{C}$ and **Balance-Small** is run, $V(C) \leq (1 + \frac{\varepsilon}{4})k$ thereafter. The latter follows since $D < \frac{\varepsilon}{4}$ and there always exists a cluster C_1 such that $V(C_1) \leq k$.

3.2 The algorithm

For a request (u_t, v_t) where $u_t \in P_1, v_t \in P_2$, the algorithm \mathcal{A}_S proceeds as follows.

Proof Theorem 2. We bound the total migration cost incurred by the algorithm \mathcal{A}_S during a phase. For the large merge case, the migration cost is bounded by $k\ell$. To pay for this cost, we charge each vertex in P_m a cost at most $\frac{\ell}{D}$. Every vertex can be charged $O(c_\ell)$ times in this manner within any phase, since a component size is bounded by k . For all $k\ell$ vertices, this gives a total charge of $O(\frac{k\ell^2}{D}) = O(k\ell^2)$.

■ **Algorithm \mathcal{A}_S .**

Input: Distinct components P_1 and P_2 in clusters C_1 and C_2 , respectively; $|P_1| \leq |P_2|$

- 1: Merge P_1 and P_2 into P_m and update $\mathcal{P}, \mathcal{P}_S$ and \mathcal{P}_L accordingly.
- 2: **if** $C_1 \neq C_2$:
- 3: **if** P_m is small: ▷ Small merge case
- 4: Assign P_m to C_2 .
- 5: **if** $V(C_2) \leq (1 + \frac{\varepsilon}{2})k$: Migrate all vertices of P_1 from C_1 to C_2 .
- 6: **else**: Run **Balance-Small**.
- 7: **else**: ▷ Large merge Case
- 8: Run **Reassign-Large**.
- 9: **if** **Reassign-Large** returns NULL: Start a new phase.
- 10: **else**: Run **Balance-Small**.

For the small merge case, there are two cases. If $V(C_2) \leq (1 + \frac{\varepsilon}{2})k$, then each vertex in P_1 is charged unit cost. Any vertex can be charged at most $O(\log k)$ in this way since $|P_m| \geq 2|P_1|$ yielding a total charge of $O(k\ell \log k)$. If $V(C_2) > (1 + \frac{\varepsilon}{2})k$ the migration cost incurred due to **Balance-Small** is at most $k\ell$. Let X denote the set of vertices that migrated to C_2 since the last invocation of **Balance-Small**. Then, $|X| > \frac{\varepsilon k}{4}$. Each vertex in X is charged $\frac{4\ell}{\varepsilon}$. Note that any vertex can be included in such a set X only $O(\log k)$ times before it is part of a large component. For all $k\ell$ vertices, this charge sums to $O(\frac{k\ell^2 \log k}{\varepsilon})$. Thus, the total amount charged to all vertices during a phase is $O(k\ell^2 \log k)$, completing the proof of the theorem. ◀

4 An $O(k\ell \log k)$ -competitive algorithm

In this section, we present algorithm \mathcal{A}_G . A major shortcoming of \mathcal{A}_S is that a cost of $\Omega(k\ell^2)$ can be incurred for both small and large merge cases. For a large merge case, \mathcal{A}_G addresses this by ensuring that the total volume $O(k)$ large components migrated is $O(k)$ by employing a sensitivity analysis. The $O(k\ell \log k)$ -competitiveness of \mathcal{A}_G crucially hinges on bounding the migration cost of small components after a large merge case by $O(k)$. To this end, we give a simple “any-fit” assignment procedure for small components. Effectively, the algorithm guarantees that the total migration cost for both merge cases is $O(|P_m|)$, which can be charged to P_m . This yields the desired competitive ratio.

The pseudo code of Algorithm \mathcal{A}_G is given below. The algorithm executes as follows. At any given time, the algorithm maintains the property that the volume assigned to every class i component is given by $(1 + \frac{\varepsilon}{4})^i$. Thus, the total assigned volume for a cluster C overestimates the total volume of components assigned to C by a $(1 + \frac{\varepsilon}{4})$ factor. For the large merge case, an ILP is solved to handle assignment of large components similarly to \mathcal{A}_S . The assignment of large components is completely independent of small components. Thus, the reassignment of large components can displace small components. A displacement of small component P is viewed as a deletion and successive (re)insertion of P . In the next section, we give a procedure to handle the large merge case and show that the total volume of large components migrated is $O(k)$ if P_m is large.

4.1 Handling large components

To handle the large merge case, we use ILP (1). Additionally, we employ a well known bound on the sensitivity of optimal ILP solutions.

■ **Algorithm** \mathcal{A}_G .

Input: Components P_1 and P_2 in clusters C_1, C_2 of class i, j respectively; $i \leq j$.

- 1: Merge P_1 and P_2 into P_m and update $\mathcal{P}, \mathcal{P}_S$ and \mathcal{P}_L respectively.
 - 2: **if** P_m is large ▷ **Large merge case** (see **Section 4.1**)
 - 3: Solve ILP(1).
 - 4: Run algorithm **Assign Signatures** and let $\mathcal{C}' \subseteq \mathcal{C}$ be the set of clusters whose signatures changed.
 - 5: **for** all $C \in \mathcal{C}'$
 - 6: **for** all $P \in \mathcal{P}_S$ assigned to C
 - 7: **if** $U(C) < \lceil |P| \rceil_{(1+\frac{\varepsilon}{4})}$
 - 8: Assign and migrate P to $C_3 \in \mathcal{C}$ where $U(C_3) \geq \lceil |P| \rceil_{(1+\frac{\varepsilon}{4})}$.
 - 9: $U(C_3) \leftarrow U(C_3) - \lceil |P| \rceil_{(1+\frac{\varepsilon}{4})}$.
 - 10: **else**
 - 11: $U(C) \leftarrow U(C) - \lceil |P| \rceil_{(1+\frac{\varepsilon}{4})}$. ▷ The assignment of P remains unchanged
 - 12: **else** ▷ **Small merge case** (see **Section 4.2**)
 - 13: **if** $(1 + \frac{\varepsilon}{4})^j \geq |P_1| + |P_2|$
 - 14: Migrate vertices of P_1 to C_2 .
 - 15: **else**
 - 16: **if** $U(C_2) \geq (1 + \frac{\varepsilon}{4})^m - (1 + \frac{\varepsilon}{4})^j$
 - 17: Migrate vertices of P_1 to C_2 .
 - 18: $U(C_2) \leftarrow U(C_2) - (1 + \frac{\varepsilon}{4})^m + (1 + \frac{\varepsilon}{4})^j$.
 - 19: **else**
 - 20: Migrate vertices of P_m to C_3 where $U(C_3) \geq (1 + \frac{\varepsilon}{4})^m$.
 - 21: $U(C_3) \leftarrow U(C_3) - (1 + \frac{\varepsilon}{4})^m$.
-

► **Theorem 9** (reproduced verbatim from [19]). *Let A be an integral $n_r \times n_c$ matrix, such that each subdeterminant of A is at most Δ in absolute value; let b' and b'' be column n_r -vectors, and let c be a row n_c -vector. Suppose $\max\{cx \mid Ax \leq b' : x \text{ integral}\}$ and $\max\{cx \mid Ax \leq b'' : x \text{ integral}\}$ are finite. Then for each optimum solution z' of the first maximum there exists an optimum solution z'' of the second maximum such that $\|z' - z''\|_\infty \leq n_c \Delta (\|b' - b''\|_\infty + 2)$.*

Following the merge, the RHS vector in our ILP changes by at most 1 in the infinity norm. To bound the sub-determinant, we use the Hadamard inequality to derive that $\Delta \leq n_c^{n_c/2} A_{max}^{n_c/2}$, where A_{max} denotes the maximum entry (in absolute value) of the constraint matrix A . Each entry in the constraint matrix of our ILP has value either 1 or T_{ij} so that $A_{max} \leq \frac{k}{Dk} = O(1/\varepsilon^2)$. As a result, $\Delta = O((|T|/\varepsilon^2)^{|T|})$. Thus, the optimal solution to the ILP changes by $O(|T|\Delta)$ in the infinity norm. Since x has dimension $|T|$ the number of signatures which change between any two optimal solutions is $O(|T|^2\Delta)$.

Assigning signatures to clusters

Let $x = (x_1, \dots, x_{|T|})$ denote the optimal solution obtained after solving the ILP. The procedure **Assign Signatures** greedily assigns signatures to clusters. Following greedy assignment of signatures, large components are migrated between clusters whose assigned signatures changed to reflect new component assignments. The pseudo code is given as follows.

► **Lemma 10.** *The number of clusters whose assigned signatures change whenever a large component is created is $O(|T|^2\Delta) = O(1)$.*

Algorithm Assign Signatures.

```

1: Unmark all clusters  $C \in \mathcal{C}$ .
2:  $\mathcal{C}' \leftarrow \emptyset$ 
3: for  $i = 1$  to  $|T|$ :
4:    $z_i = x_i$ .
5:   while  $z_i \neq 0$ :
6:     if there is an unmarked cluster  $C$  which has assigned signature  $T_i$ 
7:       Mark  $C$ .
8:     else
9:       Pick an arbitrary unmarked cluster  $C$ , assign it signature  $T_i$ .
10:      Mark  $C$  and set  $\mathcal{C}' \leftarrow \mathcal{C}' \cup \{C\}$ .
11:       $z_i \leftarrow z_i - 1$ .
12:  $\mathcal{P}_{\mathcal{C}'} \leftarrow \{P \in \mathcal{P}_L \text{ and } P \text{ is assigned to some } C \in \mathcal{C}'\}$ .
13: for  $C \in \mathcal{C}'$  ▷ Migrate large components to reflect the change in signature.
14:    $\tau \leftarrow$  assigned signature of  $C$ .
15:   for  $i \in [c_i]$ 
16:     for  $j \in [\tau_i]$ 
17:        $P \leftarrow$  class  $i$  component in  $\mathcal{P}_{\mathcal{C}'}$ .
18:       Assign  $P$  to  $C$  and migrate if necessary.
19:    $\mathcal{P}_{\mathcal{C}'} \leftarrow \mathcal{P}_{\mathcal{C}'} \setminus \{P\}$ .
    $U(C) \leftarrow (1 + \varepsilon)k - A_L(C)$ .

```

Proof. The greedy procedure ensures that at most $O(|T|\Delta)$ clusters previously assigned a signature T_i for $i \in [|T|]$ are subsequently assigned a new signature. Thus, at most $O(|T|^2\Delta) = O(1)$ clusters change their assigned signatures. ◀

4.2 Handling small components

In this section, we give a simple procedure to assign small components. This procedure is used for both small and large merge cases. In the latter case, small components may need to be re-assigned due to displacements following a re-assignment of large components. Each small component P of class i is allocated volume exactly $(1 + \frac{\varepsilon}{4})^i$ on a cluster to which it is assigned, i.e. the allocated volume of a component is equal to $\lceil |P| \rceil_{(1 + \frac{\varepsilon}{4})}$ where $\lceil x \rceil_{(1 + \frac{\varepsilon}{4})}$ denotes the value x rounded up to the nearest multiple of $(1 + \frac{\varepsilon}{4})$. We introduce some notation. Let $A_L(C)$ and $A_S(C)$ denote volume allocated to large and small components respectively on a cluster $C \in \mathcal{C}$. Let $\mathcal{P}_S(C), \mathcal{P}_L(C) \subseteq \mathcal{P}_S$ denote the set of small and large components respectively assigned to a cluster C . Note that $A_L(C) = Dk \sum_{i=1}^{c_i} \tau_i (1 + \frac{\varepsilon}{4})^i$ where τ is the signature assigned to C . If \mathcal{P} does not have any large components, then $A_L(C) = 0$ for all $C \in \mathcal{C}$. Moreover, $A_S(C) = \sum_{P \in \mathcal{P}_S(C)} \lceil |P| \rceil_{1 + \frac{\varepsilon}{4}}$. We define the unallocated volume $U(C)$ of cluster $C \in \mathcal{C}$ as $U(C) = (1 + \varepsilon)k - A_L(C) - A_S(C)$.

A small component P of class i which is currently unassigned, is assigned to an arbitrary cluster C whose unallocated volume $U(C)$ is greater than $(1 + \frac{\varepsilon}{4})^i$. Note that such a cluster C must always exist since otherwise this implies that the total volume of components exceeds kl , a contradiction. Below, we outline the assignment of small components.

Small merge case

Consider the small merge case in which components P_1 and P_2 of class i (resp. j) currently assigned to C_1 (resp. C_2) are merged into P_m of class m . W.l.o.g., let $i \leq j$. If $(1 + \frac{\epsilon}{4})^j \geq |P_1| + |P_2|$, vertices of P_1 are migrated to C_2 . In this case, $m = j$. On the other hand, if $m \neq j$ there are two cases to consider. If $U(C_2) \geq (1 + \frac{\epsilon}{4})^m - (1 + \frac{\epsilon}{4})^j$ then vertices of P_1 are migrated to C_2 . Else, vertices in $P_1 \cup P_2$ are migrated to cluster C_3 where $U(C_3) \geq (1 + \frac{\epsilon}{4})^m$. In all cases, P_m is allocated a volume of $(1 + \frac{\epsilon}{4})^m$.

Handling displacements

Consider the large merge case in which re-assignment of large components may displace small components. Each small component P assigned to a cluster C whose signature changes after a large merge is assigned to a cluster C' where $U(C') \geq (1 + \frac{\epsilon}{4})^i$. Since only $O(1)$ clusters change signatures, the total volume of small components displaced is bounded by $O(k)$.

Proof of Theorem 3. The migration cost of large and small merge cases is analyzed separately. For the large merge case, it follows by Lemma 10 that the total volume of large components migrated is $O(k)$, since the assigned signatures change for only $O(1)$ clusters. Let $\mathcal{C}' \subseteq \mathcal{C}$ denote the set of clusters whose signatures changed. The total volume of small components assigned to \mathcal{C}' is bounded by $O(k)$. As a result, the total migration cost to reassign both small and large components is $O(k)$ which is charged uniformly to all vertices in P_m . Since P_m is large, each vertex in P_m is charged $O(1)$. Noting that the number of large component classes, $c_\ell = O(1)$, the total amount charged to all vertices during the time they are part of large components is bounded by $O(k\ell)$.

For the small merge case involving components P_1 and P_2 (assigned to C_1 and C_2 respectively), we consider two types of charges. If $U(C_2)$ is sufficient, vertices of the smaller component P_1 are migrated to C_2 , and the migration cost of $|P_1|$ is charged to vertices in P_1 . Each vertex can be charged $O(\log k)$ many times in this manner before it is part of a large component. For all vertices, this type of charge amounts to $O(k\ell \log k)$. On the other hand, if $U(C_2)$ is insufficient and vertices in $P_1 \cup P_2$ are migrated, the migration cost of $O(|P_m|)$ is charged to all vertices in P_m . However, in this case $m > j$. Since $c_s = O(\log k)$, the total charge of this type for all vertices across the phase is $O(k\ell \log k)$.

As a result, the total migration cost during a phase for both small and large cases during any phase is bounded by $O(k\ell \log k)$. ◀

5 Lower bound for the learning model with arbitrary assignment

In this section, we give a lower bound for any deterministic or randomized algorithm for the learning problem in which the initial assignment of vertices by an offline-optimal algorithm \mathcal{A}_{OPT} and an online algorithm can be arbitrary. Our argument follows an approach implicit in an $\Omega(\log k)$ lower bound established in [12] for randomized OBGR in the learning model.

Let $\Gamma_{\mathcal{A}} = (V_1, V_2, \dots, V_\ell)$, where $V_i \subseteq V$ and $|V_i| = k$ for all $i \in [\ell]$ denote an initial assignment of vertices to clusters that an algorithm \mathcal{A} begins with. The initial assignment of vertices that the algorithm \mathcal{A}_{OPT} begins with is analogously defined and denoted by $\Gamma'_{OPT} = (V'_1, V'_2, \dots, V'_\ell)$. Let $\pi : [\ell] \rightarrow [\ell]$ denote a permutation of integers in $[\ell]$ and Π denote the set of all such permutations. Define $d(\Gamma_{\mathcal{A}}, \Gamma_{OPT}) = \min_{\pi \in \Pi} \sum_{i=1}^{\ell} |V_{\pi(i)} \setminus V'_{\pi(i)}|$ as the initial distance between vertex assignments that \mathcal{A} and \mathcal{A}_{OPT} begin with respectively. Note that $d(\Gamma_{\mathcal{A}}, \Gamma_{OPT}) \leq k\ell$. In the learning problem with arbitrary assignments, the initial distance can be arbitrary. We prove the following result.

► **Theorem 4.** *For any online deterministic (resp., randomized) algorithm with $(1 + \varepsilon)$ -augmentation for the learning model where $\varepsilon > 0$ is an arbitrary constant, there exists a sequence of requests for which the cost (resp., expected cost) is $\Omega(\alpha k \ell \log k)$.*

Proof. Let \mathcal{A} denote an algorithm that begins with an initial assignment $\Gamma_{\mathcal{A}}$. We show that there exists an assignment Γ_{OPT} satisfying $d(\Gamma_{\mathcal{A}}, \Gamma_{OPT}) = \Theta(k\ell)$ such that \mathcal{A} incurs at least $\Omega(k\ell \log k)$ while \mathcal{A}_{OPT} incurs no cost. The idea is to construct a sequence σ composed of batches B_j of requests for $j = \Omega(\log k)$ such that \mathcal{A} incurs cost $\Omega(k\ell)$ on each batch. For the sake of the proof, let k be a power of 2. We assume $\varepsilon < \ell - 1$ is a constant and $\ell \geq 2$.

We give some terminology which will be useful. Let \mathcal{P}_i denote the set of components induced by the set of requests $\cup_{j=1}^i B_j$. Within any batch, we define a saturating sequence of requests between components P_1 and P_2 as a sequence of requests of the form (u, v) where $u \in P_1, v \in P_2$ for vertices u and v which are not currently co-located by \mathcal{A} . By definition a saturating sequence of requests terminates once P_1 and P_2 are co-located by \mathcal{A} . Let $C_0 = \{\{u\} | u \in V\}$ denote the set of singletons before \mathcal{A} services the first request.

For the first batch of requests B_1 , each singleton component $\{u\}$ is paired with another component $\{v\}$ such that u and v are not co-located by \mathcal{A} under the initial assignment $\Gamma_{\mathcal{A}}$. For all such pairs $\{u\}, \{v\}$, B_1 consists of the union of all saturating sequence of requests between $\{u\}$ and $\{v\}$ until they are co-located. If at any point in time while the current batch of requests is being served, \mathcal{A} does not co-locate any pair of components P_1, P_2 , a saturating sequence of requests is issued between P_1 and P_2 . Observe that for \mathcal{A} to be competitive, \mathcal{A} must co-locate all request pairs. Moreover, \mathcal{P}_1 consists of $\frac{k\ell}{2}$ components of size 2.

For any batch B_j for $j > 1$, we proceed similarly. Each component P of size $\frac{k}{2^{j-1}}$ is paired with another component Q such that P and Q are not co-located by \mathcal{A} before any request in batch B_j is issued. Thereafter, for all pairs of components P and Q , a saturating sequence of requests is issued. Once all pairs have been co-located, the next batch of requests B_{j+1} is served.

Note that since requests are issued between only two components of similar size with size less than k at any given time, there exists an assignment $\Gamma_{OPT} = (V'_1, V'_2, \dots, V'_k)$ which satisfies that for any $u, v \in V'_i$ for all $i \in [\ell]$, no request of the form (u, v) was included in σ . Thus, \mathcal{A}_{OPT} incurs zero cost.

On the other hand, the migration cost incurred by \mathcal{A} on any batch of requests B_j is $\Omega(k\ell)$. To this end, note that for all $j \in [\log k]$, \mathcal{P}_{j-1} consists of exactly $\frac{k\ell}{2^{j-1}}$ components, each of size 2^{j-1} . At any point where batch B_j is issued, \mathcal{A} utilizes at least $\frac{k\ell}{(1+\varepsilon)k} = \Omega(\ell)$ clusters to assign components. Thus, there exist $\Omega(\frac{k\ell}{2^{j-1}})$ pairs of components that are not co-located by \mathcal{A} and communication requests during batch B_j necessitate migration of at $\Omega(\frac{k\ell}{2^{j-1}})$ components each of size 2^{j-1} . Thus, the total migration cost incurred by \mathcal{A} to service B_j is $\Omega(\alpha k \ell)$. For all $\Omega(\log k)$ batches, this amounts to $\Omega(\alpha k \ell \log k)$.

A similar approach can be employed to construct a probability distribution over request sequences for which every deterministic algorithm incurs an expected cost of at least $\Omega(\alpha k \ell \log k)$. From Yao's minimax principle [23], this yields a lower bound on the expected cost of any randomized algorithm. The distribution of requests is as follows. As above, the sequence proceeds in batches. The probability distribution for a batch is dependent on the components constructed in the preceding batch. For every batch B_j , two components P and Q of size 2^{j-1} are selected at random. Next, all possible requests are issued between vertices in P (resp. Q) and repeated $\Omega(\alpha)$ times. Then, requests of the form (u, v) where $u \in P, v \in Q$ are issued for all possible u, v and repeated $\Omega(\alpha)$ times. This is repeated for batch B_j until there are no components of size 2^{j-1} . It can be shown that for any batch the expected total cost for any deterministic algorithm is $\Omega(\alpha k \ell)$. Since there are $\Omega(\log k)$ batches, this yields the desired $\Omega(\alpha k \ell \log k)$ lower bound, thus completing the proof. ◀

A From learning to the general model

► **Observation 1.** *Any ρ -competitive algorithm for OBGR in the learning model can be transformed to a $O(\rho k \ell)$ -competitive algorithm for OBGR in the general model.*

Proof. We give an $\rho k \ell$ -competitive algorithm \mathcal{A} for OBGR in the general model using the ρ -competitive algorithm \mathcal{A}_L as a subroutine. We say an assignment $\Gamma : V \rightarrow \mathcal{C}$ is perfect if every cluster is assigned exactly k vertices. The algorithm partitions the request sequence into phases, and treats each phase as an independent sequence of requests. Here, the definition of a phase is slightly different: phase p of σ is a maximal sub-sequence of requests such that there exists a perfect assignment of vertices which satisfies the property that for all $(u, v) \in p$, $\Gamma(u) = \Gamma(v)$, i.e. u and v are assigned to the same cluster. Before a new phase begins, \mathcal{A} sets \mathcal{P} to the set of singletons and migrates vertices so that every cluster has exactly k vertices. During a phase p , \mathcal{A} simply simulates \mathcal{A}_L ; \mathcal{A}_L starts with the same assignment of vertices as \mathcal{A} at the beginning of p . Let \mathcal{A}_{OPT} denote an offline-optimal algorithm.

It is easy to observe that the cost incurred by \mathcal{A}_{OPT} increases by at least 1 in every phase. We claim that \mathcal{A} incurs a cost no more than $\rho k \ell$. To this end, suppose \mathcal{A} incurred a cost more than $\rho k \ell$. Consider an algorithm which an identical assignment of vertices as \mathcal{A} at

the beginning of phase p and immediately moves to a perfect assignment Γ of vertices such that for any $(u, v) \in p$, $\Gamma(u) = \Gamma(v)$ and incurs no cost thereafter throughout p . The cost of this algorithm is at most $k\ell$ which contradicts that \mathcal{A}_L is ρ -competitive. \blacktriangleleft

B The case of general α

In this section, we show how to adapt our algorithms which were given for $\alpha = 1$ to arbitrary α without a degradation in the asymptotic competitive ratio.

► **Theorem 11.** *Let $\mathcal{A} \in \{\mathcal{A}_S, \mathcal{A}_G\}$ denote a $O(\rho)$ competitive algorithm for OBGR for $\alpha = 1$, where $\rho = \Omega(k\ell \log k)$. Then, \mathcal{A} can be modified to an $O(\rho)$ competitive algorithm \mathcal{A}_M to handle the case of arbitrary α .*

Proof. In the case of arbitrary α , merging of two components is beneficial only when sufficient number of requests have been encountered between them. Let $w(P_i, P_j)$ denote the number of requests of the form (u_t, v_t) between components P_i and P_j where $u_t \in P_i, v_t \in P_j$ during a phase. \mathcal{A}_M initializes a phase by setting \mathcal{P} to the set of singletons and $w(\{u\}, \{v\}) = 0$ for all $u, v \in V$. For components P_i and P_j where w.l.o.g. $|P_i| \leq |P_j|$, \mathcal{A}_M merges them into P_m when $w(P_i, P_j) \geq \alpha|P_i|$. For every component $P_r \neq P_i, P_j$, $w(P_m, P_r)$ is set to $w(P_i, P_r) + w(P_j, P_r)$. Due to this reason, it is possible P_r may become eligible to be merged with P_m . A request (u_t, v_t) is *special* if it leads to one or more component merges.

During any phase, \mathcal{A}_M works as follows: on any request (u_t, v_t) between components P_i and P_j it first increments $w(P_i, P_j)$. Next, it determines whether the request is special. If it is special, \mathcal{A}_M simulates \mathcal{A} on this request. Note that if P_i and P_j are in the same cluster, then nothing needs to be done besides updating data structures and merging P_i and P_j into P_m . However, if this makes a component P_r eligible to be merged with P_m , \mathcal{A}_M creates an artificial request (u^A, v^A) where $u^A \in P_m, v^A \in P_r$ and simulates the action of \mathcal{A} on (u^A, v^A) . Recursive component merges are handled similarly. A phase of \mathcal{A}_M ends whenever a phase of \mathcal{A} ends. Note that requests to \mathcal{A} only consist of special and artificial requests.

We bound the total communication and migration cost incurred by \mathcal{A}_M during a phase. Since \mathcal{A} incurs a cost of $O(\rho)$ per phase, the migration cost of \mathcal{A}_M is bounded by $O(\alpha\rho)$. We claim the communication cost per phase of \mathcal{A}_M is $O(\alpha k\ell \log k)$. For this purpose, consider charging any vertex in a small component P_i a cost of α whenever P_i is merged with P_j . This is sufficient to bound the total communication cost, which is $\alpha|P_i|$ incurred due to communication between vertices in P_i and P_j . Thus, every vertex is charged $O(\alpha \log k)$ per phase yielding a total communication cost of $O(\alpha k\ell \log k)$.

To lower bound the cost of an optimal offline algorithm during the phase, note that either it migrated a vertex or not. If a vertex was migrated during the phase, then $OPT \geq \alpha$. On the other hand, if no vertex was migrated, a communication cost of at least α must have been incurred. To see why, note that at the termination of the phase, the ILP 1 solved by \mathcal{A} determines that no feasible solution exists. Each edge in the graph that \mathcal{A} maintains during the phase corresponds to at least α paid communication requests handled by \mathcal{A}_M . Thus, for both cases $OPT \geq \alpha$ per phase.

This yields $O(\rho + k\ell \log k)$ competitiveness. Since $\rho = \Omega(k\ell \log k)$, the theorem follows. \blacktriangleleft

An Empirical Evaluation of k -Means Coresets

Abstract

Coresets are among the most popular paradigms for summarizing data. In particular, there exist many high performance coresets for clustering problems such as k -means in both theory and practice. Curiously, there exists no work on comparing the quality of available k -means coresets.

In this paper we perform such an evaluation. There currently is no algorithm known to measure the distortion of a candidate coreset. We provide some evidence as to why this might be computationally difficult. To complement this, we propose a benchmark for which we argue that computing coresets is challenging and which also allows us an easy (heuristic) evaluation of coresets. Using this benchmark and real-world data sets, we conduct an exhaustive evaluation of the most commonly used coreset algorithms from theory and practice.

1 Introduction

The design and analysis of scalable algorithms has become an important research area over the past two decades. This is particularly important in data analysis, where even polynomial running time might not be enough to handle proverbial *big data* sets. One of the main approaches to deal with the scalability issue is to compress or sketch large data sets into smaller, more manageable ones. The aim of such compression methods is to preserve the properties of the original data, up to some small error, while significantly reducing the number of data points.

Among the most popular and successful paradigms in this line of research are *coresets* [40]. Informally, given a data set A , a coreset $\Omega \subset A$ with respect to a given set of queries Q and query function $f : A \times Q \rightarrow \mathbb{R}_{\geq 0}$ approximates the behaviour of A for all queries up to some multiplicative distortion D via $\sup_{q \in Q} \max \left(\frac{f(\Omega, q)}{f(A, q)}, \frac{f(A, q)}{f(\Omega, q)} \right) \leq D$. Coresets have been applied to a number of problems such as computational geometry [2, 9], linear algebra [30, 34], and machine learning [36, 41]. But the by far most intensively studied and arguably most successful applications of the coreset framework is the k -clustering problem.

84:2 An Empirical Evaluation of k -Means Coresets

Here we are given n points A with (potential unit) weights $w : A \rightarrow \mathbb{R}_{\geq 0}$ in some metric space with distance function dist and aim to find a set of k centers C such that

$$\text{cost}_A(C) := \frac{1}{n} \sum_{p \in A} \min_{c \in C} w(p) \cdot \text{dist}^z(p, c)$$

is minimized. The most popular variant of this problem is probably the k -means problem in d -dimensional Euclidean space where $z = 2$ and $\text{dist}(x, y) = \sqrt{\sum_{i=1}^d (x_i - y_i)^2}$.

A (k, ε) -coreset is now a subset $\Omega \subset A$ with weights $w : \Omega \rightarrow \mathbb{R}_{\geq 0}$ such that for any set of k centers C

$$\sup_C \max \left(\frac{\text{cost}_A(C)}{\text{cost}_\Omega(C)}, \frac{\text{cost}_\Omega(C)}{\text{cost}_A(C)} \right) \leq 1 + \varepsilon. \quad (1)$$

The coreset definition in Equation (1) provides an upper bound for the distortion of all candidate solutions i.e., all possible sets of k centers. A *weak coreset* is a relaxed guarantee that holds for optimal or nearly optimal clusterings of A instead of all clusterings.

In a long line of work spanning the last 20 years [4, 8, 10, 14, 15, 19, 20, 26, 25, 27, 29, 8, 33, 44], the size of coresets has been steadily improved with the current state of the art yielding a coreset with $\tilde{O}(k\varepsilon^{-2} \cdot \min(d, k, \varepsilon^{-2}))$ points for a distortion $D \leq (1 + \varepsilon)$ due to [13]¹.

While we have a good grasp of the theoretical guarantees of these algorithms, our understanding of the empirical performance is somewhat lacking. There exist a number of coreset implementations, but it is usually difficult to assess which implementation summarizes the data best. To accurately evaluate a given coreset, we would need to come up with a k clustering C which results in a maximal distortion. Solving this problem is likely difficult: related questions such as deciding whether a 3-dimensional point set A is an ε -net of a set B with respect to convex ranges is co-NP hard [24].

Due to this difficulty, a common heuristic for evaluating coresets is as follows [1, 22]. First, compute a coreset Ω with the available algorithm(s) using some input data A . Then, run an optimization algorithm on Ω to compute a k clustering. The *best* coreset algorithm is considered to be the one which yields a clustering with the smallest cost.

This practice has substantial drawbacks. The first is that this evaluation method conflates the two separate tasks of coreset construction and optimization. It is important to note that the first step of virtually all coreset algorithms is a low-cost (bicriteria) constant factor approximation, i.e. a solution with $\beta \cdot k$ clusters that costs at most $\alpha \cdot \text{OPT}$, where OPT is the cost of an optimal k clustering. Given that this initial solution has an α approximation to the cost, a routine calculation shows that the additive error of the coreset, i.e. the maximum difference $|\text{cost}_A(C) - \text{cost}_B(C)|$ over all solutions C is at most $O(\alpha) \cdot \text{cost}_A(C)$. In particular, in the case that the initial bicriteria approximation has $\alpha \ll 2$, which is not too difficult to achieve with more than k centers, any γ approximation algorithm will find solutions with approximation factor $O(\gamma + \alpha) \cdot \text{OPT}$. In particular, the distortion may be unbounded, for example if B only consists of the k centers, while simply returning B itself yields a low cost clustering. Thus, it is difficult to measure coreset quality in this way.

The second drawback is that this practice will mainly measure the performance of the optimization algorithm, rather than the performance of the coreset algorithms. During its execution it might simply not consider any solution with high distortion. For example, if the

¹ We use $\tilde{O}(x)$ to hide $\log^c x$ terms for any constant c .

approximation factor γ of the solution returned by the algorithm is large then this solution (as well as any even higher cost solution considered during the algorithm's execution) will have a low distortion.

The third drawback of this evaluation method is that it does not consider the main use cases of coresets, nor the full power of their guarantee. Indeed, if speeding up the computation of an optimization algorithm, one would hardly need a strong coreset; approximating the cost of every candidate solution, as weaker coreset definitions (or indeed a bicriteria approximation) would be suitable as well. A coreset's main and most powerful feature is *composability*, i.e. given two disjoint point sets X and Y , the union of a coreset of X and a coreset of Y is a coreset. Composability is what enables coresets to scale to massively parallel computation models and enables simple streaming algorithms via the merge and reduce technique. To which degree a coreset is composable is generally not a property of an optimal clustering of the point set, as optimal solutions C_X of X or C_Y of Y may have little in common with an optimal solution of $X \cup Y$.

The purpose of this study is to systematically evaluate the quality of various coreset algorithms for k -means. As such, we develop a new evaluation procedure which estimates the distortion of coreset algorithms. On real-world data sets, we observe that while the evaluated coreset algorithms are generally able to find solutions with comparable costs, there is a stark difference in their distortions. This shows that differences between optimization and compression are readily observable in practice.

As a complement to our evaluation procedure on real-world data sets, we propose a benchmark framework for generating synthetic data sets. We argue why this benchmark has properties that results in hard instances for all known coreset constructions. We also show how to efficiently estimate the distortion of a candidate coreset on the benchmark.

2 Coreset Algorithms

Though the algorithms vary in details, coreset constructions come in one of the following two flavours:

1. **Movement-based constructions:** Such algorithms compute a coreset Ω with T points given some input point set A such that $\text{cost}_\Omega(C) \ll \text{OPT}$, where OPT is the cost of an optimal k -means clustering of A . The coreset guarantee then follows as a consequence of the triangle inequality. These algorithms all have an exponential dependency on the dimension d , and therefore have been overtaken by sampling-based methods. Nevertheless, these constructions are more robust to various constrained clustering formulations [28, 43] and continue to be popular. Examples from theory include [23, 26].
2. **Importance sampling:** Points are sampled proportionate to their impact on the cost of any given candidate solution. The idealized distribution samples proportionate to the sensitivity which for a point p is defined as $\text{sens}(p) := \sup_C \frac{\min_{c \in C} \text{dist}^2(p, c)}{\text{cost}_A(C)}$ and weighted by their inverse sampling probability. The sensitivities are hard to compute exactly but much work exists on how to find other distributions with very similar properties. In terms of theoretical performance, sensitivity sampling has largely replaced movement-based constructions, see for example [19, 33].

Of course, there exist algorithms that draw on techniques from both, see for example [15]. In what follows, we will survey implementations of various coreset constructions that we will evaluate later.

StreamKM++ [1]. The popular k -means++ algorithm [3] computes a set of centers K by iteratively sampling a point p in A proportionate to $\min_{q \in K} \text{dist}^2(p, q)$ and adding it to K . The procedure terminates once the desired number of centers has been reached. The

first center is typically picked uniformly at random. The StreamKM++ paper runs the k -means++ algorithms for T iterations, where T is the desired coreset size. At the end, every point q in K is weighted by the number of points in A closest to it. While the construction has elements of importance sampling, the analysis is largely movement-based. The provable bound required for the algorithm to compute a coreset is $O\left(\frac{k \log n}{\delta^{d/2} \epsilon^d} \cdot \log^{d/2} \frac{k \log n}{\delta^{d/2} \epsilon^d}\right)$. Despite its simplicity, its running time compares unfavourably to all other constructions.

BICO [22]. BICO combines the very fast, but poor quality clustering algorithm BIRCH [47] with the movement-based analysis from [23, 26]. The clustering is organized by way of a hierarchical decomposition: When adding a point p to one of the coreset points Ω at level i , it first finds the closest point q in Ω . If p is too far away from q , a new cluster is opened with center at p . Otherwise p is either added to the same cluster as q , or, if adding p to q 's cluster increases the clustering cost beyond a certain threshold, the algorithm attempts to add p to the child-clusters of q . The procedure then continues recursively. The provable bound required for the algorithm to compute a coreset is $O(k\epsilon^{-d-2} \log n)$.

Ray Maker [25]. The algorithm computes an initial solution with k centers which is a constant factor approximation of the optimal clustering. Around each center, $O(1/\epsilon^{d-1})$ random rays are created which span the hyperplane. Next, each point $p \in A$ is snapped to its closest ray resulting in a set of one-dimensional points associated with each ray. Afterwards, a coreset is created for each ray by computing an optimal 1D clustering with k^2/ϵ^2 centers and weighing each center by the number of points in each cluster. The final coreset is composed of the coresets computed for all the rays. The provable bound required for the algorithm to compute a coreset is $O(k^3 \cdot \epsilon^{-d-1})$. The algorithm has recently received some attention due to its applicability to the fair clustering problem [28].

Sensitivity Sampling [19]. The simplest implementation of sensitivity sampling first computes an $(O(1), O(1))$ bicriteria approximation², for example by running k -means++ for $2k$ iterations [46]. Let K be the $2k$ clustering thus computed and let K_i be an arbitrary cluster of K with center q_i . Subsequently, the algorithm picks points proportionate to $\frac{\text{dist}^2(p, q)}{\text{cost}_{K_i}(\{q_i\})} + \frac{1}{|K_i|}$ and weighs any point by its inverse sampling probability. Let $|\hat{K}_i|$ be the estimated number of points in the sample. Finally, the algorithm weighs each q_i by $(1 + \epsilon) \cdot |K_i| - |\hat{K}_i|$. The provable bound required for the algorithm to compute a coreset is $\tilde{O}(kd\epsilon^{-4})$ ([19]), $\tilde{O}(k\epsilon^{-6})$ ([29]), or $\tilde{O}(k^2\epsilon^{-4})$ ([8]).

Group Sampling [15]. First, the algorithm computes an $O(1)$ approximation (or a bicriteria approximation) K . Subsequently, the algorithm preprocesses the input into groups such that (1) for any two points $p, p' \in K_i$, their cost is identical up to constant factors and (2) for any two clusters K_i, K_j , their cost is identical up to constant factors. In every group, Group Sampling now samples points proportionate to their cost. The authors of [15] show that there always exist a partitioning into $\log^2 1/\epsilon$ groups. Points not contained in a group are snapped to their closest center q in K . q is weighted by the number of points snapped to it. The provable bound required for the algorithm to compute a coreset is $\tilde{O}(k\epsilon^{-2} \min(d, k, \epsilon^{-2}))$ ([13]). While this improves over sensitivity sampling, it is generally slower and not as easy to implement.

² An (α, β) bicriteria approximation computes an α approximation using $\beta \cdot k$ many centers.

Finally, we note that some of the more popular algorithms in theory have not been mentioned here. For example, Chen’s [10] construction is particularly popular among theoreticians. The Group Sampling algorithm by [15] is an extension and improvement of Chen’s method. Thus, the performance of Group Sampling is also indicative of Chen’s algorithm.

Dimension Reduction

Finally, we also combine coresets with a variety of dimension reduction techniques. Starting with [17], a series of results [4, 5, 6, 7, 12, 16, 20, 21, 32, 37, 44] explored the possibility of using dimension reduction methods for k -clustering, with a particular focus on principal component analysis (PCA) and random projections. The seminal paper by Feldman, Schmidt, and Sohler [20] was the first to use dimension reduction to obtain smaller coresets for k -means. Movement-based coresets in particular often have an exponential dependency on the dimension, which can be alleviated with some form of dimension reduction, both in theory [43] and in practice [31]. There are essentially two main dimension reduction techniques for coresets.

Principal Component Analysis. Feldman, Schmidt, and Sohler [20] showed that projecting an input A onto the first $O(k/\varepsilon^2)$ principal components is a coreset. This coreset still consists of n points, but they now lie in low dimension. The analysis was subsequently tightened by [12] and extended to other center-based cost functions by [44]. Although its target dimension is generally worse than those based on random projections and terminal embeddings, there is nevertheless reasons for using PCA regardless: It removes noise and thus may make it easier to compute a high quality coreset. For more applications of PCA to k -means clustering, we refer to

Terminal Embeddings. Given a set of points A in \mathbb{R}^D , a terminal embedding $f : \mathbb{R}^D \rightarrow \mathbb{R}^d$ preserves the pairwise distance between any point $p \in A$ and any point $q \in \mathbb{R}^D$ up to a $(1 \pm \varepsilon)$ factor. The statement is related to the famous Johnson-Lindenstrauss lemma but it is stronger as it does not apply to only the pairwise distances of A . Nevertheless, the same target dimension is sufficient. Terminal embeddings were studied by [11, 18, 35, 42], with Narayanan and Nelson [42] achieving an optimal target dimension of $O(\varepsilon^{-2} \log n)$, where n is the number of points. We note that terminal embeddings, combined with an iterative application of the coreset construction from [8], can reduce the target dimension to a factor $\tilde{O}(\varepsilon^{-2} \log k)$. This is mainly of theoretical interest, as in practice the deciding factor wrt the target dimension is the precision, rather than dependencies on $\log n$ and $\log k$. For applications to coresets, we refer to [4, 15, 29]. For an empirical evaluation of random projections, which form the basis of all known terminal embeddings, we refer to Venkatasubramanian and Wang [45].

3 Benchmark Construction

In this section, we describe our benchmark. We start by describing the aims of the benchmark, followed by giving the construction. Our aim is to generate a data set containing many clusterings with the following properties.

1. The benchmark has many clusterings that, in a well defined sense, are highly dissimilar. Specifically, we want the overlap between any two clusters of different clusterings to be small.

2. The different clusterings have very similar and low cost. This ensures that despite the solutions being different in terms of composition and center placement, a good coreset has to consider them equally regarding distortion.
3. The clusterings are induced by a minimal cost assignment of input points to a set of centers in \mathbb{R}^d . This final property ensures that the coreset guarantee has to apply to these clusterings.

To generate the benchmark, we now use the following construction. The benchmark has a parameter α which controls the number of points and dimensions of the generated data instance. For a given value of k , the benchmark instance consists of $n = k^\alpha$ points and $d = \alpha \cdot k$ dimensions, i.e. we will construct an $n \times d$ matrix A where every row corresponds to an input point and every column corresponds to one of the dimensions.

Let $\mathbf{1}_k$ be the k -dimensional all-one vector and v_i^1 be the k -dimensional vector with entries $(v_i^1)_j = \begin{cases} -\frac{1}{k} & \text{if } i \neq j \\ \frac{k-1}{k} & \text{if } i = j \end{cases}$. For $\ell \leq \alpha$, recursively define the k^ℓ dimensional vector

$$v_i^\ell = v_i^{\ell-1} \otimes \mathbf{1}_k, \text{ where } \otimes \text{ denotes the Kronecker product, i.e. } v_i^{\ell-1} \otimes \mathbf{1}_k = \begin{bmatrix} (v_i^{\ell-1})_1 \cdot \mathbf{1}_k \\ (v_i^{\ell-1})_2 \cdot \mathbf{1}_k \\ \vdots \\ (v_i^{\ell-1})_{k^{\ell-1}} \cdot \mathbf{1}_k \end{bmatrix}.$$

Finally, set the t -th column of A , for $t = a \cdot k + b$, $a \in \{0, \dots, \alpha - 1\}$ and $b \in \{1, \dots, k\}$, to be $\mathbf{1}_{k^{\alpha-a+1}} \otimes v_b^{a+1}$.

To get a better feel for the construction, we have given two small example instances for $k = 2$ and $k = 3$ in Figure Figure 1.

$$\begin{bmatrix} \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \end{bmatrix} \quad \begin{bmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \end{bmatrix}$$

■ **Figure 1** Benchmark construction for $k = 2$ and $\alpha = 3$ (left) and $k = 3$ and $\alpha = 2$ (right).

Properties of the Benchmark

We now summarize the key properties of the benchmark. To this end, we require a few notions. Let A be the input matrix. We slightly abuse notation and refer to A_i as both the i th point as well as the i th row of the matrix A . For a clustering $\mathcal{C} = \{C_1, \dots, C_k\}$, we define that the $n \times k$ indicator matrix \tilde{X} induced by \mathcal{C} via $\tilde{X}_{i,j} = \begin{cases} 1 & \text{if } A_i \in C_j \\ 0 & \text{else.} \end{cases}$ Furthermore, we

will also use the $n \times k$ normalized clustering matrix X defined as $X_{i,j} = \begin{cases} \frac{1}{\sqrt{|C_j|}} & \text{if } A_i \in C_j \\ 0 & \text{else.} \end{cases}$

We also recall the following lemma which will allow us to express the k -means cost of a clustering \mathcal{C} with optimally chosen centers in terms of the cost of X and A .

► **Lemma 1** (Folklore). *Let A be an arbitrary set of points and let $\mu(A) = \frac{1}{|A|} \sum_{p \in A} p$ be the mean. Then $\sum_{p \in A} \|p - c\|^2 = |A| \cdot \|\mu(A) - c\|^2 + \sum_{p \in A} \|p - \mu(A)\|^2$ for any point c .*

This lemma proves that for any given cluster C_j , the mean is the optimal choice of center. We also note that any two distinct columns of X are orthogonal. Furthermore $\frac{1}{n} \mathbf{1}\mathbf{1}^T A$ copies the mean into every entry of A . Combining these two observations, we see that the matrix $XX^T A$ maps the i th row of A onto the mean of the cluster it is assigned to. Finally, define the Frobenius norm of an $n \times d$ A by $\|A\|_F = \sqrt{\sum_{i=1}^n \sum_{j=1}^d A_{i,j}^2}$. Then the k -means cost of the clustering \mathcal{C} is precisely $\|A - XX^T A\|_F^2$.

We also require the following distance measure on clusterings as proposed by Meila [38, 39]. Given two clusterings \mathcal{C} and \mathcal{C}' , the $k \times k$ confusion matrix M is defined as $M_{i,j} = |C_i \cap C'_j|$. Furthermore for the indicator matrices \tilde{X} and \tilde{X}' induced by \mathcal{C} and \mathcal{C}' we have the identity $M = \tilde{X}^T \tilde{X}'$. Denote by Π_k the set of all permutations over k elements. Then the distance between \mathcal{C} and \mathcal{C}' is defined as $d(\mathcal{C}, \mathcal{C}') = 1 - \frac{1}{n} \max_{\pi \in \Pi_k} \sum_{i=1}^k M_{i,\pi(i)}$. Observe that for clusters that are identical, their distance is 0. The maximum distance between any two k clusterings is always $\frac{k-1}{k}$.

The solutions we consider are given as follows. For the columns $a \cdot k + 1, \dots, (a+1) \cdot k$, we define the clustering $\mathcal{C}^a = \{C_1^a, \dots, C_k^a\}$ with $A_i \in C_j^a$ if and only if $A_{i,j} > 0$. Let \tilde{X}^a and X^a denote the indicator matrix and clustering matrix, respectively, as induced by \mathcal{C}^a . These clusterings satisfy the properties we stated at the beginning of this section, that is:

1. The distance between these clustering is $1 - \frac{1}{k}$, i.e. it is maximized.
2. The clusterings have equal cost and the centers in each clustering have equal cost.
3. The clusterings are induced by a set of centers in \mathbb{R}^d .

Benchmark Evaluation

We now describe how we use the benchmark to measure the distortion of a coresets. Assume for now that the coresets are subsets of the original input points. The extension to coresets that do not consist of input points is described at the end of this section.

Consider the clustering $\mathcal{C}^a = \{C_1^a, \dots, C_k^a\}$ for some a and let Ω with weights $w : \Omega \rightarrow \mathbb{R}_{\geq 0}$ be the coresets and let $\delta > 0$ be a parameter. Note that there are α many such clusterings, for each value of a . We use $w(C_i^a \cap \Omega) := \sum_{p \in C_i^a \cap \Omega} w(p)$ to denote the mass of points of C_i^a in Ω . For every cluster C_i^a with $w(C_i^a \cap \Omega) \geq |C_i^a|(1 - \delta)$, we place a center at $\mu(C_i^a)$. Conversely, if $w(C_i^a \cap \Omega) < |C_i^a|(1 - \delta)$, we do not place a center at $\mu(C_i^a)$. We call such clusters *deficient*. Let \mathcal{S} be the centers of these deficient clusters.

We now compare the cost as computed on the coresets and the true cost of \mathcal{S} . Due to Lemma 1 and the fact that all clusters have equal cost, we may write for any deficient cluster C_i^a $\text{cost}_{C_i^a}(\mathcal{S}) = \text{cost}_{C_j^a}(\{\mu(C_j^a)\}) + k^{\alpha-1} \|\mu(C_j^a) - \mu(C_i^a)\|_2^2$, where C_h^a is a non-deficient cluster. Thus, the cost is $\text{cost}_{C_i^a}(\mathcal{S}) \approx (1 + \frac{2}{\alpha}) \cdot \text{cost}_{C_j^a}(\{\mu(C_j^a)\})$.

Conversely, the cost on the coresets is

$$\text{cost}_{\Omega \cap C_i^a}(\mathcal{S}) \approx \frac{w(C_i^a \cap \Omega)}{\text{cost}_{C_j^a}(\{\mu(C_j^a)\})} \left(1 + \frac{2}{\alpha}\right) \cdot \text{cost}_{C_j^a}(\{\mu(C_j^a)\}).$$

Thus for each deficient clustering individually, the distortion will be close to $\frac{k^{\alpha-1}}{w(C_i^a \cap \Omega)} \geq \frac{1}{1-\delta}$. If there are many deficient clusters, then this will also be the overall distortion. For all possible (suitably discretized) thresholds for deficiency, i.e. all values of δ , we can now identify the clustering \mathcal{C}^a with a maximum number of deficient clusters and use the aforementioned construction to get a lower bound on the distortion.

To extend this evaluation to coresets where the points are not part of the input, we consider a point $p \in \Omega$ to be in C_i^a if it is closer to $\mu(C_i^a)$ than to $\mu(C_j^a)$.

4 Experiments

In this section, we present how we evaluated different algorithms. First, we propose our evaluation procedure which gauges the quality of coresets. Then, we describe the data sets used for the empirical evaluation and our experimental setup. Finally, we detail the outcome of the experiments and our interpretation of the results.

Evaluation Procedure

Accurately evaluating a k -means coreset of a real-world data set requires constructing a solution (a set of k centers) which results in a maximal distortion. Finding such a solution, however, is difficult. Instead, we can estimate the quality of a given coreset by finding meaningful candidate solutions.

A first attempt can be to randomly generate candidate solutions. It is not readily apparent how to define a distribution of meaningful solutions from which to sample. One could, for instance, generate k random points inside the convex hull or the minimum enclosing ball (MEB) of a coreset Ω . Convex hulls in high dimensions are infeasible to compute, so we sample a center by choosing random convex combination of the centers of the initial bicriteria approximation computed for every coreset. A better way to generate candidate solutions turns out to be k -means++, where we sample k points with respect to the k -means++ distribution and use the resulting centers as a solution. The main advantage of this approach is that k -means++ can uncover natural cluster structures in the data, which uniform sampling generally does not. For all variants, we generated 5 candidate solutions, where the candidate solution with the largest distortion being a lower bound for the true distortion of the coreset.

Given the usefulness of evaluating coresets on real-world data sets, it can be tricky to gauge the general performance of coreset algorithms using only a small selection of data sets. For this reason, we used our benchmark to complement the evaluation on real-world data sets. The benchmark accomplishes two important tasks. First, the benchmark allows us to quickly find a bad solution because both good and bad clusterings are known a priori. It is unclear how to find bad clusterings for real-world data sets. Second, it is easier to make a fair comparison of different coreset constructions because the benchmark is known to generate hard instances for all known coreset algorithms. This cannot be said for real-world data sets. For the benchmark, we computed the distortion following the evaluation procedure described in Section 3.

Every randomized coreset construction was repeated 10 times. We aggregated the reported maximum distortions for every run by taking the average over all 10 evaluations. It is important to not aggregate the distortions here by taking the maximum over all runs: If one run of the coreset algorithm fails but the others succeed, then such an aggregation predicts far worse distortion than what we could typically expect.

Data sets

We conducted experiments on five real-world data sets *Census*, *Coverttype*, *Tower*, *Caltech*, *NYTimes*, and four instances of our benchmark. Benchmark instances were generated to match approximately the sizes of the real-world data sets. The sizes of the considered data sets are given in Table 1.

■ **Table 1** The sizes of the real-world datasets used for the experimental evaluation.

	Data points	Dimensions
<i>Caltech</i>	3,680,458	128
<i>Census</i>	2,458,285	68
<i>Covertypes</i>	581,012	54
<i>NYTimes</i>	500,000	102,660
<i>Tower</i>	4,915,200	3

■ **Table 2** The parameter values and the sizes of the benchmark instances used for the experimental evaluation.

k	α	Data points	Dimensions
10	6	1,000,000	60
20	5	3,200,000	100
30	4	810,000	120
40	4	2,560,000	160

The *Census*³ dataset is a small subset of the Public Use Microdata Samples from 1990 US census. It consists of demographic information encoded as 68 categorical attributes of 2,458,285 individuals.

*Covertypes*⁴ is comprised of cartographic descriptions and forest cover type of four wilderness areas in the Roosevelt National Forest of Northern Colorado in the US. It consists of 581,012 records, 54 cartographic variables and one class variable. Although *Covertypes* was originally made for classification tasks, it is often used for clustering tasks by removing the class variable [1].

The data set with the fewest number of dimensions is *Tower*⁵. This data set consists of 4,915,200 rows and 3 features as it is a 2,560 by 1,920 picture of a tower on a hill where each pixel is represented by a RGB color value.

Inspired by [22], *Caltech* was created by computing SIFT features from the images in the Caltech101⁶ image database. This database contains pictures of objects partitioned into 101 categories. Disregarding the categories, we concatenated the 128-dimensional SIFT vectors from each image into one large data matrix with 3,680,458 rows and 128 columns.

*NYTimes*⁷ is a dataset composed of the bag-of-words (BOW) representations of 300,000 news articles from The New York Times. The vocabulary size of the text collection is 102,660. Due to the BOW encoding, *NYTimes* has a very large number of dimensions and is highly sparse. To make processing feasible, we reduced the number of dimensions to 100 using terminal embeddings.

Preprocessing & Experimental Setup

To understand how denoising effects the quality of the outputted coresets, we applied Principal Component Analysis (PCA) on *Caltech*, *Census*, *Coverttype*, and *NYTimes* by using the k singular vectors corresponding to the largest singular values. We did not perform any preprocessing on *Tower* due to its low dimensionality.

We followed the same experimental procedure with respect to the choice of parameter values for the algorithms as prior works [1, 22]. For the target coreset size T , we experimented with $T = mk$ for $m = \{50, 100, 200, 500\}$. On *Caltech*, *Census*, *Coverttype*, and *NYTimes*, we used values k in $\{10, 20, 30, 40, 50\}$, while for *Tower* we used larger cluster sizes $k \in \{20, 40, 60, 80, 100\}$. On the benchmark, we used $k \in \{10, 20, 30, 40\}$.

We implemented Sensitivity Sampling, Group Sampling, Ray Maker, and StreamKM++ in C++. The source code can be found on GitHub⁸. For BICO, we used the authors' reference implementation⁹. The source code was compiled with gcc 9.3.0. The experiments were performed on a machine with Intel Core i9 10940X 3.3GHz 14-Core and 2x DDR4 PC3200 128GB RAM.

Outcome of Experiments

We observed that in the majority of our experiments, varying the coreset sizes does not significantly change the performance profiles of individual algorithms when comparing them against each other. Therefore, in the following sections, we focus on a cross-section of the experiments where $m = 200$ i.e., coreset sizes $T = 200k$. For numerical results including variances of all the experiments and tables containing distortions, costs and running times, we refer to the full version of this paper.

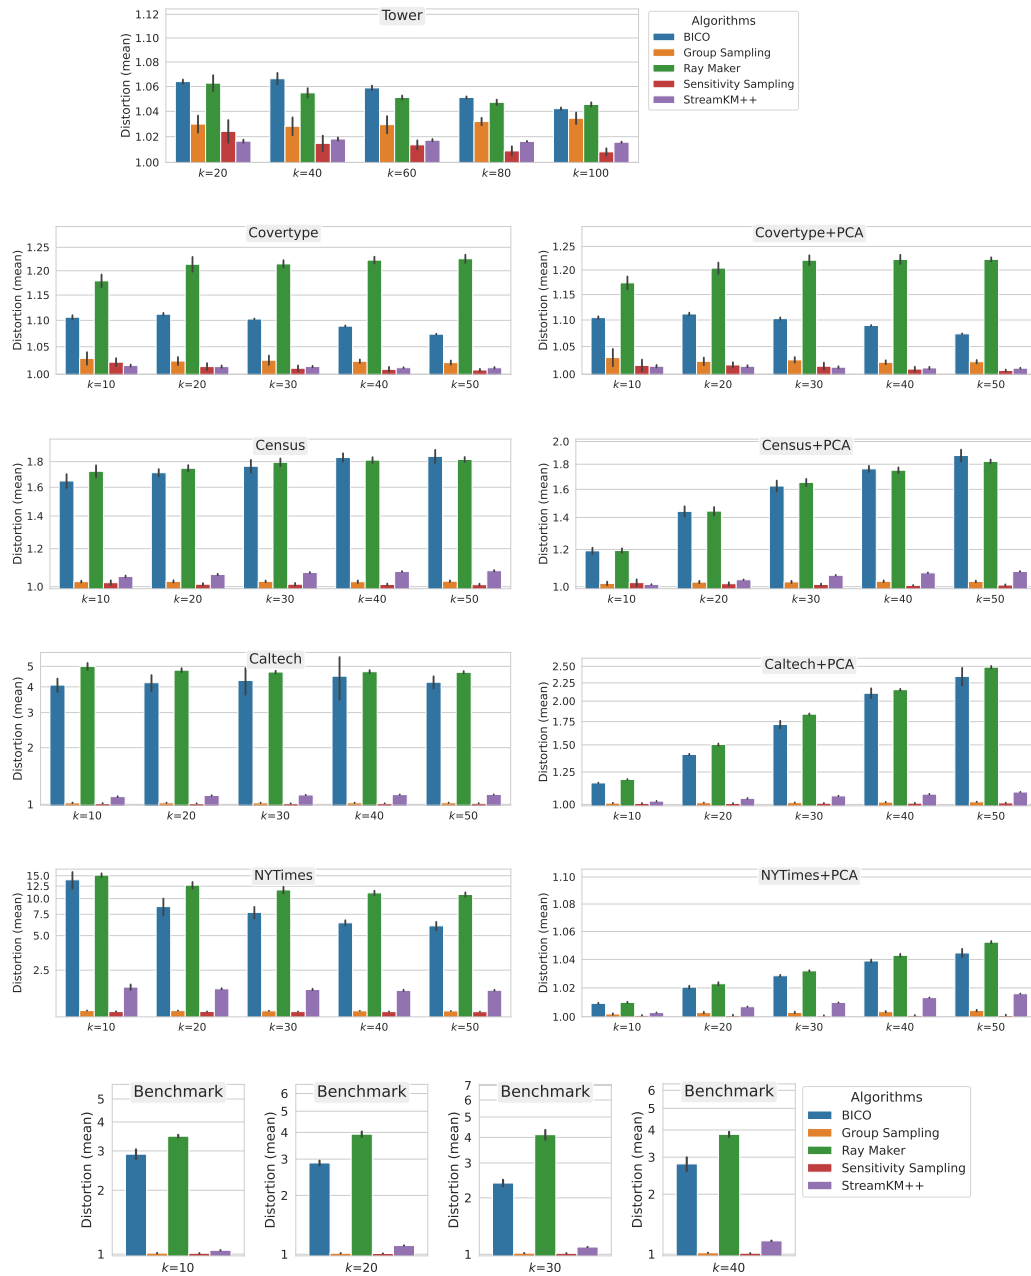

In Figure 2, we summarized the distortions of the experiments with coreset sizes $T = 200k$. All five algorithms are matched on the *Tower* dataset. The worst distortions across the algorithms are close to 1, and performance between the algorithms is negligible. The performance difference between sampling-based and movement-based methods become more pronounced as the number of dimensions increase. On *Coverttype* with its 54 features, Ray Maker performs the worst followed by BICO and Group Sampling while Sensitivity Sampling and StreamKM++ perform the best. Differences in performance are more noticeable on *Census*, *Caltech*, and *NYTimes* where methods based on importance sampling perform much better. Sensitivity Sampling and Group Sampling perform the best, StreamKM++ come in second while BICO and Ray Maker perform the worst across these data sets. On the *Benchmark*, Ray Maker is the worst while Sensitivity Sampling and Group Sampling are the best. StreamKM++ performs also very well compared to BICO.

Interpretation of Experimental Results

Optimization versus Compression. While all five algorithms are equally matched when optimizing on the candidate coresets, coreset quality performance differ significantly (see Figure 2). For all data sets, the obtained costs differed insignificantly for all values of k , irrespective of the coreset algorithm used, while distortions varied strongly, depending on the coreset algorithm.

⁹ <https://ls2-www.cs.tu-dortmund.de/grav/en/bico>

■ **Figure 2** The average distortions of the evaluated coreset algorithms with coreset size $T = 200k$ on five real-world data sets and on four benchmark instances. Black bars indicate standard deviations. Notice that the axis is non-linear as otherwise the bars for Sensitivity Sampling and Group Sampling would disappear on the plots as their distortions are close to 1.

■ **Figure 3** Depicts how clustering costs of five real-world data sets decrease as the number of centers increase. Plotting the cost curve allows us to study whether we can observe a difference between coreset construction and optimization in a data set when evaluating a coreset based on cost.

Nevertheless, the cost drop with increasing values of k is a predictor for the quality of certain coresets. It is not uncommon for the k -means cost of real-world data sets to drop significantly for larger values of k . Figure 3 illustrates this behavior for several real-world data sets. The more the curve bends, the less of a difference there is between computing a coreset and a clustering with low cost. For data sets with an L-shaped cost curve, a coreset algorithm adding more centers to the coreset will seem to be performing well when evaluating it based on the outcome of the optimization. *Tower* is a good example of a data set where optimization is very close to compression. Its cost curve bends the most which indicates that adding more centers help reduce the cost. One of the strengths of the benchmark is that there is no way of reducing the cost without capturing the right subclusters within a benchmark instance. This means that the cost does not decrease markedly beyond a certain value of k even if more centers are added.

For BICO, Ray Maker, and StreamKM++, there is a correlation between the steepness of the cost curve for a data set and the distortion of the generated coreset. On data sets where the curve is less steep, we observed higher distortions. The effect is more pronounced for BICO and Ray Maker than for StreamKM++. Importance sampling approaches (Group Sampling and Sensitivity Sampling) seem to be free from this behavior as they consistently generate high quality coresets irrespective of the shape of cost curve.

Movement-based versus Sampling-based Approaches. In general, movement-based constructions perform the worst in terms of coreset quality. We observed that BICO and Ray Maker have the highest distortions across all data sets including on the benchmark instances. Among the sampling-based algorithms, Sensitive Sampling performs well with Group Sampling generally being competitive. This runs contrary to theory where Group Sampling has the better (currently known) theoretical bounds. StreamKM++ is an interesting case. Like the movement-based methods, its distortion increases with the dimension. Nevertheless, it generally performs significantly better than BICO and Ray Maker. This can be attributed to the fact that the coreset produced by StreamKM++ consists entirely of

k -means++ centers weighted by the number of points of a minimal cost assignment. This is similar to movement-based algorithms such as BICO. Nevertheless, it also retains some of the performance from pure importance schemes.

In practice as well as in theory, the distortion of movement-based algorithms are affected by the dimension. By comparison, sampling-based algorithms are affected very little. Theoretically, there should not exist a difference, as the sampling bounds are independent of the dimension. What little effect can be observed is likely due to PCA making it easier to find low cost solutions that form the backbone of all coresets constructions. StreamKM++ is an interesting case, as it is still affected by the dimension, though less than the other movement based methods.

A notable exception is the benchmark. Here, sensitivity sampling generally found the lowest cost clustering, with BICO finding the second lowest cost clustering. This happens *despite* BICO generally having a worse distortion than for example Group Sampling or StreamKM++.

Impact of PCA. On almost all our data sets, the performance improves when input data is preprocessed with PCA, especially for the movement-based algorithms. Empirically, the more noise is removed (i.e., small k value), the lower the distortion. Notice that k is the number of principal components that the input data is projected on to. The rest of the low variance components are treated as noise and removed. Method utilizing sampling (Group Sampling, Sensitivity Sampling and StreamKM++) are less effected by the preprocessing step. On *Covertime*, PCA does not change the distortions by much because almost all the variance in the data is explained by the first five principal components. On *Caltech* and *NYTimes*, the quality of the coresets by BICO and Ray Maker improves greatly because the noise removal is more aggressive. Even if the quality is much better for movement-based coresets constructions due to PCA, importance sampling methods are still superior when it comes to the quality of the compression. Summarizing, all methods benefit from PCA, and in case of movement-based constructions, we consider PCA a necessary preprocessing step. For the sampling-based methods, the computational expense of using PCA in preprocessing does not seem justify the comparatively meager gains in coresets distortion.

5 Conclusion

In this work, we studied how to assess the quality of k -means coresets computed by state-of-the-art algorithms. Previous work generally measured the quality of optimization algorithms run on the coresets, which we empirically observed to be a poor indicator of coresets quality. For real-world data sets, we sampled candidate clusterings and evaluated the worst case distortion on them. Complementing this, we also proposed a benchmark framework which generates hard instances for known k -means coresets algorithms. Our experiments indicate a general advantage for algorithms based on importance sampling over movement-based methods. Despite movement-based methods running on very efficient code, it is necessary to complement them with rather expensive dimension reduction methods, rendering what efficiency they might have over importance sampling somewhat moot.

Two results bear further investigation. First, the currently known provable coresets sizes for Sensitivity Sampling are worse than those provable via Group Sampling. Empirically, we observed the opposite: While Group Sampling is competitive, Sensitivity Sampling always outperforms it. Since Group Sampling requires somewhat cumbersome computational overhead, practical applications should prefer Sensitivity Sampling. In light of these results, a theoretical analysis for Sensitivity Sampling matching the performance of Group Sampling would be welcome.

The second point of interest focuses on the performance of StreamKM++. The distortion of this algorithm is significantly better than what one would expect from its theoretical analysis. Empirically, StreamKM++ is notably better than the other movement-based constructions across all data sets, and especially on high dimensional data. While it is not competitive to the pure importance sampling algorithms, there are several reasons for investigating it further. It essentially only requires running k -means++ for additional iterations, which is already a nearly ubiquitous algorithm for the k -means problem. Although the other sampling-based coreset algorithms can also be readily implemented, doing so might be cumbersome. In particular, the theoretically (but not empirically) best algorithm Group Sampling requires extensive preprocessing steps. This begs the question whether there exist a better theoretical analysis for StreamKM++.

In addition, StreamKM++ currently weighs each point by the number of points assigned to it. It may also be possible to improve the performance of the algorithm in both theory and practice by using a different weighting scheme. We leave this as an open problem for future research.

Abstract

A synchronizing word of a deterministic finite complete automaton is a word whose action maps every state to a single one. Finding a shortest or a short synchronizing word is a central computational problem in the theory of synchronizing automata and is applied in other areas such as model-based testing and the theory of codes. Because the problem of finding a shortest synchronizing word is computationally hard, among *exact* algorithms only exponential ones are known. We redesign the previously fastest known exact algorithm based on the bidirectional breadth-first search and improve it with respect to time and space in a practical sense. We develop new algorithmic enhancements and adapt the algorithm to multithreaded and GPU computing. Our experiments show that the new algorithm is multiple times faster than the previously fastest one and its advantage quickly grows with the hardness of the problem instance. Given a modest time limit, we compute the lengths of the shortest synchronizing words for random binary automata up to 570 states, significantly beating the previous record. We refine the experimental estimation of the average reset threshold of these automata. Finally, we develop a general computational package devoted to the problem, where an efficient and practical implementation of our algorithm is included, together with several well-known heuristics.

1 Introduction

A *deterministic finite complete semi-automaton* (called simply an *automaton*) is a 3-tuple (Q, Σ, δ) , where Q is a finite set of *states*, Σ is an *input alphabet*, and $\delta: Q \times \Sigma \rightarrow Q$ is a completely defined *transition function*. The transition function is naturally extended to a function $Q \times \Sigma^* \rightarrow Q$. Throughout the paper, by n we denote the number of states in Q and by k we denote the size of the input alphabet Σ . A word is *reset* (or *synchronizing*) if $|\delta(Q, w)| = 1$; in other words, for every two states $p, q \in Q$ we have $\delta(q, w) = \delta(p, w)$. An automaton that admits a reset word is called *synchronizing*.

The classical synchronization problem is, for a given synchronizing automaton, to find a reset word. Preferably, this word should be as short as possible. Therefore, the main property of a synchronizing automaton is its *reset threshold*, which is the length of the shortest reset words. We denote the reset threshold by r . Synchronizing automata and the synchronization problem are known for both their theoretical properties and practical applications.

1.1 Theoretical Developments

On the theoretical side, there is a famous long-standing open problem from 1969 called the Černý conjecture; see an old [44] and a recent survey [18]. The conjecture claims that the reset threshold is at most $(n-1)^2$. If true, the bound would be tight, as the Černý automata meet the bound for each n [8].

Until 2017, the best known upper bound on the reset threshold was $(n^3 - n)/6 - 1 \sim 0.1666\dots n^3 + \mathcal{O}(n^2)$ ($n \geq 4$) [26] by the well-known Frankl-Pin's bound. The current best known upper bound is $\sim 0.1654n^3 + o(n^3)$ by Shitov [37], which was obtained by refining the previous improvement $\sim 0.1664n^3 + \mathcal{O}(n^2)$ by Szykuła [39]. Apart from that, better bounds were obtained for many special subclasses of automata. Synchronizing automata are also applied in other theoretical areas, e.g., matrix theory [14], theory of codes [7], Markov processes [43]. Several new results around the topic appear every year. Recently, a special journal issue was dedicated to the problem [45] for the occasion of the 50th anniversary of the problem.

Reset thresholds were also studied for the average case. Berlinkov showed that a random binary automaton is synchronizing with high probability [5]. Moreover, Nicaud showed that such an automaton with high probability has a reset threshold in $\mathcal{O}(n \log^3 n)$ [24]. Based on that, the upper bound $\mathcal{O}(n^{3/2+o(1)})$ on the expected reset threshold of a random binary automaton was obtained [4]. These studies were accompanied by experiments, and the best estimation obtained so far was $2.5\sqrt{n-5}$ [19].

There were also performed massive experiments directly aimed at verifying the Černý conjecture and other theoretical properties for automata with small numbers of states [9, 21, 42]. For all such studies, finding (the length of) a shortest reset word is a crucial problem.

1.2 Synchronization in Applications

Apart from the theory, the synchronization problem finds applications in practical areas, e.g., testing of reactive systems [29, 34], networks [17], robotics [1], and codes [15].

Automata are frequently used to model the behavior of systems, devices, circuits, etc. The idea of synchronization is natural: we aim to restore control over a device whose current state is not known or we do not want our actions to be dependent on it. For instance, for digital circuits, where we need to test the conformance of the system according to its model, each test is an input word and before we run the next one, we need to restart the device. In another setting, we are an observer who knows the structure of the automaton but does not see its current state and wants to eventually learn it by observing the input; once a reset word appears, the state is revealed unambiguously. See a survey [34] explaining synchronizing sequences and their generalization to automata with output: *homing sequences*, which allow determining the (hidden) current state of the automaton by additionally observing the generated automaton's output.

Another particular application comes from the theory of codes, where finite automata act as *decoders* of a compressed input. Synchronizing words can make a code resistant to errors, since if an error occurs, after reading such a word, decoding is restored to the correct path. See a book for the role of synchronization in the theory of codes [7] and recent works [6] explaining synchronization applied to prefix codes.

1.3 Algorithms Finding Reset Words

Determining the reset threshold is computationally hard. The decision problem, whether the reset threshold is smaller than a given integer, is NP-complete [10], and it remains hard even for very restrictive classes such as binary Eulerian automata [47]. The functional problems of computing the reset threshold and a shortest reset word are respectively $\text{FP}^{\text{NP}^{\lceil \log \rceil}}$ -complete and FP^{NP} -complete [25]. Moreover, approximating the reset threshold is hard even for approximation factors in $\mathcal{O}(n^{1-\varepsilon})$, for every $\varepsilon > 0$ [12]. This inapproximability also holds for subclasses related to prefix codes [33]. On the other hand, there exists a simple general $\mathcal{O}(n)$ -approximating polynomial algorithm [13]. It is open whether there exists a polynomial algorithm approximating within some sublinear factor, e.g., in $\mathcal{O}(n/\log n)$.

From the perspective of fixed-parameter tractability, the main parameter determining the hardness is the reset threshold itself (and the alphabet size, if not fixed). It plays a similar role as the number of variables in the SAT problem, yet, in contrast, it is not given but is the result to be computed. It is trivial to compute the reset threshold in time $\mathcal{O}(n \cdot k^r)$ simply by checking all words of length $1, 2, \dots, r$ (we need $\mathcal{O}(n)$ time for computing the image of a subset of Q under the action of one letter). This essentially cannot be much better, as assuming the Strong Exponential Time Hypothesis (SETH), the problem cannot be solved in time $\mathcal{O}^*((k - \varepsilon)^r)$, for every $\varepsilon > 0$ [11, Theorem 8], where \mathcal{O}^* suppresses all polynomial factors in the size of the input.

Therefore, exponential exact algorithms that hopefully find a shortest reset word faster in typical or average cases are used. Alternatively, there are many polynomial heuristics proposed that find a relatively short reset word in practice.

1.3.1 Exact Algorithms

In general, exact algorithms can be used for automata that are not too large. They also play an important role in testing heuristics, providing the baseline for comparison (e.g., [30]).

The naive algorithm of checking all words is practically slow, as it does not involve any optimization and works always in time $\mathcal{O}^*(k^r)$. The standard algorithm, e.g., [23, 34, 42], for computing a shortest reset word is finding a path of state subsets in the power automaton (that is, the automaton whose set of states is 2^Q) from Q to a singleton. This works in at most $\mathcal{O}(kn \cdot 2^n)$ time but is practically faster as we usually traverse through fewer sets. Note that n may be much smaller than r (we know examples where r can be quadratic in n , e.g., [2]), but in the average case it is the opposite. The main drawback of this algorithm is its requirement of $\mathcal{O}(2^n)$ space, which is acceptable only up to small $n \sim 30$.

Alternative approaches include utilizing SAT solvers [38] by suitable reductions of the problem and binary search over possible values of r . SAT solvers were also recently tried for partial deterministic finite automata and *careful synchronization* [36]. In the reported results, such solutions reach random binary automata with about 100 states.

The fastest algorithm so far is based on a bidirectional search of the power automaton, equipped with several enhancements [19, 20]. This algorithm was able to deal with binary random automata up to 350 states. Despite several later attempts, no faster solutions were developed and the algorithm was not improved until now.

1.3.2 Heuristic Algorithms

The most classic polynomial algorithm is Eppstein’s one [10]. It works in $\mathcal{O}(n^3 + kn^2)$ time and finds a reset word of length at most $(n^3 - n)/3$ (due to the Frankl-Pin’s bound). Several heuristic improvements were proposed, e.g., Cycle, SynchroP, and SynchroPL algorithms [23, 42], which do not improve guarantees but behave better in experimental settings, even at the cost of increased worst-case time complexity. Recent works also involve attempts to speed-up heuristics by adapting to parallel and GPU computation [35, 41].

A remarkable heuristic is the *beam* algorithm based on inverse breadth-first search ([30, *CutOff-IBFS*]), i.e., starting from a singleton and ending with Q , which significantly beats other algorithms based on the forward search. Yet, curiously, it does not provide any worst-case guarantees, as it theoretically may not find any reset word at all.

Alternative approaches involve artificial intelligence methods, e.g., hierarchical classifier [28], genetic algorithms [22], and machine learning approaches [27].

1.4 Contribution

We reinvestigate the so-far best exact algorithm [19, 20] and significantly improve it. We develop a series of algorithmic enhancements involving better data structures, decision mechanisms, and reduction procedures. Altogether, we obtain a significant speed-up and decrease the memory requirements. Additionally, the remodeled algorithm is adapted for effective usage of multithreading and GPU computing, which was not possible in the original.

On the implementation side, we develop an open computational package containing the new exact algorithm as well as several known polynomial heuristics. We apply a series of technical optimizations and fine-tune the algorithm to maximize efficiency. The package supports configurable just-in-time compiled computation plans and can be extended with new algorithms.

In the experimental section, we test the efficiency of the algorithm and compute the reset thresholds of binary random automata up to 570 states. We refine the previous estimation formula for the expected reset threshold of these automata.

The computational package is available at [40] (the version related to this paper is 1.1.0).

2 The New Exact Algorithm

Our algorithm is based on the former best exact algorithm [19, 20]. While the new version differs in the choice of data structures and subprocedures, at a high level it is similar and uses two main phases – bidirectional breadth-first search and then inverse depth-first search.

The input to the algorithm is an automaton $\mathcal{A} = (Q, \Sigma, \delta)$ with n states and k input letters. The goal is to find its reset threshold r . In the first step, we check if \mathcal{A} is synchronizing by the well-known procedure [44], which checks for every two states $p, q \in Q$ whether they can be mapped to one state; this is doable in $\mathcal{O}(kn^2)$. Then we get upper bounds on the reset threshold by using polynomial-time heuristics. For this, we use the Eppstein algorithm [10] at first, and then the enhanced *beam* algorithm [30, *CutOff-IBFS*]. The found upper bound helps the main procedure make better decisions.

Given a subset $S \subseteq Q$ and a word $w \in \Sigma^*$, the *image* of S under the action of w is $\delta(S, w) = \{\delta(q, w) \mid q \in S\}$. The *preimage* of S under the action of w is $\delta^{-1}(S, w) = \{q \in Q \mid \delta(q, w) \in S\}$.

The key idea is to simultaneously run a breadth-first search (BFS) starting from the set Q and computing images, together with an inverse breadth-first search (IBFS) starting from all of the singletons and computing preimages. While both algorithms on their own

require computation of at most k^r or at most nk^r sets respectively, combining them lets us compute no more than $nk^{r/2}$ sets, provided that we can somehow test if the searches have met. To do this, we need to check if there exists a pair X, Y of sets, belonging respectively to the BFS and IBFS lists, such that $X \subseteq Y$. Indeed, then we know that there are words $x, y \in \Sigma^*$ such that $X = \delta(Q, x)$ and $Y = \delta^{-1}(\{q\}, y)$ for some $q \in Q$. Because $X \subseteq Y$, we get $\delta(Q, xy) = \{q\}$, which means that xy is a reset word. Due to the *Orthogonal Vectors Conjecture* [16], there is probably no subquadratic solution to this subset problem¹. Such a solution would also contradict the mentioned fact that we cannot find the reset threshold in $\mathcal{O}^*((k - \varepsilon)^r)$ time assuming SETH. Nevertheless, we employ procedures that work well in our practical case. They are also used to reduce the number of sets in the lists during the searches, which effectively lowers the branching factor. Finally, we do not actually run the two searches until they meet. Instead, we switch to the second phase with inverse DFS (which takes the steps only on the IBFS side computing preimages), when either the memory runs out or we calculate that it should be faster based on the upper bound from the heuristics and the collected statistics.

These high-level ideas are derived from the previous algorithm. However, we design different, more efficient procedures and optimizations for these steps so that it is possible to solve the problem significantly faster and for larger automata. First, we modify data structures and redesign how a single iteration of BFS / IBFS works. Apart from making the bidirectional-search phase faster, it allows completing more iterations before switching to the DFS phase due to the lower memory consumption, which is crucial in the case of large automata. The decision-making part of the algorithm is also extended. We use five types of steps, and the decision on which step to take is based on statistics from the current algorithm's run and forward prediction. In the DFS phase, we enhance the radix trie data structure in terms of both efficiency and memory overhead. We also apply some forms of list reductions, which decrease the branching factor. Finally, every part of the new algorithm can be parallelized in one way or the other, which was not possible before; the general difficulty of parallelization comes from large shared data structures and a lot of branching.

In the next sections, we describe the new algorithmic techniques. For the sake of brevity, we consider a version that only calculates the reset threshold. The algorithm can be trivially modified to also return the reset word by storing pointers to predecessors along with the sets, although then either time or memory footprint is slightly increased.

2.1 Bidirectional Breadth-First Search

The first phase of the algorithm consists of running the two breadth-first searches. The BFS starts with a list L_{BFS} containing just the set Q . When the search starts a new iteration, L_{BFS} is replaced with $\{\delta(S, a) \mid S \in L_{\text{BFS}}, a \in \Sigma\}$. Conversely, L_{IBFS} is initialized with all the singletons and the list is replaced with $\{\delta^{-1}(S, w) \mid S \in L_{\text{IBFS}}, w \in \Sigma\}$.

We say that the two searches *meet* if there exist $X \in L_{\text{BFS}}$ and $Y \in L_{\text{IBFS}}$ for which $X \subseteq Y$ holds. The meet condition implies that the lists can be reduced by removing the elements which are not minimal (and respectively maximal for IBFS) with respect to inclusion. We can reduce the lists further by ensuring that no new set is a superset (subset for IBFS) of a set belonging to some list from any previous iteration. To make this possible, we keep track

¹ The *Orthogonal Vectors problem* gives two sets A, B of Boolean vectors of the same length and asks if there exists a pair $(u \in A, v \in B)$ such that u and v are orthogonal, i.e., $u \cdot v = \mathbf{0}$. We can reduce our problem to *OV* by transforming the sets in Y to their complements and then representing all the sets as their characteristic vectors.

of all the visited sets in two additional *history* lists H_{BFS} , H_{IBFS} . This reduction, although usually helpful during most of the iterations, at the end may turn out to be unprofitable, in which case the algorithm will drop the history list(s).

The original idea for the subprocedure to check the meet condition was to keep the lists as dynamic *radix tries*, supporting insertion and subset (or superset) checking operations. Now, instead, we take a somewhat simpler approach and operate directly on the lists, stored as random access containers (such as vectors in C++). We call this subprocedure $\text{MarkSupersets}(A, B)$ (and a similar one – $\text{MarkProperSupersets}(A, B)$, which additionally restricts the marked supersets to be non-equal to their subsets).

We split the reductions into three subprocedures: removing duplicates, self-reduction, and then reduction by history. In contrast to performing only one and the most expensive reduction by history (which could also include the first two reductions), after each subprocedure the list size gets smaller, which makes the next one run faster.

Alg. 1 shows the pseudocode of the bidirectional-search phase.

2.1.1 Subset and Superset Checking

There exist several algorithms solving the extremal sets problem in practical settings, e.g., [3]. They take a list of sets and mark all those that are not a subset of any other set.

We use a similar method to those utilizing a lexicographic sort, but we operate on two lists and are allowed to change the order of the second list during computation. MarkSupersets (Alg. 2) takes lists A and B and swaps sets in B so that those sets that are supersets of some sets from A appear at the end. The sets are treated like binary strings, i.e., their characteristic vectors, of length n . The procedure recursively splits the sets in A into those containing the d -th state and those not containing it, where d is the recursion depth. In this sense, it works by implicitly building a radix trie on A . We require that A is sorted lexicographically and its elements are unique, which can be guaranteed relatively cheaply before calling the procedure, as sorting is much faster than subset checking. The order gives us the property that the sets containing the d -th state and those not containing it are stored in continuous segments, so we can effectively split A . This lets us simulate in-place trie traversal with a recursive procedure that takes intervals of the lists as inputs. When the intervals are small (determined by the constant parameter MIN , Alg. 2 line 2), we can use a brute-force check instead of recursing further, which makes the procedure faster (especially important with GPU).

MarkSupersets is used to reduce the BFS list and to check the meet condition. To implement the MarkSubsets procedure needed on the IBFS side, we simply convert the sets to their complements and call MarkSupersets . The procedure $\text{MarkProperSupersets}$ is identical except for checking the containment for a pair of sets, where we additionally check that the two sets are different. When we use multithreading, we split the B list into equal parts after shuffling and execute parallel calls of the procedure. On GPU, we increase the MIN parameter and run the brute-force part there.

2.1.2 Decision Procedure

As the algorithm progresses, some steps may become unprofitable. The history lists, though helpful at the beginning, increase memory usage and cause a slow down if used in late iterations. Similarly, list reductions via MarkSupersets decrease the branching factor, but they are not that crucial when the search is approaching the reset threshold upper bound.

Algorithm 1 Bidirectional breadth-first search.

Input: A synchronizing automaton $\mathcal{A} = (Q, \Sigma, \delta)$ with $n = |Q|$ states and $k = |\Sigma|$ input letters. An upper bound R on the reset threshold.

Output: Reset threshold r .

```

1:  $L_{\text{BFS}}, H_{\text{BFS}} \leftarrow \{Q\}$ 
2:  $L_{\text{IBFS}}, H_{\text{IBFS}} \leftarrow \{\{q\} \mid q \in Q\}$ 
3: for  $r$  from 1 to  $R - 1$  do
4:   switch  $\text{CalculateBestStep}()$  do
5:     case BFS
6:       if  $H_{\text{BFS}}$  has grown significantly since its last reduction then
7:         Delete subsets from  $H_{\text{BFS}}$  that are larger than the largest ones from  $L_{\text{BFS}}$ 
8:         Delete non-minimal subsets from  $H_{\text{BFS}}$  ( $\text{MarkProperSupersets}$ )
9:       end if
10:       $L_{\text{BFS}} \leftarrow \text{CalculateImages}(L_{\text{BFS}})$ 
11:      Delete duplicates from  $L_{\text{BFS}}$  (lex. sort)
12:      Delete non-minimal subsets from  $L_{\text{BFS}}$  ( $\text{MarkProperSupersets}$ )
13:      Delete supersets of  $H_{\text{BFS}}$  from  $L_{\text{BFS}}$  ( $\text{MarkSupersets}$ )
14:       $H_{\text{BFS}} \leftarrow H_{\text{BFS}} \cup L_{\text{BFS}}$ 
15:     case  $\text{BFS}^{\text{NH}}$  (without history)
16:        $L_{\text{BFS}} \leftarrow \text{CalculateImages}(L_{\text{BFS}})$ 
17:       Delete duplicates from  $L_{\text{BFS}}$  (lex. sort)
18:       Delete non-minimal subsets from  $L_{\text{BFS}}$  ( $\text{MarkProperSupersets}$ )
19:     case IBFS
20:       ... ▷ Analogous to BFS
21:     case  $\text{IBFS}^{\text{NH}}$  (without history)
22:       ... ▷ Analogous to BFS (without history)
23:     case DFS
24:        $\text{DFS}(\text{BuildStaticTrie}(L_{\text{BFS}}), L_{\text{IBFS}}, r, R)$ 
25:       return  $R$  ▷ DFS sets  $R \leftarrow$  the reset threshold
26:   if  $\text{MarkSupersets}(L_{\text{BFS}}, L_{\text{IBFS}})$  has found at least one superset then
27:     return  $r$ 
28:   end if
29: end for
30: return  $R$ 

```

We distinguish five types of steps from which the algorithm always chooses one for the next iteration – DFS, BFS, IBFS, BFS without the history list (denoted by BFS^{NH}) and IBFS without the history list (denoted by IBFS^{NH}). To assess which option to choose, we roughly estimate the cost subset checking operations each of them will require.

We reuse some of the equations previously defined in [20]. In particular, under simplifying assumptions about the uniform distribution of the states in sets we take their upper bound from [20, Theorem 4] previously applied to tries. Since our procedure can be interpreted as building a trie implicitly on the fly, this bound can also serve as a rough bound on the expected number of subset checking operations in a call to MarkSupersets . Let A_s, B_s be the size of the lists and A_d, B_d be their densities, i.e., for a list L let $\text{density}(L) = \frac{\sum_{s \in L} |S|}{n|L|}$.

Algorithm 2 Recursive procedure *MarkSupersets*.

Input: Lexicographically sorted list intervals A and B of sets with unique elements. Current depth of recursion d ($d = 0$ for the initial call).

```

1: procedure MARKSUPERSETS( $A, B, d$ )
2:   if  $|A| < MIN$  then                                     ▷ Brute-force for small  $|A|$ 
3:     Check each pair in  $A \times B$  and delete the supersets from  $B$  (move at the end and
       shrink the interval).
4:   else
5:      $A_0, A_1 \leftarrow A$  split by the  $d$ -th bit           ▷  $A$  is sorted, so a binary search suffices
6:     MarkSupersets( $A_0, B, d + 1$ )
7:     Sort  $B$  by the  $d$ -th bit.                               ▷ Linear time scan
8:      $B_1 \leftarrow$  interval in which the  $d$ -th bit is set   ▷ Suffix of  $B$ 
9:     MarkSupersets( $A_1, B_1, d + 1$ )
10:  end if
11: end procedure

```

Then, analogously to [20, EXPNVN in 4.2], we define:

$$ExpMark(A_s, B_s, A_d, B_d) = B_s \left(\frac{1 + B_d}{B_d} + \frac{1}{A_d - A_d B_d} \right) A_s^{\log_w(1 + B_d)},$$

where $w = (1 + B_d)/(1 + A_d B_d - A_d)$.

To estimate the sizes of the lists after (and in between) the reductions, we store the ratios $r_{\text{BFS}}^{\text{dupl}}, r_{\text{BFS}}^{\text{self}}, r_{\text{BFS}}^{\text{hist}}$ of the reduced sets respectively by the removal of duplicates, the removal of non-minimal subsets, and the reduction by history list. For instance, $r_{\text{BFS}}^{\text{dupl}}$ is the fraction of the removed duplicates during the first reduction. Similarly, separate ones are stored for the IBFS counterpart. In addition to the cost of subset checking, we also add the cost of computing sets themselves and reduction of duplicates (the constant *SetCost*, set to 512 in the implementation); however, in most cases, the cost of subset checking is dominant.

For instance, the cost of the next BFS step is calculated as follows:

$$BFS_{\text{cost}} = SetCost \cdot k \cdot |L_{\text{BFS}}| \tag{1}$$

$$+ ExpMark(k \cdot (1 - r_{\text{BFS}}^{\text{dupl}}) \cdot |L_{\text{BFS}}|, \quad k \cdot (1 - r_{\text{BFS}}^{\text{dupl}}) \cdot |L_{\text{BFS}}|, \tag{2}$$

$$density(L_{\text{BFS}}), \quad density(L_{\text{BFS}}))$$

$$+ ExpMark(|H_{\text{BFS}}|, \quad k \cdot (1 - r_{\text{BFS}}^{\text{dupl}}) \cdot (1 - r_{\text{BFS}}^{\text{self}}) \cdot |L_{\text{BFS}}|, \tag{3}$$

$$density(H_{\text{BFS}}), \quad density(L_{\text{BFS}}))$$

$$+ ExpMark(k \cdot (1 - r_{\text{BFS}}^{\text{dupl}}) \cdot (1 - r_{\text{BFS}}^{\text{self}}) \cdot (1 - r_{\text{BFS}}^{\text{hist}}) \cdot |L_{\text{BFS}}|, \quad |L_{\text{IBFS}}|, \tag{4}$$

$$density(L_{\text{BFS}}), \quad density(L_{\text{IBFS}})).$$

The formula is the sum of the four costs: the set cost (1), which estimates the cost of computing the successors' list with images and reduction of duplicates, the self-reduction cost (2), which assumes that the list size was already reduced by the factor $r_{\text{BFS}}^{\text{dupl}}$, the reduction by history cost (3), which assumes both preceding reductions, and the meet condition check cost (4).

The formulas for BFS^{NH} , IBFS , and IBFS^{NH} are analogous. Additionally, if we cannot perform a step because there is not enough memory, we set its expected cost to ∞ . Once we choose BFS^{NH} , we free the history and no longer consider the BFS step with it, so in this case, we also set its cost to ∞ (this is symmetrical for IBFS^{NH} and IBFS).

Next, we try to predict the full costs of choosing these steps by estimating the number of operations under the assumption that the algorithm will transition into the DFS phase one iteration later (or in the current iteration in the case of the *DFS* option). First, we calculate the expected branching factor in the DFS phase

$$f = k \cdot (1 - r_{\text{IBFS}}^{\text{dupl}} \cdot \text{DFSReductionOfReduction}),$$

where we take the average reduction of duplicates from the IBFS step and reduce it by some factor for a more pessimistic estimation ($\text{DFSReductionOfReduction} = 1/k$ in the implementation). $r_{\text{IBFS}}^{\text{dupl}}$ is the ratio of duplicates removed in the IBFS list during the latest reduction (since the DFS also removes duplicates). We assume conservatively that the reset threshold is equal to the known upper bound R and from that, we get the estimated number of iterations $R - r$ that still need to be done, where r is the number of the current iteration, which just begins. The predicted full cost of the BFS option is as follows (the number of sets multiplied by the set computing costs together with the meet condition cost):

$$\begin{aligned} \text{DFS}_{\text{pred}} = & f \cdot \frac{f^{R-r} - 1}{f - 1} \cdot (\text{SetCost} \cdot \text{DFSSetCostWeight} \cdot k/f \\ & + \text{DFSCheckCostWeight} \cdot \text{ExpMark}(|L_{\text{BFS}}|, |L_{\text{IBFS}}|, \text{density}(L_{\text{BFS}}), \text{density}(L_{\text{IBFS}}))), \end{aligned}$$

where DFSSetCostWeight and $\text{DFSCheckCostWeight}$ are constants (both set to 0.25 in the implementation) compensating for the fact that the operations are faster in the DFS phase, as additional optimizations are possible.

Finally, the step with the lowest predicted full cost is chosen. As an exception to this rule, if we do not expect to switch into the DFS phase soon (the steps without the history have both larger costs than the regular steps), instead of comparing the prediction costs of every choice, we consider only the BFS and IBFS costs and greedily choose the one with the lower single-step cost. This makes the bidirectional search more balanced in the short term. Otherwise, BFS is strongly preferred due to the assumption that the rest of the steps will be (inverse) DFS, which computes preimages, but the early statistics are less relevant for its estimation.

2.1.3 Heuristic Upper Bound

Having a good upper bound R on the reset threshold, preferably tight, is crucial for making the right decisions, i.e., not giving away history or entering the DFS phase too late. On the other hand, we do not want to spend too much time computing the bound.

The beam algorithm has its parameter *beam size*, which limits the size of the list and thus directly controls the quality (i.e., how close R is to the reset threshold) and complexity trade-off. Instead of setting the beam size to be a function of n ([20, 30]), we use an adaptive approach. We run it first with a relatively small beam size to find some reasonable bound, and then use this bound to calculate a rough estimation of the running time of the exact algorithm. The beam size is selected so that the beam algorithm's cost is a small fraction of that of the exact algorithm. In practice, this means that the beam size is larger for automata with larger (upper bounds on) reset thresholds than for those automata with smaller ones, even when n is the same.

2.2 Depth-First Search

In the second phase, the algorithm switches to an inverse depth-first search, which allows staying within the memory limit by adjusting the maximum list size. During this phase, the steps are taken only on the IBFS side. The fact that the BFS list no longer changes allows the meet condition check to be optimized.

2.2.1 Static Radix Trie

The L_{BFS} list is stored in an optimized data structure that supports the *ContainsSubset* operation. It is based on a radix trie, in which the characteristic vectors of the sets are stored. The queries rely on traversing the trie and, in each step, descending to either both children or just the left (zero) child, depending on the queried set.

In contrast with the usual radix trie, we apply a few specific optimizations:

Variable state ordering. In each node at a depth d , instead of splitting the subtrees by the d -th state, we split by a state x chosen specifically for the node. The state x is chosen so that the number of sets stored in the current subtree that also contain x is the largest possible. In practice, this makes the queries faster, since, in vertices such that x does not belong to the queried set, a large number of sets is immediately skipped.

This optimization also implies path compression, as we do not have nodes that do not split the sets into two non-empty parts. To ensure this, we also exclude the case that x is contained in all the sets and do not use it as a division state.

Leaf threshold. For a fixed constant parameter MIN ($= 10$ in the implementation), when the number of sets in a subtree is less or equal to MIN , we store them all in one vertex and do not recurse further. This does not increase running time and lowers the memory overhead. Technically, we can already store the sets in a node whose left (zero) subtree contains at most MIN sets, which avoids creating an additional node.

Joint queries. Instead of checking each subset separately, we group them by the same cardinality and check one group in a call using the swapping technique as in Alg. 2. Grouping saves operations responsible for traversing the trie, and additionally, grouping by cardinality allows to make cheap size elimination checks as below.

Size elimination. Every node v stores the minimal size m_v of the sets in its subtree. When we query for subsets of size s , if $m_v \leq s$ does not hold, we do not recurse into the subtree of v . This enhancement is derived from the previous algorithm [20], yet due to joint queries, we make these checks cheaper by executing at most one such check in a node for one cardinality. A similar optimization from the previous algorithm is mask elimination – checking if the intersection of all subsets in the subtree is contained in the queries set, yet we do not use it as it does not improve performance in our case.

Our trie can be built in time $\mathcal{O}(|L_{\text{BFS}}| \cdot n^2)$ ($< n$ levels processed in time $\mathcal{O}(|L_{\text{BFS}}| \cdot n)$).

2.2.2 DFS Procedure

During the search, at each depth, the current list is split into parts of size at most $\text{available_memory}/((k+1)(R-r))$, where $R-r$ is the upper bound on the remaining number of steps to be done. Then, it recurses with each of these parts one by one, to make sure we do not run out of memory. The elements are sorted in order of descending cardinality so that the most promising sets are recursed first, which in turn can quickly improve the upper bound if it was not tight. The cardinality sort is also necessary for joint queries. The lists are reduced by the removal of duplicates and calls to *MarkSubsets* only once every few iterations, which still lowers the branching factor significantly. Parallel computation is performed by a thread pool with tasks being these separate calls for each cardinality.

3 Experiments

The implementation used for experiments is available at [40]. The tests were using `exact_reduce` configuration. The *old* algorithm [20] was run with the original code provided to us by the authors. The experiments with time measurement were run on computers with

■ **Figure 1** The mean running time for random binary automata with different numbers of states (left) and with different reset thresholds (right).

AMD Ryzen Threadripper 3960X 24-Core Processor, 64GB RAM, and two RTX3080 Nvidia GPU cards. We compiled the code using `gcc 9.3.0` and `nvcc 10.1` (run with `gcc 7.5.0`). We have tested the algorithm in both the *single-threaded* (only one thread without GPU) and *parallel* modes (6 threads and GPU enabled).

A *random* automaton with n states and k letters is generated by choosing each transition $\delta(q, a) \in Q$ uniformly at random, for $q \in Q, a \in \Sigma$. There is a negligible number of non-synchronizing automata obtained in this way, which were excluded (cf. [5]).

3.1 The Efficiency

Fig. 1 shows the efficiency comparison of our algorithm in both single-threaded and parallel modes, together with the old algorithm. This experiment was run for 1,000 random binary automata for each $n \in \{250, 255, \dots, 395\}$. We managed to test automata with up to 395 with the old algorithm, which took 3,177h computation time of a single process in total (we have used more memory, better hardware, and computed 10 times fewer automata per n than in the original experiments [20], which were done up to $n = 350$). The (unfinished) attempt to compute 1,000 automata with $n = 400$ by the old algorithm took over 770h, whereas our algorithm (single-threaded) finished in 48h. The total computation time of our algorithm up to $n = 395$ was resp. 299h in the single-threaded mode and 135h in the parallel mode.

Fig. 2 shows the average increase in running time when the reset threshold grows. The general observed tendency is a factor of about 1.5 for our algorithm.

■ **Figure 2** The mean running time growth factor in relation to reset threshold (left) and the mean running time in a logarithmic scale (right).

■ **Figure 3** The mean reset threshold of binary automata with n states. For every $n \in \{5, 10, \dots, 300\}$, $n \in \{305, 310, \dots, 400, 410, 420, \dots, 500\}$, and $n \in \{510, 520, \dots, 570\}$ we calculated resp. 10,000, 1,000, and 100 automata.

Hard instances

Most automata have their reset thresholds sublinear, but there exist other examples (though they are rare). As the reset threshold is the main indicator of difficulty, even instances with a small number of states should be difficult for algorithms.

From the known constructions, the most extreme automata with respect to the reset threshold are *slowly synchronizing* ones [2]. They have reset thresholds close to $(n-1)^2$, and the Černý series meets this bound. Yet, they all have the property that the IBFS list reduces to a constant number of sets in every iteration, thus our algorithm works in polynomial time for them, just as the old algorithm. An example of extreme automata without this property could be the unique series of automata with a *sink* state (i.e., a state $q \in Q$ such that $\delta(q, a) = q$ for all $a \in \Sigma$), that reaches the maximum reset threshold $n(n-1)/2$ in this class [31]. (A synchronizing automaton can have at most one sink state and a reset word must map all the states to it.) A *slowly sink* automaton from this series with 26 states has 25 letters and its reset threshold 325 is computed by the old algorithm in 34m 14s, whereas the new algorithm computes it in 7m 22s (parallel).

3.2 Mean reset threshold

In the second experiment, we computed reset thresholds of random binary automata with $n \in \{410, 420, \dots, 570\}$ states with our algorithm in parallel mode. The mean computation time for $n = 500$ was 9m 42s. Fig. 3 shows the mean reset threshold. In addition, up to $n = 5,000$ we computed a good upper bound using the beam algorithm with beam size $n \log n$ (we made the beam algorithm much faster due to GPU computation; the previous such experiments were done up to $n = 1000$ [30]).

It is now visible that the previous formula $2.5\sqrt{n-5}$ is underestimated. On the other hand, a standard approach² of deriving a function of the form $a(n+b)^c + d$ yields a wrong formula, lately exceeding the upper bound obtained by the beam. We decrease the exponent to fit with a more accurate estimation $2.284n^{0.515}$.

² We use the algorithm from `scipy.optimize.curve_fit` with the Levenberg-Marquardt algorithm.

4 Conclusions

We have improved the best-known algorithm for computing the (length of the) shortest reset words. While the overall idea of employing bidirectional breadth-first search is the same, we replace each of its subprocedures with more efficient ones.

The algorithm can be easily adapted to alternative synchronization settings and other related problems. For instance, it is trivial to use it for *careful* synchronization [36], where some transitions can be forbidden. It can also be adapted to, e.g, non-careful settings [6], *mortal words* [32], or subset synchronization [46].

For future work, we plan to use this new algorithmic tool to perform more extensive experiments concerning reset thresholds, especially with larger automata and with a larger alphabet. Finally, it can be used to experimentally verify or extend the current verification range of certain conjectures.

Fast RSK Correspondence by Doubling Search

Alexander Tiskin 

Department of Mathematics and Computer Science, St. Petersburg State University, Russia

Abstract

The Robinson–Schensted–Knuth (RSK) correspondence is a fundamental concept in combinatorics and representation theory. It is defined as a certain bijection between permutations and pairs of Young tableaux of a given order. We consider the RSK correspondence as an algorithmic problem, along with the closely related k -chain problem. We give a simple, direct description of the symmetric RSK algorithm, which is implied by the k -chain algorithms of Viennot and of Felsner and Wernisch. We also show how the doubling search of Bentley and Yao can be used as a subroutine by the symmetric RSK algorithm, replacing the default binary search. Surprisingly, such a straightforward replacement improves the asymptotic worst-case running time for the RSK correspondence that has been best known since 1998. A similar improvement also holds for the average running time of RSK on uniformly random permutations.

1 Introduction

The Robinson–Schensted–Knuth (RSK) correspondence is a fundamental concept in combinatorics and representation theory; for the background on the combinatorial aspects of RSK, see e.g. [20, 17]. It is defined as a certain bijection between pairs of standard Young tableaux and permutations of a given order, and represents a far-reaching generalisation of the longest increasing subsequence problem in a permutation. A common definition of RSK correspondence is algorithmic, via Robinson–Schensted tableau insertions or, alternatively, via the Viennot geometric construction.

The combinatorial properties of RSK are well-studied. In this paper, we consider the RSK correspondence as an algorithmic problem, along with the closely related k -chain problem. In particular, we are interested in both the worst-case and the average asymptotic running time of algorithms for these problems. This aspect of the RSK correspondence seems to have been studied relatively less thoroughly than its combinatorial aspects.

In the rest of this paper, we recall the definition of the RSK correspondence, using the geometric construction of Viennot [23, 24]. We then describe the standard RSK algorithm by Robinson [15] and Schensted [18]. Further, we give a simple, direct description of the symmetric RSK algorithm, which is implied by the k -chain algorithms of Viennot [24] and of Felsner and Wernisch [9]. Next, we recall the doubling search algorithm of Bentley and Yao [1], and show how it can be used as a subroutine by the symmetric RSK algorithm, replacing the default binary search. Surprisingly, such a straightforward replacement improves the asymptotic worst-case running time for the RSK correspondence from $O(n^{3/2} \log n)$, which has been the best known since [9], to $O(n^{3/2})$. A similar improvement also holds for the average running time of RSK on uniformly random permutations.

2 The RSK correspondence

Partial orders. We will use the standard terminology related to partial orders: *downset*, *principal downset*, *chain*, *antichain*. We consider two mutually inverse (strict) total orders on \mathbb{R} : $<$ and $>$. We also consider the corresponding (strict) partial *dominance* orders on \mathbb{R}^2 : \ll , \leq , \geq , \gg , where $(x, y) \ll (x', y')$ if $x < x'$ and $y < y'$, and similarly for the other three orders. Dominance orders \ll , \gg are mutually inverse, and so are \leq , \geq . When considering a point set P as a partial order, we will indicate it by a superscript, e.g. P^{\ll} . We will always assume that P is finite, and that all x -coordinates in P are distinct, and so are all the y -coordinates.

Young tableaux. Let \mathbb{N}_+ denote the set of all positive integers. Given $n \in \mathbb{N}_+$, let $\mathbb{N}_n = \{1, \dots, n\} \subset \mathbb{N}_+$.

► **Definition 1.** A Young diagram of order n is a subset of \mathbb{N}_+^2 of cardinality n , that is a downset in the dominance partial order \ll . A Young tableau¹ of order n is an order-preserving bijection from a Young diagram of order n (called the tableau's shape) to a subset of \mathbb{R} with total order $<$.

We use the so-called French notation for visual representation of Young diagrams and tableaux. The elements of a diagram are represented by cells of an integer grid, arranged in left-aligned rows and bottom-aligned columns. Columns are ordered from left to right, and rows from below upwards. The value of each cell of a tableau is written within that cell; these values increase from left to right in rows, and from below upwards in columns.

► **Example 2.** Figure 1 (middle and right columns) gives several examples of Young tableaux with cell values in \mathbb{N}_{10} .

Canonical antichain partitioning. The theory of Young tableaux is intimately connected with the combinatorics of permutations. We take a symmetric view of this connection, due to Viennot [23, 24]. A permutation, viewed as a mapping $\pi : \mathbb{N}_n \rightarrow \mathbb{N}_n$, is identified with the mapping's graph, i.e. the point set $P_\pi = \{(x, \pi(x)) \mid x \in \mathbb{N}_n\}$.

► **Definition 3.** The height of an element in a finite partial order O is the maximum cardinality of a chain in the principal downset generated by that element. A canonical antichain is formed by all the elements of a given height. The partitioning of O into disjoint canonical antichains is called the canonical antichain partition (CAP), denoted $\text{cap}(O)$.

Canonical antichains in \mathbb{R}^2 are also sometimes called *layers of minima (maxima)* [4, 3], *Pareto fronts* [5], or *terraces* [14]. The canonical antichain partition of a point set in \mathbb{R}^2 is also sometimes called *greedy cover* [12], *patience sorting* [2], or *non-dominated sorting* [5].

► **Example 4.** Figure 1 (top-left) shows a point set P of cardinality 10, and its partitioning $\text{cap}(P^{\ll})$ into five antichains.

We recall the following standard result.

► **Proposition 5.** The partitioning $\text{cap}(O)$ of a finite partial order has the minimum possible number of antichains among all antichain partitionings of O . This number is also equal to the maximum cardinality of a chain in O .

Proof. Straightforward; see e.g. [9]. ◀

¹ Young tableaux as defined here are often called “standard”, to distinguish them from more general types of tableaux; we omit this qualifier, since it is the only type of Young tableaux we are dealing with.

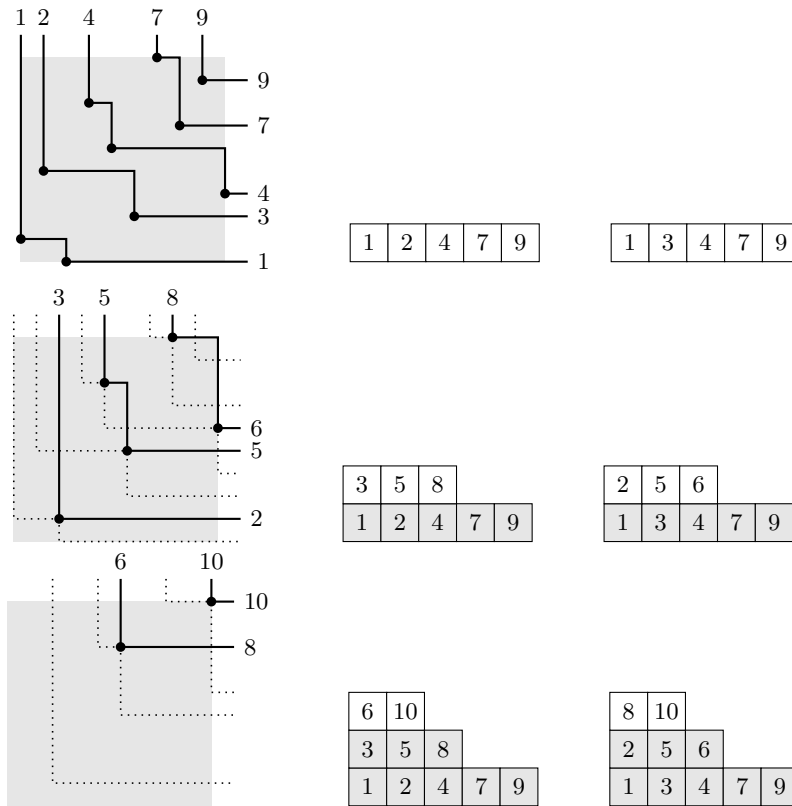

Figure 1 The standard RSK algorithm for $rsk(P^{\ll}) = (H, T)$; tableaux H, T obtained by rows.

Figure 2 The symmetric RSK algorithm for $rsk(P^{\ll}) = (_, T)$ and $rsk(P^{\gg}) = (_, T^\dagger)$: tableau T obtained by principal hooks.

Given a permutation π , the problem of finding the cardinality of $\text{cap}(P_\pi^{\ll})$ is equivalent to the problem of finding the length of a longest increasing subsequence (LIS) in π . The LIS problem has a long history, going back to Erdős and Szekeres [8] and Robinson [15]. Based on their ideas, the classical LIS algorithm running in time $O(n \log n)$ was made explicit by Knuth [13], Fredman [10] and Dijkstra [6].

► **Definition 6.** Let P be a point set with dominance order \ll . Let $A = \{(x_1, y_1) \leq (x_2, y_2) \leq \dots \leq (x_r, y_r)\} \subseteq P$ be an antichain of cardinality $r \geq 1$. Values x_1 and y_r will be called respectively the head and the tail of A . The skeleton of A is the antichain $\text{sk}(A) = \{(x_2, y_1) \leq (x_3, y_2) \leq \dots \leq (x_r, y_{r-1})\}$ of cardinality $r - 1$. The skeleton of P is the point set $\text{sk}(P^{\ll}) = \bigcup_{A \in \text{cap}(P^{\ll})} \text{sk}(A)$. The heads, tails and skeletons with respect to dominance orders \leq, \geq, \gg are defined analogously.

The RSK correspondence. The Robinson–Schensted–Knuth (RSK) correspondence, discovered independently by Robinson [15] and Schensted [18] (see also Romik [17]), is a bijection between permutations of a given order and pairs of Young tableaux of the same order and identical shape. The two tableaux in the pair will be called the *head* and the *tail* tableaux (such a terminology is chosen for its symmetry and consistency with the rest of our exposition, whereas the traditional terminology calls them the *recording* and the *insertion* tableaux).

► **Definition 7.** Let P be a point set with dominance order \ll . The RSK image² of P is a pair of Young tableaux $\text{rsk}(P^{\ll}) = (H, T)$, defined recursively as follows. The initial row in H (respectively, T) is formed by the heads (respectively, the tails) of the antichains in $\text{cap}(P^{\ll})$. The remaining rows of H, T are formed as $\text{rsk}(\text{sk}(P^{\ll}))$. The RSK image with respect to dominance orders \leq, \geq, \gg is defined analogously.

► **Example 8.** Figure 1 (top row) shows the construction of the initial rows in tableaux $\text{rsk}(P^{\ll}) = (H, T)$ from a point set $P \subseteq \mathbb{N}_{10}^2$ (top left). Figure 1 (middle and bottom rows) shows the recursive construction of the remaining rows in the tableaux H, T .

The RSK correspondence has some beautiful symmetries, exposed by Schützenberger [19].

► **Definition 9.** Let P be a point set. Its transpose is the point set $P^\dagger = \{(x, y) \mid (y, x) \in P\}$ obtained by exchanging the x - and y -coordinates of every point.

► **Observation 10.** Let π be a permutation. We have $P_\pi^\dagger = P_{\pi^{-1}}$.

► **Definition 11.** Let Y be a Young diagram. Its transpose Y^\dagger is the Young diagram obtained by exchanging the x - and y -coordinates of every cell.

We now state the theorem by Schützenberger [19] on the symmetries of the RSK correspondence; for completeness, we also present its proof.

► **Theorem 12 (Schützenberger).** Let P be a point set, $\text{rsk}(P^{\ll}) = (H, T)$. We have

- (i) $\text{rsk}(P^{\dagger \ll}) = (T, H)$,
- (ii) $\text{rsk}(P^{\geq}) = (H^{*\dagger}, T^\dagger)$,
- (iii) $\text{rsk}(P^{\leq}) = (H^\dagger, T^{*\dagger})$,
- (iv) $\text{rsk}(P^{\gg}) = (H^*, T^*)$.

Here, H^*, T^* are Young diagrams of the same shape as H, T , called the Schützenberger dual of H, T , respectively.

² The terms “RSK correspondence”, “RSK image” as defined here are often called just “Robinson–Schensted”, reserving the name “RSK” for a more general type of combinatorial bijection. Since this is an algorithmic study, we use the term RSK throughout, in order to highlight the contribution of Donald Knuth to the development of RSK algorithms.

Proof. Part (i) is obvious by symmetry.

Let us establish part (ii). Let (x_0, y_0) be the point with the least y -coordinate in $sk(P^{\ll})$, so y_0 is the tail of the least-height antichain in $cap(sk(P^{\ll}))$. Let A be an antichain in $cap(P^{\ll})$ such that $(x_0, y_0) \in sk(A)$. Then, there is a pair of points $(x_0, y) \geq (x, y_0)$ in A . Let B be the subset of points in P with y -coordinate less than y_0 . Subset B must consist of a single chain including point (x_0, y) : otherwise, there would be two points with y -coordinate less than y_0 in some antichain A' of $cap(P^{\ll})$, and then $sk(A')$ would contain a point of $sk(P^{\ll})$ with y -coordinate less than y_0 , which would contradict the minimality of y_0 . Now consider the points of B with the partial order \geq ; these points, including point (x_0, y) , form a subset of the least height antichain in $cap(P^{\geq})$. Point (x, y_0) must belong to the second-least height antichain in $cap(P^{\geq})$, and must have the least y -coordinate in that antichain. Therefore, y_0 is the tail of the second-least height antichain in $cap(P^{\geq})$.

We have established that the tail of the least height antichain in $cap(sk(P^{\ll}))$ is equal to the tail of the second-least height antichain in $cap(P^{\geq})$. Now (ii) follows by (i) and the recursive construction of Definition 7, and (iii), (iv) follow from (ii) by symmetry. ◀

Multichains. A notion closely related to the subject of this paper is that of a k -chain.

► **Definition 13.** Let O be a finite partial order. A k -chain is a subset of O that can be represented as a union of k chains.

The connection between the RSK correspondence and k -chains is given by the classical theorem of Greene [11].

► **Theorem 14 (Greene).** Let P be a point set with dominance order \ll . The maximum cardinality of a k -chain in P is equal to the number of cells in the initial k rows of the shape of $rsk(P^{\ll})$.

In fact, the RSK algorithm by Felsner and Wernisch [9] is presented entirely in the language of k -chains. While we use the language of Young tableaux in this paper, our results translate immediately into the corresponding statements on maximum k -chains in a set of points, and thus relate to the results of [9].

3 RSK algorithms

Standard RSK algorithm. Definition 7 leads directly to the following standard algorithm for computing the RSK image of a given point set.

Given a point set P , the pair of tableaux $rsk(P^{\ll}) = (H, T)$ are constructed by rows. To obtain the initial rows of H, T , the points in P are scanned in order of increasing x -coordinate. For the subset Q of points seen so far, we maintain the partitioning $cap(Q^{\ll})$; in particular, the heads and the tails of antichains in that partitioning are kept in sorted order. We also maintain the skeleton $sk(Q^{\ll})$ in order of increasing x -coordinate. When the scan of P is complete ($Q = P$), the heads (respectively, tails) of antichains in $cap(P^{\ll})$ become the initial row of tableau H (respectively, T) in $rsk(P^{\ll})$. To obtain the remaining rows of $rsk(P^{\ll})$, we repeat the above procedure on point set $sk(P^{\ll})$. Algorithm 1 gives the algorithm's pseudocode.

► **Example 15.** Figure 1 shows the execution of the standard RSK algorithm in three successive iterations: the point set at the beginning of each iteration and its CAP (left column), and the state of the tableaux H and T at the end of the respective iteration (middle and right columns).

■ **Algorithm 1** Standard RSK. The choice of a search method in line 7 is either linear or binary (Section 3) or doubling (Section 4).

```

1: procedure RSK( $P$ )      ▷ given point set  $P$  sorted by  $x$ -coordinate, returns  $rsk(P^{\ll})$ 
2:   if  $P = \emptyset$  then return  $(\emptyset, \emptyset)$ 
3:    $H_{init} \leftarrow \emptyset$ ;  $T_{init} \leftarrow \emptyset$            ▷ initialise variables for initial rows of  $H, T$ 
4:    $S \leftarrow \emptyset$                                        ▷ initialise variable for  $sk(P^{\ll})$ 
5:   while  $P \neq \emptyset$  do
6:      $(x, y) \leftarrow$  point in  $P$  with least  $x$ -coordinate
7:      $y' \leftarrow$  least value in  $T_{init}$  greater than  $y$ ;  $+\infty$  if none exists           ▷ search
8:     if  $y' = +\infty$  then
9:       append  $x$  to  $H_{init}$ ; append  $y$  to  $T_{init}$            ▷ start new antichain
10:    else
11:      replace  $y'$  by  $y$  in  $T_{init}$ ; append  $(x, y')$  to  $S$            ▷ extend antichain
12:      remove  $(x, y)$  from  $P$ 
13:     $(H_+, T_+) \leftarrow$  RSK( $S$ )                               ▷ recursive call
14:     $H \leftarrow$  tableau with initial row  $H_{init}$  and remaining rows  $H_+$ 
15:     $T \leftarrow$  tableau with initial row  $T_{init}$  and remaining rows  $T_+$ 
16:    return  $(H, T)$                                            ▷  $rsk(P^{\ll}) = (H, T)$ 

```

The computation of the initial row in the standard RSK algorithm (before the recursive call in line 13 of Algorithm 1) is essentially identical to the classical algorithm for the LIS problem [13, 10, 6]. In line 7, the canonical antichain for each of the n points can be found by binary search, therefore the whole initial row is obtained in time $O(n \log n)$. In total, there are at most n rows in $rsk(P^{\ll})$, therefore the overall time is $n \cdot O(n \log n) = O(n^2 \log n)$.

Apart from the worst-case running time, it is of interest to consider the average-case running time of RSK algorithms on a uniformly random permutation; in this case, the shape of tableaux H, T turns out to be sampled from the *Plancherel* probability distribution (see, e.g. [17]). Romik [16] established this average-case running time to be $O(n^{3/2} \log n)$.

RSK with linear search. Paradoxically, a speedup can be obtained by replacing binary search with (a carefully controlled) linear search. Indeed, for a given x -coordinate, the value of the search target y' in line 7 of Algorithm 1 can only increase. Therefore, as long these different search invocations are performed as a linear search continuing from the search target of the previous invocation, the combined search time for a given x -coordinate will be $O(n)$, so the overall running time across all x -coordinates is reduced to $n \cdot O(n) = O(n^2)$. This observation may be considered part of the folklore; it is made e.g. by Thomas and Yong [21], who attribute it to an anonymous referee. A simple and elegant alternative description of this algorithm can be obtained by using edge local rules of Viennot [25], giving the same asymptotic running time $O(n^2)$.

Symmetric RSK algorithm. Felsner and Wernisch [9] proposed a more efficient, symmetric approach to developing an RSK algorithm. Their algorithm was described in the language of k -chains. In particular, they gave an algorithm for computing maximum k -chains (and, by symmetry, also k -antichains) of a planar point set in time $O(kn \log n)$. In combination with the algorithm for the same problem by Viennot [24], running in time $O((n^2/k) \log n)$, maximum k -chains can be obtained in time $O(n^{3/2} \log n)$ for all k .

Here, we give a simpler, more direct description of this combined algorithm of [24, 9], as an extension of the standard RSK algorithm. The main idea of the symmetric RSK algorithm is to construct the pair of tableaux $rsk(P^{\ll}) = (H, T)$ simultaneously by rows and by columns. The successive rows of tableaux H, T are constructed as in the standard RSK algorithm. At the same time, the successive columns in tableau H (respectively, T) are obtained by running the standard RSK algorithm for $rsk(P^{\leq})$ (respectively, $rsk(P^{\geq})$), using the symmetries exposed by Theorem 12.

There is clearly some redundancy in running the standard algorithm three times on partial orders $P^{\ll}, P^{\leq}, P^{\geq}$. However, this constant-factor redundancy allows one to reduce the overall asymptotic running time. Notice that as a result of the first iteration of each of the three runs, we obtain the union of the initial row and initial column in each of H and T ; this union is called the initial *principal hook* of the respective tableau. Likewise, as a result of the second iteration, we obtain the second principal hook of both H and T (i.e. the union of the second row and column, minus the initial principal hook). Crucially, while the number of both rows and columns in a Young tableau of order n can be as high as n , the number of its principal hooks is always at most $n^{1/2}$. Thus, the algorithm can be terminated after at most $\lfloor n^{1/2} \rfloor$ iterations made by each of the three simultaneous runs on $P^{\ll}, P^{\leq}, P^{\geq}$. The worst-case running time of the symmetric RSK algorithm is $n^{1/2} \cdot O(n \log n) = O(n^{3/2} \log n)$.

► **Example 16.** Figure 2 shows the execution of the symmetric RSK algorithm on the same input point set as in Figure 1. For the sake of brevity, only the computation of tableau T from partial orders P^{\ll}, P^{\geq} is shown explicitly, while the symmetric computation of tableau H from partial orders P^{\ll}, P^{\leq} is omitted. Compared to the three iterations of the standard algorithm in Figure 1, now only two iterations are required.

4 Speeding up RSK by doubling search

Doubling search. The *doubling search* technique (also called *exponential search*) was introduced by Bentley and Yao [1], and represents a hybrid between linear and binary search. Doubling search is particularly efficient for a non-uniform distribution of the target index, skewed towards an end of the array being searched.

We describe doubling search with the starting point at the upper end of the array, in order to be consistent with its intended application as a subroutine for RSK. Given an array $a_i, 1 \leq i \leq s$, sorted in increasing order, and a value q distinct from all a_i , we consider the problem of finding the greatest value in a less than q , that is index $k \geq 0$ such that $a_{s-k} < q < a_{s-k+1}$. We assume $a_i = -\infty$ for $i \leq 0$, and $a_{s+1} = +\infty$.

The search begins at the upper end of the array, comparing q against a_s . If $a_s < q$, we have found $k = 0$. Otherwise, the search continues in two phases. In the *doubling phase*, we compare q against $a_{s-1}, a_{s-2}, a_{s-4}, a_{s-8}, \dots$, until we find a subtrahend t that is the least power of 2 such that $a_{s-t} < q$. This phase takes $\lfloor \log k \rfloor + 1$ comparisons.

We now know that $1 \leq k \leq t$, and move on to the *binary search phase*. In this phase, we find the exact value of k in this range by binary search, taking at most $\lfloor \log t \rfloor \leq \lfloor \log k \rfloor + 1$ comparisons. Overall, the doubling search algorithm takes at most $2\lfloor \log k \rfloor + 3$ comparisons. Algorithm 2 shows the pseudocode for the doubling search algorithm.

Symmetric RSK with doubling search. Unfortunately, the asymptotic speedup by a factor of $n^{1/2}$ to the standard RSK algorithm, which is provided by the symmetric algorithm, is not compatible with the speedup by a factor of $\log n$ provided by linear search. However, we are still able to obtain both speedups simultaneously by employing doubling search.

■ **Algorithm 2** Doubling search.

```

1: procedure DSEARCH( $a, q$ )      ▷ given sorted array  $a$  and  $q$ , returns index for  $q$  in  $a$ 
2:   if  $a_s < q$  then return 0
3:    $t \leftarrow 1$ 
4:   while  $a_{s-t} > q$  do  $t \leftarrow 2t$                                 ▷ doubling phase
5:   return index  $k$  in  $\{1, \dots, t\}$ , such that  $a_{s-k} < q < a_{s-k+1}$     ▷ binary search

```

Consider a specific value x for a point's x -coordinate, as the RSK algorithm iterates on P , $sk(P^{\ll})$, $sk(sk(P^{\ll}))$, etc. These iterations form respectively row 1, 2, 3, ... of diagrams H, T . Let l_r denote the length of row r before a point with coordinate x is processed for that row. Let b_r denote the index of the search target y' in row r of a point with coordinate x (as per lines 9 or 11 of Algorithm 1); b_r is undefined if no point with coordinate x is left in iteration r (that is, in the $r - 1$ -th skeleton of P). Let the *displacement interval* in row r be $\{b_r, b_r + 1, \dots, \min(l_r, b_{r-1} - 1)\}$, where $b_0 = +\infty$. We denote this interval's length by $d_r = \min(l_r + 1, b_{r-1}) - b_r$; in particular, $d_r = 0$ if $b_r = b_{r-1}$. We also define $d_r = 0$ if b_r is undefined due to no point with coordinate x being left in iteration r .

► **Example 17.** Consider the computation of $rsk(P^{\ll})$ by the standard and the symmetric RSK algorithms in Figures 1 and 2. Let us fix $x = 6$.

In the first iteration, the bottom row of tableaux H, T is formed. Just before the processing of point $(6, 3) \in P$ begins, the current state of the tableaux rows is $H_{init} = (1, 2, 4)$, $T_{init} = (1, 5, 6)$, and their common length is $l_1 = 3$. The least value in T_{init} greater than $y = 3$ is 5, and its index in T_{init} is $b_1 = 2$. The displacement interval is between $b_1 = 2$ and $l_1 = 3$ inclusive, and its length is $d_1 = l_1 + 1 - b_1 = 2$.

In the second iteration, the middle row of tableaux H, T is formed. Just before the processing of point $(6, 5) \in sk(P^{\ll})$ begins, the current state of the tableaux rows is $H_{init} = (3, 5)$, $T_{init} = (2, 8)$, and their common length is $l_2 = 2$. The least value in T_{init} greater than $y = 5$ is 8, and its index in T_{init} is $b_2 = 2$. The displacement interval is empty (being defined between $b_2 = 2$ and $b_1 - 1 = 1$ inclusive), and its length is $d_2 = b_1 - b_2 = 0$.

In the third and final iteration (which is absent from the symmetric algorithm in Figure 2), the top row of tableaux H, T is formed. Just before the processing of point $(6, 8) \in sk(sk(P^{\ll}))$ begins, the tableaux rows H_{init}, T_{init} are both empty, and their common length is $l_3 = 0$. The least value in T_{init} greater than $y = 5$ is by convention $+\infty$, and its index in T_{init} is by convention $b_3 = 1$. The displacement interval is between $b_3 = 1$ and $b_2 = 2$, and its length is $d_3 = b_3 - b_2 = 1$.

► **Theorem 18.** *The symmetric RSK algorithm with doubling search solves the RSK correspondence problem in worst-case time $O(n^{3/2})$.*

Proof. Without loss of generality, assume that n is a perfect square (otherwise, the input can be extended by extra points with a suitably high y -value). Let $m = n^{1/2}$.

For a fixed x -coordinate, consider the displacement interval in a given row r . The rectangle of tableau cells below and including this interval consists of rd_r cells. All these rectangles for different values of r are pairwise disjoint. The symmetric RSK algorithm terminates after processing at most m rows. The total number of cells in the rectangles defined by the displacement intervals in these rows is obviously at most n :

$$\sum_{r=1}^m rd_r \leq n$$

We also have $\sum_{r=1}^m r = \frac{m(m+1)}{2} \leq m^2 = n$. Let $d'_r = d_r + 1$. By the above, we have

$$\sum_{r=1}^m r d'_r \leq n + n = 2n$$

While working on a point with coordinate x within row r , doubling search makes at most $\lfloor 2 \log d'_r \rfloor + 3$ comparisons. For the total number of comparisons made for the given x -coordinate, we have by the arithmetic-geometric mean inequality and the Stirling lower bound on the factorial (cancelling the rounding down of the logarithms, and omitting the constant factor 2 and the additive term $\sum_{r=1}^m 3 = O(m)$):

$$\begin{aligned} \sum_{r=1}^m \log d'_r &= \sum_{r=1}^m \log \frac{r d'_r}{r} = \log \prod_{r=1}^m \frac{r d'_r}{r} = \log \left(\frac{1}{m!} \prod_{r=1}^m r d'_r \right) \leq \\ &\log \left(\frac{1}{m!} \left(\frac{1}{m} \sum_{r=1}^m r d'_r \right)^m \right) \leq \log \frac{(2n/m)^m}{m!} = \log \frac{(2m)^m}{m!} \leq \log \frac{(2m)^m}{(m/e)^m} = \\ &m \log(2e) = O(m) \end{aligned}$$

There are n different x -coordinates to consider, therefore the algorithm makes $n \cdot O(m) = O(n^{3/2})$ comparisons in total. \blacktriangleleft

5 Conclusion

We have given a simple, direct description of the symmetric RSK algorithm by Felsner and Wernisch [9]. We have shown how this algorithm can be enhanced with doubling search, improving the asymptotic running time from $O(n^{3/2} \log n)$ to $O(n^{3/2})$. It is also worth noticing that the (worst-case) running time of our algorithm is lower than the average-case running time of the standard (or the symmetric) RSK algorithm on uniformly random permutations, as analysed by Romik [16]. Our result implies a similar improvement for the k -chain problem for arbitrary k .

A natural lower bound on the running time of RSK correspondence is provided by the LIS problem, which is a subproblem for RSK, and requires $\Omega(n \log n)$ comparisons in the comparison model [10]. Thus, there remains a substantial gap between the known upper and lower bounds for the asymptotic complexity of the RSK correspondence.

Apart from potential improvements in the algorithm or the lower bound, there is scope for future work in extending the algorithm for more general versions of the RSK correspondence, e.g. that between positive integer matrices and semistandard Young tableaux. An experimental confirmation of the efficiency of our algorithm also remains an endeavor for future work; this is a non-trivial task, since most existing experiments with RSK, e.g. those by Vasilyev and Duzhin [7, 22], concentrate on either Plancherel-random Young diagrams, or on Young diagrams with (near-)maximum dimensions; such a diagram shape seems to be far away from the worst-case shape suggested by the proof of Theorem 18.

Insertion Time of Random Walk Cuckoo Hashing below the Peeling Threshold

Stefan Walzer  

Universität zu Köln, Germany

Abstract

Most hash tables have an insertion time of $\mathcal{O}(1)$, often qualified as “expected” and/or “amortised”. While insertions into cuckoo hash tables indeed seem to take $\mathcal{O}(1)$ expected time in practice, only polylogarithmic guarantees are proven in all but the simplest of practically relevant cases. Given the widespread use of cuckoo hashing to implement compact dictionaries and Bloom filter alternatives, closing this gap is an important open problem for theoreticians.

In this paper, we show that random walk insertions into cuckoo hash tables take $\mathcal{O}(1)$ expected amortised time when any number $k \geq 3$ of hash functions is used and the load factor is below the corresponding *peeling threshold* (e.g. ≈ 0.81 for $k = 3$). To our knowledge, this is the first meaningful guarantee for constant time insertion for cuckoo hashing that works for $k \in \{3, \dots, 9\}$.

In addition to being useful in its own right, we hope that our key-centred analysis method can be a stepping stone on the path to the true end goal: $\mathcal{O}(1)$ time insertions for all load factors below the *load threshold* (e.g. ≈ 0.91 for $k = 3$).

1 Introduction

Cuckoo Hashing Basics. Cuckoo hashing is an elegant approach for constructing compact and efficient dictionaries that has spawned both a rich landscape of theoretical results and popular practical applications. Briefly, each key x in a set of m keys is assigned k positions $h_1(x), \dots, h_k(x)$ in an array of $n \geq m$ buckets via hash functions h_1, \dots, h_k . Each bucket can hold at most ℓ keys and the challenge is to choose for each key one of its assigned buckets while respecting bucket capacities. We follow many previous works in assuming $k \geq 2$ and $\ell \geq 1$ to be constants and h_1, \dots, h_k to be uniformly random functions (but see e.g. [1, 2, 3] for works pursuing cuckoo hashing with explicit hash families).

Since the term cuckoo hashing was coined for $(k, \ell) = (2, 1)$ [27] and then generalised to $k \geq 3$ [12] and $\ell \geq 2$ [7], a major focus of theory papers has been to determine the load thresholds $c_{k,\ell}^*$, which are constants such that for a load factor $\frac{m}{n} < c_{k,\ell}^* - \varepsilon$ a placement of all keys exists with high probability (whp, defined in this paper as probability $1 - n^{-\Omega(1)}$) and for $\frac{m}{n} > c_{k,\ell}^* + \varepsilon$ a placement does not exist whp. This project has since been completed [11, 4, 6, 14, 13, 24] and we reproduce some thresholds in Table 1 for reference. Further research pursued cuckoo hashing variants with reduced failure probability [21], improved

load thresholds [7, 23, 30] or weaker randomness requirements for h_1, \dots, h_k [1, 2, 3, 25, 22]. Moreover, cuckoo filters [9, 10, 8], which are Bloom filter alternatives based on cuckoo hashing, are now widely popular in the data base community.

■ **Table 1** For each $2 \leq k \leq 7$ and $1 \leq \ell \leq 6$ a cell shows $c_{k,\ell}^\Delta/\ell$ (left) and $c_{k,\ell}^*/\ell$ (right), rounded to three decimal places. The thresholds are divided by ℓ to reflect the corresponding memory efficiency (populated space over allocated space).

Cuckoo Insertions. An important concern in all variants of cuckoo hashing is how to insert a new key x into an existing data structure. If all buckets $h_1(x), \dots, h_k(x)$ are full, then one key that is currently placed in those buckets has to be moved out of the way into one of its alternative buckets, which might require additional relocations of keys. Two natural strategies for organising insertions have been proposed [12]. Breadth-first search (BFS) insertion systematically pursues all possibilities for relocating keys in parallel. Random walk (RW) insertion starts by optimistically placing x into bucket $h_i(x)$ for a uniformly random $i \in [k]$ (where in this paper $[a] := \{1, \dots, a\}$ for $a \in \mathbb{N}$), without first considering any of the $k - 1$ other buckets. If $h_i(x)$ was already full, then a random key is evicted from $h_i(x)$ and is itself placed into one of its $k - 1$ alternative buckets. This chain of evictions continues until a bucket with leftover space is reached (see Figure 1 for the case with $\ell = 1$).

```

1 Algorithm RW( $x$ ):
2    $i_{\text{old}} \leftarrow \perp$ 
3   repeat
4     pick random  $i \in \{h_1(x), \dots, h_k(x)\} \setminus \{i_{\text{old}}\}$ 
5     swap( $x, B[i]$ )
6      $i_{\text{old}} \leftarrow i$ 
7   until  $x = \perp$ 

```

■ **Figure 1** The random walk insertion algorithm for $\ell = 1$. The array B of buckets is initialised with \perp .

Experiments suggest that, regardless of k and ℓ , and for any load factor $\frac{m}{n} < c_{k,\ell}^* - \varepsilon$ where insertions still succeed whp, the expected insertion time is independent of n , hence “ $\mathcal{O}(1)$ ” (neglecting dependence on the constants k, ℓ, ε), for both RW and BFS. Despite some partial success (see below), this claim has not been proven for any k and ℓ , neither for RW nor for BFS, with the exception of $(k, \ell) = (2, 1)$, which behaves very differently compared to other cases. A theoretical explanation for the good performance of cuckoo hashing in practical applications is therefore seriously lacking in this aspect. While this paper does not solve the problem, it puts a new kind of dent into it.

Contribution. Like most previous papers on cuckoo hashing insertions (an exception [18] is mentioned below) we focus on the case $\ell = 1$. Our analysis shows that RW insertions take $\mathcal{O}(1)$ expected amortised time for all $k \geq 3$, but it only works for $\frac{m}{n} < c_{k,1}^\Delta - \varepsilon$ where $c_{k,\ell}^\Delta < c_{k,\ell}^*$ is known as the *peeling threshold* or threshold for the occurrence of an $(\ell + 1)$ -core in a random k -uniform hypergraph [28, 26, 5, 19], see Table 1. Our analysis extends to a setting where the m insertions are carried out by m threads in parallel, each executing RW. We consider the worst case, where a (possibly adversarial) scheduler arbitrarily assigns the available computation time to threads that have not yet terminated. We only assume that the scheduler is oblivious of future random choices and that swaps are atomic, i.e. when several threads perform swaps concurrently, the effect is the same as executing these swaps in *some* sequential order (see e.g. [29, Sec. 2.4] for common parallel programming models).

- **Theorem 1.** *Let $k \in \mathbb{N}$ with $k \geq 3$ and $\varepsilon > 0$ be constants and $n, m \in \mathbb{N}$ with $\frac{m}{n} < c_{k,1}^\Delta - \varepsilon$.*
- (i) *Conditioned on a high probability event, sequentially inserting m keys into a cuckoo hash table with n buckets of size 1 using RW takes $\mathcal{O}(n)$ steps in expectation.*
 - (ii) *The same applies if the m insertions are started in parallel with arbitrary scheduling, only assuming that swaps are atomic. In other words, the combined work is $\mathcal{O}(n)$.*

Related Work and Comparison. Table 2 summarises related work that we now discuss from left to right.

[20] is only included here to show that the case of *static* cuckoo hash tables is well understood with optimal results in all considered categories.

[12] offers a strong analysis of BFS. The only downside is that it does not work for some small k and does not reach all the way to $c_{k,1}^*$. These issues might be resolvable by modernising the proof (the values $c_{k,1}^*$ were not known at the time of writing). Note, however, that even full success on this front would not render an analysis of RW irrelevant as several authors, including [12], see significant *practical* benefits of RW over BFS.

[17, 15] propose and improve, respectively, an analysis of RW via graph expansion. It guarantees most desired properties, including a concentration bound on insertion times. The major downside is an only polylogarithmic bound on expected insertion time.

[16] are first to prove an $\mathcal{O}(1)$ bound on expected random walk insertion time. The proof extends to any load factor $1 - \varepsilon$ with $\varepsilon > 0$. There is a downside, however. Instead of using $k = \mathcal{O}(\log(1/\varepsilon))$ hash functions as would be required for the existence of a placement of all keys (and as are used by [12] in their BFS analysis), the authors use $k = \mathcal{O}(\log(1/\varepsilon)/\varepsilon)$ hash functions. To give an example, while $k = 3$ hash functions suffice for $\varepsilon = 0.2$ (because $80\% < c_{3,1}^* \approx 92\%$), the analysis of [16] requires $k \geq 50$ hash

■ **Table 2** Guarantees offered by analyses on cuckoo table insertions. The motivation for the third line is that any load factor $< 50\%$ can be achieved with $k = 2$.

	[20]	[12]	[17, 15]	[16]	new

supports deletions	-	✓	✓	✗	✗

functions for that ε . Even if the analysis can be tuned to some degree (which seems probable), useful guarantees for practically relevant k would likely remain out of reach. We remark that they use a variant RW' of RW where a key x searches all its buckets $h_1(x), \dots, h_k(x)$ for a free space and only moves to a random bucket if all are full.

[18], not shown in the table, considers $k = 2$ hash functions, buckets of size $\ell \geq 2$ and random walk insertion. The result resembles [16] in its merits and downsides: Expected insertion time of $\mathcal{O}(1)$ is supported at any load factor $1 - \varepsilon$, provided that ℓ is large enough; the value $\ell = \ell(\varepsilon)$ required in the analysis is exponentially larger than what is needed for the existence of a placement; and meaningful guarantees for small values of ℓ seem out of reach.

This paper is the first to guarantee constant time insertions into cuckoo hash tables using $k \in \{3, \dots, 9\}$ hash functions. Like [16] our proof does not consider deletions. The main downside is that our analysis only works for $\frac{m}{n} < c_{k,1}^\Delta - \varepsilon$. Paradoxically, this means that the load factor supported by our analysis decreases when more hash functions are used (indeed, $c_{k,1}^\Delta \rightarrow 0$ for $k \rightarrow \infty$) and the supremum of supported load factors is $c_{3,1}^\Delta \approx 0.818$ for $k = 3$ hash functions. We mention a potential avenue for overcoming this problem in the conclusion.

Technical Overview. A central idea in our approach is to not count the number of evictions caused by a single insertion operation but to take the perspective of a single key and count how often it moves in the course of all m insertion operations combined.

Our proof is inspired by a simple observation: If a key x is assigned a bucket $h_i(x)$ that is assigned to no other key, then x is safely out of the way of other keys as soon as it has been placed in $h_i(x)$. In expectation, this happens after x has moved k times. A constant fraction of keys is “harmless” in this way. Moreover, there are keys y that are assigned a bucket $h_i(y)$ that is assigned to no other key, *except* for some harmless keys. It seems plausible that y , too, can quickly find a home in $h_i(y)$ and is only expected to be evicted from it a few times until the harmless keys live up to their name.

A formalisation attempt goes like this: Let F be an injective placement function assigning to each key x a bucket $F(x) \in \{h_1(x), \dots, h_k(x)\}$ (such an F exists whp for $c < c_{k,\ell}^* - \varepsilon$). We say a key x *depends* on a key y if $F(x) \in \{h_1(y), \dots, h_k(y)\}$, i.e. if the position designated for x is admissible for y . Let $D(x)$ be the set of all keys that x depends on. Finally, let $\text{moves}(x)$ be the total number of times that x moves during the insertion of all keys. We then have

$$\mathbb{E}[\text{moves}(x)] \leq k + \sum_{y \in D(x)} \mathbb{E}[\text{moves}(y)]. \quad (1)$$

The “ k ” is due to x being first placed in $F(x)$ after k moves in expectation. It can then only be evicted from $F(x)$ by a key from $D(x)$. Each movement of a key in $D(x)$ has a chance of $\frac{1}{k}$ to evict x from $F(x)$, causing k more moves of x in expectation until x is back in $F(x)$. Hence each move of a key from $D(x)$ can cause at most one move of x in expectation, as (1) suggests. The claim is even true in a more general context we call the *random eviction process* where in each round an adversary choses the key y to be moved among all keys not currently placed in their designated location $F(y)$.

As a way of bounding $\mathbb{E}[\text{moves}(x)]$, Equation (1) is hopelessly circular at first, but it is useful for specific F . Indeed, assume that the configuration of keys and buckets is *peelable*, i.e. for every subset X' of keys there is a bucket b^* assigned to only one key $x^* \in X'$. In that case, we can iteratively construct F , always picking such a pair (x^*, b^*) uniformly at random, setting $F(x^*) = b^*$ and removing x^* from further consideration. This yields an

acyclic dependence relation and an *acyclic dependence graph* (the directed graph with one vertex for each key that has the dependence relation as its edge relation). We can then upper bound $\mathbb{E}[\text{moves}(x)]$ by a multiple of $\text{peel}_F(x)$, which is the number of paths in the dependence graph that start at x . Bounding the expected number of moves of all insertion operations combined by $\mathcal{O}(n)$ then amounts to bounding the total number of paths in the dependence graph by $\mathcal{O}(n)$.

The second part of our argument – contained in the full version of this paper – is intimately related to the analysis of 2-cores in random hypergraphs. We extend Janson and Luczak’s “simple solution to the $(\ell + 1)$ -core problem” [19], which uses a random process embedded in continuous time where peeling is applied to the configuration model of a random hypergraph. We establish two guarantees concerning the peeling process.

- Firstly, the guarantee that during “early” rounds of peeling (when $\Omega(n)$ keys still remain) there are always $\Omega(n)$ candidate pairs (x^*, b^*) to choose from. Intuitively, this large number of choices for the peeling process makes it likely that the dependence graph becomes very “wide” with few long paths. For illustration (the formal argument works differently) assume the maximum path length is w with $w = \mathcal{O}(1)$. Since the indegree of the dependence graph is bounded by $k - 1$ this gives a bound of $m \cdot (k - 1)^w = \Theta(m)$ on the total number of paths as desired.
- Secondly, the technically demanding guarantee that in the “late” phase of peeling (when only $o(n)$ keys remain) almost all buckets have at most one remaining key assigned to them. Most steps of the peeling process will then not create further edges in the dependence graph. This implies that for each of the paths that already exist in the dependence graph less than one additional path is created in future rounds.

Outline. The rest of this paper is devoted to proving Theorem 1. We introduce two notable auxiliary concepts we call the *random eviction process* (REP) and *peeling numbers*. We reduce Theorem 1 to a claim about REP (Section 2) and reduce this claim to an upper bound on peeling numbers (Section 3). The remaining technical content is found in the full version of this paper. A deep dive into hypergraph peeling is required (full version Section 4). We then establish the upper bound on peeling numbers by counting paths in the dependence graph (full version Section 5).

2 Orientations, Peeling and the Random Eviction Process

In this section, we introduce the *random eviction process* (REP), which generalises sequential RW insertions, and formulate a claim on REP’ that implies Theorem 1.

From Hashing to Hypergraphs. A well-subscribed model for cuckoo hashing involves hypergraph terminology. The set of buckets corresponds to the set V of vertices and each key x corresponds to the hyperedge $\{h_1(x), \dots, h_k(x)\}$ in the set E of hyperedges. The task of placing all keys then becomes the task of *orienting* $H = (V, E)$ as explained below.

Under the *simple uniform hashing assumption*, the distribution of $H = H_{n,m,k}$ is simple: Each of the km incidences of the m hyperedges are chosen independently and uniformly at random from V . Formally this means that hyperedges are multisets of size k , possibly containing multiple copies of the same vertex (though in expectation only $\mathcal{O}(1)$ do) and E is a multiset possibly containing identical hyperedges (though whp E does not). This issue complicates a few definitions but does not cause any real trouble.

<pre> 1 Algorithm REP(V, E): 2 $f \leftarrow \{(e, \perp) \mid e \in E\}$ // i.e. $f \equiv \perp$ 3 while $\exists e \in E : f(e) = \perp$ do 4 pick such an e arbitrarily 5 pick a random $v \in e$ 6 if $\exists e' \neq e : f(e') = v$ then 7 $f(e') \leftarrow \perp$ 8 $f(e) \leftarrow v$ </pre>	<pre> 1 Algorithm REP'(V, E, F): 2 $f \leftarrow \{(e, \perp) \mid e \in E\}$ 3 while $\exists e \in E : f(e) \neq F(e)$ do 4 pick such an e arbitrarily 5 pick a random $v \in e$ 6 if $\exists e' \neq e : f(e') = v$ then 7 $f(e') \leftarrow \perp$ 8 $f(e) \leftarrow v$ </pre>
---	---

■ **Figure 2** The random eviction process (REP) is a generalisation of sequential random walk insertion. A variant REP' only terminates when a specific target orientation $F : E \rightarrow V$ is reached. Changes are highlighted in bold.

Orientations and Peelings. A *partial orientation* of a hypergraph $H = (V, E)$ is a function $f : E \rightarrow V \cup \{\perp\}$ with $f(e) \in e \cup \{\perp\}$ for each $e \in E$ that is injective except for collisions on \perp . If $f(e) = \perp$ then we say that e is *unoriented*, otherwise e is *oriented* (to $f(e)$). We call f an *orientation* if all $e \in E$ are oriented.

We can try to construct an orientation F of H greedily by repeatedly selecting a vertex v of degree 1 arbitrarily as long as one such vertex exists, setting $F(e) = v$ for the unique hyperedge e incident to v , and removing e from H . We call the resulting partial orientation F a *peeling* of H . If H does not contain a subhypergraph of minimum degree at least 2 (i.e. when the 2-core of H is empty [26]) then F is an orientation and we say H is *peelable*. We call F a *random peeling* if the choice of v is made uniformly at random whenever there are several vertices of degree 1.

The Random Eviction Process. The *random eviction process* (REP), see Figure 2 (left), is run on a hypergraph $H = (V, E)$ and maintains a partial orientation f of H . The process continues in a sequence of rounds as long as unoriented hyperedges remain, possibly indefinitely. In each round, an unoriented hyperedge e is chosen and oriented to a random incident vertex. If a different hyperedge e' was oriented to that vertex, then this e' is *evicted*, i.e. becomes unoriented.

A variant of REP is the *random eviction process with target orientation* (REP'), see Figure 2 (right). It is run on a hypergraph H and an orientation F of H . REP' works just like REP, except that it terminates only when $f = F$ is reached, and in every round any hyperedge e with $f(e) \neq F(e)$ may be chosen. We claim:

► **Proposition 2.** *Let $k \in \mathbb{N}$ with $k \geq 3$ and $\varepsilon > 0$ be constants and $n, m \in \mathbb{N}$ with $\frac{m}{n} < c_{k,1}^{\Delta} - \varepsilon$. Conditioned on a high probability event, $H = H_{n,m,k}$ is peelable and the random peeling F of H satisfies the following. REP' with target orientation F and an arbitrary¹ policy for choosing e in line 4 terminates after $\mathcal{O}(n)$ rounds in expectation.*

Proposition 2 is proved in the following section. We now show that it implies Theorem 1.

¹ This allows these choices to be made *adversarially*. The adversary may know all about H and the state of the algorithm but cannot predict future random choices made in line 5.

Proof of Theorem 1. The case of m sequential insertions is equivalent to the case of m parallel insertions where the scheduler only assigns computation time to the thread of least index that has not yet terminated. It therefore suffices to prove (ii), where the parallel case with *arbitrary* scheduling is considered.

We deal with m threads, each running RW, executed in an arbitrarily interleaved way. However, the only point where RW interacts with data visible to other threads is the swap, which is assumed to be atomic. A sufficiently general case is therefore one where the scheduler always picks an arbitrary thread that has not yet terminated and that thread is then allowed to run for one iteration of the loop. The correspondence between this process and REP should be clear: The scheduler's arbitrary choice of a thread implicitly chooses an unplaced key in that thread's local variable x , which is then placed into a random bucket, possibly evicting a different key. Likewise, REP arbitrarily chooses an unoriented hyperedge, which is then randomly oriented, possibly evicting another hyperedge.

For Proposition 2's claim on REP' to apply to RW, there are two differences to consider. **REP vs. REP'.** Assume an adversary wants to *maximise* the expected running times of REP and REP' by making bad choices for e in line 4. Her job is *harder* for REP for two reasons: Firstly, the termination condition is strictly weaker, such that REP may terminate when REP' does not. Secondly, her choices for e are restricted to unoriented hyperedges, where REP' additionally permits oriented hyperedges with $f(e) \neq F(e)$.

Intuitively speaking, the relatively weaker adversary in REP means that the upper bound on expected running time in Proposition 2 carries over from REP' to REP. More formally, every policy P for line 4 of REP is also valid for REP' and under the natural coupling random coupling REP' with P takes always at least as long as REP with P .

REP vs. RW: i_{old} . In RW an evicted key is not allowed to immediately move back into the bucket i_{old} it was just evicted from. The intuition is that this avoids a needless back-and-forth that otherwise occurs in 1 out of every k evictions. However, the author is not aware of a simple proof that the use of i_{old} is an improvement. Instead, we will check that the relevant part of the argument (Lemma 3) works for both cases. ◀

3 Bounding the Number of Evictions using Peeling Numbers

We now introduce the concept of peeling numbers and bound the number of evictions occurring in REP' in terms of them. This proves Proposition 2 but leaves the task of bounding peeling numbers for the full version of this paper.

Direct Dependence and Numbers of Moves. Consider a peelable hypergraph $H = (V, E)$ and a peeling $F : E \rightarrow V$ of H . For $e \neq e' \in E$ we say that e *directly depends* on e' if $F(e) \in e'$. This implies that e is peeled after e' , making the transitive closure of direct dependence an acyclic relation. We define $D(e) = D_F(e)$ as the set of all e' that e directly depends on, or more precisely: $D(e)$ is a multiset containing e' with the same multiplicity with which e' contains $F(e)$.

Now consider a run of REP' with target orientation F (and an arbitrary policy for line 4). For $e \in E$ let $\text{moves}(e)$ be the number of times that e is selected in line 4 of REP' (this is one more than the number of times that e is evicted).

► **Lemma 3.** For any $e \in E$ we have $\mathbb{E}[\text{moves}(e)] \leq k + \sum_{e' \in D(e)} \mathbb{E}[\text{moves}(e')]$.

Proof. For clarity, we ignore complications that are due to multisets at first. Let m_1 be the number of times that e moves until $f(e) = F(e)$ holds for the first time. Whenever e is selected to be moved, the chance to select $f(e) = F(e)$ is $\frac{1}{k}$, so clearly $\mathbb{E}[m_1] = k$. Afterwards,

e may not be selected anymore until evicted. Only hyperedges in $D(e)$ can evict e from $F(e)$ and when selected they do so with probability $\frac{1}{k}$, causing another k moves of e in expectation. It follows that $\mathbb{E}[m_+] = \mathbb{E}[m_D]$ where $m_+ := \text{moves}(e) - m_1$ and where m_D is the number of times that a hyperedge from $D(e)$ moves *while* $f(e) = F(e)$. The claim now follows from $m_D \leq \sum_{e' \in D(e)} \text{moves}(e')$ and linearity of expectation.

When $D(e)$ is a multiset the argument can be adapted: Whenever a hyperedge e' moves that is contained in $D(e)$ with multiplicity $a > 1$ it has an increased chance of $\frac{a}{k}$ to move to $F(e)$. But this is reflected in our bound since $\mathbb{E}[\text{moves}(e')]$ is counted a times.

Let us now consider a variant of the claim that incorporates the “ i_{old} ” feature of RW as promised in the proof of Theorem 1. In particular, a hyperedge never moves into the position it was last evicted from. We now have $\mathbb{E}[m_1] < k$ because all moves after the first move have an improved chance of $\frac{1}{k-1}$ to select $F(e)$. To compare $\mathbb{E}[m_+]$ and $\mathbb{E}[m_D]$, we can distinguish two kinds of moves. Concerning moves *away from* $F(e)$, m_D counts the same or one more compared to m_+ . All other moves have a chance of $\frac{1}{k-1}$ to end in $F(e)$ and contribute the same amount to $\mathbb{E}[m_+]$ and $\mathbb{E}[m_D]$ as before. The same adaptation to multisets applies. ◀

The Peeling Number. We define the peeling number of $e \in E$ recursively as

$$\text{peel}(e) = \text{peel}_F(e) := \sum_{e' \in D_F(e)} (1 + \text{peel}(e')). \quad (2)$$

Peeling numbers are well-defined by acyclicity of direct dependence, the base case being $\text{peel}(e) = 0$ for any e with $D(e) = \emptyset$. The idea is that $\text{peel}(e)$ counts the number of hyperedges that e directly *or indirectly* depends on, in other words, those hyperedges e' that must be peeled before e can be peeled. However, some e' may be counted multiple times. The relevance of peeling numbers lies in the following lemma.

► **Lemma 4.** *Let H be a peelable hypergraph with a peeling F . Let R be the number of rounds until REP' with target orientation F terminates. We have $\mathbb{E}[R] \leq k \cdot (m + \sum_{e \in E} \text{peel}_F(e))$.*

Proof. For a single $e \in E$ we have $\mathbb{E}[\text{moves}(e)] \leq k \cdot (1 + \text{peel}(e))$ because

$$\begin{aligned} \mathbb{E}[\text{moves}(e)] &\stackrel{\text{Lem.3}}{\leq} k + \sum_{e' \in D(e)} \mathbb{E}[\text{moves}(e')] \stackrel{\text{Induction}}{\leq} k + \sum_{e' \in D(e)} k \cdot (1 + \text{peel}(e')) \\ &\stackrel{\text{Eq.(2)}}{=} k + k \cdot \text{peel}(e) = k \cdot (1 + \text{peel}(e)). \end{aligned}$$

Since the total number R of rounds of REP' is the sum of all moves we conclude

$$\mathbb{E}[R] = \mathbb{E}\left[\sum_{e \in E} \text{moves}(e)\right] \leq \sum_{e \in E} k \cdot (1 + \text{peel}(e)) = k \cdot (m + \sum_{e \in E} \text{peel}(e)). \quad \blacktriangleleft$$

The remaining technical challenge is to bound the sum of all peeling numbers:

► **Proposition 5.** *Let H be as in Proposition 2. There is a high probability event \mathcal{E} such that, conditioned on \mathcal{E} , H is peelable and the peeling numbers with respect to the random peeling F of H satisfy*

$$\mathbb{E}\left[\sum_{e \in E} \text{peel}_F(e) \mid \mathcal{E}\right] = \mathcal{O}(n).$$

A prove is found in the full version of this paper (Section 5) and requires a detailed analysis of the peeling process (Section 4). We conclude this extended abstract with showing how Proposition 5 implies Proposition 2.

Proof of Proposition 2. We take the opportunity to clarify the structure of our probability space. There are three random experiments, performed in sequence: First, we pick a random hypergraph H . Second, if H is peelable, we pick a random peeling F of H and observe the peeling numbers. Last, we execute $\text{REP}'(H, F)$ and observe which moves are made. Note that the high probability event \mathcal{E} from Proposition 5 only relates to the first two steps (it does not relate to any moves). Lemma 4 only relates to the last step and does not require H and F to be random. For the number R of rounds of REP' we obtain:

$$\begin{aligned} \mathbb{E}[R \mid \mathcal{E}] &= \mathbb{E}[\mathbb{E}[R \mid H, F, \mathcal{E}] \mid \mathcal{E}] = \mathbb{E}[\mathbb{E}[R \mid H, F] \mid \mathcal{E}] \stackrel{\text{Lem. 4}}{\leq} \mathbb{E}\left[k \cdot (m + \sum_{e \in E} \text{peel}(e)) \mid \mathcal{E}\right] \\ &= km + k \cdot \mathbb{E}\left[\sum_{e \in E} \text{peel}(e) \mid \mathcal{E}\right] \stackrel{\text{Prop. 5}}{=} km + k \cdot \mathcal{O}(n) = \mathcal{O}(n). \quad \blacktriangleleft \end{aligned}$$

4 Conclusion and Future Work

This paper proves $\mathcal{O}(1)$ expected amortised running times for random walk insertions into cuckoo hash tables and is the first to yield meaningful results for small values of k such as $k = 3$. Our proof strategy is to link the number of times that a key x moves to the number of times that certain other keys move, where these other keys all precede x in the peeling process. The main technical challenge (addressed in the full version of this paper) was to extend an existing analysis of this peeling process in order to obtain stronger guarantees on its late stages when a sublinear number of keys remain. There are several ways in which our result might be strengthened.

- While amortisation is central to our argument, it seems unlikely to be required for the result itself. Indeed, the plausible claim that the expected time for inserting the i -th key is monotonically increasing in i already implies a non-amortised result.
- To make the result more relevant to practitioners, it is natural to pursue a generalisation to long sequences of insertions *and deletions* and to buckets of size $\ell \geq 2$. The author suspects that the given argument can be correspondingly extended with moderate technical complications.

If deletions are allowed then it seems natural to partition the data structure's lifetime into time slices of εn operations such that the set S_t of all keys present at some point during time slice t yields a peelable configuration whp. One would hope to conclude that $\mathcal{O}(n)$ evictions occur during the time slice in expectation whp. However, the peeling number of a key is no longer sufficient for bounding its expected number of moves for the simple reason that the key itself might be inserted and deleted frequently within the time slice.

- The most important goal, however, is to obtain a result that works up to the load threshold (for all $c < c_{k,1}^* - \varepsilon$), not just up to the peeling threshold (for $c < c_{k,1}^\Delta - \varepsilon$). There is at least one reason for optimism, namely the recent discovery of a variant of cuckoo hashing that raises the peeling threshold to the load threshold [31]. Briefly, a key's k hashes are randomly distributed in a random window of γn consecutive buckets. The peeling threshold of this variant is equal to $c_{k,\ell}^* - \varepsilon$ where $\varepsilon(\gamma)$ can be made arbitrarily small. However, when using this variant, an analysis can no longer rely on the configuration model due to a lack of symmetry between the vertices, meaning that even if the general idea is still sound, the proof would have to use different methods.

Regardless of whether such improvements are achievable, we believe this paper to be a promising step forward in the ongoing project of retrofitting the widespread use of cuckoo hash tables and cuckoo filters with strong theoretical guarantees.

Abstract

This paper presents ParGeo, a multicore library for computational geometry. ParGeo contains modules for fundamental tasks including k d-tree based spatial search, spatial graph generation, and algorithms in computational geometry.

We focus on three new algorithmic contributions provided in the library. First, we present a new parallel convex hull algorithm based on a reservation technique to enable parallel modifications to the hull. We also provide the first parallel implementations of the randomized incremental convex hull algorithm as well as a divide-and-conquer convex hull algorithm in \mathbb{R}^3 . Second, for the smallest enclosing ball problem, we propose a new sampling-based algorithm to quickly reduce the size of the data set. We also provide the first parallel implementation of Welzl's classic algorithm for smallest enclosing ball. Third, we present the BDL-tree, a parallel batch-dynamic k d-tree that allows for efficient parallel updates and k -NN queries over dynamically changing point sets. BDL-trees consist of a log-structured set of k d-trees which can be used to efficiently insert, delete, and query batches of points in parallel.

On 36 cores with two-way hyper-threading, our fastest convex hull algorithm achieves up to 44.7x self-relative parallel speedup and up to 559x speedup against the best existing sequential implementation. Our smallest enclosing ball algorithm using our sampling-based algorithm achieves up to 27.1x self-relative parallel speedup and up to 178x speedup against the best existing sequential implementation. Our implementation of the BDL-tree achieves self-relative parallel speedup of up to 46.1x. Across all of the algorithms in ParGeo, we achieve self-relative parallel speedup of 8.1–46.61x.

1 Introduction

Computational geometry algorithms have important applications in various domains, including computer graphics, robotics, computer vision, and geographic information systems [29, 43]. It is important to provide users with libraries of efficient computational geometry algorithms that they can easily use in their own higher-level applications. Furthermore, due to the growing sizes of data sets that need to be processed today, and the ubiquity of parallel (multicore) machines, it is beneficial to use parallel algorithms to speed up computations. In this paper, we present the ParGeo library for parallel computational geometry, which includes a rich set of parallel algorithms for geometric problems and data structures, including *kd*-trees, *k*-nearest neighbor search, range search, well-separated pair decomposition, Euclidean minimum spanning tree, spatial sorting, and geometric clustering. ParGeo also contains a collection of geometric graph generators, including *k*-nearest neighbor graphs and various spatial networks. Algorithms from ParGeo can either run sequentially, or run using parallel schedulers such as OpenMP, Cilk, or ParlayLib.

While there exist numerous libraries for computational geometry, most of them are not designed for parallel processing. For example, Libigl [35] is a library that specializes in the construction of discrete differential geometry operators and finite-element matrices. However, only some aspects of Libigl take advantage of parallelism. In comparison, the algorithms and implementations of ParGeo are designed for parallelism, and target a different set of problems. CGAL (Computational Geometry Algorithms Library) [2] is a well-known library of computational geometry algorithms that includes a wide range of algorithms, but most implementations are not parallel. Batista et al. [15] targeted a few important algorithms, including spatial sorting, box intersection, and Delaunay triangulation for shared-memory parallel processing, with code in CGAL. In comparison, ParGeo targets similar classes of problems as CGAL, but *all* of our implementations are highly parallel. PMP [47], Cinolib [39], and Tetwild [34] are libraries for polygonal and polyhedron meshes, tackling different problems from ParGeo. MatGeom [5] is a library for sequential geometric computing with MATLAB. The Problem Based Benchmark Suite [46, 12] is a multicore benchmark suite that has some overlap in algorithms with ParGeo. LEDA [40] is a library of data structures and algorithms for sequential combinatorial and geometric processing. ArborX [38] is a parallel library for spatial search.

In this paper, in addition to providing an overview of work on ParGeo, we describe new parallel algorithms implemented in ParGeo for convex hull, smallest enclosing ball, and batch-dynamic *kd*-tree that we developed. For convex hull, we develop new parallel algorithms for both \mathbb{R}^2 and \mathbb{R}^3 , where our key algorithmic novelty is a reservation technique to enable parallel modifications to the hull. For smallest enclosing ball, we propose a new sampling-based algorithm based on Larsson et al.'s [37] approach to quickly reduce the size of the data set. We also provide the first parallel implementation of the classic randomized incremental algorithm [27]. For *kd*-trees, we develop the BDL-tree, a new parallel data structure that supports batch-dynamic operations (construction, insertions, and deletions) as well as exact *k*-NN queries. BDL-trees consist of a set of exponentially growing *kd*-trees and perform batched updates in parallel.

To demonstrate the efficiency of our proposed algorithms and library, we perform a comprehensive set of experiments on synthetic and real-world geometric data sets, and compare the performance across our parallel implementations as well as optimized sequential baselines. On 36 cores with two-way hyper-threading, our best convex hull implementations achieve up to 44.7x (42.8x on average) self-relative speedup and up to 559x (325x on average) speedup against the best existing sequential implementation for \mathbb{R}^2 , and up to 24.9x (11.81x

■ **Figure 1** The figure shows an overview of modules in ParGeo. An arrow indicates that a component is used inside another component. In this paper, we present new algorithms and techniques for the modules highlighted in green.

on average) self-relative speedup and up to 124x (61.4x on average) speedup against the best existing sequential implementation for \mathbb{R}^3 . Our sampling-based smallest enclosing ball algorithm achieves up to 27.1x (20.08x on average) self-relative speedup and up to 178x (109x on average) speedup against the best existing sequential implementation for \mathbb{R}^2 and \mathbb{R}^3 . Our BDL-tree achieves self-relative speedup of up to 35.4x (30.0x on average) for construction, up to 35.0x (28.3x on average) for batch insertion, up to 33.1x (28.5x on average) for batch deletion, and up to 46.1x (40.0x on average) for full k -NN. Finally, across all implementations in ParGeo, we achieve self-relative parallel speedup of 8.1–46.6x (on average 23.2x).

2 The ParGeo Library

Our main goal in designing ParGeo was to enable reusable and efficient parallel implementations of geometric algorithms and data structures. We present an overview of the modules of ParGeo in Figure 1, highlighting how the modules interact with each other. ParGeo contains efficient multicore implementations of static and batch-dynamic kd -trees (Module (1)). The code supports kd -tree based spatial search, including k -nearest neighbor and range search. Our code is optimized for fast kd -tree construction by performing the split in parallel (either by spatial median or by object median), and performing the queries in a data-parallel fashion, which we will introduce in Section 5.

ParGeo contains a module for parallel computational geometry algorithms (Module (2)). Our kd -tree can be used to generate a well-separated pair decomposition [26] (WSPD), which can in turn be used to compute the hierarchical DBSCAN [52], ParGeo contains parallel implementations for the bichromatic closest pair, closest pair, convex hull, smallest enclosing ball, and Morton sorting.

In addition, ParGeo contains a collection of geometric graph generators (Module (3)) for point data sets. Our kd -tree’s k -NN search is used to generate the k -NN graph, and the range search is used to generate the β -skeleton graph [36]. Our WSPD generated from the kd -tree can also be used to compute the Euclidean minimum spanning tree [25, 52], and spanners [26]. ParGeo also generates the Delaunay graph.

■ **Table 1** Runtimes (seconds) and parallel speedups (T_1/T_{36h}) for PARGEO implementations on uniform hypercube data sets of varying dimensions and 10 million points. T_1 and T_{36h} denote the single-threaded and the 36-core hyper-threaded times, respectively. For batch-dynamic kd -tree updates, each batch contains 10% of the data set.

Implementation	T_1	T_{36h}	Speedup
<i>kd-tree Build (2d)</i>	5.51	0.43	12.70x
<i>kd-tree Build (5d)</i>	8.39	0.89	9.40x

<i>Closest Pair (3d)</i>	28.00	2.32	12.07x
<i>k-NN Graph (2d)</i>	37.89	1.46	25.99x
<i>Delaunay Graph (2d)</i>	55.91	2.03	27.53x
<i>Gabriel Graph (2d)</i>	59.61	1.99	29.99x
<i>β-skeleton Graph (2d)</i>	113.27	3.20	35.37x
<i>Spanner (2d)</i>	27.19	2.15	12.67x

ParGeo contains a point data generator module (Module (4)) for which can generate uniformly distributed data sets, and clustered data sets of varying densities [31]. These data sets are used for benchmarking the other modules.

As shown in Table 1, on a machine with 36 cores with two-way hyper-threading, ParGeo achieves self-relative parallel speedups of 8.1–46.61x (23.15x on average) on a uniformly distributed data set, across all of the benchmarks. In the subsequent sections, we present three new algorithmic contributions provided in the library.

3 Convex Hull

The convex hull of a set of points P in \mathbb{R}^d is the smallest convex polyhedron containing P . It is common to represent the convex hull using a set of **facets**. The boundary of two facets is a **ridge**. For example, in \mathbb{R}^3 , assuming the points are in general position (no four points are on the same plane), each facet is a triangle, and each ridge is a line that borders two facets (see Figure 2(a)).

■ **Figure 2** (a) A facet and a ridge of a convex hull in \mathbb{R}^3 . (b) The support of the smallest enclosing ball in \mathbb{R}^2 .

The randomized incremental algorithm and the quickhull algorithm are the most widely used algorithms for solving convex hull in practice. The randomized incremental algorithm for \mathbb{R}^d was proposed by Clarkson and Shor [27]. Given a point data set P in \mathbb{R}^d , the randomized incremental algorithm first constructs a d -simplex, a generalization of a tetrahedron in d -dimensions as the initial hull. Then, the algorithm adds the points to the polyhedron in a random order, updating the hull if necessary. In practice, the quickhull algorithm [33, 14], another incremental algorithm, is often used. Unlike the randomized algorithm, the quickhull algorithm processes a point that is furthest from a facet, which enables the hull to be expanded more quickly. The quickhull algorithm is by far one of the most common implementations for convex hull due to its simplicity and efficiency [4, 6, 7, 1, 3, 2]. There have also been works that study parallel implementations of quickhull, but they are either limited to \mathbb{R}^2 [41, 48], or do not return the exact convex hull for \mathbb{R}^3 [49, 51]. Recently, Blleloch et al. [24] proposed a new randomized incremental algorithm that is highly parallel in theory. However, the algorithm does not seem to be practical due to numerous data structures required for bookkeeping.

In this section, we describe our new parallel reservation-based algorithm. Our algorithm is able to express both the randomized incremental convex hull algorithm and the quickhull algorithm. Specifically, unlike a sequential incremental algorithm that adds one point per round, we add multiple points in parallel per round. We resolve conflicts caused by the parallel insertion using a reservation technique. We also apply a general parallelization technique based on divide-and-conquer, which in combination with our parallel incremental algorithm, leads to faster implementations in practice.

Parallel Reservation-Based Algorithm. Our parallel reservation-based algorithm can be implemented as either a randomized incremental algorithm or a quickhull algorithm. We will first introduce the overall structure of the algorithm. Then, we will describe the details about the implementations, and compare with existing approaches. We will base our description in the context of \mathbb{R}^3 for the sake of clarity, but the algorithm can be extended to \mathbb{R}^d for any constant integer $d \geq 2$.

We first give a high-level overview of the algorithm. Given an ordered set of points $P = \{p_1, p_2, \dots, p_n\}$, we let $P_r = \{p_1, p_2, \dots, p_r\}$ be the prefix of P of size r , and $CH(P_r)$ be the convex hull on P_r . We start the construction by first arbitrarily selecting four points from P that do not lie on the same plane and putting them at the beginning of P , forming a tetrahedron $CH(P_4)$. Then, the algorithm proceeds iteratively, but on each round, rather than inserting just p_r to form $CH(P_r)$, we process a batch of points in parallel. On each round, let each point outside of $CH(P_{r-1})$ be called a **visible point**. We first select a batch of visible points, and try to add them to $CH(P_{r-1})$ in parallel in the same round.

The key challenge of this approach is that some of these points cannot be processed in parallel due to concurrent modifications on the shared structures of the convex polyhedron. We use a reservation algorithm to resolve these conflicts, such that we only process the points that modify disjoint facets of the polyhedron. Specifically, each point will perform a priority write [45] with its ID to reserve all of its visible facets. Points that have their ID written to all of its visible facets are *successful*. We then process the successful points in parallel by enabling them to make modifications to $CH(P_{r-1})$. At the end of the round, in parallel, we filter out points that are no longer visible. The algorithm will terminate when there are no more visible points.

We now describe the algorithm in more detail. Figure 3 illustrates the processing of a visible point p_r . We denote a facet as a **visible facet** of p_r if point p_r is in the half space away from the center of the convex hull. We first retrieve the set of visible facets of p_r via

■ **Figure 3** Illustration of adding a visible point p_r to the convex hull. (a) shows the convex hull prior to the addition of p_r . The visible facets are in white, while the non-visible facets are in gray. The thicker line segments correspond to the horizon. (b) shows the convex hull after adding p_r with newly created facets.

■ **Figure 4** This figure illustrates the attempt to add p_r and p_{r+1} in parallel. The visible points and horizons of p_r and p_{r+1} are in red and blue, respectively. The visible facets to either visible points are in white/yellow, while the other facets are in gray. The overlap of the three visible facets between the p_r and p_{r+1} is in yellow.

facets stored in it. The visible facets of p_r form a closed region, whose boundary is a set of ridges, known as the **horizon**. We delete the visible facets from $CH(P_{r-1})$, and replace them with new facets, where each new facet is formed by adding two ridges from a horizon ridge to p_r .

Because of the structural changes to the convex hull that occur when adding a visible point, concurrent structural changes can cause data races, which need to be avoided. We show an example of the conflict in Figure 4, where we are attempting to add two visible points p_r and p_{r+1} in parallel. As shown in the figure, the closed regions formed by the visible facets of each visible point overlap with each other in three facets, which are highlighted in yellow. Should the two visible points be processed in parallel, the resulting polyhedron may not be well-defined due to data races. When processed sequentially, p_{r+1} 's visible facets would have been different, involving newly created facets by p_r .

Our reservation algorithm allows only a subset of the visible points that update disjoint facets of the convex hull to be processed in parallel on each round. At a high level, we use the lexicographical order of the visible points to determine the priority in processing a facet (a smaller ID has higher priority). In the example shown in Figure 4, since p_r has a smaller ID than p_{r+1} , the three conflicting facets can only be processed by p_r in that round. The pseudocode for the algorithm is shown in Figure 5. P is processed iteratively until it is empty (Line 4). We allocate an extra data field in each facet for performing reservations (Lines 6–8). For each visible point in parallel, we iterate through its visible facets and use a parallel priority write (**WriteMin**) to write its ID to the facets' "reservation" fields. Then on Lines 9–11, we determine which visible points successfully reserved all of its facets. Again, in

```

1  Input: 3-dimensional points P, batch size r
2  Output: 3-dimensional convex hull
3  CH := initialize with 4 points
4  while (P is not empty):
5      Q := a batch of size r of visible points in P
6      par_for (q in Q): /* reservation */
7          for (f in q.visibleFacets):
8              WriteMin(&f.reservation, q.id)
9      par_for (q in Q): /* check reservation */
10         for (f in q.visibleFacets):
11             q.success &&= (f.reservation == q.id)
12     par_for (q in Q): /* process successful points */
13         if (q.success):
14             delete q's visible facets
15             create new facets of q
16             update CH
17     P := ParallelPack(P, visible)

```

■ **Figure 5** Pseudocode for the parallel reservation-based convex hull algorithm (which includes the randomized incremental algorithm and the quickhull algorithm).

parallel for each visible point, we check each of its visible facets for a successful reservation by comparing the value of the reservation field with its token. The reservation of a visible point is only successful if its ID is stored in all of its visible facets. Then, on Lines 12–16, we process the visible points whose reservations are successful, adding them to the hull and updating the appropriate data structures. Finally, on Line 17, we process the points in P such that those remaining as visible points are packed to replace the original P , and the non-visible points are discarded. Note that the visible points that succeeded in the reservation are no longer visible points because they are now part of the convex hull. Some of the remaining points will also no longer be visible points due to the growth of the convex hull.

We use a simple and fast data structure to keep track of the visibility relationship between the visible points and the facets. At each step of the algorithm, when a visible point is processed, it needs to identify the set of visible facets. On the other hand, for the facets undergoing structural changes, they need to identify and redistribute their visible points to new facets. To find the set of visible facets of p_r , it is inefficient to iterate through all of the facets of $CH(P_{r-1})$. While existing approaches [29] keep track of the visibility between visible points and *all* of their visible facets, we found such an approach to be slow because each vertex is associated with multiple facets, making the cost of storing and updating the data structure high. We only store the reference of an arbitrary visible facet to each visible point, from which we use a local breadth-first search to retrieve all of the visible facets only when needed. For storing the visible points in the facets, we assign each point to one of its visible facets. During point redistribution, we gather the points stored in each visible facet into an array, and in parallel distribute each point to a new visible facet replacing the original visible facet. Each such point also stores a reference to this visible facet.

Our reservation-based algorithm can be used to implement the parallel randomized incremental algorithm or the quickhull algorithm for convex hull. For the randomized incremental algorithm, we randomly permute the input points at the beginning, and on each round attempt to add a prefix of the permuted points to the convex hull. For the quickhull algorithm, on each round, we instead select a set of points furthest from a subset of facets.

We describe the implementation of the two algorithms in greater detail in the full version of our paper. Our reservation-based algorithm is inspired by the idea of “deterministic reservations” from Blleloch et al. [22], who introduce this approach to implement parallel algorithms for other problems. In the full version of our paper, we show the work overhead of doing reservations compared to the sequential algorithm is small.

Parallel Divide-and-Conquer. We adopt a common parallelization strategy using divide-and-conquer, which calls our reservation-based algorithm as a subroutine. Some early convex hull algorithms are based on divide-and-conquer, notably, the algorithm by Preparata and Hong [42]. The algorithm splits the input into two spatially disjoint subsets by a mid-point along one of the axis, recursively computes the convex hull on each subset, and then merges the results together. Later work [10, 28, 11] extended this approach to the parallel setting. However, most of these approaches rely on complicated subroutines to merge convex hulls, which are not practical and have not been implemented, to the best of our knowledge.

We implement a practical divide-and-conquer algorithm by partitioning the input into $c \cdot numProc$ equal subsets, where c is a small constant and $numProc$ is the number of processors. For each subset, the convex hull of the subset is computed by a single processor using the sequential quickhull algorithm, but run in parallel across the different subsets. Then, the vertices of the outputs of the subproblems are collected to form a new input, from which the final convex hull is computed using our reservation-based parallel algorithm described earlier.

Point Culling via Pseudohull Computation. We also implement a multicore variant of Tang et al.’s pseudohull heuristic [50], originally proposed for the GPU. Starting from an initial tetrahedra, we recursively grow each facet into three new facets, using the furthest point from the facet, similar to the quickhull algorithm. The visible points associated with the facet are redistributed to the new facets. This results in a polyhedron, and the points in the interior of the polyhedron will not be part of the convex hull. Therefore, we can prune away the points inside the polyhedron and compute the convex hull on the rest of the points.

There are several differences in our implementation from Tang et al.’s algorithm. Our implementation executes the recursive calls on different facets asynchronously in parallel, whereas Tang et al.’s implementation maps the algorithm to the GPU architecture by pre-allocating space for the facets and visible points, and runs the algorithm in an iterative manner in lock-step. Specifically, successively generated facets and points associated with them are updated by multiple threads in parallel in each iteration. We use a parallel maximum-finding routine to find the furthest point of each facet in each call. Rather than growing the pseudohull until there are no more visible points as done by Tang et al., we set a threshold on the number of points associated with a facet, below which we stop growing the pseudohull. This prevents stack overflow on large and skewed data sets due to too many recursive calls, and the extra unpruned points do not contribute significantly to the work of the final computation of the convex hull. At the end of pruning, we use our parallel reservation-based quickhull algorithm to compute the final hull on the remaining points, whereas Tang et al. uses a sequential implementation.

4 Smallest Enclosing Ball

The smallest enclosing ball of P in \mathbb{R}^d is the smallest d -sphere containing P . It is well known that the smallest enclosing ball is unique and defined by a **support set** of $d + 1$ points on the surface of the ball (see Figure 2(b)).

Welzl [53] showed that by using a randomized incremental algorithm, the smallest enclosing ball can be computed in $O(n)$ time in expectation for constant d . The algorithm iteratively expands the support set of the ball by adding points in a random order until the ball contains all of the points. The algorithm was later improved by Gartner [32] with practical optimizations for speed and robustness. Larsson et al. [37] proposed practical parallel algorithms that use a new method for expanding the support set, and their implementations work on both CPUs and GPUs. Later, Blleloch et al. [23] proposed a parallel algorithm based on Welzl’s algorithm, but without any implementations.

In this section, we describe our new algorithms for the smallest enclosing ball problem based on Larsson et al.’s approach [37]. We propose a sampling-based algorithm to quickly reduce the size of the data set. We also provide the first parallel implementation of Welzl’s classic algorithm.

Given a ball B , we define **visible points** to be points that lie outside of B . Existing approaches for computing the smallest enclosing ball focus on expanding the support set in an iterative manner, and output the enclosing ball when there are no more visible points. Welzl’s algorithm expands the support set by adding points in a random order [53]. In comparison, Larsson et al.’s approach scans the input to search for good support sets in a round-based manner. In \mathbb{R}^3 , Larsson’s algorithm divides the space into eight orthants centered at the center of B . On each round, the input is scanned to find the furthest visible points in each orthant. B is then updated to the next intermediate solution using the existing support set of B and the new visible points found during the scan. The algorithm iterates until there are no more visible points. It is parallelized within each round by performing the scan on the input in parallel.

Sampling-Based Algorithm. We find each iteration in Larsson et al.’s algorithm to be unnecessarily expensive due to having to scan the entire data set on every round. Our approach is to use a sampling heuristic to first obtain a good initial ball, inspired by Welzl’s randomized algorithm. Specifically, we use small random samples to obtain good estimates of the support set at a negligible cost.

We show the pseudocode of our algorithm in Figure 6. Our sampling-based algorithm consists of two phases: the sampling phase (Line 5–13) and the final compute phase (Line 15–20). First, we initialize the ball using a few arbitrary points (Line 3). Then, we iterate through a random permutation of the input to take multiple samples (Line 5–13). On each iteration, we scan through a constant-sized segment of the unseen part of the input, which is equivalent to a random sample. We perform an orthant scan similar to Larsson’s approach. Our implementation of orthant scan will return a new estimate of the support set based on the sample, and a boolean *hasOutlier* indicating whether the sample contains visible points with respect to the current smallest enclosing ball B (Line 7). We recompute B using the new support set. If there are visible points in the current sample, we will continue the sampling process with our new B . If there are no visible points in the sample, the support set likely contains most of the points, and so we terminate sampling and move on to the next phase. Now, with a good estimate of the optimal smallest enclosing ball, we run Larsson’s orthant scan to compute the final smallest enclosing ball (Line 15–20). The sampling phase allows us to generate good support sets without having to scan the entire input.

We parallelize the orthant scan, which is the most expensive operation of the algorithm. Specifically, we divide the input array to orthant scan into blocks, and process each block sequentially, but in parallel across different blocks. Afterward, the extrema for the orthants obtained from the blocks are merged, and a new support set is computed on these points and the existing support set of B .

```

1 Input: d-dimensional points P, batch size c
2 Output: d-dimensional smallest enclosing ball
3 B = ball()
4 /* Sampling phase */
5 scanned = 0
6 while (scanned < n):
7   hasOutlier, support =
8     orthantScan(P[scanned:min(scanned+c,n)-1],B)
9   scanned += c
10  if (!hasOutlier):
11    break /* current sample does not violate B */
12  else
13    B = constructBall(support)
14 /* Final computation phase */
15 while (hasOutlier):
16   hasOutlier, support = orthantScan(P, B)
17   if (!hasOutlier):
18     return B
19   else
20     B = constructBall(support)

```

■ **Figure 6** Pseudocode for the parallel sampling-based algorithm for smallest enclosing ball.

We parallelize the orthant scan, which is the most expensive operation of the algorithm. Specifically, we divide the input array to orthant scan into blocks, and process each block sequentially, but in parallel across different blocks. Afterward, the extrema for the orthants obtained from the blocks are merged, and a new support set is computed on these points and the existing support set of B .

Parallel Welzl's Algorithm and Optimizations. We also implemented and optimized the parallel version of Welzl's algorithm described by Blelloch et al. [23]. Welzl's sequential algorithm uses a random permutation of the input P and processes the points one by one. If the algorithm encounters a visible point p_i with respect to the current bounding ball B , B is recomputed on P_i , the prefix of points up until p_i , using recursive calls to the algorithm. Blelloch et al.'s parallel algorithm also uses a random permutation of P . Across iterations, the algorithm processes prefixes of P of exponentially increasing size. If the prefix contains at least one visible point, the earliest visible point p_i is identified, and B is recomputed on prefix P_i by recursively calling the parallel algorithm. Each prefix is processed in parallel.

We implement the algorithm with some practical optimizations. When there are numerous visible points in the prefix, the work of the parallel algorithm will increase significantly, because each time a visible point is discovered, the points after the visible point in the same prefix will have to be reprocessed in the next round. Therefore, given that there will be more visible points in the initial rounds when the prefix size is small (< 500000), we process these prefixes sequentially by calling Welzl's sequential algorithm. This also reduces the amount of overhead from parallel primitives, since there is limited parallelism for small prefixes.

In addition, we extend existing optimizations of Welzl's sequential algorithm to the parallel setting. We implement the move-to-front heuristic [53], which upon encountering a visible point, moves the visible point to the front of P , so that it will be processed earlier in recursive calls, reducing the number of subsequent visible points. We also parallelize the pivoting heuristic proposed by Gartner [32]. In this heuristic, upon encountering a visible

point, rather than processing the visible point directly, we search P for a *pivot point* furthest away from the center of the current B , and use the pivot point to compute the new B instead of the visible point. We use a parallel maximum-finding algorithm to identify the pivot point.

5 Parallel Batch-Dynamic k d-tree

The k d-tree, first proposed by Bentley [16], is a binary tree data structure that arranges and holds spatial data to speed up spatial queries. At each node, the data set is split into two using an axis-aligned hyperplane along a dimension, until the node holds a small constant number of points. k d-trees are used in a wide range of applications, such as in databases, machine learning, data compression, and cluster analysis.

In this section, we introduce the BDL-tree, a parallel batch-dynamic k d-tree implemented using the logarithmic method [17, 18]. Our BDL-trees build on ideas from the Bkd-Tree by Procopiuc et al. [44] and the cache-oblivious k d-tree by Agarwal et al. [9]. The logarithmic method [17, 18] for converting static data structures into dynamic ones is a very general idea. At a high level, the idea is to partition the static data structure into multiple structures with exponentially growing sizes (powers of 2). Then, inserts are performed by only rebuilding the smallest structure necessary to account for the new points. In the specific case of the k d-tree, a set of N_s static k d-trees is allocated, with capacities $[2^0, 2^1, \dots, 2^{N_s-1}]$, as well as an extra buffer tree with size 2^0 . Then, when an insert is performed, the insert cascades up from the buffer tree, rebuilding into the first empty tree with all the points from the lower trees. If desired, the sizes of all of the trees can be multiplied by a buffer size X , which is a constant that is tuned for performance.

We implement the underlying static k d-trees in an BDL-tree using the van Emde Boas (vEB) [13, 30, 9] recursive layout. Agarwal et al. [9] show that this memory layout can be used with k d-trees to make traversal cache-oblivious. We provide more details of the static tree structure, and parallel algorithms for the construction, deletion, and k -NN search in the full version of our paper.

Parallel Batch Insertion. Batch insertions are performed in the style of the logarithmic method [17, 18], with the goal of maintaining the minimum number of full trees within BDL-tree. Thus, upon inserting a batch P of points, we rebuild larger trees if it is possible using the existing points and the newly inserted batch. We use a bitmask to determine which static trees in the structure to destroy and reconstruct after each insertion. Specifically, we build a bitmask F of the current set of full static trees. Given the buffer k d-tree size X , we add the value $\lfloor |P|/X \rfloor$ to F when a point set P is inserted, after which the bitwise difference with the previous F indicates which trees need to be changed. We gather the points in the trees to be destroyed, and with P , we construct a subset of new trees in parallel. As an implementation detail, note that we first add $|P| \bmod X$ points to the buffer k d-tree – if we fill up the buffer k d-tree, then we gather the X points from it and treat them as part of P , effectively increasing the size of P by X . Refer to Figure 7 for an example of this insertion method ($X > 2$ in this example). In Figure 7a, the BDL-tree contains X points, giving a bitmask of $F = 1$ (because only the smallest tree is in use). If we insert $X + 1$ points, then we put one point in the buffer tree and compute $F_{new} = 1 + \lfloor \frac{X}{X} \rfloor = 2$, and so we have to deconstruct static tree 0 and build static tree 1, as shown in Figure 7b. Then, if we insert $X + 1$ points again, then we again put one point in the buffer tree and compute $F_{new} = 2 + \lfloor \frac{X}{X} \rfloor = 3$, and so we simply construct tree 0 on the X new points (leaving tree 1 intact), as seen in Figure 7c. Finally, if we then insert $X - 1$ points, this would fill the buffer

■ **Figure 7** A BDL-tree in various configurations with $X > 2$; starting from (a), inserting $X + 1$ points gives (b), then inserting $X + 1$ points gives (c), and then inserting $X - 1$ points gives (d).

up, and so we take 1 point from the buffer and insert X points; then, $F_{new} = 3 + \lfloor \frac{X}{X} \rfloor = 4$, and so we deconstruct trees 0 and 1, and construct tree 2, as seen in Figure 7d. We include a more detailed explanation of the algorithm, and explain the batch deletion algorithm in the full version of our paper.

Data-Parallel k -NN. In the data-parallel k -NN implementation, we parallelize over S , the set of points to search for nearest neighbors for. First, we allocate a k -NN buffer for each of the points in S . Then, iterating over each of the non-empty trees in the BDL-tree sequentially, we call the data-parallel k -NN subroutine on the tree, passing in the set S of points and the k -NN buffers. Because we reuse the same set of k -NN buffers for each k -NN call (note that each k -NN call is internally parallel), we end up with the k -nearest neighbors of the entire pointset for each point in S . We include a more detailed explanation in the full version of our paper.

6 Experimental Evaluation

Data Sets. We use several types of synthetic data sets. The first is **Uniform (U)**, consisting of points distributed uniformly at random inside a hypercube with side length \sqrt{n} , where n is the number of points. The second type **InSphere (IS)** is similar to the first, but the points are distributed in a hypersphere instead. We also use **OnSphere (OS)** and **OnCube (OC)** data sets, where points are uniformly distributed on the surface of a hypersphere and a hypercube, respectively. The surfaces have a thickness equal to 0.1 times the diameter or side length of the sphere or cube. We name the data sets in the format of **Dimension-Name-Size**.

We also use the following real-world data sets from the Stanford 3D Scanning Repository [8]: **3D-Thai-5M** is a 3-dimensional point data set of size 4999996 from a scanned thai-stature; and **3D-Dragon-3.6M** is a 3-dimensional point data set of size 3609600 from a scanned statue of a dragon.

Testing Environment. The experiments are run on an AWS c5.18xlarge instance with 2 Intel Xeon Platinum 8124M CPUs (3.00 GHz), for a total of 36 two-way hyper-threaded cores and 144 GB RAM. We compile our benchmarks with the g++ compiler (version 9.3.0) with the `-O3` flag, and use ParlayLib [20] for parallelism.

6.1 Convex Hull

We test the following implementations for convex hull (our new implementations are underlined). All implementations are for both \mathbb{R}^2 and \mathbb{R}^3 .

- **CGAL**: sequential C++ implementation of quickhull in CGAL [2].
- **Qhull**: sequential C++ implementation of quickhull [6] by Barber et al. [14].

■ **Figure 8** Running times of implementations across different data sets for 2-dimensional convex hull on 36 cores with 2-way hyper-threading.

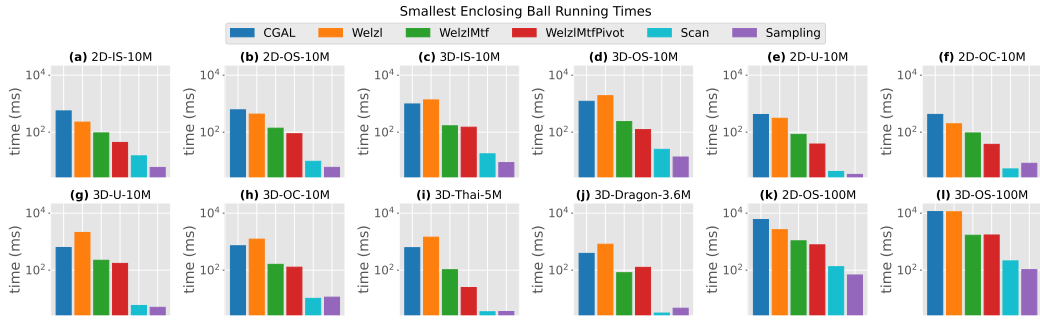

■ **Figure 9** Running times of implementations across different data sets for 3-dimensional convex hull on 36 cores with 2-way hyper-threading.

- **RandInc**: our implementation of the parallel randomized incremental algorithm described in Section 3.
- **QuickHull**: for \mathbb{R}^2 , it is a simple recursive parallel algorithm [19], and we use the implementation in PBBS [46]; for \mathbb{R}^3 , we use our parallel quickhull algorithm described in Section 3.
- **Pseudo**: our implementation of the pseudoHull heuristic proposed by Tang et al. [50] for 3-dimensional convex hull described in Section 3. The final stage of the computation uses our *quickHull* algorithm for \mathbb{R}^3 .
- **DivideConquer**: our divide-and-conquer algorithm described in Section 3.

In Figures 8 and 9, We show a comparison of running times across different methods using 36 cores with two-way hyper-threading. Our implementations achieve significant speedup compared to existing sequential implementations. Our fastest parallel implementations achieve speedups of 190–559x (325x on average) over *CGAL* for 2-dimensional convex hull, and speedups of 10.5–124x (61.4x on average) over *CGAL* for 3-dimensional convex hull. Our fastest parallel implementations have speedups of 147–1673x (605x on average) over 2-dimensional *Qhull*, and speedups of 5.68–43.8x (19.9x on average) over 3-dimensional *Qhull*. When run using a single thread, our parallel implementations achieve speedups of 3.26–12.4x and 1.31–5.05x over *CGAL* for 2 and 3 dimensions, respectively; and 3.39–47.6x and 0.99–2.06x speedups over *Qhull* for 2 and 3 dimensions, respectively.

For \mathbb{R}^2 , *DivideConquer* is always the fastest method due to having high scalability from processing many independent subproblems in parallel. For \mathbb{R}^3 , the fastest two methods are *DivideConquer* and *Pseudo*. We observe that on data sets with a larger output size, *Pseudo* is slower than *DivideConquer* (Figures 9(a), (b), and (g)). This is because the final computation after pruning takes longer given that there are a higher number of remaining points after pruning. For instance, the number of remaining points for *3D-IS-10M* and

■ **Figure 10** Running times of implementations across different data sets for smallest enclosing ball on 36 cores with 2-way hyper-threading.

3D-U-10M after pruning are 83669 and 2316, respectively, and *Pseudo* is relatively slower on the former. We observe that *RandInc* and *QuickHull* take relative longer compared with the fastest methods for data sets with a smaller output size (Figures 9(c)–(e) and (h)). This is caused by higher contention during the reservation of facets, since there are fewer facets on the intermediate hull. For example, for *3D-IS-10M* and *3D-U-10M*, the output sizes are 14163 and 423, respectively. During the computation, *3D-U-10M* exposes fewer facets for reservation, leading to a lower success rate during the reservations.

DivideConquer achieves the best parallel speedup (42.78x and 16.55x on average for \mathbb{R}^2 and \mathbb{R}^3 , respectively). This is because the bulk of the time is spent in computing independent convex hulls across different threads. On the other hand, the incremental algorithms, *RandInc* and *QuickHull*, demonstrate lower scalability because of load imbalance caused by the different amounts of work for each conflict point being processed in parallel.

6.2 Smallest Enclosing Ball

We test the following implementations for smallest enclosing ball (our new implementations are underlined). All implementations work for both \mathbb{R}^2 and \mathbb{R}^3 .

- **CGAL**: sequential C++ implementation of Welzl’s algorithm in CGAL [2].
- **Orthant-scan**: our implementation of Larsson et al.’s orthant-scan algorithm [37].
- **Sampling**: our parallel sampling algorithm described in Section 4.
- **Welzl**: our parallel implementation of Welzl’s algorithm described in Section 4.
- **WelzlMtf**: the same as *Welzl*, but with the move-to-front heuristic [10].
- **WelzlMtfPivot**: the same as *Welzl*, but with both the move-to-front and the pivoting heuristic [32].

For smallest enclosing ball, we show the comparison across implementations using 36 cores with two-way hyper-threading in Figure 10. Our fastest parallel implementations have speedups of 70–178x (109x on average) over *CGAL*. On one thread, our fastest implementations achieve speedup of 2.81–7.05x (4.96x on average) over *CGAL*.

Our sampling-based method is the fastest for eight out of the twelve data sets, whereas *Orthant-scan* without sampling is the fastest for the other four. We observe that the sampling phase on average scans only about 5% of the data set, and results in up to 2.55x (1.47x on average) speedup compared to just running *Orthant-scan*. Comparing across different implementations of Welzl’s algorithms, we see that the move-to-front, and the pivoting heuristic implemented in parallel consistently improve the running times. Specifically, *WelzlMtf* is 2.09–13.9x faster than *Welzl*, and *WelzlMtfPivot* is 3.4–58.6x faster than *Welzl*. We also see that *Sampling* and *Orthant-scan* are 4.63–34.8x and 2.96–40.3x faster than *WelzlMtfPivot*, respectively.

6.3 BDL-tree

We designed a set of experiments to investigate the performance and scalability of BDL-tree and compare it to two baselines that we also implemented. **B1** is a baseline where the kd -tree is rebuilt on each batch insertion and deletion in order to maintain balance. This allows for improved query performance (as the tree is always perfectly balanced) at the cost of slowing down updates. **B2** is another baseline that inserts points directly into the existing tree structure without recalculating the splits. This results in very fast updates at the cost of potentially skewed trees (which slows down query performance). **BDL** is our BDL-tree described in Section 5. We consider splitting the points based on either using the object median (median among the points along a dimension) or the spatial median (splitting the space along a dimension in half).

Construction. Figure 11a shows the scalability of the throughput on the 7D-U-10M data set. As we can see from the results, **BDL** achieves similar or better performance both serially and in parallel than both **B1** and **B2**, and has similar or better scalability than both. With the object median splitting, it achieves up to $34.8\times$ self-relative speedup, with an average self-relative speedup of $28.4\times$. We also note that the single-threaded runtimes are faster with spatial median splitting than with object median splitting. This is because spatial median only involves splitting points at each level compared with finding the median for object median, hence it is less expensive to compute; however, we also note that the scalability for spatial median is lower because there is less work to distribute among parallel threads. The construction of **B2** is significantly slower than that of **B1**, because a separate memory buffer is allocated at each leaf node in **B2** to allow for future insertions. The construction of the BDL-tree is faster than both **B1** and **B2** because splitting the construction across multiple trees while keeping the number of elements the same reduces the total work, and provides ample parallelism when running on multiple threads.

Batch Insertion. In this benchmark, we measure the performance of our batch insertion implementation as compared to the baselines. We measure the time required to insert 10 batches each containing 10% of the points in the data set into an initially empty tree for each of our two baselines as well as our BDL-tree.

From Figure 11b, we see that **B2** achieves the best performance on batched insertions – this is due to the fact that it does not perform any extra work to maintain balance and simply directly inserts points into the existing spatial structure. **BDL** achieves the second-best performance – this is due to the fact that it does not have to rebuild the entire tree on every insert, but amortizes the rebuilding work across the batches. Finally, **B1** has the worst performance, as it must fully rebuild on every insertion. Similar to construction, we note that spatial median splitting performs better in the serial case but has lower scalability. With object median splitting, **BDL** achieves parallel self-relative speedup of up to $35.5\times$, with an average self-relative speedup of $27.2\times$.

Batch Deletion. We measure the time required to delete 10 batches each containing 10% of the points in the data set from an initially full tree for each of our two baselines as well as the BDL-tree. From Figure 11c, we observe that **B2** has vastly superior performance – it does almost no work other than tombstoning the deleted points so it is extremely efficient. Next, we see that **BDL** has the second-best performance, as it amortizes the rebuilding across the batches, rather than having to rebuild across the entire point set for every delete. Finally, **B1** has the worst performance as it rebuilds on every delete. With object median splitting, **BDL** achieves parallel speedup of up to $33.1\times$, with an average speedup of $28.5\times$.

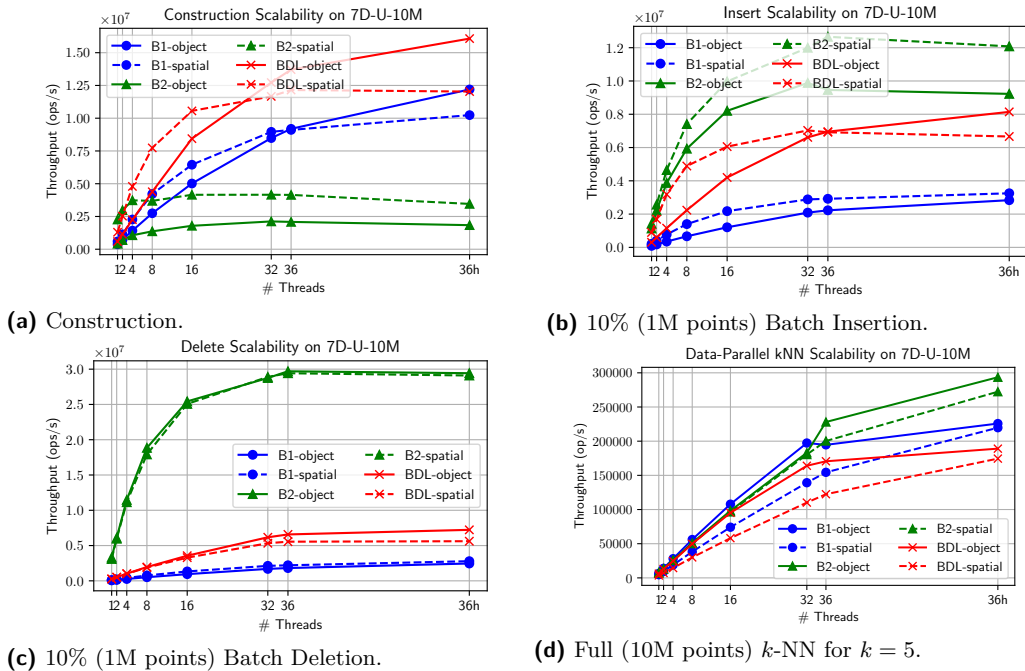

Figure 11 Plot of throughput (operations per second) of batch operations over thread count for both object and spatial median implementations for the 7D-U-10M data set. The prefix of the implementation name refers to the median splitting heuristic. “36h” corresponds to 36 cores with two-way hyper-threading.

Data-Parallel k -NN. We measure the performance and scalability of our k -NN implementation as compared to the baselines. As shown in in Figure 11d, the results show that **B1** and **B2** have similar performance. Furthermore, they are both faster than BDL-tree. This is to be expected, because the k -NN operation is performed directly over the tree after it is constructed over the entire data set in a single batch. Thus, both baselines will consist of fully balanced trees and will be able to perform very efficient k -NN queries. On the other hand, **BDL** consists of a set of multiple trees, which adds overhead to the k -NN operation, as it must be performed separately on each of these individual trees. In the full version of our paper, we show that when the trees are constructed via a set of batch insertions rather than all at once, the performance of **B2** suffers significantly due to the tree being unbalanced.

Comparison with Zd-tree. We compared with the Zd-tree recently proposed by Blelloch and Dobson [21]. The Zd-tree data structure combines the approach of a kd -tree and Morton ordering of the data set, and supports parallel batch-dynamic insertions and deletions, and k -NN. The implementation currently only supports 2 and 3 dimensional data sets, whereas our implementation is not restricted to 2 and 3 dimensions. We tested their implementation on 3D-U-10M. Using all threads, their implementation takes 0.12 seconds to construct, and an average of 0.026 and 0.024 seconds for insertion and deletion of 10% of the data points, and takes 1.65 seconds for k -NN. Our BDL-tree implementation is $3.3\times$, $23.1\times$, and $45.83\times$ slower, for construction, insertion, and deletion, respectively, but achieves roughly the same speed for k -NN search. The reason is that the Morton sort used in their implementation is fast and highly optimized for 2 and 3 dimensions; however, extending this technique to higher dimensions would result in overheads due to more bits needed for the Morton ordering.

7 Conclusion

In this paper, we presented ParGeo, a multicore library for computational geometry containing modules for fundamental tasks including kd -tree based spatial search, spatial graph generation, and algorithms in computational geometry. We also presented new parallel algorithms, implementations, and optimizations for convex hull, smallest enclosing ball, and parallel batch-dynamic kd -tree. We performed a comprehensive experimental study showing that our new implementations achieve significant speedups over prior work and obtain high parallel scalability.

Combining Predicted and Live Traffic with Time-Dependent A* Potentials

Nils Werner

Karlsruhe Institute of Technology, Germany

Tim Zeitz  

Karlsruhe Institute of Technology, Germany

Abstract

We study efficient and exact shortest path algorithms for routing on road networks with realistic traffic data. For navigation applications, both current (i.e., live) traffic events and predictions of future traffic flows play an important role in routing. While preprocessing-based speedup techniques have been employed successfully to both settings individually, a combined model poses significant challenges. Supporting predicted traffic typically requires expensive preprocessing while live traffic requires fast updates for regular adjustments. We propose an A*-based solution to this problem. By generalizing A* potentials to time dependency, i.e. the estimate of the distance from a vertex to the target also depends on the time of day when the vertex is visited, we achieve significantly faster query times than previously possible. Our evaluation shows that our approach enables interactive query times on continental-sized road networks while allowing live traffic updates within a fraction of a minute. We achieve a speedup of at least two orders of magnitude over Dijkstra's algorithm and up to one order of magnitude over state-of-the-art time-independent A* potentials.

1 Introduction

An important feature of modern routing applications and navigation devices is the integration of traffic information into routing decisions. The more comprehensive the considered traffic information, the better the suggested routes, the more accurate the predicted arrival times and ultimately, the more satisfied the users. For routing, we can distinguish between two aspects of traffic: On the one hand, there are *predictable* traffic flows. For example, certain highways will consistently have traffic jams on weekday afternoons due to commuters driving home. On the other hand, unexpected events such as accidents may also have significant influence on the *current* (i.e., *live*) traffic situation. While it may be sufficient to focus on the current traffic situation to answer short-range routing requests, mid- and long-range queries require taking both types of traffic into account. We therefore aim to provide routing algorithms which incorporate *combined* predicted and live traffic information.

A common approach for routing in road networks is to model the network as a directed graph where intersections are represented by vertices and road segments by edges. With edge weights representing travel times, routing requests can be answered by solving the classical shortest path problem. When considering predicted traffic, edge weights can be modeled as functions of the time of day, which is commonly referred to as *time-dependent routing*. Dijkstra’s algorithm can be used to solve these problems exactly and, at least from a theoretical perspective, efficiently [8]. However, on the continental-sized road networks used in modern routing applications, it may take seconds to answer mid- or long-range queries, which is too slow for most practical applications. We therefore study algorithms to compute shortest paths significantly faster than Dijkstra’s algorithm while retaining exactness.

One approach to accelerate Dijkstra’s algorithm is goal-directed search, i.e. the A* algorithm [13]. Dijkstra’s algorithm uses a priority queue to explore vertices by ascending distance from the source until it reaches the target. A* changes this slightly and employs a *potential* function which estimates the remaining distance from vertices to the target to change the queue order and explore vertices closer to the target earlier. The performance of A* crucially depends on the tightness of these estimates. The core algorithmic idea of this work is to use A* with time-dependent potential functions, i.e. we obtain tighter estimates and therefore faster queries by taking the time of day when a vertex is visited into account.

1.1 Related Work

Efficient and exact route planning in road networks has received a significant amount of research effort in the past decade. Since a comprehensive discussion is beyond the scope of this paper, we refer to [1] for an overview. An approach that has proven effective is to exploit the fact that usually many queries have to be answered on the same network, which rarely changes. Thus, these queries can be accelerated by computing auxiliary data in an off-line preprocessing phase.

A popular technique which follows this approach is *Contraction Hierarchies* (CH) [9]. During the preprocessing vertices are ranked heuristically by “importance” where more important vertices are part of more shortest paths. Shortcut edges are inserted to skip over unimportant vertices. This allows for a very fast query where only a few vertices are explored. On typical continental-sized networks, queries take well below a millisecond. *Multi-Level Dijkstra* (MLD) [17] is a similar approach that also utilizes shortcut edges but inserts them based on a multi-level partitioning. It achieves slightly slower query times of around a millisecond. MLD is the first algorithm to operate under the *Customizable Route Planning* (CRP) framework [5], i.e. it has a second, faster preprocessing phase called *customization* which allows integrating arbitrary weight functions (or live traffic updates for the current weights) into the auxiliary data without rerunning the entire first preprocessing phase, which is much slower. The MLD customization takes a few seconds, which allows for running it every minute. This three-phase setup has proven to be instrumental to support live traffic scenarios in practical applications [14]. Therefore, CH was generalized to Customizable Contraction Hierarchies (CCH) [7] to support customizability as well.

Both CH and MLD have been extended to time-dependent routing. However, dealing with weight functions instead of scalar weights makes the preprocessing much harder and leads to difficult trade-offs. TCH [2] has fast queries but a very expensive preprocessing phase (up to several hours) and may produce prohibitive amounts of auxiliary data (> 100 GB). TD-CRP [3], an extension of MLD, even follows a three-phase approach and has a relatively fast customization phase. However, this is only possible by giving up exactness. Also, TD-CRP does not support path unpacking. CATCHUp [19] adapts CCH to the time-dependent

setting and has fast and exact queries with significantly reduced memory consumption. While it has a customization phase, running it takes significantly longer than a traditional CCH or CRP customization. On the networks used in this paper, a CATCHUp customization may even take hours, which is too slow for a setting with live traffic updates. Time-dependent Sampling (TDS) [18] is another CH-based approach. While TDS does support both predicted and dynamic traffic information, it cannot guarantee exactness.

ALT [10, 11] is an early A*-based speedup technique for routing in road networks. It combines precomputed distances to a few *landmark* vertices with the triangle inequality to obtain distance estimates to the target vertex. However, query times are significantly slower than with shortcut-based approaches such as CH or MLD. ALT also has been extended to dynamic and time-dependent settings [6]. While this approach allows incremental modifications of the input travel times, it is not as flexible as customization based approaches allowing arbitrary updates.

CH-Potentials [20] is another more recent A*-based approach. CH-Potentials use Lazy RPHAST [20], an incremental many-to-one CH query variant, to compute exact distances toward the target. This allows for tighter estimates and faster queries than what is possible with ALT. CH-Potentials can be applied to a variety of routing problem variants. The original publication even mentions a combination of live and predicted traffic. However, the reported query times are above 100 ms. We consider this too slow for practical applications.

1.2 Contribution

In this work, we introduce a time-dependent generalization of A* potentials. We present two Lazy RPHAST extensions that realize a time-dependent potential function and discuss how to apply them to queries in a setting that combines live and predicted traffic. An extensive evaluation confirms the effectiveness of our potentials. Queries incorporating both predicted and current traffic can be answered within few tens of milliseconds. Live traffic updates can be integrated within a fraction of a minute. Our time-dependent potentials are up to an order of magnitude faster than CH-Potentials and about two orders of magnitude faster than Dijkstra's algorithm. To the best of our knowledge, this makes our approach the first to achieve interactive query performance while allowing fast updates in this setting.

2 Preliminaries

We consider simple directed graphs $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges. We use uv as a short notation for an edge from a *tail* vertex u to a *head* vertex v . Weight functions $w : E \rightarrow (\mathbb{Z} \rightarrow \mathbb{N}^0)$ map edges to time-dependent functions, which in turn map a departure time τ at the tail u to a travel time $w(uv)(\tau)$. To simplify notation, we will often write $w(uv, \tau)$. When it is clear from the context that we are writing about constant functions, we omit the time argument and write $w(uv)$. The reversed graph $\overleftarrow{G} = (V, \overleftarrow{E})$ contains a reversed edge vu for every edge $uv \in E$. In this paper, we only need time-independent corresponding reversed weight functions. Therefore, we define $\overleftarrow{w}(vu) = w(uv)$. The travel time of a path $P = (v_1, \dots, v_k)$ is defined recursively $w(P, \tau) = w(v_1v_2, \tau) + w((v_2, \dots, v_k), \tau + w(v_1v_2, \tau))$ with the base case of an empty path having a travel time of zero. A path's travel time can be obtained by successively evaluating travel times of the edges of the path. We denote the travel time of a *shortest* path between vertices s and t for the departure time τ^{dep} as $\mathcal{D}_w(s, t, \tau^{\text{dep}})$. We assume that all travel time functions adhere to the *First-In First-Out* (FIFO) property, i.e. departing later may never lead to an earlier arrival. Formally stated, this means $\tau + w(\tau) \leq \tau + \epsilon + w(\tau + \epsilon)$ for any $\epsilon \geq 0$. With non-FIFO travel time functions, the shortest path problem becomes NP-hard [15, 22].

■ **Figure 1** Combined travel time function $c(e, \tau) = \max(p(e, \tau), \min(\ell(e), p(e, \tau^{\text{end}}(e)) + \tau^{\text{end}}(e) - \tau))$ with both predicted and live traffic information. The predicted traffic $p(e)$ is indicated in black. The live travel time $\ell(e)$ with expected end $\tau^{\text{end}}(e)$ is depicted in red. The switch back to the predicted function is colored in blue. The solid line indicates the combined function $c(e)$ for the current day. For later days, only p will be used. Dotted lines only serve the purpose of visualization.

2.1 Problem Model

We consider an application model with three phases. During the *preprocessing* phase, the graph $G = (V, E)$ and a weight function p of time-dependent traffic predictions are given. Predicted travel time functions are periodic piecewise linear functions represented by a sequence of breakpoints covering one day. A preprocessing algorithm may now precompute auxiliary data, which may take several hours. In the *update* phase, a weight function ℓ of currently observed live travel times are given for the current moment τ^{now} . These live travel times are time-independent and can be represented by a single scalar value. Further, each edge e has a point in time $\tau^{\text{end}}(e)$ when we switch back to the predicted travel time. For edges without live traffic data, we set $\tau^{\text{end}}(e) = \tau^{\text{now}}$. We assume that traffic predictions are conservative estimates and that live traffic will only be slower than the predicted traffic due to accidents and other traffic incidents, i.e. $p(e, \tau^{\text{now}}) < \ell(e)$. Therefore, we define the combined travel time function $c(e, \tau) = \max(p(e, \tau), \min(\ell(e), p(e, \tau^{\text{end}}(e)) + \tau^{\text{end}}(e) - \tau))$. It follows that $p(e, \tau) \leq c(e, \tau)$. The update phase will be repeated frequently and should therefore be as fast as possible. During the final *query* phase, many shortest path queries $(s, t, \tau^{\text{dep}})$ where $\tau^{\text{dep}} \geq \tau^{\text{now}}$ should be answered as quickly as possible by obtaining a path $P = (s, \dots, t)$ that minimizes $c(P, \tau^{\text{dep}})$. Figure 1 depicts an example of such a combined travel time function.

Our model has two important restrictions. First, the dynamic real-time traffic information ℓ is handled separately from the traffic predictions p . Fast updates to the predicted traffic functions p are not the goal of our work. While this might seem less flexible than dynamic traffic predictions p , we believe that our model is actually more practical. This is because the traffic predictions are *periodic* functions. But live traffic incidents are inherently tied to the current moment and are not expected to repeat in 24 hours. Second, our model assumes predicted traffic to be a lower bound of the real-time traffic. If the observed live travel time were faster than the predicted travel time, the live travel time would be ignored. While this a severe restriction from a theoretical perspective, it is only a minor limitation for our practical problem. Live traffic should account for unexpected traffic events which will almost always only make traffic worse. If the live traffic is frequently better than the predicted traffic, the predictions should be adjusted at some point. We discuss these restrictions further and compare our problem to similar models in related work in the full version of this paper [21].

2.2 Fundamental Algorithms

Dijkstra's algorithm [8] computes $\mathcal{D}_w(s, t, \tau^{\text{dep}})$ by exploring vertices in increasing order of distance from s until t is reached. The distances from s to each vertex u are tracked in an array $D[u]$, initially set to ∞ for all vertices. A priority queue of vertices ordered by their distance from s is maintained. The priority queue is initialized with s and $D[s]$ set to τ^{dep} . In each iteration, the next closest vertex u is extracted from the queue and *settled*. Outgoing edges uv are *relaxed*, i.e. the algorithm checks if $D[u] + w(uv, D[u])$ improves $D[v]$. If so, the queue position of v is adjusted accordingly. Once t has been settled, the final distance is known, and the search terminates. We denote visited vertices as the *search space* of a query.

A* [13] is a goal-directed extension of Dijkstra's algorithm. It applies a *potential* function π_t which maps vertices to an estimate of the remaining distance to t . This estimate is added to the queue key. Thus, vertices closer to the target are visited earlier, and the search space becomes smaller. It can be guaranteed that A* has computed the shortest distance once t is settled when the estimates of the potential function are lower bounds of the remaining distances. However, with only lower bound potentials, the theoretical worst case running time of A* is exponential. Therefore, a stronger correctness property is often used. A potential function is called *feasible* if $w(uv) - \pi_t(u) + \pi_t(v) \geq 0$ for any edge $uv \in E$. Feasibility guarantees correctness and polynomial running time. When the potential of the target is zero, i.e. $\pi_t(t) = 0$, it also implies the lower bound property.

Contraction Hierarchies (CH) [9] is a speedup technique to accelerate shortest path searches on time-independent road networks through precomputation. During the preprocessing, a total order $v_1 \prec \dots \prec v_n$ of all vertices $v_i \in V$ by "importance" is determined heuristically, where more important vertices should lie on more shortest paths. Then, an *augmented graph* $G^+ = (V, E^+)$ with additional *shortcut edges* and weights w^+ is constructed. Shortcut edges uv allow to "skip over" paths $(u, \dots, x_i, \dots, v)$ where $x_i \prec u$ and $x_i \prec v$. Therefore, $w^+(uv)$ is assigned the length of the shortest such path. We sometimes split G^+ into an upward graph $G^\uparrow = (V, E^\uparrow)$ which contains only edges uv where $v \succ u$ and a downward graph $G^\downarrow = (V, E^\downarrow)$ defined analogously. The augmented graph has the property that between any two vertices s and t , there exists an *up-down-path* P with $w^+(P) = \mathcal{D}_w(s, t)$ which uses first only edges from E^\uparrow and then only edges from E^\downarrow . Such a path can be found by running the bidirectional variant of Dijkstra's algorithm from s on G^\uparrow and from t on G^\downarrow . Because only a few vertices are reachable in this *CH search space*, queries are very fast, i.e. about a tenth of a millisecond on continental-sized networks.

In this work we build on *Customizable Contraction Hierarchies* (CCH) [7]. For CCH, the construction of the augmented graph is split into two phases. In the first phase, the topology of the augmented graph is constructed without considering any weight functions. It is therefore valid for *all* weight functions. In the second *customization* phase, the weights w^+ of the augmented graph are computed for a given weight function w . The customization can be parallelized efficiently [4] and takes a couple of seconds on typical networks.

Lazy RPHAST [20] is a CH query variant to incrementally compute distances from many sources toward a common target. The first step is to run Dijkstra's algorithm on G^\downarrow from t , similarly to a regular CH query. The second Dijkstra search is replaced with a recursive depth-first search (DFS) which memoizes distances. Algorithm 1 depicts this routine which will be called for all sources. If the distance of a vertex u was previously computed, the routine terminates immediately and returns the memoized value $D[u]$. Otherwise, the distance for all upward neighbors v is obtained recursively. The final distance is the minimum over the path distances $w^+(uv) + D[v]$ via the upward neighbors v and the distance possibly found

■ **Algorithm 1** Computing the distance from a single vertex u to t with Lazy RPHAST.

Data: $D^\downarrow[u]$: tentative distance from u to t computed by Dijkstra's algorithm on G^\leftarrow
Data: $D[u]$: memoized final distance from u to t , initially \perp
Function `ComputeAndMemoizeDist(u):`

```

  if  $D[u] = \perp$  then
     $D[u] \leftarrow D^\downarrow[u]$ ;
    for all edges  $uv \in E^\uparrow$  do
       $D[u] \leftarrow \min(D[u], \text{ComputeAndMemoizeDist}(v) + w^+(uv))$ ;
  return  $D[u]$ ;

```

in the backward search $D^\downarrow[u]$. Using a DFS to compute shortest distances works because G^\uparrow is a directed acyclic graph. Using the distance to t obtained by Lazy RPHAST as an A* potential is called *CH-Potentials*. Just like a regular CH query, Lazy RPHAST can be used on CCH without modifications. In [20] additional optimizations for A* are discussed which we also utilize. The goal is to reduce the impact of the potential evaluation overhead by avoiding unnecessary potential evaluations, for example for chains of degree-two vertices.

3 Time-Dependent A* Potentials

We now propose a time-dependent generalization $\pi_t : V \rightarrow (T \rightarrow \mathbb{Z}^{\geq 0})$ of A* potentials, i.e. estimates are a function of the time. This allows us to obtain tighter estimates and enables faster queries. Analogue to classical potentials, there are properties of time-dependent potentials to consider for the correctness of A*:

- Strong First-In First-Out (FIFO): $\pi_t(v, \tau) < \pi_t(v, \tau + \epsilon) + \epsilon$ for $v \in V$, $\tau > \mathcal{D}_w(s, u, \tau^{\text{dep}})$ and $\epsilon > 0$. This ensures that queue keys increase monotonically with the distance from s . This property has no time-independent equivalent because it holds trivially in this case.
- Feasibility: $w(uv, \tau) + \pi_t(v, \tau + w(uv, \tau)) - \pi_t(u, \tau) \geq 0$ for all edges $uv \in E$ and times $\tau > \mathcal{D}_w(s, u, \tau^{\text{dep}})$. A* can be analyzed as an equivalent run of Dijkstra's algorithm with a modified weight function derived from the input weights and the potentials. With feasibility, these modified weights are non-negative, which implies correctness and polynomial running time. When $\pi_t(t, \tau) = 0$, feasibility also implies the lower bound property. However, feasibility is not strictly necessary to guarantee correctness.
- Lower bound: $\pi_t(v, \tau) \leq \mathcal{D}_w(v, t, \tau)$ for every vertex $v \in V$ and time $\tau = \mathcal{D}_w(s, v, \tau^{\text{dep}})$. This ensures that the search has found the correct distance once the target vertex is settled. This is also sufficient for correctness. However, without feasibility, A* may settle vertices multiple times. In theory, this can lead to an exponential running time.

We discuss these properties in detail and prove the correctness in the full version of this paper [21]. Note that these properties only need to hold for specific times τ , not all possible times of the day. Our practical potentials heavily rely on this and only compute data for the specific times necessary to answer a query correctly.

In the following, we present two practical realizations of time-dependent A* potentials. Both are extensions of Lazy RPHAST. Lazy RPHAST/CH-Potentials is already a very efficient potential and obtains exact distances for scalar lower bound weights, i.e. the tightest possible estimates with a time-independent potential definition. To outperform CH-Potentials, on the one hand, we have to obtain significantly tighter estimates. On the other hand, we

also must avoid the potential evaluation becoming too expensive. Therefore, we avoid costly operations on functions and work with scalar values as much as possible. As a result, even though our potentials are time-dependent, computed estimates during a single query usually will *not* change depending on the visit time of a vertex.

3.1 Multi-Metric Potentials

Let $(s, t, \tau^{\text{dep}})$ be a query and τ^{max} an upper bound on the optimal arrival time at the target. Consider any $\tau' \leq \tau^{\text{dep}}$, $\tau^{\text{max}} \leq \tau''$ and the weight function $l[\tau', \tau''](e) := \min_{\tau' \leq \tau \leq \tau''} p(e, \tau)$. Clearly, $\mathcal{D}_{l[\tau', \tau'']}(v, t)$ provides lower bound estimates of distances to the target vertex during the time relevant for this query. If τ' and τ'' are close to τ^{dep} and τ^{max} and, if the difference between τ' and τ'' is not too big, the estimates will be significantly tighter than global lower bound distances. The *Multi-Metric Potentials* (MMP) approach is based on this observation. Instead of using a single potential based on a global lower bound valid for the entire time, we process multiple lower bound weight functions for different time intervals. At query time, we then select an appropriate weight function. The upper bound τ^{max} is computed with a time-independent CCH query on a scalar upper bound function c_{max}^+ computed during the update phase. Efficiently computing distances with respect to the selected weight function is done with Lazy RPHAST. Therefore, no time-dependent computations need to be performed to evaluate this potential function. MMP only depend on the departure time of the query but not of the potential evaluation time. Still, MMP will be significantly tighter than any time-independent potential can be.

Phase Details. The first step of the preprocessing for this potential is to perform the regular CCH preprocessing, i.e. compute an importance ordering and construct the unweighted augmented graph. Now let I be a set of time intervals. In our implementation, we cover the time between 6:00 and 22:00 with intervals of a length of one, two, four, and eight hours, starting every 30 minutes, and one interval covering the entire day. We do not maintain any additional intervals between 22:00 and 6:00 as most edge weights correspond to their respective free-flow travel time during this period. Thus, the lower bound weights would be equal to the full-day lower bounds. During preprocessing, for each interval $[\tau'_i, \tau''_i] \in I$, we extract lower bound functions $l[\tau'_i, \tau''_i]$ and run the CCH customization algorithm to obtain $l[\tau'_i, \tau''_i]^+$. This can be parallelized trivially. Also, the customization can be parallelized internally. For further engineering details, we refer to [7, 4, 12].

During the update phase, we compute an additional lower bound weight function starting at τ^{now} with duration δ derived from the combined weights c and run the basic customization for it. We use $\delta = 59$ minutes to reasonably cover the live traffic but keep the live interval shorter than any other interval. Further, we extract an upper bound weight function c_{max} which is valid for the entire day for both the predicted and the live traffic, and perform the CCH basic customization to obtain c_{max}^+ .

The query starts with a classical CCH query on the customized upper bound c_{max}^+ to obtain a pessimistic estimate of τ^{max} . We then select the smallest interval $[\tau'_i, \tau''_i]$ such that $[\tau^{\text{dep}}, \tau^{\text{max}}] \subseteq [\tau'_i, \tau''_i]$. Running Lazy RPHAST on G_l^+ with the customized weight function $l[\tau'_i, \tau''_i]^+$ yields the desired potential function. See the full version of this paper [21] for additional optimizations.

Correctness. For any given single query, the estimates obtained by MMP are actually time-independent. They return the exact shortest distances with respect to a lower bound weight function valid for the query. Constant potentials trivially adhere to the strong FIFO property. Also, shortest distances for a lower bound weight function are feasible potentials [20].

3.2 Interval-Minimum Potentials

Interval-Minimum Potentials (IMP) is a time-dependent adaptation of the Lazy RPHAST algorithm. While Lazy RPHAST has a single scalar weight for each edge, the Interval-Minimum Potential uses a time-dependent function. This allows for tighter estimates but introduces new challenges. First, we need an augmented graph with sufficiently accurate time-dependent lower bounds. We utilize the existing CATCHUp customization [19] because it is based on CCH. Second, storing the shortcut travel time functions w^+ may consume a lot of memory. Further, the representation as a list of breakpoints makes the evaluation more expensive than looking up a scalar weight. Therefore, we resort to a different representation and store functions as piecewise constant values in buckets of equal duration. Third, evaluating these functions requires a time argument. While $\pi_t(v, \tau)$ includes the time argument τ for the time at v , Lazy RPHAST also needs a time for every recursive invocation. Therefore, we apply Lazy RPHAST a second time on global upper and lower bound weight functions c_{\max}^+ and p_{\min}^+ to quickly obtain arrival intervals for arbitrary vertices. We then use these intervals to evaluate the edge weights and obtain tight time-dependent lower bounds.

Phase Details. The first preprocessing step is the CCH preprocessing. For the second step, we need to obtain time-dependent travel times for the augmented graph G^+ based on the predicted traffic weights p . For this, we utilize CATCHUp [19], a time-dependent adaptation of CCH. The CATCHUp customization yields for each edge in $uv \in E^+$ approximated *time-dependent* lower bound functions $b^+(uv)$. We transform the time-dependent piecewise linear lower bound functions b^+ into piecewise *constant* lower bound functions $b'^+(uv, \tau) := \min \left\{ b^+(uv, \tau') \mid \beta \lfloor \frac{\tau}{\beta} \rfloor \leq \tau' < \beta (\lfloor \frac{\tau}{\beta} \rfloor + 1) \right\}$ where β is the length of each constant segment. This enables a compact representation. Functions can be represented with a fixed number of values per edge. We use 96 buckets of length $\beta = 15$ minutes. Additionally, we derive a scalar lower bound b_{\min}^+ . Note that b_{\min}^+ is typically tighter than bounds obtained by a time-independent customization on lower bounds of the input functions, i.e. w_{\min}^+ .

In the update phase, we extract a combined traffic upper bound weight function c_{\max} for the entire day and run the CCH customization to obtain c_{\max}^+ .

The query consists of two instantiations of the Lazy RPHAST algorithm. The first one uses the scalar bounds b_{\min}^+ and c_{\max}^+ and computes an interval of possible arrival times at arbitrary vertices when departing from s at τ^{dep} . Since arrival intervals are distances from the source vertex, we have to apply Lazy RPHAST in reverse direction. This means we first run Dijkstra's algorithm from s on G^\uparrow , and then, we apply the recursive distance-memoizing DFS on G^\downarrow for any vertex for which we want to obtain an arrival interval. We denote this instance as AILR for *Arrival Interval Lazy RPHAST*. With these arrival intervals, we can now compute lower bounds to the target with the second Lazy RPHAST instantiation, which uses the time-dependent lower bounds b'^+ . The first step is to run Dijkstra's algorithm from t on G^\downarrow . To relax an edge $uv \in E^\downarrow$, we first need to obtain an arrival interval $[\tau_{\min}, \tau_{\max}]$ at v using AILR. This allows us to determine for vu at the relevant time a tight lower bound $d := \min_{\tau \in [\tau_{\min}, \tau_{\max}]} b'^+(vu, \tau)$. Then, we check if we can improve the lower bound from v to t , i.e. $D^\downarrow[v] \leftarrow \min(D^\downarrow[v], D^\downarrow[u] + d)$. Having established preliminary backward distances for all vertices in the CH search space of t , we can now compute estimates with the recursive distance-memoizing DFS. To obtain a distance estimate for vertex u , we first recursively compute distance estimates $D^\downarrow[v]$ for all upward neighbors v where $uv \in E^\uparrow$. Then, we use AILR to obtain an arrival interval $[\tau_{\min}, \tau_{\max}]$ at u . Finally, we relax the upward edges uv set $D^\downarrow[u] \leftarrow \min(D^\downarrow[u], D^\downarrow[v] + \min_{\tau \in [\tau_{\min}, \tau_{\max}]} b'^+(uv, \tau))$. This yields the final estimate for u .

Choosing a good memory layout for the bucket weights is crucial for the performance. We store all edge weights of each bucket consecutively. Typically, only a few buckets per edge are relevant because the arrival intervals are relatively small. Also, all outgoing edges of each vertex are evaluated consecutively. Thus, having their weights for the same bucket close to each other increases cache hits. See [21] for additional optimizations.

Correctness. Estimates obtained by IMP are lower bounds of the actual time-dependent shortest distances. This directly follows from the correctness of the CATCHUP preprocessing and the Lazy RPHAST algorithm. Also, they do satisfy the strong FIFO property because, for any given single query, the estimates are constant. However, they are not feasible due to the piecewise constant approximation schema. We could not observe any practical negative consequences of this, though.

3.3 Compression

Both of our time-dependent potentials use many weight functions. This can lead to problematic memory consumption. However, since we only need lower bounds, we can merge weight functions. Consider two MMP intervals with weight functions l_1 and l_2 . A combined function $l_{1 \cup 2}(uv) = \min(l_1(uv), l_2(uv))$ is valid for both intervals, albeit less tight. We can merge IMP buckets analogously. Thus, we can reduce memory consumption by trading tightness. Both potentials can handle merged lower bound functions with a layer of indirection: Buckets and intervals are mapped to a weight function ID. The weight of an edge in a merged weight function is the minimum weight of this edge in all included functions.

We now discuss an efficient and well-parallelizable algorithm to iteratively merge weight functions until only k functions remain. In each step, we merge the pair of weight functions with the minimal sum of squared differences of all edge weights. Since comparing all pairs of weight functions is expensive, we track the minimum difference sum Δ_{\min} we have found so far and stop any comparison where the sum exceeds Δ_{\min} . However, even when stopping a comparison, we store the preliminary sum and the edge ID up to which we have summed up the differences. Then, we do not need to start from scratch should we continue to compare this particular pair of weight functions. Finally, we maintain all pairs of weights along with the (possibly preliminary) difference sums in a priority queue ordered by the difference sums. When merging two weight functions, all other associated queue entries are removed from the queue and new entries for comparisons between the new weight function and all other functions are inserted. To determine the next weight function pair to merge, unfinished weight function pairs are popped from the queue and processed in parallel. The minimum difference is tracked in an atomic variable.

4 Evaluation

Environment. Our benchmark machine runs openSUSE Leap 15.3 (kernel 5.3.18), and has 192 GiB of DDR4-2666 RAM and two Intel Xeon Gold 6144 CPUs, each of which has 8 cores clocked at 3.5 GHz and 8×64 KiB of L1, 8×1 MiB of L2, and 24.75 MiB of shared L3 cache. Hyperthreading was disabled and parallel experiments use 16 threads. We implemented our algorithms in Rust¹ and compiled them with `rustc 1.61.0-nightly (c84f39e6c 2022-03-20)` in the release profile with the `target-cpu=native` option.

¹ Our code and experiment scripts are available at <https://github.com/kit-algo/tdpot>.

Datasets. We evaluate our algorithms on two networks for which we have proprietary traffic data available. Sadly, we cannot provide access to these datasets due to non-disclosure agreements. We are not aware of any publicly available real-world traffic feeds or predictions. However, as these datasets are the same ones used in [19, 20], at least some comparability is given. Our first network, PTV Europe, has been provided by PTV² in 2020 and is based on TomTom³ routing data covering Western Europe. It has 28.5M vertices and 61M edges. 76% of the edges have a non-constant travel time. The data includes a traffic incident snapshot from 2020/10/28 07:47 with live speeds and estimated incident durations for 215k vertex pairs. Our second network, OSM Germany, is derived from an early 2020 snapshot of OpenStreetMap and was converted into a routing graph using RoutingKit⁴. It has 16.2M vertices and 35.2M edges. For this instance, we have proprietary traffic data provided by Mapbox⁵. This includes traffic predictions for 38% of the edges in the form of predicted speeds for all five-minute periods over the course of a week. We only use the predictions for one day. Also, we exclude speed values which are faster than the free-flow speed computed by RoutingKit. The data also includes two live traffic snapshots in the form of OSM node ID pairs and live speeds for the edge between the vertices. One is from Friday 2019/08/02 15:41 and contains 320k vertex pairs and the other from Tuesday 2019/07/16 10:21 and contains 185k vertex pairs. The datasets do not contain any estimate for how long the observed live speeds will be valid. We set τ^{end} to one hour after the snapshot time. Note that even though it is smaller and has fewer time-dependent edges, OSM Germany is actually the harder instance. This is because it has more breakpoints per time-dependent edge (124.8 compared to 22.5 on PTV Europe) and the predicted travel times fluctuate more strongly.

Methodology. We evaluate our algorithms by sequentially solving batches of 100k shortest path queries with three different query sets: First, there are *random* queries where source and target are drawn from all vertices uniformly at random. These are mostly long-range queries. Second are *1h* queries where we draw a source vertex uniformly at random, run Dijkstra’s algorithm from it and pick the first node with a distance greater than one hour as the target. Third, we generate queries following the Dijkstra rank methodology [16] to investigate the performance with respect to query distance. For these *rank* queries, we pick a source uniformly at random and run Dijkstra’s algorithm from it. We use every 2^i -th settled vertex as the target for a query of Dijkstra rank 2^i . For queries with only predicted traffic, we pick τ^{dep} uniformly at random. When using live traffic, we set $\tau^{\text{dep}} = \tau^{\text{now}}$. To evaluate the performance of the preprocessing and update phases, we run them 10 and 100 times, respectively. Preprocessing and update phases utilize all cores using 16 threads.

We compare our time-dependent potentials MMP and IMP against time-independent CH-Potentials algorithm realized on CCH. Therefore, we denote this approach as CCH-Potentials. All three potentials use the same CCH vertex order and augmented graph. CCH-Potentials provide heuristic estimates based on a lower bound without any real-time or predicted traffic. Thus, no update phase is necessary to integrate real-time traffic updates. It is the only other speedup technique we are aware of that supports exact queries for our problem model. Dijkstra’s algorithm without any acceleration is our baseline.

Experiments. In Table 1, we report key performance results for our time-dependent potentials on random queries. We observe that IMP is the fastest approach by a significant margin, up to an order of magnitude faster than time-independent CCH-Potentials and roughly two orders of magnitude faster than Dijkstra’s algorithm. The search space reduction is even greater, but this does not fully translate to running times due to the higher evaluation overhead of IMP. With only predicted traffic, IMP is only two to three times slower than CATCHUp [19]. This shows that using A* to gain algorithmic flexibility comes at a price, but the overhead compared to purely hierarchical techniques is manageable. In contrast, MMP is only slightly faster than CCH-Potentials. This is expected since random queries are mostly long-range for which MMP is not particularly well suited.

Preprocessing times are within a couple of minutes for CCH-Potentials and MMP. IMP preprocessing is significantly more expensive because of the time-dependent CATCHUp preprocessing. This is especially pronounced on OSM Germany where the time-dependent travel time functions fluctuate strongly. Still, running preprocessing algorithms on a daily basis is quite possible. This also underlines that frequently running a CATCHUp customization to include live traffic is not feasible. For both our approaches, real-time traffic updates are possible within a fraction of a minute. MMP is slightly slower because it uses a few more weight functions. Both our approaches are quite expensive in terms of memory consumption, but this can be mitigated through the use of compression (see Figure 4).

Introducing live traffic decreases the quality of the estimates and thus increases search space sizes and running times. For IMP, this increases running times by roughly a factor of two. Even with heavy rush hour traffic, IMP is still more than 90 times faster than Dijkstra’s algorithm. Surprisingly, for CCH-Potentials and MMP, this scenario seems easier to handle than light midday traffic. This actually is an effect of the *predicted* traffic. It also has a strong influence on the performance of CCH-Potentials and MMP depending on the departure time.

89:12 Combining Predicted and Live Traffic with Time-Dependent A* Potentials

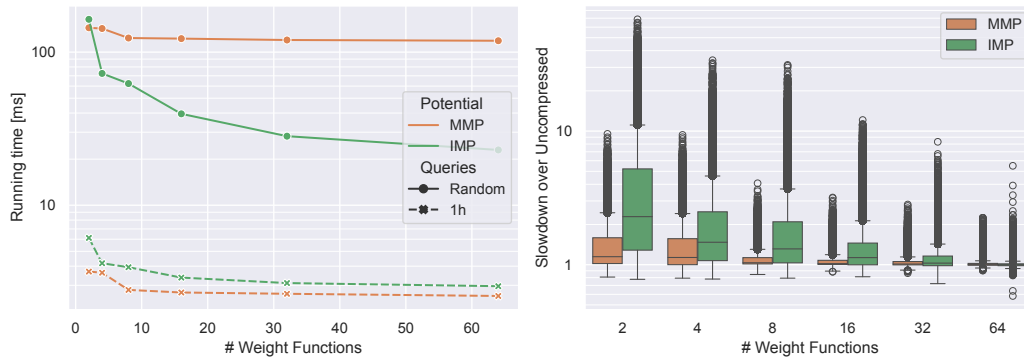

■ **Figure 2** Average running time of 100k uniform and 1h queries on OSM Germany with only predicted traffic. Each query has a departure time drawn uniformly at random. The resulting running times are grouped by the departure time hour.

We investigate this behavior with Figure 2 which depicts query performance by departure time over the course of the day. Clearly, the departure time has a significant influence both for short-range and long-range queries. For long-range queries, the peaks are shifted and smeared because of the travel time (4–5 hours on average on OSM Germany) covered by the query. This is the reason why the heavy afternoon traffic appears to be easier than the light midday traffic for MMP and CCH-Potentials. For IMP, the influence of the departure time is much smaller, which makes it consistently the fastest approach on long-range queries. For short-range queries, the overhead of IMP make it the slowest during the night. Moreover, MMP is roughly as fast as IMP for 1h queries during the daytime. Therefore, MMP may actually be a simple and effective approach for practical applications where short-range queries are more prominent.

■ **Figure 3** Box plot of running times for 1000 queries per Dijkstra-rank on PTV Europe with live traffic and fixed departure at 07:47. The boxes cover the range between the first and third quartile. The band in the box indicates the median; the whiskers cover 1.5 times the interquartile range. All other running times are indicated as outliers.

■ **Figure 4** Left: Mean running times of 100k queries on OSM Germany with only predicted traffic by number of remaining weight functions. Right: Boxplot of the per-query relative slowdown over the running time of the respective query with all weight functions.

Figure 3 depicts the performance by query distance. For short-range queries, IMP is slower than the other approaches because the potential is expensive to evaluate, but it scales much better to long-range queries because of its estimates are tighter. Also, the variance in running times is significantly smaller. Even for rank 2^{24} , most queries can be answered within a few tens of milliseconds. Nevertheless, MMP is actually faster on most ranks. Only at rank 2^{24} , MMP running times become as slow as the CCH-Potentials baseline. A jump in MMP running times can be observed from rank 2^{23} to 2^{24} . This is because the mean query distance jumps from five to six hours on rank 2^{23} to over eight hours on rank 2^{24} , which is longer than the longest covered interval. Thus, on rank 2^{24} , MMP fall back to classical CCH-Potentials on many queries. We also observe a few strong outliers. This happens because of blocked streets in the live traffic data. When the target vertex of a query is only reachable through a blocked road segment, A* will traverse large parts of the networks until the blocked road opens up. This affects all three potentials in the same way and demonstrates an inherent weakness of A*-based approaches: the performance always depends on the quality of the estimates. However, on realistic instances, the time-dependent preprocessing algorithms of purely hierarchical approaches are too expensive for frequent rerunning. This makes our approach the first to enable interactive query times across all distances in a setting with combined live and predicted traffic.

Finally, Figure 4 showcases the effects of reducing the number of weight functions. MMP appears to be very robust against compression. We can reduce the number of weight functions to 16 (a memory usage reduction of about a factor of 6) before the slowdowns become noticeable in the mean running time. However, MMP only achieves relatively small speedups compared to CCH-Potentials, i.e. rarely more than a factor of three. Therefore, its robustness is not particularly surprising. IMP, which achieves stronger speedups, is less robust against compression. Nevertheless, we can reduce the memory consumption by a factor of about three to 32 functions and still achieve very decent query times. With 32 functions, the absolute memory consumption decreases to less than 20 GB, which is at least manageable. Surprisingly, even with only four weight functions, IMP is still faster than MMP on long-range queries. This clearly shows the superiority of IMP for long-range queries. The compression algorithm itself takes less than a minute, depending on the final number of weight functions. Thus, its running time is dominated by the regular preprocessing. See the full paper version [21] for further details on the effectiveness of the parallelization.

5 Conclusion

In this paper, we proposed time-dependent A* potentials for efficient and exact routing in time-dependent road networks with both predicted and live traffic. We presented two realizations of time-dependent potentials with different trade-offs. Both allow fast live traffic updates within a fraction of a minute. IMP achieves query times two orders of magnitude faster than Dijkstra’s algorithm and up to an order of magnitude faster than state-of-the-art time-independent potentials. To the best of our knowledge, this makes our approach the first to achieve interactive query performance while allowing fast updates in this setting. For future work, we would like to apply our time-dependent potentials to other extended scenarios in time-dependent routing, for example to incorporate turn costs.

Approximating Dynamic Time Warping Distance Between Run-Length Encoded Strings

Zoe Xi

William Kuszmaul 

Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

Dynamic Time Warping (DTW) is a widely used similarity measure for comparing strings that encode time series data, with applications to areas including bioinformatics, signature verification, and speech recognition. The standard dynamic-programming algorithm for DTW takes $O(n^2)$ time, and there are conditional lower bounds showing that no algorithm can do substantially better.

In many applications, however, the strings x and y may contain long runs of repeated letters, meaning that they can be compressed using run-length encoding. A natural question is whether the DTW-distance between these compressed strings can be computed efficiently in terms of the lengths k and ℓ of the compressed strings. Recent work has shown how to achieve $O(k\ell^2 + \ell k^2)$ time, leaving open the question of whether a near-quadratic $\tilde{O}(k\ell)$ -time algorithm might exist.

We show that, if a small approximation loss is permitted, then a near-quadratic time algorithm is indeed possible: our algorithm computes a $(1 + \epsilon)$ -approximation for $DTW(x, y)$ in $\tilde{O}(k\ell/\epsilon^3)$ time, where k and ℓ are the number of runs in x and y . Our algorithm allows for DTW to be computed over any metric space (Σ, δ) in which distances are $O(\log n)$ -bit integers. Surprisingly, the algorithm also works even if δ does not induce a metric space on Σ (e.g., δ need not satisfy the triangle inequality).

1 Introduction

Dynamic Time Warping (DTW) distance is a well-known similarity measure for comparing strings that represent time-series data. DTW distance was first introduced by Vintsyuk in 1968 [40], who applied it to the problem of speech discrimination. In the decades since, DTW has become one of the most widely used similarity heuristics for comparing time series [28] in applications such as bioinformatics, signature verification, and speech recognition [20, 34, 33, 1, 14, 43].

Consider any two strings x and y , with characters taken from some metric space (Σ, δ) . For example, in many applications, we have that $\Sigma = \mathbb{R}^c$ for some parameter c and that $\delta(a, b) = \|a - b\|_2$ computes ℓ_2 distance. Define a *time warp* of x (and similarly of y) to be any string x' that can be obtained by *warping* the letters in x , where warping a letter means replacing it with ≥ 1 consecutive copies of itself. The DTW-distance $DTW(x, y)$ is defined to be

$$\min_{|x'|=|y'|} \sum_{i=1}^{|x'|} \delta(x'_i, y'_i),$$

where x' and y' range over all time warps of x and y .

The most fundamental question concerning DTW is how to compute it efficiently. Vintsyuk showed that, given strings x and y of length n , it is possible to compute $DTW(x, y)$ in $O(n^2)$ time [40]. His algorithm, which was one of the earliest uses of dynamic programming, continues to be taught in textbooks and algorithms courses today.

For many decades, it was an open question whether any algorithm could achieve a running time of $O(n^{2-\Omega(1)})$. (Interestingly, it is known that one *can* shave small sub-polynomial factors off of the running time [22].) A major breakthrough occurred in 2015, when Abboud, Backurs, and Williams [2] and Bringmann and Künnemann [12] established conditional lower bounds prohibiting any strongly subquadratic-time algorithm for DTW, unless the Strong Exponential Time Hypothesis (SETH) fails.

This lower bound puts us in an interesting situation. On one hand, the classic $O(n^2)$ -time algorithm is often too slow for practical applications. On the other hand, we have good reason to believe that it is nearly optimal. This has led researchers to focus on forms of beyond-worst-case analysis when studying the DTW problem.

An especially appealing question [39, 21] is what happens if x and y both contain long runs of repeated letters. In this case, the strings can be compressed using run-length encoding (RLE). For example, the string “aaaaabbc” has RLE encoding “(a, 5), (b, 2), (c, 1)”. If a string x has k runs, then it is said to have an RLE representation of length k .

It is known that, if x and y each contain k runs, then $DTW(x, y)$ can be computed in $O(k^3)$ time [21].¹ It is still an open question whether it is possible to significantly reduce this cubic running time, and in particular, whether a near-quadratic time algorithm might be possible.

This paper: A Near-Quadratic Approximation Algorithm

We show that, if a small approximation loss is permitted, then a near-quadratic time algorithm is indeed possible. Consider any two run-length encoded strings $x \in \Sigma^n$ and $y \in \Sigma^n$, where x has k runs and y has ℓ runs. Let δ be an arbitrary distance function $\delta : \Sigma \times \Sigma \rightarrow [\text{poly}(n)]$ mapping pairs of characters to $O(\log n)$ -bit nonnegative integers. (Perhaps surprisingly, our algorithms will not require δ to satisfy the triangle inequality, or even to be symmetric.)

Our main result is an algorithm that computes a $(1 + \epsilon)$ -approximation for $DTW(x, y)$ in $\tilde{O}(k\ell/\epsilon^3)$ time². In the special case where Σ is over Hamming space (i.e., $\delta(a, b)$ is either 0 or 1 for all $a, b \in \Sigma$), the running time of our algorithm further improves to $\tilde{O}(k\ell/\epsilon^2)$.

¹ More generally, if x contains k runs and y contains ℓ runs, then the time becomes $O(k\ell^2 + \ell k^2)$.

² Here we are using soft-O notation to mean that $\tilde{O}(k\ell/\epsilon^3)$ is equivalent to $O((k\ell/\epsilon^3) \text{polylog}(n))$.

Our algorithm takes a classical geometric interpretation of DTW in terms of paths through a grid, and shows how to decompose each path in such a way that its components can be efficiently approximated. This allows for us to reduce the problem of approximating DTW-distance between RLE strings to the problem of computing pairwise distance in a small directed acyclic graph.

Other related work

In addition to work on run-length-encoded strings [39, 21], there has been a recent push to study other theoretical facets of the DTW problem. This includes work on approximation algorithms [25, 3, 42], low-distance-regime algorithms [25], communication complexity [11], slightly-subquadratic algorithms [22], reductions to other similarity measures [25, 37, 36], binary DTW [26, 38], etc.

All of these results (along with the results in this paper) can be viewed as part of a larger effort to close the gap between what is known about DTW and what is known about its closely related cousin *edit distance*, which measures the number of insertions, deletions, and substitutions of characters needed to turn one string x into another string y . Like DTW, edit distance can be computed in $O(n^2)$ time using dynamic programming [40, 35] (and can be computed in *slightly* subquadratic time using lookup-table techniques [31]). Also like DTW, edit distance has conditional lower bounds [12, 2, 25] prohibiting strongly subquadratic time algorithms.

When it comes to beyond-worst-case analysis, however, edit distance has yielded much stronger results than DTW: it is known how to compute a constant-approximation for edit distance in strongly subquadratic time [5, 24, 10, 15, 4, 9, 6, 17]; it is known how to compute the edit distance between RLE strings in $\tilde{O}(k\ell)$ time [19, 8, 18, 29, 13, 7, 32, 23, 30]; and if two strings x and y have small edit distance k , it is known how to compute the edit distance in $O(|x| + |y| + k^2)$ time [16, 27].

Whether or not any of these results can be replicated for DTW remains the central open question in modern theoretical work on DTW. There are several reasons to believe that DTW computation should be more challenging than edit distance. Whereas edit distance satisfies the triangle inequality, DTW does not (for example, if we take $\Sigma = \{0, 1\}$, then $DTW(111110, 100000) = 0$, $DTW(100000, 000000) = 1$, and $DTW(111110, 000000) = 5$). This erratic behavior of DTW seems to make it especially difficult to approximate. Additionally, whereas almost all work on edit distance focuses on insertion/deletion/substitution costs of 1, work on DTW must consider arbitrary cost functions δ for comparing characters. Finally, it is known that the problem of computing edit distance actually *reduces* to that of computing DTW [25], indicating that the latter problem is at least as hard (although, interestingly, this reduction *does not* apply in the run-length encoded setting).

Our paper represents the first evidence that an $\tilde{O}(k\ell)$ -time algorithm for DTW may be within reach. Such an algorithm would finally unify edit distance and DTW in the run-length-encoded setting.

2 Technical Overview

This section gives a technical overview of how we approximate DTW -distance between run-length encoded strings. To simplify exposition, we focus here only on the big ideas in the algorithm design and we defer the detailed analysis to later sections.

Throughout the section, we consider two strings x and y of length n whose characters are taken from a set Σ with a symmetric distance function $\delta : \Sigma \times \Sigma \rightarrow \mathbb{N} \cup \{0\}$. Our only assumption on δ is that $\delta(a, b) \in \{0, 1, 2, \dots, \text{poly}(n)\}$ for all $a, b \in \Sigma$. (We do not need the triangle inequality on δ .) Let k and ℓ be the number of runs in x and y , respectively. We will describe a $(1 + O(\epsilon))$ -approximate algorithm that takes $\tilde{O}(k\ell / \text{poly}(\epsilon))$ time.

How to think about DTW

There are several mathematically equivalent ways (see, e.g., [25, 22, 21]) to define the dynamic time warping distance between x and y . In this paper, we work with the geometric interpretation: consider an $n \times n$ grid where cell (i, j) has *cost* $\delta(x_i, y_j)$; consider the *paths* through the grid that travel from $(1, 1)$ to (n, n) via steps of the form $\langle 1, 0 \rangle$ (a horizontal step (h-step) to the right), $\langle 0, 1 \rangle$ (a vertical step (v-step) up), and $\langle 1, 1 \rangle$ (a diagonal step (d-step) to the upper right); the *cost* of such a path is the sum of the costs of the cells that it encounters, and $DTW(x, y)$ is defined to be the smallest cost of any such path. For an example, see Figure 1, which shows an optimal full path for computing $DTW(\text{aaabbbbddd}, \text{aabcbdd}) = 1$, where the δ -function measures the distance between characters in the alphabet.

Note that the i -th column of the grid corresponds to x_i and the j -th row of the grid corresponds to y_j . Thus, each run x_{i_0}, \dots, x_{i_1} in x corresponds to a sequence of adjacent columns i_0, \dots, i_1 in the grid, and each run y_{j_0}, \dots, y_{j_1} in y corresponds to a sequence of adjacent rows j_0, \dots, j_1 in the grid.

If we want to design an algorithm that approximates $DTW(x, y)$ in $\tilde{O}(k\ell / \text{poly}(\epsilon))$ time, then it is natural to think about the grid as follows. We break the grid into *blocks* by drawing a vertical line between every pair of runs in x and a horizontal line between every pair of runs in y ; and label the blocks $\{\mathbf{B}_{i,j}\}_{i \in [k], j \in [\ell]}$, where block $\mathbf{B}_{i,j}$ corresponds horizontally to the i -th run in x and vertically to the j -th run in y . All of the cells within a given block B have the same cost, which we refer to as $\delta(B)$. We may also use $\delta_{i,j}$ for $\delta(\mathbf{B}_{i,j})$. We refer to the first/last row of each block as a lower/upper *horizontal boundary* and to the first/last column of each block as a left/right *vertical boundary*.

Finally, it will be helpful to talk about sequences of blocks that are adjacent horizontally or vertically. An *h-block segment* consists of a sequence of consecutive blocks lined up horizontally. Formally, given $i_1 \leq i_2$ in $[k]$ and j in $[\ell]$, we use $\mathbf{B}_{[i_1, i_2], j}$ for the h-block segment $\mathbf{B}_{i_1, j}, \mathbf{B}_{i_1+1, j}, \dots, \mathbf{B}_{i_2, j}$. Similarly, a *v-block segment* consists of a sequence of consecutive blocks lined up vertically – we use $\mathbf{B}_{i, [j_1, j_2]}$ for the v-block segment $\mathbf{B}_{i, j_1}, \mathbf{B}_{i, j_1+1}, \dots, \mathbf{B}_{i, j_2}$. In the same way that we can talk about the four boundaries of a block, we can talk about the four boundaries of a given h-block or v-block segment.

Intuitively, since there are $O(k\ell)$ blocks, our goal is to design an algorithm that runs in time roughly proportional to the number of blocks.

How to think about the optimal path

Let P be a minimum-cost path through the grid. We can decompose the path into a sequence of disjoint *components* P_1, P_2, P_3, \dots , where each component takes one of two forms:

1. A **horizontal-to-vertical** (h-to-v) component connects a cell on the lower boundary of some v-block segment to another cell on the right boundary of the same v-block segment.
 2. A **vertical-to-horizontal** (v-to-h) component connects a cell on the left boundary of some h-block segment to another cell on the upper boundary of the same h-block segment.
- The components P_1, P_2, P_3, \dots are defined such that the end cell of each P_r connects to the the start cell of each P_{r+1} via a single step (either horizontal, vertical, or diagonal).

We will now describe a series of simplifications that we can make to P while increasing its total cost by at most a $(1 + O(\epsilon))$ -factor. The simplifications are central to the design of our algorithm.

Simplification 1: Rounding each component to start and end on “snap points”

Let us call a grid cell (i, j) an *intersection point* if it lies in the intersection of a horizontal boundary and a vertical boundary. (Each block contains at most four intersection points.) We call a grid cell a *snap point* if either it is an intersection point, or it is of the form $(i + (1 + \epsilon)^t, j)$ on the upper boundary of a block B , or it is of the form $(i + 1 + (1 + \epsilon)^t, j)$ on the lower boundary of a block B , or it is of the form $(i, j + (1 + \epsilon)^t)$ on the right boundary of a block B , or it is of the form $(i, j + 1 + (1 + \epsilon)^t)$ on the left boundary of a block B , where (i, j) is an intersection point of the block B and t is nonnegative integer (since this is a technical overview, we ignore floor and ceiling issues). For each boundary cell p in the grid, define $\text{snap}(p)$ to be the nearest snap point to the right of p , if p is on a horizontal boundary, and to be the nearest snap point above p , if p is on a vertical boundary. If p is on both a horizontal boundary and a vertical boundary, then p is an intersection point, so $\text{snap}(p) = p$.

How much would the cost of P increase if we required each of its components to start and end on snap points? Suppose, in particular, that we replace each component P_r with a component P'_r whose start point p_r has been replaced with $\text{snap}(p_r)$ and whose end point q_r has been replaced with $\text{snap}(q_r)$. It may be that $\text{snap}(q_r)$ does not connect to $\text{snap}(p_{r+1})$, meaning that P'_r and P'_{r+1} do not connect properly. If this happens, however, then one can simply modify the starting-point of P'_{r+1} in order to connect it to P'_r (and it turns out this only makes P'_{r+1} cheaper).

Let P' be the concatenation of P'_1, P'_2, P'_3, \dots . To bound the cost of P' , we can argue that the cost of each P'_r is at most $(1 + \epsilon)$ times that of P_r . To transform P_r into P'_r , the first step is to round the start point p_r of P_r to $\text{snap}(p_r)$ – one can readily see that this only decreases (or leaves unchanged) the cost of P_r . The second step is to round the end point q_r of P_r to $\text{snap}(q_r)$. For simplicity, assume that P_r is an h-to-v component that starts on the lower boundary of some block \mathbf{B}_{i,j_1} and finishes on the right boundary of some block \mathbf{B}_{i,j_2} . Let (u, v) be the lower-right intersection point of \mathbf{B}_{i,j_2} and suppose that P_r finishes in cell $(u, v + s)$. Then P_r incurs cost at least $(s + 1) \cdot \delta_{i,j_2}$ in block \mathbf{B}_{i,j_2} . Moreover, the snap point $\text{snap}(q_r) = \text{snap}(u, v + s)$ is guaranteed to be in the set $\{(u, v + s + t)\}_{t \in \{0, 1, \dots, \epsilon \cdot s\}}$. Thus the cost of traveling from q_r to $\text{snap}(q_r)$ is at most $\epsilon \cdot s \cdot \delta_{i,j_2}$. So the cost of P'_r is at most $(1 + \epsilon)$ times that of P_r .

By analyzing each component in this way, we can argue that $\text{cost}(P') \leq (1 + \epsilon) \text{cost}(P)$. Throughout the rest of the section, we will assume that P has been replaced with P' , meaning that each component starts and ends with a snap point.

Simplification 2: Understanding the structure of each component

Next we observe that each individual component can be assumed to have a relatively simple structure. For simplicity, let us focus on an h-to-v component P_r in a v-block segment $\mathbf{B}_{i,[j_1,j_2]}$. We may assume without loss of generality that all of P_r 's h-steps occur together on the lower boundary of some block; and that all of P_r 's v-steps occur at the end of P_r . In other words, P_r is of the form $D_1 \oplus H \oplus D_2 \oplus U$ where \oplus is for path concatenation, D_1 consists of d-steps, H consists of h-steps (along a lower boundary), D_2 again consists of d-steps, and U consists of v-steps (along a right boundary).³ (See Figure 2 where the path $p_1q_1q_2p_2p_3$ in solid lines is such an example.)

³ Note that the components D_1, H, D_2 , and U are each individually allowed to be length 0.

Combined, these assumptions make it so that P_r is fully determined by four quantities: (1) P_r 's start point p_r , (2) the block $\mathbf{B}_{i,j}$ in which H occurs, (3) the length of H , and (4) the length of U .

Define \overline{P}_r to be the prefix of P_r that terminates as soon as U hits its first snap point. (See Figure 2 where the path $p_1q_1q_2p_2p'_2$ is such a prefix of the path $p_1q_1q_2p_2p_3$.) We will see later that \overline{P}_r is, in some sense, the ‘‘important’’ part of P_r to our algorithm. Observe that \overline{P}_r is fully determined by just three quantities: (1) P_r 's start point p_r , (2) the block $\mathbf{B}_{i,j}$ in which H occurs, and (3) the length of H .

Simplification 3: Reducing the number of options for each component

We will now argue that, if we fix the start point p_r , and we are willing to tolerate a $(1 + O(\epsilon))$ -factor approximation loss, then we only need to consider $\text{poly}(\epsilon^{-1} \log n)$ options for \overline{P}_r .

We begin by considering block $\mathbf{B}_{i,j}$ in which H occurs. Let us define the sequence of blocks B_0, B_1, B_2, \dots so that $B_s = \mathbf{B}_{i,j+s}$ and define the sequence of costs $\delta_0, \delta_1, \delta_2, \dots$ so that $\delta_s = \delta_{i,j+s}$. We say that a block B_s is *extremal* if $(1 + \epsilon)\delta_s \leq \delta_t$ for all $t < s$. If we are willing to tolerate a $(1 + O(\epsilon))$ -factor increase in \overline{P}_r 's cost, then we can assume without loss of generality that H occurs in an extremal block. On the other hand, there are only $O(\log_{1+\epsilon}(n))$ extremal blocks, so this means that we only need to consider $O(\log_{1+\epsilon}(n)) \leq \text{poly}(\epsilon^{-1} \log n)$ options for the starting point of H .

Next we consider the length of the horizontal sub-component H . If we are willing to tolerate a $(1 + O(\epsilon))$ -factor increase in \overline{P}_r 's cost, then we can round $|H|$, the length of H , up to be a power of $(1 + \epsilon)$ (or to be whatever length brings us to the next vertical boundary). Thus we only need to consider $O(\log_{1+\epsilon}(n)) \leq \text{poly}(\epsilon^{-1} \log n)$ options for $|H|$.

Together, the block $\mathbf{B}_{i,j}$ in which H occurs and the length of H fully determine \overline{P}_r . Thus, we have reached the following conclusion: if the start point p_r of the component \overline{P}_r is known, then there are only $\text{poly}(\epsilon^{-1} \log n)$ options that we must consider for what \overline{P}_r could look like. Moreover, although we have considered only h-to-v components here, one can make a similar argument for v-to-h components.

Approximating DTW in $\tilde{O}(kl/\text{poly}(\epsilon))$ time

We will now construct a weighted directed acyclic graph $G = \langle V, E \rangle$ that has two special vertices \mathbf{v}_0 and \mathbf{v}_* and that satisfies the following properties:

- G has a total of $\tilde{O}(kl/\text{poly}(\epsilon))$ vertices/edges, and
- the distance from \mathbf{v}_0 to \mathbf{v}_* in G is a $(1 + O(\epsilon))$ -approximation for $DTW(x, y)$.

This reduces the problem of approximating $DTW(x, y)$ to the problem of computing a distance in a weighted directed acyclic graph. The latter problem, of course, can be solved in linear time with dynamic programming; thus the graph G give us a $\tilde{O}(kl/\text{poly}(\epsilon))$ -time $(1 + O(\epsilon))$ -approximation algorithm for DTW .

We construct G to capture the different ways in which path components P_r can connect together (assuming that the path components take the simplified forms described above). As the vertices $v \in V$ correspond to the snap points p in the grid, we can use a vertex to refer to its corresponding snap point and vice versa. We define \mathbf{v}_0 to be the cell $(1, 1)$ in the grid and \mathbf{v}_* to be the cell (n, n) . We add edges E as follows:

- We connect each snap point p on a horizontal (resp. vertical) boundary to the next snap point q to its right (resp. above it).
- We connect each snap point p on a right (resp. upper) boundary to any snap points q on the adjacent left (resp. lower) boundary that can be reached from p in a single step.
- Each snap point $p \in V$ has $\text{poly}(\epsilon^{-1} \log n)$ out-edges corresponding to the $\text{poly}(\epsilon^{-1} \log n)$ options for what a (truncated) component \overline{P}_r starting at p could look like.⁴

Note that, although we only add edges for *truncated* path components \overline{P}_r (rather than full components P_r), these edges can be combined with edges of the first type in order to obtain the full component. This is why we said earlier that the truncated component is the “important” part of the component.

The paths from \mathbf{v}_0 to \mathbf{v}_* in G correspond to the ways in which we can concatenate path components together to get a full path through the grid; if we assign the appropriate weights to the edges, then the cost of a path through G corresponds to the cost of the same path through the grid. The distance from \mathbf{v}_0 to \mathbf{v}_* is therefore a $(1 + O(\epsilon))$ -approximation for $DTW(x, y)$.

Finally, we must bound the size of G . Each block contains at most four intersection points; so there are $O(k\ell)$ total intersection points. Each intersection point creates at most $O(\log_{1+\epsilon}(n))$ snap points; so there are $O(k\ell\epsilon^{-1} \log n)$ snap points (which are the vertices in V). Each snap point has an out-degree of at most $\text{poly}(\epsilon^{-1} \log n)$. Hence we have:

$$|E| \leq O(k\ell\epsilon^{-1} \log n) \text{poly}(\epsilon^{-1} \log n) = \tilde{O}(k\ell / \text{poly}(\epsilon)).$$

We can therefore compute the distance from \mathbf{v}_0 to \mathbf{v}_* in $\tilde{O}(k\ell / \text{poly}(\epsilon))$ time, as desired.

Paper outline

For the sake of simplicity, there are a number of details that we chose to ignore in this section (such as a time-efficient construction of G and a careful proof that the modifications to P incur only a $(1 + O(\epsilon))$ -factor change in its cost). In the remainder of the paper, we give a formal presentation and analysis of the algorithm outlined above.

3 Preliminaries

We use $[n_1, n_2]$ for the set $\{n_1, n_1 + 1, \dots, n_2\}$ consisting of all the integers between n_1 and n_2 , inclusive, and use $[n]$ as a shorthand for $[1, n]$. We use $T_{m,n}$ for a table consisting of m columns and n rows and $T_{m,n}[i, j]$ for the entry on the i -th column and j -th row, where $(i, j) \in [m] \times [n]$ is assumed. We may use T for $T_{m,n}$ if m and n can be readily inferred from the context. Please note that an entry $T_{m,n}[i, j]$ in a table should be distinguished from the value stored in the entry – when discussing the value, we shall refer to it as the content of the entry $T_{m,n}[i, j]$.

Letters

Let us assume an alphabet Σ , which is possibly infinite. We use δ for a distance function on letters such that $\delta(a, a) = 0$ for any $a \in \Sigma$. We do not require that δ be symmetric or the triangular inequality $\delta(a, c) \leq \delta(a, b) + \delta(b, c)$ hold for δ .

⁴ Note that G is not necessarily simple. If there are multiple ways that a component \overline{P}_r could connect two vertices p_1 and p_2 , then there will be multiple edges from p_1 to p_2 .

Strings

We use x and y for strings. We write $x = (a_1, \dots, a_m)$ for a string consisting of m letters such that $x[i]$ (often written as x_i), the i -th letter in x , is a_i for each $i \in [m]$. We use a^n for a string of n occurrences of a , which is also referred to as a *run* of a , and \hat{x} for a run-length encoded (RLE) string, which consists of a sequence of runs. We use $|\hat{x}|$ and $\|\hat{x}\|$ for the length and r-length of \hat{x} , which are $m_1 + \dots + m_k$ and k , respectively, in the case $\hat{x} = (a_1^{m_1}, \dots, a_k^{m_k})$.

A run in a string x is maximal if it is not contained in a longer run in x . There is a unique run-length encoding \hat{x} of x that consists of only maximal runs in x , and this encoding \hat{x} is referred to as the RLE representation of x . We also use $\|x\|$ for the number of maximal runs in x (and thus $\|x\| = \|\hat{x}\|$).

We use p for points, which are just integer pairs.

► **Definition 1.** Given a point $p_1 = (i_1, j_1)$, another point $p_2 = (i_2, j_2)$ is a successor of p_1 if (1) $i_2 = i_1 + 1$ and $j_2 = j_1$, or (2) $i_2 = i_1$ and $j_2 = j_1 + 1$, or (3) $i_2 = i_1 + 1$ and $j_2 = j_1 + 1$.

► **Definition 2.** Let $P = \langle p_1, \dots, p_R \rangle$ be a sequence of points such that $p_r \in [m] \times [n]$ holds for each $1 \leq r \leq R$. We call P a path of order (m, n) if p_{r+1} is a successor of p_r for each $1 \leq r < R$ (and this P is sometimes also called a “warping path” [21]). Also, we refer to a path of length 2 as a step that connects a point to one of its successors.

We use $\mathcal{P}(m, n)$ for the set of paths of order (m, n) . A path $P_1 \in \mathcal{P}(m, n)$ is a subpath of another path $P_2 \in \mathcal{P}(m, n)$ if P_1 is contained in P_2 (as a consecutive segment).

► **Definition 3.** Let P_1 and P_2 be two non-empty paths. We use $P_1 \simeq P_2$ to mean that P_1 and P_2 begin at the same point and end at the same point.

► **Definition 4.** Let P_1 and P_2 be two paths such that the first point of P_2 , if it exists, is the successor of the last point of P_1 , if it exists. We write $P_1 + P_2$ to mean the concatenation of P_1 and P_2 (as sequences of points) that forms a path containing both P_1 and P_2 as its subpaths. In the case where both P_1 and P_2 are non-empty, there is a step in $P_1 + P_2$ connecting P_1 and P_2 that consists of the last point in P_1 and the first point in P_2 .

Also, we write $P_1 \oplus P_2$ to mean $P_1 + P'_2$ where the last point of P_1 is assumed to be the first point of P_2 and P'_2 is the tail of P_2 , that is, P'_2 is obtained from removing the first point in P_2 . In other words, $P_1 + P_2$ implies that P_1 and P_2 share no point while $P_1 \oplus P_2$ implies that P_1 and P_2 share one point, which is the last point of P_1 and the first point of P_2 .

► **Definition 5.** Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two strings. For each path $P \in \mathcal{P}(m, n)$, there is a value $\text{cost}_{x,y}(P) = \sum_{r=1}^R \delta(a_{i_r}, b_{j_r})$, where P equals $((i_1, j_1), \dots, (i_R, j_R))$. This value is often referred to as the cost of P . We may write $\text{cost}(P)$ for $\text{cost}_{x,y}(P)$ if it is clear from the context what x and y should be.

We call each $P \in \mathcal{P}(m, n)$ a full path if $(i_1, j_1) = (1, 1)$ and $(i_R, j_R) = (m, n)$. The DTW distance between x and y , denoted by $\text{DTW}(x, y)$, is formally defined as the minimum of $\text{cost}_{x,y}(P)$, where P ranges over the set of full paths of order (m, n) . Also, a full path P is referred to as an optimal full path if $\text{cost}_{x,y}(P) = \text{DTW}(x, y)$. Given there are only finitely many paths of order (m, n) , there must exist one full path that is optimal. As an example, the shaded squares in Figure 1 illustrate the following full path of the order $(10, 6)$:

$$\langle (1, 1), (2, 2), (3, 2), (4, 3), (5, 3), (6, 3), (7, 4), (8, 5), (9, 6), (10, 6) \rangle$$

where the number in each square is the assumed distance between the two corresponding letters (computed here as the difference between their positions in the alphabet).

► **Definition 6.** Let $P = \langle (i_1, j_1), \dots, (i_R, j_R) \rangle$.

1. P is a v -path if all the i_r are the same for $1 \leq r \leq R$.
2. P is a h -path if all the j_r are the same for $1 \leq r \leq R$.
3. P is a d -path if $i_{r+1} = i_r + 1$ and $j_{r+1} = j_r + 1$ for $1 \leq r < R$.

Please recall that a step is a path of length 2. If a step is a h -path/ v -path/ d -path, respectively, then it is a h -step/ v -step/ d -step, respectively.

► **Definition 7.** Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two strings. We use $T_{\text{DTW}}(x, y)$ for the table $T_{m,n}$ such that the content of $T_{m,n}[i, j]$ is $\delta(a_i, b_j)$ for each $i \in [m]$ and $j \in [n]$.

We may use T_{DTW} for $T_{\text{DTW}}(x, y)$ if x and y can be readily inferred from the context. If a table T_{DTW} can be readily inferred from the context, we often associate a point (i, j) with the entry $T_{\text{DTW}}[i, j]$ and think of a path $P = \langle (i_1, j_1), \dots, (i_R, j_R) \rangle$ as the sequence of entries $T_{\text{DTW}}[i_r, j_r]$ for $1 \leq r \leq R$. As an example, a full path of the order $(10, 6)$ is given in Figure 1, where the path is indicated with the 10 shaded entries.

Suppose that the i th run (j th) in x (y) consists of the letters in x (y) from position i_1 (j_1) to position i_2 (j_2), inclusive. Then there is a corresponding block $\mathbf{B}_{i,j}$ consisting of all the entries $T_{\text{DTW}}[u, v]$ for $i_1 \leq u \leq i_2$ and $j_1 \leq v \leq j_2$. Finally, we introduce notation for discussing specific blocks:

► **Definition 8.** If there exists a block B to the right of $\mathbf{B}_{i,j}$ such that $\delta(B) < \delta(\mathbf{B}_{i,j})$, we use $\beta_h(\mathbf{B}_{i,j})$ for such a B that is the closest to $\mathbf{B}_{i,j}$. In other words, $\beta_h(\mathbf{B}_{i,j})$ is $\mathbf{B}_{i',j}$ for the least i' satisfying $i < i'$ and $\delta(\mathbf{B}_{i',j}) < \delta(\mathbf{B}_{i,j})$. Similarly, if there exists a block B above $\mathbf{B}_{i,j}$ such that $\delta(B) < \delta(\mathbf{B}_{i,j})$, then $\beta_v(\mathbf{B}_{i,j})$ is $\mathbf{B}_{i,j'}$ for the least j' satisfying $j < j'$ and $\delta(\mathbf{B}_{i,j'}) < \delta(\mathbf{B}_{i,j})$.

3.1 Computing DTW Distance with Graphs

It is well known [40] that one can turn the problem of computing $\text{DTW}(x, y)$ for two given strings x and y into a problem of finding the shortest distance between two given vertices in some graph, as follows.

Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$. We can construct a directed graph $G_0 = \langle V_0, E_0 \rangle$ such that

1. there is a vertex $\mathbf{v}_{i,j} \in V_0$ for each pair $(i, j) \in [m] \times [n]$, and
2. there is a directed edge $\mathbf{e}(\mathbf{v}_{i_1, j_1}, \mathbf{v}_{i_2, j_2})$ of length $\delta(a_{i_1}, b_{j_1})$ connecting \mathbf{v}_{i_1, j_1} to \mathbf{v}_{i_2, j_2} whenever (i_2, j_2) is a successor of (i_1, j_1) .

90:10 Approximating DTW Distance Between RLE Strings

We use $G_{DTW}(x, y)$ for this graph G_0 and use v and e to range over V_0 and E_0 , respectively. We may also refer to each vertex $\mathbf{v}_{i,j} \in V_0$ simply as point (i, j) if there is no risk of confusion. Clearly, $|V_0|$, the size of V_0 , is mn , and $|E_0|$, the size of E_0 , is bounded by $3mn$ (since each point can have at most 3 successors).

As every warping path is naturally mapped to a path in the graph $G_{DTW}(x, y)$ and vice versa, we can use P to range over both warping paths in $T_{DTW}(x, y)$ and paths in $G_{DTW}(x, y)$ without risking confusion. Given a (non-empty) warping path P in $T_{DTW}(x, y)$, we use $len(P)$ for the length of the corresponding path of P in $G_{DTW}(x, y)$, which equals the cost of P minus the cost associated with the last point in P . Therefore, finding the value of $DTW(x, y)$ is equivalent to finding the shortest distance from $\mathbf{v}_{1,1}$ to $\mathbf{v}_{m,n}$, which can be done by running some version of Dijkstra's shortest distance algorithm. Alternatively, since $G_{DTW}(x, y)$ is acyclic, one can use dynamic programming to find the shortest distance, in which case the running time becomes $O(mn)$. This yields the classic dynamic-programming solution for computing $DTW(x, y)$ [40].

The basic strategy that we use in this paper to design a DTW approximation algorithm can be outlined as follows. Let $G_0 = \langle V_0, E_0 \rangle$ be the graph $G_{DTW}(x, y)$ given above. We try to construct a graph $G = \langle V, E \rangle$ such that $V \subseteq V_0$ holds and the length of each edge e in E that connects a vertex v_1 to another vertex v_2 equals the shortest distance from v_1 to v_2 as is defined in G_0 . Let $dist_0$ and $dist$ be the shortest distance functions on the graphs G_0 and G , respectively. We attempt to prove that

$$dist_0(\mathbf{v}_{1,1}, \mathbf{v}_{m,n}) \leq dist(\mathbf{v}_{1,1}, \mathbf{v}_{m,n}) \leq \alpha \cdot dist_0(\mathbf{v}_{1,1}, \mathbf{v}_{m,n})$$

for some approximation ratio $\alpha > 1$ (e.g., $\alpha = 1 + \epsilon$ for $\epsilon > 0$). By running a shortest-path algorithm on G , we are able to compute $dist(\mathbf{v}_{1,1}, \mathbf{v}_{m,n})$ and thus obtain an α -approximation algorithm for $DTW(x, y)$. As the time complexity of such an algorithm can be bounded by $O(|E|)$ plus the time needed for constructing G , the key to finding a fast algorithm is try to minimize $|E|$, the size of E (while ensuring that the construction of G can be done in $O(|E|)$ time).

4 A $(1+\epsilon)$ -Approximation Algorithm for DTW

In this section, we present and analyze a $(1 + \epsilon)$ -approximation algorithm for approximating the DTW distance between two run-length encoded strings in near-quadratic time.

Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two non-empty strings. Following Section 3.1, our approach will be to construct a graph $G = \langle V, E \rangle$ based on $G_{DTW}(x, y)$, reducing the problem of computing a $(1 + \epsilon)$ -approximation of $DTW(x, y)$ to finding the shortest distance between the vertex $\mathbf{v}_{1,1}$ and the vertex $\mathbf{v}_{m,n}$ in G .

We begin by describing the notions of h-to-v paths and v-to-h paths. The role that these will play in our algorithm is that we will show how to decompose any full path P into a concatenation $P_1 + P_2 + \dots$ of h-to-v and v-to-h paths.

► **Definition 9.** *Let x and y be two non-empty strings. A horizontal-to-vertical (h-to-v) path in $T_{DTW}(x, y)$ is a path that connects a point on the lower boundary of a block B_{i,j_1} to another point on the right boundary of B_{i,j_2} . An h-to-v component in a full path is a maximal h-to-v path that is not contained in any longer h-to-v path in the same full path. A vertical-to-horizontal (v-to-h) path can be defined similarly.*

■ **Figure 2** For illustrating h-to-v path approximation.

Note that an h-to-v path matches characters from a *single run* in x to characters from (possibly multiple) runs in y . We now make the (standard) observation that, when we are comparing a single run to characters to a multi-run string, DTW behaves in a very natural way:

► **Observation 10.** Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two non-empty strings. Assume that x is a run of some letter a_0 , that is, $a_0 = a_i$ for $1 \leq i \leq m$.

1. If $m \leq n$, then we have: $DTW(x, y) = \sum_{j=1}^n \delta(a_0, b_j)$. This case corresponds to a path of the form $D \oplus U$, where D consists of only d-steps and U only v-steps.
2. If $m \geq n$, then we have: $DTW(x, y) = \sum_{j=1}^n \delta(a_0, b_j) + (m - n) \cdot \delta(a_0, b_0)$, where b_0 is some b_j closest to a_0 , that is, $\delta(a_0, b_0)$ equals the minimum of $\delta(a_0, b_j)$ for $1 \leq j \leq n$. This case corresponds to a path of the form $D_1 \oplus H \oplus D_2$, where D_1 and D_2 consist of only d-steps and H only h-steps. It should be further noted that, in this case, H can be assumed to travel along the lower boundary of some block, without loss of generality.

We say that a path connecting p and q is optimal if its cost is the least among all the paths connecting p and q . By merging the two cases in Observation 10, we can assume that each optimal h-to-v path is of the form $D_1 \oplus H \oplus D_2 \oplus U$, where any of the four sub-components can vanish. From now on, we can use a 5-tuple $(p_1, q_1, q_2, p_2, p_3)$ (which may also be written as $p_1q_1q_2p_2p_3$) to refer to an h-to-v path, where p_1q_1 is D_1 , q_1q_2 is H , q_2p_2 is D_2 , and p_2p_3 is U . Similarly, each optimal v-to-h path is of the form $D_1 \oplus U \oplus D_2 \oplus H$, and we use a corresponding 5-tuple representation to refer to a v-to-h path as well.

Next we argue that any full path P_0 can be decomposed into h-to-v and v-to-h paths.

► **Lemma 11.** Let x and y be two non-empty strings. Given a full path P_0 in $T_{DTW}(x, y)$, we have $P_0 = P_1 + \dots + P_R$ where P_r is an h-to-v path for each odd $1 \leq r \leq R$ and P_r is a v-to-h path for each even $1 \leq r \leq R$.

Proof. The proof follows directly from the definitions of h-to-v paths and v-to-h paths. For brevity, we defer the full proof to the extended version of the paper [41]. ◀

Given two non-empty strings $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$, we outline as follows a strategy for approximating $DTW(x, y)$. Let P_0 be an optimal full path on $T_{DTW}(x, y)$ such that $cost(P_0) = DTW(x, y)$. By Lemma 11, we have $P_0 = P_1 + \dots + P_R$, where P_1 is an h-to-v path and P_1, \dots, P_R are a sequence of alternating h-to-v paths and v-to-h paths. Let us choose an h-to-v path P_r for some $1 \leq r \leq R$. By Observation 10, we can assume that P_r is of the form of solid lines depicted in Figure 2.⁵

⁵ The meaning of the dashed lines in the figure is to be explained later.

90:12 Approximating DTW Distance Between RLE Strings

In more detail, the path P_r moves diagonally from a point p_1 on the lower boundary of a block B_1 until it meets the lower boundary of another block; it moves horizontally along that lower boundary for some distance; it then moves diagonally to reach a point p_2 on the right boundary of another block B_2 (which is either B_1 or sits above B_1); and finally it moves vertically to reach a point p_3 on the right boundary of another block B_3 (which is either B_2 or sits above B_2). Note that the horizontal moves contained in P_r must be inside a block where those moves cost the least.⁶

Let $G_0 = \langle V_0, E_0 \rangle$ be the graph $G_{DTW}(x, y)$ described in Section 3.1 for computing $DTW(x, y)$. We may use a point (that is, an integer pair) to refer to the corresponding vertex in V_0 . We may also use a path P in $T_{DTW}(x, y)$ to denote its counterpart in G_0 .

Given $\epsilon > 0$, we will construct a graph $G = \langle V, E \rangle$ such that:

- The point $(1, 1)$ is in V and $V \subseteq V_0$ holds.
- Every point in V is on a boundary. Each point in V that is on either a right or upper boundary is connected by an edge to the next snap point on the same boundary (if there is one).
- If there is a step (either an h-step, v-step, or d-step) connecting two boundary points p_1 and p_2 in E_0 , then there is also a step connecting $\text{snap}(p_1)$ and $\text{snap}(p_2)$ in E , where $\text{snap}(p_1)$ (resp. $\text{snap}(p_2)$) is the nearest point in V above or to the right of p_1 (resp. p_2) on the same boundary as p_1 .
- For each h-to-v (resp. v-to-h) path P from p_1 to p_2 (depicted by some solid lines in Figure 2) in G_0 and any point p'_1 in G to the right of p_1 (resp. above p_1) such that p_1 and p'_1 are on the same block boundary, there exists a path P' (depicted by some dashed lines in Figure 2) in G connecting p'_1 and the point $p'_2 = \text{snap}(p_2)$ in G such that $\text{dist}(P') \leq (1 + \epsilon)\text{dist}_0(P)$, where dist and dist_0 are the shortest distance functions on the graphs G and G_0 , respectively.

We remark that our construction of G will repeatedly make use of the following basic fact.

► **Observation 12.** Let $\Delta(t) = \lfloor (1 + \epsilon)^t \rfloor$ for integers $t \geq 0$. For each integer $d \geq 1$, we have a $(1 + \epsilon)$ -approximation of d that is of the form $\Delta(t)$. In other words, $d \leq \Delta(t) \leq (1 + \epsilon) \cdot d$ holds for some t .

We now describe how to construct the graph G . We construct the set V of vertices as follows:

1. Each vertex in G_0 corresponding to a corner point in $T_{DTW}(x, y)$ should be added into V . There are at most $4k\ell$ such vertices, where $k = \|x\|$ and $\ell = \|y\|$.
2. Assume (i, j) is the lower-left corner of block B .
 - If a point $(i + 1 + \Delta(t), j)$ is on the lower boundary of B for some $t \geq 0$, then this point should be added into V . There are at most $\log_{1+\epsilon}(m)$ such points for the block B .
 - If a point $(i, j + 1 + \Delta(t))$ is on the left boundary of B for some $t \geq 0$, then this point should be added into V . There are at most $\log_{1+\epsilon}(n)$ such points for the block B .
3. Assume (i, j) is the upper-left corner of block B . If a point $(i + \Delta(t), j)$ is on the upper boundary of B for some $t \geq 0$, then this point should be added into V . There are at most $\log_{1+\epsilon}(m)$ such points for the block B .
4. Assume (i, j) is the lower-right corner of block B . If a point $(i, j + \Delta(t))$ is on the right boundary of B for some $t \geq 0$, then this point should be added into V . There are at most $\log_{1+\epsilon}(n)$ such points for the block B .

⁶ If there are several blocks in which such horizontal moves can take place, we simply assume that the moves are inside the lowest of these blocks.

The points in V are referred to as **snap points**. Given a snap point p' on the upper or right boundary of some block, if $p'q'$ is a d -step for some point q' , then q' is also a snap point. This can be readily verified by inspecting the construction of V . Also, for each block B , there are at most $O(\log(m+n)/\epsilon)$ points added to V . Therefore, $|V|$, the size of V , is $O(k\ell \cdot \log(m+n)/\epsilon)$ or simply $\tilde{O}(k\ell/\epsilon)$.

► **Definition 13.** *Given a point $p \in V_0$ on a horizontal boundary of a block B , we use $\text{snap}_h(p)$ for the point $p' \in V$ such that p' is p if $p \in V$ or p' is the closest point to the right of p that is on the same boundary of B . The existence of such a point is guaranteed as all of the corner points are included in V . Similarly, $\text{snap}_v(p)$ can be defined for each point p on a vertical boundary of a block.*

We can use $\text{snap}(p)$ for either $\text{snap}_h(p)$ or $\text{snap}_v(p)$ without confusion: If both $\text{snap}_h(p)$ and $\text{snap}_v(p)$ are defined for p , then p must be a corner of some block B , implying $p = \text{snap}_h(p) = \text{snap}_v(p)$ since $p \in V$ holds. We argue as follows that finding $\text{snap}(p)$ for each given p can be done in $\tilde{O}(1)$ time.⁷

► **Definition 14.** *Let $x = (a_1, \dots, a_m)$ be a string and $\hat{x} = (a'_1 \hat{m}_1, \dots, a'_k \hat{m}_k)$ be its RLE representation. Let M_r be $m_1 + \dots + m_r$ for each $0 \leq r < k$. For each $1 \leq i \leq m$, we use \hat{i}_x for the pair (i_0, i_1) such that $i = M_{i_0} + i_1$ for $1 \leq i_1 \leq m_{i_0+1}$.*

We may use \hat{i} for \hat{i}_x if x can be readily inferred from the context.

It is worth taking a moment to verify that we can compute \hat{i}_x efficiently. Assume that an array storing M_r for $0 \leq r < k$ is already built (in $O(k)$ time). Given $i \in [m]$, we can perform binary search on the array to find i_0 in $O(\log(k))$ time such that $M_{i_0} < i \leq M_{i_0+1}$; we can then compute \hat{i}_x as $(i_0, i - M_{i_0})$.

It is also worth verifying that we can compute $\text{snap}(p)$ in $\tilde{O}(1)$ time. Given a point $p = (i, j)$ on a boundary of some block B in $T_{DTW}(x, y)$, we can compute $\hat{i}_x = (i_0, i_1)$ in $O(\log(k))$ time. Similarly, we can compute $\hat{j}_y = (j_0, j_1)$ in $O(\log(\ell))$ time. We can locate the block B as $\mathbf{B}_{i_0+1, j_0+1}$, and then find $\text{snap}(p)$ in $O(1)$ time (assuming $\log_{1+\epsilon}(i_1)$ and $\log_{1+\epsilon}(j_1)$ can be computed in $O(1)$ time). Therefore, given p , we can compute $\text{snap}(p)$ in $\tilde{O}(1)$ time.

Having established that we can compute \hat{i} and $\text{snap}(p)$ efficiently, we are nearly ready to describe the construction of the edges E . Our final task before doing so is to establish a bit more notation for how to talk about blocks.

Please recall that $\beta_h(\mathbf{B}_{i,j})$ (resp. $\beta_v(\mathbf{B}_{i,j})$) refers to the closest block $\mathbf{B}_{i',j}$ (resp. $\mathbf{B}_{i,j'}$) such that $\delta(\mathbf{B}_{i',j}) < \delta(\mathbf{B}_{i,j})$ (resp. $\delta(\mathbf{B}_{i,j'}) < \delta(\mathbf{B}_{i,j})$) holds. If there is no such a block, $\beta_h(\mathbf{B}_{i,j})$ (resp. $\beta_v(\mathbf{B}_{i,j})$) is undefined.

► **Definition 15.** *We refer to $\mathbf{B}_{i_1,j}, \dots, \mathbf{B}_{i_s,j}$ as a β_h -sequence if $\mathbf{B}_{i_{s+1},j} = \beta_h(\mathbf{B}_{i_s,j})$ for $1 \leq s < S$. Let $\beta_h^*(x, y)$ be the length of a longest β_h -sequence. Clearly, we have $\beta_h^*(x, y) \leq \|x\|$. Similarly, we refer to $\mathbf{B}_{i,j_1}, \dots, \mathbf{B}_{i,j_s}$ as a β_v -sequence if $\mathbf{B}_{i,j_{s+1}} = \beta_v(\mathbf{B}_{i,j_s})$ for $1 \leq s < S$. Let $\beta_v^*(x, y)$ be the length of a longest β_v -sequence. Clearly, we have $\beta_v^*(x, y) \leq \|y\|$. Let $\beta^*(x, y) = \max(\beta_h^*(x, y), \beta_v^*(x, y))$.*

Observe that if the underlying distance function δ on letters is from Hamming space, then $\beta^*(x, y) \leq 2$ for any x and y . Slightly more generally, if δ is bounded by a constant, then $\beta^*(x, y)$ is bounded by the same constant plus one. Later in the section, in the proof of Theorem 21, we will also see an important (and much more general) case where $\beta^*(x, y)$ is guaranteed to be $\tilde{O}(1)$.

⁷ We slightly abuse the \tilde{O} notation here as the parameters m and n for the implicit log-terms are not explicitly mentioned.

We are now ready to explain the construction of the set E of edges for connecting vertices in V . The basic idea is to construct E in such a way that, for any constructed path $p'_1 q'_1 q'_2 q'_3 p'_2$ (as is depicted in Figure 2), there should be a path in G going from p'_1 to p'_2 whose cost is at most the cost of the path in G_0 – this allows for the graph G to capture all such paths, and ultimately allows for G to be used in our approximation algorithm. Formally, the construction of E can be performed with the following steps:

1. Note that the corner points in V_0 are all in V . The edges connecting these corner points in E_0 should be added into E .
2. Given a point $p'_1 \in V$ on the upper boundary of a block B , if there is a d-step from p'_1 to p'_2 (on the lower boundary of the block above B), then p'_2 is in V and an edge from p'_1 to p'_2 should be added into E whose length equals $\delta(B)$.
3. Given a point $p'_1 \in V$ on the right boundary of a block B , if there is a d-step from p'_1 to p'_2 (on the left boundary of the block to the right of B), then p'_2 is in V and an edge from p'_1 to p'_2 should be added into E whose length equals $\delta(B)$.
4. If two points $p'_1 = (i_1, j_1)$ and $p'_2 = (i_2, j_2)$ in V are on the same horizontal or vertical boundary of a block B such that p'_2 is the closest point above or to the right of p'_1 , then an edge from p'_1 to p'_2 should be added into E whose length equals $(i_2 - i_1) \cdot \delta(B)$ (horizontal) or $(j_2 - j_1) \cdot \delta(B)$ (vertical).
5. Let p'_1 be a point in V on the lower boundary of a block B_1 . This step adds into E edges between p'_1 and certain chosen snap points q'_4 such that there are h-to-v paths connecting p'_1 and q'_4 .

Let us use B_1^1, \dots, B_1^S for the sequence where $B_1 = B_1^1$ and $B_1^{s+1} = \beta_v(B_1^s)$ for $1 \leq s < S$ and $\beta_v(B_1^S)$ is undefined. Clearly, S is bounded by $\beta_v^*(x, y)$ (according to the definition of $\beta_v^*(x, y)$). Let B'_1 range over B_1^1, \dots, B_1^S .

Let $q'_1 = (i'_1, j'_1)$ be the point on the lower boundary of B'_1 such that the path connecting p'_1 and q'_1 consists of only d-steps. Let $\text{snaps}_h(q'_1)$ be the set consisting of the point q'_1 , the points on the lower boundary of B'_1 of the form $(i'_1 + \Delta(t), j'_1)$ for some $t \geq 0$, and the lower-right corner point of B'_1 . For each q'_2 ranging over the set $\text{snaps}_h(q'_1)$, there exists at most one point q'_3 on the right boundary of some B_2 (which is either B'_1 or sits above B'_1) such that the path connecting q'_2 and q'_3 consists of only d-steps. As this q'_3 may not be in V , we choose q'_4 to be $\text{snap}_v(q'_3)$, which is in V by definition. Note that the path $p'_1 q'_1 q'_2 q'_3 q'_4$ is an h-to-v path in $T_{DTW}(x, y)$. We add into E an edge between p'_1 and q'_4 for each q'_4 . The length of each added edge connecting p'_1 and q'_4 is the shortest distance between p'_1 and q'_4 , which, by Lemma 17, can be computed in $\tilde{O}(1)$ time.

There is one q'_1 for each B'_1 , and there are at most $\log_{1+\epsilon}(m)$ many of q'_2 for each q'_1 , and there is at most one q'_3 for each q'_2 and one q'_4 for each q'_3 . Therefore, for each p'_1 , there are at most $\beta_v^*(x, y) \cdot \log_{1+\epsilon}(m)$ edges added into E .

6. Let p'_1 be a point in V on the left boundary of a block B_1 . This step adds into E edges between p'_1 and certain chosen snap points q'_4 such that there are v-to-h paths connecting p'_1 and q'_4 . We omit the details that are parallel to those in the previous step. There are at most $\beta_h^*(x, y) \cdot \log_{1+\epsilon}(n)$ edges added into E for each p'_1 .

Let us take a moment to discuss how to efficiently compute the lengths of the edges added to E during the construction of $G = \langle V, E \rangle$. That is, how to construct and determine the cost of each dotted path $p'_1 q'_1 q'_2 q'_3 q'_4$ depicted in Figure 2. (Note that $q'_4 = \text{snap}_v(q'_3)$ is not shown in the figure.)

► **Lemma 16.** *Let x and y be two non-empty strings. For $k = \|x\|$ and $\ell = \|y\|$,*

1. *we can compute $\beta_h(B)$ for all the blocks B in $T_{DTW}(x, y)$ in $O(k\ell \cdot \log(k))$ time, and*
2. *we can compute $\beta_v(B)$ for all the blocks B in $T_{DTW}(x, y)$ in $O(k\ell \cdot \log(\ell))$ time.*

Proof. We defer the full proof to the extended version of the paper [41]. ◀

► **Lemma 17.** *For each h-to-v path $(p'_1, q'_1, q'_2, q'_3, q'_4)$, its length can be computed in $\tilde{O}(1)$ time if the five snap points $p'_1, q'_1, q'_2, q'_3,$ and q'_4 are given.*

Proof. We defer the full proof to the extended version of the paper [41]. ◀

For brevity, we omit the obvious lemma parallel to Lemma 17 that is instead on computing the lengths of v-to-h paths in $\tilde{O}(1)$ time.

We are now in a position to state and prove the main theorems of the paper. As noted earlier, the basic idea behind our $(1 + \epsilon)$ -approximation algorithms is to compute a path-distance through the graph $G = (V, E)$, and show that this distance closely approximates $DTW(x, y)$.

We begin by stating a theorem that parameterizes its running time by $\beta^*(x, y)$ – we will then apply this result to obtain fast running times in the cases where the distance function δ outputs either $O(\log n)$ -bit integer values (Theorem 21) or $\{0, 1\}$ -values (Theorem 22).

► **Theorem 18.** *Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two non-empty strings, and let \hat{x} and \hat{y} denote the run-length encoded versions of the two strings. There exists a $(1 + \epsilon)$ -approximation algorithm (ApproxDTW) for each $\epsilon > 0$ that takes \hat{x} and \hat{y} as its input and returns a value $\tilde{DTW}(x, y)$ satisfying $DTW(x, y) \leq \tilde{DTW}(x, y) \leq (1 + \epsilon) \cdot DTW(x, y)$. Moreover, the worst-case time complexity of this algorithm is $\tilde{O}(k\ell \cdot \beta^*(x, y)/\epsilon^2)$ for $k = \|x\|$ and $\ell = \|y\|$, where $\beta^*(x, y)$ is defined in Definition 15.*

Proof. The analysis of the approximation ratio follows as in Section 2. ◀

4.1 Time-Bound for Polynomially-Bounded Letter Distances

In this section, we present a variant of the algorithm ApproxDTW for approximating $DTW(x, y)$ under the general condition that the distances between letters are integer values bounded by some polynomial of the lengths of x and y . The time complexity of this variant, which takes \hat{x} and \hat{y} as its input to compute $DTW(x, y)$, is $\tilde{O}(k\ell/\epsilon^3)$ for $k = \|x\|$ and $\ell = \|y\|$.

► **Definition 19.** *Let δ be a distance function on letters such that $\delta(a, b) \geq 1$ if $\delta(a, b) \neq 0$. Given $\epsilon_1 > 0$, we use δ_{ϵ_1} for the distance function such that $\delta_{\epsilon_1}(a, b) = 0$ if $\delta(a, b) = 0$, or $\delta_{\epsilon_1}(a, b) = \text{cpow}(1 + \epsilon_1, \delta(a, b))$ if $\delta(a, b) \geq 1$, where $\text{cpow}(1 + \epsilon_1, \alpha)$ equals $(1 + \epsilon_1)^t$ for the least integer t such that $\alpha \leq (1 + \epsilon_1)^t$ holds.*

Please note that $\delta(a, b) \leq \delta_{\epsilon_1}(a, b) \leq (1 + \epsilon_1) \cdot \delta(a, b)$ holds for any letters a and b .

► **Lemma 20.** *Let $DTW(\delta)$ be the DTW distance function where the underlying distance function for letters is δ . Given $\epsilon_1 > 0$, we have the following inequality for each pair of strings x and y :*

$$DTW(\delta_{\epsilon_1})(x, y) \leq (1 + \epsilon_1) \cdot DTW(\delta)(x, y)$$

Proof. Let P be an optimal full path such that its length based on δ equals $DTW(\delta)(x, y)$. We know that the length of P based on δ_{ϵ_1} is bounded by $(1 + \epsilon_1) \cdot DTW(\delta)(x, y)$ since $\delta_{\epsilon_1}(a, b) \leq (1 + \epsilon_1) \cdot \delta(a, b)$ holds for any letters a and b . As $DTW(\delta_{\epsilon_1})(x, y)$ is bounded by the length of P based on δ_{ϵ_1} , we have the claimed inequality. ◀

90:16 Approximating DTW Distance Between RLE Strings

Let $\epsilon_1 > 0$ and $\epsilon_2 > 0$. By Lemma 20, every $(1 + \epsilon_2)$ -approximation algorithm for DTW based on δ_{ϵ_1} is a $(1 + \epsilon_1) \cdot (1 + \epsilon_2)$ -approximation algorithm for DTW based on δ . For each $\epsilon > 0$, if we choose, for example, $\epsilon_1 = \epsilon/2 - \epsilon^2/2$ and $\epsilon_2 = \epsilon/2$, then we have $(1 + \epsilon_1) \cdot (1 + \epsilon_2) < 1 + \epsilon$, implying that every $(1 + \epsilon_2)$ -approximation algorithm for DTW based on δ_{ϵ_1} is a $(1 + \epsilon)$ -approximation algorithm for DTW based on δ .

► **Theorem 21.** *Let $x = (a_1, \dots, a_m)$ and $y = (b_1, \dots, b_n)$ be two non-empty strings.*

Assume that the underlying distance function δ satisfies (1) $\delta(a, b) \geq 1$ if $\delta(a, b) \neq 0$ and (2) $\delta(a, b)$ is $\text{poly}(m+n)$ for any letters a in x and b in y . There exists a $(1 + \epsilon)$ -approximation algorithm for each $\epsilon > 0$ that takes \hat{x} and \hat{y} as its input and returns a value w satisfying $DTW(x, y) \leq w \leq (1 + \epsilon) \cdot DTW(x, y)$. And the worst-case time complexity of this algorithm is $\tilde{O}(k\ell/\epsilon^3)$ for $k = \|x\|$ and $\ell = \|y\|$.

Proof. Let $\epsilon_1 = \epsilon/2 - \epsilon^2/2$ and $\epsilon_2 = \epsilon/2$. By Theorem 18, ApproxDTW (as is presented in the proof of Theorem 18) takes \hat{x} and \hat{y} as input and returns a $(1 + \epsilon_2)$ -approximation of $DTW(\delta_{\epsilon_1})(x, y)$. And the time complexity of the algorithm is $\tilde{O}(k\ell \cdot \beta^*(x, y)/\epsilon_2^2)$.

Note that there are only $O(\log_{1+\epsilon_1}(m+n))$ -many distinct values of $\delta_{\epsilon_1}(a, b)$ for a and b ranging over letters in x and y , respectively. Hence, for the underlying distance function δ_{ϵ_1} on letters, $\beta_h^*(x, y)$ is $O(\log_{1+\epsilon_1}(m+n))$ and $\beta_v^*(x, y)$ is also $O(\log_{1+\epsilon_1}(m+n))$, which implies that $\beta^*(x, y)$ is $O(\log_{1+\epsilon_1}(m+n))$ or simply $\tilde{O}(1/\epsilon_1)$. Therefore, we can use ApproxDTW to compute a $(1 + \epsilon_2)$ -approximation of $DTW(\delta_{\epsilon_1})(x, y)$ in $\tilde{O}(k\ell/\epsilon_1\epsilon_2^2)$ time. Since any $(1 + \epsilon_2)$ -approximation of $DTW(\delta_{\epsilon_1})(x, y)$ is a $(1 + \epsilon)$ -approximation of $DTW(\delta)(x, y)$, we are done. ◀

4.2 Time-Bound for Constant-Bounded Letter Distances

Assume that there exists a constant N such that $\delta(a, b)$ is an integer less than N for each pair a and b in Σ . For instance, (Σ, δ) satisfies this condition if it is Hamming space (for which N can be set to 2).

► **Theorem 22.** *Assume that $\delta(a, b)$ are $O(1)$ for $a, b \in \Sigma$. Then ApproxDTW, the $(1 + \epsilon)$ -approximation algorithm for DTW given in the proof of Theorem 18, runs in $\tilde{O}(k\ell/\epsilon^2)$ time for $k = \|x\|$ and $\ell = \|y\|$, where \hat{x} and \hat{y} are the input of the algorithm.*

Proof. This theorem follows from Theorem 18 immediately since $\beta^*(x, y)$ is $O(1)$. ◀

5 Conclusion

We have presented in this paper an algorithm for approximating the DTW distance between two RLE strings. Trading accuracy for efficiency, this algorithm is of (near) quadratic-time complexity and thus, as can be expected, asymptotically faster than the exact DTW algorithm of cubic-time complexity [21], which is currently considered the state-of-art of its kind.

It will be interesting to further investigate whether there exist asymptotically faster approximation algorithms for DTW than the one presented in this paper. In particular, it seems both interesting and challenging to answer the open question as to whether there exists a (near) quadratic-time algorithm for computing the (exact) DTW distance between two RLE strings.

Abstract

We study the correlated stochastic knapsack problem of a submodular target function, with optional additional constraints. We utilize the multilinear extension of submodular function, and bundle it with an adaptation of the relaxed linear constraints from Ma [Mathematics of Operations Research, Volume 43(3), 2018] on correlated stochastic knapsack problem. The relaxation is then solved by the stochastic continuous greedy algorithm, and rounded by a novel method to fit the contention resolution scheme (Feldman et al. [FOCS 2011]). We obtain a pseudo-polynomial time $(1 - 1/\sqrt{e})/2 \simeq 0.1967$ approximation algorithm with or without those additional constraints, eliminating the need of a key assumption and improving on the $(1 - 1/\sqrt[4]{e})/2 \simeq 0.1106$ approximation by Fukunaga et al. [AAAI 2019].

Acknowledgements We would like to thank the reviewers for comments on a previous version of this draft, who found a flaw in the algorithm and its analysis. The old algorithm imposes the partition matroid *while* doing the first rounding step, leading to dependency between items. This seemingly convenient step actually breaks the correctness of contention resolution scheme, which is built on FKG inequality and intrinsically needs an independent rounding step. We fixed the issue by replacing it with a true independent rounding step, and fix the solution to fit the partition matroid later on. While this breaks the symmetry between items, the gap of 2 turns out to be large enough to fix everything. Check the use of union bound in Case 1 for the proof of Lemma 10 for details.

1 Introduction

The knapsack problem is one of the most celebrated frameworks to model profit maximization with limited resources. Though well understood in its basic form, many new variants were proposed to model and target more complicated problems. One line of variants take

randomness into consideration. Such randomness may appear on item sizes only, on item profits only, or on both in a correlated fashion. A significant body of work [4, 10, 22, 25, 26] connects knapsack problem with the field of stochastic optimization, greatly broadening the spectrum of knapsack problems while introducing various challenges for theoretical analysis. Another line of variants model diminishing returns in the profit, leading to the field of submodular optimization [27, 14, 6, 7, 12, 13], which enjoys tremendous popularity both in theory and in practice. The two lines of work are connected together into stochastic submodular optimization, another fruitful field [3, 20, 9, 15, 17, 18, 21, 31]. In this work, we follow this line, and consider a correlated stochastic knapsack problem with a submodular target function. We arrived at this problem when modeling the spot scheduling problem in Yang et al. [29] (see details in the full version [30]). A slight variant of the final problem was first proposed in Fukunaga et al. [16], trying to model “performance-dependent costs of items” in stochastic submodular optimization. This problem turns out to be a very powerful framework that applies to several other real world applications, like recommendation systems [32, 1], and batch-mode active learning [23].

1.1 Formal Problem Statement

There are n items, each takes a random size $\text{size}_i \in \mathbb{N}$ with probability $p_i(\text{size}_i)$, and gets a reward that *corresponds* to its size. In other words, for each item i , there is a reward function $R_i : \mathbb{N} \rightarrow [M]$, such that $r_i = R_i(\text{size}_i)$. (For simplicity, we define $[n]$ to be the set $\{0, 1, 2, \dots, n\}$, and M a positive integer that upper bounds the maximum reward.) We assume each R_i to be non-decreasing, i.e., the larger an item, the more reward it deserves. We are given a budget $B \in \mathbb{N}$ for the total size of items, and wish to extract as much profit as possible. The total profit is a lattice-submodular function¹ $f : [M]^n \rightarrow \mathbb{R}^+$ on the rewards of included items, and we wish to maximize its expectation².

Items are put in the knapsack one by one. As soon as an item is put in the knapsack, its reward and size are revealed. We halt when the knapsack overflows (not collecting the last item’s reward), and proceed to add another item otherwise. We consider adaptive policies, i.e., we can choose an item to include, observe its realized size, and make further decisions based on the realized size. At first, only the reward function and the size distribution of items are known. When the policy includes an item i , its size_i is realized, and so is its reward $r_i = R_i(\text{size}_i)$. In this work, we only consider adaptive policies without cancellation, i.e., the policy can make its decision based on all the realizations it has seen so far, and the inclusion of an item is irrevocable.

For a vector $q \in [M]^n$, let $\Pr_\gamma[q]$ denote the probability that we get outcome q when running policy γ . Note this probability is with respect to the randomness both in the state of items and in the policy γ . Let $f_{\text{avg}}(\gamma)$ denote $\sum_{q \in [M]^n} \Pr_\gamma[q] f(q)$, i.e., the average objective value obtained by γ . Our aim is to find a policy γ that maximizes $f_{\text{avg}}(\gamma)$. We say γ is an α -approximation policy if $f_{\text{avg}}(\gamma) \geq \alpha f_{\text{avg}}(\gamma^*)$ for any policy γ^* .

In addition to all the above, we further require that the chosen set of items S be an independent set of a partition matroid³ $\mathcal{I} = \{\mathcal{I}_k\}_{k \in [K]}$. This is without loss of generality as we can put each item in a separate partition, and every subset of items is valid. The

¹ See definition of partition matroid, submodular and lattice-submodular in Section 3.

² Let $S \subseteq [n]$, we sample a vector $q \in [M]^n$ as follows. Each component $q(i)$ is sampled independently. For $i \in S$, $\Pr[r_i = R_i(s)] = p_i(s)$; for $i \notin S$, $r_i = 0$ with probability 1. Denote this distribution as q_S . Then the objective is to select a (random) set $S \subseteq \mathcal{I}$ of items that maximizes $\mathbb{E}_{\theta \sim q_S}[f(\theta)]$ subject to $\sum_{i \in S} \text{size}_i \leq B$.

³ See definition of partition matroid, submodular and lattice-submodular in Section 3.

additional constraint allows us to impose conflicts between items, which is needed for the modeling in Yang et al. [29]. More importantly, it is also crucial if we are to allow the attempt to include an item that could possibly overflow the knapsack, a case unsolved and left as open problem in Fukunaga et al. [16] (see details in Section 1.3). This partition matroid is also used to ensure the correctness of our approach based on a time-indexed LP.

1.2 Our Contributions

We present a pseudo-polynomial time algorithm for the correlated stochastic knapsack problem with a submodular target function. It computes an adaptive policy for this problem which is guaranteed to achieve $(1 - 1/\sqrt{\epsilon})/2 \simeq 0.1967$ of the optimal solution on expectation. It improves on the $(1 - 1/\sqrt[4]{\epsilon})/2 \simeq 0.1106$ approximation algorithm from Fukunaga et al. [16]. Furthermore, we eliminate one key assumption in Fukunaga et al. [16] which does not allow the inclusion of any item which could possibly overflow the budget.

1.3 Eliminating An Assumption in Previous Work

In Fukunaga et al. [16], the authors considered a slightly different problem. They made two assumptions, and we managed to eliminate one of them. The first assumption states that larger size means larger reward for every particular job. This assumption is reasonable for general problems and remains crucial in our analysis. The second assumption states that we will never select an item which could overflow the budget, given the realization of selected items⁴. However, for many cases, selecting such an item is a desirable choice since additional value is obtained with high probability. If we are unlucky and the size goes beyond the remaining budget, we either receive a partial value, or do not get any value at all.

1.4 Our Techniques

If the target function is linearly additive, this problem becomes the correlated stochastic knapsack problem. For this problem, Gupta et al. [22] gave a $1/8$ approximation algorithm for adaptive policies based on LP relaxation. The approximation ratio was improved to $1/(2 + \epsilon)$ by Ma [26], via a different time indexed LP formulation and a more sophisticated rounding scheme. Fukunaga et al. [16] extends the $1/8$ approximation algorithm, and achieve a $(1 - 1/\sqrt[4]{\epsilon})/2$ approximation for a case with submodular target function. This is achieved via a combination of the stochastic continuous greedy algorithm [2] (for getting a fractional solution), and the contention resolution scheme [13] (for rounding). A natural idea for improvement is to take ingredients from the $1/(2 + \epsilon)$ algorithm by Ma [26]. While the LP can be easily adapted, its rounding exhibits complicated dependencies that can be hard to analyze. We also have no luck with a direct application of the *contention resolution scheme* [8, 12, 13], a powerful technique in submodular optimization. The difficulties come in two folds. First, the original scheme is based on FKG inequality, which requires an *independently* rounded solution (possibly invalid) to start with. Any attempt to enforce our partition matroid at this step will break the whole scheme. This invalid solution is later fixed by ignoring some items from the rounded solution, and we need a way to impose the additional partition matroid constraint. Second, the ignoring step needs a critical “monotone”

⁴ For example, suppose we are left with a remaining budget of 20 at some time, and all items have a 0.001 probability of size 21. What this assumption suggests is that none of the items are allowed to be selected.

property. At a high level, the property says that the more items you choose, the lower the probability every other items will be selected (See Section 5.1 for a rigorous definition). While this may seem trivially true for any reasonable algorithm, it is not. In particular, it does not hold for Ma’s algorithm [26], due to its complicated dependencies. The first difficulty is not hard: if we happen to pick two items from the same partition, we just throw the later one out. Unfortunately, this makes the second obstacle even harder. The second obstacle is overcome by designing a brand-new rounding scheme which allows the direct analysis on the correlated probability of events. In order to achieve the aforementioned monotone property, we insert phantom items to block some “time slots” even when no item is there to conflict with. Such phantom items may be of independent interest for other applications of the contention resolution scheme. This alternate way of achieving monotonicity simultaneously free our analysis from one assumption mentioned in Section 1.3, which was needed in Fukunaga et al. [16] in their proof of the monotone property. A factor of $(1 - 1/\sqrt{e})$ is lost for the continuous optimization part, and another factor of 2 is lost for rounding, leading to our $(1 - 1/\sqrt{e})/2 \simeq 0.1967$ approximation algorithm.

2 Other Related Works

Stochastic Knapsack Problem. The stochastic version of the knapsack problem has long been studied. Kleinberg et al. [24], and Goel and Indyk [19] consider the stochastic version to maximize profit that will overflow the budget with probability at most p . However, they assume deterministic profits and special size distributions. Dean et al. [11] relax the limit on size and allow arbitrary distributions for item sizes. They investigate the gap between non-adaptive policies (the order of items to insert is fixed) and adaptive policies (allowed to make dynamic decision based on the realized size of items) and give a polynomial-time non-adaptive algorithm that approximates the optimal adaptive policy within a factor of $1/4$ in expectation. They also give an adaptive policy that approximates within a factor of $1/(3 + \epsilon)$ for any constant $\epsilon > 0$. Bhalgat et al. [4] improves on this and give a bi-criteria $(1 - \epsilon)$ algorithm by relaxing the budget by $(1 + \epsilon)$. Dean et al. [10] show that if correlation between size and reward is allowed, the problem would be PSPACE-hard. Gupta et al. [22] considered the case where the size and reward of an item can be arbitrarily correlated, and give an $1/8$ approximation. Li and Yuan [25] improved on this and get a $1/(2 + \epsilon)$ approximation with correlations and cancellation when ϵ fraction of extra space is allowed. This was further improved by Ma [26], who gets the same approximation ratio but without the budget augmentation requirement.

Submodular Maximization. Nemhauser et al. [27] studied the problem of maximizing a monotone submodular function subject to a cardinality constraint and gave the standard greedy $(1 - 1/e)$ -approximation algorithm. For the case with a matroid constraint, Fisher et al. [14] showed that the standard greedy algorithm gives a $1/2$ -approximation. This was improved to $(1 - 1/e)$ by Calinescu et al. [6], via the *continuous greedy algorithm*, which was originally developed by Calinescu et al. [5] for the submodular welfare problem. In this algorithm, the target function is relaxed via an exponential multilinear-extension. Though exponential, this version can be approximately solved to arbitrary precision in polynomial time. The fractional solution is then rounded via pipage rounding [5, 6, 28] or other rounding schemes [7]. In order to generalize the problem for other constraints and non-monotone submodular functions, a general rounding framework *contention resolution scheme* was proposed [6, 12, 13]. In this framework, the rounding step happens in two phases, an

independent rounding phase followed by a pruning phase, where the second phase ensures an upper bound on the probability that an element is pruned. One line of stochastic submodular optimization [3] assumes items have stochastic states, and would like to maximize a monotone submodular function on the stochastic states, under constraints on the set of chosen items. In other words, the constraints only depend on the selection of items, but not on the stochastic states of them. This is a generalization of the stochastic knapsack problem where the size of items are deterministic. Various settings of this problem are investigated by a series of follow-up works [20, 9, 15, 17, 18, 21, 31]. Asadpour and Nazerzadeh [2] considers the maximization of a monotone lattice-submodular function. In this problem, each selected item has a stochastic state (a non-negative *real* number). The target function accepts a vector of such numbers, and satisfies lattice-submodularity (defined in Section 3). In their problem, only the states are stochastic, while the matroid constraint is on the set of selected items. Fukunaga et al. [16] pushed one step further and allowed the constraints to be dependent on the state of items, but limited the set of states to be non-negative integers.

3 Preliminary

We start with some notations. The description of the spot scheduling problem [29] can be found in the full version [30], together with its modeling and reduction to the problem we consider. In Section 3.1, we explain how we reduce and manage to eliminate one critical assumption in the previous work by Fukunaga et al. [16].

Given two d dimensional vectors $u, v \in [n]^d$, we write $u \leq v$ if the inequality holds coordinate wise, i.e. $\forall i \in [d], u(i) \leq v(i)$. Similarly, $u \vee v$ and $u \wedge v$ are defined coordinate wise: $(u \vee v)(i) = \max\{u(i), v(i)\}$, $(u \wedge v)(i) = \min\{u(i), v(i)\}$. Consider a base set $[n]$, a matroid is defined to be an independent set $\mathcal{I} \subseteq 2^n$. This independent set needs to contain \emptyset , and if $A \in \mathcal{I}$, so is every $A' \subseteq A$. Furthermore, if $A, B \in \mathcal{I}$ and $|A| > |B|$, then there exists an element $x \in A \setminus B$ such that $B \cup x$ is in \mathcal{I} . Particularly, for a *partition matroid* $\{\mathcal{I}_k\}_{k \in [K]}$ where $\mathcal{I}_i \cap \mathcal{I}_j = \emptyset, \forall i \neq j$, its independent set \mathcal{I} is $\{S | \forall k, S \cap \mathcal{I}_k \leq 1\}$.

A function $f : 2^d \rightarrow \mathbb{R}$ is *submodular* if for every $A, B \subseteq [d]$, $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$. An equivalent definition is that for every $A \subseteq B \subseteq [d]$ and $e \in [d]$, $f(A \cup \{e\}) - f(A) \geq f(B \cup \{e\}) - f(B)$. This definition is generalized to a domain of $[n]^d$, where function $f : [n]^d \rightarrow \mathbb{R}^+$ is called *lattice-submodular* if $f(u) + f(v) \geq f(u \wedge v) + f(u \vee v)$ holds for all $u, v \in [n]^d$. Note that the *lattice-submodularity* does not imply the property called *DR-submodularity*, which is the diminishing marginal returns along the direction of χ_i for each $i \in I$, where $\chi_i \in \{0, 1\}^n$, and only the i -th coordinate is 1. That is, $f(u + \chi_i) - f(u) \geq f(v + \chi_i) - f(v)$ does not necessarily hold for all $u, v \in [n]^d$ such that $u \leq v$ and $i \in [d]$ even if f is *lattice-submodular*. Function $f : [n]^d \rightarrow \mathbb{R}^+$ is called *monotone* if $f(u) \leq f(v)$ for all $u \leq v$.

3.1 Reduction and Eliminating an Assumption

In order to eliminate the second assumption mentioned in Section 1.3, we introduce the notion of a “size cap”. For each item i and a size cap b , we define an item (i, b) , where $p_{(i,b)}(s) = \pi_i(s)$ when $s < b$; $p_{(i,b)}(s) = \sum_{s' \geq s} \pi_i(s')$ when $s = b$; and 0 otherwise. The new reward function is exactly $R_{(i,b)}(\cdot)$.

We will be using a time-indexed LP formulation following Ma [26]. Instead of making a decision at each time step, we do it at each remaining size level. When there is enough room, we take item i itself into consideration. If the remaining size b is small, we are not able to get more reward for an item than when it has a size of b . Therefore, instead of trying to include

the original item i , we include item (i, b) , which is item i with size cap b . Obviously, we can include each item at most once. To achieve this, we impose a partition matroid $\{\mathcal{I}_i\}_{i \in [K]}$ on the items, where $\mathcal{I}_i = \{(i, b) | \forall b\}$. For the remainder of this paper, we view each (i, b) as an item, and the conflict between them is captured by the partition matroid.

4 Continuous Optimization Phase

Like most submodular maximization problems, our algorithm consists of two phases, a continuous optimization phase and a rounding phase. In this section, we describe the former.

4.1 Target Function

Given a lattice-submodular function $f : [M]^n \rightarrow \mathbb{R}^+$ and a distribution q_S of elements in set $S \subseteq [n]$, we define a set-submodular function $\bar{f} : 2^n \rightarrow \mathbb{R}_+$, where $\bar{f}(S) := \mathbb{E}_{r \sim q_S}[f(r)]$. This \bar{f} is guaranteed to be a monotone set-submodular function (See proof in [2]). Suppose the final selected (random) set is S , the value we are interested in would be $\mathbb{E}[\bar{f}(S)]$. Let \bar{x} be a vector, where $\bar{x}(i)$ denotes the probability that item i is in S . Using the well-established multi-linear extension, we define $\bar{F} : 2^n \rightarrow \mathbb{R}^+$, where $\bar{F}(\bar{x}) = \sum_{S \subseteq [n]} \prod_{i \in S} \bar{x}_i \prod_{i' \notin S} (1 - \bar{x}_{i'}) \bar{f}(S)$. This is the target function we are maximizing. Evaluating the function \bar{F} can take exponential time, but it can be approximated within a multiplicative factor of $(1 + \epsilon)$ for any constant $\epsilon > 0$. For simplicity, we assume $\bar{F}(\bar{x})$ can be evaluated exactly in this paper, which is standard in the literature (e.g. see [6]).

4.2 Stochastic Knapsack Exponential Constraints

The exponential and polynomial constraints on \bar{x} are adapted from Ma [26]. A group of exponential sized constraints describes the problem exactly. They are then relaxed to have a polynomial size, losing a factor of 2. For ease of notation, we follow Ma [26] and view an stochastic item i as an equivalent Markovian bandit, a special one that can force us to keep pulling it for a certain period of time. We use state $u_i(k, s)$ to indicate that arm i has been pulled k times, and the corresponding item has size s . From its initial state ρ_i , a single pull would decide the size s of this job, and move to state $u_i(1, s)$ respectively. We are then forced to keep pulling this arm (we will be using arm and item interchangeably) for the next $s - 1$ steps, and the last of such pulls moves us to its termination state \emptyset_i , and we can pull a new arm. Denote the probability of moving from state u to state v with $p_{u,v}$. After the first pull of item i , it moves to state $u_i(1, s)$ (having size s) with probability $p_{\rho_i, u_i(1, s)} = p_i(s)$. Therefore, if $k < s$, a pull will transit it to state $u_i(k + 1, s)$ with probability $p_{u_i(k, s), u_i(k+1, s)} = 1$. Otherwise, when $k = s$, transit to state \emptyset_i with probability $p_{u_i(k, s), \emptyset_i} = 1$, and we are allowed to pull a new arm.

Let π be a vector representing a joint state/node, where π_i denotes the state on item i . Let $S_i = \{u_i(*, *)\} \cup \{\rho_i, \emptyset_i\}$ for all $i \in [n]$, the set of all states for arm i , and $\tilde{\mathcal{S}} = S_1 \times \cdots \times S_n$, the set of all possible (maybe invalid) joint states. Let $\mathcal{S}' = \{\pi \in \tilde{\mathcal{S}} | \exists i \neq j, \pi_i \notin \{\rho_i, \emptyset_i\}, \pi_j \notin \{\rho_j, \emptyset_j\}\}$, the set of states where at least two arms are in the middle of processing at the same time, and $\mathcal{S}'' = \{\pi \in \tilde{\mathcal{S}} | \pi_i \neq \rho_i \text{ and } \pi_j \neq \rho_j, i, j \in \mathcal{I}_k \text{ for some } k\}$, the set of states where some conflicting arms (due to the partition matroid) have been started. Define $\mathcal{S} := \tilde{\mathcal{S}} \setminus (\mathcal{S}' \cup \mathcal{S}'')$, which is the set of all valid states. Let $I(\pi) = \{i | \pi_i \neq \emptyset_i\}$, the set of arms that could be played from state π . Let π^u denote the joint node where the component corresponding to u is replaced by u (note u can correspond to only one component). Let $y_{\pi, t}$

be the probability that we are at state π at time t , and $z_{\pi,i,t}$ the probability that we pulled arm i at time t , when the current state was π . Recall B is the total budget, we have the following basic constraints.

$$\sum_{i \in I(\pi)} z_{\pi,i,t} \leq y_{\pi,t} \quad \pi \in \mathcal{S}, t \in [B] \quad (1)$$

$$z_{\pi,i,t} = y_{\pi,t} \quad \pi \in \mathcal{S}, i : \pi_i \in S_i \setminus \{\rho_i, \emptyset_i\}, t \in [B] \quad (2)$$

$$z_{\pi,i,t} \geq 0 \quad \pi \in \mathcal{S}, i \in [n], t \in [B] \quad (3)$$

Let $\mathcal{A}_i = \{\pi \in \mathcal{S} : \pi_i \notin \{\rho_i, \emptyset_i\}\}$, the joint node when arm i is in the middle of processing. Note \mathcal{A}_i and \mathcal{A}_j are disjoint for $i \neq j$. We call arm i the *active* arm. Let $\mathcal{A} = \bigcup_{i \in [n]} \mathcal{A}_i$, the set of all states where some arm is *active*. For a state $\pi \in \mathcal{S}$, let $\mathcal{P}(\pi)$ denote the subset of \mathcal{S} that would transit to π with no play, which could happen when some arms turned inactive automatically: if $\pi \notin \mathcal{A}$, then $\mathcal{P}(\pi) = \{\pi\} \cup (\bigcup_{i \notin I(\pi)} \{\pi^u | u \in S_i \setminus \{\rho_i\}\})$; if $\pi \in \mathcal{A}$, then $\mathcal{P}(\pi) = \emptyset$. Suppose u corresponds to coordinate i , define $\text{Par}(u) = \{v \in S_i : p_{v,u} > 0\}$, the nodes that have a positive probability of transitioning to u . Then y -variables are updated as follows:

$$y_{(\rho_1, \dots, \rho_n), 0} = 1 \quad (4)$$

$$y_{\pi, 0} = 0, \quad \pi \in \mathcal{S} \setminus \{(\rho_1, \dots, \rho_n)\} \quad (5)$$

$$y_{\pi, t} = \sum_{\pi' \in \mathcal{P}(\pi)} \left(y_{\pi', t-1} - \sum_{i \in I(\pi')} z_{\pi', i, t-1} \right) \quad t > 0, \pi \in \mathcal{S} \setminus \mathcal{A} \quad (6)$$

$$y_{\pi, t} = \sum_{\rho_i \in \text{Par}(\pi_i)} \left(\sum_{\pi' \in \mathcal{P}(\pi^{\rho_i})} z_{\pi', i, t-1} \right) \cdot p_{\rho_i, \pi_i}, \quad t > 0, i \in [n], \pi \in \mathcal{A}_i, \pi_i \in \{u_i(1, *)\} \quad (7)$$

$$y_{\pi, t} = \sum_{u \in \text{Par}(\pi_i)} z_{\pi^u, i, t-1} \cdot p_{u, \pi_i}, \quad t > 0, i \in [n], \pi \in \mathcal{A}_i, \pi_i \notin \{u_i(1, *)\} \quad (8)$$

Equation (6) updates $y_{\pi, t}$ for $\pi \notin \mathcal{A}$, i.e. joint nodes with no active arms. Such a joint node π can only come from a no-play from a joint node in $\mathcal{P}(\pi)$. Equations (7) and (8) update $y_{\pi, t}$ for $\pi \in \mathcal{A}$. To get to the joint node π , we must have played arm i in previous step(s). In Equation (7), we consider the case if π_i is one of $u_i(1, *)$. We were at ρ_i right before, so it is possible that in the last step, we switched to π^{ρ_i} from some joint node in $\mathcal{P}(\pi^{\rho_i})$ without playing an arm. In Equation (8), we consider other cases, in which arm i was played at time $t-1$. These equations guarantee that at each time step, $y_{*, t}$ form a distribution, i.e. $\sum_{\pi \in \mathcal{S}} y_{\pi, t} = 1$. Combining this with Equation (1), we get $\sum_{\pi \in \mathcal{S}} \sum_{i \in I(\pi)} z_{\pi, i, t} \leq 1, \forall t \in [B]$. Equations (1)–(8) form the exponential constraints. We also need to relate these constraints with \bar{x} (recall $\bar{x}(i)$ is the probability that item i is included): $\bar{x}(i) = \sum_t \sum_{u \in S_i} \sum_{\pi \in \mathcal{S} : \pi_i = u} z_{\pi, i, t}$, which is the last missing piece for our exponential program, denoted as ExpP.

4.3 Stochastic Knapsack Polynomial Constraints

Obviously, we cannot solve this exponential program directly in polynomial time. In order to solve it, we relax the exponential program by disassemble the joint distribution of items. Let $s_{u, t}$ be the probability that arm i is on node u at the beginning of time t . Let $x_{u, t}$ be the probability that we pull an arm on node u at time t . Suppose $\mathcal{S} = \bigcup_i S_i$, we have the following constraints between $x_{u, t}$ and $s_{u, t}$.

$$x_{u, t} \leq s_{u, t} \quad u \in \mathcal{S}, t \in [B] \quad (9)$$

$$x_{u, t} = s_{u, t} \quad u \in \bigcup_{i \in [n]} S_i \setminus \{\rho_i, \emptyset_i\}, t \in [B] \quad (10)$$

$$x_{u, t} \geq 0 \quad u \in \mathcal{S}, t \in [B] \quad (11)$$

$$\sum_{u \in \mathcal{S}} x_{u, t} \leq 1 \quad t \in [B] \quad (12)$$

We also need constraints (13) for the partition matroid of arms (recall \mathcal{I}_k is a partition), and the state transition constraints (14)–(16).

$$\sum_{i \in \mathcal{I}_k} s_{\rho_i, 0} \leq 1, \quad \forall \mathcal{I}_k \qquad s_{\rho_i, 0} \geq 0, \quad i \in [n] \qquad (13)$$

$$s_{u, 0} = 0 \qquad u \in \mathcal{S} \setminus \{\rho_1, \dots, \rho_n\} \qquad (14)$$

$$s_{\rho_i, t} = s_{\rho_i, t-1} - x_{\rho_i, t-1} \qquad t > 0, i \in [n] \qquad (15)$$

$$s_{u, t} = \sum_{v \in \text{Par}(u)} x_{v, t-1} \cdot p_{v, u} \qquad t > 0, u \in \mathcal{S} \setminus \{\rho_1, \dots, \rho_n\} \qquad (16)$$

Relating these constraints with \bar{x} : $\bar{x}(i) = \sum_t \sum_{u \in \mathcal{S}_i} x_{u, t}$, we get the polynomial program PolyP. For any program $P \in \{\text{PolyP}, \text{ExpP}\}$, let OPT_P denote its optimal value.

4.4 Relating between the Exponential and the Polynomial Constraints

This was given in Ma [26], and we re-state for completeness without proof. The direction from ExpP to PolyP is trivial.

► **Theorem 1** (reformation of Lemma 2.3 from Ma [26]). *Given a feasible solution $\{z_{\pi, i, t}\}, \{y_{\pi, t}\}$ to ExpP, we can construct a solution to PolyP with the same objective value by setting $x_{u, t} = \sum_{\pi \in \mathcal{S}: \pi_i = u} z_{\pi, i, t}$, $s_{u, t} = \sum_{\pi \in \mathcal{S}: \pi_i = u} y_{\pi, t}$ for all $i \in [n]$, $u \in [0, 1]$, $t \in B$. Thus, the feasible region of PolyP is a projection of that of ExpP onto a subspace and $\text{OPT}_{\text{ExpP}} \leq \text{OPT}_{\text{PolyP}}$.*

For the other direction, we construct a solution $\{z_{\pi, i, t}, y_{\pi, t}\}$ of ExpP from a solution $\{x_{u, t}, s_{u, t}\}$ of PolyP, which obtains half its objective value. It will satisfy

$$\sum_{\pi \in \mathcal{S}: \pi_i = u} z_{\pi, i, t} = \frac{x_{u, t}}{2} \quad i \in [n], u \in \mathcal{S}_i, t \in [B].$$

We define specific $\{z_{\pi, i, t}, y_{\pi, t}\}$ over B iterations. On iteration t :

- Compute $y_{\pi, t}$ for all $\pi \in \mathcal{S}$.
- Define $\tilde{y}_{\pi, t} = y_{\pi, t}$ if $\pi \notin \mathcal{A}$, and $\tilde{y}_{\pi, t} = y_{\pi, t} - \sum_{a \in A} z_{\pi, i, t}$ if $\pi \in \mathcal{A}_i$ for some $i \in [n]$ (if $\pi \in \mathcal{A}_i$, then $\{z_{\pi, i, t} : a \in A\}$ is already set in a previous iteration).
- For all $i \in [n]$, define $f_{i, t} = \sum_{\pi \in \mathcal{S}: \pi_i = \rho_i} \tilde{y}_{\pi, t}$.
- For all $i \in [n]$, $\pi \in \mathcal{S}$ such that $\pi_i = \rho_i$, and $a \in A$, set $z_{\pi, i, t}^a = \tilde{y}_{\pi, t} \cdot \frac{1}{2} \cdot \frac{x_{\rho_i, t}}{f_{i, t}}$.
- For all $i \in [n]$, $\pi \in \mathcal{S}$ such that $\pi_i = \rho_i$ and $\pi_j \in \{\rho_j, \phi_j\}$ for $j \neq i$, define $g_{\pi, i, t} = \sum_{\pi' \in \mathcal{P}(\pi)} z_{\pi', i, t}$.
- For all $i \in [n]$, $u \in \mathcal{S}_i \setminus \{\rho_i\}$, $\pi \in \mathcal{S}$ such that $\pi_i = u$, and $a \in A$, set $z_{\pi, i, t + \text{depth}(u)}^a = g_{\pi, i, t} \cdot (x_{u, t + \text{depth}(u)}^a) / x_{\rho_i, t}$.

4.5 Solve the Continuous Optimization Problem

In order to solve PolyP, we follow Fukunaga et al. [16] and use the Stochastic Continuous Greedy algorithm. This algorithm maximizes the multi-linear extension G of a monotone set-submodular function g over a solvable downward-closed polytope. A polytope $\mathcal{P} \subseteq [0, 1]^{\mathcal{N}}$ is considered *solvable* if we can find an algorithm to optimize linear functions over it, and downward-closed if $x \in \mathcal{P}$ and $0 \leq y \leq x$ imply $y \in \mathcal{P}$. In our case, \mathcal{P} is solvable due to its linearity, and that solving a linear program falls in polynomial time. Note \mathcal{P} is down-monotone. The algorithm involves a controlling parameter called *stopping time*. For a stopping time $0 < b \leq 1$, the algorithm outputs a solution x such that $x/b \in \mathcal{P}$, while $G(x) \geq (1 - e^{-b} - O(n^3 \delta)) \max_{y \in \mathcal{Q}} G(y)$, where n is the size of the set over which g is defined and δ is the step size used in the algorithm. Here \mathcal{P} is assumed to include the characteristic vector of every singleton set.

► **Theorem 2** (reformation of Theorem 3 from Fukunaga et al. [16]). *If the stochastic continuous greedy algorithm with stopping time $b = 1/2 \in (0, 1]$ and step size $\delta = o(|I|^{-3})$ is applied to program PolyP , then the algorithm outputs a solution $x \in b\mathcal{P}$ such that $\bar{F}(\bar{x}) \geq (1 - e^{-b} - o(1))f_{\text{avg}}(\pi^*) \simeq 0.3935f_{\text{avg}}(\pi^*)$ for any adaptive policy π^* .*

5 Rounding Phase

Now that we have a fractional solution x , we proceed to round it to an integral policy (notice the fractional solution has already been scaled by a factor of 2). We need a variant of the contention resolution scheme that was introduced as a general framework for designing rounding algorithms that maximizes expected submodular functions ([8, 12, 13]). The variant is an extension from a set submodular function to a lattice-submodular function, first introduced in Fukunaga et al. [16]. We include its definition here for self-containment.

5.1 Contention Resolution Scheme

A contention resolution scheme (CRS) accepts a *pairwise independently* rounded solution which may violate some constraints, and fixes it without losing too much on expectation. Let $f : [B]^n \rightarrow \mathbb{R}_+$ be a monotone lattice-submodular function and the probability distribution $q_i : [B] \rightarrow [0, 1]$ on $[B]$ be given for each $i \in \{1, \dots, n\}$. We write $v \sim q$ if $v \in [B]^n$ is a random vector such that, for each $i \in \{1, \dots, n\}$, the corresponding component $v(i)$ is determined independently as $j \in [B]$ with probability $q_i(j)$. This is the independently rounded solution we feed into a CRS. Let $\mathcal{F} \subseteq [B]^n$ be a downward-closed subset of $[B]^n$, and let $\alpha \in [0, 1]$. We have the following definition for a α -CRS, its monotonicity, and one key property.

► **Definition 3** (α -Contention Resolution Scheme (α -CRS)). *A mapping $\psi : [B]^n \rightarrow \mathcal{F}$ is an α -CRS with respect to q if it satisfies:*

1. $\psi(v)(i) \in \{v(i), 0\}$ for each $i \in [n]$;
2. if $v \sim q$, then $\Pr[\psi(v)(i) = j | v(i) = j] \geq \alpha$ holds for all $i \in I$ and $j \in B$. The probability is based on randomness both in v and in ψ when ψ is randomized.

► **Definition 4** (monotone α -CRS). *An α -CRS ψ is considered monotone, if, for each $u, v \in [B]^n$ such that $u(i) = v(i)$ and $u \leq v$, $\Pr[\psi(u)(i) = u(i)] \geq \Pr[\psi(v)(i) = v(i)]$ holds. The probability is based only on the randomness of ψ .*

► **Lemma 5** (Theorem 4 from Fukunaga et al. [16]). *If ψ is a monotone α -CRS with respect to q , then $\mathbb{E}_{v \sim q}[f(\psi(v))] \geq \alpha \mathbb{E}_{v \in q}[f(v)]$.*

5.2 Rounding Algorithm

To fit in the contention resolution scheme, we need to first round everything independently. This means for each pair (i, t) , item i is scheduled at time t with probability $x_{\rho_i, t}$. Now we have a set $R' = \{(i, t)\}$ of proposed item time pairs. We sort the set according to t , and include the items one by one. Intuitively, for a pair (i, t) , we will only include item i if time t is available and does not invalidate the solution, i.e. each item is scheduled at most once, and at most one item from each partition. After including it in our solution, we get its realized size, and mark the corresponding time slots unavailable.

The main problem of this naive approach is that it does not exhibit monotonicity, which is a subtle but critical requirement for a CRS. To fix it, we schedule *phantom item* i even when we cannot fit it. We *simulate* its inclusion, and sample its size size_i should it be included. We

91:10 Correlated Stochastic Knapsack with a Submodular Objective

also mark those time slots corresponding to this *phantom item* unavailable, even when they are actually unoccupied. This seemingly wasteful step ensures that the rounding scheme is monotone. The final rounding algorithm is described in Algorithm 1.

■ **Algorithm 1** Rounding Algorithm.

```

1 foreach pair  $(i, t)$  do
2   | Sample  $(i, t)$  with probability  $x_{\rho_i, t}$ , and gets  $\emptyset$  otherwise;
3   | if not get  $\emptyset$  then  $I \leftarrow I \cup \{(i, t)\}$  ;
4 Sort  $I$  according to a non-decreasing ordering of  $t$ , break ties uniformly at random;
5  $C = 0, S = \emptyset$ , mark all times slots available;
6 for  $(i, t) \in I$  do
7   | if time slot  $t$  is available and item  $i$  does not violate constraints then
8   |   | Include item  $i$  and observe  $s_i$ ;
9   |   else
10  |   | Simulate including item  $i$ , and observe  $s_i$ ;
11  |   | Mark time slots from  $t$  to  $t + s_i$  unavailable;

```

The remaining of this section is devoted to proving the following theorem, which combined with Theorem 2 leads to our main result.

► **Theorem 6.** *Let π denote Algorithm 1, and x denote the solution we get from PolyP. Then $f_{avg}(\pi) \geq \bar{F}(\bar{x})/2$.*

To prove Theorem 6, we define two mappings $\sigma(\cdot)$ and $\omega(\cdot)$, where the first corresponds (roughly) to the step that maps x to I in Algorithm 1, and $\omega(\cdot)$ corresponds to the mapping (CRS) from set I to the final output. The mapping $\sigma(\bar{x})$ receives a real vector $\bar{x} \in [0, 1]^n$ and returns a random vector $v \in [B]^n$. From each partition \mathcal{I}_k , we pick at most one i , each $i \in \mathcal{I}_k$ is picked with probability $\bar{x}(i)$. If it is picked, the i -th component $v(i)$ independently takes value j with probability $p_i(j)$, and 0 otherwise, which happens with probability $1 - \sum_j p_i(j)$. This captures the construction of set I (only the item part, note $\Pr[\sigma(x)(i) > 0] = \Pr[\exists t, \text{s.t. } (i, t) \in I]$), together with the random outcome of the item. The mapping $\omega(\cdot)$ maps $v \in [B]^n$ to $w \in [B]^n$. To mimic Algorithm 1, we first assign time value $t(i)$ to each component $v(i)$, according to $x_{\rho_i, t}$. Based on $t(i)$, we form a precedence ordering \prec between i after random tie breaking (a random tie breaking is crucial). Then, we set $\omega(v)(i) = 0$ if there exists a component $j \prec i$ such that $t(j) \leq t(i) < t(j) + v(i)$, and $w(v)(i) = v(i)$ otherwise. We can observe that given input x , Algorithm 1 outputs exactly $\omega(\sigma(x))$ if the random realized sizes of items are the same. In order to prove Theorem 6, we need the following two lemmas. The first, whose proof in Fukunaga [16], corresponding to the independent rounding step, and the second corresponding to the CRS step.

► **Lemma 7.** $\mathbb{E}[f(\sigma(x))] \geq \bar{F}(\bar{x})$ holds for any $x \in P$.

► **Lemma 8.** ω is a 1/2-CRS with respect to \bar{x} .

► **Lemma 9.** The 1/2-CRS ω is monotone.

Lemma 7 is trivially true by the definition of $\bar{F}(\bar{x})$, which is the common starting point of contention resolution scheme. We first prove ω is a 1/2-CRS.

Proof of Lemma 8. Recall there are two properties needed for an α -CRS. The first property is obviously correct due to the definition of $\omega(\cdot)$. The second property needs to prove $\Pr[\omega(v)(i) = j | v(i) = j] \geq 1/2$. In the language of the rounding algorithm, let $\text{Drop}_{i,t}$ denotes the event (respect to the randomness in ω and v) that we drop the pair (i, t) . It is the same as proving

$$\Pr[\text{Drop}_{i,t} | \text{item } i \text{ is selected at time } t] \leq \frac{1}{2}.$$

Due to the way we round the solution, item i may be included more than once (at different times), and more than one item from the same partition may be included. Consider an item j at time t' (maybe the same as i) that could affect the pruning of item i at time t . Define $(j, t') \prec (i, t)$ if $t' < t$, or $t' = t$ and $j \prec i$. It is clear that (j, t') will affect (i, t) if and only if $(j, t') \prec (i, t)$. We slightly abuse notation, and let $\text{Drop}_{i,t}(j)$ denote the probability that the item j can causes the drop out of item i if a copy of it is scheduled at time t . Note this does not depend on whether item i is scheduled on t or not. We have:

► **Lemma 10.**

$$\text{Drop}_{i,t}(j) \leq \frac{1}{2} \sum_{u \in \{\emptyset_j\} \cup \{u_j(*,*)\}} x_{u,t} + \frac{1}{2} x_{\rho_j,t}.$$

Proof of Lemma 10. There are two cases and we bound the probability of dropping in each case.

Case 1. j belongs to the same partition as i ,

Case 2. j belongs to a different partition.

For the first case, the probability that it makes (i, t) invalid is

$$\begin{aligned} \text{Drop}_{i,t}(j) &\leq \frac{1}{2} (s_{\rho_j,0} - s_{\rho_j,t}) + \Pr[\text{item } j \text{ is considered before } i] \cdot \frac{1}{2} x_{\rho_j,t} \\ &\leq \frac{1}{2} \sum_{u \in \{\emptyset_j\} \cup \{u_j(*,*)\}} x_{u,t} + \frac{1}{2} x_{\rho_j,t}. \end{aligned}$$

The first term is the probability that at least one item j is scheduled before time t . Note this is actually an union bound due to our independent rounding. The second term is the probability that it is scheduled at time t , but will invalidate i since $j \prec i$. The second equality comes from the fact that if item j is scheduled some time before t , then it must be at some state at time t that is not the starting state ρ_j . In other words, either the end state \emptyset_j or some transient state $u_j(*,*)$.

For the second case, fix j , it can only drop i if it marked time slot t unavailable. The probability is

$$\begin{aligned} \text{Drop}_{i,t}(j) &\leq \frac{1}{2} \sum_{t'=1}^{t-1} x_{\rho_j,t'} \cdot \Pr[\text{size}_j \geq t - t'] + \Pr[\text{item } j \text{ is considered before } i] \cdot \frac{1}{2} x_{\rho_j,t} \\ &\leq \frac{1}{2} \sum_{t'=1}^{t-1} x_{\rho_j,t'} \cdot \Pr[\text{size}_j \geq t - t'] + \frac{1}{2} x_{\rho_j,t}. \end{aligned}$$

The first term is a summation of all the possible starting point of job j , times the probability that it will mark time slot t unavailable. Note this is also a union bound since there can be more than one copy of item j due to independent rounding. The second term is the probability that item j is also scheduled at time t , but is considered before i , i.e. $j \prec i$, which marks time slot t unavailable for i . We focus on the first term,

$$\begin{aligned}
& \sum_{t'=1}^{t-1} x_{\rho_j, t'} \cdot \Pr[\text{size}_j \geq t - t'] = \sum_{t'=1}^{t-1} \sum_{\tau=t-t'}^{B-t} x_{\rho_j, t'} \Pr[\text{size}_j = \tau] = \sum_{t'=1}^{t-1} \sum_{\tau=t-t'}^{B-t} x_{u_j(1, \tau), t'+1} \\
& = \sum_{t'=1}^{t-1} \sum_{\tau=t-t'}^{B-t} x_{u_j(t-t', \tau), t} \leq \sum_{u \in \{\emptyset_j\} \cup \{u_j(*, *)\}} x_{u, t}.
\end{aligned}$$

The last inequality holds because the index set of the summation on the left is a subset of that on the right. ◀

Therefore, the total probability that item i is blocked by any item is upper bounded by the union bound:

$$\begin{aligned}
\text{Drop}_{i, t} &= \sum_j \text{Drop}_{i, t}(j) \leq \frac{1}{2} \sum_j \sum_{u \in \{\emptyset_j\} \cup \{u_i(*, *)\}} x_{u, t} + \frac{1}{2} \sum_{j \in [n]} x_{\rho_j, t} \\
&\leq \frac{1}{2} \sum_{j \in [n]} \sum_{u \in \{\emptyset_j\} \cup \{u_i(*, *)\}} x_{u, t} + \frac{1}{2} \sum_{j \in [n]} x_{\rho_j, t} \leq \frac{1}{2} (1 - \sum_{j \in [n]} x_{\rho_j, t}) + \frac{1}{2} \sum_{j \in [n]} x_{\rho_j, t} = \frac{1}{2}. \quad \blacktriangleleft
\end{aligned}$$

Lastly, we show ω is monotone in the full version [30]. With everything ready, we can now prove Theorem 6, which combined with Theorem 2 leads to the main claim.

Proof of Theorem 6. The output r of Algorithm 1 satisfies $\mathbb{E}[f(r)] = \mathbb{E}[f(\omega(\sigma(x)))]$, and its feasibility is guaranteed by the algorithm. By Lemma 8 and Lemma 9, ω is a monotone $1/2$ -CRS with respect to q , where q is the probability defined in Lemma 8. Moreover, $\sigma(x) \sim q$ holds. By Lemma 5, $\mathbb{E}[f(\omega(\sigma(x)))] \geq \mathbb{E}[f(\sigma(x))]/2$. Using Lemma 7, we get $f_{\text{avg}}(\pi) = \mathbb{E}[f(r)] = \mathbb{E}[f(\omega(\sigma(x)))] \geq \mathbb{E}[f(\sigma(x))]/2 \geq \bar{F}(x)/2$. ◀

6 Conclusion

We consider the well studied correlated stochastic knapsack problem, generalizing its target function with submodularity to capture diminishing returns. An extra partition matroid constraint is added to generalize it and resolve an open question raised in a previous work to eliminate an assumption. We also make improvement on the approximation ratio. There is still a gap of 2 comparing to the variant with linear target function and we leave it as an open problem to close the gap.

Faster Algorithm for Unique $(k, 2)$ -CSP

Or Zamir

Institute for Advanced Study, Princeton, NJ, USA

Abstract

In a $(k, 2)$ -Constraint Satisfaction Problem we are given a set of arbitrary constraints on pairs of k -ary variables, and are asked to find an assignment of values to these variables such that all constraints are satisfied. The $(k, 2)$ -CSP problem generalizes problems like k -coloring and k -list-coloring. In the Unique $(k, 2)$ -CSP problem, we add the assumption that the input set of constraints has at most one satisfying assignment.

Beigel and Eppstein gave an algorithm for $(k, 2)$ -CSP running in time $O((0.4518k)^n)$ for $k > 3$ and $O(1.356^n)$ for $k = 3$, where n is the number of variables. Feder and Motwani improved upon the Beigel-Eppstein algorithm for $k \geq 11$. Hertli, Hurbain, Millius, Moser, Scheder and Szedlák improved these bounds for Unique $(k, 2)$ -CSP for every $k \geq 5$.

We improve the result of Hertli et al. and obtain better bounds for Unique $(k, 2)$ -CSP for $k \geq 5$. In particular, we improve the running time of Unique $(5, 2)$ -CSP from $O(2.254^n)$ to $O(2.232^n)$ and Unique $(6, 2)$ -CSP from $O(2.652^n)$ to $O(2.641^n)$.

Recently, Li and Scheder also published an improvement over the algorithm of Hertli et al. in the same regime as ours. Their improvement does not include quantitative bounds, we compare the works in the paper.

1 Introduction

The general Constraint Satisfaction Problem, in which we are asked to find an assignment to a set of variables that satisfies a list of arbitrary constraints, is NP-Complete. Furthermore, it is widely believed that a substantial improvement over the naive exhaustive search is unlikely for the general CSP problem and even for special cases of it like The *Boolean* Satisfiability Problem (SAT). Nevertheless, when the structure of the input is restricted in a certain manner, there are known improvements in the form of *moderately exponential* algorithms. These are algorithms that still have an exponential running time, yet achieve an exponential improvement over the exhaustive search bounds.

The study of moderately exponential algorithms for NP-Complete problems is extensive. In fact, exponential yet better-than-naive algorithms for NP-Complete problems were known for some problems, for example The Travelling Salesman Problem, long before the definition of NP. A survey of Woeginger [19] covers and refers to dozens of papers exploring such algorithms for many problems including satisfiability, graph coloring, knapsack, TSP, maximum independent sets and more. Subsequent review article of Fomin and Kaski [5] and book of Fomin and Kratsch [6] further cover the topic of exact exponential-time algorithms.

Two of the most notable problems for which the study of moderately exponential algorithms was fruitful are k -satisfiability (usually abbreviated as k -SAT) and graph coloring.

For satisfiability, the running time of the trivial algorithm enumerating over all possible assignments is $O^*(2^n)$. No algorithms solving SAT in time $O^*((2 - \epsilon)^n)$ for any $\epsilon > 0$ are known, and a popular conjecture called The *Strong* Exponential Time Hypothesis [3] states that no such algorithm exists. On the other hand, for every fixed k there exists a constant

$\varepsilon_k > 0$ such that k -SAT (i.e., SAT on formulas in CNF form with at most k literals in every clause) can be solved in $O^*((2 - \varepsilon_k)^n)$ time. A result of this type was first published by Monien and Speckenmeyer in 1985 [13]. A long list of improvements for the values of ε_k were published since, including the celebrated 1998 PPSZ algorithm of Paturi, Pudlák, Saks and Zane [15] and the recent improvement over it by Hansen, Kaplan, Zamir and Zwick [7]. The PPSZ bound was originally obtained only for the case of input formulas with a unique satisfying assignment, its analysis was extended to the general case more than a decade later by Hertli [8].

For graph coloring, i.e., the problem of deciding whether a graph is k -colorable, the naive exhaustive search algorithm takes $O(k^n)$ time. Nevertheless, it is known that computing the chromatic (or coloring) number of a graph (i.e., the smallest k for which the graph is k -colorable) can be done in exponential time that does not depend on k . The first such result was an $O^*(3^n)$ algorithm of Lawler [10]. A long line of works followed until finally an algorithm computing the chromatic number in $O^*(2^n)$ time was devised by Björklund, Husfeldt and Koivisto in 2009 [2]. This is conjectured to be optimal. For $k \leq 6$ there are algorithms solving k -colorability exponentially faster than $O(2^n)$ [1][20]. It is currently not known even if 7-coloring can be solved exponentially faster than the general $O(2^n)$ bound of computing the coloring number. One of the biggest open problems in this field is whether k -coloring can be solved in $O^*((2 - \varepsilon_k)^n)$ time for every fixed k .

Both examples are special cases of the more general Constraint Satisfaction Problem. In an (a, b) -formula, we have n variables such that each of them can take a value in $[a] := \{1, \dots, a\}$ and a list of constraints such that each constraint may depend on at most b variables. Every such constraint can be equivalently replaced by a disjunction of at most a^b constraints of the form $(x_1 \neq c_1 \vee x_2 \neq c_2 \vee \dots \vee x_b \neq c_b)$ where x_1, \dots, x_b are (not necessarily distinct) variables and $c_1, \dots, c_b \in [a]$ are possible values. Thus, we can think of every (a, b) -formula as a list of constraints of that form. In the (a, b) -CSP problem we are given a (a, b) -formula and need to decide whether or not there is an assignment to the variables that satisfies all constraints. In the Unique (a, b) -CSP problem we add the assumption that if there is such an assignment it is unique. Note that k -SAT is the same as $(2, k)$ -CSP, and that k -coloring is a special case of $(k, 2)$ -CSP. We later elaborate on the close relation between the $(k, 2)$ -CSP and k -coloring problems.

In this paper we focus on obtaining better algorithms for Unique $(k, 2)$ -CSP.

1.1 Possible running time

Denote by $c_{a,b}$ the infimum of constants c such that (a, b) -CSP on formulas with n variables can be solved in $O((c + o(1))^n)$ time. Naively, $c_{a,b} \leq a$ as we can simply try all a^n possible assignments to the variables. A simple improvement comes from the use of *down-sampling*. Given a (a, b) -formula we may randomly restrict each variable to $a' < a$ uniformly chosen values. Each satisfying assignment is not ruled out by the restriction with probability $\left(\frac{a'}{a}\right)^n$. After this down-sampling step, we are left with a (a', b) -formula. Thus, for every $a' < a$ we have $c_{a,b} \leq \frac{a}{a'} \cdot c_{a',b}$. In particular, $c_{a,b} \leq \frac{a}{2} c_{2,b}$. As we know that k -SAT can be solved exponentially faster than $O(2^n)$ for every fixed k , we have that $c_{2,b} < 2$ and in particular the strict inequality $c_{a,b} < a$ holds for every a, b .

On the other hand, (a, b) -CSP is clearly NP-Complete for every $a > 1$ except of the special case of $(a, b) = (2, 2)$ (which is the polynomial 2-SAT). The Exponential Time Hypothesis [3] states that there exists some constant $c > 0$ such that 3-SAT takes $\Omega(2^{cn})$ time to solve. Traxler [18] showed that assuming the Exponential Time Hypothesis, there exists some $c' > 0$ such that $c_{k,2} > k^{c'}$. Namely, even for $b = 2$ the $(k, 2)$ -CSP problem becomes strictly more complex as k increases.

■ **Table 1** Comparisons of the exponent base in Unique $(k, 2)$ -CSP algorithms.

k	Downsampling+2SAT	PPZ FM [4]	BE [1]	PPSZ [9]	Our algorithm
3	1.5	1.818	<i>1.365</i>	1.434	-
4	2	2.214	<i>1.808</i>	1.849	-
5	2.5	2.606	2.259	<i>2.254</i>	2.232
6	3	2.994	2.711	<i>2.652</i>	2.641
7	3.5	3.381	3.163	<i>3.045</i>	3.042

1.2 $(k, 2)$ -CSP and k -Coloring

Consider the following hierarchy of three problems:

- **k -Coloring:** given a graph with n vertices, determine whether it is k -colorable.
- **k -List-Coloring:** given a graph with n vertices and a list of at most k allowed colors (from a possibly larger universe of colors) for each vertex, determine if there is a proper coloring of the graph such that each vertex is colored with one of the allowed colors in its list.
- **$(k, 2)$ -CSP:** given n variables that can admit values from $[k]$ and a list of arbitrary constraints involving one or two variables each, determine if there is an assignment of values to the variables that satisfies all constraints.

Each problem is a special case of the next one. Every instance of k -coloring is also an instance of k -list-coloring where all lists are simply $[k]$. Every instance of k -list-coloring is also an instance of $(k, 2)$ -CSP. Nevertheless, while k -coloring and k -list-coloring can both be solved in $O^*(2^n)$ time regardless of k [2], Traxler's reduction [18] shows that there is some constant k_0 such that for every $k > k_0$ we have $c_{k,2} \geq 2$. Let k_0 be the minimal such constant. It is currently known that $c_{4,2} < 2$ and thus $k_0 \geq 4$.

In [20] it was recently shown that if k -list-coloring can be solved in $O^*((2 - \varepsilon)^n)$ time for some $\varepsilon > 0$ then $(k + 2)$ -coloring can also be solved in $O^*((2 - \varepsilon')^n)$ for some $\varepsilon' > 0$. In particular, $(k_0 + 2)$ -coloring can be solved exponentially faster than $O(2^n)$. As $k_0 \geq 4$, this resulted in the first $O^*((2 - \varepsilon)^n)$ time algorithms for 5-coloring and 6-coloring. This gives a strong motivation for improving upper bounds for $(k, 2)$ -CSP, with the goal of improving the bound on k_0 . In particular, showing that $(5, 2)$ -CSP can be solved in $O^*((2 - \varepsilon)^n)$ time would result in the first $O^*((2 - \varepsilon)^n)$ time algorithm for 7-coloring.

1.3 Previous results

By the down-sampling argument we can reduce $(k, 2)$ -CSP to the polynomial $(2, 2)$ -CSP (i.e., 2-SAT) and get an expected running time of $O\left(\left(\frac{k}{2}\right)^n\right)$. Beigel and Eppstein [1] gave an algorithm for $(k, 2)$ -CSP running in time $O((0.4518k)^n)$ for $k > 3$ and $O(1.356^n)$ for $k = 3$. Feder and Motwani [4] give a $(k, 2)$ -CSP algorithm based on the k -SAT PPZ algorithm, which is the predecessor of the PPSZ one. They improve on the bound of Beigel and Eppstein only for $k \geq 11$. Hertli, Hurbain, Millius, Moser, Scheder and Szedlák [9] improved the bounds for Unique $(k, 2)$ -CSP for every $k \geq 5$. Several other works [17] [11] [16] focus on the case where $b > 2$.

1.4 Our contribution

We present an algorithm that improves on the result of Hertli et al. and obtain better bounds for Unique $(k, 2)$ -CSP for $k \geq 5$. In particular, we improve the running time of Unique $(5, 2)$ -CSP from $O(2.254^n)$ to $O(2.232^n)$ and Unique $(6, 2)$ -CSP from $O(2.652^n)$ to $O(2.641^n)$. Our result is compared to the previous ones in Table 1.

We obtain our result by combining the strengths of both PPSZ and the Beigel-Eppstein algorithms. Intuitively, we make the following insight regarding PPSZ-type algorithms. Throughout the run of the PPSZ algorithm, it slowly manipulates the CSP formula. For every $k' < k$ there is some time-point such that if we stop the algorithm at that point then the formula roughly looks like a $(k', 2)$ -CSP formula. Furthermore, the rest of the algorithm run would have looked similar to running PPSZ on a $(k', 2)$ -formula. Thus, for $k \geq 5$ we may stop the run of the PPSZ algorithm when the formula looks similar to a $(4, 2)$ -CSP or $(3, 2)$ -CSP formula, and then switch to using the Beigel-Eppstein algorithm which is faster than PPSZ for $k \leq 4$.

In Section 2 we give an extensive overview of the previous results we need to use. Then in Section 3 we introduce our algorithm and obtain the improved bounds. In Section 4 we sketch possible improvements to the analysis of Section 3 and show that even with a completely ideal analysis of our algorithm we would improve the bound for $k = 5$ from $O(2.232^n)$ only to $O(2.223^n)$. Thus, to prove that $k_0 \geq 5$, if true, additional algorithmic tools are necessary. In Section 5 we conclude our work, discuss more possible uses for the PPSZ-related observations, and present open problems.

1.5 Comparison with a recent work of Li and Scheder

Recently, Li and Scheder [12] also published an improvement for the PPSZ-type algorithm of Hertli et al. for Unique CSP. Their algorithm does not use the Beigel-Eppstein algorithm and just modifies the PPSZ-type algorithm itself in a different manner to ours. They prove that this modification gives an exponential improvement over the bounds of Hertli et al., but do not give a quantitative bound of this improvement. We could not find a way to compute such a bound from their paper, but suspect this improvement is very small.

Li and Scheder also observe that during the run of the PPSZ-type algorithm when the number of color choices of a variable is very low (in their algorithm, when it reaches 2), then there are better ways to settle the value of the variable than continuing the run of the PPSZ algorithm. In their case, they do so by randomly picking one of the two colors for the variable.

Our work can be seen as a refinement of this idea in two different ways. First, we cut off the PPSZ run with small color sets yet larger than two. Second, we resolve the remaining instance with a variant of the Beigel-Eppstein algorithm, which is much better than a random choice.

2 Relevant overview of previous work

In this section we give an overview of all previous results that are used in our algorithm. We repeat and refine some of the theorems used in these papers for their later use in Section 3.

2.1 The algorithm of Beigel and Eppstein

The algorithm of Beigel and Eppstein [1] solves a CSP by performing a series of local reductions that either reduce the number of variables in the CSP or the number of allowed values in some of the variables.

An example for such a local reduction that is of particular interest to us follows.

► **Lemma 1** (Lemma 2 of [1]). *Let (V, F) be a CSP in which each variable $x \in V$ has $k(x)$ allowed values. Let x be a variable with $k(x) = 2$, then there exists a set F' of additional constraints, each of size two, such that (V, F) is satisfiable if and only if $(V \setminus \{x\}, F \cup F')$ is satisfiable, with the same number of allowed values for each variable $y \neq x$.*

The result claimed in [1] is that their algorithm solves $(3, 2)$ -CSPs in time $O(1.3645^n)$ and $(k, 2)$ -CSPs for $k > 3$ in time $O((0.4518k)^n)$. Note that $1.3645 > 1.3554 = 0.4518 \cdot 3$. In fact, the result proved in their paper is slightly stronger than that. The following Theorem follows from [1].

► **Theorem 2** (Section 5 of [1]). *Let (V, F) be a CSP with $|V| = n_3 + n_4$ variables such that n_3 variables have three allowed values and n_4 variables have four allowed values, then we can solve it in time $O(1.3645^{n_3} \cdot 1.8072^{n_4})$.*

The claimed results follow from Theorem 2 immediately. For $(3, 2)$ -CSPs we simply have $n_3 = n$, $n_4 = 0$ and for $(k, 2)$ -CSPs with $k > 3$ we down-sample each variable to 4 out of its k possible values and then use the theorem with $n_3 = 0$, $n_4 = n$, with a total expected run-time of $O\left(\left(\frac{k}{4}\right)^n \cdot 1.8072^n\right) = O((0.4518k)^n)$. Nevertheless, for our use we need to fully use the power of Theorem 2 and we even slightly refine it with the following statement, from now on referred to as *the extended BE algorithm*.

► **Theorem 3.** *Denote by*

$$BE(i) := \begin{cases} 1 & \text{if } i \leq 2 \\ 1.3645 & \text{if } i = 3. \\ 0.4518 \cdot i & \text{if } i \geq 4 \end{cases}$$

Let (V, F) be a CSP in which each variable $x \in V$ has $k(x)$ allowed values. Let n_i be the number of variables x in V such that $k(x) = i$. Then, we can solve (V, F) in $O(\prod_i BE(i)^{n_i})$ expected time.

Proof. The n_1 variables with a single possible value can be ignored. The n_2 variables with two possible values can be eliminated using Lemma 1. For every $i > 4$ we use down-sampling to reduce the number of allowed values to four. We finally apply Theorem 2. ◀

2.2 The PPZ and PPSZ-type algorithms

In this section we present an overview of [4] and [9]. We state theorems of both papers and their variants that are useful for our analysis, and adapt some of their notation. Throughout the section we discuss only instances with a unique satisfying assignment.

► **Definition 4** (*D-implication*). *Let F be a $(k, 2)$ -CSP formula over a set V of variables, $x \in V$ be a variable, $c \in [k]$ be a possible value, α_0 a partial assignment, and $D \in \mathbb{N}$. We say that α_0 *D-implies* $x \neq c$ and write $\alpha_0 \models_D (x \neq c)$ if there is a subset of constraints $G \subseteq F$ of size $|G| \leq D$ such that $G \wedge \alpha_0$ implies $(x \neq c)$.*

By enumeration, we can check whether $\alpha_0 \models_D (x \neq c)$ in $O(|F|^D \cdot \text{poly}(n))$ time, which is polynomial in n, k if D is a constant and sub-exponential in n even if D is a slow-enough growing function of n . For the rest of the section we fix D .

► **Definition 5** (*Eligible values*). *Let F be a $(k, 2)$ -CSP formula over a set V of variables, α_0 a partial assignment, and $x \in V \setminus V(\alpha_0)$ a variable which value is not assigned in α_0 . We denote by*

$$\mathcal{A}(x, \alpha_0) := \{c \in [k] \mid \alpha_0 \not\models_D (x \neq c)\}$$

the set of all possible values for x that are not ruled out by D -implication from α_0 .

92:6 Faster Algorithm for Unique $(k, 2)$ -CSP

We can now describe the PPSZ algorithm (adapted from SAT [14] to CSP in [9]). Given a $(k, 2)$ -CSP F , we begin with $\alpha_0 = \emptyset$ the empty assignment and incrementally add variables to it, hoping to finish with a satisfying assignment. In particular, we choose a permutation π of the variables V uniformly at random, and then choose an assignment for the variables of V one-by-one according to the order of π . When we reach a variable x , we compute $\mathcal{A}(x, \alpha_0)$ in sub-exponential time, pick a uniformly random $c \sim U(\mathcal{A}(x, \alpha_0))$, and extend α_0 by setting $\alpha_0(x) = c$.

■ **Algorithm 1** The PPSZ algorithm.

```

Pick a uniform random permutation  $\pi$  of the set  $V$  of variables;
Set  $\alpha_0 = \emptyset$ ;
for  $x \in V$  in the order dictated by  $\pi$  do
    | Draw  $c \sim U(\mathcal{A}(x, \alpha_0))$  uniformly;
    | Set  $\alpha_0(x) := c$ ;
Return  $\alpha_0$ ;

```

Algorithm 1 runs in sub-exponential time and returns some assignment α_0 to all variables of V . It is clear that the probability of α_0 to satisfy F , assuming that F is satisfiable, is at least k^{-n} . We next prove that for formulas F with exactly one satisfying assignment α , the probability that Algorithm 1 produces the satisfying assignment $\alpha_0 = \alpha$ is in fact exponentially larger. For the rest of the section we assume that F has a unique satisfying assignment and denote it by α .

► **Definition 6** (Ultimately eligible values). *Let F be a $(k, 2)$ -CSP formula uniquely satisfied by α , π be a permutation of its variables V and $x \in V$ some variable.*

We let $V_{\pi, x} := \{y \in V \mid \pi(y) < \pi(x)\}$ be the set of all variables appearing before x in π , $\alpha_{\pi, x} := \alpha|_{V_{\pi, x}}$ be the partial assignment resulting by restricting α to $V_{\pi, x}$ and then we denote by $\mathcal{A}(x, \pi) := \mathcal{A}(x, \alpha_{\pi, x})$ the set of all possible values for x that are not ruled out by D -implication when we reach x in a PPSZ iteration with permutation π , given that all previous variables were set correctly.

We observe that Algorithm 1 returns α if and only if it draws the correct value for *every* variable. In particular, for a specific permutation π the probability of success is exactly $\prod_{x \in V} \frac{1}{|\mathcal{A}(x, \pi)|}$. For a random permutation then, the probability of success is

$$\mathbb{E}_{\pi} \left[\prod_{x \in V} \frac{1}{|\mathcal{A}(x, \pi)|} \right] \geq k^{-\sum_{x \in V} \mathbb{E}_{\pi} [\log_k |\mathcal{A}(x, \pi)|]}$$

where we use Jensen's inequality. In particular, it is enough to give an upper bound on $\mathbb{E}_{\pi} [\log_k |\mathcal{A}(x, \pi)|]$ that holds for every variable x .

2.3 The PPZ-type algorithm of Feder and Motwani

In the PPZ-type variant of Feder and Motwani [4], a simpler variant where $D = 1$ is presented and analysed. Namely, a possible value c for a variable x is ruled out if and only if a variable y appeared before x in the permutation and was assigned a value c' such that the constraint $(x \neq c \vee y \neq c')$ appears in the list of constraints. When we reach the variable x , we uniformly guess a value for it out of all values that are not ruled out in that manner.

► **Lemma 7.** *Let (V, F) be the sets of variables and constraints in a Unique $(k, 2)$ -CSP. Denote by φ the unique satisfying assignment of (V, F) . For every variable $x \in V$ and every value $\varphi(x) \neq c' \in [k]$ other than the value x is assigned in φ , there exists a variable $y = y_{x,c'} \in V \setminus \{x\}$ such that $(x \neq c' \vee y \neq \varphi(y)) \in F$.*

Proof. Assume by contradiction that there exists a variable x and a value $c' \neq \varphi(x)$ for which $(x \neq c' \vee y \neq \varphi(y)) \notin F$ for every variable y . Consider the assignment φ' such that $\varphi'(x) = c'$ and $\varphi'(y) = \varphi(y)$ for every $y \neq x$. It is a satisfying assignment as well, and $\varphi' \neq \varphi$ which contradicts the uniqueness assumption. ◀

Instead of uniformly drawing a permutation $\pi \sim S_{|V|}$ of the variables, we (equivalently) independently draw a *time* value $\pi(x) \sim U([0, 1])$ uniformly for every variable x , and let π be the permutation induced by the order of the time values $\pi(x)$ for $x \in V$.

We observe that if $\pi(y_{x,c'}) < \pi(x)$ then $c' \notin \mathcal{A}(x, \pi)$. In particular, if $\pi(x) = p \in [0, 1]$ then for every $c' \neq \varphi(x)$ with probability at least p we have that $c' \notin \mathcal{A}(x, \pi)$.

► **Lemma 8.** *For every variable x , we have*

$$\mathbb{E}_\pi [\log_k |\mathcal{A}(x, \pi)| \mid \pi(x) = p] \leq \sum_{i=0}^{k-1} \binom{k-1}{i} (1-p)^i p^{k-1-i} \log_k(1+i).$$

Proof. For the analysis, we may assume that we rule out values only by the constraints involving x and one of the variables $y_{x,c'}$ for $c' \neq \varphi(x)$. This holds since ruling out more variables can only decrease the size of $\mathcal{A}(x, \pi)$.

If the variables $y_{x,c'}$ are distinct for all $c' \neq \varphi(x)$, then the right hand side of the lemma's statement is exactly the expected size of $\mathcal{A}(x, \pi)$, conditioned on $\pi(x) = p$. This is simply the expectation of $\log_k(1+i)$ where $i \sim \text{Binomial}(k-1, 1-p)$ is a binomial random variable.

Generally, let $A_{c'}$ be the indicator for the event that $\pi(y_{x,c'}) > p$. We need to upper bound $\mathbb{E}[\log_k(1 + \sum_{c' \neq \varphi(x)} A_{c'})]$. Let $A'_{c'}$ be independent Bernoulli random variables with probability $(1-p)$ to be 1 and probability p to be 0. By concavity of the function $\log_k(1+z)$ and Jensen's inequality it follows that $\mathbb{E}[\log_k(1 + \sum_{c' \neq \varphi(x)} A_{c'})] \leq \mathbb{E}[\log_k(1 + \sum_{c' \neq \varphi(x)} A'_{c'})]$, which concludes our proof. The complete proof of the last statement appears in [9] as Lemma A.1. ◀

Denote by $S'_{k,2} := \int_0^1 \sum_{i=0}^{k-1} \binom{k-1}{i} (1-p)^i p^{k-1-i} \log_k(1+i) dp$. By Lemma 8, $\mathbb{E}[\log_k |\mathcal{A}(x, \pi)|] = \int_0^1 \mathbb{E}_\pi [\log_k |\mathcal{A}(x, \pi)| \mid \pi(x) = p] dp \leq S'_{k,2}$, this concludes the analysis of the Feder-Motwani PPZ-type algorithm.

► **Theorem 9 ([4]).** *The success probability of a PPZ iteration is at least $k^{-S'_{k,2}}$.*

2.4 The PPSZ-type algorithm of Hertli et al.

In the PPSZ algorithm analysed in [9] more involved D -implications are considered. In the analysis for $D = 1$, we noticed that for every variable x and every value $c' \neq \varphi(x)$ there exists some variable $y_{x,c'}$ such that if $\pi(y_{x,c'}) < \pi(x)$ then $c' \notin \mathcal{A}(x, \pi)$.

We say that a variable y is *decided* with respect to some partial assignment α_0 if $|\mathcal{A}(y, \alpha_0)| = 1$, i.e., if α_0 already D -implies the correct value of y in φ . The main observation is that if in time $p := \pi(x)$ the variable $y_{x,c'}$ is decided then $c' \notin \mathcal{A}(x, \pi)$. The variable $y_{x,c'}$ is necessarily decided if $\pi(y_{x,c'}) < p$ but can also be decided if it is yet to appear in the permutation. Thus, the probability of $y_{x,c'}$ being decided at time p is strictly larger than p .

We give an intuitive reasoning for the probability of a variable being decided. Denote by $q_k(p)$ the probability that a variable x is decided by time p . The variable x is decided by time p if $\pi(x) < p$ or alternatively if for every $c' \neq \varphi(x)$ the variable $y_{x,c'}$ is by itself decided at time p . In particular, $q_k(p)$ is a solution to the recurrence $q_k(p) = p + (1 - p)q_k(p)^{k-1}$. We thus denote by $q_k(p)$ the smallest non-negative real solution to that recurrence, it can be analytically computed for every k as it is simply a root of a polynomial.

This intuitive argument is of course not complete and lacks many technical details. Nevertheless, this statement does hold, and the following strengthening of Lemma 8 and Theorem 9 are proven in [9].

► **Lemma 10** (A.1 in [9]). *For every variable x , we have*

$$\mathbb{E}_\pi [\log_k |\mathcal{A}(x, \pi)| \mid \pi(x) = p] \leq \sum_{i=0}^{k-1} \binom{k-1}{i} (1 - q_k(p))^i q_k(p)^{k-1-i} \log_k(1+i).$$

Denote by $S_{k,2} := \int_0^1 \sum_{i=0}^{k-1} \binom{k-1}{i} (1 - q_k(p))^i q_k(p)^{k-1-i} \log_k(1+i) dp$.

► **Theorem 11** (Correctness of [9]). *Let F be a Unique $(k, 2)$ -CSP formula, then for every variable x it holds that $\mathbb{E}_\pi [\log_k |\mathcal{A}(x, \pi)|] \leq S_{k,2} + \varepsilon_D$, where ε_D is some error parameter that depends only on D and goes to 0 as D goes to infinity.*

3 Faster Unique $(k, 2)$ -CSP algorithm

On a very high-level, our algorithm combines Hertli et al.'s PPSZ (Section 2.2) with the BE algorithm (Section 2.1). We begin by illustrating our idea intuitively (initially ignoring some crucial technical details to be discussed later). Consider a run of the PPSZ algorithm, as described in Section 2.2. For the early variables in the permutation π , it is very likely that $|\mathcal{A}(x, \pi)| = k$, since α_0 assigns values to very few variables. On the other hand, for the last variables in the permutation, it is very likely that $|\mathcal{A}(x, \pi)| = 1$. It turns out that in any point throughout the run of a PPSZ iteration, the sizes $|\mathcal{A}(x, \alpha_0)|$ for the remaining variables $x \in V \setminus V(\alpha_0)$ are quite concentrated. Furthermore, after most of the variables have $|\mathcal{A}(x, \alpha_0)| \approx k' < k$ the remaining portion of the PPSZ iteration strongly resembles a PPSZ algorithm for $(k', 2)$ -CSP formulas. As we see in Table 1, for $k < 5$ PPSZ behaves worse on $(k, 2)$ -CSP formulas than the BE algorithm.

Thus, in our algorithm, we begin with an iteration of PPSZ but halt it somewhere in the middle of the permutation when the sizes $|\mathcal{A}(x, \alpha_0)|$ are concentrated in 1, 2, 3, 4. At that point, we use the extended BE algorithm shown in Section 2.1.

We set some parameter $t \in [0, 1]$ to be chosen later and consider the following algorithm.

■ **Algorithm 2** Our algorithm.

Pick a uniform random permutation π of the set V of variables;
 Denote by $\pi_{<t}$ the prefix of π of size $t|V|$ and by $V_{<t}$ the variables appearing in it;
 Set $\varphi = \emptyset$;
for $x \in V_{<t}$ *in the order dictated by $\pi_{<t}$* **do**
 | Draw $c \sim U(\mathcal{A}(x, \varphi))$ uniformly;
 | Set $\varphi(x) := c$;
 Run the extended BE algorithm on the remaining CSP F ;
 Return the solution φ ;

Consider an iteration of Algorithm 2. Denote by R_i the number of variables that appeared in $V_{<t}$ and had $|\mathcal{A}(x, \pi)| = i$. Denote by φ' the partial assignment constructed by time t . Let B_i be the number of variables that did not appear in $V_{<t}$ and had $|\mathcal{A}(x, \varphi')| = i$.

► **Lemma 12.** *The success probability of Algorithm 2 is $\prod_{i=1}^k i^{-R_i} \cdot \prod_{i=5}^k \left(\frac{4}{i}\right)^{B_i}$.*

Proof. The probability of all PPSZ assignments to be correct is $\prod_{i=1}^k i^{-R_i}$, as follows from Section 2.2. The probability of the random down-sampling to not rule out the correct assignments is $\prod_{i=5}^k \left(\frac{4}{i}\right)^{B_i}$. ◀

► **Lemma 13.** *The running time of Algorithm 2 is $O(1.3645^{B_3} \cdot 1.8072^{B_4+\dots+B_k})$.*

Proof. The running time of the (partial) PPSZ iteration is polynomial. The running time of the BE algorithm is $O(1.3645^{n_3} \cdot 1.8072^{n_4})$. ◀

Note that all R_i and B_i are fully determined by the choice of π . Thus, for a specific choice of π , if we repeatedly run Algorithm 2 with π we expect finding a solution after $\left(\prod_{i=1}^k i^{-R_i} \cdot \prod_{i=5}^k \left(\frac{4}{i}\right)^{B_i}\right)^{-1}$ iterations. In particular, after

$$\left(\prod_{i=1}^k i^{-R_i} \cdot \prod_{i=5}^k \left(\frac{4}{i}\right)^{B_i}\right)^{-1} \cdot O(1.3645^{B_3} \cdot 1.8072^{B_4+\dots+B_k}) = \prod_{i=1}^k i^{R_i} \cdot \prod_i BE(i)^{B_i}$$

computational steps. At this point, we would like to bound the expected running time when picking a random π with $\prod_{i=1}^k i^{\mathbb{E}[R_i]} \cdot \prod_i BE(i)^{\mathbb{E}[B_i]}$. Unfortunately, as we consider the running time and not a success probability (as in the PPSZ algorithm), we need an inequality of the opposite direction to Jensen's inequality. Fortunately, this inequality *essentially still holds* in this case.

► **Lemma 14** (Wrong direction Jensen's inequality is still kind-of right). *Let \mathcal{A} be an algorithm with expected running time 2^X conditioned on the value of a random variable X . There exists an algorithm \mathcal{A}' that successfully executes \mathcal{A} with probability at least 0.99 and has an expected running time of $O(2^{\mathbb{E}[X]} \cdot \mathbb{E}[X])$.*

Proof. We apply Markov's inequality twice. First, to observe that

$$\Pr(X > \mathbb{E}[X] + 1) \leq \frac{1}{1 + \frac{1}{\mathbb{E}[X]}} = 1 - \frac{1}{\mathbb{E}[X] + 1}.$$

Hence, if we run \mathcal{A} independently for $6(\mathbb{E}[X] + 1)$ times, then with probability at least $1 - e^{-6} > 1 - \frac{1}{200}$ at least one of these runs has $X \leq \mathbb{E}[X] + 1$. Second, conditioned on any value of X , with probability at least $1 - \frac{1}{200}$ algorithm \mathcal{A} finishes in less than $200 \cdot 2^X$ computational steps. Thus, by union bound, if we run algorithm \mathcal{A} for $6(\mathbb{E}[X] + 1)$ times, and terminate each run after $400 \cdot 2^{\mathbb{E}[X]}$ computational steps, then at least one run of \mathcal{A} finishes with probability at least 0.99. ◀

► **Corollary 15.** *We find a satisfying assignment with probability greater than 0.99 in time*

$$O^* \left(\prod_{i=1}^k i^{\mathbb{E}[R_i]} \cdot \prod_i BE(i)^{\mathbb{E}[B_i]} \right). \quad (\star)$$

92:10 Faster Algorithm for Unique $(k, 2)$ -CSP

We give a simpler analysis leading to slightly sub-optimal bounds. In Section 4 we sketch the possible improvements to the analysis presented here, and also present a clear limit to the improvements that can be achieved by this algorithm.

We slightly abuse notation by equating the numbers R_i, B_i with the sets of variables they are counting. Let x be a variable. For the analysis we can assume that the algorithm rules out values for x only due to the constraints involving x and some $y_{x,c'}$. This holds as ruling out more values can only improve the success probability of each iteration.

We first consider the case in which the variables $y_{x,c'}$ for every $c' \neq \varphi(x)$ are all distinct.

► **Lemma 16.** *For each variable x , we have*

$$\mathbb{E} \left[\sum_{i=1}^k Pr(x \in R_i) \cdot \log_k i \right] \leq \int_0^t \sum_{i=0}^{k-1} \binom{k-1}{i} (1 - q_k(p))^i q_k(p)^{k-1-i} \log_k(1+i) dp.$$

Proof. This follows immediately from Lemma 10. ◀

► **Lemma 17.** *Let x be a variable for which $y_{x,c'}$ are distinct for all $c' \neq \varphi(x)$. Then,*

$$\mathbb{E} \left[\sum_{i=3}^k Pr(x \in B_i) \cdot \log_k EB(i) \right] \leq (1-t) \cdot \sum_{i=3}^k \binom{k-1}{i} (1-t)^i t^{k-1-i} \cdot \log_k EB(i).$$

Proof. For simplicity, we analyse this part with a PPZ-type analysis (rather than PPSZ-type one), this is further discussed in Section 4. The probability that $x \notin V_{<t}$ is $(1-t)$, and the probability that exactly i out of the $(k-1)$ variables $y_{x,c'}$ do not appear in $V_{<t}$ is $\binom{k-1}{i} (1-t)^i t^{k-1-i}$. ◀

Denote by

$$\begin{aligned} \text{cost}(k, t) &:= \int_0^t \sum_{i=0}^{k-1} \binom{k-1}{i} (1 - q_k(p))^i q_k(p)^{k-1-i} \log_k(1+i) dp \\ &\quad + (1-t) \cdot \sum_{i=3}^k \binom{k-1}{i} (1-t)^i t^{k-1-i} \cdot \log_k EB(i). \end{aligned}$$

If all variables had completely distinct $y_{x,c'}$'s, then by Lemma 16 and Lemma 17 we would have that (\star) and in particular the running time of our algorithm is bounded by $O(k^{\text{cost}(k,t)n})$ for any choice of t . This would give us $O(2.22936^n)$ for $k=5, t=0.23$ and $O(2.64001^n)$ for $k=6, t=0.35$. We now deal with the case in which these are not distinct.

In the proof of Lemma 8 we faced the same problem and solved it by a simple application of Jensen's inequality to the concave function $\log_k(1+i)$. Unfortunately, the function $\log_k EB(i)$ is not concave (for $i=1, \dots, k$) due to its values on $i=1, 2$. Indeed, the left-hand side of the inequality in Lemma 17 is higher than the right-hand side if these variables are not distinct. On the other hand, when these variables are not distinct then the term of Lemma 16 is much smaller.

Consider the expression

$$\mathbb{E} \left[\sum_{i=1}^k Pr(x \in R_i) \cdot \log_k i + \sum_{i=3}^k Pr(x \in B_i) \cdot \log_k EB(i) \right] \quad (\star\star)$$

again. This time, we will assume that the variables $y_{x,c'}$ are not all distinct. Denote by $k' := |\{y_{x,c'} \mid c' \neq \varphi(x)\}| < k-1$ the number of such distinct variables, and by $j_1, \dots, j_{k'}$ their cardinalities (note that $\sum_{i=1}^{k'} j_i = k-1$). Consider the following expression.

$$\mathbb{E} \left[\int_0^t \sum_{b_1, \dots, b_{k'} \in \{0,1\}} q_k(p)^{k' - \sum_{i=1}^{k'} b_i} \cdot (1 - q_k(p))^{\sum_{i=1}^{k'} b_i} \cdot \log_k \left(1 + \sum_{i=1}^{k'} j_i b_i \right) dp \quad (\star\star\star) \right. \\ \left. + (1 - t) \cdot \sum_{b_1, \dots, b_{k'} \in \{0,1\}} t^{k' - \sum_{i=1}^{k'} b_i} \cdot (1 - t)^{\sum_{i=1}^{k'} b_i} \cdot \log_k EB \left(1 + \sum_{i=1}^{k'} j_i b_i \right) \right].$$

Expression $(\star\star\star)$ is a generalized form of $\text{cost}(k, t)$ and thus upper bounds $(\star\star)$ by the same arguments. Completely analysing the behaviour of Expression $(\star\star\star)$ for different partitions is rather technically involved and thus we simply enumerate over the few possible cases (for small values of k). In Section 4 we further discuss the possible improvements to the analysis of this section.

► **Theorem 18.** *We solve Unique $(6, 2)$ -CSP in $O(2.641^n)$ time.*

Proof. For the choice $t = 0.37$ we have that $\text{cost}(6, 0.35) = \log_6(2.64001)$, this choice of t minimizes $\text{cost}(6, t)$. We verify that for $t = 0.35$ Expression $(\star\star\star)$ is always lower than $\text{cost}(6, 0.35)$ and thus finish, as this implies that for every variable Expression $(\star\star)$ is bounded by $\text{cost}(6, 0.35)$.

- For the partition $(j_1, j_2, j_3, j_4) = (2, 1, 1, 1)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.62023)$.
- For the partition $(j_1, j_2, j_3) = (2, 2, 1)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.61171)$.
- For the partition $(j_1, j_2, j_3) = (3, 1, 1)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.58391)$.
- For the partition $(j_1, j_2) = (3, 2)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.60366)$.
- For the partition $(j_1, j_2) = (4, 1)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.54819)$.
- For the partition $(j_1) = (5)$ the value of $(\star\star\star)$ in $t = 0.35$ is $\log_6(2.55566)$. ◀

► **Theorem 19.** *We solve Unique $(5, 2)$ -CSP in $O(2.232^n)$ time.*

Proof. For the choice $t = 0.23$ we have that $\text{cost}(5, 0.23) = \log_5(2.22936)$, this choice of t minimizes $\text{cost}(5, t)$. This time, unfortunately, for $t = 0.23$ Expression $(\star\star\star)$ is not always lower than $\text{cost}(5, 0.23)$. In particular, it is for every partition except of $(j_1) = 4$.

- For the partition $(j_1, j_2, j_3) = (2, 1, 1)$ the value of $(\star\star\star)$ in $t = 0.23$ is $\log_5(2.21658)$.
- For the partition $(j_1, j_2) = (2, 2)$ the value of $(\star\star\star)$ in $t = 0.23$ is $\log_5(2.21983)$.
- For the partition $(j_1, j_2) = (3, 1)$ the value of $(\star\star\star)$ in $t = 0.23$ is $\log_5(2.20499)$.
- For the partition $(j_1) = (4)$ the value of $(\star\star\star)$ in $t = 0.23$ is $\log_5(2.24925)$.

Denote by α the fraction of variables for which the $y_{x,c'}$ variables are all the same (i.e., variables with the only problematic partition). With the choice $t = 0.23$ the running time of our algorithm on a formula is $O\left((2.22936^{(1-\alpha)} \cdot 2.24925^\alpha)^n\right)$. On the other hand, if α is large we can simply run the regular PPSZ algorithm and gain much. We see that by setting $t = 1$ and computing Expression $(\star\star\star)$ for the same partition $(j_1) = (4)$, gives a value of $\log_5(2.01077)$. Thus, running regular PPSZ would give us a running time of $O\left((2.25303^{(1-\alpha)} \cdot 2.01077^\alpha)^n\right)$. We can therefore try both options ($t = 0.23$ or $t = 1$) simultaneously and thus get the running time of the faster one. Both expressions balance at $\alpha = 0.08612$, giving us a running time of $O(2.23107^n)$. ◀

Computation identical to this of Theorem 18 gives running time of $O(3.042^n)$ for $k = 7$ with $t = 0.44$.

4 Improvements and Limitations

In this section we sketch a possible improvement to the analysis of Section 3. The purpose of this section is not to tighten the upper bound but to explain the limitations of our algorithm and to convince that even with a tight analysis of Algorithm 2 it will achieve running times that are only slightly better than these we get in Section 3. In particular, if getting $O((2 - \varepsilon)^n)$ time for $(5, 2)$ -CSP is possible, new algorithmic tools are likely required.

Consider the expression $\prod_{i=1}^k i^{\mathbb{E}[R_i]} \cdot \prod_i EB(i)^{\mathbb{E}[B_i]}$ (\star) proven in Section 3 to upper bound the running time of our algorithm. In Lemma 16 we give a likely tight bound for the term involving $\mathbb{E}[R_i]$, yet in Lemma 17 we settle for a PPZ-type bound for $\mathbb{E}[B_i]$ in which we consider only the events in which the variables $y_{x,c'}$ themselves appear before time t and not the events in which they are decided by that time. The reason for this discrepancy becomes clear in the rest of the analysis. Due to the non-concave objective function in i , we can no longer assume independence between the events of each $y_{x,c'}$ being decided. Nevertheless, later in Theorem 18 and Theorem 19 we observe that while the term involving $\mathbb{E}[B_i]$ indeed gets worse with dependencies, the other term involving $\mathbb{E}[R_i]$ gets significantly better with them and thus can cover for those dependencies. Ideally, then, the simple PPZ-type bound of t in Lemma 17 can be replaced with the PPSZ-type bound of $q_k(t)$ in the total bound. This would result in the following tighter cost function.

$$\begin{aligned} \tilde{\text{cost}}(k, t) := & \int_0^t \sum_{i=0}^{k-1} \binom{k-1}{i} (1 - q_k(p))^i q_k(p)^{k-1-i} \log_k(1+i) dp \\ & + (1-t) \cdot \sum_{i=3}^k \binom{k-1}{i} (1 - q_k(t))^i q_k(t)^{k-1-i} \cdot \log_k EB(i). \end{aligned}$$

With this ideal cost function, we would get running times of $O(2.223^n)$ for Unique $(5, 2)$ -CSP (for $t = 0.32$) and $O(2.628^n)$ for Unique $(6, 2)$ -CSP (for $t = 0.46$).

5 Conclusions and Open Problems

In Section 3 we presented an algorithm for Unique $(k, 2)$ -CSP with a running time of $O(2.232^n)$ for $k = 5$. In Section 4 we argued that even with an ideal analysis, the bound we get for $k = 5$ is only the slightly better $O(2.223^n)$. Thus, it remains open and would likely require new algorithmic tools to show that $(5, 2)$ -CSP can be solved in $O((2 - \varepsilon)^n)$ time, or alternatively to rule out the existence of such algorithm by reductions to popular conjectures. More generally, we raise the following open problem.

► **Open Problem.** *What is the maximal k such that $(k, 2)$ -CSP can be solved in $O((2 - \varepsilon)^n)$ time?*

The main algorithmic observation in this paper is in fact a general insight regarding the behaviour of PPSZ-type algorithms. The Beigel-Eppstein algorithm [1] only works for $(k, 2)$ -CSP. On the other hand, the PPSZ-type algorithm [9] generalizes to $b > 2$ and is in fact currently the fastest algorithm for Unique (a, b) -CSP with $b > 2$ and any a . Using the tools we introduced in this paper, it should be possible to turn any faster algorithm for (a, b) -CSP for a specific (a, b) into a faster (a', b) -CSP algorithm for all $a' > a$.

Another follow-up question is whether our algorithm can be generalized to the non-unique $(k, 2)$ -CSP case.
