Regular Papers

Enumerating Minimal Connected Dominating Sets	
<i>Faisal N. Abu-Khzam, Henning Fernau, Benjamin Gras, Mathieu Liedloff, and Kevin Mann</i>	1:1–1:15
Non-Adaptive Edge Counting and Sampling via Bipartite Independent Set Queries	
<i>Raghavendra Addanki, Andrew McGregor, and Cameron Musco</i>	2:1–2:16
Hardness of Token Swapping on Trees	
<i>Oswin Aichholzer, Erik D. Demaine, Matias Korman, Anna Lubiw, Jayson Lynch, Zuzana Masárová, Mikhail Rudoy, Virginia Vassilevska Williams, and Nicole Wein</i>	3:1–3:15
Tight Bounds for Online Matching in Bounded-Degree Graphs with Vertex Capacities	
<i>Susanne Albers and Sebastian Schubert</i>	4:1–4:16
TSP in a Simple Polygon	
<i>Henk Alkema, Mark de Berg, Morteza Monemizadeh, and Leonidas Theocharous</i> ..	5:1–5:14
Classical and Quantum Algorithms for Variants of Subset-Sum via Dynamic Programming	
<i>Jonathan Allcock, Yassine Hamoudi, Antoine Joux, Felix Klingelhöfer, and Miklos Santha</i>	6:1–6:18
Techniques for Generalized Colorful k -Center Problems	
<i>Georg Anegg, Laura Vargas Koch, and Rico Zenklusen</i>	7:1–7:14
Simple Streaming Algorithms for Edge Coloring	
<i>Mohammad Ansari, Mohammad Saneian, and Hamid Zarrabi-Zadeh</i>	8:1–8:4
Computing Smallest Convex Intersecting Polygons	
<i>Antonios Antoniadis, Mark de Berg, Sándor Kisfaludi-Bak, and Antonis Skarlatos</i> ..	9:1–9:13
The Price of Hierarchical Clustering	
<i>Anna Arutyunova and Heiko Röglin</i>	10:1–10:14
Bounding and Computing Obstacle Numbers of Graphs	
<i>Martin Balko, Steven Chaplick, Robert Ganian, Siddharth Gupta, Michael Hoffmann, Pavel Valtr, and Alexander Wolff</i>	11:1–11:13

30th Annual European Symposium on Algorithms (ESA 2022).

Leibniz International Proceedings in Informatics

LIPIC Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Computing NP-Hard Repetitiveness Measures via MAX-SAT <i>Hideo Bannai, Keisuke Goto, Masakazu Ishihata, Shunsuke Kanda, Dominik Köppl, and Takaaki Nishimoto</i>	12:1–12:16
Online Metric Allocation and Time-Varying Regularization <i>Nikhil Bansal and Christian Coester</i>	13:1–13:13
An Upper Bound on the Number of Extreme Shortest Paths in Arbitrary Dimensions <i>Florian Barth, Stefan Funke, and Claudius Proissl</i>	14:1–14:12
Galactic Token Sliding <i>Valentin Bartier, Nicolas Bousquet, and Amer E. Mouawad</i>	15:1–15:14
When Are Cache-Oblivious Algorithms Cache Adaptive? A Case Study of Matrix Multiplication and Sorting <i>Arghya Bhattacharya, Abiyaz Chowdhury, Helen Xu, Rathish Das, Rezaul A. Chowdhury, Rob Johnson, Rishab Nithyanand, and Michael A. Bender</i>	16:1–16:17
Simple Dynamic Spanners with Near-Optimal Recourse Against an Adaptive Adversary <i>Sayan Bhattacharya, Thatchaphol Saranurak, and Pattara Sukprasert</i>	17:1–17:19
Online Spanners in Metric Spaces <i>Sujoy Bhore, Arnold Filtser, Hadi Khodabandeh, and Csaba D. Tóth</i>	18:1–18:20
Sparse Temporal Spanners with Low Stretch <i>Davide Bilò, Gianlorenzo D’Angelo, Luciano Gualà, Stefano Leucci, and Mirko Rossi</i>	19:1–19:16
Resource Sharing Revisited: Local Weak Duality and Optimal Convergence <i>Daniel Blankenburg</i>	20:1–20:14
On the External Validity of Average-Case Analyses of Graph Algorithms <i>Thomas Bläsius and Philipp Fischbeck</i>	21:1–21:14
On Polynomial Kernels for Traveling Salesperson Problem and Its Generalizations <i>Václav Blažej, Pratibha Choudhary, Dušan Knop, Šimon Schierreich, Ondřej Suchý, and Tomáš Valla</i>	22:1–22:16
Maximizing Sums of Non-Monotone Submodular and Linear Functions: Understanding the Unconstrained Case <i>Kobi Bodek and Moran Feldman</i>	23:1–23:17
List Colouring Trees in Logarithmic Space <i>Hans L. Bodlaender, Carla Groenland, and Hugo Jacob</i>	24:1–24:15
Dynamic Coloring of Unit Interval Graphs with Limited Recourse Budget <i>Bartłomiej Bosek and Anna Zych-Pawlewicz</i>	25:1–25:14
Polynomial Kernel for Immersion Hitting in Tournaments <i>Łukasz Bożyk and Michał Pilipczuk</i>	26:1–26:17
A Systematic Study of Isomorphism Invariants of Finite Groups via the Weisfeiler-Leman Dimension <i>Jendrik Brachter and Pascal Schweitzer</i>	27:1–27:14

Faster Approximate Covering of Subcurves Under the Fréchet Distance <i>Frederik Brünig, Jacobus Conradi, and Anne Driemel</i>	28:1–28:16
Efficient Fréchet Distance Queries for Segments <i>Maïke Buchin, Ivor van der Hoog, Tim Ophelders, Lena Schlipf, Rodrigo I. Silveira, and Frank Staals</i>	29:1–29:14
Search-Space Reduction via Essential Vertices <i>Benjamin Merlin Bumpus, Bart M. P. Jansen, and Jari J. H. de Kroon</i>	30:1–30:15
Width Helps and Hinders Splitting Flows <i>Manuel Cáceres, Massimo Cairo, Andreas Grigorjew, Shahbaz Khan, Brendan Mumey, Romeo Rizzi, Alexandru I. Tomescu, and Lucia Williams</i>	31:1–31:14
Counting Simplices in Hypergraph Streams <i>Amit Chakrabarti and Themistoklis Haris</i>	32:1–32:19
Approximation Algorithms for Continuous Clustering and Facility Location Problems <i>Deeparnab Chakrabarty, Maryam Negahbani, and Ankita Sarkar</i>	33:1–33:15
Distinct Elements in Streams: An Algorithm for the (Text) Book <i>Sourav Chakraborty, N. V. Vinodchandran, and Kuldeep S. Meel</i>	34:1–34:6
Approximate Circular Pattern Matching <i>Panagiotis Charalampopoulos, Tomasz Kociumaka, Jakub Radoszewski, Solon P. Pissis, Wojciech Rytter, Tomasz Waleń, and Wiktor Zuba</i>	35:1–35:19
Multi-Dimensional Stable Roommates in 2-Dimensional Euclidean Space <i>Jiehua Chen and Sanjukta Roy</i>	36:1–36:16
Spanner Approximations in Practice <i>Markus Chimani and Finn Stutzenstein</i>	37:1–37:15
Determinants from Homomorphisms <i>Radu Curticapean</i>	38:1–38:7
Conditional Lower Bounds for Dynamic Geometric Measure Problems <i>Justin Dallant and John Iacono</i>	39:1–39:17
A Simpler QPTAS for Scheduling Jobs with Precedence Constraints <i>Syamantak Das and Andreas Wiese</i>	40:1–40:11
A Polynomial-Time Algorithm for 1/3-Approximate Nash Equilibria in Bimatrix Games <i>Argyrios Deligkas, Michail Fasoulakis, and Evangelos Markakis</i>	41:1–41:14
Near Optimal Algorithm for Fault Tolerant Distance Oracle and Single Source Replacement Path Problem <i>Dipan Dey and Manoj Gupta</i>	42:1–42:18
Fast Computation of Zigzag Persistence <i>Tamal K. Dey and Tao Hou</i>	43:1–43:15
Turbocharging Heuristics for Weak Coloring Numbers <i>Alexander Dobler, Manuel Sorge, and Anaïs Villedieu</i>	44:1–44:18

A Local Search Algorithm for Large Maximum Weight Independent Set Problems <i>Yuanyuan Dong, Andrew V. Goldberg, Alexander Noe, Nikos Parotsidis, Mauricio G.C. Resende, and Quico Spaen</i>	45:1–45:16
SAT Backdoors: Depth Beats Size <i>Jan Dreier, Sebastian Ordyniak, and Stefan Szeider</i>	46:1–46:18
Finding a Cluster in Incomplete Data <i>Eduard Eiben, Robert Ganian, Iyad Kanj, Sebastian Ordyniak, and Stefan Szeider</i>	47:1–47:14
Lyndon Arrays Simplified <i>Jonas Ellert</i>	48:1–48:14
Learning-Augmented Query Policies for Minimum Spanning Tree with Uncertainty <i>Thomas Erlebach, Murilo Santos de Lima, Nicole Megow, and Jens Schlöter</i>	49:1–49:18
Faster Exponential-Time Approximation Algorithms Using Approximate Monotone Local Search <i>Bariş Can Esmer, Ariel Kulik, Dániel Marx, Daniel Neuen, and Roohani Sharma</i>	50:1–50:19
Intersection Searching Amid Tetrahedra in 4-Space and Efficient Continuous Collision Detection <i>Esther Ezra and Micha Sharir</i>	51:1–51:17
Submodular Maximization Subject to Matroid Intersection on the Fly <i>Moran Feldman, Ashkan Norouzi-Fard, Ola Svensson, and Rico Zenklusen</i>	52:1–52:14
There and Back Again: On Applying Data Reduction Rules by Undoing Others <i>Aleksander Figiel, Vincent Froese, André Nichterlein, and Rolf Niedermeier</i>	53:1–53:15
Improved Search of Relevant Points for Nearest-Neighbor Classification <i>Alejandro Flores-Velazco</i>	54:1–54:10
Longest Cycle Above Erdős–Gallai Bound <i>Fedor V. Fomin, Petr A. Golovach, Danil Sagunov, and Kirill Simonov</i>	55:1–55:15
Improved Polynomial-Time Approximations for Clustering with Minimum Sum of Radii or Diameters <i>Zachary Friggstad and Mahya Jamshidian</i>	56:1–56:14
Simple Worst-Case Optimal Adaptive Prefix-Free Coding <i>Travis Gagie</i>	57:1–57:5
Taming Graphs with No Large Creatures and Skinny Ladders <i>Jakub Gajarský, Lars Jaffke, Paloma T. Lima, Jana Novotná, Marcin Pilipczuk, Paweł Rzażewski, and Uéverton S. Souza</i>	58:1–58:8
Faster Path Queries in Colored Trees via Sparse Matrix Multiplication and Min-Plus Product <i>Younan Gao and Meng He</i>	59:1–59:15
Computing the 4-Edge-Connected Components of a Graph: An Experimental Study <i>Loukas Georgiadis, Giuseppe F. Italiano, and Evangelos Kosinas</i>	60:1–60:16
Algorithmic Meta-Theorems for Combinatorial Reconfiguration Revisited <i>Tatsuya Gima, Takehiro Ito, Yasuaki Kobayashi, and Yota Otachi</i>	61:1–61:15

Efficient Recognition of Subgraphs of Planar Cubic Bridgeless Graphs <i>Miriam Goetze, Paul Jungeblut, and Torsten Ueckerdt</i>	62:1–62:14
Adaptive-Adversary-Robust Algorithms via Small Copy Tree Embeddings <i>Bernhard Haepler, D. Ellis Hershkowitz, and Goran Zuzic</i>	63:1–63:14
Hedonic Games and Treewidth Revisited <i>Tesshu Hanaka and Michael Lampis</i>	64:1–64:16
Fine-Grained Complexity Lower Bounds for Families of Dynamic Graphs <i>Monika Henzinger, Ami Paz, and A. R. Sricharan</i>	65:1–65:14
$O(1)$ Steiner Point Removal in Series-Parallel Graphs <i>D. Ellis Hershkowitz and Jason Li</i>	66:1–66:17
Chromatic k -Nearest Neighbor Queries <i>Thijs van der Horst, Maarten Löffler, and Frank Staals</i>	67:1–67:14
Maximum Weight b -Matchings in Random-Order Streams <i>Chien-Chung Huang and François Sellier</i>	68:1–68:14
Embedding Phylogenetic Trees in Networks of Low Treewidth <i>Leo van Iersel, Mark Jones, and Mathias Weller</i>	69:1–69:14
Vertex Sparsifiers for Hyperedge Connectivity <i>Han Jiang, Shang-En Huang, Thatchaphol Saranurak, and Tian Zhang</i>	70:1–70:13
Approximation Algorithms for Round-UFP and Round-SAP <i>Debajyoti Kar, Arindam Khan, and Andreas Wiese</i>	71:1–71:19
Optimizing Safe Flow Decompositions in DAGs <i>Shahbaz Khan and Alexandru I. Tomescu</i>	72:1–72:17
Scheduling Kernels via Configuration LP <i>Dušan Knop and Martin Koutecký</i>	73:1–73:15
Abstract Morphing Using the Hausdorff Distance and Voronoi Diagrams <i>Lex de Kogel, Marc van Kreveld, and Jordi L. Vermeulen</i>	74:1–74:16
Average Sensitivity of the Knapsack Problem <i>Soh Kumabe and Yuichi Yoshida</i>	75:1–75:14
Cardinality Estimation Using Gumbel Distribution <i>Aleksander Łukasiewicz and Przemysław Uznański</i>	76:1–76:13
(In-)Approximability Results for Interval, Resource Restricted, and Low Rank Scheduling <i>Marten Maack, Simon Pukrop, and Anna Rodriguez Rasmussen</i>	77:1–77:13
Localized Geometric Moves to Compute Hyperbolic Structures on Triangulated 3-Manifolds <i>Clément Maria and Owen Rouillé</i>	78:1–78:13
Computing Treedepth in Polynomial Space and Linear FPT Time <i>Wojciech Nadara, Michał Pilipeczuk, and Marcin Smulewicz</i>	79:1–79:14
The Pareto Cover Problem <i>Bento Natura, Meike Neuwöhner, and Stefan Weltge</i>	80:1–80:12

A Unified Framework for Hopsets <i>Ofer Neiman and Idan Shabat</i>	81:1–81:13
Data Structures for Node Connectivity Queries <i>Zeev Nutov</i>	82:1–82:12
Improved Bounds for Online Balanced Graph Re-Partitioning <i>Rajmohan Rajaraman and Omer Wasim</i>	83:1–83:15
An Empirical Evaluation of k -Means Coresets <i>Chris Schwegelshohn and Omar Ali Sheikh-Omar</i>	84:1–84:17
An Improved Algorithm for Finding the Shortest Synchronizing Words <i>Marek Szykula and Adam Zyzik</i>	85:1–85:15
Fast RSK Correspondence by Doubling Search <i>Alexander Tiskin</i>	86:1–86:10
Insertion Time of Random Walk Cuckoo Hashing below the Peeling Threshold <i>Stefan Walzer</i>	87:1–87:11
ParGeo: A Library for Parallel Computational Geometry <i>Yiqiu Wang, Rahul Yesantharao, Shangdi Yu, Laxman Dhulipala, Yan Gu, and Julian Shun</i>	88:1–88:19
Combining Predicted and Live Traffic with Time-Dependent A^* Potentials <i>Nils Werner and Tim Zeitz</i>	89:1–89:15
Approximating Dynamic Time Warping Distance Between Run-Length Encoded Strings <i>Zoe Xi and William Kuszmaul</i>	90:1–90:19
Correlated Stochastic Knapsack with a Submodular Objective <i>Sheng Yang, Samir Khuller, Sunav Choudhary, Subrata Mitra, and Kanak Mahadik</i>	91:1–91:14
Faster Algorithm for Unique $(k, 2)$ -CSP <i>Or Zamir</i>	92:1–92:13

■ Preface

This volume contains the extended abstracts selected for presentation at ESA 2022, the 30th European Symposium on Algorithms. The event was organized by the Hasso Plattner Institute, Potsdam, Germany, as a part of ALGO 2022, on September 5–7, 2022.

The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions that also address real-world applications, engineering, and experimental analysis of algorithms. A new track, S for Simplicity, was added this year, inviting contributions that simplify algorithmic results. We find that simpler algorithms are easier to implement, bridging the gap between theory and practice, and we find that new simple or elegant proofs are easier to understand and to teach, and may contain interesting new insights whose relevance only the future will reveal.

In response to the call for papers for ESA 2022, 300 papers were submitted, 214 for Track A, 46 for Track B, and 40 for Track S. Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews. The program committees selected 92 papers for inclusion in the program: 68 from Track A, 14 from Track B, and 10 for Track S, yielding an overall acceptance rate of about 30%. The presentations of the accepted papers, together with two invited talks by Virginia Vassilevska (MIT) and Simon Puglisi (U. Helsinki), promise to make up a very exciting program.

The European Association for Theoretical Computer Science (EATCS) sponsored best paper and best student paper awards. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission. For track A, the best paper award was given to Stefan Walzer for the paper Insertion Time of Random Walk Cuckoo Hashing below the Peeling Threshold, and the best student paper award to Zoe Xi and William Kuszmaul for the paper Approximating Dynamic Time Warping Distance Between Run-Length Encoded Strings. For track B, the best paper award was given to Chris Schwiegelshohn and Omar Ali Sheikh-Omar for the paper An Empirical Evaluation of k -Means Coresets, and the best student paper award to Tim Zeitz and Nils Werner for the paper Combining Predicted and Live Traffic with Time-Dependent A* Potentials. The best paper award for track S was given to Alejandro Flores-Velazco for the paper Improved Search of Relevant Points for Nearest-Neighbor Classification—this was also the best student paper for this track.

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and the nearly 500 external reviewers who assisted the program committees in the evaluation process. Special thanks go to the organizing committee, who helped us with the organization of the conference.

Information on past ESA symposia, including locations and proceedings, is maintained at <http://esa-symposium.org>.

■ Program Committees

Track A (Design and Analysis) Program Committee

- Mikkel Abrahamsen, University of Copenhagen
- Peyman Afshani, Aarhus University
- Pankaj K. Agarwal, Duke University
- Sepehr Assadi, Rutgers University
- Per Austrin, KTH
- Leonid Barenboim, The Open University of Israel
- Surender Baswana, IIT Kanpur
- Maike Buchin, Ruhr University Bochum
- Jaroslaw Byrka, University of Wrocław
- Diptarka Chakraborty, National University of Singapore
- Shiri Chechik (chair), Tel Aviv University
- Vincent Cohen-Addad, Google Research
- Mark de Berg, TU Eindhoven
- Mahsa Derakhshan, UC Berkley and Northeastern University
- Michael Dinitz, Johns Hopkins University
- Michal Dory, ETH Zurich
- Matthias Englert, University of Warwick
- Thomas Erlebach, Durham University
- Fedor Fomin, University of Bergen
- Dimitris Fotakis, National Technical University of Athens
- Hsin Hao Su, Boston College
- Martin Hoefer, Goethe University
- Ravishankar Krishnaswamy, Microsoft Research
- Janardhan Kulkarni, Microsoft Research
- Divyarthi Mohan, Tel Aviv University
- Shay Mozes, Reichman University
- Wolfgang Mulzer, Freie Universität Berlin
- Ofer Neiman, Ben-Gurion University
- Aleksandar Nikolov, University of Toronto
- Sigal Oren, Ben-Gurion University
- Fahad Panolan, IIT Hyderabad
- Adi Rosén, FILOFOCS – CNRS
- Sushant Sachdeva, University of Toronto
- Stefan Schmid, University of Vienna and TU Berlin
- Roy Schwartz, Technion
- Bruce Shepherd, University of British Columbia
- Shay Solomon, Tel Aviv University
- Xiaorui Sun, University of Illinois
- Dimitrios Thilikos, LIRMM, Université de Montpellier, CNRS
- Ohad Trabelsi, The University of Michigan
- Oren Weimann, University of Haifa
- Philip Wellnitz, Max Planck Institute for Informatics
- Raphael Yuster, University of Haifa

30th Annual European Symposium on Algorithms (ESA 2022).

Editors: Shiri Chechik, Gonzalo Navarro, Eva Rotenberg, and Grzegorz Herman

Leibniz International Proceedings in Informatics

LIPIC Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B (Engineering and Applications) Program Committee

- Diego Arroyuelo, Universidad Técnica Federico Santa María
- Philip Bille, Danmarks Tekniske Universitet
- Thomas Bläsius, Karlsruhe Institute of Technology
- Christina Boucher, University of Florida
- Sándor Fekete, Technische Universität Braunschweig
- José Fuentes-Sepúlveda, Universidad de Concepción
- Gramoz Goranci, Universitat Wien
- Giuseppe Italiano, Università degli studi di Roma “Tor Vergata”
- Shweta Jain, University of Utah
- Dominik Kempa, Stony Brook University
- Veli Mäkinen, University of Helsinki
- Catherine McGeoch, Amherst College
- David Mount, University of Maryland
- Gonzalo Navarro (chair), Universidad de Chile
- Steven Skiena, Stony Brook University
- Matthias Stallmann, North Carolina State University

Track S (Simplicity) Program Committee

- Josh Alman, Columbia University
- Michael Bender, Stony Brook University
- Karl Bringmann, Saarland University
- Raphaël Clifford, University of Bristol
- Anne Driemel, Universität Bonn
- Paweł Gawrychowski, University of Wrocław
- Monika Henzinger, University of Vienna
- John Iacono, Université libre de Bruxelles
- Tomasz Kociumaka, University of California, Berkeley
- Irina Kostitsyna, Eindhoven University of Technology
- William Kuszmaul, Massachusetts Institute of Technology
- Rasmus Kyng, ETH Zürich
- Kitty Meeks, University of Glasgow
- Marcin Pilipczuk, University of Warsaw
- Kent Quanrud, Purdue University
- Eva Rotenberg (chair), Technical University of Denmark
- Shikha Singh, Williams College
- Jukka Suomela, Aalto University
- Haitao Wang, Utah State University
- Andreas Wiese, TU Munich
- Anna Zych-Pawlewicz, University of Warsaw

Abstract

The question to enumerate all (inclusion-wise) minimal connected dominating sets in a graph of order n in time significantly less than 2^n is an open question that was asked in many places. We answer this question affirmatively, by providing an enumeration algorithm that runs in time $\mathcal{O}(1.9896^n)$, using polynomial space only. The key to this result is the consideration of this enumeration problem on 2-degenerate graphs, which is proven to be possible in time $\mathcal{O}(1.9767^n)$. Apart from solving this old open question, we also show new lower bound results. More precisely, we construct a family of graphs of order n with $\Omega(1.4890^n)$ many minimal connected dominating sets, while previous examples achieved $\Omega(1.4422^n)$. Our example happens to yield 4-degenerate graphs. Additionally, we give lower bounds for the previously not considered classes of 2-degenerate and of 3-degenerate graphs, which are $\Omega(1.3195^n)$ and $\Omega(1.4723^n)$, respectively.

We also address essential questions concerning output-sensitive enumeration. Namely, we give reasons why our algorithm cannot be turned into an enumeration algorithm that guarantees polynomial delay without much efforts. More precisely, we prove that it is NP-complete to decide, given a graph G and a vertex set U , if there exists a minimal connected dominating set D with $U \subseteq D$, even if G is known to be 2-degenerate. Our reduction also shows that even any subexponential delay is not easy to achieve for enumerating minimal connected dominating sets. Another reduction shows that no FPT-algorithms can be expected for this extension problem concerning minimal connected dominating sets, parameterized by $|U|$. This also adds one more problem to the still rather few natural parameterized problems that are complete for the class W[3]. We also relate our enumeration problem to the famous open HITTING SET TRANSVERSAL problem, which can be phrased in our context as the question to enumerate all minimal dominating sets of a graph with polynomial delay by showing that a polynomial-delay enumeration algorithm for minimal connected dominating sets implies an affirmative algorithmic solution to the HITTING SET TRANSVERSAL problem.

1 Introduction

The enumeration of objects that satisfy a given property has applications in many scientific domains including biology and artificial intelligence. Enumeration can also be used as part of an exact algorithm, e.g., confer the algorithm by Lawler [27] to compute a coloring of an input graph using a minimum number of colors. The dynamic programming scheme used by this algorithm needs all the maximal independent sets of the input graph. It is worth noting that the running time depends mainly on a bound on the number of maximal independent sets as well as on the running time of an algorithm that would produce all these sets.

Clearly, the number of outputs of an enumeration algorithm can be exponential in the size of the given input. It is the case for the number of maximal independent sets: there are graphs with $3^{n/3}$ such sets [30], where n is the number of vertices in the graph. The running time of enumeration algorithms can either be measured with respect to the size of the input plus the size of the outputted set of objects, which is called *output-sensitive* analysis, or it can be measured according to the size of the input only, being called *input-sensitive* analysis. In the latter, the running time upper bound often implies an upper bound on the number of enumerated objects, *i.e.*, the maximum number of objects that can fulfill the given property.

Given a graph $G = (V, E)$, the problem of computing a minimum dominating set asks for a smallest-cardinality subset $S \subseteq V$ such that each vertex not in S has at least one neighbor in S . This well studied NP-hard problem attracted considerable attention for decades. Several exponential-time algorithms have been designed to solve the problem exactly, and the most recent are based on *Measure-and-Conquer* techniques to analyze their running times [15, 24, 31]. The problem of enumerating all inclusion-minimal dominating sets has also caught attention for general graphs as well as for special graph classes [10, 16, 19].

Many variants of the dominating set problem have also gained attention [22]. In particular, the minimum *connected* dominating set problem requires that the graph induced by S is connected. The problem has attracted great attention and various methods have been devised to solve it exactly [3, 14]. A more challenging question has been posed about the enumeration of inclusion-minimal connected dominating sets. Already designing an algorithm faster than $\text{poly}(n)2^n$ is known to be challenging, and this specific question has been asked several times as an open problem [6, 13, 20]. A recent result by Lokshantov et al. [29] shows that minimal connected dominating sets can be enumerated in time $2^{(1-\epsilon)n} \cdot n^{\mathcal{O}(1)}$, which broke the 2^n -barrier for the first time. It is worth noting that ϵ is a tiny constant, around 10^{-50} , and it has remained open whether an algorithm exists that can substantially break the 2^n -barrier. The enumeration of minimal connected dominating sets also received notable interest when the input is restricted to special graph classes [20, 21, 32, 33, 34].

On the other hand, the maximum number of minimal CDS in a graph was shown to be in $\Omega(3^{\frac{n}{3}})$ [20], which is obviously very low compared to the currently best upper bound. This gap between upper and lower bounds is narrower when it comes to special graph classes. On chordal graphs, for example, the upper bound has been recently improved to $\mathcal{O}(1.4736^n)$ [21]. Other improved lower/upper bounds have been obtained for AT-free, strongly chordal, distance-hereditary graphs, and cographs in [20]. Further improved bounds for split graphs, cobipartite and convex bipartite graphs have been obtained in [34] and [33]. Moreover, although the optimization problem seems simpler, the best-known exact algorithm solves the problem in time $\mathcal{O}(1.8619^n)$ [3]. This is already much larger than the best-known lower bounds of $3^{(n-2)/3}$ [20] to enumerate all minimal connected dominated sets.

In this paper, we show that the enumeration of all inclusion-wise minimal connected dominating sets can be achieved in time $\mathcal{O}(1.9896^n)$. Surprisingly, achieving this improvement was simply based on first considering the same enumeration on 2-degenerate graphs and

proving it to be possible in time $\mathcal{O}(1.9767^n)$. Achieving enumeration with polynomial delay is believed to be hard, since it would also lead to the same for the enumeration of minimal dominating sets, which has been open for several decades. We give further evidence of this (possible) hardness by showing that extending a subset of vertices into a minimal connected dominating set is NP-complete and also hard in a natural parameterized setting. Furthermore, we narrow the gap between upper and lower bounds by showing that the maximum number of minimal connected dominating sets in a graph is in $\Omega(1.4890^n)$, thus improving the previous lower bound of $\Omega(1.4422^n)$. Our construction yields new lower bounds on several special graph classes such as 3-degenerate planar bipartite graphs. For space restrictions, most proofs are either omitted or reduced to proof sketches; full proofs can be found in the long version of this paper [1].

2 Definitions, Preliminaries and Summary of Main Results

In this paper, we deal with undirected simple finite graphs that can be specified as $G = (V, E)$, where V is the finite vertex set and $E \subseteq \binom{V}{2}$ is the set of edges. The number of vertices $|V|$ is also called the *order* of graph G and is denoted by n . An edge $\{u, v\}$ is usually written as uv . Alternatively, E can be viewed as a symmetric binary relation, so that E^* is then the transitive closure of E , which is an equivalence relation whose equivalence classes are also known as *connected components*. A graph is called *connected* if it has only one connected component. A graph $G' = (V', E')$ is a *subgraph* of $G = (V, E)$ if $V' \subseteq V$ and $E' \subseteq E$; G' is a *partial graph* of G if $V = V'$. A set of vertices S *induces* the subgraph $G[S] = (S, E_S)$, where $E_S = \{uv \in E \mid u, v \in S\}$; S is called *connected* if $G[S]$ is connected. For a vertex $v \in V$, $N_G(v) = \{u \in V \mid uv \in E\}$ is the *open neighborhood* of v , collecting the vertices *adjacent* to v ; its cardinality $|N_G(v)|$ is also called the *degree* of v , denoted as $\deg_G(v)$. We denote the *closed neighborhood* of v by $N_G[v] = N_G(v) \cup \{v\}$. We can extend set-valued functions to set arguments; for instance, $N_G[S] = \bigcup_{v \in S} N_G[v]$ for a set of vertices S ; S is a *dominating set* if $N_G[S] = V$. Whenever clear from context, we may drop the subscript G from our notation. If $X \subseteq V$, we also write $N_X(v)$ instead of $N(v) \cap X$ and $\deg_X(v)$ for $|N(v) \cap X|$. For brevity, we write CDS for *connected dominating set*. Next, we collect some observations.

► **Observation 1.** *If S is a CDS of a partial graph G' of G , then S is a CDS of G .*

Proof. We can think of $G = (V, E)$ as being obtained from G' by adding edges. Hence, if $N_{G'}[S] = V$, then $N_G[S] = V$. Moreover, adding edges cannot violate connectivity. ◀

► **Corollary 2.1.** *Let S be a CDS both of G and of a partial graph G' of G . If S is a minimal CDS of G , then it is a minimal CDS of G' .*

A graph $G = (V, E)$ is *d-degenerate* if there exists an *elimination ordering* (v_1, \dots, v_n) , where $V = \{v_1, \dots, v_n\}$, such that, for all $i = 1, \dots, n$, $\deg_{G[\{v_i, \dots, v_n\}]}(v_i) \leq d$. In other words, we can subsequently delete v_1, v_2, \dots from G , and at the time when v_i is deleted, it has degree bounded by d in the remaining graph. The decision problem CONNECTED DOMINATING SET EXTENSION expects as inputs a graph $G = (V, E)$ and a vertex set U , and the question is if there exists a minimal CDS S that extends U , *i.e.*, for which $S \supseteq U$ holds.

In the next section, we develop a branching algorithm. It is classical to analyze its running-time by solving recurrences of type $T(\mu(\mathcal{I})) = \sum_{i=1}^t T(\mu(\mathcal{I}) - r_i)$. Here, $\mu(\mathcal{I})$ is a measure on the size of the instance. The value t is the number of recursive calls (t is equal to 1 for *reduction rules*) and each r_i is (a lower bound on) the reduction of the measure corresponding to the recursive call. We simply denote by (r_1, r_2, \dots, r_t) the *branching vector* of the recurrence. We refer to the book by Fomin and Kratsch for further details on this standard analysis [17].

As discussed in the introduction, we shall first prove that all minimal CDS can be enumerated in time $\mathcal{O}(1.9767^n)$ on 2-degenerate graphs. This result is the key to our enumeration result for general graphs. This is why we will first present the corresponding branching enumeration algorithm for 2-degenerate graphs in a simplified form and analyze it with a rather simple measure in order to explain its main ingredients, and only thereafter, we turn towards a refined analysis that finally leads to the claimed enumeration result on general graphs. We shall prove that our input-sensitive enumeration algorithm cannot be turned into an enumeration algorithm with polynomial delay by simply interleaving the branching with tests for extendibility. For possible applications of such extension algorithms, we refer to the discussions in [7].

3 A CDS enumeration algorithm for 2-degenerate graphs

We are going to present an algorithm that enumerates all inclusion-wise minimal connected dominating sets (CDS) of a 2-degenerate graph $G = (V, E)$. Based on G , in the course of our algorithm, an instance is specified by $\mathcal{I} = (V'; O_d, O_n; S)$, consisting of four vertex sets that partition V . In the beginning, $\mathcal{I} = (V; \emptyset; \emptyset; \emptyset)$. In general, V' collects the vertices not yet decided by branching or reduction rules, $O := O_d \cup O_n$ are the vertices that have been decided *not* to be put into the solution, while S is the set of vertices decided to go into the solution that is constructed by the branching algorithm. The set O is further refined into O_n , the set of vertices that are not yet dominated, *i.e.*, if $x \in O_n$, then $\deg_S(x) = 0$, and O_d , the set of vertices that are already dominated, *i.e.*, if $x \in O_d$, then $\deg_S(x) > 0$. Similarly, we will sometimes refine $V' = V'_d \cup V'_n$. Notice that also vertices known to be dominated could be still put in the dominating set, either to dominate other vertices or for connectivity purposes. In the leaves of the branching tree, only instances of the form $(\emptyset, O_d, \emptyset, S)$ are of interest. Yet, before outputting S as a solution, one has to check if S is connected and if it does not contain a smaller CDS.

The algorithm actually starts by creating n different branches, in each a single vertex is put in S as a starting point, so that S is never empty. More precisely, the n^{th} branch would decide *not* to put the previously considered $n - 1$ vertices into the solution but the n^{th} one is put into S . This binary branching avoids generating solutions twice. Also, it is trivial to check in each branch if the selected vertex already dominates the whole graph, so that we can henceforth assume that G cannot be dominated by a single vertex.

We denote by c the number of connected components of $G[S]$. Now, we are ready to define the measure that we use to analyze the running time of our algorithm, following a very simple version of the *measure-and-conquer*-paradigm, as explained in [15, 17],

$$\mu(\mathcal{I}) = |V'| + \alpha \cdot |O_n| + \delta \cdot c.$$

We decide that $0 < \alpha, \delta < 1$, but we will determine the concrete values later as to minimize the upper-bound on the running-time. At the beginning, $V' = V$, $O_n = \emptyset$ and $c = 0$, so that then the measure equals $|V|$. At the end, $V' = O_n = \emptyset$ and the measure equals δ if the solution is connected and is bigger than δ if the solution is not connected.

For the possible branchings, we only consider vertices in a partial graph G' of $G[V' \cup O_n]$. As G is 2-degenerate, G' is also 2-degenerate, so that we can always find a vertex of degree at most two in G' . Some of our branchings apply to vertices of arbitrary degree, though; in such a situation, we denote the vertex that we branch on as x . If we branch on a small-degree vertex (due to 2-degeneracy), this vertex is called u . Clearly, a binary branch that puts a selected vertex either into S or into O is a complete case distinction.

(a) $x \in V'_d$ has neighbors in O_n .

(b) Vertices from two different connected components S_1, S_2 of $G[S]$ dominate x in G .

■ **Figure 1** Simple branchings for dominated vertices: Rules 1 and 2.

We are now explaining the conventions that we follow in our illustrations of subgraphs of G' . Vertices in V' are depicted by \ominus and more specifically by \circ if in V'_n or by \bullet if in V'_d . We use black squares \blacksquare to depict vertices which are already decided to belong to the solution S . We use \square for vertices from O_n . So, circles are used for undecided vertices (these vertices might still be added to S), whereas squares are used for vertices being already decided (to belong to the solution or to be discarded). Vertices in $V' \cup O$ are depicted as half-filled diamonds \blacklozenge , and if the vertex is from $V'_n \cup O_n$, then we use an unfilled diamond \diamond to represent it. A dashed line indicates an edge that may be present. It should be clear that one could always move to the graph where vertices in S that belong to the same connected component in $G[S]$ are merged. In order to avoid drawing too many vertices from S in our pictures, we assume these mergings to have been performed. Hence, when we draw two vertices from S , they belong to different connected components.

In the following, the branching and reduction rules require to be executed in order, so that our instance will (automatically) satisfy some structural properties when we apply one of the later rules. We can separate our branching and reduction rules into three parts:

- A first set of rules (Branching Rules 1, 2, 3, 4, Reduction Rules 1, 2, 3, 5) that deals with vertices of arbitrary degree that are (possibly) dominated, but only in some special cases, as detailed later. Those rules are applied first, so that whenever we apply a rule from the next two sets, we know that any dominated vertex is dominated by vertices from exactly one connected component of $G[S]$ and none of the vertices in its neighborhood are dominated. This means that the set of vertices V'_d as well as the set of vertices O_n forms an independent set in G' , a partial graph of $G[V' \cup O_n]$.
- A second set of rules (Branching Rules 5, 6, Reduction Rule 4) that handles the cases where the small-degree vertex that exists by the 2-degeneracy is undominated. If we apply a rule from the third set, every undominated vertex is of degree at least 3.
- The last set of rules (Branching Rules 7, 8, 9, 10) handles only the cases where the small-degree vertex that exists by the 2-degeneracy is dominated.

Note that even inside those three sets, rules have to be executed in the given order.

► **Branching Rule 1.** Let $x \in V'_d$ with $\deg_{O_n}(x) \geq 1$ (Figure 1a). Then branch as follows.

- (1) Put x in O_d .
- (2) Put x in S and every vertex in $N_{O_n}(x)$ in O_d .

► **Lemma 3.1.** *The branching of rule 1 is a complete case distinction. Moreover, it leads to a branching vector that is not worse than $(1, 1 + \alpha)$.*

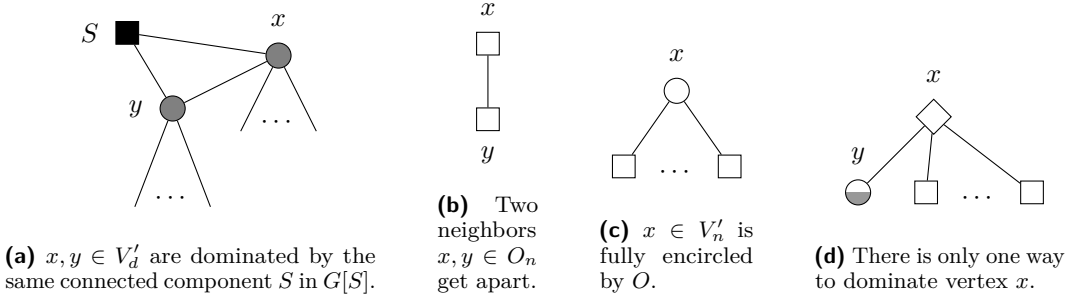

Proof. As $\deg_S(x) \geq 1$, we find that, if x is not put into the solution, then it is put into O_d , which decreases the measure by 1 in the first component of the branching vector. If x is put into the solution, then its neighbors are dominated and we decrease the measure by at least $1 + \alpha$ in the second component of the branching vector, as $\deg_{O_n}(x) \geq 1$. ◀

1:6 Enumerating Minimal Connected Dominating Sets

(a) A vertex from O_n in the second neighborhood of $x \in V'_d$ gives still an advantage. (b) $N_S(x)$ belongs to the same connected component S_x of $G[S]$, and so does $N_S(y)$ belong to S_y , but $S_x \neq S_y$.

■ Figure 2 Branching Rules 3 and 4.

(a) $x, y \in V'_d$ are dominated by the same connected component S in $G[S]$. (b) Two neighbors $x, y \in O_n$ get apart. (c) $x \in V'_n$ is fully encircled by O . (d) There is only one way to dominate vertex x .

■ Figure 3 Illustrating Reduction Rules 1, 3, 4 and 5.

We will have similar lemmas for each of the branching rules; we will summarize them at the end of this section instead of formulating them separately and point to the long version of the paper.

► **Branching Rule 2.** Let $x \in V'_d$ such that x is adjacent to two different connected components of $G[S]$; see Figure 1b. Then branch as follows. (1) Put x in O_d . (2) Put x in S .

We are now presenting two branching rules that could be viewed as variations of the first two; they always give worse branchings.

► **Branching Rule 3.** Let $x \in V'_d, y \in N_{V'_n}(x), z \in N_{O_n}(y)$ (Figure 2a). Then branch as follows. (1) Put x in O_d . (2) Put x in S, y in O_d . (3) Put x, y in S and thus $z \in O_d$.

► **Branching Rule 4.** Let $x, y \in V'_d, xy \in E$, such that $z \in \{x, y\}$ is adjacent to a connected component S_z of $G[S]$, with $S_x \neq S_y$, see Figure 2b. Then branch as follows. (1) Put x in O_d . (2) Put x in S and y in O_d . (3) Put x in S and y in S .

Notice that in the last branch, the number of connected components decreases.

► **Reduction Rule 1.** If $x, y \in V'_d$ and $xy \in E$, then delete the edge xy ; see Figure 3a.

► **Lemma 3.2.** *Reduction Rule 1 is sound and the measure does not change.*

Proof. Let M be a minimal CDS of G such that $M \setminus V' = S$. Define $e = xy$ and $\tilde{G} = (V, E \setminus \{e\})$. Now we want to show that M is also a minimal CDS in \tilde{G} . Since x and y are already dominated by S , the deletion of the edge e would not affect domination, nor could x ever be the private neighbor of y or vice versa. The connectivity is only important if $x, y \in M$. Vertices x, y are dominated by the same connected component of S , as otherwise Branching Rule 4 would have applied with priority. Hence, there exists a path $p = (x, p_1, \dots, p_l, y)$, with internal vertices in S . Let $q = (q_1, \dots, q_k)$ be a path in $G[M]$ such that there exists an $i \in \{1, \dots, k-1\}$ with $q_i = x$ and $q_{i+1} = y$. Then $\tilde{q} = (q_1, \dots, q_i, p_1, \dots, p_l, q_{i+1}, \dots, q_k)$ is a walk in $\tilde{G}[M]$. Thus, $\tilde{G}[M]$ is connected and M is a CDS of \tilde{G} . As \tilde{G} is a partial graph, M is also a minimal CDS of G by Corollary 2.1. ◀

■ **Figure 4** Branching Rules 5, 6 and 7.

We can formulate and prove similar lemmas for the following reduction rules, as well. We will summarize this in one single lemma below instead.

► **Reduction Rule 2.** If x is an isolated vertex in $G[V' \cup O_n]$, do the following:

- If x is dominated, put x into O_d .
- If x is not dominated, skip this branch. (This will always happen if $x \in O_n$.)

► **Reduction Rule 3.** Let $x, y \in O_n$ be with $xy \in E$; see Figure 3b. We delete the edge xy .

► **Reduction Rule 4.** If $x \in V'_n$ obeys $N(x) \cap V' = \emptyset$, then skip this branch (Figure 3c).

The next rule will even decrease the measure by at least $1 - \delta$.

► **Reduction Rule 5.** Let $x \in V'_n \cup O_n$, with $N_{V'}(x) = \{y\}$. Then, put y into S .

► **Branching Rule 5.** Let $u \in V'_n$ with $\deg_{V'}(u) = 2$, $\deg_{O_n}(u) = 0$ and $N_{V'}(u) = \{v_1, v_2\}$; see Figure 4a. Then branch as follows. (1) Put u in O_d , v_1 in S . (2) Put u in O_d , v_1 in O , v_2 in S . (3) Put u in S , v_1 in S . (4) Put u in S , v_1 in O_d , v_2 in S .

More precisely, in the second branch, we put v_1 into O_d if $v_1v_2 \in E$ or if v_1 was already dominated and we put v_1 into O_n , otherwise. The same is done in the Branching Rules 6, 7, 8, 9 and 10, as it can be decided whether the vertex goes into O_n or into O_d .

► **Branching Rule 6.** Let $u \in O_n$ with $N_{V'}(u) = \{v_1, v_2\}$ (Figure 4a). Then branch as follows. (1) Put v_1 in S , and thus u in O_d . (2) Put v_1 in O , v_2 in S , and thus u in O_d .

► **Observation 2.** For each rule below, as it is applied in particular after Branching Rule 5 and Reduction Rule 5, we observe: for any vertex $v \in V'_n \cup O_n$, we have $\deg_{V' \cup O_n}(v) \geq 3$.

► **Branching Rule 7.** Let $u \in V'_d$ with $N_{V'}(u) = \{v\}$ and $\deg_{O_n}(v) = 0$; see Figure 4c. Then branch as follows. (1) Put u in O_d . (2) Put u in S and v in O_d and thus all the vertices of $N_{V'}(v) \setminus \{u\}$ in O . (3) Put u in S and v in S .

► **Branching Rule 8.** Let $u \in V'_d$, with $N_{V'}(u) = \{v_1, v_2\}$ and $\deg_{O_n}(u) = 0$ (Figure 5a). If $N_{V'}(v_1) \cap N_{V'}(v_2)$ contains a vertex $y \in V'$ different from u , then branch as follows. (1) Put u in O_d . (2) Put u in S , v_1 in S . (3) Put u in S , v_1 in O_d , v_2 in S . (4) Put u in S , v_1 in O_d , v_2 in O_d and thus y in O .

► **Branching Rule 9.** Let $u \in V'_d$, $N_{V'}(u) = \{v_1, v_2\}$, $N_{V'_d}(u) = N_{O_n}(u) = \emptyset$ and $N_{V'}(v_1) \setminus \{u, v_2\} = \{y\}$; see Figure 5b. Then branch as follows. (1) Put u in O_d . (2) Put u in S , v_1 in S . (3) Put u in S , v_1 in O_d , v_2 in S . (4) Put u in S , v_1 in O_d , v_2 in O_d and y in O . (5) Put u in S , v_1 in O_d , v_2 in O_d and y in S and thus the vertices of $N_{V'}(v_2) \setminus \{u, v_1\}$ in O .

► **Branching Rule 10.** (Figure 5c) Let $u \in V'_d$, $N_{V'}(u) = \{v_1, v_2\}$, $N_{V'_d}(u) = N_{O_n}(u) = \emptyset$, such that $|N_{V'}(v_1) \setminus \{u, v_2\}| \geq 2$, as well as $|N_{V'}(v_2) \setminus \{u, v_1\}| \geq 2$. Then branch as follows. (1) Put u in O_d . (2) Put u in S , v_1 in S . (3) Put u in S , v_1 in O_d , v_2 in S . (4) Put u in S , v_1 in O_d , v_2 in O_d and all of $N_{V'}(v_1) \setminus \{u, v_2\}$ in O . (5) Put u in S , v_1 in O_d , v_2 in O_d and all of $N_{V'}(v_2) \setminus \{u, v_1\}$ in O .

■ **Figure 5** Branching Rules 8, 9 and 10.

The next and final rule will never be applied when this algorithm is applied to a 2-degenerate graph. It rather prepares the ground for the general case. However, with our current measure, this would yield an $\mathcal{O}(2^n)$ algorithm in the general case. With a modified measure, as described in the next section, we will achieve a better running time.

► **Branching Rule 11.** Let $x \in V'_d$. Then we branch as follows. (1) Put x in O_d . (2) Put x in S and thus the vertices of $N_{V'}(x)$ in V'_d .

► **Lemma 3.3.** *Each of the mentioned branching rules covers all cases in their described respective situation. The branching will lead to a branching vector as listed in Table 1.*

► **Lemma 3.4.** *The mentioned reduction rules are sound and their application never increases the measure.*

A case analysis shows the correctness of our algorithm in the following sense:

► **Lemma 3.5.** *The Reduction and Branching Rules cover all possible cases.*

Proof. As explained below, Branching Rule 11 serves as a final catch-all. For the 2-degenerate case, we should focus on all other rules and prove that they cover all cases. This means that we have to show that the proposed algorithm will resolve each 2-degenerate graph completely. Our rule priorities might remove vertices of arbitrary degree from the graph G' that is a partial graph of the graph $G[V' \cup O_n]$. This way, we again arrive at a 2-degenerate graph. Yet, what is important for dealing with 2-degenerate graphs is to consider all cases of a vertex u of degree at most 2. The degree conditions in the following case distinction refer to G' . Degree-0 vertices are treated with Reduction Rule 2. We now discuss vertices u of degrees one or two. There are two different cases: either u is in $V'_n \cup O_n$, or $u \in V'_d$.

Case 1: u is not dominated by S . Now we discuss its degree in G' , either it is 1 or it is 2.

Case 1.1: $\deg(u) = 1$ and we denote by v the neighbor in G' of u . If $v \in O_n$, then either u is in O_n and then satisfies the conditions of Reduction Rule 3, or it is in V_n and thus satisfies the conditions of Reduction Rule 4. If $v \notin O_n$, v satisfies the conditions of Reduction Rule 5.

Case 1.2: $\deg(u) = 2$. Now we discuss the number of neighbors of u in O_n . If both neighbors are in O_n , Reduction Rule 4 applies if $u \in V'_n$ and Reduction Rule 3 applies otherwise. If only one neighbor of u is in O_n , then this means that if $u \in O_n$ Reduction Rule 3 applies, and otherwise Reduction Rule 5 applies. If none of the neighbors are in O_n , then either $u \in V'_n$ and then Branching Rule 5 applies, or otherwise $u \in O_n$ and thus Branching Rule 6 applies.

Case 2: u is dominated by S .

■ **Table 1** Collection of all branching vectors for the 2-degenerate case; the branching numbers are displayed for the different cases with $\alpha = 0.106$ and $\delta = 0.106$.

Branching Rule #	Branching vector	Branching number
1	$(1, 1 + \alpha)$	always better than 3
2	$(1, 1 + \delta)$	always better than 4
3	$(1, 2, 2 + \alpha)$	< 1.9766
4	$(1, 2, 2 + \delta)$	< 1.9766
5	$(2 - \delta, 3 - \delta - \alpha, 2 - \delta, 3 - \delta)$	< 1.8269
6	$(1 + \alpha - \delta, 2 - \delta)$	< 1.6420
7	$(1, 4 - 2\alpha, 2)$	< 1.7691
8	$(1, 2, 3, 4 - \alpha)$	< 1.9333
9	$(1, 2, 3, 4 - \alpha, 5 - \delta - \alpha)$	< 1.9767
10	$(1, 2, 3, 5 - 2\alpha, 5 - 2\alpha)$	< 1.9420
11	$(\beta, 3 - 2\beta)$ where $\beta = 1$	$= 2$ not for 2-degenerate graphs

Case 2.1: $\deg(u) = 1$. We denote by v the neighbor in G' of u . If v is dominated by S then Reduction Rule 1 applies. If v is not dominated by S , then either it has no neighbors in O_n and then Branching Rule 7 applies, or it has at least one neighbor in O_n and Branching Rule 3 applies.

Case 2.2: $\deg(u) = 2$. We denote $\{v_1, v_2\} = N_{V'}(u)$. If either v_1 or v_2 is dominated, then Reduction Rule 1 applies. If both of them are not dominated by S , either they have at least one neighbor in O_n and then Branching Rule 3 applies or they do not have any neighbor in O_n . So we know that $\deg_{V'}(v_1) \geq 3$, and $\deg_{V'}(v_2) \geq 3$, otherwise we could apply one of the rules of the previous case to v_1 or v_2 . Now, either v_1 and v_2 have a common neighbor outside of u and Branching Rule 8 applies, or they do not and then either at least one of them has exactly one neighbor that is not u or v_1 (or v_2 , respectively) and Branching Rule 9 applies, or they both have at least two neighbors outside of u, v_1 and v_2 , so that Branching Rule 10 applies.

We finally have to prove the correctness of the algorithm for a general graph. If any vertex satisfies the conditions of any Branching or Reduction Rule apart from Branching Rule 11, then we apply such a rule, otherwise no such rule applies, which means that the minimum degree of $G'[V' \cup O_n]$ is 3. If at least one vertex is in V_d , then we can apply Branching Rule 11. Assume it is not the case, that means V_d is empty, so every vertex of $V' \cup O_n$ is not dominated (and it is not empty, otherwise the algorithm would have ended). Since in the beginning, S was not empty, S is never empty. Moreover, at any point in the algorithm, $N(S) = V_d \cup O_d$. So in our case, we have $N(S) = O_d$. This means that S is not a dominating set (there are vertices in $V_n \cup O_n$) and S cannot have any neighbor added, so there is no CDS $M \subset V$ such that $M \setminus V' = S$. This branch has to be discarded. ◀

► **Theorem 3.6.** *CONNECTED DOMINATING SET ENUMERATION can be solved in time $\mathcal{O}(1.9767^n)$ on 2-degenerate graphs of order n , using polynomial space only. The claimed branching number is attained by setting $\alpha = 0.106$ and $\delta = 0.106$; see Table 1.*

► **Corollary 3.7.** *2-degenerate graphs have no more than $\mathcal{O}(1.9767^n)$ minimal CDS.*

► **Remark 3.8.** We could deduce a corresponding CDS enumeration result for subcubic graphs, as they can be dealt with as 2-degenerate graphs after the initial branching. There is a clear indication that the bound that we derive in this way is not tight. Namely, Kangas et al. have shown in [25] that there are no more than 1.9351^n many connected sets of vertices in a subcubic graph of order n .

4 Getting β into the game: the general case

As indicated above, we are now refining the previous analysis by splitting the set of vertices of the currently considered graph further. More precisely, the set of vertices V' that have not been decided to come into or to be out of the solution S is split into the set of vertices V'_n that is still undominated and the set V'_d of vertices that is already dominated. From the viewpoint of the original graph, the neighbors of the solution set S are therefore partitioned into the sets V'_d and O_d . However, observe that although we do not consider O_d anymore in the present graph, we do care about V'_d , since V'_d -vertices can still be either placed into S or into O_d by future branching or reduction rules. This is also reflected in the measure of the instance I , which is now defined as:

$$\mu(I) = |V'_n| + \alpha \cdot |O_n| + \beta \cdot |V'_d| + \delta \cdot c$$

We set $\alpha = 0.110901$, $\beta = 0.984405$ and $\delta = 0.143516$. We are next working through the branching rules one by one, as in particular the branching vectors will now split off into different cases, as in our preliminary analysis, we only took care of the worst cases, not differentiating between V'_n or V'_d (which was summarized under the set name V' before). For the convenience of the reader, we repeat the formulation of the branching rules in the following, adapting the notations.

We start with a table stating the branching vectors according to this new measure for some branching rules for which it is straightforward. Branching Rule 3 and Branching Rule 4 are the tight cases in our Measure-and-Conquer analysis.

Rule	Branching vector	Br. number	Rule	Branching vector	Br. number
# 1	$(\beta, \beta + \alpha)$	< 1.9489	# 2	$(\beta, \beta + \delta)$	< 1.9297
# 3	$(\beta, \beta + 1, \beta + 1 + \alpha)$	< 1.9896	# 4	$(\beta, 2\beta, 2\beta + \delta)$	< 1.9896

Branching Rule 5 Let $u \in V'_n$ with $\deg_{V'}(u) = 2$, $\deg_{O_n}(u) = 0$ and $N_{V'}(u) = \{v_1, v_2\}$. The branching vector is different when $v_1, v_2 \in V'_d$ or $v_1, v_2 \in V'_n$. We will assume $v_1 v_2 \notin E$, as this is always the worst case. A similar analysis applies to Branching Rule 6.

Condition	Branching vector for # 5	Br. number	Br. vector for # 6	Br. number
$v_1, v_2 \in V'_n$	$(2 - \delta, 3 - \delta - \alpha, 2 - \delta, 3 - \delta)$	< 1.8463	$(1 + \alpha - \delta, 2 - \delta)$	< 1.6635
$v_1 \in V'_n, v_2 \in V'_d$	$(2 - \delta, 2 - \alpha + \beta, 2 - \delta, 2 + \beta)$	< 1.8236	$(1 + \alpha, 1 + \beta)$	< 1.5855
$v_1, v_2 \in V'_d$	$(1 + \beta, 1 + 2\beta, 1 + \beta, 1 + 2\beta)$	< 1.7785	$(\beta + \alpha, 2\beta + \alpha)$	< 1.5817

Branching Rule 7 We look at $u \in V'_d$, $\{v\} = V'_n \cap N(u)$ and the neighbors of v ; we know that $N(v)$ contains at least $u, v_1, v_2 \notin O$; differentiating between $v_i \in V'_n$ or $v_i \in V'_d$ (as before), we arrive at three cases never leading to a branching number worse than 1.78.

Branching Rule 8 Let $u \in V'_d$ be with $\deg_{V' \cup O_n}(u) = 2$, such that $v_1, v_2 \in N_{V'}(u)$ and $N_{V'}(v_1) \cap N_{V'}(v_2)$ contains a vertex $y \in V'$ different from u . We differentiate $y \in V'_n$ or $y \in V'_d$ and arrive at a branching number not worse than 1.9403.

Branching Rule 9 Let $u \in V'_d$ be with $\deg_{V' \cup O_n}(u) = 2$, such that $v_1, v_2 \in N_{V'}(u)$ and $N_{V'}(v_1) \setminus \{u, v_2\} = \{y\}$. We distinguish $y \in V'_n$ and $y \in V'_d$; the first case leads to another tight-case branching for our algorithm. In the last branch of each vector, $\min(\beta, 1 - \alpha)$ corresponds to whether $z \in N(v_2) \setminus \{u, v_1\}$ belongs to V'_d or to V'_n .

Condition	Branching vector	Branching number
$y \in V'_n$	$(\beta, 1 + \beta, 2 + \beta, 3 + \beta - \alpha, 3 + \beta - \delta + \min(\beta, 1 - \alpha))$	< 1.9896
$y \in V'_d$	$(\beta, 1 + \beta, 2 + \beta, 2 + 2\beta, 2 + 2\beta + \min(\beta, 1 - \alpha))$	< 1.9813

Branching Rule 10 Let $u \in V'_d$, $N_{V'_n}(u) = \{v_1, v_2\}$, $N_{V'_d}(u) = N_{O_n}(u) = \emptyset$. We further assume that $|N_{V'}(v_1) \setminus \{u, v_2\}| \geq 2$, as well as $|N_{V'}(v_2) \setminus \{u, v_1\}| \geq 2$. The only thing to discuss here is whether the vertices of $N_{V'}(v_1) \setminus \{u, v_2\}$, $N_{V'}(v_2) \setminus \{u, v_1\}$ are in V'_n or V'_d . This leads to nine subcases, which never produce a branching vector worse than 1.9453.

Branching Rule 11 When this branching rule applies, the sets in which the different vertices reside are all already known: as it is applied after Branching Rule 1 and Branching Rule 4, all the neighbors of $x \in V'_d$ are in V'_n , moreover, $\deg_{V' \cup O_n}(x) = \deg_{V'_n}(x) \geq 3$, as it is applied after every other rule. The branching vector $(\beta, 3 - 2\beta)$ gives a branching number < 1.9896 , which is the last tight-case branching.

► **Theorem 4.1.** *CONNECTED DOMINATING SET ENUMERATION can be solved in time $\mathcal{O}(1.9896^n)$ on graphs of order n , using polynomial space only.*

► **Corollary 4.2.** *There are no more than $\mathcal{O}(1.9896^n)$ many minimal connected dominating sets in a graph of order n .*

5 Achieving polynomial delay is not easy

How could we achieve polynomial delay for enumeration problems? If CONNECTED DOMINATING SET EXTENSION would be solvable in polynomial time, then we might cut search tree branches whenever it is clear that no solution is to be expected beyond a certain node of the search tree, as we can associate to such a node also a set of vertices U that is decided to go into the solution. For example, it has been recently exemplified with the enumeration problem of minimal Roman dominating functions in [2] that a polynomial-time algorithm for the corresponding extension problem can be adapted so that polynomial delay can be achieved for this type of enumeration problem. However, we can show that CONNECTED DOMINATING SET EXTENSION is NP-complete by a reduction from 3-SAT. This means that new ideas would be needed for showing polynomial delay for enumerating minimal connected dominating sets.

► **Theorem 5.1.** *The CONNECTED DOMINATING SET EXTENSION problem is NP-complete, even when restricted to 2-degenerate graphs.*

Due to the parsimonious nature of the reduction, we can also conclude the following result.

► **Corollary 5.2.** *Assuming that the Exponential Time Hypothesis¹ holds, there is no algorithm that solves the CONNECTED DOMINATING SET EXTENSION problem in time $\mathcal{O}(2^{o(n)})$ on (2-degenerate) graphs of order n .*

Hence, even any subexponential delay seems to be hard to achieve.

Furthermore, the CONNECTED DOMINATING SET EXTENSION with the *standard parameterization* $|U|$, where U is the given subset of V , is even W[3]-hard on split graphs. To show this, we need the W[3]-completeness of HITTING SET EXTENSION [4, 5, 7] with standard parameterization; in this problem, the input consists of a hypergraph (X, \mathcal{S}) , with $\mathcal{S} \subseteq 2^X$, and a set $U \subseteq X$, and the question if there exists a minimal hitting set H (this means that $H \cap S \neq \emptyset$ for all $S \in \mathcal{S}$) that extends U , i.e., $U \subseteq H$.

► **Theorem 5.3.** *CONNECTED DOMINATING SET EXTENSION (with standard parameterization) is W[3]-hard, even on split graphs.*

¹ For a discussion of this hypothesis, we refer to [23, 28].

On split graphs, we can also prove W[3]-completeness of CONNECTED DOMINATING SET EXTENSION. Few natural parameterized problems are known to be W[3]-complete [4, 5, 7, 8]. There is yet another stroke against hopes for obtaining a polynomial-delay enumeration algorithm for minimal CDS. Namely, we could see the reduction presented for Theorem 5.3 also as a reduction that proves the following statement, which connects our enumeration problem to HITTING SET TRANSVERSAL, a problem notoriously open for decades.

► **Theorem 5.4.** *If there was an algorithm for enumerating minimal CDS with polynomial delay in split graphs, then there would be an algorithm for enumerating minimal hitting sets in hypergraphs with polynomial delay.*

6 Lower bounds

Several attempts to construct lower bound examples are known from the literature, leading to $3^{(n-2)/3} \in \Omega(1.4422^n)$ many minimal connected dominating sets in n -vertex graphs [20, 33]. We now present an improved lower bound on the maximum number of minimal connected dominating sets in a graph. Given arbitrary positive integers k, t , we construct a graph G_t^k of order $n = k(2t + 1) + 1$ as follows. The main building blocks of G_t^k consist of k copies of a base-graph G_t , of order $2t - 1$. The vertex set of G_t consists of three layers. The first one is a set $X = \{x_1, \dots, x_t\}$ that induces a clique. The second one is an independent set $Y = \{y_1, \dots, y_t\}$, while the third layer consists of a singleton $\{z\}$. Each vertex $x_i \in X$ has exactly $t - 1$ neighbors in Y : $N(x_i) = \{y_j \in Y : i \neq j\}$. Hence, $X \cup Y$ induces a copy of $K_{t,t}$ minus a perfect matching. Finally the vertex z is adjacent to all vertices in Y . Figure 6a shows the graph G_t for $t = 4$. To finally construct the graph G_t^k , we introduce a final vertex s that is connected to all vertices of each set X of each copy of the base-graph.

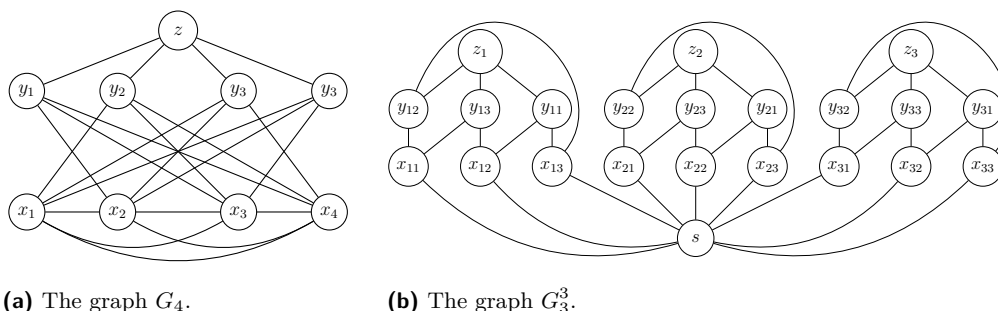

► **Lemma 6.1.** *For each $t > 0$, the graph G_t has exactly $\frac{t^3+t^2}{2} - t$ minimal connected dominating sets that have non-empty intersection with the set X .*

Proof. The set X cannot have more than two vertices in common with any minimal CDS, since any two elements of X dominate $X \cup Y$. Any minimal CDS that contains exactly one vertex x_i of X must contain the vertex z , to dominate y_i , and one of the $t - 1$ neighbors of x_i (to be connected). There are $t(t - 1)$ sets of this type. Moreover, each pair of elements of X dominates Y . So a minimal CDS can be formed by (any) two elements of X and any of the elements of Y (to dominate z). There are $t \frac{t(t-1)}{2}$ such sets. ◀

The hub-vertex s in G_t^k must be in any CDS, being a cut-vertex. Therefore, there is no need for the set X in G_t to induce a clique, being always dominated by s . In other words, the counting used in the proof above still holds if each copy of G_t is replaced by $G_t - E(X)$ in G_t^k . Here, $E(X)$ denotes the set of edges in $G_t[X]$. Figure 6b shows G_3^3 without the edges between pairs of element of X in each copy of G_3 . With the help of Lemma 6.1, we can show:

► **Theorem 6.2.** *The maximum number of minimal CDS in a connected graph of order n is in $\Omega(1.4890^n)$; an example family of graphs is (G_4^k) .*

Proof. By Lemma 6.1, each copy of the graph G_t has $\frac{t^3+t^2}{2} - t$ minimal CDS. There are k such graphs in G_t^k , in addition to the vertex s that connects them all. Every minimal CDS must contain s and at least one element from $N(s)$ in each G_t . Therefore, the total number of minimal CDS in G_t^k is $(\frac{t^3+t^2}{2} - t)^k = (\frac{t^3+t^2}{2} - t)^{\frac{n-1}{2t+1}}$. The claimed lower bound is achieved when $t = 4$, which gives a total of $36^{\frac{n-1}{9}} \in \Omega(1.4890^n)$. ◀

(a) The graph G_4 .(b) The graph G_3^3 .

■ **Figure 6** How our lower bound examples are composed.

We note that G_t^k is a t -degenerate graph that is also bipartite (since the set X in each copy of G_t can be an independent set). Furthermore, G_3^k is planar, as intentionally drawn in Figure 6b. Our general formula (Lemma 6.1) yields that G_3^k has $15^{n/7} = \Omega(1.4723^n)$ minimal CDS, improving on the previously mentioned construction for 3-degenerate graphs in [33].

► **Corollary 6.3.** *The maximum number of minimal connected dominating sets in a 3-degenerate bipartite planar graph of order n is in $\Omega(1.4723^n)$.*

Finally, G_2^k is a 2-degenerate graph of order n with $4^{n/5} = \Omega(1.3195^n)$ many minimal CDS, incidentally matching the best known lower bound in cobipartite graphs [9].

7 Conclusions and Open Problems

In our paper, we focused on developing an input-sensitive enumeration algorithm for minimal CDS. We achieved some notable progress both on the running time for such enumeration algorithms and with respect to the lower bound examples. However, the gap between lower and upper bound is still quite big, and the natural question to ask here is to bring lower and upper bounds closer; in an optimal setting, both would match. We are working on a further refined version that will bring down the upper bound a bit, but not decisively. This question of non-matching upper and lower bounds is also open for most special graph classes.

One particular such graph class that is studied in this paper is the class of 2-degenerate graphs. We like to suggest to study this graph class also for other enumeration problems, or, more generally, for problems that involve a measure-and-conquer analysis of branching algorithms, because this was the key to break the 2^n -barrier significantly for enumerating minimal CDS with measure-and-conquer, something that seemed to be impossible with other more standard approaches, like putting weights to low-degree vertices.

As we also proved that the extension problem associated to CDS is computationally intractable even on 2-degenerate graphs, it is not that straightforward to analyze our enumeration algorithm with the eyes of output-sensitive analysis. Conversely, should it be possible to find an efficient algorithm for an extension problem, also on special graph classes, then usually polynomial-delay algorithms can be shown; as a recent example in the realm of domination problems, we refer to the enumeration of minimal Roman dominating functions described in [2]. So, in the context of our problem, we can ask: Can we achieve polynomial delay for any enumeration algorithm for minimal CDS? Can we combine this analysis with a good input-sensitive enumeration approach? Notice that the corresponding questions for

enumerating minimal dominating sets are an open question for decades. This is also known as the HITTING SET TRANSVERSAL problem; see [11, 12, 18, 26]. We therefore also presented relations between polynomial-delay enumeration of minimal dominating sets and that of minimal CDS, again explaining the difficulty of the latter question. Finally, we also briefly discussed the possibility of subexponential delay. We propose to discuss this question further also for other enumeration problems when polynomial delay is not achievable, as it might well be a practical solution to know that the delay time is substantially smaller than the time needed to enumerate all solutions, but not polynomial time.

We also discussed parameterized complexity aspects of CONNECTED DOMINATING SET EXTENSION, leaving $W[3]$ -membership an open question in the general case.

Abstract

We study the problem of estimating the number of edges in an n -vertex graph, accessed via the *Bipartite Independent Set* query model introduced by Beame et al. (TALG '20). In this model, each query returns a Boolean, indicating the existence of at least one edge between two specified sets of nodes. We present a *non-adaptive* algorithm that returns a $(1 \pm \epsilon)$ relative error approximation to the number of edges, with query complexity $\tilde{O}(\epsilon^{-5} \log^5 n)$, where $\tilde{O}(\cdot)$ hides $\text{poly}(\log \log n)$ dependencies. This is the first non-adaptive algorithm in this setting achieving $\text{poly}(1/\epsilon, \log n)$ query complexity. Prior work requires $\Omega(\log^2 n)$ rounds of adaptivity. We avoid this by taking a fundamentally different approach, inspired by work on single-pass streaming algorithms. Moreover, for constant ϵ , our query complexity significantly improves on the best known adaptive algorithm due to Bhattacharya et al. (STACS '22), which requires $O(\epsilon^{-2} \log^{11} n)$ queries. Building on our edge estimation result, we give the first non-adaptive algorithm for outputting a nearly uniformly sampled edge with query complexity $\tilde{O}(\epsilon^{-6} \log^6 n)$, improving on the works of Dell et al. (SODA '20) and Bhattacharya et al. (STACS '22), which require $\Omega(\log^3 n)$ rounds of adaptivity. Finally, as a consequence of our edge sampling algorithm, we obtain a $\tilde{O}(n \log^8 n)$ query algorithm for connectivity, using two rounds of adaptivity. This improves on a three-round algorithm of Assadi et al. (ESA '21) and is tight; there is no non-adaptive algorithm for connectivity making $o(n^2)$ queries.

1 Introduction

In this work, we study sublinear query algorithms for estimating the number of edges in a simple, unweighted graph $G = (V, E)$, and for sampling uniformly random edges. Access to G is via a *Bipartite Independent Set (BIS)* oracle [10]. A query to this oracle takes as input two disjoint subsets $L, R \subseteq V$ and returns

$$\text{BIS}(L, R) = \begin{cases} '1' & \text{if there is no edge between } L \text{ and } R \\ '0' & \text{otherwise.} \end{cases}$$

Local Query Models. Prior work on sublinear query graph algorithms has largely focused on *local* queries, in particular, (i) vertex degree queries (ii) neighbor queries (output the i^{th} neighbor of a vertex) and (iii) edge existence queries [31, 33, 48]. In the literature, the first two types of queries form the *adjacency list* query model, while all three types of queries form the *adjacency matrix* query model. Under these models, a variety of graph estimation problems have been well studied, including edge counting and sampling [30, 33, 48, 51], subgraph counting [5, 17, 29], vertex cover [11, 43], and beyond [45].

For a graph with n nodes and m edges, given access only to degree queries, Feige [31] presented an algorithm for estimating m up to $(2 \pm \epsilon)$ relative error with query complexity $O(\sqrt{n} \cdot \text{poly}(1/\epsilon, \log n))$. This work also showed that any $(2 - o(1))$ -approximation algorithm requires $\Omega(n)$ queries. In the adjacency list query model, Goldreich and Ron [33] gave a $(1 \pm \epsilon)$ -approximation algorithm, with query complexity $O(n/\sqrt{m} \cdot \text{poly}(1/\epsilon, \log n))$. Recently, Eden and Rosenbaum [30] gave algorithms for near-uniform edge sampling with the same query complexity, and showed that this complexity is nearly tight.

Global Query Models. Motivated by the desire to obtain more query efficient algorithms, Beame et al. [10] studied edge estimation using *global* queries that can make use of information across the graph, including the BIS queries that we will focus on, and the related Independent Set (IS) queries, which were initially introduced in the literature on query efficient graph recovery [1, 6]. An IS query answers whether or not there exist any edges in the induced subgraph on a subset of nodes $S \subseteq V$. We refer the reader to the exposition in [10], which discusses applications of these global query models in group testing [22, 27], computational geometry [7, 18, 32], fine-grained complexity [25, 26], and decision versus counting complexity [26, 46, 49, 50].

In the IS query model, [10, 23] give a $O(\min\{\sqrt{m}, n/\sqrt{m}\} \cdot \text{poly}(\log n, 1/\epsilon))$ query algorithm for $(1 \pm \epsilon)$ approximate edge counting. In the BIS model, numerous authors [10, 26, 14] achieve $(1 \pm \epsilon)$ -approximation for edge counting and near-uniform edge sampling using just $\text{poly}(1/\epsilon, \log n)$ queries. This can be exponentially smaller than the query complexities in the IS and local queries models.

Extending the BIS query model to hypergraphs, Dell et al. [26] introduce the *coloured independence oracle* which detects the presence of a size k hyperedge. They give algorithms for hyperedge estimation and sampling using this generalized oracle. Many other variants of global queries have been studied including LINEAR, OR and CUT queries [8, 20, 47]. These queries have been applied to solving maximum matching [38, 42], minimum cut [47], triangle estimation [12, 13, 26], connectivity [8], hitting sets [15], weighted edge estimation [16], problems related to linear algebra [44], quantum algorithms [40], and full graph recovery [1, 6].

The Role of Adaptivity. Notably, for both local and global queries, most sublinear time graph algorithms are *adaptive*, i.e., a query may depend on the answers to previous queries. In many cases, it is desirable for queries to be *non-adaptive*. This allows them to be completed

independently, and might allow for the resulting algorithm to be easily implemented in massively parallel computation frameworks [37]. Non-adaptive algorithms also lead naturally to single-pass, rather than multi-pass, streaming algorithms. In fact, the BIS query model can be seen as a very restricted subset of the more general LINEAR query model, in which each query outputs the inner product of the edge indicator vector with a query vector. This model has long been studied in the graph-streaming literature [4, 39], in part due to its usefulness in giving single-pass algorithms. However, it has remained open whether non-adaptive algorithms can be given in more restricted global query models.

For these reasons, Assadi et al. [8] and Chakrabarti and Stoeckl [20] have recently sought to reduce query adaptivity under a variety of global query models, including LINEAR, OR, CUT and BIS queries. These works study the *single element recovery* problem, which is a weaker variant of uniform edge sampling, requiring that the algorithm return a single edge in G . Assadi et al. also study the problem of checking connectivity, presenting a BIS query algorithm making $\tilde{O}(n)$ queries and using three rounds of adaptivity. They give a two-round algorithm in the stronger OR query model, and show that even in this model, there is no non-adaptive algorithm for connectivity making $o(n^2)$ queries.

We note that reducing query adaptivity is also a well-studied direction in the closely related literature on group testing [28, 34]. IS and BIS oracles can be thought of as tests if there is a single element in a group of edges, where that group is required to be all edges incident on one node set (IS) or between two disjoint sets (BIS). Attempts to minimize query adaptivity have also been made for sparse recovery [35, 36, 41], submodular function maximization [9, 21], property testing [19] and multi-armed bandit learning [3].

1.1 Our Contributions

Our main result is the first *non-adaptive* algorithm for edge estimation up to $(1 \pm \epsilon)$ relative error, using $\text{poly}(1/\epsilon, \log n)$ BIS queries. Formally, we show:

► **Theorem 1** (Theorem 6 restated). *Given a graph G with n nodes and m edges, there is an algorithm that makes $O(\epsilon^{-5} \log^5 n \log^5(\log n) \log(\epsilon^{-1} \log n))$ non-adaptive BIS queries to G and returns an estimate \hat{m} satisfying: $m(1-\epsilon) \leq \hat{m} \leq m(1+\epsilon)$, with probability at least $3/5$.¹*

Prior methods for $(1 \pm \epsilon)$ error edge estimation using BIS queries are based on a binary search style approach [10, 26, 14], which is inherently adaptive, and leads to algorithms requiring $\Omega(\log^2 n)$ rounds of adaptivity. Beame et al. [10] present a non-adaptive algorithm giving a $O(\log^2 n)$ approximation factor for bipartite graphs, using $O(\log^3 n)$ queries. This algorithm can be extended to general graphs, via a simple reduction, described in Section 3.3. However, no non-adaptive results for general graphs achieving $1 \pm \epsilon$ relative error for arbitrary $\epsilon > 0$ were previously known. Even with adaptivity, the best known algorithm due to [14] has a query complexity of $O(\epsilon^{-2} \log^{11} n)$. The non-adaptive result of Theorem 1 improves upon this prior work significantly, whenever ϵ is constant with respect to n . Our second result builds on our edge estimation approach, giving the first non-adaptive BIS query algorithm that returns a near-uniformly sampled edge. Formally:

► **Theorem 2** (Theorem 7 restated). *Given a graph G with n nodes, m edges, and edge set E , there is an algorithm that makes $O(\epsilon^{-4} \log^6 n \log(\epsilon^{-1} \log n) + \epsilon^{-6} \log^5 n \log^6(\log n) \log(\epsilon^{-1} \log n))$ non-adaptive BIS queries which, with probability at least $1-\epsilon$, outputs an edge from a probability distribution P satisfying $(1-\epsilon)/m \leq P(e) \leq (1+\epsilon)/m$ for every $e \in E$.*

¹ Note that the success probability can be boosted in the standard way, by running multiple independent instantiations of the algorithm and taking their median estimate.

Prior results for near-uniform edge sampling required $\Omega(\log^3 n)$ rounds of adaptivity [14, 26]. Additionally, even ignoring adaptivity, our result improves on the best known query complexity of $O(\epsilon^{-2} \log^{14} n)$, due to [14], for large enough ϵ , including when ϵ is a constant.

By combining Theorem 2 with prior work on sublinear query graph connectivity, via edge sampling, we obtain a connectivity algorithm using two rounds for adaptivity:

► **Theorem 3** (Theorem 8 restated). *Given a graph G with n nodes, there is a 2-round adaptive algorithm that determines if G is connected with probability at least $1 - 1/n$ using $O(n \log^8 n \log(\log n))$ BIS queries.*

Theorem 3 improves on a three-round algorithm of Assadi et al. [8] and is tight in terms of adaptivity: even in the stronger OR query model (which allows checking the presence of an edge within an arbitrary subset of node pairs) no non-adaptive algorithm can make $o(n^2)$ queries. Assadi et al. gave a two-round algorithm in this stronger OR query model. Thus, Theorem 3 closes the gap between BIS queries and OR queries for the connectivity problem. We note that there is a separation from the even stronger LINEAR query model, where non-adaptive algorithms for connectivity and cut approximation are well-known [4]. Understanding if there remain natural separations between the BIS and OR query models in terms of adaptivity would be very interesting.

2 Technical Overview

In this section, we present an overview of three main results: our non-adaptive BIS query algorithm for edge estimation (Theorem 1) and near-uniform edge sampling (Theorem 2), along with our 2-round algorithm for connectivity (Theorem 3).

2.1 Edge Estimation

A simple idea to estimate the number of edges in a graph via BIS queries is to sample small random subsets of nodes and run BIS queries to check the presence of edges between them. The fraction of these queries that return ‘1’ (i.e., indicating the presence of no edge) can then be used to estimate the total number of edges in the graph. In particular, for a graph containing m edges, if the random subsets of nodes have $O(n/\sqrt{m})$ nodes in them, then we expect a ‘1’ answer with constant probability. Beame et al. [10] describe a non-adaptive algorithm along these lines, which gives a $O(\log^2 n)$ approximation using $O(\log^3 n)$ queries. Unfortunately, going beyond this coarse approximation is difficult: many dependencies due to common neighbors arise and this increases the variance of the estimators. Beame et al. handle the issue by using the coarse estimates to subdivide the graph into smaller sub-graphs, until these divided graphs only contain $\text{poly log } n$ edges, at which point all their edges can be discovered with few queries. This strategy yields a $(1 \pm \epsilon)$ approximation, however, it is inherently adaptive.

Our non-adaptive algorithm takes a different approach. Let $d(v)$ denote the degree of a node v . Suppose we could sample each node with probability $p_v \approx d(v) \cdot \epsilon^{-2}/m$ and compute the degree of the sampled nodes. Letting $\hat{m} = \sum_v \mathbb{I}[v \text{ sampled}] \cdot d(v)/p_v$, be the appropriately weighted average of the sampled degrees, it is straightforward to show that $\mathbf{E}[\hat{m}] = \sum_v d(v) = 2m$. Further, via a standard Bernstein bound, $\hat{m}/2$ gives a $(1 \pm \epsilon)$ relative error approximation to m with high probability. The challenge is showing that this type of approach can be approximated in the BIS query model.

Subsampling Nodes. The first idea, drawn from work on streaming algorithms, is to subsample the nodes of G at different rates of the form $1/\gamma^j$ where $\gamma > 1$ is constant and $j \in \{0, 1, \dots, O(\log n)\}$. At each rate, we “recover” any sampled nodes (along with a corresponding degree estimate) whose degree is roughly $d(v) \approx \epsilon^2 m / \gamma^j$. In this way, each node will be recovered with probability roughly $1/\gamma^j \approx d(v) \cdot \epsilon^{-2} / m$, as desired. We describe this subsampling procedure in Section 3.3, as part of our main algorithm EDGE-ESTIMATOR (Algorithm 3).

Recovering Heavy Nodes. The next challenge is to show that we can actually recover the appropriate nodes and degree estimates at each sampling rate. If we can approximate the degree of all nodes sampled at rate $1/\gamma^j$ up to additive error $O(\epsilon^3 \cdot m / \gamma^j)$, we will obtain a $(1 \pm \epsilon)$ relative error approximation to the degree of any node we hope to recover at that sampling rate, i.e., any node with degree roughly $\epsilon^2 m / \gamma^j$. Using these approximations, we can determine which nodes should be recovered at that rate, and form our edge estimate.

Degree Estimation via Neighborhood Size Estimation. To achieve such an additive error approximation, we use ideas from the sparse recovery and streaming literature. In particular, we implement an approach reminiscent of the Count-Min sketch algorithm [24]. The approach is described in detail in Section 3.2, where we present Algorithm ESTIMATE-DEGREE (Algorithm 2). First observe that when sampling at rate $1/\gamma^j$, conditioned on any node v being included in the sample, the expected total degree of the sampled nodes other than v is $O(m/\gamma^j)$. If we further subdivide these nodes into $\tilde{O}(1/\epsilon^3)$ random groups, the expected total degree of all nodes other than v in any group is $\tilde{O}(\epsilon^3 \cdot m/\gamma^j)$.

Now, if v is placed in group S , we can approximately upper bound its degree by the total *neighborhood size of S* . This upper bound holds approximately as long as v does not have too many neighbors in S , which it won’t with good probability. The neighborhood size of S is in turn upper bounded by the degree of v plus the total degree of other nodes in S , and thus by $d(v) + \tilde{O}(\epsilon^3 \cdot m/\gamma^j)$ in expectation. So, in expectation, this approach gives an additive $\tilde{O}(\epsilon^3 \cdot m/\gamma^j)$ error approximation to the degree of each sampled node v , with constant probability. Repeating this procedure $O(\log n)$ times, and, as in the Count-Min sketch, taking the minimum degree estimate for each node sampled at rate $1/\gamma^j$, gives us high probability approximation for such nodes.

Neighborhood Size Estimation. The final step is to implement an algorithm that can estimate the neighborhood size of the random subset of nodes S , to be used in our degree estimation procedure. We do this in Section 3.1, where we present Algorithm NEIGHBORHOOD-SIZE (Algorithm 1). This algorithm takes as input two disjoint subsets L, R and returns a $(1 \pm \epsilon)$ -approximation for the size of the neighborhood of L in R . We highlight that this may be very different than the *number of edges connecting L to R* – the neighborhood size is the number of nodes in R with at least one edge to L . This difference is critical in removing the correlations discussed previously due to common neighbors. Such correlations lead to the adaptive nature of prior algorithms [10, 26]. To estimate the size of the neighborhood of L in R , we sample the nodes in R at different rates and ask BIS queries on L and the sampled subset of R . Intuitively, when the sampling rate is the inverse of the size of the neighborhood, we will observe a ‘1’ response with constant probability. We can detect this and thus estimate the neighborhood size.

Non-adaptivity. The approach described above is inherently non-adaptive. All random sampling of nodes and random subsets can be formed ahead of time, independently of any query responses. The only catch is that to determine which nodes should be recovered at each sampling rate, i.e., those nodes with degree $d(v) \approx \epsilon^{-2} \cdot m/\gamma^j$, we need a coarse estimate to the edge count m in the first place. Fortunately, we can bootstrap such an estimate starting with a coarse $O(\log^2 n)$ -relative error approximate estimation, due to Beame et al. [10]. We then refine this estimate iteratively using Algorithm REFINE-ESTIMATE (Algorithm 4). Each refinement improves the approximation factor by ϵ , and after $O(\log_{1/\epsilon} \log n)$, refinements our estimate will result in a $(1 \pm \epsilon)$ -approximation factor. The key observation here is that each refine step does not require any additional BIS queries. Thus, our algorithm remains non-adaptive.

2.2 Uniform Edge Sampling and Connectivity

In the full version [2], we prove Theorem 2 by designing and analyzing a non-adaptive algorithm for returning a near-uniform sample among the edges of the graph. Our approach builds heavily on our edge estimation algorithm. If we knew the degree $d(v)$ of all vertices, then to sample a uniform edge, we could sample a vertex $v \in V$ with probability $d(v)/\sum_{w \in V} d(w) = \frac{d(v)}{2m}$ and return a uniform neighbor among the neighbors of v . We can observe that the probability that an edge (v, u) is sampled is $\frac{d(v)}{2m} \cdot \frac{1}{d(v)} + \frac{d(u)}{2m} \cdot \frac{1}{d(u)} = \frac{1}{m}$. I.e., this approach yields a uniformly random edge sample.

Node Sampling. We implement the above approach approximately using BIS queries. First, observe that recovered vertices in our edge estimation algorithm are sampled with probabilities roughly proportional to their degrees. We argue that we can select a random vertex from this set, which overall is equal to any vertex v with probability approximately $\frac{d(v)}{2m}$. To do so, we leverage our degree estimates, and the fact that our edge count estimator, which is the sum of scaled degrees of recovered vertices, is well-concentrated.

Random Neighbor Sampling. It remains to show how to return a uniformly random neighbor of the sampled vertex. Similar to our edge estimation procedure, we design an algorithm which takes as input two disjoint subsets L, R and returns a uniform neighbor of L in R . To do so, we demonstrate an equivalence between the substantially more powerful OR queries and BIS queries in this specific setting, and argue that an existing algorithm for OR queries can be extended to return a uniform neighbor using BIS queries. An OR query takes as input a subset of pairs of vertices and returns ‘1’ iff there is an edge in the subset queried. Building on this, in the full version [2], we present Algorithm UNIFORM-NEIGHBOR that takes as input the subset of nodes sampled at any rate $1/\gamma^j$ as in our edge estimation algorithm, and approximately returns a uniform neighbor for every vertex v sampled in this set. Similar to ESTIMATE-DEGREE (Algorithm 2), we construct $\tilde{O}(1/\epsilon^4)$ random partitions of the sampled nodes. For every vertex v in a random subset S , we return a uniform neighbor (obtained using the idea just described) of the partition of S , as the neighbor of v . If v has large degree compared to the total degree of nodes in S , which it will if it is meant to be recovered at that sampling rate, this output will most likely be a neighbor of v , and will be close to a uniformly random one.

A Two-Round Algorithm for Connectivity. Our non-adaptive edge sampling algorithm (Theorem 2) directly yields a two-round algorithm for graph connectivity (Theorem 3), improving on a prior three-round algorithm of [8]. In particular, the algorithm of [8] selects

$O(\log^2 n)$ random neighbors per vertex, and contracts the connected components of this random graph into *supernodes*. This random sampling step can be performed using one round of $\tilde{O}(n)$ BIS queries. They prove that in the contracted graph on the supernodes, there are at most $O(n \log n)$ edges. Using this fact, they then show how to identify whether all the supernodes are connected using $\tilde{O}(n)$ BIS queries and two additional rounds of adaptivity.

We follow the same basic approach: using a first round of $\tilde{O}(n)$ queries to randomly sample $O(\log^2 n)$ neighbors per vertex and contract the graph into supernodes. Once this is done, we observe that we have BIS query access to the contracted graph simply by always grouping together the set of nodes in each supernode. So, we can directly apply the non-adaptive sampling algorithm of Theorem 2 to sample edges from the contracted graph. By a coupon collecting argument, drawing $O(n \log^2 n)$ near-uniform edge samples (with replacement) from the contracted graph suffices to recover all $O(n \log n)$ edges in the graph, and thus determine connectivity of the contracted graph, and, in turn, the original graph.

2.3 Notation

Let $G(V, E)$ denote an undirected graph on vertex set V with edges $E \subseteq V \times V$. Let $|V| = n$ be the number of nodes and $|E| = m$ be the number of edges. For any set of nodes $S \subseteq V$, let $E[S] \subseteq E$ denote the edges in the induced subgraph on S . For any two disjoint sets of nodes $L, R \subseteq V$, let $E[L, R] = \{(u, v) \in E \mid u \in L, v \in R\}$ denote the edges between them. For any $v \in V$, let $\Gamma(v) = \{u \mid (u, v) \in E \text{ for some } v \in V\}$ be its set of neighbours. Let $d(v) = |\Gamma(v)|$ be its degree. For $S \subseteq V$, let $\Gamma(S) = \bigcup_{u \in S} \Gamma(u)$ and let $d(S) = \sum_{u \in S} d(u)$.

3 Non-adaptive algorithm for edge estimation

In this section, we present our non-adaptive algorithm for edge estimation using BIS queries. In Section 3.1, we describe an algorithm that takes as input two disjoint subsets L, R and returns an estimate of the size of the neighborhood $|\Gamma(L) \cap R|$. Next, in Section 3.2, we use this algorithm to give additive error approximations of degrees of all the vertices in a given subset. Finally, in Section 3.3, using the approximate degree estimates, we construct a $(1 \pm \epsilon)$ -approximate estimator for m by sampling nodes with probabilities roughly proportional to their degrees. Missing details are included in the full version [2].

3.1 Estimating the size of neighborhood

NEIGHBORHOOD-SIZE (Algorithm 1) takes as input two disjoint subsets $L, R \subseteq V$ and returns a $(1 \pm \epsilon)$ -approximation of the size of neighborhood of L in R , i.e., $|\Gamma(L) \cap R|$ using $\text{poly}(1/\epsilon, \log n)$ BIS queries. We overview the analysis of this algorithm here.

The main idea is to sample subsets of vertices in R (denoted $\hat{R}_1, \hat{R}_2, \dots$) with exponentially decreasing probability values $1/2, 1/4, 1/8, \dots$. When the sampling rate $1/2^i$ falls below $1/|\Gamma(L) \cap R|$, we expect L to no longer have any neighbors in \hat{R}_i with good probability. In particular, we can return the inverse of the smallest probability $1/2^i$ for which $\mathcal{BIS}(L, \hat{R}_i) = '1'$, as a coarse estimate for $|\Gamma(L) \cap R|$.

To boost the accuracy of this estimate, we repeat the process $T = O(\epsilon^{-2} \log(\delta^{-1} \cdot \log n))$ times, and at each sampling rate count the number of times the BIS query $\mathcal{BIS}(L, \hat{R}_i)$ returns '1'. This count is denoted $\text{count}(i)$ in Algorithm 1, and its expectation can be written in closed form as $\mathbf{E}[\text{count}(i)] = T \cdot (1 - 1/2^i)^{|\Gamma(L) \cap R|}$. Suppose $2^i \leq |\Gamma(L) \cap R| < 2^{i+1}$, then, $\mathbf{E}[\text{count}(\hat{i})] = \Theta(T)$. Via a standard Chernoff bound, it will be approximated to $(1 \pm \epsilon)$ error with high probability by $\text{count}(\hat{i})$. Thus, we can compute an accurate estimate of the

neighborhood size by inverting our estimate of $\mathbf{E}[\text{count}(\hat{i})]$, as $\log_{(1-1/2^{\hat{i}})}(\text{count}(\hat{i})/T)$. We identify the appropriate \hat{i} in line 12 of Algorithm 1, and compute the corresponding estimate in lines 13-14. There is one edge case handled in line 13: if $|\Gamma(L) \cap R| = 1$ we will have $\hat{i} = 0$, and $\text{count}(\hat{i}) = 0$. The final error bound for Algorithm 1 is stated below.

► **Lemma 4.** *Algorithm 1 uses $O(\epsilon^{-2} \log n \log(\delta^{-1} \cdot \log n))$ BIS queries and returns an estimate $\eta_{\text{est}}(L)$ of $|\Gamma(L) \cap R|$ such that with probability at least $1 - \delta$,*

$$(1 - \epsilon) \cdot |\Gamma(L) \cap R| \leq \eta_{\text{est}}(L) \leq (1 + \epsilon) \cdot |\Gamma(L) \cap R|.$$

■ **Algorithm 1** NEIGHBORHOOD-SIZE: Estimating the neighborhood size of L in R .

Input: $L, R \subseteq V$, approximation error ϵ , failure probability δ .
Output: $\eta_{\text{est}}(L)$ as an estimate of $|\Gamma(L) \cap R|$.

- 1: Initialize $\eta_{\text{est}}(L) \leftarrow 0$.
- 2: **for** $i = 0, 1, \dots, \log_2 n$ **do**
- 3: $\text{count}(i) \leftarrow 0$.
- 4: **for** $t = 1, 2, \dots, T = 2e^8 \ln(\log n / \delta) \cdot \epsilon^{-2}$ **do**
- 5: $\hat{R}_i^t \leftarrow \{u \in R \mid u \text{ is included independently with probability } 1/2^i\}$.
- 6: $\text{count}(i) = \text{count}(i) + \text{BIS}(L, \hat{R}_i^t)$
- 7: **end for**
- 8: **end for**
- 9: **if** $\text{count}(0) = T$ **then**
- 10: **return** $\eta_{\text{est}}(L) = 0$.
- 11: **else**
- 12: Set $\hat{i} \leftarrow \max \{i \mid \frac{\text{count}(i)}{T} < \frac{(1-\epsilon)}{2e^2}\}$.
- 13: **if** $\hat{i} = 0$ **then return** $\eta_{\text{est}}(L) = 1$.
- 14: **else return** $\eta_{\text{est}}(L) = \log_{(1-1/2^{\hat{i}})}(\text{count}(\hat{i})/T)$.
- 15: **end if**
- 16: **end if**

3.2 Finding good approximation for degrees of vertices

We now describe how to use NEIGHBORHOOD-SIZE (Algorithm 1) to estimate the degrees of all vertices in a given subset $S \subseteq V$ up to additive error depending on the total degree of S . Our approach is inspired by the Count-Min sketch algorithm [24]. We randomly partition S into subsets $S^1, S^2, \dots, S^\lambda$ where $\lambda = O(\epsilon^{-3} \log^2 n)$. The choice of the parameter λ is based on the analysis in Section 3.3. For each S^i , we estimate the size of the neighborhood of S^i in $V \setminus S^i$ using NEIGHBORHOOD-SIZE. We then return this neighborhood size estimate as the degree estimate for all vertices in S^i . For $v \in S^i$, $|\Gamma(S^i) \cap V \setminus S^i|$ is nearly an overestimate for $d(v)$, as long as v has few neighbors in S^i , which it will with high probability. Additionally, it is not too large an overestimate – we can observe that $|\Gamma(S^i) \cap V \setminus S^i| - d(v) \leq d(S^i \setminus v)$. I.e., the error in the overestimate is at most the total degree of the other nodes in S^i . In expectation, this error is at most $\frac{d(S)}{\lambda} = O\left(d(S) \cdot \frac{\epsilon^3}{\log^2 n}\right)$ due to our random choice of S^i .

As in the Count-Min sketch algorithm, to obtain high probability estimates, we repeat the process $T = O(\log n)$ times and assign the minimum among the neighborhood estimates as the degree estimate of $d(v)$. The full approach is given in Algorithm 2 (ESTIMATE-DEGREE) and the error bound in Lemma 5 below. We set the failure probability, $\delta = O(\epsilon^3 / \log^4 n)$, for each of the calls to NEIGHBORHOOD-SIZE, to ensure that the total failure probability of Algorithm 2 is at most $O(1/\log n)$. As we make at most $T \cdot \lambda$ calls to the Algorithm NEIGHBORHOOD-SIZE, the total BIS queries used is $O(\log n \cdot \epsilon^{-3} \log^2 n \cdot \epsilon^{-2} \log n \log(\log^4 n \cdot \log n)) = O(\epsilon^{-5} \log^4 n \log(\log n))$. Formally, we have:

► **Lemma 5.** For any $S \subseteq V$, Algorithm 2 uses $O(\epsilon^{-5} \log^4 n \log(\log n))$ BIS queries and with probability $1 - O(1/\log n)$, returns degree estimates $\widehat{d}(v)$ for every $v \in S$ satisfying:

$$d(v)(1 - \epsilon) \leq \widehat{d}(v) \leq d(v) + \frac{\epsilon^3}{\log^2 n} \cdot d(S).$$

■ **Algorithm 2** ESTIMATE-DEGREE: Obtain additive approximate degree estimates.

Input: S is a subset of V , ϵ is approximation error.

Output: Degree estimates of vertices in S .

```

1: Initialize  $\widehat{d}(v) \leftarrow n$  for every  $v \in S$ .
2: for  $t$  in  $\{1, 2, \dots, O(\log n)\}$  do
3:   Form a random partition of  $S$  into  $S^{t,1}, S^{t,2}, \dots, S^{t,\lambda}$  where  $\lambda = O(\epsilon^{-3} \log^2 n)$ .
4:   for every set  $S^{t,a}$  where  $a \in [\lambda]$  do
5:      $\eta_{\text{est}}(S^{t,a}) \leftarrow \text{NEIGHBORHOOD-SIZE}(S^{t,a}, V \setminus S^{t,a}, \epsilon/3, \delta)$ , where  $\delta = O(\epsilon^3 / \log^4 n)$ .
6:     For all  $v \in S^{t,a}$ , set  $\widehat{d}(v) \leftarrow \min\{\widehat{d}(v), \eta_{\text{est}}(S^{t,a})\}$ .
7:   end for
8: end for
9: return  $\widehat{d}(v)$  for every  $v \in S$ .

```

3.3 Edge Estimation

In this section, we describe the algorithm EDGE-ESTIMATOR (Algorithm 3) that obtains a $(1 \pm \epsilon)$ -approximation for the number of edges m . Missing details are presented in the full version [2].

Our Approach. A naive strategy to estimate the number of edges m is to sample $\widetilde{O}(\epsilon^{-2})$ nodes uniformly, and estimate m as $n/2$ times the average degree of the sampled nodes. However, the variance of such an estimator depends on the maximum degree, which could be as high as n . To fix this issue, we would like to sample vertices with probabilities proportional to their degrees. In particular, we sample vertices at different rates $1/\gamma^j$, where $\gamma > 1$ is a constant and $j \in \{0, 1, \dots, \log n\}$. We use the term j^{th} level to refer to the sampling rate $1/\gamma^j$. Our estimator is given by: $\widehat{m} = \sum_v \mathbb{I}[v \text{ sampled}] \cdot d(v)/p_v$, be the appropriately weighted average of the sampled degrees. It is straightforward to show that $\mathbf{E}[\widehat{m}] = \sum_v d(v) = 2m$ and as argued in section 1, it is also concentrated around $2m$ with high probability. It is easy to observe that when a vertex v is sampled at rate $\widetilde{O}(\epsilon^{-2}d(v)/m)$, its contribution to \widehat{m} is $\widetilde{O}(\epsilon^2m)$. In other words, we need to detect the event that $d(v) \approx \epsilon^2m/\gamma^j$, for some sampling level j . If we identify $\widetilde{O}(\epsilon^{-2})$ such vertices, \widehat{m} will be an accurate estimate of the total edges, after appropriate scaling. However, there are three main challenges in implementing this approach which we detail below.

Approximate degrees. Algorithm ESTIMATE-DEGREE returns degree estimates with an additive approximation error of $O(\epsilon^3 \log^{-2} n \cdot d(S_j))$ at sampling level j . $\widetilde{O}(\epsilon^3m/\gamma^j)$ at sampling level j . It is easy to see that $\mathbf{E}[d(S_j)] = O(m/\gamma^j)$. From Markov's inequality and union bound, we have that: $d(S_j) = O(m \log n / \gamma^j)$ for all $j \in [L]$ with probability at least $3/4$. Therefore, the additive approximation error term is $\widetilde{O}(\epsilon^3 \cdot m/\gamma^j)$. To include the contribution of a vertex v in the estimator, we must ensure that this error term is small in a relative sense – i.e., at most $O(\epsilon \cdot d(v))$. This holds whenever $d(v) = \widetilde{\Omega}(\epsilon^2m/\gamma^j)$. Observe that this corresponds to the threshold we mentioned earlier. Therefore, our goal is to identify all vertices at every level j that pass the threshold of $\widetilde{\Omega}(\epsilon^2m/\gamma^j)$. When that happens, we say that the vertex v has been recovered at level j and can be safely included in our estimator.

Knowledge of m . As we do not know the value of m , we start with an $O(\log^2 n)$ -relative error approximate estimate, obtained using the Algorithm COARSEESTIMATOR in Beame et al. [10], as follows: Given a partition $L, R \subseteq V$, Algorithm COARSEESTIMATOR returns an approximate estimate for the number of edges between L and R , given by: $\frac{m(L,R)}{8 \log n} \leq \bar{m}(L,R) \leq 8 \log n \cdot m(L,R)$, where $m(L,R) = |E[L,R]|$. However, using a simple reduction, we can convert this estimate into an $O(\log^2 n)$ -relative error approximation for total edges in the graph G . First, we partition the graph uniformly into two sets of vertices L and R . We set our estimate for edges as: $\bar{m} = O(\log n) \cdot \bar{m}(L,R)$. From Lemma 3.2 in [10], $m(L,R) = \Theta(m)$ when $m \geq 2$, with constant probability. So, our initial estimate for refinement, \bar{m} , satisfies: $m \leq \bar{m} \leq O(\log^2 n) \cdot m$.

We repeatedly refine the approximate estimate using Algorithm REFINE-ESTIMATE, until we get a $(1 \pm \epsilon)$ -relative error approximation of m . Each *refinement* improves the approximation factor from the previous stage by a multiplicative factor of ϵ . We note that each refinement does not require any additional BIS queries and uses the available approximate degree estimates.

Boundary Vertices. We partition the space of possible degrees, i.e., $[0, n]$ into geometrically decreasing partitions, called *levels*. Each level is represented by an integer in $[0, L]$. We recover a vertex at a particular level $j \in [0, L]$, if it is sampled with probability corresponding to the level, i.e., γ^{-j} and it passes the threshold mentioned earlier. It is possible that some vertices have degrees close to the threshold values at each sampling level. We denote the set of such vertices as $V_{\text{boundary}} \subseteq V$. For such boundary vertices, as we use approximate degree estimates, they might be recovered at a level different from their true levels (defined with respect to exact degrees). Such a scenario could potentially affect the contribution of the recovered vertex in our estimator by an additional multiplicative factor dependent on γ and the difference between recovered level and true level. As a result, our estimator might not be a $(1 \pm \epsilon)$ -relative error approximation anymore. We get around this limitation by dividing the region between any two consecutive levels into $B = O(1/\epsilon)$ buckets, where ϵ denotes the approximation parameter, and shifting the boundaries of all the levels by a random shift selected uniformly from the first B buckets. We account for this by changing the sampling rates to $\gamma^{-\mu(j)}$ where $\mu(j)$ encodes the random shift. We set the parameter corresponding to the sampling probability, $\gamma = 1/(1 - \epsilon)$.

With the random shift of the level boundaries, we ensure that every vertex will lie close to the boundary with probability at most ϵ . Moreover, we argue that every boundary vertex is recovered at its true level or level adjacent to its true level. Therefore, the total contribution of V_{boundary} to our edge estimator is $O(\epsilon m)$.

Random Boundary Shift. The region between two consecutive levels is divided into B buckets with the boundaries of buckets proportional to the values given by: $\{[1/\gamma^B, 1/\gamma^{B-1}), \dots, [1/\gamma^2, 1/\gamma), [1/\gamma, 1)\}$. We select a random integer offset for shifting our levels, denoted by s , which is selected uniformly at random from $[0, B)$. Now, the level boundaries are located at values proportional to $\gamma^{-\mu(j)}$ where $\mu(j) = j \cdot B - s$ and $0 \leq j \leq L$. Observe that the number of sampling levels is given by $L = \frac{2}{B} \cdot \log_\gamma n + 1 \leq \log n + 1$. Combining everything, the exact level boundaries are dependent on the estimate \bar{m} and given by $O\left(\frac{\bar{m}}{\gamma^{\mu(j)}} \cdot \frac{\epsilon^2}{\log n}\right)$, for every $j \in [0, L]$.

3.3.1 Overview of Algorithm Edge-Estimator

In Algorithm EDGE-ESTIMATOR, we construct sets $V = S_0 \supseteq S_1 \supseteq \dots \supseteq S_L$ where a set S_j (for all $j \geq 2$) is obtained by sampling vertices in S_{j-1} with probability $1/\gamma^B$. The set S_1 is obtained by sampling vertices in V with probability $1/\gamma^{-s+B}$. Our sampling scheme results in each vertex being included in a set S_j with probability $1/\gamma^{\mu(j)}$. As described previously, with constant probability, $d(S_j) = O(m \log n / \gamma^{\mu(j)})$, for all j . Using Algorithm 2, we obtain approximate degree estimates of vertices in S_j for every sampling level $j \leq L$ with an approximation error of $O(\epsilon^3 / \log^2 n \cdot d(S_j)) = O(m \epsilon^3 / \gamma^{\mu(j)} \log n)$. In order that this error is small, we need to recover vertices $v \in S_j$ with high degree, such that $d(v) = \tilde{\Omega}(\frac{m}{\gamma^{\mu(j)}} \cdot \frac{\epsilon^2}{\log n})$. As we do not know m , we bootstrap it with a $O(\log^2 n)$ -relative error approximate estimate due to [10], denoted by \bar{m}_0 . We repeatedly refine the estimate $T = 2 \log_{1/\epsilon} \log n$ times, using REFINE-ESTIMATE (Algorithm 4), where the estimate \bar{m}_{t-1} is used to construct an improved estimate \bar{m}_t . We return the estimate \bar{m}_T as our final estimate for m . The constants used c_1, c_2 satisfy $c_1 \leq c_2/10$ and $c_2 \geq 50$.

■ **Algorithm 3** EDGE-ESTIMATOR: Non-adaptive algorithm for estimating edges.

Input: V set of n vertices and $\epsilon > 0$ error parameter.

Output: Estimate \hat{m} of number of edges in G .

- 1: Scale $\epsilon \leftarrow \frac{\epsilon}{600 \log_{1/\epsilon} \log n}$ and initialize $\gamma \leftarrow 1/(1 - \epsilon)$ and $B \leftarrow 2/\epsilon$.
- 2: Let s be an integer selected uniformly at random from the interval $[0, B)$.
- 3: Let $\mu(j) \leftarrow -s + j \cdot B$ for every integer j in the interval $[0, \frac{2}{B} \cdot \log_\gamma n + 1]$.
- 4: Initialize $S_0 \leftarrow V$ and construct S_1 by sampling vertices in S_0 with probability $1/\gamma^{\mu(1)}$.
- 5: Construct $S_2 \supseteq \dots \supseteq S_L$ for $L = \frac{2}{B} \cdot \log_\gamma n$ where each S_j is obtained by sampling vertices in $S_{j-1} \forall j \geq 2$, independently with probability $1/\gamma^B$.
- 6: **for** $j = 0, 1, \dots, L$ **do**
- 7: Run ESTIMATE-DEGREE (S_j) to obtain the estimates $\hat{d}_j(v)$ for all $v \in S_j$ satisfying:

$$(1 - \epsilon)d(v) \leq \hat{d}_j(v) \leq d(v) + \frac{c_1 \epsilon^3 \cdot m}{\log n \cdot \gamma^{\mu(j)}}.$$
- 8: **end for**
- 9: Construct a random partition L, R of V . Let \bar{m}_0 be the $O(\log n)$ -approximate estimate from the Algorithm COARSEESTIMATOR in Beame et al. [10] on the partition L, R .
- 10: Set $\bar{m}_0 \leftarrow \max\{2, O(\log n) \cdot \bar{m}_0\}$, so that we have $m \leq \bar{m}_0 \leq O(\log^2 n) \cdot m$.
- 11: **for** $t = 1, 2, \dots, T = 2 \log_{1/\epsilon} \log n$ **do**
- 12: \bar{m}_t is assigned the output of REFINE-ESTIMATE that takes as input approximate degree values $\hat{d}_j(v) \forall v \in S_j \forall j \in [L]$, the previous estimate \bar{m}_{t-1} and the iteration t .
- 13: **end for**
- 14: **return** $\hat{m} \leftarrow \bar{m}_T$.

3.3.2 Overview of Algorithm REFINE-ESTIMATE

Suppose we are given an initial estimate \bar{m} satisfying $m \leq \bar{m} \leq (1 + \alpha)m$ for some unknown approximation factor α satisfying $\epsilon \leq \alpha \leq O(\log^2 n)$. We set the threshold value for recovering a vertex at a level j as $\frac{\bar{m}}{\gamma^{\mu(j)}} \cdot \frac{c_2 \epsilon^2}{\log n}$ where c_2 is a constant. So, when a vertex v , that hasn't been recovered at a smaller level yet, with degree estimate $\hat{d}_j(v)$ (obtained from Algorithm 3) satisfies $\hat{d}_j(v) \geq \frac{\bar{m}}{\gamma^{\mu(j)}} \cdot \frac{c_2 \epsilon^2}{\log n}$, we set the level of recovery $\hat{\ell}(v) = j$ and recovered flag $r(v) = 1$.

2:12 Non-Adaptive Edge Counting and Sampling via BIS Queries

From construction, we can observe that once a vertex is recovered at a particular level it is not available to be recovered at higher level later. Our estimator is the summation of terms $\gamma^{\mu(\hat{\ell}(v))} \cdot \hat{d}(v)$ for every v satisfying $r(v) = 1$. We normalize \hat{m} by adding an additional term of $(\epsilon \log \log n)^t \bar{m}_0$ in iteration t , to ensure that after every call to REFINE-ESTIMATE (Algorithm 4), the estimate returned \hat{m} , satisfies: $m \leq \hat{m} \leq m(1 + \epsilon \cdot \log \log n \cdot \alpha)$ (see the full version for additional details [2]). After $T = 2 \log_{1/\epsilon} \log n$ iterations of REFINE-ESTIMATE, we return the estimate \bar{m}_T as our final estimate in EDGE-ESTIMATOR (Algorithm 3).

■ **Algorithm 4** REFINE-ESTIMATE: Refines the current estimate of number of edges.

Input: \bar{m} satisfying $m \leq \bar{m} \leq m(1+\alpha)$, approximate degree values $\hat{d}_j(v) \forall v \in S_j \forall j \in [L]$ obtained using Algorithm 3, \bar{m}_0 , and iteration t .

Output: Estimate \hat{m} satisfying $m \leq \hat{m} \leq m(1 + \epsilon \cdot \alpha \cdot \log \log n)$ of number of edges in G .

- 1: Initialize $\hat{m} \leftarrow 0$.
- 2: Initialize $r(v) \leftarrow 0$ for all v (indicator if v has been recovered yet).
- 3: **for** $j = 0, 1, \dots, L$ **do**
- 4: **for** $v \in S_j$ **do**
- 5: **if** $r(v) = 0$ and $\hat{d}_j(v) \geq \frac{\bar{m}}{\gamma^{\mu(j)}} \cdot \frac{c_2 \epsilon^2}{\log n}$ **then**
- 6: $\hat{m} \leftarrow \hat{m} + \gamma^{\mu(j)} \cdot \hat{d}_j(v)$.
- 7: $\hat{\ell}(v) \leftarrow j$ and $r(v) \leftarrow 1$. ▷ Used in the analysis.
- 8: **end if**
- 9: **end for**
- 10: **end for**
- 11: **if** $t < T = 2 \log_{1/\epsilon} \log n$ **then**
- 12: $\hat{m} = \hat{m}/2 + (\epsilon \log \log n)^t \bar{m}_0$. ▷ We normalize \hat{m} so that we have $\hat{m} \geq m$.
- 13: **else**
- 14: $\hat{m} = \hat{m}/2$.
- 15: **end if**
- 16: **return** \hat{m} .

3.3.3 Final Guarantees of EDGE-ESTIMATOR

Using Bernstein's inequality, we argue that in iteration t , we can improve the approximation factor of the previous estimate \bar{m}_{t-1} by a multiplicative factor of ϵ in the new estimate \bar{m}_t . After $T = O(\log_{1/\epsilon} \log n)$ iterations, the edge estimate will be a $(1 \pm \epsilon)$ -relative error approximation satisfying:

► **Theorem 6.** *Given a graph G with n nodes and m edges, there is an algorithm that makes $O(\epsilon^{-5} \log^5 n \log^5(\log n) \log(\epsilon^{-1} \log n))$ non-adaptive BIS queries to G and returns an estimate \hat{m} satisfying: $m(1 - \epsilon) \leq \hat{m} \leq m(1 + \epsilon)$, with probability at least $3/5$.*

4 Uniform Edge Sampling

In this section, we give brief overview of an algorithm that returns a near-uniformly sampled edge from the graph using $\text{poly}(\log n, 1/\epsilon)$ BIS queries. We present the complete details in the full version [2]. Our algorithm extends EDGE-ESTIMATOR (Alg. 3) and is based on the following idea. Suppose we know the degrees of all the vertices. In order to sample a uniform edge, we can sample a vertex v with probability $d(v)/\sum_{w \in V} d(w) = d(v)/2m$ and return a uniform neighbor among the neighbors of v . The probability that an edge $e = (v, u)$ is sampled is $d(v)/2m \cdot 1/d(v) + d(u)/2m \cdot 1/d(u) = 1/m$.

In order to return a uniform edge, using the above approach, to our setting, there are two challenges. First, we do not know the degrees (or approximate degrees) of *all the vertices*. This is because the set of recovered vertices in REFINE-ESTIMATE (Alg. 4) at a particular level j , i.e., $r(v) = 1$, is a subset of the sampled vertices S_j . Only the recovered vertices at any particular level have accurate degree estimates, i.e., $\widehat{d}_j(v) \approx (1 \pm \epsilon)d(v)$. Secondly, vertices are recovered at different levels and are therefore sampled with different probabilities. In order to return a uniform edge using the previously discussed idea, we must return a single vertex among the set of recovered vertices with probability dependent on the sampling probability at which the vertex was recovered, and its approximate degree.

We address these two challenges, by suitably modifying EDGE-ESTIMATOR (Alg. 3) and returning a vertex v , among the recovered vertices, with probability proportional to $\gamma^{\widehat{\ell}(v)} \cdot \widehat{d}_{\widehat{\ell}(v)}(v)$ where $\widehat{\ell}(v)$ is the level at which it is recovered, and $\widehat{d}_{\widehat{\ell}(v)}(v)$ is the degree estimate at the level of recovery. From Section 3.3, we know that our estimator: $\sum_{v \text{ is recovered}} \gamma^{\widehat{\ell}(v)} \cdot \widehat{d}(v)$, is concentrated around $2m$ (Theorem 6). Combining all the above, we obtain the following result about sampling an edge:

► **Theorem 7.** *Given a graph G with n nodes, m edges, and edge set E , there is an algorithm that makes $O(\epsilon^{-4} \log^6 n \log(\epsilon^{-1} \log n) + \epsilon^{-6} \log^5 n \log^6(\log n) \log(\epsilon^{-1} \log n))$ non-adaptive BIS queries which, with probability at least $1 - \epsilon$, outputs an edge from a probability distribution P satisfying $(1 - \epsilon)/m \leq P(e) \leq (1 + \epsilon)/m$ for every $e \in E$.*

Graph Connectivity. Using the non-adaptive uniform sampling algorithm, we obtain a 2-round adaptive algorithm for determining graph connectivity, by building upon the work of [8]. See Section 2.2 for an outline of this result. Details are deferred to the full version [2].

► **Theorem 8.** *Given a graph G with n nodes, there is a 2-round adaptive algorithm that determines if G is connected with probability at least $1 - 1/n$ using $O(n \log^8 n \log \log n)$ BIS queries.*

5 Conclusion and Open Questions

In this paper, we presented the first $(1 \pm \epsilon)$ relative error non-adaptive algorithms for edge estimation and sampling using BIS queries. It would be interesting to investigate if better dependencies on ϵ than given by our algorithms can be obtained. Further, using Independent Set (IS) queries, *adaptive* algorithms for edge estimation with optimal query complexity $O(\min\{\sqrt{m}, n/\sqrt{m}\} \cdot \text{poly}(\log n, 1/\epsilon))$ were obtained only recently [10, 23]. It would be interesting to see if we can extend our techniques to study *non-adaptive* algorithms for edge estimation using IS queries or in the standard adjacency list query model, studied in the sublinear time graph algorithms literature.

Abstract

Given a graph where every vertex has exactly one labeled token, how can we most quickly execute a given permutation on the tokens? In *(sequential) token swapping*, the goal is to use the shortest possible sequence of *swaps*, each of which exchanges the tokens at the two endpoints of an edge of the graph. In *parallel token swapping*, the goal is to use the fewest *rounds*, each of which consists of one or more swaps on the edges of a matching. We prove that both of these problems remain NP-hard when the graph is restricted to be a tree.

These token swapping problems have been studied by disparate groups of researchers in discrete mathematics, theoretical computer science, robot motion planning, game theory, and engineering. Previous work establishes NP-completeness on general graphs (for both problems), constant-factor approximation algorithms, and some poly-time exact algorithms for simple graph classes such as cliques, stars, paths, and cycles. Sequential and parallel token swapping on *trees* were first studied over thirty years ago (as “sorting with a transposition tree”) and over twenty-five years ago (as “routing permutations via matchings”), yet their complexities were previously unknown.

We also show limitations on approximation of sequential token swapping on trees: we identify a broad class of algorithms that encompass all three known polynomial-time algorithms that achieve the best known approximation factor (which is 2) and show that no such algorithm can achieve an approximation factor less than 2.

1 Introduction

Imagine n distinctly labeled tokens placed without collisions on the n vertices of a graph G . For example, these n tokens might represent (densely packed) movable *agents* – robots, people, packages, shipping containers, data packets, etc. – while the n vertices represent possible agent locations. Now suppose we want to move the tokens/agents around, for example, to bring certain shipping containers to the loading side of a cargo ship. In particular, we can suppose every token has a given start vertex and destination vertex, and the goal is to move every token to its desired destination. Because every vertex has a token (agents are densely packed), a natural reconfiguration operation is to *swap* two adjacent tokens/agents, that is, to exchange the tokens on the two endpoints of a given edge in G . In this paper, we study token reconfiguration by swaps from a given start configuration to a given destination configuration with two natural objective functions:

1. **(Sequential) Token Swapping** (a.k.a. “sorting with a transposition graph” [2]): Minimize the number of swaps, i.e., the total work required to reconfigure.
2. **Parallel Token Swapping** (a.k.a. “routing permutations via matchings” [3]): Minimize the number of rounds of simultaneous swaps (where the edges defining the swaps form a matching, so avoid conflicting shared endpoints), i.e., the total execution time or makespan required to reconfigure.

These reconfiguration problems can be cast in terms of the symmetric group. Each possible reconfiguration step – swapping along one edge in the sequential problem, or swapping along every edge of a matching in the parallel problem – is a particular permutation on the n tokens (an element of the symmetric group S_n). Assuming the graph is connected, these permutations generate S_n , defining a *Cayley graph* C [9] where each node π in C corresponds to a permutation π of the tokens (a collision-free placement of the tokens) and an undirected edge connects two nodes π_1, π_2 in C if there is a reconfiguration step (swapping an edge or matching in G) that transforms between the two corresponding permutations π_1, π_2 . Minimizing the number of reconfiguration steps between two configurations of the tokens (sequential/parallel token swapping) is equivalent to finding the shortest path in the Cayley graph between two given nodes corresponding to two given permutations in S_n . In fact, sequential token swapping was first studied by Cayley in 1849 [8] who (before inventing the Cayley graph) solved the problem on a clique, i.e., without any constraint on which tokens can be swapped.

Since its introduction, token swapping has been studied by many researchers in many disparate fields, from discrete mathematics [8, 25, 27, 29, 24, 28, 21] and theoretical computer science [17, 20, 13, 30, 32, 4, 23, 7, 31, 11, 18, 10, 6] to more applied fields including network engineering as mentioned earlier [2], robot motion planning [12, 26], and game theory [16].

What is the complexity of token swapping? In general, it is PSPACE-complete to find a shortest path between two given nodes in a Cayley graph defined by given generators [17]. But when the generators include transpositions (single-swap permutations) as in both sequential and parallel token swapping, $O(n^2)$ swaps always suffice [30], so the token-swapping problems are in NP. Both sequential token swapping [23] and parallel token swapping [5, 18] are known to be NP-complete on a general graph.

Sequential token swapping on general graphs is also known to be APX-hard [23], and even W[1]-hard with respect to the number of swaps [7]. For the special case of graphs with constant treewidth and constant diameter, sequential token swapping is also known to be NP-hard [7]. Additionally, for the special case of trees, but for the variant where the tokens have “weights” and “colors” sequential token swapping is known to be NP-hard [6]. From the algorithms side, there is a 4-approximation for sequential token swapping in general graphs [23]. Polynomial-time exact algorithms are known for a number of special classes of graphs including cliques [8], paths [20], cycles [17], stars [25, 24], brooms [28, 18, 6], complete bipartite graphs [30], and complete split graphs [32]. The problem is also known to be fixed parameter tractable (where the parameter is the number of swaps) on nowhere dense graphs, which includes planar graphs and graphs of bounded treewidth [7]. See also the surveys by Kim [19] and Biniáz et al. [6].

In this paper, we study the special case when the underlying graph is a tree. Sequential token swapping on a tree was first studied over thirty years ago, even before the problem was studied on general graphs. Akers and Krishnamurthy [2] studied the problem in the context of interconnection networks. Specifically, they proposed connecting processors together in a network defined by a Cayley graph, in particular a Cayley graph of transpositions corresponding to edges of a tree (what they call a *transposition tree*), so the shortest-path problem naturally arises when routing network messages. They gave an algorithm for finding short (but not necessarily shortest) paths in the resulting Cayley graphs, and characterized the diameter of the Cayley graph (and thus found optimal paths *in the worst case* over possible start/destination pairs of vertices) when the tree is a star. Follow-up work along this line attains tighter upper bounds on the diameter of the Cayley graph in this situation when the graph is a tree [27, 13, 21, 11] and develops exponential algorithms to compute the exact diameter of the Cayley graph of a transposition tree [10], though the complexity of the latter problem remains open.

Sequential token swapping on a tree is the related problem of computing the shortest-path distance between two given nodes in the Cayley graph of a transposition tree. For sequential token swapping on a tree, the literature exhibits a curious phenomenon whereby there are three 2-approximation algorithms that were all developed independently and all use completely different techniques. These algorithms are by Akers and Krishnamurthy [2] in 1989, Vaughan and Portier [29] in 1995, and Yamanaka et al. [30] in 2015. No better approximation factor than 2 is known.

Parallel token swapping was also introduced in the context of network routing: in 1994, Alon, Chung, and Graham [3] called the problem “routing permutations via matchings”. They focused on worst-case bounds for a given graph (the diameter of the Cayley graph); in particular, they proved that any n -vertex tree (and thus any n -vertex connected graph) admits a solution with less than $3n$ rounds, a bound later improved to $\frac{3}{2}n + O(\log n)$ [33]. Like sequential token swapping, computing the exact diameter of the Cayley graph of a given tree remains open.

Parallel token swapping on a tree is the related problem of computing the shortest-path distance between two given nodes in such a Cayley graph. Parallel token swapping is known to be NP-complete in bipartite maximum-degree-3 graphs, NP-complete even when restricted

to just three rounds, but polynomial-time when restricted to one or two rounds, but NP-complete again for “colored” tokens restricted to two rounds [5, 18]. Two approximation results are known: an additive approximation for paths which uses only one extra round [18], and a multiplicative $O(1)$ -approximation for the $n \times n$ grid graph [12].¹ For other special graph classes, there are tighter worst-case bounds on the diameter of the Cayley graph [3, 22, 5].

1.1 Our Results

There have been many attempts to understand token swapping on a tree, but all have fallen short of determining its actual complexity. To summarize the previously stated results for sequential token swapping on a tree, there are three known 2-approximation algorithms, and no better approximation known. There are also exact algorithms for several special cases of trees, with the most general case being a broom (a path attached to a star). From the hardness side, attempts to prove that the problem is NP-complete have led to NP-completeness proofs for more general cases. In particular, token swapping on graphs of constant treewidth and diameter is NP-hard [7], and the “weighted, colored” variant of token swapping on trees is NP-hard [6]. This leads to our first main question:

Question: Is sequential token swapping on a tree NP-complete?

This question has been implicit since sequential token swapping on a tree was first studied over 30 years ago, and the question has been explicitly stated by Biniaz et al. [6] and by Bonnet et al. [7] who conjectured that the answer is yes.

We resolve this question in the affirmative by providing a proof that sequential token swapping on a tree is NP-complete.

Next, we turn to the approximability of token swapping on a tree. The fact that there were three independently discovered 2-approximation algorithms, and nothing better is known, suggests that perhaps there is some barrier at approximation factor 2. This leads to our second main question:

Question: Is there an inherent barrier to obtaining a $(2 - \varepsilon)$ -approximation for sequential token swapping on trees?

We address this question by showing that there is indeed a restriction on the *types* of algorithms that can achieve approximation factor better than 2. To motivate the class of algorithms we rule out, it helps to examine known algorithms. Specifically, it was previously known that neither Akers and Krishnamurthy’s “happy swap” algorithm [2] nor Yamanaka et al.’s cycle algorithm [30] can possibly achieve an approximation ratio better than 2 [6]. These two algorithms share a natural property: every token t always remains within distance 1 of the shortest path from t ’s start vertex to t ’s destination vertex. A natural question is, can a better-than-2 approximation be achieved if one allows tokens to deviate from their shortest paths more, say to distance 10 or 100?

Motivated by this question, we define an *ℓ -straying* algorithm as an algorithm that never moves a token a distance more than ℓ from its shortest path. We prove a surprisingly strong limitation on ℓ -straying algorithms: any less-than-2-approximation algorithm for sequential

¹ The results of [12] are phrased in terms of motion planning for robots, and in terms of a model where an arbitrary disjoint collection of cycles can rotate one step in a round. However, the techniques quickly reduce to the model of swapping disjoint pairs of robots, so they apply to parallel motion planning as well. They show that there is always a solution within a constant factor of the obvious lower bound on the number of rounds: the maximum distance between any token’s start and destination.

token swapping on trees must in general bring a token *arbitrarily far* – an $\Omega(n^{1-\varepsilon})$ distance away – from its shortest path. That is, no ℓ -straying algorithm for $\ell = o(n^{1-\varepsilon})$ can achieve better than a 2-approximation.

The other known 2-approximation algorithm (besides [2] and [30]), is the Vaughan-Portier algorithm [29], which in fact *does* move tokens arbitrarily far from their shortest paths. That is, our result on ℓ -straying algorithms does not imply a limitation on the Vaughan-Portier algorithm. To address this, we also obtain the first proof that the Vaughan-Portier algorithm [29] is no better than a 2-approximation; the best previous lower bound for its approximation factor was $\frac{4}{3}$ [6]. Thus, none of the known algorithms or even their generalizations can improve upon the approximation factor of 2.

For parallel token swapping on a tree, less is known than for the sequential version. In particular, there is no known approximation algorithm nor is there any known hardness for tree-like graphs. Thus, the complexity of this problem is completely unclear. This leads to our third main question:

Question: What is the complexity of parallel token swapping on a tree?

We address this question by showing that parallel token swapping on a tree is NP-hard.

In summary, our results are as follows:

1. Sequential token swapping is NP-complete on trees.
2. Parallel token swapping is NP-complete on trees, even on subdivided stars.
3. Limitations on known techniques for approximating sequential token swapping on trees:
 - a) No ℓ -straying algorithm for any $\ell = O(n^{1-\varepsilon})$ can achieve better than a 2-approximation.
 - b) The Vaughan-Portier algorithm does not achieve better than a 2-approximation.

1.2 Our Techniques

NP-hardness of sequential token swapping on trees

Our NP-hardness proof for sequential token swapping on trees is our most technical and conceptually difficult result. Prior work has built towards this result by providing NP-hardness for generalizations of the problem, but there appear to be barriers against extending these techniques. In the following, we briefly review this prior work and compare it to our own.

Token swapping on trees is known to be NP-hard for the variant where tokens have weights as well as “colors” [6]. However, the use of weights and colors appears to be crucial to the reduction. Token swapping is also known to be NP-hard on graphs with treewidth 2 and diameter 6 [7]. In particular, the graph in this construction is almost a tree in the sense that if you remove a single vertex the remaining graph is a forest. However, this single vertex has very high degree and is crucial to the construction. Given the apparent barriers against extending these known approaches to token swapping on trees, we take a completely different approach.

We reduce from the *permutation generation* problem in Garey and Johnson [14, MS6] (also called the “word problem for products of symmetric groups” (WPPSG) in [15]). In comparison, the above prior work [6, 7] reduces from the vertex cover problem, and the 3-dimensional matching problem, respectively. We observe that the permutation generation problem has a similar feel to token swapping, as it can be recast in terms of a token-swapping reachability problem as follows:

3:6 Hardness of Token Swapping on Trees

Star Subsequence Token-Swapping Reachability (Star STS): Given a star graph with center vertex 0 and leaves $1, 2, \dots, m$, where vertex i initially has a token i ; given a target permutation π of the tokens; and given a sequence of swaps s_1, s_2, \dots, s_n , where $s_j \in \{1, \dots, m\}$ indicates a swap on edge $(0, s_j)$, is there a subsequence of the given swaps that realizes π ?

As a first step towards reducing from Star STS to token swapping on trees, we reduce to *weighted* token swapping on trees, where each token has a non-negative integer *weight*, and the cost of a swap is the sum of the weights of the two tokens being swapped. Our reduction contains only tokens of weight 0 or 1. That is, the tokens of weight 0 are free to move, while the tokens of weight 1 cost to move. Our reduction from Star STS to 0/1-weighted token swapping on trees is quite simple. It is presented in Section 2.

The situation becomes much more complicated when we extend this result from the 0/1-weighted setting to the unweighted setting. Now, we need to *simulate* the weight-0 tokens using unweighted tokens. This introduces several complications.

First, we will describe why weight-0 tokens are integral to our reduction from Star STS to 0/1-weighted token swapping on trees. The Star STS problem asks whether there *exists* a subsequence of swaps that realizes the target permutation π . This subsequence could contain any number of swaps. In our reduction to 0/1-weighted token swapping, the swaps from this subsequence are represented using tokens of weight 0. This way, if there is a solution to the Star STS instance, then the cost of the 0/1-weighted token swapping is the same *regardless* of how many swaps occurred in the solution to the Star STS instance. This introduces a challenge for unweighted token swapping for the following reason. For 0/1 weighted token swapping, we prove a statement of the form “if the token swapping cost is exactly K then there is a solution to the Star STS instance”, while for unweighted token swapping, we prove a statement of the form “if the token swapping cost is within a particular *range* then there is a solution to the Star STS instance”. The second statement is much more difficult to prove because we need to argue that the additional swaps in this range do not allow the tokens to move around in a clever way to admit a solution even when there is no Star STS solution. In fact, as we discuss next, natural modifications of the weighted construction *do* admit such clever ways to create counterexamples.

The most basic first attempt to remove the weights from the weighted construction is simply to replace all weight-0 tokens with unweighted tokens. This construction admits a straightforward counterexample due to the increased cost of swapping these formerly weight-0 tokens. Thus, we would like to make the contribution of the formerly weight-0 tokens negligible in comparison to the weight-1 tokens. A natural attempt is to replace each weight-1 token with a *long path* of tokens. However, as it turns out, there is a surprising and subtle counterexample to this strategy. To overcome this counterexample, we introduce a set of “padding tokens” throughout the graph whose role is to block any deviant movement of the original tokens.

The resulting proof is very involved. To give a sense of the complexity, our 0/1-weighted hardness proof fits in just a couple of pages, while our unweighted proof spans around thirty pages. Our unweighted proof is presented in Section 3.

NP-hardness of parallel token swapping on trees

We prove that parallel token swapping on trees is NP-hard, even when restricted to *subdivided stars*. This result is presented in the extended version of this paper [1]. As for sequential token swapping, we reduce from the Star STS problem.

Our construction is reminiscent of our construction for sequential token swapping, although the details differ significantly. In particular, we use the single high-degree vertex in the subdivided star as a bottleneck to limit the available parallelism. We develop “enforcement” tokens that need to swap through the high-degree vertex to force congestion at specific times. This proof’s complexity is between the weighted and unweighted sequential hardness proofs.

Limitations on known techniques for approximation algorithms

To prove that neither an ℓ -straying algorithm nor the Vaughan-Portier algorithm can achieve better than a 2-approximation, we use a problem instance that has been previously used to prove that Akers and Krishnamurthy’s and Yamanaka et al.’s algorithms cannot achieve an approximation ratio better than 2 [6]. To prove our results, we show that while there exists a solution to the instance with K swaps (for some K), (1) every ℓ -straying algorithm performs $2K$ swaps, and (2) the Vaughan-Portier algorithm performs $2K$ swaps. The existence of a solution with K swaps was already shown by [6], so it remains to show that the above algorithms require $2K$ swaps.

We emphasize that the proofs in [6] for Akers and Krishnamurthy’s and Yamanaka et al.’s algorithms, as well as our proof for the Vaughan-Portier algorithm, are for *specific* algorithms, while our proof for ℓ -straying algorithms shows limitations against a very wide class of possible algorithms. Thus, our proof for ℓ -straying algorithms requires much more general reasoning about how tokens can possibly move around the graph.

2 Weighted sequential token swapping on trees is NP-hard

In this section, we prove that weighted token swapping on a tree is NP-hard, even when the token weights are in $\{0, 1\}$. Our purpose is to introduce the general idea that is used in our main NP-completeness proof for the unweighted case given in Section 3.

We first precisely define the decision problem *weighted sequential token swapping on trees* [6], abbreviated in this section to *weighted token swapping*. The input consists of: a tree on n vertices with distinct initial positions (vertices) and distinct target positions for the n tokens; non-negative integer weights on the tokens; and a maximum cost K . The cost of a swap is the sum of the weights of the two tokens involved. The decision problem asks whether there is a sequence of swaps that moves all the tokens to their target positions and such that the sum of the costs of the swaps is at most K .

It is not clear whether the weighted token swapping problem lies in NP; however, it is in NP if K is given in unary.²

We prove that weighted token swapping is NP-hard when K is given in unary. The reduction uses Star STS. In order to distinguish tokens and vertices in the original star from those in the tree that we construct, we will call the tokens of the Star STS instance *items* and we will call the leaves *slots*. Then the instance of Star STS consists of: a star with center 0 and slots $1, \dots, m$, each of which initially has an item of its same label; a permutation π of the items; and a sequence s_1, \dots, s_n of slots that specify the allowed swaps. Figure 1(a) shows an example input for $m = 4$ slots, 5 items and a sequence of length $n = 7$.

► **Theorem 1.** *Weighted token swapping on trees is NP-hard.*

² Consider a minimum length swap sequence of weight at most K . The number of swaps involving a nonzero weight token is at most K . Because the sequence has minimum length, it can be shown that no two zero-weight tokens swap more than once. Thus the sequence has length at most $K + n^2$ and provides a polynomial-size certificate, showing that the problem is in NP.

■ **Figure 1** (a) An instance of Star STS with $m = 4$ slots and a sequence of length $n = 7$; notation $a[b]$ indicates that token a is initially at this vertex and token b should move to this vertex. This instance has no solution because item 4 should move to slot 3, which is possible only if slot 3 appears after slot 4 in the sequence. (b) The corresponding instance of weighted token swapping with the ordering gadget on the left and $m = 4$ slot gadgets attached to the root, each with a nook vertex shown in red. After swapping item token 0 at the root with token y_1 in the first (bottom) slot gadget there is an opportunity to swap tokens 0 and 1 for free along the nook edge of the first slot gadget, before moving y_1 to its target position at the end of the ordering gadget and moving x_1 to its target position at the end of the first slot gadget.

Proof. Suppose we are given an instance of Star STS as described above. We may assume without loss of generality that every slot appears in the sequence (otherwise remove that slot from the problem) and that no slot appears twice in a row in the sequence.

Construct a tree with a root, an *ordering gadget* which is a path of length n attached to the root, and m *slot gadgets* attached to the root. Slot gadgets are defined below. See Figure 1(b) where the ordering gadget of length $n = 7$ appears on the left and there are $m = 4$ slot gadgets attached to the root. We picture the tree with the root in the middle, and use directions left/right as in the figure.

Let n_i be the number of occurrences of slot i in the input sequence. Observe that $\sum_{i=1}^m n_i = n$. *Slot gadget* i consists of a path of n_i vertices, plus an extra leaf attached to the leftmost vertex of the path. This extra leaf is called the *nook* of the slot gadget. The m nooks and the root are in one-to-one correspondence with the slots and the center of the original star (respectively), and we place *item tokens* at these vertices whose names, initial positions, and final positions correspond exactly to those of the items of the input star. These item tokens are given a weight of 0.

There are $2n$ additional *non-item tokens* x_1, \dots, x_n and y_1, \dots, y_n . These all have weight 1. The x_j 's are initially placed along the ordering gadget path, in order, with x_1 at the right and x_n at the left. The ordering path is also the target position of the y_j 's in reverse order with y_1 at the left and y_n at the right.

Suppose slot i appears in the sequence as $s_{j_1}, s_{j_2}, \dots, s_{j_{n_i}}$ with indices in order $j_1 < j_2 < \dots < j_{n_i}$. Then tokens $y_{j_1}, y_{j_2}, \dots, y_{j_{n_i}}$ are initially placed along the path of slot gadget i , in order with smallest index at the left. The path of slot gadget i is also the target position of the tokens $x_{j_1}, x_{j_2}, \dots, x_{j_{n_i}}$ in reverse order with smallest index at the right.

Consider, for each non-item token x_j or y_j , the distance from its initial location to its target location. This is a lower bound on the cost of moving that token. We set the max cost K to the sum of these lower bounds. This guarantees that every x_j or y_j only travels along its shortest path. Observe that this reduction takes polynomial time. We now prove that a YES instance of Star STS maps to a YES instance of token swapping and vice versa.

YES instance of Star STS. Suppose the Star STS instance has a solution. The “intended” solution to the token swapping instance implements each s_j for $j = 1, \dots, n$ as follows. Suppose $s_j = i$. By induction on j , we claim that token y_j will be in the leftmost vertex of slot gadget i when it is time to implement s_j . Swap token y_j with the item token t currently at the root. Then item token t has the opportunity to swap for free with the item token in nook i . We perform this free swap if and only if swap s_j was performed in the solution to Star STS. Next, swap tokens y_j and x_j – we claim by induction that x_j will be in the rightmost vertex of the ordering gadget. Finally, move token y_j to its target position in the ordering gadget, and move x_j to its target position in slot gadget i . It is straightforward to verify the induction assumptions. Every x_j and y_j moves along its shortest path so the cost of the solution is equal to the specified bound K .

YES instance of weighted token swapping. Suppose the weighted token swapping instance has a solution with at most K swaps. Because K is the sum of the distances of the non-item tokens from their target positions, each x_j and y_j can only move along the shortest path to its target position. Token x_j must move into the root before x_{j+1} , otherwise they would need to swap before that, which means moving x_j the wrong way along the ordering gadget path. Similarly, y_j must move into the root before y_{j+1} , otherwise they need to swap after that, which means moving y_{j+1} the wrong way.

Furthermore, x_j must move into the root before y_{j+1} otherwise the ordering gadget would contain x_j, \dots, x_n , and y_1, \dots, y_j , a total of $n + 1$ tokens, which is more tokens than there are vertices in the ordering gadget.

We also claim y_j must move into the root before x_{j+1} . The nooks can only contain item tokens, since no x_j or y_j can move into a nook. This accounts for every item token except for one “free” item token. Now suppose x_{j+1} moves into the root before y_j . Then the ordering gadget contains x_{j+2}, \dots, x_n , and y_1, \dots, y_{j-1} , a total of $n - 2$ tokens. Even if the free item token is in the ordering gadget, there are not enough tokens to fill the ordering gadget.

Thus the x_j 's and y_j 's must use the root in order, first x_1 and y_1 in some order, then x_2 and y_2 in some order, etc. Finally, we examine the swaps of item tokens. A swap between two item tokens can only occur when the free item token is at the parent of a nook. Suppose this happens in slot gadget i . Then some token y_j must have left the slot gadget, and the corresponding token x_j has not yet entered the slot gadget, which means that neither of the tokens y_{j+1} or x_{j+1} has moved into the root. This implies that any swap of item tokens is associated with a unique $s_j = i$, and such swaps must occur in order of j , $1 \leq j \leq n$. Thus the swaps of item tokens can be mimicked by swaps in the original Star STS sequence, and the Star STS instance has a solution. ◀

3 Sequential token swapping on trees is NP-complete

Recall that the token swapping problem is a decision problem: given a tree with initial and target positions of the tokens, and given a non-negative integer K , can the tokens be moved from their initial to their target positions with at most K swaps. Membership in NP is easy to show: any problem instance can always be solved with a quadratic number of swaps by repeatedly choosing a leaf and swapping its target token to it. Thus, a certificate can simply be the list of swaps to execute. Here we give an overview of the construction for the unweighted case; however, most of the proof is left to the full version [1].

3.1 Overview

We reduce from Star STS and follow the same reduction plan as for the weighted case, building a tree with an ordering gadget and m slot gadgets, each with a nook for an item token. However, there are several challenges. First of all, the swaps with item tokens are no longer free, so we need to take their number into account. Secondly, we cannot know the number of item token swaps precisely since it will depend on the number of swaps (between 0 and n) required by the original Star STS instance. Our plan is to make this “slack” n very small compared to the total number of swaps needed for the constructed token swapping instance. To do this, we will make the total number of swaps very big by replacing each of the non-item tokens x_j and y_j by a long path of non-item tokens called a “segment.” This raises further difficulties, because nothing forces the tokens in one segment to stay together, which means that they can sneak around and occupy nooks, freeing item tokens to swap amongst themselves in unanticipated ways. To remedy this we add further “padding segments” to the construction. The construction details are given in Section 3.2.

Proving that our unweighted construction is correct is much more involved than in the weighted case. There are two parts to the proof.

Part 1: YES instance of Star STS \rightarrow YES instance of token swapping. In the full version [1] we show that if there is a solution to an instance of Star STS then the constructed token swapping instance can be solved with at most K swaps (where K will be specified in the construction). This solution uses exactly $H = K - n$ swaps to get the non-item tokens to their target positions, and uses between 0 and n additional swaps to get the item tokens to their target positions. Note that H counts swaps of both item and non-item tokens and is more than just the cost of moving each non-item token along its shortest path.

Part 2: YES instance of token swapping \rightarrow YES instance of Star STS. In the full version [1] we show that if the constructed token swapping instance can be solved with at most K swaps then the original Star STS instance has a solution. We show that H swaps are needed to get the non-item tokens to their destinations. We then show that with only n remaining swaps, the motion of item tokens is so constrained that they must behave “as intended” and therefore correspond to swaps in the original Star STS instance.

3.2 Construction of token swapping instance

Suppose we have an instance of Star STS where the star has center 0 and leaves $1, \dots, m$ and each vertex has a token of its same label. We have a permutation π of the tokens with $\pi(0) = 0$ and a sequence s_1, \dots, s_n with $s_j \in \{1, \dots, m\}$ that specifies the allowed swaps. As in the weighted case in Section 2, we will refer to the tokens of the Star STS instance as *items* and the leaves as *slots*. We assume without loss of generality that every slot appears in the sequence (otherwise remove that slot from the problem) and that no slot appears twice in a row in the sequence.

Construct a tree as in the weighted case except that each individual x_j and y_j is replaced by a sequence of k vertices (and tokens) with $k = (mn)^c$ for a large constant c , to be set later. Each such sequence of length k is called a *big segment*. Refer to Figure 2 where the tree is drawn with the root in the middle, the ordering gadget to the left, and the slot gadgets to the right. We will refer to left and right as in the figure. The target ordering of tokens within a big segment behaves as though the segment just slides along the shortest path to its target, i.e., the left to right order of tokens in a segment is the same in the initial and the final configurations.

■ **Figure 2** (a) An instance of Star STS with $m = 4$ slots and a sequence of length $n = 5$. (b) The corresponding instance of token swapping with the initial token positions. The root has item token 0 (coloured red). The ordering gadget lies to the left of the root. There are 4 slot gadgets to the right of the root. A long oval indicates a big segment of length k , and a short oval indicates a padding segment of length $k' = k/n^8$. Each nook vertex (coloured red) is attached to the k^{th} vertex from the root along the slot gadget path. Item tokens are coloured red; non-slot tokens are in the segment ovals coloured gray; and slot tokens are in the segment ovals coloured white. (c) The target token positions. In the first round of the “intended” solution, big segments y_1 and x_1 first change places. As y_1 moves left, item token 0 moves to nook parent 1 where it may swap with item token 1. As x_1 moves right, the item token moves back to the root. Then segment y_1 moves to the far left of the ordering gadget and x_1 moves to the far right of the first slot gadget. Next, padding segments $p_{3,1}$ and $q_{3,1}$ change places across the root and move to their target locations; then $p_{2,1}$ and $q_{2,1}$; then $p_{4,1}$ and $q_{4,1}$; and finally $p_{1,1}$ and $q_{1,1}$. Note the ordering $q_{3,1}, q_{2,1}, q_{4,1}, q_{1,1}$ of padding segments that lie to the right of y_1 in the final configuration – $q_{1,1}$ is last because $s_1 = 1$ and $q_{3,1}$ is first because $s_2 = 3$.

The nook vertex in each slot gadget is attached to the vertex at distance k from the root in the slot gadget, and this vertex is called the *nook parent*. The edge between the nook vertex and the nook parent is called the *nook edge*, see Figure 2. In the “intended” solution, the big segments leave the slot gadgets and enter the ordering gadget in the order y_1, \dots, y_n .

Although we will not give details, the construction so far allows “cheating” via interference between slot gadgets. To prevent this, we add a total of $2nm$ padding segments each of length $k' = k/n^8$. The intuition is in the “intended” solution, after y_j enters the ordering gadget, one padding segment from each slot gadget will enter the ordering gadget, and then y_{j+1} will do so. We now give the details of the padding segments in the initial/final configurations of the slot/ordering gadgets. In the initial configuration there are nm padding segments $q_{i,j}, i = 1, \dots, m, j = 1, \dots, n$ in the slot gadgets, and nm padding segments $p_{i,j}, i = 1, \dots, m, j = 1, \dots, n$ in the ordering gadget. In the final configuration, the $q_{i,j}$'s

are in the ordering gadget and the $p_{i,j}$'s are in the slot gadgets. In the initial configuration, slot gadget i , $i = 1, \dots, m$, contains n padding segments $q_{i,j}$, $j = 1, \dots, n$. They appear in order from left to right with big segments mixed among them. Specifically, if $y_{j'}$ is a big segment in slot gadget i then $y_{j'}$ appears just before $q_{i,j'}$. In the final configuration of the ordering gadget there are m padding segments after each of the n big segments. The padding segments after y_j are $q_{i,j}$, $i = 1, \dots, m$. They appear in a particular left-to-right order: $q_{s_j,j}$ is last, $q_{s_{j+1},j}$ is first, and the others appear in order of index i . Within one padding segment, the left-to-right ordering of tokens is the same in the initial and final configurations.

The initial configuration of the ordering gadget is obtained from the final configuration by: reversing (from left to right) the pattern of big segments and padding segments; changing y 's to x 's, and changing q 's to p 's. Similarly, the final configuration of slot gadget i is obtained from the initial configuration of slot gadget i in the same way.

Let A be the set of non-item tokens, and for any token t , let d_t be the distance between t 's initial and target positions. To complete the reduction, we will set H to be $\frac{1}{2} \sum_{t \in A} (d_t + 1)$ and set the bound K to be $H + n$. The decision question is whether this token swapping instance can be solved with at most K swaps. The reduction takes polynomial time.

The remainder of the proof can be found in the full version [1].

4 Known techniques preclude approximation factors less than 2

Previous results about sequential token swapping on trees include three different polynomial time 2-approximation algorithms and some lower bounds on approximation factors. The three algorithms all have the property that if a token at a leaf is at its destination (i.e., it is a “happy leaf token”) then the algorithm will not move it. Biniáz et al. [6] proved that any algorithm with this property has a (worst case) approximation factor at least $\frac{4}{3}$. They also proved via ad-hoc arguments that the approximation factor is exactly 2 for two of the known 2-approximation algorithms (the “Happy Swap Algorithm” and the “Cycle Algorithm”). For the third 2-approximation algorithm, the Vaughan-Portier algorithm, they could not prove a lower bound better than $\frac{4}{3}$.

We prove that the Vaughan-Portier algorithm has approximation factor exactly 2. We also extend the approximation lower bounds of Biniáz et al. by proving that the approximation factor is at least 2 for a larger family of algorithms. We formalize this family as follows. For token t let P_t be the path from t 's initial position to its final position. A sequence of token swaps is **ℓ -straying** if at all intermediate points along the sequence, every token t is within distance ℓ of the last vertex of P_t that it has reached up to this point. A token swapping algorithm is **ℓ -straying** if it produces ℓ -straying sequences.

Both approximation lower bounds will be proved for the same family of trees that was used by Biniáz et al. [6]. For any k and any odd b we define a tree $T_{k,b}$ together with initial and final positions of tokens. The tree $T_{k,b}$ has b paths of length k attached to a central vertex c , and a set L of k leaves also attached to c . See Figure 3. The tokens at c and L are **happy** – they are at their final positions. The tokens in branch i , $0 \leq i \leq b - 1$, have their final positions in branch $i + 1$, addition modulo b , with the initial and final positions equally far from the center c .

Biniáz et al. [6] proved that the optimum number of swaps for $T_{k,b}$ is at most $(b + 1) \binom{k+1}{2} + 2k$. The solution repeatedly exchanges the tokens in branch i , $0 \leq i \leq b - 1$, modulo b , with the tokens at L . The first exchange moves the tokens initially at L into branch 0, and the $(b + 1)^{\text{st}}$ exchange moves those tokens back to L . In the full version [1] we prove that for $T_{k,b}$ the approximation factor is not better than 2 for ℓ -straying algorithms and for the Vaughan-Portier algorithm.

■ **Figure 3** Tree $T_{k,b}$ with $b = 3$ branches each of length $k = 4$, and with $k = 4$ leaves attached to the center node. The dashed arrows go from a token's initial to final position. The figure is from [6].

5 Open Problems

Many interesting related problems remain open. For sequential token swapping on trees, where is the divide between NP-complete and polynomial-time? Our reduction's tree is a subdivided star (as for parallel token swapping) with the addition of one extra leaf (the nook) per path. By contrast, there is a polynomial-time algorithm for the case of a broom (a star with only one edge subdivided) [28, 18, 6]. What about a star with two subdivided edges?

For parallel token swapping, even the case of a single long path is open. Kawahara et al. [18] gave an additive approximation algorithm that uses at most one extra round. Is there an optimal algorithm, or is parallel token swapping NP-hard on paths?

There are also open problems in approximation algorithms. In parallel token swapping, we know that there is no PTAS [18]. Is there an $O(1)$ -approximation for trees or general graphs? For sequential token swapping, there is a 4-approximation algorithm [23]. Is 4 a lower bound on the approximation factor of this algorithm? Is 4-approximation the best possible for general graphs?

Although this paper focused on the best reconfiguration sequence, much research is devoted to understanding the worst-case behavior for a given graph; is it NP-hard to determine the diameter of the Cayley graph, i.e., the maximum number of reconfiguration steps that can be required for any pair of token configurations? This problem is open for both sequential token swapping (implicit in [10]) and parallel token swapping [3].

Abstract

We study the b -matching problem in bipartite graphs $G = (S, R, E)$. Each vertex $s \in S$ is a server with individual capacity b_s . The vertices $r \in R$ are requests that arrive online and must be assigned instantly to an eligible server. The goal is to maximize the size of the constructed matching. We assume that G is a (k, d) -graph [19], where k specifies a lower bound on the degree of each server and d is an upper bound on the degree of each request. This setting models matching problems in timely applications.

We present tight upper and lower bounds on the performance of deterministic online algorithms. In particular, we develop a new online algorithm via a primal-dual analysis. The optimal competitive ratio tends to 1, for arbitrary $k \geq d$, as the server capacities increase. Hence, nearly optimal solutions can be computed online. Our results also hold for the vertex-weighted problem extension, and thus for AdWords and auction problems in which each bidder issues individual, equally valued bids.

Our bounds improve the previous best competitive ratios. The asymptotic competitiveness of 1 is a significant improvement over the previous factor of $1 - 1/e^{k/d}$, for the interesting range where $k/d \geq 1$ is small. Recall that $1 - 1/e \approx 0.63$. Matching problems that admit a competitive ratio arbitrarily close to 1 are rare. Prior results rely on randomization or probabilistic input models.

1 Introduction

Maximum matching is a fundamental problem in computer science. In a seminal paper Karp, Vazirani and Vazirani [15] introduced online matching in bipartite graphs $G = (S \cup R, E)$. The vertices of S are known in advance, while the vertices of R (requests) arrive one by one and must be matched immediately to an eligible partner. The b -matching problem is a generalization where the vertices of S (servers) have capacities and may be matched multiple times, see e.g. [14]. Online bipartite matching and capacitated extensions have received tremendous research interest over the past 30 years. In this paper we study the b -matching problem in bounded-degree graphs, defined in [19]. We assume that there is a lower bound on the degree of each server $s \in S$, meaning that there is a certain demand for each server. Furthermore we assume that there is an upper bound on the degree of each $r \in R$, i.e. each request can only be assigned to a subset of the servers. This setting models matching problems in many timely applications, as we will describe below.

4:2 Tight Bounds for Online b -Matching in Bounded-Degree Graphs

More formally, we investigate the following problem. Again, let $G = (S \cup R, E)$ be a bipartite graph, where the vertices of S are servers and the vertices of R are requests. The set S is known in advance. Each server $s \in S$ has an individual capacity $b_s \in \mathbb{N}$, indicating that the server can be matched with up to b_s requests. The vertices of R arrive online, one by one. Whenever a new request $r \in R$ arrives, its incident edges are revealed. The request has to be matched immediately and irrevocably to an eligible server, provided that there is one. The goal is to maximize the number of matching edges. We will also examine the *vertex-weighted* problem extension, where additionally each server $s \in S$ has a weight w_s and the value of every matching edge incident to s is multiplied by w_s . Now the goal is to maximize the total weight of the constructed matching.

We assume that G is a (k, d) -graph, defined by Naor and Wajc [19], where k and d are positive integers. Each server $s \in S$ has a degree $d(s) \geq k \cdot b_s$. Each request $r \in R$ has a degree $d(r) \leq d$. Naor and Wajc [19] defined these graphs for the general AdWords problem. Note that the inequality $d(s) \geq k \cdot b_s$ expresses a degree bound in terms of the server capacity. This is essential. As we shall see, the performance of algorithms depends on the degrees $d(s)$ as a function of b_s . A degree bound independent of b_s is vacuous for larger b_s . Also, a company operating a high-capacity server expects the server to be attractive and a potential host for a large number of requests. Otherwise it might be beneficial to reduce the server capacity.

The best results will be obtained if $k \geq d$. In this case the average demand for each server slot is high, compared to the number of servers a request can be assigned to. This setting is also very relevant in applications. We will assume that $d \geq 2$. If $d = 1$, any GREEDY algorithm constructs an optimal matching. We remark that (k, d) -graphs are loosely related to d -regular graphs in which each vertex has a degree of exactly d and a capacity of 1. This graph class has been studied extensively in computer science and discrete mathematics, see e.g. [5, 6, 7, 10, 20].

The b -matching problem in (k, d) -graphs models many problems in modern applications, cf. [4, 12, 19]. The following description also addresses the degree constraints.

Video content delivery, web hosting, remote data storage: Consider a collection of servers in a video content delivery network, a web hosting provider, or a remote data storage service. A sequence of clients arrives, each with a request that videos be streamed, web pages be hosted, or data be stored. Based on the servers' geographic distribution, average performance, technology used or pricing policies, each request can only be hosted at a small subset of the servers or server locations. Each server has a large capacity and is well suited to service a huge number of requests in the arriving client sequence.

Job scheduling: Consider a collection of compute servers, each with certain capabilities, located for instance in a data center. Over a time horizon jobs arrive, requesting service. Based on computing demands, expected response time, hardware and software requirements, each job can only be executed on a subset of the servers. During the given time horizon, each server can process a large number of jobs and is a suitable platform to execute very many of the incoming jobs.

AdWords and ad auctions: Consider a search engine company or digital advertising platform. There is a set of advertisers, each with a daily budget, who wish to link their ads to users of the search engine/digital platform and issue respective bids. The users arrive online and must be allocated instantly to the advertisers. Based on his search keywords, browsing history and possible profile, each user is interesting to a small set of advertisers. Each advertiser has a decent budget and targets a large population of the users. Obviously, in this application the advertisers correspond to the servers and the users are the incoming

requests. The b -matching problem models the basic setting where the bids of all advertisers are either 0 or 1. The vertex-weighted extension captures the scenario where all the bids of an advertiser $s \in S$ have a value of 0 or w_s . These base cases are also studied in recent work by Vazirani [21].

We analyze the performance of online algorithms using competitive analysis. Given an input graph G , let $\text{ALG}(G)$ denote the size (or weight) of the matching constructed by an online algorithm ALG . Let $\text{OPT}(G)$ be the corresponding value of an optimal offline algorithm OPT . Algorithm ALG is c -competitive if $\text{ALG}(G) \geq c \cdot \text{OPT}(G)$ holds, for all G . In our analyses we will focus on bipartite (k, d) -graphs G .

Related work. As mentioned above, Karp et al. [15] introduced online matching in bipartite graphs, in which every vertex has a capacity of 1. The best competitive ratio of deterministic online algorithms is equal to $1/2$. Karp et al. proposed a randomized RANKING algorithm that achieves an optimal competitive ratio of $1 - 1/e \approx 0.63$. Aggarwal et al. [1] defined online vertex-weighted bipartite matching and devised a $(1 - 1/e)$ -competitive algorithm.

Kalyanasundaram and Pruhs [14] investigated the b -matching problem if all servers have equal capacity, i.e. $b_s = b$ for all $s \in S$. They presented a deterministic BALANCE algorithm that matches a new request to an adjacent server whose current load is smallest. BALANCE achieves an optimal competitive ratio of $1 - 1/(1 + 1/b)^b$. As b grows, the latter expression tends from below to $1 - 1/e$. Grove et al. [12] and Chaudhuri et al. [4] studied b -matchings with a different objective. At any time an algorithm must maintain a matching between the requests that have arrived so far and the servers. The goal is to minimize the total number of switches, reassigning requests to different servers.

The AdWords problem was formally defined by Mehta et al. [18]. They presented a deterministic online algorithm that achieves a competitive ratio of $1 - 1/e$, under the *small-bids assumption* where the bids are small compared to the advertisers' budgets. No randomized algorithm can obtain a better competitive factor. Buchbinder et al. [3] examined a setting where the degree of each incoming user is upper bounded by d and gave an algorithm with a competitive ratio of nearly $1 - (1 - 1/d)^d$. Azar et al. [2] showed that this ratio is best possible, also for randomized algorithms. The expression $1 - (1 - 1/d)^d$ is always greater than $1 - 1/e$ but approaches the latter value as d increases.

The class of (k, d) -graphs was defined by Naor and Wajc [19], who studied online bipartite matching and the AdWords problem. They proposed an algorithm HIGHDEGREE that matches a new request to an available neighbor of highest current degree. Naor and Wajc proved that HIGHDEGREE and generalizations attain a competitive factor of $1 - (1 - 1/d)^k$. This ratio holds for online bipartite matching and the vertex-weighted extension, where all vertices have a capacity of 1. Furthermore, it holds for AdWords with equal bids per bidder. For AdWords with arbitrary bids, the ratio is $(1 - R_{\max})(1 - (1 - 1/d)^k)$, where R_{\max} is the maximum ratio between the bid of any bidder and its total budget. Naor and Wajc showed that no deterministic online algorithm for bipartite matching can achieve a competitive ratio greater than $1 - (1 - 1/d)^k$ if $k \geq d$. For the general AdWords problem, they proved an upper bound of $(1 - R_{\max})(1 - (1 - 1/d)^{k/R_{\max}})$ if $k \geq d$. For increasing k/d , the expression $1 - (1 - 1/d)^k$ tends to 1. For $k \approx d$ increasing, it approaches again $1 - 1/e$.

Cohen and Wajc [5] studied online bipartite matching in d -regular graphs and developed a randomized algorithm with a competitive ratio of $1 - O(\sqrt{\log d/d})$, which tends to 1 as d increases.

Online bipartite matching and the AdWords problem have also been examined in stochastic input models. A random permutation of the vertices of R may arrive. Alternatively, the vertices of R are drawn i.i.d. from a known or unknown distribution. For online bipartite

matching, the best online algorithms currently known achieve competitive ratios of 0.696 and 0.706 [13, 16]. The best possible performance ratios are upper bounded by 0.823 [17], and hence bounded away from 1. For AdWords, $(1 - \varepsilon)$ -competitive algorithms are known, based on the small-bids assumption [8, 9].

Our contributions. We present a comprehensive study of the b -matching problem in (k, d) -graphs. Specifically, we develop tight lower and upper bounds on the performance of deterministic online algorithms. The optimal competitive ratio tends to 1, for any choice of k and d with $k \geq d$, as the server capacities increase.

First, in Section 2 we investigate the setting that all servers have the same capacity, i.e. $b_s = b$ for all $s \in S$. We develop an optimal online algorithm `WEIGHTEDASSIGNMENT` via a primal-dual analysis. The resulting strategy is simple. Associated with each server of current load l and current degree δ is a value $V(l, \delta)$. An incoming request is assigned to an eligible server for which the increment $V(l, \delta + 1) - V(l, \delta)$ is maximized. The values $V(l, \delta)$ can be calculated in a preprocessing step and retrieved by table lookup when the requests of R are served. The best values $V(l, \delta)$, for variable l and δ , are determined using recurrence relations. Solving them is non-trivial because two parameters are involved.

We prove that `WEIGHTEDASSIGNMENT` achieves a competitive ratio of c^* , where

$$c^* = 1 - \frac{1}{b} \left(\sum_{i=1}^b i \binom{kb}{b-i} \frac{1}{(d-1)^{b-i}} \right) \left(1 - \frac{1}{d} \right)^{kb}.$$

This is a slightly complex expression, but it is exact in all terms. In Section 3 we prove that no deterministic online algorithm can attain a competitive ratio greater than c^* , for any choices of k and d that fulfill $k \geq d$.

In Section 4 we consider two generalizations. We assume that each server $s \in S$ has an individual capacity b_s and adapt `WEIGHTEDASSIGNMENT`. As for the competitive factor, in c^* the capacity b has to be replaced by $b_{\min} := \min_{s \in S} b_s$. The resulting competitiveness is again optimal for $k \geq d$. Furthermore, we study the vertex-weighted problem extension and again adjust our algorithm. The competitive ratios are identical to those in the unweighted setting, for uniform and variable server capacities. Our results also hold for the AdWords problem where bidders issue individual, equally valued bids.

In Section 5 we analyze the optimal competitive ratio c^* . We prove that it tends to 1, for any $k \geq d$, as b increases. Furthermore, we show that it is strictly increasing in b . The analyses are involved and make non-trivial use of Gauss hypergeometric functions.

A strength of our results is that the optimal competitiveness tends to 1, for increasing server capacities. Hence almost optimal solutions can be computed online. For the AdWords problem, high server capacities correspond to the small-bids assumption. Remarkably, in this setting near-optimal ad allocations can be computed based on structural properties of the input graph if bidders issue individual, equally valued bids. Recall that, without degree bounds, the competitive ratio for the b -matching problem tends from below to $1 - 1/e \approx 0.63$. The competitiveness of c^* improves upon the previous best ratio of $1 - (1 - 1/d)^k$ [19]. The ratio c^* is equal to $1 - (1 - 1/d)^k$ for $b = 1$ and strictly increasing in b , for any $k \geq d$. Our asymptotic competitiveness of 1 is a significant improvement over $1 - (1 - 1/d)^k \approx 1 - 1/e^{k/d}$, for the interesting range of small $k/d \geq 1$. For $k < d$, $1 - (1 - 1/d)^k$ and c^* can become small. The algorithms are still $\frac{1}{2}$ -competitive since they match requests whenever possible. We are aware of only two other online matching problems that admit competitive ratios arbitrarily close to 1. As mentioned above, a randomized algorithm is known for online matching in d -regular unit-capacity graphs [5]. For the general AdWords problem, respective algorithms exist if the input R is generated according to probability distributions [8, 9].

2 An optimal online algorithm

In this section we study the setting that all servers have a uniform capacity of b . We develop our algorithm `WEIGHTEDASSIGNMENT`. While serving requests, the algorithm maintains a value $V(l_s, \delta_s)$, for each server s with load l_s and current degree δ_s . At any point in time during the execution of the online algorithm, the load of a server s denotes the amount of matched edges incident to s , while the current degree indicates the total number of edges incident to s . In order to construct the function V and for the purpose of analysis, we formulate `WEIGHTEDASSIGNMENT` as a primal-dual algorithm. The primal and dual linear programs of the b -matching problem are given below. The primal variables $m(s, r)$ indicate if an edge $\{s, r\} \in E$ belongs to the matching. We have dual variables $x(s)$ and $y(r)$.

In the pseudocode of `WEIGHTEDASSIGNMENT`, also stated below, Line 7 is the actual matching step. A new request r is assigned to a neighboring server s for which the difference $V(l_s, \delta_s + 1) - V(l_s, \delta_s)$ is maximized. $N(r)$ is the set of adjacent servers with remaining capacity. All other instructions essentially update primal and dual variables so that a primal and a dual solution are constructed in parallel.

Observe that no dual variable $y(r)$ of any request r is ever increased by `WEIGHTEDASSIGNMENT`. The dual variable $x(s)$ of a server s can be increased in Lines 9 and 11. It is increased if s is matched to a neighboring request r and, importantly, $x(s)$ is also increased if this r is assigned to a different server.

$$\begin{array}{ll}
 \mathbf{P:} \max & \sum_{\{s,r\} \in E} m(s,r) \\
 \text{s.t.} & \sum_{r:\{s,r\} \in E} m(s,r) \leq b, \quad (\forall s \in S) \\
 & \sum_{s:\{s,r\} \in E} m(s,r) \leq 1, \quad (\forall r \in R) \\
 & m(s,r) \geq 0, \quad (\forall \{s,r\} \in E) \\
 \mathbf{D:} \min & \sum_{s \in S} b \cdot x(s) + \sum_{r \in R} y(r) \\
 \text{s.t.} & x(s) + y(r) \geq 1, \quad (\forall \{s,r\} \in E) \\
 & x(s), y(r) \geq 0, \quad (\forall s \in S, \forall r \in R)
 \end{array}$$

Algorithm 1 `WEIGHTEDASSIGNMENT`.

```

1 Initialize  $x(s) = 0, y(r) = 0$  and  $m(s, r) = 0, \forall s \in S$  and  $\forall r \in R$ ;
2 while a new request  $r \in R$  arrives do
3   | Let  $N(r)$  denote the set of neighbors  $s$  of  $r$  with remaining capacity;
4   | if  $N(r) = \emptyset$  then
5   |   | Do not match  $r$ ;
6   | else
7   |   | Match  $r$  to  $\arg \max \{V(l_s, \delta_s + 1) - V(l_s, \delta_s) : s \in N(r)\}$ ;
8   |   | Update  $m(s, r) \leftarrow 1$ ;
9   |   | Set  $x(s) \leftarrow V(l_s + 1, \delta_s + 1)$ ;
10  |   | forall  $s' \neq s \in N(r)$  do
11  |   |   | Set  $x(s') \leftarrow V(l_{s'}, \delta_{s'} + 1)$ ;
12  |   | end
13  | end
14 end

```

In the analysis, we will see how the function V has to be defined so that `WEIGHTEDASSIGNMENT` achieves the desired competitive ratio c^* . Note that we always construct a feasible dual solution if $x(s) = 1$ holds, for all servers $s \in S$, by the end of the algorithm.

4:6 Tight Bounds for Online b -Matching in Bounded-Degree Graphs

Here lies a crucial idea of the algorithm and the construction of V . We demand $V(b, \delta) = 1$, for all $\delta \geq b$, and $V(l, \delta) = 1$ if $\delta \geq kb$, for all $0 \leq l \leq b$. Also, $V(0, 0) = 0$. These constraints have two important implications.

1. The dual variable $x(s)$ of a server s with load l_s and degree δ_s is always equal to $V(l_s, \delta_s)$: Consider an incoming request r that is a neighbor of s . While $l_s < b$, it holds $N(r) \neq \emptyset$ and r is matched to some server. Lines 9 and 11 correctly update $x(s)$ with respect to the new load and degree values. If $l_s = b$, then inductively by the first constraint $x(s) = 1$ and no update is necessary.
2. The constructed dual solution is feasible: Implication 1 and the second constraint ensure that $x(s) = 1$ holds for all $s \in S$ by the end of the algorithm, since every server s has a degree of at least kb .

Let P and D denote the value of the primal and dual solution constructed by the algorithm, respectively. We denote a change in the value of the primal and dual solution by ΔP and ΔD , respectively. It holds that the size of the matching constructed by `WEIGHTEDASSIGNMENT` is exactly $|\text{ALG}| = P$. Moreover, by weak duality, we get that the size of the optimum matching is $|\text{OPT}| \leq D$. Hence, if we were able to bound $\Delta D \leq \Delta P/c$ at every step, we would obtain a competitive ratio of c .

$$\frac{|\text{ALG}|}{|\text{OPT}|} \geq \frac{P}{D} \geq \frac{P}{\frac{1}{c} \cdot P} = c.$$

Recall that the value of the dual solution is only increased if a request r is matched to a server s . Then, the value of the primal solution is increased by 1, while the value of the dual solution is increased by

$$\Delta D = b \cdot \left(V(l_s + 1, \delta_s + 1) - V(l_s, \delta_s) + \sum_{s' \in N(r) \setminus \{s\}} V(l_{s'}, \delta_{s'} + 1) - V(l_{s'}, \delta_{s'}) \right).$$

The algorithm chooses s such that $V(l_s, \delta_s + 1) - V(l_s, \delta_s) \geq V(l_{s'}, \delta_{s'} + 1) - V(l_{s'}, \delta_{s'})$ holds for all $s' \in N(r)$. Furthermore, $|N(r)| \leq d$ implies that we can bound this increase by

$$\Delta D \leq b \cdot \left(V(l_s + 1, \delta_s + 1) - V(l_s, \delta_s) + (d - 1) \cdot (V(l_s, \delta_s + 1) - V(l_s, \delta_s)) \right).$$

This means, that we need to determine the biggest possible constant $c^* \in (0, 1]$ such that

$$b \cdot \left(V(l + 1, \delta + 1) - V(l, \delta) + (d - 1) \cdot (V(l, \delta + 1) - V(l, \delta)) \right) \leq \frac{1}{c^*} \quad (1)$$

holds for all $0 \leq l < b$ and all $\delta \geq l$, while still satisfying our constraints that $V(b, \cdot) = 1$ and $V(\cdot, \delta') = 1$ for $\delta' \geq kb$. For this, we define

$$p(l, \delta) := V(l + 1, \delta + 1) - V(l, \delta) \quad \text{and} \quad q(l, \delta) := V(l, \delta + 1) - V(l, \delta).$$

In other words, the dual variable $x(s)$ of a server s with load l and current degree δ is increased by $p(l, \delta)$, when a request is assigned to s , and increased by $q(l, \delta)$, when a neighboring request is assigned to a different server. Our constraints immediately give $p(l, \delta) = q(l, \delta) = 0$, if $l = b$ or $\delta \geq kb$. Hence, we will focus on the case $0 \leq l < b$ and $l \leq \delta < kb$ in the following. Rewriting and rearranging inequality (1) in terms of p and q yields

$$q(l, \delta) \leq \frac{1}{d-1} \left(\frac{1}{b \cdot c} - p(l, \delta) \right).$$

We treat the values $p(i, i)$, for $0 \leq i < b - 1$, as the variables of our optimization, since every other p and q value can then be computed based on these choices. To get comfortable with the recursions and ideas in the latter part of this section, we do the following warm-up, where we consider $V(b - 1, \delta)$. It holds

$$V(b - 1, \delta) = \sum_{i=0}^{b-2} p(i, i) + \sum_{j=b-1}^{\delta-1} q(b - 1, j).$$

Our first constraint $V(b, \delta) = 1$, for all $\delta \geq b$, implies that $p(b - 1, \delta) = 1 - V(b - 1, \delta)$. We do not want to waste any potential increases in our dual variables, since we want to maximize c . Thus, we will choose the maximum possible value for $q(b - 1, \delta)$, which is

$$q(b - 1, \delta) = \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - p(b - 1, \delta) \right) = \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - 1 + V(b - 1, \delta) \right).$$

It follows that

$$V(b - 1, \delta + 1) = V(b - 1, \delta) + q(b - 1, \delta) = \frac{d}{d - 1} V(b - 1, \delta) + \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - 1 \right), \quad (2)$$

for all $b - 1 \leq \delta < kb$ and with $V(b - 1, b - 1) = \sum_{i=0}^{b-2} p(i, i)$. To ease notation in the future, we further define $P_i := \sum_{j=0}^{i-1} p(j, j)$, for all $0 \leq i \leq b - 1$, so that we get $P_i = V(i, i)$. Note that $P_0 = 0$. Solving the recurrence relation (2) yields

$$\begin{aligned} V(b - 1, \delta) &= \left(\frac{d}{d - 1} \right)^{\delta - (b-1)} P_{b-1} + \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - 1 \right) \cdot \sum_{i=0}^{\delta - (b-1) - 1} \left(\frac{d}{d - 1} \right)^i \\ &= \left(\frac{d}{d - 1} \right)^{\delta - (b-1)} P_{b-1} + \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - 1 \right) \cdot \frac{\left(\frac{d}{d - 1} \right)^{\delta - (b-1)} - 1}{\left(\frac{d}{d - 1} \right) - 1} \\ &= \left(\frac{d}{d - 1} \right)^{\delta - (b-1)} \left(P_{b-1} + \frac{1}{b \cdot c} - 1 \right) + 1 - \frac{1}{b \cdot c}. \end{aligned}$$

The following lemma generalizes the computation above to all other load levels.

► **Lemma 1.** *For all l , $0 \leq l \leq b$, and for all δ , $l \leq \delta \leq kb$, it holds that*

$$V(l, \delta) = \sum_{i=l}^{b-1} (-1)^{i-l} \frac{1}{(d - 1)^{i-l}} \binom{\delta - l}{i - l} \left(\frac{d}{d - 1} \right)^{\delta - i} \left(P_i + \frac{b - i}{b \cdot c} - 1 \right) + 1 - \frac{b - l}{b \cdot c}. \quad (3)$$

Proof. By induction over l , starting with $l = b$ and going down to $l = 0$. The induction base $l = b$ is true, because we have $V(b, \delta) = 1$. Thus, we focus on the induction step $l + 1 \rightsquigarrow l$. Similar arguments as before yield for $l \leq \delta < kb$

$$q(l, \delta) = \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - p(l, \delta) \right) = \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - V(l + 1, \delta + 1) + V(l, \delta) \right).$$

We can now define the recurrence relation for $V(l, \delta)$

$$V(l, \delta + 1) = V(l, \delta) + q(l, \delta) = \frac{d}{d - 1} V(l, \delta) + \frac{1}{d - 1} \left(\frac{1}{b \cdot c} - V(l + 1, \delta + 1) \right),$$

4:8 Tight Bounds for Online b-Matching in Bounded-Degree Graphs

with $V(l, l) = P_l$. Solving this recurrence yields

$$\begin{aligned} V(l, \delta) &= \left(\frac{d}{d-1}\right)^{\delta-l} P_l + \frac{1}{d-1} \frac{1}{b \cdot c} \sum_{i=0}^{\delta-l-1} \left(\frac{d}{d-1}\right)^i \\ &\quad - \frac{1}{d-1} \sum_{i=0}^{\delta-l-1} \left(\frac{d}{d-1}\right)^i V(l+1, \delta-i). \end{aligned} \tag{4}$$

In the next step, we will need the following fact [11].

► **Fact 2.** For $n, k \in \mathbb{N}_0$, it holds that

$$\sum_{i=0}^n \binom{i}{k} = \binom{n+1}{k+1}.$$

Next, we apply the induction hypothesis to determine $V(l, \delta)$. For clarity, we focus on the last sum of equality (4) first

$$\begin{aligned} &\sum_{i=0}^{\delta-l-1} \left(\frac{d}{d-1}\right)^i V(l+1, \delta-i) \stackrel{\text{IH}}{=} \sum_{i=0}^{\delta-l-1} \left(\frac{d}{d-1}\right)^i \left[\sum_{j=l+1}^{b-1} (-1)^{j-(l+1)} \frac{1}{(d-1)^{j-(l+1)}} \right. \\ &\quad \cdot \left. \binom{\delta-i-(l+1)}{j-(l+1)} \left(\frac{d}{d-1}\right)^{\delta-i-j} \left(P_j + \frac{b-j}{b \cdot c} - 1\right) + 1 - \frac{b-(l+1)}{b \cdot c} \right] \\ &= \sum_{j=l+1}^{b-1} \left[(-1)^{j-(l+1)} \frac{1}{(d-1)^{j-(l+1)}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1\right) \right. \\ &\quad \cdot \left. \sum_{i=0}^{\delta-l-1} \binom{\delta-i-(l+1)}{j-(l+1)} \right] + \left(1 - \frac{b-(l+1)}{b \cdot c}\right) \sum_{i=0}^{\delta-l-1} \left(\frac{d}{d-1}\right)^i \\ &= \sum_{j=l+1}^{b-1} (-1)^{j-(l+1)} \frac{1}{(d-1)^{j-(l+1)}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1\right) \sum_{i=0}^{\delta-l-1} \binom{i}{j-(l+1)} \\ &\quad + \left(1 - \frac{b-(l+1)}{b \cdot c}\right) (d-1) \left(\left(\frac{d}{d-1}\right)^{\delta-l} - 1 \right) \\ &= \sum_{j=l+1}^{b-1} (-1)^{j-(l+1)} \frac{1}{(d-1)^{j-(l+1)}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1\right) \binom{\delta-l}{j-l} \\ &\quad + \left(1 - \frac{b-(l+1)}{b \cdot c}\right) (d-1) \left(\left(\frac{d}{d-1}\right)^{\delta-l} - 1 \right), \end{aligned}$$

where we used Fact 2 in the last step. Now, we can finish the induction step by plugging this into (4)

$$\begin{aligned}
V(l, \delta) &= \left(\frac{d}{d-1}\right)^{\delta-l} P_l + \frac{1}{b \cdot c} \left(\left(\frac{d}{d-1}\right)^{\delta-l} - 1 \right) \\
&\quad + \sum_{j=l+1}^{b-1} (-1)^{j-l} \frac{1}{(d-1)^{j-l}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1 \right) \binom{\delta-l}{j-l} \\
&\quad - \left(1 - \frac{b-(l+1)}{b \cdot c} \right) \left(\left(\frac{d}{d-1}\right)^{\delta-l} - 1 \right) \\
&= \left(\frac{d}{d-1}\right)^{\delta-l} \left(P_l + \frac{1}{b \cdot c} + \frac{b-(l+1)}{b \cdot c} - 1 \right) + 1 - \frac{1}{b \cdot c} - \frac{b-(l+1)}{b \cdot c} \\
&\quad + \sum_{j=l+1}^{b-1} (-1)^{j-l} \frac{1}{(d-1)^{j-l}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1 \right) \binom{\delta-l}{j-l} \\
&= \sum_{j=l}^{b-1} (-1)^{j-l} \frac{1}{(d-1)^{j-l}} \left(\frac{d}{d-1}\right)^{\delta-j} \left(P_j + \frac{b-j}{b \cdot c} - 1 \right) \binom{\delta-l}{j-l} + 1 - \frac{b-l}{b \cdot c}. \quad \blacktriangleleft
\end{aligned}$$

So far, we have only leveraged our constraint $V(b, \cdot) = 1$. With our description of $V(l, \delta)$, for all $0 \leq l \leq b$ and $l \leq \delta \leq kb$, we can also leverage $V(\cdot, kb) = 1$ to determine P_i , for all $0 \leq i \leq b-1$. For this, we will need the following technical lemma. The proof is given in the full version of the paper.

► **Lemma 3.** For $k, n, m \in \mathbb{N}$, with $m \geq n \geq k$, it holds that

$$\sum_{i=1}^{n-k} (-1)^i \binom{m}{i} \binom{m-i}{n-k-i} = -\binom{m}{n-k}.$$

► **Lemma 4.** For all l , $0 \leq l \leq b-1$, it holds that

$$\left(\frac{d}{d-1}\right)^{kb-l} \left(P_l + \frac{b-l}{b \cdot c} - 1 \right) = \frac{1}{b \cdot c} \left(\sum_{i=1}^{b-l} i \binom{kb-l}{b-l-i} \frac{1}{(d-1)^{b-l-i}} \right). \quad (5)$$

Proof. By induction over l from $l = b-1$ down to $l = 0$. We start with the induction base $l = b-1$. Our second constrain yields $V(b-1, kb) = 1$. It then follows from Lemma 1 that

$$V(b-1, kb) = \left(\frac{d}{d-1}\right)^{kb-(b-1)} \left(P_{b-1} + \frac{1}{b \cdot c} - 1 \right) + 1 - \frac{1}{b \cdot c} \stackrel{\text{def.}}{=} 1,$$

which immediately finishes the induction base, since the right-hand side of (5) is simply $1/(b \cdot c)$.

We can now move on to the induction step $\forall i > l \rightsquigarrow l$. We use $V(l, kb) = 1$ and rearrange with the help of Lemma 1

$$\begin{aligned}
\left(\frac{d}{d-1}\right)^{kb-l} \left(P_l + \frac{b-l}{b \cdot c} - 1 \right) &= \frac{b-l}{b \cdot c} \\
- \sum_{i=l+1}^{b-1} (-1)^{i-l} \frac{1}{(d-1)^{i-l}} \binom{kb-l}{i-l} \left(\frac{d}{d-1}\right)^{kb-i} \left(P_i + \frac{b-i}{b \cdot c} - 1 \right) &. \quad (6)
\end{aligned}$$

4:10 Tight Bounds for Online b -Matching in Bounded-Degree Graphs

It is now possible to apply the induction hypothesis. For clarity, we focus on the second line of (6)

$$\begin{aligned} & \sum_{i=l+1}^{b-1} (-1)^{i-l} \frac{1}{(d-1)^{i-l}} \binom{kb-l}{i-l} \frac{1}{b \cdot c} \left(\sum_{j=1}^{b-i} j \binom{kb-i}{b-i-j} \frac{1}{(d-1)^{b-i-j}} \right) \\ &= \frac{1}{b \cdot c} \left(\sum_{a=1}^{b-l-1} (-1)^a \sum_{j=1}^{b-(l+a)} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-l}{a} \binom{kb-(l+a)}{b-(l+a)-j} \right), \end{aligned}$$

where we substituted $a := i - l$. Next, we carefully swap these nested sums. For this, observe that, for a fixed value j , we have exactly $b - l - j$ addends, more precisely, one addend for each $1 \leq a \leq b - l - j$

$$\begin{aligned} & \frac{1}{b \cdot c} \left(\sum_{a=1}^{b-l-1} (-1)^a \sum_{j=1}^{b-(l+a)} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-l}{a} \binom{kb-l-a}{b-l-a-j} \right) \\ &= \frac{1}{b \cdot c} \left(\sum_{j=1}^{b-l-1} j \frac{1}{(d-1)^{b-l-j}} \sum_{a=1}^{b-l-j} (-1)^a \binom{kb-l}{a} \binom{kb-l-a}{b-l-a-j} \right) \\ &= -\frac{1}{b \cdot c} \left(\sum_{j=1}^{b-l-1} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-l}{b-l-j} \right), \end{aligned}$$

where we applied Lemma 3 with $k = j$, $n = b - l$ and $m = kb - l$ in the last step. Plugging this back into (6) gives

$$\begin{aligned} \left(\frac{d}{d-1} \right)^{kb-l} \left(P_l + \frac{b-l}{b \cdot c} - 1 \right) &= \frac{b-l}{b \cdot c} + \frac{1}{b \cdot c} \left(\sum_{j=1}^{b-l-1} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-l}{b-l-j} \right) \\ &= \frac{1}{b \cdot c} \left(\sum_{j=1}^{b-l} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-l}{b-l-j} \right). \quad \blacktriangleleft \end{aligned}$$

With the help of Lemma 4, we can finally determine the resulting constant c^* . For $l = 0$, we have $P_0 = 0$, and thus

$$\left(\frac{d}{d-1} \right)^{kb} \left(\frac{1}{c^*} - 1 \right) = \frac{1}{b \cdot c^*} \left(\sum_{i=1}^b i \binom{kb}{b-i} \frac{1}{(d-1)^{b-i}} \right),$$

where solving for c^* yields

$$c^* = 1 - \frac{1}{b} \left(\sum_{i=1}^b i \binom{kb}{b-i} \frac{1}{(d-1)^{b-i}} \right) \left(1 - \frac{1}{d} \right)^{kb}.$$

► **Theorem 5.** *WEIGHTEDASSIGNMENT achieves a competitive ratio of c^* for the online b -matching problem with uniform server capacities on (k, d) -graphs.*

Lemma 1, together with Lemma 4 and c^* , specifies the function V . Its values can be calculated in a preprocessing step and accessed by table lookup when WEIGHTEDASSIGNMENT serves requests. The parameters k and d must be known. In an application, they can be learned over time. Alternatively, one can work with conservative estimates. Figure 1 shows

Figure 1 The function V for $k = d = 2$ and $b = 4$. All values are multiplied by 221.

the function V for a small example with $k = d = 2$ and $b = 4$. In this case, we have $c^* = 221/256$ and $1/(bc^*) = 64/221$. The arrows depict the possible increases in V for every l , $0 \leq l < b$, and δ , $l \leq \delta < kb$, i.e. horizontal arrows denote the $q(l, \delta)$ values and diagonal arrows the $p(l, \delta)$ values. All actual values are multiplied by 221 in order to eliminate fractions. Observe that $p(l, \delta) + (d - 1)q(l, \delta) = 1/(bc^*)$ holds for all l and δ . This is what allows us to bound the total increase in the dual solution by $1/c^*$, if we always pick the neighboring server s that maximizes $q(l_s, \delta_s)$. For the matching decisions, WEIGHTEDASSIGNMENT only uses the horizontal arrows. Notice that WEIGHTEDASSIGNMENT is different from a BALANCE algorithm that breaks ties by HIGHDEGREE, or from a HIGHDEGREE algorithm that breaks ties by BALANCE. For example, WEIGHTEDASSIGNMENT prefers a server with load 1 and degree 5 to a server with load 0 and degree 1, whom it then prefers to a server with load 3 and degree 6.

3 Upper bounds

We will show that WEIGHTEDASSIGNMENT is optimal for (k, d) -graphs with $k \geq d$, i.e. no deterministic online algorithm can achieve a competitive ratio better than c^* . We start by proving this for the online b -matching problem with uniform server capacities, and later extend it to the more general problems.

First, we show that any (k, d) -graph with uniform server capacities b has a perfect b -matching, i.e. a matching where every server $s \in S$ is matched exactly b times, if $k \geq d$. This generalizes Lemma 6.1 in [19], which states this for $b = 1$. The proof is given in the full version of this paper.

► **Lemma 6.** *Every (k, d) -graph $G = (S \cup R, E)$, where $k \geq d$, with uniform server capacities b has a perfect b -matching.*

We move on to describing the adversary input. We start by following the construction of the previously known upper bound detailed in [19]. There are $N = d^{kb}$ servers, and the requests arrive in kb rounds. Let S_i denote the set of unmatched servers at the beginning

4:12 Tight Bounds for Online b -Matching in Bounded-Degree Graphs

of round i , $0 \leq i < kb$. It will hold that every server in S_i has a current degree of i and that $|S_i| = N(1 - 1/d)^i$. Note that this number is always a multiple of d , by choice of N . During round i , $|S_i|/d$ requests are introduced, such that every request is adjacent to exactly d distinct servers in S_i and every server in S_i gains one new neighboring request. If the online algorithm decides not to match an introduced request, we consider it matched to an arbitrary neighbor. This will only improve the performance of said algorithm. This means that a $(1 - 1/d)$ fraction of the servers in S_i are still unmatched after round i , explaining the previously mentioned $|S_i| = N(1 - 1/d)^i$. Thus, there are $N \cdot (1 - 1/d)^{kb}$ servers with degree kb and load 0 after round $kb - 1$, irrespective of what choices the algorithm makes. In a final round, further requests are introduced to all matched servers arbitrarily, such that we get a valid (k, d) -graph. The online algorithm will have matched at most $bN \cdot (1 - (1 - 1/d)^{kb})$ requests, while Lemma 6 implies that an optimal offline algorithm matches bN requests. This yields the previously known upper bound of $(1 - (1 - 1/d)^{kb})$.

However, it seems suboptimal to introduce requests arbitrarily after the initial kb rounds. In fact, we will show that we can further limit the number of requests matched by the online algorithm if we introduce the requests more carefully. Note that all the servers that are matched during round i of the previous input are similar in the sense that they all have degree i and load 1. We will apply the ideas above recursively to the sets of matched servers of all rounds. More precisely, let T denote the set of matched server during some round. Say all servers in T have load l , $0 \leq l < b$, and degree δ , $l \leq \delta < kb$. We then schedule $kb - \delta$ rounds for T using the same construction as above. Let T_j denote the set of servers that still have load l at the beginning of round j , $0 \leq j < kb - \delta$. It will now hold that every server in T_j has a current degree of $\delta + j$ and that $|T_j| = |T|(1 - 1/d)^j$. We have to make sure that all the possible values of $|T_j|$ are multiples of d . This is done by increasing the initial number of servers N adequately. After these $kb - \delta$ round, we have $|T| \cdot (1 - 1/d)^{kb - \delta}$ servers with degree kb and load l . This process is repeated for all the sets of matched servers until we eventually obtain a valid (k, d) -graph, in which every server has degree kb .

For this, we formally define a function F , where $F(x, l, \delta)$ denotes how many units of capacity we can force a deterministic online algorithm to leave empty when starting with x servers that all have load l and degree δ . This allows us to upper bound the number of matched requests by $bN - F(N, 0, 0)$, yielding the following upper bound

$$c \leq \frac{bN - F(N, 0, 0)}{bN} = 1 - \frac{F(N, 0, 0)}{bN}. \quad (7)$$

We cannot create any empty spots on full servers, so we have $F(x, b, \delta) = 0$, for all $b \leq \delta \leq kb$. Once a server has kb adjacent requests, we have satisfied the (k, d) -graph property locally, so we do not need to introduce any more adjacent requests for this server. This is captured by $F(x, l, kb) = x \cdot (b - l)$, for all $0 \leq l \leq b$. For all other combinations of l and δ , it is possible to define F recursively. Recall that we introduce $kb - \delta$ rounds when starting with x servers all with load l and degree δ . During each of these rounds, exactly a $1/d$ fraction of the servers that still had load l at the start of the round are discarded. Moreover, every server gets exactly one new neighbor during each round until they are matched. This implies

$$F(x, l, \delta) = x \cdot \left(1 - \frac{1}{d}\right)^{kb - \delta} (b - l) + \sum_{i=1}^{kb - \delta} F\left(x \cdot \frac{1}{d} \left(1 - \frac{1}{d}\right)^{i-1}, l + 1, \delta + i\right), \quad (8)$$

for all $0 \leq l < b$ and $l \leq \delta < kb$. The following lemma solves this recurrence, which we can then apply in (7) to obtain the theorem.

► **Lemma 7.** For all l , $0 \leq l \leq b$, and all δ , $l \leq \delta \leq kb$, it holds that

$$F(x, l, \delta) = x \left(1 - \frac{1}{d}\right)^{kb-\delta} \left(\sum_{i=1}^{b-l} i \binom{kb-\delta}{b-l-i} \frac{1}{(d-1)^{b-l-i}} \right). \quad (9)$$

Proof. By induction over l , starting with $l = b$ and going down to $l = 0$. The induction base is satisfied as we get the empty sum in (9), making the whole expression zero. In the induction step $l+1 \rightsquigarrow l$, we can apply our induction hypothesis to F in (8).

$$\begin{aligned} & \sum_{i=1}^{kb-\delta} F \left(x \cdot \frac{1}{d} \left(1 - \frac{1}{d}\right)^{i-1}, l+1, \delta+i \right) \\ & \stackrel{\text{IH}}{=} \sum_{i=1}^{kb-\delta} x \frac{1}{d} \left(1 - \frac{1}{d}\right)^{i-1} \left(1 - \frac{1}{d}\right)^{kb-(\delta+i)} \left(\sum_{j=1}^{b-(l+1)} j \binom{kb-\delta-i}{b-(l+1)-j} \frac{1}{(d-1)^{b-(l+1)-j}} \right) \\ & = x \frac{1}{d} \left(1 - \frac{1}{d}\right)^{kb-\delta-1} \left(\sum_{j=1}^{b-(l+1)} j \frac{1}{(d-1)^{b-(l+1)-j}} \sum_{i=1}^{kb-\delta} \binom{kb-\delta-i}{b-(l+1)-j} \right) \\ & = x \left(1 - \frac{1}{d}\right)^{kb-\delta} \frac{1}{d-1} \left(\sum_{j=1}^{b-(l+1)} j \frac{1}{(d-1)^{b-l-j-1}} \sum_{i=0}^{kb-\delta-1} \binom{i}{b-l-j-1} \right) \\ & = x \left(1 - \frac{1}{d}\right)^{kb-\delta} \left(\sum_{j=1}^{b-(l+1)} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-\delta}{b-l-j} \right), \end{aligned}$$

where we used Fact 2 in the last step. Finally, we can plug this result back into (8) to obtain

$$\begin{aligned} F(x, l, \delta) & = x \cdot \left(1 - \frac{1}{d}\right)^{kb-\delta} (b-l) + \sum_{i=1}^{kb-\delta} F \left(x \cdot \frac{1}{d} \left(1 - \frac{1}{d}\right)^{i-1}, l+1, \delta+i \right) \\ & = x \cdot \left(1 - \frac{1}{d}\right)^{kb-\delta} \left((b-l) + \sum_{j=1}^{b-(l+1)} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-\delta}{b-l-j} \right) \\ & = x \cdot \left(1 - \frac{1}{d}\right)^{kb-\delta} \left(\sum_{j=1}^{b-l} j \frac{1}{(d-1)^{b-l-j}} \binom{kb-\delta}{b-l-j} \right). \quad \blacktriangleleft \end{aligned}$$

► **Theorem 8.** No deterministic online algorithm for the b -matching problem with uniform server capacities b can achieve a competitiveness better than c^* on (k, d) -graphs with $k \geq d$.

We extend this upper bound to the more general case with variable server capacities, which we will examine in the next section. Let $b_{\min} = \min_{s \in S} b_s$. The optimal competitiveness is then

$$c_{\min}^* = 1 - \frac{1}{b_{\min}} \left(\sum_{i=1}^{b_{\min}} i \binom{kb_{\min}}{b_{\min}-i} \frac{1}{(d-1)^{b_{\min}-i}} \right) \left(1 - \frac{1}{d}\right)^{kb_{\min}}.$$

► **Corollary 9.** No deterministic online algorithm for the b -matching problem with variable server capacities can achieve a competitive ratio better than c_{\min}^* on (k, d) -graphs with $k \geq d$.

The proof is detailed in the full version of this paper. Obviously, Theorem 8 and Corollary 9 also hold for the more general vertex-weighted b -matching problem, addressed in the next section.

4 Variable server capacities and vertex weights

We detail the necessary changes to `WEIGHTEDASSIGNMENT` such that it can handle variable server capacities as well as vertex weights, while still achieving the optimal competitive ratio.

4.1 Variable server capacities

Recall that every server $s \in S$ now has a server capacity b_s , and thus a degree of at least $d(s) \geq k \cdot b_s$. This changes the objective function of the dual linear program to

$$\sum_{s \in S} b_s \cdot x(s) + \sum_{r \in R} y(r).$$

We handle this by computing the function V_s for every server individually, for its capacity b_s . This means that we construct V_s according to Section 2, such that

$$b_s \cdot \left(V_s(l+1, \delta+1) - V_s(l, \delta) + (d-1) \cdot (V_s(l, \delta+1) - V_s(l, \delta)) \right) \leq \frac{1}{c_s^*}, \quad (10)$$

where c_s^* is equal to c^* , but b is replaced by b_s . Moreover, we have $V_s(b_s, \cdot) = 1$ and $V_s(\cdot, \delta') = 1$ if $\delta' \geq kb_s$, meaning that we again construct a feasible dual solution. However, we still have to adapt the decision criterion of `WEIGHTEDASSIGNMENT`. We change Line 7 in Algorithm 1 to

$$\text{Match } r \text{ to } \arg \max \{ b_s \cdot (V_s(l_s, \delta_s + 1) - V_s(l_s, \delta_s)) : s \in N(r) \}.$$

This allows us to upper bound the total increase in the dual solution when the adapted strategy, called `WEIGHTEDASSIGNMENT(VC)`, assigns a request r to a server s by

$$\begin{aligned} \Delta D &= b_s \cdot \left(V_s(l_s + 1, \delta_s + 1) - V_s(l_s, \delta_s) \right) \\ &\quad + \sum_{s' \in N(r) \setminus \{s\}} b_{s'} \cdot \left(V_{s'}(l_{s'}, \delta_{s'} + 1) - V_{s'}(l_{s'}, \delta_{s'}) \right) \\ &\leq b_s \cdot \left(V_s(l_s + 1, \delta_s + 1) - V_s(l_s, \delta_s) + (d-1) \cdot (V_s(l_s, \delta_s + 1) - V_s(l_s, \delta_s)) \right) \leq \frac{1}{c_s^*}. \end{aligned}$$

Thus, `WEIGHTEDASSIGNMENT(VC)` achieves a competitive ratio of $\min_{s \in S} c_s^*$. In Section 5 we will show that c^* is monotonically increasing in b for $k \geq d$, meaning that $\min_{s \in S} c_s^* = c_{\min}^*$, cf. Section 3.

► **Theorem 10.** *`WEIGHTEDASSIGNMENT(VC)` achieves a competitive ratio of $\min_{s \in S} c_s^*$ the b -matching problem with variable server capacities on (k, d) -graphs. The ratio equals c_{\min}^* and is optimal for $k \geq d$.*

4.2 Vertex weights

At last, we consider the vertex-weighted extension of the online b -matching problem. Every server $s \in S$ now has a weight w_s assigned to it, and the value of every matching edge incident to s is multiplied by w_s . This problem is modelled by the following linear programs.

$$\begin{aligned}
\text{Primal: } \max \quad & \sum_{\{s,r\} \in E} w_s \cdot m(s,r) \\
\text{s.t.} \quad & \sum_{r:\{s,r\} \in E} w_s \cdot m(s,r) \leq w_s \cdot b_s, & (\forall s \in S) \\
& \sum_{s:\{s,r\} \in E} m(s,r) \leq 1, & (\forall r \in R) \\
& m(s,r) \geq 0, & (\forall \{s,r\} \in E).
\end{aligned}$$

$$\begin{aligned}
\text{Dual: } \min \quad & \sum_{s \in S} w_s \cdot b_s \cdot x(s) + \sum_{r \in R} y(r) \\
\text{s.t.} \quad & w_s \cdot x(s) + y(r) \geq w_s, & (\forall \{s,r\} \in E) \\
& x(s), y(r) \geq 0, & (\forall s \in S, \forall r \in R).
\end{aligned}$$

Observe that $x(s) = 1$, for all $s \in S$, by the end of the algorithm still implies dual feasibility. Hence, we do not need to change the construction of V_s , and still obtain a feasible dual solution. All we need to do is to change the decision criterion of `WEIGHTEDASSIGNMENT(VC)` once more to

$$\text{Match } r \text{ to } \arg \max \{w_s \cdot b_s \cdot (V_s(l_s, \delta_s + 1) - V_s(l_s, \delta_s)) : s \in N(r)\}.$$

Whenever the resulting algorithm `WEIGHTEDASSIGNMENT(VW)` assigns a request r to a server s , we increase the primal solution by w_s , while we can upper bound the increase in the dual solution by

$$\Delta D \leq w_s b_s \cdot \left(V_s(l_s + 1, \delta_s + 1) - V_s(l_s, \delta_s) + (d-1)(V_s(l_s, \delta_s + 1) - V_s(l_s, \delta_s)) \right) \leq \frac{w_s}{c_s^*}.$$

This again yields a competitiveness of $\min_{s \in S} c_s^*$.

► **Theorem 11.** *`WEIGHTEDASSIGNMENT(VW)` achieves a competitive ratio of $\min_{s \in S} c_s^*$ for the vertex-weighted b -matching problem with variable server capacities on (k, d) -graphs. The ratio equals c_{\min}^* and is optimal for $k \geq d$.*

5 Analysis of the competitive ratio

► **Theorem 12.** *If $k \geq d \geq 2$, the competitive ratio c^* converges to one as b tends to infinity, that is $\lim_{b \rightarrow \infty} c^* = 1$.*

► **Theorem 13.** *If $k \geq d \geq 2$, the competitive ratio c^* is strictly increasing in b , for $b \geq 1$.*

The proofs of these two theorems are given in the full version of the paper. Theorem 12 is shown with the help of Gaussian hypergeometric functions. They allow us to upper bound c^* with a closed expression. The convergence of this expression can then be shown with the help of Stirling's approximation. Since this does not prove monotonicity, we consider the fraction of c^* with $b+1$ over c^* with b in the proof of Theorem 13. We show that this fraction is lower bounded by 1, again with the help of hypergeometric functions.

Abstract

We study the Traveling Salesman Problem inside a simple polygon. In this problem, which we call TSP IN A SIMPLE POLYGON, we wish to compute a shortest tour that visits a given set S of n sites inside a simple polygon P with m edges while staying inside the polygon. This natural problem has, to the best of our knowledge, not been studied so far from a theoretical perspective. It can be solved exactly in $\text{poly}(n, m) + 2^{O(\sqrt{n} \log n)}$ time, using an algorithm by Marx, Pilipczuk, and Pilipczuk (FOCS 2018) for SUBSET TSP as a subroutine. We present a much simpler algorithm that solves TSP IN A SIMPLE POLYGON directly and that has the same running time.

1 Introduction

The TRAVELING SALESMAN PROBLEM, or TSP for short, is a classic algorithmic problem. Given an edge-weighted graph, the goal is to compute a *tour* – a cycle that visits each node exactly once – of minimum total weight. The problem has been studied widely; in fact, TSP is probably one of the most intensely studied problems in optimization and computer science. There are even several books devoted to TSP [2, 9, 15, 29]. Important special cases of TSP are METRIC TSP and EUCLIDEAN TSP. In METRIC TSP, the edge weights in the input graph form a metric and, in particular, satisfy the triangle inequality. The algorithm by Christofides [8] gives a $(3/2)$ -approximation for this version of the problem. A special case of METRIC TSP is EUCLIDEAN TSP. Here the input is a set S of n points in \mathbb{R}^d and the goal is to visit all points with a tour of minimum total Euclidean length. Due to its natural setting, EUCLIDEAN TSP is among the most studied versions of TSP. EUCLIDEAN TSP is NP-hard [12, 27] but, unlike METRIC TSP, it admits a PTAS as was shown in the celebrated papers of Arora [3] and (for 2D) Mitchell [26]. A PTAS with a better running time was later presented by Rao and Smith [28]. Recently, Kisfaludi-Bak *et al.* [20] presented a PTAS with $2^{O(1/\varepsilon^{d-1})} n \log n$ running time, which they proved to be optimal under Gap-ETH. There are also PTASs for TSP in planar graphs [4, 21] and in spaces of constant doubling dimension [5] – as Trevisan [33] proved, the restriction to bounded dimension is necessary for a PTAS, even in Euclidean spaces – and in spaces of so-called bounded global growth [7].

Our focus is on exact algorithms for TSP. The general TSP problem can be solved exactly in $O(2^{n^2})$ time using dynamic programming, as was shown independently by Held and Karp [16] and Bellman [6]. There is no subexponential algorithm – that is, no algorithm

with $2^{o(n)}$ running time – for the general problem, under the Exponential-Time Hypothesis (ETH) [10, Theorem 14.6]. This lower bound even holds for METRIC TSP. On the other hand, EUCLIDEAN TSP can be solved in subexponential time. Already in the early 1990s, Kann [18] and Hwang, Chang and Lee [17] gave $2^{O(\sqrt{n} \log n)}$ algorithms for the planar version of the problem.¹ This was generalized by Smith and Wormald [31], who presented an $2^{O(n^{1-1/d} \log n)}$ algorithm for EUCLIDEAN TSP in \mathbb{R}^d ; here and in the sequel we consider the dimension d to be a fixed constant. For a long time it was open if EUCLIDEAN TSP in \mathbb{R}^d admits an exact algorithm with a running time $2^{O(n^{1-1/d})}$. Recently, the question was settled by De Berg *et al.* [11], who presented such an algorithm and showed that no $2^{o(n^{1-1/d})}$ algorithm exists unless ETH fails. There is also an exact algorithm for TSP in hyperbolic spaces of Gaussian curvature -1 , which runs in quasi-polynomial time if the minimum distance between any two points is at least some fixed constant $\alpha > 0$ [19]. Finally, Klein and Marx [22] presented an algorithm for SUBSET TSP on planar graphs with integer edge weights, where the goal is to compute a shortest tour visiting a given subset of the vertices. Their algorithm runs in time $\text{poly}(|V|) \cdot 2^{O(\sqrt{n} \log n)} + W$, where $|V|$ is the total number of vertices, n is the number of vertices to be visited, and W is the maximum edge weight. This was later improved by Marx, Pilipczuk, and Pilipczuk [24] who presented an algorithm with running time $\text{poly}(|V|) \cdot 2^{O(\sqrt{n} \log n)}$ that does not need the weights to be bounded or integral.

A natural generalization of EUCLIDEAN TSP is to consider a salesman who is moving among a set of obstacles in the plane, or some higher-dimensional space. We call this problem TSP WITH OBSTACLES. As far as we know, and to our surprise, TSP WITH OBSTACLES seems not to have been studied at all from a theoretical perspective, although it has appeared in a behavioural study where subjects were tested on finding the optimal tour [30]. (There is also a paper describing a genetic algorithm for TSP in the presence of obstacles [13], although the setting is slightly different.) A somewhat related problem is where one is given two simple disjoint polygons, and the salesman must visit all vertices of the polygons without crossing the boundary of the polygons. This problem is markedly different from TSP WITH OBSTACLES, however. In particular, it is not a generalization of EUCLIDEAN TSP, and it has been shown by Abrahamson and Shokoufandeh [1] to be solvable in polynomial time.

The fact that TSP WITH OBSTACLES has not been studied is remarkable, since motion-planning and shortest-path problems are among the most widely studied problems in computational geometry. It is beyond the scope of our paper to give an overview of this area, so we just mention one result that we will need. Guibas and Hershberger [14] show how to construct, for a simple polygon P with m vertices and a source point s , a shortest-path map in $O(m)$ time. The shortest-path map allows us to compute, for a point set S of n points in P and a given source point $s \in S$, the shortest-path tree rooted at s and going to all other points in S , in $O(m + n \log m)$ time. If we do this for all points from S as source point, we obtain all shortest paths (and all distances) between the points in S in $O(nm + n^2 \log n)$ time.

TSP WITH OBSTACLES can be solved by computing a shortest path between each pair of points in S , and then running the Bellman-Held-Karp algorithm [6, 16] using the computed pairwise distances, but this leads to an exponential running time. In the plane a much faster algorithm can be obtained if one uses an algorithm for SUBSET TSP as a subroutine, as follows. First, compute all pairwise shortest paths. Next, turn this collection of paths

¹ Comparing the exact lengths of two given tours in the plane is in fact non-trivial, as it involves comparing sums of square roots. To focus on the combinatorial complexity of the problem, such algebraic issues are typically ignored by working in the real-RAM model, which we do as well.

in the plane into a weighted planar graph by inserting a vertex at every intersection point between two paths, where the weight of an edge in the graph is the shortest-path distance between its endpoints. Note that some pairs of path may overlap instead of intersect; in that case, insert a vertex at the two outermost points where they overlap. The resulting graph has $O(n^4)$ vertices – the points in S plus the intersection points – of which n nodes must be visited. Solving SUBSET TSP using the algorithm of Marx, Pilipczuk, and Piliczuk [24] leads to an algorithm with $\text{poly}(n, m) + O(n^2) \cdot 2^{O(\sqrt{n} \log n)} = \text{poly}(n, m) + 2^{O(\sqrt{n} \log n)}$ running time, where m is the total number of edges of the obstacles.

Our contribution. We are interested in the variant of TSP WITH OBSTACLES where the salesman is moving inside a simple polygon P with m edges in total, which contains the set S of points to be visited. In other words, there is a single obstacle which is the region outside the polygon. We call this variant TSP IN A SIMPLE POLYGON. From now on, we refer to the points in S as *sites*, to distinguish them from arbitrary points in P .

As mentioned, TSP WITH OBSTACLES in the plane can be solved in subexponential time using the algorithm of Marx, Pilipczuk, and Piliczuk for SUBSET TSP as a subroutine. Hence, TSP IN A SIMPLE POLYGON can be solved in $\text{poly}(n, m) + 2^{O(\sqrt{n} \log n)}$ time. Unfortunately, the algorithm of Marx, Pilipczuk, and Piliczuk for SUBSET TSP is complicated: the description of the algorithm and its correctness proof take 27 pages in total [23]. Here we only count the overview of the algorithm (Section 2, comprising 7 pages) and the detailed description of the algorithm and proof of correctness (Section 5, comprising 20 pages), and not the description of some of the tools being used (Sections 3 and 4, comprising 2.5 pages).

We present a much simpler algorithm with the same running time, based on the elegant algorithm by Hwang, Chang and Lee [17] for EUCLIDEAN TSP in the plane. We also prove several basic properties of optimal solutions for TSP WITH OBSTACLES, which are of independent interest.

2 Notation and basic properties

In this section we introduce the notation and terminology used throughout paper, and we prove several basic properties of optimal TSP tours in a simple polygon.

Let P be a simple polygon, which is the region in which the salesman can move. We consider P to be a closed set, so that shortest paths are well defined. Let $S = \{s_1, \dots, s_n\} \subset P$ denote the set of sites to be visited by the salesman. We say that a vertex v of P is *reflex* if the angle between the two edges incident to v , measured inside P , is more than 180 degrees.

Whenever we speak of a *path*, we mean a path that stays in P , unless stated otherwise. We denote the length of the line segment pq connecting points p and q by $|pq|$. Similarly, we denote the (Euclidean) length of a path π by $|\pi|$. For two points $p, q \in P$ we use $\pi(p, q)$ to denote the (unique) shortest path between them, that is, the path from p to q that has minimum length while staying inside P . Finally, for a path π and two points $a, b \in \pi$, the subpath of π between a and b is denoted by $\pi[a, b]$.

Consider a polygonal path π (that is, a path consisting of straight-line segments) and let v be a reflex vertex of P . We say that π *bends around* v if v coincides with an interior vertex (not an endpoint) of π and π is *locally shortest* at v . In other words, if e_1, e_2 are the two edges of π meeting at v , then the two edges of P meeting at v lie in the convex wedge defined by e_1 and e_2 . Observe that a shortest path π inside P must bend around a reflex vertex of P at each of the path's interior vertices. The next lemma shows that in a simple polygon, local optimality implies global optimality. It is folklore, but for completeness we give a proof.

5:4 TSP in a Simple Polygon

■ **Figure 1** (i) Illustration for the proof of Lemma 1. (ii) An optimal tour may pass through the same site twice, and can contain (partially) overlapping line segments. (iii) Crossing and non-crossing paths. Note: paths in parts (ii) and (iii) are shown slightly displaced where they overlap.

► **Lemma 1.** *Let p, q be two points inside a simple polygon P and let π be a path between p and q such that every interior vertex of π bends around a reflex vertex of P . Then, π is the shortest path from p to q in P .*

Proof. Let v_1, \dots, v_k be the interior vertices of π , so $\pi = (p, v_1, \dots, v_k, q)$. We will prove the lemma by induction on k . For $k = 0$ the lemma trivially holds, so assume $k > 0$.

Consider the ray from p through v_1 , and let z be the first point where the ray hits ∂P after v_1 . Then the segment v_1z splits P into two parts. Let P_1 be the part that contains p , and let P_2 be the other part. We claim that $q \in P_2$. Indeed, if this was not the case then π must cross v_1z at some point y . Consider the region $R \subset P$ enclosed by v_1y and $\pi[v_1, y]$; see Fig. 1(i). (Our assumptions do not immediately rule out that π intersects itself, so R need not be simple. But this does not invalidate the coming argument.) Since P is simple, R cannot contain any part of ∂P . Let v_i denote a vertex of π on $\pi[v_1, y]$ that has maximal distance from v_1y . Then the angle between the two edges of π incident to v_i has to be convex when measured inside R , otherwise v_i cannot be a vertex of maximal distance from v_1y . By assumption, π has to bend around a vertex of P at v_i , but this cannot happen since $R \subset P$. Hence, $q \in P_2$, as claimed.

We now observe that the shortest path from p to any point in P_2 passes through v_1 . Moreover, by the induction hypothesis we know that the path (v_1, \dots, v_k, q) is the shortest path from v_1 to q . We conclude that π is the shortest path from p to q in P . ◀

It is well known that optimal tours for EUCLIDEAN TSP in \mathbb{R}^2 are non-self-intersecting, that is, if $s_i s_j$ and $s_k s_t$ are non-consecutive edges in an optimal tour then $s_i s_j$ and $s_k s_t$ do not intersect (except when all sites are collinear). This is no longer true for TSP IN A SIMPLE POLYGON: two paths $\pi(s_i, s_j)$ and $\pi(s_k, s_t)$ that are part of an optimal tour can meet in one or more points, and sites may be visited more than once; see Fig. 1(ii). However, we can still formulate a non-crossing property for TSP WITH OBSTACLES, as shown next.

Let $\pi_1 = \pi(p_1, q_1)$ and $\pi_2 = \pi(p_2, q_2)$ be two shortest paths in P . Observe that their intersection $\pi_1 \cap \pi_2$, may contain at most one connected component, due to the uniqueness of shortest paths. Let γ denote this component. We give an arbitrary orientation to the path π_1 . We say that π_1 and π_2 are *crossing* when π_2 lies on opposite sides of π_1 just before γ and just after γ , relative to the chosen orientation of π_1 ; otherwise π_1 and π_2 are *non-crossing*. See Fig. 1(iii) for an example.

We now state the main result of this section.

► **Theorem 2.** *Let P be a simple polygon and let S be a set of n sites in P . Then there is an optimal tour T_{opt} through S such that*

1. T_{opt} passes at most twice through any point of P , and
2. any two paths of T_{opt} are non-crossing.

■ **Figure 2** Illustrations for the proof of Theorem 2.

► **Remark 3.** A site s_i may lie on the shortest path between two other sites s_j, s_k , in which case T_{opt} may use $\pi(s_j, s_k)$ plus two shortest paths with s_i as endpoint; see site s_3 in Fig. 1(ii). This does not contradict Property 1 of the theorem: T_{opt} still passes through s_i only twice.

Proof.

Proof of part 1. We first observe the following. Let r be a point through which T_{opt} passes at least twice. Give T_{opt} an arbitrary orientation, and suppose T_{opt} first arrives at r along a segment e_1 and later along a segment e_2 that is not collinear with e_1 . Then r must be a reflex vertex of P , and P must, locally at r , lie in the convex wedge defined by e_1 and e_2 ; otherwise we could shortcut T_{opt} at r as shown in Fig. 2(i).

Now suppose T_{opt} passes at least three times through some point r . Then there are at least three segments e_1, e_2, e_3 through which T_{opt} arrives at r . If two of these segments overlap then we can shortcut T_{opt} , which is a contradiction. Otherwise at least two of the three wedges defined by e_1, e_2, e_3 have an opening angle less than 180 degrees. The point r can be a reflex vertex of R , but locally at r , the polygon P can lie in only one of these two wedges; see Fig. 2(ii). Hence, we can shortcut at the other wedge, which is a contradiction.

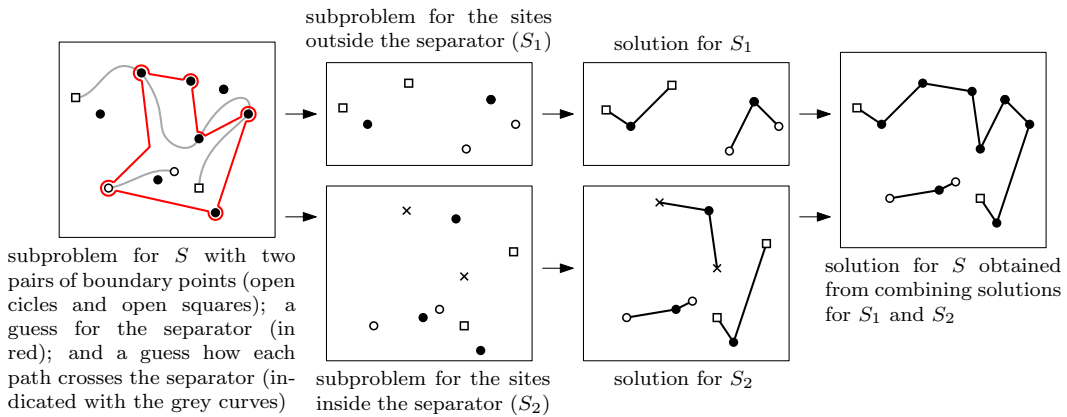

Proof of part 2. Number the sites in order along T_{opt} so that $T_{\text{opt}} = \bigcup_{\ell=1}^n \pi_\ell$, where we define $\pi_\ell := \pi(s_\ell, s_{\ell+1})$ and $s_{n+1} := s_1$. Suppose there are two paths π_i and π_j that cross each other. Notice that the paths $\pi(s_i, s_j)$ and $\pi(s_{i+1}, s_{j+1})$ do not cross each other; see Fig. 1, where the two crossing paths shown at the top can be “uncrossed”, resulting in the non-crossing paths shown at the bottom. Let Γ_1 be the part of T_{opt} from s_{i+1} to s_j and let Γ_2 be the part of T_{opt} from s_{j+1} to s_i . Then $T_{\text{opt}}^* := \Gamma_1 \cup \pi(s_{i+1}, s_{j+1}) \cup \Gamma_2 \cup \pi(s_i, s_j)$, where the direction of Γ_1 is reversed, is a tour of the same length as T_{opt} . Moreover, T_{opt}^* has fewer crossings; this is true because uncrossing π_i and π_j cannot generate new crossings by part 1 of the theorem. Hence, we can repeat the process until we are left with an optimal tour without any crossings. ◀

3 A subexponential algorithm for TSP IN A SIMPLE POLYGON

In this section we give a subexponential algorithm for TSP IN A SIMPLE POLYGON, based on the work by Hwang *et al.* [17]. The algorithm of Hwang *et al.* solves a problem that is slightly more general than TSP, so that it can be used in a recursive algorithm. In a recent paper, De Berg *et al.* [11] define the same generalized problem, but with a different terminology that will be more convenient for us. In what follows we will mostly use their terminology to define the problem, which De Berg *et al.* call EUCLIDEAN PATH COVER. (Hwang *et al.* called it GENERALISED EUCLIDEAN TSP).

Let $S' \subset S$ be a subset of n of the sites of the initial set of sites, let $B \subset S'$ be a set of *boundary sites*, and let M be a perfect matching on B . We say that a collection of paths² $\mathcal{P} = \{\pi_1, \pi_2, \dots, \pi_{|B|/2}\}$ *realizes* M on S' if (i) for each pair $(s_i, s_j) \in M$ there is a path

² Note that we are now temporarily back in the standard EUCLIDEAN TSP setting. Thus the paths mentioned here are not shortest paths between sites, but paths in the complete graph on the sites. In the current setting, the edges of these paths are straight-line segments between the corresponding sites; when we go back to TSP IN A SIMPLE POLYGON, they will be shortest paths between sites.

■ **Figure 3** An example of how the algorithm works. After trying all possible separators and all possible ways the paths cross the separator, we will have found the optimal solution.

$\pi_{ij} \in \mathcal{P}$ with s_i and s_j as endpoints, and (ii) the paths together visit each site in S' exactly once. The goal of EUCLIDEAN PATH COVER is to find a collection of paths of minimum total length that realizes M on S' . Note that we can solve EUCLIDEAN TSP by solving $n - 1$ instances of EUCLIDEAN PATH COVER on S' , namely for $B = \{s_1, s_i\}$ where $i \in \{2, \dots, n\}$, and taking the best solution found. Next we describe how an instance of EUCLIDEAN PATH COVER can be solved using the triangulation approach. For simplicity, and with a slight abuse of notation, we will denote the set of sites that need to be visited by S (rather than S').

The triangulation approach. Hwang *et al.* solve EUCLIDEAN PATH COVER with a separator-based divide-and-conquer algorithm, which we will refer to as the *triangulation approach*. It works as follows. We start by creating Q , a set of three points defining an arbitrarily large triangle containing all the points in S . Suppose we have a maximal triangulation \mathcal{T} of $S \cup Q$ that uses all segments from each path in an optimal solution \mathcal{P}_{opt} . Since \mathcal{T} is a maximal planar graph, Miller's separator theorem [25] implies that there exists a simple cycle \mathcal{C} in \mathcal{T} of at most $2\sqrt{2(n+3)}$ points from $S \cup Q$ such that at most $2(n+3)/3$ sites are inside \mathcal{C} , and at most $2(n+3)/3$ sites are outside \mathcal{C} . The idea is to use the separator \mathcal{C} to split the problem into two subproblems: one inside \mathcal{C} and one outside \mathcal{C} , and glue the solutions to these subproblems together to get the solution to the original problem. However, we have to make sure that the solutions inside and outside match with each other. To ensure this, we guess all possible ways in which \mathcal{P}_{opt} can cross \mathcal{C} , and handle each of them separately. Since the triangulation uses all segments from each path in \mathcal{P}_{opt} , no edge in \mathcal{P}_{opt} crosses an edge in \mathcal{C} . Hence, \mathcal{P}_{opt} only goes from inside \mathcal{C} to outside \mathcal{C} via nodes of \mathcal{C} . Thus guessing where \mathcal{P}_{opt} crosses \mathcal{C} amounts to guessing for each path in \mathcal{P}_{opt} at which nodes of \mathcal{C} it crosses \mathcal{C} (as well as the order of these crossing nodes). Each guess will lead to different pairs of subproblems to be solved inside and outside the separator. The optimal solution will then be the best solution over all guesses. See Fig. 3 for an example.

Above we assumed that we had a triangulation \mathcal{T} of $S \cup Q$ that uses all segments from each path in \mathcal{P}_{opt} . But we do not know \mathcal{P}_{opt} , since \mathcal{P}_{opt} is what we want to compute. We therefore try all possible simple cycles \mathcal{C} of at most $2\sqrt{2(n+3)}$ sites, and for each of them compute an optimal solution under the assumption that the solution does not use any edge that intersects an edge in the cycle. One of these guesses must correspond to the separator for

the (unknown) triangulation \mathcal{T} . Algorithm 1 gives a high-level description of the algorithm. Next we show how to apply the algorithm to TSP IN A SIMPLE POLYGON, and fill in the details for the various steps.

■ **Algorithm 1** *Triangulation-Approach*(S, B, M).

Input: set S of n sites; set $B \subseteq S$ of boundary points; perfect matching M on B

Output: A solution for EUCLIDEAN PATH COVER for the instance (S, B, M)

- 1: **if** $|S|$ is a sufficiently small constant **then**
 - 2: Compute an optimal solution \mathcal{P}_{opt} by brute-force
 - 3: **else**
 - 4: Generate all candidate separators \mathcal{C} for S , as explained in the text
 - 5: **for** each candidate separator \mathcal{C} **do**
 - 6: Generate all pairs of subproblems $(S_1, B_1, M_1), (S_2, B_2, M_2)$ for \mathcal{C} ,
as explained in the text. Recursively solve each pair of subproblems, and let
 $\mathcal{P}_{\text{opt}}(S_1, B_1, M_1, S_2, B_2, M_2)$ be the solution obtained by concatenating
the solutions to the subproblems.
 - 7: $\mathcal{P}_{\text{opt}} \leftarrow$ best of all solutions $\mathcal{P}_{\text{opt}}(S_1, B_1, M_1, S_2, B_2, M_2)$ from the previous step
 - 8: **return** \mathcal{P}_{opt}

3.1 Applying the triangulation approach to TSP IN A SIMPLE POLYGON

We now return to TSP IN A SIMPLE POLYGON. As above, we will solve a path-cover problem, which we call GENERALIZED EUCLIDEAN PATH COVER. This problem is the same as EUCLIDEAN PATH COVER, except that the edges used by the paths, which used to be straight-line segment connecting sites, are now going to be shortest paths connecting sites.

To apply the triangulation approach in our new setting, we need a maximal triangulation of an optimal solution \mathcal{P}_{opt} to the given instance of the GENERALIZED EUCLIDEAN PATH COVER. The existence of such a maximal triangulation implies that there is a small separator by Miller’s separator theorem, which we can then guess. There exists of course a triangulation of \mathcal{P}_{opt} if we are allowed to use all internal vertices of these paths as vertices in the triangulation: we just need to construct a so-called *constrained triangulation* on the set of all sites and internal shortest-path vertices, which uses the given segments on the paths. But the number of nodes of such a triangulation would not only depend on the number of sites, but also on the total complexity of the shortest paths, which depends on the complexity of the polygon P . The key idea to overcome this, is to work with a triangulation whose nodes are the sites in S and whose edges are shortest paths. Next, we show that such a triangulation always exists, and show how to create a maximal triangulation from this triangulation. After that we will describe the various steps of the algorithm in more detail, and we will prove its correctness and analyze its running time.

Triangulating \mathcal{P}_{opt} . Recall that a set $X \subseteq P$ is called *geodesically convex* if for any two points $p, q \in X$ the shortest path $\pi(p, q)$ in P is contained in X . The *relative convex hull* [32] of a set S of sites inside a simple polygon P , denoted by $\text{RCH}(S)$, is defined as the intersection of all geodesically convex sets containing S . Intuitively, $\text{RCH}(S)$ is obtained by placing a rubber band on ∂P , and then releasing the band so that it “snaps” around S , without crossing over any site and while staying inside P . The boundary of $\text{RCH}(S)$ consists of shortest paths connecting points of S ; see Fig. 4(i) for an illustration.

Let $E(S) := \{\pi(s_i, s_j) : s_i, s_j \in S \text{ and } i \neq j\}$ to be the set of all shortest paths between the sites in S . We now define an *sp-triangulation* (see Figure 4(ii)) of S to be a collection $\mathcal{T}_{\text{sp}}(S) \subset E(S)$ of pairwise non-crossing shortest paths between the sites in S such that

- $\mathcal{T}_{\text{sp}}(S)$ includes the shortest paths that form ∂RCH , and
- each face in the subdivision of $\text{RCH}(S)$ defined by $\mathcal{T}_{\text{sp}}(S)$ (after moving pieces of the paths slightly apart where they overlap) is bounded by exactly three paths.

► **Lemma 4.** *For any set S of sites inside a simple polygon P , and any given collection $E^* \subset E(S)$ of pairwise non-crossing paths, there exists an sp-triangulation $\mathcal{T}_{\text{sp}}(S)$ that includes the paths from E^* .*

Proof. Consider the subdivision of $\text{RCH}(S)$ induced by (the boundary of $\text{RCH}(S)$ and) the prescribed shortest paths in E^* . We will show how to triangulate each face F in this subdivision using paths from $E(S)$.

The face F has an outer boundary and it contains zero or more additional shortest paths. Let $E_{\text{out}}(F)$ denote the shortest paths forming the outer boundary, let $E_{\text{in}}(F)$ denote the remaining shortest paths, and let $E(F) := E_{\text{out}}(F) \cup E_{\text{in}}(F)$. Let $S_{\text{out}}(F)$ denote the sites from S on the outer boundary of F , let $S_{\text{in}}(F)$ denote the remaining sites, and let $S(F) = S_{\text{out}}(F) \cup S_{\text{in}}(F)$. If $S_{\text{in}}(F) = \emptyset$ and $|S_{\text{out}}(F)| = 3$ then F is already a triangle and we are done. Otherwise we will argue that there exist two sites $s_i, s_j \in S(F)$ such that

- the shortest path $\pi(s_i, s_j)$ lies inside F
- $\pi(s_i, s_j)$ is not yet present in $E(F)$ and
- $\pi(s_i, s_j)$ does not cross any shortest path in $E(F)$

These properties imply that we can add $\pi(s_i, s_j)$ to $E(F)$. This either splits F into two faces, or it adds a path to $E_{\text{in}}(F)$. In both cases we can continue recursively on the resulting face(s), until every face is a triangle. It remains to argue the existence of the pair s_i, s_j . We consider two cases:

Case I: $S_{\text{in}}(F) = \emptyset$ and all sites from $S_{\text{out}}(F)$ are convex vertices of F .

Then take two sites $s_i, s_j \in S(F)$ that are not already connected by a shortest path in $E_{\text{out}}(F)$. Such a pair exists because $|S_{\text{out}}(F)| > 3$. Consider the shortest path π from s_i to s_j that is restricted to lie inside F . All interior vertices of π must bend around reflex vertices of F . Since all vertices from $S_{\text{out}}(F)$ are convex, these reflex vertices are not sites but reflex vertices of P . By Lemma 1, π must also be the shortest path in P between p and q and so $\pi \in E(S)$. Since π stays inside F , it does not cross any other shortest path.

Case II: $S_{\text{in}}(F) \neq \emptyset$ or $S_{\text{out}}(F)$ contains a site that is a reflex vertex of F .

We start by identifying a “reflex” site, from which we will then be able to add a path.

► **Claim.** There is a site $s_i \in S(F)$ with the following property: there is a line ℓ through s_i such that all paths from $E(F)$ that have s_i as an endpoint lie to the same side of ℓ , locally near s_i . (In other words, the edges of these paths that have s_i as an endpoint all lie to the same side of ℓ).

■ **Figure 4** (i) The relative convex hull of a set of points. (ii) An sp-triangulation. (iii) The corresponding maximal triangulation. Note: paths are shown slightly displaced where they overlap.

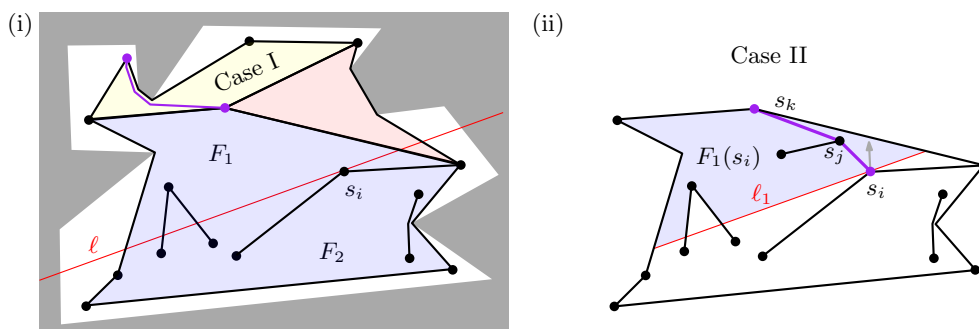

Figure 5 Illustrations for the proof of Lemma 4. (i) An example with three faces inside $\text{RCH}(S)$. The red face is already a triangle. The yellow face falls into Case 1 and can be triangulated by adding the purple path. The blue face falls into Case 2 of the proof. (ii) The ray from s_i hits a shortest path that has s_k as an endpoint in $F_1(s_i)$. The purple path is the shortest path from s_i to s_k inside $F_1(s_i)$, and therefore $\pi(s_i, s_j)$ is added to the triangulation.

Proof. First suppose that $S_{\text{in}}(F) = \emptyset$. Then $S_{\text{out}}(F)$ contains a site s_i that is a reflex vertex of F and, hence, has the required property. (Note that, except for the two paths on the outer boundary of F meeting at s_i , the site s_i has no other incident paths, since $S_{\text{in}}(F) = \emptyset$.)

Now suppose $S_{\text{in}}(F) \neq \emptyset$. Consider a connected component C in $E_{\text{in}}(F)$. (Or more precisely, a connected component of the set $\bigcup E_{\text{in}}(F) \subset \mathbb{R}^2$.) Then C may contain at most one site from $S_{\text{out}}(F)$ – indeed, if it would contain two such sites then it would split F and some paths in the component would be part of the outer boundary of F , a contradiction. Now see $E_{\text{out}}(F)$ as a simple polygon and consider the relative convex hull of $C \cap S(F)$ within this simple polygon. Then choose s_i to be any vertex of $\text{RCH}(C \cap (S(F)))$ that is a site from $S_{\text{in}}(F)$. Then there is a line ℓ through s_i such that the path edges incident to s_i lie to the same side of ℓ , namely a line ℓ that is (locally) tangent to $\text{RCH}(C \cap S(F))$. \triangleleft

Consider the site s_i and the line ℓ provided by the above claim. Let $\ell_1 \subset \ell$ denote the maximal subsegment of ℓ containing s_i and lying inside F . The segment ℓ_1 splits F in two pieces, F_1 and F_2 . Let F_2 denote the piece containing the edges incident to s_i and let F_1 denote the other piece. We claim that F_2 must contain all sites s_k already connected to s_i , that is, all sites $s_k \in S(F)$ such that $\pi(s_i, s_k) \in E(F)$. Indeed, if some neighbor s_k of s_i was in F_1 then $\pi(s_i, s_k)$ would intersect ℓ_1 at some point s and therefore we would be able to shorten $\pi(s_i, s_k)$ by using the straight segment $s_i s$ as a shortcut. Now, ℓ_1 together with the paths in $E_{\text{in}}(F)$ induces a subdivision of F into planar regions. Denote by $F_1(s_i)$ the region in this subdivision within F_1 that contains s_i on its boundary; see Fig. 5(ii), where this region is shown in purple.

Now shoot a ray from s_i into $F_1(s_i)$, and let π denote the first path from $E(F)$ hit by this ray. At least one of the two endpoints of π must be in $F_1(s_i)$, otherwise π would intersect ℓ_1 twice, contradicting that π is a shortest path. Let s_k be this endpoint. Consider the shortest path γ from s_i to s_k , restricted to lie in $F_1(s_i)$. Then γ has to bend around vertices of $F_1(s_i)$, which are either reflex vertices of P or sites in $S(F)$. Let s_j be the first vertex on γ that is a site; such a vertex exists, since the endpoint s_k of γ is a site. Then all interior vertices of $\gamma[s_i, s_j]$, the subpath of γ from s_i to s_j , bend around reflex vertices of P . By Lemma 1, the subpath $\gamma[s_i, s_j]$ is a shortest path in P . Hence, we have found a shortest $\pi(s_i, s_j)$ that we can add to $E(F)$. \blacktriangleleft

Note that $\mathcal{T}_{\text{sp}}(S)$, when viewed as a graph, may not be maximally planar. The reason is that the face outside $\text{RCH}(S)$ is not necessarily a triangle. However, we can easily turn $\mathcal{T}_{\text{sp}}(S)$ into a maximally planar graph, as follows. Let s_1, \dots, s_r be the sites on $\partial\text{RCH}(S)$, in the same order as they are encountered while following $\partial\text{RCH}(S)$ clockwise. For every pair (s_1, s_i) with $3 \leq i \leq r - 1$, we add the path from s_1 to s_i that follows ∂RCH clockwise, as an edge to our triangulation. We denote this set of “outside edges” by $\overline{E}(S)$; see the purple paths in Figure 4(iii) for an example. By adding these edges to $\mathcal{T}_{\text{sp}}(S)$, we triangulate the outer face and thus obtain a maximally planar graph, which we denote by $\mathcal{G}_{\text{sp}}(S)$.

Now that we have established the existence of a suitable triangulation, we can explain how to implement the various steps in Algorithm 1.

Preprocessing. As a preprocessing step we compute the shortest path $\pi(s_i, s_j)$ for each pair $s_i, s_j \in S$, which also gives us all pairwise distances. We then check for each pair of shortest paths whether they cross or not, so that later on in the algorithm we have this information readily available. Clearly, the preprocessing can be done in $\text{poly}(n, m)$ time. As it turns out, Algorithm 1 will not need the actual shortest paths or other geometric information – knowing pairwise distances (for solving the constant-size subproblems at the base of the recursion) and whether or not pairs of shortest paths cross (for larger subproblems) is all that is needed.

Generating all candidate separators. Miller’s theorem [25] guarantees that $\mathcal{G}_{\text{sp}}(S)$ has a simple-cycle separator of at most $2\sqrt{2n}$ nodes. The edges in this separator are edges in $\mathcal{G}_{\text{sp}}(S)$, which correspond to paths in $E(S) \cup \overline{E}(S)$. Note that for every pair of sites, there are at most two different paths in $E(S) \cup \overline{E}(S)$. We now generate our collection of candidate separators as follows:

- 1: **for** every circular sequence $s_1, s_2, \dots, s_t, s_1$ of at most $2\sqrt{2n}$ sites from S **do**
- 2: **for** every choice of paths from $E(S) \cup \overline{E}(S)$ to connect consecutive sites **do**
- 3: Check if the paths used in the resulting cycle \mathcal{C} are pairwise non-crossing and if the number of sites inside and outside \mathcal{C} is at most $2n/3$. If so, add \mathcal{C} to the collection of cycles.

Clearly, the collection of generated separators is guaranteed to contain the separator that would result from applying Miller’s theorem to $\mathcal{G}_{\text{sp}}(S)$. The total number of candidate separators is $n^{O(\sqrt{n})}$ (for choosing the circular sequence) times $2^{O(\sqrt{n})}$ (for choosing the paths to connect consecutive sites), so $n^{O(\sqrt{n})} \cdot 2^{O(\sqrt{n})} = 2^{O(\sqrt{n} \log n)}$ in total.

Note that for each candidate separator \mathcal{C} we need to check if it is simple, that is, if its paths are pairwise non-crossing. With the pre-computed information, this can be done in $O(|\mathcal{C}|^2) = O(n)$ time. Note that the paths from $\overline{E}(S)$ do not cross any other path by definition, so these paths need not be checked.

If \mathcal{C} is simple, we need to determine which sites are inside \mathcal{C} and which are outside \mathcal{C} . In fact, what is “inside” and what is “outside” is not important, we just need to partition the set of sites (that are not on the separator) into two subsets: the sites on one side of \mathcal{C} and the sites on the other side of \mathcal{C} . We can do that as follows.

Take any site s_i that is not on the separator \mathcal{C} , and consider another site s_j (that is not on \mathcal{C} either). We can decide if s_j is on the same side of \mathcal{C} as s_i by counting how often $\pi(s_i, s_j)$ crosses \mathcal{C} : site s_j is on the same side if and only if $\pi(s_i, s_j)$ crosses \mathcal{C} an even number of times. Because we determined in the preprocessing step for each pair of shortest paths whether they cross or not, we can do this counting in $O(\sqrt{n})$ time in total. The separator may also use paths from $\overline{E}(S)$ and these paths depend on the subproblem being solved. Hence, they have

not been considered in the preprocessing step. However, such paths cannot cross $\pi(s_i, s_j)$ by definition, so they can be ignored. This also means that we do not have to compute the paths in $\overline{E}(S)$ explicitly. We conclude that, for each candidate separator \mathcal{C} , we can partition the sites not on \mathcal{C} into subsets on either side of the separator in $O(n\sqrt{n})$ time.

Hence, in total we spend $O(n\sqrt{n}) \cdot 2^{O(\sqrt{n} \log n)} = 2^{O(\sqrt{n} \log n)}$ time to generate all possible separators and their corresponding partitions.

► **Lemma 5.** *The number of separators generated in Step 4 of Algorithm 1 is $2^{O(\sqrt{n} \log n)}$, and they can be generated in the same amount of time. This includes determining for each candidate \mathcal{C} a partitioning of $S \setminus \mathcal{C}$ into sites on one side of \mathcal{C} and on the other side of \mathcal{C} .*

Generating the subproblems for a given separator \mathcal{C} . This can be done as in the algorithms of Hwang *et al.* [17] and De Berg *et al.* [11]; see Fig. 3. For completeness we give a sketch.

Consider the set $\mathcal{C} \setminus B$, which contains the sites from \mathcal{C} that are not boundary sites. The path $\xi_{ij} \in \mathcal{P}_{\text{opt}}$ corresponding to a pair $(s_i, s_j) \in M$ may or may not visit sites of $\mathcal{C} \setminus B$. To generate our subproblems, we need to guess for every pair $(s_i, s_j) \in M$, which points of $\mathcal{C} \setminus B$ are visited by ξ_{ij} and in which order. (A site from $\mathcal{C} \setminus B$ should be used by at most one path ξ_{ij} .) Given such a guess, we can generate the corresponding subproblems, one for each side, as follows. Let $s_{k_1}, s_{k_2}, \dots, s_{k_t}$ be the ordered sequence of sites from $\mathcal{C} \setminus B$ that is our guess for where ξ_{ij} crosses \mathcal{C} . Define $\xi'_{ij} := s_i, s_{k_1}, s_{k_2}, \dots, s_{k_t}, s_j$. Then every pair of consecutive sites of ξ'_{ij} becomes a pair in the matching of one of the subproblems; which subproblem depends on which side we have guessed the corresponding part of ξ_{ij} to be on. After doing this for all ξ_{ij} corresponding to a pair in M , we have the matchings M_1 and M_2 of our subproblems. The sets of sites S_1 and S_2 for the recursive calls are generated as follows. First we add the sites inside \mathcal{C} to S_1 and the sites outside \mathcal{C} to S_2 . Then we add the sites of M_1 to S_1 , and the sites of M_2 to S_2 . Note that causes some sites to appear in both subproblems. Finally, the remaining sites on \mathcal{C} are all added to S_1 . In other words, we consider all points on \mathcal{C} to be on the same side of \mathcal{C} . See Fig. 3 for an example.

The total number of subproblems generated for a given separator \mathcal{C} is $n^{O(\sqrt{n})} = 2^{O(\sqrt{n} \log n)}$, since we have to guess for each separator node by which (if any) of the paths it is used and then choose an ordering for the crossings.

A proof of correctness. Next we prove that this gives an optimal solution.

► **Lemma 6.** *Let s_i be such that there is an optimal solution T_{opt} with non-crossing shortest paths that uses the path $\pi(s_1, s_i)$. Then $\text{Triangulation-approach}(S, B, M)$ with $B = \{s_1, s_i\}$ computes an optimal solution for TSP IN A SIMPLE POLYGON. Moreover, all other calls report valid solutions.*

Proof. We first argue that each reported solution is valid, by showing that any recursive call gives a valid solution of EUCLIDEAN PATH COVER. This is trivially true for the base case in the algorithm. The way in which the subproblems are generated and their solutions are combined, ensures that when the solutions to the subproblems are valid (which we can assume by induction) then the combined solution is valid. (Note: the generation of the subproblems and how they are combined is based on the original triangulation approach by Hwang *et al.* [17], so this part in fact follows from the correctness of their algorithm.)

Now consider a call $\text{Triangulation-approach}(S, B, M)$. Let $\mathcal{P}_{\text{opt}}(S, B, M)$ be an optimal solution to the subproblem. We will prove that if the parameters S, B, M are consistent with T_{opt} – that is, $\mathcal{P}_{\text{opt}}(S, B, M)$ is a subset of the global T_{opt} – then the algorithm computes an optimal solution to the subproblem. Since the initial call with $B = \{s_1, s_i\}$ is consistent

with T_{opt} by definition, this will prove the lemma. Note that if $\mathcal{P}_{\text{opt}}(S, B, M) \subset T_{\text{opt}}$, then $\mathcal{P}_{\text{opt}}(S, B, M)$ consists of non-crossing paths. Lemma 4 then implies that there exists an sp-triangulation $\mathcal{T}_{\text{sp}}(S)$ that includes the edges from $\mathcal{P}_{\text{opt}}(S, B, M)$. This can be extended to a maximally planar graph $\mathcal{G}_{\text{sp}}(S)$, which has separator of size at most $2\sqrt{2n}$. As argued earlier, this separator will be one of the generated candidate separators, and the way in which $\mathcal{P}_{\text{opt}}(S, B, M)$ crosses it will be corresponds to one of the generated subproblems. The parameters $S_{\text{in}}, B_{\text{in}}, M_{\text{in}}$ and $S_{\text{out}}, B_{\text{out}}, M_{\text{out}}$ of these subproblems are thus consistent with T_{opt} , and so we can assume by induction that they are solved optimally, thus leading to an optimal solution for the call to *Triangulation-approach*(S, B, M). ◀

Putting it all together. Lemma 6 gives the correctness of our algorithm so it remains to analyze the running time. The preprocessing takes $\text{poly}(n, m)$ time. The running time of *Triangulation-approach* satisfies the recurrence $T(n) = 2^{O(\sqrt{n} \log n)} + 2^{O(\sqrt{n} \log n)} \cdot T(\frac{2n}{3} + O(\sqrt{n}))$, which solves to $T(n) = 2^{O(\sqrt{n} \log n)}$. This leads to our final theorem.

► **Theorem 7.** TSP IN A SIMPLE POLYGON for a set S of n sites in a polygon P with m edges can be solved in $\text{poly}(n, m) + 2^{O(\sqrt{n} \log n)}$ time.

4 Conclusion

We introduced TSP IN A SIMPLE POLYGON, a natural variant of TSP that seems not to have been studied at all so far. The problem can be solved in $\text{poly}(n, m) + 2^{O(\sqrt{n} \log n)}$ time using a complicated algorithm of Marx, Pilipczuk, and Pilipczuk [24] as a subroutine. We presented a much simpler algorithm with the same running time. Our work raises several questions:

- It was recently shown that EUCLIDEAN TSP in \mathbb{R}^2 can be solved in $2^{O(\sqrt{n})}$ time [11]. Can we also get rid of the log-factor in the exponent for TSP IN A SIMPLE POLYGON?
- Can our approach be extended to polygons with holes? A major obstacle is that in this case a triangulation using shortest paths not always exists. We have been able to generalize our approach, by working with a suitable *collection* of paths between every pair of sites, but this significantly complicates matters, thus defeating the purpose.
- Can ideas from our approach be used to get a simplified solution to the more general SUBSET TSP problem for planar graphs?
- What about TSP WITH OBSTACLES in higher dimensions? Here neither our approach nor the approach by Marx, Pilipczuk, and Pilipczuk can be used.

Abstract

SUBSET-SUM is an NP-complete problem where one must decide if a multiset of n integers contains a subset whose elements sum to a target value m . The best known classical and quantum algorithms run in time $\tilde{O}(2^{n/2})$ and $\tilde{O}(2^{n/3})$, respectively, based on the well-known meet-in-the-middle technique. Here we introduce a novel classical dynamic-programming-based data structure with applications to SUBSET-SUM and a number of variants, including EQUAL-SUMS (where one seeks two disjoint subsets with the same sum), 2-SUBSET-SUM (a relaxed version of SUBSET-SUM where each item in the input set can be used twice in the summation), and SHIFTED-SUMS, a generalization of both of these variants, where one seeks two disjoint subsets whose sums differ by some specified value.

Given any modulus p , our data structure can be constructed in time $O(np)$, after which queries can be made in time $O(n)$ to the lists of subsets summing to any value modulo p . We use this data structure in combination with variable-time amplitude amplification and a new quantum pair finding algorithm, extending the quantum claw finding algorithm to the multiple solutions case, to give an $O(2^{0.504n})$ quantum algorithm for SHIFTED-SUMS. This provides a notable improvement on the best known $O(2^{0.773n})$ classical running time established by Mucha et al. [27]. We also study PIGEONHOLE EQUAL-SUMS, a variant of EQUAL-SUMS where the existence of a solution is guaranteed by the pigeonhole principle. For this problem we give faster classical and quantum algorithms with running time $\tilde{O}(2^{n/2})$ and $\tilde{O}(2^{2n/5})$, respectively.

1 Introduction

SUBSET-SUM is the problem of deciding whether a given multiset of n integers has a subset whose elements sum to a target integer m .

► **Problem 1** (SUBSET-SUM). Given a multiset $\{a_1, \dots, a_n\}$ of positive integers and a target integer m , find a subset $S \subseteq [n]$ such that $\sum_{i \in S} a_i = m$.

It is often useful to express SUBSET-SUM using inner product notation. We set $\bar{a} = (a_1, \dots, a_n) \in \mathbb{N}^n$, where the elements are taken in arbitrary order, and the task is to find $\bar{e} \in \{0, 1\}^n$ such that $\bar{a} \cdot \bar{e} = \sum_{i=1}^n a_i e_i = m$. The problem is famously NP-complete, and featured on Karp's list of 21 NP-complete problems [23] in 1972 (under the name of knapsack). It can be solved classically in time $\tilde{O}(2^{n/2})$ via the *meet-in-the-middle* technique [19]. Whether this problem can be solved in time $\tilde{O}(2^{(1/2-\delta)n})$, for some $\delta > 0$, is an important open question, but we know that the Exponential Time Hypothesis implies that SUBSET-SUM cannot be computed in time $m^{o(1)} 2^{o(n)}$ [13, 21]. SUBSET-SUM can also be solved in pseudopolynomial time, for instance in $O(nm)$ by a textbook dynamic programming approach, which was improved to a highly elegant $\tilde{O}(n+m)$ randomized algorithm by Bringmann [12]. However, assuming the Strong Exponential Time Hypothesis (SETH), it can be shown that for all $\epsilon > 0$, there exists $\delta > 0$, such that SUBSET-SUM cannot be computed in time $O(m^{1-\epsilon} 2^{n\delta})$ [2]. On a quantum computer, meet-in-the-middle can be combined with Quantum Search to solve SUBSET-SUM in time $\tilde{O}(2^{n/3})$.

1.1 Some Variants of Subset-Sum

SUBSET-SUM has several close relatives we will be concerned with in this paper.

► **Problem 2** (EQUAL-SUMS [32]). Given a set $\{a_1, \dots, a_n\}$ of positive integers, find two distinct subsets $S_1, S_2 \subseteq [n]$ such that $\sum_{i \in S_1} a_i = \sum_{i \in S_2} a_i$. In inner product notation we are looking for a nonzero vector $\bar{e} \in \{-1, 0, 1\}^n$ such that $\bar{a} \cdot \bar{e} = 0$.

The folklore classical algorithm [31] for EQUAL-SUMS runs in time $\tilde{O}(3^{n/2}) \leq O(2^{0.793n})$, and is also based on a meet-in-the-middle approach. In the classical case we arbitrarily partition the input into two sets of the same size, giving rise to vectors $\bar{a}_1, \bar{a}_2 \in \mathbb{N}^{n/2}$. Then we compute and sort the possible $3^{n/2}$ values $\bar{a}_1 \cdot \bar{e}$, for $\bar{e} \in \{-1, 0, 1\}^{n/2}$. Finally we compute the possible $3^{n/2}$ values of the form $\bar{a}_2 \cdot \bar{e}$ and, for each value, check via binary search if it has a collision (i.e. an item of the same value) in the first set of values. In the quantum case we use a different balancing, dividing the input into a set of size $n/3$ and a set of size $2n/3$, and then use Quantum Search over the larger set to find a collision. This folklore quantum algorithm has running time $\tilde{O}(3^{n/3}) \leq O(2^{0.529n})$. The classical running time of EQUAL-SUMS was reduced in a recent work by Mucha et al. [27] to $O(2^{0.773n})$, and it is an open problem whether this can be further improved.

A natural generalization of SUBSET-SUM is to allow each item in the input set to be used more than once in the summation, where the maximum number of times each item can be used is specified as part of the input to the problem. This is the analog of bounded knapsack, a well studied problem in the literature (see for example [24]). In particular, we will study the case when every item can be used at most twice.

► **Problem 3** (2-SUBSET-SUM). Given a multiset $\{a_1, \dots, a_n\}$ of positive integers and a target integer $0 < m < 2 \sum_{i=1}^n a_i$, find a vector $\bar{e} \in \{0, 1, 2\}^n$ such that $\bar{a} \cdot \bar{e} = m$.

There is a natural variant of SUBSET-SUM that generalizes both EQUAL-SUMS and 2-SUBSET-SUM. We call this variant SHIFTED-SUMS, whose investigation is the main subject of this paper.

► **Problem 4** (SHIFTED-SUMS). Given a multiset $\{a_1, \dots, a_n\}$ of positive integers and a shift $0 \leq s < \sum_{i=1}^n a_i$, find two distinct subsets $S_1, S_2 \subseteq [n]$ such that $\sum_{i \in S_1} a_i = s + \sum_{i \in S_2} a_i$.

The condition $S_1 \neq S_2$ is necessary in the case $s = 0$ to exclude the trivial solutions $S_1 = S_2$. The problem EQUAL-SUMS is a special case of SHIFTED-SUMS in this case, and it is easy to show (see the full version of the paper [3]) that 2-SUBSET-SUM can also be reduced to SHIFTED-SUMS without increasing the size of the input. This means that any algorithm for SHIFTED-SUMS automatically gives rise to an algorithm of the same complexity for EQUAL-SUMS and 2-SUBSET-SUM, and therefore we focus on constructing a quantum algorithm for SHIFTED-SUMS.

We additionally study the following variant of EQUAL-SUMS where, by the pigeonhole principle, a solution is guaranteed to exist. This search problem is total in the sense that its decision version is trivial because the answer is always “yes”. Such problems belong to the complexity class TFNP [26] consisting of NP-search problems with total relations. Problems in TFNP cannot be NP-hard unless NP equals co-NP. More precisely, the following problem belongs to the Polynomial Pigeonhole Principle complexity class PPP, defined by Papadimitriou [28], where the totality of the problem is syntactically guaranteed by the pigeonhole principle.

► **Problem 5** (PIGEONHOLE EQUAL-SUMS). Given a set $\{a_1, \dots, a_n\}$ of positive integers such that $\sum_{i=1}^n a_i < 2^n - 1$, find two distinct subsets $S_1, S_2 \subseteq [n]$ such that $\sum_{i \in S_1} a_i = \sum_{i \in S_2} a_i$.

There are 2^n subsets $S \subseteq [n]$. Since they all verify $0 \leq \sum_{i \in S} a_i \leq 2^n - 2$ there must exist two distinct subsets S_1, S_2 that sum to the same value, according to the pigeonhole principle.

1.2 Our Contributions and Techniques

We give new classical and quantum algorithms for SUBSET-SUM and several closely related problems. Our main contribution is a quantum algorithm for SHIFTED-SUMS (and for its special cases of EQUAL-SUMS and 2-SUBSET-SUM) that improves on the currently best known $O(2^{0.773n})$ classical algorithm [27] and on the folklore $O(2^{0.529n})$ quantum meet-in-the-middle algorithm. We also initiate the study of the PIGEONHOLE EQUAL-SUMS problem in the classical and quantum settings, where we obtain better complexities than what is known for the general EQUAL-SUMS problem.

► **Theorem** (Theorem 18 (Restated)). *There is a quantum algorithm for SHIFTED-SUMS that runs in time $O(2^{0.504n})$.*

► **Theorem** (Theorems 25, 26 (Restated)). *There are classical and quantum algorithms for PIGEONHOLE EQUAL-SUMS that run in time $\tilde{O}(2^{n/2})$ and $\tilde{O}(2^{2n/5})$, respectively.*

In the full version of the paper [3], we give new $\tilde{O}(2^{n/2})$ and $\tilde{O}(2^{n/3})$ classical and quantum algorithms for SUBSET-SUM, not based on the seminal meet-in-the-middle approach of Horowitz and Sahni [19]. We also describe partial results and potential directions for future work on modular versions of the problems studied in this paper.

At a high level, all of our algorithms use a *representation technique* approach. While this technique was originally designed to solve SUBSET-SUM when the instances are drawn from some specific distribution [20], here we follow the path of Mucha et al. [27] and use it in a

worst case analysis. Among our new algorithms, the quantization of this technique for the SHIFTED-SUMS problem is the most challenging and requires using several quantum tools. We will therefore explain first, via this algorithm, the difficulties we had to address and the methods we used to tackle them.

Shifted-Sums. The representation technique approach for SHIFTED-SUMS consists first of selecting a random prime $p \in \{2^{bn}, \dots, 2^{bn+1}\}$, where $b \in (0, 1)$ is some appropriate constant, and a random integer $k \in \{0, \dots, p-1\}$. Then we consider the *random bin* $T_{p,k}$, defined as $T_{p,k} = \{S \subseteq \{1, \dots, n\} : \sum_{i \in S} a_i \equiv k \pmod{p}\}$, and we search that bin and $T_{p,(k-s) \bmod p}$ for a colliding solution (i.e. $(S_1, S_2) \in T_{p,k} \times T_{p,(k-s) \bmod p}$ such that $\sum_{i \in S_1} a_i = s + \sum_{i \in S_2} a_i$). The choice of the bin size (which, on average, is roughly $2^{(1-b)n}$) should balance two opposing requirements: the bins should be sufficiently large to contain a solution and also sufficiently small to keep the cost of collision search low.

To satisfy the above two requirements, our algorithm uses the concept of a *maximum solution*. This is the maximum of $|S_1| + |S_2|$, when S_1, S_2 are disjoint and form a solution. Let this maximum solution size be ℓn , for some $\ell \in (0, 1)$. The algorithm consists of two different procedures, designed to handle different maximum solution sizes. For ℓ close to 0 or close to 1, the quantization of the meet-in-the-middle method adapted to solutions of size ℓn is used because it performs better. In this case, the quantization does not present any particular difficulties: it is a straightforward application of Quantum Search with the appropriate balancing. We therefore focus the discussion on the representation technique procedure used for values of ℓ away from 0 or 1. When S_1, S_2 form a maximum solution of size ℓn then, for every $X \subseteq \overline{S_1 \cup S_2}$, the pairs $S_1 \cup X, S_2 \cup X$ also form a solution, and all these solutions have different values (see Lemma 20). This makes it possible to bound from below, not only the number of solutions, but also the number of *solution values* by $2^{(1-\ell)n}$, which makes the use of the representation technique successful.

The most immediate way to quantize the procedure is to replace classical collision finding by the quantum element distinctness algorithm of Ambainis [4]. However, in a straightforward application of this algorithm we face a difficulty. For concreteness, we explain this when $\ell = 3/5$. In that case, by the above, the total number of solutions with different values is at least $2^{2n/5}$. This is handy for applying quantum element distinctness: we can select a random prime $p \in \{2^{2n/5}, \dots, 2^{2n/5+1}\}$ and expect to have a solution in the random bin $T_{p,k}$ with reasonable probability. The expected size $|T_{p,k}|$ of the bin is about $2^{3n/5}$, and therefore the running time of Ambainis' algorithm should be of the order of $|T_{p,k}|^{2/3}$ which is also about $2^{2n/5}$. However, the quantum element distinctness algorithm requires us to perform queries to $T_{p,k}$. That is, for some indexing $T_{p,k} = \{S_1, \dots, S_{|T_{p,k}|}\}$ of the elements of $T_{p,k}$, we need to implement the oracle $O_{T_{p,k}}|I\rangle|0\rangle = |I\rangle|S_I\rangle$, where $1 \leq I \leq |T_{p,k}|$. In other words, given $1 \leq I \leq |T_{p,k}|$, we have to be able to find the I th element in $T_{p,k}$ (for some ordering of that set). In the usual description of the element distinctness algorithm there is a simple way to do that (for example, the set over which the algorithm is run is just a set of consecutive integers). However, finding a simple bijection among the first $|T_{p,k}|$ integers and $T_{p,k}$ is not a trivial task. Unlike in the classical case, explicitly enumerating $T_{p,k}$ is not an option because this would take too long, requiring about $2^{3n/5}$ time steps. Instead, we use dynamic programming to compute the table $t_p[i, j] = |\{S \subseteq \{1, \dots, i\} : \sum_{s \in S} a_s \equiv j \pmod{p}\}|$. Computing the cardinality of the bins is cheaper than computing their contents, and can be done in time $O(np) = \tilde{O}(2^{2n/5})$. Crucially, once the table is constructed, one can deduce the paths through it that led to $t_p[n, k] = |T_{p,k}|$, in order to find each element of $T_{p,k}$ in time $O(n)$. More precisely, we define a strict total order \prec over $\mathcal{P}([n])$ and prove:

► **Theorem** (Theorem 11 (Restated)). *Let $T_{p,k}$ be enumerated as $T_{p,k} = \{S_1, \dots, S_{|T_{p,k}|}\}$ where $S_1 \prec \dots \prec S_{|T_{p,k}|}$. Given any integer $I \in \{1, \dots, |T_{p,k}|\}$ and random access to the elements of the table t_p , the set S_I can be computed in time $O(n)$.*

This novel data structure will be used in our algorithms for SUBSET-SUM (see the full version [3]), SHIFTED-SUMS and PIGEONHOLE EQUAL-SUMS. We now describe the additional quantum tools we use for SHIFTED-SUMS. The algorithm randomly chooses a bin size of about $2^{(1-b)n}$ where b is defined differently depending on whether ℓ is above or below $3/5$, as different tools are required in these two regions. When $\ell \leq 3/5$, with high probability a random bin contains multiple solutions from which we can profit. To that end, we construct a quantum algorithm for finding a pair marked by a binary relation $\mathcal{R}(x, y) := \mathbb{1}_{f(x)=g(y)}$ that tests if two values $f(x)$ and $g(y)$ are equal. Our algorithm generalizes the element distinctness [4] and claw finding [30] algorithms to the case of multiple marked pairs. Using an appropriate variant of the birthday paradox (see Lemma 5) we prove:

► **Theorem** (Theorem 6 (QUANTUM PAIR FINDING - Restated)). *Consider two sets of $N \leq M$ elements, respectively, and an evaluation function on each set. Suppose that there are K disjoint pairs in the product of the two sets such that in each pair the elements evaluate to the same value. There is a quantum algorithm that finds such a pair in time $\tilde{O}((NM/K)^{1/3})$ if $N \leq M \leq KN^2$ and $\tilde{O}((M/K)^{1/2})$ if $M \geq KN^2$.*

The best complexity when $\ell \leq 3/5$ is then obtained by choosing the bin size parameter b as a function of ℓ , which balances the cost of the construction of the dynamic programming table and the Quantum Pair Finding. When $\ell > 3/5$, choosing a bin size $2^{(1-b)n}$, for $b \leq 1 - \ell$, guarantees that a random bin contains at least one solution with high probability. However, a better running time at first seems to be achievable by the following argument: Choose $b > 1 - \ell$, for which there is exponentially small probability that a random bin contains a solution, and use amplitude amplification to boost the success probability. Balancing again the dynamic programming and Quantum Pair Finding costs would then give an optimal bin size of $2^{3n/5}$, independent of ℓ . However, this argument contains a subtlety. Standard amplitude amplification requires that the random bins $T_{p,k}$ simultaneously satisfy two conditions: beside containing a solution, they should also have sizes close to the expected size of about $2^{(1-b)n}$. But there is no guarantee that these two events coincide, and a priori it could be that the exponentially small fraction of $T_{p,k}$ containing a solution also happen to have sizes that far exceed the expectation. Fortunately, by carefully bounding the expectation of the product of bin sizes, we can use the Variable-Time Amplitude Amplification algorithm of Ambainis [5], and achieve the same running time as given by the above argument. We believe that this a nice and natural application of this method. The running time of our algorithm for SHIFTED-SUMS, as a function of ℓ , is shown in Fig. 1.

Pigeonhole Equal-Sums. This problem can be solved by any (classical or quantum) algorithm which solves the general EQUAL-SUMS (or SHIFTED-SUMS) problem. However, one can make use of the explicit promise of $a_1 + \dots + a_n < 2^n - 1$ to design faster algorithms than provided for by the general case when $\ell > 3/5$. Indeed, by the pigeonhole principle, for any value of p , if a bin $T_{p,k}$ has size larger than $2^n/p$ then it must contain a solution (see Lemma 24). Moreover, there must exist at least one such oversized bin. The array t_p can now be constructed both for *locating the index k* of one oversized bin and searching for a solution in it. We thus obtain a classical algorithm running in time $\tilde{O}(p + 2^n/p)$, and a quantum algorithm running in time $\tilde{O}(p + (2^n/p)^{2/3})$. These two quantities are minimized by *deterministically* choosing $p = 2^{n/2}$ and $p = 2^{2n/5}$ respectively (see Section 5).

■ **Figure 1** Running time exponent $\gamma(\ell)$ of the quantum SHIFTED-SUMS algorithm, as a function of the maximum solution ratio ℓ (see Theorem 18). The maximum value of $\gamma(\ell)$ is ≈ 0.504 which occurs at $\ell = \ell_2 \approx 0.809$. For reference, the curve $(h(\ell) + \ell)/3$ corresponding to Theorem 23 is plotted for all values of ℓ , as is the value of 0.529 corresponding to the exponent of the folklore (quantized) meet-in-the-middle algorithm, as applied to SHIFTED-SUMS.

1.3 Related Works

The closest work to our contribution is the paper of Mucha et al. [27] solving EQUAL-SUMS classically in time $O(2^{0.773n})$. Their algorithm and ours use the same two basic procedures, based respectively on the meet-in-the-middle method and the representation technique. Let us point out some of the differences. Unlike our algorithm which is based around the concept of the size of a maximum solution, the classical algorithm is analyzed as function of a *minimum size* solution, defined as $|S_1| + |S_2|$, where this sum is minimized over all solutions. The use the classical algorithm makes from a minimum solution S_1, S_2 of size ℓn is that when $\ell > 1/2$ the number of *solution values* can be bounded from below by $2^{(1-\ell)n}$. However, this does not hold for 2-SUBSET-SUM when ℓn is the size of a minimum solution, but *is* valid for both EQUAL-SUMS and 2-SUBSET-SUM when it is the size of a maximum solution. Another difference with [27] is that their classical representation technique algorithm always samples p from the same set $\{2^{(1-\ell)n}, \dots, 2^{(1-\ell)n+1}\}$, while we randomly choose $p \in \{2^{bn}, \dots, 2^{bn+1}\}$ where b is defined differently depending on in which of two distinct regions ℓ lies. This makes it possible to use different quantum techniques in these two regions.

The representation technique was designed by Howgrave-Graham and Joux [20] to solve random SUBSET-SUM instances under some hypotheses (heuristics) about how such instances behave during the run of the algorithm. The idea is to decompose a single solution to the initial problem into many distinct decompositions of a sum of half-solutions. To compensate for this blow-up, an additional linear constraint is added to select approximately one of these decompositions. Under some rather strong assumptions, which are satisfied for a large fraction of randomly chosen instances, [20] can solve SUBSET-SUM instances in time $O(2^{0.337n})$. Since then, several variants of this classical method have been proposed [8, 15, 10, 14], while others have investigated quantum algorithms based on the representation technique. Bernstein et al. [9] improved on [20] using quantum walks, and their algorithm (again under some hypotheses) runs in time $O(2^{0.242n})$. Further quantum improvements were made in this

context by [18] and [10]. However, we emphasize that the algorithms in all these papers work for random inputs generated from some distributions. The paper [27] gave the first classical algorithm based on the representation technique that works for worst case inputs and with proven bounds. To our knowledge, for worst case inputs with provable guarantees, the first quantum algorithm based on the representation technique is given in our work.

Dynamic programming is notoriously hard to quantize, with a key obstacle being the intrinsically sequential way in which the solution to a large problem is constructed from the solutions to smaller subproblems. Certain basic dynamic programming algorithms can be trivially accelerated by Quantum Search or Minimum Finding (see, e.g. [1]) but beyond that few other quantum improvements are known. One notable exception is the work of Ambainis et al. [6] who gave faster quantum algorithms for several NP-hard problems for which the best classical algorithms use dynamic programming. Their algorithms precompute solutions for smaller instances via dynamic programming and then use non-trivial Quantum Search recursively on the rest of the problem. In our work, the dynamic programming subroutine that we use is classical (although for SHIFTED-SUMS it is performed in superposition) and the sequential nature of the process is therefore not an issue. Rather than using quantum computing to accelerate classical dynamic programming, we instead use dynamic programming to enable fast queries, required for Quantum Search and Pair Finding, to be performed on complicated sets.

The class PPP is arguably less studied than other syntactically definable subclasses of TFNP, such as PLS (Polynomial Local Search) and PPA (Polynomial Parity Argument), and it is not known whether PIGEONHOLE EQUAL-SUMS is complete in PPP. In fact, the first complete problem for the class was only identified relatively recently [29]. Our results for PIGEONHOLE EQUAL-SUMS suggest that the problem is indeed simpler to solve than EQUAL-SUMS. In spirit, a similar result was obtained in [7] where it was shown that, for an optimization problem closely related to EQUAL-SUMS, better approximation schemes can be obtained for instances with guaranteed solutions.

1.4 Structure of the Paper

In Section 2.1, we define the notations and provide some basic facts. The quantum computational model and the algorithmic primitives used in the paper, such as our Quantum Pair Finding algorithm, are given in Section 2.2. In Section 3.1, we introduce the dynamic programming data structure and show how it can be used to implement fast subset-sum queries. The properties of this data structure needed for our work are proved in Section 3.2. The main application to the SHIFTED-SUMS problem is described in Section 4. Finally, we study the pigeonhole variant of EQUAL-SUMS in Section 5.

2 Preliminaries

2.1 Notations and Basic Facts

We use the $\tilde{O}(x)$ and $\tilde{\Omega}(x)$ notations to hide factors that are polylogarithmic in the argument x . For integers $0 \leq m < n$, we denote by $[m..n]$ the set $\{m, m+1, \dots, n\}$, and by $[n]$ the set $[1..n]$. For sets $S, S' \subseteq [n]$ we denote by \bar{S} the set $[n] \setminus S$, and by $S \Delta S'$ the symmetric difference of S and S' . Given a multiset $A = \{a_1, \dots, a_n\}$ and subset $S \subseteq [n]$ we denote $\Sigma_A(S) := \sum_{i \in S} a_i$. When the set A is clear from the context, we will omit the subscript and simply denote the subset sum by $\Sigma(S)$. The power set of $[n]$ will be denoted by $\mathcal{P}([n]) := \{S : S \subseteq [n]\}$. For arbitrary integers a and b and a modulus p we say that a is

congruent to b modulo p , and we write $a \equiv b \pmod{p}$ or $a \equiv_p b$ if $a - b$ is divisible by p . By $a \pmod{p}$ we denote the unique integer in $\{0, \dots, p - 1\}$ which is congruent to a modulo p . The binary entropy function will be denoted by $h(x) = -x \log_2(x) - (1 - x) \log_2(1 - x)$.

► **Fact 1** ([16], page 530). *For every constant $\ell \in (0, 1)$ and for every large enough integer n , the following bounds hold: $\frac{2^{nh(\ell)}}{\sqrt{8n\ell(1-\ell)}} \leq \binom{n}{\ell n} < \frac{2^{nh(\ell)}}{\sqrt{2\pi n\ell(1-\ell)}}$.*

► **Fact 2.** *Let $b > 0$ be a constant, n a large enough integer and $a_1 \neq a_2$ two integers. Then, for a random prime $p \in [2^{bn} \dots 2^{bn+1}]$ we have $\Pr_p[a_1 \equiv_p a_2] \leq \frac{\log(|a_1 - a_2|)}{2^{bn}}$.*

Proof. The number of primes that belong to the interval $[2^{bn} \dots 2^{bn+1}]$ is at least $2^{bn}/bn$ for n large enough (see [17, p.371]). Moreover, there are at most $\frac{\log(|a_1 - a_2|)}{bn}$ prime numbers larger than 2^{bn} that divide $a_1 - a_2$. The result follows by a union bound. ◀

2.2 Quantum Algorithms

Quantum Computational Model. Similar to previous works on quantum element distinctness [4], quantum dynamic programming [6] and quantum subset sum algorithms [9], in our quantum algorithm running time analysis we assume the standard circuit model (where computational time corresponds to the number of single and two qubit gates) augmented with random access to quantum memory. That is, coherent access to any element of an m -qubit array can be performed in time polylogarithmic in m . Note that fully quantum memory is required in Algorithm 2 for SHIFTED-SUMS since multiple bins $T_{p,k}$ must be computed and stored in superposition.

Algorithmic primitives. We use the following generalization of Grover's search to the case of an unknown number of solutions.

► **Fact 3** (QUANTUM SEARCH, Theorem 3 in [11]). *Consider a function $f : [N] \rightarrow \{0, 1\}$ with an unknown number $K = |f^{-1}(1)|$ of marked items. Suppose that f can be evaluated in time τ . Then, the Quantum Search algorithm finds a marked item in f in expected time $\tilde{O}(\sqrt{N/K} \cdot \tau)$.*

Given a classical subroutine with stopping time τ that returns a marked item with probability ρ , we can convert it into a constant success probability algorithm with expected running time $O(\mathbb{E}[\tau]/\rho)$ by repeating it $O(1/\rho)$ times. Ambainis proved a similar result for the case of quantum subroutines, with a dependence on the second moment of the stopping time τ , and a Grover-like speed-up for the dependence on ρ .

► **Fact 4** (VARIABLE-TIME AMPLITUDE AMPLIFICATION, Theorem 2 in [5]). *Let \mathcal{A} be a quantum algorithm which looks for a marked element in some set. Let τ be the random variable corresponding to the stopping time of the algorithm, and let ρ be its success probability. Then the Variable-Time Amplitude Amplification algorithm finds a marked element in the above set with constant success probability in maximum time $\tilde{O}(\sqrt{\mathbb{E}[\tau^2]/\rho})$.*

The next result is a variant of the Birthday paradox over a product space $[N] \times [M]$, where at least K disjoint pairs are marked by some binary relation \mathcal{R} . Two pairs (x, y) and (x', y') are said to be disjoint if $x \neq x'$ and $y \neq y'$. The disjointness assumption is made to simplify the analysis and will be satisfied in our applications.

► **Lemma 5** (VARIANT OF THE BIRTHDAY PARADOX). *Consider three integers $1 \leq K \leq N \leq M$. Let $\mathcal{R} : [N] \times [M] \rightarrow \{0, 1\}$ be a binary relation such that there exist at least K mutually disjoint pairs $(x_1, y_1), \dots, (x_K, y_K) \in [N] \times [M]$ with $\mathcal{R}(x_k, y_k) = 1$ for all $k \in [K]$. Given an integer $r \leq O(\sqrt{NM/K})$, define $\epsilon(r)$ to be the probability of obtaining both elements from at least one marked pair when r numbers from $[N]$ and r numbers from $[M]$ are chosen independently and uniformly at random. Then, $\epsilon(r) \geq \Omega\left(\frac{r^2 K}{NM}\right)$.*

Proof. Fix any K disjoint marked pairs $(x_1, y_1), \dots, (x_K, y_K)$. Let X_1, \dots, X_r (resp. Y_1, \dots, Y_r) be r independent and uniformly distributed random variables over $[N]$ (resp. $[M]$). For any indices i, j , let $Z_{i,j}$ denote the binary random variable that takes value 1 if $\{X_i, X_j\}$ is one of the K fixed pairs, and set $Z = \sum_{i,j} Z_{i,j}$. By definition, we have $\epsilon(r) \geq \Pr[Z \neq 0]$. We lower bound this quantity by using the inclusion-exclusion principle,

$$\epsilon(r) \geq \sum_{i,j} \Pr(Z_{i,j} = 1) - \frac{1}{2} \sum_{(i,j) \neq (k,\ell)} \Pr(Z_{i,j} = 1 \wedge Z_{k,\ell} = 1).$$

The first term on the right-hand side is equal to $\sum_{i,j} \Pr(Z_{i,j} = 1) = \frac{r^2 K}{NM}$. For the second term, the analysis depends on whether the indices i, k and j, ℓ are distinct or not. If they are distinct then $\Pr(Z_{i,j} = 1 \wedge Z_{k,\ell} = 1) = \frac{K^2}{(NM)^2}$ since $Z_{i,j}$ and $Z_{k,\ell}$ are independent. Otherwise, suppose for instance that $i = k$. Since the K fixed pairs are disjoint, we have $\Pr(Z_{i,j} = 1 \wedge Z_{i,\ell} = 1) = \Pr(Z_{i,j} = 1 \wedge Y_j = Y_\ell) = \frac{K}{NM^2}$. Finally, there are $4\binom{r}{2}^2$ ways of choosing the indices i, j, k, ℓ when $i \neq k$ and $j \neq \ell$, and $4r\binom{r}{2}$ ways when $i = k$ or $j = \ell$. By putting everything together we obtain that, $\epsilon(r) \geq \frac{r^2 K}{NM} - 2\binom{r}{2}^2 \frac{K^2}{(NM)^2} - 2r\binom{r}{2} \frac{K}{NM^2} \geq \Omega\left(\frac{r^2 K}{NM}\right)$. ◀

We use the above result to construct a quantum algorithm for finding a marked pair when the relation $\mathcal{R}(x, y)$ is determined by checking if two underlying values $f(x)$ and $g(y)$ are equal or not. Our analysis essentially generalizes the quantum element distinctness [4] and claw finding [30] algorithms to the case of $K > 1$.

► **Theorem 6** (QUANTUM PAIR FINDING). *There is a bounded-error quantum algorithm with the following properties. Consider four integers $1 \leq K \leq N \leq M \leq R$ with $R \leq N^{O(1)}$. Let $f : [N] \rightarrow [R]$ and $g : [M] \rightarrow [R]$ be two functions that can be evaluated in time τ . Define $\mathcal{R} : [N] \times [M] \rightarrow \{0, 1\}$ to be any of the two following binary relations:*

1. $\mathcal{R}(x, y) = 1$ if and only if $f(x) = g(y)$.
2. $\mathcal{R}(x, y) = 1$ if and only if $f(x) = g(y)$ and $x \neq y$.

Suppose that there exist at least K mutually disjoint pairs $(x, y) \in [N] \times [M]$ such that $\mathcal{R}(x, y) = 1$. Then, the algorithm returns one such pair in time $\tilde{O}((NM/K)^{1/3} \cdot \tau)$ if $N \leq M \leq KN^2$ and $\tilde{O}((M/K)^{1/2} \cdot \tau)$ if $M \geq KN^2$.

Proof. If $N \leq M \leq KN^2$ the algorithm consists of running a quantum walk over the product Johnson graph $J(N, r) \times J(M, r)$ with $r = (NM/K)^{1/3}$. This walk has spectral gap $\delta = \Omega(1/r)$ and the fraction ϵ of vertices containing both elements from at least one marked pair satisfies $\epsilon \geq \Omega\left(\frac{r^2 K}{NM}\right)$ by Lemma 5. Using the MNRS framework [25], the query complexity of finding one marked pair is then $O(S + \frac{1}{\sqrt{\epsilon}}(\frac{U}{\sqrt{\delta}} + C))$, where the setup cost is $S = r$, the update cost is $U = O(1)$, and the checking cost is $C = 0$. This leads to a query complexity of $O(r + 1/\sqrt{\epsilon\delta}) = O((NM/K)^{1/3})$. By a simple adaptation of the data structures described in [4, Section 6.2] or [22, Section 3.3.4], this can be converted to a similar upper bound on the time complexity with a multiplicative overhead of τ .

If $M \geq KN^2$, the algorithm instead stores all pairs $\{(x, f(x))\}_{x \in [N]}$ in a table – sorted according to the value of the first coordinate – and then runs the Quantum Search algorithm on the function $F : [M] \rightarrow \{0, 1\}$ where $F(x') = 1$ if there exists $x \in [N]$ such that $\mathcal{R}(x, y) = 1$.

There are at least K marked items and F can be evaluated in time $O(\tau + \log N)$ using the sorted table. Thus, the running time is $\tilde{O}(N \cdot \tau + (M/K)^{1/2} \cdot (\tau + \log N)) = \tilde{O}((M/K)^{1/2})$ by Fact 3. ◀

3 Dynamic Programming Data Structure

3.1 Construction of the Data Structure

Here we introduce our dynamic programming data structure, and show how it can be used to implement low cost subset-sum queries to the elements of the set $T_{p,k}$ defined as follows.

► **Definition 7.** Let $A = \{a_1, \dots, a_n\}$ be a multiset of n integers. For integers $p \geq 2$ and $k \in \{0, 1, \dots, p-1\}$, define the set $T_{p,k}$ by $T_{p,k} = \{S \subseteq [n] : \Sigma_A(S) \equiv k \pmod{p}\}$, and denote the cardinality of $T_{p,k}$ by $t_{p,k} := |T_{p,k}|$.

Our main tool is the table t_p , defined below, constructed by dynamic programming. As $t_{p,k} = t_p[n, k]$, once the table is constructed, the size $t_{p,k}$ of $T_{p,k}$ can be read off the last row.

► **Lemma 8.** Let n, p be non-negative integers. In time $O(np)$, the $(n+1) \times p$ table $t_p[i, j] = |\{S \subseteq \{1, \dots, i\} : \Sigma(S) \equiv j \pmod{p}\}|$ can be constructed by dynamic programming, where $i \in [0..n]$ and $j \in [0..p-1]$.

Proof. To compute the elements of the table, observe that $t_p[0, 0] = 1$ and $t_p[0, j] = 0$ for $j > 0$. The remaining elements can be deduced from the relation $t_p[i, j] = t_p[i-1, j] + t_p[i-1, (j-a_i) \bmod p]$. The i^{th} row of t_p can thus be deduced from the $(i-1)^{\text{th}}$ row and a_i in time $O(p)$ and the computation of all rows can be completed in time $O(np)$. ◀

We now show how to use the table t_p to quickly query any element of $T_{p,k}$. To do so, we first define an ordering of the elements of $T_{p,k}$.

► **Definition 9.** Let \prec be the relation over $\mathcal{P}([n])$ defined as follows: for all $S_1, S_2 \subseteq [n]$, $S_1 \prec S_2$ if and only if $\max\{i : i \in S_1 \Delta S_2\} \in S_2$.

► **Lemma 10.** The relation \prec is a strict total order.

Proof. For every subset $S \subseteq [n]$, we define $\chi(S) = \sum_{i \in S} 2^i$. Then, $S_1 \prec S_2$ if and only if $\chi(S_1) < \chi(S_2)$. Since $<$ is a total order over the integers, so is \prec over $\mathcal{P}([n])$. ◀

Using the above relation, we now show that the query function $f : [1..t_{p,k}] \rightarrow T_{p,k}$, defined by $f(I) = S_I$, can be computed in time $O(n)$.

► **Theorem 11.** Let $T_{p,k}$ be enumerated as $T_{p,k} = \{S_1, \dots, S_{t_{p,k}}\}$ where $S_1 \prec \dots \prec S_{t_{p,k}}$. Given any integer $I \in [1..t_{p,k}]$ and random access to the elements of the table t_p , the set S_I can be computed in time $O(n)$.

Proof. Algorithm 1 gives a process which starts from $t_p[n, k]$ (i.e. the total number of subsets $S \subseteq [n]$ that sum to k modulo p) and an empty set Z , and constructs S_I by going backwards ($i = n, \dots, 1$) through the rows of t_p . At the i -th step we examine $t_p[i-1, j]$ and decide whether to include i in Z or not. If we do include i then we examine another element in that row to decide a new value of I , and we also reset j .

The algorithm consists of n iterations, each of which can be performed in constant time assuming random access to the elements of t_p , and therefore the running time is $O(n)$. What is left to prove is that the output of the algorithm is indeed S_I .

■ **Algorithm 1** Fast Subset-Sum oracle.

Input: Table t_p , integers $k \in [0..p-1]$ and $I \in [1..t_{p,k}]$.
Output: The I th subset $Z \subseteq [n]$ (according to \prec) such that $\Sigma(Z) \equiv k \pmod{p}$.

- 1 Set $j = k$ and $Z = \emptyset$.
- 2 **for** $i = n, \dots, 1$ **do**
- 3 **if** $I \leq t_p[i-1, j]$ **then**
- 4 | Do nothing.
- 5 **else**
- 6 | Update $Z = Z \cup \{i\}$, $I = I - t_p[i-1, j]$ and $j = j - a_i \pmod{p}$.
- 7 **Return** Z .

Here, we provide a high level explanation of why the algorithm works, and defer a formal proof to the full version of the paper [3]. The total ordering defined by \prec implies that $T_{p,k}$ can be written as the disjoint union of two sets, $T_{p,k} = \{S_1, \dots, S_{t_p[n-1,k]}\} \cup \{S_{t_p[n-1,k]+1}, \dots, S_{t_p[n,k]}\}$, where n is not contained in any S_i in the first (left) set, and is contained in every S_i of the second (right) set. Thus, we add n to the working set Z only if $I > t_p[n-1, k]$. If this is the case, S_I is the $I - t_p[n-1, k]$ -th element of the right set. We note that removing n from each S_i in the right set gives the next bin defined over a smaller universe of size $n-1$, $\{S \subseteq [n-1] : \Sigma(S) \equiv k - a_n \pmod{p}\}$ which has $t_p[n-1, (k - a_n) \bmod p]$ elements. Therefore, by updating $n \leftarrow n-1$, $I \leftarrow I - t_p[n-1, k]$ and $k \leftarrow (k - a_n) \bmod p$ we can repeat the process to determine whether to add $n-1$ to the working set, and so on, until we reach the value 1. ◀

► **Corollary 12** (Enumerating solutions to SUBSET-SUM via dynamic programming). *Let $A = \{a_1, \dots, a_n\}$ and $T_{p,k} = \{S \subseteq [n] : \Sigma_A(S) \equiv k \pmod{p}\}$. For any $c \leq |T_{p,k}|$, it is possible to find c elements of $T_{p,k}$ in time $\tilde{O}(p+c)$.*

Proof. By Lemma 8 the table $t_p[i, j]$ can be constructed in time $O(np)$. Thereafter, by Theorem 11 each set S_I for $I \in [1..t_{p,k}]$ can be computed in time $O(n)$. ◀

An alternative method for enumerating solutions was previously known:

► **Fact 13** (Enumerating solutions to SUBSET-SUM [8]). *Let $A = \{a_1, \dots, a_n\}$ where $a_i = 2^{O(n)}$ for all i . Let $p = 2^{O(n)}$, $0 \leq k \leq p-1$, and $T_{p,k} = \{S \subseteq [n] : \Sigma_A(S) \equiv k \pmod{p}\}$. Then, for any $c \leq |T_{p,k}|$, it is possible to find c elements of $T_{p,k}$ in time $\tilde{O}(2^{n/2} + c)$.*

In comparison with Fact 13, enumerating solutions via dynamic programming is advantageous when $p < 2^{n/2}$.

3.2 Statistics about Random Bins

We describe some statistics about the distribution of the sets $T_{p,k}$ (Definition 7) when $b \in (0, 1)$ is a constant, p is a random integer in $[2^{bn}..2^{bn+1}]$, and k is a random integer in $[0..p-1]$. Therefore, in this section, we stress out that $T_{p,k}$ is a random bin and its cardinality $t_{p,k}$ is a random integer.

► **Lemma 14.** *The expected bin size can be upper bounded as $\mathbb{E}_{p,k}[t_{p,k}] \leq 2^{(1-b)n}$.*

Proof. The expected size of $T_{p,k}$ is at most $\mathbb{E}_{p,k}[t_{p,k}] \leq 2^{(1-b)n}$ since $\{T_{p,k} : 0 \leq k < p\}$ is a partition of $\mathcal{P}([n])$ with $p \geq 2^{bn}$. ◀

This result is extended to an upper-bound on the second moment of $t_{p,k}$, under the assumption that the input does not contain too many solution pairs. This bound is needed to analyze the complexity of the Variable-Time Amplitude Amplification algorithm.

► **Lemma 15.** *Fix any integer $s \geq 0$ and any real $b \in [0, 1]$. If there are at most $2^{(2-b)n}$ pairs $(S_1, S_2) \in \mathcal{P}([n])^2$ such that $\Sigma(S_1) = \Sigma(S_2) + s$, then the expected product of the sizes of two bins at distance $s \bmod p$ from each other is at most $\mathbb{E}_{p,k}[t_{p,k}t_{p,(k-s) \bmod p}] \leq \tilde{O}(2^{2(1-b)n})$.*

Proof. The expectation of $t_{p,k}t_{p,(k-s) \bmod p}$ is equal to the expected number of pairs (S_1, S_2) such that $\Sigma(S_1)$ and $\Sigma(S_2) + s$ are congruent to k modulo p , that is $\mathbb{E}_{p,k}[t_{p,k}t_{p,(k-s) \bmod p}] = \mathbb{E}_{p,k}[\sum_{S_1, S_2} \mathbb{1}_{\Sigma(S_1) \equiv_p \Sigma(S_2) + s} k]$. Since k is uniformly distributed in $[0, p-1]$, this is equal to $\sum_{S_1, S_2} \mathbb{E}_p[\frac{1}{p} \mathbb{1}_{\Sigma(S_1) \equiv_p \Sigma(S_2) + s}] \leq 2^{-bn} \sum_{S_1, S_2} \Pr_p[\Sigma(S_1) \equiv_p \Sigma(S_2) + s]$, using that $p \geq 2^{bn}$. It decomposes as $2^{-bn} (\sum_{\Sigma(S_1) = s + \Sigma(S_2)} 1 + \sum_{\Sigma(S_1) \neq s + \Sigma(S_2)} \Pr_p[\Sigma(S_1) \equiv_p \Sigma(S_2) + s])$, where the first inner term is at most $2^{(2-b)n}$ by assumption, and the second term is at most $2^{2n}n2^{-bn}$ by Fact 2. Thus, $\mathbb{E}[t_{p,k}t_{p,(k-s) \bmod p}] \leq O(2^{-bn}(2^{(2-b)n} + 2^{2n}n2^{-bn})) \leq \tilde{O}(2^{2(1-b)n})$. ◀

Finally, we provide a lower bound on the number of *distinct* subset sum values that get hashed to the random bin $T_{p,k}$.

► **Lemma 16.** *Let V be any subset of the image set $\{v \in \mathbb{N} : \exists S \subseteq [n], \Sigma(S) = v\}$. Let $v_{p,k}$ denote the number of values $v \in V$ such that $v \equiv k \pmod{p}$. Suppose that $|V| \geq 2^{(1-\ell)n}$ for some $\ell \in [0, 1]$. Then,*

$$\begin{cases} \Pr_{p,k}[v_{p,k} \geq 2^{(1-\ell-b)n-2}] = \Omega(1/n), & \text{when } \ell \leq 1-b, \\ \Pr_{p,k}[v_{p,k} \geq 1] = \Omega(\min(1/n, 2^{(1-\ell-b)n})), & \text{when } \ell > 1-b. \end{cases}$$

Proof. The expected size of $V_{p,k}$ is at least $\mathbb{E}_{p,k}[v_{p,k}] \geq |V|/p \geq |V|2^{-bn-1}$ since $\{V_{p,k} : 0 \leq k < p\}$ is a partition of V . Similarly to Lemma 15, the second moment satisfies that $\mathbb{E}_{p,k}[v_{p,k}^2] \leq O(2^{-bn}(|V| + |V|^2n2^{-bn}))$ by using Fact 2. If $\ell \leq 1-b$ we can further simplify this bound into $\mathbb{E}_{p,k}[v_{p,k}^2] \leq O(2^{-bn}|V|)$ since $|V| \geq 2^{(1-\ell)n}$ by assumption. Finally, the result is obtained by applying the Paley–Zygmund inequality $\Pr[v_{p,k} \geq \mathbb{E}[v_{p,k}]/2] \geq \frac{\mathbb{E}[v_{p,k}]^2}{4\mathbb{E}[v_{p,k}^2]}$ and the fact that $\Pr[v_{p,k} \geq 1] = \Pr[v_{p,k} > 0]$ since $v_{p,k}$ is an integer. ◀

4 Shifted-Sums

Our approach for solving SHIFTED-SUMS relies on two different quantum algorithms. In Section 4.1, we present the first algorithm (based on the representation technique), which is more involved. The description of the second algorithm (based on meet-in-the-middle) is given in Section 4.2. The running time of both algorithms, expressed in Theorems 21 and 23, are functions of the size of a *maximum solution* of the input.

► **Definition 17 (Maximum solution).** *We say that two disjoint subsets $S_1, S_2 \subseteq [n]$ that form a solution to an instance of SHIFTED-SUMS are a maximum solution if the size $|S_1| + |S_2| = \ell n$ is largest among all such solutions. We call $\ell \in (0, 1)$ the maximum solution ratio.*

By choosing the faster of these two algorithms for each $\ell \in \{1/n, 2/n, \dots, (n-1)/n\}$ until a solution has been found (or it can be concluded that no solution exists), we obtain an overall quantum algorithm for SHIFTED-SUMS the following performance:

► **Theorem 18** (SHIFTED-SUMS, quantum). *There is a quantum algorithm which, given an instance of SHIFTED-SUMS with maximum solution ratio $\ell \in (0, 1)$, outputs a solution with at least inverse polynomial probability in time $\tilde{O}(2^{\gamma(\ell)n})$ where*

$$\gamma(\ell) = \begin{cases} (1 + \ell)/4 & \text{if } \ell_1 \leq \ell \leq 3/5, & \text{(Theorem 21)} \\ \ell/2 + 1/10 & \text{if } 3/5 < \ell < \ell_2, & \text{(Theorem 21)} \\ (h(\ell) + \ell)/3 & \text{otherwise} & \text{(Theorem 23)} \end{cases}$$

and $\ell_1 \approx 0.190$ and $\ell_2 \approx 0.809$ are solutions to the equations $(h(\ell) + \ell)/3 = (1 + \ell)/4$ and $(h(\ell) + \ell)/3 = \ell/2 + 1/10$ respectively. In particular, the worst case complexity is $O(2^{0.504n})$.

Since a potential solution can be verified in polynomial time in n , in what follows we describe our algorithms on yes instances with maximum solution ratio ℓ . As presented, the algorithms find a solution with inverse polynomial probability in n , which can be amplified to constant probability in polynomial time.

4.1 Representation Technique Algorithm

Our representation technique based algorithm is given in Algorithm 2, and uses the dynamic programming table of Section 3. Before constructing that table, we first check whether the input contains many solution pairs (in which case a simple quantum search is sufficient). Depending on the value of the maximum solution ratio ℓ , we may also need to apply Variable-Time Amplitude Amplification (Fact 4) on top of Quantum Pair Finding (Theorem 6).

■ **Algorithm 2** Quantum representation technique for SHIFTED-SUMS.

Input: Instance (a, s) of SHIFTED-SUMS with $\sum_{i=1}^n a_i < 2^{4n}$ and maximum solution ratio ℓ .

Output: Two subsets $S_1, S_2 \subseteq [n]$.

- 1 Set $b = (1 + \ell)/4$ if $\ell \leq 3/5$ and $b = 2/5$ if $\ell > 3/5$.
 - 2 Run the Quantum Search algorithm (Fact 3) over the set of pairs $(S_1, S_2) \in \mathcal{P}([n])^2$, where a pair is marked if $\Sigma(S_1) = \Sigma(S_2) + s$ and $S_1 \neq S_2$. Stop it and proceed to step 3 if the running time exceeds $\tilde{O}(2^{bn/2})$, otherwise output the pair it found within the allotted time.
 - 3 If $\ell > 3/5$ then run Variable-Time Amplitude Amplification (Fact 4) on steps 4 - 6, otherwise run them once:
 - 4 Choose a random prime $p \in [2^{bn} \dots 2^{bn+1}]$ and a random integer $k \in [0 \dots p - 1]$.
 - 5 Construct the table $t_p[i, j]$ for $i = 0, \dots, n$ and $j = 0, \dots, p - 1$ (see Section 3).
 - 6 Run the quantum Pair Finding algorithm (Theorem 6) to find if there exists two sets $S_1 \in T_{p,k}$ and $S_2 \in T_{p,(k-s) \bmod p}$ such that $\Sigma(S_1) = \Sigma(S_2) + s$ and $S_1 \neq S_2$. If so, output the pair (S_1, S_2) it found.
-

Note that ‘run Variable-Time Amplitude Amplification on steps 4 - 6’ means that one should apply the procedure implicit in Fact 4 to the algorithm \mathcal{A} defined by the following process (i) create a uniform superposition over all primes $p \in [2^{bn} \dots 2^{bn+1}]$ and, for each p , all $k \in [0 \dots p - 1]$. (ii) For each p , coherently construct the table t_p . (iii) Run Quantum Pair Finding coherently on each pair of sets $T_{p,k}, T_{p,(k-s) \bmod p}$, marking the (p, k) tuple if a pair is found.

The analysis of Algorithm 2 relies on the random bins statistics presented in Section 3.2. We first define the *collision values set* which contains the values of all the possible solution pairs.

► **Definition 19** (COLLISION VALUES SET). *Given an instance (a, s) to the SHIFTED-SUMS problem, the collision values set is the set $V = \{v \in \mathbb{N} : \exists S_1 \neq S_2, v = \Sigma(S_1) = \Sigma(S_2) + s\}$.*

We show that the collision values set V is of size at least $2^{(1-\ell)n}$ when the maximum solution ratio is ℓ . Thus, by Lemma 16, we can lower bound the number of values in V that get hashed to a random bin $T_{p,k}$.

► **Lemma 20.** *If the maximum solution ratio is ℓ then $|V| \geq 2^{(1-\ell)n}$.*

Proof. Let $S_1, S_2 \subseteq \{1, \dots, n\}$ be a maximum solution of size $|S_1| + |S_2| = \ell n$. Then for any $S \subseteq [n] \setminus (S_1 \cup S_2)$ the sets $S_1 \cup S$ and $S_2 \cup S$ form a solution, and for $S \neq S'$, the values $\Sigma(S_1 \cup S)$ and $\Sigma(S_1 \cup S')$ must be distinct. If this were not the case then $S_1 \cup (S \setminus S')$ and $S_2 \cup (S' \setminus S)$ would form a disjoint solution of size larger than ℓ . ◀

We now prove the correctness of Algorithm 2.

► **Theorem 21** (SHIFTED-SUMS, representation). *Given an instance of SHIFTED-SUMS with $\sum_{i=1}^n a_i < 2^{4n}$ and maximum solution ratio $\ell \in (0, 1)$, Algorithm 2 finds a solution with inverse polynomial probability in time $\tilde{O}(2^{(1+\ell)n/4})$ if $\ell \leq 3/5$, and $\tilde{O}(2^{(\ell/2+1/10)n})$ if $\ell > 3/5$.*

Proof. Step 2 of Algorithm 2 handles the case where the total number of solution pairs exceeds $2^{(2-b)n}$. In this situation, the Quantum Search algorithm can find a solution pair in time $\tilde{O}(\sqrt{2^{2n}/2^{(2-b)n}}) = \tilde{O}(2^{bn/2})$, which is smaller than the complexity given in Theorem 21.

Analysis when $\ell \leq 3/5$. In this case the algorithm executes steps 4 - 6 only once. From Lemma 8, the table t_p can be constructed in time $O(n2^{bn})$, after which each query to the elements of $T_{p,k}$ can be performed in time $O(n)$ (Theorem 11). By Lemma 16, the number of disjoint solution pairs contained in $T_{p,k} \times T_{p,(k-s) \bmod p}$ is at least $v_{p,k} \geq 2^{(1-\ell-b)n-2}$ with probability $\Omega(1/n)$. By Lemma 14 and Markov's inequality, the sizes of $T_{p,k}$ and $T_{p,(k-s) \bmod p}$ are at most $t_{p,k}, t_{p,(k-s) \bmod p} \leq n^2 2^{(1-b)n}$ with probability at least $1 - 1/n^2$. Thus, with probability $\Omega(1/n)$ we can assume that both of these events occur. If this is the case, then the time to execute step 6 of the algorithm is $\tilde{O}\left((t_{p,k} t_{p,(k-s) \bmod p} / v_{p,k})^{1/3}\right) = \tilde{O}(2^{(1+\ell-b)n/3})$ since the first complexity given in Theorem 6 is the largest one for our choice of parameters. This is at most $\tilde{O}(2^{(1+\ell)n/4})$ when $b = (1 + \ell)/4$.

Analysis when $\ell > 3/5$. We assume that the total number of solution pairs is at most $2^{(2-b)n}$ (otherwise we would have found a collision at step 2 with high probability). Given p and k , the base algorithm (steps 4 - 6) succeeds if there is a solution in $T_{p,k} \times T_{p,(k-s) \bmod p}$, i.e. $v_{p,k} \geq 1$. Therefore by Lemmas 20 and 16, we have for its success probability $\rho = \Omega(\min(1/n, 2^{(1-\ell-b)n}))$. We claim that $\mathbb{E}[\tau^2] = \tilde{O}(2^{2bn})$ where τ is the stopping time of the base algorithm. Constructing the table t_p takes time $\tilde{O}(p)$, and by summing the two complexities given in Theorem 6 the Quantum Pair Finding algorithm takes time at most $\tilde{O}\left((t_{p,k} t_{p,(k-s) \bmod p})^{1/3} + \sqrt{\max(t_{p,k}, t_{p,(k-s) \bmod p})}\right)$. Therefore we have $\mathbb{E}[\tau^2] = \tilde{O}(\mathbb{E}_{p,k}[(p + (t_{p,k} t_{p,(k-s) \bmod p})^{1/3} + \sqrt{\max(t_{p,k}, t_{p,(k-s) \bmod p})})^2]) \leq \tilde{O}(\mathbb{E}_{p,k}[p^2] + \mathbb{E}_{p,k}[t_{p,k}^{2/3} t_{p,(k-s) \bmod p}^{2/3}] + \mathbb{E}_{p,k}[t_{p,k}] \leq \tilde{O}(\mathbb{E}_{p,k}[p^2] + \mathbb{E}_{p,k}[t_{p,k} t_{p,(k-s) \bmod p}]^{2/3} + \mathbb{E}_{p,k}[t_{p,k}]) \leq \tilde{O}(2^{2bn}) + \tilde{O}(2^{4(1-b)n/3}) + 2^{(1-b)n}$, where the second inequality uses that the moment function is non-decreasing and the last inequality uses Lemmas 14 and 15. Since $b = 2/5$ we obtain that $\mathbb{E}[\tau^2] \leq \tilde{O}(2^{2bn})$. Finally, by Fact 4, the overall time of steps 3 - 6 is $\tilde{O}(\sqrt{\mathbb{E}[\tau^2]/\rho}) = \tilde{O}(2^{bn}/2^{(1-\ell-b)n/2}) = \tilde{O}(2^{(\frac{2}{5} + \frac{1}{10})n})$. ◀

4.2 Quantum Meet-in-the-Middle Algorithm

We describe the second quantum algorithm for solving SHIFTED-SUMS based on the meet-in-the-middle technique combined with Quantum Search. We first state a lemma that if we randomly partition the input into two sets of relative sizes 1:2, then with at least inverse polynomial probability a maximum solution will be distributed in the same proportion between the two sets.

► **Lemma 22.** *Let S_1, S_2 be a maximum solution of ratio ℓ . Then with at least inverse polynomial probability the random partition $X_1 \cup X_2$ satisfies $|(S_1 \cup S_2) \cap X_1| = \ell n/3$, $|(S_1 \cup S_2) \cap X_2| = 2\ell n/3$.*

Proof. There are $\binom{n}{n/3}$ ways to partition $[n]$ into two subsets X_1 and X_2 of respective sizes $n/3$ and $2n/3$. Of these, there are $\binom{\ell n}{\ell n/3} \cdot \binom{n-\ell n}{\frac{n-\ell n}{3}}$ partitions such that $|(S_1 \cup S_2) \cap X_1| = \ell n/3$, $|(S_1 \cup S_2) \cap X_2| = 2\ell n/3$. The probability that $|(S_1 \cup S_2) \cap X_1| = \ell n/3$, $|(S_1 \cup S_2) \cap X_2| = 2\ell n/3$ is thus $\frac{\binom{\ell n}{\ell n/3} \cdot \binom{n-\ell n}{\frac{n-\ell n}{3}}}{\binom{n}{n/3}}$. Fact 1 gives that this quantity is at least $\Omega(n^{-1/2})$. ◀

We use the above result in the design of Algorithm 3, which is analyzed in the next theorem. We observe that the obtained time complexity is at most $\tilde{O}(3^{n/3})$ and it is maximized at $\ell = 2/3$.

■ **Algorithm 3** Quantum meet-in-the-middle technique for SHIFTED-SUMS.

Input: Instance (a, s) of SHIFTED-SUMS with maximum solution ratio ℓ .

Output: Two subsets $S_1, S_2 \subseteq [n]$.

- 1 Randomly split $[n]$ into disjoint subsets $X_1 \cup X_2$ such that $|X_1| = n/3, |X_2| = 2n/3$.
 - 2 Classically compute and sort $V_1 = \{\Sigma(S_{11}) - \Sigma(S_{21}) : S_{11}, S_{21} \subseteq X_1 \text{ and } S_{11} \cap S_{21} = \emptyset \text{ and } |S_{11}| + |S_{21}| = \ell n/3\}$.
 - 3 Apply Quantum Search (Fact 3) over the set $V_2 = \{\Sigma(S_{12}) - \Sigma(S_{22}) : S_{12}, S_{22} \subseteq X_2 \text{ and } S_{12} \cap S_{22} = \emptyset \text{ and } |S_{12}| + |S_{22}| = 2\ell n/3\}$, where an element $v_2 \in V_2$ is marked if there exists $v_1 \in V_1$ such that $v_1 + v_2 = s$. For a marked v_2 , output $S_1 = S_{11} \cup S_{12}$ and $S_2 = S_{21} \cup S_{22}$.
-

► **Theorem 23** (SHIFTED-SUMS, meet-in-the-middle). *Given an instance of SHIFTED-SUMS with maximum solution ratio $\ell \in (0, 1)$, Algorithm 3 finds a solution with at least inverse polynomial probability in time $\tilde{O}(2^{n(h(\ell)+\ell)/3})$.*

Proof. There are $\binom{n/3}{\ell n/3} 2^{\ell n/3}$ different ways to select two sets $S_{11}, S_{21} \subseteq X_1$ such that $S_{11} \cap S_{21} = \emptyset$, $|S_{11}| + |S_{21}| = \ell n/3$. Computing and sorting V_1 thus takes time $\tilde{O}(\binom{n/3}{\ell n/3} 2^{\ell n/3})$. In the next step of the algorithm, Quantum Search is performed over all $\binom{2n/3}{2\ell n/3} 2^{2\ell n/3}$ sets $S_{12}, S_{22} \subseteq X_2$ such that $S_{12} \cap S_{22} = \emptyset$, $|S_{12}| + |S_{22}| = 2\ell n/3$. We mark an element $v_2 \in V_2$ if there exists $v_1 \in V_1$ such that $v_1 + v_2 = s$. Since V_1 is sorted this check can be done in time $\text{polylog}(|V_1|)$. The total time required is therefore $\tilde{O}\left(\binom{n/3}{\ell n/3} 2^{\ell n/3} + \sqrt{\binom{2n/3}{2\ell n/3} 2^{2\ell n/3}}\right) = \tilde{O}\left(2^{\ell n/3} \left(\binom{n/3}{\ell n/3} + \sqrt{\binom{2n/3}{2\ell n/3}}\right)\right) = \tilde{O}\left(2^{\frac{2}{3}(h(\ell)+\ell)n}\right)$. By Lemma 22, when the instance has a maximum solution of size ℓn , the set V_2 has a marked element with at least inverse polynomial probability, and in that case a solution is found. ◀

5 Pigeonhole Equal-Sums

We give classical and quantum algorithms for the PIGEONHOLE EQUAL-SUMS problem, based on dynamic programming and which run in time $\tilde{O}(2^{n/2})$ and $\tilde{O}(2^{2n/5})$, respectively. In contrast with our quantum algorithm for SHIFTED-SUMS which made use of a random prime modulus, in the case of PIGEONHOLE EQUAL-SUMS we can deterministically choose a modulus p , and the pigeonhole principle guarantees a collision in at least one bin.

► **Lemma 24.** *There is a classical deterministic algorithm such that, given an instance of PIGEONHOLE EQUAL-SUMS and a modulus p that divides 2^n , it finds in time $\tilde{O}(p)$ an integer k such that there exists two distinct subsets S_1, S_2 with $\Sigma(S_1) \equiv \Sigma(S_2) \equiv k \pmod{p}$.*

Proof. Denote by $\bar{0}, \bar{1}, \dots, \overline{p-1}$ the congruence classes modulo p . Each of these classes contains exactly $2^n/p$ numbers between 0 and $2^n - 2$, except the last class $\overline{p-1}$ that has only $2^n/p - 1$ numbers. Since all 2^n subsets $S \subseteq [n]$ have a sum $\Sigma(S)$ between 0 and $2^n - 2$ there are two possible cases:

- either there is some class \bar{k} such that $\Sigma(S) \in \bar{k}$ for strictly more than $2^n/p$ subsets S ,
- or there are $2^n/p$ subsets S such that $\Sigma(S) \in \overline{p-1}$.

Denote by \bar{k} a class that verifies one of these two points. By definition, there are *strictly more* subsets S such that $\Sigma(S) \in \bar{k}$ than the number of elements between 0 and $2^n - 2$ that belong to \bar{k} . However, for all $S \subseteq [n]$, we have $\Sigma(S) \leq 2^n - 2$. Thus, there must be two subsets $S_1 \neq S_2$ such that $\Sigma(S_1), \Sigma(S_2) \in \bar{k}$ and $\Sigma(S_1) = \Sigma(S_2)$.

From Lemma 8, the table $t_p[i, j] = |\{S \subseteq \{1, \dots, i\} : \Sigma(S) \equiv j \pmod{p}\}|$ can be constructed in time $\tilde{O}(p)$. From the table, we can read off a value k that satisfies the above condition. ◀

► **Theorem 25** (PIGEONHOLE EQUAL-SUMS, classical). *There is a classical deterministic algorithm for the PIGEONHOLE EQUAL-SUMS problem that runs in time $\tilde{O}(2^{n/2})$.*

Proof. Choose $p = 2^{n/2}$. By Lemma 24, in time $\tilde{O}(2^{n/2})$ we can find k such that there exists $S_1 \neq S_2$ satisfying $\Sigma(S_1) \equiv \Sigma(S_2) \equiv k \pmod{2^{n/2}}$. Once we know a bin that contains a collision, by Corollary 12, we can enumerate in time $\tilde{O}(2^{n/2})$ a sufficient number of subsets in that bin to locate a collision. ◀

► **Theorem 26** (PIGEONHOLE EQUAL-SUMS, quantum). *There is a quantum algorithm for the PIGEONHOLE EQUAL-SUMS problem that runs in time $\tilde{O}(2^{2n/5})$.*

Proof. We set $p = 2^{2n/5}$ and, by Lemma 24, in time $\tilde{O}(2^{2n/5})$ we can identify k such that there exists $S_1 \neq S_2$ satisfying $\Sigma(S_1) \equiv \Sigma(S_2) \equiv k \pmod{2^{2n/5}}$. By Theorem 11, each query to $T_{p,k} = \{S \subseteq [n] : \Sigma(S) \equiv k \pmod{p}\}$ can be made in time $O(n)$. We use Ambainis' element distinctness algorithm [4] on these elements to find a collision. We do not want to run it on an unnecessarily large set. Therefore, if $t_{p,k} > 2^{3n/5+1}$ then we run it only on the first $2^{3n/5+1}$ elements of $T_{p,k}$, according to the ordering defined by \prec . A collision is then found in time $\tilde{O}((2^{3n/5})^{2/3}) = \tilde{O}(2^{2n/5})$. The overall running time of the algorithm is thus $\tilde{O}(2^{2n/5})$. ◀

In the full version [3], we give an $\tilde{O}(2^{n/2})$ classical deterministic algorithm for the following modular version of PIGEONHOLE EQUAL-SUMS. We also ask the open question of finding a faster quantum algorithm.

► **Problem 6** (PIGEONHOLE MODULAR EQUAL-SUMS). Given a set $\{a_1, \dots, a_n\}$ of positive integers and a modulus q such that $q \leq 2^n - 1$, find two distinct subsets $S_1, S_2 \subseteq [n]$ such that $\sum_{i \in S_1} a_i \equiv \sum_{i \in S_2} a_i \pmod{q}$.

Abstract

Fair clustering enjoyed a surge of interest recently. One appealing way of integrating fairness aspects into classical clustering problems is by introducing multiple covering constraints. This is a natural generalization of the robust (or outlier) setting, which has been studied extensively and is amenable to a variety of classic algorithmic techniques. In contrast, for the case of multiple covering constraints (the so-called colorful setting), specialized techniques have only been developed recently for k -Center clustering variants, which is also the focus of this paper.

While prior techniques assume covering constraints on the clients, they do not address additional constraints on the facilities, which has been extensively studied in non-colorful settings. In this paper, we present a quite versatile framework to deal with various constraints on the facilities in the colorful setting, by combining ideas from the iterative greedy procedure for Colorful k -Center by Inamdar and Varadarajan with new ingredients. To exemplify our framework, we show how it leads, for a constant number γ of colors, to the first constant-factor approximations for both Colorful Matroid Supplier with respect to a linear matroid and Colorful Knapsack Supplier. In both cases, we readily get an $O(2^\gamma)$ -approximation.

Moreover, for Colorful Knapsack Supplier, we show that it is possible to obtain constant approximation guarantees that are independent of the number of colors γ , as long as $\gamma = O(1)$, which is needed to obtain a polynomial running time. More precisely, we obtain a 7-approximation by extending a technique recently introduced by Jia, Sheth, and Svensson for Colorful k -Center.

1 Introduction

As more and more decisions are automated, there has been an increasing interest in incorporating fairness aspects in algorithms by design. This applies in particular to clustering problems, where considerable attention has recently been dedicated to developing and studying various models of fair clustering, see, e.g., [8], [3], and [2].

In this paper, we focus on the so-called colorful setting, which was introduced in [3]. In colorful clustering, each client is a member of certain subgroups and every clustering is required to cover at least a given number of clients of each subgroup. This may be considered under various clustering objectives (like k -median and k -mean), though only the k -center case has been studied so far.

Colorful clustering is an appealing notion as it is a natural generalization of the robust (or outlier) setting, where there is only a single group which every client belongs to. Various clustering problems have been studied in depth in the robust setting, see, e.g., [5], [9], and [2].

While the robust setting is amenable to a variety of well-known and basic algorithmic techniques, the only constant-factor approximations for the colorful setting, which imposes multiple covering constraints leading to more balanced clusterings, are based on significantly more sophisticated techniques, tailored specifically to those settings. More precisely, three distinct techniques have been successful at achieving constant-factor approximations in the context of colorful k -center clustering, namely the combinatorial approach of [11], the round-or-cut-based approach of [1], and the iterative greedy reductions of [10].

However, these approaches do not immediately generalize to variants with constraints on the facilities, even for the common Matroid Center or Knapsack Center clustering variants. On the other hand, techniques for the Knapsack and Matroid k -Center problems in the robust setting (see [5] and [9]) do not easily extend to multiple covering constraints.

Thus, prior to this work, no approaches have been known that lead to constant-factor approximations for colorful variants of otherwise well-studied k -center problems like Matroid Center or Knapsack Center. Filling this gap is the goal of this paper.

1.1 Our contributions

Our main contribution is a partitioning procedure which leads to a general reduction of colorful k -center clustering problems with constraints on the facilities to a significantly simpler multi-dimensional covering problem (see Theorem 3). This reduction comes at the cost of a constant factor depending on the number of colors.

It is inspired by recent insights of [10] on decoupling multiple covering constraints and iteratively applying a greedy partitioning procedure of [6]. By taking into account multiple colors at the same time, our framework gives an improved way of dealing with multiple covering constraints while also becoming more versatile. Our framework also extends and simplifies ideas of the approximation algorithm for Robust Matroid Center of [7].

We start by introducing the γ -Colorful \mathcal{F} -Supplier problem, which formalizes colorful k -center problems with (down-closed) constraints on the facilities.

► **Definition 1** (γ -Colorful \mathcal{F} -Supplier problem). *Let $(C \dot{\cup} F, d)$ be a finite metric space on a set of clients C and facilities F , let $\mathcal{F} \subseteq 2^F$ be a down-closed family of subsets of F , and let $\gamma \in \mathbb{Z}_{\geq 0}$. Moreover, we are given for each $\ell \in [\gamma]$:*

- *a unary encoded weight/color function $w_\ell : C \rightarrow \mathbb{Z}_{\geq 0}$, and*
- *a covering requirement $m_\ell \in \mathbb{Z}_{\geq 0}$.*

The γ -Colorful \mathcal{F} -Supplier problem asks to find the smallest radius r together with a set $S \subseteq \mathcal{F}$ such that $w_\ell(B_C(S, r)) \geq m_\ell$ for all $\ell \in [\gamma]$.¹

¹ We use the common notation $w(T) := \sum_{t \in T} w(t)$ for functions $w : U \rightarrow \mathbb{R}_{\geq 0}$ and $T \subseteq U$, as well as $B(q, r) := \{v \in C \cup F \mid d(q, v) \leq r\}$ for the ball of radius r around point q . Moreover, we use the shorthand $B_U(V, r) := \{U \cap \bigcup_{v \in V} B(v, r)\}$ for sets $U, V \subseteq C \cup F$.

We note that it is also common to define colorful k -center versions in an unweighted way (thus not using weight functions w_ℓ) by assigning to each client a subset of the γ many colors and requiring that, for each color, m_ℓ many clients of that color are covered. The definition we use clearly captures this case (and can easily be seen to be equivalent). This connection also explains why the weights w_ℓ are assumed to be given in unary encoding.

Following common terminology in the literature, when \mathcal{F} is the family of independent sets of a matroid or feasible sets with respect to a knapsack constraint, we call the problem γ -Colorful Matroid Supplier and γ -Colorful Knapsack Supplier, respectively.

Our main contribution is a general reduction of γ -Colorful \mathcal{F} -Supplier to an auxiliary problem, which we call \mathcal{F} -COVER-PROMISE (\mathcal{F} -CP). \mathcal{F} -CP, which is formally defined below, is a multi-dimensional cover problem with the added promise that highly structured solutions exist. The promise is key, as the problem without the promise can be thought of as a multi-dimensional max-cover problem.

► **Definition 2** (\mathcal{F} -COVER-PROMISE (\mathcal{F} -CP)). *In the \mathcal{F} -COVER-PROMISE problem (\mathcal{F} -CP), we are given a set family $\mathcal{H} \subseteq 2^{\mathcal{U}}$ over a finite universe \mathcal{U} , a family $\mathcal{F} \subseteq 2^{\mathcal{H}}$ of feasible subsets of \mathcal{H} , and γ many unary encoded weight functions $w_1, \dots, w_\gamma : \mathcal{U} \rightarrow \mathbb{R}_{\geq 0}$ each with a requirement m_ℓ (for $\ell \in [\gamma]$). The task is to find a feasible family of sets $S \in \mathcal{F}$ such that*

$$w_\ell \left(\bigcup_{H \in S} H \right) \geq m_\ell \quad \forall \ell \in [\gamma] .$$

The promise is that there exists a family $S \subseteq \mathcal{F}$ and a way to pick for each $H \in S$ a single representative $u_H \in H$ such that

$$w_\ell (\{u_H : H \in S\}) \geq m_\ell \quad \forall \ell \in [\gamma] .$$

In words, the promise is that there is a solution that picks a family of sets and the requirements can be fulfilled by only using a single representative u_H in each set. However, the solution we are allowed to build is such that the weight of all elements covered by our sets are counted instead of just a single representative per set.

We are now ready to state our main reduction theorem, which, as we discuss later, readily leads, for a constant number of colors γ , to the first constant-factor approximations for γ -Colorful Matroid Supplier for linear matroids and γ -Colorful Knapsack Supplier. Our reduction to \mathcal{F} -CP comes at the cost of an $O(2^\gamma)$ -factor in the approximation guarantee.

► **Theorem 3.** *For any family of down-closed set systems, we have that if \mathcal{F} -CP can be solved efficiently for any \mathcal{F} in that family, then there is an $O(2^\gamma)$ -approximation algorithm for γ -Colorful \mathcal{F} -Supplier for any \mathcal{F} in the family.²*

While the dependence of the approximation factor on γ may be undesirable, the algorithmic barriers for prior approaches remain even when $\gamma = 2$ and, for hardness reasons, we do not expect approximation algorithms to exist at all when γ grows too quickly. In particular, [1] showed that even a simple version of colorful clustering, where any k centers can be chosen, does not admit an $O(1)$ -approximation algorithm when $\gamma = \omega(\log |C \dot{\cup} F|)$ under the Exponential Time Hypothesis. Thus, in what follows, we restrict ourselves to $\gamma = O(1)$.

² When talking about the same set system \mathcal{F} both in the context of \mathcal{F} -CP and γ -Colorful \mathcal{F} -Supplier, we consider \mathcal{F} to be the same set system in both settings even if the ground sets are different, as long as there is a one-to-one relation between the ground sets mapping sets of one system to sets of the other one and vice versa.

We now discuss implications of Theorem 3 to γ -Colorful Matroid Supplier for linear matroids and γ -Colorful Knapsack Supplier. When \mathcal{F} is the family of independent sets of a linear matroid, we show how \mathcal{F} -CP can be solved with techniques relying on an efficient randomized procedure for the *Exact Weight Basis* (XWB) problem for linear matroids.³ Linear matroids include as special cases many other well-known matroid classes, including uniform matroids, and more generally partition and laminar matroids, graphic matroids, transversal matroids, gammoids, and regular matroids.

► **Theorem 4.** *For $\gamma = O(1)$ and \mathcal{F} being the independent sets of a linear matroid, \mathcal{F} -CP can be solved efficiently by a randomized algorithm. Hence (by Theorem 3), there is a randomized $O(2^\gamma)$ -approximation algorithm for γ -Colorful Matroid Supplier for linear matroids.*

The restriction to linear matroids and the fact that the algorithm is randomized are not artifacts of our framework. Indeed, by an observation in [11], rephrased for matroids below, we do not only have that XWB implies results for γ -Colorful Matroid Supplier (which will follow from our reduction), but also a reverse implication. More precisely, even for 2-Colorful Matroid Supplier, deciding whether there is a solution of radius zero requires being able to solve XWB on that matroid. However, it is unknown whether XWB can be solved efficiently on general matroids, and the only technique known for XWB on linear matroids is inherently randomized [4]. (Derandomization is a long-standing open question in this context.)

► **Lemma 5** (based on [11]). *If there is an efficient algorithm for deciding whether 2-Colorful Matroid Supplier with respect to a given class of matroids admits a solution of radius zero, then XWB can be solved efficiently on the same class of matroids.*

Note that if we cannot decide the existence of a radius zero solution, then no approximation algorithm with any finite approximation guarantee can exist.

For the case where \mathcal{F} are the feasible sets for a knapsack problem, one can use standard dynamic programming techniques to see that \mathcal{F} -CP can be solved efficiently, which readily leads to a $O(2^\gamma)$ -approximation for γ -Colorful Knapsack Supplier.

Whereas our reduction given by Theorem 3 is broadly applicable and readily leads to first constant-factor approximations for γ -Colorful \mathcal{F} -Supplier problems, it remains open whether and in which settings a dependence of the approximation factor on the number of colors is necessary. We make first progress toward this question for γ -Colorful Knapsack Supplier, where we show how techniques from [11] can be modified and extended to give a 7-approximation (independent of the number of colors).

► **Theorem 6.** *For $\gamma = O(1)$, there is a 7-approximation algorithm for γ -Colorful Knapsack Supplier.*

Our technical contribution here lies in handling the knapsack constraint in this approach – modifying the algorithm of [11] to the supplier setting and to weighted instances is straightforward. In fact, their algorithm can be seen to give a 3-approximation even for γ -Colorful k -Supplier, which is tight in light of a hardness result in [6], namely that it is NP-hard to approximate Robust k -center with forbidden centers to within $3 - \epsilon$. This remains the strongest hardness result even for γ -Colorful \mathcal{F} -Supplier problems.

³ In XWB, one is given a matroid on a ground set with unary encoded weights and a target weight; the goal is to find a basis of the matroid of weight equal to the target weight. The technique in [4] to solve XWB for linear matroids needs an explicit linear representation of the linear matroid. We make the common assumption that this is the case whenever we make a statement about linear matroids.

1.2 Organization of this paper

Our main reduction, Theorem 3, is based on what we call (L, r) -partitions, which is a way to judiciously partition the clients into parts that we want to cover together. We introduce (L, r) -partitions in Section 2 and show how the existence of certain strong (L, r) -partitions implies Theorem 3. In Section 3, we show how our reduction framework can be used to obtain first constant-factor approximations for γ -Colorful Matroid Supplier for linear matroids (thus showing Theorem 4) and γ -Colorful Knapsack Supplier. Finally, in Section 4 we prove existence of strong (L, r) -partitions. The proof of Lemma 5 as well as our 7-approximation for γ -Colorful Knapsack Supplier, i.e., the proof of Theorem 6, can be found in the extended version of this paper.

2 Reducing to \mathcal{F} -CP through (L, r) -partitions

Consider a γ -Colorful \mathcal{F} -Supplier problem on a metric space $(X = (C \dot{\cup} F), d)$ with weights $w_\ell: C \rightarrow \mathbb{Z}_{\geq 0}$ for $\ell \in [\gamma]$ and covering requirements $m_\ell \in \mathbb{Z}_{\geq 0}$ for $\ell \in [\gamma]$. An (L, r) -partition is a partition of the clients into parts of small diameter each of which we consider in our analysis to be either fully covered or not covered at all. The key property of an (L, r) -partition is that, if our instance admits a radius- r solution, then there is a radius- $(L + 1)r$ solution where we allow each center to cover only *a single part* of the partition. It is the existence of such highly structured solutions that we exploit to design $O(1)$ -approximation algorithms.

A crucial property of (L, r) -partitions is that they neither depend on \mathcal{F} nor the covering requirements m_ℓ , but only on the metric space and the weight functions, which we call a γ -colorful space for convenience.

- **Definition 7** (γ -colorful space (X, d, w)). A γ -colorful space $(X = C \dot{\cup} F, d, w)$ consists of
1. a metric space (X, d) , and
 2. color functions $w_\ell: C \rightarrow \mathbb{R}_{\geq 0}$ for $\ell \in [\gamma]$.

We assume for convenience that the supports of the color functions, i.e., $\text{supp}(w_\ell)$ for $\ell \in [\gamma]$, are pairwise disjoint. One can reduce to this case without loss of generality by co-locating copies of clients. We are now ready to formally define the notion of (L, r) -partition.

- **Definition 8** ((L, r) -partition). Let $(X = C \dot{\cup} F, d, w)$ be a γ -colorful space and $r, L \in \mathbb{R}_{\geq 0}$. A partition $\mathcal{P} \subseteq 2^C$ is an (L, r) -partition if

1. $\text{diam}(A) := \max_{u, v \in A} d(u, v) \leq L \cdot r \quad \forall A \in \mathcal{P}$, and
2. for any $Z \subseteq F$, there exists a subfamily $\mathcal{A} \subseteq \mathcal{P}$ and injection $h: \mathcal{A} \rightarrow Z$ such that
 - a. $d(A, h(A)) \leq r$,⁴ and
 - b. $w_\ell(\bigcup_{A \in \mathcal{A}} A) \geq w_\ell(B_C(Z, r)) \quad \forall \ell \in [\gamma]$.

To connect (L, r) -partitions to colorful clustering problems, think of $Z \in \mathcal{F}$ as centers of a γ -Colorful \mathcal{F} -Supplier problem that satisfy the covering requirements with radius r . The definition of an (L, r) -partition \mathcal{P} then implies that there is a subset $\mathcal{A} \subseteq \mathcal{P}$ of the parts such that (i) for each $A \in \mathcal{A}$ there exists an element $h(A) \in Z$ such that any client in A has distance at most $(L + 1) \cdot r$ from $h(A)$, which follows from property 1 and 2a of the definition, and (ii) the clients in \mathcal{A} cover as much as $B_C(Z, r)$ in each color. Thus, the set of facilities $h(\mathcal{A})$ satisfies the covering requirements with respect to the radius $(L + 1) \cdot r$, and,

⁴ For any set $V \subseteq F \dot{\cup} C$ and $x \in F \dot{\cup} C$, we use the shorthand $d(V, x) := \min\{d(v, x) : v \in V\}$.

■ **Figure 1** Illustration of an (L, r) -partition of a 1-colorful space (where all points have unit weight). For $Z = \{z_i \mid i \in [4]\}$, the mapping h maps A_i to z_i for $i \in [4]$. Note that $\cup_{i \in [4]} A_i$ contains at least as many points than $\cup_{i \in [4]} B(r, z_i)$ and that $d(z_i, A_i) \leq r$ for $i \in [4]$. Furthermore, the largest distance between any two points in a set A_i is bounded by Lr .

furthermore, $h(\mathcal{A})$ is feasible because $h(\mathcal{A}) \subseteq Z$ and \mathcal{F} is down-closed. In short, $h(\mathcal{A})$ is an $(L + 1)$ -approximate solution to the γ -Colorful \mathcal{F} -Supplier problem. Hence, to obtain an $(L + 1)$ -approximation, the problem reduces to deciding which of the parts of \mathcal{P} to cover. A key simplification we gain from this connection is that the client sets in \mathcal{P} are non-overlapping because \mathcal{P} is a partition, which we will heavily exploit later to design our algorithms.

The key structural result of our work is to show that (L, r) -partitions with constant L (for a fixed γ) exist and can also be constructed efficiently, which is summarized below.

► **Lemma 9.** *For every γ -colorful space (X, d, w) and $r \in \mathbb{R}_{\geq 0}$, one can construct in polynomial time a $(10(2^\gamma - 1), r)$ -partition.⁵*

We defer the proof of Lemma 9 to Section 4, and first show how it implies our main reduction theorem, Theorem 3, and how this reduction readily leads to $O(1)$ -approximations for γ -Colorful Matroid Supplier for linear matroids and γ -Colorful Knapsack Supplier.

Proof of Theorem 3. Consider an instance of the γ -Colorful \mathcal{F} -Supplier Problem on a γ -colorful space (X, d, w) . We can guess the radius r of an optimal solution to the problem. This can be achieved by considering all pairwise distances between facilities F and clients C , repeating the steps below for each guess and only considering the best output (and discarding outputs where the procedure fails). Hence, assume that r is the optimal radius from now on.

By Lemma 9, we can efficiently construct an (L, r) -partition \mathcal{P} of (X, d, w) for $L = 10(2^\gamma - 1) = O(2^\gamma)$. Consider the \mathcal{F} -CP instance with universe $\mathcal{U} := \mathcal{P}$, family of sets

$$\mathcal{H} := \{H_f : f \in F\} \quad , \text{ where}$$

$$H_f := \{A \in \mathcal{P} \text{ with } d(A, f) \leq r\} \quad \forall f \in F \quad .$$

⁵ As we highlight later, a more careful analysis of our approach allows for a slight improvement in the constant factor, leading to the construction of $(8 \cdot 2^\gamma - 10, r)$ -partitions. However, in the interest of simplicity, we present a simpler analysis that shows the bound claimed in the lemma.

The family of feasible subsets of \mathcal{H} is the same as \mathcal{F} when identifying H_f with the element f . To make this relation explicit, if we denote by $\mathcal{F}_{\mathcal{H}}$ the family of feasible subsets, then some subset of \mathcal{H} , say $\{H_f: f \in I\}$ where $I \subseteq F$, is in $\mathcal{F}_{\mathcal{H}}$ if and only if $I \in \mathcal{F}$. Moreover, the weights and coverage thresholds are inherited from those of the given γ -Colorful \mathcal{F} -Supplier problem; formally, for $\ell \in [\gamma]$, the ℓ -th weight of $A \in \mathcal{U}$ is given by $w_\ell(A)$.

To make sure that this indeed leads to an \mathcal{F} -CP problem, we have to verify that the promise holds. Thus, let $Z \subseteq F$ be a solution to the given γ -Colorful \mathcal{F} -Supplier problem for radius r , which exists because we assume that r was guessed correctly. As \mathcal{P} is an (L, r) -partition of (X, d, w) , there is a subfamily $\mathcal{A} \subseteq \mathcal{P}$ and injection $h: \mathcal{A} \rightarrow Z$ satisfying property 2 of Definition 8. We claim that a solution fulfilling the promise is given by choosing

$$S = \{H_f: f \in h(\mathcal{A})\} \in \mathcal{F}_{\mathcal{H}} ,$$

and setting as representative element $u_{H_f} \in H_f$ the element $u_{H_f} = A_f$, where $A_f = h^{-1}(f)$. Note that because $h(\mathcal{A}) \subseteq Z \in \mathcal{F}$ and \mathcal{F} is down-closed, we indeed have $S \in \mathcal{F}_{\mathcal{H}}$. Furthermore, because the injection h satisfies $d(A_f, h(A_f)) \leq r$, we have $u_{H_f} \in H_f$, as desired. Moreover,

$$\sum_{f \in h(\mathcal{A})} w_\ell(u_{H_f}) = \sum_{f \in h(\mathcal{A})} w_\ell(A_f) = \sum_{A \in \mathcal{A}} w_\ell(A) \geq w_\ell(B_C(Z, r)) \geq m_\ell \quad \forall \ell \in [\gamma] ,$$

where the first inequality follows because \mathcal{A} fulfills the second property of Definition 8, and the last inequality is a consequence of Z being centers that are a radius- r solution to the given γ -Colorful \mathcal{F} -Supplier problem. Hence, the promised solution exists.

Thus, we can compute an \mathcal{F} -CP solution $S_{\mathcal{H}} \subseteq \mathcal{F}_{\mathcal{H}}$, which can be written as $S_{\mathcal{H}} := \{H_f: f \in S\}$ for some $S \in \mathcal{F}$. We claim that S is a solution to the given γ -Colorful \mathcal{F} -Supplier problem with radius $(L+1) \cdot r$, which finishes the proof. This follows from the fact that $S_{\mathcal{H}}$ is an \mathcal{F} -CP solution, and that, for any $f \in F$, each client in $\bigcup_{A \in H_f} A$ has distance at most $(L+1) \cdot r$ from f because \mathcal{P} is an (L, r) -partition. Hence, the clustering solution with centers S and radius $(L+1) \cdot r$ covers all clients in

$$\bigcup_{f \in S} \bigcup_{A \in H_f} A ,$$

and the w_ℓ -weight (for any $\ell \in [\gamma]$) that it covers is at least

$$w_\ell \left(\bigcup_{f \in S} \bigcup_{A \in H_f} A \right) = \sum_{A \in \bigcup_{f \in S} H_f} w_\ell(A) \geq m_\ell ,$$

where the equality uses that the ground set $\mathcal{U} = \mathcal{P}$ consists of sets A that are disjoint, and the inequality holds because $S_{\mathcal{H}} = \{H_f: f \in S\}$ is a solution to \mathcal{F} -CP. Thus, all coverage requirements are fulfilled by the clustering with centers S and radius $(L+1) \cdot r$, as desired. \blacktriangleleft

3 Applications of our reduction framework

We now discuss implications of our reduction framework, Theorem 3, to γ -Colorful Matroid Supplier for linear matroids and γ -Colorful Knapsack Supplier.

3.1 γ -Colorful Matroid Supplier

To apply our reduction framework to γ -Colorful Matroid Supplier for linear matroids, we have to solve \mathcal{F} -CP when \mathcal{F} are the independent sets of a linear matroid. We show how this problem can be reduced to XWB in a suitably defined matroid. More precisely, we use a

7:8 Techniques for Generalized Colorful k -Center Problems

reduction to the *Exact Weight Independent Set* (XWI) problem for matroids. This problem is identical to XWB except that an *independent set* with the desired target weight needs to be returned, instead of a basis. However, XWI easily reduces to XWB on linear matroids, by adding zero weight copies of the elements.

This reduction relies on Rado matroids, which is a way to construct a matroid from another one (see, e.g., [13, Section 8.2]).⁶ It relies on the notation of a *system of representatives*, where, for a finite universe \mathcal{U} and a set system $S \subseteq 2^{\mathcal{U}}$, a *system of representatives of S* is any set $\{u_H\}_{H \in S}$ with $u_H \in H$ for $H \in S$. In words, a system of representatives is obtained by replacing each set in S by an element in that set (its representative). (Note that an element can be chosen more than once as a representative, but, as defined above, only appears once in the system of representatives.)

► **Definition 10** (Rado matroid). *Let \mathcal{U} be a finite universe, $\mathcal{H} \subseteq 2^{\mathcal{U}}$ be some set system, and let $M = (\mathcal{H}, \mathcal{I})$ be a matroid. The Rado matroid $(\mathcal{U}, \bar{\mathcal{I}})$ induced by $(\mathcal{U}, \mathcal{H}, M)$ is a matroid on the ground set \mathcal{U} with independent sets*

$$\{U \subseteq \mathcal{U} : U \text{ is a system of representatives for some } I \in \mathcal{I}\} .$$

A proof that a Rado matroid is indeed a matroid can be found, e.g., in [13, Section 8.2]. We will reduce \mathcal{F} -CP to XWI on a Rado matroid obtained from a linear matroid. For this, we need that also the Rado matroid we obtain is linear and, moreover, that an explicit linear representation of it can be found efficiently, which is the case due to a result from [12].

► **Lemma 11** (see Theorem 3 of [12]). *For a set family $\mathcal{H} \subseteq 2^{\mathcal{U}}$ and a linear matroid $M = (\mathcal{H}, \mathcal{I})$, the Rado matroid $\bar{M} = (\mathcal{U}, \bar{\mathcal{I}})$ induced by $(\mathcal{U}, \mathcal{H}, M)$ is a linear matroid. Moreover, given a linear representation of M , one can find a linear representation of \bar{M} in time polynomial in $|\mathcal{H}|$, $|\mathcal{U}|$, and the size of the linear representation of M .*

We are now ready to show that \mathcal{F} -CP can be solved efficiently for linear matroids, which implies Theorem 4.

► **Lemma 12.** *\mathcal{F} -CP can be solved efficiently when \mathcal{F} is the family of independent sets of a linear matroid.*

Proof. We recall that we are given an \mathcal{F} -CP instance, which defines a set system $\mathcal{H} \subseteq 2^{\mathcal{U}}$ over a finite universe \mathcal{U} , and a family $\mathcal{F} \subseteq 2^{\mathcal{H}}$ such that $M = (\mathcal{H}, \mathcal{F})$ is a linear matroid. Let $\bar{M} = (\mathcal{U}, \bar{\mathcal{I}})$ be the Rado matroid induced by $(\mathcal{U}, \mathcal{H}, M)$. \bar{M} is a linear matroid by Lemma 11 and we can obtain a linear representation of \bar{M} in polynomial time. The promise of \mathcal{F} -CP implies the existence of an independent set T of \bar{M} satisfying the covering requirements, i.e.,

$$w_\ell(T) \geq m_\ell \quad \forall \ell \in [\gamma] . \tag{1}$$

To solve \mathcal{F} -CP, we guess, for each color $\ell \in [\gamma]$, the weight $\lambda_\ell := w_\ell(T)$ that T covers. Note that λ_ℓ is at most $W_\ell := w_\ell(\mathcal{U})$, which, due to the unary encoding of w_ℓ , is polynomially bounded in the input. Hence, the guessing of the λ_ℓ , for $\ell \in [\gamma]$, can be performed in time $\prod_{\ell \in [\gamma]} W_\ell$, which is polynomially bounded because $\gamma = O(1)$.

We now determine an independent set \tilde{T} in \bar{M} with $w_\ell(\tilde{T}) = \lambda_\ell$ for each $\ell \in [\gamma]$. This can be achieved by encoding all ℓ many (unary encoded) weight functions w_ℓ for $\ell \in [\gamma]$ into a single one \bar{w} and then solving an appropriate XWI problem with respect to \bar{w} . More precisely,

⁶ This construction of Rado matroids is also called the *induction of a matroid by a bipartite graph*.

for an element $u \in \mathcal{U}$, we obtain a new single weight $\bar{w}(u)$ whose first $\lceil \log_2(|W_1| + 1) \rceil$ bits represent the weight $w_1(u)$, the next $\lceil \log_2(|W_2| + 1) \rceil$ bits the weight $w_2(u)$, and so on. Because $\gamma = O(1)$ and all w_ℓ have unary encoding, this leads to combined weights \bar{w} whose unary encoding is polynomially bounded. Analogously, we encode the guessed weights λ_ℓ for $\ell \in [\gamma]$ into a single one $\bar{\lambda}$. We now solve XWI on \bar{M} with weights \bar{w} and target weight $\bar{\lambda}$. As \bar{M} is linear, this is possible by a randomized algorithm in time pseudo-polynomial in the total weight [4]. Moreover, because the weights are unary encoded in our setting, this implies a polynomial running time as desired.

Let \tilde{T} be a solution of this XWI problem, which must exist for the correct guess of the λ_ℓ because of the promised solution T . \tilde{T} being independent in \bar{M} implies that it is a system of representatives for some independent set $S \in \mathcal{F}$ of M . Such a set S can be found through matroid intersection. More precisely, it is known that the minimal (inclusion-wise) sets $I \subseteq \mathcal{H}$ such that \tilde{T} is a system of representatives for I form the basis of a matroid \tilde{M} , for which an efficient independence oracle can be obtained. (See [13, Section 7.3].) Hence, the desired set S can be obtained by finding a basis of \tilde{M} that is independent in M , which can be computed through matroid intersection algorithms. The set S is the solution of \mathcal{F} -CP that we return. Because $\tilde{T} \subseteq \bigcup_{H \in S} H$, the set S fulfills the covering requirements due to (1). ◀

3.2 γ -Colorful Knapsack Supplier

To showcase the versatility of our reduction, we now show how it implies an $O(2^\gamma)$ -approximation for γ -Colorful Knapsack Supplier, by discussing an efficient way to solve \mathcal{F} -CP when \mathcal{F} are the feasible solutions to a knapsack constraint. Even though there is a stronger (and more sophisticated) approximation result for this problem (as stated in Theorem 6), this application is a nice example of how one can readily obtain constant-factor approximations through our reduction technique combined with known methods; in this case, by solving \mathcal{F} -CP through a standard dynamic programming approach.

► **Lemma 13.** *Let \mathcal{F} be the feasible sets of a knapsack constraint, i.e., $\mathcal{F} = \{S \subseteq \mathcal{H} : \kappa(S) \leq K\}$ for some $\kappa : \mathcal{H} \rightarrow \mathbb{R}_{\geq 0}$ and budget $K \in \mathbb{R}_{\geq 0}$. Then \mathcal{F} -CP can be solved efficiently.*

Proof. Recall that the \mathcal{F} -CP problem to be solved defines a family $\mathcal{H} \subseteq 2^{\mathcal{U}}$ over a finite universe \mathcal{U} , and a family $\mathcal{F} \subseteq 2^{\mathcal{H}}$, which is defined by a knapsack constraint, i.e., $\mathcal{F} = \{S \subseteq \mathcal{H} : \kappa(S) \leq K\}$. We define the following weight function on \mathcal{U} :

$$\eta(u) := \min\{\kappa(H) : H \in \mathcal{H} \text{ with } u \in H\} .$$

In words, $\eta(u)$ corresponds to the cost of the cheapest set in \mathcal{H} that covers u . Consider the following binary program, which can be solved efficiently by standard dynamic programming techniques due to the unary encoding of the weights w_ℓ for $\ell \in [\gamma]$ (see, e.g., [1] for details):

$$\begin{aligned} \min \quad & \sum_{u \in \mathcal{U}} \eta(u) \cdot z(u) \\ & \sum_{u \in \mathcal{U}} w_\ell(u) \cdot z(u) \geq m_\ell \quad \forall \ell \in [\gamma] \\ & z \in \{0, 1\}^{\mathcal{U}} . \end{aligned}$$

We compute an optimal solution z^* to the above binary program. Let $Q := \{u \in \mathcal{U} : z^*(u) = 1\}$. For each $u \in Q$, let $H_u \in \mathcal{H}$ be a set of minimum cost that contains u ; hence, $\kappa(H_u) = \eta(u)$. We claim that $\{H_u : u \in Q\}$ is a solution to \mathcal{F} -CP. Because

z^* fulfills the constraints of the binary program, we have that $\{H_u : u \in Q\}$ fulfills the covering requirements. It remains to show that it fulfills the knapsack constraint, i.e., its cost is at most K . This reduces to show that the optimal value of the binary program is at most K . We claim that this holds because of the promise of \mathcal{F} -CP. Indeed, the promise guarantees that there is $S \subseteq \mathcal{F}$ and a system of representatives u_H for $H \in S$ such that $w_\ell(\{u_H : H \in S\}) \geq m_\ell$ for $\ell \in [\gamma]$. Hence, setting $z_{u_H} = 1$ for all $H \in S$, and setting all other coordinates of $z \in \{0, 1\}^{\mathcal{U}}$ to zero, is a solution to the binary program which has objective value at most $\kappa(S) \leq K$. \blacktriangleleft

4 Existence and construction of strong (L, r) -partitions

We now prove our key structural result, Lemma 9, which guarantees the existence and efficient constructability of $(O(2^\gamma), r)$ -partitions for γ -colorful spaces. Our proof proceeds by induction on γ . The base case, i.e., $\gamma = 0$, holds because the family $\{\{c\} : c \in C\}$ is a $(0, r)$ -grouping on every 0-colorful space $(C \dot{\cup} F, d, w)$. The key step is extending an (L, r) -partition of a $(\gamma - 1)$ -colorful space to a suitable partition of a γ -colorful space.

To this end, we extend ideas on the greedy algorithm of [6], which was originally introduced to deal with a single color k -center problem. More precisely, to augment a partition of a $(\gamma - 1)$ -colorful space, we apply a greedy subroutine on the points of color γ . A careful construction and analysis (which takes into account the earlier colors) then shows that this yields a $(2L + 10, r)$ -partition of the γ -colorful space. Our refined charging scheme improves on a decoupled analysis of [10] (which gives an $O(5^\gamma)$ approximation algorithm for γ -Colorful k -Center).

The lemma below formalizes the induction step.

► **Lemma 14.** *Given a (L, r) -partition for a $(\gamma - 1)$ -colorful space, then one can efficiently construct a $(2L + 10, r)$ -partition for any γ -colorful space obtained by adding one color to the $(\gamma - 1)$ -colorful space.*

Proof. Let $(C \dot{\cup} F, d, w)$ be a γ -colorful space, and let $\widehat{w} = (w_1, \dots, w_{\gamma-1})$ be the first $\gamma - 1$ colors. (Hence, we omitted the last color.) Let $C_\gamma := \text{supp}(w_\gamma)$ and $C_{<\gamma} := C \setminus C_\gamma$, and let \mathcal{P} be a (L, r) -partition of the $(\gamma - 1)$ -colorful space $(C_{<\gamma} \dot{\cup} F, d, \widehat{w})$. Note that we assumed that the supports of the weights w_ℓ are disjoint. Hence, $w_\ell(C_\gamma) = 0$ for $\ell \in [\gamma - 1]$. Moreover, without loss of generality, we assume that for every client $c \in C$, there is a facility $f \in F$ with $d(f, c) \leq r$. All clients not fulfilling this condition can be deleted from the instance without changing the statement as they can never be covered by any radius- r solution. Indeed, a partition of the clients of this purged instance can simply be extended to a partition of all clients by adding the deleted clients as singleton sets to the partition.

We now prove that Algorithm 1 returns an (\overline{L}, r) -partition $\overline{\mathcal{P}}$ of $(C \dot{\cup} F, d, w)$, where $\overline{L} := 2L + 10$. Algorithm 1 goes through all facilities in a well-chosen order and iteratively builds new parts consisting of parts in \mathcal{P} together with a subset of C_γ . (See Figure 2 for an illustration of this procedure.)

First, observe that $\overline{\mathcal{P}}$ is a partition. It clearly covers all clients as no client is farther than distance r away from its nearest facility, and we consider all facilities. Moreover, the sets in $\overline{\mathcal{P}}$ are disjoint by construction. Now, observe that any $\overline{A}_i \in \overline{\mathcal{P}}$ has small diameter, because

$$\text{diam}(\overline{A}_i) \leq 2 \cdot \max_{c \in \overline{A}_i} d(g_i, c) \leq 10r + 2Lr \quad ,$$

where the second inequality holds because $d(g_i, c) \leq 5r + Lr$ for any $c \in \overline{A}_i$ due to the following. Consider $c \in \overline{A}_i$. If $c \in C_\gamma$, then we even have $d(g_i, c) \leq 3r$. Otherwise, let

■ **Algorithm 1** GREEDYPARTITIONING($C, F, d, \mathcal{P}, w_\gamma$).

```

for  $i_{A_i} = 1$  to  $|F|$  do
   $g_i = \operatorname{argmax}_{f \in F \setminus \{g_1, \dots, g_{i-1}\}} w_\gamma \left( B_C(f, r) \setminus \bigcup_{t=1}^{i-1} \bar{A}_t \right);$ 
   $\bar{A}_i \leftarrow \left( B_{C_\gamma}(g_i, 3r) \cup \bigcup_{\substack{A \in \mathcal{P} \text{ with} \\ d(g_i, A) \leq 5r}} A \right) \setminus \bigcup_{t=1}^{i-1} \bar{A}_t;$ 
end
return  $\bar{\mathcal{P}} := \{\bar{A}_i : i \in [|F|]\};$ 

```

■ **Figure 2** Visualization of an (L, r) -partition and of Algorithm 2. The black polygons depict an (L, r) -partition \mathcal{P} of the clients $C_{<\gamma}$. The blue polygons shows how the clients $C_{<\gamma}$ are partitioned by $\bar{\mathcal{P}}$. Moreover, the blue $3r$ -balls around g_i illustrate which clients of C_γ get assigned to the part $\bar{A}_i \in \bar{\mathcal{P}}$. The dashed circles have radius r and $3r$ respectively, while the dotted circles have radius $5r$. We assume $Z = \{z_i \mid i \in [4]\}$ is given and we construct the respective $\bar{\mathcal{A}}$ and \bar{h} , given \mathcal{A} and h . We have $\mathcal{A} = \{A_i \mid i \in [4]\}$ (the orange areas) and $\bar{\mathcal{A}} = \{\bar{A}_i \mid i \in [3]\}$. Moreover $h(A_i) = z_i$ for $i \in [4]$ (depicted by an orange arrow), while $\bar{h}(\bar{A}_i) = z_i$ for $i \in [3]$.

$A \in \mathcal{P}$ be the set in the partition \mathcal{P} containing c . Note that $c \in \bar{A}_i$ implies $A \subseteq \bar{A}_i$. Hence, $d(g_i, c) \leq d(g_i, A) + \max\{d(b, c) : b \in A\} \leq 5r + Lr$, where we use $d(g_i, A) \leq 5r$, because $A \subseteq \bar{A}_i$, and $\text{diam}(A) \leq Lr$, which holds because \mathcal{P} is an (L, r) -partition. Thus, property 1 of the definition of an $(2L + 10, r)$ -partition (Definition 8) is fulfilled for $\bar{\mathcal{P}}$.

It remains to show that property 2 holds for a given selection Z . To this end, we use that \mathcal{P} is an (L, r) -partition, which implies that there is a subfamily $\mathcal{A} \subseteq \mathcal{P}$ and a corresponding injection $h : \mathcal{A} \rightarrow Z$ fulfilling property 2 of Definition 8 for the $(\gamma - 1)$ -colorful space $(C_{<\gamma} \cup F, d, \hat{w})$. In the following we construct $\bar{\mathcal{A}} \subseteq \bar{\mathcal{P}}$ and $\bar{h} : \bar{\mathcal{A}} \rightarrow Z$ such that property 2 of Definition 8 is satisfied for $\bar{\mathcal{A}}$ and \bar{h} . At the same time when constructing $\bar{\mathcal{A}}$, we employ a careful charging argument that makes sure that $w_\gamma(\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}) \geq w_\gamma(B_C(Z, r))$, i.e., that the constructed $\bar{\mathcal{A}}$ covers at least as much as Z of color γ . For the remaining colors, we show that the new selection $\bar{\mathcal{A}}$ includes all of \mathcal{A} ; formally, we show that for each $A \in \mathcal{A}$, there is an $\bar{A} \in \bar{\mathcal{A}}$ such that $A \subseteq \bar{A}$. This, as well as $d(\bar{A}, \bar{h}(\bar{A})) \leq r$ for all $\bar{A} \in \bar{\mathcal{P}}$ and injectivity of \bar{h} , are proved later.

7:12 Techniques for Generalized Colorful k -Center Problems

For $i \in [|F|]$, we define

$$U_i := C \setminus \bigcup_{t=1}^{i-1} \bar{A}_t$$

to be the clients that are “uncovered” at step i . By the way Algorithm 1 selects g_i in each iteration $i \in [|F|]$, we have

$$w_\gamma(B_C(g_i, r) \cap U_i) \geq w_\gamma(B_C(f, r) \cap U_i) \quad \forall i \in [|F|] \text{ and } f \in F,$$

which we call the *greediness property*.

We now describe the construction of $\bar{\mathcal{A}}$ and the charging scheme in detail. We successively add sets $\bar{A}_i \in \bar{\mathcal{P}}$ to $\bar{\mathcal{A}}$, where the sets \bar{A}_i are considered in increasing order of their index. When adding a set \bar{A}_i to $\bar{\mathcal{A}}$, we also perform two further steps: (i) we identify an element $f \in Z$ and set $\bar{h}(\bar{A}_i) = f$, and (ii) we mark f as assigned to make sure that we never assign it again in the future (as \bar{h} needs to be an injection). For convenience, for $i \in [|F|]$ and $f \in Z$, we write $\text{ASSIGN}(i, f)$ for performing these steps, i.e., adding \bar{A}_i to $\bar{\mathcal{A}}$, setting $\bar{h}(\bar{A}_i)$ to f , and marking f as assigned.

The charging argument charges the coverage of color γ of $B_C(Z, r)$ against the γ -coverage in $\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$. Whenever we charge a set $Q \subseteq B_C(Z, r)$ against some subset $W \subseteq \bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$, we make sure that $w_\gamma(Q) \leq w_\gamma(W)$. Algorithm 2 shows our procedure to construct both $\bar{\mathcal{A}}$ and the desired injection $\bar{h}: \bar{\mathcal{A}} \rightarrow Z$ together with the charging argument. (See also Figure 2.)

■ **Algorithm 2** Construction of $\bar{\mathcal{A}}$ and injection $\bar{h}: \bar{\mathcal{A}} \rightarrow Z$ together with charging argument.

Mark all facilities in Z as unassigned.

for $i = 1$ **to** $|F|$ **do**

- **Rule 1** If there is an unassigned $f \in Z$ with $B_C(f, r) \cap B_C(g_i, r) \cap U_i \neq \emptyset$:
ASSIGN(i, f).
- **Rule 2** Else if there is an unassigned $f \in Z$ with $B_C(f, r) \cap B_C(g_i, 3r) \cap U_i \neq \emptyset$:
ASSIGN(i, f) and charge $B_C(f, r) \cap U_i$ against $B_C(g_i, r) \cap U_i$.
- **Rule 3** Else if there is an $A \in \mathcal{A}$ such that $A \subseteq \bar{A}_i$:
ASSIGN($i, h(A)$) and charge $B_C(h(A), r) \cap U_i$ against $B_C(g_i, r) \cap U_i$.

If ASSIGN was called, charge against themselves all points in \bar{A}_i that have not been charged yet.

end

We start by showing that \bar{h} is an injection. Suppose f is assigned using Rule 1 or 2. Then f was not assigned so far as we only assign unassigned facilities. Now suppose $h(A) = \bar{h}(\bar{A}_i)$ is assigned using Rule 3. We claim that $h(A)$ is not assigned so far. Assume by the sake of deriving a contradiction that it was assigned in a previous iteration $j < i$. It cannot have been assigned by Rule 3, since h is injective. So assume it was assigned by Rule 1 or 2. Hence, g_j satisfies $B_C(g_j, 3r) \cap B_C(h(A), r) \cap U_j \neq \emptyset$. This implies that $d(g_j, h(A)) \leq 4r$ and thus $A \subseteq \bar{A}_j$, which contradicts $A \subseteq \bar{A}_i$.

Moreover, \bar{A}_i fulfills property 2a of a $(2L + 10, r)$ -partition because of the following. Let $f \in Z$ and $\bar{A}_i := \bar{h}^{-1}(f)$, and we have to show that $d(\bar{A}_i, f) \leq r$. Because $h(\bar{A}_i) = f$, we called at some point during Algorithm 2 the procedure $\text{ASSIGN}(i, f)$. In both Rule 1 and Rule 2 we have $B_C(f, r) \cap B_C(g_i, 3r) \cap U_i \neq \emptyset$, which implies that \bar{A}_i contains a client in $B_C(f, r)$, as desired. If $\text{ASSIGN}(i, f)$ was called in Rule 3, then we have $h^{-1}(f) \subseteq \bar{A}_i$, which implies $d(\bar{A}_i, f) \leq d(h^{-1}(f), f) \leq r$ by the fact that \mathcal{P} is an (L, r) -partition.

It remains to show that \bar{A} fulfills property 2b of an $(2L+10, r)$ -partition. We first consider the last color (color γ) and show $w_\gamma(\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}) \geq w_\gamma(B_C(Z, r))$. To this end, observe that the charging indeed charges clients in $B_C(Z, r)$ against clients in $\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$. We allow for charging a client in $B_C(Z, r)$ against more than one client in $\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$. However, no client in $\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$ gets charged against more than once because in iteration i we only charge against clients in \bar{A}_i , and the sets $\bar{\mathcal{A}} = \{\bar{A}_1, \dots, \bar{A}_{|F|}\}$ form a partition of C . Also note that we always charge clients of $B_C(Z, r)$ against clients of $\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}$ of at least the same w_γ -weight. This is true whenever charging happens in Rule 2 or Rule 3, because of the greediness property, and holds trivially for all other charging operations, which only charge clients against themselves. To conclude that $w_\gamma(\bigcup_{\bar{A} \in \bar{\mathcal{A}}} \bar{A}) \geq w_\gamma(B_C(Z, r))$, it remains to observe that all of $B_C(Z, r)$ gets charged against something.

To this end, fix a facility $f \in Z$. Consider an iteration j of Algorithm 2 such that $B_C(g_j, 3r) \cap U_j$ intersects $B_C(f, r)$. We claim that for each such iteration, either $\text{ASSIGN}(j, f)$ is called, or $B_C(f, r) \cap B_C(g_j, 3r) \cap U_j$ is charged. To prove the claim, suppose f is not assigned in iteration j . By Algorithm 2, either Rule 1 or Rule 2 must have applied in this iteration j , as f satisfies the condition of Rule 2. Thus ASSIGN was called on j and all points in \bar{A}_j have been charged. Now suppose the first case applies, i.e., $\text{ASSIGN}(j, f)$ is called for some j . Then all of $B_C(f, r) \cap U_j$ is charged (and $B_C(f, r) \setminus U_j$ is already charged by the second case). If the first case never applies, then all of $B_C(f, r)$ is charged by the second case since $U_{|F|}$ is empty. Hence, all of $B_C(f, r)$ is charged, as desired.

To see that property 2b of Definition 8 is fulfilled also for all colors $\ell \in [\gamma - 1]$, observe that Rule 3 makes sure that any component that was in \mathcal{A} will still be selected in $\bar{\mathcal{A}}$. Thus, $w_\ell(\bar{\mathcal{A}}) \geq w_\ell(B_C(Z, r))$ for all colors $\ell \in [\gamma]$.

It remains to show that $d(\bar{A}_i, \bar{h}(\bar{A}_i)) \leq r$. If Rule 1 or Rule 2 is applied, this is satisfied as there is a client $c \in B_C(g_i, 3r) \cap B_C(\bar{h}(\bar{A}_i), r) \cap U_i$; because $c \in \bar{A}_i$ by construction, we have $d(\bar{h}(\bar{A}_i), \bar{A}_i) \leq d(\bar{h}(\bar{A}_i), c) \leq r$. If Rule 3 is applied for $A \subseteq \bar{A}_i$, we also have $d(\bar{h}(\bar{A}_i), \bar{A}_i) \leq d(\bar{h}(\bar{A}_i), A) = d(h(A), A) \leq r$, where the last inequality follows from \mathcal{P} being an (L, r) -partition. \blacktriangleleft

Lemma 9 now follows readily from Lemma 14.

Proof of Lemma 9. The proof follows by induction on γ . For the induction start, consider $\gamma = 0$. The set $\{\{c\} : c \in C\}$ is a $(0, r)$ -partition on every 0-colorful space $(C \cup F, d, w)$. The induction step is given by Lemma 14. Note that $2(10(2^{\gamma-1} - 1)) + 10 = 10(2^\gamma - 1)$. The running time is clearly $O(\text{poly}(|X|, \gamma))$ as every step in the induction takes time $O(\text{poly}(|X|, \gamma))$.⁷ \blacktriangleleft

⁷ As briefly mentioned earlier, one can obtain slightly better constants, leading to existence and conductivity of $(8 \cdot 2^\gamma - 10, r)$ -partitions. This can be achieved by using $\gamma = 1$ as base case, for which our techniques can be shown to imply that there are $(6, r)$ -partitions. In the interest of simplicity, we use the slightly weaker bound in Lemma 9.

Abstract

We revisit the classical edge coloring problem for general graphs in the streaming model. In this model, the input graph is presented as a stream of edges, and the algorithm must report colors assigned to the edges in a streaming fashion, using a memory of size $O(n \text{ polylog } n)$ on graphs of up to $O(n^2)$ edges. In ESA 2019 and SOSA 2021, two elegant randomized algorithms were presented for this problem in the adversarial edge arrival model, where the latest one colors any input graph using $O(\Delta^2/s)$ colors with high probability in $\tilde{O}(ns)$ space. In this short note, we propose two extremely simple streaming algorithms that achieve the same color and space bounds deterministically. Besides being surprisingly simple, our algorithms do not use randomness at all, and are very simple to analyze.

1 Introduction

An edge coloring of a graph G is an assignment of colors to the edges such that no two adjacent edges receive the same color. The chromatic index of a graph G is the smallest number of colors required to properly color edges of G . Although determining the chromatic index is NP-hard [10], a classic theorem by Vizing states that any graph can be colored with at most $\Delta + 1$ colors, where Δ is the maximum degree of the graph. On the other hand, Δ colors are always required to properly color edges of a graph.

In this short note, we revisit the edge coloring problem in the streaming model, where edges of the input graph are presented to the algorithm one at a time in an adversarially chosen order. In this model, the memory available to the algorithm is less than the input size, and hence, we cannot store all the edges of the graph. We consider one-pass algorithms in which the amount of available space is $O(n \text{ polylog } n)$, which is also known as the semi-streaming model [9]. Moreover, since output in the edge coloring problem is as large as the input, we cannot wait to report the output after the whole stream is processed. Instead, we need to report colors of the edges in a streaming fashion, a typical approach usually referred to as W-streaming in the literature [8].

The edge coloring problem has been studied in various models of computation. In the offline model, there are polynomial-time algorithms that compute $(\Delta + 1)$ -edge colorings for general graphs [1, 11]. In the online model, Bar-Noy et al. [3] were the first to show that no algorithm can do better than the greedy algorithm, which uses at most $2\Delta - 1$ colors, no matter if the input graph is revealed edge by edge or vertex by vertex. However, their lower bound only holds when $\Delta = O(\log n)$. Therefore, research has been shifted towards online edge coloring of higher-degree graphs, i.e., when $\Delta = \omega(\log n)$. In particular, Cohen et al. [7] achieved the first positive result by giving an algorithm that uses $(1 + o(1))\Delta$ colors for

■ **Table 1** Summary of streaming algorithms for edge coloring in the adversarial edge arrival model. Here, $s = o(\Delta)$ is a space parameter.

ALGORITHM	TYPE	# COLORS	SPACE	REF
Behnezhad et al.	randomized	$O(\Delta^2)$ (w.h.p.)	$\tilde{O}(n)$	[4]
Charikar and Liu	randomized	$(1 + o(1))\Delta^2/s$ (w.h.p.)	$\tilde{O}(ns)$	[6]
This work	deterministic	$(1 + o(1))\Delta^2/s$	$O(ns)$	[here]

bipartite graphs in the adversarial vertex arrival setting. In the same setting, Saberi and Wajc [12] have recently presented a $(1.9 + o(1))\Delta$ algorithm for general graphs. In the random-order edge arrival, where edges of the graph are presented in a uniformly random order, the best current algorithm uses $(1 + o(1))\Delta$ colors due to Bhattacharia et al. [5], improving upon the previous 1.26Δ algorithm of Bahmani et al. [2].

In the streaming model, existing results in the online model cannot be typically applied due to memory restriction. Behnezhad et al. [4] were the first to provide $O(n \text{ polylog } n)$ -space streaming algorithms for the edge coloring problem. They proposed an algorithm reporting a $2e\Delta$ -coloring in the random edge arrival case, and another $O(\Delta^2)$ algorithm, when edges arrive in an arbitrary (adversarial) order. Charikar and Liu [6] improved these results by presenting an algorithm that uses $(1 + o(1))\Delta$ colors on random streams, and another algorithm in the adversarial edge arrival case that uses $O(\Delta^2/s)$ colors with high probability in $\tilde{O}(ns)$ space.

In this work, we focus on the adversarial edge arrival model, where edges of the input graph are revealed in an arbitrary order. In this setting, the algorithm of Behnezhad et al. [4] randomly decomposes the input graph into $O(\log n)$ bipartite subgraphs, and uses a distinct palette of colors for each subgraph. In particular, for each vertex v and each bipartite subgraph i , a counter $C_{v,i}$ is stored to denote the degree of v in the subgraph i . For each incoming edge (u, v) belonging to subgraph i , the color $(C_{u,i}, C_{v,i}, i)$ is assigned to that edge, and both $C_{u,i}$ and $C_{v,i}$ are incremented by one. Behnezhad et al. showed that with high probability, the number of colors used this way is $O(\Delta^2)$. Charikar and Liu [6] used a similar technique, but modified the way each edge is randomly assigned to bipartite subgraphs. They showed that their new algorithm uses $O(\Delta^2/s)$ colors with high probability, when available space is $\tilde{O}(ns)$.

In this short note, we propose two simple deterministic algorithms for the edge coloring problem in the adversarial arrival streams. Besides being extremely simple, our algorithms achieve the current state-of-the-art bounds on the space and number of colors, without using randomization. More precisely, our algorithms use $(1 + o(1))\Delta^2/s$ colors in the worst case using $O(ns)$ space, where $s = o(\Delta)$ ¹. To our knowledge, these are the first deterministic algorithms for the problem in the adversarial edge arrival streams. A summary of the results for edge coloring in the adversarial edge arrival model is presented in Table 1.

2 A Simple Greedy Algorithm

Our first algorithm uses a simple greedy approach to color edges of the input graph in an online manner. The algorithm simply colors each edge arrived with the first available color, and continues coloring until the memory is full. At that point, the algorithm deletes the most

¹ Note that when $s = \Omega(\Delta)$, an $O(ns)$ space is enough to store the entire graph.

frequently used color and discards all edges which use that color to free up some memory. The pseudocode of the algorithm is presented in Algorithm 1. Throughout the algorithm, we say that a color c is *available* for coloring an edge e , if no other edge incident to either endpoint of e has already received color c . Note that during the course of the algorithm, a deleted color will never be used again.

■ **Algorithm 1** A Simple Greedy Algorithm.

```

start with a color palette of size 1
for each edge  $e$  in the stream do
    if no color is available in the palette to color  $e$  then
        | add a new color to the palette
    end
    color  $e$  with an available color in the palette
    if the memory capacity is hit then
        | delete the most frequently used color  $c$  from the palette
        | remove all edges colored with  $c$  from memory
    end
end

```

► **Theorem 1.** *Algorithm 1 colors any input graph with $(1 + o(1))\Delta^2/s$ colors in $O(ns)$ space.*

Proof. It is easy to see that the algorithm reports a proper coloring. Consider two edges e_1 and e_2 incident to a vertex v , where e_1 arrives earlier than e_2 in the stream. Upon arrival of e_2 , if e_1 is still in memory, then its color will not be considered for coloring e_2 by the algorithm. On the other hand, if e_1 is not in memory, then its color has been permanently deleted from the palette, and hence will not be considered for coloring e_2 again.

To bound the number of colors used by the algorithm, first note that at any point of time during the execution of the algorithm, the color palette has size at most $2\Delta - 1$. This is because for any edge $e = (u, v)$ in the stream, at most $2(\Delta - 1) = 2\Delta - 2$ distinct colors are used by the edges incident to either u or v , as both endpoints have degree at most Δ . As such, a color palette of size $2\Delta - 1$ has at least one color available for coloring e , and hence, no new color is added to such palette by the algorithm. Therefore, for a memory of size ns , whenever the memory capacity is hit, the most popular color deleted by the algorithm has frequency at least $ns/2\Delta$. Thus, the total number of colors deleted during the course of the algorithm is at most $|E|/(ns/2\Delta)$, which is upper bounded by Δ^2/s , since $|E| \leq n\Delta/2$. Therefore, the total number of colors used by the algorithm is at most $(2\Delta - 1) + \Delta^2/s$ which is $(1 + o(1))\Delta^2/s$, for $s = o(\Delta)$. ◀

3 A Simple Buffering Algorithm

Algorithm 1 colors each arrived edge instantly in an online manner. In the streaming model, however, we can use our limited space to “buffer” a chunk of input stream before processing it and producing output. Using this buffering technique, we can achieve an even simpler algorithm. The idea behind our second algorithm is to simply buffer every chunk of $O(ns)$ edges and color it using a distinct palette of $\Delta + 1$ colors. We can use any offline $\Delta + 1$ coloring algorithm to color each chunk of the input. The pseudocode of our algorithm is presented in Algorithm 2.

► **Theorem 2.** *Algorithm 2 colors any input graph with $(1 + o(1))\Delta^2/s$ colors in $O(ns)$ space.*

8:4 Simple Streaming Algorithms for Edge Coloring

■ **Algorithm 2** A Simple Buffering Algorithm.

```
partition the stream into chunks of size  $ns$ 
for each chunk of edges do
  | color the chunk using a distinct palette of  $\Delta + 1$  colors
end
```

Proof. As a new palette is used for coloring each chunk, it is clear that the algorithm reports a proper edge coloring. To analyze the number of colors, we observe that the number of chunks is $|E|/ns$. Therefore, the total number of colors used is

$$\frac{|E|}{ns}(\Delta + 1) \leq \frac{n\Delta}{2ns}(\Delta + 1) = \left(\frac{1}{2} + o(1)\right)\Delta^2/s,$$

where the above inequality holds because $|E| \leq n\Delta/2$. ◀

► **Remark.** Algorithm 2 can be easily modified to work online by just replacing the offline $\Delta + 1$ coloring algorithm with an online $2\Delta - 1$ greedy one. The resulting algorithm uses $(1 + o(1))\Delta^2/s$ colors in the worst case.

Abstract

A polygon C is an *intersecting polygon* for a set \mathcal{O} of objects in \mathbb{R}^2 if C intersects each object in \mathcal{O} , where the polygon includes its interior. We study the problem of computing the minimum-perimeter intersecting polygon and the minimum-area convex intersecting polygon for a given set \mathcal{O} of objects. We present an FPTAS for both problems for the case where \mathcal{O} is a set of possibly intersecting convex polygons in the plane of total complexity n .

Furthermore, we present an exact polynomial-time algorithm for the minimum-perimeter intersecting polygon for the case where \mathcal{O} is a set of n possibly intersecting segments in the plane. So far, polynomial-time exact algorithms were only known for the minimum perimeter intersecting polygon of lines or of disjoint segments.

1 Introduction

Convex hulls are among the most fundamental objects studied in computational geometry. In fact, the problem of designing efficient algorithms to compute the convex hull of a planar point set \mathcal{O} – the smallest convex set containing \mathcal{O} – is one of the problems that started the field [5, 11]. Since the early days, the problem has been studied extensively, resulting in practical and provably efficient algorithms, in the plane as well as in higher dimensions; see the survey by Seidel [13, Chapter 26] for an overview.

A natural generalization is to consider convex hulls for a collection \mathcal{O} of geometric objects (instead of points) in \mathbb{R}^2 . Note that the convex hull of a set of polygonal objects is the same as the convex hull of the vertices of the objects. Hence, such convex hulls can be computed using algorithms for computing the convex hull of a point set. A different generalization, which leads to more challenging algorithmic questions, is to consider the smallest convex set that *intersects* all objects in \mathcal{O} . Thus, instead of requiring the convex set to fully contain each object from \mathcal{O} , we only require that it has a non-empty intersection with each object.

Notice that in case of points, the “smallest” set is well-defined: if convex sets C_1 and C_2 both contain a point set \mathcal{O} , then $C_1 \cap C_2$ also contains \mathcal{O} . Hence, the convex hull of a point set \mathcal{O} can be defined as the intersection of all convex sets containing \mathcal{O} . When \mathcal{O} consists of objects, however, this is no longer true, and the term “smallest” is ambiguous. In the present

paper we consider two variants: given a set \mathcal{O} of possibly intersecting convex polygons in \mathbb{R}^2 of total complexity n , find a convex set of minimum perimeter that intersects all objects in \mathcal{O} , or a convex set of minimum area that intersects all objects in \mathcal{O} .

Observe that a minimum-perimeter connected intersecting set C for \mathcal{O} must be a convex polygon. To see this, observe that for any object $o \in \mathcal{O}$ we can select a point $p_o \in o \cap C$, and take the convex hull of these points; the result is a feasible convex polygon whose perimeter is no longer than that of C . Thus the convexity of the solution could be omitted from the problem statement. This contrasts with the minimum-area problem, where there is always an intersecting polygon of zero area, namely, a tree. The convexity requirement is therefore essential in the problem statement. Note that it is still true that the minimum-area convex intersecting set is a polygon: given a convex solution, we can again take the convex hull of the points p_o and get a feasible solution whose area is not greater than the area of the initial convex solution. We also remark that the two problems typically have different optima. If \mathcal{O} consists of the three edges of an equilateral triangle, then the minimum-area solution is a line segment (that is, a degenerate polygon of zero area), whereas the minimum-perimeter solution is the triangle whose vertices are the midpoints of the edges.

The problem of computing minimum-area or minimum-perimeter convex intersecting polygons, as well as several related problems, have already been studied. Dumitrescu and Jiang [4] considered the minimum-perimeter intersecting polygon problem. They gave a constant-factor approximation algorithm as well as a PTAS for the case when the objects in \mathcal{O} are segments or convex polygons. They achieved a running time of $n^{O(1)/\varepsilon} + 2^{O(1/\varepsilon^{2/3})}n$. They also prove that computing a minimum-perimeter intersecting polygon for a set \mathcal{O} of non-convex polygons (or polygonal chains) is NP-hard. For convex input objects, however, the hardness proof fails. Hence, Dumitrescu and Jiang ask the following question.

Question 1. Is the problem of computing a minimum-perimeter intersecting polygon of a set of segments NP-hard?

In case of *disjoint* segments, a minimum-perimeter intersecting polygon can be found in polynomial time [6, 7], but for intersecting segments the question is still open.

The problem of computing smallest intersecting polygons for a set \mathcal{O} of objects has also been studied in works on *imprecise points*. Now the input is a set of points, but the exact locations of the points are unknown. Instead, for each point one is given a region where the point can lie. One can then ask questions such as: what is the largest possible convex hull of the imprecise points? And what is the smallest possible convex hull? If we consider the objects in our input set \mathcal{O} as the regions for the imprecise points, then the latter question is exactly the same as our problem of finding smallest intersecting convex sets. In this setup both the minimum-perimeter and minimum-area problem have been considered, for sets \mathcal{O} consisting of convex regions of total complexity n . There are exact polynomial-time algorithms for minimum (and maximum) perimeter and area, for the special case where \mathcal{O} consists of horizontal line segments or axis-parallel squares [10]. Surprisingly, some of these problems are NP-hard, such as the *maximum*-area/perimeter problems for segments. This gave rise to the study of approximation algorithms and approximation schemes [9].

In some cases, the minimum-perimeter problem can be phrased as a travelling salesman problem with neighborhoods (TSPN). Here the goal is to find the shortest closed curve intersecting all objects from the given set \mathcal{O} . In general, an optimal TSPN tour need not be convex, but one can show that in the case of lines or rays, an optimal tour is always convex: if a convex polygon intersects a line (or a ray) then its boundary intersects the line (resp. the ray). Therefore, computing a minimum-perimeter intersecting polygon of lines (or rays) is the same problem as TSPN with line neighborhoods (resp. ray neighborhoods). TSPN of

lines in \mathbb{R}^2 admits a polynomial-time algorithm [2]. In higher dimensions, TSPN has a PTAS for hyperplane neighborhoods [1], but notice that this is not the natural generalization of the minimum-intersecting polygon problem. Tan [12] proposed an exact algorithm for TSPN of rays in \mathbb{R}^2 , but there seems to be an error in the argument; see the full version for details. At the time of writing this article, we believe that a polynomial-time algorithm for TSPN of rays is not known, but there is a constant-factor approximation algorithm due to Dumitrescu [3], as well as a PTAS [4].

Our results. In order to resolve Question 1, we first need to establish a good structural understanding and a dynamic programming algorithm. It turns out that the algorithm can also be used for approximation. We give dynamic-programming-based approximation schemes for the minimum-perimeter and minimum-area convex intersecting polygon problems. Our first algorithm is a fully polynomial time approximation scheme (FPTAS) for the minimum-perimeter problem of arbitrary convex objects of total complexity n .

► **Theorem 1.** *Let \mathcal{O} be a set of convex polygons of total complexity n in \mathbb{R}^2 and let OPT be the minimum perimeter of an intersecting convex polygon for \mathcal{O} . For any given $\varepsilon > 0$, we can compute an intersecting polygon for \mathcal{O} whose perimeter is at most $(1 + \varepsilon) \cdot \text{OPT}$, in $O(n^{2.373}/\varepsilon + n/\varepsilon^8)$ time.*

This is a vast improvement over the PTAS given by Dumitrescu and Jiang [4], as the dependence on $1/\varepsilon$ is only polynomial in our algorithm. Our approximation algorithms work in a word-RAM model, where input polygons are defined by the coordinates of their vertices, and where each coordinate is a word of $O(\log n)$ bits.

We also get a similar approximation scheme for the minimum area problem, albeit with a slower running time. Here we rely more strongly on the fact that the objects of \mathcal{O} are convex *polygons*, and an extension to (for example) disks is an interesting open question. The full version details how the minimum-perimeter FPTAS needs to be adapted to the minimum-area setting.

► **Theorem 2.** *Let \mathcal{O} be a set of convex polygons of total complexity n in \mathbb{R}^2 and let OPT be the minimum area of an intersecting convex polygon for \mathcal{O} . For any given $\varepsilon > 0$, we can compute a convex intersecting polygon for \mathcal{O} whose area is at most $(1 + \varepsilon) \cdot \text{OPT}$, in $O(n^{17} \log(1/\varepsilon) + n^{11}/\varepsilon^{24})$ time.*

We remark that both Theorem 1 and Theorem 2 work if the input has *polytopes* instead of polygons, that is, when each object is the intersection of some half-planes.

While the dynamic programming algorithm developed above is crucial to get an exact algorithm, we are still several steps from being able to resolve Question 1. The main challenge here is that the vertices of the optimum intersecting polygon can be located at arbitrary boundary points in \mathcal{O} , and there is no known way to discretize the problem. We introduce a subroutine that uses an algorithm of Dror et al. [2] to compute parts of the minimum-perimeter intersecting polygon that contain no vertices of input objects. We are able to achieve a polynomial-time algorithm (on a real-RAM machine) for the minimum perimeter intersecting polygon problem only when the objects are line segments.

► **Theorem 3.** *Let \mathcal{O} be a set of n line segments in the plane. Then we can compute a minimum-perimeter intersecting polygon for \mathcal{O} in $O(n^9 \log n)$ time.*

If $P \neq NP$, then this gives a direct negative answer to Question 1. The theorem also extends to the case of rays (this is the scenario studied by Tan [12]; see the discussion in the full version).

Our techniques. Our approximation algorithms both compute an approximate solution whose vertices are from some fine grid. To determine a suitable grid resolution, we need to be able to compute lower bounds on OPT , which is non-trivial. It is also non-trivial to know where to place the grid, such that it is guaranteed to contain an approximate solution. The problem is that our lower bound gives us the location of a solution that is a constant-factor approximation, but this can be far from the location of a $(1 + \varepsilon)$ -approximation. Hence, for the minimum-area problem we generate a collection of grids, one of which is guaranteed to contain a $(1 + \varepsilon)$ -approximate solution. Finally, we face some further difficulties since a square grid may be insufficient: the optimum intersecting polygon may be extremely (exponentially) thin and long, and of area close to zero. In such cases there is no square grid of polynomial size that would contain a good solution. These problems are resolved in Section 2.

Section 3 presents our dynamic programming algorithm for minimum perimeter. In the dynamic programming the main technical difficulty lies in the fact that it is not clear what subset of objects should be visited in each subproblem. A portion of the optimum’s boundary could in principle be tasked with intersecting an arbitrary subset of \mathcal{O} , while some of the objects in \mathcal{O} need not be intersected by the optimum boundary and will simply be covered by the interior of the optimum intersecting polygon: a naïve approach therefore would not yield a polynomial-time algorithm. Our carefully designed subproblems have a clear corresponding set of objects to “visit”, using orderings of certain tangents of input objects for this purpose. The minimum area problem uses a similar dynamic program, see the full version for its details.

Finally, in order to present our exact algorithm in Section 4, we need to modify our dynamic program to deal with subproblems where the vertices of a convex chain do not come from a discretized set. In such cases, we have to find the order in which the objects of \mathcal{O} are visited by the chain. We are able to prove a specific ordering only in the case when the objects are line segments. The order then allows us to invoke the algorithm of Dror et al. [2] in a black-box manner.

2 Locating an optimal solution

The algorithms to be presented in subsequent sections need to approximately know the size and location of a smallest intersecting polygon. We use an algorithm from [4] to locate the minimum-perimeter intersecting polygon. With respect to the minimum-area intersecting polygon we prove that either there is a solution with a constant number of vertices (that can be computed with a different algorithm), or it is sufficient to consider polygons whose vertices are from a grid which comes from a polynomial collection of different grids.

Locating the minimum-perimeter optimum. For the minimum-perimeter intersecting polygon of a set \mathcal{O} of convex objects, Dumitrescu and Jiang [4] present an algorithm $A1$ that, for a given $\varepsilon_1 > 0$, outputs a rectangle R intersecting all input objects \mathcal{O} and with perimeter at most $\frac{4}{\pi}(1 + \varepsilon_1)\text{OPT}$. At a high level, $A1$ guesses an orientation of the rectangle among $\lceil \frac{\pi}{4\varepsilon_1} \rceil$ many discrete orientations and then uses a linear program to identify the smallest perimeter rectangle of that orientation that intersects \mathcal{O} . In [4] it is described how Algorithm $A1$ is used to locate an optimal solution if the input objects are convex polygons. In particular, for any $\varepsilon > 0$ running $A1$ with $\varepsilon_1 = \frac{\varepsilon}{2 + \varepsilon}$ gives a rectangle R . Let σ be the square that is concentric and parallel to R and has a side length of $3 \cdot \text{per}(R)$. Then the following holds.

► **Lemma 4** (Lemma 3 in [4]). *Suppose that $\text{per}(R) \geq (1 + \varepsilon)\text{OPT}$. Then there is an optimum polygon C_{opt} that is covered by σ .*

■ **Figure 1** (i) If v and adjacent sides of C_{opt} are disjoint from X , then we can slide v without increasing the area of C_{opt} . (ii) The points of Q (green) and their circumscribed ellipse E .

Algorithm A1 needs to solve $O(1/\varepsilon)$ many linear programs with $O(n)$ variables and $O(n)$ constraints each. Thus R and σ can be found in $O(T_{\text{LP}}(n)/\varepsilon)$ time, where $O(T_{\text{LP}}(n))$ is the running time of an LP solver with $O(n)$ variables and $O(n)$ constraints. The state-of-the-art LP solver by Jiang et al. [8] achieves a running time better than $O(n^{2.373})$. Lemma 4 directly implies that if $\text{per}(R) \geq (1 + \varepsilon)\text{per}(C_{\text{opt}})$, then

$$\text{diam}(C_{\text{opt}}) \leq \text{diam}(\sigma) = 3\sqrt{2}\text{per}(R) \leq 3\sqrt{2}\frac{4}{\pi}(1 + \varepsilon)\text{per}(C_{\text{opt}}) = O(\text{diam}(C_{\text{opt}})). \quad (1)$$

The shape and location of the minimum-area optimum. For the rest of this section, let X denote the set of vertices in the planar arrangement given by \mathcal{O} .

► **Lemma 5.** *Let C_{opt} be a minimum-area intersecting polygon for the input \mathcal{O} that has the minimum number of vertices, and among such polygons has the maximum number of points from X on its boundary. Then for any vertex v of C_{opt} that is not in X , the relative interior of at least one side of C_{opt} adjacent to v contains a point of X .*

Proof. Suppose for a contradiction that $v \notin X$ and that the relative interior of the sides in C_{opt} adjacent to v are disjoint from X . Observe that v must be on the boundary of an input object, so it is in the relative interior of an edge e of an input object, see Fig. 1(i). Then there exists a vector parallel to e along which we can move v while fixing its neighboring vertices in C_{opt} , without increasing the area of C_{opt} . This movement can be continued until we hit a point in X , or the angle of the polygon becomes π at v_1 or v_2 . As a result, we end up with a feasible polygon S whose area is no greater than that of C_{opt} , and it has one less vertex or at least one more point of X on its boundary. This contradicts the properties of C_{opt} . ◀

The following lemma is more involved. Its full proof can be found in the full version.

► **Lemma 6.** *For any given set of input polygons \mathcal{O} and $0 < \varepsilon < 1$ there is an intersecting polygon C of area $(1 + \varepsilon)\text{OPT}$ which either has at most 8 vertices, or its vertices are in a rectangular grid G of size $O(1/\varepsilon^3) \times O(1/\varepsilon^3)$ where G belongs to a collection \mathcal{G} of grids that can be generated in polynomial time.*

Proof sketch. Let $Q = X \cap \partial C_{\text{opt}}$. By Lemma 5 we can show that $|Q| \geq \lceil |V(C_{\text{opt}})|/2 \rceil$, so if $|V| \geq 9$, then $|Q| \geq 4$. We guess the circumscribed ellipse of Q , and use an affinity on the entire instance and C_{opt} which transforms the ellipse into a circle E . Wlog. we assume that E is the unit circle centered at the origin. It is known that the disk with boundary $\frac{1}{2}E$ is covered by $\text{conv}(Q)$ and thus by C_{opt} .

Consider the division of ∂C_{opt} defined by the points of Q . A *section* of ∂C_{opt} between two consecutive points of Q is a *spike* if it has a vertex $v \in V(C_{\text{opt}})$ that is at distance $\Omega(1/\varepsilon)$ from the origin. One can show that if such a spike exists, then $\text{area}(C_{\text{opt}})$ is $\Omega(1/\varepsilon)$.

On the other hand, we can show that C_{opt} cannot have more than 2 spikes. We then claim that if C_{opt} has a spike, then there is a polygon on at most 8 vertices that has area at most $(1 + \varepsilon)\text{area}(C_{\text{opt}})$. This is because C_{opt} can be covered by the intersection of the “cones” defined by the spike(s), which defines a polygon C . We can show that the extra area in the intersection of the (at most two) spike cones is $O(1)$, thus $\text{area}(C) \leq (1 + \varepsilon)\text{area}(C_{\text{opt}})$, and C has at most 8 vertices, as desired.

If C_{opt} has no spikes, then all of its vertices are within distance $O(1/\varepsilon)$ from the origin. We define a fine grid G (that depends on the guessed ellipse E) in the radius $O(1/\varepsilon)$ square around the origin, and use standard arguments to show that the minimum area intersecting polygon whose vertices are from G has area at most $(1 + \varepsilon)\text{OPT}$. We can therefore return all the grids G for each guess of the circumscribed ellipse of Q . ◀

3 An FPTAS for the minimum-perimeter problem of convex objects in the plane

Let \mathcal{O} be a set of n convex objects in the plane for which we want to compute a minimum-perimeter convex intersecting polygon. We assume that \mathcal{O} cannot be stabbed by a single point – this is easy to test without increasing the total running time. Since a minimum-perimeter intersecting polygon is necessarily convex, we will from now on drop the adjective “convex” from our terminology. We do this even when referring to convex intersecting polygons that are not necessarily of minimum perimeter.

In the previous section we have seen that for any $\varepsilon > 0$, we can find a feasible rectangle R and a square σ with the following property: Either $\text{per}(R) \leq (1 + \varepsilon)\text{OPT}$, or $C_{\text{opt}} \subseteq \sigma$ with $\text{diam}(C_{\text{opt}}) = \Omega(1)\text{diam}(\sigma)$. Next we describe an algorithm that, given a parameter $\varepsilon > 0$ and a corresponding square σ , outputs an intersecting polygon $C^* \subseteq \sigma$ for \mathcal{O} such that if $\text{per}(R) \geq (1 + \varepsilon)\text{per}(C_{\text{opt}})$ then $\text{per}(C^*) \leq (1 + \varepsilon)\text{OPT}$, where $\text{OPT} = \text{per}(C_{\text{opt}})$ (cf. Lemma 4 and Equation 1). Finally, we output either R or C^* , whichever has smaller perimeter.

Our algorithm starts by partitioning σ into a regular grid $G(\sigma)$ of $O(1/\varepsilon^2)$ cells of edge length at most $(\varepsilon/8) \cdot \text{OPT}$. We say that a convex polygon is a *grid polygon* if its vertices are grid points from $G(\sigma)$. The following observation is standard, but a full proof can be found in the full version.

► **Observation 7.** *Suppose σ contains an optimal solution C_{opt} . Let $C(\sigma)$ be a minimum-perimeter grid polygon that is an intersecting polygon for \mathcal{O} . Then $\text{per}(C(\sigma)) \leq (1 + \varepsilon) \cdot \text{OPT}$.*

Next we describe an algorithm to compute a minimum-perimeter grid polygon $C(\sigma)$ that is an intersecting polygon for \mathcal{O} .

First, we “guess” the lexicographically smallest vertex v_{bot} of $C(\sigma)$, see Figure 2(i). We can guess v_{bot} in $O(1/\varepsilon^2)$ different ways. For each possible guess we will find the best solution (if it exists), and then we report the best solution found over all guesses.

Now consider a fixed guess for the lexicographically smallest vertex v_{bot} of $C(\sigma)$. With a slight abuse of notation we will use $C(\sigma)$ to denote a minimum-perimeter grid polygon that is an intersecting polygon of \mathcal{O} and that has v_{bot} as lexicographically smallest vertex. (If the polygon $C(\sigma)$ does not exist, the algorithm described below will detect this.) We will compute $C(\sigma)$ by dynamic programming.

The vertices of $C(\sigma)$ are grid points in the region $h^+ \setminus \rho_0$, where h^+ is the closed half-plane above the horizontal line through v_{bot} and ρ_0 is the horizontal ray emanating from v_{bot} and pointing to the left. Let V be the set of such grid points, excluding v_{bot} . We first order the points from V in angular order around v_{bot} . More precisely, for a point $v \in V$, let $\phi(v)$ denote

Figure 2 (i) The wedge defined by ρ_0 and $\rho(w)$ is shown in light grey. Objects in $\mathcal{O}(v, w)$ are red, objects in $\mathcal{O} \setminus \mathcal{O}(v, w)$ are blue. (ii) The partial solution $C(\Gamma)$ must be contained in the red region, while $C \setminus C(\Gamma)$ must lie in the blue region. There are four situations, depending on whether the angle between ρ_0 and $\rho(w)$ is acute or not, and whether the line containing vw intersects ρ_0 or not.

the angle over which we have to rotate ρ_0 in clockwise direction until we hit v . For two points $v, w \in V$, we write $v \prec w$ if $\phi(v) < \phi(w)$. Let $V^+ := V \cup \{v_{\text{bot}}, \bar{v}_{\text{bot}}\}$, where \bar{v}_{bot} is a copy of v_{bot} , and define $v_{\text{bot}} \prec v$ and $v \prec \bar{v}_{\text{bot}}$ for all $v \in V$. The copy \bar{v}_{bot} serves to distinguish the start and the end vertex of the clockwise circular sequence of vertices of $C(\sigma)$. Note that if $v_{\text{bot}}, v_1, \dots, v_k, \bar{v}_{\text{bot}}$ denotes this circular sequence then $v_{\text{bot}} \prec v_1 \prec \dots \prec v_k \prec \bar{v}_{\text{bot}}$ (since $C(\sigma)$ will never have two vertices that make the same angle with v_{bot}).

We now describe our dynamic-programming algorithm. Consider a polyline from v_{bot} to some point $v \in V$. We say that this polyline is a *convex chain* if, together with the line segment vv_{bot} , it forms a convex polygon. We denote the convex polygon induced by such a chain Γ by $C(\Gamma)$. The problem we now wish to solve is as follows:

Compute a minimum-length convex chain Γ^* from v_{bot} to \bar{v}_{bot} such that $C(\Gamma^*)$ is an intersecting polygon for \mathcal{O} .

Our dynamic-programming algorithm uses the partial order \prec defined above. We now want to define a subproblem for each point $v \in V^+$, which is to find the “best” chain Γ_v ending at v . For this to work, we need to know which objects from \mathcal{O} should be covered by the partial solution $C(\Gamma_v)$. This is difficult, however, because objects that intersect the ray from v_{bot} and going through v could either be intersected by $C(\Gamma_v)$ or by the part of the solution that comes after v . To overcome this problem we let the subproblems be defined by the last edge on the chain, instead of by the last vertex. This way we can decide which objects should be covered by a partial solution, as explained next.

Consider a convex chain from v_{bot} to a point $w \in V^+$ whose last edge is vw . Let $\rho(w)$ be the ray emanating from v_{bot} in the direction of w , and let $\rho^*(w)$ be the part of the ray starting at w . For $w = \bar{v}_{\text{bot}}$ we define $\rho(w)$ to be the horizontal ray emanating from v_{bot} and going to the right, and we define $\rho^*(w) = \rho(w)$. For an object $o_i \in \mathcal{O}$ that intersects $\rho^*(w)$, let $\ell_w(o_i)$ be a line that is tangent to o_i at the first intersection point of $\rho^*(w)$ with o_i . We now define the set $\mathcal{O}(v, w)$ to be the subset of objects $o_i \in \mathcal{O}$ such that one of the following conditions is satisfied; see also Figure 2(i).

- (i) o_i intersects the wedge defined by ρ_0 and $\rho(w)$, but not $\rho(w)$ itself; or
- (ii) o_i intersects $v_{\text{bot}}w$; or
- (iii) o_i intersects $\rho^*(w)$ but not $v_{\text{bot}}w$, and the tangent line $\ell_w(o_i)$ intersects the half-line containing vw and ending at w .

The next lemma shows that we can use the sets $\mathcal{O}(v, w)$ to define our subproblems.

► **Lemma 8.** *Let C be any convex polygon that is an intersecting polygon for \mathcal{O} and that has v_{bot} as lexicographically smallest vertex and vw as one of its edges. Let Γ_w be the part of ∂C from v_{bot} to w in clockwise direction. Then all objects in $\mathcal{O}(v, w)$ intersect $C(\Gamma_w)$ and all objects in $\mathcal{O} \setminus \mathcal{O}(v, w)$ intersect $C \setminus C(\Gamma_w)$.*

9:8 Computing Smallest Convex Intersecting Polygons

We can now state our dynamic program. To this end we define, for two points $v, w \in V^+$ with $v \prec w$, a table entry $A[v, w]$ as follows.

$A[v, w] :=$ the minimum length of a convex chain Γ from v_{bot} to w whose last edge is vw and such that all objects in $\mathcal{O}(v, w)$ intersect $C(\Gamma)$,

where the minimum is ∞ if no such chain exists. Lemma 8 implies the following.

► **Observation 9.** *Let Γ^* be a shortest convex chain from v_{bot} to \bar{v}_{bot} such that $C(\Gamma^*)$ is an intersecting polygon for \mathcal{O} . Then $\text{length}(\Gamma^*) = \min\{A[v, \bar{v}_{\text{bot}}] : v \in V \text{ and } \mathcal{O}(v, \bar{v}_{\text{bot}}) = \mathcal{O}\}$.*

Hence, if we can compute all table entries $A[v, w]$ then we have indeed solved our problem. (The lemma only tells us something about the value of an optimal solution, but given the table entries $A[v, w]$ we can compute the solution itself in a standard way.)

The entries $A[v, w]$ can be computed using the following lemma. Define $\Delta(v_{\text{bot}}, v, w)$ to be the triangle with vertices v_{bot}, v, w .

► **Lemma 10.** *Let $v, w \in V^+$ with $v \prec w$. Let $V(v, w)$ be the set of all points $u \in V \cup \{v_{\text{bot}}\}$ with $u \prec v$ such that u lies below the line $\ell(v, w)$ through v and w and such that all objects in $\mathcal{O}(v, w) \setminus \mathcal{O}(u, v)$ intersect $\Delta(v_{\text{bot}}, v, w)$. Then*

$$A[v, w] = \begin{cases} |v_{\text{bot}}w| & \text{if } v = v_{\text{bot}} \text{ and all objects in } \mathcal{O}(v, w) \text{ intersect } v_{\text{bot}}w \\ \infty & \text{if } v = v_{\text{bot}} \text{ and not all objects in } \mathcal{O}(v, w) \text{ intersect } v_{\text{bot}}w \\ |vw| + \min_{u \in V(v, w)} A[u, v] & \text{otherwise} \end{cases}$$

Putting everything together, we can finish the proof of Theorem 1.

Proof of Theorem 1. We first use algorithm A1 from [4] to compute the rectangle R and the square σ , which as discussed can be done in $O(n^{2.373}/\varepsilon)$ time. For a square σ we guess the vertex v_{bot} in $O(1/\varepsilon^2)$ different ways.

For each guess we run the dynamic-programming algorithm described above. There are $O(1/\varepsilon^4)$ entries $A[u, v]$ in the dynamic-programming table. The most time-consuming computation of a table entry is in the third case of Lemma 10. Here we need to compute the set $\mathcal{O}(v, w)$, which can be done in $O(n)$ time by checking every $o_i \in \mathcal{O}$. For each of the $O(1/\varepsilon^2)$ points with $u \prec v$ such that u lies below the line $\ell(v, w)$ we then check in $O(n)$ time if all objects in $\mathcal{O}(v, w) \setminus \mathcal{O}(u, v)$ intersect $\Delta(v_{\text{bot}}, v, w)$, so that we can compute $A[v, w]$. Hence, computing $A[v, w]$ takes $O(n/\varepsilon^2)$ time, which implies that the whole dynamic program needs $O(n/\varepsilon^6)$ time.

Thus the algorithm takes $O(n^{2.373}/\varepsilon) + O(1/\varepsilon^2) \cdot O(n/\varepsilon^6) = O(n^{2.373}/\varepsilon + n/\varepsilon^8)$ time. ◀

► **Remark 11.** Although Theorem 1 is stated only for the case where \mathcal{O} is a set of convex polygons, it is not too hard to extend it to other convex objects, for example disks: one just needs to replace the approximate rectangle-finding linear program of Dumitrescu and Jiang [4] with some other polynomial-time algorithm to find an (approximate) minimum perimeter intersecting rectangle in each of the $O(1/\varepsilon)$ orientations.

■ **Figure 3** (i) Subroutine I computes a minimum perimeter intersecting polygon whose vertices are not segment endpoints. (ii) Subroutine II computes a polygon with fixed edge uv for some (sub)set of segments. With the exception of u and v , the polygon's vertices are not allowed to be segment endpoints.

4 An exact algorithm for the minimum-perimeter intersecting polygon of segments

We describe an exact algorithm to compute a minimum-perimeter intersecting object for a set \mathcal{O} of line segments¹ in the plane. Consider an optimal solution C_{opt} , and let Y be the set of all endpoints of the segments in \mathcal{O} . The exact algorithm is based on two subroutines for the following two problems. As before, whenever we talk about intersecting polygons, we implicitly require them to be convex. Figure 3 illustrates the polygons computed by these subroutines.

- *Subroutine I*: If \mathcal{O} admits a minimum-perimeter intersecting polygon with none of its vertices being in Y , then compute such a polygon. Otherwise compute a feasible intersecting polygon, or report $+\infty$.
- *Subroutine II*: Given two points $u, v \in \mathbb{R}^2$ and a subset $\mathcal{O}' \subseteq \mathcal{O}$, decide if \mathcal{O}' admits a minimum-perimeter intersecting polygon that has uv as one of its edges and none of whose other vertices belongs to Y and, if so, compute a minimum-perimeter such intersecting polygon. If no such minimum-perimeter intersecting polygon exists, report $+\infty$. Note that we allow $u = v$, in which case the edge uv degenerates to a point.

In the full version we show:

► **Theorem 12.** *There exist exact algorithms for Subroutine I and Subroutine II that run in time $O(n^6 \log n)$ and $O(n^3 \log n)$, respectively.*

Setting the stage for the dynamic program

With Subroutine I available, it remains to find the minimum-perimeter intersecting polygon that has at least one vertex from Y . To this end we will develop an algorithm that, for a given point $p_{\text{bot}} \in Y$, finds a minimum-perimeter convex intersecting polygon that has p_{bot} as a vertex (if it exists). We will run this algorithm for each choice of $p_{\text{bot}} \in Y$.

Let $p_{\text{bot}} \in Y$ be given, and assume that \mathcal{O} admits an intersecting polygon that has p_{bot} as a vertex (this can be tested in $O(n \log n)$ time). In contrast to Section 3, p_{bot} need not be the lexicographically smallest point and our algorithm therefore relies on guessing the

¹ Although we describe our algorithm for non-degenerate segments, all our arguments also work if some (or all) of the segments are in fact lines, rays, or even points.

9:10 Computing Smallest Convex Intersecting Polygons

■ **Figure 4** (i) The grey double wedge indicates the region containing the tangent at p_{bot} . (Note that then there must be more segments than the blue and red segments that are shown. In particular, there must be segments parallel to the lines delimiting the double wedge.) The blue segments are in $\mathcal{O}(\rho_0)^+$ so they must be intersected by C_{opt}^+ , while the red segment is in $\mathcal{O}(\rho_0)^-$ and must be intersected by C_{opt}^- . (ii) The definition of $\psi_w(o_i)$.

orientation of a line tangent to C_{opt} at p_{bot} . More specifically, we are able to find a set $\Psi = \{\psi_1, \psi_2, \dots\}$, of $O(n)$ possible angles with $\psi_j < \psi_{j+1}$ for all $0 \leq j \leq |\Psi|$ (where we set $\psi_0 := 0$ and $\psi_{|\Psi|+1} = \pi$) and reduce the problem to:

Given a point p_{bot} and value j with $0 \leq j \leq |\Psi|$, find a minimum-perimeter intersecting polygon C_{opt} for \mathcal{O} such that

- p_{bot} is a vertex of C_{opt} ,
- the horizontal ray ρ_0 going from p_{bot} to the left does not intersect C_{opt} ,
- C_{opt} has a tangent line ℓ at p_{bot} such that the clockwise angle from ρ_0 to ℓ lies in the range $[\psi_j, \psi_{j+1}]$.

In the above, each angle ψ_j corresponds to the angle over which we have to rotate ρ_0 clockwise so that it becomes parallel with some segment $o_j \in \mathcal{O}$. An extensive description of this reduction can be found in the full version.

The dynamic program

We will now develop our dynamic program for the problem that we just stated, for a given point $p_{\text{bot}} \in Y$, a ray ρ_0 , and range $[\psi_j, \psi_{j+1}]$; see Figure 4(i).

Let $\mathcal{O}(\rho_0) \subseteq \mathcal{O}$ denote the set of segments that intersect the ray ρ_0 , and let ℓ_0 be the line containing ρ_0 . The line ℓ_0 may split the optimal solution C_{opt} into two parts: a part C_{opt}^+ above ℓ_0 and a part C_{opt}^- below ℓ_0 . Let $\psi(o_i)$ denote the angle over which we have to rotate ρ_0 in clockwise direction until it becomes parallel to o_i . Since we have fixed the range of the tangent at p_{bot} to lie in the range $[\psi_j, \psi_{j+1}]$, we can split $\mathcal{O}(\rho_0)$ into two subsets, $\mathcal{O}(\rho_0)^+ := \{o_i \in \mathcal{O}(\rho_0) : \psi(o_i) \geq \psi_{j+1}\}$ and $\mathcal{O}(\rho_0)^- := \{o_i \in \mathcal{O}(\rho_0) : \psi(o_i) \leq \psi_j\}$.

Note that $\mathcal{O}(\rho_0) = \mathcal{O}(\rho_0)^+ \cup \mathcal{O}(\rho_0)^-$, because ψ_j and ψ_{j+1} are consecutive angles in Ψ . Because the orientation of the tangent at p_{bot} lies in the range $[\psi_j, \psi_{j+1}]$, we know that the segments in $\mathcal{O}(\rho_0)^+$ must be intersected by C_{opt}^+ , while the segments in $\mathcal{O}(\rho_0)^-$ must be intersected by C_{opt}^- ; see Figure 4(i). Intuitively, the segments in $\mathcal{O}(\rho_0)^+$ must be intersected by “the initial part” of C_{opt} , while the segments in $\mathcal{O}(\rho_0)^-$ are intersected by “the later part”. We will use this when we define the subproblems in our dynamic program.

In Section 3 we defined subproblems for pairs of grid points v, w . The goal of such a subproblem was to find the minimum-length convex chain Γ such that $C(\Gamma)$ intersects a certain subset $\mathcal{O}(v, w)$ and whose last edge is vw . The fact that we knew the last edge vw was crucial to define the set $\mathcal{O}(v, w)$, since the slope of vw determined which objects should be intersected by $C(\Gamma)$. In the current setting this does not work: we could define a subproblem for pairs $v, w \in Y$, but “consecutive” vertices v, w from Y along Γ are now connected by a

polyline Z_{vw} whose inner vertices are disjoint from Y . The difficulty is that the polyline Z_{vw} depends on the segments that need to be intersected by $C(\Gamma)$. Hence, there is a cyclic dependency between the set of segments to be intersected by $C(\Gamma)$ (which depends on the slope of zw , where z is the vertex of Z_{vw} preceding w) and the vertex z (which depends on the segments that need to be intersected by $C(\Gamma)$). We overcome this problem as follows.

Similarly to the previous section, we call a polyline Γ from p_{bot} to some point $v \in Y$ a *convex chain* if, together with the line segment vp_{bot} , it forms a convex polygon. We denote this polygon by $C(\Gamma)$. Consider a convex chain Γ_w ending in a point $w \in Y$. Let $\rho(w)$ denote the ray from p_{bot} through w and let $\rho^*(w)$ be the part of this ray starting at w . Let $\mathcal{O}(w)$ be the set of input segments that intersect $\rho^*(w)$. Of those segments, $C(\Gamma_w)$ must intersect the ones such that the line $\ell(o_i)$ containing² the segment o_i intersects the half-line containing zw and ending at w , where z is the (unknown) vertex preceding w . For a segment $o_i \in \mathcal{O}(w)$, let $\psi_w(o_i)$ be the angle over which we have to rotate $\rho(w)$ in clockwise direction to make it parallel to o_i ; see Figure 4(ii). Let $\Psi(w) = \{\psi_1, \psi_2, \dots\}$, for all $1 \leq j < |\Psi(w)|$, be the sorted set of (distinct) angles $\psi_w(o_i)$ defined by the segments in $\mathcal{O}(w)$. For an index j with $1 \leq j \leq |\Psi(w)|$, define $\mathcal{O}(w, j) := \{o_i \in \mathcal{O}(w) : \psi_w(o_i) \leq \psi_j\}$, and define $\mathcal{O}(w, 0) = \emptyset$. We call $\mathcal{O}(w, j)$ a *prefix set*. The key observation is that $C(\Gamma_w)$ must intersect the segments from some prefix set $\mathcal{O}(w, j)$, where j depends on the unknown vertex z preceding w . So our dynamic program will try all possible prefix sets $\mathcal{O}(w, j)$, and make sure that subproblems are combined in a consistent manner.

We now have everything in place to describe our dynamic-programming table. It consists of entries $A[w, j]$, where w ranges over all points in Y , and j ranges over all values for which $\mathcal{O}(w, j)$ is defined. For convenience add two special entries, $A[p_{\text{bot}}, 0]$ and $A[\bar{p}_{\text{bot}}, 0]$; the former will serve as the base case, and the latter will contain (the value of) the final solution. Note that these are the only ones for p_{bot} and \bar{p}_{bot} , and that we have at most $|Y| \cdot n = O(n^2)$ entries. We define the set $\mathcal{O}^*(w, j)$ of segments to be covered in a subproblem.

For a point $w \in Y$, the set $\mathcal{O}^*(w, j)$ consists of the segments $o_i \in \mathcal{O}$ that satisfy one of the following conditions:

- (i) o_i intersects the clockwise wedge from ρ_0 to $\rho(w)$ – note that this wedge need not be convex – but not $\rho(w)$ itself, and $o_i \notin \mathcal{O}^-(\rho_0)$; or
- (ii) o_i intersects $p_{\text{bot}}w$; or
- (iii) $o_i \in \mathcal{O}(w, j)$.

Furthermore, $\mathcal{O}^*(p_{\text{bot}}, 0) := \emptyset$ and $\mathcal{O}^*(\bar{p}_{\text{bot}}, 0) := \mathcal{O}$.

We would like now to define $A[w, j]$ to be the minimum length of a convex chain Γ from p_{bot} to w such that all objects in $\mathcal{O}^*(w, j)$ intersect $C(\Gamma)$. There is, however, a technicality to address: the minimum-perimeter polygon that intersects all segments from \mathcal{O} need not be convex when we require it to have p_{bot} as a vertex. Such a non-convex polygon cannot be the final solution – if the optimum for a given choice of p_{bot} is non-convex, then p_{bot} was not the correct choice – but it makes a clean definition of our subproblems awkward. Therefore, instead of first defining the subproblems and then giving the recursive formula, we will immediately give the recursive formula and then prove that it computes what we want.

For two points $v, w \in Y^+$ (where $Y^+ = Y \cup \{\bar{p}_{\text{bot}}\}$) with $v \prec w$ and a set $\mathcal{O}' \subseteq \mathcal{O}$, let $L(v, w, \mathcal{O}')$ be the minimum length of a convex chain Γ from v to w such that the convex polygon defined by Γ and vw is an intersecting set for \mathcal{O}' and all inner vertices of Γ are disjoint from Y . Recall that we can compute $L(v, w, \mathcal{O}')$ using subroutine II. As before, let $\Delta(p_{\text{bot}}, v, w)$ denote the triangle with vertices p_{bot}, v, w .

² Since the input objects are now segments, the tangent line $\ell_w(o_i)$ is just the line containing o_i .

9:12 Computing Smallest Convex Intersecting Polygons

► **Definition 13.** Let $w \in Y^+$ and j be a value for which $\mathcal{O}[w, j]$ is defined. Thus $0 \leq j \leq |\Psi(w)|$, where we set $|\Psi(w)| := 0$ for $w \in \{p_{\text{bot}}, \bar{p}_{\text{bot}}\}$. For $v \prec w$ and $0 \leq j' \leq |\Psi(v)|$, let

$$\mathcal{O}^*(w, j, v, j') := \mathcal{O}^*(w, j) \setminus \left(\mathcal{O}^*(v, j') \cup \{o_i \in \mathcal{O} : o_i \text{ intersects } \Delta(p_{\text{bot}}, v, w)\} \right)$$

and define

$$A[w, j] := \begin{cases} 0 & \text{if } w = p_{\text{bot}} \\ \min_{\substack{v \prec w \\ 0 \leq j' \leq |\Psi(v)|}} L(v, w, \mathcal{O}^*(w, j, v, j')) + A[v, j'] & \text{otherwise.} \end{cases}$$

The next lemma implies that the table entry $A[\bar{p}_{\text{bot}}, 0]$ defined by this recursive formula gives us what we want. Part (a) implies that $A[\bar{p}_{\text{bot}}, 0]$ will never return a value that is too small, while part (b) implies that for the correct choice of p_{bot} and range of orientations for the tangent to C_{opt} at p_{bot} , the entry $A[\bar{p}_{\text{bot}}, 0]$ gives us (the value of) the optimal solution.

► **Lemma 14.** Consider the table entry $A[\bar{p}_{\text{bot}}, 0]$ defined by Definition 13 for a given point p_{bot} and range $[\psi_i, \psi_{i+1}]$.

- (a) There exists a convex intersecting polygon for \mathcal{O} of perimeter at most $A[\bar{p}_{\text{bot}}, 0]$.
- (b) If p_{bot} is a vertex of the minimum-perimeter convex intersecting polygon C_{opt} for \mathcal{O} , and ρ_0 does not intersect C_{opt} , and there is a tangent line ℓ at p_{bot} whose orientation is in the range $[\psi_i, \psi_{i+1}]$, then $\text{per}(C_{\text{opt}}) = A[\bar{p}_{\text{bot}}, 0]$.

Putting everything together

Lemma 14 implies that after solving the dynamic programs for all choices of p_{bot} and the range $[\psi_i, \psi_{i+1}]$, we have found the minimum perimeter intersecting set for \mathcal{O} . (Computing the intersecting set itself, using the relevant dynamic-program table, is then routine.) This leads to the proof of Theorem 3.

Proof of Theorem 3. The number of dynamic programs solved is $O(|Y| \cdot n) = O(n^2)$. The dynamic-programming tables have $O(n^2)$ entries. Computing an entry takes $O(|Y| \cdot n) = O(n^2)$ calls to Subroutine II, at $O(n^3 \log n)$ time each. The dynamic programs thus take $O(n^2) \cdot O(n^2) \cdot O(n^2) \cdot O(n^3 \log n) = O(n^9 \log n)$ time. If the optimal solution does not go through any point of Y , then by Theorem 12 it will be found in $O(n^6 \log n)$ time. The optimum of these two algorithms is the global optimum. ◀

5 Conclusion

We gave fully polynomial time approximation schemes for the minimum perimeter and minimum area convex intersecting polygon problems for convex polygons. Additionally, we developed a polynomial-time algorithm for the minimum perimeter problem of segments.

It is likely that the running times of our algorithms can be improved further. One could also try to generalize the set of objects, for example, adapting the minimum area algorithm to arbitrary convex objects. We propose the following open questions for further study.

- Is there a polynomial-time exact algorithm for the minimum area convex intersecting polygon of segments?
- Is there a polynomial-time exact algorithm for minimum perimeter or minimum area convex intersecting polygon of convex polygons, or are these problems NP-hard?

- Is there a polynomial-time approximation scheme for the minimum volume or minimum surface area convex intersecting polytope of convex polytopes in \mathbb{R}^3 ? Can we at least approximate the diameter of the optimum solution to these problems?

It would be especially interesting to see an NP-hardness proof for minimum volume or surface area convex intersecting set of convex objects in higher dimensions.

The Price of Hierarchical Clustering

Anna Arutyunova ✉

Universität Bonn, Germany

Abstract

Hierarchical Clustering is a popular tool for understanding the hereditary properties of a data set. Such a clustering is actually a sequence of clusterings that starts with the trivial clustering in which every data point forms its own cluster and then successively merges two existing clusters until all points are in the same cluster. A hierarchical clustering achieves an approximation factor of α if the costs of each k -clustering in the hierarchy are at most α times the costs of an optimal k -clustering. We study as cost functions the maximum (discrete) radius of any cluster (k -center problem) and the maximum diameter of any cluster (k -diameter problem).

In general, the optimal clusterings do not form a hierarchy and hence an approximation factor of 1 cannot be achieved. We call the smallest approximation factor that can be achieved for any instance the *price of hierarchy*. For the k -diameter problem we improve the upper bound on the price of hierarchy to $3 + 2\sqrt{2} \approx 5.83$. Moreover we significantly improve the lower bounds for k -center and k -diameter, proving a price of hierarchy of exactly 4 and $3 + 2\sqrt{2}$, respectively.

1 Introduction

Clustering is an ubiquitous task in data analysis and machine learning. In a typical clustering problem, the goal is to partition a set of objects into different clusters such that only similar objects belong to the same cluster. There are numerous ways how clustering can be modeled formally and many different models have been studied in the literature in the last decades. In many theoretical models, one assumes that the data comes from a metric space and that the desired number of clusters is given. Then the goal is to optimize some objective function like k -center, k -median, or k -means. In most cases the resulting optimization problems are NP-hard and hence approximation algorithms have been studied extensively.

One aspect of real-world clustering problems that is not captured by these models is that it is often already a non-trivial task to determine for a given data set the right or most reasonable number of clusters. One particularly appealing way to take this into account is hierarchical clustering. A hierarchical clustering of a data set is actually a sequence of clusterings, one for each possible number of clusters. It starts with the trivial clustering in which every data point forms its own cluster and then successively merges two existing clusters until all points are in the same cluster. This way for every possible number of clusters, a clustering is obtained. These clusterings help to understand the hereditary properties of the data and they provide information at different levels of granularity.

While hierarchical clustering is successfully used in many applications, it is not as well understood from a theoretical point of view as the models in which the number of clusters is given as part of the input. One reason for this is that it is not obvious how the quality of a hierarchical clustering should be measured. A possibility that has been explored in the literature is to define the quality of a hierarchical clustering based on its worst level. To be precise, let (\mathcal{X}, d) be a metric space and $\mathcal{P} \subset \mathcal{X}$ a set of n points. Furthermore let $\mathcal{H} = (\mathcal{H}_n, \dots, \mathcal{H}_1)$ be a hierarchical clustering of \mathcal{P} , where \mathcal{H}_k denotes a k -clustering, i.e., a clustering with at most k non-empty clusters. Then \mathcal{H}_{k-1} arises from \mathcal{H}_k by merging some of the existing clusters. We assume that some objective function like k -center, k -median, or k -means is selected and denote by $\text{cost}(\mathcal{H}_k)$ the objective value of \mathcal{H}_k with respect to the selected objective function. Furthermore, let \mathcal{O}_k denote an optimal k -clustering and let $\text{cost}(\mathcal{O}_k)$ denote its objective value. Then we say that \mathcal{H} achieves an approximation factor of $\alpha \geq 1$ if $\text{cost}(\mathcal{H}_k) \leq \alpha \cdot \text{cost}(\mathcal{O}_k)$ for every k , assuming that cost is an objective that is to be minimized. In this work we consider the radius objective, which is well-known from the k -center problem. Here the cost is defined as the maximum radius of a cluster. Furthermore we consider the diameter objective, where the cost is defined as the maximum distance between any two points lying in the same cluster.

An α -approximation for small α yields a strong guarantee for the hierarchical clustering on every level. However, in general there do not exist optimal clusterings $\mathcal{O}_n, \dots, \mathcal{O}_1$ that form a hierarchy. So even with unlimited computational resources, a 1-approximation usually cannot be achieved. In the literature different algorithms for computing hierarchical clusterings with respect to different objective functions have been developed and analyzed. Dasgupta and Long [13] and Charikar et al. [8] initiated this line of research and presented both independently from each other an algorithm that computes efficiently an 8-approximate hierarchical clustering with respect to the radius and diameter objective. That is, for every level k , the maximal radius or diameter of any cluster in the k -clustering computed by their algorithms is at most 8 times the maximal radius or diameter in an optimal k -clustering. Inspired by [13], Plaxton [21] proposed a constant-factor approximation for the k -median and k -means objective. Later a general framework that also leads constant approximation guarantees for many objective functions including in particular k -median and k -means has been proposed by Lin et al. [19].

Despite these articles and other related work, which we discuss below in detail, many questions in the area of hierarchical clustering are not yet resolved. We find it particularly intriguing to find out which approximation factors can be achieved for different objectives. This question comes in two flavors depending on the computational resources available. Of course it is interesting to study which approximation factors can and cannot be achieved in polynomial time, assuming $P \neq NP$. Since in general there do not exist hierarchical clusterings that are optimal on each level, it is also interesting to study which approximation factors can and cannot be achieved in general without the restriction to polynomial-time algorithms.

For an objective function like radius or diameter we define its *price of hierarchy* as the smallest α such that for any instance there exists an α -approximate hierarchical clustering. Hence, the price of hierarchy is a measure for how much quality one has to sacrifice for the hierarchical structure of the clusterings.

Our main results are tight bounds for the price of hierarchy for the radius, discrete radius and diameter objective. Here the difference between radius and discrete radius lies in the choice of centers. For the radius objective we allow to choose the center of a cluster $C \subset \mathcal{P}$ from the whole metric space \mathcal{X} , while for the discrete radius objective the center must be contained in C itself. We will see that this has an impact on the price of hierarchy.

For all three objectives the algorithms in [13, 8] compute an 8-approximate hierarchical clustering in polynomial time. Until recently this was also the best known upper bound for the price of hierarchy in the literature for hierarchical radius and diameter. For discrete radius, Großwendt [17] shows an upper bound for the price of hierarchy of 4. The best known lower bounds are 2, proven by Das and Kenyon-Mathieu [11] for diameter and by Großwendt [17] for (discrete) radius. We improve the framework in [19] for radius and diameter and show an upper bound on the price of hierarchy of $3 + 2\sqrt{2} \approx 5.83$. The upper bound of $3 + 2\sqrt{2}$ for the radius was also recently proved by Bock [5] in independent work. However our main contribution lies in the design of clustering instances to prove a lower bound of 4 for discrete radius and $3 + 2\sqrt{2}$ for radius and diameter.

Related work. Gonzales [14] presents a simple and elegant incremental algorithm for k -center. The algorithm exhibits the following nice property: given a set \mathcal{P} which has to be clustered, it returns an ordering of the points, such that the first k points constitute the centers of the k -center solution, and this solution is a 2-approximation for every $1 \leq k \leq |\mathcal{P}|$. However the resulting clusterings are usually not hierarchically compatible. Dasgupta and Long [13] use the ordering computed by Gonzales' algorithm to compute a hierarchical clustering. The authors present an 8-approximation for the objective functions (discrete) radius and diameter. In an independent work Charikar et al. [8] also present an 8-approximation for the three objectives which outputs the same clustering as the algorithm in [13] under some reasonable conditions [11]. In a recent work, Mondal [20] gives a 6-approximation for hierarchical (discrete) radius. In the full version of this paper [4] we present an instance where this algorithm computes only a 7-approximation contradicting the claimed guarantee.

Plaxton [21] shows that a similar approach as in [13] yields a hierarchical clustering with constant approximation guarantee for the k -median and k -means objectives. Later a general framework for a variety of incremental and hierarchical problems was introduced by Lin et al. [19]. Their framework can be applied to compute hierarchical clusterings for any cost function which satisfies a certain nesting property, especially those of k -median and k -means. This yields a 20.71α -approximation for k -median and a 576β -approximation for k -means. Here $\alpha = 2.675$ and $\beta = 6.357$ are the currently best approximation guarantees for k -median [6] and k -means [2]. The algorithms presented in [8, 13, 19, 21] run in polynomial time. Unless $P=NP$ there is no polynomial-time α -approximation for $\alpha < 2$ for hierarchical (discrete) radius and diameter. For (discrete) radius this is an immediate consequence of the reduction from dominating set presented by [18]. A similar reduction from clique cover yields the statement for hierarchical diameter.

However even without time constraints it is not clear what approximation guarantee can be achieved for hierarchical clustering. It is easy to find examples, where the approximation guarantee of any hierarchical clustering for all three objectives is greater than one. Das and Kenyon-Mathieu [11] and Großwendt [17] present instances for diameter and (discrete) radius, where no hierarchical clustering has an approximation guarantee smaller than 2. On the other hand Großwendt [17] proves an upper bound of 4 on the approximation guarantee of hierarchical discrete radius by using the framework of Lin et al. [19]. In recent independent work Bock [5] improved the bound for hierarchical radius to $3 + 2\sqrt{2}$. While his approach is inspired by Dasgupta and Long [13], the resulting algorithm is similar to the algorithm we present in this paper as an improvement of [19].

Aside from the theoretical results, there also exist greedy heuristics, which are more commonly used in applications. One very simple bottom up, also called agglomerative, algorithm is the following: starting from the clustering where every point is separate, it

merges in every step the two clusters whose merge results in the smallest increase of the cost function. For (discrete) radius and diameter this algorithm is known as complete linkage and for the k -means cost this is Ward's method [23]. Ackermann et al. [1] analyze the approximation guarantee of complete linkage in the Euclidean space. They show an approximation guarantee of $O(\log(k))$ for all three objectives assuming the dimension of the Euclidean space to be constant. This was later improved by Großwendt and Röglin [15] to $O(1)$. In arbitrary metric spaces complete linkage does not perform well. There Arutyunova et al. [3] prove a lower bound of $\Omega(k)$ for all three objectives. For Ward's method Großwendt et al. [16] show an approximation guarantee of 2 under the strong assumption that the optimal clusters are well separated.

Recently other cost functions for hierarchical clustering were proposed, which do not compare to the optimal clustering on every level. Dasgupta [12] defines a new cost function for similarity measures and presents an $O(\alpha \log(n))$ -approximation for the respective problem. This was later improved to $O(\alpha)$ independently by Charikar and Chatziafratis [7] and Cohen-Addad et al. [9]. Here α is the approximation guarantee of sparsest cut. However Cohen-Addad et al. [9] prove that every hierarchical clustering is an $O(1)$ -approximation to the corresponding cost function for dissimilarity measures when the dissimilarity measure is a metric. A cost function more suitable for Euclidean spaces was developed by Wang and Moseley [22]. They prove that a randomly generated hierarchical clustering performs poorly for this cost function and show that bisecting k -means computes an $O(1)$ -approximation.

Our results. We define the *price of hierarchy* ρ_{cost} with respect to an objective function cost as the smallest number such that for every clustering instance there exists a hierarchical clustering which is a ρ_{cost} -approximation with respect to cost . Observe that the results [8, 11, 13, 17] imply that the price of hierarchy for radius and diameter is between 2 and 8 and for discrete radius between 2 and 4. We close these gaps and prove that the price of hierarchy for radius and diameter is exactly $3 + 2\sqrt{2}$ and for discrete radius exactly 4. Notice that this does not imply the existence of polynomial-time algorithms with approximation guarantee ρ_{cost} . Especially our algorithm which computes a $3 + 2\sqrt{2}$ -approximation for radius and diameter does not run in polynomial time. This is also the case for the $3 + 2\sqrt{2}$ -approximation for radius presented by Bock [5] in independent work. Our upper bound of $3 + 2\sqrt{2}$ can be achieved by a small improvement in the framework of Lin et al. [19]. However our most technically demanding contribution is the design of a clustering instance for every $\epsilon > 0$ such that every hierarchical clustering has approximation guarantee at least $3 + 2\sqrt{2} - \epsilon$ for radius and diameter and $4 - \epsilon$ for discrete radius. It requires a careful analysis of all possible hierarchical clusterings, which is highly non-trivial for complex clustering instances.

2 Preliminaries

A clustering instance $(\mathcal{X}, \mathcal{P}, d)$ consists of a metric space (\mathcal{X}, d) and a finite subset $\mathcal{P} \subset \mathcal{X}$. For a set (or cluster) $C \subset \mathcal{P}$ we denote by

$$\text{diam}(C) = \max_{p, q \in C} d(p, q)$$

the *diameter* of C . By $\text{rad}(C, c) = \max_{p \in C} d(c, p)$ we denote the radius of C with respect to a center $c \in \mathcal{X}$. This is the largest distance between c and a point in C . The *radius* of C is defined as the smallest radius of C with respect to a center $c \in \mathcal{X}$, i.e.,

$$\text{rad}(C) = \min_{c \in \mathcal{X}} \text{rad}(C, c)$$

while the *discrete radius* of C is defined as the smallest radius of C with respect to a center $c \in C$, i.e.,

$$\text{drad}(C) = \min_{c \in C} \text{rad}(C, c).$$

A k -clustering of \mathcal{P} is a partition of \mathcal{P} into at most k non-empty subsets. We consider three closely related clustering problems.

The k -diameter problem asks to minimize $\text{diam}(\mathcal{C}_k) = \max_{C \in \mathcal{C}_k} \text{diam}(C)$, i.e., the maximum diameter of a k -clustering \mathcal{C}_k . In the k -center problem we want to minimize the maximum radius $\text{rad}(\mathcal{C}_k) = \max_{C \in \mathcal{C}_k} \text{rad}(C)$, and in the discrete k -center problem we want to minimize the maximum discrete radius $\text{drad}(\mathcal{C}_k) = \max_{C \in \mathcal{C}_k} \text{drad}(C)$.

► **Definition 1.** Given an instance $(\mathcal{X}, \mathcal{P}, d)$, let $n = |\mathcal{P}|$. We call two clusterings \mathcal{C} and \mathcal{C}' of \mathcal{P} with $|\mathcal{C}| \geq |\mathcal{C}'|$ hierarchically compatible if for all $C \in \mathcal{C}$ there exists $C' \in \mathcal{C}'$ with $C \subset C'$. A hierarchical clustering of \mathcal{P} is a sequence of clusterings $\mathcal{H} = (\mathcal{H}_n, \dots, \mathcal{H}_1)$, such that

1. \mathcal{H}_i is an i -clustering of \mathcal{P}
2. for $1 < i \leq n$ the two clusterings \mathcal{H}_{i-1} and \mathcal{H}_i are hierarchically compatible.

For $\text{cost} \in \{\text{diam}, \text{rad}, \text{drad}\}$ let \mathcal{O}_i denote the optimal i -clustering with respect to cost . We say that \mathcal{H} is an α -approximation with respect to cost if for all $i = 1, \dots, n$ we have

$$\text{cost}(\mathcal{H}_i) \leq \alpha \cdot \text{cost}(\mathcal{O}_i).$$

Since optimal clusterings are generally not hierarchically compatible, there is usually no hierarchical clustering with approximation guarantee $\alpha = 1$. We have to accept that the restriction on hierarchically compatible clusterings comes with an unavoidable increase in the cost compared to an optimal solution.

► **Definition 2.** For $\text{cost} \in \{\text{diam}, \text{rad}, \text{drad}\}$ the price of hierarchy $\rho_{\text{cost}} \geq 1$ is defined as follows.

1. For every instance $(\mathcal{X}, \mathcal{P}, d)$, there exists a hierarchical clustering \mathcal{H} of \mathcal{P} that is a ρ_{cost} -approximation with respect to cost .
2. For any $\alpha < \rho_{\text{cost}}$ there exists an instance $(\mathcal{X}, \mathcal{P}, d)$, such that there is no hierarchical clustering of \mathcal{P} that is an α -approximation with respect to cost .

Thus ρ_{cost} is the smallest possible number such that for every clustering instance there is a hierarchical clustering with approximation guarantee ρ_{cost} .

3 An Upper Bound on the Price of Hierarchy

It is already known that the framework of Lin et al. [19] yields an upper bound of 4 on the price of hierarchy for the discrete radius [17]. This framework also yields upper bounds for the price of hierarchy for radius and diameter, which are not tight, however. We present an improved version that yields the following better upper bound on the price of hierarchy for radius and diameter.

► **Theorem 3.** For $\text{cost} \in \{\text{diam}, \text{rad}\}$ we have $\rho_{\text{cost}} \leq 3 + 2\sqrt{2} \approx 5.828$.

For the details we refer to the full version [4].

4 A Lower Bound on the Price of Hierarchy

The most challenging contributions of this article are matching lower bounds on the price of hierarchy for diameter, radius, and discrete radius.

► **Theorem 4.** *For $\text{cost} \in \{\text{diam}, \text{rad}\}$ we have $\rho_{\text{cost}} \geq 3 + 2\sqrt{2}$ and for $\text{cost} = \text{drad}$ we have $\rho_{\text{cost}} \geq 4$.*

There is already existing work in this area by Das and Kenyon-Mathieu [11] for the diameter and Großwendt [17] for the radius. Both show a lower bound of 2 for the respective objective. To improve upon these results we have to construct much more complex instances which differ significantly from those in [11, 17].

For every $\epsilon > 0$ we will construct a clustering instance $(\mathcal{X}, \mathcal{P}, d)$ such that for any hierarchical clustering $\mathcal{H} = (\mathcal{H}_{|\mathcal{P}|}, \dots, \mathcal{H}_1)$ of \mathcal{P} there is $1 \leq i \leq |\mathcal{P}|$ such that $\text{cost}(\mathcal{H}_i) \geq \alpha \cdot \text{cost}(\mathcal{O}_i)$, where \mathcal{O}_i is an optimal i -clustering of \mathcal{P} with respect to cost and $\alpha = (3 + 2\sqrt{2} - \epsilon)$ for $\text{cost} \in \{\text{diam}, \text{rad}\}$ and $\alpha = 4 - \epsilon$ for $\text{cost} = \text{drad}$.

The proof is divided in three parts. First we introduce the clustering instance $(\mathcal{X}, \mathcal{P}, d)$ and determine its optimal clusterings. In the second part we develop the notion of a *bad* cluster. We prove that any hierarchical clustering contains such bad clusters and develop a lower bound on their cost. In the third part we compare the lower bound to the cost of optimal clusterings and prove Theorem 4.

4.1 Definition of the Clustering Instance

For $n \in \mathbb{N}$ we denote by $[n]$ the set of numbers from 1 to n .

Let $k \in \mathbb{N}$ and $\Gamma = k + 1$. For $0 \leq \ell \leq k$ we define point sets \mathcal{Q}_ℓ and \mathcal{P}_ℓ recursively as follows:

1. For $\ell = 0$ let $\mathcal{P}_0 = \mathcal{Q}_0 = [1]$ and denote by N_0 the cardinality of \mathcal{P}_0 .
 2. For $\ell > 0$ let $\mathcal{Q}_\ell = [\Gamma \cdot N_{\ell-1}]^{N_{\ell-1}}$ and $\mathcal{P}_\ell = \prod_{i=0}^{\ell} \mathcal{Q}_i$. Furthermore set $N_\ell = |\mathcal{P}_\ell|$.
- Moreover let $\phi_\ell: \mathcal{P}_\ell \rightarrow [N_\ell]$ be a bijection for $0 \leq \ell \leq k$.

We refer to a point $X \in \mathcal{P}_k$ as a matrix with $k + 1$ rows and $N_{\ell-1}$ entries in the ℓ -th row. Thus we write

$$X = (x_{01} \mid \dots \mid x_{\ell 1}, \dots, x_{\ell N_{\ell-1}} \mid \dots \mid x_{k1}, \dots, x_{k N_{k-1}}).$$

Let $X_\ell = (x_{\ell 1}, \dots, x_{\ell N_{\ell-1}}) \in \mathcal{Q}_\ell$ for $0 \leq \ell \leq k$. For a shorter representation we can replace the ℓ -th row directly by X_ℓ and for $0 \leq i \leq j \leq k$ we can replace the i -th up to j -th row by $X_{[i:j]} = (X_i \mid \dots \mid X_j)$.

Let $X \in \mathcal{P}_k$ and $1 \leq \ell \leq k$. Notice that $X_{[0:\ell-1]} \in \mathcal{P}_{\ell-1}$ and let $m = \phi_{\ell-1}(X_{[0:\ell-1]})$, we define

$$A_\ell^X = \{(X_{[0:\ell-1]} \mid x_{\ell 1}, \dots, x_{\ell m-1}, \star, x_{\ell m+1}, \dots, x_{\ell N_{\ell-1}} \mid X_{[\ell+1:k]}) \mid \star \in [\Gamma \cdot N_{\ell-1}]\}.$$

Thus all coordinates of points in A_ℓ^X are fixed and agree with those of X except one which is variable. Here $X_{[0:\ell-1]}$ serves as prefix which indicates through $\phi_{\ell-1}$ which coordinate of X_ℓ can be changed.

We define $\mathcal{A}_\ell = \{A_\ell^X \mid X \in \mathcal{P}_k\}$ as the set containing all subsets of this form. It is clear that \mathcal{A}_ℓ is a partition of \mathcal{P}_k and that it contains only sets of size $\Gamma \cdot N_{\ell-1}$. Furthermore we set $\mathcal{A}_0 = \{\{X\} \mid X \in \mathcal{P}_k\}$.

► **Example 5.** If we perform the first three steps of the construction, we get $\mathcal{Q}_0 = [1]$, $\mathcal{Q}_1 = [\Gamma]$, $\mathcal{Q}_2 = [\Gamma^2]^\Gamma$ and

$$\mathcal{P}_1 = \{(1 \mid x_{11}) \mid x_{11} \in [\Gamma]\},$$

$$\mathcal{P}_2 = \{(1 \mid x_{11} \mid x_{21}, \dots, x_{2\Gamma}) \mid x_{11} \in [\Gamma], x_{2i} \in [\Gamma^2] \text{ for } 1 \leq i \leq \Gamma\}.$$

Since ϕ_0 is a map between two sets of cardinality one, this map is always unique. Now suppose that we picked ϕ_1 such that $\phi_1((1 \mid x_{11})) = x_{11}$ for all $(1 \mid x_{11}) \in \mathcal{P}_1$. Then the partition \mathcal{A}_1 consists of the sets

$$\{(1 \mid \star \mid x_{21}, \dots, x_{2\Gamma}) \mid \star \in [\Gamma]\}$$

with $x_{2i} \in [\Gamma^2]$ for all $1 \leq i \leq \Gamma$. The partition \mathcal{A}_2 consists of the sets

$$\{(1 \mid x_{11} \mid x_{21}, \dots, x_{2x_{11}-1}, \star, x_{2x_{11}+1}, \dots, x_{2\Gamma}) \mid \star \in [\Gamma^2]\}$$

with $x_{11} \in [\Gamma]$ and $x_{2i} \in [\Gamma^2]$ for all $1 \leq i \leq \Gamma$ with $i \neq x_{11}$. ┘

Now let $G = (V, E, w)$ denote the weighted hyper-graph with $V = \mathcal{P}_k$ and $E = \bigcup_{i=1}^k \mathcal{A}_i$. The weight of a hyper-edge $e \in E$ is set to ℓ iff $e \in \mathcal{A}_\ell$. For $0 \leq \ell \leq k$, the sub-graph $G_\ell = (V_\ell, E_\ell, w_\ell)$ is given by $V_\ell = \mathcal{P}_k$, $E_\ell = \bigcup_{i=0}^\ell \mathcal{A}_i$ and $w_\ell = w|_{E_\ell}$.

We extend G to a hyper-graph $H = (V', E', w')$ as follows. Let $V' = V \cup \bigcup_{i=0}^k \{v_A \mid A \in \mathcal{A}_i\}$ and $E' = E \cup \bigcup_{i=0}^k \{\{v, v_A\} \mid A \in \mathcal{A}_i, v \in A\}$. Thus H contains one vertex for every $A \in \bigcup_{i=0}^k \mathcal{A}_i$ and this vertex is connected by edges to every vertex $v \in A$. For $e \in E$ we set $w'(e) = w(e)$ and for $e = \{v, v_A\}$ for some $A \in \mathcal{A}_\ell$ and $v \in A$ we set $w'(e) = \ell/2$.

The clustering instance $(\mathcal{X}, \mathcal{P}, d)$ is given by $\mathcal{X} = V'$, $\mathcal{P} = V$, and d as the shortest path metric on H . Observe that the extension of G to H is only necessary for the lower bound for the radius but not for the diameter and the discrete radius. This is because the additional points $V' \setminus V$ do not belong to \mathcal{P} and are hence irrelevant for the clustering instance for the diameter and discrete radius. In the lower bound for the radius they will be used as centers, however.

► **Example 6.** For $k = 2$ we obtain $\Gamma = 3$ and $\mathcal{P} = \mathcal{P}_2$. Suppose that we again picked ϕ_1 such that $\phi_1((1 \mid x_{11})) = x_{11}$ for all $(1 \mid x_{11}) \in \mathcal{P}_1$. By the above definition the shortest path between the two points $X = (1 \mid 1 \mid 1, 1, 1)$, $Y = (1 \mid 1 \mid 2, 2, 1) \in \mathcal{P}_2$ in G is of the form

$$X = (1 \mid 1 \mid 1, 1, 1), (1 \mid 1 \mid 2, 1, 1), (1 \mid 2 \mid 2, 1, 1), (1 \mid 2 \mid 2, 2, 1), (1 \mid 1 \mid 2, 2, 1) = Y.$$

Thus the distance is given by $d(X, Y) = 2 + 1 + 2 + 1 = 6$. ┘

► **Lemma 7.** *Let $p, q \in V$, then $d(p, q)$ is the length of a shortest path between p and q in G .*

Proof. By definition $d(p, q)$ is the length of a shortest path between p and q in H . Suppose the shortest path contains a vertex v_A for some $A \in \bigcup_{i=0}^k \mathcal{A}_i$ with $v \in A$ as predecessor and $w \in A$ as ancestor. Since v and w are connected in H by the hyper-edge A we can delete v_A from the path and the length of the path does not change. The resulting path is also a path in G , so $d(p, q)$ is also the length of a shortest path between p and q in G . ◀

Next we state some structural properties of the graph G and the clustering instance $(\mathcal{X}, \mathcal{P}, d)$. To establish a lower bound on the approximation factor of a hierarchical clustering we first focus on the optimal clusterings of the instance $(\mathcal{X}, \mathcal{P}, d)$. One can already guess that \mathcal{A}_ℓ is an optimal clustering with $\frac{N_k}{\Gamma N_{\ell-1}}$ clusters with respect to $\text{cost} \in \{\text{diam}, \text{rad}, \text{drad}\}$ and we will prove this in this section. First we need the following statement about the connected components of G_ℓ .

■ **Figure 1** Here we see the construction of the path. It corresponds to changing the coordinates of Y successively until they match Z . We use an edge in \mathcal{A}_ℓ to change $y_{\ell s}$ to $z_{\ell s}$, next we change $y_{\ell s'}$ to $z_{\ell s'}$ and proceed like this until we obtain Z . The respective edges are then connected to a path from $V_{\ell-1}^X$ to $V_{\ell-1}^Z$.

► **Lemma 8.** *The vertex set of every connected component in G_ℓ has cardinality N_ℓ and is of the form $V_\ell^X = \{(X' \mid X) \mid X' \in \mathcal{P}_\ell\}$ for a given $X = (X_{\ell+1} \mid \dots \mid X_k) \in \prod_{i=\ell+1}^k \mathcal{Q}_i$.*

Proof. Notice that $|V_\ell^X| = N_\ell$ and that $\{V_\ell^X \mid X \in \prod_{i=\ell+1}^k \mathcal{Q}_i\}$ is a partition of V . Furthermore since $E_\ell = \bigcup_{i=0}^{\ell} \mathcal{A}_i$ any edge $e \in E_\ell$ is either completely contained in or disjoint to V_ℓ^X .

It is left to show that V_ℓ^X is connected. We prove this via induction over ℓ . For $\ell = 0$ this is clear because $|V_0^X| = 1$. For $\ell > 0$ let $Y = (Y_\ell \mid X), Z = (Z_\ell \mid X) \in \prod_{i=\ell}^k \mathcal{Q}_i$. By the induction hypothesis we know that the sets $V_{\ell-1}^Y, V_{\ell-1}^Z$ are connected. To prove that V_ℓ^X is connected it is sufficient to show that there is a path from a point in $V_{\ell-1}^Y$ to a point in $V_{\ell-1}^Z$. We show this claim by induction over the number m of coordinates in which Y and Z differ. For $m = 0$ there is nothing to show. If $m > 0$ pick $1 \leq s \leq N_{\ell-1}$ such that $y_{\ell s} \neq z_{\ell s}$ and let $P = \phi_{\ell-1}^{-1}(s) \in \prod_{i=0}^{\ell-1} \mathcal{Q}_i$. Consider the point $(P \mid Y_\ell \mid X)$ which is contained in $V_{\ell-1}^Y$. This point is also contained in the set

$$\{(P \mid y_{\ell 1}, \dots, y_{\ell s-1}, \star, y_{\ell s+1}, \dots, y_{\ell N_{\ell-1}} \mid X) \mid \star \in [\Gamma \cdot N_{\ell-1}]\} \in E_\ell.$$

Thus there is an edge in G_ℓ connecting a point in $V_{\ell-1}^Y$ to a point in $V_{\ell-1}^{Y'}$ with $Y' = (y_{\ell 1}, \dots, y_{\ell s-1}, z_{\ell s}, y_{\ell s+1}, \dots, y_{\ell N_{\ell-1}} \mid X)$. Now Y' and Z differ in $m - 1$ coordinates, thus there is a path between two points in $V_{\ell-1}^{Y'}$ and $V_{\ell-1}^Z$ by induction hypothesis. If we combine this with the induction hypothesis that $V_{\ell-1}^{Y'}$ is connected this yields the claim (see Figure 1 for an illustration). ◀

► **Lemma 9.** *Any clustering of $(\mathcal{X}, \mathcal{P}, d)$ with less than $\frac{N_k}{N_{\ell-1}}$ clusters costs at least ℓ if $\text{cost} \in \{\text{diam}, \text{drad}\}$ and $\ell/2$ if $\text{cost} = \text{rad}$.*

Proof. The shortest path in G between any two points which lie in different connected components of $G_{\ell-1}$ must contain an edge of weight $\geq \ell$. Thus any set of points $M \subset V$ which is disconnected in $G_{\ell-1}$ has diameter $\geq \ell$. Remember that the discrete radius of M is given by $\text{drad}(M) = \min_{c \in M} \max_{p \in M} d(p, c)$. For every possible choice of $c \in M$ there exists a point $p \in M$ which is not in the same connected component of $G_{\ell-1}$ as c , thus $d(c, p) \geq \ell$ and therefore $\text{drad}(M) \geq \ell$ and $\text{rad}(M) \geq \text{diam}(M)/2 \geq \ell/2$.

We conclude that if $\text{cost} \in \{\text{diam}, \text{drad}\}$ any cluster of cost smaller than ℓ is contained in one of the sets $V_{\ell-1}^X$ for some $X \in \prod_{i=\ell}^k \mathcal{Q}_i$ by Lemma 8 and any clustering with less than $|\prod_{i=\ell}^k \mathcal{Q}_i|$ clusters costs at least ℓ . By the same argument if $\text{cost} = \text{rad}$ any cluster of cost smaller than $\ell/2$ is contained in one of the sets $V_{\ell-1}^X$ for some $X \in \prod_{i=\ell}^k \mathcal{Q}_i$ by Lemma 8 and any clustering with less than $|\prod_{i=\ell}^k \mathcal{Q}_i|$ clusters costs at least $\ell/2$. Since

$$\left| \prod_{i=\ell}^k \mathcal{Q}_i \right| = \frac{\left| \prod_{i=0}^k \mathcal{Q}_i \right|}{\left| \prod_{i=0}^{\ell-1} \mathcal{Q}_i \right|} = \frac{N_k}{N_{\ell-1}}$$

this proves the lemma. \blacktriangleleft

► **Corollary 10.** For $1 \leq \ell \leq k$ and $\text{cost} \in \{\text{diam}, \text{rad}, \text{drad}\}$ the clustering \mathcal{A}_ℓ is an optimal $\frac{N_k}{\Gamma N_{\ell-1}}$ -clustering for the instance $(\mathcal{X}, \mathcal{P}, d)$. Furthermore $\text{diam}(\mathcal{A}_\ell) = \text{drad}(\mathcal{A}_\ell) = \ell$ and $\text{rad}(\mathcal{A}_\ell) = \ell/2$.

4.2 Characterization of Hierarchical Clusterings

Let from now on $\mathcal{H} = (\mathcal{H}_{N_k}, \dots, \mathcal{H}_1)$ denote a hierarchical clustering of $(\mathcal{X}, \mathcal{P}, d)$. We introduce the notion of *bad clusters* in $\mathcal{H}_{\frac{N_k}{\Gamma N_{\ell-1}}}$ which are clusters whose cost increases repeatedly, as we will see later. In this section we prove the existence of such clusters in \mathcal{H} and we give a lower bound on their cost.

► **Definition 11.** We call all clusters $C \in \mathcal{H}_{N_k}$ bad at time 0 and denote by $\text{Ker}_0(C) = C$ the kernel of C at time 0 and set $\text{Bad}(0) = \mathcal{H}_{N_k}$.

For $1 \leq \ell \leq k$ we say that a cluster $C \in \mathcal{H}_{\frac{N_k}{\Gamma N_{\ell-1}}}$ is anchored at $\ell \leq \ell' \leq k$ if the set

$$\bigcup_{D \in \text{Bad}(\ell-1): D \subset C} \text{Ker}_{\ell-1}(D) \text{ is}$$

1. connected in $G_{\ell'}$,
2. disconnected in $G_{\ell'-1}$.

We call C bad at time ℓ if C is anchored at some $\ell' \geq \ell$. We denote by $\text{Bad}(\ell) \subset \mathcal{H}_{\frac{N_k}{\Gamma N_{\ell-1}}}$ the set of all bad clusters at time ℓ . If C is bad we define the kernel of C as the union of all kernels of bad clusters at time $\ell - 1$ contained in C , i.e.,

$$\text{Ker}_\ell(C) = \bigcup_{D \in \text{Bad}(\ell-1): D \subset C} \text{Ker}_{\ell-1}(D).$$

All clusters in $\mathcal{H}_{\frac{N_k}{\Gamma N_{\ell-1}}} \setminus \text{Bad}(\ell)$ are called good.

The example in Figure 2 shows that a bad cluster at time ℓ can contain clusters which are good at time $\ell - 1$. However we are only interested in points that are contained exclusively in bad clusters at any time $t < \ell$. The set $\text{Ker}_\ell(C)$ contains exactly such points.

We will use two crucial properties to prove the final lower bound on the approximation factor of any hierarchical clustering \mathcal{H} of $(\mathcal{X}, \mathcal{P}, d)$. We first observe that bad clusters exist in \mathcal{H} for every time-step $1 \leq \ell \leq k$ and second that these clusters have a large cost compared to the optimal clustering.

► **Lemma 12.** For all $0 \leq \ell \leq k$ we have $\sum_{C \in \text{Bad}(\ell)} |\text{Ker}_\ell(C)| \geq \frac{\Gamma - \ell}{\Gamma} N_k$.

An immediate consequence of Lemma 12 is the existence of bad clusters at time ℓ for any $0 \leq \ell \leq k$. To prove that their (discrete) radius and diameter is indeed large we need a lower bound on the distance between two points $X, Y \in \mathcal{P}$ that lie in different connected components of G_{j-1} for some $1 \leq j \leq k$.

Suppose that the points X and Y only differ in one coordinate, i.e., there is a $1 \leq s \leq N_{j-1}$ such that $x_{js} \neq y_{js}$, while X and Y agree in all other coordinates. There is only one edge in G_j connecting $V_{j-1}^{X_{[j:k]}}$ with $V_{j-1}^{Y_{[j:k]}}$. Let $P = \phi_{j-1}^{-1}(s)$, then this edge connects the points

10:10 The Price of Hierarchical Clustering

■ **Figure 2** An illustration of the evolution of good and bad clusters: In the example, we see five clusters at time $\ell - 1$. The clusters A, B, D, E are assumed to be bad, with their kernels depicted in dark gray, while C is assumed to be a good cluster. At time ℓ , clusters A, B and C are merged. The resulting cluster is bad because the kernels of A and B lie in different connected components of $G_{\ell-1}$. Clusters D and E are still present at time ℓ , but now D is a good cluster since its kernel is completely contained in $V_{\ell-1}^Z$, while E is still bad, since its kernel is disconnected in $G_{\ell-1}$.

■ **Figure 3** A shortest path between X and Y . It consists of two shortest paths inside the connected components of G_{j-1} and the unique edge of weight j between these components.

$(P | X_{[j:k]})$ and $(P | Y_{[j:k]})$. If we connect X to $(P | X_{[j:k]})$ and $(P | Y_{[j:k]})$ to Y via a shortest path, this results in a path from X to Y , see Figure 3. We show that this path is indeed a shortest path between X and Y and generalize this to arbitrary X and Y which are disconnected in G_{j-1} .

► **Lemma 13.** *Let $X, Y \in \mathcal{P}$ be two points and suppose there is $1 \leq j \leq k$ and $1 \leq s \leq N_{j-1}$ such that $x_{js} \neq y_{js}$. Let $P = \phi_{j-1}^{-1}(s) \in \prod_{i=0}^{j-1} \mathcal{Q}_i$. Then*

$$d(X, Y) \geq d(X, (P | X_{[j:k]})) + j + d(Y, (P | Y_{[j:k]})).$$

We now define the so called *anchor set* $\text{Anc}_\ell(C)$ of a bad cluster C at time ℓ . If C is anchored at ℓ' then $\text{Anc}_\ell(C)$ is the union of ℓ' and the anchor set of some bad cluster $D \subset C$ at time $\ell - 1$. If we choose D appropriately the sum of anchors in $\text{Anc}_\ell(C)$ is a lower bound on the discrete radius of C , as we show later. It is clear that ℓ' itself is a lower bound on the discrete radius since $\text{Ker}_\ell(C)$ is disconnected in $G_{\ell'-1}$ by definition. If we additionally assume that the discrete radius of D is large, e.g., lower bounded by the sum of anchors in $\text{Anc}_{\ell-1}(D)$, then it is reasonable to assume that the discrete radius of C is lower bounded by some function in ℓ' and the sum of anchors in $\text{Anc}_{\ell-1}(D)$. First we give a formal definition of $\text{Anc}_\ell(C)$ and how to choose D .

► **Definition 14.** *Let $1 \leq \ell \leq k$ and C be a bad cluster at time ℓ which is anchored at $\ell' \geq \ell$. If $\ell = 1$ we define the anchor set of C as $\text{Anc}_1(C) = \{\ell'\}$ and set $\text{prev}(C) = \{X\}$ for some $X \in C$.*

For $\ell > 1$ we distinguish two cases.

Case 1: C contains a bad cluster D which is bad at time $\ell - 1$ and anchored at ℓ' . We then set $\text{Anc}_\ell(C) = \text{Anc}_{\ell-1}(D)$ and $\text{prev}(C) = D$.

Case 2: C does not contain such a cluster. Then let $D \subset C$ be a bad cluster at time $\ell - 1$ minimizing

$$\sum_{a \in \text{Anc}_{\ell-1}(D)} a$$

among all clusters $D' \in \text{Bad}(\ell - 1)$ with $D' \subset C$. We set $\text{Anc}_\ell(C) = \text{Anc}_{\ell-1}(D) \cup \{\ell'\}$ and $\text{prev}(C) = D$.

Observe that in Case 2 of the previous definition, the bad cluster D must be anchored at some $\ell_D < \ell'$.

With the help of Lemma 13 we are able to show how the discrete radius and diameter of a bad cluster, depends on the sum of anchors.

► **Lemma 15.** *Let $1 \leq \ell \leq k$ and C be a bad cluster at time ℓ anchored at ℓ' . Then for any point $Z \in \mathcal{P}$ there is $X \in \text{Ker}_\ell(C)$ such that*

$$d(Z, X) \geq \sum_{a \in \text{Anc}_\ell(C)} a.$$

► **Lemma 16.** *Let $1 \leq \ell \leq k$ and C be a bad cluster at time ℓ anchored at ℓ' . Then there are two points $X, Y \in \text{Ker}_\ell(C)$ such that*

$$d(X, Y) \geq \ell' + 2 \sum_{a \in \text{Anc}_\ell(C) \setminus \{\ell'\}} a.$$

4.3 Comparison to Optimal Clusterings

Our initial motivation was to construct an instance where any hierarchical clustering has a high approximation ratio. If we consider an arbitrary time $1 \leq \ell \leq k$ then the hierarchical clustering \mathcal{H} on $(\mathcal{X}, \mathcal{P}, d)$ may be even optimal at time ℓ . Thus the bounds which we develop in Lemma 15 and Lemma 16 on the discrete radius and diameter of bad clusters are useless without linking the cost of a bad cluster at time ℓ to the cost of bad clusters at other time steps. Therefore we construct a sequence of clusters $C_1 \subset C_2 \dots \subset C_k$ where C_i is a bad cluster at time i such that $\text{Anc}_1(C_1) \subset \text{Anc}_2(C_2) \subset \dots \subset \text{Anc}_k(C_k)$. We then show with the help of Lemma 15 and Lemma 16 that at least one of these clusters has a high discrete radius and diameter compared to the optimal cost.

► **Lemma 17.** *Let C_k be a bad cluster at time k . For $1 \leq i \leq k - 1$ we define $C_i = \text{prev}(C_{i+1})$. For all $1 \leq i \leq k - 1$ cluster C_i is bad at time i and one of the following two cases occurs:*

1. $\text{Anc}_i(C_i) = \text{Anc}_{i+1}(C_{i+1})$,
2. $\text{Anc}_{i+1}(C_{i+1}) \setminus \{\ell\} = \text{Anc}_i(C_i)$, where $\ell = \max \text{Anc}_{i+1}(C_{i+1})$.

Proof. For $i = k$ cluster C_k is bad at time k by assumption. If C_{i+1} is a bad cluster at time $i + 1$ then $C_i = \text{prev}(C_{i+1})$ is a bad cluster at time i , by definition of prev .

Let C_i be anchored at $\ell' \geq i$ and C_{i+1} be anchored at $\ell \geq i + 1$. Since C_i is a bad cluster at time i with $C_i \subset C_{i+1}$ we have by definition of $\text{Ker}_{i+1}(C_{i+1})$ that $\text{Ker}_i(C_i) \subset \text{Ker}_{i+1}(C_{i+1})$ and thus $\ell' \leq \ell$. If $\ell' = \ell$ we obtain by Definition 14, that $\text{Anc}_i(C_i) = \text{Anc}_{i+1}(C_{i+1})$, so the lemma holds in this case.

If $\ell' < \ell$ we know by Definition 14 that $\text{Anc}_i(C_i) = \text{Anc}_{i+1}(C_{i+1}) \setminus \{\ell\}$. So the lemma also holds in this case. ◀

10:12 The Price of Hierarchical Clustering

► **Corollary 18.** *Let C_k be a bad cluster at time k . For $1 \leq i \leq k-1$ we define $C_i = \text{prev}(C_{i+1})$. Let $\text{Anc}_k(C_k) = \{\ell_1, \dots, \ell_s\}$ such that $\ell_{t-1} < \ell_t$ for all $2 \leq t \leq s$ and let $\ell_0 = 0$. Then for any $1 \leq t \leq s$ and for any i with $\ell_{t-1} < i \leq \ell_t$, we have $\{\ell_1, \dots, \ell_t\} \subset \text{Anc}_i(C_i)$.*

Proof. We prove this via induction over i , starting from $i = k$ in decreasing order. There is nothing to show for $i = k$. For $i < k$ we distinguish two cases. If $\text{Anc}(C_i) = \text{Anc}_{i+1}(C_{i+1})$, the lemma follows from the induction hypothesis.

Otherwise remember that $\text{Anc}_i(C_i) \subset \text{Anc}_k(C_k)$ and $\ell_{t-1} < i$. Since $\max \text{Anc}_i(C_i) \geq i$ we obtain that $\max \text{Anc}_i(C_i) \in \{\ell_t, \dots, \ell_s\}$ and therefore $\ell_t \leq \max \text{Anc}_i(C_i)$.

By Lemma 17 we know that $\text{Anc}_i(C_i) = \text{Anc}_{i+1}(C_{i+1}) \setminus \{\ell\}$, where $\ell = \max \text{Anc}_{i+1}(C_{i+1})$. Thus $\ell_t \leq \max \text{Anc}_i(C_i) < \max \text{Anc}_{i+1}(C_{i+1}) = \ell$ and by induction hypothesis we obtain

$$\{\ell_1, \dots, \ell_t\} \subset \text{Anc}_{i+1}(C_{i+1}) \setminus \{\ell\} = \text{Anc}_i(C_i). \quad \blacktriangleleft$$

Before we are able to prove the theorem we need some final lemma.

► **Lemma 19.** *For every $\epsilon > 0$ there exists $k \in \mathbb{N}$ such that for every $s \in \mathbb{N}$ any sequence of $s+1$ numbers $(\ell_0, \dots, \ell_s) \in \mathbb{R}_{\geq 0}^{s+1}$ with $\ell_0 = 0$ and $\ell_s = k$ satisfies the following.*

1. *There exists $1 \leq t \leq s$ such that for $\alpha_1 = 4 - \epsilon$ and $\Delta_1 = 1$ we have*

$$\frac{\ell_t + \Delta_1 \sum_{i=0}^{t-1} \ell_i}{\ell_{t-1} + 1} > \alpha_1.$$

2. *There exists $1 \leq t \leq s$ such that for $\alpha_2 = 3 + 2\sqrt{2} - \epsilon$ and $\Delta_2 = 2$ we have*

$$\frac{\ell_t + \Delta_2 \sum_{i=0}^{t-1} \ell_i}{\ell_{t-1} + 1} > \alpha_2.$$

► **Theorem 4.** *For $\text{cost} \in \{\text{diam}, \text{rad}\}$ we have $\rho_{\text{cost}} \geq 3 + 2\sqrt{2}$ and for $\text{cost} = \text{drad}$ we have $\rho_{\text{cost}} \geq 4$.*

Proof. Let $\epsilon > 0$ and k be the respective number from Lemma 19. We claim that the approximation factor of any hierarchical clustering $\mathcal{H} = (\mathcal{H}_{N_k}, \dots, \mathcal{H}_1)$ on the instance $(\mathcal{X}, \mathcal{P}, d)$ is larger than $3 + 2\sqrt{2} - \epsilon$ if $\text{cost} \in \{\text{diam}, \text{rad}\}$ and larger than $4 - \epsilon$ if $\text{cost} = \text{drad}$. First we use Lemma 12 to observe that there is a cluster $C_k \in \mathcal{H}_{\frac{N_k}{\Gamma N_{k-1}}}$ that is bad at time k . For $1 \leq i \leq k-1$ we define $C_i = \text{prev}(C_{i+1})$. Let $\text{Anc}_k(C_k) = \{\ell_1, \dots, \ell_s\}$ with $\ell_{t-1} < \ell_t$ for $2 \leq t \leq s$ and let $\ell_0 = 0$. We know by Corollary 18, that for any $1 \leq t \leq s$ and for $i = \ell_{t-1} + 1$ we have $\{\ell_1, \dots, \ell_t\} \subset \text{Anc}_i(C_i)$. Let $\ell' = \max \text{Anc}_i(C_i)$, we obtain by Lemma 16 and Lemma 15 that

$$\begin{aligned} \text{diam}(C_i) &\geq \ell' + 2 \sum_{a \in \text{Anc}_i(C_i) \setminus \{\ell'\}} a \geq \ell_t + 2 \sum_{u=1}^{t-1} \ell_u, \\ \text{rad}(C_i) &\geq \frac{\text{diam}(C_i)}{2} \geq \frac{\ell_t + 2 \sum_{u=1}^{t-1} \ell_u}{2}, \\ \text{drad}(C_i) &\geq \sum_{a \in \text{Anc}_i(C_i)} a \geq \sum_{u=1}^t \ell_u. \end{aligned}$$

Remember that by Corollary 10 \mathcal{A}_i is an optimal $\frac{N_k}{\Gamma N_{i-1}}$ -clustering with $\text{cost}(\mathcal{A}_i) = i$ if $\text{cost} \in \{\text{diam}, \text{drad}\}$ and $\text{cost}(\mathcal{A}_i) = i/2$ if $\text{cost} = \text{rad}$. We obtain

$$\frac{\text{rad}(C_i)}{\text{rad}(\mathcal{A}_i)} = \frac{2\text{rad}(C_i)}{2\text{rad}(\mathcal{A}_i)} \geq \frac{\text{diam}(C_i)}{\text{diam}(\mathcal{A}_i)} \geq \frac{\ell_t + 2\sum_{u=1}^{t-1} \ell_u}{\ell_{t-1} + 1}$$

$$\frac{\text{drad}(C_i)}{\text{drad}(\mathcal{A}_i)} \geq \frac{\sum_{u=1}^t \ell_u}{\ell_{t-1} + 1}$$

which are lower bounds on the approximation factor of \mathcal{H} .

We apply Lemma 19 on (ℓ_0, \dots, ℓ_s) to observe that there is $1 \leq t' \leq s$ such that

$$\frac{\ell_{t'} + 2\sum_{u=1}^{t'-1} \ell_u}{\ell_{t'-1} + 1} > 3 + 2\sqrt{2} - \epsilon$$

and an $1 \leq t'' \leq s$ such that

$$\frac{\sum_{u=1}^{t''} \ell_u}{\ell_{t''-1} + 1} > 4 - \epsilon.$$

This proves the theorem. ◀

5 Conclusions and Open Problems

We have proved tight bounds for the price of hierarchy with respect to the diameter and (discrete) radius. It would be interesting to also obtain a better understanding of the price of hierarchy for other important objective functions like k -median and k -means. The best known upper bound is 16 for k -median [10] and 32 for k -means [17] but no non-trivial lower bounds are known. Closing this gap also for these objectives is a challenging problem for further research.

Another natural question is which approximation factors can be achieved by polynomial-time algorithms. The algorithm we used in this article to prove the upper bounds is not a polynomial-time algorithm because it assumes that for each level k an optimal k -clustering is given. The approximation factors worsen if only approximately optimal clusterings are used instead. It is known that 8-approximate hierarchical clusterings can be computed efficiently with respect to the diameter and (discrete) radius [13]. It is not clear whether or not it is NP-hard to obtain better hierarchical clusterings. The only NP-hardness results come from the problems with given k . Since computing a $(2 - \epsilon)$ -approximation for k -clustering with respect to the diameter and (discrete) radius is NP-hard, this is also true for the hierarchical versions. However, this is obsolete due to our lower bound, which shows that in general there does not even exist a $(2 - \epsilon)$ -approximate hierarchical clustering.

Abstract

An *obstacle representation* of a graph G consists of a set of pairwise disjoint simply-connected closed regions and a one-to-one mapping of the vertices of G to points such that two vertices are adjacent in G if and only if the line segment connecting the two corresponding points does not intersect any obstacle. The *obstacle number* of a graph is the smallest number of obstacles in an obstacle representation of the graph in the plane such that all obstacles are simple polygons.

It is known that the obstacle number of each n -vertex graph is $O(n \log n)$ [Balko, Cibulka, and Valtr, 2018] and that there are n -vertex graphs whose obstacle number is $\Omega(n/(\log \log n)^2)$ [Dujmović and Morin, 2015]. We improve this lower bound to $\Omega(n/\log \log n)$ for simple polygons and to $\Omega(n)$ for convex polygons. To obtain these stronger bounds, we improve known estimates on the number of n -vertex graphs with bounded obstacle number, solving a conjecture by Dujmović and Morin. We also show that if the drawing of some n -vertex graph is given as part of the input, then for some drawings $\Omega(n^2)$ obstacles are required to turn them into an obstacle representation of the graph. Our bounds are asymptotically tight in several instances.

We complement these combinatorial bounds by two complexity results. First, we show that computing the obstacle number of a graph G is fixed-parameter tractable in the vertex cover number of G . Second, we show that, given a graph G and a simple polygon P , it is NP-hard to decide whether G admits an obstacle representation using P as the only obstacle.

1 Introduction

An *obstacle* is a simple polygon in the plane. For a set S of points in the plane and a set \mathcal{O} of obstacles, the *visibility graph* of S with respect to \mathcal{O} is the graph with vertex set S where two vertices s and t are adjacent if and only if the line segment \overline{st} does not intersect any obstacle in \mathcal{O} . For convenience, we identify vertices with the points representing them and edges with the corresponding line segments. An *obstacle representation* of a graph G consists of a set \mathcal{O} of pairwise disjoint obstacles and a bijective mapping between the vertex set of G and a point set $S \subseteq \mathbb{R}^2 \setminus \bigcup \mathcal{O}$ such that the visibility graph of S with respect to \mathcal{O} is isomorphic to G . We consider finite point sets and finite collections of obstacles. All obstacles are closed. For simplicity, we consider point sets to be in *general position*, that is, no three points lie on a common line.

Given a straight-line drawing D of a graph G , we define the *obstacle number* of D , $\text{obs}(D)$, to be the smallest number of obstacles that are needed in order to turn D into an obstacle representation of G . Since every *non-edge* of G (that is, every pair of non-adjacent vertices) must be blocked by an obstacle and no edge of G may intersect an obstacle, $\text{obs}(D)$ is the cardinality of the smallest set of faces of D whose union is intersected by every non-edge of G . For a graph G , the *obstacle number* of G , $\text{obs}(G)$, is the smallest value of $\text{obs}(D)$, where D ranges over all straight-line drawings of G . For a positive integer n , let $\text{obs}(n)$ be the maximum value of $\text{obs}(G)$, where G is any n -vertex graph. The *convex obstacle number* $\text{obs}_c(\cdot)$ is defined analogously, except that here all obstacles are convex polygons.

For positive integers h and n , let $f(h, n)$ be the number of graphs on n vertices that have obstacle number at most h . Similarly, we denote the number of graphs on n vertices that have convex obstacle number at most h by $f_c(h, n)$.

Alpert, Koch, and Laison [2] introduced the obstacle number and the convex obstacle number. Using Ramsey theory, they proved that for every positive integer k , there is a (huge) complete k -partite graph with convex obstacle number k . They also showed that $\text{obs}(n) \in \Omega(\sqrt{\log n / \log \log n})$. This lower bound was subsequently improved to $\Omega(n / \log n)$ by Mukkamala, Pach, and Pálvölgyi [18] and to $\Omega(n / (\log \log n)^2)$ by Dujmović and Morin [8], who conjectured the following.

► **Conjecture 1** ([8]). *For all positive integers n and h , we have $f(h, n) \in 2^{g(n) \cdot o(h)}$, where $g(n) \in O(n \log^2 n)$.*

On the other hand, we trivially have $\text{obs}(n) \leq \text{obs}_c(n) \leq \binom{n}{2}$ as one can block each non-edge of an n -vertex graph with a single obstacle. Balko, Cibulka, and Valtr [4] improved this upper bound to $\text{obs}(n) \leq \text{obs}_c(n) \leq n \lceil \log n \rceil - n + 1$, refuting a conjecture by Mukkamala, Pach, and Pálvölgyi [18] stating that $\text{obs}(n)$ is around n^2 . For every graph G with chromatic number χ , Balko, Cibulka, and Valtr [4] showed that $\text{obs}_c(G) \leq (n - 1)(\lceil \log \chi \rceil + 1)$, which is in $O(n)$ if the chromatic number is bounded by a constant.

Alpert, Koch, and Laison [2] differentiated between an *outside obstacle*, which lies in (or simply is) the outer face of the visibility drawing, and *inside obstacles*, which lie in (or are) inner faces of the drawing. They proved that every outerplanar graph has an outside-obstacle representation, that is, a representation with a single outside obstacle. Later, Chaplick, Lipp, Park, and Wolff [6] showed that the class of graphs that admit a representation with a single inside obstacle is incomparable with the class of graphs that have an outside-obstacle representation. They found the smallest graph with obstacle number 2; it has eight vertices

and is co-bipartite. They also showed that the following *sandwich version* of the outside-obstacle representation problem is NP-hard: Given two graphs G and H with $V(G) = V(H)$ and $E(G) \subseteq E(H)$, is there a graph K with $V(K) = V(G)$ and $E(G) \subseteq E(K) \subseteq E(H)$ that admits an outside-obstacle representation? Analogous hardness results hold with respect to inside and general obstacles. Every partial 2-tree has an outside-obstacle representation [10]. For (partial) outerpaths, cactus graphs, and grids, it is possible to construct outside-obstacle representations where the vertices are those of a regular polygon [10].

For planar graphs, Johnson and Sariöz [16] investigated a variant of the problem where the visibility graph G is required to be plane and a plane drawing D of G is given. They showed that computing $\text{obs}(D)$ is NP-hard (by reduction *from* planar vertex cover) and that there is a solution-value-preserving reduction *to* maximum-degree-3 planar vertex cover. For computing $\text{obs}(D)$, this reduction yields a polynomial-time approximation scheme and a fixed-parameter algorithm with respect to $\text{obs}(D)$. Gimbel, de Mendez, and Valtr [13] showed that, for some planar graphs, there is a large discrepancy between this planar setting and the usual obstacle number.

A related problem deals with *point visibility graphs*, where the points are not only the vertices of the graph but also the obstacles. Recognizing point visibility graphs is contained in $\exists\mathbb{R}$ [12] and is $\exists\mathbb{R}$ -hard [5], and thus $\exists\mathbb{R}$ -complete.

Our Contribution. Our results span three areas. First, we improve existing bounds on the (convex and general) obstacle number (see Section 2), on the functions $f(n, h)$ and $f_c(n, h)$ (see Section 3), and on the obstacle number of drawings (see Section 4). Second, we provide an algorithmic result: computing the obstacle number of a given graph is fixed-parameter tractable with respect to the vertex cover number of the graph (see Section 5). Third, we show that, given a graph G and a simple polygon P , it is NP-hard to decide whether G admits an obstacle representation using P as the only obstacle (see Section 6). The omitted proofs are available in the full version of this paper [3]. We now describe our results in more detail.

First, we prove the currently strongest lower bound on the obstacle number of n -vertex graphs, improving the estimate of $\text{obs}(n) \in \Omega(n/(\log \log n)^2)$ by Dujmović and Morin [8].

► **Theorem 2.** *There is a constant $\beta > 0$ such that, for every $n \in \mathbb{N}$, there exists a graph on n vertices with obstacle number at least $\beta n / \log \log n$, that is, $\text{obs}(n) \in \Omega(n / \log \log n)$.*

This lower bound is quite close to the currently best upper bound $\text{obs}(n) \in O(n \log n)$ by Balko, Cibulka, and Valtr [4]. In fact, Alpert, Koch, and Laison [2] asked whether the obstacle number of any graph with n vertices is bounded from above by a linear function of n . This is supported by a result of Balko, Cibulka, and Valtr [4] who proved $\text{obs}(G) \leq \text{obs}_c(G) \in O(n)$ for every graph G with n vertices and with constant chromatic number. We remark that we are not aware of any argument that would give a strengthening of Theorem 2 to graphs with constant chromatic number.

Next, we show that a linear lower bound holds for convex obstacles.

► **Theorem 3.** *There is a constant $\gamma > 0$ such that, for every $n \in \mathbb{N}$, there exists a (bipartite) graph on n vertices with convex obstacle number at least γn , that is, $\text{obs}_c(n) \in \Omega(n)$.*

The previously best known bound on the convex obstacle number was $\text{obs}_c(G) \in \Omega(n/(\log \log n)^2)$ [8]. Recall that the upper bound proved by Balko, Cibulka, and Valtr [4] actually holds for the convex obstacle number as well and gives $\text{obs}_c(n) \in O(n \log n)$. Furthermore, the linear lower bound on $\text{obs}_c(n)$ from Theorem 3 works for n -vertex graphs with bounded chromatic number, asymptotically matching the linear upper bound on the obstacle number of such graphs proved by Balko, Cibulka, and Valtr [4]; see the remark in Section 2.

11:4 Bounding and Computing Obstacle Numbers of Graphs

The proofs of Theorems 2 and 3 are both based on counting arguments that use the upper bounds on $f(h, n)$ and $f_c(h, n)$. To obtain the stronger estimates on $\text{obs}(n)$ and $\text{obs}_c(n)$, we improve the currently best bounds $f(h, n) \in 2^{O(hn \log^2 n)}$ and $f_c(h, n) \in 2^{O(hn \log n)}$ by Muckkamala, Pach, and Pálvölgyi [18] as follows.

► **Theorem 4.** *For all positive integers h and n , we have $f(h, n) \in 2^{O(hn \log n)}$.*

► **Theorem 5.** *For all positive integers h and n , we have $f_c(h, n) \in 2^{O(n(h + \log n))}$.*

The upper bound in Theorem 5 is asymptotically tight for $h < n$ as Balko, Cibulka, and Valtr [4] proved that for every pair of integers n and h satisfying $0 < h < n$ we have $f_c(h, n) \in 2^{\Omega(hn)}$. Their result is stated for $f(h, n)$, but it is proved using convex obstacles only. This matches our bound for $h \in \Omega(\log n)$. Moreover, they showed that $f_c(1, n) \in 2^{\Omega(n \log n)}$, which again matches the bound in Theorem 5.

Since trivially $h \leq \binom{n}{2} \leq n^2$, we get $\log h \leq 2 \log n$, and thus the bound in Theorem 4 can be rewritten as $f(h, n) \leq 2^{g(n) \cdot (h/\log n)} \leq 2^{g(n) \cdot (2h/\log h)} \in 2^{g(n) \cdot o(h)}$, where $g(n) \in O(n \log^2 n)$. Therefore, we get the following corollary, confirming Conjecture 1.

► **Corollary 6.** *For all positive integers h and n , we have $f(h, n) \in 2^{g(n) \cdot (2h/\log h)}$, where $g(n) \in O(n \log^2 n)$.*

It is natural to ask about estimates on obstacle numbers of fixed drawings, that is, considering the problem of estimating $\text{obs}(D)$. The parameter $\text{obs}(D)$ has been considered in the literature; e.g., by Johnson and Sariöz [16]. Here, we provide a quadratic lower bound on $\max_D \text{obs}(D)$ where the maximum ranges over all drawings of graphs on n vertices.

► **Theorem 7.** *There is a constant $\delta > 0$ such that, for every n , there exists a graph G on n vertices and a drawing D of G such that $\text{obs}(D) \geq \delta \cdot n^2$.*

The bound from Theorem 7 is asymptotically tight as we trivially have $\text{obs}(D) \leq \text{obs}_c(D) \leq \binom{n}{2}$ for every drawing D of an n -vertex graph. This also asymptotically settles the problem of estimating the convex obstacle number of drawings.

Next, we turn our attention to algorithms for computing the obstacle number. We establish fixed-parameter tractability for the problem when parameterized by the size of a minimum vertex cover of the input graph G , called the *vertex cover number* of G .

► **Theorem 8.** *Given a graph G and an integer h , the problem of recognizing whether G admits an obstacle representation with h obstacles is fixed-parameter tractable parameterized by the vertex cover number of G .*

The proof of Theorem 8 is surprisingly non-trivial. On a high level, it uses Ramsey techniques to identify, in a sufficiently large graph G , a set of vertices outside a minimum vertex cover which not only have the same neighborhood, but also have certain geometric properties in a hypothetical solution S . We then use a combination of topological and combinatorial arguments to show that S can be adapted to an equivalent solution for a graph G' whose size is bounded by the vertex cover number of G – i.e., a kernel [7].

While the complexity of deciding whether a given graph has obstacle number 1 is still open, the sandwich version of the problem [6] and the version for planar visibility drawings [16] have been shown NP-hard. We conclude with a simple new NP-hardness result.

► **Theorem 9.** *Given a graph G and a simple polygon P , it is NP-hard to decide whether G admits an obstacle representation using P as (outside-) obstacle.*

2 Improved Lower Bounds on Obstacle Numbers

We start with the estimate $\text{obs}(n) \in \Omega(n/\log \log n)$ from Theorem 2. The proof is based on Theorem 4 (cf. Section 3) and the following result by Dujmović and Morin [8], which shows that an upper bound for $f(h, n)$ translates into a lower bound for $\text{obs}(n)$.

► **Theorem 10** ([8]). *For every $k \in \mathbb{N}$, let $H(k) = \max\{h : f(h, k) \leq 2^{k^2/4}\}$. Then, for any constant $c > 0$, there exist n -vertex graphs with obstacle number at least $\Omega\left(\frac{nH(c \log n)}{c \log n}\right)$.*

Proof of Theorem 2. By Theorem 4, we have $f(h, k) \in 2^{O(hk \log k)}$ for every positive integer k and thus $H(k) \in \Omega(k/\log k)$. Plugging this estimate with $k \in \Omega(\log n)$ into Theorem 10, we get the lower bound $\text{obs}(n) \in \Omega(n/\log \log n)$. ◀

It remains to prove the lower bound $\text{obs}_c(n) \in \Omega(n)$ from Theorem 3.

Proof of Theorem 3. By Theorem 5, we have $f_c(h, n) \leq 2^{\beta n(h+\log n)}$ for some constant $\beta > 0$. Since the number of graphs with n vertices is $2^{\binom{n}{2}}$, we see that if $2^{\binom{n}{2}} > 2^{\beta n(h+\log n)}$, then there is an n -vertex graph with convex obstacle number larger than h . The inequality $\binom{n}{2} > \beta n(h + \log n)$ is satisfied for $h < \binom{n}{2}/(\beta n) - \log n \in \Theta(n)$. Thus, $\text{obs}_c(n) \in \Omega(n)$. ◀

► **Remark.** Observe that the proof of Theorem 3 also works if we restrict ourselves to bipartite graphs, as the number of bipartite graphs on n vertices is at least $2^{n^2/4}$. Thus, the convex obstacle number of an n -vertex graph with constant chromatic number can be linear in n , which asymptotically matches the linear upper bound proved by Balko, Cibulka, and Valtr [4].

3 On the Number of Graphs with Bounded Obstacle Number

In this section we outline the proofs for Theorems 4 and 5, which provide improved upper bounds on the number of n -vertex graphs with (convex) obstacle number at most h .

3.1 Sketch of the Proof of Theorem 4

We prove that the number $f(h, n)$ of n -vertex graphs with obstacle number at most h is bounded from above by $2^{O(hn \log n)}$. We follow the approach of Mukkamala, Pach, and Pálvölgyi [18] and encode the obstacle representations using point set order types for the vertices of the graph and the obstacles. They used a bound of $O(n \log n)$ for the number of vertices of a single obstacle. We show that this bound can be reduced to $O(n)$. As a result, the upper bound on $f(h, n)$ improves by a factor of $\Theta(\log n)$ in the exponent.

An obstacle representation (D, \mathcal{O}) of a graph G is *minimal* if it uses the minimum number $|\mathcal{O}|$ of obstacles and there is no obstacle representation (D', \mathcal{O}') of G with $|\mathcal{O}'| = |\mathcal{O}|$ such that the total number of vertices in \mathcal{O}' is strictly smaller than in \mathcal{O} . Consider a graph G that admits an obstacle representation using at most h obstacles and an obstacle $O \in \mathcal{O}$. If O is a triangle, it contributes three vertices to our linear bound, which is fine. So suppose that O has four or more vertices. We want to charge the “excess” vertices to some vertex of G such that every vertex of G pays for at most a constant number of obstacle vertices.

A vertex v of a simple polygon P is *convex* if the internal angle of P at v is less than π ; otherwise v is a *reflex* vertex of P . Let v be a convex vertex of an obstacle O from \mathcal{O} and let e_1 and e_2 be the two edges of O adjacent to v . If the interior of the triangle that is spanned by e_1 and e_2 does not contain any vertex of D or \mathcal{O} , we call the vertex v *blocking*.

■ **Figure 1** (a) An illustration of the polygonal chain $\gamma_{t,z,w}^u$ used in the definition of responsibility. (b) An example where u is responsible for t and w but not for v . The vertex u' is responsible for v .

If v is blocking, then there is a non-edge e of G that crosses e_1 and e_2 , since otherwise we could reduce the number of obstacle vertices by removing the triangle spanned by e_1 and e_2 from O . If e has no other intersections with the obstacles, we say that e *forces* v . Then each convex vertex of O is forced by at least one non-edge of G . Let uu' be an edge that forces v and let z be a crossing of uu' with an edge of O incident to v . We say that u is *responsible* for v unless there are non-edges of G incident to u and forcing two other vertices t and w of O that span a polygonal chain $\gamma_{t,z,w}^u$ formed by the part of the boundary of O between t and w such that $\gamma_{t,z,w}^u$ intersects the ray \vec{uz} at some point different from z ; see Fig. 1.

With this definition of responsibility, we can show that every blocking vertex v of O has at least one vertex of G that is responsible for v and that each vertex of G is responsible for at most two blocking vertices of O . It then follows from a simple double-counting argument that O has at most $2n$ blocking vertices. A similar argument based on a different notion of responsibility is used to show that O contains at most $2r_O$ non-blocking convex vertices where r_O is the number of reflex vertices of O . Accounting for the reflex vertices is more challenging, but we can show that each reflex vertex of an obstacle can be charged to a vertex of G , so that there are no more than $2n + 5$ reflex vertices overall. Let s denote the total number of obstacle vertices, and let $r = \sum_{O \in \mathcal{O}} r_O$ denote the total number of reflex vertices. Then $s \leq r + \sum_{O \in \mathcal{O}} (2r_O + 2n) \leq 3r + |\mathcal{O}| \cdot 2n \leq (2h + 6)n + 15$.

First, it is not difficult to show that we can restrict ourselves without loss of generality to connected graphs. To bound the number $g(h, n)$ of connected n -vertex graphs with obstacle number at most h , we use a combinatorial description of point sets using order types. The *order type* of a set P of points in the plane in general position is a mapping χ that assigns $\chi(a, b, c) \in \{+1, -1\}$ to each ordered triple (a, b, c) of points from P , indicating whether a, b, c make a left turn (+1) or a right turn (-1). The order type captures which pairs of line segments spanned by P cross. Hence, for the purposes of plane straight-line embeddings of graphs, two point sets with the same order type are equivalent. The following classical result by Goodman and Pollack [14, 15] gives an estimate on the number of order types.

▶ **Theorem 11** ([14, 15]). *The number of order types on n labeled points in \mathbb{R}^2 is at most $\left(\frac{n}{2}\right)^{4(1+o(1))n} \in 2^{O(n \log n)}$.*

We encode G by the order type of all $n + s$ vertices. By Theorem 11, the number of such order types is at most $2^{\alpha(n+s) \log(n+s)}$ for some $\alpha > 0$. Since $s \leq 2hn + 6n + 15$ and $h \leq \binom{n}{2}$, we obtain $g(h, n) \in 2^{\alpha(n+2hn+6n+15) \log(n+2hn+6n+15)} \subseteq 2^{O(hn \log n)}$.

3.2 Sketch of the Proof of Theorem 5

We show that the number of graphs on n vertices that have convex obstacle number at most h is bounded from above by $2^{O(n(h+\log n))}$. That is, we prove $f_c(h, n) \in 2^{O(n(h+\log n))}$.

To this end, we give an efficient encoding for an obstacle representation (D, \mathcal{O}) of an n -vertex graph $G = (V, E)$ that uses at most h convex obstacles. The first part of the encoding is formed by the order type of V . Then, it remains to encode the obstacles and their interaction with the line segments between points from V . To do that, we use so-called radial systems. The *clockwise radial system* R of V assigns to each vertex $v \in V$ the clockwise cyclic ordering $R(v)$ of the $n - 1$ rays in D that start from v and pass through a vertex from $V \setminus \{v\}$. The order type of V uniquely determines the radial system R of V . Essentially, this also holds in the other direction: There are at most $n - 1$ order types that are compatible with a given radial system [1].

For a vertex $v \in V$ and an obstacle $O \in \mathcal{O}$, let $I_O(v)$ be the subsequence of rays in $R(v)$ that intersect O . We say that a subset I of $R(v)$ is an *interval* if there are no four consecutive elements a, b, c, d in the radial order $R(v)$ such that $a, c \in I$ and $b, d \notin I$. Since O is connected, each set $I_O(v)$ forms an interval in $R(v)$, the *blocking interval* of the pair (v, O) . By the following lemma the blocking intervals suffice to determine which edges are blocked.

► **Lemma 12.** *For two vertices $u, v \in V$, the pair $\{u, v\}$ is a non-edge of G if and only if there is an obstacle $O \in \mathcal{O}$ such that $u \in I_O(v)$ and $v \in I_O(u)$.*

Thus it suffices to encode all blocking intervals. In the following we describe how to obtain an encoding of size $2^{O(hn)}$, which together with the order type of V yields the claimed bound on $f_c(h, n)$. In order to describe our approach it is more convenient to move to the dual setting, using the standard *projective duality transformation* that maps a point $p = (p_x, p_y) \in \mathbb{R}^2$ to the line $p^* = \{(x, y) \in \mathbb{R}^2 : y = p_x x - p_y\}$, and that maps a non-vertical line $\ell = \{(x, y) \in \mathbb{R}^2 : y = mx + b\}$ to the point $\ell^* = (m, -b)$. This map is an involution, that is, $(p^*)^* = p$ and $(\ell^*)^* = \ell$. Moreover, it preserves incidences, that is, $p \in \ell \iff \ell^* \in p^*$, and is order-preserving as a point p lies above $\ell \iff \ell^*$ lies above p^* .

Consider the arrangement \mathcal{A} of the n lines dual to the points in V . The combinatorial structure of \mathcal{A} , that is, the sequences of intersections with other lines along each line, can be obtained from the radial system of V ; see [20]. (To identify the vertical direction and the x -order of the vertices, we add a special point very high above all other points.) Let $O \in \mathcal{O}$ be an obstacle. Define a map τ that assigns to each $x \in \mathbb{R}$ the *upper tangent* of slope x to O , that is, the line $\tau(x)$ of slope x that is tangent to O and such that O lies below $\tau(x)$; see Fig. 2. Now, consider the dual τ^* of τ , defined by $\tau^*(x) = (\tau(x))^*$. Note that, by definition, every line $\tau(x)$ passes through a vertex of the upper envelope O^+ of the convex hull of O . Consequently, each point $\tau^*(x)$ lies on a line that is dual to a vertex of O^+ . In other words, τ^* is a piece-wise linear function that is composed of line segments along the lines dual to the vertices of O^+ . The order of these line segments from left to right corresponds to primal tangents of increasing slope and, therefore, to the order of the corresponding vertices of O^+ from right to left. As primal x -coordinates correspond to dual slopes, the slopes of the line segments along τ^* monotonically decrease from left to right, and so τ^* is concave.

The primal line of a point in $v^* \cap \tau^*$, for some $v \in V$, passes through v and is an upper tangent to O . So such an intersection corresponds to an endpoint of the blocking interval $I_O(v)$. In order to obtain all endpoints of the blocking intervals, we also consider the *lower tangents* to O in an analogous manner. The corresponding function β^* is convex and consists of segments along lines dual to the vertices of the lower convex hull of O , from left to right.

It remains to compactly encode the intersections of τ^* with \mathcal{A} . To do so, we apply a result by Knuth [17]; see also the description by Felsner and Valtr [9]. A set \mathcal{A}' of biinfinite curves in \mathbb{R}^2 forms an *arrangement of pseudolines* if each pair of curves from \mathcal{A}' intersects in a unique point, which corresponds to a proper, transversal crossing. A curve α is a *pseudoline*

■ **Figure 2** An example of a vertex set V with its dual line arrangement \mathcal{A} . Points and lines of the same color are dual to each other. The curve τ^* for the upper envelope O^+ of the obstacle O is denoted black and the curve β^* for the lower envelope O^- of the obstacle O is denoted gray.

■ **Figure 3** Splitting the n lines of \mathcal{A} into two parts so that τ^* is a pseudoline with respect to the resulting arrangement \mathcal{A}' of at most $2n$ pseudolines.

with respect to \mathcal{A}' if α intersects each curve in \mathcal{A}' at most once. Let γ be a curve that intersects each curve from \mathcal{A}' in a finite number of points. The *cutpath* of γ in \mathcal{A}' is the sequence of intersections of γ with the pseudolines from \mathcal{A}' along γ .

► **Theorem 13** ([17]). *If α is a pseudoline with respect to an arrangement \mathcal{A}' of n pseudolines, then there are at most $O(3^n)$ cutpaths of α in \mathcal{A}' .*

Using Theorem 13, we can now estimate the number of cutpaths of τ^* with respect to \mathcal{A} .

► **Lemma 14.** *There are at most $O(9^n)$ cutpaths of τ^* in \mathcal{A} .*

Proof. If τ^* was a pseudoline with respect to \mathcal{A} , then we were done by Theorem 13. However, τ^* is not a pseudoline with respect to \mathcal{A} in general because a vertex $v \in V$ can have two tangents to O^+ , in which case τ^* intersects v^* twice. Therefore, we split the lines of \mathcal{A} that correspond to vertices vertically above O into two parts, by removing the part of each line in a close neighborhood of its leftmost intersection with τ^* . Then both parts have only one intersection with τ^* . Each of the two stubs can be extended by following τ^* and crossing whatever needs to be crossed so that both together with all other split curves, the remaining lines from \mathcal{A} , and τ^* form a pseudoline arrangement \mathcal{A}' of at most $2n + 1$ pseudolines; see Fig. 3. Then, by Theorem 13, there are at most $O(3^{2n}) = O(9^n)$ cutpaths of τ^* in \mathcal{A}' . ◀

To summarize, we encode the obstacle representation (D, \mathcal{O}) of G by first encoding the order type of V . By Theorem 11, there are at most $2^{O(n \log n)}$ choices for the order type of a set of n points. The order type of V determines the arrangement \mathcal{A} of n lines that are dual to the points from V . By Lemma 12, it suffices to encode the endpoints of the blocking

intervals $I_O(v)$ for every $v \in V$ and $O \in \mathcal{O}$, which are defined using the radial system of V that is also determined by the order type of V . For each obstacle $O \in \mathcal{O}$, the endpoints of all the intervals $I_V(O)$ are determined by the cutpath of the curve τ^* in \mathcal{A} constructed for the upper tangents of O and the analogous curve β^* constructed for the lower tangents of O . By Lemma 14, there are at most $O(9^n)$ cutpaths of τ^* in \mathcal{A} and the same estimate holds for β^* . This gives at most $O((9^n)^2) = O(81^n)$ possible ways how to encode a single obstacle. Altogether, we thus obtain $f_c(h, n) \in 2^{O(n \log n)} \cdot O(81^{hn}) \subseteq 2^{O(n \log n + hn)}$.

4 A Lower Bound on the Obstacle Number of Drawings

Here, we prove Theorem 7 by showing that there is a constant $\delta > 0$ such that, for every n , there exists a graph G on n vertices and a drawing D of G such that $\text{obs}(D) \geq \delta \cdot n^2$. The proof is constructive. We first assume that n is even.

A set of points in the plane is a *cup* if all its points lie on the graph of a convex function. Similarly, a set of points is a *cap* if all its points lie on the graph of a concave function. For an integer $k \geq 3$, a convex polygon P is *k-cap free* if no k vertices of P form a cap of size k . Note that P is *k-cap free* if and only if it is bounded from above by at most $k - 1$ segments (edges of P). We use $e(P)$ to denote the leftmost edge bounding P from above; see Fig. 4(a).

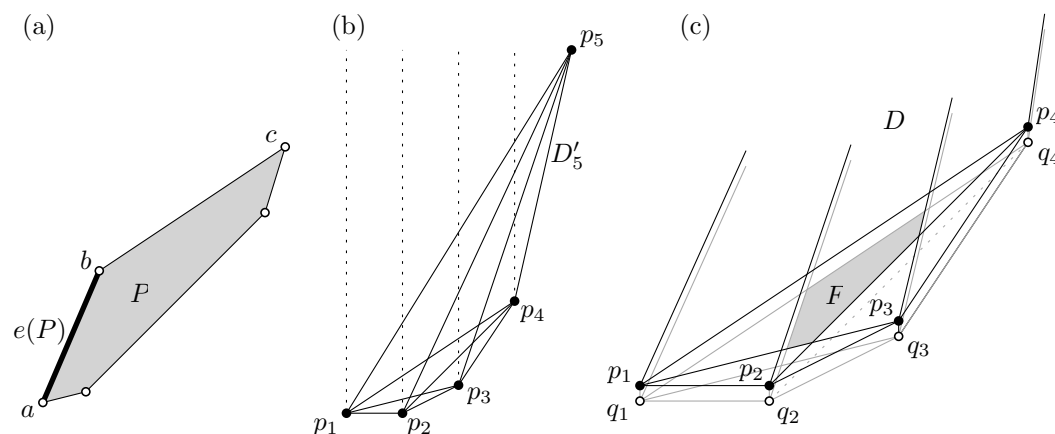

Figure 4 (a) A 4-cap free polygon P that is not 3-cap free. (b) An example of the drawing D'_m for $m = 5$. If the point p_m is chosen sufficiently high above C_{m-1} , then each line segment $\overline{p_i p_m}$ with $i < m$ is very close to the vertical line containing p_i and thus all faces of D'_m will be 4-cap free. (c) An example of a part of the drawing D with an example of a face F of D . The line segments that are not in D'_m are drawn grey and the non-edge from X is dotted. For better readability of the picture, edges $p_i q_j, i \neq j$, are not drawn.

Let $m = n/2$. First, we inductively construct a set C_m of m points p_1, \dots, p_m in the plane that form a cup and have x -coordinates $x(p_i) = i$. We let $C_1 = \{(1, 0)\}$ and $C_2 = \{(1, 0), (2, 0)\}$. Now, assume that we have already constructed a set $C_{m-1} = \{p_1, \dots, p_{m-1}\}$ for some $m \geq 3$. Let D'_{m-1} be the drawing of the complete graph with vertices p_1, \dots, p_{m-1} . We choose a sufficiently large number y_m , and we let p_m be the point (m, y_m) and $C_m = C_{m-1} \cup \{p_m\}$. We also let D'_m be the drawing of the complete graph with vertices p_1, \dots, p_m . The number y_m is chosen large enough so that the following three conditions are satisfied:

1. for every $i = 1, \dots, m - 1$, every intersection point of two line segments spanned by points of C_{m-1} lies on the left side of the line $p_i p_m$ if and only if it lies to the left of the vertical line $x = i$ containing the point p_i ,

11:10 Bounding and Computing Obstacle Numbers of Graphs

2. if F is a 4-cap free face of D'_m that is not 3-cap free, then there is no point p_i below the (relative) interior of $e(F)$,
3. no crossing of two edges of D'_m lies on the vertical line containing some point p_i .

Note that choosing the point p_m is possible as choosing a sufficiently large y -coordinate y_m of p_m ensures that for each i , all the intersections of the line segments $p_i p_m$ with line segments of D'_{m-1} lie very close to the vertical line $x = i$ containing the point p_i . Furthermore, the construction implies that no line segment of D'_m is vertical and that no point is an interior point of more than two line segments of D'_m . The drawing D'_m also satisfies the next claim.

▷ **Claim 15.** Each inner face of D'_m is a 4-cap free convex polygon.

For some (small) $\varepsilon > 0$ and every $i \in \{1, \dots, m\}$, where $m = n/2$, we let q_i be the point $(i, y_i - \varepsilon)$. That is, q_i is a point slightly below p_i . We choose ε sufficiently small so that decreasing ε to any smaller positive real number does not change the combinatorial structure of the intersections of the line segments spanned by the n points $p_1, \dots, p_m, q_1, \dots, q_m$. We let $D = D_n$ be the drawing with n vertices $p_1, \dots, p_m, q_1, \dots, q_m$ containing all the line segments between two vertices, except the line segments $\overline{q_i q_j}$ where i and j are both even.

We have to show that at least quadratically many obstacles are needed to block all non-edges of G in D . Let X be the set of line segments $\overline{q_i q_j}$ where both i and j are even. Note that each line segment from X corresponds to a non-edge of G and that $|X| = \binom{\lfloor n/4 \rfloor}{2} \geq n^2/40$ for a sufficiently large n . The proof of the following claim is based on Claim 15.

▷ **Claim 16.** Every face of D is intersected by at most two line segments from X .

Now, let \mathcal{O} be a set of obstacles such that D and \mathcal{O} form an obstacle representation of G . Then each non-edge of G corresponds to a line segment from X that is intersected by some obstacle from \mathcal{O} . Each obstacle O from \mathcal{O} lies in some face F_O of D as it cannot intersect an edge of G . Thus, O can intersect only line segments from X that intersect F_O . It follows from Claim 16 that each obstacle from \mathcal{O} intersects at most two line segments from X . Since $|X| \geq n^2/40$, we obtain $|\mathcal{O}| \geq |X|/2 \geq n^2/80$. Consequently, $\text{obs}(D) \geq n^2/80$, which finishes the proof for n even. If n is odd, we use the above construction for $n - 1$ and add an isolated vertex to it.

5 Obstacle Number is FPT Parameterized by Vertex Cover Number

As our first step towards a fixed-parameter algorithm, we need to establish a bound on the obstacle number of every graph with bounded vertex cover number.

► **Lemma 17.** *Let G be a graph with vertex cover number k . Then G admits an obstacle representation with $1 + \binom{k}{2} + k \cdot 2^k$ obstacles.*

Proof Sketch. We construct an obstacle representation for G as follows. We place the vertices in the vertex cover X somewhere in a central area, and dedicate at most $\binom{k}{2}$ obstacles to handle the visibilities between these. Next, we partition the vertices outside of X into at most 2^k equivalence classes called *types* based on the following equivalence: two vertices $a, b \notin X$ have the same type if and only if they have the same neighborhood. We place these vertices on a line ℓ sufficiently far from the other vertices, and group them by type. We then use a single obstacle to block the pairwise visibilities of vertices on ℓ , and at most $k \cdot 2^k$ obstacles to block visibilities between each type and each vertex in X where necessary. ◀

Our proof will also rely on a Ramsey-type argument based on the following formulation of Ramsey's theorem [19]:

► **Theorem 18** ([19]). *There exists a function $\text{Ram}: \mathbb{N}^2 \rightarrow \mathbb{N}$ with the following property. For each pair of integers q, s and each clique H of size at least $\text{Ram}(q, s)$ such that each edge has a single label (color) out of a set of q possible labels, it holds that H must contain a subclique K of size at least s such that every edge in K has the same label.*

We can now proceed towards a proof of Theorem 8, which establishes the fixed-parameter tractability of computing the obstacle number with respect to the vertex cover number.

Proof Sketch for Theorem 8. Let X be a computed vertex cover of size at most k in the input graph G . If $h > 1 + \binom{k}{2} + k \cdot 2^k$ we immediately output “Yes” by Lemma 17, and so for the rest of the proof, we proceed assuming that $h \leq 1 + \binom{k}{2} + k \cdot 2^k$. We also note that if G contains only types of size bounded by a fixed, sufficiently large function of k (which we will hereinafter denote $\text{typesize}(k)$), then the instance can be solved by brute force. Hence, we assume that G contains at least one type T with more than $\text{typesize}(k)$ vertices.

Our proof strategy will be to show that under these conditions, G is a **Yes**-instance (i.e., admits a representation with at most h obstacles) if and only if the graph G'' obtained by deleting an arbitrary vertex from T is a **Yes**-instance; in other words, that we may prune a vertex from T . This claim would immediately yield fixed-parameter tractability of the problem: one could iterate the procedure of computing a vertex cover for the input graph, checking whether the types are sufficiently large, and based on that check one either brute-forces the problem or restarts on a graph that contains one fewer vertex (notice that the number of restarts is upper-bounded by n).

As a first step, let us consider a hypothetical “optimal” solution S for (G, h) , i.e., S is an obstacle representation of G with the minimum number of obstacles. It is easy to observe that simply using the same placement of obstacles for the graph G'' obtained by *removing* a single vertex from T yields a desired solution S' for (G'', h) . It is the converse direction that is the difficult one: for that, it suffices to establish the equivalent claim that the graph G' obtained by *adding* a vertex to T admits an obstacle representation S' with the same number of obstacles as S .

Given S , we will now consider an auxiliary edge-labeled clique H whose vertices are precisely the vertices in T , which can be assumed to be ordered by \prec in an arbitrary but fixed way. For each pair of vertices $a, b \in T$ where $a \prec b$, the a - b edge in H is labeled by the first obstacle encountered when traversing the line segment \overline{ab} . Crucially, by Theorem 18 and the selection of $\text{typesize}(k) \geq \text{Ram}(h, 10k^3 \cdot 2^k)$, H must contain a subclique K of size at least $\text{cliquesize}(k) = 10k^3 \cdot 2^k$ such that each edge in K has the same label, say p .

Intuitively, our aim in the rest of the proof will be to show that the obstacle p can be “safely” extended towards some vertex z in K , where by safely we mean that it neither intersects another obstacle nor blocks the visibility of an edge; this extension will either happen directly from S , or from a slightly altered version of S . Once we create such an extension, it will be rather straightforward to show that p can be shaped into a tiny “comb-like” slot for a new vertex z' next to z which will have the same visibilities (and hence neighborhood) as z , which means we have constructed a solution S' for G' as desired.

To this end, we show that almost all vertices in K must be placed in a system of *crevices* formed by p (these can be imagined as “openings” in p , each containing a specific *crevice vertex* from K ; see Fig. 5). By a sequence of claims, we can then restrict our attention to a still sufficiently large subsystem of these crevices which are *good*, meaning that they contain no obstacle other than p , no vertex from the vertex cover, and where visibilities between pairs of vertices outside the crevice would not be obstructed by extending p towards the crevice vertex. However, other vertices may still be present in good crevices, and so such an extension could still obstruct the visibility of vertices inside the crevice.

■ **Figure 5** The crevices of obstacle p are the light blue regions containing the vertices $\dots, v_{i-1}, v_i, v_{i+1}, \dots$ of K .

To deal with this final issue and extend p to a crevice vertex as required to conclude the proof, we will seek out a crevice which is not just good but also *perfect*, meaning that it contains no vertex other than the crevice vertex. While S itself need not contain a perfect crevice, in the last part of the proof we use a swapping argument on S to argue the existence of an equivalent solution which is guaranteed to contain one. ◀

6 NP-Hardness of Deciding Whether a Given Obstacle is Enough

In this section, we investigate the complexity of the obstacle representation problem for the case that a single (outside) obstacle is given.

► **Theorem 9.** *Given a graph G and a simple polygon P , it is NP-hard to decide whether G admits an obstacle representation using P as (outside-) obstacle.*

Proof Sketch. We reduce from 3-PARTITION, which is NP-hard [11]. An instance of 3-PARTITION is a multiset S of $3m$ positive integers a_1, \dots, a_{3m} , and the question is whether S can be partitioned into m groups of cardinality 3 such that the numbers in each group sum up to the same value B , which is $(\sum_{i=1}^{3m} a_i)/m$. The problem remains NP-hard if B is polynomial in m and if, for each $i \in [3m]$, it holds that $a_i \in (B/4, B/2)$.

Given a multiset S , we construct a graph G and a simple polygon P with the property that the vertices of G can be placed in P such that their visibility graph with respect to P is isomorphic to G if and only if S is a yes-instance of 3-PARTITION.

Let G be a clique with vertices v_1, \dots, v_{3m} where, for $i \in [3m]$, *clique vertex* v_i is connected to a_i leaves $\ell_{i,1}, \dots, \ell_{i,a_i}$. The polygon P (see Fig. 6) is an orthogonal polygon with m groups of B bays (red in Fig. 6) that are separated from each other by corridors (of height $B/4$ and width $4B$; light blue in Fig. 6). Each bay is a unit square; any two consecutive bays are one unit apart. The height of P (including the bays) is $B/2 + 1$. Note that the sizes of G and P are polynomial in m . ◀

■ **Figure 6** Idea of the reduction from 3-PARTITION. The drawing is not to scale.

Abstract

Repetitiveness measures reveal profound characteristics of datasets, and give rise to compressed data structures and algorithms working in compressed space. Alas, the computation of some of these measures is NP-hard, and straight-forward computation is infeasible for datasets of even small sizes. Three such measures are the smallest size of a string attractor, the smallest size of a bidirectional macro scheme, and the smallest size of a straight-line program. While a vast variety of implementations for heuristically computing approximations exist, exact computation of these measures has received little to no attention. In this paper, we present MAX-SAT formulations that provide the first non-trivial implementations for exact computation of smallest string attractors, smallest bidirectional macro schemes, and smallest straight-line programs. Computational experiments show that our implementations work for texts of length up to a few hundred for straight-line programs and bidirectional macro schemes, and texts even over a million for string attractors.

1 Introduction

Text compression is a fundamental topic in computer science with countless practical applications. *Dictionary compression* is a type of text compression where the original input is transformed into a sequence of elements taken from a dictionary, where the dictionary is usually constructed in some way from the input. Due to the advent of *highly repetitive* datasets such as multiple genome sequences from the same species or versioned document collections (e.g., Wikipedia, GitHub), dictionary compression methods have recently (re)gained massive attention since they can better capture more widespread repetitions in such data compared to statistical compression methods [30], and further allow space-efficient full-text

indices to be built [31]. Some well known methods that fall in this category are Lempel–Ziv 76/77 factorization based methods [20, 23, 43], grammar-based compression such as LZ78 [44], Re-Pair [22], SEQUITUR [34], LCA [38], LZD [11], and methods involving bidirectional referencing, such as the run-length encoded Burrows–Wheeler transform (RLBWT) [25], and more recently, lpccomp [10], plpccomp [9], lexcomp [32], a method by Russo et al. [36], and LZRR [35].

A vital issue in evaluating and comparing these various methods is to understand how well they can compress a given input compared to the “optimum”. While the theoretically smallest representation (aka Kolmogorov complexity) is incomputable [24], Kempa and Prezza [16] regarded the output sizes of these methods as *repetitiveness measures* and characterized them with respect to the new notion of *string attractors*. Namely, they showed that for any input text, the size of the smallest string attractor is a lower bound for the output sizes of all known dictionary compressors. Since then, relations between these various repetitiveness measures have been heavily investigated [2, 4, 14, 17, 19, 30, 32].

In this paper, we consider three such repetitiveness measures: the size γ of the smallest string attractor, the size g of the smallest straight-line program (SLP) [13], and the size b of the smallest bidirectional macro scheme (BMS) [42], all of which are known to be NP-hard to compute [16, 39, 42]. Thus, any efficient dictionary compression algorithm can (most likely) merely compute approximations of γ , b , or g . Although for any text, the relation $\delta \leq \gamma \leq b \leq z \leq g$ is known, where δ [19] and z [23] are repetitiveness measures known to be computable in linear time (cf. [7, Lemma 5.7] for δ and [8] for z), the gap between the measures can be quite large; string families giving a logarithmic factor gap are known for each pair of measures [2, 30]. Since the sizes of some recent data structures such as [7, 33], depend on these repetitiveness measures, their exact sizes are crucial knowledge.

While there exist a vast variety of approximation algorithms for computing smallest BMSs and grammars as mentioned above, development of exact algorithms have received very little to almost no attention. For string attractors, the results of Kempa et al. [15] imply a straightforward $O(n2^n)$ time algorithm. For the smallest grammar, Casel et al. [6, Theorem 13] show an $O^*(3^n)^1$ time algorithm. However, we are unaware of any non-trivial implementations or empirical evaluations for computing these measures. In fact, the only publicly available implementation we could find was a straight-forward Python script to compute γ by Michael S. Branicky [12].

The main contribution of this paper is to present MAX-SAT formulations [3] for computing the smallest string attractor, BMS, and SLP, thereby providing the first non-trivial implementation for exact computation of the measures γ , b , and g . The rationale for this approach is that although MAX-SAT is NP-hard, there are highly optimized solvers whose performance has made incredible progress in recent years. These solvers can cope with very large instances and can be leveraged, provided that suitable encodings can be designed [18]. While straight-forward (non-MAX-SAT) implementations become infeasible even for very small text lengths (e.g. 40), computational experiments show that our implementations work for texts of length up to a few hundred for b , g , and even more than 1 million for γ . Since our addressed problems are all NP-hard, there is perhaps little hope for our implementations to obtain exact solutions for larger but practically interesting datasets. Nevertheless, we believe they can make significant impact as a tool for analyzing these repetitiveness measures. We stress that our solutions not only report the sizes γ , b and g , but also give valid instances having exactly these sizes (e.g., an SLP that has size g). It may therefore be possible to

¹ The abstract of [6] mentions $O(3^n)$ while the statement of the theorem is $O^*(3^n)$.

improve compression heuristics by studying some of these optimal instances on smaller input strings. As an example application, we analyzed the recently introduced notion of *sensitivity* [1] of γ by conducting an exhaustive computation of γ for strings up to certain lengths. From these computations, we were able to discover a family of strings that exhibit a multiplicative sensitivity of 2.5, improving the previously known lower bound of 2.0 [1].

Related Work

The exact values for γ , b , and g have been characterized only for a few families of strings. For standard Sturmian words, $\gamma = 2$ [26] and $b = O(1)$ since the RLBWT has constant size [27] and can be regarded as a BMS. For the n th Thue–Morse word, $\gamma = 4$ for $n \geq 4$ [21], and $b = n + 2$ for $n \geq 2$ [2]. For the n th Fibonacci word, $g = n$ [28]. The smallest attractor sizes of automatic sequences have also been studied [40].

2 Preliminaries

Let Σ be a set of σ symbols called the *alphabet*, and let Σ^* denote the set of strings over Σ . Given a string T , if $T = xyz$ for strings x, y, z , then x, y, z are respectively called a *prefix*, *substring*, and *suffix* of T . They are called *proper* if they are not equal to T . The length of T is denoted by $|T|$. For any $i \in [1, |T|]$, let $T[i]$ denote the i th symbol of T , i.e., $T = T[1] \cdots T[|T|]$. For any $1 \leq i \leq j \leq |T|$, let $T[i..j] = T[i] \cdots T[j]$ and $T[i..j) = T[i] \cdots T[j - 1]$.

For the rest of this paper, we fix a string T , and let $n := |T|$ denote its length. Further, we assume that each symbol of Σ appears in T . Let $occ(P) = \{i \mid T[i..i + |P| - 1] = P, 1 \leq i \leq n - |P| + 1\}$ be the set of starting positions of all occurrences of a substring P in T , and let $cover(P) = \{i + k - 1 \mid i \in occ(P), 1 \leq k \leq |P|\}$ be the set of all text positions covered by all occurrences of P in T .

A set of positions $\Gamma \subseteq [1, n]$ is a *string attractor* [16] of T if every substring P of T has an occurrence in T that contains an element of Γ , that is, $\Gamma \cap cover(P) \neq \emptyset$. We denote the size of the smallest string attractor of T by γ . For example, $[1, n]$ is a trivial string attractor. $\{1, 2, 3\}$ is a (smallest) string attractor of $T = \text{banana}$. (See also Figure 2)

A *straight-line program* (SLP) [13] is a grammar in Chomsky normal form whose language consists solely of T . In other words, (1) each production rule is of the form $X \rightarrow X_\ell X_r$ or $X \rightarrow c$, where X_ℓ, X_r are non-terminals and $c \in \Sigma$, (2) there is exactly one such production rule for any given non-terminal symbol X , and (3) there is a start symbol whose iterative expansion finally leads to T . The *size* of an SLP is the number of its production rules, or equivalently (assuming that each non-terminal is used at least once), the number of distinct non-terminals. We denote the size of the smallest SLP that produces T by g . For example, the set of production rules $\{X_9 \rightarrow X_6 X_8, X_8 \rightarrow X_7 X_7, X_7 \rightarrow X_1 X_3, X_6 \rightarrow X_4 X_5, X_5 \rightarrow X_3 X_3, X_4 \rightarrow X_3 X_1, X_3 \rightarrow X_1 X_2, X_2 \rightarrow \mathbf{b}, X_1 \rightarrow \mathbf{a}\}$ is an SLP of size 9 for $T = \text{abaababaabaab}$. See also Figure 3.

A *bidirectional macro scheme* (BMS) [42] of size m representing T , is a factorization $T = F_1 \cdots F_m$, where each factor (or phrase) is a single symbol (which we call a ground phrase), or, is encoded as a pair of integers (i, j) indicating that it references (i.e., is a copy of) substring $T[i..j]$. A BMS is said to be *valid*, if T can be reconstructed from the representation of such a factorization, i.e., the implied references of each symbol in a non-ground phrase is acyclic, and eventually leads to a ground phrase. We denote the size of the smallest valid BMS that represents T by b . Figure 1 shows a valid BMS $(7, 8), (4, 5), \mathbf{a}, \mathbf{b}, (5, 7)$ representing the string abaaababa . For example, the \mathbf{a} at position 9 references position 7, which in turn references position 5, a ground phrase.

■ **Figure 1** A bidirectional macro scheme (BMS) of $T = \text{abaaababa}$. The figure depicts the BMS $(7, 8), (4, 5), a, b, (5, 7)$. The reference of each non-ground phrase is visualized by an arrow. The phrase references imply a reference for each symbol in non-ground phrases.

The satisfiability (SAT) problem asks for an assignment of variables that satisfies a given Boolean formula [3, 18]. The input formula is usually given in *conjunctive normal form* (CNF), which consists of a conjunction of clauses, and each clause is a disjunction of literals. A *literal* is a Boolean variable or its negation. In this form, the given formula is satisfied if and only if all the clauses (which we will sometimes call constraints) are satisfied. The *size* of a CNF is the sum of the literals in all clauses.

A *maximum satisfiability* (MAX-SAT) problem is an extension of SAT, where two types of clauses, *hard* and *soft*, are considered [3]. A solution to a MAX-SAT instance is a truth assignment of the variables such that the number of satisfied soft clauses is maximized under the restriction that all hard clauses must be satisfied.

We will use 1 to denote true, and 0 to denote false. Furthermore, for a set $\{v_i\}_{i=1}^k$ of Boolean variables, cardinality constraints of the form $\sum_{i=1}^k v_i \leq 1$ are known as *atmost-one constraints*. Although a straightforward encoding has size $\Theta(k^2)$, $O(k)$ size encodings are known [41]. Constraints of the form $\sum_{i=1}^k v_i = 1$ can be encoded using a combination of an atmost-one constraint and a simple disjunction of all the variables (i.e., at least-one) and thus can also be encoded in $O(k)$ size.

3 Reductions to MAX-SAT

In what follows, we present our encodings for the aforementioned problems. Common to all encodings is the idea that we have a Boolean variable p_i for each text position $i \in [1, n]$, which counts, when set to true, an element of a string attractor, a non-terminal (actually, to be precise, a factor in a grammar parsing) of an SLP, or a phrase of a BMS. Since our goal is to have as few p_i 's set to true as possible, our soft clauses have the form $D_i = \neg p_i$ for $i \in [1, n]$. Consequently, all our encodings have the same number of soft clauses, and only differ in how the hard clauses are defined.

3.1 Smallest String Attractor as MAX-SAT

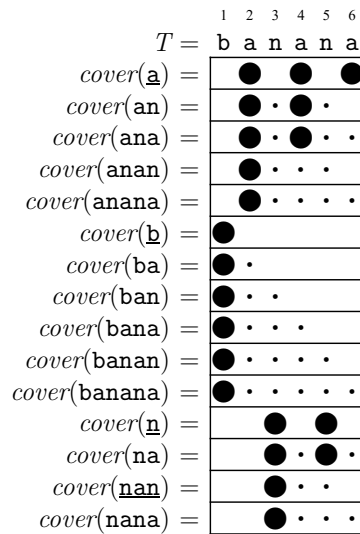

We start with a simple encoding based on the definition of string attractors. Subsequently, we utilize an observation similar to but slightly more generalized than that made in [15], in order to reduce the size of hard clauses.

3.1.1 Simple Encoding

Our idea is to design a CNF so that a MAX-SAT solution will encode a string attractor Γ , where $p_i = 1$ if and only if position i is an element of Γ (i.e., $\Gamma = \{i \mid 1 \leq i \leq n, p_i = 1\}$). Let \mathcal{S}_T denote the set of all non-empty substrings of T , i.e., $\mathcal{S}_T = \{T[i..j] \mid 1 \leq i \leq j \leq n\}$.

For each substring S of \mathcal{S}_T , we define a hard clause $C_S = \bigvee_{i \in \text{cover}(S)} p_i$. (See Figure 2 for an example.) By the definition of $\text{cover}(S)$, the set Γ corresponding to any truth assignment for p_i will be a string attractor if and only if all hard clauses C_S are satisfied. Since our soft clauses have the form $D_i = \neg p_i$ for $i \in [1, n]$, the soft clauses ensure that the MAX-SAT solution minimizes the number of p_i 's being true. Thus, we can obtain the smallest string attractor by solving the MAX-SAT on C_S and D_i .

Each hard clause C_S has size $|\text{cover}(S)| = O(n)$. Since there are $O(n^2)$ substrings, the number of hard clauses is $O(n^2)$. Hence, the total size of the CNF is $O(n^3)$. In the next subsection, we reduce the size to $O(n^2)$.

■ **Figure 2** String $T = \text{banana}$ and the positions that each distinct substring of T covers. We list all distinct substrings of T on the left hand side, and show on the right hand side their covers. A dot at position k in the row for substring S indicates that k is included in $\text{cover}(S)$ (i.e. is covered by S), and a large dot indicates $k \in \text{occ}(S)$. Underlined substrings are minimal substrings of T . For example, $\text{cover}(\underline{an}) = \{2, 3, 4, 5\}$. The clause defined for \underline{an} in our encoding is $C_{\underline{an}} = p_2 \vee p_3 \vee p_4 \vee p_5$.

3.1.2 Reducing CNF Clauses via Minimal Substrings

We can reduce the number of hard clauses in our CNF by considering only members of \mathcal{S}_T that are *minimal substrings*². A substring S of string T is called a minimal substring of T if all proper substrings of S occur more often than S in T (i.e., $|\text{occ}(S[i..j])| > |\text{occ}(S)|$ for every proper substring $S[i..j]$ of S). By the definition of minimal substrings, the following lemma holds.

► **Lemma 1.** *For every non-minimal substring S of T , there is a minimal substring S_{\min} of S with $\text{cover}(S_{\min}) \subseteq \text{cover}(S)$.*

² Kempa et al. [15] use a similar idea when reducing the problem to set cover. Their formulation can be regarded as considering only right-minimal substrings (i.e., $|\text{occ}(S[1..|S| - 1])| > |\text{occ}(S)|$), while we consider a potentially smaller subset requiring both right-minimality and left-minimality. For texts in the Calgary corpus, we observed that the difference between minimal and right-minimal substrings can result in a difference as large as 50 times in their total lengths (prog and trans), i.e., the total size of hard clauses.

Proof. Because S is not minimal, it has substrings that have the same number of occurrences as S . Let $S_{\min} = S[e..e+|S_{\min}|-1]$ be one of these substrings that is minimal, for some e . Then by definition, for each occurrence $i_{\min} \in \text{occ}(S_{\min})$ of S_{\min} , there exists an occurrence $i \in \text{occ}(S)$ of S such that $i = i_{\min} - e + 1$. $\{i_{\min}, i_{\min} + 1, \dots, i_{\min} + |S_{\min}| - 1\} \subseteq \{i, i + 1, \dots, i + |S| - 1\}$, and hence, $\text{cover}(S_{\min}) \subseteq \text{cover}(S)$. \blacktriangleleft

In the example $T = \text{banana}$, $|\text{occ}(\text{nan})| < |\text{occ}(\text{na})|, |\text{occ}(\text{an})|, |\text{occ}(\text{a})|, |\text{occ}(\text{n})|$, and thus, substring nan is a minimal substring of T . Furthermore, nan is a substring of nana , and $|\text{occ}(\text{nana})| = |\text{occ}(\text{nan})|$. Thus, $\text{cover}(\text{nan}) \subseteq \text{cover}(\text{nana})$ by Lemma 1. (See also Figure 2)

Lemma 1 ensures that if an assignment of variables satisfies the hard clauses C_S for all minimal substrings S of T , then the assignment satisfies the hard clauses C_S for all substrings S of T . With this observation we can conclude that we can omit the hard clauses for all substrings S of T that are not minimal.

The number m of minimal substrings is $O(n)$ because minimal substrings correspond to minimal strings, defined by Blumer et al. [5] based on an equivalence relation over substrings of T , and their number is known to be $O(n)$ (Lemma 3 in [29]). Hence, the total size of the CNF is reduced to $O(mn) \subseteq O(n^2)$.

In particular, the size of the CNF is $o(n^2)$ if $m = o(n)$. We can show that there exists a family of strings $\{T_d\}_{d \in \mathcal{I}}$ for a non-finite set of natural numbers \mathcal{I} with $|T_d| = d^2$ having $o(d^2)$ minimal substrings (hence, for $n = d^2$, $m = o(n)$). To this end, let T_d be the string $S_1 S_2 \cdots S_d$ of length $n = d^2$ over the alphabet $\Sigma = \{\mathbf{a}, \$1, \$2, \dots, \$d\}$, where $S_i = \mathbf{a}^{d-1} \$i$, and \mathbf{a}^{d-1} is the repetition of character \mathbf{a} with length $d - 1$. Then $m = 2\sqrt{n} - 1$ because the minimal substrings of T_d are $\mathbf{a}^1, \mathbf{a}^2, \dots, \mathbf{a}^{\sqrt{n}-1}, \$1, \$2, \dots, \\sqrt{n} .

3.2 Smallest Straight-Line Program as MAX-SAT

To encode a grammar in SAT, we utilize a notion called *grammar parsing* introduced by Rytter [37]. Given an SLP G that produces T , the *parse tree* of T with respect to G is a derivation tree of T , where internal nodes are non-terminal symbols that derive two non-terminal symbols, and leaves are non-terminal symbols that derive a single terminal symbol. The *partial parse tree* of T with respect to G is the tree obtained by pruning the parse tree of T with respect to G so that any internal node is always a first occurrence in a left to right pre-order traversal of the parse tree, i.e., the non-terminal symbol of an internal node is not used in the partial parse tree for any corresponding substring to its left. In other words, if a non-terminal symbol X that derives two non-terminal symbols is a leaf of the partial parse tree, the existence of a unique internal node having the same non-terminal symbol X corresponding to a substring to its left is implied. We will say that the leaf *references* the internal node. The *grammar parsing* of T with respect to G , is the factorization of T consisting of substrings corresponding to the leaves of the partial parse tree of T with respect to G . See Figure 3 for an example.

The *size* of the grammar parsing is equal to the number of leaves in the partial parse tree. It is easy to see that by definition, the internal nodes in the partial parse tree are distinct, consisting of (all) non-terminal symbols that derive two non-terminal symbols. There are σ more non-terminal symbols that derive a single terminal symbol. Therefore, $(\# \text{ of internal nodes}) + \sigma$ is the size of the SLP. Since the partial parse tree is a full binary tree, $(\# \text{ of internal nodes}) = (\# \text{ of leaves}) - 1$, and thus the size of the SLP is equal to $(\text{size of the grammar parsing}) + \sigma - 1$. As σ is independent of the choice of the SLP for T , minimizing the size of the grammar parsing is equivalent to minimizing the SLP.

Our formulation is based on the following lemma.

Figure 3 The partial parse tree and the grammar parsing of an SLP for the string $T = \text{abaababaabaab}$. Each internal node is a unique non-terminal symbol. The grammar parsing represented by the rectangles partitioning T is $\text{a, b, a, ab, ab, a, ab, aab}$ of size 8. The size of the SLP is $8 + |\{\text{a, b}\}| - 1 = 9$.

► **Lemma 2.** A factorization $T = F_1 \cdots F_m$ for T is the grammar parsing of an SLP for T if and only if (i) for each factor F_k longer than 1, there exist $i_k < j_k < k$ such that: $F_k = F_{i_k} \cdots F_{j_k}$ and (ii) for any pair of factors $F_x = F_{i_x} \cdots F_{j_x}$ and $F_y = F_{i_y} \cdots F_{j_y}$ longer than 1, (i.e., $(x, y) \in \{(x', y') \mid 1 \leq x', y' \leq m, |F_{x'}| > 1, |F_{y'}| > 1\}$), the intervals $[i_x..j_x]$ and $[i_y..j_y]$ are either disjoint or one is a sub-interval of the other.

Proof. (\Rightarrow) Suppose $F_1 \cdots F_m$ is the grammar parsing of some SLP for T . Then, any F_k longer than 1 has an implied corresponding internal node to the left in the partial parse tree. Since an internal node derives at least two leaves, it derives $F_{i_k} \cdots F_{j_k}$ corresponding to the interval $[i_k..j_k]$ of the factorization for some $i_k < j_k < k$. Furthermore, since all of these intervals are derived from internal nodes of a tree, they must respect the tree structure, i.e., any two of them must be disjoint or contained in one another.

(\Leftarrow) Suppose we are given a factorization $T = F_1 \cdots F_m$ of T , as well as for each F_k , a corresponding interval $[i_k..j_k]$ of the factorization satisfying the conditions of the lemma. Since, for any pair of factors $F_x = F_{i_x} \cdots F_{j_x}$ and $F_y = F_{i_y} \cdots F_{j_y}$, the intervals $[i_x..j_x]$ and $[i_y..j_y]$ are disjoint or contained in one another, we can construct a tree with the internal nodes corresponding to the intervals and the leaves corresponding to the factors of the factorization, where a node is a descendant of another if and only if it is a sub-interval. Although such a tree can be multi-ary in general, we can add internal nodes and transform it into a full binary tree while preserving ancestor/descendant relations of nodes/leaves in the original tree (note that the resulting tree may not be determined uniquely, but its size will always be the same). We assign to each internal node a distinct non-terminal symbol. To each leaf corresponding to a factor F_k longer than 1, we assign the same non-terminal symbol that we assigned to the internal node corresponding to $F_{i_k} \cdots F_{j_k}$. Finally, we assign each leaf corresponding to a factor of length 1 a non-terminal symbol that derives the corresponding terminal symbol. The resulting tree is a partial parse tree for an SLP of size $m + \sigma - 1$ for T with $F_1 \cdots F_m$ as its grammar parsing. ◀

12:8 Computing NP-Hard Repetitiveness Measures via MAX-SAT

We define Boolean variables as follows to encode Lemma 2.

- $f_{i,\ell}$ for $i \in [1, n], \ell \in [1, n + 1 - i]$: $f_{i,\ell} = 1$ if and only if $T[i..i + \ell]$ is a factor of the grammar parsing.
- p_i for $i \in [1, n + 1]$: For $i \neq n + 1$, $p_i = 1$ if and only if i is a starting position of a factor of the grammar parsing. p_{n+1} is for technical reasons. We set $p_1 = p_{n+1} = 1$.
- $ref_{i' \leftarrow i, \ell}$ for $i, \ell, i' \in [1, n]$, s.t. $\ell \geq 2, i' \leq i - \ell$ and $T[i'..i' + \ell] = T[i..i + \ell]$: $ref_{i' \leftarrow i, \ell} = 1$ if and only if $T[i..i + \ell]$ is a factor of the grammar parsing, and the implied internal node of the partial parse tree corresponds to $T[i'..i' + \ell]$.
- $q_{i', \ell}$ for $i' \in [1, n - 1], \ell \in [2, n + 1 - i']$ s.t. $T[i'..i' + \ell]$ has an occurrence in $T[i' + \ell..n]$: $q_{i', \ell} = 1$ if and only if $T[i'..i' + \ell]$ corresponds to an internal node of the partial parse tree that is referenced by at least one factor of the grammar parsing.

We next define constraints that the above variables must satisfy.

First, since each factor of the grammar parsing is disjoint and the concatenation of all factors must be equal to T , the truth values of $f_{i,\ell}$ must uniquely define the truth values for p_i and vice versa. This can be encoded as

$$\forall i \in [1, n], \ell \in [1, n + 1 - i] : f_{i,\ell} \iff p_i \wedge (\neg p_{i+1}) \cdots (\neg p_{i+\ell-1}) \wedge p_{i+\ell} \quad (1)$$

For all i and $\ell \geq 2$ such that $T[i..i + \ell]$ is the first occurrence of a substring $S = T[i..i + \ell]$ of T , $T[i..i + \ell]$ cannot be a factor of a grammar parsing. Thus, we require:

$$\forall i \in [1, n - 1], \ell \in [2, n - i + 1] \text{ s.t. } T[i..i + \ell] \text{ does not occur in } T[1..i] : \neg f_{i,\ell} \quad (2)$$

If $T[i..i + \ell]$ is not the first occurrence of S , $T[i..i + \ell]$ can be a factor. If $T[i..i + \ell]$ is a factor of the grammar parsing of length at least 2, then, there must exist at least one $i' \leq i - \ell$ such that $T[i'..i' + \ell] = S$ and $T[i'..i' + \ell]$ corresponds to an internal node of the partial parse tree. This can be encoded as

$$\begin{aligned} & \forall i \in [1, n], \ell \in [2, n + 1 - i] \text{ s.t. } T[i..i + \ell] \text{ occurs in } T[1..i] : \\ & f_{i,\ell} \implies \bigvee_{i' \in \{k \mid T[k..k + \ell] = T[i..i + \ell], k \in [1, i - \ell]\}} ref_{i' \leftarrow i, \ell}. \end{aligned} \quad (3)$$

Furthermore, for any i, ℓ , a factor $T[i..i + \ell]$ references at most one position, i.e.,

$$\forall i \in [1, n], \ell \in [2, n + 1 - i] : \sum_{i' \in \{k \mid T[k..k + \ell] = T[i..i + \ell], k \in [1, i - \ell]\}} ref_{i' \leftarrow i, \ell} \leq 1. \quad (4)$$

On the other hand, $ref_{i' \leftarrow i, \ell} = 1$ implies that $T[i..i + \ell]$ is a factor of the grammar parsing. Therefore,

$$\begin{aligned} & \forall i \in [1, n], \ell \in [2, n + 1 - i], i' \in \{k \mid T[k..k + \ell] = T[i..i + \ell], k \in [1, i - \ell]\} : \\ & ref_{i' \leftarrow i, \ell} \implies f_{i,\ell} \end{aligned} \quad (5)$$

By definition, it holds that

$$\begin{aligned} & \forall i' \in [1, n - 1], \ell \in [2, n + 1 - i'] \text{ s.t. } T[i'..i' + \ell] \text{ has an occurrence in } T[i' + \ell..n] : \\ & q_{i', \ell} \iff \bigvee_{1 \leq i' + \ell \leq i \leq n} ref_{i' \leftarrow i, \ell} \end{aligned} \quad (6)$$

Next, as shown in Lemma 2, we require that the implied internal node that is referenced by some factor must be an interval of size at least 2 of the factorization. We encode this as:

$$\begin{aligned} & \forall i' \in [1, n-1], \ell \in [2, n+1-i'] \text{ s.t. } T[i'..i'+\ell] \text{ has an occurrence in } T[i'+\ell..n] : \\ & q_{i',\ell} \implies \neg f_{i',\ell} \wedge p_{i'} \wedge p_{i'+\ell} \end{aligned} \quad (7)$$

Also, for any two such implied internal nodes $T[i_1..i_1+\ell_1]$ and $T[i_2..i_2+\ell_2]$, they must either be disjoint, or one is a sub-interval of the other. In other words, it cannot be that a proper prefix interval of one is a proper suffix interval of the other, i.e.,

$$\begin{aligned} & \forall i_1, i_2, \ell_1, \ell_2 \text{ s.t. } i_1 < i_2 < i_1 + \ell_1 < i_2 + \ell_2 \text{ s.t.} \\ & T[i_k..i_k + \ell] \text{ has an occurrence in } T[i_k + \ell..n] \text{ for } k \in \{1, 2\} : \\ & \neg q_{i_1, \ell_1} \vee \neg q_{i_2, \ell_2} \end{aligned} \quad (8)$$

In total, we have $O(n^3)$ Boolean variables dominated by $ref_{i' \leftarrow i, \ell}$. The size of each clause is at most $O(n)$. The total size of the resulting CNF is $O(n^4)$, dominated by Constraint (8) where there are $O(n^4)$ clauses of $O(1)$ size each.

Correctness of the Encoding

We now prove the correctness of our formulation. From Lemma 2, if we are given some SLP producing T , it is clear that the above Boolean variables corresponding to its partial parse tree, referencing structure, and grammar parsing will satisfy all of the constraints.

Next, suppose we are given T and a truth assignment satisfying the above constraints. Starting from the truth assignments of p_i and Constraint (1), we can obtain a factorization of T where we regard $T[i..i+\ell]$ as a factor if and only if $f_{i,\ell} = 1$. For any $i \in [1, n]$ and $\ell \in [2, n-i+1]$, Constraint (2) ensures that $T[i..i+\ell]$ having an occurrence in $T[1..i]$ is a necessary condition for $f_{i,\ell} = 1$. If $f_{i,\ell} = 1$, Constraint (3) implies that there is some $i' \in [1..i-\ell]$ such that $T[i'..i'+\ell] = T[i..i+\ell]$ and $ref_{i' \leftarrow i, \ell} = 1$. From Constraint (4), we know that there is exactly one such i' . On the other hand, Constraint (5) ensures that $ref_{i' \leftarrow i, \ell} = 0$ for all i' when $f_{i,\ell} = 0$. Thus, for each $f_{i,\ell} = 1$ with $\ell > 1$ there exists exactly one i' such that $ref_{i' \leftarrow i, \ell} = 1$, and all other $ref_{\leftarrow \cdot, \cdot}$ are 0. From Constraint (6), it holds that $q_{i',\ell} = 1$ if and only if there is at least one i, ℓ with $ref_{i' \leftarrow i, \ell} = 1$ and thus $f_{i,\ell} = 1$. If $q_{i',\ell} = 1$, from Constraint (7), we have $f_{i',\ell} = 0$, $p_{i'} = p_{i'+\ell} = 1$, implying that $T[i'..i'+\ell]$ is not a factor, but is a concatenation of two or more factors. Constraint (8) requires that all such $T[i'..i'+\ell]$ are either disjoint or that one is a sub-interval of the other.

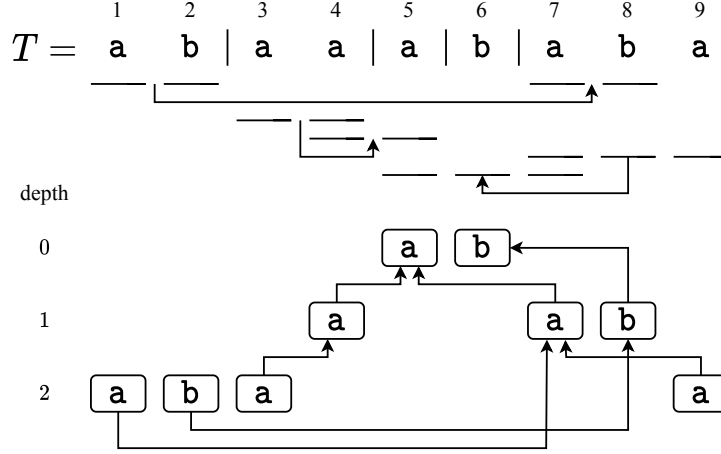

Thus, from the above arguments, we can see that for the factorization defined by the p_i 's, we can associate for each factor, a subinterval of the factorization that satisfies the conditions of Lemma 2, thus implying that the factorization is a grammar parsing of some SLP.

3.3 Smallest Bidirectional Macro Scheme to MAX-SAT

For our SLP encoding, we used the fact that only the leftmost occurrences of the non-terminals are internal nodes – we modeled every later occurrence as a leaf referring to this leftmost occurrence. We could therefore evade the problem of constructing reference cycles since all references point in the same direction. However, in a bidirectional scheme, the references can point in either direction, and the difficulty in defining the encoding is how to ensure that no cycles are introduced in the referencing.

Here, we present a solution that again works with a tree structure, but this time we have multiple trees – a forest that represents the references. In detail, we follow Dinklage et al. [9, Definition 6], who represented a bidirectional macro scheme by a reference forest,

12:10 Computing NP-Hard Repetitiveness Measures via MAX-SAT

■ **Figure 4** Reference forest of the BMS of Figure 1. The forest consists of two trees. The root of each tree corresponds to one of the two ground phrases of the BMS. For instance, to decode $T[1]$, we first need to decode $T[7]$ (the parent of $T[7]$), which has the tree root $T[5]$ as its parent. Hence, the number of ancestors of a node $T[i]$ is the number of references we need to traverse to obtain a ground phrase storing the character of $T[i]$.

where a text position i has text position j as its parent if the phrase covering $T[i]$ has a reference stating that $T[i]$ is copied from $T[j]$. Figure 4 visualizes such a forest. The roots of this reference forest are the positions of the ground phrases.

In order to find a BMS, we go in the inverse direction, and first encode a reference forest from which we subsequently derive a BMS. Since a forest has no cycles, we can use the edges of the forest to define a valid BMS, where each factor has length one (each factor is represented by a node in the reference forest). The final step is to glue together adjacent positions that have adjacent references into larger factors to obtain BMSs with fewer factors.

We start with the encoding for our reference forest. The nodes of the forest coincide with the text positions, and are therefore enumerated from 1 to n . Since a text position i can reference text position j only when $T[i] = T[j]$, it makes sense to restrict j to belong to the set $M_i := \{j \in [1, n] \mid T[i] = T[j], i \neq j\}$. In that case, we say that j is the parent of i . We make use of the following variables.

- $root_i$ for $i \in [1, n]$: $root_i = 1$ if and only if node i is the root of a tree. All roots are at depth 0.
- $dref_{d,i \rightarrow j}$ for $d \in [1, n-1], i \in [1, n], j \in M_i$: $dref_{d,i \rightarrow j} = 1$ if and only if node i at depth d has a parent node j at depth $d-1$.

To obtain a valid reference forest, we define the following constraints. First, each node is a root node or has a parent.

$$\forall i \in [1, n] : root_i + \sum_{d \in [1, n], j \in M_i} dref_{d,i \rightarrow j} = 1 \quad (9)$$

According to Constraint (9), a node i at depth $d \geq 2$ must have exactly one parent j , and j must also have a parent node k (since $d \geq 2$). To enforce acyclicity, we additionally want that k is exactly two levels above of i .

$$\forall d \in [2, n], \forall i \in [1, n], \forall j \in M_i : dref_{d,i \rightarrow j} \implies \sum_{k \in M_j} dref_{d-1, j \rightarrow k} = 1 \quad (10)$$

Next, to translate our reference forest to a BMS, we additionally introduce the following Boolean variables.

- $ref_{i \rightarrow j}$ for $i \in [1, n], j \in M_i$: $ref_{i \rightarrow j} = 1$ if and only if position i references position j .
- p_i for $i \in [1, n]$: $p_i = 1$ if and only if position i is a beginning of a phrase. Note that $p_1 = 1$.

The connection between the variables of the reference forest and our BMS is as follows. For each position $i \in [1, n]$, i can reference at most one position $j \in M_i$, i.e.,

$$\forall i \in [1, n] : \sum_{j \in M_i} ref_{i \rightarrow j} \leq 1 \quad (11)$$

A position i references j if, on any depth d of the reference forest, there is an edge from i to its parent j modeled by $dref_{d,i \rightarrow j}$.

$$\forall d \in [1, n], \forall i \in [1, n], \forall j \in M_i : dref_{d,i \rightarrow j} \implies ref_{i \rightarrow j} \quad (12)$$

Finally, the roots in our reference forest model the ground phrases of the BMS. The roots therefore cannot have a reference, but instead introduce a factor (of length one).

$$\forall i \in [1, n] : root_i \implies p_i. \text{ Additionally, } \forall j \in M_i : root_i \implies \neg ref_{i \rightarrow j} \quad (13)$$

Remembering that the phrases are determined by the variables p_i 's witnessing their starting positions, it is left to model the constraints for the truth assignment of the p_i 's. For that, let us conceptually fix a text position i for which we assume that it references text position j . We consider two cases where $T[i-1]$ and $T[i]$ cannot be in the same phrase. The first case is when i or j are at the start of the text or $j-1 \notin M_{i-1}$:

$$\forall i \in [1, n], j \in M_i \text{ s.t. } i = 1 \text{ or } j = 1 \text{ or } T[i-1] \neq T[j-1] : ref_{i \rightarrow j} \implies p_i \quad (14)$$

The second case is when $j-1 \in M_{i-1}$ but the position $i-1$ does not reference position $j-1$ (it may reference a different position, or it could be a ground phrase):

$$\begin{aligned} \forall i \in [2, n], \forall j \in M_i \text{ s.t. } j > 1 \text{ and } T[i-1] = T[j-1], \\ \neg ref_{i-1 \rightarrow j-1} \wedge ref_{i \rightarrow j} \implies p_i \end{aligned} \quad (15)$$

In total, we have $O(n^3)$ Boolean variables, dominated by $dref_{d,i \rightarrow j}$. The size of the largest clause is $O(n^2)$ due to Constraint (9). The total size of the resulting CNF is $O(n^4)$, dominated by Constraint (10) where there are $O(n^3)$ clauses of $O(n)$ size each.

Correctness of the Encoding

It is easy to see that any valid BMS satisfies the above constraints. We now show that any solution that satisfies the hard clauses yields a valid BMS. The truth assignments for all p_i define a factorization of T . We claim that each position is either a ground phrase, or is assigned exactly one reference consistent with the factorization forming a valid BMS, i.e., the references are acyclic, and, adjacent positions in the same non-ground phrase will refer to adjacent positions thus allowing the phrase to be encoded with the pair of references at both ends of the phrase.

Suppose $p_i = 1$. If $root_i = 1$, then Constraint (9) ensures that all $dref_{\cdot, i \rightarrow \cdot} = 0$ and Constraint (13) ensures that all $ref_{i \rightarrow \cdot} = 0$, i.e., i does not have a reference. Note that, $p_{i+1} = 0$ implies $ref_{i \rightarrow j}$ for some j (shown in the next paragraph), so $p_{i+1} = 1$ must hold. Thus, position i is properly factorized as a ground phrase. If $root_i = 0$, then Constraint (9) ensures that there exist unique d, j such that $dref_{d, i \rightarrow j} = 1$. Furthermore, Constraint (12) ensures that $ref_{i \rightarrow j} = 1$.

Next, consider the case for $p_i = 0$ (which implies $i > 2$). From Constraint (13) we have $root_i = 0$, and from Constraint (15) we have $\forall j > 1 \in M_i$ s.t. $T[i - 1] = T[j - 1]$, $ref_{i \rightarrow j} \implies ref_{i-1 \rightarrow j-1}$. Since $root_i = 0$, Constraint (9) ensures that there exists unique d, j such that $dref_{d, i \rightarrow j} = 1$. Furthermore, Constraint (12) ensures that $ref_{i \rightarrow j} = 1$. Note that due to Constraint (14), neither $j = 1$ nor $T[i - 1] \neq T[j - 1]$ is possible, since this would imply $p_i = 1$, contradicting the assumption that $p_i = 0$. Thus $j > 1$ and $T[i - 1] = T[j - 1]$, and thus we have $ref_{i-1 \rightarrow j-1} = 1$.

The uniqueness of the reference j for each position i of a non-ground phrase is ensured by Constraint (11). Thus, we have that references in adjacent positions in the same non-ground phrase point to adjacent positions. Since the acyclicity of the references are ensured by Constraint (10), we have a valid BMS.

4 Computational Experiments

We have implemented our encodings in PySAT (<https://pysathq.github.io/>) written in the Python language³. As datasets we used the files TRANS, NEWS, E.COLI, and PROGC from the Canterbury and Calgary corpus (<https://corpus.canterbury.ac.nz/>).

Here, we evaluated the sum of the literals in all hard clauses, i.e., the size of the encoded CNF, and the execution time of the SAT solver for computing a solution. In Figure 5, we evaluated our approach on different prefix lengths of the chosen datasets, starting from a prefix of 10 characters up to a prefix with 3000 characters. We aborted an execution after reaching one hour of computation or after exceeding 16 GB of RAM, and hence the lines for computing b and g prematurely end due to these limits on all datasets. Our experiments ran on an Ubuntu 20.04 machine with an AMD Ryzen Threadripper 3990X CPU.

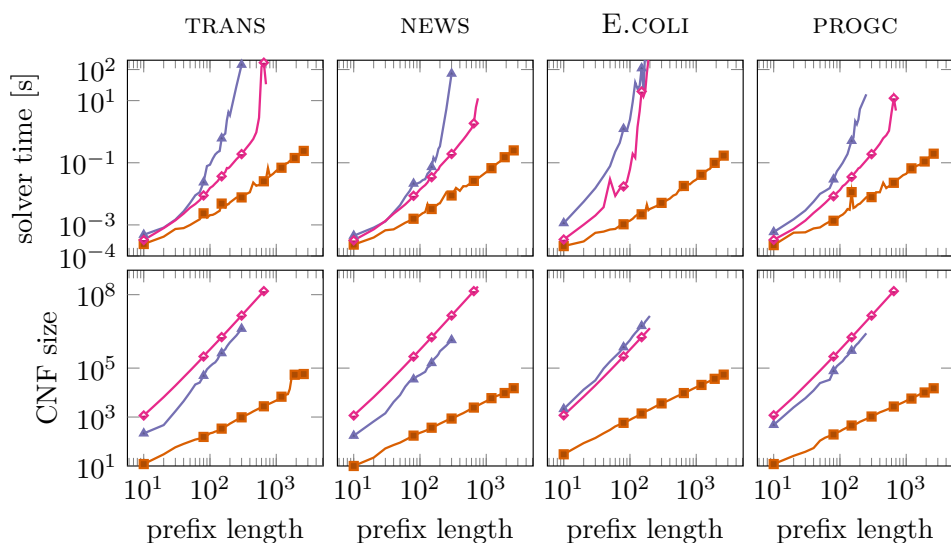

As expected, the size of the encoded CNF correlates with the execution time in all instances. We can see that the encoding for γ needs the least number of literals, and is consequently not only the fastest, but also uses the least amount of memory, allowing us to compute γ for moderately large texts. This is followed by g , and lastly by b . Although the size of the CNF for b is smaller than for g in most cases, clauses formed by Constraint (9) for computing b can become quite large, making the computation cumbersome.

5 Application: Sensitivity of γ

Akagi et al. [1] introduced and studied the notion of *sensitivity* of a repetitiveness measure. Given a repetitiveness measure C (such as γ) for a string T , the sensitivity of C measures how much C can increase when a single character edit operation is performed on T . The authors studied an additive and a multiplicative sensitivity measure. The latter, denoted MS_{op} , is defined as:

$$MS_{op}(C, n) := \max_{T \in \Sigma^n, T' \in \Sigma^*} \left\{ \frac{C(T')}{C(T)} \mid ed_{op}(T, T') = 1 \right\},$$

³ As far as we are aware of, this implementation is single threaded.

■ **Figure 5** Evaluation of our encoded CNFs. The first row shows the running time of PySAT on our CNF instance in seconds. We omit the time needed to specify the CNFs, which is negligible for larger instances. The second row plots the size of the respective CNF. All axes are in logscale.

i.e., the maximum multiplicative increase over all strings with the same length n , where $ed_{op}(T, T') = 1$ means that T' can be built from T by inserting a character into T , or deleting/replacing a character of T . Parameterizing γ with the input string T , for $C(T) = \gamma(T)$, Akagi et al. showed $2 \leq MS_{op}(\gamma, n) \in O(\log n)$.

To improve the lower bound, we conducted exhaustive search for short binary strings when inserting a unique character. This search led us to the string family $\{T_k\}_{k \geq 2}$ with $T_k := \text{abbbaaab}^k$, with which we can improve the lower bound of 2 to $5/2$. For that, let us consider $\gamma(T_k)$ and its size after an insertion of a new character c . First, we observe that $\gamma(T_k) = \gamma(\text{abbbaaab}^k) = 2$. This is because a smallest string attractor is given by $\Gamma(T_2) = \{4, 7\}$ and $\Gamma(T_k) = \{5, 8\}$ for $k \geq 3$ (the characters at the positions in $\Gamma(T_k)$ are underlined). Now let T'_k denote T_k after inserting the character c at text position 9. For $k \geq 5$, it holds that T'_k has a string attractor of size 5, i.e., $\gamma(T'_{k'}) = \gamma(\text{abbbaaabcb}^{k'}) = 5$ for $k' \geq 4$. A minimal string attractor is given by $\Gamma(T'_{k'}) = \{1, 4, 6, 9, 10\}$. We cannot remove a position from $\Gamma(T'_{k'})$ since abb , ba , aab , c , and $\text{b}^{k'}$ are five substrings of $T'_{k'}$, having exactly one occurrence in $T'_{k'}$, and all of them are non-overlapping. Since a string attractor has to be in the cover set of all substrings, we need a string attractor with at least five text positions. Consequently, $MS_{op}(\gamma, n) \geq 2.5$ for any $n \geq 13$ with the insertion or replacement operation.

The availability of computer-aided search facilitated the discovery of strings having certain string attractors.

Online Metric Allocation and Time-Varying Regularization

University of Sheffield, UK

Abstract

We introduce a general online allocation problem that connects several of the most fundamental problems in online optimization. Let M be an n -point metric space. Consider a resource that can be allocated in arbitrary fractions to the points of M . At each time t , a convex monotone cost function $c_t: [0, 1] \rightarrow \mathbb{R}_+$ appears at some point $r_t \in M$. In response, an algorithm may change the allocation of the resource, paying movement cost as determined by the metric and service cost $c_t(x_{r_t})$, where x_{r_t} is the fraction of the resource at r_t at the end of time t . For example, when the cost functions are $c_t(x) = \alpha x$, this is equivalent to randomized MTS, and when the cost functions are $c_t(x) = \infty \cdot \mathbb{1}_{x < 1/k}$, this is equivalent to fractional k -server.

Because of an inherent *scale-freeness* property of the problem, existing techniques for MTS and k -server fail to achieve similar guarantees for metric allocation. To handle this, we consider a generalization of the online multiplicative update method where we decouple the rate at which a variable is updated from its value, resulting in interesting new dynamics. We use this to give an $O(\log n)$ -competitive algorithm for weighted star metrics. We then show how this corresponds to an extension of the online mirror descent framework to a setting where the regularizer is time-varying. Using this perspective, we further refine the guarantees of our algorithm.

We also consider the case of non-convex cost functions. Using a simple ℓ_2^2 -regularizer, we give tight bounds of $\Theta(n)$ on tree metrics, which imply deterministic and randomized competitive ratios of $O(n^2)$ and $O(n \log n)$ respectively on arbitrary metrics.

1 Introduction

We introduce a natural online problem that generalizes and is closely related to several fundamental and well-studied problems in online computation such as Metrical Task Systems (MTS), the k -server problem and convex body chasing. We call this the *metric allocation* problem (MAP) and it is defined as follows.

There is an underlying metric space M on n points with distances $d(i, j)$ between points i and j . An algorithm maintains an allocation of a resource to the points of M , represented by a vector $x = (x_1, \dots, x_n)$ in the simplex $\Delta = \{x \in \mathbb{R}_+^M \mid \sum_{i \in M} x_i = 1\}$, where x_i denotes the

amount of resource at point i . At each time step t , tasks arrive at the points of M . The task at $i \in M$ is specified by a non-increasing and convex cost function $c_{t,i} : [0, 1] \rightarrow \mathbb{R}_+$, which describes the cost of completing the task as function of resource available at i .¹ Given the tasks at time t , the algorithm can modify its previous allocation $x(t-1) \in \Delta$ to $x(t) \in \Delta$. It then incurs a *service cost* $c_t(x(t)) = \sum_{i \in M} c_{t,i}(x_i(t))$ and a *movement cost* of modifying $x(t-1)$ to $x(t)$ according to the distances in M (i.e., sending an ϵ amount of resource from i to j incurs cost $\epsilon \cdot d(i, j)$).

The problem is already very interesting when M is a uniform metric. In particular, this case already goes beyond the reach of existing techniques and highlights a key issue of *scale-freeness* (details in Section 1.2), which seems closely related to current barriers for improving bounds for k -server. For this reason, we will mostly focus on uniform metrics and, more generally, on weighted star metrics. Later, we also describe some results for non-convex cost functions on general metrics.

Besides the connections to other classical problems, that we describe below, MAP also has a natural motivation on its own. For example, the resource may represent workers that can be allocated to various locations. At step t , one could transfer extra workers to locations with high cost to execute tasks more efficiently. This also motivates our assumption on the cost functions being non-increasing (having more resources can only help) and convex (adding extra resources has diminishing returns). If M is a uniform or weighted star metric, this means there is a central depot that workers must return to between switching tasks.

Connections. MAP generalizes several fundamental and well-studied problems in online computation. We describe these next, as they play a key role in our discussion below.

- **Metrical Task Systems.** Here, there is a metric space (M, d) on n points, and the algorithm resides at some point in M at any time. At time t , a cost vector $\alpha_t \in \mathbb{R}_+^M$ arrives. The algorithm can then move from its old location $i_{t-1} \in M$ to a new $i_t \in M$, paying movement cost $d(i_{t-1}, i_t)$ and service cost α_{t,i_t} .

The state of a *randomized* algorithm for MTS is given by a probability distribution $x(t) = (x_1(t), \dots, x_n(t))$ on the n points. Its expected service cost at time t is given by $\sum_i \alpha_{t,i} \cdot x_i(t)$ and its expected movement cost is measured just like in MAP. Thus, randomized MTS is the special case of MAP with cost functions of the form $c_{t,i}(x_i) = \alpha_{t,i} x_i$, i.e., linear and increasing. (We show in the full version that MAP with non-decreasing cost functions is equivalent to MAP with non-increasing cost functions.)

- **k -server.** Here, there is a metric space (M, d) and k servers that reside at points of M . At time t , some point r_t is requested, which must be served by moving a server to r_t . The goal is to minimize the total movement cost. The *fractional* k -server problem is the relaxation² of the randomized k -server problem where points can have a fractional server mass. A request at r_t is served by having a server mass of at least 1 at r_t .

Observe that fractional k -server is the special case of MAP with cost functions $c_{t,i} = 0$ for $i \neq r_t$ and $c_{t,r_t}(x_{r_t}) = \infty$ if $x_{r_t} < 1/k$ and 0 if $x_{r_t} \geq 1/k$, by viewing $kx_i(t)$ as the fractional server mass at location i at time t . Also notice that these $c_{t,i}$ are convex and non-increasing. If M is a uniform metric (or weighted star), this is equivalent to randomized (weighted) paging.

¹ Wlog, we can assume that a task appears at only one point r_t at time t , i.e., $c_{t,i} = 0$ for $i \neq r_t$. See Section 2.

² All known randomized k -server algorithms with poly-logarithmic competitive ratios use this relaxation.

- **Convex function chasing.** Here, the request at time t is a convex function $f_t : \mathbb{R}^n \rightarrow \mathbb{R}_+ \cup \{\infty\}$. The algorithm maintains a point in \mathbb{R}^n , and given f_t it can move from its old position $x(t-1) \in \mathbb{R}^n$ to a new $x(t) \in \mathbb{R}^n$, incurring cost $\|x(t) - x(t-1)\| + f_t(x(t))$.

MAP is a special case of convex function chasing where the norm $\|\cdot\|$ is induced by a metric, cost functions are supported on the unit simplex and have separable form (i.e., $f_t(x) = \sum_{i=1}^n f_{ti}(x_i)$ with f_{ti} monotone).

The convex function chasing problem has seen tremendous progress recently, with the first competitive algorithm for arbitrary dimension given in [14], and $O(n)$ -competitive algorithms shown in [27, 1]; this implies a trivial $O(n)$ upper bound for MAP with convex cost functions.

In recent years there has also been remarkable progress on obtaining polylogarithmic-competitive algorithms for special cases of MAP such as MTS [8, 26, 6, 7, 22, 3, 11, 19, 21] and the k -server problem [20, 4, 5, 2, 12, 25, 16, 24]. However, these solutions are based on rather ad hoc and problem-specific formulations (e.g., considering anti-server mass for k -server vs. server mass for MTS). Due to these inconsistencies, it is also still open, for example, whether for k -server one can achieve the same competitive ratios as for MTS.³

One of our key goals for studying MAP is to develop a systematic and unified approach for understanding a wide class of online problems.⁴

Our contribution. Below we list the results we obtain for MAP, and the new algorithmic design and analysis techniques that we develop. We give more details in Section 1.3.

- We give a tight $O(\log n)$ -competitive algorithm for uniform metrics.
- This result already requires new algorithmic techniques to handle a *scale-freeness* property of the problem. In particular, our algorithm differs from classical multiplicative update algorithms by decoupling the rate at which a variable is updated from its value. The analysis also requires new ideas including a scale-mismatch potential function to handle the differences in the algorithm's perceived scale from the true scale.
- Next, we generalize the $O(\log n)$ bound above to weighted stars, and also refine this guarantee to be $(1 + \epsilon)$ -competitive with respect to the service cost.
- To achieve the refinement, we extend the online mirror descent framework pioneered by Bubeck et al. [12, 11] to a setting with a *time-varying regularizer*. The time-varying nature of the regularizer causes various complications for Bregman divergence based analysis techniques of prior works, and handling them requires several modifications.
- For the generalization of MAP where cost functions can be non-convex, we show an $\Omega(n)$ lower bound for arbitrary metrics. We give a matching $O(n)$ upper bound on tree metrics. This implies an $O(n^2)$ deterministic and $O(n \log n)$ randomized bound on general metrics.
- The $O(n)$ upper bound is also based on the mirror descent framework, but in contrast to all prior works in this framework, we do not use an entropic regularizer, but work with a *simple weighted ℓ_2^2 -regularizer* instead.

³ This contrasts with the deterministic setting, where the competitive ratio of MTS (which is $2n - 1$) is known to be achievable for k -server (where $2k - 1 \leq 2n - 1$ is known). Indeed, this is achieved by the same algorithm for both problems (the work function algorithm; see the book [9] for details) rather than by problem-specific algorithms as in the randomized setting.

⁴ k -server on an n -point metric is also a special case of MTS on a $N = \binom{n}{k}$ point metric. But as the competitive ratio of MTS depends on N , this does not give any interesting bounds for k -server. In contrast, MAP generalizes both fractional k -server and randomized MTS in the *same* metric space.

We next discuss the relevance of allocation problems on star metrics and associated refined guarantees, and then describe the issue of scale-freeness that arises in MAP.

1.1 Allocation problems on star metrics and refined guarantees

Certain special cases of *allocation problems* on star metrics have been studied previously, either implicitly or explicitly, as they capture a lot of the difficulty of *general* metrics. This idea already goes back to Bartal et al. [7]; roughly, one can approximate a general metric space by a hierarchically-separated tree (HST), and recursively run the star algorithm at the internal nodes of the HST to decide how much server mass to allocate to each child subtree. In this way, known algorithms for MTS on general metrics [7, 22, 11, 19] are obtained by using an algorithm for stars as central building blocks.

For k -server, a certain allocation problem on weighted stars was studied in [4] as a first step towards obtaining $\text{polylog}(n, k)$ -competitive algorithms for k -server on general metrics. This allocation problem corresponds to the special case of MAP where the convex functions $c_{t,i}$ are piece-wise linear determined by values $c_{t,i}(j)$ at $j = 0, 1/k, 2/k, \dots, 1$. In subsequent work [2], this step was completed to obtain the first $\text{polylog}(n, k)$ -competitive algorithm for k -server on general metrics.

Refined guarantees. We say that an algorithm has α -competitive service cost and β -competitive movement cost if, up to some fixed additive constant, its service cost is at most α times the *total* (movement plus service) offline cost and its movement cost is at most β times the total offline cost.

For k -server and MTS, polylog-competitive algorithms on general metrics rely on star algorithms with $(1 + \epsilon)$ -competitive service cost and $\text{poly}(\log n, 1/\epsilon)$ -competitive movement cost, for $\epsilon \approx 1/\log n$. The reason is that when the algorithm for stars is used recursively to obtain an algorithm on HSTs, then roughly, the service cost guarantee multiplies across levels and the movement cost guarantee increases additively. See, e.g., [7, 2] for more details.

The algorithm for the special case of MAP considered in [4] has $(1 + \epsilon)$ -competitive service cost and $O(\log k/\epsilon)$ -competitive movement cost. However, the general cost functions that we consider for MAP (in this paper) correspond to this problem as $k \rightarrow \infty$; for this case, the $O(\log k/\epsilon)$ bound of [4] becomes unbounded and does not give anything useful.

1.2 Scale-freeness

The reason for the failure of the algorithm in [4] when $k \rightarrow \infty$ is not just technical, but an inherent one: roughly, for general cost functions, it is unclear how to do *multiplicative updates*, as there is no inherent notion of *scale* in the resulting problem. We elaborate on this issue now, as handling this *scale-freeness* is one of the key conceptual and technical contributions of this paper.

Multiplicative updates. A key underlying idea, sometimes used implicitly, for achieving poly-logarithmic guarantees for k -server, MTS and various other problems (e.g., those based on the online primal dual-framework [18, 17]) is that of multiplicative updates.

Let us see how this works for k -server and MTS on a star metric. For k -server, if a point r is requested, the fractional server amount z_i at other points i is decreased at rate proportional to $1 - z_i + \delta$ (i.e., the amount of server already missing at i plus a small constant δ). On the other hand for MTS, if a cost is incurred at point r , then the other points are increased at rate proportional to $x_i + \delta$.

Multiplicative update for MAP? As MAP generalizes these problems, clearly we also need to do some kind of multiplicative update. However, after some thought one soon realizes that completely unclear is “multiplicative update with respect to what?”.

In particular, if we model k -server as MAP (as described above), then the update rule above becomes $x'_i \propto (1/k - x_i) + \delta$. This is natural as $1/k$ is a fixed parameter with a special meaning as $c_t(x) = \infty$ for $x_{r_t} < 1/k$ and 0 otherwise. On the other hand, for MTS the reason why $x'_i \propto (x_i + \delta)$ is natural is that the $c_{t,i}$ always have x -intercept at 0. In contrast, cost functions in MAP are lacking such an intrinsic *scale*.

We give a more concrete and instructive example to show the difficulty due to this lack of scale.

Example. We saw above how to model k -server via MAP by interpreting $z_i := kx_i$ as the amount of server mass at i , and a request to point i corresponds to the cost function $c_t(x) = \infty \cdot \mathbb{1}_{\{x_i < 1/k\}}$. However, this correspondence between the server mass z_i and the variable x_i is quite arbitrary.

A different way of modeling k -server via MAP is to choose any *offset* vector $a \in [0, 1]^n$ with $s := 1 - \sum_i a_i > 0$, and interpret $z_i := k \cdot (x_i - a_i)/s$ as the server mass at i . Then, a request to page i corresponds to the cost function $c_t(x) = \infty \cdot \mathbb{1}_{\{x_i < a_i + s/k\}}$, and we can additionally intersperse cost functions $c_t(x) = \infty \cdot \mathbb{1}_{\{x_j < a_j\}}$ for each j to ensure that $z_j \geq 0$. In other words, an adversary can simulate a k -server request sequence in various *regions* of the simplex and at different *scales*.

Active region and active scale. Thus, the challenge for an algorithm is to find out the “active region” and “active scale”. Since the adversary can keep changing this region and scale arbitrarily over time, any online algorithm for MAP needs to learn this region dynamically and determine how to do multiplicative updates with respect to the scale and offset of the current region.

At a higher level, the difficulty of learning an “active region” also relates to the difficulty in obtaining a $\text{polylog}(k)$ -competitive algorithm for k -server on general metrics, which seems to require learning a region of $\text{poly}(k)$ many points where the adversary is currently playing its strategy. A step in this direction was made recently in [12].

1.3 Results and techniques

We will first show the following tight bound for uniform metrics.

► **Theorem 1.** *There is an $O(\log n)$ -competitive algorithm for MAP on uniform metrics.*

This bound is the best possible, due to the $\Omega(\log n)$ lower bound for the special case of randomized MTS [10]. Our algorithm is deterministic as randomization does not help for MAP.⁵ The proof of Theorem 1 also extends to weighted stars (and we give a stronger result in Theorem 2 below). However, to introduce the key ideas in a modular way and avoid notational overhead, we focus on uniform metrics first.

To show Theorem 1, a key new idea is to handle the scale-freeness of MAP by decoupling the position x_i and its rate of change x'_i by using separate *rate* variables ρ_i for x'_i . The update of ρ_i is driven by trying to learn the active region and scale (details in Section 3).

⁵ Any randomized algorithm for MAP can be derandomized by tracking its expected location. As cost functions are convex, this can only decrease the algorithm’s cost.

Remark. Theorem 1 has an interesting consequence for the natural case of convex function chasing described above (with separable cost functions supported on the simplex and $\|\cdot\| = \|\cdot\|_1$). The competitive ratio of $O(\log n)$ improves exponentially on the $O(n)$ bound that follows from [1, 27] and breaks the $\Omega(\sqrt{n})$ lower bound that holds for the general case [23, 13].

The following theorem refines the previous guarantee via an improved algorithm for weighted stars.

► **Theorem 2.** *For any $\epsilon > 0$, there exists an algorithm for MAP on weighted stars with $(1 + \epsilon)$ -competitive service cost and $O(\frac{1}{\epsilon} + \log n)$ -competitive movement cost.*

As explained above, a possible application of such refined guarantees is an extension to general metrics.

Time-varying regularization. To achieve the $(1 + \epsilon)$ -competitive service cost, we extend the powerful framework of *regularization* and *online mirror descent* to a setting where the regularizer is *time-varying*. This contrasts with previous works in this framework [15, 12, 11, 16, 19], which all used a *static* regularizer. Also as discussed in Section 1.1, a possible application of such refined guarantees is an extension to general metrics.

A time-varying regularizer is necessary as the regularizer must adapt to the current scale and region over time. This leads to substantial complications in the analysis. In particular, the default potential function for mirror descent analyses – the *Bregman divergence* – is not well-behaved when the offline algorithm moves (actually, it is not even well-defined), and changes of the regularizer lead to uncontrollable changes of the potential. We show how to adapt the Bregman divergence in several ways to obtain a modified potential function that has all the desired properties necessary to carry out the analysis.

Non-convex costs and arbitrary metric spaces. We also consider the version of MAP where the cost functions can be non-convex. Here, the competitive ratio must be exponentially worse.

► **Theorem 3.** *On any n -point metric space, any deterministic algorithm for MAP with non-convex cost functions has competitive ratio at least $\Omega(n)$.*

On tree metrics, we provide a matching upper bound:

► **Theorem 4.** *There is an $O(n)$ -competitive deterministic algorithm for MAP on tree metrics, even if the cost functions are non-convex.*

By known tree embedding techniques, this implies the following result for general metrics:

► **Corollary 5.** *There is an $O(n^2)$ -competitive deterministic and $O(n \log n)$ -competitive randomized algorithm for MAP on arbitrary metric spaces, even for non-convex cost functions.*

ℓ_2^2 -regularization. Our algorithm achieving the tight guarantee on trees is also based on mirror descent, but again with a crucial difference to previous mirror-descent based online algorithms in the literature. While previous algorithms all used some version of an entropic regularizer, our regularizer is a weighted ℓ_2^2 -norm. Here, again, the Bregman divergence is not suitable as a potential function, but the issues are more fundamentally rooted in the non-convex structure of cost functions, and addressing them with changes to the Bregman divergence seems unlikely to work. Instead, our analysis uses two different potential functions, one of which resembles ideas of “weighted depth potentials” used in [12, 11] and the other one is a kind of “one-sided matching”.

1.4 Organization

In Section 2, we define an equivalent version of MAP that will be easier to work with. We will give a first algorithm for uniform metrics in Section 3, where we also describe the ideas to overcome scale-freeness. In Section 4, we discuss a modified algorithm for weighted stars via mirror descent with a time-varying regularizer. However due to space constraints, most of the details are only given in the full version. Our upper and lower bounds for non-convex cost functions on general metrics are proved in the full version, which includes in particular the algorithm based on ℓ_2^2 -regularization.

2 Preliminaries

For $a \in \mathbb{R}$, we write $[a]_+ := \max\{a, 0\}$. A metric space M is called a *weighted star* if there are weights $w_i > 0$ for $i \in M$ and the distance between two points $i \neq j$ is given by $d(i, j) = w_i + w_j$.

Continuous-time model and simplified cost functions. It will be more convenient to work with the following continuous-time version of MAP. Instead of cost functions being revealed at discrete times $t = 1, 2, \dots$, we think of cost functions c_t arriving continuously over time, and that c_t changes only finitely many times. At any time $t \in [0, \infty)$, the algorithm maintains a point $x(t) \in \Delta$, where $\Delta := \{x \in \mathbb{R}_+^M : \sum_{i \in M} x_i = 1\}$, and the dynamics of the algorithm is specified by the derivative $x'(t)$ at each time t . The movement cost and the service cost are given by $\int_0^\infty \|x'(t)\| dt$ and $\int_0^\infty c_t(x(t)) dt$ respectively, where the norm $\|\cdot\|$ is induced by the metric.⁶ On a weighted star metric, the norm $\|\cdot\|$ is given by $\|z\| := \sum_i w_i |z_i|$.

Further, we assume that $c_{t,i}$ is non-zero for only a single location $r_t \in M$ at any time, and $c_{t,i}$ is linear with slope -1 and truncated at 0 (see Figure 1(a)). Formally, $c_t(x) = [s_t - x_{r_t}]_+$ for some $s_t \in [0, 1]$ and $r_t \in M$. A useful consequence of this view is that if the service cost $c_t(x(t))$ incurred by the online algorithm is α_t , then the (one-dimensional) cost function c_{t,r_t} intercepts the x -axis (becomes 0) at the point $x_{r_t}(t) + \alpha_t$. The cost of an offline algorithm at $y \in \Delta$ is then given by $[\alpha_t + x_{r_t}(t) - y_{r_t}]_+$. For a cost function c_t of this form, we will say that $x(t)$ is *charged cost α_t at r_t* .

To simplify the description and analysis of our algorithms, we will further allow them to decrease x_i to a negative value. In the full version, we show that these assumptions are all without loss of generality.

3 A first algorithm for uniform metrics

We describe here an $O(\log n)$ -competitive algorithm for MAP on uniform metrics, proving Theorem 1. Although the algorithm also extends to weighted stars, we assume in this section that all weights are 1 to avoid technicalities and focus on the key ideas.

3.1 Overview

Before we state the formal algorithm, we first give an overview and intuition behind the ideas needed to handle the difficulties due to scale-freeness.

Fix a time t , and let $x = x(t)$ and $y = y(t)$ denote the online and offline position and suppose a cost of $\alpha = \alpha_t$ is received (charged) at point $r = r_t$. We drop t from now for notational ease, as everything is a function of t . Clearly, an algorithm that wishes to be

⁶ In general, $\|z\| = \min_f \sum_{i,j \in M} f(i,j) d(i,j)$, where the minimum is taken over all flows $f: M \times M \rightarrow \mathbb{R}_+$ satisfying $z_i = \sum_{j \in M} (f(j,i) - f(i,j))$ for all $i \in M$.

competitive must necessarily increase x_r (otherwise the offline algorithm can move to some y with $y_r > x_r$ and keep giving such cost functions forever). So, the key question is how to decrease other coordinates x_i for $i \neq r$ to offset the increase of x_r (and maintain $\sum_i x_i = 1$).

Separate rate variables and how to update them. As discussed in Section 1.2, due to scale-freeness, the rate of update of x_i , denoted x'_i , cannot simply be some function of x_i , as in standard multiplicative update algorithms. So we maintain separate *rate* variables ρ_i (decoupled from x_i) that specify the rate at which to reduce x_i , i.e., $x'_i = -\rho_i$ (plus a small additive term and suitably normalized, but we ignore this technicality for now). Now the key issue becomes how to update these ρ_i variables themselves?

Consider the following two scenarios, which suggest two conflicting updates to ρ_r , depending upon the offline location y_r .

(i) $x_r < y_r$. Here, the adversary can make us incur the service cost while possibly not paying anything itself. However this is not problematic, as we will increase x_r and hence get closer to y_r . Also, decreasing ρ_r is good as it will prevent us in future from decreasing x_r again too fast and move away from y_r when requests arrive at locations $i \neq r$.

(ii) $y_r < x_r$. Here, increasing x_r is fine, as even though we are moving *away* from y_r , the offline algorithm is paying a higher service cost than online. However, decreasing ρ_r is very bad, as this makes it much harder for online to catch up with the offline position y_r later.

To summarize, in case (i), we should decrease ρ_i and in case (ii), we should leave it unchanged or increase it. However, the algorithm does not know the offline location y_r , and hence which option to choose.

■ **Figure 1** Illustration of cost functions.

Indirectly estimating y_r . We note that even though the algorithm does not know y_r , it can reasonably estimate whether $y_r < x_r$ or not, by looking at the structure of requests from the adversary’s point of view. Suppose $y_r < x_r$ (see Figure 1(b)). In this case, the adversary will want to give us requests with *large* α ; because for small α , the offline algorithm pays much higher cost in proportion to that of online; indeed, as α gets larger, the ratio between the offline to online service cost tends to 1. On the other hand, if $y_r > x_r$ (see Figure 1(c)), the adversary will tend to give requests so that $x_r + \alpha \leq y_r$ (so offline incurs no service cost at all), and hence keep α *small*.

A problem however is that even though the online algorithm sees α when the request arrives, whether this α is large or small has no intrinsic meaning as this depends on the current scale at which the adversary is giving the instance. The final piece to make this idea work is that the algorithm will also try to learn the scale at which the adversary is playing its strategy. We describe this next.

A region estimate. At each time t , and for each point i , we maintain a real number $b_i \geq 0$ where $b_i \geq x_i$. Intuitively, we can view b_i as an (online) estimate of the “region” where the adversary is playing the strategy, and we set the rate variable $\rho_i = b_i - x_i$. The observations above now suggest the following algorithm. For an incoming request at point r ,

(i) if $x_r + \alpha \leq b_r$ (this corresponds to small α in the discussion above, which suggested that $y_r > x_r$) the algorithm increases x_r and decreases b_r at roughly the same rate (and hence decreases $\rho_r = b_r - x_r$ at roughly twice the rate), and

(ii) if $x_r + \alpha > b_r$ (this corresponds to α being large, which suggested that $y_r < x_r$), the algorithm increases both b_r and x_r at roughly the same rate (and ρ_r only increases slowly). Note that even though the location r is incurring a service cost, we do not necessarily decrease ρ_r .

■ **Figure 2** Illustration of the update rule for ρ_r . If $\alpha > \rho_r$ (left), then x_r and b_r increase and ρ_r changes slowly. If $\alpha < \rho_r$ (right), then x_r and b_r move towards each other and ρ_r decreases.

For other points $i \neq r$, b_i stays fixed. So as x_i decreases, this corresponds to increasing the rate ρ_i . This step is analogous to multiplicative updates, but where the update rate is given by distance of x_i from b_i , where b_i itself might change over time. We also call b_i the “baseline”.

A complication (in the analysis) will be that the b_i themselves are only estimates and could be wrong. E.g., even if b_i is accurate at some given time, the offline algorithm can move y_i somewhere far at the next step, and start issuing requests in that region. The current b_i would be completely off now and the algorithm may make wrong moves. What will help here in the analysis is that the algorithm is quickly trying learn the new b_i .

3.2 Formal description of the algorithm

At any instantaneous time t , the algorithm maintains a point $x(t) \in \Delta$. In addition, it also maintains a point $b(t) \in \mathbb{R}^M$, where $b_i(t) \geq x_i(t)$ for all $i \in M$. Let $\rho_i(t) = b_i(t) - x_i(t)$, for each $i \in M$. We specify the formal algorithm by describing how it updates the points $x(t)$ and $b(t)$ in response to a cost function c_t . Again, we drop t from the notation hereafter.

Suppose the cost function at a given time charges cost α at point r . Then, we increase x_r at rate α and simultaneously decrease all x_i (including x_r) at rate

$$-\alpha \cdot \frac{\rho_i + \delta S}{2S},$$

where $\delta = 1/n$ and $S := \sum_i \rho_i$. Intuitively, one can think of S as the current *scale* of the problem (which is changing over time).

Then the overall update of x can be summarized as

$$x'_i = \alpha \left(\mathbb{1}_{i=r} - \frac{\rho_i + \delta S}{2S} \right) \quad \text{for all } i \in M. \tag{1}$$

13:10 Online Metric Allocation and Time-Varying Regularization

The baseline vector b is updated as follows:

- (i) For $i \neq r$, b_i stays fixed.
- (ii) For $i = r$, if $x_r + \alpha > b_r$ (or equivalently $\alpha > \rho_r$), then $b'_r = \alpha$.
- (iii) For $i = r$, if $x_r + \alpha \leq b_r$ (or equivalently $\alpha \leq \rho_r$), then $b'_r = -\alpha$.⁷

See Figure 2 for an illustration. Notice that the update rules for x'_i and b'_i also ensure that $b_i \geq x_i$. Finally, using that $\rho_i = b_i - x_i$ and writing compactly, this gives the following update rule for ρ_i .

$$\rho'_i = \alpha \left(\frac{\rho_i + \delta S}{2S} - 2 \cdot \mathbb{1}_{i=r \text{ and } \rho_r > \alpha} \right). \quad (2)$$

This completes the description of the algorithm.

Feasibility. Notice that $\sum_i (\rho_i + \delta S)/(2S) = 1$ and hence $\sum_i x'_i = 0$ and the update for x maintains that $\sum_i x_i = 1$. In the algorithm description above, we do not explicitly enforce that $x_i \geq 0$. As we show in the full version, allowing the online algorithm to decrease x_i to negative values is without loss of generality. It is possible to enforce this directly in the algorithm, but this would make the notation more cumbersome.

3.3 Analysis sketch

Due to space constraints, and because our proof of Theorem 2 yields a stronger result anyway, we only provide a brief sketch of the analysis of our algorithm here. It is based on potential functions. Specifically, we define a (bounded) potential Θ that is a function of the online and offline states, and show that at any time t it satisfies

$$\text{On}' + \Theta' \leq O(\log n) \cdot \text{Off}', \quad (3)$$

where On' (resp. Off') denote the change in cost of the online (resp. offline) algorithm, and Θ' is the change in the potential. The potential function Θ consists of two parts defined as

$$\begin{aligned} \text{(Primary potential)} \quad P &:= \sum_{i: x_i \geq y_i} (b_i - y_i) \log \frac{(1 + \delta)(b_i - y_i)}{\rho_i + \delta(b_i - y_i)} \\ \text{(Scale-mismatch potential)} \quad Q &:= \sum_i [\rho_i + 2(x_i - y_i)]_+, \end{aligned}$$

where $y \in \Delta$ is the position of the offline algorithm. The overall potential is given by

$$\Theta = 12P + 6Q.$$

One can verify, by taking derivative with respect to y_i and using $\delta = 1/n$ and $\rho_i = b_i - x_i \geq 0$, that Θ is $O(\log n)$ -Lipschitz in y_i . Thus, the potential increases by at most $O(\log n)$ times the offline movement cost when y changes. It therefore suffices to show (3) for the case that y stays fixed and only the online algorithm moves (i.e., while x , ρ and b are changing).

Recall that $S = \sum_i \rho_i$ is the algorithm's estimate of the current "scale", and define $L := \sum_i |x_i - y_i|$, which we may think of as the true scale of the error between the online position x and the (unknown) offline position y . If the current estimate of the scale is accurate, one would expect $S \approx L$, but in general this need not be true. In the full version, we prove the following two lemmas:

⁷ Strictly speaking, if $x_r + \alpha = b_r$ both rules (ii) and (iii) apply simultaneously and b_r stays fixed.

► **Lemma 6** (Change of the primary potential). *When y is fixed and the online algorithm moves, the change of P is bounded by*

$$P' \leq O(\log n)[\alpha + x_r - y_r]_+ - (\alpha/2) \min\{L/2S, 1\}.$$

► **Lemma 7** (Change of the scale-mismatch potential). *When y is fixed and the online algorithm moves, the change of Q is bounded by*

$$Q' \leq 2\alpha \cdot \mathbb{1}_{y_r \leq x_r + \alpha/2} - (\alpha/2) [1 - L/S]_+.$$

Note that the offline algorithm incurs service cost at rate $[\alpha + x_r - y_r]_+$, and the online algorithm incurs both service and movement cost at rate $O(\alpha)$. In the bound on P' in Lemma 6, the positive term can be charged against the offline service cost. If $S = O(L)$, then the negative term can be used to pay for the online cost. However, if $S \gg L$, then the negative term may be negligibly small. Intuitively, this corresponds to the case that the algorithm's estimate of the scale is far off from the true scale, and this possibility is the reason why we need the scale-mismatch potential.

If $y_r \leq x_r + \alpha/2$, the offline service cost is at least $\alpha/2$, so the positive part in the change of Q is at most 4 times the offline service cost. The negative part in Lemma 7 pays for the online cost if $S \gg L$, which is precisely the case not covered by the primary potential. So,

$$\begin{aligned} \Theta' &= 12P' + 6Q' \leq O(\log n) \cdot \text{Off}' - 3\alpha (\min\{L/S, 2\} + [1 - L/S]_+) \\ &\leq O(\log n) \cdot \text{Off}' - 3\alpha, \end{aligned}$$

which yields the desired inequality (3) because the online service cost is α and online movement cost is at most 2α .

4 Time-varying regularization and refined guarantees on weighted stars

We now turn to an improved algorithm for weighted stars, achieving the refined guarantees of Theorem 2 that the service cost is $(1 + \epsilon)$ -competitive. To do so, we first reinterpret our previous algorithm through the lens of mirror descent.

4.1 Online mirror descent

The online mirror descent framework has been useful to derive optimally competitive algorithms for problems where the state of an algorithm can be described by a point in a convex body (e.g., set cover, k -server, MTS [15, 12, 11, 16, 19]). That is, the algorithm can be described by a path $x: [0, \infty) \rightarrow K$ for a convex body $K \subset \mathbb{R}^n$, such that $x(t)$ describes the state of the algorithm at time t (in our case, $K = \Delta$ is the simplex). In the framework, the dynamics of an algorithm x is specified by a differential equation of the form

$$\nabla^2 \Phi(x(t)) \cdot x'(t) = f(t) - \lambda(t) \tag{4}$$

where $\Phi: K \rightarrow \mathbb{R}$ is a suitable convex function called the *regularizer*, $\nabla^2 \Phi(x(t))$ is its Hessian at $x(t)$, $f: [0, \infty) \rightarrow \mathbb{R}^n$ is called a *control function*, and $\lambda(t)$ is an element of the normal cone of K at $x(t)$, given by

$$N_K(x(t)) := \{\lambda \in \mathbb{R}^n: \langle \lambda, y - x(t) \rangle \leq 0, \forall y \in K\}.$$

Under suitable conditions (which are all satisfied here), the path x is uniquely defined by (4) and absolutely continuous in t [12]. The equation (4) is easiest to read if we imagine that $\nabla^2\Phi(x(t))$ were the identity matrix. Then (4) says that x tries to move in direction $f(t)$, and the normal cone element λ ensures that $x(t)$ does not leave the body K . The case when $\nabla^2\Phi(x(t))$ is different from the identity matrix corresponds to imposing a different (e.g., non-Euclidean) geometry on K . When Φ is fixed, the framework allows a black-box way to prove 1-competitive service cost using the Bregman divergence $D_\Phi(y||x) := \Phi(y) - \Phi(x) + \langle \nabla\Phi(x), x - y \rangle$ as a potential function.

We show in the full version that the dynamics (1) of x defined in the previous section is precisely equivalent to equation (4) when choosing the *time-varying* regularizer

$$\Phi_t(x) := \sum_i (b_i(t) - x_i + \delta S(t)) \log \left(\frac{b_i(t) - x_i}{S(t)} + \delta \right) \quad (5)$$

for $S(t) := \sum_i b_i(t) - 1$, and the control function

$$f(t) := \frac{\alpha_t}{b_{r_t}(t) - x_{r_t}(t) + \delta S(t)} e_{r_t},$$

where e_{r_t} denotes the 0-1-vector with a 1 only in the r_t -coordinate, and α_t is the cost charged at r_t at time t .

To achieve the refined guarantees, we replace α_t by $b_{r_t}(t) - x_{r_t}(t)$ in the control function, and use a very similar regularizer that incorporates a scaling factor and the weights of the star. The most subtle parts in the proof of Theorem 2 are the way the baseline vector b_i is updated (which differs from how it was done in the previous section) and several modifications to the Bregman divergence in order to handle the time-varying nature of Φ_t . Due to space constraints, we defer all details to the full version.

An Upper Bound on the Number of Extreme Shortest Paths in Arbitrary Dimensions

Universität Stuttgart, Germany

Abstract

Graphs with multiple edge costs arise naturally in the route planning domain when apart from travel time other criteria like fuel consumption or positive height difference are also objectives to be minimized. In such a scenario, this paper investigates the number of *extreme shortest paths* between a given source-target pair s, t . We show that for a fixed but arbitrary number of cost types $d \geq 1$ the number of extreme shortest paths is in $n^{O(\log^{d-1} n)}$ in graphs G with n nodes. This is a generalization of known upper bounds for $d = 2$ and $d = 3$.

1 Introduction

Given a finite set of points $P \subset \mathbb{R}^d$, what is the number of vertices (or extreme points) of the convex hull of P ? This is a frequently asked question, for instance, in the area of Multi-objective Linear Programming [3] or in probability theory [4]. In this work, we examine this question for the case when P is the set of cost vectors of paths in a graph $G(V, E)$ with multiple edge costs.

Multi-objective path computation has obvious applications in the transportation domain, where the cost values (also called metrics) might correspond to quantities like travel time, fuel consumption, or positive height difference.

Figure 1 shows example cost vectors with two metrics. The red points are non-dominated (or Pareto-optimal) and, thus, may be the solution to constrained minimization problems. However, optimizing over all non-dominated cost vectors often turns out to be too expensive as, for instance, in the constrained shortest path problem [12, 14]. A typical strategy in such cases is to restrict the set of possible solutions to the non-dominated extreme points of the convex hull (circled in blue). The extreme points have the property that for any convex combination of the metrics there is at least one extreme point optimal for it. Therefore, extreme points are interesting on their own and one can hope that restricting the search to extreme points will lead to a good approximation of the optimal solution.

Let P_{st} be the set of cost vectors of all simple paths from a node s to a node t in a graph G . While it is easy to see that the number of non-dominated points in P_{st} can be exponential in the size of G , there is little known about the complexity of the extreme points in P_{st} . In this work we tackle the problem of counting the extreme points in P_{st} , which we call *extreme shortest paths*. We show that the number of extreme shortest paths in P_{st} is in $n^{O(\log^{d-1} n)}$, where n is the number of nodes in G and d is the fixed number of metrics. Thus, complexity-wise there is indeed a considerable gap between extreme points and non-dominated points in P_{st} .

There are multiple ways to model multi-objective shortest path problems. A well established one is the parametric shortest path problem, which is typically formulated for the two-metric case. We have decided to use the variant developed in the context of personalized route planning [10, 8] as it fits very well to practical application scenarios. Complexity-wise there is no difference between these two models.

■ **Figure 1** Paths in cost space (black and red dots); Pareto-optimal paths (red); (lower left part of) the boundary of the convex hull of all Pareto-optimal paths in green; extreme shortest paths/extreme points of the CH circled in blue; shortest (but not extreme) path dot-circled in blue.

Related Work

For the comparison with related work let us first define the well-studied parametric shortest path problem as in [9]. Given an acyclic, directed graph $G(V, E)$ the weights w_e of the edges $e \in E$ are linear functions of the form

$$w_e(\lambda) := a_e \lambda + b_e.$$

The cost of a path p is then given by $C(p, \lambda) := \sum_{e \in p} w_e(\lambda)$. Clearly, if we compute the shortest path from a node $s \in V$ to a node $t \in V$ for different values of λ , we may get different paths. Let Π_{st} bet the set of all paths from s to t . Then

$$C(\lambda) := \min_{p \in \Pi_{st}} C(p, \lambda)$$

is the shortest path cost function, which is a concave, piece-wise linear function. The maximum possible number of pieces of $C(\lambda)$ with respect to the size of G is called the *parametric shortest path complexity*. Complexity-wise, counting the pieces of $C(\lambda)$ is equivalent to counting extreme shortest paths from s to t . Therefore, all results regarding the parametric shortest path complexity are closely related to our work.

For the two-metric case, it is well known that the number of pieces in $C(\lambda)$ is upper bounded by $n^{O(\log n)}$, where n is the number of nodes in G [11]. This upper bound is tight [5, 6, 15], even for planar graphs [9].

Gajjar and Radhakrishnan [9] extend the parametric shortest path problem to three dimensions by setting

$$w_e(\lambda := (\lambda_1, \lambda_2, \lambda_3)) := a_e \lambda_1 + b_e \lambda_2 + c_e \lambda_3.$$

They show that in this case the number of extreme shortest paths is in $n^{(\log n)^2 + O(\log n)}$.

We are not aware of any results regarding the parametric shortest path complexity beyond three dimensions. Parts of our way (especially Section 3.2) to prove the general upper bound are inspired by the proof for three dimensions in [9].

Both, Pareto-optimal paths as well as extreme shortest paths have been instrumented to create alternative route recommendations. The former approach, pursued e.g. in [7, 13], unfortunately only seems to be viable on rather small graphs due to the too rapidly growing number of Pareto-optimal paths. Restricting to extreme shortest paths, though, as in [8], has been shown to be feasible in different practical application scenarios [2, 1].

2 Preliminaries

In this section, we introduce the notions used in Section 3 and show some basic, well known properties.

For a set $f \subseteq \mathbb{R}^d$, we define its dimension $\dim(f)$ to be the maximum number of affinely independent points in f minus one. For a finite set $P \subset \mathbb{R}^d$ we denote the number of elements in P with $|P|$.

► **Definition 1.** *The d -metric preference space \mathcal{P}_d is defined as follows.*

$$\mathcal{P}_d := \{(\alpha_1, \alpha_2, \dots, \alpha_d) \in \mathbb{R}_{\geq 0}^d \mid \sum_{i=1}^d \alpha_i = 1\}$$

Note that the d -metric preference space is a $(d-1)$ -dimensional simplex in d dimensions. Given a finite set of points $P \subset \mathbb{R}^d$ with $v \in P$, let $f_P(v) \subseteq \mathcal{P}_d$ be the set of preferences for which αv^T is minimal, where αv^T is the dot product of the (row) vectors α, v . Or more formally,

$$f_P(v) := \{\alpha \in \mathcal{P}_d \mid \alpha(v - v')^T \leq 0 \forall v' \in P\}. \quad (1)$$

► **Definition 2.** *Given a finite set of points $P \subset \mathbb{R}^d$, a subset $P' \subseteq P$ is a preference cover (PC) of P if and only if*

$$\bigcup_{v \in P'} f_P(v) = \mathcal{P}_d. \quad (2)$$

The following lemma states that there is a special, minimal PC for each finite point set P .

14:4 An Upper Bound on the Number of Extreme Shortest Paths in Arbitrary Dimensions

► **Lemma 3.** *Given a finite set of points $P \subset \mathbb{R}^d$ and let $X := \{v \in P \mid \dim(f_P(v)) = d-1\}$, then X is a PC of P and it holds*

$$|X| = \min_{P' \text{ is PC of } P} |P'|.$$

Proof. Let $\mathcal{M} := \min_{P' \text{ is PC of } P} |P'|$. As the number of points in P is finite and because the inequality in (1) is not strict, it holds

$$\bigcup_{v \in X} f_P(v) = \mathcal{P}_d.$$

Thus, X is a PC of P and $|X| \geq \mathcal{M}$. Moreover, for each $v \in X$ one can find an $\alpha \in \mathcal{P}_d$ with

$$\alpha v^T < \alpha v'^T \quad \forall v' \in P \setminus \{v\}.$$

It follows that $|X| \leq \mathcal{M}$ and, thus, $|X| = \mathcal{M}$. ◀

The following definition is motivated by Lemma 3.

► **Definition 4.** *Given a finite set of points $P \subset \mathbb{R}^d$, we call the subset*

$$\mathcal{M}(P) := \{v \in P \mid \dim(f_P(v)) = d-1\}$$

minimum preference cover (MPC) of P .

► **Definition 5.** *Given a finite set of points $P \subset \mathbb{R}^d$, the d -metric preference space subdivision (PSS) $\mathcal{S}_d(P)$ (or simply $\mathcal{S}(P)$) is the arrangement induced by the set $\{f_P(v) \mid v \in P\}$. We write $f_P^r \in \mathcal{S}_d(P)$ for an r -dimensional facet of $\mathcal{S}_d(P)$.*

Figure 2 shows an example 3-metric PSS. The following lemma motivates the term *subdivision*.

► **Lemma 6.** *Given a finite set of points $P \subset \mathbb{R}^d$ with $d > 1$, for any two $v, v' \in \mathcal{M}(P)$ we have $\dim(f_P(v) \cap f_P(v')) < d-1$. Furthermore, for any $v \in P$ there is a $v' \in \mathcal{M}(P)$ with $f_P(v) \subseteq f_P(v')$.*

Proof. Given two points $v, v' \in \mathcal{M}(P)$, let H be the hyperplane described by $\alpha(v-v')^T = 0$, $\alpha \in \mathbb{R}^d$. For the first part of the lemma we have to show that $\dim(H \cap \mathcal{P}_d) \leq d-2$. This is the case if $\mathcal{P}_d \not\subseteq H$. The vector $v-v'$ must have at least one positive and one negative entry (otherwise, one vector would dominate the other). Thus, H cannot be parallel to $\sum_{i \leq d} \alpha_i = 1$ and $\mathcal{P}_d \not\subseteq H$ follows.

Now we come to the second part of the lemma. If $\dim(f_P(v)) = d-1$, then $v \in \mathcal{M}(P)$ and we are finished. Thus, we may assume that $0 < \dim(f_P(v)) < d-1$. From Lemma 3 we know that

$$f_P(v) = \{\alpha \in \mathbb{R}^d \mid \alpha(v-v')^T \leq 0 \quad \forall v' \in \mathcal{M}(P)\}.$$

Therefore, if $\dim(f_P(v)) < d-1$, there must be a point $v' \in \mathcal{M}(P)$ and a hyperplane H' described by $\alpha(v-v')^T = 0$ with $f_P(v) \subseteq H'$. It follows that $f_P(v) \subseteq f_P(v')$. ◀

In fact, a PSS looks similar to a Voronoi diagram.

► **Definition 7.** *Given a finite set of points $P \subset \mathbb{R}^d$, then $\varphi_d^r(P)$ is the number of r -dimensional facets in the PSS $\mathcal{S}(P)$.*

■ **Figure 2** Example 3-metric preference space subdivision \mathcal{S}_3 .

Throughout this work, we assume that a graph $G(V, E)$ with directed edges, without multi-edges and with n nodes is given. A path $\pi := u_1 e_1 u_2 e_2 \dots e_l u_{l+1}$ in G is an alternating sequence of nodes and edges that starts and ends with a node. Furthermore, for each edge $e_i \in \pi$ it holds $e_i = (u_i, u_{i+1})$. We say that a path π is simple if it contains each node $u \in V$ at most once.

A d -metric (or d -dimensional) cost function $c : E \rightarrow \mathbb{R}_{\geq 0}^d$ maps edges to (non-negative) cost vectors. We extend c to paths π as follows.

$$c(\pi) := \sum_{e \in \pi} c(e)$$

We define \mathcal{C}_d to be the set of all d -metric cost functions of E .

Let Π be a set of paths (or: path set) in G and c a cost function for E . Then we define the point set $P(\Pi, c)$ as follows.

$$P(\Pi, c) := \{c(\pi) \mid \pi \in \Pi\}$$

With $\Pi_{st}(l)$ we denote all simple paths from $s \in V$ to $t \in V$ (with s and t being arbitrary but fixed nodes) with at most $\lceil l \rceil$ edges (l is a real number as we need to divide it by two in a recursion later on). We call $\Pi_{st}(l)$ a *complete path set*.

► **Definition 8.** Given a path set Π , we define $\varphi_d^r(\Pi)$ with $1 \leq r \leq d-1$ as

$$\varphi_d^r(\Pi) := \max_{c \in \mathcal{C}_d} \varphi_d^r(P(\Pi, c)).$$

Note that, by Lemma 6, it holds $\varphi_d^{d-1}(\Pi) = \max_{c \in \mathcal{C}_d} |\mathcal{M}(P(\Pi, c))|$.

► **Definition 9.** Given a path set Π and a cost function $c \in \mathcal{C}_d$, an element $v \in P(\Pi, c) =: P$ is an extreme shortest path with respect to Π and c if and only if $v \in \mathcal{M}(P)$. Furthermore, for a preference $\alpha \in \mathcal{P}_d$ we call a cost vector $v \in \mathcal{M}(P)$ α -shortest path with respect to P if and only if $\alpha \in f_P(v)$.

There are a few possibly confusing things to clarify here. First, we call the elements in $\mathcal{M}(P)$ extreme shortest paths even though they are mere cost vectors. The reason is that there is a bijective relationship between elements in P and Π as long as no two paths in Π have the

same cost vector. However, if there are multiple paths in Π with the same cost vector we prefer to count them only once. This is the reason why we focus on the set P instead of the set Π .

Second, if a cost vector v is an extreme shortest path depends on the path set Π . For instance, if $\Pi := \{\pi\}$, then any cost vector $v = c(\pi)$ is an extreme shortest path. Thus, if we say that v is an extreme shortest path, this is always with respect to some path set Π and cost function c that we either mention explicitly or that should be clear from the context.

Third, a cell of a d -metric PSS $\mathcal{S}_d(P)$ is a $(d - 1)$ -dimensional and not a d -dimensional facet. The reason is that the preference space \mathcal{P}_d lives in d dimensions but is itself a $(d - 1)$ -dimensional object (because the preferences sum up to one).

This work is about finding an upper bound for the number of extreme shortest paths in $P(\Pi_{st}(n), c)$ in arbitrary dimensions d and for arbitrary cost functions $c \in \mathcal{C}_d$.

Comparison of Personalized Route Planning and Parametric Shortest Path Problem

In the parametric shortest path problem, as defined for three dimensions in [9], the edge costs have the form

$$c(e \in E, \lambda \in \mathbb{R}^d) := \lambda c(e)^T \tag{3}$$

with $c : E \rightarrow \mathbb{R}^d$. In contrast to the definition in [9], λ_1 is typically set to one. However, note that the shortest path problem is homogeneous in the sense that if we scale all edge costs by a factor $\delta > 0$ we also scale the extreme shortest paths by δ . Thus, as argued in [9], (3) can always be scaled to either $\lambda_1 = 1$ or $\lambda_1 = -1$. The complexity of these two versions therefore can only differ by a factor of two.

In the personalized route planning model the edge costs are defined as

$$c(e \in E, \alpha \in \mathcal{P}_d) := \alpha c(e)^T \tag{4}$$

with $c : E \rightarrow \mathbb{R}_{\geq 0}^d$. The differences between (4) and (3) are that the preferences $\alpha \in \mathcal{P}_d$ and cost vectors are non-negative and the preferences sum up to one. We can handle the normalization with the same scaling argument as above. The non-negativity makes sure that there are no negative cost cycles in G regardless of α . This issue is treated differently in the parametric shortest path problem by requiring G to be acyclic. In the end, it is a matter of taste which requirement to choose. With minor adjustments our proofs also work for the case when G is acyclic and the costs and preferences are allowed to be negative.

3 A General Upper Bound on the Number of Extreme Shortest Paths

In this section we prove the following theorem.

► **Theorem 10.** *For any fixed but arbitrary $d \geq 1$ and any cost function $c \in \mathcal{C}_d$ the number of extreme shortest paths in $P(\Pi_{st}(n), c)$ is upper bounded by $n^{O(\log^{d-1} n)}$.*

► **Definition 11.** *We define $\varphi_d^r(n, l)$ to be the maximum of $\varphi_d^r(\Pi_{st}(l))$ over all possible graphs $G(V, E)$ with n nodes and all possible node pairs $s, t \in V$.*

Thus, Theorem 10 is equivalent to the statement $\varphi_d^{d-1}(n, n) \in n^{O(\log^{d-1} n)}$. We prove Theorem 10 with a recursion of the form $\varphi_d^{d-1}(n, n) \leq f(\varphi_{d-1}^{d-2}(n, n))$. Thus, we upper bound $\varphi_d^{d-1}(n, n)$ with a recursion in the dimension d , which is an idea also used in the proof of the upper bound for $d = 3$ in [9].

■ **Figure 3** Example preference space subdivision with red hyperplane intersection.

We obtain the function f as follows. First, we show that the intersection of a d -dimensional PSS and a hyperplane can have at most the complexity of a $(d - 1)$ -dimensional PSS (Lemma 12). In fact, this observation is based on a similar result shown in [9] in the context of parametric shortest paths. Second, we use this insight to upper bound $\varphi_d^{d-2}(n, l)$ for special path sets (Lemma 13 and 14), which then allows us to construct a second recursion of the form $\varphi_d^{d-2}(n, l) \leq g(\varphi_d^{d-2}(n, \frac{l}{2}))$. This leads to an upper bound for $\varphi_d^{d-2}(n, l)$ based on $\varphi_{d-1}^{d-2}(n, l)$ (Lemma 15). The proof of Theorem 10 then uses Lemma 15 together with an observation we discuss in Section 3.1 to construct the function f . We consider Lemma 13 and 14 in Section 3.3 as our main contributions as these ingredients allow us to generalize the ideas shown in [9] to arbitrary values d .

3.1 A First Upper Bound on the Number of Cells

The number of $(d - 2)$ -dimensional facets in a PSS is an upper bound of the number of $(d - 1)$ -dimensional facets in the same PSS for the following reasons. Given any finite point set $P \subset \mathbb{R}^d$ with $d > 1$. Each facet f_P^{d-2} of $\mathcal{S}_d(P)$ supports at most two $(d - 1)$ -dimensional facets. Moreover, every facet f_P^{d-1} is supported by at least d $(d - 2)$ -dimensional facets. This is true because the preference space \mathcal{P}_d is bounded itself and, thus, there is no unbounded cell in $\mathcal{S}_d(P)$. Therefore, we have

$$\varphi_d^{d-1}(P) \leq \frac{2}{d} \varphi_d^{d-2}(P). \quad (5)$$

For the case $d = 1$, our task of counting extreme shortest paths is simple. It holds

$$\varphi_1^0(P) \leq 1 \quad (6)$$

for any finite point set P because $\mathcal{M}(P) = \{\min_{v \in P} v\}$.

3.2 Bounding the Complexity of PSS Intersections

In this section we show that the complexity of the intersection of a hyperplane with a d -metric PSS is upper bounded by the complexity of a $(d - 1)$ -metric PSS. This observation is a crucial ingredient of our proof of Theorem 10 as it allows us to construct recursive upper bounds in the dimension d . The authors of [9] prove a similar statement in the context of parametric shortest paths. As their setting and notation slightly differ from ours, we decided to give a proof of the following lemma.

► **Lemma 12.** *Let $d > 1$ and let H_d be a hyperplane in d dimensions with $\mathcal{P}_d \not\subseteq H_d$ that intersects the preference space \mathcal{P}_d . Then for any path set Π and cost function $c \in \mathcal{C}_d$ the set $Y := \{f_{P(\Pi, c)}^{d-1} \cap H_d \mid \dim(f_{P(\Pi, c)}^{d-1} \cap H_d) = d - 2\}$ has at most $\varphi_{d-1}^{d-2}(\Pi)$ elements.*

Proof. We fix an arbitrary cost function $c \in \mathcal{C}_d$ and define $P := P(\Pi, c)$. See Figure 3 for an example of the intersection $H_d \cap \mathcal{P}_d$. The set $Z := \{f \cap H_d \mid f \in \mathcal{S}_d(P)\}$ looks like a $(d - 1)$ -metric PSS. However, it is unclear whether the complexity bounds for $(d - 1)$ -metric PSS also apply for sets like Z , which live in d dimensions. This lemma says that the answer is yes in the case of extreme shortest paths.

Our strategy to prove Lemma 12 looks as follows.

1. We show that for each $v \in P$ there is at most one $f \in Y$ with $\dim(f_P(v) \cap f) = d - 2$.
2. We define mappings $\eta : \mathbb{R}^d \rightarrow \mathbb{R}^{d-1}$ and $\beta : H_d \cap \mathcal{P}_d \rightarrow \mathcal{P}_{d-1}$ such that for each $\alpha \in H_d \cap \mathcal{P}_d$ and each $v \in P$ it holds $\alpha v^T = \beta(\alpha) \eta(v)^T$.

We prove these points later on and first show that they are sufficient to prove the lemma. Let $\eta(P)$ and $\beta(f_P)$ be the mapped sets P and f_P . It follows from the second point that for any $v \in P$ with $\dim(f_P(v) \cap H_d) = d - 2$ it holds

$$\beta(f_P(v) \cap H_d) \subseteq f_{\eta(P)}(\eta(v)).$$

Therefore, for each $f \in Y$ there is also an extreme shortest path $v' \in \mathcal{M}(\eta(P))$ with $\beta(f_P(v)) \subseteq f_{\eta(P)}(\eta(v'))$ (see Lemma 6).

Let $v' \in \mathcal{M}(\eta(P))$ be any extreme shortest path with respect to $\eta(P)$. Then the set $W := \{f \in Y \mid \beta(f) \subseteq f_{\eta(P)}(v')\}$ contains at most one element. Otherwise, we could take any cost vector $v \in P$ with $\eta(v) = v'$ and show, using point two, that all elements of W are subsets of $f_P(v)$. This contradicts the first point.

In summary, for each element $f \in Y$ we find an extreme shortest path $v' \in \mathcal{M}(\eta(P))$ with $\beta(f) \subseteq f_{\eta(P)}(v')$. Furthermore, for each extreme shortest path $v' \in \mathcal{M}(\eta(P))$ we find at most one $f \in Y$ with $\beta(f) \subseteq f_{\eta(P)}(v')$. Thus, it is possible to injectively map Y to $\mathcal{M}(\eta(P))$. As $|\mathcal{M}(\eta(P))| \leq \varphi_{d-1}^{d-2}(\Pi)$ by definition and because we chose the cost function c arbitrarily, this finishes the proof.

It remains to show that the two points are correct. Assume that we find a cost vector $v \in P$ and two elements $f_1, f_2 \in Y$ with $f_1 \subseteq f_P(v)$ and $f_2 \subseteq f_P(v)$. We know from Lemma 6 that there is a $v' \in \mathcal{M}(P)$ with $f_P(v) \subseteq f_P(v')$. Let $f_3 := f_P(v') \cap H_d$. Clearly, $f_1 \subseteq f_3$ and $f_2 \subseteq f_3$. As $f_1 \neq f_2$ at least one of them cannot be equal to f_3 . W.l.o.g. let $f_2 \subset f_3$.

By definition of Y , we find a shortest path $v_2 \in \mathcal{M}(P)$ with $f_2 = f_P(v_2) \cap H_d$. As $f_2 \subset H_d$ and $f_3 \subset H_d$ it follows that H_d is described by $\alpha(v' - v_2)^T = 0$. But then $f_P(v_2) \cap H_d = f_P(v') \cap H_d = f_3$, which is a contradiction to $f_2 \subset f_3$.

We come to the second point. W.l.o.g. let the intersection $H_d \cap \mathcal{P}_d$ be describable by an equation of the form

$$\alpha_1 = x_2 \cdot \alpha_2 + x_3 \cdot \alpha_3 + \dots + x_{d-1} \cdot \alpha_{d-1} + b =: f(\alpha)$$

with $x_i, b \in \mathbb{R}$. We map each point $v := (v_1, v_2, \dots, v_d) \in P$ to

$$\eta(v) := (v_2 + v_1 \cdot \tilde{v}_{2,1} + v_d \cdot \tilde{v}_{2,d}, v_3 + v_1 \cdot \tilde{v}_{3,1} + v_d \cdot \tilde{v}_{3,d}, \dots, v_d + v_1 \cdot \tilde{v}_{d,1} + v_d \cdot \tilde{v}_{d,d})$$

with $\tilde{v}_{i,1} = x_i + b$, $\tilde{v}_{i,d} = -(x_i + b)$ and $x_d = 0$. Note that η reduces the number of dimensions by one. Let $\eta(P)$ be the set of mapped points of P . By definition, $\mathcal{S}_{d-1}(\eta(P))$ has at most $\varphi_{d-1}^{d-2}(n, l)$ $(d - 2)$ -dimensional facets. Thus, there are at most $\varphi_{d-1}^{d-2}(n, l)$ extreme shortest paths in $\eta(P)$.

Let the map $\beta : H_d \cap \mathcal{P}_d \rightarrow \mathcal{P}_{d-1}$ be defined as follows.

$$\beta(\alpha) = (\alpha_2, \alpha_3, \dots, \alpha_d + \alpha_1)$$

For any $v \in P$ and $\alpha \in H_d \cap \mathcal{P}_d$ we have

$$\begin{aligned} \alpha \cdot v^T &= \left(f(\alpha), \alpha_2, \dots, 1 - f(\alpha) - \sum_{1 < i < d} \alpha_i \right) \cdot (v_1, \dots, v_d)^T \\ &= f(\alpha)(v_1 - v_d) + v_d + \sum_{1 < i < d} \alpha_i(v_i - v_d) \\ &= b(v_1 - v_d) + (\alpha_1 + \alpha_d)v_d + \sum_{1 < i < d} \alpha_i x_i(v_1 - v_d) + \sum_{1 < i < d} \alpha_i v_i \\ &= (\alpha_1 + \alpha_d)(v_d + v_1 \tilde{v}_{d,1} + v_d \tilde{v}_{d,d}) + \sum_{1 < i < d} \alpha_i(v_i + v_1 \tilde{v}_{i,1} + v_d \tilde{v}_{i,d}) \\ &= \beta(\alpha) \eta(v)^T. \end{aligned}$$

3.3 Decomposing Path Sets

In this section we first look at path sets Π_{sut} that can be written as the pairwise concatenation of two path sets Π_{su} and Π_{ut} that end/start at a common node u . We will see that in such a scenario the PSS $\mathcal{S}(P(\Pi_{sut}, c))$ is the overlay of $\mathcal{S}(P(\Pi_{su}, c))$ and $\mathcal{S}(P(\Pi_{ut}, c))$ for any cost function c (see Figure 4 for an example). Thus, we can upper bound $\varphi_d^{d-2}(\Pi_{sut})$ with the help of Lemma 12.

► **Lemma 13.** *Let Π_{su} and Π_{ut} be two path sets such that each path in Π_{su} ends at node $u \in V$ and each path in Π_{ut} starts at node u . Furthermore, let $\Pi_{sut} := \{\pi_1 \pi_2 \mid \pi_1 \in \Pi_{su}, \pi_2 \in \Pi_{ut}\}$ be the pairwise concatenation of Π_{su} and Π_{ut} . Then it holds*

$$\varphi_d^{d-2}(\Pi_{sut}) \leq \varphi_{d-1}^{d-2}(\Pi_{ut}) \cdot \varphi_d^{d-2}(\Pi_{su}) + \varphi_{d-1}^{d-2}(\Pi_{su}) \cdot \varphi_d^{d-2}(\Pi_{ut}).$$

Proof. We fix an arbitrary cost function $c \in \mathcal{C}_d$ and prove the inequality for c . Let $P_{sut} := P(\Pi_{sut}, c)$, $P_{su} := P(\Pi_{su}, c)$ and $P_{ut} := P(\Pi_{ut}, c)$. Given any $\alpha \in \mathcal{P}_d$, let v_{su} and v_{ut} be the α -shortest paths in P_{su} and P_{ut} . Then with $v_{sut} := v_{su} + v_{ut}$ it holds $v_{sut} \in P_{sut}$ and v_{sut} is the α -shortest path in P_{sut} . This is true because all paths in Π_{sut} go via node u . Thus, $\mathcal{S}(P_{sut})$ is the overlay of $\mathcal{S}(P_{su})$ and $\mathcal{S}(P_{ut})$.

Every facet $f_{P_{su}}^{d-2}$ is part of a hyperplane H_d . If we let H_d intersect the preference subdivision $\mathcal{S}_d(P_{ut})$ we know from Lemma 12 that this intersection contains no more than $\varphi_{d-1}^{d-2}(\Pi_{ut})$ $(d-2)$ -dimensional facets. Thus, in the overlay of $\mathcal{S}(P_{su})$ and $\mathcal{S}(P_{ut})$ the facet $f_{P_{su}}^{d-2}$ can be split into at most $\varphi_{d-1}^{d-2}(\Pi_{ut})$ $(d-2)$ -dimensional facets as well. An analogous statement holds for the facets $f_{P_{ut}}^{d-2}$, which finishes the proof. ◀

The following lemma addresses the problem of upper bounding $\varphi_d^{d-2}(\Pi')$ if the path set Π' is the union of multiple path sets.

► **Lemma 14.** *Given k path sets $\Pi_1, \Pi_2, \dots, \Pi_k$ and let $\Pi' := \bigcup_{1 \leq i \leq k} \Pi_i$, then it holds for every $d > 1$*

$$\varphi_d^{d-2}(\Pi') \leq 2 \cdot k \cdot \varphi' \cdot \sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i),$$

with $\varphi' := \max_{1 \leq i \leq k} \varphi_{d-1}^{d-2}(\Pi_i)$.

■ **Figure 4** This figure illustrates the meaning of Lemma 13. With the two path sets Π_{su} and Π_{ut} the PSS $\mathcal{S}(P_{sut})$, as defined in Lemma 13, is the overlay of $\mathcal{S}(P_{su})$ and $\mathcal{S}(P_{ut})$. An edge $f_{P_{su}}^1$ can cause multiple edges in the PSS $\mathcal{S}_3(P_{sut})$ by intersecting the PSS $\mathcal{S}_3(P_{ut})$. Lemma 13 says that $f_{P_{su}}^1$ can be split into at most $\varphi_2^2(\Pi_{ut})$ many edges in $\mathcal{S}_3(P_{sut})$.

Proof. We fix an arbitrary cost function $c \in \mathcal{C}_d$ and define $P' := P(\Pi', c)$ and $P_i := P(\Pi_i, c)$ for all $1 \leq i \leq k$.

Now, let us fix a facet $f_{P'}^{d-2} \in \mathcal{S}(P')$. The facet is part of a hyperplane H that is described by $\alpha(v_1 - v_2)^T = 0$ with $v_1, v_2 \in \mathcal{M}(P')$ and $v_1 \neq v_2$.

We first assume that v_1 and v_2 belong to the same set P_i . As $P_i \subseteq P'$, we have $v_1, v_2 \in \mathcal{M}(P_i)$ and $f_{P'}(v_1) \cap f_{P'}(v_2) \subseteq f_{P_i}(v_1) \cap f_{P_i}(v_2)$. Therefore, $\dim(f_{P_i}(v_1) \cap f_{P_i}(v_2)) = d-2$ and there is a facet $f_{P_i}^{d-2} = f_{P_i}(v_1) \cap f_{P_i}(v_2)$. Thus, we have at most $\varphi_d^{d-2}(\Pi_i)$ such pairs v_1, v_2 in $\mathcal{M}(P_i)$.

We now assume that v_1 and v_2 belong to different sets P_i and P_j . From $P_i \cup P_j \subseteq P'$ it follows that $f_{P'}(v_1) \cap f_{P'}(v_2) \subseteq f_{P_i}(v_1) \cap f_{P_j}(v_2)$. Thus, $\dim(f_{P_i}(v_1) \cap f_{P_j}(v_2)) \geq d-2$.

Therefore, there must be a facet $f_{P_i}^{d-2}$ or $f_{P_j}^{d-2}$ (or both) that intersects with $f_{P_i}(v_1) \cap f_{P_j}(v_2)$.

In summary, for each facet $f_{P'}^{d-2}$ we either find a corresponding facet $f_{P_i}^{d-2}$ with $f_{P'}^{d-2} \subseteq f_{P_i}^{d-2}$ (case one) or an intersection $f_{P_i}^{d-2} \cap f_{P_j}^{d-2}$ (or $f_{P_i}^{d-1} \cap f_{P_j}^{d-2}$) with $\dim(f_{P_i}^{d-2} \cap f_{P_j}^{d-2}) = d-2$ (case two). Clearly, we can upper bound the first case with $\sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i)$.

The second case we handle with the help of Lemma 12. The intersection of the facet $f_{P_i}^{d-2}$ with any PSS $\mathcal{S}_d(P_j)$ can contain at most $\varphi_{d-1}^{d-2}(\Pi_j) \leq \varphi'(d-2)$ -dimensional facets (Lemma 12). Moreover, there are at most two extreme shortest paths in P_i that are adjacent to $f_{P_i}^{d-2}$. Thus, in total the facet $f_{P_i}^{d-2}$ can contribute to at most $2 \cdot (k-1) \cdot \varphi'$ intersections of case two. Therefore, the number of facets $f_{P'}^{d-2}$ of case two can be upper bounded by $2 \cdot (k-1) \cdot \varphi' \cdot \sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i)$.

With $\sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i) + 2 \cdot (k-1) \cdot \varphi' \cdot \sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i) \leq 2 \cdot k \cdot \varphi' \cdot \sum_{1 \leq i \leq k} \varphi_d^{d-2}(\Pi_i)$ the statement follows. ◀

3.4 Proving the Upper Bound via Recursion

In the following lemma we describe a recursive upper bound for $\varphi_d^{d-2}(n, l)$ in the dimension d , which we then use to prove Theorem 10.

► **Lemma 15.** $\varphi_d^{d-2}(n, l) \leq d \cdot l^2 \cdot n^{2 \log l} \cdot \varphi_{d-1}^{d-2}(n, l)^{2 \log l}$ for $d > 1$.

Proof. We prove Lemma 15 for an arbitrary complete path set $\Pi_{st}(l)$ and cost function $c \in \mathcal{C}_d$ and define $P_{st} := P(\Pi_{st}(l), c)$. We first introduce path sets $\Pi_{sut} := \{\pi \in \Pi_{st}(l) \mid u \in V \text{ divides } \pi \text{ into subpaths of at most } \lceil \frac{l}{2} \rceil \text{ edges}\}$. Clearly, each path $\pi \in \Pi_{st}(l)$ is contained in at least one path set Π_{sut} . Thus, we can apply Lemma 14 and get

$$\varphi_d^{d-2}(\Pi_{st}(l)) \leq 2 \cdot n \cdot \varphi_{d-1}^{d-2}(n, l) \cdot \sum_{u \in V} \varphi_d^{d-2}(\Pi_{sut}), \quad (7)$$

as one can easily show that $\varphi_{d-1}^{d-2}(n, l) \geq \max_{u \in V} \varphi_{d-1}^{d-2}(\Pi_{sut})$.

The path sets Π_{sut} can be written as the pairwise concatenation of the path sets $\Pi_{su}(\frac{l}{2})$ and $\Pi_{ut}(\frac{l}{2})$. Thus, they satisfy the requirements to apply Lemma 13 such that for each node u we get

$$\begin{aligned} \varphi_d^{d-2}(\Pi_{sut}) &\leq \varphi_{d-1}^{d-2}\left(\Pi_{ut}\left(\frac{l}{2}\right)\right) \cdot \varphi_d^{d-2}\left(\Pi_{su}\left(\frac{l}{2}\right)\right) + \varphi_{d-1}^{d-2}\left(\Pi_{su}\left(\frac{l}{2}\right)\right) \cdot \varphi_d^{d-2}\left(\Pi_{ut}\left(\frac{l}{2}\right)\right) \\ &\leq 2 \cdot \varphi_{d-1}^{d-2}\left(n, \frac{l}{2}\right) \cdot \varphi_d^{d-2}\left(n, \frac{l}{2}\right). \end{aligned} \quad (8)$$

If we combine (7) and (8), we get

$$\begin{aligned} \varphi_d^{d-2}(\Pi_{st}(l)) &\leq 4 \cdot n^2 \cdot \varphi_{d-1}^{d-2}(n, l) \cdot \varphi_{d-1}^{d-2}\left(n, \frac{l}{2}\right) \cdot \varphi_d^{d-2}\left(n, \frac{l}{2}\right) \\ &\leq 4 \cdot n^2 \cdot \varphi_{d-1}^{d-2}(n, l)^2 \cdot \varphi_d^{d-2}\left(n, \frac{l}{2}\right). \end{aligned} \quad (9)$$

Using this recursion in l we obtain with $\varphi_d^{d-2}(n, 1) = d$

$$\begin{aligned} \varphi_d^{d-2}(\Pi_{st}(l)) &\leq d \cdot 4^{\log l} \cdot n^{2 \log l} \cdot \varphi_{d-1}^{d-2}(n, l)^{2 \log l} \\ &= d \cdot l^2 \cdot n^{2 \log l} \cdot \varphi_{d-1}^{d-2}(n, l)^{2 \log l}. \end{aligned} \quad (10)$$

Proof of Theorem 10. We need to show that $\varphi_d^{d-1}(n, n) \in n^{O(\log^{d-1} n)}$ for a fixed but arbitrary number of cost types $d \geq 1$. From Lemma 15 we know that $\varphi_d^{d-2}(n, n) \leq d \cdot n^{2+2 \log n} \cdot \varphi_{d-1}^{d-2}(n, n)^{2 \log n}$. With (5) we get $\varphi_d^{d-1}(n, n) \leq 2 \cdot n^{2+2 \log n} \cdot \varphi_{d-1}^{d-2}(n, n)^{2 \log n}$. With $\varphi_1^0(n, n) = 1$ this leads to $\varphi_d^{d-1}(n, n) \in n^{O((2 \log n)^{d-1})}$, which is, for a fixed d , equal to $\varphi_d^{d-1}(n, n) \in n^{O(\log^{d-1} n)}$. ◀

4 Conclusions

In this paper we showed that the number of extreme shortest paths in a graph G is upper bounded by $n^{O(\log^{d-1} n)}$, where n is the number of nodes and d is the fixed but arbitrary number of edge costs in G . This is a generalization of previous results in the context of parametric shortest paths for two and three dimensions.

An open question is whether one can also generalize the matching two-dimensional lower bounds shown in [5].

Abstract

Given a graph G and two independent sets I_s and I_t of size k , the INDEPENDENT SET RECONFIGURATION problem asks whether there exists a sequence of independent sets (each of size k) $I_s = I_0, I_1, I_2, \dots, I_\ell = I_t$ such that each independent set is obtained from the previous one using a so-called reconfiguration step. Viewing each independent set as a collection of k tokens placed on the vertices of a graph G , the two most studied reconfiguration steps are token jumping and token sliding. In the TOKEN JUMPING variant of the problem, a single step allows a token to jump from one vertex to any other vertex in the graph. In the TOKEN SLIDING variant, a token is only allowed to slide from a vertex to one of its neighbors. Like the INDEPENDENT SET problem, both of the aforementioned problems are known to be $W[1]$ -hard on general graphs (for parameter k). A very fruitful line of research [5, 14, 27, 25] has showed that the INDEPENDENT SET problem becomes fixed-parameter tractable when restricted to sparse graph classes, such as planar, bounded treewidth, nowhere-dense, and all the way to biclique-free graphs. Over a series of papers, the same was shown to hold for the TOKEN JUMPING problem [17, 22, 26, 8]. As for the TOKEN SLIDING problem, which is mentioned in most of these papers, almost nothing is known beyond the fact that the problem is polynomial-time solvable on trees [11] and interval graphs [6]. We remedy this situation by introducing a new model for the reconfiguration of independent sets, which we call galactic reconfiguration. Using this new model, we show that (standard) TOKEN SLIDING is fixed-parameter tractable on graphs of bounded degree, planar graphs, and chordal graphs of bounded clique number. We believe that the galactic reconfiguration model is of independent interest and could potentially help in resolving the remaining open questions concerning the (parameterized) complexity of TOKEN SLIDING.

1 Introduction

Many algorithmic questions can be posed as follows: given the description of a system state and the description of a state we would “prefer” the system to be in, is it possible to transform the system from its current state into the more desired one without “breaking” the system in the process? And if yes, how many steps are needed? Such problems

naturally arise in the fields of mathematical puzzles, operational research, computational geometry [23], bioinformatics, and quantum computing [13] for instance. These questions received a substantial amount of attention under the so-called *combinatorial reconfiguration framework* in the last few years [9, 28, 30]. We refer the reader to the surveys by van den Heuvel [28] and Nishimura [24] for more background on combinatorial reconfiguration.

In this work, we focus on the reconfiguration of independent sets. Given a simple undirected graph G , a set of vertices $S \subseteq V(G)$ is an *independent set* if the vertices of S are all pairwise non-adjacent. Finding an independent set of maximum cardinality, i.e., the INDEPENDENT SET problem, is a fundamental problem in algorithmic graph theory and is known to be not only NP-hard, but also W[1]-hard and not approximable within $\mathcal{O}(n^{1-\epsilon})$, for any $\epsilon > 0$, unless $P = NP$ [31].

We view an independent set as a collection of tokens placed on the vertices of a graph such that no two tokens are adjacent. This gives rise to two natural adjacency relations between independent sets (or token configurations), also called *reconfiguration steps*. These two reconfiguration steps, in turn, give rise to two combinatorial reconfiguration problems. In the TOKEN JUMPING (TJ) problem, introduced by Kamiński et al. [20], a single reconfiguration step consists of first removing a token on some vertex u and then immediately adding it back on any other vertex v , as long as no two tokens become adjacent. The token is said to *jump* from vertex u to vertex v . In the TOKEN SLIDING (TS) problem, introduced by Hearn and Demaine [15], two independent sets are adjacent if one can be obtained from the other by a token jump from vertex u to vertex v with the additional requirement of uv being an edge of the graph. The token is then said to *slide* from vertex u to vertex v along the edge uv . Note that, in both the TJ and TS problems, the size of independent sets is fixed. Generally speaking, in the TOKEN JUMPING and TOKEN SLIDING problems, we are given a graph G and two independent sets I_s and I_t of G . The goal is to determine whether there exists a sequence of reconfiguration steps – a *reconfiguration sequence* – that transforms I_s into I_t (where the reconfiguration step depends on the problem).

Both problems have been extensively studied, albeit under different names [6, 7, 11, 12, 16, 19, 20, 22]. It is known that both problems are PSPACE-complete, even on restricted graph classes such as graphs of bounded bandwidth (and hence pathwidth) [29] and planar graphs [15]. On the positive side, it is easy to prove that TOKEN JUMPING can be decided in polynomial time on trees (and even on chordal graphs) since we simply have to iteratively jump tokens to leaves (resp. vertices that only appear in the bag of a leaf in the clique tree) to transform an independent set into another. Unfortunately, for TOKEN SLIDING, the problem becomes more complicated because of what we call the *bottleneck effect*. Indeed, there might be a lot of empty leaves in the tree but there might be a bottleneck in the graph that prevents us from reaching these desirable vertices. For instance, consider a star plus a long subdivided path attached to the center of the star. One cannot move any token from the leaves of the star to the path if there are at least two tokens on the leaves (in other words, two tokens adjacent to a cut-vertex prevent us from using the cut vertex). Even if we can overcome this issue for instance on trees [11] and on interval graphs [6], the TOKEN SLIDING problem remains much “harder” than the TOKEN JUMPING problem. In split graphs for instance (which are chordal), TOKEN SLIDING is PSPACE-complete [4]. Lokshtanov and Mouawad [21] showed that, in bipartite graphs, TOKEN JUMPING is NP-complete while TOKEN SLIDING remains PSPACE-complete.

In this paper we focus on the parameterized complexity of the TOKEN SLIDING problem. While the complexity of TOKEN JUMPING parameterized by the size of the independent set is quite well understood, the comprehension of the complexity of TOKEN SLIDING remains

evasive. A problem Π is FPT (fixed-parameterized tractable) parameterized by k if one can solve it in time $f(k) \cdot \text{poly}(n)$, for some computable function f . In other words, the combinatorial explosion can be restricted to a parameter k . In the rest of the paper, our parameter k will be the size of the independent set (i.e. number of tokens). Both TOKEN JUMPING and TOKEN SLIDING are known to be W[1]-hard¹ parameterized by k on general graphs [22]. On the positive side, Lokshantov et al. [22] showed that TOKEN JUMPING is FPT on bounded degree graphs. This result has been extended in a series of papers to planar graphs, nowhere-dense graphs, and finally strongly $K_{\ell,\ell}$ -free graphs [18, 8], a graph being strongly $K_{\ell,\ell}$ -free if it does not contain any $K_{\ell,\ell}$ as a subgraph. For TOKEN SLIDING, it was proven in [2] that the problem is W[1]-hard on bipartite graphs and C_4 -free graphs (a similar result holds for TOKEN JUMPING but based on weaker assumptions for the bipartite case [1]).

Almost no positive result is known for TOKEN SLIDING even for incredibly simple cases like graphs of bounded degree. Our main contributions are to develop two general tools for the design of parameterized algorithms for TOKEN SLIDING, namely galactic reconfiguration and types. Galactic reconfiguration is a general simple tool that allows us to reduce instances. Using it, we will derive that TOKEN SLIDING is FPT on bounded degree graphs. Our second tool, called types, will in particular permit to show that when the deletion of a small subset of vertices leaves too many components, then one of them can be removed. Combining both tools with additional rules, we prove that TOKEN SLIDING is FPT on planar graphs and on chordal graphs of bounded clique number. We complement these results by proving that TOKEN SLIDING is W[1]-hard on split graphs.

Our first result is the following:

► **Theorem 1.1.** *TOKEN SLIDING is FPT on bounded degree graphs parameterized by k .*

Much more than the result itself, we believe that our main contribution here is the general framework we developed for its proof, namely galactic reconfiguration. Before explaining exactly what it is, let us explain the intuition behind it. As we already said, even if there are vertices which are far apart from the vertices of an independent set, we are not sure we can reach them because of the bottleneck effect. Our intuition was that it should be possible to reduce a part of large diameter of the graph that does not contain any tokens (just as we can find irrelevant vertices when we have large grid minors). The idea is that since the diameter is large, we should be able to hide tokens far apart from each other in this structure, avoiding the “bottleneck issue”. And thus the structure should be reducible. However, proving that a structure can be reduced in reconfiguration is usually very technical. To overcome this problem, we introduce a new kind of vertices called *black holes* which can swallow as many tokens of the independent set as we like. A *galactic graph* is a graph that might contain black holes. A *galactic independent set* is a set of vertices on which tokens lie, such that the set of non black hole vertices holding tokens is an independent set and such that each black hole might contain any number of tokens.

Our main result is to prove that if there exists a long shortest path that is at distance at least two from the initial and target independent sets, then we can replace it by a black hole (whose neighborhood is the union of the neighborhoods of the path vertices). This rule, together with other simple rules on galactic graphs, allows us to reduce the size of bounded-degree graphs until they reach a size of at most $f(k)$ in polynomial time. Since a kernel ensures the existence of an FPT algorithm, Theorem 1.1 holds.

¹ Informally, it means that they are very unlikely to admit an FPT algorithm.

In the rest of the paper, we combine galactic graphs with other techniques to prove that TOKEN SLIDING is FPT on several other graph classes. We first prove the following:

► **Theorem 1.2.** *TOKEN SLIDING is FPT on planar graphs parameterized by k .*

To prove Theorem 1.2, we cannot simply use our previous long path reduction since, in a planar graph, there might be a universal vertex which prevents the existence of a long shortest path. Note that the complexity of TOKEN SLIDING is open on outerplanar graphs and it was not known to be FPT prior to our work.

Our strategy consists in reducing to planar graphs of bounded degree and then applying Theorem 1.1. To do so, we provide another general tool to reduce graphs for TOKEN SLIDING. Namely, we show that if there is a set X of vertices such that $G - X$ contains too many connected components (in terms of k and $|X|$) then at least one of them can be safely removed. The idea of the proof consists in defining the *type* of a connected component of $G - X$. From a very high level perspective, the type² of a path in a component of $G - X$ is the sequence of its neighborhoods in X . The type of a component C is the union of the types of the paths starting on a vertex of C . We then show that if too many components of $G - X$ have the same type then one of them can be removed.

However, this component reduction is not enough since, in the case of a vertex x universal to an outerplanar graph, the deletion of x does not leave many connected components. We prove that, we can also reduce a planar graph if (i) there are too many vertex-disjoint (x, y) -paths for some pair x, y of vertices or, (ii) if a vertex has too many neighbors on an induced path. Since one can prove that in an arbitrarily large planar graph with no long shortest path (i) or (ii) holds, it will imply Theorem 1.2.

Note that our proof techniques can be easily adapted to prove that the problem is FPT for any graph of bounded genus. We think that the notion of types may be crucial to derive FPT algorithms on larger classes of graphs such as bounded treewidth graphs.

We finally provide another application of our method by proving that the following holds:

► **Theorem 1.3.** *TOKEN SLIDING is FPT on chordal graphs of bounded clique number.*

The proof of Theorem 1.3 consists in proving that, since there is a long path in the clique tree, we can either find a long shortest path (and we can reduce the graph using galactic rules) or find a vertex x in a large fraction of the bags of this path. In the second case, we show that we can again reduce the graph. We complement this result by proving that it cannot be extended to split graphs, contrarily to TOKEN JUMPING.

► **Theorem 1.4.** *TOKEN SLIDING is $W[1]$ -hard on split graphs.*

We show hardness via a reduction from the MULTICOLORED INDEPENDENT SET problem, known to be $W[1]$ -hard [10]. The crux of the reduction relies on the fact that we have a clique of unbounded size and hence we can use different subsets of the clique to encode vertex selection gadgets and non-edge selection gadgets.

The first natural generalization of our result on chordal graphs of bounded clique size would be the following:

► **Question 1.1.** *Is TOKEN SLIDING FPT on bounded treewidth graphs? Or simpler, on bounded pathwidth graphs?*

² The exact definition is actually more complicated.

We did not succeed in answering Question 1.1 but we think that the method we used for Theorem 1.3 is a good starting point (with a much more involved analysis). Recall that the problem is PSPACE-complete on graphs of constant bandwidth for a large enough constant that is not explicit in the proof [29]. Note that our galactic reconfiguration rules directly ensure that TOKEN SLIDING is FPT on bounded bandwidth graphs and the multi-component reduction ensures that the problem is FPT for graphs of bounded treedepth. But even for bounded pathwidth, the situation is unclear. There are good indications to think that solving the bounded pathwidth case is the hardest step to obtain an FPT algorithm for bounded treewidth graphs. On the positive side, we simply know that the problem is polynomial time solvable on graphs of treewidth one (namely forests) [11] and the problem is open for outerplanar graphs, which are graphs of treewidth 2:

► **Question 1.2.** *Is TOKEN SLIDING polynomial-time solvable on outerplanar graphs? Triangulated outerplanar graphs?*

Organization of the paper. In Section 2, we formally introduce galactic graphs and provide our main reduction rules concerning such graphs, including the long shortest path reduction lemma. In Section 3, we introduce the notion of types and journeys and prove that if there are too many connected components in $G - X$ then at least one of them can be removed. In Section 4, we briefly describe our results for TOKEN SLIDING on planar graphs and chordal graphs of bounded clique number. Our hardness reduction for split graphs and all omitted proofs can be found in the full version of the paper [3].

2 Galactic graphs and galactic token sliding

We say that a graph $G = (V, E)$ is a *galactic graph* when $V(G)$ is partitioned into two sets $A(G)$ and $B(G)$ where the set $A(G) \subseteq V(G)$ is the set of vertices that we call *planets* and the set $B(G) \subseteq V(G)$ is the set of vertices that we call *black holes*. For a given graph G' , we write $G' \prec G$ whenever $|A(G')| < |A(G)|$ or, in case of equality, $|B(G')| < |B(G)|$. In the standard TOKEN SLIDING problem, tokens are restricted to sliding along edges of a graph as long as the resulting sets remain independent. This implies that no vertex can hold more than one token and no two tokens can ever become adjacent. In a galactic graph, the rules of the game are slightly modified. When a token reaches a black hole (a special kind of vertex), the token is *absorbed* by the black hole. This implies that a black hole can hold more than one token, in fact it can hold all k tokens. Moreover, we allow tokens to be adjacent as long as one of the two vertices is a black hole (since black holes are assumed to make tokens “disappear”). On the other hand, a black hole can also “project” any of the tokens it previously absorbed onto any vertex in its neighborhood (be it a planet or a black hole). Of course, all such moves require that we remain an independent set in the galactic sense. We say that a set I is a *galactic independent set* of a galactic graph G whenever $G[I \cap A]$ is edgless. To fully specify a galactic independent set I of size k containing more than one token on black holes, we use a weight function $\omega_I : V(G) \rightarrow \{0, \dots, k\}$. Hence, $\omega_I(v) \leq 1$ whenever $v \in A(G)$, $\omega_I(v) \in \{0, \dots, k\}$ whenever $v \in B(G)$, and $\sum_{v \in V(G)} \omega_I(v) = k$.

We are now ready to define the GALACTIC TOKEN SLIDING problem. We are given a galactic graph G , an integer k , and two galactic independent sets I_s and I_t such that $|I_s| = |I_t| = k \geq 2$ (when $k = 1$ the problem is trivial). The goal is to determine whether there exists a sequence of token slides that will transform I_s into I_t such that each intermediate set remains a galactic independent set. As for the classical TOKEN SLIDING problem, given a galactic graph G we can define a reconfiguration graph which we call the *galactic*

reconfiguration graph of G . It is the graph whose vertex set is the set of all galactic independent sets of G , two vertices being adjacent if their corresponding galactic independent sets differ by exactly one token slide. We always assume the input graph G to be a connected graph, since we can deal with each component independently otherwise. Furthermore, components without tokens can be safely deleted. Given an instance (G, k, I_s, I_t) of GALACTIC TOKEN SLIDING, we say that (G, k, I_s, I_t) can be *reduced* if we can find an instance (G', k', I'_s, I'_t) which is positive (yes-instance) if and only if (G, k, I_s, I_t) is positive and $G' \prec G$.

Let G be a galactic graph. A *planetary component* is a maximal connected component of $G[A]$. A *planetary path* P , or *A-path*, composed only of vertices of A , is called *A-geodesic* if, for every x, y in P , $\text{dist}_{G[A]}(x, y) = \text{dist}_P(x, y)$. We use the term *A-distance* to denote the length of a shortest path between vertices $u, v \in A$ such that all vertices of the path are also in A . Let us state a few reduction rules that allow us to safely reduce an instance (G, k, I_s, I_t) of GALACTIC TOKEN SLIDING to an instance (G', k', I'_s, I'_t) .

- Reduction rule R1 (adjacent black holes rule): If two black holes u and v are adjacent, we contract them into a single black hole w . If there are tokens on u or v , the merged black hole receives the union of all such tokens. In other words, $\omega_{I'_s}(w) = \omega_{I_s}(u) + \omega_{I_s}(v)$ and $\omega_{I'_t}(w) = \omega_{I_t}(u) + \omega_{I_t}(v)$. Loops and multi-edges are ignored.
- Reduction rule R2 (dominated black hole rule): If there exists two black holes u and v such that $N(u) \subseteq N(v)$, $\omega_{I_s}(u) = 0$, and $\omega_{I_t}(u) = 0$, we delete u .
- Reduction rule R3 (absorption rule): If there exists u, v such that u is a black hole, $v \in N(u) \cap A$ (v is a neighboring planet that could be in $I_s \cup I_t$) and $|((I_s \cup I_t) \cap A) \cap N[v]| \leq 1$, then we contract the edge uv . We say that v is *absorbed* by u . If $v \in I_s \cup I_t$ then we update the weights of u accordingly.
- Reduction rule R4 (twin planets rule): Let $u, v \in A(G)$ be two planet vertices that are *twins* (true or false twins). That is, either $uv \notin E(G)$ and $N(u) = N(v)$ or $uv \in E(G)$ and $N[u] = N[v]$. If $u \notin I_s \cup I_t$ then delete u . If both u and v are in I_s (resp. I_t) and at least one of them is not in I_t (resp. I_s) then return a trivial no-instance. If both u and v are in I_s as well as I_t then delete $N[u] \cup N[v]$, decrease k by two, and set $I'_s = I_s \setminus \{u, v\}$ and $I'_t = I_t \setminus \{u, v\}$.
- Reduction rule R5 (path reduction rule): Let G be a galactic graph and P be a A -geodesic path of length at least $5k$ such that $(A \cap N[P]) \cap (I_s \cup I_t) = \emptyset$. Then, P can be contracted into a black hole (we ignore loops and multi-edges). That is, we contract all edges in P until one vertex remains.

► **Lemma 2.1.** *Reduction rule R5, the path reduction rule, is safe.*

Sketch of the proof. Let P be an A -geodesic path of length $5k$ in G such that no vertex of $A \cap N[P]$ are in the initial or target independent sets, I_s and I_t . Let G' be the graph obtained after contracting P into a single black hole b . Let I'_s and I'_t be the galactic independent sets corresponding to I_s and I_t . If there is a transformation from I_s to I_t in G , then one can show that there is a transformation from I'_s to I'_t in G' by simply absorbing tokens that become adjacent to the black hole and then projecting them appropriately when needed.

Now we consider a transformation from I'_s to I'_t in G' and show how to adapt it in G . We first prove (in the full version of the paper [3]) that we can always assume the existence of a sequence in G' where the number of tokens in $N(b) \cap A$ is at most one throughout the sequence, for any black hole b . Now, assuming such a sequence, we can simulate the sequence in G with the hard case being when multiple tokens slide into b . Note, however, that P is of length $5k$ and is A -geodesic. Hence, every vertex $a \in A$ has at most three neighbors in P and any independent set of size at most k in A has at most $3k$ neighbors in P . This leaves

$2k$ vertices on P which we can use to hold as many as k tokens that need to slide into b (in G'). In other words, whenever more than one token slides into b in G' , we simulate this by sliding the tokens in P onto the $2k$ vertices of P that are free. ◀

As immediate consequences, the following properties hold in an instance where reduction rules R1 to R5 cannot be applied.

► **Corollary 2.2.** *Every planetary component must contain at least one token and therefore G can have at most k planetary components, when $k \geq 2$.*

► **Corollary 2.3.** *Let (G, k, I_s, I_t) be an instance of GALACTIC TOKEN SLIDING where reduction rules R1, R3, and R5 (adjacent black holes rule, absorption rule, and the path reduction rule) have been exhaustively applied. Then, the graph G has diameter at most $O(k^2)$. Moreover, any planetary component has diameter at most $O(k^2)$.*

We now show how the galactic reconfiguration framework combined with the previous reduction rules immediately implies that TOKEN SLIDING is fixed-parameter tractable for parameter $k + \Delta(G)$, where $\Delta(G)$ denotes the maximum degree of G . Theorem 2.4 immediately implies positive results for graphs of bounded bandwidth/bucketwidth.

► **Theorem 2.4.** *TOKEN SLIDING is fixed-parameter tractable when parameterized by $k + \Delta(G)$. Moreover, the problem admits a bikernel³ with $k\Delta(G)^{O(k^2)} + (2k + 2k\Delta(G))\Delta(G)$ vertices.*

Proof. Let (G, k, I_s, I_t) be an instance of TOKEN SLIDING. We first transform it to an instance of GALACTIC TOKEN SLIDING where all vertices are planetary vertices. We then apply all of the reduction rules R1 to R5 exhaustively. By a slight abuse of notation we let (G, k, I_s, I_t) denote the irreducible instance of GALACTIC TOKEN SLIDING.

The total number of planetary components in G is at most k by Corollary 2.2 and the diameter of each such component is at most $O(k^2)$ by Corollary 2.3. Hence the total number of planet vertices is at most $k\Delta(G)^{O(k^2)}$.

To bound the total number of black holes, it suffices to note that no black hole can have a neighbor in $B \cup (A \setminus N[I_s \cup I_t])$. In other words, no black hole can be adjacent to another black hole (since the adjacent black holes reduction rule would apply) and no black hole can be adjacent to a planet without neighboring tokens (otherwise the absorption reduction rule would apply). Hence, combined with the fact that each black hole must have degree at least one, the total number of black holes is at most $(2k + 2k\Delta(G))\Delta(G)$. ◀

3 The multi-component reduction rule (R6)

General idea. The goal of this section is to show how we can reduce a graph when we have a small vertex separator with many components attached to it. We let X be a subset of vertices and H be an induced subgraph of $G - X$ (for simplicity we assume G is a non-galactic graph in this section). Let I_s and I_t be two independent sets which are disjoint from H and consider a reconfiguration sequence from I_s to I_t in G . Let v be a vertex of H and assume that there is a token t that is *projected* on v at some point of the reconfiguration sequence, meaning that the token t is moved from a vertex of X to v . This token may stay a few steps on v , move to some other vertex w of H , and so on until it eventually goes back to X . Let this sequence of vertices (allowing duplicate consecutive vertices) be denoted by $v_1 = v, v_2, \dots, v_r$. We call this sequence the *journey* of v (formal definitions are given in the next subsection).

³ A kernel where the resulting instance is not an instance of the same problem.

Assume now that the number of connected components attached to X is arbitrarily large. Our goal is to show that one of those components can be safely deleted, that is, without compromising the existence of a reconfiguration sequence if one exists. Suppose that we decide to delete the component H . The transformation from I_s to I_t does not exist anymore since, in the reconfiguration sequence, the token t was projected on $v \in V(H)$. But we can ask the following question: Is it possible to simulate the journey of v in another connected component of $G - X$? In fact, if we are able to find a vertex w in a connected component $H' \neq H$ of $G - X$ and a sequence $w_1 = w, \dots, w_r$ of vertices such that $w_i w_{i+1}$ is an edge for every i and such that $N(w_i) \cap X = N(v_i) \cap X$, then we could project the token t on w instead of v and perform this journey instead of the original journey⁴ of t . One possible issue is that the number r of (distinct) vertices in the journey can be arbitrarily large, and thus the existence of w and H' is not guaranteed *a priori*. This raises more questions: What is important in the sequence $v = v_1, \dots, v_r$? Why do we go from v_1 to v_r ? Why many steps in the journey if r is large? The answers are not necessarily unique. We distinguish two cases.

First, suppose that in the reconfiguration sequence, the token t was projected from X to v , performed the journey without having to “wait” at any step (so no duplicate consecutive vertices in the journey), and then was moved to a vertex $x' \in X$. Then, the journey only needs to “avoid” the neighbors of the vertices in X that contain a token. Let us denote by s_1 the step where the token t is projected on v and by s_2 the last step of the journey (that is, the step where t is one move/slide away from X). Let Y be the vertices of X that contain a token between the steps s_1 and s_2 . The journey of t can then be summarized as follows: a vertex whose neighborhood in X is equal to $N(v) \cap X$, a walk whose vertices all belong to H and are only adjacent to subsets of $X \setminus Y$, and then a vertex whose neighborhood in X is equal to $N(v_r) \cap X$. In particular, if we can find, in another connected component of $G - X$, a vertex w for which such a journey (with respect to the neighborhood in X) also exists, then we can project t on w instead of v . Clearly, the obtained reconfiguration sequence would also be feasible (assuming again no other tokens in the component of w).

However, we might not be able to go “directly” from $v_1 = v$ to v_r . Indeed, at some point in the sequence, there might be a vertex v_{i_1} which is adjacent to a token in X . This token will eventually move (since the initial journey with t in H is valid), which will then allow the token t to go further on the journey. But then again, either we can reach the final vertex v_r or the token t will have to wait on another vertex v_{i_2} for some token on X to move, and so on (until the end of the journey). We say that there are *conflicts*⁵ during the journey⁵.

So we can now “compress” the path as a path from v_1 to v_{i_1} , then from v_{i_1} to v_{i_2} (together with the neighborhood in X of these paths), as we explained above. However, we cannot yet claim that we have reduced the instance sufficiently since the number of conflicts is not known to be bounded (by a function of k and/or the size of X). The main result of this section consists in proving that, if we consider a transformation from I_s to I_t that minimizes the number of moves “related” to X , then (almost) all the journeys have a “controllable” amount of (so-called important) conflicts. Actually, we prove that, in most of the connected components H of $G - X$, we can assume that we have a “controllable” number of important conflicts for every journey on H in a transformation that minimizes the number of token modifications involving X . The idea consists in proving that, if there are too many important conflicts during a journey of a token t , we could mimic the journey of t on another component to reduce the number of token slides involving X . Finally, we will only have to prove that if all the vertices have a controllable number of conflicts (and there are too many components), then we can safely delete a connected component of $G - X$.

⁴ We assume for simplicity in this outline that the component of w does not contain tokens.

⁵ Actually, there might exist another type of conflict we do not explain in this outline for simplicity.

Journeys and conflicts. We denote a reconfiguration sequence from I_s to I_t by $\mathcal{R} = \langle I_0, I_1, \dots, I_{\ell-1}, I_\ell \rangle$. Let $X \subseteq V(G)$ and H be a component in $G - X$ such that $I_s \cap V(H) = I_t \cap V(H) = \emptyset$. All along this section, we are assuming that tokens have labels just so we can keep track of them. For every token t , let $v_i(t)$, $0 \leq i \leq \ell$, denote the vertex on which token t is at position i in the reconfiguration sequence \mathcal{R} .

Whenever a token enters H and leaves it, we say that the token makes a journey in H . Let I_i denote the first independent set in \mathcal{R} where $v_i(t) \in V(H)$ and let I_j , $i \leq j$, denote the first independent set after I_i where $v_{j+1}(t) \notin V(H)$. Then the *journey J of t in H* is the sequence $(v_i(t), \dots, v_j(t))$. The journey is a sequence of vertices (with multiplicity) from H such that consecutive vertices are either the same or connected by an edge. We associate each journey J with a walk W in H . The *walk W of t in H* is the journey of t where duplicate consecutive vertices have been removed.

We say that a token is *waiting at step i* if $v_i(t) = v_{i-1}(t)$; otherwise the token is *active*. Given a journey J and its associated walk W , we say that $w \in W$ is a *waiting vertex* if there is a step where the vertex w is a waiting vertex in the journey. Otherwise w is an *active vertex* (with respect to the reconfiguration sequence). So we can now decompose the walk W into waiting vertices and transition walks. That is, assuming the walk starts at y and ends at z , we can write $W = yP_0w_0P_1w_1 \dots w_\ell P_\ell z$, where each w_i is a waiting vertex and each P_i is a *transition walk* (consisting of the walk of active vertices between two consecutive waiting vertices). Note that the transition walks could be empty.

We are interested in why a token t might be waiting at some vertex w . In fact, we will only care about waiting vertices that we will call important waiting vertices. Let w_1, \dots, w_ℓ be the waiting vertices of the journey and, for every $i \leq \ell$, let us denote by $[s_i, s'_i]$ the time interval of the reconfiguration sequence where the token t is staying on the vertex w_i . Note that $s_i < s'_i$ and when t is active the other tokens are not moving; thus the position of any token different from t is the same all along the interval $[s'_i + 1, s_{i+1}]$ for every $i \leq \ell - 1$.

Let $i < j \leq \ell$ and let w_i be a waiting vertex. We say that w_j is the *important waiting vertex after w_i* if $j > i$ and j is the largest integer such that no vertex along the walk of token t between w_i (included) and w_j (included) is adjacent to a token $t' \neq t$ or contains a token $t' \neq t$ between steps s'_i and s_j (note that the important waiting vertex after w_i might be the last vertex of the sequence). Since token t is active from $s'_i + 1$ to s_{i+1} and is moving from w_i to w_{i+1} during that interval, the important waiting vertex after w_i is well-defined and is at least w_{i+1} . Let $Q_{i,j}$ denote the walk in H that the token t follows to go from w_i to w_j (both w_i and w_j are included in $Q_{i,j}$). In other words, $Q_{i,j} = w_i P_{i+1} w_{i+1} \dots P_j w_j$. Now, note that since w_j is the important waiting vertex after w_i (i.e. we cannot replace w_j by w_{j+1}), then we claim that the following holds:

- ▷ **Claim 3.1.** If w_j is not the last vertex of the walk W , either
- (i) there is a token on or adjacent to a vertex of $P_{j+1} w_{j+1}$ (the transition walk after w_j) at some step in $[s'_i, s'_j]$ or,
 - (ii) there is a token on or adjacent to a vertex of $Q_{i,j} - w_j$ in the interval $[s_j, s_{j+1}]$.

We now define the notion of conflicts. Since we cannot replace w_j by w_{j+1} , it means that, by definition, there is at least one step s_q in $[s'_i, s_{j+1}]$ where a token $t_q \neq t$ is adjacent to (or on a vertex) v_q of $Q_{i,j+1}$. We call such a step a *conflict*. We say that (s_q, v_q, t_q) is the *conflict triplet* associated to the conflict (we will mostly refer to a triplet as a conflict).

The conflicts of type (i) are called *right conflicts* and the conflicts of type (ii) are called *left conflicts*. It might be possible that w_j is the important waiting vertex because we have (several) left and right conflicts. We say that w_j is a *left important vertex* if there is at least one left conflict and a *right important vertex* otherwise.

If w_j is a left important vertex, we let the *important conflict* (s_*, v_*, t_*) denote the first conflict associated with $Q_{i,j}$ between steps s_j and s'_j , i.e., there exists no s such that $s_j \leq s < s_* \leq s'_j$ such that there is a conflict at step s with a token $t' \neq t$ which is either on $Q_{i,j}$ or incident to $Q_{i,j}$. Note that v_* cannot be a vertex of $Q_{i,j}$ since that would imply at least one more conflict before s_* , hence $v_* \in N(V(Q_{i,j}))$. If w_j is a right important vertex, we let (s_*, v_*, t_*) denote the *important conflict* associated with $P_{j+1}w_{j+1}$ between steps s'_i and s'_j as the last conflict associated to $P_{j+1}w_{j+1}$, i.e., there exists no s such that $s'_i \leq s_* < s \leq s'_j$ and there is a conflict (s, v_s, t_s) such that v_s in $P_{j+1}w_{j+1}$ or incident to $P_{j+1}w_{j+1}$. Note that v_* cannot be a vertex of $P_{j+1}w_{j+1}$ since that would imply at least one more conflict after s_* , hence $v_* \in N(V(P_{j+1}w_{j+1}))$. We use $\mathcal{C}(Q_{i,j+1})[s'_i, s'_j]$ to denote all conflict triplets (left and right conflicts) associated with $Q_{i,j+1}$ between steps s'_i and s'_j .

To conclude this section, let us remark that the conflicts might be due to vertices of H or vertices of X . In other words, for a conflict triple $(s, v, t) \in \mathcal{C}(Q_{i,j+1})[s'_i, s'_j]$, v is an H -conflict or an X -conflict depending on whether v is in H or in X . In what follows we will only be interested in X -conflicts. The *X-important waiting vertex after w_i* is w_j where $j > i$ is the smallest integer such that $\mathcal{C}(Q_{i,j+1})[s'_i, s'_j]$ contains at least one triplet (s, v, t') where $t' \neq t$, $v \in X$, and $s'_i \leq s \leq s'_j$. Now given a journey we can define the sequence of X -important waiting vertices as the sequence w'_1, \dots, w'_r starting with vertex w_1 and such that w'_{j+1} is the X -important waiting vertex after w_j . What will be important in the rest of the section is the length r of this sequence. If this sequence is short (bounded by $f(k)$), then we can check if we can simulate a similar journey in other components efficiently. If the sequence is long, we will see that it implies that we can find a “better” transformation.

Since we will mostly be interested in how a journey interacts with X , we introduce the notion of the X -walk associated with journey J . The X -walk is written as $W^X = yP_0w_0P_1w_1 \dots w_\ell P_\ell z$, where each w is an X -important waiting vertex and each P is the walk that the token takes (this walk could have non-important waiting vertices) before reaching the next X -important waiting vertex. We call each P in an X -walk an *X-transition walk*.

Types and signatures. Let X be a subset of vertices and H be a component of $G - X$. An ℓ -type is defined as a sequence $IY_1W_1Y_2W_2 \dots Y_\ell W_\ell Y_{\ell+1}F$ such that for every i , W_i is a (possibly empty) subset of X and Y_i is a (possibly empty) subset of X or a special value \perp (the meaning of \perp will become clear later on). We call I the *initial value* and F the *final value* and they are both non-empty subsets of vertices of X . The 0-type is defined as IY_0F and we allow I to be equal to F . We will often represent an ℓ -type by $(I(Y_iW_i)_{i \leq \ell} Y_{\ell+1}F)$. Note that if X is bounded, then the number of ℓ -types is bounded. More precisely, we have:

► **Remark 3.2.** The number of ℓ -types is at most $(2^{|X|} + 1)^{2(\ell+2)}$.

The neighborhood of a set of vertices $S \subseteq V(H)$ in X is called the *X-trace* of S . A journey J is *compatible* with an ℓ -type $IY_1W_1Y_2W_2 \dots Y_\ell W_\ell Y_{\ell+1}F$ if it is possible to partition the X -walk W of J into $W^X = yP_0w_0P_1w_1 \dots P_\ell w_\ell P_{\ell+1}z$ such that:

- the X -trace of each vertex w_i is W_i ,
- for every walk P_i which is not empty, the X -trace of P_i is Y_i , i.e., $\cup_{x \in P_i} N(x) \cap X = Y_i$ (note that we can have $Y_i = \emptyset$),
- for every empty walk P_i , we have $Y_i = \perp$, and
- the X -trace of y is I and the X -trace of z is F .

The ℓ -signature of a vertex $v \in V(H)$ (with respect to X) is the set of all ℓ' -types with $\ell' \leq \ell$ that can be *simulated* by v in H . That is, for every ℓ -type, there exists a walk W starting at v such that $W = vP_0w_0P_1w_1 \dots P_\ell w_\ell P_{\ell+1}z$ is compatible with the ℓ -type if and only if the ℓ -type is in the signature. Two vertices are *ℓ -equivalent* if their ℓ -signatures are the same.

► **Lemma 3.3.** *One can compute in $O^*((2^{|X|} + 1)^{2(\ell+2)})$ the ℓ -signature of a vertex v in H .*

X-reduced sequences and equivalent journeys. Let J be a journey with exactly r X -important waiting vertices (in its X -walk). Let w_i and P_i be respectively the i -th X -important waiting vertex and the i -th X -transition walk. Let P_{r+1} be the final X -transition walk. Let us denote by W_i the neighborhoods of w_i in X , and by Y_i the neighborhood of P_i in X . Let I and F be the neighborhoods of the initial and final vertices of the walk associated with J , respectively. The *type* T of the journey J is $I(Y_i W_i)_{i \leq r} Y_{r+1} F$.

► **Definition 3.4.** *Two journeys are X -equivalent whenever the following holds:*

- *They have the same number of X -important waiting vertices;*
- *The initial and final vertex of the X -walk have the same X -trace;*
- *For every i , the X -trace of the i th X -important waiting vertex is the same in both journeys;*
- *For every i , the X -trace of the i th X -transition walk is the same in both journeys.*

Let I, J be two independent sets and X be a subset of vertices of G . A slide of a token *is related to* X if the token is moving from or to a vertex in X (possibly from some other vertex in X). We call such a move an X -move.

► **Definition 3.5.** *A transformation \mathcal{R} from I to J is X -reduced if the number of X -moves is minimized and, among the transformations that minimize the number of X -moves, \mathcal{R} minimizes the total number of moves.*

The multi-component reduction. Let H be a connected component of $G - X$. The ℓ -signature of H is the union of the ℓ -signatures of the vertices in H . Let \mathcal{H} be a subset of connected components of $G - X$. We say that $H \in \mathcal{H}$ is ℓ -dangerous for \mathcal{H} if there is a ℓ -type in the ℓ -signature of H that appears in at most ℓ connected components of \mathcal{H} . Otherwise we say that H is ℓ -safe. If there are no ℓ -dangerous components, we say that \mathcal{H} is ℓ -safe. One can easily prove the following using iterated extractions:

► **Lemma 3.6.** *Let $\ell = 5|X|k$. If there are more than $\ell(2^{|X|} + 1)^{2(\ell+2)} + 2k + 1$ components in $G - X$, then there exists a collection of at least $2k + 1$ components that are ℓ -safe which can be found in $f(k, |X|) \cdot n^{O(1)}$ -time, for some computable function f .*

We can now prove the main result of this section:

► **Lemma 3.7.** *Let I_s, I_t be two independent sets and X be a subset of $V(G)$. Let \mathcal{R} be an X -reduced transformation from I_s to I_t . Assume that there exists a subset \mathcal{H} of at least $2k + 1$ connected components of $G - X$ that is $(5|X|k)$ -safe. Then, for every $C \in \mathcal{H}$, any journey on the component C has at most $5|X|k - 1$ X -important waiting vertices in its X -walk.*

Sketch of the proof. Assume for a contradiction that there exists a safe component $C \in \mathcal{H}$ and a journey J of some token t in C that has at least $5|X|k$ X -important waiting vertices. Amongst all such journeys, select the one that reaches first its $(5|X|k)$ -th X -important waiting vertex. Let us denote by $I(Y_i W_i)_{i \leq 5k} Y_{5k+1}$ the type of the journey J that we truncate after Y_{5k+1} . And, let us denote by $v(P_i w_i)_{i \leq 5k} P_{5k+1}$ the partition of the walk into X -important waiting vertices and X -transition walks (we assume the walk starts at vertex $v \in V(C)$).

For each X -important waiting vertex w_i , let (q_i, x_i, t_i) be the important conflict associated to it. Since there are at most k labels of tokens and $|X|$ vertices in X , there exists a vertex $x \in X$ and a token with label t' such that there exists at least 5 waiting vertices such that the important conflict is of the form (q, x, t') for some q . In other words, there exists

15:12 Galactic Token Sliding

P_{i_1}, \dots, P_{i_5} such that for each P_i we have a triplet (q, x, t') (recall that q denotes the step in the reconfiguration sequence). Let us denote by s_1, \dots, s_5 the steps of those conflicts whose token label is t' and whose vertex in X is x and such that these conflicts are important conflict triples in five different X -transition walks.

The rest of the proof consists in proving that, rather than making the initial transformation, we can project t' on an appropriately chosen component C' of \mathcal{H} distinct from C and mimic the journey of t between steps s_1 and s_5 . In other words, t' can simply follow a journey on C' of the same type as that of t between s_1 and s_5 and we can then safely project it back on x at step s_5 without creating any X -conflicts. This implies that we can strictly reduce the number of X -conflicts, a contradiction to the assumption that the transformation is X -reduced. We also manage H -conflicts by using the minimality of the journey. ◀

► **Lemma 3.8.** *Let I_s, I_t be two independent sets and X be a subset of $V(G)$. If $G - X$ contains at least $4k + 2$ $(5|X|k)$ -safe components, then we can delete one of those components, say C , such that there is a transformation from I_s to I_t in G if and only if there is a transformation in $G - V(C)$.*

Sketch of the proof. The proof consists in proving that, since all the journeys have at most $5|X|k - 1$ X -important waiting vertices by Lemma 3.7, one can replace a journey in a safe component by a journey in another component either by not creating any conflicts or by creating some conflicts on shorter “time periods” which ensures the procedure converges. ◀

► **Corollary 3.9.** *Given a cutset X , we can assume that $G - X$ has at most $5|X|k(2^{|X|} + 1)^{2(5|X|k+2)} + 4k + 2 = 2^{O(|X|^2k)}$ connected components. Moreover, when the number of components is larger we can find a component to delete in $f(k, |X|) \cdot n^{O(1)}$ -time.*

4 Applications

Due to space restriction we only very briefly explain the main steps of the proofs.

Planar graphs. First note that, using galactic reconfiguration, we can reduce the diameter of the graph to $O(k^2)$ by Corollary 2.3. The core of the proof then consists in reducing high degree vertices. If the degree is bounded by a function of k , then the conclusion will follow from Theorem 2.4. To reduce the degree, we prove that, for every pair x, y of large degree vertices, 1) $V(G) \setminus \{x, y\}$ does not contain too many components by Corollary 3.9 (Rule R6), 2) the graph can be reduced if there are not too many internally vertex-disjoint paths from x to y and, 3) the graph can be reduced if it contains a few other slightly more general structures. All these results together permit to ensure that G does not contain any large degree vertices after applying all the rules, which completes the proof.

Chordal graphs of bounded clique number. A *chordal graph* is a graph with no induced cycle of length at least four. Equivalently, it also has a clique-tree (see full version [3] for formal definitions). If a node v of the clique-tree has large degree then $V(G) \setminus B_v$ (where B_v denotes the bag of v) has many connected components, and one of them can be removed by Corollary 3.9. So we can assume that the degree of the clique-tree is bounded. Thus, if the graph is large, the clique-tree should contain a long path P . If no vertex belongs to a large fraction of the bags of P , then the diameter is large and we can reduce the graph by Corollary 2.3. So a vertex belongs to a large fraction of the bags of P . We can actually prove that, there exists a sub-path P' of P and $X \subseteq V(G)$ such that X belongs to all the bags of P' and no other vertex appears in a significant fraction of the bags of P' . Together with a few other properties, we prove that some vertices in the bags of P' can be deleted without modifying the existence of a reconfiguration sequence from I_s to I_t .

Abstract

Cache-adaptive algorithms are a class of algorithms that achieve optimal utilization of dynamically changing memory. These memory fluctuations are the norm in today’s multi-threaded shared-memory machines and time-sharing caches.

Bender et al. [8] proved that many cache-oblivious algorithms are optimally cache-adaptive, but that some cache-oblivious algorithms can be relatively far from optimally cache-adaptive on worst-case memory fluctuations. This worst-case gap between cache obliviousness and cache adaptivity depends on a highly-structured, adversarial memory profile. Existing cache-adaptive analysis does not predict the relative performance of cache-oblivious and cache-adaptive algorithms on non-adversarial profiles. Does the worst-case gap appear in practice, or is it an artifact of an unrealistically powerful adversary?

This paper sheds light on the question of whether cache-oblivious algorithms can effectively adapt to realistically fluctuating memory sizes; the paper focuses on matrix multiplication and sorting. The two matrix-multiplication algorithms in this paper are canonical examples of “ (a, b, c) -regular” cache-oblivious algorithms, which underlie much of the existing theory on cache-adaptivity. Both algorithms have the same asymptotic I/O performance when the memory size remains fixed, but one is optimally cache-adaptive, and the other is not. In our experiments, we generate both adversarial and non-adversarial memory workloads. The performance gap between the algorithms for matrix multiplication grows with problem size (up to $3.8\times$) on the adversarial profiles, but the gap does not grow with problem size (stays at $2\times$) on non-adversarial profiles. The sorting algorithms in this paper are not “ (a, b, c) -regular,” but they have been well-studied in the classical external-memory model when the memory size does not fluctuate. The relative performance of a non-oblivious (cache-aware) sorting algorithm degrades with the problem size: it incurs up to $6\times$ the number of disk I/Os compared to an oblivious adaptive algorithm on both adversarial and non-adversarial profiles.

To summarize, in all our experiments, the cache-oblivious matrix-multiplication and sorting algorithms that we tested empirically adapt well to memory fluctuations. We conjecture that cache-obliviousness will empirically help achieve adaptivity for other problems with similar structures.

1 Introduction

Applications running on multi-threaded and multi-core systems often experience fluctuations in the amount of physical memory available. For example, when concurrently running programs share RAM, the amount of RAM allocated to any particular program can change as other programs start or finish. Interestingly, even when identical copies of the same program run concurrently, these copies may acquire an unequal fraction of the RAM [20], resulting in further unpredictability.

These memory fluctuations can cause an application's performance to suffer [24, 26]. If the available memory becomes scarce, an application may **thrash**, which means that the application pages excessively, crippling performance [18, 19, 28]. If memory becomes abundant, the program may not take advantage of the larger available RAM and thus perform extraneous I/Os.

In this paper, we empirically show that some optimal cache-oblivious algorithms [21, 22, 31] – specifically matrix multiplication and sorting – adapt gracefully to most memory fluctuations, except for some adversarially constructed worst-case instances. Optimal **cache-oblivious** algorithms are asymptotically optimal for all fixed memory sizes without the knowledge of the memory size. Past theoretical work shows that optimal cache-oblivious algorithms can perform poorly on adversarially constructed memory fluctuations [7, 8].

Experimental approaches to adaptivity. Past experimental work [29, 30, 34, 35] focused on developing improved algorithms that adapt to a variety of memory profiles, where a **memory profile** is a curve representing the memory size as a function of time. For example, Pang et al. [29] introduced a memory-adaptive merge sort that dynamically adjusts the size of each subproblem at each level of the recursion as memory fluctuates. A similar technique is used by Pang et al. [30] to modify the GRACE hash join algorithm [23] so that it can adapt to changes in memory size. Zhang and Larson [34, 35] introduced techniques that balance the memory usage among many sorting programs running concurrently on a single machine sharing its memory.

Researchers have also explored environment-level modifications to adapt to dynamic memory profiles. For example, Brown et al. [12] introduced memory-management techniques for a DBMS that accommodate multiple concurrently running database workloads, where each workload may have its own individual memory requirements. Mills et al. [24–26] proposed a user interface that enables a user to request sufficient memory for their application.

Theoretical approaches to adaptivity. Barve and Vitter [2, 3] designed algorithms that have provable performance guarantees even when the memory size changes. They gave memory-adaptive algorithms for sorting, matrix multiplication, FFT, LU decomposition,

and permutation. To prove optimality, they extended the traditional **external-memory model** [1] – also called the **disk-access machine (DAM)** – to allow for changes in the memory size over time.

More recently, Bender et al. [8] showed that many cache-oblivious algorithms could adapt well to memory fluctuations. A **cache-oblivious algorithm** is a platform-independent algorithm that is not parameterized by properties of the memory hierarchy such as RAM or cache-line size [21, 22, 31]. An optimal cache-oblivious algorithm is universal in the sense that the algorithm is optimal for any value of the cache parameters, provided that these values do not change over time. (Past theoretical work on cache-oblivious algorithms use the terms memory, cache, and RAM interchangeably) [4, 5]. On the other hand, a cache-adaptive algorithm remains cache-optimal even when memory size changes over time. One possible way to deal with memory fluctuations is to start with an algorithm already known to be cache-oblivious and hope it also happens to be cache adaptive.

Cache-obliviousness and cache-adaptivity. Bender et al. [8] showed that cache-oblivious algorithms are often (but not always) cache adaptive. For example, they showed that Lazy Funnel Sort (LFS) [10, 21], a cache-oblivious sorting algorithm, is optimally cache-adaptive. Follow-up work [7] provided an analytical framework for determining whether cache-oblivious algorithms having a certain recursive form (“ (a, b, c) -regular”) are also cache adaptive. Algorithms with (a, b, c) -regular recursive structure have a common form of divide-and-conquer cache-oblivious design [6, 7]; see Section 2 for more details. Depending on the settings of the parameters a , b , and c , these cache-oblivious algorithms are either asymptotically optimal or a logarithmic factor away from optimal. For example, cache-oblivious algorithms exist for matrix multiplication [21, 22], some of which are optimally cache-adaptive (MM-INPLACE) and some are a log factor away from optimally cache-adaptive (MM-SCAN) [7, 8]. MM-SCAN ($a = 8$, $b = 4$, and $c = 1$) performs an out-of-place matrix addition at the end of each recursive call and is suboptimal in the cache-adaptive model, while MM-INPLACE ($a = 8$, $b = 4$, and $c < 1$) performs the additions in-place and is optimally cache-adaptive; see Section 3.

Connections between experimental and theoretical approaches. Existing theoretical approaches to cache adaptivity provide worst-case guarantees but leave open the question of how algorithms perform under arbitrary memory workloads. Specifically, past work showed that cache-oblivious (a, b, c) -regular algorithms are always at most a log factor away from being optimally cache-adaptive. However, this log factor is based on a worst-case memory workload that seems brittle and unlikely to appear in practice. Furthermore, this worst-case analysis does not capture how cache-oblivious algorithms actually perform under practical memory workloads.

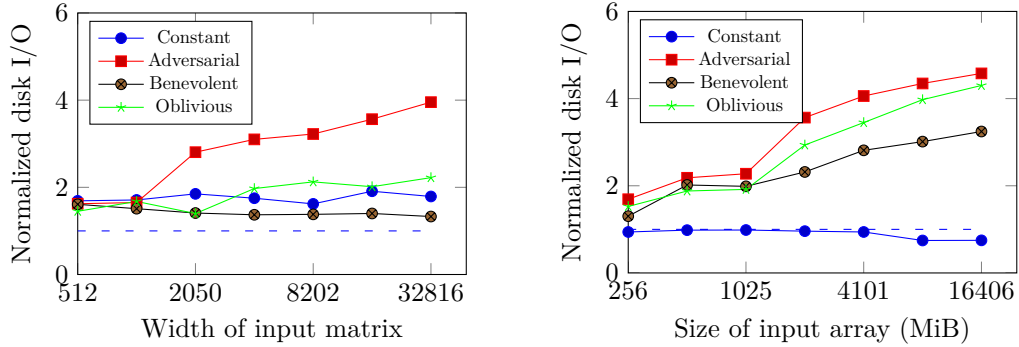

In contrast, empirical solutions [12, 23–26, 29, 30, 34, 35] are designed to improve performance under practical memory workloads. However, they lack worst-case analysis and therefore do not have worst-case performance guarantees.

Recent work [6] has gone beyond worst-case analysis. The authors apply smoothing techniques [32] on memory profiles and explore how well cache-oblivious algorithms adapt to smoothed memory profiles. They observe that the I/O-performance gap between cache-obliviousness and cache-adaptivity disappears given sufficient smoothing. Their results leave open the question of whether the performance gap between cache-oblivious and cache-adaptive algorithms persists across a larger space of memory profiles. If the performance gap turns out to be only a theoretical artifact rarely seen in practice, cache-oblivious algorithms

16:4 When Are Cache-Oblivious Algorithms Cache Adaptive?

could be an exciting way to solve a wide range of problems with no known cache-adaptive solutions. Examples of such problems include Gaussian elimination [15], triangle counting [9], min-weight cycle [33], negative triangle detection and counting [33], replacement paths problem [33], etc.

Do these worst-case memory workloads arise naturally when no adversary controls the available memory? How feasible is it to construct such worst-case memory profiles?

(a) Normalized I/O of MM-SCAN to MM-INPLACE.

(b) Normalized I/O of EMS to LFS.

■ **Figure 1** Normalized disk I/O of the non-adaptive algorithm to the cache-adaptive algorithm as a function of input size for matrix multiplication and sorting for four memory profiles: adversarial (worst-case), benevolent, constant, and oblivious. An increase in the y-axis means that the non-adaptive algorithm performs progressively worse relative to the adaptive algorithm.

Results

We empirically study how cubic-time matrix multiplication (MM) algorithms and external-memory sorting algorithms adapt to a range of different memory profiles. MM is a particularly interesting test case because not only is it the canonical example of an (a, b, c) -regular algorithm but also we can find a pair of MM algorithms, both with the same I/O-complexity in the cache-oblivious model, where one is optimally cache-adaptive and the other is a logarithmic factor away from optimal. For the case of MM, we evaluate MM-INPLACE and MM-SCAN and find that both can adapt to a wide range of memory profiles even though MM-SCAN is not provably cache-adaptive. In contrast, for the case of sorting, we evaluate LFS [10, 21] and External-memory Merge Sort (EMS) [1], a non-oblivious and non-adaptive algorithm, and find that EMS does not adapt well to a wide range of memory fluctuations. Table 1 illustrates some of the key properties of the tested algorithms.

Since the worst-case profile is tightly coupled with an algorithm’s structure, we designed a **memory profile generator** that can simulate an adversarial by looking into a program’s execution. It can generate the worst-case **adversarial memory profile** by increasing the available memory when the program cannot benefit from the extra memory and decreasing the memory when the program would benefit. It can also generate non-adversarial profiles that follow a program’s execution.

First, we empirically study the MM-SCAN and MM-INPLACE algorithms for matrix multiplication, and we find that even though MM-SCAN is not optimally cache-adaptive, it adapts well to a wide range of memory fluctuations except the most adversarially constructed profiles. We measure how well an algorithm adapts to the memory fluctuations by measuring

■ **Table 1** Properties of the algorithms for cubic-time matrix multiplication and external-memory sorting studied in this paper.

<i>Algorithm</i>	<i>Cache-oblivious</i>	<i>Cache-adaptive</i>
MM-SCAN [21, 22]	✓	✗
MM-INPLACE [21, 22]	✓	✓
EM Merge Sort [1]	✗	✗
Lazy Funnel Sort [10]	✓	✓

the disk I/Os it incurs during its execution. MM-SCAN and MM-INPLACE are both theoretically optimal when the memory does not fluctuate; empirically, Figure 1a shows that MM-INPLACE performs roughly $1.8\times$ better than MM-SCAN across all problem sizes under a **constant memory profile** (fixed memory size). We used the memory profile generator to create profiles coupled with algorithm execution. Under the adversarial memory workload, MM-SCAN performs $1.6 - 3.8\times$ more disk I/Os than MM-INPLACE. Critically, the performance gap grows with the input size. We also created a **benevolent memory profile** that is tightly synchronized with the algorithm’s execution but non-adversarial in nature. Under the benevolent memory profile, MM-SCAN and MM-INPLACE perform roughly within $1.5\times$ of each other for all problem sizes. Under **oblivious memory profiles**, i.e., profiles that are not tightly coupled with the algorithms’ execution, we found that MM-SCAN incurs about $1.8\times$ more I/Os than MM-INPLACE for all problem sizes. These results suggest that MM-SCAN possesses almost all the benefits of cache-adaptivity.

Next, we evaluate the cache-oblivious Lazy Funnel Sort (LFS) [10, 21] and the non-oblivious External-memory Merge Sort (EMS) [1] (both are I/O-optimal when the memory is fixed), and we find that even though LFS has a computational overhead over EMS stemming from its cache-obliviousness; it outperforms EMS on a wide range of fluctuating memory profiles. Figure 1b suggests that External-memory Merge Sort has better I/O-performance than Lazy Funnel Sort for all problem sizes under the constant memory profile (roughly incurring $0.9\times$ disk I/Os on average). On the other hand, LFS adapts when the memory fluctuates, whereas EMS fails to adapt. EMS performs progressively worse than LFS as the input size increases under all types of fluctuating memory workloads (adversarial, benevolent, and oblivious), incurring $1.3 - 7\times$ more disk I/Os. Despite the computational overhead of cache-obliviousness, LFS performs significantly better than EMS under a range of fluctuating memory profiles.

These results suggest that for the problems of MM and sorting, cache-oblivious but non-adaptive algorithms adapt well, while non-oblivious algorithms do not. The tested cache-oblivious algorithms adapt well because they are agnostic to the cache size, while the cache-aware algorithms are optimized for specific cache sizes. We conjecture that cache-oblivious algorithms have most of the empirical benefits of cache adaptivity, and our results are consistent with the conjecture.

Paper overview. The rest of this paper is organized as follows. Section 2 reviews preliminaries about the cache-adaptive model and analysis necessary to understand the experimental design in this paper. Section 3 explains the memory profiles that we tested on. Section 4 describes the experimental setup and the algorithms’ performance with fixed memory. Section 5 describes the memory-profile generator and the algorithms’ performance under adaptively constructed memory profiles. Section 6 explores the algorithms’ performance under obliviously constructed memory profiles. Section 7 provides concluding remarks and future directions.

2 Cache-adaptive analysis

This section reviews fundamentals of cache-adaptive and cache-oblivious analysis. It also explains how (a, b, c) -regular algorithms play a key role in the analysis.

Cache-adaptive model. The cache-adaptive model is an extension of the disk-access machine (DAM) model [1], where the size of memory available to an algorithm can change. In the DAM model, the machine has a two-level memory hierarchy comprising a cache/memory of size M and a disk of unbounded size. Data is transferred between disk and memory in blocks of size B , called I/Os. The cache-adaptive model extends the traditional DAM model by allowing the memory size to be a function of time. Each I/O takes one time step and computation is modeled as free and instantaneous. At time t , the memory available to a program is $M(t)$, which can change after each time step.

Cache-oblivious algorithms and (a, b, c) -regularity. An algorithm is cache-oblivious [21, 22, 31] if it is not parameterized by M and B . An optimal cache-oblivious algorithm is universal, in the sense that it runs optimally in the DAM model for all possible (fixed) values of M and B .

Cache-oblivious algorithms with a particular kind of divide-and-conquer structure, are said to be (a, b, c) -**regular**. An algorithm is (a, b, c) -regular for constants $a \geq 1$, $b > 1$, and $0 \leq c \leq 1$, if, for problem size N , its I/O complexity satisfies the following recurrence: $Q(N) = a \cdot Q(N/b) + \Theta(1 + N^c/B)$.

Specifically, the algorithm has a recursive calls on sub-problems of size N/b and $\Theta(1)$ **linear/sequential scans** before, between, or after the recursive calls, where the size of the largest scan is $\Theta(N^c)$.

The worst-case performance gap between obliviousness and adaptivity. DAM-optimal (a, b, c) -regular algorithms can be up to an $O(\log N)$ -factor away from being optimally cache-adaptive [7]. Specifically, they are suboptimal in the cache-adaptive model when $a \geq b$ and $c \geq 1$ [7]. Intuitively, (a, b, c) -regular algorithms are not optimal when they contain large sequential reads through memory at each level of the recursion.

The worst-case memory profile. The logarithmic gap in I/O-performance of some (a, b, c) -regular algorithms from being optimally cache-adaptive is based on a worst-case memory workload that adaptively mimics the recursive structure of the algorithm and is tightly synchronized with the execution of the algorithm. Specifically, the worst-case profile provides extra memory to the non-adaptive algorithm during the linear scans (when it cannot benefit from the extra memory) and takes away the extra memory at the end of the linear scans (when it would be able to use the extra memory). The worst-case memory profile is constructed in an adaptive manner by following the execution of the non-adaptive algorithm, MM-SCAN in case of matrix multiplication and EMS in case of sorting.

Example: MM-SCAN and MM-INPLACE. To illustrate the parameter choices for (a, b, c) -regular algorithms, Bender et al. [7] compare two cache-oblivious cubic matrix multiplication algorithms: MM-SCAN and MM-INPLACE [16, 21, 22, 31], and show that only MM-INPLACE is optimally cache adaptive, whereas MM-SCAN is a logarithmic-factor away from being optimally cache adaptive. MM-SCAN divides each input matrix into $b = 4$ blocks and perform $a = 8$ recursive multiplications on the blocks. It uses extra space to store an

intermediate matrix and performs all additions at once with a linear scan. The recurrence relation of MM-SCAN for problem size N (to multiply two matrices of size $\sqrt{N} \times \sqrt{N}$) is $Q(N) = 8Q(N/4) + O(1 + N/B)$. Hence, MM-SCAN has $c = 1$. MM-INPLACE has the same recursive structure, but it avoids the linear scan by performing the multiplications and additions in-place. The recurrence for MM-INPLACE has the same a and b as MM-SCAN, but has $c = 0$: $Q(N) = 8Q(N/4) + O(1)$. Both MM-SCAN and MM-INPLACE are optimal cache-oblivious algorithms, having an I/O cost of $O(N^{3/2}/(\sqrt{M}B))$.

In contrast, MM-INPLACE (with $c < 1$) is optimally cache-adaptive while MM-SCAN (with $c = 1$) is not. This example of MM-SCAN and MM-INPLACE exemplifies how changing the values of a , b , and c can determine whether a cache-oblivious algorithm is optimally cache adaptive or not. Here, the answer depends on whether $c < 1$ or $c = 1$.

From the above discussion, MM-SCAN may seem to be a strictly worse algorithm than MM-INPLACE because MM-SCAN is provably not cache adaptive. However, MM-SCAN is more parallelizable than MM-INPLACE [16] as it can achieve 8-way parallelism whereas MM-INPLACE can only achieve 4-way parallelism.

Example: EMS and LFS. Finally, we will review the gap between cache-adaptive and non-adaptive sorting algorithms to see an example of cache-adaptive analysis outside of (a, b, c) -regular algorithms. Both EMS and LFS achieve the disk I/O complexity, $O((N/B) \log_{M/B}(N/B))$ in the external-memory model [1], which is the lower bound for sorting when the cache-parameters remain fixed. However, EMS is not cache-adaptive [7] as it has large linear scans involved and any reduction of memory from the promised amount M during these phases affects the performance of the algorithm heavily. On the other hand, despite not having the same recursive structure as that of the (a, b, c) -regular algorithms, LFS [10, 21] is provably cache-adaptive [8]).

3 Memory profile design

This section presents the high-level design of our evaluation of cache-adaptive and non-adaptive algorithms on a variety of memory profiles for matrix multiplication and external-memory sorting. We test on adaptively constructed memory profiles (e.g. the worst-case profile) as well as “oblivious” memory profiles that are erratic but not adaptively constructed. To perform this evaluation, this study uses a memory profile that does not fluctuate with respect to time. We refer to this as the **constant memory profile** and we use it as a baseline in our experiments.

It is theoretically shown that under **adaptively constructed** worst-case memory workload the performance of two DAM-optimal algorithm diverges. Between two (a, b, c) -regular algorithms, MM-INPLACE is cache adaptive and MM-SCAN is non-adaptive as it is log-factor away from being optimally cache adaptive under this worst-case memory profile. We construct this worst-case **adversarial memory profile** by adapting to the execution of the non-adaptive algorithm and allowing it enough memory to store each recursive sub-problem during its linear scan, and low memory when the algorithm is not performing a linear scan. Since linear scans do not employ any locality of reference, the algorithm only requires $O(1)$ memory; any memory given more than that is not utilized during linear scan. For example, MM-SCAN contains a linear scan at the end of each recursion; in each linear scan of size $N \times N$, memory is increased to $5N^2$ to hold the input and output matrices as well as the intermediate results. However, the cache-adaptive algorithm opportunistically benefits from

16:8 When Are Cache-Oblivious Algorithms Cache Adaptive?

■ **Figure 2** Sample adversarial memory profile generated from running MM-SCAN to multiply two square matrices of width **8192**. The structure of the memory profile mimics the recursive structure of MM-SCAN.

these memory increases, causing its I/O-performance to improve considerably relative to that of the non-adaptive algorithm. Figure 2 shows a sample adversarial memory profile for matrix multiplication.

Similarly, we construct another category of adaptive memory profiles, i.e., the **benevolent memory profile**, but these are designed to be benevolent to the non-adaptive algorithm. The non-adaptive algorithms are unable to use any extra memory that adversarial memory provides during the recursive sequential scans. In the case of the benevolent memory profile, during the sequential scans, instead of increasing the memory we adaptively decrease memory. When the linear scan ends, the memory is again increased to the initial value.

Both the adversarial and benevolent memory profiles are tightly synchronized with the execution of the non-adaptive algorithm. In fact, the adversarial memory profile mimics the recursive structure of the non-adaptive algorithm to bring out the worst performance relative to the adaptive algorithm. In contrast, the benevolent profile aims to minimize the advantage of the cache-adaptive algorithm over the non-adaptive algorithm. However, adversarial and benevolent memory profiles might be too pessimistic or too optimistic in terms of the relative performance of the non-adaptive algorithm and rarely found in the real-world applications. The beyond-worst-case analysis [6] shows the performance gap between MM-SCAN and MM-INPLACE disappears with sufficient smoothing on the worst-case profile, otherwise, the performance gap remains even under smoothed memory profiles. Hence the question remains, how do the non-adaptive algorithms perform under a range of memory profiles that are not generated in an adaptive manner (i.e. the profiles which do not adapt to the execution of the algorithm)?

To gain a more complete view of algorithm performance under memory fluctuations, we run algorithms under **oblivious memory profiles** that are generated non-synthetically and non-adaptively. These profiles are created independently of a given algorithm's execution. A sample oblivious profile can be obtained by running several programs concurrently in shared memory without limiting any of their memory usages [13, 14]. An evaluation under such oblivious workloads accounts for the fact that in practice, often a running process is forced to share available RAM with other concurrent memory-intensive programs. Hence, these oblivious profiles enable us to observe a more complete view of an algorithm's performance under memory fluctuations in a multi-program environment.

4 Evaluation on constant profiles

This section presents details of the experimental setup and studies the performance of the matrix multiplication and external-memory sorting algorithms described in Section 3 on constant memory profiles. All of the tested algorithms are theoretically optimal when the memory does not fluctuate. The empirical results confirm the theory: the performance gap between the cache-adaptive and non-adaptive algorithms does not grow with the problem size when the memory size is fixed.

Experimental setup. All experiments were conducted on a Dell Precision 5820 with an Intel®Core™i9-9900X 3.50GHz processor, two Samsung 16GB M378A2K43DB1-CTD Dual Rank Memory Modules, and Seagate Barracuda ST2000DM001 Desktop SATA Hard Drive. The operating system used is Linux Mint 19.1, Tessa, with kernel version 4.15.0-88. We used C++14 to implement the algorithms, g++ 9.3.0-17ubuntu1 20.04 as compiler, and bash scripts to run the experiments. We measure performance in disk I/Os using `/proc`. At the start of each experiment, we use the `sync` system call to free page-cache and slab objects. We use Linux control groups (`cgroups`) to limit the memory available to a program. We run all the experiments with 25 trials and average the measured I/Os.

Algorithm implementation descriptions. We implemented the two algorithms for MM-SCAN and MM-INPLACE directly from their description in past work on cache-adaptivity [7]. Section 2 provides a detailed description of the divide-and-conquer recursion of these two algorithms.

We explored two algorithms for sorting: External-memory Merge Sort (EMS) and Lazy Funnel Sort (LFS). We implemented an (M/B) -way external-memory merge sort that is compatible with the memory profile generator and chose $M = 256$ MiB and $B = 8$ MiB. Previous work [11] on engineering external sorting algorithms demonstrate that carefully engineered cache-aware sorting algorithms can perform up to $2\times$ better than cache-oblivious ones when the memory does not fluctuate. We expect our results regarding relative algorithm performance in the face of memory fluctuations to hold for other implementations of EMS and LFS because of the difference in the algorithm structure between the two algorithms. For LFS, we used an implementation from Olsen and Skov [27].

Problem sizes. We evaluate the relative performance of MM-SCAN to MM-INPLACE on the constant memory workloads as a function of input size. For each matrix multiplication experiment, we multiply two square matrices. We increase the input matrix width from 512 to 32768. For all the experiments, we provide a fixed memory of 10 MiB to the programs.

Similarly, we study the relative performance of EMS to LFS on the constant memory workloads. For each sorting experiment, we sort an integer array. We increase the input array length from 67 million to 1 billion. We provide a fixed memory of 256 MiB to the programs.

Results. Figure 1a shows that when memory size is fixed, cache-adaptive MM-INPLACE performs roughly $1.8\times$ better than non-adaptive MM-SCAN for all input sizes, i.e., their performance gap does not grow with problem size. On the other hand, Figure 1b shows that cache-aware non-adaptive EMS incurs less disk I/Os (roughly $0.9\times$ on average) than cache-adaptive LFS. This result shows the cache-oblivious sorting algorithm does not bear a major computational overhead when the memory does not fluctuate.

5 Evaluation on adaptive profiles

This section presents details of how we generate the memory fluctuations and studies the performance of the matrix multiplication and sorting algorithms described in Section 3 on adaptively-generated memory workloads. Specifically, it first introduces the memory profile generator used to construct the adaptive profiles. Using this profile generator, we explore two types of adaptive memory profiles: the adversarial profile, and the benevolent profile. Under adversarial workloads, the cache-adaptive algorithms perform up to $4.5\times$ better than the non-adaptive algorithms with increasing problem size. On the other hand, the benevolent memory profile demonstrates that oblivious algorithms adapt well to non-adversarial memory fluctuations while non-oblivious algorithms suffer. MM-INPLACE is up to $1.5\times$ better than MM-SCAN, but the gap does not grow with the problem size. In contrast, LFS performs increasingly better (up to $3.2\times$) than EMS as the problem size grows.

Memory profile generator. We designed a **memory profile generator** that runs a program under a particular memory workload. To fluctuate the memory available to a program, we first used *cgroups*, however *cgroups* does not allow us to decrease the memory available to a program (that the program already claimed) efficiently while the program is running. To address this, the memory profile generator uses *cgroups* to set an initial memory limit available to a program and runs a *balloon* program concurrently with the program within the *cgroups*. The balloon program uses the memory complement to what we intend the program to use. For example, if we want a program to use memory M until time t and thereafter memory $M + \delta$, and the *cgroups* has memory C , the balloon program uses memory $C - M$ until time t and thereafter it uses memory $C - M - \delta$. The initial memory given to a program remains the same as for the constant memory workload.

Using this memory profile generator, we generate two types of profiles, adversarial and benevolent; see Section 3. We measure algorithm performance using the same problem sizes as in Section 4.

Results for the adversarial memory profile

First, let us turn our attention to the adversarial memory workloads. Figure 1 illustrates that under the adversarial memory workloads, the cache-adaptive algorithms perform better than the non-adaptive algorithms, and the gap increases as the problem sizes grow. MM-INPLACE performs roughly up to $4\times$ better than MM-SCAN and LFS performs roughly up to $4.5\times$ better than EMS.

Time spent in linear scan. The performance gap between the cache-adaptive and non-adaptive algorithms grows with the problem size because the relative time spent in scans by the non-adaptive algorithms (MM-SCAN and EMS) grows with problem size. Table 2 shows that the relative time spent in scans grows with problem size for both MM-SCAN (up to 13%) and EMS (up to 76%). Hence, the performance gap also increases between the adaptive and non-adaptive algorithms with problem size. Cache-adaptive algorithms do not perform any such linear scans and take advantage of the extra memory in the adversarial profile. Cache-adaptive algorithms do not perform any such linear scans and take advantage of the extra memory in the adversarial profile.

■ **Table 2** Percentage of running time that the non-adaptive algorithms spend on linear scans.

<i>Algorithm</i>	<i>Input size</i>	<i>% of runtime</i>
MM-SCAN	1024 × 1024	0.1
MM-SCAN	2048 × 2048	4.7
MM-SCAN	4096 × 4096	13.2
EM Merge Sort	512 MiB	43.6
EM Merge Sort	1 GiB	57.9
EM Merge Sort	2 GiB	76.8

Results for the benevolent memory profile

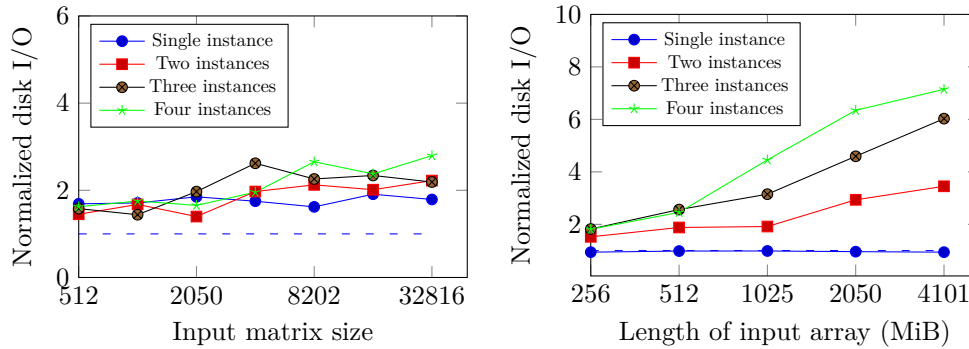

Next, let us turn our attention to the algorithms’ performance under the benevolent memory workloads. Figure 1a shows that MM-SCAN performs very close to MM-INPLACE (between $1.3 \times - 1.6 \times$) on the benevolent profiles since MM-SCAN is not affected by the memory reductions that occurred during the linear scans whereas MM-INPLACE is affected. On the other hand, Figure 1b shows that the gap between EMS and LFS grows with the problem size – EMS incurs up to $3.2 \times$ more I/Os than LFS on the largest input. EMS is unable to adapt to memory reductions during linear scans while LFS adapts to all changes in memory.

6 Evaluation on oblivious profiles

This section explains the setup for the oblivious memory workloads that are not synchronized with the recursive execution of the algorithm and shows that the I/O-performance gap between the two cache-oblivious MM algorithms disappears, but remains between the cache-oblivious and non-oblivious algorithm for sorting. Figure 1a illustrates that MM-SCAN incurs roughly $2 \times$ more disk I/Os on average than MM-INPLACE for oblivious memory profiles as we increase the input size. Figure 1b, on the other hand, shows that EMS incurs increasingly worse than LFS with problem size incurring up to $4.3 \times$ I/Os on average under oblivious memory profiles. In fact, Figure 3b shows EMS may perform up to $7 \times$ more I/Os under oblivious memory workloads.

Experimental setup. This study runs multiple memory-intensive programs concurrently, all sharing the same RAM, to ensure that each program instance experiences memory fluctuations that do not follow the recursive execution of the algorithm. We create these oblivious memory fluctuations in two ways: by creating a **uniform** environment where multiple identically-sized copies of the same program runs concurrently, and by creating a **nonuniform** environment by creating nonuniformity in the concurrent programs. Such nonuniform concurrent programs may include program instances of the same program of different problem sizes, or different programs of same problem sizes. The concurrent programs share a fixed memory that is given at the starting of the experiment. For all the MM experiments, it is 10 MiB, and for all the sorting experiments, it is 256 MiB, if not stated otherwise. We keep the rest of the experimental setup the same as in the case of constant memory profiles (see Section 4).

16:12 When Are Cache-Oblivious Algorithms Cache Adaptive?

(a) Normalized disk I/O of MM-SCAN to MM-INPLACE, instances share a memory of 10 MiB. (b) Normalized disk I/O of EMS to LFS, instances share a memory of 256 MiB.

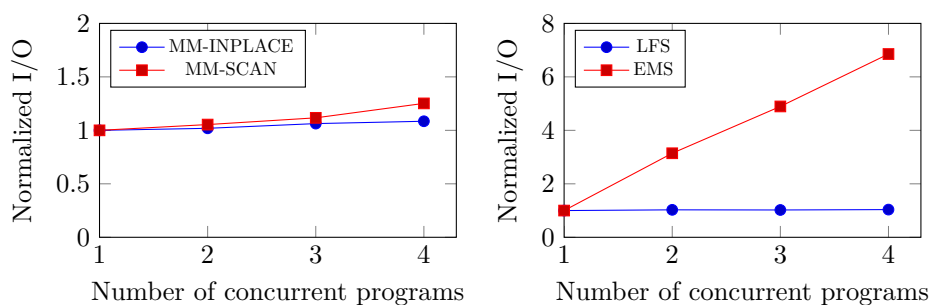

■ **Figure 3** Average disk I/O of a non-adaptive program to the cache-adaptive program as a function of problem size when running up to 4 instances concurrently normalized to the same when a single instance runs concurrently.

Running uniform instances concurrently

First, let us turn our attention to the oblivious memory workloads that are generated by running multiple concurrent instances of the same program that share a memory [13, 14]. Figure 3a illustrates that cache-oblivious non-adaptive algorithm MM-SCAN performs close to cache-adaptive MM-INPLACE and incurs roughly up to $2\times$ disk I/Os across all problem sizes. On the other hand, Figure 3b shows that the I/O-performance for the cache-aware algorithm EMS rapidly declines relative to the cache-adaptive LFS with increasing problem size ($1.4 - 7.1\times$). Dice et al. [20] showed that multiple threads in shared memory may exhibit a “winner-takes-all” phenomenon where a thread may take memory from the others. However, Figure 3 shows that even if uniformly-sized program instances unevenly share the cache, cache-oblivious algorithms adapt well to memory fluctuations.

Setup. We evaluate the average I/O-performance of the cache-adaptive and non-adaptive algorithms by running concurrent uniform instances, i.e., multiple identically-sized copies of the same program. This multi-program environment setup ensures that each program instance runs under a memory profile that is erratic due to the uncertainty stemming from the concurrent programs’ memory requirement but independent of the recursive structure of the particular program under consideration. We perform the study on uniform instances in two ways. First, we vary the input problem sizes given a number of concurrent program instances. Next, we vary the number of concurrent instances in the range of $1 - 4$ for a given problem size and observe **slowdown**, the degradation of average I/O-performance of a program instance.

Slowdown. Figure 4 illustrates that cache-oblivious algorithms incur relatively small slowdowns even as the number of concurrent instances increases. When we run up to 4 MM-SCAN instances concurrently, the average disk I/Os stays within $1.2\times$ than the disk I/Os incurred by MM-SCAN when a single concurrent instance runs. The MM-INPLACE instances also face almost no slowdown in a similar environment. In contrast, concurrent EMS instances face up to $6\times$ more disk I/Os when compared to an EMS program that does not share memory with other concurrent programs. However, LFS faces a negligible slowdown in the same scenario.

■ **Figure 4** Average normalized disk I/O of a program instance when up to four program instances run concurrently normalized to the disk I/O when a single instance runs.

(a) 3 concurrent instances of the same size. (b) 3 concurrent instances of different sizes. (c) 3 concurrent instances each of MM-SCAN and MM-INPLACE.

■ **Figure 5** Average normalized disk I/O of non-adaptive MM-SCAN to cache-adaptive MM-INPLACE as a function of problem size with 30 MiB memory given. The y-axis indicates that MM-SCAN performs within a constant factor of MM-INPLACE.

Running nonuniform instances concurrently

Next, let us turn our attention to how the algorithms perform when nonuniform program instances run concurrently and share a fixed memory. The nonuniform programs have different memory requirements at every time step, and therefore are more likely to cause more dramatic memory fluctuations compared to the uniform case. We observe that along with the cache-adaptive algorithms, cache-oblivious MM-SCAN also adapts to the fluctuations caused by nonuniform instances. MM-SCAN incurs up to $2.5\times$ more disk I/Os than MM-INPLACE even when the memory fluctuations are more dramatic in the nonuniform case than in the uniform case, as shown in Figure 5. On the other hand, EMS incurs up to $6\times$ more disk I/Os than LFS, which is more than the gap in the uniform case as demonstrated in Figure 6. Since the memory fluctuations in the nonuniform environment are likely to be more dramatic compared to the uniform environment, the performance gap between EMS and LFS is likely to be more than in the uniform environment because EMS is non-oblivious. Indeed, EMS performs increasingly worse than LFS under the oblivious memory workloads generated in nonuniform environments.

Setup. We create nonuniformity among the program instances in two different manners. In all experiments in Figures 5 and 6, we set the memory size to 30 MiB for MM and to 768 MiB for sorting and retain the problem sizes as mentioned in Section 4.

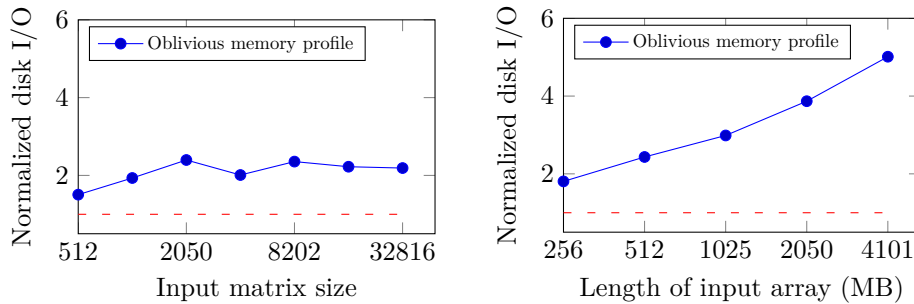

First, we concurrently run 3 instances of the same algorithm on different input sizes. For each experiment, we select 3 input sizes from the available set of sizes uniformly at random. The algorithm in each instance runs sequentially, but the instances run concurrently with

(b) Normalized disk I/O of EMS to LFS.

■ **Figure 7** Normalized disk I/O of the non-adaptive to the cache-adaptive algorithm for variable problem size for oblivious memory workloads that we generated by running TPC-C concurrently with the programs. An increase in the y-axis means that the non-adaptive algorithm performs progressively worse relative to the adaptive algorithm.

each other. For each experiment, since the smaller instances may complete earlier than the larger ones, we repeat any instances that have finished until all instances have finished. To measure I/O, we report only the first run of each instance per experiment. As a baseline, we also run 3 uniform program instances to evaluate the effect of nonuniform input sizes.

Second, we concurrently run different algorithms for the same problem on the same input size. Specifically, we run 3 instances of the cache-adaptive algorithm (MM-INPLACE or LFS) and 3 instances of the non-adaptive algorithm (MM-SCAN or EMS) concurrently.

Running a database program concurrently

Finally, we turn our attention to how the MM and sorting algorithms perform when run under oblivious memory workloads that we simulated by running a memory-intensive database program concurrently. The database program is not adversarial and therefore not tied to any particular algorithm structure, so we expect the cache-oblivious algorithms to adapt better to the resulting memory fluctuations. Figure 7 confirms this hypothesis – MM-SCAN performs very close to MM-INPLACE (roughly incurring $2.1\times$ disk I/Os), while EMS performs increasingly worse (up to $6\times$) than LFS as the problem size grows.

Setup. As the oblivious memory profiles are generated in a non-synthetic manner (see Section 3), and the memory fluctuations are oblivious to what the algorithm does, we choose to run a concurrent memory-intensive database program with the desired algorithm to evaluate the algorithm’s performance. We generated such an oblivious memory workload by running the TPC-C [17] workload concurrently with either a cache-adaptive or a non-adaptive program and present the normalized disk I/Os of the non-adaptive algorithms to the adaptive algorithms. TPC-C is a popular online transaction processing (OLTP) benchmark used to measure database management systems. Both the MM and sorting algorithms share the memory with the memory-intensive TPC-C program.

7 Conclusion

We investigated how some cache-oblivious and cache-adaptive (and neither) algorithms perform under a wide range of memory profiles. Specifically, we focused on matrix-multiplication algorithms as representatives of (a, b, c) -regular algorithms and sorting algorithms as representatives of cache-optimized but not (a, b, c) -regular algorithms. We experimentally exhibited the gap in I/O-performance between the cache-adaptive and non-adaptive algorithms for MM and sorting under adversarially-generated memory workloads. To do so, we needed to design a profile generator that can dynamically change the amount of available memory depending on a program’s execution. On the other hand, under our oblivious memory workloads, cache-oblivious MM algorithms performed close to each other, whereas the non-oblivious sorting algorithm still performed worse than the cache-oblivious (and adaptive) algorithm. We conjecture that what we have seen in our experiments applies more generally. That is, we conjecture that cache-oblivious programming is a powerful way of empirically achieving cache-adaptivity. This could be important because as mentioned in Section 1, there are many more known cache-oblivious algorithms than known cache-adaptive algorithms. Our results provide hope for the large body of work on cache-oblivious algorithms to empirically perform well even when the cache size fluctuates.

Abstract

Designing dynamic algorithms against an adaptive adversary whose performance match the ones assuming an oblivious adversary is a major research program in the field of dynamic graph algorithms. One of the prominent examples whose oblivious-vs-adaptive gap remains maximally large is the *fully dynamic spanner* problem; there exist algorithms assuming an oblivious adversary with near-optimal size-stretch trade-off using only $\text{polylog}(n)$ update time [Baswana, Khurana, and Sarkar TALG'12; Forster and Goranci STOC'19; Bernstein, Forster, and Henzinger SODA'20], while against an adaptive adversary, even when we allow infinite time and only count recourse (i.e. the number of edge changes per update in the maintained spanner), all previous algorithms with stretch at most $\log^5(n)$ require at least $\Omega(n)$ amortized recourse [Ausiello, Franciosa, and Italiano ESA'05].

In this paper, we completely close this gap with respect to recourse by showing algorithms against an adaptive adversary with near-optimal size-stretch trade-off and recourse. More precisely, for any $k \geq 1$, our algorithm maintains a $(2k - 1)$ -spanner of size $O(n^{1+1/k} \log n)$ with $O(\log n)$ amortized recourse, which is optimal in all parameters up to a $O(\log n)$ factor. As a step toward algorithms with small update time (not just recourse), we show another algorithm that maintains a 3-spanner of size $\tilde{O}(n^{1.5})$ with $\text{polylog}(n)$ amortized recourse *and* simultaneously $\tilde{O}(\sqrt{n})$ worst-case update time.

1 Introduction

Increasingly, algorithms are used interactively for data analysis, decision making, and classically as data structures. Often it is not realistic to assume that a user or an adversary is *oblivious* to the outputs of the algorithms; they can be *adaptive* in the sense that their updates and queries to the algorithm may depend on the previous outputs they saw. Unfortunately, many classical algorithms give strong guarantees only when assuming an oblivious adversary. This calls for the design of algorithms that work against an adaptive adversary whose performance match the ones assuming an oblivious adversary. Driven by this question, there have been exciting lines of work across different communities in theoretical computer science, including streaming algorithms against an adaptive adversary [10, 52, 66, 3, 56, 28], statistical algorithms against an adaptive data analyst [51, 37, 7, 63], and very recent algorithms for machine unlearning [47].

In the area of this paper, namely dynamic graph algorithms, a continuous effort has also been put on designing algorithms against an adaptive adversary. This is witnessed by dynamic algorithms for maintaining spanning forests [53, 60, 67, 61, 34], shortest paths [13, 11, 14, 35, 36, 49, 50, 48, 33], matching [20, 21, 22, 24, 64, 23], and more. This development led to new powerful tools, such as the expander decomposition and hierarchy [62, 42, 59] applicable beyond dynamic algorithms [57, 58, 1, 68], and other exciting applications such as the first almost-linear time algorithms for many flow and cut problems [27, 26, 33, 17]. Nevertheless, for many fundamental dynamic graph problems, including graph sparsifiers [2], reachability [18], directed shortest paths [49], the performance gap between algorithms against an oblivious and adaptive adversary remains large, waiting to be explored and, hopefully, closed.

One of the most prominent dynamic problems whose oblivious-vs-adaptive gap is maximally large is the *fully dynamic spanner* problem [5, 38, 8, 25, 40, 16, 12]. Given an unweighted undirected graph $G = (V, E)$ with n vertices, an α -spanner H is a subgraph of G whose pairwise distances between vertices are preserved up to the *stretch* factor of α , i.e., for all $u, v \in V$, we have $\text{dist}_G(u, v) \leq \text{dist}_H(u, v) \leq \alpha \cdot \text{dist}_G(u, v)$.¹ In this problem, we want to maintain an α -spanner of a graph G while G undergoes both edge insertions and deletions, and for each edge update, spend as small update time as possible.

Assuming an oblivious adversary, near-optimal algorithms have been shown: for every $k \geq 1$, there are algorithms maintaining a $(2k - 1)$ -spanner containing $\tilde{O}(n^{1+1/k})$ edges², which is nearly tight with the $\Omega(n^{1+1/k})$ bound from Erdős' girth conjecture (proven for the cases where $k = 1, 2, 3, 5$ [65]). Their update times are either $O(k \log^2 n)$ amortized [8, 40] or $O(1)^k \log^3 n$ worst-case [16], both of which are polylogarithmic when k is a constant.

In contrast, the only known dynamic spanner algorithm against an adaptive adversary by [5] requires $O(n)$ amortized update time and it can maintain a $(2k - 1)$ -spanner of size $O(n^{1+1/k})$ only for $k \leq 3$. Whether the $O(n)$ bound can be improved remained open until very recently. Bernstein et al. [12] show that a $\log^6(n)$ -spanner can be maintained against an adaptive adversary using $\text{polylog}(n)$ amortized update time. The drawback, however, is that their expander-based technique is too crude to give any stretch smaller than $\text{polylog}(n)$. Hence, for $k \leq \log^6(n)$, it is still unclear if the $\Theta(n)$ bound is inherent. Surprisingly, this holds even if we allow infinite time, and only count *recourse*, i.e., the number of edge changes per update in the maintained spanner. The stark difference in performance between the two adversarial settings motivates the main question of this paper:

Is the $\Omega(n)$ recourse bound inherent for fully dynamic spanners against an adaptive adversary?

Recourse is an important performance measure of dynamic algorithms. There are dynamic settings where changes in solutions are costly while computation itself is considered cheap, and so the main goal is to directly minimize recourse [45, 44, 6, 46]. Even when the final goal is to minimize update time, there are many dynamic algorithms that crucially require the design of subroutines with recourse bounds *stronger than* update time bounds to obtain small final update time [31, 42, 32]. Historically, there are dynamic problems, such as planar embedding [55, 54] and maximal independent set [29, 9, 30], where low recourse algorithms were first discovered and later led to fast update-time algorithms. Similar to dynamic spanners, there are other fundamental problems, including topological sorting [15] and edge coloring [19], for which low recourse algorithms remain the crucial bottleneck to faster update time.

¹ Here, $\text{dist}_G(u, v)$ denotes the distance between u and v in graph G .

² $\tilde{O}(\cdot)$ hides a $\text{polylog}(n)$ factor.

In this paper, we successfully break the $O(n)$ recourse barrier and completely close the oblivious-vs-adaptive gap with respect to recourse for fully dynamic spanners against an adaptive adversary.³

► **Theorem 1.** *There exists a deterministic algorithm that, given an unweighted graph G with n vertices undergoing edge insertions and deletions and a parameter $k \geq 1$, maintains a $(2k - 1)$ -spanner of G containing $O(n^{1+1/k} \log n)$ edges using $O(\log n)$ amortized recourse.*

As the above algorithm is deterministic, it automatically works against an adaptive adversary. Each update can be processed in polynomial time. Both the recourse and stretch-size trade-off of Theorem 1 are optimal up to a $O(\log n)$ factor. When ignoring the update time, it even dominates the current best algorithm assuming an oblivious adversary [8, 40] that maintains a $(2k - 1)$ -spanner of size $O(n^{1+1/k} \log n)$ using $O(k \log^2 n)$ recourse. Therefore, the oblivious-vs-adaptive gap for amortized recourse is closed.

The algorithm of Theorem 1 is as simple as possible. As it turns out, a variant of the classical greedy spanner algorithm [4] simply does the job! Although the argument is short and “obvious” in hindsight, for us, it was very surprising. This is because the greedy algorithm *sequentially* inspects edges in some fixed order, and its output solely depends on this order. Generally, long chains of dependencies in algorithms are notoriously hard to analyze in the dynamic setting. More recently, a similar greedy approach was dynamized in the context of dynamic maximal independent set [9] by choosing a *random order* for the greedy algorithm. Unfortunately, the random order must be kept secret from the adversary and so this fails completely in our adaptive setting. Despite these intuitive difficulties, our key insight is that we can *adaptively choose the order* for the greedy algorithm after each update. This simple idea is enough, see Section 2 for details.

Theorem 1 leaves open the oblivious-vs-adaptive gap for the update time. Below, we show a partial progress on this direction by showing an algorithm with near-optimal recourse and simultaneously non-trivial update time.

► **Theorem 2.** *There exists a randomized algorithm that, given an unweighted graph G with n vertices undergoing edge insertions and deletions, with high probability maintains against an adaptive adversary a 3-spanner of G containing $\tilde{O}(n^{1.5})$ edges using $\tilde{O}(1)$ amortized recourse and $\tilde{O}(\sqrt{n})$ worst-case update time.*

We note again that, prior to the above result, there was no algorithm against an adaptive adversary with $o(n)$ amortized update time that can maintain a spanner of stretch less than $\log^6(n)$. Theorem 2 shows that for 3-spanners, the update time can be $\tilde{O}(\sqrt{n})$ worst-case, while guaranteeing near-optimal recourse.

We prove Theorem 2 by employing a technique called *proactive resampling*, which was recently introduced in [12] for handling an adaptive adversary. We apply this technique on a modification of a spanner construction by Grossman and Parter [43] from distributed computation community. The modification is small, but seems inherently necessary for bounding the recourse.

To successfully apply proactive resampling, we refine the technique in two ways. First, we present a simple abstraction in terms of a certain load balancing problem that captures the power of proactive resampling. Previously, the technique was presented and applied specifically for the dynamic cut sparsifier problem [12]. But actually, this technique is

³ We wish to mention here that our algorithm works against an adaptive adversary that, in addition to just seeing the algorithm’s output, also has access to the internal randomness of the algorithm.

■ **Table 1** The state of the art of fully dynamic spanner algorithms.

Ref.	Stretch	Size	Recourse	Update Time	Deterministic?
Against an oblivious adversary					
[8]	$2k - 1$	$O(k^8 n^{1+1/k} \log^2 n)$	$O(7^{k/2})$ amortized		rand. oblivious
[8, 40]	$2k - 1$	$O(n^{1+1/k} \log n)$	$O(k \log^2 n)$ amortized		rand. oblivious
[16]	$2k - 1$	$\tilde{O}(n^{1+1/k})$	$O(1)^k \log^3 n$ worst-case		rand. oblivious
Against an adaptive adversary					
[5]	3	$O(n^{1+1/2})$	$O(\Delta)$ amortized		deterministic
	5	$O(n^{1+1/3})$	$O(\Delta)$ amortized		deterministic
[12]	$\tilde{O}(1)$	$\tilde{O}(n)$	$\tilde{O}(1)$ amortized		rand. adaptive
	$n^{o(1)}$	$\tilde{O}(n)$	$n^{o(1)}$ worst-case		deterministic
Ours	$2k - 1$	$O(n^{1+1/k} \log n)$	$O(\log n)$ amortized	$\text{poly}(n)$ worst-case	deterministic
	3	$\tilde{O}(n^{1+1/2})$	$\tilde{O}(1)$ amortized	$\tilde{O}(\sqrt{n})$ worst-case	rand. adaptive
	3	$O(n^{1+1/2})$	$O(\min\{\Delta, \sqrt{n}\} \log n)$ worst-case		deterministic

conceptually simple and quite generic, so our new abstraction will likely facilitate future applications. Our second technical contribution is to generalize and make the proactive resampling technique more flexible. At a very high level, in [12], there is a single parameter about sampling probability that is *fixed* throughout the whole process, and their analysis requires this fact. In our load-balancing abstraction, we need to work with multiple sampling probabilities and, moreover, they change through time. We manage to analyze this generalized process using probabilistic tools about *stochastic domination*, which in turn simplifies the whole analysis.

If a strong recourse bound is not needed, then proactive resampling can be bypassed and the algorithm becomes very simple, deterministic, and has slightly improved bounds as follows.

► **Theorem 3.** *There exists a deterministic algorithm that, given an unweighted graph G with n vertices undergoing edge insertions and deletions, maintains a 3-spanner of G containing $O(n^{1.5})$ edges using $O(\min\{\Delta, \sqrt{n}\} \log n)$ worst-case update time, where Δ is the maximum degree of G .*

Despite its simplicity, the above result improves the update time of the fastest deterministic dynamic 3-spanner algorithm [5] from $O(\Delta)$ amortized to $O(\min\{\Delta, \sqrt{n}\} \log n)$ worst-case. In fact, all previous dynamic spanner algorithms with worst-case update time either assume an oblivious adversary [38, 25, 16] or have a very large stretch of $n^{o(1)}$ [12]. See Table 1 for detailed comparison.

Organization. In Section 2, we give a very short proof of Theorem 1. In Section 3, we prove Theorem 2 assuming a crucial lemma (Lemma 8) needed for bounding the recourse. To prove this lemma, we show a new abstraction for the proactive resampling technique in Section 4 and complete the analysis in Section 5. Our side result, Theorem 3, is based on the the static construction presented in Section 3.1 and its simple proof is given in Section 3.2.

2 Deterministic Spanner with Near-optimal Recourse

Below, we show a decremental algorithm that *handles edge deletions only* with near-optimal recourse. This will imply Theorem 1 by a known reduction formally stated in Lemma 6. To describe our decremental algorithm, let us first recall the classic greedy algorithm.

The Greedy Algorithm. Althöfer et al. [4] showed the following algorithm for computing $(2k - 1)$ -spanners. Given a graph $G = (V, E)$ with n vertices, fix some *order* of edges in E . Then, we inspect each edge one by one according to the order. Initially $E_H = \emptyset$. When we inspect $e = (u, v)$, if $\text{dist}_H(u, v) \geq 2k$, then add e into E_H . Otherwise, ignore it. We have the following:

► **Theorem 4** ([4]). *The greedy algorithm above outputs a $(2k - 1)$ -spanner $H = (V, E_H)$ of G containing $O(n^{1+1/k})$ edges.*

It is widely believed that the greedy algorithm is extremely bad in dynamic setting: an edge update can drastically change the greedy spanner. In contrary, when we allow the order in which greedy scans the edges to be changed adaptively, we can avoid removing spanner edges until it is deleted by the adversary. This key insight leads to optimal recourse. When recourse is the only concern, prior to our work this result was known only for spanners with polylog stretch, which is a much easier problem.

The Decremental Greedy Algorithm. Now we describe our deletion-only algorithm. Let G be an initial graph with m edges and $H = (V, E_H)$ be a $(2k - 1)$ -spanner with $O(n^{1+1/k})$ edges. Suppose an edge $e = (u, v)$ is deleted from the graph G . If $(u, v) \notin E_H$, then we do nothing. Otherwise, we do the following. We first remove e from E_H . Now we look at the only remaining non-spanner edges $E \setminus E_H$, one by one in an arbitrary order. (Note that the order is *adaptively* defined and not fixed through time because it is defined only on $E \setminus E_H$.) When we inspect $(x, y) \in E \setminus E_H$, as in the greedy algorithm, we ask if $\text{dist}_H(x, y) \geq 2k$ and add (x, y) to E_H if and only if it is the case. This completes the description of the algorithm.

Analysis. We start with the most crucial point. We claim that the new output after removing e is as if we run the greedy algorithm that first inspects edges in E_H (the order within E_H is preserved) and later inspects edges in $E \setminus E_H$.

To see the claim, we argue that if the greedy algorithm inspects E_H first, then the whole set E_H must be included, just like E_H remains in the new output. To see this, note that, for each $(x, y) \in E_H$, $\text{dist}_H(x, y) \geq 2k$ when (x, y) was inspected according to some order. But, if we move the whole set E_H to be the prefix of the order (while the order within E_H is preserved), it must still be the case that $\text{dist}_H(x, y) \geq 2k$ when (x, y) is inspected and so e must be added into the spanner by the greedy algorithm.

So our algorithm indeed “simulates” inspecting E_H first, and then it explicitly implements the greedy algorithm on the remaining part $E \setminus E_H$. So we conclude that it simulates the greedy algorithm. Therefore, by Theorem 4, the new output is a $(2k - 1)$ -spanner with $O(n^{1+1/k})$ edges.

The next important point is that, whenever an edge e added into the spanner H , the algorithm never tries to remove e from H . So e remains in H until it is deleted by the adversary. Therefore, the total recourse is $O(m)$. With this, we conclude the following key lemma:

► **Lemma 5.** *Given a graph G with n vertices and m initial edges undergoing only edge deletions, the algorithm above maintains a $(2k - 1)$ -spanner H of G of size $O(n^{1+1/k})$ with $O(m)$ total recourse.*

By plugging Lemma 5 to the fully-dynamic-to-decremental reduction by [8] below, we conclude Theorem 1.

► **Lemma 6** ([8]). *Suppose that for a graph G with n vertices and m initial edges undergoing only edge deletions, there is an algorithm that maintains a $(2k - 1)$ -spanner H of size $O(S(n))$ with $O(F(m))$ total recourse where $F(m) = \Omega(m)$, then there exists an algorithm that maintains a $(2k - 1)$ -spanner H' of size $O(S(n) \log n)$ in a fully dynamic graph with n vertices using $O(F(U \log n))$ total recourse. Here U is the total number of updates, starting from an empty graph.*

3 3-Spanner with Near-optimal Recourse and Fast Update Time

In this section, we prove Theorem 2 by showing an algorithm for maintaining a 3-spanner with small update time *in addition* to having small recourse. We start by explaining a basic static construction and needed data structures in Section 3.1 and show the dynamic algorithm in Section 3.2. Assuming our key lemma (Lemma 8) about proactive resampling, most details here are quite straight forward. Hence, due to space constraint, some proofs are omitted. They will appear in our full version.

Throughout this section, we let $N_G(u) = \{v \in V : (u, v) \in E\}$ denote the set of neighbors of a node $u \in V$ in a graph $G = (V, E)$, and we let $\deg_G(u) = |N_G(u)|$ denote the degree of the node u in the graph G .

3.1 A Static Construction and Basic Data Structures

A Static Construction. We now describe our static algorithm. Though our presentation is different, our algorithm is almost identical to [43]. The only difference is that we do not distinguish small-degree vertices from large-degree vertices.

We first arbitrarily partition V into \sqrt{n} equal-sized *buckets* $V_1, \dots, V_{\sqrt{n}}$. We then construct three sets of edges E_1, E_2, E_3 . For every bucket $V_i, i \in [1, \sqrt{n}]$, we do the following. First, for all $v \in V \setminus V_i$, if $V_i \cap N_G(v)$ is not empty, we choose a neighbor $c_i(v) \in V_i \cap N_G(v)$ and add $(v, c_i(v))$ to E_1 . We call $c_i(v)$ an *i -partner* of v . Next, for every edge $e = (u, v)$, where both $u, v \in V_i$, we add e to E_2 . Lastly, for $u, u' \in V_i$ with overlapping neighborhoods, we pick an arbitrary common neighbor $w_{uu'} \in N_G(u) \cap N_G(u')$ and add $(u, w_{uu'}), (w_{uu'}, u')$ to E_3 . We refer to the node $w_{uu'}$ as the *witness* for the pair u, u' .

► **Claim 7.** The subgraph $H = (V, E_1 \cup E_2 \cup E_3)$ is a 3-spanner of G consisting of at most $O(n\sqrt{n})$ edges.

Proof. We need to show that (1) H is a 3-spanner and (2) $E_H = E_1 \cup E_2 \cup E_3$ has size at most $O(n\sqrt{n})$.

Stretch. Consider an edge $e = (u, v)$ where $u \in V_i, v \in V_j$. We show that H has a path of length at most 3 between u and v . The easy case is when $(u, v) \in E_H$. This gives us a path of one edge. It happens when $u = c_i(v)$ or $v = c_j(u)$, or $i = j$. Suppose $(u, v) \notin E_H$. Consider $v' = c_j(u)$. Since u is a common neighbor between v and v' , $P(v, v')$ is not empty. As $e \notin E_H, u \neq w_{vv'}$. As, the path $u, v', w_{vv'}, v$ has length exactly 3, the stretch part is concluded.

Size. Each vertex u has upto \sqrt{n} partners. Since we have n vertices, $|E_1| = O(n\sqrt{n})$. For E_2 , the graph induced on V_i has at most $O(n)$ edges. Since we have \sqrt{n} buckets, $|E_2| = O(n\sqrt{n})$. For E_3 , $|E_3|$ is bounded by the number of witnesses we need. Since we have $O\sqrt{n}$ buckets, and we have $O(n)$ pairs of vertices within the same bucket, for all buckets, $|E_3|$ must be bounded by $O(n\sqrt{n})$. We conclude the proof by saying that $|E_H| = O(|E_1| + |E_2| + |E_3|) = O(n\sqrt{n})$

◁

Dynamizing the Construction. Notice that it suffices to separately maintain E_1, E_2, E_3 , in order to maintain the above dynamic 3-spanner. Maintaining E_1 and E_2 is straightforward and can be done in a fully-dynamic setting in $O(1)$ worst-case update time. Indeed, if $e = (u, c_i(u)) \in E_1$ is deleted, then we pick a new i -partner $c_i(u) \in V_i \cap N_G(u)$ for u . Maintaining $V_i \cap N_G(u)$ for all u allows us to update $c_i(u)$ efficiently. If $e = (u, u') \in E_2$, where $u, u' \in V_i$, is deleted, then we do nothing.

The remaining task, maintaining E_3 , is the most challenging part of our dynamic algorithm. Before we proceed, let us define a subroutine and a data structure needed to implement our algorithm.

Resampling Subroutine. We define $\text{RESAMPLE}(u, u')$ as a subroutine that *uniformly samples* a witness $w_{uu'}$ (i.e. a common neighbor of u and u'), if exists. Notice that, we can obtain E_3 by calling $\text{RESAMPLE}(u, u')$ for all $u, u' \in V_i$ and for all $i \in [1, \sqrt{n}]$.

■ **Algorithm 1** Maintaining a 3-spanner after one edge deletion.

Data: $G = (V, E)$, $H = (V, E_1 \cup E_2 \cup E_3)$
Input: $e = (u, v)$ is an edge being deleted
Result: $G' = (V, E')$, $H' = (V, E'_1 \cup E'_2, E'_3)$

```

1 begin
2    $E' \leftarrow E \setminus e$ 
3   Let  $i_u$  be such that  $u \in V_{i_u}$ 
4   Let  $i_v$  be such that  $v \in V_{i_v}$ 
5
6   if  $u = c_{i_u}(v)$  then
7     Reselect  $c_{i_u}(v)$  from  $V_{i_u} \cap N_{G'}(v)$ 
8   if  $v = c_{i_v}(u)$  then
9     Reselect  $c_{i_v}(u)$  from  $V_{i_v} \cap N_{G'}(u)$ 
10   $E'_1 \leftarrow E_1 \setminus e \cup \{(u, c_{i_u}(v)), (v, c_{i_v}(u))\}$ 
11
12  if  $i_u = i_v$  then
13     $E'_2 \leftarrow E_2 \setminus e$ 
14
15   $E'_3 \leftarrow E_3 \setminus e$ 
16  for  $u' \in V_{i_u} \setminus u$  do
17    if  $v = w_{uu'}$  then
18       $w_{uu'} \leftarrow \text{RESAMPLE}(u, u')$  /* RESAMPLE( $\cdot, \cdot$ ) is drawn from  $G'$  */
19
20     $E'_3 \leftarrow E'_3 \cup \{(u, w_{uu'}), (w_{uu'}, u')\}$ 
21  for  $v' \in V_{i_v} \setminus v$  do
22    if  $u = w_{vv'}$  then
23       $w_{vv'} \leftarrow \text{RESAMPLE}(v, v')$ 
24     $E'_3 \leftarrow E'_3 \cup \{(v, w_{vv'}), (w_{vv'}, v')\}$ 

```

Partnership Data Structures. The subroutine above hints that we need a data structure for maintaining the common neighborhoods for all pairs of vertices that are in the same bucket. For vertices u and v within the same bucket, we let $P(u, v) = N_G(u) \cap N_G(v)$ be

the *partnership* between u and v . To maintain these structures dynamically, when an edge (u, v) is inserted, if $u \in V_i$ and $v \in V_j$, we add v to $P(u, u')$ for all $u' \in V_i \cap N_G(v) \setminus \{u\}$, and symmetrically add u to $P(v, v')$ for all $v' \in V_j \cap N_G(u) \setminus \{v\}$. This clearly takes $O(\sqrt{n} \log n)$ worst-case time for edge insertion, and this is symmetric for edge deletion.

As we want to prove that our final update time is $\tilde{O}(\sqrt{n})$, we can assume from now that E_1, E_2 , and all partnerships are maintained in the background. The pseudocode for maintaining the 3-spanner is provided in Algorithm 1.

3.2 Maintaining Witnesses via Proactive Resampling

Remark. For clarity of exposition, we will present an amortized update time analysis. Using standard approach, we can make the update time worst case. We will discuss this issue at the end of this section.

Our dynamic algorithm runs in *phases*, where each phase lasts for $n\sqrt{n}$ consecutive updates (edge insertions/deletions). As a spanner is decomposable⁴, it suffices to maintain a 3-spanner H of the graph undergoing only edge deletions within this phase and then include all edges inserted within this phase into H , which increases the size of H by at most $n\sqrt{n}$ edges. Henceforth, *we only need to present how to initialize a phase and how to handle edge deletions within each phase*. The reason behind this reduction is because our proactive resampling technique naturally works for decremental graphs.

Initialization. At the start of the phase, since our partnerships structures only processed edge deletions from the previous phase, we first update partnerships with all the $O(n\sqrt{n})$ inserted edges from the previous phase. Then, we call $\text{RESAMPLE}(u, u')$ for all $u, u' \in V_i$ for all $i \in [1, \sqrt{n}]$ to replace all witnesses and initialize E_3 of this phase.

Difficulty of Bounding Recourse. Maintaining E_3 (equivalently, the witnesses) in $\tilde{O}(\sqrt{n})$ worst-case time is straightforward because the partnership data structure has $O(\sqrt{n} \log n)$ update time. However, our goal is to show $\tilde{O}(1)$ amortized recourse, which is the most challenging part of our analysis. To see the difficulty, if (u, v) is deleted and $u \in V_i$, a vertex v may serve as a witness $\{w_{uu'}\}$ for all $u' \in V_i$. In this case, deleting (u, v) causes the algorithm to find a new witness $w_{uu'}$ for all $u' \in V_i$. This implies a recourse of $|V_i| = \Omega(\sqrt{n})$. To circumvent this issue, we apply the technique of *proactive resampling*, as described below.

Proactive Resampling. We keep track of a *time-variable* T ; the number of updates to G that have occurred in this phase until now. T is initially 0. We increment T each time an edge gets deleted from G .

In addition, for all $i \in [1, \sqrt{n}]$ and $u, u' \in V_i$ with $u \neq u'$, we maintain: (1) $w_{uu'}$, the *witness* for the pair u and u' and (2) a set $\text{SCHEDULE}[u, u']$ of positive integers, which is the set of timesteps where our algorithm intends to *proactively resample* a new witness for u, u' . This set grows adaptively each time the adversary deletes $(u, w_{uu'})$ or $(w_{uu'}, u')$.

Finally, to ensure that the update time of our algorithm remains small, for each $\lambda \in [1, n\sqrt{n}]$ we maintain a $\text{LIST}[\lambda]$, which consists of all those pairs of nodes (x, x') such that $\lambda \in \text{SCHEDULE}[x, x']$.

⁴ Let $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$. If H_1 and H_2 are α -spanners G_1 and G_2 respectively, then $H_1 \cup H_2$ is a α -spanner of $G_1 \cup G_2$.

When an edge (u, v) , where $u \in V_i$ and $v \in V_j$ is deleted, we do the following operations. First, for all $u' \in V_i$ that had $v = w_{uu'}$ as a common neighbor with u before deleting (u, v) , we add the timesteps $\{T + 2^k \mid T + 2^k \leq n\sqrt{n}, k \in \mathbb{N}\}$ to $\text{SCHEDULE}[u, u']$. Second, analogous to the previous one, for all $v' \in V_j$ that had $u = w_{vv'}$ as a common neighbor with v before deleting (u, v) , we add the timesteps $\{T + 2^k \mid T + 2^k \leq n\sqrt{n}, k \in \mathbb{N}\}$ to $\text{SCHEDULE}[v, v']$. Third, we set $T \leftarrow T + 1$. Lastly, for each $(x, x') \in \text{LIST}[T]$, we call the subroutine $\text{RESAMPLE}(x, x')$.

The key lemma below summarizes a crucial property of this dynamic algorithm. Its proof appears in Section 4.

► **Lemma 8.** *During a phase consisting of $n\sqrt{n}$ edge deletions, our dynamic algorithm makes at most $\tilde{O}(\sqrt{n})$ calls to the RESAMPLE subroutine after each edge deletion. Moreover, the total number of calls to the RESAMPLE subroutine during an entire phase is at most $\tilde{O}(n\sqrt{n})$ w.h.p. Both these guarantees hold against an adaptive adversary.*

Analysis of Recourse and Update Time. Our analysis are given in the lemmas below.

► **Lemma 9 (Recourse).** *The amortized recourse of our algorithm is $\tilde{O}(1)$ w.h.p., against an adaptive adversary.*

Proof. To maintain the edge-sets E_1 and E_2 , we pay a worst-case recourse of $O(1)$ per update. For maintaining the edge-set E_3 , our total recourse during the entire phase is at most $O(1)$ times the number of calls made to the $\text{RESAMPLE}(\cdot, \cdot)$ subroutine, which in turn is at most $\tilde{O}(n\sqrt{n})$ w.h.p. (see Lemma 8). Finally, while computing E_3 in the beginning of a phase, we pay $O(n\sqrt{n})$ recourse. Therefore, the overall total recourse during an entire phase is $\tilde{O}(n\sqrt{n})$ w.h.p.. Since a phase lasts for $n\sqrt{n}$ time steps, we conclude the lemma. ◀

► **Lemma 10 (Worst-case Update Time within a Phase).** *Within a phase, our algorithm handles a given update in $\tilde{O}(\sqrt{n})$ worst case time w.h.p..*

Proof. Recall that the sets E_1, E_2 can be maintained in $O(1)$ worst case update time. Henceforth, we focus on the time required to maintain the edge-set E_3 after a given update in G .

Excluding the time spent on maintaining the partnership data structure (which is $\tilde{O}(\sqrt{n})$ in the worst-case anyway), this is proportional to $\tilde{O}(1)$ times the number of calls made to the $\text{RESAMPLE}(\cdot, \cdot)$ subroutine, plus $\tilde{O}(1)$ times the number of pairs $u, u'(v, v')$ where we need to adjust $\text{SCHEDULE}[u, u']$. The former is w.h.p. at most $\tilde{O}(\sqrt{n})$ according to Lemma 8, while the latter is also at most $\tilde{O}(\sqrt{n})$ since $|V_i|, |V_j| \leq \sqrt{n}$. Thus, within a phase we can also maintain the set E_3 w.h.p. in $\tilde{O}(\sqrt{n})$ worst case update time. ◀

Although the above lemma says that we can handle each edge deletion in $\tilde{O}(\sqrt{n})$ worst-case update time, our current algorithm does not guarantee worst-case update time yet because the initialization time exceed the $\tilde{O}(\sqrt{n})$ bound. In more details, observe that the total initialization time is $O(n\sqrt{n}) \times O(\sqrt{n} \log n)$ because we need to insert $O(n\sqrt{n})$ edges into partnership data structures, which has $O(\sqrt{n} \log n)$ update time. Over a phase of $n\sqrt{n}$ steps, this implies only $\tilde{O}(\sqrt{n})$ amortized update time.

However, since the algorithm takes long time only at the initialization of the phase, but takes $\tilde{O}(\sqrt{n})$ worst-case step for each update during the phase, we can apply the standard building-in-the-background technique to de-amortized the update time.⁵ We conclude the following:

⁵ The proof for this standard technique will be included in our full version.

► **Lemma 11** (Worst-case Update Time for the Whole Update Sequence). *W.h.p., the worst-case update time of our dynamic algorithm is $\tilde{O}(\sqrt{n})$.*

4 Proactive Resampling: Abstraction

The goal of this section is to prove Lemma 8 for bounding the recourse of our 3-spanner algorithm. This is the most technical part of this paper. To ease the analysis, we will abstract the problem situation in Lemma 8 as a particular dynamic problem of assigning jobs to machines while an adversary keeps deleting machines and the goal is to minimize the total number of reassignments. Below, we formalize this problem and show how to use it to bound the recourse of our 3-spanner algorithm.

Our abstraction has two technical contributions: (1) it allows us to easily work with multiple sampling probabilities, while in [12], they fixed a single parameter on sampling probability, (2) the simplicity of this abstraction can expose the generality of the proactive resampling technique itself; it is not specific to the cut sparsifier problem as used in [12].

Jobs, Machines, Routines, Assignments, and Loads. Let J denote a set of *jobs* and M denote a set of *machines*. We think of them as two sets of vertices of the (hyper)-graph $G = (J, M, R)$.⁶ A *routine* $r \in R$ is a hyperedge of G such that r contains exactly one job-vertex from J , denoted by $\text{job}(r) \in J$, and may contain several machine-vertices from M , denoted by $M(r) \subseteq M$. Each routine r in G means there is a routine for handling $\text{job}(r)$ by *simultaneously* calling machines in $M(r)$. Note that $r = \{\text{job}(r)\} \cup M(r)$. We say that r is a *routine for* $\text{job}(r)$. For each machine $x \in M(r)$, we say that routine r *involves* machine x , or that r *contains* x . The set $R(x)$ is then defined as the set of routines involving machine x . Observe that there are $\deg_G(u)$ different routines for handling job u . An *assignment* $A = (J, M, F \subseteq R)$ is simply a subgraph of G . We say assignment A is *feasible* iff $\deg_A(u) = 1$ for every job $u \in J$ where $\deg_G(u) > 0$. That is, every job is handled by some routine, if exists. When $r \in A$, we say that $\text{job}(r)$ is *handled by* routine r . Finally, given an assignment A , the *load* of a machine x is the number of routines in A involving x , or in other words, is the degree of x in A , $\deg_A(x)$. We note explicitly that our end-goal is not to optimize loads of machines. Rather, we want to minimize the number of reassignments needed to maintain feasible assignments throughout the process.

In this section, we usually use u, v, w to denote jobs, use x, y, z to denote machines, and use e or r to denote routines or (hyper)edges.

The Dynamic Problem. Our problem is to maintain a feasible assignment A while the graph G undergoes a sequence of machine deletions (which might stop before all machines are deleted). More specifically, when a machine x is deleted, all routines r containing x are deleted as well. But when routines in A are deleted, A might not be feasible anymore and we need to add new edges to A to make A feasible. Our goal is to minimize the total number of routines ever added to A .

To be more precise, write the graph G and the assignment A after t machine-deletions as $G^t = (J, M, R^t)$ and $A^t = (J, M, F^t)$, respectively. Here, we define *recourse* at timestep t to be $|F^t \setminus F^{t-1}|$, which is the number of routines added into A at timestep t . When the adversary deletes T machines, the goal is then to minimize the total recourse $\sum_{t=1}^T |F^t \setminus F^{t-1}|$.

⁶ This graph is different from the graph that we maintain a spanner in previous sections.

The Algorithm: Proactive Resampling. To describe our algorithm, first let $\text{RESAMPLE}(u)$ denote the process of reassigning job u to a uniformly random routine for u . In the graph language, $\text{RESAMPLE}(u)$ removes the edge r such that $\text{job}(r) = u$ from A , sample an edge r' from $\{r \in R \mid \text{job}(r) = u\}$, and then add r' into A . At timestep 0, we initialize a feasible assignment A^0 by calling $\text{RESAMPLE}(u)$ for every job $u \in J$, i.e., assign each job u to a random routine for u . Below, we describe how to handling deletions.

Let T be the total number of machine-deletions. For each job u , we maintain $\text{SCHEDULE}(u) \subseteq [T]$ containing all time steps that we will invoke $\text{RESAMPLE}(u)$. That is, at any timestep t , before an adversary takes any action, we call $\text{RESAMPLE}(u)$ if $t \in \text{SCHEDULE}(u)$.

We say that an adversary *touches* u at timestep t if the routine $r \in A^t$ handling u at time t is deleted. When u is touched, we call $\text{RESAMPLE}(u)$ and, very importantly, we put $t + 1, t + 2, t + 4, \dots$ where $t + 2^i \leq T$ into $\text{SCHEDULE}(u)$. This is the action that we call *proactive resampling* because we do not just resample a routine for u only when u is touched, but do so proactively in the future as well. This completes the description of the algorithm.

Clearly, A remains a feasible assignment throughout because whenever a job u is touched, we immediately call $\text{RESAMPLE}(u)$. The key lemma below states that the algorithm has low recourse, even if the adversary is adaptive in the sense that each deletion at time t depends on previous assignment before time t .

► **Lemma 12.** *Let T be the total number of machine-deletions. The total recourse of the algorithm running against an adaptive adversary is $O(|J| \log(\Delta) \log^2 |M| + T \log^2 |M|)$ with high probability where Δ is the maximum degree of any job. Moreover, if the load of a machine never exceeds λ , then our algorithm has $O(\lambda \log T)$ worst-case recourse.*

We will prove Lemma 12 in Section 5. Before proceeding any further, however, we argue why Lemma 12 directly bounds the recourse of our 3-spanner algorithm.

Back to 3-spanners: Proof of Lemma 8. It is easy to see that maintaining E_3 in our 3-spanner algorithm can be framed exactly as the job-machine load-balancing problem. Suppose the given graph is $G = (V, E)$ where $n = |V|$ and $m = |E|$. We create a job $j_{uu'}$ for each pair of vertices $u, u' \in V_i$ with $u \neq u'$. For each edge $e \in E$, we create a machine x_e . Hence, $|J| = O(n^{1.5})$ and $|M| = |E| = m$. For each job, as we want to have a witness $w_{uu'}$, this witness is corresponding to two edges $e = (u, w_{uu'})$ and $e' = (u', w_{uu'})$. Hence, we create a routine $r = (j_{uu'}, e, e')$ for each $u, u' \in V_i$ and a common neighbor $w_{uu'}$. Since there are at most n common neighbors between each u and u' , $\Delta = O(n)$. A feasible assignment is then corresponding to finding a witness for each job. Our algorithm that maintains the spanner is also exactly this load-balancing algorithm. Hence, the recourse of the 3-spanner construction follows from Lemma 12 where we delete exactly $T = O(n^{1.5})$ machines. As $|J| = O(n^{1.5})$, the total recourse bound then becomes $O(n^{1.5} \log^3 n)$. As $T = O(n^{1.5})$, averaging this bound over all timesteps yields $O(\log^3 n)$ amortized recourse.

5 Proactive Resampling: Analysis (Proof of Lemma 12)

The first step to prove Lemma 12 is to bound the loads of machines x . This is because whenever machine x is deleted, its load of $\deg_A(x)$ would contribute to the total recourse.

What would be the expected load of each machine? For intuition, suppose that the adversary was *oblivious*. Recall that $R(x)$ denote the set of all routines involving machine x . Then, the expected load of machine x would be $\sum_{r \in R(x)} 1 / \deg_G(\text{job}(r))$ because each

17:12 Simple Dynamic Spanners with Near-Optimal Recourse

job samples its routine uniformly at random, and this is concentrated with high probability using Chernoff's bound. Although in reality our adversary is *adaptive*, our plan is to still prove that the loads of machines do not exceed its expectation in the oblivious setting too much. This motivates the following definitions.

► **Definition 13.** *The target load of machine x is $\text{target}(x) = \sum_{r \in R(x)} 1/\text{deg}_G(\text{job}(r))$. The target load of x at time t is $\text{target}^t(x) = \sum_{r \in R^t(x)} 1/\text{deg}_{G^t}(\text{job}(r))$. An assignment A has overhead (α, β) iff $\text{deg}_A(x) \leq \alpha \cdot \text{target}(x) + \beta$ for every machine $x \in M$.*

Our key technical lemma is to show that, via proactive resampling, the loads of machines are indeed close to its expectation in the oblivious setting. That is, the maintained assignment has small overhead. Recall that T is the total number of machine-deletions.

► **Lemma 14.** *With high probability, the assignment A maintained by our algorithm always has overhead $(O(\log T), O(\log |M|))$ even when the adversary is adaptive.*

We defer the proof of Lemma 14 to Section 6. Assuming Lemma 14, we formally show how to bound of machine loads implies the total recourse, which proves Lemma 12.

Proof of Lemma 12. Let T be the total number of deletions. Observe that the total recourse up to time T is precisely the total number of `RESAMPLE(.)` calls up to time T , which in turn is at most the total number of `RESAMPLE(.)` calls put into `SCHEDULE(.)` since time 1 until time T . Therefore, our strategy is to bound, for each time t , the number of `RESAMPLE(.)` calls *newly generated* at time t . Let x^t be the machine deleted at time t . Observe this is at most $O(\log T) \times \text{deg}_{A^t}(x^t)$ where $\text{deg}_{A^t}(x^t)$ is x^t 's load at time t and the $O(\log T)$ factor is because of proactive sampling.

By Lemma 14, we have $\text{deg}_{A^t}(x^t) \leq O(\log(T)\text{target}^t(x^t) + \log |M|)$. Also, we claim that $\sum_{t=1}^T \text{target}^t(x^t) = O(|J| \log \Delta)$ where Δ is the maximum degree of jobs (to be proven below). Therefore, the total recourse up to time T is at most

$$\begin{aligned} O(\log T) \sum_{t=1}^T \text{deg}_{A^t}(x^t) &\leq O(\log T) \sum_{t=1}^T O(\log(T)\text{target}^t(x^t) + \log |M|) \\ &\leq O(|J| \log(\Delta) \log^2 |M| + T \log^2 |M|) \end{aligned}$$

as $T \leq |M|$.

It remains to show that $\sum_{t=1}^T \text{target}^t(x^t) = O(|J| \log \Delta)$. Recall that $\text{target}^t(x) = \sum_{r \ni x} \frac{1}{\text{deg}_{G^t}(\text{job}(r))}$. Imagine when machine x^t is deleted at time t . We will show how to charge $\text{target}^t(x^t)$ to jobs with edges connecting to x^t . For each job u with c (hyper)edges connecting to x^t , u 's contribution of $\text{target}^t(x^t)$ is $c/\text{deg}_{G^t}(u)$. So we distribute the charge of $c/\text{deg}_{G^t}(u) \leq \frac{1}{\text{deg}_{G^t}(u)} + \frac{1}{\text{deg}_{G^t}(u)-1} + \dots + \frac{1}{\text{deg}_{G^t}(u)-c+1}$ to u . Since these edges are charged from machine x^t to job u only once, the total charge of each job u at most $\frac{1}{\text{deg}_G(u)} + \frac{1}{\text{deg}_G(u)-1} + \dots + 1/2 + 1 = O(\log \Delta)$. Since there are $|J|$ jobs, the bound $\sum_{t=1}^T \text{target}^t(x^t) = O(|J| \log \Delta)$ follows.

To see that we have worst-case recourse, one can look at any timestep t . There are $O(\log t)$ timesteps that can cause `RESAMPLE` to be invoked at timestep t , namely, $t-1, t-2, t-4, \dots$. At each of these timesteps t' , one machine is deleted, so the number of `RESAMPLE` calls added from timestep t' is also bounded by the load of the deleted machine $x_{t'}$, which does not exceed λ . Summing this up, the number of calls we make at timestep t is at most $O(\lambda \log t) = O(\lambda \log T)$. This concludes our proof. ◀

6 Proof of Lemma 14

Here, we show that the load $\deg_{A^t}(x)$ of every machine x at each time t is small. Some basic notions are needed in this analysis.

Experiments and Relevant Experiments. An *experiment* X is a binary random variable associated with an edge/routine e and time step t , where $X = 1$ iff $\text{RESAMPLE}(\text{job}(e))$ is called at time t and e is chosen to handle $\text{job}(e)$, among all edges incident to $\text{job}(e)$. Observe that $\mathbb{P}[X = 1] = 1/\deg_{G^t}(\text{job}(e))$. Note that each call to $\text{RESAMPLE}(u)$ at time t creates new $\deg_{G^t}(u)$ experiments. We order all experiments X_1, X_2, X_3, \dots by the time of their creation. For convenience, for each experiment X , we let $e(X)$, $t(X)$, and $\text{job}(X)$ denote its edge, time of creation, and job respectively.

Next, we define the most important notion in the whole analysis.

► **Definition 15.** For any time t and edge $e \in R^t$ at time t , an experiment X is (t, e) -relevant if

- $e(X) = e$, and
- there is no $t(X) < t' < t$ such that $t' \in \text{SCHEDULE}^{t(X)}(\text{job}(e))$.

Moreover, X is (t, x) -relevant if it is (t, e) -relevant and edge $e \in R^t(x)$ is incident to x .

Intuitively, X is a (t, e) -relevant experiment if X could cause e to appear in the assignment A^t at time t . To see why, clearly if $e(X) \neq e$, then X cannot cause e to appear. Otherwise, if $e(X) = e$ but there is $t' \in (t(X), t)$ where $t' \in \text{SCHEDULE}^{t(X)}(\text{job}(e))$, then X cannot cause e to appear at time t either. This is because even if X is successful and so e appears at time $t(X)$, then later at time $t' > t(X)$, e will be resampled again, and so X has nothing to do whether e appears at time $t > t'$. With the same intuition, X is (t, x) -relevant if X could contribute to the load $\deg_{A^t}(x)$ of machine x at time t .

Notice that we decide whether X is a (t, e) -relevant based on $\text{SCHEDULE}^{t(X)}(\text{job}(e))$ at time $t(X)$. If it was based on $\text{SCHEDULE}^t(\text{job}(e))$ at time t , then there would be only a single experiment X that is (t, e) -relevant (which is the one with $e(X) = e$ and maximum $t(X) < t$).

According to Definition 15, there could be more than one experiments that are (t, e) -relevant. For example, suppose X is (t, e) -relevant. At time $t(X) + 1$, the adversary could touch $\text{job}(e)$, hence, adding $t(X) + 2, t(X) + 4, \dots$ into $\text{SCHEDULE}(\text{job}(e))$. Because of this action, there is another experiment X' that is (t, e) -relevant and $t(X') > t(X)$. This motivates the following definition.

► **Definition 16.** Let $\text{Rel}(t, e)$ be the random variable denoting the number of (t, e) -relevant experiments, and let $\text{Rel}(t, x) = \sum_{e \in R^t(x)} \text{Rel}(t, e)$ denote the total number of (t, x) -relevant experiments.

To simplify the notations in the proof of Lemma 14 below, we assume the following.

► **Assumption 17 (The Machine-disjoint Assumption).** For any routines e, e' with $\text{job}(e) = \text{job}(e')$, then $M(e) \cap M(e') = \emptyset$. That is, the edges adjacent to the same job are machine-disjoint.

Note that this assumption indeed holds for our 3-spanner application. This is because any two paths of length 2 between a pair of centers u and u' must be edge disjoint in any simple graph. We show how remove this assumption in our full version. The notations there will slightly be more complicated.

17:14 Simple Dynamic Spanners with Near-Optimal Recourse

Roadmap for Bounding Loads. We are now ready to describe the key steps for bounding the load $\deg_{A^t}(x)$, for any time t and machine x .

First, we write $\mathcal{X}^{(t,x)} = X_1^{(t,x)}, X_2^{(t,x)}, \dots, X_{\text{Rel}(t,x)}^{(t,x)}$ as the sequence of all (t,x) -relevant experiments (ordered by time step the experiments are taken). The order in $\mathcal{X}^{(t,x)}$ will be important only later. For now, we write

$$\overline{\deg}_{A^t}(x) = \sum_{X \in \mathcal{X}^{(t,x)}} X,$$

as the total number of success (t,x) -relevant experiments. As any edge e adjacent to x in A^t may appear only because of some successful (t,x) -relevant experiment $X \in \mathcal{X}^{(t,x)}$, we conclude the following:

► **Lemma 18** (Key Step 1). $\deg_{A^t}(x) \leq \overline{\deg}_{A^t}(x)$.

Lemma 18 reduces the problem to bounding $\overline{\deg}_{A^t}(x)$. If all (t,x) -relevant experiments $\mathcal{X}^{(t,x)} = \{X_i^{(t,x)}\}_i$ were independent, then we could have easily applied standard concentration bounds to $\overline{\deg}_{A^t}(x) = \sum_{X \in \mathcal{X}^{(t,x)}} X$. Unfortunately, they are not independent as the outcome of earlier experiments can affect the adversary's actions, which in turn affect later experiments.

Our strategy is to relate the sequence $\mathcal{X}^{(t,x)}$ of (t,x) -relevant experiments to another sequence $\hat{\mathcal{X}}^{(t,x)} = \hat{X}_1^{(t,x)}, \hat{X}_2^{(t,x)}, \dots, \hat{X}_{\text{Rel}(t,x)}^{(t,x)}$ of *independent* random variables defined as follows. For each (t,x) -relevant experiment $\hat{X}_i^{(t,x)}$ where $e = e(\hat{X}_i^{(t,x)})$ and $u = \text{job}(e)$, we carefully define $\hat{X}_i^{(t,x)}$ as an *independent* binary random variable such that

$$\mathbb{P}[\hat{X}_i^{(t,x)} = 1] = 1/\deg_{G^t}(u),$$

which is the probability that $\text{RESAMPLE}(u)$ chooses e at time t . We similarly define

$$\widehat{\deg}_{A^t}(x) = \sum_{\hat{X} \in \hat{\mathcal{X}}^{(t,x)}} \hat{X},$$

that sums independent random variables, where each term in the sum is closely related to the corresponding (t,x) -relevant experiments. By our careful choice of $\mathbb{P}[\hat{X}_i^{(t,x)} = 1]$, we can relate $\widehat{\deg}_{A^t}(x)$ to $\overline{\deg}_{A^t}(x)$ via the notion of *stochastic dominance* defined below.

► **Definition 19.** Let Y and Z be two random variables not necessarily defined on the same probability space. We say that Z stochastically dominates Y , written as $Y \preceq Z$, if for all $\lambda \in \mathbb{R}$, we have $\mathbb{P}[Y \geq \lambda] \leq \mathbb{P}[Z \geq \lambda]$.

Our second important step is the following lemma. The proof of Lemma 20 is omitted and will appear in our full version.

► **Lemma 20** (Key Step 2). $\overline{\deg}_{A^t}(x) \preceq \widehat{\deg}_{A^t}(x)$.

Lemma 20 reduces the problem to bounding $\widehat{\deg}_{A^t}(x)$, which is indeed relatively easy to bound because it is a sum of independent random variables. The last key step of our proof does exactly this:

► **Lemma 21** (Key Step 3). $\widehat{\deg}_{A^t}(x) \leq 2 \log(t) \cdot \text{target}^t(x) + O(\log|M|)$ with probability $1 - 1/|M|^{10}$.

We show the proof Lemma 21 in our full version. Here, we only mention one important point about the proof. The $\log(t)$ factor above follows from the fact the number of (t,e) -relevant experiment is always at most $\text{Rel}(t,e) \leq \log(t)$ for any time t and edge e . This property is so crucial and, actually, is what the proactive resampling technique is designed for.

Given three key steps above (Lemmas 18, 20, and 21), we can conclude the proof of Lemma 14.

Proof of Lemma 14. Recall that we ultimately want to show that, for every timestep t , the maintained assignment A^t has overhead $O(\log(T), \log|M|)$. In other words, for every $t \in T$ and every $x \in M$, we want to show that

$$\deg_{A^t}(x) \leq \text{target}^t(x) \cdot O(\log(T)) + O(\log|M|).$$

By Lemma 18, it suffices to show that

$$\overline{\deg}_{A^t}(x) \leq \text{target}^t(x) \cdot O(\log(T)) + O(\log|M|).$$

By Lemmas 20 and 21,

$$\begin{aligned} & \mathbb{P}[\overline{\deg}_{A^t}(x) \geq 2\log(t) \cdot \text{target}^t(x) + O(\log|M|)] \\ & \leq \mathbb{P}[\widehat{\deg}_{A^t}(x) \geq 2\log(t) \cdot \text{target}^t(x) + O(\log|M|)] && \text{(Lemma 20)} \\ & \leq 1/|M|^{10}. && \text{(Lemma 21)} \end{aligned}$$

Now we apply union bound to the probability above. There are $T \leq |M|$ timesteps and $|M|$ machines, hence the probability that a bad event happens is bounded by $\frac{T|M|}{|M|^{10}} = \frac{1}{|M|^8}$. Here, we conclude the proof of Lemma 14. \blacktriangleleft

7 Conclusion

In this paper, we study fully dynamic spanner algorithms against an adaptive adversary. Our algorithm in Theorem 1 maintains a spanner with near-optimal stretch-size trade-off using only $O(\log n)$ amortized recourse. This closes the current oblivious-vs-adaptive gap with respect to amortized recourse. Whether the gap can be closed for *worst-case recourse* is an interesting open problem.

The ultimate goal is to show algorithms against an adaptive adversary with polylogarithmic amortized update time or even worst-case. Via the multiplicative weight update framework [39, 41], such algorithms would imply $O(k)$ -approximate multi-commodity flow algorithm with $\tilde{O}(n^{2+1/k})$ time which would in turn improve the state-of-the-art. We made partial progress toward this goal by showing the first dynamic 3-spanner algorithms against an adaptive adversary with $\tilde{O}(\sqrt{n})$ update time in Theorem 3 and *simultaneously* with $\tilde{O}(1)$ amortized recourse in Theorem 2, improving upon the $O(n)$ amortized update time since the 15-year-old work by [5].

Generalizing our Theorem 3 to dynamic $(2k - 1)$ -spanners of size $\tilde{O}(n^{1+1/k})$, for any $k \geq 2$, is also a very interesting and challenging open question.

Abstract

Given a metric space $\mathcal{M} = (X, \delta)$, a weighted graph G over X is a metric t -spanner of \mathcal{M} if for every $u, v \in X$, $\delta(u, v) \leq \delta_G(u, v) \leq t \cdot \delta(u, v)$, where δ_G is the shortest path metric in G . In this paper, we construct spanners for finite sets in metric spaces in the online setting. Here, we are given a sequence of points (s_1, \dots, s_n) , where the points are presented one at a time (i.e., after i steps, we have seen $S_i = \{s_1, \dots, s_i\}$). The algorithm is allowed to add edges to the spanner when a new point arrives, however, it is not allowed to remove any edge from the spanner. The goal is to maintain a t -spanner G_i for S_i for all i , while minimizing the number of edges, and their total weight.

Under the L_2 -norm in \mathbb{R}^d for arbitrary constant $d \in \mathbb{N}$, we present an online $(1 + \varepsilon)$ -spanner algorithm with competitive ratio $O_d(\varepsilon^{-d} \log n)$, improving the previous bound of $O_d(\varepsilon^{-(d+1)} \log n)$. Moreover, the spanner maintained by the algorithm has $O_d(\varepsilon^{1-d} \log \varepsilon^{-1}) \cdot n$ edges, almost matching the (offline) optimal bound of $O_d(\varepsilon^{1-d}) \cdot n$. In the plane, a tighter analysis of the same algorithm provides an almost quadratic improvement of the competitive ratio to $O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n)$, by comparing the online spanner with an instance-optimal spanner directly, bypassing the comparison to an MST (i.e., lightness). As a counterpart, we design a sequence of points that yields a $\Omega_d(\varepsilon^{-d})$ lower bound for the competitive ratio for online $(1 + \varepsilon)$ -spanner algorithms in \mathbb{R}^d under the L_1 -norm.

Then we turn our attention to online spanners in general metrics. Note that, it is not possible to obtain a spanner with stretch less than 3 with a subquadratic number of edges, even in the offline setting, for general metrics. We analyze an online version of the celebrated greedy spanner algorithm, dubbed *ordered greedy*. With stretch factor $t = (2k - 1)(1 + \varepsilon)$ for $k \geq 2$ and $\varepsilon \in (0, 1)$, we show that it maintains a spanner with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n^{1+\frac{1}{k}}$ edges and $O(\varepsilon^{-1} n^{\frac{1}{k}} \log^2 n)$ lightness for a sequence of n points in a metric space. We show that these bounds cannot be significantly improved, by introducing an instance that achieves an $\Omega(\frac{1}{k} \cdot n^{1/k})$ competitive ratio on both sparsity and lightness. Furthermore, we establish the trade-off among stretch, number of edges and lightness for points in ultrametrics, showing that one can maintain a $(2 + \varepsilon)$ -spanner for ultrametrics with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n$ edges and $O(\varepsilon^{-2})$ lightness.

1 Introduction

Let $\mathcal{M} = (P, \delta)$ be a finite metric space. Let $G = (P, E)$ be a graph on the points of P in \mathcal{M} , where the edges are weighted with the distances between their endpoints. The graph G is a t -spanner, for $t \geq 1$, if $\delta_G(u, v) \leq t \cdot \delta(u, v)$ for all $u, v \in P$, where $\delta_G(u, v)$ is the length of the shortest path between u and v in G , and $\delta(u, v)$ is the distance between u and v in \mathcal{M} .¹ The *stretch factor* t of G is the maximum distortion between the metrics δ and δ_G . Spanners were first introduced by Peleg and Schäffer [52], and since then they have turned out to be one of the fundamental graph structures with numerous applications in the area of distributed systems and communication, distributed queuing protocol, compact routing schemes, etc. [25, 43, 53, 54].

The study of Euclidean spanners, where $P \subset \mathbb{R}^d$ with L_2 -norm, was initiated by Chew [23]. Since then a large body of research has been devoted to Euclidean spanners due to its vast range of applications across domains, such as topology control in wireless networks, efficient regression in metric spaces, approximate distance oracles, data structures, and many more [34, 38, 57, 60]. Some of the results generalize to metric spaces with constant doubling dimensions [18] (the doubling dimension of \mathbb{R}^d under L_2 -norm is $\Theta(d)$).

Lightness and *sparsity* are two fundamental parameters for spanners. The lightness of a spanner $G = (P, E)$ is the ratio $w(G)/w(MST)$ between the total weight of G and the weight of a minimum spanning tree (MST) on P . The sparsity of G is the ratio $|E(G)|/|E(MST)| \approx |E(G)|/|P|$ between the number of edges of G and an MST. Since every spanner is connected and thus contain a spanning tree, the lightness and sparsity of a spanner G , resp., are trivial lower bounds for the ratio of $w(G)$ and $|E(G)|$ to the optimum weight and the number of edges.

Online Spanners. We are given a sequence of points (s_1, \dots, s_n) in a metric space, where the points are presented one-by-one, i.e., point s_i is revealed at step i , and $S_i = \{s_1, \dots, s_i\}$ for $i \in \{1, \dots, n\}$. The objective of an online algorithm is to maintain a t -spanner G_i for S_i for all i . The algorithm is allowed to *add* edges to the spanner when a new point arrives, however it is not allowed to *remove* any edge from the spanner. Moreover, the algorithm does not know the total number of points in advance.

The performance of an online algorithm ALG is measured by comparing it with the offline optimum OPT using the standard notion of competitive ratio [17, Ch. 1]. The *competitive ratio* of an algorithm ALG is defined as $\sup_{\sigma} \frac{ALG(\sigma)}{OPT(\sigma)}$, where the supremum is taken over all input sequences σ , $OPT(\sigma)$ is the minimum weight of a t -spanner for the (unordered) set of points in σ , and $ALG(\sigma)$ denotes the weight of the t -spanner produced by ALG for this input sequence. Note that, in order to measure the competitive ratio it is important that σ is a finite sequence of points.

The online spanner problem is motivated by natural application domains. For example, consider a developing area with limited resources, where new settlements are created successively. As the community grows, new roads are built, and there is no reason to remove existing roads. Alternatively, online spanners are also motivated by distributed mobile computing, where new subscribers successively join a network. Maintaining a cost-effective network is equivalent to minimum-weight online spanner problem.

¹ Often in the literature, the input metric is the shortest path metric of a graph $G = (V, E, w)$, and a spanner is required to be a subgraph of the input graph (see e.g. [4]). Here we study metric spanners where there is no such requirement.

In the online minimum spanning tree problem, points of a finite metric space arrive one-by-one, and we need to connect each new point to a previous point to maintain a spanning tree. Imase and Waxman [44] proved $\Theta(\log n)$ -competitiveness, which is the best possible bound. Later, Alon and Azar [2] studied this problem for points in the Euclidean plane, and proved a lower bound $\Omega(\log n / \log \log n)$ for the competitive ratio. Their result was the first to analyze the impact of auxiliary points (Steiner points) on a geometric network problem in the online setting. Several algorithms were proposed over the years for the online minimum Steiner tree and Steiner forest problems, on graphs in both weighted and unweighted settings; see [1, 5, 10, 40, 50]. However, these algorithms do not provide any guarantees on the stretch factor. This leads to the following open problem.

► **Problem.** *Determine the best possible bounds for the competitive ratios for the weight and the number of edges of online t -spanners, for $t \geq 1$.*

Previously, Gupta et al. [39, Theorem 1.5] constructed online spanners for terminal pairs in the same model we consider here. The analysis of [39] implicitly implies that, given a sequence of n points in an online fashion in a general metric space, one can maintain a $O(\log n)$ -spanner with $O(n)$ edges and $O(\log n)$ lightness, as pointed out by one of the authors [59]. Recent work on online *directed* spanners [36] is not comparable to our results.

In the geometric setting, $(1 + \varepsilon)$ -spanners are possible in any constant dimension $d \in \mathbb{N}$. Tight worst-case bounds $\Theta_d(\varepsilon^{-d})$ and $\Theta_d(\varepsilon^{1-d})$ on the lightness and sparsity of offline $(1 + \varepsilon)$ -spanners have recently been established by Le and Solomon [47]. Online Euclidean spanners in \mathbb{R}^d have been introduced by Bhore and Tóth [14]. In the real line (1D), they have established a tight bound of $O((\varepsilon^{-1} / \log \varepsilon^{-1}) \log n)$ for the competitive ratio of any online $(1 + \varepsilon)$ -spanner algorithm for n points. In dimensions $d \geq 2$, the dynamic algorithm DEFSPANNER of Gao et al. [33] maintains a $(1 + \varepsilon)$ -spanner with $O_d(\varepsilon^{-(d+1)}n)$ edges and $O_d(\varepsilon^{-(d+1)} \log n)$ lightness, and works under the online model (as it never deletes edges when new points arrive). However, no lower bound better than the 1-dimensional $\Omega((\varepsilon^{-1} / \log \varepsilon^{-1}) \log n)$ is currently known in higher dimensions.

1.1 Our Contribution

See Table 1 for an overview of our results.

Upper Bounds for Points in \mathbb{R}^d . Under the L_2 -norm in \mathbb{R}^d , for arbitrary constant $d \in \mathbb{N}$, we present an online algorithm for $(1 + \varepsilon)$ -spanner with lightness $O_d(\varepsilon^{-d} \log n)$ and sparsity $O(\varepsilon^{1-d} \log \varepsilon^{-1})$ (Theorem 2 in Section 2.1). This improves upon the previous lightness bound of $O_d(\varepsilon^{-(d+1)} \log n)$ by Gao et al. [33, Lemma 3.8]. In the plane, we give a tighter analysis of the same algorithm and achieve an almost quadratic improvement of the *competitive ratio* to $O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n)$ (Theorem 6 in Section 2.2). Recall that in the offline setting, $\Theta(\varepsilon^{-2})$ is a tight worst-case bound for the lightness of a $(1 + \varepsilon)$ -spanner in the plane [47]. We obtain a better dependence on ε by comparing the online spanner with an instance-optimal spanner directly, bypassing the comparison to an MST (i.e., lightness). The logarithmic dependence on n cannot be eliminated in the online setting, based on the lower bound in \mathbb{R}^1 [14].

Lower Bounds for Points in \mathbb{R}^d . As a counterpart, we design a sequence of points that yields a $\Omega_d(\varepsilon^{-d})$ lower bound for the competitive ratio for online $(1 + \varepsilon)$ -spanner algorithms in \mathbb{R}^d under the L_1 -norm (Theorem 13 in Section 3). This improves the previous bound of $\Omega(\varepsilon^{-2} / \log \varepsilon^{-1})$ in \mathbb{R}^2 under the L_1 -norm [14]. It remains open whether a similar lower bound holds in \mathbb{R}^d under the L_2 -norm; the current best lower bound is $\Omega((\varepsilon^{-1} / \log \varepsilon^{-1}) \log n)$, established in [14], holds already for the real line ($d = 1$).

■ **Table 1** Overview of online spanners algorithms. In the last three rows, we compare the spanner weight directly with the optimum weight (rather than the MST) to bound the competitive ratio.

Points in General Metrics. In Section 4, we study online spanners in general metrics. Note that it is not possible to obtain a spanner with stretch less than 3 with a subquadratic number of edges, even in the offline settings, for general metrics. We analyze an online version of the celebrated greedy spanner algorithm, dubbed *ordered greedy*. With stretch factor $t = (2k - 1)(1 + \varepsilon)$ for $k \geq 2$ and $\varepsilon \in (0, 1)$, we show that it maintains a spanner with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n^{1+\frac{1}{k}}$ edges and $O(\varepsilon^{-1} n^{\frac{1}{k}} \log^2 n)$ lightness for a sequence of n points in a metric space (Theorem 14). We show (in Theorem 19) that these bounds cannot be significantly improved, by introducing an instance where every online algorithm will have $\Omega(\frac{1}{k} \cdot n^{1/k})$ competitive ratio on both sparsity and lightness. Next, we establish the trade-off among stretch, number of edges and lightness for points in ultrametrics. Specifically, we show (in the full paper) that it is possible to maintain a $(2 + \varepsilon)$ -spanner with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n$ edges and $O(\varepsilon^{-2})$ lightness in ultrametrics. Note that as the uniform metric (shortest path on a clique) is an ultrametric, any subquadratic spanner must have stretch at least 2.

1.2 Related Work

1.2.1 Dynamic & Streaming Algorithms for Graph Spanners

A t -spanner in a graph $G = (V, E)$ is a subgraph $H = (V, E')$ such that $\delta_H(u, v) \leq t \cdot \delta_G(u, v)$ for all pairs of vertices $u, v \in V$. That is, the stretch t is the maximum distortion between the graph distances δ_G and δ_H . Importantly, when G changes (under edge/vertex insertions or deletions), the underlying metric δ_G changes, as well. The distance $\delta_G(u, v)$ may dramatically decrease upon the insertion of the edge uv . In contrast, our model assumes that the distances in the underlying metric space $\mathcal{M} = (P, \delta)$ remain fixed, but the algorithm can only see the distances between the points that have been presented. For this reason, our results are not directly comparable to models where the underlying graph changes dynamically.

For *unweighted* graphs with n vertices, the current best fully dynamic and single-pass streaming algorithms can maintain spanners that achieve almost the same stretch-sparsity trade-off available for the static case: $2k - 1$ stretch and $O(n^{1+\frac{1}{k}})$ edges, for $k \geq 1$, which is

attained by the greedy algorithm [4], and conjectured to be optimal due to the Erdős girth conjecture [28]. In the dynamic model, the objective is design algorithms and data structures that minimize the worst-case update time needed to maintain a t -spanner for S over all steps, regardless of its weight, sparsity, or lightness. See [7, 9, 11, 16] for some excellent work on dynamic spanners. In the streaming model the input is a sequence (or stream) of edges representing the edge set E of the graph G . A (single-pass) streaming algorithm decides, for each newly arriving edge, whether to include it in the spanner. The graph G is too large to fit in memory, and the objective is to optimize work space and update time [6, 8, 26, 29, 30, 49].

1.2.2 Incremental Algorithms for Geometric Spanners

We briefly review three previously known incremental $(1 + \varepsilon)$ -spanner algorithms in Euclidean d -space from the perspective of competitive analysis.

Deformable Spanners. Gao et al. [33] designed a dynamic DEFSPANNER algorithm that maintains a $(1 + \varepsilon)$ -spanner for a dynamic set S in the Euclidean d -space. For point insertions, it only adds new edges, so it is an online algorithm, as well. It maintains a $(1 + \varepsilon)$ -spanner with $O_d(\varepsilon^{-d}) \cdot n$ edges and $O_d(\varepsilon^{-(d+1)} \log n)$ lightness. Since the $\|\text{MST}(S)\|$ is a lower bound for the optimal spanner weight, its competitive ratio is also $O_d(\varepsilon^{-(d+1)} \log n)$. The key ingredient of DEFSPANNER is *hierarchical nets* [42, 46, 55], a form of hierarchical clustering, which can be maintained dynamically. Hierarchical nets naturally generalize to doubling spaces, and so DEFSPANNER also maintains a $(1 + \varepsilon)$ -spanner with $\varepsilon^{-O(d)} \cdot n$ edges and $\varepsilon^{-O(d)} \cdot \log n$ lightness for doubling dimension d [35, 55].

Well-Separated Pair Decomposition (WSPD). Well-separated pair decomposition was introduced by Callahan and Kosaraju [21] (see also [37, 41, 51, 58]). For a set S in a metric space, a WSPD is a collection of unordered pairs $W = \{\{A_i, B_i\} : i \in I\}$ such that (1) $A_i, B_i \subset S$ for all $i \in I$; (2) $\min\{\|ab\| : a \in A_i, b \in B_i\} \leq \varrho \cdot \max\{\text{diam}(A_i), \text{diam}(B_i)\}$ for all $i \in I$, where ϱ is the *separation ratio*; (3) for each point pair $\{a, b\} \subset S$ there exists a pair $\{A_i, B_i\}$ such that A_i and B_i each contain one of a and b . Given a WSPD with separation ratio $\varrho > 4$, any graph that contains at least one edge between A_i and B_i , for all $i \in I$, is a spanner with stretch $t = 1 + 8/(\varrho - 4)$. Setting $\varrho \geq 12\varepsilon^{-1}$ for $0 < \varepsilon < 1$, we obtain $t \leq 1 + \varepsilon$.

Hierarchical clustering provides a WSPD [41, Ch. 3]. Perhaps the simplest hierarchical subdivisions in \mathbb{R}^d are quadtrees. Let \mathcal{T} be a quadtree for a finite set $S \subset \mathbb{R}^d$. The root of \mathcal{T} is an axis-aligned cube of side length a_0 , which contains S ; it is recursively subdivided into 2^d congruent cubes until each leaf cube contains at most one point in S . For all pairs of cubes $\{Q_1, Q_2\}$ at level ℓ of \mathcal{T} , create a pair $\{A_i, B_i\}$ with $A_i = Q_1 \cap S$ and $B_i = Q_2 \cap S$ whenever $D_\ell \leq \text{dist}(Q_1, Q_2) < 2D_\ell$ for $D_\ell = \varrho \cdot \text{diam}(Q_1) = 12\varepsilon^{-1} \cdot \sqrt{d} \cdot a_0 / 2^\ell$; and repeat for all levels $\ell \geq 0$. Properties (1)–(3) of a WSPD are easily verified [41, Ch. 3]. The resulting $(1 + \varepsilon)$ -spanner has $O_d(\varepsilon^{-d}) \cdot n$ edges [41, 42] and lightness $O_d(\varepsilon^{-(d+1)} \log n)$ [14].

For point insertions in \mathbb{R}^d , a dynamic quadtree only adds nodes, which in turn creates new pairs in the WSPD, and new edges in the spanner. This is an online algorithm with the same guarantees as DEFSPANNER [14, 42] (see also [32] for an efficient implementation).

Ordered Yao-Graphs and Θ -Graphs. Among the first constructions for (offline) sparse $(1 + \varepsilon)$ -spanners in the Euclidean d -space were Yao- and Θ -graphs [24, 45, 56]. Incremental versions of Yao-graphs and Θ -graphs were introduced by Bose et al. [20]. Let $S = \{s_1, \dots, s_n\}$ be an ordered set of points in \mathbb{R}^2 . For each $s_i \in S$, partition the plane into k cones with apex s_i and aperture $2\pi/k$. The *ordered Yao-graph* $Y_k(S)$ contains an edge between s_i and

a closest *previous* point in $\{s_j : j < i\}$ in each cone. The graph $\Theta_k(S)$ is defined similarly, but in each cone the distance to the apex is measured by the orthogonal projection to a ray within the cone. Bose et al. [20] showed that the ordered Yao- and Θ -graphs have spanning ratio at most $1/(1 - 2\sin(\pi/k))$ for $k > 8$; tighter bounds were later obtained in [19]. In particular, the ordered Yao- and Θ -graphs are $(1 + \varepsilon)$ -spanners for $k \geq \Omega(\varepsilon^{-1})$.

The construction generalizes to \mathbb{R}^d for all $d \in \mathbb{N}$ [56]. For an angle $\alpha \in (0, \pi)$, let $A \subset \mathbb{S}^{d-1}$ be a maximal set of points in the $(d-1)$ -sphere such that $\min_{a,b \in A} \text{dist}(a,b) \leq \alpha$ (in radians). A standard volume argument shows that $|A| \leq O_d(\alpha^{1-d})$. For each $a_i \in A$, create a cone C_i with apex at the origin o , aperture α , and symmetry axis oa_i . Note that $\mathbb{R}^d \subseteq \bigcup_i C_i$. Given a finite set $P \subset \mathbb{R}^d$, we translate each cone C_i to a cone $C_i(p)$ with apex $p \in P$. For every cone $C_i(p)$, the Yao-graph contains an edge between p and a closest point in $P \cap C_i(p)$. For every $\varepsilon > 0$ and $d \in \mathbb{N}$, there exists an angle $\alpha = \alpha(d, \varepsilon) = \Theta_d(\varepsilon)$ for which the Yao-graph is a $(1 + \varepsilon)$ -spanner for every finite set $P \subset \mathbb{R}^d$.

Ordered Yao- and Θ -graphs give online algorithms for maintaining a $(1 + \varepsilon)$ -spanner for a sequence of points in \mathbb{R}^d . The sparsity of these spanners is bounded by the number of cones per vertex, $O_d(\varepsilon^{1-d})$, which matches the (offline) lower bound of $\Omega_d(\varepsilon^{1-d})$ [47]. However, their weight may be significantly higher than optimal: For n equally spaced points in a unit circle, in any order, Yao- and Θ -graphs yield $(1 + \varepsilon)$ -spanners of weight $\Omega(\varepsilon^{-1}) \cdot n$, hence lightness $\Omega(\varepsilon^{-1}) \cdot n$, while the optimum weight is $O(\varepsilon^{-2})$ [47].

Online Steiner Spanners. An important variant of online spanners is when it is allowed to use auxiliary points (Steiner points) which are not part of the input sequence of points, but are present in the metric space. An online algorithm is allowed *add* Steiner points, however, the spanner must achieve the given stretch factor only for the input point pairs. It has been observed through a series of work in recent years, that Steiner points allow for substantial improvements over the bounds on the sparsity and lightness of Euclidean spanners in the offline settings. Highly nontrivial insights are required to argue the bounds for Steiner spanners, and often they tend to be even more intricate than their non-Steiner counterpart; see [12, 13, 47, 48]. Bhore and Tóth [14] showed that if an algorithm can use Steiner points, then the competitive ratio for weight improves to $O(\varepsilon^{(1-d)/2} \log n)$ in the Euclidean d -space.

2 Upper Bounds in Euclidean Spaces

We present an online algorithm for a sequence of n points in the Euclidean d -space (Section 2.1). It combines features from several previous approaches, and maintains a $(1 + \varepsilon)$ -spanner of lightness $O_d(\varepsilon^{-d} \log n)$ and sparsity $O_d(\varepsilon^{1-d} \log \varepsilon^{-1})$ for $d \geq 1$. Lightness is an upper bound for the competitive ratio for weight; the sparsity almost matching the optimal bound $O_d(\varepsilon^{1-d})$ attained by ordered Yao-graphs. In the plane ($d = 2$), we show that the same algorithm achieves competitive ratio $O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n)$ using a tighter analysis: A charging scheme that charges the weight of the online spanner to a minimum weight spanner (Section 2.2).

2.1 An Improvement in All Dimensions

We combine features from two incremental algorithms for geometric spanners, and obtain an online $(1 + \varepsilon)$ -spanner algorithm for a sequence of n points in \mathbb{R}^d . We maintain a dynamic quadtree for hierarchical clustering, and use a modified ordered Yao-graph in each level of the hierarchy. In particular, we limit the weight of the edges in the Yao-graph in each level of the hierarchy (thereby avoiding heavy edges). We start with an easy observation.

► **Lemma 1.** *Let $G = (S, E)$ be a t -spanner and let $w > 0$. Let $G' = (S, E')$, where $E' = \{e \in E : \|e\| \leq w\}$ is the set of edges of weight at most w . Then for every $a, b \in S$ with $\|ab\| < w/t$, graph G' contains an ab -path of weights at most $t\|ab\|$.*

Proof. Since G is a t -spanner, it contains an ab -path P_{ab} of weight at most $t\|ab\| \leq w$. By the triangle inequality, every edge in this path has weight at most w , hence present in G' . Consequently G' contains P_{ab} . ◀

The input is a sequence of points (s_1, s_2, \dots) in \mathbb{R}^d , $d \geq 1$. The set of the first n points is denoted by $S_n = \{s_i : 1 \leq i \leq n\}$. For every n , we dynamically maintain a quadtree \mathcal{T}_n for S_n . Every node of \mathcal{T}_n corresponds to a cube. The root of \mathcal{T}_n , at level 0, corresponds to a cube Q_0 of side length $a_0 = \Theta(\text{diam}(S_n))$. At every level $\ell \geq 0$, there are at most $2^{d\ell}$ interior-disjoint cubes, each of side length $a_\ell = a_0 2^{-\ell}$. A cube $Q \in \mathcal{T}_n$ is *nonempty* if $Q \cap S_n \neq \emptyset$. For every nonempty cube Q , we maintain a representative $s(Q) \in Q \cap S_n$, selected at the time when Q becomes nonempty. At each level ℓ , let P_ℓ be the sequence of representatives, in the order in which they are created.

For each level ℓ , we maintain a modified ordered Yao-graph $G_\ell = (P_\ell, E_\ell)$ as follows. When a new point p is inserted into P_ℓ , cover \mathbb{R}^d with $\Theta_d(\varepsilon^{1-d})$ cones of aperture $\alpha(d, \varepsilon)$ as in the construction of Yao-graphs. In each cone C_i , find a point $q_i \in C_i \cap P_\ell$ closest to p ; and add pq_i to E_ℓ if $\|pq_i\| < 24a_\ell\sqrt{d} \cdot \varepsilon^{-1}$. The algorithm maintains the spanner $G = \bigcup_{\ell \geq 0} G_\ell$.

► **Theorem 2.** *Let $d \geq 1$ and $\varepsilon \in (0, 1)$. The online algorithm ALG_1 maintains, for a sequence of n points in Euclidean d -space, an $(1 + O(\varepsilon))$ -spanner with weight $O_d(\varepsilon^{-d} \log n) \cdot \|MST\|$ and $O_d(\varepsilon^{1-d} \log \varepsilon^{-1}) \cdot n$ edges.*

Note that Theorem 2 implies that the competitive ratio of this algorithm is also $O_d(\varepsilon^{-d} \log n)$.

Proof.

Stretch Analysis. We give a bound on the stretch factor in two steps: First, we define an auxiliary graph $H = (S, E')$ which is a $(1 + \varepsilon)$ -spanner for S by the analysis of WSPDs. Then we show that G contains an ab -path of weight at most $(1 + \varepsilon)\|ab\|$ for each edge of H . Overall, the stretch of G is at most $(1 + \varepsilon)^2 = (1 + O(\varepsilon))$ for all $a, b \in S$.

First Layer: WSPD. For each level $\ell \geq 0$, let $H_\ell = (P_\ell, E'_\ell)$ be the graph that contains an edge between two representatives $a, b \in P_\ell$ whenever $\|ab\| \leq 12a_\ell\sqrt{d} \cdot \varepsilon^{-1}$. Let $H = \bigcup_{\ell \geq 0} H_\ell$. The auxiliary graph H_ℓ contains an edge between the representatives of any such pair of cubes at level ℓ . As noted Section 1.2.2, $H = \bigcup_{\ell \geq 0} H_\ell$ is a $(1 + \varepsilon)$ -spanner (cf. [41, 42]).

Second Layer: Near-Sighted Yao-graphs. As H is a $(1 + \varepsilon)$ -spanner, for every $a, b \in S_n$, it contains an ab -path of weight at most $(1 + \varepsilon)\|ab\|$. Consider such a path $P_{ab} = (a = p_0, \dots, p_m = b)$. Each edge $p_{i-1}p_i$ is in H_ℓ for some $\ell \geq 0$. By construction, every edge in H_ℓ has weight at most $12a_\ell\sqrt{d} \cdot \varepsilon^{-1}$. For every level ℓ , the ordered Yao-graph $Y(P_\ell)$ with angle $\alpha(d, \varepsilon)$ is a $(1 + \varepsilon)$ -spanner. The graph $G_\ell = (P_\ell, E_\ell)$ constructed by ALG_1 at level ℓ is a subgraph of $Y(P_\ell)$. By Lemma 1, for every $p, q \in P_\ell$ with $\|pq\| \leq 12a_\ell\sqrt{d} \cdot \varepsilon^{-1}$, graph G_ℓ contains a pq -path of weight at most $(1 + \varepsilon)\|pq\|$.

Overall, H contains an ab -path $P_{ab} = (p_0, \dots, p_m)$ of weight at most $(1 + \varepsilon)\|ab\|$. For each edge $p_{i-1}p_i$ of P_{ab} , graph G contains a $p_{i-1}p_i$ -path of weight $(1 + \varepsilon)\|p_{i-1}p_i\|$. The concatenation of these paths is an ab -path of weight $(1 + \varepsilon)^2\|ab\| \leq (1 + O(\varepsilon))\|ab\|$.

Weight Analysis. We may assume w.l.o.g. that the root of the quadtree \mathcal{T}_n is the unit cube $[0, 1]^d \subset \mathbb{R}^d$, which has diameter \sqrt{d} . This implies $\text{diam}(S_n) \leq \sqrt{d} = O_d(1)$. Assume further that $n > 1$, and $\frac{1}{4} \leq \text{diam}(S_n) \leq \|MST(S_n)\|$.

Every edge in E_ℓ at level ℓ has weight $O_d(\varepsilon^{-1} 2^{-\ell})$. In particular, every edge at level $\ell \geq 2 \log n$ has weight $O_d(\varepsilon^{-1}/n^2)$; and the total weight of these edges is $O_d(\varepsilon^{-1}) \leq O_d(\varepsilon^{-1} \|MST(S_n)\|)$.

It remains to bound the weight of the edges on levels $\ell = 1, \dots, \lfloor 2 \log n \rfloor$. At level ℓ of the quadtree \mathcal{T}_n , there are at most $2^{d\ell}$ nodes, hence $|P_\ell| \leq 2^{d\ell}$. If $|P_\ell| < 3^d$, then G_ℓ has at most $O(3^{2d}) = O_d(1)$ edges, each of weight at most $\text{diam}(P_\ell) \leq \text{diam}(S_n) \leq \|MST(S_n)\|$, and so $\|E_\ell\| \leq O_d(\|MST(S_n)\|)$. Assume now that $|G_\ell| \geq 3^d$. By the definition of ordered Yao-graphs, each vertex inserted into P_ℓ adds $\Theta(\varepsilon^{1-d})$ new edges, each of weight $O(\varepsilon^{-1} 2^{-\ell})$. The total weight of the edges in G_ℓ is at most

$$\|E_\ell\| \leq |P_\ell| \cdot \varepsilon^{1-d} \cdot \max_{e \in E_\ell} \|e\| \leq O_d(|P_\ell| \varepsilon^{-d} 2^{-\ell}). \quad (1)$$

We next derive a lower bound for $\|MST(S_n)\|$ in terms of $|P_\ell|$, when $|P_\ell| > 1$ and $\ell > 2$, using a standard volume argument. Define a graph on the vertex set P_ℓ such that two nodes $p, q \in P_\ell$ are adjacent iff p and q lie in neighboring quadtree cells of level ℓ . Since every quadtree cell has $3^d - 1$ neighbors, this graph is $(3^d - 1)$ -degenerate, and contains an independent set I_ℓ of size at least $(3^d - 1)^{-1} |P_\ell| = \Omega_d(|P_\ell|)$. The distance between any two disjoint quadtree cells at level ℓ is at least $2^{-\ell}$. Consequently, the open balls of radius $2^{-(\ell+1)}$ centered at the points in I_ℓ are pairwise disjoint. None of the balls contains S_n for $\ell > 2$, as the diameter of each of ball is $2^{-\ell}$ while $\text{diam}(S_n) \geq \frac{1}{4}$. For all $\ell > 2$, $MST(S_n)$ contains the center of each ball and a point in its exterior; hence the intersection of $MST(S_n)$ and each ball contains a path from the center to a boundary point, which has weight at least $2^{-(\ell+1)}$. Summation over $|I_\ell|$ disjoint balls yields

$$\|MST(S_n)\| \geq |I_\ell| \cdot 2^{-(\ell+1)} \geq \Omega_d(|P_\ell| 2^{-\ell}). \quad (2)$$

Comparing inequalities (1) and (2), we obtain $\|E_\ell\| \leq O_d(\varepsilon^{-d}) \cdot \|MST(S_n)\|$. Summation over all levels $\ell \in \mathbb{N}$ yields $\|E\| \leq O_d(\varepsilon^{-d} \log n) \cdot \|MST(S_n)\|$, as claimed.

Sparsity Analysis. In the full paper, we show that G has $O(\varepsilon^{1-d} \log \varepsilon^{-1}) \cdot n$ edges. ◀

2.2 Further Improvements in the Plane

We presents a tighter analysis of algorithm ALG_1 for $d = 2$ that compares the spanner weight to the offline optimum weight, and bypasses the comparison with the MST (i.e., lightness).

Minimum-Weight Euclidean $(1 + \varepsilon)$ -Spanner. For any $a, b \in \mathbb{R}^d$, an ab -path P_{ab} of Euclidean weight at most $(1 + \varepsilon)\|ab\|$ lies in the ellipsoid \mathcal{E}_{ab} with foci a and b and great axes of weight $(1 + \varepsilon)\|ab\|$; see Figure 1. A key observation is that the minor axis of \mathcal{E}_{ab} is $((1 + \varepsilon)^2 - 1^2)^{1/2} \|ab\| \approx \sqrt{2\varepsilon} \|ab\|$. Furthermore, Bhore and Tóth [13] recently observed that the directions of “most” edges of the path P_{ab} are “close” to the direction of ab . Specifically, if we denote by $E(\alpha)$ the set of edges e in P_{ab} with $\angle(ab, e) \leq \alpha$, then the following holds.

► **Lemma 3** (Bhore and Tóth [13]). *Let $a, b \in \mathbb{R}^d$ and let P_{ab} be an ab -path of weight $\|P_{ab}\| \leq (1 + \varepsilon)\|ab\|$. Then for every $i \in \{1, \dots, \lfloor 1/\sqrt{\varepsilon} \rfloor\}$, we have $\|E(i \cdot \sqrt{\varepsilon})\| \geq (1 - 2/i^2) \|ab\|$.*

Let $R(a, b) = \mathcal{E}_{ab} \cap \mathcal{N}(a, b)$, where $\mathcal{N}(a, b)$ is the annulus bounded by two concentric spheres centered at a , of radii $\frac{1+\varepsilon}{2} \|ab\|$ and $\|ab\|$; see Figure 1 for an example.

■ **Figure 1** Any ab -path of weight at most $(1 + \varepsilon)\|ab\|$ lies in the ellipse \mathcal{E}_{ab} with foci a and b . The shaded region $R(a, b)$ is the part of the ellipse \mathcal{E}_{ab} between two concentric circles centered at a .

► **Lemma 4.** *If $0 < \varepsilon < \frac{1}{9}$, then every ab -path P_{ab} of weight at most $\|P_{ab}\| \leq (1 + \varepsilon)\|ab\|$ contains interior-disjoint line segments $s \subset R(a, b)$ of total weight at least $\frac{1}{9}\|ab\|$ such that $\angle(\vec{ab}, s) \leq 3 \cdot \sqrt{\varepsilon}$.*

Proof. Since the distance between the two concentric circles is $\frac{1-\varepsilon}{2}\|ab\|$, every ab -path contains a subpath of weight at least $\frac{1-\varepsilon}{2}\|ab\|$ in the annulus $\mathcal{N}(a, b)$.

Let P_{ab} be an ab -path of weight at most $(1 + \varepsilon)\|ab\|$. As noted above $P_{ab} \subset \mathcal{E}_{ab}$. Hence, $\|P_{ab} \cap \mathcal{N}(a, b)\| = \|P_{ab} \cap R(a, b)\| \geq \frac{1-\varepsilon}{2}\|ab\|$ in $R(a, b)$; and so $\|P_{ab} \setminus R(a, b)\| = \|P_{ab}\| - \|P_{ab} \cap R(a, b)\| \leq \frac{1+3\varepsilon}{2}\|ab\|$.

Applying Lemma 3 with $i = 3$, the total weight of the edges e of P_{ab} with $\text{dir}(ab, e) \leq 3 \cdot \sqrt{\varepsilon}$ is at least $\frac{7}{9}\|ab\|$. The parts of these edges lying outside of $R(a, b)$ have weight at most $\|P_{ab} \setminus R(a, b)\| \leq \frac{1+3\varepsilon}{2}\|ab\|$. Consequently, the remaining part of these edges are in $R(a, b)$, and their weight is at least $(\frac{7}{9} - \frac{1+3\varepsilon}{2})\|ab\| = \frac{5-27\varepsilon}{18}\|ab\| > \frac{1}{9}\|ab\|$ if $\varepsilon < \frac{1}{9}$, as claimed ◀

We also need an observation from elementary geometry; see Figure 1.

► **Lemma 5.** *For $a, b \in \mathbb{R}^d$, let cd be the minor axis of the ellipsoid \mathcal{E}_{ab} . Then $\angle cad \leq \sqrt{8\varepsilon}$.*

Proof. We may assume w.l.o.g. that $\|ab\| = 1$. Let o be the center of the ellipsoid \mathcal{E}_{ab} . Then $\sec \angle cao = (\cos \angle cao)^{-1} = \frac{\|ac\|}{\|ao\|} = 1 + \varepsilon$. The Taylor estimate $\sec(x) = 1 + \frac{1}{2}x^2 + \frac{5}{24}x^4 + \dots \geq 1 + \frac{1}{2}x^2$ for $0 < x < 1$ yields $\angle cao \leq \sqrt{2\varepsilon}$. Consequently, $\angle cad = 2\angle cao \geq \sqrt{8\varepsilon}$. ◀

► **Theorem 6.** *Let $d = 2$ and $\varepsilon \in (0, 1)$. The online algorithm ALG_1 maintains, for a sequence of n points in Euclidean plane, an $(1 + \varepsilon)$ -spanner of weight $O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n) \cdot \text{OPT}$, where OPT denotes the minimum weight of an $(1 + \varepsilon)$ -spanner for the same point set.*

Proof. Theorem 2 has established that algorithm ALG_1 maintains a $(1 + \varepsilon)$ -spanner. The tighter competitive analysis uses Lemmas 4 and 5.

Competitive Analysis. Assume w.l.o.g. that $\text{diam}(S_n) = \Theta(1)$, hence the side length of every quadtree square at level ℓ is $\Theta(2^{-\ell})$. For a set $S_n = \{s_1, \dots, s_n\} \subset \mathbb{R}^2$, let $G^* = (S_n, E^*)$ be a $(1 + \varepsilon)$ -spanner of minimum weight, and let $\text{OPT} = \|G^*\|$. Let $G = (S_n, E)$ be the spanner returned by the online algorithm ALG_1 . Recall that $G = \bigcup_{\ell \geq 0} G_\ell$, where the total weight of all edges at levels $\ell > 2 \log n$ is less than $\text{diam}(S_n)$, so it is enough to consider $\ell = 0, \dots, \lceil 2 \log n \rceil$.

▷ **Claim 7.** $\|G_\ell\| \leq O(\varepsilon^{-3/2} \log \varepsilon^{-1}) \cdot \text{OPT}$ for all $\ell \geq 0$.

Claim 7 immediately implies $\|G\| \leq O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n) \cdot \text{OPT}$. For every level $\ell \geq 0$, $G_\ell = (P_\ell, E_\ell)$ is a graph on the representatives P_ℓ . Note that G^* is a Steiner spanner with respect to the point set P_ℓ , as G^* is a spanner on all n points of the input.

We prove Claim 7 using a charging scheme: We charge the weight of every edge in G_ℓ to G^* (more precisely, to line segments along the edges of G^*), and then show that each line segment of weight w in G^* receives $O(\varepsilon^{-3/2} \log \varepsilon^{-1}) \cdot w$ charge. For every point $p \in P_\ell$,

algorithm ALG_1 greedily covers \mathbb{R}^2 by $\Theta(\varepsilon^{-1})$ cones of aperture $\pi/k = \Theta(\varepsilon^{-1})$ and apex p , and adds an edge pq_i in each nonempty cone C_i . For the competitive analysis, we greedily cover \mathbb{R}^2 by $\Theta(\varepsilon^{-1/2})$ cones of aperture $\sqrt{\varepsilon}$ and apex p . We use translates of the same cone cover for all $p \in P_\ell$. Standard volume argument implies that a cone of aperture $\sqrt{\varepsilon}$ intersects $O(\varepsilon^{-1/2})$ cones of aperture $\Theta(\varepsilon^{-1})$. We describe the charging scheme for each such cone \widehat{C} .

Charging Scheme. Consider a cone \widehat{C} with apex p and aperture $\sqrt{\varepsilon}$. Let $E(\widehat{C})$ be the set of edges pq , $q \in \widehat{C}$ that algorithm ALG_1 adds to G_ℓ when p is inserted into P_ℓ . Since \widehat{C} intersects $O(\varepsilon^{-1/2})$ cones of the ordered Yao-graph, then $|E(\widehat{C})| \leq O(\varepsilon^{-1/2})$. By construction, every edge in G_ℓ has weight at most $O(\varepsilon^{-1}2^{-\ell})$. Hence

$$\|E(\widehat{C})\| = \sum_{pq \in E(\widehat{C})} \|pq\| \leq |E(\widehat{C})| \cdot O(\varepsilon^{-1}2^{-\ell}) \leq O(\varepsilon^{-3/2}2^{-\ell}). \quad (3)$$

Let $q_0 = q_0(\widehat{C})$ be a closest point in $P_\ell \cap \widehat{C}$ to p . (Possibly, q_0 arrived after p .) We distinguish between two cases:

Case 1: $\|pq_0\| < 2 \cdot 2^{-\ell}$. Since $q_0 \in P_\ell$, and P_ℓ contains at most one point in each quadtree cell of side length $\Theta(2^{-\ell})$, this case occurs at most $O(1)$ times per apex p . On the one hand, the summation of (3) over all $p \in P_\ell$ and all cones \widehat{C} with $\|pq_0\| < 2 \cdot 2^{-\ell}$ is bounded by $O(|P_\ell| \cdot \varepsilon^{-3/2}2^{-\ell})$. On the other hand, $\text{OPT} \geq \Omega(\|\text{MST}(P_\ell)\|) \geq \Omega(|P_\ell| \cdot 2^{-\ell})$. Consequently, the total weight of all edges handled in Case 1 is $O(\varepsilon^{-3/2}) \text{OPT}$.

Case 2: $\|pq_0\| \geq 2 \cdot 2^{-\ell}$. The optimal spanner G^* contains a pq_0 -path P_0 of weight at most $(1 + \varepsilon)\|pq_0\|$. Recall P_0 lies in the ellipse \mathcal{E}_0 with foci p and q_0 , and $R(p, q_0)$ is the half of \mathcal{E}_0 that contains q_0 (cf. Figure 1). Let $E^*(\widehat{C})$ be the set of maximal line segments e along edges in E^* such that $e \subset P_0 \cap R(p, q_0)$ and $\angle(e, pq_0) \leq 3 \cdot \sqrt{\varepsilon}$. By Lemma 4, we have $\|E^*(\widehat{C})\| \geq \frac{1}{9}\|pq_0\|$. We distribute the weight of all edges in $E(\widehat{C})$ uniformly among the line segments in $E^*(\widehat{C})$. That is, each segment of weight w in $E^*(\widehat{C})$ receives a charge of

$$\frac{\|E(\widehat{C})\|}{\|E^*(\widehat{C})\|} \cdot w \leq \frac{O(\varepsilon^{-3/2}2^{-\ell})}{\Omega(2^{-\ell})} \cdot w \leq O(\varepsilon^{-3/2}) \cdot w. \quad (4)$$

This completes the description of the charging scheme in Case 2.

Charges Received. A point along an edge of the optimal spanner G^* may receive charges from several cones \widehat{C} , possibly with different apices $p \in P_\ell$. Let L be a maximal line segment along an edge of G^* such that every point in L receives the same charges.

For a cone \widehat{C} of aperture $\sqrt{\varepsilon}$, let \widehat{K} denote a cone with the same apex and axis as \widehat{C} , but aperture $3\sqrt{\varepsilon}$; refer to Figure 2.

▷ **Claim 8.** If L receives charges from \widehat{C} , then $L \subset \widehat{K}$.

Indeed, if L receive charges from \widehat{C} , then $L \subset R(p, q_0) \subset \mathcal{E}_0$, where \mathcal{E}_0 is the ellipse with foci p and the closest point $q_0 \in \widehat{C} \cap P_\ell$. By Lemma 5, $R(p, q_0)$ lies in a cone with apex p , aperture $2\sqrt{\varepsilon}$, and axis pq_0 . Consequently $L \subset R(p, q_0) \subset \widehat{K}$, which proves Claim 8.

Note that if L receives positive charge from a cone \widehat{C} with apex p and closest point q_0 , then $\angle(L, pq_0) \leq 3 \cdot \sqrt{\varepsilon}$. Since the aperture of the cones \widehat{C} is $\sqrt{\varepsilon}$, then L receives charges from cones \widehat{C} with at most $O(1)$ different orientations. We may restrict ourselves to cones \widehat{C} that are translates of each other (but have different apices in P_ℓ).

■ **Figure 2** Left: Three consecutive cones, \widehat{C}_0 , \widehat{C}_1 , and \widehat{C}_2 , with apex p and aperture $\sqrt{\varepsilon}$. Point q_0 is the closest to p in $P_\ell \cap \widehat{C}_1$; and $R(p, q_0) \subset \widehat{K}_1 = \widehat{C}_0 \cup \widehat{C}_1 \cup \widehat{C}_2$. Right: No point in P_ℓ is in the blue sector \widehat{K} , but there may be points in the pink sectors.

Let \mathcal{A} be the set of all translates of a cone \widehat{C} with aperture $\sqrt{\varepsilon}$ and apices in P_ℓ , and L receives positive charge from \widehat{C} . We partition \mathcal{A} into $O(\log \varepsilon^{-1})$ classes as follows. For $j = 1, \dots, \lceil \log(2\varepsilon^{-1}) \rceil$, let \mathcal{A}_j be the set of cones $\widehat{C} \in \mathcal{A}$ such that $2^{j-\ell} \leq \|pq_0\| < 2^{j+1-\ell}$, where $p \in P_\ell$ is the apex of \widehat{C} and q_0 is the closest point in $P_\ell \cap \widehat{C}$ to p .

▷ **Claim 9.** For each j , segment L receives $O(\varepsilon^{-3/2}) \|L\|$ total charges from all cones in \mathcal{A}_j .

For a cone $\widehat{C} \in \mathcal{A}_j$, the bound (3) is replaced by

$$\|E(\widehat{C})\| = \sum_{pq \in E(\widehat{C})} \|pq\| \leq |E(\widehat{C})| \cdot O(2^{j-\ell}) \leq O(\varepsilon^{-1/2} 2^{j-\ell}), \tag{5}$$

while $\|E^*(\widehat{C})\| \geq \frac{1}{9} \|pq_0\| \geq \Omega(2^{j-\ell})$ by Lemma 4. Refining (4), L receives a charge

$$\frac{\|E(\widehat{C})\|}{\|E^*(\widehat{C})\|} \cdot \|L\| \leq \frac{O(\varepsilon^{-1/2} 2^{j-\ell})}{\Omega(2^{j-\ell})} \cdot \|L\| \leq O(\varepsilon^{-1/2}) \cdot \|L\| \tag{6}$$

from each cone in \mathcal{A}_j . To prove Claim 9, it is enough to show that $|\mathcal{A}_j| \leq O(2^j) \leq O(\varepsilon^{-1})$.

■ **Figure 3** The union U of triangles $\widehat{C} \cap h^-$, where L receives charges from the cones \widehat{C} .

By Claim 8, L received charges from cones of $O(1)$ different orientations. We consider each orientation separately. We may assume w.l.o.g. that the symmetry axis of every cone in \mathcal{A}_j is parallel to the x -axis, and their apex is their leftmost point. Let h be a vertical line that contains the left endpoint of L , and let h^- be the left halfplane bounded by h ; see Figure 3. The intersections $\widehat{C} \cap h$ and $\widehat{K} \cap h$ are vertical line segments of length $O(2^{j-\ell} \tan \sqrt{\varepsilon})$. We have $L \cap h \subset \widehat{K} \cap h$ by Claim 8; and obviously $\widehat{C} \cap h \subset \widehat{K} \cap h$. Consequently, a vertical line segment of length $O(2^{j-\ell} \tan \sqrt{\varepsilon})$ contains $h \cap \widehat{C}$ for all $\widehat{C} \in \mathcal{A}_j$.

18:12 Online Spanners in Metric Spaces

Let U be the union of the triangles $\widehat{C} \cap h^-$ for all $\widehat{C} \in \mathcal{A}_j$. The interior of $\widehat{C} \cap h^-$ does not contain any point in P_ℓ . Consequently, the apices of all cones lie on the boundary ∂U of U . The part of ∂U in h^- is a y -monotone curve with slopes $\pm\sqrt{\varepsilon}$. It follows that the length of ∂U is $O(2^{j-\ell} \tan \sqrt{\varepsilon} / \sin \sqrt{\varepsilon}) = O(2^{j-\ell} \csc \sqrt{\varepsilon}) = O(2^{j-\ell})$. This, in turn, implies that ∂U intersects $O(2^j)$ cubes of side length $a_0 2^{-\ell}$ at level ℓ of the quadtree, and so $|\mathcal{A}_j| \leq O(2^j) \leq O(\varepsilon^{-1})$, as required. This completes the proof Claim 9, and hence the proof of Theorem 6. \blacktriangleleft

3 Lower Bounds in \mathbb{R}^d Under the L_1 Norm

In this section we introduce a strategy based on the points on the integer lattice \mathbb{Z}^d , that achieves a new lower bound for the competitive ratio of an online $(1 + \varepsilon)$ -spanner algorithm in \mathbb{R}^d under the L_1 norm.

Figure 4 A sketch of the construction for the lower bound in two dimensions. Any online algorithm is required to add the red pairs.

Construction. We describe an adversary strategy with $\Omega_d(\varepsilon^{-d})$ points and show that any online algorithm returns a $(1 + \varepsilon)$ -spanner whose weight is $\Omega_d(\varepsilon^{-d})$ times the optimum weight. One can extend this result for arbitrary number of points, but that does not necessarily improve the lower bound. The final point set X consists of the points of the integer lattice \mathbb{Z}^d in the hypercube $[0, \frac{1}{\varepsilon d}]^d$, where $\varepsilon < \frac{1}{d}$. The points are presented in stages in order to deceive the online algorithm to add more edges than needed. In step $2i$, where $0 \leq i < \frac{1}{2\varepsilon}$, points $x \in X$ such that $\|x\|_1 = i$ will be given to the algorithm. In step $2i + 1$, where $0 \leq i < \frac{1}{2\varepsilon}$, the adversary presents points $x \in X$ such that $\|x\|_1 = \lceil 1/\varepsilon \rceil - i$ (Figure 4). In other words, points are presented in batches according to their L_1 norms.

Competitive Ratio. Denote by X_i the set of points presented in step i . The idea is to show that there has to exist many edges between X_i and X_{i+1} in order to guarantee the $1 + \varepsilon$ stretch-factor. Specifically, we define an *ordered-pair* as follows.

► Definition 10 (ordered-pair). A pair of points (x, y) in \mathbb{R}^d is an ordered-pair if $x \in X_{2i}$ and $y \in X_{2i+1}$ for some i , and $x_k \leq y_k$ for all k , where x_k and y_k are the k -th coordinates of x and y respectively.

Now we show that any ordered-pair $(x, y) \in X_{2i} \times X_{2i+1}$ requires an edge in the spanner immediately after x and y are presented. To prove this, we show (in the full paper) that previously presented points cannot serve as via points in a $(1 + \varepsilon)$ -path between x and y .

► **Lemma 11.** *Let (x, y) be an ordered-pair. Then there is no $(1 + \varepsilon)$ -path between x and y that goes through any other point $z \in X_j$ with $j \leq i + 1$.*

We next show that the total weight of the edges between ordered pairs is $\Omega_d(\varepsilon^{-2d})$.

► **Lemma 12.** *The total weight of the edges between the ordered-pairs is $\Omega_d(\varepsilon^{-2d})$.*

Proof. Let $x = (x_1, \dots, x_d)$ and $y = (y_1, \dots, y_d)$ be two points in X . We show that if $x_k \in [\frac{1}{4\varepsilon(d+0.25)}, \frac{1}{4\varepsilon d}]$ for all $1 \leq k \leq d$, and $y_k \in [\frac{3}{4\varepsilon(d+0.25)}, \frac{3}{4\varepsilon d}]$ for all $1 \leq k \leq d - 1$, then there is a choice of y_d that makes (x, y) an ordered-pair. This would imply that there are $\Omega_d(\varepsilon^{-2d+1})$ ordered-pairs and by Lemma 11, each pair requires an edge of weight $\Omega_d(\varepsilon^{-1})$, thus the total weight of required edges would be $\Omega_d(\varepsilon^{-2d})$.

In order to find such a y_d , recall that $\|x\|_1 + \|y\|_1 = \lceil \varepsilon^{-1} \rceil$ holds because (x, y) is an ordered-pair. This equality uniquely determines the value of y_d ,

$$y_d = \lceil \varepsilon^{-1} \rceil - \sum_{k=1}^d x_k - \sum_{k=1}^{d-1} y_k.$$

We just need to prove the inequalities $y_k \geq x_k$ and $y_k \leq 1/(\varepsilon d)$ for this unique y_k . This can simply be done by plugging the maximum (and minimum) values of x_k s and other y_k s and calculating the result,

$$y_d \geq \frac{1}{\varepsilon} - \frac{d}{4\varepsilon d} - \frac{3(d-1)}{4\varepsilon d} = \frac{3}{4\varepsilon d} > x_d.$$

Also,

$$y_d \leq \frac{1}{\varepsilon} + 1 - \frac{d}{4\varepsilon(d+0.25)} - \frac{3(d-1)}{4\varepsilon(d+0.25)} = 1 + \frac{1}{\varepsilon(d+0.25)} < \frac{1}{\varepsilon d}. \quad \blacktriangleleft$$

Now we can prove the main theorem of this section.

► **Theorem 13.** *The competitive ratio of any online $(1 + \varepsilon)$ -spanner algorithm in \mathbb{R}^d under the L_1 -norm is $\Omega_d(\varepsilon^{-d})$.*

Proof. For the point set $X \subset \mathbb{R}^d$, the unit-distance graph is a Manhattan network: It contains a path of weight $\|xy\|_1$ for all $x, y \in X$. Its weight is $\Theta_d(\varepsilon^{-d})$ which is an upper bound for the weight of a $(1 + \varepsilon)$ -spanner for any $\varepsilon \geq 1$. By Lemma 12, any online algorithm returns a spanner of weight $\Omega_d(\varepsilon^{-2d})$. Thus its competitive ratio is $\Omega_d(\varepsilon^{-d})$. ◀

4 General Metrics: The Ordered Greedy Spanner

In this section we study the online spanners problem on general metric spaces. The points arrive one by one, where for each new point we also receive its distances to all previously introduced points.

In the offline setting, the celebrated greedy spanner algorithm [4] sorts the edges by increasing weight, and then processes them one by one, adding each edge if by the time of examination, the distance between its endpoints is too large. This algorithm achieves

18:14 Online Spanners in Metric Spaces

the existentially optimal² sparsity and lightness as a function of the stretch factor [31]. However, in the online model, we do not receive the edges in a sorted order, and therefore cannot execute the greedy algorithm. As an alternative, we propose here the *ordered greedy* algorithm. This is a deterministic algorithm working against an adaptive adversary. The algorithm receives a stretch factor t , and works naturally as follows: We maintain a spanner H . When a point v_i arrives, we order its edges³ in the original metric by weight. Each edge $\{v_{i'}, v_i\}$ is added to the spanner H if currently $\delta_H(v_{i'}, v_i) > t \cdot \delta_X(v_{i'}, v_i)$. Note that this algorithm can be easily executed in an online fashion.

► **Theorem 14.** *Given an n -point metric space (X, δ_X) in an (adaptive) adversarial order, with stretch factor $t = (2k - 1)(1 + \varepsilon)$ for $k \geq 2$ and $\varepsilon \in (0, 1)$, the ordered greedy algorithm returns a spanner with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n^{1+\frac{1}{k}}$ edges and weight $O(\varepsilon^{-1} n^{\frac{1}{k}} \log^2 n) \cdot w(\text{MST})$.*

Proof. The bounded stretch of our spanner is straightforward by construction, as every pair was examined at some point, and taken care of. Next we analyze the lightness.

In the online spanning tree problem, points of a finite metric space arrive one-by-one, and we need to connect each new point to a previous point to maintain a spanning tree. The ordered greedy algorithm connects each vertex v_i , to the closest vertex in $\{v_1, \dots, v_{i-1}\}$. As was shown by Imase and Waxman [44], the tree created by the ordered greedy algorithm has lightness $O(\log n)$, which is the best possible [44]. Denote the online spanning tree by T_G . Note that the ordered greedy spanner H will contain T_G , as a shortest edge between a new vertex to a previously introduced vertex is always added to the spanner H . The following clustering lemma is frequently used for spanner constructions (see e.g. [3, 22, 27]). We provide a proof for the sake of completeness.

▷ **Claim 15.** For every $i \in \mathbb{N}$, the point set X can be partitioned into clusters \mathcal{C}_i of diameter at most $D_i = \varepsilon \cdot (1 + \varepsilon)^i$ w.r.t. the metric δ_{T_G} such that $|\mathcal{C}_i| = O\left(\frac{w(T_G)}{\varepsilon \cdot (1 + \varepsilon)^i}\right)$.

Proof. Let N_i be a maximal set of vertices such that for every $x, y \in N_i$, $\delta_{T_G}(x, y) > \frac{1}{2} \cdot D_i$. For every vertex $x \in N_i$ let $C_x = \{z : x = \operatorname{argmin}_{y \in N_i} \delta_X(z, y)\}$ be the Voronoi cell of x . Clearly, $\operatorname{diam}(C_x) \leq D_i$ for all x . Further, consider a continuous version of T_G (where each edge is an interval). Then as the graph T_G is connected, each cluster C_x contains at least $\frac{1}{4} D_i$ length of edges (as the balls $\{B_{T_G}(x, \frac{1}{4} D_i)\}_{x \in N_i}$ are pairwise disjoint). It follows that

$$|\mathcal{C}_i| = |N_i| \leq \frac{w(T_G)}{\frac{1}{4} D_i} = O\left(\frac{w(T_G)}{\varepsilon \cdot (1 + \varepsilon)^i}\right). \quad \triangleleft$$

For every i , consider the *scale* $E_i = \{e = \{u, v\} \in H : (1 + \varepsilon)^{i-1} \leq \delta_X(u, v) < (1 + \varepsilon)^i\}$. We are now ready to bound the lightness and the sparsity of the ordered greedy spanner. This is accomplished in the next two claims, with proofs in the full paper.

▷ **Claim 16.** The weight of the ordered greedy spanner is $O(n^{\frac{1}{k}} \cdot \varepsilon^{-2} \log^2 n) \cdot w(\text{MST})$.

▷ **Claim 17.** The ordered greedy spanner has $O(\varepsilon^{-1} \log \frac{1}{\varepsilon}) \cdot n^{1+\frac{1}{k}}$ edges.

This completes the proof of Theorem 14. ◀

² Specifically, if a t -spanner construction achieves an upper bound $m(n, t)$ and $l(n, t)$, resp., on the size and lightness of an n -vertex graph then this bound also holds for the greedy t -spanner [31].

³ By edges we mean point pairs in the metric space, we will often use notation from graph theory.

5 Lower Bound for General Metrics

In this section we prove an $\Omega(\frac{1}{k} \cdot n^{\frac{1}{k}})$ lower bound on the competitive ratio of an online $(2k - 1)$ -spanner of n -vertex graphs. Our lower bound holds in both cases where the quality is measured by number of edges or the weight. It follows that our upper bound in Theorem 14 cannot be substantially improved, even if we consider competitive ratio instead of lightness/sparsity.

Recall that the Erdős Girth Conjecture [28] states that for every $n, k \geq 1$, there exists an n -vertex graph with $\Omega(n^{1+\frac{1}{k}})$ edges and girth $2k + 2$. The proof of the following lemma is based on a counting argument from the recent lower bound proof for (static) vertex fault tolerant emulators by Bodwin, Dinitz, and Nazari [15].

► **Lemma 18.** *Assuming the Erdős girth conjecture, for every $n, k \geq 1$, there exists an n -point metric space (X, δ_X) with diameter $2k - 1$, such that every $(2k - 1)$ -spanner has $\Omega(\frac{1}{k} \cdot n^{1+\frac{1}{k}})$ edges and weight $\Omega(n^{1+\frac{1}{k}})$.*

Proof. Let $G = (V, E_G)$ be the graph fulfilling the Erdős girth conjecture. That is, G is an unweighted n -vertex graph with girth $2k + 2$ and $|E_G| = \Omega(n^{1+\frac{1}{k}})$ edges. Set a metric δ_X over V as follows,⁴

$$\forall u, v \in V \quad \delta_X(u, v) = \min \{ \delta_G(u, v), 2k - 1 \}.$$

Suppose that $H = (V, E_H)$ is a $(2k - 1)$ -spanner for (V, δ_X) with weight function w_H , where the weight of an edge $e' \in \{u, v\} \in E_H$ is $w_H(e') = \delta_X(u, v)$. Let $E' = E_H \setminus E_G$ be the edges of H which are not in G . We say that an edge $e' \in E'$ covers an edge $e \in E_G$, if there is a shortest path in G between the endpoints of e' going through e of weight at most k . Note that as e' has weight at most k , there is a unique shortest path in G between its endpoints. In particular, each edge $e \in E'$ can cover at most k edges in E_G .

Consider an edge $e = \{v_0, v_s\} \in E_G \setminus E_H$. We argue that some edge $e' \in E'$ must cover e . Suppose for contradiction otherwise, and let $P = (v_0, v_1, \dots, v_s)$ be the shortest path in H between the endpoints v_0, v_s of e . Suppose first that P contains an edge v_i, v_{i+1} of weight at least $w_H(\{v_i, v_{i+1}\}) \geq k + 1$. In particular, $\delta_G(\{v_i, v_{i+1}\}) \geq k + 1$. Then by the triangle inequality, $\delta_G(v_0, v_i) + \delta_G(v_{i+1}, v_s) \geq \delta_G(v_i, v_{i+1}) - \delta_G(v_0, v_s) \geq k$. It follows that P has weight at least $2k + 1$, a contradiction to the fact that H is a $2k - 1$ spanner. We conclude that for every $i \in \{0, \dots, s - 1\}$, $\delta_X(v_i, v_{i+1}) = \delta_G(v_i, v_{i+1}) \leq k$. In particular, in G there is a unique path $P_i = (u_0^i, \dots, u_{s_i}^i)$ between v_i to v_{i+1} of weight $\delta_G(v_i, v_{i+1}) \leq k$. As no edge covers e , e does not belong to any of these paths. The concatenation of these paths $P_0 \circ P_1 \circ \dots \circ P_{s-1}$ is a path in G of at most $2k - 1$ edges between the endpoints of e . It follows that G contains a $2k$ -cycle, a contradiction.

For conclusion, as every edge in $E_G \setminus E_H$ is covered, and every edge in $E' = E_H \setminus E_G$ can cover at most k edges, it follows that $|E_H \setminus E_G| \geq \frac{1}{k} \cdot |E_G \setminus E_H|$. In particular,

$$|E_H| = |E_H \cap E_G| + |E_H \setminus E_G| \geq |E_H \cap E_G| + \frac{1}{k} \cdot |E_G \setminus E_H| \geq \frac{1}{k} \cdot |E_G|.$$

To bound the weight, for each edge $e' = \{s, t\} \in E'$, let $A_{e'}$ be the set of edges in E_G covered by e' . Note that $w_H(e') = \delta_G(s, t) = |A_{e'}|$. As all the edges in $E_G \setminus E_H$ are covered, we conclude

⁴ Note that $\forall x, y, z \in V$, $\delta_X(x, z) = \min \{ \delta_G(x, z), 2k - 1 \} \leq \min \{ \delta_G(x, y) + \delta_G(y, z), 2k - 1 \} \leq \min \{ \delta_G(x, y), 2k - 1 \} + \min \{ \delta_G(y, z), 2k - 1 \} = \delta_X(x, y) + \delta_X(y, z)$. Thus δ_X is a metric space.

$$\begin{aligned}
w_H(E_H) &= w_H(E_H \cap E_G) + w_H(E_H \setminus E_G) \\
&= |E_H \cap E_G| + \sum_{e' \in E'} |A_{e'}| \\
&\geq |E_H \cap E_G| + |E_G \setminus E_H| = |E_G| = \Omega(n^{1+\frac{1}{k}}). \quad \blacktriangleleft
\end{aligned}$$

► **Theorem 19.** *Assuming Erdős girth conjecture, the competitive ratio of any online $(2k-1)$ -spanner algorithm for n -point metrics is $\Omega(\frac{1}{k} \cdot n^{\frac{1}{k}})$, for both weight and number of edges. In more details, there is an n -point metric space (X, δ_X) with a $(2k-1)$ -spanner $H_{\text{OPT}} = (X, E_{\text{OPT}})$, and order over X for which every $(2k-1)$ -spanner produced by an online algorithm will have $\Omega(\frac{1}{k} \cdot n^{\frac{1}{k}}) \cdot |E_{\text{OPT}}|$ edges, and $\Omega(\frac{1}{k} \cdot n^{\frac{1}{k}}) \cdot w(H_{\text{OPT}})$ weight.*

Proof. Consider the metric space (X, δ_X) from Lemma 18 with parameters $n-1$ and k . Let X' be the metric space X with an additional point r at distance $\frac{2k-1}{2}$ from all the points in X . Note that no pairwise distance is changed due to the introduction of r . The adversary provides the online algorithm the points in X first (in some arbitrary order), and the point r last. After the algorithm received all the points in X' , it has a $2k-1$ -spanner H_{n-1} . According to Lemma 18, H_{n-1} has $\Omega(\frac{1}{k} \cdot (n-1)^{1+\frac{1}{k}}) = \Omega(\frac{1}{k} \cdot n^{1+\frac{1}{k}})$ edges, and $\Omega(n^{1+\frac{1}{k}})$ weight.

Next the algorithm introduces r . Consider the spanner $S = (X', E_S)$ consisting of $n-1$ edges with r as a center. Note that the maximum distance in S is $2k-1$, and hence S is a $2k-1$ spanner as required. Note that S contains $n-1$ edges of weight $\frac{2k-1}{2}$ each, and thus have total weight of $O(nk)$. We conclude

$$\begin{aligned}
|E_{H_n}| &\geq |E_{H_{n-1}}| = \Omega(\frac{1}{k} \cdot n^{1+\frac{1}{k}}) = \Omega(\frac{1}{k} \cdot n^{\frac{1}{k}}) \cdot |E_S|. \\
w(E_{H_n}) &\geq w(E_{H_{n-1}}) = \Omega(n^{1+\frac{1}{k}}) = \Omega(\frac{1}{k} \cdot n^{\frac{1}{k}}) \cdot w(S). \quad \blacktriangleleft
\end{aligned}$$

6 Conclusion

We studied online spanners for points in metric spaces. In the Euclidean d -space, we presented an online $(1+\varepsilon)$ -spanner algorithm with competitive ratio $O(\varepsilon^{1-d} \log n)$, improving the previous bound of $O_d(\varepsilon^{-(d+1)} \log n)$ from [14]. In fact, the spanner maintained by the algorithm has $O_d(\varepsilon^{1-d} \log \varepsilon^{-1}) \cdot n$ edges, almost matching the (offline) optimal bound of $O_d(\varepsilon^{1-d}) \cdot n$. Moreover, in the plane, a tighter analysis of the same algorithm provides an almost quadratic improvement of the competitive ratio to $O(\varepsilon^{-3/2} \log \varepsilon^{-1} \log n)$, by comparing the online spanner with an instance-optimal spanner directly, circumventing the comparison to an MST (i.e., lightness). Note that, the logarithmic dependence on n is unavoidable due to a $\Omega((\varepsilon^{-1}/\log \varepsilon^{-1}) \log n)$ lower bound in the real line [14]. However, our lower bound $\Omega(\varepsilon^{-d})$ under the L_1 -norm in \mathbb{R}^d shows a dependence on the dimension. This leads to the following question.

► **Question.** *Does the competitive ratio of an online $(1+\varepsilon)$ -spanning algorithm for n points in \mathbb{R}^d necessarily grow proportionally with $\varepsilon^{-f(d)} \cdot \log n$, where $\lim_{d \rightarrow \infty} f(d) = \infty$?*

Interestingly, for $t \in [(1+\varepsilon)\sqrt{2}, (1-\varepsilon)2]$, we can show that every online t -spanner algorithm in \mathbb{R}^d must have competitive ratio $2^{\Omega(\varepsilon^{2d})}$ (see the full paper for further details).

Next, we studied online spanners in general metrics. We showed that the *ordered greedy* algorithm maintains a spanner with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n^{1+\frac{1}{k}}$ edges and $O(\varepsilon^{-1} n^{\frac{1}{k}} \log^2 n)$ lightness, with stretch factor $t = (2k-1)(1+\varepsilon)$ for $k \geq 2$ and $\varepsilon \in (0, 1)$, for a sequence of n points in

a metric space. Moreover, we show that these bounds cannot be significantly improved, by introducing an instance that achieves an $\Omega(\frac{1}{k} \cdot n^{1/k})$ competitive ratio on both sparsity and lightness. Finally, we established the trade-off among stretch, number of edges and lightness for points in ultrametrics, showing that one can maintain a $(2 + \varepsilon)$ -spanner for ultrametrics with $O(\varepsilon^{-1} \log \varepsilon^{-1}) \cdot n$ edges and $O(\varepsilon^{-2})$ lightness.

Abstract

A *temporal graph* is an undirected graph $G = (V, E)$ along with a function $\lambda : E \rightarrow \mathbb{N}^+$ that assigns a time-label to each edge in E . A path in G such that the traversed time-labels are non-decreasing is called a *temporal path*. Accordingly, the distance from u to v is the minimum length (i.e., the number of edges) of a temporal path from u to v . A temporal α -spanner of G is a (temporal) subgraph H that preserves the distances between any pair of vertices in V , up to a *multiplicative* stretch factor of α . The *size* of H is measured as the number of its edges.

In this work, we study the size-stretch trade-offs of temporal spanners. In particular we show that temporal cliques always admit a temporal $(2k - 1)$ -spanner with $\tilde{O}(kn^{1+\frac{1}{k}})$ edges, where $k > 1$ is an integer parameter of choice. Choosing $k = \lfloor \log n \rfloor$, we obtain a temporal $O(\log n)$ -spanner with $\tilde{O}(n)$ edges that has almost the same size (up to logarithmic factors) as the temporal spanner given in [Casteigts et al., JCSS 2021] which only preserves temporal connectivity.

We then turn our attention to *general* temporal graphs. Since $\Omega(n^2)$ edges might be needed by any connectivity-preserving temporal subgraph [Axiotis et al., ICALP'16], we focus on approximating distances from a *single source*. We show that $\tilde{O}(n/\log(1 + \varepsilon))$ edges suffice to obtain a stretch of $(1 + \varepsilon)$, for any small $\varepsilon > 0$. This result is essentially tight in the following sense: there are temporal graphs G for which any temporal subgraph preserving exact distances from a single-source must use $\Omega(n^2)$ edges. Interestingly enough, our analysis can be extended to the case of *additive* stretch for which we prove an upper bound of $\tilde{O}(n^2/\beta)$ on the size of any temporal β -additive spanner, which we show to be tight up to polylogarithmic factors.

Finally, we investigate how the *lifetime* of G , i.e., the number of its distinct time-labels, affects the trade-off between the size and the stretch of a temporal spanner.

1 Introduction

A *temporal graph* is a graph $G = (V, E)$ in which each edge can be used only in certain time instants. This recurrent idea of time-evolving graphs has been formalized in multiple ways, and a simple widely-adopted model is the one of Kempe, Kleinberg, and Kumar [11], in which each edge $e \in E$ has an assigned time-label $\lambda(e)$ representing the instant in which e can be used. A path from a vertex to another in G is said to be a *temporal path* if the time-labels of the traversed edges are non-decreasing. Accordingly, a graph is *temporally connected* if there exists a temporal path from u to v , for every two vertices $u, v \in V$.

Notice that, unlike paths in *static* graphs, the existence of temporal paths is neither symmetric nor transitive.¹ For this reason, temporal graphs exhibit a different combinatorial structure compared to static graphs, and even problems that admit easy solutions on static graphs become more challenging in their temporal counterpart. Indeed, one of the main problems introduced in the seminal paper of Kempe, Kleinberg, and Kumar [11] is that of finding a sparse temporally connected subgraph H of an input temporal graph G . Such a subgraph H is sometimes referred to as a *temporal spanner* of G . While any spanning-tree is trivially a connectivity-preserving subgraph of a *static* graph, not all temporal graphs G admit a temporal spanner having $O(n)$ edges [11]. In particular, [11] exhibits a class of temporal graphs that contain $\Theta(n \log n)$ edges and cannot be further sparsified. Later, [4] provided a stronger negative result showing that there are temporal graphs G such that any temporal spanner of G must use $\Theta(n^2)$ edges. These strong lower bounds on general graphs motivated [7] to focus on *temporal cliques* instead. Here the situation improves significantly, as only $O(n \log n)$ edges are sufficient to guarantee temporal connectivity. This gives rise to the following natural question, which is exactly the focus of our paper: *can one design a temporal spanner that also guarantees short temporal paths between any pair of vertices?*

To address this question, we measure the *length* of a temporal path as the number of its edges,² and we introduce the notion of temporal α -spanner of a temporal graph G , i.e., a subgraph H of G such that $d_H(u, v) \leq \alpha \cdot d_G(u, v)$ for every pair of vertices $u, v \in V$, where $d_H(u, v)$ (resp. $d_G(u, v)$) denotes the length of a shortest temporal path from u to v in H (resp. G). Our main question then becomes that of understanding which trade-offs can be achieved between the *size*, i.e., the number of edges, of H and the value of its *stretch-factor* α . This same question received considerable attention on static graphs and gave rise to a significant amount of work (see, e.g., [1]), hence we deem investigating its temporal counterpart as a very interesting research direction.

To the best of our knowledge, the only temporal α -spanner currently known is actually the connectivity-preserving subgraph of [7] having size $O(n \log n)$. However, a closer inspection of its construction shows that the resulting α -spanner can have stretch $\alpha = \Theta(n)$. In particular, even the problem of achieving stretch $o(n)$ using $o(n^2)$ edges remains open.

In this paper we investigate which size-stretch trade-offs can be attained by selecting subgraphs of temporal graphs, as detailed in the following.

¹ Indeed, a temporal path from u to v is not necessarily a temporal path from v to u , even when G is undirected. Moreover, the existence of a temporal path from u to v , and of a temporal path from v to w , does not imply the existence of a temporal path from u to w .

² Alternative definitions for the length of a temporal path are also natural, e.g., the *arrival time*, *departure time*, *duration*, or *travel time* as we briefly discuss in the conclusions.

1.1 Our results

Temporal cliques. Following [7], we start by considering temporal cliques (see Section 3). Our main result is the following: given a temporal clique G and an integer $k \geq 2$, we can construct, in polynomial time, a temporal $(2k-1)$ -spanner of G having size $O(kn^{1+1/k} \log^{1-1/k} n)$. Interestingly, the special case $k = \lfloor \log n \rfloor$ shows that $O(n \log^2 n)$ edges suffice to ensure that a temporal path of length $O(\log n)$ exists between any pair of vertices. For this choice of k , the size of our spanner is only a logarithmic factor away from the size the temporal spanner of [7] that uses $O(n \log n)$ edges and only preserves connectivity. We obtain our results by constructing hierarchical clustering of the vertices that guides the constructions of temporal paths.

We also show that there are temporal cliques for which any temporal spanner with stretch smaller than 3 must have $\Omega(n^2)$ edges.

Single-source temporal spanners on general graphs. Next, in Section 4, we move our attention from temporal cliques to general temporal graphs. As already pointed out, there are temporal graphs that do not admit any connectivity-preserving subgraph with $o(n^2)$ edges [4]. Hence, we consider the special case in which we have a single source s . One can observe that any temporal graph G admits a temporal subgraph containing $O(n)$ edges and preserving the connectivity from s (see also [11]). However, to the best of our knowledge, no non-trivial result is known on the size of subgraphs preserving approximate distances from s .

We formalize this problem by introducing the notion of *single-source temporal α -spanner* of $G = (V, E)$ w.r.t. a source $s \in V$, which we define as a subgraph H of G such that $d_H(s, v) \leq \alpha \cdot d_G(s, v)$ for every $v \in V$. Our main contribution for the single-source case is the following: given any temporal graph G , we can compute in polynomial time a single-source temporal $(1 + \varepsilon)$ -spanner having size $O(\frac{n \log^4 n}{\log(1+\varepsilon)})$, where $\varepsilon > 0$ is a parameter of choice.

Furthermore, we show that any single-source temporal 1-spanner (i.e., a subgraph preserving *exact* distances from s) must have $\Omega(n^2)$ edges in general. Our construction can be generalized to provide a lower bound of $\Omega(\frac{n^2}{\beta})$ on the size of any single-source temporal β -additive spanner, namely a subgraph H that preserves single-source distances up to an *additive* term of at most $\beta \geq 1$ (i.e., we require $d_H(s, v) \leq d_G(s, v) + \beta$ for all $v \in V$).

Interestingly, the same techniques used to obtain our single-source temporal $(1 + \varepsilon)$ -spanner can be also applied to build a single-source temporal β -additive spanner of size $O(\frac{n^2 \log^4 n}{\beta})$, which essentially matches our aforementioned lower bound.

The role of lifetime. An important parameter that measures how time-dependent is a temporal graph $G = (V, E)$ is its *lifetime*, i.e., the number L of distinct time-labels associated with the edges of G . Indeed, a temporal graph with lifetime $L = 1$ is just a *static* graph, while any temporal graph trivially satisfies $L = O(n^2)$. It is not surprising that the lifetime plays a crucial role in determining the number of edges required by temporal spanners. For example, the lower bound of $\Omega(n^2)$ on the size of any connectivity-preserving temporal subgraph requires $L = \Omega(n)$ [4]. In this paper, we also present a collection of results with the goal of shedding some light on the lifetime-size trade-off of temporal spanners. In particular, our results provide the following lifetime-dependant upper bounds on the size of temporal α -spanners

- As far as temporal cliques are concerned, we show how to build, in polynomial time, a temporal 3-spanner with $O(2^L n \log n)$ edges. This implies that, when $L = O(1)$, we can achieve stretch 3 with $\tilde{O}(n)$ edges.³

³ The notation $\tilde{O}(f(n))$ is a synonym for $O(f(n) \cdot \text{polylog } f(n))$.

- If $L = 2$, we can find (in polynomial time) a temporal 2-spanner of a temporal clique having size $O(n \log n)$. We deem this result interesting since, as soon as $L > 2$, our lower bound of $\Omega(n^2)$ on the size of any temporal 2-spanner still applies.
- We show that, when L is small, *general* temporal graphs can be sparsified by exploiting known size-stretch trade-offs for spanners of static graphs. In particular, we show that if it is possible to compute, in polynomial time, an α -spanner of a static graph having size $f(n)$, then one can also build a temporal α -spanner of size $O(Lf(n))$. This yields, e.g., a temporal $\lfloor \log n \rfloor$ -spanner of size $o(n^2)$ on general temporal graphs with $L = o(n)$.

Due to space limitations, these results and some of the proofs are omitted and can be found in the full version of the paper.

1.2 Related work

The definitions of temporal graphs and temporal paths given in the literature sometimes differ from the ones we adopt here. We now discuss how our results relate to some of the most common variants. A first difference concerns the notion of temporal paths: some authors consider *strict temporal paths* [2, 7, 11], i.e., temporal paths in which edge labels must be strictly increasing (rather than non-decreasing). As observed by [11], if we adopt strict temporal paths then there are dense graphs that cannot be sparsified, indeed no edge can be removed from a temporal clique in which all edges have the same time-label. As observed in [7], one can get rid of these problematic instances by assuming that time-labels are *locally distinct*, namely that all the time-labels of the edges incident to any single vertex are distinct. In this case all temporal paths are also strict temporal paths and hence they focus on temporal paths as defined in our paper. A second difference concerns whether edges are allowed to have multiple time-labels, as in [2, 12]. In this case, each edge e is associated to a non-empty set of time instants $\lambda(e) \subseteq \mathbb{N}^+$ in which e is available. We observe that any algorithm that sparsifies a temporal clique with single time-labels can be directly used on the case of multiple time-labels by selecting an arbitrary time-label for each edge (see also the discussion in [7]). This is no longer true when we consider general temporal graphs, since removing edge labels might affect distances. However, all our algorithms work also in the case of multiple labels and, since our lower bounds are given for single labels, they also apply to the case of multiple labels.

Another research line concerns random temporal graphs. In particular, temporal cliques in which each edge has a single time-label chosen u.a.r. from the set $\{1, \dots, \alpha\}$, where $\alpha \geq 4$, admit temporal spanners with $O(n \log n)$ edges w.h.p. [2]. In [8], the authors study connectivity properties of random temporal graphs defined as an Erdős-Rényi graph $G_{n,p}$ in which each edge e has time-label chosen as the rank of e in a random permutation of the graph's edges. They show that $p = \frac{\log n}{n}$, $p = \frac{2 \log n}{n}$, $p = \frac{3 \log n}{n}$, and $p = \frac{4 \log n}{n}$ are sharp thresholds to guarantee that the resulting temporal graph G satisfies the following respective conditions asymptotically almost surely: a fixed pair of vertices can reach each other via temporal paths in G , there is some vertex s which can reach all other vertices in G via temporal paths, G is temporally connected, G and admits a temporal spanner with $2n - 4$ edges (which is tight when time-labels are locally distinct).

Besides temporal graphs, other models to represent graphs or paths that evolve over time have been considered in the literature, we refer the interested reader to [9] for a survey.

Finally, as we already mentioned, there is a large body of literature concerning spanners on static graphs (see [1] for a survey on the topic) and clustering techniques similar to the ones we employ on temporal cliques have proven to be a useful tool to design sparse spanner also in this setting (see, e.g., [5, 6]).

A reader that is already familiar with the area might notice that our upper bound of $\tilde{O}(n^{1+\frac{1}{k}})$ on the size of a temporal $(2k-1)$ -spanner of a *temporal clique*, happens to resemble the classical upper bound of $O(n^{1+\frac{1}{k}})$ on the size of a $(2k-1)$ -spanner of a *general static graph* [3]. Nevertheless, the first result only applies to complete (temporal) graphs and requires different technical arguments to handle temporal paths.

2 Model and preliminaries

Let $G = (V, E)$ be an undirected *temporal graph* with n vertices, and a labeling function $\lambda : E \rightarrow \mathbb{N}^+$ that assigns a *time-label* $\lambda(e)$ to each edge e . If G is complete we will say that it is a *temporal clique*. A temporal path π from vertex u to vertex v is a path in G from u to v such that the sequence e_1, e_2, \dots, e_k of edges traversed by π satisfies $\lambda(e_i) \leq \lambda(e_{i+1})$ for all $i = 1, \dots, k-1$. We denote with $|\pi|$ the length of π , i.e., the number of its edges. A shortest temporal path from vertex u to vertex v is a temporal path from u to v with minimum length. We denote with $d_G(u, v)$, the length of a shortest temporal path from u to v in G . Given a generic graph H , we denote by $V(H)$ its vertex-set and by $E(H)$ its edge-set.

For $\alpha \geq 1$ and $\beta \geq 0$, a temporal (α, β) -spanner of G is a (temporal) subgraph H of G such that $V(H) = V$ and $d_H(u, v) \leq \alpha \cdot d_G(u, v) + \beta$, for each $u, v \in V$. We call a temporal (α, β) -spanner: (i) temporal α -spanner if $\beta = 0$, (ii) temporal β -additive spanner if $\alpha = 1$, (iii) temporal preserver if $\alpha = 1$ and $\beta = 0$. We say that H is a *single-source* temporal (α, β) -spanner w.r.t. a vertex $s \in V$, if $d_H(s, v) \leq \alpha \cdot d_G(s, v) + \beta$, for each $v \in V$. The *size* of a temporal spanner is the number of its edges.

We define the *lifetime* L of G as the number of distinct time-labels of its edges. Furthermore, we assume w.l.o.g. that each time instant in $\{1, \dots, L\}$ is used by at least one time-label (since otherwise we can replace each time-label with its rank in the set $\{\lambda(e) \mid e \in E\}$), so that $L = \max_{e \in E} \lambda(e)$.

We will make use of the following well-known result:

► **Lemma 1.** *Given a collection \mathcal{S} of subsets of $\{1, \dots, n\}$, where each subset has size at least ℓ and $|\mathcal{S}|$ is polynomially bounded in n , we can find in polynomial time a subset $R \subseteq \{1, \dots, n\}$ of size $O((n/\ell) \log n)$ that hits all subsets in the collection, i.e., $R \cap S \neq \emptyset$ for all $S \in \mathcal{S}$.*

3 Spanners for temporal cliques

In this section, we design an algorithm such that, given a temporal clique G , returns a temporal $(2k-1)$ -spanner H of G with size $\tilde{O}(n^{1+\frac{1}{k}})$, for any integer $k > 1$. We also provide a temporal clique G for which any temporal 2-spanner of G has size $\Omega(n^2)$.

Before describing the algorithm for constructing temporal $(2k-1)$ -spanners, we show as a warm up how to construct a temporal 3-spanner and a temporal 5-spanner of size $\tilde{O}(n^{1+\frac{1}{2}})$ and $\tilde{O}(n^{1+\frac{1}{3}})$, respectively.

3.1 Our temporal 3-spanner

Given a temporal clique G , we construct a temporal 3-spanner H of G via a clustering technique. For each $u \in V$, we select a set E_u containing the $\Theta(\sqrt{n \log n})$ edges incident to u having the smallest labels (ties are broken arbitrarily). We define $S_u = \{v \in V \mid (u, v) \in E_u\}$. Next, we find a hitting set $R \subseteq V$ of the collection $\{S_u\}_{u \in V}$. Thanks to Lemma 1, we can deterministically compute a hitting set of size $|R| = O(\sqrt{n \log n})$.

■ **Figure 1** (a) A vertex u and its neighbours in G , the edges are sorted top-down by increasing time-label. The red edges are those belonging to E_u while the black edges belong to $E(G) \setminus E_u$. (b) An example of a cluster C_x where $x \in R$. The edges incident to x are sorted from left to right by increasing-time label. The black and red edges are added to $E(H)$ during the initialization phase, in particular the red edges are those belonging to $E_{z(x)}$. The blue edges are added w.r.t. u to $E(H)$ during the first augmentation. The green edges belong to $E(G) \setminus E_{z(x)}$ and are added to $E(H)$ during the second augmentation.

We partition the vertices of V into $|R|$ clusters. More precisely, we create a cluster $C_x \subseteq V$ for each vertex $x \in R$. Each vertex $u \in V$ belongs to exactly one arbitrarily chosen cluster C_x that satisfies $x \in S_u$, i.e., x hits S_u . We call x the center of cluster C_x .⁴ Moreover, we choose the special vertex of cluster C_x as a vertex $z(x)$ in C_x that maximizes the label of the edge $(x, z(x))$.

Notice that, for every $x \in R$ and $u \in C_x$, u can reach $z(x)$ via a temporal path of length at most 2 in G by using the edges (u, x) and $(x, z(x))$ since, by definition of $z(x)$ and S_u , we have $\lambda(u, x) \leq \lambda(x, z(x))$.

We now build our temporal spanner H of G . The set of edges $E(H)$ is constructed in three phases (See Figure 1 for an example of the whole construction):

Initialization: For each $u \in V$, we add the edges in E_u to $E(H)$;

First Augmentation: For every $u \in V$, we add the edges in $E_{u, z(x)} = \{u\} \times S_{z(x)}$ to $E(H)$, where x is the center of the cluster containing u ;

Second Augmentation: For each $x \in R$, we add the edges in $E_{z(x), V} = \{z(x)\} \times V$ to $E(H)$. It is easy to see that H contains $O(n\sqrt{n \log n})$ edges. We now show that for any $u, v \in V$ there is a temporal path from u to v of length at most 3 in H . Indeed, let $x \in R$ be the center of the cluster C_x containing u . If $v = z(x)$ then, since $u \in C_x$, the initialization phase ensures that $(u, x) \in E(H)$ and $(x, z(x)) \in E(H)$, which form a temporal path as we already discussed above. We hence assume that $v \neq z(x)$. If $(z(x), v) \in E_{z(x)}$ then the first augmentation phase added $(u, v) \in E_{u, z(x)}$ to $E(H)$, which is a temporal path of length one from u to v . Otherwise $(z(x), v) \in E(G) \setminus E_{z(x)}$ and, the second augmentation phase added edge $(z(x), v)$ to $E(H)$. Moreover, since $(z(x), v) \notin E_{z(x)}$, $(z(x), v)$ is not among the $\Theta(\sqrt{n \log n})$ edges incident to $z(x)$ with lowest labels. As a consequence, since $(x, z(x)) \in E_{z(x)}$, we have $\lambda(x, z(x)) \leq \lambda(z(x), v)$. Hence, the edges (u, x) , $(x, z(x))$, and $(z(x), v)$ form a temporal path of length 3 from u to v in H .

3.2 Our temporal 5-spanner

We show how to modify the construction of a temporal 3-spanner given in previous section in order to obtain a temporal 5-spanner of size $\tilde{O}(n^{4/3})$. The idea is to replace the single-level clustering of Section 3.1 with a two-level clustering, where the second-level clustering

⁴ Here and throughout the paper, the center of a cluster is not required to belong to the cluster itself.

■ **Figure 2** (a) Two vertices u and z of G , where $z \in Z_1$ and the red edges belong to $E_{1,u}$ and $E_{1,z}$, respectively. For vertex z the purple edges belong to $E_{2,z}$. (b) A two level clustering. The level one consists of three cluster C_{1,x_1} , C_{1,x_2} , C_{2,x_3} . The level-two cluster $C_{2,y}$, with $y \in R_2$, contains vertices $z_1(x_1)$, $z_1(x_2)$ and $z_1(x_3)$, where $z_2(y) = z_1(x_3)$.

partitions the special vertices of the first level clustering and the number of selected clusters decreases as we move from the first level to the second one.

The level-one clustering is built similarly to the one used in our temporal 3-spanner. For each vertex $u \in V$ we define sets $E_{1,u}$ and $S_{1,u}$ where $E_{1,u}$ consists of the $\Theta(n^{1/3} \log^{2/3} n)$ edges with the smallest label among those incident to u (ties are broken arbitrarily) and $S_{1,u} = \{v \in V \mid (u, v) \in E_{1,u}\}$. We compute a hitting set R_1 of the collection $\{S_{1,u}\}_{u \in V}$, where R_1 has size $O(n^{2/3} \log^{1/3} n)$ thanks to Lemma 1. We partition the vertices of V into $|R_1|$ clusters $C_{1,x}$, for each $x \in R_1$, as before, and let $z_1(x)$ the vertex in $C_{1,x}$ that maximizes the label of the edge $(x, z_1(x))$.

The level-two clustering is built on top of the vertices $Z_1 = \{z_1(x) \mid x \in R_1\}$. For each $u \in Z_1$, we define $E_{2,u}$ as a set of $\Theta(n^{2/3} \log^{1/3} n)$ edges with the smallest label among those that are incident to u but do not belong to $E_{1,u}$. We also define a corresponding set $S_{2,u} = \{v \in V \mid (u, v) \in E_{2,u}\}$. We once again invoke Lemma 1 to compute a hitting set R_2 of size $O(n^{1/3} \log^{2/3} n)$ of the collection $\{S_{2,u}\}_{u \in Z_1}$. Based on R_2 , we partition the special vertices in Z_1 by associating each $u \in Z_1$ to an arbitrary cluster $C_{2,y}$ centered in $y \in R_2$ such that $y \in S_{2,u}$. Each cluster $C_{2,y}$ has an associated special vertex $z_2(y) \in C_{2,y}$ chosen among the ones that maximize the label of the edge $(y, z_2(y))$, see Figure 2.

We are now ready to build our temporal 5-spanner H . As before, the set of edges $E(H)$ is constructed in three phases:

Initialization: For each $u \in V$, we add the edges in $E_{1,u}$ to $E(H)$ and, for each $u \in Z_1$, we add the edges in $E_{2,u}$ to $E(H)$;

First Augmentation: For every $u \in V$, we add the edges in $E_{u,z_1(x)} = \{u\} \times S_{1,z_1(x)}$ to $E(H)$, where x is the center of the cluster containing u . Moreover, for each $z \in Z_1$ we add the edges in $\{z\} \times (S_{1,z_2(y)} \cup S_{2,z_2(y)})$ to $E(H)$, where y is the center of the level-two cluster $C_{2,y}$ containing z ;

Second Augmentation: For each $y \in R_2$, we add the set $\{z_2(y)\} \times V$ to $E(H)$.

See Figure 3 for an example of the whole construction. We now show that H is a 5-spanner of size $O(n^{4/3} \log^{2/3} n)$.

► **Lemma 2.** *Let $u, v \in V$. There is a temporal path from u to v of length at most 5 in H .*

Proof. Let $x \in R_1$ be the center of the level-one cluster $C_{1,x}$ containing u and $y \in R_2$ be the center of the level-two cluster $C_{2,y}$ containing $z_1(x)$.

We first show that in H there exists a temporal path π of length 4 from u to $z_2(y)$ consisting of the sequence of edges (u, x) , $(x, z_1(x))$, $(z_1(x), y)$, $(y, z_2(y))$. Notice that, the edges (u, x) , $(x, z_1(x))$, $(z_1(x), y)$, $(y, z_2(y))$ belong to $E_{1,u}$, $E_{1,z_1(x)}$, $E_{2,z_1(x)}$, and $E_{2,z_2(y)}$,

■ **Figure 3** An example of a two-level cluster and of the edges added to $E(H)$ during the spanner construction. The black, red and purple edges are added during initialization phase. In particular, for every $u \in V$, the red edges are those in $E_{1,u}$ and, for every $z \in Z_1$, the purple edges are those in $E_{2,z}$. The dark blue and light blue edges are those added to $E(H)$ during the first augmentation phase. The green edges are the edges added to $E(H)$ during the second augmentation phase.

respectively. Moreover, the initialization phase ensures that they all belong to $E(H)$. Then, by definition of $z_1(x)$, we have $\lambda(u, x) \leq \lambda(x, z_1(x))$. Moreover, since $(x, z_1(x)) \in E_{1,z_1(x)}$ and $(z_1(x), y) \in E_{2,z_1(x)}$, then $\lambda(x, z_1(x)) \leq \lambda(z_1(x), y)$. Finally, $(y, z_2(y)) \in E_{2,z_2(y)}$ and, by definition of $z_2(y)$, we have $\lambda(z_1(x), y) \leq \lambda(y, z_2(y))$.

If $v = z_2(y)$, then u can reach v via a temporal path of length 4 in H , by using π . Moreover, if $v = z_1(x)$ then u can reach v via a temporal path of length 2 by using the subpath π_1 of π consisting of the edges (u, x) and $(x, z_1(x))$. Otherwise, we can build a temporal path to v by considering one of following three cases (to be checked in order):

- If $(z_1(x), v) \in E_{1,z_1(x)}$, then $v \in S_{1,z_1(x)}$ and, due to the first augmentation phase, we have that $(u, v) \in E(H)$.
- If $(z_2(y), v) \in E_{1,z_2(y)} \cup E_{2,z_2(y)}$, then vertex $v \in S_{1,z_2(y)} \cup S_{2,z_2(y)}$ and the first augmentation phase ensures that $(z_1(x), v) \in E(H)$. Moreover, since $(z_1(x), v) \notin E_{1,z_1(x)}$, we have that $\lambda(x, z_1(x)) \leq \lambda(z_1(x), v)$. Hence the concatenation of π_1 with the edge $(z_1(x), v)$ yields a temporal path of length 3 from u to v in H .
- If $(z_2(y), v) \notin (E_{1,z_2(y)} \cup E_{2,z_2(y)})$, the second augmentation phase ensures that $(z_2(y), v) \in E(H)$. Moreover, $\lambda(y, z_2(y)) \leq \lambda(z_2(y), v)$. Therefore the concatenation of π with the edge $(z_2(y), v)$ yields a temporal path of length 5 from u to v in H . ◀

▶ **Lemma 3.** *The size of H is $O(n^{4/3} \log^{2/3} n)$.*

3.3 Our temporal $(2k - 1)$ -spanner

In this section, we describe an algorithm that, given an integer $k \geq 2$ and a temporal clique G of n vertices, returns a temporal $(2k - 1)$ -spanner of G with size $O(k \cdot n^{1+\frac{1}{k}} \log^{\frac{k-1}{k}} n)$.

The idea is to define a hierarchical clustering of G , where a generic level- i clustering partitions the special vertices of the level- $(i - 1)$ clustering and determines the special vertices of level i . As we move from one clustering level to the next, the number of clusters decreases by a factor of roughly $n^{\frac{1}{k}}$, thus allowing us to add an increasing number of edges incident to the special vertices into the spanner.

We ensure that each vertex $u \in V$ can reach some special vertex by moving upwards in the clustering hierarchy. These special vertices work as hubs, i.e., each of them allows to directly reach a subset of vertices of V , and some special vertex of higher level (via a temporal path of length at most 2). Then u can reach any vertex in $v \in V$ by first reaching a suitable special vertex z in the hierarchy, and then following the edge (z, v) .

■ **Algorithm 1** Computes a temporal $(2k - 1)$ -spanner.

```

Input : A temporal clique  $G$ ;
Output : A temporal  $(2k - 1)$ -spanner of  $G$ ;

1  $Z_0 \leftarrow V$ ;
2 foreach  $u \in V$  do  $E(u) \leftarrow \{(u, v) \mid v \in V\}$ ;
3 for  $i = 1, \dots, k - 1$  do
4   foreach  $u \in Z_{i-1}$  do
5      $E_{i,u} \leftarrow$  set of the first min-time label  $n^{\frac{i}{k}} \log n$  edges of  $E(u)$ ;
6      $E(u) \leftarrow E(u) \setminus E_{i,u}$ ;
7      $S_{i,u} \leftarrow \{v \in V : (u, v) \in E_{i,u}\}$ ;
8    $R_i \leftarrow$  hitting set of  $\{S_{i,u}\}_{u \in Z_{i-1}}$  computed as in Lemma 1;
9    $C \leftarrow \emptyset$ ; // Set of vertices in  $Z_{i-1}$  that are already clustered
10  foreach  $x \in R_i$  do
11     $C_{i,x} = \{u \in Z_i \setminus C : x \in S_{i,u}\}$ ;
12     $z_i(x) \leftarrow \arg \max_{u \in C_{i,x}} \{\lambda(u, x)\}$ ;
13     $C \leftarrow C \cup C_{i,x}$ ;
14   $Z_i \leftarrow \{z_i(x) \in Z_{i-1} : x \in R_i\}$ ;
15  $H \leftarrow (V, \emptyset)$  for  $i = 1$  to  $k - 1$  do // Initialization
16   foreach  $u \in Z_{i-1}$  do  $E(H) \leftarrow E(H) \cup E_{i,u}$ ;
17 for  $i = 1, \dots, k - 1$  do // First augmentation
18   foreach  $u \in Z_{i-1}$  do
19     Let  $x \in R_i$  such that  $u \in C_{i,x}$ ;
20      $E(H) \leftarrow E(H) \cup \{u\} \times \{\bigcup_{j=1}^i S_{z_i(x),j}\}$ ;
21 foreach  $z \in Z_{k-1}$  do  $E(H) \leftarrow E(H) \cup \{z\} \times V$ ; // Second Augmentation
22 return  $H$ ;

```

We build our clustering in $k - 1$ rounds indexed from 1 to $k - 1$ (a detailed pseudocode is given in Algorithm 1), where the generic i -th round defines a set Z_i of level- i special vertices. Initially, $Z_0 = V$, i.e., all vertices are special vertices of level 0. During the i -th round, the level- i clustering is computed from the set of vertices in Z_{i-1} defined at the previous round as follows.

For each $u \in Z_{i-1}$, we let $E_{i,u}$ be a set of $\delta_i = \Theta(n^{\frac{i}{k}} \log^{\frac{k-i}{k}} n)$ edges with the smallest label among those that are incident to u but do not belong to $\bigcup_{j=1}^{i-1} E_{u,j}$, and we denote by $S_{i,u} = \{v \in V : (u, v) \in E_{i,u}\}$ the set containing the endvertices of the edges incident to u in $E_{i,u}$. We now compute a hitting set $R_i \subseteq V$ of the collection $\{S_{i,u} \mid u \in Z_{i-1}\}$ having size at most $O(\frac{n}{\delta_i} \log n)$. Lemma 1 guarantees that R_i always exists. Notice that, as i increases, the time labels of the edges in $E_{i,u}$ became larger, δ_i increases, and $|R_i|$ decreases.

We now partition the vertices in Z_{i-1} into $|R_i|$ clusters $C_{i,x}$, one for each $x \in R_i$. We do so by adding each vertex $u \in Z_{i-1}$ into an arbitrary cluster $C_{i,x}$ such that $x \in S_{i,u}$. We call x the center of the cluster $C_{i,x}$. Moreover, for each cluster $C_{i,x}$, we choose a special vertex $z_i(x) \in C_{i,x}$ as a vertex that maximizes the label of edge $(x, z_i(x))$.

Once the hierarchical clustering is built, our algorithm proceeds to construct a temporal $(2k - 1)$ -spanner H of G . At the beginning $H = (V, \emptyset)$, then edges are added to H in the following three phases:

19:10 Sparse Temporal Spanners with Low Stretch

■ **Figure 4** The set of edges selected for each vertex during the initialization phase.

Initialization: For each $u \in V$, we add to $E(H)$ all the edges in the sets $E_{i,u}$ for $i = 1, \dots, j+1$, where j is the largest integer between 0 and $k-2$ for which $u \in Z_j$, see Figure 4.

First Augmentation: For each $i = 1, \dots, k-1$ and each $u \in Z_{i-1}$, we consider the center $x \in R_i$ of the level- i cluster $C_{i,x}$ containing u , and we add to $E(H)$ all the edges (u, v) with $v \in \bigcup_{j=1}^i S_{j,z_i(x)}$.

Second Augmentation: We add to $E(H)$ all edges incident to some vertex in Z_{k-1} .

We now show that all vertices are at distance at most $2k-1$ in H , and that the size of H is $O(k \cdot n^{1+\frac{1}{k}} \log^{\frac{k-1}{k}} n)$.

► **Lemma 4.** *For every $u, v \in V(G)$, $d_H(u, v) \leq (2k-1)d_G(u, v)$.*

Proof. Let $z_0 = u$ and, for $i = 1, \dots, k-1$, let $z_i = z_i(x_i)$ where $x_i \in R_i$ is the center of the cluster C_{i,x_i} containing z_{i-1} . The initialization phase ensures that, for any i , there exists a temporal path from z_0 to z_i in H of length $2i$ entering z_i with the edge $(x_i, z_i) \in E_{i,z_i}$.⁵ Indeed, π_i can be chosen as the path that traverses edge $(z_{i-1}, x_i) \in E_{i,z_{i-1}}$ and edge $(x_i, z_i) \in E_{i,z_i}$, in this order. Notice that, by definition of z_i , $\lambda(z_{i-1}, x_i) \leq \lambda(x_i, z_i)$. Moreover, if $i < k-1$, $\lambda(x_i, z_i) \leq \lambda(z_i, x_{i+1})$ since $(x_i, z_i) \in E_{i,z_i}$ while $(z_i, x_{i+1}) \in E_{i+1,z_i}$. See Figure 5.

If $v = z_i$ for some $i = 1, \dots, k-1$ then, from the discussion above, we know that π_i is a temporal path from u to v in H of length $2i < 2k-1$. Otherwise, we distinguish two cases depending on whether there exists some $i = 1, \dots, k-1$ such that $(z_i, v) \in \bigcup_{j=1}^i E_{j,z_i}$.

Suppose that the above condition is met, and let $i > 0$ be the minimum index for which $(z_i, v) \in \bigcup_{j=1}^i E_{j,z_i}$. If $\lambda(z_i, v) \geq \lambda(x_i, z_i)$, then π_i followed by edge (z_i, v) , is a temporal path from u to v of length $2i+1 \leq 2k-1$. If $\lambda(z_i, v) < \lambda(x_i, z_i)$ then, since $(z_i, v) \in \bigcup_{j=1}^i E_{j,z_i}$, we have $v \in \bigcup_{j=1}^i S_{j,z_i}$ and the first augmentation phase adds (z_{i-1}, v) to $E(H)$. By hypothesis we have $(z_{i-1}, v) \notin \bigcup_{j=1}^{i-1} E_{j,z_{i-1}}$ and hence $\lambda(z_{i-1}, v) \geq \lambda(x_{i-1}, z_{i-1})$. This shows that π_{i-1} followed by (z_{i-1}, v) is a temporal path from u to v in H of length $2i-1 \leq 2k-1$.

It only remains to handle the case in which, for every i , we have $(z_i, v) \notin \bigcup_{j=1}^i E_{j,z_i}$. In this case, the algorithm adds (z_{k-1}, v) to $E(H)$ during the second augmentation phase. Moreover, since $\lambda(z_{k-1}, v) \geq \lambda(x_{k-1}, z_{k-1})$, the path π_{k-1} followed by edge (z_{k-1}, v) is a temporal path from u to v in H of length $2k-1$. ◀

► **Theorem 5.** *Given a temporal clique G , for any $k \geq 1$, the above algorithm computes a temporal $(2k-1)$ -spanner H of size $O(k \cdot n^{1+\frac{1}{k}} \log^{\frac{k-1}{k}} n)$.*

⁵ This path is not necessarily a simple path (e.g., when $z_i = z_{i+1}$). The existence of a non-simple temporal path of length ℓ implies the existence of simple temporal path of length at most ℓ .

■ **Figure 5** The hierarchy of clusters for vertex z_0 , where $z_i = z_i(x_i)$ where $x_i \in R_i$ is such that $z_{i-1} \in C_{i,x_i}$. The dashed line is the temporal path π_3 that goes from z_0 to z_3 .

We conclude this section with a simple lower bound on the size of any temporal 2-spanners of a temporal clique.

► **Theorem 6.** *There exists a temporal clique G of n vertices such that any temporal 2-spanner of G has size $\Omega(n^2)$.*

4 Single-source spanners for general temporal graphs

In the first part of this section we design an algorithm that, for every $0 < \varepsilon < n$, builds a single-source temporal $(1 + \varepsilon)$ -spanner of G w.r.t. s of size $O\left(\frac{n \log^4 n}{\log(1+\varepsilon)}\right)$. We observe that, for constant values of ε , the size of the computed spanner is almost linear, i.e., linear up to polylogarithmic factors. The algorithm can be extended so as, for every $1 \leq \beta < n$, it builds a single-source temporal β -additive spanner of G w.r.t. s of size $O\left(\frac{n^2 \log^4 n}{\beta}\right)$.⁶

Our upper bounds leave open the problem of deciding whether a temporal graph G admits a single-source temporal preserver w.r.t. s of size $\tilde{O}(n)$. We answer to this question negatively in the second part of this section. More precisely, we show a temporal graph G of size $\Theta(n^2)$ and a source vertex s for which no edge can be removed if we want to keep a shortest temporal path from s to every other vertex u . The construction can be extended to show a lower bound of $\Omega(n^2/\beta)$ on the size of single-source temporal β -additive spanners, for every $\beta \geq 1$. This implies that our upper bound on the size of single-source temporal additive spanners is asymptotically optimal, up to polylogarithmic factors.

4.1 Our upper bound

In this section we present an algorithm that, for every $0 < \varepsilon < n$, computes a single-source temporal $(1 + \varepsilon)$ -spanner of G w.r.t. s of size $O\left(\frac{n \log^4 n}{\log(1+\varepsilon)}\right)$ in polynomial time.⁷

In the following we say that a temporal path is τ -restricted if it uses edges of time-label of at most τ . Our algorithm computes a spanner that, for every $\tau = 1, \dots, L$, contains $(1 + \varepsilon)$ -approximate τ -restricted temporal paths from s to any vertex v (recall that L is the lifetime of G). More formally, for two vertices u and v of G , we denote by $d_G^{\leq \tau}(u, v)$ the length of a shortest τ -restricted temporal path from u to v in G . We assume $d_G^{\leq \tau}(u, v) = +\infty$ when G does not contain a τ -restricted temporal path from u to v . The single-source temporal $(1 + \varepsilon)$ -spanner H of G w.r.t. s computed by our algorithm is such that, for every $v \in V$, and for every $\tau = 1, \dots, L$, $d_H^{\leq \tau}(s, v) \leq (1 + \varepsilon)d_G^{\leq \tau}(s, v)$.

⁶ We refer the interested reader to the full version of this paper for details.

⁷ Our algorithm also works in the case of directed temporal graphs and/or multiple time-labels. Both the algorithm and the stretch analysis require no modification. Regarding the running time, we only need to observe that τ -restricted shortest paths can be computed in polynomial time even in directed/multiple-label temporal graphs.

19:12 Sparse Temporal Spanners with Low Stretch

■ **Algorithm 2** Computes a set Π_v of temporal paths from s to v in G that provides a good approximation of any shortest τ -restricted temporal path from s to v in G .

Input : A temporal graph G (with lifetime L), a source vertex $s \in V$, and a vertex $v \in V$.
Output : A set Π_v of temporal paths from s to v in G such that, for every $\tau = 1, \dots, L$, there exists a τ -restricted temporal path $\pi \in \Pi_v$ such that $|\pi| \leq (1 + \delta)d_G^{\leq \tau}(s, v)$.

```

1  $\Pi_v \leftarrow \emptyset$ ;  $t \leftarrow +\infty$ ;
2 for  $\tau = 1$  to  $L$  do
3   if  $d_G^{\leq \tau}(s, v) \neq +\infty$  and  $d_G^{\leq \tau}(s, v) < \frac{t}{1+\delta}$  then
4     Let  $\pi$  be a shortest  $\tau$ -restricted temporal path from  $s$  to  $v$  in  $G$ ;
5      $\Pi_v \leftarrow \Pi_v \cup \{\pi\}$ ;
6      $t \leftarrow |\pi|$ ;
7 return  $\Pi_v$ ;
```

For technical convenience, in the following we design an algorithm that, for any $0 < \delta < n$ and any positive integer k , builds a single-source temporal $(1 + \delta)^k$ -spanner of G w.r.t. s of size $O\left(\frac{kn^{1+\frac{1}{k}} \log^{2-\frac{1}{k}} n}{\log(1+\delta)}\right)$. The desired bound of $O\left(\frac{n \log^4 n}{\log(1+\varepsilon)}\right)$ on the size of the single-source temporal $(1 + \varepsilon)$ -spanner is obtained by choosing $k = \lceil \log n \rceil$ and $\delta = (1 + \varepsilon)^{\frac{1}{\log n}} - 1$.

Our algorithm uses a subroutine that, for a given vertex v of G , computes a set Π_v of $O\left(\frac{\log n}{\log(1+\delta)}\right)$ temporal paths from s to v of G such that, for every $\tau = 1, \dots, L$, Π_v contains a τ -restricted temporal path π satisfying $|\pi| \leq (1 + \delta)d_G^{\leq \tau}(s, v)$.

The subroutine (see Algorithm 2 for the pseudocode) builds Π_v iteratively by adding a subset of shortest τ -restricted temporal paths from s to v in G , where $\tau = 1, \dots, L$. We do so by scanning shortest τ -restricted temporal paths from s to v in increasing order of values of τ . The scanned path π is added to Π_v if no other path already contained in Π_v has a length of at most $(1 + \delta)|\pi|$. The next lemma shows the correctness of our subroutine and bounds the number of paths contained in Π_v .

► **Lemma 7.** *For every $\tau = 1, \dots, L$, there is a τ -restricted temporal path π in Π_v such that $|\pi| \leq (1 + \delta)d_G^{\leq \tau}(s, v)$. Moreover, $|\Pi_v| = O\left(\frac{\log n}{\log(1+\delta)}\right)$.*

In the rest of this section, for any given temporal path π , we denote by $\pi(\ell)$ the subpath of π containing the last $\min\{\ell, |\pi|\}$ edges of π . We observe that $\pi(\ell) = \pi$ when $|\pi| \leq \ell$. Moreover, for two vertices u and v of a temporal path π that visits u before v , we denote by $\pi[u, v]$ the temporal subpath of π from u to v .

Before diving into the technical details, we describe the main idea of our algorithm and show how we can use it to build a single-source temporal $(1 + \delta)^2$ -spanner of G w.r.t. s of size $O\left(\frac{n^{3/2} \log^{3/2} n}{\log(1+\delta)}\right)$.

For technical convenience, let $R_0 = V$ and $\mathcal{P}_0 = \bigcup_{v \in R_0} \Pi_v$. In principle, we could build our single-source temporal $(1 + \delta)$ -spanner of G w.r.t. s by simply setting its edge set to $\bigcup_{\pi \in \mathcal{P}_0} E(\pi)$. Unfortunately, Lemma 7 alone is insufficient to provide a subquadratic upper bound on the size of this spanner. Therefore, to obtain a spanner of truly subquadratic size, we compute a single-source temporal $(1 + \delta)^2$ -spanner H of G w.r.t. s instead.

We build H by adding all the *short* temporal paths in \mathcal{P}_0 , i.e., all paths with at most ℓ_0 edges for a suitable choice of ℓ_0 , and by replacing each *long* temporal path $\pi \in \mathcal{P}_0$ from s to some vertex v with the shortest temporal path from s to x in Π_x , for some vertex x that *hits* $\pi(\ell_0)$, combined with $\pi[x, v]$.

■ **Algorithm 3** Single-source temporal spanner of a temporal graph G .

Input : A temporal graph $G = (V, E)$ of n vertices and a source vertex $s \in V$.
Output : A single-source temporal spanner H of G w.r.t. s .

- 1 **for** $i = 0, \dots, k-1$ **do** $\ell_i \leftarrow n^{\frac{i+1}{k}} \log^{1-\frac{i+1}{k}} n$;
- 2 **foreach** $v \in V$ **do** use Algorithm 2 to compute Π_v ;
- 3 $R_0 \leftarrow V$; $\mathcal{P}_0 \leftarrow \{\pi \in \Pi_v \mid v \in R_0\}$;
- 4 **for** $i = 1, \dots, k-1$ **do**
- 5 $\mathcal{P}_{i-1}^{long} = \{\pi \in \mathcal{P}_{i-1} \mid |\pi| > \ell_i\}$;
- 6 $R_i \leftarrow$ hitting set of $\{\pi(\ell_{i-1}) \mid \pi \in \mathcal{P}_{i-1}^{long}\}$ computed as in Lemma 1;
- 7 $\mathcal{P}_i \leftarrow \bigcup_{v \in R_i} \Pi_v$;
- 8 **return** $H = \left(V, \bigcup_{i=0}^{k-1} \bigcup_{\pi \in \mathcal{P}_i} E(\pi(\ell_i)) \right)$;

In more details, we define $\ell_0 = \sqrt{n \log n}$ and we introduce a new parameter $\ell_1 = n$. We say that a temporal path $\pi \in \mathcal{P}_0$ is *short* if $|\pi| \leq \ell_0$; it is *long* otherwise. Let $\mathcal{P}_0^{long} = \{\pi \in \mathcal{P}_0 \mid |\pi| > \ell_0\}$ be the subset of long temporal paths in \mathcal{P}_0 . We compute a set R_1 that hits $\{\pi(\ell_0) \mid \pi \in \mathcal{P}_0^{long}\}$ using Lemma 1, and we then use this set to define a new collection of temporal paths $\mathcal{P}_1 = \bigcup_{v \in R_1} \Pi_v$.⁸ The edge set of H is defined as $E(H) = \bigcup_{i \in \{0,1\}} \bigcup_{\pi \in \mathcal{P}_i} E(\pi(\ell_i))$. The next lemma shows that this simple algorithm already computes a single-source temporal $(1 + \delta)^2$ -spanner of G w.r.t. s of truly subquadratic size.

► **Lemma 8.** *For every $\tau = 1, \dots, L$ and every $v \in V$, $d_H^{\leq \tau}(s, v) \leq (1 + \delta)^2 d_G^{\leq \tau}(s, v)$. Moreover, the size of H is $O\left(\frac{n^{3/2} \log^{3/2} n}{\log(1+\delta)}\right)$.*

The technique we used to replace each of the temporal paths in \mathcal{P}_0^{long} with a temporal path that is longer by a factor of at most $(1 + \delta)$ can be applied recursively on the set \mathcal{P}_1 , for a suitable choice of ℓ_1 , to obtain an even sparser spanner. As we show now, $k-1$ levels of recursion allow us to compute a single-source temporal $(1 + \delta)^k$ -spanner H of G w.r.t. s of size $O\left(\frac{kn^{1+\frac{1}{k}} \log^{2-\frac{1}{k}} n}{\log(1+\delta)}\right)$.

In the following we provide the technical details (see Algorithm 3 for the pseudocode). For every $i = 0, \dots, k-1$, let $\ell_i = n^{\frac{i+1}{k}} \log^{1-\frac{i+1}{k}} n$. As before, let $R_0 = V$ and $\mathcal{P}_0 = \bigcup_{v \in R_0} \Pi_v$. During the i -th iteration, the algorithm computes a set R_i that hits $\{\pi(\ell_{i-1}) \mid \pi \in \mathcal{P}_{i-1}^{long}\}$, where $\mathcal{P}_{i-1}^{long} = \{\pi \in \mathcal{P}_{i-1} \mid |\pi| > \ell_{i-1}\}$ is the set of *long* temporal paths of \mathcal{P}_{i-1} . The i -th iteration ends by computing the set $\mathcal{P}_i = \bigcup_{v \in R_i} \Pi_v$ that is used in the next iteration. The edge set of the graph H that is returned by the algorithm is $E(H) := \bigcup_{i=0}^{k-1} \bigcup_{\pi \in \mathcal{P}_i} E(\pi(\ell_i))$.

► **Theorem 9.** *For every $\tau = 1, \dots, L$, for every $i = 1, \dots, k$, and for every $v \in R_{k-i}$, we have that $d_H^{\leq \tau}(s, v) \leq (1 + \delta)^i d_G^{\leq \tau}(s, v)$. Moreover, the size of H is $O\left(\frac{kn^{1+\frac{1}{k}} \log^{2-\frac{1}{k}} n}{\log(1+\delta)}\right)$.*

Proof. We start proving the first part of the theorem statement. The proof is by induction on i . Fix a vertex $v \in R_{k-i}$ such that $d_G^{\leq \tau}(s, v)$ is finite.

For the base case $i = 1$, we observe that Π_v is entirely contained in H by construction. Therefore, by Lemma 7, $d_H^{\leq \tau}(s, v) \leq (1 + \delta) d_G^{\leq \tau}(s, v)$ and the claim follows.

We now prove the inductive case. We assume that the claim holds for $i-1$ and we prove it for i . Let $\pi \in \Pi_v$ be a shortest τ -restricted temporal path from s to v among those in Π_v . By Lemma 7, $|\pi| \leq (1 + \delta) d_G^{\leq \tau}(s, v)$. Moreover, by definition, $\pi \in \mathcal{P}_{k-i}$. If π is short, i.e.,

⁸ With a little abuse of notation, R_1 hits a temporal path π if R_1 hits $V(\pi)$.

■ **Figure 6** Example of the lower bound with $h = 2$ and $\beta = 0$. Path π_1 consists of the black edges. Path π_2 is built on top of π_1 , whose vertices have been numbered in order of a traversal from s , and consists of: the first hop from s to μ (in green), the forward hops (in blue), and the backward hops (in red). The arrows on the edges of π_2 are directed away from s along π_2 .

$|\pi| \leq \ell_{k-i}$, then π is entirely contained in H and therefore $d_H^{\leq \tau}(s, v) \leq (1 + \delta)d_G^{\leq \tau}(s, v) \leq (1 + \delta)^{k-i}d_G^{\leq \tau}(s, v)$. So, in the following we assume that π is long. Let $x \in R_{k-i+1}$ be a vertex that hits $\pi(\ell_{k-i})$. By construction, the path $\pi[x, v]$, being a subpath of $\pi(\ell_{k-i})$, is entirely contained in H . Let τ' be the label of the edge incident to x in $\pi[x, v]$. Clearly, $\tau' \leq \tau$. Moreover, by inductive hypothesis, $d_H^{\leq \tau'}(s, x) \leq (1 + \delta)^{i-1} \cdot |\pi[s, x]|$.

As a consequence, $d_H^{\leq \tau}(s, v) \leq d_H^{\leq \tau'}(s, x) + |\pi[x, v]| \leq (1 + \delta)^{i-1} \cdot |\pi[s, x]| + |\pi[x, v]| \leq (1 + \delta)^{i-1} \cdot |\pi| \leq (1 + \delta)^i d_G^{\leq \tau}(s, v)$.

To bound the size of H , we first observe that, for each $v \in V$, $|\Pi_v| = O\left(\frac{\log n}{\log(1+\delta)}\right)$ by Lemma 7. Next, using Lemma 1, we observe that each R_i , with $i \geq 1$, has size $|R_i| = O\left(\frac{n \log n}{\ell_{i-1}}\right) = O\left(n^{1-\frac{i}{k}} \log^{\frac{i}{k}} n\right)$. Furthermore, also $|R_0| = n = n^{1-\frac{0}{k}} \log^{\frac{0}{k}} n$. Therefore, for every $i = 0, \dots, k-1$, we have $|R_i| \ell_i = O\left(n^{1+\frac{1}{k}} \log^{1-\frac{1}{k}} n\right)$. As a consequence,

$$\sum_{\pi \in \mathcal{P}_i} |\pi(\ell_i)| = \sum_{v \in R_i} \sum_{\pi \in \Pi_v} |\pi(\ell_i)| = O\left(|R_i| \ell_i \frac{\log n}{\log(1+\delta)}\right) = O\left(\frac{n^{1+\frac{1}{k}} \log^{2-\frac{1}{k}}}{\log(1+\delta)}\right).$$

Hence, $|E(H)| = \sum_{i=0}^{k-1} \sum_{\pi \in \mathcal{P}_i} |\pi(\ell_i)| = O\left(\frac{kn^{1+\frac{1}{k}} \log^{2+\frac{1}{k}}}{\log(1+\delta)}\right)$. ◀

The following corollary follows by choosing $\tau = L$ and $i = k$ (so that $R_{k-i} = R_0 = V$):

► **Corollary 10.** *Let G be a temporal graph with n vertices and let s be a vertex of G . The graph H returned by Algorithm 3 is a single-source temporal $(1 + \delta)^k$ -spanner of G w.r.t. s of size $O\left(\frac{kn^{1+\frac{1}{k}} \log^{2+\frac{1}{k}}}{\log(1+\delta)}\right)$.*

4.2 Our lower bound

In this section we show that, for every $\beta \geq 0$, there is a temporal graph G of n vertices for which the size of any single-source temporal β -additive spanner of G w.r.t. s is $\Omega\left(\frac{n^2}{1+\beta}\right)$. This gives a lower bound of $\Omega(n^2)$ for the size of a single-source temporal preserver.

The temporal graph G has $n = (13 + \beta)h$ vertices, where h is an integer, and is formed by the union of h pairwise edge-disjoint temporal paths π_1, \dots, π_h . Each path π_i goes from s to a vertex z_i and has length $\Omega(n - i(1 + \beta))$. The construction guarantees that the unique temporal path of G from s to z_i of length of at most $d_G(s, z_i) + \beta$ is π_i . This implies that the size of G is $\Omega\left(\frac{n^2}{1+\beta}\right)$, as desired.

The temporal path π_1 is a Hamiltonian path that spans all the n vertices of G and goes from s to z_1 . All edges of π_1 have time-label 1. The remaining temporal paths are defined recursively. More precisely, for each $i = 2, \dots, h$, the temporal path π_i is defined on top of the temporal path π_{i-1} as follows. Let us number the vertices visited in a traversal of π_{i-1} from s to z_{i-1} in order from 0 to $|\pi_{i-1}| - 1$. The temporal path π_i is defined as a sequence of hops over the vertices of π_{i-1} . We call *offset* a value μ that is equal to $\beta + 7$ for even values of β , and to $\beta + 8$ for odd values of β . The first hop is the one from s to vertex μ ,

if it exists. The rest of the path is given by a maximal alternating sequence of *backward* and *forward* hops that do not visit z_{i-1} . A generic backward hop goes from vertex j , with j odd, to vertex $j - 3$, while a generic forward hop goes from vertex j , with j even, to vertex $j + 5$. All the edges of π_i have time-label i . A pictorial example of the definition of π_i is given in Figure 6. The choice of odd values for the offset is a necessary condition to have pairwise edge-disjoint paths, while the dependency of the offset on β guarantees that π_i is the unique temporal path from s to z_i in G such that $|\pi_i| \leq d_G(s, z_i) + \beta$. Finally, the alternating sequence of backward and forward hops guarantees that $|\pi_i| = \Omega(n - i(1 + \beta))$. The above discussion yields the following theorem, and a corollary for the case $\beta = 0$.

► **Theorem 11.** *For every positive integer n and every $\beta \geq 0$, there is a temporal graph G of n vertices and a source vertex s of G such that any single-source temporal β -additive spanner of G w.r.t. s has size $\Omega\left(\frac{n^2}{1+\beta}\right)$.*

► **Corollary 12.** *For every positive integer n , there is a temporal graph G of n vertices such that any single-source temporal preserver of G w.r.t. s has size $\Theta(n^2)$.*

5 Conclusions

In this paper we addressed the size-stretch trade-offs for temporal spanners. We showed that a temporal clique admits a temporal $(2k - 1)$ -spanner of size $\tilde{O}(n^{1+\frac{1}{k}})$, which implies a spanner having size $\tilde{O}(n)$ and stretch $O(\log n)$. The previous best-known result was the temporal-spanner of [7] which only preserves temporal connectivity between vertices. Our construction guarantees $O(\log n)$ -approximate distances at the cost of only an additional $O(\log n)$ multiplicative factor on the size. We also considered the single-source case for *general* temporal graphs, where we provided almost-tight size-stretch trade-offs, along with the special case of temporal graphs with bounded lifetime.

The main problem that remains open is understanding whether better trade-offs are achievable for temporal cliques. In particular, no superlinear lower bounds are known even for the case of 3-spanners.

Finally, as we already mentioned, temporal graphs admit other natural notions of distances between vertices (which have been used, e.g., in [10, 12, 13]). The most commonly used distances are the *earliest arrival time*, the *latest departure time*, the *fastest time* (i.e., the smallest difference between the arrival and departure time of a temporal path from u to v), and – if each edge has an associated travel time – the *shortest time* distance (i.e., the minimum sum of the travel times of the edges of a temporal path from u to v). One can wonder whether sparse temporal spanners with low stretch are attainable also in the case of the above distances. Unfortunately the answer is negative and strong lower bounds on the size of temporal α -spanners for temporal cliques can be shown even for large values of α , as we discuss in the full version of the paper.

Resource Sharing Revisited: Local Weak Duality and Optimal Convergence

Daniel Blankenburg  

Research Institute for Discrete Mathematics, Universität Bonn, Germany

Abstract

We revisit the (block-angular) min-max resource sharing problem, which is a well-known generalization of fractional packing and the maximum concurrent flow problem. It consists of finding an ℓ_∞ -minimal element in a Minkowski sum $\mathcal{X} = \sum_{C \in \mathcal{C}} X_C$ of non-empty closed convex sets $X_C \subseteq \mathbb{R}_{\geq 0}^{\mathcal{R}}$, where \mathcal{C} and \mathcal{R} are finite sets. We assume that an oracle for approximate linear minimization over X_C is given.

We improve on the currently fastest known FPTAS in various ways. A major novelty of our analysis is the concept of local weak duality, which illustrates that the algorithm optimizes (close to) independent parts of the instance separately. Interestingly, this implies that the computed solution is not only approximately ℓ_∞ -minimal, but among such solutions, also its second-highest entry is approximately minimal.

Based on a result by Klein and Young [21], we provide a lower bound of $\Omega\left(\frac{|\mathcal{C}|+|\mathcal{R}|}{\delta^2} \log |\mathcal{R}|\right)$ required oracle calls for a natural class of algorithms. Our FPTAS is optimal within this class – its running time matches the lower bound precisely, and thus improves on the previously best-known running time for the primal as well as the dual problem.

1 Introduction

1.1 Problem description

Dividing a limited set of *resources* among *customers* is an overarching theme of numerous problems in discrete and continuous optimization. A common formulation of such problems is known as *min-max resource sharing* in the literature. In this work, we consider the *block-angular min-max resource sharing problem* as it was first studied by Grigoriadis and Khachiyan [13]. The problem consists of choosing a feasible resource allocation for every customer, such that the maximum accumulated resource usage is minimized. Formally, it can be described as follows:

There is a finite set of customers \mathcal{C} and a finite set of resources \mathcal{R} . We denote their sizes by $n := |\mathcal{C}|$ and $m := |\mathcal{R}|$. For each customer $C \in \mathcal{C}$, there is a non-empty closed convex set $X_C \subseteq \mathbb{R}_{\geq 0}^m$ of *feasible resource allocations*, also referred to as *block*. The set of *feasible solutions* of the (block-angular) min-max resource sharing problem is given as the Minkowski-sum $\mathcal{X} := \sum_{C \in \mathcal{C}} X_C$.

20:2 Resource Sharing Revisited

Further, we assume that we are given, for some constant $\sigma \geq 1$, a σ -approximate *block-solver*, which is an approximate linear minimization oracle for non-negative price vectors. It is specified by functions $f_C : \mathbb{R}_{\geq 0}^m \rightarrow X_C$ for all $C \in \mathcal{C}$ that satisfy

$$\forall y \in \mathbb{R}_{\geq 0}^m : \quad \langle y, f_C(y) \rangle \leq \sigma \text{opt}_C(y), \quad (1)$$

where $\text{opt}_C(y) := \min_{x \in X_C} \langle y, x \rangle$.

The (block-angular) *min-max resource sharing problem* is to compute resource allocations $x_C \in X_C$ for every customer $C \in \mathcal{C}$, such that $x := \sum_{C \in \mathcal{C}} x_C$ attains

$$\lambda^* := \min_{x \in \mathcal{X}} \|x\|_{\infty}. \quad (2)$$

We abbreviate this problem as *resource sharing problem* in the following. In this work, we consider fully polynomial-time approximation schemes relative to σ . For $\delta > 0$, we construct a solution $x \in \mathcal{X}$ with $\|x\|_{\infty} \leq \sigma(1 + \delta)\lambda^*$ within a number of oracle calls that is polynomial in n, m , and δ^{-1} .

Algorithms that interact with the feasible region only via a linear minimization oracle are known as algorithms of the *Dantzig-Wolfe type*. An iteration consists of choosing a price vector $y \in \mathbb{R}_{\geq 0}^m$ and querying the linear minimization oracle of a customer $C \in \mathcal{C}$ with y . The computed solution is a convex combination of the solutions returned from the oracle. At their core, Dantzig-Wolfe-type algorithms are primal-dual algorithms. In the case of the resource sharing problem, the dual is to find $q \in \Delta_m := \{p \in [0, 1]^m : \|p\|_1 = 1\}$, such that $\min_{x \in \mathcal{X}} \langle q, x \rangle = \max_{p \in \Delta_m} \min_{x \in \mathcal{X}} \langle p, x \rangle$. Strong duality is implied by von Neumann's minimax theorem:

$$\max_{p \in \Delta_m} \min_{x \in \mathcal{X}} \langle p, x \rangle = \min_{x \in \mathcal{X}} \max_{p \in \Delta_m} \langle p, x \rangle = \min_{x \in \mathcal{X}} \|x\|_{\infty} = \lambda^*. \quad (3)$$

The resource sharing formulation can be used to model a large variety of packing problems in combinatorial optimization. Prominent examples include multicommodity and concurrent flow problems, where the linear minimization tasks correspond to shortest path problems, or fractional Steiner tree packing problems, where the linear minimization tasks correspond to minimum weight Steiner tree problems and can be implemented, for example, with a fast 2-approximation.

Using a linear minimization oracle to interact with the feasible region is a standard tool in convex optimization, most often encountered in the form of conditional gradient descent (a.k.a. Frank-Wolfe algorithm [9]), that has regained interest in current research as it leads to surprisingly fast algorithms in practice [17, 19]. Apart from efficiency, utilizing a linear minimization oracle has the advantage that solutions are constructed explicitly as an (often sparse) combination of extreme points. This is highly useful if one is interested in an integral solution to the packing problem, since, in practice, a close to optimal integral solution can often be recovered by applying e.g. randomized rounding to the sparse fractional solution [28].

Resource sharing has a long history of incremental generalizations and improvements since Shahrokhi and Matula [29] introduced the idea to use a linear optimization oracle with an exponential weight function in the context of multicommodity flows. At their heart, most, if not all, steps in this line of work can be interpreted as variants of the now well-known multiplicative weight update method. Since we also present a variant of that algorithm and improve on the best-known running time in this setting, our work can be regarded as another step in that line. But more than that, we study an aspect that – to the best of our knowledge – is absent from any treatment of multiplicative-weight-based algorithms even in special cases such as multicommodity flow. We are interested in the stability of such algorithms and in

(a) High congestion only in local hotspots. (b) High congestion in almost every part.

■ **Figure 1** Comparison of two fractional routing results. Congestion of global routing tiles is visualized by color (lowest congestion in green, highest in violet).

deriving guarantees that go beyond the min-max objective. For example, one might alter a given instance \mathcal{X} by adding a completely independent resource and consider $\mathcal{X} \times \{\Lambda\}$ with $\Lambda \gg \min_{x \in \mathcal{X}} \|x\|_\infty$. In this case, ℓ_∞ -guarantees of existing algorithms do not provide any insight into the quality of their computed solution on the perturbed instance when restricted to \mathcal{X} . We introduce techniques that allow a comprehensive treatment of such situations.

To provide more motivation for this pursuit, we consider the example of global routing in VLSI design, where a resource sharing formulation has proven successful in theory and practice [12, 16, 24]. Highly simplified, the problem consists of a Steiner tree packing problem in a grid graph. One seeks to find a collection of (fractional) Steiner trees that minimize the maximum edge overload. Figure 1 depicts two fractional routing results on an industrial microprocessor. The maximum edge congestion is the same in both cases, so both solutions have the same objective value w.r.t. the resource sharing problem. As indicated in Figure 1a, however, the maximum congestion might be caused by local effects that are beyond reach for global optimization. A practicable algorithm must be resilient to such local hotspots and produce solutions that are close to optimal on the set of remaining resources. The solution in Figure 1a is clearly to be preferred over that in Figure 1b. In practice, the ideal outcome might be a solution $x \in \mathcal{X}$ that minimizes the maximal entry, and among such solutions, it minimizes the second-highest entry, and among those, it minimizes the third-highest, and so on. This concept is known as *decreasingly minimal* [6].

► **Definition 1.** Let $x \in \mathbb{R}^m$. We denote by x_\downarrow the vector x with entries sorted in decreasing order. We introduce the decreasing preorder, by defining for $x, y \in \mathbb{R}^m$, $x \leq_{dec} y$ if either $x_\downarrow = y_\downarrow$ or there exists $k \in \{1, \dots, m\}$ such that $(x_\downarrow)_k < (y_\downarrow)_k$ and $(x_\downarrow)_j = (y_\downarrow)_j$ for all $j < k$. Given a set $X \subseteq \mathbb{R}^m$, we say that an element $x \in X$ is decreasingly minimal if $x \leq_{dec} y$ holds for all $y \in X$.

1.2 Our contribution

In this work, we present a fully polynomial-time approximation scheme for the primal as well as the dual of the resource sharing problem. Our algorithm is an extension of the algorithm by Müller, Radke, and Vygen [24].

We introduce the novel concept of *local weak duality* (Definition 2) to analyze the *core algorithm* (Algorithm 1) which is a variant of the multiplicative weight update method. Given local weak duality, we can prove stronger bounds on $\max_{r \in S} x_r$ for the computed solution $x \in \mathcal{X}$ and certain subsets $S \subseteq \mathcal{R}$. That provides a theoretical counterpart to the empirical observation that the algorithm optimizes (close to) independent parts of the instance separately. Moreover, it allows concluding that – with an exact block solver – our algorithm always computes a solution that is approximately decreasingly minimal on the two highest entries. Such guarantees were not known even for special cases of the problem and

could, in principle, be transferred to many other settings where the multiplicative weight update method is employed. We also provide a negative result, namely that our algorithm will not compute close to decreasingly minimal solutions on the three highest entries in general.

Furthermore, we present an iterative scaling scheme in conjunction with an amortized running time analysis that results in the currently fastest known constant factor approximation for the resource sharing problem with $\mathcal{O}((n+m) \log m)$ many oracle calls. This is then utilized as an initial scaling technique to design an FPTAS improving on the best-known running time for the resource sharing problem. Also, dual convergence, which follows immediately with our analysis, was not shown in prior work.

Moreover, we discuss the limits of algorithms in this setting. We study a class of natural extensions of the core algorithm and prove, using a result by Klein and Young [21], that any algorithm from this class requires $\Omega(\frac{n+m}{\delta^2} \log m)$ oracle calls to compute a $(1+\delta)$ -approximate solution (for a range of parameters as described in Theorem 13). This matches the running time of our algorithm precisely. As this is independent of the choice of the prices, this proves that – in a certain sense – multiplicative price updates are optimal, and that no warm-start analysis (i.e. reducing the running time by starting with a close to optimal dual solution) of such algorithms is possible.

1.3 Related work

The resource sharing problem originates from the maximum concurrent flow problem. For this special case, Shahrokhi and Matula [29] introduced the idea to use Dantzig-Wolfe-type algorithms with an exponential weight function. Another important special case of this problem is *fractional packing*, which can be described as follows. Given a polyhedron $P \subseteq \mathbb{R}^k$, a matrix $A \in \mathbb{R}^{m \times k}$ that satisfies $Ax \geq 0$ for all $x \in P$, and a vector $b \in \mathbb{R}_{>0}^m$, find an $x \in P$ that satisfies $Ax \leq b$. The width of the instance is defined as $\rho := \max_{x \in P} \max_{i=1, \dots, m} (Ax)_i / b_i$. Plotkin, Shmoys, and Tardos [26] studied this problem in the context of Dantzig-Wolfe-type algorithms. Their results were generalized and improved multiple times [5, 11, 13, 18, 20, 22, 24]. An important idea in this line of work is a step-size technique introduced by Garg and Könemann [11] and extended by Fleischer [5], which is used to design algorithms with width-independent running times.

The general version of the block-angular min-max resource sharing problem, as it is the subject of this work, was studied first by Grigoriadis and Khachiyan [13]. In their formulation, one is given non-empty closed convex blocks B_C for each $C \in \mathcal{C}$, and resource allocation functions $g^{(C)} : B_C \rightarrow \mathbb{R}_{\geq 0}^m$, which are convex and non-negative in each coordinate. Then, one seeks to compute $\min\{\max_{r \in \mathcal{R}} \sum_{C \in \mathcal{C}} g^{(C)}(b_C)_r : b_C \in B_C \forall C \in \mathcal{C}\}$. Their optimization oracle solves $\min_{b_C \in B_C} \langle y, g^{(C)}(b_C) \rangle$ for a given price vector $y \in \mathbb{R}_{\geq 0}^m$. It is easy to see that this formulation fits into our framework by defining X_C as the convex hull of $g^{(C)}(B_C)$. The currently fastest known algorithm for the general case is due to Müller, Radke, and Vygen [24]. They present a sequential algorithm that computes a solution of value at most $\sigma(1+\delta)$ within $\mathcal{O}((n+m) \log m (\delta^{-2} + \log \log m))$ oracle calls. All of the mentioned approaches can be interpreted as variants of the multiplicative weights update method [2].

Klein and Young [21] studied lower bounds on the number of iterations that are required by any Dantzig-Wolfe-type algorithm to compute a $(1+\delta)$ -approximate solution for fractional packing. They provide an asymptotic width-dependent bound of $\Omega\left(\min\left\{\rho \frac{\log m}{\delta^2}, m^{1/2-\gamma}\right\}\right)$ (for any fixed $\gamma \in (0, 1/2)$). This matches known upper bounds precisely for a range of parameters. If the width of the instance is unbounded, it is easy to see that $\Omega(m)$ oracle

calls are required to compute a constant-factor approximation [14]. If one is not restricted to algorithms of the Dantzig-Wolfe-type, then it is known how to avoid the δ^{-2} dependence on the running time for the case of fractional packing [1, 3].

Decreasingly minimal solutions to optimization problems appear under many different names in the literature, such as lexicographically optimal [10, 23], egalitarian [4], fair [8, 27] and more recently in a line of work by Frank and Murota – who study the integral case – as decreasingly minimal [6, 7]. We are going to use their notation in the following. It is known how to find such solutions with linear programming techniques [25, 27]. In our case, since \mathcal{X} is a non-empty closed convex subset of $\mathbb{R}_{\geq 0}^m$, it contains a unique decreasingly minimal element [27]. A concept related to decreasing minimization is that of *majorization* [15]. If the set of feasible solutions contains a least majorized element, it is also the decreasingly minimal element and can be extracted as the minimum of non-decreasing separable convex functions [30]. We are not aware of results w.r.t. decreasingly minimal solutions in the context of Dantzig-Wolfe-type algorithms.

1.4 Outline

The core algorithm (Algorithm 1, [24]) starts with the uniform price vector $y = \mathbb{1} \in \mathbb{R}^m$ and, after every oracle call, it updates the prices $y_r \leftarrow y_r \exp(\epsilon \xi b_r)$, where $\epsilon > 0$ is a fixed parameter of the algorithm. It runs in $T \in \mathbb{N}$ phases (iterations of the outer loop). At the end, the average solution over all phases $x^{(T)} := \frac{1}{T} \sum_{t=1}^T s^{(t)}$ is returned. The restricted step sizes in Line 8 were first proposed by Garg and Könemann [11] in the case of multicommodity flows.

The standard tool to prove primal convergence of algorithms that are based on the multiplicative weight update method is weak duality: For $y \in \mathbb{R}_{\geq 0}^m$, it holds that

$$\sum_{C \in \mathcal{C}} \langle y, f_C(y) \rangle \leq \sigma \min_{x \in \mathcal{X}} \langle y, x \rangle \leq \sigma \|y\|_1 \min_{x \in \mathcal{X}} \|x\|_\infty = \sigma \|y\|_1 \lambda^*. \quad (4)$$

This is sufficient to derive bounds on $\|x^{(T)}\|_\infty$. However, we aim to prove stronger bounds on $\max_{r \in S} x_r^{(T)}$ for certain subsets of resources $S \subseteq \mathcal{R}$. To this end, we introduce the concept of *local weak duality*, which generalizes weak duality. We briefly describe the intuition behind

(a) The decreasingly minimal solution λ with a decomposition $\lambda = \lambda^{(blue)} + \lambda^{(red)}$. Here $\lambda^{(blue)}$ ($\lambda^{(red)}$) assigns value 1 to all edges that are marked with solid blue (red) lines and value $1/2$ to all edges that are marked with dashed blue (red) lines.

(b) Example of a bad oracle. Consider edge prices $y \in \mathbb{R}_{\geq 0}^{E(G)}$, given by $y_e = 2$, $y_f = y_g = 1$, and zero otherwise. Then, a 2-approximation oracle may return the solution above, not satisfying local weak duality on $E(G_1)$ or $E(G_2)$ for any value $\mu < 2$.

■ **Figure 2** An instance of fractional Steiner tree packing in a graph G that consists of two subgraphs G_1 and G_2 which are joined by an edge. The goal is to find fractional Steiner trees that connect the blue, respectively red terminals, such that the maximum edge load is minimized.

this notion. Given $y \in \mathbb{R}_{\geq 0}^m$, one may consider the *local* objective value $\sum_{C \in \mathcal{C}} \sum_{r \in S} y_r f_C(y)_r$ of the oracles on S (e.g. the cost of the paths restricted to a subset of edges in the multicommodity flow case). A local analog to weak duality is given if this objective value can be bounded by $\mu \sum_{r \in S} y_r$ for some $\mu > 0$, independently of y_r for $r \in \mathcal{R} \setminus S$ (the prices on the remaining edges). The following definition includes a different price vector for every customer, which is necessary to deal with the sequential price updates of the core algorithm. Then, the upper bound on the local objective value is defined using the point-wise maximum of these prices.

► **Definition 2.** We say that an instance \mathcal{X} of the resource sharing problem satisfies local weak duality w.r.t. a subset of resources $S \subseteq \mathcal{R}$ and $\mu \geq 0$ if for any collection of non-negative price vectors $(y^{(C)})_{C \in \mathcal{C}} \subseteq \mathbb{R}_{\geq 0}^m$ it holds that

$$\sum_{C \in \mathcal{C}} \sum_{r \in S} y_r^{(C)} f_C(y^{(C)})_r \leq \mu \sum_{r \in S} \max_{C \in \mathcal{C}} y_r^{(C)}. \quad (5)$$

This definition generalizes weak duality, in the sense that every instance satisfies local weak duality w.r.t. $S = \mathcal{R}$ and $\mu = \sigma \lambda^*$.

Let us briefly present an exemplary application. Figure 2 displays an instance of the fractional Steiner tree packing problem with unit capacities. The goal is to find fractional Steiner trees in G that connect the blue, respectively the red terminals such that the maximum edge usage is minimized. We have $\mathcal{C} = \{blue, red\}$ and $\mathcal{R} = E(G)$. The figure also depicts an optimum solution $\lambda = \lambda^{(red)} + \lambda^{(blue)}$ to the resource sharing problem as described in the caption of Figure 2a. In this case, λ is also the decreasingly minimal solution. As the figure indicates, G can be decomposed into two subgraphs G_1 and G_2 that are joined by an edge e . It is clear that e is the bottleneck, meaning that $\lambda_e = \min_{x \in \mathcal{X}} \|x\|_\infty = 2$. However, the (local) maximum usage on G_1 and G_2 is lower, it holds $\max_{e \in E(G_1)} \lambda_e = 1$ and $\max_{e \in E(G_2)} \lambda_e = \frac{1}{2}$. We observe that the Steiner tree problems decompose into two independent subproblems in G_1 and G_2 , i.e. the blue, respectively red terminals in G_1 and G_2 need to be connected to the contained endpoint of e . Let us discuss two examples of how to apply local weak duality to this instance for different oracles.

- (i) The oracle is exact. Thus it also solves the subproblems in G_1 and G_2 exactly. Now consider price vectors $y^{(red)}, y^{(blue)} \in \mathbb{R}_{\geq 0}^{E(G)}$. Since $\lambda^{(blue)}$ and $\lambda^{(red)}$ are feasible solutions for the *blue*, respectively the *red* customer, we get:

$$\sum_{e \in E(G_1)} y_e^{(blue)} f_{blue}(y^{(blue)})_e \leq \sum_{e \in E(G_1)} y_e^{(blue)} \lambda_e^{(blue)} \leq \sum_{e \in E(G_1)} \lambda_e^{(blue)} \max\{y_e^{(blue)}, y_e^{(red)}\}.$$

Applying the analogous inequality to the red customer and using that $\lambda = \lambda^{(blue)} + \lambda^{(red)}$, we can derive

$$\sum_{e \in E(G_1)} y_e^{(blue)} f_{blue}(y^{(blue)})_e + \sum_{e \in E(G_1)} y_e^{(red)} f_{red}(y^{(red)})_e \leq \sum_{e \in E(G_1)} \lambda_e \max\{y_e^{(blue)}, y_e^{(red)}\}.$$

The right hand side can be bounded by $\max_{e \in E(G_1)} \lambda_e \sum_{e \in E(G_1)} \max\{y_e^{(blue)}, y_e^{(red)}\}$. Therefore, local weak duality is satisfied w.r.t. $S = E(G_1)$ and $\mu = \max_{e \in E(G_1)} \lambda_e = 1$. The very same argument can be applied to show that local weak duality is also satisfied w.r.t. $S = E(G_2)$ and $\mu = \max_{e \in E(G_2)} \lambda_e = \frac{1}{2}$.

- (ii) The oracle is a 2-approximation given by a path-decomposition algorithm. In this case, we know that it will solve the subproblems in G_1 exactly (as these are shortest path problems) and the approximation guarantee of 2 also holds for the subinstance in G_2 . Thus, with the same argument as above, local weak duality is satisfied with regard to $S = E(G_1)$ and $\mu = 1$, and with regard to $S = E(G_2)$ and $\mu = 2 \cdot \frac{1}{2} = 1$.

In general, we cannot assume local weak duality with $\mu < 2$ for all 2-approximation oracles as described in Figure 2b for this instance. This illustrates that our notion of local weak duality is not only a property of the convex region that we consider but also a property of the oracle. This instance is an example of a product case, which we briefly discuss in Section 3.

In Section 2.1, we analyze the core algorithm with new techniques. We prove primal-dual convergence and that, under local weak duality, $\max_{r \in S} x_r^{(T)}$ is bounded by μ plus an additive error that is linear in δ . Dual convergence was not shown in [24]. The core algorithm is sufficient to obtain fast convergence in normalized settings, i.e. when λ^* is known up to a constant factor. To derive a FPTAS for the general problem one needs to extend this algorithm by a prior constant factor approximation. In [24] this is done with a scaling/binary search approach. We present a faster constant-factor approximation in Section 2.2. This allows to transfer all results from the normalized to the general setting without increasing the asymptotic number of oracle calls. We summarize this in the following main theorem.

► **Theorem 3 (Main Theorem).** *Let \mathcal{X} be an instance of the resource sharing problem and $\delta \in (0, 1]$. One can compute a primal solution $x \in \mathcal{X}$ and a dual solution $z \in \Delta_m$ satisfying*

$$\|x\|_\infty \leq (1 + \delta)\sigma\lambda^*, \quad \min_{x \in \mathcal{X}} \langle z, x \rangle \geq (1 - \delta) \frac{\lambda^*}{\sigma}, \quad (6)$$

and, for all $S \subseteq \mathcal{R}$, $\mu \geq 0$ such that (5) holds,

$$\max_{r \in S} x_r \leq \mu + \delta \max\{\lambda^*, \mu\}, \quad (7)$$

using $\mathcal{O}\left(\frac{n+m}{\delta^2} \log m\right)$ oracle calls, and further operations taking polynomial time.

In Section 3, we show how to apply this result to product settings and that the computed solution is close to decreasingly minimal on the two highest entries in the following sense.

► **Corollary 4.** *Let $\lambda \in \mathcal{X}$ be decreasingly minimal. If the block solver is exact, i.e. $\sigma = 1$, then the returned solution $x \in \mathcal{X}$ satisfies*

$$(x_{\downarrow})_1 \leq (\lambda_{\downarrow})_1 + \delta\lambda^* \quad \text{and} \quad (x_{\downarrow})_2 \leq (\lambda_{\downarrow})_2 + \delta\lambda^*. \quad (8)$$

This analysis is best possible for the general case. In the full version we show that an analogous version of Corollary 4 does not hold for the three highest entries. Furthermore, it is not possible to reduce the additive constant of $\delta\lambda^*$ to $\delta(\lambda_{\downarrow})_2$ in the second inequality of (8). In a sense, an additive error of $\mathcal{O}(\delta\lambda^*)$ is best possible in our framework, because the core algorithm is known to make an additive error of $\mathcal{O}(\delta)$ and we scale the instance such that $\lambda^* \in [c, C]$ for some constants $0 < c < C$ before applying it.

In Section 4, we study a class of generalizations of the core algorithm. These can be described as standard block-coordinate descent algorithms. This class contains all algorithms that run in a number of phases T , and in each phase $1, \dots, T$ construct a solution for every customer by using *any* choice of prices and the restricted step size rule as in Line 8 of the core algorithm. Our algorithm is optimal within this class in the sense that any such algorithm requires $\Omega(\frac{n+m}{\delta^2} \log m)$ many oracle calls to construct a $(1 + \delta)$ -approximate solution (Theorem 13), even if $\lambda^* = 1$ is known. This follows from a result by Klein and Young [21] and matches the upper bound provided by our algorithm precisely.

2 Proof of the main theorem

2.1 Analysis on normalized instances

First, we prove the main theorem for normalized instances, meaning those for which $\lambda^* \in [c, 1]$ is known for a constant $c > 0$. Later, in Section 2.2, we show how to remove this assumption. We write $x^{(t)} := \frac{1}{t} \sum_{p=1}^t s^{(p)} \in \mathcal{X}$ for the current solution and $y^{(t)}$ for the price vector y after phase t of the core algorithm is completed. Note that $y_r^{(t)} = \exp(\epsilon \sum_{p=1}^t s_r^{(p)}) = \exp(\epsilon t x_r^{(t)})$ holds for all $r \in \mathcal{R}$ and $t = 1, \dots, T$. This can be used to deduce a simple bound for any $S \subseteq \mathcal{R}$:

$$\max_{r \in S} x_r^{(t)} = \max_{r \in S} \frac{1}{\epsilon t} \log y_r^{(t)} \leq \frac{1}{\epsilon t} \log \sum_{r \in S} y_r^{(t)}. \quad (9)$$

Especially, $\|x^{(t)}\|_{\infty} \leq \frac{1}{\epsilon t} \log \|y^{(t)}\|_1$ holds. We denote the dual objective values that correspond to the price vectors $y^{(t)}$ by

$$\Theta_t := \min_{x \in \mathcal{X}} \frac{\langle y^{(t)}, x \rangle}{\|y^{(t)}\|_1} = \frac{\sum_{C \in \mathcal{C}} \text{opt}_C(y^{(t)})}{\|y^{(t)}\|_1}. \quad (10)$$

We provide a bound that relates the number of oracle calls to the price vector $y^{(t)}$. This bound improves (slightly) on the bound that was shown in [24], which was $tn + \frac{m}{\epsilon} \log \|y^{(t)}\|_1$.

► **Lemma 5.** *The number of oracle calls of the core algorithm until termination of phase $t = 1, \dots, T$ is bounded by*

$$tn + \frac{m}{\epsilon} \log \frac{\|y^{(t)}\|_1}{m}. \quad (11)$$

A proof can be found in the full version. The following lemma states a bound on $\sum_{r \in S} y_r^{(t)}$, which implies a bound on $\max_{r \in S} x_r^{(t)}$ according to Inequality (9). In the case $S = \mathcal{R}$, this provides a bound on the primal error and the number of oracle calls. Again, we refer to the full version for a proof of the lemma.

► **Lemma 6** (Upper bound on the price increase). *Let \mathcal{X} be an instance of the resource sharing problem that satisfies local weak duality w.r.t. $S \subseteq \mathcal{R}$ and $\mu > 0$. Let $\eta := \exp(\epsilon) - 1$. Assume that $\eta\mu < 1$. Then for all $t = 0, 1, \dots, T$, it holds that*

$$\sum_{r \in S} y_r^{(t)} \leq |S| \exp\left(\frac{t\eta\mu}{1 - \eta\mu}\right). \quad (12)$$

As pointed out earlier, every instance satisfies local weak duality w.r.t. \mathcal{R} and $\sigma\lambda^*$. So the bound $\|y^{(t)}\|_1 \leq m \exp(t\eta\sigma\lambda^*/(1 - \eta\sigma\lambda^*))$ that was stated in [24] follows. In this case, however, it is possible to insert the definition of the dual values to obtain the primal-dual bound $\|y^{(t)}\|_1 \leq m \exp\left(\frac{\eta\sigma}{1 - \eta\sigma\lambda^*} \sum_{p=1}^t \Theta_p\right)$, which can be used to prove also dual convergence of the average dual solution.

► **Theorem 7** (Bound on the primal and dual error). *Assume $\epsilon \in (0, 1]$, $\eta\sigma\lambda^* < 1$. For every $t = 1, \dots, T$ the primal solution $x^{(t)}$ and the average dual solution $z^{(t)} := \frac{1}{t} \sum_{p=1}^t \frac{y^{(p)}}{\|y^{(p)}\|_1} \in \Delta_m$ satisfy*

$$\|x^{(t)}\|_\infty \leq \frac{\log m}{\epsilon t} + \frac{1 + \epsilon}{1 - \eta\sigma\lambda^*} \sigma\lambda^*, \quad \min_{x \in \mathcal{X}} \langle z^{(t)}, x \rangle \geq \frac{1 - \eta\sigma\lambda^*}{\sigma(1 + \epsilon)} \left(\lambda^* - \frac{\log m}{\epsilon t} \right). \quad (13)$$

Moreover, if \mathcal{X} satisfies local weak duality w.r.t. $S \subseteq \mathcal{R}$ and $\mu > 0$, then

$$\max_{r \in S} x_r^{(t)} \leq \frac{\log |S|}{\epsilon t} + \frac{1 + \epsilon}{1 - \eta\sigma\lambda^*} \mu. \quad (14)$$

For normalized instances, the main theorem follows with a straightforward calculation from Theorem 7 by choosing $\epsilon = \frac{\delta}{8\sigma}$ and $T = \left\lceil \frac{\log m}{2\sigma\epsilon^2} \right\rceil$. Omitted proofs can be found in the full version.

2.2 Constant-factor approximation in $\mathcal{O}((n + m) \log m)$ oracle calls

In the following, we assume $\lambda^* \in [1, \sigma m]$, which can be guaranteed in n oracle calls, by computing for each customer a solution to the uniform price vector $x := \sum_{C \in \mathcal{C}} f_C(\mathbb{1}) \in \mathcal{X}$ and scaling the instance with $\frac{\sigma m}{\|x\|_\infty}$. Our constant-factor approximation, Algorithm 2, is similar to the core algorithm, but it works with adaptive parameters, may discard the solutions of some phases, and restart them. This is done by checking a bound on the sum of the prices, in Line 13, after every oracle call. The algorithm maintains a guess on λ^* , denoted by Λ , which influences the convex coefficient ξ . A violation of the bound indicates that the guess was too low. This leads to a restart of the phase with $\epsilon \leftarrow \epsilon/2$ and $\Lambda \leftarrow 2\Lambda$.

Let $K^* := \lceil \log \lambda^* \rceil$. We denote by K the number of restarts of the algorithm (i.e. times the if-statement in Line 13 is satisfied). Further, $t_1 \leq \dots \leq t_K$ denote the (not necessarily distinct) indices of the phases in which the restarts occur. For a phase t , we write $\epsilon^{(t)}$ for the ϵ -value with which it was completed successfully. As before, we write $x^{(t)} := \frac{1}{t} \sum_{p=1}^t s^{(p)}$ for the current solution after phase t . By construction of the algorithm, we have that $y_r^{(t)} = \exp\left(\sum_{p=1}^t \epsilon^{(p)} s_r^{(p)}\right)$. Note that $\epsilon^{(p)}$ is decreasing for $p = 1, \dots, t$. Therefore, one can bound the maximum usage of the current solution at termination of phase t analogous to previously by $\|x^{(t)}\|_\infty \leq \frac{1}{\epsilon^{(t)} t} \log \|y^{(t)}\|_1$. We only sketch the analysis of the algorithm in the following. Note that after the k 'th restart, $\epsilon = \frac{1}{2^{k4\sigma}}$. So, for larger k , the price updates $y_r \leftarrow \exp(\epsilon \xi b_r)$ get smaller and smaller. Similarly to the proof of Lemma 6, one can show that after K^* restarts, ϵ is small enough to guarantee that the price bound will not be violated again.

■ **Algorithm 2** Constant-factor approximation for the resource sharing problem.

15:         $\epsilon \leftarrow \epsilon/2, \Lambda \leftarrow 2\Lambda$     ▷ Reduce  $\epsilon$ , increase the guess on  $\lambda^*$ 
16:        go to 6                                        ▷ Restart phase, solutions from this phase are discarded
17:      end if
18:    end while
19:  end for
20:   $s^{(t)} \leftarrow \sum_{C \in \mathcal{C}} s_C^{(t)}$ 
21: end for
22: return  $\frac{1}{T} \sum_{t=1}^T s^{(t)}$ 

```

► **Lemma 8.** *The total number of restarts K is bounded by K^* .*

This means that the number of restarts is bounded by $\lceil \log \lambda^* \rceil \leq \lceil \log \sigma m \rceil \in \mathcal{O}(\log m)$. Analogously to Lemma 5, one can deduce the following bound on the number of oracle calls, which depends on the indices of the phases that are restarted.

► **Lemma 9.** *There is a constant $c_1 > 0$, such that the number of oracle calls is bounded by $Tn + c_1 m \left(T + \sum_{i=1}^K t_i \right)$.*

To use this bound one exploits that (due to the price bound in Line 13)

$$\lambda^* \leq \|x^{(t)}\|_\infty \leq \frac{1}{\epsilon^{(t)} t} \log \|y^{(t)}\|_1 \leq \frac{\log m}{\epsilon^{(t)} t} + \frac{1}{\epsilon^{(t)}} \quad (15)$$

holds for every successfully completed phase t . Thus if $\lambda^* \gg 1$, then $\epsilon^{(t)}$ must be small already for low values of t . This implies that many restarts occurred in the early phases. Indeed, we provide upper bounds on the t_i , which allow estimating $\sum_{i=1}^K t_i$ by a geometric series resulting in $\sum_{i=1}^K t_i \in \mathcal{O}(\log m)$.

► **Lemma 10.** *There are constants $c_2, c_3 > 0$, such that $t_i \leq c_2 + 2^{i-K^*} c_3 \log m$ holds $\forall i = 1, \dots, K$. Thus the number of oracle calls is in $\mathcal{O}((n+m) \log m)$.*

Lemma 8 states that phase T is completed with $\epsilon^{(T)} \geq \frac{1}{2^{K^*} 4\sigma} \geq \frac{1}{\lambda^* 8\sigma}$. Inserting this into Inequality (15) shows that $\|x^{(T)}\|_\infty \leq 16\sigma\lambda^*$. The analysis is summarized in the following theorem.

► **Theorem 11.** *Algorithm 2 computes a solution $x^{(T)} \in \mathcal{X}$ to the resource sharing problem that satisfies $\|x^{(T)}\|_\infty \leq 16\sigma\lambda^*$ using $\mathcal{O}((n+m) \log m)$ oracle calls.*

Combining Algorithm 2 with the core algorithm proves the main theorem. Omitted proofs from this section can be found in the full version.

3 Decreasing Minimality on the two highest entries

In this section, we discuss the implications of local weak duality. In particular, we prove that our algorithm computes solutions that are close to decreasingly minimal on the two largest entries. Before that, let us consider a simple application, which is the *product case*. Assume that the instance of the resource sharing problem consists of multiple independent parts, that is, there exists a (perhaps unknown) partition of the resources $\mathcal{R} = \mathcal{R}_1 \cup \dots \cup \mathcal{R}_k$ on which the customers act “independently”. More precisely, we assume that each of the convex sets X_C can be decomposed into a product $X_C = X_1^{(C)} \times \dots \times X_k^{(C)}$ where $X_i^{(C)} \subseteq \mathbb{R}_{\geq 0}^{|\mathcal{R}_i|}$ for $i = 1, \dots, k$. Let us write $\mathcal{X}_i := \sum_{C \in \mathcal{C}} X_i^{(C)}$ for $i = 1, \dots, k$. Note that we have $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_k$. Let $C \in \mathcal{C}$ and $y^{(C)} \in \mathbb{R}_{\geq 0}^m$. In this case, \mathcal{X} satisfies local weak duality w.r.t. \mathcal{R}_j and $\min_{x_j \in \mathcal{X}_j} \|x_j\|_\infty$ for every $j = 1, \dots, k$. A proof can be found in the full version. So, indeed, according to the main theorem, Theorem 3, every independent part of the instance is optimized separately, i.e. the primal solution $x^{(T)}$ satisfies $\max_{r \in \mathcal{R}_i} x_r^{(T)} \leq \min_{x_i \in \mathcal{X}_i} \|x_i\|_\infty + \delta \lambda^*$ for all $i = 1, \dots, k$. We already saw a natural example of a product setting in Figure 2. As discussed in the beginning, especially in these product cases it is reasonable to assume local weak duality also for approximate block solvers (with their approximation guarantee). A more surprising observation is that any instance \mathcal{X} with an exact block solver satisfies local weak duality w.r.t. to all but one coordinate and the value of the second-highest entry in the decreasingly minimal solution.

► **Lemma 12.** *Let \mathcal{X} be an instance of the resource sharing problem with $\sigma = 1$. Let $\lambda \in \mathcal{X}$ be the decreasingly minimal element. Assume that $(\lambda_\downarrow)_1 > (\lambda_\downarrow)_2$ holds. Let $r^* \in \mathcal{R}$ be the coordinate of the unique maximum entry, i.e. $\lambda_{r^*} = (\lambda_\downarrow)_1$. Then \mathcal{X} satisfies local weak duality w.r.t. $S := \mathcal{R} \setminus \{r^*\}$ and $\mu := (\lambda_\downarrow)_2$.*

A proof of this statement can be found in the full version. Note that if $(\lambda_\downarrow)_1 = (\lambda_\downarrow)_2$ Corollary 4 is trivial due to primal convergence. In the case $(\lambda_\downarrow)_1 > (\lambda_\downarrow)_2$, Corollary 4 follows due to local weak duality with an application of the main theorem.

One might conjecture that an analogous version to Corollary 4 is valid also for the third-highest entry and so on (meaning that the computed solution $x^{(T)}$ satisfies $(x_\downarrow^{(T)})_3 \leq (\lambda_\downarrow)_3 + \delta \lambda^*$ etc.). This is not the case in general. We provide a counterexample in the full version.

4 Limits of standard Dantzig-Wolfe-type algorithms

In this section, we study a class of algorithms that can be described by the meta-algorithm Algorithm 3. This class contains all algorithms that process the customers in a number T of phases and compute a solution $s_C^{(t)} \in X_C$ for every customer in each phase $t = 1, \dots, T$. We allow to choose any price vector for the oracle queries and allow to return any convex combination at the end of the algorithm. However, we fix the restricted step size rule in Line 7. On the one hand, this class can be interpreted as a natural generalization of the core algorithm. On the other hand, it includes standard conditional gradient methods that work with this restricted step size rule. Using this step-size rule is explained by the fact that otherwise $\|\xi b\|_\infty > 1$ holds. Since ξb is added to the current solution of the given phase and the goal is to find an element with small ℓ_∞ -norm, it is a reasonable approach to restrict the step-size towards elements with large ℓ_∞ -norm. Note that the bound $1/\|b\|_\infty$ in Line 7 can be replaced by $C/\|b\|_\infty$ for any other constant $C > 0$ without affecting the asymptotic lower bound. We prove that any such algorithm needs to use $\Omega(\frac{n+m}{\delta^2} \log m)$ many oracle calls to terminate with a $(1 + \delta)$ -approximate solution.

■ **Algorithm 3** Standard block-coordinate descent with restricted steps.

```

1: for  $t = 1, \dots, T$  do
2:   for  $C \in \mathcal{C}$  do
3:      $\alpha \leftarrow 0, s_C^{(t)} \leftarrow 0$ 
4:     while  $\alpha < 1$  do
5:       Choose  $y \in \mathbb{R}_{\geq 0}^m$ 
6:        $b \leftarrow f_C(y)$ 
7:        $\xi \leftarrow \min\{1 - \alpha, 1/\|b\|_\infty\}$ 
8:        $s_C^{(t)} \leftarrow s_C^{(t)} + \xi b$ 
9:        $\alpha \leftarrow \alpha + \xi$ 
10:    end while
11:   end for
12:    $s^{(t)} \leftarrow \sum_{C \in \mathcal{C}} s_C^{(t)}$ 
13: end for
14: return a convex combination of  $s^{(1)}, \dots, s^{(T)}$ 

```

► **Theorem 13.** *For every $\gamma \in (0, 1/2)$ there exist constants $K_\gamma, \tau_\gamma > 0$, such that for every $m > K_\gamma$, $n \in \mathbb{N}$, there exists an instance of the resource sharing problem with $n+2$ customers, $2m$ resources and $\lambda^* = 1$, such that for any $\delta \in (0, 1/10)$, any version of Algorithm 3 requires*

$$\tau_\gamma(n+m) \min \left\{ \frac{\log m}{\delta^2}, m^{1/2-\gamma} \right\} \quad (16)$$

oracle calls to compute a $(1+\delta)$ -approximate solution.

For a proof we refer to the full version.

5 Conclusion

In this work, we have presented an FPTAS for the primal and the dual of the resource sharing problem and improved on the best-known running time in terms of number of oracle calls.

We were able to show that our algorithm has the natural property to optimize (close to) independent parts of the instance separately by introducing the notion of local weak duality. This implied that our algorithm computes solutions that are close to decreasingly minimal on the two largest entries. Local weak duality provides a theoretical understanding of the empirically observed resilience to local effects of multiplicative-weight-based algorithms. Extending the algorithm to achieve (approximate) decreasing minimality on the third-highest entry and beyond is subject to future work.

In the last section, we have shown that further improvements, if possible, require different types of algorithms. A mere change of the price update rule is not enough to achieve faster convergence. This also implied that no warm-start analysis of any version of Algorithm 3 is possible.

On the External Validity of Average-Case Analyses of Graph Algorithms

Thomas Bläsius  

Karlsruhe Institute of Technology (KIT), Germany

Philipp Fischbeck  

Hasso Plattner Institute (HPI), University of Potsdam, Germany

Abstract

The number one criticism of average-case analysis is that we do not actually know the probability distribution of real-world inputs. Thus, analyzing an algorithm on some random model has no implications for practical performance. At its core, this criticism doubts the existence of *external validity*, i.e., it assumes that algorithmic behavior on the somewhat simple and clean models does not translate beyond the models to practical performance real-world input.

With this paper, we provide a first step towards studying the question of external validity systematically. To this end, we evaluate the performance of six graph algorithms on a collection of 2751 sparse real-world networks depending on two properties; the heterogeneity (variance in the degree distribution) and locality (tendency of edges to connect vertices that are already close). We compare this with the performance on generated networks with varying locality and heterogeneity. We find that the performance in the idealized setting of network models translates surprisingly well to real-world networks. Moreover, heterogeneity and locality appear to be the core properties impacting the performance of many graph algorithms.

1 Introduction

The seminal papers of Cook in 1971 [16] and Karp in 1972 [26] establish that many fundamental combinatorial problems are NP-hard, and thus cannot be solved in polynomial time unless $P = NP$. Since then, the list of NP-hard problems is growing every year.

Though the non-existence of polynomial time algorithms (unless $P = NP$) is major bad news, the concept of NP-hardness is limited to the worst case. It thus leaves the possibility of imperfect algorithms that fail sometimes but run correctly and in polynomial time on most inputs. Many algorithms used today are slow in the worst case but perform well on relevant instances. An early attempt to theoretically capture this “good in practice” concept is the *average-case analysis*. There, one assumes the input to be randomly generated and then proves a low failure probability or a good expected performance.¹ On that topic, Karp wrote in 1983 [27] that

¹ We note that within the scope of this paper the term *average case* refers to exactly those situations where the input is drawn from some probability distribution. This includes proving bounds that hold with high probability (instead of in expectation), which would technically be better described as *typical case*. Moreover, it excludes the case of randomized algorithms on deterministic inputs.

One way to validate or compare imperfect algorithms for NP-hard combinatorial problems is simply to run them on typical instances and see how often they fail. [...] While probabilistic assumptions are always open to question, the approach seems to have considerable explanatory power [...]. (Karp in 1983)

With this promising starting point, one could have guessed that average-case analysis is an important pillar of algorithmic research. However, it currently plays only a minor role in theoretical computer science. The core reason for this was summarized by Karp almost forty years later in 2020 in the Lex Fridman Podcast.²

The field tended to be rather lukewarm about accepting these results as meaningful because we were making such a simplistic assumption about the kinds of graphs that we would be dealing with. [...] After a while I concluded that it didn't have a lot of bite in terms of the practical application. (Karp in 2020)

At its core, this describes the issue that an average-case analysis is lacking *external validity*, i.e., the insights on randomly generated graphs do not transfer to practical instances.

The simplistic probabilistic assumption mentioned in the above quotes is that input graphs are drawn from the Erdős–Rényi model [23], where all edges exist independently at random with the same probability. This assumption has the advantages that it is as unbiased as possible and sufficiently accessible to allow for mathematical analyses. However, in its simplicity, it is unable to capture the rich structural properties present in real-world networks, leading to the lack of external validity.

That being said, since the beginnings of average-case considerations, there have been several decades of research in the field of network science dedicated to understanding and explaining properties observed in real-world networks. This in particular includes the analysis of random network models and the transfer of insights from these models to real networks; indicating external validity. Thus, we believe that it is time to revisit the question of whether average-case analyses of graph algorithms can have external validity. With this paper, we present a first attempt at systematically studying this question.

Before describing our approach and stating our contribution, we want to give two examples from network science, where the existence of external validity is generally accepted.

Examples from Network Science. The Barabási–Albert model [2] uses the mechanism of *preferential attachment* to iteratively build a network. Each newly added vertex chooses a fixed number of neighbors among the existing vertices with probabilities proportional to the current vertex degrees. This simple mechanism yields *heterogeneous* networks, i.e., networks with power-law degree distributions where most vertices have a small degree while few vertices have very high degree.³ It is well known that networks generated by this model are highly artificial, exhibiting properties that are far from what is observed in real-world networks. Nonetheless, beyond the specific model, it is generally accepted that the mechanism of preferential attachment facilitates power-law distributions. Thus, assuming external validity, the Barabási–Albert model can serve as an explanation of why we regularly observe power-law distributions in real-world data. Moreover, whenever we deal with a process involving preferential attachment, we should not be surprised when seeing a power-law distribution.

² Transcript of the Lex Fridman Podcast #111. The quote itself starts at 1:39:59. For the full context, start at 1:37:28 (<https://youtu.be/K11CrlfLuzs?t=5848>).

³ Barabási and Albert were not the first to study a preferential attachment mechanism; see, e.g., Price's model [19]. However, there is no doubt that their highly influential paper [2] popularized the concept.

The Watts–Strogatz model [32] first starts with a ring lattice, i.e., the vertices are distributed uniformly on a circle and vertex pairs are connected if they are sufficiently close. This yields a regular graph with high *locality*, i.e., all connections are short and we observe many triangles. Moreover, ring lattices have high diameter. The second step of the Watts–Strogatz model introduces noise by randomly rewiring edges. This diminishes locality by replacing local connections with potentially long-range edges. Watts and Strogatz demonstrate that only little locality has to be sacrificed before getting a small-world network with low diameter. Again, this model is highly artificial and thus far from being a good representation for real-world networks. However, it seems generally accepted that these observations have implications beyond the specific model, namely that there is a simple mechanism that facilitates the small-world property even in networks with mostly local connections. Thus, in real-world settings where random long-range connections are possible, one should not be surprised to observe the small-world property.

Contribution. We consider algorithms for six different problems that are known to perform better in practice than the worst-case complexity would suggest. We evaluate them on network models that allow for varying amounts of locality and heterogeneity.⁴ This shows us the impact of these two properties on the algorithms’ performance in the controlled and clean setting of generated networks. We compare this with practical performance by additionally evaluating the algorithms on a collection of 2751 sparse real-world networks. Our overall findings can be summarized as follows. Though the real-world networks yield a less clean and more noisy picture than the generated networks, the overall dependence of the performance on locality and heterogeneity coincides with surprising accuracy for most algorithms. This indicates that there is external validity in the sense that if, e.g., increasing locality in the network models improves performance, we should also expect better performance for real-world networks with high locality. Moreover, it indicates that locality and heterogeneity are the core properties to impact the performance for many networks.

Our insights for the specific algorithms are interesting in their own right, independent of the question of external validity. Moreover, our experiments led to several interesting findings that are beyond the core scope of this paper. These can be found in the full version [4].

In Section 2, we introduce some basic notation and formally define measures for heterogeneity and locality. In Section 3, we describe the set of real-world and generated networks we use in our experiments. Section 4 compares generated and real-world networks for the different algorithms. Related work as well as our insights specific to the algorithms are discussed in this section. In Section 5 we conclude with a discussion of our overall results.

Our source code is available on GitHub⁵. It is additionally archived at Zenodo⁶, together with a docker image for easier reproducibility. The latter repository additionally includes the real-world network data set as well as all generated data (networks and statistics). Details omitted from this extended abstract can be found in the full version [4].

⁴ For non-local networks, we use the Erdős–Rényi and the Chung–Lu model for homogeneous and heterogeneous degree distributions, respectively. For local networks, we use geometric inhomogeneous random graphs (GIRGs), which let us vary the amount of locality and heterogeneity.

■ **Figure 1** The density (kernel density estimation) of heterogeneity, degree locality, distance locality, and locality of the networks in our data set of real-world networks.

2 Basic Definitions, Heterogeneity, and Locality

Let $G = (V, E)$ be a graph. Throughout the paper, We denote the number of vertices and edges with $n = |V|$ and $m = |E|$. For $v \in V$, let $N(v) = \{u \mid \{u, v\} \in E\}$ be the *neighborhood* of v , and let $\deg(v) = |N(v)|$ be the *degree* of v . Additionally, $N[v] = N(v) \cup \{v\}$ is the *closed neighborhood* of v . An edge $e \in E$ is a *bridge* if $G - e$ is disconnected, where $G - e$ denotes the subgraph induced by $E \setminus \{e\}$.

We define the *heterogeneity* of a graph as the logarithm (base 10) of the coefficient of variation of its degree distribution, i.e., it is $\log_{10}(\sigma/\mu)$ for the average degree $\mu = \frac{1}{n} \sum_{v \in V} \deg(v)$ and the variance $\sigma^2 = \frac{1}{n} \sum_{v \in V} (\deg(v) - \mu)^2$.

We define the locality based on two different measures. For $u, v \in V$, let $\deg(u, v) = |N(u) \cap N(v)|$ be the *common degree* of u and v . For a non-bridge edge $\{u, v\} \in E$ the *degree locality* is defined as

$$L_{\deg}(\{u, v\}) = \frac{\deg(u, v)}{\min(\deg(u), \deg(v)) - 1}.$$

It essentially measures in how many triangles $\{u, v\}$ appears. The *degree locality* $L_{\deg}(G)$ of G is the average degree locality over all non-bridge edges.

For $u, v \in V$, let $\text{dist}(u, v)$ be the distance between u and v in G . For $P \subseteq \binom{V}{2}$, we denote the average distance between vertex pairs in P with $\text{dist}(P)$. For $\{u, v\} \in E$, the *detour distance* $\text{dist}^+(u, v)$ is the distance between u and v in $G - \{u, v\}$. Let $\bar{E} = \binom{V}{2} \setminus E$ and assume that $\bar{E} \neq \emptyset$. For a non-bridge edge $\{u, v\} \in E$, define the *distance locality* as

$$L_{\text{dist}}(\{u, v\}) = 1 - \frac{\text{dist}^+(u, v) - 2}{\text{dist}(\bar{E}) - 2}.$$

It essentially measures how short the edge $\{u, v\}$ is compared to the average distance in the graph. If $\text{dist}(\bar{E}) = 2$, we define $L_{\text{dist}}(\{u, v\}) = 0$. The *distance locality* $L_{\text{dist}}(G)$ of G is the maximum of 0 and the average distance locality over all non-bridge edges.

The *locality* of G is $L(G) = (L_{\deg}(G) + L_{\text{dist}}(G))/2$. To compute the locality, we approximate average distances [12]. See Figure 1 for distribution plots.

3 Networks

Real-World Networks. We use 2751 graphs from Network Repository [29], which we selected as follows. We started with all networks with at most 1 M edges and reduced each network to its largest connected component. We removed multi-edges and self-loops and ignored weights or edge directions. We tested the resulting connected, simple, undirected, and unweighted graphs for isomorphism and kept only one copy for each group of isomorphic networks. This resulted in 3006 networks. From this we removed 255 networks for different reasons.

- We removed 105 networks that were randomly generated and thus do not count as real-world networks.⁷
- We removed 17 trees. They are not very interesting, and locality is not defined for trees.
- We removed 133 graphs with density at least 10%. Our focus lies on sparse graphs and network models for sparse graphs. Thus, dense graphs are out of scope.

Random Networks. We use three random graph models to generate networks; the Erdős–Rényi model [23] (non-local and homogeneous), the Chung–Lu model [14, 15] (non-local and varying heterogeneity), and the GIRG model [11] (varying locality and heterogeneity). For the latter, we use the efficient implementation in [8].

For each model and parameter configuration, we generate five networks with $n = 50\text{ k}$ vertices and (expected) average degree 10. As for the real-world networks, we reduce each generated graph to its largest connected component. We average the five generated graphs for each parameter configuration and represent their average as single dot in the plots.

4 Comparison Between the Models and Real-World Networks

Each of the following subsections compares the performance of a different algorithm between generated and real-world networks. For the cost c of the algorithm, we plot c depending on heterogeneity and locality using color to indicate the cost; see, e.g., Figure 2. The left and middle plot show one data point for each parameter setting of the models and each real-world network, respectively. The right plot aggregates real-world networks with similar locality and heterogeneity. Each point represents a number of networks indicated by its radius (log scale). We regularly assume the cost c to be polynomial in m (or n), i.e., $c = m^x$, and plot $x = \log_m c$. In this case, the color in the left and right plot shows the mean exponent x for the aggregated networks.

4.1 Bidirectional Search

We can compute a shortest path between two vertices s and t using a *breadth first search* (*BFS*). The BFS explores the graph layer-wise, where the i th layer contains the vertices of distance i from s . By *exploring* the i th layer, we refer to the process of iterating over all edges with an endpoint in the i th layer, thereby finding layer $i + 1$. The *bidirectional BFS* alternates the exploration of layers between a *forward BFS* from s and a *backward BFS* from t . The alternation strategy we study here greedily applies the cheaper of the two explorations in every step. The cost of exploring a layer is estimated via the sum of degrees of vertices in that layer. The search stops once the current layers of forward and backward search intersect.

The *cost* c for the bidirectional BFS is the average number of edge explorations over 100 random st -pairs. Note that $c \leq 2m$, as each edge can be explored at most twice; once from each side. Figure 2 shows the exponent x for $c = m^x$ depending on heterogeneity and locality.

Impact of Locality and Heterogeneity. For the generated networks, we see that networks with high locality and homogeneous degree distribution (top left corner) have an exponent of around 1 (red). Thus, the cost of the bidirectional search is roughly m , which matches

⁷ Finding generated networks was done manually by searching for suspicious naming patterns or graph properties. For each candidate, we checked its source to verify that it is a generated network. Though we checked thoroughly, there are probably a few random networks hiding among the real-world networks.

■ **Figure 2** The exponent x of the average cost $c = m^x$ of the bidirectional BFS over 100 st -pairs.

the worst-case bound. If the network is heterogeneous (right) or less local (bottom), we get significantly lower exponents of around 0.5, indicating a cost of roughly \sqrt{m} . The cost is particularly low for very heterogeneous networks. Overall, we get a strict separation between hard (high locality, low heterogeneity) and easy (low locality or high heterogeneity) instances.

For real-world networks, we observe the same overall behavior that instances that are local and homogeneous tend to be hard while all others tend to be easy. There are only few exceptions to this, indicating that the heterogeneity and locality are usually the crucial properties impacting the performance of the bidirectional BFS.

Discussion. Borassi and Natale [10] found that the bidirectional BFS is exceptionally efficient on many real-world networks. Though its efficiency is surprising when compared to the worst case, existing average-case considerations suggest that this is actually the expected behavior. It runs in sublinear time on the non-local Erdős–Rényi and Chung–Lu graphs [10]. It is also sublinear on the local and heterogeneous hyperbolic random graphs, but linear on geometric random graphs in Euclidean geometry [7]. The latter two models can be seen as special case of GIRGs, covering the top-right and top-left corner.

4.2 Diameter

The *eccentricity* of $s \in V$ is $\max_{t \in V} \text{dist}(s, t)$, i.e., the distance to the vertex farthest from s . The *diameter* of the graph G is the maximum eccentricity of its vertices. It can be computed using the *iFUB algorithm* [17]. It starts with a root $r \in V$ from which it computes the BFS tree T . It then processes the vertices bottom up in T and computes their eccentricities using a BFS per vertex. This process can be pruned when the distance to r is sufficiently small compared to the largest eccentricity found so far. Pruning works well if r is a central vertex in the sense that it has low distance to many vertices and a shortest path between distant vertices gets close to r . The central vertex r is selected as follows. A *double sweep* [28] starts with a vertex u , chooses a vertex v at maximum distance from u , and returns a vertex w from a middle layer of the BFS tree from v . A *4-sweep* [17] consists of two double sweeps, starting the second sweep with the result w of the first sweep. We consider the *iFUB+4-sweep* algorithm, which chooses r by doing a 4-sweep from a vertex of maximum degree.

■ **Figure 3** The exponent x of the number of BFSs $c = n^x$ of the iFUB+4-sweepshd algorithm, excluding 19 real-world networks with timeout. The GIRG ground space is a square.

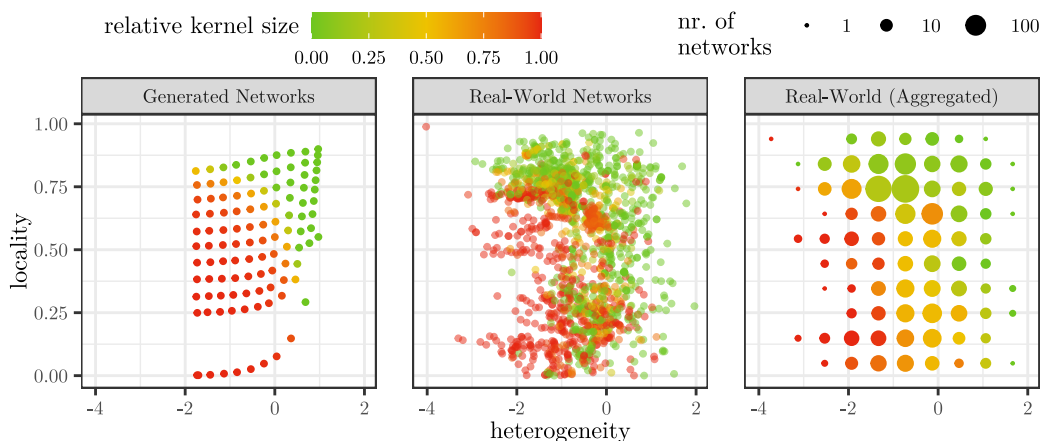

The *cost* c of iFUB+4-sweepshd is the number of BFSs it performs. Note that $c \leq n$. Figure 3 shows the exponent x for $c = n^x$ depending on heterogeneity and locality. It excludes 19 of the 2751 real-world networks that exceeded the time limit of 30 min. The GIRG model uses a square as ground space instead of the usual torus.

Impact of Locality and Heterogeneity. The general dependence is the same for generated and real-world networks. An almost linear number of BFSs is required for networks lacking locality and heterogeneity. For local or heterogeneous networks, it is substantially sublinear. The picture for real-world networks shows some noise, which indicates that there are properties besides locality and heterogeneity that impact the performance. We note that this observation agrees with the models, where we get highly varying exponents for individual parameter settings, e.g., for GIRGs with $T = 0.82$ and $\beta = 3.4$, we get exponents ranging from 0.21 to 0.92 for the five generated instances.

Discussion. The iFUB algorithm was introduced by Crescenzi, Grossi, Habib, LANZI, and Marino [17]. They note that it works well on networks with high difference between radius and diameter. This corresponds to the existence of a central vertex with eccentricity close to half the diameter. Additional experiments indicate that locality facilitates the existence of a central vertex (essentially in the center of the geometric ground space). Moreover, in heterogeneous networks, the high degree vertices serve as central vertices. The latter is also supported by the theoretical analysis of Borassi, Crescenzi, and Trevisan [9], who in particular showed that heterogeneous Chung–Lu graphs allow the computation of the diameter in sub-quadratic time, indeed using a vertex of high degree as central vertex.

4.3 Vertex Cover Domination

A vertex set $S \subseteq V$ is a *vertex cover* if every edge has an endpoint in S , i.e., removing S from G leaves a set of isolated vertices. We are interested in finding a vertex cover of minimum size. For two adjacent vertices $u, v \in V$, we say that u *dominates* v if $N[v] \subseteq N[u]$. The *dominance rule* states that there exists a minimum vertex cover that includes u . Thus, one can reduce the instance by including u in the vertex cover and removing it from the graph.

■ **Figure 4** The relative kernel size of the vertex cover domination rule.

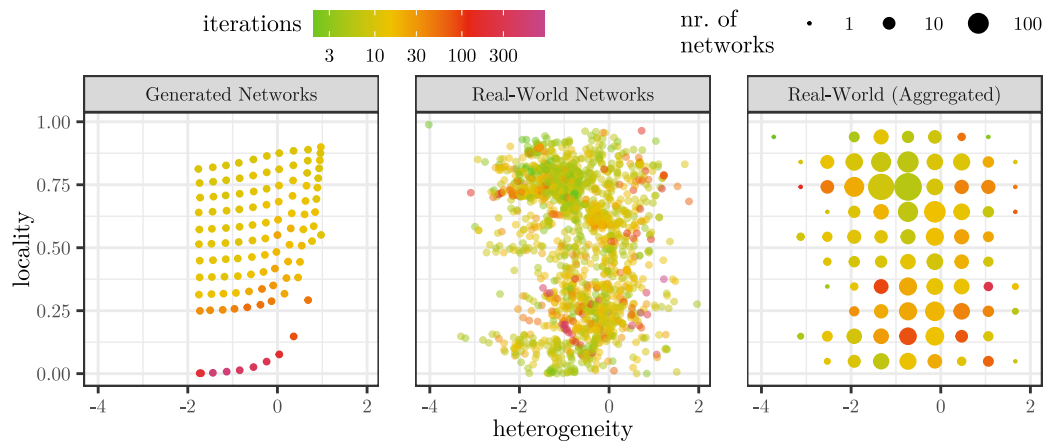

To evaluate the effectiveness of the dominance rule, we apply it exhaustively, i.e., until no dominant vertices are left. Moreover, we remove isolated vertices. We refer to the number c of vertices in the largest connected component of the remaining instances as the *kernel size*. Figure 4 shows the *relative kernel size* c/n with respect to locality and heterogeneity.

Impact of Locality and Heterogeneity. We see a sharp separation for the generated networks. For low locality and heterogeneity (bottom left), the reduction rule cannot be applied. For high locality and heterogeneity (top right), the dominance rule completely solves the instance. For real-world networks, the separation is less sharp, i.e., there is a larger range of locality/heterogeneity values in the middle where the dominance rule is effective sometimes. Nonetheless, we see the same trend that the reduction rule is more likely to be effective the higher the locality and heterogeneity. In the extreme regimes (bottom left or top right), we observe the same behavior as for the generated networks with relative kernel sizes close to 1 and 0, respectively, for almost all networks. Moreover, there is dichotomy in the sense that many instances are either (almost) completely solved by the dominance rule or the rule is basically inapplicable.

Discussion. Though vertex cover is NP-hard [26], it is rather approachable: It can be solved in $1.1996^n n^{O(1)}$ time [34] and there is a multitude of FPT-algorithms with respect to the solution size k [18], the fastest one running in $O(1.2738^k + kn)$ [13]. Moreover, there are good practical algorithms [1, 33]. Both algorithms apply a suite of reduction rules, including the dominance rule or a generalization. We note that the dominance rule is closely related to Weihe’s reduction rules for hitting set [33]. Previous experiments for Weihe’s reduction rules match our results: they work well if the instances are local and heterogeneous [6]. Concerning theoretic analysis on models, we know that on hyperbolic random graphs, the dominance rule is sufficiently effective to yield a polynomial time algorithm [5]. Thus, it is not surprising that the top-right corner in Figure 4 is mostly green.

4.4 The Louvain Algorithm for Graph Clustering

Let $V_1 \cup \dots \cup V_k = V$ be a *clustering* where each vertex set V_i is a *cluster*. One is usually interested in finding clusterings with dense clusters and few edges between clusters, which is formalized using some quality measure, e.g., the so-called modularity. A common subroutine

■ **Figure 5** Number of iterations of the first local search of the Louvain algorithm. The color scale is logarithmic. Four outliers (real-world) with more than 1 k iterations are excluded.

in clustering algorithms is to apply the following local search. Start with every vertex in its own cluster. Then, check for each vertex $v \in V$ whether moving v into a neighboring cluster improves the clustering. If so, v is moved into the cluster yielding the biggest improvement. This is iterated until no improvement can be achieved. Doing this with the modularity as quality measure (and subsequently repeating it after contracting clusters) yields the well-known Louvain algorithm [3].

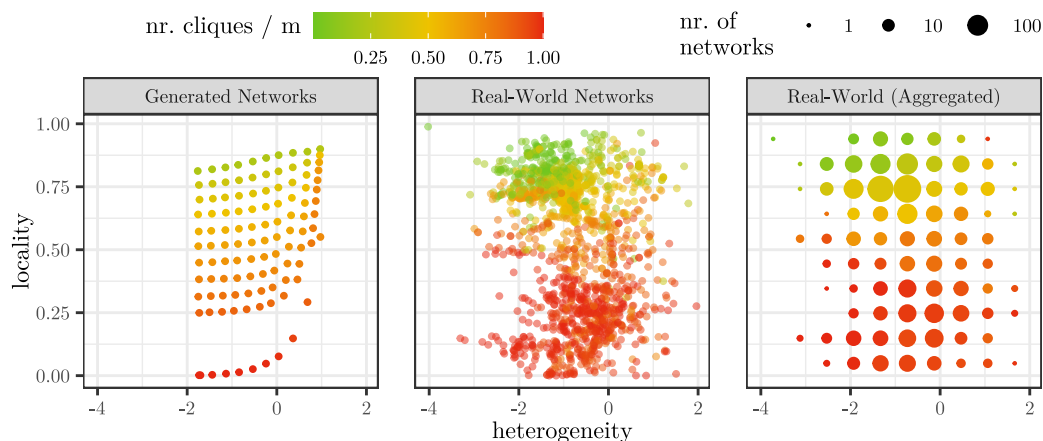

The run time of the Louvain algorithm is dominated by the number of iterations of the initial local search. Figure 5 shows this number of iterations.

Impact of Locality and Heterogeneity. For the generated instances, the number of iterations is generally low but increasing when decreasing the locality. For GIRGs, the average number of iterations ranges from 10.2 to 54.2 for the different parameter configurations. Moreover, the number of iterations starts to rise only for low localities. For 86 % of the configurations the average number of iterations lies below 20. For the Erdős–Rényi graphs we obtain an average of 196.4 iterations and for Chung–Lu graphs it goes up to 591.4 for one configuration. However, these average values over five generated instances have to be taken with a grain of salt as there is a rather high variance, e.g., the number of iterations for the five Chung–Lu graphs with power-law exponent 25 ranges from 82 up to 312.

For the real-world networks there is no clear trend depending on locality or heterogeneity. In general, the number of iterations is rather low except for some outliers. While the strongest outlier requires almost 20 k iterations, 98.6 % of the networks have at most 100 iterations.

Discussion. The worst-case number of iterations of the Louvain algorithm can be upper bounded by $O(m^2)$ due to the fact that the modularity is bounded and each vertex move improves it by at least $\Omega(1/m^2)$. Moreover, there exists a graph family that requires $\Omega(n)$ iterations for the first local search [25, Proposition 3.1].

Our experiments indicate that locality or heterogeneity are not the properties that discriminate between easy and hard instances. For generated instances, there is the trend that low locality increases the number of iterations, which does not transfer to the real-world networks (or is at least less clearly). However, the general picture that most instances require few iterations while there are some outliers coincides for generated and real-world networks.

■ **Figure 6** The number of maximal cliques relative to m depending on the heterogeneity and locality, restricted to networks where this value is at most 1 (93% of the networks).

4.5 Maximal Cliques

A *clique* is a subset of vertices $C \subseteq V$ such that C induces a complete graph, i.e., any pair of vertices in C is connected. A clique is *maximal*, if it is not contained in any other clique. In the following, we are never interested in non-maximal cliques. Thus, whenever we use the term *clique*, it implicitly refers to a maximal clique. To enumerate all cliques, we used the algorithm by Eppstein, Löffler, and Strash [20], using their implementation [21, 22].

As the cliques of a network can be enumerated in polynomial time per clique [30], the number of maximal cliques is a good indicator for the hardness of an instance. For all generated and most real-world networks, the number of cliques does not exceed the number of edges m . Out of the 2751 real-world networks, 2556 (93%) have at most m and 193 have more than m cliques. For the remaining 2 networks, the timeout of 30 min was exceeded. Figure 6 shows the number of cliques relative to m for all networks with at most m cliques.

Impact of Locality and Heterogeneity. One can see that the networks (generated and real-world) with low locality have roughly m cliques, while the number of cliques decreases for increasing locality. Moreover, among networks with locality, there is the slight trend that networks with higher heterogeneity have more cliques.

It is not surprising that networks with low locality have roughly m cliques, as graphs without triangles have exactly m cliques. For graphs with higher locality, there are two effects counteracting each other. On the one hand, multiple edges combine into larger cliques, which decreases the number of cliques. On the other hand, each edge can be contained in multiple cliques, which increases the number of cliques. Our experiments show that the former effect usually supersedes the latter, i.e., the size of the cliques increases more than the number of cliques each edge is contained in.

Discussion. There are many results on enumerating cliques and on the complementary problem of enumerating independent sets. Here, we focus on discussing two results that are closely related. Eppstein, Löffler and Strash [21] give an algorithm for enumerating all cliques that runs in $O(dn3^{d/3})$ time, where d is the degeneracy (a measure for sparsity). We use this algorithm for our experiments as it performs well in practice.

Fox, Roughgarden, Seshadhri, Wei, and Wein [24] introduced the closure as a measure that captures the tendency that common neighbors facilitate direct connections, i.e., as a measure for locality. Additionally, they introduced the weak closure as a more robust measure. Fox et al. show that weakly c -closed graphs have at most $3^{(c-1)/3}n^2$ cliques. For c -closed graphs they give the additional upper bound of $4^{(c+4)(c-1)/2}n^{2-2^{1-c}}$.

Qualitatively, at a first glance, these theoretical results seem to match our observations on real-world networks: sparse graphs contain few cliques and there are fewer cliques for more local networks (small c). However, a closer look reveals two caveats. First, both upper bounds are exponential in the parameter while 93% of real-world networks have at most m cliques. Second, the (weak) closure does not actually correlate with the number of cliques or the locality. Weak closure and degeneracy only seem to be a good measure for hardness on the remaining 7% of the instances. Thus, on the large majority of instances, the generative models yield a much better fit.

4.6 Chromatic Number

We study the effectiveness of a reduction rule for computing the chromatic number based on the size k of the maximum clique [31]. It reduces a graph to its k -core and is thus closely related to the degeneracy of the network.

Whether the reduction rule performs well comes, at its core, down to how the clique size k compares to the degeneracy d . We observe that both, k and d , mainly depend on locality and heterogeneity and behave very similar on real-world and generated networks. However, k and d have the same dependence on locality and heterogeneity, which means that (at least for some regimes) other properties have to tip the scale. We in particular observe a dependence on the average degree for the generated networks; the higher the average degree, the worse the reduction rule performs. More details on this can be found in the full version of the paper [4].

5 Discussion and Conclusion

Networks from different domains have varying structural properties. Thus, trying to find probability distributions that match or closely approximate those of real-world networks seems like a hopeless endeavor. Moreover, even if we knew such a probability distribution, it would most likely be highly domain specific and too complicated for theoretical analysis.

Our View on Average-Case Analysis. A more suitable approach to average case analysis is the use of models that assume few specific structural properties and are as unbiased as possible beyond that. If the chosen properties are the dominant factors for the algorithm's performance, we obtain external validity, i.e., the results translate to real-world instances even though they do not actually follow the assumed probability distributions. There are two levels of external validity.

- The models capture the performance-relevant properties sufficiently well that algorithms perform similar on generated and real-world networks.
- The models are too much of an idealization for this direct translation to practical performance. However, varying a certain structural property in this idealized world has the same qualitative effect on performance as it has on real-world networks.

Though an average case analysis cannot yield strong performance guarantees, with the above notions of external validity, it can give insights into what properties are crucial for performance (first level) and how the performance depends on a property (second level). Moreover, even a

lack of external validity can yield valuable insights in the following sense. Assume we have the hypothesis that property X is the crucial factor for algorithmic performance and thus we study a model with property X as null model. Then, a lack of external validity lets us refute the hypothesis as there clearly has to be a different property impacting the performance.

Impact of Locality and Heterogeneity. Non-surprisingly, the performance on real-world networks depending on locality and heterogeneity is more noisy compared to the generated networks, as real-world networks are diverse and vary in more than just these two properties. That being said, the observations on the models and in practice coincide almost perfectly for the bidirectional search and the enumeration of maximal cliques. For the maximal cliques, the match even includes constant factors, which is particularly surprising, as these numbers are below m while the worst case is exponential.

For the vertex cover domination rule as well as the iFUB algorithm, we obtain a slightly noisier picture. However, the overall trend matches well, which indicates that locality and heterogeneity are crucial factors for the performance, but not the only ones. For the iFUB algorithm, we already identified the existence of central vertices as additional factor (difference between torus and square as underlying geometry).

For the chromatic number, we observe that heterogeneity and locality are important but not the only factors impacting performance. Nonetheless, the performance is similar on the models compared to real-world networks.

For the Louvain clustering algorithm, the models and real-world networks coincide insofar, that the number of iterations is low, with few exceptions. This indicates that locality and heterogeneity are not the core properties for differentiating between hard and easy instances.

Conclusions. Locality and heterogeneity have significant impact on the performance of many algorithms. We believe that it is useful for the design of efficient algorithms to have these two dimensions of instance variability in mind. Moreover, GIRGs [11] with the available efficient generator [8] provide an abundance of benchmark instances on networks with varying locality and heterogeneity. Finally, we believe that average case analyses on the four extreme cases can help to theoretically underpin practical run times. The four extreme cases can, e.g., be modeled using geometric random graphs for local plus homogeneous, hyperbolic random graphs⁸ for local plus heterogeneous, Erdős–Rényi graphs for non-local plus homogeneous, and Chung–Lu graphs for non-local plus heterogeneous networks.

Abstract

For many problems, the important instances from practice possess certain structure that one should reflect in the design of specific algorithms. As data reduction is an important and inextricable part of today's computation, we employ one of the most successful models of such precomputation – the kernelization. Within this framework, we focus on TRAVELING SALESPERSON PROBLEM (TSP) and some of its generalizations.

We provide a kernel for TSP with size polynomial in either the feedback edge set number or the size of a modulator to constant-sized components. For its generalizations, we also consider other structural parameters such as the vertex cover number and the size of a modulator to constant-sized paths. We complement our results from the negative side by showing that the existence of a polynomial-sized kernel with respect to the fractioning number, the combined parameter maximum degree and treewidth, and, in the case of SUBSET TSP, modulator to disjoint cycles (i.e., the treewidth two graphs) is unlikely.

1 Introduction

The TRAVELING SALESPERSON PROBLEM is among the most popular and most intensively studied combinatorial optimization problems in graph theory¹. From the practical point of view, the problem was already studied in the 1950s; see, e.g., [15]. We define the problem formally as follows.

TRAVELING SALESPERSON PROBLEM (TSP)

Input: An undirected graph $G = (V, E)$, edge weights $\omega: E \rightarrow \mathbb{N}$, and a budget $b \in \mathbb{N}$.

Question: Is there a closed walk in G of total weight at most b that traverses each vertex of G at least once?

TSP is known to be NP-hard [24]. It is worth mentioning that the input to TSP is usually a complete graph and it is required that each vertex is visited exactly once (single-visit version). In this paper, we aim to study the impact of the structure of the input graph on the complexity of finding a solution to TSP. Towards this, we employ parameterized analysis [16] and therefore we also consider the decision version of TSP. Many variants of the problem have been studied in detail [29]. Our formulation is also known as GRAPHICAL TSP [14].

In this paper, we further study two natural generalizations of TSP – SUBSET TSP and WAYPOINT ROUTING PROBLEM. In SUBSET TSP (SUBTSP) the objective is to find a closed walk required to traverse only a given subset W of vertices (referred to as *waypoints*) instead of the whole vertex set as is in TSP. An instance of TSP can be interpreted as an instance of SUBTSP by letting $W = V(G)$. In WAYPOINT ROUTING PROBLEM (WRP) the edges of the input graph have capacities (given by a function $\kappa: E(G) \rightarrow \mathbb{N}$) and the objective is to find a closed walk traversing a given subset of vertices respecting the edge capacities, i.e., there is an upper limit on the number of times each edge can be traversed in a solution. As we show later, an instance of SUBTSP can be interpreted as an instance of WRP by letting $\kappa(e) = 2$ for every $e \in E(G)$. Note that both SUBTSP and WRP are NP-complete.

Related Work. TSP (and its variants) were extensively studied from the viewpoint of approximation algorithms. The single-visit version of TSP in general cannot be approximated, unless $P = NP$ [51]. For the metric single-visit version of the problem Christofides [13] provided a $\frac{3}{2}$ -approximation, while it is known that unless $P = NP$, there is no $\frac{117}{116}$ -approximation algorithm [12]. This is so far the best known approximation algorithm for the general case, despite a considerable effort, e.g., [54, 26, 10, 23, 8, 30, 37].

The problem remains APX-hard even in the case of weights 1 and 2, however, a $\frac{7}{6}$ -approximation algorithm is known for this special case [50]. A PTAS is known for the special case of Euclidean [4, 47] and planar [27, 3, 38] TSP. Also, the case of graph metrics received significant attention. Gharan et al. [25] found a $\frac{3}{2} - \epsilon_0$ approximation for this variant. Mömke and Svensson [48] then obtained a combinatorial algorithm for graphic TSP with an approximation factor of 1.461. This was later improved by Mucha [49] to $\frac{13}{9}$ and then by Sebö and Vygen [53] to 1.4. See, e.g., the monograph of Applegate et al. [2] for further information.

A popular practical approach to the single-visit version of TSP is to gradually improve some given solution using local improvements – the so-called q -OPT moves (see, e.g., [35, 36]). Marx [45] proved that TSP is W[1]-hard w.r.t. q . Later, Bonnet et al. [7] studied the q -OPT

¹ TSP Homepage: <http://www.math.uwaterloo.ca/tsp/index.html>.

technique on bounded degree graphs. They also investigated the complexity in the case where q is a fixed constant. The first significant theoretical improvement in the general case was by de Berg et al. [6] (announced at ICALP '16) who gave an $\mathcal{O}(n^{\lfloor 2q/3 \rfloor + 1})$ time dynamic programming based algorithm. Furthermore, they showed that improving upon the $\mathcal{O}(n^3)$ time for the case of 3-OPT would yield a breakthrough result by a connection with the ALL PAIRS SHORTEST PATHS (APSP) problem (see, e.g., [11]). Lancia and Dalpasso [40] observed that the DP-based approach is indeed slow in practice and implemented a practical fast algorithm tailored for 4-OPT. Later, Cygan et al. [17] improved the result of de Berg et al. [6] by presenting an $\mathcal{O}(n^{(1/4+\varepsilon_q)q})$ time algorithm. Moreover, they showed a connection of 4-OPT to APSP. Guo et al. [28] considered other suitable measures (parameters) for local search (e.g., r -swap or r -edit) and provided a W[1]-hardness result in general graphs (for both parameters). Furthermore, they gave an FPT algorithm for planar graphs and showed that the existence of polynomial kernels is unlikely even in this case.

SUBSET TSP can be solved in time $2^\ell \cdot n^{\mathcal{O}(1)}$ by first computing the distance between every pair of waypoints, and then solving the resulting ℓ -waypoint instance using the standard Bellman-Held-Karp dynamic programming algorithm [5, 31]. Klein and Marx [39] showed that if G is an undirected planar graph with polynomially bounded edge weights, then the problem can be solved significantly faster, in $2^{\mathcal{O}(\sqrt{\ell} \log \ell)} \cdot n^{\mathcal{O}(1)}$ time. It is also known that SUBSET TSP can be solved in $2^{\mathcal{O}(\sqrt{\ell} \log \ell)} \cdot n^{\mathcal{O}(1)}$ on edge-weighted directed planar graphs [46].

Amiri et al. [1] initiated the study of the variant of WRP discussed in this paper. They showed that the problem admits an XP algorithm w.r.t. the treewidth of the input graph. They also gave a randomized algorithm for the problem with running time $2^\ell \cdot n^{\mathcal{O}(1)}$, where ℓ is the number of waypoints; the algorithm can be derandomized if $\ell = \mathcal{O}((\log \log n)^{1/10})$. Schierreich and Suchý [52] improved the former algorithm by giving a deterministic algorithm with running time $2^{\mathcal{O}(\text{tw})} \cdot n$, which is tight under ETH [33]. Note that HAMILTONIAN PATH and therefore TSP is W[1]-hard w.r.t. the cliquewidth of the input graph [21].

It is somewhat surprising that, despite its popularity in theoretical computer science, the TSP problem did not receive much attention from the perspective of data reduction (kernelization). A notable exception is the work of Mannens et al. [43, 44] who studied MANY VISITS TSP and gave a polynomial kernel when the problem is parameterized by the vertex cover number of the input graph. In this work, we significantly expand the kernelization approach to TSP and its variants.

Structural parameters within the class of bounded treewidth. Even though all problems in FPT admit a kernel, not all of them admit a polynomial-sized kernel. It is not hard to see that TSP is AND-compositional and therefore we can (conditionally) exclude the existence of a polynomial kernel w.r.t. treewidth; more precisely, we show the following.

► **Lemma 1** (★). *There is no polynomial kernel for unweighted TRAVELING SALESPERSON PROBLEM with respect to either the fractioning number or the combined parameter treewidth and maximum degree, unless the polynomial hierarchy collapses.*

It follows that in order to obtain positive results we should investigate parameters within the class of bounded treewidth. Note that, roughly speaking, fractioning number is a *modulator to parameter-sized components*. A modulator is a set of vertices M such that when we remove M from a graph G the components of $G \setminus M$ fall into a specific (preferably simple) graph class (see Section 2 for formal definitions). Since almost all graph classes are closed under disjoint union, it is also popular to speak of addition of k vertices to a graph class (i.e., for a graph class \mathcal{G} we write $\mathcal{G} + kv$ if we are “adding” k vertices). Thus, it naturally models

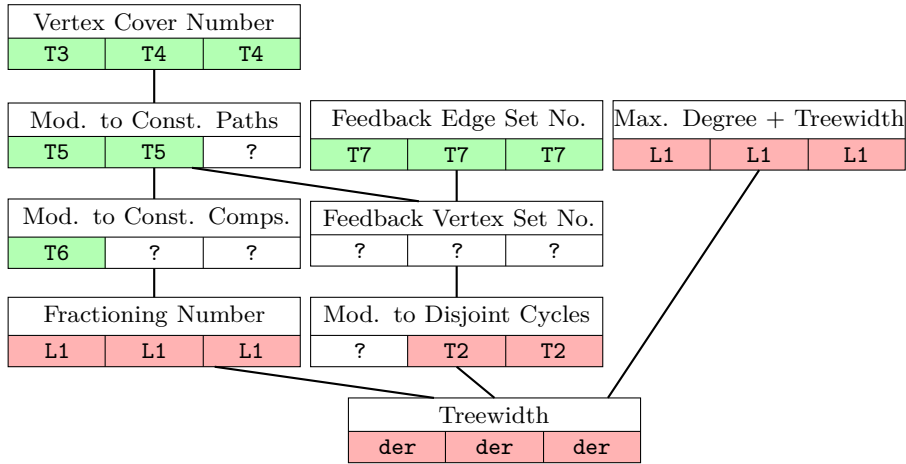

Figure 1 Overview of our results. Each node names a graph parameter and at its bottom it contains boxes representing (from left to right) TSP, SUBTSP, and WRP. If a node A is connected to a lower node B with an edge, then $B(G) = \mathcal{O}(A(G))$ for respective parameters. *Modulator*, *Constant*, and *Components* are shortened. Each box contains either a reference to the theorem which proves existence or non-existence of polynomial kernel (e.g. T2), or it contains ? if the problem is open, or it contains **der** if the result for such setting is derived from another result.

the situation when the input is close to a class of graphs where we can solve the problem efficiently (also called “Distance to \mathcal{G} ”). Modulator size is a popular structural parameter (see, e.g., [9, 41, 42]). Thus, the above result motivates us to study modulator-based parameters and their effect on kernelization of TSP and its variants. Indeed, many problems admit much more efficient algorithms w.r.t. vertex cover than for treewidth parameterization; see, e.g., [34, 19, 20]. Therefore, this is exactly the point where the positive part of our journey begins.

Before we do so, we discuss one more negative result. For SUBTSP we can, under a standard complexity-theoretic assumption, exclude the existence of a polynomial (Turing) kernel for the parameter size of a modulator to graphs of treewidth two. More specifically, we show the following.

► **Theorem 2** (★). *Unweighted SUBTSP with respect to the minimum k' such that there is a size k' modulator to cycles of size at most k' and there are at most k' non-terminals is WK[1]-hard.*

Therefore, SUBTSP parameterized by the size of a modulator to (disjoint) cycles does not admit a polynomial (Turing) kernel, unless all problems in WK[1] admit a polynomial Turing kernel. Moreover, it does not admit (classical) polynomial kernel, unless the polynomial hierarchy collapses. For more details on WK[1]-completeness, see [32].

Our Contribution. On a positive note, we begin with a polynomial kernel for TSP and WRP w.r.t. vertex cover number to demonstrate the general techniques we employ in this paper. We study the properties of a nice solution to the instance with respect to a particular structural parameter and its interaction with the modulator. We begin the study with TSP as a warm-up. In this case, we show that if there are “many” vertices in $G \setminus M$, where M is the modulator (vertex cover), then all but few of them behave in a “canonical way”. Based on the properties and cost of this canonical traversal, we identify which of these vertices can be safely discarded from the instance. In particular, we show the following.

► **Theorem 3** (★). *TRAVELING SALESPERSON PROBLEM admits a kernel with $\mathcal{O}(k^3)$ vertices, $\mathcal{O}(k^4)$ edges, and with a total bit-size $\mathcal{O}(k^{16})$, where k is the vertex cover number of G .*

In the case of SUBTSP or WRP, we cannot be sure that a solution visits all vertices in the modulator. Quite naturally, this results in the second kind of rule where we see that if there are “many” vertices attached to the modulator in the same way, we can mark some vertices in the modulator as terminals (there is a solution visiting them).

► **Theorem 4** (★). *WAYPOINT ROUTING PROBLEM admits a kernel with $\mathcal{O}(k^8)$ vertices, $\mathcal{O}(k^9)$ edges, and with a total bit-size $\mathcal{O}(k^{36})$, where k is the vertex cover number of G .*

Using similar, yet more involved results, we are able to find a polynomial kernel for SUBTSP for a modulator to constant-sized paths and for TSP for a modulator to constant-sized components.

One ingredient for our approach is that we may assume that all vertices outside the modulator are terminals, and therefore every solution visits them. It is not clear how to use our approach in the presence of capacities already in the case of modulator to paths, since the previous observation does not hold already in this simple case. Indeed, we show this by contracting some of the edges, which in the presence of capacities might have a side effect on the set of possible traversals of the component. The other and more important ingredient is the so-called blending of solutions (see Lemma 30).

► **Theorem 5** (★). *Let r be a fixed constant. SUBSET TSP admits a kernel of size $k^{\mathcal{O}(r)}$, where k is the size of a modulator to paths of size at most r .*

When we allow general constant-sized components outside the modulator, we have not yet succeeded in dealing with the highly connected non-terminals in the modulator. At this point, it is not clear whether many components with the same combination of canonical transversal and attachment to the modulator set ensure that we can safely mark a vertex in the modulator as a terminal.

► **Theorem 6** (★). *Let r be a fixed constant. TRAVELING SALESPERSON PROBLEM admits a kernel of size $k^{\mathcal{O}(r)}$, where k is the size of a modulator to components of size at most r .*

We conclude our algorithmic study by providing a rather simple polynomial kernel for WRP parametrized by the feedback edge set number. On the one hand, this result is an application of rather straightforward local reduction rules. On the other hand, these rules are heavily based on the use of edge capacities. It should be pointed out that we get a polynomial kernel for TSP as it has a polynomial compression to WRP, however, it can be shown that “local reduction rules” do not exist in the case of TSP.

► **Theorem 7** (★). *WAYPOINT ROUTING PROBLEM admits a kernel with $\mathcal{O}(k)$ vertices and edges and bit size $\mathcal{O}(k^4)$, where k is the feedback edge set number of G .*

For an overview of our results, please, refer to Figure 1.

Organization of the paper. We summarize the notation and technical results we rely on in Section 2. Section 3 contains a few useful technical lemmas and simple reduction rules. In Section 4, we begin with the core concepts applied in the case of TSP and vertex cover number. The similar approach is then applied in Section 5 to more general types of modulators; this is the most technical part of this manuscript. Finally, in Section 6 we conclude the results and discuss future research directions.

Statements where proofs or details are omitted due to space constraints are marked with ★. All missing proofs and details are available in the full version of the paper.

2 Preliminaries

We follow the basic notation of graph theory by Diestel [18]. In parameterized complexity theory, we follow the monograph of Cygan et al. [16].

A *walk* in a graph G is a non-empty alternating sequence of vertices and edges $S = v_1, e_1, \dots, e_{\ell-1}, v_\ell$ such that $v_i \in V(G)$, $e_i \in E(G)$, and $e_i = \{v_i, v_{i+1}\}$, $\forall i \in \{1, \dots, \ell-1\}$. It is *closed* if $v_\ell = v_1$. The weight of walk S is $\omega(S) = \sum_{i=1}^{\ell-1} \omega(e_i)$. If all vertices in a walk are distinct, it is called a *path*.

A *solution* to our problems is a closed walk S visiting every vertex in W of total weight at most b (traversing each edge e at most $\kappa(e)$ times). The least cost such walk is called an *optimal solution*. Given such a walk, we can construct the *corresponding multigraph* G_S which is a multigraph with vertex set being the set of vertices visited by S and each edge occurring as many times as traversed by S . We naturally extend ω to this multigraph, which yields $\omega(G_S) = \sum_{e \in E(G_S)} \omega(e) = \omega(S)$. The degree of a vertex in a multigraph is the number of the edges incident with it. Conversely, if a multigraph G_S is Eulerian (connected with all degrees even), then it admits a walk visiting every vertex of the graph and traversing each edge exactly as many times as occurring in G_S .

Structural Graph Parameters. Let $G = (V, E)$ be a graph. A set of edges $F \subseteq E$ is a *feedback edge set* of the graph G if $G \setminus F$ is an acyclic graph. *Feedback edge set number* $\text{fes}(G)$ of a graph G is the size of a smallest feedback edge set F of G . A set of vertices $C \subseteq V$ is called *vertex cover* of the graph G if it holds that $\forall e \in E$ we have $e \cap C \neq \emptyset$. The *vertex cover number* $\text{vc}(G)$ of a graph G is the least size of a vertex cover of G .

► **Definition 8.** Let \mathcal{G} be a graph family, let G be a graph, and $M \subseteq V(G)$. We say that M is a *modulator* of the graph G to the class \mathcal{G} if each connected component of $G \setminus M$ is in \mathcal{G} . The *distance* of G to \mathcal{G} , denoted $\text{modul}(G, \mathcal{G})$, is the minimum size of a modulator of G to \mathcal{G} .

Let r be a fixed constant. Let \mathcal{G}_{rc} be the class of graphs with every connected component having at most r vertices. The *distance of G to r -components* is $\text{modul}(G, \mathcal{G}_{rc})$. Similarly, if \mathcal{G}_{rp} is a class of graphs where every connected component is a path with at most r vertices, then the *distance of G to r -paths* is $\text{modul}(G, \mathcal{G}_{rp})$.

A set of vertices $C_r \subseteq V$ is called *r -fractioning set* of the graph G if $|C_r| \leq r$ and every connected component of $G \setminus C_r$ has at most r vertices. The *fractioning number* $\text{fn}(G)$ is a minimum $r \in \mathbb{N}$ such that there is an r -fractioning set C_r in graph G .

3 The Toolbox

In this section, we give formal proofs to a few technical statements we use throughout the rest of the paper. This yields a useful set of assumptions that allow us to present less technical proofs in the subsequent sections. We begin with a technical lemma we were not able to find in literature.

► **Lemma 9** (\star). *Let G be a graph with more than $2|V(G)| - 2$ edges. Then there is a cycle C in G such that the graph $G' = G \setminus E(C)$ has the same connected components as G .*

When proving the safeness of our reduction rules, it is easier to work with a solution that does not use many edges and traverses each edge at most twice. We show that we can always assume to work with such a solution.

► **Definition 10** (Nice Solution). *Let $(G, W, \omega, \kappa, \mathfrak{b})$ be an instance of TSP, SUBSET TSP, or WRP. We call a solution nice if it uses every edge at most twice and contains at most $2|V|$ edges (edge traversals) in total.*

Indeed, we may always assume that we work with a nice solution.

► **Lemma 11** (\star). *Let $(G, W, \omega, \kappa, \mathfrak{b})$ be an instance of TSP, SUBSET TSP, or WRP. There is a nice optimal solution.*

We continue with a remark about our instances. It is important to note that item (b) is applicable in general, however, one should be careful when doing so, since it increases the weights in the instance.

► **Remark 12** (\star). *Let $(G, W, \omega, \kappa, \mathfrak{b})$ be an instance of TSP, SUBSET TSP, or WRP. We assume that a) G is a connected graph and b) $\omega(e) > 0$ for all $e \in E(G)$.*

We apply the following lemma to reduce the weights of the kernelized instances. It follows in a rather straightforward way from results of Frank and Tardos [22].

► **Lemma 13** (\star). *There is a polynomial time algorithm, which, given an instance $(G, W, \omega, \kappa, \mathfrak{b})$ of TSP, SUBTSP, or WRP with at most d edges, produces ω' and \mathfrak{b}' such that the instances $(G, W, \omega, \kappa, \mathfrak{b})$ and $(G, W, \omega', \kappa, \mathfrak{b}')$ are equivalent and $(G, W, \omega', \kappa, \mathfrak{b}')$ is of total bit-size $\mathcal{O}(d^4)$.*

Finally, we present two simple reduction rules; we always assume that Reduction Rule 1 is not applicable.

► **Reduction Rule 1** (\star). *Let an instance of TSP, SUBTSP, or WRP be given. If $\mathfrak{b} < 0$, then answer no. Otherwise, if $|W| \leq 1$, then answer yes.*

► **Reduction Rule 2** (\star). *Let I be an instance of SUBSET TSP and $v \notin W$. For each pair of vertices $u, w \in N(v)$ we introduce a new edge $\{u, w\}$ into the graph with $\omega(\{u, w\}) = \omega(\{u, v\}) + \omega(\{v, w\})$ (if this creates parallel edges, then we only keep the one with the lower weight). Finally, we remove v together with all its incident edges.*

While Reduction Rule 2 is easy to apply, its application may destroy the structure of the input graph. Therefore, we only apply it to some specific vertices as explained in the subsequent sections.

4 Polynomial Kernel with Respect to Vertex Cover Number for TSP

In this (warm-up) section, we argue that TSP admits a polynomial kernel with respect to the vertex cover number. That is, we are going to present the most simple use-case of our reduction rules and therefore we can focus on the introduction of the core concept – the natural behavior. We begin with the definition of a (natural) behavior, which is a formal description of how a vertex “can behave” in a solution. Let M be a vertex cover of G of size $k = \text{vc}(G)$ and let $R = V \setminus M$.

► **Definition 14.** *For a vertex $r \in R$ a behavior of r is a multiset $F \subseteq \{\{r, m\} \mid \{r, m\} \in E, m \in M\}$ containing exactly two edges (edge occurrences). We let $B(r)$ be the set of all behaviors of r . We naturally extend the weight function such that for a behavior $F \in B(r)$ we set its weight to $\omega(F) = \sum_{e \in F} \omega(e)$. For a vertex $r \in R$ its natural behavior $b^{\text{nat}}(r)$ is a fixed minimizer of $\min \{\omega(F) \mid F \in B(r)\}$ that takes two copies of a minimum weight edge incident with r .*

The following lemma shows that in an optimal solution, most of the vertices of R actually use some behavior.

► **Lemma 15** (\star). *Let S be an optimal solution. Then the number of vertices $r \in R$ that are traversed more than once by S is at most k .*

Now, that we know what a behavior is, we can observe that each vertex can have one of two roles in the sought solution – they are either “just attached” using the natural behavior or they provide some connectivity between (two) vertices in the vertex cover. The role of a vertex is formalized as follows.

► **Definition 16**. *Let $r \in R$ and $F \in B(r)$ be a behavior of r . We say that F touches a vertex m of M if m has nonzero degree in $(\{r\} \cup M, F)$. We call the set $\text{imp}(F)$ of touched vertices the impact of behavior F .*

Let $\mathcal{I}_r = \{\text{imp}(F) \mid F \in B(r)\}$ be the set of all possible impacts of behaviors of r . Let $\mathcal{I} = \bigcup_{r \in R} \mathcal{I}_r$.

Note that we have $1 \leq |\text{imp}(F)| \leq 2$ for each behavior F . Therefore, we get $|\mathcal{I}| \leq \binom{k}{2} + k \leq k^2$. Note also that for each $r \in R$ we have $|\text{imp}(b^{\text{nat}}(r))| = 1$.

Now, we show that, in large instances, most of the vertices of R fall back to their natural behavior in an optimal solution. Towards this, we take a solution that differs from this in the fewest possible vertices $r \in R$. Then, we observe that if r is not in the natural behavior, then it is attached to (at least) two vertices in M . If there are many such “extra” edges in a solution, we can apply Lemma 9 – this would yield a contradiction. Thus, we get the following.

► **Lemma 17** (\star). *There is an optimal solution S such that for all but at most $3k$ vertices $r \in R$ the solution contains exactly the edges of $b^{\text{nat}}(r)$ among the edges incident with r .*

Now, we know that there are only a few vertices that behave unnaturally in an optimal solution, we would like to keep these in the kernel. We arrive at the question of which vertices to keep. To resolve this question, we observe that if a vertex deviates from its natural behavior, we (possibly) have to pay for this some extra price (which comes in the exchange of the provided connectivity). Thus, we would like to keep sufficiently many vertices for which this deviation is cheap. To this end, we first formalize the price.

► **Definition 18**. *For $r \in R$ and an impact $I \in \mathcal{I}$ let the price $P(r, I)$ of change from $b^{\text{nat}}(r)$ to I at r be $\omega(F_I) - \omega(b^{\text{nat}}(r))$ if there is a behavior $F_I \in B(r)$ with $\text{imp}(F_I) = I$ and we let it be ∞ otherwise.*

Note that if there is a behavior $F_I \in B(r)$ with $\text{imp}(F_I) = I$, then it is unique.

Now, based on this, we can provide the following reduction rule we employ.

► **Reduction Rule 3**. *For each $I \in \mathcal{I}$ if there are at most $3k$ vertices $r \in R$ with finite $P(r, I)$, then mark all of them. Otherwise mark $3k$ vertices $r \in R$ with the least $P(r, I)$.*

For each unmarked $r \in R$, remove r and decrease b by $\omega(b^{\text{nat}}(r))$.

Safeness. Let (G, ω, b) be the original instance and $(\widehat{G}, \widehat{\omega}, \widehat{b})$ be the new instance resulting from the application of the rule. Note that $\widehat{\omega}$ is just the restriction of ω to \widehat{G} which is a subgraph of G . Let R^- be the set of vertices of R removed by the rule. Note that $\widehat{b} = b - \sum_{r \in R^-} \omega(b^{\text{nat}}(r))$. We first show that if the new instance is a *yes*-instance, then so is the original one.

Let \widehat{S} be a solution walk in the new instance and let \widehat{G}_S be the corresponding multigraph formed by the edges of \widehat{S} . Note that the total weight of \widehat{G}_S is at most \widehat{b} . We construct a multigraph G_S by adding to \widehat{G}_S for each $r \in R^-$ the vertex r together with the edge set $b^{\text{nat}}(r)$. Since \widehat{G}_S is connected and each $b^{\text{nat}}(r)$ is incident with a vertex of $M \subseteq V(\widehat{G}_S)$, G_S is also connected. As each addition increases the degree of the involved vertex by exactly 2 and the degree of each vertex is even in \widehat{G}_S , it follows that the degree of each vertex is even in G_S . Hence G_S is Eulerian and contains all vertices of G . Since the weight of the added edges is exactly $\sum_{r \in R^-} \omega(b^{\text{nat}}(r))$ it follows that (G, ω, b) is a *yes*-instance.

Now suppose that the original instance (G, ω, b) is a *yes*-instance.

▷ **Claim 19** (\star). There is an optimal solution S for (G, ω, b) such that each $r \in R^-$ is incident exactly to the edges of $b^{\text{nat}}(r)$ in S .

Let S be a solution for (G, ω, b) as in the claim and G_S the corresponding multigraph. Let \widehat{G}_S be obtained from G_S by removing the edges of $b^{\text{nat}}(r)$ and vertex r for each $r \in R^-$. This reduces the total weight by exactly $\sum_{r \in R^-} \omega(b^{\text{nat}}(r))$, hence, as G_S is of weight at most b , \widehat{G}_S is of weight at most \widehat{b} . Furthermore, as each $r \in R^-$ has only one neighbor in G_S , \widehat{G}_S is connected. Moreover, each removal decreases the degree of exactly one remaining vertex by exactly 2, hence all degrees in \widehat{G}_S are even. Thus \widehat{G}_S is Eulerian, yielding a solution \widehat{S} for $(\widehat{G}, \widehat{\omega}, \widehat{b})$. This completes the proof. ◀

Since $|Z| \leq k^2$, the following observation is immediate.

▶ **Observation 20** (\star). After Reduction Rule 3 has been applied, the number of vertices in R is bounded by $3k^3$ and, hence, the total number of edges is $\mathcal{O}(k^4)$.

We conclude this section in the following theorem (which follows using Lemma 13).

▶ **Theorem 3** (\star). TRAVELING SALESPERSON PROBLEM admits a kernel with $\mathcal{O}(k^3)$ vertices, $\mathcal{O}(k^4)$ edges, and with a total bit-size $\mathcal{O}(k^{16})$, where k is the vertex cover number of G .

5 Polynomial Kernels with Respect to Modulator Size

In this section, we move to more general type of modulators. Recall that if M is a vertex cover, the connected components of $G \setminus M$ are single vertices. We are going to relax this a bit – we shall investigate general components of constant size and paths of constant size. For the first, more general one, we obtain a polynomial kernel for TSP. For the second, we obtain a polynomial kernel even for SUBTSP.

5.1 TSP and the Distance to Constant Size Components

For the rest of the section, we assume that we are given an undirected graph $G = (V, E)$, k is its distance to r -components, M the corresponding modulator, $E_M = \binom{M}{2}$, and $R = G \setminus M$. Let $M = \{m_1, \dots, m_k\}$ be a fixed order of the vertices of the modulator.

We begin with the definition of a behavior.

▶ **Definition 21.** For a connected component C of R we consider the graph $G_C = G[C \cup M] \setminus E_M$. A behavior of C is a multiset $F \subseteq E[G_C]$ of edges of G_C (each can be used at most twice) such that in the multigraph $(C \cup M, F)$, (i) each vertex $v \in C$ has nonzero even degree and (ii) each connected component contains a vertex of M , and the set F contains at most $2r$ edges incident with the vertices of M . We let $B(C)$ be the set of all behaviors of C . For a component C its natural behavior $b^{\text{nat}}(C)$ is a fixed minimizer of $\min \{\omega(F) \mid F \in B(C)\}$.

Now, it is not hard to see, that a solution might “visit” a component of $G \setminus M$ more than once. With this, we arrive at the key notion we introduce in this section – the segments. It is not hard to see that a solution may even revisit some terminals in a component; we shall later prove that this is the case for a few exceptional components only (see Lemma 25).

► **Definition 22.** Let C be a connected component of R and S be a walk starting and ending in $v_0 \in M$ forming a nice optimal solution to the instance. We split S into segments S_1, \dots, S_q such that each segment starts and ends in a vertex of M , whereas the inner vertices of each segment are from R . Let $\mathcal{F}(S, C)$ be obtained from the empty set by the following process: For each i , add S_i into $\mathcal{F}(S, C)$ if and only if there is a vertex $c \in C$ visited by S_i and not visited by any of the previous segments. Let $F(S, C)$ be the union of edges of S_i , $S_i \in \mathcal{F}(S, C)$, including multiplicities.

We observe that the multiset $F(S, C)$ is a behavior of C , i.e., $F(S, C) \in B(C)$.

Again, for a connected component of $G \setminus M$, we want to introduce the notion of touched vertices and the (connectivity) impact of a behavior of the component. For a better understanding of Definition 23, we refer the reader to an example in Figure 2.

► **Definition 23.** Let C be a connected component of R and $F \in B(C)$ be a behavior of C . We say that F touches a vertex m of M if m has nonzero degree in $(C \cup M, F)$. Let $T(F)$ be the set of touched vertices.

Consider the multiset $D(F)$ of edges obtained from the empty set as follows. For each connected component H of $(C \cup M, F)$ containing at least two vertices of M , let m_i be the vertex with the least index in $M \cap V(H)$. For each m_j in $(M \cap V(H)) \setminus \{m_i\}$ add to $D(F)$ a single edge $\{m_i, m_j\}$ if m_j is incident with an odd number of edges of F and a double edge $\{m_i, m_j\}$ if m_j is incident with an even number of edges of F .

We call the pair $\text{imp}(F) = (T(F), D(F))$ the impact of behavior F .

Let $\mathcal{I}_C = \{\text{imp}(F) \mid F \in B(C)\}$ be the set of all possible impacts of behaviors of C .

Let $\mathcal{I} = \bigcup_C \text{connected component of } R \mathcal{I}_C$.

From the Handshaking Lemma we get the following observation.

► **Observation 24.** Let m_i be as in Definition 23. Then m_i is incident with an even number of edges of $D(F)$ if and only if it is incident with an even number of edges of F .

It is not hard to see that $|\mathcal{I}| = k^{\mathcal{O}(r)}$.

Now, we want to give some properties that an optimal solution should have. Namely, we want to see that most of the connected components of $G \setminus M$ fallback to their natural behavior. Towards this, we first prove that there are only a few segments that are not part of a behavior of any component; recall that if the solution “revisited” some terminals in the connected component, this segment might not be part of any behavior.

► **Lemma 25** (\star). There is an optimal solution S such that there are at most $2|M|$ segments of S that are not part of any $\mathcal{F}(S, C)$, and, furthermore, for all but at most $2|\mathcal{I}|^2 + 2|M|$ components we have $F(S, C) = b^{\text{nat}}(C)$ and $F(S, C)$ contains all edges of S incident with C .

Next, we want to introduce the notion of price of a transition between two impacts of a connected component.

► **Definition 26.** For a connected component C of R and an impact $I \in \mathcal{I}$ let $\mathcal{B}(C, I)$ be the set of behaviors $F \in B(C)$ satisfying $\text{imp}(F) = I$.

For a connected component C of R and a pair $I, I' \in \mathcal{I}$ let the price $P(C, I, I')$ of change from I to I' at C be $\min\{\omega(F) \mid F \in \mathcal{B}(C, I')\} - \omega(b^{\text{nat}}(C))$ if $\mathcal{B}(C, I')$ is non-empty and $I = \text{imp}(b^{\text{nat}}(C))$ and we let it be ∞ if some of the conditions is not met.

■ **Figure 2** Illustration of Definition 23. A behavior F consists of red and green edges, and vertices m_2, \dots, m_5 made the set $T(F)$ of touched vertices. We built the multiset $D(F)$ for behavior F as follows. We start with an empty set. For the red connected component, the vertex $m_i \in M$ with least index is m_2 . Thus, for m_3 we add to $D(F)$ double edge $\{m_2, m_3\}$, because the vertex m_3 is incident with even number of edges in behavior F . For the vertex m_5 , we add to $D(F)$ the edge $\{m_2, m_5\}$ only once, as the vertex m_5 is incident with odd number of edges in F . For the green connected component, we do not extend $D(F)$ since, in this connected component, there is only one vertex from M .

Now, we are ready to introduce the reduction rule used in this section. To keep a record of the vertices that are marked towards achieving a different goal, we mark them in different colors. *Red* vertices are those that behaves unnaturally in an optimal solution and their deviation from natural behavior is cheap. The task of the vertices marked in *green* is to ensure that at least one vertex with the same impact of natural behavior remains in the instance to provide the connectivity. Finally, there are components marked in *blue*. These are supposed to cover the segments which are not part of any behavior.

▶ **Reduction Rule 4** (\star). For each pair $I, I' \in \mathcal{I}$ if there are at most $2|\mathcal{I}|^2 + 2|M|$ components C with finite $P(C, I, I')$, then mark all of them in red. Otherwise mark $2|\mathcal{I}|^2 + 2|M|$ components C with the least $P(C, I, I')$ in red.

For each pair of vertices $u, v \in M$, if there is a component C in R such that G_C contains a u - v -path, then mark a component which contains the shortest such path in blue.

For each $I \in \mathcal{I}$, if there are unmarked components C with $\text{imp}(b^{\text{nat}}(C)) = I$, then do the following. If the number of such components is odd, then mark one arbitrary such component in green. If the number of such components is even, then mark two arbitrary such components in green.

For each unmarked component C , remove C from G and reduce \mathfrak{b} by $\omega(b^{\text{nat}}(C))$.

To prove Theorem 6 we estimate the number of vertices and edges in the reduced instance; Theorem 6 then follows using Lemma 13.

▶ **Lemma 27** (\star). After Reduction Rule 4 has been applied, the number of components is bounded by $2(|\mathcal{I}|^2 + 2|M|)|\mathcal{I}|^2 + \binom{|M|}{2} + 2|\mathcal{I}| = k^{\mathcal{O}(r)}$. Hence, the number of vertices and edges in the reduced graph G is $k^{\mathcal{O}(r)}$.

5.2 Subset TSP and the Distance to Constant Size Paths

We start by applying Reduction Rule 2 to all vertices of R . Note that after each application of the reduction rule R remains a disjoint union of paths, because each vertex has degree at most 2 within R . Hence, for the rest of the section we assume that $V(R) \subseteq W$.

22:12 On Polynomial Kernels for TSP

We reuse the notions of the (natural) behavior, impact, and price (Definitions 21, 23, and 26) from the previous section.

We define *piece* of $F \in B(C)$ as any connected component of $(C \cup M, F) \setminus M$ to which we add all incident edges in G_S . We define *legs* of a piece as a subset of its edges which are incident with vertices of M . As $G \setminus M$ consists of disjoint union of paths we note that each piece of F consists of a path on C and its legs.

► **Lemma 28** (\star). *Given a SUBSET TSP instance $(G, W, \omega, \mathfrak{b})$ let S be a nice optimal solution to the instance. Let k be the size of the modulator to disjoint union of paths. There are at most k components with pieces of $F(S, C)$ with more than 2 legs in behaviors $\{F(S, C) \mid \text{imp}(F(S, C)) = I\}$ for any fixed $I \in \mathcal{I}$.*

It is the case that every natural behavior has only two-legged pieces.

► **Observation 29** (\star). *For each C component of R , each piece of $b^{\text{nat}}(C)$ has two legs.*

The most technical part of this section is the following lemma that allows us to, under some conditions, mark a non-terminal in the modulator as a terminal. For this to work, we want to do the following. Take many components which share the impact of the natural behavior which touches the particular non-terminal. Since there are many, many of them also share the impact of the actual behavior and have all pieces 2-legged. For each of them we want to find a behavior that is half-way between the actual and the natural behavior (using the following lemma). This behavior should touch the non-terminal and be of at most the same weight as the actual behavior. Then we find two components for which the half-way behavior has the same impact and change these, so that we obtain a solution that visits the particular non-terminal.

► **Lemma 30** (Blending lemma \star). *Let $M' \subseteq M$ (the set of actually visited vertices) and C a component of R (therefore a path) such that $T(b^{\text{nat}}(C)) \not\subseteq M'$. Let $v \in T(b^{\text{nat}}(C)) \setminus M'$ and $A \in B(C)$ (the actual behavior) such that $T(A) \subseteq M'$ and such that each piece has two legs. Then there is a behavior $F \in B(C)$ such that $v \in T(F)$, $T(F) \subseteq T(A) \cup T(b^{\text{nat}}(C))$, every connected component of $(C \cup M, F)$ contains a vertex of M' , and $\omega(F) \leq \omega(A)$.*

Now, we are ready to present the reduction rule used in this case. The colors have the same meaning as in Reduction Rule 4. It remains to secure that every vertex in M that is incident with some natural behavior for many vertices in R is in W . Towards this, we prove that if a vertex $m \in M$ is needed for a natural behavior for many vertices in R , it is safe to mark m as a terminal. If this is not the case, we mark the vertices $r \in R$ in *yellow*.

► **Reduction Rule 5** (\star). *For each pair $I, I' \in \mathcal{I}$ of impacts if there are at most $2|\mathcal{I}|^2 + 2|M|$ components C with finite $P(C, I, I')$, then mark all of them in red. Otherwise mark $2|\mathcal{I}|^2 + 2|M|$ components C with the least $P(C, I, I')$ in red.*

For each pair of vertices $u, v \in M$, if there is a component C in R such that G_C contains a u - v -path, then mark the component which contains the shortest such path in blue.

For each $I \in \mathcal{I}$, if there are unmarked components C with $\text{imp}(b^{\text{nat}}(C)) = I$, then let $I = (T, D)$ and do the following. If $T \subseteq W$, then if the number of such components is odd, then mark one arbitrary such component in green. If the number of such components is even, then mark two arbitrary such components in green.

If $T \not\subseteq W$ and there are at most $((r+1)^{4r} \cdot 2^{4r+1} + k) \cdot |\mathcal{I}|$ unmarked components C with $\text{imp}(b^{\text{nat}}(C)) = I$, then mark them all in yellow.

If $T \not\subseteq W$ and there are more than $((r+1)^{4r} \cdot 2^{4r+1} + k) \cdot |\mathcal{I}|$ unmarked components C with $\text{imp}(b^{\text{nat}}(C)) = I$, then add T to W .

If W was not changed, then for each unmarked component C , remove C from G and reduce b by $\omega(b^{\text{nat}}(C))$.

To prove Theorem 5 we estimate the number of vertices and edges in the reduced instance; Theorem 5 then follows using Lemma 13.

► **Lemma 31** (★). *After Reduction Rule 5 has been applied, the number of components is bounded by $2(|\mathcal{I}|^2 + 2|M|)|\mathcal{I}|^2 + \binom{|M|}{2} + 2|\mathcal{I}| + ((r+1)^{4r} \cdot 2^{4r+1} + k) \cdot |\mathcal{I}|^2 = k^{\mathcal{O}(r)}$. Hence, the number of vertices and edges in the reduced graph G is $k^{\mathcal{O}(r)}$.*

6 Conclusions

The core focus of this work is kernelization of the TRAVELING SALESPERSON PROBLEM. To stimulate further research in this area we would like to promote some follow up research directions. Design of “local” rules might be impossible (as was mentioned in the case of feedback edge set number) and therefore we occasionally have to consider generalizations of this problem that give us more power when designing the reductions. An interesting open problem that remains in this area is whether TSP does admit a polynomial kernel with respect to the feedback vertex number. Towards this we have provided several steps that suggest it should be possible to design a polynomial kernel. It should be noted that in order to do so, one could try to “lift” our arguments to modulator to trees of any size. Note that this is not possible for cycles.

Yet another interesting line of work is the one of q -path vertex cover (q -pvc). This is a generalization of the vertex cover number – a graph G has q -pvc of size k if it has a modulator M (with $|M| = k$) such that in $G \setminus M$ there is no path of length q . It is not hard to see that some of our arguments can be applied for components of $G \setminus M$ that are stars (of arbitrary size). Therefore, it should be possible to give a polynomial kernel for 3-pvc. Thus, the question arises: Is there a polynomial kernel with respect to r -pvc for constant r ? In this case we are more skeptical and believe that the correct answer should be negative.

Maximizing Sums of Non-Monotone Submodular and Linear Functions: Understanding the Unconstrained Case

Abstract

Motivated by practical applications, recent works have considered maximization of sums of a submodular function g and a linear function ℓ . Almost all such works, to date, studied only the special case of this problem in which g is also guaranteed to be monotone. Therefore, in this paper we systematically study the simplest version of this problem in which g is allowed to be non-monotone, namely the unconstrained variant, which we term **Regularized Unconstrained Submodular Maximization (RegularizedUSM)**.

Our main algorithmic result is the first non-trivial guarantee for general **RegularizedUSM**. For the special case of **RegularizedUSM** in which the linear function ℓ is non-positive, we prove two inapproximability results, showing that the algorithmic result implied for this case by previous works is not far from optimal. Finally, we reanalyze the known Double Greedy algorithm to obtain improved guarantees for the special case of **RegularizedUSM** in which the linear function ℓ is non-negative; and we complement these guarantees by showing that it is not possible to obtain $(1/2, 1)$ -approximation for this case (despite intuitive arguments suggesting that this approximation guarantee is natural).

1 Introduction

The field of submodular optimization has been rapidly developing over the last two decades, partially due to new applications. Some of these applications have also motivated the optimization of composite objective functions that can be represented as the sum of a submodular function g and a linear function ℓ . Let us briefly discuss two such applications

The first application is *optimization with a regularizer*. To avoid overfitting in machine-learning, it is customary to optimize a function of the form $g - \ell$, where g is the quantity that we would like to maximize and ℓ is a (often linear) function that favors small solutions. This function ℓ is known as “regularizer” in the machine learning jargon, or “soft constraint” in the operations research jargon.

The other application we discuss is *optimization with a curvature*. Traditionally, the theoretical study of submodular optimization problems looks for approximation guarantees that apply to all submodular functions, or at least all monotone submodular functions. However, approximation guarantees of this kind are often pessimistic, and do not capture

the practical performance of the algorithms analyzed. This has motivated studying how the optimal approximation ratios of various submodular maximization problems depend on various numerical function properties. Historically, the first property of this kind to be defined was the *curvature* property, which was suggested by Conforti and Cornuéjol [4] already in 1984. The curvature measures the distance of the submodular function from being linear, and a strong connection was demonstrated by Sviridenko et al. [17] between optimizing a submodular function with a given curvature and optimizing the sum $g + \ell$ of a monotone submodular function g and a linear function ℓ .

Motivated by the above applications, Sviridenko et al. [17] also initialized the study of the optimization of $g + \ell$ sums. In particular, they described algorithms with optimal approximation guarantees for this problem when g is a non-negative monotone submodular function, ℓ is a linear function and the optimization is subject to either a matroid or a cardinality constraint.¹ Later works obtained faster and semi-streaming algorithms for the same setting [7, 10, 11, 14]. However, in contrast to all these (often tight) results for monotone submodular functions g , much less is known about the case of non-monotone submodular functions. In fact, we are only aware of a single previous work that considered $g + \ell$ sums involving such functions [12].²

Given the rarity of results so far for optimizing $g + \ell$ with a function g that is non-monotone, this paper is devoted to a systematic study of the simplest problem of this kind, namely, unconstrained maximization of such sums. Formally, we study the **Regularized Unconstrained Submodular Maximization** (**RegularizedUSM**) problem. In this problem, we are given a non-negative submodular function $g: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$ and a linear function $\ell: 2^{\mathcal{N}} \rightarrow \mathbb{R}$ over the same ground set \mathcal{N} , and the objective is to output a set $T \subseteq \mathcal{N}$ maximizing the sum $g(T) + \ell(T)$. Unfortunately, it is not possible to prove standard multiplicative approximation ratios for **RegularizedUSM**.³ Therefore, we follow previous works (starting from [7, 17]), and look in this work for algorithms that output a (possibly randomized) set $T \subseteq \mathcal{N}$ such that $\mathbb{E}[g(T) + \ell(T)] \geq \max_{S \subseteq \mathcal{N}}[\alpha \cdot g(S) + \beta \cdot \ell(S)]$ for some coefficients $\alpha, \beta \geq 0$. For convenience, we say that an algorithm having this guarantee is an (α, β) -approximation algorithm.⁴

It is instructive to begin the study of **RegularizedUSM** with the special case in which the objective function g is guaranteed to be monotone (in addition to being non-negative and submodular). We refer below to this special case as “monotone **RegularizedUSM**”. The work of Feldman [7] on constrained maximization of $g + \ell$ immediately implies $(1 - e^{-\beta}, \beta)$ -approximation for monotone **RegularizedUSM** for every $\beta \in [0, 1]$. Our first result provides a matching inapproximability result.

► **Theorem 1.** *For every $\beta \geq 0$ and $\varepsilon > 0$, no polynomial time algorithm can guarantee $(1 - e^{-\beta} + \varepsilon, \beta)$ -approximation for monotone **RegularizedUSM** even when the linear function ℓ is guaranteed to be non-positive.*

¹ Technically, Sviridenko et al. [17] proved optimal approximation guarantees only for the case in which the coefficient β of ℓ is 1 (see details below). However, their results were extended to the general case of $\beta \geq 0$ by Feldman [7].

² Very recently, another work of this kind appeared as a pre-print [16]. However, the main result of [16] is identical to the result of [12]. In particular, it is important to note that the result of [16] applies only to non-positive ℓ functions, like the result of [12], although this is not explicitly stated in [16].

³ Formally, this is implied, e.g., by Theorem 1. Intuitively, the hurdle is that the combination of a positive g and a negative ℓ can lead to an optimal value that is very close to 0 compared to the values taken by the individual functions g and ℓ . When this happens, any algorithm with a positive multiplicative guarantee must output a solution that is close to optimal in terms of g and ℓ .

⁴ Some previous works compare their algorithms against $\alpha \cdot g(OPT) + \beta \cdot \ell(OPT)$, where OPT is a feasible set maximizing $g(OPT) + \ell(OPT)$, instead of comparing against $\max_{S \subseteq \mathcal{N}}[\alpha \cdot g(S) + \beta \cdot \ell(S)]$ like we do in this paper. This distinction is usually of little consequence.

We would like to draw attention to two properties of Theorem 1. First, for $\beta = 1$ the coefficient of g in the inapproximability proved by the theorem is $1 - 1/e$, matching the optimal approximation ratio for the problem of maximizing a monotone submodular function subject to a matroid constraint. Therefore, in a sense, adding the linear part ℓ makes the unconstrained problem as hard as this constrained problem. Interestingly, we get a similar result for `RegularizedUSM` below.

The other noteworthy property of Theorem 1 is that it applies to any $\beta \geq 0$, while the algorithmic result of Feldman [7] applies only to $\beta \in [0, 1]$. This difference between the results exists because, when ℓ can take positive values, setting the coefficient β to be larger than 1 might require the algorithm to output a set $T \subseteq \mathcal{N}$ obeying $\ell(T) > \max_{S \subseteq \mathcal{N}} \ell(S)$. However, it turns out that, when ℓ is non-positive, the algorithmic result can be extended to match Theorem 1 for every $\beta \geq 0$. To understand how this can be done, we need to discuss the previous work in a bit more detail.

Sviridenko et al. [17] designed two algorithms for maximizing $g + \ell$ sums, one of which was based on the continuous greedy algorithm of Călinescu et al. [3]. It is possible to modify this algorithm to be based instead on a related algorithm called “measured continuous greedy” due to [8]. In general, this does not lead to any result for maximizing $g + \ell$ sums. However, Lu et al. [12] recently observed that one can obtain in this way results when ℓ is non-positive. In particular, it leads to $(1 - e^{-\beta}, \beta)$ -approximation for the special case of monotone `RegularizedUSM` in which ℓ is non-positive for any constant $\beta \geq 0$, which settles the approximability of monotone `RegularizedUSM`.

We now get to the study of (not necessarily monotone) `RegularizedUSM`. The only result that is known to date for this problem is $(1/e, 1)$ -approximation for the special case in which ℓ is non-positive, which was proved by Lu et al. [12] using the technique discussed above. Our main algorithmic contribution is the first algorithm with a non-trivial approximation guarantee for general `RegularizedUSM`.

► **Theorem 2.** *For every constant $\beta \in (0, 1]$, let us define $\alpha(\beta) = \beta(1 - \beta)/(1 + \beta)$. Then, for every constant $\varepsilon \in (0, \alpha(\beta))$, there exists a polynomial time $(\alpha(\beta) - \varepsilon, \beta - \varepsilon)$ -approximation algorithm for `RegularizedUSM`.*

We also study in more detail the special cases of `RegularizedUSM` in which ℓ is either non-negative or non-positive. The above mentioned result of Lu et al. [12] for `RegularizedUSM` with a non-positive ℓ can be extended (using the ideas of Feldman [7]) to get $(\beta e^{-\beta}, \beta)$ -approximation for the same special case for any $\beta \in [0, 1]$.⁵ It is not immediately clear, however, how good this extended result is. For example, one can compare it with the inapproximability result of Theorem 1 (which applies to the current setting as well), but there is a large gap between the above algorithmic and inapproximability results when the β coefficient of ℓ is relatively large (see Figure 1). This gap exists because Theorem 1 holds even in the special case in which g is monotone. Therefore, we prove the following theorem, which provides an alternative inapproximability result designed for the non-monotone case. Since it is difficult to understand the behavior of the expression stated in Theorem 3, we numerically draw it in Figure 1, which demonstrates that Theorem 3 closes much of the gap left with regard to `RegularizedUSM` with non-positive linear function ℓ .

⁵ Technically, this result can be extended to any constant $\beta \geq 0$, but this is not interesting since $\beta e^{-\beta}$ is a decreasing function for $\beta \geq 1$.

■ **Figure 1** Graphical presentation of the existing results for **RegularizedUSM** with a non-positive linear function ℓ . The x and y axes represent the coefficients of ℓ and g , respectively. The algorithmic guarantee drawn is the $(\beta e^{-\beta}, \beta)$ -approximation obtainable by generalizing Lu et al. [12]. The shaded area represents the gap that still exists between the best known approximation guarantee and inapproximability results.

▶ **Theorem 3.** Given a value $\beta \geq 0$, let us define

$$\alpha(\beta) = \min_{\substack{t \geq 1 \\ r \in (0, 1/2]}} \left\{ \frac{t+1 + \sqrt{(t+1)^2 - 8tr}}{4t} - \frac{r}{t+1} \left[1 - \beta - 2 \ln \left(\frac{t+1 - \sqrt{(t+1)^2 - 8tr}}{2} \right) \right] \right\}.$$

Then, for every $\varepsilon > 0$, no polynomial time algorithm guarantees $(\alpha(\beta) + \varepsilon, \beta)$ -approximation for **RegularizedUSM** even when the linear function ℓ is guaranteed to be non-positive.

It is interesting to note that, for $\beta = 1$, Theorem 3 matches the state-of-the-art inapproximability result of Oveis Gharan and Vondrák [15] for maximizing a non-negative submodular function subject to matroid constraint. Therefore, at least at the level of the known inapproximability results, **RegularizedUSM** with a non-positive ℓ is as hard as maximizing a non-negative submodular function subject to a matroid constraint.

It remains to consider the special case of **RegularizedUSM** with a non-negative ℓ . Here $g + \ell$ is a non-negative submodular function on its own right, and therefore, **RegularizedUSM** becomes a special case of the well-studied problem of Unconstrained Submodular Maximization (USM). The optimal approximation ratio for USM is $1/2$ due to an inapproximability result of Feige et al. [6], and the first algorithm to obtain this approximation ratio was the “Double Greedy” algorithm of Buchbinder et al. [2]. Specifically, Buchbinder et al. [2] described two variants of their algorithm, a deterministic variant guaranteeing $1/3$ -approximation, and a randomized variant guaranteeing $1/2$ -approximation. We refer below to these two variants as **DeterministicDG** and **RandomizedDG**, respectively. Interestingly, we are able to show in the next two theorems that the performance of **DeterministicDG** and **RandomizedDG** for **RegularizedUSM** is even better than what one would expect based on the guarantees of these algorithms for general USM.

▶ **Theorem 4.** When ℓ is non-negative, the algorithm **DeterministicDG** guarantees $(\alpha, 1 - \alpha)$ -approximation for **RegularizedUSM** for all $\alpha \in [0, 1/3]$ at the same time (the algorithm is oblivious to the value of α).

► **Theorem 5.** *When ℓ is non-negative, the algorithm *RandomizedDG* guarantees $(\alpha, 1 - \alpha/2)$ -approximation for *RegularizedUSM* for all $\alpha \in [0, 1/2]$ at the same time (the algorithm is oblivious to the value of α).*

We conclude this section with an interesting observation. Up to this point, the most well studied $g + \ell$ maximization problem was maximizing the sum of a non-negative monotone submodular function g and a linear function ℓ subject to a matroid constraint. When ℓ is positive, the optimal approximation guarantee for this problem is $(1 - 1/e, 1)$ [17], which is natural since $1 - 1/e$ is the optimal approximation ratio for maximizing such a function g subject to a matroid constraint [13]. Thus, one might expect to get $(1/2, 1)$ -approximation for *RegularizedUSM* with a non-negative ℓ . However, both Theorems 4 and 5 fail to prove such a guarantee, and we are able to show that this is not a coincidence.

► **Theorem 6.** *Even when the linear function ℓ is guaranteed to be non-negative, no polynomial time algorithm can guarantee $(1/2, 1)$ -approximation for *RegularizedUSM*.*

Paper Structure. In Section 2 we give a few formal definitions and explain the notation used throughout the paper. Then, we prove our inapproximability result for monotone *RegularizedUSM* (Theorem 1) in Section 3. Our results for general *RegularizedUSM*, *RegularizedUSM* with non-positive ℓ and *RegularizedUSM* with non-negative ℓ can be found in Sections 4, 5 and 6, respectively.

2 Preliminaries

Set Functions and Notation. Given a set function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}$, an element $u \in \mathcal{N}$ and a set $S \subseteq \mathcal{N}$, the marginal contribution of u to S with respect to f is $f(u | S) \triangleq f(S \cup \{u\}) - f(S)$. A set function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}$ is called *submodular* if it satisfies the intuitive property of diminishing returns. More formally, f is submodular if $f(u | S) \geq f(u | T)$ for every two sets $S \subseteq T \subseteq \mathcal{N}$ and element $u \in \mathcal{N} \setminus T$. An equivalent definition of submodularity is that f is submodular if $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$ for every two sets $S, T \subseteq \mathcal{N}$.

The set function f is called *monotone* if $f(S) \leq f(T)$ for every two sets $S \subseteq T \subseteq \mathcal{N}$, and it is called *linear* if there exist values $\{a_u \in \mathbb{R} \mid u \in \mathcal{N}\}$ such that $f(S) = \sum_{u \in S} a_u$ for every set $S \subseteq \mathcal{N}$.⁶ One can verify that any linear set function is submodular, but the reverse does not necessarily hold. Additionally, given a set S , a set function f and an element u , we often use $S + u$, $S - u$ and $f(u)$ as shorthands for $S \cup \{u\}$, $S \setminus \{u\}$ and $f(\{u\})$, respectively.

Multilinear extension. It is often useful to consider continuous extensions of set functions, and there are multiple ways in which this can be done. The proofs of our inapproximability results employ one such extension known as the *multilinear extension* (due to [3]). Formally, given a set function $f: 2^{\mathcal{N}} \rightarrow \mathbb{R}$, its multilinear extension is the function $F: [0, 1]^{\mathcal{N}} \rightarrow \mathbb{R}$ defined, for every vector $\mathbf{x} \in [0, 1]^{\mathcal{N}}$, by $F(\mathbf{x}) = \mathbb{E}[f(\mathbf{R}(\mathbf{x}))]$, where $\mathbf{R}(\mathbf{x})$ is a random subset of \mathcal{N} including every element $u \in \mathcal{N}$ with probability x_u , independently.

One can verify that, as is suggested by its name, the multilinear extension F is a multilinear function of the coordinates of its input vector. Furthermore, F is an extension of the set function f in the sense that for every set $S \subseteq \mathcal{N}$ we have $F(\mathbf{1}_S) = f(S)$, where $\mathbf{1}_S$ is the characteristic vector of the set S (i.e., a vector that has the value 1 in coordinates corresponding to elements of S , and the value 0 in the other coordinates).

⁶ Linear set functions are also known as *modular* functions.

Value Oracle. As is standard in the submodular optimization literature, we assume in this paper that algorithms access their set function inputs only through *value oracles*. A value oracle for a set function f is a black box that given a set $S \subseteq \mathcal{N}$ returns $f(S)$. One advantage of this convention is that it makes it possible to use information theoretic arguments to prove unconditional inapproximability results (i.e., inapproximability results that are not based on any complexity assumption). Nevertheless, if necessary, these inapproximability results can usually be adapted to apply also to succinctly represented functions (instead of functions accessed via value oracles) at the cost of introducing some complexity assumption [5].

3 Inapproximability for Monotone Functions

In this section we show an inapproximability for monotone **RegularizedUSM** (Theorem 1). All our inapproximability results in this paper are proved using Theorem 7. Since the proof of this theorem is a relatively straightforward adaptation of the symmetry gap framework of Vondrák [18], we defer it to the full version of this paper [1].

► **Theorem 7.** *Consider an instance (g, ℓ) of **RegularizedUSM** consisting of a non-negative submodular function $g: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$ and a linear function $\ell: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$, and assume that there exists a group \mathcal{G} of permutations over \mathcal{N} such that the equalities $g(S) = g(\sigma(S))$ and $\ell(S) = \ell(\sigma(S))$ hold for all sets $S \subseteq \mathcal{N}$ and permutations $\sigma \in \mathcal{G}$. Let G and L be the multilinear extensions of g and ℓ respectively, and for every vector $\mathbf{x} \in [0, 1]^{\mathcal{N}}$, let us denote $\bar{\mathbf{x}} = \mathbb{E}_{\sigma \in \mathcal{G}}[\mathbf{x}]$, i.e., $\bar{\mathbf{x}}$ is the expected vector $\sigma(\mathbf{x})$ when σ is picked uniformly at random out of \mathcal{G} . For any two constants $\alpha, \beta \geq 0$, if $\max_{S \subseteq \mathcal{N}}[\alpha \cdot g(S) + \beta \cdot \ell(S)]$ is strictly positive and*

$$\max_{\mathbf{x} \in [0, 1]^{\mathcal{N}}} [G(\bar{\mathbf{x}}) + L(\bar{\mathbf{x}})] \leq \max_{S \subseteq \mathcal{N}} [\alpha \cdot g(S) + \beta \cdot \ell(S)] ,$$

*then no polynomial time algorithm for **RegularizedUSM** can guarantee $((1 + \varepsilon)\alpha, (1 + \varepsilon)\beta)$ -approximation for any positive constant ε . Furthermore, this inapproximability guarantee holds also when we restrict attention to instances (g', ℓ') of **RegularizedUSM** having the following additional properties.*

- *If ℓ is non-negative or non-positive, then we can assume that ℓ' also has the same property.*
- *If g is monotone, then we can assume that g' is monotone as well.*

In the common case in which the linear function ℓ is a non-positive, the following observation allows us to produce slightly cleaner results using Theorem 7.

► **Observation 8.** *If ℓ is non-positive and $\alpha > 0$, then one can replace the term “ $((1 + \varepsilon)\alpha, (1 + \varepsilon)\beta)$ -approximation” in Theorem 7 with the term “ $(\alpha + \varepsilon, \beta)$ -approximation”.*

Proof. Theorem 7 proves, under some conditions, that no polynomial time algorithm for **RegularizedUSM** has $((1 + \varepsilon)\alpha, (1 + \varepsilon)\beta)$ -approximation. Furthermore, if we reduce the value of the constant parameter ε of the theorem by a factor of α , then the theorem also shows that no such algorithm can guarantee $(\alpha + \varepsilon, \beta + \varepsilon\beta/\alpha)$ -approximation. This implies the observation since, when ℓ is non-positive, any $(\alpha + \varepsilon, \beta)$ -approximation algorithm for **RegularizedUSM** is also an $(\alpha + \varepsilon, \beta + \varepsilon\beta/\alpha)$ -approximation algorithm. ◀

To prove Theorem 1 using Theorem 7, we need to define an instance \mathcal{I} of monotone **RegularizedUSM**. Specifically, consider a ground set \mathcal{N} of size $n \geq 2$ and a value $r \in (0, 1]$, and let us define

$$g(S) = \min\{|S|, 1\} \quad \text{and} \quad \ell(S) = -r \cdot |S| \quad \forall S \subseteq \mathcal{N} .$$

► **Lemma 9.** *For any constants $\varepsilon > 0$, $\beta \geq 0$ and $\alpha = 1 - e^{-\beta} + \varepsilon$, when n is large enough, there exists a value $r \in (0, 1]$ such that the inequality of Theorem 7 applies to \mathcal{I} and $\max_{S \subseteq \mathcal{N}}[\alpha \cdot g(S) + \beta \cdot \ell(S)]$ is strictly positive.*

Proof. Observe that $\max_{S \subseteq \mathcal{N}}[\alpha \cdot g(S) + \beta \cdot \ell(S)] \geq \alpha - \beta r = 1 - e^{-\beta} + \varepsilon - \beta r$ because S can be chosen as a singleton subset of \mathcal{N} . Let us now study the left hand side of the inequality of Theorem 7. Since both g and ℓ are unaffected when an arbitrary permutation is applied to the ground set, we can choose \mathcal{G} as the group of all permutations over \mathcal{N} . Thus, for every vector $\mathbf{x} \in [0, 1]^{\mathcal{N}}$, $\bar{\mathbf{x}} = \frac{\|\mathbf{x}\|_1}{n} \cdot \mathbf{1}_{\mathcal{N}}$. Therefore,

$$\begin{aligned} \max_{\mathbf{x} \in [0, 1]^{\mathcal{N}}} [G(\bar{\mathbf{x}}) + L(\bar{\mathbf{x}})] &= \max_{x \in [0, 1]} [G(x \cdot \mathbf{1}_{\mathcal{N}}) + L(x \cdot \mathbf{1}_{\mathcal{N}})] \\ &= \max_{x \in [0, 1]} [1 - (1 - x)^n - xrn] = 1 - r - r(n - 1)[1 - r^{1/(n-1)}] , \end{aligned}$$

where the last equality holds since the maximum is obtained for $x = 1 - \sqrt[n-1]{r}$. Note now that if we denote $y = (n - 1)^{-1}$, then by L'Hôpital's rule,

$$\lim_{n \rightarrow \infty} (n - 1)[1 - r^{1/(n-1)}] = \lim_{y \rightarrow 0} \frac{1 - r^y}{y} = \lim_{y \rightarrow 0} \frac{-r^y \ln r}{1} = -\ln r ,$$

and therefore, for a large enough n , $(n - 1)[1 - r^{1/(n-1)}] \geq -\ln r - \varepsilon$; which implies

$$\max_{\mathbf{x} \in [0, 1]^{\mathcal{N}}} [G(\bar{\mathbf{x}}) + L(\bar{\mathbf{x}})] \leq 1 - r - r[-\ln r - \varepsilon] \leq 1 - r(1 - \ln r) + \varepsilon.$$

Given the above bounds, we get that the inequality of Theorem 7 holds for any $r > 0$ obeying $1 - e^{-\beta} + \varepsilon - \beta r \geq 1 - r(1 - \ln r) + \varepsilon$. Since the last inequality is equivalent to $r - r \ln r \geq e^{-\beta} + \beta r$, it holds for $r = e^{-\beta} \subseteq (0, 1]$. Furthermore, for this choice of r ,

$$\max_{S \subseteq \mathcal{N}} [\alpha \cdot g(S) + \beta \cdot \ell(S)] \geq 1 - e^{-\beta} + \varepsilon - \beta r = 1 - (1 + \beta)e^{-\beta} + \varepsilon \geq 1 - \frac{1 + \beta}{1 + \beta} + \varepsilon = \varepsilon > 0 . \blacktriangleleft$$

Theorem 1, which we repeat here for convenience, now follows by combining Theorem 7, Observation 8 and Lemma 9 since g is a non-negative monotone submodular function and ℓ is a non-positive linear function.

► **Theorem 1.** *For every $\beta \geq 0$ and $\varepsilon > 0$, no polynomial time algorithm can guarantee $(1 - e^{-\beta} + \varepsilon, \beta)$ -approximation for monotone **RegularizedUSM** even when the linear function ℓ is guaranteed to be non-positive.*

4 Algorithm for the General Case

In this section we describe and analyze the only non-trivial algorithm known to date (as far as we know) for general **RegularizedUSM**. Using this algorithm we prove Theorem 2, which we repeat here for convenience.

► **Theorem 2.** *For every constant $\beta \in (0, 1]$, let us define $\alpha(\beta) = \beta(1 - \beta)/(1 + \beta)$. Then, for every constant $\varepsilon \in (0, \alpha(\beta))$, there exists a polynomial time $(\alpha(\beta) - \varepsilon, \beta - \varepsilon)$ -approximation algorithm for **RegularizedUSM**.*

Our algorithm is based on a non-oblivious local search, i.e., a local search guided by an auxiliary function rather than the objective function. Non-oblivious local searches have been used previously in the context of submodular maximization by, for example, Feige et al. [6] and Filmus and Ward [9]. The auxiliary function used by our algorithm is a function $h: 2^{\mathcal{N}} \rightarrow \mathbb{R}_{\geq 0}$ defined as follows. For every set $S \subseteq \mathcal{N}$,

$$h(S) = \mathbb{E}[g(S(\beta))] + \beta(1 + \beta) \cdot \ell(S) ,$$

where $S(\beta)$ is a random subset of S that includes every element of S with probability β , independently.

Ideally, we would like to find a local maximum with respect to h , i.e., a set $T \subseteq \mathcal{N}$ such that the value of $h(T)$ cannot be increased either by adding a single element to T , or by removing a single element from T . However, there are two issues that make the task of finding such a local maximum difficult.

- We do not know how to exactly evaluate the expectation in the definition of h in polynomial time. Therefore, whenever we need to calculate expressions involving h , we have to approximate them using sampling, which introduces estimation errors that have to be taken into account.
- A straightforward local search algorithm changes its current solution whenever adding or removing a single element improves this solution. However, the time complexity of such a naïve algorithm can be exponential. Therefore, our algorithm adds or removes an element only when this is beneficial enough, which means that the algorithm finds an approximate local maximum rather than a true one. Employing this idea is not trivial given the errors introduced by the sampling, as mentioned above. However, we manage to prove that, for the value Δ defined by our algorithm, with high probability: (i) the algorithm only makes changes that increase the value of $h(T)$ by $\Delta/2$ or more, and (ii) the algorithm continues to make changes as long as there exists some possible change that increases the value of $h(T)$ by at least $3\Delta/2$.

The quality of the approximate local maximum produced by our algorithm is controlled by the parameter ε of Theorem 2. Setting a lower value for ε decreases Δ , which increases our algorithm's time complexity, but also makes the approximate local maximum produced closer to being a true local maximum, and thus, improves the approximation guarantee.

Let \hat{S} be a subset of \mathcal{N} maximizing $(\alpha(\beta) - \varepsilon) \cdot g(\hat{S}) + (\beta - \varepsilon) \cdot \ell(\hat{S})$. To implement the solutions described in the last two bullets, it is useful to assume that the ground set \mathcal{N} does not include elements that have some problematic properties. The following reduction shows that we can assume that this is indeed the case without loss of generality. Due to space constraints, the proof of this reduction and some other proofs from this section are deferred to the full version of this paper [1]. In a nutshell, the first part of Reduction 10 is proved by arguing that elements violating this part cannot belong to the set we need to compete with, and thus, can be ignored; and the second part of the reduction is proved by showing that a simple algorithm outputting the best solution of size at most 1 achieves the guarantee of Theorem 2 when this part of the reduction is violated.

► **Reduction 10.** *While proving Theorem 2, we may assume that every element $u \in \mathcal{N}$ obeys*

$$\alpha(\beta) \cdot g(u) + \beta \cdot \ell(u) \geq 0 \quad \text{and} \quad \max\{g(u) + \ell(u), g(\emptyset)\} \leq \beta \cdot [g(\hat{S}) + \ell(\hat{S})] .$$

From this point until the end of the section, we denote by n the size of the ground set \mathcal{N} . We are now ready to describe our algorithm (given as Algorithm 1). This algorithm implicitly assumes that Reduction 10 was applied, that n is large enough and that $\max\{g(\emptyset), \max_{u \in \mathcal{N}} g(u)\} > 0$.⁷ The algorithm maintains a solution T , which it updates in

⁷ Let us explain why the problem becomes easy if either of the last two assumptions is violated. If n is bounded by a constant, it is possible to use exhaustive search to find the set $T \subseteq \mathcal{N}$ maximizing $g(T) + h(T)$, and one can verify that such a set has the properties guaranteed by Theorem 2. Additionally, if $\max\{g(\emptyset), \max_{u \in \mathcal{N}} g(u)\} = 0$, then the submodularity of g guarantees that g is the zero function, which means that we can get the guarantee of Theorem 2 by outputting the set $\{u \in \mathcal{N} \mid \ell(u) > 0\}$.

iterations. In each iteration, the algorithm calculates for every element u an estimate ω_u of the contribution of u to the g component of the auxiliary function h . Then, Line 6 of the algorithm looks for an element $u \in \mathcal{N} \setminus T$ which, based on the estimate ω_u , will increase $h(T)$ by Δ if added to T . If such an element u is found, the algorithm adds it to T and continues to the next iteration. Otherwise, Line 8 looks for an element $u \in T$ which will increase $h(T)$ by Δ if removed from T (again, based on the estimate ω_T). If such an element u is found, then the algorithm removes it from T and continues to the next iteration. However, if both Lines 6 and 8 fail to find an appropriate element, the algorithm assumes that it has encountered an approximate local maximum, and terminates. Somewhat surprisingly, when this happens the algorithm outputs a sample \hat{T} of $T(\beta)$ rather than the solution T itself (unless the value of this sample is negative, in which case the algorithm falls back to the solution \emptyset). We show below that if T is an approximate local maximum of the auxiliary function h , then $T(\beta)$ is in expectation a good solution with respect to the objective function.

■ **Algorithm 1** Non-oblivious Local Search (β, ε) .

```

1 Let  $\Delta \leftarrow \frac{\varepsilon}{2n} \cdot \max\{g(\emptyset), \max_{u \in \mathcal{N}} g(u)\}$  and  $T \leftarrow \{u \in \mathcal{N} \mid \ell(u) > 0\}$ .
2 for  $i = 1$  to  $\lceil 4n^2/\varepsilon \rceil + 1$  do
3   for every  $u \in \mathcal{N}$  do
4     Let  $\omega_u$  be an estimate of  $\beta \cdot \mathbb{E}[g(u \mid T(\beta) - u)]$  obtained by taking the average
       of  $\beta \cdot g(u \mid T(\beta) - u)$  for  $k = \lceil 128n^4\varepsilon^{-2}\beta^2 \cdot \ln(10n^4/\varepsilon) \rceil$  independent samples
       of  $T(\beta)$ .
5     if there exists  $u \in \mathcal{N} \setminus T$  such that  $\omega_u + \beta(1 + \beta) \cdot \ell(u) \geq \Delta$  then
6       Update  $T \leftarrow T + u$ .
7     else if there exists  $u \in T$  such that  $\omega_u + \beta(1 + \beta) \cdot \ell(u) \leq -\Delta$  then
8       Update  $T \leftarrow T - u$ .
9     else Exit the “for” loop.
10 Let  $\hat{T}$  be a sample of  $T(\beta)$ .
11 if  $g(\hat{T}) + \ell(\hat{T}) \geq 0$  then return  $\hat{T}$ .
12 else return  $\emptyset$ .
```

It is clear that Algorithm 1 runs in polynomial time, and therefore, we concentrate in the rest of this section on proving its approximation guarantee. Algorithm 1 makes multiple estimation during its execution. We say that an estimate ω_u is *good* if $|\omega_u - \mathbb{E}[g(u \mid T(\beta) - u)]| \leq \Delta/2$ (for the set T at the time in which the estimate was made), otherwise the estimate is *bad*. The following lemma is proved by showing that every estimate strongly concentrates due to the independent samples used to compute it, and then lower bounding the probability that all the estimates are good via the union bound.

► **Lemma 11.** *With high probability (a probability approaching 1 when n tends to infinity), all the estimates made by Algorithm 1 are good.*

Using the previous lemma, we can now prove that, with high probability, Algorithm 1 terminates with T being an approximate local maximum. Specifically, in the proof of the next lemma we show that if all the estimates are good (which is a high probability event by the previous lemma), then Algorithm 1 must encounter an approximate local maximum because otherwise the value of its solution grows to an impossibly high value.

► **Lemma 12.** *With high probability, when Algorithm 1 terminates we have*

$$h(T) \geq h(T + u) - 3\Delta/2 \quad \forall u \in \mathcal{N} \setminus T \quad \text{and} \quad h(T) \geq h(T - u) - 3\Delta/2 \quad \forall u \in T .$$

23:10 Maximizing Sums of Non-Monotone Submodular and Linear Functions

The last lemma shows that with high probability the final set T is an approximate local maximum with respect to h . Lemma 14 shows that this implies that $T(\beta)$ is a good solution in expectation. To prove Lemma 14, we need the following known lemma.

► **Lemma 13** (Lemma 2.2 of [6]). *Let $f: 2^X \rightarrow \mathbb{R}_{\geq 0}$ be a submodular function, and given a set $A \subseteq X$, let us denote by A_p a random subset of A where each element appears with probability $p \in [0, 1]$ (not necessarily independently). Then, $\mathbb{E}[f(A_p)] \geq (1-p) \cdot f(\emptyset) + p \cdot f(A)$.*

Recall that \hat{S} is a subset of \mathcal{N} maximizing the expression $(\alpha(\beta) - \varepsilon) \cdot g(\hat{S}) + (\beta - \varepsilon) \cdot \ell(\hat{S})$.

► **Lemma 14.** *If the set T obeys*

$$h(T) \geq h(T+u) - 3\Delta/2 \quad \forall u \in \mathcal{N} \setminus T \quad \text{and} \quad h(T) \geq h(T-u) - 3\Delta/2 \quad \forall u \in T ,$$

then $\mathbb{E}[g(T(\beta)) + \ell(T(\beta))] \geq (\alpha(\beta) - 3\varepsilon/4) \cdot g(\hat{S}) + (\beta - 3\varepsilon/4) \cdot \ell(\hat{S})$.

Proof. By the first part of Lemma 12, for every element $u \in \mathcal{N} \setminus T$, $h(T) \geq h(T+u) - 3\Delta/2$, or equivalently $h(u | T) \leq 3\Delta/2$. Therefore, by the submodularity of g ,

$$\begin{aligned} \mathbb{E}[g(T(\beta) \cup (\hat{S} \setminus T))] + (1+\beta) \cdot \ell(\hat{S} \setminus T) & \quad (1) \\ & \leq \mathbb{E}[g(T(\beta))] + \sum_{u \in \hat{S} \setminus T} \{\mathbb{E}[g(u | T(\beta) - u)] + (1+\beta) \cdot \ell(u)\} \\ & = \mathbb{E}[g(T(\beta))] + \beta^{-1} \cdot \sum_{u \in \hat{S} \setminus T} h(u | T) \leq \mathbb{E}[g(T(\beta))] + 3\beta^{-1} |\hat{S} \setminus T| \Delta/2 , \end{aligned}$$

where the equality holds because the law of total expectation implies that, for $u \notin T$,

$$\begin{aligned} h(u | T) & = \mathbb{E}[g((T+u)(\beta)) - g(T(\beta))] + \beta(1+\beta) \cdot \ell(u) \\ & = \beta \mathbb{E}[g(T(\beta) + u) - g(T(\beta))] + (1-\beta) \cdot \mathbb{E}[g(T(\beta)) - g(T(\beta))] + \beta(1+\beta) \cdot \ell(u) \\ & = \beta \mathbb{E}[g(T(\beta) + u) - g(T(\beta))] + \beta(1+\beta) \cdot \ell(u) = \beta \mathbb{E}[g(u | T(\beta) - u)] + \beta(1+\beta) \cdot \ell(u) . \end{aligned}$$

Similarly, since the second part of Lemma 12 implies that for every $u \in T$ we have $h(u | T - u) \geq -3\Delta/2$, the submodularity of g gives us

$$\begin{aligned} \mathbb{E}[g(T(\beta) \cap \hat{S})] - \beta(1+\beta) \cdot \ell(T \setminus \hat{S}) & \quad (2) \\ & \leq \mathbb{E}[g(T(\beta))] - \sum_{u \in T \setminus \hat{S}} \{\beta \cdot \mathbb{E}[g(u | T(\beta) - u)] - \beta(1+\beta) \cdot \ell(u)\} \\ & = \mathbb{E}[g(T(\beta))] - \sum_{u \in T \setminus \hat{S}} h(u | T - u) \leq \mathbb{E}[g(T(\beta))] + 3|T \setminus \hat{S}| \Delta/2 . \end{aligned}$$

Adding β times Inequality (1) to Inequality (2) now yields

$$\begin{aligned} \beta \cdot \mathbb{E}[g(T(\beta) \cup (\hat{S} \setminus T))] + \mathbb{E}[g(T(\beta) \cap \hat{S})] + \beta(1+\beta) \cdot [\ell(\hat{S} \setminus T) - \ell(T \setminus \hat{S})] & \quad (3) \\ \leq (1+\beta) \cdot \mathbb{E}[g(T(\beta))] + 3[|\hat{S} \setminus T| + |T \setminus \hat{S}|] \Delta/2 \leq (1+\beta) \cdot \mathbb{E}[g(T(\beta))] + 3n\Delta/2 . \end{aligned}$$

We can now use Lemma 13 to lower bound the first two terms on the leftmost side of the last inequality as follows.

$$\begin{aligned} \beta \cdot \mathbb{E}[g(T(\beta) \cup (\hat{S} \setminus T))] + \mathbb{E}[g(T(\beta) \cap \hat{S})] & \\ \geq \beta(1-\beta) \cdot g(\hat{S} \setminus T) + \beta^2 \cdot g(\hat{S} \cup T) + \beta \cdot g(T \cap \hat{S}) + (1-\beta) \cdot g(\emptyset) & \\ \geq \beta(1-\beta) \cdot [g(\hat{S} \setminus T) + g(T \cap \hat{S})] \geq \beta(1-\beta) \cdot g(\hat{S}) , & \end{aligned}$$

where the second inequality follows from the non-negativity of g , and the last inequality holds by g 's submodularity (and non-negativity). Plugging this inequality into Inequality (3) now gives

$$\beta(1 - \beta) \cdot g(\hat{S}) + \beta(1 + \beta) \cdot [\ell(\hat{S} \setminus T) - \ell(T \setminus \hat{S})] \leq (1 + \beta) \cdot \mathbb{E}[g(T(\beta))] + 3n\Delta/2 ,$$

and rearranging this inequality yields

$$\begin{aligned} \mathbb{E}[g(T(\beta)) + \ell(T(\beta))] &= \mathbb{E}[g(T(\beta))] + \beta \cdot \ell(T) \\ &\geq \frac{\beta(1 - \beta) \cdot g(\hat{S}) - 3n\Delta/2}{1 + \beta} + \beta \cdot [\ell(\hat{S} \setminus T) - \ell(T \setminus \hat{S})] + \beta \cdot \ell(T) \\ &\geq \alpha(\beta) \cdot g(\hat{S}) + \beta \cdot \ell(\hat{S}) - 3n\Delta/2 . \end{aligned}$$

To complete the proof of the lemma, it remains to show that $3n\Delta/2 \leq (3\varepsilon/4) \cdot [g(\hat{S}) + \ell(\hat{S})]$. Towards this goal, observe that

$$\max_{u \in \mathcal{N}} g(u) \leq \max_{u \in \mathcal{N}} \left\{ g(u) + \frac{1 + \beta}{2\beta^2} \cdot [\alpha(\beta) \cdot g(u) + \beta \cdot \ell(u)] \right\} = \frac{1 + \beta}{2\beta} \cdot \max_{u \in \mathcal{N}} [g(u) + \ell(u)] ,$$

where the inequality follows from the first part of Reduction 10. Using this inequality and the non-negativity of g , we can get

$$\begin{aligned} \frac{3n\Delta}{2} &= \frac{3\varepsilon}{4} \cdot \max\{g(\emptyset), \max_{u \in \mathcal{N}} g(u)\} \leq \frac{3\varepsilon(1 + \beta)}{8\beta} \cdot \max\{g(\emptyset), \max_{u \in \mathcal{N}} [g(u) + \ell(u)]\} \\ &\leq \frac{3\varepsilon(1 + \beta)}{8} \cdot [g(\hat{S}) + \ell(\hat{S})] \leq \frac{3\varepsilon}{4} \cdot [g(\hat{S}) + \ell(\hat{S})] , \end{aligned}$$

where the penultimate inequality follows from the second part of Reduction 10, and the last inequality uses the observation that the second part of Reduction 10 and the non-negativity of g imply together that $g(\hat{S}) + \ell(\hat{S})$ is non-negative. \blacktriangleleft

We are now ready to prove Theorem 2.

Proof of Theorem 2. Recall that \hat{T} is a sample of $T(\beta)$ for the value of the set T when Algorithm 1 terminates. Lemmata 12 and 14 prove together that there exists a high probability event \mathcal{E} such that

$$\mathbb{E}[g(\hat{T}) + \ell(\hat{T}) \mid \mathcal{E}] \geq (\alpha(\beta) - 3\varepsilon/4) \cdot g(\hat{S}) + (\beta - 3\varepsilon/4) \cdot \ell(\hat{S}) .$$

The last two lines of Algorithm 1 guarantee that this algorithm always outputs a set whose value is at least $g(\hat{T}) + h(\hat{T})$ because $g(\emptyset) + \ell(\emptyset) = g(\emptyset) \geq 0$. Therefore, if we denote by \bar{T} the set outputted by Algorithm 1, then we also have

$$\mathbb{E}[g(\bar{T}) + \ell(\bar{T}) \mid \mathcal{E}] \geq (\alpha(\beta) - 3\varepsilon/4) \cdot g(\hat{S}) + (\beta - 3\varepsilon/4) \cdot \ell(\hat{S}) .$$

The last two lines of Algorithm 1 also guarantee that the output set \bar{T} of Algorithm 1 always has a non-negative value, and therefore, $\mathbb{E}[g(\bar{T}) + h(\bar{T}) \mid \bar{\mathcal{E}}] \geq 0$. Combining this inequality with the previous one using the law of total expectation yields

$$\begin{aligned} \mathbb{E}[g(\bar{T}) + h(\bar{T})] &\geq \Pr[\mathcal{E}] \cdot \mathbb{E}[g(\bar{T}) + \ell(\bar{T}) \mid \mathcal{E}] \\ &\geq (1 - o(1)) \cdot [(\alpha(\beta) - 3\varepsilon/4) \cdot g(\hat{S}) + (\beta - 3\varepsilon/4) \cdot \ell(\hat{S})] \\ &\geq (\alpha(\beta) - \varepsilon) \cdot g(\hat{S}) + (\beta - \varepsilon) \cdot \ell(\hat{S}) = \max_{S \subseteq \mathcal{N}} [(\alpha(\beta) - \varepsilon) \cdot g(S) + (\beta - \varepsilon) \cdot \ell(S)] , \end{aligned}$$

23:12 Maximizing Sums of Non-Monotone Submodular and Linear Functions

where the second inequality holds since $g(\bar{T}) + h(\bar{T})$ is always non-negative, the equality follows from the definition of \hat{S} , and $o(1)$ represents a term that diminishes when n goes to infinity. To justify the third inequality, note that

$$\begin{aligned} o(1) \cdot [(\alpha(\beta) - 3\varepsilon/4) \cdot g(\hat{S}) + (\beta - 3\varepsilon/4) \cdot \ell(\hat{S})] &\leq o(1) \cdot (\beta - 3\varepsilon/4) \cdot [g(\hat{S}) + \ell(\hat{S})] \\ &\leq (\varepsilon/4) \cdot [g(\hat{S}) + \ell(\hat{S})] , \end{aligned}$$

where the last inequality here holds for large enough values of n because the second part of Reduction 10 and the non-negativity of g imply together that $g(\hat{S}) + \ell(\hat{S})$ is non-negative. ◀

5 Inapproximability for Negative Linear Functions

In this section we prove Theorem 3, which we repeat here for convenience.

► **Theorem 3.** *Given a value $\beta \geq 0$, let us define*

$$\alpha(\beta) = \min_{\substack{t \geq 1 \\ r \in (0, 1/2]}} \left\{ \frac{t+1 + \sqrt{(t+1)^2 - 8tr}}{4t} - \frac{r}{t+1} \left[1 - \beta - 2 \ln \left(\frac{t+1 - \sqrt{(t+1)^2 - 8tr}}{2} \right) \right] \right\} .$$

*Then, for every $\varepsilon > 0$, no polynomial time algorithm guarantees $(\alpha(\beta) + \varepsilon, \beta)$ -approximation for **RegularizedUSM** even when the linear function ℓ is guaranteed to be non-positive.*

The proof of Theorem 3 is based on Theorem 7, and therefore, we start this proof by describing an instance \mathcal{I} of **RegularizedUSM**. This instance is very similar to the instance used by Oveis Gharan and Vondrák [15] to prove their hardness result for maximizing a non-negative (not necessarily monotone) submodular function subject to a matroid constraint. Specifically, the instance \mathcal{I} has 3 parameters: an integer $n \geq 1$, a real value $t \geq 1$ and a real value $r \in (0, 1/2]$. The ground set of \mathcal{I} is $\mathcal{N} = \{a, b\} \cup \{a_i, b_i \mid i \in [n]\}$, and its objective functions are $\ell(S) = -r \cdot |S \cap \{a_i, b_i \mid i \in [n]\}|$ and

$$\begin{aligned} g(S) = t \cdot (|S \cap \{a, b\}| \bmod 2) &+ \mathbf{1}[a \notin S] \cdot \mathbf{1}[S \cap \{a_i \mid i \in [n]\} \neq \emptyset] \\ &+ \mathbf{1}[b \notin S] \cdot \mathbf{1}[S \cap \{b_i \mid i \in [n]\} \neq \emptyset] . \end{aligned}$$

One can verify that g is indeed a non-negative submodular function. Additionally, the functions g and ℓ are both symmetric in the sense that the following types of swaps do not affect the values of these functions.

- Any swap of the identities of the elements of $\{a_i \mid i \in [n]\}$.
- Swapping the identifies of a with b plus swapping the identities of a_i and b_i for every $i \in [n]$.

Let \mathcal{G} be the group of permutations obtained by combining swaps of these two kinds in any way.

In the next lemma, G and L are the multilinear extensions of g and ℓ , respectively, and $\bar{\mathbf{x}} = \mathbb{E}_{\sigma \in \mathcal{G}}[\sigma(\mathbf{x})]$. Theorem 3 follows by combining this lemma with Theorem 7 and Observation 8. The (quite technical) proof of Lemma 15 can be found in the full version of this paper [1].

► **Lemma 15.** *Let r and t be the values for which the maximum is obtained in the definition of $\alpha(\beta)$. Then, for any constant $\varepsilon > 0$ and a large enough n , $\max_{S \subseteq \mathcal{N}}[(\alpha(\beta) + \varepsilon) \cdot g(S) + \beta \cdot \ell(S)]$ is strictly positive and $\max_{\mathbf{x} \in [0,1]^{\mathcal{N}}} [G(\bar{\mathbf{x}}) + L(\bar{\mathbf{x}})] \leq \max_{S \subseteq \mathcal{N}}[\alpha(\beta) \cdot g(S) + \beta \cdot \ell(S)]$.*

6 Results for Positive Linear Functions

In this section we study `RegularizedUSM` in the special case in which the linear function ℓ is non-negative. As explained in Section 1, following related known results, it is natural to expect a $(1/2, 1)$ -approximation for this case since $1/2$ is the best possible approximation ratio for unconstrained maximization of a non-negative submodular function. However, we show in Section 6.1 that this cannot be done (Theorem 6).

Let us now define $f \triangleq g + \ell$. As explained in Section 1, since f is a non-negative submodular function on its own right, one can optimize it using any algorithm for `Unconstrained Submodular Maximization (USM)`. The first algorithm to obtain a tight approximation ratio of $1/2$ for USM was an algorithm called “Double Greedy” due to Buchbinder et al. [2]. Buchbinder et al. [2] described two variants of their algorithm, a deterministic variant that we term `DeterministicDG` and guarantees $1/3$ -approximation, and a randomized variant that we term `RandomizedDG` and guarantees $1/2$ -approximation. It should also be noted that the original analysis of [2] proves slightly stronger results than the above stated approximation ratios. Specifically, their analysis shows that `DeterministicDG` always outputs a set of value at least $\frac{1}{3}[f(S) + f(\emptyset) + f(\mathcal{N})] \geq \frac{1}{3}g(S) + \frac{2}{3}\ell(S)$ for any set S , where the inequality holds because ℓ is non-negative; which implies that `DeterministicDG` is a $(1/3, 2/3)$ -approximation algorithm. Similarly, the analysis of Buchbinder et al. [2] shows that `RandomizedDG` outputs a set whose expected value is at least $\frac{1}{4}[2f(S) + f(\emptyset) + f(\mathcal{N})] \geq \frac{1}{2}g(S) + \frac{3}{4}\ell(S)$, which implies that `RandomizedDG` is a $(1/2, 3/4)$ -approximation algorithm.

Theorems 4 and 5 show that `DeterministicDG` and `RandomizedDG`, respectively, guarantee (α, β) -approximation for many additional pairs of α and β . The proofs of these theorems can be found in Sections 6.2 and 6.3, respectively.

6.1 Impossibility of the Naturally Expected Approximation Guarantee

In this section we prove the following theorem. We note that the technique used in the proof of this theorem can also prove a somewhat stronger result. However, since the improvement represented by this stronger result is not very significant, we chose to state in the theorem the cleaner and more conceptually important result rather than the strongest result achievable.

► **Theorem 6.** *Even when the linear function ℓ is guaranteed to be non-negative, no polynomial time algorithm can guarantee $(1/2, 1)$ -approximation for `RegularizedUSM`.*

The proof of Theorem 6 is based on Theorem 7, and therefore, we need to describe an instance \mathcal{I} of `RegularizedUSM` that has an integer parameter $n \geq 2$. The ground set of the instance \mathcal{I} is $\mathcal{N} = \{a, b\} \cup \{c_i \mid i \in [n]\}$, and its objective functions are given, for every $S \subseteq \mathcal{N}$, by $\ell(S) = 1/3$ and

$$g(S) = 2 \cdot [(S \cap \{a, b\}) \bmod 2] + \mathbf{1}[\{a, b\} \cap S \neq \emptyset] \cdot \mathbf{1}[\{c_i \mid i \in [n]\} \not\subseteq S] .$$

One can verify that g is indeed a non-negative submodular function. Additionally, the functions g and ℓ are both symmetric in the sense that swapping the identities of a and b does not change the values of these functions for any set, and the same applies to any swap of the identities of the elements of $\{c_i \mid i \in [n]\}$. Let \mathcal{G} be the group of permutations obtaining by combining swaps of these two kinds in any way.

In the next lemma, G and L are the multilinear extensions of g and ℓ , respectively, and $\bar{\mathbf{x}} = \mathbb{E}_{\sigma \in \mathcal{G}}[\sigma(\mathbf{x})]$. By combining this lemma with Theorem 7, we get that, even when the linear function ℓ is non-negative, no polynomial time algorithm for `RegularizedUSM` can guarantee $(0.4998(1 + \varepsilon) + (n - 1.0003)(1 + \varepsilon)/(n - 1))$ -approximation for any $\varepsilon > 0$ and large enough n . Theorem 6 follows by choosing $\varepsilon = 0.0003/n$. Due to space constraints, (the quite technical) proof of Lemma 16 has been deferred to the full version of this paper [1].

► **Lemma 16.** For a large enough n ,

$$\max_{\bar{\mathbf{x}} \in [0,1]^{\mathcal{N}}} [G(\bar{\mathbf{x}}) + L(\bar{\mathbf{x}})] \leq \max_{S \subseteq \mathcal{N}} \left[0.4998 \cdot g(S) + \frac{n - 1.0003}{n - 1} \cdot \ell(S) \right],$$

and the right hand side of the inequality is strictly positive.

6.2 Reanalysis of Deterministic Double Greedy

In this section we prove Theorem 4, which we repeat here for convenience. The algorithm `DeterministicDG` referred to by this theorem is given as Algorithm 2 (recall that $f \triangleq g + \ell$).

► **Theorem 4.** When ℓ is non-negative, the algorithm *DeterministicDG* guarantees $(\alpha, 1-\alpha)$ -approximation for *RegularizedUSM* for all $\alpha \in [0, 1/3]$ at the same time (the algorithm is oblivious to the value of α).

Algorithm 2 DeterministicDG.

```

1 Denote the elements of  $\mathcal{N}$  by  $u_1, u_2, \dots, u_n$  in an arbitrary order.
2 Let  $X_0 \leftarrow \emptyset$  and  $Y_0 \leftarrow \emptyset$ .
3 for  $i = 1$  to  $n$  do
4   Let  $a_i \leftarrow f(u_i \mid X_{i-1})$  and  $b_i \leftarrow -f(u_i \mid Y_{i-1} - u_i)$ .
5   if  $a_i \geq b_i$  then Let  $X_i \leftarrow X_{i-1} + u_i$  and  $Y_i \leftarrow Y_{i-1}$ .
6   else Let  $X_i \leftarrow X_{i-1}$  and  $Y_i \leftarrow Y_{i-1} - u_i$ .
7   return  $X_n (= Y_n)$ .
```

The heart of the proof of Theorem 4 is the following lemma. To state this lemma, we need to define, for every integer $0 \leq i \leq n$ and set $S \subseteq \mathcal{N}$, $S^{(i)} = (S \cup X_i) \cap Y_i$.

► **Lemma 17.** For every integer $1 \leq i \leq n$, value $\alpha \in [0, 1/3]$ and set $S \subseteq \mathcal{N}$, $\alpha \cdot [f(X_i) - f(X_{i-1})] + (1 - 2\alpha) \cdot [f(Y_i) - f(Y_{i-1})] \geq \alpha \cdot [f(S^{(i-1)}) - f(S^{(i)})]$.

Before we get to the proof of Lemma 17, let us show why it implies Theorem 4.

Proof of Theorem 4. Fix some $\alpha \in [0, 1/3]$ and set $S \subseteq \mathcal{N}$. Summing up Lemma 17 over all integer $1 \leq i \leq n$, we get

$$\alpha \cdot \sum_{i=1}^n [f(X_i) - f(X_{i-1})] + (1 - 2\alpha) \cdot \sum_{i=1}^n [f(Y_i) - f(Y_{i-1})] \geq \alpha \cdot \sum_{i=1}^n [f(S^{(i-1)}) - f(S^{(i)})].$$

The sums in the last inequality are telescopic sums, and collapsing them yields

$$\alpha \cdot [f(X_n) - f(X_0)] + (1 - 2\alpha) \cdot [f(Y_n) - f(Y_0)] \geq \alpha \cdot [f(S^{(0)}) - f(S^{(n)})].$$

One can observe that $X_n = Y_n = S^{(n)}$, $f(X_0) = g(\emptyset) \geq 0$, $f(Y_0) = g(\mathcal{N}) + \ell(\mathcal{N}) \geq \ell(S)$ and $S^{(0)} = S$. Plugging all these observations into the previous inequality yields

$$\alpha \cdot f(X_n) + (1 - 2\alpha) \cdot [f(X_n) - \ell(S)] \geq \alpha \cdot [f(S) - f(X_n)].$$

It remains to rearrange the last inequality, and plug in $f(S) = g(S) + \ell(S)$, which implies $f(X_n) \geq \alpha \cdot g(S) + (1 - \alpha) \cdot \ell(S)$. The theorem now follows since: (i) X_n is the output set of Algorithm 2, and (ii) the last inequality holds for every $\alpha \in [0, 1/3]$ and set $S \subseteq \mathcal{N}$. ◀

Let us now prove Lemma 17.

Proof of Lemma 17. Buchbinder et al. [2] showed that Algorithm 2 guarantees⁸

$$[f(X_i) - f(X_{i-1})] + [f(Y_i) - f(Y_{i-1})] \geq f(S^{(i-1)}) - f(S^{(i)}) . \quad (4)$$

Furthermore, we prove below that we also have the inequality

$$f(Y_i) - f(Y_{i-1}) \geq 0 . \quad (5)$$

These two inequalities imply the lemma together since the inequality guaranteed by the lemma is equal to $\alpha \cdot (4) + (1 - 3\alpha) \cdot (5)$ – note that the coefficients α and $1 - 3\alpha$ in this expression are non-negative for the range of possible values for α .

It remains to prove Inequality (5). If $Y_i = Y_{i-1}$, then Inequality (5) trivially holds as an equality. Consider now the case of $Y_i \neq Y_{i-1}$. By Lines 5 and 6 of Algorithm 2, this case happens only when $b_i > a_i$, and Y_i is set to $Y_{i-1} - u_i$ when this happens. Therefore, we get in this case $f(Y_i) - f(Y_{i-1}) = f(Y_{i-1} - u_i) - f(Y_{i-1}) = b_i > \frac{a_i + b_i}{2} \geq 0$, where the last inequality holds since Buchbinder et al. [2] also showed that $a_i + b_i \geq 0$. ◀

6.3 Reanalysis of Randomized Double Greedy

In this section we prove Theorem 5, which we repeat here for convenience. The algorithm `RandomizedDG` referred to by this theorem is given as Algorithm 3 (recall that $f \triangleq g + \ell$).

► **Theorem 5.** *When ℓ is non-negative, the algorithm `RandomizedDG` guarantees $(\alpha, 1 - \alpha/2)$ -approximation for `RegularizedUSM` for all $\alpha \in [0, 1/2]$ at the same time (the algorithm is oblivious to the value of α).*

Algorithm 3 `RandomizedDG`.

```

1 Denote the elements of  $\mathcal{N}$  by  $u_1, u_2, \dots, u_n$  in an arbitrary order.
2 Let  $X_0 \leftarrow \emptyset$  and  $Y_0 \leftarrow \emptyset$ .
3 for  $i = 1$  to  $n$  do
4   Let  $a_i \leftarrow f(u_i \mid X_{i-1})$  and  $b_i \leftarrow -f(u_i \mid Y_{i-1} - u_i)$ .
5   if  $b_i \leq 0$  then Let  $X_i \leftarrow X_{i-1} + u_i$  and  $Y_i \leftarrow Y_{i-1}$ .
6   else if  $a_i \leq 0$  then Let  $X_i \leftarrow X_{i-1}$  and  $Y_i \leftarrow Y_{i-1} - u_i$ .
7   else
8     with probability  $\frac{a_i}{a_i + b_i}$  do Let  $X_i \leftarrow X_{i-1} + u_i$  and  $Y_i \leftarrow Y_{i-1}$ .
9     otherwise Let  $X_i \leftarrow X_{i-1}$  and  $Y_i \leftarrow Y_{i-1} - u_i$ . // Occurs with prob.  $\frac{b_i}{a_i + b_i}$ 
10  return  $X_n (= Y_n)$ .
```

The heart of the proof of Theorem 5 is the next lemma. To state this lemma, we need to define, like in Section 6.2, $S^{(i)} = (S \cup X_i) \cap Y_i$ for every integer $0 \leq i \leq n$ and set $S \subseteq \mathcal{N}$.

► **Lemma 18.** *For every integer $1 \leq i \leq n$, value $\alpha \in [0, 1/2]$ and set $S \subseteq \mathcal{N}$, $(\alpha/2) \cdot \mathbb{E}[f(X_i) - f(X_{i-1})] + (1 - 3\alpha/2) \cdot \mathbb{E}[f(Y_i) - f(Y_{i-1})] \geq \alpha \cdot \mathbb{E}[f(S^{(i-1)}) - f(S^{(i)})]$.*

⁸ Technically, Buchbinder et al. [2] proved Inequality (4) only for the special case in which S is a set maximizing f . However, their analysis does not use this property.

23:16 Maximizing Sums of Non-Monotone Submodular and Linear Functions

Before we get to the proof of Lemma 18, let us show why it implies Theorem 5.

Proof of Theorem 5. Fix some $\alpha \in [0, 1/2]$ and set $S \subseteq \mathcal{N}$. Summing up Lemma 18 over all integer $1 \leq i \leq n$, we get

$$\frac{\alpha}{2} \sum_{i=1}^n \mathbb{E}[f(X_i) - f(X_{i-1})] + (1 - 3\alpha/2) \cdot \sum_{i=1}^n \mathbb{E}[f(Y_i) - f(Y_{i-1})] \geq \alpha \cdot \sum_{i=1}^n \mathbb{E}[f(S^{(i-1)}) - f(S^{(i)})] .$$

Due to the linearity of the expectation, the sums in the last inequality are telescopic sums. Collapsing these sums yields

$$\frac{\alpha}{2} \mathbb{E}[f(X_n) - f(X_0)] + (1 - 3\alpha/2) \cdot \mathbb{E}[f(Y_n) - f(Y_0)] \geq \alpha \cdot \mathbb{E}[f(S^{(0)}) - f(S^{(n)})] .$$

Observe now that, like in the proof of Theorem 4, we have $X_n = Y_n = S^{(n)}$, $f(X_0) = g(\emptyset) \geq 0$, $f(Y_0) = g(\mathcal{N}) + \ell(\mathcal{N}) \geq \ell(S)$ and $S^{(0)} = S$. Plugging all these observations into the previous inequality yields

$$\frac{\alpha}{2} \mathbb{E}[f(X_n)] + (1 - 3\alpha/2) \cdot \mathbb{E}[f(X_n) - \ell(S)] \geq \alpha \cdot \mathbb{E}[f(S) - f(X_n)] .$$

It remains to rearrange the last inequality, and plug in $f(S) = g(S) + \ell(S)$, which implies $\mathbb{E}[f(X_n)] \geq \alpha \cdot g(S) + (1 - \alpha/2) \cdot \ell(S)$. The theorem now follows since: (i) X_n is the output set of Algorithm 2, and (ii) the last inequality holds for every $\alpha \in [0, 1/2]$ and set $S \subseteq \mathcal{N}$. ◀

Let us now prove Lemma 18.

Proof of Lemma 18. Buchbinder et al. [2] showed that Algorithm 3 guarantees⁹

$$\mathbb{E}[f(X_i) - f(X_{i-1})] + \mathbb{E}[f(Y_i) - f(Y_{i-1})] \geq 2\mathbb{E}[f(S^{(i-1)}) - f(S^{(i)})] . \quad (6)$$

Given this inequality, to prove the lemma it suffices to show that $(1 - 2\alpha) \cdot \mathbb{E}[f(Y_i) - f(Y_{i-1})] \geq 0$ (because adding this inequality to $\alpha/2$ times Inequality (6) yields the inequality that we want to prove). Below we prove the stronger claim that the inequality $f(Y_i) \geq f(Y_{i-1})$ holds deterministically. One observe that this stronger claim indeed implies $(1 - 2\alpha) \cdot \mathbb{E}[f(Y_i) - f(Y_{i-1})]$ because $1 - 2\alpha$ is non-negative in the range of allowed values for α .

If $Y_i = Y_{i-1}$, then the inequality $f(Y_i) \geq f(Y_{i-1})$ trivially holds as an equality. Therefore, we assume from now on $Y_i \neq Y_{i-1}$, which implies $Y_i = Y_{i-1} - u_i$. Due to the condition in Line 5 of Algorithm 3, Y_i can be set to $Y_{i-1} - u_i$ only when $b_i > 0$, and thus, $f(Y_i) = f(Y_{i-1} - u_i) = f(Y_{i-1}) + b_i > f(Y_{i-1})$. ◀

Abstract

We show that LIST COLOURING can be solved on n -vertex trees by a deterministic Turing machine using $O(\log n)$ bits on the worktape. Given an n -vertex graph $G = (V, E)$ and a list $L(v) \subseteq \{1, \dots, n\}$ of available colours for each $v \in V$, a list colouring for G is a proper colouring c such that $c(v) \in L(v)$ for all v .

1 Introduction

Various applications can be modelled as an instance of LIST COLOURING, e.g., the vertices may correspond to communication units, with lists giving the possible frequencies or channels that a vertex may choose from as colours and edges showing which units would interfere if they are assigned the same colour [17, 24].

Given a graph $G = (V, E)$ and given a list $L(v)$ of colours for each vertex $v \in V$, an L -colouring c is a proper colouring (that is, $c(u) \neq c(v)$ when $uv \in E$) mapping every vertex v to a colour in the list $L(v)$. This gives rise to the following computational problem.

LIST COLOURING

Input: A graph $G = (V, E)$ with a list $L(v) \subseteq \{1, \dots, n\}$ of available colours for each $v \in V$.

Question: Is there an L -colouring for G ?

LIST COLOURING is computationally hard. It is NP-complete on cographs [19] and on planar bipartite graphs, even when all lists are of size at most 3 [18]. The problem remains hard when parameterised by “tree-like” width measures: it was first shown to be $W[1]$ -hard parameterised by treewidth in 2011 by [16] and recently shown to be XNLP-hard implying $W[t]$ -hardness for all t by [4]. On the other hand, on n -vertex trees the problem can be solved in time linear in n (using hashing) [19], but this algorithm may use $\Omega(n)$ space.

In this paper, we study the auxiliary space requirements of LIST COLOURING on trees in terms of the number of vertices n of the tree. We assume that the vertices of T have been numbered $1, \dots, n$, which gives a natural order on them, and that, given vertices v, v' in T and $i, i' \in \{1, \dots, n\}$, it can be checked in $O(\log n)$ space whether the i th colour in $L(v)$ equals the i' th colour in $L(v')$. As is usual for the complexity class L (logspace), we measure the space requirements in terms of the number of bits on the work tape of a deterministic Turing machine, where the description of the tree and the lists are written on a (read-only) input tape. In particular, the number of bits on the input tape is allowed to be much larger.

Since n -vertex trees have pathwidth $O(\log n)$, our problem can be solved non-deterministically using $O(\log^2 n)$ bits on the work tape (see Proposition 3). However, doing better than this is surprisingly challenging, even in the non-deterministic case! Our main result is as follows.

► **Theorem 1.** LIST COLOURING for trees is in L.

Our initial interest in the space complexity of LIST COLOURING on trees arose from a recent result showing that LIST COLOURING parameterised by pathwidth is XNLP-complete [4]. XNLP is the class of problems on an input of size n with parameter k , which can be solved by a non-deterministic Turing machine in $f(k)n^{O(1)}$ time and $f(k)\log n$ space for some computable f . Since the treewidth of a graph is upper bounded by the pathwidth, LIST COLOURING is also XNLP-hard parameterised by treewidth. This is conjectured¹ to imply that there is a constant k^* for which any deterministic Turing machine needs $\omega(\log n)$ space in order to solve LIST COLOURING for n -vertex graphs of treewidth k^* ; this work shows that $k^* > 1$. It seems likely that LIST COLOURING parameterised by treewidth is not in XNLP, and we conjecture that it is complete for a parameterised analogue of NAuxPDA (also known as SAC) from [1, 23]. Considering such classes which (also) have space requirements (complexity classes such as XL, XNL and XNLP [4, 5, 7, 15]) has proven successful in classifying the complexity of parameterised problems which are not known to be complete for any classes that only consider time requirements. Since some of such classes are very naturally modelled by instances of LIST COLOURING, we believe the complexity class of LIST COLOURING on trees could be of theoretical interest as well.

Another motivation for studying space requirements comes from practice, since memory can be much more of a bottleneck than processing time (e.g. for dynamic programming approaches). This motivates the development of techniques to reduce the space complexity. Although many techniques have been established to provide algorithms which are efficient with respect to time, fewer techniques are known to improve the space complexity. Notable exceptions include the logspace analogue of Bodlaender's and Courcelle's theorem [14] which allows one to check any monadic second-order formula on graphs of bounded treewidth in logspace (which in particular allows one to test membership in any minor-closed family) and Reingold's [25] work on undirected connectivity. Reachability and isomorphism questions have also been well-studied on restricted graph classes, e.g. [8, 21, 22]. Another interesting piece of related work [13] shows that for each graph H , LIST H -COLOURING is either in L or NL-hard. We remark that LIST H -COLOURING on trees (for fixed H) is easily seen to be solvable in logspace using an analogue of Proposition 3 or the logspace Courcelle's theorem [14]. The difficulty in our case comes from the fact that the sizes of the lists are unbounded.

¹ The conjecture (see [23, Conjecture 2.1] or [4, Conjecture 5.1]) states that there is no deterministic algorithm for an XNLP-hard problem that runs in XP time and FPT space. If for each k , there exists a constant $f(k)$ such that LIST COLOURING can be solved in space $f(k)\log n$ on n -vertex graphs of treewidth k , then this would in particular yield an algorithm running in $n^{f(k)}$ time and $f(k)n^{O(1)}$ space.

We also generalise our algorithm to graphs of bounded tree-partition-width (also called strong treewidth).

► **Corollary 2.** *There is a deterministic $O(k \log k \log n)$ space algorithm for LIST COLOURING on n -vertex graphs with a given tree-partition of width k .*

The algorithm of Corollary 2 does not run in FPT time. We also include a simple proof that LIST COLOURING is $W[1]$ -hard when parameterised by tree-partition-width, which shows that it is unlikely that there exists an algorithm running in FPT time.

The algorithm of Theorem 1 is highly non-trivial and requires several conceptual ideas that we have attempted to separate out by first explaining some key ideas and an easier deterministic algorithm that uses $O(\log^2 n)$ space in Section 3. We assume our given tree to be rooted and transverse it by first “recursing” on children whose subtrees are not the largest. This bounds the number of such recursions by $O(\log n)$, and so we can “spend” $O(\log n)$ space per recursion. When we move to the heaviest subtree, we have either already rejected, or may forget entirely about the colour of v , or found a single colour that “works” for the non-heavy subtrees of v (“criticality”). Along a heavy branch, we always keep at most two such colours “per recursion depth” (the colour of v , and possibly one of its parent; once we move to the child of v we may forget the colour of the parent of v).

There are two further main ideas that remove the additional $\log n$ -factor. Most importantly, when we “move” from a vertex v to one of its children u , we will let the amount of storage allocated for storing v and its colour depend on the size of the subtree of u : the larger the subtree, the less space we allow. In the extreme case in which the size of the subtree of u is linear in the size of the subtree of v , we allow only a *constant* number of bits. At specific points during the algorithm, when more space is available temporarily, we use this stored information to recompute the vertex v and its colour. Suppose that v has d children u_1, \dots, u_d . We define the list $L_j(v)$ as the colours c such that when we give v colour c , we can extend the colouring to the subtrees of u_1, \dots, u_j . If $|L_j(v)| > d - j$, then v is “non-critical”: we will always be able to assign it a colour after colouring the subtrees of u_{j+1}, \dots, u_d . This allows us to maintain that $|L_j(v)| \leq d - j$ and so the number of bits required to store the position of c in $L_j(v)$ decreases as j increases.

We need to be a bit more clever when we define the lists. The second main idea is to distribute the children of v into about $\log \log(n/2)$ brackets, where n denotes the number of vertices in the subtree below v . The distribution is done based on how much smaller the subtree of the child is compared to n . We allocate a specific number of bits per bracket: to brackets which allow bigger subtrees, we allocate less space. When “processing” brackets of smaller subtrees, we may need to store information as well for the brackets of bigger subtrees, but vice versa is not allowed. We choose the bracket sizes so that if we store information for the first j brackets, this “fits” in the space allocated to the $(j + 1)$ th bracket. In the end, the final algorithm is rather subtle and requires a careful analysis.

We outline some relevant definitions and background in Section 2. We give the simpler $O(\log^2 n)$ space algorithm in Section 3 and discuss the logspace algorithm in Section 4. We prove our results concerning tree-partition-width in Section 5 and point to some directions for future work in Section 6. Some technical details can be found in the full version [3].

2 Preliminaries

All logarithms in this paper have base 2. Let T be a rooted tree and $v \in V(T)$. We write T_v for the subtree rooted at v and $T - v$ for the forest obtained by removing v and all edges incident to v . We refer the reader to textbooks for basic notions in graph theory [9] and (parameterised) complexity [2, 12].

2.1 Simple logspace computations on trees

We repeatedly use the fact that simple computations can be done on a rooted tree using logarithmic space, such as counting the number of vertices in a subtree. We include a brief sketch below and refer to [22] for further details.

We first explain how to traverse a tree in logspace. Record the index of the current vertex and create states **down**, **next** and **up**. We start on the root with state **down**. When in state **down**, we go to the first child while remaining in the state **down**. If there is no child, we change the state to **next**. When in state **next**, we go to the next sibling if it exists and change state to **down**, or (if there is no next sibling) we change state to **up**. When in state **up**, we simultaneously go to the parent and change the state to **next**. We stop when reaching the root with state **up**. By keeping track of the number of vertices discovered, we can use the same technique to count the number of vertices in a subtree. This can then be used to compute the child with maximum subtree size and to enumerate children ordered by their subtree size. If the input tree is not rooted, we may use the indices of the vertices to root the tree in a deterministic way.

2.2 Graph width measures

Let $G = (V, E)$ be a graph. A tuple $(T, \{X_t\}_{t \in V(T)})$ is a *tree decomposition* for G if T is a tree, for $t \in V(T)$, $X_t \subseteq V$ is the *bag* of t , for each edge $uv \in E$ there is a bag such that $\{u, v\} \subseteq X_t$, and for each $u \in V$, the bags containing u form a nonempty subtree of T . If T is a path, this defines a *path decomposition*.

The width of such a decomposition is $\max_{t \in V(T)} |X_t| - 1$. The *treewidth* (resp. *pathwidth*) of G is the minimum possible width of a tree decomposition (resp. path decomposition) of G .

A *nice* path decomposition has empty bags on endpoints of the path and two consecutive bags differ by at most one vertex. Hence, either a vertex is *introduced*, or a vertex is *forgotten*.

Let G be a graph, let T be a tree, and, for all $t \in V(T)$, let X_t be a non-empty set so that $(X_t)_{t \in V(T)}$ partitions $V(G)$. The pair $(T, (X_t)_{t \in V(T)})$ is a *tree-partition* of G if, for every edge $vv' \in E(G)$, either v and v' are part of the same bag, or $v \in X_t$ and $v' \in X_{t'}$ for $tt' \in E(T)$. The width of the partition is $\max_{t \in V(T)} |X_t|$. The *tree-partition-width* (also known as strong treewidth) of G is the minimum width of all tree-partitions of G . It was introduced by Seese [26] and can be characterised by forbidden topological minors [11]. Tree-partition-width is comparable to treewidth on graphs of maximum degree Δ [10, 27]: $\text{tw} + 1 \leq 2 \text{tpw} \leq O(\Delta \text{tw})$. However, it is incomparable to treedepth, pathwidth and treewidth for general graphs.

The *treedepth* of a graph is the minimum height of a forest F with the property that every edge of G connects a pair of nodes that have an ancestor-descendant relationship to each other in F .

3 Warm up: first ideas and a simpler algorithm

3.1 Storing colours via their position in the list

It is not too difficult to obtain a non-deterministic algorithm that uses $O(\log^2 n)$ space.

► **Proposition 3.** *LIST COLOURING can be solved non-deterministically using $O(\log n \log \Delta)$ space on n -vertex trees of maximum degree Δ .*

The proposition follows from the following two lemmas.

► **Lemma 4.** *LIST COLOURING can be solved non-deterministically using $O(k \log \Delta + \log n)$ space for an n -vertex graph G of maximum degree Δ if we can deterministically compute a path decomposition for G of width k in $O(\log n)$ space.*

A deterministic logspace algorithm for computing an optimal path decomposition exists for all graphs of bounded pathwidth [20], but this does not apply directly to trees (since their pathwidth may grow with n).

► **Lemma 5.** *If T is an n -vertex tree, we can deterministically construct a nice path decomposition of width $O(\log n)$ using $O(\log n)$ space.*

We remark that Δ may be replaced by a bound on the list sizes in Proposition 3 and Lemma 4. The main observation in the proof of Lemma 4 is that for a vertex v , we only need to consider the first $d(v) + 1$ colours from its list so that we can store the *position* of the colour rather than the colour itself. Note that we cannot keep the path decomposition in memory, but rather recompute it whenever any information is needed. We keep in memory only the current position in the path decomposition and the list positions of the colours we assigned for vertices in the previous bag.

3.2 Heavy children, recursive analysis and criticality

Suppose that we are given an instance (T, L) of LIST COLOURING. We fix a root v^* of T in an arbitrary but deterministic fashion, for example the first vertex in the natural order on the vertices. Let $v \in V(T)$. We see v as a descendant and ancestor of itself. We write T_v for the subtree with root v .

► **Definition 6** (Heavy). *A child u of a vertex v in a rooted tree T is called heavy if $|V(T_u)| \geq |V(T_{u'})|$ for all children u' of v , with strict inequality whenever $u' < u$ in the natural order on V .*

Each vertex has at most one heavy child. We also record the following nice property.

► **Observation 7.** *If u is a child of v which is non-heavy, then $|V(T_u)| \leq (|V(T_v)| - 1)/2$.*

An obvious recursive approach is to loop over the possible colour $c \in L(r)$ for the root r and then to recursively check for all children v of r whether a list colouring can be extended to the subtree T_v (while not giving v the colour c). We wish to prove a space upper bound of the form $S(n) = f(n) \log n$ on the number of bits of storage required for trees on n vertices (for some non-decreasing function f). We compute

$$S(n/2) = \log(n/2)f(n/2) \leq \log(n/2)f(n) = \log n f(n) - \log 2 f(n) \leq S(n) - f(n). \quad (1)$$

This shows that while performing a recursive call on some subtree T_v with $|V(T_v)| = n/2$, we may keep an additional $f(n)$ bits in memory (on top of the space required in the recursive call). In particular, we can store the colour c using $O(\log n)$ bits when $f(n) = \Theta(\log n)$, but can only keep a *constant* number of bits for such recursions when proving Theorem 1.

We next explain how we can ensure that we only need to consider recursions done on non-heavy children. Suppose v has non-heavy children v_1, \dots, v_k and heavy child u . We will write $G_v = T_v - T_u$. Suppose the parent v' of v needs to be assigned colour c' . One of the following must be true.

- There is no colouring of G_v which avoids colour c' for v . In this case, we can reject.
- There is a unique colour $c \neq c'$ that can be assigned to v in a list colouring of G_v . We say v is *critical* and places the colour constraint on u that it cannot receive colour c .

- There are two possible colours unequal to c' that we can give v in G_v . We then say v is *non-critical*: it can be coloured for each colour we might wish to assign its heavy child u . One example of non-criticality is if the list of available colours $|L(v)| \geq k + 2$. In this case, T_v is list colourable if and only if $T_{v_1}, \dots, T_{v_k}, T_u$ are all list colourable (using lists L).

3.3 A deterministic algorithm using $O(\log^2 n)$ space and polynomial time

We define a procedure $\text{SOLVE}(v, p)$ which given a vertex v and number $p \in \{0, 1, \dots, n\}$, determines whether the subtree T_v rooted on v can be list coloured; for $p \geq 1$ there is an additional constraint that v cannot receive the p th colour in $L(v)$; for $p = 0$ the vertex v may receive any colour.

Suppose we call $\text{SOLVE}(r, p)$ for some $r \in V(T)$. Let v_1, \dots, v_k denote the non-heavy children of r and u the heavy child. The algorithm works as follows.

1. For $i = 1, \dots, k$, we recursively verify that T_{v_i} can be list coloured ($\text{SOLVE}(v_i, 0)$); we reject if any of these rejects.
2. If $|L(r)| \geq d(r) + 1 = k + 2$, then we are “non-critical”: we free up our memory (removing also (r, p)) and recursively verify whether T_u can be list coloured by calling $\text{SOLVE}(u, 0)$.
3. From now on, $|L(r)| \leq k + 1$. We check that there is some $p_1 \in \{1, \dots, |L(r)|\}$ for which we can assign v the p_1 th colour in its list, and extend to a list colouring of $T \setminus T_u$. This involves recursive calls $\text{SOLVE}(v_i, p_{i,1})$ where $p_{i,1}$ places the appropriate constraint² on v_i . If no such p_1 exists, we reject.
4. Next, we check whether r is “non-critical”, that is, whether there is some $p_2 \neq p_1$ for which there is a list colouring of $T \setminus T_u$ in which r receives the p_2 th colour from its list. If such p_2 exists, we free up our memory and recursively verify whether T_u can be list coloured. If p_2 does not exist, then we know that r must get colour p_1 . If $p_1 = p$, we reject. Otherwise, we free up our memory and run $\text{SOLVE}(u, p'_1)$, where p'_1 is either 0 or the position in the list of u of the p_1 th colour of $L(r)$.

We give a brief sketch of the space complexity; more precise arguments including also pseudocode and the time analysis of this algorithm are given in the full version [3].

For the sake of analysis, suppose we keep a counter \mathbf{r} that keeps track of the “recursion depth”. We increase this by one each time we do a call on a non-heavy child (decreasing it again once it finishes), but do not adjust it for calls on a heavy child.

Suppose \mathbf{r} has been increased due to a sequence of recursive calls on $(v_1, 0), (v_2, p_2), \dots, (v_\ell, p_\ell)$, with v_1 the root of the tree and v_{i+1} a non-heavy child of some heavy descendant of v_i for all $i \in [\ell - 1]$. Then $|V(T_{v_\ell})| \leq \frac{1}{2}|V(T_{v_{\ell-1}})| \leq \dots \leq \frac{1}{2^{\ell-1}}|V(T)|$. In particular, \mathbf{r} is always bounded by $\log n$.

Crucially, if a call $\text{SOLVE}(u, p')$ is made on the heavy descendant u of some v_i , the only information we need to store relating to the part of the tree “between v_i and u ” is p' . Therefore, if we distribute our work tape into $\lceil \log n \rceil$ parts where the i th part will be used whenever \mathbf{r} takes the value i , then each part only needs to use $10 \log n$ bits, giving a total space complexity of $O(\log^2 n)$.

² Let c_1 be the p_1 th colour in $L(r)$. If $c_1 \notin L(v_i)$, let $p_{i,1} = 0$. Otherwise, let $p_{i,1}$ be the position of c_1 in $L(v_i)$.

4 Proof of Theorem 1

In this section, we describe our $O(\log n)$ space algorithm. This also uses the ideas of using positions in a list (rather than the colours themselves), criticality and starting with the non-heavy children described in the previous section. However, we need to take the idea of first processing “less heavy” children even further.

The main idea is to store the colour c that we are trying for a vertex v using the position p_j of c in some list $L_j(v)$, and to reduce the size of the list (and therefore the storage requirement of p_j) before we process “heavier” children of v . There are two key elements:

- We can recompute c from p_j in $O(\log n)$ space. This is useful, since we can do a recursive call while only having p_j (rather than c) as overhead, discover some information, and then recompute c only at a point where we have a lot of memory available to us again.
- The space used for p_j will depend on the size of the tree that we process. It is too expensive to consider all sizes separately, and therefore we will “bracket” the sizes. Subtrees whose size falls within the same bracket are processed in arbitrary order. For example, we put all trees of size $O(\sqrt{n})$ in a single bracket: these can be processed while using $O(\log n)$ bits of information about c (which is trivially possible). At some point we reach brackets for which the subtrees have size linear in n , say of size at least $\frac{1}{4}n$. Then, we may only keep a *constant* number of bits of information about c . Intuitively, this is possible because at most four children of r can have a subtree of size $\geq \frac{1}{4}n$, so the “remaining degree” of v is small. In particular, if more than six colours for v work for all smaller subtrees, then v is “non-critical”.

We first explain our brackets in Section 4.1. We then explain how we may point to a colour using less memory in Section 4.2 and how we keep track of vertices using less memory in Section 4.3. We then sketch the proof of Theorem 1 by outlining the algorithm and its space analysis in Section 4.4.

4.1 Brackets

Recall that we fixed a root for T in an arbitrary but deterministic fashion.

Let $v \in V(T)$ and u the heavy child of v . Let $G_v = T_v - T_u$ and $n_v = |V(T_v)|$. Each subtree T' of $G_v - v$ is rooted in a non-heavy child of v and will be associated to a bracket based on $|V(T')|$. By Observation 7, $1 \leq |V(T')| \leq (n_v - 1)/2$. Let $M_v = \lceil \log \log(n_v/2) \rceil$. The brackets are given by the sets of integers in the intervals

$$[1, n_v/2^{2^{M_v-1}}), [n_v/2^{2^{M_v-1}}, n_v/2^{2^{M_v-2}}), \dots, [n_v/256, n_v/16), [n_v/16, n_v/4), [n_v/4, n_v/2).$$

There are M_v brackets: $[n_v/2^{2^j}, n_v/2^{2^{j-1}})$ is the j th bracket for $j \in \{1, \dots, M_v - 1\}$ and $[1, n_v/2^{2^{M_v-1}})$ is the M_v th bracket. Note that $n_v/2^{2^{M_v-1}} = O(\sqrt{n_v})$. This implies that while doing a recursive call on a tree in the M_v th bracket, we are happy to keep an additional $O(\log n_v)$ bits in memory.

We aim to show that for some universal constant C , when doing a recursive call on a tree in the j th bracket, we can save all counters relevant to the current call using at most $C2^j$ bits (which depending on the value of j , could be $\Omega(\log n)$). In our analysis, we save the counters in a new read-only part of the work tape. The recursive call cannot alter this (and will have to work with less space on the work space). We can then use our saved state to continue with our calculations once the recursive call finishes.

We short-cut $M = M_v$ for legibility; the dependence of M on v is only needed to ensure that we do not start storing counters for lots of empty brackets when n_v is much smaller than n , and can be mostly ignored.

4.2 The information p_j stored about a colour c

Let $v \in V(T)$ with heavy child u and $c \in L(v)$. Recall that $G_v = T_v - T_u$. We will loop over $j = M, \dots, 0$ and consider subtrees of G_v whose size falls in the j th bracket in an arbitrary, but deterministic order (e.g. using the natural order on their roots). When j decreases, we will perform recursions on larger subtrees of $G_v - v$ and can therefore keep less information about c . We first define “implicit” lists.

- Set $L_M(v) = L(v)$.
- For $j \in [0, M - 1]$, let $L_j(v)$ be the set of colours $\alpha \in L(v)$ such that all subtrees T' of $G_v - v$ with $|V(T')| < n/2^{2^j}$ can be coloured without giving the colour α to the root of T' (so that v may receive colour α according to those subtrees).

Note that $L_j(v) = L(v)$ if there are no subtrees T' with $|V(T')| < n/2^{2^j}$. Since the subtrees associated to brackets $1, \dots, j$ have size at least $n/2^{2^j}$, there can be at most 2^{2^j} of them. If $|L_j(v)| \geq 2^{2^j} + 3$ and all subtrees T' of $G_v - v$ can be coloured, then v is “non-critical”: after the parent and heavy child of v have been coloured, the colouring can always be extended to v and the rest of G_v .

Suppose we are testing if we can give colour c to v . If $c \notin L_j(v)$, then we may reject: c is not a good colour for one of the subtrees. We define $p_j = p_j(c, v)$ as the integer $x \in \{1, \dots, |L_j(v)|\}$ such that the x th element in $L_j(v)$ equals c . In particular, p_M is the position of the colour c in the list $L_M(v) = L(v)$ and p_0 gives the position of c in the list of colours for which all subtrees of G_v allow v to receive c . For $j < M$, we will reserve at least $\log(2^{2^j} + 3)$ bits for p_j . This is possible, because we can maintain that $|L_j(v)| \leq 2^{2^j} + 2$ by going into a “non-critical subroutine” if we discover the list is larger.

4.3 Position of the current vertex

Next, we describe how to obtain efficient descriptions of the vertices in the tree. When performing recursions, we find it convenient to store information using which we can retrieve the “current vertex” of the parent call. Therefore, we require small descriptions for such vertices if the call did not make much “progress”.

For any $v \in V(T)$, define a sequence $h(v, 1), h(v, 2), \dots$ of heavy descendants as follows. Let $h(v, 1) = v$. Having defined $h(v, i)$ for some $i \geq 1$, if this is not a leaf, we let $h(v, i + 1)$ be the heavy child of $h(v, i)$. Note that given the vertex $h(v, i)$, we can find the vertex $h(v, i + 1)$ (or conclude it does not exist) in $O(\log n)$ space. We give a deterministic way of determining a bit string $\text{pos}(v, i)$ that represents $h(v, i)$, where the size of the bit string will depend on the “progress” made at the vertex $h(v, i)$ that it represents. This “progress” is measured by the size t_i of the largest subtree T' of a non-heavy child of $h(v, i)$, that is, T' is the largest component of $T - h(v, i)$ which does not contain $h(v, j)$ for $j \neq i$. We define $\text{pos}(v, i)$ as follows.

- Let j be given such that $t_i \in [n_v/2^{2^j}, n_v/2^{2^{j-1}})$. Start $\text{pos}(v, i)$ with j zeros, followed by a 1.
- There are at most 2^{2^j} values of i for which $t_i \geq 2^{2^j}$. We add a bit string of length 2^j to $\text{pos}(v, i)$, e.g. the value x for which $h(v, i)$ is the x th among $h(v, 1), \dots, h(v, a)$ with $t_i \in [n_v/2^{2^j}, n_v/2^{2^{j-1}})$.

Note that, given v , we can compute $\text{pos}(v, i)$ from $h(v, i)$ and $h(v, i)$ from $\text{pos}(v, i)$ using $O(\log n)$ space. If we do a recursive call, it will be on a non-heavy child u of some $h(v, i)$. By definition, $|V(T_u)| \leq t_i$ and $\text{pos}(v, i)$ depends on t_i in a way that we are able to keep it in memory while doing the recursive call.

We use the encoding $(\text{pos}(v^*, i), j, \ell)$ for the ℓ th child u of $h(v^*, i)$ whose subtree has a size that falls in the j th bracket. We can also attach another such encoding, e.g.

$$((\text{pos}(v^*, i), j, \ell), (\text{pos}(u, i'), j', \ell')),$$

to keep track of u and the ℓ' th child v of $h(u, i')$ whose subtree has a size that falls in the j' th bracket. We can retrieve v from the encoding above in $O(\log n)$ space and therefore can retrieve it whenever we have such space available to us.

4.4 Description of the algorithm

During the algorithm, the work tape will always start with the following.

- \mathbf{r} : the recursion depth r written in unary. At the start, $r = 0$.
- $\mathbf{pos} = \text{pos}_0 | \dots | \text{pos}_r$: encodes vertices as described Section 4.3. At the start, this is empty and points at the root v^* of the tree on the input tape.
- $\mathbf{p} = \mathbf{p}_0 | \dots | \mathbf{p}_r$: encodes colour restriction information for the vertices encoded by \mathbf{pos} . At the start, this is empty and no restrictions are given. We maintain throughout the algorithm that \mathbf{p}_i gives us colour restrictions for the vertex v pointed at by pos_i . The restriction can either be “no restrictions” or “avoid c' ”; in the latter case \mathbf{p}_i contains a tuple (j, p'_j) with p'_j the position of c' in $L_j(v')$, where v' is the parent of v .
- $\mathbf{aux} = \mathbf{aux}_0 | \dots | \mathbf{aux}_r$: further auxiliary information for parent calls that may not be overwritten.

We define a procedure **process**. While the value of \mathbf{r} equals r , the bits allocated to $\text{pos}_i, \mathbf{p}_i, \mathbf{aux}_i$ for $i < r$ will be seen as part of the read-only input-tape. In particular, the algorithm will not make any changes to $\text{pos}_i, \mathbf{p}_i$ or \mathbf{aux}_i for any $i < r$, but may change the values for $i = r$.

We will only increase \mathbf{r} when we do a recursive call. If during the run of the algorithm $\mathbf{r} = r$ and a recursive call is placed, then we increase \mathbf{r} to $r + 1$ and return to the start of our instructions. However, since \mathbf{r} has increased it will now see a “different input tape”. When the call finished, we will decrease \mathbf{r} back to r and wipe everything from the work space except for $\mathbf{r}, \text{pos}_i, \mathbf{p}_i, \mathbf{aux}_i$ for $i \leq r$, and the answer of the recursive call (0 or 1). We then use \mathbf{aux}_i to reset our work space and continue our calculations.

We will ensure that \mathbf{r} is always upper bounded by $\log n$. Indeed, the vertex v_r encoded by pos_r will always be a non-heavy child of a descendant of the vertex encoded by pos_{r-1} .

While $\mathbf{r} = r$, the algorithm is currently doing calculations to determine whether the vertex v pointed at by pos_{r-1} (v^* for $r = 0$) has the property that T_v can be list coloured, while respecting the colour restrictions encoded by \mathbf{p}_{r-1} (none if $r = 0$). Recall that rather than writing down v explicitly, we use a special encoding from which we can recompute v whenever we have $C \log n$ space available on the work tape (for some universal constant C). Similarly, \mathbf{p}_{r-1} may give a position p'_j in $L_j(v')$ for some $j < M$ (for v' the parent of v), and we may need to use our current work tape to recompute the corresponding position p'_M of the colour in $L(v')$, so that we can access the colour from the input tape. This part will make the whole analysis significantly more technical.

We define an algorithm which we call **process** as follows. A detailed outline is given in the full version [3], whereas an informal description of the steps is given below.

0. Let v be the vertex pointed at by pos_r . We maintain that at most one colour c' has been encoded that v must avoid. Handle the case in which v is a leaf. If not, it has some heavy child h . We go to 1, which will eventually lead us to one of the following (recall that $G_v = T_v - T_h$):

(rej) There is no list colouring of G_v avoiding c' for v . We return **false**.

- (nc) The vertex v can get two colours (unequal to c') in list colourings of G_v . In this case, we say v is non-critical. We update pos_r to h , set p_r to “none” and repeat from 0.
- (cr) There is a unique colour $c \neq c'$ that works. Then $\{c\} \subseteq L_0(v) \subseteq \{c, c'\}$ and so can represent $p_0 = p_0(c, v)$ with a single bit. We update pos_r to h , update p_r to $(0, p_0)$ and repeat from 0.
1. We check that all subtrees can be coloured if we do not have any colour restrictions (necessary for the non-critical subroutine). This involves recursive calls on **process** where we have no colour constraint on the root of the subtree.
 2. We verify that $L_0(v)$ is non-empty. We iteratively try to compute p_M from $p_0 = 1$ via p_1, \dots, p_{M-1} . Starting from $p_0 = 1$ and $j = 0$, we compute p_{j+1} from p_j as follows.
 - (i) Initialise $\text{curr}_j = 1$. This represents a position in $L_j(v)$ (giving the number of “successes”).
Initialise $\text{prev}_j = 1$. This represents a position in $L_{j+1}(v)$ (giving the number of “tries”).
 - (ii) We check whether the prev_j th colour of $L_{j+1}(v)$ works for the trees in the j th bracket. This involves a recursive call on **process** for each tree T' in the j th bracket, putting $(j + 1, \text{prev}_j)$ as the colour constraint for the root of T' . (The colour restriction gives a position in $L_{j+1}(v)$; we do not store the corresponding colour and rather will recompute it in the recursive call!)
 - (iii) If one of those runs fails, we increase prev_j ; if this is now $> 2^{2^{j+1}} + 3$, then this implies a lower bound on $|L_{j+1}(v)|$ which allows us to move to (nc).
If $\text{curr}_j < p_j$ we increase both curr_j and prev_j .
Once $\text{curr}_j = p_j$, we have successfully computed $p_{j+1} = \text{prev}_j$ and continue to compute p_{j+2} if $j + 1 < M$. Otherwise we repeat from (ii).

Once we have p_M , we can access the corresponding colour from the input tape by looking at the p_M th colour of $L(v)$. If $p_M > |L(v)|$, we go to (rej).

3. We verified $|L_0(v)| \geq 1$. We establish whether $|L_0(v)| \geq 3$ in a similar manner. If so, we can go to (nc); else we need to start considering the colour constraints of the parent v' of v . Note that we can use aux_r to store auxiliaries such as $\alpha = |L_0(v)| \in \{1, 2\}$.

It remains to explain how we check whether the first or second colour from $L_0(v)$ satisfies the colour constraint from v' . Suppose a colour c' has been encoded via the position $p'_{j'}$ of c' in $L_j(v')$ for some $j' \in [0, M']$ (where $M' = M_{v'}$).

We can recompute $p'_{M'}$ from $p'_{j'}$ in a similar manner to the above. However, once we store $p'_{M'}$, we may no longer be able to compute p_M from $p_0 = 1$ or $p_0 = 2$, since $p'_{M'}$ may take too much space³. Therefore, we first recompute $p_{j'}$ from p_0 and then simultaneously recompute $p_{j'+1}$ from $p_{j'}$ and $p'_{j'+1}$ from $p'_{j'}$ until we computed p_M and $p'_{M'}$. We then check whether the p_M th colour of $L(v)$ equals c' , the $p'_{M'}$ th colour of $L(v')$. (It may be that $M \neq M'$, meaning that we may finish one before the other.)

The computation of p'_{x+1} from p'_x for the parent v' of v is a bit more complicated if v is a non-heavy child of v' . In this case, v is in the $(j' - 1)$ th bracket of v' . The algorithm calls again on itself for subtrees in the x th bracket of v' , but now we see a resulting call to **process** as a *same-depth call* rather than a “recursive call”. The computations work the same way, but we do not adjust r and will *add* the current state from before the call in aux_r .

³ This is one of the issues that made this write-up more technical and involved than one might expect necessary at first sight; if we do a recursion on a child in the j th bracket of v or v' , then we are only allowed to keep $O(2^j)$ bits on top of the space used by the recursion. This means we cannot simply keep $p'_{M'}$ in memory if j is much smaller than M' .

By an exhaustive case analysis, the algorithm computes the right answer. It remains to argue that it terminates and runs in the correct space complexity.

We first further explain the same-depth calls on `process`. When we make such call, we do not adjust \mathbf{r} . When the call is made, \mathbf{pos}_r will encode a vertex v_1 which is a non-heavy child of v' . After the call, \mathbf{pos}_r will point to some other non-heavy child v_2 of v' . Importantly, the bracket of v_2 will always be higher than the bracket of v_1 , so that at most M such same-depth calls are made before changing our recursion level. Each same-depth call may stack on a number of auxiliary counters which we keep track of using \mathbf{aux}_r ; since for each j , there is at most one vertex from the j th bracket which may append something to this, it suffices to ensure a vertex from bracket j adds at most $C2^j$ bits. Indeed, this ensures that the size of \mathbf{aux}_r takes at most $C \sum_{j=1}^{j'} 2^j \leq C2^{j'+1} = O(2^{j'})$ bits once \mathbf{pos}_r encodes a vertex from bracket j' .

We now argue that it terminates. Each time we do a same depth call, the value of the bracket j will increase by at least one. We therefore may only do a finite number of same-depth calls in a row. When $\mathbf{r} = 0$, each time we reach (nc) or (cr), we move one step on the heavy path from the root to a leaf, so this will eventually terminate. A similar observation holds for $\mathbf{r} > 0$ once we fix $\mathbf{pos}_1 | \dots | \mathbf{pos}_{r-1}$: this points to some vertex v and \mathbf{pos}_r will initially point to a non-heavy descendent u or v , and then “travel down the heavy path” from u to a leaf.

We next consider the space used by the algorithm. Let $S(n)$ be the largest amount of bits used for storing \mathbf{r} , \mathbf{pos} , \mathbf{p} and \mathbf{aux} during a run of `PROCESS` on an n -vertex tree. We can distribute our work space into two parts: $C_1 \log n$ space for temporary counters and for doing calculations such as computing the heavy child of a vertex, and $S(n)$ bits for storing \mathbf{r} , \mathbf{pos} , \mathbf{p} and \mathbf{aux} . It suffices to prove that $S(n) \leq C_2 \log n$; this is the way we decided to formalise keeping track of the “overhead” caused by recursive calls.

Note that \mathbf{r} is bounded by $\log n$ if the input tree has n vertices: each time it increases, we moved to a non-heavy child whose subtree consists of at most $n/2$ vertices.

Suppose we call `process` with \mathbf{pos} pointing at some vertex v whose subtree has size n_v . We will show inductively that the number of bits used by \mathbf{pos} , \mathbf{p} and \mathbf{aux} is in $O(\log n_v)$ throughout this call (note that n_v may be much smaller than n , the number of vertices of the tree on the input tape). Whenever we do a recursive call, this will be done on a tree whose size is upper bounded by $n_v/2^{2^{j-1}}$ for some $1 \leq j \leq M = \lceil \log \log(n_v/2) \rceil$. Since by induction the recursive call requires only

$$S(n/2^{2^{j-1}}) = C_2 \log(n/2^{2^{j-1}}) \leq S(n) - C_2 2^{j-1}$$

additional bits, we will allow ourselves to add at most $C_2 2^{j-1}$ bits to \mathbf{r} , \mathbf{pos} , \mathbf{p} and \mathbf{aux} before we do a recursive call that divides the number of vertices by at least $2^{2^{j-1}}$. The constant C_2 will be relatively small (for example, 1000 works).

Fix a value of j . From the definitions in Section 4.2 and 4.3, at the point that we do a recursion on a subtree whose size is upper bounded by $n_v/2^{2^{j-1}}$, \mathbf{pos}_r and \mathbf{p}_r store at most three integers (they are of the form $(\mathbf{pos}(v', i), j, \ell)$ and (x, p_x) respectively) that are bounded by $2^{2^j} + 3$. Therefore, these require at most $C' 2^{j-1}$ bits for some constant C' (e.g. $C' = 50$ works).

The worst case comes from \mathbf{aux}_r which may get stacked up on by the “same-depth calls”. There is at most one such same-depth call per $x \in \{1, \dots, j\}$. For such x , we add on a bounded number of counters (e.g. \mathbf{curr}_x and \mathbf{prev}_x) which can take at most $2^{2^{x+1}} + 3 \leq 2 \cdot 2^{2^{x+1}}$ values. Since $C \sum_{x=1}^j 2^x \leq 4C2^{j-1}$, \mathbf{aux}_r also never contains more than $O(2^{j-1})$ bits while doing a call on a tree whose size falls in bracket j .

5 Graphs of bounded tree-partition-width

5.1 Proof of Corollary 2

Here we sketch the proof of Corollary 2. Let $(T, (X_t)_{t \in V(T)})$ be a tree-partition of width k for an N -vertex graph G , where it will be convenient to write $n = |V(T)| \leq N$. We prove that there is an algorithm running in $O(k \log k \log n)$ space, for each k by induction on n .

We root T in the vertex of lowest index. We define the recursion depth, heavy children, the brackets, M and “position” for the vertices in T exactly as we did in Section 4.

Suppose pos points at some vertex $t \in V(T)$. We aim to use $O(k \log k \log(2^{2^j}))$ bits for the information p_j stored about the colouring c of the vertices in X_t while processing subtrees in bracket j . This is done as follows. For $t \in V(T)$, let $G_{t,j}$ be the graph induced on the vertices that are either in X_t or in X_s for s a non-heavy child of t in bracket j or above. For $v \in X_t$, we define $L_j(v)$ to be the list of colours $\alpha \in L(v)$ such that there is a list colouring of $G_{t,j}$ that assigns the colour α to v . There are at most 2^{2^j} subtrees of T associated to brackets $1, \dots, j$, and so these include at most $k2^{2^j}$ neighbours of v . Therefore, if $|L_j(v)| \geq k(2^{2^j} + 3)$, then G can be list coloured if and only if $G - v$ can be list coloured and we no longer need to keep track of the colour of v . We then establish v is non-critical. We use k bits to write for each vertex of X_t whether or not it has been established to be critical, and for those vertices that are critical, we use $\log(k(2^{2^j} + 3))$ bits per vertex to index a colour from $L_j(v)$.

We use $k + \log((3k)^k) = O(k \log k)$ bits of information in aux to keep track of the following.

- For each $v \in X_t$, whether or not v has been established to be critical. After processing t , the vertex $v \in X_t$ will be critical if there are at most $3k$ colours in $L(v)$ for which there exists an extension to G_t . Let $C_t \subseteq X_t$ denote the critical vertices.
- For each $p_0 \in \prod_{v \in C_t} L_0(v)$ (of which there are at most $(3k)^k$), a single bit which indicates whether or not the parent of t would allow the corresponding colouring.

While computing the information above, we still need the auxiliary information from the parent of t , but we can discard this by the point we start processing the heavy child of t .

We make two more small remarks:

- We need to redefine what we mean by “increasing” p_j for some j , since we now work with a tuple of list positions. We fix an arbitrary but deterministic way to do this, for example in lexicographical order using the natural orders on the vertices and colours.
- When we check whether the colouring c of X_t corresponding to $p_0 \in \prod_{v \in C_t} L_0(v)$ is allowed by the parent t' of t , we run over $p'_0 \in \prod_{v' \in C_{t'}} L_0(v')$, and as before we need to compute p_i, p'_i from p_{i-1}, p'_{i-1} iteratively until we obtain the colourings corresponding to p_M and p'_M . If those colourings are compatible, then we know that there is a list colouring of the graph “above t ” for which X_t is coloured “according to p_0 ”, and so we record in aux that p_0 is allowed.

The calculations in the space analysis work in the exact same way: we simply multiply everything by $Ck \log k$ (for a universal constant C).

5.2 W[1]-hardness

We give an easy reduction for the following result.

► **Theorem 8.** *LIST COLOURING parameterised by the width of a given tree-partition is W[1]-hard.*

Proof. We reduce from MULTICOLOURED CLIQUE.

Consider a MULTICOLOURED CLIQUE instance $G = (V, E), V_1, \dots, V_k$ with $k \geq 2$ colours. We denote by $\overline{G} = (V, \overline{E})$ the complement of G .

We now describe the construction of our instance graph H . We first add vertices v_1, \dots, v_k , with lists $L(v_i) = V_i$ for all $i \in [k]$. Then for each edge $e = uv \in \overline{E}$ we add a vertex x_{uv} with list $L(x_{uv}) = \{u, v\}$. Furthermore, for $\alpha \in \{u, v\}$, let i be such that $\alpha \in V_i$. We add the edge $x_{uv}v_i$.

The resulting graph has tree-partition-width at most k : we put v_1, \dots, v_k in the same bag which is placed at the centre of a star, and create a separate leaf bag containing x_{uv} for each $uv \in \overline{E}$.

▷ **Claim 9.** If there is a proper list colouring of H , then there is a multicoloured clique in G .

Proof. Suppose that H admits a list colouring. Let $a_i \in V_i = L(v_i)$ be the colour assigned to v_i for all $i \in [k]$. We will prove a_1, \dots, a_k forms a multicoloured clique in G .

Consider distinct $i, j \in [k]$ and suppose $a_i a_j$ is not an edge of G , that is, $a_i a_j \in \overline{E}$. Then there exists a vertex $x_{a_i a_j}$ adjacent to both v_i and v_j , but there is no way to properly colour it, a contradiction. So we must have $a_i a_j \in E$ as desired. ◁

▷ **Claim 10.** If there is a multicoloured clique in G , then there is a proper list colouring of H .

Proof. We denote by a_1, \dots, a_k the vertices of the multicoloured clique, where $a_i \in V_i$ for all i . We assign the colour a_i to vertex v_i . Consider now x_{uv} for some $uv \in \overline{E}$. Let i and j be given so that x_{uv} is adjacent to v_i and v_j . Then $\{u, v\} \neq \{a_i, a_j\}$ since $a_i a_j \in E$ and $uv \in \overline{E}$. Therefore, we may assign either u or v (or both) as colour to x_{uv} . ◁

Since MULTICOLOURED CLIQUE is W[1]-hard, this proves that LIST COLOURING parameterised by tree-partition-width is W[1]-hard. ◀

We remark that the above proof also shows that LIST COLOURING parameterised by vertex cover is W[1]-hard.

6 Conclusion

In this paper, we combined combinatorial insights and algorithmic tricks to give a space-efficient colouring algorithm.

By combining Logspace Bodlaender's theorem [14], Lemma 5 and Lemma 4, LIST COLOURING can be solved non-deterministically on graphs of pathwidth k in $O(k \log n)$ space and on graphs of treewidth k in $O(k \log^2 n)$ space.⁴ However, we already do not know the answer to the following question.

▶ **Problem 11.** *Can a non-deterministic Turing machine solve LIST COLOURING for n -vertex graphs of treewidth 2 using $o(\log^2 n)$ space?*

Another natural way to extend trees is by considering graphs of bounded treedepth. Such graphs then also have bounded pathwidth (but the reverse may be false). It has been observed for several problems such as 3-COLOURING and DOMINATING SET that “dynamic programming approaches” (common for pathwidth or treewidth) require space exponential in the width parameter, whereas there is a “branching approach” with space polynomial in

⁴ First compute a tree decomposition $(T, (B_t)_{t \in V(T)})$ of width k for G in $O(\log n)$ space [14], and then compute a (not necessarily optimal) path decomposition of width $O(\log |V(T)|)$ in $O(\log n)$ space for T , and turn this into a path decomposition for G of width $O(k \log n)$ by replacing $t \in V(T)$ with the vertices in its bag B_t . Then use Lemma 4.

treedepth [6]. A simple branching approach also allows LIST COLOURING to be solved in $O(k \log n)$ space on n -vertex graphs of treedepth k . We wonder if the approach in our paper can be adapted to improve this further.

► **Problem 12.** *Can LIST COLOURING be solved in $f(k)g(n) + O(\log n)$ space on graphs of treedepth k , with $g(n) = o(\log n)$ and f a computable function?*

Another interesting direction is what the correct complexity class is for LIST COLOURING parameterised by tree partition width. We do not expect this to be in the W-hierarchy because the required witness size seems to be too large. Moreover, the conjecture [23, Conjecture 2.1] mentioned in the introduction together with Corollary 2 would imply that the problem is not XNLP-hard.

Finally, it would be interesting to study other computational problems than LIST COLOURING. We remark that our results are highly unlikely to generalise to arbitrary Constraint Satisfaction Problems. Recall that there is conjectured to be a $k^* \in \mathbb{N}$ for which LIST COLOURING requires $\omega(\log n)$ space for n -vertex graphs of treewidth k^* . Since LIST COLOURING on n -vertex graphs of treewidth at most k^* can be reduced in logspace to a CSP on at most n variables, each having a lists of size at most n^{k^*} , and binary constraints on the variables, such CSP problems would then also require $\omega(\log n)$ space since k^* is a constant.

Abstract

In this paper we study the problem of coloring a unit interval graph which changes dynamically. In our model the unit intervals are added or removed one at the time, and have to be colored immediately, so that no two overlapping intervals share the same color. After each update only a limited number of intervals are allowed to be recolored. The limit on the number of recolorings per update is called the recourse budget. In this paper we show, that if the graph remains k -colorable at all times, the updates consist of insertions only, and the final instance consists of n intervals, then we can achieve an amortized recourse budget of $\mathcal{O}(k^7 \log n)$ while maintaining a proper coloring with k colors. This is an exponential improvement over the result in [10] in terms of both k and n . We complement this result by showing the lower bound of $\Omega(n)$ on the amortized recourse budget in the fully dynamic setting. Our incremental algorithm can be efficiently implemented.

As an additional application of our techniques we include a new combinatorial result on coloring unit circular arc graphs. Let L be the maximum number of arcs intersecting in one point for some set of unit circular arcs \mathcal{A} . We show that if there is a set \mathcal{A}' of non-intersecting unit arcs of size $L^2 - 1$ such that $\mathcal{A} \cup \mathcal{A}'$ does not contain $L + 1$ arcs intersecting in one point, then it is possible to color \mathcal{A} with L colors. This complements the work on circular arc coloring [4, 30, 31], which specifies sufficient conditions needed to color \mathcal{A} with $L + 1$ colors or more.

1 Introduction

In this paper we study dynamic algorithms for the graph coloring problem. The setting we focus on is as follows. We are given a graph G , which is modified over time by vertex insertions or vertex deletions, where vertices are inserted (or deleted) together with all the adjacent edges connecting them to the vertices that are already present in G . For a positive integer k , a *proper k -coloring* of a graph is an assignment of colors in $\{1, \dots, k\}$ to the vertices of the graph in such a way that no two adjacent vertices share a color. We say that a graph admitting such an assignment is k -colorable. In the dynamic setting, the ultimate goal is to design an algorithm, that (for some given $l \geq k$) efficiently maintains the proper l -coloring on a dynamically changing k -colorable graph G .

¹ corresponding author

Dynamic graph coloring is a fundamental problem in computer science and as such it has received a lot of attention in the literature. Chronologically, dynamic graph coloring was first considered in a more restricted online setting, where the updates consist of vertex insertions only, and one is not allowed to change the colors of the previously added vertices. Many pessimistic lower bounds for online graph coloring have been revealed. In particular, for general k -colorable graphs, one cannot color the graph online with less than $l = \frac{n}{\log^2 n} k$ colors [18], where n is the number of vertices added to G . This lower bound holds even for randomized algorithms. Even for trees, which are 2-colorable, one needs $l = \Omega(\log n)$ colors [3] in the online model. The situation improves if we consider k -colorable interval graphs, for which $l = 3k - 2$ colors are necessary and sufficient in the online model [20]. The case of unit interval graphs has also been extensively studied, revealing that $2k - 1$ colors suffice and $3k/2$ colors are necessary to color a k -colorable unit interval graph online [6, 15].

To go beyond the pessimistic lower bounds imposed by the online model, several settings were proposed where an algorithm is given more power. The one that received a lot of attention is the limited recourse budget framework. In this setting the algorithm is allowed to change a number of past decisions, but there is a limit on the number of such changes, referred to as the recourse budget. This model has been well established and successfully applied to a variety of optimization problems, often implying efficient dynamic algorithms [5, 7, 8, 9, 19, 23, 21, 2, 29, 10]. For the coloring problem that we study, the recourse budget is the number of vertices that change their color after an addition or removal of a vertex. Barba et al. apply the recourse budget model to coloring general graphs [2]. They devise two complementary algorithms. For any $d > 0$, the first (resp. second) algorithm maintains a $k(d+1)$ -coloring (resp. $k(d+1)n^{1/d}$ -coloring) of a k -colorable graph and recolors at most $(d+1)n^{1/d}$ (resp. d) vertices per update, which is either addition or removal of a vertex. While the second trade-off was improved in [29], the authors in [2] show that the first trade-off is tight, and the bad example is a forest. Thus, if one insists on using few colors, one has to incur a polynomial in n recourse budget on every class of graphs that contains forests. This pushed the researchers to apply the limited recourse budget model to coloring interval and unit interval graphs.

For unit interval graphs a very positive result has been obtained. The recoloring budget of $\mathcal{O}(k^2)$ (worst case) is sufficient for maintaining a $(k+1)$ -coloring of a k -colorable graph [10]. It is left open what budget is needed for maintaining an optimal k -coloring for unit interval graphs, even if we only allow vertex insertions. The lower bound given in [10] is $\Omega(\log n)$ (even when updates are only insertions), while the upper bound (which only works for vertex insertions) is $\mathcal{O}(k!\sqrt{n})$ (the same as for general interval graphs). Such a tremendous gap for such elementary graph class calls for further investigation. The main result of this paper is that we close this gap up to the factors polynomial in k . To be more precise, we show that an amortized recourse budget of $\mathcal{O}(k^7 \log n)$ is sufficient to maintain k -coloring under vertex insertions. This is an exponential improvement over [10] in terms of both n and k . It is fairly easy to see that our algorithm can be efficiently implemented. We complement this result by showing that in the fully dynamic setting one must spend an amortized recourse budget of $\Omega(n)$ per update.

It is worth emphasizing, that our results show a fine line between $(k+1)$ -coloring and optimal k -coloring of unit interval graphs in the limited recourse budget model. While $(k+1)$ -coloring admits an algorithm with the worst case recourse budget of $\mathcal{O}(k^2)$ in the fully dynamic setting, we cannot hope (in this setting) for any reasonable recourse budget for optimal k -coloring, even if we allow amortization. If we restrict to only adding intervals, we get the amortized recourse budget of $\mathcal{O}(k^7 \log n)$ and $\Omega(\log n)$ is the lower bound. The

incremental setting is interesting by itself, as it generalizes the online model (where the recourse budget is zero and only insertions are allowed). In other words, we show that if in the online model we allow a modest number of $\mathcal{O}(k^7 \log n)$ recolorings per update, we can get down from $3k/2$ to the optimum number k of colors. Our result is not only motivated by the online model, but also fits nicely in the recent line of research related to parameterized dynamic algorithms [1, 14, 12], with k being the parameter.

The techniques we develop to obtain our main result seem applicable to a wider range of problems. In particular, we apply one of our techniques to the problem of coloring unit circular arc graphs. We obtain a combinatorial result that nicely fits into the related line of research. Imagine that L is the maximum number of arcs intersecting in one point for some set of unit circular arcs \mathcal{A} . We show that if there is a set \mathcal{A}' of non-intersecting unit arcs of size $L^2 - 1$ such that $\mathcal{A} \cup \mathcal{A}'$ does not contain $L + 1$ arcs intersecting in one point, then it is possible to color \mathcal{A} with L colors. This complements the work on circular arc coloring [4, 30, 31], which specifies sufficient conditions needed to color \mathcal{A} with $L + 1$ colors or more.

The remainder of the paper is organized as follows. In Section 2 we provide basic definitions related to interval graphs and unit interval graphs, together with some elementary algorithms that solve the coloring problem for static instances of those graphs. In Section 3 we provide an overview of our results and techniques. Due to space limitations, we only sketch the proofs in Section 3, skipping most of technical details. The full proofs can be found in the full version of the paper [11]. We conclude with Section 4 in which we discuss some properties and extensions of our main result. In particular, we discuss the implementation of our incremental algorithm and its actual running time (which is amortized $\mathcal{O}(k^7 \log n)$ per interval insertion). We also discuss extending our incremental algorithm to changing values of k , and finally we briefly discuss why our main result does not easily extend to general interval graphs. We end Section 4 with the problems that we leave open.

2 Preliminaries

We consider in this paper closed-open intervals $I = [x, y)$ for some $x, y \in \mathbb{R}, x < y$. Note that this causes no loss in generality, as closed-open intervals induce the same class of graphs as open-closed, closed-closed and open-open intervals (see [13, 26]). For an interval I we define operators $x(I) \stackrel{\text{def}}{=} x$ and $y(I) \stackrel{\text{def}}{=} y$ for accessing the begin and the end coordinate. A multiset of intervals can be interpreted as a graph: the intervals are interpreted as vertices, which are adjacent if and only if the corresponding intervals intersect. Graphs obtained in this way are called interval graphs. The coloring related definitions stated in the first paragraph of Section 1 directly translate to multisets of intervals interpreted as graphs. For a multiset of intervals \mathcal{I} , the function $c : \mathcal{I} \mapsto \{1, \dots, k\}$ is a proper k -coloring if for any $I, J \in \mathcal{I}$ it holds that $c(I) \neq c(J)$ if I and J intersect. The chromatic number $\chi(\mathcal{I})$ is the minimum number k for which \mathcal{I} admits a proper k -coloring. Similarly we can adapt the definition of a clique: a multiset of intervals $\mathcal{J} = \{J_1, J_2, \dots, J_m\}$ is a clique if and only if $\bigcap \mathcal{J} \stackrel{\text{def}}{=} J_1 \cap \dots \cap J_m \neq \emptyset$, or equivalently $\max_{i=1}^m x(J_i) < \min_{i=1}^m y(J_i)$. In such case it holds that $\bigcap \mathcal{J} = [\max_{i=1}^m x(J_i), \min_{i=1}^m y(J_i))$. We refer to this intersection as span of \mathcal{J} , and denote it as $\text{span}(\mathcal{J}) \stackrel{\text{def}}{=} \bigcap \mathcal{J}$. To emphasize the size of \mathcal{J} we often refer to it as an m -clique. The clique number $\omega(\mathcal{I})$ of a multiset of intervals \mathcal{I} is the maximum number m such that \mathcal{I} contains an m -clique. It is well known that interval graphs are perfect, that is:

► **Lemma 1** (Golumbic [17]). *Let \mathcal{I} be a multiset of intervals. Then $\omega(\mathcal{I}) = \chi(\mathcal{I})$.*

We introduce two orders \sqsubset and $<$ on a multiset of intervals \mathcal{I} . For any $I, J \in \mathcal{I}$ we let $I \sqsubset J$ if $x(I) < x(J)$. If $I = J$, we solve the tie arbitrarily. Hence, \sqsubset is a linear order on \mathcal{I} . We say that $I < J$ if and only if $y(I) \leq x(J)$. Hence, $<$ is a linear order only on independent sets of intervals (i.e., multisets of intervals that are pairwise non-intersecting). Orders \sqsubset and $<$ extend to multisets of intervals in a natural manner. For two multisets of intervals \mathcal{J} and \mathcal{K} , we say that $\mathcal{J} \sqsubset \mathcal{K}$ (respectively $\mathcal{J} < \mathcal{K}$) if for all $J \in \mathcal{J}, K \in \mathcal{K}$ it holds that $J \sqsubset K$ (respectively $J < K$). For a multiset of intervals \mathcal{I} by $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$ we denote that $\mathcal{I} = \{I_1, \dots, I_m\}$ and $I_1 \sqsubset \dots \sqsubset I_m$. For an ordered multiset of intervals $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$ we now define a prefix, a suffix and an infix of \mathcal{I} . For $I_i, I_l \in \mathcal{I}, l > i$ we set $\text{prefix}_{\mathcal{I}}^{\sqsubset}(I_i) = \{I_1, \dots, I_i\}$, $\text{suffix}_{\mathcal{I}}^{\sqsubset}(I_i) = \{I_i, \dots, I_m\}$ and $\text{infix}_{\mathcal{I}}^{\sqsubset}(I_i, I_l) = \{I_i, \dots, I_l\}$.

We now move on to some basic observations that hold for multisets of unit intervals. An interval I is unit if and only if $y(I) = x(I) + 1$.

► **Observation 2.** *Let $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$ be a multiset of unit intervals. If $\omega(\mathcal{I}) < m$, then the extremal intervals are disjoint, i.e., $I_1 < I_m$.*

Proof. Suppose contrary that $I_1 \cap I_m \neq \emptyset$, i.e., $x(I_m) < y(I_1) = x(I_1) + 1$. Then $\max_{i=1}^m x(I_i) < \min_{i=1}^m y(I_i)$ and as a consequence $\bigcap \mathcal{I} \neq \emptyset$ contradicting $\omega(\mathcal{I}) < m$. ◀

For interval graphs there is a simple greedy algorithm, that can be applied to complete a coloring given on the prefix of the representation ordered by \sqsubset [24]. In this paper we need a more specific but equally simple algorithm which is restricted to unit interval graphs. The same idea was used for instance to color proper circular arc graphs [25] or to schedule round-robin tournaments [27]. Since we use it in a different context, we introduce it here from scratch and we refer to it as the MODULO COLOR COMPLETION algorithm. Informally, given some coloring on the prefix of a k -colorable instance, this algorithm looks at the first k consecutive uncolored intervals (in \sqsubset order), and copies the coloring given on the last k intervals that are colored (respecting the \sqsubset order). This proceeds until all intervals are colored. This simple procedure works given that the coloring that is being copied consists of all colors from 1 to k . We describe the MODULO COLOR COMPLETION algorithm more formally in the following observation, which also proves the correctness.

► **Observation 3.** *Let $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$ be a multiset of unit intervals such that $\omega(\mathcal{I}) \leq k$. Let $k \leq l < m$ and let $c : \text{prefix}_{\mathcal{I}}^{\sqsubset}(I_l) \mapsto [k]$ be a proper k -coloring for $\text{prefix}_{\mathcal{I}}^{\sqsubset}(I_l)$ such that c is a bijection on $\text{infix}_{\mathcal{I}}^{\sqsubset}(I_{l-k+1}, I_l)$. Let $c' : \mathcal{I} \mapsto [k]$ (referred to as MODULO COLOR COMPLETION) be defined as follows: $c'(I_i) \stackrel{\text{def}}{=} c(I_i)$ for $i \in [l]$ and $c'(I_{l+i}) \stackrel{\text{def}}{=} c(I_{l-k+(i \bmod k)})$ for $i \in [m-l]$. Then c' is a proper k -coloring on \mathcal{I} .*

Proof. It is clear that c assigns only colors in $[k]$, it remains to prove that it is also a proper coloring. Let $I_i, I_j \in \mathcal{I}$, where $i < j$ and $j > l$. If $j < i + k$, then by definition $c(I_i) \neq c(I_j)$. Otherwise, $|\{I_i, I_{i+1}, \dots, I_j\}| \geq k + 1$, so by Observation 2, $I_i \cap I_j = \emptyset$. ◀

The following observation will be useful to bring the prefix coloring to the state when we can use the MODULO COLOR COMPLETION algorithm, i.e., the coloring on the prefix ends with the bijection.

► **Observation 4.** *Let $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_{2k}\}$ be a multiset of unit intervals such that $\omega(\mathcal{I}) \leq k$ and let $c' : \text{prefix}_{\mathcal{I}}^{\sqsubset}(I_k) \mapsto [k]$ be a proper k -coloring on $\text{prefix}_{\mathcal{I}}^{\sqsubset}(I_k)$. Then there is a proper k -coloring $c : \mathcal{I} \mapsto [k]$ such that $c(I_i) = c'(I_i)$ for $i \in [k]$ and c is a bijection on $\text{suffix}_{\mathcal{I}}^{\sqsubset}(I_{k+1})$.*

Proof. To construct c , we first set $c(I_i) = c'(I_i)$ for all $i \in [k]$. Let $\mathcal{J} = \{I_l, I_{l+1}, \dots, I_k\}$ be the intervals of $\text{prefix}_{\mathcal{I}}^{\sqsubset}(I_k)$ that intersect I_k . Thus, \mathcal{J} is a $(k-l+1)$ -clique. We first assign the $l-1$ colors not used by \mathcal{J} to the first $l-1$ intervals of $\text{suffix}_{\mathcal{I}}^{\sqsubset}(I_{k+1})$. That is we assign

colors $[k] \setminus c(\mathcal{J})$ to intervals $\text{infix}_{\mathcal{I}}^{\square}(I_{k+1}, I_{k+l-1})$ in an arbitrary order. We get a proper coloring since the intervals of $\text{infix}_{\mathcal{I}}^{\square}(I_{k+1}, I_{k+l-1})$ do not intersect intervals of $\text{prefix}_{\mathcal{I}}^{\square}(I_k)$ other than \mathcal{J} . Finally, we set $c(I_i) = c(I_{i-k})$ for $i \in \{k+l, \dots, 2k\}$. By Observation 2 intervals I_i and I_{i-k} do not intersect. This completes the proof. \blacktriangleleft

Observe that Observation 3 and Observation 2 give an alternative to [24] algorithm that completes the prefix coloring on unit interval graphs. We refer to this algorithm as GREEDY COLOR COMPLETION (even though we can use the algorithm of [24] instead).

3 Overview of our results and techniques

Our final result is based on new techniques that might be of independent interest. This section outlines our techniques and gives an overview on how they are combined into obtaining the final result. Our techniques are encapsulated in Section 3.1 and Section 3.2 as completely independent results, as we see the potential of applying them to a wider range of problems. In Section 3.1 we introduce our new technique of *color sorting*, which allows to solve the UNIT PRECOLORING EXTENSION problem efficiently under a specific condition that might naturally appear in a number of applications. In Section 3.2 we introduce the FROGS game technique, which is a natural generalization of the folklore technique applied for merging sets in Find-Union like algorithms. We expect the FROGS game technique to be also applicable to a wider range of problems. Our main application of the color sorting technique and the FROGS game technique is presented in Section 3.3, where we introduce the INCREMENTAL UNIT INTERVAL RECOLORING problem and sketch the solution to this problem.

3.1 Color sorting applied to the Unit Precoloring Extension problem

Our first contribution is the color sorting technique, that we apply to the UNIT PRECOLORING EXTENSION problem. In this problem we are given a k -colorable multiset of unit intervals $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$, $m > 2k$. We are also given a proper k -coloring c' on $\text{prefix}_{\mathcal{I}}^{\square}(I_k)$ (the first k intervals) and a proper k -coloring c'' on $\text{suffix}_{\mathcal{I}}^{\square}(I_{m-k+1})$ (the last k intervals). The problem is to extend c' and c'' to a proper l -coloring of \mathcal{I} minimizing l .

The UNIT PRECOLORING EXTENSION problem was proven NP-hard [22], moreover, it is even NP-hard to decide whether one can extend the coloring using $l = k$ colors. In our application, however, we are only interested in the instances when this is possible, i.e., the UNIT PRECOLORING EXTENSION ceases to be NP-hard. We specify a condition on \mathcal{I} under which one can, using the color sorting technique, extend the precoloring to a proper k -coloring. Our condition essentially requires that there is some slack space between the colored prefix and the colored suffix, which allows color sorting. By the slack we mean that we can fit between the prefix and the suffix additional $k^2 - 1$ mutually disjoint unit intervals without increasing the chromatic number of \mathcal{I} . This slack is used to gradually sort the color permutation given on the prefix to finally obtain the color permutation given on the suffix, in an insertion sort fashion. The precise result is stated in the following lemma.

► **Lemma 5** (Precoloring Extension Lemma). *Let k be an integer and let $\mathcal{I} = \{I_1 \sqsubset \dots \sqsubset I_m\}$ be a k -colorable multiset of $m \geq 2k$ unit intervals. Let $c' : \text{prefix}_{\mathcal{I}}^{\square}(I_k) \mapsto [k]$ and $c'' : \text{suffix}_{\mathcal{I}}^{\square}(I_{m-k+1}) \mapsto [k]$ be bijections. Let there exist a set of $k^2 - 1$ pairwise non-intersecting unit intervals \mathcal{L} , such that $\text{prefix}_{\mathcal{I}}^{\square}(I_k) \sqsubset \mathcal{L} \sqsubset \text{suffix}_{\mathcal{I}}^{\square}(I_{m-k+1})$ and $\mathcal{I} \cup \mathcal{L}$ is k -colorable. Then there is a proper k -coloring $c : \mathcal{I} \mapsto [k]$ such that c extends both c' and c'' , i.e., $c(I_i) = c'(I_i)$ for $i \in [k]$ and $c(I_i) = c''(I_i)$ for $i \in \{m - k + 1, \dots, m\}$.*

The full proof of Lemma 5 can be found in the full version of the paper [11], Appendix A.

Sketch of proof of Lemma 5. The proof introduces the color sorting technique, which uses the slack intervals of \mathcal{L} to gradually transform the coloring c' into the coloring c'' , in an insertion sort like fashion. In order to accomplish that, we modify the instance (by inserting dummy intervals from \mathcal{L}) to allow the color sorting technique to work. We describe this process first.

We start by assuming that the multiset of unit intervals \mathcal{I} is connected as a graph (otherwise Lemma 5 follows from the MODULO COLOR COMPLETION algorithm, see Observation 3). An example instance for which our assumptions hold is pictured in Figure 1.

■ **Figure 1** An example illustrating the assumptions of Lemma 5 for $k = 3$.

We now partition $\mathcal{L} = \{L_1 < \dots < L_{k^2-1}\}$ into $2k - 1$ sets of unit intervals as follows: $\mathcal{L} = \mathcal{L}_1 \cup \{M_1\} \cup \mathcal{L}_2 \cup \dots \cup \{M_{k-1}\} \cup \mathcal{L}_k$, where $\mathcal{L}_i = \{L_{(i-1)k+1}, \dots, L_{ik-1}\}$ for $i \in [k]$ and $M_i = L_{ik}$ for $i \in [k-1]$. Observe that $|\mathcal{L}_i| = k - 1$. Thus, the intervals of the partition are ordered as follows: $\text{prefix}_{\mathcal{I}}^{\square}(I_k) \sqsubset \mathcal{L}_1 < \{M_1\} < \mathcal{L}_2 < \dots < \{M_{k-1}\} < \mathcal{L}_k \sqsubset \text{suffix}_{\mathcal{I}}^{\square}(I_{n-k+1})$. Next we partition \mathcal{I} into k parts: $\mathcal{I} = \mathcal{I}_1 \cup \mathcal{I}_2 \cup \dots \cup \mathcal{I}_k$, in the way that the following holds: $\text{prefix}_{\mathcal{I}}^{\square}(I_k) \subseteq \mathcal{I}_1 \sqsubset \{M_1\} \sqsubset \mathcal{I}_2 \sqsubset \dots \sqsubset \{M_{k-1}\} \sqsubset \mathcal{I}_k \supseteq \text{suffix}_{\mathcal{I}}^{\square}(I_{n-k+1})$. This partition is pictured in Figure 2. We now enlarge \mathcal{I} by adding to each \mathcal{I}_i some dummy intervals. More

■ **Figure 2** An example illustrating partitioning the intervals, $k = 3$.

precisely, to each $\mathcal{I}_i \subseteq \mathcal{I}$ we add a subset $\mathcal{L}'_i \subseteq \mathcal{L}_i$ as to make the number of intervals in the extension $\mathcal{J}_i \stackrel{\text{def}}{=} \mathcal{I}_i \cup \mathcal{L}'_i$ a multiple of k (see Figure 2). As a consequence, $\mathcal{J} \stackrel{\text{def}}{=} \bigcup_{i=1}^k \mathcal{J}_i$ and $\mathcal{J}_1, \mathcal{J}_2, \dots, \mathcal{J}_k$ satisfy the following (note that since \mathcal{I} is connected as a graph, each \mathcal{I}_i is nonempty and thus each \mathcal{J}_i is also nonempty):

1. $\omega(\mathcal{J} \cup \{M_1, \dots, M_{k-1}\}) \leq k$,
2. for each $i \in [k]$ we have $|\mathcal{J}_i| = kp_i$ for some $p_i \in \mathbb{N} \setminus \{0\}$,
3. $\text{prefix}_{\mathcal{I}}^{\square}(I_k) \subseteq \mathcal{J}_1 \sqsubset \{M_1\} \sqsubset \mathcal{J}_2 \sqsubset \dots \sqsubset \{M_{k-1}\} \sqsubset \mathcal{J}_k \supseteq \text{suffix}_{\mathcal{I}}^{\square}(I_{n-k+1})$.

Now, rather than the proper coloring for \mathcal{I} , we construct the proper coloring c for \mathcal{J} (which is obviously also proper for \mathcal{I}). The construction of c starts by copying colors of c' , so that c coincides with c' on $\text{prefix}_{\mathcal{I}}^{\square}(I_k)$. Let us now consider a block $\mathcal{J}_{j-1} = \{J_0^{j-1} \sqsubset \dots \sqsubset J_{s_{j-1}-1}^{j-1}\}$, where $(j-1) \in [k]$, $s_{j-1} = |\mathcal{J}_{j-1}|$. Suppose that c is already defined on $\text{prefix}_{\mathcal{J}_{j-1}}^{\square}(J_{k-1}^{j-1})$ (the first k intervals of \mathcal{J}_{j-1}). Note that coloring c on $\text{prefix}_{\mathcal{J}_{j-1}}^{\square}(J_{k-1}^{j-1})$ defines a permutation of colors. We use the MODULO COLOR COMPLETION algorithm to copy this permutation to $\text{suffix}_{\mathcal{J}_{j-1}}^{\square}(J_{s_{j-1}-k}^{j-1})$ (the last k intervals of \mathcal{J}_{j-1}). This works because $k | s_{j-1}$. Suppose

that this permutation already coincides with the permutation given by c'' on the last $j - 2$ positions. We now use the slack given by M_{j-1} to define c on $\text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$ in such a way that the corresponding permutation agrees with the permutation given by c'' on the last $j - 1$ positions. To be more precise, we apply one step of the insertion sort on the permutation to bring one more color to the appropriate position, as shown in Figure 3. This is possible because of the slack given by M_{j-1} . The intuition is that if we apply MODULO COLOR COMPLETION on $\text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$, then we obtain a proper k -coloring on $\text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$ that precisely copies the color permutation from $\text{suffix}_{\mathcal{J}_{j-1}}^{\square}(J_{s_{j-1}-k}^{j-1})$. On the other hand, if we apply MODULO COLOR COMPLETION to $\{M_{j-1}\} \cup \text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$, then on $\text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$ we get the same permutation with all colors shifted down by one, and this is also a proper coloring. The insertion sort step that we apply (see Figure 3) gives a permutation that alternates at most twice between the same permutation and the shifted permutation. Also, the insertion sort step moves one special color (purple in Figure 3) further away than required by the MODULO COLOR COMPLETION algorithm. Hence the obtained coloring is proper. \blacktriangleleft

■ **Figure 3** An insertion sort step, where coloring c is constructed on $\text{prefix}_{\mathcal{J}_j}^{\square}(J_{k-1}^j)$ for $j = 4$, $k = 5$.

3.2 The Frogs game

Our second contribution is a technique that generalizes a folklore trick typically used in the analysis of Union-Find data structure. The SET UNION problem, where the Union-Find data structure finds its application, can be thought of as a game. In this game we are initially given n pairwise disjoint sets of size δ , and the adversary keeps merging consecutive pairs of sets until there is only one set left. Each time the adversary merges a pair of sets, we incur the cost equal to the size of the smaller set among the ones being merged (as if we move all elements of the smaller set to the larger set, one by one). It is clear that the maximum total cost the adversary can generate is $\delta n \log n$, as each of δn elements can contribute to the total cost at most $\log n$ times.

The generalization we propose is that the cost we incur with each merging is the sum of the sizes of κ consecutive sets rather than just one. We sum κ consecutive sizes either to the left or to the right of the merged pair, whatever turns out cheaper. We show that the total cost an adversary can generate here is $\mathcal{O}(\delta \kappa n \log n)$. We refer to this generalization as the FROGS game, and we now introduce its formal definition.

► **Definition 6.** We define an instance of a FROGS game as a tuple $\mathcal{F} = (N, \kappa, \delta, J)$. There, N, κ , and δ are integers, referred to as the size of the game, the jump number, and the initial rank value respectively. It also holds that $\kappa \leq N$. Moreover J is a sequence of $N - 1$ integers $J = (j_1, j_2, \dots, j_{N-1})$, where $1 \leq j_\tau \leq N - \tau$ and J is referred to as the jump sequence.

We now define the cost of the FROGS game.

► **Definition 7.** Let $\mathcal{F} = (N, \kappa, \delta, J)$ be an instance of the FROGS game, where $J = (j_1, j_2, \dots, j_{N-1})$. Let $R_1 = (\delta, \dots, \delta)$ be a sequence of length N (R_1 is called the initial rank sequence). Let $R_{\tau+1} \stackrel{\text{def}}{=} (r_{\tau,1}, \dots, r_{\tau,j_\tau-1}, r_{\tau,j_\tau} + r_{\tau,j_\tau+1}, r_{\tau,j_\tau+2}, \dots, r_{\tau,N-\tau+1})$ (rank sequence $R_{\tau+1}$ in time $\tau + 1$ is obtained by adding two neighboring ranks in R_τ placed at positions j_τ and $j_\tau + 1$). The FROGS cost incurred in time τ is $\varsigma_\tau \stackrel{\text{def}}{=} \min(r_{\tau,j_\tau-\kappa+1} + \dots + r_{\tau,j_\tau}, r_{\tau,j_\tau+1} + \dots + r_{\tau,j_\tau+\kappa})$, where for $i < 1$ and $i > N - \tau + 1$ we set $r_{\tau,i} \stackrel{\text{def}}{=} \delta$. The total cost of the FROGS game \mathcal{F} is $\varsigma(\mathcal{F}) \stackrel{\text{def}}{=} \varsigma_1 + \dots + \varsigma_{N-1}$.

We bound the cost of any FROGS game \mathcal{F} using the following theorem.

► **Theorem 8 (Frogs theorem).** For an instance $\mathcal{F} = (N, \kappa, \delta, J)$ of the FROGS game we have

$$\varsigma(\mathcal{F}) \leq \delta(2\kappa - 1)(N + 2\kappa - 2) \log_2 \frac{N + 2\kappa - 2}{2\kappa - 1}.$$

The FROGS theorem is proved in the full version of the paper [11] in Appendix B. The technique given by FROGS theorem might be of independent interest. It seems applicable as a building block to more problems than the one studied further in this paper.

3.3 Incremental Unit Interval Recoloring problem

The main result of this paper is an algorithm for the INCREMENTAL UNIT INTERVAL RECOLORING problem. We are given a parameter k and a sequence of n unit intervals: I_1, I_2, \dots, I_n such that $\{I_1, \dots, I_n\}$ is k -colorable. This sequence defines $n + 1$ multisets of unit intervals: $\mathcal{I}_0 = \emptyset$ and $\mathcal{I}_j \stackrel{\text{def}}{=} \{I_1, \dots, I_j\}$ for $j > 0$. Instance \mathcal{I}_j differs from \mathcal{I}_{j-1} by one interval I_j . The goal is to maintain a proper k -coloring on the dynamic instance. To be more precise, after the interval I_j is presented, the algorithm needs to compute a proper k -coloring c_j for \mathcal{I}_j . Our objective is to minimize the recourse budget, which is the number of intervals with different colors in c_j and c_{j-1} . We obtain the following result.

► **Theorem 9.** There is an algorithm for the INCREMENTAL UNIT INTERVAL RECOLORING problem with a total recourse budget of $\mathcal{O}(k^7 n \log n)$.

Theorem 9 is formally proved in the full version of the paper [11], Appendix C. Here we outline how the Precoloring Extension lemma (Lemma 5) and the Frogs theorem (Theorem 8) are combined to obtain the main result, skipping the technical details that are deferred to the full proof.

Sketch of the proof of Theorem 9. Let us imagine that a new interval I_j is presented and we need to provide the coloring c_j for \mathcal{I}_j . Let us order \mathcal{I}_j according to the \sqsubset order. Let I be the direct predecessor (in \sqsubset order) of I_j in \mathcal{I}_j . Let interval $J^{(R)}$ be the interval of \mathcal{I}_j succeeding I (in \sqsubset order) such that between I and $J^{(R)}$ there is room to insert the set \mathcal{L} of $k^2 - 1$ mutually disjoint unit intervals, as required by the Precoloring Extension lemma (Lemma 5). Let $J^{(L)}$ be an analogous interval preceding I . For simplicity let us assume that both $J^{(L)}$ and $J^{(R)}$ exist. Based on the Precoloring Extension lemma (Lemma 5), it is (almost) sufficient to recolor the infix of \mathcal{I}_j between I and $J^{(R)}$, or the infix of \mathcal{I}_j between $J^{(L)}$ and I , and it is up to the algorithm which of the two infixes it chooses to recolor. Our recoloring algorithm basically chooses the infix that is smaller in size and recolors it (although there are small technical details that make the algorithm a bit more complicated in the end).

The whole weight of the proof lies now in the analysis, which shows that the size of the smaller infix is $\mathcal{O}(k^7 \log n)$ in the amortized sense. To prove that we use the Frogs theorem (Theorem 8), so we need to define the appropriate size N , jump number κ , initial rank value δ , and the jump sequence J , and all these numbers must strongly relate to what the recoloring algorithm does. We sketch here the main idea of how we do it. We look at all k -cliques of the final instance $\mathcal{I}_{n'}$, $n' \in \mathcal{O}(kn)$ (the final instance is not \mathcal{I}_n because, for a technical reason mentioned further, we may be forced to add some dummy intervals after the whole instance \mathcal{I}_n was presented). Every k -clique is a set of k overlapping intervals, whose intersection is some (not necessarily unit) interval. So we represent the k -cliques of the final instance $\mathcal{I}_{n'}$ as a set $\mathcal{S}_{n'}$ of intervals, which are mutually disjoint, and we order them by $<$ order. This is shown in Figure 4, where at the bottom the intervals of $\mathcal{I}_{n'}$ are drawn (either solid black or dashed blue), and above them the corresponding cliques of $\mathcal{S}_{n'}$ are pictured (also either solid black or dashed blue).

Figure 4 Example span partition : — – intervals of \mathcal{I}_j , - - - – intervals of $\mathcal{I}_{n'} \setminus \mathcal{I}_j$ (future intervals), — – spans of \mathcal{S}_j , - - - – spans of $\mathcal{S}_{n'} \setminus \mathcal{S}_j$ (future spans), ○ – blocks of partition \mathfrak{B}_j , $k = 3$.

We observe that $m \stackrel{\text{def}}{=} |\mathcal{S}_{n'}| = \mathcal{O}(kn)$. We assume that $\mathcal{S}_{n'}$ is tightly packed, i.e., two consecutive intervals in $\mathcal{S}_{n'}$ are at distance less than one (for this assumption to hold we add dummy intervals to \mathcal{I}_n and obtain $\mathcal{I}_{n'}$ -whenever two consecutive cliques are at distance at least one, we insert a dummy interval between them without increasing the chromatic number). The intuition now is that at the beginning each clique in $\mathcal{S}_{n'}$ is empty, but successively the cliques in $\mathcal{S}_{n'}$ are filled with the intervals, until each of them is filled up to the maximum level k . A new interval I_j adds 1 to the level of all the cliques it intersects. Let us denote by $\text{lvl}_j(S)$ the level of clique $S \in \mathcal{S}_{n'}$ in step j . In Figure 4, the intervals of \mathcal{I}_j are marked solid black, while the future intervals (not presented until step j) are marked dashed blue. Consequently, the fully filled cliques of $\mathcal{S}_{n'}$ are marked solid black, while the cliques that are not filled to the maximum level in step j are marked dashed blue.

In each step j , we partition the cliques $S \in \mathcal{S}_{n'}$ into blocks depending on their level $\text{lvl}_j(S)$. We refer to the corresponding partition as \mathfrak{B}_j . The rule is that the consecutive cliques who are entirely filled (meaning that $\text{lvl}_j(S) = k$) belong to the same block of the partition \mathfrak{B}_j , while the cliques that are not filled are placed in a separate one-element block. An example partition \mathfrak{B}_j is pictured in Figure 4. As a result, the blocks of \mathfrak{B}_j are merged over the time, but never split. The grey blocks of \mathfrak{B}_j consisting of entirely filled cliques are called passive, while the remaining blue blocks (the one-element blocks containing the cliques that are not filled) are called active.

Now for each insertion step j there is a corresponding rank sequence R_τ in the FROGS game. Each block $\mathcal{B} \in \mathfrak{B}_j$ is assigned at least one and at most $(k + 1)$ consecutive ranks $r_{\tau,i}^{(\mathcal{B})}$ in R_τ , in the way that every rank $r_{\tau,i}^{(\mathcal{B})}$ assigned to \mathcal{B} bounds the sum of the levels in \mathcal{B} , i.e., $r_{\tau,i}^{(\mathcal{B})} \geq \sum_{S \in \mathcal{B}} \text{lvl}_j(S)$. Each active block \mathcal{B} is assigned at least $k - \text{lvl}_j(S) + 1$ consecutive ranks $r_{\tau,i}^{(\mathcal{B})}$, while each passive block is assigned precisely one rank.

When the interval I_j arrives, some cliques $S \in \mathcal{S}_n$ increase their level. Such a clique S that increases its level is necessarily in an active (singleton) block $\mathcal{B} = \{S\}$, as I_j certifies that S is not completely filled up yet. To account for the insertion of I_j , we merge any two consecutive ranks assigned to $\mathcal{B} = \{S\}$ (there is at least $k - \text{lvl}_j(S) + 1 \geq 2$ ranks available). We observe that the infix recolored by the algorithm is entirely contained within $\mathcal{O}(k^3)$ consecutive blocks to the left or to the right of \mathcal{B} , and in what follows we argue why this holds. First of all, the recolored infix can intersect at most $\mathcal{O}(k^3)$ active blocks: each active block certifies that a future unit interval fits in, but k active blocks may be witnesses for the same future unit interval that fits in. Note that the infix recolored by the algorithm contains at most $(k^2 - 1)$ pairwise disjoint future intervals. Second of all, the recolored infix intersects no more passive blocks than active blocks, since each passive block has a neighboring active block.

Since every block is assigned at most $(k + 1)$ consecutive ranks, if we set the jump number $\kappa = \mathcal{O}(k^4)$, the cost incurred in the Frogs game covers the ranks assigned to the $\mathcal{O}(k^3)$ consecutive blocks, which in turn bound the recoloring cost in the recoloring algorithm for step j . Of course, upon the arrival of I_j some cliques need to be merged into one passive block, and even some passive blocks get merged together, meaning that we need to merge some extra ranks in the rank sequence, but this also can be handled by the FROGS game. ◀

3.4 Fully Dynamic Unit Interval Recoloring problem

In this section we show that for the FULLY DYNAMIC UNIT INTERVAL RECOLORING problem one cannot hope for an algorithm with a reasonably limited recourse budget. In the FULLY DYNAMIC UNIT INTERVAL RECOLORING problem, we are initially given an empty multiset of unit intervals $\mathcal{I}_0 = \emptyset$. The instance \mathcal{I}_{j+1} is obtained from \mathcal{I}_j by adding a new unit interval to \mathcal{I}_j or removing the existing chosen interval from \mathcal{I}_j . Every instance \mathcal{I}_j presented to the algorithm is k -colorable. The goal is again to maintain a proper k -coloring on the dynamic instance. After each interval insertion and removal, the algorithm needs to compute a proper k -coloring c_j for \mathcal{I}_j . Similarly as before, our objective is to minimize the recourse budget, which is the number of intervals with different colors in c_j and c_{j-1} . For this problem we get the following negative result.

► **Observation 10.** *There is a sequence of m updates for the FULLY DYNAMIC UNIT INTERVAL RECOLORING problem that forces the total number of recolorings of $\Omega(m^2)$.*

Proof. We first construct an instance $\mathcal{M} = \mathcal{I} \cup \mathcal{J} \cup \mathcal{K} \cup \mathcal{L}$, where $\mathcal{I} = \{I_1, \dots, I_n\}$, $\mathcal{J} = \{J_1, \dots, J_n\}$, $\mathcal{K} = \{K_1, \dots, K_n\}$ and $\mathcal{L} = \{L_1, \dots, L_n\}$. All four sets contain pairwise disjoint intervals. Both $\mathcal{K} \cup \mathcal{L}$ and $\mathcal{I} \cup \mathcal{J}$ are paths when interpreted as graphs. Additionally, set $\mathcal{K} \cup \mathcal{L}$ is placed to the left of $\mathcal{I} \cup \mathcal{J}$. This is shown in Figure 5.

■ **Figure 5** The update when K_1 has the same color as I_1 .

Observe that since \mathcal{M} is 2-colorable, all sets \mathcal{K} , \mathcal{L} , \mathcal{I} and \mathcal{J} are necessarily monochromatic, moreover set \mathcal{K} has different color than \mathcal{L} , and \mathcal{I} has different color than \mathcal{J} . We construct the instance so, that K_1 is the rightmost interval of $\mathcal{K} \cup \mathcal{L}$ and interval I_1 is the leftmost interval of $\mathcal{I} \cup \mathcal{J}$. Moreover, the distance between the end coordinate of K_1 and the begin coordinate of I_1 is less than one (see Figure 5). Consider the case when K_1 has the same color as I_1 . Then we insert to \mathcal{M} two intersecting intervals I and I' , such that I intersects K_1 and I' intersects I_1 (see Figure 5). This results in $\mathcal{M} \cup \{I, I'\}$ being a path when interpreted as a graph. The instance is still 2-colorable, but now \mathcal{I} needs to have the same color as \mathcal{L} and \mathcal{J} needs to have the same color as \mathcal{K} . This requires recoloring $2n$ intervals, since either $\mathcal{I} \cup \mathcal{J}$ or $\mathcal{K} \cup \mathcal{L}$ has to be recolored. Next, we remove I and I' . Consider now the case when K_1 has a different color than I_1 (see Figure 6). In that case we insert an interval I intersecting

■ **Figure 6** The update when K_1 has different color than I_1 .

both K_1 and I_1 . This causes that K_1 and I_1 have to now be assigned different colors, and again either $\mathcal{I} \cup \mathcal{J}$ or $\mathcal{K} \cup \mathcal{L}$ has to be recolored. ◀

3.5 Coloring Unit Circular Arc Graphs

In this section we present a different application of the Precoloring Extension Lemma (Lemma 5). As a result, we offer a new combinatorial result for coloring unit circular arc graphs.

Unit circular arc graphs, as a subclass of proper circular arc graphs, admit an $\mathcal{O}(n^{1.5})$ algorithm that statically finds an optimum proper coloring [28]. On the other hand, the problem of coloring circular arc graphs is NP-hard [16], and a lot of research has been devoted to find positive results regarding this problem. This line of research exposes two important parameters describing an instance \mathcal{A} of a circular arc graph: the load $\text{load}(\mathcal{A})$ and the cover number $\text{cn}(\mathcal{A})$. The load $\text{load}(\mathcal{A})$ stands for the maximum number of arcs intersecting in one point, whereas the cover number $\text{cn}(\mathcal{A})$ stands for the minimum number of arcs covering the whole circle. The research focus is on the conditions under which a circular arc graph admits a proper coloring using close to $\text{load}(\mathcal{A})$ colors. Tucker [30] shows, that if $\text{cn}(\mathcal{A}) \geq 4$, then $\lfloor 3 \text{load}(\mathcal{A}) / 2 \rfloor$ colors suffice. Valencia-Pabon [31] shows that if $\text{cn}(\mathcal{A}) \geq 5$, then $\left\lceil \frac{\text{cn}(\mathcal{A}) - 1}{\text{cn}(\mathcal{A}) - 2} \text{load}(\mathcal{A}) \right\rceil$ colors is enough. For $\text{cn}(\mathcal{A}) \geq \text{load}(\mathcal{A}) + 2$ the bound becomes $\text{load}(\mathcal{A}) + 1$. Belkale and Chandran [4] prove the Hadwiger’s conjecture for proper circular arc graphs. Neither of these results exposes a condition sufficient to color the instance with precisely $\text{load}(\mathcal{A})$ colors. We use Lemma 5 to show, that if one can add $\text{load}(\mathcal{A})^2 - 1$ non-intersecting unit arcs to an instance of a unit circular arc graph in a way that the load does not increase, then $\text{load}(\mathcal{A})$ colors is sufficient to properly color the instance. This is formalized by the following lemma, proved in the full version [11] in Appendix D.

► **Theorem 11.** *Let \mathcal{A} be a set of unit circular-arcs on the circle with a circumference at least 2, such that \mathcal{A} can be extended with $r = \text{load}(\mathcal{A})^2 - 1$ not intersecting unit circular-arcs B_1, \dots, B_r which do not increase the load, i.e., $\text{load}(\mathcal{A}) = \text{load}(\mathcal{A} \cup \{B_1, \dots, B_r\})$. Then $\chi(\mathcal{A}) \leq \text{load}(\mathcal{A})$.*

Note that our condition of Theorem 11 can be easily checked in linear time and it might be a very natural assumption for some applications.

4 Concluding remarks

In this section we discuss several interesting extensions and aspects of our main result, which is the recoloring algorithm for the INCREMENTAL UNIT INTERVAL RECOLORING problem. We conclude with future research directions and open problems.

The first interesting property of the RECOLOR algorithm is its resistance to malicious coloring. By that we mean, that the RECOLOR algorithm on its input coloring does not assume anything other than being a proper k -coloring. In other words, some evil adversary could potentially repaint the whole instance before inserting the new interval, and as long as this is a proper k -coloring, the RECOLOR algorithm works. This might be of interest for some applications, one of which is described next.

Throughout the paper we make a simplifying assumption that the chromatic number k of the final instance is given apriori to the RECOLOR algorithm (as a parameter). Using the fact that our algorithm works against malicious coloring, it is easy to get rid of this assumption by running the recoloring algorithm with changing values of k . To be more precise, let us consider each step j when the chromatic number increases: $l - 1 = \chi(\mathcal{I}_{j-1}) < \chi(\mathcal{I}_j) = l$ (we can easily detect all such steps j). Before I_j arrives, we have the $(l - 1)$ -coloring c_{j-1} of \mathcal{I}_{j-1} at our disposal. Coloring c is obviously also an l -coloring for \mathcal{I}_{j-1} , so the recoloring algorithm for \mathcal{I}_j gets the correct input. From now on, until the next step when the chromatic number increases, the algorithm runs with parameter $k = l$. It is easy to see that the algorithm modified in this way returns the proper coloring. Let K be the chromatic number of the final instance \mathcal{I}_n (not known to the algorithm). Since for every k used by the modified algorithm we have $k \leq K$, the analysis for parameter K bounds from above the total recoloring budget of the modified algorithm. Thus, using $\mathcal{O}(K^7 \log n)$ amortized recoloring budget, we can maintain an optimal coloring for each instance \mathcal{I}_j .

Our incremental algorithm can be implemented in total time $\mathcal{O}(k^7 n \log n)$, where k is the final chromatic number. It suffices to maintain a sorted list of intervals \mathcal{I}_j in an AVL tree. Such a list allows inserting a new interval in time $\mathcal{O}(\log n)$. It allows finding the predecessor and the successor of the newly inserted interval, and efficient iteration to the left and to the right. This allows detecting the infix that we want to recolor in the time proportional to the size of the infix. The coloring step can then be performed in linear time. We refer to the full version [11] of the paper for the details and the pseudocode of the algorithm.

Finally, let us shortly discuss why our approach does not seem to extend to general interval graphs, or even the intervals whose lengths vary from 1 to $(1 + \epsilon)$. The main reason for that is that the MODULO COLOR COMPLETION algorithm spectacularly fails on such graphs. In particular, Observation 2 ceases to hold, and the MODULO COLOR COMPLETION algorithm is based on this observation. It would be interesting to see if the color sorting technique could work with some algorithms other than MODULO COLOR COMPLETION, effective on any superclass of unit interval graphs. We leave this as the main open question. Note that due to our lower bound in Section 3.4, which carries over to any superclass of unit interval graphs, we cannot hope on positive results regarding the fully dynamic setting.

Polynomial Kernel for Immersion Hitting in Tournaments

Łukasz Bożyk  

University of Warsaw, Poland

Michał Pilipczuk  

University of Warsaw, Poland

Abstract

For a fixed simple digraph H without isolated vertices, we consider the problem of deleting arcs from a given tournament to get a digraph which does not contain H as an immersion. We prove that for every H , this problem admits a polynomial kernel when parameterized by the number of deleted arcs. The degree of the bound on the kernel size depends on H .

1 Introduction

Kernelization is an algorithmic framework for describing preprocessing procedures that given an instance of a hard problem, identify and reduce easily resolvable parts. The usual formalization of the concept is based on the paradigm of parameterized complexity. A *kernelization procedure*, or a *kernel* for short, for a parameterized decision problem L is a polynomial-time algorithm that given an instance (I, k) of L , where k is the parameter, outputs an equivalent instance (I', k') such that both $|I'|$ and k' are bounded by a computable function of k . If this function is a polynomial in k , we say that the kernel is *polynomial*. The search for (polynomial) kernels is an established research area within the field of parameterized algorithms. We refer to the textbook of Fomin et al. [13] for a broader discussion of classic results and techniques.

A particularly fruitful line of research within kernelization concerns the methodology of *protrusions* and *protrusion replacement*. The idea is to find a large *protrusion*: a piece of graph that is simple – for instance, has bounded treewidth – and communicates with the rest of the graph only through a small interface. If found, a protrusion can be fully understood – for instance, using dynamic programming on its tree decomposition – and replaced with a smaller one with the same functionality. So if one proves that, provided the given instance is large, a large protrusion can be efficiently found and replaced with a strictly smaller one, then applying this strategy exhaustively eventually arrives at a kernel. Protrusion-based techniques were pioneered by Bodlaender et al. [5], but by now have become a part of the standard toolbox of kernelization. We refer the interested reader to [13, Part 2] for more information.

A particularly important achievement in the development of protrusion-based kernelization procedures is the result of Fomin et al. [12], who gave a polynomial kernel for the PLANAR \mathcal{F} -DELETION problem, defined as follows. Let \mathcal{F} be a fixed family of graphs containing

at least one planar graph. Then in the problem we are given a graph G and an integer k (considered to be the parameter), and the question is whether one can hit all minor models of graphs from \mathcal{F} in G using a hitting set consisting of at most k vertices. Fomin et al. gave a polynomial kernel for this problem for every fixed family \mathcal{F} as above. The degree of the polynomial bound on the kernel size depends on \mathcal{F} and it is known that under certain complexity-theoretical assumptions, this is unavoidable [15]. The assumption that \mathcal{F} contains a planar graph is crucial in the approach: under this assumption, graphs not containing any graph from \mathcal{F} as a minor have treewidth bounded by a constant, which unlocks a multitude of tools related to tree decomposition using which one can understand the structure of the instance.

The concept of a protrusion, as described above, is quite capacious and can be applied in different settings as well. For instance, Giannopolou et al. [18] considered the \mathcal{F} -IMMERSION DELETION problem, where for a given graph G and parameter k , one wishes to hit all immersion models of graphs from \mathcal{F} using a hitting set of edges of size at most k (Recall that an *immersion model* of a graph H in a graph G consists of mapping the vertices of H to distinct vertices of G and edges of H to pairwise edge-disjoint paths in G so that the image of an edge uv connects the image of u with the image of v). By loosely following the approach of [12], Giannopolou et al. [18] gave a *linear* kernel for \mathcal{F} -IMMERSION DELETION for every family \mathcal{F} that contains a subcubic planar graph. Here, the main idea was to adjust the notions of protrusions to the graph parameter *tree-cutwidth* and corresponding *tree-cut decompositions*, which play the same role for immersions as treewidth and tree decompositions play for minors.

Motivated by this, it is interesting to consider other settings where the protrusion methodology could be applied. A particularly tempting area is that of *directed graphs*, where natural analogues of problems considered in undirected graphs can be easily stated. Unfortunately, the structural theory of directed graphs is much less understood than that of undirected graphs, and many problems become inherently harder; see e.g. [16, 17, 20]. In particular, there is even a scarcity of fixed-parameter tractability results, not to mention kernelization results.

However, there is a particular class of directed graphs where a sound structural theory has been developed: *tournaments*. (Here, recall that a *tournament* is a directed graph where every pair of vertices is connected by exactly one arc.) This theory¹ was pioneered by Chudnovsky, Ovetsky, Fradkin, Kim, and Seymour [9, 10, 26, 27, 21], while structural and algorithmic aspects connected to parameterized complexity were investigated by Fomin and Pilipczuk [14]. See the introductory section of [14] for an overview.

In particular, as proved in the aforementioned works, there are two main width notions for tournaments: *cutwidth* and *pathwidth*. The first one is tightly connected to (directed) immersions as follows: if a tournament T excludes a digraph H as an immersion, then the cutwidth of T is bounded by a constant depending only on H . Pathwidth is connected to *topological minors* and *strong minors* in the same sense. These structural results were used for the design of parameterized algorithms for containment problems in tournaments in [9, 26, 14]. Later, they were used by Raymond [28] and by Bożyk and Pilipczuk [8] to establish Erdős-Pósa properties for immersions and topological minors in tournaments.

The goal of this work is to explore the applicability of the structural theory of tournaments for kernelization, with a particular focus of developing a sound protrusion-based methodology.

¹ In this line of work, most results concern the class of *semi-complete digraphs*, which differ from tournaments by allowing that a pair of vertices can be also connected by two oppositely-oriented arcs. In this article we focus on the setting of tournaments for simplicity.

Our contribution. For a simple directed graph H without isolated vertices we define the following parameterized problem:

H -HITTING IMMERSIONS IN TOURNAMENTS

Input: A tournament T and a positive integer k .

Parameter: k

Output: Is there a set $F \subseteq A(T)$, such that $|F| \leq k$ and $T - F$ is H -immersion-free?

That this problem is fixed-parameter tractable is proved in [14]. Our main result states that for every fixed H , H -HITTING IMMERSIONS IN TOURNAMENTS admits a polynomial kernel, of degree dependent on H . Formally, we prove the following theorem.

► **Theorem 1.** *For every simple digraph H without isolated vertices there exists a constant c and an algorithm that given an instance (T, k) of H -HITTING IMMERSIONS IN TOURNAMENTS, runs in polynomial time and returns an equivalent instance (T', k) with $|T'| \leq c \cdot k^c$.*

We remark that when H is the directed triangle, H -HITTING IMMERSIONS IN TOURNAMENTS is equivalent to the FEEDBACK ARC SET IN TOURNAMENTS (FAST) problem. There is a sizeable literature on the parameterized complexity of FAST, see e.g. [1, 11, 14, 19], mostly due to the fact that it admits a subexponential parameterized algorithm with running time $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$. Kernelization procedures for FAST were investigated by Bessy et al. in [4], while kernelization of the dual problems of packing arc-disjoint triangles and packing arc-disjoint cycles in tournaments were recently studied by Bessy et al. in [3].

On a very high conceptual level, the proof of Theorem 1 follows the classic blueprint of protrusion-based kernelization, like in e.g. [12, 18]. That is, if (T, k) is a given instance of H -HITTING IMMERSIONS IN TOURNAMENTS, we perform the following steps.

- We may assume that the cutwidth of T is bounded polynomially in k , for otherwise in T one can find $k + 1$ arc-disjoint immersion models of H ; these witness a negative answer to the instance.
- Assuming that T is large – of size superpolynomial in k – but has cutwidth bounded polynomially in k , we may find in T a large *protrusion*. Here, a protrusion is an interval I in the vertex ordering σ witnessing small cutwidth such that σ restricted to I witnesses that $T[I]$ has constant cutwidth, and there is only a constant number of σ -backward arcs with one endpoint in I and the other outside of I . These are instantiations of the two desired properties of a protrusion: it has to have bounded width and communicate with the rest of the graph through a boundary of bounded size.
- We can replace the obtained protrusion with a strictly smaller one of the same “type”, thus obtaining a strictly smaller equivalent instance. Applying this strategy exhaustively eventually yields a kernel of polynomial size.

Compared to the previous works, the main difficulty is to tame the interaction between a protrusion and the remainder of the instance. Namely, this interaction is not restricted to a set of vertices or arcs of constant size: as we work with tournaments, every vertex of a protrusion will necessarily have an arc connecting it to every vertex outside of the protrusion. The idea is that all but a constant number of those arcs will be forward arcs in the fixed vertex ordering σ with bounded cutwidth. We call those well-behaved forward arcs *generic*, while the remaining constantly many backward arcs are *singular*. Understanding the interaction between a protrusion and the rest of the tournament as being governed by few singular arcs and a large number of well-behaved generic arcs is the crux of our approach.

In particular, while looking for a large replaceable protrusion, we have to be extremely careful when arguing about how such a protrusion may interact with optimum solutions. Here, a key step is to find several protrusions that appear consecutively in σ (recall that our protrusions are intervals in σ), have the same *type* (in the sense of admitting partial immersions of H), and such that their union is a protrusion of again the same type. This step is done using Simon Factorization, a tool commonly used in the theory of automata and formal languages. Simon Factorization was recently used a few times in structural graph theory [7, 23, 24], but we are not aware of any previous application in the context of kernelization.

The application of Simon Factorization is also the only step in the reasoning that causes the degree of the polynomial bounding the size of our kernel to depend on H . It is an interesting open question whether this can be improved, or in other words, whether there is a kernel of size at most $c \cdot k^d$, where c may depend on H but d does not. Judging by the results on hitting immersions in undirected graphs [18], we expect that this might be the case.

We remark that the sign \asymp denotes statements whose proofs are deferred to the full version of the paper.

2 Preliminaries

We use the standard terminology and notation for describing immersions in tournaments and for cutwidth of digraphs and of tournaments. This terminology and notation is borrowed mostly, and often in a verbatim form, from the work of Bożyk and Pilipczuk [8].

For a positive integer n , we denote $[n] := \{1, \dots, n\}$ and $[-n] = \{-1, \dots, -n\}$.

We use standard graph terminology and notation. All graphs considered in this paper are finite, simple (i.e. without self-loops or multiple arcs with same head and tail), and directed (i.e. are *digraphs*). For a digraph D , by $V(D)$ and $A(D)$ we denote the vertex set and the arc set of D , respectively. We denote

$$|D| := |V(D)| \quad \text{and} \quad \|D\| := |A(D)|.$$

For $X \subseteq V(D)$, the subgraph *induced* by X , denoted $D[X]$, comprises of the vertices of X and all the arcs of D with both endpoints in X . By $D - X$ we denote the digraph $D[V(D) \setminus X]$. Further, if F is a subset of arcs of D , then by $D - F$ we denote the digraph obtained from D by removing all the arcs of F . For $X, Y \subseteq V(D)$ we denote by $\vec{A}(X, Y)$ the set of all arcs $(u, v) \in A(D)$ such that $u \in X$ and $v \in Y$ and moreover $A(X, Y) := \vec{A}(X, Y) \cup \vec{A}(Y, X)$. For an arc $a = (u, v) \in A(D)$ we define $\text{tail}(a) := u$ and $\text{head}(a) := v$. For a directed (not necessarily simple) path P we denote by $\text{first}(P)$ and $\text{last}(P)$ the first and the last arcs on path P , respectively.

Tournaments. A simple digraph $T = (V, A)$ is called a *tournament* if for every pair of distinct vertices $u, v \in V$, either $(u, v) \in A$, or $(v, u) \in A$ (but not both). Alternatively, one can represent the tournament T by providing a pair $(\sigma, \overleftarrow{A}_\sigma(T))$, where $\sigma: V \rightarrow [|V|]$ is an *ordering* of the set V and $\overleftarrow{A}_\sigma(T)$ is the set of σ -backward arcs, that is,

$$\overleftarrow{A}_\sigma(T) := \{ (u, v) \in A \mid \sigma(u) > \sigma(v) \}.$$

All the remaining arcs are called σ -forward. If the choice of ordering σ is clear from the context, we will call the arcs simply *backward* or *forward*.

Cutwidth. Let $T = (V, A)$ be a tournament and σ be an ordering of V . For $\alpha, \beta \in \{0, 1, \dots, |V|\}$, $\alpha \leq \beta$, we define

$$\sigma(\alpha, \beta] := \{v \in V \mid \alpha < \sigma(v) \leq \beta\}.$$

Sets $\sigma(\alpha, \beta]$ as defined above will be called σ -intervals. The set

$$\text{cut}_\sigma[\alpha] = \{(u, v) \in A \mid \sigma(u) > \alpha \geq \sigma(v)\} \subseteq \overleftarrow{A}_\sigma(T)$$

is called the α -cut of σ . The *width* of the ordering σ is equal to $\max_{0 \leq \alpha \leq |V|} |\text{cut}[\alpha]|$, and the *cutwidth* of T , denoted $\text{ctw}(T)$, is the minimum width among all orderings of V .

It is perhaps a bit surprising that in tournaments, there is a very simple algorithm to compute an ordering of optimum width: just sort the vertices by outdegrees.

► **Lemma 2** (see [2, 25]). *Let T be a tournament and σ be an ordering of T satisfying the following for every pair of vertices u and v : if u appears before v in σ , then the outdegree of u is not smaller than the outdegree of v . Then the width of σ is equal to $\text{ctw}(T)$.*

If $I = \sigma(\alpha, \beta]$, then we denote

$$\partial^+(I) := \overrightarrow{A}(I, \sigma(0, \alpha]) \quad \text{and} \quad \partial^-(I) := \overrightarrow{A}(\sigma(\beta, |V|], I).$$

Note that $\partial^+(I) \subseteq \text{cut}_\sigma[\alpha]$ and $\partial^-(I) \subseteq \text{cut}_\sigma[\beta]$ and therefore $|\partial^+(I)| \leq c$ and $|\partial^-(I)| \leq c$, where c is the width of σ . These inclusions may be proper, as the arcs from the set $\widehat{\partial}(I) := \overrightarrow{A}(\sigma(\beta, |V|], \sigma(0, \alpha])$ contribute to the cuts but are not incident with I . We define $\partial(I) := \partial^+(I) \cup \partial^-(I)$ and call the elements of $\partial(I)$ *I-singular* (or simply *singular*) arcs. Moreover, we define

$$\Gamma^+(I) := \overrightarrow{A}(I, \sigma(\beta, |V|]), \quad \Gamma^-(I) := \overrightarrow{A}(\sigma(0, \alpha], I), \quad \text{and} \quad \Gamma(I) = \Gamma^+(I) \cup \Gamma^-(I),$$

and call the elements of $\Gamma(I)$ *I-generic* (or simply *generic*) arcs.

If $I' = V - I$ where $I = \sigma(\alpha, \beta]$, then we call the set I' a *co-interval* and define *I'-singular* and *I'-generic* arcs as follows

$$\partial^-(I') := \partial^+(I), \quad \partial^+(I') := \partial^-(I), \quad \partial(I') := \partial^+(I') \cup \partial^-(I') = \partial(I),$$

$$\Gamma^-(I') := \Gamma^+(I), \quad \Gamma^+(I') := \Gamma^-(I), \quad \Gamma(I') := \Gamma^-(I') \cup \Gamma^+(I') = \Gamma(I).$$

Immersion. A digraph \widehat{H} is an *immersion model* (or briefly a *copy*) of a digraph H if there exists a mapping ϕ , called an *immersion embedding*, such that:

- vertices of H are mapped to pairwise different vertices of \widehat{H} ;
- each arc $(u, v) \in A(H)$ is mapped to a directed path in \widehat{H} starting at $\phi(u)$ and ending at $\phi(v)$; and
- each arc of \widehat{H} belongs to exactly one of the paths $\{\phi(a) : a \in A(H)\}$.

If it does not lead to misunderstanding, we will sometimes slightly abuse the above notation by identifying ϕ and \widehat{H} and calling ϕ the immersion model of H .

Let H be a digraph. We say that a digraph G *contains H as an immersion* (or H can be *immersed* in G) if G has a subgraph that is an immersion model of H . Digraph G is called *H-immersion-free* (or *H-free* for brevity) if it does not contain H as an immersion.

We will use the following result of Fomin and Pilipczuk [14].

► **Theorem 3** (Theorem 7.3 of [14]). *Let T be a tournament which does not contain a digraph H as an immersion. Then $\text{ctw}(T) \in \mathcal{O}((|H| + \|H\|)^2)$.*

► **Corollary 4.** *For every digraph H there exists a constant c_H such that for every H -free tournament T , we have $\text{ctw}(T) \leq c_H$.*

Throughout this paper we fix a simple digraph H without isolated vertices and an integer $k \in \mathbb{N}$. For a tournament T , a set $F \subseteq A(T)$ is called a *solution* if $T - F$ is H -free. Moreover, F is an *optimal solution* if it is a solution of the smallest possible size. So (T, k) is a YES-instance of H -HITTING IMMERSIONS IN TOURNAMENTS if and only if there exists an optimal solution in T of size at most k .

Monoids and Simon factorization. Simon factorization was originally developed by Simon in [29] and the currently best bounds are due to Kufleitner [22]. See also the work of Bojańczyk [6] for a nice exposition; we mostly follow the notation from that source.

Let S be a finite monoid (i.e., a finite set equipped with an associative binary operation \cdot and a neutral element 1). An element $e \in S$ is called *idempotent* if $e \cdot e = e$. For a finite alphabet A , by A^* we denote the set of all finite words over A , and a *morphism* $\alpha: A^* \rightarrow S$ is a function satisfying $\alpha(\varepsilon) = 1$ (ε being the empty word) and $\alpha(w_1 w_2) = \alpha(w_1) \cdot \alpha(w_2)$ for every $w_1, w_2 \in A^*$. Note that a morphism is uniquely defined by the images of single symbols from A . The following lemma is a direct consequence of Simon Factorization.

► **Lemma 5.** *Let S be a finite monoid, A be a finite alphabet, and $\alpha: A^* \rightarrow S$ be a morphism. Suppose $w \in A^*$ is a word of length at least $\ell^{3|S|}$. Then there exists a subword w' of w and an idempotent $e \in S$ such that $w' = w_1 w_2 \dots w_\ell$, where $w_i \in A^*$ are nonempty subwords of w and*

$$\alpha(w_1) = \alpha(w_2) = \dots = \alpha(w_\ell) = e.$$

Note that in the setting of Lemma 5, given a word $w \in A^*$ of length $n \geq \ell^{3|S|}$, one can easily find w' and a suitable decomposition $w' = w_1 w_2 \dots w_\ell$ in time $\mathcal{O}(|S| \cdot n^3)$ assuming unit cost of operations in S . Indeed, one can guess e (by trying at most $|S|$ possibilities) and the first position of w' within w (by trying n possibilities), and then for every subword w'' starting at this position compute the longest possible decomposition of the form $w'' = w_1 w_2 \dots w_\ell$ such that $\alpha(w_1) = \dots = \alpha(w_\ell) = e$, if existent. The latter can be done by a standard left-to-right dynamic programming in time $\mathcal{O}(n^2)$.

3 Partial immersions

Our goal in this section is to extend the notion of an immersion to *partial immersions*. These will be used to understand possible behaviors of immersion models in a tournament T with respect to different intervals in an ordering of the vertex set of T . Let then $T = (V, A)$ be a tournament and let σ be an ordering of V . For now, fix a σ -interval $I := \sigma(\alpha, \beta]$.

Partial immersions.

► **Definition 6.** *A scattered path in I of size $q \geq 0$ is a sequence $\tilde{P} = (P_i)_{i=1}^q$ satisfying the following properties:*

- *for each $i \in [q]$, P_i is a directed (simple) path of length at least 1 consisting of arcs that belong to $A(T[I]) \cup \partial(I) \cup \Gamma(I)$;*
- *paths P_i for $i \in [q]$ are pairwise arc-disjoint;*
- *for every $i \in [q]$, $i \neq 1$, we have $\text{first}(P_i) \in \Gamma^-(I) \cup \partial^-(I)$;*
- *for every $i \in [q]$, $i \neq q$, we have $\text{last}(P_i) \in \Gamma^+(I) \cup \partial^+(I)$.*

Each term in the sequence $(P_i)_{i=1}^q$ will be called a piece of \tilde{P} . The set of arcs of all pieces of \tilde{P} is denoted $A(\tilde{P})$. If $\text{first}(P_i) \in \Gamma^-(I)$ and $\text{last}(P_i) \in \Gamma^+$, then the piece P_i is called generic.

Note that $\text{first}(P_1)$ is allowed to be an arc in the set $A(T[I]) \cup \Gamma^+(I) \cup \partial^+(I)$. If it is such, we call the vertex $\text{tail}(\text{first}(P_1)) \in I$ the *beginning* of \tilde{P} and denote it by $\text{start}(\tilde{P})$. Similarly, if $\text{last}(P_q) \in A(T[I]) \cup \Gamma^-(I) \cup \partial^-(I)$, then we call the vertex $\text{head}(\text{last}(P_q))$ the *end* of \tilde{P} and denote it by $\text{end}(\tilde{P})$. Note that the empty sequence is a scattered path of size 0. Also, a scattered path with only one piece, whose both beginning and end exist, is just a path in $T[I]$. By \mathcal{P}_I we denote the family of all scattered paths in I .

We say that a scattered path $\tilde{P} = (P_i)_{i=1}^q$ in I can be *shortened* to a scattered path \tilde{P}' (or that \tilde{P}' is a *shortening* of \tilde{P}) if:

- $\text{start}(\tilde{P}) = \text{start}(\tilde{P}')$ and $\text{end}(\tilde{P}) = \text{end}(\tilde{P}')$ (meaning either equal or simultaneously undefined);
- for each piece P_s of \tilde{P}' there exist indices $i_s^- \leq i_s^+$ such that $\text{tail}(\text{first}(P_s)) = \text{tail}(\text{first}(P_{i_s^-}))$ and $\text{head}(\text{last}(P_s)) = \text{head}(\text{last}(P_{i_s^+}))$; and
- whenever $s < s'$, we have $i_s^+ < i_{s'}^-$ and P_s appears before $P_{s'}$ in \tilde{P}' .

Intuitively, shortening of the path means removing some pieces and replacing several contiguous subsequences of the pieces with single pieces, keeping the tail of the beginning and the head of the end of the replaced subsequence. Note that in particular, some pieces of \tilde{P} can be simply omitted in \tilde{P}' (other than the initial and the terminal one).

► **Definition 7.** A partial immersion embedding of H in I (or shortly, a partial immersion in I) is a mapping $\phi: A(H) \rightarrow \mathcal{P}_I$ such that

- all scattered paths $\phi(a)$ for $a \in A(H)$ are pairwise arc-disjoint;
- if $\text{tail}(a) = \text{tail}(a')$ then $\text{start}(\phi(a))$ and $\text{start}(\phi(a'))$ are either equal, or simultaneously undefined;
- if $\text{start}(\phi(a))$ and $\text{start}(\phi(a'))$ are defined and equal, then $\text{tail}(a) = \text{tail}(a')$;
- if $\text{head}(a) = \text{head}(a')$ then $\text{end}(\phi(a))$ and $\text{end}(\phi(a'))$ are either equal, or simultaneously undefined;
- if $\text{end}(\phi(a))$ and $\text{end}(\phi(a'))$ are defined and equal, then $\text{head}(a) = \text{head}(a')$.

Intuitively, we can think of a partial immersion as of a “trace” which some immersion model \hat{H} of H in T leaves on the interval I . Some edges of H have images being paths in \hat{H} non-incident with I (these correspond to empty scattered paths in the partial immersion embedding). Some images of arcs of H come back and forth to I , intersecting with I along a non-empty scattered path (the ordering of paths on a single scattered path corresponds to the order of their appearance along the image of the respective arc of H). Finally, some arc images begin or end within I , which corresponds to the case when the beginning or the end of a scattered path is defined and is a vertex of I .

We call a partial immersion ϕ' in I a *shortening* of ϕ in I if for every $a \in A(H)$, the scattered path $\phi'(a)$ is a shortening of $\phi(a)$. We call ϕ *minimal* if there is no shortening of ϕ with at least one scattered path of strictly smaller size. Note that ϕ may be minimal even if some piece of some $\phi(a)$ can be replaced by a different single piece with equal first and last vertices. Shortening which does not decrease the size of any scattered path will be called *trivial*.

Note that each immersion model ϕ of H in T is a partial immersion in $V(T)$, in which all scattered paths $\phi(a)$, $a \in A(H)$, are paths in T beginning and ending at $\phi(\text{tail}(a))$ and $\phi(\text{head}(a))$, respectively. Moreover, each partial immersion ϕ in I gives rise to a natural partial immersion of H in $J \subseteq I$ in which all paths $\phi(a)$ where $a \in A(H)$ are “trimmed” to scattered paths consisting of precisely those arcs which are incident with J .

Formally, let I and J be σ -intervals such that $J \subseteq I$. If P is a path in I , then define the *trace* $P|_J$ of P on J to be the scattered path consisting of all arcs of P incident with J , arranged in the order of appearance along P . If $\tilde{P} = (P_i)_{i=1}^q$ is a scattered path in I , then

define the *trace* $\tilde{P}|_J$ of \tilde{P} on J to be the concatenation of scattered paths $P_i|_J$. The *trace* $\phi|_J$ of a partial immersion ϕ of H in I on J is defined by setting $\phi|_J(a) = (\phi(a))|_J$ for every $a \in A(H)$.

Consider any σ -intervals I_1, I_2 with the property that there exist $\alpha, \beta, \gamma \in \{0, 1, \dots, |V|\}$ such that $I_1 = \sigma(\alpha, \gamma]$ and $I_2 = \sigma(\gamma, \beta]$. We will call such a pair of intervals *consecutive*. Equivalently, two intervals are consecutive if their union $I = I_1 \cup I_2$ is a σ -interval as well. Let \tilde{P}_1 be a scattered path in I_1 and \tilde{P}_2 be a scattered path in I_2 . We say that \tilde{P}_1 and \tilde{P}_2 are *compatible* if

- $A(\tilde{P}_1) \cap A(I_1, I_2) = A(\tilde{P}_2) \cap A(I_1, I_2)$;
- the set of pieces whose arc set is $A(\tilde{P}_1) \cup A(\tilde{P}_2)$ can be ordered to form a scattered path \tilde{P} in I with the property that all pieces of \tilde{P}_i appear in \tilde{P} in the same order as they do in \tilde{P}_i , for $i = 1, 2$.

Every \tilde{P} described above will be called a *gluing* of \tilde{P}_1 and \tilde{P}_2 . Note that a gluing is not necessarily uniquely defined, which can be seen particularly well when $A(\tilde{P}_1) \cap A(I_1, I_2) = A(\tilde{P}_2) \cap A(I_1, I_2) = \emptyset$ – in this case the pieces of both paths can be “shuffled” in any way only keeping the order of pieces originating from the same path.

► **Observation 8.** *If \tilde{P}_1 is compatible with \tilde{P}_2 and \tilde{P}'_2 is a shortening of \tilde{P}_2 , then there exists a shortening \tilde{P}'_1 of \tilde{P}_1 such that \tilde{P}'_1 and \tilde{P}'_2 are compatible and every gluing of them is a shortening of some gluing of \tilde{P}_1 and \tilde{P}_2 .*

Proof. To construct \tilde{P}'_1 from \tilde{P}_1 it is enough to omit the pieces which do not share arcs with \tilde{P}'_2 . ◀

We will say that two partial immersions ϕ_1 in I_1 and ϕ_2 in I_2 are *compatible* if there exists a partial immersion ϕ in I such that $\phi_1 = \phi|_{I_1}$ and $\phi_2 = \phi|_{I_2}$, or – in other words – that for every $a \in A(H)$ the scattered path $\phi(a)$ is a gluing of $\phi_1(a)$ and $\phi_2(a)$. We will call every such ϕ a *gluing* of ϕ_1 and ϕ_2 . Note that gluing is not necessarily uniquely defined. Denote the set of all gluings of ϕ_1 and ϕ_2 by $\phi_1 \oplus \phi_2$.

► **Observation 9** (\times). *If $\phi \in \phi_1 \oplus \phi_2$ and ϕ is minimal, then ϕ_1 and ϕ_2 are minimal.*

The notions of a scattered path, partial immersion and trace can be naturally extended to co-intervals, by applying all definitions verbatim. If I is a σ -interval and $I' = V - I$ is the corresponding co-interval, then partial immersions ϕ_1 in I and ϕ_2 in I' are *compatible* if there exists an immersion ϕ in T such that $\phi_1 = \phi|_I$ and $\phi_2 = \phi|_{I'}$. Again, every such ϕ is called a *gluing* of ϕ_1 and ϕ_2 .

Types of intervals. The key ingredient of our analysis is a constant-size encoding of the set of possible “behaviors” of partial immersions in intervals.

A σ -interval I shall be called ℓ -*long* if $|I| \geq \ell$. Further, we shall call I c -*flat* if $|\partial^+(I)| \leq c$, $|\partial^-(I)| \leq c$, and σ restricted to $T[I]$ has width at most c .

Note that if $I = \sigma(\alpha, \beta]$ is $2r$ -long, then the intervals $I_r^- := \sigma(\alpha, \alpha+r]$ and $I_r^+ := \sigma(\beta-r, \beta]$ are disjoint. On the other hand, if I is c -flat, then we can color all backward arcs incident with I with at most $3c$ colors in such a way that each γ -cut of σ restricted to those arcs contains arcs of mutually different colors. This can be achieved e.g. by greedy coloring the γ -cuts for consecutive $\gamma = \alpha, \dots, \beta + 1$. Formally, there exists a function $\xi: \overline{A}_\sigma(T) \cap A(I, V) \rightarrow [3c]$ such that for every $\gamma \in [|V| - 1]$ and every two distinct arcs $a_1, a_2 \in \text{cut}_\sigma[\gamma] \cap A(I, V)$ we have $\xi(a_1) \neq \xi(a_2)$. In the following fix such a function.

► **Definition 10.** Let ϕ be a partial immersion in an interval I that is $2r$ -long and c -flat. For each $a \in A(H)$ we define the (r, c) -type $\tau^{(r,c)}(\phi(a))$ of the scattered path $\phi(a) = (P_i)_{i=1}^q$ as the following sequence of length $2q$:

$$(f_-(\text{first}(P_1)), f_+(\text{last}(P_1)), f_-(\text{first}(P_2)), f_+(\text{last}(P_2)), \dots, f_-(\text{first}(P_q)), f_+(\text{last}(P_q))),$$

where the functions $f_{\pm}: A(T[I]) \cup \partial(I) \cup \Gamma(I) \rightarrow [-3c] \cup [r] \cup \{X, H\}$ are defined as follows

$$f_-(a) = \begin{cases} -\xi(a) & \text{if } a \in \partial^-(I), \\ \sigma(\text{head}(a)) - \alpha & \text{if } a \in \Gamma^-(I) \text{ and } \text{head}(a) \in I_r^-, \\ X & \text{if } a \in \Gamma^-(I) \text{ and } \text{head}(a) \notin I_r^-, \\ H & \text{otherwise;} \end{cases}$$

$$f_+(a) = \begin{cases} -\xi(a) & \text{if } a \in \partial^+(I), \\ r + \sigma(\text{tail}(a)) - \beta & \text{if } a \in \Gamma^+(I) \text{ and } \text{tail}(a) \in I_r^+, \\ X & \text{if } a \in \Gamma^+(I) \text{ and } \text{tail}(a) \notin I_r^+, \\ H & \text{otherwise.} \end{cases}$$

Let S be the set of all terms of the sequences $(\tau^{(r,c)}(\phi(a)))_{a \in A(H)}$, where by term we mean a value with an assigned position (i.e. equal values in different sequences are considered different terms). The (r, c) -type of ϕ is the collection of types $\tau^{(r,c)}(\phi) = (\tau^{(r,c)}(\phi(a)))_{a \in A(H)}$ equipped with a pair of equivalence relations (R_-, R_+) on the set $S \cup [c]$ defined as follows.

- If a piece P_1 of $\phi(a_1)$ and a piece P_2 of $\phi(a_2)$ satisfy $\text{head}(\text{first}(P_1)) = \text{head}(\text{first}(P_2))$, then the corresponding terms in $\tau^{(r,c)}(\phi)$ (elements of the set $\{X\} \cup [r]$ with assigned positions in respective sequences) are in relation R_- .
- If a piece P of $\phi(a)$ is such that $\text{head}(\text{first}(P))$ is the tail of a singular arc of color $x \in [3c]$, then the corresponding term in $\tau^{(r,c)}(\phi)$ is in relation R_- with x .
- Analogously, if $\text{tail}(\text{last}(P_1)) = \text{tail}(\text{last}(P_2))$, then the terms $f_+(\text{last}(P_1))$ and $f_+(\text{last}(P_2))$ are in relation R_+ . And $x \in [3c]$ is in relation with all terms corresponding to tails of ends of paths which are simultaneously the head of the singular arc of color x .

Let us provide some intuition on what kind of information is stored in the type of ϕ defined above. First of all, the entire “singular interface” of this partial immersion is kept, i.e. in the type we remember precisely the singular arcs used to enter or exit I when traversing along each scattered path $\phi(a)$. Moreover, if we enter or exit I with a generic arc, we remember the precise vertex of entry/exit inside I , but only if it is close enough to the “border” of I (i.e. within the first or last r vertices in σ). Otherwise we remember the respective entry/exit as “generic”, which is marked by the marker X . Moreover, we keep the information about whether the scattered path begins or ends inside I – the marker H represents that a vertex of H is mapped under the partial immersion embedding to a vertex within I . Finally if the extreme (first or last) arcs of some pieces are generic and have the same first/last vertex in I , we remember this fact in the equivalence relations R_{\pm} . We shall need this information to be able to “glue” two partial immersions without using the same generic gluing arc for different pieces. The incidence with singular arcs is also stored to avoid a situation when one attempts a generic gluing along a singular arc. The reason for colors being stored as negative integers is purely technical – it ensures that $[r] \cap [-3c] = \emptyset$.

An (r, c) -type is any collection of sequences of even lengths over the set $[-3c] \cup [r] \cup \{X, H\}$ indexed by $A(H)$ and equipped with a pair of equivalence relations (R_-, R_+) on the union of the set of all terms of these sequences and $[3c]$. An I -admissible (r, c) -type is every type τ such that there exists a partial immersion ϕ in I such that $\tau = \tau^{(r,c)}(\phi)$. The size of a type is the sum of lengths of its sequences (i.e. it does not depend on the equivalence relations).

26:10 Polynomial Kernel for Immersion Hitting in Tournaments

Let γ_r be a function mapping each element from the set $[r]$ onto the single marker X , and identity otherwise. Intuitively, the function γ_r keeps only the information about generic nature of the end of a piece, and “forgets” about the closeness of this vertex to the boundary. We say that an (r, c) -type τ' is a *shortening* of an (r, c) -type τ if for every $a \in A(H)$ the sequence $\gamma(\tau'_a)$ is a subsequence of $\gamma(\tau_a)$ and the two sequences have the same first and last terms.

The following observation is a direct consequence of the definition of shortening of a partial immersion.

► **Observation 11.** *If a partial immersion ϕ' of (r, c) -type τ' is a shortening of a partial immersion ϕ of (r, c) -type τ , then τ' is a shortening of τ .*

► **Definition 12.** *An I -admissible (r, c) -type τ is called minimal (in I) if there is no I -admissible type τ' of strictly smaller size that would be a shortening of τ .*

► **Observation 13.** *Let ϕ be a partial immersion in I of (r, c) -type τ . Then ϕ is minimal if and only if τ is minimal in I .*

Proof. If ϕ is not minimal, then for any nontrivial shortening ϕ' of ϕ , $\tau^{(r,c)}(\phi')$ is a shortening of τ of strictly smaller size. Conversely, if τ is not minimal, then there exists an I -admissible type τ' of strictly smaller size. Every partial immersion ϕ' of type τ' is a nontrivial shortening of ϕ . ◀

We now observe that in a minimal partial immersion on an interval I , all scattered paths will be relatively small, that is, will visit I only a bounded number of times.

► **Lemma 14** (\times). *Suppose that $F \subseteq A(T)$ has the property that $|F| \leq f$, I is $4\|H\|(c+f+1)$ -long and c -flat, and a partial immersion ϕ in I is minimal and disjoint with F . Then for every $a \in A(H)$ the scattered path $\phi(a)$ has size at most $2c+3$.*

We call an (r, c) -type τ *short* if for every $a \in A(H)$ the length of $\tau(\phi(a))$ is at most $4c+6$.

► **Corollary 15** (\times). *For $r \geq 1$ we have the following:*

1. *If an interval I is $4\|H\|(r+c)$ -long and c -flat, and a partial immersion ϕ in I is minimal, then $\tau^{(r,c)}(\phi)$ is short.*
2. *For every pair of integers $r, c \in \mathbb{N}$ there is a constant $t(r, c)$ such that there are exactly $t(r, c)$ short (r, c) -types. In particular, for any interval I as above, there are at most $t(r, c)$ different I -admissible minimal (r, c) -types.*

Let I_1, I_2 be two consecutive c -flat, $2(r+c)$ -long σ -intervals and $I = I_1 \cup I_2$. We say that two (r, c) -types τ_1 of I_1 and τ_2 of I_2 are *compatible* if there exists a partial immersion ϕ in I such that $\phi|_{I_1}$ and $\phi|_{I_2}$ are compatible, $\phi|_{I_1}$ has type τ_1 , and $\phi|_{I_2}$ has type τ_2 .

The *gluing* of the types $\tau_1 \oplus \tau_2$ is defined as the set of all (r, c) -types of all such ϕ . The following lemma proves that this definition is correct, i.e. that types of two immersions store enough information to ensure the possibility of gluing them.

► **Lemma 16** (\times). *Let I_1, I_2 be two consecutive c -flat, $4\|H\|(r+c)$ -long σ -intervals and $I = I_1 \cup I_2$. If two (r, c) -types τ_1 of I_1 and τ_2 of I_2 are compatible, then for every partial immersion ϕ_1 in I_1 of type τ_1 and for every partial immersion ϕ_2 in I_2 of type τ_2 , the immersions ϕ_1 and ϕ_2 are compatible.*

Boundaried intervals and signatures. In the process of replacing protrusions we will need to consider intervals not as subsets of an ordered vertex set of a larger tournament, but as standalone structures which can be used to replace one another. We introduce the notion of an (r, c) -boundaried interval to enable such considerations.

► **Definition 17.** An (r, c) -boundaried interval is a digraph D on vertex set $V(D) = S^+ \cup I \cup S^-$ equipped with an ordering σ_I of I . Furthermore, we require the following:

- $|I| \geq 4\|H\|(r + c)$;
- $D[I]$ is a tournament;
- σ_I has width at most c ;
- $S^- \subseteq [3c] \times \{-\}$ and $S^+ \subseteq [3c] \times \{+\}$;
- each vertex of S^+ has only one incident arc and this arc belongs to the set $\vec{A}(I, S^+)$;
- each vertex of S^- has only one incident arc and this arc belongs to the set $\vec{A}(S^-, I)$.

The r -boundary of D is the pair of sets I^- and I^+ consisting of the first and the last r vertices of I in σ_I , respectively. For D defined above, we will shortly write $D = I \cup S^\pm$.

Note that this notion emulates a $4\|H\|(r + c)$ -long c -flat interval I in the following sense. Arcs whose heads are contained in S^+ correspond to $\partial^+(I)$, and arcs whose tails are contained in the set S^- correspond to $\partial^-(I)$. The names of the auxiliary vertices in S^\pm correspond to the ξ -colors of the respective backward arcs. The r -boundary consists of precisely those vertices whose generic entry or exit is remembered in the (r, c) -type of a partial immersion.

Formally, every $4\|H\|(r + c)$ -long c -flat σ -interval I in T can be uniquely encoded with an (r, c) -boundaried interval $D^{(r,c)}(I)$, whose structure resembles the structure of $T[I]$ and $\partial(I)$ as follows:

- the vertices and arcs of I are kept along with their ordering in T ;
- every singular arc $a \in \partial^\pm(I)$ is mapped to an arc joining $(\xi(a), \pm) \in S^\pm$ with the endpoint of a contained in I ;
- the projection of S^\pm onto the first coordinate is precisely $\{\xi(a) \mid a \in \partial^\pm(I)\}$.

The notion of a partial immersion can be naturally adjusted to the setting of boundaried intervals. The only difference is the lack of the “generic interface” i.e. there are no auxiliary edges in boundaries intervals used to emulate $\Gamma(I)$. These can be, however, emulated by storing the information from the type (marker X or number in $[r]$ if the generic arc is incident with the r -boundary, and the equivalence relations R_\pm) instead of the identity of particular generic arcs. Formally, a piece of a scattered path in (r, c) -boundaried interval can begin or end with an element in $\{X\} \cup [r]$ instead of a generic arc. In particular, this slightly modified variant of partial immersions can be equipped with precisely the same definition of admissible (r, c) -type as in the former case.

► **Definition 18.** An (r, c) -signature is a subset of the set of all short (r, c) -types. The (r, c) -signature $\Sigma^{(r,c)}(I)$ of a $4\|H\|(r + c)$ -long c -flat σ -interval I is the set of all I -admissible minimal (r, c) -types. The (r, c) -signature $\Sigma^{(r,c)}(D)$ of an (r, c) -boundaried interval $D = I \cup S^\pm$ is the set of all I -admissible minimal (r, c) -types.

The intuition behind this definition is that if I is appropriately long and flat, then the signature of I stores the information about all possible interactions of I with minimal partial immersions. Note that $\Sigma^{(r,c)}(D^{(r,c)}(I)) = \Sigma^{(r,c)}(I)$.

We say that two (r, c) -boundaried intervals $I \cup S^\pm$ and $I' \cup S'^\pm$ are *exchangeable* if they have equal (r, c) -signatures, $S^\pm = S'^\pm$ (both intervals use precisely the same colors on the boundary), and the incidence structure of r -boundaries of those intervals with backward arcs

26:12 Polynomial Kernel for Immersion Hitting in Tournaments

is the same, i.e. for every $i \in [r]$ the set of colors of singular arcs incident with both S^\mp and the i -th vertex of I^\pm is the same as analogously defined set of colors for i -th vertex of I'^\pm . Intuitively this means that in T we may replace the interval I with I' .

► **Corollary 19.** *For every pair of integers $r, c \in \mathbb{N}$ there is a constant $s(r, c)$ such that there are exactly $s(r, c)$ different (r, c) -signatures.*

Proof. We may set $s(r, c) = 2^{t(r, c)}$, where $t(r, c)$ is the constant provided by Corollary 15. ◀

For future discussion of algorithmic aspects, we will need the following observation.

► **Lemma 20** (\asymp). *Consider r and c fixed and let T , σ , and I be as in Definition 18. Then given T , σ , and I , the signature $\Sigma^{(r, c)}(I)$ can be computed in polynomial time.*

Let $\mathcal{S}^{(r, c)}$ be the set of all (r, c) -signatures; we have $|\mathcal{S}^{(r, c)}| = s(r, c)$, where $s(r, c)$ is the constant given by Corollary 19. Let $\mathcal{S}_\sigma^{(r, c)}$ be the set of those (r, c) -signatures which are equal to $\Sigma^{(r, c)}(I)$ for some σ -interval I , i.e. contain only I -admissible minimal (r, c) -types. Then $\mathcal{S}_\sigma^{(r, c)} \subseteq \mathcal{S}^{(r, c)}$, so $|\mathcal{S}_\sigma^{(r, c)}| \leq s(r, c)$. We argue that $\mathcal{S}_\sigma^{r, c}$ has a structure of a semigroup in the following sense.

► **Lemma 21** (\asymp). *Let I_1, I_2 be two $4\|H\|(r+c)$ -long c -flat σ -intervals such that $I = I_1 \cup I_2$ is a c -flat σ -interval. Then $\Sigma^{(r, c)}(I)$ is uniquely determined by $\Sigma^{(r, c)}(I_1)$ and $\Sigma^{(r, c)}(I_2)$.*

Lemma 21 implies that the set $\mathcal{S}_\sigma^{(r, c)} \cup \{0\}$ can be endowed with an associative binary product operation such that for every two consecutive intervals I_1, I_2 , the product of their signatures is the signature of their union $I_1 \cup I_2$. Formally, we set the product for all pairs of consecutive intervals as above; Lemma 21 ensures that this is well-defined. Next, for all pairs of elements $\tau_1, \tau_2 \in \mathcal{S}_\sigma^{r, c}$ for which their product is not yet defined, we set $\tau_1 \cdot \tau_2 = 0$. Also, we set $0 = 0 \cdot 0 = 0 \cdot \tau = \tau \cdot 0$ for all $\tau \in \mathcal{S}_\sigma^{(r, c)}$. In this way, $\mathcal{S}_\sigma^{(r, c)} \cup \{0\}$ becomes a monoid; the empty signature is the neutral element of multiplication.

By Lemma 5 we obtain the following.

► **Corollary 22** (\asymp). *Suppose I is a c -flat $4\|H\|(r+c)\ell^{3s(r, c)}$ -long σ -interval. Then there exists a sequence of consecutive $4\|H\|(r+c)$ -long c -flat σ -intervals $(I_i)_{i=1}^\ell$ whose (r, c) -signatures are equal and equal to the signature of their union. Moreover, given r, c, T, σ , and I , such a sequence can be found in polynomial time.*

4 Finding protrusions

In order to find an appropriately large subgraph of T which does not “affect” the behavior of T with respect to H -HITTING IMMERSIONS IN TOURNAMENTS, we roughly proceed as follows. First, we find a suitable ordering σ of $V(T)$ and an appropriately long interval X in σ such that X has a constant-size singular interface towards the remainder of T . Then, inside X , we find (again, an appropriately long) subinterval I of a very specific structure: I can be divided into $2k + 3$ subintervals with the same signatures as itself. This is where we use Simon Factorization through Corollary 22. In the next part we use this extra structure to prove that one of these subintervals can be replaced with a strictly smaller replacement in such a way that after the substitution, we obtain an equivalent instance of the problem.

We proceed to a formal implementation of this plan. The first lemma gives the ordering σ and the interval X .

► **Lemma 23** (\asymp). *Let T be a tournament with $\text{ctw}(T) \leq c$ and $|T| \geq (2c+1)(x+1)(k+1)$. If T contains at most k arc-disjoint immersion copies of H , then there exists an ordering σ of $V(T)$ and an H -free σ -interval X such that $|X| \geq x$ and X is c_H -flat with respect to σ .*

Moreover, given T, k, c, x as above, one can in polynomial time either conclude that T contains more than k arc-disjoint immersion copies of H , or find an ordering σ and an interval X satisfying the above properties.

In the remainder of this section let $x \geq 4\|H\|$, r, c be fixed positive integers. Moreover, let T be a tournament for which there exists an optimal solution of size at most k and let σ be an ordering of T . Finally let X be an H -free c -flat $x(3c+k+1)(2k+3)^{3s(r,c)}$ -long σ -interval. We assume that there is a coloring ξ mapping all σ -backward arcs incident to X to colors in $[3c]$ such that not two such arcs of the same color participate in the same σ -cut.

We may apply Corollary 22 to X to find a collection of $2k+3$ consecutive σ -intervals I_i with $|I_i| = x(3c+k+1)$ for all $i \in [2k+3]$ such that all I_i have equal (r, c) -signatures, and this common signature, call it Σ , is equal to the (r, c) -signature of their union I . Then I is an H -free c -flat $x(3c+k+1)(2k+3)$ -long σ -interval. That such I can be found in polynomial time (given r, c, x, T, X, σ , and ξ) follows from Corollary 22.

Now comes a key step in the proof: we argue that from the equality of types of I, I_1, \dots, I_{2k+3} it follows that every optimum solution will contain a bounded number of arcs incident with I .

► **Lemma 24** (\asymp). *For every optimal solution $F \subseteq A(T)$, we have $|F \cap A(I, V(T))| \leq 2c$.*

We define a digraph T° based on T and $I = I_1 \cup \dots \cup I_{2k+3}$ as follows: start with T , and

- remove all vertices of I_2 ;
- for every arc $a \in \partial^+(I_2)$, replace a with an arc with the same head as a and tail in a fresh vertex $s_{\xi(a)}^+$;
- for every arc $a \in \partial^-(I_2)$, replace a with an arc with the same tail as a and head in a fresh vertex $s_{\xi(a)}^-$.

We call the constructed graph a *c -boundaried co-interval*. The intuition of this construction is as follows. We pinch off one of the $2k+3$ intervals and keep the singular arc interface in a fashion similar as in (r, c) -boundaried intervals. The only difference is that we do not keep track of the r -boundary vertices.

Now we can define the *gluing* of T° with an (r, c) -boundaried interval $B = I \cup S^\pm$ with signature Σ , simply by identifying the singular arcs of the same color (note that different vertices from S^\pm can be therefore mapped to the same vertex) and completing the obtained structure to a tournament by making all missing arcs generic. Note that in order for this to be well-defined, we need to require that the sets of colors of the singular arcs in T° and in B are identical – if it is so, we will say that T° and B are *compatible*. Also, note that we require that the signature of B is Σ : that is, the possible types of partial immersions present in B are exactly the same as in the substituted interval I_2 .

Denote by $T^\circ \oplus B$ the tournament obtained from gluing T° and B . Note that in this tournament we have naturally defined ordering of vertices: in T° it is inherited from the ordering σ of T and within B it is inherited from the ordering σ_I of the boundaried interval. Finally all the vertices of the substituted interval appear in the ordering between the two interval parts (prefix and suffix) of the co-interval. The following observation is obvious.

► **Observation 25.** *If two exchangable (r, c) -boundaried intervals $B = I \cup S^\pm$ and $B' = I' \cup S^\pm$ are compatible with T° , then the (r, c) -signatures of I in $T^\circ \oplus B$ and I' in $T^\circ \oplus B'$ are equal.*

26:14 Polynomial Kernel for Immersion Hitting in Tournaments

We now observe, by inspecting the proof of Lemma 24, that if in I we replace one of its subintervals with an exchangeable interval, then the conclusion of Lemma 24 – that the modified I' will still have constant incidence with every optimal solution in T – will still hold. Let us summarize this section with putting together these observations and recalling all needed assumptions.

► **Corollary 26** (\asymp). *Suppose that $x \geq 4\|H\|$, r, c are fixed positive integers, T is a tournament of for which there exists an optimal solution of size at most k and σ is an ordering of T . Suppose further that X is an H -free c -flat $x(3c + k + 1)(2k + 3)^{3s(r,c)}$ -long σ -interval with all incident σ -backward arcs colored according to ξ with colors $[3c]$ so that no two arcs of the same color participate in the same σ -cut.*

Then there exists an (r, c) -signature Σ , a c -boundaried co-interval T° of this signature, and an (r, c) -boundaried interval $B = I \cup S^\pm$ such that $T = T^\circ \oplus B$ and moreover for every $B' = I' \cup S'^\pm$ exchangeable with B and for every optimal solution $F \subseteq A(T')$ where $T' = T^\circ \oplus B'$ we have: $|F \cap A(I', T')| \leq 2c$. Moreover, given x, r, c, T, σ , and X , such Σ, T° , and B can be computed in polynomial time.

5 Replacing protrusions

In the entire section we fix $c := c_H$, where c_H is the constant from Corollary 4, and $r := 6\|H\|c$. Moreover we assume that $x \geq 4\|H\|$; the precise value of x will be determined later.

► **Definition 27.** *Protrusion is any (r, c) -boundaried interval $X = I \cup S^\pm$ which is H -free and $x(3c + k + 1)$ -long. For brevity we will refer to X as to I . The set $\Sigma^{(r,c)}(X)$ is the signature of the protrusion.*

Let T be a tournament equipped with a vertex ordering σ and let I be an H -free interval and such that $T = T^\circ \oplus X$, where X is a protrusion of signature Σ . Let $I \subseteq V(T)$ be the interval defined by the protrusion. Fix the coloring ξ of σ -backward arcs incident with I .

Recall that from Corollary 26 follows that for every (r, c) -boundaried co-interval T° compatible with X if $T^\circ \oplus X$ admits an optimal solution F of size not greater than k , then there are at most $2c$ arcs in F incident with X .

For every protrusion $X = I \cup S^\pm$ define a function $f_X: 2^{\mathcal{S}^{(r,c)}} \rightarrow \{0, 1, 2, \dots, 2c\} \cup \{\infty\}$ as follows: $f_X(S)$ is the minimum number of arcs in $A(I, I)$ needed to hit all partial immersions in I whose signatures belong to S , or ∞ if this number is greater than $2c$.

We introduce an equivalence relation \sim on the set of all protrusions. Let $X = I \cup S^\pm$, $X' = I' \cup S'^\pm$. We say that $X \sim X'$ if:

- $S^\pm = S'^\pm$;
- $\Sigma^{(r,c)}(X) = \Sigma^{(r,c)}(X')$; and
- $f_X(S) = f_{X'}(S)$ for every $S \subseteq \mathcal{S}^{(r,c)}$.

Note that the number of equivalence classes of \sim is finite and bounded by a constant depending only on H . This means that if in each class we pick a representative with the minimal number of vertices (call each such element a *small* protrusion), then all small protrusions will have size bounded from above uniformly by a constant s_H depending on the digraph H only.

Same arguments as in the proof of Lemma 20 give the following.

► **Lemma 28.** *Given protrusions X and X' it can be decided in polynomial time whether $X \sim X'$.*

We now argue that equivalent protrusions are replaceable.

► **Lemma 29** (\asymp). *Suppose that $T = T^\circ \oplus X$ is a tournament satisfying the conclusion of Corollary 26, where X is a boundaried (r, c) -interval of signature Σ and T° is a c -boundaried co-interval which is compatible with X .*

Then for every X' such that $X \sim X'$, the optimal solution in $T^\circ \oplus X$ is of size not greater than k if and only if the optimal solution in $T^\circ \oplus X'$ is of size not greater than k .

We are now set up with all tools needed to prove our main theorem.

Proof of Theorem 1. We prove that provided $|T| > C \cdot k^C$, where the constant C will be defined later, one can compute an instance (T', k) equivalent to (T, k) and satisfying $|T'| < |T|$. The conclusion will follow from applying such reduction (at most) $|T|$ times.

First of all note that from Theorem 3 for a digraph being a disjoint union of k exemplars of H , we conclude that if T does not contain k arc-disjoint immersion copies of H , then $\text{ctw}(T) \leq c_0 k^2$ for some constant c_0 (depending on H). In particular, it follows that if $\text{ctw}(T) > k^2 c_0$ (which can be established in polynomial time using Lemma 2), then T is a NO-instance. So from now on we may assume that $\text{ctw}(T) \leq c_0 k^2$.

Let $c = c_H$, $r = 6\|H\|c$, $x' = \max\{4\|H\|, s_H + 1\}$ and $x = x'(3c + k + 1)(2k + 3)^{3s(r,c)}$, where $s(r, c)$ is defined in Corollary 19. Let C be a constant satisfying $Ck^C \geq (2k^2 c_0 + 1)(x + 1)(k + 1)$, e.g. $C = \max\{3s(r, c) + 4, 5^{3s(r,c)} \cdot 3c_0 \cdot 4x' \cdot (6c + 2)\}$.

Suppose that T is a tournament satisfying $\text{ctw}(T) \leq k^2 c_0$ and $|T| > Ck^C$. Applying Lemma 23, we either conclude that T admits more than k arc-disjoint copies of H (so (T, k) is a NO-instance), or find an ordering σ of $V(T)$ and an H -free c -flat x -long σ -interval J . Both conclusions can be effectively gained in polynomial time.

In the latter case, we may use Corollary 22 in a manner described in Section 4 to find in J an H -free c -flat $x'(3c + k + 1)(2k + 3)$ -long σ -interval I of (r, c) -signature Σ , which can be decomposed to $2k + 3$ consecutive $x'(3c + k + 1)$ -long σ -intervals I_i , each of (r, c) -signature Σ . Both I and Σ are found in polynomial time.

Let $T = T^\circ \oplus X$ be the decomposition where T° is a c -boundaried co-interval and $X = (I_2 \cup S^\pm, \Sigma)$ is a protrusion corresponding to I_2 . Clearly, X is compatible with T° . Using Lemma 28 we may check in polynomial time all small protrusions to find one X' such that $X' \sim X$. Let us define $T' = T^\circ \oplus X'$.

By Lemma 29 we conclude that (T', k) is an instance of H -HITTING IMMERSIONS IN TOURNAMENTS equivalent to (T, k) . Moreover as $|X'| \leq s_H < |X|$, we have that $|T'| < |T|$. ◀

A Systematic Study of Isomorphism Invariants of Finite Groups via the Weisfeiler-Leman Dimension

Jendrik Brachter

Pascal Schweitzer  

TU Darmstadt, Germany

Abstract

We investigate the relationship between various isomorphism invariants for finite groups. Specifically, we use the Weisfeiler-Leman dimension (WL) to characterize, compare and quantify the effectiveness and complexity of invariants for group isomorphism.

It turns out that a surprising number of invariants and characteristic subgroups that are classic to group theory can be detected and identified by a low dimensional Weisfeiler-Leman algorithm. These include the center, the inner automorphism group, the commutator subgroup and the derived series, the abelian radical, the solvable radical, the Fitting group and π -radicals. A low dimensional WL-algorithm additionally determines the isomorphism type of the socle as well as the factors in the derived series and the upper and lower central series.

We also analyze the behavior of the WL-algorithm for group extensions and prove that a low dimensional WL-algorithm determines the isomorphism types of the composition factors of a group.

Finally we develop a new tool to define a canonical maximal central decomposition for groups. This allows us to show that the Weisfeiler-Leman dimension of a group is at most one larger than the dimensions of its direct indecomposable factors. In other words the Weisfeiler-Leman dimension increases by at most 1 when taking direct products.

1 Introduction

Tasks of classifying finite groups up to isomorphism and generating particular classes of finite groups are fundamental and recurring themes in computational group theory. Yet, in particular the computational complexity of such problems remains most illusive to date.

For example, for most orders up to 20.000 the number of non-isomorphic finite groups has been computed and the groups have been exhaustively generated [13]. But there are currently 38 notoriously difficult, exceptional cases, for which this information is beyond our current means (see [13]). The varying difficulty across different orders is in part caused by the erratic fluctuation of the number of isomorphism classes of finite groups as the order increases. This number appears to be closely linked to the multiplicities of the prime factors of the respective order, but even estimating the number of groups of a given order is non-trivial.

Generation tasks for classes of groups have a long tradition dating back to Cayley [7]. Nowadays, there is extensive work on generating particular classes of groups. For example there are practically efficient algorithms for the generation of finite nilpotent or finite solvable groups [12]. However, the algorithms come without efficient running time guarantees.

One of the difficulties for a complexity analysis stems from the group isomorphism problem. Indeed, the group isomorphism problem for finite groups stays among the few standard tasks in computational group theory with uncertain complexity. In principle, we desire algorithms with an efficient worst case running time measured in the number of generators through which the groups are given. However, we do not even have algorithms with an efficient worst case running time when measured in the order of the group. In fact the only improvement for the worst case complexity over Tarjan's classic $n^{\log(n)+O(1)}$ algorithm are $n^{\frac{1}{c} \cdot \log(n)+O(1)}$ algorithms with a small constant c depending on the model of computation (randomization, quantum computing etc.) [21, 23, 24]. There is however a nearly-linear time algorithm that solves group isomorphism for most orders [11].

A closely related problem is that of computing isomorphism invariants to distinguish groups. Efficiently computable complete invariants are sufficient for general isomorphism testing. However, we do not know efficiently computable complete invariants even for very special cases, such as nilpotent p -groups of class 2. Partial invariants only give incomplete isomorphism tests, but they still find application in generation tasks allowing for heuristic fast pruning [13]. Given the long history of (algorithmic) group theory, there is an abundance of partial invariants.

Generally the techniques involved in generation and isomorphism computations exploit the existence of various characteristic subgroups classic to group theory. As outlined in [13], these include exploiting the Frattini subgroup $\Phi(G)$ [3], the exponent- p -central series [22], characteristic series [25] and similar.

Overall, many of the techniques currently in use are ad-hoc, focused on practical performance, and do not lead to efficient worst case upper bounds for the complexity of the algorithmic problems. As a consequence, the general picture for finite groups is somewhat chaotic. There is often no structured way of comparing or combining invariants for group isomorphism. E.g., two given invariants may be incomparable in their distinguishing power, making it unclear which invariant to use. Also the required time to evaluate an invariant may be difficult to estimate and can depend significantly on the input group. Even when we are given a class of efficiently computable invariants, it will generally be unclear which invariants to choose or how to efficiently combine their evaluation algorithmically.

In Summary, we lack the formal means to characterize, compare, or quantify the effectiveness and complexity of invariants for group isomorphism. We therefore propose a systematic study of computationally tractable invariants for finite groups.

For inspiration on how to systematize such a study, we turn to algorithmic finite model theory and specifically descriptive complexity theory. This allows us to characterize the complexity of an invariant by considering a formula within a logic that captures the invariant. A natural choice for a logic from which to choose the formulas is the powerful fixed point logic with counting. Not only can this logic express all polynomial time computable languages on ordered structures [17, 26], but in the context of graphs it has also proven to be an effective tool in comparing invariants (see [20]). As a measure for the complexity of an invariant we can then use the number of variables required to express the invariant in fixed point logic with counting. Crucially there is a corresponding algorithm, the k -dimensional Weisfeiler-Leman algorithm (WL-refinement, WL), that (implicitly) simultaneously evaluates all invariants that are expressible by formulas requiring at most $k + 1$ variables in polynomial time¹.

¹ For groups there are actually two natural, closely related versions of the logic and of the algorithm,

Thus, to enable a quantification and comparison of the complexity of invariants we suggest the Weisfeiler-Leman algorithm. More specifically we suggest to use the Weisfeiler-Leman dimension, which determines how many variables are required to express a given invariant as a formula. This gives us a natural and robust framework for studying group invariants. In fact, the k -dimensional Weisfeiler-Leman algorithm is universal for all invariants of the corresponding dimension, resolving the issue of how to combine invariants. With this approach we also include an abundance of invariants that have not been considered before. However, it is a priori not clear at all that commonly used invariants can even be captured by the framework, i.e., that they even have bounded WL-dimension.

Contribution. The first contribution of this paper is to show that a surprising number of isomorphism invariants and subgroups that are classic to group theory can be detected and identified by a low dimensional Weisfeiler-Leman algorithm.

Specifically, we show first that for a small value of k , groups not distinguished by k -WL_{II} have centers ($k \geq 2$), inner automorphism groups ($k \geq 4$), derived series ($k \geq 3$), abelian radicals ($k \geq 3$), solvable radicals ($k \geq 2$), Fitting groups ($k \geq 3$) and π -radicals ($k \geq 3$) that are indistinguishable by k -WL_{II}. They also have isomorphic socles ($k \geq 5$), stepwise isomorphic factors in the derived series ($k \geq 4$), upper central series ($k \geq 4$), and lower central series ($k \geq 4$). Our techniques regarding characteristic subgroups are fairly general. We thus expect them to be applicable to a large variety of other isomorphism invariants. In particular they should facilitate the analysis of combinations of invariants one might be interested in (such as the Fitting series or the hypercenter).

Beyond these characteristic subgroups, in our second contribution we show that composition factors are implicitly computed by a Weisfeiler-Leman algorithm of bounded dimension.

► **Theorem 1.1.** *If $k \geq 5$ and G is indistinguishable from H via k -WL_I, then G and H have the same (isomorphism types of) composition factors (with multiplicities).*

The theorem shows that the WL-algorithm, which is a purely combinatorial algorithm, can compute group theoretic invariants that do not even appear as a canonical subset of the group. In particular, the composition factors cannot be localized within the group, and at first sight it might not be clear that WL grasps quotient groups.

Our third contribution, having the most technical proof and building on our other results, regards direct products of groups. Here we consider the decomposition of a group into direct factors. We show that direct products indistinguishable by k -WL must arise from factors that are indistinguishable by $(k + 1)$ -WL.

► **Theorem 1.2.** *Let $G = G_1 \times \cdots \times G_d$ be a direct product and $k \geq 5$. If G and H are not distinguished by k -WL_{II} then there are direct factors $H_i \leq H$ such that $H = H_1 \times \cdots \times H_d$ and such that for all i the groups G_i and H_i are not distinguished by $(k - 1)$ -WL_{II}.*

In other words, the Weisfeiler-Leman dimension increases by at most 1 when taking direct products. The main difficulty here is that decompositions into direct products are not unique, and thus not definable. These complications arise mainly due to central elements. However we manage to define a canonical maximal central decomposition, that is generally finer than a decomposition into direct factors. We then show that this canonical decomposition is implicitly computed by the WL-algorithm.

k -WL_I and k -WL_{II}, see Section 3.

One way of interpreting our results is that the Weisfeiler-Leman algorithm comprises a unified way of computing all the mentioned invariants and characteristics simultaneously. The dimension can therefore be used to compare the complexity of invariants.

Techniques. To show the various results on characteristic subgroups, we prove a general result on group expressions. It essentially shows that subsets that can be defined by equation systems can be detected by k -WL (see Lemma 4.3).

The result on composition factors involves a technique that relates k -WL distinguishability of groups to detectable normal subgroups and detectable quotients (Theorem 4.8).

To deal with direct products, we extend the technique to simultaneously relate chains of subgroups in two indistinguishable groups (Lemma 4.9). Here we exploit well-known connections of pebble games to Weisfeiler-Leman algorithms. However, the main difficulty regarding our result on decompositions into direct factors is that such decompositions are not unique. In fact in general, a group element cannot be assigned to a direct factor in a well defined sense, making it impossible for WL to detect direct factors. For this purpose we develop a new technical tool, component-wise filtrations (Definition 6.8), which compensate for the non-uniqueness to extract at least the isomorphism type of the direct factors (Lemma 6.10). We also exploit the non-commuting graph of the group and show that certain subsets, which we call non-abelian components, can be detected by k -WL (Lemma 6.14). These non-abelian components lead to a WL-definable maximal central decomposition of every finite group.

Outline. Section 2 provides preliminaries. Section 3 treats WL-refinement in the context of colored groups. In Section 4, we show that invariants generated via WL-refinement fulfill group theoretic closure properties. Section 5 is an extensive collection of specific structure properties and invariants which Weisfeiler-Leman algorithms detect in finite groups. Finally, in Section 6 we investigate the ability of WL-refinement to detect direct product decompositions, building on the results of the previous sections. Throughout the paper various lemmas have been condensed and proofs are omitted. Attached is a full version of the paper (sections agree but the sections are expanded and numbers may disagree.).

Further related work. We should point out that there are various results in the literature on decomposing groups into indecomposable direct factors for various input models of groups. For example there is a polynomial time algorithm to decompose permutation groups into direct products [28]. Finally, there is a recent algorithm that finds direct product decompositions of permutation groups with factors having disjoint support [8]. There is also a polynomial time algorithm that computes direct factors efficiently for groups given by multiplication table [19]. Aspects of this algorithm are related to arguments we use for studying the behavior of WL on direct products (see the beginning of Section 6 for a discussion).

Regarding group isomorphism problems, for isomorphism of Abelian groups a linear time algorithm is known [18] and there are near linear time algorithms for some classes of non-abelian groups (e.g, [10]). Recent directions relate group isomorphism to tensor problems [15]. The Weisfeiler-Leman algorithm has also been incorporated as a subroutine within other sophisticated group isomorphism algorithms [6].

Regarding Weisfeiler-Leman algorithms, the literature is somewhat limited when it comes to groups [4, 6] but quite extensive when it comes to graphs. In [2], for example the authors investigate some graph invariants that are captured by the Weisfeiler-Leman algorithm. We refer to [20] for an introduction and extensive overview over recent results for WL on graphs.

2 Preliminaries

Sets & Partitions. We denote multisets as $\{\{\dots\}\}$. Given disjoint sets M and N , their union is $M \uplus N$. The m -th Cartesian power of M is $M^{(m)}$.

Graphs. We use $V(\Gamma)$ and $E(\Gamma)$ to refer to the vertices or edges of a graph Γ . For a subset $S \subseteq V(\Gamma)$, let $\Gamma[S]$ denote the subgraph induced by the set S .

Groups. Groups are assumed to be finite. The symmetric group on m symbols is denoted by S_m . The order of a group element $g \in G$ is the order of the group generated by g , i.e., $|g| := |\langle g \rangle|$. Given a finite set of primes π , a π -group is a group whose order is only divisible by primes in π . A group element is called a π -element if it generates a π -group. For any $d \in \mathbb{Z}$, set $(G)^d := \langle \{g^d \mid g \in G\} \rangle$ in contrast to the d -fold direct power G^d . Given $g, h \in G$, we define the commutator $[g, h] := ghg^{-1}h^{-1}$. Conjugation is denoted by $g^h := hgh^{-1}$. If $M, N \subseteq G$ we set $[M, N] := \langle [m, n] \mid m \in M, n \in N \rangle$ and we write $G' := [G, G]$.

3 Colored Groups & Weisfeiler-Leman Algorithms

We recapitulate various notions regarding WL-algorithms on groups. For WL on graphs we refer to [20]. For uncolored groups, versions of WL were defined in [4]. For our purpose, we need to generalize the concepts to the setting of colored groups. Let us point out that in the case of graphs, colors can be replaced by gadget constructions to obtain uncolored graphs while maintaining the graph's combinatorial properties. However, for groups it is unclear how to do this. Nevertheless, we can still use colors to restrict the set of possible automorphisms.

3.1 Colorings on Finite Groups

Given a natural number k and a finite group G , a (k) -coloring (over G) is just a map $\gamma : G^{(k)} \rightarrow \mathcal{C}$ where \mathcal{C} denotes some finite set of colors. A k -coloring γ partitions $G^{(k)}$ into color classes. We refer to 1-colorings as *element-colorings*.

The color set \mathcal{C} is often omitted. Considering two natural numbers $m < k$, a k -coloring $\gamma : G^{(k)} \rightarrow \mathcal{C}$ induces an m -coloring $\gamma^{(m)} : G^{(m)} \rightarrow \mathcal{C}$ via $\gamma^{(m)}((g_1, \dots, g_m)) := \gamma((g_1, \dots, g_m, 1, \dots, 1))$. To simplify notation, we may write γ again instead of $\gamma^{(m)}$ and instead of $\gamma^{(1)}$ we use $\gamma^{(G)}$ to emphasize that the coloring is pulled back to group elements.

► **Definition 3.1.** A colored group is a group G together with an element-coloring γ over G . We say $M \subseteq G$ is γ -induced if $\gamma(M) \cap \gamma(G \setminus M) = \emptyset$ holds, i.e., M is a union of γ -color classes. Colored groups (G, γ_G) and (H, γ_H) are isomorphic if there is a group isomorphism $\varphi : G \rightarrow H$ that respects colors, i.e., $\gamma_H \circ \varphi = \gamma_G$. We set $\text{Aut}_{\gamma_G}(G) := \{\varphi \in \text{Aut}(G) \mid \gamma_G \circ \varphi = \gamma_G\}$.

3.2 Weisfeiler-Leman Refinement on Colored Groups

In [4], three versions of Weisfeiler-Leman algorithms on groups were defined. For us it is sufficient to consider two of these versions. The relevant definitions and results are discussed below. They are essentially taken from [4], but we added colorings.

For $k \geq 2$ we devise a *Weisfeiler-Leman algorithm of dimension k (k -WL)* that takes as input a colored group (G, γ) and computes an $\text{Aut}_{\gamma}(G)$ -invariant coloring on $G^{(k)}$. The algorithm computes an initial coloring from isomorphism invariant properties of k -tuples and then iteratively refines color classes until the process stabilizes. The *stable colorings* arising from k -WL provide (possibly incomplete) polynomial-time non-isomorphism tests.

Version I (k -WL_I). The initial coloring $\chi_{\gamma,0}^{I,k}$ is defined via the group's multiplication relation while also taking into account element colors. Two tuples $\bar{g} := (g_1, \dots, g_k)$ and $\bar{h} := (h_1, \dots, h_k)$ obtain the same initial color if and only if for all indices i, j , and m between 1 and k it holds $\gamma(g_i) = \gamma(h_i)$, $g_i = g_j \iff h_i = h_j$, and $g_i g_j = g_m \iff h_i h_j = h_m$. The subsequent refinements are defined iteratively via $\chi_{\gamma,i+1}^{I,k}(\bar{g}) := \left(\chi_{\gamma,i}^{I,k}(\bar{g}), \mathcal{M}(\bar{g}) \right)$. Here, $\mathcal{M}(\bar{g})$ is the multiset of k -tuples of colors given by $\mathcal{M}(\bar{g}) := \{ \{ \chi_{\gamma,i}^{I,k}(\bar{g}_{1 \leftarrow x}), \dots, \chi_{\gamma,i}^{I,k}(\bar{g}_{k \leftarrow x}) \} \mid x \in G \}$, where $\bar{g}_{j \leftarrow x}$ is obtained by replacing the j -th entry of \bar{g} by x .

Version II (k -WL_{II}). The initial coloring $\chi_{\gamma,0}^{II,k}$ is defined in terms of *colored, ordered isomorphism* of tuples. Thus, $\bar{g} = (g_1, \dots, g_k)$ and $\bar{h} = (h_1, \dots, h_k)$ obtain the same initial color if and only if there exists an isomorphism of colored subgroups $\varphi : \langle \bar{g} \rangle \rightarrow \langle \bar{h} \rangle$ such that $\varphi(g_i) = h_i$ for all i . The refinement step is unchanged from Version I.

For finite G there is a smallest i such that $\chi_{\gamma,i}^{I,k}$ and $\chi_{\gamma,i+1}^{I,k}$ induce the same color class partition on $G^{(k)}$. At this point color classes become stable and we obtain the *stable coloring* $\chi_{\gamma}^{I,k} := \chi_{\gamma,i}^{I,k}$. Define $\chi_{\gamma}^{II,k}$ analogously. For uncolored groups write $\chi_G^{I,k}$ and $\chi_G^{II,k}$, respectively.

By definition, the initial colorings are invariant under isomorphisms that respect γ . This property then holds for the iterated colorings as well. In particular, whenever (G, γ_G) and (H, γ_H) are isomorphic as colored groups, there is a bijection $f : G^{(k)} \rightarrow H^{(k)}$ such that $\chi_{\gamma_G}^{I,k} = \chi_{\gamma_H}^{I,k} \circ f$ (and the same holds for Version II). So we obtain a non-isomorphism test by comparing stable colorings computed by k -WL_I or k -WL_{II} as follows.

► **Definition 3.2.** Let (G, γ_G) and (H, γ_H) be colored groups. We say G is distinguished from H by k -WL_I if there is no bijection $f : G^{(k)} \rightarrow H^{(k)}$ with $\chi_{\gamma_G}^{I,k} = \chi_{\gamma_H}^{I,k} \circ f$. We say k -WL_I identifies G if it distinguishes G from all other (non-isomorphic) groups. We write $G \equiv_k^1 H$ to indicate that G and H are not distinguished by k -WL_I. Furthermore, for $m \leq k$, tuples of group elements $\bar{g} \in G^{(m)}$ and $\bar{h} \in H^{(m)}$ are distinguished by k -WL_I if they obtain different colors in the respective induced m -colorings $(\chi_{\gamma_G}^{I,k})^{(m)}$ and $(\chi_{\gamma_H}^{I,k})^{(m)}$. All definitions also apply to Version II in the obvious way.

The different versions of WL on groups are closely related: in particular, $(k+1)$ -WL_I subsumes k -WL_{II}. For the colored versions this is briefly discussed in Lemma 3.4 below.

Finally, we note that in [4], a run time bound of $\mathcal{O}(|G|^{k+1} \log(|G|))$ is given for both versions of k -WL to compute the stable coloring on $G^{(k)}$. The same bound applies to colored groups. In particular, the initial coloring of k -WL_{II} is efficiently computable, since we only have to compute isomorphism types of k -generated subgroups *relative* to a fixed and ordered generating set of size k .

3.3 Bijective k -Pebble Games

As with graphs and uncolored groups, WL-algorithms on colored groups can be characterized via pebble games. For details we refer to the full version (contained in the appendix).

► **Lemma 3.3** (see [4, Theorem 3.2]). Let $J \in \{I, II\}$ and $k \geq 2$. Consider colored groups (G, γ_G) and (H, γ_H) with $\bar{g} \in G^{(k)}$ and $\bar{h} \in H^{(k)}$. Then $\chi_{\gamma_G}^{J,k}(\bar{g}) = \chi_{\gamma_H}^{J,k}(\bar{h})$ if and only if Spoiler has a winning strategy in the configuration $[(g_1, \dots, g_k, \perp), (h_1, \dots, h_k, \perp)]$ in the $(k+1)$ -pebble game (Version J).

In [4] (see [5, Section 3]), relationships for the different versions of WL for uncolored groups are discussed, for the convenience of the reader we sketch the corresponding statement for colored groups here.

► **Lemma 3.4.** *Let (G, γ_G) and (H, γ_H) be colored groups.*

1. *Consider $\bar{g} \in G^{(m)}$, $\bar{h} \in H^{(m)}$ and $k \geq m$. If \bar{g} is distinguished from \bar{h} by k -WL_I then \bar{g} is distinguished from \bar{h} by k -WL_{II}. If \bar{g} is distinguished from \bar{h} by k -WL_{II} then \bar{g} is distinguished from \bar{h} by $(k+1)$ -WL_I.*
2. *It holds that $(G, \gamma_G) \equiv_{k+1}^I (H, \gamma_H) \implies (G, \gamma_G) \equiv_k^{II} (H, \gamma_H) \implies (G, \gamma_G) \equiv_k^I (H, \gamma_H)$.*

Proof Sketch. Part 2) follows from Part 1). For Part 1), the first claim is true by definition. For the second claim, using Lemma 3.4, we compare the $(k+1)$ -pebble game (ver. II) and the $(k+2)$ -pebble game (ver. I) with initial configurations given by placing pebble pairs on (g_i, h_i) for all i . In the version I game, Spoiler copies the winning strategy from the version II game. By assumption, Spoiler eventually reaches a winning configuration in the version II game, meaning that the pebble pairs in this eventual configuration induce a map that does not extend to an isomorphism between the subgroups generated by the respectively pebbled group elements. Then, for each bijection Duplicator may further choose, there must be a witness of this fact, i.e., a word over the currently pebbled group elements in G that is not mapped multiplicatively by Duplicator's bijection. Spoiler can use the extra pebble to win immediately or reduce the length of the witness. A very similar argument is spelled out in the proof of [5, Lemma 3.10, Part 3)] in full detail. ◀

3.4 Induced Colorings & Refinements

We say that a coloring $\gamma_2 : G^{(k)} \rightarrow \mathcal{C}_2$ *refines* a coloring $\gamma_1 : G^{(k)} \rightarrow \mathcal{C}_1$, denoted $\gamma_2 \preceq \gamma_1$, if each γ_1 -color class is a union of γ_2 -color classes.

► **Lemma 3.5.** *Let γ_1, γ_2 be colorings on G such that $(\chi_{\gamma_1}^{I,k})^{(G)} \preceq \gamma_2 \preceq \gamma_1$. Then $\chi_{\gamma_1}^{I,k}$ and $\chi_{\gamma_2}^{I,k}$ induce the same color classes on $G^{(k)}$.*

4 WL-Refinement on Quotient Groups

We investigate the interplay between WL and basic group structure, e.g., subgroups, normal closures or quotients. We use *subset selectors* to compare substructures of different groups.

► **Definition 4.1.** *A subset selector \mathcal{S} associates with each colored group (G, γ) a subset $\mathcal{S}(G, \gamma) \subseteq G$. For each version $J \in \{I, II\}$, a subset selector \mathcal{S} is called k -WL_J-detectable, if $\chi_{\gamma_G}^{J,k}(\mathcal{S}(G, \gamma_G)) \cap \chi_{\gamma_H}^{J,k}(H \setminus \mathcal{S}(H, \gamma_H)) = \emptyset$ holds for all pairs of colored groups $(G, \gamma_G), (H, \gamma_H)$.*

When the dependency of $\mathcal{S}(G, \gamma_G)$ on (G, γ_G) is clear from the context, we also say that $\mathcal{S}(G, \gamma_G)$ is k -WL_J-detectable (instead of $(G, \gamma) \mapsto \mathcal{S}(G, \gamma)$ being detectable). Examples of 2-WL_J-detectable subset selectors include the association of every group with its center ($J = II$) or the subset selector associating with each group the subset of elements of order 2.

We should remark that in our sense detectable means that the subset of interest is a union of $\chi_{\gamma_G}^{J,k}$ -color classes, but we make no statement on how to algorithmically determine which color classes form the set. It might a priori not be clear that the subset is even computable.

If \mathcal{S} is k -WL_J-detectable then $\mathcal{S}(G, \gamma_G)$ is $\chi_{\gamma_G}^{J,k}$ -induced, hence $\text{Aut}_{\gamma_G}(G)$ -invariant. If \mathcal{S} and \mathcal{T} are k -WL_J-detectable, so are their union (intersection) in G and $G \setminus \mathcal{S}(G, \gamma_G)$.

► **Definition 4.2.** *A group expression $\mathcal{E} := (\mathcal{S}_1, \dots, \mathcal{S}_t; \mathcal{R})$ of length t is a sequence of subset selectors \mathcal{S}_i together with a set \mathcal{R} of words $w(x_1, \dots, x_t)$ over t variables x_1, \dots, x_t , allowing inverses. Let (G, γ) be a colored group, then a t -tuple $(g_1, \dots, g_t) \in G^{(t)}$ is a solution to \mathcal{E} if for each i it holds that $g_i \in \mathcal{S}_i(G, \gamma)$ and for each $w \in \mathcal{R}$ it holds that $w(g_1, \dots, g_t) = 1$. Let $\text{Sol}_{\mathcal{E}}(G, \gamma) \subseteq G^{(t)}$ denote the set of all solutions to \mathcal{E} over (G, γ) .*

► **Lemma 4.3.** Consider a group expression $\mathcal{E} := (\mathcal{S}_1, \dots, \mathcal{S}_t; \mathcal{R})$. Let $k \geq t$ and assume that each \mathcal{S}_i is k - WL_{II} -detectable.

1. Let (G, γ_G) and (H, γ_H) be colored groups. Then all t -tuples in $Sol_{\mathcal{E}}(G, \gamma_G)$ can be distinguished from all t -tuples in $H^{(t)} \setminus Sol_{\mathcal{E}}(H, \gamma_H)$ via k - WL_{II} .
2. For $1 \leq j \leq t$ and colored groups (G, γ) define

$$Sol_j^{\exists}(G, \gamma) := \{x \in G \mid \exists(x_1, \dots, x_t) \in Sol_{\mathcal{E}}(G, \gamma) : x_j = x\}$$

$$Sol_j^{\forall}(G, \gamma) := \{x \in G \mid (\forall x_i \in \mathcal{S}_i(G, \gamma))_{1 \leq i \leq t} : (x_1, \dots, x_{j-1}, x, x_{j+1}, \dots, x_t) \in Sol_{\mathcal{E}}(G, \gamma)\}.$$

Then Sol_j^{\exists} and Sol_j^{\forall} are k - WL_{II} -detectable subset selectors for all j .
The same holds for k - WL_I , provided $k > t$.

We can now argue that WL is powerful enough to incorporate various basic group theoretic concepts. This in particular includes generated subgroups, normal closures, powers, conjugacy classes, centralizers, and normalizers. All these statements are relative to inductively detected structures, so the processes can be iterated. Let us record this in the following lemma.

► **Lemma 4.4.** Consider k - WL_{II} -detectable subset selectors \mathcal{S}, \mathcal{T} . Then the following subset selectors are k - WL_{II} -detectable:

1. \mathcal{S}^e for each $e \in \mathbb{Z}$, where $\mathcal{S}^e(G, \gamma) := \{s^e \mid s \in \mathcal{S}(G, \gamma)\}$,
 2. $C_{\mathcal{S}}(\mathcal{T})$, where $C_{\mathcal{S}}(\mathcal{T})(G, \gamma) := \{s \in \mathcal{S}(G, \gamma) \mid [s, \mathcal{T}(G, \gamma)] = \{1\}\}$.
- Provided k is at least 3, k - WL_{II} further detects the following subset selectors:
3. $\{s_1 \dots s_e \mid s_i \in \mathcal{S}(G, \gamma)\}$ for each $e \in \mathbb{N}$, in particular also $\langle \mathcal{S}(G, \gamma) \rangle$,
 4. $\{s^t := tst^{-1} \mid s \in \mathcal{S}(G, \gamma), t \in \mathcal{T}(G, \gamma)\}$, hence the normal closure $\langle \mathcal{S}(G, \gamma)^G \rangle$,
 5. $\mathcal{N}_{\mathcal{S}}(\mathcal{T})$, where $\mathcal{N}_{\mathcal{S}}(\mathcal{T})(G, \gamma) := \{s \in \mathcal{S}(G, \gamma) \mid \mathcal{T}(G, \gamma)^s = \mathcal{T}(G, \gamma)\}$,
 6. $[\mathcal{S}, \mathcal{T}]$, where $[\mathcal{S}, \mathcal{T}](G, \gamma) := \langle [s, t] \mid s \in \mathcal{S}(G, \gamma), t \in \mathcal{T}(G, \gamma) \rangle$.

All statements remain true if we replace Version II by Version I everywhere (including the assumptions), provided $k > 2$ in Parts 1 and 2 and $k > 3$ in Parts 3–6.

We point out how to identify groups as direct products of detectable subgroups.

► **Example 4.5.** Let $G \equiv_3^{\text{II}} H$ and assume that $G = G_1 \times G_2$ with $\chi_G^{\text{II},3}$ -induced subgroups G_i . We use element-colors in G_i to define a detectable subset selector $K \mapsto K_i := \{x \in K \mid \chi_K^{\text{II},k}(x) \in \chi_G^{\text{II},k}(G_i)\}$. Since $G \equiv_3^{\text{II}} H$, also $H_i \equiv_3^{\text{II}} G_i$. By the previous lemma, 3- WL_{II} detects $[G_1, G_2]$ and $G_1 \cap G_2$, which are both trivial, as well as $\langle G_1, G_2 \rangle$, which is equal to G . By definition of detectability, the same must hold for H_1 and H_2 , thus $H = H_1 \times H_2$.

In Section 6 we discuss the (much harder) case of arbitrary direct decompositions, without the assumption that each direct factor is detectable as a subgroup.

Next, we prove that WL is capable of exploiting properties of quotients over detectable subgroups. Later, this can be inductively leveraged along chains of subgroups.

► **Definition 4.6.** Given a coloring $\gamma : G \rightarrow \mathcal{C}$ and a normal subgroup $N \trianglelefteq G$ define the induced quotient coloring $\bar{\gamma}$ on G/N via $\bar{\gamma}(gN) := \{\{\gamma(gn) \mid n \in N\}\}$.

► **Lemma 4.7.** Let $k \geq 4$ and consider colored groups (G, γ_G) and (H, γ_H) . Assume that there are normal subgroups $N_G \trianglelefteq G$ and $N_H \trianglelefteq H$ which are induced by γ_G and γ_H , respectively, such that $\gamma_G(N_G) = \gamma_H(N_H)$. Then

$$\chi_{\bar{\gamma}_G}^{\text{I},k}(g_1 N_G, \dots, g_k N_G) \neq \chi_{\bar{\gamma}_H}^{\text{I},k}(h_1 N_H, \dots, h_k N_H) \implies \chi_{\gamma_G}^{\text{I},k}(g_1, \dots, g_k) \neq \chi_{\gamma_H}^{\text{I},k}(h_1, \dots, h_k)$$

for all choices of $g_i \in G$ and $h_i \in H$.

Proof sketch. The idea is to simulate the pebble game on quotient groups in the pebble game on G and H . Spoiler can first win modulo N_G and N_H , respectively, and then use a constant number of pebbles to manipulate the configuration into one that fulfills the winning condition over the original groups. For details, we refer to the full version. ◀

We synthesize the previous results into our first main theorem, stating that whenever $G \equiv_k^I H$ holds, there is a color preserving correspondence between detectable substructures.

► **Theorem 4.8.** *Let k be at least 4.*

1. *Consider subset selectors N, U and U/N such that for all (G, γ) it holds that $N(G, \gamma) \trianglelefteq G$, $N(G, \gamma) \leq U(G, \gamma)$ and $U/N(G/N(G), \bar{\gamma}) = U(G)/N(G)$. If N and U/N are k - WL_I -detectable then so is U .*
2. *Consider colored groups $(G, \gamma_G) \equiv_k^I (H, \gamma_H)$. Let $\Psi : G \rightarrow H$ be a bijection with $(\chi_{\gamma_G}^{I,k})^{(G)} \circ \Psi = (\chi_{\gamma_H}^{I,k})^{(H)}$. Then $M \subseteq G$ is $\chi_{\gamma_G}^{I,k}$ -induced if and only if $\Psi(M) \subseteq H$ is $\chi_{\gamma_H}^{I,k}$ -induced. In this case it holds that $\Psi(\langle M \rangle) = \langle \Psi(M) \rangle$. In particular, if M is a subgroup then so is $\Psi(M)$ and it holds $(M, \gamma_G|_M) \equiv_k^I (\Psi(M), \gamma_H|_{\Psi(M)})$. Additionally, M is normal if and only if $\Psi(M)$ is and then it also holds that $(G/M, \bar{\gamma}_G) \equiv_k^I (H/\Psi(M), \bar{\gamma}_H)$.*

Finally let us point out that detectable substructures can be used to limit Duplicator-strategies. This technique will be needed towards the main result of Section 6. More precisely, we show that Spoiler can “trade off” one pebble pair to enforce that Duplicator’s bijections are simultaneously compatible with detectable substructures in the following sense.

► **Lemma 4.9.** *Let $k \geq 3$ and $J \in \{I, II\}$. Consider groups G and H with $G \equiv_k^J H$, so Duplicator has a winning strategy in the $(k+1)$ -pebble game (Version J). Assume $\chi_G^{J,k}$ and $\chi_H^{J,k}$ induce chains of subgroups $G_s \leq \dots \leq G_1 \leq G$ and $H_s \leq \dots \leq H_1 \leq H$, respectively, such that $\chi_G^{J,k}(G_i) = \chi_H^{J,k}(H_i)$ for all i . Then Duplicator has a winning strategy in the k -pebble game (Version J) on (G, H) such that each bijection $f : G \rightarrow H$ chosen by Duplicator’s strategy fulfills the following condition: $\forall x \in G \forall i : f(xG_i) = f(x)H_i$.*

The proof actually works in a context more general than groups, replacing subgroup chains by nested equipartitions. This generalization might find applications in different contexts.

5 WL-dimension of certain isomorphism invariants

We just briefly summarize our results in what follows. A detailed treatment can be found in the full version, for group theoretic foundations see for example [16].

► **Lemma 5.1.** *For $k \geq 2$, k - WL_{II} identifies all finite k -generated groups and all finite abelian groups.*

5.1 Derived & Central Series

► **Lemma 5.2.**

1. *For $k \geq 3$, $G' := [G, G]$ is k - WL_{II} -detectable.*
2. *Assume that $k \geq 4$ and $G \equiv_k^I H$ hold. Let $G_0 \geq G_1 \geq \dots \geq G_t$ denote the derived, upper central or lower central series of G (without redundancies, starting at $G_0 := G$). Define the corresponding series of H via $H_0 \geq \dots \geq H_s$. Then $s = t$ holds and for all i we have that $G_i \equiv_k^I H_i$, as well as $G_i/G_{i+1} \cong H_i/H_{i+1}$.*

27:10 Isomorphism Invariants of Groups and the WL-Dimension

The requirement $k \geq 3$ is necessary in the first statement as computations on `SmallGroup(128,171)` and `SmallGroup(128,1122)` from the Small Groups Library in GAP [14] show.

► **Corollary 5.3.** *For $k \geq 4$, k -WL_I distinguishes solvable from non-solvable groups and k -WL_I distinguishes between groups of different nilpotency classes.*

5.2 Radicals

Let \mathcal{F} be a class of finite groups that is closed under isomorphism and normal products. Then the \mathcal{F} -radical $\mathcal{O}_{\mathcal{F}}(G)$ of G is defined as the largest normal \mathcal{F} -subgroup in G .

► **Lemma 5.4.** *Let $k \geq 3$. If \mathcal{F} is closed under normal subgroups and $(k-1)$ -WL_{II} distinguishes \mathcal{F} -groups from all non- \mathcal{F} -groups, then k -WL_{II} detects $\mathcal{O}_{\mathcal{F}}(G)$ in G .*

► **Lemma 5.5.** *The solvable radical is 2-WL_{II}-detectable. The nilpotent radical $\text{Fit}(G)$ and all π -radicals $\mathcal{O}_{\pi}(G)$ (π a collection of primes) are 3-WL_{II}-detectable.*

► **Lemma 5.6.** *If G contains a unique maximal abelian normal subgroup, then it is 3-WL_{II}-detectable.*

5.3 Simple Groups & Composition Factors

Recall that finite (almost) simple groups can be generated with 2 (respectively 3) elements [9].

► **Lemma 5.7.** *2-WL_{II} identifies finite simple groups. 3-WL_{II} identifies finite almost simple groups and finite direct products of simple groups.*

In the case of simple groups there is a stronger result, stating that simple groups are uniquely identified among all groups up to isomorphism by their order and the orders of their elements [27].

► **Theorem 5.8.** *The socle of a finite group G is 4-WL_{II}-detectable. Let $k \geq 5$ and $G \cong_k H$, then G and H have the same composition factors (with multiplicities).*

6 WL-Refinement and Direct Products

In this final section we study the detectability of direct product structures in finite groups. The section is organized similar to [19], in the sense that we first consider direct products where one factor is an abelian group (the semi-abelian case) and reduce to these in the general case later on. A crucial difference between our setting and the one in [19] is that in the latter, computations can be executed as long as they are efficient, where in our case, we are analyzing a fixed algorithm that cannot make non-canonical choices.

► **Definition 6.1.** *A group G is the (internal) central product of subgroups $G_1, G_2 \leq G$, if it holds that $G = \langle G_1, G_2 \rangle$ and $[G_1, G_2] = \{1\}$.*

Our main difficulty is that a group can admit several inherently different central decompositions. In contrast to that recall that indecomposable *direct* decompositions are unique in the following sense.

► **Lemma 6.2.** *Let $G = G_1 \times \cdots \times G_m = H_1 \times \cdots \times H_n$ be two decompositions of G into directly indecomposable factors. Then $n = m$ and there is a permutation $\sigma \in S_m$ such that for all i we have $G_i \cong H_{\sigma(i)}$ and $G_i Z(G) = H_{\sigma(i)} Z(G)$.*

Proof. The first part is the well-known Krull-Remak-Schmidt Theorem and the addition that $G_i Z(G) = H_{\sigma(i)} Z(G)$ can be easily derived (see for example [19, Corollary 6]) ◀

In particular, the collection of subgroups $\{G_i Z(G)\}_{1 \leq i \leq m}$ is invariant under automorphisms as a whole. Later we show that $\bigcup_{i=1}^m G_i Z(G)$ is 5-WL₁-detectable.

► **Lemma 6.3.** *If $J \in \{I, II\}$, $k \geq 3$, $G_1 \cong_k^J H_1$ and $G_2 \cong_k^J H_2$, then $G_1 \times G_2 \cong_k^J H_1 \times H_2$.*

The opposite direction is investigated below and turns out to be highly non-trivial.

6.1 Abelian and Semi-Abelian Case

Direct products with abelian groups serve as a basis for reduction later on.

► **Definition 6.4.** *An element $x \in G$ splits from G if there is a complement $H \leq G$ of x in G , i.e., $G = \langle x \rangle \times H$.*

A detailed treatment of splitting elements can be found in the full version.

► **Corollary 6.5.** *The set of elements splitting from a finite group is 4-WL₁-detectable.*

The splitting of elements can reveal information about direct decompositions of a group.

► **Lemma 6.6.** *Consider a direct product $G = G_1 \times G_2$ and a p -element $z := (z_1, z_2) \in Z(G)$. Then z splits from G if and only if z_i splits from G_i for some $i \in \{1, 2\}$ which fulfills $|z_i| = |z|$.*

This can be inductively leveraged to handle the semi-abelian case, by which we mean groups of the form $H \times A$ where A is abelian and H does not have abelian direct factors.

► **Lemma 6.7.** *Let $G = H \times A$ with A a maximal abelian direct factor. The isomorphism type of A is identified by 4-WL₁, i.e., if $\hat{G} \cong_4^1 G$ then \hat{G} has a maximal abelian direct factor isomorphic to A .*

Controlling the non-abelian part is more complicated and led us to introduce a new technical framework.

► **Definition 6.8.** *Let $G = L \times R$. A component-wise filtration of $U \leq G$ w.r.t. L and R is a chain of subgroups $\{1\} = U_0 \leq \dots \leq U_r = U$ such that for all $1 \leq i < r$, we have $U_{i+1} \leq U_i(L \times \{1\})$ or $U_{i+1} \leq U_i(\{1\} \times R)$. The filtration is k -WL₁-detectable if all subgroups in the chain are.*

► **Lemma 6.9.** *Let $G = H \times A$ with maximal abelian direct factor A . There exists a component-wise filtration of $Z(G)$ with respect to H and A that is 4-WL₁-detectable.*

► **Lemma 6.10.** *Consider $G := H \times A$ and $\hat{G} = \hat{H} \times \hat{A}$ where A and \hat{A} are maximal abelian direct factors. Then, for $k \geq 5$, $G \cong_k^1 \hat{G}$ implies $H \cong_{k-1}^1 \hat{H}$.*

6.2 General Case

The general case is reduced to the semi-abelian case. Consider an indecomposable direct decomposition $G = G_1 \times \dots \times G_d$. We first show that $\bigcup_i G_i Z(G)$ can be detected by WL and then we exploit the fact that the non-commuting graph induces components on $\bigcup_i G_i Z(G)$ which correspond to the groups $G_i Z(G)$.

► **Definition 6.11.** *Given a group G , we define the non-commuting graph Γ_G with vertex set G , in which two elements $g, h \in G$ are joined by an edge if and only if $[g, h] \neq 1$.*

► **Lemma 6.12** ([1], Prop. 2.1). *If G is non-abelian then $\Gamma_G[G \setminus Z(G)]$ is connected.*

We now approximate $\bigcup_i G_i Z(G)$ from below by constructing a canonical central decomposition of G which is WL-detectable.

► **Definition 6.13.** *Consider a finite, non-abelian group G . Define $M_1 \subseteq G$ to be the set of non-central elements g whose centralizers $C_G(g)$ have maximal order among all non-central elements. Iteratively define M_{i+1} by adding those elements g to M_i that have maximal centralizer order $|C_G(g)|$ among the remaining elements $G \setminus \langle M_i \rangle$. Set $M := M_\infty$ to be the stable set resulting from this process. Consider the subgraph of Γ_G induced on M and let K_1, \dots, K_m be its connected components. Set $N_i := \langle K_i \rangle$. We call N_1, \dots, N_m the non-abelian components of G .*

► **Lemma 6.14.** *In the notation of the previous definition, the following hold:*

1. M is detectable in G by 3-WL_{II}.
2. $G = N_1 \cdots N_m$ is a central decomposition of G . For all i , $Z(G) \leq N_i$ and N_i is non-abelian. In particular M generates G .
3. If $G = G_1 \times \cdots \times G_d$ is an arbitrary direct decomposition, then for each $1 \leq i \leq m$ there is exactly one $1 \leq j \leq d$ with $N_i \subseteq G_j Z(G)$. Collect all such i for one fixed j in an index set I_j . Then the product over all N_i for $i \in I_j$ is equal to $G_j Z(G)$.

► **Definition 6.15.** *Let $G = N_1 \cdots N_m$ be the decomposition into non-abelian components and let $G = G_1 \times \cdots \times G_d$ be an arbitrary direct decomposition. We say $x \in G$ is full for $(G_{j_1}, \dots, G_{j_r})$, if $\{1 \leq i \leq m \mid [x, N_i] \neq 1\} = I_{j_1} \cup \cdots \cup I_{j_r}$. For all $x \in G$ define $C_x := \prod_{[x, N_i] = \{1\}} N_i$ and $N_x := \prod_{[x, N_i] \neq \{1\}} N_i$.*

Overall, when grouped adequately, the full elements with maximal centralizers generate the direct factors modulo central elements (see full version).

► **Lemma 6.16.** *Let $G = N_1 \cdots N_m$ be the decomposition into non-abelian components and $G = G_1 \times \cdots \times G_d$ a decomposition into indecomposable direct factors. For $k \geq 5$, k -WL_{II} detects the set of elements that are full for only one G_i as well as the pairs of elements that are full for the same collection of direct factors.*

► **Corollary 6.17.** *If $G = G_1 \times \cdots \times G_d$ is a decomposition into indecomposable direct factors then $\bigcup_i G_i Z(G)$ is detected in G by 5-WL_{II}.*

► **Theorem 6.18.** *Let $G = G_1 \times \cdots \times G_d$ be a decomposition into indecomposable direct factors and $k \geq 5$. If $G \cong_k^{\Pi} H$ then there are indecomposable direct factors $H_i \leq H$ such that $H = H_1 \times \cdots \times H_d$ and $G_i \cong_{k-1}^{\Pi} H_i$ for all i . Moreover G and H have isomorphic maximal abelian direct factors and $G_i Z(G) \cong_k^{\Pi} H_i Z(H)$.*

Proof. Since $\mathcal{F}_G := \bigcup_i G_i Z(G)$ is 5-WL_{II}-detectable, the group H must be decomposable into indecomposable direct factors $H = \times_j H_j$ such that $\mathcal{F}_H = \bigcup_j H_j Z(H) \subseteq H$ is indistinguishable from \mathcal{F}_G . Consider the non-commuting graphs of G and H induced on these sets and recall that non-commuting graphs of non-abelian groups are connected (Lemma 6.12). Since different direct factors in a fixed decomposition centralize each other, we obtain that for each non-singleton connected component K of $\Gamma_G[\mathcal{F}_G]$ there exists a unique indecomposable direct factor G_i such that $K = G_i Z(G) \setminus Z(G)$ and thus $\langle K \rangle = G_i Z(G)$. Again by Lemma 6.12, all non-abelian direct factors appear in this way.

The same holds for H and so if G is not distinguishable from H , there must be a bijection between the components of $\Gamma_G[\mathcal{F}_G]$ and $\Gamma_H[\mathcal{F}_H]$, such that the subgroups generated by corresponding components are indistinguishable via 5-WL_{II}. This defines a correspondence $G_i Z(G) \cong_k^{\Pi} H_i Z(H)$ after reordering the factors of H in an appropriate way. From Lemma 6.10 it follows that $G_i \cong_{k-1}^{\Pi} H_i$. By Lemma 6.9, G and H must have isomorphic maximal abelian direct factors, so for abelian factors we even have $G_i \cong H_i$. ◀

7 Conclusion

We studied the Weisfeiler-Leman dimension of numerous isomorphism invariants of groups, showing that a low dimensional WL-algorithm in fact captures a plethora of isomorphism invariants, characteristic subgroups, and group properties classic to algorithmic group theory. Particularly tricky was the treatment of direct indecomposable factors, for which we had to circumvent the fact that they do not correspond to canonical substructures of the groups. Our techniques lead us to a canonical maximal central decomposition.

The observation that many efficiently computable isomorphism invariants are captured by a low dimensional WL-algorithm raises the question whether there are actually invariants that are not captured at all. Here we should emphasize that it is an open problem whether some fixed dimension of WL represents a complete invariant. The question is equivalent to the well-known open question whether the Weisfeiler-Leman dimension of groups is bounded in general (stated explicitly in [4]).

For this open question, our results show that it suffices to consider directly indecomposable groups. We wonder whether there are other, similar reductions to confine the search for groups of high WL-dimension.

Abstract

Subtrajectory clustering is an important variant of the trajectory clustering problem, where the start and endpoints of trajectory patterns within the collected trajectory data are not known in advance. We study this problem in the form of a set cover problem for a given polygonal curve: find the smallest number k of representative curves such that any point on the input curve is contained in a subcurve that has Fréchet distance at most a given Δ to a representative curve. We focus on the case where the representative curves are line segments and approach this NP-hard problem with classical techniques from the area of geometric set cover: we use a variant of the multiplicative weights update method which was first suggested by Brönniman and Goodrich for set cover instances with small VC-dimension. We obtain a bicriteria-approximation algorithm that computes a set of $O(k \log(k))$ line segments that cover a given polygonal curve of n vertices under Fréchet distance at most $O(\Delta)$. We show that the algorithm runs in $\tilde{O}(k^2 n + kn^3)$ time in expectation and uses $\tilde{O}(kn + n^3)$ space. For input curves that are c -packed and lie in the plane, we bound the expected running time by $\tilde{O}(k^2 c^2 n)$ and the space by $\tilde{O}(kn + c^2 n)$. In addition, we present a variant of the algorithm that uses implicit weight updates on the candidate set and thereby achieves near-linear running time in n without any assumptions on the input curve, while keeping the same approximation bounds. This comes at the expense of a small (polylogarithmic) dependency on the relative arclength.

1 Introduction

The advancement of tracking technology made it possible to record the movement of single entities at a large scale in various application areas ranging from vehicle navigation over sports analytics to the socio-ecological study of animal and human behaviour. The types of trajectories that are analyzed range from GPS-trajectories [25] to full-body-motion trajectories [22] and complex gestures [24], and even include the positions of the focus point of attention from a human eye [15, 21].

In many such applications, a flood of data presents us with the challenging task of extracting useful information. If a long trajectory is given as a sequence of positions in some parameter space, it is rarely known in advance which specific movement patterns occur. In particular, it is challenging to find the start and endpoints of such patterns, which is why popular clustering algorithms heuristically partition the trajectories into smaller subtrajectories. An example is the popular algorithm by Lee, Han and Whang [23].

Since the criteria according to which one should detect, group and represent behaviour patterns vary greatly among different kinds of application, there are many different variants of the subtrajectory clustering problem, see also the survey papers [12, 26, 27]. One line of research uses the well-established Fréchet distance to define similarity between subcurves, for example the works of Agarwal et al. [1], Buchin et al. [11] and Akitaya et al. [2].

In an attempt to unify previous definitions of the underlying algorithmic problem, Akitaya et al. [2] define the following geometric set cover problem. Given a polygonal curve, the goal is to “cover” the whole curve with a minimum number of simpler representative curves, such that each point of the trajectory is contained in a subcurve with small Fréchet distance to its closest representative curve. This is in line with traditional clustering formulations such as metric k -center, where clusters may overlap. In this paper, we study the set cover problem introduced by Akitaya et al. and improve upon their results.

Preliminaries. For any $n > 1$, a sequence of points $p_1, \dots, p_n \in \mathbb{R}^d$ defines a **polygonal curve** P by linearly interpolating consecutive points, that is, for each i , we obtain the **edge** $e_i : [0, 1] \rightarrow \mathbb{R}^d; t \mapsto (1 - t)p_i + tp_{i+1}$. We may write $e_i = \overline{p_i p_{i+1}}$ for edges. We may think of P as a continuous function $P : [0, 1] \rightarrow \mathbb{R}^d$ by fixing n values $0 = t_1 < \dots < t_n = 1$, and defining $P(t) = e_i \left(\frac{t - t_i}{t_{i+1} - t_i} \right)$ for $t_i \leq t \leq t_{i+1}$. We call the set (t_1, \dots, t_n) the **vertex parameters** of the parametrized curve $P : [0, 1] \rightarrow \mathbb{R}^d$. For $n = 1$, we may slightly abuse notation to view a point p_1 in \mathbb{R}^d as a polygonal curve defined by an edge of length zero with $p_2 = p_1$. We call the number of vertices n the **complexity** of the curve. For any two $a, b \in [0, 1]$ we denote with $P[a, b]$ the **subcurve** of P that starts at $P(a)$ and ends at $P(b)$. Note, that $a > b$ is specifically allowed and results in a subcurve in reverse direction. We call the subcurves of edges **subedges**. Let $\mathbb{X}_\ell^d = (\mathbb{R}^d)^\ell$, and think of the elements of this set as the set of all polygonal curves of ℓ vertices in \mathbb{R}^d .

For two parametrized curves P and Q , we define their **Fréchet distance** as

$$d_F(P, Q) = \inf_{\alpha, \beta: [0,1] \rightarrow [0,1]} \sup_{t \in [0,1]} \|P(\alpha(t)) - Q(\beta(t))\|,$$

where α and β range over all functions that are non-decreasing, surjective and continuous. We call the pair (α, β) a traversal. Every traversal has a distance $\sup_{t \in [0,1]} \|P(\alpha(t)) - Q(\beta(t))\|$ associated to it.

We call a curve X in \mathbb{R}^d **c -packed**, if for any point p and and radius r , the length of X inside the disk is bounded by $\|X \cap b_r(p)\| \leq cr$, where $b_r(p) = \{x \in \mathbb{R}^d \mid \|p - x\| \leq r\}$. Let X be a set. We call a set \mathcal{R} where any $r \in \mathcal{R}$ is of the form $r \subseteq X$ a **set system** with **ground set** X .

We say a subset $A \subseteq X$ is **shattered** by \mathcal{R} if for any $A' \subseteq A$ there exists an $r \in \mathcal{R}$ such that $A' = r \cap A$. The **VC-dimension** of \mathcal{R} is the maximal size of a set A that is shattered by \mathcal{R} . For a weight function w on the ground set X and a real value $\varepsilon > 0$, we say that a subset $C \subseteq X$ is an **ε -net** if every set of \mathcal{R} of weight at least $\varepsilon \cdot w(X)$ contains at least one element of C . For any $A \subseteq X$, we write $w(A)$ short for $\sum_{a \in A} w(a)$.

Computational Model. We describe our algorithms in the real-RAM model of computation, which allows to store real numbers and to perform simple operations in constant time on them. We call the following operations **simple operations**. The arithmetic operations $+$, $-$, \times , $/$. The comparison operations $=$, \neq , $>$, \geq , \leq , $<$, for real numbers with output 0 or 1. In addition to the simple operations, we allow the square-root operation. In the full version [7], we describe how to circumvent the square-root operation with little extra cost.

■ **Figure 1** Illustration of the Δ -coverage of a set $C = \{Q_1, Q_2\}$ and a curve P . Here we have $\Psi_\Delta(P, C) = [s_1, s'_1] \cup [s_2, s'_2] \cup [s_3, s'_3] \cup [s_4, s'_4]$, since the subcurves $P[s_1, s'_1]$ and $P[s_3, s'_3]$ have Fréchet distance Δ to Q_1 , the subcurves $P[s_2, s'_2]$ and $P[s_4, s'_4]$ have Fréchet distance Δ to Q_2 and each other subcurve of P that has Fréchet distance at most Δ to Q_1 or Q_2 is a subcurve of $P[s_i, s'_i]$ for some $1 \leq i \leq 4$.

Problem definition. We study the same problem as Akitaya, Chambers, Brünig and Driemel [2]. Let $P : [0, 1] \rightarrow \mathbb{R}^d$ be a polygonal curve of n vertices and let $\ell \in \mathbb{N}$ and $\Delta \in \mathbb{R}$ be fixed parameters. Define the Δ -coverage of a set of center curves $C \subseteq \mathbb{X}_\ell^d$ as follows:

$$\Psi_\Delta(P, C) = \bigcup_{q \in C} \bigcup_{0 \leq t \leq t' \leq 1} \{s \in [t, t'] \mid d_F(P[t, t'], q) \leq \Delta\}.$$

The Δ -coverage corresponds to the part of the curve P that is covered by the set of all subtrajectories that are within Fréchet distance Δ to some curve in C . If for some P, C, Δ it holds that $\Psi_\Delta(P, C) = [0, 1]$, then we call C a Δ -covering of P . The problem is to find a Δ -covering $C \subseteq \mathbb{X}_\ell^d$ of P of minimum size. We study bicriterial approximation algorithms for this problem, which we formalize as follows.

► **Definition 1** ((α, β) -approximate solution). Let $P \in \mathbb{X}_n^d$ be a polygonal curve, $\Delta \in \mathbb{R}_+$ and $\ell \in \mathbb{N}$. A set $C \subseteq \mathbb{X}_\ell^d$ is an (α, β) -approximate solution to the Δ -coverage problem on P , if C is an $\alpha\Delta$ -covering of P and there exists no Δ -covering $C' \subseteq \mathbb{X}_\ell^d$ of P with $\beta|C'| < |C|$.

Related work. Buchin, Buchin, Gudmundsson, Löffler and Luo were the first to consider the problem of clustering subtrajectories under the Fréchet distance [10]. They consider the problem of finding a single cluster of subtrajectories with certain qualities, like the number of distinct subtrajectories, or the length of the longest subtrajectory assigned to it. In their paper, they suggested a swepline approach in the parameter space of the curves and obtain constant-factor approximation algorithms for finding the largest cluster. They also show NP-completeness of the corresponding decision problems. This hardness result extends to $(2 - \varepsilon)$ -approximate algorithms. For their 2-approximation algorithm, Buchin et al. [10] develop an algorithm that finds a legible cluster center among the subcurves of the input curve. Gudmundsson and Wong [19] present a cubic conditional lower bound for this problem and show that it is tight up to a factor of $O(n^{o(1)})$, where n is the number of vertices.

The algorithmic ideas presented in [10] were implemented and extended by Gudmundsson and Valladares [18] who obtained practical speed ups using GPUs. In a series of papers, these ideas were also applied to the problem of reconstructing road maps from GPS data [8, 9]. In a similar vein, Buchin, Kilgus and Kölzsch [11] studied the trajectories of migrating animals and defined so-called group diagrams which are meant to represent the underlying migration patterns in the form of a graph. In their algorithm, to build the group diagram, they repeatedly find the largest cluster and remove it from the data, inspired by the classical greedy set cover algorithm.

The above cited works however do not offer theoretical guarantees when used for computing a clustering of subtrajectories, nor do they explicitly formulate a clustering objective. Agarwal, Fox, Munagala, Nath, Pan, and Taylor [1] define an objective function for clustering subtrajectories based on the metric facility location problem, which consists of a weighted sum over different quality measures such as the number of centers and the distances between cluster centers and their assigned trajectories. While they show NP-hardness for determining whether an input curve can be covered with respect to the Fréchet distance, they also present a $O(\log^2 n)$ -approximation algorithm for clustering κ -packed curves (for some constant κ) under the discrete Fréchet distance, where n denotes the total complexity of the input. The overall running time of their algorithm is roughly quadratic in n , cubic in κ and depends logarithmically on the spread of the vertex coordinates.

In our paper, we focus on the clustering formulation previously studied by Akitaya, Chambers, Brüning, and Driemel [2]. They present a pseudo-polynomial algorithm that computes a bi-criterial approximation in the sense of Definition 1 with expected running time in $\tilde{O}(k(\frac{\lambda}{\Delta})^2 + \frac{\lambda}{\Delta}n)$, where λ denotes the total arclength of the input trajectory. The algorithm finds an (α, β) -approximate solution with $\alpha \in O(1)$ and $\beta \in O(\ell^2 \log(k\ell))$. In combination with our Lemma 2, below, this can be directly improved to $O(\ell \log(k))$. It should be noted that in this problem formulation some complexity constraint on the eligible cluster centers is needed to prevent the entire input curve being a cluster center in a trivial clustering.

Our contribution. Our main result is an algorithm that computes an (α, β) -approximate solution with $\alpha \in O(1)$ and $\beta = O(\ell \log k)$, where k is the size of an optimal solution. For general curves, the algorithm runs in $\tilde{O}(k^2n + kn^3)$ time in expectation and uses $\tilde{O}(kn + n^3)$ space. (The $\tilde{O}(\cdot)$ notation hides polylogarithmic factors in n to simplify the exposition.) If the input curve is a c -packed polygonal curve in the plane, the expected running time can be bounded by $\tilde{O}(k^2c^2n)$ and the space is in $\tilde{O}(kn + c^2n)$. In higher dimensions, the bound for c -packed curves becomes quadratic in n . Our second result is an algorithm that achieves near-linear running time in n – even for general polygonal curves – while keeping the same approximation bounds at the expense of a small dependency on the arclength in the running time. The algorithm needs in expectation $\tilde{O}(nk^3 \log^4(\frac{\lambda}{\Delta k}))$ time and $\tilde{O}(nk \log(\frac{\lambda}{\Delta k}))$ space, where λ is the total arclength of the input curve. Here, we stated our results for general ℓ using the reduction described below (Lemma 2).

In our algorithms we use a variant of the multiplicative weights update method [5], which has been used earlier for set cover problems with small VC-dimension [6, 13]. The difficulty in our case is that the set system initially has high VC-dimension, as shown by Akitaya et al [2] – namely $\Theta(\log n)$ in the worst case. We circumvent this by defining an intermediate set cover problem where the VC-dimension is significantly reduced. We then show how to compute a finite set system using a carefully chosen set of candidate curves on which the multiplicative weight update method can be applied. A key idea that enables our results is a curve simplification that requires the curve to be locally maximally simplified, a notion that is borrowed from de Berg, Cook, and Gudmundsson [14]. To the best of our knowledge, our candidate generation yields the first strongly polynomial algorithm for approximate subtrajectory clustering under the continuous Fréchet distance. In the full version [7], we also discuss how our candidate set can be used for the related problem of maximizing the coverage. Our second algorithm improves the dependency on the relative arclength from quadratic to polylogarithmic as compared to [2].

Reduction to line segments. In the remainder of the paper, we will focus on finding a Δ -covering with line segments, that is $\ell = 2$. The following lemma provides the reduction for general ℓ at the expense of an increased approximation factor.

► **Lemma 2.** *Let $P \in \mathbb{X}_n^d$ be a polygonal curve, $\Delta \in \mathbb{R}_+$ and $\ell \in \mathbb{N}$. Let $C \subseteq \mathbb{X}_\ell^d$ be a Δ -covering of P of minimum cardinality. There exists a set of line segments $C' \subseteq \mathbb{X}_2^d$ that is a Δ -covering of P with $|C'| \leq (\ell - 1)|C|$.*

Proof. Choose as set C' the union of the set of edges of the polygonal curves of C . Clearly, this set has the claimed cardinality and is a Δ -covering of P . ◀

Roadmap. In Section 2 we develop a structured variant of our problem that allows us to apply the multiplicative weight update method in the style of Brönniman and Goodrich [6] in an efficient way. Our intermediate goal is to obtain a structured set of candidates for a modified coverage problem that is on the one hand easy to compute and on the other hand sufficient to obtain good approximation bounds for the original problem. We first define our notion of curve simplification. A crucial property of this simplification is that the relevant subcurves of the input are within small Fréchet distance to subcurves of constant complexity of the simplification. We then define a structured notion of Δ -coverage and a candidate space, which lets us take advantage of this fact. We show that we can narrow our choice down even further, to a finite set of subedges of the simplification, and still sufficiently preserve the quality of the solution. In Section 3, we present our main algorithm. The algorithm uses the concepts and techniques developed in Section 2 in combination with the multiplicative weights update method. In Section 4, we analyze the approximation factor and running time of this algorithm. Crucially, we show that the VC-dimension of the induced set system which is implicitly used by our algorithm is small by design.

2 Structuring the solution space

In this section, we introduce key concepts that allow us to transfer the problem to a set cover problem on a finite set system with small VC-dimension and still obtain good approximation bounds. The main result of this section is Theorem 14.

Simplifications and containers. We start by defining the notion of curve-simplification that we will use throughout the paper.

► **Definition 3 (simplification).** *Let P be a polygonal curve in \mathbb{R}^d . Let (t_1, \dots, t_n) be the vertex-parameters of P , and $p_i = P(t_i)$ the vertices of P . Consider an index set $1 \leq i_1 < \dots < i_k \leq n$ that defines vertices p_{i_j} . We call a curve S defined by such an ordered set of vertices $(p_{i_1}, \dots, p_{i_k}) \in (\mathbb{R}^d)^k$ a **simplification** of P . We say the simplification is **Δ -good**, if the following properties hold:*

- (i) $\|p_{i_j} - p_{i_{j+1}}\| \geq \frac{\Delta}{3}$ for $1 \leq j < k$
- (ii) $d_F(P[t_{i_j}, t_{i_{j+1}}], \overline{p_{i_j} p_{i_{j+1}}}) \leq 3\Delta$ for all $1 \leq j < k$.
- (iii) $d_F(P[t_1, t_{i_1}], \overline{p_{i_1} p_{i_1}}) \leq 3\Delta$ and $d_F(P[t_{i_k}, t_n], \overline{p_{i_k} p_{i_k}}) \leq 3\Delta$
- (iv) $d_F(P[t_{i_j}, t_{i_{j+2}}], \overline{p_{i_j} p_{i_{j+2}}}) > 2\Delta$ for all $1 \leq j < k - 1$

Our intuition is the following. Property (i) guarantees that S does not have short edges. Property (ii) and (iii) together tell us, that the simplification error is small. Property (iv) tells us, that the simplification is (approximately) maximally simplified, that is, we cannot remove a vertex, and hope to stay within Fréchet distance 2Δ to P .

■ **Figure 2** Example of the structured Δ -coverage of a set $C = \{Q_1, Q_2\}$ and a curve P . Here we have $\Psi'_\Delta(P, C) = [s_1, s'_1] \cup [s_2, s'_2]$ since the subcurves $P[s_1, s'_1]$ and $P[s_2, s'_2]$ have Fréchet distance Δ to Q_1 and $P[s_3, s'_3]$ has Fréchet distance Δ to Q_2 . Note that $[s_4, s'_4]$ is not part of the coverage since the subcurve $P[s_4, s'_4]$ consists of 4 edges.

► **Definition 4 (Container).** Let P be a polygonal curve, let $\pi = P[s, t]$ be a subcurve of P , and let (t_1, \dots, t_n) be the vertex-parameters of P . For a simplification S of P defined by index set $I = (i_1, \dots, i_k)$, define the **container** $c_S(\pi)$ of π on S as $S[t_a, t_b]$, with $a = \max(\{i_1\} \cup \{i \in I \mid t_i \leq s\})$ and $b = \min(\{i \in I \mid t_i \geq t\} \cup \{i_k\})$.

The following lemma has been proven by de Berg et al. [14]. We restate and reprove it here with respect to our notion of simplification.

► **Lemma 5 ([14]).** Let P be a polygonal curve in \mathbb{R}^d , and let S be a Δ -good simplification of P . Let Q be an edge in \mathbb{R}^d and let π be a subcurve of P with $d_F(Q, \pi) \leq \Delta$. Then $c_S(\pi)$ consists of at most 3 edges.

Proof. Assume for the sake of contradiction, that $c_S(\pi)$ contains 4 edges, that is it has three internal vertices s_1, s_2, s_3 . By Definition 4 these three vertices are also interior vertices of π . As the Fréchet distance $d_F(Q, \pi) \leq \Delta$, there are points $q_1, q_2, q_3 \in Q$, that get matched to s_1, s_2 and s_3 respectively during the traversal, with $\|s_i - q_i\| \leq \Delta$. This implies $d_F(\pi[s_1, s_3], \overline{q_1 q_3}) \leq \Delta$. It also implies, that $d_F(\overline{s_1 s_3}, \overline{q_1 q_3}) \leq \Delta$. But then

$$d_F(\overline{s_1 s_3}, P[s_1, s_3]) = d_F(\overline{s_1 s_3}, \pi[s_1, s_3]) \leq d_F(\overline{s_1 s_3}, \overline{q_1 q_3}) + d_F(\pi[s_1, s_3], \overline{q_1 q_3}) \leq 2\Delta,$$

contradicting the assumption that S is a Δ -good simplification. ◀

Structured coverage and candidate space. We want to make use of the property of Δ -good simplifications shown in Lemma 5. For this we adapt the notion of Δ -coverage from Section 1 as follows.

► **Definition 6.** Let S be a polygonal curve in \mathbb{R}^d . Let (t_1, \dots, t_n) be the vertex-parameters of S . Let $\ell \in \mathbb{N}$ and $\Delta \in \mathbb{R}$ be fixed parameters. Define the **structured Δ -coverage** of a set of center curves $C \subset \mathbb{X}_\ell^d$ as

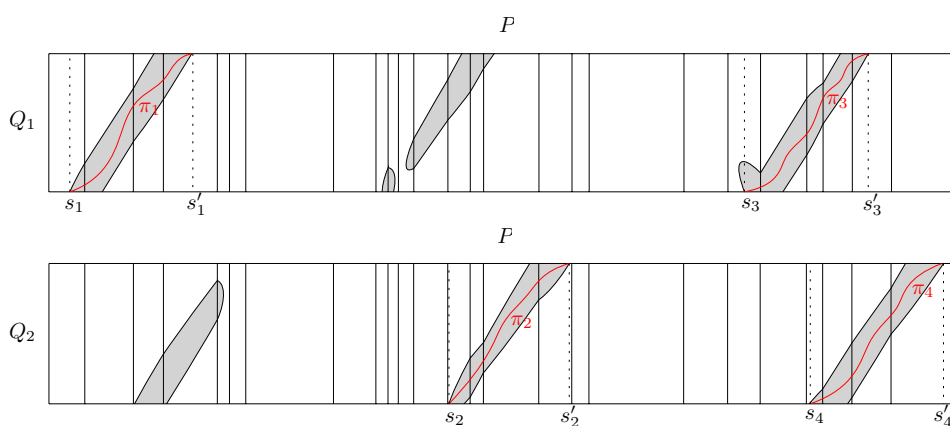

$$\Psi'_\Delta(S, C) = \bigcup_{q \in C} \bigcup_{(i,j) \in J} \Psi_\Delta^{(i,j)}(S, q)$$

where

$$\Psi_\Delta^{(i,j)}(S, q) = \{s \in [t, t'] \mid t_i \leq t \leq t_{i+1}; t \leq t'; t_{j-1} \leq t' \leq t_j; d_F(S[t, t'], q) \leq \Delta\},$$

and where $J = \{1 \leq i \leq j \leq n \mid 1 \leq j - i \leq 4\}$.

If it holds that $\Psi'_\Delta(S, C) = [0, 1]$, then we call C a **structured Δ -covering** of S .

■ **Figure 3** Free space diagrams of the curves P and Q_1 (resp. Q_2) depicted in Figure 1. The monotone paths π_i illustrate that the Fréchet distance between $P[s_i, s'_i]$ and Q_1 (resp. Q_2) is equal to Δ for $1 \leq i \leq 4$.

► **Observation 7.** *In general for any polygonal curve S and set of center curves C it holds that $\Psi'_\Delta(S, C) \subseteq \Psi_\Delta(S, C)$.*

We now want to restrict the candidate set to subedges of a simplification of the input curve, thereby imposing more structure on the solution space. For this we begin by defining a more structured parametrization of the set of edges of a polygonal curve.

► **Definition 8 (Edge space).** *We define the **edge space** $\mathbb{T}_n = \{1, \dots, n-1\} \times [0, 1]$. We denote the set of edges of P with $E(P)$.*

► **Definition 9 (Candidate space).** *Let $E = \{e_1, \dots, e_{n-1}\}$ be an ordered set of edges in \mathbb{R}^d . We define the **candidate space** induced by E as the set $\mathcal{Z}_E = \{(i_1, t_1, i_2, t_2) \in \mathbb{T}_n \times \mathbb{T}_n \mid i_1 = i_2\}$. We associate an element $(i, t_1, i, t_2) \in \mathcal{Z}_E$ with the subedge $e_i(t_1) e_i(t_2)$.*

The following theorem summarizes and motivates the above definitions of structured coverage and candidate space. Namely, we can restrict the search space to subedges of the simplification S and still obtain a good covering of P . Moreover, we can evaluate the coverage of our solution solely based on S . The structured coverage only allows subcurves of S that consist of at most three edges to contribute to the coverage. This technical restriction is necessary to obtain a small VC-dimension in our main algorithm later on, and it is well-motivated by Lemma 5.

► **Theorem 10.** *Let S be a Δ -good simplification of a curve P . Let C be a set of subedges of edges of S . If C is a structured 8Δ -covering of S , then C is an 11Δ -covering of P . Moreover, if k is the size of an optimal Δ -covering of P , then there exists such a set C of size at most $3k$.*

Partial traversals and coverage. Our algorithm and analysis use the notion of the free space diagram which was first introduced by Alt and Godau [3]. It is instructive to consider this concept in the context of the coverage problem. Refer to Figure 3.

► **Definition 11 (Free space diagram).** *Let P and Q be two polygonal curves parametrized over $[0, 1]$. The free space diagram of P and Q is the joint parametric space $[0, 1]^2$ together with a not necessarily uniform grid, where each vertical line corresponds to a vertex of P and each horizontal line to a vertex of Q . The Δ -free space of P and Q is defined as*

$$\mathcal{D}_\Delta(P, Q) = \{(x, y) \in [0, 1]^2 \mid \|P(x) - Q(y)\| \leq \Delta\}$$

■ **Figure 4** An illustration of a Δ -feasible $(2, 4)$ -partial traversal π from (a, c) to (b, d) of P and Q . π covers all points between a and b on P , and all points between c and d on Q .

This is the set of points in the parametric space, whose corresponding points on P and Q are at a distance at most Δ . The edges of P and Q segment the free space into cells. We call the intersection of $\mathcal{D}_\Delta(P, Q)$ with the boundary of cells the **free space intervals**.

Alt and Godau [3] showed that the Δ -free space inside any cell is convex and has constant complexity. More precisely, it is an ellipse intersected with the cell. Furthermore, the Fréchet distance between two curves is less than or equal to Δ if and only if there exists a path $\pi : [0, 1] \rightarrow \mathcal{D}_\Delta(P, Q)$ that starts at $(0, 0)$, ends in $(1, 1)$ and is monotone in both coordinates.

► **Definition 12** (Partial traversal). Let P be a polygonal curve in \mathbb{R}^d , and let (t_1, \dots, t_n) be the vertex-parameters of P . Let $1 \leq i < j \leq n$ be integer values. Let Q be an edge in \mathbb{R}^d . We define an (i, j) -**partial traversal** as a pair of continuous, monotone increasing and surjective functions, $f : [0, 1] \rightarrow [a, b]$ and $g : [0, 1] \rightarrow [c, d]$, where $t_i \leq a \leq t_{i+1}$, $t_{j-1} \leq b \leq t_j$, $0 \leq a \leq b \leq 1$, and $0 \leq c \leq d \leq 1$. We say that (f, g) is a partial traversal from (a, c) to (b, d) .

► **Definition 13** (Δ -feasible). We say that a partial traversal is **Δ -feasible** if the image of the path $\pi : [0, 1] \rightarrow [0, 1]^2$ defined by $\pi(t) = (f(t), g(t))$ is contained inside the Δ -free space $\mathcal{D}_\Delta(P, Q)$. We say that π **covers** a point t on P if $t \in [a, b]$ and we say that π covers a point t on Q if $t \in [c, d]$.

A finite set of candidates. By Theorem 10, it is sufficient to find a structured covering using a suitable simplification of the input curve. However the corresponding search space would still be infinite, even for a single edge. We will next define a finite set of candidates and show that it contains a good solution. In particular, our goal is to prove the following theorem.

► **Theorem 14.** Let P be a polygonal curve of complexity n in \mathbb{R}^d and let $\Delta > 0$ be given. Let S be a Δ -good simplification of P . Assume there exists a Δ -covering C of P of cardinality k . Then, there exists an algorithm that computes in $O(n^3)$ time and space a set of candidates $B \subset \mathcal{Z}_E(S) \subset \mathbb{X}_2^d$ with $|B| \in O(n^3)$, such that B contains a structured 8Δ -covering C_B of S of size at most $12k$. Moreover, C_B is a 11Δ -covering of P .

The main steps to constructing this set of candidates B are as follows. We first define a special set of subcurves of the simplification S . Intuitively, these are the containers of S of subcurves of P that may contribute to the coverage.

■ **Figure 5** Examples of extremal points. Shown on the right are the two free space intervals $[a_1, b_1]$ and $[a_2, b_2]$ as well as the left- and rightmost points l_e and r_e of the Δ -free space of e and Y . The extremal points are defined by b_2 and r_e . All points considered for the first extremal point are shown in blue. Similarly all points considered for the second extremal point are shown in red. A traversal from the first extremal point to the second extremal point is illustrated. On the left the resulting subedge $e[s^*, t^*]$ and the maximal subcurve of Y that can be matched are illustrated.

► **Definition 15** (Generating subcurves). Let S be a Δ -good simplification of a polygonal curve P . Let (t_1, \dots, t_m) be the vertex-parameters of S . For any $1 \leq i, 1 \leq j \leq 3$ and $i + j \leq m$, we say the subcurve $S[t_i, t_{i+j}]$ is a **generating subcurve**. In particular, this defines all subcurves of at most three edges starting and ending at vertices of S .

Now, for every generating subcurve Y of S and every edge e of S , we can identify an interval defining a subedge of e , that maximizes the Δ -coverage on Y over all subedges of e . For this reason, we call the endpoints of this interval extremal. Using this definition we define the finite candidate set induced by S via generating triples.

► **Definition 16** (Δ -extremal points). Given a value of $\Delta > 0$, a polygonal curve $Y : [0, 1] \rightarrow \mathbb{R}^d$ of m edges and an edge $e : [0, 1] \rightarrow \mathbb{R}^d$, such that they permit a Δ -feasible $(1, m)$ -partial traversal. As e is a single edge, the Δ -free space of Y and e consists of a single row. Let $[a_i, b_i]$ be the i th vertical free space interval of the Δ -free space of Y and e . Denote by $l = (l_Y, l_e)$ the leftmost point in the Δ -free space of Y and e and $r = (r_Y, r_e)$ the rightmost point (in case l is not unique, chose the point with smallest y -coordinate, and r as the point with the biggest y -coordinate). We define the **Δ -extremal points** induced by Y on e as the tuple $\mathcal{E}_\Delta(Y, e) = (s, t) \in [0, 1]^2$ with $s = \min(\{l_e\} \cup \{b_1, \dots, b_{n-1}\})$ and $t = \max(\{r_e\} \cup \{a_1, \dots, a_{n-1}\})$. We explicitly allow that $t < s$.

► **Definition 17** (Generating triples). Let S be a Δ -good simplification of a polygonal curve P . We define the set of **generating triples** T_S as a set of triples (e, Y_1, Y_2) , where e is any edge of S , and Y_1 and Y_2 are generating subcurves of S (not necessarily distinct). We include the triple (e, Y_1, Y_2) in the set T_S if and only if there are points $p \in e$, $p_1 \in Y_1$ and $p_2 \in Y_2$ such that $\|p - p_1\| \leq 8\Delta$ and $\|p - p_2\| \leq 8\Delta$.

► **Definition 18** (Candidate set). Let $\Delta > 0$ be a given value and let S be a Δ -good simplification of a polygonal curve P . Let T_S be the set of generating triples of S . We define the **candidate set** induced by S with respect to Δ as the set of line segments

$$B = \{e[s_1, t_2] \mid \exists (e, S_1, S_2) \in T_S, \text{ s.t. } \mathcal{E}_{8\Delta}(S_i, e) = (s_i, t_i) \text{ for } i \in \{1, 2\}\}$$

Clearly, the set B can be computed in $O(|T_S|)$ time and space, if the set T_S is given.

In the full version [7], we show that, for any suitable covering, we can deform each subedge of the solution to one of our candidates while retaining the coverage on a fixed subcurve. However, while retaining coverage on one subcurve, we may lose coverage on

another subcurve in the same cluster. We show, through a case analysis, how to deal with all subcurves at once while increasing the number of clusters by a factor of at most 4. We use this fact together with Theorem 10 to prove Theorem 14.

3 The main algorithm

We describe the main algorithm below with pseudocode specified in Algorithm 1 and Algorithm 2. Specifications of the missing subroutines are given in Table 1. Several additional building blocks of the algorithm are described in the full version [7]: computing candidates, computing the structured coverage, testing feasibility and computing simplifications.

Algorithm. The algorithm receives as input a polygonal curve P in \mathbb{R}^d and a parameter $\Delta \geq 0$. The goal is to compute a small set of edges C , such that all points on P are covered by the Δ' -coverage of C on P for some $\Delta' \in O(\Delta)$. The algorithm APPROXCOVER (see Algorithm 1), when called with input P and Δ , first computes a Δ -good simplification S of P and generates a finite subset B of the candidate space $\mathcal{Z}_{E(S)} \subset \mathbb{X}_2^d$ defined on the edges of this simplification. For this, we use the construction of the candidate set presented in Section 2. The algorithm then performs an exponential search with the variable k that controls the target size of the solution. Starting with a constant k , the algorithm tries to find a solution of size approximately k and if this fails, the algorithm doubles k and continues. For finding a solution with fixed target size, the algorithm KAPPROXCOVER is used (see Algorithm 1). This algorithm is called with the simplification S , the candidate set B and set of parameters r, Δ', k' , and i_{\max} . The algorithm KAPPROXCOVER uses a variant of the multiplicative weight update method with a maximum number of (proper) iterations bounded by i_{\max} . In the i th iteration, we take a sample from a discrete probability distribution \mathcal{D}_i that is defined on B via a weight function $w_i : B \rightarrow \mathbb{R}$, where the probability of an element $e \in B$ being in the sample is defined as $w_i(e) / \sum_{e \in B} w_i(e)$. For the initial distribution \mathcal{D}_1 , all weights are set to 1, which corresponds to the uniform distribution over B . During the course of the algorithm, we repeatedly update this distribution thereby generating distributions $\mathcal{D}_1, \mathcal{D}_2, \dots$ (up to $\mathcal{D}_{i_{\max}}$, unless the algorithm finds a solution in an earlier iteration). The update step performed by a call to subroutine UPDATEWEIGHT proceeds by doubling the weight of the subset F of B . This can be done in $O(|B|)$ time and space by storing the cumulative probability distribution.

With this basic mechanism in place, the algorithm KAPPROXCOVER now proceeds as follows. In each iteration, the algorithm computes a set $C \subset B$ by taking k' independent draws from the current distribution \mathcal{D}_i . Then, the algorithm checks, if C is a solution to our problem by a call to the subroutine POINTNOTCOVERED. The subroutine should either return that all points on S are in the Δ' -coverage of the solution C , or return a point t on S that is not covered in this way. This can be done by computing the structured coverage $\Psi'_{\Delta'}(S, C)$ explicitly. In the former case, the algorithm returns the solution and terminates. In the latter case, we compute the subset F of candidates B that would cover t with respect to the subcurves that contain t and which have at most 3 edges. To compute F , we simply iterate over all elements of B and check if t is covered by a call to ISFEASIBLE (see Algorithm 2). (For technical reasons, we parametrize the curve P via the edge space of the set of edges of P , so that we can locate the edge that contains t in constant time.) It is important that F is not a multiset, so repeated additions of an element will not increase its weight.

At this point we would like to perform the weight update step which we described above with respect to the set F , however, we only do this if the weight of the set F is small. If the total weight of the set F is larger than a $\frac{1}{r}$ -fraction of the total weight of B , then we simply skip the update step and continue by taking another sample from the current distribution.

Procedure	Input	Output
SIMPLIFYCURVE	$P \in \mathbb{X}_n^d, \Delta \geq 0$	Δ -good simplification of P (Def. 3)
GENERATECANDIDATES	$S \in \mathbb{X}_n^d, \Delta \geq 0$	candidate set (Def. 18)
POINTNOTCOVERED	$C \subset \mathbb{X}_2^d, S \in \mathbb{X}_n^d, \Delta \geq 0$	either $t \in \mathbb{T}_n \setminus \Psi_{\Delta'}(S, C)$ or -1 if this set is empty
WEIGHTUPDATE	distribution \mathcal{D} given by weight function $w : B \rightarrow \mathbb{R}, F \subset B$	\mathcal{D}' with $w' : B \rightarrow \mathbb{R}$ where weight is doubled for all elements of F

■ **Figure 6** Example for the construction of the rectangle $R = [\alpha_1, \alpha_2] \times [\beta_1, \beta_2]$ for fixed P, i, j, t, Δ and e . The left image shows the curves $P[t_i, t_j]$ and e with two circles of radius Δ around $P(t_{i+1})$ and $P(t_{j-1})$. The middle image shows the corresponding Δ -free space diagram with a (i, j) -partial traversal from a_i to b_u and the right image shows the rectangle R in the parameter space $[0, 1]^2$ of e .

4 Analysis of the main algorithm

The algorithm described in Section 3 is based on the set cover algorithm by Brönniman and Goodrich [6]. A crucial step in the analysis of this algorithm is the analysis of the VC-dimension of the dual set system. In our case this is a set system formed by the sets F computed in the main algorithm. For the formal analysis of this set system, we introduce the notion of feasible sets.

► **Definition 19** (Feasible set). Let $S : \mathbb{T}_n \rightarrow \mathbb{R}^d$ be a polygonal curve and let $B \subset \mathbb{X}_2^d$ be a candidate set of edges and let $\Delta \geq 0$ be a real value. For any point $t \in \mathbb{T}_n$, we define the **feasible set** of t as the set of elements $Q \in B$ that admit an (i, j) -partial traversal with S that fully covers Q and that covers t on S , with the additional condition that $j - i \leq 3$. We denote the feasible set of t with $F_\Delta(t)$.

Note that for any fixed S and Δ the set of feasible sets $\{F_\Delta(t) \mid t \in \mathbb{T}_n\}$ is exactly the set system determined by the subroutine ISFEASIBLE described in Algorithm 2. We claim that any feasible set can be split into sets corresponding to the edges of the simplification, where each set consists of a constant union of rectangles in the candidate space restricted to the respective edge. Figure 6 illustrates one of those rectangles. The following lemma provides the formal statement.

► **Lemma 20.** Let P be a polygonal curve in \mathbb{R}^d and let $e \in \mathbb{X}_2^d$ be an edge. Let (t_1, \dots, t_n) be the vertex-parameters of P . For any integer values $1 \leq i < j \leq \min(i + 3, n)$ and real value $t \in [0, 1]$ with $t_i \leq t \leq t_j$, either there exist $\alpha_1, \alpha_2, \beta_1, \beta_2$ such that

$$R := \{(\alpha, \beta) \in [0, 1]^2 \mid t \in \Psi_\Delta^{i,j}(P, e[\alpha, \beta])\} = [\alpha_1, \alpha_2] \times [\beta_1, \beta_2],$$

or the set R is empty. Moreover, each α_v (respectively β_v) for $v \in \{1, 2\}$ can be written as $\alpha_v = c_v + \sqrt{d_v}$ (respectively $\beta_v = e_v + \sqrt{f_v}$), where the parameters c_v and d_v (respectively e_v and f_v) can be computed by an algorithm that takes $(i, j), t$ and e as input and needs $O(d)$ simple operations.

To prove a VC-dimension bound of $O(d)$, we combine the above lemma with the following general theorem which can be attributed to Goldberg and Jerrum [16]. We use the variant by Anthony and Bartlett [4], which is stated as follows.

► **Theorem 21** (Theorem 8.4 [4]). Suppose h is a function from $\mathbb{R}^a \times \mathbb{R}^b$ to $\{0, 1\}$ and let $H = \{x \rightarrow h(\alpha, x) \mid \alpha \in \mathbb{R}^a\}$ be the class determined by h . Suppose that h can be computed by an algorithm that takes as input the pair $(\alpha, x) \in \mathbb{R}^a \times \mathbb{R}^b$ and returns $h(\alpha, x)$ after no more than t simple operations. Then, the VC-dimension of H is $\leq 4a(t + 2)$.

► **Lemma 22.** *Let $S : \mathbb{T}_n \rightarrow \mathbb{R}^d$ be a polygonal curve and let $\Delta \in \mathbb{R}_+$. Consider the set system $\{F_\Delta(t) \mid t \in \mathbb{T}_n\}$ with ground set \mathbb{X}_2^d . The VC-dimension of this set system is in $O(d)$.*

Proof. Define a function $h : \mathbb{T}_n \times \mathbb{X}_2^d \rightarrow \{0, 1\}$ with $h(t, Q) = 1$ if and only if a call to $\text{ISFEASIBLE}(Q, S, t, \Delta)$ returns true. We analyse the VC-dimension of the class of functions determined by h :

$$H = \{x \rightarrow h(t, x) \mid t \in \mathbb{T}_n\}$$

As a consequence, we obtain the same bounds on the VC-dimension of the corresponding set system \mathcal{R} with ground set \mathbb{X}_2^d where a set $r_t \in \mathcal{R}$ is defined by a $t \in \mathbb{T}_n$ with

$$r_t = \{Q \in \mathbb{X}_2^d \mid h(t, Q) = 1\}$$

In order to show the lemma, we first argue that for any given $t \in \mathbb{T}_n$ and $Q \in \mathbb{X}_2^d$ the expression $h(t, Q)$ can be evaluated with $O(d)$ simple operations.

Let $(t', i') = t$ and recall the index set $J = \{(i, j) \mid i' - 3 \leq i \leq i' \leq j \leq i + 3\}$ as in the procedure ISFEASIBLE . Note that $|J| = 9$ and that J can be determined by $O(1)$ simple operations from i' . Note that ISFEASIBLE returns true if and only if $t \in \Psi_\Delta^{i,j}(S, Q)$ for some $(i, j) \in J$. So, for fixed (i, j) , consider the set

$$R = \{(\alpha, \beta) \in [0, 1]^2 \mid t \in \Psi_\Delta^{i,j}(S, Q[\alpha, \beta])\}$$

Lemma 20 implies that R is either empty or can be written as a rectangle $[\alpha_1, \alpha_2] \times [\beta_1, \beta_2]$. Note that $t \in \Psi_\Delta^{i,j}(S, Q)$ if and only if R is non-empty and $(0, 1) \in R$. By Lemma 20, this test can be performed using $O(d)$ simple operations. Thus, we can apply Theorem 21 and conclude that the VC-dimension of H is in $O(d)$. ◀

With proper bounds on the VC-dimension in place, we obtain the following main result. The proof is based on the well-known $\frac{1}{r}$ -net theorem by Haussler and Welzl [20], which provides a bound on the probability that our sample chosen in line 5 is a $\frac{1}{r}$ -net of the weighted set system, based on the VC-dimension of this set system. We use this to bound the expected number of iterations of the main loop in KAPPROXCOVER within our analysis of the multiplicative weights update algorithm.

► **Theorem 23.** *Given a polygonal curve $P \in \mathbb{X}_n^d$ and $\Delta \in \mathbb{R}_+$, there exists an algorithm that computes an (α, β) -approximate solution to the Δ -coverage problem on P with $\alpha = 11$ and $\beta = O(\log k^*)$, where k^* is the minimum size of a solution to the Δ -coverage problem on P . The algorithm needs in expectation $\tilde{O}((k^*)^2 n + k^* n^3)$ time and $\tilde{O}((k^*) n + n^3)$ space.*

In the full version [7], we show improved bounds for c -packed curves. The only modification to the algorithm is a more careful generation of the triples that generate the candidate set.

► **Theorem 24.** *Let $P \in \mathbb{X}_n^d$ be c -packed and $\Delta \in \mathbb{R}_+$. Let k^* be the minimum size of a solution to the Δ -coverage problem on P . There exists an algorithm that outputs an $(11, O(\log(k^*)))$ -approximate solution. The algorithm needs*

1. $\tilde{O}((k^*)^2 n + nc^2 k^*)$ expected time and $\tilde{O}(k^* n + nc^2)$ space in \mathbb{R}^2 ,
2. $\tilde{O}((k^*)^2 n + nc^2 k^* + n^2)$ expected time and $\tilde{O}(k^* n + nc^2)$ space in \mathbb{R}^d .

In the full version [7], we also show that the property of the feasible sets as testified by Lemma 20 can be exploited to implicitly update the weights of a much larger set of candidates chosen from a uniform grid in the candidate space, thereby circumventing the explicit computation of the candidates. This improves the overall dependency on the complexity of the input curve in the running time, when compared to the previous algorithm – at the cost of a logarithmic factor of the relative arc-length of the curve.

► **Theorem 25.** Let $P \in \mathbb{X}_n^d$ and $\Delta \in \mathbb{R}_+$. Let k^* be the minimum size of a solution to the Δ -coverage problem on P . Let further $\lambda(P)$ be the arc length of the curve P . There exists an algorithm that outputs a $(12, O(\log(k^*)))$ -approximate solution. The algorithm needs in expectation $O(nk^{*3}(\log^4(\frac{\lambda(P)}{\Delta}) + \log^3(\frac{n}{k^*}) + n \log^2(n)))$ time and $O(nk^* \log(\frac{n\lambda(P)}{\Delta k^*}))$ space.

5 Conclusions

With the algorithm variants presented in this paper, we can find bicriteria-approximate solutions to the Δ -coverage problem on a polygonal curve P . The new algorithms improve upon previously known algorithms for the Δ -coverage problem both in terms of known running time and space requirement bounds [2], as well as approximation factors. To the best of our knowledge, our candidate generation leads to the first strongly polynomial algorithm for subtrajectory clustering under the continuous Fréchet distance that does not depend on the relative arclength λ/Δ of the input curve or the spread of the coordinates. The running time is at most cubic in n , the number of vertices of the input curve (Theorem 23). In practice, we expect this to be lower as testified by our analysis for c -packed curves (Theorem 24). The work of Gudmundsson et. al. [17] suggest that in practice most curves are c -packed for a c that is considerably smaller than the complexity of the curve. However, it remains to be seen if this also holds for the typically long curves which appear as input in the subtrajectory clustering setting. We also present a variant of the algorithm with implicit weight updates which achieves a linear dependency on n (Theorem 25) and this holds in general, without any c -packedness assumption on the input.

There are several avenues for future research. We mention some of them here. An interesting question that remains open for now is whether the implicit weight update can be performed directly on the candidate set (Definition 18). For this, we need to develop a dynamic data structure that can maintain the distribution on this candidate set to perform updates with rectangles and to sample from it. Another future research direction is to improve the dependency of the approximation factor on the parameter that controls the complexity of the input curves. Currently, the dependency is linear, and we did not try to improve it, since our focus was on clustering with line segments. Another interesting question is, how the low complexity center curves obtained by our algorithm can be best connected to center curves of higher complexity or even a geometric graph while retaining the Δ -covering.

Abstract

We study the problem of constructing a data structure that can store a two-dimensional polygonal curve P , such that for any query segment \overline{ab} one can efficiently compute the Fréchet distance between P and \overline{ab} . First we present a data structure of size $O(n \log n)$ that can compute the Fréchet distance between P and a horizontal query segment \overline{ab} in $O(\log n)$ time, where n is the number of vertices of P . In comparison to prior work, this significantly reduces the required space. We extend the type of queries allowed, as we allow a query to be a horizontal segment \overline{ab} together with two points $s, t \in P$ (not necessarily vertices), and ask for the Fréchet distance between \overline{ab} and the curve of P in between s and t . Using $O(n \log^2 n)$ storage, such queries take $O(\log^3 n)$ time, simplifying and significantly improving previous results. We then generalize our results to query segments of arbitrary orientation. We present an $O(nk^{3+\varepsilon} + n^2)$ size data structure, where $k \in [1, n]$ is a parameter the user can choose, and $\varepsilon > 0$ is an arbitrarily small constant, such that given any segment \overline{ab} and two points $s, t \in P$ we can compute the Fréchet distance between \overline{ab} and the curve of P in between s and t in $O((n/k) \log^2 n + \log^4 n)$ time. This is the first result that allows efficient exact Fréchet distance queries for arbitrarily oriented segments.

We also present two applications of our data structure. First, we show that our data structure allows us to compute a local δ -simplification (with respect to the Fréchet distance) of a polygonal curve in $O(n^{5/2+\varepsilon})$ time, improving a previous $O(n^3)$ time algorithm. Second, we show that we can efficiently find a translation of an arbitrary query segment \overline{ab} that minimizes the Fréchet distance with respect to a subcurve of P .

1 Introduction

Comparing the shape of polygonal curves is an important task that arises in many contexts such as GIS applications [2, 9], protein classification [20], curve simplification [7], curve clustering [1] and even speech recognition [21]. Within computational geometry, there are two well studied distance measures for polygonal curves: the Hausdorff and the Fréchet distance. The Fréchet distance has proven particularly useful as it takes the course of the curves into account. However, the Fréchet distance between curves is costly to compute: as its computation requires roughly quadratic time [3, 8]. When a large number of Fréchet distance queries are required, we would like to have a data structure, a so-called *distance oracle*, to answer these queries more efficiently. This leads to a fundamental data structuring problem: preprocess a polygonal curve such that, given a query polygonal curve, their Fréchet distance can be computed efficiently (query curves are assumed to be comparatively small). It turns out that this problem is extremely challenging. Indeed, even though great efforts have been devoted to design data structures to answer Fréchet distance queries, there is still no distance oracle known that is able to answer *exact* queries for a general query curve.

To make progress on this important problem, in this work we focus on a more restrictive but fundamental setting: when the query curve is a single segment. The reasons to study this variant of the problem are twofold. On the one hand, it is a necessary step to solve the general problem. On the other hand, it is a setting that has its own applications. For example, in trajectory simplification, or when trying to find subtrajectories that are geometrically close to a given query segment (e.g. when computing shortcut-variants of the Fréchet distance [12], or in trajectory analysis [5] on sports data). A similar strategy of tackling segment queries has also been successfully applied in nearest neighbor queries with the Fréchet distance [4].

We study preprocessing a polygonal curve P to determine the *exact continuous* Fréchet distance between P and a query segment in sublinear time. Specifically, we study preprocessing a polygonal curve P of n vertices in the plane, such that given a query segment \overline{ab} , traversed from a to b , the Fréchet distance between P and \overline{ab} can be computed in sublinear time. Without preprocessing, this problem can be solved in $O(n \log n)$ time.

Related work. Data structures that support (approximate) nearest neighbor queries with respect to the Fréchet distance have received considerable attention throughout the years [4, 13, 15]. In these problems, the goal is typically to store a set of polygonal curves such that given a query curve and a query threshold Δ one can quickly report (or count) the curves that are (approximately) within (discrete) Fréchet distance Δ of the query curve. Some of these data structures even allow approximately counting the number of curves that have a subcurve within Fréchet distance Δ [5]. Highlighting its practical importance, the near neighbor problem using Fréchet distance was posed as ACM Sigspatial GIS Cup in 2017 [24].

Here, we want to compute the Fréchet distance of (part of) a curve to a low complexity *query* curve. For the *discrete* Fréchet distance, efficient $(1 + \varepsilon)$ -approximate distance oracles are known, even when P is given in an online fashion [14]. For the *continuous* Fréchet distance, Driemel and Har-Peled [12] present an $O(n\varepsilon^{-4} \log \varepsilon^{-1})$ size data structure that given a query segment \overline{ab} can compute a $(1 + \varepsilon)$ -approximation of the Fréchet distance between P and \overline{ab} in $O(\varepsilon^{-2} \log n \log \log n)$ time. Their approach extends to higher dimensions and low complexity polygonal query curves. However, in contrast to our solution, this approximation uses techniques that do not provide insight into the structure of the algorithmic problem.

Gudmundsson et al. [17] present an $O(n \log n)$ sized data structure that can *decide* if the Fréchet distance to \overline{ab} is smaller than a given value Δ in $O(\log^2 n)$ time (so with some parametric search approach one could consider computing the Fréchet distance itself). However, their result holds only when the length of \overline{ab} and all edges in P is relatively large compared to Δ . De Berg et al. [6] presented an $O(n^2)$ size data structure that does not have any restrictions on the length of the query segment or the edges of P . However, the orientation of the query segment is restricted to be horizontal. Queries are supported in $O(\log^2 n)$ time, and even queries asking for the Fréchet distance to a vertex-to-vertex subcurve are allowed (in that case, using $O(n^2 \log^2 n)$ space). Recently, Gudmundsson et al. [18] extended this result to allow the subcurve to start and end anywhere within P . Their data structure has size $O(n^2 \log^2 n)$ and queries take $O(\log^8 n)$ time. In their journal version, Gudmundsson et al. [19] directly apply the main result of a preliminary version of this paper [10] to immediately improve space usage of their data structure to $O(n^{3/2})$; their preprocessing time remains $O(n^2 \log^2 n)$. The current version of this paper significantly improves these results. Moreover, we present data structures that allow for arbitrarily oriented query segments.

Problem statement & our results. Let P be a polygonal curve in \mathbb{R}^2 with n vertices p_1, \dots, p_n . For ease of exposition, we assume that the vertices of P are in general position, i.e., all x - and y -coordinates are unique, no three points lie on a line, and no four points are cocircular. We consider P as a function mapping any time $t \in [0, 1]$ to a point $P(t)$ in the plane. Our ultimate goal is to store P such that we can quickly compute the *Fréchet distance* $\mathcal{D}_{\mathcal{F}}(P, Q)$ between P and a query curve Q . The Fréchet distance is defined as

$$\mathcal{D}_{\mathcal{F}}(P, Q) = \inf_{\alpha, \beta} \max_{t \in [0, 1]} \|P(\alpha(t)) - Q(\beta(t))\|,$$

where $\alpha, \beta: [0, 1] \rightarrow [0, 1]$ are nondecreasing surjections, also called reparameterizations of P and Q , respectively, and $\|p - q\|$ denotes the Euclidean distance between p and q .

In this work we focus on the case where Q is a single line segment \overline{ab} starting at a and ending at b . Note that P may self-intersect and \overline{ab} may intersect P . Our first main result deals with the case where \overline{ab} is horizontal:

► **Theorem 1.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices. There is an $O(n \log n)$ size data structure that can be built in $O(n \log^2 n)$ time such that given a horizontal query segment \overline{ab} it can report $\mathcal{D}_{\mathcal{F}}(P, \overline{ab})$ in $O(\log n)$ time.*

This significantly improves over the earlier result of de Berg et al. [6], as we reduce the required space and preprocessing time from quadratic to near linear. We simultaneously improve the query time from $O(\log^2 n)$ to $O(\log n)$. We further extend our results to allow queries against subcurves of P . Let s, t be two points on P , we use $P[s, t]$ to denote the subcurve of P from s to t . For horizontal query segments we then get:

► **Theorem 2.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices. There is an $O(n \log^2 n)$ size data structure that can be built in $O(n \log^2 n)$ time such that given a horizontal query segment \overline{ab} and two query points s and t on P it can report $\mathcal{D}_{\mathcal{F}}(P[s, t], \overline{ab})$ in $O(\log^3 n)$ time.*

De Berg et al. presented a data structure that could handle such queries in $O(\log^2 n)$ time (using $O(n^2 \log^2 n)$ space), provided that s and t were vertices of P . Compared to their data structure we thus again significantly improve the space usage, while allowing more general queries. The recently presented data structure of Gudmundsson et al. [18] does allow s and t

to lie on the interior of edges of P (and thus supports queries against arbitrary subcurves). Their original data structure uses $O(n^2 \log^2 n)$ space and allows for $O(\log^8 n)$ time queries. Compared to their result we use significantly less space, while also improving the query time.

Using the insights gained in this restricted setting, we then present the first data structure that allows exact Fréchet distance queries with arbitrarily oriented query segments in sublinear time. With near quadratic space we obtain a query time of $O(n^{2/3} \log^2 n)$. If we insist on logarithmic query time the space usage increases to $O(n^{4+\varepsilon})$. In particular, we present a data structure with the following time-space tradeoff. At only a small additional cost we can also support subcurve queries.

► **Theorem 3.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices, and let $k \in [1..n]$ be a parameter. There is an $O(nk^{3+\varepsilon} + n^2)$ size data structure that can be built in $O(nk^{3+\varepsilon} + n^2)$ time such that given an arbitrary query segment \overline{ab} it can report $\mathcal{D}_{\mathcal{F}}(P, \overline{ab})$ in $O((n/k) \log^2 n)$ time. In addition, given two query points s and t on P , it can report $\mathcal{D}_{\mathcal{F}}(P[s, t], \overline{ab})$ in $O((n/k) \log^2 n + \log^4 n)$ time.*

In Theorem 3 and throughout the rest of the paper $\varepsilon > 0$ is an arbitrarily small constant. In both Theorem 2 and Theorem 3 the query time can be made sensitive to the number of vertices $m = |P[s, t]|$ in the query subcurve $P[s, t]$. That is, we can get query times $O(\log^3 m)$ and $O((m/k) \log^2 m + \log^4 m)$, respectively.

To achieve our results, we also develop data structures that allow us to efficiently query the directed Hausdorff distance $\overrightarrow{\mathcal{D}}_H(P[s, t], \overline{ab}) = \max_{p \in P[s, t]} \min_{q \in \overline{ab}} \|p - q\|$ from (a subcurve $P[s, t]$ of) P to the query segment \overline{ab} . For an arbitrarily oriented query segment \overline{ab} and a query subcurve $P[s, t]$ our data structure uses $O(n \log n)$ space and can answer such queries in $O(\log^2 n)$ time. Using more space, queries can be answered in $O(\log n)$ time, see Section 4.

Applications. In the full version [11] we show how to efficiently solve two problems using our data structure. First, we show how to compute a local δ -simplification of P – that is, a minimum complexity curve whose edges are within Fréchet distance δ to the corresponding subcurve of P – in $O(n^{5/2+\varepsilon})$ time. This improves existing $O(n^3)$ time algorithms [16].

Recently, Gudmundsson et al. [18] (full version [19]) studied the query version of this problem, where the goal is to preprocess P , such that given a query curve Q and two points s and t on P , one can find the translation of Q that minimizes the Fréchet distance between (a subcurve) $P[s, t]$ and Q efficiently. They study this query version in a restricted setting, where Q is a horizontal segment. Their original data structure uses $O(n^2 \log^2 n)$ space and allows for $O(\log^{32} n)$ time queries. By applying our data structure, we solve their problem using $O(n \log^2 n)$ space whilst supporting $O(\log^{12} n)$ time queries. In addition, we answer one of their open question to find optimal translations for arbitrarily oriented query segments. Finally, we answer another of their open problems by showing how to find a scaling of a query segment that minimizes the Fréchet distance. Specifically, we show a $O(n \log^2 n)$ size data structure that for any horizontal query segment, can compute the scaling of the segment that minimizes its Fréchet distance to $P[s, t]$ in $O(\log^4 n)$ time. We also show a version for arbitrarily oriented queries.

2 Global approach

We illustrate the main ideas of our approach, in particular for the case where the query segment \overline{ab} is horizontal, with a left of b . We can build a symmetric data structure in case a lies right of b . We now first review some definitions based on those in [6].

■ **Figure 1** (a) A polygonal curve and query segment. (b) The red vertex p_j forms a backward pair with all but one blue vertex. (c) For a fixed backward pair (p_i, p_j) , we consider the distance between the intersection (cross) of their bisector (dashed) and \overline{ab} , and either p_i or p_j .

Let P^{\leq} be the set of ordered pairs of vertices $(p, q) \in P \times P$ where p precedes or equals q along P . An ordered pair $(p, q) \in P^{\leq}$ forms a *backward pair* if $x_q \leq x_p$. Throughout the rest of the paper, x_p and y_p denote the x - and y -coordinates of point p , respectively. We denote by $\mathcal{B}(P)$ the backward pairs and say $(p, q) \in \mathcal{B}(P)$ is *trivial* if $p = q$ (Figure 1). For two points $p, q \in P$, we then define $\delta_{pq}(y) = \min_x \max \{ \| (x, y) - p \|, \| (x, y) - q \| \}$ (See Figure 1(c)). That is, $\delta_{pq}(y)$ is a function that for any y , gives the minimum distance between a point at height y and both p and q . We will use the function δ_{pq} only when $(p, q) \in \mathcal{B}(P)$ is a backward pair. We define the function $\mathcal{D}_B(y) = \max \{ \delta_{pq}(y) \mid (p, q) \in \mathcal{B}(P) \}$, which we refer to as the *backward pair distance* of a horizontal segment at height y with respect to P . Note that $\mathcal{D}_B(y)$ is the upper envelope of the functions δ_{pq} for all backward pairs (p, q) of P . De Berg et al. [6] prove that the Fréchet distance is the maximum of four terms:

$$\mathcal{D}_{\mathcal{F}}(P, \overline{ab}) = \max \left\{ \|p_1 - a\|, \|p_n - b\|, \overrightarrow{\mathcal{D}}_H(P, \overline{ab}), \mathcal{D}_B(y_a) \right\}. \quad (1)$$

The first two terms are trivial to compute in $O(1)$ time. Like de Berg et al., we build separate data structures that allow us to efficiently compute the third and fourth terms.

A key insight is that we can compute $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$ by building the furthest segment Voronoi diagrams (FSVD) of two sets of horizontal halflines, and querying these diagrams with the endpoints a and b . See Section 3.1. This allows for a linear space data structure that supports querying $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$ in $O(\log n)$ time, improving both the space and query time over [6].

However, in [6] the data structure that supports computing the backward pair distance dominates the required space and preprocessing time, as there may be $\Omega(n^2)$ backward pairs, see Figure 1. Via a divide and conquer argument we show that the number of backward pairs that show up on the upper envelope \mathcal{D}_B is only $O(n \log n)$, see Section 3.2. The crucial ingredient is that there are only $O(n)$ backward pairs (p, q) contributing to \mathcal{D}_B in which p is a vertex among the first $n/2$ vertices of P , and q is a vertex in the remaining $n/2$ vertices. Surprisingly, we can again argue this using furthest segment Voronoi diagrams of sets of horizontal halflines. This allows us to build \mathcal{D}_B in $O(n \log^2 n)$ time in total. We can then extend these results to support queries against an arbitrary subcurve $P[s, t]$ of P (see [11]).

For arbitrarily oriented query segments we similarly decompose $\mathcal{D}_{\mathcal{F}}(P, \overline{ab})$ into four terms (Section 4). The directed Hausdorff term can still be queried efficiently using an $O(n \log^2 n)$ size data structure. However, our initial data structure for the backward pair distance uses $O(n^{4+\varepsilon})$ space. The main reason for this is that functions δ_{pq} expressing the cost of a backward pair are now bivariate, depending on both the slope and intercept of the supporting line of \overline{ab} . The upper envelope of a set of n such functions may have quadratic complexity.

While our divide and conquer strategy does not help us to directly bound the complexity of the (appropriately generalized function) \mathcal{D}_B in this case, it does allow us to support queries against subcurves of P . Moreover, we can use it to obtain a favourable query time vs. space trade off. In the full version [11] we then apply our data structure to efficiently solve various Fréchet distance related problems. Omitted proofs can be found in the full version [11].

■ **Figure 2** (a) A set $S := \{p, u, v\}$ with \overleftarrow{S} in blue. The distance $h_{\overleftarrow{p}}(q)$ is the distance to the apex of \overleftarrow{p} , whilst the distance $h_{\overleftarrow{u}}(q)$ is their vertical difference. (b) the distance between a point q and p is the maximum of the distance to the left and right halfline from p .

3 Horizontal queries

3.1 The Hausdorff term

In this section we introduce some definitions that will be used throughout the paper, and state the fact that there is a linear-size data structure to query the Hausdorff term in $O(\log n)$ time, which can be built in $O(n \log n)$ time. The proof of this result is in the full version [11].

For a point $p \in \mathbb{R}^2$, define \overleftarrow{p} to be the “leftward” horizontal halfline starting at p and containing all points directly to the left of p . Refer to Figure 2. Analogously, we define \overrightarrow{p} as the “rightward” horizontal halfline starting at p , so that $p = \overleftarrow{p} \cap \overrightarrow{p}$. We extend this notation to any set of points S , that is, $\overleftarrow{S} = \{\overleftarrow{s} \mid s \in S\}$ denotes the set of “leftward” halflines starting at the points in $S \subseteq \mathbb{R}^2$. We define \overrightarrow{S} analogously. Let S and T be two (possibly overlapping) point sets in the plane. We define the following distance functions for rays $\overleftarrow{p}, \overleftarrow{S}$ (definitions for $\overrightarrow{p}, \overrightarrow{S}$ are analogous):

$$h_{\overleftarrow{p}}(q) = \overrightarrow{\mathcal{D}}_H(\{q\}, \overleftarrow{p}) = \min \left\{ \|p' - q\| \mid p' \in \overleftarrow{p} \right\}, \quad h_{\overleftarrow{S}}(q) = \max \left\{ h_{\overleftarrow{p}}(q) \mid p \in S \right\}$$

Note that $h_{\overrightarrow{S}}$ (resp., $h_{\overleftarrow{S}}$) is the upper envelope of the distance functions to the halflines in \overrightarrow{S} (resp., \overleftarrow{S}). Since $h_{\overrightarrow{S}}$ and $h_{\overleftarrow{S}}$ map each point in the plane to a distance, the envelopes live in \mathbb{R}^3 . Combining furthest segment Voronoi diagrams with point location data structures, we can show how to compute $\overrightarrow{\mathcal{D}}_H(S, \overline{ab})$ efficiently:

► **Theorem 4.** *Let S be a set of n points in \mathbb{R}^2 . In $O(n \log n)$ time we can build a data structure of linear size so that given a horizontal query segment \overline{ab} , $\overrightarrow{\mathcal{D}}_H(S, \overline{ab})$ can be computed in $O(\log n)$ time.*

Note that the directed Hausdorff distance from a polygonal curve P to a (horizontal) line segment is attained at a vertex of P [6], thus, we can use Theorem 4 to compute it.

3.2 The backward pairs term

Here we show that the function \mathcal{D}_B , representing the backward pair distance, has complexity $O(n \log n)$, can be computed in $O(n \log^2 n)$ time, and evaluated for some query value y in $O(\log n)$ time. This leads to an efficient data structure for querying P for the Fréchet distance to a horizontal query segment \overline{ab} , proving Theorem 1. See the full version [11] for details.

Recall that $\mathcal{D}_B(y)$ is the maximum over all function values $\delta_{pq}(y)$ for all backward pairs $(p, q) \in \mathcal{B}(P)$. To avoid computing $\mathcal{B}(P)$, we define a new function $\delta'_{pq}(y)$ that applies to any ordered pair of points $(p, q) \in P^{\leq}$. We show that for all backward pairs $(p, q) \in \mathcal{B}(P)$, we have $\delta'_{pq}(y) = \delta_{pq}(y)$. For any pair $(p, q) \in P^{\leq}$ that is not a backward pair, we show that there exists a (trivial) backward pair $(p', q') \in \mathcal{B}(P)$ such that $\delta'_{pq}(y) \leq \delta'_{p'q'}(y) = \delta_{p'q'}(y)$. Consequently, we can compute the value $\mathcal{D}_B(y)$ by computing the maximum value of $\delta'_{pq}(y)$ over all pairs in P^{\leq} . We will show how to do this in an efficient manner.

■ **Figure 3** The distance $\delta'_{pq}(y)$ is realised by either (a) the point of intersection between y and the bisector between \overleftarrow{q} and \overrightarrow{p} or, (b) the vertical distance between a line at height y and p or q .

For a pair of points $(p, q) \in P^{\leq}$, we define the *pair distance* between a query \overline{ab} at height y and (p, q) as the Hausdorff distance from a horizontal line of height y to $(\overrightarrow{p} \cup \overleftarrow{q})$, that is:

$$\delta'_{pq}(y) = \min_x \max \left\{ h_{\overleftarrow{q}}((x, y)), h_{\overrightarrow{p}}((x, y)) \right\}.$$

See Figure 3. The following key lemma states that, for our purposes we can use δ' instead of δ .

► **Lemma 5.** For any y , $\mathcal{D}_B(y) = \max \{ \delta_{pq}(y) \mid (p, q) \in \mathcal{B}(P) \} = \max \{ \delta'_{pq}(y) \mid (p, q) \in P^{\leq} \}$.

3.2.1 Relating $\mathcal{D}_B(y)$ to furthest segment Voronoi diagrams

Now we devise a divide and conquer algorithm that computes $\mathcal{D}_B(y)$ by computing it for subsets of vertices of P . Lemma 5 allows us to express $\mathcal{D}_B(y)$ in terms of P^{\leq} instead of $\mathcal{B}(P)$. Next we refine the definition of $\mathcal{D}_B(y)$ to make it decomposable. To that end, we define $\mathcal{D}_B(y)$ on pairs of subsets of P . Let S, T be any two subsets of vertices of P , we define:

$$\mathcal{D}_B^{S \times T}(y) = \max \{ \delta'_{pq}(y) \mid (p, q) \in (S \times T) \cap P^{\leq} \}.$$

We show that we can compute $\mathcal{D}_B^{S \times T}(y)$ efficiently using the δ' functions. For this, we fix a value of y and show that computing $\mathcal{D}_B^{S \times T}(y)$ is equivalent to computing an intersection between two curves that consist of a linear number of pieces, each of constant complexity. We then argue that as y changes, the intersection point moves along a linear complexity curve that can be computed in $O(n \log n)$ time. This will allow us to query $\mathcal{D}_B(y) = \mathcal{D}_B^{P \times P}(y)$ in $O(\log n)$ time, for any query height y .

From distance to intersections. For a fixed value y' , computing $\mathcal{D}_B^{S \times T}(y')$ is equivalent to computing an intersection point between two curves:

► **Lemma 6.** Let $y' \in \mathbb{R}$ be a fixed height, let p be a point in P , and let T be a subset of the vertices of $P[p, p_n]$. The graphs of the functions $x \mapsto h_{\overrightarrow{p}}((x, y'))$ and $x \mapsto h_{\overleftarrow{T}}((x, y'))$ intersect at a single point (x^*, y') . Moreover, $\mathcal{D}_B^{\{p\} \times T}(y') = h_{\overleftarrow{T}}((x^*, y')) = h_{\overrightarrow{p}}((x^*, y'))$

► **Lemma 7.** Let $y' \in \mathbb{R}$ be a fixed height, and let S, T be subsets of vertices of P such that all vertices in S precede all vertices in T . The graphs of the functions $x \mapsto h_{\overrightarrow{S}}((x, y'))$ and $x \mapsto h_{\overleftarrow{T}}((x, y'))$ intersect at a single point (x^*, y') . Moreover, $\mathcal{D}_B^{S \times T}(y') = h_{\overrightarrow{S}}((x^*, y')) = h_{\overleftarrow{T}}((x^*, y'))$.

Proof. If all points in S precede all points in T , then all elements in $S \times T$ are in P^{\leq} and we note: $\mathcal{D}_B^{S \times T}(y') = \max_{p \in S} \left\{ \mathcal{D}_B^{\{p\} \times T}(y') \right\}$. The equality then follows from Lemma 6. ◀

Given such a pair S, T , for a fixed value y' , we can compute a linear-size representation of $x \mapsto h_{\overleftarrow{T}}((x, y'))$ in $O(n \log n)$ time as follows (see Figure 4). We compute the *FSVD* of \overleftarrow{T} in $O(n \log n)$ time. Then, we compute the Voronoi cells intersected by a line of height y' (denoted by $\ell_{y'}$) in left-to-right order in $O(n \log n)$ time. Suppose that a segment of $\ell_{y'}$ intersects only the Voronoi cell belonging to a halfline $\overleftarrow{q} \in \overleftarrow{T}$, then on this domain the function $h_{\overleftarrow{T}}((x, y')) = h_{\overleftarrow{q}}((x, y'))$, and thus it has constant complexity. A horizontal line can intersect at most a linear number of Voronoi cells, hence the function has total linear complexity. Analogous arguments apply to $x \mapsto h_{\overrightarrow{S}}((x, y'))$.

Varying the y -coordinate. Let $f_{\overrightarrow{S}, \overleftarrow{T}} : y \mapsto x^*$ be the function that for each y gives the intersection point x^* such that $h_{\overrightarrow{S}}((x^*, y)) = h_{\overleftarrow{T}}((x^*, y))$. The intersection point (x^*, y) lies on a Voronoi edge of the *FSVD* of $(\overleftarrow{T} \cup \overrightarrow{S})$. More precisely, it lies on the bichromatic bisector of the *FSVD* of \overleftarrow{T} and the one of \overrightarrow{S} .

When we vary the y -coordinate, the intersection point traces this bisector. This implies that, given the *FSVD* of \overrightarrow{S} and the *FSVD* of \overleftarrow{T} , the graph of $f_{\overrightarrow{S}, \overleftarrow{T}}$ can be computed in $O(n)$ time. Using these properties, we can prove the following.

► **Lemma 8.** *Let S, T be subsets of vertices of P such that all vertices in S precede all vertices in T . The function $\mathcal{D}_B^{S \times T}$ has complexity $O(n)$ and can be computed in $O(n \log n)$ time. Evaluating $\mathcal{D}_B^{S \times T}(y)$, for some query value $y \in \mathbb{R}$, takes $O(\log n)$ time.*

3.2.2 Applying divide and conquer

We begin by analyzing the complexity of the function $\mathcal{D}_B(y)$. Consider a partition of P into subcurves S and T with at most $\lceil n/2 \rceil$ vertices each, and with S occurring before T along P . Our approach relies on the following fact.

► **Observation 9.** *Let P be partitioned into two subcurves S and T with all vertices in S occurring on P before the vertices of T . We have that*

$$\mathcal{D}_B(y) = \mathcal{D}_B^{P \times P}(y) = \max \{ \mathcal{D}_B^{S \times S}(y), \mathcal{D}_B^{S \times T}(y), \mathcal{D}_B^{T \times T}(y) \}.$$

Note that we can omit $\mathcal{D}_B^{T \times S}$ because $(T \times S) \cap P^{\leq} = \emptyset$. We obtain the following lemma.

■ **Figure 4** (a) A set \overleftarrow{T} of rays arising from a set T of points, with their *FSVD*. (b) $h_{\overleftarrow{T}}((x, y))$ is the distance from (x, y) to the ray corresponding to the Voronoi cell at (x, y) . (c) For a fixed y' , $x \mapsto h_{\overleftarrow{T}}((x, y'))$ is monotonically increasing. (d) The value x for which $h_{\overleftarrow{T}}((x, y')) = h_{\overrightarrow{S}}((x, y'))$ corresponds to $f_{\overrightarrow{S}, \overleftarrow{T}}(y')$, and to $\mathcal{D}_B^{S \times T}(y')$.

► **Lemma 10.** *Let P be a polygonal curve with n vertices. The function \mathcal{D}_B has complexity $O(n \log n)$ and can be computed in $O(n \log^2 n)$ time. Evaluating $\mathcal{D}_B(y)$, for a given $y \in \mathbb{R}$, takes $O(\log n)$ time.*

Eq. 1 together with Theorem 4 and Lemma 10 thus imply that we can store P in an $O(n \log n)$ size data structure, so that we can compute $\mathcal{D}_{\mathcal{F}}(P, \overline{ab})$ for some horizontal query segment \overline{ab} in $O(\log n)$ time. That is, we have established Theorem 1.

Subcurve queries. We can extend our data structure to support Fréchet distance queries to subcurves of P , establishing Theorem 2. The two main ideas are (i) to store all intermediate data structures constructed in the above divide and conquer algorithm, and that (ii) we can actually achieve the result of Lemma 8 – evaluating $\mathcal{D}_B^{S \times T}(y')$ for some query value y' in $O(\log n)$ time – by *separately* storing a data structure on S and a data structure on T . See the full version [11] for details. Our data structure has total size $O(n \log^2 n)$ and allows us to find $O(\log n)$ nodes whose associated subcurves make up the query subcurve $P[s, t]$. For each such pair of nodes μ, ν we use the (extended) Lemma 8 data structures associated with these nodes to compute the contribution $\mathcal{D}_B^{P_\mu \times P_\nu}(y)$ of backward pairs with one vertex in subcurve P_ν and one vertex in P_μ . We thus spend $O(\log^3 n)$ time to compute the backward pair distance. This dominates the $O(\log^2 n)$ time required to query the Theorem 4 data structures associated with each node to compute the Hausdorff distance term.

4 Arbitrary orientation queries

In this section we extend our results to arbitrarily oriented query segments, proving Theorem 3. Let α be the slope of the line containing the query segment \overline{ab} , and let β be its intercept (note that vertical query segments can be handled by a rotated version of our data structure for horizontal queries). We again consider the case where a is left of b ; the other case is symmetric. Following Eq. 1, we can write $\mathcal{D}_{\mathcal{F}}(P, \overline{ab})$ as the maximum of four terms: $\|p_1 - a\|$, $\|p_n - b\|$, $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$, and the *backward pair distance* $\mathcal{D}_B(\alpha, \beta)$ with respect to α . The backward pair distance is now defined as

$$\begin{aligned} \mathcal{D}_B(\alpha, \beta) &= \max \{ \delta_{pq}(\alpha, \beta) \mid (p, q) \in \mathcal{B}(P) \}, & \text{where} \\ \delta_{pq}(\alpha, \beta) &= \min_x \max \{ \| (x, \alpha x + \beta) - p \|^2, \| (x, \alpha x + \beta) - q \|^2 \}. \end{aligned}$$

In Section 4.1 we present an $O(n \log n)$ size data structure that supports querying $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$ in $O(\log^2 n)$ time. The key insight is that we can use furthest *point* Voronoi diagrams instead of furthest *segment* Voronoi diagrams. In Section 4.2 we present a data structure that efficiently supports querying $\mathcal{D}_B(\alpha, \beta)$. In Section 4.3 we extend our results to support queries against subcurves of P as well. This combines our insights from the horizontal queries with our results from Sections 4.1 and 4.2. Finally, in Section 4.4 we then show how this also leads to a space-time trade off.

4.1 The Hausdorff distance term

For any point p and slope α we will denote by \overleftarrow{p}^α the ray with apex p and slope α that points in the leftward direction. Similarly, for any point set T , we define $\overleftarrow{T}^\alpha = \{ \overleftarrow{p}^\alpha \mid p \in T \}$. Furthermore, we define $h_{\overleftarrow{p}^\alpha}(x, y)$ to be the directed Hausdorff distance from (x, y) to the ray \overleftarrow{p}^α , and $h_{\overleftarrow{T}^\alpha}(x, y) = \max \{ h_{\overleftarrow{p}^\alpha}(x, y) \mid p \in T \}$.

29:10 Efficient Fréchet Distance Queries for Segments

We can show that we can use the furthest point Voronoi diagram instead of the furthest segment Voronoi diagram and obtain the following results.

► **Lemma 11.** *Let T be a set of n points in \mathbb{R}^2 . In $O(n^2)$ time we can construct an $O(n^2)$ size data structure so that given a query point (x, y) and slope α we can compute $h_{T, \alpha}^{\leftarrow}(x, y)$ in $O(\log n)$ time.*

► **Theorem 12.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices.*

■ *In $O(n \log n)$ time we can construct a data structure of size $O(n \log n)$ so that given a query segment \overline{ab} , $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$ can be computed in $O(\log^2 n)$ time.*

■ *In $O(n^2)$ time we can construct a data structure of size $O(n^2)$ so that given a query segment \overline{ab} , $\overrightarrow{\mathcal{D}}_H(P, \overline{ab})$ can be computed in $O(\log n)$ time.*

4.2 The backward pair distance term

Let $(p, q) \in P^{\leq}$ be an ordered pair. We restrict $\delta_{pq}(\alpha, \beta)$ to the interval of α values for which (p, q) is a backward pair with respect to orientation α . Hence, each δ_{pq} is a partially defined, constant algebraic degree, constant complexity, bivariate function. The backward pair distance \mathcal{D}_B is the upper envelope of $O(n^2)$ such functions. This envelope has complexity $O(n^{4+\varepsilon})$, for some arbitrarily small $\varepsilon > 0$, and can be computed in $O(n^{4+\varepsilon})$ time [23]. Evaluating $\mathcal{D}_B(\alpha, \beta)$ for some given α, β takes $O(\log n)$ time. The following lemma, together with Theorem 12 then gives an $O(n^{4+\varepsilon})$ size data structure that supports $O(\log n)$ time Fréchet distance queries.

► **Lemma 13.** *Let P be an n -vertex polygonal curve in \mathbb{R}^2 . In $O(n^{4+\varepsilon})$ time we can construct a size $O(n^{4+\varepsilon})$ data structure so that given a query segment \overline{ab} , $\mathcal{D}_B(\overline{ab})$ can be computed in $O(\log n)$ time.*

4.3 Subcurve queries

Next, we sketch how to support querying against subcurves $P[s, t]$ of P in $O(\log^4 n)$ time as well. Refer to the full version [11] for details. We use the same approach as in the horizontal query segment case: we store the vertices of P into the leaves of a range tree where each internal node ν corresponds to some canonical subcurve P_ν , so that any subcurve $P[s, t]$ can be represented by $O(\log n)$ nodes.

The Hausdorff distance term. Computing the directed Hausdorff distance is decomposable, so using this approach with the data structure of Theorem 12 immediately gives us a data structure that allows us to compute $\overrightarrow{\mathcal{D}}_H(P[s, t], \overline{ab})$ in $O(\log^2 n)$ time. Since the space usage satisfies the recurrence $S(n) = 2S(n/2) + O(n^2)$, this uses $O(n^2)$ space in total.

The backward pair distance term. By storing the data structure of Lemma 13 at every node of the tree, we can efficiently compute the contribution of the backward pairs inside each of the $O(\log n)$ canonical subcurves that make up $P[s, t]$. However, as before, we are still missing the contribution of the backward pairs from different canonical subcurves. We again store additional data structures at every node of the tree that allow us to efficiently compute this contribution.

Let S and T be (the vertices of) two such canonical subcurves, with all vertices of S occurring before T along P . As before we will argue that for some given α and β the functions $x \mapsto h_{T, \alpha}^{\leftarrow}(x, \alpha x + \beta)$ and $x \mapsto h_{S, \alpha}^{\rightarrow}(x, \alpha x + \beta)$ are monotonically increasing and decreasing,

respectively, and that the intersection point of (the graphs of) these functions corresponds to the contribution of the backward pairs in $S \times T$. So, our goal is to build data structures storing S and T that given a query α, β allow us to compute the intersection point of these functions. We will show that we can use the data structure of Lemma 11 to support such queries in $O(\log^2 n)$ time.

We generalize some of our earlier geometric observations to arbitrary orientations. Let p, q be vertices of P , and let S and T be subsets of vertices of P . We define

$$\delta'_{pq}(\alpha, \beta) = \min_x \max \left\{ h_{\leftarrow q}^\alpha((x, \alpha x + \beta)), h_{\rightarrow p}^\alpha((x, \alpha x + \beta)) \right\} \quad \text{and}$$

$$\mathcal{D}_B^{S \times T}(\alpha, \beta) = \max \left\{ \delta'_{pq}(\alpha, \beta) \mid (p, q) \in (S \times T) \cap P^\leq \right\}.$$

and prove the following lemmas (by essentially rotating the plane so that the query segment becomes horizontal, and applying the appropriate lemmas from earlier sections):

► **Lemma 14.** *Let P be partitioned into two subcurves S and T with all vertices in S occurring on P before the vertices of T . We have that*

$$\mathcal{D}_B(\alpha, \beta) = \mathcal{D}_B^{P \times P}(\alpha, \beta) = \max \left\{ \mathcal{D}_B^{S \times S}(\alpha, \beta), \mathcal{D}_B^{T \times T}(\alpha, \beta), \mathcal{D}_B^{S \times T}(\alpha, \beta) \right\}.$$

► **Lemma 15.** *Let S and T be subsets of vertices of P , with S occurring before T along P , and let α, β denote some query parameters. The function $x \mapsto h_{\leftarrow T}^\alpha(x, \alpha x + \beta)$ is monotonically increasing, whereas $x \mapsto h_{\rightarrow S}^\alpha(x, \alpha x + \beta)$ is monotonically decreasing. These functions intersect at a point $(x^*, \alpha x^* + \beta)$, for which $\mathcal{D}_B^{S \times T}(\alpha, \beta) = h_{\leftarrow T}^\alpha(x^*, \alpha x^* + \beta) = h_{\rightarrow S}^\alpha(x^*, \alpha x^* + \beta)$.*

Querying $\mathcal{D}_B^{S \times T}(\alpha, \beta)$. Consider the predicate $Q(x) = h_{\leftarrow T}^\alpha(x, \alpha x + \beta) < h_{\rightarrow S}^\alpha(x, \alpha x + \beta)$. It follows from Lemma 15 that there is a single value x^* so that $Q(x) = \text{FALSE}$ for all $x < x^*$ and $Q(x) = \text{TRUE}$ for all $x \geq x^*$. Moreover, x^* realizes $\mathcal{D}_B^{S \times T}(\alpha, \beta)$. By storing S and T , each in a separate copy of the data structure of Lemma 11, we can evaluate $Q(x)$, for any value x , in $O(\log n)$ time. We then use parametric search [22] to find x^* in $O(\log^2 n)$ time. Note that this approach is an $O(\log n)$ factor slower compared to the approach we used for horizontal queries only.

► **Lemma 16.** *Let S, T be subsets of vertices of P such that all vertices in S precede all vertices in T , stored in the data structure of Lemma 11. For any query α, β we can compute $\mathcal{D}_B^{S \times T}(\alpha, \beta)$ in $O(\log^2 n)$ time.*

For every node ν of the recursion tree on P we store: (i) the data structure of Lemma 13 built on its canonical subcurve P_ν , and (ii) the data structure of Lemma 11 built on the vertices of P_ν . The total space usage of the data structure follows the recurrence $S(n) = 2S(n/2) + O(n^{4+\varepsilon})$, which solves to $O(n^{4+\varepsilon})$. To query the data structure with some subcurve $P[s, t]$ from some vertex s to a vertex t we again find the $O(\log n)$ nodes whose canonical subcurves together define $P[s, t]$, query the Lemma 13 data structure for each of them, and run the algorithm from Lemma 16 for each pair. The total running time is then $O(\log^4 n)$. As before, the procedure can be easily extended to the case where s and t lie on the interior of an edge. We conclude:

► **Lemma 17.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices, and $\varepsilon > 0$. There is an $O(n^{4+\varepsilon})$ size data structure that can be built in $O(n^{4+\varepsilon})$ time that for an arbitrary query segment \overline{ab} (and two points s and t on P) can report $\mathcal{D}_B^{P[s, t] \times P[s, t]}(\alpha, \beta)$ in $O(\log^4 n)$ time.*

Since we can compute all four terms $\|s-a\|$, $\|t-b\|$, $\vec{\mathcal{D}}_H(P[s, t], \overline{ab})$, and $\mathcal{D}_B^{P[s, t] \times P[s, t]}(\alpha, \beta)$ in $O(\log^4 n)$ time, it follows that we can efficiently answer Fréchet distance queries against subcurves.

4.4 Space vs. Query time tradeoff

We can use our approach for subcurve queries from Section 4.3 to obtain a space vs. query time trade off for queries against the entire curve. Let $k \in [1..n]$ be a parameter. We trim the recursion tree on P at a node ν of size $O(k)$. Let \mathcal{T} denote the resulting tree (i.e., the top $\log(n/k)$ levels of the full recursion tree), and let $L(\mathcal{T})$ denote the set of leaves of \mathcal{T} , each of which thus corresponds to a subcurve of length $O(k)$. Let $\ell(\nu)$ and $r(\nu)$ be the left and right child of ν , respectively. By repeated application of the second equality in Lemma 14 we have

$$\mathcal{D}_B^{P \times P}(\alpha, \beta) = \max \left\{ \max_{\nu \in \mathcal{T}} \mathcal{D}_B^{P_{\ell(\nu)} \times P_{r(\nu)}}(\alpha, \beta), \max_{\nu \in L(\mathcal{T})} \mathcal{D}_B^{P_\nu \times P_\nu}(\alpha, \beta) \right\}.$$

At every leaf of \mathcal{T} we now store the data structure of Lemma 13, and at every internal node the data structure of Lemma 11. The space required by all Lemma 13 data structures is $O((n/k)k^{4+\varepsilon}) = O(nk^{3+\varepsilon})$. The total size for all Lemma 11 data structures follows the recurrence $S(n) = 2S(n/2) + O(n^2)$ which solves to $O(n^2)$. Hence, the total space used is $O(nk^{3+\varepsilon} + n^2)$. The preprocessing time is $O(nk^{3+\varepsilon} + n^2)$ as well.

To answer a query (α, β) we query the Lemma 13 data structures at the leaves of \mathcal{T} in $O(\log k)$ time each. For every internal node ν we use Lemma 16 to compute the contribution of $\mathcal{D}_B^{P_{\ell(\nu)} \times P_{r(\nu)}}(\alpha, \beta)$ in $O(\log^2 n)$ time. Hence, the total query time is $O((n/k) \log k + (n/k) \log^2 n) = O((n/k) \log^2 n)$. So, e.g., choosing $k = n^{1/3}$ yields an $O(n^{2+\varepsilon})$ size data structure supporting $O(n^{2/3} \log^2 n)$ time queries. We can extend this idea to support subcurve queries in $O((n/k) \log^2 n + \log^4 n)$ time as well, giving us the following result:

► **Lemma 18.** *Let P be a polygonal curve in \mathbb{R}^2 with n vertices, and let $k \in [1..n]$ be a parameter. In $O(nk^{3+\varepsilon} + n^2)$ time we can construct a data structure of size $O(nk^{3+\varepsilon} + n^2)$ so that given a query segment \overline{ab} , $\mathcal{D}_B(\overline{ab})$ can be computed in $O((n/k) \log^2 n)$ time. If, in addition we are also given two points s and t on P , $\mathcal{D}_B^{P[s,t] \times P[s,t]}(\overline{ab})$ can be computed in $O((n/k) \log^2 n + \log^4 n)$ time.*

Since computing $\overrightarrow{\mathcal{D}}_H(P[s,t], \overline{ab})$ can be done in $O(\log^2 n)$ time using only $O(n^2)$ space, we thus established Theorem 3. Once again, it is possible to make the query time proportional to the complexity of $P[s,t]$ rather than to n .

5 Concluding Remarks

We presented data structures for efficiently computing the Fréchet distance of (part of) a curve to a query segment. This constitutes an important step towards the more ambitious goal of finding data structures to efficiently answer queries for general polygonal curves.

Our results improve over previous work for horizontal segments and are the first for arbitrarily oriented segments. However, we are left with the challenge of reducing the space used for arbitrary orientations. There are two main issues. The first issue is that even for a small interval of query orientations (e.g., one of the $O(n^2)$ angular intervals defined by lines through a pair of points) it is difficult to limit the number of relevant backward pairs to $o(n^2)$. The second issue is how to combine the backward pair distance values contributed by various subcurves. For (low algebraic degree) univariate functions, the upper envelope has near linear complexity, whereas for bivariate functions the complexity is near quadratic. The combination of these issues makes it hard to improve over the somewhat straightforward $O(n^{4+\varepsilon})$ space bound we build upon.

Abstract

We investigate preprocessing for vertex-subset problems on graphs. While the notion of kernelization, originating in parameterized complexity theory, is a formalization of provably effective preprocessing aimed at reducing the total instance size, our focus is on finding a non-empty vertex set that belongs to an optimal solution. This decreases the size of the remaining part of the solution which still has to be found, and therefore shrinks the search space of fixed-parameter tractable algorithms for parameterizations based on the solution size. We introduce the notion of a c -essential vertex as one that is contained in all c -approximate solutions. For several classic combinatorial problems such as ODD CYCLE TRANSVERSAL and DIRECTED FEEDBACK VERTEX SET, we show that under mild conditions a polynomial-time preprocessing algorithm can find a subset of an optimal solution that contains all 2-essential vertices, by exploiting packing/covering duality. This leads to FPT algorithms to solve these problems where the exponential term in the running time depends only on the number of *non-essential* vertices in the solution.

1 Introduction

Background and motivation. Due to the enormous potential of preprocessing to speed up the algorithmic solution to combinatorial problems [1, 2, 3, 43, 44], a large body of work in theoretical computer science is devoted to understanding its power and limitations. Using the notion of *kernelization* [4, 20, 21, 25, 29, 33] from parameterized complexity [12, 15] it is possible to formulate a guarantee on the size of the instance after preprocessing based on the parameter of the original instance. Under this model, a good preprocessing algorithm is a *kernelization algorithm*: given a parameterized instance (x, k) , it outputs an equivalent instance (x', k') of the same decision problem such that $|x'| + k' \leq f(k)$ for some function f that bounds the size of the kernel. Research into kernelization led to deep algorithmic insights, including connections to protrusions and finite-state properties [5], well-quasi ordering [22], and matroids [30]; these positive results were complemented by impossibility results [13, 16, 30] delineating the boundaries of tractability.

Results on kernelization led to profound insights into the limitations of polynomial-time data compression for NP-hard problems. However, as recently advocated [14], the definition of kernelization only gives guarantees on the *size* of the instance after preprocessing, which

does not directly correspond to the running time of subsequently applied algorithms. If the preprocessed instance is not solved by brute force, but via a fixed-parameter tractable algorithm whose running time is of the form $f(k) \cdot n^{\mathcal{O}(1)}$, then the exponential dependence in the running time is on the value of the *parameter* k , which is not guaranteed to decrease via kernelization. In fact, if $P \neq NP$ then no polynomial-time preprocessing algorithm can guarantee to always decrease the parameter of an NP-hard fixed-parameter tractable problem, as iterating the preprocessing algorithm would lead to its solution in polynomial time. In this work, we develop a new analysis of preprocessing aimed at reducing the search space of the follow-up algorithm. We apply this framework to combinatorial optimization problems on graphs, whose goal is to find a minimum vertex-subset satisfying certain properties. The main idea behind the framework is to define formally what it means for a vertex to be *essential* for making reasonable solutions to the problem, and to prove that an efficient preprocessing algorithm can detect a subset of an optimal solution that contains all such essential vertices.

Before stating our results, we introduce and motivate the model. We consider vertex-subset minimization problems on (possibly directed) graphs, in which the goal is to find a minimum vertex subset having a certain property. Examples of the problems we study include VERTEX COVER, ODD CYCLE TRANSVERSAL, and DOMINATING SET. The analysis of such minimization problems, parameterized by the size of the solution, has played an important role in the literature (cf. [9, 17, 27, 38, 40]). Our starting point is the thesis that a good preprocessing algorithm should reduce the *search space*. Since many graph problems are known to be fixed-parameter tractable when parameterized by the size of the solution, we can reduce the search space of these FPT algorithms by finding one or more vertices which are part of an optimal solution, thereby decreasing the size of the solution still to be found in the reduced instance (i.e. the parameter value).

Since in general no polynomial-time algorithm can guarantee to identify at least one vertex that belongs to an optimal solution, the guarantee of the effectiveness of the preprocessing algorithm should be stated in a more subtle way. When solving problems by hand, one sometimes finds that certain vertices v are easily identified to belong to an optimal solution, as avoiding them would force the solution to contain a prohibitively large number of alternative vertices and therefore be suboptimal. Can an efficient preprocessing algorithm identify those vertices that cannot be avoided when making an optimal solution?

Since many NP-hard problems remain hard even when there is a unique solution [42], this turns out to be too much to ask as it would allow instances with unique solutions to be solved in polynomial time, which leads to $NP = RP$. We therefore have to relax the requirements on the preprocessing guarantee slightly, as follows. For an instance of a vertex-subset minimization problem Π on a graph G , we denote the minimum size of a solution on G by $\text{OPT}_{\Pi}(G)$. For a fixed $c \in \mathbb{R}_{\geq 1}$, we say a vertex $v \in V(G)$ is *c-essential* for Π on G if all feasible solutions $S \subseteq V(G)$ for Π whose total size is at most $c \cdot \text{OPT}_{\Pi}(G)$ contain v . Based on this notion, we can ask ourselves: can an efficient preprocessing algorithm identify part of an optimal solution if there is at least one *c-essential* vertex?

Phrased in this way, the algorithmic task becomes more tractable. For example, for the VERTEX COVER problem, selecting all vertices that receive the value 1 in an optimal half-integral solution to the LP-relaxation results in a set S which is contained in some optimal solution (by the Nemhauser-Trotter theorem [37], cf [12, §2.5]), and at the same time includes all 2-essential vertices: any vertex $v \notin S$ only has neighbors of value $\frac{1}{2}$ and 1, which implies that the set X of vertices other than v whose value in the LP relaxation is at least $\frac{1}{2}$, forms a feasible solution which avoids v . Its cardinality is at most twice the cost of the LP relaxation and therefore X is a 2-approximation. Hence S contains all 2-essential vertices.

This example shows that a preprocessing step that detects c -essential vertices without any additional information is sometimes possible. However, to be able to extend the scope of our results also to problems which *do not* have polynomial-time constant-factor approximations, we slightly relax the requirements on the preprocessing algorithm as follows. Let Π be a minimization problem on graphs whose solutions are vertex subsets and let $c \in \mathbb{R}_{\geq 1}$.

c -ESSENTIAL DETECTION FOR Π

Input: A graph G and integer k .

Task: Find a vertex set $S \subseteq V(G)$ such that:

G1 if $\text{OPT}_{\Pi}(G) \leq k$, then there is an optimal solution in G containing all of S , and

G2 if $\text{OPT}_{\Pi}(G) = k$, then S contains all c -essential vertices.

In this model, the preprocessing task is facilitated by supplying an additional integer k in the input. The correctness properties of the output S are formulated in terms of k . If $\text{OPT}_{\Pi}(G) \leq k$, then the set S is required to be part of an optimal solution. The upper bound on $\text{OPT}_{\Pi}(G)$ is useful to the algorithm: whenever the algorithm establishes that avoiding v would incur a cost of more than k , it is safe to add v to S . If $\text{OPT}_{\Pi}(G) = k$, then the algorithm should guarantee that S contains all c -essential vertices. Knowing a lower bound on $\text{OPT}_{\Pi}(G)$ is useful to the algorithm in case it can establish that any optimal solution containing v can be transformed into one avoiding v whose cost is $(c - 1) \cdot k$ larger, which yields a c -approximation if $(c - 1) \cdot k \leq (c - 1) \text{OPT}_{\Pi}(G)$. Hence vertices for which such a replacement exists are not c -essential and may safely be left out of S .

Results. We present polynomial-time algorithms for c -ESSENTIAL DETECTION FOR Π for a range of vertex-deletion problems Π and small values of c ; typically $c \in \{2, 3\}$. Example applications include VERTEX COVER and FEEDBACK VERTEX SET, and also CHORDAL VERTEX DELETION (for which no $O(1)$ -approximation is known), ODD CYCLE TRANSVERSAL (for which no $O(1)$ -approximation exists, assuming the Unique Games Conjecture [28, 45]), and even DIRECTED ODD CYCLE TRANSVERSAL (which is $W[1]$ -hard parameterized by solution size [35]).

The model of c -ESSENTIAL DETECTION FOR Π is chosen such that the detection algorithms whose correctness is formulated with respect to the value of k , can be used as a preprocessing step to optimally solve vertex-subset problems without any knowledge of the optimum. Let $\mathcal{E}_c^{\Pi}(G)$ denote the set of c -essential vertices in G , which is well-defined since all optimal solutions contain all c -essential vertices. By using a preprocessing step that detects a superset of the c -essential vertices in the solution, we can effectively improve the running-time guarantee for FPT algorithms parameterized by solution size from $f(\text{OPT}_{\Pi}(G)) \cdot |V(G)|^{\mathcal{O}(1)}$, to $f(\text{OPT}_{\Pi}(G) - |\mathcal{E}_c^{\Pi}(G)|) \cdot |V(G)|^{\mathcal{O}(1)}$. This leads to the following results.

► **Theorem 1.1.** *For each problem Π with coefficient c and parameter dependence f listed in Table 1 that is not $W[1]$ -hard, there is an algorithm that, given a graph G , outputs an optimal solution in time $f(\ell) \cdot |V(G)|^{\mathcal{O}(1)}$, where $\ell := \text{OPT}_{\Pi}(G) - |\mathcal{E}_c^{\Pi}(G)|$ is the number of vertices in an optimal solution which are not c -essential.*

Hence the running time for solving these problems does not depend on the total size of an optimal solution, only on the part of the solution that does not consist of c -essential vertices. The theorem effectively shows that by employing c -ESSENTIAL DETECTION FOR Π as a preprocessing step, the size of the search space no longer depends on the total solution size but only on its non-essential vertices.

■ **Table 1** For each problem Π , there is a polynomial-time algorithm for c -ESSENTIAL DETECTION for the stated value of c . Combined with the state of the art algorithm for the natural parameterization, this leads to an algorithm solving the problem in time $f(\ell) \cdot |V(G)|^{\mathcal{O}(1)}$ where $\ell = \text{OPT}_{\Pi}(G) - |\mathcal{E}_c^{\Pi}(G)|$.

Problem	c	$f(\ell)$	Reference
VERTEX COVER	2	1.2738^{ℓ}	[9]
FEEDBACK VERTEX SET	2	2.7^{ℓ}	[31]
DIRECTED FEEDBACK VERTEX SET	2	$4^{\ell} \cdot \ell!$	[10]
ODD CYCLE TRANSVERSAL	2	2.3146^{ℓ}	[34]
DIRECTED ODD CYCLE TRANSVERSAL	3	W[1]-hard	[35]
CHORDAL VERTEX DELETION	13	$2^{\mathcal{O}(\ell \log \ell)}$	[8]

We also prove limitations to this approach. Assuming $\text{FPT} \neq \text{W}[1]$, for DOMINATING SET, PERFECT DELETION (in which the goal is to obtain a perfect graph by vertex deletions) and WHEEL-FREE DELETION, there is no polynomial-time algorithm for c -ESSENTIAL DETECTION for any $c \in \mathbb{R}_{\geq 1}$. In fact, we can even rule out such algorithms running in time $f(k) \cdot |V(G)|^{\mathcal{O}(1)}$. These results are based on FPT-inapproximability results for DOMINATING SET [40] and existing reductions [26, 32] to the mentioned vertex-deletion problems.

Techniques. The main work lies in the algorithms for c -ESSENTIAL DETECTION, which are all based on covering/packing duality for forbidden induced subgraphs to certain graph classes, or variations thereof in terms of (integer) solutions to certain linear programs and their (integer) duals. To understand the relation between detecting essential vertices and covering/packing duality, consider the ODD CYCLE TRANSVERSAL problem (OCT). Following the argumentation for the classic Erdős-Pósa theorem [18], in general there is no constant c such that any graph either has an odd cycle transversal of size $c \cdot k$, or a packing of k vertex-disjoint odd cycles. However, we show that a linear packing/covering relation holds in the following slightly different setting. If $G - v$ is bipartite (so all odd cycles of G intersect v), then the minimum size of an OCT avoiding v equals the maximum cardinality of a packing of odd cycles which pairwise intersect only at v . We can leverage this statement to prove that any vertex v which is not at the center of a flower (see Definition 3.1) of more than $\text{OPT}_{\text{oct}}(G)$ odd cycles, is not 2-essential: for any optimal solution X containing v , the graph $G' := G - (X \setminus \{v\})$ becomes bipartite after removal of v and by assumption does not contain a packing of more than $\text{OPT}_{\text{oct}}(G)$ odd cycles pairwise intersecting at v . So by covering/packing duality on G' , it has an OCT X' of size at most $\text{OPT}_{\text{oct}}(G)$ avoiding v , so that $(X \setminus \{v\}) \cup X'$ is a 2-approximation in G which avoids v , showing that v is not 2-essential. Since v is clearly contained in an optimal solution whenever there is a flower of more than $\text{OPT}_{\text{oct}}(G)$ odd cycles centered at v , this yields a method for c -ESSENTIAL DETECTION when using a known reduction [23] to MAXIMUM MATCHING to test for a flower of odd cycles.

Organization. After presenting preliminaries in Section 2, we give algorithms to detect essential vertices based on covering/packing duality in Section 3 and based on integrality gaps in Section 4. In Section 5 we show how these detection subroutines can be used to improve the parameter dependence of FPT algorithms parameterized by solution size. The lower bounds are presented in Section 6. The investigation of c -essential vertices has close connections to the area of perturbation stability, which we briefly explore in Section 7. We conclude in Section 8. Due to space limitations, proofs of statements marked (★) are deferred to the full version [7].

2 Preliminaries

We consider finite simple graphs, some of which are directed. We use standard notation for graph algorithms; any terms not defined here can be found in the textbook by Cygan et al. [12]. We consider vertex-deletion problems on graphs. For a graph class \mathcal{C} , a \mathcal{C} -modulator in a graph G is a vertex set $S \subseteq V(G)$ such that $G - S \in \mathcal{C}$. The minimum size of a \mathcal{C} -modulator in G is denoted $\text{OPT}_{\mathcal{C}}(G)$. The corresponding minimization problem is defined as follows.

\mathcal{C} -DELETION

Input: A graph G .

Task: Find a minimum-size vertex-subset $S \subseteq V(G)$ such that $G - S \in \mathcal{C}$.

Throughout this paper we consider hereditary graph classes \mathcal{C} . These can be characterized by a (possibly infinite) set of forbidden induced subgraphs denoted $\text{forb}(\mathcal{C})$. The \mathcal{C} -DELETION problem is equivalent to finding a minimum set $S \subseteq V(G)$ such that no induced subgraph of $G - S$ is isomorphic to a graph in $\text{forb}(\mathcal{C})$. We say that such a set S hits all graphs from $\text{forb}(\mathcal{C})$ in G . For these classes the vertex set $V(G)$ is a trivial \mathcal{C} -modulator (since the empty graph is in all hereditary classes), which ensures that the task of finding a smallest modulator is always well-defined.

A graph is perfect if for every induced subgraph the size of a largest clique is equivalent to its chromatic number. Equivalently, a graph is perfect if it has no induced cycle of odd length at least five or its edge complement (cf. [24]). A graph is chordal if it has no induced cycle of length at least four. A graph is bipartite if its vertex set can be partitioned into two independent sets, or equivalently, it does not contain an odd-length cycle. Given a graph G and a set $T \subseteq V(G)$, a T -path is a path with at least one edge with both endpoints contained in T . A T -path is odd if it has an odd number of edges. For $u, v \in V(G)$, a (u, v) -separator is a set $S \subseteq V(G) \setminus \{u, v\}$ that disconnects u from v . If G is a directed graph, then in $G - S$ there is no directed path from u to v instead.

3 Positive results via Packing Covering

In this section we provide polynomial-time algorithms for c -ESSENTIAL DETECTION FOR II for various problems II. The case for the VERTEX COVER problem was given in Section 1. The results in this section are all based on packing/covering duality (cf. [11], [41, §73]). Towards this end, we generalize the notion of *flowers*, which played a key role in kernelization for FEEDBACK VERTEX SET [6]. While flowers were originally formulated as systems of cycles (forbidden structures for FEEDBACK VERTEX SET) pairwise intersecting in a single common vertex, we generalize the notion to near-packings of arbitrary structures here.

► **Definition 3.1.** *Let \mathcal{F} be a set of graphs. For a graph G and $v \in V(G)$, a (v, \mathcal{F}) -flower with p petals in G is a set $\{C_1, C_2, \dots, C_p\}$ of induced subgraphs of G such that each C_i (with $i \in [p]$) is isomorphic to some member of \mathcal{F} and such that $V(C_i) \cap V(C_j) = \{v\}$ for all distinct $i, j \in [p]$. The \mathcal{F} -flower number of a vertex $v \in V(G)$, denoted $\Gamma_{\mathcal{F}}(G, v)$, is the largest integer p for which there is a (v, \mathcal{F}) -flower in G with p petals.*

We show a general theorem for finding 2-essential vertices for \mathcal{C} -deletion if a maximum $(v, \text{forb}(\mathcal{C}))$ -flower can be computed in polynomial-time. It applies to those classes \mathcal{C} where graphs with $G - v \in \mathcal{C}$ obey a min-max relation between \mathcal{C} -modulators avoiding v and packings of forbidden induced subgraphs intersecting only at v .

► **Theorem 3.2.** *Let \mathcal{C} be a hereditary graph class such that, for any graph G and vertex $v \in V(G)$ with $G - v \in \mathcal{C}$, the minimum size of a \mathcal{C} -modulator avoiding v in G equals $\Gamma_{\text{forb}(\mathcal{C})}(G, v)$. Suppose there exists a polynomial-time algorithm \mathcal{A} that, given a graph G and vertex $v \in V(G)$, computes $\Gamma_{\text{forb}(\mathcal{C})}(G, v)$. Then there is a polynomial-time algorithm that solves 2-ESSENTIAL DETECTION FOR \mathcal{C} -DELETION.*

Proof. Apply algorithm \mathcal{A} to each vertex $v \in V(G)$ and let S be the set of vertices for which it finds that $\Gamma_{\text{forb}(\mathcal{C})}(G, v) > k$. We argue that Properties G1 and G2 are satisfied. If $\text{OPT}_{\mathcal{C}}(G) \leq k$, then every vertex in S is contained in every optimal solution for G since a size- k solution cannot hit a flower of $k + 1$ petals from $\text{forb}(\mathcal{C})$ without using v . Therefore Property G1 is satisfied. Next suppose that $\text{OPT}_{\mathcal{C}}(G) = k$ and let X be an optimal solution. We argue that each vertex $v \notin S$ is not 2-essential. Clearly this holds for any vertex $v \notin X$, so suppose that $v \in X$. Note that for every vertex $v \notin S$ we have $\Gamma_{\text{forb}(\mathcal{C})}(G, v) \leq k$, which implies that $\Gamma_{\text{forb}(\mathcal{C})}(G', v) \leq k$ where $G' := G - (X \setminus \{v\})$. Note that since $G' - v \in \mathcal{C}$, by assumption there exists a \mathcal{C} -modulator $X' \subseteq V(G') \setminus \{v\}$ in G' of size $\Gamma_{\text{forb}(\mathcal{C})}(G', v) \leq k$. Observe that $(X \setminus \{v\}) \cup X'$ is a \mathcal{C} -modulator in G of size at most $2k$ that avoids v and therefore v is not 2-essential. ◀

Theorem 3.2 allows us to conclude the following result for FEEDBACK VERTEX SET (FVS) and its directed variant (DFVS) using Gallai's theorem and Menger's theorem, respectively.

► **Lemma 3.3 (★).** *There are polynomial-time algorithms for 2-ESSENTIAL DETECTION FOR Π for $\Pi \in \{\text{FVS}, \text{DFVS}\}$.*

Next, we consider ODD CYCLE TRANSVERSAL (OCT), which corresponds to \mathcal{C} -DELETION where \mathcal{C} is the class of bipartite graphs and $\text{forb}(\mathcal{C})$ consists of all odd cycles. In order to apply Theorem 3.2 to OCT, we first argue that the class of bipartite graphs satisfies the preconditions. The proof is similar to that of Geelen et al. [23, Lemma 11] who reduce the problem of packing odd cycles containing v to a matching problem. We note that, although their result can be used to obtain a 3-essential detection algorithm, we will show (Lemma 3.7) how to efficiently detect 2-essential vertices as well. If the graph resulting from their construction has a large matching, then there is a large $(v, \text{forb}(\mathcal{C}))$ -flower. If on the other hand there is no large matching, then the Tutte-Berge formula is used to obtain a set of size $2k$ that hits all the odd cycles passing through v . We show that if the graph $G - v$ is bipartite instead, then this second argument can be improved to obtain a hitting set of size k by noting that the lack of a large matching implies that there is a small vertex cover due to König's theorem. This is below, using the viewpoint that odd cycles in G correspond to odd T -paths in $G - v$ for $T = N_G(v)$.

► **Lemma 3.4.** *For any undirected graph G and set $T \subseteq V(G)$, a maximum packing of odd T -paths can be computed in polynomial time. Moreover, if G is bipartite then the cardinality of a maximum packing of odd T -paths is equal to the minimum size of a vertex set which intersects all odd T -paths.*

Proof. We reduce to matching as in [23, Lemma 11]. Construct a graph H as follows. For each $v \in V(G) \setminus T$, let $v' \notin V(G)$ be a copy of v . Let $V(H) = V(G) \cup \{v' \mid v \in V(G) \setminus T\}$ and $E(H) = E(G) \cup \{u'v' \mid uv \in E(G - T)\} \cup \{vv' \mid v \in V(G) \setminus T\}$. Note that the graph H consists of the disjoint union of G and a copy of $G - T$, with an added edge between $v \in V(G) \setminus T$ and its copy v' . Geelen et al. [23] mention that there is a 1-1 correspondence between odd T -paths in G and certain augmenting paths in H . For completeness we give a self-contained argument.

▷ **Claim 3.5.** Graph G contains k vertex-disjoint odd T -paths if and only if H has a matching M of size $|V(G) \setminus T| + k$. Furthermore, given a matching M in H of size $|V(G) \setminus T| + k$ we can compute a set of k vertex-disjoint odd T -paths in polynomial time.

Proof. (\Rightarrow) Let $\mathcal{P} = (P_1, \dots, P_k)$ be a set of k vertex-disjoint odd T -paths in G . Consider a path $P = (v_1, \dots, v_{2\ell}) \in \mathcal{P}$, where $\ell \geq 1$. First note that we can assume that $V(P) \cap T = \{v_1, v_{2\ell}\}$, since if $v_i \in T$ for some $1 < i < 2\ell$, then either (v_1, \dots, v_i) or $(v_i, \dots, v_{2\ell})$ is an odd T -path and we can update \mathcal{P} accordingly. Construct a matching M in H as follows. For any path $P = (v_1, \dots, v_{2\ell}) \in \mathcal{P}$, add the edges $v_1v_2, v'_2v'_3, \dots, v_{2\ell-1}v_{2\ell}$, alternating between original vertices and copy vertices. This is possible as P is of odd length. For any vertex in $u \in V(G) \setminus T$ that is not contained in an odd T -path, we add uu' to M . Observe that at least $2|V(G) \setminus T| + 2k$ vertices are matched, therefore $|M| \geq |V(G) \setminus T| + k$ as desired.

(\Leftarrow) Let M be a matching of size $|V(G) \setminus T| + k$. If M contains both uv and $u'v'$ for $u, v \in V(G) \setminus T$, then update M by removing them and inserting uu' and vv' instead. If for $v \in V(G) \setminus T$ only one of v and v' is matched, and it is not matched to its copy, then match it to its copy instead. Afterwards let $E' := \{uv \in E(G) \mid uv \in M \vee u'v' \in M\}$. Observe that in $G[E']$, each vertex in $V(G) \setminus T$ has degree 0 or 2. For each $v \in V(G) \setminus T$ such that v has degree 0 in $G[E']$, add vv' to M if it is not in already. Note that all vertices of $H - T$ are matched. It follows that at least $2k$ vertices in T are matched by M and they have degree 1 in $G[E']$. Observe that $G[E']$ is a collection of paths and cycles with all degree-1 vertices in T . We get that there are k T -paths in G that are of odd length by construction (every even numbered edge in $G[E']$ originated from the copy part of H). Note that we can find them in polynomial time. \triangleleft

Since a maximum matching can be computed in polynomial time, by the claim above we get that a maximum packing of vertex-disjoint odd T -paths can be computed in polynomial time. Next we prove the second part of the statement.

▷ **Claim 3.6.** If G is bipartite and a maximum matching M in H has size $|V(G) \setminus T| + k$, then there is a set $S \subseteq V(G)$ of size at most k such that $G - S$ has no odd-length T -path.

Proof. Observe that since G is bipartite, the graph H is bipartite as well. By König's theorem [41, Theorem 16.2], H has a vertex cover X of size $|V(G) \setminus T| + k$. Let $S = (X \cap T) \cup \{u \mid \{u, u'\} \subseteq X\}$. Note that for each $u \in V(G) \setminus T$, at least one of $u \in X$ or $u' \in X$ must hold to cover the edge uu' , thereby already accounting for $|V(G) \setminus T|$ vertices of the cover. It follows that $|S| \leq k$. We argue that S hits all odd-length T -paths in G .

For the sake of contradiction suppose there is some odd-length T -path from $t_1 \in T$ to $t_2 \in T \setminus \{t_1\}$ in $G - S$. Let $P = (t_1, v_1, \dots, v_{2\ell}, t_2)$ be a (not necessarily induced) shortest odd T -path. Note that neither of t_1 and t_2 belong to X by construction of S . Furthermore $P \setminus \{t_1, t_2\} \subseteq V(G) \setminus T$, as otherwise we could construct a shorter odd-length T -path. Consider the vertices $V(P) \cup \{v'_1, \dots, v'_{2\ell}\} \subseteq V(H)$. By construction of S , the vertex cover X has exactly one of v_i and v'_i for each $i \in [2\ell]$. Observe that for it to be a vertex cover, X must contain vertices of $P \setminus \{t_1, t_2\}$ and their copies in an alternating fashion since for each edge v_i, v_{i+1} of P , the graph H contains edges $v_iv'_i, v_{i+1}v'_{i+1}, v_iv_{i+1}, v'_iv'_{i+1}$. Without loss of generality, let $v_1 \in X$. It follows that $v_{2\ell} \notin X$. But this contradicts that X is a vertex cover as $v_{2\ell}t_2$ is not covered. We conclude that S hits all odd-length T -paths in G . \triangleleft

By Claim 3.5, a maximum packing of k of vertex-disjoint odd T -paths in G implies a matching in H of size $|V(G) \setminus T| + k$. By Claim 3.6, we can create a set of size at most k that intersects all odd T -paths in the bipartite graph G . Clearly such a set has size at least k . It follows that if G is bipartite, then the cardinality of a maximum packing of odd

T -paths is equal to the minimum size of a vertex set which intersects all odd T -paths. (For completeness, we remark that this last property can also be derived from Menger's theorem: in a bipartite graph with bipartition into $A \cup B$, a T -path is odd if and only if its endpoints belong to different partite sets, so a maximum packing of odd T -paths is equivalent to a maximum set of vertex-disjoint paths between $A \cap T$ and $B \cap T$.) ◀

By observing that odd T -paths in $G - v$ directly correspond to flowers with odd cycles pairwise intersecting at v in G , Lemma 3.4 and Theorem 3.2 imply the following.

► **Lemma 3.7.** *There is a polynomial-time algorithm for 2-ESSENTIAL DETECTION FOR OCT.*

The DOCT problem corresponds to \mathcal{C} -deletion where $\text{forb}(\mathcal{C})$ consists of all directed cycles of odd length. Using Menger's theorem on an auxiliary graph, we can detect 3-essential vertices for this problem.

► **Lemma 3.8 (★).** *There is a polynomial-time algorithm for 3-ESSENTIAL DETECTION FOR DOCT.*

We cannot use the approach based on computing a maximum (v, \mathcal{F}) -flower for the CHORDAL DELETION problem; a simple reduction¹ from DISJOINT PATHS [39] shows that it is NP-hard to compute a maximum (v, \mathcal{F}) -flower when \mathcal{F} is the set of chordless cycles of length at least four. In the next section, we will therefore use an approach based on the linear-programming relaxation to deal with CHORDAL DELETION.

4 Positive results via Linear Programming

Consider the following natural linear program for \mathcal{C} -DELETION for hereditary graph classes \mathcal{C} . The LP corresponding to an input graph G is defined on the variables $(x_u)_{u \in V(G)}$, as follows.

\mathcal{C} -DELETION LP

Objective: minimize $\sum_{u \in V(G)} x_u$.

Subject to:

- $\sum_{u \in V(H)} x_u \geq 1$ for each induced subgraph H of G isomorphic to a graph in $\text{forb}(\mathcal{C})$,
- $0 \leq x_u \leq 1$ for each $u \in V(G)$.

In the corresponding integer program, the constraint $0 \leq x_u \leq 1$ is replaced by $x_u \in \{0, 1\}$. We say that a minimization LP has *integrality gap* at most c for some $c \in \mathbb{R}$ if the cost of an integer optimum is at most c times the cost of a fractional optimum. In general, the number of constraints in the \mathcal{C} -DELETION LP can be exponential in the size of the graph. Using the ellipsoid method (cf. [41]), this can be handled using a separation oracle: a polynomial-time algorithm that, given an assignment to the variables, outputs a violated constraint if one exists. It is well-known (cf. [41, Thm. 5.10]) that linear programs with an exponential number of constraints can be solved in polynomial time using a polynomial-time separation oracle. To detect essential vertices, the integrality gap of a slightly extended LP will be crucial. We define the v -AVOIDING \mathcal{C} -DELETION LP for a graph G and distinguished vertex $v \in V(G)$ as the \mathcal{C} -DELETION LP with the additional constraint that $x_v = 0$. Hence its integral solutions correspond to \mathcal{C} -modulators avoiding v .

¹ Starting from an instance $(G, (s_1, t_1), \dots, (s_\ell, t_\ell))$ of DISJOINT PATHS satisfying $s_i t_i \notin E(G)$ for all $i \in [\ell]$ (which is without loss of generality), insert a vertex v adjacent to $A = \bigcup_{i=1}^{\ell} \{s_i, t_i\}$ and insert all edges between vertices in A except $s_i t_i$ for each $i \in [\ell]$.

► **Theorem 4.1 (★).** *Let \mathcal{C} be a hereditary graph class such that for each graph G and $v \in V(G)$ satisfying $G - v \in \mathcal{C}$, the integrality gap of v -AVOIDING \mathcal{C} -DELETION on G is at most $c \in \mathbb{R}_{\geq 1}$. If there is a polynomial-time separation oracle for the \mathcal{C} -DELETION LP, then there is a polynomial-time algorithm for $(c + 1)$ -ESSENTIAL DETECTION FOR \mathcal{C} -DELETION.*

Using known results on covering versus packing for chordless cycles in near-chordal graphs, the approach above can be used to detect essential vertices for CHORDAL DELETION. For the class of chordal graphs, the corresponding set of forbidden induced subgraphs is the class hole of all holes, i.e., induced chordless cycles of length at least four.

► **Lemma 4.2 (★).** *There is a polynomial-time algorithm for 13-ESSENTIAL DETECTION FOR CHORDAL DELETION.*

5 Consequences for Parameterized Algorithms

In this section we show how the algorithms for c -ESSENTIAL DETECTION from the previous section can be used to solve \mathcal{C} -DELETION for various classes \mathcal{C} , despite the fact that the detection algorithms only work when certain guarantees on k are met. The main theorem connecting the detection problem to solving \mathcal{C} -DELETION is the following.

► **Theorem 5.1.** *Let \mathcal{A} be an algorithm that, given a graph G and an integer k , runs in time $f(k) \cdot |V(G)|^{\mathcal{O}(1)}$ for some non-decreasing function f and returns a minimum-size \mathcal{C} -modulator if there is one of size at most k . Let \mathcal{B} be a polynomial-time algorithm for c -ESSENTIAL DETECTION FOR \mathcal{C} -DELETION. Then there is an algorithm that, given a graph G , outputs a minimum-size \mathcal{C} -modulator in time $f(\ell) \cdot |V(G)|^{\mathcal{O}(1)}$, where $\ell = \text{OPT}_{\mathcal{C}}(G) - |\mathcal{E}_c(G)|$ is the c -non-essentiality.*

Proof. First we describe the algorithm as follows. For each $0 \leq k \leq |V(G)|$, let S_k be the result of running \mathcal{B} on (G, k) , let $G_k := G - S_k$, and let $b_k := k - |S_k|$.

Letting L be the list of all triples (G_k, S_k, b_k) sorted in increasing order by their third component b_k , proceed as follows. For each $(G_k, S_k, b_k) \in L$, run \mathcal{A} on (G_k, b_k) to find a minimum \mathcal{C} -modulator $S_{\mathcal{A}}$ of size at most b_k , if one exists. If $|S_{\mathcal{A}}| = b_k$, then output $S_{\mathcal{A}} \cup S_k$ as a minimum \mathcal{C} -modulator in G .

To analyze the algorithm, we first argue it always outputs a solution. For the call with $k^* = \text{OPT}_{\mathcal{C}}(G)$, both conditions of the detection problem are met. Hence by Property G1 the set S_{k^*} is contained in a minimum modulator in G , so that $\text{OPT}_{\mathcal{C}}(G - S_{k^*}) = \text{OPT}_{\mathcal{C}}(G) - |S_{k^*}| = k^* - |S_{k^*}|$. Therefore graph $G_{k^*} = G - S_{k^*}$ has a modulator of size at most $b_{k^*} = \text{OPT}_{\mathcal{C}}(G - S_{k^*})$ and none which are smaller, so that \mathcal{A} correctly outputs a modulator of size b_{k^*} . In turn, this causes the overall algorithm to terminate with a solution.

Having established that the algorithm outputs a solution, we proceed to show that it outputs a minimum-size modulator whenever it outputs a solution (which may be in an earlier iteration than for $k^* = \text{OPT}_{\mathcal{C}}(G)$). Let k' be the value of k that is reached when the algorithm outputs a solution $S_{\mathcal{A}} \cup S_{k'}$. Then we know:

1. algorithm \mathcal{A} found a minimum-size modulator $S_{\mathcal{A}}$ in $G_{k'}$ of size at most $b_{k'}$, and
2. the set $S_{\mathcal{A}} \cup S_{k'}$ is a modulator in G , since $S_{\mathcal{A}}$ is a modulator in $G_{k'} = G - S_{k'}$, and therefore $\text{OPT}_{\mathcal{C}}(G) \leq b_{k'} + |S_{k'}| = k'$.

To see that the algorithm is correct, notice that, since $\text{OPT}_{\mathcal{C}}(G) \leq k'$, the set $S_{k'}$ is contained in some minimum-size modulator for G (since \mathcal{B} satisfies Property G1). Hence $\text{OPT}_{\mathcal{C}}(G_{k'}) = \text{OPT}_{\mathcal{C}}(G) - |S_{k'}|$. Since \mathcal{A} outputs a minimum-size modulator if there is one of size at most b_k , we have $|S_{\mathcal{A}}| = \text{OPT}_{\mathcal{C}}(G) - |S_{k'}|$, so that $\mathcal{A}(G_{k'}) \cup S_{k'}$ is a feasible modulator of size $\text{OPT}_{\mathcal{C}}(G)$ and therefore optimal.

30:10 Search-Space Reduction via Essential Vertices

Now we prove the desired running-time bound. First of all, notice that we can determine the list L in polynomial time by running \mathcal{B} once for each value of k (which is at most $|V(G)|$). By how we sorted L , we compute $\mathcal{A}(G_k, b_k)$ only when $b_k \leq b_{k^*}$, as we argued above that if the algorithm has not already terminated, it does so after reaching $k^* = \text{OPT}_c(G)$. Hence the calls to algorithm \mathcal{A} are for values of the budget b_k which satisfy $b_k \leq b_{k^*}$. We bound the latter, as follows.

Since $k^* = \text{OPT}_c(G)$, the set S_{k^*} found by \mathcal{B} is a superset of the set $\mathcal{E}_c(G)$ of all of the c -essential vertices in G (Property G2). This means that we have

$$b_{k^*} = \text{OPT}_c(G) - |S_{k^*}| \leq \text{OPT}_c(G) - |\mathcal{E}_c(G)| = \ell,$$

so the parameter of each call to \mathcal{A} is at most ℓ , giving the total time bound $f(\ell) \cdot |V(G)|^{\mathcal{O}(1)}$. ◀

Theorem 1.1 now follows from Theorem 5.1 via the algorithms for c -ESSENTIAL DETECTION given in the previous sections and the state-of-the-art algorithms for the natural parameterizations listed in Table 1. Although the latter may be originally stated for the decision version, using self-reduction they can easily be adapted to output a minimum solution if there is one of size at most k .

6 Hardness results

Given the positive results we saw in Sections 3 and 4, it is natural to seek problems Π for which c -ESSENTIAL DETECTION FOR Π is intractable. Here we show that c -ESSENTIAL DETECTION FOR DOMINATING SET is intractable for any $c \in \mathcal{O}(1)$ and then use this as a starting point to prove similar results for HITTING SET, PERFECT DELETION, and WHEEL-FREE DELETION.

A dominating set is a vertex set whose closed neighborhood is the entire graph. The domination number of a graph is the size of a minimum dominating set. The starting point for our reductions is the following result which states that it is $W[1]$ -hard to solve DOMINATING SET parameterized by solution size even on instances which have “solution-size gaps”.

► **Lemma 6.1** ([40], cf. [19, Thm. 4]). *Let $F, f: \mathbb{N} \rightarrow \mathbb{N}$ be any computable functions. Assuming $\text{FPT} \neq W[1]$, there does not exist an algorithm that, given a graph G and integer k , runs in time $f(k) \cdot |V(G)|^{\mathcal{O}(1)}$ and distinguishes between the following two cases:*

- *Completeness: G has a dominating set of size k .*
- *Soundness: Every dominating set of G is of size at least $k \cdot F(k)$.*

All of our reductions in this section share a leitmotif. We start with a *gap* instance (G, k) of DOMINATING SET and map it to an instance G' of c -ESSENTIAL DETECTION FOR Π (for appropriate Π) equipped with a distinguished vertex v^* with the following property: (1) if G has domination number at most k , then no optimal solution in G' contains v^* ; (2) if G has domination number strictly greater than $c \cdot F(k)$ (for some appropriate F), then v^* is contained in every solution of size at most $c \cdot F(k)$ in G' . Thus our hardness results will follow by combining reductions of this kind with Lemma 6.1.

► **Lemma 6.2** (★). *There is a polynomial-time algorithm R that, given a graph G and integer k , outputs a graph $R(G, k)$ containing a distinguished vertex v^* such that:*

- *if G has dominating number at most k , then the domination number of $R(G, k)$ is exactly k and every optimal dominating set avoids v^* ;*
- *if G has domination number strictly greater than $c \cdot (k + 1)$ for some $c \in \mathbb{R}_{\geq 1}$, then $R(G, k)$ has domination number $k + 1$ and the distinguished vertex v^* is contained in all $R(G, k)$ -dominating sets of size at most $c \cdot (k + 1)$.*

Proof sketch. The graph $R(G, k)$ is defined formally as follows:

1. initialize $R(G, k)$ as the graph on vertex set $\{v_i \mid v \in V(G), 0 \leq i \leq k\}$ with edges $\{v_i u_j \mid uv \in E(G), 0 \leq i, j \leq k\}$,
2. for each $i \in [k]$ insert an apex a_i which is adjacent to $\{v_i \mid v \in V(G)\}$,
3. insert a vertex v^* which is adjacent to $\{v_i \mid v \in V(G), 0 \leq i \leq k\}$.

The proof that $R(G, k)$ has the desired properties is given in the full version [7], together with a figure of the construction. ◀

Lemma 6.1 combined with the reduction provided by Lemma 6.2 yields the following.

► **Theorem 6.3.** *Unless $FPT = W[1]$, there is no FPT-time algorithm for c -ESSENTIAL DETECTION FOR DOMINATING SET parameterized by k for any $c \in \mathbb{R}_{\geq 1}$.*

Proof. Suppose such an algorithm \mathcal{A} exists for c ; we will use it with Lemma 6.1 to show $FPT = W[1]$ for the function $F(k) = c(k + 1)$.

Given an input (G, k) in which the goal is to distinguish between the completeness and soundness cases, the algorithm proceeds as follows. Using the reduction R of Lemma 6.2, consider the graph $R(G, k)$ and let S be the output of an algorithm for c -ESSENTIAL DETECTION FOR DOMINATING SET on the pair $(R(G, k), k + 1)$; note that the solution size for which we ask is $k + 1$ rather than k . Without loss of generality we may assume $k \geq 2$, as the distinction can trivially be made otherwise. We will show that in the completeness case we have $v^* \notin S$, while in the soundness case we have $v^* \in S$, which allows us to distinguish between these cases by checking whether v^* belongs to the output of $\mathcal{A}(R(G, k), k + 1)$.

For the completeness case, suppose G has domination number at most k . Then, by Lemma 6.2, so does $R(G, k)$. This means that Property G1 holds for the call to $\mathcal{A}(R(G, k), k + 1)$, so that there is some optimal solution S' of size k which contains S and hence we have $v^* \notin S$ by Lemma 6.2.

For the soundness case, suppose G has domination number at least $k \cdot F(k) = c(k + 1)k > c(k + 1)$ (we use $k \geq 2$ here). Then by Lemma 6.2, graph $R(G, k)$ has domination number $k + 1$ and v^* is contained in all its dominating sets of size at most $c(k + 1)$. In other words: v^* is c -essential in $R(G, k)$. Consequently, $v^* \in S$ by Property G2 since the argument $k + 1$ we supplied to \mathcal{A} coincides with the optimum in $R(G, k)$ in this case.

If \mathcal{A} runs in FPT-time, then the overall procedure runs in FPT-time which implies $FPT = W[1]$ by Lemma 6.1. ◀

Combining Lemma 6.2 with the standard reduction S from DOMINATING SET to HITTING SET (where hyperedges are given by closed neighborhoods) yields a composite mapping $S \circ R$ which relates c -essentiality to gaps in solution quality in much the same way as R did. We leverage this together with known reductions from HITTING SET to PERFECT DELETION [26] and WHEEL-FREE DELETION [32] to show the following.

► **Theorem 6.4 (★).** *Unless $FPT = W[1]$, both c -ESSENTIAL DETECTION FOR PERFDEL and c -ESSENTIAL DETECTION FOR WHEELDEL do not admit FPT-time algorithms parameterized by k for any $c \in \mathbb{R}_{\geq 1}$.*

7 Connections to Perturbation Resilience

In the area of perturbation resilience [36] there is a notion of so-called c -perturbation resilient instances to optimization problems. Roughly, these are instances G in which there is a unique optimal solution S which far outperforms (by a factor of c) every other solution S' in G .

More formally, for a vertex-weighted graph minimization problem Π whose solution is a vertex-subset, we say that an instance $(G, w: V(G) \rightarrow \mathbb{N})$ with a *unique* optimal solution S is *c-perturbation resilient* if for any perturbed weight function w' satisfying $w(v) \leq w'(v) \leq c \cdot w(v)$ for all $v \in V(G)$, the instance $(G, w'(x))$ has a unique optimal solution and furthermore this solution is S . (Of course, one can define an analogous notion for maximization problems as well and what follows in this section applies to both.)

Classes of c -perturbation resilient instances have been shown to be “islands of tractability” where many intractable problems become polynomial-time-solvable [36] and the suggestive intuition behind this fact is that perturbation resilient instances have unique optima which “stand out” and are “obvious” in some sense. Viewing stability through the lens of parameterized complexity, it is natural to ask whether one can quantify in an algorithmically useful way how distant an input is from being stable. The following proposition supports our claim that the *non-essentiality* (recall Theorem 5.1) is a good such measure since on $(> c)$ -stable inputs, the c -non-essentiality is smallest possible (namely it is 0).

► **Proposition 7.1.** *Given constants $c' > c \geq 1$, if G is a c' -stable input to a graph optimization problem Π whose solutions are vertex-subsets, then $\mathcal{E}_c^\Pi(G)$ is the unique optimum of G .*

Proof. Consider the unique optimum S for Π on G . If S' is a c -approximation for Π on G , then we must have $S' = S$ (since otherwise G would not be c' -stable). As a consequence we know that every vertex of S must be c -essential and hence we have $S \subseteq \mathcal{E}_c(G) \subseteq S$. ◀

Proposition 7.1 and Theorem 5.1 allow us to immediately deduce that any algorithm for c -ESSENTIAL DETECTION solves all $(> c)$ -perturbation resilient instances exactly.

► **Corollary 7.2.** *Given a minimization problem Π , any algorithm for c -ESSENTIAL DETECTION FOR Π solves $(> c)$ -stable instances exactly.*

8 Conclusion

We introduced the notion of c -essential vertices for vertex-subset minimization problems on graphs, to formalize the idea that a vertex belongs to all *reasonable* solutions. Using a variety of approaches centered around the theme of covering/packing duality, we gave polynomial-time algorithms that detect a subset of an optimal solution containing all c -essential vertices, which decreased the search space of parameterized algorithms from exponential in the size of the solution, to exponential in the number of non-essential vertices in the solution.

Throughout the paper we have restricted ourselves to working with unweighted problems. However, many of the same ideas can be applied in the setting where each vertex has a positive integer weight of magnitude $\mathcal{O}(|V(G)|^{\mathcal{O}(1)})$ and we search for a minimum-weight solution. Since integral vertex weights can be simulated for many problems by making twin-copies of a vertex, our approach can be extended to WEIGHTED VERTEX COVER, WEIGHTED ODD CYCLE TRANSVERSAL, and WEIGHTED CHORDAL DELETION.

Our results shed a new light on which instances of NP-hard problems can be solved efficiently. FPT algorithms for parameterizations by solution size show that instances are easy when their optimal solutions are small. Theorem 1.1 refines this view: it shows that instances with large optimal solutions can still be easy, as long as only a small number of vertices in the optimum is not c -essential.

We remark that there is an alternative route to algorithms for c -ESSENTIAL DETECTION, which is applicable to \mathcal{C} -DELETION problems which admit a constant-factor approximation. If there is a polynomial-time algorithm that, given a graph G and vertex v , outputs a

c -approximation for the problem of finding a minimum-size \mathcal{C} -modulator avoiding v , it can be used for c -ESSENTIAL DETECTION. A valid output S for the detection problem with input (G, k) is obtained by letting S contain all vertices for which the approximation algorithm outputs a v -avoiding modulator of size more than $c \cdot k$. Using this approach (cf. [22]) one can solve $\max_{F \in \mathcal{F}} |V(F)|^{\mathcal{O}(1)}$ -ESSENTIAL DETECTION FOR \mathcal{F} -MINOR-FREE DELETION for any finite family \mathcal{F} containing a planar graph. As the results for problems for which no constant-factor approximation exists are more interesting, we focused on those.

Our work opens up several questions for future work. Is the integrality gap for v -AVOIDING PLANAR VERTEX DELETION constant, when $G - v$ is planar? Can $\mathcal{O}(1)$ -ESSENTIAL DETECTION FOR PLANAR VERTEX DELETION be solved in polynomial time? Can 2-ESSENTIAL DETECTION FOR CHORDAL DELETION be solved in polynomial time? Can the constant c for which we can detect c -essential vertices be lowered below 2?

Considering a broader horizon, it would be interesting to investigate whether there are less restrictive notions than c -essentiality which can be used as the basis for guaranteed search-space reduction.

Abstract

Minimum flow decomposition (MFD) is the NP-hard problem of finding a smallest decomposition of a network flow X on directed graph G into weighted source-to-sink paths whose superposition equals X . We focus on a common formulation of the problem where the path weights must be non-negative integers and also on a new variant where these weights can be negative. We show that, for acyclic graphs, considering the *width* of the graph (the minimum number of s - t paths needed to cover all of its edges) yields advances in our understanding of its approximability. For the non-negative version, we show that a popular heuristic is a $O(\log |X|)$ -approximation ($|X|$ being the total flow of X) on graphs satisfying two properties related to the width (satisfied by e.g., series-parallel graphs), and strengthen its worst-case approximation ratio from $\Omega(\sqrt{m})$ to $\Omega(m/\log m)$ for sparse graphs, where m is the number of edges in the graph. For the negative version, we give a $(\lceil \log \|X\| \rceil + 1)$ -approximation ($\|X\|$ being the maximum absolute value of X on any edge) using a power-of-two approach, combined with parity fixing arguments and a decomposition of unitary flows ($\|X\| \leq 1$) into at most width paths. We also disprove a conjecture about the linear independence of minimum (non-negative) flow decompositions posed by Kloster et al. [ALENEX 2018], but show that its useful implication (polynomial-time assignments of weights to a given set of paths to decompose a flow) holds for the negative version.

1 Introduction

Minimum flow decomposition (MFD) is the problem of finding a smallest sized decomposition of a network flow X on directed graph $G = (V, E)$ into weighted source-to-sink paths whose superposition equals X . We focus on the case where path weights are restricted to be integers. It is a textbook result [1] that if G is acyclic (a DAG) a decomposition using no more than $m = |E|$ paths always exists. However, MFD is strongly NP-hard [25], even on DAGs, and

even when the flow values come only from $\{1, 2, 4\}$ [12]. Recent work has shown that the problem is FPT in the size of the minimum decomposition [14] and that it can be formulated as an ILP of quadratic size [7].

While difficult to solve, MFD is a key step in many applications. For example, MFD on DAGs is used to reconstruct biological sequences such as RNA transcripts [18, 23, 11, 3, 22, 26] and viral strains [2]. MFD can also be used to model problems in networking [25, 12, 15] and transportation planning [16], although in some of these applications there may be cycles in the input. Despite the ubiquity of the MFD problem, the gap in our knowledge about the approximability of MFD is large, even when restricting to DAGs. It is known [12] that MFD (even on DAGs) is APX-hard (i.e., there is some $\epsilon > 0$ such that it is NP-hard to approximate within a $(1 + \epsilon)$ factor), so in particular, MFD does not admit a PTAS, unless $P=NP$. Furthermore, it can be approximated with a factor of $\lambda^{\log \|X\|} \log \|X\|$ [15], where λ is the length of the longest source-to-sink path and $\|X\|$ is the largest flow value in the network. In this work, we attempt to fill in some of the gaps between these results.

A natural lower bound for the size of an MFD of a DAG is the size of a *minimum path cover* of the set of edges with non-zero flow (i.e., the minimum number of paths such that every such edge appears in *at least* one path) – this size is called the *width* of the network. This trivially holds because every flow decomposition is also such a path cover. These two notions are analogies of the more standard notions of path cover and width of the *node set*. The node-variants are classical concepts, with algorithmic results dating back to Dilworth and Fulkerson [8, 10]. Despite this, the width has not been given any attention in the MFD problem, and in particular it has never been used in approximation algorithms. In this paper, we show that the width can play a key role both in the analysis of popular heuristics, and in obtaining the first approximation algorithm for a natural variant of MFD.

We start with a relaxation of MFD in which flow decomposition may also use negative integer weights on flow paths, rather than strictly positive weights as has traditionally been considered [25, 12, 14]. An important observation that we leverage for this variant (unlike the positive-only version) is that “the width does not increase” as flow paths are chosen and removed. Using this, we give a $(\lceil \log \|X\| \rceil + 1)$ approximation algorithm for this variant. To differentiate both versions, we use $\text{MFD}_{\mathbb{N}}$ and $\text{MFD}_{\mathbb{Z}}$ throughout the paper. While $\text{MFD}_{\mathbb{Z}}$ is a natural version of the problem, to our knowledge it has not been previously considered in the MFD literature. However, it can also have natural applications, since by applying $\text{MFD}_{\mathbb{Z}}$ on the difference between two flows, one can minimally explain the *differences* between them, e.g. to explain the differences in RNA expression between two tissue samples with the fewest number of up/down regulated transcripts, which is often the goal of RNA sequencing experiments [21]. Our approximation follows a *power-of-two* approach where the weights of the paths chosen are (positive or negative) powers of two. More specifically, observe that if all flow values are even, then one can divide them by 2 and obtain a flow X with smaller $\|X\|$ whose decomposition can be transformed back into a decomposition of X . In order to obtain such an even flow, we prove a basic property that can be of independent interest: given any integer flow X , there exists a *unitary* flow (its values are 0, +1, or -1) Y , such that $X + Y$ is even on every edge (Lemma 5). In addition, given a unitary flow Y , we show that Y can be decomposed into k paths of weight +1 or -1 , such that k is at most the width of the graph (Corollary 8). We obtain the $(\lceil \log \|X\| \rceil + 1)$ approximation ratio (Theorem 11) by iteratively removing the unitary flow, dividing all flow values by 2, and preprocessing the graph so that its width is a lower bound on the size of the $\text{MFD}_{\mathbb{Z}}$.

In Section 4 we consider connections between the width and a popular heuristic algorithm for $\text{MFD}_{\mathbb{N}}$ which we call *greedy-weight*¹ [25], which builds a flow decomposition by successively choosing the path that can carry the largest flow. Greedy-weight is commonly used in applications (see e.g., [23, 2, 18] among many), and it seems to be mentioned in nearly every publication addressing flow decomposition. First, on sparse graphs we improve (i.e., increase) the worst-case lower bound for the greedy-weight approximation factor from $\Omega(\sqrt{m})$ [12] to $\Omega(m/\log m)$, showing for the first time that greedy-weight can be exponentially worse than the optimum. For this we use a class of sparse graphs where the optimum flow decomposition has size $O(\log m)$ whereas the greedy-weight algorithm returns a solution of size $\Omega(m)$, only a constant factor away from the trivial decomposition. The key to this new bound is to design an input where the width increases exponentially when a path is greedily removed. We also show that the same bound also holds for other greedy heuristics choosing instead the longest or shortest paths. Second, we show that if the input satisfies the properties that its width does not increase as source-to-sink paths are removed (Property 15) and that it is possible to remove a path of large weight (Property 16), then greedy-weight is a $O(\log |X|)$ -approximation, where $|X|$ is the flow value (i.e., total flow out of s). A notable class of graphs satisfying these properties is the class of *series-parallel graphs*; see [9, 24] for fast recognition algorithms and pointers to other NP-hard problems that are easier on this class of graphs. Series-parallel graphs are also of great interest for network flow problems (see, e.g., [13, 4]).

Finally, in Section 5 we consider a closely related problem, called *k-Flow Weight Assignment* [14]. In addition to the flow X , in this problem we are also given a set of k paths, and we need to decide if there is an assignment of weights to the paths such that they form a decomposition of X . If the weights belong to \mathbb{N} , this was shown to be NP-complete in [14]. In this work, we first observe that in the same way that allowing negative integer weights simplifies the approximability of MFD, allowing weights to belong to \mathbb{Z} fully changes the complexity of the k -Flow Assignment Problem, making it polynomial. This is due to the fact that the linear system defined by the given paths loses its only inequality of restricting the weights to positive integers. It thus transforms an ILP to a system of linear Diophantine equations, which can be solved in polynomial time (see e.g. [19]). Second, we consider a conjecture from [14] stating that if the weights belong to \mathbb{N} , and k is the size of a $\text{MFD}_{\mathbb{N}}$ for X , then the problem admits a unique solution (i.e., a unique assignment of weights to the given paths). If true, this would speed up the FPT algorithm of [14] for $\text{MFD}_{\mathbb{N}}$, because a step solving an ILP could be executed by solving a standard linear program returning a rational solution and checking if the (supposedly unique) solution to this system is integer. Moreover, the same conjecture (with the same implication) was also a motivation behind the greedy algorithm of [20] for $\text{MFD}_{\mathbb{N}}$. In this paper, we disprove the conjecture of [14], further corroborating the gap between $\text{MFD}_{\mathbb{N}}$ and $\text{MFD}_{\mathbb{Z}}$.

2 Preliminaries

We are given a directed graph $G = (V, E)$. Without loss of generality, we assume a unique source s and a unique sink t with no in-edges and no out-edges respectively; otherwise, the graph can be converted to such a graph by adding a pseudo source and sink and connecting them to all sources and sinks respectively with appropriately weighted edges. We also assume

¹ Previous work has consistently referred to this algorithm as *greedy-width*. To avoid confusion with the width of the graph, we introduce the name *greedy-weight* in this work.

31:4 Width Helps and Hinders Splitting Flows

(a) If paths and -

(b) With positive weights only, five paths are needed, since the edge (v_1, v_2) must be decomposed by a weight 1 path, leaving 4 edges that must be covered separately. The paths shown are one such decomposition.

■ **Figure 1** A positive flow admitting a decomposition into four paths only if negative weights are allowed.

that every node is on some s - t path. We use n and m to denote the number of nodes and edges of G , respectively. Additionally, we assume that G is a DAG throughout the paper. While the problem is also studied for graphs with cycles (see, e.g., [25, 12]), the task is still to decompose into simple paths, and so our inapproximability result on DAGs also applies for graphs with cycles. We call functions $X : E \rightarrow \mathbb{Y}$ *pseudo-flows*, where \mathbb{Y} is some set of allowed flow values (numbers). We treat pseudo-flows as vectors over E and use the notation $X + Y$ and aX to denote the (element-wise) sum of pseudo-flows and multiplication by a scalar, respectively. The numbers 0 and 1 also denote (depending on context) pseudo-flows that are 0 (resp. 1) everywhere. We write $X \leq Y$ (and similarly $<$) to mean $X(u, v) \leq Y(u, v)$ for every $(u, v) \in E$.

Given G , a *flow* is a pseudo-flow satisfying conservation of flow (incoming flow equal to outgoing flow) on internal nodes $V \setminus \{s, t\}$. It is known that the sum of two flows $X + Y$, the multiplication of a flow with a scalar aX , and the empty flow 0 are themselves flows. Let $|X|$ denote the total flow out of s (or into t) for flow X . Given an s - t path P , let P also denote the flow defined by setting 1 to every edge in P and 0 elsewhere. With these definitions, we are ready to formally define MFD.

► **Definition 1.** Given a flow X , a flow decomposition of (G, X) of size k is a family of s - t paths $\mathcal{P} = (P_1, \dots, P_k)$ with weights $(w_1, \dots, w_k) \in \mathbb{Y}^k$ such that $X = w_1P_1 + \dots + w_kP_k$.

► **Definition 2.** Given a flow X , let $\text{mfd}_{\mathbb{Y}}(G, X)$ be the smallest size of a flow decomposition of (G, X) with weights in \mathbb{Y} .

We omit \mathbb{Y} if it is clear from the context. We call the problem of producing a flow decomposition of (G, X) of minimum size the *minimum flow decomposition (MFD) problem*. In this paper, we study two integer versions of the problem, $\text{MFD}_{\mathbb{N}}$ ($0 \in \mathbb{N}$) and $\text{MFD}_{\mathbb{Z}}$. Note that the reduction showing $\text{MFD}_{\mathbb{N}}$ to be strongly NP-hard from [25] also holds for $\text{MFD}_{\mathbb{Z}}$. However, a positive flow may admit a decomposition using fewer paths if negative weights are allowed, as shown in Figure 1. We explore further differences between $\text{MFD}_{\mathbb{N}}$ and $\text{MFD}_{\mathbb{Z}}$ in Sections 3 and 5.

Let $\|X\| = \max_{(u,v) \in E} |X(u, v)|$ denote the infinity norm on flows. In particular, notice that if $\mathbb{Y} \subseteq \mathbb{Z}$, then $\|X\| \leq 1$ means that $X(u, v) \in \{0, \pm 1\}$ for every $(u, v) \in E$. Let $X \equiv_2 Y$ if X and Y have the same parity everywhere, i.e., for every $(u, v) \in E$, we have that $X(u, v)$ is odd iff $Y(u, v)$ is odd.

► **Definition 3.** Given $S \subseteq E$, we define $\text{width}_S(G)$ as the minimum number of s - t paths in G needed to cover all edges of S . If $S = E$ we just write $\text{width}(G)$.

Just like its more common node variant, $\text{width}(G)$ can be computed in $O(mn)$ time. As described by, e.g., [1, 6], this is done by reduction to a min-flow instance with demand one on every edge; the minimum flow of this instance is $\text{width}(G)$, and the flow can be found by reduction to a max-flow instance. Moreover, the problem can be relaxed to only require the coverage of $S \subseteq E$ and solved in the same running time by setting the demands only on the edges of S .

► **Lemma 4** ([1, 17]). *Let $G = (V, E)$ be a DAG, and $S \subseteq E$. A flow $C : E \rightarrow \mathbb{N}$ can be computed in $O(mn)$ time, such that $C(e) \geq 1$ for all $e \in S$ and $|C| = \text{width}_S(G)$.*

The flow C with total flow $\text{width}_S(G)$ suffices in this paper, and we do not need to calculate a path cover achieving that minimum. However, we note that it can be directly computed given the flow C . We can think of this path cover as a flow decomposition of C into $\text{width}_S(G)$ weight-one paths, which can be found by greedily removing such paths from C until it is completely decomposed. Since each path has no more than $n - 1$ edges and since $\text{width}_S(G) \leq m$, the overall runtime of finding the path cover is $O(mn)$.

3 Width helps solve $\text{MFD}_{\mathbb{Z}}$

The idea behind our approximation algorithm for $\text{MFD}_{\mathbb{Z}}$ is that a flow $X : E \rightarrow \mathbb{Z}$ on DAG G can always be decomposed into $(\lceil \log \|X\| \rceil + 1) \cdot \text{width}(G)$ paths. We show this using two key facts: first, that X can be decomposed into $(\lceil \log \|X\| \rceil + 1)$ flows with a particular structure, and, second, that each of these flows can be decomposed into $\text{width}(G)$ paths. A key step in proving both these facts is a subroutine which, given an input flow X , finds another flow Y with only values from $\{0, \pm 1\}$ (a *unitary* flow) that matches the parity of X on all the edges. Intuitively, given an input flow X , such a unitary flow Y can be added to X to “fix” its odd edges to be even, with only a small change to X .

► **Lemma 5.** *For any flow $X : E \rightarrow \mathbb{Z}$ on $G = (V, E)$, there exists a flow $Y : E \rightarrow \mathbb{Z}$ such that $X \equiv_2 Y$ and $\|Y\| \leq 1$.*

Proof. Consider the undirected graph $G_{\text{odd}} = (V, E_{\text{odd}})$ where $E_{\text{odd}} = \{\{u, v\} \mid (u, v) \in E \text{ and } X(u, v) \text{ is odd}\}$.

Notice that every node of G_{odd} , except possibly s and t , has even degree, due to conservation of flow. Thus, G_{odd} can be written as the edge-disjoint union of cycles and s - t paths. Assign an arbitrary orientation to each cycle and s - t path, and let E_{odd}^+ be the set of edges oriented in this way. Define

$$Y(u, v) = \begin{cases} +1 & \text{if } (u, v) \in E_{\text{odd}}^+ \\ -1 & \text{if } (v, u) \in E_{\text{odd}}^+ \\ 0 & \text{if } \{u, v\} \notin E_{\text{odd}} \end{cases}$$

Notice that Y is a flow decomposed as a sum of flows, each along one of the edge-disjoint cycles and s - t paths. Moreover, $X \equiv_2 Y$ and $\|Y\| \leq 1$ by construction. ◀

Repeatedly applying Lemma 5 and dividing the resulting even flow by 2, we obtain the the first key ingredient of the approach (proof in [5, Appendix B]).

► **Corollary 6.** *Any (non-zero) flow $X : E \rightarrow \mathbb{Z}$ can be written as $X = \sum_{i=0}^{\lceil \log \|X\| \rceil} 2^i \cdot Y_i$, where $Y_i : E \rightarrow \mathbb{Z}$ is a flow with $\|Y_i\| \leq 1$ for all i .*

(f) Flow $B = (C - D - X)/2$ and a decomposition of it into two paths of weight 1.

■ **Figure 2** Example of Lemma 7 and Corollary 8 applied to a unitary flow X on a graph G (for clarity, 0 flow values are not shown). Positive flows A and B can be constructed so that $|A| + |B| \leq \text{width}(G)$ holds. Flows A and B can be trivially decomposed into $|A|$ and $|B|$ paths, respectively. We obtain a decomposition of X by taking the paths of A with weight 1 and the paths of B with weight -1 .

The following result is the second key ingredient of our approach. It guarantees (together with Corollary 8) that any unitary flow can be decomposed into at most $\text{width}(G)$ paths of weight ± 1 (see Figure 2 for an example). This is by no means obvious since, among other problems, a unitary flow may contain positive and negative values which merge and cancel each other out (as in Figure 2a). The proof is based on another application of Lemma 5, along with some algebra on flows.

► **Lemma 7.** For any flow $X : E \rightarrow \mathbb{Z}$, $\|X\| \leq 1$, there exist flows $A, B : E \rightarrow \mathbb{Z}$ such that:

1. $A, B \geq 0$
2. $X = A - B$
3. $|A| + |B| \leq \text{width}(G)$

Proof. Take C such that $C \geq 1$ and $|C| = \text{width}(G)$, according to Lemma 4. Take D such that $D \equiv_2 X + C$ and $\|D\| \leq 1$, according to Lemma 5. Also, assume $|D| \geq 0$ without loss of generality (otherwise, take $-D$, which satisfies the same properties).

Since $D \equiv_2 X + C$, we have $C - D \pm X \equiv_2 0$. So we can take $A = (C - D + X)/2$ and $B = (C - D - X)/2$.

1. Notice that $C - D \pm X \geq C - 2$ since $\|D\|, \|X\| \leq 1$. So, $C - D \pm X \geq -1$, since $C \geq 1$. But $C - D \pm X \equiv_2 0$ so $C - D \pm X \geq 0$, whence $A, B \geq 0$.
2. $A - B = \frac{C - D + X}{2} - \frac{C - D - X}{2} = X$.
3. $|A| + |B| = |A + B| = \left| \frac{C - D + X}{2} + \frac{C - D - X}{2} \right| = |C - D| = |C| - |D| \leq |C|$ since $|D| \geq 0$, and $|C| = \text{width}(G)$. ◀

► **Corollary 8.** For any flow $X : E \rightarrow \mathbb{Z}$ with $\|X\| \leq 1$, there exist paths P_1, \dots, P_k with $k \leq \text{width}(G)$ such that $X = P_1 + \dots + P_\ell - P_{\ell+1} - \dots - P_k$ (for some $0 \leq \ell \leq k$).

Proof. Take A, B according to Lemma 7, with $A, B \geq 0$, $X = A - B$ and $|A| + |B| \leq \text{width}(G)$. Since $A, B \geq 0$, there exist paths $P_1, \dots, P_{|A|+|B|}$ such that $A = P_1 + \dots + P_{|A|}$ and $B = P_{|A|+1} + \dots + P_{|A|+|B|}$ [1]. Since $X = A - B$, we can write $X = P_1 + \dots + P_{|A|} - P_{|A|+1} - \dots - P_{|A|+|B|}$. Finally, recall that $|A| + |B| \leq \text{width}(G)$, concluding the proof. ◀

Finally, expressing any flow as a sum of at most $\lceil \log \|X\| \rceil + 1$ unitary flows (Corollary 6), and decomposing each unitary flow into at most $\text{width}(G)$ positive or negative paths (Corollary 8), we can decompose the flow into at most $\lceil \log \|X\| \rceil + 1$ paths whose weight are positive and negative powers of two.

► **Theorem 9.** *Given a DAG $G = (V, E)$, for any flow $X: E \rightarrow \mathbb{Z}$, there exist paths P_1, \dots, P_k and weights $\{w_1, \dots, w_k\} \subseteq \{\pm 2^i \mid i \in \mathbb{N}\}$, with $k \leq (\lceil \log \|X\| \rceil + 1) \cdot \text{width}(G)$ such that $X = w_1 P_1 + \dots + w_k P_k$.*

Proof. Combine Corollaries 6 and 8, getting

$$X = \sum_{i=0}^{\lceil \log \|X\| \rceil} 2^i \cdot Y_i = \sum_{i=0}^{\lceil \log \|X\| \rceil} 2^i \cdot (P_{\ell_i} + \dots + P_{\ell_i} - P_{\ell_i+1} - \dots - P_{k_i})$$

where $k_i \leq \text{width}(G)$. ◀

The proof of Theorem 9 suggests a straightforward algorithm for $\text{MFD}_{\mathbb{Z}}$, which we detail in Algorithm 2 and describe at a high level here. First, iteratively decompose X , yielding $\lceil \log \|X\| \rceil + 1$ unitary flows. Then use Lemma 7 to decompose each into $\text{width}(G)$ paths. However, as we explained at the beginning of this section, $\text{width}(G)$ is not a lower bound on $\text{MFD}_{\mathbb{Z}}$, and thus this approach does not directly derives an approximation. To overcome this issue, we instead find a flow decomposition of a spanning subgraph G' of G whose width lower bounds $\text{mfd}_{\mathbb{Z}}(G, X)$. Namely, we first find a minimum path cover flow in G of the subset S of edges with non-zero flow in $O(mn)$ time (according to Lemma 4), and then remove from G any edge not covered by the flow, obtaining G' . By construction, the size of this path cover is a lower bound of $\text{mfd}_{\mathbb{Z}}(G, X)$. Moreover, the size of this path cover is exactly $\text{width}(G')$, since every path cover of G' is also a path cover of S in G .

To prove the correctness of Algorithm 2, we first define a subroutine implementing Lemma 5.

► **Lemma 10.** *Algorithm 1 returns a unitary flow from input flow Y such that $X \equiv_2 Y$, as in Lemma 5, in $O(m)$ time.*

Proof. The correctness of the algorithm is given by Lemma 5. Finally, the first 3 subroutines as well as the entire **for**-loop takes $O(m)$ time. ◀

► **Theorem 11.** *Algorithm 2 is a $\log \lceil \|X\| \rceil + 1$ -approximation for $\text{MFD}_{\mathbb{Z}}$ with runtime $O(m(\log \|X\| \cdot \text{mfd}_{\mathbb{Z}}(G, X) + n)) = O(m^2 \log \|X\|)$.*

Proof. By Theorem 9 and our previous discussion, Algorithm 2 returns a flow decomposition for X with no more than $(\lceil \log \|X\| \rceil + 1) \cdot \text{width}(G') = (\lceil \log \|X\| \rceil + 1) \cdot \text{mfd}_{\mathbb{Z}}(G, X)$ paths. We analyze the runtime line by line. Lines 2 and 5 take $O(mn)$ time by Lemma 4. The call to Algorithm 1 on line 6 takes $O(m)$ time by Lemma 10, and checking the flow of D and flipping signs (if necessary) also takes $O(m)$ time. By Corollary 6, the while loop on line 8 executes at most $\log \lceil \|X\| \rceil + 1$ times, meaning that the entire execution takes $O(m \log \|X\|)$ time since line 9 takes $O(m)$ time by Lemma 10. Since there are at most $\log \lceil \|X\| \rceil + 1$ Y_i 's, the for loop on line 14 executes at most $\log \lceil \|X\| \rceil + 1$ times. Each

15: end procedure

```

execution of the for-loop naively finds $\text{width}(G')$ paths, each of which can be found in $O(m)$ time, so the whole loop takes $O(\log \|X\| \cdot \text{width}(G') \cdot m)$ time. Thus, the overall runtime is $O(m \log \|X\| \cdot \text{width}(G') + n) = O(m \log \|X\| \cdot \text{mfd}_{\mathbb{Z}}(G, X) + n)$. ◀

A theorem analogous to Theorem 9 for $\text{MFD}_{\mathbb{N}}$ is desirable, but cannot be achieved directly with the previous methods. Lemma 5 makes use of negative weights, and yields positive weights only if the flow graph solely consists of s - t paths. However, the approach can be adapted for $\text{MFD}_{\mathbb{N}}$ if the input flows are stable (Property 15), and if it is possible to “fix” the odd flows to be even with only $\text{width}(G)$ paths, which we leave as an open question.

4 Width matters for greedy approaches

Since the difference of two flows is still a flow, it is very natural to consider successively removing the most obvious type of flow – that is to say, paths – as an algorithmic strategy for $\text{MFD}_{\mathbb{N}}$. Indeed, the particular greedy path removal strategy of finding the *heaviest path* (*greedy-weight*) is commonly used as a heuristic in applications (e.g., [18, 2, 23, 12]) and it seems to be mentioned in nearly every paper addressing flow decomposition. More formally, a path P is said to *carry* flow p if $X(u, v) \geq p$ for all edges (u, v) of P . The *heaviest path* is an s - t path carrying the largest flow. Such a path can be easily found in linear time in the size of the DAG by dynamic programming (see, e.g., [25]).

4.1 Width hinders greedy on $\text{MFD}_{\mathbb{N}}$

We define a family of $\text{MFD}_{\mathbb{N}}$ instances $(G_{\ell}, X_{\ell, B})$, depending on two parameters $\ell \in \mathbb{N} \setminus \{0\}$ and $B \in \mathbb{N}$. The family is defined recursively on ℓ . The base case $(G_1, X_{1, B})$ for $\ell = 1$ is shown in Figure 3a. For $\ell > 1$, we build $(G_{\ell}, X_{\ell, B})$ from two disjoint copies of $(G_{\ell-1}, X_{\ell-1, B})$, by adding 5 extra edges and flow values as shown in Figure 3b. We call the edge connecting the two copies of $G_{\ell-1}$ a *central edge*. Edges whose flow value depends on B are called *backbone* edges, and they form a s - t path. Choosing $B = 2^{\ell+1}$, we show that the flow $X_{\ell, 2^{\ell+1}}$ can be decomposed using a number of paths linear in ℓ , thanks to the heavy backbone

■ **Algorithm 2** Finds the flow decomposition of Theorem 9.

```

edges, whereas the greedy-weight algorithm fully saturates the central edges with its first path and is left with a remaining flow requiring $2^{\ell+1}$ paths to be decomposed (proofs in [5, Appendix B]).

► **Lemma 12.** *Let G_ℓ with flow $X_{\ell, 2^{\ell+1}}$ be constructed as described before. Greedy-weight uses $1 + 2^{\ell+1}$ paths to decompose $X_{\ell, 2^{\ell+1}}$.*

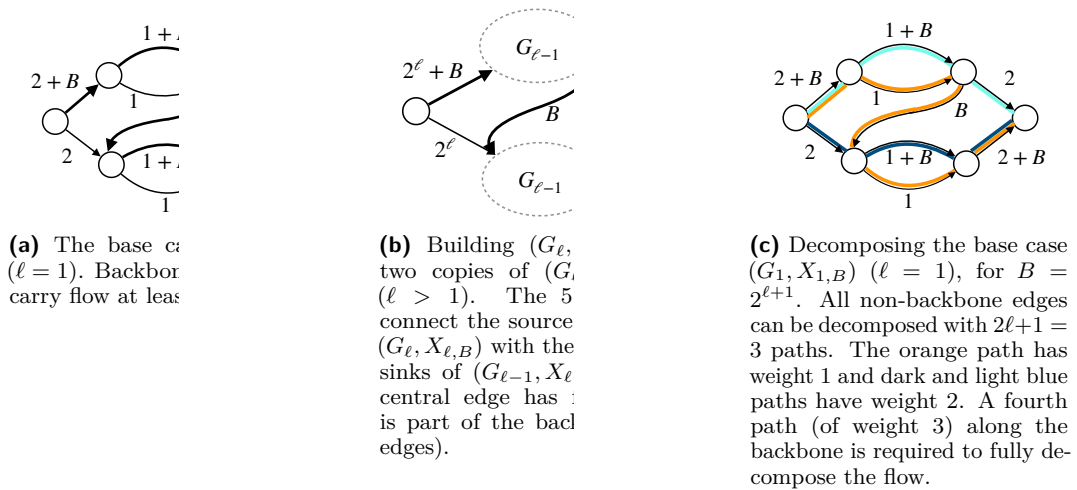

► **Lemma 13.** *Let G_ℓ with flow $X_{\ell, 2^{\ell+1}}$ be constructed as described before. It is possible to decompose $X_{\ell, 2^{\ell+1}}$ using $2\ell + 2$ paths.*

► **Theorem 14.** *The approximation ratio for greedy-weight on $\text{MFD}_{\mathbb{N}}$ is $\Omega(m/\log m)$ for sparse graphs, in the worst case.*

Proof. By Lemmas 12 and 13, greedy-weight uses $\Theta(2^\ell)$ paths to decompose the flow $X_{\ell, 2^{\ell+1}}$ described above, whereas it is possible to decompose the flow with only $\Theta(\ell)$ paths. It can be easily verified by induction that the number of edges of G_ℓ is $7 \cdot 2^\ell - 5$. So the ratio between greedy-weight and optimal for this instance is $\Omega(\frac{m}{\log m})$. ◀

While greedy-weight is most commonly used in applications, the approach was first presented as part of a general framework [25]: pick any optimality criteria for s - t paths that is *saturating* (i.e., fully decomposes at least one edge), and successively remove optimal paths. Since each path is saturating, the algorithm must decompose the flow in m or fewer paths. Another optimality criterion sometimes used in DNA assembly (e.g., in vg-flow [2]) is the *longest path* (with its maximum possible flow so that it is saturating). To adapt our construction of $(G_\ell, X_{\ell, 2^{\ell+1}})$ so that this approach has the same approximation ratio, consider $(G_\ell^*, X_{\ell, 2^{\ell+1}}^*)$, constructed as in $(G_\ell, X_{\ell, 2^{\ell+1}})$ except that we replace every backbone edge (u, v) with two edges, (u, w) and (w, v) . See [5, Figure 6] for an example. Then a path

31:10 Width Helps and Hinders Splitting Flows

■ **Figure 3** Construction for $(G_\ell, X_{\ell,B})$. Setting $B = 2^{\ell+1}$ gives MFD instances where greedy-weight uses $\Theta(\frac{m}{\log m})$ times more paths than optimal to decompose the flow.

along the backbone edges will be the longest from s to t and the above asymptotic analysis holds, since we no more than doubled the number of edges. Yet another optimality criterion, studied in [12] for its application to network routing, is the shortest path (again with its maximum possible flow). $(G_\ell^*, X_{\ell,2^{\ell+1}}^*)$ will also force this approach to take an exponential number of paths, since first the algorithm will take all $2^{\ell+1}$ weight-1 edges with $2^{\ell+1}$ different paths.

4.2 Greedy approximation for series-parallel graphs

As exploited in Section 4.1, one sticking point for greedy path removal algorithms is the fact that the width of a graph can increase after an edge is fully decomposed. We now show that if, in a particular instance, a graph does not increase its width during the execution of the algorithm, and greedy-weight can decompose “enough” flow at each step, then greedy-weight is a $O(\log |X|)$ -approximation for $\text{MFD}_{\mathbb{N}}$.

If G is a directed graph and $X \geq 0$ a flow on G , we write $G|_X$ (G restricted to X) to mean the spanning subgraph of G made up of the edges $e \in E$ such that $X(e) \neq 0$. Conversely, if S is a subgraph of G , we write $X|_S$ (X restricted to S) to mean the pseudo-flow X only on the edges of S . In the case of $\text{MFD}_{\mathbb{N}}$, once an edge is fully decomposed, it cannot be used in future paths, possibly increasing the width of the graph that can be used to decompose the rest of the flow and sometimes triggering an increase of the size of a minimum flow decomposition as well. We call a graph *stable* if it does not have this issue.

► **Property 15** (Stable graph). We say that G is *stable* if, for any non-negative flow X on G , it holds that $\text{width}(G|_X) \leq \text{width}(G)$.

Many useful $\text{MFD}_{\mathbb{N}}$ instances do in fact satisfy Property 15. For example, the first proof of MFD 's NP-hardness [25] was a reduction to a very simple graph of this form; this means that $\text{MFD}_{\mathbb{N}}$ restricted to stable graphs is also NP-hard.

The second property that we need is that there is always, during the execution of the algorithm, a path carrying “enough” flow from s to t .

► **Property 16** (Paths of large weight). We say that G has *paths of large weight* if, for any flow $X \geq 0$ on G , there exists an s - t path in $G|_X$ carrying at least $|X|/\text{width}(G)$ flow.

Note that this property does not hold in general; see [5, Figure 7].

► **Lemma 17.** *Let $G = (V, E)$ be a graph, $\text{width}(G) \geq 2$, satisfying Properties 15 and 16. Greedy-weight uses at most $\lfloor \log |X| / \log \frac{\text{width}(G)}{\text{width}(G)-1} \rfloor + 1$ paths to decompose any flow $X : E \rightarrow \mathbb{N}$.*

Proof. Let $b = \text{width}(G)$. Since G satisfies Properties 15 and 16, greedy-weight removes a path of weight at least $|X'|/b$ at every step, where X' is the remaining flow of the corresponding step. As such, after c steps $|X'| \leq |X| \left(\frac{b-1}{b}\right)^c$. If $|X| \left(\frac{b-1}{b}\right)^c < 1$, then $|X'| = 0$, since $|X|$ and the weights of the removed paths belong to \mathbb{N} . Solving for c we obtain $c > \log |X| / \log \frac{b}{b-1}$. Therefore, greedy-weight takes (uses) at most $c = \lfloor \log |X| / \log \frac{b}{b-1} \rfloor + 1$ steps (paths). ◀

► **Theorem 18.** *Let $G = (V, E)$ be a graph satisfying Properties 15 and 16 and $X : E \rightarrow \mathbb{N}$ a flow. Greedy-weight is a $O(\log |X|)$ -approximation for $\text{MFD}_{\mathbb{N}}$ on (G, X) .*

Proof. Assume $X > 0$ (otherwise, replace G with $G|_X$). Thus, $b = \text{width}(G) \leq \text{mfd}_{\mathbb{N}}(G, X)$, since any flow-decomposition of X induces a path cover of E . If $b \leq 1$ greedy-weight finds an optimal solution. Otherwise $b \geq 2$, and Lemma 17 implies that greedy-weight is a $O\left(\frac{\log |X|}{b \log \frac{b}{b-1}}\right) = O(\log |X|)$ -approximation for $\text{MFD}_{\mathbb{N}}$ ($b \log \frac{b}{b-1} = O(1)$ for $b \geq 2$). ◀

Finally, we define series-parallel graphs, and apply Theorem 18 to them, by proving (in [5, Appendix B]) that they satisfy Properties 15 and 16.

► **Definition 19** (Series-parallel graph [9]). *A graph is a two-terminal series-parallel (series-parallel for short) graph with terminal nodes s and t if:*

- *it consists of a single edge directed from s to t , and no other nodes, or*
- *it can be obtained from two (smaller) two-terminal series-parallel graphs G_1 and G_2 , with terminal nodes s_1, t_1 , and s_2, t_2 , respectively, by either*
 - *identifying $s = s_1 = s_2$ and $t = t_1 = t_2$ (parallel composition of G_1 and G_2), or*
 - *identifying $s = s_1, t_1 = s_2$, and $t = t_2$ (series composition of G_1 and G_2).*

► **Corollary 20.** *Greedy-weight is a $O(\log |X|)$ -approximation for $\text{MFD}_{\mathbb{N}}$ on series-parallel graphs.*

5 Solving the k -Flow Weight Assignment Problem

In this section, we consider a restriction of MFD from [14] (see Figure 4 for an example).

► **Definition 21** (k -Flow Weight Assignment). *Given a flow $X : E \rightarrow \mathbb{Y}$ on a graph $G = (V, E)$ and a set of s - t paths $\{P_1, \dots, P_k\}$, the problem of finding an assignment of weights to the paths, such that they form a flow decomposition of (G, X) , is called k -Flow Weight Assignment (k -FWA). We write $k\text{-FWA}_{\mathbb{Y}}$ if we require the path weights to belong to \mathbb{Y} .*

Given k s - t paths, k -FWA can be solved by a linear system defined by $Lw = X$, where $X_j \in \mathbb{Y}$ is equal to the flow $X(e_j)$ of the edge e_j (we identify flows $X : E \rightarrow \mathbb{Y}$ with vectors $X \in \mathbb{Y}^m$) and L is the $m \times k$ 0/1 matrix with $L_{i,j} = 1$ if and only if path P_j crosses edge e_i . The resulting solution $w \in \mathbb{Y}^k$ is the weight assignment to each path. For a flow graph (G, X) , we denote by $L_{\mathbb{Y}} = L_{\mathbb{Y}}(P_1, \dots, P_k) = \{w \in \mathbb{Y}^k | X = \sum_{j=1}^k P_j w_j\}$ the linear system corresponding to the paths P_1, \dots, P_k .

■ **Figure 4** Paths A_i and B_i ($i \in \{0, 1, 2, 3\}$), each edge being labeled with the paths it appears in. Assign to each path A_i weight a_i , and to each path B_i weight b_i , such that $a_0 = b_0 = 3$, and $a_i = 6^{2i} + 1$ and $b_i = 6^{2i+1} + 5$ for $i = 1, 2, 3$. Define the flow X on G as $X = \sum_{i=0}^3 a_i A_i + \sum_{i=0}^3 b_i B_i$. Note that these weights are a solution of k -FWA $_{\mathbb{N}}$ on input (G, X) with given paths A_i, B_i ($i \in \{0, 1, 2, 3\}$).

We shortly discuss how to solve k -FWA $_{\mathbb{Z}}$. It is possible to find an integer-weighted solution or decide that it does not exist in polynomial time. The reason for this is that, having no non-negativity constraint, the linear system defined by the paths is a system of linear Diophantine equations. It is well known that integer solutions to such systems can be found in polynomial time; see, e.g., [19, Chapter 5].

On the other hand, solving k -FWA $_{\mathbb{N}}$ turns out to be more difficult. Here, the linear system contains the inequality $w \geq 0$. In fact, it was shown [14] that k -FWA $_{\mathbb{N}}$ is NP-hard. The program Toboggan [14] implements a linear FPT algorithm for MFD $_{\mathbb{N}}$. One step of the algorithm is to solve k -FWA $_{\mathbb{N}}$ using an ILP [14]. The authors state the following conjecture.

► **Conjecture 22** ([14]). *If (P_1, \dots, P_k) are the paths of a minimum flow decomposition of (G, X) , then the linear system $L_{\mathbb{N}}(P_1, \dots, P_k)$ has full rank k .*

As mentioned in the introduction, if the conjecture turned out to be true, then Toboggan could avoid resorting to solving an ILP, since just solving the standard linear system at hand would return its unique solution. As observed by the authors, this would decrease the asymptotic worst case upper bound of Toboggan.

We show that this conjecture is false using a counterexample. Consider the input for k -FWA $_{\mathbb{N}}$ from Figure 4 and the solution therein. We now give another solution for k -FWA $_{\mathbb{N}}$ on this input, namely the following path weights: $a_0 = 5, b_0 = 1$, and $a_i = 6^{2i} + 2, b_i = 6^{2i+1} + 4$, for $i = 1, 2, 3$. One can easily verify that this is another solution to k -FWA $_{\mathbb{N}}$ on the input in Figure 4, thus proving that the rank of the corresponding linear system is strictly less than 8.

To disprove Conjecture 22, it remains to show that any flow decomposition contains at least 8 paths. Due to the technicality of this proof (and its exhaustive case-by-case analysis), in this paper we only explain the intuition behind the construction in Figure 4 and behind the correctness proof. However, as an additional check we also ran both Toboggan [14] and a recently developed ILP solver for MFD $_{\mathbb{N}}$ [7] on this instance, both returning $\text{mfd}_{\mathbb{N}}(G, X) = 8$.

The intuition is as follows. The graph can be divided into two parts: the graph induced by the first 5 vertices in topological order (left part) and the one induced by the last 5 (right part). The exponential growth of the paths A_i and B_i for growing i , together with the different permutations of the paired labels $A_i B_j$ on the left part, fix the choice of the paths A_i and B_i for $i = 1, 2, 3$. This allows us to interpret flow decompositions of less than 8 paths as decompositions with 8 paths, where either A_0 or B_0 carries weight 0. Consider a flow decomposition where we assign two paths of weights λ_1 and λ_2 on the edges labeled $A_0 B_0$. For any $\delta \geq 0$, $(\lambda_1 - \delta) + (\lambda_2 + \delta) = a_0 + b_0$ and equivalently for all other edges on the left part. If we decrease λ_1 by some $\delta > 0$, the weights of B_1 and B_2 each increase by $\delta/2$. And thus, δ must be even. Due to the parity of a_0 and b_0 , they can never reach 0.

6 Conclusions

In this paper we have shown for the first time that width, a natural lower bound for MFD, is also useful when investigating its approximability. On the one hand, using width is a key insight in understanding where greedy path removal heuristics fail. On the other hand, graphs where width is well-behaved (e.g., series-parallel graphs) have a guaranteed approximation factor. Moreover, when combined with parity arguments, i.e., about parity fixing unitary flows, and a width-sized decomposition of such flows, it guarantees an even better approximation factor for $\text{MFD}_{\mathbb{Z}}$ for all DAGs. Finally, we have corroborated the complexity gap between the positive integer and the full integer case by disproving a conjecture from [14] (also motivating the heuristic in [20]), which would have had sped up their FPT algorithm for $\text{MFD}_{\mathbb{N}}$.

Our results open up new avenues for further research on MFD. For example, can the width help find larger classes of graphs for which some greedy path removal (or even some sort of greedy *path cover* removal) algorithms have a guaranteed approximation factor? Can we get $\Omega(n)$ worst case approximation ratio of greedy-weight for dense graphs without parallel edges? Can the power-of-two decomposition approach be applied with other factors besides two? Can better path cover-like lower bounds help (e.g., path covers which cannot use an edge more times than its flow value, also computable in polynomial time)? How do our algorithms perform in practice?

Counting Simplices in Hypergraph Streams

Amit Chakrabarti

Abstract

We consider the problem of space-efficiently estimating the number of *simplices* in a hypergraph stream. This is the most natural hypergraph generalization of the highly-studied problem of estimating the number of *triangles* in a graph stream. Our input is a k -uniform hypergraph H with n vertices and m hyperedges, each hyperedge being a k -sized subset of vertices. A k -simplex in H is a subhypergraph on $k + 1$ vertices X such that all $k + 1$ possible hyperedges among X exist in H . The goal is to process the hyperedges of H , which arrive in an arbitrary order as a data stream, and compute a good estimate of $T_k(H)$, the number of k -simplices in H .

We design a suite of algorithms for this problem. As with triangle-counting in graphs (which is the special case $k = 2$), sublinear space is achievable but only under a promise of the form $T_k(H) \geq T$. Under such a promise, our algorithms use at most four passes and together imply a space bound of

$$O\left(\varepsilon^{-2} \log \delta^{-1} \text{polylog } n \cdot \min\left\{\frac{m^{1+1/k}}{T}, \frac{m}{T^{2/(k+1)}}\right\}\right)$$

for each fixed $k \geq 3$, in order to guarantee an estimate within $(1 \pm \varepsilon)T_k(H)$ with probability $\geq 1 - \delta$. We also give a simpler 1-pass algorithm that achieves $O\left(\varepsilon^{-2} \log \delta^{-1} \log n \cdot (m/T) \left(\Delta_E + \Delta_V^{1-1/k}\right)\right)$ space, where Δ_E (respectively, Δ_V) denotes the maximum number of k -simplices that share a hyperedge (respectively, a vertex), which generalizes a previous result for the $k = 2$ case. We complement these algorithmic results with space lower bounds of the form $\Omega(\varepsilon^{-2})$, $\Omega(m^{1+1/k}/T)$, $\Omega(m/T^{1-1/k})$ and $\Omega(m\Delta_V^{1/k}/T)$ for multi-pass algorithms and $\Omega(m\Delta_E/T)$ for 1-pass algorithms, which show that some of the dependencies on parameters in our upper bounds are nearly tight. Our techniques extend and generalize several different ideas previously developed for triangle counting in graphs, using appropriate innovations to handle the more complicated combinatorics of hypergraphs.

1 Introduction

Estimating the number of triangles in a massive input graph is a fundamental algorithmic problem that has attracted over two decades of intense research [1, 3, 22, 8, 40, 41, 28, 35, 6, 36, 21, 7, 32, 5, 13, 25, 20]. It is easy to see why. On the one hand, the problem arises in applications where a complex real-world network is naturally modeled as a graph and the number of triangles is a crucial statistic of the network. Such applications are found in many different domains, such as social networks [11, 29, 33], the web graph [4, 44], and biological networks [38]; see [41] for a more detailed discussion of such applications. On the other hand, a triangle is perhaps *the* most basic nontrivial pattern in a graph and as such, triangle counting is a problem with a rich theory and connections to many areas within computer science [1, 15, 18, 34, 14] and combinatorics [31, 17, 27, 37].

In this work, we study the natural generalization of this problem to massive *hypergraphs*. Just as graphs model pairwise interactions between entities in a network, hypergraphs model higher arity interactions. For instance, in an academic collaboration network with researchers being the vertices, it would be natural to model coauthorships on research papers and articles using *hyperedges*, each of which can be incident to more than two vertices. Just as we may use triangle counts to study clustering behaviors in graphs or even in different portions of a single graph, we may analyze higher-order clustering behaviors in the 3-uniform hypergraph H formed by all three-way coauthorships by counting 3-*simplices* in H . A 3-simplex on four vertices $\{u, v, w, x\}$ is the structure formed by the hyperedges $\{uvw, uvx, uwx, vwx\}$: it is the natural 3-dimensional analog of a triangle in an ordinary graph.

1.1 Our Results

We design several algorithms for space-efficiently estimating the number of k -simplices in a k -uniform hypergraph H given as a stream of hyperedges. A k -*simplex* is a complete k -uniform hypergraph on $k + 1$ vertices. The special case $k = 2$ is the triangle counting problem which, as noted, is intensely investigated. Indeed, even in this setting of streaming algorithms, triangle counting is highly studied, with new algorithmic techniques being developed as recently as 2021 [20]. There is also a body of work on generalizing these results to the problem of estimating the number of occurrences of patterns (a.k.a. *motifs*) more complicated than triangles, e.g., fixed-size cliques and cycles [30, 26, 36, 5, 24, 42]. Our work adds to this literature by generalizing in a different direction: we generalize the class of *inputs* from graphs to hypergraphs and focus on counting the simplest nontrivial symmetric motifs: k -simplices.

Our algorithms provide optimal space bounds (up to log factors) in certain parameter regimes; we prove this optimality by giving a set of matching lower bounds. In certain other parameter regimes, there remains a gap between our best upper bounds and lower bounds, which immediately provides a goal for future work on this problem. Below are informal statements of our major algorithmic results.

► **Theorem 1** (Upper bounds; informal). *Let H be an n -vertex k -uniform hypergraph, presented as a stream of m hyperedges, that is promised to contain T or more k -simplices. Suppose that each hyperedge is contained in at most Δ_E such simplices and each vertex is contained in at most Δ_V of them. Then, there are algorithms for $(1 \pm \varepsilon)$ -estimating $T_k(H)$, the number of k -simplices in H , with the following guarantees:*

(1.1) *a 4-pass algorithm using $\tilde{O}(m^{1+1/k}/T)$ space;*

(1.2) *a 2-pass algorithm using $\tilde{O}(m/T^{2/(k+1)})$ space, provided $k \geq 3$; and*

(1.3) *a 1-pass algorithm using $\tilde{O}(m(\Delta_E + \Delta_V^{1-1/k})/T)$ space.*

*Each of these algorithms is randomized and fails with probability at most δ .*¹

Formal versions of these results appear as Theorem 14 in Section 3, Theorem 16 in Section 4.2, and in the full paper [9], respectively. Along the way, we also obtain some other algorithmic results that, despite being dominated by the algorithms behind Theorem 1, are technically interesting and possibly useful in future work. These are briefly described at the start of Sections 3 and 4 with full details appearing in the full paper [9]. As we shall see, we take several ideas from triangle-counting algorithms as inspiration, but the “correct” way to extend these ideas to hypergraphs is far from obvious. Indeed, some of the more “obvious” extensions lead to the less-than-best algorithms hinted at above.

¹ Throughout this paper, the notation $\tilde{O}(\cdot)$ hides factors of $O(\varepsilon^{-2} \log \delta^{-1} \text{polylog } n)$ and, in the context of k -uniform hypergraphs, treats k as a constant. Also, “log” with an unspecified base means \log_2 .

Next, we informally state our lower bound results. These are not the main technical contributions of this paper, but they play the important role of clarifying where our algorithms are optimal and where there might be room for improvement. As in Theorem 1, we denote the number of k -simplices in H by $T_k(H)$.

► **Theorem 2** (Lower bounds; informal). *Let $k, n, m, H, \Delta_E, \Delta_V$ be as above. Suppose an algorithm makes p passes over a stream of hyperedges of H , using at most S bits of working memory, and distinguishes between the cases $T_k(H) = 0$ and $T_k(H) \geq T$ with probability at least $2/3$. Then the following lower bounds apply.*

(2.1) *With $T = 1$ and $p = O(1)$, sublinear space is impossible: we must have $S = \Omega(n^k)$.*

(2.2) *With $p = 1$, we must have $S = \Omega(m\Delta_E/T)$.*

(2.3) *With $p = O(1)$, we need $S = \Omega(\min\{m^{1+1/k}/T, m/T^{1-1/k}\})$, and $S = \Omega(m\Delta_V^{1/k}/T)$.*

[(2.1)] *If, instead, the streaming algorithm distinguishes between the cases $T_k(H) < (1 - \varepsilon)T$ and $T_k(H) > (1 + \varepsilon)T$, then the following lower bound applies.*

(2.4) *With $p = O(1)$, we must have $S = \Omega(\varepsilon^{-2})$.*

The full version of the paper [9] further discusses and proves these lower bounds.

1.2 Closely Related Previous Work

To the best of our knowledge, this is the first work to study the simplex counting problem in hypergraphs in the setting just described (the work of [23] on counting general hypergraph patterns is not closely related; see Section 1.3). We now summarize some highlights of previous work on the triangle counting problem (in graphs), with a focus on streaming algorithms, so as to provide context for our contributions.

Suppose an n -vertex m -edge graph G is given as a stream of edges and we wish to estimate the number of triangles, $T_3(G)$. It is not hard to show that, absent any promises on the structure of G , this problem requires $\Omega(n^2)$ space, even with multiple passes, thus precluding a sublinear-space solution. Therefore, all work in this area seeks bounds under a promise that $T_3(G) \geq T$, for some nontrivial threshold T . Intuitively, the larger this threshold, the easier the problem, so we expect the space complexity to decrease. The earliest nontrivial streaming solution [3] reduced triangle counting to a combination of ℓ_0 , ℓ_1 , and ℓ_2 estimation and achieved $\tilde{O}((mn/T)^2)$ space by using suitable linear sketches. Almost all algorithms developed since then have instead used some sort of *sampling* to extract a small portion of G , perform some computation on this sample, and then extrapolate to estimate $T_3(G)$.

Over the years, a number of different sampling strategies have been developed, achieving different, sometimes incomparable, guarantees. Here is a whirlwind tour through this landscape of strategies. One could sample an edge uniformly at random (using reservoir sampling), then count common neighbors of its endpoints [22]; or sample an edge uniformly and sample a vertex not incident to it [8]; or sample a subset of edges by independently picking each with a carefully adjusted probability p [28, 6]; or choose a random color for each vertex and collect all monochromatic edges [35]; or sample a subset of vertices at random and collect all edges incident to the sample [6]. One could collect two random subsets of vertices at different sampling rates and further sample edges between the two subsets [25]; or, as in a very recent algorithm, sample a subset of vertices at rate p and further sample edges incident to this sample at rate q , for well-chosen p and q [20]. Notice that in the just-mentioned algorithms, the sampling technique is not actively trying to “grow” a triangle around a sampled edge. Instead, elements of the graph (vertices or edges) are sampled indiscriminately (typically in one streaming pass) and the triangles seen inside the sample are counted in another pass. We shall call such sampling strategies *oblivious*.

Besides the above oblivious sampling strategies, another set of works used what we shall call *targeted sampling* strategies,² where information previously stored about the stream guides what gets sampled subsequently. Here is another quick tour through these. One could sample *wedges* (defined as length-2 paths) in the input graph, using a more sophisticated reservoir sampling approach [21]; or sample an edge uniformly and then sample a second edge that touches the first [36]; or sample a vertex with probability proportional to its squared degree, then sample two neighbors of that vertex [32]; or sample an edge uniformly and then sample a neighbor of the lower-degree endpoint of that edge [5].

There are also a handful of algorithms that add further twists on top of the sample-count-extrapolate framework. The algorithm of [7] combines the vertex coloring idea of [35] with ℓ_2 estimation sketches to obtain a solution that can handle *dynamic* graph streams, where each stream update may either insert or delete an edge. The algorithm of [13] combines multiple runs of [35] with a *heavy/light edge partitioning* technique: an edge is deemed “heavy” if it participates in “too many” triangles. A key observation is that the variance of an estimator constructed by oblivious sampling – which needs to be small in order to guarantee good results in small space – can be bounded better if no heavy edges are involved. On the other hand, triangles involving a heavy edge are easier to pick up (because there are many of them!) by randomly sampling vertices at a low rate. Thus, by carefully picking the threshold for heaviness, one can combine an algorithm that counts all-light triangles efficiently with one that counts heavy-edged triangles efficiently for a good overall space bound. In this way, [13] obtains a space bound of $O(\varepsilon^{-2.5} \log \delta^{-1} \text{polylog } n \cdot m/\sqrt{T})$, while [32] provides a tight dependence on ε (i.e., ε^{-2}) by achieving $\tilde{O}(m/\sqrt{T})$ space.

Separately, the aforementioned targeted sampling strategies of [32] and [5] provide 4-pass algorithms for estimating $T_3(G)$ using space $\tilde{O}(m^{3/2}/T)$. When T is large enough – specifically, $T = \Omega(m)$ – this space bound is better than the $\tilde{O}(m/\sqrt{T})$ bound obtained via heavy/light edge partitioning. By picking the better of the two algorithms, one obtains a space bound of $\tilde{O}(\min\{m^{3/2}/T, m/\sqrt{T}\})$. Both portions of this bound are tight, thanks to lower bounds of $\Omega(m^{3/2}/T)$ and $\Omega(m/\sqrt{T})$ that follow by reducing from the SET-DISJOINTNESS communication problem [13, 5].

The algorithm of [20] is optimal in a different sense: it runs in a single pass and $\tilde{O}((m/T)(\Delta_E + \sqrt{\Delta_V}))$ space, where Δ_E and Δ_V are as defined in Theorem 1. Each term in this bound is tight; reductions from DISJOINTNESS [5] and the BOOLEAN-HIDDEN-MATCHING problem [25] imply $\Omega(m\sqrt{\Delta_V}/T)$ lower bounds and a reduction from the INDEX communication problem implies an $\Omega(m\Delta_E/T)$ bound for 1-pass algorithms [6]. Note, however, that this result is incomparable to the multi-pass upper bounds noted above. It must be so: a lower bound of $\Omega(m^3/T^2)$ holds for 1-pass algorithms [5].

1.3 Other Related Work

This work is focused on streams that simply *list* the input hypergraph’s hyperedges. This is sometimes called the *insert-only* streaming model, in contrast to the *dynamic* or *turnstile* streaming model where the stream describes a sequence of (hyper)edge insertions or deletions. A small subset of works mentioned in Section 1.2 do provide results in a turnstile model. Besides these, there is the recent seminal work [23] that fully settles the complexity of triangle counting in turnstile streams for *constant-degree* graphs. This work also considers the very

² To be perfectly honest, the terms “targeted sampling” and “oblivious sampling” do not have precise technical definitions, but we hope the conceptual distinction is helpful to the reader as it was to us.

general problem of counting copies of an arbitrary fixed-size hypergraph motif M inside a large input hypergraph H , again in a turnstile setting. Because of the way their upper bound results depend on the structure of M , they cannot obtain sublinear-space solutions for counting k -simplices without a strong constant-degree assumption on the input H .

A handful of works on triangle counting consider adjacency list streams [8, 28, 32], where the input stream provides all edges incident to each vertex contiguously. This setting can somewhat simplify algorithm design, though the basic framework is still sample-count-extrapolate. We do not consider adjacency list streams in this work.

There are important related algorithms that predate the now-vast literature on streaming algorithms. In particular, [1] gives the current best run-time for exact triangle counting in the RAM model and [10] gives time-efficient algorithms for listing all triangles (and more general motifs). A version of the heavy/light partitioning idea appears in these early works.

More recently, a handful of works [15, 2, 16] have designed *sublinear-time* algorithms for approximately counting triangles and other motifs given query access to a large input graph. Triangle detection, listing, and counting have connections to other important problems in the area of fine-grained complexity [18, 43]. Triangle counting has also been studied in distributed, parallel, and high-performance computing models [40, 35, 39, 19].

2 Preliminaries

We now define our key terminology, set up notation, and establish some basic facts that we shall refer to in the algorithms and analyses to come.

► **Definition 3** (Hypergraph, degrees, neighborhoods). *A hypergraph is a pair $H = (V, E)$ where V is a nonempty finite set of vertices and $E \subseteq 2^V$ is a set of hyperedges. In certain contexts, this structure is instead called a set system over V . If $|e| = k \geq 1$ for all $e \in E$, then H is said to be k -uniform. For simplicity, we shall often shorten “ k -uniform hypergraph” to k -graph and “hyperedge” to “edge.”*

For each $S \subseteq V$ with $|S| < k$, the joint degree or codegree $\text{codeg}(S)$ of S is the number of edges that strictly extend S . The neighborhood $N(S)$ of S is the set of non- S vertices that share an edge with S . Formally,

$$\text{codeg}(S) := |\{e \in E : e \supseteq S\}|; \quad (1)$$

$$N(S) := \{v \in V : v \notin S \text{ and } \exists e \in E \text{ such that } e \supseteq S \cup \{v\}\}. \quad (2)$$

For a singleton set $S = \{u\}$, we define $\text{deg}(u) := \text{codeg}(\{u\})$ and $N(u) := N(\{u\})$. Further, given $S \subseteq V$, we define the S -relative degrees of vertices $x \in V \setminus S$ by

$$\text{deg}(x | S) := \text{codeg}(S \cup \{x\}). \quad (3)$$

Note that this is meaningful only when $|S| \leq k - 2$. Note, also, that $\text{deg}(x) = \text{deg}(x | \emptyset)$.

Throughout the paper, hypergraphs will be k -uniform unless qualified otherwise. We shall consistently use the notation $H = (V, E)$ for a generic k -graph and define $n := |V|$ and $m := |E|$. We shall assume that each vertex $v \in V$ has a unique ID, denoted $\text{ID}(v)$, which is an integer in the range $[n] := \{1, \dots, n\}$.

In general, there isn’t an equation relating $|N(S)|$ to $\text{codeg}(S)$. However, all k -graphs satisfy the following useful lemmas.

► **Lemma 4.** *For $S \subseteq V$ with $|S| < k$, $\text{codeg}(S) \leq |N(S)| \leq (k - |S|) \text{codeg}(S)$.*

Proof. Each edge that extends S adds ≥ 1 and $\leq k - |S|$ new neighbors to the sum. ◀

► **Lemma 5.** For $1 \leq r < k$, we have $\sum_{S \subseteq V: |S|=r} \text{codeg}(S) = \binom{k}{r} m = O(m)$.

Proof. The sum counts each edge exactly $\binom{k}{r}$ times. ◀

► **Definition 6 (Simplices).** A k -simplex is a k -graph on $k + 1$ vertices such that all possible k -sized edges are present. If $H = (V, E)$ is a k -graph and $X \subseteq V$ with $|X| = k + 1$, we say that H has a simplex at X if the induced subhypergraph $H[X] := (X, \{e \in E : e \subseteq X\})$ is a simplex. Abusing notation, we also use X to denote this simplex.

We use $\mathcal{T}_k(H)$ to denote the set of all k -simplices in H and $T_k(H) := |\mathcal{T}_k(H)|$ to denote the number of such simplices. We define $\Delta_E = \Delta_E(H)$ and $\Delta_V = \Delta_V(H)$ as follows:

$$\Delta_E := \max_{e \in E} |\{X \in \mathcal{T}_k(H) : X \text{ contains edge } e\}|; \quad (4)$$

$$\Delta_V := \max_{v \in V} |\{X \in \mathcal{T}_k(H) : X \text{ contains vertex } v\}|. \quad (5)$$

Drawing inspiration from the *link* operation for abstract and simplicial complexes in topology, we define a couple of operations that derive $(k - 1)$ -graphs from k -graphs.

► **Definition 7 (Neighborhood and shadow hypergraphs).** Let $k \geq 3$ and let $H = (V, E)$ be a k -graph. For each $u \in V$, the neighborhood hypergraph of H at u is the $(k - 1)$ -graph $H \downarrow u = (N(u), E_u)$, where

$$E_u := \{\{x_1, \dots, x_{k-1}\} : \{u, x_1, \dots, x_{k-1}\} \in E\} = \{e \setminus u : e \in E \text{ and } e \ni u\}.$$

The shadow hypergraph of H is the $(k - 1)$ -graph $H' = (V', E') = (\bigcup_{u \in V} V'_u, \bigcup_{u \in V} E'_u)$, where

$$V'_u := \{x^{(u)} : x \in V\} \text{ is a copy of } V \text{ “flavored” with } u, \text{ and}$$

$$E'_u := \{\{x_1^{(u)}, \dots, x_{k-1}^{(u)}\} : \{u, x_1, \dots, x_{k-1}\} \in E \text{ and } \text{ID}(u) \leq \text{ID}(x_i) \forall i \in [k - 1]\}.$$

Note that E'_u is subtly different from E_u in that it is induced by hyperedges incident on u in which u is the minimum-ID vertex. Observe that, as a result, $|E'| = |E|$.

We use neighborhood hypergraphs to analyze our first major algorithm, in Section 3. We use shadow hypergraphs in a crucial way to obtain our second major algorithm, in Section 4.2.

In the literature on triangle counting in graphs, the structure formed by two edges sharing a common vertex is called a *wedge*. It will be useful to define an analog of the notion for hypergraphs.

► **Definition 8 (Hyperwedge).** A k -hyperwedge is the hypergraph obtained by deleting one hyperedge from a k -simplex. Thus, if its vertex set is X , then $|X| = k + 1$ and it has k hyperedges with exactly one common vertex, which we call the apex of the hyperwedge. The only k -sized subset of X that is not present in the hyperwedge is called the base of the hyperwedge. Adding this base as a new hyperedge produces a k -simplex.

Fix a k -graph H and a k -simplex X in H . Observe that X contains $k + 1$ distinct hyperwedges; each such hyperwedge W corresponds to a $(k - 1)$ -simplex in the neighborhood hypergraph of H at the apex of W . On the other hand, X corresponds to exactly one $(k - 1)$ -simplex in the shadow hypergraph H' , namely the simplex at $\{u_1^{(z)}, \dots, u_k^{(z)}\}$, where z is the minimum-ID vertex in X and $\{u_1, \dots, u_k\} = X \setminus \{z\}$.

Our algorithm analyses often use the following standard boosting lemma from the theory of randomized algorithms. A random variable \tilde{Q} is said to be an (ε, δ) -estimate of a statistic Q if $\Pr[\tilde{Q} \in (1 \pm \varepsilon)Q] \geq 1 - \delta$.

► **Lemma 9** (Median-of-Means improvement). *If \hat{Q} is an unbiased estimator of some statistic, then one can obtain an (ε, δ) -estimate of that statistic by suitably combining*

$$K := \frac{C}{\varepsilon^2} \ln \frac{2}{\delta} \cdot \frac{\text{Var}[\hat{Q}]}{\mathbb{E}[\hat{Q}]^2}$$

independent samples of \hat{Q} , where C is a universal constant. ▮

3 An Optimal Algorithm Based on Targeted Sampling

In this section, we establish Subresult (1.1) of Theorem 1 by giving a formal description of the relevant algorithm (as Algorithm 1) followed by its analysis. This algorithm is based on “targeted sampling,” as outlined in Section 1.2. It runs in $\tilde{O}(m^{1+1/k}/T)$ space, which is optimal in view of Subresult (2.3) in Theorem 2. It is the method of choice for the “abundant” case, when T is large enough: specifically, in view of the guarantees of Algorithm 2 to follow (see Theorem 16), “large enough” should be defined as $T \geq m^{(k+1)/(k^2-k)}$.

The full version of the paper [9] additionally gives a more straightforward targeted-sampling algorithm, achieving a suboptimal space bound of $\tilde{O}(m^{2-1/k})$. Although suboptimal, that algorithm’s analysis contains novel ideas about the structure of hypergraphs that might be useful in subsequent research, such as the notion of “hyperabroricity.”

3.1 The Algorithm

The basic setup is as in the algorithm of [5] for counting odd cycles in graphs (and an analogous algorithm of [32]). We use one pass to pick an edge $e \in E$ uniformly at random and, in subsequent passes, use further sampling to estimate the number of suitable apex vertices z at which there is a hyperwedge with base e , which would complete a simplex together with e . In order to control the variance of the resulting unbiased estimator, we want the vertices of a detected simplex $e \cup \{z\}$ to respect a certain ordering “by degree.”

We let the sampled edge e determine the ordering, for which we use *relative* degrees, relative to certain subsets of e . Moreover, this ordering – which we call the e -relative ordering – is only partial, as we never need to compare two vertices that both lie outside e . Let $c_i(e)$ be the i th vertex of e according to this ordering that we shall soon define. In our algorithm, we shall look for a suitable apex z only in the neighborhood $N(\{c_1(e), \dots, c_{k-1}(e)\})$. Furthermore, we shall require that z have a larger degree than $c_1(e)$, a larger $\{c_1(e)\}$ -relative degree than $c_2(e)$, a larger $\{c_1(e), c_2(e)\}$ -relative degree than $c_3(e)$, and so on. As we shall see, the analysis of the resulting algorithm uses the recursive structure of k -graphs and k -simplices through the notion of neighborhood hypergraphs (Definition 7).

These next two, somewhat elaborate, definitions formalize the above ideas.

► **Definition 10** (e -relative ordering). *Fix a hyperedge $e \in E$. The e -relative ordering, \prec_e , is a partial order on V defined as follows. Set $S_0(e) = \emptyset$ and define the following, iteratively, for i running from 1 to k .*

Let $c_i(e)$ be the vertex in $e \setminus S_{i-1}(e)$ that minimizes $\deg(c_i(e) \mid S_{i-1}(e))$, with ties resolved in favor of the vertex with smallest ID. Set $S_i(e) := S_{i-1}(e) \cup \{c_i(e)\} = \{c_1(e), \dots, c_i(e)\}$.

Then declare $c_1(e) \prec_e \cdots \prec_e c_k(e)$. Further, for each $z \in V \setminus e$, declare $c_k(e) \prec_e z$ if the following two things hold: (a) for $1 \leq i \leq k-1$, we have $\deg(c_i(e) \mid S_{i-1}(e)) \leq \deg(z \mid S_{i-1}(e))$, and (b) we also have $\deg(c_k(e) \mid S_{k-2}(e)) \leq \deg(z \mid S_{k-2}(e))$. Ties in degree comparisons are resolved by declaring the vertex with smaller ID to be smaller.³

► **Definition 11** (Simplex labeling). Suppose that H has a simplex at X , where $X \subseteq V$. Number the vertices in X as u_1, \dots, u_{k+1} iteratively, as follows. For i from 1 to $k-1$, let u_i be the vertex in X that minimizes $\deg(u_i \mid \{u_1, \dots, u_{i-1}\})$. Let u_k be the vertex among $\{u_k, u_{k+1}\}$ that minimizes $\deg(u_k \mid \{u_1, \dots, u_{k-2}\})$. This automatically determines u_{k+1} . Based on this, define the label of the simplex at X to be $(e(X), z(X))$, where $e(X) := \{u_1, \dots, u_k\}$ and $z(X) := u_{k+1}$.

Notice that if a simplex is labeled (e, z) , then the e -relative ordering satisfies $\max_{\prec_e}(e) \prec_e z$. Conversely, if there is a simplex at X and an edge e of this simplex such that $X = e \cup \{z\}$ and $\max_{\prec_e}(e) \prec_e z$, then the label of this simplex is (e, z) .

For each $e \in E$, let τ_e denote the number of simplices that have a label of the form (e, \cdot) . Thanks to the uniqueness of labels, we immediately have

$$\sum_{e \in E} \tau_e = T_k(H). \quad (6)$$

Our algorithm is described in Algorithm 1. Our analysis will make use of the following two combinatorial lemmas at key moments. The proofs of these lemmas can be found in the full paper [9].

► **Lemma 12.** For every edge $e \in E$, we have $\tau_e \leq km^{1/k}$.

► **Lemma 13.** If H is k -uniform and $k \geq 3$, then $\sum_{e \in E} \text{codeg}(S_{k-1}(e)) = O(m^{1+1/k})$.

3.2 Analysis of the Algorithm

We begin by proving that the estimator Y computed by Algorithm 1 is unbiased. Let \mathcal{E}_e denote the event that the edge sampled in pass 1 is e . For each $j \in [R]$, the vertex x_j is picked uniformly at random from $N(S_{k-1}(e))$ and exactly τ_e choices cause Z_j to be set to the nonzero value $\text{codeg}(S_{k-1}(e))$. Therefore,

$$\mathbb{E}[Z_j \mid \mathcal{E}_e] = \frac{\tau_e}{|N(S_{k-1}(e))|} \cdot \text{codeg}(S_{k-1}(e)) = \tau_e \quad (7)$$

because $\text{codeg}(S_{k-1}(e)) = |N(S_{k-1}(e))|$, by Lemma 4. By the law of total expectation and Equation (6),

$$\mathbb{E}[Y] = \frac{m}{R} \sum_{j=1}^R \sum_{e \in E} \frac{1}{m} \mathbb{E}[Z_j \mid \mathcal{E}_e] = \frac{1}{R} \sum_{j=1}^R \sum_{e \in E} \tau_e = T_k(H). \quad (8)$$

Next, we bound the variance of the estimator. Proceeding along similar lines, we have $\mathbb{E}[Z_j^2 \mid \mathcal{E}_e] = \text{codeg}(S_{k-1}(e)) \cdot \tau_e$ and $\mathbb{E}[Z_{j_1} Z_{j_2} \mid \mathcal{E}_e] = \tau_e^2$ for all $j_1 \neq j_2$, because Z_{j_1} and Z_{j_2} are independent conditioned on \mathcal{E}_e . So,

³ This is how ties are resolved from now on, even when not mentioned.

■ **Algorithm 1** Counting k -simplices in k -uniform hypergraph streams: the “abundant” case.

```

1: procedure  $k$ -SIMPLEX-COUNT-ABUNDANT( $\sigma$  : stream of edges of  $k$ -graph  $H = (V, E)$ )
2:   pass 1: ▷  $O(1)$  space
3:     pick edge  $e = \{u_1, u_2, \dots, u_k\} \in E$  u.a.r. using reservoir sampling
4:   pass 2: ▷  $O(2^k) = O(1)$  space
5:     compute  $\text{codeg}(S)$  for all non-trivial  $S \subset e$ 
6:   pass 3: ▷  $O(R)$  space
7:     re-arrange (if needed)  $u_1, \dots, u_k$  so that  $u_i = c_i(e)$  for  $i \in [k]$ , using co-degrees
       from pass 2
8:      $R \leftarrow \lceil \text{codeg}(S_{k-1}(e)) \cdot m^{-1/k} \rceil$  ▷ note that  $\text{codeg}(S_{k-1}(e)) = |N(S_{k-1}(e))|$ 
9:     for  $j \leftarrow 1$  to  $R$ , in parallel, do
10:       $Z_j \leftarrow 0$ 
11:      pick vertex  $x_j \in N(S_{k-1}(e))$  u.a.r. using reservoir sampling from relevant
       substream of  $\sigma$ 
12:   pass 4: ▷  $O(kR) = O(R)$  space
13:     compute the relative degrees  $\text{deg}(x_j \mid S_{i-1}(e))$  for all  $i \in [k-1]$  and  $j \in [R]$ 
14:     for  $j \leftarrow 1$  to  $R$ , in parallel, do
15:       if  $e \cup \{x_j\}$  determines a simplex with label  $(e, x_j)$  then
16:          $Z_j \leftarrow \text{codeg}(S_{k-1}(e))$ 
17:   return  $Y \leftarrow (m/R) \sum_{j=1}^R Z_j$  ▷ Average out the trials and scale

```

$$\begin{aligned} \mathbb{E}[Y^2 \mid \mathcal{E}_e] &= \mathbb{E} \left[\left(\frac{m}{R} \sum_{j=1}^R Z_j \right)^2 \mid \mathcal{E}_e \right] = \frac{m^2}{R^2} \sum_{j=1}^R \mathbb{E}[Z_j^2 \mid \mathcal{E}_e] + \frac{m^2}{R^2} \sum_{j_1 \neq j_2} \mathbb{E}[Z_{j_1} Z_{j_2} \mid \mathcal{E}_e] \\ &\leq \frac{m^2 \cdot \text{codeg}(S_{k-1}(e)) \cdot \tau_e}{R} + \frac{m^2 R(R-1) \tau_e^2}{R^2} \leq m^{2+1/k} \tau_e + m^2 \tau_e^2, \end{aligned}$$

since $\text{codeg}(S_{k-1}(e)) \leq m^{1/k} R$ by the definition of R . Using $\sum_{e \in E} \tau_e = T_k(H)$, we get

$$\begin{aligned} \text{Var}[Y] &\leq \mathbb{E}[Y^2] = \sum_{e \in E} \frac{1}{m} \mathbb{E}[Y^2 \mid \mathcal{E}_e] \leq m^{1+1/k} \sum_{e \in E} \tau_e + m \sum_{e \in E} \tau_e^2 \\ &\leq m^{1+1/k} T_k(H) + m \cdot (\max_{e \in E} \tau_e) \cdot \sum_{e \in E} \tau_e = O\left(m^{1+1/k} T_k(H)\right), \end{aligned}$$

where we invoked Lemma 12 and used Equation (6) twice.

Having bounded the variance, we may apply the median-of-means technique (Lemma 9) to the basic estimator of Algorithm 1 to obtain a final algorithm that provides an (ε, δ) -estimate. As noted in the comments within Algorithm 1, the basic estimator uses $O(R)$ space, where R is a random variable. Therefore, the final algorithm, which still uses four passes, has expected space complexity $\tilde{O}(\mathbb{E}[R] \cdot \text{Var}[Y]/\mathbb{E}[Y]^2) = \mathbb{E}[R] \cdot \tilde{O}(m^{1+1/k}/T_k(H)) = \mathbb{E}[R] \cdot \tilde{O}(m^{1+1/k}/T)$, thanks to the promise that $T_k(H) \geq T$.

Finally, we need to bound R in expectation. We find that

$$\mathbb{E}[R] = \frac{1}{m} \sum_{e \in E} \mathbb{E}[R \mid \mathcal{E}_e] = \frac{1}{m} \sum_{e \in E} \left\lceil \frac{\text{codeg}(S_{k-1}(e))}{m^{1/k}} \right\rceil \leq 1 + m^{-1-1/k} \sum_{e \in E} \text{codeg}(S_{k-1}(e)).$$

Invoking Lemma 13, we conclude that $\mathbb{E}[R] = O(1)$, giving our first main algorithmic result.

► **Theorem 14.** *There is a 4-pass algorithm that reads a stream of m hyperedges specifying a k -uniform hypergraph H and produces an (ε, δ) -estimate of $T_k(H)$; under the promise that $T_k(H) \geq T$, the algorithm runs in expected space $O(\varepsilon^{-2} \log \delta^{-1} \log n \cdot m^{1+1/k}/T)$. ◻*

We conclude with two remarks about this algorithm. First, the space bound can easily be made worst-case, by applying the following modification to the median-of-means boosting process. Notice that in each instance of the basic estimator, at the end of pass 2, we know the value of R and thus the actual space that this instance would use. For each batch of estimators for which we compute a mean, we determine whether this batch would use more than A times its expected space bound, for some large constant A . If so, we abort this batch and don't use it in the median computation. By Markov's inequality, the probability that we abort a batch is at most $1/A$, which does not affect the rest of the standard analysis of the quality of the final median-of-means estimator.

Second, while we have not dwelt on *time* complexity in our exposition, it is not hard to convince oneself that the algorithm processes each incoming edge in $\tilde{O}(R)$ time, which is $\tilde{O}(1)$ in expectation.

4 Algorithms Based on Oblivious Sampling

We now turn to our second family of algorithms, which use “oblivious sampling,” as outlined in Section 1.2. To recap, whereas the algorithms in the previous section used an initially-sampled edge to guide their subsequent sampling, an oblivious sampling strategy decides whether or not to store an edge based only coin tosses specific to that edge and perhaps its constituent vertices (and not on any edges in store). The main result of this section is an $\tilde{O}(m/T^{2/(k+1)})$ -space algorithm, given as Algorithm 2, which is the method of choice for the “meager” case, when T is not too large (specifically, $T < m^{(k+1)/(k^2-k)}$). Simpler versions of our ideas give algorithms with worse space guarantees: namely, $\tilde{O}(m/T^{1/k})$ and $\tilde{O}(m/T^{2/(k+2)})$. The full version of the paper [9] gives the details.

The full paper additionally describes a 1-pass algorithm – also based on oblivious sampling – whose space guarantee depends on additional structural parameters of the input hypergraph H , proving Subresult (1.3) of Theorem 1.

4.1 A Unifying Framework for Oblivious Sampling Strategies

We find it useful to set up a framework for analyzing algorithms based on oblivious sampling and view our eventual algorithm as an instantiation of the framework. Further, this framework unifies a number of approaches seen in previous work on triangle counting [32, 20, 25, 6].

Suppose that we are trying to estimate the number, $T(H)$, of copies of a target substructure (motif) Ξ in a streamed hypergraph H . Suppose we do this by collecting certain edges into a random sample Q , using some random process parameterized by a quantity p . The sample Q determines which of the $T(H)$ copies of Ξ get “detected” by the rest of the logic of the algorithm. Let $\Xi_1, \dots, \Xi_{T(H)}$ be the copies of Ξ in H (under some arbitrary enumeration scheme) and let Λ_i be the indicator random variable for the event that Ξ_i is detected.

In our framework, we will want to identify parameters α, β , and γ such that the following conditions hold for all $i, j \in [T(H)]$ with $i \neq j$ and all $e \in E$:

$$\Pr[\Lambda_i = 1] = p^\alpha; \quad \Pr[\Lambda_i = \Lambda_j = 1] \leq p^\beta; \quad \Pr[e \in Q] = p^\gamma. \quad (9)$$

In instantiations of the framework, we will of course have $\beta > \alpha$ and further, we will have $\beta < 2\alpha$, which is natural because for certain pairs i, j , the variables Λ_i and Λ_j will be positively correlated. We shall further require that our detection process satisfy the *separation property*, where $\Xi \cap \Xi'$ denotes the set of *edges* common to Ξ and Ξ' and the notation “ $X \perp Y$ ” means that random variables X and Y are independent.

SEPARATION PROPERTY: If $\Xi_i \cap \Xi_j = \emptyset$, then $\Lambda_i \perp \Lambda_j$. (10)

The logic of the algorithm will count the number of detected copies of Ξ in an accumulator $A := \sum_{i=1}^{T(H)} \Lambda_i$. Defining the estimator $\tilde{T} := A/p^\alpha$, we see that $\mathbb{E}[\tilde{T}] = \sum_{i=1}^{T(H)} p^{-\alpha} \mathbb{E}[\Lambda_i] = T(H)$, which makes it unbiased. To establish concentration, we estimate

$$\begin{aligned} \text{Var}[A] &= \text{Var} \sum_{i=1}^{T(H)} \Lambda_i = \sum_{i=1}^{T(H)} \text{Var}[\Lambda_i] + \sum_{i \neq j} \text{Cov}[\Lambda_i, \Lambda_j] \leq \sum_{i=1}^{T(H)} \mathbb{E}[\Lambda_i^2] + \sum_{i \neq j} \text{Cov}[\Lambda_i, \Lambda_j] \\ &\leq T(H)p^\alpha + \sum_{\Lambda_i \not\perp \Lambda_j} \mathbb{E}[\Lambda_i \Lambda_j] \leq T(H)p^\alpha + \sum_{\Lambda_i \not\perp \Lambda_j} p^\beta = T(H)p^\alpha + p^\beta \cdot \underbrace{\sum_{e \in E} \sum_{\Xi_i \cap \Xi_j = \{e\}} 1}_{s_{\text{cor}}}, \end{aligned} \quad (11)$$

where the penultimate step uses (9) and the last step holds because of the separation property and the reasonable structural assumption (true of simplices) that two distinct copies of the motif Ξ can intersect in at most one edge.

The term s_{cor} captures the amount of correlation in the sampling process. Let us now specialize the discussion to the problem at hand, where the motif Ξ is a k -simplex and so, $T(H) = T_k(H)$. Let M_e be the number of simplices that share hyperedge e (note that this is subtly different from τ_e in Section 3). Recalling the definition of Δ_E in Equation (4), we see that $\max_{e \in E} M_e = \Delta_E$. We can therefore upper bound s_{cor} as follows:

$$s_{\text{cor}} \leq \sum_{e \in E} \binom{M_e}{2} \leq \sum_{e \in E} \frac{M_e^2}{2} \leq \frac{\Delta_E}{2} \sum_{e \in E} M_e = \frac{(k+1)\Delta_E T_k(H)}{2}. \quad (12)$$

Plugging this bound into (11) and applying Chebyshev’s inequality gives the following “error probability” bound, where $B > 0$ will be chosen later.

$$P_{\text{err}}^{(B)}[\tilde{T}] := \Pr \left[|\tilde{T} - T(H)| \geq \varepsilon B \right] \leq \frac{\text{Var}[A]}{p^{2\alpha} \varepsilon^2 B^2} \leq \frac{T_k(H)}{\varepsilon^2 p^\alpha B^2} + \frac{(k+1)\Delta_E T_k(H)}{2\varepsilon^2 p^{2\alpha-\beta} B^2}. \quad (13)$$

Heavy/Light Edge Partitioning via an Oracle. Using the above estimator \tilde{T} directly on the input hypergraph H does not give a good bound in general, because the quantity Δ_E appearing in Equation (13) could be as large as $T_k(H)$, making the upper bound on P_{err} useless. One remedy is to apply the technique so far to a subgraph of H where Δ_E is *guaranteed* to be a fractional power of $T_k(H)$ and deal separately with simplices that don’t get counted in such a subgraph. Such a subgraph can be obtained by taking only the “light” edges in H , where an edge e is considered to be light if $M_e = O(T_k(H)^\theta)$, for some parameter $\gamma < 1$ that we will soon choose. We remark that this kind of heavy/light partitioning is a standard technique in this area: it occurs in the triangle counting algorithms of [12, 32] and in fact in the much earlier triangle listing algorithm of [10].

More precisely, we create an *oracle* to label each edge as either HEAVY or LIGHT. Thus:

$$T_k(H) = T_k^L(H) + T_k^H(H), \quad (14)$$

32:12 Counting Simplices in Hypergraph Streams

where $T_k^L(H)$ is the number of simplices containing only light edges, and $T_k^H(H)$ is the number of simplices containing at least one heavy edge. The key insight in the partitioning technique is that we can estimate the two terms in Equation (14) separately, using the estimator \tilde{T} described above for $T_k^L(H)$ and a different estimator for $T_k^H(H)$ that we shall soon describe. In what follows, we allow an additive error of $\pm \varepsilon T_k(H)$ in the estimate of each term, leading to a multiplicative error of $1 \pm 2\varepsilon$ in the estimation of $T_k(H)$.

The oracle is implemented by running the following one-pass randomized streaming algorithm implementing a function $\text{orcl}: E \rightarrow \{\text{HEAVY}, \text{LIGHT}\}$ to label the edges of H . Form a random subset $Z \subseteq V$ by picking each vertex $v \in V$, independently, with probability

$$q := \xi \varepsilon^{-2} \ln n \cdot T^{-\theta}, \quad (15)$$

where T is the promised lower bound on $T_k(H)$ given to the algorithm, and $\xi \geq 12k(k+1)$ is a constant. Then, in one pass over the input stream, collect all hyperedges e containing at least one vertex from Z . Let S denote the random sample of edges thus collected. Note that this is distinct from (and independent of) the sample Q collected by the oblivious sampling scheme discussed above. Now, for each hyperedge $e = \{u_1, \dots, u_k\} \in E$, let $\widetilde{M}_e := |\{z \in Z : e \cup \{z\} \in \mathcal{T}_k(H)\}|$ be the number of simplices that e completes with respect to Z . Then we define:

$$\text{orcl}(e) = \begin{cases} \text{HEAVY}, & \text{if } \widetilde{M}_e < qT^\theta, \\ \text{LIGHT}, & \text{otherwise.} \end{cases} \quad (16)$$

The next lemma (whose proof, via Chernoff bounds, we omit) says that the oracle's predictions correspond, with high probability, to our intuitive definition of heavy/light edges, up to a factor of 2.

► **Lemma 15.** *W.h.p., the oracle given by (16) is “correct,” meaning that it satisfies*

$$\forall e \in E : \text{orcl}(e) = \text{LIGHT} \Rightarrow M_e < 2T^\theta \quad \wedge \quad \text{orcl}(e) = \text{HEAVY} \Rightarrow M_e > \frac{1}{2}T^\theta.$$

The space required to implement the oracle is that required to store the sample S . Since

$$\mathbb{E}[|S|] = O\left(\sum_{v \in V} q \deg(v)\right) = O(qm), \quad (17)$$

the expected space is $O(qm \log n) = O(\varepsilon^{-2} \log^2 n \cdot T^{-\theta} m) = \tilde{O}(m/T^\theta)$, by Equation (15).

Counting the Light and Heavy Simplices. We can now describe our overall algorithm. We use two streaming passes. In the first pass, we collect the samples S and Q . At the end of the pass, we have the information necessary to prepare the heavy/light labeling oracle and using it, we remove all heavy edges from Q . In the second pass, for each edge e encountered, we use the oracle to classify it. If e is light, we feed it into the detection logic for the oblivious sampling scheme (which uses Q). If e is heavy, we use S to estimate M_e , the number of simplices containing e ; this requires a little care, as we explain below.

In analyzing the algorithm, we start by assuming that the oracle is correct (which happens w.h.p., by Lemma 15). Let \tilde{T}^L be the estimator for $T_k^L(H)$ produced by the oblivious sampling scheme. We analyze its error probability using Equation (13), noting that $\Delta_E \leq 2T^\theta$ in the light-edges subgraph and choosing $B = T_k(H)$. This leads to

$$\begin{aligned}
P_{\text{err}}[\tilde{T}^L] &:= \Pr \left[|\tilde{T}^L - T_k^L(H)| \geq \varepsilon T_k(H) \right] \\
&\leq \frac{T_k^L(H)}{\varepsilon^2 p^\alpha T_k(H)^2} + \frac{(k+1) \cdot 2T^\theta \cdot T_k^L(H)}{2\varepsilon^2 p^{2\alpha-\beta} T_k(H)^2} \leq \frac{1}{\varepsilon^2 p^\alpha T} + \frac{k+1}{\varepsilon^2 p^{2\alpha-\beta} T^{1-\theta}}, \quad (18)
\end{aligned}$$

where we used the inequalities $T_k^L(H) \leq T_k(H)$ and $T_k(H) \geq T$. This bound on the error probability will inform our choices of parameters p, α, β , and θ , below.

Finally, we estimate $T_k^H(H)$. Define a simplex in $\mathcal{T}_k(H)$ to be *i-heavy* if it has exactly i heavy edges. For each edge e and $1 \leq i \leq k+1$, let M_e^i be the number of i -heavy simplices containing e . Notice that

$$\sum_{e \text{ heavy}} M_e^i = i \cdot |\{\Xi \in \mathcal{T}_k(H) : \Xi \text{ is } i\text{-heavy}\}|, \quad \text{whence } T_k^H(H) = \sum_{e \text{ heavy}} \sum_{i=1}^{k+1} \frac{M_e^i}{i}. \quad (19)$$

During our second streaming pass, we compute unbiased estimators for each M_e^i as follows. Recall that S is the set of all edges incident to some vertex in the set Z of sampled vertices. Define \tilde{M}_e^i to be the number of vertices in Z that combine with e to form an i -heavy simplex; we consult the oracle to test whether a simplex in question is indeed i -heavy. Notice that $\tilde{M}_e^i \sim \text{Bin}(M_e^i, q)$. Therefore, by Equation (19),

$$\tilde{T}^H := \frac{1}{q} \sum_{e \text{ heavy}} \sum_{i=1}^{k+1} \frac{\tilde{M}_e^i}{i} \quad (20)$$

is an unbiased estimator for $T_k^H(H)$. To establish concentration, consider the inner sum corresponding to any particular edge e . The sum can be rewritten as a sum of M_e mutually independent indicator variables scaled by factors in $\{1, 1/2, \dots, 1/(k+1)\}$. Since the oracle is correct, the heaviness of e implies that $M_e \geq \frac{1}{2}T^\theta$ and then a Chernoff bound gives

$$\Pr \left[\sum_{i=1}^{k+1} \frac{\tilde{M}_e^i}{i} \notin (1 \pm \varepsilon) q \sum_{i=1}^{k+1} \frac{M_e^i}{i} \right] \leq 2 \exp \left(-\frac{1}{3} \varepsilon^2 q \cdot \frac{1}{2} T^\theta \cdot \frac{1}{k+1} \right) \leq n^{-2k},$$

where the final step uses $\xi \geq 12k(k+1)$. By a union bound over the $\leq n^k$ heavy edges,

$$\begin{aligned}
P_{\text{err}}[\tilde{T}^H] &:= \Pr \left[|\tilde{T}^H - T_k^H(H)| \geq \varepsilon T_k(H) \right] \leq \Pr \left[\tilde{T}^H \notin (1 \pm \varepsilon) T_k^H(H) \right] \\
&\leq \Pr \left[\bigvee_{e \text{ heavy}} \left\{ \sum_{i=1}^{k+1} \frac{\tilde{M}_e^i}{i} \notin (1 \pm \varepsilon) q \sum_{i=1}^{k+1} \frac{M_e^i}{i} \right\} \right] \leq n^{-O(1)}. \quad (21)
\end{aligned}$$

Determining the Parameters and Establishing a Space Bound. We have now described the overall logic of a generic algorithm in our framework. To instantiate it, we must plug in a specific oblivious sampling scheme, whose logic will determine the parameters α, β , and γ as given by Equation (9). Now we choose p to ensure that $P_{\text{err}}[\tilde{T}^L]$ is less than a small constant. Thanks to Equation (18), it suffices to ensure that

$$\frac{1}{\varepsilon^2 p^\alpha T} + \frac{k+1}{\varepsilon^2 p^{2\alpha-\beta} T^{1-\theta}} = o(1).$$

32:14 Counting Simplices in Hypergraph Streams

Setting $p = (\log n / (\varepsilon^2 T))^{1/\alpha}$ reduces the first term to $1/\log n$. To make the second term small as well, we set the threshold parameter θ used by the heavy/light partitioning oracle to $\theta := \beta/\alpha - 1$; as we remarked after Equation (9), we will have $\alpha < \beta < 2\alpha$, which implies $0 < \theta < 1$. The second term now reduces to

$$\frac{(k+1)p^{\beta-\alpha}T^\theta}{\log n} = \frac{k+1}{(\log n)^{1-\theta}\varepsilon^{2\theta}} = o(1),$$

for n sufficiently large. We therefore obtain $P_{\text{err}}[\tilde{T}^L] = o(1)$ and, putting this together with Equation (21) and Lemma 15, we conclude that the overall algorithm computes a $(1 \pm 2\varepsilon)$ -approximation to $T_k(H)$ with probability at least $1 - o(1)$.

With these parameters now set, the space complexity analysis is straightforward. The space usage is dominating by the storing of the samples S and Q . By Equation (17) and Equation (15), we have $\mathbb{E}[|S|] = \tilde{O}(m/T^\theta)$ and by Equation (9), we have

$$\mathbb{E}[|Q|] = p^\gamma m = \left(\frac{\log n}{\varepsilon^2}\right)^{\gamma/\alpha} \frac{m}{T^{\gamma/\alpha}}.$$

It is natural that the probability of detecting a particular simplex is at most the probability of storing one particular edge, so $\gamma \leq \alpha$. Therefore, $\mathbb{E}[|Q|] \leq \varepsilon^{-2} \log n \cdot m/T^{\gamma/\alpha}$. Altogether, since storing a single edge uses $O(\log n)$ bits, the total space usage is $\tilde{O}(m/T^\lambda)$, where

$$\lambda = \min \left\{ \frac{\gamma}{\alpha}, \theta \right\} = \min \left\{ \frac{\gamma}{\alpha}, \frac{\beta}{\alpha} - 1 \right\}. \quad (22)$$

This completes the description of our framework for designing and analyzing simplex counting algorithms based on oblivious sampling.

4.2 Instantiation: Oblivious Sampling Using the Shadow Hypergraph

It is time to instantiate our framework with a specific sampling and simplex-detection strategy. The simplest instantiation samples edges at rate p and detects light simplices composed of sampled edges, leading to a $\tilde{O}(m/T^{1/k})$ space bound. We get a better bound of $\tilde{O}(m/T^{2/(k+2)})$ algorithm by adapting the vertex-coloring-based graph algorithm of [35]: a key insight is that we color $(k-1)$ -sized *subsets* of V and then pick fully monochromatic edges in the sample. Coloring single vertices would have run into the technical problem that the separation property would not hold. Our full paper [9] describes these ideas in detail.

Our best algorithm combines ideas from these initial approaches, eventually achieving a space complexity of $\tilde{O}(m/T^{2/(k+1)})$, which is our best bound of the form $\tilde{O}(m/T^\lambda)$. It is therefore our method of choice for the “meager” case. Comparing with Theorem 14, we see that this bound wins when $T < m^{(k+1)/(k^2-k)}$. We continue to use the coloring idea with two added twists: we color appropriately-sized *subsets* of vertices, and we do so with vertices of the *shadow hypergraph* $H' = (V', E')$, defined in Definition 7.

To be more specific, we uniformly and independently color $(k-2)$ -sized subsets of vertices V' of H' using N colors. Since each vertex in V' is essentially an ordered pair of vertices in V , we need a coloring function that maps $\binom{V \times V}{k-2}$ to $[N]$. Recall that $H' = (V', E')$ is a $(k-1)$ -uniform hypergraph. During the first pass, when an edge $e = \{u_1, \dots, u_k\}$ arrives in the stream, it implies the arrival of an edge $e' = E'$ which we store in Q iff all $(k-2)$ -sized subsets within e' receive the same color. We call such an edge e' *monochromatic*.

We detect simplices using this sample Q as follows. As observed after Definition 8, each k -simplex in H corresponds to exactly one $(k-1)$ -simplex in H' ; we try to detect this “shadow simplex.” In greater detail, let Ξ be a particular simplex in H . Let z be its minimum-ID vertex, let e_z be the edge of Ξ not incident to z and let W_z be the hyperwedge

of Ξ with apex z . Note that the edges of W_z correspond to edges in H' that lie in E'_z (see Definition 7) and, since W_z is a hyperwedge, these edges form a $(k-1)$ -simplex in the z -flavored component of H' . In the second pass, when e_z arrives in the stream, we detect Ξ iff this entire $(k-1)$ -simplex has been stored in Q , i.e., iff all its edges are monochromatic. Algorithmically, when we see an edge e in the second pass, we go over all vertices $z \in V$, detecting a simplex whenever this e plays the role of e_z for a simplex on the vertices in $e \cup \{z\}$ in the manner just described.

The remaining details are as described in Section 4.1: we apply the heavy/light edge partitioning technique on top of the above sampling scheme and proceed as in our framework. We formalize the overall algorithm, with full details, as Algorithm 2. Note that the coloring function need not be fully random and can be chosen from a d -wise independent hash family for an appropriate constant d . The update logic for the accumulator A_L (Section 4.2) implements the detection method just described. The update logic for the accumulator A_H (Section 4.2) implements the estimator in Equation (20). Note that the heavy-simplex estimator does not use the shadow hypergraph.

■ **Algorithm 2** Simplex counting in the “meager” case using $\tilde{O}(m/T^{2/(k+1)})$ bits of space.

```

1: procedure  $k$ -SIMPLEX-COUNT-MEAGER( $\sigma$  : stream of edges of  $k$ -graph  $H = (V, E)$ )
2:    $d \leftarrow 2\binom{k}{k-2}$ ;  $r \leftarrow \binom{n^2}{k-2}$ ;  $\alpha \leftarrow \binom{k}{k-2} - 1$ ;  $p \leftarrow (\varepsilon^{-2}T^{-1} \log n)^{1/\alpha}$ ;  $N \leftarrow \lceil 1/p \rceil$ 
3:    $\theta \leftarrow (2\binom{k}{2} - k) / (\binom{k}{2} - 1)$ ;  $q \leftarrow \xi \varepsilon^{-2} \log n \cdot T^{-\theta}$ 
4:    $\triangleright \xi$  is a suitable constant; see Equation (15)
5:    $Z \leftarrow$  sample of  $V$ , picking each vertex independently with probability  $q$ 
6:    $\mathcal{F} \subseteq [N]^{[r]} \leftarrow$   $d$ -wise independent family of hash functions of the form  $h: [r] \rightarrow [N]$ 
7:   select a function  $\text{col}(\cdot)$  uniformly at random from  $\mathcal{F}$  to color the elements of  $\binom{V'}{k-2}$ 
8:   pass 1:
9:      $(Q, S) \leftarrow (\emptyset, \emptyset)$ 
10:    for each hyperedge  $e = \{u_1, \dots, u_k\}$  in the stream do
11:      let  $i \in [k]$  be such that  $u_i$  is the vertex in  $e$  with the smallest ID
12:      if all  $(k-2)$ -sized subsets of  $e \setminus \{u_i\} \in E_{u_i}$  are colored the same then
13:         $Q \leftarrow Q \cup \left\{ \{u_1^{(u_i)}, \dots, u_{i-1}^{(u_i)}, u_{i+1}^{(u_i)}, \dots, u_k^{(u_i)}\} \right\}$ 
14:      if  $e \cap Z \neq \emptyset$  then
15:         $S \leftarrow S \cup \{e\}$ 
16:    create heavy/light oracle based on  $S$ 
17:   pass 2:
18:      $(A_L, A_H) \leftarrow (0, 0)$ 
19:     let  $Q^L$  be the set of hyperedges in  $Q$  corresponding to light hyperedges in  $E$ 
20:     for each hyperedge  $e = \{u_1, \dots, u_k\}$  in the stream do
21:       if  $\text{orcl}(e) = \text{LIGHT}$  then
22:          $A_L \leftarrow A_L + \left| \left\{ z \in V : \bigwedge_{i=1}^k \left\{ \{u_1^{(z)}, \dots, u_{i-1}^{(z)}, u_{(i+1)}^{(z)}, \dots, u_k^{(z)}\} \subseteq Q^L \right\} \right\} \right|$ 
23:       else
24:         Let  $\hat{M}_e^i := |\{z \in Z : e \cup \{z\} \text{ a simplex with } i \text{ heavy edges}\}|$ 
25:          $A_H \leftarrow A_H + \sum_{i=1}^{k+1} \hat{M}_e^i / i$ 
26:   return  $A_L/p^\alpha + A_H/q$ 

```

Analysis. We proceed in the now-established manner within our framework: we need to work out the parameters α , β , and γ .

Consider a particular k -simplex Ξ in H and let the $(k-1)$ -simplex Ξ' be its “shadow simplex” in H' , as in the above discussion. Then, if Ξ is light, it is detected at most once, when the hyperedge opposite to its lowest-ID vertex arrives in the stream. For this detection to actually happen, all edges of Ξ' must be monochromatic, i.e., all $\binom{k}{k-2}$ possible $(k-2)$ -sized subsets of vertices in Ξ' must receive the same color. Let $p = 1/N$. The probability of this event is p^α , where $\alpha = \binom{k}{k-2} - 1 = \binom{k}{2} - 1$.

Next, we observe that for two distinct simplices Ξ_1 and Ξ_2 in H , the events of their detection have nonzero correlation iff they have an edge in common. Thus, the separation property (10) holds. Moreover, when $\Xi_1 \cap \Xi_2 = \{e\}$, the correlation is in fact nonzero only if both Ξ_1 and Ξ_2 have the same minimum-ID vertex and that vertex lies in e . When this happens, the simultaneous detection event occurs iff all $(k-2)$ -sized subsets of shadow vertices arising from vertices of Ξ_1 and Ξ_2 receive the same color. Counting the number of such subsets shows that the probability of simultaneous detection is p^β , for

$$\beta = 2 \binom{k}{k-2} - (k-1) - 1 = 2 \binom{k}{2} - k$$

Finally, an edge in E' is made monochromatic (and thus, stored in Q) with probability p^{k-2} because $k-1$ different subsets must all be colored identically. This gives $\gamma = k-2$, so

$$\lambda = \min \left\{ \frac{2 \binom{k}{2} - k}{\binom{k}{2} - 1} - 1, \frac{k-2}{\binom{k}{2} - 1} \right\} = \frac{k-2}{\binom{k}{2} - 1} = \frac{2}{k+1}$$

for $k \geq 3$. Thus, our algorithm runs in $\tilde{O}(m/T^\lambda) = \tilde{O}(m/T^{2/(k+1)})$ bits of memory in the worst case. We have therefore proved the following result.

► **Theorem 16.** *There is a 2-pass algorithm that reads a stream of m hyperedges specifying a k -uniform hypergraph H and produces an $(\varepsilon, o(1))$ -estimate of $T_k(H)$; under the promise that $T_k(H) \geq T$, the algorithm runs in expected space $O(\varepsilon^{-2} \log^2 n \cdot m/T^{2/(k+1)})$. ◻*

5 Concluding Remarks

We initiated a systematic study of the simplex counting problem in a streamed hypergraph, a natural generalization of the much-studied triangle counting problem. We obtained several sublinear-space algorithms: which of them is best depends on some combinatorial parameters of the problem instance. Overall, we learned that established methods for triangle and substructure counting in graph streams are not by themselves enough and considerable effort is required to deal with the more intricate structures occurring in hypergraphs.

In some parameter regimes (what we called the “abundant” case), we obtained provably space-optimal algorithms. However, in the “meager” case, seeking algorithms with space complexity of the form m/T^λ , we established an upper bound with $\lambda = 2/(k+1)$ and a lower bound with $\lambda = 1 - 1/k$. Closing this gap seems to us to be the most compelling follow-up research question.

The simplex counting problem has the potential to impact research on pattern detection and enumeration. As triangle counting has done in the past two decades, simplex counting may offer new insights on how sampling techniques can exploit the structure of graphs and hypergraphs to extract meaningful information.

Abstract

In this paper, we consider center-based clustering problems where C , the set of points to be clustered, lies in a metric space (X, d) , and the set X of candidate centers is potentially infinite-sized. We call such problems *continuous* clustering problems to differentiate them from the *discrete* clustering problems where the set of candidate centers is explicitly given. It is known that for many objectives, when one restricts the set of centers to C itself and applies an α_{dis} -approximation algorithm for the discrete version, one obtains a $\beta \cdot \alpha_{\text{dis}}$ -approximation algorithm for the continuous version via the triangle inequality property of the distance function. Here β depends on the objective, and for many objectives such as k -median, $\beta = 2$, while for some others such as k -means, $\beta = 4$. The motivating question in this paper is *whether this gap of factor β between continuous and discrete problems is inherent, or can one design better algorithms for continuous clustering than simply reducing to the discrete case as mentioned above?* In a recent SODA 2021 paper, Cohen-Addad, Karthik, and Lee prove a factor-2 and a factor-4 hardness, respectively, for the continuous versions of the k -median and k -means problems, even when the number of cluster centers is a constant. The discrete problem for a constant number of centers is easily solvable exactly using enumeration, and therefore, in certain regimes, the “ β -factor loss” seems unavoidable.

In this paper, we describe a technique based on the *round-or-cut* framework to approach continuous clustering problems. We show that, for the continuous versions of some clustering problems, we can design approximation algorithms attaining a better factor than the β -factor blow-up mentioned above. In particular, we do so for: the uncapacitated facility location problem with uniform facility opening costs (λ -UFL); the k -means problem; the individually fair k -median problem; and the k -center with outliers problem. Notably, for λ -UFL, where $\beta = 2$ and the discrete version is NP-hard to approximate within a factor of 1.27, we describe a 2.32-approximation for the continuous version, and indeed $2.32 < 2 \times 1.27$. Also, for k -means, where $\beta = 4$ and the best known approximation factor for the discrete version is 9, we obtain a 32-approximation for the continuous version, which is better than $4 \times 9 = 36$.

The main challenge one faces is that most algorithms for the discrete clustering problems, including the state of the art solutions, depend on Linear Program (LP) relaxations that become infinite-sized in the continuous version. To overcome this, we design new linear program relaxations for the continuous clustering problems which, although having exponentially many constraints, are amenable to the round-or-cut framework.

1 Introduction

Clustering is a ubiquitous problem arising in various areas ranging from data analysis to operations research. One popular class of clustering problems are the so-called *center-based clustering* problems where the quality of the clustering is determined by a function of the distances of every point in C to the “centers” of the clusters they reside in. Two extensively studied measures are the sum of these distances, with the resulting problem called the k -median problem, and the sum of squares of these distances, with the resulting problem called the k -means problem.

In most settings, these center-based clustering problems are NP-hard and one considers approximation algorithms for the same. Traditionally, however, approximation algorithms for these problems have been studied in *finite/discrete* metric spaces and, in fact, usually under the constraint that the set of centers, aka facilities, can be selected only from a prescribed subset $F \subseteq X$ of the metric space. Indeed, this model makes perfect sense when considering applications in operations research where the possible depot-locations may be constrained. These discrete problems have been extensively studied [33, 45, 16, 30, 17, 15, 35, 34, 5, 37, 39, 40, 8] over the last three decades. For instance, for the k -median problem, the best known approximation algorithm is a 2.675-approximation [9], while the best known hardness is $(1 + 2/e) \approx 1.74$ [34]. For the k -means problem, the best known approximation algorithm is a $(9 + \varepsilon)$ -approximation algorithm [1, 31, 37], while the best hardness is $1 + 8/e \approx 3.94$ [34].

Restricting to a finite metric space, however, makes the problem easier, and indeed many of the above algorithms in the papers mentioned above would be infeasible to implement if X were extremely large – for instance, if X were \mathbb{R}^m for some large dimension m , and the distance function were the ℓ_p -metric, for some p . On the other hand, it is reasonably easy to show using triangle inequality that if one considers opening centers from C itself, and thus reduces the problem to its discrete version, then one incurs a hit of a factor β in the approximation factor, where β is a constant depending on the objective function. In particular, if we look at the sum-of-distances objectives such as in k -median, then $\beta = 2$, while if one looks at the sum-of-squared-distances such as in k -means, then $\beta = 4$. Therefore, one immediately gets a 5.35-approximation for the *continuous k -median* problem and a $36 + \varepsilon$ -approximation for the *continuous k -means* problem. The question we investigate is

Is this factor β hit necessary between the continuous and discrete versions of center based clustering problems, or can one design better approximation algorithms for the continuous case?

It is crucial to note that when considering designing algorithms, we do not wish to make *any* assumptions on the underlying metric space (X, d) . For instance, we do not wish to assume $X = \mathbb{R}^m$ for some m . This is important, for we really want to compare ourselves with the β which is obtained using only the triangle-inequality and symmetry property of d . On the other hand, to exhibit that a certain algorithm does not work, any candidate metric space suffices.

Recently, in a thought-provoking paper [21], Cohen-Addad, Karthik, and Lee show that, unless $\text{P} = \text{NP}$, the k -median and k -means problem defined on $(\mathbb{R}^m, \ell_\infty)$ cannot have an approximation ratio better than 2 and 4, respectively, *even when k is a constant!* Since the discrete problems have trivial exact algorithms via enumeration when k is a constant, this seems to indicate that in certain cases the above factor β hit is unavoidable. Is it possible that the *inapproximability* of the continuous problem is indeed β times the inapproximability of the discrete version?

1.1 Our Results

Our main contribution is a direct approach towards the continuous versions of clustering problems. We apply this to the following clustering problems where we obtain a factor better than $\beta \cdot \alpha_{\text{dis}}$, where α_{dis} is the best known factor for the discrete version of the problem.

- In the continuous λ -UFL problem, a “soft” version of the continuous k -median problem, one is allowed to pick any number of centers but has to pay a parameter λ for each picked center. The objective is to minimize the sum of distances of points in C to picked centers plus the cost for opening these centers. Again, note that the centers can be opened anywhere in X . For the discrete version, where the only possible center locations are in C , there is a 1.488-approximation due to Li [39], and a hardness of approximation within a factor of 1.278 is known due to Guha and Khuller [30]. We describe a 2.32-approximation algorithm. Note that $2.32 < 2 \cdot 1.278$ and thus, for this problem, the inapproximability is *not* β times that of the discrete case. We also show how the reduction of [21] carries over, to prove a hardness of 2 for this problem.
- In the continuous k -means problem, we wish to minimize the sum of squares of distances of clients to the closest open center. Recall that for this problem we have $\beta = 4$, and thus one gets a 36-factor algorithm for the continuous k -means using the best known 9-factor [1, 31, 37] algorithm for the discrete problem. We describe an improved 32-approximation for the continuous k -means problem.
- For the continuous k -median problem, our techniques fall short of improving $2\times$ the best known approximation factor for the discrete k -median problem. On the other hand, we obtain better algorithms for the the *individually fair* or *priority* version of the continuous k -median problem. In this problem, every point $v \in C$ has a specified radius $r(v)$ and desires a center opened within this distance. The objective is the same as the k -median problem: minimize the sum of all the distances. This problem arises as a possible model [36, 13, 41, 47, 43, 7] in the study of fair clustering solutions, since the usual k -median algorithms may place certain clients inordinately far away. At a technical level, this problem is a meld of the k -median and the k -center problems; the latter is NP-hard, which forces one to look at *bicriterion* approximations. An (α, γ) -approximation would return a solution within α times the optimum but may connect v to a point as far as $\gamma r(v)$ away. Again, any (α, γ) -approximation for the *discrete* version where $X = C$ would imply a $(2\alpha, 2\gamma)$ -approximation for the continuous version.

The best discrete approximation is (8, 3) due to Vakilian and Yalçınar [47] which would imply an (16, 3)-approximation for the continuous version. We describe an (8, 8)-approximation for the continuous version of the problem.

- In the k -center with outliers (kCwO) problem, we are given a parameter $m \leq |C|$, and we need to serve only m of the clients. The objective is the maximum distance of a served client to its center. The k -center objective is one of the objectives for which most existing discrete algorithms can compare themselves directly with the continuous optimum. The 3-approximation algorithm in [17] for the kCwO problem is one such example. However, the best known algorithm for kCwO for the discrete case (when $X = C$) is a 2-approximation by Chakrabarty, Goyal, and Krishnaswamy [11] which proceeds via LP rounding, and does not give a 2-approximation for continuous kCwO. This was explicitly noted in a work by Ding, Yu, and Wang (“... unclear if the resulting approximation ratio for the problem in Euclidean space.”) [26], that describes a 2-approximation for kCwO in Euclidean space, however, violating the number of clients served. We give a proper 2-approximation for the continuous kCwO problem (with no assumptions on the metric space) with no violations.

1.2 Our Technical Insight

Most state of the art approximation algorithms for center-based clustering problems are based on LP relaxations where one typically has variables y_i for *every* potential location of a center. When the set X is large, this approach becomes infeasible. Our main technical insight, underlying all our results, is to use a different style of linear program with polynomially many variables but exponentially many constraints. We then use the *round-or-cut* framework to obtain our approximation factor. More precisely, given a *potential* solution to our program, we either “round” it to get a desired solution within the asserted approximation factor, or we find a *separating hyperplane* proving that this potential solution is infeasible. Once this hyperplane is fed to the ellipsoid algorithm [29], the latter generates another potential solution, and the process continues. Due to the ellipsoid method’s guarantees, we obtain our approximation factor in polynomial time.

For every client $v \in C$, our LP relaxation has variables of the form $y(v, r)$, indicating whether there is some point $x \in X$ in an r -radius around v which is “open” as a center. Throughout the paper we use r as a quantity varying “continuously”, but it can easily be discretized, with a loss of at most $\frac{1}{\text{poly}(n)}$, to arise from a set of size $\leq \text{poly}(n)$. Thus there are only polynomially many such variables. We add the natural “monotonicity” constraints: $y(v, r) \leq y(v, s)$ whenever $r \leq s$. Interestingly, for one of the applications, we also need the monotonicity constraints for non-concentric balls: if $B(v, r) \subseteq B(u, s)$, then we need $y(v, r) \leq y(u, s)$.

We have a variable C_v indicating the cost the client v pays towards the optimal solution. Next, we connect the C_v ’s and the $y(v, r)$ ’s in the following ways (when $\beta = 1$, and something similar when $\beta = 2$). One connection states that for any r , $C_v \geq r \cdot (1 - y(v, r))$ and we add these to our LP. For the last two applications listed above, this suffices. However, one can also state the stronger condition of $C_v \geq \int_0^\infty (1 - y(v, r)) dr$. Indeed, the weaker constraint is the “Markov-style inequality” version of the stronger constraint.

Our second set of constraints restrict the $y(v, r)$ ’s to be “not too large”. For instance, for the fair k -median or kCwO problems where we are only allowed k points from X , we assert that for *any* set \mathcal{B} of disjoint balls $B(v, r)$, we must have the sum of the respective $y(v, r)$ ’s to be at most k . This set of constraints is exponentially many, and this is the set of constraints that need the round-or-cut machinery. For the λ -UFL problem, we have that the sum of the $y(v, r)$ ’s scaled by λ plus the sum of the C_v ’s should be at most opt_g , which is a running guess of opt .

Once we set up the framework above, then we can *port many existing rounding* algorithms for the discrete clustering problems without much hassle. In particular, this is true for rounding algorithms which use the C_v ’s as the core driving force. For the continuous λ -UFL problem, we port the rounding algorithm from the paper [45] by Shmoys, Tardos, and Aardal. For the continuous k -means problem, we port the rounding algorithm from the paper [16] by Charikar, Guha, Shmoys, and Tardos. For the continuous fair k -median problem, we port the rounding algorithm from the paper [13] by Chakrabarty and Negahbani, which itself builds on the algorithm present in the paper [2] by Alamdari and Shmoys. For the continuous kCwO problem, we port the rounding algorithm present in the paper [11] by Chakrabarty, Goyal, and Krishnaswamy.

Our results fall short for the continuous k -median problem (without fairness), where we can port the rounding algorithm from the paper [16] and get a 6.67-approximation. This, however, does not improve upon the 5.35-factor mentioned earlier.

1.3 Other Related Works and Discussion

The continuous k -means and median problems have been investigated quite a bit in the specific setting when $X = \mathbb{R}^m$ and when $d(u, v)$ is the ℓ_2 distance. The paper [42] by Matoušek describes an $(1 + \varepsilon)$ -approximation (PTAS) that runs in time $O(n \log^k n \cdot \varepsilon^{-O(k^2 m)})$. This led to a flurry of results [32, 25, 38, 18, 27] on obtaining PTASes with better dependencies on k and m via the applications of coresets. There is a huge and growing literature on coresets, and we refer the interested reader to the paper [24] by Cohen-Addad, Saulpic, and Schwiegelshohn, and the references within, for more information. Another approach to the continuous k -means problem has been local search. The paper [37] which describes a $9 + \varepsilon$ -approximation was first stated for the geometric setting, however it also went via the discretization due to Matoušek [42] and suffered a running time of exponential dependency on the dimension. More recent papers [28, 22] described local-search based PTASes for metrics with doubling dimension D , with running time exponentially depending on D . These doubling metrics generalize (\mathbb{R}^m, ℓ_2) -metrics. However, none of the above ideas seem to suggest better constant factor approximations for the continuous k -median/means problem in the general case, and indeed even when $X = \mathbb{R}^m$ but m is part of the input.

The k -means problem in the metric space (\mathbb{R}^m, ℓ_2) , where m and k are not constants, has been studied extensively [46, 6, 19, 23, 1, 20], and is called the Euclidean k -means problem. The discrete version of this problem was proved APX-hard in 2000 [46], but the APX-hardness of the continuous version was proved much later, in 2015 [6]. More recently, the hardness results for both versions have been improved: the discrete Euclidean k -means problem is hard to approximate to factor 1.17, while the continuous problem is hard to approximate to factor 1.07 [19]. Moreover, under assumption of a complexity theoretic hypothesis called the Johnson coverage hypothesis, these numbers have been improved to 1.73 and 1.36, respectively [23]. On the algorithmic side, the discrete Euclidean k -means problem admits a better approximation ratio than the general case: a 6.36 approximation was described in 2017 [1], which was very recently improved to 5.912 [20].

We believe that our paper takes the first stab at getting approximation ratios better than $\beta \times$ the best discrete factor for the *continuous* clustering problems. Round-or-cut is a versatile framework for approximation algorithm design with many recent applications [44, 10, 3, 12, 4], and the results in our paper is yet another application of this paradigm. However, many questions remain. We believe that the most interesting question to tackle is the continuous k -median problem. The best known discrete k -median algorithms are, in fact, combinatorial in nature, and are obtained via applying the primal-dual/dual-fitting based methods [35, 34, 40, 9] on the discrete LP. However, their application still needs an explicit description of the facility set, and it is interesting to see if they can be *directly* ported to the continuous setting.

All the algorithms in our paper, actually *still* open centers from C . Even then, we are able to do better than simply reducing to the discrete case, because we do not commit to the β loss upfront, and instead round from a fractional solution that can open centers anywhere in X . This raises an interesting question for the k -median problem (or any other center based clustering problem): consider the potentially infinite-sized LP which has variables y_i for all $i \in X$, but restrict to the optimal solution which only is allowed to open centers from C . How big is this “integrality gap”? It is not too hard to show that for the k -median problem this is between 2 and 4. The upper bound gives hope we can get a true 4-approximation for the continuous k -median problem, but it seems one would need new ideas to obtain such a result.

Organization of Extended Abstract

Due to space constraints, in this extended abstract we have decided to focus on the continuous λ -UFL and the continuous fair k -median results since we believe that they showcase the technical ideas in this paper. Proofs of certain statements have also been deferred to the full version of the paper [14]. The description of the results on continuous k -means and continuous k -center with outliers can be found in the full version [14, Appendices B and C].

2 Preliminaries

Given a metric space (X, d) on points X with pairwise distances d , we use the notation $d(v, S) = \min_{i \in S} d(v, i)$ for $v \in X$ and $S \subseteq X$ to denote v 's distance to the set S .

► **Definition 1** (Continuous k -median (Cont- k -Med)). *The input is a metric space (X, d) , clients $C \subseteq X$, $|C| = n \in \mathbb{N}$, and $k \in \mathbb{N}$. The goal is to find $S \subseteq X$, $|S| = k$ minimizing $\text{cost}(S) := \sum_{v \in C} d(v, S)$.*

► **Definition 2** (Continuous Fair k -median (ContFair- k -Med)). *Given the Cont- k -Med input, plus fairness radii $r : C \rightarrow [0, \infty)$, the goal is to find $S \subseteq X$, $|S| = k$ such that $\forall v \in C$, $d(v, S) \leq r(v)$, minimizing $\text{cost}(S)$.*

In the Uncapacitated Facility Location (UFL) problem, the restriction of opening only k facilities is replaced by having a cost associated with opening each facility. When these costs are equal to the same value λ for all facilities, the problem is called λ -UFL.

► **Definition 3** (Continuous λ -UFL (Cont- λ -UFL)). *Given a metric space (X, d) , clients $C \subseteq X$, $|C| = n \in \mathbb{N}$, and $\lambda \geq 0$, find $S \subseteq X$ that minimizes the sum of “connection cost” $\text{cost}_C(S) := \sum_{v \in C} d(v, S)$ and “facility opening cost” $\text{cost}_F(S) := \lambda|S|$.*

Let $\Delta = \max_{u, v \in C} d(u, v)$ denote the diameter of a metric (X, d) . For $x \in X$, $0 \leq r \leq \Delta$, the ball of radius r around x is $B(x, r) := \{x' \in X \mid d(x', x) \leq r\}$. Throughout the paper, we use balls of the form $B(v, r)$ where v is a client and $r \in \mathbb{R}$. To circumvent the potentially infinite number of radii, the radii can be discretized into $I_\varepsilon = \{\varepsilon, 2\varepsilon, \dots, \lceil \Delta/\varepsilon \rceil \varepsilon\}$ for a small constant $\varepsilon = O(1/n^2)$. Thereupon, we can appeal to the following lemma to bound the size of I_ε by $O(n^5)$.

► **Lemma 4** (Rewording of Lemma 4.1, [1]). *Losing a factor of $(1 + \frac{100}{n^2})$, we can assume that for any $u, v \in C$, $1 \leq d(u, v) \leq n^3$.*

For simplicity of exposition, we present our techniques using radii in \mathbb{R} , and observe that discretizing to I_ε incurs an additive loss of at most $O(n\varepsilon) = O(1/n)$ in our guarantees. We also note that $\log \text{opt} \leq \log(n\Delta) = O(\log n)$ by the above, which enables us to efficiently binary-search over our guesses opt_g .

3 Continuous λ -UFL

We start this section with our 2.32-approximation for Cont- λ -UFL (Theorem 5). For this, we introduce a new linear programming formulation, and adapt the rounding algorithm of Shmoys-Tardos-Aardal to the new program. The resulting procedure exhibits our main ideas, and serves as a warm-up for the remaining sections. Also, in Section 3.2, we prove that it is NP-hard to approximate Cont- λ -UFL within a factor of $2 - o(1)$, using ideas due to Cohen-Addad, Karthik, and Lee [21]. This shows that the continuous version cannot be approximated as well as the discrete version, which has a best-known approximation factor of 1.463 [39].

3.1 Approximation algorithm

This subsection is dedicated to proving the following theorem:

► **Theorem 5.** *There is a polynomial time algorithm that, for an instance of Cont- λ -UFL with optimum opt , yields a solution with cost at most $(\frac{2}{1-e^{-2}} + \varepsilon)\text{opt} < 2.32 \cdot \text{opt}$. Here $\varepsilon = O(\frac{1}{n^2})$.*

We design the following linear program for Cont- λ -UFL. We use variables C_v for the connection cost of each client v , and $y(v, r)$ for the number of facilities opened within each ball of the form $B(v, r)$. We also use a guess of the optimum opt_g , which we will soon discuss how to obtain. Throughout, we use $y(B)$ as shorthand for $y(v, r)$ where $B = B(v, r)$.

$$\lambda \sum_{B \in \mathcal{B}} y(B) + \sum_{v \in C} C_v \leq \text{opt}_g \quad \forall \mathcal{B} \subseteq \{B(v, r)\}_{\substack{v \in C \\ r \in \mathbb{R}}} \text{ pairwise disjoint} \quad (\text{UFL})$$

$$\int_0^\infty (1 - y(v, r)) dr \leq C_v \quad \forall v \in C, r \in \mathbb{R} \quad (\text{UFL-1})$$

$$y(v, r) \leq y(v, r') \quad \forall v \in C, r, r' \in \mathbb{R} \text{ s.t. } r \leq r' \quad (\text{UFL-2})$$

$$y(v, r) \geq 0, C_v \geq 0 \quad \forall v \in C, r \in \mathbb{R}$$

Observe that, given a solution $S \subseteq X$ of cost at most opt_g , we can obtain a feasible solution of UFL as follows. For client $v \in C$, we set $C_v = d(v, S)$. For $v \in C, r \in \mathbb{R}$, we set $y(v, r) = 0$ for $r < d(v, S)$ and $y(v, r) = 1$ for $r \geq d(v, S)$.

Our approach is to round a solution (C, y) of UFL. Observe that there are polynomially many constraints of the form (UFL-1) and (UFL-2); hence, we can efficiently obtain a solution (C, y) that satisfies them. So for the remainder of this section, we assume that those constraints are satisfied. On the other hand, there are infinitely many constraints of type (UFL). This is why we employ a round-or-cut framework via the ellipsoid algorithm [29]. We begin with an arbitrary opt_g , and when ellipsoid asks us if a proposed solution (C, y) is feasible, we run the following algorithm.

The algorithm inputs $\alpha < 1$, and defines $r_\alpha(v)$ as the minimum radius at which client $v \in C$ has at least α mass of open facilities around it. First, all clients are deemed *uncovered* ($U = C$). Iteratively, the algorithm picks the j , i.e. the uncovered client, with the smallest $r_\alpha(j)$. j is put into the set $\text{Reps}_{(C, y), \alpha}$. Any client v within distance $r_\alpha(j) + r_\alpha(v)$ of j is considered a child of j and is now *covered*. When all clients are covered, i.e. $U = \emptyset$, the algorithm outputs $\text{Reps}_{(C, y), \alpha}$.

■ **Algorithm 1** Filtering for Cont- λ -UFL.

Input: A proposed solution $(\{C_v\}_{v \in C}, \{y(v, r)\}_{v \in C, r \in \mathbb{R}})$ for UFL, parameter $\alpha \in (e^{-2}, 1)$

- 1: $r_\alpha(v) \leftarrow \min\{r \in \mathbb{R} \mid y(v, r) \geq \alpha\}$ for all $v \in C$
- 2: $\text{Reps}_{(C, y), \alpha} \leftarrow \emptyset$ ▷ “representative” clients
- 3: $U \leftarrow C$ ▷ “uncovered” clients
- 4: **while** $U \neq \emptyset$ **do**
- 5: Pick $j \in U$ with minimum $r_\alpha(j)$
- 6: $\text{child}(j) \leftarrow \{v \in U \mid d(v, j) \leq r_\alpha(v) + r_\alpha(j)\}$
- 7: $U \leftarrow U \setminus \text{child}(j)$
- 8: $\text{Reps}_{(C, y), \alpha} \leftarrow \text{Reps}_{(C, y), \alpha} \cup j$
- 9: **end while**

Output: $\text{Reps}_{(C, y), \alpha}$

Notice that, by construction, the collection of balls $\{B(j, r_\alpha(j))\}_{j \in \text{Reps}_{(C,y),\alpha}}$ is pairwise disjoint. Hence, the following constraint, which we call $\text{Sep}_{(C,y),\alpha}$, is of the form (UFL):

$$\lambda \sum_{j \in \text{Reps}_{(C,y),\alpha}} y(j, r_\alpha(j)) + \sum_{v \in C} C_v \leq \text{opt}_g \quad (\text{Sep}_{(C,y),\alpha})$$

We will show that

► **Lemma 6.** *If (C, y) satisfies (UFL-1), (UFL-2), and $\text{Sep}_{(C,y),\alpha}$, then there exists a suitable $\alpha \in (e^{-2}, 1)$ for which the output of Algorithm 1 has cost at most $\frac{2}{1-e^{-2}} \text{opt}_g$.*

Thus, if we find that the desired approximation ratio is not attained, then it must be that $\text{Sep}_{(C,y),\alpha}$ was not satisfied, and we can pass it to ellipsoid as a separating hyperplane. If ellipsoid finds that the feasible region of our linear program is empty, then we increase opt_g and try again. Otherwise, we obtain a solution $\text{Reps}_{(C,y),\alpha}$ that attains the desired guarantees.

We now analyze Algorithm 1 to prove Lemma 6.

Proof of Lemma 6. For this proof, we will fix (C, y) , and refer to $\text{Reps}_{(C,y),\alpha}$ as Reps_α .

To prove a suitable α exists, assume α is picked uniformly at random from $(\beta, 1)$ for some $0 < \beta < 1$; we will see later that $\beta = e^{-2}$ is optimal. Take Reps_α , the output of Algorithm 1 on (C, y) . By definition of r_α , $\sum_{j \in \text{Reps}_\alpha} y(j, r_\alpha(j)) \geq \alpha |\text{Reps}_\alpha|$. Thus $\text{cost}_F(\text{Reps}_\alpha) = \lambda |\text{Reps}_\alpha| \leq \frac{1}{\alpha} \cdot \lambda \sum_{j \in \text{Reps}_\alpha} y(j, r_\alpha(j))$, which implies

$$\mathbf{Exp}[\text{cost}_F(\text{Reps}_\alpha)] \leq \frac{\ln(1/\beta)}{(1-\beta)} \lambda \sum_{j \in \text{Reps}_\alpha} y(j, r_\alpha(j)). \quad (1)$$

To bound the expected connection cost, take $v \in C$ and observe that, since all the clients are ultimately covered in Algorithm 1, there has to exist $j \in \text{Reps}_\alpha$ for which $v \in \text{child}(j)$. By construction of child , $d(v, j) \leq r_\alpha(v) + r_\alpha(j)$, which is at most $2r_\alpha(v)$ by our choice of j in Line 5. Thus, for any client v , we get $d(v, \text{Reps}_\alpha) \leq d(v, j) \leq 2r_\alpha(v)$. So we are left to bound $\mathbf{Exp}[r_\alpha(v)]$ for an arbitrary client $v \in C$.

We have that

$$\mathbf{Exp}[r_\alpha(v)] = \frac{1}{1-\beta} \int_\beta^1 r_\alpha(v) d\alpha \leq \frac{1}{1-\beta} \int_0^1 r_\alpha(v) d\alpha.$$

We notice that at $\alpha = y(v, r)$, $r_\alpha(v) = r$. Also, $r_0(v) = 0$. So given (UFL-2) for all balls $B(v, r)$ with $r \in \mathbb{R}$, we can apply a change of variable to the integral to get $\int_0^1 r_\alpha(v) d\alpha = \int_{r_0(v)}^{r_1(v)} (y(v, r_1(v)) - y(v, r)) dr \leq \int_0^\infty (1 - y(v, r)) dr \leq C_v$, where the last inequality is by (UFL-1). Thus we have $\mathbf{Exp}[r_\alpha(v)] \leq \frac{C_v}{1-\beta}$. Summing $d(v, \text{Reps}_\alpha)$ over all $v \in C$ we have

$$\mathbf{Exp}[\text{cost}_C(\text{Reps}_\alpha)] = \sum_{v \in C} \mathbf{Exp}[d(v, \text{Reps}_\alpha)] \leq 2 \sum_{v \in C} \mathbf{Exp}[r_\alpha(v)] \leq \frac{2}{1-\beta} \sum_{v \in C} C_v. \quad (2)$$

To balance cost_F from (1) and cost_C from (2), we set $\beta = e^{-2}$. The expected Cont- λ -UFL cost of Reps_α is, using $\text{Sep}_{(C,y),\alpha}$,

$$\mathbf{Exp}[\text{cost}_F(\text{Reps}_\alpha) + \text{cost}_C(\text{Reps}_\alpha)] \leq \frac{2}{1-e^{-2}} \left(\lambda \sum_{j \in \text{Reps}_\alpha} y(j, r_\alpha(j)) + \sum_{v \in C} C_v \right) \leq \frac{2 \cdot \text{opt}_g}{1-e^{-2}}.$$

Since the bound holds in expectation over a random α , there must exist an $\alpha \in (\beta, 1)$ that satisfies it deterministically. ◀

To obtain a suitable α , we can adapt the derandomization procedure from the discrete version [45]. The procedure relies on having polynomially many interesting radii; for this, we recall that while we have used $r \in \mathbb{R}$ for simplicity, our radii are actually $r \in I_\varepsilon$, $|I_\varepsilon| = O(n^5)$.

3.2 Hardness of approximation

Our hardness result for this problem is as follows:

► **Theorem 7.** *Given an instance of Cont- λ -UFL and $\varepsilon > 0$, it is NP-hard to distinguish between the following:*

- *There exists $S \subseteq X$ such that $\text{cost}_F(S) + \text{cost}_C(S) \leq (1 + 6\varepsilon)n$*
- *For any $S \subseteq X$, $\text{cost}_F(S) + \text{cost}_C(S) \geq (2 - \varepsilon)n$*

Thus we exhibit hardness of approximation up to a factor of $\frac{2-\varepsilon}{1+6\varepsilon}$, which tends to 2 as $\varepsilon \rightarrow 0$. Our reduction closely follows the hardness proof for Cont- k -Med [21]. The details appear in the full version of this paper [14, Appendix D].

4 Continuous Fair k -Median

The main result of this section is the following theorem.

► **Theorem 8.** *There exists a polynomial time algorithm for ContFair- k -Med that, for an instance with optimum cost opt , yields a solution with cost at most $8\text{opt} + \varepsilon$, in which, each client $v \in C$ is provided an open facility within distance $8r(v) + \varepsilon$ of itself. Here $\varepsilon = O\left(\frac{1}{n^2}\right)$.*

We create a round-or-cut framework, via the ellipsoid algorithm [29], that adapts the Chakrabarty-Negahbani algorithm [13] to the continuous setting. For this, we will modify the UFL linear program to suit ContFair- k -Med. As before, opt_g is a guessed optimum, C_v is the cost share of a client $v \in C$, and $y(v, r)$ represents the number of facilities opened in $B(v, r)$. There are two key modifications. First, we expand the monotonicity constraints of the form (UFL-2) to include *non-concentric* balls, which are crucial for adapting the fairness guarantee of Chakrabarty and Negahbani [13]. Second, we enforce the fairness constraints by requiring $y(v, r(v)) \geq 1$ for each client $v \in C$.

$$\sum_{v \in C} C_v \leq \text{opt}_g \quad (\text{LP})$$

$$\sum_{B \in \mathcal{B}} y(B) \leq k \quad \forall \mathcal{B} \subseteq \{B(v, r)\}_{\substack{v \in C \\ r \in \mathbb{R}}} \text{ pairwise disjoint} \quad (\text{LP-1})$$

$$\int_0^\infty (1 - y(v, r)) dr \leq C_v \quad \forall v \in C \quad (\text{LP-2})$$

$$y(u, r) \leq y(v, r') \quad \forall u, v \in C, r, r' \in \mathbb{R}, B(u, r) \subseteq B(v, r') \quad (\text{LP-3})$$

$$y(v, r(v)) \geq 1 \quad \forall v \in C \quad (\text{LP-4})$$

$$y(v, r) \geq 0, C_v \geq 0 \quad \forall v \in C, r \in \mathbb{R}$$

We will frequently use the following property of LP. See the full version of our paper [14, Appendix A.2] for the proof.

► **Lemma 9.** *Consider a solution (C, y) of LP. If for a client v , (C, y) satisfies all constraints of the form (LP-2) and (LP-3) involving v , then for any $r_0 \in \mathbb{R}$, $C_v \geq r_0(1 - y(v, r_0))$.*

As before, we will only worry about the constraints that are exponentially many. These are (LP-1). For this, we use ellipsoid [29]. Given a proposed solution (C, y) of LP, we construct $\text{Reps}_{(C,y)} \subseteq C$, as follows.

We first perform a filtering step. For each $v \in C$, we define $R(v) := \min r(v), 2C_v$. In the beginning, all clients are “uncovered” (i.e. $U = C$). In each iteration, let $j \in U$ be the uncovered client with the minimum $R(j)$; and add j to our set of “representatives” $\text{Reps}_{(C,y)}$. Any $v \in U$ within distance $2R(v)$ of j (including j itself) will be added to the set $\text{child}(j)$, and will be removed from U . After all clients are covered, i.e. $U = \emptyset$, the algorithm outputs $\text{Reps}_{(C,y)}$. For a formal description of this algorithm, see the full version [14, Appendix A.1].

For a $j \in \text{Reps}_{(C,y)}$, let $s(j)$ be the closest client to j in $\text{Reps}_{(C,y)} \setminus \{j\}$. Let $a(j) := \frac{d(j,s(j))}{2}$. So the collection of balls $\{B(j, a(j))\}_{j \in \text{Reps}_{(C,y)}}$ is pairwise disjoint, and the following constraint, which we call $\text{Sep}_{(C,y)}$, is of the form (LP-1).

$$\sum_{j \in \text{Reps}_{(C,y)}} y(j, a(j)) \leq k \quad (\text{Sep}_{(C,y)})$$

We have that

► **Lemma 10.** *If (C, y) satisfies (LP-2)-(LP-4) and $\text{Sep}_{(C,y)}$, then*

1. $\forall j \in \text{Reps}_{(C,y)}, y(j, a(j)) \geq \frac{1}{2}$
2. $|\text{Reps}_{(C,y)}| \leq 2k$

Proof. Fix $j \in \text{Reps}_{(C,y)}$. By construction of $\text{Reps}_{(C,y)}$,

$$a(j) = \frac{d(j, s(j))}{2} \geq R(j) \quad (3)$$

So if $R(j) = r(j)$, then by (LP-3) and (LP-4), $y(j, a(j)) \geq y(j, r(j)) \geq 1$. Else $R(j) = 2C_j$. By Lemma 9, $C_j \geq a(j)(1 - y(j, a(j)))$.

If $C_j = 0$, then this implies $y(j, a(j)) \geq 1$. Otherwise, substituting $a(j)$ by $R(j)$ from (3) and setting $R(j) = 2C_j$ gives $C_j \geq 2C_j(1 - y(j, a(j)))$, i.e. $y(j, a(j)) \geq \frac{1}{2}$. Now, by $\text{Sep}_{(C,y)}$, we have $k \geq \sum_{j \in \text{Reps}_{(C,y)}} y(j, a(j)) \geq \frac{1}{2} \cdot |\text{Reps}_{(C,y)}|$. ◀

So if we find that $|\text{Reps}_{(C,y)}| > 2k$, then $\text{Sep}_{(C,y)}$ must be violated, and we can pass it to ellipsoid as a separating hyperplane. Hence in polynomial time, we either find that our feasible region is empty, or we get (C, y) and $\text{Reps}_{(C,y)}$ such that (C, y) satisfies (LP), (LP-2)-(LP-4), and $\text{Sep}_{(C,y)}$. In the first case, we increase opt_g and try again. In the latter case, we round (C, y) further to attain our desired approximation ratios, via a rounding algorithm that we will now describe. This algorithm focuses on $\text{Reps}_{(C,y)}$ and ignores other clients, as justified by the following lemma.

► **Lemma 11.** *$S \subseteq X$ be a solution to ContFair- k -Med. Consider a proposed solution (C, y) of LP that satisfies (LP). Then $\sum_{v \in C} d(v, S) \leq \sum_{j \in \text{Reps}_{(C,y)}} |\text{child}(j)| d(j, S) + 4\text{opt}_g$.*

The proof closely follows from a standard technique for the discrete version [16, 13]. We provide the proof in the full version [14, Appendix A.3].

Our algorithm will also ignore facilities outside $\text{Reps}_{(C,y)}$, so our solution will be a subset of $\text{Reps}_{(C,y)}$. For the remainder of this section, we fix (C, y) , and refer to $\text{Reps}_{(C,y)}$ as Reps . We write the following polynomial-sized linear program, DLP, where Reps are the only clients and the only facilities. The objective function of DLP is a lower bound on $\sum_{j \in \text{Reps}} |\text{child}(j)| d(j, S)$, so hereafter we compare our output with DLP. We do not include fairness constraints in this program, and we will see later that it is not necessary to do so.

In DLP, the variables z_i for each $i \in \text{Reps}$ denote whether i is open as a facility. The variables x_{ij} for $i, j \in \text{Reps}$ denote whether the client j uses the facility i .

$$\text{minimize } \sum_{j \in \text{Reps}} |\text{child}(j)| \sum_{i \in \text{Reps}} x_{ij} d(j, i) \quad (\text{DLP})$$

$$\sum_{i \in \text{Reps}} z_i \leq k \quad (\text{DLP-1})$$

$$\sum_{i \in \text{Reps}} x_{ij} = 1 \quad \forall j \in \text{Reps} \quad (\text{DLP-2})$$

$$x_{ij} \leq y_i \quad \forall i, j \in \text{Reps} \quad (\text{DLP-3})$$

$$x_{ij} \geq 0, z_i \geq 0 \quad \forall i, j \in \text{Reps}$$

We will now round (C, y) to an integral solution of DLP. Our first step is to convert (C, y) to a fractional solution (\bar{x}, \bar{z}) of DLP. To do this, for each $j \in \text{Reps}$, we consolidate the y -mass in $B(j, a(j))$ onto j , i.e. we set $\bar{z}_j = y(j, a(j))$. By Lemma 10.1, each \bar{z}_j is then at least $\frac{1}{2}$. This allows j to use only itself and $s(j)$ as its fractional facilities.

■ **Algorithm 2** Consolidation for ContFair- k -Med.

Input: A proposed solution $(\{C_v\}_{v \in C}, \{y(v, r)\}_{v \in C, r \in I_\epsilon})$ for LP, and Reps as defined above

- 1: **for** $j \in \text{Reps}$ **do**
- 2: $s(j) \leftarrow \arg \min_{v \in \text{Reps} \setminus j} d(j, v)$
- 3: $a(j) \leftarrow d(j, s(j))/2$
- 4: $\bar{z}_j \leftarrow \min\{y(j, a(j)), 1\}$
- 5: $\bar{x}_{jj} \leftarrow \bar{z}_j$
- 6: $\bar{x}_{js(j)} \leftarrow 1 - \bar{z}_j$
- 7: **end for**

Output: (\bar{x}, \bar{z})

► **Lemma 12.** $\forall j \in \text{Reps}, \bar{z}_j \geq \frac{1}{2}$, and (\bar{x}, \bar{z}) is a feasible solution of DLP with cost at most 2opt_g .

Proof. For a $j \in \text{Reps}$, if $y(j, a(j)) = 1$ then $\bar{z}_j = 1$. Otherwise, by Lemma 10.1, $\bar{z}_j = y(j, a(j)) \geq \frac{1}{2}$.

Hence $1 - \bar{z}_j \leq \frac{1}{2} \leq \bar{z}_{s(j)}$, which implies feasibility by construction and $\text{Sep}_{(C, y)}$. It also implies that $\sum_{i \in \text{Reps}} \bar{x}_{ij} d(j, i) = (1 - \bar{z}_j) d(j, s(j))$. If $y(j, a(j)) = 1$, then the RHS above is $0 \leq 2C_j$. Otherwise $\sum_{i \in \text{Reps}} \bar{x}_{ij} d(j, i) = (1 - y(j, a(j))) d(j, s(j)) = 2(1 - y(j, a(j))) a(j) \leq 2C_j$ where the last inequality follows from Lemma 9. Multiplying by $|\text{child}(j)|$ and summing over all $j \in \text{Reps}$, we have by construction of Reps ,

$$\sum_{j \in \text{Reps}} |\text{child}(j)| \sum_{i \in \text{Reps}} \bar{x}_{ij} d(j, i) \leq 2 \sum_{j \in \text{Reps}} |\text{child}(j)| C_j \leq 2 \sum_{j \in \text{Reps}} \sum_{v \in \text{child}(j)} C_v = 2 \sum_{v \in C} C_v$$

which is at most 2opt_g by (LP). ◀

Now, to round (\bar{x}, \bar{z}) to an integral solution, we appeal to an existing technique [16, 13]. We state the relevant result here, and provide the proof in the full version [14, Appendix A.4].

► **Lemma 13** ([16, 13]). *Let (\bar{x}, \bar{z}) be a feasible solution of DLP with cost at most 2opt_g , such that $\forall j \in \text{Reps}, \bar{z}_j \geq \frac{1}{2}$. Then there exists a polynomial time algorithm that produces $S \subseteq \text{Reps}$ such that*

1. $|S| = k$;
2. If $\bar{z}_j = 1$, then $j \in S$;
3. $\forall j \in \text{Reps}$, at least one of $j, s(j)$ is in S ; and
4. $\sum_{j \in \text{Reps}} |\text{child}(j)| d(j, S) \leq 4\text{opt}_g$.

Thus, by Lemma 11, we have shown that $\sum_{v \in C} d(v, S) \leq \sum_{j \in \text{Reps}} |\text{child}(j)| \sum_{i \in S} d(j, S) + 4\text{opt}_g \leq 8\text{opt}_g$. Now we show the fairness ratio, adapting a related result [13, Lemma 3] from the discrete version. This is where we crucially require the monotonicity constraints (LP-3) for *non-concentric* balls.

► **Lemma 14.** $\forall v \in C, d(v, S) \leq 8r(v)$.

Proof. Fix $v \in C$, and let $j \in \text{Reps}$ such that $v \in \text{child}(j)$. By construction of $\text{child}(j)$,

$$d(v, j) \leq 2R(v) \leq 2r(v) \tag{4}$$

So if $j \in S$, then we are done. Otherwise, by Lemma 13.2, $\bar{z}_j < 1$, i.e. by Algorithm 2, $y(j, a(j)) < 1$. But by the fairness constraints (LP-4), $y(v, r(v)) \geq 1$. So by the monotonicity constraints (LP-3), $B(v, r(v)) \not\subseteq B(j, a(j))$, as otherwise we would have $1 \leq y(v, r(v)) \leq y(j, a(j)) < 1$, a contradiction.

So fix $w \in B(v, r(v)) \setminus B(j, a(j))$. We have

$$a(j) < d(j, w), \quad d(v, w) \leq r(v) \tag{5}$$

By Lemma 13.3, either $j \in S$ or $s(j) \in S$, so

$$\begin{aligned} d(j, S) &\leq d(j, s(j)) = 2a(j) < 2d(j, w) && \dots \text{ by (5)} \\ &\leq 2(d(v, j) + d(v, w)) \leq 2(2r(v) + r(v)) && \dots \text{ by (4) and (5)} \\ &= 6r(v) \end{aligned}$$

So, by (4), $d(v, S) \leq d(v, j) + d(j, S) \leq 2r(v) + 6r(v) = 8r(v)$. ◀

Thus we have proved Theorem 8.

We observe here that, by the simple reduction of setting all $r(v)$'s to ∞ , Theorem 8 implies a solution of cost $8\text{opt} + \varepsilon$ for *Cont- k -Med*. We improve this ratio via an improved rounding procedure by Charikar, Guha, Shmoys, and Tardos [16], which rounds (\bar{x}, \bar{z}) such that $\sum_{j \in \text{Reps}} |\text{child}(j)| d(j, S) \leq \frac{8}{3}\text{opt}_g$, instead of the 4opt_g that we obtain above. This yields:

► **Corollary 15.** *There exists a polynomial time algorithm for Cont- k -Med that, on an instance with optimum cost opt , yields a solution of cost at most $6\frac{2}{3}\text{opt} + \varepsilon$.*

This improved rounding, however, no longer guarantees to open either j or $s(j)$ for each $j \in \text{Reps}$. Such a guarantee (Lemma 13.3) is crucial to our fairness bound in Lemma 14. So the improvement is not naively adaptable to *ContFair- k -Med*.

Abstract

Given a data stream $\mathcal{D} = \langle a_1, a_2, \dots, a_m \rangle$ of m elements where each $a_i \in [n]$, the Distinct Elements problem is to estimate the number of distinct elements in \mathcal{D} . Distinct Elements has been a subject of theoretical and empirical investigations over the past four decades resulting in space optimal algorithms for it. All the current state-of-the-art algorithms are, however, beyond the reach of an undergraduate textbook owing to their reliance on the usage of notions such as pairwise independence and universal hash functions. We present a simple, intuitive, sampling-based space-efficient algorithm whose description and the proof are accessible to undergraduates with the knowledge of basic probability theory.

1 Introduction

We consider the fundamental problem of estimating the number of distinct elements in a data stream (Distinct Elements problem or the F_0 estimation problem). For a data stream $\mathcal{D} = \langle a_1, a_2, \dots, a_m \rangle$, where each $a_i \in [n]$, $F_0(\mathcal{D})$ is the number of distinct elements in \mathcal{D} : $F_0(\mathcal{D}) = |\{a_1, a_2, \dots, a_m\}|$.

► **Problem 1.** *Given a stream $\mathcal{D} = \langle a_1, a_2, \dots, a_m \rangle$ of m elements where each $a_i \in [n]$, parameters ε, δ , output an (ε, δ) -approximation of $F_0(\mathcal{D})$. That is, output c such that $\Pr[(1 - \varepsilon) \cdot F_0(\mathcal{D}) \leq c \leq (1 + \varepsilon) \cdot F_0(\mathcal{D})] \geq 1 - \delta$.*

We are interested in streaming algorithms that uses $\text{poly}(\log m, \log n, \varepsilon^{-1}, \log \delta^{-1})$ bits of memory. Since \mathcal{D} is clear from the context, we also use F_0 to refer to $F_0(\mathcal{D})$.

F_0 estimation problem is a fundamental problem with a long history of theoretical and practical investigations. The seminal work of Flajolet and Martin [9] provided the first algorithm assuming the existence of hash functions with full independence. Subsequent

¹ The authors decided to forgo the old convention of alphabetical ordering of authors in favor of a randomized ordering, denoted by . The publicly verifiable record of the randomization is available at <https://www.aeaweb.org/journals/policies/random-author-order/search>

investigations relying on the usage of limited-independence hash functions have led to design of algorithms with optimal space complexity $O(\log n + \frac{\log \delta^{-1}}{\varepsilon^2})$. We defer detailed bibliographical remarks to Section 3. However, all the current space-efficient algorithms are beyond the reach of an undergraduate textbook due to their reliance on notions such as pairwise independence and universal hash functions.

We present a very simple algorithm for the F_0 estimation problem using a sampling strategy that only relies on basic probability for its analysis. In particular, it does not use universal hash functions. While the simplicity of the code makes it appealing to be used in practical implementation, we believe that only using basic probability theory for the analysis makes the algorithm presentable to undergraduates right after the introduction of basic tail bounds. Our algorithm builds and refines ideas introduced in the recent work on estimating the size of the union of sets in the general setting of *Delphic sets* [13].

2 F_0 -Estimator: A simple algorithm for F_0 estimation

Algorithm 1 F_0 -Estimator.

Input Stream $\mathcal{D} = \langle a_1, a_2, \dots, a_m \rangle$, ε, δ

- 1: **Initialize** $p \leftarrow 1$; $\mathcal{X} \leftarrow \emptyset$; $\text{thresh} \leftarrow \frac{12}{\varepsilon^2} \log(\frac{8m}{\delta})$
- 2: **for** $i = 1$ to m **do**
- 3: $\mathcal{X} \leftarrow \mathcal{X} \setminus \{a_i\}$
- 4: With probability p , $\mathcal{X} \leftarrow \mathcal{X} \cup \{a_i\}$
- 5: **if** $|\mathcal{X}| = \text{thresh}$ **then**
- 6: Throw away each element of \mathcal{X} with probability $\frac{1}{2}$
- 7: $p \leftarrow \frac{p}{2}$
- 8: **if** $|\mathcal{X}| = \text{thresh}$ **then**
- 9: **Output** \perp
- 10: **Output** $\frac{|\mathcal{X}|}{p}$

The algorithm F_0 -Estimator uses a simple sampling strategy: it keeps a set \mathcal{X} of samples at all times such that every element seen so far is independently in \mathcal{X} with equal probability. In order to keep the set of samples small, it makes sure that \mathcal{X} does not grow beyond the value thresh by adjusting the sampling rate p accordingly. After all the elements of the stream are processed, it outputs $\frac{|\mathcal{X}|}{p}$ where p is the final sampling rate.

2.1 Theoretical Analysis

We present the theoretical analysis entirely based on first principles, which adds to its length. For readers who are familiar with randomized algorithms, the proof is standard.

We state the following well-known concentration bound, Chernoff bound, for completeness.

► **Fact 2 (Chernoff's Bound).** *Let v_1, \dots, v_k be independent random variables taking values in $\{0, 1\}$. Let $V = \sum_{i=1}^k v_i$ and $\mu = \mathbb{E}[V]$. Then $\Pr(|V - \mu| \geq \delta\mu) \leq 2e^{-\frac{\delta^2\mu}{3}}$*

The following theorem captures the correctness and space complexity guarantee of F_0 -Estimator.

► **Theorem 3.** *For any data stream \mathcal{D} and any $0 < \delta, \varepsilon < 1$, the algorithm F_0 -Estimator outputs an (ε, δ) -approximation of $F_0(\mathcal{D})$. The algorithm uses $O(\frac{1}{\varepsilon^2} \cdot \log n \cdot (\log m + \log 1/\delta))$ space in the worst case.*

Proof. The stated space complexity bound of the algorithm follows because, from the description, it is clear that the size of the set of samples kept by the algorithm is always $\leq \text{thresh}$, and each item requires $\lceil \log_2 n \rceil$ bits to store.

In order to prove the algorithm outputs the correct estimate with high probability, we show that when the algorithm terminates, every distinct element of stream \mathcal{D} is in \mathcal{X} with a probability p , where $p \geq \frac{\text{thresh}}{4F_0}$. This guarantee, together with the Chernoff bound, implies the correctness of the algorithm. We give a formal proof of correctness below.

Consider the following two events:

Error : ‘The algorithm F_0 -Estimator does not return a value in the range $[(1 - \varepsilon)F_0, (1 + \varepsilon)F_0]$ ’
Fail : ‘The algorithm F_0 -Estimator outputs \perp .’

We will bound $\Pr[\text{Error}]$ by δ . Observe that $\Pr[\text{Error}] \leq \Pr[\text{Fail}] + \Pr[\text{Error} \cap \overline{\text{Fail}}]$.

▷ **Claim 4.** $\Pr[\text{Fail}] \leq \frac{\delta}{8}$

Proof of Claim. Let Fail_j denote the event that Algorithm 1 returns \perp when $i = j$. Formally, Fail_j : ‘ $|\mathcal{X}| = \text{thresh}$ and none of the elements of \mathcal{X} are thrown away at line 6’ for $i = j$. The probability that Fail_j happens is $(\frac{1}{2})^{\text{thresh}}$. Therefore,

$$\Pr[\text{Fail}] \leq \sum_{j=1}^m \Pr[\text{Fail}_j] \leq m \cdot \left(\frac{1}{2}\right)^{\text{thresh}} \leq \frac{\delta}{8} \quad \triangleleft$$

▷ **Claim 5.** $\Pr[\text{Error} \cap \overline{\text{Fail}}] \leq \frac{\delta}{2}$.

We give a detailed proof of this claim below. Theorem follows from the above two claims. ◀

Proof of Claim 5

To bound $\Pr[\text{Error} \cap \overline{\text{Fail}}]$, we consider a relaxed version of Algorithm F_0 -Estimator, which is stated as Algorithm 2. Algorithm 2 is nothing but F_0 -Estimator with lines 8 and 9 removed. Observe that for a given input, the algorithm F_0 -Estimator behaves identically to Algorithm 2 as long as $|\mathcal{X}| \leq \text{thresh}$ after each element of \mathcal{X} is thrown away with probability $\frac{1}{2}$ (i.e., the event **Fail** does not happen). Now, we consider the following event:

Error₂ : ‘The Algorithm 2 does not output a value in the range $[(1 - \varepsilon)F_0, (1 + \varepsilon)F_0]$ ’

Observe that $\Pr[\text{Error} \cap \overline{\text{Fail}}] \leq \Pr[\text{Error}_2]$. In Claim 7, we obtain the desired bound on $\Pr[\text{Error}_2]$ and hence on $\Pr[\text{Error} \cap \overline{\text{Fail}}]$.

To prove an upper bound on $\Pr[\text{Error}_2]$ in Claim 7, we will need the following claim. In the following, we use S_j to denote $\{a_1, a_2, \dots, a_j\}$ – distinct elements that appear in the first j items in the stream.

▷ **Claim 6.** The following loop invariant holds in the **for** loop (lines 2– 7) of Algorithm 2:

Every element in S_j is in \mathcal{X} independently with probability p .

Proof. First, we show that if the loop invariant holds after execution of line 4, then it holds after the execution of if-then-block (line 5–7). Since every element of \mathcal{X} is thrown away independently with probability $\frac{1}{2}$ and p is updated to $p/2$, the invariant holds after the execution of the if-then-block (line 5–7).

Now we return our attention to proving that the invariant holds after the execution of line 4 for every iteration j . The proof proceeds via induction.

Algorithm 2

Input Stream $\mathcal{D} = \langle a_1, a_2, \dots, a_m \rangle$, ε , δ

- 1: **Initialize** $p \leftarrow 1$; $\mathcal{X} \leftarrow \emptyset$; $\text{thresh} \leftarrow \frac{12}{\varepsilon^2} \log\left(\frac{8m}{\delta}\right)$
- 2: **for** $i = 1$ to m **do**
- 3: $\mathcal{X} \leftarrow \mathcal{X} \setminus \{a_i\}$
- 4: With probability p , $\mathcal{X} \leftarrow \mathcal{X} \cup \{a_i\}$
- 5: **if** $|\mathcal{X}| = \text{thresh}$ **then**
- 6: Throw away each element of \mathcal{X} with probability $\frac{1}{2}$
- 7: $p \leftarrow \frac{p}{2}$
- 8: **Output** $\frac{|\mathcal{X}|}{p}$

Base Case. After line 4, $\Pr[a_1 \in \mathcal{X}] = p$. Since $\text{thresh} > 1$, the condition in line 5 is not satisfied, therefore the desired invariant holds true.

Inductive Step. Let us assume by induction hypothesis, the desired invariant holds true after iteration $j - 1$. Note that the execution of line 3–line 4 only affects whether $a_j \in \mathcal{X}$ independently of all $a_k \in S_j \setminus a_j$. There are two cases:

- $a_j \notin S_{j-1}$, then after the execution of line 4, we have $\Pr[a_j \in \mathcal{X}] = p$.
- $a_j \in S_{j-1}$, then after line 3, we have $\Pr[a_j \in \mathcal{X}] = 0$. After line 4, we have $\Pr[a_j \in \mathcal{X}] = p$. \triangleleft

▷ **Claim 7.** $\Pr[\text{Error}_2] \leq \frac{\delta}{2}$

Proof. Given the loop invariant stated in Claim 6, we have that every element of S_m is in \mathcal{X} with probability p . In order to upper bound that the probability that $\frac{|\mathcal{X}|}{p}$ lies outside $[(1 - \varepsilon)F_0, (1 + \varepsilon)F_0]$ we will use Chernoff's bound. For this we first establish a lower bound on p . To this end, we decompose $\Pr[\text{Error}_2]$ conditioned on lower bound on p . In particular, we define the following event:

Bad: “The value of p at line 8 in Algorithm 2 is less than $\frac{\text{thresh}}{4F_0}$.”

Let $\ell = \lceil \log\left(\frac{\text{thresh}}{4F_0}\right) \rceil$. Since every value of p can be expressed as power of 2, we have that $p < 2^\ell$ if and only if $p < \frac{\text{thresh}}{4F_0}$. Observe that $\Pr[\text{Error}_2] \leq \Pr[\text{Bad}] + \Pr[\text{Error}_2 \mid \overline{\text{Bad}}]$. We will upper bound $\Pr[\text{Bad}]$ and $\Pr[\text{Error}_2 \mid \overline{\text{Bad}}]$ separately.

Bounding $\Pr[\text{Bad}]$. For $j \in [1, m]$, let Bad_j denote the event that ‘ j th iteration of the **for** loop is the first iteration where the value of p goes below 2^ℓ ’ i.e., the value of p at the end of iteration $(j - 1)$ is 2^ℓ and the value of p is $2^{\ell-1}$ at the end of iteration j . Therefore, by definition of Bad_j , we have $|\mathcal{X}| = \text{thresh}$ and $p = 2^\ell$ in line 5 of Algorithm 2. Recall that in every iteration of the loop, the value of p can decrease at most by a factor of $\frac{1}{2}$ and cannot increase. Therefore, we have $\Pr[\text{Bad}] \leq \sum_{j=1}^m \Pr[\text{Bad}_j]$. We will now compute $\Pr[\text{Bad}_j]$ for a fixed j .

For $a \in S_m$ let r_a denote the indicator random variable indicating whether a is in the set \mathcal{X} . By Claim 6 the random variables $\{r_a\}_{a \in S_m}$ are independent and for all $a \in S_m$ $\Pr[r_a = 1] = p$. Since, $|\mathcal{X}| = \sum_{a \in S_j} r_a$ we have $\mathbb{E}[|\mathcal{X}|] = \mathbb{E}\left[\sum_{a \in S_j} r_a\right] = \sum_{a \in S_j} \Pr[r_a = 1] = p \cdot |S_j| = p \cdot F_0$. Thus,

$$\begin{aligned} \Pr[\text{Bad}_j] &\leq \Pr[|\mathcal{X}| = \text{thresh} \mid p = 2^\ell] \leq \Pr[|\mathcal{X}| \geq \text{thresh} \mid p = 2^\ell] \leq 2e^{-\frac{\text{thresh}^2}{3 \cdot p F_0}} \\ &= 2e^{-\frac{\text{thresh}^2}{3 \cdot 2^\ell F_0}} \leq \frac{\delta}{4m}, \end{aligned}$$

the last inequality follows from the values of ℓ and thresh . Therefore, $\Pr[\text{Bad}] \leq \frac{\delta}{4}$.

Bounding $\Pr[\text{Error}_2 \mid \overline{\text{Bad}}]$. Similar to the above, for $a \in S_m$, let r_a denote the indicator random variable indicating whether a is in the set \mathcal{X} . By Claim 6 the random variables $\{r_a\}_{a \in S_m}$ are independent and for all $a \in S_m$, we have $\Pr[r_a = 1] = p$. Thus $|\mathcal{X}| = \sum_{a \in \mathcal{D}} r_a$ and thus $\mathbb{E}[|\mathcal{X}|] = pF_0$. Conditioned on $\overline{\text{Bad}}$, we have $p \geq \frac{\text{thresh}}{4F_0}$. Thus,

$$\begin{aligned} \Pr[\text{Error}_2 \mid \overline{\text{Bad}}] &= \Pr[(1 - \epsilon)pF_0 \leq |\mathcal{X}| \leq (1 + \epsilon)pF_0 \mid \overline{\text{Bad}}] \\ &\leq 2e^{-\frac{\epsilon^2 \text{thresh}}{12}} \quad \left[\text{Using Chernoff bound with } p \geq \frac{\text{thresh}}{4F_0} \right] \\ &\leq \frac{\delta}{4m} \leq \frac{\delta}{4}. \end{aligned} \quad \triangleleft$$

3 Bibliographic Remarks

Distinct Elements problem (or F_0 estimation problem) is one of the most investigated problem in the data streaming model [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12]. While the Distinct Elements problem has a wide range of applications in several areas of computing, it was first investigated in the algorithms community by Flajolet and Martin [9]. They provided the first approximation under the assumption of the existence of hash functions with full independence. The seminal work of Alon, Matias, and Szegedy [1] that introduced the data streaming model of computation revisited this problem as a special case of F_k estimation problem and achieved space complexity of $O(\log n)$ for $\epsilon > 1$ and constant δ . The first (ϵ, δ) approximation for Distinct Elements problem was Gibbson and Tirthpura who achieved $O(\frac{\log n}{\epsilon^2})$ space complexity [10]. Bar-Yossef, Jayram, Kumar, Sivakumar and Trevisan improved the space complexity bound to $\tilde{O}(\log n + 1/\epsilon^2)$ [2]. Subsequently, Kane, Nelson, and Woodruff achieved $O(\log n + 1/\epsilon^2)$ which is optimal in n and ϵ [12]. All the above bounds are for a fixed confidence parameter δ , which can be amplified to achieve confidence bounds for arbitrary δ by simply running $\log(1/\delta)$ -estimators in parallel and returning the median. This incurs a multiplicative factor of $\log(1/\delta)$. Błasiok designed an (ϵ, δ) approximation algorithm for F_0 estimation problem with space complexity of $O(\frac{\log \delta^{-1}}{\epsilon^2} + \log n)$, thereby matching the lower bound in all the three parameters n, ϵ and δ [4]. As is expected, every subsequent improvement added to the complexity of the algorithm or the analysis, and a majority of these work remain beyond the reach of non-experts. A crucial technical ingredient for all the works mentioned above is their careful usage of limited-independence hash functions in order to make space $\text{poly}(\log n)$. Monte Carlo-based approaches have been utilized in the context of size estimation of the union of sets, but their straightforward adaptation to the streaming setting did not seem to yield progress. Recently, a new sampling-based approach was proposed in the context of estimating the size of the union of sets in the streaming model that achieves space complexity with $\log m$ -dependence [13]. The algorithm we presented adapts ideas from this work to the context of F_0 estimation.

Abstract

We investigate the complexity of approximate *circular pattern matching* (CPM, in short) under the *Hamming* and *edit* distance. Under each of these two basic metrics, we are given a length- n text T , a length- m pattern P , and a positive integer threshold k , and we are to report all starting positions (called occurrences) of fragments of T that are at distance at most k from some cyclic rotation of P . In the decision version of the problem, we are to check if there is any such occurrence. All previous results for approximate CPM were either average-case upper bounds or heuristics, with the exception of the work of Charalampopoulos et al. [CKP⁺, JCSS'21], who considered only the Hamming distance. For the reporting version of the approximate CPM problem, under the Hamming distance we improve upon the main algorithm of [CKP⁺, JCSS'21] from $\mathcal{O}(n + (n/m) \cdot k^4)$ to $\mathcal{O}(n + (n/m) \cdot k^3 \log \log k)$ time; for the edit distance, we give an $\mathcal{O}(nk^2)$ -time algorithm. Notably, for the decision versions and wide parameter-ranges, we give algorithms whose complexities are almost identical to the state-of-the-art for standard (i.e., non-circular) approximate pattern matching:

- For the decision version of the approximate CPM problem under the Hamming distance, we obtain an $\mathcal{O}(n + (n/m) \cdot k^2 \log k / \log \log k)$ -time algorithm, which works in $\mathcal{O}(n)$ time whenever $k = \mathcal{O}(\sqrt{m \log \log m / \log m})$. In comparison, the fastest algorithm for the standard counterpart of the problem, by Chan et al. [CGKKP, STOC'20], runs in $\mathcal{O}(n)$ time only for $k = \mathcal{O}(\sqrt{m})$. We achieve this result via a reduction to a geometric problem by building on ideas from [CKP⁺, JCSS'21] and Charalampopoulos et al. [CKW, FOCS'20].
- For the decision version of the approximate CPM problem under the edit distance, the $\mathcal{O}(nk \log^3 k)$ runtime of our algorithm near matches the $\mathcal{O}(nk)$ runtime of the Landau–Vishkin algorithm [LV, J. Algorithms'89] for approximate pattern matching under edit distance; the latter algorithm remains the fastest known for $k = \Omega(m^{2/5})$. As a stepping stone, we propose an $\mathcal{O}(nk \log^3 k)$ -time algorithm for solving the Longest Prefix k' -Approximate Match problem, proposed by Landau et al. [LMS, SICOMP'98], for all $k' \in \{1, \dots, k\}$. Our algorithm is based on Tiskin's theory of *seaweeds* [Tiskin, Math. Comput. Sci.'08], with recent advancements (see Charalampopoulos et al. [CKW, FOCS'22]), and on exploiting the seaweeds' relation to *Monge matrices*.

In contrast, we obtain a conditional lower bound that suggests a polynomial separation between approximate CPM under the Hamming distance over the binary alphabet and its non-circular counterpart. We also show that a strongly subquadratic-time algorithm for the decision version of approximate CPM under edit distance would refute the Strong Exponential Time Hypothesis.

1 Introduction

Pattern matching is one of the most widely-studied problems in computer science. Given a string P of length m , known as the *pattern*, and a string T of length $n \geq m$, known as the *text*, the task is to compute all occurrences of P in T . In the standard setting, the matching relation between P and the fragments of T assumes that the leftmost and rightmost positions of the pattern are conceptually important. In many real-world applications, however, any rotation (cyclic shift) of P is a relevant pattern. For instance, in bioinformatics [3, 6, 27, 33], the position where a sequence starts can be totally arbitrary due to arbitrariness in the sequencing of a circular molecular structure or due to inconsistencies introduced into sequence databases as a result of different linearisation standards [3]. In image processing [2, 40, 41, 42], the contours of a shape may be represented through a directional chain code; the latter can be interpreted as a cyclic sequence if the orientation of the image is not important [2].

With such scenarios in mind, when matching a pattern P against a text T , one is interested in computing all fragments of T that match some rotation of P . Let us introduce necessary basic notation. The positions of a string U are numbered from 0 to $|U| - 1$, with $U[i]$ denoting the i -th letter, and $U[i..j] = U[i..j+1)$ denoting the substring $U[i] \cdots U[j]$, which is empty if $i > j$. We now formally define the circular pattern matching problem.

CIRCULAR PATTERN MATCHING (CPM)

Input: A text T of length n and a pattern P of length m .

Output: The set $\{i : T[i..i+m) = P' \text{ for some rotation } P' \text{ of } P\}$.

A textbook solution for CPM works in $\mathcal{O}(n \log \sigma)$ time (or $\mathcal{O}(n)$ time with randomization), where σ is the alphabet’s size, using the suffix automaton of $P \cdot P$ [39]. There is a simple deterministic $\mathcal{O}(n)$ -time algorithm which we discuss in the full version. Many practically fast algorithms for CPM also exist; see [17, 23, 43] and references therein. For the indexing version of the CPM problem (searching a collection of circular patterns), see [31, 32, 33].

■ **Figure 1** For a pattern $P = UV$, with $|U| = x$, we denote the rotation VU of P by $\text{rot}_x(P)$. Middle: a circular 2-mismatch occurrence of pattern P (left) at position 4 in text T . Right: a circular 2-edit occurrence of pattern P with the same rotation at position 3 in text T' (note that there is no circular 2-mismatch occurrence of P in T' at this position).

As in the standard pattern matching setting, a single surplus or missing letter in P or in T may result in many occurrences being missed. In bioinformatics, this may correspond to a single-nucleotide polymorphism; in image processing, this may correspond to data corruption. Thus, a relatively large body of works has been devoted to practically fast algorithms for *approximate* CPM; see [2, 4, 5, 7, 8, 24, 29, 30] and references therein. All previous results for approximate CPM were either average-case upper bounds or heuristics, with the exception of the work of Charalampopoulos et al. [14].

Here, like in the previous works on approximate CPM, we consider two well-known approximate matching relations of two strings U and V : the Hamming distance, denoted as $\delta_H(U, V)$ (the number of mismatches for two equal-length strings, otherwise equal to ∞), and the edit distance $\delta_E(U, V)$ (the minimum number of insertions, deletions and substitutions required to transform U to V). For two strings U and V , an integer $k > 0$, and a distance function d on strings, we write $U \stackrel{d}{=} V$ if $d(U, V) \leq k$ and $U \stackrel{d}{\approx} V$ if there exists a rotation U' of U such that $U' \stackrel{d}{=} V$. We define $\text{CircOcc}_k^d(P, T) = \{i : P \stackrel{d}{\approx} T[i..p] \text{ for some } p \geq i\}$; we call it the set of *circular k -mismatch (k -edit) occurrences of P in T* if $d = \delta_H$ ($d = \delta_E$, respectively). We omit the d -superscript when it is clear from the context. We next formally define four variants of k -approximate CPM; see Figure 1 for an example.

k -APPROXIMATE CPM: k -MISMATCH CPM AND k -EDIT CPM

Input: A text T of length n , a pattern P of length m , a positive integer k , and a distance function d : $d = \delta_H$ for k -Mismatch CPM and $d = \delta_E$ for k -Edit CPM.

Output: (**Reporting**) $\text{CircOcc}_k^d(P, T)$.
 (**Decision**) Any position $i \in \text{CircOcc}_k^d(P, T)$, if it exists.

Our upper bounds for k -Mismatch CPM. A summary of the best previous and our new worst-case upper bounds on approximate CPM for strings over a polynomially-bounded integer alphabet (we omit “polynomially-bounded” henceforth) is provided in Table 1.

■ **Table 1** Comparison of previous upper bounds and our results on k -approximate CPM.

Distance Metric	Time Complexity	Version	Reference
Hamming distance	$\mathcal{O}(nk)$	reporting	[14]
	$\mathcal{O}(n + (n/m) \cdot k^4)$		
	$\mathcal{O}(n + (n/m) \cdot k^3 \log \log k)$	reporting	this work
	$\mathcal{O}(n + (n/m) \cdot k^2 \log k / \log \log k)$	decision	
Edit distance	$\mathcal{O}(nk^2)$	reporting	this work
	$\mathcal{O}(nk \log^3 k)$	decision	

35:4 Approximate Circular Pattern Matching

In Section 2 we prove the following results.

► **Theorem 1.** *The reporting version of k -Mismatch CPM for strings over an integer alphabet can be solved in $\mathcal{O}(n + (n/m) \cdot k^3 \log \log k + \text{Output})$ time.*

► **Theorem 2.** *The decision version of k -Mismatch CPM for strings over an integer alphabet can be solved in $\mathcal{O}(n + (n/m) \cdot k^2 \log k / \log \log k)$ time.*

Our upper bounds for k -Edit CPM. A proof of the following theorem, based on the classic Landau–Vishkin algorithm [38], is given in Section 3.

► **Theorem 3.** *The reporting version of k -Edit CPM for strings over an integer alphabet can be solved in $\mathcal{O}(nk^2)$ time.*

We reduce the decision version of k -Edit CPM to the following problem.

LONGEST PREFIX k -APPROXIMATE MATCH (k -LPAM)

Input: A text T of length n and a pattern P .

Output: An array $\text{LPref}_k[0..n]$ such that $\text{LPref}_k[i]$ is the length of the longest prefix of P that matches a prefix of $T[i..n)$ with at most k edits.

Specifically, we introduce a problem called *All- k -LPAM* that consists in solving k' -LPAM for all $k' \in [0..k]$. We show that k -Edit CPM can be reduced to All- k -LPAM on the same pattern and text and on the reversed pattern and text. Landau et al. [37] gave an $\mathcal{O}(nk)$ -time solution to k -LPAM, which provides an $\mathcal{O}(nk^2)$ -time solution to All- k -LPAM. In Section 4 we show the following result for All- k -LPAM (Theorem 4) which implies Theorem 5; All- k -LPAM can find further applications in approximate pattern matching; for example see [9].

► **Theorem 4.** *All- k -LPAM for strings over an integer alphabet can be solved in $\mathcal{O}(nk \log^3 k)$ time.*

► **Theorem 5.** *The decision version of k -Edit CPM for strings over an integer alphabet can be solved in $\mathcal{O}(nk \log^3 k)$ time.*

The complexities of our algorithms for the decision versions of k -Mismatch and k -Edit CPM match, up to $\log^{\mathcal{O}(1)} k$ factors, the complexities of some of the fastest known algorithms for pattern matching with up to k mismatches [12, 15, 21, 26] and edits [38], respectively.

In [37], an algorithm for a weaker problem of computing, given two strings U and V each of length at most n , the rotation of U with the minimum edit distance to V is given. The algorithm works in $\mathcal{O}(ne)$ time, where e is the minimum edit distance achieved.

Our conditional lower bounds. We reduce known problems to approximate CPM, as shown in Table 2.

■ **Table 2** Our conditional lower bounds for approximate CPM for alphabets of constant size.

Problem	Conditioned on	Complexity	Reference
Mismatch-CPM (unbounded)	BJI	$\Omega(n^{1.5-\varepsilon})$ for all const. $\varepsilon > 0$	Theorem 30
k -Edit CPM (decision)	SETH	$\Omega(n^{2-\varepsilon})$ for all const. $\varepsilon > 0$	Theorem 31

For the Hamming distance, we consider the Mismatch-CPM problem where the number of allowed mismatches is unbounded (see Section 5 for a precise definition). The breakthrough work constructing a Binary Jumbled Index (BJI) in $\mathcal{O}(n^{1.859})$ time [13] was very recently improved to $\mathcal{O}(n^{1.5} \log^{\mathcal{O}(1)} n)$ time [18]. We show that obtaining an $\mathcal{O}(n^{1.5-\varepsilon})$ -time algorithm, for any constant $\varepsilon > 0$, for Mismatch-CPM over the binary alphabet would require a further improvement to BJI. A similar problem of (non-circular) pattern matching with mismatches has a classic $\mathcal{O}(n \log n)$ -time solution for constant-size alphabets using convolutions [22]; and the fastest known solution for a general alphabet works in $\mathcal{O}(n^{1.5} \sqrt{\log n})$ time [1, 36]. Our conditional lower bound for k -Edit CPM is based on the conditional hardness of computing the edit distance of two binary strings [10], which in turn is based on the Strong Exponential Time Hypothesis (SETH) [34]. It implies conditional optimality of our algorithm for the decision version of k -Edits CPM for a general $k \leq n$ up to a subpolynomial factor.

The PILLAR model. For k -Mismatch CPM, we work in the PILLAR model that was introduced in [15] with the aim of unifying approximate pattern matching algorithms across different settings. In this model, we assume that the following primitive PILLAR operations can be performed efficiently, where the argument strings are substrings of strings in a collection \mathcal{X} , represented via handles:

- **Extract**(S, ℓ, r): Retrieve string $S[\ell..r]$.
- **LCP**(S, T), **LCP_R**(S, T): Compute the length of the longest common prefix/suffix of S, T .
- **IPM**(S, T): Assuming that $|T| \leq 2|S|$, compute the starting positions of all exact occurrences of S in T , expressed as an arithmetic sequence.
- **Access**(S, i): Retrieve the letter $S[i]$.
- **Length**(S): Compute the length $|S|$ of the string S .

In fact, in the standard setting, where the strings are given explicitly and are over an integer alphabet, all primitive PILLAR operations can be performed in $\mathcal{O}(1)$ time after a linear-time preprocessing. The runtime of algorithms in this model can be expressed in terms of the number of primitive PILLAR operations. (Any extra time required by our algorithms is explicitly specified.)

In the full version we obtain fast algorithms for k -Mismatch CPM in the internal, dynamic and fully compressed setting, by using Theorems 1 and 2 with known implementations of the primitive PILLAR operations in these settings.

2 k -Mismatch CPM

For a string S and an integer $x \leq |S|$, we denote $\text{rot}_x(S) = S[x..|S|] \cdot S[0..x]$. For $i \in [0..|S| - m]$, we denote $S^{(i)} = S[i..i + m]$. Also, we denote the set of standard (non-circular) k -mismatch occurrences of P in T by $\text{Occ}_k(P, T) = \{i \in [0..n - m] : T^{(i)} =_k P\}$.

Let $P = P_1 P_2$, where $|P_1| = \lfloor m/2 \rfloor$. Each circular k -mismatch occurrence of P in T implies a standard k -mismatch occurrence of at least one of P_1 and P_2 . Henceforth, we assume, without loss of generality, that it implies a k -mismatch occurrence of P_1 , as the remaining case is symmetric. Our goal is to consider all k -mismatch occurrences of P_1 in T as anchors for computing circular k -mismatch occurrences of P in T . We call P_1 *the sample*.

By the so-called standard trick, we will consider $\mathcal{O}(n/m)$ substrings of T of length $\mathcal{O}(m)$ and process each of them separately. We denote one such substring by T' . All positions (occurrences) of the sample can be efficiently computed in such a small *window* T' :

► **Theorem 6** ([15, Main Theorems 5 and 8]). *Given a text T' and a pattern P_1 , satisfying $|T'| = \mathcal{O}(|P_1|)$, we can compute a representation of the set $\text{Occ}_k(P_1, T')$ as $\mathcal{O}(k^2)$ pairwise disjoint arithmetic progressions in $\mathcal{O}(k^2 \log \log k)$ time plus $\mathcal{O}(k^2)$ PILLAR operations.¹*

We want to find in T extensions of occurrences of P_1 in T' , which approximately match some rotation of P . Consider only rotations of P of the form YP_1X , where $P = P_1XY$. Define the set of circular k -mismatch occurrences i of P in T that imply a k -mismatch standard occurrence of P_1 in a substring $T' = T[a..b]$ as follows (such occurrences are *anchored* in (P_1, T')):

$$\text{Anchored}_k(P, T, P_1, T') = \{i : T^{(i)} =_k YP_1X, P = P_1XY, i + |Y| - a \in \text{Occ}_k(P_1, T')\}.$$

Our algorithms compute a superset of $\text{Anchored}_k(P, T, P_1, T')$ that may also contain other circular k -mismatch occurrences of P in T (some of the ones that contain a k -mismatch occurrence of P_2). Let $A = \text{Occ}_k(P_1, T')$, and recall that this refers to standard k -mismatch occurrences.

2.1 Few k -mismatch Occurrences of the Sample: $|A| = \mathcal{O}(k)$

We assume that $|A| = \mathcal{O}(k)$. Let us denote by $\text{PAIRMATCH}_k(T, P, i, j)$ the set of all circular k -mismatch occurrences of P in T such that position i in T is aligned with position j in P :

$$\text{PAIRMATCH}_k(T, P, i, j) = \{p \in [i - m + 1 .. i] : T^{(p)} =_k \text{rot}_x(P), i - p \equiv j - x \pmod{m}\}.$$

In particular $\text{PAIRMATCH}_k(T, P, i, 0)$ is the set of circular k -mismatch occurrences of P such that the first position of P is aligned with position i in T .

The following lemma was shown without explicitly mentioning the PILLAR model.

► **Lemma 7** ([14, see Lemma 10]). *$\text{PAIRMATCH}_k(T, P, i, j)$ can be computed in $\mathcal{O}(k)$ time in the PILLAR model for any given k, i, j , with the output represented as $\mathcal{O}(k)$ intervals.*

► **Lemma 8.** *Given $A = \text{Occ}_k(P_1, T')$ of size $\mathcal{O}(k)$, a superset of $\text{Anchored}_k(P, T, P_1, T')$, represented as $\mathcal{O}(k^2)$ intervals, can be computed in $\mathcal{O}(k^2)$ time in the PILLAR model. The computed superset contains only circular k -mismatch occurrences of P in T .*

Proof. Suppose that $T' = T[a..b]$. We then have

$$\text{Anchored}_k(P, T, P_1, T') \subseteq \bigcup_{i \in A} \text{PAIRMATCH}_k(T, P, i + a, 0) \subseteq \text{CircOcc}_k(P, T).$$

By the hypothesis $|A| = \mathcal{O}(k)$, the result, represented as a union of $\mathcal{O}(k^2)$ intervals, can be computed in $\mathcal{O}(k^2)$ time in the PILLAR model by means of Lemma 7. ◀

2.2 Many k -mismatch Occurrences of the Sample: $|A| > 864k$

We assume that $|A| = |\text{Occ}_k(P_1, T')| > 864k$. By [15], these k -mismatch occurrences imply approximate periodicity in both P_1 and the portion of T' spanned by k -mismatch occurrences of P_1 . We show that, except for $\mathcal{O}(k^2)$ intervals of circular k -mismatch occurrences of P that we can compute using $\mathcal{O}(k)$ calls to PAIRMATCH_k as in Section 2.1, our problem reduces to matching length- m substrings of an approximately periodic substring V in T and of an

¹ When referring to statements of [15], we use their numbering in the full (arxiv) version of the paper.

approximately periodic substring U in P^2 with aligned approximate periodicity. Afterwards, testing a match of two length- m substrings for U and V reduces to the test only on positions breaking periodicity, called *misperiods*, since the equality on other positions is guaranteed due to common approximate periodicities. The number of misperiods in U and V is only $\mathcal{O}(k)$, so the complexity of our algorithms, in terms of PILLAR operations, depends only on k .

By S^p we denote the concatenation of p copies of a string S . A string Q is called primitive if $Q = B^p$ for a string B and a positive integer p implies that $p = 1$. We introduce the following problem.

PERIODICSUBSTRINGMATCH(U, V)

Input: Positive integers m, k , and q , an integer $r \in [0..q)$, and strings U, V , and Q such that $m \leq |U|, |V| \leq 2m$, $q = |Q|$, and U, V are at Hamming distance $\mathcal{O}(k)$ from prefixes of $Q^\infty, (\text{rot}_r(Q))^\infty$, respectively.

Output: The set of positions p in U for which there exists a position x in V such that $U^{(p)} =_k V^{(x)}$ and $p - x \equiv r \pmod{q}$.

Our goal is to reduce k -Mismatch CPM in this case to PERIODICSUBSTRINGMATCH. To this end, we use the idea of repetitive regions from [15].

► **Definition 9.** A k -repetitive region in a string S of length m is a substring R of S of length $|R| \geq 3m/8$ for which there exists a primitive string Q such that

$$|Q| \leq m/(128k) \text{ and } \delta_H(R, Q^\infty[0..|R|]) = \lceil 8k|R|/m \rceil.$$

The following lemma is a simplified version of a lemma from [15] with one repetitive region.

► **Lemma 10** ([15, see Lemma 3.11]). Given a pattern P of length m , a text T of length $n \leq \frac{3}{2}m$, and a positive integer threshold $k \leq m$, if the pattern P contains a k -repetitive region, then $|\text{Occ}_k(P, T)| \leq 864k$.

Intuitively, in our main lemma in this section (Lemma 12), we show that if P_1 has many k -mismatch occurrences in T' , then each circular k -mismatch occurrence of P in T that is an element of $\text{Anchored}_k(P, T, P_1, T')$ is: (a) either computed in an instance of PERIODICSUBSTRINGMATCH; or (b) implies a k -mismatch occurrence of one of at most two k -repetitive regions of $P_2P_1P_2$. The occurrences of the second type can be computed using $\mathcal{O}(k)$ calls to PAIRMATCH $_k$ by viewing k -repetitive regions as samples and applying Lemma 10 to bound the number of k -mismatch occurrences.

In the proof of Lemma 12 we use the following theorem from [15]; part 1 follows from [15, Theorem 3.1] (existence of Q) and [15, Lemmas 3.8, 3.11, 3.14, and 4.4] (computation of Q), whereas the remaining parts are due to [15, Main Theorem 5].

► **Theorem 11** ([15]). Assume that we are given a pattern P of length m , a text T of length $n \leq \frac{3}{2}m$, and a positive integer threshold $k \leq m$. If $|\text{Occ}_k(P, T)| > 864k$ and T starts and ends with k -mismatch occurrences of P , that is, $0, |T| - m \in \text{Occ}_k(P, T)$, then:

1. there is a substring Q of P satisfying $|Q| \leq m/(128k)$ and $\delta_H(P, Q^\infty[0..|P|]) < 2k$, which can be computed in $\mathcal{O}(k)$ time in the PILLAR model;
2. each element of $\text{Occ}_k(P, T)$ is a multiple of $|Q|$;
3. $\delta_H(T, Q^\infty[0..n]) \leq 6k$;
4. $\text{Occ}_k(P, T)$ can be decomposed into $\mathcal{O}(k^2)$ arithmetic progressions with difference $|Q|$.

► **Lemma 12** (Reduction to PERIODICSUBSTRINGMATCH). *If we have $|T'| \leq \lfloor \frac{3}{4}m \rfloor$ and $|\text{Occ}_k(P_1, T')| > 864k$, then there is a superset of $\text{Anchored}_k(P, T, P_1, T')$ containing circular k -mismatch occurrences of P in T that is a union of $\mathcal{O}(k^2)$ intervals and of the output of PERIODICSUBSTRINGMATCH with U and V being substrings of T and P^2 , respectively. The intervals and the input to the PERIODICSUBSTRINGMATCH call can be computed in $\mathcal{O}(k^2 \log \log k)$ time plus $\mathcal{O}(k^2)$ PILLAR operations.*

Proof. We apply Theorem 11 to P_1 and the part T'' of T' spanned by the k -mismatch occurrences in $\text{Occ}_k(P_1, T')$, obtaining a short primitive string Q . Consider the occurrence of P_1 at position $|P_2|$ of $P_2P_1P_2$. Let us extend this substring to the right, trying to accumulate enough mismatches with a prefix of Q^∞ in order to reach the threshold specified in Definition 9, which is $\Theta(k)$. In order to compute the next mismatch, it suffices to perform an LCP query between the remaining suffix of $P_2P_1P_2$ and some rotation of Q^∞ . An analogous process was described in detail in [15, Lemma 4.4], and the fact that the PILLAR model supports the described LCP queries is shown in [15, Corollary 2.9]. If we manage to accumulate enough mismatches, we call the resulting k -repetitive region R_R . We perform the same process by extending this occurrence of P_1 to the left, possibly obtaining a k -repetitive region R_L . Then, we let V be the shortest substring $(P_2P_1P_2)[v..v']$ of $P_2P_1P_2$ that spans both R_L (or P_2P_1 if R_L does not exist) and R_R (or P_1P_2 if R_R does not exist). Let us observe that V is at distance at most $2 \cdot \lceil 8km/m \rceil = 16k$ from a prefix of $(\text{rot}_{r(P)}(Q))^\infty$, where $r(P) = v - |P_2| \pmod{|Q|}$, by the definition of k -repetitive regions and the fact that $|R_R|, |R_L| \leq m$. Moreover, obviously, $|V| \leq 2m$.

The rotations of P that contain P_1 are in one-to-one correspondence with the length- m substrings of $P_2P_1P_2$. Each such substring either contains (at least) one of R_L and R_R or is contained in V . We now show that we can efficiently compute circular k -mismatch occurrences of P that imply k -mismatch occurrences of either R_L or R_R (if they exist) using the tools that developed in Section 2.1. We focus on R_R as R_L can be handled symmetrically. Due to Lemma 10, R_R has $\mathcal{O}(k)$ k -mismatch occurrences in T' , and they can be found in $\mathcal{O}(k^2 \log \log k)$ time plus $\mathcal{O}(k^2)$ PILLAR operations using Theorem 6. For each such occurrence at some position i of T , we perform a call PAIRMATCH_k as in Lemma 8.

We are left with computing elements of $\text{Anchored}_k(P, T, P_1, T')$ corresponding to k -mismatch occurrences of length- m substrings of V in T in the case where $|V| \geq m$. Let us take the considered occurrence $T[a..b]$ of T'' in T , which is at distance at most $6k$ from a prefix of Q^∞ , and extend it to the right until either of the following three conditions is satisfied: (a) we reach the end of T ; (b) we have appended $\lceil m/2 \rceil$ letters; or (c) the resulting substring has $18k$ additional mismatches with the same-length prefix of Q^∞ . We extend the obtained substring to the left until either of the following three conditions is satisfied: (a) we reach the beginning of T ; (b) we have prepended $\lceil m/2 \rceil$ letters; or (c) the prepending substring has $18k$ mismatches with the same-length suffix of $Q^{|T|}$. We set the obtained substring $T[u..u']$ of T to be U . We observe that $|U| \leq 2m$ (since $\lfloor 3m/4 \rfloor \geq |T'| > 864k \Rightarrow m > 1152$ and $|U| \leq |T'| + 2 \lceil m/2 \rceil \leq 7m/4 + 2$) and U is at distance at most $6k + 2 \cdot 18k = 42k$ from a prefix of $(\text{rot}_{r(T)}(Q))^\infty$, where $r(T) = u - a \pmod{|Q|}$. If $|U| < m$, we do not construct the instance of PERIODICSUBSTRINGMATCH.

In the call to PERIODICSUBSTRINGMATCH, we set $Q := \text{rot}_{r(T)}(Q)$ and $r := (r(P) - r(T)) \pmod{|Q|}$. Now, since Q is primitive, it does not match any of its non-trivial rotations. Further, as we have at least $128k - 42k - 1$ (resp. $128k - 16k - 1$) exact occurrences of Q in any length- m fragment of U (resp. V), the periodicities must be synchronized in any circular k -mismatch occurrence. Hence, for any $p \in \text{Anchored}_k(P, T, P_1, T')$ that corresponds to $U^{(p)} =_k V^{(x)}$ we must have $p + r(T) \equiv x + r(P) \pmod{|Q|}$, and hence $p - x \equiv r(P) - r(T) \equiv r \pmod{|Q|}$.

It suffices to show that there is no position $i \in \text{Anchored}_k(P, T, P_1, T')$ such that $T^{(i)}$ is at distance at most k from a substring of V and $[i..i+m] \not\subseteq [u..u']$. Suppose that this is the case towards a contradiction, and assume without loss of generality that $i < u$; the other case is symmetric. We notice that this can only be the case if we stopped extending to the left because we accumulated enough mismatches. Further, let the implied k -mismatch occurrence of P_1 start at some position t of T , let x be an integer such that $\min_y \delta_H(V^{(y)}, T^{(i)}) = \delta_H(V^{(x)}, T^{(i)})$, and let F be the length- $(t-i)$ suffix of $Q^{|T|}$, i.e., $Q^{|T|}[[T] \cdot |Q| - (t-i) .. |T| \cdot |Q|]$. Then, via the triangle inequality, we have

$$\begin{aligned} \delta_H(V^{(x)}, T^{(i)}) &\geq \delta_H(V^{(x)}[0..t-i], T[i..t]) \\ &\geq \delta_H(T[i..t], F) - \delta_H(F, V^{(x)}[0..t-i]) \geq 18k - 16k > k, \end{aligned}$$

thus obtaining a contradiction. This completes the proof of this lemma. \blacktriangleleft

2.3 The Reporting Version of k -Mismatch CPM

In this section, we give a solution to PERIODICSUBSTRINGMATCH. Let us recall the notion of misperiods that was introduced in [14].

► **Definition 13.** A position a in S is a misperiod with respect to a substring Q of S if $S[a] \neq Q^\infty[a]$. We denote the set of misperiods by $\text{Misp}(S, Q)$.

In $\mathcal{O}(k)$ time in the PILLAR model we can compute the sets $I = \text{Misp}(U, Q)$ and $J = \text{Misp}(V, \text{rot}_r(Q))$. This is due to [15, Corollary 2.9], which allows us to answer queries of the form $\text{LCP}(S[i..j], Q^\infty[a..b])$ in $\mathcal{O}(1)$ time in the PILLAR model. For an integer z , let us denote $\mathbf{W}_z = [z..z+m)$ (a window of size m). We define $\text{Mispers}(i, j) = |\mathbf{W}_i \cap I| + |\mathbf{W}_j \cap J|$.

The following problem is a simpler version of PERIODICSUBSTRINGMATCH that was considered in [14]. (Actually, [14] considered a slightly more restricted problem which required that no two misperiods in $U^{(p)}$ and $V^{(x)}$ are aligned and computed a superset of its solution that corresponds exactly to the statement below.)

PERIODICPERIODICMATCH(U, V)

Input: Same as in PERIODICSUBSTRINGMATCH

Output: The set of positions p in U for which there exists a position x in V such that $U^{(p)} =_k V^{(x)}$, $p - x \equiv r \pmod{q}$, and $\text{Mispers}(p, x) \leq k$.

For an integer set A and an integer r , let $A \oplus r = \{a + r : a \in A\}$. An *interval chain* for an interval I and non-negative integers a and q is a set of the form $I \cup (I \oplus q) \cup (I \oplus 2q) \cup \dots \cup (I \oplus aq)$. Here q is called the *difference* of the interval chain.

► **Lemma 14** ([14, Lemma 15]). Given sets $I = \text{Misp}(U, Q)$ and $J = \text{Misp}(V, \text{rot}_r(Q))$, we can compute in $\mathcal{O}(k^2)$ time a solution to PERIODICPERIODICMATCH represented as $\mathcal{O}(k^2)$ interval chains, each with difference q .

Next we observe that if $U^{(p)} =_k V^{(x)}$, then either some two misperiods in $U^{(p)}$ and $V^{(x)}$ are aligned, or the total number of misperiods in these substrings is at most k .

► **Observation 15.** We have $\text{PERIODICSUBSTRINGMATCH}(U, V) =$

$$\text{PERIODICPERIODICMATCH}(U, V) \cup \bigcup_{i \in I, j \in J} \text{PAIRMATCH}_k(U, V, i, j).$$

By the observation, there are $\mathcal{O}(k^2)$ instances of PAIRMATCH_k , each taking $\mathcal{O}(k)$ time in the PILLAR model, and $\text{PERIODICPERIODICMATCH}$ can be solved in $\mathcal{O}(k^2)$ time. This results in total time complexity $\mathcal{O}(k^3)$ for $\text{PERIODICSUBSTRINGMATCH}$. Together with the previous reductions in Lemmas 8 and 12, this leads to Theorem 1. We only need to transform the output from a union of intervals and interval chains to a list of circular k -mismatch occurrences without duplicates. A full proof of Theorem 1 can be found in the full version.

2.4 A Faster Algorithm for the Decision Version of k -Mismatch CPM

Two aligned misperiods can correspond to zero or one mismatch, while two misaligned misperiods always yield two mismatches. Let us recall that $I = \text{Misp}(U, Q)$ and $J = \text{Misp}(V, \text{rot}_r(Q))$. We define the following *mismatch correcting* function:

$$\nabla(i, j) = \begin{cases} 0 & \text{if } (i, j) \notin I \times J, \text{ otherwise:} \\ 1 & \text{if } U[i] \neq V[j], \\ 2 & \text{if } U[i] = V[j]. \end{cases}$$

This function corrects *surplus mismatches*. Let $\text{Surplus}(i, j) = \sum_{t=0}^{m-1} \nabla(i+t, j+t)$.

DECISION $\text{PERIODICSUBSTRINGMATCH}(U, V)$

Input: Same as before, with the sets I, J stored explicitly.

Output: Any position $p \in [0..|U| - m]$ such that $\text{Mispers}(p, x) - \text{Surplus}(p, x) \leq k$ for some $x \in [0..|V| - m]$ such that $p - x \equiv r \pmod{q}$.

We consider an $(|U| - m + 1) \times (|V| - m + 1)$ grid \mathcal{G} . The δ -th diagonal in \mathbb{Z}^2 consists of points (i, j) that satisfy $i - j = \delta$. It is called an *essential* diagonal if $\delta = i - j$ for some $i \in I, j \in J$ and $\delta \equiv r \pmod{q}$. A point (i, j) on an essential diagonal is called *essential* if $i \in I$ and $j \in J$. Let us observe that only essential points influence the function Surplus , and the number of these points is $\mathcal{O}(k^2)$. This implies the following lemma using a simple 1D sweeping algorithm.

► **Lemma 16** (Compact representation of Mispers and Surplus). *In $\mathcal{O}(k^2 \log \log k)$ time we can:*

- (a) *Partition the grid \mathcal{G} by $\mathcal{O}(k)$ vertical and $\mathcal{O}(k)$ horizontal lines into $\mathcal{O}(k^2)$ disjoint rectangles such that for each point (i, j) in a single rectangle the value $\text{Mispers}(i, j)$ is the same. Each rectangle stores the value $\text{Mispers}(i, j)$ for an arbitrary point (i, j) that it contains.*
- (b) *Partition all essential diagonals in \mathcal{G} into $\mathcal{O}(k^2)$ pairwise disjoint diagonal segments, such that for each point (i, j) in a single segment the value $\text{Surplus}(i, j)$ is the same. Each segment stores the value $\text{Surplus}(i, j)$ for an arbitrary point (i, j) that it contains.*

Proof. Partitioning (a): We partition the first axis (second axis) into axis segments such that for all i in the same segment, the set $\mathbf{W}_i \cap I$ ($\mathbf{W}_j \cap J$, respectively) is the same. Then we create rectangles being Cartesian products of the segments.

Partitioning of an axis is performed with a 1D sweep; we describe it in the context of the first axis. For each $i \in I$, we create an event at position $i - m + 1$ where the misperiod i is inserted and an event at position $i + 1$ (if $i + 1 \leq |U| - m + 1$) where it is removed. We can now sort all events in $\mathcal{O}(k \log \log k)$ time using integer sorting [28] and process them in order,

storing the number of misperiods. For all i in a segment without events, the set $\mathbf{W}_i \cap I$ is the same. We obtain $\mathcal{O}(k)$ segments on each axis which yields $\mathcal{O}(k^2)$ rectangles. Part (a) works in $\mathcal{O}(k^2)$ time.

Partitioning (b): First we bucket sort essential points by (essential) diagonals using integer sorting. On each essential diagonal, we sort the essential points bottom-up and perform the same kind of 1D sweep as in (a), using ∇ to compute the weights of the events. The whole algorithm works in $\mathcal{O}(k^2 \log \log k)$ time. ◀

We assume that the grid \mathcal{G} is partitioned by selected horizontal and vertical lines into disjoint rectangles, called *cells*. These cells and some diagonal segments are weighted. Let us denote by $\text{cell}(i, j)$ and $\text{diag}(i, j)$ the weight of the cell and the diagonal segment containing (i, j) , respectively. In the following problem, we care only about points on diagonal segments.

DIAGONALSEGMENTS

Input: A grid partitioned by $\mathcal{O}(k)$ vertical and $\mathcal{O}(k)$ horizontal lines into $\mathcal{O}(k^2)$ weighted rectangles, called cells, and $\mathcal{O}(k^2)$ pairwise disjoint weighted diagonal line segments, all parallel to the line that passes through $(0, 0)$ and $(1, 1)$.

Output: Report a point $(x, y) \in \mathbb{Z}^2$ on some diagonal line segment with minimum $\text{val}(x, y) := \text{cell}(x, y) + \text{diag}(x, y)$.

■ **Figure 2** The weight of the distinguished cell is equal to $\text{Mispers}(i, j)$ for all points (i, j) in that cell. The diagonals are partitioned into segments. The weight of a single diagonal segment is equal to $-\text{Surplus}(i, j)$ for all points (i, j) that lie on that segment. In DIAGONALSEGMENTS we are to find any point (i, j) on some diagonal that minimizes the sum of the weight of its cell and of its diagonal segment, i.e., $\text{Mispers}(i, j) - \text{Surplus}(i, j)$. To this end, it suffices to consider endpoints of diagonal segments and crossings of diagonal segments with rectangles' boundaries.

An intuition of the solution to DIAGONALSEGMENTS is shown in Figure 2.

► **Lemma 17.** *The DIAGONALSEGMENTS problem can be solved in $\mathcal{O}(k^2 \log k / \log \log k)$ time.*

Proof. A sought point (x, y) that minimizes $\text{val}(x, y)$ either (1) is an endpoint of a diagonal segment or (2) lies on an intersection of a diagonal segment and an edge of a cell.

▷ **Claim 18.** Given $\mathcal{O}(p)$ horizontal lines and $\mathcal{O}(p)$ points, one can compute for each point the nearest line above it in $\mathcal{O}(p \log \log p)$ time.

Proof. We create a list of integers containing the vertical coordinates of all queried points and of all lines. Then we sort all of them in $\mathcal{O}(p \log \log p)$ time. The required answers can then be retrieved by a simple traversal of the sorted list. ◀

35:12 Approximate Circular Pattern Matching

In case (1) it suffices to identify, for all end points of all diagonal segments, the cells which they belong to. Let us assume that vertical and horizontal lines partition the grid into columns and rows, respectively. Then each cell can be uniquely identified by its column and row. With Claim 18 we can compute in $\mathcal{O}(k^2 \log \log k)$ time, for all queried points, the rows they belong to; the computation of columns is symmetric.

In case (2), let us consider intersections with horizontal edges; the intersections with vertical edges can be handled symmetrically. Assume x is the horizontal coordinate. We perform an affine transformation of the plane $(x, y) \mapsto (y - x, y)$ after which diagonal line segments become vertical, but horizontal line segments remain horizontal. The sought points can be computed using the following claim in $\mathcal{O}(k^2 \log k / \log \log k)$ time.

▷ **Claim 19.** Given s vertical and horizontal weighted line segments such that no two line segments of the same direction intersect, an intersection point of a vertical and a horizontal line segment with minimum total weight can be computed in $\mathcal{O}(s \log s / \log \log s)$ time.

Proof. We perform a left-to-right line sweep. The events in the sweep are the beginnings and endings of horizontal line segments and vertical line segments. The events can be sorted by their x -coordinates in $\mathcal{O}(s \log \log s)$ time with integer sorting. The horizontal line segments are stored using a dynamic predecessor data structure [46], and their weights in the same order are stored in a dynamic RMQ data structure of size $\mathcal{O}(s)$ that supports insertions, deletions, and range minimum queries in amortized $\mathcal{O}(\log s / \log \log s)$ time [11]. This way, when considering a vertical line segment, we can compute the minimum-weight horizontal line segment that intersects it in $\mathcal{O}(\log s / \log \log s)$ time. ◀

This concludes the solution to DIAGONALSEGMENTS. ◀

► **Theorem 2.** *The decision version of k -Mismatch CPM for strings over an integer alphabet can be solved in $\mathcal{O}(n + (n/m) \cdot k^2 \log k / \log \log k)$ time.*

Proof. Assume that P_1 is the sample. We use the so-called standard trick that covers T by a collection of its substrings T' of length $\lfloor \frac{3}{4}m \rfloor$ starting at positions divisible by $\lfloor \frac{1}{4}m \rfloor$. The following computations are performed for each T' .

In this paragraph all complexities are stated in the PILLAR model. We use Theorem 6 to compute a representation of the set $A = \text{Occ}(P_1, T')$. If $|A| \leq 864k$, we can use Lemma 8 that outputs $\mathcal{O}(k^2)$ intervals of circular k -mismatch occurrences in $\mathcal{O}(k^2)$ time. Otherwise, we apply Lemma 12 which in $\mathcal{O}(k^2 \log \log k)$ time outputs $\mathcal{O}(k^2)$ intervals of circular k -mismatch occurrences and returns an instance of PERIODICSUBSTRINGMATCH. Next we use the geometric interpretation of PERIODICSUBSTRINGMATCH. The weight of a cell is the value $\text{Mispers}(i, j)$ common to all points (i, j) in this cell. Similarly, the weight of a diagonal segment equals $-\text{Surplus}(i, j)$, common to all points in this segment (it is the number of surplus misperiods which we have to subtract). These values are computed in $\mathcal{O}(k^2 \log \log k)$ time in Lemma 16. Now, the decision version of the PERIODICSUBSTRINGMATCH problem is reduced to the computation of the minimum value of $\text{Mispers}(i, j) - \text{Surplus}(i, j)$, which corresponds to the sum of weights of a cell and diagonal segment meeting at the same point (i, j) . The decision version of PERIODICSUBSTRINGMATCH can be reduced in $\mathcal{O}(k^2 \log \log k)$ time to one instance each of the DIAGONALSEGMENTS (if the sought point is on a diagonal segment) and PERIODICPERIODICMATCH (in the opposite case) problems. The thesis follows from Lemmas 14 and 17. ◀

► **Remark 20.** Using this geometric approach, the reporting version of k -Mismatch CPM can also be solved in $\mathcal{O}(n + (n/m) \cdot k^2 \log^{\mathcal{O}(1)} k + k \cdot \text{Output})$ time.

3 *k*-Edit CPM

In the proof of the following lemma, we rely on the Landau–Vishkin algorithm [38]; cf. Figure 3a for an illustration. The details can be found in the full version.

► **Lemma 21.** *Given a text T of length n , a pattern P of length m , and an integer $k > 0$, we can compute in $\mathcal{O}(k^2)$ time in the PILLAR model an $\mathcal{O}(k^2)$ -size representation of the edit distance between all pairs of prefixes of T and P that are at edit distance at most k , that is, the set $LV := \{(a, b, d) \in (0..n] \times (0..m] \times [0..k] : \delta_E(T[0..a], P[0..b]) = d \leq k\}$. Our representation of LV consists of $\mathcal{O}(k^2)$ sets of the form $\{(a + \Delta, b + \Delta, d) : \Delta \in [0..x]\}$.*

(a) Example for Lemma 21:
 $T = abaabaa$, $P = aabaabaa$, $k = 2$.

(b) Notation used in the proof of Lemma 22.

■ **Figure 3** Illustrations for Lemmas 21 and 22.

► **Lemma 22.** *Given a text T of length n , a pattern P of length m , an integer $k > 0$, and a position j of T , after $\mathcal{O}(nk^2)$ preprocessing we can compute in $\mathcal{O}(k^2)$ time in the PILLAR model all positions $i \in \text{CircOcc}_k(P, T) \cap [0..j]$ such that $\delta_E(T[i..j], P_2) + \delta_E(T[j..r], P_1) \leq k$ for some position r of T and some strings P_1 and P_2 that satisfy $P = P_1P_2$, represented as $\mathcal{O}(k^2)$ intervals, possibly with duplicates.*

Proof. We start with the calculation of the compact representation of LV from Lemma 21 for the reversals of strings $T[0..j]$ and P , and k . Next, for each element $\{(a + \Delta, b + \Delta, d) : \Delta \in I\}$ of this compact representation, we will calculate an interval $I' \subseteq I$ such that positions from $\{j - a - \Delta : \Delta \in I'\}$ are in $\text{CircOcc}_k(P, T)$.

From the definition of LV we know that for any $\Delta \in I$, $i = j - a - \Delta$ and $P_2 = P[m - b - \Delta..m]$, we have $\delta_E(T[i..j], P_2) = d$. All we have to do is to verify if there exists P_1 fulfilling requirements of the lemma.

For each $k' \in [0..k]$, we compute $\text{LPref}_{k'}$ in $\mathcal{O}(nk)$ time [37]. Then, the maximal possible length of P_1 (within our edit distance budget) is $\alpha := \text{LPref}_{k-d}[j]$. Now, we need to define I' in such a way that it corresponds to pairs (P_1, P_2) with total length $|P|$, that is, we set $I' := \{\Delta \in I : b + \Delta + \alpha \geq m\}$. The notation used in this proof is illustrated in Figure 3b. The most time consuming part of this procedure is the calculation of the compact representation of LV , which takes $\mathcal{O}(k^2)$ time in the PILLAR model by Lemma 21. ◀

By applying the above lemma for P , T , and all positions j of T , and merging the obtained $\mathcal{O}(nk^2)$ intervals using bucket sort, we obtain Theorem 3.

Let us now move to the decision version of k -Edit CPM. For any integer $k \geq 0$, we define array $\text{LSuf}_k[0..n]$ such that $\text{LSuf}_k[i] = t$ if and only if $P[m-t..m]$ is the longest suffix of P at edit distance at most k from a suffix of $T[0..i]$. We make the following easy observation.

► **Observation 23.** *The pattern P has a circular k -edit occurrence in the text T if and only if $\text{LPref}_{k'}[j] + \text{LSuf}_{k-k'}[j] \geq m$ holds for some $j \in [0..n]$ and $k' \in [0..k]$.*

Due to Observation 23, Theorem 4, which is proved in Section 4, yields Theorem 5.

4 An Algorithm for All- k -LPAM: Proof of Theorem 4

We will show how to compute, given a position p in the text, values $\text{LPref}_{k'}[i]$ for all $k' \in [0..k]$ and $i \in [p.. \min\{p+k, n+1\}]$ in $\mathcal{O}(k^2 \log^3 k)$ time in the PILLAR model. This will yield the desired solution to All- k -LPAM by taking values of p which are multiples of k .

The *deletion distance* $\delta_D(U, V)$ of two strings U and V is the minimum number of letter insertions and deletions required to transform U to V ; in comparison to edit distance, substitutions are not allowed. For a string S , by $S_\$$ we denote the string $S[0]\$S[1]\$\cdots S[|S|-1]\$$. By the following known fact, we can easily transform the pattern and the text, doubling k , and henceforth consider the deletion distance instead of the edit distance.

► **Fact 24.** *For any two strings U and V over an alphabet Σ that does not contain $\$$, we have $2 \cdot \delta_E(U, V) = \delta_D(U_\$, V_\$)$.*

Note that an LCP query on suffixes of $U_\$$ and $V_\$$ trivially reduces in $\mathcal{O}(1)$ time to an LCP query on suffixes of U and V .

► **Definition 25.** *For two strings U and V and an integer range I , we define the alignment graph $G(U, V, I)$ as the weighted undirected graph over the set of vertices \mathbb{Z}^2 with the following edges for each $(a, b) \in \mathbb{Z}^2$:*

- $(a, b) \leftrightarrow (a+1, b)$ with weight 1, $(a, b) \leftrightarrow (a, b+1)$ with weight 1,
- $(a, b) \leftrightarrow (a+1, b+1)$ with weight 0 unless $a \in [0..|U|)$, $b \in [0..|V|)$, $U[a] \neq V[b]$, and $b-a \in I$.

For an alignment graph $G(U, V, I)$, there are $|I|$ diagonals on which diagonal edges may be missing. Intuitively, everything outside these diagonals is considered as a match.

► **Observation 26** ([16, see Lemma 8.5]). *For all fragments $U[a..a']$ and $V[b..b']$ of U and V , respectively, $\delta_D(U[a..a'], V[b..b'])$ is the length of the shortest $(a, b) \rightsquigarrow (a', b')$ path in $G(U, V, \mathbb{Z})$.*

Let $G := G(P, T, [p-k..p+2k])$. For each $t \in [0..m]$, we define a $(3k+2) \times (3k+2)$ distance matrix D_t such that $D_t[i, j]$ is the length of the shortest path between $(0, i+p-k-1)$ and $(t, t+j+p-k-1)$ in the alignment graph G . Let us recall that a matrix M is a *Monge matrix* if for every pair of rows $i < j$ and every pair of columns $\ell < r$, $M[i, \ell] + M[j, r] \leq M[i, r] + M[j, \ell]$. The planarity of G and the fact that all vertices of the considered shortest paths lie in $[0..t] \times \mathbb{Z}$, imply the following.

► **Observation 27.** *For every $t \in [0..m]$, the matrix D_t is a Monge matrix.*

Let us recall that a permutation matrix is a square matrix over $\{0, 1\}$ that contains exactly one 1 in each row and in each column. A permutation matrix P of size $s \times s$ corresponds to a permutation π of $[0..s)$ such that $P[i, j] = 1$ if and only if $\pi(i) = j$. For two permutations π_1, π_2 and their corresponding permutation matrices P_1, P_2 , by $\Delta(\pi_1, \pi_2) = \Delta(P_1, P_2)$ we

denote a shortest sequence of transpositions f_1, \dots, f_q of neighboring elements such that $f_q \circ \dots \circ f_1 \circ \pi_1 = \pi_2$. For an $s \times s$ matrix A , we denote by A^Σ an $(s+1) \times (s+1)$ matrix such that

$$A^\Sigma[i, j] = \sum_{i' \geq i} \sum_{j' < j} A[i', j'], \quad \text{for } i, j \in [0..s].$$

The lemma below follows readily from the tools developed in [16, Sections 8, 9] which, in turn, are based on the ideas of Tiskin [44, 45].

► **Lemma 28.**

- (a) Let $t \in [0..m]$, $i \in [p..p+k]$, $j \in [i-k..i+k] \cap [i-t..n-t]$, and $k' \in [0..k]$. Then, $\delta_D(T[i..j+t], P[0..t]) \leq k'$ if and only if $D_t[i-p+k+1, j-p+k+1] \leq k'$.
- (b) For each $t \in [0..m]$, there is a $(3k+1) \times (3k+1)$ permutation matrix P_t such that $D_t[i, j] = 2P_t^\Sigma[i, j] + i - j$ holds for all $i, j \in [0..3k+1]$. P_0 is an identity permutation matrix. A sequence $\Delta(P_0, P_1), \dots, \Delta(P_{m-1}, P_m)$ contains at most $3k(3k+1)/2$ transpositions of neighboring elements in total and all its non-empty elements can be computed in $\mathcal{O}(k^2 \log \log k)$ time plus $\mathcal{O}(k^2)$ LCP queries on pairs of suffixes of P and T .

In the following lemma, whose proof is omitted here, we extend a known result on answering submatrix maximum queries on Monge matrices [35] (see also [25]) to a dynamic (the matrix changes by sub-row increments) and partially persistent (we need to be able to query all previously created matrices) setting. Sub-column queries are sufficient for our purposes; such queries were considered as a simpler case also in [35, 25]. We further consider minimum queries instead of maximum queries, which is a fairly straightforward change.

► **Lemma 29.** Let $M_0 = M$ be an $s \times s$ Monge matrix such that each entry of M_0 can be retrieved in $\mathcal{O}(1)$ time. We consider a sequence of operations:

- A sub-row increment takes the most recent matrix M_i and creates a matrix M_{i+1} resulting after this operation.
- A sub-column minimum query extracts the minimum in a given sub-column of a specified previously created matrix M_i .

The data structure for M_0 can be initialized in $\mathcal{O}(s \log^2 s)$ time. If each created matrix is a Monge matrix, then each incrementation can be performed in $\mathcal{O}(\log^3 s)$ time and each query can be answered in $\mathcal{O}(\log^2 s)$ time.

Proof of Theorem 4. Let us recall that we make all computations for $\mathcal{O}(n/k)$ values of p . We will store D_t for $t \in [0..m]$ using the data structure of Lemma 29. The initialization of D_0 takes $\mathcal{O}(k \log^2 k)$ time; we have $D_0[a, b] = |a - b|$. Each transposition in the maintained matrix P_t corresponds to a sub-column increment in D_t . Note that, for each $t \in [0..m]$, D_t is a Monge matrix due to Observation 27. Any intermediate matrix D is also Monge as it satisfies $D[i, j] = 2P^\Sigma[i, j] + i - j$ for a (maintained) permutation matrix P . Thus, for each t such that $\Delta(P_t, P_{t+1}) \neq \emptyset$, we can update the maintained Monge matrix as necessary using Lemma 29. By Lemma 28(b), the number of updates will be $\mathcal{O}(k^2)$ and the updates can be computed in $\mathcal{O}(k^2 \log \log k)$ time after $\mathcal{O}(n)$ -time preprocessing for LCP queries. The updates are performed in $\mathcal{O}(k^2 \log^3 k)$ total time.

We are to compute, for all $k' \in [0..k]$ and $i \in [p..p+k]$, the length of the longest prefix of P that matches a prefix of $T[i..n]$ with deletion distance at most k' . By Lemma 28(a) it suffices to find the maximum $t \in [0..m]$ such that $\min\{D_t[i-p+k+1, j-p+k+1] : j \in [i-k..i+k] \cap [i-t..n-t]\} \leq k'$. To this end, we apply binary search with $\mathcal{O}(\log k)$ steps on the set of all t that satisfy $\Delta(P_t, P_{t+1}) \neq \emptyset$, using $\mathcal{O}(\log^2 k)$ -time queries of Lemma 29. Thus, all binary searches take $\mathcal{O}(k^2 \log^3 k)$ time in total. The total time is $\mathcal{O}(n + (n/k) \cdot k^2 \log^3 k) = \mathcal{O}(nk \log^3 k)$. ◀

5 Conditional Hardness of Approximate CPM

We consider the following problem where the number of allowed mismatches is unbounded.

MISMATCH-CPM
Input: A text T of length n and a pattern P of length m .
Output: An array $\text{CPM}[0..n-m]$ with $\text{CPM}[i] = \min\{k \geq 0 : P \approx_k^{\delta_H} T[i..i+m]\}$.

In jumbled indexing, we are to answer pattern matching queries in the jumbled (abelian) sense. More precisely, given a Parikh vector of a pattern that specifies the quantity of each letter, we are to check if there is a substring of the text with this Parikh vector. In the case of a binary text, the problem of constructing a jumbled index is known to be equivalent (up to a log n -factor in the case where a concrete substring needs to be identified; see [20]) to constructing the following data structure.

Given a text X of length n over alphabet $\{0, 1\}$, for each $t \in [1..n]$ compute the values:

$$\min_t := \min \left\{ \sum_{j=i}^{i+t-1} X[j] : i \in [0..n-t] \right\}, \max_t := \max \left\{ \sum_{j=i}^{i+t-1} X[j] : i \in [0..n-t] \right\}.$$

For a few years since its introduction [19] the problem of constructing a binary jumbled index in $\mathcal{O}(n^{2-\epsilon})$ time for $\epsilon > 0$ was open. Chan and Lewenstein [13] settled this question affirmatively by proposing an $\mathcal{O}(n^{1.859})$ -time randomized construction; very recently it was improved to $\mathcal{O}(n^{1.5} \log^{\mathcal{O}(1)} n)$ time [18]. We make the following reduction.

► **Theorem 30.** *If Mismatch-CPM on binary strings can be solved in $S(n)$ time, then the BJI can be constructed in $\mathcal{O}(n + S(3n))$ time.*

Proof. We show how to compute \max_t for all $t \in [1..n]$. For computing \min_t , we can negate all the letters of X . An illustration of our reduction is provided in Figure 4.

$X = 0100101001001$	$n = 13$	$j = 5$	$t = 6$	$i = n - t = 7$
$\min_1 = 0$	$\max_1 = 1$	$\text{CPM}[i] = t - \max_t + j - \max_t = \text{CPM}[7] = 5$		
$\min_2 = 0$	$\max_2 = 1$	$P = 01001010010010000000000000$		
$\min_3 = 1$	$\max_3 = 2$	$T = \overset{0}{1}111111\overset{7}{1}11111000000000000000000000000000$		
$\min_4 = 1$	$\max_4 = 2$	$\text{rot}_4(P) = 101001001000000000000000100$		
$\min_5 = 1$	$\max_5 = 2$			
$\min_6 = 2$	$\max_6 = 3$			
\dots				

■ **Figure 4** $\text{CPM}[7] = 5$ corresponds to a Hamming distance of 5 between $T[7..7+|P|)$ and some rotation of P , namely of $\text{rot}_4(P)$.

It suffices to consider an instance of Mismatch-CPM with $P = X0^n$, $T = 1^n0^{2n}$. A prefix of a rotation of P of length at most n is also a substring of a string 0^nX0^n . For each $i \in [0..n)$, to compute $\text{CPM}[i]$ we need to choose a substring of 0^nX0^n of length $t = n - i$ with the most number of 1s as the prefix of some rotation of P . Indeed, if U is this prefix and P' is this rotation, that is, $P' = UV$, the remaining 0s in U and 1s in V will correspond to

mismatches between P' and $T[i..i+|P|)$. The maximum number of 1s among the substrings of $0^n X 0^n$ is the same as the maximum for X since it is never worse to choose a length- t prefix (suffix) of X than a shorter prefix (suffix) and a part from 0^n .

Thus, we have $\text{CPM}[i] = t - \max_t + j - \max_t$, where j is equal to the number of 1s in X . Hence, $\max_t = (t + j - \text{CPM}[n - t])/2$. These values can be recovered from the output of Mismatch-CPM in linear time. ◀

The following theorem shows how to compute the edit distance of two strings with the use of an algorithm for the decision version of k -Edit CPM, and thus also that a strongly subquadratic such algorithm would refute SETH [34]. The proof is omitted in this version.

► **Theorem 31.** *If k -Edit CPM on quaternary strings can be solved in $\mathcal{O}(n^{2-\varepsilon})$ time for some constant $\varepsilon > 0$, then the edit distance of two binary strings each of length at most n can be computed in $\mathcal{O}(n^{2-\varepsilon} \log n)$ time.*

Abstract

We investigate the EUCLIDEAN d -DIMENSIONAL STABLE ROOMMATES problem, which asks whether a given set V of $d \cdot n$ points from the 2-dimensional Euclidean space can be partitioned into n disjoint (unordered) subsets $\Pi = \{V_1, \dots, V_n\}$ with $|V_i| = d$ for each $V_i \in \Pi$ such that Π is *stable*. Here, *stability* means that no point subset $W \subseteq V$ is blocking Π , and W is said to be *blocking* Π if $|W| = d$ such that $\sum_{w' \in W} \delta(w, w') < \sum_{v \in \Pi(w)} \delta(w, v)$ holds for each point $w \in W$, where $\Pi(w)$ denotes the subset $V_i \in \Pi$ which contains w and $\delta(a, b)$ denotes the Euclidean distance between points a and b . Complementing the existing known polynomial-time result for $d = 2$, we show that such polynomial-time algorithms cannot exist for any fixed number $d \geq 3$ unless $P=NP$. Our result for $d = 3$ answers a decade-long open question in the theory of Stable Matching and Hedonic Games [18, 1, 10, 26, 21].

1 Introduction

We study the computational complexity of a geometric and multi-dimensional variant of the classical stable matching problem, called EUCLIDEAN d -DIMENSIONAL STABLE ROOMMATES (EUCLID- d -SR). This problem is to decide whether a given set V of $d \cdot n$ agents, each represented by a point in the two-dimensional Euclidean space \mathcal{R}^2 , has a d -dimensional *stable matching* (in short, d -stable matching). Here, each agent $x \in V$ has a preference list over all (unordered) size- d agent sets containing x which is derived from the Euclidean distances between the points. More precisely, agent x *prefers* subset S to subset T if the sum of Euclidean distances from x to S is smaller than the sum of the distances to T . We call preferences over subsets of agents which are based on the sum of Euclidean distances *Euclidean preferences*. A d -dimensional matching is a partition of V into n disjoint agent subsets $\Pi = \{V_1, \dots, V_n\}$ with $|V_i| = d$ for all $i \in \{1, \dots, n\}$. In this way, each agent $v \in V$ is assigned to a subset in Π . An agent subset V' is *blocking* the d -dimensional matching Π if $|V'| = d$ and each agent in V' prefers V' to its “assigned” agent subset in Π . A d -stable matchings is a d -matchings that is not blocked by a subset of agents of size d .

When allowing agents to have arbitrary preferences, we arrive at the d -DIMENSIONAL STABLE ROOMMATES (d -SR) problem with 2-SR being equivalent to the classical STABLE ROOMMATES problem [14, 17]. It is well-known that *not* every instance of STABLE ROOMMATES admits a 2-stable matching, but deciding whether there exists one is polynomial-time solvable [17]. Fortunately, if we restrict the preferences to be Euclidean, then a 2-stable matching always exists and it can be found in polynomial time: Iteratively pick two remaining agents who are closest to each other and match them [1]. One may be tempted to apply this greedy approach to the case when $d = 3$. However, this would only work if it can find and match a triple of agents in each step such that this triple is the most preferred one of all three. Since such a “most-preferred” triple may not always exist, the prospects become less clear. Indeed, Arkin et al. [1] showed that not every instance of EUCLID-3-SR admits a 3-stable matching. To the best of our knowledge, nothing about the existence of EUCLID- d -SR is known for any fixed $d \geq 4$. In particular, the no instance by Arkin et al. will not work for any fixed $d \geq 4$. Arkin et al. left open the computational complexity of finding a 3-stable matching. The same question has been repeatedly asked since then [18, 21, 10, 26, 6]. Nevertheless, d -SR (i.e., for general preferences) has been known to be NP-complete for $d = 3$. Hence, it is of particular importance to search for natural restricted subcases, e.g., under Euclidean preferences, which may allow for efficient algorithms.

Our contribution. In this work, we aim at settling the computational complexity of EUCLID- d -SR for all fixed $d \geq 3$. Arkin et al. [1] showed that there is always a 3-dimensional matching which is approximately stable, which sparks hope for a polynomial-time algorithm for $d = 3$. We destroy such hope by showing that EUCLID-3-SR is NP-hard. We achieve this by reducing from an NP-complete planar variant of the EXACT COVER BY 3 SETS problem, where we make use of a novel chain gadget (see the orange and blue parts in Figure 3) and a star gadget (see Figure 1) which is adapted from the no-instance of Arkin et al. See the idea part in Section 3 for more details.

The same construction does not work for $d \geq 4$ since a no-instance for EUCLID-3-SR does not remain a no-instance for EUCLID-4-SR. However, we manage to derive two extended star structures, one for odd d and the other for even d (see the right and left figures of Figure 4, respectively), adapt the remaining component gadgets to show hardness for all fixed $d \geq 4$. Together, we show the following.

► **Theorem 1.** EUCLID- d -SR is NP-complete for every fixed $d \geq 3$.

Related work. Knuth [19] proposed to generalize the well-known STABLE MARRIAGE problem (a bipartite restriction of the STABLE ROOMMATES problem) to the 3-dimensional case. There are many such generalized variants in the literature, including the NP-complete 3-SR problem [18]. Huang [16] strengthen the result by showing that 3-SR remains NP-hard even for *additive* preferences. Herein, each agent $x \in V$ has cardinal preferences $\mu_x: V \setminus \{x\} \rightarrow \mathbb{R}$ over all other agents such that x prefers $\{x, s_1, s_2\}$ to $\{x, t_1, t_2\}$ if and only if $\mu_x(s_1) + \mu_x(s_2) > \mu_x(t_1) + \mu_x(t_2)$. Deineko and Woeginger [10] strengthen the result of Huang by showing that 3-SR remains NP-hard even for metric preferences: $\mu_x(y) = \mu_y(x) \geq 0$ and $\mu_x(y) + \mu_y(z) \leq \mu_x(z)$ such that x prefers $\{x, s_1, s_2\}$ to $\{x, t_1, t_2\}$ if and only if $\mu_x(s_1) + \mu_x(s_2) < \mu_x(t_1) + \mu_x(t_2)$. It is straightforward to see that Euclidean preferences are metric preferences and metric preferences are additive. We thus strengthen the results of Deineko and Woeginger, and Huang, by showing that the hardness remains even for Euclidean preferences. Recently, McKay and Manlove [22] strengthen the result of Huang [16] by showing that the NP-hardness remains even if the cardinal preferences are binary, i.e.,

$\mu_x(y) \in \{0, 1\}$ for all other agents y . This result is not comparable to ours since binary preferences and Euclidean preferences are not comparable. They also show that 3-SR becomes polynomial-time solvable when the preferences are binary and symmetric.

Multi-dimensional stable matchings are equivalent to the so-called *fixed-size stable cores* in hedonic games [12], where each coalition (i.e., a non-empty subset of agents) in the core must have the same size, and stability only needs to be guaranteed for any other coalition of the same size.¹ Hence, our NP-hardness result also transfers to the case of finding a fixed-size stable core in the scenario where the agents in the hedonic game have Euclidean preferences. Hedonic games have been studied under graphical preference models [11, 24], where there is an underlying social network (a directed graph) such that agents correspond to the vertices in the graph. The general idea is to assume that agents prefer to be with their own out-neighbors more than non-out-neighbors. The Euclidean preference model is related to the graphical preference model where the underlying graph is planar. However, the Euclidean model is more fine-grained and assumes that the intensity of the preferences also depends on the distance of the agents. Notably, under the graphical model, a stable core always exists and it can be found in linear time [11], but verifying whether a given partition is stable is NP-hard [7]. Hedonic games with fixed-size coalitions have been studied for other solution concepts such as strategy-proofness [27], Pareto optimality [9], and exchange stability [3].

Other generalized variants include the study of 3-stable matching with cyclic preferences [13, 4, 20], with preferences over individuals [18], and the study of the higher-dimensional case [6] and of other restricted preference domains [5]. We refer to the textbook by Manlove [21] for more references.

Paper outline. In Section 2, besides introducing necessary concepts and notations used throughout the paper, we describe a crucial star-structured instance of EUCLID-3-SR (see Example 2), which serves as a tool of our NP-hardness reduction. The proof of Theorem 1 is divided into two sections: In Section 3, we consider the case of $d = 3$ and show-case in detail how to combine the star-structured instance with two new gadgets, one for the local replacement and one for the enforcement, to obtain NP-hardness. In Section 4, we show how to carefully adapt the star-structured instance (which only works for $d = 3$) and modify the reduction to show hardness for any fixed $d \geq 4$. We conclude in Section 5. Due to space constraints, some figures, examples, and (part of) the proofs for results marked by \star are deferred to the full version [8].

2 Preliminaries

Given a non-negative integer t , we use “[t]” (without any prefix) to denote the set $\{1, \dots, t\}$. Throughout the paper, if not stated explicitly, we assume that ε and ε_d are small fractional values with $0 < \varepsilon < 0.001$ and $0 < \varepsilon_d < \frac{1}{1000d}$, where $d \geq 3$. By “close to zero” we mean a value which is smaller than ε and ε_d .

For each fixed integer $d \geq 2$, an instance of EUCLIDEAN d -DIMENSIONAL STABLE ROOMMATES (EUCLID- d -SR) consists of a set $V = \{1, \dots, d \cdot n\}$ of $d \cdot n$ agents and an embedding $E: V \rightarrow \mathbb{R}^d$ of the agents into d -dimensional Euclidean space. We call a non-empty subset $V' \subseteq V$ of agents a *coalition*. The preference list \succeq_x of each agent $x \in V$ over

¹ A stable core is a *partition* Π of the agents into disjoint coalitions such that no subset of agents would block the partition Π by forming its own new coalition.

all possible size- d coalitions containing x is derived from the sum of the Euclidean distances from x to the coalition. More precisely, for each two size- d coalitions $S = \{x, a_1, \dots, a_{d-1}\}$ and $T = \{x, b_1, \dots, b_{d-1}\}$ containing x we say that x *weakly prefers* S to T , denoted as $S \succeq_x T$, if the following holds:

$$\sum_{j \in [d-1]} \delta(E(x), E(a_j)) \leq \sum_{j \in [d-1]} \delta(E(x), E(b_j)),$$

where $\delta(p, q) := \sqrt{(p[1] - q[1])^2 + (p[2] - q[2])^2}$. We use $S \succ_x T$ (i.e., x preferring S to T) and $S \sim_x T$ (i.e., x indifferent between S and T) to refer to the asymmetric and symmetric part of \succeq_x , respectively. To ease notation, for an agent x and a preference list \mathcal{L} over a subset \mathcal{F} of size- d coalitions, we use $\mathcal{L} \succ_x \dots$ to indicate that agent x prefers every size- d coalition in \mathcal{F} over every size- d coalition not in \mathcal{F} and her preferences over \mathcal{F} are according to \mathcal{L} . Further, we use the agent and her embedded points interchangeably, and the distance between two agents means the distance between their embedded points. For each agent x and each coalition $S \subseteq V$, we use $\delta(x, S)$ to refer to the sum of Euclidean distances from x to each member in S : $\delta(x, S) = \sum_{y \in S} \delta(x, y)$.

See the introduction for the definition of *d-matchings*, *blocking coalitions*, and *d-stable matchings*. Given a d -matching Π and an agent $x \in V$, let $\Pi(x)$ denote the coalition that contains x . The problem studied in this paper is defined as follows:

EUCLID- d -SR

Input: An agent set $V = \{1, \dots, d \cdot n\}$ and an embedding $E: V \rightarrow \mathbb{R}^2$.

Question: Is there a d -stable matching?

Note that since stability for each fixed d can be checked in polynomial time, EUCLID- d -SR is contained in NP for every fixed d .

Not every EUCLID-3-SR instance admits a 3-stable matching. Arkin et al. [1] provided a star-structured instance which does not. In Example 2, we describe an *adapted* variant of their instance, which is a decisive component of our hardness reduction.

► **Example 2.** Consider an instance which contains *at least* 12 agents called $W = \{0, \dots, 11\}$ where the 12 agents are embedded as given in Figure 1. In the embedding of $W \setminus \{10, 11\}$, the five inner-most points, namely 0 to 4, form a regular pentagon with edge length a . For each $i \in \{0, \dots, 4\}$, the three points $i, i + 1 \bmod 5$, and $i + 5$ form a triangle with side lengths a, b, c such that $a < b < c < \ell$, where ℓ denotes the diagonal of the regular pentagon. Moreover, the angle θ at points $i + 1 \bmod 5, i, i + 5$ is at most 90 degrees. This ensures that the distance between points $(i + 1 \bmod 5) + 5$ and i is strictly larger than ℓ (we will use this fact later). Except for point 5 (marked in red), the closest neighbor of each point $i + 5$ is i , followed by $i + 1 \bmod 5$. Point 5's two closest neighbors are points 10 and 11 with $a < \delta(5, 10) < b$ and $a < \delta(5, 11) < b$, followed by points 0 and 1. The distance between 10 and 11 is close to zero, with the intention to ensure that every 3-stable matching must match them together. The distance from 10 (resp. 11) to any agent in $W \setminus \{5, 10, 11\}$ is larger than the diagonal length ℓ while the distance from 10 (resp. 11) to any agent not in W is larger than $\delta(5, 10) - \varepsilon$. Finally, the distance between any agent from $W \setminus \{10, 11\}$ to any agent *not* from $W \setminus \{10, 11\}$ is strictly larger than ℓ .

To specify the embedding of the agents from W , we use the polar coordinate system. We first fix the embeddings of 5, 10, 11 to ensure the distances between them are as stated above. Then, we fix points 0 and 1 and the centroid of the regular pentagon to ensure the distances satisfy $a < b < c < \ell$, and the angle θ at points 1, 0, 5 is at most 90 degrees, and the angle at points 0, 5, $j, j \in \{10, 11\}$, is more than 90 degrees. Once these points are fixed we can determine the other points by a simple calculation.

■ **Figure 1** A star-structured instance adapted from Arkin et al. [1]; see Example 2. We use different colors to highlight the distances between the points. For instance, the smallest distance between any two points is a (highlighted in green). We also draw a dashed circle of radius b , centered at point 5 to indicate that points both 10 and 11 are with distance smaller than b to 5.

The instance of Arkin et al. [1] embeds the two extra points 10 and 11 differently than ours (see Example 2). Hence, their instance is a no-instance, while ours may be a yes-instance, provided some specific triple is matched together, formulated as follows:

► **Lemma 3.** *Every 3-stable matching of an instance satisfying the embedding described in Example 2 must contain triple $\{5, 10, 11\}$.*

Proof. Towards a contradiction, suppose that Π is a 3-stable matching with $\{5, 10, 11\} \notin \Pi$. We infer that $\{10, 11\} \subseteq \Pi(10)$ since otherwise $\{5, 10, 11\}$ is blocking Π due the following: $\delta(5, \Pi(5)) \geq \min(\delta(5, 10), \delta(5, 11)) + b > \delta(5, \{5, 10, 11\})$, and for each $x \in \{10, 11\}$ it holds that $\delta(x, \Pi(x)) \geq 2(\delta(x, 5) - \varepsilon) > \delta(x, 5) + \delta(10, 11)$ for any $\varepsilon > 0$. This implies that $\{10, 11\} \cap \Pi(5) = \emptyset$. Next, we observe that there must be a triple in Π that contains the two agents of at least one pentagon edge as otherwise $\{2, 3, 7\}$ is blocking: $\delta(2, \Pi(2)) \geq b + c > a + b$, $\delta(3, \Pi(3)) \geq b + c > a + c$, and $\delta(7, \Pi(7)) \geq b + \ell > b + c$. Thus, at least one triple in Π contains the agents of some pentagon edge, say $\{2, 3\}$; the other cases are analogous. Let $\{2, 3, x\} \in \Pi$. We distinguish between three subcases:

Case 1: $x \notin \{1, 4, 7, 8\}$. Then, one can verify that $\{2, 3, 7\}$ is blocking; recall that every agent not in $W \setminus \{2, 3\}$ is at distance larger than ℓ to agent 7.

Case 2: $x \in \{1, 7\}$. Then, $\Pi(4) = \{0, 4, 9\}$ or $\Pi(4) = \{0, 4, 8\}$ since otherwise $\{3, 4, 8\}$ blocks Π due to: $\delta(3, \Pi(3)) \geq a + \min(\delta(3, 1), \delta(3, 7)) = a + c > a + b$, $\delta(4, \Pi(4)) > a + c$, $\delta(8, \Pi(8)) > b + c$ (recall that the distance from every agent not in $W \setminus \{3, 4\}$ to agent 8 is larger than ℓ). However, both cases imply that $\{0, 1, 5\}$ is blocking since $\delta(0, \Pi(0)) \geq a + c > a + b = \delta(0, \{0, 1, 5\})$, $\delta(1, \Pi(1)) \geq a + \ell > a + c = \delta(1, \{0, 1, 5\})$, and $\delta(5, \Pi(5)) \geq c + \ell > b + c = \delta(5, \{0, 1, 5\})$; recall that $\Pi(5) \cap \{10, 11\} = \emptyset$.

Case 3: $x \in \{4, 8\}$. Then, $\delta(2, \Pi(2)) \geq a + \ell > a + c$. This implies that $\{0, 1, 6\} \in \Pi$ since otherwise $\{1, 2, 6\}$ is blocking Π . However, this implies that $\{0, 4, 9\}$ is blocking Π .

Since we have just shown that no agent x exists which is in the same triple as 2 and 3, no 3-stable matching exists that does not contain $\{5, 10, 11\}$. ◀

3 NP-hardness for EUCLID-3-SR

In this section, we prove Theorem 1 for the case of $d = 3$ by providing a polynomial reduction from the NP-complete PLANAR AND CUBIC EXACT COVER BY 3 SETS problem [23], which is an NP-complete restricted variant of the EXACT COVER BY 3 SETS problem [15].

PLANAR AND CUBIC EXACT COVER BY 3 SETS (PC-X3C)

Input: A $3n$ -element set $X = \{1, \dots, 3n\}$ and a collection $\mathcal{S} = (S_1, \dots, S_m)$ of 3-element subsets of X of cardinality $3n$ such that each element occurs in exactly three sets and the associated graph is planar.

Question: Does \mathcal{S} contain an *exact cover* for X , i.e., a subcollection $\mathcal{K} \subseteq \mathcal{S}$ such that each element of X occurs in exactly one member of \mathcal{K} ?

Herein, given a PC-X3C instance $I = (X, \mathcal{S})$, the associated graph of I , denoted as $G(I)$, is a bipartite graph $G(I) = (U \uplus W, E)$ on two partite vertex sets $U = \{u_i \mid i \in X\}$ and $W = \{w_j \mid S_j \in \mathcal{S}\}$ such that there exists an edge $e = \{u_i, w_j\} \in E$ if and only if $i \in S_j$. We call the vertices in U and W the *element-vertices* and the *set-vertices*, respectively.

In our reduction, we crucially utilize the fact that the associated graph G of the input instance is planar and cubic, and hence by Valiant [25] admits a specific planar embedding in \mathbb{Z}^2 , called *orthogonal drawing*, which maps each vertex to an integer grid point and each edge to a chain of non-overlapping horizontal and vertical segments along the grid (except at the endpoints). To simplify the description of the reduction, we use the following more restricted orthogonal drawing:

► **Proposition 4** ([2]). *In polynomial time, a planar graph with maximum vertex degree three can be embedded in the grid \mathbb{Z}^2 such that its vertices are at the integer grid points and its edges are drawn using at most one horizontal and one vertical segment in the grid.*

We call the intersection point of the horizontal and vertical segments the *bending point*.

3.1 The construction

The idea. Given an instance $I = (X, \mathcal{S})$ of PC-X3C, we first use Proposition 4 to embed the associated graph $G(I) = (U \uplus W, E)$ into a 2-dimensional grid with edges drawn using line segments of length at least $L \geq 200$, and with parallel lines at least $4L$ grid squares apart. The idea is to replace each element-vertex $u_i \in U$ with four agents which form a “star” with three close-by “leaves” (see Figure 2a). These leaves one-to-one correspond to the sets S_j with $i \in S_j$. In this way, exactly one set S_j is unmatched with the center and will be chosen to the exact cover solution. Furthermore, we replace each set-vertex $w_j \in W$ with three agents w_j^i , $i \in S_j$, which form an equilateral triangle (see Figure 2b). We replace each edge in $G(I)$ with a chain of copies of three agents, which, together with a private enforcement gadget (the star structure with a tail in Figure 3), ensure that either all three agents w_j^i are matched in the same triple (indicating that the corresponding set is in the solution) or none of them is matched in the same triple (indicating that the corresponding set is not in the solution). The agents in the star structure can be embedded “far” from other agents due to the tail.

Gadgets for the elements and the sets. For each element-vertex $u_i \in U$, assume that the three connecting edges in $G(I)$ are going horizontally to the right (rightward), vertically up (upward), and vertically down (downward); we can mirror the coordinate system if this is not the case. Let w_j, w_k, w_r denote the set-vertices on the endpoints of the rightward, upward, and downward edge, respectively. We create four element-agents, called u_i , u_i^j , u_i^k , and u_i^r . We embed them into \mathbb{R}^2 in such a way that u_i^j, u_i^k, u_i^r are on the segment of the rightward, upward, and downward edge, respectively, and are of equal distance δ to each other. Agent u_i is in the center of the other three agents. See Figure 2a for an illustration.

■ **Figure 2** Element- and set-gadgets described in Subsection 3.1.

Similarly, for each set-vertex $w_j \in W$, assume that the three connecting edges in $G(I)$ are going rightward, leftward, and upward, connecting the element-vertices u_i, u_p, u_q , respectively. We create three set-agents, called w_j^i, w_j^p, w_j^q . We embed them into \mathbb{R}^2 in such a way that w_j^i, w_j^p, w_j^q are on the segment of the rightward, leftward, and upward edge, respectively, and are of equidistance $\frac{1}{3}$ to each other. See Figure 2b for an illustration.

The edge- and the enforcement gadget. For each edge $e = \{u_i, w_j\}$ in $G(I)$, we create \hat{n} (a constant value to be determined later) copies of the triple $A_i^j[z] = \{\alpha_i^j[z], \beta_i^j[z], \gamma_i^j[z]\}$, $1 \leq z \leq \hat{n}$, of agents and embed them around the line segments of edge e in the grid (refer to Figure 3). To connect to the set-gadget, we merge agent $\gamma_i^j[\hat{n}]$ and set-agent w_j^i together. For technical reasons, we also use $\gamma_i^j[0]$ to refer to u_i^j . To define the distances, let $\varepsilon_1, \varepsilon_2, \dots, \varepsilon_{2\hat{n}}$ be a sequence of increasing positive values with $2(2\hat{n} - 1)/(2\hat{n} + 1) \leq \varepsilon_{2\hat{n}-1} \leq 2(2\hat{n} - 1)/(2\hat{n}) < \varepsilon_{2\hat{n}} = 2 - \varepsilon$. Now, we embed the newly added agents so that the distances between “consecutive agents” on the line increase with $z \in [\hat{n}]$:

- The distance between agents $\alpha_i^j[z]$ and $\beta_i^j[z]$ (marked in blue) is close to zero.
- The distance between agents $\alpha_i^j[z]$ (resp. $\beta_i^j[z]$) and $\gamma_i^j[z]$ is $8 + \varepsilon_{2z}$.
- The distance between $\alpha_i^j[z]$ (resp. $\beta_i^j[z]$) and $\gamma_i^j[z - 1]$ is $8 + \varepsilon_{2z-1}$.

In this manner, we will ensure that either all $A_i^j[z]$, $z \in [\hat{n} - 1]$, or all $\{\gamma_i^j[z - 1], \alpha_i^j[z], \beta_i^j[z]\}$, $i \in [\hat{n}]$ belong to a 3-stable matching (to be proved later).

To determine the value \hat{n} , let the lengths of the segments for edge $\{u_i, w_j\}$ in the orthogonal drawing of graph $G(I)$ be L_1 and L_2 , respectively; L_2 is zero if there is only one straight segment. We set \hat{n} to the largest value satisfying $\sum_{z=1}^{2\hat{n}} (8 + 0.01 \cdot z) \leq L_1 + L_2$, which is clearly a constant. For brevity’s sake, when using \hat{n} , we mean the constant associated to an edge $\{u_i, w_j\}$ in the drawing which will be clear from the context. It is also fairly straightforward to check that one can choose the sequence ε_i so that the bending point of the chain is some agent $\gamma_i^j[z']$, $z' \in [n - 1]$ as shown in Figure 3.

By the construction of the gadgets above, each set-agent w_j^i strictly prefers triple $A_i^j[\hat{n}]$ to triple $\{w_j^i, w_j^p, w_j^q\}$ since $\delta(w_j^i, x) < \frac{1}{3} = \delta(w_j^i, y)$ for all $x \in \{\alpha_i^j[\hat{n}], \beta_i^j[\hat{n}]\}$ and $y \in \{w_j^p, w_j^q\}$; recall that $w_j^i = \gamma_i^j[\hat{n}]$ and $\delta(x, \gamma_i^j[\hat{n}]) = 10 - \varepsilon$. To ensure that exactly one of the two triples is chosen, we make use of the star-gadget from Example 2. More precisely, we introduce an agent triple $H_j^i = \{f_j^i, g_j^i, h_j^i\}$ and embed them in such a way that the distances between two “consecutive” agents on the line towards the star-gadget increase:

- The distance between f_j^i and g_j^i is close to zero.
- The distance between agent h_j^i and each of $\{f_j^i, g_j^i\}$ is $10 + 2\varepsilon$.
- The distance between f_j^i (resp. g_j^i) and each of $A_i^j[\hat{n}]$ is in range $[10 + \varepsilon, 10 + 2\varepsilon)$.

This means that the most preferred triple of agent h_j^i is H_j^i , while both f_j^i and g_j^i prefer triple S to H_j^i where $S = \{f_j^i, g_j^i, x\}$ and $x \in A_i^j[\hat{n}]$.

■ **Figure 3** Gadget for edge $\{u_i, w_j\}$ in $G(I)$ with $S_j = \{i, p, q\}$. Here, the fractional values ε_z satisfy $0 < \varepsilon_1 < \dots < \varepsilon_{\hat{n}} = 2 - \varepsilon$. The star-gadget, adapted from Arkin et al. [1], is described in Example 2. To highlight the distances between the points in the star-gadget, we use different colors. For instance, the smallest distance between any two points in the star is a (highlighted in green). We also draw a dashed circle of radius b , centered at point 5 to indicate that points both 10 and 11 are with distance smaller than b to 5.

Finally, we create 12 agents, namely, $W = \{0, \dots, 11\}$, according to Example 2 such that agents 10 and 11's most preferred triple is $\{10, 11, h_j^i\}$, followed by $\{5, 10, 11\}$. More precisely:

- The distance between agent 10 (resp. agent 11) and h_j^i is $10 + 3\varepsilon$.
- The distance between agent 10 (resp. agent 11) and 5 is $10 + 4\varepsilon$.
- The five agents from $\{0, \dots, 4\}$ form a regular pentagon with edge length a . Each two agents on the pentagon form with a private agent a triangle with edge lengths a (marked in green), b (marked in red), and c . We set $b = 10.1$ and $c = 10.2$. The length of the diagonal of the pentagon is ℓ .

Altogether, the lengths satisfy the relation $a < b < c < \ell$ and the specific angle θ is at most 90 degrees. Due to the chain, including f_j^i , g_j^i , and h_j^i , the distance from every agent not from $W \cup \{h_j^i\}$ to every agent from W is larger than ℓ . We call the gadget, consisting of the

star-agents and the triple H_j^i , the *star-gadget* for set-agent w_j^i and element-agent u_i^j . Figure 3 provides an illustration of how the element-gadget, the set-gadget, and the star-gadget are embedded. Note that since the angle between any two line segments is 90 degrees and the line segment has length at least 200, we can make sure that such embedding is feasible.

This completes the description of the construction, which clearly can be done in polynomial time. In total, we constructed $O(4 \cdot 3n + 3 \cdot 3n + 3 \cdot 2\hat{n} \cdot 3n + 15 \cdot 3n) = O(n)$ agents. Note that we only need to have a good approximation of the embedding of the agents in the star-gadget and the equilateral triangle.

3.2 The correctness proof for $d = 3$

Before we proceed with the correctness proof, we summarize the preferences derived from the embedding via the the following observation.

► **Observation 5** (\star). *For each element $i \in X$ and each set $S_j \in \mathcal{S}$ with $S_j = \{i, p, q\}$, let $0, \dots, 11$ denote the 12 agents in the associated star-gadget. Then, the following holds.*

- (i) *The preference list of each agent $x \in \{10, 11\}$ satisfies $\{h_j^i, 10, 11\} \succ_x \dots$.*
- (ii) *For each triple $B \neq \{h_j^i, f_j^i, g_j^i\}$ with $B \succeq_{h_j^i} \{h_j^i, 10, 11\}$ it holds that $B \cap \{10, 11\} \neq \emptyset$.*
- (iii) *For each agent $x \in \{f_j^i, g_j^i\}$ and each triple $B \neq \{f_j^i, g_j^i, h_j^i\}$:*
 - *If $B = \{f_j^i, g_j^i, y\}$ (where $y \in \{\alpha_i^j[\hat{n}], \beta_j^i[\hat{n}], \gamma_j^i[\hat{n}]\}$), then $B \succ_x \{f_j^i, g_j^i, h_j^i\}$.*
 - *If $B \succeq_x \{f_j^i, g_j^i, h_j^i\}$, then $B = \{f_j^i, g_j^i, y\}$ for some $y \in \{\alpha_i^j[\hat{n}], \beta_j^i[\hat{n}], \gamma_j^i[\hat{n}]\}$.*
- (iv) *For each $z \in [\hat{n}]$ the preference list of agent $\gamma_i^j[z]$ satisfies $\{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z]\} \succ_{\gamma_i^j[z]} \dots$.*
- (v) *For each $z \in [\hat{n}]$ the preference list of each agent $x \in \{\alpha_i^j[z], \beta_j^i[z]\}$ satisfies $\{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z-1]\} \succ_x \{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z]\} \succ_x \dots$.*
- (vi) *For each $z \in [\hat{n}-1]$ and each triple $B \neq \{\alpha_i^j[z+1], \beta_j^i[z+1], \gamma_i^j[z]\}$ with $B \succeq_{\gamma_i^j[z]} \{\alpha_i^j[z+1], \beta_j^i[z+1], \gamma_i^j[z]\}$ it holds that $B \cap \{\alpha_i^j[z], \beta_j^i[z]\} \neq \emptyset$.*
- (vii) *For each $B \neq \{w_j^i, w_j^p, w_j^q\}$ with $B \succeq_{w_j^i} \{w_j^i, w_j^p, w_j^q\}$ we have $B \cap \{\alpha_i^j[\hat{n}], \beta_j^i[\hat{n}]\} \neq \emptyset$.*

Finally, we show the correctness, i.e., “ $I = (X, \mathcal{S})$ admits an exact cover if and only if the constructed instance admits a 3-stable matching” via the following lemmas. Lemma 6 shows the “only if” direction and Lemma 8 the other.

► **Lemma 6** (\star). *If $\mathcal{K} \subset \mathcal{S}$ is an exact cover of I , then the following 3-matching Π is stable.*

- *For each $S_j \in \mathcal{K}$ with $S_j = \{i, p, q\}$ add $\{w_j^i, w_j^p, w_j^q\}$ to Π .*
- *For each element $i \in X$ and each set $S_j \in \mathcal{S}$ with $i \in S_j$, call the agents in the associated star-gadget along with the tail agents $0, \dots, 11, h_j^i, f_j^i$, and g_j^i .*
 - *Add $H_j^i, \{5, 10, 11\}, \{1, 6, 8\}, \{2, 3, 7\}$, and $\{0, 4, 9\}$ to Π .*
 - *If $S_j \in \mathcal{K}$, then add all triples $\{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z-1]\}$, $z \in [\hat{n}]$, to Π . Otherwise, add all triples $A_i^j[z]$, $z \in [\hat{n}]$, to Π .*
- *For each element $i \in X$ let S_k, S_r be the two sets which contain i , but are not chosen in the exact cover \mathcal{K} . Add $\{u_i, u_i^k, u_i^r\}$ to Π .*

The proof of the other direction is based on the following properties.

► **Lemma 7** (\star). *Let Π be a 3-stable matching of the constructed instance. For each element $i \in X$ and each set S_j with $S_j = \{i, p, q\}$, the following holds:*

- (i) $H_j^i \in \Pi$.
- (ii) Π contains either all triples $\{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z]\}$ or all triples $\{\alpha_i^j[z], \beta_j^i[z], \gamma_i^j[z-1]\}$, $z \in [\hat{n}]$.

Now, we consider the “if” direction.

► **Lemma 8.** *If Π is a 3-stable matching, then the subcollection \mathcal{K} with $\mathcal{K} = \{S_j \in \mathcal{S} \mid \{\alpha_i^j[1], \beta_i^j[1], \gamma_i^j[0]\} \in \Pi \text{ for some } i \in S_j\}$ is an exact cover.*

Proof. First of all, for each two chosen $S_j, S_k \in \mathcal{K}$ we observe that it cannot happen that $S_j \cap S_k \neq \emptyset$ as otherwise $\{u_i, u_i^j, u_i^k\}$ is a blocking triple; recall that $\gamma_i^j[0] = u_i^j$ and $\gamma_i^k[0] = u_i^k$. It remains to show that \mathcal{K} covers each element at least once.

Now, for each element $i \in X$, let S_j, S_k, S_r denote the three sets that contain i . We claim that at least one of S_j, S_k, S_r belongs to \mathcal{K} because of the following. If $S_j \notin \mathcal{K}$, then by construction, it follows that $T = \{\alpha_i^j[1], \beta_i^j[1], \gamma_i^j[0]\} \notin \Pi$. By Lemma 7(ii), it follows that $A_i^j[1] \in \Pi$. Since T is the most-preferred triple of both $\alpha_i^j[1]$ and $\beta_i^j[1]$ (see Observation 5(v)), by stability, u_i^j must be matched in a triple which she weakly prefers to T . Since $A_i^j[1] \in \Pi$, it follows that either $\{u_i^j, u_i^k, u_i^r\} \in \Pi$ or $\{u_i^j, u_i, v\} \in \Pi$ for some $v \in \{u_i^k, u_i^r\}$. It cannot happen that $\{u_i^j, u_i^k, u_i^r\} \in \Pi$ as otherwise there will be at least three blocking triples, including $\{u_i, u_i^j, u_i^r\}$. Hence, $\{u_i^j, u_i, v\} \in \Pi$ for some $v \in \{u_i^k, u_i^r\}$. Without loss of generality, assume that $v = u_i^k$. Then, it is straightforward to check that $\{u_i^r, \alpha_i^r[1], \beta_i^r[1]\} \in \Pi$. This implies that $S_r \in \mathcal{K}$.

To complete the correctness proof, we show that for each element $p \in S_r \setminus \{i\}$ it holds that $\{\alpha_p^r[1], \beta_p^r[1], \gamma_p^r[0]\} \in \Pi$. Let $S_r = \{i, p, q\}$. Since $S_r \in \mathcal{K}$, by definition and by Lemma 7(ii), we infer that $\{\alpha_i^r[\hat{n}], \beta_i^r[\hat{n}], \gamma_i^r[\hat{n}-1]\} \in \Pi$ (for some constant \hat{n} defined in the construction). We infer that $\{w_r^i, w_r^p, w_r^q\} \in \Pi$ due to the following: By Lemma 7(i), we know that $H_r^i \in \Pi$; recall that $H_r^i = \{f_r^i, g_r^i, h_r^i\}$. Since both f_r^i and g_r^i prefer $\{f_r^i, g_r^i, w_r^i\}$ to H_r^i (see the first part of Observation 5(iii)), it follows by stability that $\Pi(w_r^i) \succeq_{w_r^i} \{f_r^i, g_r^i, w_r^i\}$. By Observation 5(vii), we infer that $\Pi(w_r^i) = \{w_r^i, w_r^p, w_r^q\}$ since $\alpha_i^r[\hat{n}]$ and $\beta_i^r[\hat{n}]$ are not available anymore. This means that $A_p^r[\hat{n}'], A_q^r[\hat{n}''] \notin \Pi$ since $w_r^p = \gamma_p^r[\hat{n}']$ and $w_r^q = \gamma_q^r[\hat{n}'']$ (for some constants \hat{n}' and \hat{n}''). Consequently, we infer by Lemma 7(ii) that $\{\alpha_p^r[1], \beta_p^r[1], \gamma_p^r[0]\}, \{\alpha_q^r[1], \beta_q^r[1], \gamma_q^r[0]\} \in \Pi$, as desired. ◀

This concludes the proof of Theorem 1 for $d = 3$.

4 EUCLID-d-SR with $d \geq 4$

In this section we look at the cases where $d \geq 4$, and let $\kappa := \lfloor (d-1)/2 \rfloor$. The general idea of the reduction is similar to the case where $d = 3$, and we still reduce from PC-X3C. Briefly put, we adapt the star-gadget from Example 2. However, depending on whether d is even or not, we need to carefully revise the star-gadget from Example 2 to make sure the enforcement gadget works. We will replace each pentagon-agent with a subset of agents of size κ , and each further agent from the triangle with two agents if d is even. We also need to update both the replacement and the enforcement gadget. In Subsection 4.1, we describe in detail what the new star-gadgets and the the remaining gadgets look like, and how they are connected to each other. In Subsection 4.2 we show the correctness.

4.1 The construction

We first describe the adapted star-gadgets through the following example (also see Figure 4).

► **Example 9.** We first consider the construction for even d , i.e., $d = 2\kappa + 2$. Consider an instance with $7\kappa + 11$ agents called W where 5κ agents are embedded as the five vertices of a pentagon with κ agents at each vertex of the pentagon. We denote the five sets of points at the five vertices of the pentagon as X_0, \dots, X_4 . All points in each cluster $X_i, 0 \leq i \leq 4$,

■ **Figure 4** A star-structured instance adapted from Arkin et al. [1], similar to Example 2. The left one is for even d , while the right one is for odd d , both described in Example 9. See the caption of Example 2 for further explanation regarding the colors of the edges.

are embedded within an enclosing circle of radius close to zero, with the intention that a d -matching is stable only if all agents in X_i are matched together. For each $i \in \{0, \dots, 4\}$, the distance between each point X_i and each point in $X_{i+1 \bmod 5}$ is in the range of $[a, a + \varepsilon_d]$, while the distance between each point in X_i and each point in $X_{i+2 \bmod 5}$ is in the range of $[\ell, \ell + \varepsilon_d]$. There are 10 points $\{0, \dots, 9\}$ that form a star with the pentagon, as shown in Figure 4 (left). For each $i \in \{0, \dots, 4\}$, embed the points $2i$ and $2i + 1$ as follows: point $2i$ is at a distance between c and $c + \varepsilon_d$ to every point in X_i , and at a distance between b' and $b' + \varepsilon_d$ to every point in $X_{i+1 \bmod 5}$. Point $2i + 1$ is at a distance between c' and $c' + \varepsilon_d$ to every point in X_i , and at a distance between b and $b + \varepsilon_d$ to every point in $X_{i+1 \bmod 5}$. Finally, the distance $\delta(2i, 2i + 1)$ is close to 0. Here the mentioned values satisfy the following relations $a < b < c < \ell$, $b < b' < \ell$, $c < c' < \ell$, $b + b' < 3a$, $c + c' < 3a$, $b + b' < a + \ell$, and $c + c' < b + \ell$.

The remaining $2\kappa + 1$ points, denoted by $10, \dots, 10 + 2\kappa$ in the figure, are called Y ; note that $|Y| = 2\kappa + 1 = d - 1$. Together, $W := \bigcup_{i \in \{0, \dots, 4\}} X_i \cup \{0, \dots, 9\} \cup Y$. All points in Y are embedded within an enclosing ball with radius close to zero. For each point y in Y , it holds that $b - \varepsilon_d \leq \delta(0, y) < b$ and $b - \varepsilon_d \leq \delta(1, y) < b$, and for each each point w in $W \setminus (\{0, 1\} \cup Y)$ it holds that $\delta(w, y) > \ell$. Points 0 and 1 are the two points from $W \setminus Y$ which are closest to the points in Y .

To specify the embedding, We first fix points 0, 1, and Y such that the distances between them are as stated above and they are embedded roughly around a straight line. Then, we fix the positions of X_0, X_1 , and the centroid of the pentagon to ensure the values a, b, b', c, c' , and ℓ satisfy the above relations. For each $i \in \{0, 1, 2, 3, 4\}$ and each two points $x \in X_i$ and $x' \in X_{i+1 \bmod 5}$, the angle α (resp. β) at the points $2i, x$, and x' (resp. $2i + 1, x'$, and x) is less than 90 degrees. The angle at points y, j , and x ($y \in Y, \{i, j\} = \{0, 1\}, x \in X_i$) is more than 90 degrees. After fixing $X_0, X_1, 0$, and 1, we can determine the other points by simple calculations.

Now, we turn to odd d , i.e., $d = 2\kappa + 1$. Instead of having ten points $\{0, \dots, 9\}$, we create five points that form a star with the pentagon. Consider an instance with $7\kappa + 5$ agents called W where 5κ agents are embedded to replace the five vertices of a pentagon with κ agents at each vertex of the pentagon. That is, each vertex of the pentagon is a cluster of points. note the five clusters of points by X_0, X_1, X_2, X_3 , and X_4 . There are five points $\{0, 1, 2, 3, 4\}$ that form a star with the pentagon, as in Example 2 (see Figure 4 (right)). Point i is at a distance b from X_i and c from $X_{i+1 \bmod 5}$, for each $i \in \{0, \dots, 4\}$ where $a < b < c < \ell$ and $b < 2a$.

36:12 Multi-Dimensional Stable Roommates in 2-Dimensional Euclidean Space

■ **Figure 5** Element and set gadgets described in Subsection 4.1.

The remaining 2κ points are called Y . Together, $W := \bigcup_{i \in \{0, \dots, 4\}} X_i \cup \{0, 1, 2, 3, 4\} \cup Y$.

All points in Y are embedded within an enclosing circle with radius close to zero. For each point y in Y , it holds that $b - \varepsilon \leq \delta(0, y) < b$, and for each each point w in $W \setminus (\{0\} \cup Y)$ it holds that $\delta(y, w) > \ell$. Point 0 is the only point from $W \setminus Y$ which is closest to the points in Y . The remaining unmentioned points are at distance at least $b/2$ to the points Y . We specify the embeddings of the agents similarly to the one for even d .

Using a similar reasoning as to Example 2, we claim that the above embeddings are feasible.

Since the distance between each two points in X_i is close to zero, we assume it to be 0 for ease of reasoning. The following lemma summarizes the crucial effect of the star-gadget.

► **Lemma 10** (\star). *Every d -stable matching Π of the instance in Example 9 satisfy the following.*

- If d is even, then $\Pi(0) \cap Y \neq \emptyset$ or $\Pi(1) \cap Y \neq \emptyset$.
- If d is odd, then $\Pi(0) = Y \cup \{0\}$.

The remaining gadgets. Let $I = (X, \mathcal{S})$ be an instance of PC-X3C. Similarly to the case with $d = 3$, we first embed the associated graph $G(I) = (U \uplus W, E)$ into a 2-dimensional grid with edges drawn using line segments of length at least $L \geq 200$, and with parallel lines at least $4L$ grid squares apart. The element- and the edge-gadget are almost the same as the ones describe in Subsection 3.1. The only difference is that we replace each element-agent u_i (for $u_i \in U$) with a size- $(d - 2)$ coalition U_i that are embedded so close to each other that any stable matching must match them together. Similarly, for each $z \in [\hat{n}]$ (recall that \hat{n} is a constant as defined in the Subsection 3.1) and $w_j \in W$, we replace the two agents $\alpha_i^j[z]$ and $\beta_i^j[z]$ with a size- $(d - 1)$ coalition $\hat{A}_i^j[z]$ such that the distance between each pair of points in $\hat{A}_i^j[z]$ is close to zero, and define $A_i^j[z] := \hat{A}_i^j[z] \cup \{\gamma_i^j[z]\}$. For each set-vertex $w_j \in W$, assume that the three connecting edges in $G(I)$ are going rightward, leftward, and upward, connecting the element-vertices u_i, u_p, u_q , respectively. We create three set-agents, called w_j^i, w_j^p, w_j^q , and an additional coalition W_j of size $d - 3$ and as before, define $w_j^i = \gamma_j^i[\hat{n}]$. We embed them into \mathbb{R}^2 in such a way that w_j^i, w_j^p, w_j^q are on the segment of the rightward, leftward, and upward edge, respectively, and are of equidistance 17.5 to each other, and the coalition W_j is embedded in the center so that the distance between any two of them is close to zero. Moreover, the largest distance from any agent of W_j to any agent of $\{w_j^i, w_j^p, w_j^q\}$ is 10. See Figure 5 for an illustration.

We remark that by the construction of the set-gadget and the edge-gadget, each set-agent w_j^i prefers coalition $A_i^j[\hat{n}]$ (recall that $\gamma_i^j[z] = w_j^i$) to coalition $\{w_j^i, w_j^p, w_j^q\} \cup W_j$ since the sum of distances from w_j^i to the latter coalition is $17.5 + 17.5 + 10(d - 3) > (d - 1) \cdot (10 - \varepsilon)$.

To ensure that one of the two coalitions is chosen, we make use of the star-gadgets from Example 9. Define $b := 22.6$ and $c := 22.7$. We create an agent-subset F_j^i of size $d - 1$ and agent h_j^i and a star-gadget W as described in Example 9, with Y being the extra $d - 1$ agents such that the most preferred coalition of each agent in Y is $Y \cup \{h_j^i\}$. Note that F_j^i has the same role as $\{f_j^i, g_j^i\}$ in the case for $d = 3$.

- The distance between each two agents in F_j^i is close to zero.
- The distance from each agent in F_j^i to each agent in $\hat{A}_i^j[\hat{n}]$ is in the range of $[10 + \varepsilon, 10 + 2\varepsilon)$.
- The distance from each agent in F_j^i to agent w_j^i is $10 + \frac{15}{d-1}$.
- The distance from each agent in F_j^i to agent h_j^i is $15 + 2\varepsilon$.
- The distance from agent h_j^i and each agent Y is $15 + 3\varepsilon$.
- The distance from each agent Y to 0 (and also to 1 if d is even) is $15 + 4\varepsilon$.

Finally, we create two types of garbage collector agents to match with some left over agents. For each added star gadget corresponding to S_j and $i \in S_j$, we create $O(\kappa)$ garbage collector agents R_j^i as follows: If d is odd, set $|R_j^i| := d - \kappa - 2$. Otherwise if $d \leq 6$, set $|R_j^i| := 2d - \kappa - 5$, and otherwise set $|R_j^i| := d - \kappa - 5$. These agents have distance close to zero to each other. For each $y \in R_j^i$ it holds that $\ell < \delta(y, x) < 2\ell < \delta(y, x')$, where x is an agent from the same star and x' is an agent from neither R_j^i or the same star. It is straightforward to see that the distance between any two agents from different star-gadgets is larger than ℓ , and the distance from an agent in W to an agent to a set-gadget is at larger ℓ , where a, b, b', c' , and ℓ are as defined in Example 9. Lastly, we add $m - n$ triples of additional garbage collector agents. The agents in each triple have distance close to zero to each other but is far away from the other agents. Note that each triple will be matched to some W_j whenever S_j is not chosen to the exact cover. See Figure 6 (for even d , without the garbage collector agents) for an illustration. This completes the description of the construction, which clearly can be done in polynomial time.

4.2 The correctness proof for $d \geq 4$

The reasoning for the correctness is similar to the one for $d = 3$. For the forward direction, assume that (X, \mathcal{S}) admits an exact cover \mathcal{K} . Then, using a reasoning similar to the one for $d = 3$, one can verify that the following d -matching Π is stable; recall that $\kappa = \lfloor (d - 1)/2 \rfloor$.

- For each $S_j \in \mathcal{K}$ with $S_j = \{i, p, q\}$ add $\{w_j^i, w_j^p, w_j^q\} \cup W_j$ to Π .
- For each element $i \in X$ let S_k, S_r be the two sets which contain i , but are not chosen in the exact cover \mathcal{K} . Add $U_i \cup \{u_i^k, u_i^r\}$ to Π . For each $S_j \notin \mathcal{K}$, take a triple of garbage collector agents (of the second type) and match them with W_j .
- For each element $i \in X$ and each set $S_j \in \mathcal{S}$ with $i \in S_j$, call the agents in the associated star-gadget along with the tail $X_0 \cup \dots \cup X_4 \cup \{0, 1, 2, 3, 4, h_j^i\} \cup Y \cup \{F_j^i\} \cup \{5, 6, 7, 8, 9 \mid \text{if } d \text{ odd}\}$. If $S_j \in \mathcal{K}$, then add all $\hat{A}_i^j[z] \cup \{\gamma_j^i[z - 1]\}$, $z \in [\hat{n}]$, to Π . Otherwise, add all $A_i^j[z]$, $z \in [\hat{n}]$, to Π . Add $F_j^i \cup \{h_j^i\}$ and $Y \cup \{0\}$ to Π . If d is odd, add $X_1 \cup X_2 \cup \{1\}$ and $X_3 \cup X_4 \cup \{3\}$ to Π . Otherwise, add $X_1 \cup X_2 \cup \{2, 3\}$ and $X_3 \cup X_4 \cup \{6, 7\}$ to Π . Next, if $d \leq 6$, then match X_0 with $d - \kappa$ agents from $(1, 8, 9, 4)$ (in this sequence) to Π . In any case, match the remaining star-agents with R_j^i .

The proof for the backward direction works analogously to $d = 3$ and is deferred to the full version [8].

■ **Figure 6** Gadget for edge $\{u_i, w_j\}$ in $G(I)$ with $S_j = \{i, p, q\}$ for the case when d is even, omitting the garbage collector agents for the sake of brevity.

5 Conclusion and Outlook

Establishing the first complexity results in the study of multi-dimensional stable matchings for Euclidean preferences, we show that d -SR remains NP-hard for Euclidean preferences and for all fixed $d \geq 3$. The gadgets in the reductions may be useful for other matching and hedonic games problems with Euclidean preferences.

Our Euclidean preference model assumes that the preferences over coalitions are based on the sum of distances to all individual agents in the coalition. It would be interesting to see whether taking the maximum or the minimum distance to the coalition members instead of the sum would change the complexity. Furthermore, it would be interesting to see whether restricting the agents' embedding to 1-dimensional Euclidean space could lower the complexity. We were not able to identify the complexity for this restricted variant, but conjecture that it can be solved in polynomial time. Note that in 1-dimensional Euclidean space, a 3-stable matching for the maximum distance setting always exists, which can be found by greedily finding three consecutive agents which are closest to each other and matching them.

Spanner Approximations in Practice

Markus Chimani

Theoretical Computer Science, Universität Osnabrück, Germany

Abstract

A multiplicative α -spanner H is a subgraph of $G = (V, E)$ with the same vertices and fewer edges that preserves distances up to the factor α , i.e., $d_H(u, v) \leq \alpha \cdot d_G(u, v)$ for all vertices u, v . While many algorithms have been developed to find good spanners in terms of approximation guarantees, no experimental studies comparing different approaches exist. We implemented a rich selection of those algorithms and evaluate them on a variety of instances regarding, e.g., their running time, sparseness, lightness, and effective stretch.

1 Introduction

Consider a directed or undirected graph $G = (V, E)$ with n vertices and m edges. The distance $d_G(u, v)$ is the length of a shortest path between two vertices u and v , possibly subject to edge weights $w: E \rightarrow \mathbb{R}^+$. A *spanner* is a sparse subgraph of G that preserves these distances to some quality degree. Spanners were introduced by Peleg and Schäffer [38] after the first mention by Awerbuch [5]. There are many spanner variants, see Ahmed et al [1] for a survey. In this paper we are going to focus on the probably most popular variant:

► **Definition 1** (Multiplicative α -Spanner [38]). *Given a directed or undirected graph $G = (V, E)$ and a stretch $\alpha \geq 1$, a multiplicative α -spanner $H = (V, E')$ is a subgraph of G with $E' \subseteq E$ such that $d_H(u, v) \leq \alpha \cdot d_G(u, v)$ holds for all pairs $(u, v) \in V \times V$.*

For simplicity we use the term *spanner* for the multiplicative α -spanner in the following.

Given a graph G , finding any spanner is trivial since G is a spanner of itself. The problem we are interested in is to find a *good* spanner. Next to the stretch α itself, there are three basic measures of a spanner's quality: the *size* is the number of edges $|E'|$; the *sparseness* $s(H) = \frac{|E'|}{|E|}$ is the relative size w.r.t. the original graph, with a lower value indicating a sparser spanner; the *lightness* $\ell(H) = \frac{W(E')}{W(\text{MST}(G))}$ with $W(F) = \sum_{e \in F} w(e)$ compares the weight of the spanner to the weight a minimum spanning tree in G .

► **Definition 2** (Sparsest (Lightest) α -Spanner). *Given a graph $G = (V, E)$ and a stretch $\alpha \geq 1$, find a sparsest (lightest) multiplicative α -spanner $H = (V, E')$ such that $s(H) \leq s(H')$ ($\ell(H) \leq \ell(H')$, respectively) for all other spanners H' of G .*

Finding good spanners is motivated by several applications, e.g., ranging from routing problems [5, 40, 17, 43] to distributed computing [39, 18]. Also many theoretical applications require spanners, e.g., approximate distance oracles [37, 45], almost shortest paths [25, 22], or access control hierarchies [31, 9]. Thus, while finding a sparsest or lightest spanner is NP-hard [38, 11], a multitude of algorithms was developed to find sparse or light spanners.

We are interested in the computation of spanners in practice. Farshi and Gudmundsson [27] compared specialized algorithms based on WSPD-graphs [12] and Θ -graphs [16, 32] for the geometric case; Bouts et al. [10] presented experiments, e.g., on multilevel subset additive spanners. Regarding exact algorithms, Sigurd and Zachariassen [44] developed in 2004 an exact spanner algorithm based on an ILP with an exponential number of variables, each representing a shortest path. Graphs with up to 64 vertices were tested but not all instances could be solved within the time limit of 30 minutes. Ahmed et al. [2] published a compact ILP based on multicommodity flow in 2019, which can be solved by standard B&B-techniques. They tested graphs with up to 100 vertices, but the solver needed up to 40 hours to solve the largest instances on a high-performance 400-node cluster. They did not compare the results to [44] or other popular heuristics. Apart from these studies, there seem to be no further experimental studies, in particular none for the arguably most prominent base case of multiplicative α -spanners in non-geometric settings.

Contribution. Despite the multitude of applications, there is an obvious total lack of practical experience with polynomial algorithms for non-geometric spanners. While there are various intrinsically different algorithmic ideas known in literature, there is no understanding which of these concepts lend themselves to fruitful practical applications. The main focus of this paper is thus to gain some insight in the practical consequences of these algorithmically diverse ideas. – In Sect. 2, we provide an overview of the known algorithms. We argue our selection of algorithms and give implementation details in Sect. 3. In Sect. 4, we present the results of our experimental study.

2 Known Algorithms

Much work and effort has been put into developing different approaches to find spanners. We will categorize the existing literature into three main categories: greedy algorithms, approximation algorithms, and other methods. For a rich theoretical survey of graph spanners, their theoretical background and algorithms, see Ahmed et al. [1].

Greedy algorithms. One of the earliest algorithms is by Althöfer et al. [4] and is reminiscent of Kruskal’s algorithm. The algorithm ADDJS, often named *Basic Greedy Spanner Algorithm*, starts with a spanner without edges and adds edges $\{u, v\}$ with increasing weight to the spanner, if the shortest path between u and v is currently too long, i.e., $d_H(u, v) > \alpha \cdot w(\{u, v\})$. For a stretch $\alpha = 2k - 1$ ($k \in \mathbb{N}_{\geq 1}$), this algorithm creates a spanner of size $\mathcal{O}(n^{1+1/k})$ and lightness $\mathcal{O}(n/k)$. The running time is mostly dominated by a Dijkstra run for each edge: $\mathcal{O}(m(n^{1+1/k} + n \log n))$. – Roditty and Zwick [42] sped up to the distance calculation in the spanner by incrementally maintaining a shortest-path tree, but lose any lightness guarantee in the process. Thorup and Zwick [45] explored *approximate distance oracles*, yielding a spanner algorithm as a byproduct, but as before, no lightness guarantee can be given.

To further improve the quality measures, more refined analyses using ε -parameterized algorithms were introduced. Thereby, one allows the spanner to violate the stretch requirement by a factor of up to $1 + \varepsilon$, while the approximation ratio of the sparsity and lightness is measured against the best spanner not violating this requirement. Chandra et al. [13], Elkin and Solomon [26] and Elkin et al. [24] use various techniques (e.g., dynamic shortest-path trees, further auxiliary graphs, and distance oracles) and refined analyses to create a spanner with guarantees for size and lightness as well as maintaining a low running time. Alstrup et al. [3] provide the currently best guarantees; their algorithm creates a $((2k - 1)(1 + \varepsilon))$ -spanner

with size $\mathcal{O}_\varepsilon(n^{1+1/k})$ and lightness $\mathcal{O}_\varepsilon(n^{1/k})$ within a running time of $\mathcal{O}(n^{2+1/k+\varepsilon'})$. Thereby, \mathcal{O}_ε ignores polynomial factors depending on $1/\varepsilon$. However, ADDJS still has the best lightness guarantee while strictly providing an $\alpha = 2k - 1$ stretch and is existentially optimal, see Ahmed et al. [1, Chapter 4] for a more thorough theoretical insight. Additionally, most above modifications lead to very complex algorithms that are often not practically implementable due to the intricate additionally required data structures mentioned above.

Clustering algorithms. Baswana and Sen [6] (BS) gave a method based on growing clusters around sampled vertices. It is special compared to all other algorithms as it does not do any local or global distance calculation. It computes an $\alpha = 2k - 1$ spanner for a weighted, undirected graph in two phases. First, there are $k - 1$ rounds of growing clusters by sampling vertices and successively adding nearest neighbors to each cluster. Then, clusters are joined by adding all non-clustered vertices to the nearest adjacent cluster and interconnecting all clusters. This yields a spanner of size $\mathcal{O}(kn^{1+1/k})$ in an expected running time of $\mathcal{O}(km)$, but no lightness guarantee. For an unweighted graph, the size is bounded by $\mathcal{O}(n^{1+1/k} + kn)$.

Approximation algorithms. An early $\mathcal{O}(\log(m/n))$ -approximation in terms of size by Kortsarz and Peleg [34] was published in 1994 for the special case of a 2-spanner for unweighted and undirected graphs (algorithm KP). An edge e is *covered*, if it is not part of the spanner, but part of a triangle in the original graph and both other edges are in the spanner, so the spanner property holds for e . The idea is to cover a large number of edges while not adding too many edges to the spanner by finding dense subsets of vertices and adding connecting edges to the spanner. KP calculates *dense subsets* U_v of neighboring vertices $N(v)$ for each vertex v and continues with the densest subset, say U_w . The star $\{\{u, w\} | u \in U_w\}$ is added to the spanner. The edges within the dense subset are now covered and finding the densest subgraph allows for covering the most edges. This is repeated while there exists a dense subset with a density larger than 1. The running time is bounded by $\mathcal{O}(nm \cdot \text{MDS}(n, m))$ where $\text{MDS}(n, m)$ is the running time of the algorithm to solve the maximum density subgraph problem. Using Goldberg's algorithm [30], the resulting time complexity is $\mathcal{O}(m^2 n^3 \log n)$. There exist more advanced algorithms for the maximum density problems so the theoretical running time can be lowered to $\mathcal{O}(m^2 n^2 \log(n^2/m))$ [28].

For undirected graphs we know of no explicit further approximation results. One reason may be that ADDJS already has an $\mathcal{O}(n^{1+1/k})$ guarantee for the spanner size. For a connected original graph, a spanner must have at least $n - 1$ edges, as it has to be connected as well. This lower bound for an optimal solution thus results in a straight-forward $\mathcal{O}(n^{1/k})$ -approximation in terms of size for every undirected graph.

For directed graphs, Elkin and Peleg [25] gave the first $\tilde{\mathcal{O}}(n^{2/3})$ -approximation in the special case $\alpha = 3$. For general $\alpha \geq 3$, Bhattacharyya et al. [9] published an $\tilde{\mathcal{O}}(n^{1-1/\alpha})$ -approximation combining two techniques: The spanner is the union of the arc sets of two graphs. The first graph is obtained by solving an LP relaxation and rounding the solution. The second one is created by sampling vertices and growing BFS arborescences from them. Dinitz and Krauthgamer [20] improved the techniques and Berman et al. [8] gave the currently best solution for general stretch $\alpha \geq 1$ (algorithm BBMR): They introduced an $\mathcal{O}(n^{1/2} \log n)$ -approximation for weighted, directed graphs. For the special case $\alpha = 3$ (later extended to $\alpha = 4$ by Dinitz and Zhang [21]) a slightly modified approach can be taken to achieve an $\tilde{\mathcal{O}}(n^{1/3})$ -approximation for directed and unweighted graphs. The techniques used are similar to the approach of Bhattacharyya et al. [9]: The arcs of the original graphs are categorized as either *thin* or *thick* by the number of shortest paths connecting the endpoints of the

■ **Table 1** Considered algorithms. The letters G, A, C and P in the second column stand for greedy, approximation, clustering, and probabilistic, respectively. *Assume $\alpha = 2k - 1$, $k \in \mathbb{N}_{\geq 1}$.

Algorithm		$w(e)$	Stretch	Spanner Properties*	Running time
ADDJS [4]	G	✓	$\alpha \in \mathbb{R}_{\geq 1}$	$s(H) \in \mathcal{O}(n^{1+1/k})$ $\ell(H) \in \mathcal{O}(n/k)$ [see text]	$\mathcal{O}(m(n^{1+1/k} + n \log n))$
KP [34]	A	×	$\alpha = 2$	$\mathcal{O}(\log(m/n))$ -approx. in size	$\mathcal{O}(m^2 n^3 \log n)$
BBMRY [8]	A	✓	$\alpha \in \mathbb{R}_{> 1}$	$\mathcal{O}(n^{1/2} \log n)$ -approx. in size	poly
BS [6]	C	×	$\alpha \in \mathbb{N}_{\geq 3}$, odd	$s(H) \in \mathcal{O}(n^{1+1/k} + kn)$	expected $\mathcal{O}(km)$
BS [6]	C	✓	$\alpha \in \mathbb{N}_{\geq 3}$, odd	$s(H) \in \mathcal{O}(kn^{1+1/k})$	expected $\mathcal{O}(km)$
EN [23]	P	×	$\alpha \in \mathbb{N}_{\geq 1}$, odd	$s(H) \in \mathcal{O}(n^{1+1/k}/\varepsilon)$ $0 < \varepsilon < 1$	expected $\mathcal{O}(m)$, success prob. $\geq 1 - \varepsilon$

arc. An LP rounding covers all thin arcs, and growing arborescences from sampled vertices cover all thick arcs. For the (I)LP, *antispanners* were introduced. Given an arc (u, v) , an antispanner is an arc set A , such that no shortest path with a distance less than $\alpha \cdot d_G(u, v)$ exists between u and v in $G \setminus A$. A is a minimal antispanner for (u, v) if no $A' \subset A$ is an antispanner for (u, v) . The ILP tries to cover arcs so that at least one arc of each minimal antispanner is used. If this is achieved, the selected arcs resemble a feasible solution. Due to the exponential number of minimal antispanners, we require a separation oracle to solve the LP relaxation of this ILP with cutting planes. The separation oracle has an exponentially small probability in n of failing.

Randomized Algorithms. A probabilistic method was presented by Elkin and Neiman [23] to calculate a spanner with stretch $2k - 1$ for undirected, unweighted graphs (algorithm EN). They built upon Miller et al. [36, 35] and improved the size to $\mathcal{O}(n^{1+1/k}/\varepsilon)$. For each vertex u , a random value r_u is drawn from an exponential distribution. Each vertex broadcasts a message with r_u as the content to all vertices within distance k . A vertex x , receiving messages from some vertices $U \subset V$, stores $m_u(x) = r_u - d_G(u, x)$ for each vertex $u \in U$ together with an edge adjacent to x that lies on a shortest path between u and x . The edges belonging to the messages with $m_u(x) \geq \max_{u \in V} \{m_u(x)\} - 1$ are added to the spanner. Since the algorithm has a success probability of at least $1 - \varepsilon$, we can obtain an expected running time of $\mathcal{O}(m)$ by iterating.

3 Considered Algorithms and Implementation Details

As motivated in Sect. 1, we aim at covering very diverse algorithmic approaches and investigating their relative merits, rather than several algorithmic variants finetuning a common idea. Only once an understanding on the most worthwhile algorithmic concepts has been achieved, deeper comparisons of algorithmic variants would seem worthwhile.

Thus, we select five, intrinsically different, algorithmic approaches to analyze; Table 1 provides an overview of the characteristics of each algorithm. With the goal of small running times and larger instances, we decided against reestablishing the performance of the exact algorithms [44, 2]; as summarized in Sect. 1, their running times are nowhere competitive on the instances we aim to consider. As the representative for the fundamental greedy algorithms, we selected ADDJS. While the algorithms of Thorup and Zwick [45] and Roditty and Zwick [42] improve the running time, ADDJS promises better results w.r.t. size and lightness. As such, there was no good argument to consider these or the algorithmically

and implementationwise much more involved ε -parameterized variants at this stage of the scientific knowledge discovery (but see Sect. 5). This argument is further amplified by the fact that many of these variants require very sophisticated subalgorithms (see above) which are by themselves unknown territory from the algorithm engineering viewpoint.

From the approximation algorithms we selected KP and BBMRV as they are the state-of-the-art. For BBMRV, we implemented the variant for arbitrary α , not the special improvements for $\alpha = 3$ and $\alpha = 4$. In the following, we list some implementation specific details; all our implementations guarantee the running time of the algorithmic descriptions.

Althöfer et al. (ADDJS). We include a straightforward observation to speed-up the computation: We bound the shortest-path search for each pair of vertices by $\alpha \cdot w(\{u, v\})$ since finding a longer path (or no path at all) results in adding the edge $\{u, v\}$ to the spanner. Note that one is not limited to a stretch $\alpha \in \mathbb{N}_{\text{odd}}$; the algorithm works for arbitrary $\alpha \geq 1 \in \mathbb{R}$, but may only provide the size and lightness guarantees for the next odd integer.

Baswana and Sen (BS). We broadly follow the detailed algorithmic description of [6]. We changed only one small aspect: The second and third step of the first phase can be combined in a single pass. After sampling clusters, it is not necessary to first calculate the nearest neighboring sampled cluster for each vertex and store it in some data structure because the third step can directly follow and does not depend on other vertices.

Kortsarz and Peleg (KP). The algorithm mainly depends on an implementation for the *maximum density subgraph problem*. We use Goldberg's algorithm [30] due to its simplicity of implementation. It resembles a binary search with $\mathcal{O}(\log n)$ steps: A source and target vertex (s, t) are added to the graph and connected to all original vertices. In each step the weights of the new edges are chosen depending on the current search value. A minimum s - t -cut is calculated and based on the resulting cut it is decided, whether the lower or upper half of the search interval is used. To solve the minimum s - t -cut problem we use Goldberg-Tarjan's max-flow algorithm [29] with global relabeling and gap relabeling heuristic requiring $\mathcal{O}(n^2m)$ time. This results in a running time for Goldberg's maximum density subgraph algorithm of $\mathcal{O}(n^2m \log n)$ and, as described above, in a complete running time of $\mathcal{O}(m^2n^3 \log n)$ for KP.

The algorithm has to maintain three sets H^s , H^c , and H^u for the spanner edges, covered edges, and uncovered edges. In the implementation it is sufficient to only use the original graph's edge set $E = H^u$ (by shrinking G on the fly) and the spanner's edge set $E' = H^s$. There is no need to explicitly store covered edges H^c in some data structure. For each maximum dense subset U_w , the star edges are added to E' . The star edges and the edges of the implied dense subset graph $E(U_w) = \{\{u, v\} \in E \mid u, v \in U_w\}$, which are the covered edges, are removed from E , so that the covered edges are simply entirely removed. Since we have to calculate the density of the maximum density subset, we have $E(U_w)$ already available, so no extra work is required to calculate the edges induced by the subset of vertices.

Berman et al. (BBMRV). The original algorithmic description leaves some implementation details open. First, the property of an arc (s, t) being *thin* or *thick* has to be efficiently evaluated [8, Definition 2.2]. The definition uses a *local graph* $G^{s,t} = (V^{s,t}, E^{s,t})$ induced by all vertices belonging to paths from s to t with a length of at most $\alpha \cdot d_G(s, t)$. An arc (s, t) is thick, if $|V^{s,t}| \geq n^{1/2}$. Calculating all possible paths is not an option, so in- and out-arborescences can be used. First, we precalculate these arborescences since we need them for evaluating the local graphs and during sampling afterwards. For each vertex r , an in-

and out-arborescence rooted at r is calculated. The distances to other vertices x are saved in $d_{\text{in}}(r, x)$ ($d_{\text{out}}(r, x)$, respectively) together with the respective predecessor to be able to access the actual trees during sampling. To check if $|V^{s,t}| \geq n^{1/2}$ holds, we can use the equivalence: $x \in V^{s,t} \iff d_{\text{out}}(s, x) + d_{\text{in}}(t, x) \leq \alpha \cdot d_G(s, t)$. Checking each vertex x , we count $|V^{s,t}|$ and decide the property for each arc. This could be done by using either an in- or out-arborescence, but both types are needed for the sampling, so we can precalculate both anyhow. Consequently, the subsequent sampling does not involve any shortest-path calculations and can be done by looking up predecessor relations.

Next, given an arc (s, t) it must be checked, if a set $R \subseteq E$ settles the arc [8, Definition 2.3], i.e., R satisfies the α -spanner property for (s, t) . This is done by running a bounded Dijkstra on R with a running time of $\mathcal{O}(|R| + n \log n)$. The check whether an arc is settled is done quite often, e.g., during the separation method and in the minimization of an antispanner.

Finally, let us focus on the separation method and the creation of antispanners. The former is straightforward: After rounding the fractional solution, obtaining R , we check every thin arc, whether it is settled by R . For an unsettled thin arc (s, t) , we create an antispanner w.r.t. R (see [8, Claim 2.4]). Similar to the thin arc property where the vertices $V^{s,t}$ are required, we need the arc set $E^{s,t}$, as $A = E^{s,t} \setminus R$ is an antispanner. An arc (u, v) is an element of $E^{s,t}$ if and only if $d_{\text{out}}(s, u) + w(u, v) + d_{\text{in}}(t, v) \leq \alpha \cdot d_G(s, t)$; this check can reuse the precalculated arborescences. After finding the antispanner it has to be minimized. We greedily remove arcs from A , while the unsettled thin arc remains unsettled. If no further arc can be removed, A is a minimal antispanner.

Elkin and Neiman (EN). Provided the very compact description of the algorithm and no explicit pseudocode, one has to be very careful not to gloss over intricate important details. We implemented the algorithm in the standard centralized model. The authors also highlight the distributed and PRAM models (as the algorithm can be parallelized well), but we aim to keep it comparable to all other algorithms.

To start, remember that the edges saved together with the received messages must belong to *some* shortest u - x -path. Naturally, we store the edge where x received the message from. To ensure that the messages travel along shortest paths, we use a breadth-first-search (BFS) starting at u with a depth limit of k , without the need of a Dijkstra computation.

The algorithm includes two feasibility checks. If one fails, the algorithm does not provide a feasible solution. The first check, that $r_u < k$ holds for all $u \in V$, can be done directly while generating values r_u to let the algorithm fail quickly if the property does not hold. The second check at the end of the algorithm asserts that there are sufficiently many edges. Elkin and Neiman state that the spanner must have at least $n - 1$ edges and the algorithm fails, if $|E'| < n - 1$. This is only correct if the original graph is connected. If it has $c \geq 2$ components, we can use the condition $|E'| < n - c$ instead.

A major improvement in terms of memory consumption can be made when reversing the way the algorithm is formulated. The original formulation can chiefly be described as:

1. For each $u \in V$, broadcast messages $m_u(x)$ to every vertex x within distance k .
 2. For each receiving $x \in V$: Calculate $\max_{u \in V} \{m_u(x)\}$ and add edges to the spanner.
- Following this order, one has to save two $n \times n$ matrices containing the message values $m_u(x)$ and the edge where the messages are received. In a pilot study, this resulted in out-of-memory errors for very sparse graphs ($m \approx 2n$) with $n \approx 40,000$, which other algorithms can handle. To lower the memory consumption, we reversed the logic to focus on each receiving vertex x : A BFS starting at x identifies all vertices u that can broadcast a message to x . Then, the aggregation and edge addition can directly be done afterwards, before proceeding with the next x . To summarize all improvements, the code is provided in [15, Appendix A].

We note that it is possible to provide values for ε that are not in the interval $(0, 1)$. Especially $\varepsilon \geq 1$ can produce good spanners in practice with the downside of an increasing possibility to fail. For results of a pilot study to choose ε , see [15, Appendix B].

4 Experimental Results

We are now ready to present the main content of this paper. The considered algorithms are tested with a variety of instances and parameter settings, as described in the following. In Sect. 4.1 we take a look at the running time of each algorithm. We compare the quality of the resulting spanners in Sect. 4.2. Finally, in Sect. 4.3, we propose and briefly investigate two further graph measures we deem interesting in their own right: We ask about the mean degrees and the mean lengths of the shortest paths in weighted spanners (compared to the input graphs). Investigating these measures can help us to better understand the different behaviors and results of the various algorithms.

Setup. Since BBMR is the only algorithm that would work (with known quality guarantees) on directed graphs, we consider only undirected graphs. Edge weights are often a requirement in applications, but not all algorithms can take weighted graphs as inputs; thus we use each graph twice, once with and once without weights. In the following we will use the absolute density $\varrho_a(G) = m/n$ and the relative density $\varrho_r(G) = m/\binom{n}{2}$ to categorize graphs. In the experiments we consider integer stretches 2, 3, 4, 5, and 7. To test a variety of graph types, three instance libraries are used:

1. *Steinlib* [33]: This well-known library was originally created for the Steiner tree problem, but has also been used in many studies for related problems. Since several application areas of Steiner trees and spanners overlap, it seems judicious to consider this set. It contains 1207 graphs in 44 subsets. Over 62% of the graphs have $\varrho_r = m/\binom{n}{2} < 2.5\%$ (mostly sparse). On average, the graphs have 1189 vertices and 8549 edges; the largest graph has 38418 vertices.
2. *Tsplib* [41]: The well-established Tsplib contains complete weighted graphs. We omitted 27 of the 122 graphs as they have edge weights 0 or are directed. About half of the graphs have < 200 vertices; the largest graph has 7397 vertices. The graphs have 771 (250) vertices on average (median).
3. *Random*: We generated random Erdős-Rényi graphs with $|V| \in \{10, 20, 50, 100, 200, 500, 1000, 2000\}$, a relative density of $i/10$ for $i \in \{1, 2, \dots, 9\}$ and 10 graphs of each combination. Apart from the unweighted instances, we also consider two different random weight function: weights in the range $1 \pm 1/3$ (**W1**), and integer weights between 1 and n (**W2**). The former ensures that each edge is a shortest path between its end vertices, as is the case for unweighted instances, whereas the latter includes “obviously superfluous” edges. All graphs are available at [7].
